The facial nerve may be somewhat variable in its anatomical course through the temporal bone (Proctor and Nasger 1982, Proctor 1991). It may split into two or three strands, starting at the geniculate ganglion, and then make its way across the promontory to the stylomastoid foramen, or pass a few millimetres posteriorly to its second genu, before it turns inferiorly posterior to the fossa incudis, a position where it is particularly vulnerable during surgical exploration of the mastoid antrum. The more proximal the division into strands, the more bizarre is the subsequent course. More distal bifurcations pass either side of the fenestra vestibuli. It may be dehiscent, particularly in its second part, when it occasionally overhangs the stapes, or run inferior to the stapedial superstructure, a position that renders it vulnerable during surgery to the stapes (Barnes et al 2001). The motor fibres to the face may be carried through the chorda tympani, which is then enlarged. When this is the case, the distal facial nerve dwindles to a fibrous strand in a narrowed stylomastoid foramen. In chronic bone disease in the tympanic cavity, the facial nerve may be exposed in its canal. Inflammation may lead to facial paralysis of the infranuclear or lower motor neurone type.

Bell's palsy

Bell's palsy is the eponym given to an idiopathic lower motor neurone facial palsy. It may be complete or partial, and is characterized by a flaccid paralysis of the ipsilateral muscles of facial expression; decreased lacrimation in the ipsilateral eye (which is controlled by neurones in the greater petrosal nerve); and hyperacusis or decreased tolerance of loud noises in the ipsilateral ear as a result of paralysis of stapedius. Its cause remains the subject of speculation but is most probably a herpes virus infection (Zandian et al 2014). Magnetic resonance imaging studies suggest that there are inflammatory changes in labyrinthine and perigeniculate segments of the facial nerve. In the vast majority of cases, spontaneous full recovery takes place after a few weeks.

Tympanic mucosa

The mucosa of the tympanic cavity is pale, thin and slightly vascular. It is continuous with that of the pharynx, via the pharyngotympanic tube, and covers the ossicles, muscles and nerves in the cavity to form the inner layer of the tympanic membrane and the outer layer of the secondary tympanic membrane. It also spreads into the mastoid antrum and air cells. The middle ear mucosa is a mucus-secreting respiratory mucosa bearing cilia on its surface. The precise distribution of the mucociliary epithelium varies in normal middle ears, being more widespread in the young. Three distinct mucociliary pathways have been identified – epitympanic, promontorial and hypotympanic – the latter being the largest. Each of these pathways coalesces at the tympanic orifice of the pharyngotympanic tube (Gleeson et al 1991).

The mucosa forms several vascular folds that extend from the tympanic walls to the ossicles: one descends from the roof of the cavity to the head of the malleus and the upper margin of the body of the incus, and a second surrounds the stapedius. Other folds invest the chorda tympani nerve and tensor tympani. The folds separate off saccular recesses that give the interior of the tympanic cavity a somewhat honeycombed appearance; these mucosal folds have been described in greater detail by Proctor (1964). Of note, the superior recess of the tympanic membrane, Prussak's space, lies between the neck of the malleus and the pars flaccida, bounded by the lateral malleolar fold (Marchioni et al 2013). This space can play an important role in the retention of keratin and subsequent development of cholesteatoma.

Cholesteatoma

Cholesteatoma is the name given to keratinizing squamous epithelium within the middle ear. There is debate as to how such epithelium comes to be in the middle ear. Theories include development from embryological cell rests, metaplasia from inflamed mucoperiosteum, and aberrant migration of squamous epithelium either through a perforation in the tympanic membrane (usually in the pars flaccida or posterosuperior pars tensa) or within an area of tympanic membrane atelectasis where the tympanic membrane becomes adherent to the medial wall of the tympanic cavity. It is likely that all of these processes may be implicated at some time. A feature of cholesteatoma that remains poorly understood is its ability to erode bone, by activating osteoclasts, thus allowing the epithelium to proliferate and invade, destroying the temporal bone and carrying infection to the soft tissues. Cholesteatoma can therefore cause deafness through damage to the ossicles and inner ear; problems with balance through damage to the vestibule and semicircular canals; facial palsy through ischaemia and necrosis of the facial nerve; and intracranial sepsis. Treatment involves microsurgical dissection of the invading sac of epithelium with, wherever possible, preservation of the delicate structures just listed.

CHAPTER
43

Inner ear

The inner ear contains the organ of hearing and the organs of balance. All are located within the labyrinth, a series of interlinked cavities in the petrous temporal bone containing interconnected membranous sacs and ducts. All spaces within the labyrinth are filled with fluid. The different sacs contain sensory epithelia consisting of supporting cells and mechanosensory cells, the hair cells that underlie acoustico-lateralis sensory systems in all vertebrates. In humans, there are six such mechanosensory epithelia: the organ of Corti within the cochlea (the hearing organ); the utricle and saccule (static balance organs); and the cristae of the semicircular canals (dynamic balance organs). Whilst sharing the same basic structure, hair cells and the accessory systems that surround them show specific adaptations to each of the different sensory modalities.

The disarticulated temporal bone is described in detail in Chapter 42. The internal acoustic meatus (internal auditory canal) and bony and membranous labyrinths are described here.

OSSEOUS (BONY) LABYRINTH

The bony labyrinth consists of the vestibule (sacculus and utriculus/saccule and utricle), semicircular canals and cochlea, which are all cavities lined by periosteum and which contain the membranous labyrinth (**Fig. 43.1**). The bone is denser and harder than the other parts of the petrous bone, and it is therefore possible, particularly in young skulls, to dissect the bony labyrinth out from the petrous temporal bone.

The osseous and membranous labyrinths are filled with fluid (**Fig. 43.2**). The gap between the internal wall of the osseous labyrinth and the external surface of the membranous labyrinth is filled with perilymph, a clear fluid with an ionic composition similar to that of other extracellular fluids, i.e. low in potassium ions and high in sodium and calcium. The membranous labyrinth contains endolymph, a fluid with an ionic composition more like that of cytosol, i.e. high in potassium ions and low in sodium and calcium. Moreover, the endolymphatic compartment has an electrical potential that, at least within the cochlea, is approximately 80 mV more positive than the perilymphatic compartment (the endolymphatic potential). These differences in ionic composition and potential, maintained by homeostatic tissues in the walls of the labyrinth, are essential to maximize the sensitivity of the mechanosensory hair cells that convert the vibrations set up in the inner ear fluids by head or sound movements into electrical signals that are transmitted via the vestibulocochlear nerve to the vestibular and cochlear nuclei, respectively, in the brainstem.

Vestibule

The vestibule is the central part of the bony labyrinth and lies medial to the tympanic cavity, posterior to the cochlea and anterior to the semicircular canals (see Fig. 43.1). It is somewhat ovoid in shape but flattened transversely, and (on average) measures 5 mm from front to back and vertically, and 3 mm across. In its lateral wall is the opening of the oval window (fenestra vestibuli), into which the base of the stapes inserts, and to which the base of the stapes is attached by an annular ligament. Anteriorly, on the medial wall, is a small spherical recess that contains the saccule; it is perforated by several minute holes, the macula cribrosa media, which transmit fine branches of the vestibular nerve to the saccule. Behind the recess is an oblique vestibular crest, the anterior end of which forms the vestibular pyramid. This crest divides below to enclose a small depression, the cochlear recess, which is perforated by vestibulocochlear fascicles as they pass to the vestibular end of the cochlear duct. Posterosuperior to the vestibular crest, in the roof and medial wall of the vestibule, is the elliptical recess (**Fig. 43.1B**), which contains the utricle. The pyramid and adjoining part of the elliptical recess are perforated by a number of holes, the macula cribrosa superior; those in the former transmit nerves to the utricle and those in the latter transmit

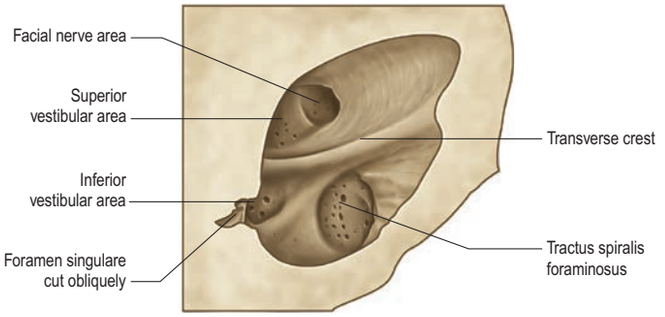

Fig. 43.3 The fundus of the left internal acoustic meatus, exposed by a section through the petrous part of the left temporal bone nearly parallel to the line of its superior border.

nerves to the ampullae of the anterior and lateral semicircular canals (see Fig. 43.1B). The region of the pyramid and elliptical recess corresponds to the superior vestibular area in the internal acoustic meatus (see Fig. 43.3). The vestibular aqueduct opens below the elliptical recess. It reaches the posterior surface of the petrous bone and contains one or more small veins and part of the membranous labyrinth, the endolymphatic duct (**Fig. 43.1C**). In the posterior part of the vestibule are the five openings of the semicircular canals; in its anterior wall is an elliptical opening that leads into the scala vestibuli of the cochlea.

Semicircular canals

The three semicircular canals – anterior (superior), posterior and lateral (horizontal) – are located posterosuperior to the vestibule (see Fig. 43.1). They are compressed from side to side and each forms approximately two-thirds of a circle. They are unequal in length but similar in diameter along their lengths, except where they bear a terminal swelling, an ampulla, which is almost twice the diameter of the canal.

The anterior semicircular canal is 15–20 mm long. It is vertical in orientation and lies transverse to the long axis of the petrous temporal bone under the anterior surface of its arcuate eminence. The eminence may not accurately coincide with this semicircular canal but may instead be adapted to the occipitotemporal sulcus on the inferior surface of the temporal lobe of the brain. The ampulla at the anterior end of the canal opens into the upper and lateral part of the vestibule. Its other end unites with the upper end of the posterior canal to form the crus commune (common limb), which is 4 mm long, and opens into the medial part of the vestibule.

The posterior semicircular canal is also vertical but curves backwards almost parallel with the posterior surface of the petrous bone. It is 18–22 mm long and its ampulla opens low in the vestibule, below the cochlear recess where the macula cribrosa inferior transmits nerves to it. Its upper end joins the crus commune.

The lateral canal is 12–15 mm long and its arch runs horizontally backwards and laterally. Its anterior ampulla opens into the upper and lateral angle of the vestibule, above the oval window and just below the ampulla of the anterior canal; its posterior end opens below the opening of the crus commune.

The two lateral semicircular canals of the two ears are often described as being in the same plane and the anterior canal of one side as being almost parallel with the opposite posterior canal. However, measurements of the angular relations of the planes of the semicircular osseous canals in 10 human skulls led Blanks et al (1975) to suggest that the planes of the three ipsilateral canals are not completely perpendicular to each other. The angles were measured as: lateral/anterior 111.76 ± 7.55°,

(With permission from Van den Boogert T, van Hoof, Handschuh S et al 2018 Optimization of 3D-visualization of micro-anatomical structures of the human inner ear in osmium tetroxide contrast enhanced micro-CT scans. Front Neuroanat 12:1–11.)

anterior/posterior 86.16 ± 4.72°, posterior/lateral 95.75 ± 4.66°. The planes of similarly orientated canals of the two sides also showed some departure from being parallel: left anterior/right posterior 24.50 ± 7.19°, left posterior/right anterior 23.73 ± 6.71°, left lateral/right lateral 19.82 ± 14.93°. The same observers (Curthoys et al 1977) also measured the dimensions of the canals. The mean radii of the osseous canals were found to be as follows: lateral 3.25 mm, anterior 3.74 mm, posterior 3.79 mm. The diameters of the osseous canals are 1 mm (minor axis) and 1.4 mm (major axis). The membranous ducts within them are much smaller, but are also elliptical in transverse section, and have major and minor axes of 0.23 and 0.46 mm (see Fig. 43.2). Representative means for ampullary dimensions are as follows: length 1.94 mm, height 1.55 mm. Phylogenetic studies suggest that the arc sizes of the semicircular canals in humans and other primates may be functionally linked to sensory control of body movements. The angulation and dimensions of the canals may be related to locomotor behaviour and possibly to agility, or more specifically to the frequency spectra of natural head movements (see review by Spoor and Zonneveld (1998)).

Cochlea

The cochlea (from the Greek *cochlos* for snail) is the most anterior part of the labyrinth, lying in front of the vestibule (see Figs 43.1, 43.9A). It is 5 mm from base to apex, and 9 mm across its base. Its apex, or cupula, points towards the anterosuperior area of the medial wall of the tympanic cavity (see Fig. 43.9A). Its base faces the bottom of the internal acoustic meatus and is perforated by numerous apertures for the cochlear nerve. The cochlea has a conical central bony core, the modiolus, and a spiral canal runs around it. A delicate osseous spiral lamina (or ledge) projects from the modiolus, partially dividing the canal (see Fig. 43.9B). Within this bony spiral lies the membranous cochlear duct, attached to the modiolus at one edge and to the outer cochlear wall by its other edge. There are therefore three longitudinal channels within the cochlea. The middle canal (the cochlear duct or scala media) is blind and ends at the apex of the cochlea; its flanking channels communicate with each other at the modiolar apex at a narrow slit, the helicotrema (see Fig. 43.1C). Two distensible membranes form the upper and lower bounds of the scala media. One is Reissner's membrane, the thin vestibular membrane that separates the scala media from the scala vestibuli. The other is the basilar membrane, which forms the partition between the scala media and the scala tympani. The organ of Corti, the sensory epithelium of hearing, sits on the inner surface of the basilar membrane. At the base of the scala vestibuli is the oval window (fenestra vestibuli), which leads on to the vestibular cavity but is sealed by the footplate of the stapes. The scala tympani is separated from the tympanic cavity by the secondary tympanic membrane at the round window (fenestra cochleae). The central cochlear core, the modiolus, has a broad base near the lateral end of the internal acoustic meatus, where it corresponds to the spiral tract (tractus spiralis foraminosus). There are several openings in this area for the fascicles of the cochlear nerve: those for the first 1½ turns run through the small holes of the spiral tract, and those for the apical turn run through the hole that forms the centre of the tract. Canals from the spiral tract go through the modiolus and open in a spiral sequence into the base of the osseous spiral lamina. Here the small canals enlarge and fuse to form Rosenthal's canal, a spiral canal in the modiolus that follows the course of the osseous spiral lamina and contains the spiral ganglion (see Fig. 43.9B). The main tract continues through the centre of the modiolus to the cochlear apex.

The osseous cochlear canal spirals for about 2¾ turns around the modiolus and is 35 mm long. At its first turn, the canal bulges towards the tympanic cavity, where it underlies the promontory. At the base of the cochlea, the canal is 3 mm in diameter but it becomes progressively reduced in diameter as it spirals apically to end at the cupula. In addition to the round and oval windows, which are the two main openings at its base, the canal has a third, smaller opening for the cochlear aqueduct or canaliculus. The latter is a minute funnel-shaped canal that runs to the inferior surface of the petrous temporal bone; it transmits a small vein to the inferior petrosal sinus and connects the subarachnoid space to the scala tympani.

The osseous or primary spiral lamina is a ledge that projects from the modiolus into the osseous canal like the thread of a screw (see Fig. 43.9B). It is attached to the inner edge of the basilar membrane and ends in a hook-shaped hamulus at the cochlear apex, partly bounding the helicotrema (see Fig. 43.1C). From Rosenthal's canal, many tiny canals, the habenula perforata, radiate through the osseous lamina to its rim, where they each carry a fascicle of the cochlear nerve through the foramen nervosum to the organ of Corti. A secondary spiral lamina projects inwards from the outer cochlear wall towards the osseous spiral lamina and is attached to the outer edge of the basilar membrane. It is most prominent in the lower part of the first turn; the gap between the two laminae increases progressively towards the cochlear apex, which means that the basilar membrane is wider at the apex of the cochlea than at the base.

Microstructure of the bony labyrinth

The wall of the bony labyrinth is lined by fibroblast-like perilymphatic cells and extracellular matrix fibres (see Fig. 43.2). The morphology of the cells varies in different parts of the labyrinth. Where the perilymphatic space is narrow, as in the cochlear aqueduct, the cells are reticular or stellate in form; they give off sheet-like cytoplasmic extensions that cross the extracellular space. Where the space is wider, as in the scalae vestibuli and tympani of the cochlea and much of the vestibule, the perilymphatic cells on the periosteum and the external surface of the membranous labyrinth are extremely flat and resemble a squamous epithelium. Elsewhere, on parts of the perilymphatic surface of the basilar membrane, the cells are cuboidal.

Recent evidence suggests that micropores or canaliculi (canaliculi perforantes) (0.2–23.0 μm diameter) are more widely distributed within the bony surfaces lining the perilymphatic space than was previously suspected; they are numerous in the peripheral and modiolar portions of the osseous spiral lamina and the floor of the scala tympani, but sparse in the osseous wall of the scala vestibuli. The proposal that these canaliculi normally provide an extensive fluid communication channel between the scala tympani and the spiral canal of the cochlea could have implications not only for novel drug-based cochlear therapies delivered via the scala tympani and the delivery of stem cells or appropriate cell lines into the deafened cochlea, but also for the design of implanted perimodiolar electrode arrays (Shepherd and Colreavy 2004). (For further reading about the changes in the inner ear that are induced by implanted cochlear electrodes, both acute and long-term, see Keifer et al (2006).)

Composition of inner ear fluids

Perilymph resembles cerebrospinal fluid in ionic composition, particularly in the scala tympani. Its composition differs a little between the two cochlear scalae: concentrations of potassium, glucose, amino acids and proteins are greater in the scala vestibuli. This has led to the suggestion that perilymph in the scala vestibuli is derived from plasma via the endothelial boundary of the cochlear blood vessels, whereas the perilymph in the scala tympani contains some cerebrospinal fluid derived from the subarachnoid spaces via the cochlear canaliculus. However, the lack of significant bulk flow suggests that perilymph homeostasis is predominantly locally regulated. Perilymph contains approximately 5 mM K^+, 150 mM Na^+, 120 mM Cl^- and 1.5 mM $Ca2^+$.

The membranous labyrinth is filled with endolymph, a fluid produced by the marginal cells of the stria vascularis and the dark cells of the vestibule (see review by Wangemann and Schacht (1996)) (see Figs 43.9B, C). Whatever their relative contributions, endolymph probably circulates in the labyrinth; it enters the endolymphatic sac, where it is transferred into the adjacent vascular plexus via the specialized epithelium of the sac. Pinocytotic removal of fluid may also take place in other labyrinthine regions.

Endolymph contains greater K^+ (150 mM) and Cl^- (130 mM) concentrations and lower Na^+(2 mM) and $Ca2^+$ (20 μM) concentrations than perilymph. The high K^+ concentration is important for the function of the mechanosensory hair cells and is maintained by the actions of the lateral wall, which contains two tissues, namely: the spiral ligament and the stria vascularis. Together, these tissues promote the recirculation of K^+ from perilymph back to endolymph by uptake via potassium channels and gap junctional communication. Gap junctions are formed from connexins; their importance to this process is emphasized by the fact that mutations in connexins, the most common being GJB2 (connexin 26), are significant causes of genetic hearing loss (Duman and Tekin 2013). The vestibular regions may not have an endolymphatic potential, as their lateral wall structure is simplified compared to that of the cochlea, although the difference in K^+ concentration between endolymph and perilymph remains important.

Internal acoustic meatus

The internal acoustic meatus (internal acoustic/auditory canal) is separated from the internal ear at its lateral fundus by a vertical plate divided unequally by a transverse (falciform) crest (**Fig. 43.3**). Five nerves – facial, nervus intermedius, cochlear, superior and inferior vestibular – pass

through openings in the vertical plate, above and below the transverse crest. The facial and superior vestibular nerves enter canals that are superior to the crest. The facial nerve is anterior to the superior vestibular nerve, from which it is separated at the lateral end of the meatus by a vertical ridge of bone (Bill's bar). The nervus intermedius lies between the facial motor root and the superior vestibular nerve, to which it may be adherent. The superior vestibular area contains openings for nerves to the utricle and anterior and lateral semicircular ducts. Below the crest, an anterior cochlear area contains a spiral of small holes, the tractus spiralis foraminosus, which encircles the central cochlear canal. Behind this, the inferior vestibular area contains openings for saccular nerves, and most posteroinferiorly, a single hole (foramen singulare) admits the nerve to the posterior semicircular duct. High-resolution synchrotron radiation phase contrast imaging with 3D renderings of undecalcified human temporal bones has delineated a blind-ending extension of the cerebellopontine cistern into the fundus of the internal acoustic meatus (the acoustic-facial cistern) and a system of arachnoid pillars that pass between the walls of this cistern and the cranial nerves that lie within the meatus and possibly provide structural support for the nerves (Mei et al 2019). It has been suggested that vascular loops in the internal acoustic meatus from the anterior inferior cerebellar artery might be a source of pulsatile tinnitus, but loops are found just as commonly in patients without pulsatile tinnitus.

MEMBRANOUS LABYRINTH

The membranous labyrinth is separated from the periosteum by a space that contains perilymph and a web-like network of fine blood vessels (see Figs 43.1C, 43.2). It can be divided into two major regions: the vestibular apparatus and the cochlear duct.

Vestibular apparatus

The vestibular apparatus consists of three semicircular ducts that communicate with the utricle, a membranous sac leading into a smaller chamber, the saccule, via the utriculosaccular duct. This Y-shaped duct has a side branch to the endolymphatic duct, which passes to the endolymphatic sac, a small but functionally important expansion situated under the dura of the petrous temporal bone. From the saccule, a narrow canal, the ductus reuniens, leads to the base of the cochlear duct. These various ducts and sacs form a closed system of intercommunicating channels (see Fig. 43.1C). Endolymph is resorbed into the cerebrospinal fluid from the endolymphatic sac, which therefore provides the site for the drainage of endolymph for the entire membranous labyrinth.

The terminal fibres of the vestibular nerve are connected to the five specialized sensory epithelia (two maculae and three cristae) in the walls of the membranous labyrinth. Maculae are flat plaques of sensory hair cells and supporting cells, and are found in the utricle and saccule. The cristae (crests) are ridges bearing sensory hair cells and supporting cells. They are found in the walls of the ampullae near the utricular openings of the three semicircular canals, one for each canal.

Utricle

The utricle is the larger of the two major vestibular sacs. It is an irregular, oblong, dilated sac that occupies the posterosuperior region of the vestibule (see Fig. 43.1C) and contacts the elliptical recess (where it is a blind-ended pouch) and the area inferior to it.

The macula of the utricle (or utriculus) is a specialized neurosensory epithelium lining the membranous wall and is the largest of the vestibular sensory areas (**Fig. 43.4**). It is triangular or heart-shaped in surface view and lies horizontally with its long axis orientated anteroposteriorly and its sharp angle pointing posteriorly (**Fig. 43.5**). It is flat except at the anterior edge, where it is gently folded in on itself, and it measures 2.8 mm long by 2.2 mm wide. The mature form of the macula is reached early in development, but in the adult a bulge is often present on the anterolateral border; there is sometimes an indentation at the anteromedial border. The epithelial surface is covered by the otolithic membrane (statoconial membrane), a gelatinous structure in which many small crystals, the otoconia (otoliths, statoliths), are embedded. A curved ridge, the 'snowdrift line', runs along the length of the otolithic membrane. It corresponds to a narrow crescent of underlying sensory epithelium termed the striola, 0.13 mm wide. The density of sensory hair cells in this strip of epithelium is 20% less than in the rest of the macula. The striola is convex laterally and runs from the medial aspect of the anterior margin in a posterior direction towards, but not reaching, the posterior pole. The part of the macula medial to the striola is called the pars interna and is slightly larger than the pars externa, which is lateral to it. The significance of this area is that the sensory cells are functionally and anatomically polarized with respect to the midline of the striola (see Fig. 43.5). The macula in each utricle is approximately horizontal when the head is in its normal position. Linear acceleration of the head in the horizontal plane will result in the otolithic membrane lagging behind the movement of the membranous labyrinth as a result of the inertia produced by its mass. The membrane thus maximally stimulates one group of hair cells by deflecting their bundles towards the striola whilst inhibiting others by deflecting their bundles away from it. Hence each horizontal movement of the head will produce a specific pattern of firing in utricular afferent nerve fibres.

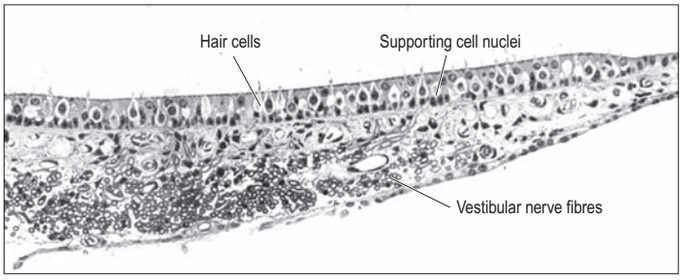

Fig. 43.4 A section of the utricular macula from a guinea pig, showing the relative positions of the hair cells and supporting cell nuclei. Semi-thin resin section, toluidine blue stain. (The inner ear is extremely vulnerable to hypoxia and situated in one of the hardest bones in the body, which means that well-fixed human tissue is rarely obtained for histology. Guinea pigs are one of the most frequently used animal models of human hearing and their inner ear ultrastructure is very similar.) (Courtesy of RM Walsh, DN Furness and CM Hackney, The Institute of Science and Technology in Medicine, School of Life Sciences, Keele University.)

Saccule

The saccule (or sacculus) is a slightly elongated, globular sac lying in the spherical recess near the opening of the scala vestibuli of the cochlea (see Fig. 43.1C). The saccular macula is an almost elliptical structure, 2.6 mm long and 1.2 mm at its widest point. Its long axis is orientated anteroposteriorly but, in contrast to the utricular macula, the saccular macula lies in a vertical plane on the wall of the saccule. Its elliptical shape is very slightly distorted by a small anterosuperior bulge. Like the utricular macula, it is covered by an otolithic (statoconial) membrane and possesses a striola similar to that of the utricle, 0.13 mm wide, which extends along its long axis as an S-shaped strip about which the sensory cells are functionally and anatomically polarized (see Fig. 43.5). The part of the macula above the striola is termed the pars interna, and that below it, the pars externa. The operation of the saccule is similar to that of the utricle. However, because of its vertical orientation, the saccule is particularly sensitive to linear acceleration of the head in the vertical plane and is, therefore, a major gravitational sensor when the head is in an upright position. It is also particularly sensitive to movement along the anteroposterior axis.

Semicircular ducts

The lateral, anterior and posterior semicircular ducts follow the course of their osseous canals. Throughout most of their length they are securely attached, by much of their circumference, to the osseous walls. They are approximately one-quarter of the diameter of their osseous canals (see Fig. 43.2). The medial ends of the anterior and posterior ducts fuse to form a single common duct, the crus commune, before entering the utricle. The lateral end of each canal is dilated to form an ampulla, within the ampulla of the osseous canal. The short segment of duct between the ampullae and utricle is the crus ampullaris.

The membranous wall of each ampulla contains a transverse elevation (septum transversum), on the central region of which is a saddle-shaped sensory ridge, the ampullary crest, containing hair cells and supporting cells. It is broadly concave on its free edge along most of its length and has a concave gutter (planum semilunatum) at either end between the ridge and the duct wall. Sectioned across the ridge, the crests of the lateral and anterior semicircular ducts have smoothly rounded corners; the posterior crest is more angular. A vertical plate of gelatinous extracellular material, the cupula, is attached along the free edge of the crest (**Fig. 43.6**). It projects far into the lumen of the ampulla so that it is

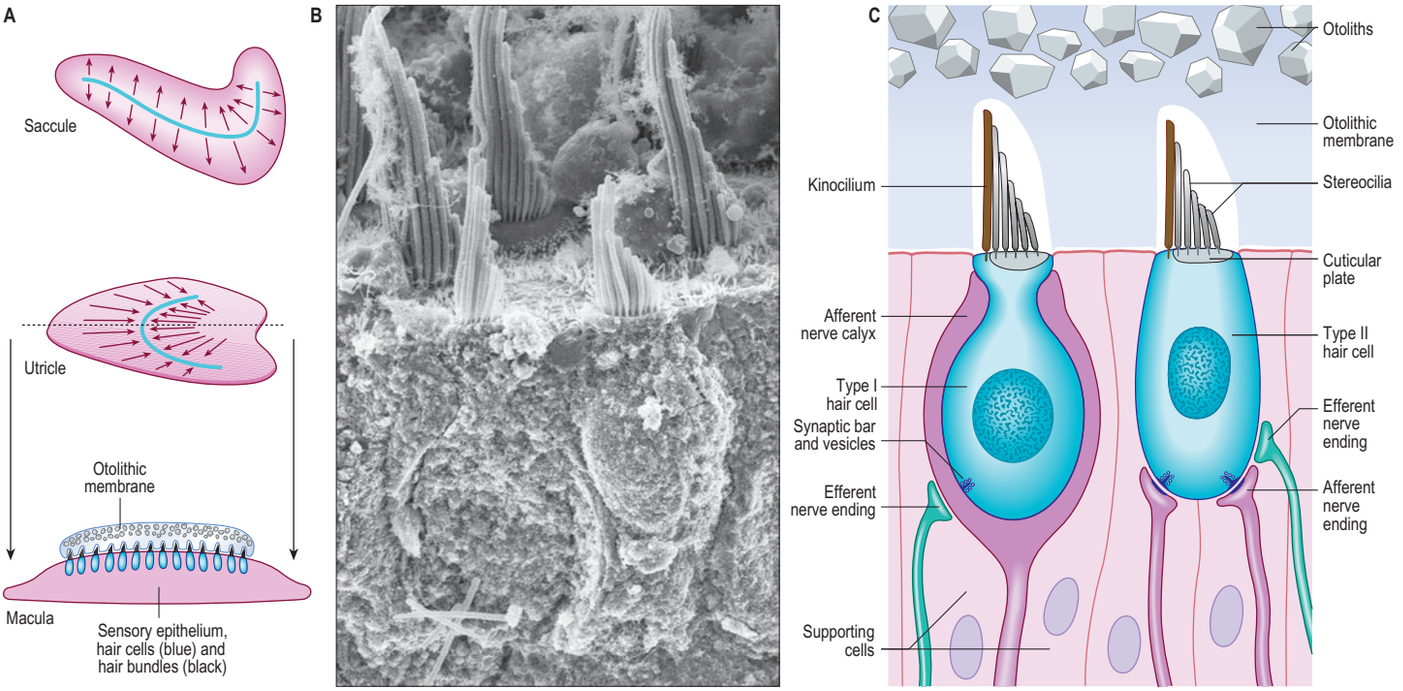

Fig. 43.5 A, The morphological organization of the saccular and utricular maculae and the relationship of their hair cells to the otolithic membrane. The utricular macula has been tilted in the plane of the page to emphasize that it lies horizontally, whereas the saccular macula lies vertically when the head is in an upright position. Note the different shapes of the maculae, the position of the striola as indicated by a curved line in each case, and the different orientations of their stereociliary bundles. The arrows indicate the excitatory direction of deflection. **B**, A scanning electron micrograph of a fracture of a utricular macula (guinea pig) showing a type I hair cell (left) and a type II hair cell (right). **C**, The differing innervation patterns of the two types of hair cell. Fig. 43.6 A section of an ampullary crest.

readily deflected by movements of endolymph derived from head rotations within the duct, by means of which stimuli are delivered to the sensory hair cells. The three semicircular ducts in their canals thus detect angular accelerations during tilting or turning movements of the head in all three different planes of three-dimensional space.

Microstructure of the vestibular system

The maculae and crests detect the orientation of the head with respect to gravity and changes in head movement by means of the mechanosensitive hair cells. These hair cells are in synaptic contact with afferent and efferent endings of the vestibular nerve on their basolateral aspect. The entire epithelium lies on a bed of thick, fibrous connective tissue containing myelinated vestibular nerve fibres and blood vessels. The axons lose their myelin sheaths as they perforate the basal lamina of the sensory epithelium. There are two types of sensory hair cell in the vestibular system, type I and type II (see Figs 43.5, 43.8).

Type I vestibular sensory cells measure 25 µm in length, with a free surface of 6–7 µm in diameter. The basal part of the cell does not reach the basal lamina of the epithelium. Each cell is typically bottle-shaped, with a narrow neck and a rather broad, rounded basal portion containing the nucleus (see Fig. 43.5). The apical surface is characterized by 30–50 stereocilia (large, regularly arranged, modified microvilli about 0.25 µm across) and a single kinocilium (with the typical '9+2' arrangement of microtubules characteristic of true cilia). The kinocilium is considerably longer than the stereocilia, and may attain 40 µm, whereas the stereocilia are of graded lengths. They are characteristically arranged in regular rows behind the kinocilium in descending order of height, the longest being next to the kinocilium (**Fig. 43.7**). The kinocilium emerges basally from a typical basal body, with a centriole immediately beneath it.

Close to the inner surface of their basal two-thirds, every cell contains numerous synaptic ribbons with associated synaptic vesicles. The postsynaptic surface of an afferent nerve ending encloses the greater part of the sensory cell body in the form of a cup (chalice or calyx). Efferent nerve fibres make synapses with the external surface of the calyx, rather than directly with the sensory cell.

The kinocilium confers structural polarity on the bundle, which relates to functional polarity. The stereocilia and kinocilium are all interconnected by fine extracellular filaments of various types, called cross links. One in particular, the tip link, connects the shorter stereocilia in each row with adjacent stereocilia in the taller row next to it (see Fig. 43.7). The tip link is common to all types of hair cell and is thought to play a central role in transduction; mutations in the proteins that comprise the tip link are significant in Usher syndrome, which is characterized by decreased vestibular function, hearing loss and visual abnormalities. Deflection of the bundle towards the kinocilium results in depolarization of the hair cell and increases the rate of neurotransmitter release from its base. Deflection away from the kinocilium hyperpolarizes the hair

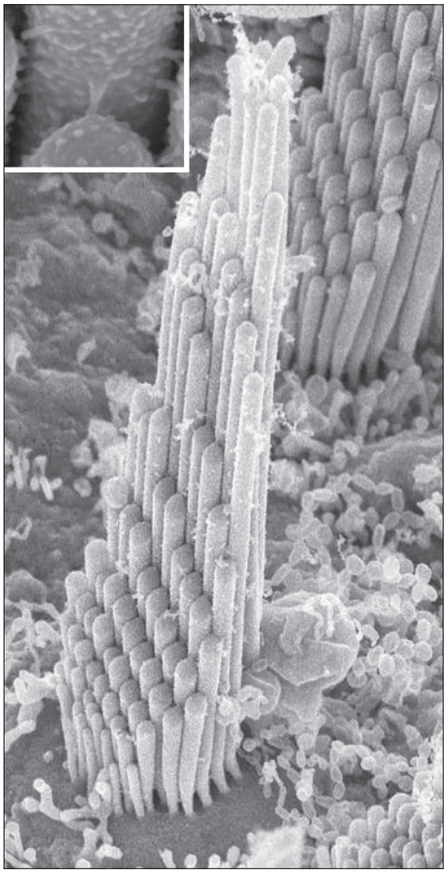

Fig. 43.7 A scanning electron micrograph of a stereociliary bundle from the utricle (guinea pig). The stereocilia are arranged in rows of increasing height towards the tallest element, the kinocilium. Deflection in the direction of the kinocilium results in depolarization of the hair cell. The inset shows a tip link connecting a short stereocilium tip to the tall stereocilium side behind. (Courtesy of DN Furness, School of Life Sciences, Keele University.)

cell and reduces the release of neurotransmitter. How deflections produce these responses will be considered in more detail later.

There is much greater variation in the sizes of type II sensory cells (see Fig. 43.5B,C; **Fig. 43.8**). Some are up to 45 µm long and almost span the entire thickness of the sensory epithelium, whereas others are shorter than type I cells. They are mostly cylindrical, but otherwise resemble type I cells in their contents and the presence of an apical kinocilium and stereocilia. However, their kinocilia and stereocilia tend to be shorter and less variable in length. The most striking difference between type I and II cells is their efferent nerve terminals: type II cells receive several efferent nerve boutons containing a mixture of small clear and dense-core vesicles around their bases, and afferent endings are small expansions rather than chalices.

Polarization allows the hair cells to have specific orientations that optimize their function within each sensory organ. In the maculae, they are arranged symmetrically on either side of the striola. In the utricle, the kinocilia are positioned on the side of the sensory cell nearest to the striola so that the excitatory direction is towards the midline. In the saccule, the structural and functional polarity is the opposite, i.e. away from it. In the ampullary crests, the cells are orientated with their rows of stereocilia at right-angles to the long axis of the semicircular duct. In the lateral crest, the kinocilia are on the side towards the utricle, whereas in the anterior and posterior crests they are away from it. These different arrangements are important functionally because any given acceleration of the head maximally depolarizes one group of hair cells and maximally inhibits a complementary set, thus providing a unique representation of the magnitude and orientation of any movement (for further details, see Furness (2002)).

The type I and II sensory cells are set within a matrix of supporting cells that reach from the base of the epithelium to its surface and form rosettes round the sensory cells, as seen in surface view. Although their form is irregular, they can easily be recognized by the position of their nuclei, which tend to lie below the level of sensory cell nuclei and just above the basal lamina (see Fig. 43.4). The apices of the supporting cells are attached by tight junctions to neighbouring supporting cells and to the hair cells to produce the reticular lamina, a composite layer that forms a plate that is relatively impermeable to cations other than via the mechanosensitive transduction channels of the hair cells.

The otolithic membrane is a layer of extracellular material divided into two strata. The external layer is composed of otoliths or otoconia, which are barrel-shaped crystals of calcium carbonate with angular ends, up to 30 µm long, and heterogeneous in distribution. They are attached to a more basal gelatinous layer into which the stereocilia and kinocilia of the sensory cells are inserted (see Fig. 43.5). The gelatinous material consists largely of glycosaminoglycans associated with fibrous protein.

Endolymphatic duct and sac

The endolymphatic duct runs in the osseous vestibular aqueduct and becomes dilated distally to form the endolymphatic sac. This is a structure of variable size, which may extend through an aperture on the posterior surface of the petrous bone to end between the two layers of the dura on the posterior surface of the petrous temporal bone near the sigmoid sinus (see Fig. 43.1C). The surface cells throughout the entire endolymphatic duct resemble those lining the non-specialized parts of the membranous labyrinth and consist of squamous or low cuboidal epithelium. The epithelial lining and subepithelial connective tissue become more complex where the duct dilates to form the endolymphatic sac. An intermediate or rugose segment and a distal sac can be distinguished. In the intermediate segment, the epithelium consists of light and dark cylindrical cells. Light cells are regular in form and have numerous long surface microvilli with endocytic invaginations between them and large clear vesicles in their apical region. In contrast, dark cells are wedge-shaped and have a narrow base, few apical microvilli and dense, fibrillar cytoplasm.

The endolymphatic sac has important roles in the maintenance of vestibular function. Endolymph produced elsewhere in the labyrinth is absorbed in this region, probably mainly by the light cells. Damage to the sac, or blockage of its connection to the rest of the labyrinth, causes endolymph to accumulate; this produces hydrops, which affects both vestibular and cochlear function. The epithelium is also permeable to leukocytes, including macrophages, which can remove cellular debris from the endolymph, and to various cells of the immune system that contribute antibodies to this fluid.

Cochlear duct

The cochlear duct is a spiral tube that runs within the bony cochlea (see Figs 43.1C, **Fig. 43.9**). The osseous spiral lamina projects for part of the distance between the modiolus and the outer wall of the cochlea and is attached to the inner edge of the basilar membrane. Above it is a thickened ridge of endosteum called the spiral limbus. The endosteum of the outer wall is thickened to form a spiral cochlear ligament that projects inwards as a triangular basilar crest attached to the outer rim of the basilar membrane. Immediately above this is a concavity, the external spiral sulcus (sulcus spiralis externus), above which the thick, highly vascular periosteum projects as a spiral prominence. Above the prominence is a specialized, thick epithelial layer, the stria vascularis. A second, thinner vestibular membrane, Reissner's membrane, extends from the spiral limbus to the outer wall of the cochlea, where it is attached above the stria. Reissner's membrane consists of two layers of squamous epithelial cells separated by a basal lamina. The side facing the scala vestibuli bears flattened perilymphatic cells, with tight junctions between them, creating a diffusion barrier. The endolymphatic side is lined by squamous epithelial cells with many microvilli; these are also joined by tight junctions and are involved in ion transport. The canal thus enclosed between the scala tympani and the scala vestibuli is the cochlear duct (see Fig. 43.9B). It is triangular in cross-section throughout the length of the cochlea. The closed upper end, the lagena, is attached to the cupula. The lower end of the duct turns medially, narrowing into the ductus reuniens, and connects with the saccule (see Fig. 43.1C).

The organ of Corti, the sensory epithelium of the cochlea, sits on the basilar membrane. The apices of the sensory hair cells and the supporting cells it contains are joined by tight junctions to form the reticular lamina. The diffusion barriers that line the cochlear duct ensure that the apices of the sensory hair cells are bathed in endolymph, whereas their lateral and basal regions are bathed in perilymph.

The stria vascularis lies on the outer wall of the cochlear duct, above the spiral eminence (see Fig. 43.9B–C). It has a special stratified epithelium containing a dense intraepithelial capillary plexus and three cell types: superficial marginal, dark or chromophil cells; intermediate light, or chromophobe cells; and basal cells. The endolymphatic surface consists only of the apices of marginal cells. The intermediate and basal cells lie deeper within the stria and send cytoplasmic processes towards the surface, between the deeper parts of the marginal cells. The long descending cytoplasmic processes of the marginal dark cells and the ascending processes of the intermediate and basal cells envelop the intraepithelial capillaries. The stria vascularis is involved in ion transport and helps to produce the unusual ionic composition of endolymph. It is the source of the large positive endocochlear electrical potential, maintenance of which is directly dependent on adequate oxygenation of the epithelial cells, provided by the intraepithelial capillary plexus.

The osseous spiral lamina consists of two plates of bone between which are canals for the cochlear nerve fibres. On the upper plate, the periosteum is thickened to form the spiral limbus (limbus laminae spiralis) (see Fig. 43.9B). It ends externally in the internal spiral sulcus, which in section is shaped like a C. Its upper part, the overhanging limbic edge, is the vestibular labium, and the lower tapering part is the tympanic labium, which is perforated by small holes (the habenula perforata) for branches of the cochlear nerve. The upper surface of the vestibular labium is crossed at right-angles by furrows, separated by numerous elevations, the auditory teeth (dentes acustici). The limbus is covered by a layer that appears superficially to be squamous epithelium; however, only the cells over the 'teeth' are flat, and those in the furrows are flask-shaped interdental cells. The epithelium is continuous with the epithelium in the internal spiral sulcus and on the inferior surface of Reissner's membrane. During development, the interdental cells secrete some of the material that forms the tectorial membrane. The limbus contains fibrocytic cells interspersed with extracellular matrix.

Basilar membrane

The basilar membrane stretches from the tympanic lip of the osseous spiral lamina to the basilar crest of the spiral ligament (see Fig. 43.9B–C). It consists of two zones. The thin zona arcuata stretches from the spiral limbus to the bases of the outer pillar cells and supports the organ of Corti. It is composed of compact bundles of small (8–10 nm diameter) collagenous filaments, mainly radial in orientation. The outer, thicker zona pectinata starts beneath the bases of the outer pillar cells and is attached to the crista basilaris. The basilar membrane is trilaminar in the zona pectinata, but the upper and lower layers fuse at its attachment to the crista basilaris. The length of the basilar membrane is 35 mm; its width increases from 0.21 mm basally to 0.36 mm at its

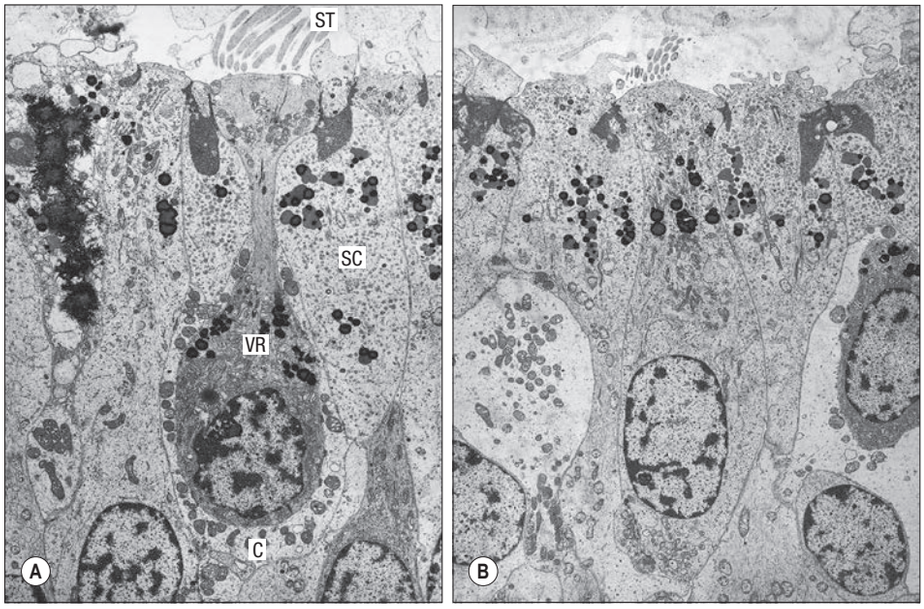

Fig. 43.8 Human vestibular hair cells (transmission electron micrographs). **A**, Type I cell (VR) bearing an apical group of stereocilia (ST) seen in a vertical section through the macula. Benign paroxysmal positional vertigo is a condition in which a sensation of rotation with associated nystagmus is induced by adopting a particular position (with the abnormal ear dependent). It is believed that calcium carbonate crystals from the otoliths become freed from the otolithic membrane and, in certain positions, drop into the ampulla of the posterior semicircular duct, possibly becoming adherent to the cupula and rendering it gravity-sensitive. In certain positions, the alignment of the axis of the posterior semicircular canal with gravity results in the displacement of the cupula and the activation of the vestibulo-ocular reflex, leading to compensatory nystagmoid eye movements in response to apparent head movements.

Epley's canalith repositioning procedure relies on the adoption of a series of body postures designed to allow the aberrant crystals (or canaliths) to float out of the posterior semicircular duct and to stick to the wall of the vestibule. Cure rates in excess of 80% have been recorded and the procedures have largely superseded surgical procedures designed to denervate the ampulla of the posterior semicircular duct in its canal (singular neurectomy) or obliterate the canal completely (Furman and Cass 1999).

The spiral ligament is lateral to the stria vascularis. It is composed of thick collagenous fibres interspersed with fibrocytic cells of several different types, and root cells that send large processes into the ligament from the region of the basilar crest. There is an extensive capillary network that parallels that of the stria vascularis. The fibrocytes and the root cells express connexins and have gap junctional systems (Jagger et al 2010) that allow transcellular transport of ions, although the two types of cell are not directly coupled. It is thought that potassium recycling from perilymph to endolymph is mediated partly through these gap junctional networks emanating from the Deiters' cells underlying the sensory hair cells. Late-onset hearing loss (DFN3) is thought to be the result of fibrocyte degeneration (Minowa et al 1999).

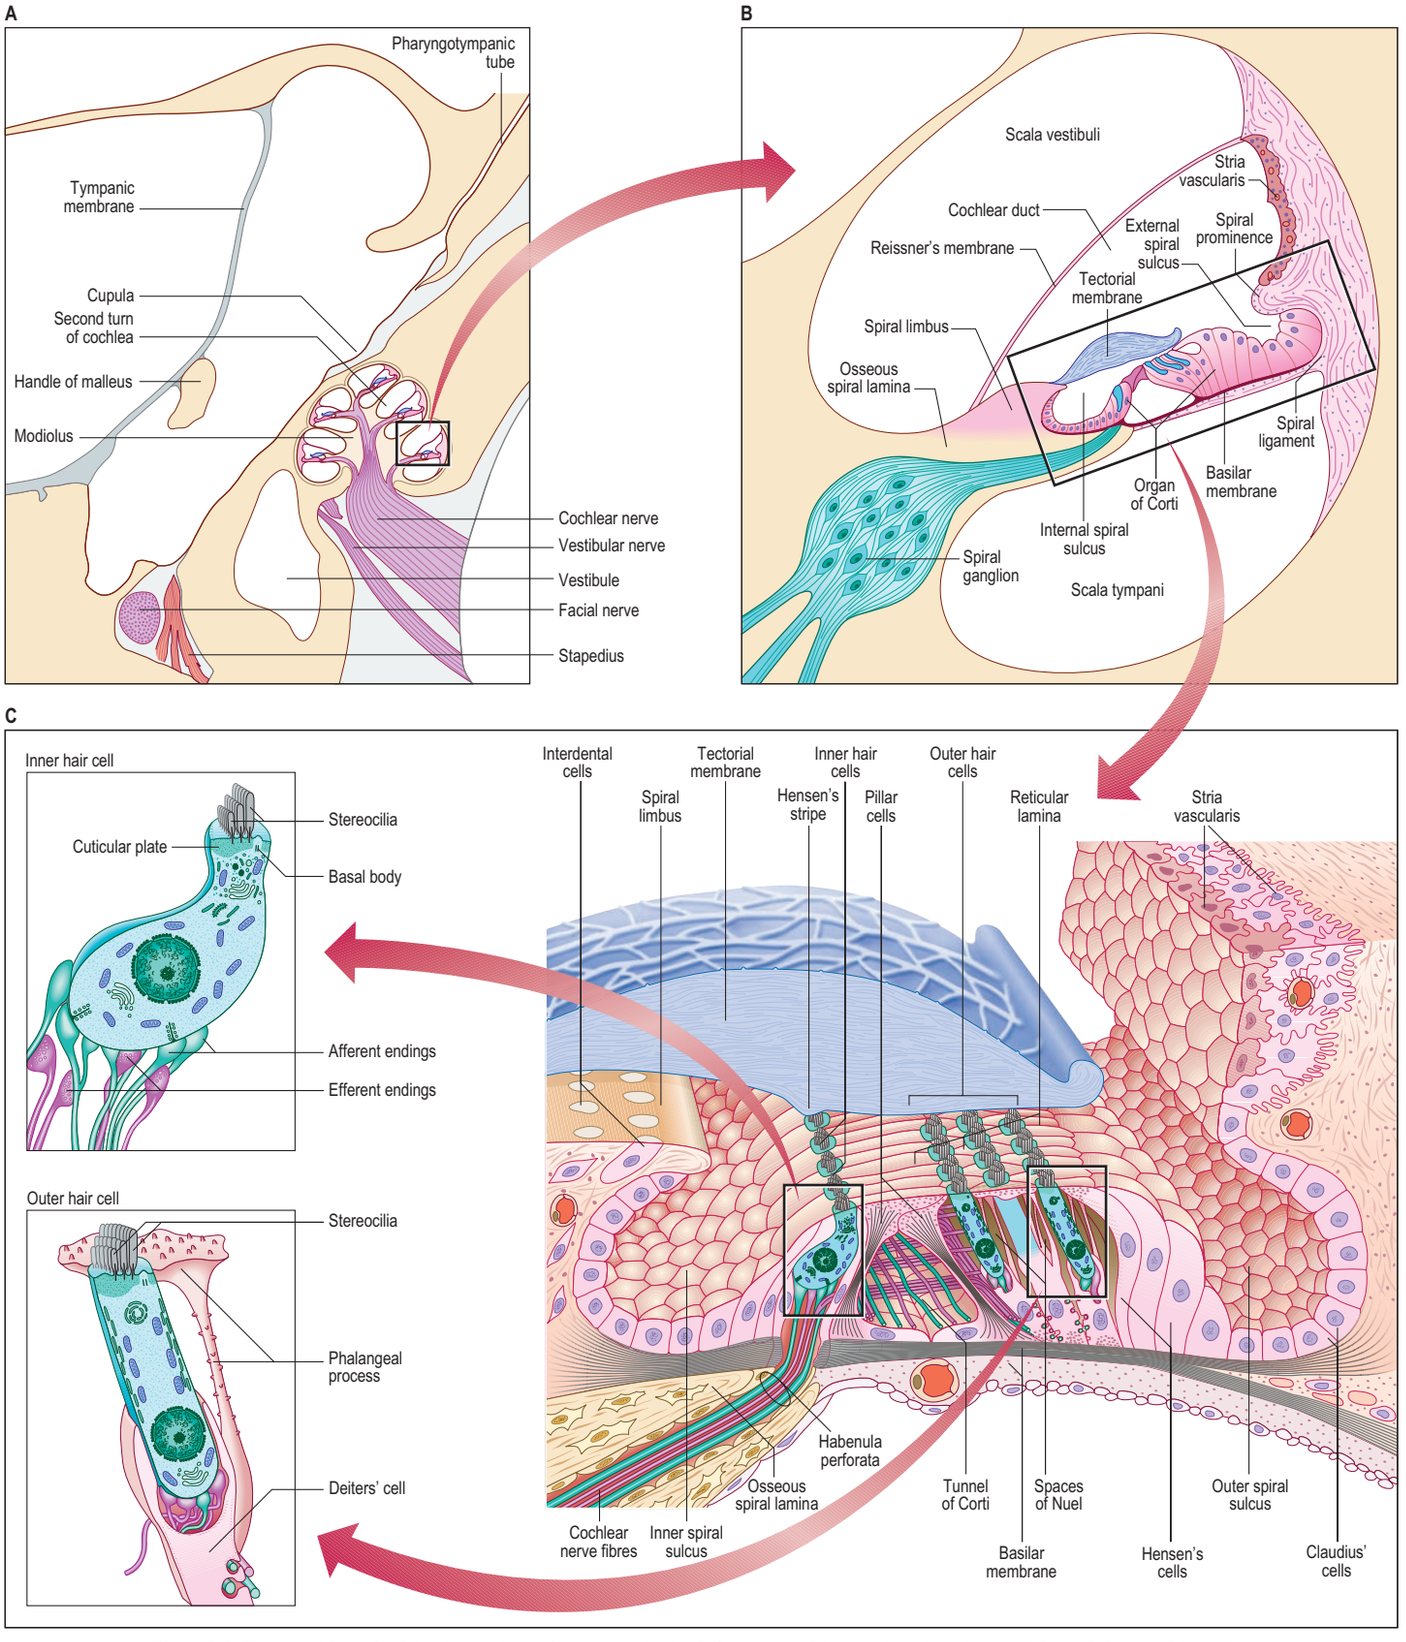

Fig. 43.9 The cochlea. **A**, A horizontal section through the left temporal bone showing the position of the cochlea with respect to the tympanic cavity. **B**, A section through the second turn of the cochlea seen in **A**. The modiolus is to the left. **C**, The structure of the cochlear organ of Corti and stria vascularis, showing the arrangement of the various types of cell and their overall innervation. The organization of the inner and outer hair cells and their synaptic connections are also depicted. **A** and **B** are drawn from histological sections.

apex, accompanied by corresponding narrowing of the osseous spiral lamina and a decrease in the thickness of the basilar crest. The lower or tympanic surface of the basilar membrane is covered by a layer of vascular connective tissue and elongated perilymphatic cells. One vessel, the spiral vessel (vas spirale), is larger; it lies immediately below the tunnel of Corti.

Organ of Corti

The organ of Corti consists of a series of epithelial structures that lie on the zona arcuata of the basilar membrane (see Fig. 43.9B–C). The more central of these structures are two rows of cells: the internal (inner) and external (outer) pillar cells. The bases of the pillar cells are expanded,

and rest contiguously on the basilar membrane, but their rod-like cell bodies are widely separated. The two rows incline towards each other and come into contact again at the heads of the pillars, enclosing between them and the basilar membrane the tunnel of Corti, which has a triangular cross-section (see Fig. 43.9C). Internal to the inner pillar cells is a single row of inner hair cells. External to the outer pillar cells are three or four rows of outer hair cells. The bases of the outer hair cells are cupped by supporting cells called outer phalangeal (Deiters') cells, except for a gap where cochlear axons synapse with them. The apical ends of the hair cells and apical processes of the supporting cells form a regular mosaic called the reticular lamina, which is covered by the tectorial membrane, a gel-like structure projecting from the spiral limbus. The reticular lamina is impervious to ions and thus maintains the electrochemical gradient between the fluids surrounding the apices and the basolateral membranes of the sensory hair cells. A narrow gap separates the tectorial membrane from the reticular lamina except where the apical stereocilia of the outer hair cells project to make contact with it.

In addition to the tunnel of Corti, other intercommunicating spaces, the spaces of Nuel, surround the outer hair cells. This entire intercommunicating complex of spaces of Nuel and tunnel of Corti is filled with perilymph, which diffuses through the matrix of the basilar membrane. The fluid in these spaces is also sometimes called the cortilymph; it is possible that there are minor alterations in perilymphatic composition within it because it is exposed to the activities of synaptic endings and specialized excitable cells.

Each pillar cell has a base or crus, an elongated scapus (rod) and an upper end or caput (head) (see Fig. 43.9C); each crus and caput are in contact, but the scapi are separated by the tunnel of Corti. Electron microscopy shows many microtubules, 30 nm in diameter, arranged in linked parallel bundles of 2000 or more in the scapus, originating in the crus and diverging above the scapus to terminate in the head region. The nucleus is situated in the foot-like expansion resting on the basal lamina.

There are almost 6000 inner pillar cells. Their bases rest on the basilar membrane near the tympanic lip of the internal spiral sulcus, and their bodies form an angle of approximately 60° with the basilar membrane. Their heads resemble the proximal end of the ulna, with deep concavities for the heads of the outer pillar cells, which they overhang to form the top of the tunnel of Corti. There are almost 4000 outer pillar cells. They are longer and more oblique than the inner pillar cells and form an angle of approximately 40° with the basilar membrane. Their heads fit into the concavities on the heads of the inner pillar cells and project externally between the first row of outer hair cells as thin processes that contact the processes of the Deiters' cells. The distances between the bases of the inner and outer pillar cells increase from the cochlear base to its apex, whereas the angles they make with the basilar membrane diminish.

Cochlear hair cells are the sensory transducers of the cochlea; collectively, they detect the amplitude and frequency of the sound waves that enter the cochlea. All cochlear hair cells have a common pattern of organization. They are elongated cells with a group of modified apical microvilli or stereocilia (which contain parallel arrays of actin filaments), similar to those of vestibular hair cells, and a group of synaptic contacts with cochlear nerve fibres at their rounded bases (**Fig. 43.10**). The inner hair cells form a single row along the inner edge of inner pillar cells (and the spiral tunnel), whereas the outer hair cells are arranged in three or, in some regions of the human cochlea, in four or even five rows, interspersed with supporting cells (**Fig. 43.10A**). These two groups have distinctive roles in sound reception; the differences in their detailed structure reflect this functional divergence. There are 3500 inner hair cells and 12,000 outer hair cells. The two sets of hair cells lean towards each other apically at about the same angles as the neighbouring inner and outer pillar cells. The geometric arrangement of these cells is very precise, and this pattern is closely related to the sensory performance of the cochlea.

The inner hair cells are pear-shaped and slightly curved; the narrower end is directed towards the surface of the organ of Corti and the wider basal end is positioned some distance above the inner end of the basilar membrane (see Fig. 43.9C). The inner hair cells are surrounded by inner border cells and by inner phalangeal cells, which are attached externally to the heads of the inner pillar cells. The flat apical surface of each inner hair cell is elliptical when viewed from above, its long axis directed in the direction of the row of hair cells (see Fig. 43.10A). The breadth of the apex exceeds that of the inner pillar cells so that each inner hair cell is related to more than one inner pillar cell. The apex bears 50–60 stereocilia, arranged in several ranks of progressively ascending height, the tallest on the strial side. The tips of the shorter rows are connected diagonally to the sides of the adjacent taller stereocilia by thin filaments called tip links; each stereocilium is also connected to all its neighbours

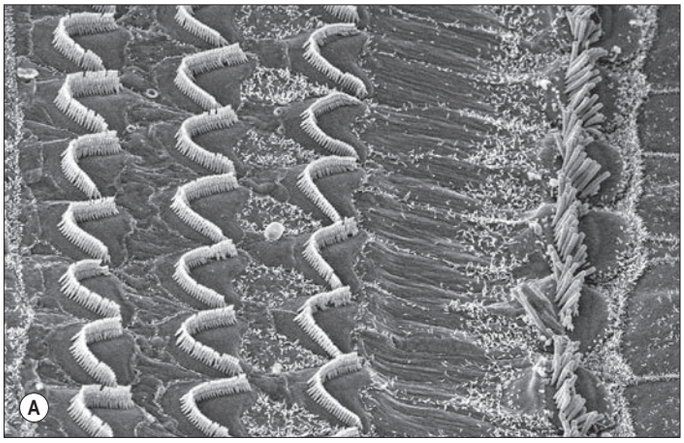

Fig. 43.10 Scanning electron micrographs of the surface of the organ of Corti (guinea pig). **A**, The reticular lamina. Three rows of V-shaped stereociliary bundles can be seen protruding from the apices of the outer hair cells. They are separated from the single row of inner hair cells (which have relatively linear stereociliary bundles) by the apices of the inner pillar cells. (Courtesy of DN Furness, School of Life Sciences, Keele University.) (B, *continued online*)

by a variety of lateral links. The height of a stereociliary row varies along the length of the cochlea, being tallest at the apex and shortest at its base. The stereociliary bases insert into a transverse lamina of dense fibrillar material, the cuticular plate, which lies immediately beneath the apical surface of each inner hair cell. The cuticular plate includes a small aperture containing a basal body. During development, a kinocilium containing microtubules is anchored here, a condition that persists in vestibular hair cells.

At its base, each inner hair cell forms 10 or more synaptic contacts with afferent endings, each being marked by a presynaptic structure similar to the ribbon synapses of the retina. Occasionally, an efferent synapse makes direct contact with a hair cell base but these are usually presynaptic to the terminal expansions of afferent endings, rather than to the hair cell itself.

Outer hair cells are long cylindrical cells that are nearly twice as tall as the inner hair cells (see Figs 43.9C, 43.10A). There is a gradation of length: the outermost row is longest in any one cochlear region, and those of the cochlear apex are taller than those of the base. They are surrounded by the apical or phalangeal processes of the Deiters' cells or, on the internal side of the inner row, by the heads of the outer pillar cells. The stereocilia, which may number up to 100 per cell, are arranged in three rows of graded heights; the tallest is on the outer side. The rows are arranged in the form of a V or W, depending on cochlear region, the points of the angles directed externally. The stereocilia are also graded in height according to cochlear region; those of the cochlear base are shortest. Like those of inner hair cells, the stereocilia possess tip links (see Fig. 43.10B) and other filamentous connections with their neighbours and are inserted at their narrow bases into a cuticular plate. The tallest stereocilia are embedded in shallow impressions on the underside of the tectorial membrane.

The rounded nucleus is positioned near the base of the cell. Below the nucleus are a few ribbon-like synapses associated with afferent endings of the cochlear nerve. The latter are fewer in number and smaller than the cluster of efferent boutons that contact the base of the cell. The neurotransmitter at the afferent synapse in both inner and outer hair cells is glutamate whereas that of the efferent endings is acetylcholine, although other neurotransmitters or neuromodulators have been demonstrated.

Cochlear hair cells respond with phenomenal speed and sensitivity to sound vibrations that cause submicron deflections of their stereociliary hair bundles. Outer hair cells not only detect these vibrations but also generate force to increase auditory sensitivity and frequency discrimination. (See Fettiplace and Hackney (2006) for further details about the sensory and motor functions of auditory hair cells.)

Deiters' or phalangeal cells lie between the rows of outer hair cells. Their expanded bases lie on the basilar membrane and their apical ends partially envelope the bases of the outer hair cells (see Fig. 43.9C; **Fig. 43.11**). Each has a finger-like (phalangeal) process that extends diagonally upwards between the hair cells to the reticular membrane, where it forms a plate-like expansion that fills the gaps between hair cell apices.

Five or six rows of columnar supporting cells or external limiting cells, such as Hensen's cells and Claudius' cells, lie external to the Deiters' cells (see Fig. 43.9C).

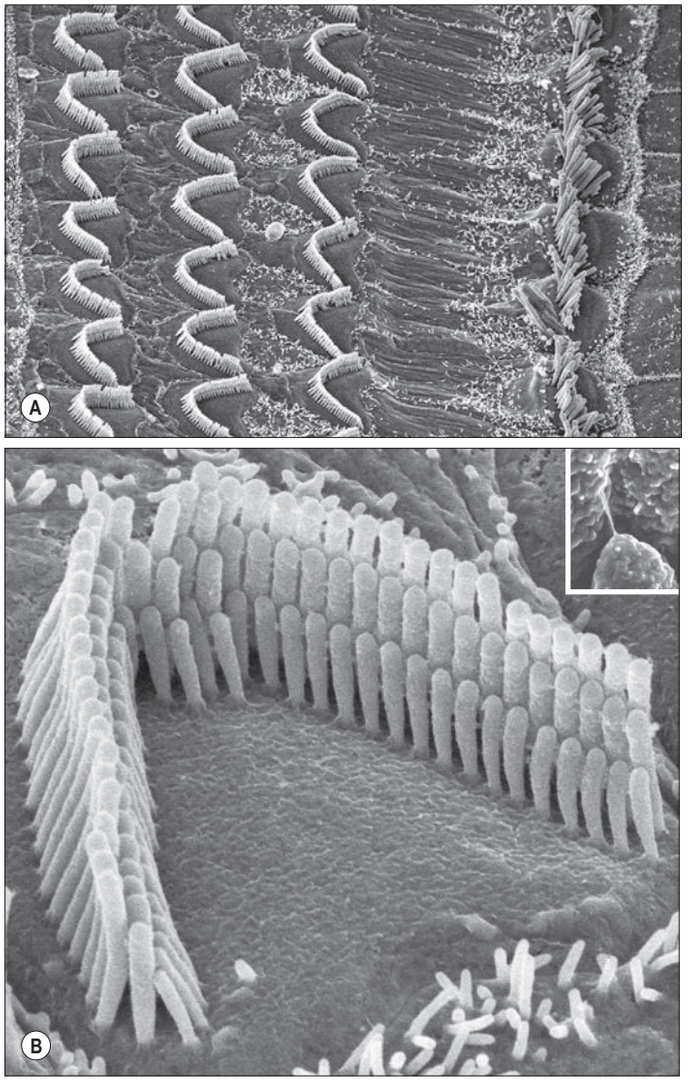

Fig. 43.10 Scanning electron micrographs of the surface of the organ of Corti (guinea pig). **A**, The reticular lamina. Three rows of V-shaped stereociliary bundles can be seen protruding from the apices of the outer hair cells. They are separated from the single row of inner hair cells (which have relatively linear stereociliary bundles) by the apices of the inner pillar cells. **B**, The stereociliary bundle of one outer hair cell, showing three rows of stereocilia increasing in height; deflection of the stereocilia in the direction of the tallest row results in depolarization of the hair cell. Microvilli can be seen on the surface of Deiters' cells (front right). The inset shows a tip link connecting a short stereocilium tip to the side of the tall stereocilium behind. (Courtesy of DN Furness, School of Life Sciences, Keele University.)

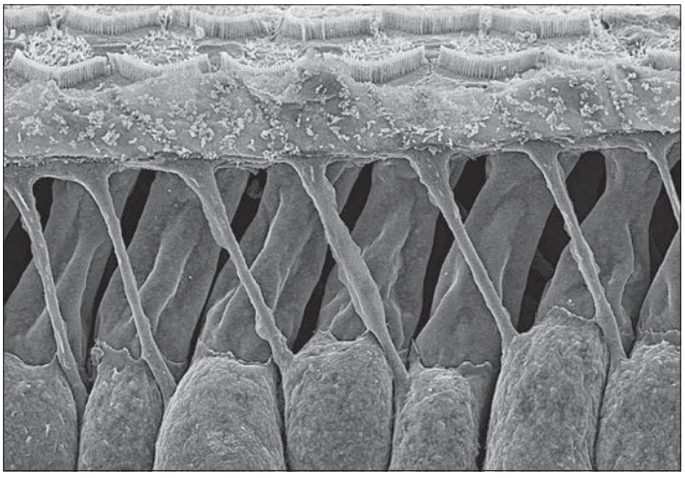

Fig. 43.11 A scanning electron micrograph of a portion of the organ of Corti (guinea pig), dissected to expose the outer row of outer hair cells and their attendant Deiters' cells with narrow phalangeal processes. The stereociliary bundles of two rows of outer hair cells are visible above the reticular lamina. (Courtesy of DN Furness, School of Life Sciences, Keele University.)

The apices of the hair cells and supporting cells that form the reticular lamina are linked by tight junctions, adherens junctions and desmosomes. This arrangement is significant for two reasons. The reticular lamina creates a highly impermeable barrier to the passage of ions other than via the mechanotransducer channels in the stereociliary membranes. It also forms a rigid support between the apices of the hair cells, coupling them mechanically to the movements of the underlying basilar membrane, which causes lateral shearing movements between the stereocilia and the overlying tectorial membrane. If there is hair cell loss as a result of trauma such as excessive noise, or ototoxic drugs, the supporting cells expand rapidly to fill the gap, disturbing the regular pattern of the reticular lamina (phalangeal scars) but restoring its function.

Hair cell mechanotransduction

Mechanotransduction is central to both hearing and balance and is a phenomenon that is shared by all the sensory hair cells of vestibular and auditory epithelia. The basic mechanism is the same in all of the different types of hair cell and is dependent on common features of the hair bundle: specifically, the 'staircase' array of stereocilia and the tip links connecting the tips of shorter and adjacent taller stereocilia. Deflections of the bundle in an excitatory (depolarizing) direction cause tension in the tip link, which acts to open non-specific cationic mechanoelectrical transduction channels. The identity of these channels is now thought to be a protein, transmembrane channel-like protein 1 (TMC1), which, together with several known accessory proteins, is located in the membrane at the lower end of the tip link. Mutations in TMC1 are one of the commonest forms of genetic hearing loss. Influx of potassium and calcium ions through these channels, depolarizes the cell and leads to calcium influx through basolateral voltage-gated calcium channels, which causes release of neurotransmitter. The hair cells also have basolateral potassium channels that allow efflux of potassium into perilymph. The tip link that is central to this process consists of two molecules of cadherin 23 and two molecules of protocadherin 15, forming a strong twisted strand (Hackney and Furness 2013). The importance of this structure is emphasized by the fact that mutations in these cadherins underlie deaf-blindness conditions (Usher syndrome).

The sensitivity of mechanotransduction is greatly increased by the combination of the hair-cell membrane potential (−70 mV) and the endolymphatic potential (+80 mV), producing an overall driving potential of up to 150 mV. It is therefore vital to maintain a high potassium concentration, despite its depletion from endolymph during detection of acoustic or balance stimuli.

Tectorial membrane

The tectorial membrane overlies the sulcus spiralis internus and organ of Corti, and is a stiff, gelatinous plate (see Fig. 43.9B–C). It contains collagen types II, V and IX, interspersed with glycoproteins (tectorins), which contribute approximately half of the total protein.

In transverse section, the tectorial membrane has a characteristic shape. The underside is nearly flat and the upper surface is convex, and it is thin on the modiolar side where it is attached to the vestibular labium of the spiral limbus. Its outer part forms a thickened ridge, overhanging the edge of the reticular lamina. The lower surface is relatively smooth, except where the stereocilia of the outer hair cells are embedded in the membrane, leaving a pattern of W- or V-shaped indentations and an S-shaped ridge called Hensen's stripe, which projects towards the stereocilia of the inner hair cells. The interdental cells of the spiral limbus are believed to secrete the membrane.

VASCULAR SUPPLY

Arteries

The inner ear is principally supplied by the labyrinthine artery. The stylomastoid branch of either the occipital artery or the posterior auricular artery (see Fig. 35.8) also supplies the semicircular canals.

Labyrinthine artery

The labyrinthine artery arises from the basilar artery, sometimes from the anterior inferior cerebellar artery. It divides at the bottom of the internal acoustic meatus into cochlear and vestibular branches. The cochlear branch divides into 12–14 twigs, which traverse the canals in the modiolus and are distributed as a capillary plexus to the spiral lamina, basilar membrane, stria vascularis and other cochlear structures. Vestibular arterial branches supply the utricle, saccule and semicircular ducts.

Veins

Descriptions of the venous drainage of the inner ear are often conflicting, presumably reflecting both normal variation and the existence of connections between the veins that provide the potential for collateral circulation. Veins draining the vestibule and semicircular canals accompany the arteries. They pass towards the utricle to form the vein of the vestibular aqueduct, which empties into either the sigmoid or inferior petrosal sinus. The vein of the cochlear aqueduct (inferior cochlear vein) usually drains into either the inferior petrosal sinus or the superior bulb of the internal jugular vein. It is formed by the union of the common modiolar and vestibulocochlear veins and provides almost all of the venous outflow of the cochlea (Wright and Roland 2013). The common modiolar vein is formed by the union of the anterior and posterior spiral veins near the basal cochlear turn; the vestibulocochlear vein is formed by the confluence of the anterior and posterior vestibular veins and the vein of the round window. When present, a labyrinthine vein drains the apical and middle cochlear coils into either the posterior part of the superior petrosal sinus or the transverse sinus or the inferior petrosal sinus.

For details of the microvasculature of the cochlea of humans and other mammals, see Axelsson (1988).

INNERVATION

Vestibulocochlear nerve

The vestibulocochlear nerve emerges from the cerebellopontine angle. It courses through the posterior cranial fossa in close association with the facial nerve, nervus intermedius and labyrinthine vessels. Together with these structures, it enters the petrous temporal bone via the porus acusticus of the internal acoustic meatus, and divides into an anterior trunk, the cochlear nerve, and a posterior trunk, the vestibular nerve (**Fig. 43.12A**). Both contain the centrally directed axons of bipolar neurones, together with a smaller number of efferent fibres that arise from brainstem neurones and terminate on cochlear and vestibular sensory cells. In humans, the intratemporal portion of the vestibulocochlear nerve consists of two histologically distinct portions: a central glial zone adjacent to the brainstem, and a peripheral or non-glial zone (Bridger and Farkashidy 1980). In the glial zone, the axons are supported by central neuroglia, whereas in the non-glial zone they are ensheathed by Schwann cells. The non-glial zone sometimes extends into the cerebellopontine angle medial to the internal acoustic meatus in human vestibulocochlear nerves. During development, a gap of several weeks has been reported between the onset of Schwann cell myelination distally and glial myelination proximally; it has been suggested that the gap may coincide with the time of the final maturation of the organ of Corti.

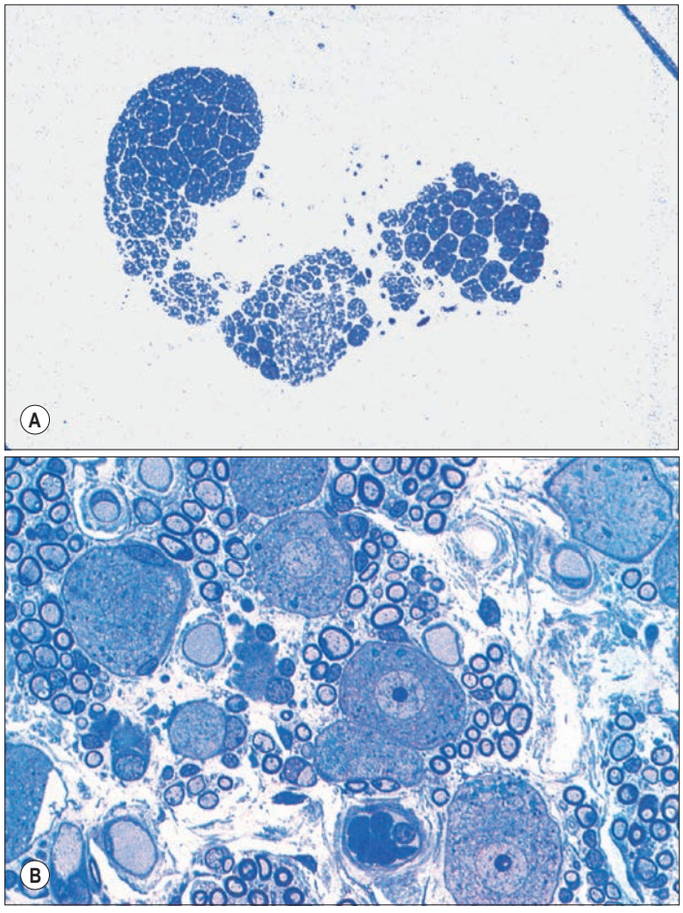

Fig. 43.12 The vestibulocochlear nerve (human). **A**, A transverse section. The cochlear nerve (the comma-shaped profile on the left) abuts the inferior division of the vestibular nerve (right). The singular nerve is a separate fascicle between the superior and inferior divisions of the vestibular nerve. **B**, A portion of a vestibular ganglion, showing neuronal perikarya, myelinated axons and small blood vessels. (Toluidine blue stained resin sections courtesy of H Felix, M Gleeson and L-G Johnsson, ENT Department, University of Zurich and School of Medicine, King's College London.)

(For further details about the development of the human cochlear nerve, see Ray et al (2005).)

In audiological practice, it is important to distinguish between intratemporal and intracranial lesions. However, this surgical distinction does not correlate with the precise anatomical description of peripheral and central portions of the auditory and vestibular systems. Clinically, the term 'peripheral auditory lesion' is used to describe lesions peripheral to the spiral ganglion, and the term 'peripheral vestibular disturbance' includes lesions of the vestibular ganglion and the entire vestibular nerve.

Vestibular nerve

The cell bodies of the bipolar neurones that contribute to the vestibular nerve lie in the vestibular ganglion, which is situated in the trunk of the nerve within the lateral end of the internal acoustic meatus (**Fig. 43.12B**). Their peripheral processes innervate the maculae of the utricle and saccule and the ampullary crests of the semicircular ducts (see below). Their axons travel to the central nervous system in the vestibular nerve, which enters the brainstem at the cerebellopontine angle and terminates in the vestibular nuclear complex. Neurones in this complex project to motor nuclei in the brainstem and upper spinal cord, and to the cerebellum and thalamus. Thalamic efferent projections pass to a cortical vestibular area that is probably located near the intraparietal sulcus in area 2 of the primary somatosensory cortex.

Vestibular (Scarpa's) ganglion

The cell bodies of the neurones in the vestibular ganglion vary considerably in size: their circumferences range from 45 to 160 µm (Felix et al 1987). No topographically ordered distribution relating to size has been found. The cell bodies are notable for their abundant granular endoplasmic reticulum, which in places forms Nissl bodies, and prominent Golgi complexes. They are covered by a thin layer of satellite cells and are often arranged in pairs, closely abutting each other so that only a thin layer of endoneurium separates the adjacent coverings of satellite cells. This arrangement has led to speculation that ganglion cells may affect each other directly by electrotonic spread (ephaptic transmission: see Felix et al (1987)).

Two distinct sympathetic components have been identified in the vestibular ganglion: a perivascular adrenergic system derived from the stellate ganglion, and a blood vessel-independent system derived from the superior cervical ganglion.

Intratemporal vestibular nerve

The peripheral processes of the vestibular ganglion cells are aggregated into definable nerves, each with a specific distribution. The main nerve divides at and within the ganglion into superior and inferior divisions, which are connected by an isthmus. The superior division, the larger of the two, passes through the small holes in the superior vestibular area at the fundus of the internal acoustic meatus (see Fig. 43.3) and supplies the ampullary crests of the lateral and anterior semicircular ducts via the lateral and anterior ampullary nerves, respectively. A secondary branch of the lateral ampullary nerve supplies the macula of the utricle; however, the greater part of the utricular macula is innervated by the utricular nerve, which is a separate branch of the superior division. Another branch of the superior division supplies part of the saccule.

The inferior division of the vestibular nerve passes through small holes in the inferior vestibular area (see Fig. 43.3) to supply the remainder of the saccule and the posterior ampullary crest via saccular and singular branches, respectively; the latter passes through the foramen singulare. Occasionally, a very small supplementary or accessory branch innervates the posterior crest; it is probably a vestigial remnant of the crista neglecta, an additional area of sensory epithelium found in some other mammals but seldom in humans.

Afferent and efferent cochlear fibres are also present in the inferior division of the vestibular nerve but leave at the anastomosis of Oort to join the main cochlear nerve (see review by Warr (1992)). Another anastomosis, the vestibulofacial anastomosis, is situated more centrally between the facial and vestibular nerves and is the point at which fibres originating in the intermediate nerve pass from the vestibular nerve to the main trunk of the facial nerve.

There are approximately 20,000 fibres in the vestibular nerve, of which 12,000 travel in the superior division and 8000 travel in the inferior division. The distribution of fibre diameters is bimodal, with peaks at 4 µm and 6.5 µm. The smaller fibres go mainly to the type II hair cells and the larger fibres tend to supply the type I hair cells. In addition to the afferents, efferent and autonomic fibres have been identified. Efferent fibres synapse exclusively with the afferent calyceal terminals around type I cells and usually with the afferent boutons on type II cells, although a few are in direct contact with the cell bodies of type II cells. The autonomic fibres do not contact vestibular sensory cells but terminate beneath the sensory epithelia.

Anatomy of balance and posture

The vestibular labyrinths on each side of the head are arranged symmetrically with respect to each other. Vestibular sensory pathways are concerned with perception of the position of the head in space and movement of the head; they also establish important connections for reflex movements that govern the equilibrium of the body and the fixity of gaze.

The vestibular system consists of two otolithic organs – the utricle and the saccule – and three semicircular ducts in their osseous canals. The otolithic organs detect linear acceleration due to gravitational pull (gravito-inertial acceleration) and the direction of other linear accelerations such as the up-and-down movements of the head that occur in running. They also respond when the head is tilted relative to gravity: so-called pitch (forward and backward tilting) and roll (side-to-side tilting) movements. The semicircular canals detect angular accelerations resulting from rotations of the head or body.

The stereocilia in the apical hair bundles of the mechanosensitive hair cells in each of these organs are embedded in an overlying accessory gel-like structure, the otolithic membrane (in the utricle and the saccule) and the cupula (in the semicircular ducts). Their apical surfaces are bathed in endolymph; tight junctional complexes between the apices of the hair cells and their adjacent supporting cells separate the endolymph from the perilymph that bathes their basolateral surfaces. As noted earlier, deflection of the stereocilia (caused by displacements of their overlying accessory membranes by fluid movements in the membranous labyrinth) produces either an increased or a decreased rate of opening of the mechanotransduction channels at their tips, depending

on whether they are deflected towards or away from the tallest row, respectively. The change in the membrane potential of the receptor cell is signalled to the brain as a change in the firing frequency of the vestibular nerve afferents (either an increase or a decrease of the basal resting discharge, depending on the direction of stimulation). The signals are compared centrally with visual and somatosensory signals, which also signal the position of the head in space (for a more detailed account, see Furness (2002)).

Semicircular canals

Angular acceleration and deceleration of the head cause a counterflow of endolymph in the semicircular ducts in the semicircular canals, which deflects the cupula of each crista and displaces the stereociliary/kinociliary bundles. When a steady velocity of head movement is reached, the endolymph rapidly adopts the same velocity as the surrounding structures because of friction with the canal walls, so that the cupula and receptor cells return to their resting state. The three semicircular canals are orientated approximately at right-angles to each other, which means that all possible directions of acceleration can be detected. Directional sensitivity to head movement is coded by opposing receptor signals: the left and right semicircular canals of each functional pair (e.g. the left and right anterior canals) respond oppositely to any movement of the head that affects them (**Fig. 43.13**). Some vestibular neurones receive a bilateral input from vestibular receptors, enabling them to compare the discharge rates of right and left canal afferents, a mechanism that increases the sensitivity of the system.

Maculae

In the maculae, the weight of the otoconial crystals creates a gravitational pull on the otoconial membrane and thus on the stereociliary bundles of the sensory cells that are inserted into its base. Because of this, they are able to detect the static orientation of the head with respect to gravity. They also detect shifts in position according to the extent to which the stereocilia are deflected. The two maculae are set at right-angles to each other, and the cells of both are orientated functionally in opposite directions across their striolar boundaries. Movement causes depolarization of the hair cells on one side of the striola and hyperpolarization of cells on the other side; because the striola is curved, small groups of hair cells on the macular epithelium each respond to a specific direction of head tilt or linear acceleration (**Fig. 43.14**). Moreover, because the otoconia have a collective inertia/momentum, linear acceleration and deceleration along the anteroposterior axis can be detected by the lag or overshoot of the otoconial membrane with respect to the epithelial surface, and so the saccular macula is able to signal these changes of velocity.

The macular receptors can also be stimulated by low-frequency sound, which sets up vibratory movements in the otoconial membrane, although this appears to require relatively high sound levels. Efferent synapses on the afferent endings of the type I sensory cells and on the bases of type II cells receive inputs from the brainstem that appear to be inhibitory. They serve to reduce the activity of the afferent fibres either indirectly, in the case of the type I cells, or directly, for the type II cells.

Visual reflexes

The vestibular system plays a major role in the control of visual reflexes, which allow the fixation of gaze on an object in spite of movements of the head, and require the coordinated movements of the eye, neck and upper trunk. Constant adjustments of the visual axes are achieved chiefly through the medial longitudinal fasciculus, which connects the vestibular nuclear complex with neurones in the oculomotor, trochlear and abducens nuclei and with upper spinal motor neurones (**Fig. 43.15**; see Fig. 44.12), and also by the vestibulospinal tracts. See Chapter 29 for further information about the vestibulo-ocular reflex.

Abnormal activity of the vestibular input or central connections has various effects on these reflexes, e.g. the production of nystagmus. This can be elicited by the caloric test, a clinical test of vestibular function, by syringing the external acoustic meatus with water above or below body temperature, a procedure that appears to stimulate the cristae of the lateral semicircular duct directly. Spontaneous high activity in the afferent fibres of the vestibular nerve is seen in Ménière's disease, in which those affected experience a range of disturbances, including the sensation of dizziness and nausea, the latter reflecting the vestibular input to the vagal reflex pathway.

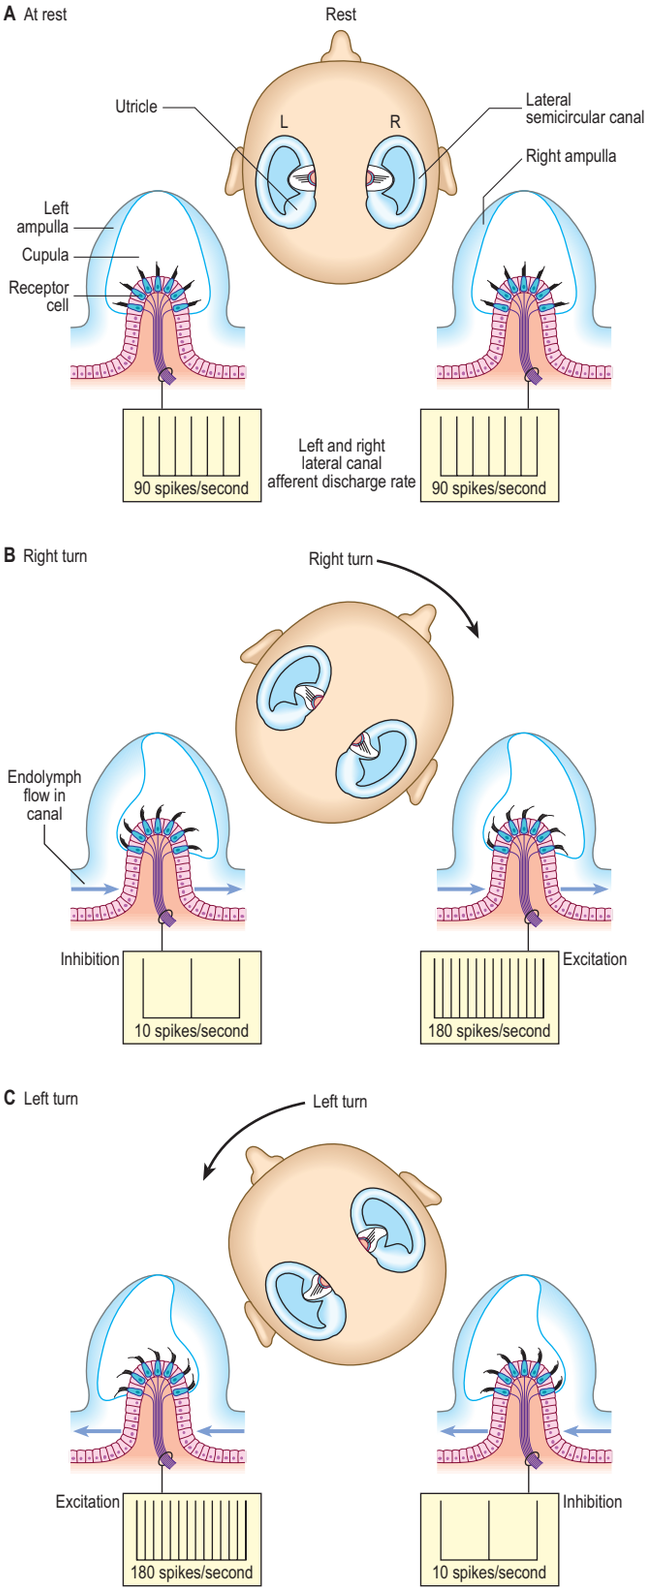

Fig. 43.13 The response of the lateral semicircular canals to head rotation in the horizontal plane. The firing rates of afferents from the left and right lateral canals are equivalent at rest (**A**). However, when the head is turned to the right (**B**) or to the left (**C**), receptor depolarization and afferent fibre excitation occurs on the side to which the head turns; there is inhibition on the contralateral side.

Cochlear nerve

Intratemporal cochlear nerve

The cochlear nerve connects the organ of Corti to the cochlear nuclei and related nuclei of the brainstem. The cochlear nerve lies inferior to the facial nerve throughout the internal acoustic meatus (see above). It becomes intimately associated with the superior and inferior divisions of the vestibular nerve, which are situated in the posterior compartment of the canal and leaves the internal acoustic meatus in a common fascicle (see Fig. 43.12A).

There are 30,000–40,000 nerve fibres in the human cochlear nerve (for review, see Nadol (1988)). Their fibre diameter distribution is

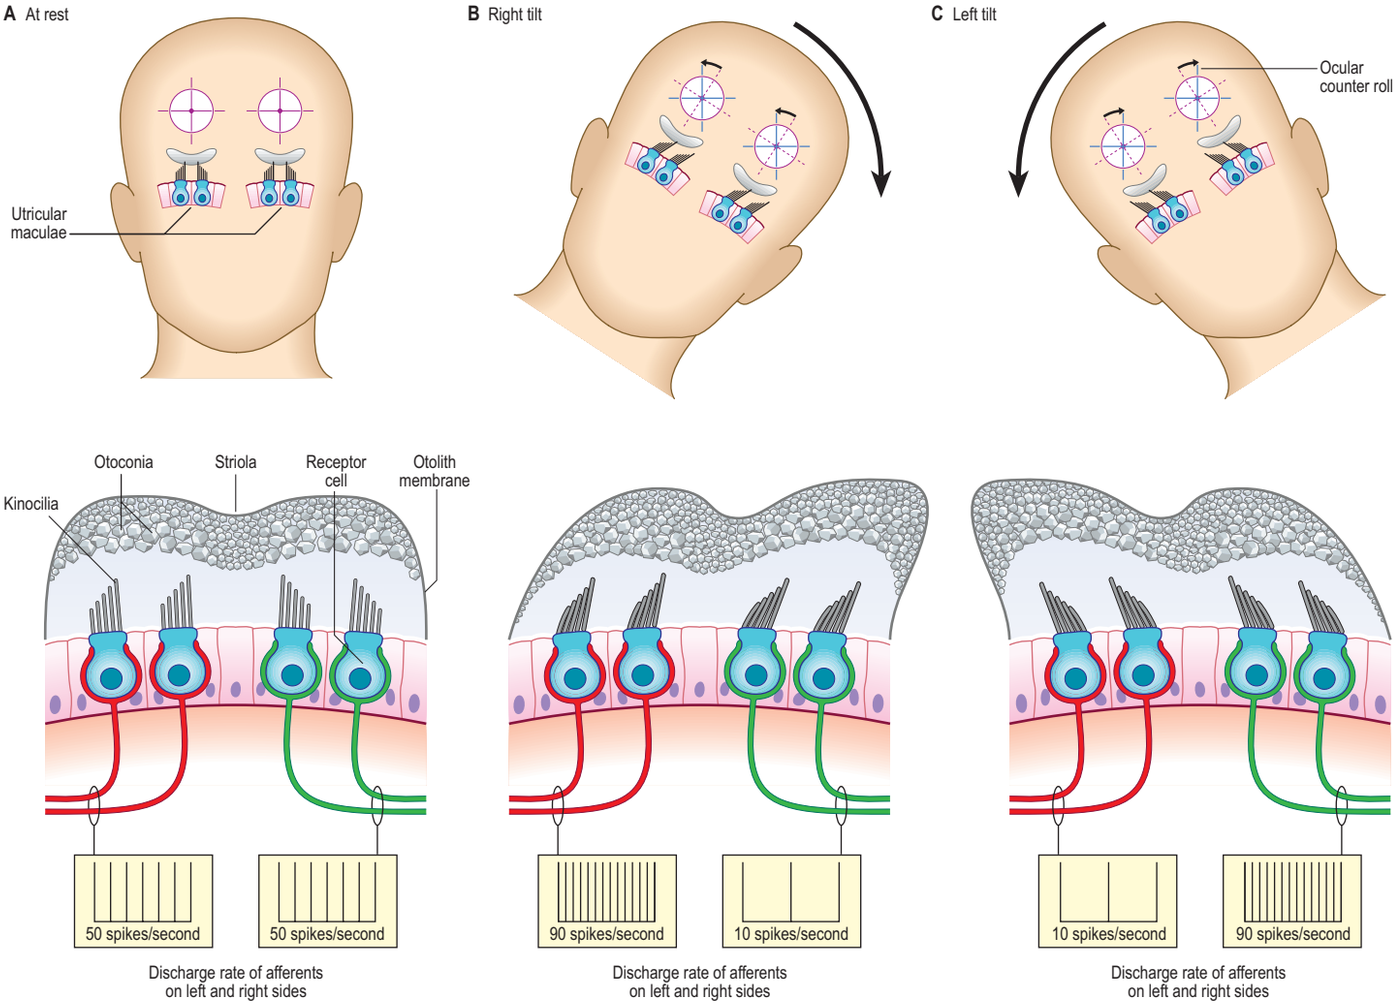

Fig. 43.14 Head tilt is encoded by a macular map of directional space. These diagrams depict the responses of the utricular maculae to head tilt. Firing rates in the vestibular afferents that innervate receptors on either side of the striola (red and green lines) are equivalent when the head is upright (**A**). When the head is tilted to the right (**B**) or to the left (**C**) the stereocilia are deflected by displaced otoconia; hair cells on the upward slope side of the striola increase their firing rate, while those on the downward slope decrease their firing rate.

unimodal, and ranges from 1 to 11 µm, with a peak at 4–5 µm. Functionally, the nerve contains both afferent and efferent somatic fibres, together with adrenergic postganglionic sympathetic fibres from the cervical sympathetic system.

Afferent cochlear innervation

The afferent fibres are the axons of bipolar neurones that lie in the spiral ganglion in the modiolus (see Fig. 43.9B; **Fig. 43.16**). There are two types of ganglion cell: most (90–95%) are large type I cells, while the remainder are smaller type II cells (see review by Nadol (1988)). Type I cells contain a prominent spherical nucleus, abundant ribosomes and many mitochondria; in many mammals (although possibly not in humans), they are surrounded by myelin sheaths. In contrast, type II cells are smaller and always unmyelinated, and have a lobulated nucleus. The cytoplasm of type II cells is enriched with neurofilaments but has fewer mitochondria and ribosomes than type I cells.

Basilar fibres Basilar fibres are the peripheral processes of type II ganglion cells and are afferent to the outer hair cells. They take an independent spiral course, turning towards the cochlear apex near the bases of the inner hair cells. They run for a distance of about five pillar cells before turning radially again and crossing the floor of the tunnel of Corti, often diagonally, to form part of the outer spiral bundle.

Outer spiral bundles The afferent fibres of the bundles of the outer spiral group course towards the basal part of the cochlea, continually branching off *en route* to supply several outer hair cells. The outer spiral bundles also contain efferent fibres (see below).

Efferent cochlear fibres

The efferent nerve fibres in the cochlear nerve are derived from the olivocochlear system (see reviews by Warr (1992), Guinan (1996)). Within the modiolus, the efferent fibres form the intraganglionic spiral bundle, which may be one or more discrete groups of fibres situated at the periphery of the spiral ganglion (**Fig. 43.17**). There are two main groups of olivocochlear efferents: lateral and medial. The lateral efferents come from small neurones in and near the lateral superior olivary nucleus and arise mainly, but not exclusively, ipsilaterally. They are organized into inner spiral fibres that run in the inner spiral bundle before terminating on the afferent axons that supply the inner hair cells. The medial efferents originate from larger neurones in the vicinity of the medial superior olivary nucleus, and the majority arise contralaterally. They are myelinated and cross the tunnel of Corti to synapse with the outer hair cells mainly by direct contact with their bases, although a few synapse with the afferent terminals. The efferent innervation of the outer hair cells decreases along the organ of Corti from cochlear base to apex, and from the first (inner) row to the third. The efferents use acetylcholine, γ-aminobutyric acid (GABA) or both as their neurotransmitter. They may also contain other neurotransmitters and neuromodulators.

Activity of the medial efferents inhibits cochlear responses to sound; the strength of the activity grows slowly with increasing sound level. They are believed to modulate the micromechanics of the cochlea by altering the mechanical responses of the outer hair cells, thus changing their contribution to frequency selectivity and sensitivity. The lateral efferents related to the inner hair cells also respond to sound. They make contacts most commonly with the inner radial afferent fibres rather than the inner hair cell base (see Fig. 43.9C) and appear to modify transmission through the afferents. The cholinergic fibres may excite the radial fibres, while those containing GABA may inhibit them, although

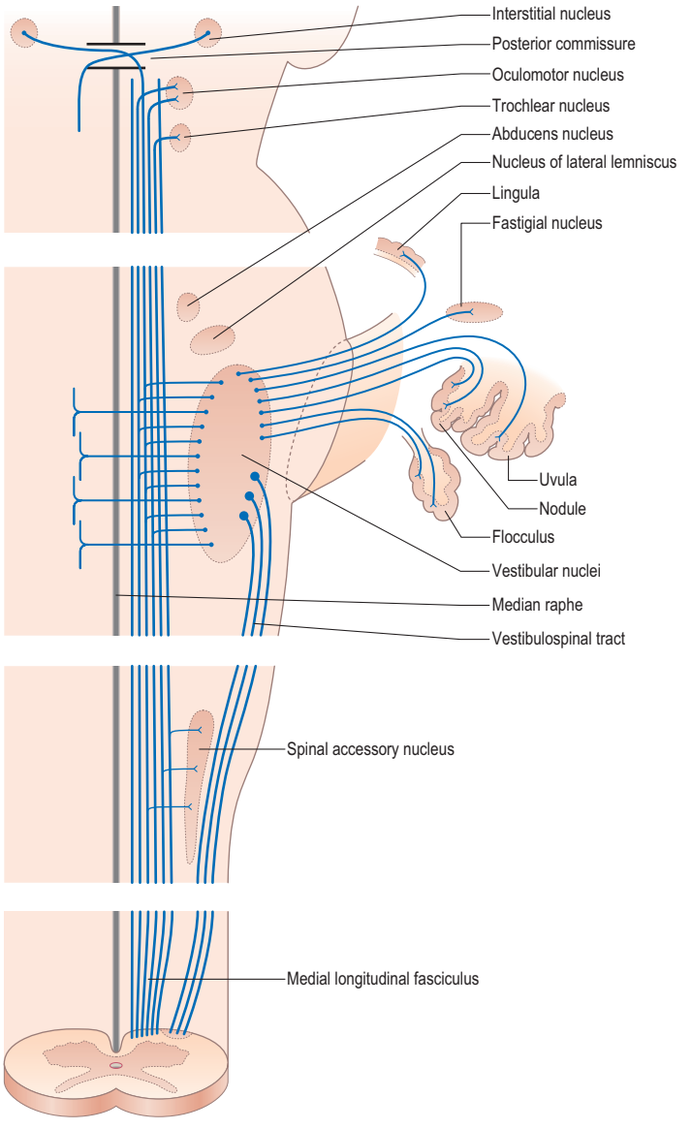

Fig. 43.15 Some of the fibre components of the medial longitudinal fasciculus.

Fig. 43.16 A transmission electron micrograph showing several type II ganglion cells and axons in a human spiral ganglion. Note the absence of myelin from the surrounding sheaths of the ganglion cells. (Courtesy of H Felix, M Gleeson and L-G Johnsson, ENT Department, University of Zurich and GKT School of Medicine, London.)

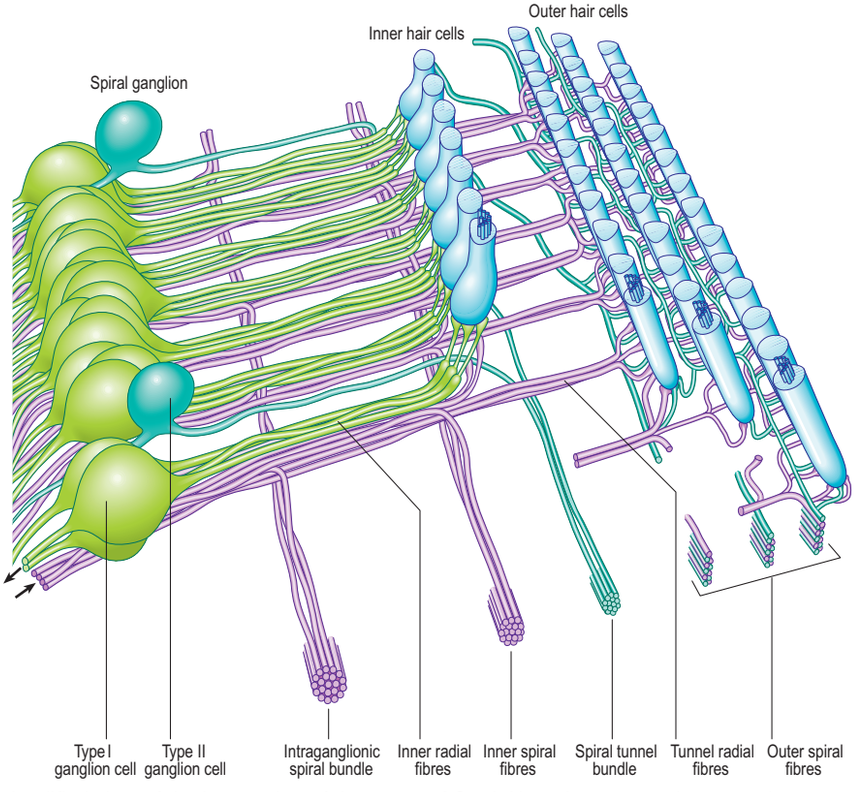

Fig. 43.17 A simplified view of the innervation of the organ of Corti. Note the contrast between the convergent afferent innervation of the inner hair cells (approximately 10 fibres to each cell) and the divergent supply of the outer hair cells (1 afferent fibre to 10 cells).

their role is less well understood than that of the medial efferents (see review by Guinan (1996)).

Autonomic cochlear innervation

Autonomic nerve endings appear to be entirely sympathetic. Two adrenergic systems have been described within the cochlea: a perivascular plexus derived from the stellate ganglion and a blood vessel-independent system derived from the superior cervical ganglion. Both systems travel with the afferent and efferent cochlear fibres and seem to be restricted to regions away from the organ of Corti. The sympathetic nervous system may cause primary and secondary effects in the cochlea by remotely altering the metabolism of various cell types and by influencing the blood vessels and nerve fibres with which it makes contact.

ANATOMY OF HEARING

Sound waves entering the external ear are converted into electrical signals in the cochlear nerve by the peripheral auditory system (**Fig. 43.18**). The axons in the cochlear nerve constitute the auditory component of the vestibulocochlear nerve and terminate in the dorsal and ventral cochlear nuclei (Ch. 28); onward connections make up the ascending (central) auditory pathway.

Peripheral auditory system

Vibrations in the air column in the external acoustic meatus cause a comparable set of vibrations in the tympanic membrane and auditory ossicles. The chain of ossicles acts as a lever that increases the force per unit area at the round window by 1.2 times while the reduction in size of the round window compared with the tympanic membrane increases the force per unit area of the oscillating surface a further 17 times. This overcomes the inertia of the cochlear fluids and produces in them pressure waves that are conducted almost instantaneously to all parts of the basilar membrane. The latter varies continuously in width, mass and stiffness from the basal to the apical end of the cochlea. Each part of the basilar membrane vibrates, but only the region tuned to a specific frequency will respond maximally to a pure tone entering the ear. A wave of mechanical motion, the travelling wave, is propagated along the basilar membrane to the position where it responds maximally and then dies away again. With increasing frequency, the locus of maximum amplitude moves progressively from the apical to the basal end of the cochlea. The pattern of vibrations in the basilar membrane thus varies with the intensity and frequency of the acoustic waves reaching the perilymph. Because of the arrangement of the hair cells on the basilar membrane, these oscillations generate a largely transverse shearing force between the outer hair cells and the overlying tectorial membrane (in which the apices of the hair cell stereocilia are embedded). This movement depends on the mechanical properties of the entire organ of Corti, including its cytoskeleton, which stiffens this structure. The inner hair cell stereocilia, which probably do not touch the tectorial membrane, although they come very close to it, are likely to be stimulated by local movements of the endolymph. Displacement of the stereociliary bundle of a hair cell activates mechanoelectrical transduction channels near the tips of its stereocilia, and this allows potassium and calcium ions from the endolymph to enter the hair cell (see earlier and overview by Fettiplace and Hackney (2006)). This induces a depolarizing receptor potential

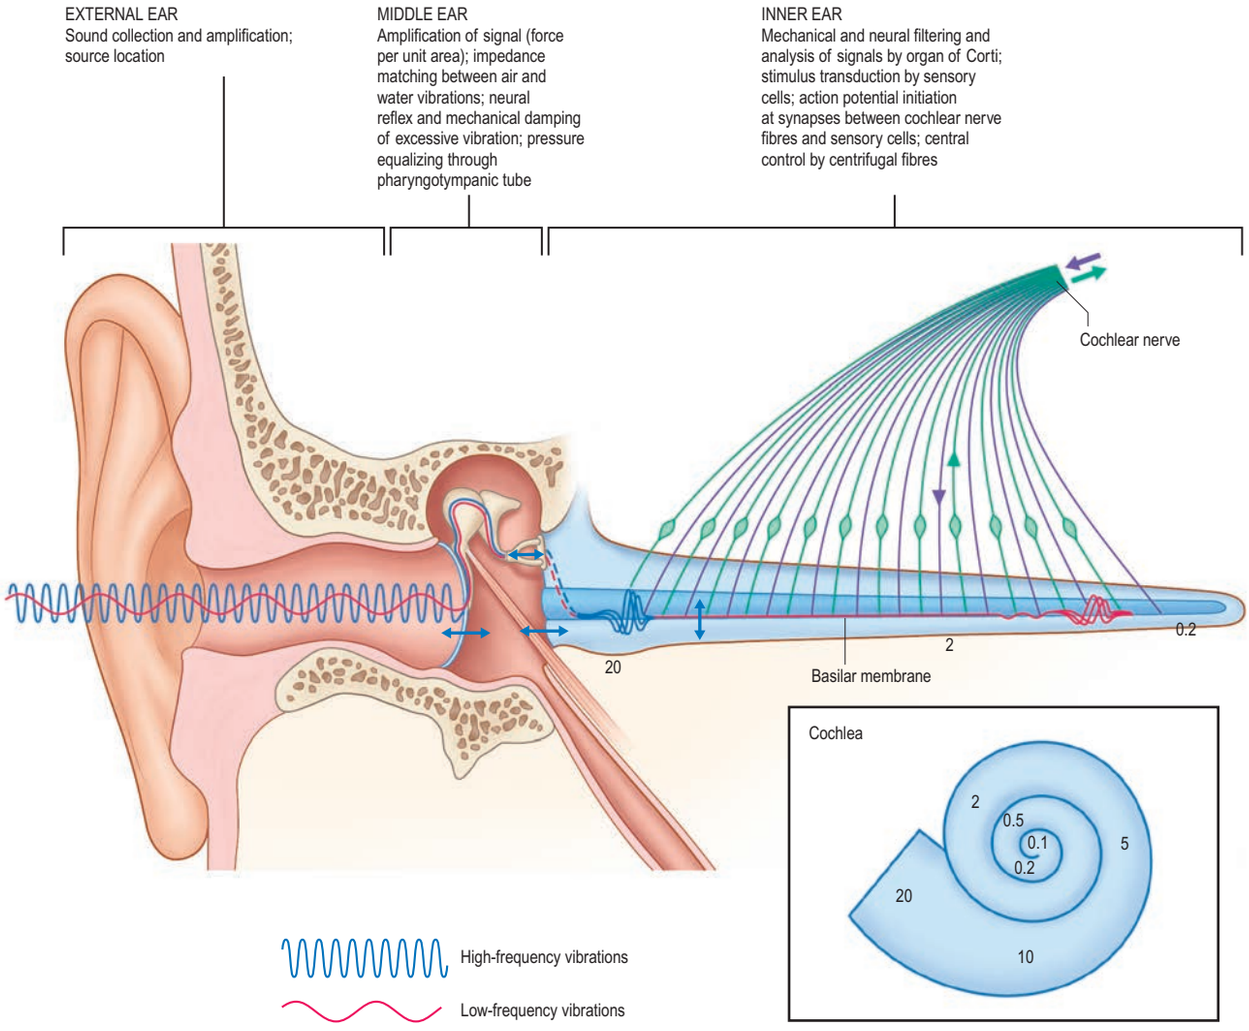

Fig. 43.18 The principal activities of the peripheral auditory apparatus. For clarity, the cochlea is depicted as though it had been uncoiled, but it is normally coiled as in the inset. Different sound frequencies differentially excite different regions of the cochlea, the specific locations being given in kHz from 0.1 to 20 kHz in humans. Note that the frequency map is logarithmic, so that each decade occupies an equivalent distance on the basilar membrane. The components are drawn roughly to scale for the human ear, in which the cochlea is 35 mm in length. The points of maximal stimulation of the basilar membrane by high-frequency and low-frequency vibrations, together with their transmission pathways through the external and middle ear, are also indicated.

and the release of neurotransmitter on to the cochlear afferents at the base of the cell. In this way, a specific group of auditory axons is activated at the position of maximal basilar membrane vibration.

The mechanical behaviour of the basilar membrane is responsible for a broad discrimination between different frequencies (passive tuning; see overview by Ashmore (2002)), but fine frequency discrimination in the cochlea appears to be related to physiological differences between the hair cells. Individual tuning of hair cells may result from differences in shape, stereociliary length, or possibly variations in the molecular composition of sensory membranes and may have a role in cochlear amplification (active tuning).

The activity of the outer hair cells appears to play an important part in regulating inner hair-cell sensitivity at specific frequencies. Outer hair cells can change length when stimulated electrically at frequencies of many thousands of cycles per second. The rapidity of these changes in length indicates a novel type of motile mechanism, which is believed to depend on conformational changes in prestin, a protein that displays piezoelectricity and is located in the plasma membrane of the cells (Fettiplace and Hackney 2006, Hudspeth 2014) (**Fig. 43.19**). When the membrane potential of the outer hair cells changes, they generate forces along their axes. When the mechanoelectrical transduction channels open, they are thought to oppose the viscous forces that tend to damp down the vibration of the cochlear partition and adjust the mechanics of the organ of Corti on a cycle-by-cycle basis. Alternatively, they may alter the mechanics of the partition more slowly under the influence of the efferent pathway. At a particular frequency, an increase in the intensity of stimulus is signalled by an increase in the rate of discharge in individual cochlear axons. At greater intensities, it is signalled by the number of activated cochlear axons (recruitment).

The respective roles of the two groups of hair cells have been much debated, particularly since differences in their innervation and physiological behaviour have become apparent. Because of their rich afferent supply, inner hair cells are believed to be the major source of auditory signals in the cochlear nerve. Some evidence for this view is based on the finding that animals treated with antibiotics that are specifically toxic to outer hair cells are still able to hear, but their sensitivity and frequency discrimination is impaired.

Some electrical responses of the cochlea can be recorded with extracellular electrodes. The most significant is the endolymphatic potential, a steady potential recordable between the cochlear duct and the scala tympani, which is caused by the different ionic compositions of their fluids. As the resting potential of hair cells is approximately 70 mV (negative inside) and the endolymphatic potential is positive in the cochlear duct, the total transmembrane potential across the apices of hair cells is 150 mV. This is a greater resting potential than is found anywhere else in the body and provides the driving force for mechanotransduction and for the cochlear amplifier.

Under stimulation by sound, a rapid oscillatory cochlear microphonic potential can be recorded. It matches the frequency of the stimulus and movements of the basilar membrane precisely and appears to depend on fluctuations in the conductance of hair cell membranes, probably of the outer hair cells. At the same time, an extracellular summating potential develops, a steady direct current shift related to the (intracellular) receptor potentials of the hair cells. Cochlear nerve fibres then begin to respond with action potentials that are also recordable from the cochlea. Intracellular recording of auditory responses from inner hair cells has confirmed that these cells resemble other receptors; their steady receptor potentials are related in size to the amplitude of the acoustic stimulus. At the same time, afferent axons are stimulated by synaptic action at the bases of the inner hair cells. They fire more rapidly as the vibration of the basilar membrane increases in amplitude, up to a threshold that depends on the sensitivity of the specific nerve fibre involved. Each inner hair cell is contacted by axons with response thresholds that range from 0 decibels sound pressure level (dBSPL), the approximate threshold of human hearing, to those that respond to intensities in excess of 100 dBSPL; the loudest sound tolerable is around 120 dBSPL. Each axon responds most sensitively to the frequency represented by its particular cochlear location, its characteristic frequency (see Fig. 43.18).

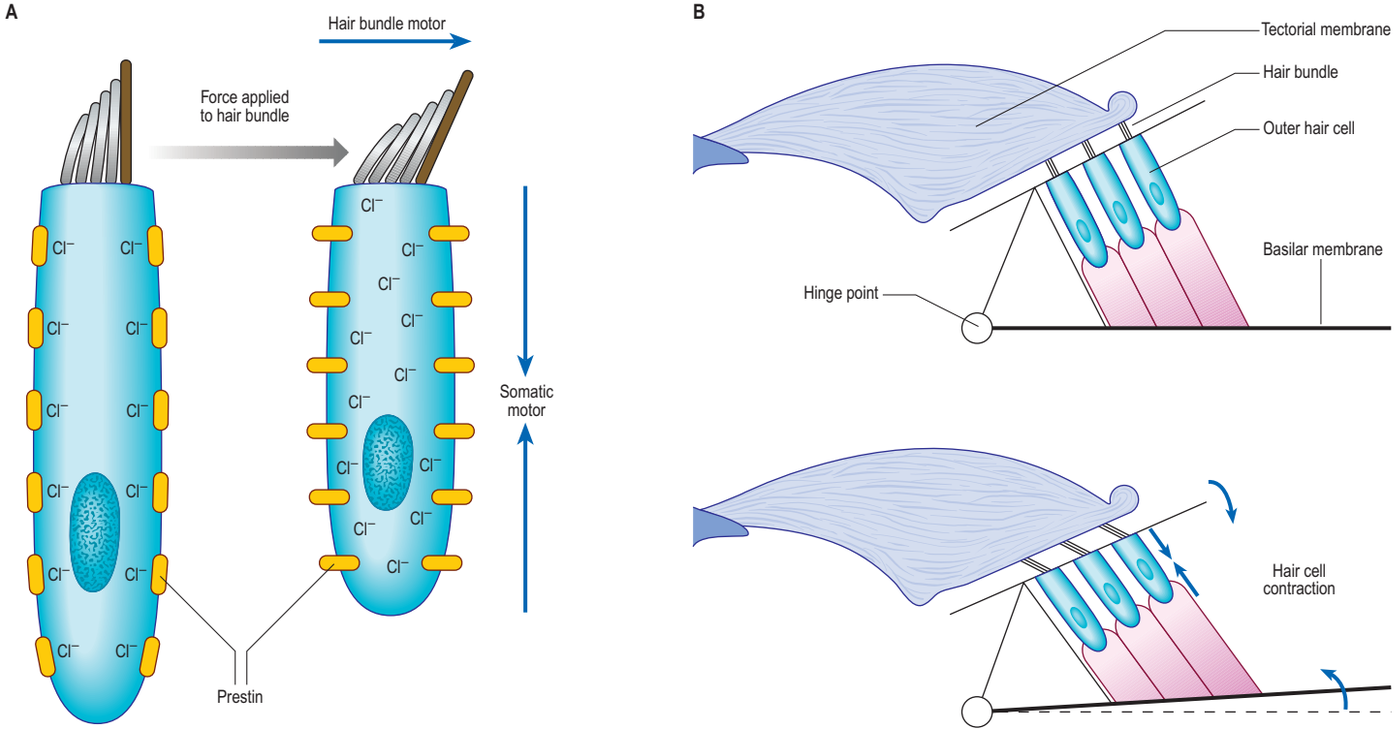

Fig. 43.19 The putative motors of outer hair cells. Outer hair cells can generate force, mechanically boosting sound-induced vibrations of the hair bundle and augmenting frequency tuning. Two mechanisms have been advanced to explain this cochlear amplifier: the somatic motor and the hair bundle motor. **A**, In the resting state, Cl^- ions are bound to prestin molecules in the lateral membrane of the hair cell. When force is applied to the hair bundle, the cell is depolarized, the Cl^- ions dissociate and the prestin changes conformation, reducing its area in the plane of the membrane and shortening the hair cell body (the somatic motor). Adaptation of mechanoelectrical transduction (MET) channels, which are activated by bending of the stereocilia at their tapered base, also causes the hair bundle to produce extra force in the direction of the stimulus (the hair bundle motor). The amplitudes of the hair bundle movements have been exaggerated to illustrate the concept. **B**, The effects of the somatic motor (blue arrows) on the organ of Corti mechanics, which leads to downward motion of the reticular lamina (the upper surface of the organ of Corti) and a negative deflection of the hair bundle. This is a negative feedback pathway, as a positive deflection of the hair bundle causes outer hair cell depolarization, cell contraction and opposing motion of the bundle (see Fettiplace and Hackney (2006)).

Central auditory pathway

The primary afferents of the auditory pathway arise from cell bodies in the spiral ganglion of the cochlea. The axons travel in the vestibulocochlear nerve, which enters the brainstem at the cerebellopontine angle. Afferent fibres bifurcate, and terminate in the dorsal and ventral cochlear nuclei (**Fig. 43.20**; Ch. 28). The dorsal cochlear nucleus projects via the dorsal acoustic stria to the contralateral inferior colliculus. The ventral cochlear nucleus projects via the trapezoid body or the intermediate acoustic stria to relay centres in either the superior olivary complex, the nuclei of the lateral lemniscus, or the inferior colliculus. The superior olivary complex is dominated by the medial superior olivary nucleus, which receives direct input from the ventral cochlear nucleus on both sides and is involved in localization of sound by measuring the time difference between afferent impulses arriving from the two ears.

The inferior colliculus consists of a central nucleus and two cortical areas. The dorsal cortex lies dorsomedially, and the external cortex lies ventromedially. Secondary and tertiary fibres ascend in the lateral lemniscus. They converge in the central nucleus, which projects to the ventral division of the medial geniculate body of the thalamus. The external cortex receives both auditory and somatosensory input. It projects to the medial division of the medial geniculate body and, together with the central nucleus, also projects to olivocochlear cells in the superior olivary complex and to cells in the cochlear nuclei. The dorsal cortex receives input from the auditory cortex and projects to the dorsal division of the medial geniculate body. Connections also run from the nucleus of the lateral lemniscus to the deep part of the superior colliculus, to coordinate auditory and visual responses.

The ascending auditory pathway crosses the midline at several points both below and at the level of the inferior colliculus. However, the input to the central nucleus of the inferior colliculus and higher centres has a clear contralateral dominance; during the initial stages of cortical auditory processing, each hemisphere responds most strongly to the contralateral ear. The medial geniculate body is connected reciprocally to the primary auditory cortex, which lies in the posterior half of the superior temporal gyrus and also dives into the lateral sulcus as the transverse temporal gyri (Heschl's gyri). Secondary areas of the auditory cortex are located in an adjacent belt region, and other regions of auditory association cortex have been described in a parabelt region beyond the secondary cortex.

The corpus callosum, particularly the posterior third of the body, contains auditory interhemispheric fibres that originate from the primary and second auditory cortices. Asymmetries of minicolumn number in primary and auditory association cortex have been correlated with axonal fibre numbers in the subregions of the corpus callosum through which they project (Chance et al 2006).

The presence of tonotopic gradients in the primary auditory cortex is well established in animals and in humans. Hemispheric differences for frequency selectivity (i.e. the ability of the cochlea to separate the acoustic frequencies along its length like an acoustic prism) and tonotopic organization have been reported, e.g. the right hemisphere appears to be most responsive to acoustic sound features such as pitch, whereas the left hemisphere seems to be more involved in processing temporal dynamics such as the phonological aspects of speech. Morphological asymmetries favouring the left hemisphere in the planum temporale and Heschl's gyri have been correlated with left hemispheric dominance for language functions but a direct link between structure and function has not been clearly established; studies often show relative rather than absolute differences in hemispheric specialization for particular attributes.

The transformation of the physical characteristics of sound into 'auditory objects' is thought to occur in the transition from primary to secondary auditory cortex. (For a critical perspective on auditory objects, see Griffiths and Warren (2004).)

Hearing loss

Sensorineural hearing loss is the most prevalent form of hearing impairment. It refers commonly to loss or damage of the sensory hair cells or their innervation but can also result from lateral wall degeneration and loss of the endolymphatic potential. The hair cells are particularly

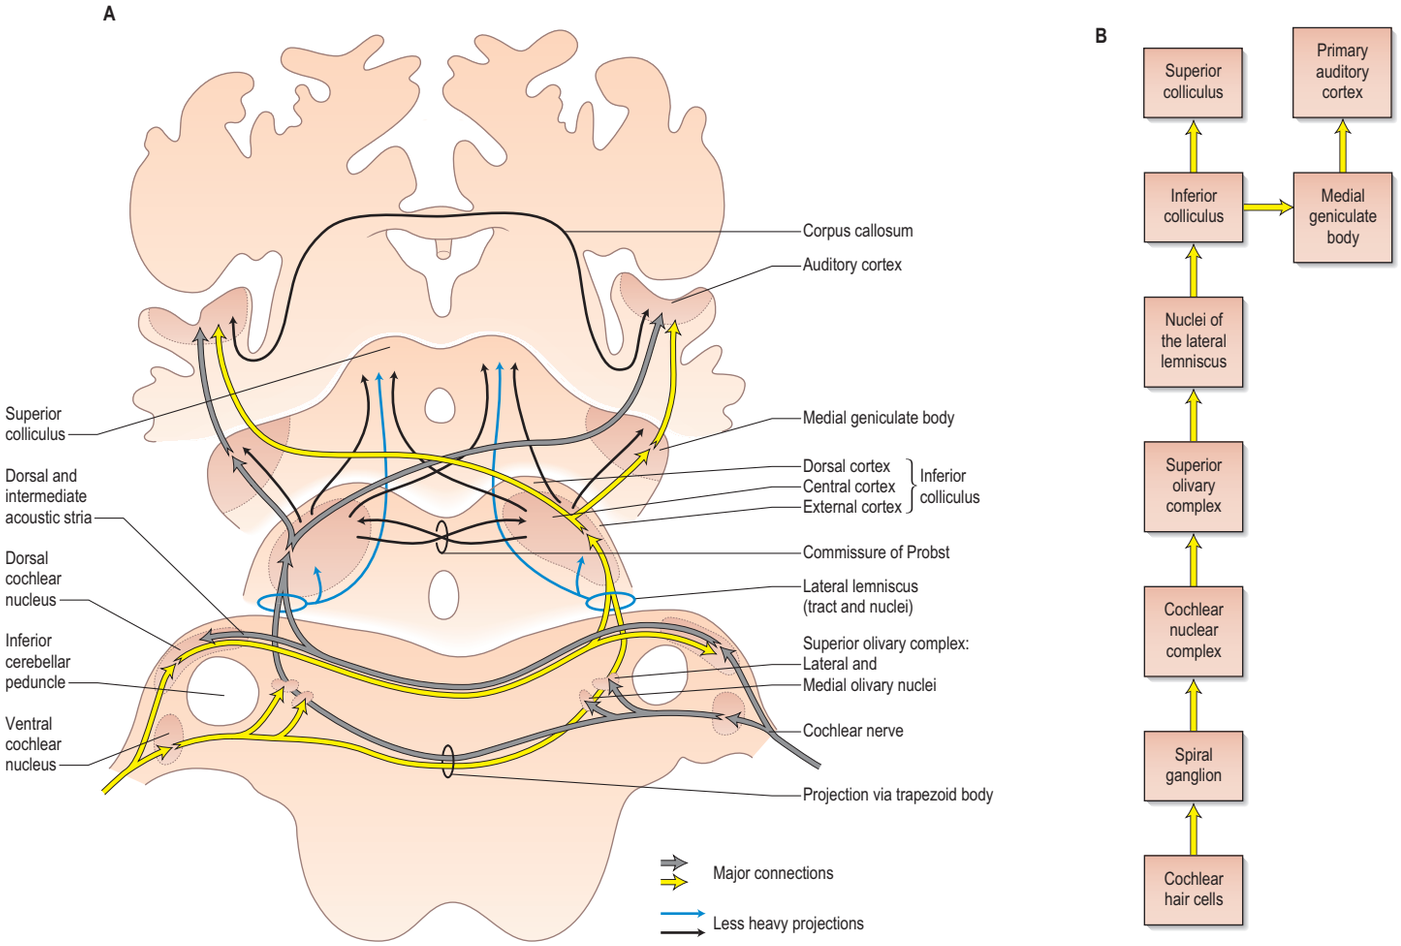

Fig. 43.20 The main features of the human ascending auditory pathway. **A**, A series of sections showing that ipsilateral and commissural connections occur at most levels in this system. The major connections are shown by the thicker arrows; thinner arrows denote less heavy projections. **B**, The main stations of the auditory pathway.

vulnerable to mechanical trauma produced by high-intensity noise and to changes in their physiological environment caused by infection or hypoxia. These can lead to rapid degenerative processes that result in hair cell loss, often by apoptosis, and produce either hearing loss or vestibular dysfunction. These changes can be induced by drugs such as the aminoglycoside antibiotics, some diuretics and certain anticancer drugs. A decrease in cochlear sensitivity, presbyacusis, almost invariably occurs with age; hair cells at the high frequency end of the cochlea tend to be lost first. At least 60% of hearing loss may have a genetic basis, a significant proportion may be non-syndromic, and most of these genes are inherited in an autosomal recessive mode (Ch. 16).

Ménière's disease is a distressing disorder of the inner ear characterized by episodes of hearing loss, tinnitus and vertigo. Histological examination of an affected ear reveals endolymphatic hydrops (swelling of the endolymphatic spaces), suggesting poor drainage of the endolymph via the endolymphatic sac.

Whilst some forms of conductive deafness are amenable to treatment, at present sensorineural hearing loss is irreversible. The main treatment options are an external hearing aid or a cochlear implant (CI). The external hearing aid is inserted into the auditory canal and provides amplified input to the inner ear, utilizing the residual hearing of the patient.

Hearing impairment is the most common disabling sensory defect in humans. Two causes of deafness are usually distinguished: conductive hearing loss and sensorineural hearing loss.

Conductive hearing loss may result from trauma to the external or middle ears, blockage of the external acoustic meatus, or disruption of the tympanic membrane (e.g. by intense sounds or extreme pressure changes). It may also result from acute or chronic infection associated with a perforation of the tympanic membrane, as in acute otitis media. The ossicular chain may be disrupted by trauma, avascular necrosis of the long process of the incus following a middle ear infection or cholesteatoma. The most common cause of a conductive hearing loss is a middle ear effusion (glue ear), in which fluid that has replaced the normally air-filled middle ear impedes the movements of the tympanic membrane. Other less common causes include tympanosclerosis, in which calcium plaques are formed in the tympanic membrane and middle ear mucosa that stiffen the tympanic membrane and limit the mobility of the ossicular chain. Similarly, new bone laid down around the oval window and footplate of the stapes, otosclerosis, impedes stapes mobility and imparts a conductive hearing loss.

Cochlear implants consist of an external microphone and sound processor on the side of the head behind the external ear, adjacent to a subcutaneous receiver attached to a multichannel electrode. The electrode is inserted into the inner ear (see below for surgical approaches) and is advanced as far as feasible along the cochlear spiral (**Fig. 43.21**). The sound processor transmits a digitized representation of environmental sound to the implant which converts it to electrical pulses along the electrode. The signal is spatially segregated through the different channels of the electrode and stimulates functional cochlear nerve fibres that remain within the deaf ear. Thus the different frequency components of the sound stimulus are presented along the tonotopic axis to stimulate as closely as possible the spiral ganglion neurones that in the intact ear would represent them. This generates a pattern of auditory nerve firing representing different frequency components along the auditory pathway, restoring some measure of sensitivity and frequency selectivity.

The design of cochlear and, more recently, vestibular implants, particularly their electrodes and processing algorithms, is a rapidly advancing science, but is hampered by suboptimal information about the three-dimensional (3-D) neural architecture of the labyrinth and cochlea. Improved imaging techniques that preserve some of the smaller neural structures that might otherwise be destroyed by dissection techniques are being developed to answer this deficiency. For example, osmium tetroxide (OsO_4) contrast enhanced micro-CT scanning of the inner ear in combination with post acquisition image processing using noise reduction and edge preserving filters before segmentation (see Fig. 43.1D–I) (van den Boogert et al 2018).

The inner ear may be approached surgically in a number of ways. Many drugs, e.g. gentamicin and steroids, are now injected through the intact tympanic membrane, where they diffuse through the round window membrane to access the inner ear. The promontory that overlies the basal turn of the cochlea and the oval window may be opened through a tympanotomy (per-meatal elevation of the tympanic membrane). The semicircular canals are generally accessed by a transmastoid approach. In days gone by, such an approach would be used to fenestrate the lateral canal in the management of otosclerosis. The advent of stapes prostheses and stapedectomy rendered this operation obsolete. However, the transmastoid approach is the workhorse for much middle and inner ear surgery because it gives a wide exposure of all the vital structures. For patients with profound hearing loss, enlarging the mastoid aditus inferiorly (posterior tympanotomy) to produce a triangle bounded above by the fossa incudis, superficially by the chorda tympani and deeply by the descending portion of the facial nerve, gives access to the round window so that it can be instrumented and a multichannel cochlear electrode inserted into the scala tympani of the cochlea so that it lies against the spiral lamina and can stimulate the adjacent fibres of the cochlear nerve. This is then connected to the cochlear implant device, which is housed in an extension of the mastoid cavity. Posterior canal obliteration for cupulolithiasis not responsive to Epley's manoeuvre is also undertaken through the mastoid. The endolymphatic sac may be approached by elevating the cortical bone of the anterolateral wall of the posterior cranial fossa, anterior to the sigmoid venous sinus and posterior to the posterior semicircular canal (below a line extended from the axis of the lateral semicircular canal). Decompression of the sac or a shunt procedure is favoured by some for the management of Ménière's disease. Superior canal dehiscences, as seen in Minor's syndrome, are repaired either through the mastoid or by using a middle fossa approach. In patients with intractable Ménière's disease, the whole of the labyrinth can be removed through the mastoid. Vestibular nerve section and the removal of vestibular schwannomas are generally undertaken through retrosigmoid, retrolabyrinthine, translabyrinthine or middle fossa approaches. The choice of approach is dictated or influenced by the size of the tumour, desire or need to preserve hearing, and the surgeon's choice. In recent years, the development of auditory brainstem implants has brought hope to those with profound hearing loss associated with neurofibromatosis type 2 or cochlear nerve aplasia. These devices are similar to a cochlear implant but the electrodes are placed directly into the cochlear nucleus within the brainstem through a retrosigmoid approach.

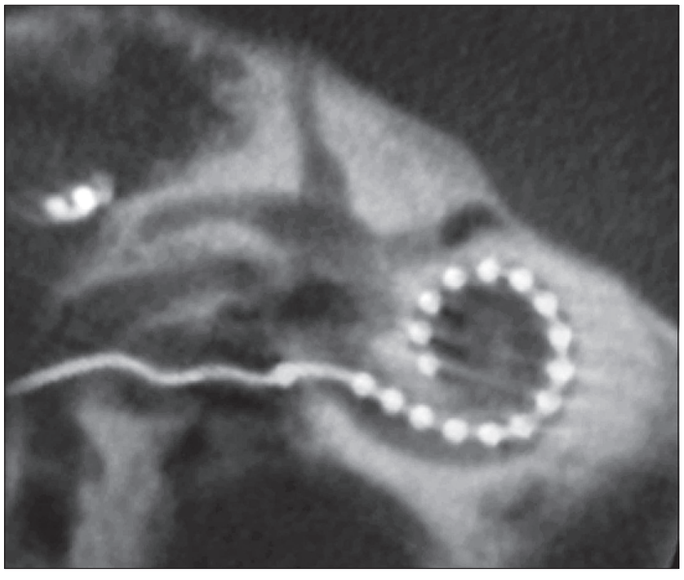

Fig. 43.21 Radiographic image of a cochlear implant (CI) *in situ*. The CI has an external microphone that detects the acoustic signal and converts it to a digital signal with both temporal and spatial components. The signal is transmitted via an external coil using radiofrequencies to an internal telemetry coil connected to a sound processor: the two coils are held in place by magnets. The processed signal is sent to an intracochlear multichannel electrode array and the electrodes in the CI stimulate the the surviving spiral ganglion neurones. The internal device includes a ground electrode that is placed beneath the temporalis muscle for current return.

Orbit and accessory visual apparatus

CHAPTER 44

BONY ORBIT

The bony orbits are skeletal cavities located on either side of the root of the nose that serve as sockets for the eyes and associated tissues. The walls of each orbit protect the eye from injury, provide points of attachment for six extraocular muscles that allow the accurate positioning of the visual axis, and determine the spatial relationship between the two eyes, which is essential for both binocular vision and conjugate eye movements.

By convention, each cavity is considered to approximate to a quadrilateral pyramid with its base at the orbital opening, narrowing to its apex along a posteromedially directed axis. Each orbit has a roof, floor and medial and lateral walls. The medial walls lie approximately 25 mm apart in adults and are nearly parallel. The angle between the medial and lateral walls is about 45°. The compromise between protection and ensuring a good field of view dictates that each eyeball is located anteriorly within the orbit. The eyeball thus occupies only one-fifth of the volume of the orbit (**Fig. 44.1**); the remainder of the cavity is filled with extraocular muscles, vessels and nerves that are contained within and supported by orbital fat and connective tissue. In brief, the orbit transmits the optic, oculomotor, trochlear and abducens nerves, branches of the ophthalmic and maxillary divisions of the trigeminal nerve and the ophthalmic vessels. The ciliary parasympathetic ganglion is located towards the rear of the orbit, lateral to the optic nerve and medial to lateral rectus. The orbit also contains components of the lacrimal system, which is responsible for the production and drainage of tears.

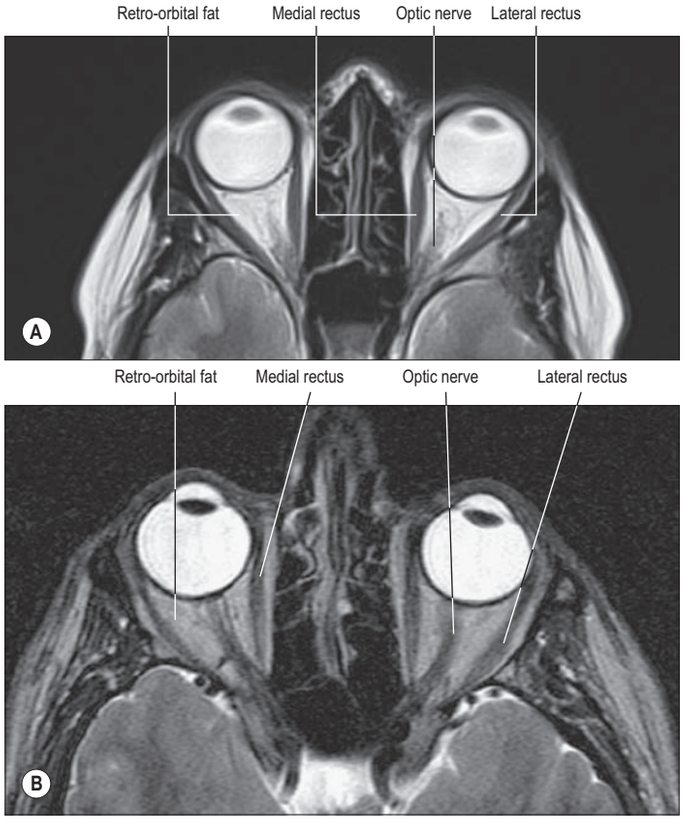

Fig. 44.1 **A**, A T2-weighted axial magnetic resonance imaging (MRI) scan through the mid-orbit. **B**, Note the optic nerve in its entirety. (Courtesy of Dr Timothy Beale FRCR, Royal National Throat Nose and Ear Hospital, London.)

There is a strong correlation between the pattern of orbital growth and eyeball growth. Orbital growth is most rapid during the first 12–24 months of life and most parameters reach 86–96% of adult values by the age of 8 years (Escaravage and Dutton 2013). Orbital volumes are larger in boys than in girls throughout childhood (Bentley et al 2002).

Roof

The roof of the orbit is formed principally by the thin orbital plate of the frontal bone (**Fig. 44.2**). It is gently concave on its orbital aspect, which separates the contents of the orbit and the brain in the anterior cranial fossa. Anteromedially, it contains the frontal sinus and displays a small trochlear fovea, sometimes surmounted by a small spine, where the cartilaginous trochlea (pulley) for superior oblique is attached. Anterolaterally, there is a shallow fossa that houses the orbital part of the lacrimal gland. The roof slopes down significantly towards the apex, joining the lesser wing of the sphenoid, which completes the roof. The optic canal lies between the roots of the lesser wing and is bounded medially by the body of the sphenoid.

Medial wall

The medial wall of the orbit is formed principally by the orbital plate (lamina papyracea) of the ethmoid bone (see Fig. 44.2). This paper-thin, rectangular plate covers the middle and posterior ethmoidal air cells, providing a route by which infection can spread into the orbit. The ethmoid articulates with the medial edge of the orbital plate of the frontal bone at a suture that is interrupted by anterior and posterior ethmoidal foramina. Posteriorly, it articulates with the body of the sphenoid, which forms the medial wall of the orbit to its apex. The lacrimal bone lies anterior to the ethmoid; it contains a fossa for the nasolacrimal sac that is limited in front by the anterior lacrimal crest on the frontal process of the maxilla and behind by the posterior lacrimal crest of the lacrimal bone (to which the lacrimal part of orbicularis oculi and lacrimal fascia are attached). A descending process of the lacrimal bone at the lower end of the posterior lacrimal crest contributes to the formation of the upper part of the nasolacrimal canal, which is completed by the maxilla (**Fig. 44.3**). During development, the medial wall of the orbit doubles in length, with disproportionate enlargement of its anterior half. Growth is rapid during the first 6 years of life and gradual between 7 years and adulthood (Isaacson and Monge 2003).

Floor

The floor of the orbit is mostly formed by the orbital plate of the maxilla, which articulates with the zygomatic bone anterolaterally and the small triangular orbital process of the palatine bone posteromedially (see Fig. 44.3). The floor is thin and forms most of the roof of the maxillary sinus. Not quite horizontal, it ascends a little laterally. Anteriorly, it curves into the lateral wall, and posteriorly, it is separated from the lateral wall by the inferior orbital fissure, which connects the orbit posteriorly to the pterygopalatine fossa, and more anteriorly to the infratemporal fossa. The medial lip is notched by the infraorbital groove. The latter passes forwards and sinks into the floor to become the infraorbital canal, which opens on the face at the infraorbital foramen; the infraorbital groove, canal and foramen contain the infraorbital nerve and vessels. Proportionally more pure orbital fractures involve the floor, particularly in the region of the infraorbital groove (Burm et al 1999). The classic 'blowout fracture' leaves the orbital rim intact and typically entraps soft tissue structures, leading to diplopia, impaired ocular motility and enophthalmos; infraorbital nerve involvement leads to ipsilateral sensory disturbance of the skin of the midface.

Lateral wall

The lateral wall of the orbit is formed by the orbital surface of the greater wing of the sphenoid posteriorly and the frontal process of the zygomatic bone anteriorly; the bones meet at the sphenozygomatic suture. The

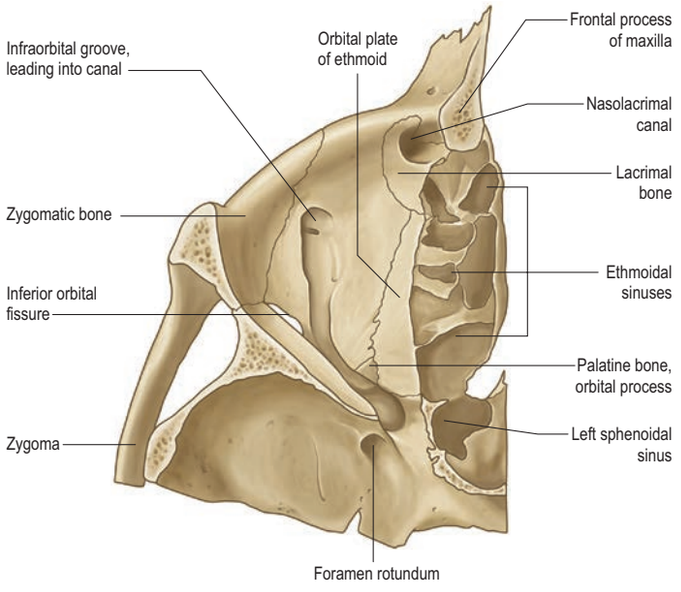

Fig. 44.3 A horizontal section through the floor of the left orbit and the adjacent ethmoidal and sphenoidal sinuses, viewed from above.

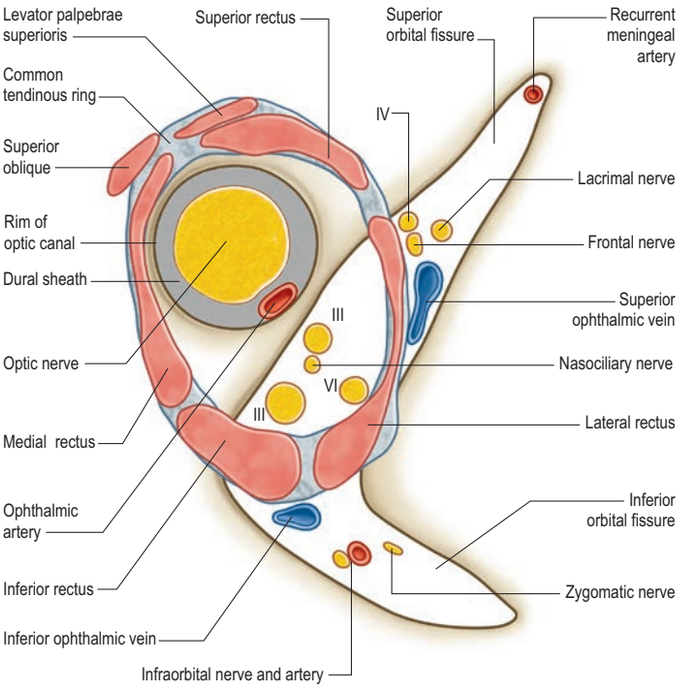

Fig. 44.4 The common tendinous ring: muscle origins have been superimposed. The relative positions of the nerves and vessels that enter the orbital cavity by passing through the superior orbital fissure or optic canal are shown. Note that the attachments of levator palpebrae superioris and superior oblique lie external to the common tendinous ring but are attached to it. The ophthalmic veins frequently pass through the ring. The recurrent meningeal artery (a branch of the ophthalmic artery) is often conducted from the orbit to the cranial cavity through its own foramen. Abbreviations: III, oculomotor nerve; IV, trochlear nerve; VI, abducens nerve.

zygomatic surface contains the openings of minute canals for the zygomaticofacial and zygomaticotemporal nerves, the former near the junction of the floor and lateral wall, and the latter at a slightly higher level, sometimes near the suture. The orbital tubercle, to which the lateral palpebral ligament, the check ligament of lateral rectus and the aponeurosis of levator palpebrae are all attached, lies just inside the midpoint of the lateral orbital margin. The lateral wall is the thickest wall of the orbit, especially posteriorly, where it separates the orbit from the middle cranial fossa. Anteriorly, the lateral wall separates the orbit and the infratemporal fossa. The lateral wall and roof are continuous anteriorly but are separated posteriorly by the superior orbital fissure, which lies between the greater wing (below) and lesser wing (above) of the sphenoid, and communicates with the middle cranial fossa. The fissure tapers laterally but widens at its medial end, its long axis descending posteromedially. Where the fissure begins to widen, its inferolateral edge shows a projection, often a spine, for the lateral attachment of the common tendinous ring (see Fig. 44.4). An inferior orbital fissure, which runs from the superolateral end of the superior orbital fissure towards the orbital floor, is sometimes associated with an anastomosis between the middle meningeal and infraorbital arteries.

Orbital fissures and foramina

Optic canal

The lesser wing of the sphenoid is connected to the body of the sphenoid by a thin, flat anterior root and a thick, triangular posterior root. The optic canal lies between these (see Fig. 44.2) and connects the orbit to the middle cranial fossa, transmitting the optic nerve and its meningeal sheaths, and the ophthalmic artery. The common tendinous ring, which gives origin to the four recti, is attached to the bone near the superior,

medial and lower margins of the orbital opening of the canal (see Fig. 44.4). The growth of the optic canal continues from the fetal period into adulthood with an increase in both the length and width of the canal (Prado et al 2007).

Superior orbital fissure

The superior orbital fissure is the gap between the greater and lesser wings of the sphenoid, bounded medially by the body of the sphenoid, and closed at its anterior extremity by the frontal bone (see Fig. 44.2). It connects the cranial cavity with the orbit and transmits the oculomotor, trochlear and abducens nerves, branches of the ophthalmic nerve and the ophthalmic veins (see Fig. 44.4).

Inferior orbital fissure

The inferior orbital fissure is bounded above by the greater wing of the sphenoid, below by the maxilla and the orbital process of the palatine bone, and laterally by the zygomatic bone (see Fig. 44.2). The maxilla and sphenoid often meet at the anterior end of the fissure, excluding the zygomatic bone. The inferior orbital fissure connects the orbit with the pterygopalatine and infratemporal fossae and transmits the infraorbital and zygomatic branches of the maxillary nerve and accompanying vessels (see Fig. 44.4), orbital rami from the pterygopalatine ganglion and a connection between the inferior ophthalmic vein and pterygoid venous plexus. A small maxillary depression may mark the attachment of inferior oblique anteromedially, lateral to the lacrimal hamulus.

Ethmoidal foramina

The anterior and posterior ethmoidal foramina usually lie in the frontoethmoidal suture (see Fig. 44.2). The posterior foramen may be absent, and occasionally there is a middle ethmoidal foramen. The foramina open into canals that transmit their vessels and nerves into the ethmoidal sinuses, anterior cranial fossa and nasal cavity.

Orbitomeningeal (cranio-orbital) foramina

Available with the *Gray's Anatomy* e-book

Common tendinous ring

The common tendinous ring is a fibrous anulus that surrounds the optic canal and part of the superior orbital fissure at the apex of the orbit and gives origin to the four recti (**Fig. 44.4**). The optic nerve and ophthalmic artery enter the orbit via the optic canal, and so lie within the common tendinous ring. The superior and inferior divisions of the oculomotor nerve, the nasociliary branch of the ophthalmic nerve, and the abducens nerve also enter the orbit within the common tendinous ring, but they do so via the superior orbital fissure (see Fig. 44.15). The trochlear nerve and the frontal and lacrimal branches of the ophthalmic nerve all enter the orbit through the superior orbital fissure but lie outside the common tendinous ring. Structures that enter the orbit through the inferior orbital fissure lie outside the common tendinous ring. The close anatomical relationship of the optic nerve and other cranial nerves at the orbital apex means that lesions in this region may lead to a combination of visual loss from optic neuropathy and ophthalmoplegia from multiple cranial nerve involvement (Yeh and Foroozan 2004).

ORBITAL CONNECTIVE TISSUE AND FAT

The orbit contains a complex arrangement of connective tissue that forms a supporting framework for the eyeball and also influences ocular rotations and compartmentalizes orbital fat (**Fig. 44.5**). Certain regions have anatomical and clinical significance, including the orbital septum, fascial sheath of the eye, 'check' ligaments, suspensory ligament and periosteum. The notion that orbital connective tissues function as extraocular muscle pulleys and influence ocular motility has gained widespread acceptance (Demer 2002, Miller 2007, Guo et al 2016).

Orbital septum

The orbital septum is a weak membranous sheet, attached to the orbital rim where it becomes continuous with the periosteum (see Fig. 44.5). It extends into each eyelid and blends with the tarsal plates and, in the upper eyelid, with the superficial lamella of levator palpebrae superioris. The orbital septum is thickest laterally, where it lies in front of the lateral palpebral ligament. It passes behind the medial palpebral ligament and nasolacrimal sac, but in front of the pulley of superior oblique. The septum is pierced above by levator palpebrae superioris and below by a fibrous extension from the sheaths of inferior rectus and inferior oblique. The lacrimal, supratrochlear, infratrochlear and supraorbital nerves and vessels pass through the septum from the orbit *en route* to the face and scalp. Clinically, the septum is an important anatomical reference that differentiates pre- and post-septal (orbital) cellulitis.

Fascial sheath of the eyeball

A thin fascial sheath, the fascia bulbi (Tenon's capsule), envelops the eyeball from the optic nerve to the corneoscleral junction, separating it from the orbital fat and forming a socket for the eyeball (see Fig. 44.5;**Fig. 44.6**). The ocular aspect of the sheath is loosely attached to the sclera by delicate bands of episcleral connective tissue. Posteriorly, it is traversed by ciliary vessels and nerves. It fuses with the sclera and with the sheath of the optic nerve where the latter enters the eyeball; attachment to the sclera is strongest in this position and again anteriorly, just behind the corneoscleral junction at the limbus. Injection of local anaesthetics via a cannula into the space between the fascia bulbi and the sclera (sub-Tenon's anaesthesia) has become a popular technique for many ophthalmic surgical procedures (Davison et al 2007).

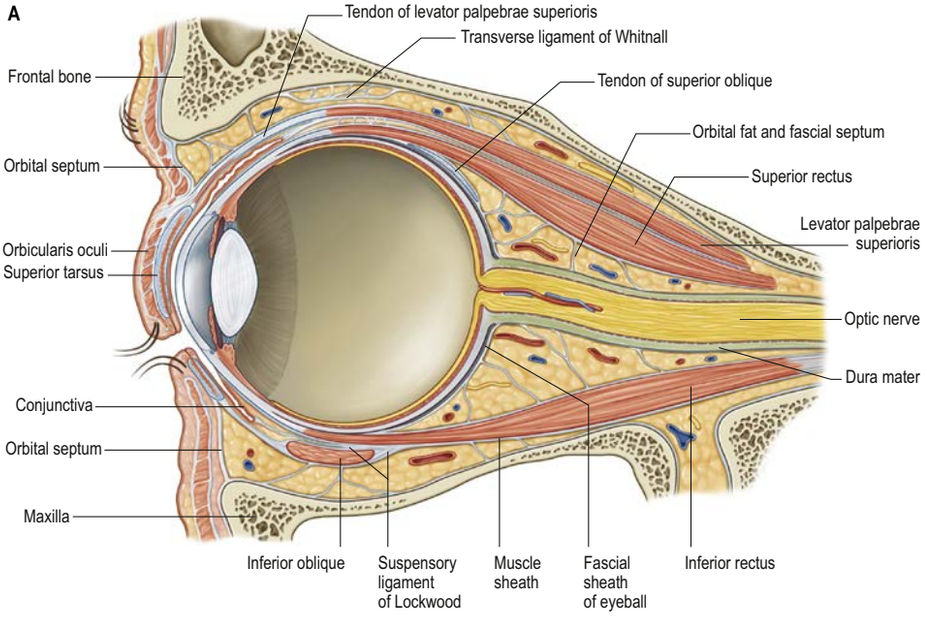

Fig. 44.5 A, The contents of the orbit, sagittal section. (B, *continued online*)

The orbit may also be connected with the cranial cavity via inconstant canals, including an A-type orbitomeningeal foramen with the anterior cranial fossa, or a metopic canal, Warwick's foramen, accessory opening of the foramen rotundum or an M-type orbitomeningeal foramen with the middle cranial fossa (Regoli and Bertelli 2017).

One or more orbitomeningeal (cranio-orbital) foramina are present in at least one orbital cavity in approximately 60% of individuals (Macchi et al 2016). These foramina usually lie close to the superior orbital fissure, either in the frontal bone, or the greater wing of the sphenoid, or along the frontosphenoidal suture. They typically transmit the meningolacrimal artery (an orbital branch of the middle meningeal artery that supplies the lacrimal gland), but may also also transmit the anastomosis between the recurrent branch of the lacrimal artery and the middle meningeal artery. Although usually small in calibre, approximately 5% of orbits have an orbitomeningeal foramen large enough to transmit important vessels that could be a source of severe bleeding during deep orbital surgery.

The fascia bulbi is perforated by the tendons of the extraocular muscles and is reflected on to each as a tubular sheath, the muscular fascia. The sheath of superior oblique reaches the fibrous pulley (trochlea) associated with the muscle. The sheaths of the four recti are very thick anteriorly but are reduced posteriorly to a delicate perimysium. Just before they blend with the fascia bulbi, the thick sheaths of adjacent recti become confluent and form a fascial ring.

Expansions from the muscular fascia are important for the attachments they make. Those from the medial and lateral recti are triangular and strong, and are attached to the lacrimal and zygomatic bones, respectively; since they may limit the actions of the two recti, they are termed the medial and lateral check ligaments (see Fig. 44.6). Other extraocular muscles have less substantial check ligaments, and the capacity of any of them actually to limit movement has been questioned.

The sheath of inferior rectus is thickened on its underside and blends with the sheath of inferior oblique. These two, in turn, are continuous with the fascial ring noted earlier and therefore with the sheaths of the medial and lateral recti. Since the latter are attached to the orbital walls by check ligaments, a continuous fascial band, the suspensory ligament of the eye, is slung like a hammock below the eye, providing sufficient support such that, even when the maxilla (forming the floor of the orbit) is removed, the eye will retain its position.

The thickened fused sheath of inferior rectus and inferior oblique also has an anterior expansion into the lower eyelid, where, augmented by some fibres of orbicularis oculi, it attaches to the inferior tarsus as the inferior tarsal muscle; contraction of inferior rectus in downward gaze therefore also draws the lid downward. The sheath of levator palpebrae superioris is also thickened anteriorly, and just behind the aponeurosis it fuses inferiorly with the sheath of superior rectus. It extends forwards between the two muscles and attaches to the upper fornix of the conjunctiva.

Other extensions of the fascia bulbi pass medially and laterally, and attach to the orbital walls, forming the transverse ligament of the eye. This structure is of uncertain significance, but presumably plays a part in drawing the fornix upwards in gaze elevation and may act as a fulcrum for levator movements. Other numerous finer fasciae form radial septa that extend from the fascia bulbi and the muscle sheaths to the periosteum of the orbit, and so provide compartments for orbital fat (Koornneef 1977). They also prevent the gross displacement of orbital fat, which could interfere with the accurate positioning of the two eyes that is essential for binocular vision.

The periosteum of the orbit is only loosely attached to bone. Behind, it is united with the dura mater surrounding the optic nerve and, in front, it is continuous with the periosteum of the orbital margin, where it gives off a stratum that contributes to the orbital septum. It also attaches to the trochlea and, as the lacrimal fascia, forms the roof and lateral wall of the fossa for the nasolacrimal sac.

Orbital connective tissue pulleys

There is mounting evidence that challenges the traditional view that the recti are attached only at their origin and scleral insertion. The concept that orbital connective tissue sheaths elastically coupled to the orbital walls function as pulleys was initially proposed as an explanation for the observed orbital stability of rectus muscle paths (Miller 1989). Each pulley consists of an encircling sleeve of collagen located within the fascia bulbi, near the equator of the globe. Elastic fibres and bundles of smooth muscle confer the required internal rigidity to the structure (Demer 2002). Although the original model described a passive pulley system, the current view is that fibres from the orbital surface of the muscle insert into the pulley sleeve to allow small longitudinal movements. This 'active pulley hypothesis' provides a better explanation for normal ocular kinematics (Miller 2007, Guo et al 2016).

Orbital fat

The spaces between the main structures of the orbit are occupied by fat, particularly in the region between the optic nerve and the surrounding cone of muscles (see Fig. 44.5; **Fig. 44.7**). Fat also lies between the muscles and periosteum, and is limited anteriorly by the orbital septum. Collectively, the fat helps to stabilize the position of the eyeball and also forms a socket within which the eye can rotate. Conditions resulting in an increased overall volume of orbital fat with associated swelling of

the extraocular muscles, e.g. hyperthyroidism (Graves' disease), may lead to forward protrusion of the eyeball (exophthalmos).

EXTRAOCULAR MUSCLES

Extraocular muscles are specialized skeletal muscles with several unique morphological, cellular and molecular properties (Spencer and Porter 2006). There are seven extraocular (extrinsic) muscles associated with the eye. Levator palpebrae superioris is an elevator of the upper eyelid, and the other six, i.e. four recti (superior, inferior, medial and lateral) and two obliques (superior and inferior), are capable of moving the eye in almost any direction. Complete congenital absence of the extraocular muscles, thought to represent a severe form of congenital fibrosis syndrome, has been described (Brady et al 1992). Rarely, humans have deep orbital bands consistent with supernumerary extraocular muscles (Khitri and Demer 2010).

Levator palpebrae superioris

Levator palpebrae superioris is a thin, triangular muscle that arises from the inferior aspect of the lesser wing of the sphenoid, above and in front of the optic canal, and separated from it by the attachment of superior rectus (see Fig. 44.4). It has a short narrow tendon at its posterior attachment and broadens gradually, then more sharply as it passes anteriorly above the eyeball. The muscle ends in front in a wide aponeurosis. Some of its tendinous fibres pass straight into the upper eyelid to attach to the anterior surface of the tarsus, while the rest radiate and pierce orbicularis oculi to pass to the skin of the upper eyelid. A thin lamina of smooth muscle, the superior tarsal muscle, passes from the underside of levator palpebrae superioris to the upper margin of the superior tarsus (see Fig. 44.20).

The connective tissue sheaths of the adjoining surfaces of levator palpebrae superioris and superior rectus are fused (see Fig. 44.5). Where the two muscles separate to reach their anterior attachments, the fascia between them forms a thick mass to which the superior conjunctival fornix is attached; this is usually described as an additional attachment of levator palpebrae superioris. Traced laterally, the aponeurosis of the levator passes between the orbital and palpebral parts of the lacrimal gland to attach to the orbital tubercle of the zygomatic bone. Medially, it loses its tendinous nature as it passes closely over the reflected tendon of superior oblique, and continues on to the medial palpebral ligament as loose strands of connective tissue.

Vascular supply Levator palpebrae superioris receives its arterial supply both directly from the ophthalmic artery and indirectly from its supraorbital branch.

Innervation Levator palpebrae superioris is innervated by a branch of the superior division of the oculomotor nerve that enters the inferior surface of the muscle. Sympathetic fibres to the smooth muscle component of levator palpebrae superioris (superior tarsal muscle) are derived from the plexus surrounding the internal carotid artery; these nerve fibres may join the oculomotor nerve in the cavernous sinus and pass forwards in its superior branch.

Actions Levator palpebrae superioris elevates the upper eyelid. During this process, the lateral and medial parts of its aponeurosis are stretched and thus limit its action; the elevation is also checked by the orbital septum. Elevation of the eyelid is opposed by the palpebral part of orbicularis oculi. Levator palpebrae superioris is linked to superior rectus by a check ligament, and so the upper eyelid elevates when the gaze of the eye is directed upwards.

The position of the eyelids depends on reciprocal tone in orbicularis oculi and levator palpebrae superioris, and on the degree of ocular protrusion. In the opened position, the upper eyelid covers the upper part of the cornea, while the lower lid lies just below its lower margin. The eyes are closed by movements of both lids, produced by the contraction of the palpebral part of orbicularis oculi and relaxation of levator palpebrae superioris. In looking upwards, the levator contracts and the upper lid follows the ocular movement. At the same time, the eyebrows are usually raised by the frontal parts of occipitofrontalis to diminish their overhang. The lower lid lags behind ocular movement, so that more sclera is exposed below the cornea and the lid is bulged a little by the lower part of the elevated eye. When the eye is depressed, both lids move; the upper retains its normal relation to the eyeball and still covers about a quarter of the cornea, whereas the lower lid is depressed because the extension of the thickened fascia of inferior rectus and inferior oblique pull on its tarsus as the former contracts.

The palpebral apertures are widened in states of fear or excitement by contraction of the superior and inferior tarsal muscles as a result of increased sympathetic activity. Lesions of the sympathetic supply result in drooping of the upper eyelid (ptosis), as seen in Horner's syndrome.

The recti

The four recti are approximately strap-shaped; each has a thickened middle part that thins gradually to a tendon (**Figs 44.8–44.9**). They are attached posteriorly to a common tendinous ring that encircles the superior, medial and inferior margins of the optic canal, continues laterally across the inferior and medial parts of the superior orbital fissure, and is attached to a tubercle or spine on the margin of the greater wing of the sphenoid (see Fig. 44.4). The tendinous ring is closely adherent to the dural sheath of the optic nerve medially and to the surrounding periosteum. Inferior rectus, part of medial rectus and the lower fibres

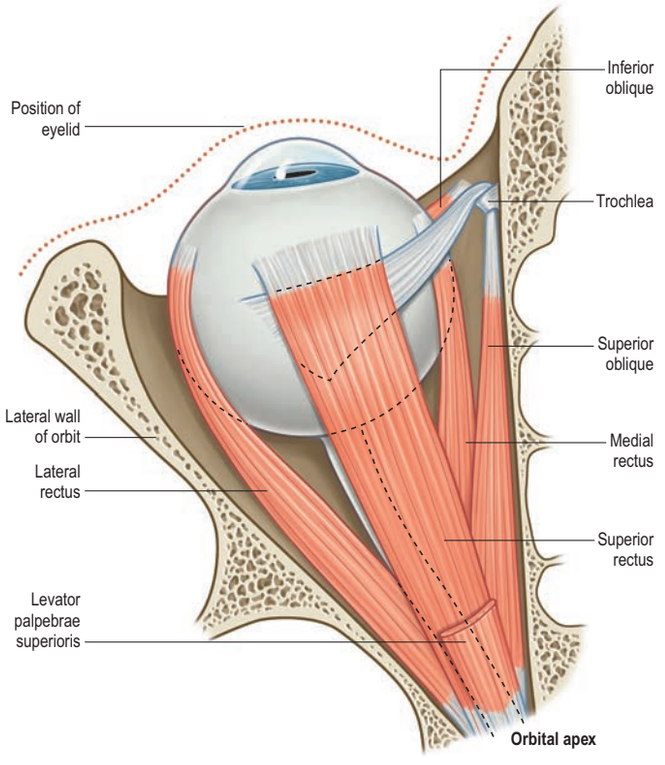

Fig. 44.8 The extraocular muscles viewed from above.

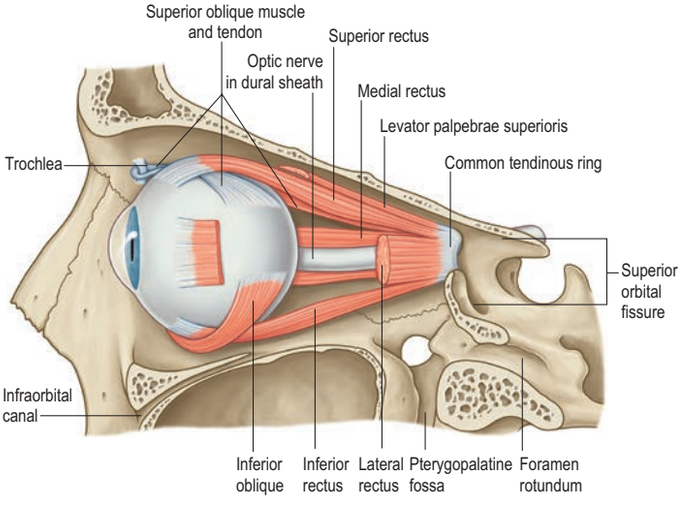

Fig. 44.9 The muscles of the left orbit, lateral view.

of lateral rectus are all attached to the lower part of the ring, whereas superior rectus, part of medial rectus and the upper fibres of lateral rectus are all attached to the upper part. A second small tendinous slip of lateral rectus is attached to the orbital surface of the greater wing of the sphenoid, lateral to the common tendinous ring.

Each rectus muscle passes forwards, in the position implied by its name, to be attached anteriorly by a tendinous expansion into the sclera. However, before their scleral attachment, the recti make functionally important connections with orbital connective tissue that influence muscle action (see p. 772).

Superior rectus

Superior rectus is slightly larger than the other recti. It arises from the upper part of the common tendinous ring, above and lateral to the optic canal. Some fibres also arise from the dural sheath of the optic nerve. The fibres pass forwards and laterally (at an angle of approximately 25° to the median plane of the eye in the primary position) to insert into the upper part of the sclera, approximately 8 mm from the limbus (see Fig. 44.8). The insertion is slightly oblique, the medial margin more anterior than the lateral margin.

Vascular supply Superior rectus receives its arterial supply both directly from the ophthalmic artery and indirectly from its supraorbital branch.

Innervation Superior rectus is innervated by the superior division of the oculomotor nerve that enters the inferior surface of the muscle.

Actions Superior rectus moves the eye so that the cornea is directed upwards (elevation) and medially (adduction). To obtain upward movement alone, the muscle must function with inferior oblique. Superior rectus also causes intorsion of the eye (i.e. medial rotation). Because a check ligament extends from superior rectus to levator palpebrae superioris, elevation of the eye also results in elevation of the upper eyelid. For more detailed discussion of its actions, see page 775.

Inferior rectus

Inferior rectus arises from the common tendinous ring, below the optic canal. It runs along the orbital floor in a similar direction to superior rectus (i.e. forwards and laterally) and inserts obliquely into the sclera below the cornea, approximately 6.5 mm from the limbus (see Fig. 44.9).

Vascular supply Inferior rectus receives its arterial supply from the ophthalmic artery and from the infraorbital branch of the maxillary artery.

Innervation Inferior rectus is innervated by a branch of the inferior division of the oculomotor nerve that enters the superior surface of the muscle.

Actions The principal activity of inferior rectus is to move the eye so that it is directed downwards (depression). It also causes the eye to deviate medially and extorts the eye (i.e. produces lateral rotation). To obtain downward movement alone, inferior rectus must function with superior oblique. A fibrous extension from inferior rectus to the inferior tarsus of the eyelid causes the lower eyelid to be depressed when the muscle contracts. For more detailed discussion of its actions, see page 775.

Medial rectus

Medial rectus is slightly shorter than the other recti but is the strongest of the group. It arises from the medial part of the common tendinous ring, and also from the dural sheath of the optic nerve, passing horizontally forwards along the medial wall of the orbit, below superior oblique (see Figs 44.8–44.9). It inserts into the medial surface of the sclera, approximately 5.5 mm from the limbus and slightly anterior to the other recti.

Vascular supply Medial rectus receives its arterial supply from the ophthalmic artery.

Innervation Medial rectus is innervated by a branch from the inferior division of the oculomotor nerve that enters the lateral surface of the muscle.

Actions Medial rectus moves the eye so that it is directed medially (adducted). The two medial recti acting together are responsible for convergence of the eyes. For more detailed discussion of its actions, see page 775.

Lateral rectus

Lateral rectus arises principally from the lateral part of the common tendinous ring and bridges the superior orbital fissure (see Fig. 44.4); some fibres also arise from a spine on the greater wing of the sphenoid. The muscle passes horizontally forwards along the lateral wall of the orbit to insert into the lateral surface of the sclera, approximately 7 mm from the limbus (see Fig. 44.8).

Vascular supply Lateral rectus receives its arterial supply from the ophthalmic artery directly and/or from its lacrimal branch.

Innervation Lateral rectus is innervated by the abducens nerve by branches that enter the medial surface of the muscle.

Actions Lateral rectus moves the eye so that it is directed laterally (abducted). For more detailed discussion of its actions, see page 775.

The obliques

Superior oblique

Superior oblique is a fusiform muscle that arises from the body of the sphenoid superomedial to the optic canal and the tendinous attachment of the superior rectus (see Fig. 44.4). It runs forwards to end in a round tendon that passes through a fibrocartilaginous loop, the trochlea, attached to the trochlear fossa of the frontal bone (see Fig. 44.8). Tendon and trochlea are separated by a delicate synovial sheath. The tendon subsequently descends posterolaterally and inferior to superior rectus, and is attached to the sclera in the superolateral part of the posterior quadrant behind the equator, between the superior and lateral recti.

Vascular supply Superior oblique receives its arterial supply directly from the ophthalmic artery and indirectly from its supraorbital branch.

Innervation Superior oblique is innervated by the trochlear nerve, which enters the superior surface of the muscle.

Actions Superior oblique is inserted into the posterior part of the eyeball; when it contracts, the back of the eyeball is elevated, and the front of the eyeball is depressed (particularly in the adducted position). Superior oblique also moves the eye laterally (abducted) and intorts the eyeball. For more detailed discussion of its actions, see page 775.

Inferior oblique

Inferior oblique is a thin, narrow muscle that lies near the anterior margin of the floor of the orbit. It arises from the orbital surface of the maxilla lateral to the nasolacrimal fossa and ascends posterolaterally, at first between inferior rectus and the orbital floor, and then between the eyeball and lateral rectus. It is inserted into the lateral part of the sclera behind the equator of the eyeball, in the inferolateral part of the posterior quadrant between the inferior and lateral recti, near, but slightly posterior to, the attachment of superior oblique (see Fig. 44.9). The muscle broadens and thins, and, in contrast to the other extraocular muscles, its tendon is barely discernible at its scleral attachment.

Vascular supply Inferior oblique receives its arterial supply from the ophthalmic artery and from the infraorbital branch of the maxillary artery.

Innervation Inferior oblique is innervated by a branch of the inferior division of the oculomotor nerve that enters the orbital surface of the muscle.

Actions Inferior oblique is inserted into the posterior part of the eyeball; when it contracts, the back of the eyeball is depressed and the front of the eyeball is elevated (particularly in the adducted position). The muscle moves the eye laterally (abduction) and also causes extorsion. For more detailed discussion of its actions, see page 775.

Minor muscles of the eyelids

Several smooth muscles are associated with the orbit, although they are not directly attached to the eyeball. Orbitalis, the orbital muscle of Müller, lies at the back of the orbit and spans the infraorbital fissure. Its functions are uncertain but its contraction may produce a slight forward protrusion of the eyeball. The superior and inferior tarsal muscles are small muscle laminae inserted into the upper and lower

eyelids, and are described in more detail with the tarsal plates (p. 775). All three minor muscles receive a sympathetic innervation from the superior cervical ganglion via the internal carotid plexus.

Movements of the eyes

Movements of the eyes involve rotations around a centre of rotation within the globe. For practical purposes, this can be considered to lie 13.5 mm behind the corneal apex. Normal eye movements are binocular. Movements of the eyes in the same direction are termed versions, whilst those in opposite directions are termed vergences. Eye movements are often accompanied by corresponding movements of the eyelids, particularly in upgaze, where the activity of levator palpebrae superioris is closely coupled to that of superior rectus. The following section describes the ocular motor system in terms of the actions of individual extraocular muscles, the diversity of eye movements and their neural control.

Actions of the extraocular muscles

Levator palpebrae superioris elevates the upper lid, and its antagonist is the palpebral part of orbicularis oculi. The degree of elevation, which, apart from blinking, is maintained for long periods during waking hours, is a compromise between ensuring an adequate exposure of the cornea and controlling the amount of incident light. In bright sunshine, the latter can be reduced by lowering the upper lid, so limiting glare. The role of the superior tarsal muscle is less clear. Its tonus is related to sympathetic activity, and since ptosis is a consequence of impairment of its sympathetic nerve supply, it may function as an accessory elevator of the upper eyelid.

Six extraocular muscles rotate the eyeball in directions that depend on the geometrical relation between their bony and global (scleral) attachments (**Fig. 44.10**), which are altered by the ocular movements themselves. For convenience, each muscle will be considered in isolation, but it must be appreciated that any movement of the eyeball alters the tension and/or length in all six muscles. It is useful to consider the four recti and two obliques as separate groups (remembering always that they act in concert) because they form more obvious groupings as antagonists or synergists. The extrinsic ocular muscles collectively position the eyeball in the orbital cavity and prevent its anteroposterior movements, other than a slight retraction during blinks, because the recti exert a posterior traction while the obliques pull the eyeball to some degree anteriorly. They may be assisted by various 'check ligaments' (see above). A simplified description of the actions of the extraocular muscles is summarized in **Fig. 44.11**.

Of the four recti, the medial and lateral exert comparatively straightforward forces on the eyeball. Being approximately horizontal, when the visual axis is in its primary position, i.e. directed to the horizon, they rotate the eye medially (adduction) or laterally (abduction) about an imaginary vertical axis. They are antagonists. The visual axis can be swept through a horizontal arc by reciprocal adjustment of their lengths. When, as is usual, both eyes are involved, the medial and lateral recti of each eye either can adjust both visual axes in a conjugate movement from point to point at infinity (their axes remaining parallel), or they can converge or diverge the axes to or from nearer or more distant objects of attention in the visual field.

The medial and lateral recti do not rotate the eye around its horizontal axis and so cannot elevate or depress the visual axes as gaze is transferred from nearer to more distant objects or the reverse. This movement requires the superior and inferior recti (aided by the two oblique muscles). It is important to remember that the orbital axis does not correspond with the visual axis in its primary position but diverges from it at an angle of approximately 23° (**Fig. 44.10A**) (the value varies between individuals, and depends on the angle between the orbital axes and the median plane). Thus, the simple rotation caused by an isolated superior rectus, analysed with reference to the three hypothetical ocular axes, appears more complex, being primarily elevation (horizontal axis), and secondarily a less powerful medial rotation (vertical axis) and slight intorsion (anteroposterior axis) in which the midpoint of the upper rim of the cornea (often referred to as '12 o'clock') is rotated medially. These actions, compounded as a single, simple rotation, are easily appreciated when it is seen that the direction of traction of superior rectus runs in a posteromedial direction from its attachment in front, which is anterior to the equator and superior to the cornea, to its bony attachment near the orbital apex (see Fig. 44.10). Inferior rectus pulls in a similar direction to superior rectus but rotates the visual axis downwards about the horizontal axis. It rotates the eye medially on a vertical axis but its action around the anteroposterior axis extorts the eye, i.e. rotates it so that the corneal '12 o'clock' point turns laterally. The combined, equal contractions of the superior and inferior recti therefore rotate the eyeball medially, since their effects around the horizontal and anteroposterior axes are opposed. In binocular movements, they assist the medial recti in converging the visual axes, and by reciprocal adjustment can elevate or depress the visual axes. As the eyeball is rotated laterally, the lines of traction of the superior and inferior recti approach the plane of the anteroposterior ocular axis (see Fig. 44.10), and so their rotational effects about this and the vertical ocular axis diminish. In abduction to approximately 23°, they become almost purely an elevator and depressor, respectively, of the visual axis.

Superior oblique acts on the eye from the trochlea and, since the attachment of inferior oblique is, for practical purposes, vertically below this, both muscles approach the eyeball at the same angle, being attached in approximately similar positions in the superior and inferior posterolateral ocular quadrants (see Fig. 44.10). Superior oblique elevates the posterior aspect of the eyeball, and inferior oblique depresses it, which means that the former rotates the visual axis downwards and the latter rotates it upwards, and both movements occur around the horizontal axis. When the eye is in the primary position, the obliquity of both muscles means that they pull in a direction posterior to the vertical axis and both therefore rotate the eye laterally around this axis. With regard to the anteroposterior axis, in isolation, superior oblique intorts the eye and inferior oblique extorts it. Like the superior and inferior recti, therefore, the two obliques have a common turning movement around the vertical axis but are opposed forces in respect of the other two. Acting in concert, they could therefore assist the lateral rectus in abducting the visual axis, as in divergence of the eyes in transferring attention from near to far. Again, like the superior and inferior recti, the directions of traction of the oblique muscles also vary with ocular position, such that they become more nearly a pure elevator and a depressor as the eye is adducted.

Ocular rotations are, for the most part, under voluntary control, whereas torsional movements cannot be initiated at will. When the head is tilted in a frontal plane, reflex torsions occur. Any small lapse in the concerted adjustment of both eyes produces diplopia.

Movements that shift or stabilize gaze

The role of eye movements is to bring the image of objects of visual interest on to the fovea of the retina and to hold the image steady in order to achieve the highest level of visual acuity. Several types of eye movement are required to ensure that these conditions are met. Moreover, the movements of both eyes must be near perfectly matched to achieve the benefits of binocularity. Both voluntary and reflex movements are involved and may be so classified. Alternatively, they may be grouped into those movements that shift gaze as visual interest changes, and those that stabilize gaze by maintaining a steady image on the retina. They have distinct characteristics, and are generated by different neural mechanisms in response to different stimuli, but share a common final motor pathway. Movements that shift or stabilize gaze include saccades, vergence, pursuit and vestibular-generated reflexes (Leigh and Zee 2015).

Saccadic activity is almost omnipresent in human vision. Thus, both visual axes are endlessly and rapidly transferred to new points of interest in any part of the visual field. Binocular gaze is frequently made to travel routes of the most variable complexity in examining objects of interest in the field, and both visual axes must be maintained with sufficient accuracy to avoid diplopia. In so-called 'fixation' of a focus of attention, whether uniocular or binocular, the visual axis is not 'fixed' in a perfectly steady manner but undergoes minute, but measurable, flicking (of a few minutes or even seconds of arc) across the true line of fixation. These microsaccades are rapid and surprisingly complex. When interest changes to another feature of the visual scene, the eyes execute a fast or saccadic movement to take up fixation. If the required rotation is small, the saccade is accurate, whereas small supplementary corrective saccades are needed if the shift is substantial. Saccades may also occur in response to other, i.e. non-visual, exteroceptive stimuli (e.g. auditory, tactile or centrally evoked). They may be volitional or reflex. As an example of the latter, in reading a line of print, the eyes make three or four jerky saccades rather than following the line smoothly; the line is usefully imaged only when the eye is stationary, which means that little of the line is seen by the centre of the fovea. In general, reaction times and movements are measured in microseconds, amplitude varies from seconds of arc to many degrees, with an accuracy of 0.2° or better, and the velocity of a large saccade may reach 500° sec^{-1}. The speed of saccades is assured by an initial, slightly excessive, contraction of the appropriate muscles to overcome orbital viscous resistance. The necessary deceleration when the target is fixated is largely dependent on the elasticity of the extraocular muscles and orbital soft tissues, and not on antagonistic muscular activity.

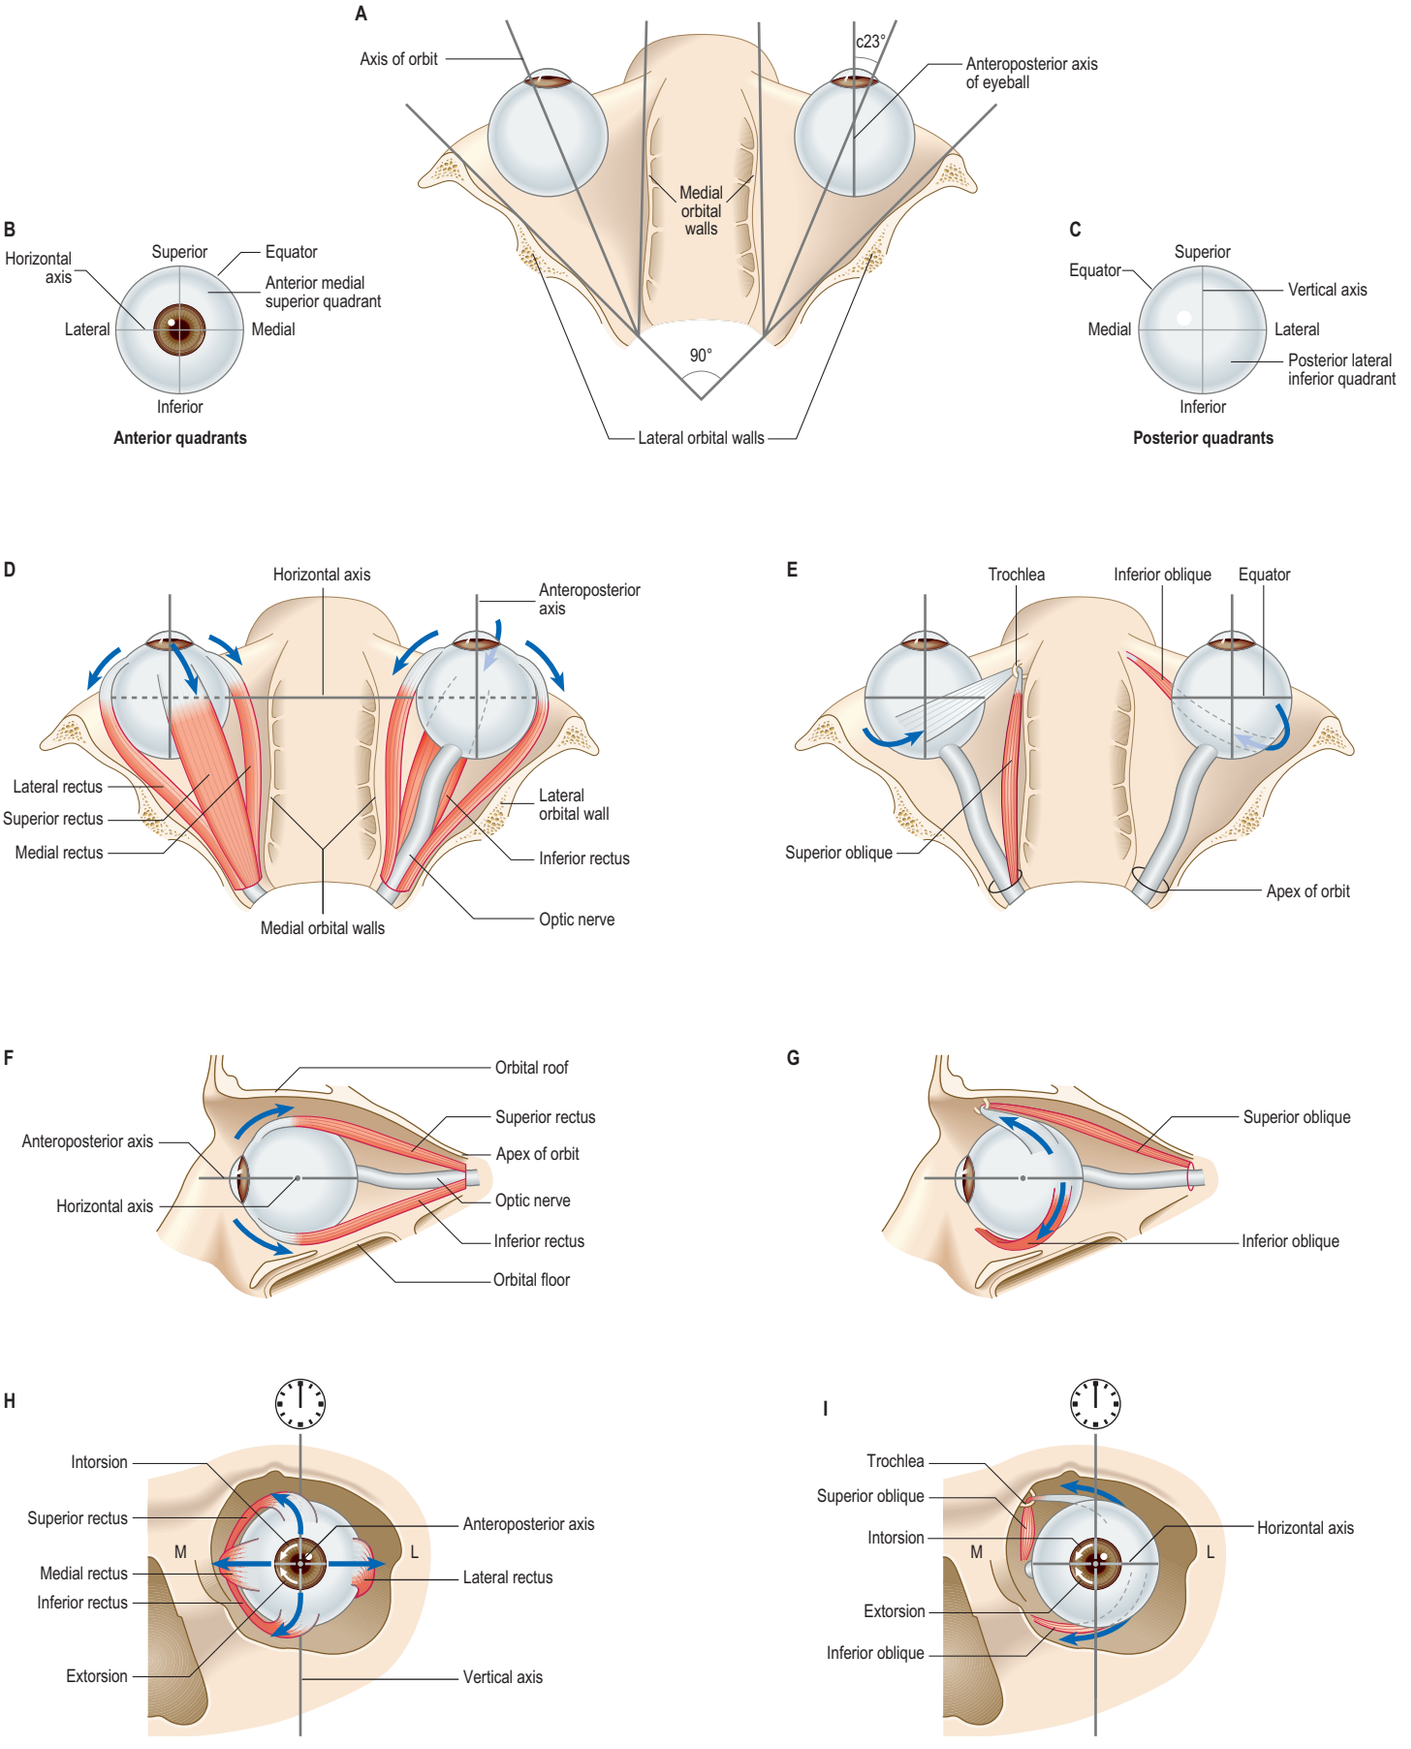

Fig. 44.10 The geometrical basis of ocular movements. **A**, The relationship between the orbital and ocular axes, with the eyes in the primary position, where the visual axes are parallel. **B–C**, The ocular globe in anterior and posterior views to show conventional geometry. **D**, The orbits from above, showing the medial and lateral recti and the superior rectus (left) and the inferior rectus (right), indicating turning moments primarily around the vertical axis. **E**, The superior (left) and inferior (right) oblique muscles showing turning moments primarily around the vertical and also anteroposterior axes. **F**, A lateral view to show the actions of the superior and inferior recti around the horizontal axis. **G**, A lateral view to show the action of the superior and inferior oblique muscles around the anteroposterior axis. **H**, An anterior view to show the medial rotational movement of the superior and inferior recti around the vertical axis. Conventionally, the 12 o'clock position indicated is said to be intorted (superior rectus) or extorted (inferior rectus), as indicated by the small arrows on the cornea. **I**, An anterior view to show the torsional effects of the superior oblique (intorsion) and inferior oblique (extorsion) around the anteroposterior axis, as indicated by the small arrows on the cornea.

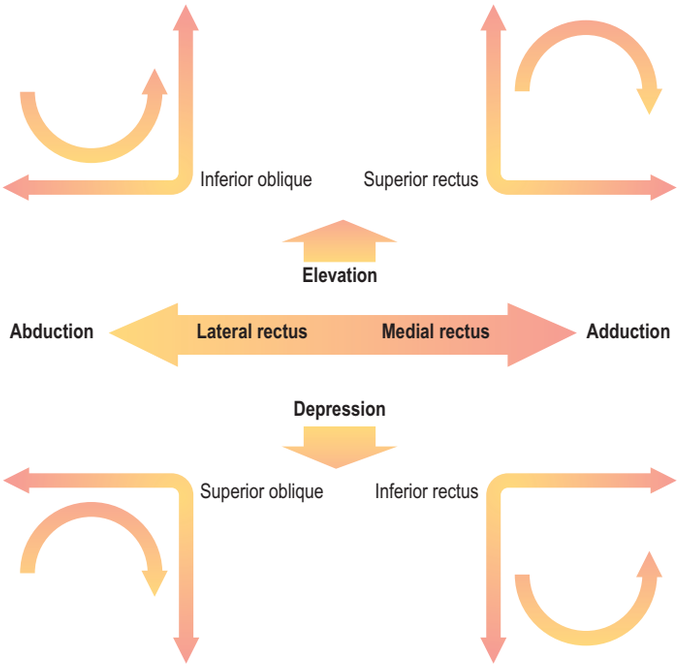

Fig. 44.11 A simplified summary of the actions of the extraocular muscles. Clockwise and anticlockwise curved arrows represent intorsion and extorsion, respectively.

Vergence is a relatively slow movement permitting maintenance of single binocular vision of close objects. The eyes converge towards the midline between the two eyes to achieve imagery of the object on both foveas. The view of the object at the two eyes is not quite the same and the disparity is used to assess depth. In addition, the pupils constrict and the eyes accommodate to achieve sharp, focused images. These three activities constitute the near reflex (Ch. 45).

Pursuit eye movements are used to track a moving object of visual interest, maintaining the image approximately on the fovea. They are usually preceded by a saccade to capture the image but, unlike saccades, pursuit movements are slow and motivated by vision. If the angular shift required to track a moving object is large or the object is moving swiftly, the initial saccade is frequently inaccurate and one or more small corrective saccades are made before tracking begins. Because the stimulus is visual, the pursuit system response is subject to a relatively long latency (approximately 100 msec); the limitation in performance this imposes may be offset by a predictive capacity when object movement follows a regular pattern, and the eye movements adjust in anticipation of the speed and direction of the object. Smooth pursuit performance declines with age and is commonly impaired in cerebellar disease.

The vestibular apparatus induces a variety of reflex eye movements to compensate for the potentially disruptive effects on vision caused by head and body movement (Ch. 43). Receptors in the semicircular canals respond to active or passive rotational (angular) accelerations of the head. When the body makes substantial rotational movements, a vestibulo-ocular reflex generates a cycle of responses involving both the shifting and stabilizing of gaze. Body rotation is matched by counter-rotation of the eyes so that gaze direction is unaltered and clear vision is maintained. Physical constraint limits the rotation to 30° or less and is followed by a rapid saccadic movement of the eyes to another object in the visual scene and the cycle is repeated. Vision is therefore clear throughout most of the cycle while the image is stationary, but at the cost of no useful vision during the brief periods of the saccades. The reflex is efficient and rapid; this speed could not be generated by the visual system, which is slow relative to the short latency of vestibular receptors.

Other reflexes generated by the vestibular system, which induce compensatory eye movements to stabilize gaze, are activated during brief head movements. When the head is sharply rotated in any direction, the eyeball rotates by an equal amount in the opposite direction in response to the stimulation of semicircular canal cristae (angular acceleration), and gaze is undisturbed. Brief rotational movements are commonly combined with translational movements (linear acceleration) that are monitored by otolith organs. For example, a linear displacement occurs in walking as the head bobs vertically with each stride, and a rotational displacement occurs as the head rolls, invoking otolith and canal responses, respectively, to stabilize the retinal image. Vestibular disease incurring the loss of the rapid, fine compensatory eye movements in locomotion destabilizes the retinal image, blurs vision and may render locomotion intolerable.

The otoliths also respond to the pull of gravity, generating static vestibulo-ocular reflexes associated with head tilt. When static otolith orientation is changed, e.g. when the head is tilted upwards or downwards, the eyes counter-rotate to maintain fixation of the horizontal meridian. Lateral tilt towards a shoulder generates a torsional counter-rotation equal and in opposite direction by the two eyes, a movement that cannot be made voluntarily: because the foveal image is unaffected by torsional movements, there is no visual penalty.

The optokinetic response is another visually mediated reflex that stabilizes retinal imagery when a visual scene is rotated about a stationary subject. As the scene changes, the eyes follow and hold the retinal image steady until the eyes shift rapidly in the opposite direction to another area of the visual scene. The stimulus is the full field of vision, rather than small objects within it, and the alternating slow and fast phases of movement that are generated describe optokinetic nystagmus. This reflex functions in collaboration with the rotational vestibulo-ocular reflex. In sustained rotations of the body, the vestibulo-ocular reflex fades because of the mechanical arrangements of the semicircular canals. In darkness, the reflex, which is initially compensatory, loses velocity, and after approximately 45 seconds the eyes become stationary. With a visual input, the reflex is sustained by the optokinetic response, and because the reflex is already initiated, the relative delay of visual input is overcome. The usual method of evoking optokinetic nystagmus in the laboratory or clinic is to present a horizontally moving pattern of vertical black-on-white stripes while the head of the subject is held stationary.

Neural control of gaze

Although the detailed anatomical substrates for the different types of eye movement differ, they share common neural circuitry that lies mainly in the pons and midbrain, for horizontal and vertical gaze movements, respectively (**Fig. 44.12**). The common element for all types of horizontal gaze movements is the abducens nucleus. It contains motor neurones that innervate the ipsilateral lateral rectus and interneurones that project via the medial longitudinal fasciculus to the contralateral oculomotor nucleus, which controls medial rectus. A lesion of the abducens nucleus leads to a total loss of ipsilateral horizontal conjugate gaze. A lesion of the medial longitudinal fasciculus produces slowed or absent adduction of the ipsilateral eye, usually associated with jerky movements (nystagmus) of the contralateral abducting eye, a syndrome called internuclear ophthalmoplegia (Leigh and Zee 2015). The gaze motor command involves specialized areas of the reticular formation of the brainstem, which receive a variety of supranuclear inputs. The main region for the generation of horizontal saccades is the paramedian pontine reticular formation, located on each side of the midline in the central paramedian part of the tegmentum, and extending from the pontomedullary junction to the pontopeduncular junction. Each paramedian pontine reticular formation contains excitatory neurones (referred to as 'burst' neurones) that discharge at high frequencies just prior to and during ipsilateral saccades. Excitatory burst neurones make monosynaptic connections with the ipsilateral abducens nucleus. Omnipause neurones in the pontine nucleus raphe interpositus, located in the midline between the rootlets of the abducens nerves, discharge tonically during fixation but stop firing immediately prior to a saccade. They appear to exert an inhibitory influence on the burst neurones and act as a switch to change from fixation to saccadic mode (Ramat et al 2007).

The tonic activity of neurones in the nucleus prepositus hypoglossi and medial vestibular nucleus is thought to provide an eye position signal to maintain the eccentric position of the eye against the viscoelastic forces in the orbit. These forces tend to move the eyeball back to looking straight ahead, i.e. the primary position, after a saccade. Vestibular nuclei and the perihypoglossal complex project directly to the abducens nuclei: these projections probably also carry smooth pursuit signals, via the cerebellum.

The final common pathway for vertical gaze movements is formed by the oculomotor and trochlear nuclei. The rostral interstitial nucleus of the medial longitudinal fasciculus contains both excitatory burst neurones that discharge in relation to up-and-down vertical saccadic movements and project to motor neurones involved in vertical gaze, and omnipause neurones that act similarly to those for horizontal gaze. The rostral interstitial nucleus of the medial longitudinal fasciculus projects through the posterior commissure to its equivalent on the other side of the mesencephalon for upgaze, as well as directly to the ipsilateral

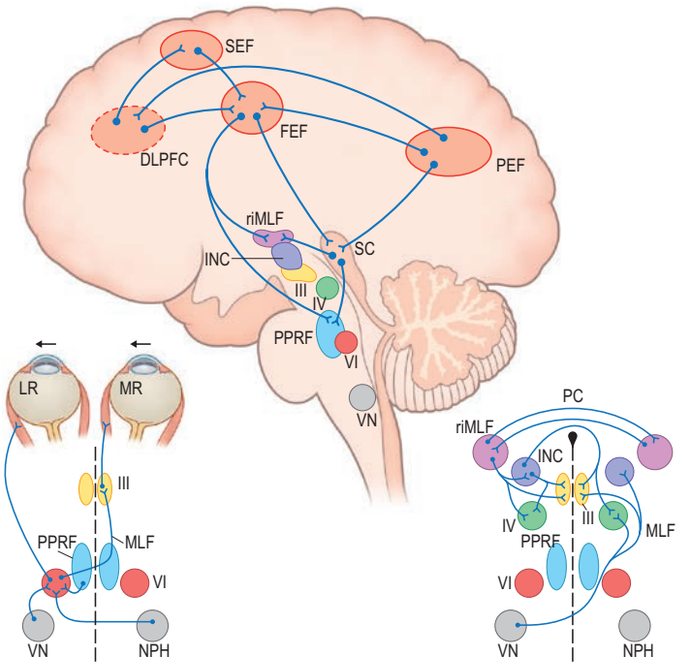

Fig. 44.12 A summary of the control of eye movements. The central drawing shows the supranuclear connections from the frontal eye field (FEF) and the posterior eye field (PEF) to the superior colliculus (SC), rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), and the paramedian pontine reticular formation (PPRF). The diagram on the left shows the brainstem pathways for horizontal gaze. Axons from the PPRF travel to the ipsilateral abducens nucleus innervating lateral rectus (LR). Abducens internuclear axons cross the midline and travel in the medial longitudinal fasciculus (MLF) to the neuronal pool in the oculomotor nucleus (III) that innervates medial rectus (MR) of the contralateral eye. The diagram on the right shows the brainstem pathways for vertical gaze. Important structures include the riMLF, PPRF, the interstitial nucleus of Cajal (INC) and the posterior commissure (PC). Other abbreviations: DLPFC, dorsolateral prefrontal cortex; IV, trochlear nucleus; NPH, nucleus propositus hypoglossi; SEF, supplementary eye field; VI, abducens nucleus; VN, vestibular nucleus.

oculomotor and trochlear nuclei for downgaze (see Fig. 44.12). Neurones in and around the interstitial nucleus of Cajal, which lies slightly caudal to the rostral interstitial nucleus of the medial longitudinal fasciculus, provide signals for vertical gaze holding. Vertical gaze palsies can affect upgaze, downgaze or both. Lesions within the posterior commissure predominantly give rise to disturbances in upgaze, associated with other signs of dorsal midbrain syndrome, e.g. pupillary abnormalities (light–near dissociation). Discrete lesions placed more ventrally in the region of the rostral interstitial nucleus of the medial longitudinal fasciculus may cause mixed up-and-down, or mainly downgaze disturbances (Leigh and Zee 2015).

The cerebellum and cerebral hemispheres play important roles in the control of eye movements. The vestibulocerebellum (flocculus and nodule) is involved in gaze holding, smooth pursuit and the vestibulo-ocular reflex (Ch. 29). The dorsal vermis and fastigial nucleus are involved in programming accurate saccades and smooth pursuit. The cerebral hemispheres are also involved in the programming and coordination of saccadic and pursuit conjugate eye movements. The frontal eye field, the supplementary eye field, the dorsolateral prefrontal cortex and the parietal eye field are all involved in eye movement control: these areas are interconnected and send projections to the superior colliculus and other brainstem ocular motor centres. Although the anatomical location of cortical gaze control areas has been well characterized in non-human primates, their precise location in the human brain is yet to be definitively established and appears to vary depending on the method used (Amiez and Petrides 2009).

Two parallel pathways are involved in the cortical generation of saccades. An anterior system originates in the frontal eye field and projects, both directly and via the superior colliculus, to the brainstem saccadic generators. This pathway also passes indirectly via the basal ganglia to the superior colliculus. Projections from the frontal cortex influence cells in the pars reticularis of the substantia nigra, via a relay in the caudate nucleus. An inhibitory pathway from the pars reticulata projects directly to the superior colliculus. This may be a gating circuit related to voluntary saccades, especially of the memory-guided type. A posterior pathway originates in the parietal eye field and passes to the brainstem saccadic generators via the superior colliculus. This pathway is important for triggering reflexive saccades.

The smooth pursuit system has developed relatively independently of the saccadic oculomotor system to maintain foveation of a moving target, although there are inevitable interconnections between the two. The first task is to identify and code the velocity and direction of a moving target. This is largely performed by secondary visual areas at the parietal–occipital–temporal lobe junction (human homologue of the middle temporal visual area (V5) and medial superior temporal visual area of monkeys). Descending pathways from these posterior cortical areas project to a group of nuclei that lie in the basal part of the pons, which in turn transfer the pursuit signal bilaterally to the cerebellum and ultimately to ocular motor neurones.

The vestibulo-ocular reflex maintains coordination of vision during movement of the head and results in a compensatory conjugate eye movement that is equal but opposite to the movement of the head. This essentially three-neurone arc consists of primary vestibular neurones that project to the vestibular nuclei; secondary neurones that project from these nuclei directly to the abducens and oculomotor nuclei; and tertiary neurones that innervate the extraocular muscles. Vestibular neurones responding to head rotation also respond to optokinetic stimuli, which means that the neural substrate is likely to include both the visual and vestibular systems.

Several cortical areas contribute to vergence movements. Posterior visual areas are responsible for sensory processing and generating reflexive, stimulus-linked movements, whereas the frontal cortex (frontal and supplementary eye fields) is more concerned with volitional, self-initiated movements (Leigh and Zee 2015). These cortical regions project to the midbrain supraocular motor area, which encodes vergence eye movements and sends excitatory projections to medial rectus and lateral rectus motoneurones that generate convergence and divergence, respectively.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

Orbital vascular anatomy displays noteworthy inter-individual variation (Hayreh 2006): the usual pattern and more common variations are presented below. The main vessel supplying orbital structures is the ophthalmic artery (**Fig. 44.13**). Its terminal branches anastomose on the face and scalp with those of the facial, maxillary and superficial temporal arteries, and in so doing establishing connections between the external and internal carotid arteries. The infraorbital branch of the maxillary artery, which anastomoses with the middle meningeal artery, may also supply orbital structures.

Ophthalmic artery

The ophthalmic artery leaves the internal carotid artery as it exits the cavernous sinus medial to the anterior clinoid process. It enters the orbit by the optic canal, inferolateral to the optic nerve and continues forwards for a short distance before turning medially by crossing (almost always) over or under the optic nerve (see Fig. 44.13A). The main trunk of the artery continues along the medial wall of the orbit between the superior oblique and lateral rectus, and divides into supratrochlear (frontal) and dorsal nasal branches at the medial end of the upper eyelid. Although the order of branches from the ophthalmic artery is quite variable, there are several consistent branches, including the central retinal artery, muscular branches, ciliary arteries, lacrimal artery, supraorbital artery, anterior and posterior ethmoidal arteries, meningeal branch, medial palpebral arteries, supratrochlear artery and dorsal nasal artery (Hayreh and Dass 1962a). Many of the branches of the ophthalmic artery accompany sensory nerves with the same name and have a similar distribution to these nerves. Variations in the origin and course of the ophthalmic artery have been described (Huynh-Le et al 2005, Hayreh 2006, Bertelli et al 2017).

Central retinal artery

The small central artery of the retina is the first branch of the ophthalmic artery. It begins below the optic nerve and, for a short distance, lies in the dural sheath of the nerve. It enters the inferomedial surface of the nerve 6.4–15.2 mm behind the eye, and runs to the retina (accompanying the central retinal vein) along its axis. The further distribution of the central retinal artery is described in Chapter 45.

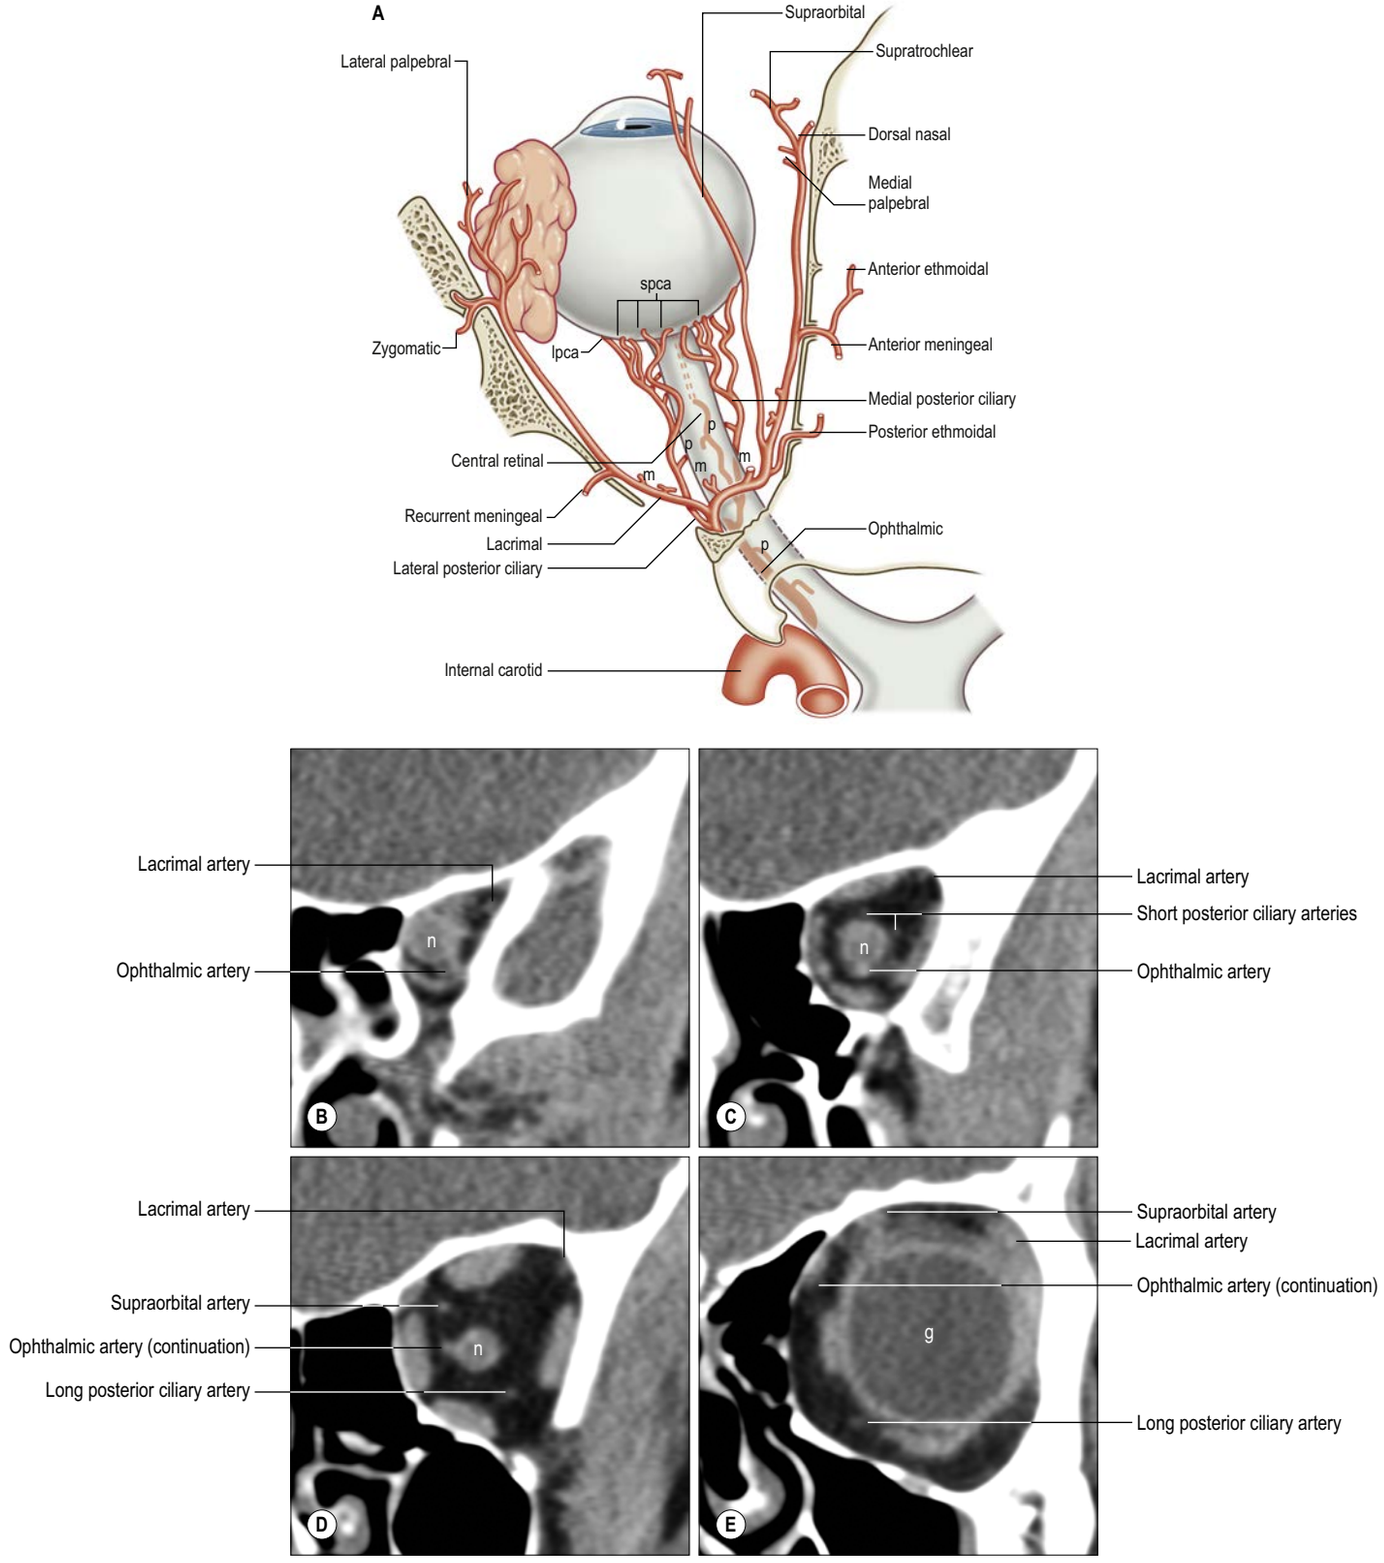

Fig. 44.13 A, Dorsal view of the left eye showing the orbital distribution of the ophthalmic artery. **B–E**, Coronal CT sections through the left orbit from posterior to anterior, showing arterial branches. Contrast medium has been given to the patient. Abbreviations: g, globe; lpca, long posterior ciliary artery; m, muscular arteries; n, optic nerve; p, pial arteries; spca, short posterior ciliary arteries.

Muscular branches

Branches to the extraocular muscles frequently spring from a common trunk to form superior and inferior groups, most of which accompany branches of the oculomotor nerve. The inferior branch contains most of the anterior ciliary arteries. Other muscular vessels branch from the lacrimal and supraorbital arteries or from the trunk of the ophthalmic artery.

Ciliary arteries

The ciliary arteries are distributed in long and short posterior, and in anterior groups (see Fig. 44.13A). Long posterior ciliary arteries, usually two, pierce the sclera near the optic nerve, pass anteriorly along the horizontal meridian and join the major arterial circle of the iris (see Fig. 45.8). About seven short posterior ciliary arteries pass close to the optic nerve to reach the eyeball, where they divide into 15–20 branches. They pierce the sclera around the optic nerve to supply the choroid, and anastomose with twigs of the central retinal artery at the optic disc (see Fig. 45.30). Anterior ciliary arteries arise from muscular branches of the ophthalmic artery. They reach the eyeball on the tendons of the recti, form a circumcorneal subconjunctival vascular zone, and pierce the sclera near the sclerocorneal junction to end in the major arterial circle of the iris.

Lacrimal artery

The lacrimal artery is a large branch that usually leaves the ophthalmic artery near its exit from the optic canal (see Fig. 44.13A), although it occasionally arises before the ophthalmic artery enters the orbit. It accompanies the lacrimal nerve along the upper border of lateral rectus, supplies and traverses the lacrimal gland, and ends in the eyelids and conjunctiva as the lateral palpebral arteries. The latter run medially in the upper and lower lids and anastomose with the medial palpebral arteries. The lacrimal artery gives off one or two zygomatic branches. One reaches the temporal fossa via the zygomaticotemporal foramen and anastomoses with the deep temporal arteries. The other reaches the cheek by the zygomaticofacial foramen and anastomoses with transverse facial and zygomatico-orbital arteries. A recurrent meningeal branch, usually small, passes back via the lateral part of the superior orbital fissure to anastomose with the middle meningeal artery. This branch is sometimes large and replaces the lacrimal artery, in which case it becomes a more significant contributor to the orbital blood supply (Hayreh and Dass 1962b, Uchino et al 2013).

Supraorbital artery

The supraorbital artery leaves the ophthalmic artery where it crosses the optic nerve (see Fig. 44.13A), and ascends medial to superior rectus and levator palpebrae superioris. It accompanies the supraorbital nerve between the periosteum and levator palpebrae superioris, passes through the supraorbital foramen or notch, and divides into superficial and deep branches. These supply the skin, muscles and frontal periosteum, and anastomose with the supratrochlear artery and with the frontal branch of the superficial temporal artery and its contralateral fellow (see Fig. 36.20). The supraorbital artery supplies superior rectus and levator palpebrae superioris, sends a branch across the trochlea to the medial canthus, and often sends a branch to the diploë of the frontal bone at the supraorbital margin; it may also supply the mucoperiosteum in the frontal sinus.

Posterior ethmoidal artery

The posterior ethmoidal artery runs through the posterior ethmoidal canal and supplies the posterior ethmoidal air sinuses. Entering the cranium, it gives off a meningeal branch to the dura mater, and nasal branches that descend into the nasal cavity via the cribriform plate, and anastomoses with branches of the sphenopalatine artery (see Fig. 39.9).

Anterior ethmoidal artery

The anterior ethmoidal artery passes with its accompanying nerve through the anterior ethmoidal canal to supply the ethmoidal and frontal air sinuses. Entering the cranium, it gives off a meningeal branch to the dura mater, and nasal branches that descend into the nasal cavity with the anterior ethmoidal nerve (see Fig. 39.9). It runs in a groove on the deep surface of the nasal bone to supply the lateral nasal wall and septum. A terminal branch appears on the nose between the nasal bone and the upper nasal cartilage (see Fig. 39.9).

Meningeal branch

A meningeal branch, usually small, passes back through the superior orbital fissure or its own foramen to the middle cranial fossa, where it anastomoses with the middle meningeal artery. It is sometimes large, in which case it becomes a major contributor to the orbital blood supply.

Medial palpebral arteries

Above the trochlea, two medial palpebral arteries branch separately from the ophthalmic artery and join the lateral palpebral arteries to complete the arterial arcades supplying the upper and lower eyelids.

Supratrochlear artery

The supratrochlear artery is a terminal branch of the ophthalmic artery. It leaves the orbit superomedially with the supratrochlear nerve, ascends on the forehead to supply the skin, muscles and pericranium, and anastomoses with the supraorbital artery and with its contralateral fellow.

Dorsal nasal artery

The dorsal nasal artery is the other terminal branch of the ophthalmic artery and emerges from the orbit between the trochlea and medial palpebral ligament. It gives a branch to the upper part of the nasolacrimal sac and then divides into two branches. One branch anastomoses with the terminal part of the facial artery, and the other runs along the dorsum of the nose, supplies its outer surface and anastomoses with its contralateral fellow and the lateral nasal branch of the facial artery.

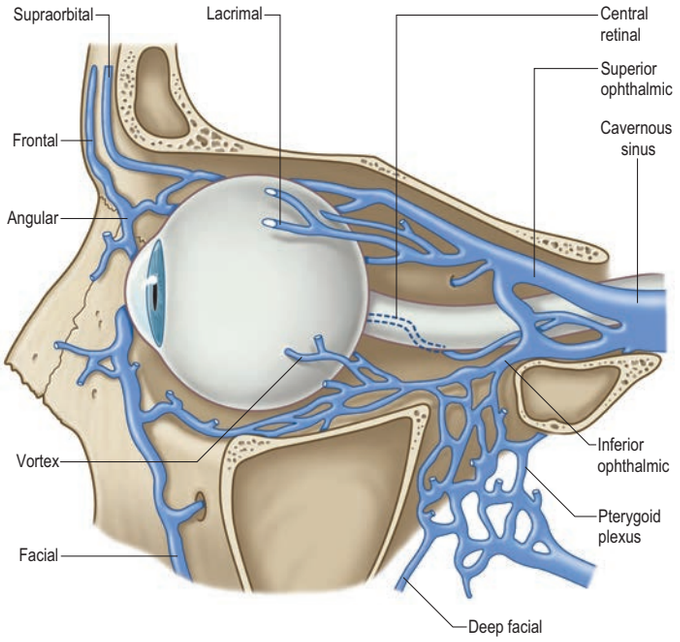

Fig. 44.14 The principal veins of the orbit.

Infraorbital branch of the maxillary artery

The infraorbital branch of the maxillary artery enters the orbit through the inferior orbital fissure (see Fig. 38.20). Accompanying the infraorbital nerve, it passes along the infraorbital groove of the maxilla in the floor of the orbit before entering the infraorbital canal, and comes out on to the face through the infraorbital foramen. While in the infraorbital groove, it gives off branches that supply inferior rectus and inferior oblique, the nasolacrimal sac and, occasionally, the lacrimal gland.

Veins

The orbit is drained by the superior and inferior ophthalmic veins and the infraorbital vein (Fig. 44.14). The veins of the eyeball mainly drain into the vortex veins; the retinal veins drain into the central retinal vein.

Superior and inferior ophthalmic veins

The superior and inferior ophthalmic veins link the facial and intracranial veins, and are devoid of valves. The superior ophthalmic vein forms posteromedial to the upper eyelid from two tributaries that connect anteriorly with the facial and supraorbital veins. It runs with the ophthalmic artery, lying between the optic nerve and superior rectus, and receives the corresponding tributaries, the two superior vortex veins of the eyeball, and the central vein of the retina. The central retinal vein sometimes drains directly into the cavernous sinus, although it still gives a communicating branch to the superior ophthalmic vein. The superior ophthalmic vein may also receive the inferior ophthalmic vein. It traverses the superior orbital fissure, usually above the common tendinous ring of the recti, and ends in the cavernous sinus.

The inferior ophthalmic vein begins in a network near the anterior region of the orbital floor and medial wall. It runs backwards on inferior rectus and across the inferior orbital fissure, and then either joins the superior ophthalmic vein or passes through the superior orbital fissure, within or below the common tendinous ring, to drain directly into the cavernous sinus. The inferior ophthalmic vein receives tributaries from inferior rectus and inferior oblique, the nasolacrimal sac, the eyelids and the two inferior vortex veins of the eyeball. It communicates with the pterygoid venous plexus by a branch that passes through the inferior orbital fissure, and may also communicate with the facial vein across the inferior margin of the orbit.

Infraorbital vein

The infraorbital vein runs with the infraorbital nerve and artery in the floor of the orbit, and passes backwards through the inferior orbital fissure into the pterygoid venous plexus. It drains structures in the floor of the orbit and communicates with the inferior ophthalmic vein; it may also communicate with the facial vein on the face.

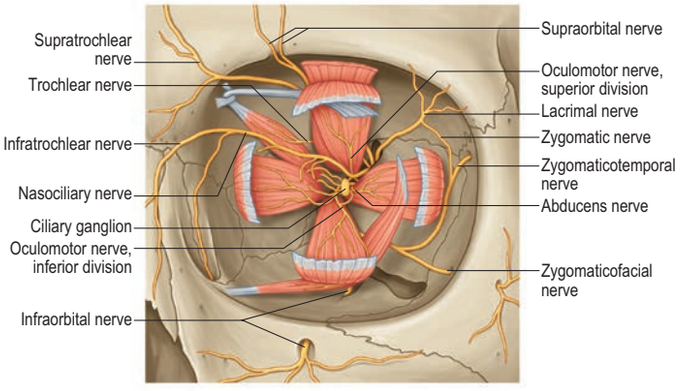

Fig. 44.15 The left orbit viewed from in front, showing motor and sensory nerves and the origins of the extraocular muscles. Note that in this figure the trochlear nerve is shown inserting on the inferior aspect of the superior oblique, whereas it more commonly inserts on the superior surface of the muscle. (With permission from Dutton JJ 1994 Atlas of Clinical and Surgical Orbital Anatomy. Philadelphia: Saunders.)

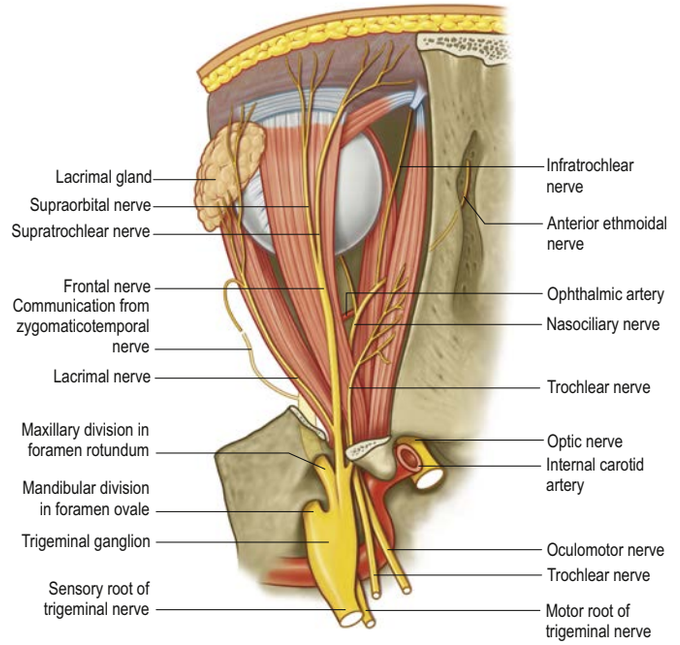

Fig. 44.16 The nerves of the left orbit, superior aspect.

Lymphatic drainage

Lymphatic vessels other than those draining the conjunctiva have not been identified.

INNERVATION

Somatic and autonomic motor and somatic sensory nerves are found in the orbit (Figs 44.15–44.17). The oculomotor, trochlear and abducens nerves supply the extraocular muscles. Parasympathetic fibres travelling in the oculomotor nerve (from cell bodies in the Edinger–Westphal nucleus) supply sphincter pupillae and the ciliary muscle (ciliaris) via the ciliary ganglion, and those travelling in the facial nerve (from cell bodies in the lacrimal portion of the superior salivatory nucleus) innervate the lacrimal gland and choroid via the pterygopalatine ganglion. Postganglionic sympathetic fibres arising (from cell bodies in the superior cervical ganglion) supply dilator pupillae. Both sympathetic and parasympathetic nerves supply the arteries. The sensory nerves within the orbit are the optic, ophthalmic and maxillary nerves (the maxillary nerve and most of the ophthalmic branches only pass through the orbit *en route* to supply the face and jaws).

Oculomotor nerve

The oculomotor nerve is the third cranial nerve (see Fig. 44.15). It innervates levator palpebrae superioris and four of the extraocular muscles (superior, inferior and medial rectus and inferior oblique), and also conveys parasympathetic fibres that relay in the ciliary ganglion.

For descriptive purposes, the nerve is usually divided into cisternal, cavernous and orbital portions: surgically oriented classifications derived from combined microsurgical and endoscopic cadaveric dissection studies have proposed five or seven parts (Iaconetta et al 2010, Park et al 2017).

The cisternal portion of the oculomotor nerve emerges from the midbrain, either through the medial sulcus of the crus cerebri in the caudal part of the interpeduncular fossa or through the medial or the middle part of the crus cerebri. It usually passes forwards and laterally through the interpeduncular cistern between the posterior communicating artery and the superior cerebellar artery: this portion of the nerve is supplied by the P1 and P2 segments of the posterior cerebral artery. The pupilloconstrictor fibres lie superficially on the dorsomedial surface of the cisternal portion of oculomotor nerve, a location that renders them vulnerable to aneurysmal compression (Kerr and Hollowell 1964, Shechtman et al 2007): in contrast, a pupil-sparing palsy of the oculomotor nerve is pathognomonic of an ischaemic lesion, which tends to involve the central region of the nerve.

The oculomotor nerve next passes inferolateral to the posterior communicating artery and inferomedial to the uncus and enters the roof of the cavernous sinus through the oculomotor trigone. This cavernous portion of the nerve passes along the lateral dural wall of the cavernous sinus, dividing into superior and inferior divisions that run beneath the trochlear and ophthalmic nerves. The two divisions enter the orbit through the superior orbital fissure, within the common tendinous ring of the recti, separated by the nasociliary branch of the ophthalmic nerve.

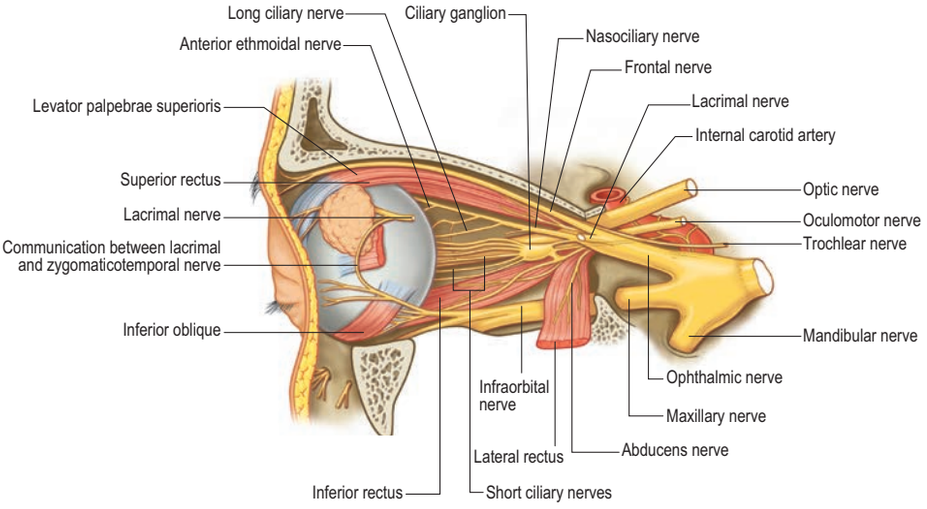

Fig. 44.17 The nerves of the left orbit and the ciliary ganglion, lateral aspect.

The superior division of the oculomotor nerve passes above the optic nerve to enter the inferior (ocular) surface of superior rectus. It supplies this muscle and gives off a branch that runs to innervate levator palpebrae superioris. The inferior division of the oculomotor nerve divides into medial, central and lateral branches. The medial branch passes beneath the optic nerve to enter the lateral (ocular) surface of medial rectus; the central branch runs downwards and forwards to enter the superior (ocular) surface of inferior rectus; the lateral branch travels forwards on the lateral side of inferior rectus to enter the orbital surface of inferior oblique and also communicates with the ciliary ganglion to distribute parasympathetic fibres to sphincter pupillae and the ciliary muscle.

Trochlear nerve

The trochlear nerve is the fourth cranial nerve and innervates superior oblique exclusively. It has the longest intracranial course and the smallest diameter of all of the cranial nerves, and is also the only cranial nerve to emerge from the dorsal surface of the brainstem, lateral to the lower edge of the inferior colliculus. The cisternal portion of the nerve courses anterolaterally, winding round the cerebral peduncle toward the tentorium cerebelli through the quadrigeminal and ambient cisterns. It passes anteriorly along the infratentorial groove of the tentorium cerebelli and penetrates the roof of the cavernous sinus at the junction of the anterior and posterior petroclinoid dural folds. The cavernous portion continues along the lateral wall of the cavernous sinus below the oculomotor nerve, crossing this nerve at the level of the optic strut to become the most superior structure in the cavernous sinus. The trochlear nerve enters the orbit through the superior orbital fissure outside the common tendinous ring, above levator palpebrae superioris and medial to the frontal and lacrimal nerves (see Fig. 44.16). The orbital portion runs medially across levator palpebrae superioris and superior rectus to reach superior oblique: its branches typically end on the posterior one-third of the muscle, most often on the medial aspect (Joo and Rhoton 2015).

Abducens nerve

The abducens nerve is the sixth cranial nerve and exclusively innervates lateral rectus. It has a long and tortuous intracranial course and is tightly attached to the skull base at the level of the petrous apex. The nerve usually exits the pontomedullary sulcus as a single trunk medial to the facial nerve, runs upward, anteriorly and laterally between the pons and clivus, pierces the inner layer of dura mater and runs through the inferior venous compartment of the petroclival venous confluence in a bow-shaped canal, Dorello's canal. It then bends sharply across the upper border of the petrous part of the temporal bone to enter the cavernous sinus, where it lies lateral to the internal carotid artery (unlike the oculomotor, trochlear, ophthalmic and maxillary nerves, which merely invaginate the lateral dural wall of the sinus) but medial to all the other nerves coursing through the cavernous sinus. It enters the orbit through the inferomedial part of the superior orbital fissure, within the common tendinous ring, at first below, and then between, the two divisions of the oculomotor nerve and lateral to the nasociliary nerve (see Fig. 44.15). It passes forwards to enter the medial (ocular) surface of lateral rectus, most often in the posterior one-third of the muscle (Joo et al 2012).

Optic nerve

The optic nerve is the second cranial nerve and contains the axons of retinal ganglion cells (Ch. 45). The two optic nerves join to form the optic chiasma, which is usually positioned over the diaphragma sellae and pituitary gland (normofixed), although it may be prefixed (above the tuberculum sellae) or postfixed (above the dorsum sellae). The axons representing the temporal visual fields decussate within the chiasma. The optic nerve is usually described in four parts, intracranial (~10 mm), intracanalicular (~10 mm), intraorbital (25–30 mm) and intraocular (1 mm). The intracranial part arises from the optic chiasma in the suprasellar cistern. It is surrounded by the optic sheath and its dorsal surface is covered by the falciform ligament. The intracanalicular part passes through the optic canal together with the ophthalmic artery. This is the weakest point of the anterior visual pathway because the nerve is fixed to its bony surroundings by fibrous adhesions. The intraorbital part passes forwards, laterally and downwards, and pierces the sclera at the lamina cribrosa, slightly medial to the posterior pole. It has a somewhat tortuous course within the orbit to allow for movements of the eyeball (Demer 2016). The subarachnoid space surrounding the intracranial part is continuous with the subarachnoid space around the intracanalicular and intraorbital parts; the dural sheath surrounding the optic nerve originates at the level of the optic canal and accompanies the optic nerve to the sclera.

The intraorbital part of optic nerve has important relationships with other orbital structures (see Fig. 44.4). As it leaves the optic canal, it lies superomedial to the ophthalmic artery, and is separated from lateral rectus by the oculomotor, nasociliary and abducens nerves, and sometimes by the ophthalmic veins. It is closely related to the origins of the four recti, whereas more anteriorly, where the muscles diverge, it is separated from them by a substantial amount of orbital fat. Just beyond the optic canal, the ophthalmic artery and the nasociliary nerve cross the optic nerve to reach the medial wall of the orbit. The central artery of the retina enters the substance of the optic nerve about halfway along its length. Near the back of the eyeball, the optic nerve becomes surrounded by the long and short ciliary nerves and vessels.

Ophthalmic nerve

The ophthalmic division of the trigeminal nerve arises from the trigeminal ganglion in the middle cranial fossa. It passes forwards along the lateral dural wall of the cavernous sinus, giving off three main branches – the lacrimal, frontal and nasociliary nerves – just before it reaches the superior orbital fissure (see Figs 44.16–44.17). These branches subsequently travel through the orbit to supply targets that are primarily in the upper part of the face (see Fig. 36.22).

Lacrimal nerve

The lacrimal nerve enters the orbit through the superior orbital fissure, outside the common tendinous ring and lateral to the frontal and trochlear nerves. It passes forwards along the lateral wall of the orbit on the superior border of lateral rectus, and travels through the lacrimal gland and the orbital septum to supply the conjunctiva and skin covering the lateral part of the upper eyelid. The nerve also communicates with the zygomatic branch of the maxillary nerve, which may carry some postganglionic parasympathetic fibres from the pterygopalatine ganglion to the lacrimal gland (see orbital branches from pterygopalatine ganglion, below).

Frontal nerve

The frontal nerve is the largest branch of the ophthalmic nerve. It enters the orbit through the superior orbital fissure outside the common tendinous ring, and lies between the lacrimal nerve laterally and the trochlear nerve medially. It passes forwards towards the rim of the orbit on levator palpebrae superioris; about halfway along this course, it divides into the supraorbital and supratrochlear nerves.

Supraorbital nerve

The supraorbital nerve, the larger of the two terminal branches of the frontal nerve, continues forwards along levator palpebrae superioris until it leaves the orbit through the supraorbital notch or foramen. It emerges on to the forehead and supplies the mucous membrane that lines the frontal sinus, the conjunctiva and skin covering the upper eyelid, and the skin over the forehead and scalp. The postganglionic sympathetic fibres that innervate the sweat glands of the supraorbital area probably travel in the supraorbital nerve, having entered the ophthalmic nerve via its communication with the abducens nerve within the cavernous sinus.

Supratrochlear nerve

The supratrochlear nerve runs medially above the trochlea for the tendon of superior oblique. It gives a descending branch to the infratrochlear nerve and ascends on to the forehead through the supraorbital notch (or foramen) to supply the conjunctiva and skin covering the upper eyelid and the forehead.

Nasociliary nerve

The nasociliary nerve is intermediate in size between the frontal and lacrimal nerves, and is more deeply placed in the orbit, which it enters through the common tendinous ring, lying between the two rami of the oculomotor nerve. It crosses the optic nerve with the ophthalmic artery and runs obliquely below superior rectus and superior oblique to reach the medial orbital wall, where it gives off the anterior and posterior ethmoidal nerves. The nasociliary nerve also has long ciliary and infratrochlear branches and a connection with the ciliary ganglion.

Anterior ethmoidal nerve

The anterior ethmoidal nerve passes through the anterior ethmoidal foramen and canal, and enters the cranial cavity. It runs forwards in a groove on the upper surface of the cribriform plate beneath the dura mater, and descends through a slit lateral to the crista galli into the nasal cavity, where it occupies a groove on the internal surface of the nasal bone and gives off the medial and lateral internal nasal branches. For a description of the subsequent distribution of the anterior ethmoidal nerve, see Chapter 39.

Posterior ethmoidal nerve
The posterior ethmoidal nerve leaves the orbit by the posterior ethmoidal foramen and supplies the ethmoidal and sphenoidal sinuses.

Infratrochlear nerve
The infratrochlear nerve leaves the orbit below the trochlea and supplies the skin of the eyelids, the conjunctiva, lacrimal sac, lacrimal caruncle and the side of the nose above the medial canthus.

Long ciliary nerves
Two or three long ciliary nerves branch from the nasociliary nerve as it crosses the optic nerve. They accompany the short ciliary nerves, pierce the sclera near the attachment of the optic nerve, and run forwards between the sclera and choroid. They supply the ciliary body, iris and cornea, and contain postganglionic sympathetic fibres for the dilator pupillae from neurones in the superior cervical ganglion. An alternative pathway for the supply of the dilator pupillae is via the sympathetic root associated with the ciliary ganglion (**Fig. 44.18**; see p. 799).

Ramus communicans to the ciliary ganglion
The ramus communicans to the ciliary ganglion usually branches from the nasociliary nerve as the latter enters the orbit lateral to the optic nerve. It is sometimes joined by a filament from the internal carotid sympathetic plexus or from the superior ramus of the oculomotor nerve as it enters the posterosuperior angle of the ganglion.

Maxillary nerve
Most of the branches of the maxillary division of the trigeminal nerve arise in the pterygopalatine fossa. They include the zygomatic and infraorbital nerves, which pass into the orbit through the inferior orbital fissure (see Figs 38.30, 44.17).

Zygomatic nerve
The zygomatic nerve lies close to the base of the lateral wall of the orbit. It divides soon after entering the orbit into two branches, the zygomaticotemporal and the zygomaticofacial nerves, which run within the orbit for only a short distance before passing on to the face through the lateral wall of the orbit. Either they may enter separate canals within the zygomatic bone or the zygomatic nerve itself may enter the bone before dividing. For a description of the distribution of the zygomaticotemporal and zygomaticofacial nerves on the face, see Chapter 36.

Infraorbital nerve
The infraorbital nerve initially lies in the infraorbital groove on the floor of the orbit (see Fig. 44.2). As it approaches the rim of the orbit, it runs into the infraorbital canal, through which it passes to emerge onto the face at the infraorbital foramen. It supplies the skin of the lower eyelid and possibly the conjunctiva. For a description of the subsequent distribution of the infraorbital nerve on the face, see Chapter 36.

Ciliary ganglion
The ciliary ganglion is a parasympathetic ganglion concerned with the innervation of the ciliary muscle and sphincter pupillae. It is a small, flat, reddish-grey swelling, 1–2 mm in diameter, connected to the nasociliary nerve, and located near the apex of the orbit in loose fat approximately 1 cm in front of the medial end of the superior orbital fissure (see Fig.44.17). It lies between the optic nerve and lateral rectus, usually lateral to the ophthalmic artery. Its neurones, which are multipolar, are larger than those found in typical autonomic ganglia; a very small number of more typical neurones are also present.

Its connections or roots (motor, sensory and sympathetic) enter or leave the ganglion posteriorly (see Fig. 44.18). Eight to ten delicate filaments, termed the short ciliary nerves, emerge anteriorly from the ganglion, arranged in two or three bundles, the lower being larger. They run forwards sinuously with the ciliary arteries, above and below the optic nerve, and divide into 15–20 branches that pierce the sclera around the optic nerve and run in small grooves on the internal scleral surface. They convey parasympathetic, sympathetic and sensory fibres between the eyeball and the ciliary ganglion; only the parasympathetic fibres synapse in the ganglion.

The parasympathetic root, derived from the branch of the oculomotor nerve to the inferior oblique, consists of preganglionic fibres from the Edinger–Westphal nucleus, which relay in the ganglion. Postganglionic fibres travel in the short ciliary nerves to the sphincter pupillae and ciliary muscle. More than 95% of these fibres supply the ciliary muscle, which is much the larger muscle in volume.

The sympathetic root contains fibres from the plexus around the internal carotid artery within the cavernous sinus. These postganglionic fibres, derived from the superior cervical ganglion, form a fine branch that enters the orbit through the superior orbital fissure inside the common tendinous ring. The fibres may pass directly to the ganglion, or may join the nasociliary nerve and travel to the ganglion in its sensory root; either way, they traverse the ganglion without synapsing to emerge into the short ciliary nerves and are distributed to the blood vessels of the eyeball. Sympathetic fibres innervating dilator pupillae may sometimes travel via the short ciliary nerves (rather than the more usual route via the ophthalmic, nasociliary and long ciliary nerves).

The sensory fibres that pass through the ciliary ganglion are derived from the nasociliary nerve. They enter the short ciliary nerves and carry sensation from the cornea, the ciliary body and the iris.

Orbital branches of the pterygopalatine ganglion
Several rami orbitales arise dorsally from the pterygopalatine ganglion and enter the orbit through the inferior orbital fissure. Branches leave the orbit through the posterior ethmoidal air sinus. There is strong experimental evidence from animal studies that postganglionic parasympathetic branches pass directly to the lacrimal gland, ophthalmic artery and choroid.

EYELIDS, CONJUNCTIVA AND LACRIMAL SYSTEM
The exposed ocular surface is protected by retractable eyelids and by a tear film produced mainly by the lacrimal gland, with contributions from glands within the eyelid and conjunctiva (a transparent mucous membrane that covers the inner surface of the eyelid and the exposed surface of the sclera) (see Fig. 45.1).

Eyelids
The eyelids (palpebrae) are two folds of modified skin that cover the anterior surface of the eye (**Fig. 44.19**). By their reflex closure, achieved by contraction of orbicularis oculi, they protect the eyes from injury and shield them from excessive light. Periodic blinking maintains a thin film

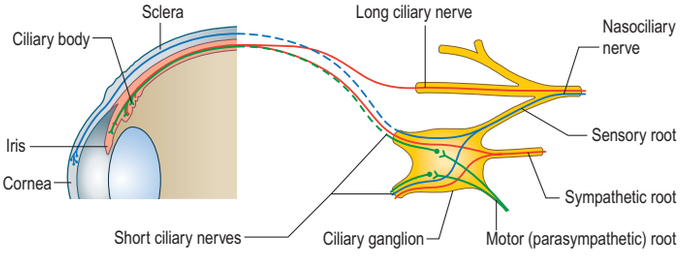

Fig. 44.18 The ciliary ganglion, with its roots and branches of distribution. Key: red, sympathetic fibres; green, parasympathetic fibres; blue, sensory fibres. Alternative pathways are given for the sympathetic fibres.

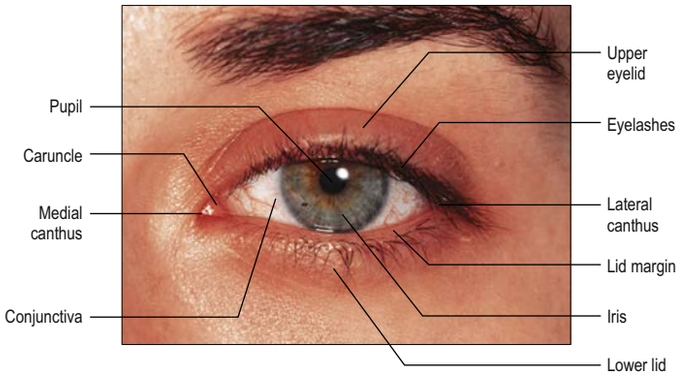

Fig. 44.19 The eyelids and anterior aspect of the eyeball. (With permission from Berkovitz BKB, Moxham BJ 2002 Head and Neck Anatomy. London: Martin Dunitz.)

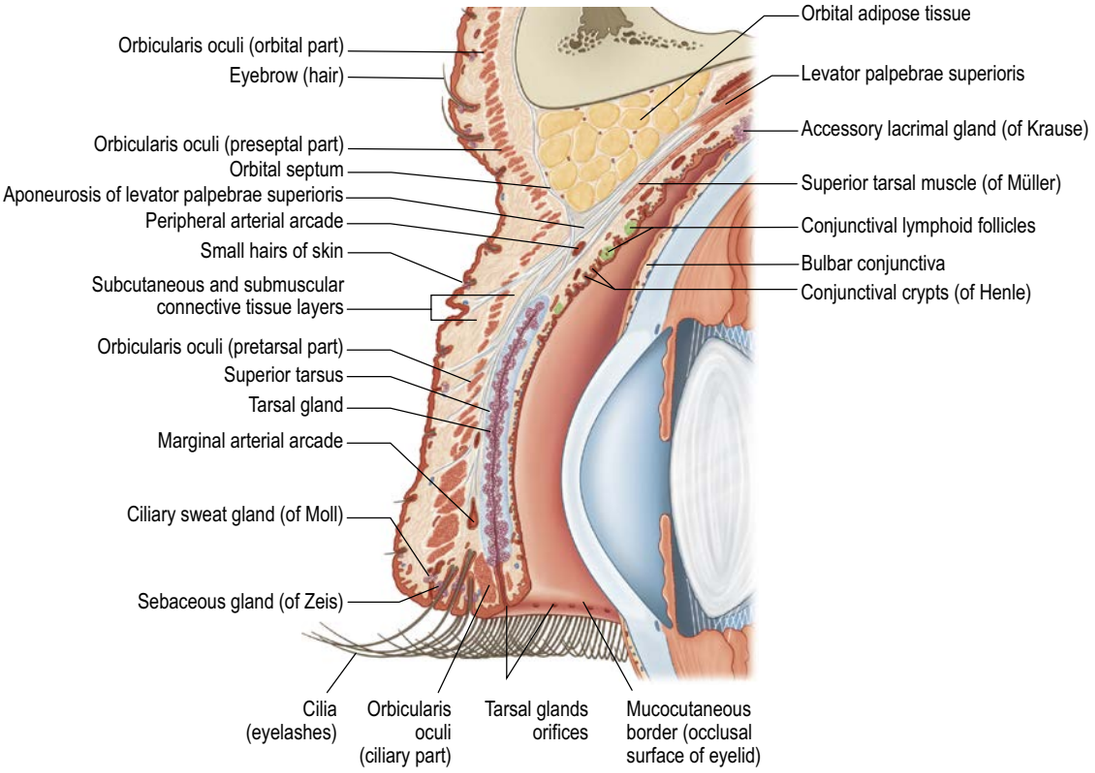

Fig. 44.20 The upper eyelid and anterior segment of the eye, sagittal section.

of tears over the cornea that prevents desiccation; movement of the eyelids during blinking helps ensure the even distribution of the tear film and facilitates tear outflow through the nasolacrimal drainage system.

The upper eyelid is larger and more mobile than the lower eyelid and contains an elevator muscle, levator palpebrae superioris (see above). A transverse opening, the palpebral fissure, lies between the free margins of the lids, which join at their extremities (termed the medial and lateral canthus). The lateral canthus is relatively featureless. The medial canthus is approximately 2 mm lower than the lateral canthus; this distance is increased in some Asiatic groups. It is separated from the eyeball by a small triangular space, the lacrimal lake (lacus lacrimalis), in which a small, reddish body called the lacrimal caruncle is situated. The caruncle represents an area of modified skin containing some fine hairs and is mounted on the plica semilunaris, a fold of conjunctiva that is believed by some to be a vestige of the nictitating membrane of other animals.

A small elevation, the lacrimal papilla, is located on each palpebral margin approximately one-sixth of the way along from the medial canthus of the eye. A small aperture in the centre of the papilla, the punctum lacrimale, forms the opening to the lacrimal drainage system. The mean external diameter of the punctum is 0.6 mm (assessed on anterior segment optical coherence tomography *in vivo*): previous values of 0.2–0.3 mm diameter derived from cadaveric studies likely reflect fixation-induced tissue shrinkage (Timlin et al 2016). The margin of the eyelid lateral to the lacrimal papilla bears the eyelashes and is termed the ciliary part of the eyelid. The margin medial to the papilla lacks eyelashes and forms the lacrimal part of the eyelid.

When looking straight ahead, the upper eyelid overlaps the upper part of the cornea by 2–3 mm, whereas the lower lid margin lies just below the corneoscleral junction (limbus). When the eyelids are closed, the upper lid moves down to cover the whole of the cornea. Malposition of the lower eyelid is common, particularly in the elderly. Ectropion describes the rolling out of the lower eyelid so that it is no longer in contact with the cornea, leading to epiphora (watering). Entropion describes the inversion of the eyelid with corresponding inturning of the eyelashes (trichiasis), which contact the cornea and cause irritation.

Each eyelid margin is 2–3 mm from front to back. The anterior two-thirds is skin and the posterior third is conjunctival mucosa. A narrow 'grey line' lies anterior to the mucocutaneous junction and corresponds to the location of the ciliary (marginal) part of orbicularis oculi. It is an important surgical landmark, since an incision at this point affords a relatively bloodless plane along which the eyelid can be split into anterior and posterior lamellae. The eyelashes lie in front of the grey line, and the circular openings of the tarsal (Meibomian) glands lie behind it. The tarsal glands are often visible through the palpebral conjunctiva, when the eyelids are everted, as a series of parallel, faint yellow lines arranged perpendicular to the lid margins.

Eyelashes are short, thick, curved hairs, arranged in double or triple rows. The upper lashes, which are longer and more numerous, curve upwards, while those in the lower lid curve down, so that upper and lower lashes do not interlace when the lids are closed.

The eyelids pass to adjacent facial skin without obvious demarcation, although their limits are clearly defined in pathological conditions such as oedema. Various skin folds or furrows are of topographical interest. A prominent superior palpebral furrow or fold lies approximately opposite the upper margin of the tarsal plate and is deeply recessed when the lids are open. A prominent feature of Asian eyes is an absent or very low eyelid skin fold, which together with an inferior extension of the pre-aponeurotic fat pad gives rise to a fuller upper eyelid appearance and a narrower palpebral fissure (Saonanon 2014). Furthermore, Asians typically have a skin flap, the epicanthus, which begins laterally in the superior palpebral fold and progresses medially to cover the medial canthus. Infant Caucasians frequently have a transient epicanthus that sometimes persists in the adult. A less prominent inferior palpebral furrow occupies a similar position in the skin of the lower lid and deepens on downward gaze. A nasojugal furrow extends obliquely from the medial lower margin of the bony orbit to the cheek, and a malar furrow may be seen laterally along the inferior orbital rim in middle age, but only infrequently and faintly in the young.

The palpebral fissure undergoes complex changes during infancy (Fox 1966, Paiva et al 2001). At birth, the fissure is relatively narrow, but then widens considerably giving rise to the rounder appearance of the palpebral fissure in infancy as compared to that of the adult. The peak level of growth in the horizontal dimension of the palpebral fissure is reached between the ages of 17 and 19 years, in the vertical dimension between 10 and 13 years (Park et al 2008).

Structure

From its anterior surface inwards, each eyelid consists of skin, subcutaneous connective tissue, fibres of the palpebral part of orbicularis oculi (see Fig. 36.18A), submuscular connective tissue, the tarsal plate (tarsus), tarsal glands and orbital septum, and the palpebral conjunctiva (**Fig. 44.20**). The upper lid also contains the aponeurosis of levator palpebrae superioris. The skin is extremely thin and is continuous at the palpebral margins with the conjunctiva. The subcutaneous connective tissue is very delicate, seldom contains any adipose tissue, and lacks elastic fibres.

The palpebral part of orbicularis oculi is subdivided anatomically into marginal, pretarsal and preseptal parts. The palpebral muscle fibre bundles are thin and pale, and lie parallel with the palpebral margins. Deep to them is the submuscular connective tissue, a loose fibrous layer that is continuous in the upper lid with the subaponeurotic layer of the scalp; effusions of blood or pus at this level can therefore pass down from the scalp into the upper eyelid. The main nerves lie in the submuscular layer, which means that local anaesthetics should be injected deep to orbicularis oculi.

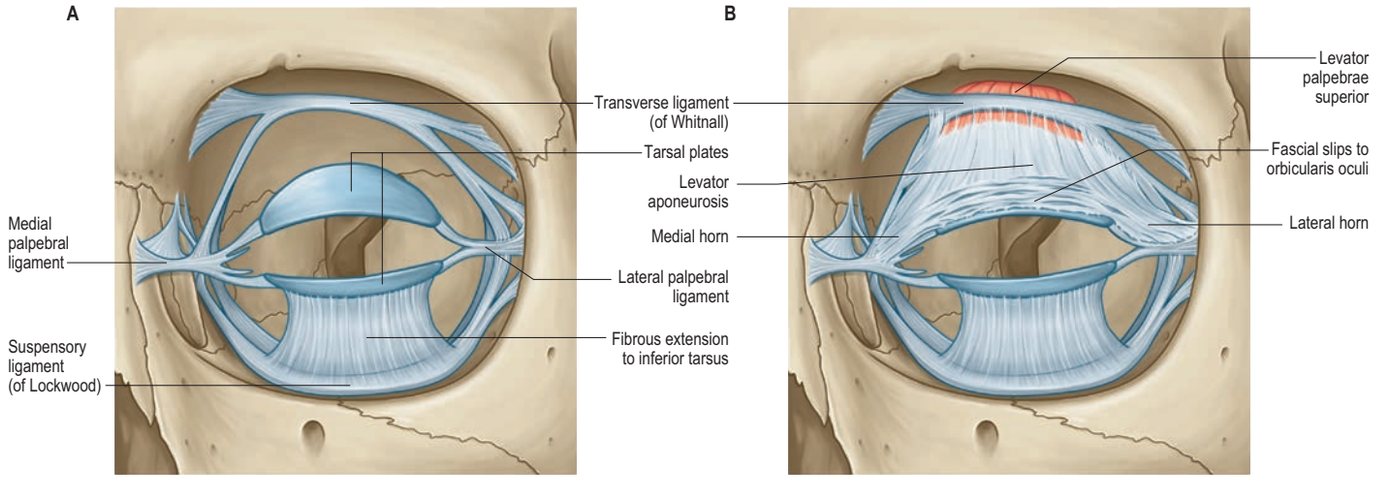

Fig. 44.21 **A**, The tarsal plates and their attachments. **B**, The anterior insertion of levator palpebrae superioris.

Tarsal plates

The tarsal plates (**Fig. 44.21A**) are thin, elongated, crescent-shaped plates of firm, dense fibrous tissue approximately 2.5 cm long. There is one in each eyelid to provide support and determine eyelid form. Each is convex and conforms to the configuration of the anterior surface of the eyeball. The free ciliary border is straight and adjacent to the eyelash follicles. The orbital border is convex and attached to the orbital septum. The superior tarsus, the larger of the two, is semi-oval, approximately 10 mm in height centrally; its inferior edge is parallel to, and approximately 2 mm from, the lid margin. The smaller inferior tarsus is narrower and approximately 4 mm in vertical height.

The tarsal plates are connected to the margins of the orbit by the orbital septum and by the medial and lateral palpebral (canthal) ligaments (see Fig. 44.21A). The medial palpebral ligament passes from the medial ends of the two tarsal plates to the anterior lacrimal crest and the frontal process of the maxilla. It splits at its insertion into the tarsal plates to surround the lacrimal canaliculi, and lies in front of the nasolacrimal sac and the orbital septum. The lateral palpebral ligament is relatively poorly developed. It passes from the lateral ends of the tarsal plates to a small tubercle on the zygomatic bone within the orbital margin and is more deeply situated than the medial palpebral ligament. It lies beneath the orbital septum and the lateral palpebral raphe of orbicularis oculi.

The deepest fibres of the aponeurosis of levator palpebrae superioris are attached to the anterior surface of the superior tarsus (see Fig. 44.21B). The superior and inferior tarsal plates are also associated with a thin lamina of smooth muscle forming the superior and inferior tarsal muscles, respectively. Opposite the equator of the eye, the superior tarsal muscle passes from the inferior face of levator palpebrae superioris to a fibrous extension that projects to the upper margin of the superior tarsus (see Fig. 44.20). The muscle is innervated by the sympathetic nervous system and, on contraction, elevates the eyelid. Although it may be regarded as supplementing the action of the levator muscle, its full role is not clear. The mild ptosis that is a characteristic feature of Horner's syndrome is the result of an interruption to the sympathetic supply to the superior tarsal muscle. A corresponding but less prominent inferior tarsal muscle in the lower eyelid unites the inferior border, and possibly also the anterior surface, of the inferior tarsus to the capsulopalpebral fascia, which is the anterior expansion of the fused fascial sheath of inferior rectus and inferior oblique. Contraction of inferior rectus during downward gaze therefore also pulls the lower lid downwards. The lower lid is capable of depressing by 4–5 mm, although it is not equipped with a striated muscle counterpart to the levator of the upper lid.

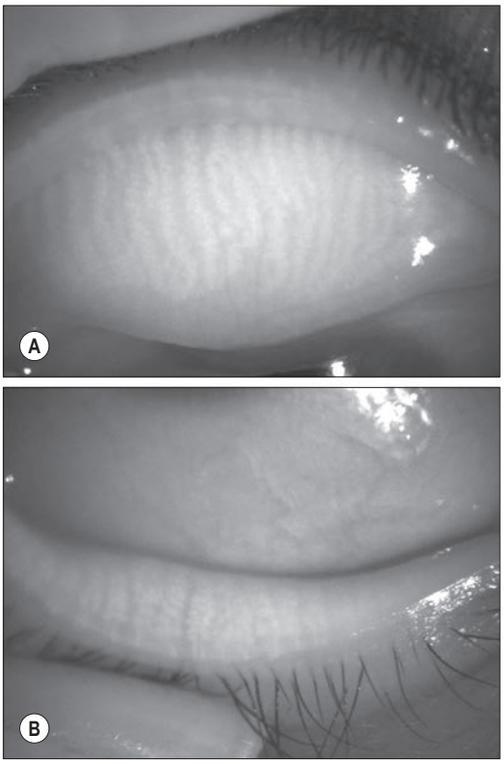

Fig. 44.22 Tarsal (Meibomian) glands in the upper (**A**) and lower (**B**) eyelids imaged by noninvasive infrared meibography. Meibomian glands can be seen as areas of high reflectivity. Glands in the upper lid are longer and more slender. (From Arita R, Fukuoka S, Morishige N 2017 New insights into the morphology and function of Meibomian glands. Exp Eye Res. 163:64–71.)

Palpebral glands

Tarsal (Meibomian) glands are modified sebaceous glands embedded in the tarsi (**Fig. 44.22**): they secrete meibum, a lipid rich secretion that mixes with aqueous tears during the blink to form the tear film (Butovich 2017). There are between 20 and 40 individual tarsal glands in the upper eyelid and 20 to 30 in the lower, arranged in approximately parallel rows perpendicular to the eyelid margin: their number declines with age (Arita et al 2017). Tarsal glands occupy the full tarsal height and are therefore longer centrally where the tarsi are higher. Each gland consists of a long central canal surrounded by numerous rounded secretory acini (Obata 2002). Differentiated acinar cells secrete into the central canal in a holocrine process. Basal cells in the acini do not contain lipid droplets: differentiating cells undergo a centripetal movement accompanied by enlargement of the cells and lipogenesis. Each canal is lined at its orifice by stratified epithelium and opens on the free palpebral margin just anterior to the mucocutaneous junction.

The secretion of the tarsal glands spreads over the margins of the eyelids, and so an oily layer is drawn over the tear film as the palpebral fissure opens after a blink, reducing evaporation and contributing to tear film stability. The presence of the oily, hydrophobic secretions of tarsal glands along the margins of the eyelids also inhibits the spillage of tears on to the face. Obstruction of the tarsal gland ducts by lipid and cellular debris may result in lipogranulomatous inflammation and the clinical manifestations of an internal hordeolum or chalazion: glandular dysfunction is a major cause of evaporative dry eye.

Small sebaceous glands (of Zeis) and sweat glands (of Moll) are associated with the eyelashes (see Fig. 44.20) and are prone to infection, producing an external hordeolum (stye).

Vascular supply and lymphatic drainage

The arterial supply to the eyelids is derived principally from the medial and lateral palpebral branches of the ophthalmic artery. Their branches course laterally along the tarsal edges to form superior and inferior arcades (two in the upper eyelid and one in the lower). The eyelids are also supplied by branches of the infraorbital, facial, transverse facial and superficial temporal arteries.

The veins that drain the eyelids are larger and more numerous than the arteries; they pass either superficially to veins on the face and forehead, or deeply to the ophthalmic veins within the orbit.

The lymph vessels that drain the eyelids and conjunctiva start in a superficial plexus beneath the skin, and in a deep plexus in front of and behind the tarsi. These plexuses communicate with one another, and medial and lateral sets of vessels arise from them. The lateral lymph vessels drain the whole thickness of the lateral part of the upper and lower lids and pass laterally from the lateral canthus to end in the superficial and deep parotid lymph nodes. The medial lymph vessels drain the skin over the medial part of the upper eyelid, the whole thickness of the medial half of the lower lid and the caruncle and follow the course of the facial vein to end in the submandibular group of lymph nodes.

Innervation

The ophthalmic and maxillary divisions of the trigeminal nerve innervate the eyelids. The upper eyelid is supplied mainly by the supraorbital branch of the frontal nerve. Additional contributions come from the lacrimal nerve, the supratrochlear branch of the frontal nerve, and the infratrochlear branch of the nasociliary nerve. The nerve supply to the lower eyelid is derived principally from the infraorbital branch of the maxillary nerve, with small contributions from the lacrimal and infratrochlear nerves.

Conjunctiva

The conjunctiva is a thin, transparent mucous membrane that extends from the eyelid margins anteriorly, providing a lining to the lids, before turning sharply on itself to form the fornices; from here, it is reflected on to the globe to cover the sclera up to its junction with the cornea. The conjunctiva thus forms a sac that opens anteriorly through the palpebral fissure (Fig. 44.23). At the free palpebral margins, the conjunctiva is continuous with the skin of the eyelids, the lining epithelium of the ducts of the tarsal glands, and with the lacrimal canaliculi and lacrimal sac (see below). The continuity between the conjunctiva and the nasolacrimal duct and nasal mucosa is important in the spread of infection.

Conjunctival goblet cells contribute the mucin component of the preocular tear film and play a central role in the defence of the ocular surface against microbial infection. The conjunctiva is conventionally divided into five regions: marginal, tarsal, orbital, bulbar and limbal): the marginal, tarsal and orbital regions are collectively referred to as the palpebral conjunctiva (see Fig. 44.23).

The marginal zone extends from a line immediately posterior to the openings of the tarsal glands and passes around the eyelid margin to continue on the inner surface of the lid as far as the subtarsal groove (a shallow sulcus that marks the marginal border of the tarsus). The tarsal conjunctiva is highly vascular and is firmly attached to the underlying tarsal plate. The orbital zone extends as far as the fornices, which mark the line of reflection of the conjunctiva from the lids on to the eyeball. The conjunctiva is more loosely attached to underlying tissues over the orbital zone and so folds readily. Elevations of the conjunctival surface in the form of papillae and lymphoid follicles (part of the mucosa-associated lymphoid tissue, MALT) are commonly observed in this region (Knop and Knop 2002).

Ducts of the lacrimal gland open into the lateral part of the superior fornix. The bulbar conjunctiva is loosely connected to the eyeball over the exposed sclera; it is thin and transparent, and readily permits the visualization of conjunctival and episcleral blood vessels. The loose attachment of the conjunctiva to the fascial sheath of the globe (Tenon's capsule) in this region means that the conjunctiva is freely movable here, but as the bulbar conjunctiva approaches the cornea, its surface becomes smoother and its attachment to the sclera increases. The limbal conjunctiva extends approximately 1–1.5 mm around the cornea and contains a dense network of capillaries.

Structure

The conjunctiva is composed of an epithelial layer and an underlying fibrous layer or substantia propria. The type of the epithelium and the thickness of the substantia propria vary with location. At the margin of the lids, the epithelium is non-keratinized stratified squamous and 10–12 cells thick. The epithelium of the tarsal conjunctiva thins to two or three layers and consists of columnar and flat surface cells. Near the fornices, the cells are taller, and a trilaminar conjunctival epithelium covers much of the bulbar conjunctiva. It thickens closer to the corneoscleral junction and then changes to stratified squamous epithelium typical of the cornea. A proportion of limbal conjunctival epithelial cells serve as stem cells for the corneal epithelium, which means that this region of the conjunctiva is essential for maintaining corneal integrity.

Mucous-secreting goblet cells are scattered within the conjunctival epithelium. They show a marked regional variation in density, being most frequent in conjunctival regions normally covered by the eyelids, and reduced in number within exposed inter-palpebral locations (Doughty 2012).

The substantia propria, or fibrous layer, is thickest at the fornix and thinnest over the tarsi where conjunctival attachment is firmest. With the exception of the tarsal conjunctiva, the substantia propria adjacent to the epithelium is mainly loose. It merges with the fibrous fascia bulbi and episclera in the limbal and bulbar regions, and is loosely attached to the sheaths of the recti. At the fornix, it is continuous with orbital fascial tissues and has loose attachments to the overlying tendon of levator palpebrae superioris and the superior tarsal muscle fascia superiorly, an arrangement that provides support for the fornix during eyeball rotation.

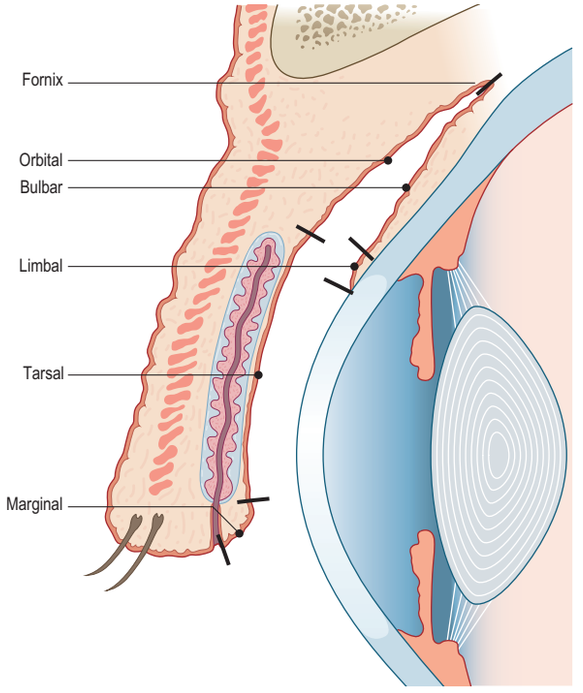

Fig. 44.23 The regions of the conjunctiva, sagittal section.

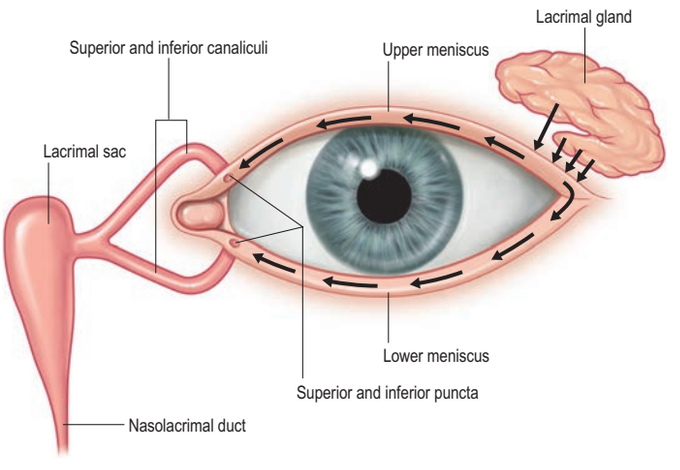

Fig. 44.24 A representation of tear dynamics on the ocular surface. Tears are produced by the lacrimal gland and flow within the upper and lower meniscus. Tears drain sequentially through the puncta, canaliculi, lacrimal sac and nasolacrimal duct.

Vascular supply and lymphatic drainage

The arteries of the palpebral conjunctiva are derived from the vascular arcades of the eyelids. Many of the small vessels of the eyelid drain to the conjunctival veins, which, in turn, pass back to the orbital and facial veins. The substantia propria of the tarsal and orbital conjunctiva is richly vascular. A dense capillary network is arranged in a single subepithelial lamina, a distribution that meets the metabolic requirement of the cornea during sleep, when oxygen is available to the cornea only through this vascular system. The bulbar conjunctiva receives blood from the palpebral arcades and from the anterior ciliary arteries that reach the conjunctiva on the orbital surface of the recti. The veins drain by the same route and join the ophthalmic veins.

Lymphatics drain into pre-auricular and submandibular lymph nodes.

Innervation

The conjunctiva is innervated by sensory nerves from the same ophthalmic and maxillary branches of the trigeminal nerve that serve the eyelids. Autonomic nerve fibres are abundant in the conjunctiva, particularly in bulbar and limbal regions, and are probably vasomotor in function.

Lacrimal system

The lacrimal system consists of structures responsible for the production of tears (principally, the main lacrimal gland with a contribution from accessory lacrimal glands) and the lacrimal drainage pathway that collects the tear fluid and conveys it into the nasal cavity (paired lacrimal canaliculi, lacrimal sac and nasolacrimal duct) (**Fig. 44.24**).

The total tear volume is approximately 7 µl. It is distributed within the precorneal tear film (1–2 µl), and along the upper and lower marginal tear strips (5–6{ ts}µl), wedge-shaped menisci that run along the posterior border of the lid margins and join together at the canthi. Reflex tear secretion, as measured by the Schirmer test in the unanaesthetized eye, decreases with increasing age when investigated in the 20–80-year-old age range. Tear volume and the concentration of the tear proteins lysozyme and lactoferrin also decrease with age (Rocha et al 2008).

Lacrimal gland

The lacrimal gland is the primary producer of the aqueous component of the tear layer. Its secretion is a watery fluid with an electrolyte content similar to that of plasma. It contains several proteins that play key roles in protecting the ocular surface from microbial infection (e.g. lysozyme, lactoferrin, immunoglobulin A (IgA)) and in maintaining ocular surface epithelial integrity.

The lacrimal gland consists of orbital and palpebral parts that are continuous posterolaterally around the concave lateral edge of the aponeurosis of levator palpebrae superioris. The orbital part, about the size and shape of an almond, lodges in a shallow fossa on the medial aspect of the zygomatic process of the frontal bone, just within the orbital margin. It lies above levator palpebrae superioris and, laterally, above lateral rectus. Its lower surface is connected to the sheath of levator palpebrae superioris and its upper surface is connected to the orbital periosteum. Its anterior border is in contact with the orbital septum and its posterior border attached to the orbital fat. The palpebral part, about one-third the size of the orbital part, is subdivided into two or three lobules and extends below the aponeurosis of levator palpebrae superioris into the lateral part of the upper lid, where it is attached to the superior conjunctival fornix and is visible through the conjunctiva when the lid is everted. The lacrimal gland reduces in size with age (Tamboli et al 2011) and may be congenitally absent (Keith and Boldt 1986).

The main ducts of the lacrimal gland, up to 12 in number, discharge into the conjunctival sac at the superior lateral fornix. Those from the orbital part penetrate the aponeurosis of levator palpebrae superioris to join those from the palpebral part, which means that excision of the palpebral part is functionally equivalent to total removal of the gland (Maitchouk et al 2000).

Numerous small accessory lacrimal glands (of Krause and of Wolfring) account for approximately 10% of the total lacrimal secretory mass: their presence may in part explain why the ocular surface does not dry up after extirpation of the main lacrimal gland (Stevenson et al 2016), although their contribution to basal tear secretion is controversial (Conrady et al 2016). The glands of Krause are found in the conjunctival fornices, particularly in the superior fornix. The glands of Wolfring lie along the nonmarginal border of both tarsal plates. The accessory lacrimal glands are structurally and histologically similar to the main lacrimal gland (Obata 2006) but apparently lack parasympathetic innervation.

Microstructure

The lacrimal gland is lobulated and tubulo-acinar in form. Its secretory units are acini similar to those found in the salivary glands (**Fig. 44.25**) (Ruskell 1975). Acini consist of secretory cells that discharge their product into a central lumen continuous with an intercalated duct

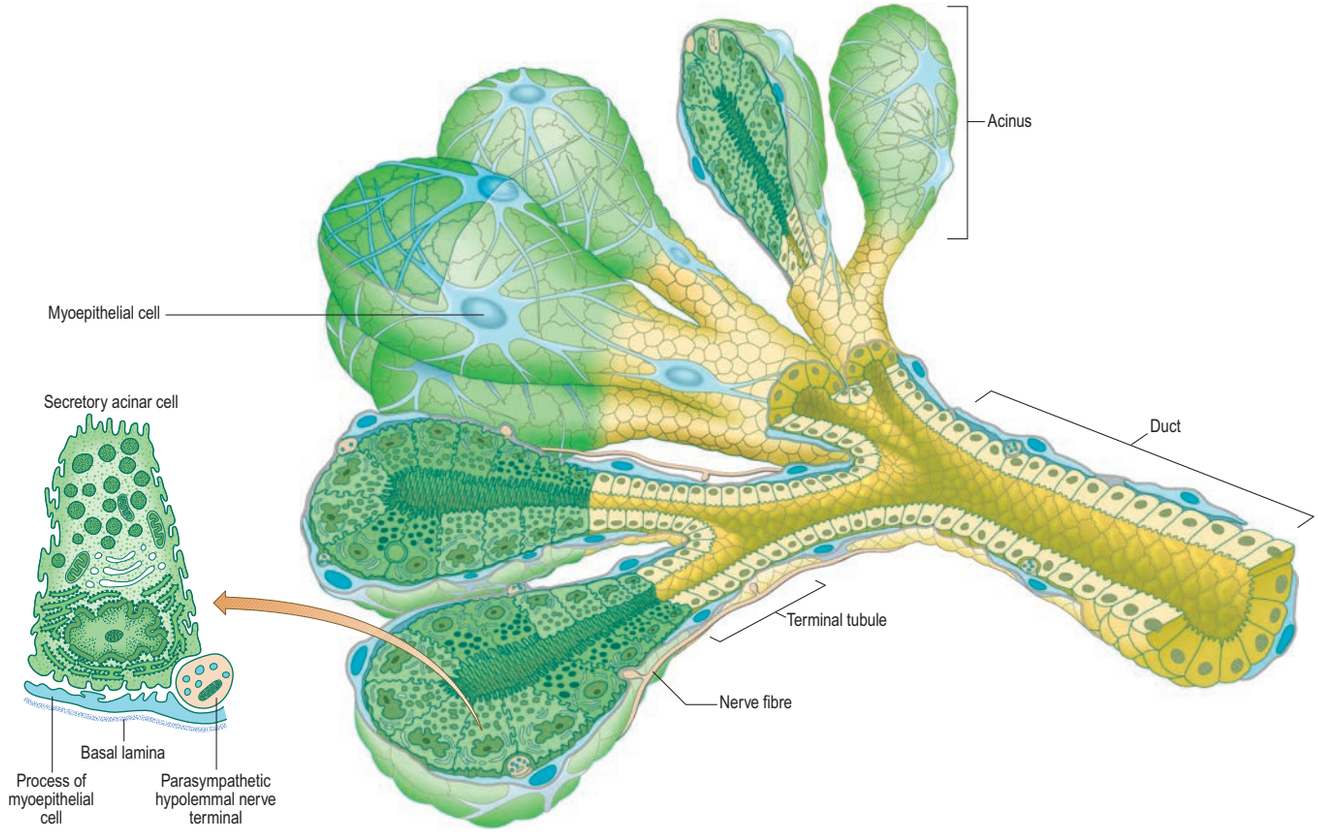

Fig. 44.25 The organization of the secretory units in the lacrimal gland.

formed from a single layer of epithelial cells that lack secretory granules. Myoepithelial cells extend processes around the perimeter of acini and ducts; their contraction imparts a mechanical force on the acini and ducts, which promotes the expulsion of tears from the gland. The interstices of the gland are composed of loose connective tissue that contains numerous immune cells, mainly B-lymphocytes and plasma cells (particularly IgA-secreting cells). The ageing gland exhibits histological changes including diffuse atrophy and periductal fibrosis.

Vascular supply

The lacrimal gland receives its arterial blood supply from the lacrimal branch of the ophthalmic artery. It may also receive blood from the infraorbital artery. Venous drainage is into the superior ophthalmic vein.

Innervation

The lacrimal gland is innervated by secretomotor postganglionic parasympathetic fibres from the pterygopalatine ganglion (Ch. 38). They reach the gland either via zygomatic and lacrimal branches of the maxillary nerve, or by passing directly from the ganglion (Ruskell 2004). Postganglionic sympathetic fibres from the superior cervical ganglion supply the lacrimal gland and may be involved in the regulation of blood flow and the modulation of gland secretion (Dartt 2009).

Lacrimation reflex

The lacrimation reflex produces a significant increase in tear volume and is elicited by thermal, mechanical or chemical stimulation of polymodal nociceptors in the conjunctiva and cornea (Situ and Simpson 2010). The afferent limb of the reflex involves branches of the ophthalmic nerve, with an additional contribution from the infraorbital nerve if the conjunctiva of the lower eyelid is involved. Corneal afferents travelling in these nerves terminate in the nucleus of the spinal tract of the trigeminal nerve: experimental tract tracing studies in animals have implicated the transition between the trigeminal subnuclei caudalis and interpolaris as an important area that projects to preganglionic parasympathetic neurones lying close to or within the superior salivatory nucleus and to the facial motor nucleus, both regions involved in the efferent limb of the blinking reflex (Meng and Kurose 2013). The neural mechanism for controlling and maintaining basal tear production is less clear. Lacrimation may also occur in response to emotional triggers without any irritation of ocular structures, when it may be accompanied by alterations in the mimetic facial muscles, vocalizations and sobbing (Gračanin et al 2014): emotional lacrimation is thought to be mediated by limbic projections to the superior salivatory nucleus.

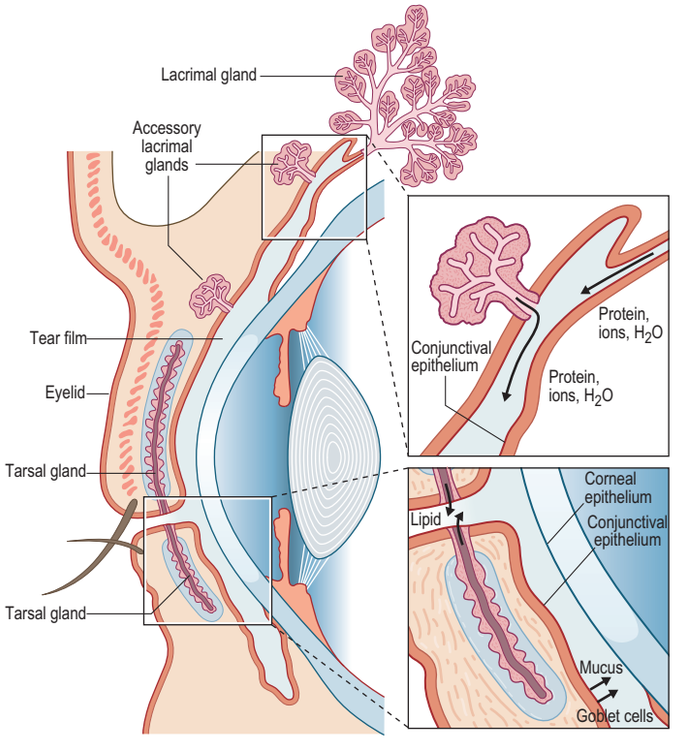

Fig. 44.26 Orbital glands that contribute the various components of the preocular tear film. The aqueous component (consisting primarily of proteins, ions and water) is produced by the main and accessory lacrimal glands. Tarsal glands in the eyelids produce the lipid layer of the tear film, and the mucous component is derived from conjunctival goblet cells.

Preocular tear film

The tear film is a complex fluid 2–5 μm thick that covers the exposed parts of the ocular surface framed by the eyelid margins. Classically, the tear film has been regarded as a trilaminar structure, with a superficial lipid layer (secreted by the tarsal glands) that overlies an aqueous phase (derived from the main and accessory lacrimal glands) and an inner mucinous layer (produced mainly by conjunctival goblet cells) (**Fig. 44.26**). Recent evidence suggests that the preocular tear film behaves as a single dynamic functional unit consisting of a muco-aqueous gel layer, lying beneath, but partially integrated with, an overlying lipid layer (Willcox et al 2017).

The tear film performs a number of important functions. By smoothing out irregularities of the corneal epithelium, it creates an even surface of good optical quality that is reformed with each blink. The air–tear interface forms the principal refractive surface of the optical system of the eye. Since the cornea is avascular, it is dependent on the tear film for its oxygen provision. When the eye is open, the tear film is in a state of equilibrium with the oxygen in the atmosphere, and gaseous exchange takes place across the tear–epithelial interface. The constant turnover of the tear film also provides a mechanism for the removal of metabolic waste products. Tears play a major role in the defence of the eye against microbial colonization; the washing action of the tear fluid reduces the likelihood of microbial adhesion to the ocular surface, and the tears contain a host of protective antimicrobial proteins. There is clinical evidence that tear fluid secretion may increase as a compensatory response to the loss of tear film stability caused by deficiency of the oily layer (Arita et al 2017).

Lacrimal drainage pathway

There is a constant turnover of tears; their production is matched by elimination. Some tears are lost by evaporation or absorption across the conjunctiva, but the majority are eliminated via the nasolacrimal drainage system (see Fig. 44.24). Tears collect at the medial canthal angle, where they drain into the puncta of the upper and lower lids. The puncta drain into lacrimal canaliculi running just below the margins of the eyelids. Each lid contains one canaliculus, approximately 10 mm long, that passes vertically from its punctum for about 2 mm, then widens to form an ampulla, before passing medially (horizontally) towards the lacrimal sac: the superior canaliculus is smaller and shorter than its inferior counterpart. The canaliculi are at first anterior to the crura of the medial canthal ligament, then pass either through or around the crura to lie posterior to the canthal ligament and continue to the lacrimal sac within the fascial tissue of the posterior arm of the canthal ligament (Dutton 2011). The canaliculi almost always unite to form a common canaliculus (1–2 mm long) before entering the posterolateral wall of the lacrimal sac at the common internal punctum (Maliborski and Różycki 2014). An inconstant fold has been described at this point, but it is not clear whether it constitutes a barrier to reflux of tears into the lacrimal sac. Effective drainage involves a number of mechanisms, including capillary attraction, contraction of the lacrimal part of orbicularis oculi associated with the vertical part of each canaliculus and the closing and opening phases of blinking (Beigi et al 2015). Overproduction of tears or their inadequate or blocked drainage leads to epiphora (welling of tears in the eye and lid margin overspill onto the cheek). Congenital absence of lacrimal puncta, supernumerary lacrimal puncta and canaliculi, have all been described (Satchi and McNab 2010).

The mucosa lining the canaliculi is a non-keratinized stratified squamous epithelium lying on a basement membrane and surrounded by a lamina propria rich in elastic fibres: the canaliculi are therefore easily dilated when probed. Striated muscle fibres of orbicularis oculi interweave on each side of a canaliculus in a manner suggesting a sphincter-like spiralling, and supporting the claim that lumen size is regulated on blinking, possibly facilitating tear drainage.

The lacrimal sac is the closed upper end of the nasolacrimal duct. It is approximately 12 mm long and lies in a fossa in the lacrimal bone (with a variable contribution from the frontal process of the maxilla) in the anterior part of the medial wall of the orbit (see Fig. 44.2). The sac is bounded anteriorly by the anterior lacrimal crest of the maxilla and posteriorly by the posterior lacrimal crest of the lacrimal bone. Its closed upper end is laterally flattened, its lower part is rounded and merges into the nasolacrimal duct, and the lacrimal canaliculi open into its lateral wall near its upper end.

A layer of lacrimal fascia, continuous with the orbital periosteum, passes between the lacrimal crest of the maxilla and the lacrimal bone. It forms a roof and lateral wall to the lacrimal fossa and separates the lacrimal sac from the medial palpebral ligament anteriorly and the lacrimal part of orbicularis oculi posteriorly. A plexus of minute veins lies between the fascia and the sac. The upper half of the lacrimal fossa is related medially to the anterior ethmoidal sinuses, and the lower half to the anterior part of the middle meatus. The lacrimal sac has a fibroelastic wall and is lined internally by mucosa that is continuous with the conjunctiva through the lacrimal canaliculi, and with the nasal mucosa through the nasolacrimal duct (Paulsen 2003).

The nasolacrimal duct is approximately 18 mm long, and descends from the lacrimal sac to open anteriorly in the inferior meatus of the nose at an expanded orifice. A fold of mucosa (plica lacrimalis) forms an imperfect valve just above its opening (ostium lacrimalis). The duct runs down an osseous canal formed laterally and anteriorly by the lacrimal sulcus of the frontal process and the body of maxilla, and medially and posteriorly by the lacrimal sulcus of the lacrimal bone and the lacrimal process of the inferior nasal concha. It is narrowest in the middle and is directed downwards, backwards and a little laterally. The mucosa of the lacrimal sac and the nasolacrimal duct has a bilaminar columnar epithelium, ciliated in places. A rich plexus of veins forms erectile tissue around the duct; engorgement of these veins may obstruct the duct. Congenital nasolacrimal duct obstruction has been reported to trouble 5–20% of newborns: the obstruction is due to the failure of nasolacrimal duct to fully canalise at birth and typically resolves spontaneously during the early months of life (Sathiamoorthi et al 2018).

CHAPTER
45

Eye

The outer surface of the eye is composed of parts of two spheres with different radii. The anterior segment, part of the smaller sphere, is formed by the transparent cornea and accounts for approximately 7% of the ocular surface. The posterior segment of the eyeball is part of the larger sphere formed externally by the opaque sclera (Fig. 45.1).

Internal to the sclera is a vascular, pigmented layer consisting of three continuous parts that collectively make up the uveal tract: a thin choroid lying posteriorly, a thicker ciliary body and an anterior iris that is displaced from the outer coat and terminates at the pupillary aperture. The internal surface of the choroid is covered by the photosensory retina, which terminates anteriorly at the ora serrata; the latter also marks the junction between the ciliary body and choroid. The vasculature of the choroid supplies nutrients to the avascular outer retina.

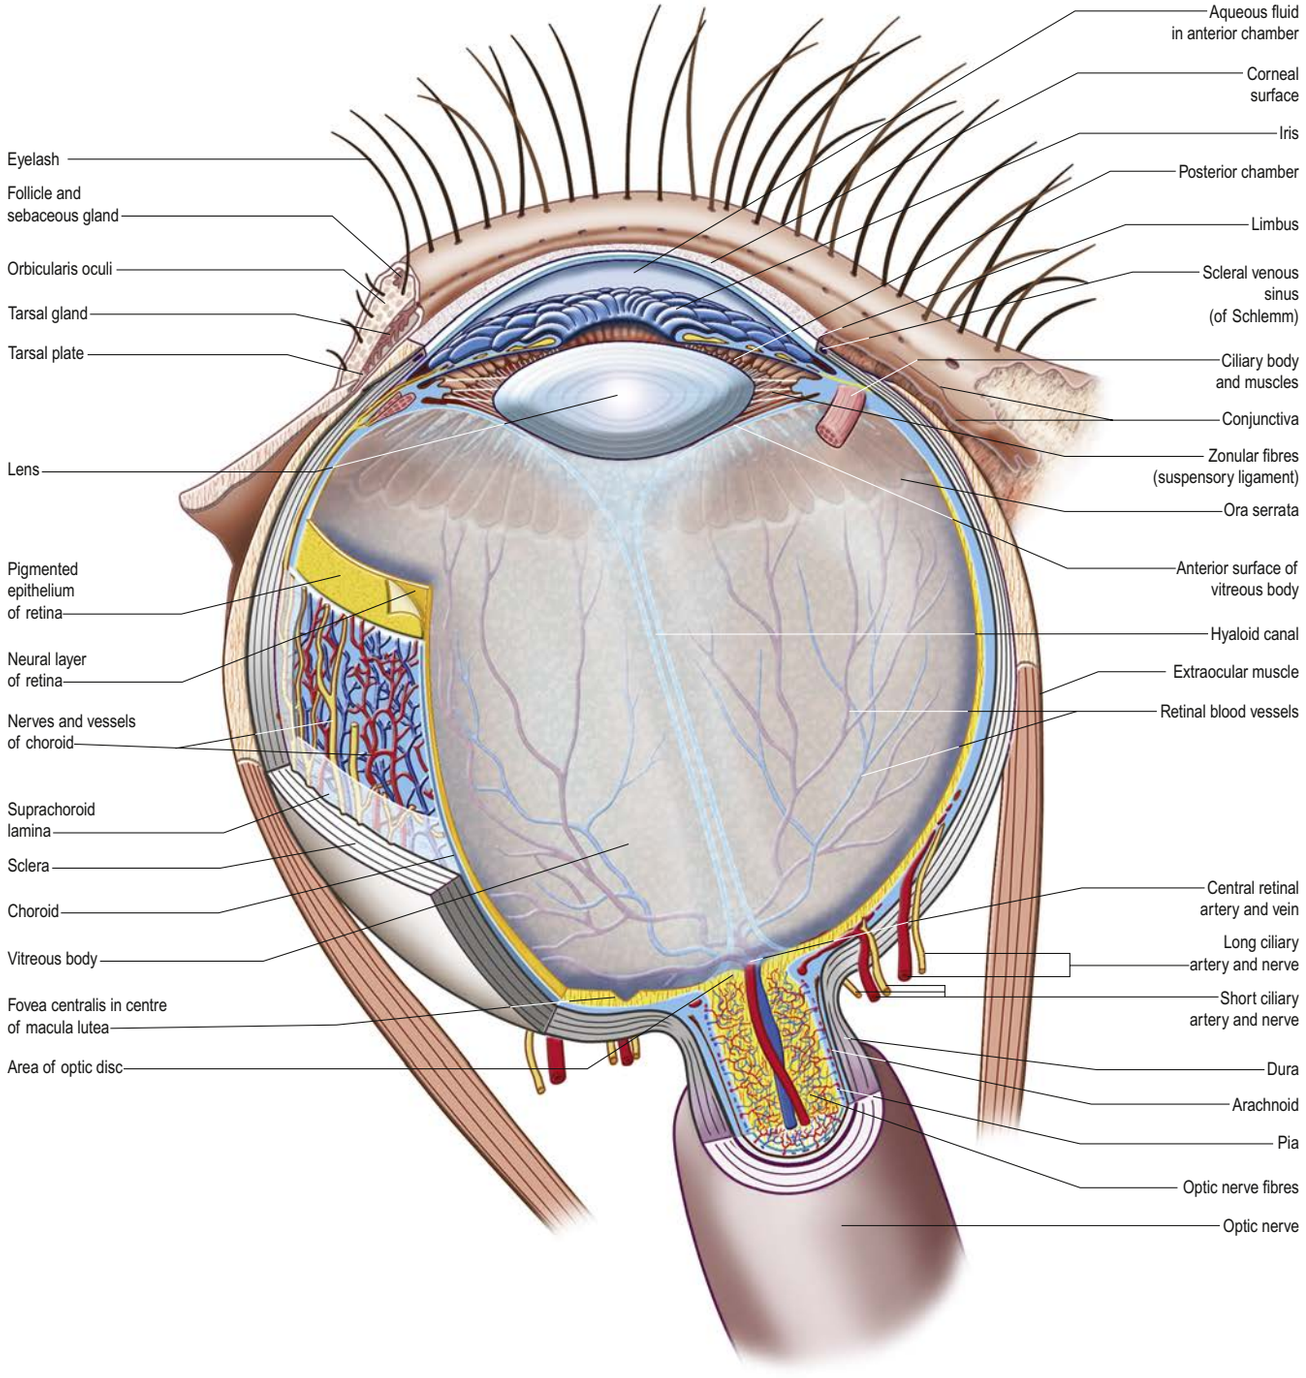

Fig. 45.1 The left eye and part of the lower eyelid in horizontal section, viewed from above. Parts have been cut away to show internal structures.

The ocular lens is located immediately behind the iris and is suspended from the ciliary body via zonular fibres (suspensory ligament) (see Fig. 45.1). Smooth muscles within the ciliary body regulate the tension exerted on the elastic lens and hence determine its shape, thereby adjusting the focus of the eye in the process of accommodation. The iris, which does not allow the transmission of light due to a heavily pigmented posterior surface, also contains smooth muscle, allowing it to regulate the size of the pupillary aperture.

The iris and lens separate the eye into three chambers. The largest, the vitreous chamber, is filled with the gel-like vitreous humour, and lies posterior to the lens, comprising about two-thirds of the volume of the eye (see Fig. 45.1). The spaces between the lens and iris, and the iris and cornea, are, respectively, the posterior and anterior chambers of the eye. Both are filled with aqueous humour, which is produced by the epithelium of the ciliary body, travels through the pupil, circulates in the anterior chamber and is drained principally through the canal of Schlemm at the iridocorneal filtration angle. Aqueous humour provides metabolic support to the avascular lens and cornea.

The sole purpose of the eyes and their associated structures within the bony orbit is to form a good image on a healthy retina. The photoreceptors of the retina transduce the optical radiation into neurobiological activity and other cells within the retina then begin to process the output of the photoreceptors. The retinal signal is transferred via the optic nerve, along the visual pathway (see Fig. 45.32) to various regions within the brain, where further processing results in visual perception.

OUTER COAT

The fibrous outer coat of the eye consists of the opaque posterior sclera and the transparent anterior cornea. Together they form a semi-elastic protective covering enclosing the eye, which, when made turgid by intraocular pressure, determines the optical geometry of the eye and ensures its shape is not distorted when it moves. The sclera also provides attachments for the extraocular muscles, and its smooth external surface rotates easily on the adjacent tissues of the orbit when these muscles contract (Ch. 44). The opacity of the sclera helps ensure that only light that enters the eye through the pupil reaches the retina. The cornea, on the other hand, not only admits light but also its covering tear film is the major refractive surface of the eye.

Sclera

The sclera accounts for approximately 93% of the outer coat of the eye. Anteriorly, it is continuous with the cornea at the corneoscleral junction, known as the limbus (see Fig. 45.1). It is punctured by a number of foramina containing nerves and blood vessels, most notably the optic foramen, which lies 3 mm medial to the midline and 1 mm below the horizontal and houses the optic nerve. Smaller openings contain anterior ciliary arteries that penetrate anteriorly, vortex veins that cross the sclera equatorially, and the long and short ciliary nerves and arteries that enter posteriorly. There is considerable individual variation in scleral dimensions; for example, it is often thicker in males. The sclera is thickest at the posterior pole (just less than 1 mm) and decreases anteriorly, reaching a minimum equatorially at about half this thickness, before increasing somewhat on approaching the limbus. It also thins approaching the optic nerve. The sclera is thinner when the eye is elongated in myopia.

The external surface of the sclera is covered by a delicate episcleral lamina of loose fibrovascular tissue, which contains blood vessels and is in contact with the inner surface of the fascial sheath of the eyeball. Anteriorly, the external scleral surface is covered by conjunctiva, which is reflected onto it from the posterior surfaces of the eyelids. The scleral internal surface adjacent to the choroid is attached to it by a delicate fibrous layer, the suprachoroid lamina, which contains numerous fibroblasts and melanocytes. Anteriorly, the inner sclera is attached to the ciliary body by the lamina supraciliaris. Posteriorly, at the optic nerve, the outer half of the sclera turns back to become continuous with the dura mater, while the inner half is modified to form a perforated plate, the lamina cribrosa sclerae. The optic nerve fascicles pass through these minute orifices, while the central retinal artery and vein pass through a larger, central aperture. The lamina cribrosa sclerae is the weakest part of the sclera and bulges outwards (a cupped disc) when intraocular pressure is raised chronically, as in glaucoma.

Like the cornea, the scleral stroma is composed mainly of densely packed collagen embedded in a matrix of proteoglycans, which are mixed with occasional elastic fibres and fibroblasts. However, in contrast to the cornea, scleral collagen fibrils show a large variation in diameter and spacing, and the lamellae branch and interlace extensively. This arrangement of fibres results in increased light scatter, which is responsible for the opaque, dull-white appearance of the sclera, and imparts a high tensile strength to the sclera to resist the pull of the extraocular muscles and contain the intraocular pressure. Collagen fibre bundles are arranged circumferentially around the optic disc and the orifices of the lamina cribrosa. The fibres of the tendons of the recti intersect scleral fibres at right-angles at their attachments, and then interlace deeper in the sclera. Although the sclera acts as a conduit for blood vessels, scleral vessels are few and mainly disposed in the episcleral lamina, especially close to the limbus. Its sensory nerve supply is surprisingly rich, accounting for the intense pain associated with scleral inflammation (Watson and Young 2004).

A forward pointing ridge of scleral tissue, the scleral spur, lies between the anterior ciliary body and the posterior edges of the canal of Schlemm and trabecular meshwork (**Figs 45.2, 45.3A**). Collagen fibres within this spur are orientated in a circular fashion, and it contains an increased number of elastic fibres.

Scleral development is under active regulation to ensure an eye of the correct axial length to produce a focused image (Wallman and Winawer 2004).

Filtration angle and aqueous drainage

Aqueous humour drains from the eye mainly through the trabecular meshwork into the canal of Schlemm at the iridocorneal (filtration) angle, formed between the posterior aspect of the limbus and the base of the iris (see Fig 45.2; **Fig. 45.3**). The trabecular meshwork is continuous anteriorly with Descemet's membrane and the endothelium of the cornea. Aqueous humour filters from the anterior chamber through interconnected spaces among loose trabecular fibres, most of which are attached to the anterior, external aspect of the scleral spur. Of the remainder, most are continuous with longitudinal fibres of the ciliary muscle, some of which attach to the posterior internal aspect of the scleral spur. The trabecular meshwork provides sufficient resistance to aqueous humour outflow to

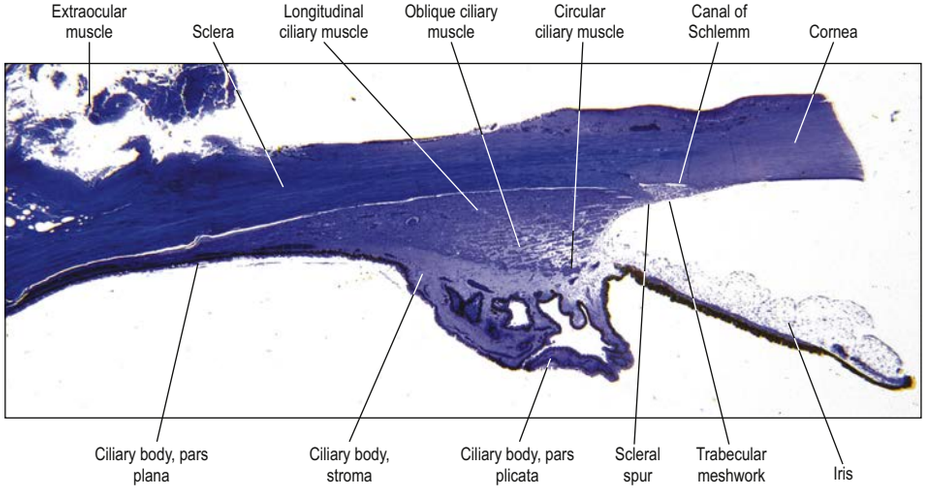

Fig. 45.2 A meridional section through the anterior eye, highlighting the ciliary body and drainage apparatus.

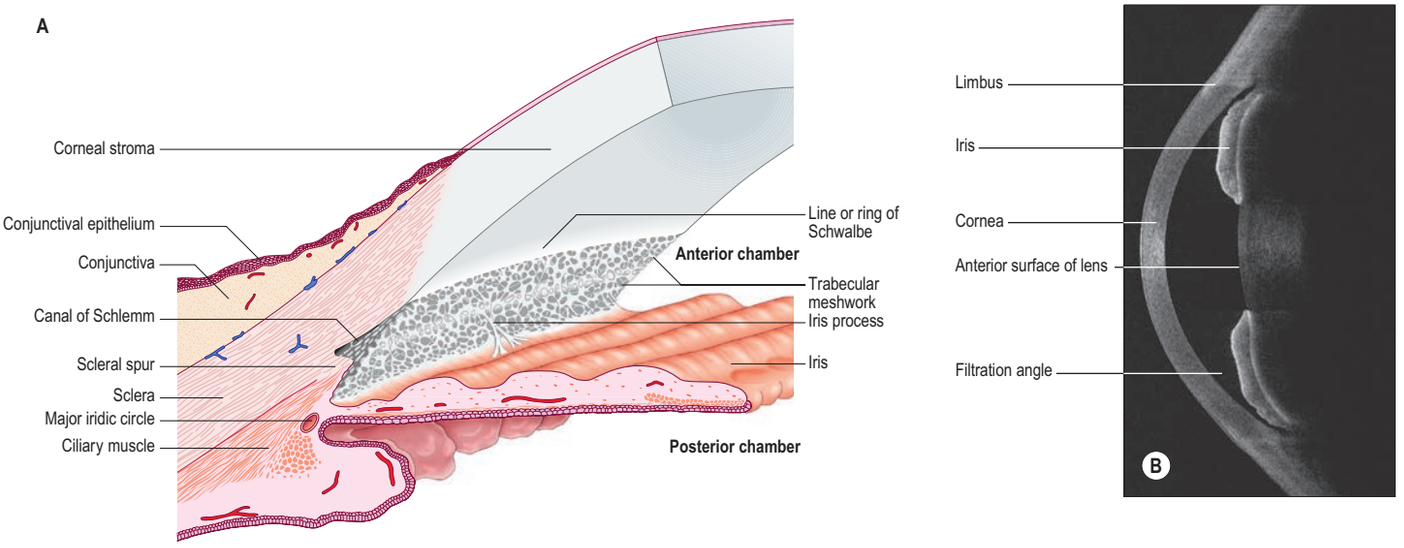

Fig. 45.3 A, A schematic representation of the tissues bordering the anterior chamber angle. The trabecular meshwork is an anulus of tissue spanning the angle; its meshes are shown in transverse section opposite the canal of Schlemm and partly attached to the scleral spur. A single iris process bridges the angle, connecting the trabecular meshwork to the anterior tissues of the iris. **B**, An optical coherence tomography (OCT) *in vivo* image of the anterior segment of a 60-year-old Caucasian female taken in dim room light. (B, Courtesy of Mr Gus Gazzard, Consultant Ophthalmic Surgeon, Moorfields Eye Hospital, London.)

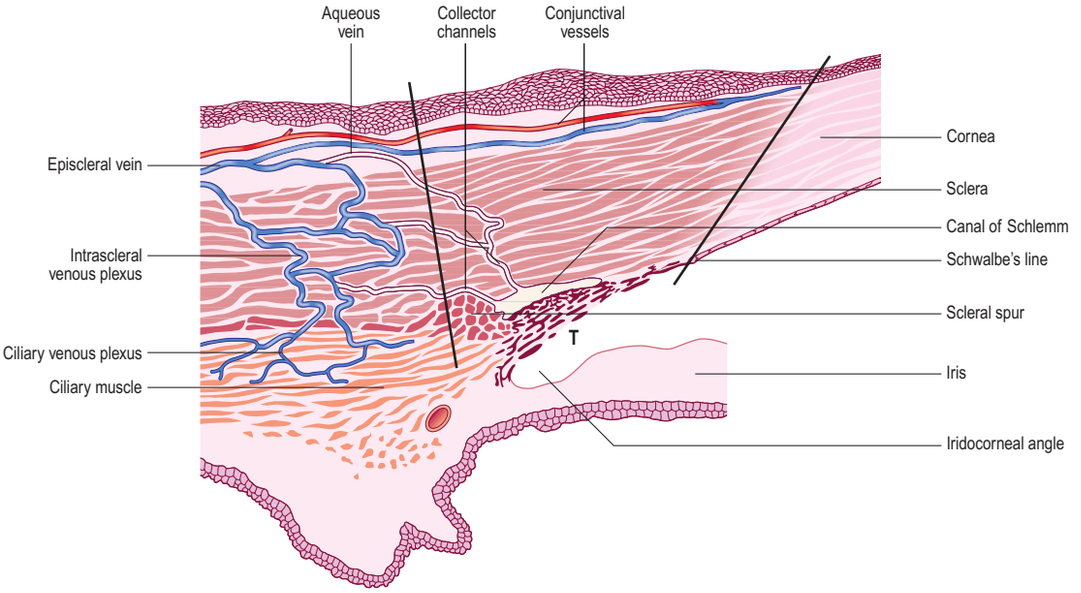

Fig. 45.4 Tissues of the filtration angle in section. The approximate borders of the limbal region are indicated by the solid lines. Aqueous humour drains from the anterior chamber at T through the trabecular meshwork into the canal of Schlemm, from where it flows through collector channels, either to the intrascleral venous plexus, where it mixes with blood from the ciliary venous plexus, or directly to the surface tissues of the eye as an aqueous vein. The aqueous vein is shown joining an episcleral vein at the surface to form a laminated vessel. Aqueous and blood drain posteriorly in episcleral veins, which, in turn, join anterior ciliary veins.

generate an intraocular pressure of approximately 15 mmHg. It also acts as a filter and has the capacity to phagocytose particulate matter.

The canal of Schlemm (sinus venosus sclerae) is an anular endothelial canal located near the internal surface of the sclera close to the limbus. In cross-section, the canal appears as an oval cleft, with an outer wall that grooves the sclera. Posteriorly, it extends as far as the anterior edge of the scleral spur. The canal of Schlemm may be double or multiple in parts of its course, and its walls are constructed of a continuous single thin endothelial layer. Passage of aqueous humour to the canal probably occurs via giant pinocytotic vacuoles and associated transcellular pores, which form on the inner face of the endothelium and discharge into the canal at the outer face. Aqueous humour passes through a plexus of fine intrascleral vessels that connect the canal of Schlemm with episcleral veins (Fig. 45.4). Normally, the canal does not contain blood; pressure gradients prevent the reflux of blood, even though the channels between the canal and veins have no valves. However, in venous congestion, blood may enter the canal; the continuous endothelial outer wall of the canal prevents further reflux.

An alternative route for aqueous outflow, the uveoscleral pathway, has been described (Fautsch and Johnson 2006, Goel et al 2010). Estimates of aqueous drained by this route in humans vary from under 5% to as much as 54% (Alm and Nilsson 2009). Since there is no epithelial barrier between the anterior chamber and the ciliary body, aqueous humour is able to enter the loose connective tissue in front of the ciliary muscle and pass between the muscle fibres into the supraciliary and suprachoroidal spaces, where it can be absorbed by vessels that drain the uvea. Clinically, aqueous outflow via this route can be increased by topical prostaglandin analogues, which are first-line therapy for the treatment of open angle glaucoma.

Any interference with the drainage of aqueous increases intraocular pressure and may lead to glaucoma, which can be either 'primary', or secondary to a specific ocular anomaly or disease. Primary glaucoma can be either 'closed angle', where the filtration angle is narrowed by the proximity of the iris root to the cornea, or, more commonly 'open angle', where aqueous access to angle tissues is unimpeded. In the most common form of primary open angle glaucoma, age-related pathological changes within the trabecular meshwork reduce the facility of aqueous drainage, thus raising intraocular pressure (Gabelt and Kaufman 2005). Sustained raised pressure leads to progressive defects in the visual field, because of either direct mechanical damage to retinal ganglion cell axons (particularly at the optic nerve head), or impairment of the optic nerve head blood supply, or both.

Differences in drainage angle morphology most probably underlie variations in the prevalence of primary angle closure glaucoma (Wang et al 2012); drainage through both the canal of Schlemm and the uveoscleral pathway is decreased in old age. As the lens grows throughout life, while

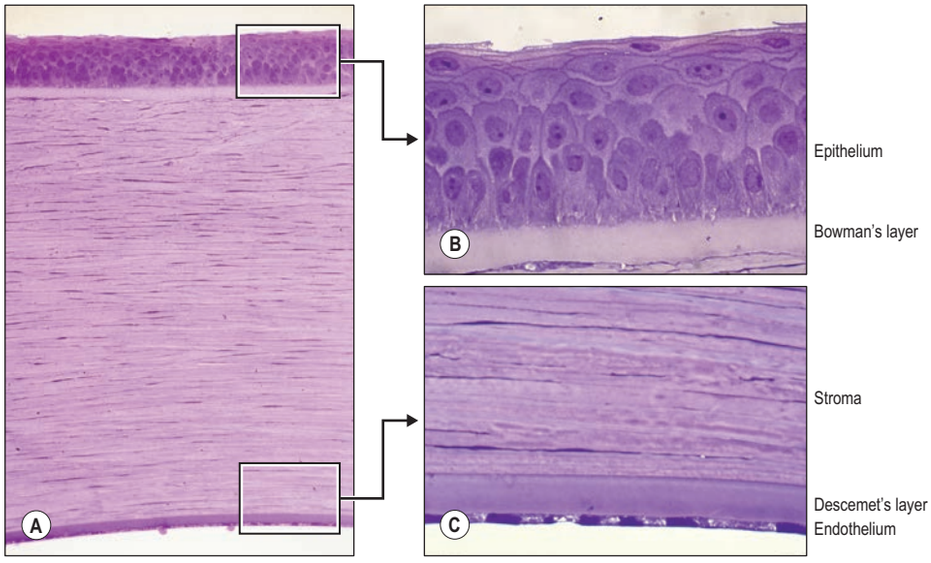

Fig. 45.5 **A**, A low-power light micrograph of the five layers of the cornea. **B**, A high-power light micrograph of the corneal epithelium and Bowman's layer. **C**, A high-power light micrograph of the corneal endothelium, Descemet's layer and part of the stroma. The darkly staining cells in the stroma are keratocytes.

the eye ceases to enlarge after the age of about 15, the depth of the anterior chamber will decrease with age, impairing aqueous drainage.

Cornea

The avascular cornea is the anterior transparent part of the outer coat. Convex anteriorly, it projects from the sclera as a dome-shaped elevation with an area of 1.1 cm^2 in adults, forming approximately 7% of the external tunic area. Since it is more curved (average radius, r = 7.8 mm) than the sclera (r = 11.5 mm), a slight sulcus sclerae marks the corneoscleral junction. The high corneal curvature of the neonate cornea decreases to reach adult levels within a relatively short space of time (Friling et al 2004).

The cornea is approximately 670 µm thick close to the corneoscleral junction, and on average 537 µm at its centre (Wolfs et al 1997). At the nasal and temporal limbus, the transition from cornea to sclera is in a line that is approximately perpendicular to the cornea; this transition is more oblique superiorly and inferiorly, with the sclera overlapping the cornea to a greater extent anteriorly. Consequently, when viewed from the front, the corneal perimeter is slightly elliptical, because its horizontal diameter (11.7 mm) is a little greater than its vertical (10.6 mm). Its posterior perimeter is circular (diameter 11.7 mm).

Since the cornea carries most of the optical power of the eye, changes to its shape can have a significant impact on the refractive state of the eye (p. 802). This has been used to advantage in numerous techniques for correcting refractive error, such as laser refractive surgery.

Microscopically, the cornea traditionally consists of five layers. Arranged anterioposteriorly, these are the corneal epithelium, anterior limiting lamina (Bowman's layer), substantia propria (stroma), posterior limiting lamina (Descemet's membrane) and endothelium (Fig. 45.5).

Corneal epithelium

The corneal epithelium accounts for approximately 10% of the corneal thickness (50 µm). It usually consists of 5–6 layers of cells (Fig. 45.5B) that protect the ocular surface from mechanical abrasion, form a permeability barrier (to small molecules, water and ions) and prevent the entry of pathogens. The deepest cells are columnar with flat bases, rounded apices and large round or oval nuclei. Outside these are 2–3 layers of polyhedral (often wing-shaped) cells. In the more superficial layers, the cells become progressively flatter and present a smooth, optically perfect surface when covered by the tear film. Scanning electron microscopy of surface cells reveals extensive finger-like and ridge-like projections (microvilli and microplicae). A complex network of tight junctions links the superficial cells, consistent with their barrier function.

Anterior limiting lamina (Bowman's layer)

The anterior limiting lamina, which lies internal to the corneal epithelium, contains a dense mass of collagen fibrils set in a matrix similar to that of the substantia propria. It is 12 µm thick, is readily distinguishable from the substantia propria because it does not contain fibroblasts, and appears amorphous by light microscopy (see Fig. 45.5B).

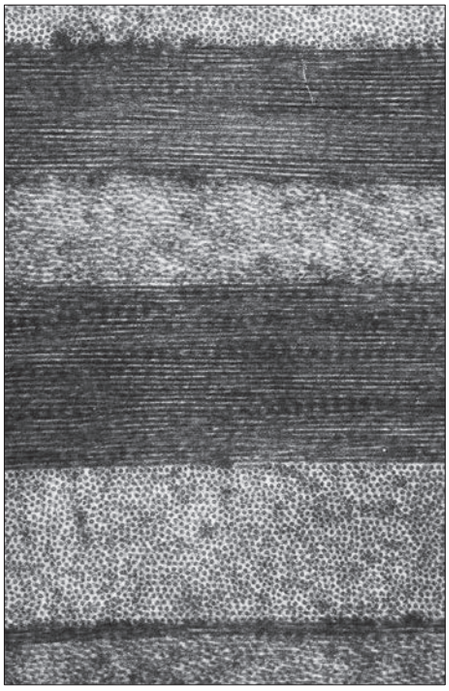

Fig. 45.6 An electron micrograph of the stroma of the human cornea, showing the geometric precision of the alternation in direction of adjacent layers of fibres. (Courtesy of John Marshall, St Thomas' Hospital, London.)

Substantia propria (stroma)

The substantia propria is approximately 500µm thick and forms the bulk of the cornea. It is a compact and transparent layer, composed of 200–250 sequential lamellae, each made up of fine parallel collagen fibrils mainly of type I collagen. Flat dendritic interconnecting fibroblasts (keratocytes) form a coarse mesh between the lamellae. Alternate lamellae are typically orientated at large angles to each other (Fig. 45.6). X-ray diffraction indicates that they run along two preferred directions, superior–inferior and nasal–temporal, to account for the additional tensile stress exerted by the recti along these meridians (Boote et al 2005). Each lamella is approximately 2 µm thick and of variable width (10–250 µm or, rarely, more). In the central cornea, fibrils within the lamellae have a similar diameter of approximately 31 nm. This increases slightly with age and approaching the limbus. The small size of the fibrils (much smaller than the wavelength of light), the regularity of their spacing (maintained by collagen–proteoglycan interactions) and the careful control of corneal hydration, are the principal factors that determine stromal transparency. Light scattered by the collagen fibrils is eliminated by destructive interference in all directions other than forwards.

Surgically, the anterior cornea can be separated from the posterior Descemet's membrane and the endothelium by the injection of air into the corneal stroma. However, the cleavage plane is somewhat anterior to Descemet's layer and it has been suggested that the remaining posterior corneal stroma represents a distinct, sixth, layer within the cornea. This pre-Descemet's layer, which is approximately 10 µm wide in aged eyes, is characterized by lamellae of collagen and a lack of keratocytes (Dua et al 2013): unlike the traditional five layers of the cornea, it is not readily discernible in light micrographs (**Fig. 45.5C**) and is probably best regarded as a posterior variation of the corneal stroma rather than a distinct corneal layer.

A common finding in the elderly is arcus senilis, a complete or partial ring, usually white or grey in colour, seen externally at the corneal margin caused by cholesterol, phospholipid and triglyceride deposits within the stroma.

Posterior limiting lamina (Descemet's layer)

The posterior limiting lamina covers the substantia propria posteriorly. It is thin and apparently homogeneous, and is regarded as the basement membrane of the endothelium (see Fig. 45.5C). Some 4 µm thick at birth, it may increase to 12 µm by the eighth decade.

Endothelium

The endothelium covers the posterior surface of the cornea and consists of a single layer of squamous cells (see Fig. 45.5C) with prominent interdigitations between adjacent cells, which are also connected by tight and gap junctions. When viewed *en face*, the endothelium appears as a mosaic of polygonal (typically hexagonal) cells. As these cells have a limited capacity for mitosis, in response to pathology, trauma, age and prolonged contact lens wear, the endothelial mosaic becomes less regular, and shows a greater variation in cell size (pleomorphism) and shape (polymegathism), as cells spread to fill gaps caused by cell loss. The numerous mitochondria and prominent rough endoplasmic reticulum within these cells reflects their high metabolic activity. Thus, for example, active pumping mechanisms largely control the degree of corneal hydration.

Corneal innervation

The cornea is innervated by numerous branches of the ophthalmic nerve, which either form an anular plexus around the periphery of the cornea or pass directly from the sclera and enter the corneal stroma radially as 70–80 small groups of fibres. On entering the cornea, the few myelinated nerves lose their myelin sheaths and ramify throughout the anterior corneal stroma in a delicate reticulum, their terminal filaments forming an intricate subepithelial plexus. Axon bundles from this plexus cross the anterior limiting membrane and form a sub-basal plexus from which individual beaded axons pass to more superficial epithelial layers, eventually terminating as free nerve endings. Corneal nerves provide the afferent arm of the blink and lacrimation reflexes (Ch. 44) and may also have a neurotrophic function (Müller et al 2003). Corneal sensitivity to mechanical and chemical stimuli declines with age, and may be related to a decrease in the density or sensitivity of corneal nociceptors.

Corneoscleral junction (limbus)

The limbus marks the transitional zone between the cornea and sclera (see Fig. 45.3B). Here, the corneal epithelium merges with the epithelium of the conjunctiva, which thickens (up to 12 cells). Bowman's layer terminates, and the corneal stromal collagen loses its regularity. The capillaries of the conjunctiva and episclera end in loops near the limbus, ensuring the avascularity of the cornea. Internally, Descemet's membrane disperses into the fibres of the trabecular meshwork and the corneal endothelium is continuous with that covering the trabeculae. The limbus forms a convenient surface landmark for ocular surgery and intravitreal injection. A position 4 mm posterior to the limbus, for example, indicates the pars plana of the ciliary body (orbiculus ciliaris) in adults, through which safe surgical access to the posterior segment of the eye can be achieved.

The corneal epithelium does not possess stem cells and its replacement depends on the centripetal migration of cells from the edges of the cornea. These cells are the progeny of mitotic limbal stem cells located within radially orientated epithelial ingrowths (palisades of Vogt).

UVEA

The vascular tunic of the eye consists of the choroid, ciliary body and iris, which collectively form a continuous structure, the uvea (see Fig. 45.1). The choroid covers the internal scleral surface and extends forwards to the ora serrata. The ciliary body continues forwards from the choroid to the circumference of the iris, which is a circular diaphragm behind the cornea and in front of the lens, forming an almost central aperture, the pupil.

Choroid

The choroid is a thin, highly vascular, pigmented layer that lines almost five-sixths of the eye posteriorly. Its mean thickness, measured by optical coherence tomography, is approximately 230 µm (Arora et al 2012), and is greatest behind the macula. These dimensions are influenced by several factors because the choroid thins with age (Park and Oh 2013), and its thickness is correlated with axial length, central corneal thickness, time of day and various pathological conditions such as angle closure.

The choroid is pierced by the optic nerve where it is firmly adherent to the sclera. Elsewhere, its external surface is only loosely connected to the sclera by the suprachoroid layer (lamina fusca). Internally, it is attached to the retinal pigment epithelium, and at the optic disc is continuous with the pia-arachnoid tissues around the optic nerve.

Four layers can be identified in transverse section. Starting externally, these are the suprachoroid, vascular stroma, choriocapillaris and lamina vitrea (Bruch's membrane) (**Fig. 45.7**; see also Fig. 45.22).

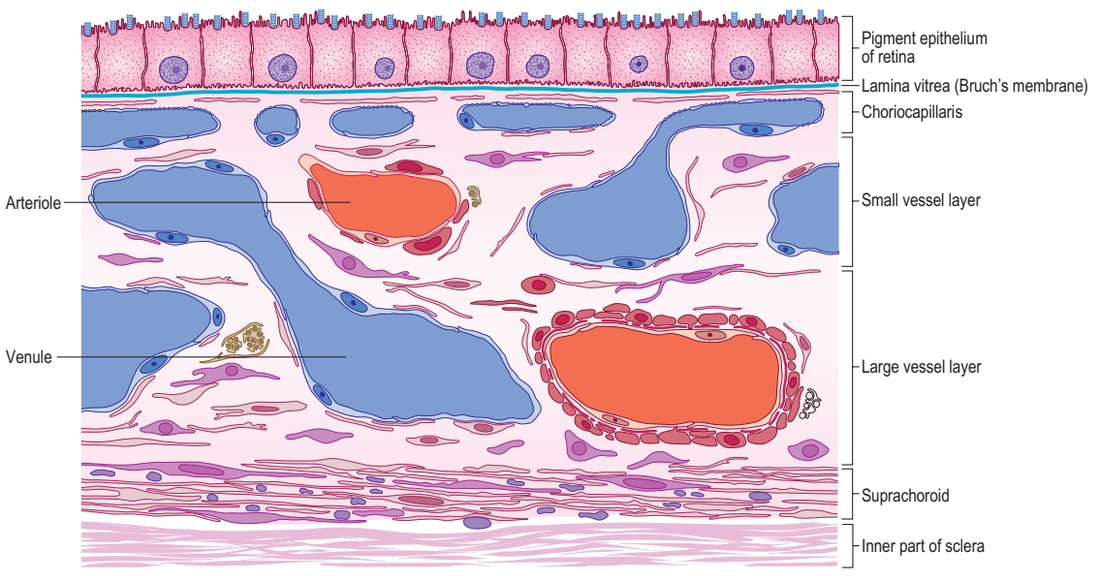

Fig. 45.7 A drawing of a histological section through the choroid close to the posterior pole.

Suprachoroid

The suprachoroid covers the external surface of the choroid; it is approximately 30 μm thick and composed of delicate non-vascular lamellae, each one a network of fine collagen and elastic fibres, fibroblasts and melanocytes. Ciliary nerves and long posterior ciliary arteries pass forwards to the anterior uvea in this layer.

Vessel layer (stroma)

Internal to the suprachoroid is a layer composed mainly of arteries and veins, but with some loose connective tissue containing scattered pigment cells. Like the retinal pigment epithelium, these melanocytes absorb light that traverses the retina but is not absorbed by the photoreceptors, so preventing internal reflection. They also help limit the passage of light through the sclera to the retina.

The blood supply of the choroid, as well as the rest of the uvea, is summarized in **Fig. 45.8**. Short posterior ciliary arteries enter the eye through the sclera near the optic nerve and supply the posterior choroid. These vessels branch and gradually decrease in size as they approach the retinal border. The choroidal stroma can be divided into an outer layer of larger vessels (Haller's layer) and an inner layer of smaller vessels (Sattler's layer), which eventually give rise to the choriocapillaris (see Fig. 45.7). Long posterior ciliary arteries and recurrent branches of anterior ciliary arteries supply the anterior part of the choriocapillaris.

Veins within the choroid converge spirally onto four, or very occasionally more, principal vortex veins that pierce the sclera behind the equator to reach tributaries of the ophthalmic veins.

The vessels of the choroid have a rich autonomic vasomotor supply.

The blood flow through the choroid is high, a feature probably associated with an intraocular pressure of 15–20 mmHg: a venous pressure above 20 mmHg is therefore required to maintain circulation. The choroidal perfusion rate exceeds that required to supply nutrients and may serve to cool the retina during exposure to bright light.

Choriocapillaris

The choriocapillaris provides nutrients to the avascular outer five layers of the retina and is composed of large (up to 20 μm thick), densely packed, freely anastomosing, fenestrated capillaries. Pericytes are found mainly on the scleral surface, while most fenestrations face the retina. The permeability of choriocapillaris is exceptionally high, compared to other structures that are invested with fenestrated capillaries.

Lamina vitrea (Bruch's membrane)

The lamina vitrea lies between the choriocapillaris and the retinal pigment epithelium, and is derived from both. Under the light microscope, it appears as a thin (2–4 μm) homogeneous layer: its thickness increases with age. It consists of five layers: a central elastic fibre mesh with flanking internal and external layers of collagen and the basal laminae of the choriocapillaris and retinal pigment epithelium.

The lamina vitrea regulates the passage of fluid and solutes from the choroidal capillaries to the retina. With increasing age, lipid-containing extracellular deposits (drusen) may accumulate between the basal lamina of the retinal pigment epithelium and the inner collagenous layer of this membrane. The deposits impair the exchange of gases, nutrients and metabolites between the choroidal blood and the outer layers of the retina, contributing to chorioretinal diseases such as age-related macular degeneration (Curcio and Johnson 2013). The age-related impairment of the transport of retinoids across the lamina vitrea

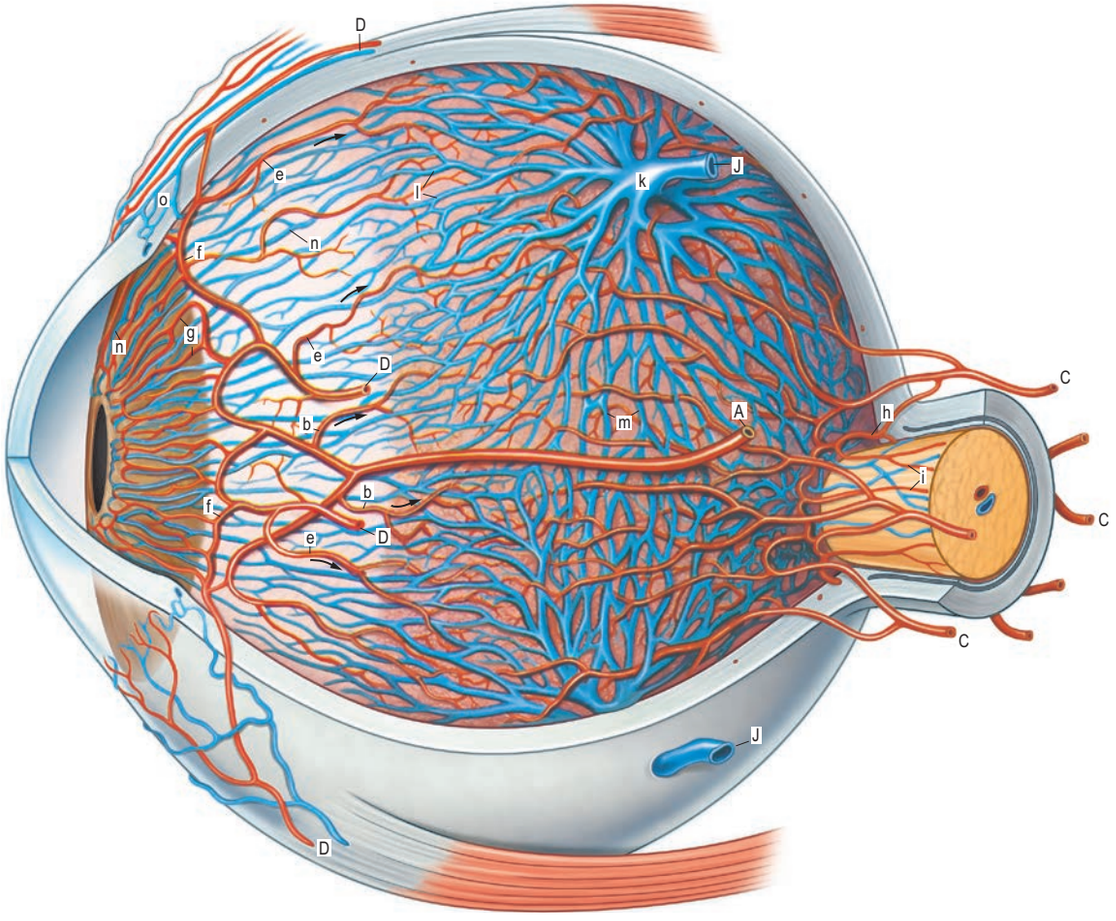

Fig. 45.8 The vasculature of the uveal tract. The long posterior ciliary arteries, one of which is visible (A), branch at the ora serrata (b) and feed the capillaries of the anterior part of the choroid. Short posterior ciliary arteries (C) divide rapidly to form the posterior part of the choriocapillaris. Anterior ciliary arteries (D) send recurrent branches to the choriocapillaris (e) and anterior rami to the major arterial circle (f). Branches from the circle extend into the iris (g) and to the limbus. Branches of the short posterior ciliary arteries (C) form an anastomotic circle (of Zinn) (h) round the optic disc, and twigs from this (i) join an arterial network on the optic nerve. The vortex veins (J) are formed by the junctions (k) of suprachoroidal tributaries (l). Smaller tributaries are also shown (m, n). The veins draining the scleral venous sinus (o) join anterior ciliary veins and vorticose tributaries. (With permission from Hogan MJ, Alvarado JA, Weddell JE 1971 Histology of the Human Eye. Philadelphia: WB Saunders.)

contributes to the slower rate of dark adaptation in older individuals. During sight-threatening choroidal neovascularization, as develops with wet age-related macular degeneration, vessels enter the retina from the choroid through breaks in the lamina vitrea.

Ciliary body

The ciliary body serves to anchor the lens via zonular fibres (suspensory ligaments) and by the contraction of its smooth muscle, it changes the refractive power of the lens (accommodation). Its anterior internal surface is also the source of aqueous humour, while posteriorly its inner surface is contiguous with the vitreous humour and secretes several of its components. The anterior ciliary arteries and the long posterior ciliary arteries meet in the anterior ciliary body at the major iridic circle; the major nerves to all anterior tissues of the eyeball pass through the ciliary body.

Externally, the ciliary body may be represented by a line that extends from approximately 1.5 mm posterior to the limbus (corresponding also to the scleral spur) to a line 7.5–8 mm posterior to this on the temporal side, and 6.5–7 mm on the nasal side. The ciliary body is thus slightly eccentric. It projects posteriorly from the scleral spur, which is its attachment, with a meridional width varying from 5.5 to 6.5 mm. Internally, it exhibits a posteriorly crenated or scalloped periphery, the ora serrata, where it is continuous with the choroid and retina (**Figs 45.9–45.10**). Anteriorly, it is confluent with the periphery of the iris, and externally, it bounds the iridocorneal angle of the anterior chamber.

In cross-section, the ciliary body is composed of four layers. From internal to external, these are a double layer of epithelial cells, the stroma, ciliary muscle and a supraciliary layer (see Fig. 45.2).

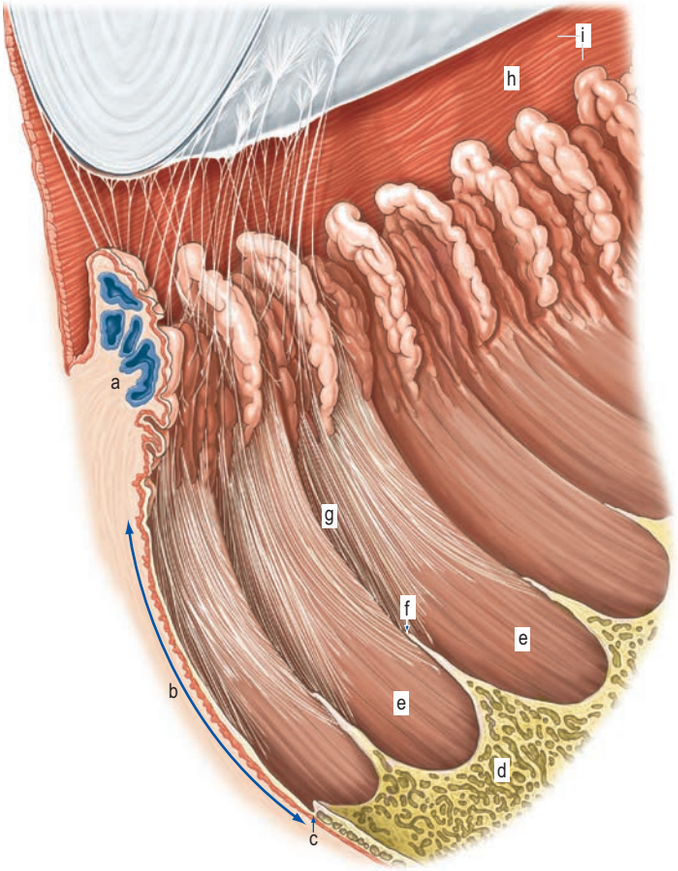

Fig. 45.9 The ciliary region seen from the ocular interior. Above is the periphery of the lens, attached by the zonular fibres (suspensory ligament) to the processes of the pars plicata (corona ciliaris) of the ciliary body (a). The pars plana ciliaris (orbiculus ciliaris) (b) has a scalloped boundary, the ora serrata (c), which separates it from the retina (d). Flanking the 'dentate bays' (e) of the ora serrata are the dentate processes (f), with which linear ridges or striae (g) are continuous; the striae extend forwards between the main ciliary processes, providing an attachment for the longer zonular fibres. The posterior aspect of the iris shows radial (h) and circumferential (i) sulci. (With permission from Hogan MJ, Alvarado JA, Weddell JE 1971 Histology of the Human Eye. Philadelphia: WB Saunders.)

Meridionally, the ciliary body can be divided into two parts (see Figs 45.2, 45.9–45.10). Anteriorly, the ridged pars plicata (corona ciliaris) surrounds the base of the iris and accounts for about one-third of the ciliary body. Posteriorly, the relatively smooth and thin pars plana (orbiculus ciliaris) lies adjacent to the ora serrata and forms a convenient access point for instruments during vitreoretinal surgery and for intraocular injection. The whole ciliary body is covered internally by a double epithelium, in which the inner layer is unpigmented, while the outer layer contains melanin. At the ora serrata, the retinal pigment epithelium is continuous with the outer pigmented epithelium of the pars plana, while the neural retina is replaced by inner unpigmented ciliary epithelium (see Fig. 45.24). Anteriorly, this double epithelium continues over the pars plicata until it merges with the double epithelium on the posterior surface of the iris (where the inner layer of cells also accumulates melanin). The anterior pars plicata is ridged meridionally by 70–80 ciliary processes radiating from the base of the iris (see Figs 45.9–45.10). In the young eye, these process are approximately parallel-sided structures, but in the adult, their flanks become less regular and appear thicker. A minor ridge, or ciliary plica, lies in the valley between most of the processes. The crests of the processes are less pigmented, giving them the appearance of light striae, from which the name ciliary is derived. The zonular fibres attached to the lens extend into the valleys between the ciliary processes and pass beyond them to fuse with the basal lamina of the superficial epithelial layer of pars plana. Their sites of attachment are marked by striae that pass back from the valleys of the pars plicata, across the pars plana, almost as far as the apices of the dentate processes of the ora serrata (see Fig. 45.9).

Ciliary epithelium

The ciliary epithelium consists of two layers of cells that are derived embryonically from the two layers of the optic cup. The inner, superficial, layer consists of columnar cells over the pars plana, and cuboidal cells over the ciliary processes of the pars plicata; it becomes irregular and more flattened between the processes. These cells contain little or no pigment. The outer layer of the ciliary epithelium, in contrast, contains cuboidal cells that are loaded with melanin. Normally, the two layers are firmly united, but fluid may separate them pathologically. The pigment layer is attached to the stroma of the ciliary body by its basal lamina, which continues back into the basal lamina of the choroid. Because of the invagination of the optic cup during development, a basal lamina covers the free surface of the bilayer, which is continuous with the internal limiting membrane of the retina.

The ciliary epithelium is responsible for the secretion of aqueous humour, while the outer pigmented epithelium additionally contributes to the eye's 'black box effect', like the retinal pigment epithelium, choroidal pigment and posterior iris epithelium, absorbing stray light to enhance image quality. Several changes in epithelial cell morphology may contribute to an age-related decrease in aqueous humour secretion (Gabelt and Kaufman 2005).

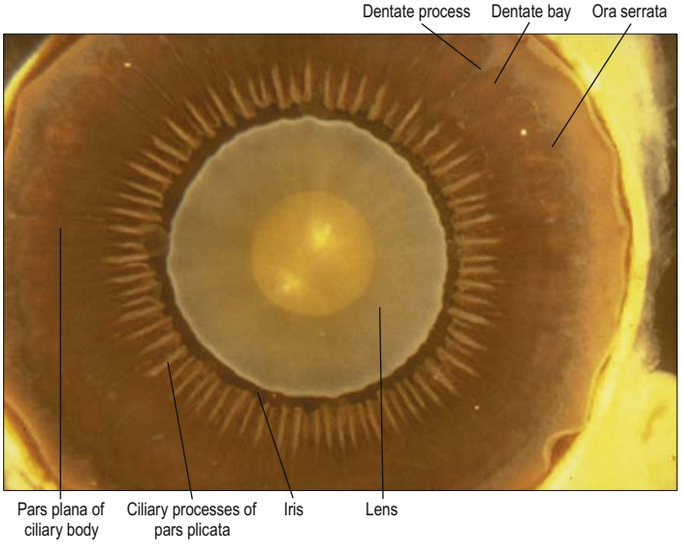

Fig. 45.10 The posterior aspect of the anterior half of the eye, showing the termination of the neural retina at the ora serrata and the ciliary body. The lens has retained sufficient transparency to reveal the iris border; the crenated perimeter of the lens is due to tension imposed by the attached zonular fibres (unseen).

Ciliary stroma

The ciliary stroma is composed largely of loose bundles of collagen between the ciliary muscle and overlying processes and extending into both of them. It also contains numerous larger branches of the ciliary vessels. A dense reticulum of large (up to 35 μm in diameter) fenestrated capillaries is concentrated in the ciliary processes, facilitating the passage of substances from the blood plasma during aqueous production. Anteriorly, near the root of the iris, the major iridic (arterial) circle (see Fig. 45.8) is formed by anastomosis between the anterior ciliary arteries and long posterior ciliary arteries, branches of the ophthalmic artery (see Fig. 44.13). Ciliary veins, also draining the iris, pass posteriorly to join the vortex veins of the choroid.

Ciliary muscle

Ciliary muscle is composed of smooth muscle cells, most of which are attached to the scleral spur and arranged in three different orientations. The outermost fibres are meridional or longitudinal and pass posteriorly into the stroma of the choroid. The innermost fibres swerve acutely from the spur to run circumferentially as a sphincter near the periphery of the lens. Obliquely interconnecting radial fibres run between these two muscular strata, frequently forming an interweaving lattice (see Fig. 45.2; **Fig. 45.11**). Contraction of ciliary muscle results in changes in lens curvature during the process of accommodation. Its contraction also increases aqueous drainage through the trabecular meshwork.

Accommodation reflex

At rest, distant objects are focused on the retina in an emmetropic eye. In order to focus closer things, the dioptric power of the eye has to be increased, which is achieved by increasing the curvature of the lens. At rest, the lens is under tension from the zonular fibres (suspensory ligaments) and hence flattened. On accommodation, the ciliary muscle contracts, moving the ciliary body forwards and inwards towards the optic axis. All parts of the muscle act in concert and tension on the zonular fibres is relaxed. As the lens is covered by an elastic capsule, once tension on it is released, it assumes a more convex shape suitable for focusing closer objects. The radius of curvature of the anterior lens surface changes most during accommodation. This classic view of accommodation, first proposed in principal by Helmholtz over 100 years ago, remains generally accepted, although details of the roles of various ocular structures continue to be debated (Charman 2008).

Information from the retina passing to the visual cortex does not constitute the afferent limb of a simple reflex in the usual sense of the term but permits the visual areas to assess the clarity of objects in the visual field. Cortical efferent information passes to the pretectal area and thence to the Edinger–Westphal nucleus, which contains preganglionic parasympathetic neurones whose axons travel in the oculomotor nerve and synapse in the ciliary ganglion within the orbit (**Fig. 45.12**). Postganglionic fibres (short ciliary nerves) innervate the ciliary muscle, causing it to contract. There is also a sparse sympathetic innervation of ciliary muscle, which has a very limited capacity to relax the muscle.

Accommodation is usually accompanied by constriction of the pupil following contraction of the sphincter pupillae, and convergent eye movements caused by contraction of the medial, superior and inferior recti (all innervated by the oculomotor nerve). This near triad, which serves to improve image quality, may become disrupted in various diseases.

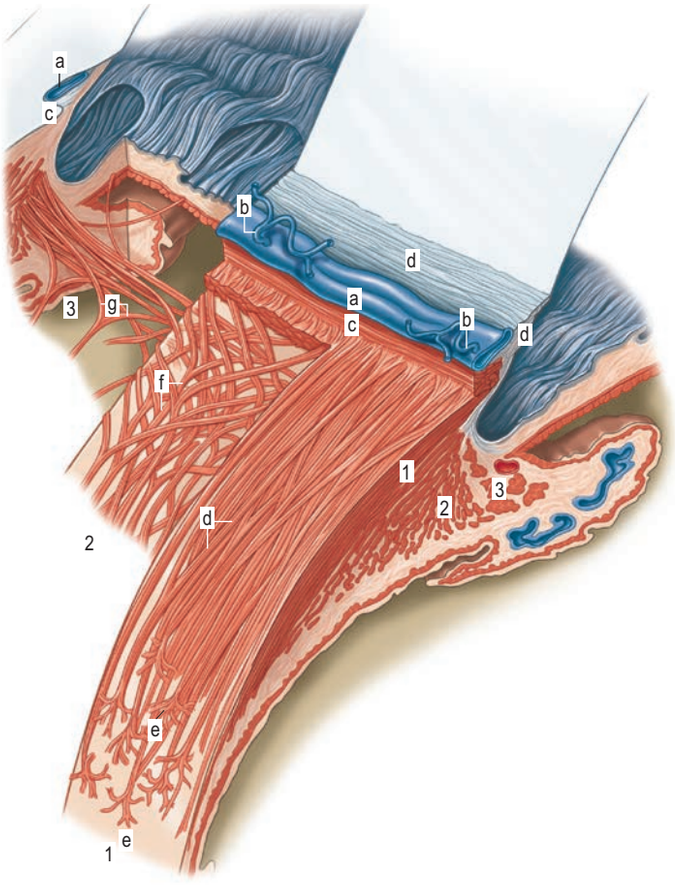

Fig. 45.11 The ciliary muscle and its components. The meridional or longitudinal (1), radial or oblique (2), and circular or sphincteric (3) layers of muscle fibres are displayed by successive removal towards the ocular interior. The cornea and sclera have been removed, leaving the canal of Schlemm (a), collecting venules (b), scleral spur (c) and trabecular meshwork (d). The meridional fibres (1) often display acutely angled junctions (d) and terminate in epichoroidal stars (e). The radial fibres meet at obtuse angles (f) and similar junctions, at even wider angles (g), occur in the circular ciliary muscle. (With permission from Hogan MJ, Alvarado JA, Weddell JE 1971 Histology of the Human Eye. Philadelphia: WB Saunders.)

Supraciliary layer

The thin supraciliary layer separates the sclera from the ciliary muscle and is largely composed of collagen fibres derived from the two layers it divides. It also forms the alternative uveoscleral route (other than the canal of Schlemm) for the drainage of aqueous humour (pp. 791-792).

Iris

The iris is an adjustable diaphragm around a central aperture (slightly medial to true centre), the pupil. It lies between the cornea and lens and is immersed in aqueous fluid (see Fig. 45.1), partially dividing the anterior segment into an anterior chamber, enclosed by the cornea and iris, and a posterior chamber, situated between the iris and the lens anterior to the vitreous. The efficacy of the iris as a light stop is mainly due to a densely pigmented posterior double epithelium. The pupillary aperture is adjusted by the action of two muscles, the dilator and sphincter pupillae.

Seen from the front, the iris is divided into a large ciliary zone adjacent to the ciliary body and a smaller, inner, pupillary zone (**Fig. 45.13**). The two regions join at the collarette. The anterior surface of the iris often contains large depressions (crypts of Fuchs), and at the pupillary margin, the posterior pigmented epithelium is visible as the pupillary ruff.

In transverse section, several subdivisions of the iris are evident (**Fig. 45.14**). From anterior to posterior, they are an anterior border layer, the stroma (which contains the sphincter pupillae), and two pigmented epithelial layers, the most anterior of which contains the dilator pupillae. It is thinnest at its root (approximately 200 μm), where the ciliary body is attached, and thickest at the collarette.

Anterior border layer

The anterior surface of the iris is not a distinct epithelium but a modified layer of the iris stroma, formed mainly by an increased number of fibroblasts that constitute a network on the anterior surface with a layer of underlying melanocytes. At the outer periphery of the iris, the anterior border layer blends with the trabecular connective tissue of the iridocorneal angle; at the pupillary margin, it meets the epithelium of the posterior surface of the iris.

The colour of the iris is a product of the combined effect of reflection/absorption by the iridial connective tissue and the concentration of pigment in the anterior border layer and, to a lesser extent, in the iris stroma. The distribution of pigment is often irregular, which produces a flecked appearance. When pigment is largely absent, other than in the posterior epithelial layers (the condition at birth), the iris is light blue. Those with dark irises are not only less likely to be dazzled by bright light, they also have a lower corneal sensitivity to chemical irritants, and mydriatic drugs are less effective. Iris colour also correlates with the incidence of ocular diseases such as cataract and uveal melanoma (Sun et al 2014). The insubstantial and variable nature of the anterior iris

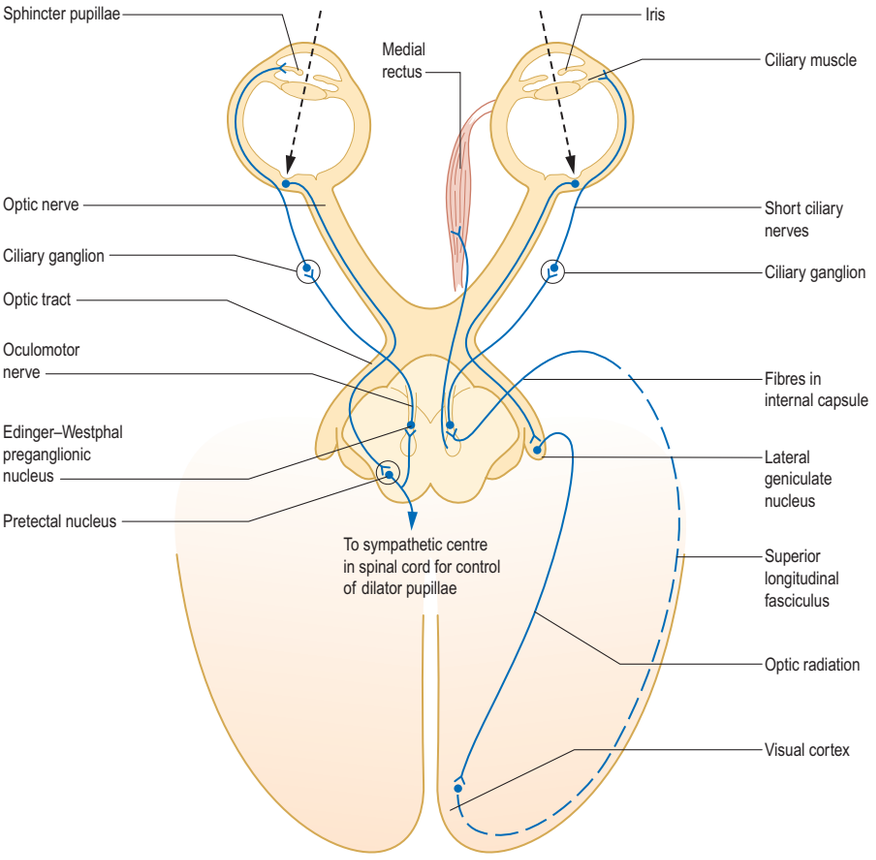

Fig. 45.12 The neural pathways of the pupillary light reflex (left) and the accommodation reflex (right). (From Oxford Textbook of Functional Anatomy, Vol 3 Head and Neck, MacKinnon P, Morris J (eds) 1990. With permission of Oxford University Press.)

gives every iris a unique external appearance, which can be used for individual identification.

Stroma

The stroma of the iris is formed of fibroblasts, melanocytes and a loose collagenous matrix but no elastic tissue. The intercellular spaces appear to communicate freely with the anterior chamber. A few large, heavily pigmented 'clump cells' may be present; these are phagocytes and contain lysosomes and ingested melanosomes. The stroma also contains vessels and nerves. An aggregation of smooth muscle cells near the pupillary margin forms the anular contractile sphincter pupillae (see below).

Epithelial layers

The epithelial surface covering the iris posteriorly is a continuation of the bilaminar epithelium of the ciliary body and is formed from the two layers of the optic cup. The pupil, through which this epithelium curves for a short distance on to the anterior surface as the pigment ruff, corresponds to the opening of the optic cup.

The layer of epithelial cells nearest the stroma is, perhaps confusingly, termed the anterior epithelium, although it lies posterior to the stroma. Its cells are pigmented, as are those of the corresponding layer in the ciliary epithelium. They give rise to the dilator pupillae. Vitreal to this stratum is a layer of heavily pigmented cells, the posterior epithelium, which is continuous with the inner non-pigmented layer of the ciliary epithelium. As is readily apparent from *in vivo* scans, the pupillary region of the iris rests on the front surface of the lens (see Fig. 45.3B). Its posterior surface therefore bears numerous radial ridges that facilitate the movement of aqueous humour from the posterior to the anterior chamber. Adjacent epithelial cells are extensively joined by various junctions that ensure the layer can withstand the excursions of the iris during changes in pupillary size (**Fig. 45.15**).

Muscles of the iris

Sphincter pupillae

The sphincter pupillae is a flat anulus of smooth muscle approximately 750 µm wide and 150 µm thick that lies anterior to, and largely separated from, the epithelium covering the posterior iris. Its densely packed, fusiform muscle cells are often arranged in small bundles, as in the ciliary muscle, and pass circumferentially around the pupil (see Fig. 45.13). Collagenous connective tissue lies in front of and behind the muscle fibres. It is very dense posteriorly, where it binds the sphincter to the pupillary end of the dilator muscle and is attached to the epithelial layer at the pupil margin. Small axons, mostly non-myelinated, ramify in the connective tissue between bundles.

Dilator pupillae

The dilator (dilatator) pupillae forms a thin layer that lies immediately anterior to the epithelium of the posterior surface of the iris. Its 'fibres' are the muscular processes of the anterior layer of this epithelium, whose cells are therefore myoepithelial. Myofilaments are present throughout these cells but are more abundant in their fusiform basal muscular processes, which are approximately 4 µm thick, 7 µm wide and 60 µm in length. They form a layer 3–5 elements thick through most of the iris, from its periphery to the outer perimeter of the sphincter, which it slightly overlaps. Here the dilator thins out and sends spurs to blend with the sphincter. Unlike the apical parts of the myoepithelial cells, these have a basal lamina and are joined by gap junctions like those between the sphincteric muscle cells. Small, unmyelinated axons pass between, and terminate on, their muscular processes (see Fig. 45.15).

Innervation of muscles of the iris

The iris is innervated mainly by the long and short ciliary nerves. Short ciliary nerves, which contain parasympathetic, postganglionic, myelinated axons derived from the ciliary ganglion (see Figs 44.17, 44.18, 45.12), innervate the sphincter pupillae, losing their myelin well before entering the muscle. The dilator is supplied with sympathetic, non-myelinated, postganglionic fibres from the superior cervical ganglion whose routes are less well established. An additional small fraction of nerve endings in the dilator and sphincter muscles have been identified as parasympathetic and sympathetic, respectively, in experimental animal studies, including those on primates. The nerve fibres form plexuses within the iris, from which fibres extend to innervate the two muscles, the vessels and the anterior border layer; some fibres may be afferent (trigeminal) and others are vasomotor.

Pupillary light reflex

In young adults pupillary diameter normally varies from around 2 mm when fully constricted (miosis) in bright light to at least 8 mm when dilated in darkness (mydriasis), and has an even wider range under the influence of drugs. Resting pupil size over a range of light levels declines with age (senile miosis), contributing to reduced visual sensitivity in

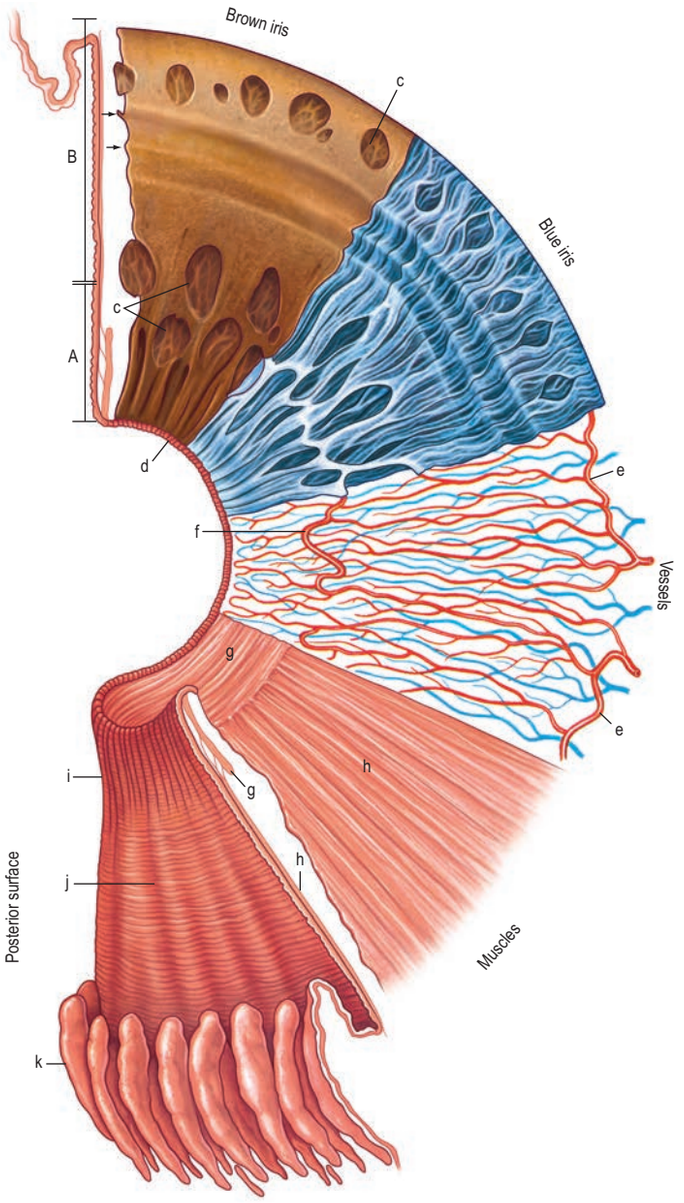

Fig. 45.13 The surfaces and internal strata of the iris, composite view. In a clockwise direction from above, the pupillary (A) and ciliary (B) zones are shown in successive segments. The first (brown iris) shows the anterior border layer and the openings of crypts (c). In the second segment (blue iris), the layer is much less prominent and the trabeculae of the stroma are more visible. The third segment shows the iridial vessels, including the major arterial circle (e) and the incomplete minor arterial circle (f). The fourth segment shows the muscle stratum, including the sphincter (g) and dilator (h) of the pupil. The everted 'pupillary ruff' of the epithelium on the posterior aspect of the iris (d) appears in all segments. The final segment, folded over for pictorial purposes, depicts this aspect of the iris, showing radial folds (i and j) and the adjoining ciliary processes (k). Circular contraction furrows are shown (arrows) in the ciliary portion of the iris. (With permission from Hogan MJ, Alvarado JA, Weddell JE 1971 Histology of the Human Eye. Philadelphia: WB Saunders.)

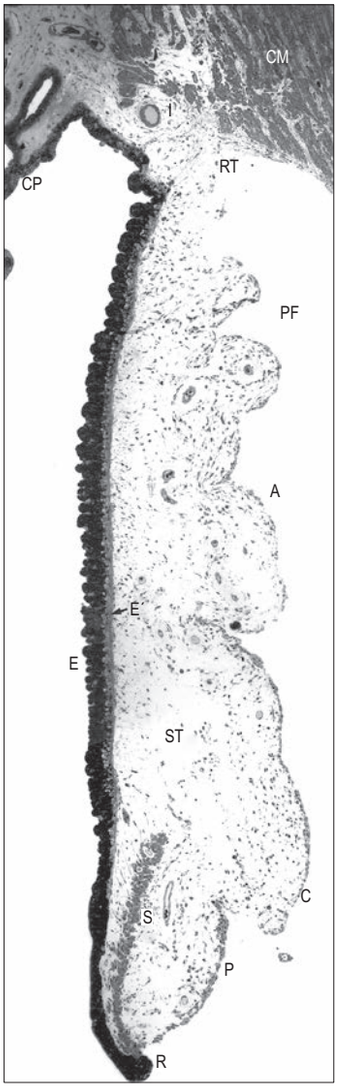

Fig. 45.14 A meridional section of the iris. The posterior surface is lined with a double epithelium (E, E'); the arrow points to the processes of the anterior layer of the epithelium forming the dilator pupillae muscle. The iris is in a contracted state, as shown by the thickened epithelium opposite the dilator muscle and thinning opposite the sphincter, and by the shortness of the pupillary zone. Abbreviations: A, anterior border layer; C, collarette; CM, ciliary muscle; CP, ciliary processes; I, major iridic circle; P, pupillary region of the iris; PF, folds in anterior surface towards the root; R, pupillary ruff; RT, root; S, sphincter pupillae muscle; ST, stroma.

the elderly. Variations in pupil area in different light levels (maximally a factor of 16) will obviously affect the amount of light impinging on the retina. However, compared to the total range of illumination within which humans can maintain some degree of vision (approximately 10 log units), this effect, though important, is small. Most mechanisms for dark/light adaptation are retinal, and neural or biochemical in nature. Enhancing visual acuity by restricting light to the centre of the lens, and thereby decreasing the amount of spherical aberration, is at least as important a function of pupillary constriction.

If only one eye is illuminated, the pupil of that eye constricts (direct response), as does the pupil of the contralateral, unilluminated, eye (consensual response). While change in pupillary diameter is usually considered a reflex response to changes in light level, the pupil also constricts on viewing near objects and in response to painful stimuli; it can also be influenced by more complex cortical factors.

In pupillary constriction, light acting on both traditional retinal photoreceptors (rods and cones) and on intrinsically photosensitive retinal ganglion cells (p. 807) gives rise to activity in retinal ganglion cells that is conducted along the optic nerve, through the optic chiasma and along the optic tract. Although the majority of tract fibres end in the lateral geniculate nucleus of the thalamus (see Fig. 45.32), a small number leave the optic tract before it reaches the thalamus, at the superior brachium, and synapse in the olivary pretectal nucleus. The information is relayed from the pretectal nucleus by short neurones that synapse bilaterally on preganglionic parasympathetic neurones in the Edinger–Westphal nucleus (in the oculomotor nerve complex in the rostral midbrain). Efferent impulses pass along parasympathetic fibres carried by the oculomotor nerve to the orbit, where they synapse in the ciliary ganglion. Postganglionic fibres travel in the short ciliary nerves to the sphincter pupillae, which reduces the size of the pupil when it contracts (see Fig. 45.12).

Pupillary dilation is brought about by lessening the parasympathetic drive to the sphincter (see above) and by sympathetic activation of the dilator. Sympathetic preganglionic fibres arise from neurones in the intermediolateral cell column in segments C8–T2 of the spinal cord, a region termed the ciliospinal center of Budge (and Waller), and pass via the sympathetic trunk to the superior cervical ganglion. Postganglionic neurones travel up the neck next to the internal carotid artery as the internal carotid nerve; at the level of the cavernous sinus, the nerve breaks up to form an interweaving network of fibres, the carotid plexus, around the carotid artery. Some of the axons from the plexus form the sympathetic root of the ciliary ganglion, passing through the ciliary ganglion without synapsing (see Fig. 44.18), and innervating the iris dilator via short ciliary nerves travelling within the choroid. Other postganglionic sympathetic fibres bypass the ciliary ganglion and reach the dilator in long ciliary nerves, which are branches of the nasociliary nerve. Neurones supplying the long and short ciliary nerves enter the orbit by the superior orbital fissure (Ch. 44). Some sympathetic fibres additionally reach the eye via the optic canal (Ruskell 2003).

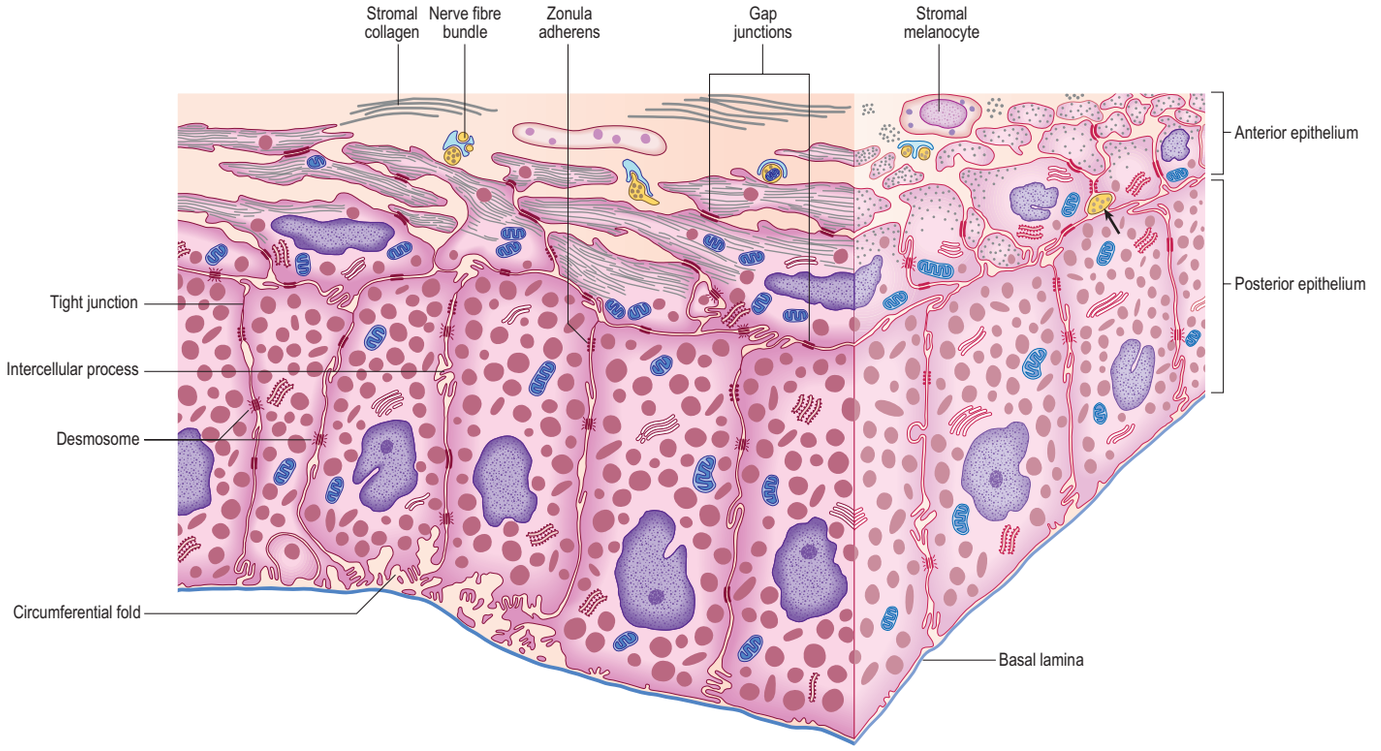

Fig. 45.15 The posterior structures of the iris. The dilator pupillae is shown in transverse section on the right and in longitudinal section on the left (the arrow shows a rarer deeper nerve terminal).

Vascular supply of the iris

The iris receives its blood supply from the long posterior and anterior ciliary arteries (see Fig. 45.8). On reaching the attached root of the iris, both long ciliary arteries divide into an upper and a lower branch. The branches anastomose with the corresponding contralateral arteries, and with the anterior ciliary arteries, to form the major iridic circle (circulus arteriosus major) at the base of the iris (see Figs 45.13–45.14). Vessels converge from this circle towards the free margin of the iris, where they form loops and become veins. At the level of the collarette, arteries and veins anastomose to form an incomplete minor iridic circle (circulus arteriosus minor). The smaller arteries and veins are very similar in their structure and are often slightly helical when the pupil is dilated, allowing them to adapt to changes in iridial shape as the pupil varies in size. All of the vessels, including the capillaries, have a non-fenestrated endothelium and a prominent, often thick, basal lamina. There is no elastic lamina in the arteries or veins, and there are few smooth muscle cells, especially in the veins. Connective tissue in the tunica media is loose, whereas the adventitia is remarkably dense and collagenous, so that it appears to form almost a separate tube.

LENS AND HUMOURS

The cornea, aqueous humour, lens and vitreous humour, often collectively termed the ocular media, serve to form an image on the retina by transmitting and refracting light. Additionally, the aqueous provides nutrients to the avascular cornea and lens, and removes their metabolic waste, as well as generating the intraocular pressure that maintains the shape of the eye.

Aqueous humour

Aqueous humour is derived from the plasma within the fenestrated capillaries of the ciliary processes and is actively secreted into the posterior chamber by the overlying epithelium. Thereafter, it passes around the equator of the lens and flows through the pupil into the anterior chamber, where it circulates before being drained at the iridocorneal angle either through the trabecular meshwork into the canal of Schlemm or via the ciliary muscle using an alternative uveoscleral pathway (pp. 791–792).

The major component of aqueous, like plasma, is water and the composition of the two fluids is broadly similar, although they do differ in the concentration of some electrolytes and organic solutes. In the interests of optical clarity, the blood–aqueous barrier also ensures a very low concentration of protein in the aqueous (generally less than 1% of the level in plasma). Inflammation of the anterior uvea can lead to a breakdown of this barrier and the presence of protein in the aqueous, resulting in light scatter that is manifest clinically as ‘flare’.

Lens

The lens is an encapsulated, biconvex body bathed in aqueous humour, which serves to selectively transmit light and adjust the focus of the eye. Posteriorly, it contacts the hyaloid fossa of the vitreous humour. Anteriorly, it forms a ring of contact with the posterior border of the pupillary region of the iris but, further away from the axis of the lens, the gap between the lens and iris increases to form the posterior chamber of the eye (see Fig. 45.1; **Fig. 45.16**). The lens is encircled by the ciliary processes and is attached to the ciliary body by the zonular fibres (suspensory ligaments), which issue mainly from the pars plana. Collectively, the zonular fibres form the zonule that holds the lens in place and transmits the forces that stretch the lens.

The anterior convexity of the lens is less steep than that of the posterior surface. The central points of these surfaces are the anterior and posterior poles of the lens and a line connecting them is its axis. The marginal circumference of the lens is its equator.

The dimensions of the lens are optically and clinically important, and change with age as a consequence of continuous growth. Its equatorial diameter at birth is 6.5 mm, increasing rapidly at first, then more slowly to 9.0 mm at 15 years of age, and even more gradually to reach 9.5 mm in the ninth decade. Its axial dimension increases from 3.5–4.0 mm at birth to 4.75–5.0 mm at age 95. The lens flattens during the first decade of life (Mutti et al 1998). Average adult radii of the anterior and posterior surfaces of the lens are 10 mm and 6 mm, respectively. These reduce in later life, the anterior surface increasing most in curvature as the lens thickens, so that, in old age, the lens pushes the iris forwards slightly, predisposing the elderly eye to angle closure glaucoma.

The lens consists of three layers (**Fig. 45.17**). Its bulk is composed of elongated cells (lens fibres), which anteriorly, as far as the equator, are covered by a single layer of epithelial cells, and the whole is enclosed by the outer lens capsule. The lens is avascular and devoid of nerve fibres or other structures that might affect its transparency. Its surface forms a very effective barrier against invasion by cells or elements of the immune system, and so creates an immunologically sequestered environment. It is unique as it retains all the cells formed throughout its life.

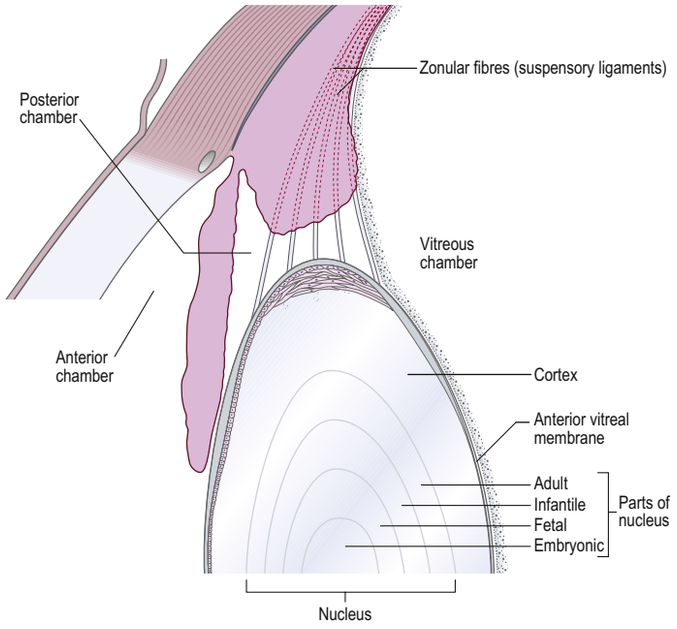

Fig. 45.16 A sagittal section through part of the lens and related structures. The cortex is distinguished from the nucleus, which is composed of embryonic, fetal, infantile and adult parts. The capsule is drawn in blue, exaggerated in thickness 100 times, and is based on observations from a 35-year-old.

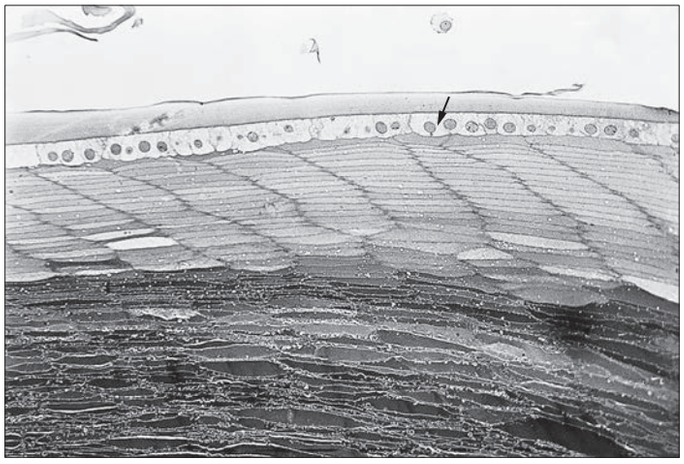

Fig. 45.17 A section through the anterior layers of the lens. The thin capsule covers the single row of epithelial cells (arrow), and the lens substance is composed of regularly stacked younger fibres and more densely stained and complex older deeper fibres.

Lens capsule

The lens capsule is a basement membrane that covers the surface of the lens. Although it is thick compared to most membranes, its molecular composition is similar to that of other, thinner, membranes, consisting of various classes of collagen as well as a range of glycosaminoglycans and glycoproteins (Danysh and Duncan 2009). Its thickness, and the fact it remains intact for decades after removal of the lens fibres, permits cataract removal and the implantation of intraocular lenses.

The capsule is derived from the anterior lens epithelial cells and their fetal precursors, and is firmly attached to the epithelium anteriorly and to lens fibres posteriorly. It is elastic, a property it owes mainly to the arrangement of its collagen, and which is central to the process of accommodation. Capsule thickness varies with position on the lens surface and age. One view is that, in adults, it is thicker at the anterior pole (11–15 μm) and equator (7.2 μm) than at the posterior pole (3.5 μm), with a band of increased thickness in the midperiphery between the anterior pole and equator (13.5–16 μm) and a lesser maximum between the posterior pole and the equator (4–9 μm) (see Fig. 45.16). While capsular thickness at the anterior pole and in the anterior midperiphery increases with age, thickness at the posterior pole and equator remains unchanged, while in the posterior midperiphery it decreases in older individuals

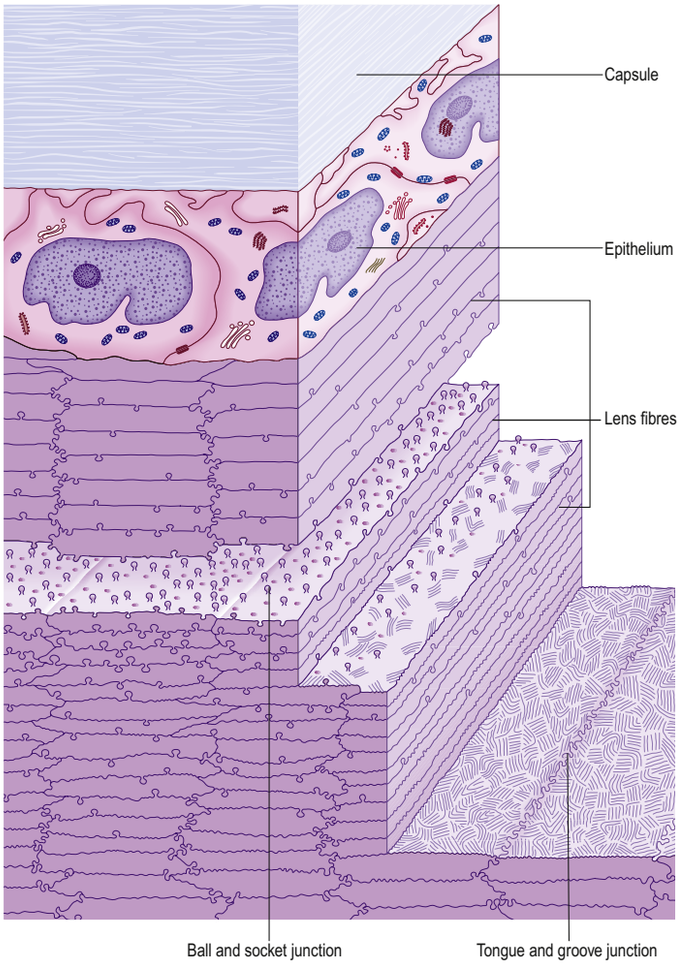

Fig. 45.18 The mechanical junctions between lens fibres. There are no junctions immediately below the epithelium. Ball and socket junctions develop in deeper layers; these are subsequently eliminated towards the nucleus, where tongue and groove junctions gradually form. Angle joints are present at most levels.

(Barraquer et al 2006). Zonular fibres, composed of thin (4–7 nm) fibrils with hollow centres resembling fibrils associated with elastic connective tissue, insert into the capsule near the equator.

Lens epithelium

The anterior surface of the lens between the outer capsule and the underlying lens fibres is covered by a layer of simple, roughly cuboidal (10 μm high and 13 μm wide), epithelial cells that, in surface view, are polygonal (see Fig. 45.17). These cells differentiate into lens fibres; they undergo mitosis at a germinative zone just anterior to the equator and are displaced towards the equator, where they synthesize characteristic lens fibre proteins and undergo extreme elongation. As other cells follow suit, the earlier cells come to occupy a deeper position within the lens stroma.

Lens fibres

The inwardly displaced epithelial cells elongate further in both an anterior and a posterior direction, becoming up to 12 mm long, depending on age and position in the lens. Fibres near the surface at the equator are nucleated; the nuclei form a short, S-shaped bow, which extends inwards from the surface. The deeper fibres lose their nuclei and most other organelles.

Variations in lens fibre structure and composition make it possible to distinguish a softer cortical zone, made up of younger fibres, and a firmer central part, representing the older nucleus. The nucleus can be further subdivided into layers representing the age at which the fibres within them were formed.

In cross-section, individual fibres are flattened hexagons measuring approximately 10 μm by 2 μm (see Fig. 45.16). They are tightly packed, and fibres are firmly attached to their neighbours by a variety of interlocking junctions (Fig. 45.18). Lens fibres are also in contact through desmosomes and numerous gap junctions.

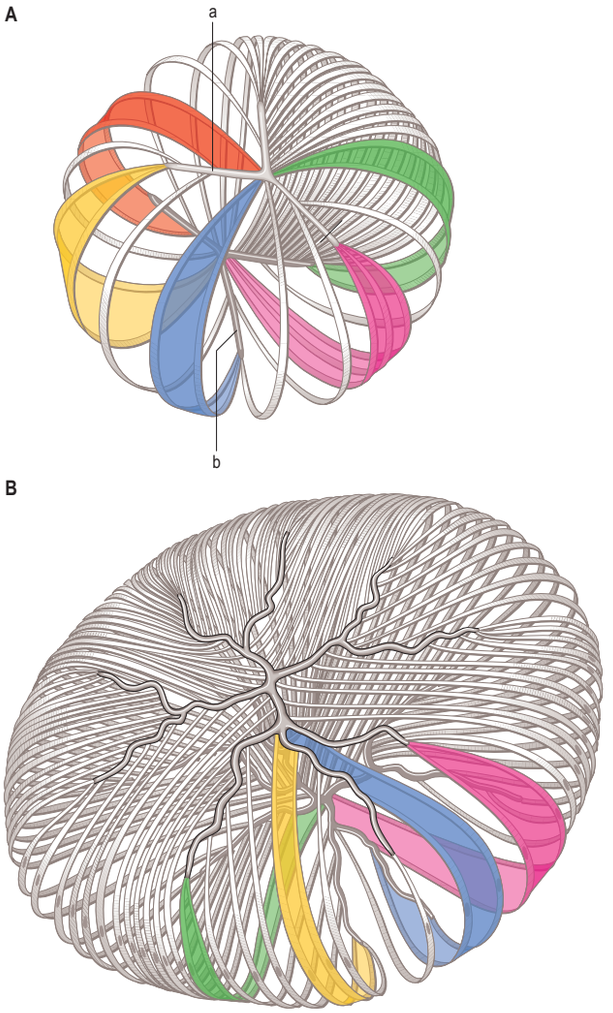

Fig. 45.19 The structure of the fetal (**A**) and adult (**B**) human lens, showing the major details of arrangement of the lens fibres. The anterior (a) and posterior (b) triradiate sutures are shown in the fetal lens. Fibres pass from the apex of an arm of one suture to the angle between two arms at the opposite pole, as shown in the coloured segments. Intermediate fibres show the same reciprocal behaviour. The suture pattern becomes much more complex as successive strata are added to the exterior of the growing lens, and the original arms of each triradiate suture show secondary and tertiary dichotomous branchings. (With permission from Hogan MJ, Alvarado JA, Weddell JE 1971 Histology of the Human Eye. Philadelphia: WB Saunders.)

All lens fibres cross a plane passing through the equator and terminate on both the anterior and posterior lens surfaces at 'sutures'. These radiate out from the poles towards the equator and represent lines of linearly registered, interlocking junctions between terminating lens fibres. In fetuses, the sutures on the anterior surface of the lens form a triradiate pattern centred on the anterior pole resembling the limbs of an upright letter Y (**Fig. 45.19A**). Posteriorly, the sutural configuration is similar but inverted. The sutures increase in number and complexity as a consequence of lens growth and other changes in the arrangement of lens fibres (**Fig. 45.19B**). Fibres that start near the central axis of the lens anteriorly terminate posteriorly on a suture near the periphery, and *vice versa*.

Lens fibres contain crystallins, proteins that are responsible for the transparency and refractile properties, and for much of the elasticity, of the lens. At least three varieties coexist – α, β and γ, their relative proportions changing throughout life. They have very high concentrations and form up to 60% of the lens fibre mass, giving these cells a higher protein content than any other bodily tissue. Variations in their concentration in different parts of the lens give rise to regional differences in refractive index, correcting for the spherical and chromatic aberrations which might otherwise be the case in a homogeneous lens.

Lens transparency is largely the result of the regular packing of crystallins within its fibres, as well as the avascularity of the lens and the absence of fibre organelles. Apart from transmitting the visible spectrum, the lens also serves to prevent potentially damaging UVA radiation from reaching the retina using a variety of chromophores such as various kynurenine derivatives. Shorter wavelengths (UVB) are removed by the cornea. At birth, the lens is colourless and transmits all wavelengths from the infra-red to the near-ultraviolet well. However, throughout life, due largely to post-translational modification of its proteins, the amount of short wavelength radiation transmitted diminishes until, in old age, the lens takes on an amber tinge as it absorbs visible radiation too, decreasing blue sensitivity in older people. In cataract, these changes are more pronounced. Lens fluorescence also increases with age, reducing contrast of the retinal image (Zelentsova et al 2017).

Ocular refraction

Refraction takes place when light is obliquely incident on the interface between media of different refractive indices. Approximately two-thirds (40 dioptres) of the total refractive power of the unaccommodated eye is effected by the tear film covering the curved cornea, as its refractive index is similar to that of water (1.333), while that of air is close to unity. The remaining approximately 20 dioptres of the eye's power is the result of refraction by the lens, whose refractive index varies from 1.386 at its periphery to 1.406 at its core, which is higher than that of the surrounding media. The main value of the lens is its ability to vary its dioptric power during the process of accommodation, allowing an increase in refraction of 12 dioptres when viewing close objects in the young. This decreases with age, being halved at 40 years and reduced to one dioptre or less at 60 years (presbyopia).

Disorders of refraction

An unaccommodated eye is said to be emmetropic when the refracting structures are so related to its length that the retina receives a focused image of a distant object. Although the majority of eyes are emmetropic, a large, and increasing, minority have errors of refraction (ametropia) that can take three different forms. In myopia, the eye is too long for its refractive power and distant objects are focused in front of the retina when relaxed; closer objects will be in focus and, consequently, the eye is said to be 'short-sighted'. Conversely, in hyperopia (long sight), the eye is too short for its refractive power and, when it is relaxed, distant objects are focused behind the retina. In astigmatism, the refractive power of the eye is not the same in different meridians, which are approximately 90° apart in regular astigmatism.

Normally, emmetropia is assured during development both by the active control of the sclera's biomechanical and biochemical properties and changes in the optical features of the eye's refractive elements, a process known as emmetropization (Wallman and Winawer 2004). A resting focal plane behind the retina results in scleral growth causing axial elongation of the globe until the focused image and the position of the retina are coincident. On the other hand, light focused in front of the retina retards scleral growth, reducing axial length. In ametropia, this process fails.

The causes of refractive errors such as myopia are both genetic and environmental. Not only have several candidate genes been identified, but also factors such as increased near work and lack of outdoor activity have all been linked to myopia (Wallman and Winawer 2004, Flitcroft 2013). This has led to a recent increase in the incidence of myopia to epidemic proportions, with a prevalence of over 80% in the adult population of some East Asian cities (Rose et al 2008). Fortunately, errors of refraction are amenable to correction using spectacle or contact lenses and by various forms of refractive surgery.

As noted above, the ability to change the power of the lens through accommodation diminishes during the fifth decade to an extent that neither the corrected ametrope nor the emmetrope is able to focus near objects clearly, and reading spectacles become necessary. Many factors could potentially result in such loss of accommodation, but it seems likely that the main cause is the continued growth of the lens, rather than a reduced ability of the ciliary muscle to contract (Strenk et al 2005). This is offset to a very limited extent by the reduction of the pupil aperture with age, which increases the depth of focus but at the cost of creating the further problem of requiring greater illumination.

Other errors of refraction are the concomitants of eye disease, especially those that affect the cornea. Corneal curvature, for example, may be sufficiently altered as a residual defect of past disease to cause irregular astigmatism. In keratoconus, the cornea is thinned and steepened centrally, distorting the refracting surface. A dislocated lens, caused, for example, by Marfan syndrome, also disrupts the refractive status of the eye.

Vitreous humour

The vitreous humour occupies about four-fifths of the eyeball. Posteriorly, it is in contact with the retina, while further forwards it abuts the ciliary

body, zonular fibres and lens. Its anterior surface is hollowed into a deep concavity, the hyaloid fossa, fitting the shape of the lens (see Fig. 45.1). It is colourless, consisting of approximately 99% water, but is not entirely structureless. At its perimeter (cortex), it has a gel-like consistency (100–300 µm thick); nearer the centre, it contains a more liquid zone. Hyaluronan, in the form of long glycosaminoglycan chains, fills the whole vitreous. In addition, the vitreous contains a random loose network of type II collagen fibrils, which are densest in the cortex and occasionally grouped into fibres. The cortex also contains scattered cells, hyalocytes, which possess the characteristics of mononuclear phagocytes and may contribute to the production of hyaluronan. Normally in a resting state, they can be actively phagocytic in inflammatory conditions. Hyalocytes are not present in the cortex bordering the lens.

The liquid vitreous is absent at birth, appears first at 4 or 5 years, and increases to occupy half the vitreous space by the seventh decade. Vitreous liquefaction results in an increased incidence of posterior vitreous detachment and associated floaters in the elderly. The cortex is most dense at the pars plana of the ciliary body adjacent to the ora serrata, where attachment is strongest, and this is often referred to as the vitreous base. Elsewhere, the vitreous also has a firm (peripapillary) attachment at the edge of the optic disc. The adherence of the vitreous to the retina can result in traction on the retina if the vitreous shrinks, such as happens in old age, producing macular holes or peripheral breaks, possibly leading to retinal detachment.

A narrow hyaloid canal runs from the optic nerve head to the central posterior surface of the lens (see Fig. 45.1). In the fetus, this contains the hyaloid artery, which normally disappears about 6 weeks before birth. The canal persists in adult life as a very delicate fibrous structure and is of no functional importance.

RETINA

The retina is a sheet of cells, ranging in thickness from less than 100 µm at its edge to a maximum of around 300 µm at the foveal rim. It lines the inner posterior surface of the eyeball, sandwiched between the choroid externally and the vitreous humour internally, and terminates anteriorly at the ora serrata: it covers around 70% of the inner surface area of the globe (see Fig. 45.1).

When viewed with an ophthalmoscope to show the fundus oculi, the most prominent feature is the blood vessels emanating from and entering the optic disc (**Fig. 45.20A**).The 'central retina' or macula (diameter 5–6 mm) is centred temporal and inferior to the disc. The middle of the macula, the fovea and foveola, is easily identified with an ophthalmoscope as an avascular area with a yellow tinge (see Fig. 45.20A). The lack of blood vessels at the foveola is even more apparent in a fluorescein angiogram (**Fig. 45.20B**). The peripheral retina lies outside the macula.

Microstructure

The retina is composed of a variety of epithelial, neural and glial cell types. When seen in transverse section, their distribution is conventionally described in 10 layers (**Fig. 45.21**). These layers are evident in histological sections (**Fig. 45.22**), but can also be seen *in vivo* using optical coherence tomography (**Fig. 45.23**). Embryologically, the retina is derived from the two layers of the invaginated optic vesicle (Ch. 15). Nine layers develop from the inner layer of the optic vesicle and form the neural retina. The outermost layer becomes a stratum of cuboidal pigment cells, the retinal pigment epithelium (layer 1), that separates the choroid from the neural retina.

The outermost layer of the neural retina contains the light-sensitive parts of the photoreceptors, which convert the optical image into neural activity. From the photoreceptors, neural activity flows radially to bipolar and ganglion cells, and laterally via horizontal cells in the outer retina and amacrine cells in the inner retina. Photoreceptors synaptically contact each other and bipolar and horizontal cells in the outer plexiform layer (layer 5), while bipolar, amacrine and ganglion cells synapse in the inner plexiform layer (layer 7). The axons of ganglion cells run towards the optic disc in the nerve fibre layer (layer 9), where they leave the retina as the optic nerve, which transmits the retinal output to the visual areas of the brain where visual processing is completed. Although most neural activity flows from the photoreceptors towards the brain, some information flow takes place in the opposite direction via centripetal fibres in the optic nerve and interplexiform cells in the retina that connect the inner and outer plexiform layers.

The classic 10-layered appearance of the retina is absent in the optic nerve head, the fovea and foveola, and the ora serrata. At the optic nerve head, the axons of the retinal ganglion cells leave the retina to form the optic nerve and all the other neural cell types are missing. At the fovea and foveola, the inner five layers of the retina are 'pushed aside'. At the ora serrata, where the retina borders the ciliary body (see Fig. 45.10), the retinal pigment epithelium merges with the outer pigmented epithelium of the ciliary body, while the neural retina borders the inner unpigmented ciliary epithelium; the retina is thinnest at this point. The normal layered arrangement of the neural retina approaching the ora serrata is frequently

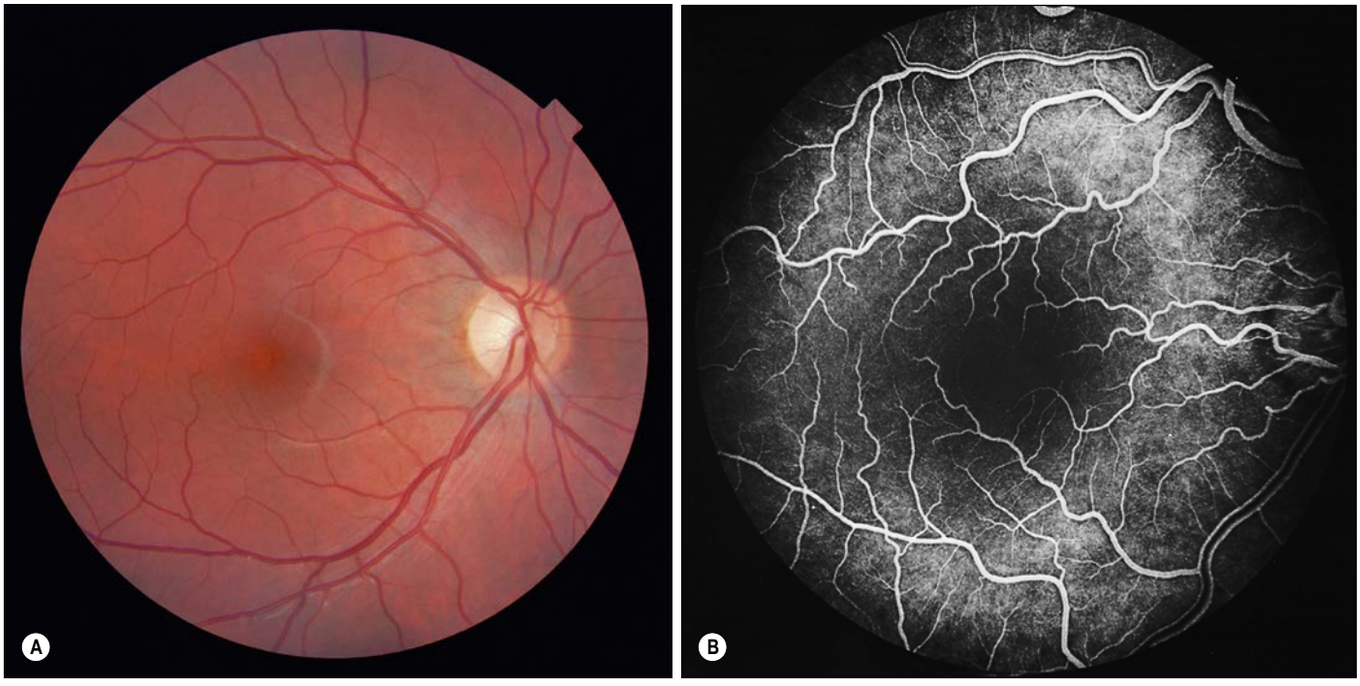

Fig. 45.20 A, A fundus photograph of the right eye of a 19-year-old Caucasian female. The central retinal vessels are seen emanating from the optic disc. Retinal arteries are narrower and lighter in colour, and generally are vitreal to the veins. The avascular centre of the macular region, with its associated macular pigment, can be seen temporal to the disc. **B**, A fluorescein angiogram showing the macular region of a right eye. The main macular vessels are approaching from the right. The elderly subject has considerable macular pigmentation that masks fluorescence from the choroidal circulation.

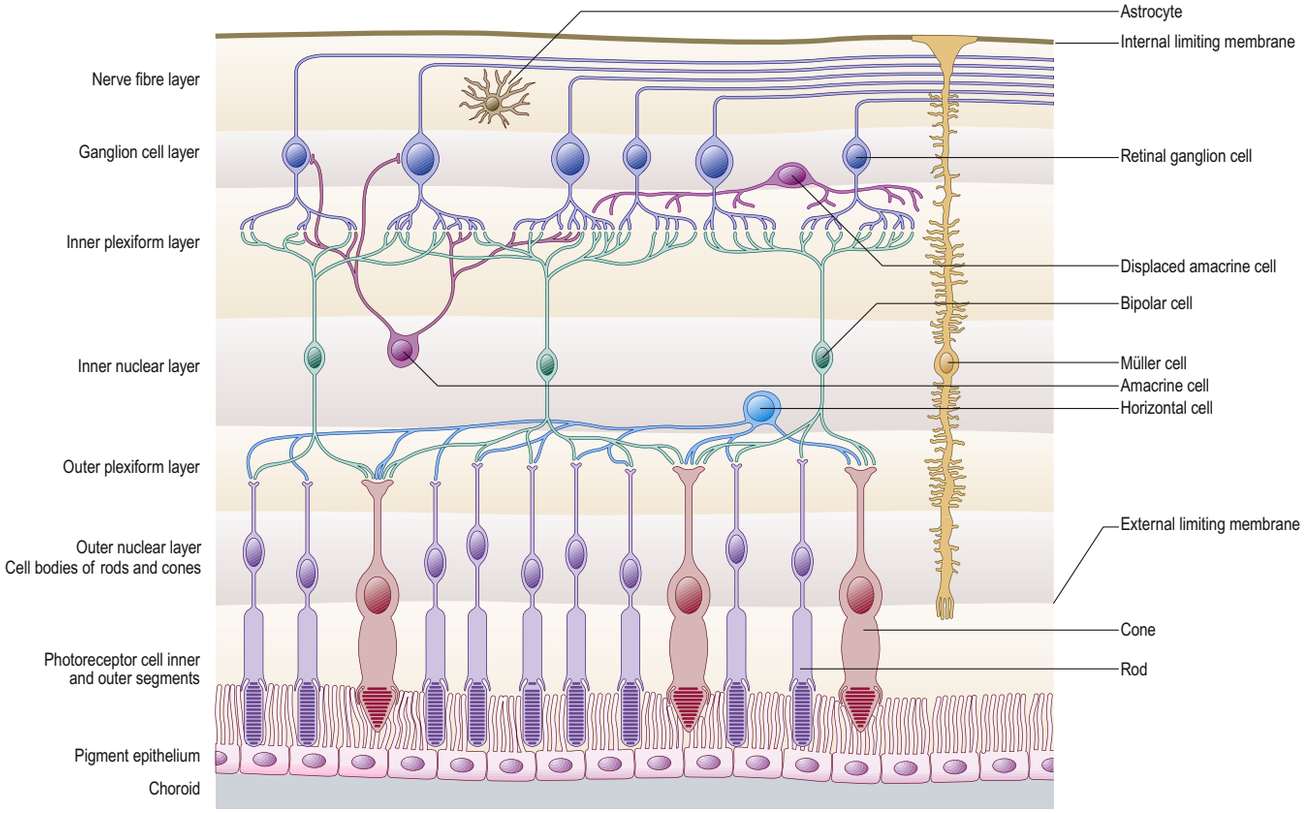

Fig. 45.21 Neural cells whose cell bodies and interconnections account for the layered appearance of the retina in histological section (compare with Fig. 45.22). Also shown are the two principal types of neuroglial cell in the retina (although microglia are also present, they are not shown).

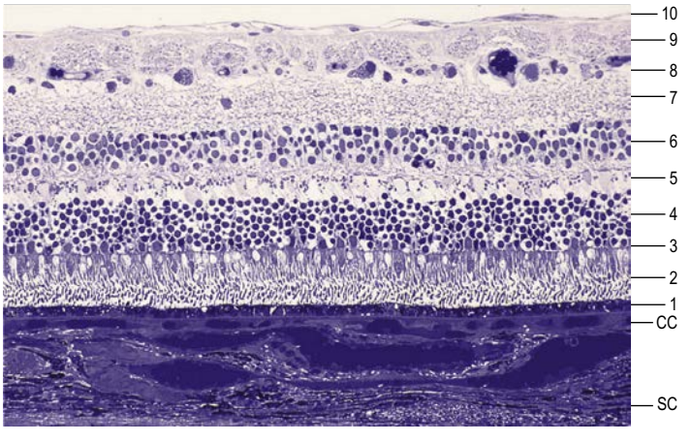

Fig. 45.22 A transverse section of the retina and choroid. The 10 layers of the retina are shown. Key: 1, pigment epithelial layer; 2, rod and cone layer; 3, external limiting membrane; 4, outer nuclear layer; 5, outer plexiform layer; 6, inner nuclear layer; 7, inner plexiform layer; 8, ganglion cell layer; 9, nerve fibre layer; 10, internal limiting membrane. Abbreviations: CC, choriocapillaris; SC, suprachoroid.

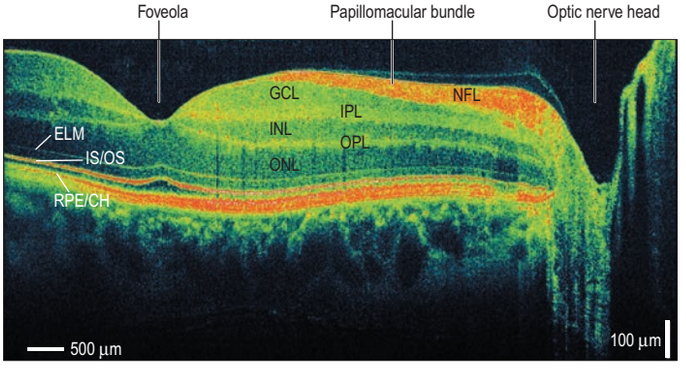

Fig. 45.23 A high-definition optical coherence tomography (OCT) *in vivo* image of the human retina. The image has approximately 2 µm axial resolution, is 8 mm long and consists of 10,000 axial scans. The image is expanded in the vertical direction to permit better visualization of retinal layers. Abbreviations: ELM, external limiting membrane; GCL, ganglion cell layer; INL, inner nuclear layer; IPL, inner plexiform layer; IS/OS, boundary between the photoreceptor inner and outer segments; NFL, nerve fibre layer; ONL, outer nuclear layer; OPL, outer plexiform layer; RPE/CH, retinal pigment epithelium and choriocapillaris. (Courtesy of Professor James Fujimoto, Department of Electrical Engineering and Computer Science, MIT, Boston, USA.)

disrupted by cysts in older individuals (Fig. 45.24). Insufficiency in the vascular supply from the choriocapillaris leads to localized ovoid areas of outer retinal atrophy, known as paving stone (cobblestone) degeneration in the peripheral retina: the condition occurs in about one-third of adults, especially older individuals or those with increased axial length.

Cells of the retina

Retinal pigment epithelium

In the central retina the retinal pigment epithelium is composed of approximately cuboidal cells (12 µm height × 14 µm diameter) that become flatter and wider (60 µm) in the periphery. They form a single continuous layer that extends from the periphery of the optic disc to the ora serrata. The cells are flat in radial section, hexagonal or pentagonal in surface view, and number 4–6 million. Their cytoplasm, especially the apical portion, contains numerous melanosomes. The basal surface contains many small invaginations that increase the surface area for exchange of substances with the choriocapillaris. Apically, the cells bear longer (5–7 µm), heavily pigmented, microvilli that contact, or project between, the outer segments of the photoreceptors. The tips of rod outer segments are more deeply inserted into these invaginations than those of cones. The different embryological origins of the retinal pigment epithelium and neural retina mean that the attachments between these two layers are unsupported by junctional complexes; the neural retina and retinal pigment epithelium are therefore easily parted (retinal detachment).

Retinal pigment epithelium cells play a major role in the turnover of rod and cone photoreceptive components. Their cytoplasm contains the phagocytosed tips of rods and cones undergoing lysosomal

destruction. The final products of this process are lipofuscin granules. Disturbances in this phagocytic activity of the retinal pigment epithelium can lead to retinal disease (Kevany and Palczewski 2010).

Light reaching the outer retina but missing the photoreceptors is absorbed by the retinal pigment epithelium, which, like melanin elsewhere in the eye, prevents such stray light degrading image quality. A zone of tight junctions between adjacent cells also allows the epithelium to function as a blood–retinal barrier between the neural retina and the vascular system of the choroid. The retinal pigment epithelium is required for the regeneration of bleached visual pigment and may have antioxidant properties. It also secretes a variety of growth factors necessary for the integrity of the choriocapillaris endothelium and the photoreceptors and produces a number of immunosuppressive factors. A failure of any of the diverse functions of the retinal pigment epithelium could result in compromised retinal function (Strauss 2005).

The cells of the retinal pigment epithelium undergo several age-related morphological changes, many of which precede the onset of age-related macular degeneration (Boulton and Dayhaw-Baker 2001). In addition to various pleomorphic changes, lipofuscin granules accumulate with age, while the density of melanin granules decreases: the fundus therefore appears darker in the young. Retinal pigment epithelial cells are amitotic: an overall decrease in cell density with age has often been reported, although this is not a universal observation.

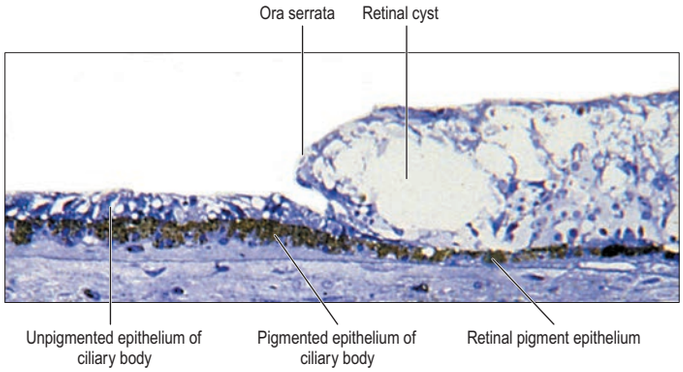

Fig. 45.24 The junction between the retina and ciliary body (ora serrata). The retinal pigment epithelium is continuous with the outer, pigmented epithelium of the ciliary body, while the neural retina abuts the inner, unpigmented epithelium of the ciliary body. The layered appearance that is apparent elsewhere in the neural retina is disrupted adjacent to the ora serrata by cystic degeneration.

Rods and cones

Rods and cones are the 'image-forming' photoreceptors of the outer retina and function at low (scotopic) and higher (photopic) light levels, respectively. Both are long, radially orientated structures with a similar organization, although details differ (Fig. 45.25). From the choroidal end inwards, the cells consist of outer and inner segments connected by a thin connecting cilium (together making up layer 2 of the retina), a cell body containing the nucleus, and a synaptic terminal (either a more complex pedicle for cones or a simpler rod spherule) where they

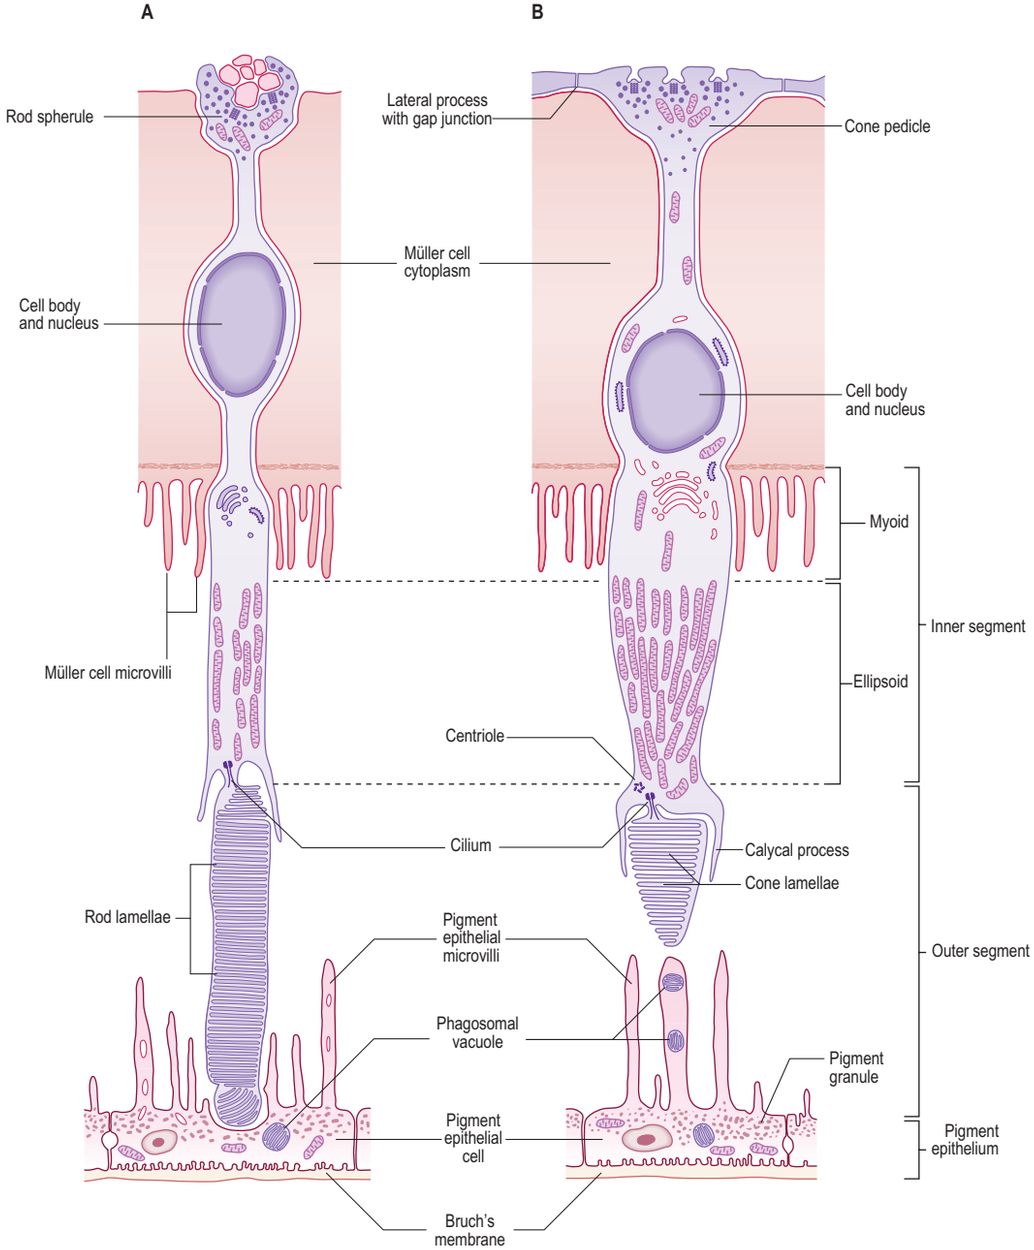

Fig. 45.25 The major features of a retinal rod cell (**A**) and a retinal cone cell (**B**). The relative size of the pigment epithelial cells has been exaggerated for illustrative purposes.

make synaptic connections with adjacent bipolar and horizontal cells and with other cone or rod cells within the outer plexiform layer.

The nuclei of the rods and cones form the outer nuclear layer (layer 4). The cone nuclei are relatively large and oval, and generally form a single layer that often penetrates the external limiting membrane (layer 3). They also contain less heterochromatin than those of rods and thus usually stain more lightly. Rod nuclei are round and smaller, stain more darkly, and form several layers vitreal to the cone nuclei.

The external limiting membrane is not, in fact, a membrane at all, although it appears as such in the light microscope; rather, it is a series of zonulae adherentes between photoreceptors and the glial (Müller) cells that separate them. These junctions most likely serve to anchor the photoreceptors and prevent leakage of the interphotoreceptor matrix that surrounds the photoreceptor outer and inner segments.

Rod outer segments are cylindrical and consist of around 1000 flattened, lobulated, membranous discs. These form as deep infoldings of the plasma membrane at the base of the outer segment; they 'bud off' after formation so that the discs are not attached to the plasma membrane and are free-floating within the outer segment. Cone outer segments are generally shorter and, as their name implies, often conical (especially in the peripheral retina). Cone discs do not bud off after formation and remain as infoldings of the plasma membrane.

The inner segment of both rods and cones is divided into an outer, mitochondria-rich, ellipsoid and an inner myoid that contains endoplasmic reticulum. In most of the retina, these inner segments are much wider in cones (5–6 µm at their widest point) than rods (1.5 µm) (**Fig. 45.26**). In both rods and cones, proteins are manufactured within the myoid and incorporated into the newly formed discs at the base of the outer segment. In rods, as new discs are added, old discs are pushed up the outer segment and eventually phagocytosed by the retinal pigment epithelium. Cone discs are also phagocytosed but the incorporation of new proteins within the discs is more diffuse (Nguyen-Legros and Hicks 2000). While all rods within the retina have a similar structure, the cones at the foveola are highly modified compared to those situated more peripherally and, in many ways, resemble rods with a longer outer segment and a thinner inner segment.

Light is absorbed by rhodopsins, visual pigments consisting of a protein, opsin, that spans the membrane of the outer segment discs, bound to a light-absorbing chromophore, retinal, which is an aldehyde of vitamin A_1. Such rhodopsins have a smooth, bell-shaped absorption profile with a point of maximum absorbance (λ_{max}), indicating the wavelength at which they are most sensitive. Humans possess four different opsins, resulting in four spectrally distinct visual pigments: one located within the rods (λ_{max} 498 nm) and three within different populations of cones absorbing maximally at the short (λ_{max} 420 nm), middle (λ_{max} 534 nm) and longer (λ_{max} 563 nm) wavelength end of the visible spectrum.

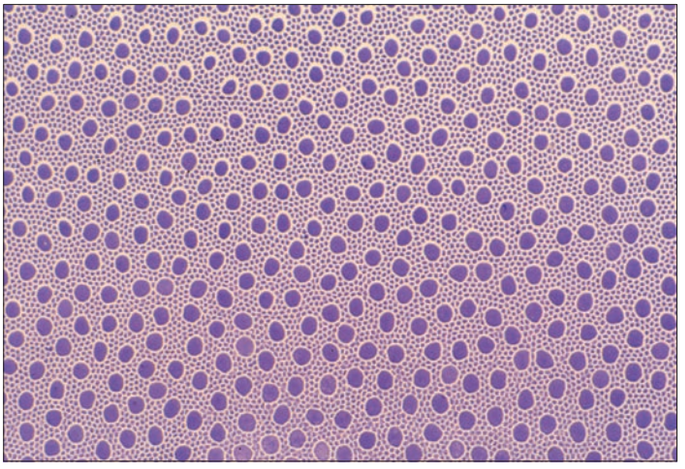

Fig. 45.26 Tangential section of a human retina in the parafovea cut at the level of the inner/outer segments, showing the 'mosaic' of both the larger cones and the more numerous, but smaller, rods. Photoreceptors at the top of the image are sectioned at a level closer to the retinal pigment epithelium than receptors lower in the figure. The reduction in size of the cones at the top of the figure is explained by the conical shape of their outer segment. If the figure were continued upwards, representing sections closer to the retinal pigment epithelium, the size of the cones would continue to decrease and the amount of surrounding white space would increase. Rod outer segment diameter, however, would change little.

The three cone classes are sometimes referred to as the blue, green and red cones but are better classed as S, M and L cones. The action of light is to isomerize the retinal, separating it from the opsin, a process which, via a G-protein coupled enzyme cascade and a second messenger system, results in the closure of cation channels in the receptor outer segment membrane, leading to a hyperpolarization of the photoreceptor, and a consequent decrease in the release of glutamate from its synapses.

The human retina contains, on average, 4.6 million cones and 92 million rods, although there is significant inter-individual variation (Curcio et al 1990). The number of central rods declines by about 30% with age, whereas the number of foveal cones remains stable (Curcio et al 1993). Although cones populate the whole retina, their density is highest in the foveola, where approximately 7000 cones reach an average density equivalent to 199,000 cones/mm^2; this area is entirely rod-free. Going outwards from the foveola, rod numbers rise, reaching a peak density (>150,000 rods/mm^2) in a horizontal elliptical ring at an eccentricity of 2–5 mm, thereafter declining once more towards the periphery. Cone density is 40–45% higher in the nasal retina compared to the temporal retina, and slightly higher inferiorly than superiorly.

The number of S cones in all human retinae is similar, making up less than 10% of all cones (Curcio et al 1991, Hofer et al 2005). The distribution of S cones is relatively even throughout the retina, although they are absent from the central fovea. The relative proportions of L and M cones shows a much greater degree of variation between individuals, the L:M cone ratio varies from close to unity to over 10. The distribution of L and M cones is more irregular than that of S cones and appears random with some indication of clumping (Bowmaker et al 2003, Hofer et al 2005).

The high packing density of cones at the foveola, achieved by decreasing inner segment diameter, ensures maximal resolution, while the presence of more than one spectral cone type allows colour vision. S cones probably contribute little to spatial resolution because they are absent from the foveola. Rod-based vision provides high sensitivity, but with relatively low spatial discrimination and no ability to distinguish wavelengths. Although many of the functional differences between rods and cones rely on the different properties of the photoreceptors themselves, their connectivity to other retinal neurones is equally important.

Horizontal cells

Horizontal cells are inhibitory interneurones. Their dendrites and axons extend laterally within the outer plexiform layer, making synaptic contacts with cone pedicles and rod spherules, and, via gap junctions at the tips of their dendrites, with each other. Their cell bodies lie in the outer part of the inner nuclear layer (layer 6). Three morphological types of horizontal cell can be distinguished in the human retina (Kolb et al 1992). The dendrites of HI and HIII cells contact cones, and their axons terminate on rods. Both the axons and dendrites of HII cells synapse only with cones.

Bipolar cells

Bipolar cells are radially orientated neurones. Their dendrites synapse on photoreceptors, horizontal cells and interplexiform cells in the outer plexiform layer. Their somata are located in the inner nuclear layer, and axonal branches in the inner plexiform layer synapse with dendrites of ganglion cells or amacrine cells. Golgi staining has identified nine distinct types of bipolar cell in the human retina (Kolb et al 1992), eight of which contact cones exclusively, and the remaining type synapses only on rods.

Cone bipolars are of three major morphological types: midget, S (blue) cone and diffuse, according to their connectivity and size. Midget cone bipolar cells either invaginate the cone pedicle or synapse on its base (flat subtype). In the central retina, each midget bipolar cell contacts only a single cone (2–3 in the periphery), forming part of a one-to-one channel from cone to ganglion cell that mediates high spatial resolution. S cones form part of a short-wavelength mediating channel, while the larger diffuse cone bipolars are connected to up to 10 cones and are thought to signal luminosity rather than colour.

Cone bipolar cells can also be of two physiological types, according to their response to the light-induced decrease in glutamate release from the photoreceptors to which they are synaptically connected. If illumination of the photoreceptors with a point of light causes a depolarization of the connected bipolar cell, it is said to be an 'ON' bipolar, contacting the cone by 'sign-inverting' synapses with metabotropic receptors. However, if cones are connected to an 'OFF' bipolar cell via 'sign-conserving' synapses with ionotropic receptors, illumination of the photoreceptor will result in hyperpolarization of the bipolar cell. Illumination of a concentric area of surrounding photoreceptors causes the opposite response in bipolar cells to illumination within their dendritic field. This inhibition is mediated via horizontal cells and gives rise to the

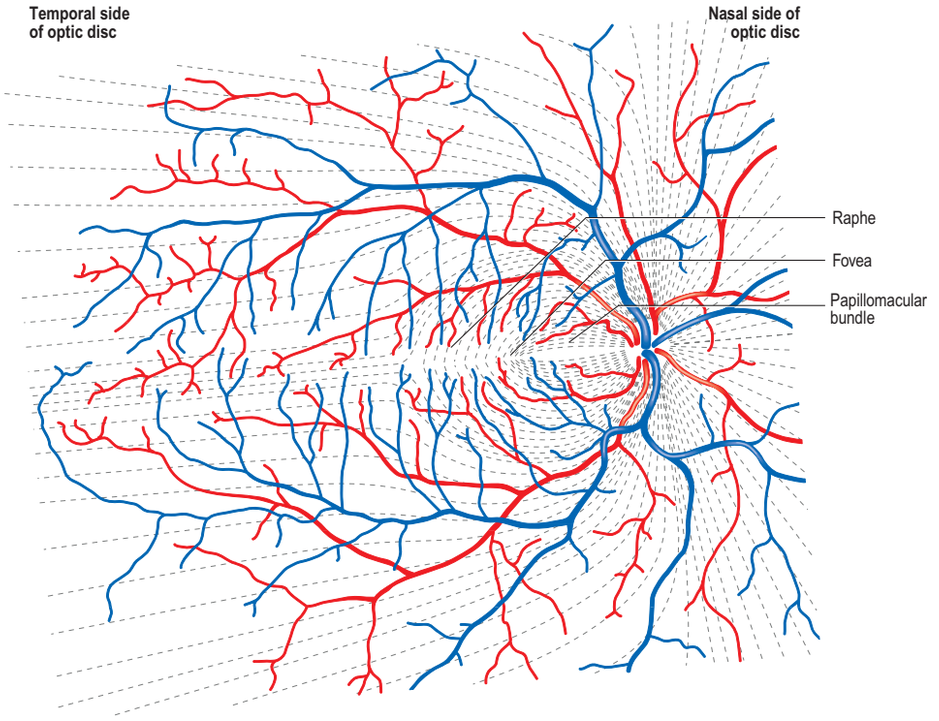

Fig. 45.27 Directions of axons (dashed lines) and blood vessels of the nerve fibre layer of the retina of the right eye. Axons pass radially on the nasal side of the optic disc, whereas fibres on the temporal side avoid crossing the fovea by arching around it. Some of the fibres from the fovea and central region pass straight to the optic disc and others arch above and below the horizontal; together, these form the papillomacular bundle. A raphe is formed by the central fibres temporal to the fovea. Venules are shown crossing in front of arteries; the reverse relationship is probably the more common pattern. All vessels issue from the disc on the right of the figure; the larger temporal branches tend to arch around the central region of the retina and do not approach the fovea. The peripheral retina and most of the nasal retina are not shown.

antagonistic centre-surround type receptive field that is characteristic of all levels of the visual system up to and including the occipital cortex.

The single morphological type of rod bipolar cell contacts 30–35 rods in the central retina, increasing to 40–45 rods in the periphery. Such convergence serves to increase the absolute sensitivity of the rod system. All rod bipolar cells are 'ON-centre' and do not contact ganglion cells directly, but synapse with a class of amacrine cell (AII), which then contacts cone bipolar cells.

The inner plexiform layer can be divided into two main layers: an outer layer containing the synaptic endings of 'OFF' cone bipolar cells, and an inner layer of 'ON' cone and rod bipolar cell synapses.

Amacrine cells

Most amacrine cells lack typical axons and, consequently, their dendrites make both incoming and outgoing synapses. Each neurone has a cell body either in the inner nuclear layer near its boundary with the inner plexiform layer, or on the outer aspect of the ganglion cell layer, when it is known as a displaced amacrine cell. The processes of amacrine cells make a variety of synaptic contacts in the inner plexiform layer with bipolar and ganglion cells, as well as with other amacrine cells.

The various classes of amacrine cell serve a number of important functions. AII cells play an essential role in the rod pathway (see above). Other cells appear to be important modulators of photoreceptive signals and serve to adjust or maintain relative colour and luminosity inputs under changing light conditions. They are probably also responsible for some of the complex forms of image analysis known to take place within the retina, such as directional movement detection. Up to 24 different morphological types of amacrine cell are recognized in humans (Kolb et al 1992); coupled to their neurochemical complexity, this makes them perhaps the most diverse neural cell type in the body.

Interplexiform cells

Interplexiform cells, often regarded as a subclass of amacrine cells, generally have cell bodies in the inner nuclear layer. They are postsynaptic to cells in the inner retina and send signals against the general direction of information flow in the retina, synapsing with bipolar, horizontal and photoreceptor cells in the outer plexiform layer. Although their function is uncertain, it is likely that, through the release of γ-aminobutyric acid (GABA) and dopamine, they adjust some aspect of retinal function such as sensitivity.

Ganglion cells

The human retina contains 0.7–1.5 million ganglion cells, the output neurones of the retina (Curcio and Allen 1990). Their number declines with age, in glaucoma, and possibly other conditions such as Alzheimer's disease.

Ganglion cell dendrites synapse with processes of bipolar and amacrine cells in the inner plexiform layer. Ganglion cell bodies, together with displaced amacrine cells, form the ganglion cell layer of the retina (layer 8). They form a single layer throughout most of the retina, but become progressively more numerous near the macula, where they are ranked in up to 10 rows, reaching a peak density of up to 38,000/mm^2 in a horizontally orientated elliptical ring 0.4–2.0 mm from the foveal centre. Their number diminishes again towards the fovea, from which they are almost totally excluded.

Up to 15 ganglion cell types have been identified in the mammalian retina based on their morphology, physiology and target area in the brain; each type is presumed to be functionally distinct. For example, some project to different regions of the lateral geniculate nucleus and form three parallel visual pathways involved in conscious visual perception: the magnocellular and parvocellular systems and a pathway carrying the S cone signal (Wässle 2004). Midget ganglion cells (P cells) contact only single midget bipolar cells in the central retina, which, in turn, connect to single cones, giving each cone a 'private line' out of the retina and ensuring optimal acuity. The large dendritic field of parasol cells (M cells) is consistent with a role in motion detection. Parasol and midget ganglion cells together make up around 80% of human retinal ganglion cells. The remaining cells (approximately 200,000) project to the superior colliculus of the midbrain, the thalamic pulvinar, the pretectum and the accessory optic system, and contribute to various subconscious visual reflexes such as the pupillary and accommodation responses (see Fig. 45.12). A population of around 3000 large, intrinsically light-sensitive ganglion cells, containing the retinal-based visual pigment melanopsin (λ_{max} 479 nm), form a network of extensive overlapping dendrites (Dacey et al 2005). These 'inner retinal photoreceptors' also receive input from the rods and cones and provide a 'non-image forming' system that monitors overall levels of illumination. They are the major route by which the eye influences circadian rhythms via the suprachiasmatic nucleus and they contribute to light-evoked pupillary constriction via projections to the olivary pretectal nucleus. Axons of some of these photosensitive ganglion cells project to the lateral geniculate nucleus, where they are thought to provide the visual system with information relating to brightness, for example contributing to light adaptation and contrast sensitivity.

Ganglion cell axons form the nerve fibre layer on the inner surface of the retina. They run parallel to the surface of the retina, converging on the optic nerve head where they leave the eye as the optic nerve. Fibres from the medial (nasal) retina approach the disc in a simple radial pattern (**Fig. 45.27**), whereas axons from the lateral (temporal) retina take an arcuate route as they avoid the fovea. Axons from the macula form a papillomacular fasciculus that passes almost straight to the disc. The thickness of the nerve fibre layer increases dramatically near the optic disc as fibres from the peripheral retina traverse more central areas. The other retinal layers thin towards the edge of the disc; all neural elements of the retina other than ganglion cell axons are excluded at the disc.

Axons of retinal ganglion cells are surrounded by the processes of radial glial cells and retinal astrocytes. They are almost always unmyelinated within the retina; an optical advantage because myelin is refractile. Although a few small axons may be myelinated, in general myelination does not start until axons enter the optic disc and become part of the optic nerve.

Retinal glial cells

There are three types of retinal glial cells: radial Müller cells, astrocytes and microglia. Müller cells form the predominant glial element of the retina. Astrocytes are largely confined to the ganglion cell and nerve fibre layers. Small numbers of microglial cells are scattered throughout the neural part of the retina.

Müller cells span almost the entire thickness of the neural retina, ensheathing and separating the various neural cells except at synaptic sites. They constitute much of the total retinal volume, and almost totally fill the space between neural elements. Their nuclei lie within the inner nuclear layer; from this region each cell body extends a single thick fibre that runs radially outwards, giving off complex lateral lamellae that branch among the processes of the outer plexiform layer. Apically, each central process terminates at the external limiting membrane, from which microvilli project for a short distance into the space between the rod and cone inner segments (fibre baskets) (see Fig. 45.25). On the inner surface of the retina, the main Müller cell process expands into a terminal foot plate that contacts those of neighbouring glial cells and forms part of the internal limiting membrane (see below).

Müller cells have numerous functions (Reichenbach and Bringmann 2013). Like astrocytes, they contact blood vessels, especially capillaries of the inner nuclear layer; their basal laminae fuse with those of perivascular cells or vascular endothelia, contributing to the formation of the blood–retinal barrier. They maintain the stability of the retinal extracellular environment, for example by regulation of potassium levels, uptake of neurotransmitter, removal of debris, storage of glycogen, provision of neuroprotective support to the photoreceptors and mechanical support to the whole neural retina. They are also involved in the regeneration of cone visual pigments; some may be a source of stem cells; and they may act as light guides, conveying light from the inner retina to the photoreceptors, overcoming some of the optical disadvantages of an 'inverted' retina.

The cell bodies of retinal astrocytes lie within the nerve fibre layer and their processes branch to form sheaths around ganglion cell axons. The close association between astrocytes and blood vessels in the inner retina suggests that they contribute to the blood–retinal barrier. Retinal microglia are scattered mostly within the inner plexiform layer. Their radiating branched processes spread mainly parallel to the retinal plane, giving them a star-like appearance when viewed microscopically from the surface of the retina. They can act as phagocytes; their number increases in the injured retina.

The inner border of the retina is formed by the internal limiting membrane (layer 10), which consists of collagen fibres and proteoglycans from the vitreous, a basement membrane (which is continuous with the basal lamina of the ciliary epithelium), and the plasma membrane of expanded Müller cell terminal foot plates. It is 0.5–2 µm thick in the posterior retina and thickens with age. The internal limiting membrane is involved in fluid exchange between the vitreous and the retina, and, perhaps through the latter, with the choroid. Its other functions include anchorage of retinal glial cells, and inhibition of cell migration into the vitreous humour.

Modifications of the central retina

The central retina, or area centralis, clinically referred to as the macula, constitutes around 3% of the retinal surface area. It is composed of four concentric areas: starting with the innermost, these are the foveola (0.35 mm diameter, equivalent of an angular subtense at the nodal point of around 1.25°); the fovea (1.5 mm, 5.2°); the parafovea (2.5 mm, 8.6°); and the loosely defined perifovea (5–6 mm, 20°). The foveola, which contains no rods or S cones, is centred about 3 mm temporal and 1 mm inferior to the optic disc (see Fig. 45.20A). In the foveola and surrounding fovea, all the inner retinal layers beyond the outer nuclear layer have been displaced peripherally, so that the retina is approximately half as thick as it is elsewhere (see Fig. 45.23; **Fig. 45.28**). This foveal pit is created by the processes that connect foveal and foveolar photoreceptor cell bodies to their synapses running almost parallel to the retinal surface before connecting to postreceptoral retinal neurones outside the fovea. These oblique 'axons', along with associated Müller cells, form the Henle fibre layer. Aspects of normal macular morphology, such as the central retinal thickness and the steepness of the foveal slope, show significant individual variation. Aged foveas are less symmetric along the midline than their younger counterparts and have steeper slopes.

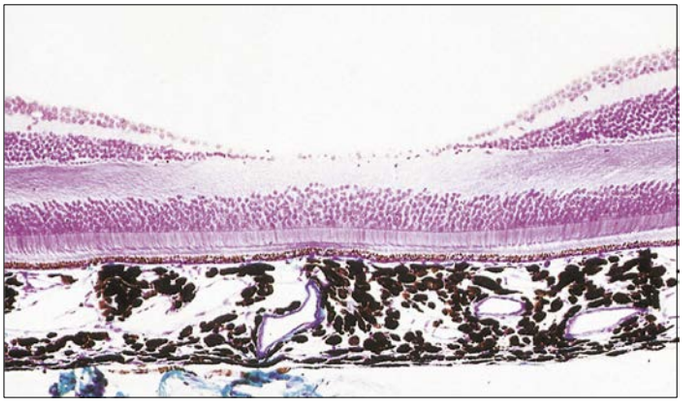

Fig. 45.28 A section through the fovea centralis. (With permission from Young B, Heath JW 2000 Wheater's Functional Histology. Edinburgh: Churchill Livingstone.)

The macula lutea is a horizontally elliptical yellow area centred on the foveola. It is formed by high concentrations of a macular pigment composed of the carotenoids lutein, zeaxanthin and mesozeaxanthin and which absorb short wavelengths (400–530 nm). This pigment is localized in the fibrous Henle and inner plexiform layers, mainly within Müller cells and therefore largely absent in the central foveola. The density of pigment and its spatial distribution vary by more than an order of magnitude between individuals, and are influenced by factors including age, gender, smoking and diet. One function of macular pigment is to protect the photoreceptors from photo-oxidative damage; it has been hypothesized that low levels may be associated with retinal pathologies such as age-related macular degeneration (Lima et al 2016).

The increased packing density of cones in the foveola and their lack of convergence with ganglion cells, combined with the absence of the inner retinal layers, including blood vessels, from the central macula (reducing light scatter), collectively ensure that visual resolution is highest in this part of the retina. Acuity may be further enhanced by the macular pigment, which, apart from having antioxidant properties and removing potentially harmful short-wave radiation, will absorb those wavelengths most prone to chromatic aberration and Rayleigh scatter.

Vascular supply

The retina has a dual arterial supply and both parts are necessary to maintain retinal function. The outer five layers of the retina are avascular and rely on an indirect supply from the choroidal capillaries (p. 795). The inner retina receives a direct blood supply through capillaries connected to branches of the central retinal artery and vein. Only the inner retinal circulation will be described here.

The central retinal artery enters the optic nerve as a branch of the ophthalmic artery 6.4–15.2 mm behind the eyeball (Kocabiyik et al 2005), and travels within the optic nerve to its head, where it passes through the lamina cribrosa. At this level, it divides into equal superior and inferior branches, each of which, after a few millimetres, give off nasal and temporal branches that supply the 'quadrants' of the retina (see Fig. 45.27). Although similar retinal veins unite to form the central retinal vein, the courses of the arteries and veins do not correspond exactly. These vessels mainly run within the nerve fibre and ganglion cell layers of the retina, a course that accounts for their clarity when seen through an ophthalmoscope (see Fig. 45.20A), and explains why they can serve as an easily accessible indicator of cardiovascular disease. Arteries often cross veins, usually lying superficial to them; in severe hypertension, the arteries may press on the veins and cause visible dilations distal to these crossings. The vitreal location of arteries, their lighter, bright red coloration and smaller diameter in comparison to veins allow the two vessel types to be distinguished ophthalmoscopically. The detailed pattern of the inner retinal vessels is unique and therefore can be used as a source of biometric information for individual recognition.

From the four major arteries within the inner retina, dichotomous branches run from the posterior pole to the periphery, supplying the whole retina (Zhang 1994). Arteries and veins ramify in the nerve fibre

layer, near the internal limiting membrane, and arterioles pass deeper into the retina to supply capillary beds. Venules return from these beds to larger superficial veins that converge towards the disc to form the central retinal vein.

Retinal capillary networks are often in three different layers, the number of layers depending on location. Radial peripapillary capillaries are the most superficial of the capillary networks and lie within the inner nerve fibre layer. A layer of inner capillaries runs within the nerve fibre and ganglion cell layers, and an outer capillary layer is located in the inner plexiform and inner nuclear layers (**Fig. 45.29**). Approaching the fovea, capillaries are restricted to two layers, and terminal capillaries eventually join to form a single-layered macular capillary ring, producing a capillary-free zone 450–500 µm in diameter at the fovea. This avascular region is clearly visible in a fluorescein angiogram (Fig. 45.20B). Capillaries become less numerous in the peripheral retina and are absent from a zone approximately 1.5 mm wide adjoining the ora serrata.

The territories of the arteries that supply a particular quadrant do not overlap, nor do the branches within a quadrant anastomose with each other, which means that a blockage in a retinal artery causes loss of vision in the corresponding part of the visual field. The only exception to this end-arterial pattern is in the vicinity of the optic disc. Here, the posterior ciliary arteries enter the eye near the disc and their rami not only supply the adjacent choroid, but also form an anastomotic circle in the sclera around the head of the optic nerve (circle of Zinn/Haller) (**Fig. 45.30**). Branches from this ring join the pial arteries of the nerve (see below). Small cilioretinal arteries derived from any arteries in this region may enter the eye in up to 50% of individuals and contribute to the central retinal vasculature; they may preserve visual function following occlusion of the central retinal artery. Small retinociliary veins may sometimes be present.

The structure of retinal blood vessels resembles that of vessels elsewhere, except that the arteries lack an internal elastic lamina, and their adventitia may contain muscle cells. Capillaries are non-fenestrated; endothelial cells are joined by complex tight junctions, fulfilling the requirements of a blood–retinal barrier. Perivascular cells, including pericytes and glia, play key roles in the development and maintenance of the blood–retinal barrier (Bharadwaj et al 2013). Selective loss of pericytes happens early in the development of diabetic retinopathy and has been linked to the characteristic pathological changes seen in this condition (Park et al 2017). Within the optic nerve, the central artery is innervated by sympathetic and parasympathetic nerves; this innervation does not extend to the retinal vessels. The cholinergic parasympathetic supply is derived mainly from the pterygopalatine ganglion and is vasodilatory (Ch. 38). The adrenergic postganglionic sympathetic supply originates in the superior cervical ganglion and travels via a plexus around the internal carotid and ophthalmic arteries; it is unclear whether it elicits vasoconstriction or dilation (Bergua et al 2013).

Although inner retinal blood vessels lie between the incoming light and the photoreceptors, they are not perceived because their location is constant. In marked contrast, the growth of new retinal vessels (neovascularization) is one of the major sight-threatening complications of diseases such as diabetes and retinopathy of prematurity.

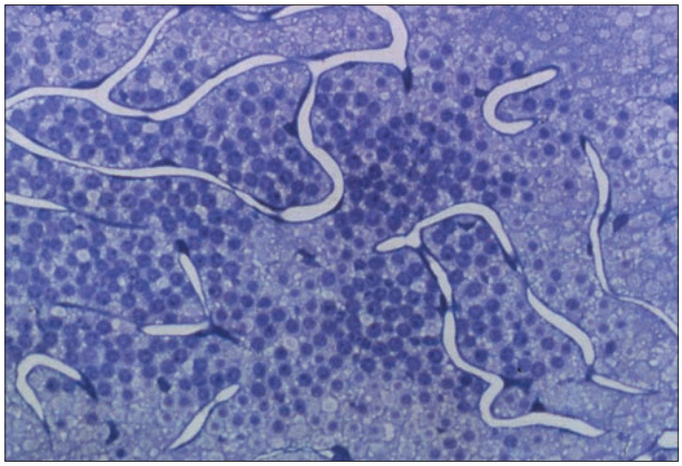

Fig. 45.29 A tangential section of the retina at the level of the inner nuclear layer, highlighting the dense network of capillaries.

Retinopetal innervation

The human retina receives efferent innervation via axons within the optic nerve. Although there are only a small number of these retinopetal neurones, they branch extensively within the retina. They emerge at the optic disc, course through the nerve fibre layer, and give off orthogonal branches that ramify in the inner plexiform layer (Repérant et al 2006). One set of axons arises from perikarya in the posterior hypothalamus and uses histamine as a neurotransmitter, while other serotoninergic fibres arise from cell bodies in the dorsal raphe. These neurones are not specialized for vision; they project to many other targets in the central nervous system besides the retina, forming components of an ascending arousal system (Gastinger et al 2006). Histamine is released during the day in the inner plexiform layer and activates receptors located on cone pedicles, horizontal cell perikarya and ON bipolar cell dendrites via volume transmission. Histamine also decreases the absolute sensitivity of the retina to light and, possibly, modulates retinal blood flow (Vila et al 2012).

Optic nerve head

The axons of more than a million retinal ganglion cells converge at the optic nerve head and leave the eye by penetrating the sclera to form the optic nerve. The optic nerve head represents that part of the optic nerve lying within the bulb of the eye. Since all retinal neural elements, apart from ganglion cell axons, are absent from this region, it is insensitive to light and forms the 'blind spot'.

Histologically, the optic nerve head can be divided into three zones (see Fig. 45.30): prelaminar (the anterior part terminating at the vitreous); laminar (formed by the lamina cribrosa); and postlaminar (continuous with the retrobulbar optic nerve). The surface view of the optic nerve head, usually seen with an ophthalmoscope, is referred to as the optic disc (Fig. 45.20A).

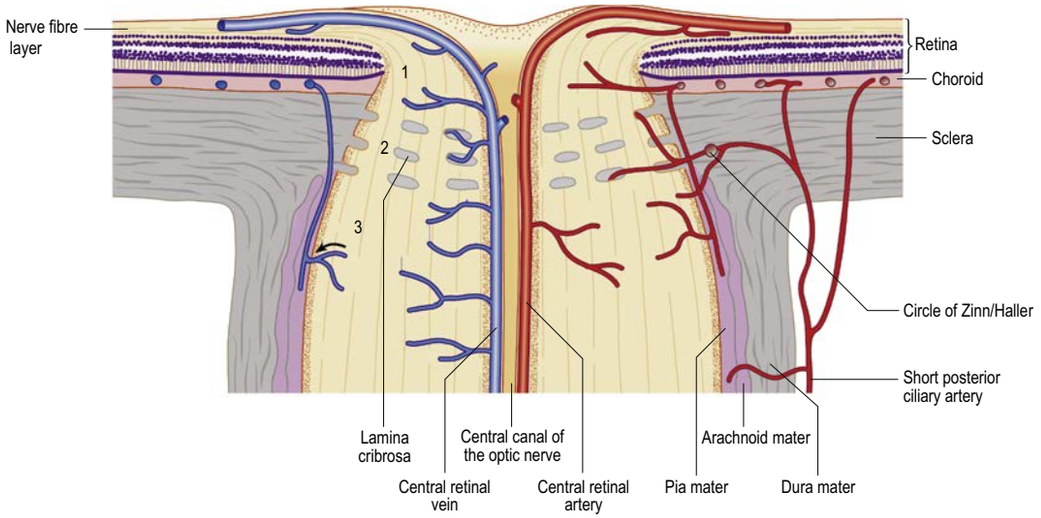

Fig. 45.30 Vessels of the optic nerve head. The dotted areas represent the principal glial membranes. Arteries are represented on the right and veins on the left. The prelaminar, laminar and postlaminar zones are indicated by 1–3, respectively.

Prelaminar zone

The inner surface of the optic nerve head is covered by an astroglial membrane (of Elschnig) that is continuous with the internal limiting membrane of the retina. At the centre of the disc, the layer of astrocytes thickens into a central meniscus (of Kuhnt). Retinal ganglion cells turn into the optic nerve head accompanied by astrocytes that gradually increase in number posteriorly, eventually forming a sieve-like structure, the glial lamina cribrosa, through which the nerve fibres pass as separate fasciculi. A collar of astrocytes several cells thick (the intermediary tissue of Kuhnt) separates the optic nerve from the terminating outer layers of the retina at the perimeter of the optic nerve head. It continues posteriorly and forms a barrier between the optic nerve head and the choroid (the border tissue of Jacoby) (Anderson and Hoyt 1969).

Laminar zone

The lamina cribrosa is composed of discrete trabeculae of collagenous and elastic connective tissue that extend from the sclera to form a meshwork through which the optic nerve fascicles and central retinal vessels pass. Each trabecula has a lining of astrocytes continuous with the astrocytes that form the glial lamina cribrosa.

Postlaminar zone

The optic nerve thickens in the postlaminar zone as its axons become myelinated. The reflected sclera, and the dura mater with which it is continuous, invest the nerve together with the arachnoid and pia mater. Fine fibrous septa penetrate the optic nerve from the pia mater, dividing it into 300–400 fascicles, and giving pial blood vessels access to the nerve.

Optic disc

The optic disc is a region of great clinical importance because it is visible by ophthalmoscopy (see Fig. 45.20A). Oedema of the disc (papilloedema) may be the first sign of raised intracranial pressure that has been transmitted into the subarachnoid space around the optic nerve. The disc is also sensitive to raised intraocular pressure present in glaucoma and shows characteristic structural changes as a result of loss of retinal ganglion cells.

The optic disc is superomedial to the posterior pole of the eye, and so lies away from the visual axis. It is round or oval, and usually approximately 1.6 mm in transverse diameter and 1.8 mm in vertical diameter, although its appearance is very variable. In light-skinned individuals, the general retinal hue is a bright terracotta-red, with which the pale pink of the disc contrasts sharply; the central part of the disc is usually even paler and may be light grey. These differences are due in part to the degree of vascularization of the two regions, which is much less at the optic disc, and to the total absence of choroidal or retinal pigment cells. In individuals with strongly melanized skin, both the retina and disc are darker. The optic disc rarely projects sufficiently to justify the term papilla, although it is usually a little elevated on its lateral side, where the papillomacular nerve fibres turn into the optic nerve (see Fig. 45.27). Typically, there is a slight depression where the retinal vessels traverse its centre.

Vascular supply

The prelaminar region is supplied mainly by branches of the central retinal artery. Branches from the short posterior ciliary arteries form a circle, often incomplete, within the sclera around the optic nerve head (circle of Zinn/Haller) and centripetal branches from this structure supply the laminar region of the optic nerve head (see Fig. 45.30). The short posterior ciliary arteries may also give off centripetal branches directly to supply the lamina, as well as branches that pass anteriorly to augment the prelaminar blood supply. In the postlaminar region, arteries from the prepapillary choroid and circle of Zinn pass retrogradely as pial vessels, providing centripetal branches that supply the optic nerve. More posteriorly, the optic nerve receives pial arterioles directly from the posterior ciliary arteries. The central retinal artery may also contribute some centrifugal branches in this region.

The central retinal vein drains the optic nerve head at all levels; other drainage pathways are minor.

VISUAL PATHWAY

The visual pathway includes the interneurones of the retina, retinal ganglion cells whose axons project via the optic nerve, chiasma and optic tract to the lateral geniculate nucleus and neurones within the lateral geniculate nucleus that project via the optic radiation to the primary visual cortex (Fig. 45.31). It is important to remember that visual space is optically inverted by the crystalline lens when relating the spatial location of neurones within the visual pathway to corresponding visual field locations.

Retinal ganglion cell axons, on entering the optic nerve, initially maintain their relative retinal positions, with axons from the fovea forming a lateral wedge. Such retinotopic mapping is largely maintained within the optic nerve, although nearer the chiasma the foveal axons take a position in the centre of the optic nerve while temporal fibres occupy their previous lateral location.

At the chiasma, a substantial rearrangement of axons takes place. Most axons arising from the nasal half of a line bisecting the fovea within each retina cross in the chiasma to enter the contralateral optic tract. Fibres from the temporal hemi-retinas do not generally cross in the chiasma. Classically, the axons within the optic tract were thought to maintain their topographic order and each tract was assumed to be a single representation of the contralateral hemifield. However, it is now clear that axons are mainly organized in functional groupings, larger superficial axons representing the magnocellular pathway and deeper axons originating from midget ganglion cells and forming the parvocellular pathway. This arrangement is chronotopic, the deeper axons developing earlier during axogenesis than the more superficial ones (Reese 1993).

The lateral geniculate nucleus contains cells arranged in six laminae (see Fig. 30.6). The contralateral nasal retina projects to laminae 1, 4 and 6, whereas the ipsilateral temporal retina projects to layers 2, 3 and 5. Layers 1 and 2 contain magnocellular cells; the remaining layers are parvocellular. Unlike the optic tract, there is a point-to-point retinotopic arrangement between corresponding points in each hemiretina so that the contralateral visual field is mapped within each lateral geniculate nucleus.

Axons from the lateral geniculate nucleus run in the retrolenticular part of the internal capsule and form the optic radiation. This curves dorsomedially to the primary visual cortex, located around and within the depths of the calcarine sulcus in the occipital lobe (also known as the striate cortex, Brodmann area 17, or V1) (see Fig. 32.12). The visual cortex also has a strict retinotopic organization. Fibres representing the lower half of the visual field sweep superiorly to reach the visual cortex above the calcarine sulcus, while those representing the upper half of the visual field curve inferiorly into the temporal lobe (Meyer's loop) before reaching the visual cortex below the calcarine sulcus. The periphery of the retina is represented anteriorly within the visual cortex, and the macula is mapped towards the posterior pole, occupying a disproportionately large area that reflects the high number of foveal retinal ganglion cells that subserve the enhanced acuity of this region.

The primary visual cortex is connected to prestriate and other cortical regions where further processing of visual stimuli takes place.

Almost all (90%) of the retinal ganglion cell axons terminate on neurones in the lateral geniculate nucleus. Extrageniculate axons (10%) leave the optic tract before the lateral geniculate nucleus: they may leave the optic chiasma dorsally and project to the suprachiasmatic nucleus of the hypothalamus, or may branch off the optic tract at the superior brachium and project to the superior colliculus, pretectal areas and inferior pulvinar.

Visual field defects

The basis for clinical assessment of damage to the visual pathway is an understanding of the retinotopic projections within the pathway. Plotting visual field loss frequently reveals the approximate location of the causative lesion and sometimes its nature. Since retinal lesions can be visualized with an ophthalmoscope, field testing might appear to be redundant for such defects, but is still helpful in assessing the extent of the damage and may be the key factor in confirming a diagnosis. For example, field defects in glaucoma that are a consequence of damage to the nerve fibre bundles at the optic nerve head, may be detectable ophthalmoscopically, but confirmation of the diagnosis frequently depends on field assessment. Early defects consist of one or more areas of paracentral focal field loss, progressing to arcuate scotomas. The shape of the defect corresponds to the anatomical arrangement of ganglion cell axons.

As far as the location of lesions central to the retina is concerned, deficits in the vision of one eye are usually attributable to optic nerve lesions. Lesions of the optic chiasma, involving crossing nerve fibres, produce a bilateral field loss, as exemplified by a pituitary adenoma. The tumour expands upwards from the pituitary fossa, usually compressing the inferior midline of the chiasma, and eventually produces bitemporal hemianopia, starting with an early loss in the upper temporal quadrants (bitemporal quadrantanopia).

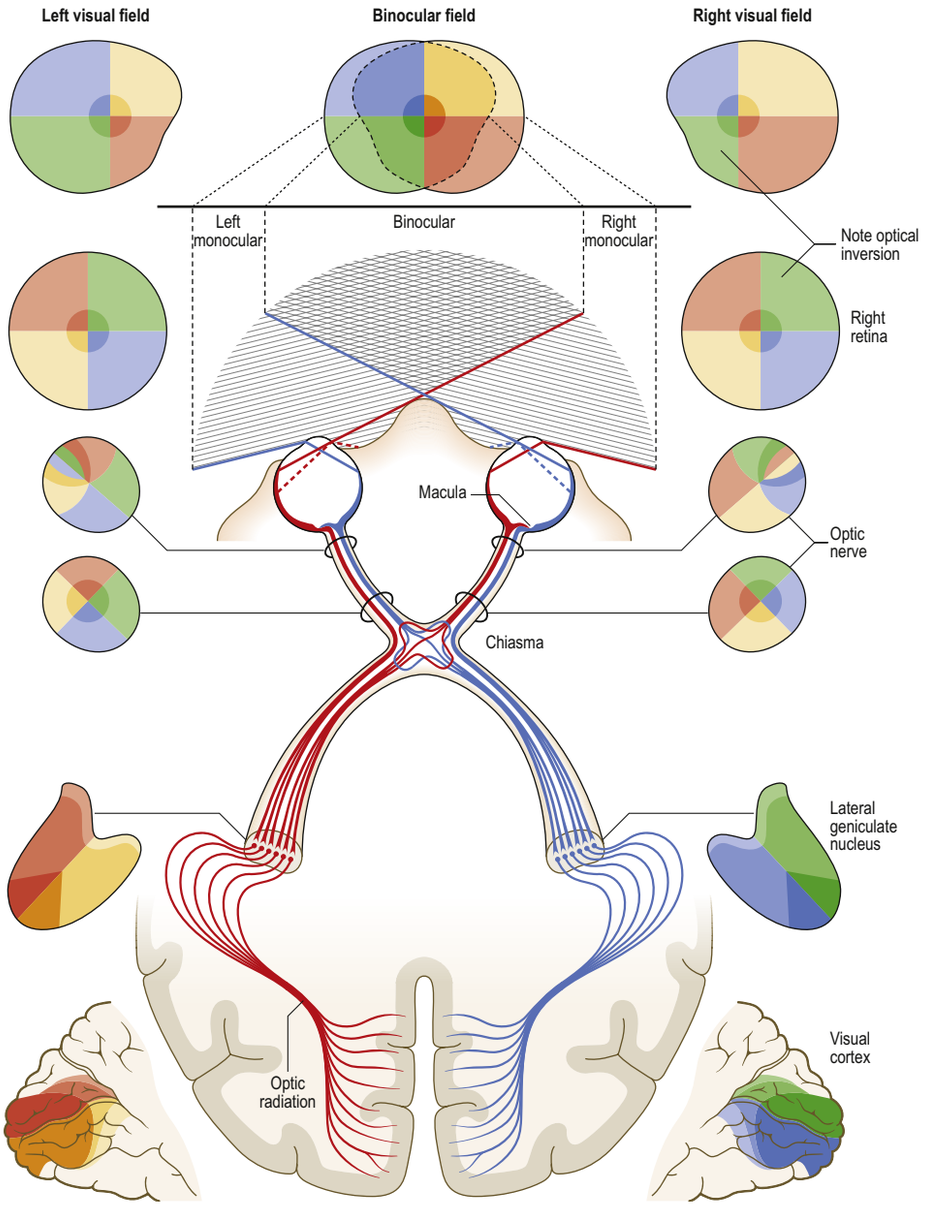

Fig. 45.31 The visual pathway (simplified), showing the spatial arrangement of neurones and their fibres in relation to the quadrants of the retinae and visual fields. The proportions at various levels are not exactly to scale. In particular, the macula is exaggerated in size in the visual fields and retinae. In each quadrant of the visual field, and in the parts of the visual pathway subserving it, two shades of each respective colour are used; the paler shade denotes the peripheral field and the darker shade denotes the macular part of the quadrant. From the lateral geniculate nucleus onwards, these two shades are both made more saturated to denote intermixture of neurones from both retinae, the palest shade being reserved for parts of the visual pathway concerned with monocular vision.

Since the optic tract contains contralateral nasal and ipsilateral temporal retinal projections, damage to the tract will cause a homonymous contralateral visual field loss. Although complete disruption of the tract results in contralateral hemianopia, the incomplete spatial segregation of axons within the tract, described above, makes the field losses following smaller lesions harder to interpret. However, they do show substantial incongruity (dissimilar defects in the fields of the two eyes) and often specific functional deficits, consistent with the partial segregation of functionally distinct axons from the two half-retinas (Reese 1993). Incongruity is most marked in defects of the optic tract, less obvious in optic radiation defects, and usually absent in cortically induced field defects, thus providing an additional clue in assessing location of the cause.

Lesions of the optic radiations are usually unilateral, and commonly vascular in origin. Field defects therefore develop abruptly, in contrast to the slow progression of defects associated with tumours, and the resulting hemifield loss follows the general rule that visual field defects central to the chiasma are on the opposite side to the lesion. Little or no incongruity is seen in visual cortical lesions, but they commonly display the phenomenon of macular sparing, the central 5–10° visual field being retained in an otherwise hemianopic defect.

CHAPTER
46

Back

Most clinical disorders of the back present as low back pain with or without associated lower limb pain, weakness or numbness, and so, historically, most attention has been paid to the anatomy of the lower (lumbosacral) back. In this Section, the term 'back' will include the whole of the posterior aspect of the trunk and of the neck. The whole of this region has great clinical importance but its anatomy has often been neglected. Recent understanding of the detailed topography of the bony and soft tissue elements of the lower back owes much to the work of Bogduk (2012).

The soft tissues of the back of the trunk and neck include the skin and subcutaneous fat, the underlying fascial layers and the musculature. The deep, 'true' or epaxial muscles lie within compartments in their own fascial 'skeleton'. The bony framework to which the muscles and fasciae attach includes elements of the axial skeleton, i.e. the vertebral column and occiput, elements of the pectoral and pelvic girdles, and the ribs. The occiput is described below, the scapula in Chapter 49, the ribs in Chapter 53 and the pelvis in Chapter 77.

SKIN

The skin of the back of the trunk is thick and highly protective, but has low discriminatory sensation. The superficial fascia is thick and fatty in most areas of the back. Its attachment to the deeper fascial layers is strong in the midline, especially in the neck, but becomes weaker more laterally. The skin of the back of the neck is thicker than that of the front of the neck, but thinner than that of the back of the trunk. The quantity, texture and distribution of hair vary with sex, race and the individual, though well-defined hair tracts have been delineated (**Fig. 46.1**).

Lines of skin tension run horizontally in the cervical and lumbosacral regions but form segments of two adjacent circles in the thoracic region (**Fig. 46.2**).

Fig. 46.2 Lines of skin tension on the dorsum of the trunk and head. (With permission from Kraissl CL, Plast Reconstruct Surg 8: 1–28, 1951, Lippincott Williams and Wilkins.)

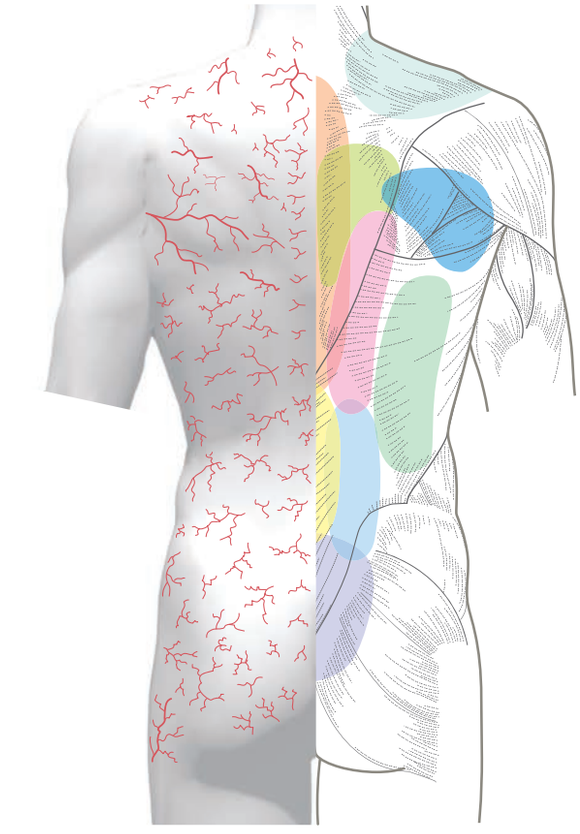
Cutaneous innervation and dermatomes

The skin of the back of the neck and trunk is innervated by the dorsal (posterior primary) rami of the spinal nerves (see Fig. 47.8). The spinal nerves involved include C2–C5, T2–L3, S2–S4 and Co1. The pattern of their dermatomes is shown in **Fig. 46.3**. There is about half a segment of overlap between these cutaneous 'strips'; the strips supplied by the dorsal rami do not correspond exactly to those served by ventral rami, and differ slightly in both width and position. In the cervical and upper thoracic regions (down to T6) skin is supplied by the medial branches of the dorsal rami, while in the lower thoracic, lumbar and sacral regions it is supplied by the lateral branches.

Cutaneous vascular supply and lymphatic drainage

The skin of the back of the trunk receives its arterial blood supply mainly from musculocutaneous branches of posterior intercostal, lumbar and lateral sacral arteries (**Fig. 46.4**), which all accompany the cutaneous branches of their respective dorsal rami. In addition, there is a supply from the dominant vascular pedicles of the superficial (extrinsic) back muscles. The skin over the scapula is supplied by branches of the suprascapular, dorsal scapular and subscapular arteries. The skin of the back of the neck is supplied mainly from the occipital and deep cervical arteries. The superficial cervical or transverse cervical artery supplies the skin of the lower part of the back of the neck (Cormack and Lamberty 1994).

Veins drain the skin of the back of the neck into tributaries of the occipital and deep cervical veins. The skin of the back of the trunk drains into the azygos system, via tributaries of the posterior intercostal and lumbar veins.



Lymph from the skin of the back of the neck drains into occipital, lateral deep cervical and axillary nodes (**Fig. 46.5**). From the back of the trunk, drainage is to the posterior (subscapular) axillary nodes and to the lateral superficial inguinal nodes.

FASCIAL LAYERS

The main fascial layers in the axial and paraxial regions of the trunk and neck are the thoracolumbar fascia, the deep cervical fascia and the prevertebral, endothoracic, retroperitoneal and posterior parts of the pelvic fasciae (the latter four layers collectively form the continuous prevertebral plane). Other important structures with fascial components are the ligamentum nuchae and the aponeurosis of erector spinae (see below).

Thoracolumbar fascia

The thoracolumbar (lumbodorsal) fascia covers the deep muscles of the back and the trunk. Above, it passes anterior to serratus posterior superior and is continuous with the superficial lamina of the deep cervical fascia on the back of the neck. In the thoracic region, the

Intercostal arteries – medial dorsal cutaneous branches
Intercostal arteries – lateral dorsal cutaneous branches
Lumbar arteries – medial dorsal cutaneous branches
Lumbar arteries – lateral dorsal cutaneous branches
Sacral arteries
Circumflex scapular artery – horizontal and parascapular branches
Deep branch of transverse cervical artery/dorsal scapular artery
Superficial branch of transverse cervical artery/superficial cervical artery
Musculocutaneous perforators through latissimus dorsi arising from the intercostal and lumbar arteries

Fig. 46.4 Areas of cutaneous arterial supply on the dorsum of the trunk. (Redrawn with permission from Cormack GC, Lamberty BGH 1994 The Arterial Anatomy of Skin Flaps. Edinburgh: Churchill Livingstone.)

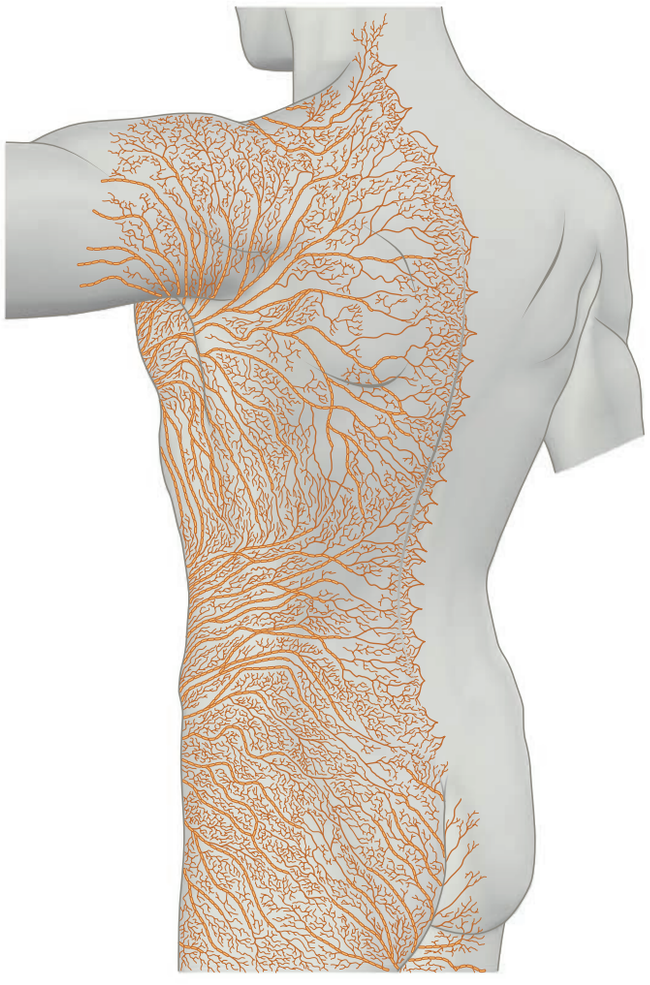


Fig. 46.5 Cutaneous lymphatics on the dorsum of the trunk. (With permission from Romanes GJ (ed) 1964 Cunningham's Textbook of Anatomy, 10th ed. London: Oxford University Press.)

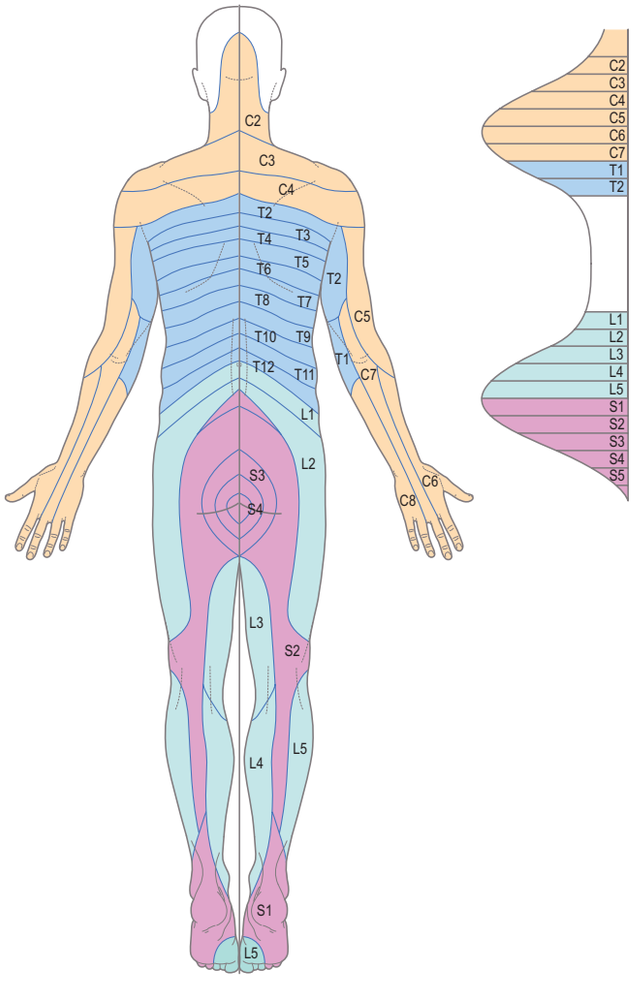
thoracolumbar fascia provides a thin fibrous covering for the extensor muscles of the vertebral column and separates them from the muscles connecting the vertebral column to the upper extremity. Medially, it is attached to the spines of the thoracic vertebrae, and laterally to the angles of the ribs. In the lumbar region, the thoracolumbar fascia is in three layers (Fig. 46.6; see Fig. 61.1). The posterior layer is attached to the spines of the lumbar and sacral vertebrae and to the supraspinous ligaments. The middle layer is attached medially to the tips of the lumbar transverse processes and the intertransverse ligaments, below to the iliac crest, and above to the lower border of the twelfth rib and the lumbocostal ligament. The anterior layer covers quadratus lumborum and is attached medially to the anterior surfaces of the lumbar transverse processes behind the lateral part of psoas major; below, it is attached to the iliolumbar ligament and the adjoining part of the iliac crest; above, it forms the lateral arcuate ligament. The posterior and middle layers unite to form a tough raphe at the lateral margin of erector spinae, and at the lateral border of quadratus lumborum they are joined by the anterior layer to form the aponeurotic origin of transversus abdominis. At sacral levels, the posterior layer is attached to the posterior superior iliac spine and posterior iliac crest, and fuses with the underlying erector spinae aponeurosis. Bogduk (2012) describes two laminae in the posterior layer at lumbar levels, with varying orientation of the constituent collagen fibres relating to the biomechanical function of the fascia. The posterior and middle layers of the thoracolumbar fascia and the vertebral column together form an osteofascial compartment that encloses the erector spinae muscle group.

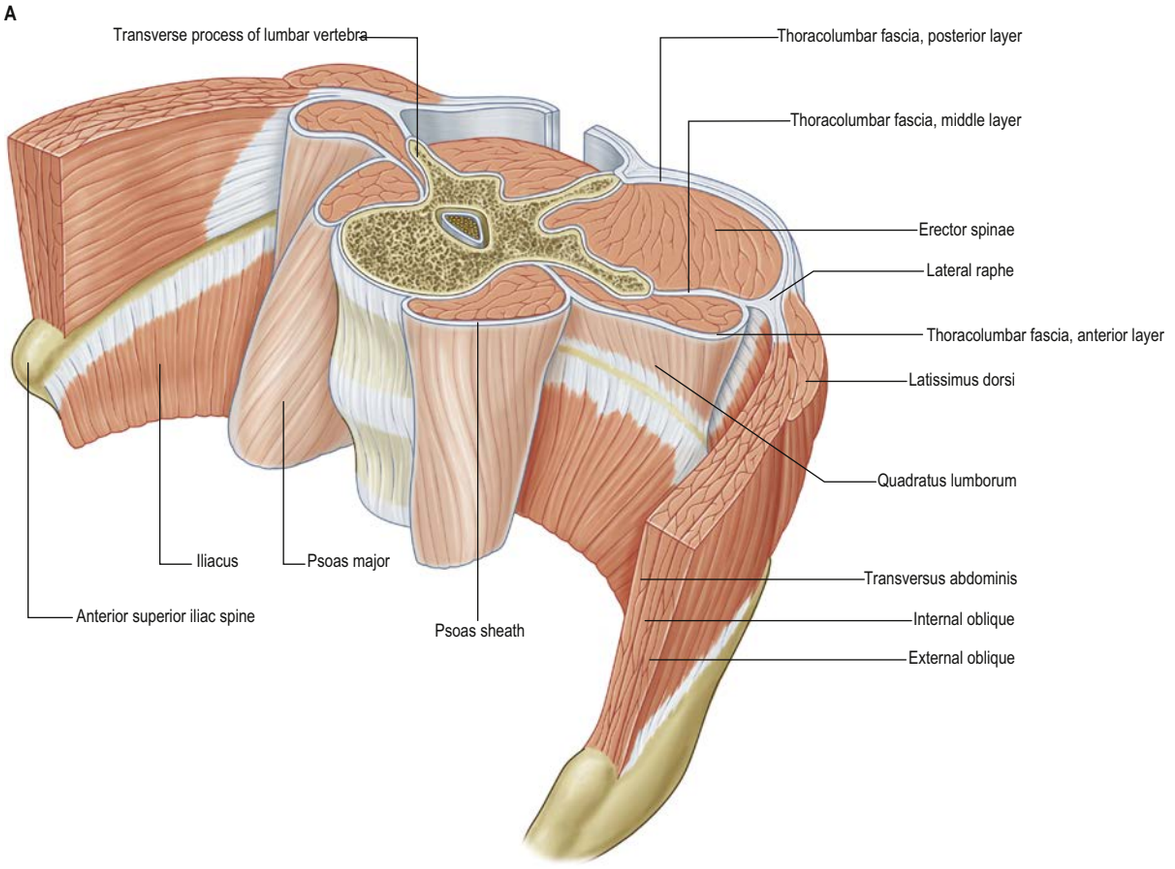
The attachments of the fascia, especially those that assure continuity with the abdominal wall musculature, putatively give it an important role in lifting, though the exact details of this role remain controversial. The fascia may also play an important role in load transfer between the trunk and the limbs: its tension is affected by the actions of latissimus dorsi, gluteus maximus and the hamstrings. Additionally, the thoracolumbar fascia contains nociceptive nerve endings that may be responsible for some forms of back pain. Other mechanisms related to the thoracolumbar fasciae that have been implicated as a possible source of back pain include tissue deformation due to injury or immobility, resulting in impaired proprioceptive signalling and possibly an increase in pain sensitivity, and increased sensitivity of the thoracolumbar fascia in conditions involving other tissues innervated by the same spinal nerve (Willard et al 2012).

Deep cervical fascia

The investing layer of the deep cervical fascia forms the deep fascia of the posterior aspect of the neck (see Fig. 35.4A). It attaches in the midline to the external occipital protuberance, the ligamentum nuchae and the spine of the seventh cervical vertebra, and splits to enclose trapezius on each side. Inferiorly, the posterior part of the investing layer attaches with trapezius to the spine and acromion of the scapula.

Fig. 46.1 Hair tracts on the dorsal surface of the body. (Adapted with permission from Wood Jones F (ed) 1949 Buchanan's Manual of Anatomy, 8th ed. London: Baillière Tindall and Cox.)





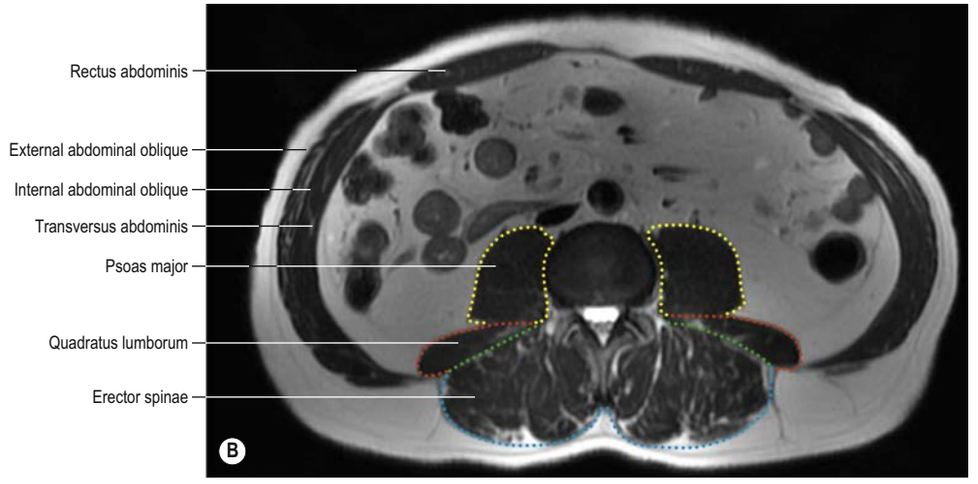


Fig. 46.3 Dermatomes on the dorsal surface of the body. The small diagram shows the regular arrangement of dermatomes in the upper and lower limbs of the embryo. Maps of dermatome distribution are useful in clinical neurology as a guide to identify the location of pathology in patients with peripheral sensory deficits, but it is important to remember that they are approximations (Ch. 24). (Adapted with permission from Moffat DB 1993 Lecture Notes on Anatomy, 2nd ed. Oxford: Blackwell Scientific.)

Psoas sheath (yellow); thoracolumbar fascia, anterior layer (red), middle layer (green), posterior layer (blue).

BONES

Occipital bone

The occipital bone forms much of the back and base of the cranium (Fig. 46.7). It is trapezoid and internally concave, and encloses the foramen magnum. It has four parts: basilar (basioccipital), which is the quadrilateral part in front of the foramen magnum; squamous, which is the expanded plate posterosuperior to the foramen; and two lateral (condylar or exoccipital), one on each side of the foramen magnum. The latter is anteromedian and wider behind, with an anteroposterior diameter greater than its transverse diameter.

The occipital bone provides attachment for a number of the muscles of the neck and upper part of the back (longus capitis; recti capitis anterior, lateralis, posterior major and minor; superior oblique; semispinalis capitis; splenius capitis; occipitofrontalis; trapezius; sternocleidomastoid), and articulates with the first cervical vertebra at the atlanto-occipital joints.

Squamous part

The squamous part is an expanded plate posterosuperior to the foramen magnum, convex externally and concave internally. On its external surface, the external occipital protuberance lies midway between its summit and the foramen magnum. On each side, two curved lines extend laterally from this protuberance. The upper one, faintly marked and often almost imperceptible, is the highest nuchal line, and the lower one is the superior nuchal line. The epicranial aponeurosis is attached to the medial part of the highest nuchal line. The median external occipital crest is often faint; it descends from the external occipital protuberance to the foramen magnum. On each side, an inferior nuchal line spreads laterally from the midpoint of the crest.

The internal surface of the squamous part is divided into four deep fossae by an irregular internal occipital protuberance and by ridged sagittal and horizontal extensions from the protuberance. The two superior fossae are triangular and adapted to the occipital poles of the cerebral hemispheres; the inferior fossae are quadrilateral and shaped to accommodate the cerebellar hemispheres. A wide groove with raised banks, the superior sagittal sulcus, ascends from the protuberance to the superior angle of the squamous part. The posterior part of the falx cerebri is attached to the margins of the sulcus. A prominent internal occipital crest descends from the protuberance and bifurcates near the foramen magnum, and provides an attachment for the falx cerebelli. The occipital sinus, sometimes double, lies in this attachment. A small vermian fossa may exist at the lower end of the internal occipital crest; when present, it is occupied by part of the inferior cerebellar vermis. On each side, a wide sulcus for the transverse sinus extends laterally from the internal occipital protuberance; the tentorium cerebelli is attached to the margins of these sulci. The right sulcus is usually larger than the left, and passes into the sulcus for the superior sagittal sinus, whereas the left usually receives the straight sinus. The position of the confluence of the sinuses is indicated by a depression on one side of the protuberance.

The position of the fetal posterior fontanelle coincides with the junction between the superior angle of the squamous part of the occipital bone and the occipital angle of the parietal bone on either side. The lateral angles of the squamous part are marked internally by the ends of the transverse sulci and project between the parietal and temporal bones. The lambdoid borders extend from superior to lateral angles and are serrated for articulation with the occipital borders of the parietal bones at the lambdoid suture. The mastoid borders extend from the lateral angles to the jugular processes, articulating with the mastoid parts of the temporal bones. A variety of sutural bones (ossicles) may occur at or near the lambda, e.g. the 'interparietal' (Inca bone or ossicle of Goethe).

Muscle attachments The occipital part of occipitofrontalis is attached to the lateral part of the highest nuchal line (Fig. 46.7C). Trapezius attaches to the medial third of the superior nuchal line and to the external occipital protuberance. Sternocleidomastoid attaches to the lateral half of the superior nuchal line, with splenius capitis just below the lateral third of that line. Semispinalis capitis is attached to the medial part of the area between the superior and inferior nuchal lines; obliquus capitis superior attaches to the lateral part of this area. Rectus capitis posterior major attaches to the lateral part of the inferior nuchal line and to the bone immediately below, and rectus capitis posterior minor attaches to the medial part of the inferior nuchal line and to the bone between that line and the foramen magnum.

Basilar part

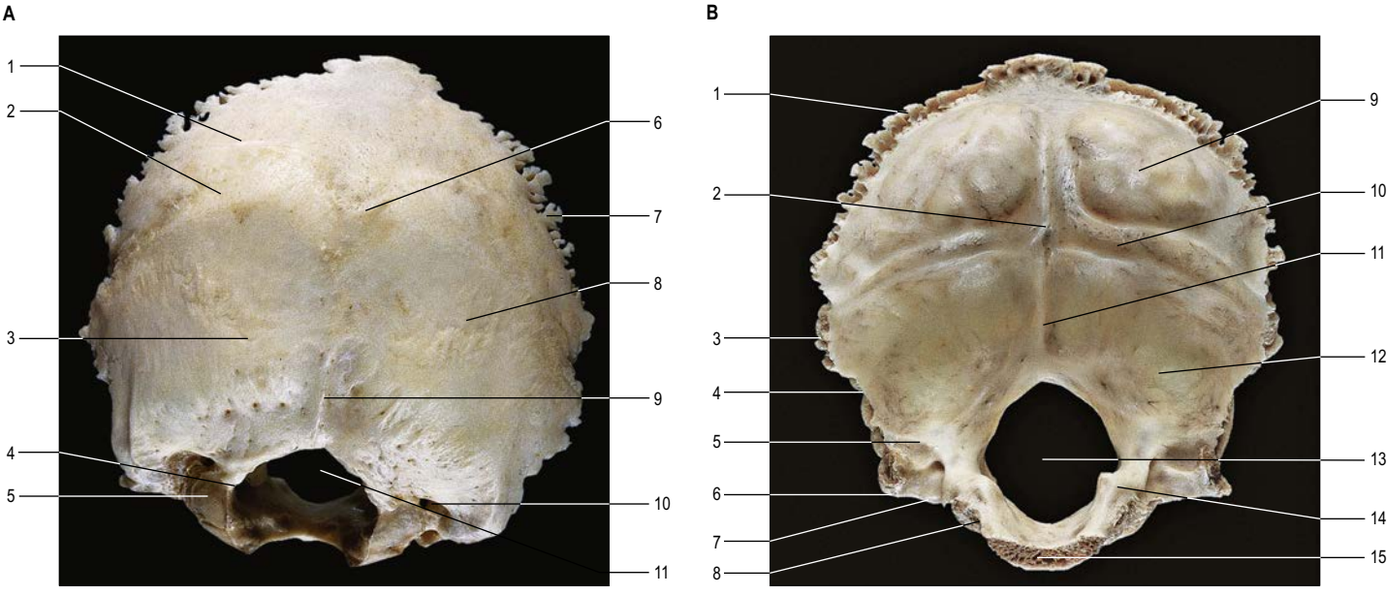
The basilar part extends anterosuperiorly from the foramen magnum. In young skulls, it presents a rough and uneven surface where it is joined to the body of the sphenoid by a growth cartilage (spheno-occipital synchondrosis). This plate has fully ossified by the twenty-fifth year, at which time the occipital and sphenoid bones are fused.

The inferior surface bears a small pharyngeal tubercle, about 1 cm in front of the foramen magnum, which gives attachment to the fibrous pharyngeal raphe. A small depression immediately anterior to the occipital condyle may occasionally be replaced by a small precondylar tubercle. The anterior atlanto-occipital membrane is attached to the anterior margin of the foramen magnum.

The superior surface has the form of a broad groove that slopes upwards and forwards from the foramen magnum, directly into the basilar part of the sphenoid; together, these bones form the clivus. The lateral margins articulate below with the petrous part of the temporal bones.

Muscle attachments Longus capitis is attached anterolateral to the pharyngeal tubercle, and rectus capitis anterior is attached to the small depression anterior to the occipital condyle (see Fig. 46.7C).

Lateral (condylar) parts



The lateral (condylar) parts of the occipital bone flank the foramen magnum. On their inferior surfaces are occipital condyles for articulation with the superior articular facets of the atlas vertebra. The condyles are oval or reniform, their long axes converging anteromedially. The articular surfaces, wholly convex, face inferolaterally. They are occasionally constricted and a condyle may be in two parts (as may be the reciprocal surfaces of the atlas vertebra). A tubercle gives attachment to an alar ligament medial to each articular facet. The hypoglossal (anterior condylar) canal, which is situated anteriorly above each condyle, starts internally a little above the anterolateral part of the foramen magnum and continues anterolaterally. It may be partly or wholly divided by a spicule of bone and transmits the hypoglossal nerve and a meningeal branch of the ascending pharyngeal artery. A condylar fossa, behind each condyle, fits the posterior margin of the superior facet of the atlas vertebra in full extension of the skull. Its floor is sometimes perforated by a posterior condylar canal for a sigmoid emissary vein. A quadrilateral plate, the jugular process, projects laterally from the posterior half of each condyle, and contributes the posterior part of the jugular foramen. The jugular process is indented in front by a jugular notch, which may be partly divided by a small intrajugular process projecting anterolaterally. A paramastoid process sometimes projects downwards and may even articulate with the transverse process of the atlas vertebra. Laterally, the jugular process has a rough quadrilateral or triangular area that is joined to the jugular surface of the temporal bone by cartilage; it begins to ossify at around 25 years.

An oval jugular tubercle overlies the hypoglossal canal on the superior surface of the occipital condyle. Its posterior part often bears a shallow furrow for the glossopharyngeal, vagus and accessory nerves. A deep groove containing the end of the sigmoid sinus curves anteromedially around a hook-shaped process to end at the jugular notch. The posterior condylar canal opens into the posterior cranial fossa near the medial end of the groove.

Muscle attachments Rectus capitis lateralis attaches to a roughened area on the inferior surface of the jugular process (see Fig. 46.7C).

Ossification

Above the highest nuchal lines, the squamous part of the occipital bone is developed in a fibrous membrane and is ossified from two centres (one on each side) from about postmenstrual week 10. This part of the occipital bone may remain separate as the interparietal bone. The remainder of the occipital bone is preformed in cartilage. Below the highest nuchal lines, the squamous part ossifies from two centres that appear in about postmenstrual week 10 and soon unite. The two components of the squamous part unite during postmenstrual weeks 9–12; the line of their union is recognizable at birth. The remainder of the cartilage of the occipital bone is ossified from five centres: two each for the lateral parts appear during postmenstrual week 11, and one for the basilar part appears around postmenstrual week 9.

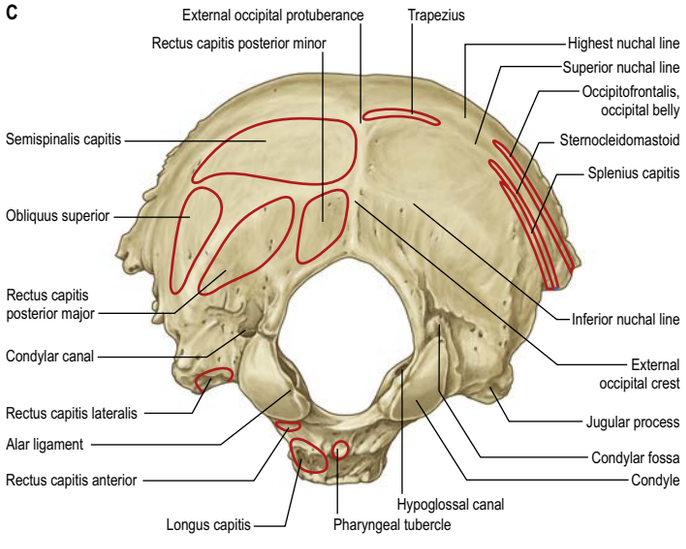


Fig. 46.7 The occipital bone. **A**, External surface. Key: 1, highest nuchal line; 2, superior nuchal line; 3, inferior nuchal line; 4, hypoglossal canal; 5, occipital condyle; 6, external occipital protuberance; 7, lambdoid margin; 8, squamous part; 9, external occipital crest; 10, condylar canal; 11, foramen magnum. **B**, Internal surface. (A, B, With permission from Berkovitz BKB, Moxham BJ 1994 Colour Atlas of the Skull. London: Mosby.)

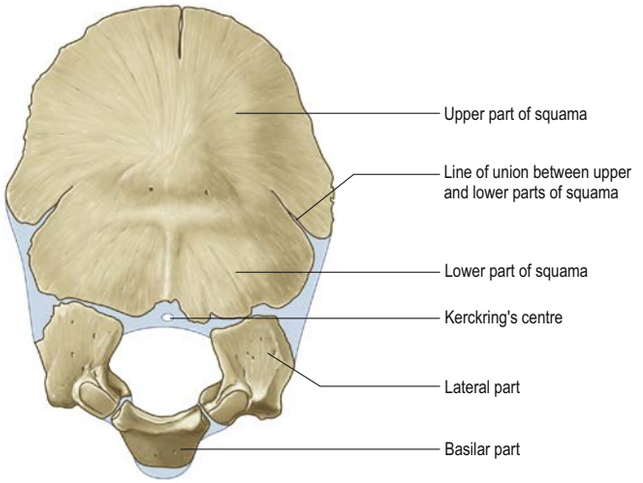

Fig. 46.8 The occipital bone of a neonate, external surface. Parts of the chondrocranium that are still unossified are shown in blue.

At birth, the occipital bone consists of four separate parts (Fig. 46.8) – a basilar part, two lateral parts and a squamous part – all joined by cartilage and forming a ring around the foramen magnum. The squamous and lateral parts fuse together from the second year. The lateral parts fuse with the basilar part during years three and four, but fusion may be delayed until the seventh year.

Vertebral column

The vertebral column is a curved linkage of individual bones or vertebrae (Fig. 46.9). A continuous series of vertebral foramina runs through the articulated vertebrae posterior to their bodies, and collectively constitutes the vertebral canal, which transmits and protects the spinal cord and nerve roots, their coverings and vasculature (Fig. 46.10; see Fig. 47.2). A series of paired lateral intervertebral foramina transmits the spinal nerves and their associated vessels between adjacent vertebrae. The linkages between the vertebrae include cartilaginous interbody joints and paired synovial facet (zygapophysial) joints, together with a complex of ligaments and overlying muscles and fasciae. The muscles directly concerned with vertebral movements and attached to the column lie mainly posteriorly. Several large muscles producing major spinal movements lie distant from the column and without direct attachment to it, e.g. the anterolateral abdominal wall musculature. Movements of the column and the muscles concerned are described on page 840. The column as a whole receives its vascular supply and innervation according to general anatomical principles, which are considered below.

Vertebral column morphology is influenced externally by mechanical and environmental factors and internally by genetic, metabolic and hormonal factors. These all affect its ability to react to the dynamic forces of everyday life, such as compression, traction and shear. These dynamic forces can vary in magnitude and are much influenced by occupation, locomotion and posture.

The adult vertebral column usually consists of 33 vertebral segments. Each presacral segment (except the first two cervical) is separated from its neighbour by a fibrocartilaginous intervertebral disc. The functions of the column are to support the trunk, to protect the spinal cord and nerves, and to provide attachments for muscles. It is also an important site of haemopoiesis throughout life. Its total length in males is about 70 cm and in females about 60 cm. The intervertebral discs contribute about one-quarter of this length in young adults, though there is some diurnal variation in this contribution. Approximately 8% of overall body length is accounted for by the cervical spine, 20% by the thoracic, 12% by the lumbar and 8% by the

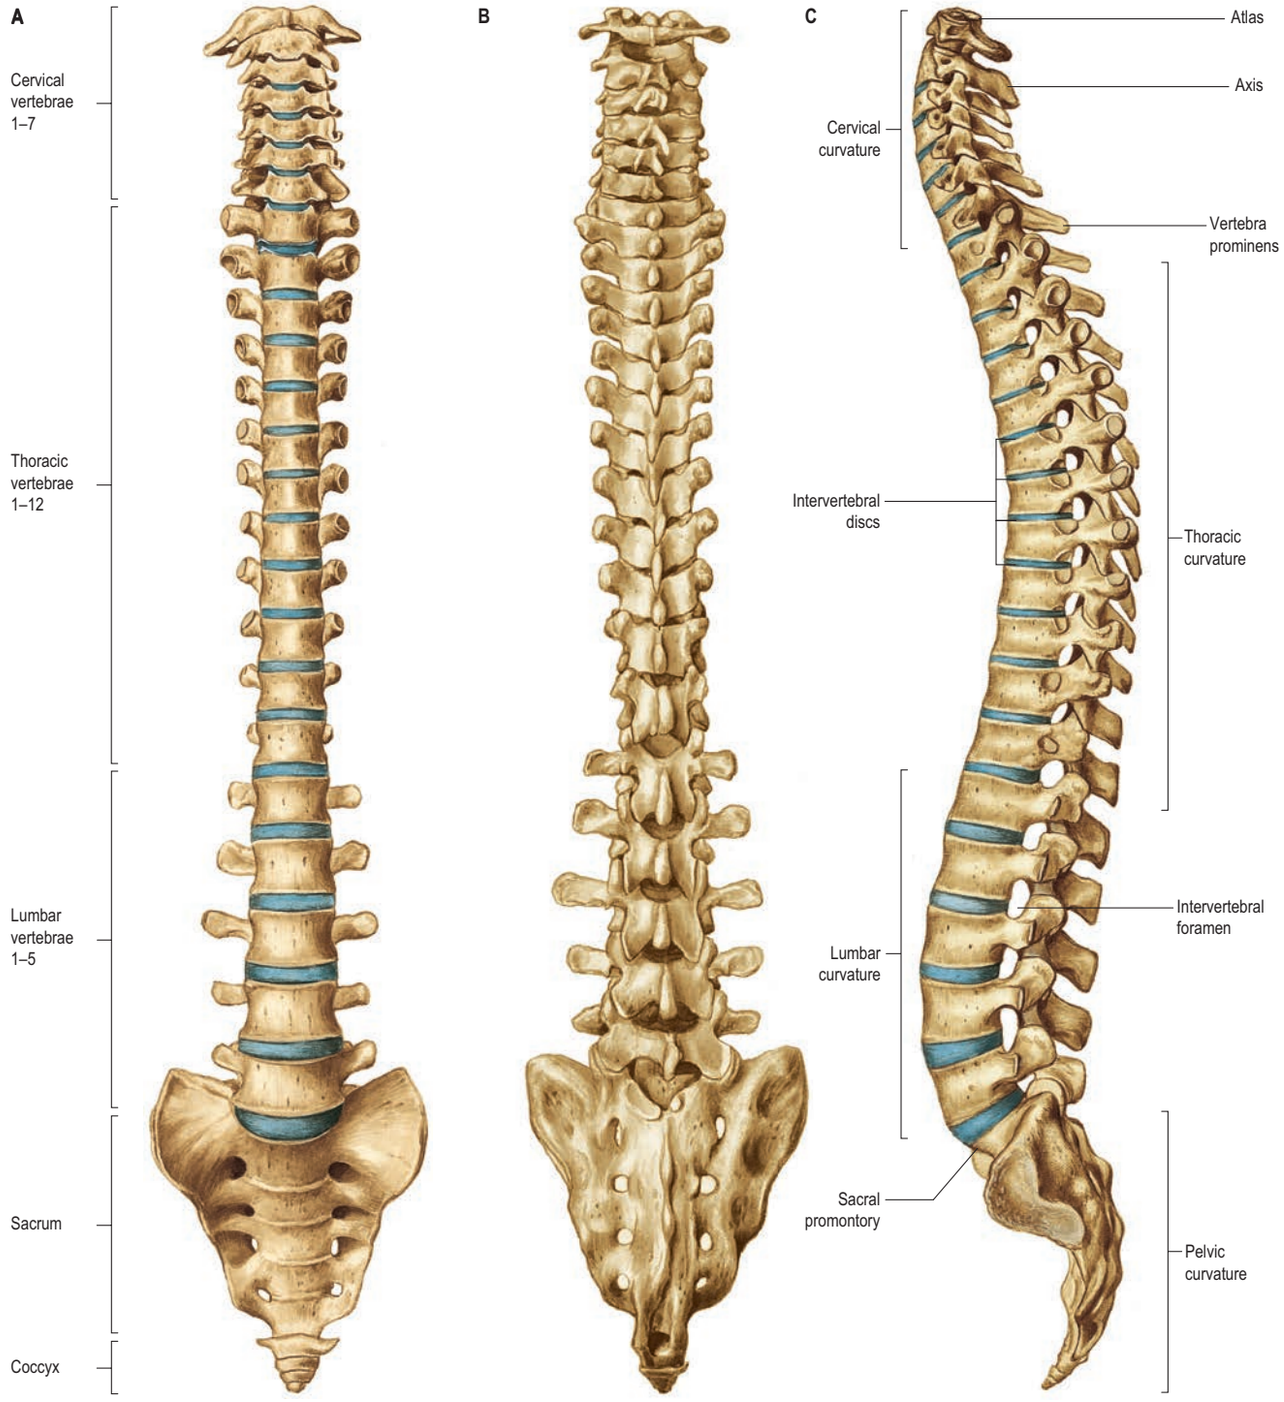

Fig. 46.9 The vertebral column. **A**, Anterior aspect. **B**, Posterior aspect. **C**, Lateral aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

sacrococcygeal regions. Although the usual number of vertebrae is 7 cervical, 12 thoracic, 5 lumbar, 5 sacral and 4 coccygeal, this total is subject to frequent variability, and there have been reports of variation between 32 and 35 bones. The demarcation of groups by their morphological characteristics may be blurred: thus there may be thoracic costal facets on the seventh cervical vertebra, giving it the appearance of an extra thoracic vertebra; lumbar-like articular processes may be found on the lowest thoracic vertebra; or the fifth lumbar vertebra may be wholly or partially incorporated into the sacrum. As a result of these changes in transition between vertebral types, there may be 23–25 mobile presacral vertebrae.

Anterior aspect

The anterior aspect of the column is formed by the anterior surfaces of the vertebral bodies and of the intervertebral discs (see Fig. 46.9A). It has important anatomical relations at all levels and should be considered in continuity. It forms part of several clinically significant junctional or transitional zones, including the prevertebral/retropharyngeal zone of the neck, the thoracic inlet, the diaphragm and the pelvic inlet. The anterior aspect of the column is covered centrally by the anterior longitudinal ligament, which forms a fascial plane with the prevertebral and endothoracic fascia and with the subperitoneal areolar tissue of the posterior abdominal wall. Infection and other pathological processes may spread along this fascial plane.

Lateral aspect

The lateral aspect of the vertebral column is arbitrarily separated from the posterior by articular processes in the cervical and lumbar regions and by transverse processes in the thoracic region (see Fig. 46.9C). Anteriorly, it is formed by the sides of vertebral bodies and intervertebral discs. The oval intervertebral foramina, behind the bodies and between the pedicles, are smallest at the cervical and upper thoracic levels, and increase progressively in size in the thoracic and upper

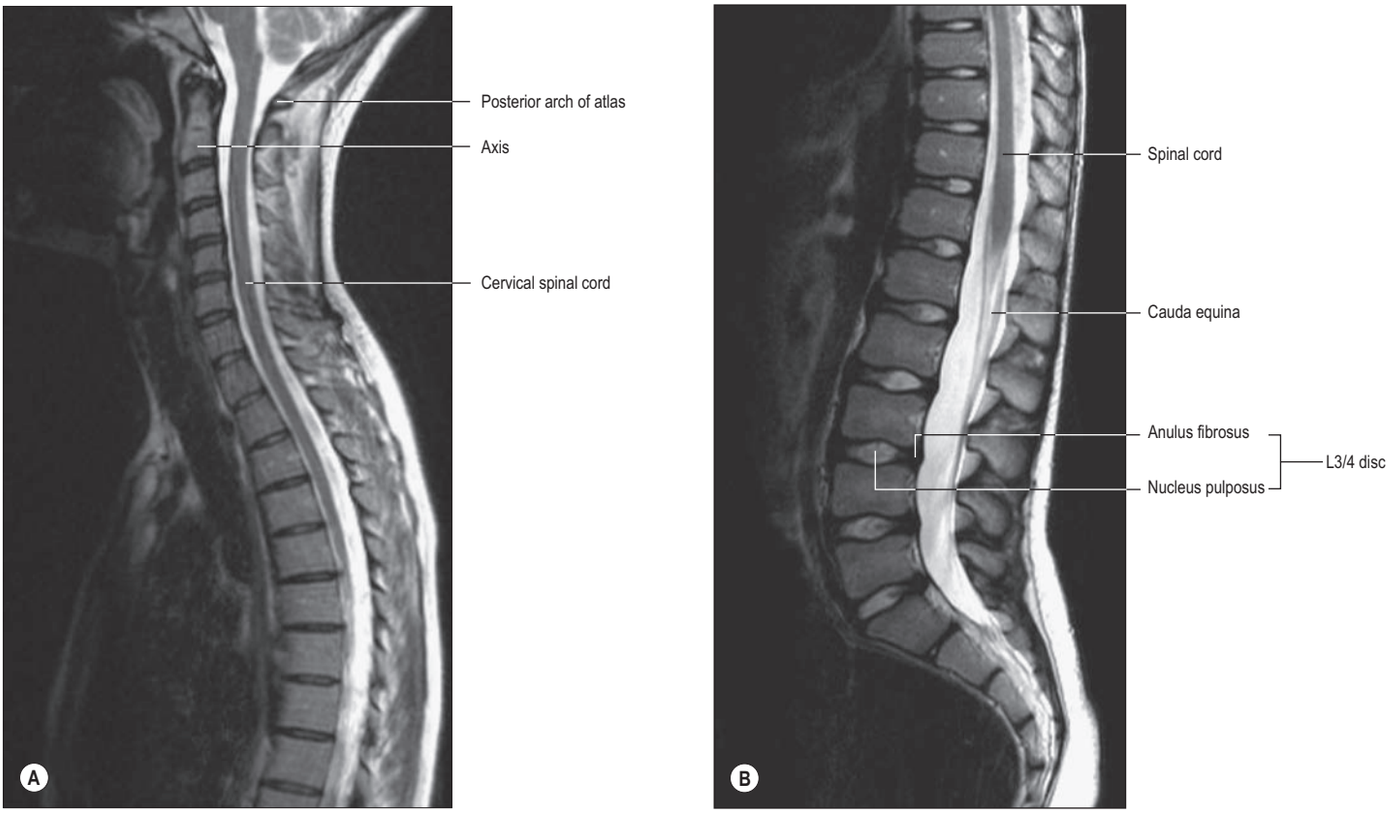

Fig. 46.10 A sagittal magnetic resonance (MR) image of the cervical and upper thoracic (**A**) and lower thoracic and lumbar (**B**) spine.

lumbar regions. The lumbosacral (L5/S1) intervertebral foramen is the smallest of the lumbar foramina (Fig. 46.11). The foramina permit communication between the lumen of the vertebral canal and the paravertebral soft tissues (a 'paravertebral space' is sometimes described), which may be important in the spread of tumours and other pathological processes. The lateral aspects of the column have important anatomical relations, some of which vary considerably between the two sides.

Posterior aspect

The posterior aspect of the column is formed by the posterior surfaces of the laminae and spinous processes, their associated ligaments and the facet joints (Fig. 46.9B). It is covered by the deep muscles of the back.

Structural defects of the posterior bony elements

Deformity and bony deficiency may occur at several sites within the posterior elements. The laminae may be wholly or partially absent, or the spinous process alone may be affected, with no abnormalities in the overlying soft tissues (spina bifida occulta). A defect may occur in the bone that joins the superior and inferior articular processes (pars interarticularis): this condition is spondylolysis, and may be developmental or result from acute or fatigue fracture. If such defects are bilateral, the column becomes unstable at that level, and forward displacement of that part of the column above (cranial to) the defects may occur: this is spondylolisthesis (Fig. 46.12). Abnormality of the laminar bone, or degenerative changes in the facet joints, may also lead to similar displacement in the absence of pars defects. The deformity of the vertebral canal resulting from severe spondylolisthesis may lead to neural compression and subsequent damage (Fig. 46.13). Much more rarely, bony defects may occur elsewhere in the posterior elements, e.g. in the pedicles.

Detailed anatomical relations of all aspects of the vertebral column at the various levels are best appreciated by the study of horizontal (axial) sections and images (see Figs 46.47B and 46.74).

Curvatures

Embryonic and fetal curvatures

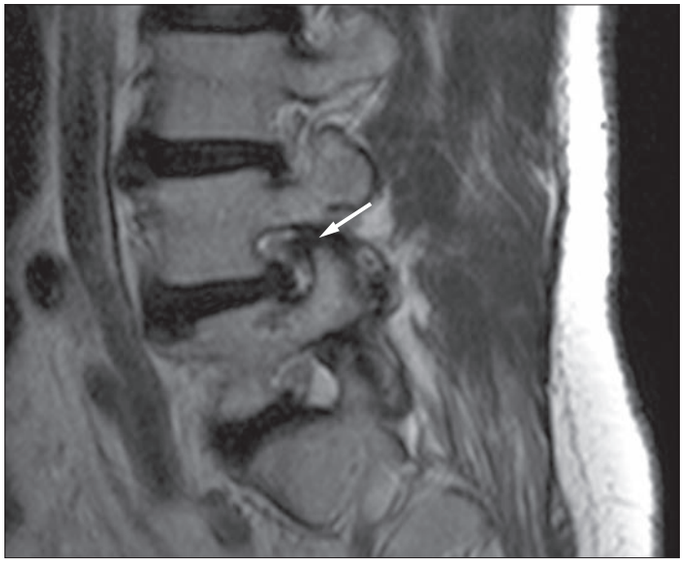
The embryonic body appears flexed, with primary thoracic and pelvic curves that are convex dorsally. The fetal body is affected by the available space for movement, for example, increased flexion of the spine is seen in oligohydramnios (Albequerque et al 2002). The general fetal movements that have been observed from 11–14 postmenstrual weeks may lead to the appearance of secondary spinal curvatures in the sagittal plane (Bagnall et al 1977, Lu et al 2016). A cervical lordosis appears towards the end of the first trimester and reflects the development of function in the muscles responsible for head extension: the early development of a gasp reflex, which involves head extension and flexion of the arms, may be a contributory factor. A lumbosacral lordosis has been demonstrated in fetuses of 23–-40 postmenstrual weeks, but does not appear to be correlated with gestational age, suggesting that it is not related to growth but may be genetically determined (Been and Kalichman 2014).

Neonatal curvatures

In the neonate, the vertebral column has no fixed curvatures. It is particularly flexible and, if dissected free from the body, it can easily be bent (flexed or extended) into a perfect half-circle. A slight sacral curvature can be seen, which develops as the sacral vertebrae ossify and fuse. The thoracic part of the column is the first to develop a relatively fixed curvature, which is concave anteriorly. An infant can usually support its head at 3 or 4 months, sit upright at around 9 months, and will commence walking between 12 and 15 months. These functional changes exert a major influence on the development of the secondary curvatures in the vertebral column and changes in the proportional size of the vertebrae, in particular in the lumbar region. The secondary lumbar curvature becomes important in maintaining the centre of gravity of the trunk over the legs when walking starts, and thus changes in body proportions exert a major influence on the subsequent shape of curvatures in the vertebral column.

Adult curvatures

In adults, the cervical curve is a lordosis (convex forwards), and the least marked. It extends from the atlas to the second thoracic vertebra, with its apex between the fourth and fifth cervical vertebrae. Sexual dimorphism has been described in the cervical curvatures. The thoracic curve is a kyphosis (convex dorsally). It extends between the second and the eleventh and twelfth thoracic vertebrae, and its apex lies between the sixth and ninth thoracic vertebrae. This curvature is caused by the increased posterior height of the thoracic vertebral bodies. The lumbar curve is also a lordosis. It has a greater



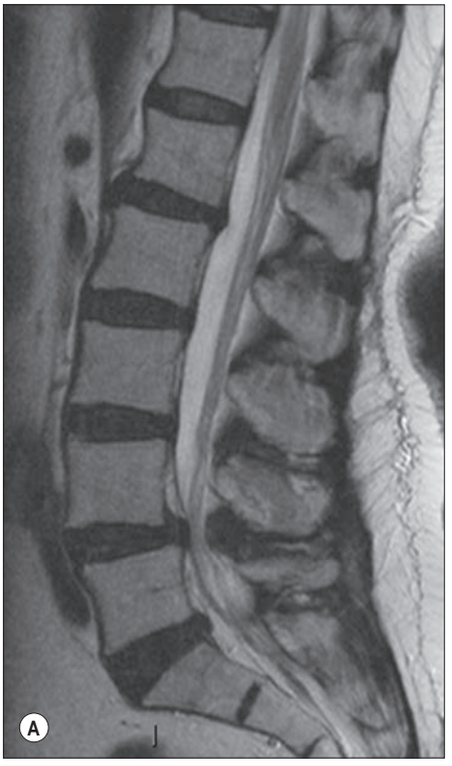


Fig. 46.11 A sagittal MR image of the lumbar spine showing the L5–S1 intervertebral foramen (neuroforamen) and a pathologically narrowed L4–L5 intervertebral foramen (arrow). This narrowing, known as lumbar foraminal stenosis, results in leg pain with an L4 sensory distribution.

Fig. 46.12 A sagittal CT image of the lumbar spine showing the left side of an isthmic spondylolisthesis resulting from bilateral fractures of the pars interarticularis (arrow).

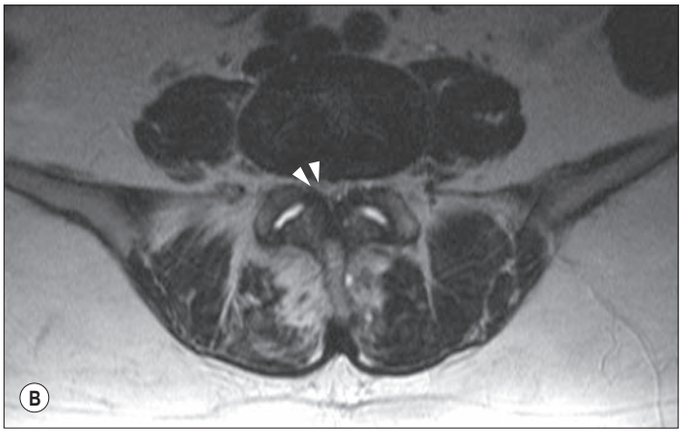

Fig. 46.13 (**A**) Sagittal and (**B**) axial MR images of a degenerative spondylolisthesis at L4–L5. This condition is accompanied by massive superior articular facet hypertrophy and subsequent critical central and lateral recess stenosis (arrowheads).

magnitude in females and extends from the twelfth thoracic vertebra to the lumbosacral angle; there is an increased convexity of the last three segments as a result of the greater anterior height of the intervertebral discs and some posterior wedging of the vertebral bodies. Its apex is at the level of the third lumbar vertebra. The pelvic curve is concave anteroinferiorly and involves the sacrum and coccygeal vertebrae. It extends from the lumbosacral junction to the apex of the coccyx.

The presence of these curvatures means that the cross-sectional profile of the trunk changes with spinal level. The anteroposterior diameter of the thorax is much greater than that of the lower abdomen. In the normal vertebral column, there are well-marked curvatures in the sagittal plane and no lateral curvatures other than in the upper thoracic region, where there is often a slight lateral curvature, convex to the right in right-handed persons, and to the left in the left-handed. Compensatory lateral curvature may also develop to cope with pelvic obliquity, such as that imposed by inequality of leg length. The sagittal curvatures are present in the cervical, thoracic, lumbar and pelvic regions (see Fig. 46.9). These curvatures have developed with rounding of the thorax and pelvis as an adaptation to bipedal gait.

Vertebral column in the elderly

In older people, age-related changes in the structure of bone lead to broadening and loss of height of the vertebral bodies. These changes are more severe in females. The bony changes in the vertebral column are accompanied by changes in the collagen content of the discs and by decline in the activity of the spinal muscles. This leads to progressive decline in vertebral column mobility, particularly in the lumbar spine. The development of a 'dowager's hump' in the mid-thoracic region in females, caused by age-related osteoporosis, increases the thoracic kyphosis and cervical lordosis. Overall, these changes in the vertebral column lead directly to loss of total height in the individual.

As discs desiccate, there is often a straightening of the cervical spine and development of subsequent cervical kyphosis. This, coupled with narrowing of the spinal canal, can lead to increased risk of neurological damage of the cervical spinal cord, in addition to pain.

In mid-lumbar vertebrae, the width of the body increases with age. In males there is a relative decrease of posterior to anterior body height: anterior height decreases relative to width in both males and females. Twomey et al (1983) observed a reduction in bone density of lumbar vertebral bodies with age, principally as a result of a reduction in transverse trabeculae (more marked in females as a result of postmenopausal osteoporosis), which was associated with increased diameter and increasing concavity in their juxtadiscal surfaces (end-plates).

Other changes affect the vertebral bodies. Osteophytes (bony spurs) may form from the compact cortical bone on the anterior and lateral surfaces of the bodies. Although individual variations occur, these changes appear in most individuals from 20 years onwards. They are most common on the anterior aspect of the body and never involve the ring epiphysis. Osteophytic spurs are frequently asymptomatic but may result in diminished movements within the spine.

Vascular supply and lymphatic drainage

Arteries

The vertebral column, its contents and its associated soft tissues all receive their arterial supply from derivatives of dorsal branches of the embryonic intersegmental somatic arteries (see Fig. 13.18). The named artery concerned depends on the level of the column. These intersegmental vessels persist in the thoracic and lumbar regions as the posterior intercostal and lumbar arteries (**Figs 46.14–46.16**). In the cervical and sacral regions, longitudinal anastomoses between the intersegmental vessels persist as longitudinal vessels, which themselves give spinal branches to the vertebral column. In the neck, the postcostal anastomosis becomes most of the vertebral artery, while the post-transverse anastomosis forms most of the deep cervical artery (**Figs 46.17–46.19**). The ascending cervical artery and the lateral sacral artery are persistent parts of the precostal anastomosis.

In the thorax and abdomen, the primitive arterial pattern is retained by the paired branches of the descending aorta, which supply the vertebral column (**Fig. 46.20**; see Fig. 46.14). On each side, the main trunk of the artery (posterior intercostal or lumbar) passes around the vertebral body, giving off primary periosteal and equatorial branches to the body, and then a major dorsal branch. The latter gives off a spinal branch that enters the intervertebral foramen, before itself supplying the facet joints, the posterior surfaces of the laminae and the overlying muscles and skin. There is free anastomosis between these dorsal articular and soft tissue branches, extending over several segments (Crock and Yoshizawa 1976, Boelderl et al 2002). At cervical and sacral levels, the longitudinally running arteries described above have direct spinal branches. The spinal branches are the main arteries of supply to all bony elements of the vertebrae and to the dura and epidural tissues, and also contribute to the supply of the spinal cord and nerve roots via radicular branches. As they enter the vertebral canal, the spinal arteries divide into postcentral, prelaminar and radicular branches. The postcentral branches, which are the main nutrient arteries to the vertebral bodies and to the periphery of the intervertebral discs, anastomose beneath the posterior longitudinal ligament with their fellows above and below, as well as across the midline (**Fig. 46.20B**). This anastomosis also supplies the anterior epidural tissues and dura. The majority of the vertebral arch, the posterior epidural tissues and dura, and the ligamentum flavum are supplied by the prelaminar branches and their anastomotic plexus on the posterior wall of the vertebral canal. (For further reading on the arterial supply and venous drainage of the vertebral column and spinal cord, see Crock (1996), Parke et al (2011).)

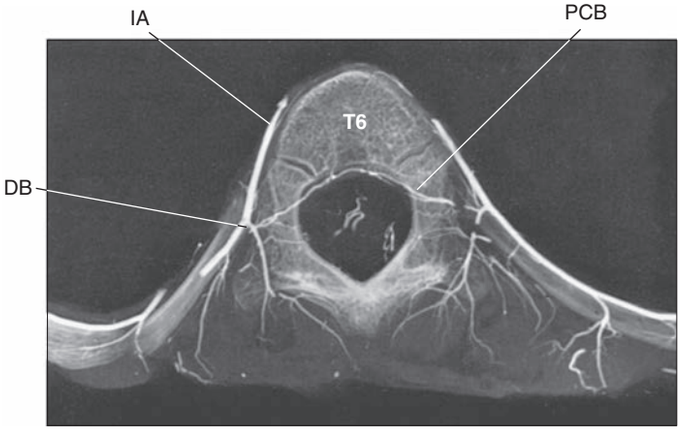

Fig. 46.14 A vertical radiograph of a section through T6 of a specimen from a 6-year-old child injected with barium sulphate. The intercostal arteries (IA) give rise to dorsal branches (DB) that provide spinal branches to the vertebral canal and posterior branches to the arch and dorsal musculature. Posterior central branches (PCB) send vessels into the vertebral body. Note the fine anterior central and anterior laminar and posterior laminar vessels and the neurocentral synchondrosis. (With permission from Parke WW, Bono CM, Garfin SR 2011 Applied anatomy of the spine. In: Herkowitz HN, Garfin SR, Eismont FJ et al (eds) Rothman-Simeone The Spine, 6th ed. Saunders, Elsevier.)

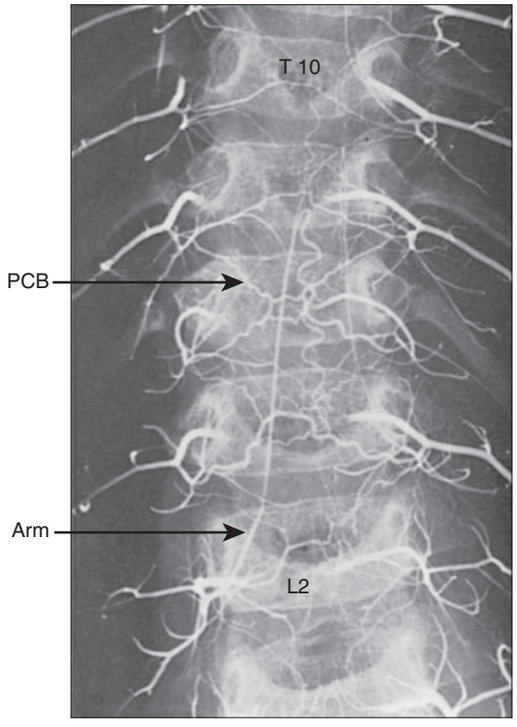

Fig. 46.15 Anteroposterior arteriogram of the lower thoracic and upper lumbar vertebrae in a 6-year-old child injected with barium sulphate. The interlocking anastomotic pattern formed by the posterior central branches (PCB) and the manner in which four branches converge over the centre of the dorsum of the body of each vertebra are well shown. The arteria radicularis magna (Arm) forms a major contribution to the anterior spinal artery of the cord and can be seen arising at L2. (With permission from Parke WW, Bono CM, Garfin SR 2011 Applied anatomy of the spine. In: Herkowitz HN, Garfin SR, Eismont FJ et al (eds) Rothman-Simeone The Spine, 6th ed. Saunders, Elsevier.)

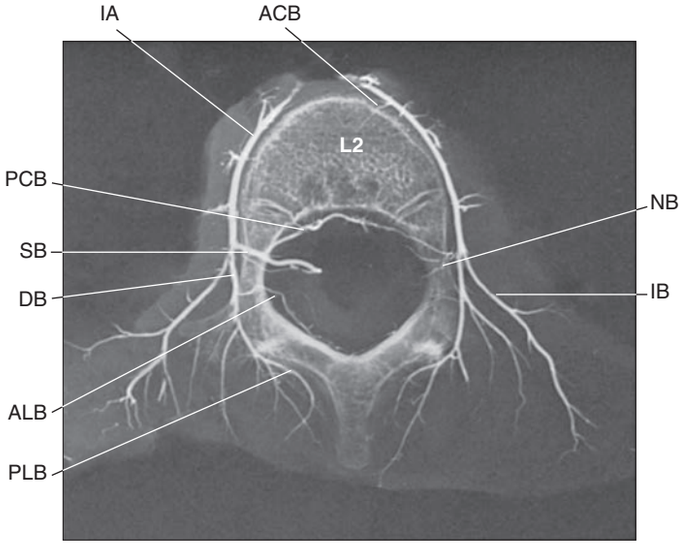

Fig. 46.16 Vertical radiograph of a section through a lumbar vertebra of a 6-year-old child injected with barium sulphate. The vascularity of the lumbar vertebra may be regarded as the archetypal pattern from which other regions evolved variations. The segmental lumbar artery gives rise to numerous anterior central branches (ACB) that penetrate the cortical bone of the body. The spinal branch (SB) sends prominent posterior central branches (PCB) to the dorsum of the body, whereas the dorsal branch (DB) supplies the anterior (ALB) and posterior (PLB) laminar branches. Neural branches (NB) follow the nerve roots to the cord. In this section, the arteria radicularis magna is seen as a neural branch on the right side. Other abbreviations: IA, intercostal arteries; IB, intercostal branches. (With permission from Parke WW, Bono CM, Garfin SR 2011 Applied anatomy of the spine. In: Herkowitz HN, Garfin SR, Eismont FJ et al (eds) Rothman-Simeone The Spine, 6th ed. Saunders, Elsevier.)

Veins

Veins of the vertebral column form intricate plexuses along the entire column, external and internal to the vertebral canal (Fig. 46.21) (Groen et al 2004). Both groups are devoid of valves, anastomose freely with each other, and join the intervertebral veins. Interconnections are widely established between these plexuses and longitudinal veins early in fetal life. When development is complete, the plexuses drain into the caval and azygos/ascending lumbar systems via named veins that accompany the arteries described above.

The veins also communicate with cranial dural venous sinuses and with the deep veins of the neck and pelvis. The venous complexes associated with the vertebral column can dilate considerably, and can form alternative routes of venous return in patients with major venous obstruction in the neck, chest or abdomen. The absence of valves allows pathways for the wide and sometimes paradoxical spread of malignant disease and sepsis. Pressure changes in the body cavities are transmitted through these venous plexuses and thus to the cerebrospinal fluid, though the cord itself may be protected from such congestion by valves in the small veins that drain from the cord into the internal vertebral plexus.

External vertebral venous plexuses

The external vertebral venous plexuses are anterior and posterior. They anastomose freely, and are most developed in the cervical region. Anterior external plexuses are anterior to the vertebral bodies, communicate with basivertebral and intervertebral veins, and receive tributaries from vertebral bodies. Posterior external plexuses lie posterior to the vertebral laminae and around spines and transverse and articular processes. They anastomose with the internal plexuses and join the vertebral, posterior intercostal and lumbar veins.

Internal vertebral venous plexuses

The internal vertebral venous plexuses are embedded in epidural fat, supported by a network of collagenous fibres (Chaynes et al 1998). These thin-walled channels receive tributaries from the bones, red bone marrow and spinal cord. (For the venous drainage of the spinal cord, see Fig. 47.15). They form a denser network than the external plexuses and are arranged vertically as four interconnecting longitudinal vessels: two anterior and two posterior.

The anterior internal plexuses are large plexiform veins on the posterior surfaces of the vertebral bodies and intervertebral discs. They flank the posterior longitudinal ligament, beneath which they are connected by transverse vessels into which the large basivertebral veins open. The posterior internal plexuses, on each side in front of the vertebral arches and ligamenta flava, anastomose with the posterior external plexuses via veins that pass through and between the ligaments. The internal plexuses interconnect by venous rings near each vertebra. Around the foramen magnum, they form a dense network connecting with vertebral veins, occipital and sigmoid sinuses, the basilar plexus, the venous plexus of the hypoglossal canal and the condylar emissary veins.

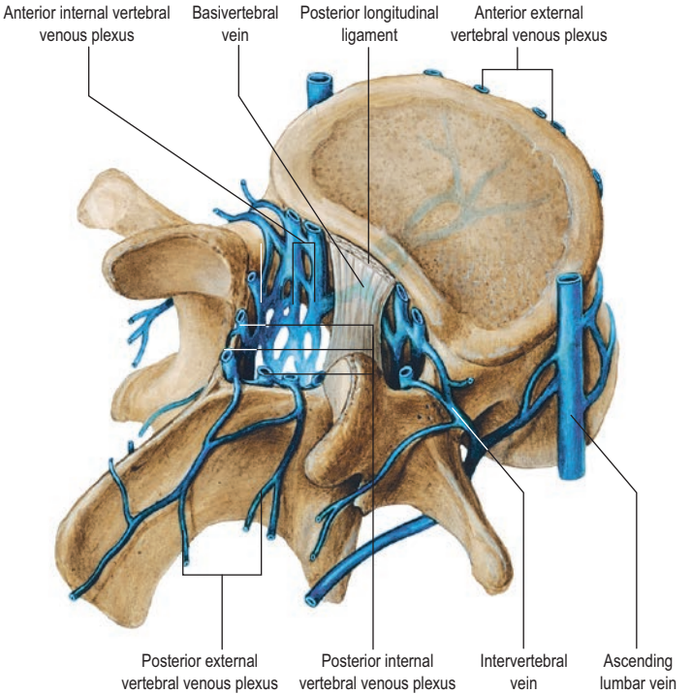

Fig. 46.21 Venous drainage of the vertebral column. Note that the basivertebral vein is shown beneath (i.e. anterior to) the posterior longitudinal ligament. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Basivertebral veins

The basivertebral veins are paired valveless veins that drain the pars spongiosa of the vertebral bodies into the internal and external vertebral venous plexuses. In each segment, they emerge horizontally from foramina in the vertebral bodies. Posteriorly, they drain into the transverse branches of the anterior internal vertebral plexuses. Anteriorly, they drain directly into the anterior external vertebral venous plexus. The basivertebral veins enlarge in advanced age.

Intervertebral veins

Branches of the anterior internal plexuses drain into retrocorporal veins that join the posterior internal venous plexuses to form intervertebral veins. As their name suggests, these veins accompany the spinal nerves through intervertebral foramina; they drain in craniocaudal sequence into the vertebral, posterior intercostal, lumbar and lateral sacral veins. Upper posterior intercostal veins may drain into the caval system via brachiocephalic veins, whereas the lower intercostals drain into the azygos system. Lumbar veins are joined longitudinally in front of the transverse processes by the ascending lumbar veins, in which they may terminate. Alternatively, they may proceed around the vertebral bodies to drain into the inferior vena cava. Whether the basivertebral or intervertebral veins contain effective valves is uncertain, but experimental evidence strongly suggests that their blood flow can be reversed (Batson 1957). This may explain how pelvic neoplasms, e.g. carcinoma of the prostate, may metastasize in vertebral bodies: the cells spread into the internal vertebral plexuses via their connections with the pelvic veins when blood flow is temporarily reversed by raised intra-abdominal pressure or postural alterations (Pearce 2006).

Lymphatic drainage

Little is known in detail about the lymphatic drainage of the vertebral column and its associated soft tissues. In general, deep lymphatic vessels tend to follow the arteries. The cervical vertebral column drains to deep cervical nodes, the thoracic to (posterior) intercostal nodes and the lumbar column to lateral aortic and retro-aortic nodes. The pelvic part of the column drains to lateral sacral and internal iliac nodes.

Innervation

The innervation of the vertebral column and its associated soft tissues has been studied in greatest detail in the lumbar region (see Fig. 46.61). The account given here relies particularly on the work of Bogduk (2012), to whose textbook on the lumbosacral spine the interested reader is referred. See also the work of Groen et al (1990).

Innervation is derived from the spinal nerves where they branch, in and just beyond the intervertebral foramina. There is an input from the sympathetic system either via grey rami communicantes or directly from thoracic sympathetic ganglia. The branches of the spinal nerve concerned are the dorsal ramus and the recurrent meningeal or sinuvertebral nerves (usually more than one at each level) (see Fig. 47.7). The dorsal ramus branches to supply the facet joints, periosteum of the posterior bony elements, overlying muscles and skin. The exact origin and branching pattern of the sinuvertebral nerves is controversial, but they may be best considered as recurrent branches of the ventral rami. They receive the sympathetic input described above, then re-enter the intervertebral foramina to supply the structures that form the walls of the vertebral canal, the dura and epidural soft tissues. Their subsequent course is described on page 867.

Vertebrae: general features

A typical vertebra has a ventral body; a dorsal vertebral (neural) arch, extended by lever-like processes; and a vertebral foramen, which is occupied in life by the spinal cord, meninges and their vessels (Fig. 46.22).

Opposed surfaces of adjacent bodies are bound together by intervertebral discs of fibrocartilage. The complete column of bodies and discs forms the strong but flexible central axis of the body and supports the

Fig. 46.22 The fourth thoracic vertebra, superior aspect. Fig. 46.23 **A**, A median sagittal section through a lumbar vertebra. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.) (B, *continued online*)

full weight of the head and trunk. It also transmits even greater forces generated by muscles attached to it directly or indirectly. The foramina form a vertebral canal for the spinal cord, and between adjoining vertebral arches, near their junctions with vertebral bodies, intervertebral foramina transmit mixed spinal nerves, smaller recurrent nerves, and blood and lymphatic vessels.

The cylindroid vertebral body varies in size, shape and proportions in different regions of the vertebral column. Its superior and inferior (discal) surfaces vary in shape from approximately flat (but not parallel) to sellar, with a raised peripheral smooth zone, formed from an 'anular' epiphysial disc, within which the surface is rough. These differences in texture reflect variations in the early structure of intervertebral discs. In the horizontal plane, the profiles of most bodies are convex anteriorly, but concave posteriorly where they complete the vertebral foramen. Most sagittal profiles are concave anteriorly but flat posteriorly. Small vascular foramina appear on the front and sides, and posteriorly there are small arterial foramina and a large irregular orifice (sometimes double) for the exit of basivertebral veins (Fig. 46.23). The adult vertebral body is not coextensive with the developmental centrum but includes parts of the neural arch posterolaterally.

Viewed anteriorly, there is a cephalocaudal increase in vertebral body width from the second cervical to the third lumbar vertebra, which is associated with an increased load-bearing function. The increase is linear in the neck but not in the thoracic and lumbar regions. There is some variation in size of the last two lumbar bodies, but thereafter width diminishes rapidly to the coccygeal apex. In the two lowest lumbar vertebrae, there is an inverse relation between the areas of the upper and lower surfaces of the bodies and the size of the pedicles and transverse processes.

On each side, the vertebral arch has a vertically narrower ventral part – the pedicle – and a broader lamina dorsally. Paired transverse, superior and inferior articular processes project from their junctions. There is a median dorsal spinous process.

Pedicles are short, thick, rounded dorsal projections from the superior part of the body at the junction of its lateral and dorsal surfaces; the concavity formed by the curved superior border of the pedicle is shallower than the inferior one (see Fig. 46.23). When vertebrae articulate by the intervertebral disc and facet joints, these adjacent vertebral notches contribute to an intervertebral foramen. The complete perimeter of an intervertebral foramen consists of the notches, the dorsolateral aspects of parts of adjacent vertebral bodies and the intervening disc, and the capsule of the synovial facet joint (see Fig. 46.25). The laminae are directly continuous with the pedicles. They are vertically flattened and curve dorsomedially.

Lateral to the spinous processes, vertebral grooves contain the deep dorsal muscles. At cervical and lumbar levels, these grooves are shallow and mainly formed by laminae. In the thoracic region, they are deeper, broader and formed by the laminae and transverse processes. The laminae are broad for the first thoracic vertebra and narrow for the second to seventh, then broaden again from the eighth to eleventh, but become narrow thereafter down to the third lumbar vertebra.

The spinous process (vertebral spine) projects dorsally and often caudally from the junction of the laminae. Spines vary considerably in size, shape and direction. They lie approximately in the median plane and project posteriorly, although in some individuals a minor deflection of the processes to one side may be seen. The spines act as levers for muscles that control posture and active movements (flexion/extension, lateral flexion and rotation) of the vertebral column.

The paired superior and inferior articular processes (zygapophyses) arise from the vertebral arch at the pediculolaminar junctions. The superior processes project cranially, bearing dorsal facets that may also have a lateral or medial inclination, depending on level. Inferior processes run caudally with articular facets directed ventrally, again with a medial or lateral inclination that depends on vertebral level. Articular processes of adjoining vertebrae thus contribute to the synovial zygapophysial or facet joints, and form part of the posterior boundaries of the intervertebral foramina. These joints permit limited movement between vertebrae; mobility varies considerably with vertebral level.

Transverse processes project laterally from the pediculolaminar junctions as levers for muscles and ligaments, particularly those concerned in rotation and lateral flexion. In the cervical region, the transverse processes are anterior to the articular processes, lateral to the pedicles and between the intervertebral foramina. In the thoracic region, they are posterior to the pedicles, considerably behind those of the cervical and lumbar processes. In the lumbar region, the transverse processes are anterior to the articular processes, but posterior to the intervertebral foramina. There is considerable regional variation in the structure and length of the transverse processes. In the cervical region, the transverse process of the atlas is long and broad, which allows the rotator muscles maximum mechanical advantage. Breadth varies little from the second to the sixth cervical vertebra, but increases in the seventh. In thoracic vertebrae, the first is widest, and breadth decreases to the twelfth, where the transverse elements are usually vestigial. The transverse processes become broader in the upper three lumbar vertebrae, and diminish in the fourth and fifth. The transverse process of the fifth lumbar vertebra is the most robust. It arises directly from the body and pedicle to allow for force transmission to the pelvis through the iliolumbar ligament.

The thoracic transverse processes articulate with ribs, but at other levels the mature transverse process is a composite of a 'true' transverse process and an incorporated costal element. Costal elements develop as basic parts of neural arches in mammalian embryos, but become independent only as thoracic ribs. Elsewhere, they remain less developed and fuse with the 'transverse process' of descriptive anatomy (see Fig. 18.11C).

Vertebrae are internally trabecular and have an external shell of compact bone perforated by vascular foramina (see Fig. 46.23). The shell is thin on the superior and inferior body surfaces but thicker in the arch and its processes. The trabecular interior contains red bone marrow and one or two large ventrodorsal canals that contain the basivertebral veins. Pubertal adolescents have higher trabecular bone density than prepubertal children.

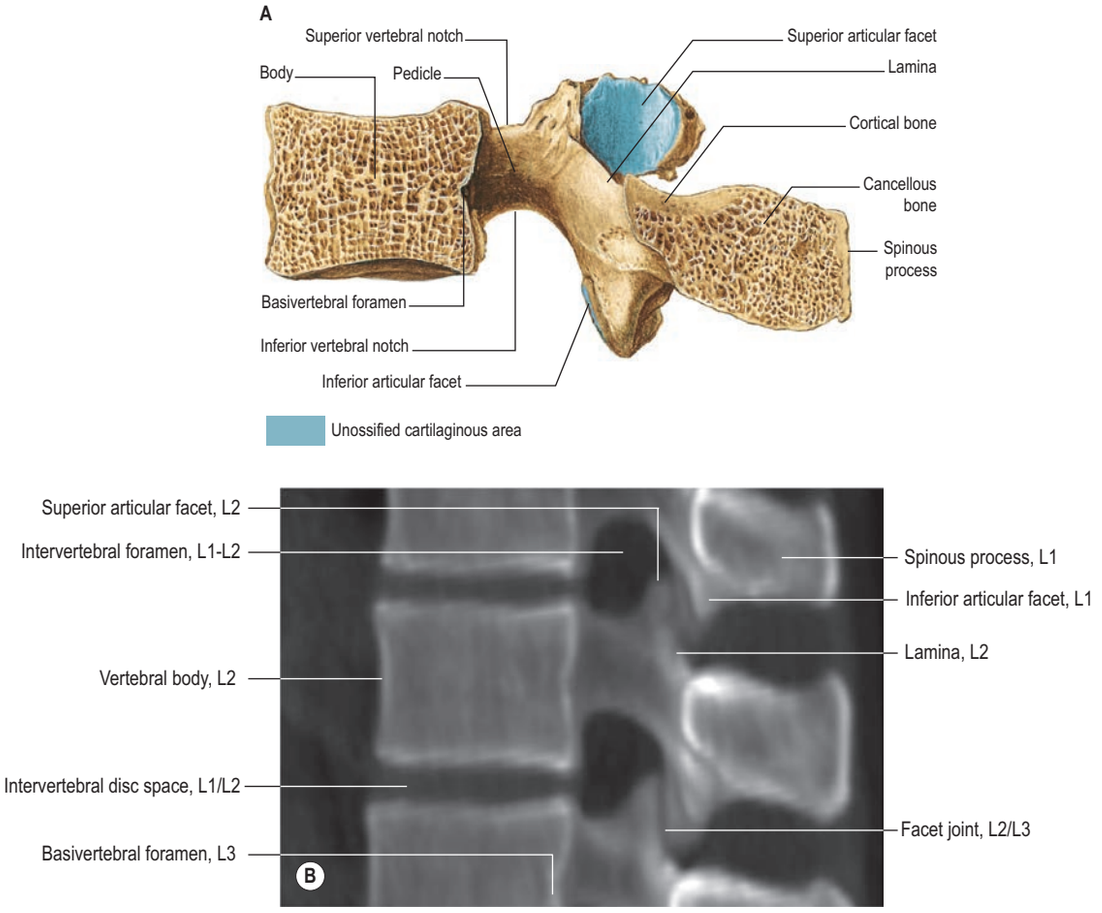

Fig. 46.23 **A**, A median sagittal section through a lumbar vertebra. **B**, A volume rendered sagittal CT slab through the right half of the body of the second lumbar vertebra, viewed from the left; compression trabeculae of the cancellous bone can be seen running vertically in the central aspect of the body. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Sexual dimorphism in vertebrae has received little attention, but Taylor and Twomey (1984) have described radiological differences in adolescent humans and have reported that female vertebral bodies have a lower ratio of width to depth. Vertebral body diameter has also been used as a basis for sex prediction in the analysis of skeletal material (MacLaughlin and Oldale 1992).

Vertebral canal

The vertebral canal (Fig. 46.24) extends from the foramen magnum to the sacral hiatus, and follows the vertebral curves. In the cervical and lumbar regions, which exhibit free mobility, it is large and triangular, but in the thoracic region, where movement is less, it is small and circular. These differences are matched by variations in the diameter of the spinal cord and its enlargements. In the lumbar region, the vertebral canal decreases gradually in size between L1 and L5, with a greater relative width in the female.

For clinical purposes, it is useful to consider the vertebral canal as having three zones. These are a central zone, between the medial margins of the facet joints, and two lateral zones, beneath the facet joints and entering the intervertebral foramina. Each lateral zone, which passes into and just beyond the intervertebral foramen, can be further subdivided into subarticular (lateral recess), foraminal and extraforaminal regions (MacNab and McCulloch 1990). The lateral zone thus described forms the canal of the spinal nerve (the radicular or 'root' canal). The central zone of the canal is a little narrower than the radiological interpedicular distance if the lateral recess is considered to be part of the radicular canal rather than part of the central zone.

Spinal stenosis

Narrowing (stenosis) of the vertebral canal may occur at single or multiple spinal levels, and mainly affects the lumbar and cervical regions. Stenosis may affect the central canal and the 'root canals', either together or separately. There is a developmental form of the condition that mainly affects the central canal but more commonly the stenosis is degenerative, and results from intervertebral disc narrowing and osteoarthritic changes in the facet joints. This latter combination is more likely to narrow the intervertebral foramen and the 'root canal', even though the sectional profile of the vertebral canal in affected lumbar vertebrae typically changes from the shape of a bell to that of a trefoil. The lumbosacral intervertebral foramen, which is normally the smallest in the region, is particularly liable to such stenosis. Severe spinal stenosis may compress the spinal cord and compromise its arterial supply. More localized 'root canal' stenosis will present with the clinical features of spinal nerve compression, but without the tension signs that characterize the stretching of nerve roots over a prolapsed disc. Ischaemia of the nerves and roots may provoke more damage than the actual physical compression of the neural tissue.

Intervertebral foramina

Intervertebral foramina are the principal routes of entry to and exit from the vertebral canal, and are closely related to the main intervertebral articulations. (Minor routes occur between the median, often partly fused, margins of the ligamenta flava.) The same general arrangement applies throughout the vertebral column, between the axis and sacrum, although there are some quantitative and structural regional variations. Because of their construction, contents and susceptibilities to multiple disorders, the intervertebral foramina are loci of great biomechanical, functional and clinical significance. The specializations cranial to the axis and at sacral levels are described with the individual bones and articulations.

The boundaries of a generalized intervertebral foramen (Fig. 46.25) are, anteriorly, from above downwards, the posterolateral aspect of the superior vertebral body, the posterolateral aspect of the intervertebral symphysis (including the disc), and a small (variable) posterolateral part of the body of the inferior vertebra; superiorly, the compact bone of the deep arched inferior vertebral notch of the vertebra above; inferiorly, the compact bone of the shallow superior vertebral notch of the vertebra below; and posteriorly, a part of the ventral aspect of the fibrous capsule of the facet synovial joint. Cervical intervertebral foramina are distinct in having superior and inferior vertebral notches of almost equal depth, which, in accord with the direction of the pedicles, face anterolaterally. External to them, and oriented in the same direction, is a transverse process. The thoracic and lumbar intervertebral foramina face laterally and their transverse processes are posterior. In addition, the anteroinferior boundaries of the first to tenth thoracic foramina are formed by the articulations of the head of a rib and the capsules of double synovial joints (with the demifacets on adjacent vertebrae and the intra-articular ligament between the costocapitular ridge and the intervertebral symphysis). Lumbar foramina lie between the two principal lines of vertebral attachment of psoas major. The walls of each foramen are covered throughout by fibrous tissue, which is in turn periosteal (though the presence of a true periosteum lining the vertebral canal is controversial: Newell (1999)), perichondrial, anular and capsular. The more lateral parts of the foramina may be crossed at a variable level by narrow fibrous bands, the transforaminal ligaments (for detail of these ligaments, see Bogduk (2012)). The true foramen is the foraminal region of the canal of the spinal nerve (the radicular or 'root' canal). A foramen contains a segmental mixed spinal nerve and its sheaths, from two to four recurrent meningeal (sinuvertebral) nerves, variable numbers of spinal arteries, and plexiform venous connections between the internal and external vertebral venous plexuses. These structures, particularly the nerves, may be affected by trauma or one of the many disorders that may affect tissues bordering the foramen. In particular, nerve compression and irritation may be caused by intervertebral disc prolapse, or by bony entrapment as the size of the foramen decreases (Fig. 46.26). This decrease may result from facet joint osteoarthritis, osteophyte formation, disc degeneration and degenerative spondylolisthesis, all of which may lead to lateral or foraminal spinal stenosis.

Cervical vertebrae

The cervical vertebrae (Figs 46.27–46.28) are the smallest of the moveable vertebrae, and are characterized by a foramen in each transverse process. The first, second and seventh have special features and will be considered separately. The third, fourth and fifth cervical are almost identical, and the sixth, while typical in its general features, has minor distinguishing features.

Typical cervical vertebra

A typical cervical vertebra (Figs 46.29–46.30) has a small, relatively broad vertebral body. The pedicles project posterolaterally and the longer laminae posteromedially, enclosing a large, roughly triangular vertebral foramen; the vertebral canal here accommodates the cervical enlargement of the spinal cord. The pedicles attach midway between the discal surfaces of the vertebral body, so the superior and inferior vertebral notches are of similar depth. The laminae are thin and slightly curved, with a thin superior and slightly thicker inferior border. The spinous process ('spine') is short and bifid, with two tubercles that are often unequal in size. The junction between lamina and pedicle bulges laterally between the superior and inferior articular processes to form an articular pillar ('lateral mass') on each side. The transverse process is morphologically composite around the foramen transversarium. Its dorsal and ventral bars terminate laterally as corresponding tubercles. The tubercles are connected, lateral to the foramen, by the costal (or intertubercular) lamella; these three elements represent morphologically the capitellum, tubercle and neck of a cervical costal element (see Fig. 18.11C). The attachment of the dorsal bar to the pediculolaminar junction represents the morphological transverse process, and the attachment of the ventral bar to the ventral body represents the capitellar process. In all but the seventh cervical vertebra, the foramen transversarium normally transmits the vertebral artery and vein and a branch from the cervicothoracic ganglion (vertebral nerve).

The vertebral body has a convex anterior surface. The discal margin gives attachment to the anterior longitudinal ligament. The posterior surface is flat or minimally concave, and its discal margins give attachment to the posterior longitudinal ligament. The central area displays several vascular foramina, of which two are commonly relatively larger. These are the basivertebral foramina, which transmit basivertebral veins to the anterior internal vertebral plexus. The superior discal surface is saddle-shaped, formed by flange-like lips, uncinate processes, which arise from most of the lateral circumference of the upper margin of the vertebral body. Uncinate processes are rudimentary at birth and are usually found on the third to seventh cervical vertebra in the adult. The uncinate processes on the vertebra below articulate with the corresponding bevelled surfaces on the inferior aspect of the vertebra above. Whether uncovertebral joints are synovial joints has proved controversial since their description by von Luschka in 1858; the demonstration of synoviocytes in the lateral joint capsule tissue of elderly uncovertebral joints suggests that they should be regarded as synovial joints (Hartman 2014) (see Fig.

46.59). The inferior discal surface is also concave; the concavity is produced mainly by a broad projection from the anterior margin, which partly overlaps the anterior surface of the intervertebral disc. The discal surfaces of cervical vertebrae are so shaped in order to restrict both lateral and anteroposterior gliding movements during articulation. The paired ligamenta flava extend from the superior border of each lamina below to the roughened inferior half of the anterior surfaces of the lamina above. The superior part of the anterior surface of each lamina is smooth, like the immediately adjacent surfaces of the pedicles, which are usually in direct contact with the dura mater and cervical root sheaths to which they may become loosely attached. The spinous process of the sixth cervical vertebra is larger and is often not bifid.

The superior articular facets, flat and ovoid, are directed superoposteriorly, whereas the corresponding inferior facets are directed mainly anteriorly, and lie nearer the coronal plane than the superior facets. In children, facet joint angle decreases until 10 years of age and remains unchanged thereafter (Kasai et al 1996). The dorsal rami of the cervical spinal nerves curve posteriorly, close to the anterolateral aspects of the lateral masses, and may actually lie in shallow grooves, especially on the third and fourth pairs. The dorsal root ganglion of each cervical spinal nerve lies between the superior and inferior vertebral notches of adjacent vertebrae. The large anterior ramus passes posterior to the vertebral artery, which lies on the concave upper surface of the costal lamella; the concavity of the lamellae increases from the fourth to the sixth vertebra. The fourth to sixth anterior tubercles are elongated and rough for muscle attachment. The sixth, the carotid tubercle (Chassaignac's tubercle), is the longest (**Fig. 46.31**). The carotid artery can be forcibly compressed in the groove formed by the vertebral bodies and the larger anterior tubercles, especially the sixth. The posterior tubercles are rounded and more laterally placed than the anterior, and all but the sixth are also more caudal; the sixth is at about the same level as the anterior.

Muscle attachments The ligamentum nuchae and numerous deep extensors, including semispinalis thoracis and cervicis, multifidus, spinales and interspinales, are all attached to the spinous processes. Tendinous slips of scalenus anterior, longus capitis and longus colli are attached to the fourth to sixth anterior tubercles. Splenius, longissimus and iliocostalis cervicis, levator scapulae and scalenus posterior and

medius are all attached to the posterior tubercles. Shallow anterolateral depressions on the anterior surface of the body lodge the vertical parts of longus colli.

Ossification Cervical vertebrae ossify according to the standard vertebral pattern described in Chapter 18. Incomplete segmentation ('block vertebra') is common in the cervical spine and most commonly involves the axis and third cervical vertebra. There is a general caudal to cranial gradient in the growth of ossification centres and closure of synchondroses in the atlas and axis (Karwacki and Schneider 2012).

Atlas, C1

The atlas, the first cervical vertebra (Fig. 46.32), supports the head. It is unique in that it fails to incorporate a centrum, whose expected

position is occupied by the dens, a cranial protuberance from the axis. The atlas consists of two lateral masses connected by a short anterior and a longer posterior arch. The transverse ligament retains the dens against the anterior arch.

The transverse ligament divides the vertebral canal into two compartments (Fig. 46.33). The anterior third (approximately) of the canal is occupied by the dens. The posterior compartment is occupied by the

spinal cord and its coverings, and the cord itself takes up about half of this space (i.e. the cord, like the dens, occupies one-third of the canal).

The anterior arch is slightly convex anteriorly, and carries a roughened anterior tubercle to which is attached the anterior longitudinal ligament (which is cylindrical at this level). Its upper and lower borders provide attachment for the anterior atlanto-occipital membrane and diverging lateral parts of the anterior longitudinal ligament. The posterior surface of the anterior arch carries a concave, almost circular, facet for the dens.

The lateral masses are ovoid, their long axes converging anteriorly. Each bears a kidney-shaped superior articular facet for the respective occipital condyle, which is sometimes completely divided into a larger anterior and a smaller posterior part (Lang 1986). The inferior articular facet of the lateral mass is almost circular and is flat or slightly concave. It is orientated more obliquely to the transverse plane than the superior facet, and faces more medially and very slightly backwards. On the medial surface of each lateral mass is a roughened area that bears vascular foramina and a tubercle for attachment of the transverse ligament. In adults, the distance between these tubercles is shorter than the transverse ligament itself, with a mean value of approximately 16 mm.

The posterior arch forms three-fifths of the circumference of the atlantal ring. The superior surface bears a wide groove for the vertebral artery and venous plexus immediately behind, and is variably overhung by the lateral mass; the first cervical nerve intervenes. The flange-like superior border gives attachment to the posterior atlanto-occipital membrane, and the flatter inferior border to the highest pair of ligamenta flava. The posterior tubercle is a rudimentary spinous process, roughened for attachment of the ligamentum nuchae.

The transverse processes are longer than those of all cervical vertebrae except the seventh (see Fig. 46.27). They act as strong levers for the muscles that make fine adjustments to keep the head balanced. Maximum atlantal width varies from 74 to 95 mm in males and 65 to 76 mm in females, and this affords a useful criterion for assessing sex in human remains. The apex of the transverse process, which is usually broad, flat and palpable between the mastoid process and ramus of the mandible, is homologous with the posterior tubercle of typical cervical vertebrae; the remaining part of the transverse process consists of the costal lamella. A small anterior tubercle is sometimes visible on the anterior aspect of the lateral mass. The costal lamella is sometimes deficient, which leaves the foramen transversarium open anteriorly.

Muscle attachments The superior oblique parts of longus colli are attached on each side of the anterior tubercle. The anterior surface of the lateral mass gives attachment to rectus capitis anterior. Rectus capitis posterior minor is attached just lateral to the posterior tubercle. Rectus capitis lateralis is attached to the transverse process superiorly, and obliquus capitis superior is located more posteriorly. Obliquus capitis inferior is attached laterally on the apex, below which are slips of levator scapulae, splenius cervicis and scalenus medius.

Ossification The atlas is commonly ossified from three centres arising from postmenstrual week 10 (Fig. 46.34). One appears in each lateral mass from postmenstrual week 10 onwards, gradually extending into the posterior arch where they unite between the third and fourth years, usually directly but occasionally through a separate centre. At birth, the anterior arch is fibrocartilaginous, and a separate centre appears about the end of the first year. This unites with the lateral masses between the sixth and eighth years, the lines of union extending across anterior parts of the superior articular facets. Occasionally, the anterior arch is formed by the extension and ultimate union of centres in the lateral masses and sometimes from two lateral centres in the arch itself.

The central part of the posterior arch may be absent and replaced by fibrous tissue. Frequently, bony spurs arise from the anterior and posterior margins of the groove for the vertebral artery. These are sometimes referred to as ponticles; they occasionally convert the

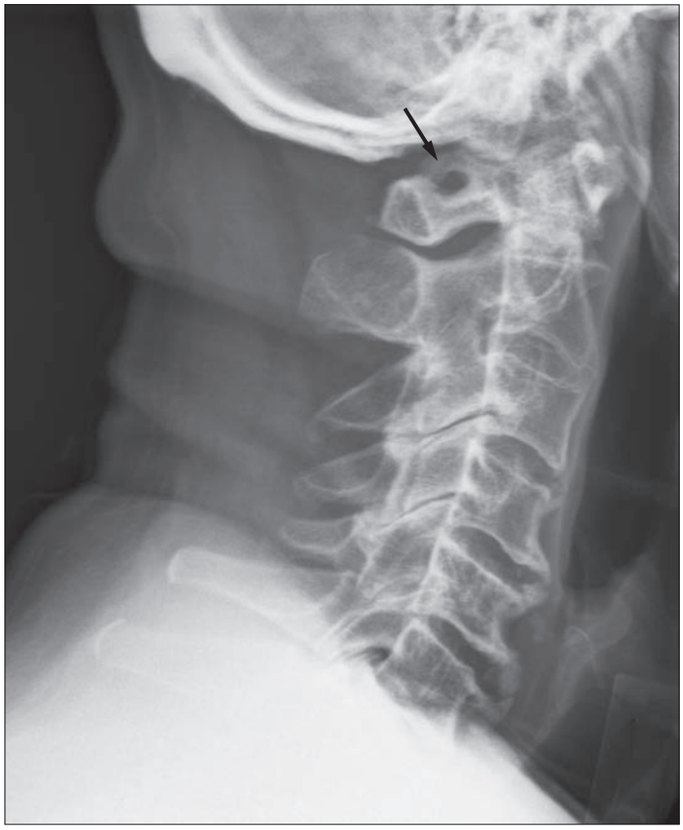

Fig. 46.35 A lateral cervical radiograph demonstrating a posterior ponticle forming the roof of a tunnel over the vertebral artery (arrow).

groove into a foramen, the arcuate foramen or posticus ponticus (Fig. 46.35), which may increase the risk of injury to the vertebral artery in surgical procedures involving the C1 arch (Klimo et al 2007). More often, the foramen is incomplete superiorly. Rarely, the atlas may be wholly or partially assimilated into (fused with) the occiput.

Axis, C2

The axis, the second cervical vertebra (Figs 46.36–46.37), acts as an axle for rotation of the atlas and head around the strong dens (odontoid process), which projects cranially from the superior surface of the body.

The dens is conical in shape with a mean length of 15 mm in adults. It may be tilted a little, up to 14°, posteriorly or, less often, anteriorly on the body of the axis; it may also tilt laterally up to 10°. The posterior surface bears a broad groove for the transverse ligament, which is covered in cartilage. The apex is pointed, and from this point arises the apical ligament. The alar ligaments are attached to the somewhat flattened posterolateral surfaces above the groove for the transverse ligament. The anterior surface bears an ovoid articular facet for the anterior arch of the atlas, and the surface is pitted by many vascular foramina, which are most numerous near the apex.

The body consists of less compact bone than the dens. It is composite, and consists of the partly fused centra of the atlas and axis, and a rudimentary disc (synchondrosis) between them, which usually remains detectable deep within the body of the axis throughout life. Large ovoid articular facets are present on either side of the dens at the junction of the body and vertebral arch; they are flat or slightly convex for articulation with the masses of the atlas. The facets lie in a plane anterior to the plane of the uncovertebral (Luschka) articulations, with which they are, in part, homologous. The somewhat triangular, downward-projecting anterior border gives attachment to the anterior longitudinal ligament. Posteriorly, the lower border receives the posterior longitudinal ligament and the membrana tectoria.

The pedicles are stout, and the superior surface carries part of the superior articular facet, which also projects laterally and downwards on to the transverse process. The anterolateral surface is deeply grooved by the vertebral artery, running beneath the thin lateral part of the inferior surface of the superior articular facet, which can become quite thin. The inferior surface of each pedicle bears a deep, smooth inferior intervertebral notch, in which the large root sheath of the third cervical nerve lies. The interarticular part of the pedicle is short and lies between the relatively small inferior posterior articular process (which is located at the pediculolaminar junction and bears a small anteriorly facing facet) and the superior articular surface.

The transverse process is pointed, projects inferiorly and laterally, and arises from the pediculolaminar junction and the lateral aspect of the interarticular area of the pedicle. The rounded tip is homologous with the posterior tubercle of a typical cervical vertebrae. The foramen transversarium is directed laterally as the vertebral artery turns abruptly laterally under the superior articular facet. Small anterior tubercles may be present near the junction of the costal lamella with the body.

The laminae are thick and give attachment to the ligamenta flava.

The spinous process is large, with a bifid tip and a broad base, which is concave inferiorly. The ligamentum nuchae is attached to the apical notch.

Muscle attachments The anterior surface of the body carries a deep depression on each side for the attachment of the vertical part of longus colli. Levator scapulae, scalenus medius and splenius cervicis are all attached to the tips of the transverse processes, and the intertransverse muscles are attached to their upper and lower surfaces. The lateral surfaces of the spinous process give origin to obliquus capitis inferior, and rectus posterior major is attached a little more posteriorly. The inferior concavity of the process receives semispinalis and spinalis cervicis, multifidus more deeply, and the interspinales near the apex.

Arterial supply Small branches arise mainly from the vertebral artery at the level of the intervertebral foramen for the third cervical nerve and form paired anterior and posterior longitudinal channels, branches of which enter the dens near the base and near the apex. The anterior channel also receives numerous twigs from nearby branches of the external carotid artery via branches to longus colli and the ligaments of the apex; hence avascular necrosis does not occur after fracture of the base of the dens.

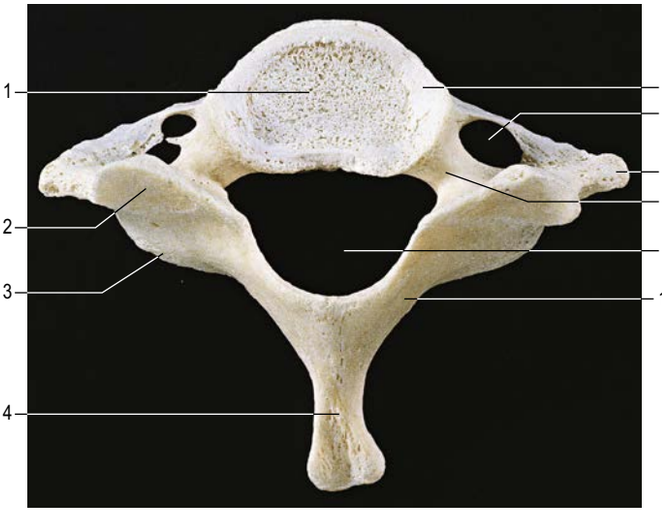

Fig. 46.40 The seventh cervical vertebra, superior aspect. Key: 1, body; 2, superior articular facet; 3, inferior articular process; 4, spinous process; 5, uncinate process; 6, foramen transversarium (foramina are asymmetric in this specimen); 7, transverse process; 8, pedicle; 9, vertebral foramen; 10, lamina.

Ossification The axis is ossified from five primary and two secondary centres (see Fig. 46.34). The vertebral arch has two primary centres and the centrum one, as in a typical vertebra. The former appear from about postmenstrual week 10, and that for the centrum during postmenstrual weeks 13–20. The dens is largely ossified from bilateral centres, identified from postmenstrual week 16 and joining before birth to form a conical mass, deeply cleft above by cartilage. This cuneiform cartilage forms the apex of the odontoid process. A centre appears in it which shows considerable individual variation in both time of appearance and time of fusion to the rest of the dens; it most often appears between 5 and 8 years, but sometimes even later, fusing with the main mass in about the twelfth year. The cartilage was thought to be part of the cranial sclerotomal half of the first cervical segment or pro-atlas. It has also been suggested that the apical centre for the dens is itself derived from the pro-atlas, which may also contribute to lateral atlantal masses. The dens is separated from the body by a cartilaginous disc, the circumference of which ossifies while its centre remains cartilaginous until old age; possible rudiments of adjacent epiphyses of atlas and axis may occur in the disc. A thin epiphysial plate is formed inferior to the body around puberty.

Ossification may sometimes be incomplete. Thus the apical cuneiform centre may fail to fuse with the dens, or the dens itself may fail to fuse with the body, instead forming an os odontoideum (Fig. 46.38). This is likely to result from minor trauma in early childhood causing disruption of the developing dens rather than being a congenital failure (Klimo et al 2007). Interposition of the transverse ligament may prevent union of fractures through the base of the dens (Fig. 46.39). Hypoplasia of the dens is usually accompanied by atlanto-occipital assimilation and basilar invagination. Abnormalities of the dens are common, and can result in atlanto-axial subluxation. In some skeletal dysplasias there is abnormal ossification in which the dens ossifies separately and much later than the atlantal centrum. This is probably a result of abnormal mobility in the cartilaginous anlage, and normal ossification may be restored if motion is prevented by surgical fusion.

Seventh cervical vertebra, vertebra prominens, C7

The seventh cervical vertebra, the vertebra prominens (Fig. 46.40), has a long spinous process that is visible at the lower end of the nuchal furrow. It ends in a prominent tubercle for the attachment of the ligamentum nuchae and the muscles detailed below. The thick and prominent transverse processes lie behind and lateral to the foramina transversaria. The latter transmit vertebral veins but not the vertebral artery, and each is often divided by a bony spicule. The costal lamella is relatively thin and may be partly deficient. It is grooved superiorly for the anterior ramus of the seventh cervical nerve and usually carries a small and inconspicuous anterior tubercle. The posterior tubercle is prominent. The suprapleural membrane is attached to the anterior border of the transverse process.

Fig. 46.38 A sagittal CT scan reconstructed image demonstrating an os odontoideum (arrow).

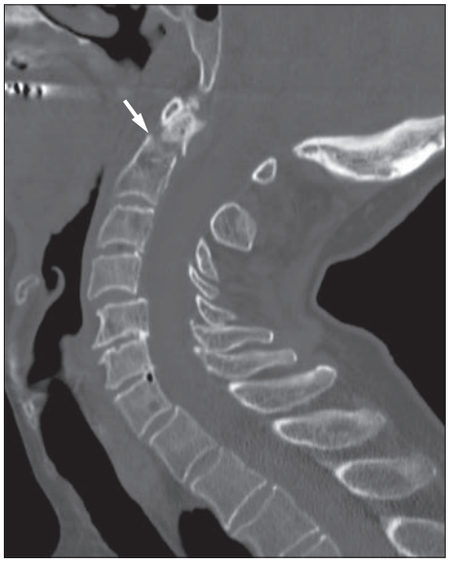

Fig. 46.39 A sagittal CT scan reconstructed image of a type II odontoid fracture (arrow). These fractures involve the base of the dens and have a high non-union rate.

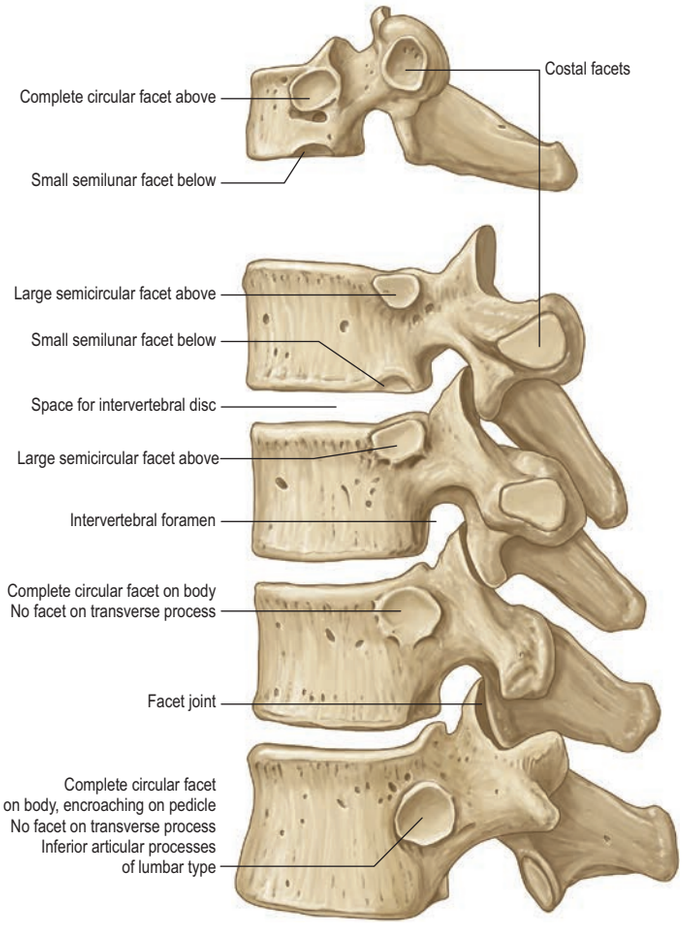

Fig. 46.41 The first, ninth, tenth, eleventh and twelfth thoracic vertebrae, lateral aspect.

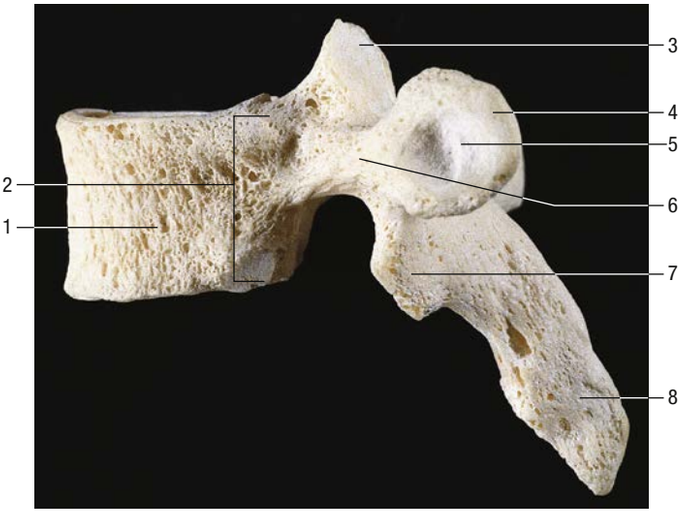

Fig. 46.42 The fourth thoracic vertebra, lateral aspect. Key: 1, body; 2, costocapitular demifacets; 3, superior articular facet; 4, transverse process; 5, costotubercular facet; 6, pedicle; 7, inferior articular process; 8, spinous process.

The costal lamella of the transverse process may be separate as a cervical rib. The foramina transversaria may be asymmetric; sometimes one is absent if the costal lamella is undeveloped.

Muscle attachments Trapezius, spinalis capitis, semispinalis thoracis, multifidus and interspinales all attach to the tubercle of the spinous process. The anterior border of the transverse process receives the attachment of scalenus minimus (pleuralis), when present. The first pair of levatores costarum is attached to the transverse processes.

Ossification Ossific centres for the costal processes appear between postmenstrual weeks 21 and 24 and join the body and transverse processes between the fifth and sixth years; they may remain separate and grow anterolaterally as cervical ribs. Separate ossific centres may, on occasion, also occur in the costal processes of the fourth to sixth cervical vertebrae.

Thoracic vertebrae

Thoracic vertebrae in general

All thoracic vertebral bodies display lateral costal facets and all but the lowest two or three transverse processes also have facets (Fig. 46.41). The facets articulate with the head of the rib (costocapitular facet) and its tubercle (costotubercular facet), respectively.

The body is typically a waisted cylinder (Fig. 46.42) except where the vertebral foramen encroaches, and transverse and anteroposterior dimensions are almost equal. On each side there are two costal facets (which are really demifacets): the superior and usually larger pair at the upper border are anterior to the pedicles, while the inferior pair at the lower border are anterior to the vertebral notches. The vertebral foramen (see Fig. 46.22) is small and circular, so the pedicles do not diverge as they do in cervical vertebrae; the thoracic spinal cord is smaller and more circular than the cervical cord. The laminae are short, thick and broad, and overlap from above downwards. The spinous process slants downwards. The thin and almost flat superior articular processes project from the pediculolaminar junctions and face posteriorly and a little superolaterally. The inferior processes project down from the laminae and their facets are directed forwards and a little superomedially. The large, club-like transverse processes also project from the pediculolaminar junctions. Each passes posterolaterally and bears, near its tip, anterior oval facets for articulation with the tubercle of the corresponding rib.

The bodies of upper thoracic vertebrae gradually change from cervical to thoracic in type, and the lower change from thoracic to lumbar. The body of the first is typically cervical, its transverse diameter being almost twice the anteroposterior; the second retains a cervical shape but its two diameters differ less. The third body is the smallest, and has a convex anterior aspect unlike the flattened first and second thoracic vertebrae. The remaining bodies increase in size and, because of its increased anteroposterior diameter, the fourth is typically 'heart-shaped'. The fifth to eighth increase their anteroposterior dimension but change little transversely. These four, in transverse section, are asymmetric, their left sides being flattened by pressure of the thoracic aorta. The rest increase more rapidly in all measurements, so that the body of the twelfth resembles that of a typical lumbar vertebra. These modifications may contribute to the greater range of flexion–extension seen at the cervical and lumbar ends of the thoracic vertebral column.

The anterior and posterior longitudinal ligaments are attached to the borders of the bodies. The capsular and radiate ligaments of the costovertebral joints are attached around the margins of the costal facets.

The dimensions and angles of thoracic pedicles change progressively from the upper thoracic spine distally: there is a successive caudal increase in thickness. These changing relationships have a significant bearing on the placement of pedicle screws in spinal surgery (Wood 2013). The superior vertebral notch is recognizable only in the first thoracic vertebra, whereas the inferior notch is deep in all. Ligamenta flava are attached at the upper borders and lower anterior surfaces of the laminae.

Thoracic transverse processes shorten in caudal succession. In the upper five or six vertebrae, the costal facets are concave and face anterolaterally, and at lower levels the facets are flatter and face superolaterally and slightly forwards. The costotransverse ligament is attached to the anterior surface medial to the facet; the lateral costotransverse ligament is attached to its tuberculated apex and the superior costotransverse ligament is attached to its lower border.

Thoracic spines overlap from the fifth to the eighth vertebra, whose spine is the longest and most oblique. Supraspinous and interspinous ligaments are attached to the spines.

The first and ninth to twelfth thoracic vertebrae

The first and ninth to twelfth thoracic vertebrae display additional atypical features. The first thoracic vertebra (see Fig. 46.41) resembles a cervical vertebra in its body, both in shape and in the distinctive posterolateral 'lipping' that forms the anterior border of the superior vertebral notch. There are circular superior costal facets for articulation with the whole facet on the head of the first rib. The smaller, semilunar inferior facets articulate with a demifacet on the head of

the second rib. The upper costal facet is often incomplete, in which case the first rib articulates with the seventh cervical vertebra and the intervening disc. A small, deep depression often occurs below the facet. The long, thick spine is horizontal and commonly as prominent as that of the seventh cervical vertebra. The ninth vertebra (see Fig. 46.41) often fails to articulate with the tenth ribs, in which case the inferior demifacets are absent. The tenth thoracic vertebra (see Fig. 46.41) only articulates with the tenth pair of ribs, so that superior facets only appear on the body. These are usually large and semilunar, but are oval when the tenth ribs fail to articulate with the ninth vertebra and intervening disc. The transverse process may or may not bear a facet for the tubercle of the tenth rib. The eleventh thoracic vertebra (see Fig. 46.41) articulates only with the heads of the eleventh ribs. The circular costal facets are close to the upper border of the body and extend on to the pedicles. The small transverse processes lack articular facets. The eleventh and twelfth thoracic spinous processes are triangular, with blunt apices and a horizontal lower and an oblique upper border. The twelfth thoracic vertebra (see Fig. 46.41) articulates with the heads of the twelfth ribs by circular facets somewhat below the upper border, spreading on to the pedicles. The body is large and the vertebra has some lumbar features. The transverse process is replaced by three small tubercles: the superior is largest, projects upwards and corresponds to a lumbar mammillary process, though it does not lie as close to the superior articular process; the lateral tubercle is the homologue of a transverse process; and the inferior is the homologue of a lumbar accessory process. The superior and inferior processes are surprisingly long in some specimens.

A change in orientation of articular processes from thoracic to lumbar type usually occurs at the eleventh thoracic vertebra, but sometimes at the twelfth or tenth. In the transitional vertebra the superior articular processes are thoracic, and face posterolaterally, while the inferior are transversely convex and face anterolaterally. The transitional vertebra marks the site of a sudden change of mobility from predominantly rotational to predominantly flexion–extension.

Muscle attachments Longus colli arises from the upper three thoracic vertebral bodies, lateral to the anterior longitudinal ligament, and psoas major and minor arise from the sides of the twelfth near its lower border. Upper and lower borders of the transverse processes provide attachment for the intertransverse muscles or their fibrous vestiges. The posterior surfaces of the transverse processes provide attachment for the deep dorsal muscles, and levator costae is attached posteriorly on the apex. Trapezius, rhomboid major and minor, latissimus dorsi, serratus posterior superior and inferior, and many deep dorsal muscles are attached to the spines. Rotatores attach to the posterior aspects of the laminae.

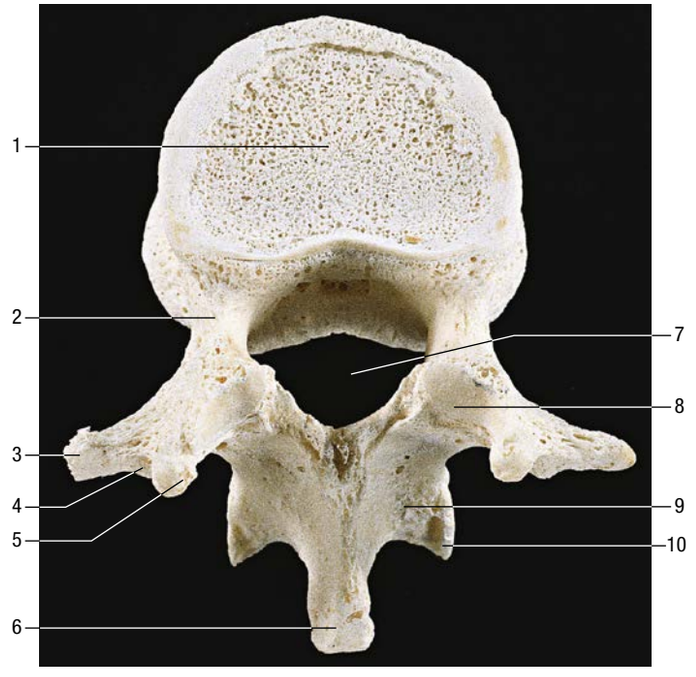

Fig. 46.43 The first lumbar vertebra, superior aspect. Key: 1, body; 2, pedicle; 3, transverse process; 4, accessory process; 5, mammillary process; 6, spinous process; 7, vertebral foramen; 8, superior articular facet; 9, lamina; 10, inferior articular facet.

Ossification Thoracic vertebrae all ossify according to the standard vertebral pattern described in Chapter 18.

Lumbar vertebrae

Lumbar vertebrae in general

The five lumbar vertebrae are distinguished by their large size and the absence of costal facets and transverse foramina. The body is wider transversely (**Fig. 46.43**; see Fig. 46.47B). The vertebral foramen is triangular, larger than at thoracic levels but smaller than at cervical levels. The pedicles are short. The spinous process is almost horizontal, quadrangular and thickened along its posterior and inferior borders. The superior articular processes bear vertical concave articular facets facing posteromedially, with a rough mammillary process on their posterior borders (**Fig. 46.44A**). The inferior articular processes have vertical convex articular facets that face anterolaterally. The transverse processes are thin and long, except on the more substantial fifth pair. A small accessory process marks the posteroinferior aspect of the root of each transverse process. The accessory and mammillary processes are linked by a fine ligament, the mammillo-accessory ligament, which is sometimes ossified, and beneath which runs the medial branch of the dorsal primary ramus of the spinal nerve (Bogduk 2012).

Strong paired pedicles arise posterolaterally from each body near its upper border. Superior vertebral notches are shallow and the inferior ones are deep. The laminae are broad and short, but do not overlap as much as those of the thoracic vertebrae. The fifth spine is the smallest, and its apex is often rounded and down-turned. Upper lumbar superior articular processes are further apart than inferior ones, but the difference is slight in the fourth and negligible in the fifth. The articular facets are reciprocally concave (superior) and convex (inferior), which allows flexion, extension, lateral bending and some degree of rotation. There are sex differences in the angle of inclination and depth of curvature of the articular facets. The facets are sometimes asymmetric.

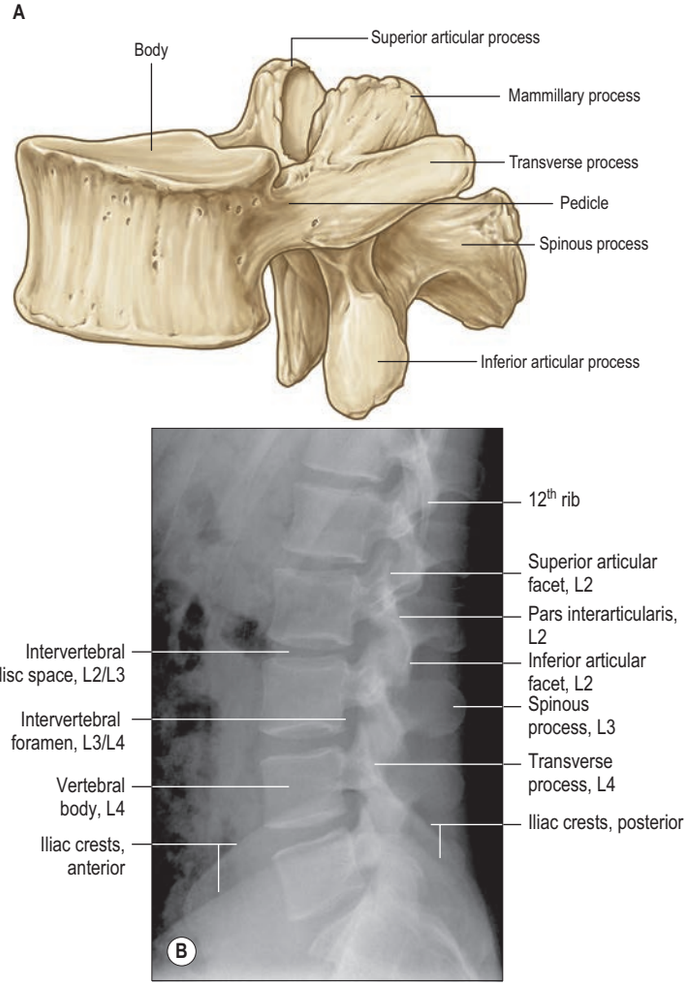

Fig. 46.44 The lumbar spine. **A**, A typical lumbar vertebra, lateral aspect. **B**, Lateral radiograph of the lumbar spine.

Transverse processes, except the fifth, are anteroposteriorly compressed and project posterolaterally. The lower border of the fifth transverse process is angulated, and passes laterally and then superolaterally to a blunt tip; the whole process presents a greater upward inclination than the fourth. The angle on the inferior border may represent the tip of the costal element and the lateral end the tip of the true transverse process. The lumbar transverse processes increase in length from first to third and then shorten (**Fig. 46.45**). The fifth pair incline both upwards and posterolaterally. The costal element is incorporated in the mature transverse process.

On average, the adult spinal cord ends at the level of the middle third of the body of the first lumbar vertebra, which means that the first lumbar vertebral foramen usually contains the conus medullaris. The cord may terminate above or below this level (Saifuddin et al 1998) (Ch. 47); lower lumbar vertebral foramina contain the cauda equina and spinal meninges (**Fig. 46.46**; see Fig. 46.10B). Variation occurs in the sagittal and coronal dimensions of the lumbar vertebral canal, both within and between normal populations.

The fifth lumbar vertebra (**Fig. 46.47**) has a massive transverse process that is continuous with the whole of the pedicle and encroaches on the body. The body is usually the largest and markedly deeper anteriorly, so contributing to the lumbosacral angle.

Segmentation anomalies (sacralization) are considered below with the sacrum. The costal element of the first lumbar vertebra may form a short lumbar rib, which articulates with the transverse process, but not usually with the body, of the vertebra.

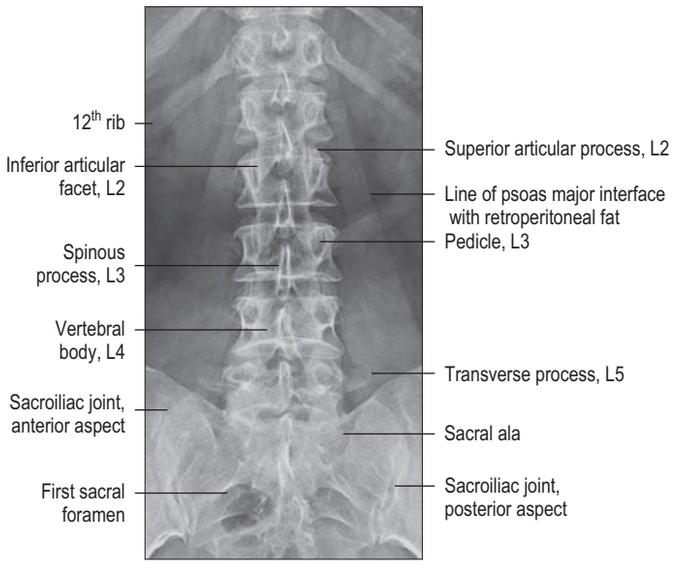

Fig. 46.45 An anteroposterior radiograph of the lumbar spine.

Muscle and fascial attachments Upper and lower borders of lumbar bodies give attachment to the anterior and posterior longitudinal ligaments. The upper bodies (three on the right, two on the left) give attachments to the crura of the respiratory diaphragm lateral to the anterior longitudinal ligament. Posterolaterally, psoas major is attached to the upper and lower margins of all the lumbar bodies, and between them, tendinous arches carry its attachments across their concave sides (see Fig. 61.7). The posterior lamella of the thoracolumbar fascia, erectores spinae, spinales thoracis, multifidi, interspinal muscles and ligaments, and supraspinous ligaments are all attached to spinous processes. All lumbar transverse processes present a vertical ridge on the anterior surface, nearer the tip, which marks the attachment of the anterior layer of the thoracolumbar fascia, and separates the surface into medial and lateral areas for psoas major and quadratus lumborum, respectively. The middle layer of the fascia is attached to the apices of the transverse processes; the medial and lateral arcuate ligaments attach to the vertical ridge on the anterior aspect of the first pair, and the iliolumbar ligament attaches to the apices of the fifth pair. Posteriorly, the transverse processes are covered by deep dorsal muscles, and fibres of longissimus thoracis are attached to them and to their accessory processes. The ventral lateral intertransverse muscles are attached to their upper and lower borders, while the dorsal attach cranially to the accessory process and caudally to the upper border of the transverse process. The mammillary process, homologous with the superior tubercle of the twelfth thoracic vertebra, gives attachment to multifidus and the medial intertransverse muscle. The latter also attaches to the accessory process, which is sometimes difficult to identify.

Ossification Lumbar vertebrae ossify according to the standard vertebral pattern described in Chapter 18 but also have two additional centres for the mammillary processes. A pair of scale-like epiphyses usually appear on the tips of the costal elements of the fifth lumbar vertebra (see Fig. 46.34C).

Sacrum

The sacrum is a large, triangular fusion of five vertebrae and forms the posterosuperior wall of the pelvic cavity, wedged between the two hip (innominate) bones (see Fig. 77.8). Its blunted, caudal apex articulates with the coccyx and its superior, wide base with the fifth lumbar vertebra at the lumbosacral angle. It is set obliquely and curved longitudinally, the dorsal surface is convex, and the pelvic surface is concave; this ventral curvature increases pelvic capacity (**Figs 46.48–46.51**). Between base and apex are dorsal, pelvic and lateral surfaces and a sacral canal. In childhood, individual sacral vertebrae are connected by cartilage, and the adult bone retains many vertebral features. The sacrum

consists of trabecular bone enveloped by a shell of compact bone of varying thickness.

Base The base (see Fig. 46.48) is the upper surface of the first sacral vertebra, the least modified from the typical vertebral plan. The body is large and wider transversely, and its anterior projecting edge is the sacral promontory. The vertebral foramen is triangular; its pedicles are short and diverge posterolaterally. The laminae are oblique, inclining down posteromedially to meet at a spinous tubercle. The superior articular processes project cranially, with concave articular facets directed posteromedially to articulate with the inferior articular processes of the fifth lumbar vertebra. The posterior part of each process projects backwards and its lateral aspect bears a rough area homologous with a lumbar mammillary process.

The transverse process is much modified as a broad, sloping mass that projects laterally from the body, pedicle and superior articular process. It is formed by the fusion of the transverse process and the costal element to each other and to the rest of the vertebra, and forms the upper surface of the sacral lateral mass or ala.

Terminal fibres of the anterior and posterior longitudinal ligaments are attached to the ventral and dorsal surfaces of the first sacral body. Its upper laminar borders receive the lowest pair of ligamenta flava. The ala is smooth superiorly, concave medially and rough laterally, and covered almost entirely by psoas major. The smooth area is grooved obliquely by the lumbosacral trunk. The rough area is for the lower band of the iliolumbar ligament, which lies lateral to the fifth lumbar spinal nerve and to the anterior sacroiliac ligament.

Pelvic surface The anteroinferior pelvic surface (see Fig. 46.49) is vertically and transversely concave, but the second sacral body may produce a convexity. Four pairs of pelvic sacral foramina communicate with the sacral canal through intervertebral foramina, and transmit ventral rami of the upper four sacral spinal nerves. The large area between the right and left foramina, which is formed by the flat pelvic aspects of the sacral bodies, bears evidence of their fusion at four transverse ridges. The longitudinal bars between the foramina are costal elements, which fuse to the vertebrae. Lateral to the foramina, the costal elements unite. Posteriorly, they unite with the transverse processes to form the lateral part of the sacrum, which expands basally as the ala.

The first three sacral ventral rami emerge from the pelvic sacral foramina and pass anterior to piriformis. The sympathetic trunks descend in contact with bone, medial to the foramina, as do the median sacral vessels in the midline. Lateral to the foramina, lateral sacral vessels are related to bone. Ventral surfaces of the first, second and part of the third sacral bodies are covered by parietal peritoneum and crossed obliquely, left of the midline, by the attachment of the sigmoid mesocolon. The rectum is in contact with the pelvic surfaces of the third to fifth sacral vertebrae and with the bifurcation of the superior rectal artery between the rectum and third sacral vertebra.

Dorsal surface The posterosuperior aspect of the dorsal surface bears a raised, interrupted, median sacral crest with four (sometimes three) spinous tubercles, which represent fused sacral spines (see Fig. 46.50). Below the fourth (or third) tubercle there is an arched sacral hiatus in the posterior wall of the sacral canal. This hiatus is produced by the failure of the laminae of the fifth sacral vertebra to meet in the median plane, and as a result the posterior surface of the body of that vertebra is exposed on the dorsal surface of the sacrum. Flanking the median crest, the posterior surface is formed by fused laminae, and lateral to this are four pairs of dorsal sacral foramina. Like the pelvic foramina, they lead into the sacral canal through intervertebral foramina, and each transmits the dorsal ramus of a sacral spinal nerve. Medial to the foramina, and vertically below each articular process of the first sacral vertebra, is a row of four small tubercles, which collectively constitute the intermediate sacral crest. These are sometimes termed articular tubercles, and represent fused contiguous articular processes. The inferior articular processes of the fifth sacral vertebra are free and project downwards at the sides of the sacral hiatus as sacral cornua, connected to coccygeal cornua by intercornual ligaments. The interrupted roughened crest to the lateral side of the dorsal sacral foramina is the lateral sacral crest, which is formed by fused transverse processes, whose apices appear as a row of transverse tubercles.

The upper three sacral spinal dorsal rami pierce multifidus as they emerge via dorsal foramina.

Lateral surface The lateral surface (**Fig. 46.51A**) is a fusion of transverse processes and costal elements. It is wide above and rapidly narrows in its lower part. The broad upper part bears an auricular surface for articulation with the ilium, and the area posterior to this is rough and deeply pitted by the attachment of ligaments. The auricular surface, borne by costal elements, is like an inverted letter L. The shorter, cranial limb is restricted to the first sacral vertebra; the caudal limb descends to the middle of the third. Beyond this, the lateral surface is non-articular and reduced in breadth. Caudally, it curves medially to the body of the fifth sacral vertebra at the inferior lateral angle, beyond which the surface becomes a thin lateral border. A variable accessory sacral articular facet sometimes occurs, posterior to the auricular surface.

The auricular surface is covered by hyaline cartilage, and formed entirely by costal elements. It shows cranial and caudal elevations and

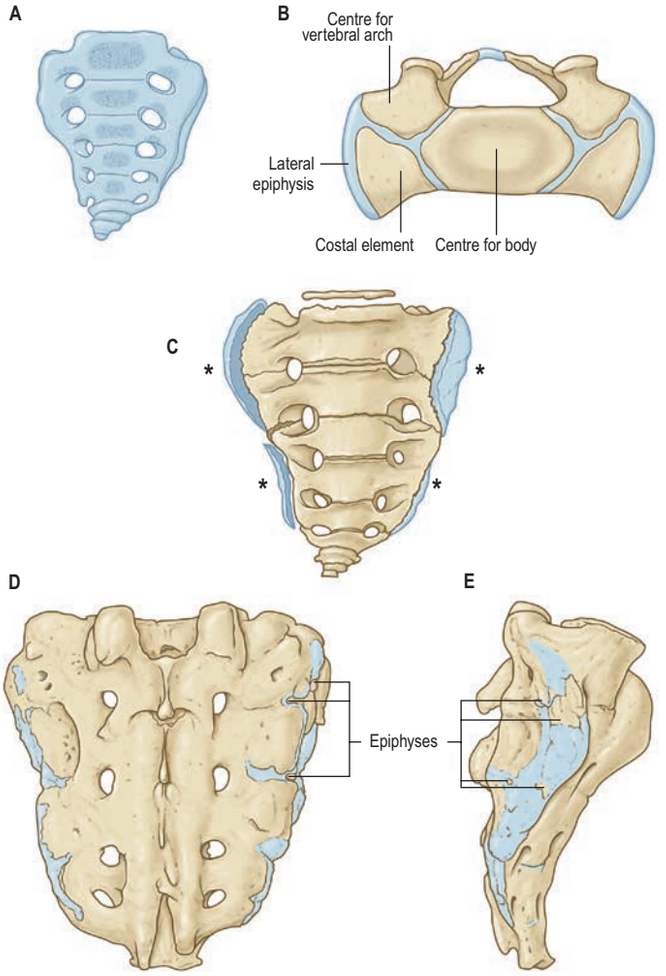

Fig. 46.52 Ossification of the sacrum and coccyx. **A**, At birth. **B**, The base of the sacrum of a child about 4 years old. **C**, At the twenty-fifth year: epiphysial plates for each lateral surface are marked by asterisks. **D–E**, The epiphyses of the costal and transverse process of the sacrum at the eighteenth year.

an intermediate depression, behind which a third elevation is visible in the elderly. The surface becomes more corrugated with age. The rough area behind the auricular surface shows two or three marked depressions for the attachment of strong interosseous sacroiliac ligaments. Below the auricular surface the sacrotuberous and sacrospinous ligaments are attached between gluteus maximus dorsally and coccygeus ventrally.

Apex The apex is the inferior aspect of the fifth sacral vertebral body, and bears an oval facet for articulation with the coccyx.

Sacral canal The sacral canal (Fig. 46.51B) is formed by sacral vertebral foramina, and is triangular in section (see Fig. 46.48). Its upper opening, seen on the basal surface, appears to be set obliquely. The inclination of the sacrum means that it is directed cranially in the standing position. Each lateral wall presents four intervertebral foramina, through which the canal is continuous with pelvic and dorsal sacral foramina. Its caudal opening is the sacral hiatus. The canal contains the cauda equina and the filum terminale, and the spinal meninges. Opposite the middle of the sacrum, the subarachnoid and subdural spaces close; the lower sacral spinal roots and filum terminale pierce the arachnoid and dura mater at that level. The filum terminale with its meningeal coverings emerges below the sacral hiatus and passes downwards across the dorsal surface of the fifth sacral vertebra and sacrococcygeal joint to reach the coccyx. The fifth sacral spinal nerves also emerge through the hiatus medial to the sacral cornua, and groove the lateral aspects of the fifth sacral vertebra.

Muscle attachments The pelvic surface gives attachment to piriformis in its second to fourth segments, to iliacus superolaterally, and to coccygeus inferolaterally. The dorsal surface gives attachment to the aponeurosis of erector spinae along a U-shaped area of spinous and

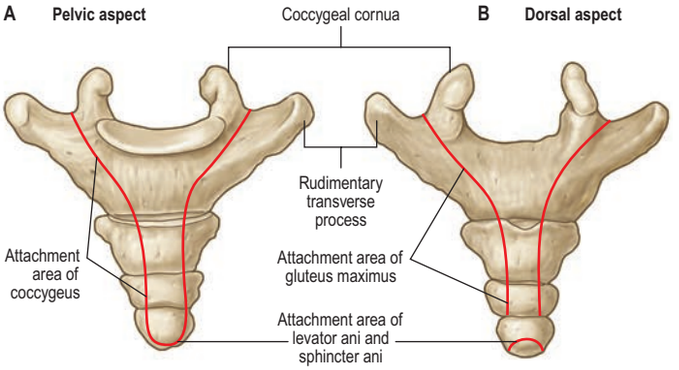

Fig. 46.53 The coccyx. **A**, Anterior (pelvic) aspect. **B**, Posterior (dorsal) aspect.

transverse tubercles, covering multifidus, which occupies the enclosed area (see Fig. 46.50). On the lateral border below the auricular surface, gluteus maximus is attached dorsal and coccygeus is attached ventral to the sacrotuberous and sacrospinous ligaments.

Ossification The sacrum resembles typical vertebrae in the ossification of its segments (Fig. 46.52). Primary centres for the centrum and each half vertebral arch appear from postmenstrual week 19. Primary centres for the costal elements of the upper three or more segments appear superolateral to the pelvic sacral foramina, from postmenstrual weeks 21–24. Each costal element unites with its half vertebral arch between the second and fifth years, and the conjoined element so formed unites anteriorly with the centrum and posteriorly with its opposite fellow at about the eighth year. Thereafter, the upper and lower surfaces of each sacral body are covered by an epiphysial plate of hyaline cartilage, which is separated from its neighbour by the fibrocartilaginous precursor of an intervertebral disc. Laterally, successive conjoined vertebral arches and costal elements are separated by hyaline cartilage; a cartilaginous epiphysis, sometimes divided into upper and lower parts, develops on each auricular and adjacent lateral surface. Soon after puberty, the fused vertebral arches and costal elements of adjacent vertebrae begin to coalesce from below upwards. At the same time, individual epiphysial centres develop for the upper and lower surfaces of bodies, spinous tubercles, transverse tubercles and costal elements.

The costal epiphysial centres appear at the lateral extremities of the hyaline cartilages between adjacent costal elements; two anterior and two posterior centres appear in each of the intervals between the first, second and third sacral vertebrae. Ossification spreads from these into the auricular epiphysial plates. One costal epiphysial centre, placed anteriorly, occurs in each remaining interval and from them ossification spreads to the epiphysial plate covering the lower part of the lateral surface of the sacrum. Sacral bodies unite at their adjacent margins after the twentieth year, but the central and greater part of each intervertebral disc remains unossified up to or beyond middle life.

Variants The sacrum may contain six vertebrae, by development of an additional sacral element or by incorporation of the fifth lumbar or first coccygeal vertebra. Inclusion of the fifth lumbar vertebra (sacralization) is usually incomplete and limited to one side. In the most minor degree of the abnormality, a fifth lumbar transverse process is large and articulates, sometimes by a synovial joint, with the sacrum at the posterolateral angle of its base. Reduction of sacral constituents is less common but lumbarization of the first sacral vertebra does occur; it remains partially or completely separate. The bodies of the first two sacral vertebrae may remain unfused when the lateral masses are fused. The dorsal wall of the sacral canal may be variably deficient, due to imperfect development of laminae and spines. Orientation of the superior sacral articular facets displays wide variation, as does the sagittal curvature of the sacrum. Asymmetry (facet tropism) of the superior facets alters the relation between the planes of the two lumbosacral facet joints.

Coccyx

The coccyx (Fig. 46.53) is a small, triangular bone and is often asymmetric in shape. It usually consists of four fused rudimentary vertebrae, although the number varies from three to five, and the first is sometimes

separate. The bone is directed downwards and ventrally from the sacral apex; its pelvic surface is tilted upwards and forwards, its dorsum downwards and backwards. Orientation varies with mobility and between individuals.

The base or upper surface of the first coccygeal vertebral body has an oval, articular facet for the sacral apex. Posterolateral to this, two coccygeal cornua project upwards to articulate with sacral cornua; they are homologues of the pedicles and superior articular processes of other vertebrae. A rudimentary transverse process projects superolaterally from each side of the first coccygeal body and may articulate or fuse with the inferolateral sacral angle, completing the fifth sacral foramina.

The second to fourth coccygeal vertebrae diminish in size and are usually mere fused nodules. They represent rudimentary vertebral bodies, though the second may show traces of transverse processes and pedicles.

The gap between the fifth sacral body and the articulating cornua represents, on each side, an intervertebral foramen that transmits the fifth sacral spinal nerve. The dorsal ramus descends behind the rudimentary transverse process, and the ventral ramus passes anterolaterally between the transverse process and sacrum.

Muscle and ligament attachments The lateral parts of the pelvic surface, including the rudimentary transverse processes, give attachment to the levatores ani and coccygei. The anterior sacrococcygeal ligament is attached to the front of the first and sometimes second coccygeal vertebral bodies. The cornua give attachment to the intercornual ligaments. The lateral sacrococcygeal ligament connects the transverse process to the inferolateral sacral angle. Gluteus maximus is attached to the dorsal surface, and both levator ani and sphincter ani externus are attached to the tip of the bone. The median area gives attachment to the deep and superficial posterior sacrococcygeal ligaments, the superficial descending from the margins of the sacral hiatus and sometimes closing the sacral canal. The filum terminale, which is situated between the two ligaments, blends with them on the dorsum of the first coccygeal vertebra.

Ossification Each coccygeal segment is ossified from one primary centre. A centre in the first segment appears about birth and its cornua may soon ossify from separate centres. Remaining segments ossify at wide intervals up to the twentieth year or later. Segments slowly unite: union between the first and second is frequently delayed until 30 years. The coccyx often fuses with the sacrum in later decades, especially in females.

LIGAMENTS OF THE VERTEBRAL COLUMN

Anterior longitudinal ligament

The anterior longitudinal ligament (Fig. 46.54B) is a strong band extending along the anterior surfaces of the vertebral bodies. It is broader caudally, and thicker and narrower in thoracic than in cervical and lumbar regions, and is also relatively thicker and narrower opposite vertebral bodies than at the levels of intervertebral symphyses. It extends from the basilar part of the occipital bone to the anterior tubercle of C1 and the front of the body of C2, and then continues caudally to the front of the upper sacrum. Its longitudinal fibres are strongly adherent to the intervertebral discs, hyaline cartilage end-plates and margins of adjacent vertebral bodies, and are loosely attached at intermediate levels of the bodies, where the ligament fills their anterior concavities, flattening the vertebral profile. At these various levels, ligamentous fibres blend with the subjacent periosteum, perichondrium and periphery of the anulus fibrosus. The anterior longitudinal ligament has several layers. The most superficial fibres are the longest and extend over three or four vertebrae, the intermediate extend between two or three, and the deepest from one body to the next. Laterally, short fibres connect adjacent vertebrae.

Posterior longitudinal ligament

The posterior longitudinal ligament (Fig. 46.55) lies on the posterior surfaces of the vertebral bodies in the vertebral canal, attached between the body of C2 and the sacrum, and continuous with the membrana tectoria above. Its smooth, glistening fibres, attached to intervertebral discs, hyaline cartilage end-plates and adjacent margins of vertebral bodies, are separated between attachments by basivertebral veins and

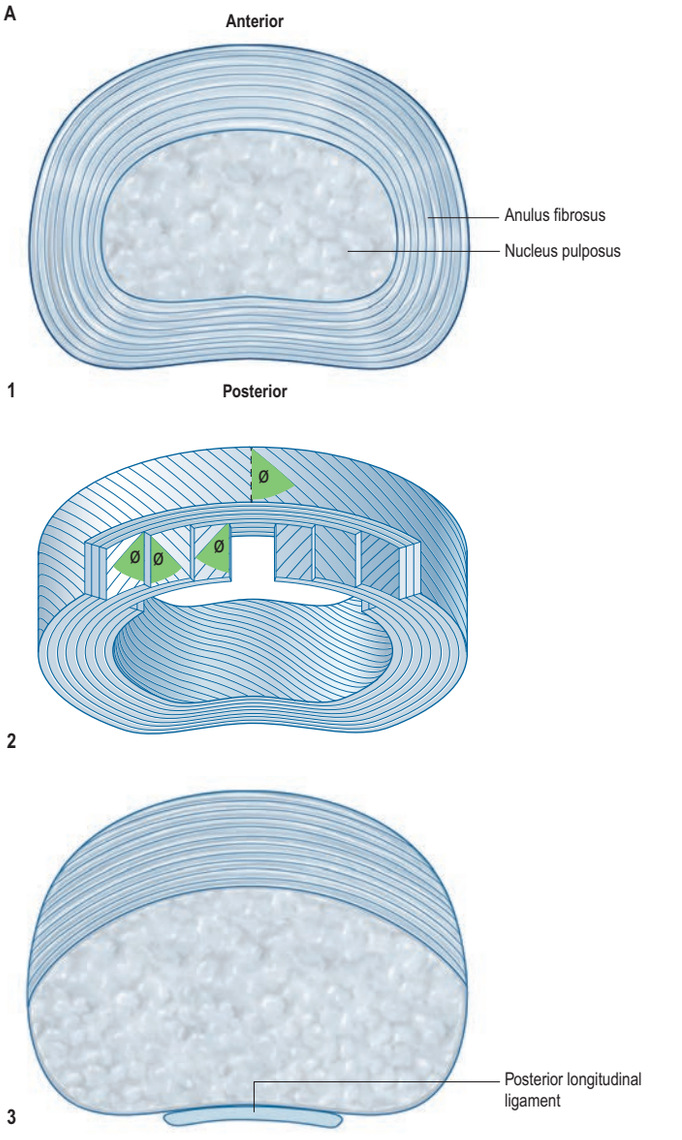

Fig. 46.54 A, The main structural features of an intervertebral disc. For clarity, the number of fibrocartilaginous laminae has been greatly reduced. Note the alternating obliquity of collagen fascicles in adjacent laminae. Key: 1, lumbar disc; 2, detailed structure of anulus fibrosus; ø = approximately 65°; 3, cervical disc. **B**, A median sagittal section through the upper lumbar vertebral column showing discs and ligaments. the venous channels that drain them into anterior internal vertebral plexuses. At cervical and upper thoracic levels the ligament is broad and of uniform width, but in lower thoracic and lumbar regions it is denticulated, narrow over vertebral bodies and broad over discs. Its superficial fibres bridge three or four vertebrae, while deeper fibres extend

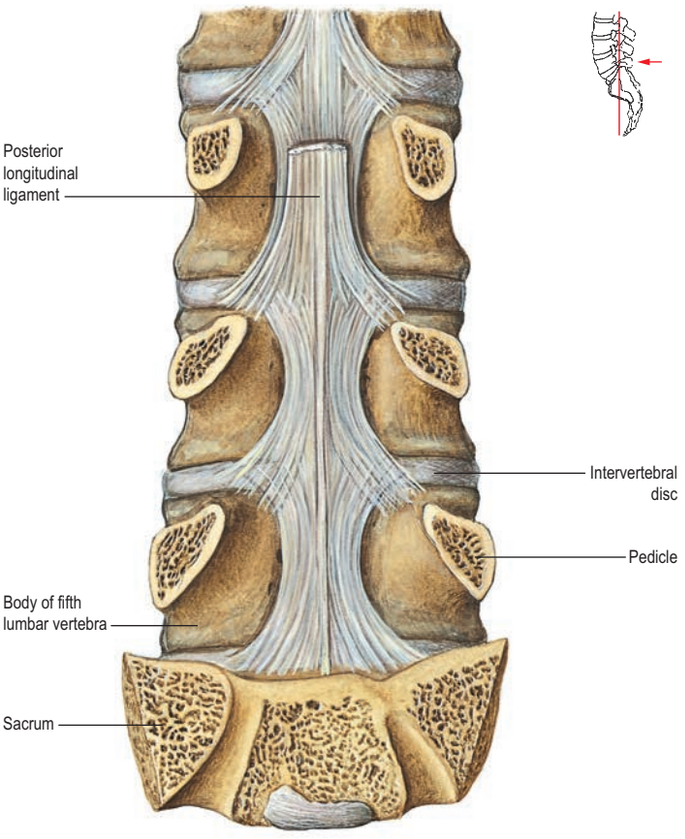

Fig. 46.55 The posterior longitudinal ligament in the lumbar region. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

between adjacent vertebrae as perivertebral ligaments, which are close to and, in adults, fused with the anulus fibrosus of the intervertebral disc. The layers of the posterior longitudinal ligament and the relationship of the ligament to associated membranes in the epidural space are fully discussed by Loughenbury et al (2006).

Ligamenta flava

The ligamenta flava (see Fig. 46.54B; **Fig. 46.56**) connect laminae of adjacent vertebrae in the vertebral canal. Their attachments extend from facet joint capsules to the point where laminae fuse to form spines. Here their posterior margins meet and are partially united; the intervals between them admit veins that connect the internal and posterior external vertebral venous plexuses. Their predominant tissue is yellow elastic tissue, whose almost perpendicular fibres descend from the lower anterior surface of one lamina to the posterior surface and upper margin of the lamina below. The anterior surface of the ligaments is covered by a fine, continuous, smooth lining membrane (Newell 1999). The ligaments are thin, broad and long in the cervical region, thicker in the thoracic and thickest at lumbar levels. They arrest separation of the laminae in spinal flexion, preventing abrupt limitation, and also assist restoration to an erect posture after flexion, perhaps protecting discs from injury.

The morphology and histology of the ligamentum flavum have been studied in the thoracolumbar region (Viejo-Fuertes et al 1998). On a macroscopic level, it has two layers, superficial and deep, where the fibres run in opposite directions. The superficial layer is innervated by medial branches from the dorsal roots of the spinal nerves. The deep layer is innervated by sinuvertebral nerves. This innervation appears to become increasingly poorer with age-related degeneration.

Interspinous ligaments

Interspinous ligaments (see Fig. 46.54B) connect the facing edges of consecutive spinous processes, and extend ventrally as far as the ligamentum flavum and dorsally to the supraspinous ligament, when this ligament is present (see below). They differ structurally at thoracic, lumbar and cervical levels. The thoracic interspinous ligaments are narrow and elongated, whereas those at lumbar levels are thick and quadrilateral, and occur as closely applied pairs, the left and right ligaments being separated by a narrow or potential cleft. In the lumbar ligaments, collagen fibres run obliquely inferiorly and ventrally, and only the deepest fibres are truly ligamentous. The more dorsal fibres are derived from tendons of longissimus thoracis that dip into the interspinous space to gain attachment to the superior edge of the spinous process rather than to its tip. Distinctive interspinous ligaments are not evident at cervical levels, where they are represented by the median septum of the ligamentum nuchae as it passes between the cervical spinous processes.

Supraspinous ligament

The supraspinous ligament (see Fig. 46.54B) is a strong, fibrous cord that connects the tips of spinous processes from C7 to L3 or L4. It is regularly deficient. The most superficial fibres extend over three or four vertebrae, the deeper span two or three, and the deepest connect adjacent spines and are continuous with the interspinous ligament. Most of the ligament is formed by the tendons of muscles with posterior midline attachments, i.e. semispinalis, longissimus, trapezius and latissimus dorsi. Only the most superficial fibres lack any connection with muscle. Below L4, the ligament is replaced by the decussating fibres of latissimus dorsi.

Intertransverse ligaments

Intertransverse ligaments run between adjacent transverse processes. At cervical levels, they consist of a few, irregular fibres that are largely replaced by intertransverse muscles; in the thoracic region, they are cords intimately blended with adjacent muscles; and in the lumbar region, they are thin and membranous. For the detailed anatomy of the lumbar intertransverse ligaments, see Bogduk (2012).

Ligamentous instability

Damage to the ligaments controlling stability of the column may occur in the absence of evident bony pathology. This is particularly prevalent in inflammatory disease of the upper cervical spine, where rheumatoid arthritis may weaken or destroy the ligaments on which atlanto-axial stability depends (**Fig. 46.57**). The transverse ligament is stronger than the dens, which therefore usually fractures before the ligament ruptures. The alar ligaments are weaker, and combined head flexion and rotation may avulse one or both alar ligaments; rupture of one side results in an increase of about one-third in the range of rotation to the opposite side. Pathological softening of the transverse and adjacent ligaments or of the lateral atlanto-axial joints results in atlanto-axial subluxation,

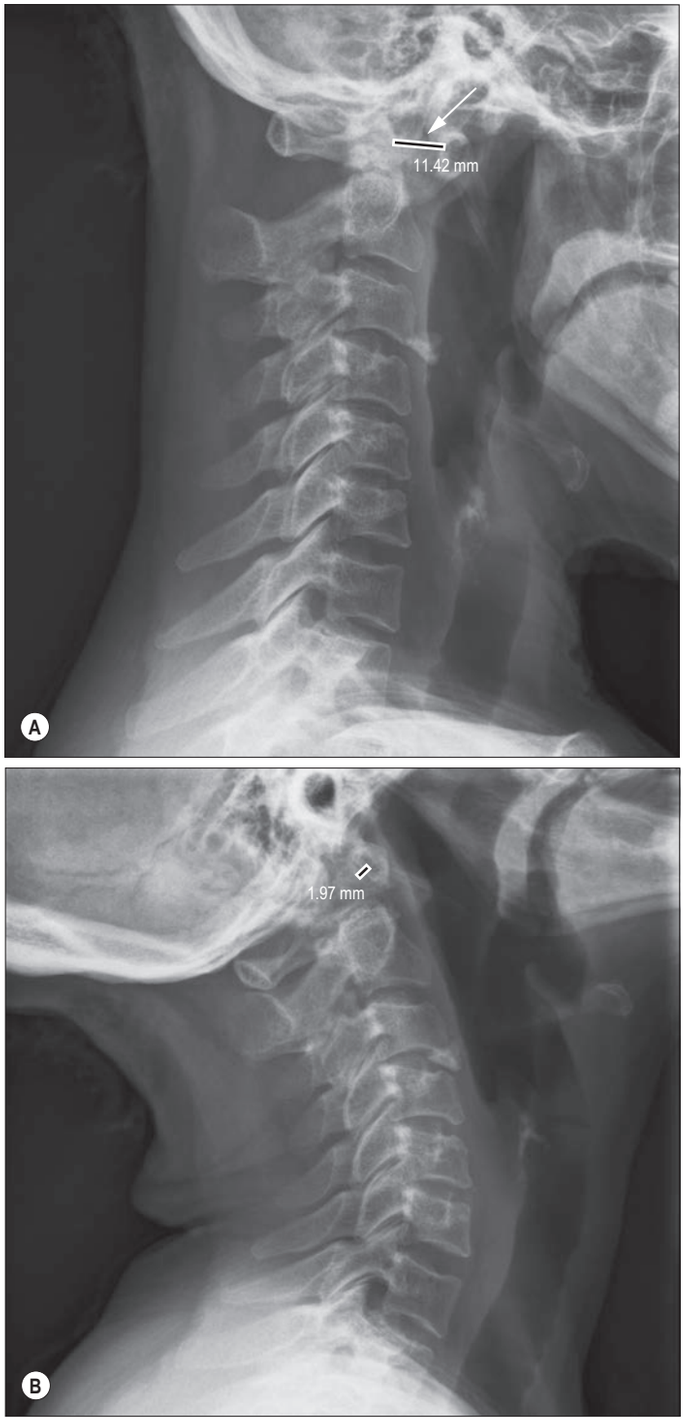

Fig. 46.57 Atlanto-axial instability in the setting of rheumatoid arthritis. Note the marked widening of the atlanto–dens interval seen on extension radiographs (arrow) (**A**), when compared with flexion (**B**).

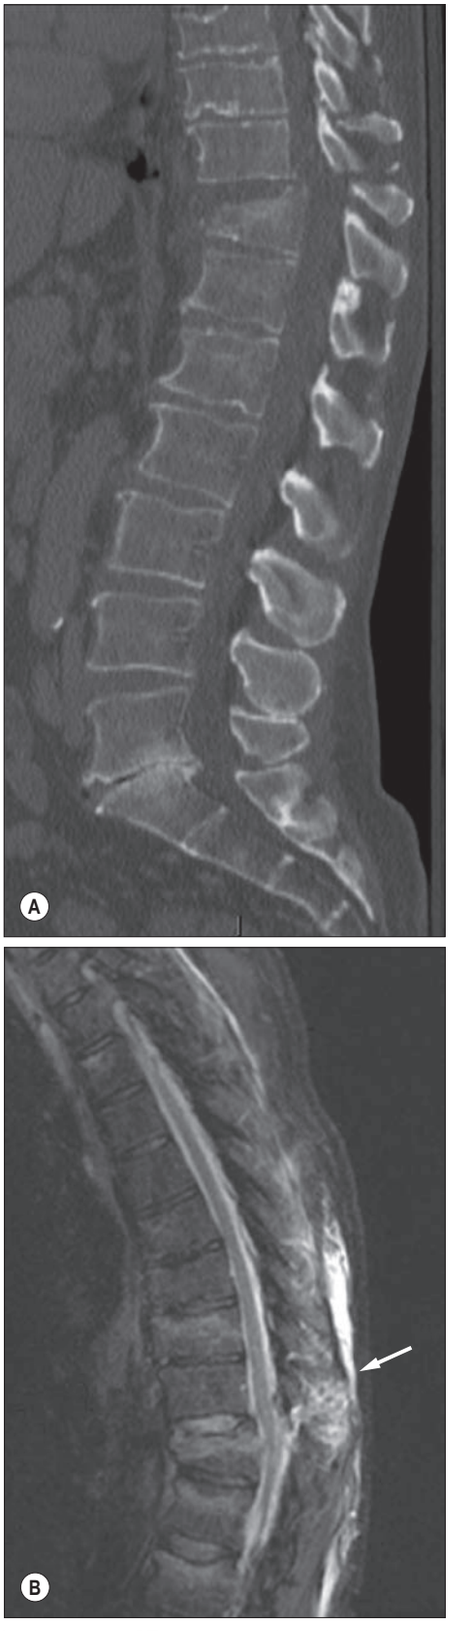

Fig. 46.58 A, A sagittal CT reconstruction showing an osseous and ligamentous injury at T10–T11 sustained by a 54-year-old male after a major compression injury. **B**, The MR image shows gross disruption of the supraspinous and interspinous ligaments (arrow).

Fig. 46.59 A coronal CT reconstruction: note uncovertebral 'joint' (arrow).

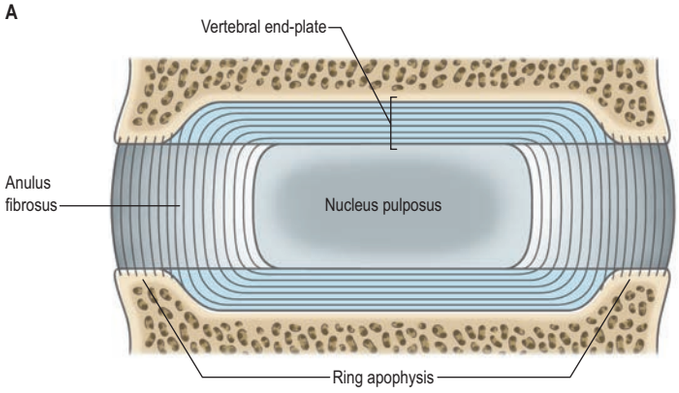

Fig. 46.60 A, The structure of the vertebral end-plate: the collagen fibres of the inner two-thirds of the anulus fibrosus sweep around into the vertebral end-plate and form its fibrocartilaginous component. The peripheral fibres of the anulus are anchored into the bone of the ring apophysis. (With permission from Bogduk N 2012 Clinical Anatomy of the Lumbar Spine and Sacrum, 5th ed. Edinburgh: Churchill Livingstone.) (B–D, *continued online*)

which may cause spinal cord injury. Ligamentous damage may also occur in spinal injuries (Fig. 46.58), particularly at cervical levels. Damage may also occur as a result of spinal surgery where ligament removal in addition to bone removal (such as partial facet resection) may result in iatrogenic instability.

Developmental laxity of ligaments may also lead to problems with instability, especially if there is an episode of trauma; this combination is probably responsible for atlanto-axial rotational instability. Laxity of cervical spinal ligaments may be a normal variant in children and lead to diagnostic difficulties. In radiographs of the upper cervical spine in children aged less than 8 years, a deceptive appearance of subluxation ('pseudosubluxation') may result from a combination of ligamentous laxity and facet orientation. This usually occurs between C2 and C3 but may occasionally be seen at C3/C4. Clinical and other radiological features should facilitate the correct diagnosis.

JOINTS

All vertebrae from C2 to S1 articulate by secondary cartilaginous joints (symphyses) between their bodies, synovial joints between their articular processes, and fibrous joints between their laminae, transverse and spinous processes. In the cervical region, from C3 to C7, joints have been described between the uncinate or neurocentral processes of the inferior vertebral body and the bevelled lateral border of the superior body at each level. These small uncovertebral or neurocentral 'joints' are absent at birth, do not contain synovium, and are probably clefts in the intervertebral discs (Fig. 46.59).

Intervertebral joints

Joints between the vertebral bodies

Joints between vertebral bodies are symphyses. Typical vertebral bodies are united by anterior and posterior longitudinal ligaments and by fibrocartilaginous intervertebral discs between sheets of hyaline cartilage (vertebral end-plates).

Articulating surfaces: intervertebral discs The intervertebral discs are the chief bonds between the adjacent surfaces of vertebral bodies from C2 to the sacrum. Except at the sites of the uncovertebral (neurocentral) joints of Luschka, disc outlines correspond with the adjacent bodies. Their thickness varies in different regions and within individual discs. Each disc consists of an outer lamellated anulus fibrosus and an inner nucleus pulposus (see Fig. 46.54A).

In cervical and lumbar regions the discs are thicker anteriorly, contributing to the anterior convexity of the vertebral column. In the thoracic region they are nearly uniform, and the anterior concavity is largely due to the vertebral bodies. Discs are thinnest in the upper thoracic region and thickest in the lumbar region. They adhere to thin layers of cartilage on the superior and inferior vertebral surfaces, the vertebral end-plates. The latter do not reach the periphery of the vertebral bodies but are encircled by ring apophyses. The end-plates contain both hyaline cartilage and fibrocartilage. The fibrocartilaginous component lies nearer to the disc and is sometimes considered not to be part of the end-plate itself. The fibrocartilaginous components of the end-plates above and below the nucleus pulposus, together with the innermost lamellae of the anulus fibrosus, form a flattened sphere of collagen that surrounds and encloses the nucleus (Fig. 46.60). The overall proportion of fibrocartilage in the end-plate increases with age. While all discs are attached to the anterior and posterior longitudinal ligaments, discs in the thoracic region are additionally tied laterally, by intra-articular ligaments, to the heads of ribs articulating with adjacent vertebrae. Intervertebral discs form about one-quarter of the length of the postaxial vertebral column; cervical and lumbar regions make a greater contribution than the thoracic and are thus more pliant.

Anulus fibrosus. The anulus fibrosus has a narrow outer collagenous zone and a wider inner fibrocartilaginous zone. Its lamellae, which are convex peripherally when seen in vertical section, are incomplete collars. The internal vertical concavity of the lamellae conforms to the surface profile of the nucleus pulposus. In all quadrants of the anulus, about half the lamellae are incomplete; the proportion increases in the posterolateral region. The exact nature of the interlamellar substance remains in some doubt. Posteriorly, lamellae join in a complex manner. Fibres in the rest of each lamella are parallel and run obliquely between vertebrae at about 65° to the vertical (see Fig. 46.54A). Fibres in successive lamellae cross each other obliquely in opposite directions, thus limiting rotation. The obliquity of fibres in deeper zones varies in different lamellae. Posterior fibres may sometimes be predominantly vertical, which possibly predisposes them to herniation.

This standard description of the anulus may not apply at all spinal levels; a cadaveric study indicates that the anulus is usually incomplete posteriorly in adult cervical discs (Mercer and Bogduk 1999) (see Fig. 46.54A).

Nucleus pulposus. The nucleus pulposus is better developed in cervical and lumbar regions and lies between the centre of the disc and its posterior surface. At birth it is large, soft and gelatinous, and is composed of mucoid material. It contains a few multinucleated notochordal cells and is invaded by cells and collagen fibres from the inner zone of the adjacent anulus fibrosus. Notochordal cells disappear in the first decade, and the mucoid material is gradually replaced by fibrocartilage,

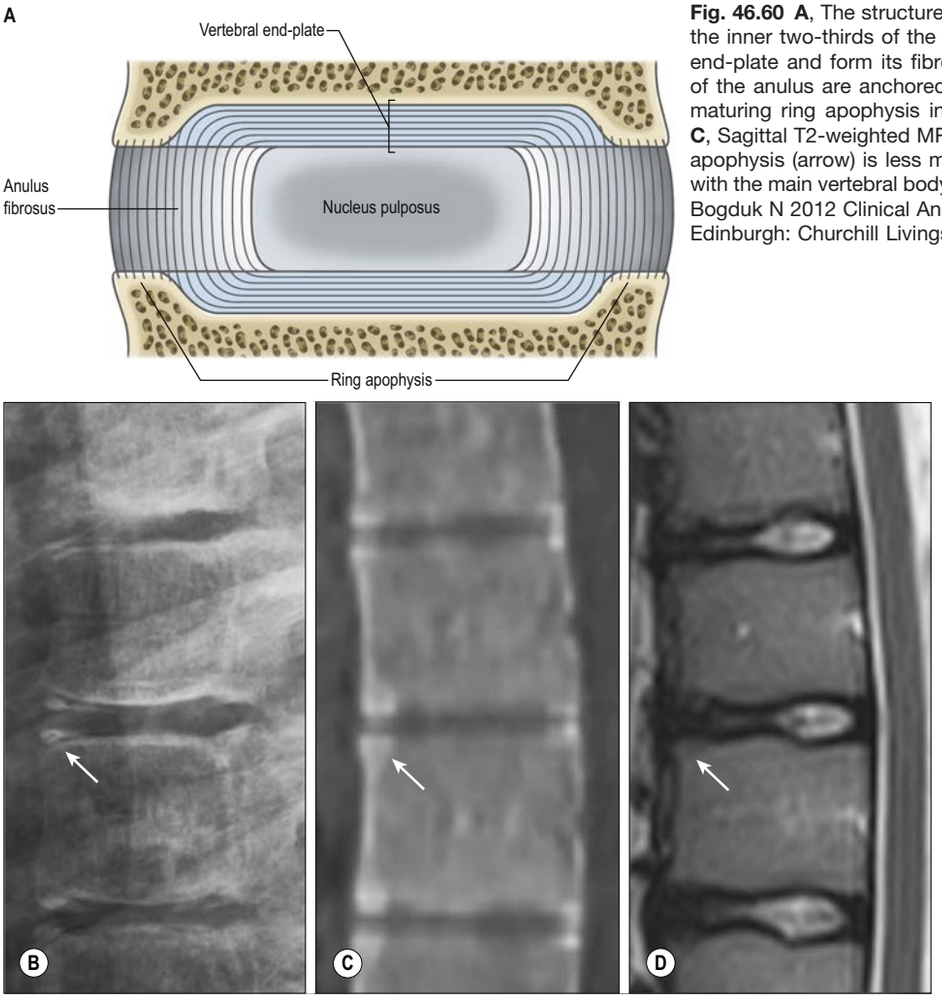

Fig. 46.60 **A**, The structure of the vertebral end-plate: the collagen fibres of the inner two-thirds of the anulus fibrosus sweep around into the vertebral end-plate and form its fibrocartilaginous component. The peripheral fibres of the anulus are anchored into the bone of the ring apophysis. **B**–**D**, The maturing ring apophysis in the mid-thoracic spine. **B**, Lateral radiograph. **C**, Sagittal T2-weighted MRI. **D**, Sagittal CT multiplanar reconstruction. The apophysis (arrow) is less mature in **B** (16 years old), having started to fuse with the main vertebral body in **C** and **D** (late teens). Fig. 46.61 Innervation of a lumbar intervertebral disc. Branches of the grey rami communicantes and the sinuvertebral nerves are shown entering the disc and the anterior and posterior longitudinal ligaments. Branches of the sinuvertebral nerves also supply the ventral aspect of the dural sac and the dural nerve root sleeve.

derived mainly from the anulus fibrosus and the plates of hyaline cartilage adjoining the vertebral bodies. The nucleus pulposus becomes less differentiated from the remainder of the disc as age progresses, and gradually becomes less hydrated and increasingly fibrous. The type II collagen of the nucleus becomes more like the type I of the anulus as its fibril diameter increases. The quantity of aggregated proteoglycans in the nucleus decreases, while the keratan sulphate/chondroitin sulphate ratio increases. As increased cross-linking occurs between collagen and the proteoglycans, the discs lose their water-binding capacity and become stiffer and more liable to injury. Contrary to what was previously thought, it has now been shown that lumbar discs do not decrease in overall height as a part of normal ageing. The anulus gradually loses height as its radial bulge increases, but the nucleus retains height and may increase in convexity as it increasingly indents the endplate. Loss of trunk height with age results from a decrease in vertebral body height (Bogduk 2012). When the disc is not loaded, pressure in the nucleus pulposus is low at all ages.

For a review of the structure and function of the human intervertebral disc, see Adams and Dolan (2005).

Ligaments The ligaments associated with the joints between the vertebral bodies are described on pages 853.

Vascular supply Small offshoots of spinal branches of arteries supplying the vertebral column form an anastomosis on the outer surface of the anulus fibrosus and supply its most peripheral fibres. Normal discs are otherwise avascular and are dependent for their nutrition on diffusion from vertebral bone beneath adjacent end-plates and from the peripheral anulus. Vascular and avascular parts differ in their reaction to injury. Venous drainage is via the external and internal vertebral venous plexuses to the intervertebral veins and thence to the larger named veins that drain the vertebral column. Lymphatic drainage of the vertebral column is briefly considered above. Nothing specific is known about the lymphatic drainage of the disc.

Innervation The nerve supply of intervertebral discs has been studied in detail in the lumbar region (Fig. 46.61). The outer third of the anulus is innervated by the sinuvertebral nerves; each sinuvertebral nerve supplies both the disc at the level of its spinal nerve of origin and the disc one level above. The anterior part of the anulus is supplied by the sympathetic (preganglionic, grey ramus communicans) rather than by the mixed nerve. In damaged and degenerate discs, the nerves may penetrate more centrally into the disc substance. The sinuvertebral nerves are condensations within extensive nerve plexuses that lie on the posterior longitudinal ligament. Similar plexuses have been demonstrated anteriorly, covering the anterior longitudinal ligament, and laterally in the fetus.

Relations and 'at risk' structures Posterior, lateral and anterior relations of the intervertebral disc are important in the planning of

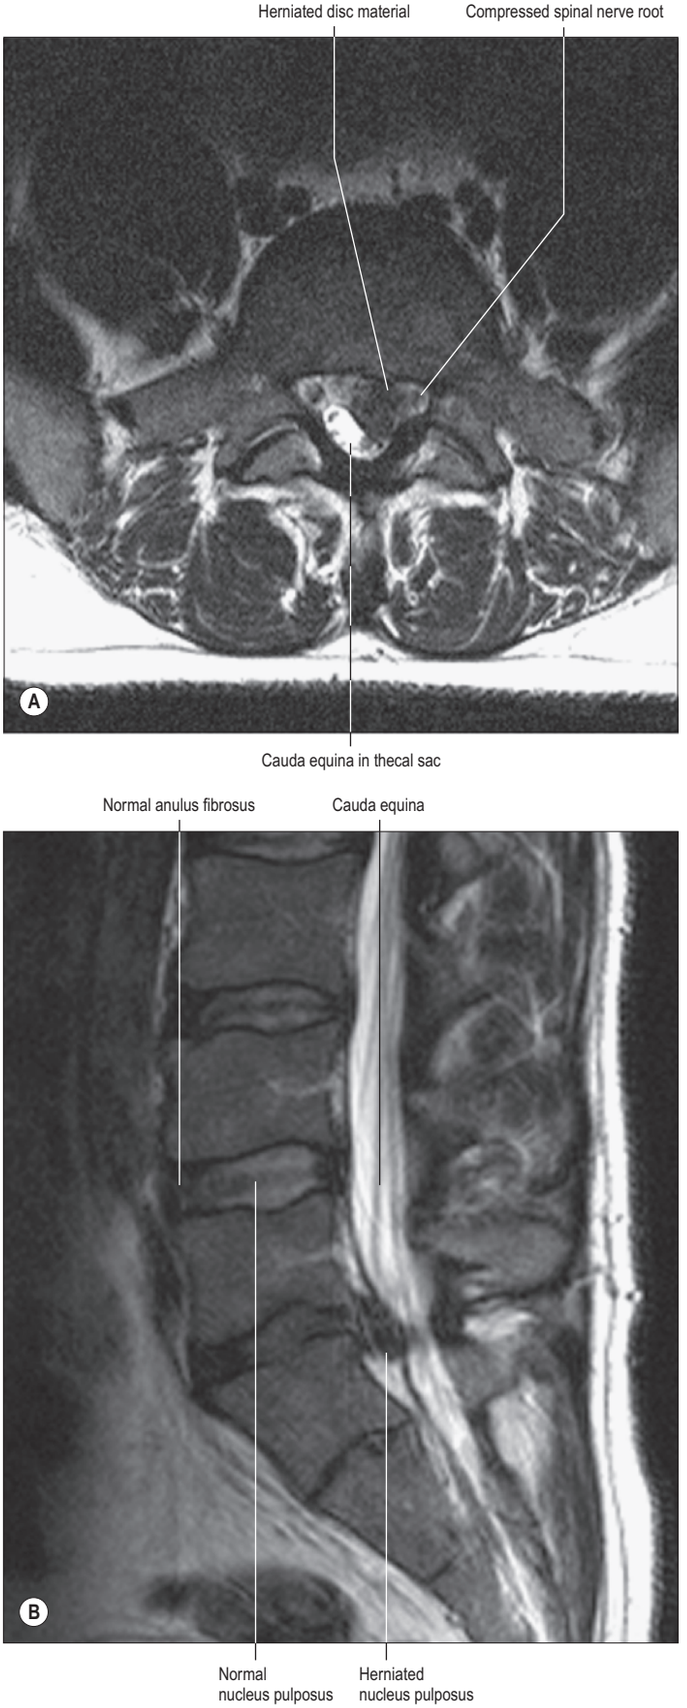

Fig. 46.62 Left posterolateral disc extrusion. **A**, Axial view. **B**, Sagittal view.

interventional investigative and therapeutic procedures ranging from discography to open disc surgery. The posterolateral surface of the disc forms the anterior boundary of the intervertebral foramen on each side, and so is closely related to the spinal nerve and its accompanying vessels. More centrally, the disc is related posteriorly to the dura mater covering the spinal cord and the cauda equina. Anterior relations of the discs vary considerably with vertebral level, but important 'at risk' structures include the pharynx and oesophagus, the descending aorta and

the inferior vena cava. Laterally, relations change with level, but the parietal pleura in the thorax, and the sympathetic trunk and psoas muscles in the lumbar region, are important examples.

Prolapsed intervertebral disc A prolapsed intervertebral disc most commonly affects the 20–55-year age group and is most often seen at the L4/L5 and lumbosacral levels. It may also affect the cervical discs, particularly at C5/C6 and C6/C7. The thoracic discs are rarely affected. Acute tearing or chronic degeneration of the posterior lamellae of the anulus fibrosus allows deformation and herniation of the disc contents. The disc most often prolapses just lateral to the posterior longitudinal ligament and can compress one or two spinal nerves unilaterally (**Fig. 46.62**). Much less commonly, the prolapse is central, in the midline posteriorly. The compression of neural structures may then be bilateral, affecting the cord itself or the whole cauda equina. If the damaged anulus ruptures completely, some of the nuclear tissue may escape into the vertebral and 'root' canals. This sequestrated material may migrate within the canals and cause nerve compression at spinal levels distant from that of the disc rupture. The disc material itself may have an irritative effect on the spinal nerve.

Regarding the anatomy of the vertebral canal and intervertebral foramen in relation to disc prolapse, it is important to understand that one or both of two spinal nerves and their roots may be affected by a single prolapse, depending on the exact site of the prolapse in the horizontal plane. At the level of each disc and foramen, there are two spinal nerves (and their roots) to consider: these are the exiting nerve and the traversing nerve (**Fig. 46.63**) (MacNab and McCulloch 1990). The nerve usually affected at lumbar levels is the traversing nerve, which crosses the back of the disc on its way to become the exiting nerve at the level below. Thus a lumbosacral (i.e. L5/S1) disc prolapse usually compresses the S1 nerve. However, a prolapse may affect the exiting nerve at its own level. This is especially likely if the prolapse is in the extraforaminal zone of the 'root' canal, the so-called 'far lateral' prolapse. At cervical levels, because the roots and nerve leave the vertebral canal almost horizontally, the prolapse usually affects the exiting nerve. This nerve will still bear the number of the vertebra below the affected disc because cervical nerves exit the canal above the pedicle of their numerically corresponding vertebra. Neurological presentation will include signs and symptoms of spinal nerve damage at the affected level. Thus pain and sensory loss will be dermatomal in distribution. Sensory changes usually precede motor loss.

Internal disruption of a lumbar intervertebral disc is more common than disc prolapse and is now an increasingly recognized cause of back pain. Typically, the nucleus is decompressed and the inner lamellae of the anulus appear to collapse into it.

For more detail on disc pathology and its consequences, see Adams and Dolan (2005).

Facet (zygapophysial) joints

Joints between the vertebral articular processes (zygapophyses) are synovial and have long been called zygapophysial joints by anatomists. However, in current clinical practice they are commonly called 'facet joints'. Detailed description of the anatomy of these joints is to be found in Bogduk (2012), where the author explains why the term 'facet joint' is both incorrect and essentially ambiguous, on the grounds that facets are not restricted to zygapophysial articular processes and occur, for example, in both costovertebral and costotransverse joints.

Articulating surfaces Facet joints are of the simple (cervical and thoracic) or complex (lumbar) synovial variety; the articulating surfaces are covered in hyaline cartilage and are carried on mutually adapted articular processes. The size and shape of these processes vary with spinal level and are described with the individual vertebrae.

Fibrous capsule The fibrous capsule is thin and loose and attached peripherally to the articular facets of adjacent articular processes. The capsules are longer and looser in the cervical region. According to Bogduk (2012), the anterior fibrous capsule is replaced entirely by the ligamentum flavum in the lumbar spine.

Intracapsular structures. Bogduk describes two types of intra-articular structure in lumbar facet joints: namely, subcapsular fat and 'meniscoid' structures. The latter structures may be collagenous, fibroadipose or purely adipose, and project into the crevices between non-congruent articular surfaces. They resemble inclusions seen in the small joints of the hand; their function is conjectural.

Ligaments Ligaments that work in conjunction with, and modify the function of, the facet joints throughout the vertebral column are described on pages 853–854.

Synovial membrane The synovium is attached around the periphery of the articular cartilages and lines the fibrous capsule. In the lumbar region, it is reflected over the intracapsular structures described above.

Vascular supply The posterior spinal branches of the arteries that supply the vertebral column form arterial anastomoses around the facet joints. Venous drainage is via the external and internal posterior vertebral venous plexuses to the intervertebral veins and thence to the larger named veins that drain the vertebral column. Lymphatic drainage follows the principles described for the vertebral column.

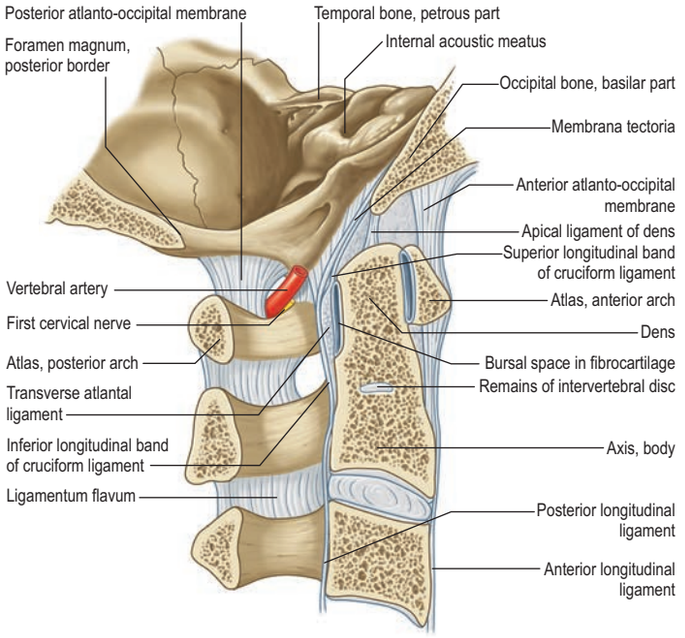

Fig. 46.67 Median sagittal section through the occipital bone and first to third cervical vertebrae.

Innervation The facet joints are profusely innervated by medial branches of the dorsal primary rami of the spinal nerves, which give articular branches to the joints above and below them.

Relations and 'at risk' structures Anteriorly, the capsules of the facet joints form the posterior boundaries of the intervertebral foramina. Posteriorly and laterally, the joints are related to the deep muscles of the back, some of whose fibres attach to the capsules. The joints also lie in close relation to the medial branches of the dorsal rami of the spinal nerves and to their accompanying arteries and veins. Damage to the medial branches of the dorsal rami may denervate the deep back muscles. Access to the facet joints and their related nerves may be required in the diagnosis and treatment of spinal pain.

Additionally, facet joints can be subluxed or fractured with trauma. This may compromise the neuroforamen. It is often also associated with displacement of adjacent vertebrae and disc, and so the spinal canal and its contents may be compromised (Fig. 46.64).

Lumbar articular tropism In the lumbar region, asymmetric orientation of the facet joints occurs in about one-fifth of the population. Such facet tropism does not appear to predispose to degenerative disc disease.

Craniovertebral joints

The articulation between the cranium and vertebral column is specialized to provide a wider range of movement than those that occur in the rest of the axial skeleton. It consists of the occipital condyles, the atlas and the axis. It functions like a universal joint that permits horizontal and vertical scanning movements of the head, and is adapted for eye–head coordination.

Atlanto-occipital joints

The atlas articulates with the occipital bone of the skull by a pair of synovial joints. The bones are connected by articular capsules and by the anterior and posterior atlanto-occipital membranes (Figs 46.65–46.66).

Articulating surfaces Each joint consists of two reciprocally curved articular surfaces, one on the occipital condyle and the other on the lateral mass of the atlas. The atlantal facets are concave and tilted medially.

Fibrous capsules The fibrous capsules surround the occipital condyles and superior atlantal articular facets. They are thicker posteriorly and laterally, where the capsule is sometimes deficient, and may communicate with the joint cavity between the dens and the transverse atlantal ligament.

Ligaments The ligaments are the anterior and posterior atlanto-occipital membranes.

Anterior atlanto-occipital membrane. The anterior atlanto-occipital membrane (see Fig. 46.65; **Fig. 46.67**) is a broad, dense fibrous structure that connects the anterior margin of the foramen magnum to the upper border of the anterior arch of the atlas. Laterally, it blends with the joint capsule; medially, it is strengthened by a median cord, which is the anterior longitudinal ligament stretching between the basilar occipital bone and anterior atlantal tubercle.

Posterior atlanto-occipital membrane. The posterior atlanto-occipital membrane (see Figs 46.66–46.67) is broad but relatively thin, and connects the posterior margin of the foramen magnum to the upper border of the posterior atlantal arch, blending laterally with the joint capsules. It arches over the grooves for the vertebral arteries, venous plexuses and first cervical nerve, and forms the 'floor' of the suboccipital triangle. The ligamentous border of this arch is sometimes ossified. The membrane is usually attached by a soft tissue 'bridge', which may contain muscle or tendon fibres, to rectus capitis posterior minor, and is firmly attached anteriorly to the spinal dura in the same area (Zumpano et al 2006). The ligaments connecting the axis and the occipital bone are functionally involved with the posterior atlanto-occipital membrane.

Synovial membrane The synovial cavities of one or both joints may communicate with that of the posterior component of the median atlanto-axial joint.

Vascular supply The arterial supply of this region is derived from an anastomosis between branches of the deep cervical, occipital and vertebral arteries.

Innervation The joints are innervated by branches of the ventral primary ramus of the first cervical spinal nerves.

Factors maintaining stability Factors maintaining stability include the fibrous capsules, the atlanto-occipital membranes, the shape of the articular surfaces, the ligaments connecting the axis and the occipital bone, the ligamentum nuchae and the posterior neck muscles. The suboccipital muscles play an important proprioceptive and postural role.

Muscles producing movements The orientation and shape of the atlanto-occipital joints allow mainly for flexion–extension, which has a total range of about 15°. Axial rotation and lateral flexion have not been measured in living subjects, but a few degrees of motion in these directions can be produced by forceful movement in cadavers.

The following muscles produce these movements: for flexion – longus capitis and rectus capitis anterior; for extension – recti capitis posteriores major and minor, obliquus capitis superior, semispinalis capitis, splenius capitis and trapezius (cervical part); for lateral flexion – rectus capitis lateralis, semispinalis capitis, splenius capitis, sternocleidomastoid and trapezius (cervical part); and for rotation – obliquus capitis superior, rectus capitis posterior minor, splenius capitis and sternocleidomastoid.

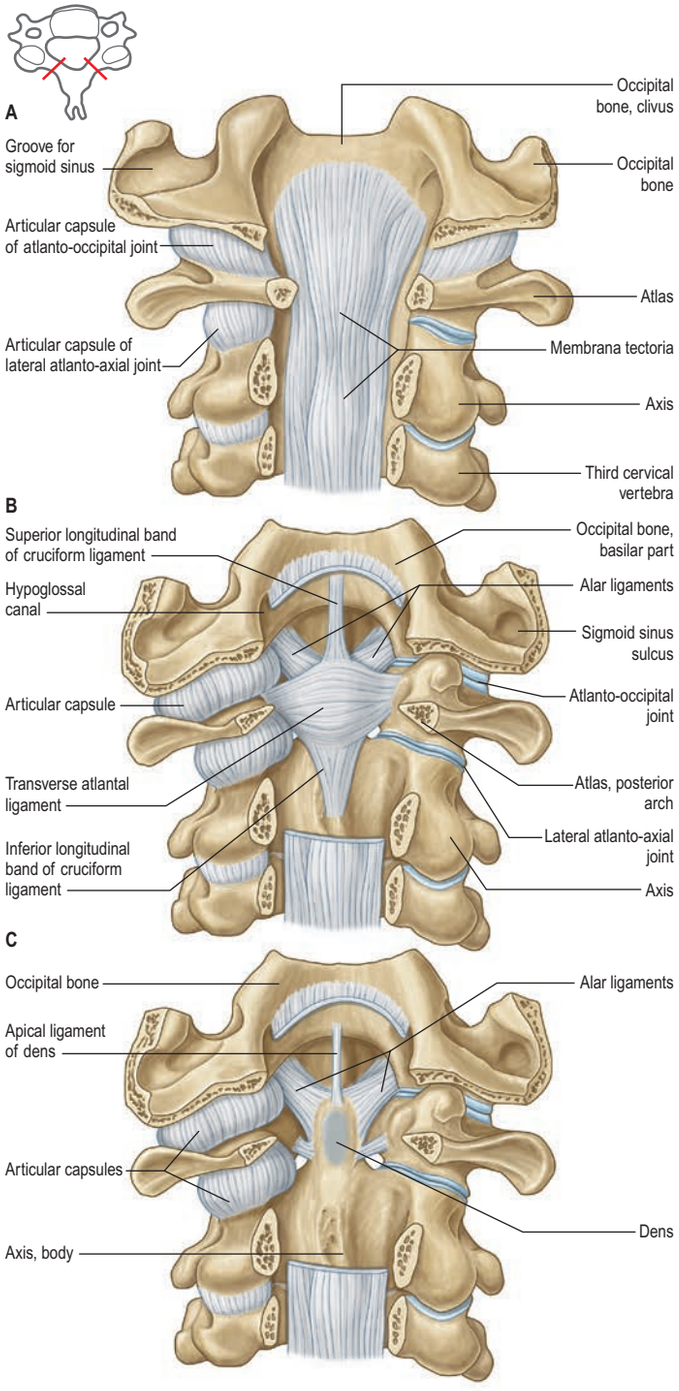

Fig. 46.68 The posterior aspect of the atlanto-occipital and atlanto-axial joints. The posterior part of the occipital bone and the laminae of the cervical vertebrae have been removed and the atlanto-occipital joint cavities opened. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Relations and 'at risk' structures Posteriorly, the joints are closely related to the vertebral arteries as they pass from the foramina transversaria into the foramen magnum. The dorsal primary ramus of the first cervical nerve and rectus capitis posterior major lie posteromedially and rectus capitis anterior lies anteriorly.

Atlanto-axial joints

The atlas articulates with the axis at three synovial joints. These are a pair between the lateral masses, and a median complex between the dens of the axis and the anterior arch and transverse atlantal ligament.

Articulating surfaces The articular surfaces of the joints between the lateral masses are often classified as planar. The bony articular surfaces are more complex in shape and are usually reciprocally concave in the coronal plane; the medial parts are somewhat convex in the sagittal plane (especially that of the axis). The cartilaginous articular surfaces are usually less concave. The median joint is a pivot between the dens and a ring formed by the anterior arch and transverse atlantal ligament. A vertically ovoid facet on the anterior dens articulates with a facet on the posterior aspect of the anterior atlantal arch.

Fibrous capsules The fibrous capsules for the lateral joints are attached to the articular margins and are thin and loose. Each has a posteromedial accessory ligament attached below to the axial body near the base of its dens, and above to the lateral atlantal mass near the transverse ligament. The fibrous capsule for the median joint is also relatively weak and loose, especially superiorly.

Ligaments Anteriorly, the vertebral bodies are connected by the anterior longitudinal ligament (see Figs 46.65, 46.67): here, a strong, thickened band attaches above to the lower border of the anterior tubercle of the anterior arch of the atlas and below to the front of the axial body. Posteriorly, the vertebral arches are joined by the ligamenta flava (see Figs 46.66–46.67), which are attached to the lower border of the atlantal arch above and to the upper borders of the axial laminae. At this level, these ligaments form a thin membrane, pierced laterally by the second cervical nerves.

Transverse atlantal and cruciform ligaments. The transverse atlantal ligament (**Fig. 46.68**; see Fig. 46.33) is a broad, strong band that arches across the atlantal ring behind the dens; its length varies about a mean of 20 mm. It is attached laterally to a small but prominent tubercle on the medial side of each atlantal lateral mass, and broadens medially where it is covered anteriorly by a thin layer of articular cartilage. It consists almost entirely of collagen fibres, which, in the central part of the ligament, cross one another at an angle to form an interlacing mesh. From its upper margin a strong median longitudinal band arises that inserts into the basilar part of the occipital bone between the apical ligament of the dens and membrana tectoria, and from its inferior surface a weaker and less consistent longitudinal band passes to the posterior surface of the axis. These transverse and longitudinal components together constitute the cruciform ligament. The transverse ligament divides the ring of the atlas into unequal parts (see Figs 46.32–46.33). The posterior two-thirds surrounds the spinal cord and meninges, and the anterior third contains the dens, which the transverse ligament retains in position even when all other ligaments are divided.

Ligaments connecting axis and occipital bone. Ligaments connecting the axis and the occipital bone consist of the membrana tectoria, the paired alar ligaments, the median apical ligament, and the longitudinal components of the cruciform ligament (see Figs 46.67–46.68).

Membrana tectoria Inside the vertebral canal, the membrana tectoria is a broad strong band representing the upward continuation of the posterior longitudinal ligament. Its superficial and deep laminae are both attached to the posterior surface of the axial body. The superficial lamina expands as it ascends to the upper surface of the basilar occipital bone, and attaches above the foramen magnum, where it blends with the cranial dura mater. The deep lamina consists of a strong median band that ascends to the foramen magnum, and two lateral bands that pass to, and blend with, the capsules of the atlanto-occipital joints as they reach the foramen magnum. The membrane is separated from the cruciform ligament of the atlas by a thin layer of loose areolar tissue, and sometimes by a bursa.

Alar ligaments The alar ligaments are thick cords, about 11 mm long, which pass horizontally and laterally from the longitudinally ovoid flattenings on the posterolateral aspect of the apex of the dens to the roughened areas on the medial side of the occipital condyles. In most individuals there is also an anteroinferior band, approximately 3 mm long, which inserts into the lateral mass of the atlas in front of the transverse ligament. Fibres occasionally pass from the dens to the anterior arch of the atlas. In addition, in some 10% of cases a continuous transverse band of fibres, the transverse occipital ligament, passes between the occipital condyles immediately above the transverse ligament. The ligaments consist mainly of collagen fibres arranged in parallel. The main function of the alar ligaments is now considered to be limitation of atlanto-axial rotation, the left becoming taut on rotation to the right and vice versa. The slightly downward movement of the atlas during rotation helps permit a wider range of movement by reducing tension in the alar ligaments, and in the capsules and accessory ligaments of the lateral atlanto-occipital joint.

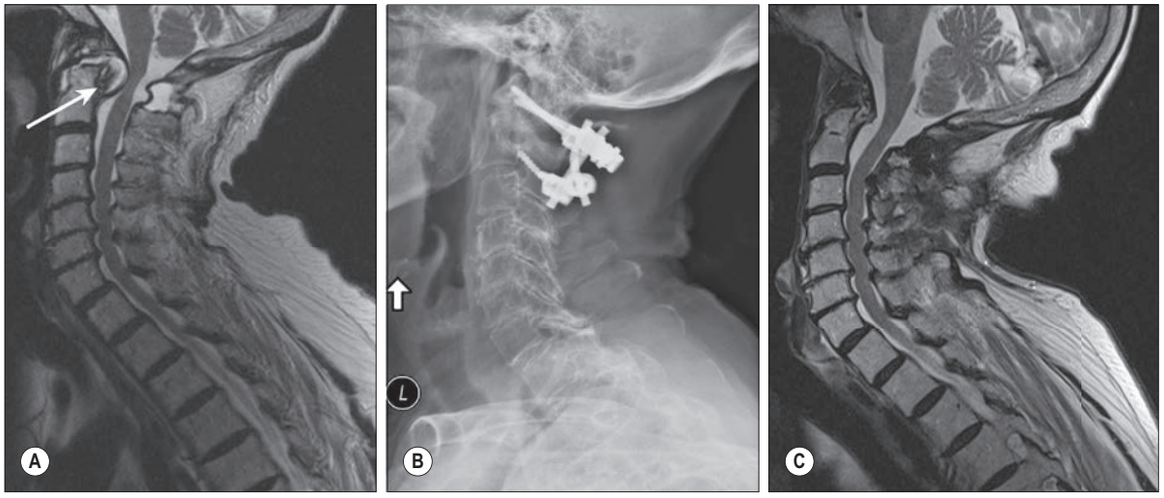

Fig. 46.69 **A**, A T2-weighted MRI showing soft tissue pannus (arrow) compressing the ventral cervicomedullary junction. **B**, A lateral X-ray showing a C1–C2 surgical fusion. **C**, A T2-weighted MRI, 1 year postoperative, showing resorption of the pannus that occurred with stabilization and surgical fusion.

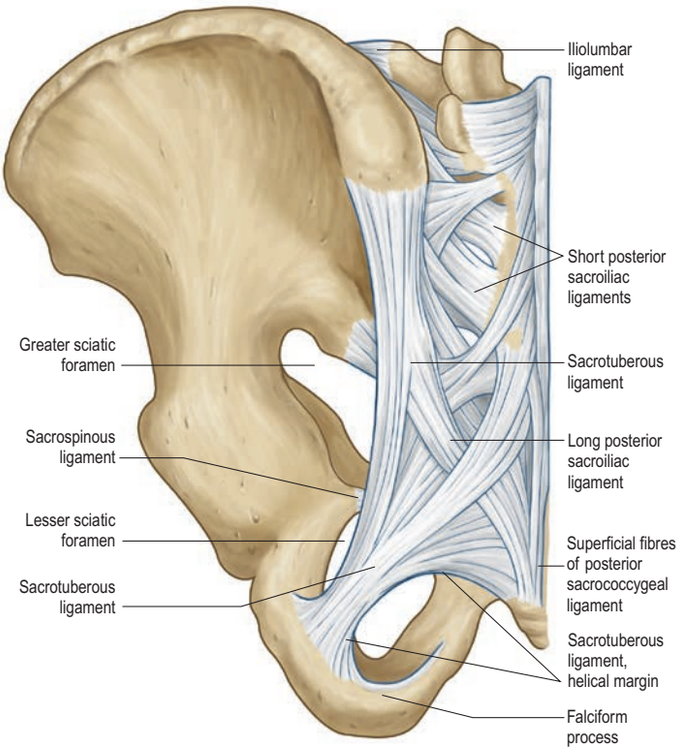

Fig. 46.70 Joints and ligaments on the posterior aspect of the left half of the pelvis and the fifth lumbar vertebra.

Apical ligament of the dens The apical ligament of the dens fans out from the apex of the dens into the anterior margin of the foramen magnum between the alar ligaments, and represents the cranial continuation of the notochord and its sheath. It is separated for most of its extent from the anterior atlanto-occipital membrane and cruciform ligament by pads of fatty tissue, though it blends with their attachments at the foramen magnum, and with the alar ligaments at the apex of the dens.

The ligamentum nuchae and the anterior longitudinal ligament also connect cervical vertebrae with the cranium.

Synovial membrane The synovial membranes of the lateral joints have no special features. The median joint has two synovial cavities that sometimes communicate. The synovial cavity of the posterior component of the median joint complex is larger, lying between the horizontally orientated ovoid facet, on the posterior surface of the dens and the cartilaginous anterior surface of the transverse ligament; communication often exists with one or both of the atlanto-occipital joint cavities.

Vascular supply The arterial supply of this region is derived from an anastomosis between branches of the deep cervical, occipital and vertebral arteries.

Innervation The joints are innervated by branches of the ventral primary ramus of the second cervical spinal nerve.

Factors maintaining stability The most important factors maintaining stability are the ligaments, of which the transverse atlantal ligament is the strongest (see Fig. 46.33). The alar ligaments are weaker. Other ligaments connecting the axis and the occipital bone, the fibrous capsules, the ligamentum nuchae and the posterior neck muscles also contribute to stability; the suboccipital muscles play an important proprioceptive and postural role.

Muscles producing movements Movement is simultaneous at all three joints and consists almost exclusively of rotation around the axis. The shape of the articular surfaces is such that, when rotation occurs, the axis ascends slightly into the atlantal ring, limiting stretch on the lateral atlanto-axial joint capsules. Rotation is limited mainly by the alar ligaments, with a minor contribution from the accessory atlanto-axial ligament. The normal range of atlanto-axial rotation is about 40°.

The muscles that produce atlanto-axial rotation act on the cranium, transverse processes of the atlas and spinous process of the axis. They are mainly obliquus capitis inferior, rectus capitis posterior major and splenius capitis of one side, and the contralateral sternocleidomastoid.

Relations and 'at risk' structures The most important 'at risk' relation is the spinal cord, lying posterior to the median atlanto-axial joint. Anteriorly, the atlanto-axial articulations, capsules and ligaments are separated from the buccopharyngeal fascia and superior constrictor by longus capitis and longus colli, the prevertebral fascia and the retropharyngeal (potential) space. Fractures or instability in this region may result in pathological development of soft tissue known as a pannus that may result in spinal cord compromise (Fig. 46.69).

Variants of craniovertebral joints

Anomalies of the craniovertebral joints are sometimes seen. Many are minor segmentation anomalies and may be incidental radiological or osteological findings. More severe anomalies may lead to craniocervical instability (Piper and Traynelis 1998).

Lumbosacral junction

Articulations between the fifth lumbar and first sacral vertebrae resemble those between other vertebrae. The bodies are united by a symphysis that includes a large intervertebral disc. The latter is deeper anteriorly at the lumbosacral angle. The synovial facet joints are separated by a wider interval than those above.

Articulating surfaces The reciprocally curved surfaces of the facet joints show considerable individual variation in alignment and shape. Asymmetry (facet tropism) is not unusual.

Ligaments The major ligament associated with the lumbosacral junction is the iliolumbar ligament (see Fig 77.9A; Fig. 46.70).

Iliolumbar ligament The iliolumbar ligament is attached to the tip and anteroinferior aspect of the fifth lumbar transverse process, and sometimes has a weak attachment to the fourth transverse process. It radiates laterally and is attached to the pelvis by two main bands. A lower band passes from the inferior aspect of the fifth lumbar transverse process and the body of the fifth lumbar vertebra across the anterior sacroiliac ligament to reach the posterior margin of the iliac fossa. An upper band, part of the attachment of quadratus lumborum, passes to the iliac crest anterior to the sacroiliac joint, and is continuous above with the anterior layer of the thoracolumbar fascia. The lower ligament has a more vertical component that reaches the posterior iliopectineal line; this component is a lateral relation of the L5 ventral ramus. A posterior component of the iliolumbar ligament passes behind quadratus lumborum to attach to the ilium.

In neonates and children, the iliolumbar 'ligament' is muscular; the muscle is gradually replaced by ligament up to the fifth decade of life.

Vascular supply The vascular supply of the lumbosacral junction is derived mainly from the iliolumbar and superior lateral sacral arteries.

Innervation The lumbosacral junction is innervated by branches derived from the fourth and fifth lumbar spinal nerves.

Relations and 'at risk' structures The lumbosacral disc is related anteriorly to the common iliac veins, the median sacral vessels, and the superior hypogastric plexus of nerves. The sympathetic trunks cross it anterolaterally, while the obturator nerves and lumbosacral trunks pass close laterally. The relations of the lumbosacral facet joints are similar to those of the lumbar facet joints (see above).

Sacrococcygeal junction

The sacrococcygeal joint is usually a symphysis between the sacral apex and coccygeal base, united by a thin fibrocartilaginous disc that is somewhat thicker in front and behind than laterally. Its surfaces carry hyaline cartilage that varies from thin veils to small islands. Occasionally, the coccyx is more mobile and the joint is synovial.

Ligaments The anterior sacrococcygeal ligament consists of irregular fibres that descend on the pelvic surfaces of both sacrum and coccyx, and is attached in the same way as the anterior longitudinal ligament.

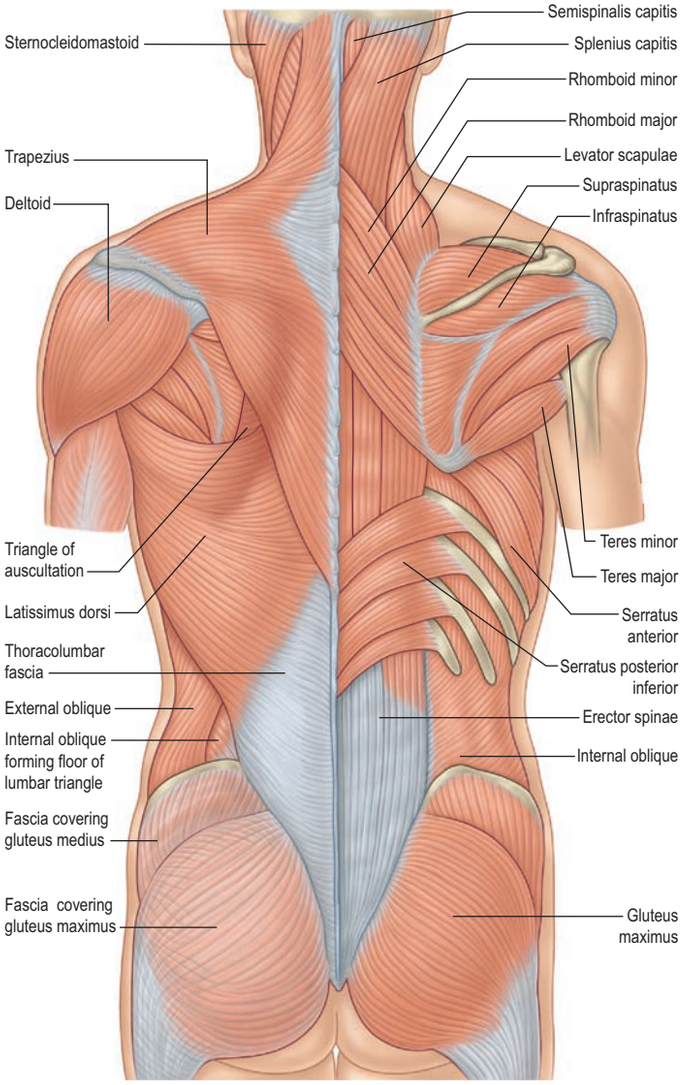

Fig. 46.71 Superficial muscles of the back of the neck and trunk. The skin, superficial and deep fasciae (other than gluteofemoral) have been removed on the left; sternocleidomastoid, trapezius, latissimus dorsi, deltoid and external abdominal oblique have been dissected away on the right.

The flat superior posterior sacrococcygeal ligament passes from the margin of the sacral hiatus to the dorsal coccygeal surface, roofing the lower sacral canal (see Fig. 46.70). The deep posterior sacrococcygeal ligament passes from the back of the fifth sacral vertebral body to the dorsum of the coccyx and corresponds to the posterior longitudinal ligament. On each side, the lateral sacrococcygeal ligaments connect the coccygeal transverse processes to the inferolateral sacral angles, completing foramina for the fifth sacral spinal nerves. Similarly, the intercornual ligaments connect the sacral and coccygeal cornua, and a fasciculus connects the sacral cornua to the coccygeal transverse processes.

Vascular supply The arterial supply of the sacrococcygeal junction is derived from the inferior lateral sacral and median sacral arteries.

Innervation The innervation of the sacrococcygeal junction is derived from the lower two sacral and the coccygeal nerves.

Intercoccygeal joints

In the young the intercoccygeal joints are symphyses, with thin discs of fibrocartilage between coccygeal segments. Segments are also connected by extensions of the anterior and posterior sacrococcygeal ligaments. In adult males all segments unite comparatively early, but in females union is later. In advanced age the sacrococcygeal joint becomes obliterated. Occasionally, the joint between the first and second segments is synovial. The apex of the terminal segment is connected to overlying skin by white fibrous tissue.

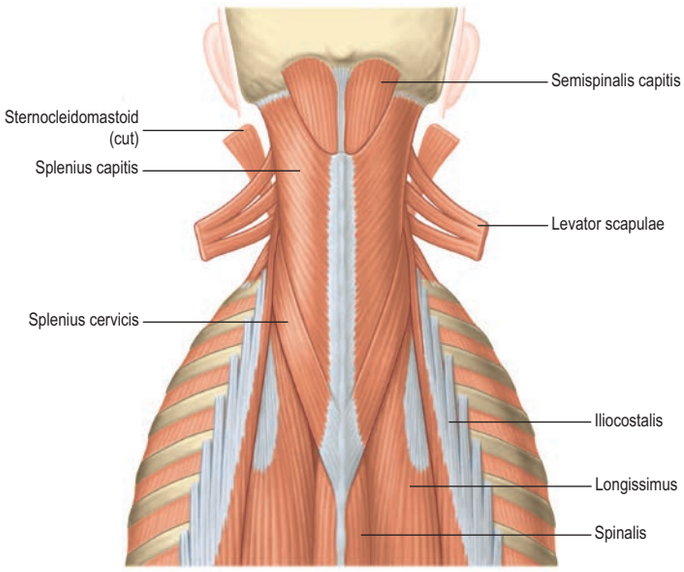

Fig. 46.72 An axial T2-weighted MRI of the lumbar spine at the level of the L3-L4 intervertebral disc.

MUSCLES

The musculature of the back is arranged in a series of layers, of which only the deeper are true, intrinsic, back muscles (**Fig. 46.71**). The true back muscles are characterized by their position and by their innervation by branches of the posterior (dorsal) rami of the spinal nerves. The true back muscles below the neck lie deep to the posterior layer of the thoracolumbar fascia. In the lumbar region, where the layers of the thoracolumbar fascia are well defined, they occupy the compartment between its posterior and middle layers.

Lying superficial to the true, intrinsic muscles are the extrinsic, 'immigrant' muscles (see Fig. 46.71). The most superficial of these run between the upper limb and the axial skeleton, and consist of trapezius, latissimus dorsi, levator scapulae and the rhomboid muscles. Beneath this layer lie the serratus posterior group, superior and inferior, which are variably developed but usually thin muscles whose function may be respiratory or possibly proprioceptive. All the extrinsic muscles are innervated by ventral rami.

Trapezius, levator scapulae, rhomboid major, rhomboid minor and latissimus dorsi are described in Chapter 49, serratus posterior superior and inferior are described in Chapter 53. The muscles of the posterior abdominal wall are described in Chapter 61.

The intrinsic muscles are also arranged in layers. The more superficial layers contain the splenius muscles in the neck and upper thorax, and the erector spinae group in the trunk as a whole. The deeper layers include the spinotransverse group, which is itself layered into semispinalis, multifidus and the rotatores, and the suboccipital muscles. Deepest of all lie the interspinal and intertransverse muscles. The latter group constitute a mixture of dorsal and ventral spinal muscles. The lumbar intertransversarii mediales, thoracic intertransversarii and medial parts of cervical posterior intertransversarii are innervated by dorsal rami, but the others are supplied by ventral rami.

Muscle attachments and fibre direction Although developmentally the muscles of the back extend caudally as the vertebral column elongates, drawing their nerve supply with them, they have traditionally been described as if their fibres ran caudocranially, so that the 'origins' of the muscles lay distal to their 'insertions'.

It has been shown that in the lumbar spine it is more appropriate morphologically and biomechanically to view the muscles in the reverse direction – from above downwards (Bogduk 2012). It is reasonable to argue that this view may also be applied to the cervical and thoracic muscles, and so for uniformity in this section, all muscles have been described in this way.

Ligamentum nuchae

The ligamentum nuchae is not a ligament of the neck, for it does not connect adjacent bones and lacks the internal structure typical of a ligament. It is a unique arrangement of tendons and fascia between the posterior muscles of the neck. It consists of a dorsal raphe and a median septal portion. The dorsal raphe lies superficially

along the posterior midline of the neck. It is attached to the external occipital protruberance superiorly, and the tip of the C7 spinous process inferiorly. In its superior half it consists of the aggregated tendons of the most medial fibres of the cervical portion of trapezius. Because of their longitudinal arrangement, these tendons have been described as forming the funicular portion of the ligamentum nuchae (Mercer and Bogduk 2003). In its inferior half, the funicular portion is joined by the obliquely orientated tendons of splenius capitis and rhomboid minor. Across the midline the tendons of splenius capitis are continuous with those of rhomboid minor on the other side, and they interweave with the tendons of the reciprocal sets of muscles to produce the raphenous structure of the ligamentum nuchae. From the ventral surface of the dorsal raphe, a median fascial septum extends deeply towards the vertebral column and separates semispinalis capitis from its opposite partner. A lateral expansion of the septum extends laterally ventral to semispinalis capitis, separating it from multifidus and semispinalis cervicis. The median continuation of the septum reaches the tips of the cervical spinous processes, and extends into the cervical interspinous spaces as far as the ligamentum flavum. At upper cervical levels, the septum is attached to the external occipital crest and the posterior tubercle of the atlas, and it blends with the posterior atlanto-occipital and posterior atlanto-axial membranes. Passing through these membranes, it is attached to the posterior surface of the dura mater (Dean and Mitchell 2002). Only the dorsal raphe affords attachment to muscles; no muscles arise from the median septum.

Splenius capitis

Attachments Splenius capitis arises from the mastoid process and the rough surface on the occipital bone just below the lateral third of the superior nuchal line. Its fibres pass downwards and medially to reach the midline. The lower fibres insert into the tips of the spinous processes of the seventh cervical and upper three or four thoracic vertebrae and the intervening supraspinous ligaments. The tendons of the upper fibres interlace in the midline with those of the opposite side in the dorsal raphe of the ligamentum nuchae in the lower half of the cervical region (**Fig. 46.72**).

Relations Splenius capitis lies deep to trapezius and covers semispinalis capitis and longissimus capitis. The upper part of the muscle lies beneath sternocleidomastoid. Between sternocleidomastoid and trapezius it forms part of the floor of the posterior triangle of the neck, above and behind levator scapulae.

Vascular supply See below.

Innervation Splenius capitis is innervated by lateral branches of the second and third cervical dorsal rami.

Actions Acting unilaterally, and synergistically with the contralateral sternocleidomastoid, splenius capitis rotates the head to the same side. Acting bilaterally, splenius capitis extends the head.

Splenius cervicis

Attachments Splenius cervicis is confluent with splenius capitis, but covers more caudal regions of the neck and thoracic region (see Fig. 46.72). It arises from the transverse process of the atlas, the tip of the transverse process of the axis and the posterior tubercle of the third cervical vertebra. Its fibres pass downwards and medially, wrapping around the other posterior intrinsic neck muscles, to insert into the third to sixth thoracic spinous processes.

Relations Splenius cervicis lies deep to serratus posterior superior, the rhomboids and trapezius. It covers the upper parts of the erector spinae and the lower semispinalis muscles.

Vascular supply See below.

Innervation Splenius cervicis is innervated by lateral branches of the lower cervical dorsal rami.

Actions Acting unilaterally, splenius cervicis rotates the upper cervical vertebra, in the same way that the splenius capitis rotates the head. Acting bilaterally, splenius cervicis extends the upper cervical spine.

Variations The splenii may be absent or vary in their vertebral attachments. Accessory slips also occur.

Erector spinae

Erector spinae (see Fig. 46.6; **Figs 46.73–46.74**) is a large musculotendinous mass that differs in size and composition at different vertebral levels. It consists of fascicles that assume systematic attachments to homologous parts of the skull, the cervical, thoracic and lumbar vertebrae, the sacrum and the ilium. Individual muscles are defined by the attachments of their fascicles and the regions that they span. There are three muscles, each with three regional parts (**Table 46.1**).

Spinalis Spinalis thoracis is the most medial portion of erector spinae in the thoracic region. It consists of fascicles that arise from the spinous processes of the upper thoracic vertebra and insert into the spinous processes of the eleventh and twelfth thoracic and first two lumbar vertebrae. The number of fascicles and their segmental attachments vary. The fascicles are arranged in an overlapping series of increasingly longer, flat arcs. The shortest fascicles have the lowest origin and highest insertion, and the longest fascicles have the highest origin and lowest

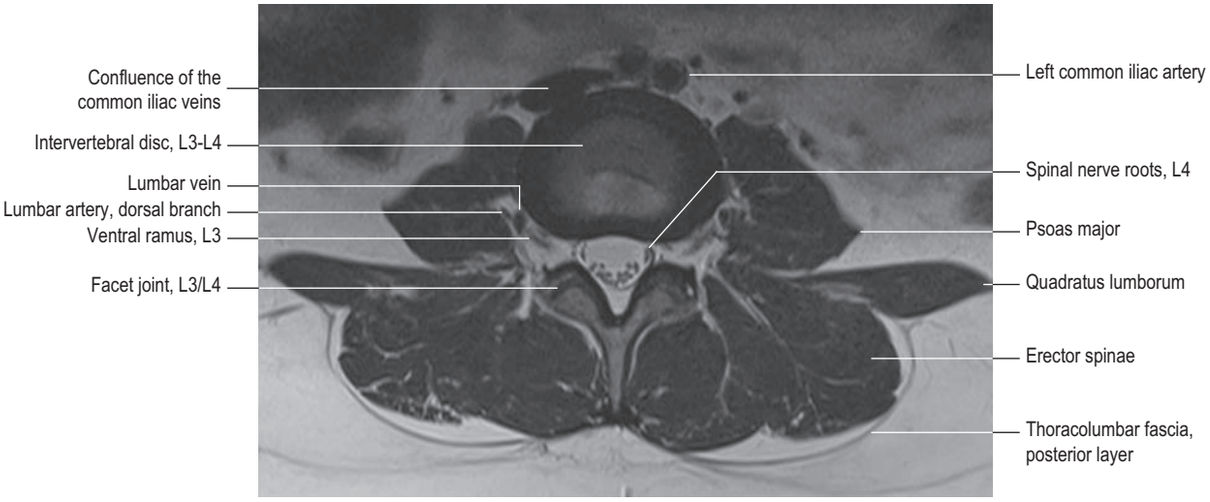

Fig. 46.74 An axial MRI of the lumbar spine at the level of the L4-L5 intervertebral disc.

insertion. Laterally, the muscle blends intimately with longissimus thoracis and is considered by some to be a component of that muscle.

Spinalis is irregularly and poorly developed in other regions. When present, spinalis cervicis consists of paramedian fibres that arise variously from the spinous processes of the axis and the third and fourth cervical vertebrae, and insert into the lower part of the ligamentum nuchae and the spine of the seventh cervical vertebra (sometimes also to the first and second thoracic vertebrae). Spinalis capitis is represented by occasional fibres of semispinalis capitis that insert into the spines of the seventh cervical and first thoracic vertebrae instead of reaching the thoracic transverse processes.

Longissimus Longissimus is the central component of erector spinae. It assumes a series of attachments at sites that are homologous to the junction of the transverse and costal elements of the segment. These sites are represented at thoracic levels by the tip of a transverse process and the immediately adjacent posterior surface of the rib; at cervical levels by the transverse process and posterior tubercle; and at lumbar levels by the accessory process (the transverse element) and medial half of the transverse process (the costal element).

Longissimus capitis is a narrow flat band of muscle that arises from the posterior edge of the mastoid process, under cover of splenius capitis and sternocleidomastoid. It descends across the lateral surface of semispinalis capitis and inserts by a series of tendons into the transverse processes of the lower three or four cervical and upper four or so thoracic vertebrae.

Longissimus cervicis is a long thin muscle that arises by tendons from the posterior tubercles of the transverse processes of the second to sixth cervical vertebra. It descends into the thoracic region, between the tendons of longissimus capitis and longissimus thoracis, to insert by tendons into the transverse processes of the upper four or five thoracic vertebrae.

Longissimus thoracis is the largest component of erector spinae. It consists of many small fascicles that are aggregated in a particular manner to produce a very long, and in some places thick, muscle. It has lumbar and thoracic parts.

The lumbar part is formed by fleshy bundles that arise from the accessory process and the medial half or so of the posterior surface of the transverse process of each of the five lumbar vertebrae. The fascicles pass inferiorly and slightly laterally. Those from the first four lumbar vertebrae converge on to a common flat tendon that covers the lateral surface of the muscle and separates it from the lumbar fibres of iliocostalis, for which reason it is called the lumbar intermuscular aponeurosis. The aponeurosis commences in the mid-lumbar region, with a broad irregular base, and inferiorly it tapers to a truncated point that inserts into the medial surface of the ilium just dorsal to the ala of the sacrum. The fascicle from the first lumbar vertebra attaches rostrally and dorsally to the aponeurosis. Successive fascicles attach to it more ventrally and caudally. The fascicle from the fifth lumbar vertebra inserts separately, deep to the intermuscular aponeurosis, into the ventromedial aspect of the ilium and the upper fibres of the dorsal sacroiliac ligament. Medially, the lumbar fibres of longissimus are separated from the multifidus by a wide cleavage plane filled with fat and veins.

The thoracic part consists of fascicles with small, fusiform muscle bellies that have short rostral tendons and long caudal tendons. The muscle bellies are arranged in a tiered fashion across the length of the posterior thoracic wall, with the highest lying medially and the lowest lying laterally. The upper four fascicles arise from the tips of the first four thoracic transverse processes. The succeeding fascicles have bifid tendons that arise from the transverse process and the adjacent rib at each of the lower eight thoracic segments. The long caudal tendons of the thoracic fascicles of longissimus are aggregated in parallel to form a wide aponeurosis, which allows them to assume a variety of caudal insertions. The tendons of the uppermost fascicles insert into the lumbar spinous processes and their supraspinous ligament. Those from the first thoracic segment reach the L1–L2 level, and those from the sixth thoracic segment reach the L5 level. The fascicles from the seventh to ninth thoracic segments reach the median sacral crest, and those from the tenth and eleventh thoracic segments attach transversely across the posterior surface of the third segment of the sacrum. The fascicle from the twelfth thoracic segment reaches the sacrum and dorsal segment of the iliac crest just below where the intermuscular aponeurosis of the lumbar fibres of longissimus inserts into the ilium. The aponeurosis covers the multifidus and the lumbar fibres of longissimus; it extends from the midline as far laterally as the dorsal edge of the lumbar intermuscular aponeurosis, with which it fuses. Within the lumbar intermuscular aponeurosis, the lumbar fibres of longissimus, from L1 to L5, complete the systematic progression of attachments exhibited by the thoracic fibres.

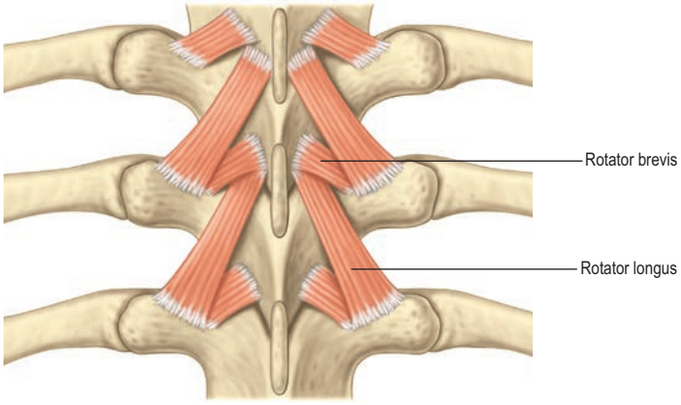

Fig. 46.75 Rotatores (thoracic region). (With permission from Benninghoff, Anatomie, 15th edition © Urban and Schwarzenberg, 1994.)

Iliocostalis Iliocostalis is the most lateral component of the erector spinae. Its fascicles are attached to sites that are homologous with the ribs.

Iliocostalis cervicis consists of slender fascicles that arise by long tendons from the posterior tubercles of the fourth, fifth and sixth cervical vertebrae. They descend over the posterior thorax to insert into the third to sixth ribs at their angles.

Iliocostalis thoracis is a narrow, fusiform muscle. The fibres arise from the back of the transverse process of the seventh cervical vertebra and the superior borders of the angles of the upper six ribs; they lie lateral to iliocostalis cervicis, and insert into the upper borders of the angles of the lower six ribs.

Iliocostalis lumborum consists of lumbar and thoracic parts. The lumbar part is formed by fleshy fascicles that arise from the tips of the first four lumbar transverse processes and the posterior surface of the middle layer of thoracolumbar fascia lateral to these tips. These fascicles descend to the ilium in a laminated fashion, such that those from higher levels cover those from lower levels. They insert into the medial end of the iliac crest and the dorsal segment of the iliac crest, with the fascicle from L4 assuming the most ventral and lateral attachment, and the fascicle from L1 assuming the most dorsal and medial attachment. The attachment to the ilium is largely by fleshy fibres but the more superficial fibres are aponeurotic. The thoracic part consists of eight or nine small fascicles that respectively arise from the lower eight or nine ribs at their angles, lateral to the iliocostalis thoracis. Each fascicle arises from its rib by a ribbon-like tendon. The tendons are longer at high levels but become progressively shorter at lower levels. The muscle bellies of the fascicles are uniform in length, and each gives rise to a caudal tendon. These tendons are aggregated to form a dorsal aponeurosis that covers the lumbar part of iliocostalis lumborum and inserts in a linear fashion into the medial end of the iliac crest and its dorsal segment. Along this line the fascicles are represented serially, such that the fascicle from the twelfth rib attaches most laterally and that from the fourth or fifth rib attaches most medial and inferiorly.

Erector spinae aponeurosis Together, the dorsal aponeuroses of the thoracic fibres of longissimus and the thoracic fibres of iliocostalis lumborum form a wide sheet of parallel tendons known as the erector spinae aponeurosis. It is attached to the lumbar spinous processes and supraspinous ligaments, the median sacral crest, the third sacral segment, the dorsal segment of the iliac crest and the medial end of the iliac crest, and covers multifidus and the lumbar fibres of both longissimus and iliocostalis. Significantly, the erector spinae aponeurosis is formed exclusively by the tendons of the thoracic fibres of longissimus thoracis and iliocostalis lumborum; it does not give rise to the lumbar fibres of these muscles, which are attached independently to the ilium. Some of the more superficial fibres of multifidus may insert into the

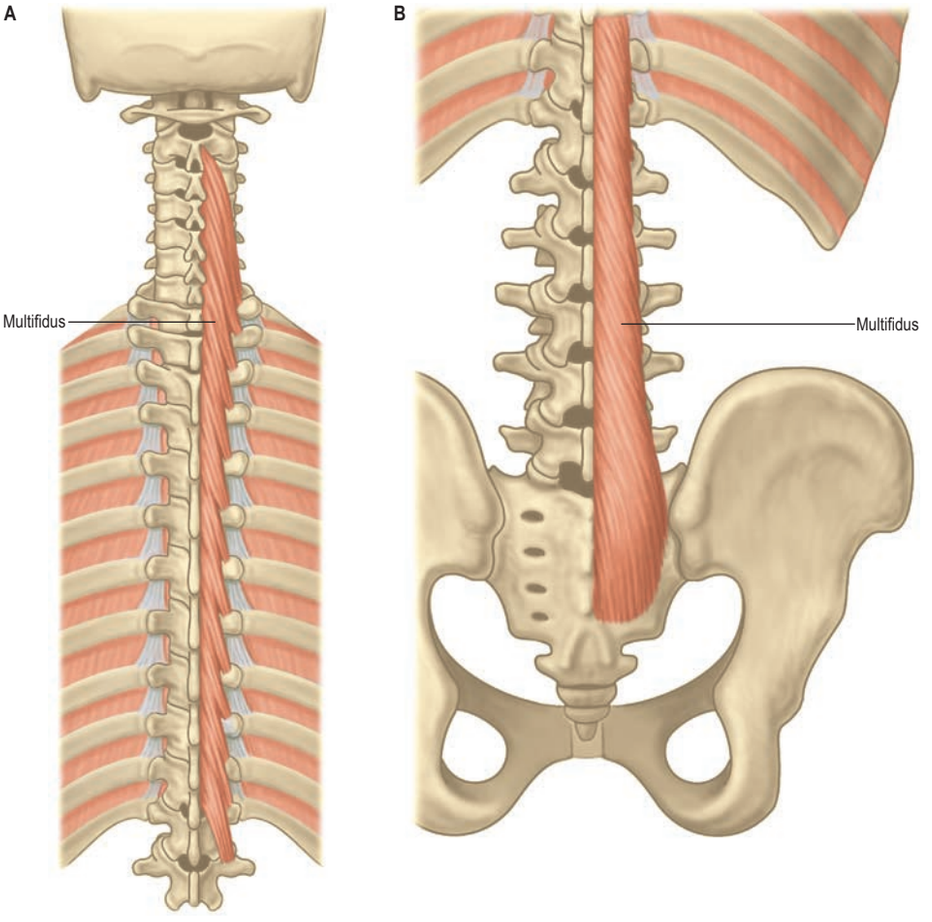

Fig. 46.76 Multifidus. **A**, Cervicothoracic parts. **B**, Lumbosacral parts.

deep surface of the erector aponeurosis over the sacrum, but otherwise the substantive insertion of multifidus is into the sacrum. A portion of the uppermost fibres of gluteus maximus arise from the dorsal surface of the inferolateral corner of the erector spinae aponeurosis. The lumbar intermuscular aponeurosis is a ventral extension of the erector spinae aponeurosis, separating the lumbar fibres of longissimus from those of iliocostalis.

Relations Erector spinae is covered in the lumbar and thoracic regions by the thoracolumbar fascia, and by serratus posterior inferior below and the rhomboids and splenii above. In the lumbar region, it lies in the compartment between the posterior and middle layers of the thoracolumbar fascia.

Vascular supply See below.

Innervation Erector spinae is innervated by the lateral branches of the dorsal rami of the cervical, thoracic and lumbar spinal nerves. At lumbar levels, lateral branches innervate iliocostalis and intermediate branches innervate longissimus.

Actions The thoracic and lumbar components of erector spinae are powerful extensors of the vertebral column. Acting concentrically and bilaterally they can extend the thoracic and lumbar spines whereas acting unilaterally they can laterally flex the trunk. However, more commonly, erectores spinae act eccentrically.

From the upright posture, the trunk can flex forwards under the influence of gravity. This movement is initiated by flexor muscles, such as rectus abdominis, in order to bring the centre of gravity of the trunk forwards. Thereafter, erectores spinae control the descent of the thorax under gravity. When the trunk is fully flexed, many parts of erector spinae cease to contract and become electromyographically silent. In this position, flexion is limited by passive tension in the back muscles, and tension in the thoracolumbar fascia, the posterior spinal ligaments and the intervertebral discs. Similarly, lateral flexion under gravity is controlled by the contralateral erector spinae, with input from the oblique abdominal muscles.

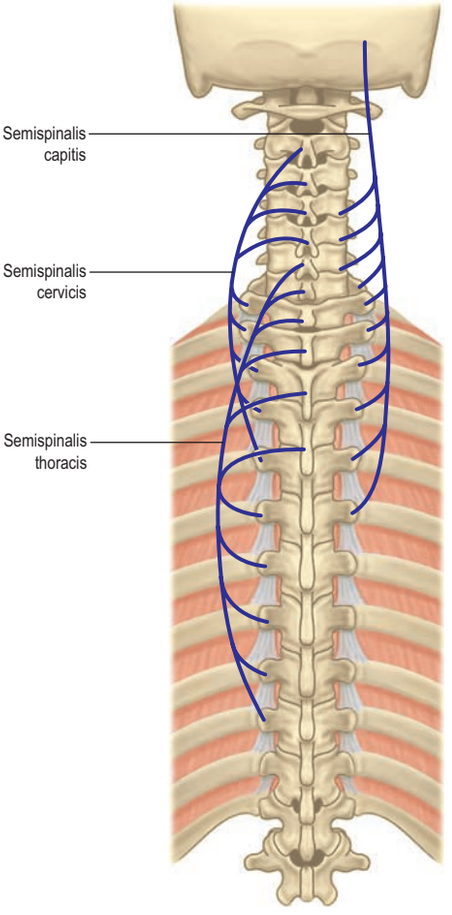

Fig. 46.77 The attachments of semispinalis.

The function of the cervical and capital components of erector spinae has not been determined. These are small muscles with very little force capacity, and are poorly orientated to exercise extension or to control flexion of the head or cervical spine. As putative extensors they are dwarfed by semispinalis and splenius. Axial rotation of the head draws longissimus capitis around the perimeter of the cervical spine, orientating it perhaps so that it is able to restore the head to neutral from the rotated position.

Spinotransverse group

The spinotransverse muscle group consists of muscles where the fascicles span between a spinous process and the transverse elements of vertebrae at various levels below. The muscles are grouped according to the length of their fascicles and the region that they cover (**Table 46.2**).

Rotatores have the deepest and shortest fascicles, and span one and two segments, whereas the fascicles of multifidus span two, three, four or five segments, and those of semispinalis span about six segments.

Rotatores Rotatores thoracis (**Fig. 46.75**) consist of 11 pairs of small quadrilateral muscles. The first pair lies between the first and second thoracic vertebrae, and the last between the eleventh and twelfth thoracic vertebrae. One or more may be absent from the upper or lower ends of the series. In each segment, a rotator brevis connects the lower border and lateral surface of the lamina above to the upper, posterior part of the transverse process of the vertebra immediately below; a rotator longus connects the base of the spinous process above to the transverse process two levels below. Rotatores are not obviously present at lumbar and cervical levels, where they may be represented by some of the deeper fascicles of multifidus.

Multifidus At cervical, thoracic and upper lumbar levels, multifidus lies lateral to the spinous processes and covers the laminae of the underlying vertebrae, but at lumbosacral levels it expands to cover the posterior surface of the sacrum (**Fig. 46.76**). At each segmental level, multifidus is formed by several fascicles that arise from the caudal edge of the lateral surface of the spinous process and from the caudal end of its tip. They radiate caudally to insert into the transverse elements of vertebrae two, three, four and five levels below (Macintosh et al 1986). These sites are represented at cervical levels by the superior articular processes, at thoracic levels by the posterior surface of each transverse process near its base, and at lumbar levels by the mammillary processes. Fascicles that extend beyond the fifth lumbar vertebra insert into the dorsal surface of the sacrum. The longest fascicles from the first and second lumbar vertebrae insert into the dorsal segment of the iliac crest. From each spinous process the shortest fascicles pass inferiorly and laterally to their insertion; the longer fascicles assume a progressively steeper course and are arranged progressively more medially. The fascicles from a given segment are flanked and overlapped dorsolaterally by fascicles from successively higher segments, an arrangement that endows the intact muscle with a laminated structure.

Semispinalis The semispinalis muscles are formed by the longest fascicles of the spinotransverse group. Three divisions are defined essentially by their origins (**Fig. 46.77**).

Semispinalis cervicis arises from the spinous processes of the second to fifth cervical vertebrae. Its fascicles span about six segments and cover the cervical and thoracic multifidus. They insert by fleshy or tendinous fibres into the posterior surfaces of the upper five or six thoracic transverse processes. The fascicle from the axis is the largest and is composed chiefly of muscle.

Semispinalis thoracis consists of thin, fleshy fascicles that have long tendons at both ends. They arise from the lower two cervical and the upper four thoracic spinous processes, and insert into the transverse processes of the sixth to tenth thoracic vertebrae. They cover the thoracic multifidus.

Semispinalis capitis covers semispinalis cervicis. It arises from the medial part of the area between the superior and inferior nuchal lines of the occipital bone and forms a thick muscle bundle in the suboccipital region. Individual fascicles pass inferiorly, laterally and ventrally from the muscle, ending as flat tendons that insert successively into the superior articular processes of the lower four cervical vertebrae and the tips of the transverse processes of the upper six or seven thoracic vertebrae. The medial part of the muscle in the cervical region is formed by the thoracic fascicles, which are more or less distinct from the rest, and has been called biventer cervicis because it is traversed by an incomplete tendinous intersection.

Semispinalis is not formed in the lumbar region, but vestiges of its caudal tendons are represented as the mammillo-accessory ligaments of the lumbar vertebrae.

Relations At cervical, thoracic and lumbar levels, components of erector spinae lie lateral to the spinotransverse group of muscles. They are covered at cervical levels by splenius, at thoracic levels by spinalis thoracis, and at lumbar levels by the erector spinae aponeurosis. In the neck, semispinalis capitis lies mainly deep to splenius and trapezius, but a small portion may be exposed to form the uppermost part of the floor of the posterior triangle of the neck.

Vascular supply See below.

Innervation Rotatores, multifidus, semispinalis thoracis and semispinalis cervicis are all innervated by the medial branches of the dorsal rami of the appropriate spinal nerves. Semispinalis capitis is innervated by descending branches of the greater occipital nerve (C2) and the third cervical nerve (C3).

Actions All the spinotransverse muscles are extensors. They extend the vertebrae from which they arise, or the head in the case of semispinalis capitis. The predominantly longitudinal orientation of their fascicles precludes any substantive action as rotators. Although rotatores have been presumed to rotate the thoracic vertebrae, this action has not been validated. Axial rotation has been expressly refuted as an action of the lumbar multifidus.

Interspinales

Interspinales are short, paired muscular fasciculi attached above and below to the apices of the spines of contiguous vertebrae, one on either side of the interspinous ligament. They are most distinct in the cervical region, where they consist of six pairs, the first between the axis and third vertebra, and the last between the seventh cervical and first thoracic vertebrae. In the thoracic region they occur between the first and second vertebrae (sometimes between the second and third), and the eleventh and twelfth vertebrae. In the lumbar region there are four pairs between the five lumbar vertebrae. A pair is occasionally found between the last thoracic and first lumbar vertebrae, and another between the fifth lumbar vertebra and the sacrum. Sometimes cervical interspinales span more than two vertebrae.

Intertransversarii

Intertransversarii are small muscles between the transverse processes of the vertebrae. They are best developed in the cervical region, where they consist of posterior and anterior sets of muscles separated by the ventral rami of spinal nerves. Posterior intertransverse muscles are divisible into medial and lateral slips. Each medial slip, the intertransverse muscle 'proper', is often further subdivided into medial and lateral parts by the passage through it of the dorsal ramus of a spinal nerve. There are seven pairs of these muscles, the highest between the atlas and axis, and the lowest between the seventh cervical vertebra and the first thoracic vertebra; the anterior muscles between atlas and axis are often absent. In the thoracic region, intertransversarii consist of single muscles that span between the transverse processes of the last three thoracic and the first lumbar vertebrae. In the lumbar region, they again consist of two sets of muscles. One set, intertransversarii mediales, connects the accessory process of one vertebra with the mammillary process of the next. The other set, intertransversarii laterales, can be divided into ventral and dorsal parts; the ventral parts connect the transverse processes of the lumbar vertebrae, and the dorsal parts connect the accessory processes to the transverse processes of succeeding vertebrae.

Different parts of the intertransversarii in the cervical and lumbar regions are homologous with certain muscles found in the thoracic region. The homologies are determined according to whether the muscle attaches between consecutive transverse elements of the vertebrae, or between transverse and costal elements, or between consecutive costal elements. They are reinforced by the nerve supply of the muscle, and by the relationship between the muscles and certain nerves.

The medial slips of the 'proper' posterior intertransverse muscles of the neck connect consecutive transverse elements, as do the intertransversarii mediales of the lumbar region. These muscles are homologous with the thoracic intertransverse muscles and ligaments. All are supplied by dorsal rami. The lateral slips of the 'proper' posterior intertransverse muscles connect a transverse element to a costal element, as do the intertransversarii laterales dorsales. They are homologous with levatores costarum and are supplied by the ventral rami of spinal nerves. At each level, the medial branch of a dorsal ramus separates the true

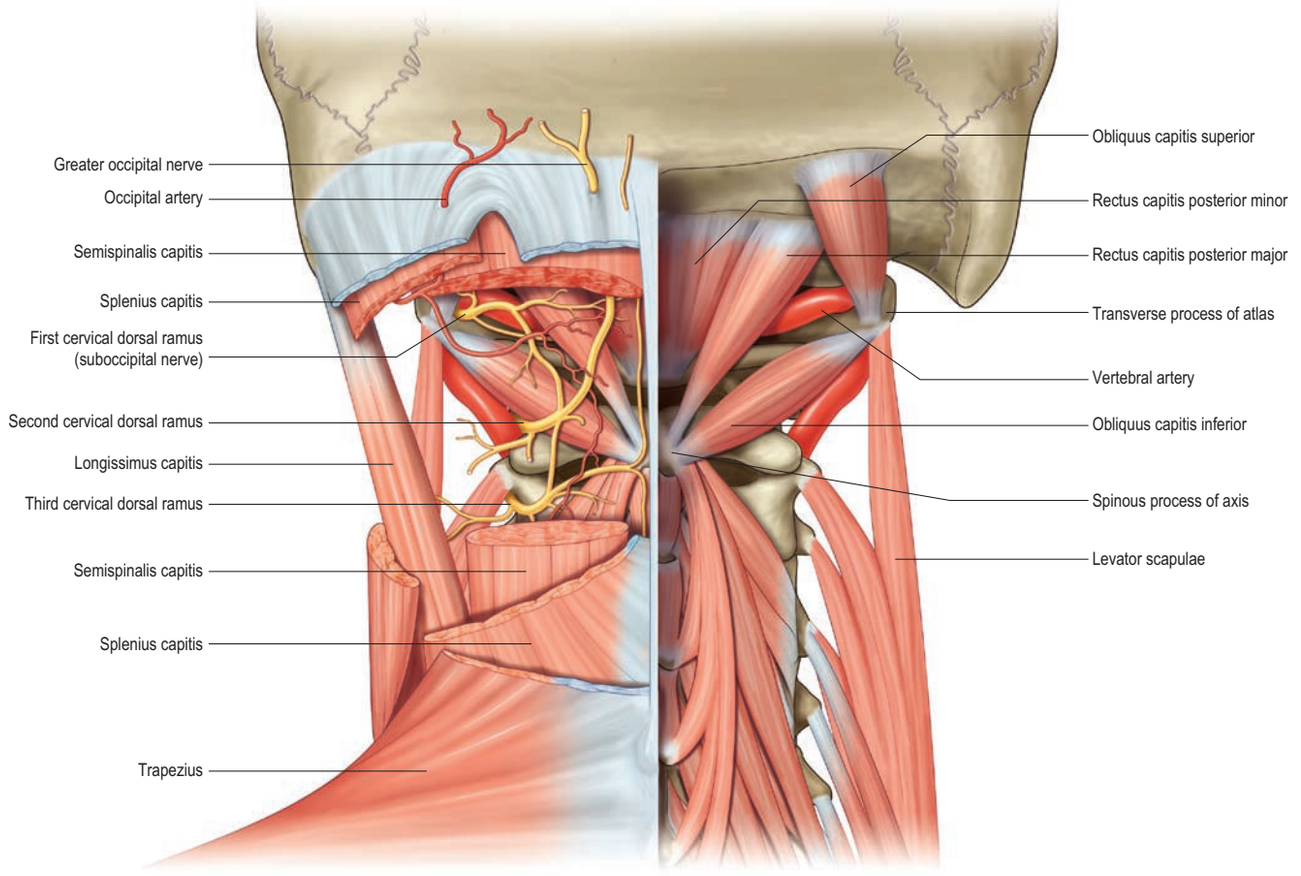

Fig. 46.78 Suboccipital triangles, posterior view. (From Drake RL, Vogl AW, Mitchell A et al (eds), Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008.)

intertransverse muscle from levator costae or its equivalent. The anterior intertransverse muscles of the neck and lateral parts of the posterior intertransversarii connect the costal processes of consecutive vertebrae, as do the intertransversarii laterales ventrales of the lumbar region; they are homologous with the intercostal muscles and are supplied by ventral rami.

Actions of interspinales and intertransversarii The functions of interspinales and intertransversarii have not been established. They are very small muscles and are unlikely to be able to generate enough force to be prime movers of the vertebrae. However, they are richly endowed with muscle spindles; the density approaches that found in the lumbricals of the hand and in the extraocular muscles. It therefore seems reasonable to assume that the short muscles of the back may serve a proprioceptive function in controlling the position of the vertebral column and its movements.

Vascular supply of the true back muscles

The true (intrinsic) muscles of the back receive their blood supply from: the vertebral artery; deep cervical artery; superficial and deep descending branches of the occipital artery; deep branch of the transverse cervical artery (when present); supreme intercostal artery, via dorsal branches of the upper two posterior intercostal arteries; posterior intercostal arteries of the lower nine spaces via dorsal branches; dorsal branches of the subcostal arteries; dorsal branches of the lumbar arteries; dorsal branch of arteria lumbalis ima; and dorsal branches of the lateral sacral arteries.

The detailed pattern of the arterial supply of the deep muscles of the back has been described by Michel Salmon (1994). These muscles are supplied by dorsal branches of the posterior intercostal and lumbar arteries. In the thoracic and upper lumbar regions, where the components of erector spinae run in well-defined longitudinal columns, arterial trunks from these dorsal branches run in the sulci between the columns and between erector spinae and multifidus, giving off branches to supply the muscles. This vascular pattern is less regular in the lumbar region.

Suboccipital muscles

The suboccipital muscles (Fig. 46.78) are four small muscles that connect the occipital bone, atlas and axis posteriorly. They lie inferior to the anterior part of the occipital bone, where three of the muscles form the boundaries of the suboccipital triangle: rectus capitis posterior major lies above and medially; obliquus capitis superior lies above and laterally, and obliquus capitis inferior lies below and laterally. With the head in the anatomical position, the suboccipital triangle lies almost in the horizontal plane.

Rectus capitis posterior major Rectus capitis posterior major is attached by a pointed tendon to the spine of the axis, becomes broader as it ascends, and is attached to the lateral part of the inferior nuchal line and the occipital bone immediately below it. As the muscles of the two sides pass upwards and laterally, they leave between them a triangular space in which parts of recti capitis posteriores minores are visible.

Rectus capitis posterior minor Rectus capitis posterior minor is attached by a narrow pointed tendon to the tubercle on the posterior arch of the atlas. As it ascends, it broadens before attaching to the medial part of the inferior nuchal line and to the occipital bone between the inferior nuchal line and the foramen magnum. Either muscle may be doubled longitudinally. There is usually a soft tissue attachment to the posterior atlanto-occipital membrane, which itself is firmly attached anteriorly to the spinal dura in the same area (Zumpano et al 2006).

Obliquus capitis inferior Obliquus capitis inferior, the larger of the two oblique muscles, passes laterally and slightly upwards from the lateral surface of the spine and the adjacent upper part of the lamina of the axis to the inferoposterior aspect of the transverse process of the atlas.

Obliquus capitis superior Obliquus capitis superior is attached by tendinous fibres to the upper surface of the transverse process of the atlas. It expands in width as it ascends dorsally, and is attached to the occipital bone between the superior and inferior nuchal lines, lateral to semispinalis capitis and overlapping the insertion of rectus capitis posterior major.

Relations of the suboccipital triangle Medially, the suboccipital triangle is covered by a layer of dense adipose tissue, deep to

semispinalis capitis. Laterally, it lies under longissimus capitis and sometimes splenius capitis, both of which overlap obliquus capitis superior. The 'floor' of the triangle is formed by the posterior atlanto-occipital membrane and the posterior arch of the atlas. The vertebral artery and the dorsal ramus of the first cervical nerve lie in a groove on the upper surface of the posterior arch of the atlas.

Vascular supply The suboccipital muscles receive their blood supply from the vertebral artery and deep descending branches of the occipital artery.

Innervation All the suboccipital muscles are supplied by the dorsal ramus of the first cervical spinal nerve.

Actions of the suboccipital muscles The suboccipital muscles are involved in extension of the head at the atlanto-occipital joints and rotation of the head and atlas on the axis. Obliquus capitis superior and the two recti are probably more important as postural muscles than as prime movers but this is difficult to confirm by direct observation. Rectus capitis posterior major extends the head and, acting with obliquus capitis inferior, rotates the face towards the ipsilateral side. Rectus capitis posterior minor extends the head. Obliquus capitis superior extends the head and laterally flexes it to the ipsilateral side.

MOVEMENTS OF THE VERTEBRAL COLUMN

Spinal movements between individual vertebrae cannot be measured accurately by skin-surface techniques; only biplanar radiography is sufficient for this purpose. Movements of the entire lumbar spine can be measured using skin-surface techniques, but the results are of limited clinical use because there is high inter- and intra-observer variation (Pearcy et al 1984, Pearcy and Tibrewal 1984).

The intervertebral discs are the principal sites of vertebral column movement. Conversely, at most levels, the extent to which the discs may be deformed is also the limiting factor for motion. Bony deformation in the subchondral bone and articular cartilage may contribute to movement. Regional variations in mobility of the spine depend on the geometry, orientation and properties of the facet joints and related ligamentous complexes. Physiological intervertebral movements usually combine tilting (bending) and gliding (shear), so the instantaneous centre of rotation moves continually during the movement. During flexion and extension of the lumbar vertebrae, the centre of rotation usually lies near the centre of the intervertebral disc when viewed in the transverse plane, close to the superior end-plate of the vertebra below.

The oblique and ovoid articular surfaces of the facet joints ensure that spinal movements in different planes are usually 'coupled' to a certain extent. For example, lateral flexion would cause impingement of the articular surfaces on that side, leading to a posteriorly directed force on the upper vertebra that would act to rotate it about its long axis. Physiologically, coupled movements are variable. Although movements between individual vertebrae are small, their summation gives a large total range to the vertebral column in flexion, extension, lateral flexion and axial rotation. Each pair of vertebrae with its interposed disc and ligaments is termed a motion segment or functional spinal unit.

In flexion, the anterior longitudinal ligament becomes relaxed as the anterior parts of the intervertebral discs are compressed. At its limit, the posterior longitudinal ligament, ligamenta flava, interspinous and supraspinous ligaments, and the posterior fibres of the intervertebral discs are all tensed, the interlaminar intervals widen, the inferior articular processes glide on the superior processes of subjacent vertebrae, and their capsules become taut. Tension of extensor muscles is also important in limiting flexion, e.g. when carrying a load on the shoulders. Flexion is effectively absent in the thoracic region. In forward flexion of the lumbar spine, the muscles normally protect the osteoligamentous spine from injury. However, the margin of safety can be compromised during repetitive or sustained bending by a failure of the spinal reflexes. Once the muscle protection is lost, flexion injury affects first the interspinous ligaments and then the capsules of the facet joints. The ligamentum flavum has such a high content of elastin that it is always under tension, and can be stretched by 80% without damage. This ligament probably functions to provide a constant smooth lining to the vertebral canal, which is never overstretched in flexion and which never goes slack in extension.

In extension, the opposite events occur and there is compression of posterior discal fibres. Extension is limited by tension of the anterior longitudinal ligament, anterior discal fibres and impaction of spines or articular processes. It is marked in cervical and lumbar regions, and much less at thoracic levels, partly because the discs are thinner, but also because of the presence of the ribs and chest musculature. In full extension, the axis of movement passes posterior to the disc, moves forwards as the column straightens and passes into flexion, and reaches the centre of the intervertebral disc in full flexion.

In lateral flexion, which is always combined with 'coupled' axial rotation, intervertebral discs are laterally compressed and contralaterally tensed and lengthened, and motion is limited by tension of antagonist muscles and ligaments. Lateral movements occur in all parts of the column but are greatest in cervical and lumbar regions.

Axial rotation involves twisting of vertebrae relative to each other with accompanying torsional deformation of intervening discs. About 50% of cervical rotation occurs at the atlanto-axial joint. Elsewhere in the column, although movement is slight between individual vertebrae, the range summates to become considerable for the column as a whole. In the postcervical column, the effective range of rotation is greatest at the thoracolumbar junction. There is very little rotation in the remainder of the lumbar region.

In the cervical region, the upward inclination of the superior articular facets allows free flexion and extension. The latter is usually greater, and is checked above by locking of the posterior edges of the superior facets of C1 in the occipital condylar fossae, and below by slipping of the inferior processes of C7 into grooves inferoposterior to the first thoracic superior articular processes. Flexion stops where the cervical convexity is straightened, checked by apposition of the projecting lower lips of vertebral bodies on subjacent bodies. Cervical lateral flexion and rotation are always coupled, and the superomedial inclination of the superior articular facets imparts rotation during lateral flexion.

Cervical motion can be considered to involve the upper (i.e. the atlanto-occipital and atlanto-axial complexes) and the lower cervical spine (C3–C7). Two physiological movements take place at the atlanto-occipital joints: those of flexion–extension and lateral flexion. The atlanto-axial joints allow flexion–extension and rotation. Some studies have suggested that maximum flexion–extension occurs between the occiput and C1; however, Frobin et al (2002) noted between 12.6° and 14.5° at this level, which is less than at some of the other cervical levels. Global cervical flexion ranges from 45° to 58°, depending on the method of assessment, age and sex; older subjects and females exhibit less motion (Trott et al 1996, Ordway et al 1997). At an intersegmental level, motion increases from the second cervical level and peaks at the mid-cervical level (14–17° recorded at C4/C5), before reducing at the junction of the cervical and thoracic spine (9.8–11.5° noted at C6/C7) (Frobin et al 2002). Global ranges of lateral flexion range from 32° to 47°, with a gradual reduction in range with age and sex, while rotational movements range from 63° to 78°. Intersegmental ranges of motion vary from 4.7° to 6° for lateral flexion between C2 and C7, and 2–12° for rotation (White and Panjabi 1990).

In the thoracic region, especially superiorly, all movements are limited, reducing interference with respiration. Lack of upward inclination of the superior articular facets prohibits much flexion, and extension is checked by contact of the inferior articular margins with the laminae and of adjacent spines. Thoracic rotation is freer, though limited by the ribs at upper levels. Its axis is in the vertebral bodies in the mid-thoracic region, and in front of them elsewhere, so that rotation involves some lateral displacement. The direction of articular facets would allow free lateral flexion but this is limited in the upper thoracic region by the resistance of the ribs and sternum. Rotation is usually combined with slight lateral flexion to the same side.

Movement in the thoracic spine is frequently regionalized to upper, mid- and lower thoracic. In the upper thoracic, flexion ranges from 7.8° to 9.5°, increasing to 10–11.4° in the mid-thoracic and 12.5–12.8° in the lower thoracic (Willems et al 1996). Extension is more consistent, ranging from 7.1° to 9.7° throughout the thoracic spine. Lateral flexion is greater in the lower thoracic spine, ranging from 5.6° to 6.2° in the upper thoracic, 7.9° to 8.1° in the mid-thoracic and 11.9° to 13.2° in the lower thoracic. However, rotation is greatest in the mid-thoracic region, being 11.8–15.9° in the upper thoracic, 21.5–25.3° in the mid-thoracic, and 8.3–11.8° in the lower thoracic.

Flexion movements are generally greater than extension or lateral flexion in the lumbar region. Axial rotation occurs about a centre of rotation in the posterior anulus, and is limited by bony contact in the facet joints after only 1–2° of movement. Functional transition between thoracic and lumbar regions is usually between the eleventh and twelfth thoracic vertebrae, where the facet joints usually fit so tightly that slight compression locks them, and prevents all movements but flexion.

During flexion of the lumbar spine there is an unfolding or straightening of the lumbar lordosis. Thus in full flexion the lumbar spine assumes a straight alignment or is curved slightly forwards. Normal ranges of global lumbar flexion are 58° to 72° in those under 40 years old and 40° to 60° in the over-forties; females exhibit a reduced range compared with males (Dvorak et al 1995, McGregor et al 1995). At an intersegmental level, the L3/L4 junction and L4/L5 junction exhibit the greatest mobility – approximately 12° and 13° respectively, while at the lowest level (L5/S1) there is only 9°, and at the upper lumbar levels only 8° and 10°, respectively (Pearcy et al 1984). Movements into extension are the converse of those seen in flexion. Normal ranges of global extension are from 25° to 30° in those under 40 years old and 15° to 20° in those over forty. At an intersegmental level, L5/S1 and L1/L2 exhibit the greatest mobility at approximately 5°, while the remaining levels exhibit less than 5° of extension. Ranges of lateral flexion and rotation in the lumbar spine are reduced compared to other regions of the spine. Global lateral flexion ranges from 20° to 35°, and rotation ranges from 25° to 40°; the ranges of both movements are reduced with age. Assessment of intersegmental rotation and lateral flexion has proven difficult because of the limitations of measurement techniques.

Role of musculature

Although muscles will move the spinal column, the majority of muscular activity is involved in providing stability to maintain posture and to provide a firm platform for limb function. Hence the concept of 'core stability' in modern rehabilitation programmes, especially in sports-related problems.

It is important to recognize the way in which the muscles of the back work in conjunction with those of the abdominal wall, particularly the oblique and transversus muscles, and with those of the lower limbs. The erector spinae group and internal abdominal oblique and transversus abdominis are anatomically and functionally connected by the thoracolumbar fascia (which encloses the former, and into which the latter are inserted). This fascia, together with collagenous tissue within the back muscles, plays an important role in resisting forward bending of the trunk, and during manual handling. The fascia is tensioned primarily by flexing the trunk, although this tension may be enhanced slightly by the lateral pull of the abdominal muscles. It is functionally advantageous to generate tension in the fascia and muscle sheaths because the elastic strain energy stored in these stretched tissues can be used to help bring the trunk to an upright position and so reduce the metabolic cost of the movement (Adams et al 2006). The thoracolumbar fascia may also have an important function in transferring load between the trunk and the lower limbs; tension in the fascia can be increased by the actions of gluteus maximus and the hamstrings as well as by trunk flexion.

Muscles producing vertebral movements

The spinal column is moved both directly by muscles attached to it, and indirectly by muscles attached to other bones. Gravity always plays a part: movements with gravity usually involve the eccentric contraction of antagonists. Flexion is effected by longus capitis and longus colli, scaleni, sternocleidomastoid and rectus abdominis of both sides, aided in the lumbar region by the abdominal obliques; extension by the erector spinae complex and the transversospinalis group, splenius, semispinalis capitis and trapezius of both sides, together with the suboccipital muscles; lateral flexion by ipsilateral longissimus, iliocostalis, abdominal obliques and flexors, and quadratus lumborum; and rotation by sternocleidomastoid, splenius cervicis, abdominal obliques, rotatores and multifidus.

Factors involved in stability

The vertebral column is remarkable in that it combines mobility, stability and load-bearing capacity and also protects its contained neural structures, irrespective of its position. Much of the stability of the vertebral column depends on dynamic muscular control but there are also bony and ligamentous 'static' stabilizers. There is considerable variation between segments of the column in terms of stability and mobility; the most mobile levels are the least stable. The latter are those in which the ratio of intervertebral disc height to vertebral body height is highest. Stability may be compromised by damage to any of these structures.

Trauma may affect any vertebral region. Levels of specialized mobility (e.g. atlanto-axial joint) and the junctions of mobile and relatively fixed regions (e.g. cervicothoracic, thoracolumbar) are particularly vulnerable to severe structural damage, often accompanied by spinal cord and nerve injury. Injuries of the vertebral column may affect purely soft tissue (ligaments, joint capsules and muscles) or may affect bony structures (see Fig. 46.58). Pure ligamentous/capsular injuries leading to instability may be particularly difficult to diagnose in the absence of gross radiological signs. In the cervical spine, subluxation and dislocation of the facet joints commonly occur without or with minimal bony injury because of the orientation of the articular facets (see Fig. 46.65).

Chronic infections of many types (e.g. tuberculosis) may involve the vertebrae and lead to their deformity and collapse, affect their mechanical properties and compromise their neuroprotective function. Acute infections, spreading locally or via the blood stream, may lead to the collection of pus within the vertebral canal, causing spinal cord compression (epidural abscess).

The integrity of the vertebrae may also be affected by malignant disease, most commonly metastatic. Vertebrae have a copious blood supply throughout life, and many of the common cancers (e.g. breast, bronchus) spread via the arterial system. Cancers of the haemopoietic system (e.g. multiple myeloma) also commonly affect the vertebrae. Prostatic carcinoma has a predilection to metastasize to the vertebral column, often using the venous (Batson's plexus) rather than the arterial route (Batson 1957). Metastatic deposits may occur within the epidural space, compressing the contents of the dural sac at multiple levels.

Systemic inflammatory diseases may cause both deformity and instability of the vertebral column. Rheumatoid arthritis inflames facet joints and weakens ligaments, leading to instability, especially in the cervical spine (see Fig. 46.57). Ankylosing spondylitis and other seronegative arthritides affect joints and ligamentous attachments (entheses), leading to ectopic ossification of collagenous structures, fusion (ankylosis) of interbody and facet joints, and loss of the normal spinal curvatures. Widespread new bone formation at and around the joints of the column occurs in DISH (diffuse idiopathic skeletal hyperostosis). Such conditions would seem to increase stability of the column, at the expense of its mobility and function, but an ankylosed spine is very liable to fracture, with an associated risk of neural damage (**Fig. 46.79**).

Full stability and load-bearing capacity both require intact vertebral bodies and intervertebral discs. Earlier views regarding the relative importance of the disc-body complex and the posterior elements have proved somewhat simplistic. Clinical observation led to the 'three-column concept' of spinal stability, in which the column is divided into three longitudinal parts rather than two (Denis 1983). The anterior column is formed by the anterior longitudinal ligament, the anterior half of the vertebral body and the anterior anulus fibrosus. The middle column is made up of the posterior longitudinal ligament, the posterior half of the vertebral body and pedicles, and the posterior anulus fibrosus. The posterior column consists of the vertebral arch and facet joints and the posterior ligamentous complex. The more columns that are affected, the worse is the instability; an injury to two columns is usually unstable.

Although regarded as the most influential system for classifying thoracolumbar spinal injuries, the concept was criticized for oversimplifying the biomechanics of injury. A more recent classification system, aided by improved computed tomographic imaging and magnetic resonance imaging, stresses the importance of the posterior ligamentous complex in determining the stability of the injured spine in addition to the morphology of the injury (compression, translational/rotational or distraction injuries) and the neurological status of the patient (intact, nerve root injury, complete or incomplete spinal cord injury, cauda equina syndrome) (Lee et al 2005).

The elastic deformability of intervertebral discs permits tilting and axial rotation between vertebral bodies, and also helps to reduce vertical accelerations of the head. The main shock-absorbing mechanism of the column stems from the spinal curves, which increase and decrease slightly during locomotion against the restraining tension of the trunk muscles. The elastic strain energy in the stretched tendons of the muscle is responsible for shock absorption.

All ligaments of the column, as well as the facet joint capsules, are important in the maintenance of stability. The anterior longitudinal ligament is very strong, and resists translational displacement (shear) of the vertebrae as well as extension. All the ligaments of the posterior complex resist flexion and rotation, and their integrity determines the range of movements allowed. These ligaments can support the whole column when the muscles are inactive, e.g. in quiet standing. At the limit of lumbar flexion, the column is supported mainly by the thoracolumbar fascia and by collagenous tissue within the electrically silent muscles of the back.

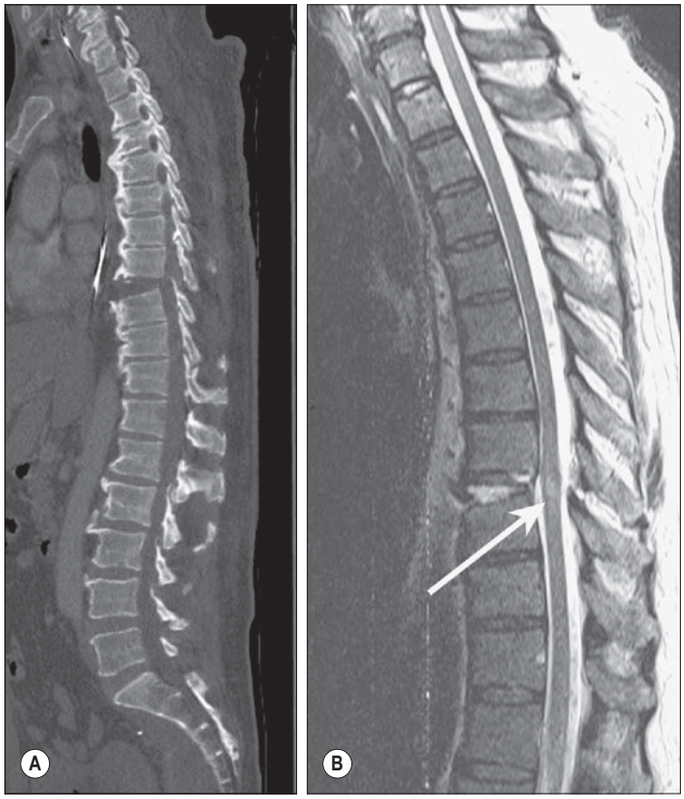

Fig. 46.79 A, A sagittal CT reconstruction showing a T8–T9 distraction extension injury in the setting of diffuse idiopathic skeletal hyperostosis. The patient was paraplegic at presentation. **B**, T2-weighted MRI shows abnormal signal throughout the disc space but also spinal cord signal abnormality (arrow) indicating a spinal cord injury.

Both body height and spinal stability are subject to a marked diurnal variation. Body height is affected by changes from recumbency to the upright posture. These diurnal variations appear to be due to changes that occur within the cervical, thoracic and lumbar regions of the spine. Investigations using stereophotogrammetry have demonstrated that 40% of diurnal changes occur in the thoracic spine and affect the degree of kyphosis, and a further 40% in the lumbar spine, but do not affect the lordosis (Wing et al 1992). The greatest change in vertebral column length is found in adolescents and young adults. The height loss occurs within 3 hours of rising in the morning, with an overall loss of about 15 mm.

Although the curvatures within the vertebral column contribute to the changes in height, changes within the intervertebral disc contribute both to observed height loss and to variation in stability. Magnetic resonance imaging investigations reveal a dynamic movement of fluid into and out of an intervertebral disc and adjacent vertebral body over a 24-hour period. Body position affects the movement of fluid. In the early morning, the discs are swollen with water, the intervertebral ligaments and the anulus fibrosus are taut, and the intrinsic bending stiffness and stability of the osteoligamentous spine are relatively high. After several hours of normal activity, the discs lose approximately 20% of their water and height. This change makes the ligaments slack and greatly reduces the bending stiffness of the spine, so that relatively more of the stability of the spine must then be provided by the musculature. The diurnal expulsion of water from intervertebral discs also affects the distribution of compressive loading in the spine. As the day progresses, the hydrostatic pressure in the nucleus pulposus falls, and stress concentrations arise in the anulus fibrosus and facet joints.

Movements are both determined and constrained by the shape and orientation of the facet joints, whose articular surfaces stabilize the column primarily by resisting horizontal gliding (shear) movements and axial rotation. In the most mobile regions, the joint surfaces are flatter and more horizontally placed, as will become apparent if a typical cervical facet joint is compared with a typical lumbar joint.

Certain regions of the vertebral column are further stabilized by additional extraspinal factors. The thoracic spine is stabilized by its position as an integral part of the thoracic cage and by its strong ligamentous linkages with the ribs. The sacrum is effectively a virtually fixed integral element of the bony pelvis.

The contribution to stability conferred by the musculature has been grossly underrated. The whole vertebral column is stabilized by the 'guy-rope' or staying effect of the long muscles that attach it to the girdles, the head and the appendicular skeleton. This effect is particularly marked for erector spinae, which controls global posture and movement. The small and deep muscles of the back are best able to resist shear movements between vertebrae because only they have sufficient angulation to the long axis of the vertebral column to do this effectively. The deep muscles can also fine-tune intervertebral movements.

For most back problems in clinical practice, especially chronic low back pain, enhancing muscle strength, stamina and coordination with the many other muscle groups that contribute to stability, e.g. pelvic girdle muscles, is the most appropriate and effective therapeutic avenue. Only a minority of cases benefit from surgery. Furthermore, iatrogenically damaging the neurovascular supply and neglecting the musculature may explain the relatively high failure rates from surgery. Minimally invasive spine surgery with emphasis on the preservation of soft tissue and muscle envelope may be a useful adjunct in maintaining spinal stability.

Mechanical injury to the vertebral column may be produced by flexion, extension, distraction, rotation, shear or compression; movements that cause damage are commonly combined, e.g. flexion, axial rotation and compression.

POSTURE AND ERGONOMICS

Posture is a descriptive term for the relative position of the body segments during rest or activity. The maintenance of good posture is a compromise between minimizing the load on the spine and minimizing the muscle work required.

The well-balanced erect body has a line of gravity that extends from the level of the external auditory meatus, through the dens of the axis just anterior to the body of the second thoracic vertebra, through the centre of the body of the twelfth thoracic vertebra, and through the rear of the body of the fifth lumbar vertebra to lie anterior to the sacrum. The position of the line of gravity may move anteriorly with locomotion and may vary between individuals.

The normal curvature of the cervical spine is a lordosis. However, as a result of pain, injury or poor ergonomics, this curve can become flattened to give a 'protruding chin' stance, i.e. hypolordosis in the lower cervical spine.

The thoracic spine is held convex posteriorly, and this posture primarily results from the structure of the underlying vertebrae. However, this curve or kyphosis can become exaggerated to give the impression of a rounded back. Poor posture and ergonomics can lead to this exaggerated curvature but other important causes include tuberculosis, a wedge or compression fracture of a vertebral body, Scheuermann's osteochondritis, ankylosing spondylitis, osteoporosis and metastatic carcinoma.

The lumbar spine is held in a lordosis. The degree of this lordosis is determined by the lumbosacral angle and is normally 30–45°. The muscles responsible for this posture include erector spinae, rectus abdominus, the internal and external abdominal obliques, psoas major, iliacus, the gluteal and hamstring muscles. The lordosis can be increased (as a result of weak abdominal muscles and tight hamstring muscles), decreased, flattened (common in people with either acute or chronic low back pain) or reversed.

A common postural deviation seen throughout the spine is scoliosis or lateral curvature of the spine. It can be structural, compensatory or protective. In structural scoliosis, the lateral curvature is associated with vertebral rotation, and both the curve and the rotation become more accentuated on forward flexion. Such a scoliosis is common in adolescent girls and its cause is unknown. Various factors have been proposed as common causes including various genetic and hereditary factors (Latalski et al. 2017). It may also be secondary to an underlying disorder, e.g. muscular dystrophy, spinal muscular atrophy or spina bifida. A compensatory scoliosis occurs when the pelvis is tilted laterally, e.g. as a result of unequal leg length or a fixed abduction or adduction deformity at the hip joint. Usually there is no intrinsic abnormality of the spine itself and the scoliosis disappears when the pelvic tilt is corrected. A sciatic or antalgic scoliosis is a temporary deformity produced by the protective action of muscles in certain painful conditions of the spine.

Spinopelvic balance refers to an ideal spinal alignment that would allow an individual to maintain a standing posture with minimal expenditure of energy (Schwab et al. 2009). Too much of a deviation in the coronal or sagittal planes may lead to increased effort in standing and eventually fatigue, pain and disability.

Ergonomics has been defined as 'the way humans work', and it permits an appreciation of the effects of tasks and the work environment on underlying postural biomechanics. Nachemson (1975) showed that discs were loaded maximally in sitting and in lifting in a forward-leaning position, so sitting posture and lifting have received considerable ergonomic attention.

In sitting, the goal has been to determine the seat type and reclining angle associated with lowest disc pressure and the least paraspinal muscle activity. When sitting with the hips and knees flexed to 90°, the pelvis rotates posteriorly, flattening the lumbar lordosis and consequently increasing the load on the intervertebral discs. Thus it is now advised that, in sitting, the angle between trunk and thigh should be between 105° and 135°, with the sacrum tilted at 16° and the fourth and fifth lumbar vertebrae supported.

In lifting heavy weights, there is considerable initial compression of lumbar intervertebral discs, and large increases in thoracic and intra-abdominal pressure. The compressive force acting on the spine is shared between the vertebral bodies and the vertebral arch. In the lumbar spine, the vertebral arch typically resists 20% of this force once the disc height has been reduced by diurnal fluid expulsion, and when the spine is positioned upright. However, age-related narrowing of the disc can cause more than 50% of the compressive force to be resisted by the vertebral arch, which may explain why osteoarthritis of the facet joints commonly follows disc degeneration.

When lifting, manual handling advisers emphasize the importance of leg lifting as opposed to back lifting. Loads should also be kept close to the body to reduce the lever arm of the load. The use of deep inspiration to raise intra-abdominal pressure while lifting has also been advised, as this is believed to offer further support to the lumbar spine. The spine is at risk when lifting is combined with twisting, lateral bending and asymmetric postures. However, heavy lifting remains one of the key work-related risk factors for the spine together with whole-body vibration, prolonged sitting, twisting and bending.

SURFACE ANATOMY

Skeletal landmarks

Vertebral spines

A furrow runs along the posterior median line from the external occipital protuberance above to the intergluteal cleft (anal cleft, natal cleft) below (**Figs 46.81–46.82**). The furrow is bordered laterally by muscles attaching to, and acting upon, the vertebral column; it is deepest in the mid-lumbar region and shallowest in the distal cervical region. Inferiorly, it widens out into a flattened, triangular area, with an inferior apex that lies at the start of the intergluteal cleft and corresponds approximately to the spinous process of S3. Palpation of the median furrow reveals the sagittal curves of the vertebral column (see Fig. 46.82): the cervical curve is convex anteriorly (lordosis) and extends from the C1 to the T2 vertebra; the thoracic curvature is concave anteriorly (kyphosis) and extends from the T2 to the T12 vertebra; and the lumbar curvature is convex anteriorly and extends from the T12 vertebra to the lumbosacral prominence. The external occipital protuberance is subcutaneous and is palpable on the postero-inferior aspect of the cranium in the midline, especially when it is approached from below. The inion is the most prominent part of this protuberance. The tubercle on the posterior arch of C1 (atlas) is impalpable, whereas the transverse process of C1 is palpable as an indistinct mass through sternocleidomastoid just inferior to the apex of the mastoid process. The spinous process of C2 is the first palpable feature in the median furrow, located several centimetres inferior to the inion (see Fig. 46.81B). The tips of the spinous processes of C3 to C6 are more difficult to palpate because the overlying ligamentum nuchae forms a palpable raised midline ridge, especially when the neck is flexed. The ligamentum nuchae terminates inferiorly at the spinous process of C7 (vertebra prominens), which is the most

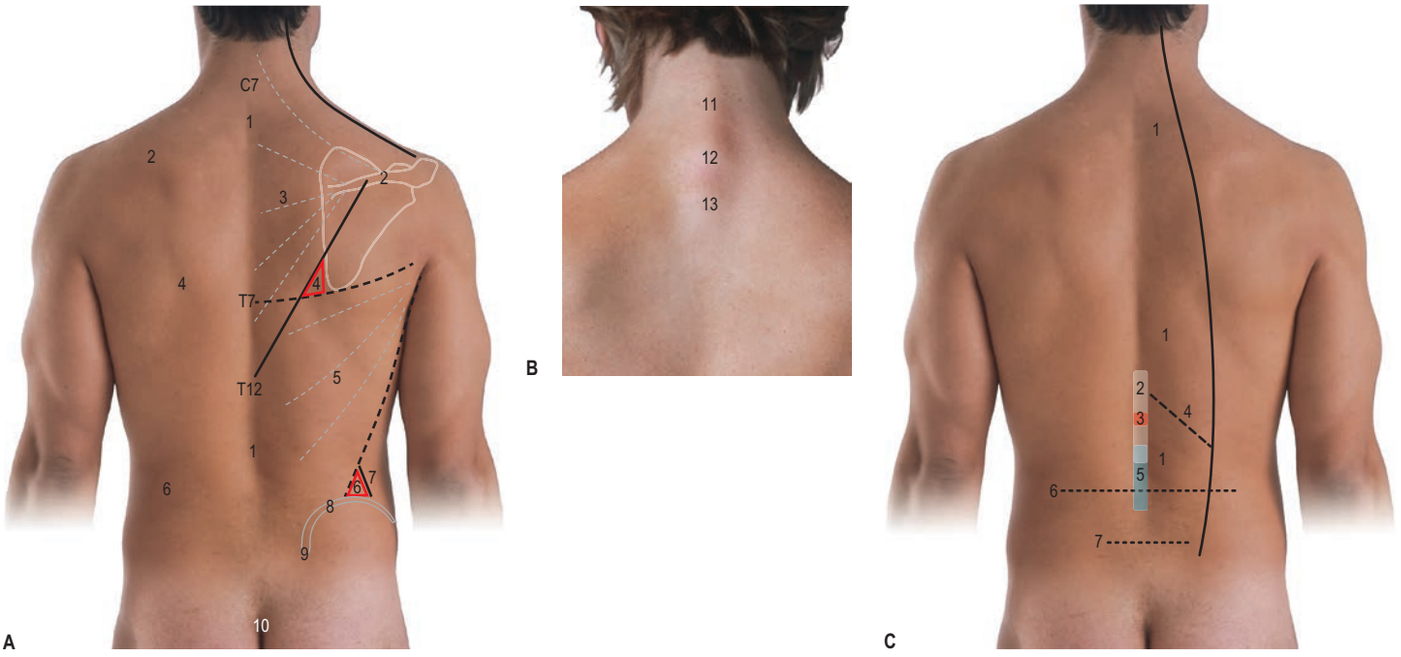

Fig. 46.81 A–C, Surface anatomy of the back. Key: **A**, 1, posterior median line and the median furrow; 2, spine of the scapula; 3, trapezius (between solid black lines); 4, triangle of auscultation; 5, latissimus dorsi (between dashed black lines); 6, inferior lumbar (Petit's) triangle; 7, external abdominal oblique; 8, iliac crest; 9, posterior superior iliac spine; 10, superior part of intergluteal cleft (approximates the spinous process of S3). **B**, 11, ligamentum nuchae (raised by neck flexion); 12, spinous process of C7 (vertebra prominens); 13, spinous process of T1. **C**, 1, erector spinae (black line represents lateral border); 2, zone of spinal cord termination (white): ranges from the middle third of the vertebral body of T11 to the middle third of the vertebral body of L3; 3, most common level of spinal cord termination (red) at the middle third of the vertebral body of L1; corresponds with the lower part of the T12–L1 interspinous space; 4, rib 12 (dashed black line); 5, zone of supracristal plane intersection with vertebral column (blue): ranges from the L2–L3 interspinous space to the spinous process of L5; 6, highest point of iliac crest marked by the supracristal plane (Tuffier's line): almost always intersects the vertebral column from the vertebral body of L4 to the L4–L5 intervertebral disc; 7, posterior superior iliac spine and interspinous plane, marked by an indentation in the overlying skin. Note the potential overlap between zone 5 (supracristal plane) and the zone 2 (termination of the spinal cord).

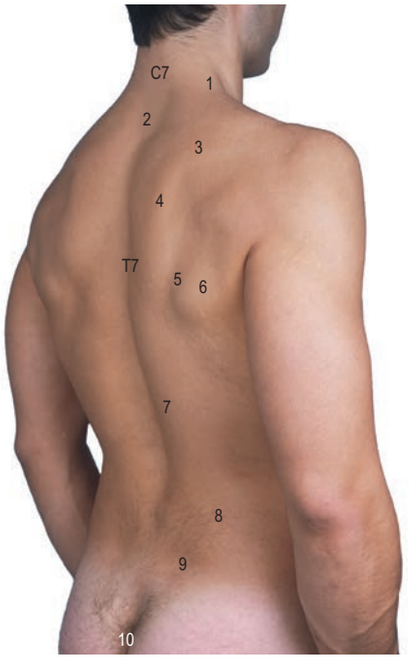

Fig. 46.82 Surface anatomy of the back, oblique view. Key: 1, trapezius (descending part); 2, posterior median line and median furrow; 3, spine of scapula; 4, trapezius (ascending part) overlying erector spinae; 5, triangle of auscultation; 6, inferior angle of scapula; 7, erector spinae; 8, inferior lumbar (Petit's) triangle; 9, posterior superior iliac spine; 10, superior part of intergluteal cleft (approximates the spinous process of S3); C7, T7, spinous processes of C7 and T7, respectively.

superior visible projection in this region. The spinous process of T1 is palpable immediately inferior to that of C7 and is usually more prominent. Identification of the remaining spinous processes of the thoracic vertebrae is not easy, even in a thin subject when the trunk is fully flexed, because they overlap one another in the mid-thoracic region. In the upper and mid-thoracic regions, the tips of the spinous processes lie level with the superior part of the bodies of the vertebrae immediately below, whereas in the lower thoracic region, they lie either opposite the inferior part of their own vertebral body, or the intervertebral disc articulating with the vertebra immediately below (see Table 46.4). The tips of the spinous processes of the lumbar vertebrae can usually be palpated without difficulty, especially if the trunk is flexed. Each lies opposite the inferior part of its own vertebral body and the intervertebral disc articulating with the vertebra below. The interspinous spaces are represented by a palpable depression between adjacent spinous processes.

Spinal levels of viscera

In adults, the spinal cord usually terminates level with the middle third of the vertebral body of L1 (range, middle third of the vertebral body of T11 to middle third of the vertebral body of L3); 25% of spinal cords end below the level of the L1–L2 intervertebral disc (Macdonald et al 1999). In children, the reported level of spinal cord termination varies with age (Van Schoor et al 2015). In children aged 1 year and above, the spinal cord terminates most commonly at the lower third of the vertebral body of L1 (range, lower third of the vertebral body of T12 to L2–L3 intervertebral disc), but may terminate as low as the middle third of the vertebral body of L3 in infants under 1 year of age (Malas et al 2001, Kesler et al 2007, Van Schoor at al 2015). The spinous processes of the vertebrae can be used as landmarks to approximate the levels of thoracic and abdominal viscera. Some of the more important are shown in **Table 46.4** (minor differences between the two sides have been ignored).

Spinal balance and alignment are intimately related to the pelvis. Pelvic parameters have been proposed that allow the relationship of the pelvis to the spine to be mathematically assessed (Schwab et al 2009). Three common measurements include pelvic tilt, pelvic incidence and sacral slope (**Fig. 46.80**). Pelvic tilt is defined as the angle between the vertical and a line through the midpoint of the sacral plate to femoral heads axis. It often reflects a compensatory mechanism: when the spine tilts forward (age- related change, loss of lordosis, increase of kyphosis) an individual will try his/her best to maintain an economic posture and to keep the spine as vertical as possible (i.e. bring the spine over the pelvis). By increasing the pelvic tilt through pelvic retroversion, spinopelvic balance may be maintained, but eventually this may lead to increased fatigue and pain. If decompensation occurs, standing with a forward stooped posture is likely.

Pelvic incidence is defined as the angle between the perpendicular to the sacral plate at its midpoint and the line connecting this point to the axes of the femoral heads. Sacral slope is the angle between the horizontal and the sacral plate. A noted geometric relationship is pelvic incidence = pelvic tilt + sacral slope (Schwab et al 2009) (**Table 46.3**). Lumbar lordosis can be approximated by the equation LL = PI ±9° (based on data from asymptomatic adults with a mean age of 48 years) (Schwab et al 2009). This relationship is useful in surgical planning by spinal surgeons because it allows the surgeon to optimize the extent of lordosis created using various fusion techniques. If too little lordosis is created, there may be continued pain or decompensation because appropriate spinopelvic balance has not been achieved.

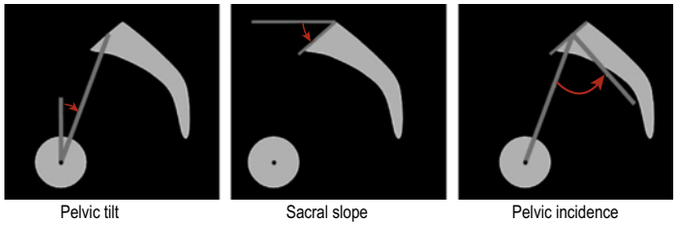

Fig. 46.80 Analysis of the pelvis in the sagittal plane is commonly assessed with three angular measurements: pelvic tilt, sacral slope and pelvic incidence. (With permission from Schwab F, Lafage V, Patel A 2009 Sagittal plane considerations and the pelvis in the adult patient. Spine (Phila Pa 1976) 34:1828–33. Figure 2.)

TABLE 46.3 Normative values of pelvic parameters on adult population (mean ± SD)

Age group (years)	Pelvic incidence (°)	Pelvic tilt (°)	Sacral slope (°)
21–40	52 ± 10	13 ± 7	39 ± 9
41–60	53 ± 8	14 ± 6	40 ± 7
>60	51 ± 9	16 ± 9	36 ± 9

TABLE 46.4 Vertebral spines and interspinous spaces as landmarks for the viscera

Spine/space	Vertebral body level	Viscera
C5	C6	Cricoid cartilage; start of oesophagus
C7	C7 or C7-T1 disc	Superior limit of the apex of the lung
T3	Superior T4	Common upper level of sternal plane intersection; medial part of scapular spine; superior limit of the oblique fissure of left lung
T4	Superior T5	Common lower level of sternal plane intersection; superior limit of the oblique fissure of right lung
T5 or T5-T6 space	Superior T6	Tracheal bifurcation
T7	Superior T8	Inferior angle of scapula; triangle of auscultation located laterally
T10-T11 space	Superior T11	Inferior vena cava traverses the respiratory diaphragm (classically reported as T8); superior limit of superior pole of the kidney
T11	Inferior T11 or T11-T12 disc	Oesophagus traverses the respiratory diaphragm (classically reported as T10)
T11-T12 space	Superior T12	Aorta traverses the respiratory diaphragm; Origin of the coeliac trunk from the aorta
T12-L1 space	Superior L1	Lowest level of pleural cavity; common level of spinal cord termination (middle of L1) in an adult
L1	Inferior L1 or L1-L2 disc	Transpyloric plane; origin of the superior mesenteric artery from the aorta; renal hilum (classically reported level)
L1-L2 space	Superior/mid L2	Subcostal plane; sometimes marks the transpyloric plane; renal hilum
L2-L3 space	Superior/mid L3	Origin of the inferior mesenteric artery from the aorta; inferior limit of the spinal cord in infants (0-1 year of age)
L3-L4 space	Superior/mid L4	Bifurcation of aorta; possible lumbar puncture insertion site (adult)
L4	Inferior L4 or L4-L5 disc	Supracristal plane (the plane may also align with the L4-L5 interspinous space); used to landmark the needle insertion site for adult lumbar puncture either above (L3-L4 interspinous space) or below (L4-L5 interspinous space)
S2	S2	Termination of subarachnoid space

Scapular landmarks

The shape of the back in the upper thoracic region is determined largely by the scapula and the muscles attached to it. Bony scapular landmarks are most evident when the upper limbs hang by the sides in the anatomical position (see Figs 46.81A, 46.82).

The scapula overlies rib 2 to rib 7. Its superior angle is palpable through trapezius, and its inferior angle through latissimus dorsi; these angles are joined by the medial border of the scapula, which runs vertically. The spine of the scapula runs subcutaneously and is easily palpable from its root medially to the acromial angle and acromion laterally. With the upper limb in the anatomical position, the spinous process of T3 is located level with the spine of the scapula, and the spinous process of T7 is level with the inferior angle.

Posterior pelvic and sacrococcygeal bony landmarks

The entire iliac crest can be palpated in the lower part of the lumbar region of the back. It can be traced posteriorly and superiorly from the anterior superior iliac spine to its tubercle, then around to its highest point, which is located posteriorly, and finally downwards and medially to the posterior superior iliac spine, which is overlaid by an indentation in the skin. For landmarking during lumbar puncture (see Fig. 47.20), a line joining the highest points of the iliac crests (supracristal plane, Tuffier's line) is used. In the majority of individuals, the line intersects the vertebral column at the level of the vertebral body of L4 or L4–L5 intervertebral disc, but it can range from the L2–L3 interspinous space to spinous process of L5 (Render 1996, Walsh et al 2006, Chakraverty et al 2007, Pak et al 2016, Shen et al 2016, Uzun et al 2016) (see Figs 46.81C, 76.19). In most adults the plane intersects the vertebral column inferior to the termination of the spinal cord. Localizing the supracristal plane via palpation may place it at a higher level in females and individuals with a higher body mass index (Kim et al 2007, Hale et al 2010). It is important to remember that the median furrow may not coincide with the median plane when an individual lies in the lateral decubitus position, especially in the lumbar region in subjects with a higher body mass. Careful palpation may be necessary to identify the vertebral spinous processes in this position. The spinous processes of the sacral vertebrae are smaller and less well defined than those of the other vertebrae. When determined by palpation, the plane passing through the posterior superior iliac spines intersects the spinous process of S1 or S2 (range, spinous process of L5 to spinous process of S3) (Chakraverty et al 2007, Kim et al 2007), whereas radiographic assessment shows the plane most commonly intersects the spinous process of S2 (McGaugh et al 2007) (see Fig. 76.19). The latter serves as a useful landmark for the inferior limit of the dural sac in an adult, which is most commonly located level with the inferior part of the vertebral bodies of S1 to S2 (range, L5–S1 intervertebral disc to vertebral body of S4). The tip of the coccyx can be felt deeply near the centre of the intergluteal cleft. Moving the examining finger cranially enables palpation of the raised ridges of the sacral cornua on either side of the midline; they demarcate the sacral hiatus and so form the landmark for performing a caudal anaesthetic block (see Figs 47.21, 47.22, 76.19). The sacral cornua are not developed in very young children, which means that the sacral hiatus cannot be located via palpation (Mirjalili et al 2015).

Musculotendinous landmarks

In the posterior cervical region, a median furrow lies between the cylindrical muscular prominences that are formed mainly by the semispinalis muscles and are accentuated by neck extension against resistance. In the thoracic and lumbar regions, broad elevations produced by the erector spinae muscle group extend for about one hand's breadth on either side of the median furrow between the iliac crest and rib 12 (see Fig. 46.82). The lateral border of this elevation then crosses the ribs in the region of their angles, passing medially as it ascends. The erector spinae muscle group can be demonstrated, or accentuated, by extending the vertebral column against resistance.

Trapezius is a flat, triangular muscle that covers the back of the neck and shoulder (see Figs 46.71 and 46.81A). The two trapezius muscles resemble a trapezium in which two of the angles correspond to the shoulders, the third to the external occipital protuberance and the fourth to the spinous process of T12. On each side, the anterosuperior border of the muscle forms the posterior boundary of the posterior triangle of the neck; it can be seen in muscular subjects, especially during shoulder elevation against resistance or by extension and lateral flexion of the neck against resistance. The ascending (lower) fibres are best seen when an erect individual pushes both hands against a wall with their elbows extended.

Latissimus dorsi occupies the lower half of the back. It passes from the spinous processes of the lower six thoracic vertebrae, the thoracolumbar fascia and the posterior iliac crest, to the posterior axillary fold. In lean individuals, with the arm adducted against resistance, the inferolateral border can easily be traced to the iliac crest. The upper border passes horizontally from the spinous process of T7 to the inferior angle of the scapula and then on to the posterior axillary fold.

The triangle of auscultation (see Figs 46.71, 46.82) lies between the upper border of latissimus dorsi, the lower inferolateral border of trapezius and the inferomedial border of rhomboid major, although for simplicity the medial border of the scapula is often substituted for the latter muscle.

The inferior lumbar (Petit's) triangle (see Figs 46.71, 46.82), one of the sites of a rare primary lumbar hernia, lies inferiorly just lateral to the highest point of the iliac crest, between the inferolateral border of latissimus dorsi, the posterior free border of external abdominal oblique and the iliac crest. The corridor bordered by the triangle is used to enter the retroperitoneal space: the fascia covering the triangle is detached from the iliac crest and the retroperitoneal space can be entered.

CLINICAL EXAMINATION

Clinical examination of the back of the trunk and neck best follows the order of inspection, palpation and movement. The examination will be determined by the circumstances of presentation and by the history, and may include musculoskeletal, neurological and vascular observations. Information relevant to the neurological and vascular examination of the skin and material relating to spinal movements and deeper innervation are found above. Palpation of the region involves careful assessment of the bony and musculotendinous landmarks described above, looking in particular for asymmetry, deformity and tenderness. Note that, apart from the spinous processes, most of the bony elements of the vertebrae and almost all of the intervertebral joints are not palpable from behind. In regions of lordosis (sagittal plane curves of the spine with anterior convexity, i.e. mid-cervical and mid- and lower

lumbar), parts of the vertebral column can often be palpated anteriorly with care in well-relaxed, thin subjects. .Examination of the spine requires a careful neurological exam, and may also involve manoeuvres that assess neurology in relation to potential anatomical derangements. For example, the straight leg raise stretches caudal lumbar spinal nerve roots and exacerbates pain in the presence of caudal lumbar pathology such as an L4–L5 or L5–S1 intervertebral disc herniation. Examination of other joints such as the hip or shoulder is also important when examining the spine because pain related to these structures may present similar to radiculopathy and other spinal problems. A careful history and examination of the spine along with neurological and orthopaedic examination should allow the clinician to be fairly certain of the spinal localization of pathological processes.

CHAPTER
47

Spinal cord and spinal nerves: gross anatomy

The gross anatomy of the structures that lie within the vertebral canal and their extensions through the intervertebral foramina, the spinal nerve or radicular ('root') canals, is described in this chapter. The internal organization of the spinal cord is described in Chapter 27.

The spinal cord and its blood vessels and nerve roots lie within a meningeal sheath, the theca, which occupies the central zone of the vertebral canal and extends from the foramen magnum, where it is in continuity with the meningeal coverings of the brain, to the level of the second sacral vertebra in the adult. Distal to this level, the dura extends as a fine cord, the filum terminale externum, which fuses with the posterior periosteum of the first coccygeal segment. Tubular prolongations of the dural sheath extend around the spinal roots and nerves into the lateral zones of the vertebral canal and out into the root canals, eventually fusing with the epineurium of the spinal nerves. Between the theca and the walls of the vertebral canal is the epidural (spinal extradural) space, which is loosely filled with fat, connective tissue containing small arteries and lymphatics, and an important venous plexus. Three-dimensional appreciation of the anatomy of the spinal theca and its surroundings is essential for the efficient management of spinal pain and of spinal injuries, tumours and infections. Equally significant clinically is the anatomy of the often-precarious blood supply of the spinal cord and its associated structures. The increasing application and refinement of diagnostic imaging and endoscopic procedures lend a new importance to topographical detail here.

SPINAL CORD

The spinal cord occupies the superior two-thirds of the vertebral canal (**Figs 47.1–47.2**). It is continuous cranially with the medulla oblongata, just below the level of the foramen magnum, at the upper border of the atlas. It terminates caudally as the conus medullaris. During development, the vertebral column elongates more rapidly than the spinal cord, so that there is an increasing discrepancy between the anatomical level of spinal cord segments and their corresponding vertebrae. At stage 23, the vertebral column and spinal cord are the same length and the cord ends at the last coccygeal vertebra. In later fetal life, the conus medullaris lies between the third lumbar and fifth sacral vertebrae. In premature and term neonates, it lies between the first and third lumbar vertebrae, and in children between the ages of 1 and 7 years, it lies between the twelfth thoracic and third lumbar vertebrae (Barson 1970, Vettivel 1991, Malas et al 2001, Kesler et al 2007, Suresh et al 2013). In the adult, the spinal cord terminates on average at the level of the middle third of the body of the first lumbar vertebra (Macdonald et al 1999) (see Fig. 46.81), which corresponds approximately to the transpyloric plane. However, it may end as high as the middle third of the body of the eleventh thoracic vertebra or as low as the middle third of the body of the third lumbar vertebra (Macdonald et al 1999). Its position rises slightly in vertebral flexion, and there is some correlation with the length of the trunk, especially in females. (For dimensional data, consult Barson and Sands (1977).)

The filum terminale, a filament of connective tissue approximately 20 cm long, descends from the apex of the conus medullaris. Its upper 15 cm, the filum terminale internum, is continued within extensions of the dural and arachnoid meninges and reaches the caudal border of the second sacral vertebra. Its final 5 cm, the filum terminale externum, fuses with the investing dura mater, and then descends to the dorsum of the first coccygeal vertebral segment. The filum is continuous above with the spinal pia mater. A few strands of nerve fibres, which probably represent the roots of rudimentary second and third coccygeal spinal nerves, adhere to its upper part. The central canal is continued into the filum for 5–6 mm. A capacious part of the subarachnoid space surrounds the filum terminale internum, and is the site of election for access to the cerebrospinal fluid (CSF) via a lumbar puncture (see below).

The spinal cord varies in transverse width, gradually tapering craniocaudally, except at the levels of the enlargements. It is not cylindrical, being wider transversely at all levels, especially in the cervical segments. The cervical enlargement, the source of the large spinal nerves that supply the upper limbs, extends from the third cervical to the second thoracic segments. Its maximum circumference (approximately 38 mm) is in the sixth cervical segment (a spinal cord segment provides the attachment of the rootlets of a pair of spinal nerves). The lumbar enlargement, the source of the large spinal nerves that supply the lower limbs, extends from the first lumbar to the third sacral segments; the equivalent vertebral levels are the ninth to twelfth thoracic vertebrae. Its greatest circumference (approximately 35 mm) is near the lower part of the body of the twelfth thoracic vertebra, below which it rapidly dwindles into the conus medullaris.

Fissures and sulci extend along most of the external surface. A ventral (anterior) median fissure (sulcus) and a posterior median sulcus and septum almost completely separate the cord into right and left halves; they are joined by a commissural band of nervous tissue that contains a central canal (see Fig. 27.1).

The ventral median fissure extends along the whole ventral surface with an average depth of 3 mm, although it is deeper at caudal levels. It contains a reticulum of pia mater. Dorsal to it is the anterior white commissure. Perforating branches of the spinal vessels pass from the fissure to the commissure to supply the central spinal region. The posterior median sulcus is shallower, and from it a posterior median septum penetrates more than halfway into the cord, almost to the central canal. The septum varies in anteroposterior extent from 4 to 6 mm, and diminishes caudally as the canal becomes more dorsally placed and the cord contracts. The patency of the central canal diminishes with age: a postmortem study found the canal to be patent along the length of the cord in infants under 1 year of age, but occluded in most segments with increasing age after the second decade (Yasui et al 1999).

Dorsal rootlets of spinal nerves enter the cord along a posterolateral sulcus that lies from 1.5 to 2.5 mm lateral to each side of the posterior median sulcus. The white matter between the posteromedian and posterolateral sulci on each side is the dorsal (posterior) funiculus. In cervical and upper thoracic segments, a longitudinal posterointermediate sulcus marks a septum dividing each posterior funiculus into two large tracts on either side, a medial fasciculus gracilis and a lateral fasciculus cuneatus. A ventrolateral (anterolateral) funiculus lies between the posterolateral sulcus and ventral median fissure, and is subdivided into ventral (anterior) and lateral funiculi by ventral spinal rootlets that pass through its substance to issue from the surface of the cord. The ventral funiculus is medial to, and includes, the emerging ventral rootlets, whilst the lateral funiculus lies between the roots and the posterolateral sulcus. In upper cervical segments, nerve rootlets emerge through each lateral funiculus to form the accessory nerve, which ascends in the vertebral canal lateral to the spinal cord and enters the posterior cranial fossa via the foramen magnum (see Fig. 35.11).

Dorsal and ventral roots

The paired dorsal and ventral roots of the spinal nerves are continuous with the spinal cord (**Fig. 47.1F**). They cross the subarachnoid space and traverse the dura mater separately, uniting in or close to their intervertebral foramina to form the (mixed) spinal nerves. Since the spinal cord is shorter than the vertebral column, the more caudal spinal roots descend for varying distances around and beyond the cord to reach their corresponding foramina. In so doing, they form a divergent sheaf of spinal nerve roots, the cauda equina, which is gathered round the filum terminale in the spinal theca, mostly distal to the apex of the cord.

Ventral spinal roots contain efferent somatic and, at some levels, preganglionic sympathetic, axons that extend from neuronal cell bodies in the ventral horns and intermediolateral columns, respectively. There are also afferent nerve fibres in these roots. The rootlets comprising each ventral root emerge from the anterolateral sulcus in groups over an

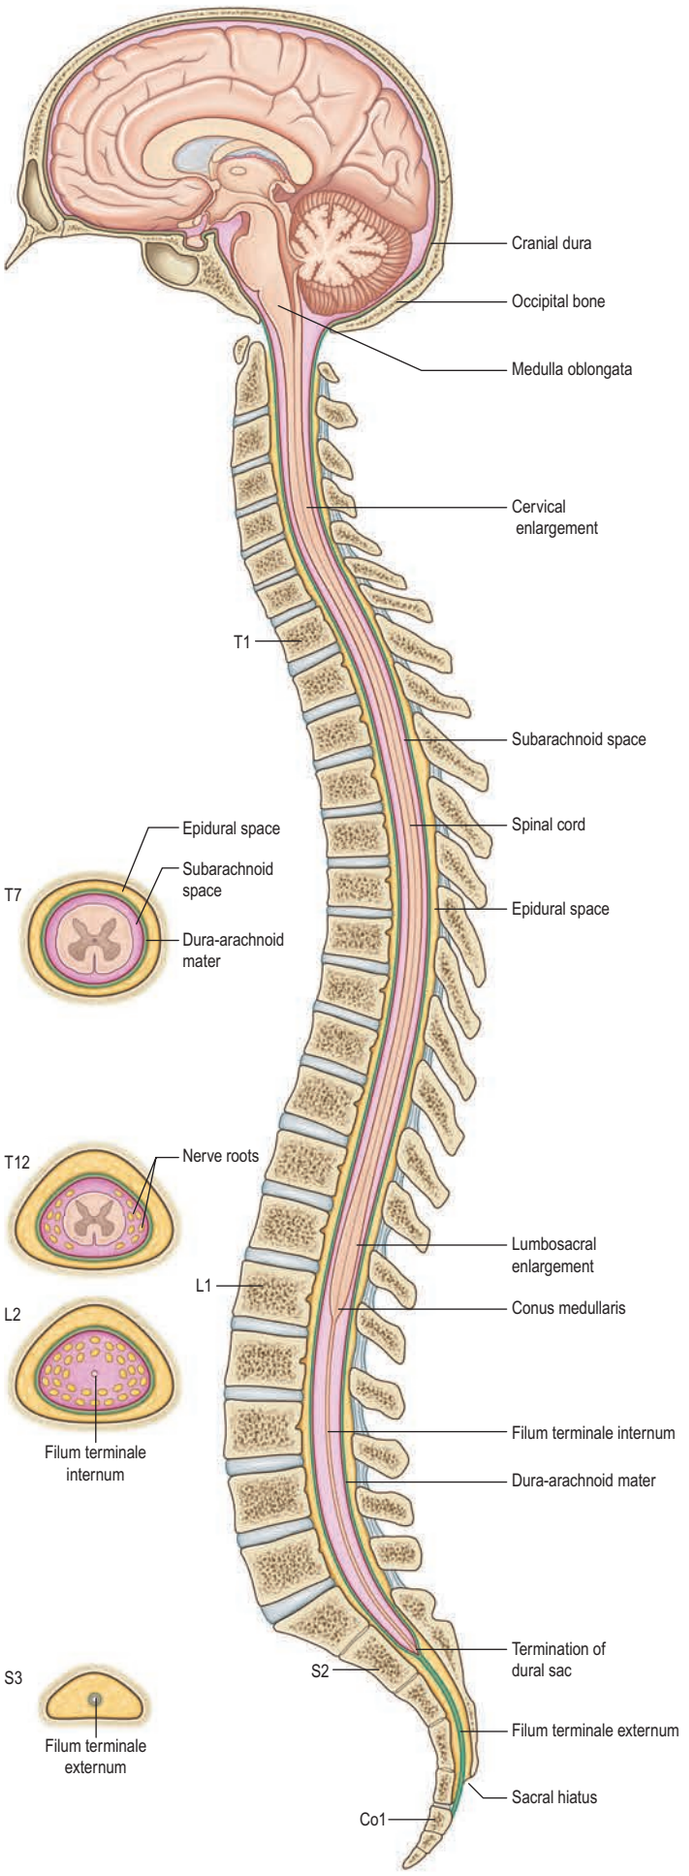

Fig. 47.2 The epidural and subarachnoid spaces.

elongated vertical elliptical area (see Fig. 47.1F). Dorsal spinal roots bear ovoid swellings, the spinal ganglia, one on each root proximal to its junction with a corresponding ventral root in an intervertebral foramen. Each root fans out into 6–8 rootlets before entering the cord in a vertical row in the posterolateral sulcus. Dorsal roots are usually said to contain only afferent axons (both somatic and visceral), which are the central processes of unipolar neurones in the spinal root ganglia, but they may also contain a small number (3%) of efferent fibres and autonomic vasodilator fibres.

Each ganglionic neurone has a single short stem that divides into a medial (central) branch that enters the spinal cord via a dorsal root, and a lateral (peripheral) branch that passes peripherally to a sensory end organ. The central branch is an axon while the peripheral one is an elongated dendrite (but when traversing a peripheral nerve is, in general structural terms, indistinguishable from an axon). The region of spinal cord associated with the emergence of a pair of nerves is a spinal segment but there is no actual surface indication of segmentation. Moreover, the deep neural sources or destinations of radicular fibres may lie far beyond the confines of the 'segment' so defined.

MENINGES

Dura mater

In some areas within the skull, the dura mater can be distinguished from the endosteum, but at the base of the skull around the foramen magnum the two layers are fused and adherent to the bone. Distal to the foramen magnum, within the vertebral column, the dura is distinct from the tissues that line the vertebral canal, and separated from them by the epidural space (see below). The spinal dura mater forms a tube whose upper end is attached to the edge of the foramen magnum and to the posterior surfaces of the second and third cervical vertebral bodies, and also by fibrous bands to the posterior longitudinal ligament, especially towards the caudal end of the vertebral canal. The dural tube narrows at the lower border of the second sacral vertebra. It invests the thin spinal filum terminale, descends to the back of the coccyx, and blends with the periosteum.

Epidural space

The epidural space lies between the spinal dura mater and the tissues that line the vertebral canal (see Fig. 47.2). It is closed above by fusion of the spinal dura with the edge of the foramen magnum, and below by the posterior sacrococcygeal ligament that closes the sacral hiatus. It contains loosely packed connective tissue, fat, a venous plexus, small arterial branches, lymphatics and fine fibrous bands that connect the theca with the lining tissue of the vertebral canal. These bands, the meningovertebral ligaments, are best developed anteriorly and laterally. Similar bands tether the nerve root sheaths or 'sleeves' within their canals. There is also a midline attachment from the posterior spinal dura to the ligamentum nuchae at atlanto-occipital and atlanto-axial levels (Dean and Mitchell 2002). The venous plexus consists of longitudinally arranged chains of vessels, connected by circumdural venous 'rings'. The anteriorly placed vessels receive the basivertebral veins.

The shape of the space within each spinal segment is not uniform, though the segmental pattern is metamerically repeated. It is difficult to define the true shape of the 'space' because it changes with the introduction of fluid or as a result of preservation techniques. In the lumbar region, the dura mater is apposed to the walls of the vertebral canal anteriorly and attached by connective tissue in a manner that permits displacement of the dural sac during movement and venous engorgement. Adipose tissue is present posteriorly in recesses between the ligamentum flavum and the dura. The connective tissue extends for a short distance through the intervertebral foramina along the sheaths of the spinal nerves. Like the main thecal sac, the root sheaths are partially tethered to the walls of the foramina by fine meningovertebral ligaments.

Epidural injections

Contrast media and other fluids injected into the epidural space at the sacral level can spread up to the cranial base. Local anaesthetics injected near the spinal nerves, just outside the intervertebral foramina, may spread up or down the epidural space to affect the adjacent spinal nerves or may pass to the opposite side. The paravertebral spaces of each side communicate via the epidural space, particularly at lumbar levels.

For a review of the morphology of the epidural space and a discussion of the nature of the lining layer of the vertebral canal, see Newell (1999).

A variety of pathological processes can occur within the epidural space, compressing the dura and resulting in pain and potential neurological disturbance. Among the more common pathological entities seen are infection, haematoma and tumours (Figs 47.3–47.4).

Fig. 47.3 A T1 post-contrast sagittal lumbar spinal magnetic resonance (MR) image showing a spinal epidural abscess (arrow) adherent to the lumbar dura and spinal nerves in a 28-year-old female with a history of intravenous drug abuse.

Fig. 47.4 A sagittal thoracic MR image showing a large ventral spinal epidural haematoma (arrow) resulting in severe neck and upper thoracic pain and ataxia.

Subdural space

The subdural space is a potential space in the normal spine because the arachnoid and dura are closely apposed (Haines et al 1993). It does not connect with the subarachnoid space but continues for a short distance along the cranial and spinal nerves. Accidental subdural catheterization may occur during epidural injections. Injection of fluid into the subdural space may damage the cord either by direct toxic effects or by compression of the vasculature.

Arachnoid mater

The spinal arachnoid mater surrounds the spinal cord and is continuous with the cranial arachnoid mater (**Fig. 47.5**). It is closely applied to the deep aspect of the dura mater. At sites where vessels and nerves enter or leave the subarachnoid space, the arachnoid mater is reflected on to the surface of these structures and forms a thin coating of leptomeningeal cells over the surface of both vessels and nerves. Thus a subarachnoid angle is formed as nerves pass through the dura into the intervertebral foramina. At this point, the layers of leptomeninges (arachnoid and pia) fuse and become continuous with the perineurium. The epineurium is in continuity with the dura. Such an arrangement seals the subarachnoid space so that particulate matter does not pass directly from the subarachnoid space into nerves. The existence of a pathway of lymphatic drainage from the CSF is controversial.

Pia mater

The spinal pia mater (see Fig. 47.5) closely invests the surface of the spinal cord and passes into the ventral median fissure. The subpial collagenous layer in the spinal subpial 'space' is thicker than it is in the cerebral region and is continuous with the collagenous core of the ligamentum denticulatum (denticulate ligament).

The ligamentum denticulatum is a flat, fibrous sheet on either side of the spinal cord between the ventral and dorsal spinal roots. Its medial border is continuous with the subpial connective tissue of the cord and its lateral border forms a series of triangular processes, the apices of which are fixed at intervals to the dura mater. The first crosses behind the vertebral artery where it is attached to the dura mater, and is separated by the artery from the first cervical ventral root. Its site of attachment to the dura mater is above the rim of the foramen magnum, just behind the hypoglossal nerve; the accessory nerve ascends on its posterior aspect (see Fig. 35.11). The last of the dentate ligaments lies between the exiting twelfth thoracic and first lumbar spinal nerves and is a narrow, oblique band that descends laterally from the conus medullaris. Changes in the form and position of the dentate ligaments during spinal movements have been demonstrated by cine-radiography. Beyond the conus medullaris, the pia mater continues as a coating of the filum terminale.

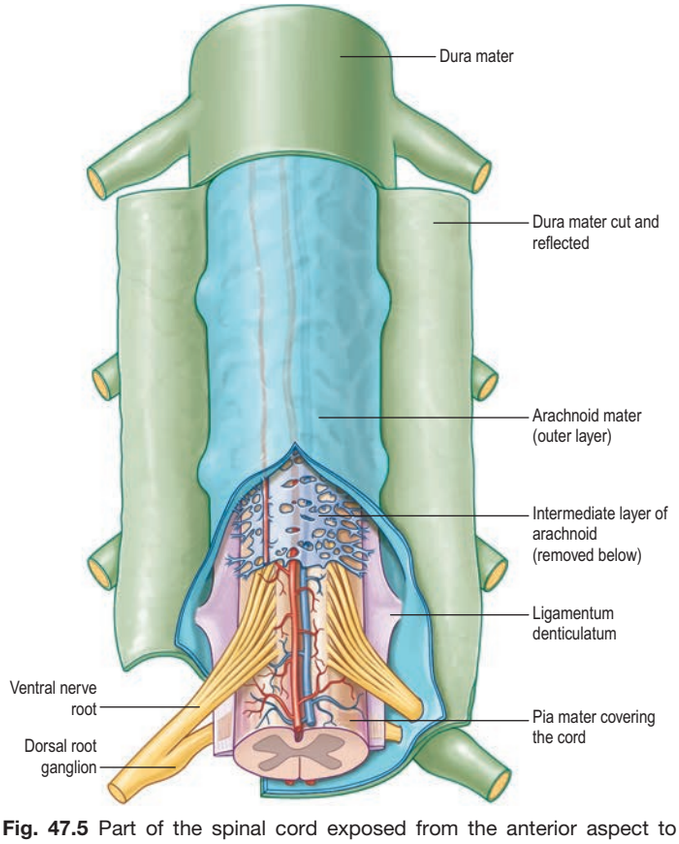

Fig. 47.5 Part of the spinal cord exposed from the anterior aspect to show the meningeal coverings.

Intermediate layer

In addition to the well-defined coats of arachnoid and pia mater, the cord is also surrounded by an extensive intermediate layer of leptomeninges. This layer is concentrated in the dorsal and ventral regions, and forms a highly perforated, almost lace-like structure that is focally compacted to form the dorsal, dorsolateral and ventral ligaments of the spinal cord. Dorsally, the intermediate layer is adherent to the deep aspect of the arachnoid mater and forms a discontinuous series of dorsal ligaments that attach the spinal cord to the arachnoid. The dorsolateral ligaments are more delicate and fenestrated, and they extend from the dorsal roots to the parietal arachnoid. As the intermediate layer spreads laterally over the dorsal surface of the dorsal roots, it becomes increasingly perforated and eventually disappears. A similar arrangement is seen over the ventral aspect of the spinal cord but the intermediate layer is less substantial.

The intermediate layer is structurally similar to the trabeculae that cross the cranial subarachnoid space, i.e. it has a collagenous core coated by leptomeningeal cells. The intermediate layers of leptomeninges around the spinal cord may act as a baffle within the subarachnoid space to dampen waves of CSF movement in the vertebral canal. Inflammation within the spinal subarachnoid space may result in extensive fibrosis within the intermediate layer and the complications of chronic arachnoiditis (**Fig. 47.6**).

Coverings and relations of the spinal roots and nerves in the radicular canal

Tubular prolongations of spinal dura mater, closely lined by arachnoid, extend around the spinal roots and nerves as they pass through the lateral zone of the vertebral canal and through the intervertebral foramina (see Fig. 47.5; **Fig. 47.6A**). These prolongations, the spinal nerve sheaths or root sheaths, gradually lengthen as the spinal roots become increasingly oblique. Each individual dorsal and ventral root runs in the subarachnoid space with its own covering of pia mater. Each root pierces the dura separately, taking a sleeve of arachnoid with it, before joining within the dural prolongation just distal to the spinal ganglion. The dural sheaths of the spinal nerves fuse with the epineurium, within or slightly beyond the intervertebral foramina. The arachnoid prolongations within the sheaths do not extend as far distally as their dural coverings, but the subarachnoid space and the CSF it contains extend sufficiently distally to form a radiologically demonstrable root sleeve for each nerve. Shortening or obstruction of this sleeve seen on magnetic resonance imaging (MRI) indicates compression of the spinal nerve. At the cervical level, where the nerves are short and the vertebral movement is greatest, the dural sheaths are tethered to the periosteum of the adjacent transverse processes. In the lumbosacral region, there is less tethering of the dura to the periosteum, though there may be an attachment posteriorly to the facet joint capsule.

CEREBROSPINAL FLUID (CSF)

The cerebrospinal fluid is described in detail in Chapter 25. Although there is free communication between the spinal and cerebral subarachnoid spaces, the mode of circulation of the spinal CSF and the contribution that it makes to the overall circulation of CSF remain uncertain in humans: CSF may be absorbed from the spinal subarachnoid space; spinal arachnoid granulations and villi have been described (Kido et al 1976).

SPINAL NERVES

In those body segments that largely retain a metameric (segmental) structure, e.g. the thoracic region, spinal nerves show a common plan (**Fig. 47.7**). The dorsal, epaxial, ramus passes back lateral to the articular processes of the vertebrae and divides into medial and lateral branches that penetrate the deeper muscles of the back; both branches innervate

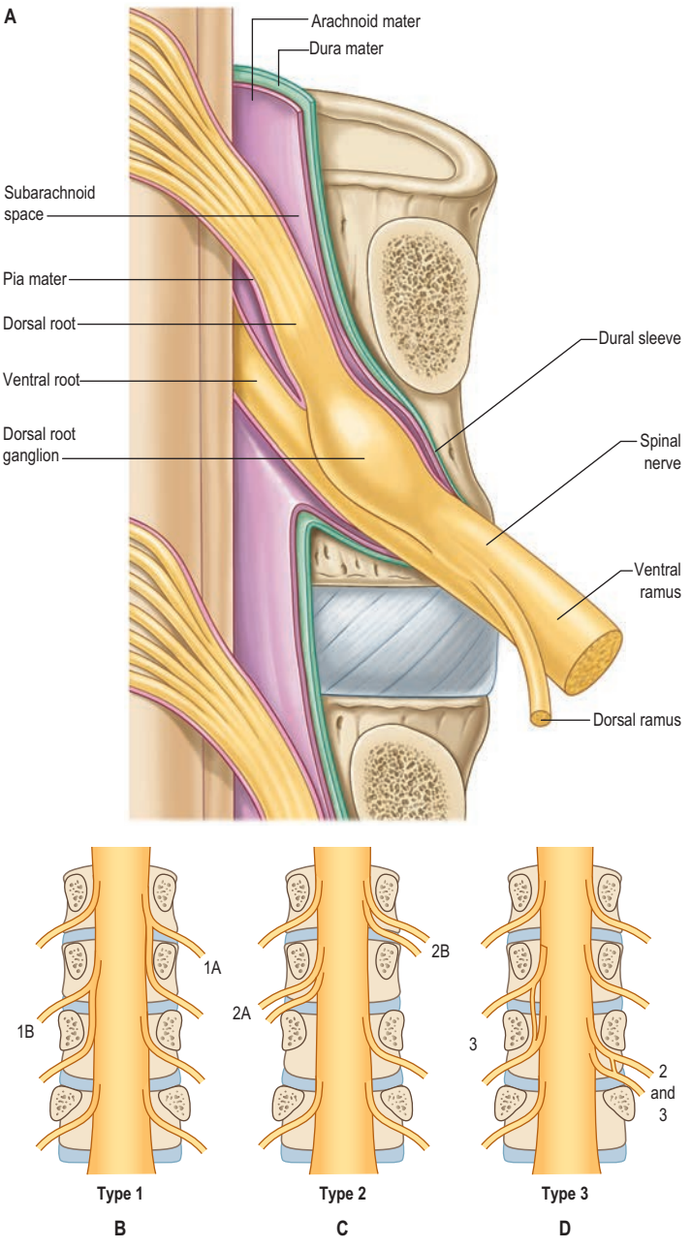

Fig. 47.6 **A**, A lumbar spinal nerve and its roots and meningeal coverings. **B–D**, Extradural anomalies of the lumbar nerve roots.

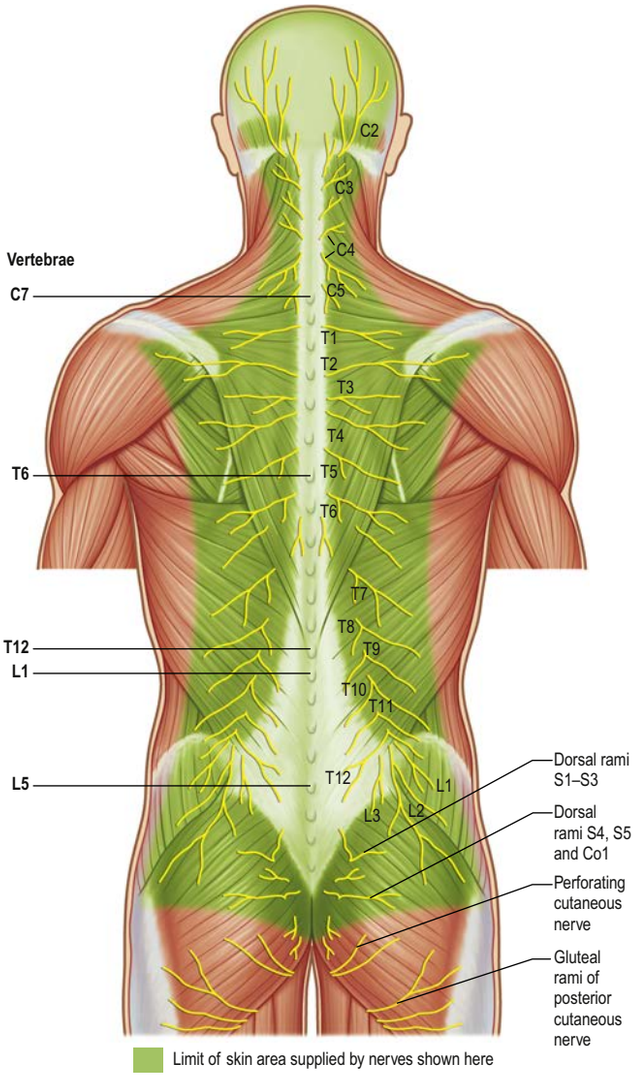

Fig. 47.8 The cutaneous distribution of the dorsal rami of the spinal nerves. The nerves are shown lying on the superficial muscles. The nerves are numbered on the right side; the spines of the seventh cervical, sixth and twelfth thoracic, and first and fifth lumbar vertebrae are labelled on the left side.

the adjacent muscles and supply a band of skin from the posterior median line to the lateral border of the scapula (Fig. 47.8). The ventral, hypaxial, ramus is connected to a corresponding sympathetic ganglion by white and grey rami communicantes. It innervates the prevertebral muscles and curves around in the body wall to supply the lateral muscles of the trunk. Near the mid-axillary line, it gives off a lateral branch that pierces the muscles and divides into anterior and posterior cutaneous branches. The main nerve advances in the body wall, where it supplies the ventral muscles and terminates in branches to the skin.

Spinal nerves are united ventral and dorsal spinal roots, attached in series to the sides of the spinal cord. The term spinal nerve strictly applies only to the short segment after union of the roots and before branching occurs. This segment, the spinal nerve proper, lies in the intervertebral foramen; it is sometimes mistakenly called the 'nerve root'. There are 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 1 coccygeal. The abbreviations C, T, L, S and Co, with appropriate numerals, are commonly applied to individual nerves as individual 'root values'. The peripheral nerves emerge through the intervertebral foramina. At thoracic, lumbar, sacral and coccygeal levels, the numbered nerve exits the vertebral canal by passing below the pedicle of the corresponding vertebra, e.g. L4 nerve exits the intervertebral foramen between L4 and L5. However, in the cervical region, nerves C1–C7 pass above their corresponding vertebrae. C1 leaves the vertebral canal between the occipital bone and atlas, and hence is often termed the suboccipital nerve. The last pair of cervical nerves does not have a correspondingly numbered vertebra and C8 passes between the seventh cervical and first thoracic vertebrae. Each nerve is continuous with the spinal cord by ventral and dorsal roots; each dorsal root bears a spinal, sensory ganglion (dorsal root ganglion).

Spinal roots and ganglia

Ventral (anterior) roots

Ventral roots contain axons of neurones in the ventral (anterior) and lateral spinal grey columns. Each emerges as a series of rootlets in two or three irregular rows in an area approximately 3 mm in horizontal width.

Dorsal (posterior) roots

Dorsal roots contain centripetal processes of neurones sited in the spinal ganglia. Each consists of medial and lateral fascicles that both diverge into rootlets that enter the spinal cord along the posterolateral sulcus. The rootlets of adjacent dorsal roots are often connected by oblique filaments, especially in the lower cervical and lumbosacral regions.

Little is known of the detail of the regions of entry and emergence of afferent and efferent rootlets in humans, but these zones of transition between the central and peripheral nervous systems have been extensively described in rodents (Fraher 2000).

Appearance and orientation of roots at each spinal level

The size and direction of spinal nerve roots vary. The upper four cervical roots are small, while the lower four are large. Cervical dorsal roots have a thickness ratio to the ventral roots of 3 : 1, which is greater than in other regions. The first dorsal root is an exception, being smaller than the ventral, and it is occasionally absent. The conventional view is that the first and second cervical spinal roots are short, running almost horizontally to their exits from the vertebral canal, and that from the third to the eighth cervical levels the roots slope obliquely down. Obliquity and length increase successively, although the distance between spinal attachment and vertebral exit never exceeds the height of one vertebra. An alternative view states that upper cervical roots descend, the fifth is horizontal, the sixth to eighth ascend, the first two thoracic roots are horizontal, the next three ascend, the sixth is horizontal and the rest descend (Kubik and Müntener 1969). This view is based on the observation that the cervicothoracic part of the spinal cord grows more in length than other parts.

Thoracic roots, except the first, are small, and the dorsal root only slightly exceeds the ventral in thickness. They increase successively in length. In the lower thoracic region, the roots descend in contact with the spinal cord for at least two vertebrae before emerging from the vertebral canal.

Lower lumbar and upper sacral roots are the largest, and their rootlets are the most numerous. Coccygeal roots are the smallest. Kubik and Müntener (1969) confirm that lumbar, sacral and coccygeal roots descend with increasing obliquity to their exits. The spinal cord ends near the lower border of the first lumbar vertebra, and so the lengths of successive roots rapidly increase; the consequent collection of roots is the cauda equina (**Fig. 47.1A**). The largest roots, and hence the largest spinal nerves, are continuous with the spinal cervical and lumbar enlargements and innervate the upper and lower limbs.

Spinal ganglia (dorsal root ganglia)

Spinal ganglia (dorsal root ganglia, DRG) are large groups of neurones on the dorsal spinal roots. Each is oval and reddish: its size is related to that of its root. A ganglion is bifid medially where the two fascicles of the dorsal root emerge to enter the cord. Ganglia are usually sited in the intervertebral foramina, immediately lateral to the perforation of the dura mater by the roots (see **Fig. 47.1B**). However, the first cervical ganglion lies on the vertebral arch of the atlas, the second lies behind the lateral atlanto-axial joint, the sacral lie inside the vertebral canal, and the coccygeal ganglion usually lies within the dura mater. The first cervical ganglia may be absent. Small aberrant ganglia sometimes occur on the upper cervical dorsal roots between the spinal ganglia and the cord.

Spinal nerves proper

Immediately distal to the spinal ganglia, ventral and dorsal roots unite to form spinal nerves. These very soon divide into dorsal and ventral rami, both of which receive fibres from both roots (see Fig. 47.6A). At all levels above the sacral, this division occurs within the intervertebral foramen. Division of the sacral spinal nerves occurs within the sacral vertebral canal, and the dorsal and ventral rami exit separately through posterior and anterior sacral foramina at each level. Spinal nerves trifurcate at some cervical and thoracic levels, in which case the third branch is called a ramus intermedius. At or distal to its origin, each ventral ramus gives off recurrent meningeal (sinuvertebral) branches and receives a grey ramus communicans from the corresponding sympathetic ganglion. The thoracic and first and second lumbar ventral rami each contribute a white ramus communicans to the corresponding sympathetic ganglia. The second, third and fourth sacral nerves also supply visceral branches, unconnected with sympathetic ganglia, which carry a parasympathetic outflow direct to the pelvic plexuses.

Cervical spinal nerves enlarge from the first to the sixth nerve. The seventh and eighth cervical and the first thoracic nerve are similar in size to the sixth cervical nerve. The remaining thoracic nerves are relatively small. Lumbar nerves are large, increasing in size from the first to the fifth. The first sacral is the largest spinal nerve; thereafter the sacral nerves decrease in size. The coccygeal nerves are the smallest spinal nerves. The size of the spinal nerve and its associated structures within the intervertebral foramen is not in direct relation to the size of the foramen. At lumbar levels, though L5 is the largest nerve, its foramen is smaller than those of L1–L4, which renders this nerve particularly liable to compression.

In the radicular ('root') canal and intervertebral foramen, the spinal nerve is related to the spinal artery of that level and its radicular branch, and to a small plexus of veins. At the outer end of the foramen, the nerve may lie above or below transforaminal ligaments.

Meningeal nerves

Recurrent meningeal (or sinuvertebral) nerves (**Fig. 47.9**) occur at all vertebral levels. They are mixed sensory and sympathetic nerves, represented by numerous fine filaments amongst which one, or two to four, larger trunks may be evident. At cervical levels, the autonomic roots arise from the grey rami that form the vertebral nerve. At thoracic and lumbar levels, each nerve is formed by a somatic root from the ventral ramus and by an autonomic root from the grey ramus communicans of that segment. Each nerve pursues a recurrent course through the intervertebral foramen, passing ventral to the spinal nerve, to enter the vertebral canal, where it divides into ascending, descending and transverse branches. These branches communicate with corresponding branches from the segments above and below, and from the opposite side, forming arcades along the floor of the vertebral canal. Meningeal branches of the arcades form a plexus on the ventral surface of the dural sac and nerve root sleeves that attenuates laterally; the posterior paramedian dura is devoid of nerve endings. Skeletal branches are distributed to the posterior longitudinal ligament, the periosteum of the vertebral bodies, and

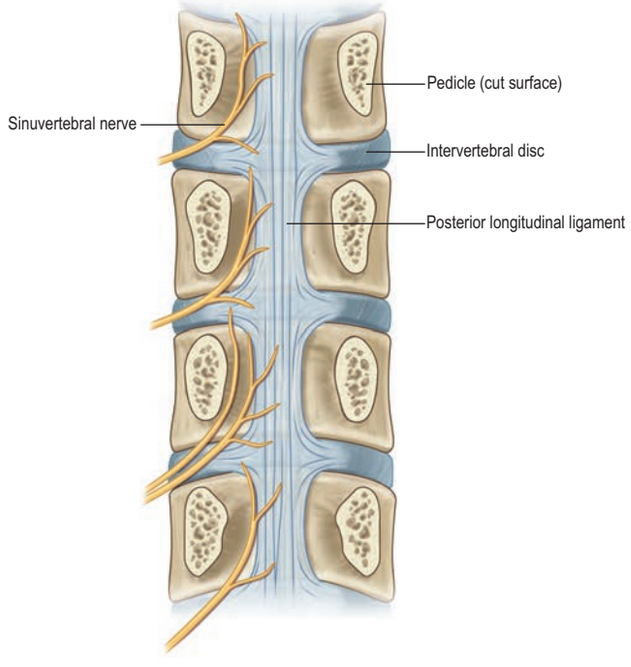

Fig. 47.9 The course and skeletal distribution of the lumbar sinuvertebral nerves. Each nerve supplies the intervertebral disc at its level of entry into the vertebral canal, the disc above, and the intervening posterior longitudinal ligament. In about one-third of cases, the nerve at a particular level may be represented by more than one filament.

to the posterior and posterolateral aspects of the intervertebral discs (Garcia-Cosamalon et al 2010). Vascular branches accompany the veins and arteries of the vertebral canal and those of the vertebral bodies. The upper three cervical meningeal nerves ascend through the foramen magnum into the posterior cranial fossa, where they innervate the dura mater that covers the clivus. *En route*, they innervate the median atlanto-axial joint and its ligaments.

Functional components of spinal nerves

A typical spinal nerve contains somatic efferent fibres and somatic and visceral afferent fibres. Some, but not all, spinal nerves also contain preganglionic autonomic fibres.

Somatic components

Somatic efferent fibres innervate skeletal muscles and are axons of α, β and γ neurones in the spinal ventral grey column. Somatic afferent fibres convey impulses into the central nervous system from receptors in the skin, subcutaneous tissue, muscles, tendons, fasciae and joints; they are peripheral processes of unipolar neurones in the spinal ganglia.

Visceral components

Preganglionic visceral efferent sympathetic fibres are axons of neurones in the spinal intermediolateral grey column throughout the thoracic and upper two or three lumbar segments; they join the sympathetic trunk via corresponding white rami communicantes and synapse with postganglionic neurones that are distributed to smooth muscle, myocardium or exocrine glands. The preganglionic visceral efferent parasympathetic fibres are axons of neurones in the spinal lateral grey column of the second to fourth sacral segments; they leave the ventral rami of corresponding sacral nerves and synapse in pelvic ganglia. The postganglionic axons are distributed mainly to smooth muscle or glands in the walls of the pelvic viscera. Visceral afferent fibres have cell bodies in the spinal ganglia. Their peripheral processes pass through white rami communicantes and, without synapsing, through one or more sympathetic ganglia to end in the walls of the viscera. Some visceral afferent fibres may enter the spinal cord in the ventral roots.

Central processes of ganglionic unipolar neurones enter the spinal cord by dorsal roots and synapse on somatic or sympathetic efferent neurones, usually through interneurones, completing reflex paths. Alternatively, they may synapse with other neurones in the spinal or brainstem grey matter that give origin to a variety of ascending tracts.

Variations of spinal roots and nerves

The courses of spinal roots and nerves in relation to the thecal sac and vertebral and radicular canals may be aberrant. An individual intervertebral foramen may contain a duplicated sheath, nerve and roots, which will then be absent at an adjacent level. Abnormal communications between roots may occur within the vertebral canal. These anomalies have been described and classified for the lumbosacral spine by Neidre and MacNab (1983) (see Fig. 47.6).

Rami of the spinal nerves

Ventral (anterior) primary rami supply the limbs and the anterolateral aspects of the trunk, and in general are larger than the dorsal rami. Thoracic ventral rami run independently and retain a largely segmental distribution. Cervical, lumbar and sacral ventral rami connect near their origins to form plexuses. Dorsal rami do not join these plexuses. The ventral rami are described in the appropriate regional sections.

Dorsal (posterior) primary rami of spinal nerves are usually smaller than the ventral rami and are directed posteriorly. Retaining a segmental distribution, all, except for the first cervical, fourth and fifth sacral and the coccygeal, divide into medial and lateral branches that supply the muscles and skin of the posterior regions of the neck and trunk (see Fig. 47.8).

Cervical dorsal spinal rami

Each cervical spinal dorsal ramus, except the first, divides into medial and lateral branches that all innervate muscles. In general, only medial branches of the second to fourth, and usually the fifth, supply the skin. Except for the first and second, each dorsal ramus passes posteriorly around an articular pillar as far as the root of the transverse process medial to a posterior intertransverse muscle, which it supplies.

First cervical dorsal ramus (suboccipital nerve)

The first cervical dorsal ramus, the suboccipital nerve, is larger than the ventral (see Fig. 46.78). It emerges superior to the posterior arch of the atlas and inferior to the vertebral artery, and enters the suboccipital triangle to supply rectus capitis posterior major and minor, obliquus capitis superior and inferior, and semispinalis capitis. A filament from the branch to inferior oblique joins the second dorsal ramus. The suboccipital nerve occasionally has a cutaneous branch that accompanies the occipital artery to the scalp, and connects with the greater and lesser occipital nerves. It may also communicate with the accessory nerve.

Second cervical dorsal ramus

The second cervical dorsal ramus is slightly larger than the ventral and all the other cervical dorsal rami (see Figs 36.22, 46.78). It runs between the lamina of the axis and inferior oblique, below which it divides into a large medial and smaller lateral branch. The dorsal ramus or its medial branch receives communicating branches from the first cervical dorsal ramus that pass both through and around inferior oblique. A descending communicating branch crosses the C2–C3 facet joint to reach the third cervical dorsal ramus.

Greater occipital nerve

The medial branch, termed the greater occipital nerve, passes transversely across inferior oblique deep to semispinalis capitis, which it innervates. Near the origin of inferior oblique, it turns rostrally along rectus capitis posterior major, where it receives a communicating branch from the third occipital nerve before turning dorsally to pierce semispinalis capitis. It emerges on to the scalp by passing above an aponeurotic sling between trapezius and sternocleidomastoid near their occipital attachments. It ascends with the occipital artery and divides into branches that connect with the third occipital and lesser occipital nerves, and which supply the back of the auricle and the skin of the scalp as far forwards as the coronal suture. The lateral branch of the second cervical dorsal ramus supplies longissimus capitis, semispinalis capitis and splenius capitis, and sends a communicating branch to the lateral branch of the third cervical dorsal ramus.

Greater occipital neuralgia

Greater occipital neuralgia is a syndrome of pain and paraesthesiae felt in the distribution of the greater occipital nerve. This is usually caused by damage or irritation to the greater occipital nerve but more rarely can result from a similar process in the lesser occipital nerve or both greater and lesser occipital nerves. A similar syndrome may be caused by upper facet joint arthritis involving the second cervical root (Vanelderen et al 2010).

Third cervical dorsal ramus

The third cervical dorsal ramus is intermediate in size between the second and fourth. It courses back round the articular pillar of the third cervical vertebra, medial to the posterior intertransverse muscle, and divides into medial and lateral branches. The lateral branch passes dorsally across the surface of semispinalis capitis to supply it and the overlying longissimus capitis and splenius capitis. It receives a communicating branch from the lateral branch of the second cervical dorsal ramus, and sends a similar branch to the lateral branch of the fourth cervical dorsal ramus. The deep medial branch curves dorsally and medially around the waist of the articular pillar before ending in multifidus. It sends an articular branch to the C3–C4 facet joint, and may also send a branch into semispinalis capitis. The superficial medial branch, the third occipital nerve, curves around the lateral and dorsal surfaces of the C2–C3 facet joint, which it supplies. It continues transversely, deep to semispinalis, which it supplies, and sends a communicating branch to the greater occipital nerve. Just above the second cervical spinal process, the third occipital nerve turns dorsally to pierce semispinalis capitis, splenius capitis and trapezius, and becomes cutaneous over a small area immediately below the superior nuchal line. Communicating branches join the cutaneous branches of the greater and lesser occipital nerves.

Dorsal rami of the lower five cervical nerves

The dorsal rami of the lower five cervical nerves curve back round the vertebral articular pillars and divide into lateral and medial branches. The lateral branches supply longissimus cervicis, splenius cervicis and iliocostalis cervicis. The medial branches curve around the lateral and dorsal surfaces of the articular pillar of their segment, deep to semispinalis capitis. They send articular branches to the facet joints above and below their course before entering and supplying multifidus. Terminal branches reach interspinalis at each segment. Cutaneous branches arise consistently from the fourth, and commonly from the fifth, sixth and eighth, but

not usually from the seventh medial branches. These branches pass across multifidus or through semispinalis cervicis and turn dorsally around the medial border of semispinalis capitis, to pierce splenius cervicis and trapezius and reach the skin.

Thoracic dorsal spinal rami

At each segmental level, the thoracic dorsal rami pass dorsally through an aperture bounded by the transverse processes superiorly and inferiorly, the facet joint medially, and the superior costotransverse ligament laterally. Thereafter, each dorsal ramus follows a prolonged course laterally, between the anterior lamella of the superior costotransverse ligament anteriorly, and the costolamellar ligament and the posterior lamella of the superior costotransverse ligament posteriorly. In this narrow space, the dorsal ramus divides into lateral and medial branches. The lateral branches continue laterally as far as the costotransverse joint, above which they turn dorsally and inferiorly to supply the levatores costarum, and enter the longissimus thoracis and iliocostalis muscles. Lateral branches from the upper six thoracic dorsal rami remain intramuscular. Those from the lower six levels emerge from iliocostalis lumborum to pierce serratus posterior inferior and latissimus dorsi in line with the costal angles. They descend across as many as four ribs before becoming superficial. The twelfth thoracic lateral branch sends a filament medially along the iliac crest and then passes down to the anterior gluteal skin. Some upper thoracic lateral branches may become cutaneous.

Each medial branch hooks dorsally around the lateral margin of the posterior lamella of the superior costotransverse ligament, lying a variable distance above the tip of the transverse process. At the first to fourth, and at the ninth and tenth thoracic levels, the medial branches cross the superior tip of the transverse process to turn inferiorly and medially across the posterior surface of the transverse process, lying between the attachment sites of multifidus medially and semispinalis laterally. Each nerve continues this oblique course to supply multifidus and semispinalis. At the fifth to eighth thoracic levels, the medial branches assume a course parallel to that of other levels, but do not reach the transverse process, instead passing superior and dorsal to the plane of the transverse processes. At the eleventh and twelfth levels, in keeping with the relatively short transverse processes at these levels, the medial branches run close to the superior articular processes. Each medial branch supplies articular branches to the facet joints above and below its course. Medial branches of the upper six thoracic dorsal rami furnish cutaneous branches that pierce trapezius and the rhomboids to reach the skin near the spinous processes. Cutaneous branches may occasionally arise from the medial branches of the lower six thoracic dorsal rami.

Lumbar dorsal spinal rami

After leaving its spinal nerve, each of the first to fourth lumbar dorsal rami passes through an aperture in the dorsal leaf of the intertransverse ligament just above a transverse process (Fig. 47.10). Each dorsal ramus supplies the overlying medial intertransverse muscle before dividing into lateral and medial branches. The lateral branches supply the longissimus and iliocostalis components of the lumbar erector spinae. The upper three lumbar lateral branches emerge from the lateral border of iliocostalis lumborum and pierce the aponeurosis of latissimus dorsi to become cutaneous. They cross the iliac crest to reach the gluteal skin; some reach as far as the level of the greater trochanter. Medial branches cross the junction of the superior articular process and transverse process, and hook medially between the mammillary and accessory processes, deep to the mammillo-accessory ligament. Medial to the ligament, each medial branch sends articular branches to the facet joints above and below its course, before entering multifidus, which it supplies. Medial branch blocks (see below in the clinical procedure section) are quite useful in the treatment of facet-mediated low back pain. Terminal branches reach interspinalis at each segment.

The fifth dorsal ramus has a longer course than other dorsal rami. It arches over the ala of the sacrum, lying against the root of the first sacral superior articular process. Opposite the base of the lumbosacral joint, it sends a branch into the lowest fibres of longissimus thoracis, and a communicating branch to the first sacral dorsal ramus, before terminating as a branch that hooks around the lumbosacral joint to end in multifidus.

Sacral dorsal spinal rami

Sacral dorsal rami are small, diminishing in size inferiorly; other than the fifth, all emerge through the dorsal sacral foramina. The upper three are covered at their exit by multifidus, and divide into medial and lateral branches. Medial branches are small and end in multifidus. Lateral branches join together and with branches of the last lumbar and fourth sacral dorsal rami to form loops dorsal to the sacrum. Branches from these loops run dorsal to the sacrotuberous ligament and form a second series of loops under gluteus maximus. From these, two or three gluteal branches pierce gluteus maximus (along a line from the posterior superior iliac spine to the coccygeal apex) to supply the posterior gluteal skin.

The dorsal rami of the fourth and fifth sacral nerves are small and lie caudal to multifidus. They unite with each other and with the coccygeal dorsal ramus to form loops dorsal to the sacrum; filaments from these supply the skin over the coccyx.

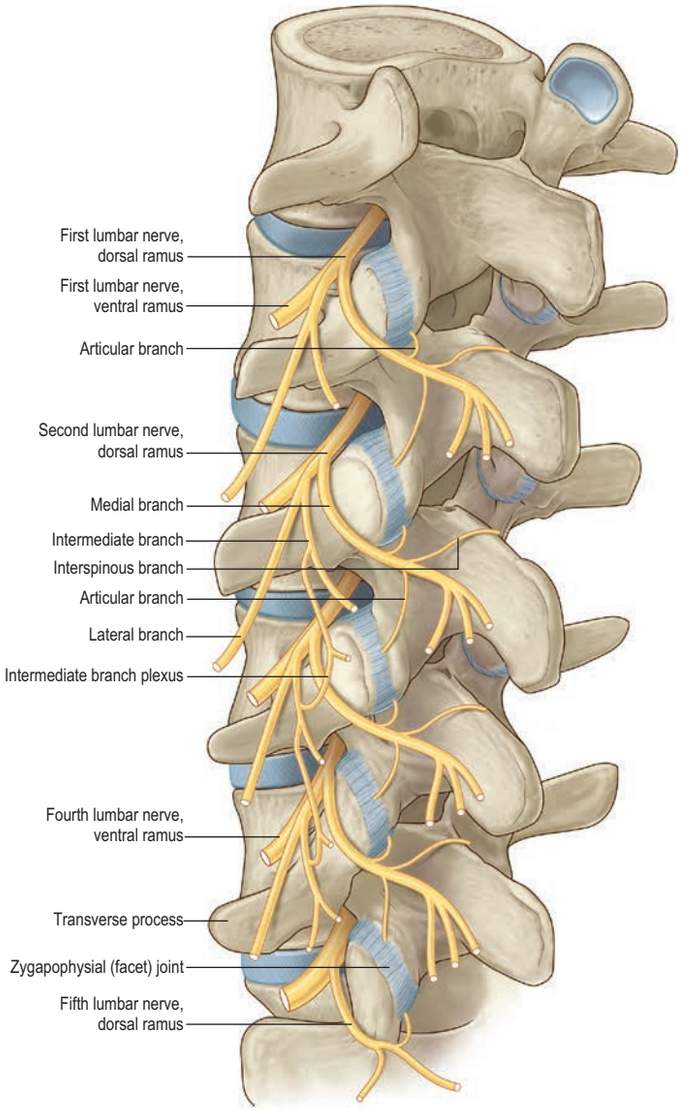

Fig. 47.10 Left posterolateral view of the lumbar spine showing the branches of the lumbar dorsal rami.

Coccygeal dorsal spinal ramus

The coccygeal dorsal spinal ramus does not divide into medial and lateral branches. It communicates with the fourth and fifth sacral dorsal rami to supply the skin over the coccyx.

VASCULAR SUPPLY OF SPINAL CORD, ROOTS AND NERVES

Arteries

The spinal cord and its roots and nerves are supplied with blood by both longitudinal and segmental vessels (Fig. 47.11). Three major longitudinal vessels, a single anterior and two posterior spinal arteries (each of which is sometimes doubled to pass on either side of the dorsal rootlets) originate intracranially from the vertebral artery and terminate in a plexus around the conus medullaris. The anterior spinal artery forms

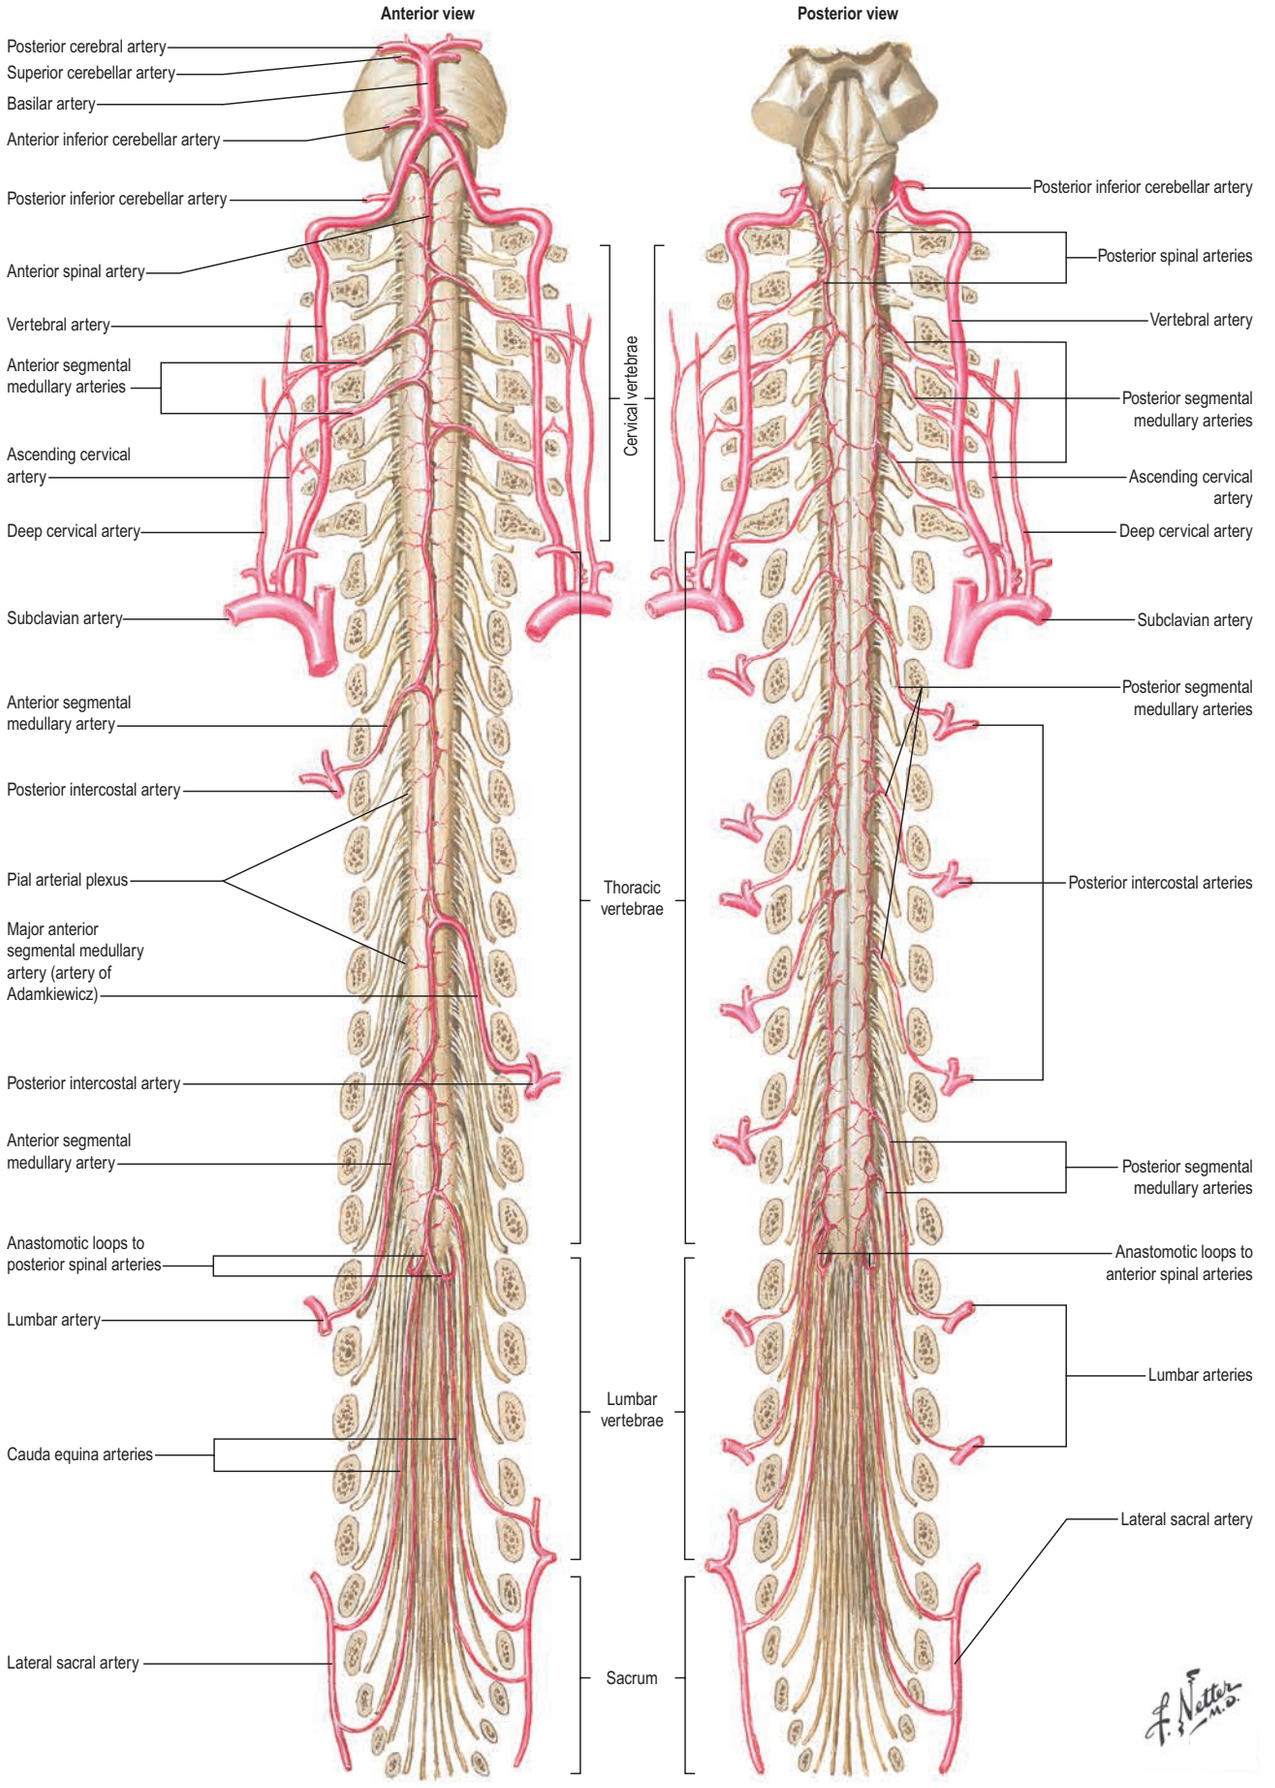

Fig. 47.11 Arteries of the spinal cord. (Reprinted from Netter Anatomy Illustration Collection, © Elsevier Inc. All Rights Reserved.)

from the fused anterior spinal branches of the vertebral artery, and descends in the ventral median fissure of the cord. Each posterior spinal artery originates either directly from the ipsilateral vertebral artery or from its posterior inferior cerebellar branch, and descends in a posterolateral sulcus of the cord. The segmental arteries are derived in craniocaudal sequence from spinal branches of the vertebral, deep cervical, intercostal and lumbar arteries. These vessels enter the vertebral canal through the intervertebral foramina and anastomose with branches of the longitudinal vessels to form a pial plexus on the surface of the cord. The segmental spinal arteries send anterior and posterior radicular branches to the spinal cord along the ventral and dorsal roots. Most anterior radicular arteries are small and end in the ventral nerve roots or in the pial plexus of the cord. The small posterior radicular arteries also supply the dorsal root ganglia; branches enter at both ganglionic poles to be distributed around ganglion cells and nerve fibres (see also Crock (1996).)

Segmental radiculomedullary feeder arteries

Some radicular arteries, mainly situated in the lower cervical, lower thoracic and upper lumbar regions, are large enough to reach the ventral median fissure, where they divide into slender ascending and large descending branches. These are the anterior radiculomedullary feeder arteries (Dommisse 1975). They anastomose with the anterior spinal arteries to form a single or partly double longitudinal vessel of uneven calibre along the ventral median fissure. The largest anterior medullary feeder, the great anterior radiculomedullary artery of Adamkiewicz, varies in level, arising from a spinal branch of either one of the lower posterior intercostal arteries (T9–T11), or of the subcostal artery (T12), or less frequently of the upper lumbar arteries (L1 and L2). It most often arises on the left side (Carmichael and Gloviczki 1999). Reaching the spinal cord, it sends a branch to the anterior spinal artery below and another to anastomose with the ramus of the posterior spinal artery, which lies anterior to the dorsal roots. It may be the main supply to the lower two-thirds of the cord. Central branches of the anterior spinal artery enter the ventral median fissure, and then turn right or left to supply the ventral grey column, the base of the dorsal grey column, including the dorsal nucleus, and the adjacent white matter (Fig. 47.12).

Each posterior spinal artery contributes to a pair of longitudinal anastomotic channels, anterior and posterior to the dorsal spinal roots. These are reinforced by posterior medullary feeders from the posterior radicular arteries. The latter are variable in number and size, but smaller, more numerous and more evenly distributed than the anterior medullary feeders. The anterior channel is joined by a ramus from the descending branch of the great anterior segmental medullary artery of Adamkiewicz. In all longitudinal spinal arteries the width of the lumen is uneven and complete interruptions may occur. At the conus medullaris they communicate by anastomotic loops. Anastomoses other than those between the pial or peripheral spinal arterial branches may be important, e.g. a posterior spinal series of anastomoses between rami of the dorsal divisions of segmental arteries near the spinous processes.

Intramedullary arteries

The central branches of the anterior spinal artery supply about two-thirds of the cross-sectional area of the cord. The rest of the dorsal grey and white columns and peripheral parts of the lateral and ventral white columns are supplied by numerous small radial vessels that branch from posterior spinal arteries and the pial plexus. In a microangiographic study of the human cervical spinal cord, up to six anterior, and eight posterior, radicular spinal arteries were described, and up to eight central branches arose from each centimetre of the anterior spinal artery (Turnbull et al 1966). Abnormalities of blood vessels in the spinal cord can result in clinically significant haemorrhages and neurological events (Fig. 47.13)

Spinal cord ischaemia

The spinal cord can rely for neither its transverse nor its longitudinal blood supply entirely on the longitudinal arteries. The anterior longitudinal artery and the intramedullary arteries are functional end-arteries, although overlap of territories of supply has been described (Backes and Nijenhuis 2008). Damage to the anterior longitudinal artery can result in loss of function of the anterior two-thirds of the cord (Fig. 47.14). The longitudinal arteries cannot supply the whole length of the cord, and the input of the segmental medullary feeder vessels is essential. This is especially true of the artery of Adamkiewicz, which may effectively carry the major supply for the lower cord; damage to this individual artery compromises perfusion of the distal cord and may be responsible for paraplegia following aortic bypass procedures. For many years, it was assumed that the anterior spinal artery system provided the dominant supply to the cord, but clinical evidence implies that the posterior spinal arteries may be as important as the anterior system in protecting the cord. The mid-thoracic cord, distant from the main anterior medullary feeders, is particularly liable to become ischaemic after periods of hypotension; T4–T9 has been described as the critical vascular zone of the spinal cord, where interference with the circulation is most likely to result in paraplegia.

Veins

Intramedullary veins within the substance of the spinal cord drain into a circumferential plexus of surface veins, the coronal plexus (venous plexus of the pia mater). Six tortuous longitudinal channels are usually identified within this plexus: anterior and posterior spinal veins (anterior and posterior median veins) and four others that run on either side of the ventral and dorsal nerve roots (Fig. 47.15). Only the anterior spinal vein, which drains the central grey matter, is consistently complete. It receives sulcal veins and small pial veins from the coronal plexus and is largest in calibre in the lumbosacral region. The posterior spinal vein is frequently variable, appearing plexiform in some segments and as a single channel in others. These vessels connect freely and drain superiorly into the cerebellar veins and cranial sinuses, and segmentally into medullary veins mainly. The segmental veins drain into the intervertebral veins and thence into the external vertebral venous plexuses (see Fig. 46.21), the caval and azygos systems.

Segmental veins

Anterior and posterior radiculomedullary veins run along some of the ventral and dorsal roots. Like the medullary feeder arteries, they are largest in the cervical and lumbar regions of the cord, but do not necessarily occur in the same segments as the medullary feeders. They drain the cord but not the roots themselves. Very small anterior and posterior radicular veins occur in most spinal segments, accompanying and draining the ventral and dorsal roots and some of the cord at the points of entry and exit of the rootlets; they usually drain into the intervertebral veins.

THE EFFECTS OF INJURY

Spinal cord injury and vertebral column injury

Various clinical definitions have been described in the *International Standards Booklet for Neurological and Functional Classification of Spinal Cord Injury*, which was a landmark publication in standardizing the language of the neurological examination as it relates to spinal cord injury (Ditunno et al 1994). 'Tetraplegia' refers to impairment or loss of neural function secondary to a cervical injury. 'Paraplegia' refers to loss of function in the thoracic, lumbar or sacral segments of the cord. 'Dermatome' refers to the area of skin innervated by cutaneous axons in the distribution of a single spinal nerve. 'Myotome' refers to the muscle fibres innervated by the motor axons of a single spinal nerve. 'Neurological level' is the first level where motor and sensory function is normal on both sides of the body. 'Sensory level' refers to the most caudal level with normal sensation on both sides of the body. 'Motor level' refers to the most caudal segment with antigravity strength, providing that the next most rostral level is stronger. 'Complete injury' occurs when there is an absence of motor and sensory function below the motor and sensory levels and absence of function in the lowest sacral segment. 'Incomplete injury' refers to partial preservation of sensory and/or motor function below the neurological levels, as well as evidence of 'sacral sparing' (evidence of preserved function of the lowest sacral segment) (Ditunno et al 2004). 'Spinal shock' refers to the absence of reflexes and motor/sensory function below the level of injury and occurs typically from the time at which spinal cord injury is sustained to 24 hours after injury, followed by a phase of reflex return (Ditunno et al 2004).

In the assessment of a patient with spinal injury and neurological damage, it is important to remember that the level of cord and root injury will not coincide with that of the skeletal damage to the vertebral column. In estimating the vertebral levels of cord segments in the adult, a useful approximation is that, in the cervical region, the tip of a vertebral spinous process corresponds to the succeeding cord segment (i.e. the sixth cervical spine is opposite the seventh spinal segment); at upper thoracic levels, the tip of a vertebral spine corresponds to the cord two segments lower (i.e. the fourth spine is level with the sixth segment),

and in the lower thoracic region, there is a difference of three segments (i.e. the tenth thoracic spine is level with the first lumbar segment). The eleventh thoracic spine overlies the third lumbar segment and the twelfth is opposite the first sacral segment. In making this estimate by palpation of the vertebral spines, it is important to remember the relationship of the individual spines to their vertebral bodies. Clinical localization may be off by several levels because other factors may come into play, such as vascular insufficiency or venous obstruction, resulting in the lesion being localized as significantly lower than it actually is (Rousseff and Tzvetanov 2006, Sonstein et al 1996).

Complete division above the fourth cervical segment causes respiratory failure because of the loss of activity in the phrenic and intercostal nerves. Lesions between C5 and T1 paralyse all four limbs (quadriplegia), the effects in the upper limbs varying with the site of injury: at the fifth cervical segment, paralysis is complete; and at the sixth, each arm is positioned in abduction and lateral rotation, with the elbow flexed and the forearm supinated, due to unopposed activity in deltoid, supraspinatus, rhomboid and the brachial flexors (all supplied by the fifth cervical spinal nerves). Upper limb paralysis is less marked in lower cervical lesions. Lesions of the first thoracic segment paralyse small muscles in the hand and damage the sympathetic outflow to the head and neck, resulting in contraction of the pupil, recession of the eyeball, narrowing of the palpebral fissure and loss of sweating in the face and neck (Horner's syndrome). However, sensation is retained in areas innervated by segments above the lesion; thus cutaneous sensation is retained in the neck and chest down to the second intercostal space because this area is innervated by the supraclavicular nerves (C3 and C4). At thoracic levels, division of the cord paralyses the trunk below the segmental level of the lesion, and both lower limbs (paraplegia). The first sacral neural segment is approximately level with the thoracolumbar vertebral junction; injury, which commonly occurs here, paralyses the urinary bladder, the rectum and muscles supplied by the sacral segments, and cutaneous sensibility is lost in the perineum, buttocks, the back of the thighs and the legs, and soles of the feet. The roots of lumbar nerves descending to join the cauda equina may be damaged at this level, causing complete paralysis of both lower limbs. Lesions below the first lumbar vertebra may divide or damage the cauda equina, but severe nerve damage is uncommon and is usually confined to the spinal roots at the level of the trauma. Neurological symptoms may also occur as a result of interference with the spinal blood supply, particularly in the lower thoracic and upper lumbar segments.

Spinal cord injury without radiological abnormality: 'SCIWORA'

The spinal cord may be damaged without radiological evidence of skeletal injury to the vertebral column. This most commonly occurs with motor vehicle accidents but also has been reported with sports injuries and falls. MRI may or may not show evidence of cord injury after SCIWORA occurs; the majority of patients sustaining these injuries have an abnormal MRI scan.

Spinal cord syndromes

Available with the *Gray's Anatomy* e-book

Lesions of the spinal roots, nerves and ganglia

Spinal roots, nerves and ganglia may be damaged in the vertebral and root canals and at the intervertebral foramina. Neurofibromas and schwannomas may occur on the roots and nerves in the root canals (Fig. 47.16). As they enlarge, these tumours become dumbbell-shaped, with both an intraspinal and an extraspinal component in continuity; the clinical picture may thus include paradoxical features as the asymmetric space-occupying lesion grows. Root compression usually presents acutely with pain, which may be severe. The pain, paraesthesias and numbness occur in a dermatomal distribution; dermatomal overlap may make it difficult to demonstrate sensory loss on the trunk. Severe traction injuries of the upper limbs may cause avulsion of spinal roots from the cord in the cervical region.

Typical neural abnormalities include cord oedema, haemorrhage, contusion or transection. Typical extraneural abnormalities include intervertebral disc protrusion or herniation, ligamentum flavum bulging, cervical spondylitis, prevertebral soft tissue oedema, ligamentous abnormalities and/or ossification of the posterior longitudinal ligament. Originally, this was considered a paediatric diagnosis but it has now been shown to be equally common in adults. Spinal stenosis and pre-existing cord compression have been postulated as a risk factor for SCIWORA but clinical series have not supported this (Boese and Lechler 2013, Boese et al 2013).

For cervical spinal injury, several cord syndromes have been described, relating the clinical picture to the anatomy of the neurological lesion within the cord. The most common of these is central cord syndrome, which usually results from hyperextension injury to an osteoarthritic neck, when the major injury is to the central grey matter. This typically gives an incomplete cord injury pattern with greater motor loss in the upper extremities than in the lower limbs. There is also variable sensory loss and neurogenic bladder dysfunction (Pouw et al 2010). In anterior cord syndrome, which may occur in flexion–compression injuries of the neck, the damage occurs in the area of supply of the anterior spinal artery, sparing the posterior columns; the motor loss is usually proportionately greater in the lower than in the upper limbs, while sensory loss is less of a problem. A third syndrome that may be seen with penetrating trauma is Brown–Séquard syndrome. This is an injury directed to one side of the spinal cord, where there is ipsilateral loss of motor function and pinprick sensation and contralateral loss of pain and temperature sensation (Lee et al 1990). The anatomical basis for these symptoms is injury to the ipsilateral posterior columns and corticospinal tract, and injury to the lateral spinothalamic tract, which conveys contralateral pain and temperature sensation (see Ch. 27).

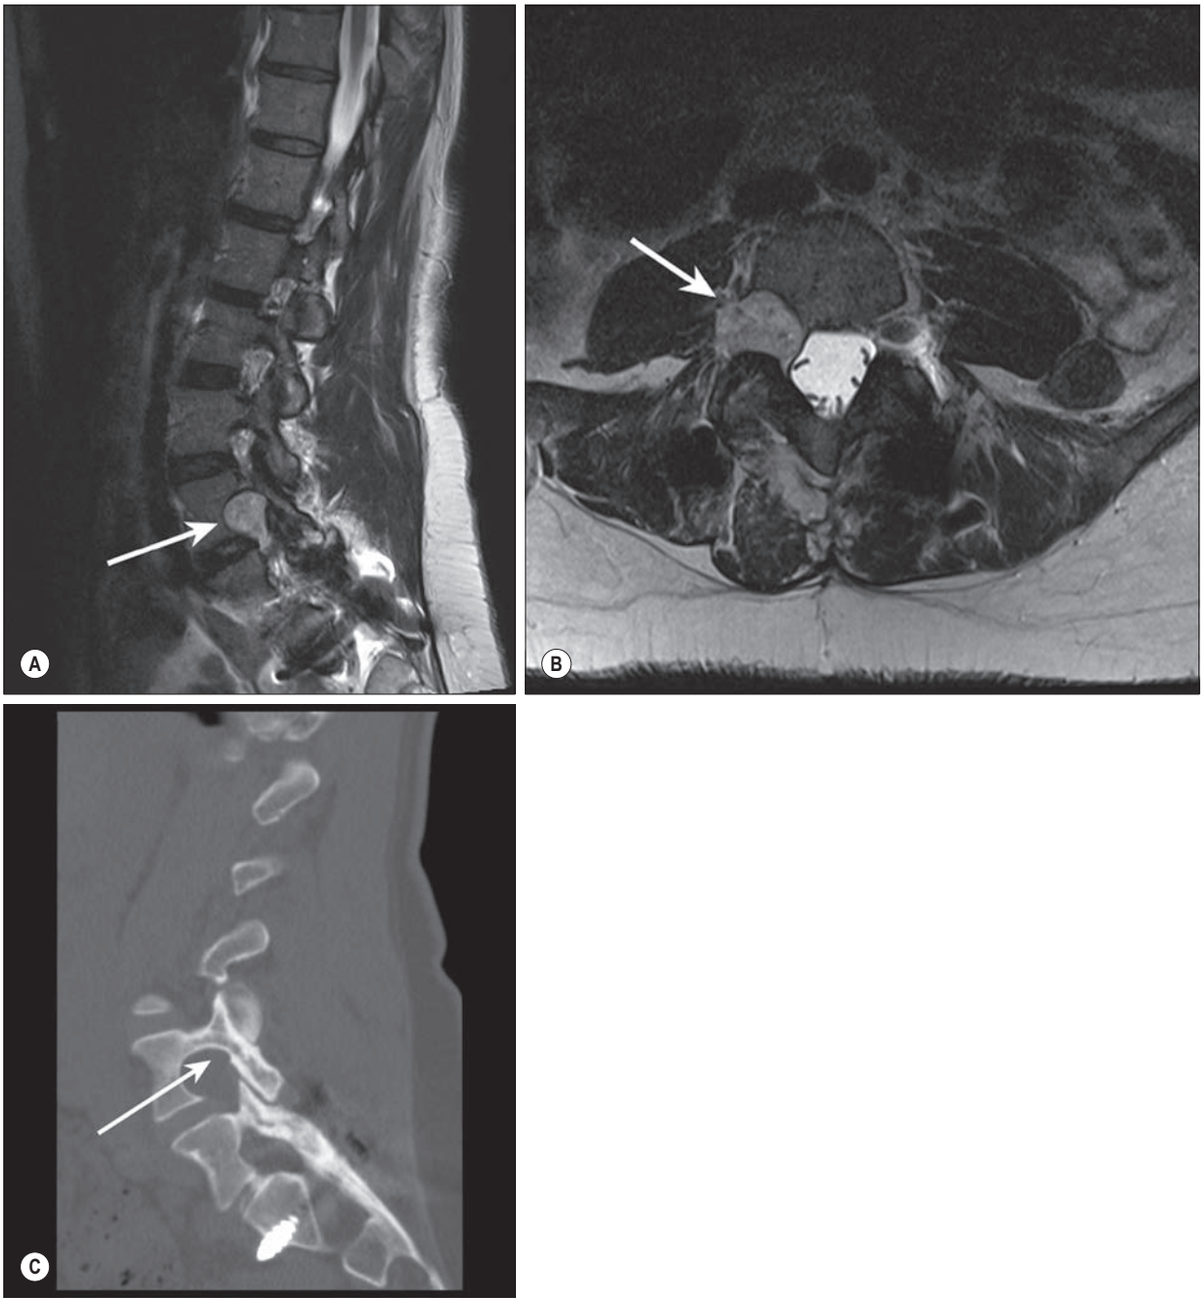

Fig. 47.16 A–B, MRI sagittal and axial images showing a right L4 nerve root schwannoma (arrows) in a 51-year-old female who presented with right foot numbness and weakness 11 years after L5–S1 spinal fusion procedure. **C**, CT scan shows an enlarged neuroforamen and erosion of the right L4 pedicle (arrow).

The anatomical basis for pain of spinal origin

In the diagnosis and description of pain of spinal origin, it is particularly important to distinguish between radicular pain and somatic referred pain.

Radicular pain is caused by disorders that affect a spinal nerve or its dorsal root ganglion. This type of pain characteristically radiates, along a narrow band, into the area of the limb (or trunk wall) that the spinal nerve supplies, and is typically (although not always) lancinating in quality, not unlike an electric shock.

Referred pain is pain felt in the distribution of a nerve that is not the nerve that innervates the source of pain, although typically these nerves are derived from the same spinal cord segment. Referred pain is felt deeply across a broad area, and is usually aching in quality; although it may radiate into a limb (or around the trunk wall), it is typically constant in location. Patients may find it hard to define the outer boundaries of this pain but they can clearly identify the centre of its distribution. Referred pain can be subdivided into somatic referred pain and visceral referred pain, according to its origin. As its name implies, visceral referred pain is caused by disorders in viscera; in some cases, the referral can be quite remote from the viscus, e.g. cardiac pain that radiates into the neck. Somatic referred pain is caused by disorders of muscular and skeletal structures. Examples include lumbar spinal pain referred to the gluteal region, thigh or leg; cervical spinal pain referred to the upper limb girdle; and cervical or thoracic spinal pain referred to the chest wall, where it may mimic cardiac pain. Often the source of somatic referred pain cannot be determined by clinical examination, and invasive tests are required to pinpoint its location.

Lesions of the conus and cauda equina

Lesions of the conus and cauda equina, e.g. tumours, cause bilateral deficit, often with pain in the back extending into the sacral segments and to the legs. Loss of bladder and erectile function can be early features (Fig. 47.17). There are lower motor neurone signs in the legs with fasciculation and muscle atrophy. Sensory loss usually involves the perineal or 'saddle area', as well as other lumbar and sacral dermatomes. There may be congenital abnormalities, e.g. spina bifida, lipomata or diastematomyelia, and the conus may extend below the lower border of L1, often with a tethered filum terminale (Fig. 47.18). Extramedullary lesions include prolapsed intervertebral discs. A midline (central) disc protrusion in the lumbar region may present with involvement of the sacral segments only.

Two distinct clinical syndromes, conus medullaris syndrome and cauda equina syndrome, have been described, the latter being much more common. Cauda equina syndrome typically presents in men who have a lumbar disc herniation in the setting of lumbar spinal stenosis, with symptoms of asymmetric saddle anaesthesia and asymmetric lower extremity weakness, and delayed presentation of atonic bladder and flaccid anal sphincter. Conus medullaris syndrome typically presents with symmetric saddle anaesthesia, symmetric motor deficit and earlier atonic bladder and sphincter dysfunction. The usual causes are intradural tumours or vascular lesions (Radcliff et al 2011).

Tethered cord syndrome may be associated with occult or non-occult spinal dysraphism. In its classic form, it refers to an unusually low conus medullaris (although in some 14–18% of cases the position of the conus is anatomically normal). There is some debate as to what constitutes an abnormally low conus, whether below the L1–2 disc space or below the lower border of the body of the L2 vertebra. Most commonly, tethered cord syndrome is associated with a short filum terminale more than 2 mm wide, but it also may be related to an intradural lipoma. Traction on the caudal cord and loss of filum terminale elasticity are thought to predispose to decreased blood flow in the cord, leading to symptoms (Filippidis et al 2010). The clinical presentation varies according to age. In children, the most common presentation includes foot deformities, neurological deficits, spinal deformity and various cutaneous findings such as a lumbar capillary angioma. In adults, the syndrome more commonly presents with perianal pain and leg weakness (see Fig. 47.18) (Pang and Wilberger 1982).

Fig. 47.17 Sagittal MR image showing a spinal ependymoma (arrow), a tumour arising from the filum terminale, which can be seen just below the conus medullaris. The patient presented with pain in the back radiating to the legs. At surgery to resect the ependymoma, it was found to be adherent to the filum terminale.

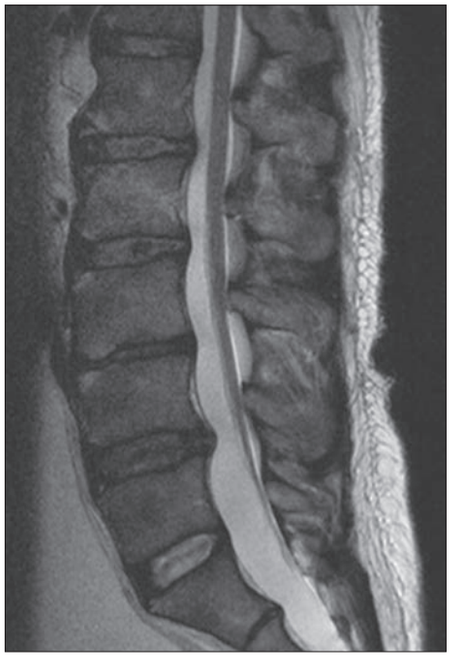

Fig. 47.18 Sagittal MR image showing a tethered filum terminale resulting in low-lying conus. The patient presented with back pain and perineal disturbances consistent with 'tethered cord syndrome'. The end of the conus medullaris was noted to be at the L5 level.

Access to cerebrospinal fluid

The safest approach to the cerebrospinal fluid (CSF) is to enter the lumbar cistern of the subarachnoid space in the midline, well below the level at which the spinal cord normally terminates (see above). The fine needle employed is unlikely to damage the mobile nerve roots of the cauda equina. This procedure is called lumbar puncture. It is also possible to access the CSF by midline puncture of the cerebellomedullary cistern (cisterna magna) (Ch. 25): this is cisternal puncture.

Lumbar puncture: adult

Lumbar puncture in the adult may be performed with the patient either sitting or lying on their side (lateral decubitus) on a firm, flat surface. In each position, the lumbar spine must be flexed as far as possible, in order to separate the vertebral spines maximally and expose the ligamentum flavum in the interlaminar window (Fig. 47.19). A line is then taken between the highest points of the iliac crests: this line almost always intersects the vertebral column at the vertebral body of L4 or the L4/L5 intervertebral disc level, but it may range from the L2/L3 interspinous space to the spinous process of L5 (see Fig.76.19). In most adults the plane intersects the vertebral column inferior to the termination of the spinal cord (see Fig. 46.81C). Localizing the supracristal plane via palpation may place it at a higher level in females and individuals with a higher body mass index (Kim et al 2007, Hale et al 2010). With the spines now identified, the skin is anaesthetized and a needle is inserted between the spines of L3 and L4 (or L4 and L5). Exact identification of the level by palpation is difficult (Broadbent et al 2000). The soft tissues that the needle will traverse should also be anaesthetized; care should be taken that the injection of an excessive amount of local anaesthetic does not compromise appreciation of the structures being traversed. These will be, in order: subcutaneous tissue, supraspinous ligament, interspinous ligament, ligamentum flavum, epidural space containing

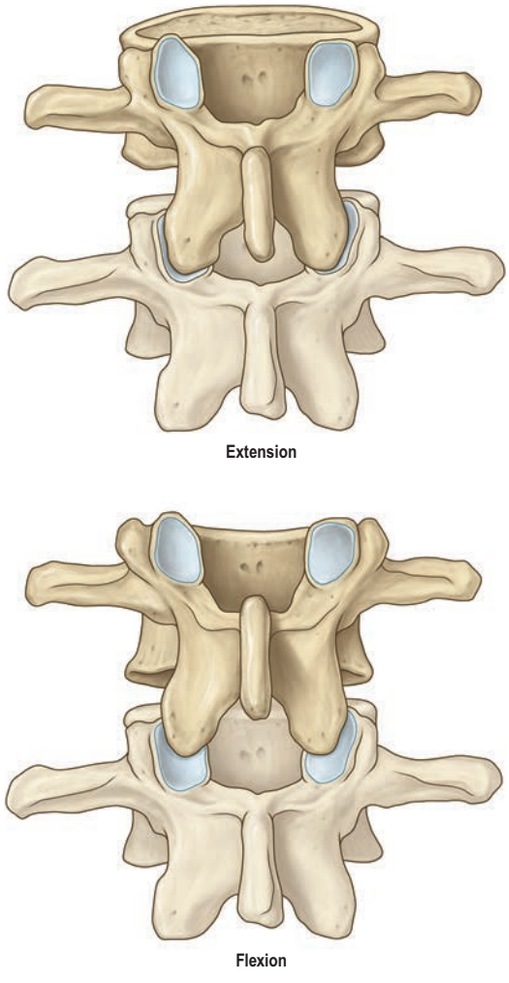

Fig. 47.19 The lumbar interlaminar window in extension and flexion.

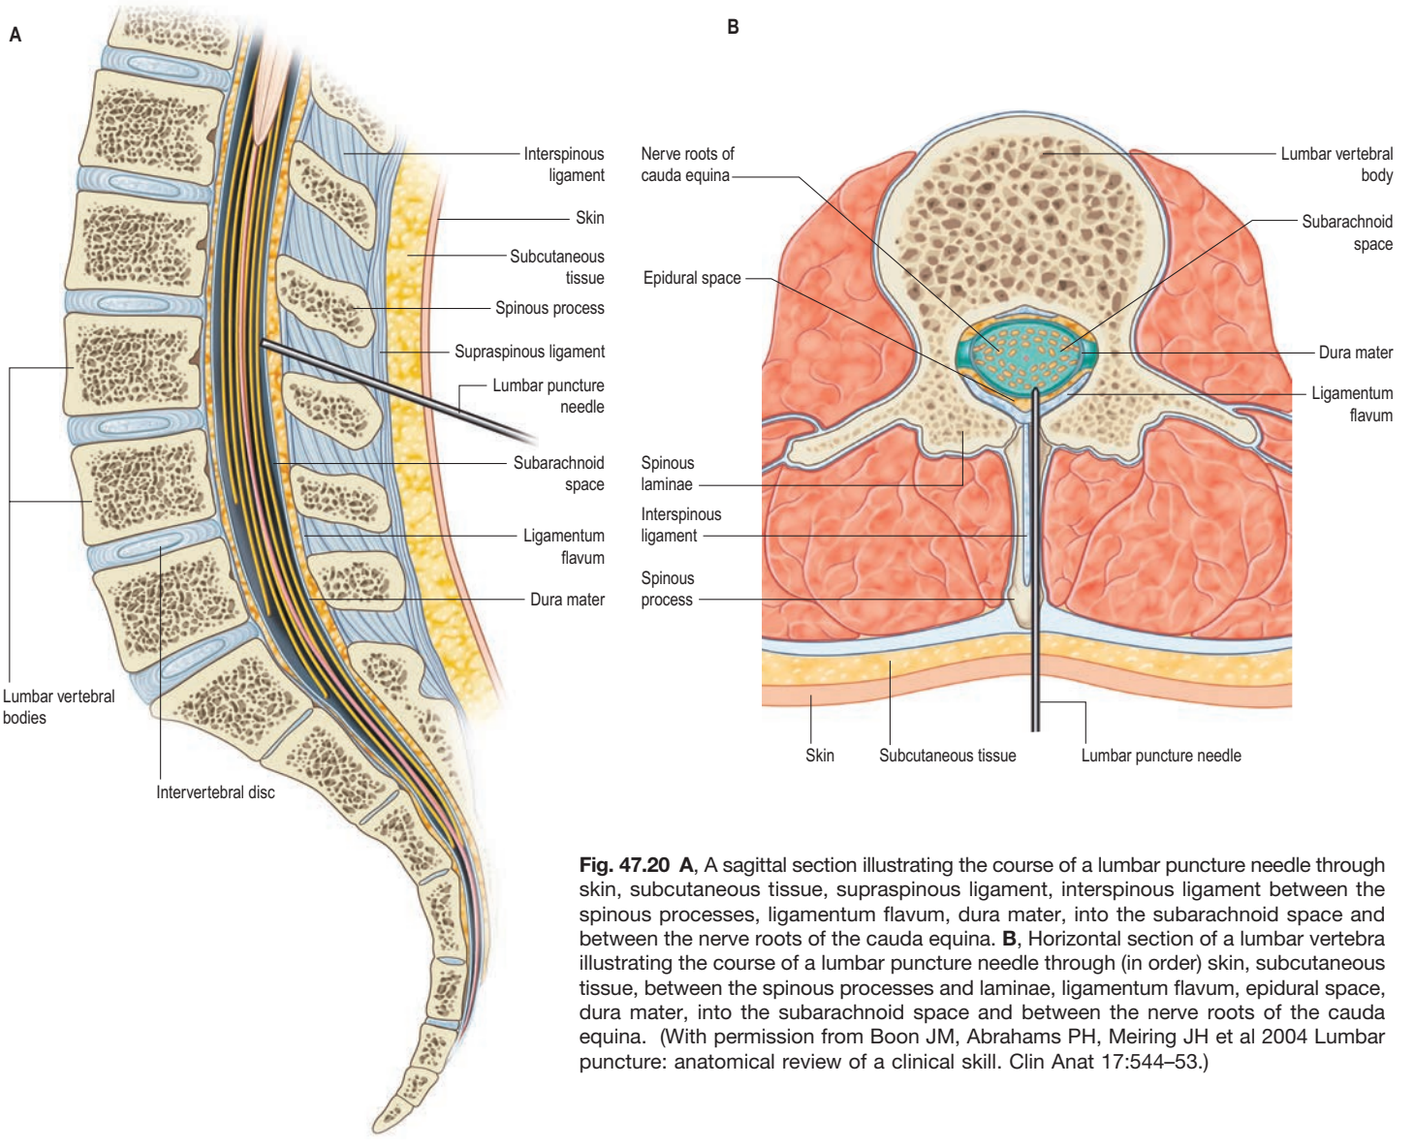

Fig. 47.20 **A**, A sagittal section illustrating the course of a lumbar puncture needle through skin, subcutaneous tissue, supraspinous ligament, interspinous ligament between the spinous processes, ligamentum flavum, dura mater, into the subarachnoid space and between the nerve roots of the cauda equina. **B**, Horizontal section of a lumbar vertebra illustrating the course of a lumbar puncture needle through (in order) skin, subcutaneous tissue, between the spinous processes and laminae, ligamentum flavum, epidural space, dura mater, into the subarachnoid space and between the nerve roots of the cauda equina. (With permission from Boon JM, Abrahams PH, Meiring JH et al 2004 Lumbar puncture: anatomical review of a clinical skill. Clin Anat 17:544–53.)

the internal vertebral venous plexus, dura, arachnoid, and finally, the subarachnoid space (Fig. 47.20). The lumbar puncture needle may then be inserted in the midline or just to one side, and angled in the horizontal and sagittal planes sufficiently to pierce the ligamentum flavum in or very near the midline. There is then a slight loss of resistance as the needle enters the epidural space; careful advancement will next pierce the dura and arachnoid to release CSF. For further details about the clinical anatomy of lumbar puncture, see Boon et al (2004).

Lumbar puncture: neonate and infant

The spinal cord usually terminates between the bodies of L1 and L3 lumbar vertebrae from postmenstrual week 28 onwards. In infants (postnatal month 2 to 3 years) and children (3–7 years), the conus medullaris lies most commonly at the lower third of the vertebral body of L1 (range, lower third of the vertebral body of T12 to the L2/L3 intervertebral disc) (Barson 1970, Barson and Sands 1977, Vettivel 1991, Malas et al 2001, Kesler et al 2007, Suresh et al 2013). The supracristal plane most commonly intersects the vertebral column at a slightly higher level in children (L3–L4) than in adults (L4–L4/L5); when located via palpation it may range in position from the L2/L3 to the L5/S1 interspinous space. These differences and the potential overlap between the level of the supracristal plane and the termination of the spinal cord must be borne in mind before undertaking lumbar puncture in the neonate and infant. Ultrasound guidance may be preferable (Baxter et al 2016). A lumbar puncture is performed by placing the infant in a position, either lying or sitting, that gives maximum convex curvature to the lumbar spine. A trocar needle is inserted into the back between the spinous processes of either L3 and L4 or L4 and L5 lumbar vertebrae and into the subarachnoid space below the level of the conus medullaris. The space between L3 and L4 is approximately level with the iliac crests and it is usual to insert the trocar needle into the intervertebral space immediately above or below the iliac crests. The distance from the skin to the subarachnoid space is approximately 1.4 cm in neonates; it increases progressively with age.

Cisternal puncture

In cisternal puncture, the cisterna magna (see Fig. 25.25) is entered by midline puncture through the posterior atlanto-occipital membrane. Further details of this difficult specialist technique are beyond the scope of this book.

Access to the epidural space

The epidural space lies between the spinal dura and the wall of the vertebral canal. It contains epidural fat and a venous plexus. Access to this space, usually in the lumbar region, is required for the administration of anaesthetic and analgesic drugs, and for endoscopy. The caudal route is used mainly for analgesic injections.

Thoracic and cervical epidurals

It is possible to access the epidural space at thoracic and cervical levels, but the specialist techniques required are beyond the scope of this book.

Lumbar epidural

For access to the lumbar epidural space, the approach is as for lumbar puncture. The intention in epidural injection is to avoid dural puncture, so the epidural space should be entered in the midline posteriorly, where the depth of the space is greatest. The skin/epidural distance has been assessed in children at the L3/L4 interspace; 1 mm/kg of body weight is considered to be a useful guideline for infants and children between the ages of 6 months and 10 years (Bösenberg and Gouws 1995). Techniques for entering the epidural space rely on the appreciation of loss of resistance to injection of saline (air is used by some) as the space is entered: saline cannot be injected into the dense ligamentum flavum, but can be injected into the loose tissues of the epidural space. As there is very little distance between the ligamentum flavum and the underlying dura, care must be taken not to continue advancing the needle once loss of resistance has occurred.

Caudal epidural

The route of access to the caudal epidural space is via the sacral hiatus. This means that the space is entered below the level of termination of the dural sac (the subarachnoid space and its contained CSF), which usually extends only to the level of the second sacral segment. Occasionally, the dural sac ends as high as the fifth lumbar vertebra, and very rarely it may extend to the third part of the sacrum, in which case it is occasionally possible to enter the subarachnoid space inadvertently during the course of a sacral nerve block.

With the patient in the lateral position or lying prone over a pelvic pillow, the sacral hiatus is identified by palpation of the sacral cornua (Fig. 47.21). These are felt at the upper end of the natal cleft approximately 5 cm above the tip of the coccyx. Alternatively, the sacral hiatus may be approximated by constructing an equilateral triangle based on a line joining the posterior superior iliac spines where the the inferior apex of the triangle overlies the hiatus (see Fig. 76.19). After local anaesthetic infiltration, a needle is introduced at 45° to the skin, in order to penetrate the posterior sacrococcygeal ligament and enter the sacral canal. The puncture of the ligament can usually be felt as the needle is advanced. Once the canal is entered, the hub of the needle is lowered so that the needle may be fed along the canal (Fig. 47.22). If the needle is angled too obliquely, it will strike bone, whereas if it is placed too superficially, it will lie outside the canal and any fluid injected can be felt subcutaneously.

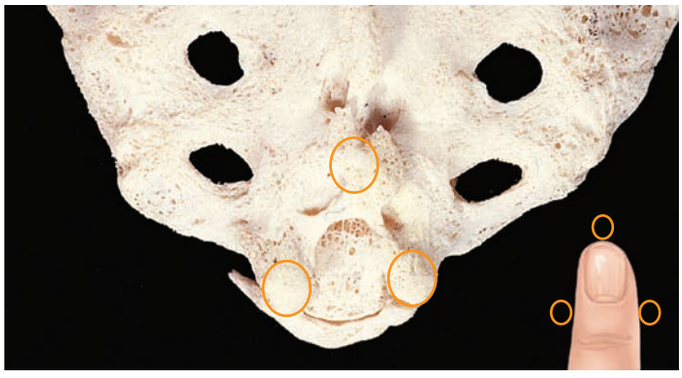

Fig. 47.21 Palpation of the sacral cornua for caudal epidural injection.

Medial branch block

Medial branch block is a clinical procedure that can be used in the diagnosis and treatment of facet-mediated low back pain. The medial branch of the dorsal ramus of each lumbar spinal nerve runs beneath the mammillo-accessory ligament in a groove at the root of the superior articular process of the adjacent facet joint. Each medial branch innervates not only the adjacent facet joint capsule but also the capsule of the facet joint located at the level immediately below it, which means that each facet joint has a dual innervation (Amrhein et al 2016). The L5 spinal nerve is unusual because its dorsal ramus does not have a medial branch; it lies in the groove between the sacral ala and the superior articular facet of S1 (Iannuccilli et al 2013). To achieve complete sensory blockade of a single lumbar facet joint, two separate injections are necessary (to block conduction in the medial branches of the spinal nerves exiting at the level of the joint and at the level immediately above) (Fig. 47.23).

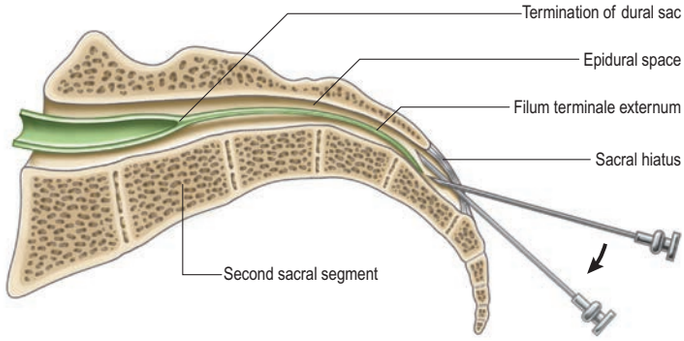

Fig. 47.22 Position of the needle in a caudal epidural injection.

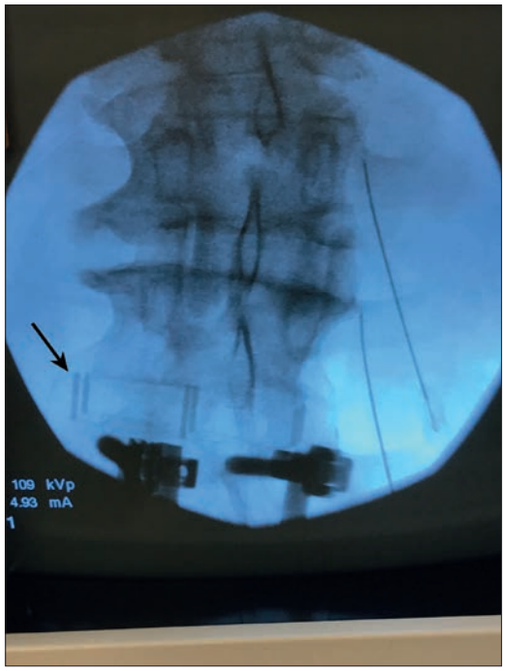

Fig. 47.23 Anteroposterior fluoroscopic image showing a right medial branch block of the L1 and L2 medial branches. The L2–L3 facet joint, which was suspected of being a pain generator after an attempted fusion from a lateral approach was felt to have resulted in nonunion, was rendered anaesthetic. An intervertebral cage is seen in the L3 disc space (arrow). (Image courtesy of Dr Avrom Gart.)

CHAPTER 48

Pectoral girdle and upper limb: overview and surface anatomy

The upper limb is, in mechanical terms, a series of powered, articulated segments which enable the hand to be positioned accurately in space so that it can sense and manipulate its surrounding environment. It is attached to the bony thorax at the sternoclavicular joint, and to the chest wall by a series of powerful flat muscles which stabilize the scapula, allowing it to act as a stable but mobile base on which the limb can function. An extensive range of movement is enabled by a number of factors. The glenohumeral joint is remarkably little constrained and the muscles that both stabilize and move it are powerful. Elbow flexion allows movements close to the trunk, such as eating and attention to personal hygiene, while extension achieves a wide arc of reach for daily activities. Pronation and supination markedly increase the functional capacity of the hand by rotating the forearm through nearly 180°.

In the soft tissues, the deep fascial planes and the synovial sheaths permit the excursion of muscles and tendons against each other and their adjacent structures. Condensations of fascia around the neurovascular bundles segregate them and enhance gliding.

The innervation of the upper limb is complex and rich. There is a particular concentration of specialized sensory organelles in the wrist and hand, not only in the skin but also in the deep afferent system from muscles, tendons and joints. The postganglionic sympathetic vasomotor and sudomotor nerves are especially dense in the palmar skin. The basis of stereognosis, the ability to recognize the qualities of objects and textures, is a combination of stimuli from skin, tendon, muscle and joints. Movement is vital; blindfolded patients cannot identify the nature of an object if it is simply placed on the finger, but recognize it immediately if allowed to create spatial and temporal patterns by feeling the object or material between moving fingers and thumb.

BONES AND JOINTS

The bones of the upper limb include the scapula, clavicle, humerus, radius and ulna (connected by the interosseous membrane along most of their length), the eight bones forming the carpus, five metacarpals and fourteen phalanges (Figs 48.1–48.2). There are two phalanges in the thumb and three in each finger.

The thoracoscapular joint is the platform for function of the upper limb: paralysis of either of the two great muscles, trapezius and serratus anterior, is crippling. The limb is directly attached to the axial skeleton by one bony articulation, the sternoclavicular joint. The glenohumeral joint is shallow and little constrained, whereas the acromioclavicular joint is a plane joint stabilized by strong ligaments. The range of movements provided by these joints and the muscles acting across them is enormous. Arthrodesis of the thoracoscapular joint for facioscapulohumeral dystrophy improves flexion and abduction of the glenohumeral joint, but protraction and retraction are lost. A correctly performed glenohumeral arthrodesis retains powerful adduction, protraction and retraction, but rotation and the limited elevation achieved is dependent on rotation of the scapula. The elbow includes a hinge between the humerus and ulna, and two pivot joints, between the humerus and radius, and between the proximal radius and ulna. This permits a range of about 150° of flexion and extension, and 180° of pronosupination in conjunction with the distal radio-ulnar joint. The wrist complex allows a range of flexion and extension of about 140°, supplemented by some 70° of adduction and abduction. The condylar metacarpophalangeal joint enables 120° of flexion and extension, about 40° of abduction and adduction, and some rotation. Pronation and supination are unique to the primate upper limb. The range of movement of the thumb ray, which rests on the 'saddle' carpometacarpal joint, the qualities of the long muscles and the thenar muscles acting on the ray and the skin of the web space, are unique to humans.

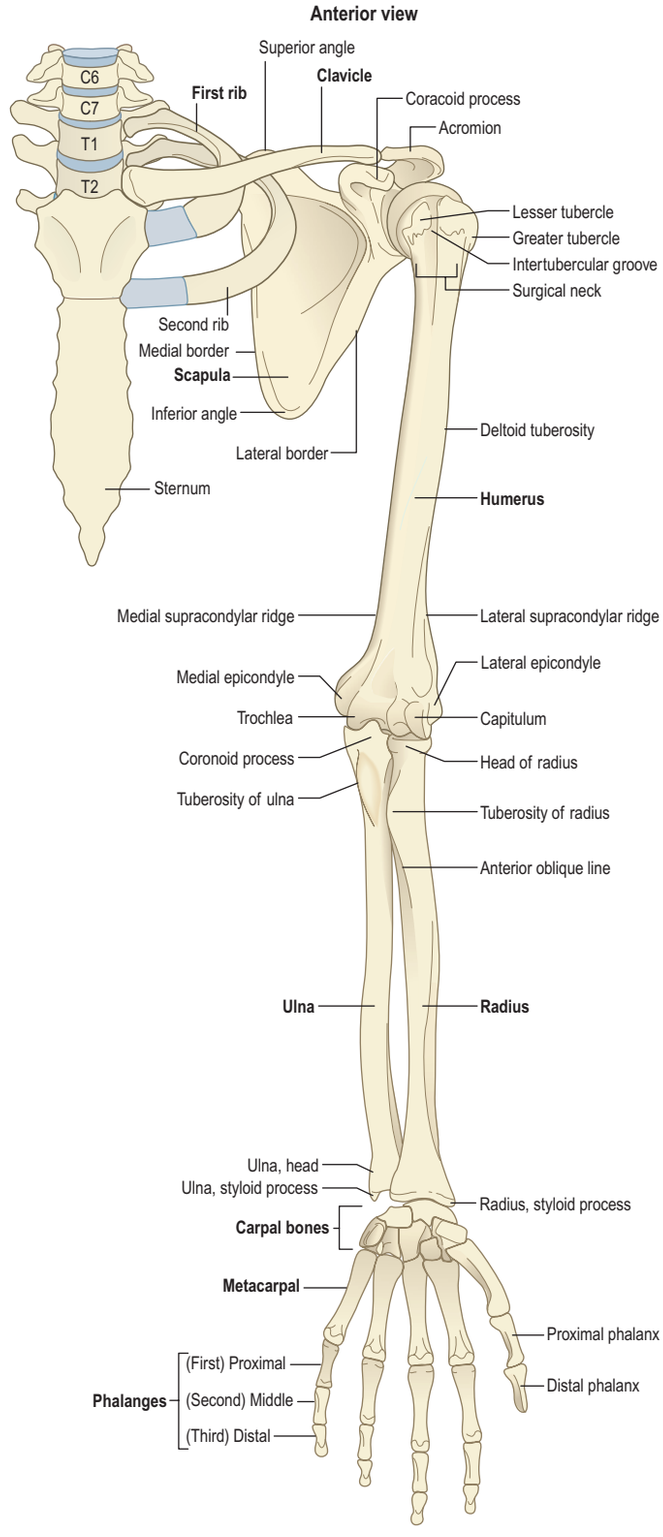

Fig. 48.1 The bones of the pectoral girdle and upper limb: anterior view.

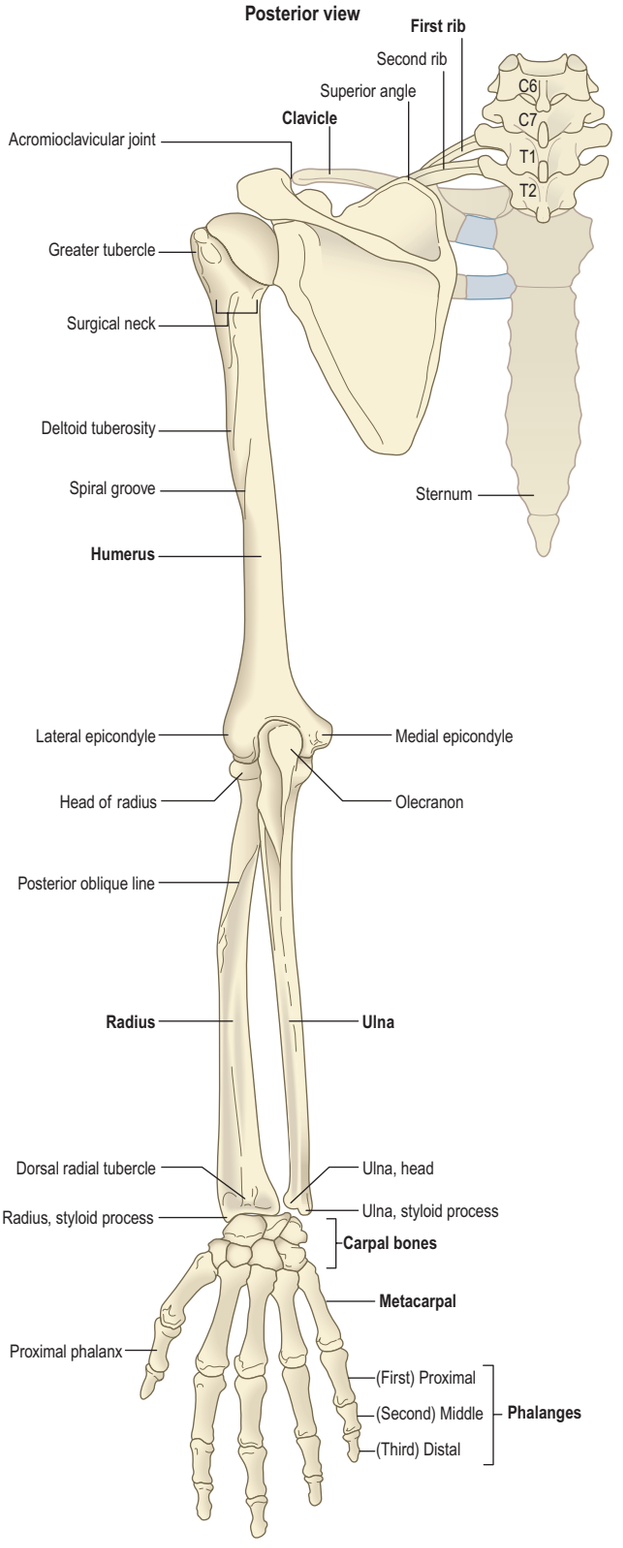

Fig. 48.2 The bones of the pectoral girdle and upper limb: posterior view.

SKIN AND FASCIA

The skin over the front of the neck and posterior triangle is mobile and is sustained by the underlying platysma. Large flaps may be raised safely when platysma is included with the skin. The postaxial skin of the posterior aspect of the neck, shoulder, arm and forearm is thicker and hairy, whereas the glabrous preaxial skin on the anterior surface of the arm and forearm is thinner and more mobile. The situation is reversed in the hand, where the thick palmar skin is firmly secured by a fibrous skeleton to the palmar aponeurosis, whereas the dorsal skin is thinner and more mobile, especially across the joints. The characteristic furrows or creases at the elbow, wrist and interphalangeal joints represent places of anchorage of the deep fascia. The hairy skin of the axilla is especially mobile, permitting the extensive range of movement at the glenohumeral joint; it is rich in sweat glands and their sympathetic nerves. The dense sympathetic innervation in the axilla, the hand and forearm is important in temperature homeostasis. The consequences of scarring from burns or other injury, or badly placed incisions, are severe, and nowhere more so than after a deep burn of the axilla.

The superficial fascia is generally thicker on the dorsal aspect of the neck, shoulder, arm and forearm. Measurement of its thickness in the arm provides a useful measure of obesity. It is an important gliding plane between the skin and the underlying deep fascia. Nerves and vessels are at risk of entrapment or even rupture where they perforate the deep fascia to ramify into the superficial fascia and skin.

The deep fascia, intermuscular septa and the interosseous membrane between the radius and ulna define discrete compartments that enable gliding of segregated structures against one another. The medial and lateral intermuscular septa of the arm and the interosseous membrane also provide wide areas for the attachment of muscles. The various fascial compartments are relevant to the spread of infection and tumour, and are especially important in ischaemia (compartment syndrome).

The prevertebral fascia (see Fig. 35.4A) envelops the phrenic nerve, scalene muscles, cervical ventral rami, cervical sympathetic trunk, and subclavian and vertebral arteries. It projects below the clavicle as the axillary sheath, enveloping the divisions and cords of the brachial plexus with the axillary artery, and continues into the arm as the brachial sheath, surrounding the brachial artery with its venae comitantes, the median nerve and the proximal part of the radial and ulnar nerves. The great muscles of the shoulder and axilla, deltoid, pectoralis major and latissimus dorsi are covered by deep fascia that winds around their deep surfaces to blend with the deep fascia of the arm. This latter is drawn upwards by suspensory condensations of fascia to form the cone-shaped axillary space, an arrangement that is obvious to the reader who traces the anterior surface of pectoralis major with a finger, then follows it round and deep, before thrusting the finger upwards as far at least as the lateral part of the second rib.

The deep fascia of the arm and forearm forms a sleeve that is attached to the medial and lateral intermuscular septa in the arm, to the periosteum of the medial and lateral epicondyles and olecranon at the elbow, and to the periosteum of the ulna and radius. Important condensations, such as the bicipital aponeurosis at the elbow, and the flexor and extensor retinacula at the wrist, are, in turn, subdivided by septa. Discrete compartments within the forearm separate the superficial muscles from the deep. The reader will note the relative mobility of the extensor muscles that traverse the elbow: brachioradialis and the radial extensor muscles of the wrist form the 'mobile wad' of Henry, overlying the deeper compartment containing the posterior interosseous nerve and vessels, supinator, the digital extensors, extensor carpi ulnaris and the long muscles acting on the thumb ray.

Three compartments are found in the anterior aspect of the forearm. The deep flexor compartment contains the anterior interosseous nerve and vessels, flexor pollicis longus, flexor digitorum profundus and pronator quadratus. The superficial compartment contains the radial artery, pronator teres, flexor carpi radialis, palmaris longus and flexor digitorum superficialis. The ulnar nerve and vessels pass in a separate sheath close to the ulna. The anterior deep fascia of the forearm continues into the hand as the palmar aponeurosis, from which a complex arrangement of septa forms the fibrous skeleton of the hand (see Fig. 51.12A). The range of excursion of the main nerves of the upper limb across fixed points such as the first rib, the distal humerus and the distal radius, is some 10–15 mm and is enabled by gliding between the adventitia and the epineurium. More movement occurs within the plane between the epineurium and perineurium, and also within the perineurium itself (Commentary 1.5).

Cutaneous innervation

Bundles of nerves enter the skin deep in the dermis and course towards the skin surface, giving off axons, nearly all unmyelinated, that innervate the associated end organs. The few myelinated axons terminate at hair follicles, Meissner corpuscles and Merkel complexes. The density of innervation of the epidermis is greatest in the proximal segment of the limb and there is little change between the twentieth and eightieth years.

MUSCLES

The sensorimotor cortex controls movements, not individual muscles. Reaching out to catch a flying object, such as a cricket ball, requires the coordination and integrated action of every muscle group in the upper

limb, and indeed beyond. This system of complex and refined muscle patterning depends on the integrity of the somatic afferent and efferent pathways in the central nervous system.

The muscles of the upper limb may be grouped according to their origin and the joints on which they act. Muscles arising from the axial skeleton to act on the scapula include trapezius, levator scapulae, the rhomboids and serratus anterior. Muscles arising from the axial skeleton to act on the glenohumeral joint include the sternal head of pectoralis major, pectoralis minor and latissimus dorsi. Muscles passing between the scapula and the proximal humerus control the glenohumeral joint. They include supra- and infraspinatus, subscapularis, teres major and minor, and coracobrachialis. Deltoid and the clavicular head of pectoralis major also belong here, even though they arise in part from the clavicle. The main muscles controlling the elbow include biceps brachii and triceps: the long heads of both muscles traverse the glenohumeral joint to insert on the scapula. The main muscles controlling supination and pronation are biceps brachii and supinator, pronator teres and pronator quadratus. The radiocarpal joint is controlled by extensors carpi radialis longus and brevis, extensor carpi ulnaris, flexors carpi ulnaris and radialis, and palmaris longus. The muscles acting on the thumb ray include the powerful flexor pollicis longus, the much weaker abductor pollicis longus, and extensors pollicis longus and brevis. These last three are essential for thumb function. The unopposed action of flexor pollicis longus leads to the virtually useless thumb in palm posture. The extension and flexion of the metacarpophalangeal and interphalangeal joints of the fingers rest on coordinated activity in extensor digitorum, flexors digitorum superficialis and profundus, and the interosseous and lumbrical muscles. Extensor digitorum alone extends the metacarpophalangeal joints; the long flexors alone flex the interphalangeal joints. The imbalance caused by paralysis of the small muscles leads to 'clawing' deformity (see Fig. 48.27). The small muscles of the hand may be considered as those controlling the thumb ray and web space; adductor pollicis lies deep to the first dorsal interosseous; abductor and flexor pollicis brevis and opponens pollicis are superficial and form the ball of the thumb. The interosseous muscles acting with the lumbricals flex, abduct and adduct the metacarpophalangeal joints and, in conjunction with the long flexor and extensor muscles, enable full extension of the proximal interphalangeal joints. Abductor and opponens digiti minimi and flexor digiti minimi brevis form the hypothenar eminence and act on the little finger.

Many muscles act on more than one joint, for example, the long heads of biceps and triceps flex and extend, respectively the glenohumeral joint as well as the elbow. In addition, biceps brachii is a powerful supinator of the forearm. Extensor carpi radialis longus not only extends the wrist, but also is a powerful abductor of that joint and a flexor of the elbow in pronation. Flexor carpi ulnaris is the most powerful muscle in the forearm; it contributes to elbow flexion, flexes and adducts the wrist, and is active in all sustained movements of the wrist.

Certain muscles are functionally segregated, e.g. the anterior part of deltoid is a powerful flexor of the glenohumeral joint, whereas the posterior part is the most powerful extensor of that joint.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The detailed regional descriptions of these systems in the upper limb are found in Chapters 49–51.

Arteries

The axial vessel is the subclavian artery, which arises from the brachiocephalic trunk on the right and directly from the arch of the aorta on the left (Fig. 48.3). The artery is described in three parts that are successively anteromedial, deep and lateral to scalenus anterior. The second and third parts are in close relation to the seventh and eighth cervical and first thoracic ventral rami, and to the middle and lower trunks of the brachial plexus. The subclavian artery becomes the axillary artery at the outer border of the first rib. The axillary artery is closely related to the divisions of the brachial plexus deep to the clavicle, and to the cords below it. It continues deep to pectoralis minor and becomes the brachial artery at the inferior margin of teres major.

The brachial artery is closely related to the median nerve; both move from the medial side of the arm to the anterior aspect of the elbow, lying medial to the tendon of biceps brachii and deep to the bicipital aponeurosis. The artery divides into the radial and ulnar arteries just distal to the elbow. The ulnar artery is consistently the larger of the two. The common interosseous artery arises close to its origin and subsequently divides into the anterior and posterior interosseous arteries. The anterior interosseous artery, accompanied by the anterior interosseous nerve, lies

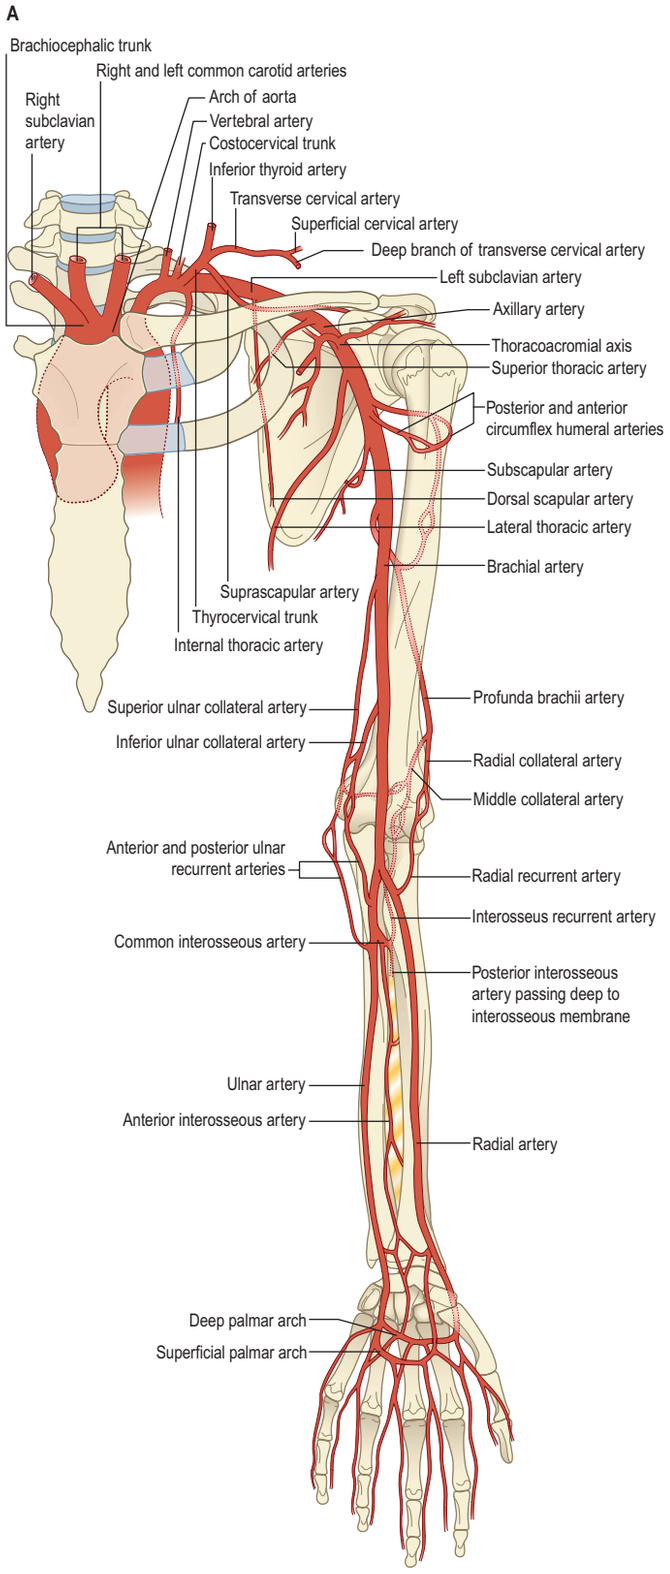

Fig. 48.3 A, Arteries of the upper limb. (B–E, *continued online*)

on the interosseous membrane in the deepest part of the deep flexor compartment. The posterior interosseous artery is separated from the membrane by the deep extensor muscles. The radial and ulnar arteries remain in the flexor compartment of the forearm, the ulnar artery moving towards the ulnar nerve in the proximal quarter of the forearm; it is usually the dominant vessel for the hand. At the wrist, the radial artery passes dorsally and crosses the scaphoid and trapezium.

Important branches from the main axial vessels form extensive anastomoses that provide a collateral circulation. For example, the collateral circulation formed by branches of the thyrocervical trunk with the circumflex humeral and subscapular arteries permits survival of the limb after occlusion of either the third part of the subclavian artery, or of the axillary artery deep to the clavicle and pectoralis minor. The

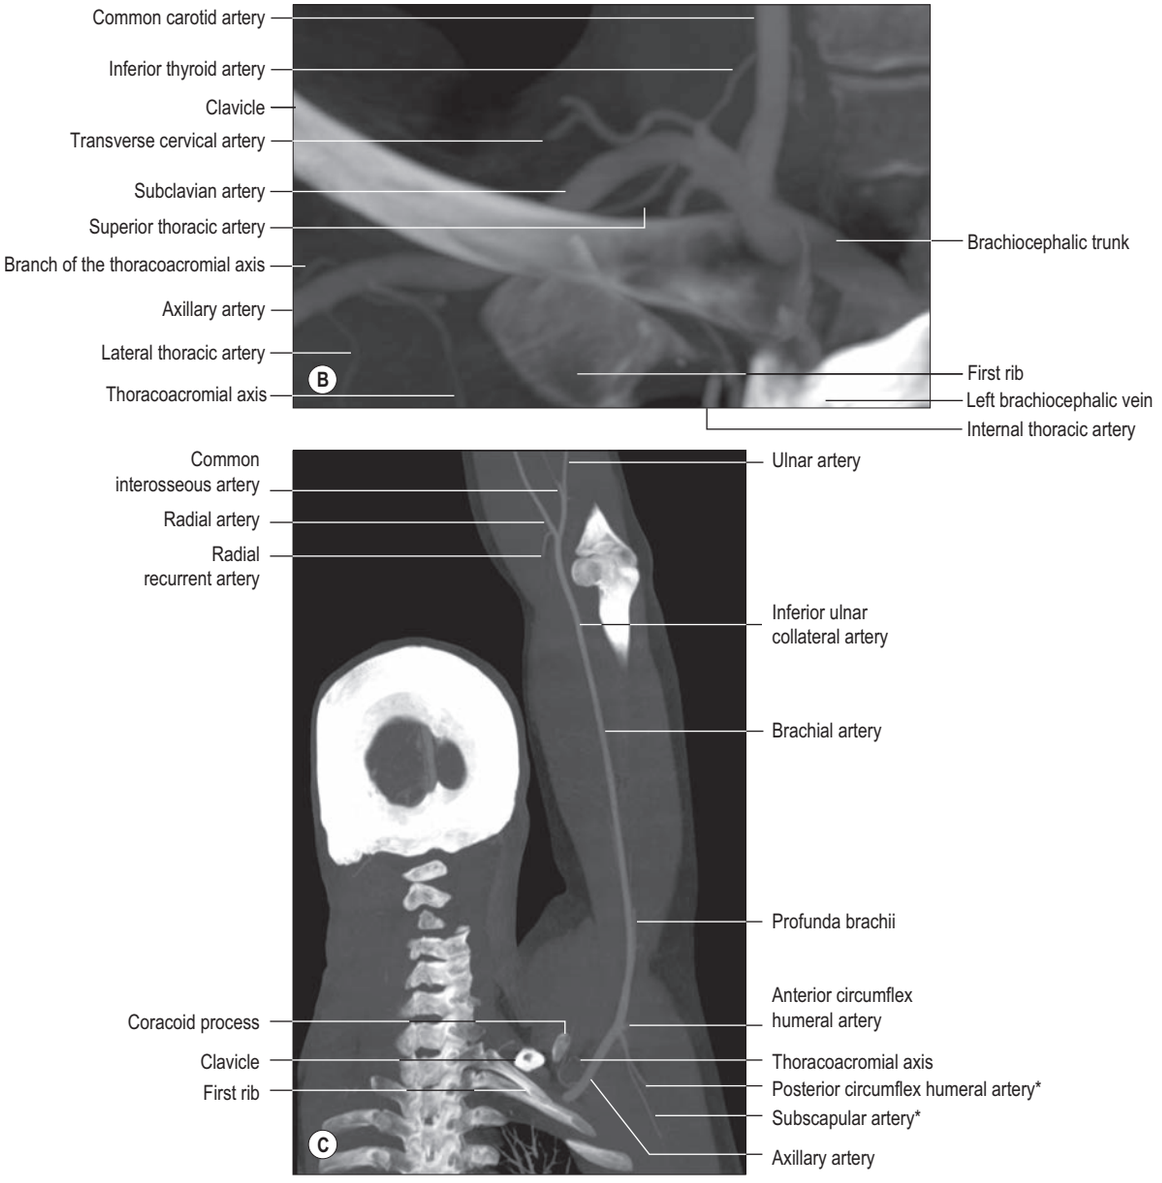

Fig. 48.3, cont'd B, Coronal oblique maximum intensity projection view of the right subclavian and axillary arteries and their branches from a CT carotid angiogram. Contrast medium was injected via the left arm and can be seen in the brachiocephalic vein. **C**, Coronal oblique maximum intensity projection from a CT angiogram of the left arm from the axillary artery to the arteries in the forearm. The whole arm is abducted above the head to reduce the effect of radiation beam attenuation that would occur if left by the side of the body, hence reducing noise and increasing image quality. *The posterior circumflex humeral and subscapular arteries arise from a common trunk.

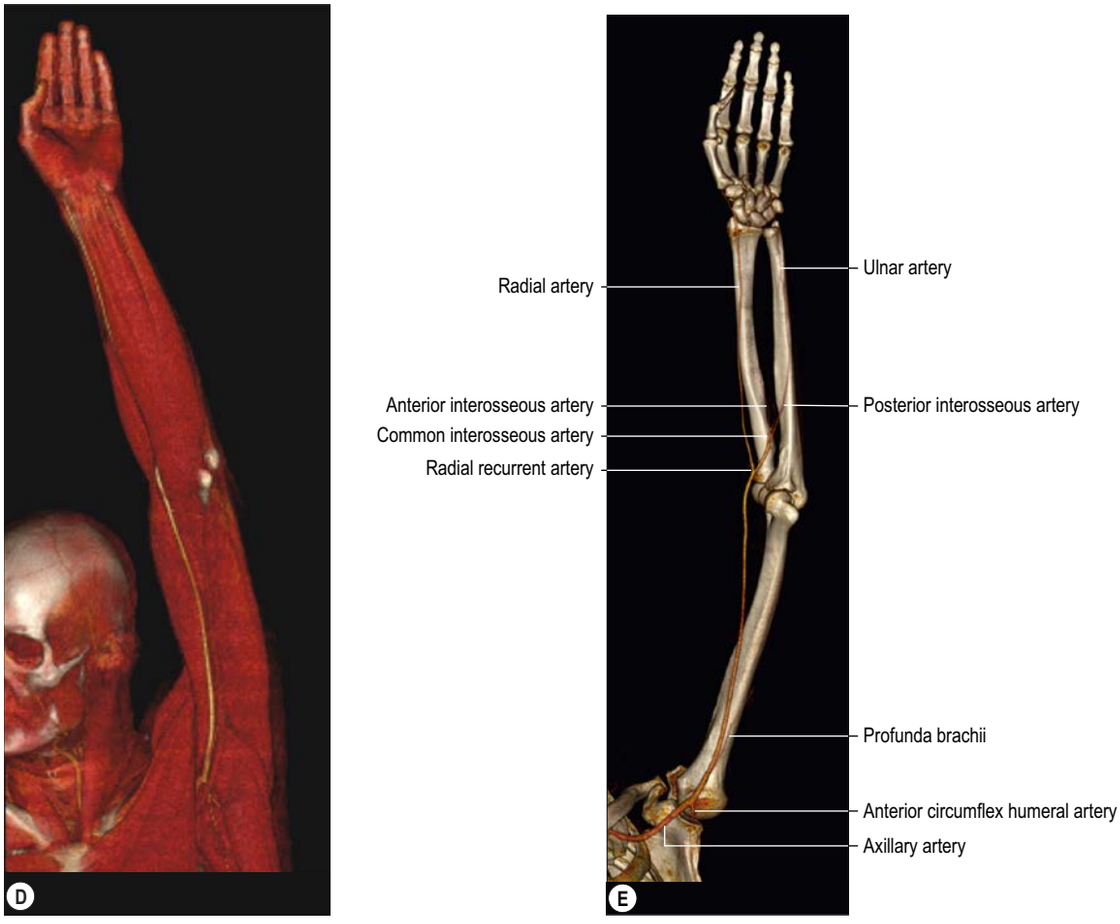

Fig. 48.3, cont'd D, **E**, A volume rendered CT angiogram of the left arm acquired with the arm abducted and prone.

profunda brachii is an important channel for the posterior muscles of the arm. It accompanies the radial nerve and contributes to the collateral circulation about the elbow with the ulnar collateral and recurrent vessels and the radial collateral and recurrent vessels. The anterior interosseous artery is effectively an end artery. A series of anastomoses between the radial and ulnar arteries, such as the transversely orientated palmar and dorsal arches and the superficial and deep palmar arches, maintain a rich blood supply to the wrist and hand. There are extensive interconnections between these arches and between the dorsal and palmar phalangeal arteries.

Pulses

The pulsation of the subclavian artery is palpable at the lateral margin of sternocleidomastoid and is easily blocked by digital pressure against the first rib. This simple maoeuvre has saved lives and limbs, and should be widely known and rehearsed because it is the best method for emergency control of bleeding from the deeply placed axillary artery. The method was used successfully for high amputation or disarticulation of the shoulder in the Napoleonic wars.

The brachial artery is palpable in the arm in the groove, or valley, between biceps brachii anteriorly and the medial head of triceps brachii posteriorly; it can be traced down to the anterior aspect of the elbow, where it moves towards the midline. The radial and ulnar pulses are palpable at the wrist, where the vessels emerge from under the cover of overlying muscles.

Veins

The upper limb is drained by superficial and deep groups of vessels.

The superficial group starts as an irregular dorsal arch on the back of the hand. The cephalic vein begins at the radial extremity of the arch, and ascends along the lateral aspect of the arm within the superficial fascia to enter the deltopectoral groove. It pierces the deep fascia above the superior margin of pectoralis minor and enters the axillary vein near the tip of the coracoid (Fig. 48.4). The basilic vein drains the ulnar end of the arch, passes along the medial aspect of the forearm, pierces the deep fascia at the elbow, and joins the venae comitantes of the brachial artery to form the axillary vein. The prominent median cubital vein links the cephalic and basilic veins on the flexor aspect of the elbow. It receives a number of tributaries from the flexor aspect of the forearm and gives off the deep median vein, which pierces the fascial roof of the antecubital fossa to join the venae comitantes of the brachial artery.

The deep group of veins drains the tissues beneath the deep fascia of the upper limb and is connected to the superficial system by perforating veins. The deep veins accompany the arteries, usually as venae comitantes, ultimately becoming the axillary, and subsequently the subclavian, vein.

The subclavian vein is the central continuation of the axillary vein. It starts at the outer border of the first rib, which it crosses. Initially deep to the clavicular head of pectoralis major and then to subclavius, which is a buffer between it and the overlying medial portion of the clavicle, the vein then runs deep to the insertion of sternocleidomastoid. Sometimes, only the superior margins of the vein rise above the medial end of the clavicle; sometimes, the entire vein does so. The phrenic nerve and the inferior part of scalenus anterior lie posteriorly. The subclavian vein joins the internal jugular vein to form the brachiocephalic vein at the medial border of scalenus anterior, behind the sternoclavicular joint (see Fig. 35.14). A pair of valves usually lies within 2 cm of this junction. The subclavian vein receives, as tributaries, the external jugular, dorsal scapular and, sometimes, the anterior jugular veins. The trifurcation of subclavian, external and internal jugular veins is demonstrable by a forced expiration (Valsalva) manœuvre, when the distended veins rise up above the sternoclavicular joint, filling the fossa above the jugular notch of the sternum (**Video 48.1**). Main lymphatic vessels join the subclavian veins at, or very close to, this junction with the internal jugular vein. The left subclavian vein receives the thoracic duct; the right receives the right lymphatic duct (see Fig. 35.16). There is a risk of air embolism after wounding of the subclavian, external or internal jugular veins.

Cutaneous blood supply

The blood supply of the skin of the upper limb is generally abundant (Fig. 48.5) and rather more robust than that in the lower limb. Proximally based flaps of skin caused by 'degloving' injury are more likely to survive; even a distally based flap of palmar skin may do so. The skin of the lower leg is notoriously sensitive to the effects of fracture because of rupture of the vessels perforating the deep fascia; this problem is less severe in the upper limb. Three interconnected pathways may be recognized in the

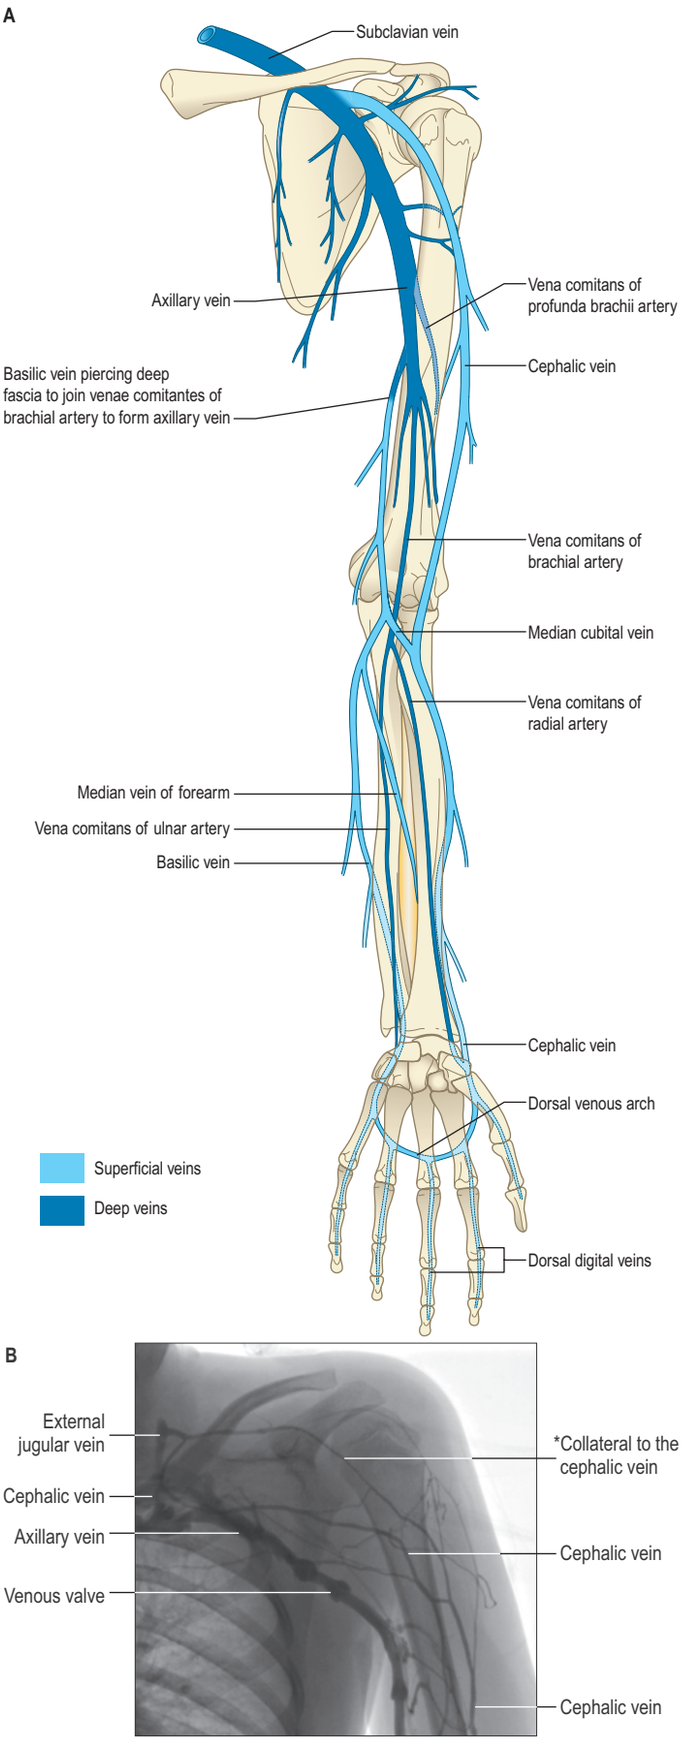

Fig. 48.4 A, The veins of the upper limb. **B**, Venogram of the left arm. There are multiple cephalic vein collaterals, one of which drains into the external jugular vein (*). (C, D, E, *continued online*)

Lymphatic drainage

Superficial tissues

The subcutaneous tissues of the limbs can be divided into five layers: skin (layer 1); subcutaneous fat (2); superficial fascia (3); loose areolar tissue (4) and deep fascia (5). Layer 2 can be subdivided into a superficial (2a) and deep layer (2c) by a thin transparent horizontal septum (2b) (Tourani et al 2014). The main superficial veins and the superficial nerves are found in layer 4 and the lymphatic collectors in layer 2c and layer 4.

Superficial lymphatic vessels begin in cutaneous plexuses. In the hand, the palmar plexus is denser than the dorsal plexus. Digital plexuses drain along the digital borders to their webs, where they join the distal palmar vessels, which pass back to the dorsal aspect of the hand. The proximal palm drains towards the carpus, medially by vessels that run along its ulnar border, and laterally to join vessels draining the thumb. Several vessels from the central palmar plexus form a trunk that winds round the second metacarpal bone to join the dorsal vessels that drain the index finger and thumb.

In the forearm and arm, superficial vessels run with the superficial veins. Collecting vessels from the hand pass into the forearm on all carpal aspects. Dorsal vessels, after running proximally in parallel, curve successively round the borders of the limb to join the ventral vessels. Anterior carpal vessels run through the forearm parallel with the median vein of the forearm to the cubital region, then follow the medial border of biceps brachii before piercing the deep fascia at the anterior axillary fold to end in the lateral axillary lymph nodes.

Lymph vessels that lie laterally in the forearm receive vessels that curve round the lateral border from the dorsal aspect of the limb. They follow the cephalic vein to the level of the tendon of deltoid, where most incline medially to reach the lateral axillary nodes; a few continue with the vein and drain into the infraclavicular nodes. Vessels lying medially in the forearm are joined by vessels that curve round the medial border of the limb and follow the basilic vein. Proximal to the elbow, some end in supratrochlear lymph nodes whose efferents, together with the medial vessels that have bypassed them, pierce the deep fascia with the basilic vein and end in the lateral axillary nodes or deep lymphatic vessels.

Collecting vessels from the deltoid region pass round the anterior and posterior axillary folds to end in the axillary nodes. The scapular skin drains either to subscapular axillary nodes or by channels that follow the transverse cervical vessels to the inferior deep cervical nodes.

Vessels pass from the deep axial vessels through muscle, perforate the deep fascia and supply the overlying skin. The latissimus dorsi myocutaneous flap based on the thoracodorsal vessels was an important development in plastic and reconstructive surgery, not only for the replacement of lost skin or reconstruction of the breast, but also in the evolution of the free-functioning muscle transfer.

The fasciocutaneous system rests on branches that arise from deep vessels and pass along the intermuscular septa to perforate the deep fascia and ramify over its surface: extensive areas of skin are supplied in this way. The development of fasciocutaneous flaps, either as pedicle flaps or free grafts, has been a revolutionary advance in the treatment of severe wounds. Not only is it possible to replace large areas of lost skin, but also to improve the tissue bed that supports the main nerves thereby enhancing regeneration and relieving neuropathic pain.

The direct cutaneous supply is exemplified in the palmar skin, where branches from the underlying digital vessels pass directly into the overlying skin.

Deeper tissues

Deep lymph vessels follow the main neurovascular bundles (radial, ulnar, interosseous and brachial) to the lateral axillary nodes. They are less numerous than the superficial vessels and communicate with them at intervals. A few lymph nodes occur along the vessels. Scapular muscles drain mainly to the subscapular axillary nodes, and pectoral muscles drain mainly to the pectoral, central and apical nodes.

Efferent vessels from the deep cervical nodes form the jugular trunk. The right jugular trunk drains the right upper limb, the right half of the thorax and the right head and neck, and enters the right thoracic duct or directly enters the right subclavian vein close to its junction with the internal jugular. The left jugular trunk usually enters the thoracic duct, but it may directly enter either the subclavian or internal jugular vein (see Figs 35.16, 49.45).

ACUTE ISCHAEMIA AND COMPARTMENT SYNDROMES IN THE UPPER LIMB

Available with the *Gray's Anatomy* e-book

INNERVATION

The accessory nerve, dorsal scapular nerve, long thoracic nerve (nerve to serratus anterior), suprascapular nerve and nerve to subclavius all innervate muscles that act on the scapulothoracic 'joint' and will therefore be summarized here.

Accessory nerve

The integrity of the accessory nerve is fundamental to thoracoscapular function and essential for scapulohumeral rhythm (Camp and Birch 2011). The intraspinal and intracranial course of the accessory nerve and of the segment of the nerve that lies in the anterior triangle of the neck are described in Chapter 35.

The accessory nerve passes either deep to or through sternocleidomastoid, to enter the posterior triangle in a consistent and important relation to the ascending nerves of the cervical plexus. The great auricular nerve is the key to exposure of the accessory nerve, which emerges, usually as one trunk, 5–10 mm cephalad to the point where the great auricular nerve winds around sternocleidomastoid, and moves from a plane posterior to the muscle to one that is anterior. The general relations of the posterior triangle vary with individual physique, but this relation between the two nerves is reliably consistent. The nerve now runs across the fatty areolar tissue at the apex of the posterior triangle, in close relation to the superior superficial cervical lymph nodes deep to platysma. It is separated from the underlying levator scapulae by this areolar tissue, and then, more deeply, by the prevertebral fascia. One slender branch passes to the upper fibres of trapezius either deep to sternocleidomastoid or just beyond it. The nerve pierces the fascia covering the deep surface of trapezius close to the anterior border of the muscle and then runs caudally about 2 cm from that border. The nerve passes down in a characteristic sinuous fashion, accompanied by slender vessels to the deep, inner face of trapezius. A branch from the cervical plexus (third and fourth cervical ventral rami) joins the nerve just above the clavicle. Intraoperative stimulation of this branch rarely evokes a muscular response; it probably conveys afferent fibres from the middle and lower parts of trapezius. The nerve now turns medially, continuing in parallel to the spine of the scapula about 4 cm above it. At the medial end of the spine, the nerve turns caudally again, passing down parallel to the medial border of the scapula. It divides into terminal muscular branches about 7 cm distal to the scapular spine. Although sternocleidomastoid, and the middle and the lower portions of trapezius, may be partially supplied by branches from the cervical plexus, the upper part of trapezius is innervated solely by the accessory nerve.

Dorsal scapular nerve

The dorsal scapular nerve arises above the clavicle from the proximal segment of the the fifth cervical ventral ramus. It passes posteriorly, piercing scalenus medius, to run down in the plane between levator scapulae and serratus posterior superior and the posterior scalene muscles. It continues along the anterior border of the rhomboid muscles about 1.5 cm medial to the vertebral border of the scapula and is closely related to the dorsal scapular artery. The dorsal scapular nerve innervates the rhomboid muscles and, together with branches from the third and fourth cervical ventral rami, it supplies levator scapulae.

Long thoracic nerve (nerve to serratus anterior)

The long thoracic nerve is formed by branches that arise above the clavicle from the proximal segments of the fifth, sixth and seventh cervical ventral rami. It innervates serratus anterior, a muscle that is essential for the function of the thoracoscapular joint. The muscular branches from the rami join deep to scalenus medius, and the trunk passes down posterolateral to the muscle, on the floor of the posterior triangle deep to the suprascapular nerve. The branches from the fifth and sixth cervical ventral rami are the largest. The nerve follows a sinuous course deep to the investing fascia covering the anterior faces of the digitations of serratus anterior. It is accompanied here by a branch of the thoracodorsal artery, and inclines posterolaterally towards the mid-axillary line.

Suprascapular nerve

The suprascapular nerve, from the fifth and sixth cervical ventral rami, is usually the first branch of the upper trunk, but frequently arises directly from the fifth cervical ventral ramus. It gives motor branches to supraspinatus and infraspinatus and articular branches to the glenohumeral and acromioclavicular joints

Nerve to subclavius

The slender nerve to subclavius, from the fifth and sixth cervical ventral rami, springs from the upper trunk and passes anteriorly. It descends anterior to the plexus and the subclavian artery and passes above the subclavian vein to supply subclavius.

Brachial plexus

The muscles, joints and skin of the upper limb are innervated by the fifth, sixth, seventh and eighth cervical ventral rami and nearly all of the first thoracic ventral ramus, collectively forming the brachial plexus (Figs 48.6–48.7). A branch from the fourth to the fifth cervical ventral ramus which contributes to the innervation of the glenohumeral and elbow flexor muscles is seen occasionally at operation. A muscular contribution from the second thoracic ventral ramus is rare. The rami enter the posterior triangle of the neck between scalenus anterior and medius. Rami from the seventh and eight cervical ventral rami are the largest (C8 contains about 30,000 myelinated axons) and those from the fifth cervical and the first thoracic ventral rami are the smallest (between 15,000 and 20,000 myelinated axons). An adult brachial plexus contains between 120,000 and 150,000 myelinated axons, of which 25% innervate the shoulder girdle and glenohumeral joint. The proportion of motor fibres is greatest in the fifth and eighth cervical

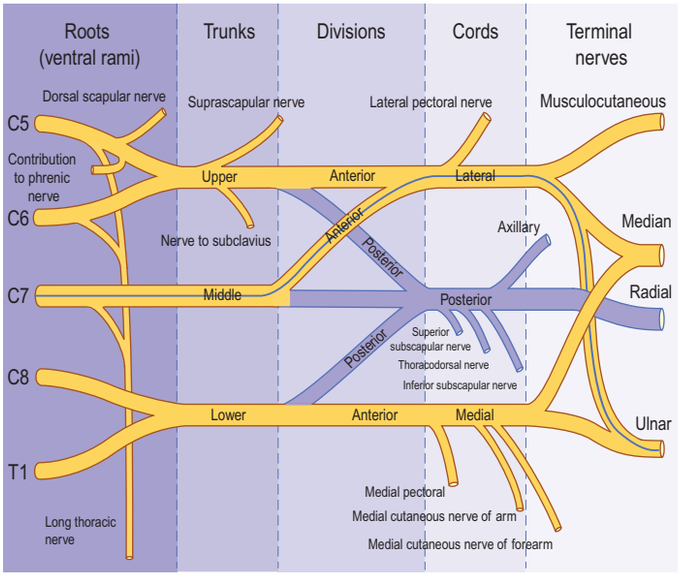

Fig. 48.6 A schematic plan of the brachial plexus. (Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Common examples of the classical compartment syndrome in the upper limb occur in the flexor and extensor compartments of the forearm. Although nerve conduction is lost before muscle contractility, ischaemia is more likely to produce infarction of muscle than necrosis of nerve. Decompression of a nerve embedded within muscle that has become fibrosed by ischaemia usually leads to relief of pain and considerable improvement in sensation and sympathetic function, even when delayed for some months.

Anoxia occurs either because of cessation of flow through a main axial artery or as a result of increasing pressure within an osseofascial compartment caused by bleeding, infusion of fluid or sepsis. It destroys the integrity of the cell membrane and capillary endothelium, which means that the homeostatic balance between the intravascular, extracellular and intracellular spaces is lost. Tissue death is imminent.

The increased permeability of the vascular endothelium leads to an increase in intracompartmental pressure by exudation, which collapses the low-pressure lymphatic and venous systems. The final event is the closure or obstruction of perfusing arterioles to muscles and the extrinsic supply to nerves, when tissue or extravascular pressure exceeds the cortical closing pressure of those vessels. The vicious circle is complete. The fluid entering the compartment cannot get out and continues to leak into the compartment until the pressure is so high that inflow is blocked. Increasing intracompartmental pressure occurs when the collateral circulation is inadequate after occlusion of the main artery or after restoration of flow through that vessel, unless the compartments have been decompressed adequately by fasciotomy. The vascular anastomoses about the joints of the upper limb provide a richer collateral circulation than those found in the lower limb. In a study of nearly 2500 World War II battle casualties, at a time when ligation of damaged arteries was common, ligation of the popliteal artery led to amputation in 346 of 502 limbs. By contrast, the incidence of amputation after ligation was about one-quarter for the subclavian artery, one-third for the axillary artery and more than one-half when the brachial artery was ligated proximal to the profunda brachii artery. These figures are certainly lower in the less contaminated injuries of civilian life, but some degree of post-ischaemic fibrosis is almost inevitable after failure to repair these vessels. The principles of arterial repair include urgent restoration of flow by repair of the artery and restoration of tissue perfusion by decompression. Temporary intraluminal shunts are invaluable, as they buy time and permit adequate stabilization of the skeleton. Application of these principles in current conflicts ensures a remarkably high rate of limb survival and a remarkably low incidence of post-ischaemic fibrosis.

Flow through the brachial artery in adults and in children has been measured by high-resolution ultrasonography. Flow was calculated by the Laplace equation: BF (blood flow) = $[\pi \times (D/2)]^2 \times$ FV (flow velocity). The mean diameter of the brachial artery in children aged between 4 and 5 years is 2.7 mm, which provides a resting flow of about 200 ml per minute. The significance of the diameter of the vessel is emphasized by Poiseuille's law. This is the physical law describing the volume of flow (Φ) of an incompressible uniform viscous liquid, where R is the internal radius of the tube, P the pressure difference between the two ends, η the dynamic fluid viscosity and L the total length of the tube.

$$\Phi = \frac{\pi R^4}{8\eta} \frac{[\Delta P]}{L}$$

The diameter of the superior ulnar collateral artery at the elbow in a 5-year-old child is, at most, 1 mm. This calibre provides flow of about 20 ml per minute, assuming that the pressure gradient is the same as that in the brachial artery itself. These facts must be borne in mind by any clinician inclined to the view that cessation of flow through the brachial artery is a matter of little consequence. The collateral channels take hours or days to develop and may be compromised by the original injury or during operation. The radial and ulnar nerves are often entrapped or compressed in fracture dislocations at the elbow, blocking flow through the ulnar and radial collateral systems that accompany these nerves.

The presence of peripheral pulses does not indicate adequate perfusion of the deep intracompartmental tissues, neither does the perfusion of skin or the nail bed when pulses are absent. The cardinal symptom of ischaemic anoxia is severe pain and the cardinal sign is loss of nerve conduction. This can be confirmed during exposure of limb nerves with an inflated tourniquet cuff in position proximally. For about 20 minutes, stimulation of the nerve evokes a brisk muscular response as a consequence of transmission through the neuromuscular junction. This response diminishes and disappears after about 30 minutes, although conduction within the nerve itself can still be detected for up to another 20 minutes. However, direct stimulation of the muscle provokes a twitch that can be elicited for up to several hours. Indeed, it is the loss of this direct response that signifies impending death of the muscle, and with it, death of the limb. The earliest nerve fibres to suffer are the largest, i.e. those conveying vibration and proprioception sense.

Ischaemia and acute compression within neurovascular fascial compartments

Sleeves of fascia surround main nerves and main vessels in some regions, an arrangement that predisposes nerves to injury from ischaemia or compression, or both. The seventh and eighth cervical and first thoracic ventral rami are enclosed in semi-rigid space after they enter the posterior triangle of the neck. This is bounded, posteriorly, by the dorsal part of the first rib, the transverse processes of the cervical vertebrae and by the fascia of levator scapulae. The nerves are embraced by scalenus anterior and scalenus medius, both of which are invested in an unyielding fascia. This is one envelope of the prevertebral fascia that also serves to bind the phrenic nerve down to the anterior face of scalenus anterior. The prevertebral fascia is particularly well developed in front of the vertebral column and also at the base of the posterior triangle, where it envelops the seventh and eighth cervical and first thoracic ventral rami, the phrenic nerve, the cervical sympathetic chain, and the subclavian and vertebral arteries. Infusion of relatively large volumes of fluid, from 10 to 20 ml, deep to the prevertebral fascia for the purpose of inducing regional block may cause tamponade of the radicular vessels that enter the spinal canal and contribute to the anterior spinal artery. Wilbourn (2005) has described the medial brachial fascial compartment, which extends from the axilla to the elbow and is bounded by the tough medial intramuscular septum and the axillary sheath. Bleeding into this compartment is responsible for the majority of infraclavicular plexopathies that follow regional block, and for many of the neurological lesions that result from closed or even open injuries in this region. The anterior interosseous nerve and its accompanying artery may be damaged by compression because of swelling in the deepest part of the flexor compartment of the forearm. The ulnar nerve, accompanied by the ulnar artery, lies in a discrete fascial compartment in the distal two-thirds of the forearm.

Bleeding into the axillary fascia (the medial antebrachial compartment) causes a characteristic, progressive lesion. There is, almost always, pain accompanied by dysaesthesiae; loss of sensation soon follows and then, over the next 2–3 hours, paralysis ensues. Wilbourn's comment bears repeating: Distal pulses are normal as they are with most compartment syndromes because the elevated pressure, although sufficient to collapse the vasa nervorum, is far below mean arterial pressure. Ultrasound, MR and CT may reveal the vascular lesion, but, considering the very brief time available for surgical decompression before irreversible nerve damage occurs, obtaining these is rarely justified.

In one series of 16 patients (Stenning et al 2005), there was, in all cases, an injury to the axillary artery or one of its offsets, caused by dislocation of the shoulder or fracture of the proximal humerus. The diagnosis of continuing bleeding into the axillary sheath was made by the delayed onset of nerve palsy or the deepening of the lesion whilst under observation. A favourable outcome was seen in 87 nerve palsies, where urgent repair of the artery and decompression of the axillary sheath were performed. However, delay in diagnosis and treatment may lead to permanent loss of function.

Case report

After a fracture/dislocation of the shoulder in a 59-year-old man, the patient's complaints of pain and the signs of a deepening nerve lesion were not appreciated for several days. Angiography showed bleeding from the subscapular artery. Two unsuccessful attempts were made to occlude this by embolization. The patient was reviewed at six weeks in right heart failure; haemoglobin was 4.9 g/litre (49 g/dl). He was in great pain and there was a total and deep plexopathy. MRI scan showed an enormous haematoma occupying the axilla and the arm, and suggested continuing bleeding. Treatment was simple: the axillary artery was exposed and controlled above pectoralis minor and the brachial artery exposed and controlled in the arm. More than 4 litres of altered blood were removed from the sac. The defect in the axillary artery was, at most, 2 mm in diameter and it was closed by direct suture. The pain was relieved and there was gradual recovery of the nerves, but the small muscles of the hand never recovered.

ventral rami; the sensory contribution is greatest in the seventh cervical ventral ramus. A complex interchange of branches, before the main nerves of the upper limb are formed, produces the trunks, divisions and cords of the brachial plexus.

Blood supply The blood supply to the brachial plexus is derived from vessels which arise from the subclavian and vertebral arteries. Important branches pass from the vertebral artery to the fifth and sixth cervical ventral rami and the more proximal cervical nerves. Branches from the costocervical trunk provide a rich supply to the eighth cervical and first thoracic ventral rami. Extensive contributions come from the suprascapular and superficial cervical arteries that arise from the thyrocervical trunk. In at least one-third of cases, the superficial cervical and dorsal scapular arteries arise from the thyrocervical trunk as the transverse cervical artery. In clinical terms, the arteries arising from the thyrocervical trunk have become the lifeline to the upper limb and must be preserved during operations in cases when the ruptured subclavian artery has not been repaired. The dorsal scapular artery may arise from the third part of the subclavian artery to pass between the upper and middle trunks of the brachial plexus.

Trunks of the brachial plexus

The upper trunk is formed by the fifth and sixth cervical ventral rami, where these nerves emerge from deep to scalenus anterior. The middle trunk is the continuation of the seventh cervical ventral ramus. The lower trunk is formed by the eighth cervical and first thoracic ventral rami, and passes over the anterosuperior surface of the first rib. The first thoracic ventral ramus takes an upward course across the deep face of the neck of the first rib behind the pleura and the vertebral and subclavian arteries towards the lower trunk. The formation of the trunks is fairly consistent; they lie in front of one another rather than side by side, with the subclavian artery passing anteromedially. The phrenic nerve crosses the fifth cervical ventral ramus to pass anteromedially on the surface of scalenus anterior. The upper trunk, its divisions and the suprascapular nerve can all be palpated in the supraclavicular fossa in a subject of normal physique. The examining finger identifies first the subclavian pulse and then the nerves, whilst rolling the fingertip laterally (see Video 48.1).

Divisions of the brachial plexus

The trunks divide into anterior and posterior divisions. The upper trunk divides 2–3 cm above the clavicle, and the divisions of the middle and lower trunk are formed deep to the clavicle. The posterior divisions of the upper and middle trunks are consistently larger than their anterior divisions. The posterior division of the lower trunk is consistently smaller than the anterior division and is absent in about 10% of cases.

Cords of the brachial plexus

The cords are formed by the confluence of divisions: the lateral cord from the anterior divisions of the upper and middle trunks; the posterior cord by all three posterior divisions; and the medial cord by the anterior division of the lower trunk and, sometimes, by a branch from the anterior division of the middle trunks. The divisions of the trunks and the formation of the cords represent an important anatomical and functional differentiation. The posterior divisions and posterior cord innervate postaxial (extensor) musculature; the anterior divisions and the lateral and medial cords innervate preaxial (flexor) musculature.

The formation and relations of the three cords are variable and, indeed, their designations somewhat misleading. Immediately inferior to the clavicle, the posterior cord is lateral, the medial cord is posterior, and the lateral cord is anterior, in relation to the axillary artery; the cords assume their appropriate relations about the axillary artery deep to pectoralis minor. There is considerable variation in this arrangement; most commonly, the axillary artery lies anterior to the three cords and the median nerve.

The branches of the posterior cord, the largest of the three trunks, are consistent. In sequence, they are the upper subscapular, thoracodorsal, lower subscapular, axillary and radial nerves. The branches of the medial cord are usually predictable; the medial pectoral nerve and medial cutaneous nerve of the forearm are succeeded by the division into the medial root of the median nerve and the ulnar nerve. The ulnar nerve may arise as two or three branches. The greatest variation in formation of trunk nerves is found within the lateral cord. Occasionally, the musculocutaneous nerve arises more distally than usual, either directly from the lateral cord as two or three branches or even from the median nerve itself. Sometimes, the highest of these branches enters coracobrachialis no more than 2 or 3 cm below the coracoid process. The lateral root of the median nerve may arise as two or three branches, and in some cases, it appears as a branch of the musculocutaneous nerve.

Terminal branches of the brachial plexus

Axillary (circumflex) nerve

The axillary nerve (fifth and sixth cervical ventral rami) (Fig. 48.8) runs freely in loose fatty tissue in the axilla before turning around subscapularis to pass almost horizontally through the quadrilateral tunnel, where it is accompanied by the posterior circumflex humeral vessels (see Fig. 49.33). It innervates teres minor and deltoid, and the skin overlying deltoid on the lateral aspect of the shoulder.

Radial nerve

The radial nerve (fifth, sixth, seventh and eighth cervical and first thoracic ventral rami) is the terminal branch of the posterior cord (Fig. 48.9). It is the largest nerve in the upper limb and the most commonly damaged. Between its origin at the level of the base of the coracoid and its entrance into the spiral groove, where it is accompanied by the profunda brachii artery, the radial nerve is supplied by fewer arteries than elsewhere along its course. The first 8–10 cm of the nerve may not have a nutrient artery and will, therefore, be relatively avascular if the nerve is transected at its origin. The nerve lies closest to the bone where it pierces the lateral intermuscular septum to pass through a short tunnel bounded by bone and unyielding fascia. The nerve is tethered here, a common level of rupture, entrapment or compression.

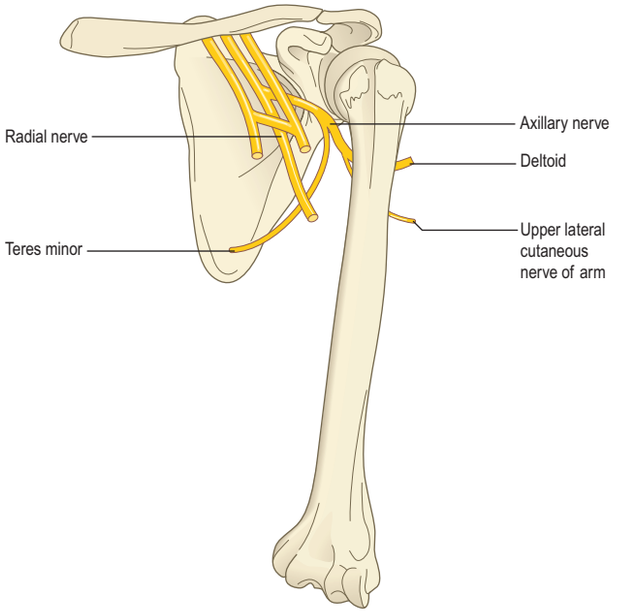

Fig. 48.8 Motor and sensory branches of the axillary nerve. (With permission from O'Brien M, Aids to the Examination of the Peripheral Nervous System, 5th ed. Saunders, Elsevier. Copyright 2010.)

The nerve to the medial head of triceps arises in the axilla and accompanies the main nerve as it passes through the intermuscular septum. The nerve(s) to the lateral head of triceps arise(s) within the spiral groove; that to the lateral head just before the radial nerve re-enters the anterior compartment. Two cutaneous nerves, the lower lateral cutaneous nerve of the arm and the posterior cutaneous nerve of the forearm, pass away from the main nerve in the final part of the spiral groove and course along the anterior face of the lateral head of triceps to perforate the deep fascia about four fingers'-breadths above the lateral epicondyle. They innervate the skin of the lower lateral arm and the posterior aspect of the forearm. The nerve to brachioradialis is formed about three fingers'-breadths proximal to the lateral epicondyle; the nerve to extensor carpi radialis longus about one finger's-breadth more distal; and that to extensor carpi radialis brevis about one finger's-breadth above the epicondyle. These branches spring from the main nerve as it runs in the valley between brachialis anteriorly and brachioradialis posteriorly, where the nerve may be palpated. At the level of the tip of the lateral epicondyle, the radial nerve divides into the posterior interosseous and superficial radial nerves. Another branch to extensor carpi radialis brevis is usually given off here. The superficial radial nerve innervates the skin over the dorsum of the radial half of the ring, middle and index fingers, and that of the thumb as far as the distal interphalangeal joint. It often provides important sensation on the skin of the thumb web space and the skin on the adjacent sides of the thumb and index.

Median nerve

The median nerve is formed by the union of the lateral root from the lateral cord (sixth and seventh cervical ventral rami), and the medial root from the medial cord (eighth cervical and first thoracic ventral rami), which meet anterior to the third part of the axillary artery (Fig. 48.10). Fibres in the lateral root innervate the palmar skin of the thumb, index and most of the middle finger, pronator teres, flexor carpi radialis and some of flexor digitorum superficialis (Fig. 48.11). The lateral root conveys most of the sympathetic fibres to the median distribution in the hand. The medial root carries fibres to the skin of the medial side of the middle and the lateral side of the ring finger, and also fibres to palmaris longus, flexor digitorum superficialis and the lateral part of flexor digitorum profundus, flexor pollicis longus, pronator quadratus and the median innervated muscles within the hand.

The first branch of the median nerve, to pronator teres, arises 2–3 cm above the medial epicondyle. A second branch, or leash of

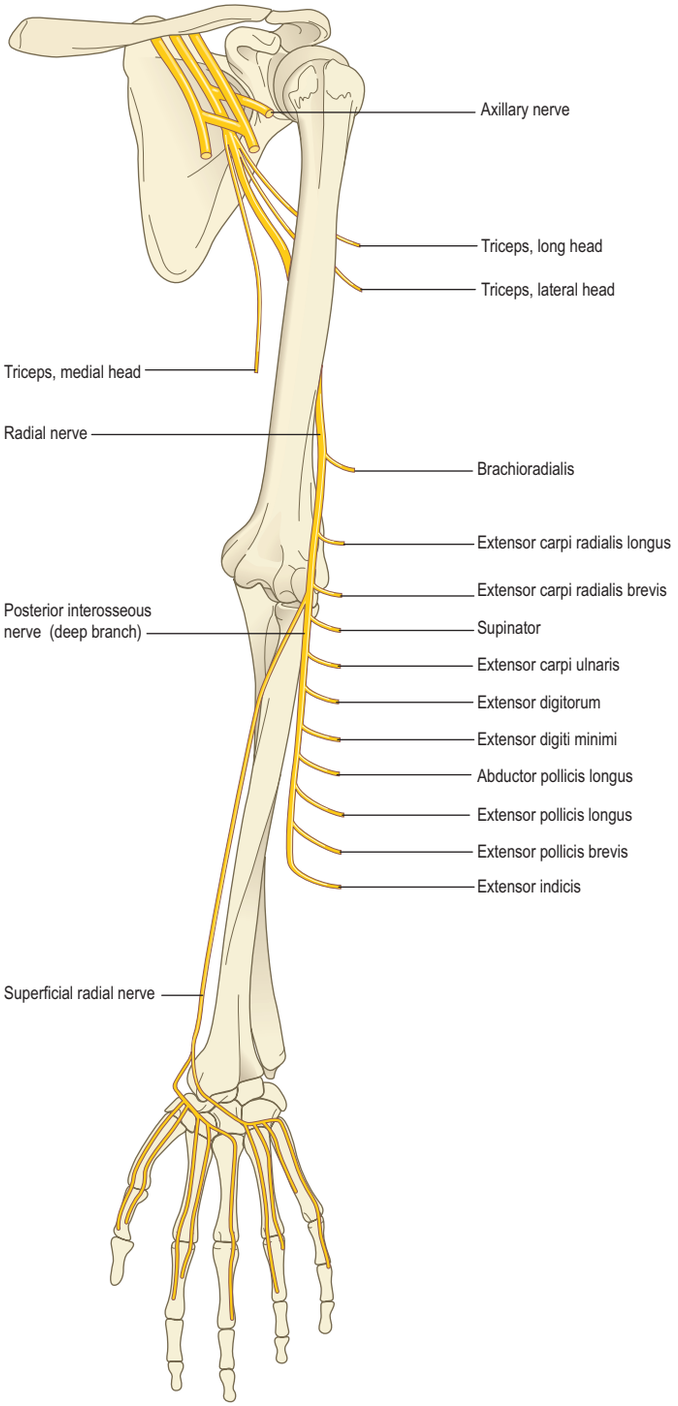

Fig. 48.9 Motor and sensory branches of the radial nerve. Variation exists in the cutaneous innervation of the dorsal aspects of the digits. Here, the radial nerve is shown to supply all five digits; the skin of the dorsum of the ring and little fingers is frequently innervated by the dorsal branch of the ulnar nerve. (With permission from O'Brien M, Aids to the Examination of the Peripheral Nervous System, 5th ed. Saunders, Elsevier. Copyright 2010.)

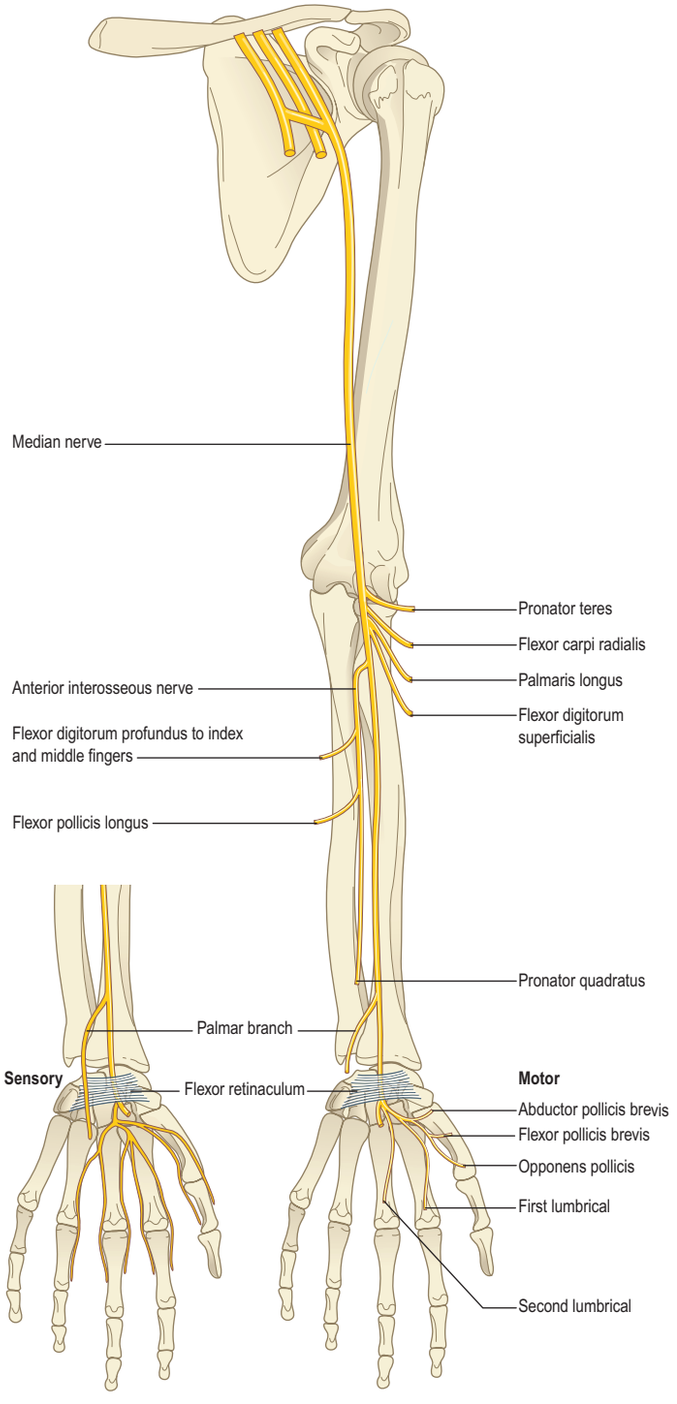

Fig. 48.10 Motor and sensory branches of the median nerve. Flexor pollicis brevis may be supplied by both median and ulnar nerves. (With permission from O'Brien M, Aids to the Examination of the Peripheral Nervous System, 5th ed. Saunders, Elsevier. Copyright 2010.)

branches, arises at the level of the tip of the medial epicondyle and innervates palmaris longus, flexor carpi radialis and flexor digitorum superficialis. Just proximal to the tendinous arcade of flexor digitorum superficialis, the median nerve gives off the anterior interosseous nerve. Accompanied by the anterior interosseous vessels, this large branch dives deeply to pass down along the interosseous membrane and supplies flexor pollicis longus, the radial half of flexor digitorum profundus and pronator quadratus. There is no cutaneous distribution. The main nerve continues in the plane between the superficial and deep digital flexors, supplying two or three branches to the former. The palmar cutaneous nerve arises about 3 cm proximal to the proximal wrist crease (when there are two creases), and passes lateral to the main nerve and superficial to the flexor retinaculum to innervate the skin of the proximal palm. The median nerve passes deep to the flexor retinaculum, into the carpal tunnel, to enter the palm. The nerve to the thenar muscles arises within, or just distal to, the tunnel, usually on the lateral side of the main nerve. The palmar digital nerves are formed within the palm of the hand.

The nerve is palpable along its course in the arm, where it is covered by deep fascia and skin, after emerging from deep to coracobrachialis. It is palpable on the flexor aspect of the elbow, deep to the bicipital aponeurosis, and is accompanied by the brachial artery in this segment of the limb. The median nerve is palpable at the wrist where it emerges from behind the superficial flexor tendons, just lateral to palmaris longus.

Ulnar nerve

The ulnar nerve (seventh and eighth cervical and first thoracic ventral rami) is the continuation of the medial cord (Fig. 48.12). It inclines posteromedially to perforate the medial intermuscular septum about 10 cm proximal to the medial epicondyle and passes through a fibrous

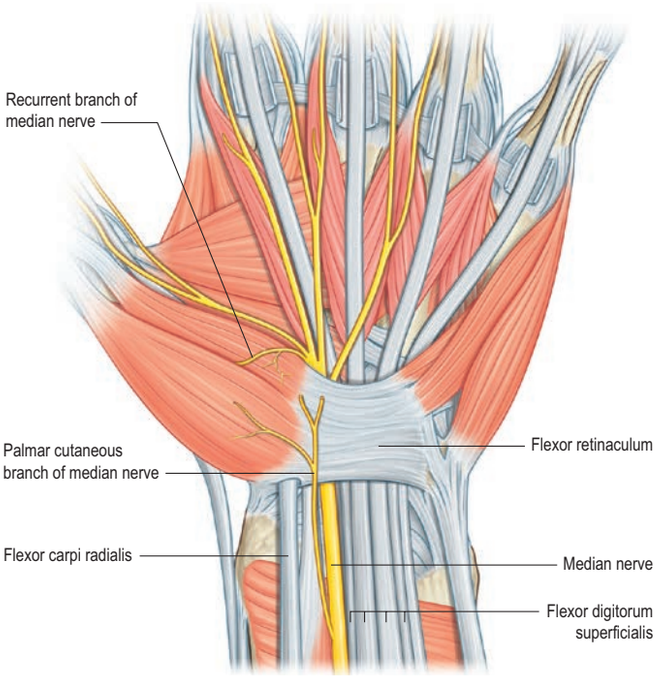

Fig. 48.11 The normal course of the median nerve and the palmar cutaneous nerve at the wrist. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

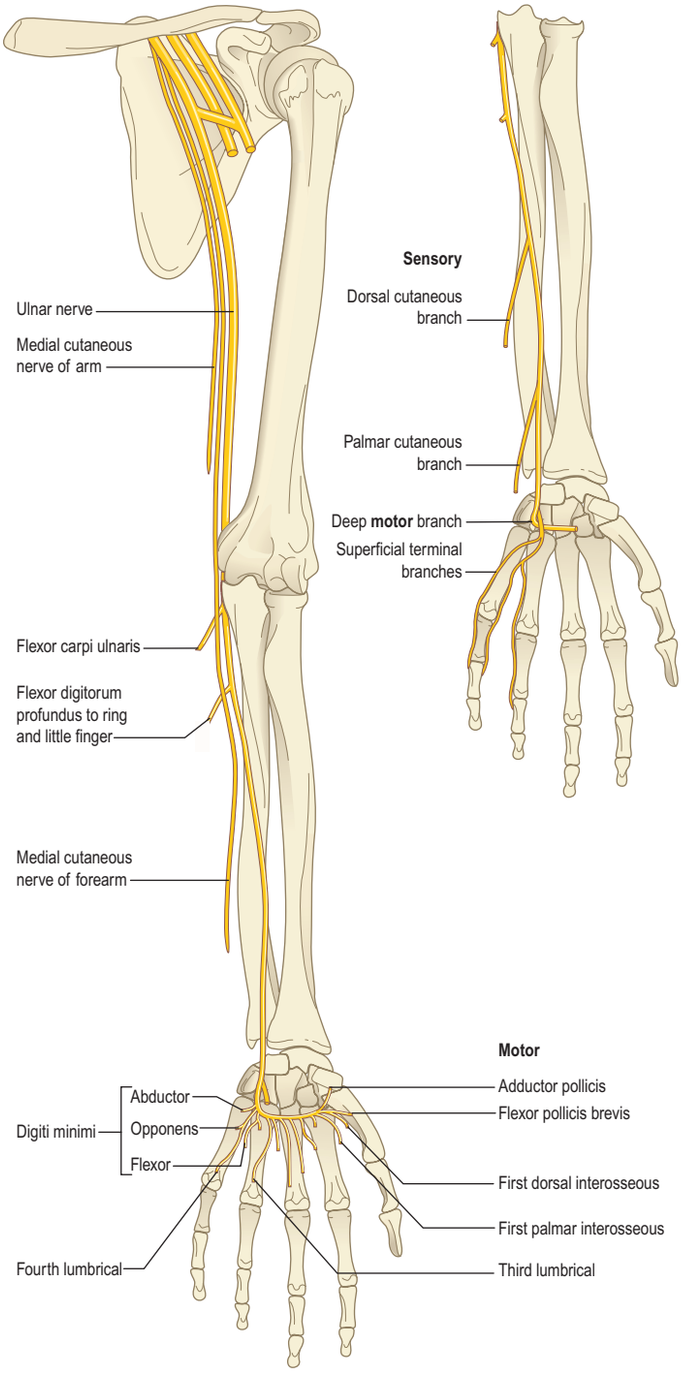

Fig. 48.12 Motor and sensory branches of the ulnar nerve and the medial cutaneous nerves of the arm and the forearm. Flexor pollicis brevis may be supplied by both median and ulnar nerves. (With permission from O'Brien M, Aids to the Examination of the Peripheral Nervous System, 5th ed. Saunders, Elsevier. Copyright 2010.)

canal, the arcade of Struthers, which is between 5 and 6 cm long. The walls of the canal include the medial intermuscular septum and the fascial sheath which invests the medial head of triceps brachii. The nerve next passes behind the medial epicondyle, then between the capsule of the humero-ulnar joint and the overlying arcuate ligament, which joins the two origins of flexor carpi ulnaris, i.e. the nerve passes through the cubital tunnel. It is accompanied by the superior collateral ulnar vessels in the lower third of the arm as far as the entrance to the cubital tunnel, and then by the posteroinferior ulnar collateral vessels. The anastomosis between these vessels permits the use of most of the ulnar nerve as a free vascularized graft, in cases where the parent roots, the seventh and eighth cervical ventral rami and the first thoracic ventral ramus, are irreparable. In the forearm, the nerve runs with the ulnar vessels in a well-defined sheath deep to the anterior margin of flexor carpi ulnaris. It divides into superficial (sensory) and deep (motor) components at the wrist, both passing through the ulnar (Guyon's) canal.

The superficial division innervates the skin of the medial two digits and palmaris brevis. The deep branch passes, with the deep branch of the ulnar artery, between abductor and flexor digiti minimi, pierces opponens digiti minimi and then runs across the deep palmar space with the deep palmar arch. It innervates all the muscles of the hand, except for the first and second (index and middle) lumbricals, abductor pollicis brevis, opponens pollicis and part of flexor pollicis brevis.

A branch to the medial head of triceps is often given off in the distal third of the arm. There are usually two neurovascular pedicles to flexor carpi ulnaris, the first at the exit from the cubital tunnel, the second about one-quarter of the way down the forearm. Several branches pass to flexor digitorum profundus. The dorsal cutaneous nerve arises about 6 cm proximal to the ulnar styloid, winds around the ulna, at first deep to flexor carpi ulnaris, and then subcutaneously. It innervates the skin of the dorsum of the hand and little finger, and the medial side of the ring finger.

The ulnar nerve is palpable in the lower arm and behind the medial epicondyle, where it is subcutaneous. There is an important relation here: a posterior branch of the medial cutaneous nerve of the forearm sweeps across the cubital tunnel and gets in the way of medial surgical exposures. Inadvertent injury may cause severe pain. The ulnar nerve is palpable at the wrist where it emerges from under flexor carpi ulnaris. The dorsal cutaneous branch can be palpated in those of slender physique where it crosses the subcutaneous ulna.

Musculocutaneous nerve

The musculocutaneous nerve (fifth, sixth and seventh cervical ventral rami) is one of the two terminal branches of the lateral cord, the other being the lateral root of the median nerve (Fig. 48.13). This division usually occurs at the level of the third part of the axillary artery, where the lateral cord lies lateral to the vessel, but it may occur more proximally, where the cord is anterior to the second part of the artery. The nerve may also arise as two or three branches from the cord, or even from the median nerve. It supplies coracobrachialis, both heads of biceps brachii and most of brachialis, and continues as the lateral cutaneous nerve of forearm, deep to biceps, before emerging lateral to it about 11 cm above the lateral epicondyle, and then running down the lateral aspect of the forearm. The nerve sometimes innervates the skin over the first metacarpal and the lateral part of the thenar eminence.

Segmental innervation of the upper limb

There is a segmental pattern to the innervation of the upper limb. The most proximal muscles are supplied by branches of the uppermost rami, and the most distal muscles are supplied by branches derived from the

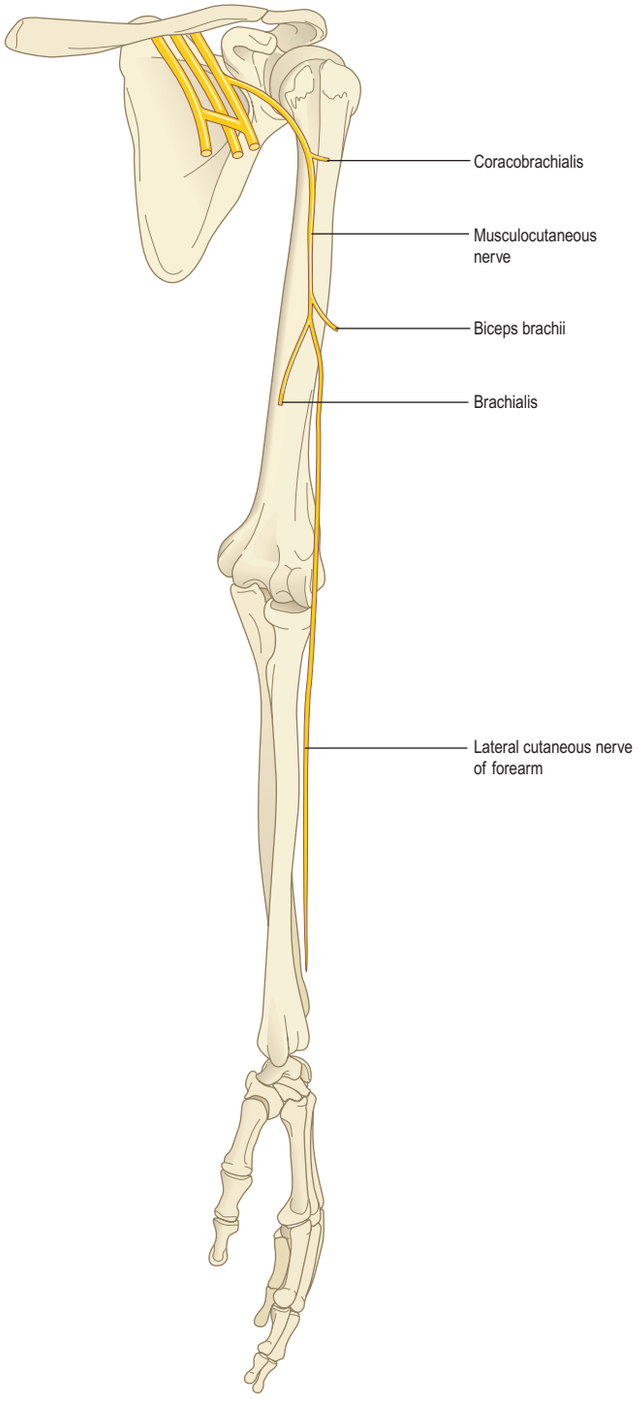

Fig. 48.13 Motor and sensory branches of the musculocutaneous nerve. (With permission from O'Brien M, Aids to the Examination of the Peripheral Nervous System, 5th ed. Saunders, Elsevier. Copyright 2010.)

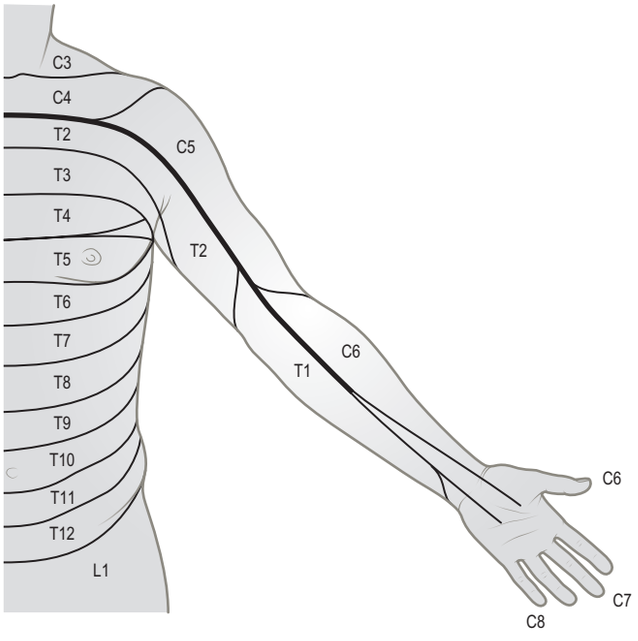

Fig. 48.15 Approximate distribution of the dermatomes on the anterior aspect of the upper limb. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

eighth cervical and first thoracic ventral rami. The segmental pattern of innervation is shown more clearly in the cutaneous supply. The cervical supply has been, as it were, extruded from the supply to the trunk. Thus, in the transition of cutaneous innervation from the skin of the neck to that of the trunk, there is a change from the fourth cervical to the second thoracic segment anteriorly, and a change from the fifth cervical to the second thoracic segment posteriorly (**Figs 48.14–48.15**; see Figs 24.10, 48.55). (For further reading, see Ladak et al (2014).) The truly autonomous area of cutaneous supply of each main component nerve is small and variable in extent and location.

C5 regularly controls extension, abduction and lateral rotation of the shoulder. C6 usually innervates biceps brachii, brachialis, lateral head of triceps, brachioradialis, extensor carpi radialis longus, and sometimes contributes to the innervation of pronator teres, supinator and flexor carpi radialis. C7 gives widespread innervation throughout the limb; in those unusual instances where it alone is damaged, the patient will note a rather diffuse loss of function throughout the upper limb, often without complete anaesthesia and sometimes without paralysis of any single significant muscle group. C7 consistently supplies latissimus dorsi. C8 innervates the extensors of the digits and of the thumb in at least one-third of cases. T1 innervates these muscles and also the medial head of triceps in at least 10%. Muscles, movements and segmental innervation in the upper limb are set out in **Tables 48.1–48.3**. **Table 48.4** helps to distinguish between upper and lower motor neurone lesions.

Autonomic nerves

The preganglionic sympathetic inflow to the upper limb is derived from neurones in the intermediolateral horn of spinal cord segments T2–T6/7. Myelinated preganglionic axons pass from the spinal nerves to the thoracic

Muscles and movements that have diagnostic value are marked in red. Spinal roots have been given the same colour (light peach, dark peach, red) when they innervate a muscle to a similar extent. Red has been used to indicate roots from which there is known to be a dominant contribution.

* These movements occur at the radio-ulnar joints.

Abbreviations: DIP, distal interphalangeal; IP, interphalangeal; MP, metacarpophalangeal; PIP, proximal interphalangeal.

TABLE 48.2 Segmental innervation of the muscles of the upper limb

Nerves	Muscles
C3, C4	Trapezius, levator scapulae
C5	Rhomboids, deltoids, supraspinatus, infraspinatus, teres minor, biceps
C6	Serratus anterior, latissimus dorsi, subscapularis, teres major, pectoralis major (clavicular head), biceps, coracobrachialis, brachialis, brachioradialis, supinator, extensor carpi radialis longus
C7	Serratus anterior, latissimus dorsi, pectoralis major (sternal head), pectoralis minor, triceps, pronator teres, flexor carpi radialis, flexor digitorum superficialis, extensor carpi radialis longus, extensor carpi radialis brevis, extensor digitorum, extensor digiti minimi
C8	Pectoralis major (sternal head), pectoralis minor, triceps, flexor digitorum superficialis, flexor digitorum profundus, flexor pollicis longus, pronator quadratus, flexor carpi ulnaris, extensor carpi ulnaris, abductor pollicis longus, extensor pollicis longus, extensor pollicis brevis, extensor indicis, abductor pollicis brevis, flexor pollicis brevis, opponens pollicis
T1	Flexor digitorum profundus, intrinsic muscles of the hand (except abductor pollicis brevis, flexor pollicis brevis, opponens pollicis)

Finger abduction	First dorsal interosseous	++	T1		Ulnar
	Abductor pollicis brevis		T1		Median

The muscles listed in the 'Upper motor neurone' column are those that are preferentially affected in upper motor neurone lesions. The root level is the principal supply to a muscle.

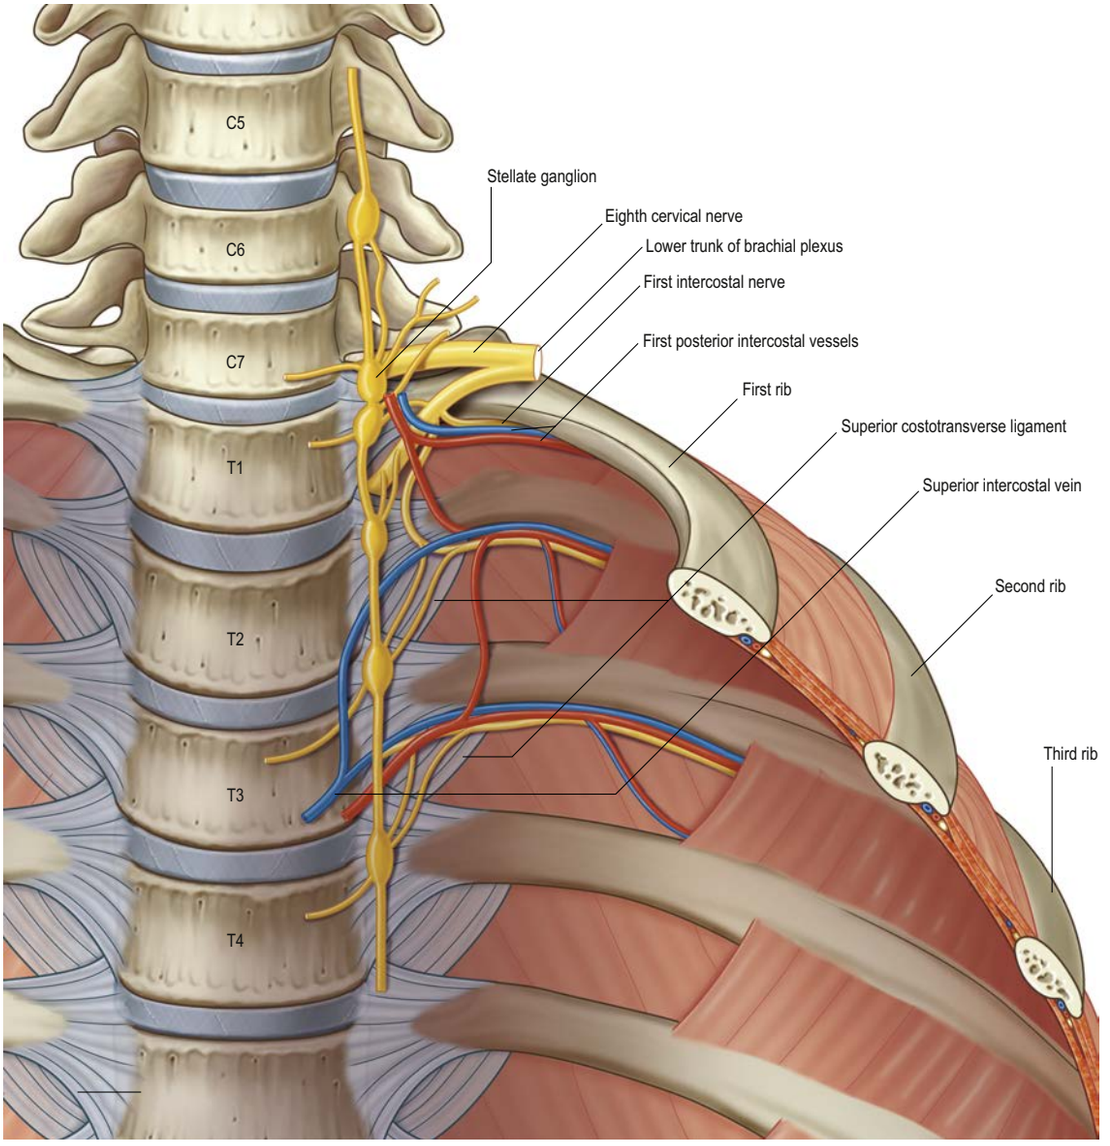

Fig. 48.16 The relations of the left cervicothoracic (stellate) ganglion. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

sympathetic trunk via white rami communicates. They pass up the trunk to the middle cervical and inferior cervical (stellate or cervicothoracic) ganglia, where they relay.

The unmyelinated postganglionic fibres are distributed by grey rami communicantes to the nerves of origin of the brachial plexus. The fifth and sixth cervical ventral rami receive grey rami from the middle cervical ganglion; the seventh and eighth cervical ventral rami receive grey rami from the inferior cervical ganglion; the first thoracic ventral ramus not only receives a grey ramus from the inferior cervical ganglion but also contributes a white ramus to it (see Fig. 24.13; Fig. 48.16). Interruption of this white ramus is one cause of Horner's (Bernard–Horner) syndrome: drooping eyelid, narrow palpebral fissure, a contracted pupil, and vasomotor with sudomotor paralysis in the ipsilateral face and neck. The sympathetic outflow to the upper limb passes with the peripheral nerves and is particularly rich in the palmar skin of the hand and in the skin of the axilla.

SURFACE ANATOMY

Skeletal landmarks

The clavicle is both visible and palpable from its prominent and relatively rounded medial (sternal) end, which forms the lateral boundary of the jugular (suprasternal) notch, to its flattened lateral end, where it joins the acromion (Fig. 48.53A). The acromioclavicular joint line is palpable as an anteroposteriorly aligned ridge or groove. The anterior, superior and lateral surfaces of the acromion are subcutaneous and palpable (Fig. 48.53C). Posteriorly, the palpable acromial angle marks the junction of the acromion with the spine of the scapula. From this point, the spine of the scapula is subcutaneous and easily visible in subjects of lower body mass, and is palpable to the medial (vertebral) border of the scapula, where it lies opposite the spinous process of T3.

In the acute injury, the object of the clinician must be to recognize the fact of injury as soon as possible after the event, and later, to go on to determine the nerve or nerves affected, the level(s) of injury, and the extent and depth of the lesion(s). The history is important: high injury transfer, open fracture and wounding (be it accidental, criminal, surgical, or all three) indicate a serious lesion and advice from witnesses or emergency paramedical staff is always valuable. Injuries that potentially threaten life or limb complicate closed traction lesions of the supraclavicular brachial plexus in about 20% of cases. It is important to seek occult injuries to the head, spine, thorax, abdomen and pelvis before embarking on treatment of the nerve lesion(s).

The early symptoms of acute nerve injury include: abnormal spontaneous sensations; alteration or loss of sensibility; weakness and paralysis; impairment of function; an awareness of warming and dryness of all or part of an extremity (sometimes); and pain (sometimes). Neuropathic pain is never easy to recognize in an injured patient, who is probably confused, distressed and in pain. It can be distinguished from the pain of fracture or dislocation by loss of sensation; painful, spontaneous sensory symptoms, expressed throughout the territory of the nerve; and by lancinating or shooting pain, radiating into the distribution of the nerve. Constant crushing, bursting or burning pain in an otherwise undamaged hand indicates serious and continuing injury to major trunk nerves more proximally. Progression of sensory loss, with a deep bursting or crushing pain within the muscles of the limb, signifies critical ischaemia.

The main nerves are stretched, ruptured or avulsed from muscle by violent hyperextension–abduction injuries of the arm. The axillary or brachial artery may be damaged by fracture of the proximal humerus or fracture-dislocation of the shoulder but such injuries are relatively uncommon (Menendez and Ring 2015). The axillary nerve and posterior circumflex vessels, which pass almost horizontally posterior to the neck of the humerus, are particularly at risk from anterior dislocation of the head of the humerus. The radial nerve and the profunda brachii artery are relatively fixed where they pass from the anterior to the posterior compartment by perforating the medial intermuscular septum in the axilla, and again when they re-emerge into the anterior compartment by perforating the lateral intermuscular septum. They may be stretched, ruptured or entrapped by displaced fractures of the shaft of the humerus. The median, ulnar and radial nerves may be subjected to traction, or entrapment, by fracture or dislocation about the elbow. The median nerve is severely compressed by fractures or dislocations impinging on the carpal tunnel. All nerves may be transected by wounds from a knife, glass, a bullet or other missile anywhere along their course. The axillary artery and its main branches are commonly involved in nerve injuries. Wounds of the median nerve in the arm commonly extend to the brachial artery, and the ulnar artery is usually involved in wounds to the ulnar nerve in the forearm and at the wrist.

Nerves and their related structures may be displaced by fracture, dislocation or haematoma. The ensuing fibrosis distorts normal anatomical relations; this increases the risk of intraoperative damage when nerves and accompanying vessels are not formally exposed. The incidence of such iatrogenic injuries is increasing and accounts for one-quarter of lesions of the radial nerve: the incidence is even higher for nerves around the elbow.

Injuries to nerves of cutaneous sensation are common after wounds, incisions or vessel puncture. It is remarkable that the elective removal of nerves such as the medial cutaneous nerve of the forearm for the purpose of grafting is followed by pain only very rarely, while lesions of the terminal branches are usually painful. The medial cutaneous nerve of the arm and the intercostobrachial nerve are at risk during operations in the axilla. The posterior cutaneous nerves of the arm and forearm are vulnerable during the lateral approach to the shaft of the humerus. The medial and lateral cutaneous nerves of the forearm are frequently damaged during operations around the elbow. The dorsal branch of the ulnar nerve is at risk during operations on the distal third of the ulna. The superficial radial and lateral cutaneous nerves are frequently injured by interventions on the lateral side of the wrist. Injuries to the palmar cutaneous branch of the median nerve and to the digital nerves are unwelcome complications of operations on the hand. These injuries cause pain, which may become severe. Mechanical allodynia, the perception of light touch as pain, is common; the spread of pain and allodynia beyond the territory of an injured nerve is frequent and indicates central sensitization of other neurones in the dorsal horn of the spinal cord.

Examination

Examination complements the history and the interpretation of symptoms to provide an accurate diagnosis. All findings should be set down in an intelligible record. Unfortunately, the signs of acute nerve injury have to be sought at a time when the patient may be least able to cooperate in an examination: soon after wounding, when there is likely to be distress and when the general condition may be affected by loss of blood and other injuries and/or by drink and drugs. The examination often has to be undertaken in the frequently unfavourable surroundings of an accident department. When the lesion has been inflicted by a surgeon or anaesthetist, the patient's response is likely to be distorted by postoperative pain, by the effects of recent general anaesthesia or by sedative or analgesic drugs. These are inappropriate conditions for a quiet and comprehensive 'neurological examination', and yet this is the time when the fact of nerve injury must at least be recognized if the best result is to be obtained from treatment. The examiner should, at all times, bear in mind the fact that, if there is a wound over the line of a main nerve and if there is any suggestion of loss of sensibility or impairment of motor function in the distribution of that nerve, it must be regarded as having been cut until and unless it is proved otherwise.

Local signs in closed injury

In closed injuries, swelling or ecchymosis and linear abrasions indicate severe soft tissue injury and also the line of application of force (see Fig. 48.29). Peripheral pulses and limb perfusion must be examined and re-examined.

Wound characteristics

It is useful to distinguish between the tidy wound caused by a knife and the untidy, and usually contaminated, wound of open fracture, machinery or gunshot. A further distinction is made between wounds caused by a handgun, rifle and close-range shotgun, the latter being particularly destructive. The injuries of current conflicts are classed as penetrating missile wound; (small) fragment wound; and blast wound, those from mines or improvised explosive devices (IEDs).

Sensation

Sensory loss is determined by response to light touch and pinprick. If circumstances permit, the patient outlines the area of sensory loss, which is then marked by a black skin-marker pen. The surrounding zone of incomplete sensory loss can be similarly marked in red, and the limb then photographed. For clinical examples, see **Figs 48.17–48.27**

Examination of muscles

Selected muscles are examined. The patient lying supine is usually able to demonstrate activity in serratus anterior by lifting the shoulders away from the couch, by means of 'forward shrugging'. It is usually possible to observe the presence of flexion and abduction at the shoulder, flexion and extension of the elbow and wrist, and flexion and extension of the

fingers. The radial, median and ulnar nerves are tested by asking the patient to form an 'O' between the thumb and little finger, to give the 'thumbs up' sign, and to open and close the fingers like a fan. The palmar skin is scrutinized for changes in colour and in sweating (Fig. 48.28). Although this may be more difficult in pigmented skin, such changes are detectable. The standard tendon reflexes are examined.

Secondary examination

A more detailed examination is possible when the patient's condition is stable, and when pain has been controlled. Limb dominance, occupation, marital status, underlying disease and continuing medication are recorded, if this has not already been done. Neuropathic pain is now somewhat easier to recognize because it is less responsive to analgesics than is pain from skeletal injury.

Recognition of the level of a lesion and the depth of injury

A sound grasp of the distribution of the spinal nerves and of the location of the formation and branching of the trunk nerves allows accurate diagnosis of the level of a lesion.

Posterior cord and radial nerve

The extent of the sensory loss is variable. There is no cutaneous sensory loss in lesions confined to the posterior interosseous nerve. The examination of selected muscles is reliable in guiding the clinician to the level of injury. They include, in order: teres major (inferior scapular nerve), latissimus dorsi (thoracodorsal nerve) and deltoid (axillary nerve). Subscapularis (superior scapular nerve) is not an easy muscle to examine.

Paralysis of all three heads of triceps places the injury in the axilla. The nerves to the lateral head of triceps leaves the main nerve rather distally, so that radial palsy, with paralysis of the lateral head but active medial and long heads, points to a lesion in the spiral groove. The nerve to brachioradialis consistently passes away from the main trunk about three fingers'-breadths above the lateral epicondyle, and the nerve to extensor carpi radialis longus leaves the main trunk about 1 cm more distally. One nerve to extensor carpi radialis brevis leaves the main nerve about 1 cm proximal to the lateral epicondyle, and another leaves at the site of division into the superficial radial and posterior interosseous nerves.

Lateral cord, musculocutaneous nerve and lateral root of the median nerve

It seems that most of the median nerve fibres that innervate the skin of the hand pass through the lateral cord. Paralysis involves biceps brachii, brachialis, flexor carpi radialis and pronator teres. That portion of brachialis innervated by the radial nerve may be intact. Division of the musculocutaneous nerve does not lead to loss of elbow flexion because brachioradialis acts as a powerful flexor of the joint (see Fig. 48.21).

Medial cord, medial head of the median and ulnar nerves

The sensory loss does not extend into the arm. If it does, then the medial cutaneous nerve of the arm must be involved. Paralysis is extensive, and includes the long flexor muscles to the digits, the small muscles of the hand, and the smooth muscle associated with the vessels and sweat glands supplying the whole of the ulnar two fingers.

Median nerve

Involvement of the palmar cutaneous nerve is useful in localizing a lesion at the wrist (see Figs 48.25, 48.26), but the extent of paralysis is a more precise guide to the level of a lesion. Injuries in the arm cause paralysis of all muscles innervated by the median nerve, including those arising from the medial epicondyle (flexor carpi radialis, pronator teres, palmaris longus, and part of flexor digitorum superficialis), as well as those innervated by the anterior interosseous nerve (flexor pollicis longus, flexor digitorum profundus to index finger) (see Fig. 48.24). Anterior interosseous palsy is distinguished from high median injury by the absence of any loss of skin sensation. Abductor pollicis brevis is the one small muscle of the hand that is consistently innervated by the median nerve.

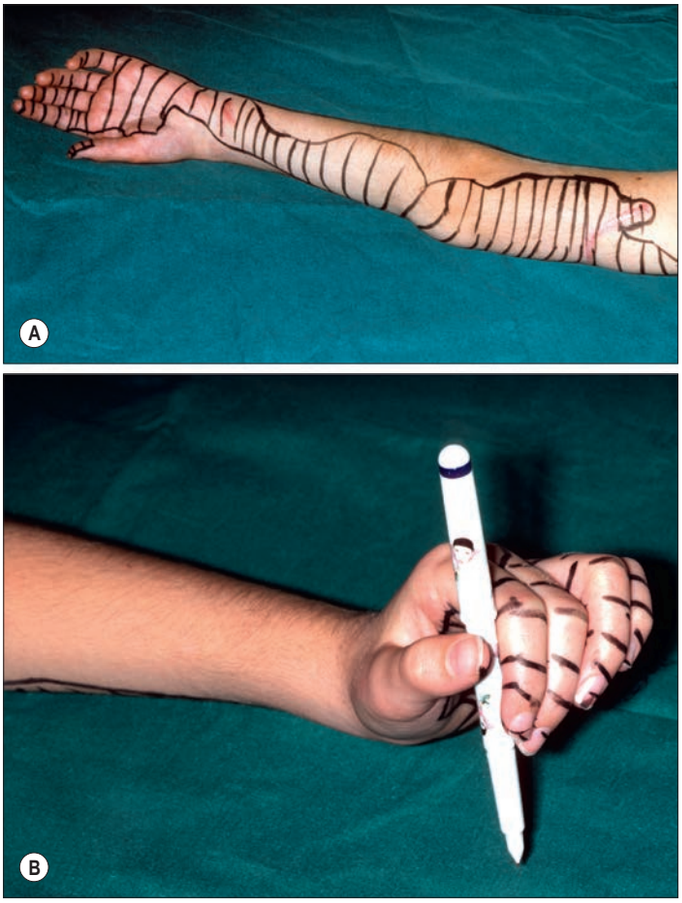

Fig. 48.23 A–B, Transection of the median nerve, ulnar nerve, medial cutaneous nerve of the forearm, and brachial artery, in the arm of a 14-year-old boy. Note the extent of skin innervation provided by the superficial radial and lateral cutaneous nerves of the forearm. The intact radial nerve permits a sort of grasp. Fig. 48.25 Section of the median nerve and the palmar cutaneous nerve at the wrist. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

Ulnar nerve

The sensory loss is related to the involvement of the dorsal and palmar cutaneous branches (see Fig. 48.27). Ulnar palsy with paralysis of flexor carpi ulnaris places a lesion in the arm. Paralysis confined to the hand places a lesion in the distal half of the forearm. Preservation of the hypothenar muscles with paralysis of the other hand muscles innervated by the ulnar nerve places a lesion in the proximal part of the palm of the hand. There is no cutaneous sensory loss in a palsy of the deep branch of the ulnar nerve. The posture of the digits is characteristic in ulnar nerve lesions.

The examiner should bear in mind the possibility of anatomical variation and also the ability for other muscles to compensate for the actions of those paralysed by what are termed 'trick movements'. In fact, these muscles are acting appropriately and the movements are real enough (see Fig. 48.23B).

Depth of a lesion

The distinction between conduction block and severance of an axon (axonotmesis or neurotmesis) is sometimes difficult. Serious injuries are likely to cause serious lesions of nerves. Severance of a nerve with a cutaneous sensory component will lead to well-defined loss of sensibility and to complete motor, sudomotor and vasomotor paralysis in the distribution of the nerve. Simple conduction block is likely to produce a patchy loss of sensibility and patchy motor loss. Further, it is likely to bear more heavily on the large axons than on the small ones. Vibration sense and sensibility to light touch are likely to be impaired, whereas pain sensibility may be unaffected. There is a risk of underestimating the severity of a nerve lesion in cases of closed injury and after intraoperative events. Different populations of nerve fibres within a main nerve that has been violently stretched but not ruptured sustain lesions of all grades of severity. Some remain intact, whilst conduction is blocked in others. Some ruptured axons will recover spontaneously, whilst others will not, depending on their cellular microenvironment (see Commentary 1.6).

Testing of sensibility is often difficult soon after wounding, or when nerve injury is associated with fracture of a long bone. The actions of some muscles can be simulated by the actions of others, so that the fact of paralysis can be missed in the early stages after nerve injury. Thus, when the median nerve has been cut, opposition of the thumb can be mimicked by the action of extensor pollicis brevis (posterior interosseous nerve) and abductor pollicis longus (radial nerve). Similarly, abductor

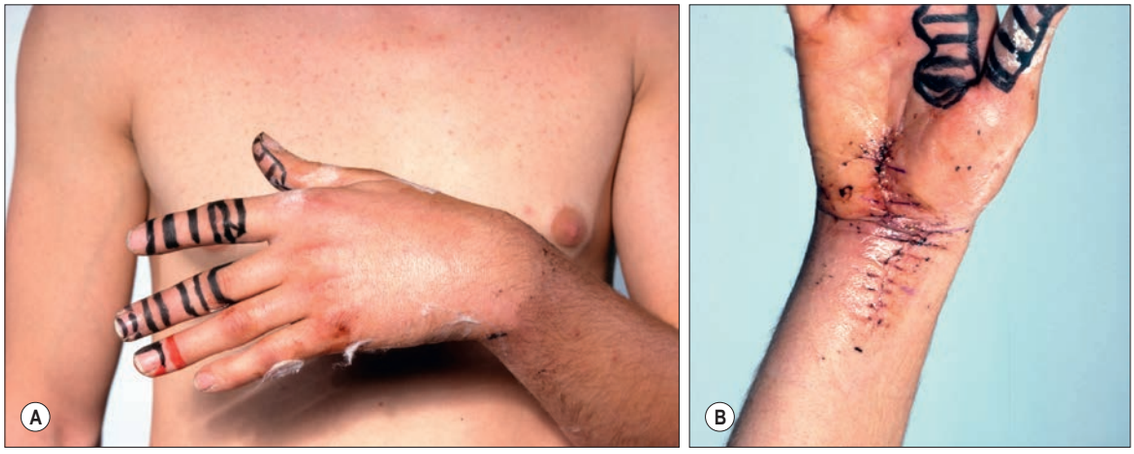

Fig. 48.26 A–B, Typical area of loss of sensibility after division of the median nerve at the wrist, sparing the palmar cutaneous branch. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

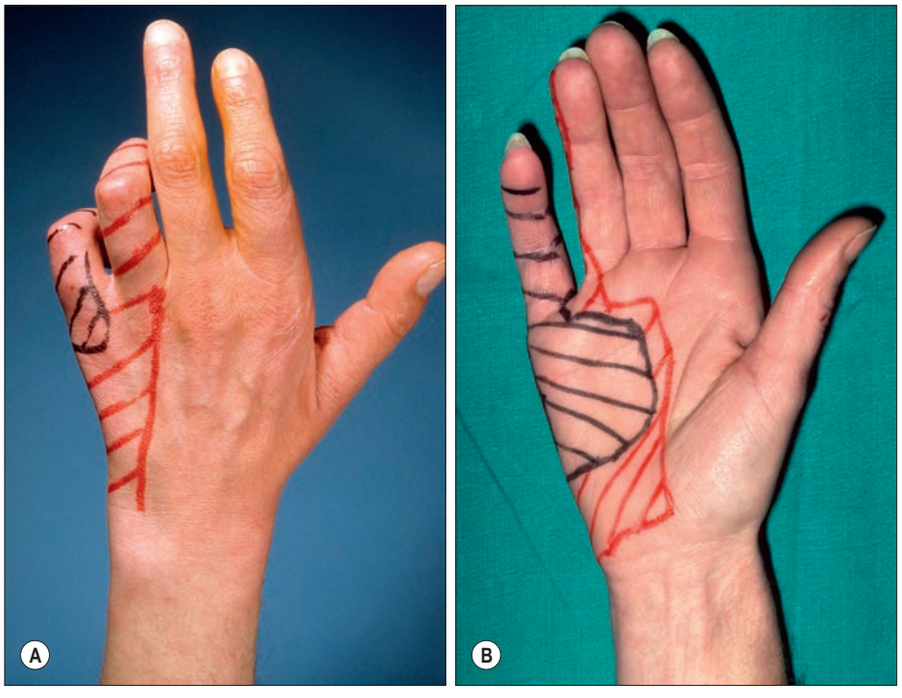

Fig. 48.27 A–B, Area of sensory loss and 'clawing' of little and ring fingers after division of the ulnar nerve in the forearm. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

pollicis longus can imitate the action of the abductor pollicis brevis. It is important to examine both hands, especially in the early days, when there is no wasting to guide the examiner. One almost infallible sign is always present in the first 48 hours after deep injury of a nerve with a cutaneous sensory component: because small, as well as large, fibres are affected, the skin in the distribution of the damaged nerve is warm and dry. In a small child, there may be an abnormal posture of the denervated digits; the 'immersion test' is also helpful. The injured hand or foot is placed, for a few minutes, in warm water; the skin of the denervated digits fails to wrinkle. In ischaemia, the large fibres conveying discriminative sensibility and vibration sense are first affected. It is not easy to test these modalities when ischaemia is developing because of the damage to a main vessel that is associated with a fracture of a long bone, but if action is not taken until superficial sensibility is lost, it will come too late.

Tinel's sign

In closed injuries, percussion of the skin over a nerve in which axons have been ruptured evokes sensations usually described as a wave or surge of pins and needles into the cutaneous distribution of the nerve. This is Tinel's sign and it is a most useful aid to diagnosis. The sign can be elicited on the day of injury in most conscious patients. It indicates not only where the nerve has been injured but also the fact that at least some axons have been ruptured. Tinel's sign can be detected from such 'motor' nerves as the posterior interosseous nerve; sensory symptoms radiate into muscular territory rather than into skin. It is more difficult to elicit the sign over deep-seated nerves such as the axillary, eighth cervical or first thoracic nerves.

Eliciting Tinel's sign in closed lesions

The examiner's finger taps along the course of the nerve from distal to proximal, starting below the presumed level of the lesion. The patient is asked to say when the advancing finger elicits a wave or a surge of pins and needles or abnormal sensations, which may be painful, into the distribution of the nerve, which must be clearly indicated by the examiner. The level of the sign should be measured from a fixed bony point and the distance recorded. At times, the examination is painful and patients need to be warned of this. A Tinel's sign that remains static at the level of a lesion strongly suggests rupture of the nerve or persisting local conditions inimical to spontaneous regeneration.

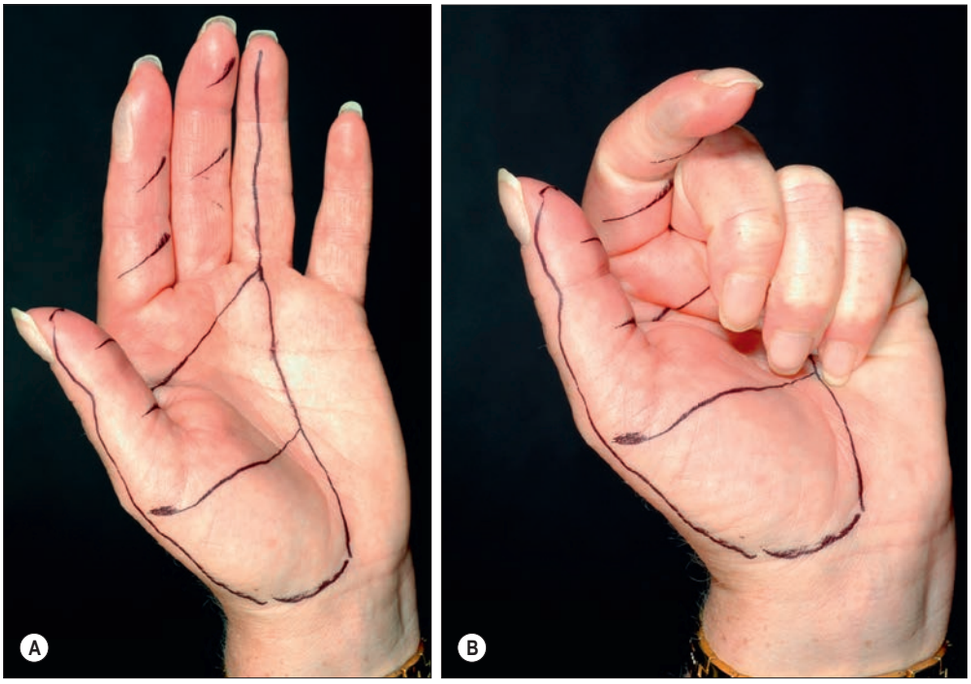

Fig. 48.28 Sympathetic paralysis seen within a few days of transection. **A–B,**Transection of the median nerve at the elbow. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

Fig. 48.29 Linear abrasions in the neck indicate separation of the forequarter from the trunk. The abrasion at the tip of the shoulder marks the point of impact against a roadside kerb. Rupture of C5, preganglionic C6–T1. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

The closed traction lesion of the supraclavicular brachial plexus is amongst the worst of all peripheral nerve injuries because of the frequent association with injury to the spinal cord and the usual complication of severe pain. There is one common element: the violent distraction of the forequarter from the head, neck and chest so that the angle between the head and the shoulder is opened. One important physical sign that illustrates this point is the presence of linear abrasions and bruising at the tip of the shoulder (Fig. 48.29). These are often injuries of great violence and motor cyclists in high-speed accidents are particularly at risk. Associated injuries to the head, spine, chest, abdomen, pelvis, long bones and subclavian artery are common.

The most common site of the nerve lesion lies within the spinal canal, affecting the intradural segments of the spinal nerves. These injuries are called preganglionic because the lesion lies between the dorsal root ganglion and the spinal cord. This concept of pre- and postganglionic injury, introduced by Bonney in 1954, is fundamental to diagnosis and treatment. The preganglionic injury is the most common lesion because the union of the ventral and dorsal roots is the weakest link in the long chain between the central nervous system and the periphery. Postganglionic rupture usually involves the ventral ramus, distal to the branching of the dorsal ramus (see Figs 47.1, 47.7). In one series of 200 patients operated on between the years 2000 and 2004, 429 spinal nerves sustained preganglionic rupture, 223 were postganglionic ruptures and the remaining 298 spinal nerves were intact or recovering. The fifth and sixth cervical nerves are somewhat protected by proximal branches to such nerves as the phrenic and long thoracic, and also by the transverse radicular ligaments. The vulnerability of C8 and T1 is enhanced by the increasing obliquity of the roots in the spinal canal and the angulated course of T1.

There are two types of preganglionic, intradural, injury: rupture peripheral to the transitional zone and avulsion central to it (**Figs 48.30–48.31**; see also Fig. 3.37). The former is more common. The extent of the displacement of the dorsal root ganglion, and the level of rupture of the dura, vary. These patterns are outlined in a classification by Bonney (Birch 2011a) and examples are illustrated in **Figs 48.32 and 48.33**. Bonney (1954, 1959) showed that the neuronal cell bodies in the dorsal root ganglion in preganglionic injuries remained alive and that conduction within their peripheral axons was maintained, even though the cell body was separated from the spinal cord (**Figs 48.34–48.35**); the axon reflex is probably maintained by the unmyelinated C fibres. Bonney and Gilliatt (1958) recorded sensory action potentials from peripheral nerves in cases of preganglionic injury; the measurements of persisting peripheral conduction stimulated a profound and lasting interest in conduction in the central pathways. Intraoperative studies of motor and sensory conduction are essential in emergency or urgent exploration of the brachial plexus. The demonstration that myelinated afferent fibres pass through the ventral root in the human (Schenker and Birch 2000) (**Fig. 48.36**) may be significant in operations to reattach the ruptured ventral root to the spinal cord.

Diagnosis

It is important always to search for occult injuries to the head, chest and spine. Once the diagnosis of injury to the brachial plexus has been made, it should be put to one side while a systematic examination is made of the whole patient. Analysis, history and precise clinical

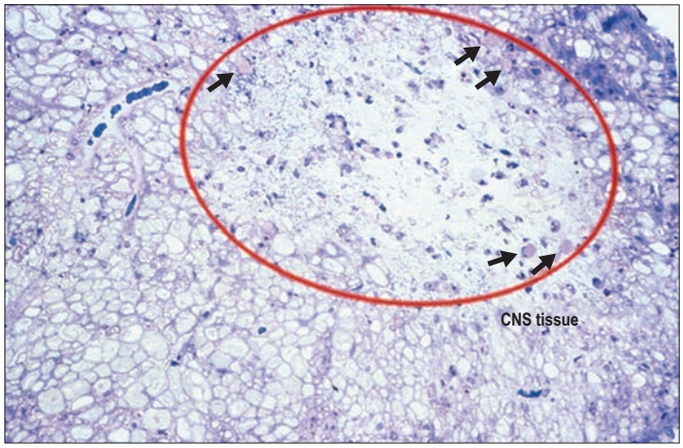

Fig. 48.30 Transverse section of the tip of an avulsed dorsal root at C6 4 days after injury, showing a central avulsion. The tissue in the centre of the section is central nervous system (CNS) tissue, in which glial cells show post-traumatic lytic changes. Corpora amylacea are indicated by arrows. Springer-Verlag, London.)

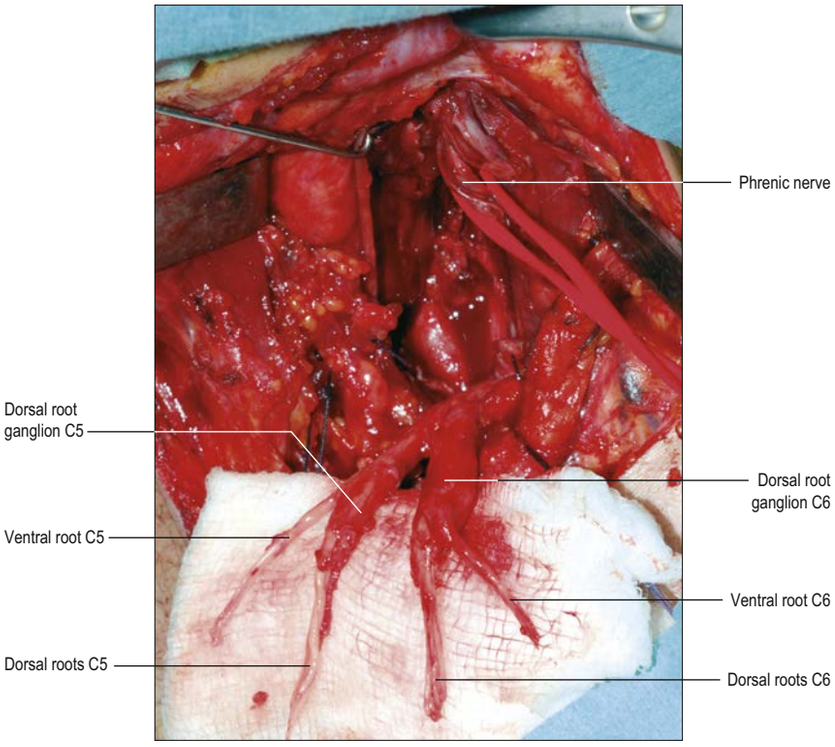

Fig. 48.32 The fifth and sixth cervical nerves avulsed from the spinal cord. The ventral root is easily distinguishable from the dorsal rootlets. Note the dorsal root ganglion, the dural sleeve merging into the epineurium, and the spinal nerve itself. The small pieces of tissue on the proximal ends of the dorsal rootlets (below) are probably portions of the spinal cord. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

examination usually permit an accurate diagnosis of the extent and the level of the neurological injury.

History An understanding of the axis of application of force to the injured limb is very important. A description from witnesses or the patient of the shoulder being violently arrested by an object – stone, tree, kerb or vehicle – while the body is flying through the air confirms that there has been violent stretching of the structures in the posterior triangle of the neck.

Pain Severe pain within a paralysed and anaesthetic limb indicates very serious injury to the spinal nerves. It may be constant, described as crushing, burning or intense pins and needles, and is usually felt in the forearm and hand. Two-thirds of conscious patients who developed such pain did so on the day of injury. The superimposed shooting pain coursing into the dermatome of a spinal nerve signifies preganglionic injury to the nerve (Fig. 48.37). More than one-half of conscious patients experienced this pain on the day of injury (Birch 2011b).

Inspection Inspection of the limb may reveal linear cuts and abrasions passing from the face to the shoulder, indicating distraction of the limb when injury was sustained. Deep bruising is an important sign of tearing of prevertebral muscle or even of the subclavian artery. Increasing swelling in the posterior triangle indicates a collection of spinal fluid, either from nerves avulsed from the spinal cord or from an expanding haematoma, or both. Horner's (Bernard–Horner) syndrome is a strong indicator of preganglionic injury to C8 and T1 and is the result of interruption of the rami between the spinal nerves and the stellate ganglion (see Fig. 48.16).

Sensory loss Sensory loss extending above the clavicle is a sign of preganglionic injury to at least the upper nerves of the brachial plexus (Figs 48.38-48.41).

Muscle weakness Paralysis of serratus anterior and of the ipsilateral hemidiaphragm shows that the lesion is in the most proximal segments of C4–C7 and that these nerves are likely to have sustained preganglionic injury.

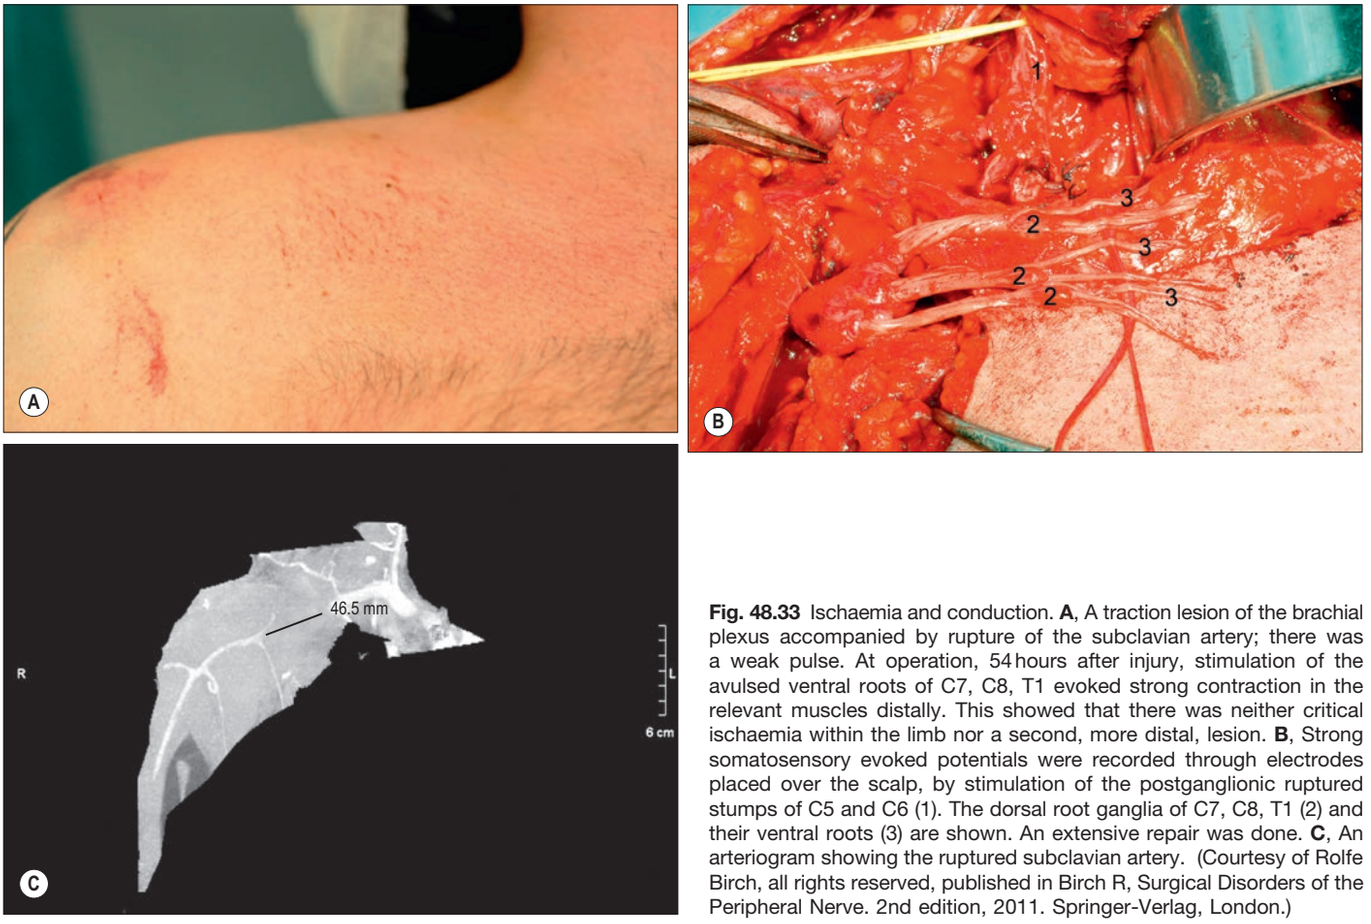

Fig. 48.33 Ischaemia and conduction. **A**, A traction lesion of the brachial plexus accompanied by rupture of the subclavian artery; there was a weak pulse. At operation, 54 hours after injury, stimulation of the avulsed ventral roots of C7, C8, T1 evoked strong contraction in the relevant muscles distally. This showed that there was neither critical ischaemia within the limb nor a second, more distal, lesion. **B**, Strong somatosensory evoked potentials were recorded through electrodes placed over the scalp, by stimulation of the postganglionic ruptured stumps of C5 and C6 (1). The dorsal root ganglia of C7, C8, T1 (2) and their ventral roots (3) are shown. An extensive repair was done. **C**, An arteriogram showing the ruptured subclavian artery. Fig. 48.40 Sensory loss in a preganglionic lesion of C4–C7. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Recognition of postganglionic rupture Tinel's sign is most valuable in the early detection of ruptures. It is important to advise the patient that percussion in the posterior triangle of the neck may be painful – at times, extremely so. The patient is asked to indicate the region into which they experience radiation of intense 'pins and needles'. When these extend down the outer arm and proximal forearm, then rupture of C5 is likely. When they extend to the lateral aspect of the forearm and thumb, then a similar lesion of C6 may be anticipated. Percussion over a rupture of C7 evokes sensations into the dorsum of the hand; that over a rupture of the lower trunk evokes sensations in the inner aspect of the forearm and little fingers.

It is difficult to overstate the significance of a strong positive Tinel's sign in detecting rupture of a spinal nerve within the posterior triangle: the stronger the sign, the more likely the chances of finding a robust stump. It should be emphasized that Tinel's sign is detectable, in a conscious patient, on the day of injury.

Fig. 48.41 Sensory loss in a preganglionic lesion of C5. The area of sensory loss is usually larger than that seen after rupture of the axillary (circumflex) nerve (see Fig. 49.2). (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Investigations Radiological and imaging studies confirm or modify the clinical diagnosis, but they may also confirm or reveal associated injuries to the spinal column, the spinal cord and the chest. Plain radiographs confirm elevation of the ipsilateral hemidiaphragm and may show tilting of the cervical spine away from the side of injury, which is often associated with fracture or dislocation of the first rib. The condition of roots and evidence of displacement or other abnormalities of the spinal cord are revealed by myelography: more precisely, by computed tomographic (CT) myelography and, increasingly in current practice, by magnetic resonance imaging (MRI).

Patterns of lesions

A survey of the incidence of these lesions in the UK, conducted through the auspices of the British Orthopaedic Association, uncovered 328 patients admitted with complete or partial lesions in 1987 (Goldie and Coates 1992). The lesion was complete in 26.2% of patients; the subclavian artery was ruptured in 5.5%; there were other major injuries in 40%, and a wound in the neck in 5.5%. **Table 48.5** sets out the patterns of injury in 301 patients operated on in 1989–93. Complete lesions accounted for 141 of the cases; 52 patients sustained preganglionic injury to all five spinal nerves. Over the years, there has been a modest decrease in the severity of injury; the proportion of cases with complete preganglionic injury of the fifth to the eighth cervical ventral rami and the first thoracic ventral ramus was 18.7% in the series reported by Rosson (Rosson 1987); 17.3% in those operated on between 1989 and 1993; and less than 8% in patients operated on between 2000 and 2004 (Birch 2011a). However, the incidence of injury to the subclavian artery in the operated cases remains steady over this time at about 10%.

Treatment

The direct object of treatment is rehabilitation. This entails the following steps: provision of accurate diagnosis and prognosis; improvement of prognosis by repair of damaged nerves; relief of pain; palliation of paralysis by custom-made orthoses and by musculotendinous transfers (**Fig. 48.42**); and assistance towards a return to original, appropriately modified or new work or study and to independent living.

Operations should be undertaken as soon as the patient's general condition permits in cases where there is evidently a serious nerve injury (Birch 2011a). There have been important improvements in outcomes over the years. The possibility of reconnection of the avulsed ventral roots to the spinal cord has been realized in a few carefully selected

Fig. 48.42 A–B, A woman aged 28 at the time of injury with left-sided rupture of C5, C7, C8 and T1, and a preganglionic lesion of C6. Function is shown at 96 months after repair: wrist extension was regained by transfer of flexor carpi ulnaris to extensor carpi radialis brevis. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

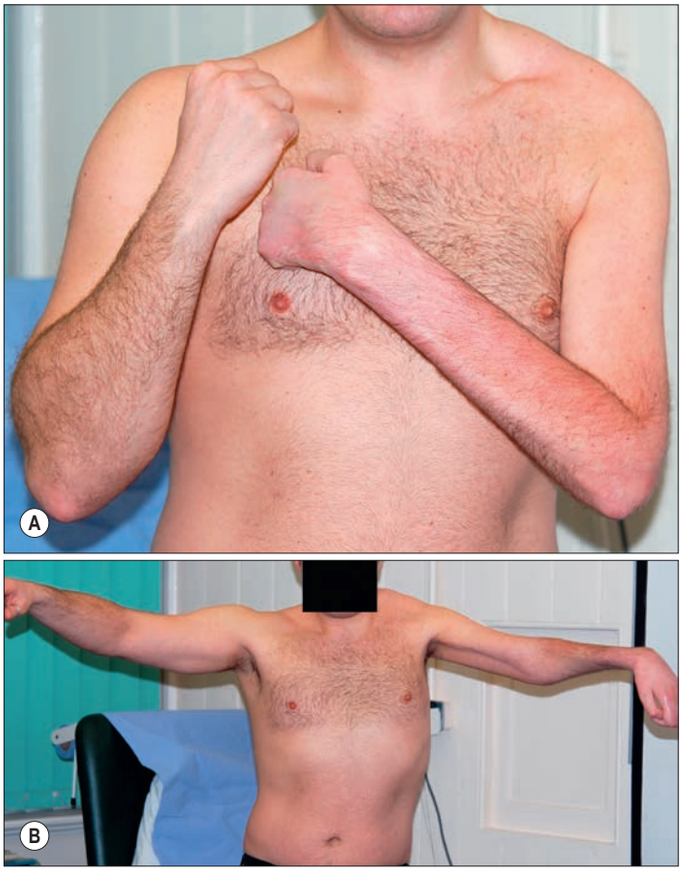

Fig. 48.43 A–B, A 23-year-old man with a left-sided preganglionic lesion of C5–T1. Function is shown at the shoulder and elbow 11 years after reimplantation of the ventral roots of C5, C6, C7. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

TABLE 48.5 Patterns of injury in 301 consecutively operated supraclavicular lesions (1989–1993)

Pattern of injury	No. of patients
Complete lesions: pre- and postganglionic injuries	141
Ruptures of upper nerves C5 (C6, C7) Intradural ruptures of lower nerves (C6–C8) T1	83
Ruptures of middle nerves (C6) C7 (C8) Intradural above and below	5
Ruptures of lower nerves C8, T1 Intradural ruptures of upper nerves C5–C7	1
Total intradural ruptures of C5–T1	52
Incomplete lesions: some roots intact	153
Damage C5, C6 (C7) Recovering or intact (C7) C8, T1	117
Damage C6–C8 Recovering or intact C5, T1	23
Damage C7, C8, T1 Recovering or intact C5, C6	13

cases (Fig. 48.43). The return of fluid and coordinated muscle action, and of the biceps tendon jerk, suggests some regeneration into the deep afferent pathway, perhaps through myelinated afferent fibres in the ventral root.

Pain relief One of the most pleasing aspects of surgical endeavour has been the finding that reinnervation of muscle is regularly successful in improving pain and this is a strong indication for securing reinnervation of a limb, no matter how limited, in even the most severe injuries (Berman et al 1996, 1998, Kato et al 2006; see Birch 2011a, 2011b, 2011c).

The anatomical arrangements of some of the peripheral nerves make them particularly vulnerable to damage from musculoskeletal injury.

Fractures and dislocations

In the upper limb, the cords of the brachial plexus and the axillary vessels pass in a space bounded by subscapularis (deep) and pectoralis minor (superficial). Anterior displacement of the humeral head or bone fragments forces the nerves and vessels against the deep surface of pectoralis minor, which acts as a guillotine. Rupture of nerves and vessels is frequent in high-energy transfer injuries in younger adults and is common in many lower-energy transfer injuries in the elderly (Fig. 48.44). The proximity to bone of all three main nerves at the elbow renders them vulnerable to skeletal injuries.

In the lower limb, nerve injuries are more common and more serious because of the greater forces involved in serious skeletal injuries. The lumbosacral plexus is at risk in fracture dislocations of the sacroiliac joints, especially when fractures extend into the sacral foramina. The sciatic nerve is damaged by posterior displacement of the femoral head (see Fig. 76.11B).

Tethering of nerves

In the upper limb, the axillary nerve runs in loose fatty tissue in its course anterior to subscapularis. When it turns around that muscle, it enters a quadrilateral tunnel formed by the union of the fasciae of subscapularis cranially, teres major caudally and coracobrachialis laterally, which surrounds the nerve and the posterior circumflex vessels. The neurovascular bundle curves around the inferior border of the tendon of subscapularis, and passes over the superior border of the tendon of teres major, entering a near-horizontal tube. This arrangement puts the nerve at risk during anterior dislocation of the head of the humerus and the frequent complication of bleeding from the posterior circumflex vessels, which strangles the nerve. The radial nerve is at risk from fractures of the shaft of the humerus between the two relatively fixed points of the nerves to the lateral head of triceps and the tunnel through the lateral intermuscular septum.

In the lower limb, the common fibular nerve, which passes above or through piriformis in as many as 30% of cases, is tethered above in relation to piriformis and below at the neck of the fibula. The fascia surrounding biceps femoris and its tendon sweeps around to embrace the nerve; in dislocation of the knee, the muscle frequently avulses the tip of the head of the fibula and is displaced anteriorly, pulling the nerve

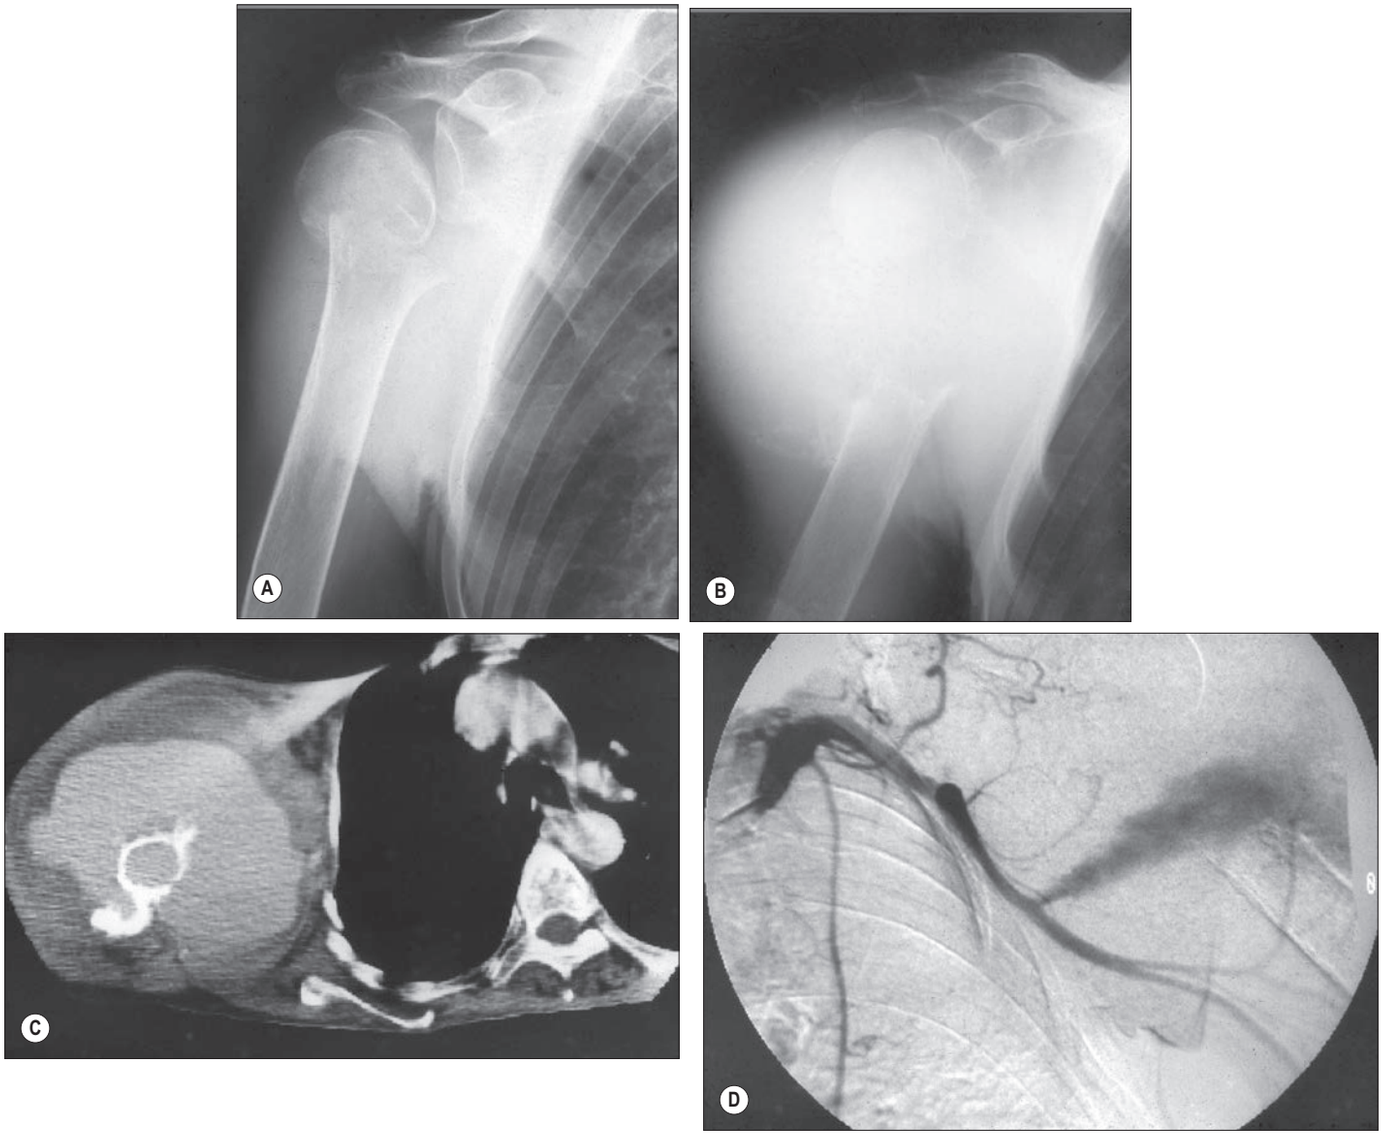

Fig. 48.44 A leaking aneurysm 20 weeks after fracture of the neck of the humerus in an 83-year-old woman. She made a good recovery after repair of the defect. **A**, A radiograph on the day of injury. **B**, A radiograph at 18 weeks. **C**, A magnetic resonance imaging (MRI) scan at 18 weeks. **D**, An angiogram on the day of operation. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

with it. The deep fibular nerve passes rather acutely forwards to enter the anterior compartment of the leg. Refer to Commentary 9.1 for further information on nerve biomechanics.

Fascial arrangements

Sleeves of fascia surround main nerves and main vessels in some regions, an arrangement that predisposes the nerves to injury from ischaemia and compression from bleeding. After the seventh and eighth cervical and first thoracic ventral rami enter the posterior triangle of the neck, they are enclosed in quite a rigid space bounded posteriorly by the dorsal part of the first rib, the transverse processes of the cervical vertebrae and the fascia of levator scapulae. The nerves are embraced by scalenus anterior and scalenus medius, both of which are invested in an unyielding fascia (this is one envelope of the prevertebral fascia that also serves to bind the phrenic nerve down to the anterior face of scalenus anterior). The prevertebral fascia is particularly well developed anterior to the vertebral column and at the base of the posterior triangle, where it envelops the seventh and eight cervical and first thoracic ventral rami, the phrenic nerve, the cervical sympathetic chain, and subclavian and vertebral arteries. Infusion of relatively large volumes of fluid, from 10 to 20 ml, deep to the prevertebral fascia, for the purpose of inducing regional block, may cause tamponade of the radicular vessels that enter the spinal canal and contribute to the anterior spinal artery (Fig. 48.45; see also Figs 47.11–47.12). The medial brachial fascial compartment extends from the axilla to the elbow and is bounded by the tough medial intramuscular septum and the axillary sheath. Bleeding into this compartment is responsible for many infraclavicular plexopathies following regional block or fracture dislocation of the shoulder (Fig. 48.46).

Fig. 48.45 The hands of an 11-year-old boy 7 years after anterior cord infarction caused by interscalene block. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Fig. 48.46 Fracture of the left proximal humerus, complicated by expanding haematoma in a 63-year-old man. Two attempts to occlude the torn posterior circumflex artery by interventional radiology failed. He was seen at 8 weeks, by which time he was in right heart failure and in great pain; he had a complete infraclavicular plexopathy on the left side. Six litres of altered blood were removed from the axilla; his pain was relieved. Recovery was particularly poor in the radial and median nerves. **A**, An MR angiogram before operation. **B**, The left hand 4 years after operation. Neurovascular compartments

The anterior interosseous nerve and its accompanying artery may be damaged by compression because of swelling in the deepest part of the flexor compartment of the forearm. The ulnar nerve is accompanied by the ulnar artery in a discrete fascial compartment in the distal two-thirds of the forearm. The deep fibular nerve is accompanied by the anterior tibial artery, an end artery, throughout most of the anterior compartment of the leg; occlusion of this artery causes death of the nerves and muscles of the anterior compartment. The femoral nerve is damaged by haematoma where it passes deep to the thick fascia over iliacus, and it is also at risk from bleeding into the femoral triangle (Fig. 48.47; see Fig. 77.48). The tibial nerve is accompanied by the posterior tibial artery in the distal half of the leg in a sheath of fascia similar to the arrangements for the ulnar vessels and nerve (Fig. 48.48).

Collateral circulation

The collateral circulation at the elbow depends on vessels that run with the three main nerves. This network may maintain an adequate supply to the hand and the extensor muscles of the forearm after acute loss of flow through the brachial artery if there is no associated fracture dislocation. The situation is much worse if the ulnar or radial nerves, with their accompanying vessels, are displaced into a fracture or compressed by haematoma. The collateral circulation at the knee is particularly poor. Acute loss of flow through the popliteal artery, unless urgently restored, invariably leads to extensive death of muscle and nerve, and often to amputation.

Fig. 48.47 Recovering femoral palsy from a haematoma in the femoral triangle in a 69-year-old farmer who was taking warfarin after aortic valve replacement. Two months previously he had injured his thigh whilst vaulting a gate. He experienced severe pain for 24 hours but this recovered spontaneously. The area of sensory loss is outlined and the site of the Tinel's sign is also marked. Recovery was good but not complete by 6 months. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Thoracic outlet syndromes (TOS) are amongst the most confusing and controversial of peripheral nerve disorders. Several different entities are grouped under this one heading but they have little in common beyond the presumed site of the lesion. The lower part of the brachial plexus, and the lower trunk in particular, joined at the first rib by the subclavian vessels, run a regular obstacle course on their way to the lower borders of pectoralis minor. Some of the more important obstacles will be described here.

Suprapleural membrane (Sibson's fascia)

In its pure form, the suprapleural membrane is a thin, fan-shaped structure attached anteriorly to the internal border of the first rib, and posteriorly to the anterior border of the transverse process of the seventh cervical vertebra. It covers the apical pleura and intervenes between it and the subclavian artery. The deep part of the membrane may be quite tough and aponeurotic (Fig. 48.49). The extent of its peripheral attachment varies. Scalenus minimus is the muscle that sometimes replaces the deep or posterior part of the membrane; it may be up to 10 mm in diameter in its widest part but is usually much smaller than that. The posterior border of the membrane forms, with the edge of the first rib, the foramen through which the first thoracic nerve escapes.

First rib

The broad first rib (see Fig. 53.9) has a surface that is more horizontal than vertical. It extends over the apical pleura and curves round to the costochondral junction and then to the manubrium (see Fig. 53.8). In the healthy state, the apical pleura is easily separable from the head and neck, and most of the underside of the first rib; anteriorly, it becomes rather adherent to the underside of the rib, in relation to the costochondral junction. Scalenus medius is attached to the upper surface of the rib posteriorly. The upper portion of the nerve to serratus anterior is usually formed in scalenus medius by branches from the fourth, fifth and sixth cervical ventral rami; it emerges from the lateral surface of the muscle to be joined by a contribution from the seventh cervical ventral ramus. Anterior to scalenus medius, the surface of the rib is, in the adult, grooved by the passage of the first thoracic ventral ramus and the lower trunk of the brachial plexus. There is a distinct tubercle at the attachment of scalenus anterior; the subclavian artery lies in a slight depression posterior to the tubercle, and the subclavian vein runs over the upper surface of the rib anterior to the tubercle. The intercostal muscles are attached to

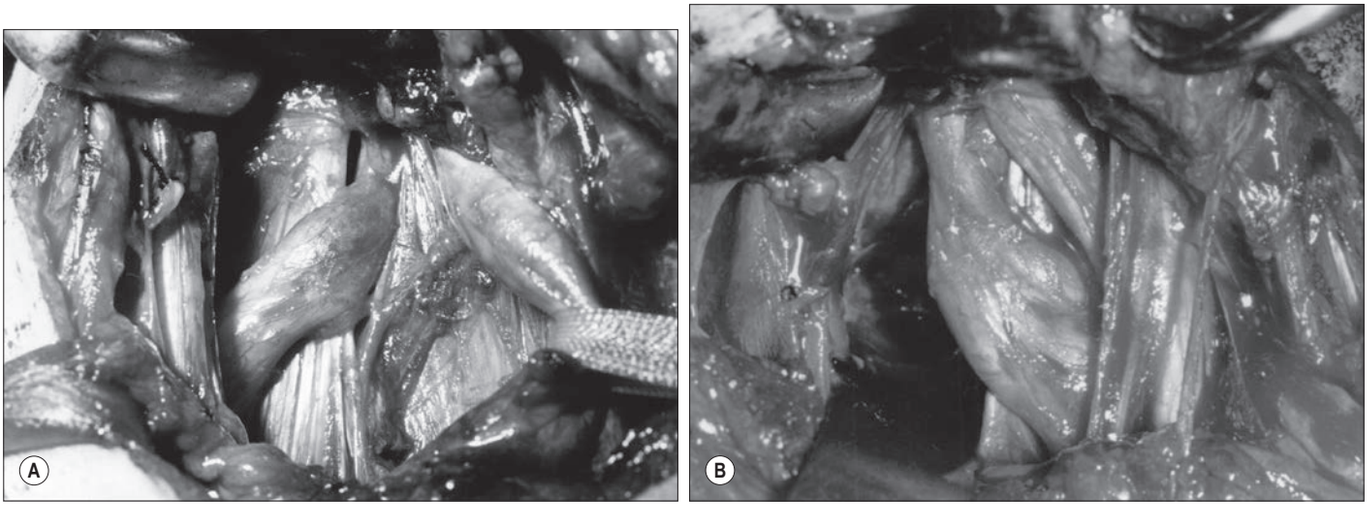

Fig. 48.49 Entrapment of the lower trunk through an anomaly of the suprapleural membrane and scalenus medius. **A**, The right lower trunk is trapped between the aponeurotic edge of scalenus medius posteriorly and the suprapleural membrane anteriorly. **B**, A 'scalenus sickle' and an anomalous scalenus anterior. The left lower trunk passes over the edge of the sickle and behind the part of scalenus anterior that passes posterior to the subclavian artery. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

the edge of the rib. The lower part of the cervicothoracic (stellate) ganglion lies on the head of the first rib, deep to the proximal part of the vertebral artery as it arises from the first part of the subclavian artery (see Fig. 35.18). The major part of the first thoracic ventral ramus is at first below the rib, then medial to its edge. The preganglionic (sympathetic) ramus of the first thoracic ventral ramus connects it to the stellate ganglion; the postganglionic ramus is less noticeable. The size and disposition of scalenus anterior vary: it may bifurcate to include the artery; it may be bulky and its tendon may curve posteriorly round the artery to form a kind of snare. Deep to scalenus anterior, a very thin fascia covers the artery. The phrenic nerve, chiefly derived from the fourth cervical ventral ramus, curves round the muscle to run down anterior to it into the thorax, lying, at first, posterior to the internal jugular vein and crossing behind the subclavian vein. The thoracic duct and the right lymphatic duct enter the brachiocephalic vein at the subclavian–jugular (triradiate) junction on the left and right, respectively. All of the scalene muscles vary in formation and size. Bridges of muscle and fascia may pass between them, altering and diminishing the space available for the neurovascular bundles.

Seventh cervical rib

Estimates of incidence range from 0.004% to 1%. Cervical ribs are asymptomatic in most people. The extent of the rib, which is rarely symmetric bilaterally, ranges from a prolongation and pointing of the seventh cervical transverse process to a complete rib in all respects like a first thoracic rib. The classification proposed by Sargent (1921) is as follows: type 1, prolongation and pointing of the seventh cervical transverse process; type 2, short articulating rib with fibrous prolongation; type 3, jointed rib long enough to carry the eighth cervical nerve; type 4, jointed rib fused at its end with the first rib or articulating with it; and type 5, a complete seventh cervical rib with cartilaginous union to the first costal cartilage or to the manubrium (Fig. 48.50).

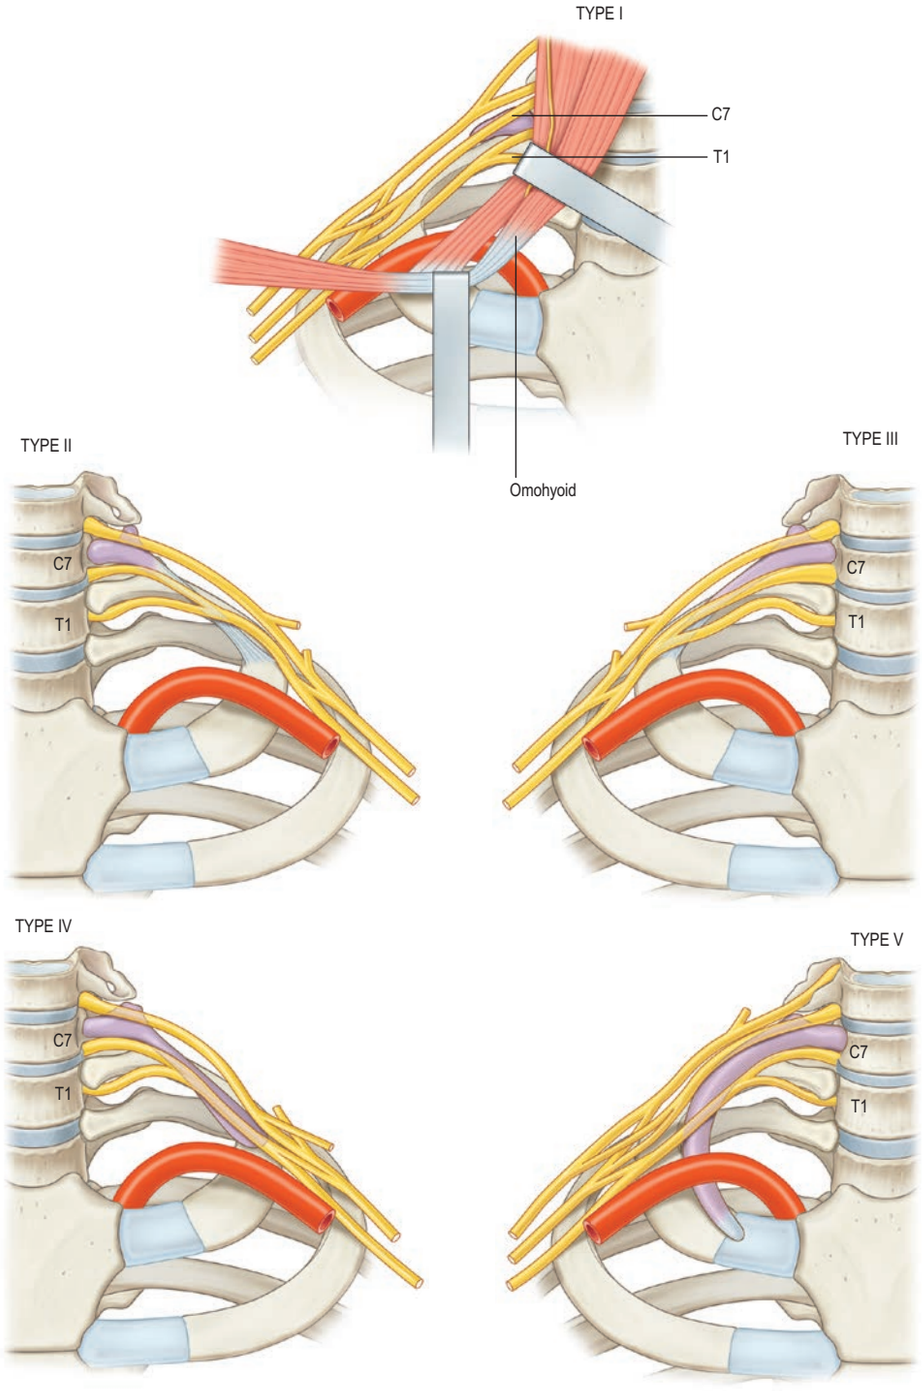

Fig. 48.50 Variations of the seventh cervical rib (purple), ranging from elongation of the seventh cervical transverse process to a virtually complete additional rib (after Sargent 1921). Arterial thoracic outlet syndrome

Arterial TOS was the first of the syndromes to be recognized and the first to be treated surgically. Astley Cooper wrote, 'I have seen an exostosis arise from the 6th or 7th cervical vertebrae or perhaps from both' (Cooper and Travers 1817). He went on to describe the case of a woman who came into Guy's Hospital with no pulse at the wrist or elbow and with 'venous redness' of the upper limb, which was cold, 'ennumbed' and painful; she also had a projection of the lower cervical vertebrae towards the clavicle, with consequent pressure on the subclavian artery. Coote (1861) reported the removal of a left seventh cervical rib causing aneurysm of the subclavian artery. Two physicians, Lewis and Pickering (1934), pointed to the mechanism of production of the arterial lesion, namely: intimal breakage with local thrombosis and distal embolization. Arterial affection occurs as the subclavian artery crosses a 'normal' first rib or a seventh cervical rib, commonly one with bony union to, or synchondrosis or synostosis with, a boss on the first rib at about its middle part. The vessel is distorted by the bone and constricted by a leash formed by the tendon of insertion of scalenus anterior. There is commonly dilation of the artery distal to the point of constriction, and the dilation may proceed to the formation of a true aneurysm (Wickham and Martin 1962). Complete obstruction of the main vessel with distal embolization may lead to critical ischaemia. The most dangerous complication is contralateral hemiplegia, doubtless from embolization from a thrombus extending proximally to the carotid vessel (Symonds 1927).

The arterial form of this outlet syndrome is a condition predominantly affecting young women; the occurrence of such symptoms in older individuals must suggest a primary diagnosis of atherosclerosis or other systemic disorder. The symptoms are initially those of Raynaud's disease with episodic blanching and temperature change, episodic pain with muscular activity, and distal ulceration and necrosis. The extremity may be cooler than the unaffected limb and there is likely to be a pulse

Fig. 48.51 Arterial thoracic outlet syndrome: angiographic appearances. **A**, Complete occlusion over a cervical rib. **B**, Complete occlusion at the thoracic outlet in a 40-year-old woman, a heavy smoker. **C**, Obstruction of the artery at the thoracic outlet on elevation of the limb. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

difference, even the absence of a pulse. Even if the hands are the same colour at rest and slightly dependent, there is likely to be blanching of the affected hand on elevation. The artery is prominent, displaced upwards and anteriorly by the underlying rib; there is a loud bruit and there may be a thrill. Doppler ultrasound examination is likely to show an abnormality: principally, a clamped, monophasic velocity signal anywhere over the arterial tree of the upper limb (Parry and Eastcott 1992). Radiographs will, of course, show a seventh cervical rib if one is present. Magnetic resonance angiography and duplex ultrasonography have generally superseded arteriography in this field, as in others, and will confirm the site and extent of the obstruction, the extent of stenosis and aneurysm formation, and the degree of distal occlusion (**Fig. 48.51**).

Operation is required urgently in cases of critical ischaemia, and soon in cases in which ischaemia is threatened. It may be indicated when a cervical rib is present, causing no symptoms but producing deformity of the subclavian artery sufficient to cause a steady bruit over the vessel, which must surely indicate distortion of the vessel that is likely, in time, to cause intimal breakage and thrombosis. Arterial TOS is uncommon rather than rare and it is potentially dangerous. The bruit from a prominent subclavian artery associated with an underlying seventh cervical rib cannot be ignored and investigations need to be pursued to define the extent of distortion of the artery.

True neurogenic thoracic outlet syndrome

Neurogenic TOS is rare. As Gilliatt (1984) pointed out, a number of cases were seen at the National Hospital for Nervous Diseases, Queen Square, London, UK, in the early years of the last century, with wasting of the thenar muscles that was attributed to a cervical rib. In fact, these patients probably had a carpal tunnel syndrome. The confusion was not resolved for more than 40 years until the application of nerve conduction studies defined the much more common disorder. Gilliatt put the annual incidence of cervical rib syndrome with muscle wasting as low as 1 in 1 million in the general population. The patients are usually young to middle-aged women and the abnormalities are usually confined to one upper limb. The symptoms are insidious and often mild; presentation is delayed for some years, and is usually occasioned by the sudden realization that the hand has become wasted. There is pain in the medial aspect of the forearm and there may also be some blunting of sensibility in that area and in the little finger. The latter is frequently shorter than it is in a normal, age-matched hand, suggesting that the affliction of the fibres in the lower trunk commenced before skeletal maturity. There is wasting of the superficial thenar muscles, which sometimes extends to all of the small muscles of the hands (**Fig. 48.52**) and there may be weakness of the flexor muscles of the forearm, most evident in those innervated by the ulnar nerve. There may be a bruit over the subclavian artery. Radiographs of the neck show rudimentary cervical ribs or elongated transverse processes of the seventh cervical vertebrae. The diagnostic electrophysiological findings were characterized by Gilliatt, Le Quesne and Logue in 1970 and include a small or absent sensory response in the ulnar nerve and the medial cutaneous nerve of the forearm; a normal sensory response in the median nerve; an attenuated compound motor action potential amplitude from abductor pollicis brevis; and a low-amplitude ulnar motor response (Smith and Knight 2011). Operation is indicated in these patients in the expectation of alleviation of pain, improvement in sensation and some improvement in strength; recovery of the wasted small muscles of the hand is rare.

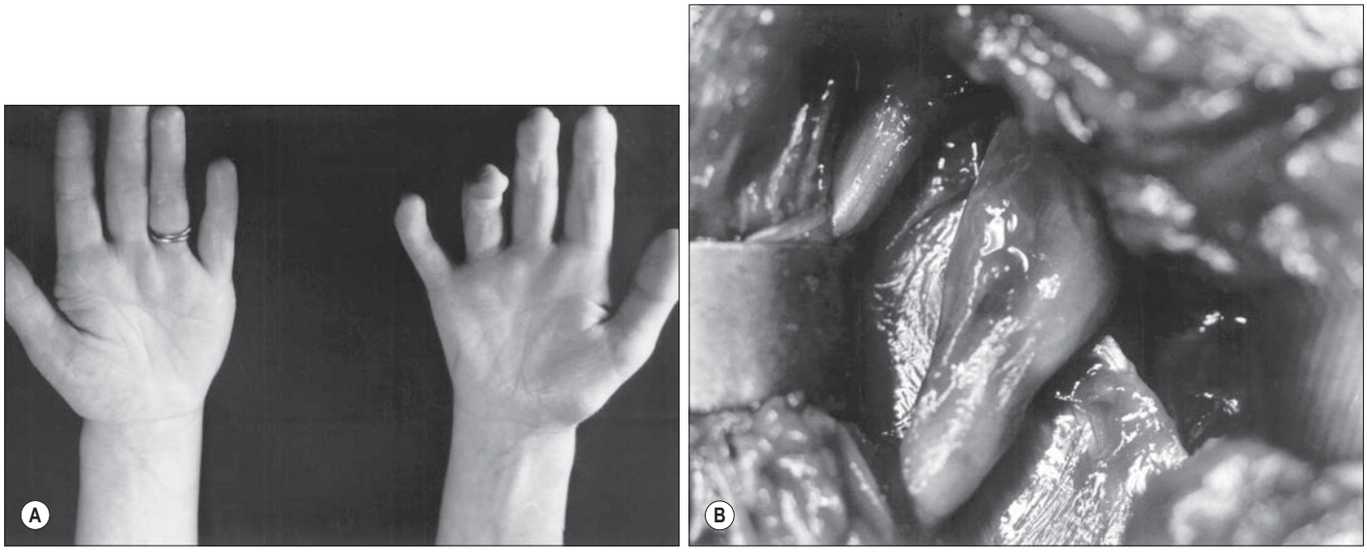

Fig. 48.52 The classical neurogenic outlet syndrome; shortening of the little finger is often evident. **A**, Severe wasting of the intrinsic muscles of the right hand in a 35-year-old woman. **B**, The right lower trunk is seen angulated over a 'scalenus sickle' and there is extreme attenuation of the trunk, which, in the photograph, appears to be rather lateral to the sickle. When the nerve was first exposed at operation, the zone of attenuation was, in fact, at the site of angulation. There was slow improvement after decompression. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve. 2nd edition, 2011. Springer-Verlag, London.)

Neural (non-specific/disputed) thoracic outlet syndrome without plain motor signs

Neural TOS without plain motor signs is more common and more difficult. Patients present with symptoms and signs consistent with a diagnosis of TOS but studies of blood flow and nerve conduction are normal. It is important to seek causes of the symptoms beyond the apparent diagnosis and to remember that the presence of a cervical rib does not, of itself, permit a diagnosis of TOS. The urge to advise operation should be tempered with knowledge of the possibility of complications and the high rate of recurrence of symptoms as time passes (Birch 2011d).

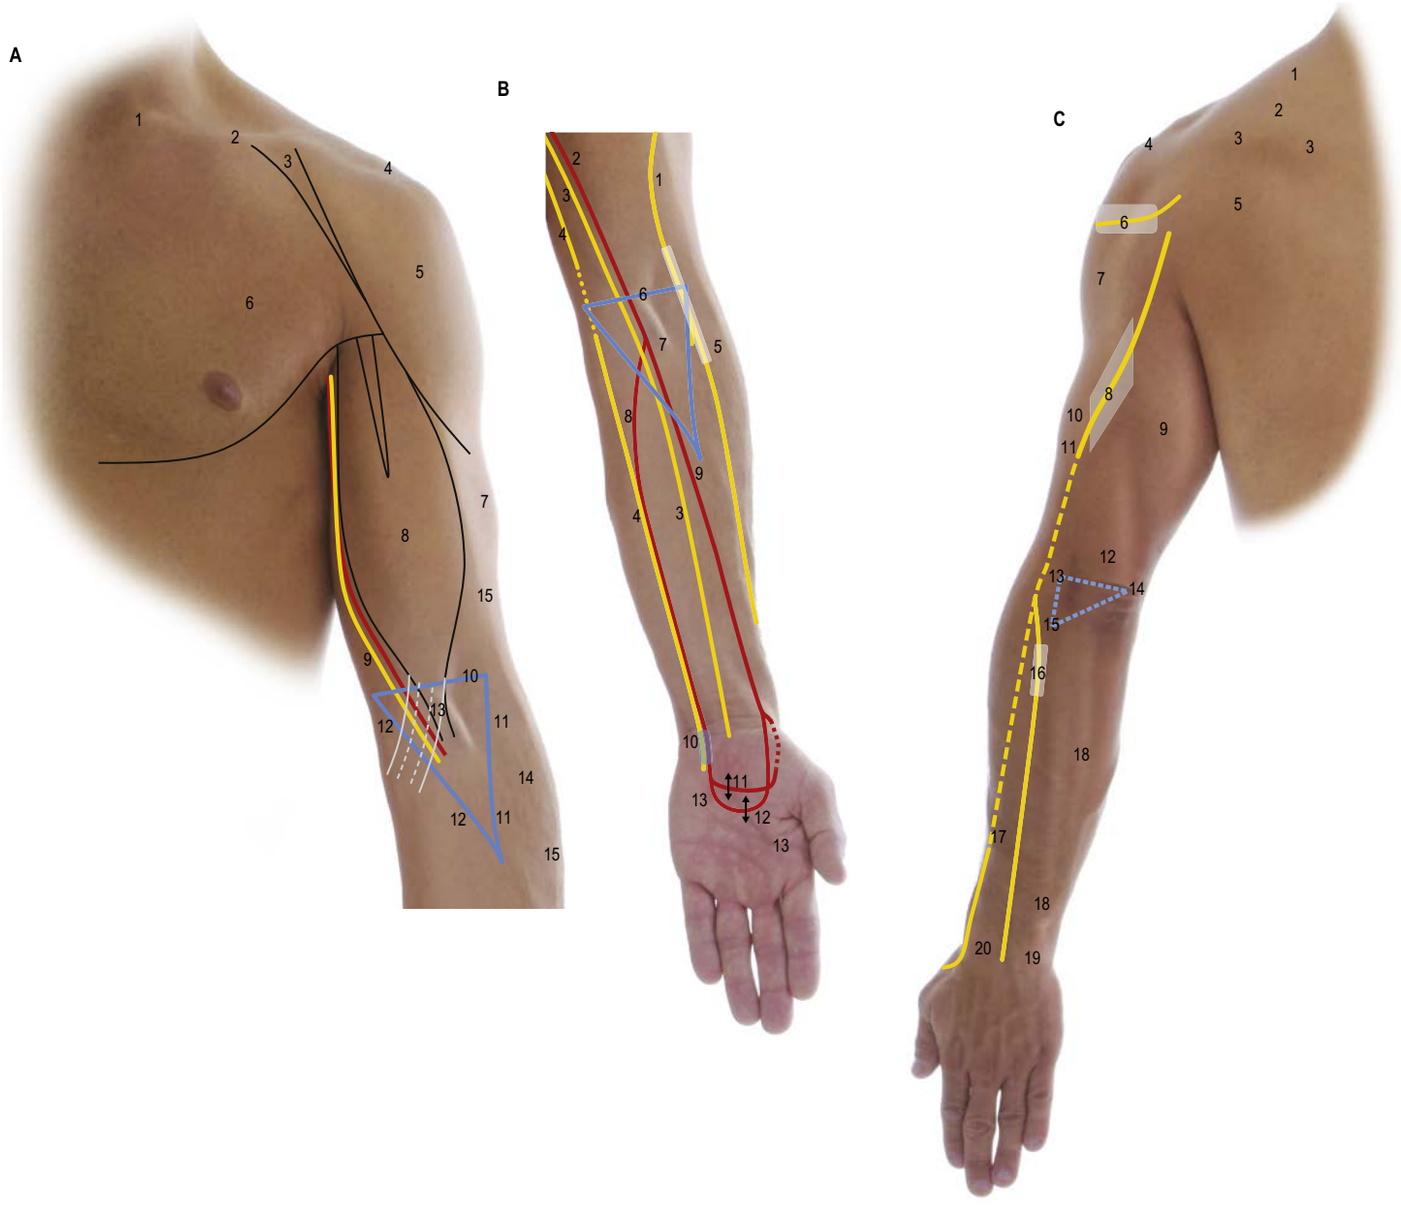

Fig. 48.53 The surface anatomy of the upper limb. **A**, The anterior aspect of the left pectoral girdle, arm and elbow. Key: 1, sternoclavicular joint; 2, clavicle; 3, infraclavicular fossa/deltopectoral triangle, and deltopectoral groove running inferolaterally; 4, acromion; 5, deltoid; 6, pectoralis major; 7, lateral head of triceps; 8, biceps brachii; 9, median nerve and brachial artery running anterior to triceps medial head; 10, epicondylar line and borders of cubital fossa (blue); 11, brachioradialis; 12, pronator teres; 13, biceps tendon (black) and aponeurosis (grey) passing inferomedially; 14, extensor muscle mass of the forearm; 15, cephalic vein. **B**, The anterior aspect of the left elbow, forearm and hand. Key: 1, radial nerve; 2, brachial artery; 3, median nerve; 4, ulnar nerve (dashed part of line shows nerve passing posterior to the medial epicondyle); 5, zone of radial nerve bifurcation (white): 1.0 ± 2.8 cm distal to the lateral epicondyle; 6, cubital fossa borders (blue); 7, biceps tendon with brachial artery bifurcation located medially; 8, ulnar artery; 9, radial artery; 10, pisiform with the ulnar (Guyon's) canal (blue) laterally; 11, deep palmar arch, located 4.0 ± 0.8 cm distal to the distal wrist crease); 12, superficial palmar arch located 5.2 ± 0.8 cm distal to the distal wrist crease); 13, proximal palmar crease. **C**, A posterior view of the left pectoral girdle, arm, elbow and forearm. Key: 1, trapezius; 2, supraspinatus; 3, spine of scapula; 4, acromion; 5, infraspinatus; 6, zone of axillary nerve passing around proximal humerus (white): 6.0 ± 1 cm from proximal humeral margin; 7, deltoid; 8, radial nerve and its zone of passage around spiral (radial) groove (white): enters the spiral groove 47 ± 3% and leaves it 61 ± 3% of the way down a line from greater tubercle to lateral epicondyle of the humerus; 9, triceps, long head; 10, triceps, lateral head; 11, radial nerve piercing lateral intermuscular septum 67 ± 5% of the way down a line from greater tubercle to lateral epicondyle of the humerus; 12, triceps tendon; 13, lateral epicondyle and borders of anconeus triangle (blue dashed line); 14, olecranon and olecranon bursa; 15, radial head; 16, zone of posterior interosseous nerve winding around radial neck (white): 2.5 ± 0.5 cm distal to radial head; 17, superficial radial nerve emerging from between the tendons of brachioradialis and extensor carpi radialis longus approximately 8.5 ± 1.5 cm proximal to radial styloid process; 18, posterior border of ulna; 19, ulnar head; 20, dorsal radial tubercle.

The medial border of the scapula, superior to the level of the scapular spine, is covered by trapezius and, therefore, difficult to palpate. Below the spine, the medial border is palpable down to the inferior angle. Although covered by teres major and latissimus dorsi, the inferior angle is also palpable when approached from below, and can be seen and/or palpated as it moves around the thoracic wall during movements of the pectoral girdle. The inferior angle is located at the level of the spinous process of T7 and overlies the seventh rib; it is a convenient landmark from which the ribs can be counted along the lateral chest wall, e.g. when a thoracotomy is being performed.

The infraclavicular fossa is visible as a small depression in the skin located over the deltopectoral triangle, inferior to the clavicle between

the clavicular attachments of pectoralis major and deltoid, at the junction of the convex medial and concave lateral parts of the clavicle (see Fig. 48.53A). The apex of the coracoid process lies approximately 2.5 cm below the clavicle immediately lateral to this fossa, and is covered by the anterior fibres of deltoid. Deep palpation lateral to the coracoid process and through deltoid reveals the lesser tubercle of the humerus below the anterior border of the acromion. The greater tubercle of the humerus is the most lateral bony prominence in the shoulder region and is palpable lateral and inferior to the acromion. The greater and lesser tubercles can be felt moving under an examining finger during lateral and medial glenohumeral joint rotation. The vertical groove of the intertubercular sulcus (bicipital groove) is palpable between the tubercles; regional tenderness occurs in bicipital tendinitis. When the arm is abducted, the head of the humerus can be palpated on deep pressure at the apex of the axilla.

The shaft of the humerus is covered by overlying muscles and is not easily palpable. Distally, the medial epicondyle of the humerus is both visible and palpable, particularly when the elbow is flexed, and can be traced proximally to the medial supracondylar ridge. The ulnar nerve passes posterior to the medial epicondyle and can be rolled from side to side just proximal to the epicondyle (**Fig. 48.53B**). The lateral epicondyle of the humerus is less prominent, but its posterior surface is palpable and its lateral margin can be traced proximally on deep palpation to the lateral supracondylar ridge. Inspection of the posterior surface of an extended elbow reveals a depression lateral to the midline, bounded laterally by the raised mass of the superficial forearm extensor muscles, and medially by the lateral side of the olecranon. The floor of this depression contains the posterior surface of the lateral epicondyle of the humerus superiorly, and the head of the radius covered by the anular ligament inferiorly. Rotations of the radial head are palpable during forearm pronation and supination. The humero-radial part of the elbow joint forms a palpable transverse depression/sulcus between the lateral epicondyle and the radial head.

The posterior surface of the olecranon is subcutaneous; the freely mobile subcutaneous olecranon bursa overlies the olecranon. When the elbow is extended, the apex (tip) of the olecranon lies on a line level with the medial and lateral humeral epicondyles (see Fig. 48.53B). When the elbow is flexed, the apex of the olecranon descends and the three bony points then form a triangle. This relationship is lost following elbow dislocation or avulsion fracture of the olecranon.

The elbow joint is situated 2 cm below a line joining the two humeral epicondyles. It slopes downwards and medially from its lateral extremity. When the elbow is fully extended with the forearm and hand in supination, the valgus angulation at the elbow (carrying angle) is normally 165° in females and 175° in males. The angle is obscured in full forearm pronation and disappears on full elbow flexion, when the shafts of the ulna and humerus are moved into the same plane. The elbow joint can be accessed with a needle from a posterior perspective via the anconeus triangle; the borders of the triangle join the olecranon, radial head and lateral epicondyle of the humerus.

The posterior border of the ulna is subcutaneous and palpable from the olecranon superiorly to the styloid process inferiorly (see Fig. 48.53C). Its position corresponds to the longitudinal furrow that is visible on the posterior forearm when the elbow is fully flexed and marks the border between the anterior and posterior compartments of the forearm. In contrast, the radial shaft is covered by muscles and can only be felt indistinctly. The rounded head of the ulna forms a surface elevation on the medial side of the posterior surface of the wrist (**Fig. 48.54B**), especially when the forearm and hand are pronated. The ulnar styloid process projects distally from the posteromedial aspect of the ulnar head: a palpable depression distal to the ulnar head overlies the ulnar collateral ligament and triangular articular (fibrocartilage) disc covering the distal ulna.

The expanded distal end of the radius forms a slight surface elevation on the lateral side of the wrist and can be traced inferiorly to the radial styloid process, located immediately posterior to the tendon of abductor pollicis longus. The posterior aspect of the lower end of the radius is partly obscured by the extensor tendons but is easily palpated. The prominent dorsal radial (Lister's) tubercle is both visible and palpable, and aligns with the web space between digits 2 (index) and 3 (middle) (see Fig. 48.54B; **Fig. 48.54C**). The tendon of extensor pollicis longus sits medial to the tubercle in extensor compartment III, and the tendons of extensor carpi radialis longus and brevis sit lateral to the tubercle in extensor compartment II.

The dorsal aspects of the trapezium and of each of the metacarpal bones are partially palpable around the margins of the corresponding extensor tendons (see Fig. 48.54B). The heads of the metacarpal bones form the prominences of the knuckles, and are most obvious during flexion of the digits. On the dorsal aspect of the hand, each metacarpophalangeal joint line forms a palpable depression passing lateral and medial to the digital extensor tendon, and alternating digit flexion/extension aids identification. The joint can be aspirated or injected from this perspective. Palpation distal to the metacarpal head reveals the flared base of the corresponding proximal phalanx. The interphalangeal joints are palpable on the dorsolateral and dorsomedial aspects of a flexed digit just distal to the prominences formed by the heads of the proximal and middle phalanges.

The radiocarpal (wrist) joint is identified between the distal ends of the radius and ulna and the proximal carpal bones on flexion and extension of the wrist. There may be three transverse creases, proximal, intermediate and distal, on the flexor aspect of the wrist. Only the distal and intermediate creases are constant; the intermediate may be the de facto proximal crease when there are only two creases. When three creases are present, the most proximal marks the proximal limit of the flexor synovial sheaths, the intermediate overlies the radiocarpal joint and the distal crease sits 0.5 ± 0.3 cm proximal to the proximal border of the flexor retinaculum. The crease overlying the radiocarpal joint gently curves between the radial and ulnar styloid processes (**Fig. 48.54A**). The radial styloid process normally sits 1 cm distal to the ulnar styloid process. Alteration of this arrangement can indicate a fracture.

Four of the carpal bones are palpable. The pisiform is both visible and palpable on the palmar aspect of the medial wrist at the base of the hypothenar eminence. It is often overlain by the distal wrist crease. It can be moved over the articular surface of the triquetrum when the wrist is flexed passively. The hook of the hamate lies approximately 2.5 cm distal to the pisiform, in line with the ulnar border of the ring finger. It can also be located at the intersection of two lines: the index–metacarpal–pisiform line, that joins a point centred on the pisiform to a point overlying the midline of the metacarpal of the index finger at the proximal palmar crease, and the ring–metacarpal line, that joins a point centred on the metacarpal head of the ring finger to a point at the junction of the medial and middle one-thirds of the distal wrist crease (Cobb et al 1993). The hook of the hamate can be felt on deep palpation; the superficial division of the ulnar nerve can often be rolled from side to side over the palmar surface of the hook. The tubercle of the scaphoid is situated at the base of the thenar eminence, in line with the tendon of flexor carpi radialis, and in many individuals forms a small visible elevation. Immediately distal to it, but covered by the muscles of the thenar eminence, the tubercle of the trapezium can be identified on deep palpation.

The distal wrist crease normally sits distal to the lunate, overlies the pisiform and sits within 0.5 ± 0.3 cm (range 0.4–1.1 cm) of the proximal border of the flexor retinaculum (Cobb et al 1993). The proximal and distal edges of the flexor retinaculum, and therefore the surface position of the carpal tunnel, can be mapped according to its palpable bony attachments; medially to the pisiform and the hook of the hamate and laterally to the tubercles of the scaphoid and trapezium (superficial lamina) and to the medial lip of the groove on the trapezium (deep lamina) (see Fig. 48.54A).

Musculotendinous landmarks

Deltoid can be identified when the arm is abducted against resistance. The deltoid tendon is palpable approximately halfway down the lateral aspect of the shaft of the humerus. Its anterior border can be traced superomedially across the anterior aspect of the humerus and the tendon of pectoralis major, to the lateral clavicle; it forms the lateral boundary of the deltopectoral triangle (see Fig. 48.53A, Video 48.1). The posterior border runs superomedially from the posterior aspect of the deltoid tendon and reaches the crest of the scapular spine near its medial end. The normal rounded contour of the shoulder is produced by deltoid covering the lateral aspect of the greater tubercle of the humerus. Shoulder dislocation results in the loss of the normal rounded contour of the shoulder because the greater tubercle is displaced medially, and deltoid consequently descends vertically to its humeral attachment. Supraspinatus and infraspinatus are visible and palpable above and below the scapular spine, respectively (see Fig. 48.53C).

The lower border of pectoralis major forms the anterior axillary fold. It is visible and palpable when an abducted shoulder is adducted against resistance, e.g. by firmly pressing a hand on to the hip. The clavicular head of pectoralis major can be felt and seen to contract when flexing the shoulder from 90° against resistance; the sternocostal head becomes visible when extending a flexed shoulder against resistance.

The posterior axillary fold formed by latissimus dorsi and the underlying teres major reaches a lower level on the humerus than the anterior axillary fold. When the abducted shoulder is adducted against resistance, the posterior axillary fold is accentuated and the lateral border of latissimus dorsi can be traced inferomedially to its attachment to the iliac crest. When the upper limb is raised above the head, the lower five

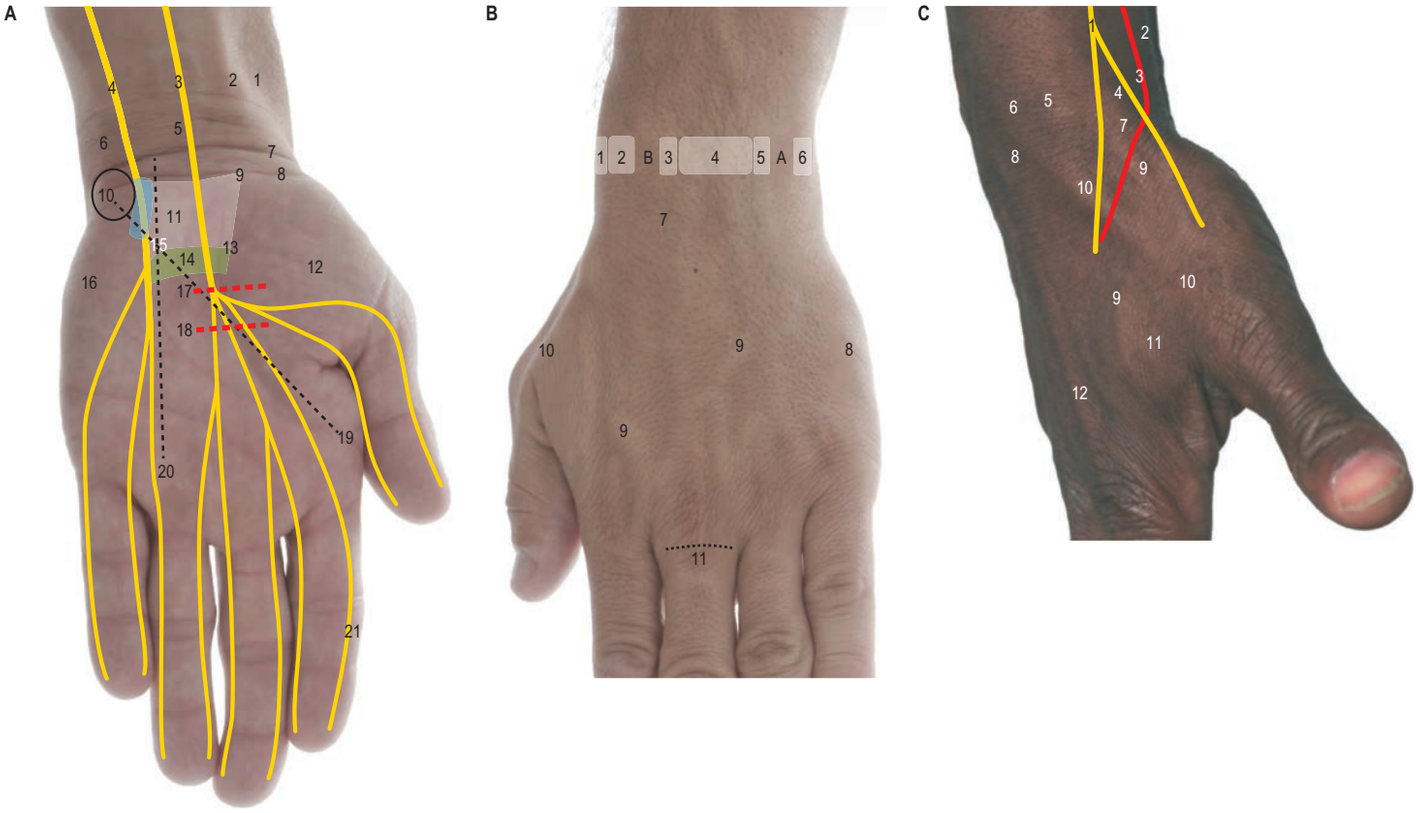

Fig. 48.54 The surface anatomy of the wrist and hand. **A**, The ventral hand and wrist. Key: 1, radial artery; 2, flexor carpi radialis tendon; 3, median nerve; 4, ulnar nerve, passing through the ulnar (Guyon's) canal (blue) in the palm; 5, palmaris longus tendon; 6, flexor carpi ulnaris tendon; 7, proximal transverse wrist crease: marks the line of the radiocarpal (wrist) joint; 8, distal transverse wrist crease: sits 0.5 ± 0.3cm proximal to the proximal boundary of the carpal tunnel; 9, scaphoid tubercle; 10, pisiform (black oval): aligned with distal wrist crease; 11, flexor retinaculum (white shading); 12, thenar eminence; 13, trapezium tubercle; 14, aponeurotic continuation of the flexor retinaculum (green shading); 15, hook of hamate at the intersection of (19) and (20), with the superficial branch of ulnar nerve passing anteriorly; 16, hypothenar eminence; 17, distal extent of deep palmar arterial arch (4.0 ± 0.8 cm from the distal wrist crease); 18, distal extent of superficial palmar arterial arch (5.2 ± 0.8 cm from the distal wrist crease); 19, index–metacarpal–pisiform line; 20, ring–metacarpal line; 21, positions of palmar neurovascular bundles. **B**, The dorsal hand and wrist. Key: 1–6, first to sixth extensor compartments of the wrist; 7, radiocarpal joint needle insertion point; 8, hypothenar eminence; 9, dorsal venous network of the hand; 10, extensor pollicis longus tendon; 11, extensor tendon and metacarpophalangeal joint line; A, head of the ulna; B, dorsal radial (Lister's) tubercle. **C**, The anatomical snuff-box. Key: 1, superficial branch of radial nerve branching 4–5cm proximal to the radial styloid process; 2, flexor carpi radialis tendon; 3, radial artery; 4, extensor compartment I, containing abductor pollicis longus and extensor pollicis brevis; 5, extensor compartment II, containing the tendons of extensors carpi radialis longus and brevis; 6, dorsal radial (Lister's) tubercle; 7, radial styloid process; 8, radiocarpal (wrist) joint needle insertion point; 9, cephalic vein; 10, extensor pollicis longus tendon; 11, first dorsal interosseous muscle; 12, extensor digitorum tendon.

or six serrations of serratus anterior are visible on the lateral aspect of the thorax, curving downwards and forwards to interdigitate with the serrations of external abdominal oblique.

Biceps brachii produces a visible elevation on the anterior arm; the shallow medial and lateral bicipital grooves marking its medial and lateral borders (see Fig. 48.53A). It tapers superiorly, where it is covered by pectoralis major, and inferiorly where it continues as the biceps tendon just above the elbow joint. Flexion of the elbow against resistance aids identification of the muscle and of the bicipital tendon, which can be held between finger and thumb and traced inferiorly into the cubital fossa. With the elbow held in resisted flexion, the sharp upper margin of the bicipital aponeurosis can be traced passing inferomedially over the elevated mass of the superficial group of forearm flexor muscles. Coracobrachialis passes inferolaterally from the coracoid process, emerges from the lateral axillary wall and forms a rounded ridge near to the upper part of the medial side of biceps.

On the posterior arm, the lateral head of triceps forms a laterally placed elevation, inferior to the posterior border of deltoid (see Fig. 48.53C). Triceps can be made visible by extending the elbow against resistance. On the medial side, the rounded mass produced by the long head of triceps passes superiorly and disappears deep to deltoid.

Brachioradialis is the most superficial muscle on the lateral side of the anterior forearm. When the elbow is flexed against resistance whilst in a mid-pronation–supination position, brachioradialis stands out as a prominent ridge extending upwards beyond the level of the elbow joint to the lower lateral side of the arm. The medial border of brachioradialis marks the boundary between the anterior and posterior compartments of the forearm.

The three borders of the cubital fossa can be mapped out anterior to the elbow by a line joining the medial and lateral humeral epicondyles (superiorly), brachioradialis (laterally) and pronator teres (medially) (see Fig. 48.53A–B). Pronator teres passes inferolaterally from the medial epicondyle to a point approximately halfway down the radial shaft; its rounded belly is palpable and often visible during resisted forearm pronation.

The rounded mass of the superficial forearm flexor muscles is visible in the upper medial forearm, and that of the extensor muscle mass is visible in the upper lateral forearm. The lines of travel of the superficial forearm muscles can be mapped out according to their attachment points. Inflammation of the common flexor or extensor tendons (epicondylitis) can be indicated by tenderness to palpation over their respective tendinous origins on the humeral epicondyles.

Palpating lateral to flexor carpi radialis, 3–4cm proximal to the wrist crease, reveals the muscle belly of flexor pollicis longus (flexing and extending the thumb will confirm the correct placement of the examining finger). The area on the medial side of flexor carpi radialis tendon is packed with important structures. The median nerve is either covered by, or situated just lateral to, the tendon of palmaris longus. The latter can be identified by gently pinching the tips of the digits together and partially flexing the wrist (see Fig. 48.54A). Near to the wrist, the median nerve lies very close to the skin and can, therefore, be injured by relatively superficial lacerations. When palmaris longus is absent, only a thin

covering of subcutaneous fat and deep fascia separate the skin and nerve. The four tendons of flexor digitorum superficialis lie deep to the median nerve; the tendons to the middle and ring fingers lie anterior to those for the index and little fingers as they pass deep to the flexor retinaculum, and can be felt and seen to move during finger flexion and extension. Deeper still are the tendons of flexor digitorum profundus. The broad tendon of flexor carpi ulnaris is easily palpated passing to the pisiform on the medial (ulnar) side of the anterior wrist; the ulnar nerve, artery and venae comitantes lie along its lateral (radial) edge. Any sharp injury that cuts through the tendon usually has enough energy to sever the ulnar neurovascular bundle.

When the thumb is fully extended, the depression of the anatomical snuff-box is visible on the lateral aspect of the wrist immediately distal to the radial styloid process (see Fig. 48.54C). The snuff-box is bounded on its anterolateral side by the tendons of abductor pollicis longus (laterally) and extensor pollicis brevis (immediately medial), and on its posteromedial side by the tendon of extensor pollicis longus. Running a finger along extensor pollicis brevis may enable palpation of the superficial radial nerve, which can be rolled from side to side on the tendon. The cephalic vein passes over the roof of the snuff-box, where it is visible and palpable, and the pulsation of the radial artery can be palpated deeply on its floor.

The tendons located within the six extensor compartments of the wrist are subcutaneous and palpable (see Fig. 48.54B). Compartment I (containing abductor pollicis longus and extensor pollicis brevis) sits over the lateral radius. Regional tenderness to palpation occurs in de Quervain's tenosynovitis. Compartment II (containing extensors carpi radialis longus and brevis) and III (containing extensor pollicis longus) flank the lateral and medial sides of the dorsal radial (Lister's) tubercle, respectively. Compartments V (containing extensor digiti minimi) and VI (containing extensor carpi ulnaris) flank the posterior and medial sides of the ulnar head, respectively. Compartment IV (containing extensors digitorum and indicis) sits between the ulnar head and compartment III. The tendons of extensors carpi radialis longus and brevis can be identified passing over the dorsum of the wrist when the fist is repeatedly clenched and relaxed. The tendons of extensor digitorum are visible and palpable on the dorsal hand with the fingers fully extended. With the wrist in extension and adduction, the tendon of extensor carpi ulnaris is palpable distal to the ulnar styloid as it crosses the wrist. The first dorsal interosseous forms a visible muscular mass on the lateral side of the dorsal hand between the index finger and thumb, especially whilst abducting the index finger against resistance.

The first metacarpal is both visible and palpable on the dorsolateral hand. Its dorsal aspect forms the lateral border of the hand. The raised muscular mass of the thenar eminence, produced by abductor and flexor pollicis brevis overlying opponens pollicis, is located on the lateral side of the palm (see Fig. 48.54A). The less prominent hypothenar eminence is located on the medial side of the palm and is formed by the comparable muscles of the little finger. The medial aspect of the hypothenar eminence forms the medial border of the hand.

Vessels, pulses and nerves

Arteries

The brachial artery travels along the medial arm in the depression posterior to coracobrachialis and subsequently along the groove to the medial side of biceps, to a point just medial to the bicipital tendon at the level of the radial head/neck (see Fig. 48.53A–B). Its pulsations are palpable along this line of travel and proximal to the bicipital aponeurosis, via compression against the humerus. Brachial artery catheterization just proximal to the aponeurosis is used for coronary angiography or cardiac catheterization. The ability to compress the brachial artery against the humerus makes the arm the favoured site for non-invasive blood pressure measurement. The median nerve is intimately related to the brachial artery throughout its course in the arm. Proximally, it sits lateral to the artery; around the midpoint of the arm, it passes anterior to the artery and descends on its medial side to the cubital fossa.

The radial and ulnar arteries originate in the anterior forearm at a point situated medial to the bicipital tendon at the level of the lower head/neck of the radius (see Fig. 48.53B). From here, the ulnar artery passes inferomedially to a point one-third of the way down flexor carpi ulnaris (which passes along a line joining the medial humeral epicondyle to the pisiform). The ulnar artery and nerve then pass inferiorly to a point just lateral to the pisiform along the line of flexor carpi ulnaris, with the ulnar artery lying on the lateral (radial) side of the nerve. The radial artery passes inferolaterally through the forearm, from its point of origin to a point just lateral to the tendon of flexor carpi radialis, anterior to the distal radius. The upper part of its course can be represented by a line that passes deep to the medial part of the elevation produced by brachioradialis on the anterior aspect of the forearm. At the wrist it passes posteriorly, deep to the tendons of abductor pollicis longus and extensor pollicis brevis, and enters the anatomical snuff-box, where its pulsations are palpable.

The radial pulse is palpable on the anterior (volar) aspect of the wrist between the tendon of flexor carpi radialis medially and the radial styloid process laterally. This is the simplest pulse to palpate during routine patient examination. The pulse of the ulnar artery is usually only palpable using deep pressure immediately lateral to the tendon of flexor carpi ulnaris at the wrist; it is difficult to palpate.

The cardinal line of Kaplan is often used to position arteries within the hand and wrist, however, multiple different descriptions of the line are used (Vella et al 2006) thus making it an unreliable reference. The use of bony landmarks and skin creases is preferable. At their most distal extent, the superficial and deep palmar arterial arches are located 5.2 ± 0.8 cm and 4.0 ± 0.8 cm, respectively, distal to the distal wrist crease (McLean et al 2008). Both arterial arches sit proximal to the proximal palmar crease (see Figs 48.53B, 48.54A). The digital neurovascular bundles pass along the medial and lateral sides of the dorsal and palmar (volar) surfaces of the digits, and can be anaesthetized in these positions via the web space.

Sites for arterial cannulation

At the wrist, the radial artery is commonly used for arterial cannulation for arterial blood sampling and blood pressure monitoring. Thrombosis or vasospasm of the radial artery at this site should not normally jeopardize the circulation to the hand since the interconnecting palmar arterial arches provide a collateral circulation to the hand. Allen's test, and ideally Doppler ultrasound, should be performed prior to invasive procedures to determine the presence of collateral circulation from the ulnar artery.

Allen's test

Allen's test examines the patency of the interconnection between the superficial and deep palmar arches, and determines whether either artery is capable of maintaining the arterial supply to the hand in isolation. To perform the test, the radial and ulnar arteries of one hand are compressed by the examiner's thumbs. The forearm is then elevated and the hand exsanguinated by clenching the fist. The hand is then opened while arterial compression is continued. The palm of the hand appears pale, unless there is an anomalous arterial supply, e.g. from a persistent median artery. The rapid return of a normal pink colour to the palmar skin following removal of digital pressure from the ulnar artery suggests it is capable of perfusing the hand adequately in isolation. If the palmar skin remains pale, it must be assumed either that there is a distal obstruction to the artery or that the artery cannot adequately perfuse the hand in isolation. For comparison, the test may be repeated with release of digital pressure on the radial artery.

Veins

The superficial veins of the upper limb are usually visible and palpable, especially when a tourniquet occludes venous return proximally. At the wrist, the cephalic vein consistently passes over the roof of the anatomical snuff-box (see Fig. 48.54C) and the dorsolateral aspect of the distal radius. Here, it sits next to the superficial branch of the radial nerve. The cephalic vein ascends the anterolateral forearm and the lateral arm in the groove lateral to biceps brachii. Superiorly, it ascends the deltopectoral groove to the deltopectoral triangle, where it pierces the clavipectoral fascia to enter the axillary vein.

The median cubital and basilic veins may be identified over the cubital fossa. In the proximal forearm, the cephalic vein runs alongside the lateral cutaneous nerve of the forearm. The veins are frequently covered by fat, especially in the female, which makes them difficult to identify. The median cubital vein usually arises from the cephalic vein approximately 2.5 cm distal to the lateral epicondyle of the humerus, and runs upwards and medially over the bicipital aponeurosis to join the basilic vein approximately 2.5 cm above the transverse skin crease of the elbow. The median vein of the forearm drains the venous plexuses on the palmar surface of the hand. It ascends the anterior forearm and usually joins either the basilic vein or the median cubital vein; sometimes, it divides into two branches, just distal to the elbow, one of which joins the basilic vein and the other the cephalic vein.

Venepuncture

Commonly accessed superficial veins include the cephalic or median cubital vein at the cubital fossa, and the dorsal venous network of the hand. The cephalic vein may also be accessed over the distal radius and anatomical snuff-box. The latter site has many advantages for placing an indwelling cannula when a lengthy period is contemplated, although the vein lies close to the superficial branch of the radial nerve. The superficial veins of the upper limb often sit in close proximity to cutaneous nerves, and may be vulnerable to iatrogenic injury during venepuncture (Wallis et al 2018).

A high bifurcation of the brachial artery is seen occasionally and may produce an anomalous superficial ulnar artery that descends superficial to the common origin of the forearm flexor muscles. When this occurs, the ulnar artery, although deep to the deep fascia, may lie subcutaneously and pass superficial to the bicipital aponeurosis where its pulsation may be observed. Such an artery is therefore at risk of puncture during median cubital vein access.

Lymph nodes

Supratrochlear lymph nodes lie next to the basilic vein in the region of the medial supracondylar ridge of the humerus. If enlarged, they may be palpated along the line of the vein, a few centimetres above the elbow joint.

Nerves

The trunks of the brachial plexus lie in the posterior triangle of the neck posterior to the subclavian artery (its pulsations are palpable), in the angle between the clavicle and the lower posterior border of the clavicular head of sternocleidomastoid. The upper trunk can be palpated by passing the fingers inferiorly along the vertical groove between scalenus anterior and scalenus medius. This interscalene groove can be visualized by asking the subject to sniff (inhale) rapidly through their nose. The divisions of the brachial plexus pass posterior to the middle one-third of the clavicle; the cords of the plexus sit deep to pectoralis minor (landmarked passing inferomedially from the coracoid process) around the second part of the axillary artery. Several of the main branches of the brachial plexus may be damaged along their course in the upper limb by relatively minor procedures (**Table 48.6**).

The axillary nerve and circumflex humeral vessels pass around the posterior and lateral sides of the proximal humerus, close to the surgical neck, approximately 5 cm from the posterior edge, and 6 cm from the anterior edge, of the acromion (Cetik et al 2006). Bono et al (2000) found the axillary nerve to lie 6 ± 1 cm from the proximal humerus, passing within 2 ± 1 cm of the surgical neck of the humerus (see Fig. 48.53C).

The radial nerve passes inferolaterally along, or within 2 cm of, the spiral groove on the posterior humerus (see Fig. 48.53C). The distance from the acromion to a line passing through the humeral epicondyles can be used as a baseline measurement; the radial nerve reaches the spiral groove 47 ± 3%, leaves it 61 ± 3%, and pierces the lateral intermuscular septum 67 ± 5% of the way down this line (Cox et al 2010, Cho et al 2013). The radial nerve then passes inferiorly, approximately 1 cm lateral to the tendon of biceps, and bifurcates into the posterior interosseous and superficial branch of the radial nerve 1 ± 2.8 cm distal to the lateral humeral epicondyle (Cox et al 2010) (see Fig. 48.53B). The posterior interosseous nerve winds around the radial neck 2.5 ± 0.5 cm distal to the radial head (Cox et al 2010); this is an important surgical consideration when making an incision to expose the radial head. The nerve then passes inferiorly through the posterior forearm to a point midway between the ulnar head and the dorsal radial tubercle. The superficial branch of the radial nerve passes inferiorly, deep to brachioradialis, and becomes superficial by passing between brachioradialis and extensor carpi radialis longus approximately 8.5 cm proximal to the radial styloid process (Auerbach et al 1994, Park et al 2010). It then branches 4–5 cm proximal to the radial styloid process and its branches are palpable as they pass over the tendon of extensor pollicis longus where it borders the anatomical snuff-box.

The median nerve is intimately related to the brachial artery throughout its course in the arm. In the forearm, it passes along a line joining a point just medial to the pulsating brachial artery in the cubital fossa to either the tendon of palmaris longus, or to a point just lateral to the tendon at the wrist (see Fig. 48.53B).

The ulnar nerve passes posterior to the medial epicondyle and can be rolled from side to side just proximal to the epicondyle (see Fig. 48.53B). In the forearm and proximal hand, its course corresponds to a line drawn from the base of the posterior aspect of the medial epicondyle of the humerus to the lateral side of the pisiform, where the nerve passes through the ulnar (Guyon's) canal and its superficial branch often passes superficial to the hook of the hamate. Deep pressure at these bony landmarks can produce paraesthesia in the distribution of the nerve. Proximally, the ulnar nerve sits deep to flexor carpi ulnaris; distally, it sits lateral to the tendon of flexor carpi ulnaris and medial to the ulnar artery and its venae comitantes.

Dermatomes

Knowledge of the extent of individual dermatomes is largely based on clinical evidence. The dermatomes of the upper limb arise from the fifth to the eighth cervical and first thoracic ventral rami. The seventh cervical ventral ramus supplies the central part of the hand (**Fig. 48.55**, see Figs 48.14, 48.15). Considerable overlap exists between adjacent dermatomes innervated by nerves derived from consecutive spinal cord segments.

Myotomes

The predominant segmental origin of the nerve supply for each of the muscles of the upper limb and for the movements that take place at the joints of the upper limb are summarized in Tables 48.1–48.4.

Reflexes

Biceps jerk (C5, C6) The elbow is flexed to a right-angle (90°) and the forearm slightly pronated. A finger is placed on the biceps tendon and struck with a percussion hammer; this should elicit elbow flexion and slight supination of the forearm.

Triceps jerk (C6–C8) The upper limb is supported at the wrist and the elbow flexed to a right-angle. Triceps tendon is struck with a percussion hammer just proximal to the olecranon; this should elicit extension of the elbow.

Radial jerk (C7, C8) The radial jerk is a periosteal, and not a tendon, reflex. The elbow is flexed to a right-angle and the forearm placed in the mid-pronation/supination position. The radial styloid is struck with the percussion hammer. This elicits contraction of brachioradialis, which should elicit flexion of the elbow.

Nerve blocks

Brachial plexus There are three common approaches to achieve anaesthetic blockade of the brachial plexus: the interscalene,

TABLE 48.6 Common sites for iatrogenic upper limb nerve injury in primary care

Nerve	Site	Procedure
Axillary	Lateral surface of deltoid	Intramuscular injection
Median	Roof of the cubital fossa	Venepuncture into the basilic or median cubital vein
	Carpal tunnel or midline anterior wrist	Steroid injection into the carpal tunnel
Radial	Lateral border of the cubital fossa or in the groove between brachioradialis and biceps brachialis	Venepuncture into the cephalic vein
Superficial branch of radial	Roof of the anatomical snuff-box	Venepuncture into the cephalic vein
Ulnar	Medial epicondyle	Steroid injection for medial epicondylitis
Lateral and medial cutaneous of forearm	Cubital fossa	Venepuncture

supraclavicular and axillary routes. Ultrasound guidance is commonly used.

The interscalene route requires identification of the interscalene groove. The patient is asked to sniff, an action that involves the scalene muscles as accessory muscles of respiration. A needle is inserted perpendicular to the skin and enters the interscalene groove. Paraesthesia may be elicited, and local anaesthetic solution is injected. There is a risk that some local anaesthetic may move in a retrograde direction and reach the cervical epidural space. The proximal nature of the block means that there is almost always some involvement of the phrenic nerve, and sympathetic block (as evidenced by a Horner's syndrome) is universal.

The supraclavicular route places local anaesthetic solution in the plane occupied by the trunks of the brachial plexus as they emerge between scalenus anterior and medius on the first rib, immediately posterior to the third part of the subclavian artery. The site of injection is 2 cm above the midpoint of the clavicle. The needle is directed backwards, inwards and downwards to make contact with the upper surface of the first rib. During this procedure, the patient will usually report paraesthesia within the upper limb, which indicates that the needle is correctly placed; preliminary aspiration ensures that a major vessel has not been punctured. If the first rib is missed, there is the risk of producing a pneumothorax. There is often a transient Horner's syndrome, caused by diffusion of the local anaesthetic towards the stellate ganglion.

The axillary approach blocks the nerves as they group around the axillary artery.

Wrist Anaesthesia of the palm of the hand (except for the lateral surface of the thumb base) can be achieved by blockade of the ulnar and median nerves at the wrist (see Video 51.9). The ulnar nerve may be blocked via a needle inserted lateral to the tendon of flexor carpi ulnaris at the wrist. The median nerve may be blocked via a needle inserted at the level of the proximal wrist crease between the tendons of palmaris longus and flexor carpi radialis.

The radial nerve, which supplies the dorsal skin of the hand, may be blocked by injecting local anaesthetic in the subcutaneous tissues around the dorsolateral wrist, where branches of the nerve can be palpated as they pass over tendon of extensor pollicis longus, especially during resisted extension of the thumb.

Digital nerves

The digital nerves lie on either side of the flexor sheath in a plane immediately anterior to the phalanx. Therefore, the needle should be inserted on either side of the base of the digit, just anterior to the anterolateral margin of the phalanx. A common alternative approach to blocking the digital nerves is via a dorsal skin approach; the needle is inserted through the dorsal skin on either side of the base of the proximal phalanx and advanced towards the palmar location of the digital nerves while the local anaesthetic agent is continually infused. This is thought to be less painful than the palmar approach because the dorsal skin is less sensitive than the palmar skin.

CHAPTER
49

Shoulder girdle and arm

The upper limb is differentiated to achieve the complex patterns of stereotactic, non-stereotactic and gestural movements (each with a distinct neurological basis) that enable hand function. The combined movements of the shoulder and elbow bring objects in the hand into the visual field, while the great range of the shoulder and pectoral girdle enable a wide reach. Oculospinal afferents appear to be the most important modulators of the shoulder joint stability needed for *reaching*. An object is first reached and then grasped (increasing both superficial and deep peripheral afferent inputs that enhance proximal shoulder girdle stability (Alizadehkhaiyat et al 2011)), before being *retrieved* into the visual field. The requirements of attention to the visual field define the need for stability in the shoulder girdle: the closer the attention to an object in the centre of the field of vision ('macular vision'), the finer the control of the motion and stability of the shoulder girdle.

The joints of the upper limb become more complex proximodistally. The greatest potential for stability is gained through 'close-packing' (the state of a joint where the greatest stability is achieved for the least energy) in the carpus of the hand, while the range of available motion in each joint becomes more restricted. Close-packing occurs through a lesser, more specific, range of movement in the elbow: the flexed elbow with a supinated forearm is the position for carrying the greatest load with the least energy expenditure or the greatest resistance to fatigue. Close-packing occurs in the glenohumeral joint, so providing stability, but it is almost entirely gained through muscular activity. At the extremes of range, through capsular fibre spiralling, it is costly in terms of muscular energy expenditure, especially on a background of age- and gene-dependent musculotendinous degeneration. The scapulothoracic joint is the least intrinsically stable joint in the body and is entirely dependent on muscular activity for its stability and movement around the fulcrum of the acromioclavicular joint.

For the purposes of this chapter, the junction between the 'arm' and the 'elbow joint' will be taken to be the level at which the radial nerve perforates the lateral intermuscular septum to enter the anterior compartment of the arm, and the ulnar nerve perforates the medial intermuscular septum to gain the posterior compartment of the arm at the elbow.

SKIN AND SOFT TISSUES

Skin

Cutaneous vascular supply

The skin over the lateral end of the clavicle is supplied by the supraclavicular artery, which pierces the deep fascia superior to the clavicle and anterior to trapezius. In most cases, this artery arises from the superficial cervical/transverse cervical artery, but it occasionally arises from the suprascapular artery. The area over deltoid is supplied by the anterior and posterior circumflex humeral arteries. The deltoid branch of the thoracoacromial axis contributes to the blood supply of the anterior aspect of the shoulder via musculocutaneous perforators through deltoid.

The blood supply to the skin of the upper arm may be divided into three regions with separate supplies. The deltoid region is supplied by musculocutaneous perforators, and the medial and lateral regions are supplied by fasciocutaneous perforators (Cormack and Lamberty 1994, Salmon, in Taylor and Razaboni 1994).

The deltoid region is supplied by the posterior circumflex humeral artery via musculocutaneous perforators. After exiting from the quadrangular space, it gives off a descending branch that runs down to the insertion of deltoid and the overlying skin, and an ascending branch that passes superiorly towards the acromion and pierces the edge of deltoid and the deep fascia to fan out and supply the overlying skin.

The medial side of the upper arm is supplied by five or six fasciocutaneous perforators that arise from the brachial artery, the superior ulnar collateral artery and, if present, the single artery to biceps brachii. These perforators pass along the medial intermuscular septum to spread out in the deep fascia and anastomose with perforating vessels superiorly and inferiorly, and from the lateral side. There are virtually no musculocutaneous perforators through biceps or triceps.

The lateral side of the upper arm below deltoid is supplied by perforating vessels from the middle collateral and radial collateral arteries (the terminating bifurcation of the profunda brachii). The middle collateral artery sends perforators to the skin via the lateral intermuscular septum between brachioradialis and triceps, while the radial collateral artery gives off cutaneous perforators via the intermuscular septum between brachialis and brachioradialis. These cutaneous vessels anastomose with those from the medial side.

Cutaneous innervation

The skin over the anterior shoulder region is mobile and accommodates the great mobility of the shoulder girdle. The skin over the posterior aspect of the shoulder girdle is thicker and less mobile, being held to the underlying scapula by coarse connective tissue fibres. The cutaneous innervation reflects this difference in skin quality. The supraclavicular nerves (see Fig. 35.1B) are long, mobile nerves passing deep to platysma before piercing the muscle and the investing cervical fascia over or immediately caudal to the clavicle. The medial clavicular skin, including the skin over the sternoclavicular joint, is innervated by the small, often multifilamentous, medial supraclavicular nerve. The skin over the clavicle and over a variable extent of the anterior chest skin, including a variable extent of the anterior axillary fold, is innervated by the large, middle supraclavicular nerve. This nerve is frequently injured by injudicious incisions for the surgical treatment of fractures of the clavicle; a painful neuroma is a common outcome. The skin over the lateral clavicle, acromion and deltoid region is innervated by the lateral supraclavicular nerve or nerves. The floor of the axilla, together with part of the upper medial aspect of the arm, is supplied by the intercostobrachial nerve (lateral branch of the second intercostal nerve). Occasionally, the lateral branch of the third intercostal nerve contributes to the supply of the skin in the floor of the axilla. The lower aspect of the medial side of the upper arm is supplied by the medial cutaneous nerve of the arm. The lateral aspect of the upper arm is supplied by the upper lateral cutaneous nerve (a branch of the axillary nerve) and the lower lateral cutaneous nerve (a branch of the radial nerve). The posterior aspect is supplied by the posterior cutaneous nerve of the arm (a branch of the radial nerve). Fig. 49.1–49.5 illustrate the approximate areas of sensory loss or disturbance after pre- or postganglionic lesions involving C4–T1.

Soft tissues

Deep fascia

In common with locomotor muscles in the lower limb, the upper limb muscles are attached, in varying degrees, to their surrounding deep fascial envelopes. This arrangement increases the area (footprint) of attachment of a muscle within a fascial compartment, so increasing the effectiveness and efficiency of that muscle. For example, the fasciae overlying the three muscles of the scapular fossae (subscapularis, infraspinatus and supraspinatus) are well attached and thicker medially; the fibro-osseous cuff so formed around the medial parts of the muscles affords a greater area of attachment than would be available if the muscles were attached only to the scapular fossae. The blood supply to the muscles of the upper limb is defined by their fascial compartmentation.

Compartment syndrome of the arm The muscular compartments of the arm (and thigh) are not as well defined as those of the forearm (and leg). Compartment syndrome is less common in trauma of the arm but remains a concern, particularly after extensive reconstruction procedures and high-energy or crushing injuries of the limb.

Fascia over deltoid

The deep fascia over deltoid is thickest anteriorly and posteriorly, and is adherent in a linear fashion to the external aspect of the superficial fibrous septa of the central (lateral) part of that muscle. It blends with the pectoral fascia in front, and with the thick and strong fascia overlying infraspinatus behind. Above, it blends with the periosteum of the lateral part of the clavicle, the thin periosteum of the acromion, the crest of the scapular spine and the cranial part of the medial border of the scapula, caudal to the spine of the scapula, where it blends with the infraspinatus fascia. Below, it is continuous with the deep brachial fascia, blending with the lateral intermuscular septum (Leijnse et al 2008).

Pectoral and axillary fascia

The pectoral fascia is thin over pectoralis major. It is attached medially to the sternum and is continuous with the fascia of the rectus sheath caudally. Cranially, it blends with the periosteum of the clavicle and the anterior aspect of the capsule of the sternoclavicular joint. Laterally, it is continuous with the fascia over deltoid; it forms the roof of the infraclavicular fossa between the muscular attachments of pectoralis major and deltoid to the clavicle. The fascia is loosely adherent to the septum between the sternal and clavicular parts of pectoralis major. Inferolaterally, between pectoralis major and latissimus dorsi, the fascia thickens to form the floor of the axilla as the axillary fascia. At the caudal edge of pectoralis major, a deep lamina of fascia ascends to envelop the caudal border of pectoralis minor; it becomes the clavipectoral fascia at the upper edge of pectoralis minor. The hollow of the armpit is produced mainly by the action of this fascia in tethering the axillary skin to the floor of the axilla; it is sometimes referred to as the suspensory ligament of the axilla. The axillary fascia is pierced by the tail of the breast (see Fig. 53.22A). The pectoral fascia envelops the lateral margin of latissimus dorsi; the deep and superficial layers ensheathe that muscle and are attached behind to the spines of the thoracic and lumbar vertebrae, blending with the thoracolumbar fascia medially and caudally.

Clavipectoral fascia

The clavipectoral fascia is the superior continuation of the deep lamina of the pectoral fascia and the medial continuation of the parietal layer of the subscapular bursal fascia. Laterally, it is continuous with the coraco-acromial ligament above and lateral to the coracoid. It envelops the coracoid blending with the periosteum of the tip of that process, the short head of biceps brachii and coracobrachialis. It covers the interval between those two muscles and pectoralis minor, which it envelops, and then traverses the interval between pectoralis minor and subclavius. It splits around subclavius and is attached to the clavicle anterior and posterior to the groove for subclavius. The posterior layer is contiguous with the deep cervical fascia, a condensation of which forms a tether around the central tendinous part of omohyoid, so indirectly connecting it to the clavicle. The deep aspect of the posterior lamina of the clavipectoral fascia blends with the sheath of the axillary vessels. Medially, it blends with the fascia over the first two intercostal spaces and is attached to the first rib, medial to subclavius. Occasionally, the fascia thickens to form a band between the first rib and coracoid process, the costocoracoid ligament, under which the lateral cord of the brachial plexus is closely applied (Atasoy 2004). The cephalic vein, thoraco-acromial artery and associated veins and lymphatic vessels, and the lateral pectoral nerve all pass through the fascia immediately superior to the upper border of pectoralis minor. This fascia was called the 'clavi-coraco-axillary aponeurosis' by Testut (1904).

Subscapular fascia

The subscapular fascia is thin and attached to the entire circumference of the subscapular fossa. Subscapularis is partly attached to its deep surface medially, which is an example of the extension of the attachment zone of a muscle for more effective action. The fascia extends laterally and blends with the deep layer of the subscapular bursa in front of the tendon of subscapularis and with the external layer of the capsule of the rotator interval of the glenohumeral joint. Inferiorly, it continues as the fascia enveloping teres major.

Infraspinous fascia

The infraspinous fascia covers infraspinatus and is attached to the margins of the infraspinous fossa, except cranially and medially, where there is a loose attachment to the lower aspect of the spine of the scapula. Cranially and laterally, the infraspinatus fascia is continuous with the supraspinatus fascia, creating a single muscular compartment for the two muscles. The deep fibres of deltoid are attached to the infraspinatus fascia over a strip of about 1 cm for the entire length of the spine of the scapula; the examining finger cannot palpate the spine of the scapula from within the space between deltoid and infraspinatus. The fascia is contiguous with the strong lower border of the deltoid fascia along the overlapping posterior border of deltoid.

Supraspinous fascia

The supraspinous fascia completes the osseofibrous compartment containing supraspinatus; it is attached to the scapula around the boundaries of the attachment of supraspinatus. It is thick medially, where supraspinatus attaches to its own fascia, but thinner laterally under the coraco-acromial ligament.

Brachial fascia

The deep fascia of the upper arm, the brachial fascia, is continuous with the fasciae covering deltoid and pectoralis major; it forms a thin, loose covering for the anterior muscles of the arm and a more robust covering for the posterior muscles. Medially, just below the middle of the upper arm, it is perforated by the basilic vein, lymphatic vessels and, at various levels, by branches of the brachial cutaneous nerves.

The fascia is thickest distally, where it contains the brachial muscles in distinct compartments anteriorly and posteriorly, and is defined medially and laterally by tough septa. The lateral intermuscular septum is continuous with the fascia overlying the lateral part of deltoid proximally, and has an upward, thinner extension to the lateral crest of the intertubercular sulcus (groove) contiguous with the fascia over the anterior border of deltoid. It is attached to the supracondylar ridge of the lateral epicondyle of the humerus, and is perforated at the level of the junction of the upper three-fifths and lower two-fifths of the humerus by the radial nerve and the radial collateral branch of the profunda brachii artery passing into the anterior compartment from behind. It provides extension for the zone of attachment of the lateral head of triceps posteriorly, and of brachialis, brachioradialis and extensor carpi radialis longus anteriorly. The medial intermuscular septum extends from the medial lip of the intertubercular sulcus, where it is contiguous with the fascia of teres major, next blends with the aponeurosis of attachment of coracobrachialis to the medial aspect of the humerus, and then passes as a thick septum along the medial aspect of the humerus to the medial supracondylar ridge of the medial epicondyle. It gives attachment to the medial head of triceps posteriorly, and brachialis anteriorly. It is perforated by the ulnar nerve at about the same level as the radial nerve laterally, together with the superior ulnar collateral artery and the posterior branch of the inferior ulnar collateral artery. At the elbow, the brachial fascia is attached to the epicondyles of the humerus, so completing the muscular compartments, and the olecranon of the ulna, and is continuous with the antebrachial fascia.

Axillary neurovascular sheath

The axillary neurovascular sheath is closely contiguous with the posterior aspect of the clavipectoral fascia. The second part of the axillary artery lies behind pectoralis minor; most intimal ruptures of the vessel caused by distraction trauma occur in this part of the vessel.

Spread of infection

Available with the *Gray's Anatomy* e-book

BONES

Clavicle

The clavicle lies almost horizontally at the root of the neck (see Figs 35.13, 48.7A). It is a crank-shaped cantilever that carries the scapula, so enabling the limb to swing clear of the trunk. It transmits part of the weight of the limb to the axial skeleton. The lateral or acromial end of the bone is flattened and articulates with the medial side of the acromion, whereas the medial or sternal end is enlarged and articulates with the clavicular notch of the manubrium sterni and first costal cartilage. The shaft is gently curved and resembles the italic letter *f* in shape, being convex forwards (the antecurve) in its medial two-thirds and concave forwards (the retrocurve) in its lateral third (Fig. 49.6). The inferior aspect of the intermediate two-fifths is grooved in its long axis for the attachment of subclavius. Laterally, the internal architecture of the clavicle is trabecular, with a medullary cavity in the medial two-thirds. The cortical bone is thickest at the transition zone between the antecurve and retrocurve. The female clavicle is typically shorter, thinner, less curved and smoother. Mid-shaft circumference is the most reliable single indicator of sex; a combination of this measurement with weight and length yields more reliable and consistent results. The clavicle is subcutaneous throughout its whole length and accordingly can be palpated for its entire length; the medial (sternal) end forms an expanded, blunt-faced margin of the jugular notch. The anterior border of the lateral (acromial) end is not readily distinguished from the acromion; the attachment of deltoid obscures the anterior aspect of the acromioclavicular joint. By contrast, the posterior border of the lateral end forms the anterior margin of a roughly parabolic hollow under the lateral fibres of trapezius, the posterior border being formed by the anterior border of the spine of the scapula. The hollow will admit at least one palpating finger. If the pulp of the finger is placed on the spine of the scapula as far laterally as the hollow will permit, the nail will inevitably point to the posterior capsule of the acromioclavicular joint; this landmark is always palpable,

During forceful flexion/adduction/protraction of the upper limb across the trunk (e.g. when the scapula is wrenched from the lateral end of the clavicle in thoracoscapular dissociation), the axillary sheath containing the axial vessels and cords of the brachial plexus is forced into pectoralis minor, which acts as a fulcrum or guillotine, around which the vessels angle sharply, so rupturing the arterial intima. Acute neural injuries occur as a result of direct injury (traction, compression, or both) to the nerve trunks, causing acute sensorimotor deficits, arterial adventitial haematoma or acute aneurysm expanding within the axillary sheath to cause the syndrome of causalgia (rapidly progressive, severe pain in the distribution of the affected nerve trunks with neural deficits). Arterial thrombosis following intimal rupture is associated with late nerve deficits as a result of inadequate neural perfusion, local scarring with distortion of the axillary sheath and its contents, and poor posture of the affected limb.

The neurovascular bundle enclosed within the sheath is separated from the subscapular fascia by a 'virtual space' traversed by the subscapular nerves, an arrangement that permits full excursion of subscapularis without distortion of the neurovascular bundle during normal arm movements. The tip of the coracoid can be likened to the tip of the shaft of a steering oar attached to a vessel (the scapula) tethered within the thick clavipectoral fascia: the effect of pectoralis minor acting as an antagonist of trapezius in scapular position and motion control (see below) is optimized by the wide attachment of the clavipectoral fascia and coraco-acromial ligament to the clavicle and scapula (see Fig. 49.18).

When axillary suppuration occurs, the local fascial arrangement affects the spread of pus. Suppuration may be superficial or deep to the clavipectoral fascia. In the former, an abscess would appear at the edge of the anterior axillary fold or in the groove between deltoid and pectoralis major; in the latter, pus would tend to track upwards in the axillary neurovascular sheath and appear at the root of the neck, taking the direction of least resistance. Lymphangitis in the medial aspect of the arm suggests infection deep to the clavipectoral fascia with lymphatic obstruction. When an axillary abscess is incised, the knife should enter the axillary 'base', midway between the anterior and posterior margins and near the thoracic side, to avoid the lateral thoracic, subscapular and axillary vessels on the anterior, posterior and lateral walls, respectively.

even in well-muscled individuals, when other shoulder landmarks can be obscured.

Lateral two-fifths

The lateral two-fifths of the clavicle are flattened and have superior and inferior surfaces, and anterior and posterior borders. The anterior border is concave, thin and roughened, and may be marked by a small deltoid tubercle. The posterior border, also roughened by muscular attachments, is convex backwards. The superior surface is roughened near its margins but is smooth centrally, where it can be felt through the skin. The inferior surface presents two obvious markings. Close to the posterior border, at the junction of the lateral fourth with the rest of the bone, a prominent conoid tubercle gives attachment to the conoid part of the coracoclavicular ligament. A narrow, roughened strip, the trapezoid line, runs forwards and laterally from the lateral side of this tubercle, almost as far as the acromial end (**Fig. 49.6B**). The trapezoid part of the coracoclavicular ligament is attached to it. A small, oval articular facet, for articulation with the medial aspect of the acromion, faces laterally and slightly downwards at the lateral end of the shaft.

Subclavius is attached to the groove on the inferior surface (see Fig. 49.6B). The clavipectoral fascia is attached to the edges of the groove. The posterior edge of the groove runs to the conoid tubercle, where fascia and conoid ligament merge. There is a laterally inclined nutrient foramen lateral to the groove. Deltoid (anteriorly) and trapezius (posteriorly) are attached to the lateral two-fifths of the shaft; both muscles are inserted directly into the clavicle and indirectly into the clavicular periosteum. The coracoclavicular ligaments, attached to the conoid tubercle and trapezoid line (see Fig. 49.6B), transmit the weight of the upper limb to the clavicle, and are counteracted by the cervical part of trapezius, which supports its lateral part (see Fig. 49.18).

Medial three-fifths

The medial three-fifths of the shaft of the clavicle are cylindrical or prismoid in form and have four surfaces, although the inferior surface is often reduced to a mere ridge. The anterior surface is roughened over most of its extent but is smooth and rounded laterally, where it forms the upper boundary of the infraclavicular fossa. The upper surface is roughened medially and smooth laterally. The posterior surface is smooth and featureless medially; its lateral half bears a groove in the long axis of the bone. The inferior surface is marked near its sternal end by a roughened oval impression, which is often depressed below the surface. Its margins give attachment to the costoclavicular ligament, which connects the clavicle to the upper surface of the first rib and its cartilage. Rarely, this area is smooth or raised to constitute an eminence that may form a synovial pseudarthrosis with the upper surface of the first rib; in older subjects, an extra-articular synostosis may form.

The medial three-fifths provide attachment, anteriorly, for the clavicular head of pectoralis major. The clavicular head of sternocleidomastoid is attached to the medial half of the superior surface, but the marking on the bone is not conspicuous. The smooth, posterior surface is devoid of muscular attachments, except at its lower part immediately adjoining the sternal end, where the lateral fibres of sternohyoid are attached. Medially, this surface is related to the lower end of the internal jugular vein (from which it is separated by sternohyoid), the termination of the subclavian vein, and the start of the brachiocephalic vein. More laterally, the clavicle arches in front of the trunks and divisions of the brachial plexus and the third part of the subclavian artery. The thyrocervical trunk and its branches, and the suprascapular and transverse cervical vessels are immediately behind and above the upper aspect of this surface. Subclavius is inserted in the subclavian groove on the inferior surface, and the clavipectoral fascia is attached to the edges of the groove. The posterior lip of the groove is continuous with the conoid tubercle laterally and brings the clavipectoral fascia into continuity with the conoid ligament. A nutrient foramen is found in the lateral end of the groove, running in a lateral direction; the nutrient artery is derived from the suprascapular artery.

Fig. 49.6 The left clavicle, showing sites of muscular and ligamentous attachment and articular surfaces. **A**, Superior view. Key: 1, sternocleidomastoid (clavicular head); 2, sternal end; 3, pectoralis major; 4, trapezius; 5, acromial end; 6, deltoid. **B**, Inferior view. Key: 1, pectoralis major; 2, for costoclavicular ligament; 3, for first costal cartilage; 4, for sternum; 5, sternohyoid; 6, subclavius; 7, deltoid; 8, for acromion; 9, trapezoid line; 10, trapezius; 11, conoid tubercle.

Sternal end

The sternal end of the clavicle is directed medially, downwards and forwards, and articulates with the clavicular notch of the manubrium sterni. The sternal surface, usually irregular and pitted, is quadrangular (sometimes triangular). Its uppermost part is slightly roughened for attachment of the interclavicular ligament, sternoclavicular capsule and articular disc. Elsewhere, the surface is smooth and articular; it extends on to the inferior surface for a short distance, where it articulates with the first costal cartilage. The sternal end of the clavicle projects upwards beyond the manubrium sterni and can be felt and seen easily, forming the lateral wall of the jugular notch, behind which are the cricoid cartilage, cricothyroid membrane, the lower part of the thyroid cartilage of the larynx and the brachiocephalic vein. The sternal ends of each clavicle thus form a guide to the jugular notch: if the sternal end of the clavicle is displaced backwards (by traumatic dislocation), the landmarks of the notch are lost, the trachea is displaced and there will be difficulty breathing. If the trachea is displaced to one side (for instance, by pneumothorax), the features of the larynx cannot be palpated readily.

Ossification

The clavicle begins to ossify before any other bone in the body. The shaft of the bone undergoes intramembranous ossification in two primary centres, medial and lateral, in stages 18–20 (42–50 postfertilization days). However, the clavicle does not ossify exclusively by intramembranous ossification. Endochondral ossification extends from the shaft to the sternal and acromial ends in stages 20–21. In 14 mm embryos, the clavicle is a band of condensed mesenchyme between the acromion and apex of the first rib, and is continuous with the sternal rudiment. Medial and lateral zones of early cartilage transformation ('precartilage') occur within this band; intramembranous centres of ossification appear and soon fuse in the mesenchyme between them. Sternal and acromial zones become true cartilage into which ossification extends from the shaft. Length increases by interstitial growth of these terminal cartilages, which develop zones of hypertrophy, calcification and advancing endochondral ossification like other growth cartilages. Diameter increases by subperichondral deposition in the extremities and subperiosteal deposition in the shaft. A secondary centre for the sternal end appears in the late teens, or even early twenties, usually 2 years earlier in females (**Fig. 49.7**). Fusion is probably rapid but reliable data are lacking. An acromial secondary centre sometimes develops at around 18–20 years, but this epiphysis is always small and rudimentary, and rapidly joins the shaft. Growth is usually complete by 23 years in both sexes. Epiphyses are endochondral and probably fuse in the same way as they do in long bones.

Scapula

The scapula is a large, triangular bone that lies over the posterolateral chest wall, covering parts of the second to seventh ribs (see Fig. 48.7A),

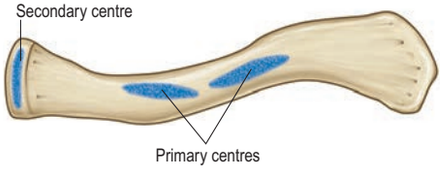

Fig. 49.7 The three constant centres of ossification of the clavicle.

The shaft of the clavicle is usually fractured as a result of a violent impact to the side of the shoulder. The fracture typically occurs at the junction of the lateral two-fifths and medial three-fifths, where the transition from antecurve to retrocurve occurs and the bone changes in cross-sectional shape from its flatter lateral part to a tubular medial part. The weight of the arm causes displacement of the lateral fragment downwards, inwards and into forward (ventral) rotation, a posture maintained even in recumbency partly by the action of subclavius. If the fracture heals in this position, the dimensions and shape of the retroclavicular space are altered, particularly during elevation of the arm above shoulder level, and the brachial plexus (and its perfusion) and the subclavian vessels can be distorted (one of the many causes of the syndrome associated with thoracic outlet obstruction).

Anomalies of clavicular growth and development include defects of ossification, morphology (shape) and length. Defects of ossification in the clavicle and those cranial bones that ossify by intramembranous ossification occasionally coincide, e.g. in cleidocranial dysostosis. Defects of morphology and length occur in the immature clavicle in birth lesions of the brachial plexus; the lateral two-fifths are affected. In a typical case, the acromial end of the clavicle is short and excessively curved ventrally, rotated by up to 90°, while the coracoclavicular ligaments are normal. The coracoid is long and more vertical than usual; the scapula is often small, and the scapular neck region is short with variable glenoid dysplasia. These characteristic defects are predominantly associated with the upper trunk lesion (C5 and C6) that results in a muscular imbalance across the acromioclavicular and glenohumeral joints; the flexor and medial (internal) rotator muscles are relatively short. The short, tight pectoralis minor and coracobrachialis produce a distorting force on the coracoid, which elongates and rotates dorsally. With retropulsion of the humeral head posteriorly, the scapula rotates ventrally, particularly if there is posterior glenoid dysplasia. Deltoid shortening creates a downward distraction on the developing acromion, which lengthens and curves distally. The spine of the scapula is parallel to the body of the scapula rather than dorsally directed, and these deformities cause the acromioclavicular joint to be orientated more horizontally. As a result, the lateral clavicle is excessively curved ventrally. The concept here is that the abnormal shape is driven by asymmetrical muscle paralysis and partial recovery, and that *form* follows the neural lesion. While poor movement (causing a lack of 'motivation' for growth in *length*) might explain the clavicular shortening, an equally valid explanation might involve a vascular insufficiency of the lateral ossification centre of the clavicle (with a similar insufficiency of the lateral ossification centres of the scapula for the glenoid): both have a contribution from the suprascapular artery, which is 'at risk' during injuries that lead to brachial plexus palsy. Length is a function of perfusion and shortening follows vascular insufficiency (Kambhampati et al 2006).

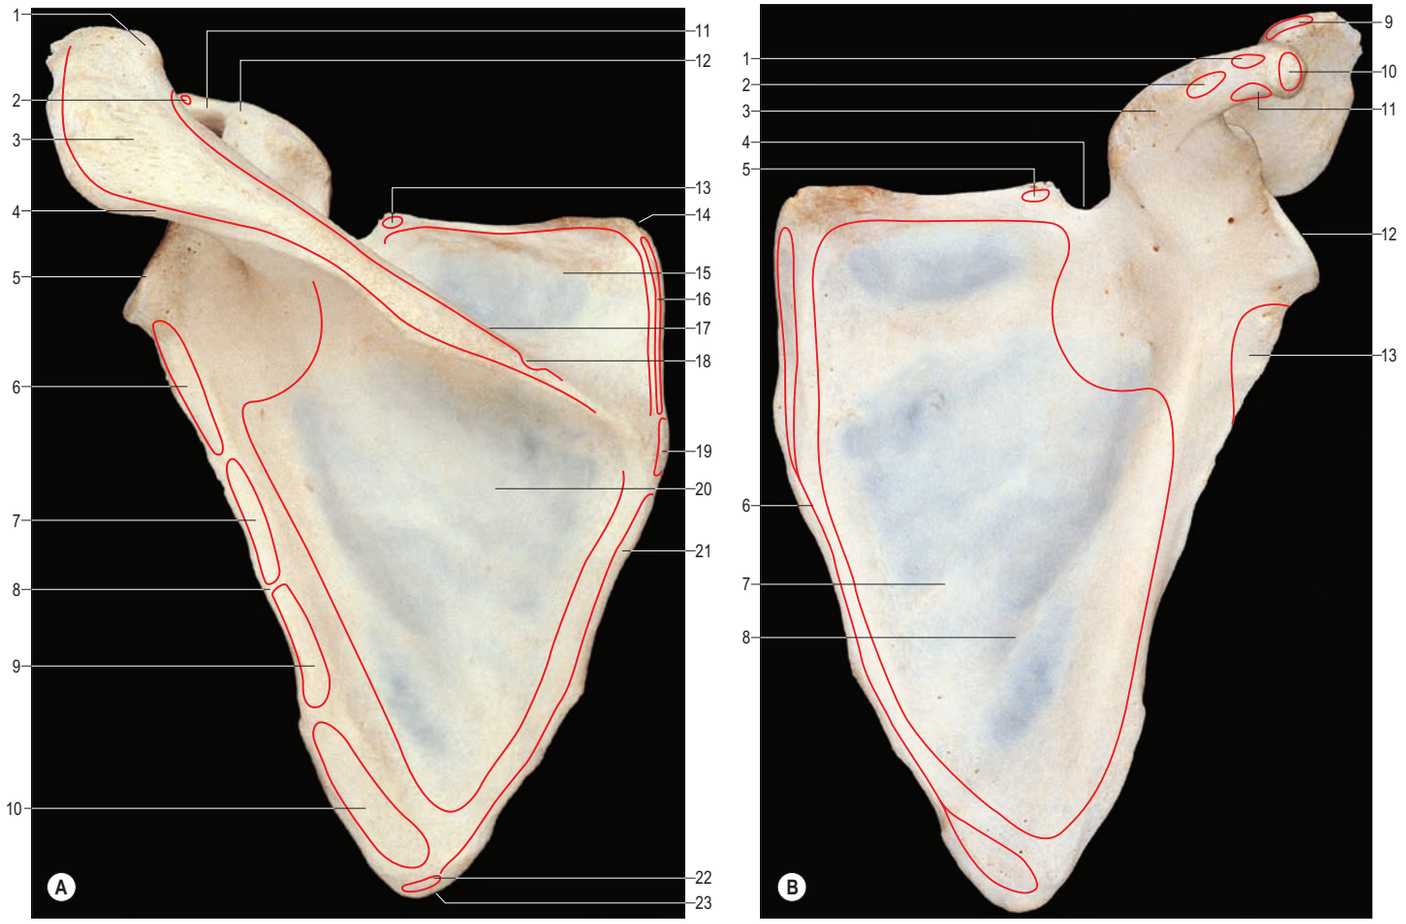

Fig. 49.8 The left scapula, showing sites of muscular and ligamentous attachment and articular surfaces. **A**, Posterior aspect. Key: 1, clavicular facet; 2, biceps brachii (short head); 3, acromion; 4, deltoid; 5, glenoid fossa; 6, triceps brachii (long head); 7 and 9, teres minor; 8, groove for circumflex scapular artery; 10, teres major; 11, conoid tubercle; 12, coracoid process; 13, omohyoid (inferior belly); 14, superior angle; 15, supraspinatus; 16, levator scapulae; 17, spine; 18, trapezius; 19, rhomboid minor; 20, infraspinatus; 21, rhomboid major; 22, latissimus dorsi; 23, inferior angle. **B**, Anterior aspect. Key: 1, attachment of trapezoid ligament; 2, attachment of conoid ligament; 3, acromion process; 4, suprascapular notch; 5, omohyoid (inferior belly); 6, serratus anterior; 7, subscapularis; 8, ridge for intermuscular tendon of subscapularis; 9, deltoid; 10, biceps brachii (short head) and coracobrachialis; 11, pectoralis minor; 12, glenoid fossa; 13, triceps brachii (long head).

with a vertical long (craniocaudal) axis. It has costal and dorsal surfaces; superior, lateral and medial borders; inferior, superior and lateral angles; and three processes: the spine, the acromion and the coracoid process (Figs 49.8–49.9).

The superior and lateral borders and the supraspinous and infraspinous fossae converge laterally at the lateral angle of the scapula. This region comprises the glenoid fossa, the coracoid process and the neck of the scapula. Three robust columns of bone, namely, the lateral border of the spine of the scapula, the coracoid and the lateral border of the scapula, thus converge at the neck region. Load applied through the glenoid fossa or through the coracoid is transmitted into the scapula through these columns, which also provide a robust framework for the scapular body. The main processes, and thicker parts of the scapula, contain trabecular bone for load-bearing; the rest consists of a thin layer of compact bone for muscular attachments.

Costal surface

The costal surface, which is directed medially and forwards when the arm is by the side, is gently concave, especially in its upper part, matching the contour of the chest wall (Fig. 49.8B).

Near the lateral border, there is a longitudinal rounded ridge, prominent near the neck but less so below, which is separated from the lateral border by a narrow, grooved area. Subscapularis arises from the subscapular fossa that comprises nearly the whole of the costal surface, including the grooved area immediately adjoining the lateral border, but excluding the area next to the neck of the bone. Small, fibrous intramuscular septa are attached to four or five roughened ridges that subdivide this surface incompletely into a number of smooth areas. The anterior aspect of the neck is separated from subscapularis by a bursal protrusion of the synovial membrane of the shoulder joint (subscapular 'bursa'). The lower five or six digitations of serratus anterior are attached to an oval area near the inferior angle. The remainder of the muscle is inserted into a narrow strip along the ventral aspect of the medial border, which is wider above, where it receives the large first digitation. The longitudinal thickening of the bone near the lateral border provides a column of the necessary strength to withstand the pull of serratus anterior on the inferior angle during lateral scapular rotation, when the glenoid cavity is turned to face more directly upwards as the arm is raised from the side and carried above the head against gravity.

Dorsal surface

The dorsal surface is divided by the transverse, shelf-like spine of the scapula into two unequal parts: a smaller supraspinous fossa above and an infraspinous fossa below. The fossae are confluent at the spinoglenoid notch between the lateral border of the spine and the dorsal aspect of the neck; their central parts may be very thin (Fig. 49.8A). The supraspinous fossa is bounded superiorly and anteriorly by the superior border, from the suprascapular notch and dorsal aspect of the root of the coracoid laterally, to the superior angle medially; and medially, by the upper part of the medial border. The infraspinous fossa is bounded by the medial and lateral borders and the inferior angle.

Supraspinatus is attached to the medial two-thirds of the supraspinous fossa on the dorsal surface; the fascia that covers the muscle is attached to the margins of the fossa. A fat pad lies between the supraspinatus fascia and the under-surface of trapezius. Teres minor is attached to the upper two-thirds of a flattened strip that adjoins the lateral border. The strip is grooved near its upper end by the circumflex scapular vessels passing between teres minor and the bone as they enter the infraspinous fossa. The lower limit of the attachment of teres minor is indicated by an oblique ridge, which runs from the lateral border to the neighbourhood

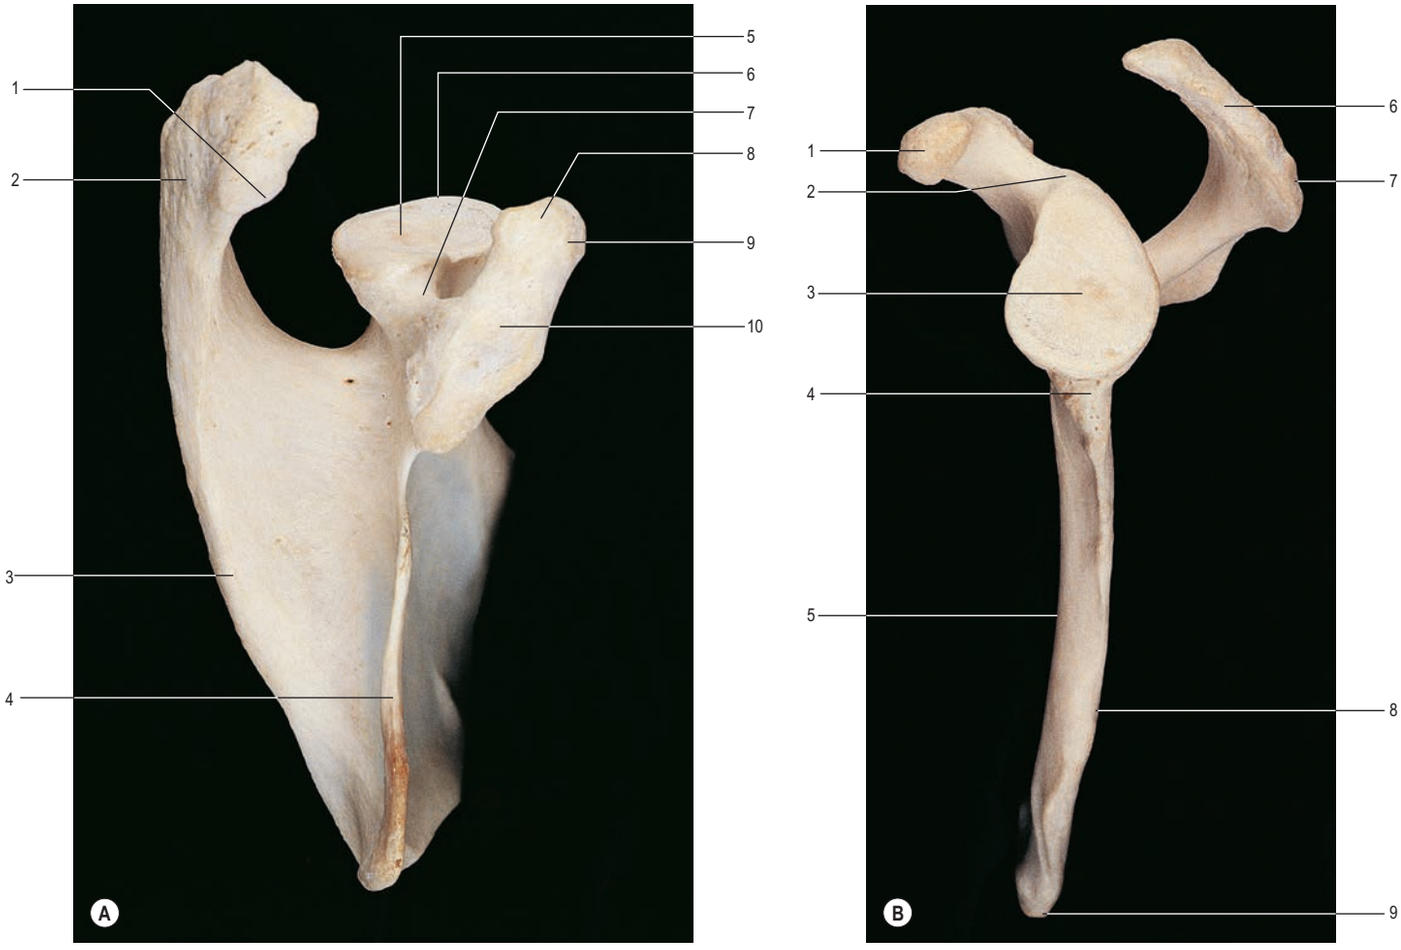

Fig. 49.9 The left scapula, showing sites of muscular and ligamentous attachment and articular surfaces. **A**, Superior aspect. Key: 1, facet for clavicle; 2, acromial process; 3, spine; 4, superior border; 5, head; 6, glenoid fossa; 7, neck; 8, conoid tubercle (for conoid ligament); 9, coracoid process; 10, attachment of trapezoid ligament. **B**, Lateral aspect. Key: 1, coracoid process; 2, supraglenoid tubercle; 3, glenoid fossa; 4, infraglenoid tubercle for long head of triceps brachii; 5, ventral surface; 6, acromion; 7, acromial angle; 8, lateral border; 9, inferior angle.

of the inferior angle and cuts off a somewhat oval area where teres major is attached. The dorsal aspect of the inferior angle may give origin to a small slip that joins the deep surface of latissimus dorsi. The infraspinous fossa is hollowed out laterally but is convex medially. Infraspinatus is attached to the infraspinous fossa, with the exception of an area near the neck of the bone. The strong infraspinatus fascia passes on to teres minor and teres major, and sends fascial partitions between them that reach the bone along the ridges marking the limits of their attachments.

Superior border

The superior border, thin and sharp, is the shortest. At its anterolateral end, it is separated from the root of the coracoid process by the suprascapular notch (see Fig. 49.8B), which can vary in shape and size. Medial to the suprascapular notch, the superior border gives origin to the inferior belly of omohyoid. The notch is bridged by the superior transverse ligament (or suprascapular ligament), which is attached laterally to the root of the coracoid process and medially to the limit of the notch. The ligament is sometimes ossified. The foramen, thus completed, transmits the suprascapular nerve to the supraspinous fossa, whereas the suprascapular vessels pass backwards above the ligament.

Lateral border

The lateral border has a triangular or rhomboidal cross-section. It forms a clearly defined, sharp, roughened ridge that runs sinuously from the inferior angle to the glenoid cavity. At its upper end, it widens into a rough, somewhat triangular, area: the infraglenoid tubercle (**Fig. 49.9B**). The lateral border separates the attachments of subscapularis and teres minor and major. These muscles project beyond the bone and, with latissimus dorsi below, cover it so completely that it cannot be felt through the skin. The long head of triceps is attached to the infraglenoid tubercle.

The grooved part of the costal surface, the narrow, flat lateral strip of the dorsal surface and the adjacent thickened ridge (see Fig. 49.9B) are often included in the 'lateral column' in surgical practice. By definition, the remainder of the scapular body (costal and dorsal surfaces) and the medial border are called the 'medial column'.

Medial border

The medial border extends from the inferior to the superior angle. It is slightly thickened and flat, and is further thickened at the medial end of the spine. In its lower two-thirds, this border can easily be felt through the skin, but its upper third is more deeply placed and more difficult to palpate. It is thin and often angled opposite the root of the spine. Levator scapulae is attached to a narrow strip, extending from the superior angle to the root of the spine, and rhomboid minor is attached below this, opposite the root of the spine. Rhomboid major is attached to the remainder of the border.

Scapular angles

The inferior angle lies over the seventh rib, or over the seventh intercostal space. It can be felt through the skin and the muscles that cover it, and, when the arm is raised above the head, it can be seen to rotate forwards (protract) around the chest wall; when the arm is lowered, the scapula should restitute (retract) to its original position without a disturbance of rhythm. It is covered on its dorsal aspect by the upper border of latissimus dorsi, a small slip from which is frequently attached to the inferior angle. The superior angle, at the junction of the superior and medial borders, is obscured by the upper part of trapezius. It lies over the dorsal surface of the second rib and can be palpated deeply above and behind the clavicle.

The lateral angle, truncated and broad, comprises the glenoid fossa (cavity) and scapular neck, with the coracoid projecting forwards. When the arm is by the side, the fossa is directed forwards, laterally and slightly upwards. When the arm is raised above the head, it is directed almost straight upwards, i.e. the plane of the fossa is horizontal. The supraglenoid tubercle is a small, rough, sloping area at the cranial margin of the fossa;

it often encroaches on the root of the coracoid process, and is the site of attachment for the tendon of the long head of biceps brachii. The infraglenoid tubercle is a larger, rough area at the caudal margin of the glenoid fossa, at the upper end of the lateral margin, and is the site of attachment for the tendon of the long head of the triceps brachii. The anatomical neck is the region of the scapula extending between the infraglenoid and supraglenoid tubercles anteriorly and posteriorly, lateral to the root of the coracoid process; anteriorly, there is no landmark to distinguish the anatomical neck from the costal surface of the body of the scapula. Posteriorly, the anatomical neck is limited by the spinoglenoid notch at the root of the spine of the scapula. The bone here has an asymmetric, triangular cross-sectional shape; the plane of the anterior surface of the neck makes an acute angle of about 60° with the plane of the glenoid fossa, but the dimension and shape of the posterior surface are more variable.

Spine of the scapula

The spine of the scapula forms a shelf-like projection on the upper part of the dorsal surface of the bone, and is triangular in shape (see Fig. 49.8A). Its lateral border is free, thick and rounded, and bounds the spinoglenoid notch, which lies between it and the dorsal surface of the neck of the bone. Its anterior aspect joins the dorsal surface of the scapula along a line that runs laterally and slightly upwards from the junction of the upper and middle thirds of the medial border. The plate-like body of the bone is bent along this line, which accounts for the concavity of the upper part of the costal surface. The dorsal border is the crest of the spine and is subcutaneous throughout nearly its whole extent. The crest expands into a smooth, triangular area at its medial end. Elsewhere, the upper and lower edges and the surface of the crest are roughened for muscular attachments. The upper surface of the spine widens as it is traced laterally and is slightly hollowed out. Together with the upper area of the dorsal surface of the bone, the upper surface of the spine forms the supraspinous fossa. The lower surface is overhung by the crest at its medial, narrow end, but is gently convex in its wider, lateral portion. Together with the lower area of the dorsal surface of the bone, the lower surface of the spine forms the infraspinous fossa, which communicates with the supraspinous fossa through the spinoglenoid notch.

Supraspinatus is attached to the upper surface of the spine of the scapula; the infraspinatus, by contrast, is not attached to the lower surface of the spine. The flattened triangular area at its root lies opposite the spine of the third thoracic vertebra and is covered by the tendon of trapezius; a bursa intervenes to enable the tendon to play over this part of the bone. The posterior fibres of deltoid are attached to the lower border of the crest and, to a variable extent, to the medial border by attachment to the infraspinatus fascia. The middle fibres of trapezius are attached to the upper border of the crest. The lowest fibres of trapezius terminate in a flat, triangular tendon that glides over the smooth area at the base of the spine and inserts into a rough prominence, erroneously called the deltoid tubercle, on the dorsal or subcutaneous aspect of the spine near its medial end.

Acromion

The acromion projects forwards, almost at right-angles, from the lateral end of the spine, with which it is continuous. The lower border of the crest of the spine becomes continuous with the lateral border of the acromion at the acromial angle, which forms a reliable, subcutaneous, bony landmark. The medial border of the acromion is short and is marked anteriorly by a small, oval facet, directed upwards and medially, for articulation with the lateral end of the clavicle. The lateral border, tip and upper surface of the acromion can all be felt through the skin without difficulty. There may be an accessory articular facet on the inferior surface of the acromion.

The acromion is subcutaneous over its dorsal surface, being covered only by the skin and superficial fascia. The lateral border, which is thick and irregular, and the tip of the process, as far round as the clavicular facet, give origin to the middle fibres of deltoid. The medial aspect of the tip gives attachment, below deltoid, to the lateral end of the coraco-acromial ligament. The articular capsule of the acromioclavicular joint is attached around the margins of the clavicular facet. Behind the facet, the medial border of the acromion gives insertion to the horizontal (middle) fibres of trapezius. The inferior aspect of the acromion is relatively smooth and forms a protective arch over the shoulder joint, together with the coraco-acromial ligament and the coracoid process. The tendon of supraspinatus passes below the overhanging acromion and is separated from it and from deltoid by the subacromial bursa.

Coracoid process

The coracoid process arises from the upper border of the neck of the scapula and its body is bent sharply so as to project forwards and slightly laterally (see Figs 49.8–49.9). When the arm is by the side, the coracoid process points almost straight forwards. Its tip can be felt through the skin and is covered by the anterior fibres of deltoid, about 2.5 cm below the clavicle at the junction of the lateral fifth with the rest of the bone, at the lateral border of the infraclavicular fossa. It forms a short, curved cantilever fixed to the scapula at its base and is displaced by the actions of the muscles attached to its body and tip. Pectoralis minor pulls the coracoid (and, therefore, the scapula) forwards and medially around the chest wall, balanced by trapezius, its antagonist; this action forms the foundation on which coracobrachialis can help support the long lever arm of the humerus during humeral motion, together with its antagonist, the deltoid. During forceful forward elevation of the protracted shoulder girdle, subclavius and pectoralis minor may contribute to deceleration of the limb.

The infraclavicular brachial plexus and the axillary vessels lie below and medial to the coracoid. The acromial branch of the thoraco-acromial artery passes above it, and the sensory branch of the lateral pectoral nerve to the rotator interval capsule, together with accompanying vessels, lies immediately below.

On the dorsal aspect of the coracoid process, at the point where it changes direction, a rough impression forms part of the region of attachment of the conoid portion of the coracoclavicular ligament. The trapezoid portion of the coracoclavicular ligament is attached to the upper aspect of the horizontal part of the process, anterior to the conoid part. Pectoralis minor is attached to the superior and medial aspects of the coracoid process. The wider, medial, end of the coraco-acromial ligament is attached to the lateral border and is continuous inferiorly with the lateral aponeurotic part of the tendon of the short head of biceps brachii. The coracohumeral ligament is attached to the root of the coracoid at its lateral border. The interval between the anterior aspect of the scapular neck immediately medial to the glenoid fossa and the deep surface of the coracoid is often bridged by the glenocoracoid ligament. The inferior aspect of the coracoid process is otherwise smooth and saddle-shaped. When the arm is elevated, the upper border of subscapularis is apposed to, and runs under, this surface, which forms a pulley for the muscle, increasing the power generated during forceful medial (internal) rotation of the shoulder in elevation, such as during a serve in tennis. Coracobrachialis is attached to the deep aspect of the lower part of the medial side and the deep surface of the tip of the process, and the short head of biceps is attached to the lateral side and superficial aspect of the tip.

Scapular movements

Scapular movement is a product of interconnected suspension, motion and articulation mechanisms. The suspension mechanism consists of the scapular articulation with the clavicle and the suspension muscles of the scapula and clavicle, notably trapezius, attached to the lateral clavicle, the acromion and the spine of scapula, and its antagonists pectoralis minor and subclavius. The articulation with the clavicle comprises two linked systems: 'clavicle – acromioclavicular joint – acromion – spine of scapula – lateral scapular angle' and 'clavicle – coracoclavicular ligament – coracoid – lateral scapular angle – spine of scapula'. This mechanism therefore subserves the function of scapular rotation or tilt limited by the ellipsoid range of motion of the lateral clavicle. The motion mechanism consists of the agonist–antagonist force couple of serratus anterior passing to the chest wall anterolaterally, and levator scapulae, rhomboid major, rhomboid minor and serratus posterior (when present), which all pass to the vertebral column medially. This mechanism therefore subserves the function of scapular protraction and retraction around the elliptic paraboloid of the chest wall. The articulation mechanism consists of the scapular neck region and the glenoid fossa, which articulates with the humeral head. The muscles that subserve the function of holding the humeral head on the glenoid through the wide range of motion of the glenohumeral joint are the rotator cuff muscles, which take their attachment from the body of the scapula. This mechanism therefore concerns the relationship between the position and orientation of the glenoid fossa and the scapular body.

Ossification

The cartilaginous scapula is ossified from eight or more centres: one in the body, two each in the coracoid process and the acromion, and one each in the medial border, inferior angle and lower part of the rim of the glenoid cavity (Fig. 49.10). The medial part originates from dermomyotomes of somites 17–24 (level of fifth cervical vertebra – level of fifth thoracic vertebra) and the lateral part from somatopleuric mesenchyme. The primary ossification centre for the body appears in stage 23 (53–58 postfertilization days). Ossification begins in the middle of the coracoid process in the first year or, in a small proportion of individuals, before birth; the process joins the rest of the bone about the fifteenth year. At or soon after puberty, centres of ossification occur in the rest of

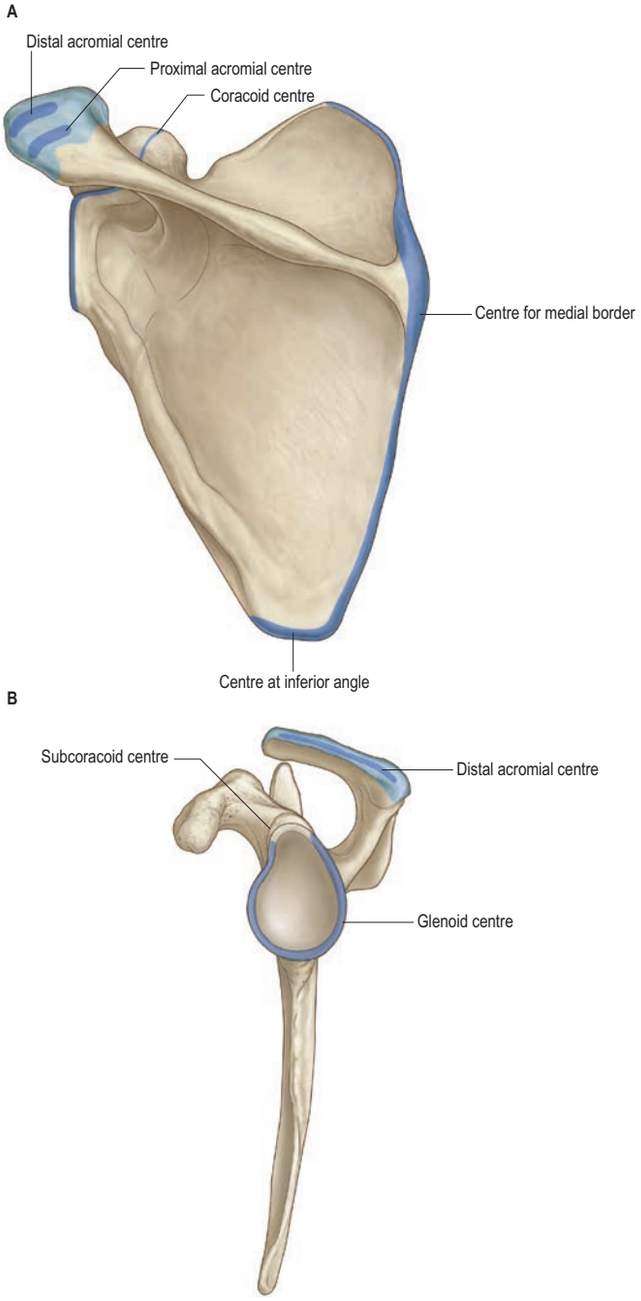

Fig. 49.10 Ossification of the scapula. **A**, Dorsal aspect. **B**, Lateral aspect. (Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

the coracoid process (subcoracoid centre), in the rim of the lower part of the glenoid cavity, frequently at the tip of the coracoid process, in the acromion, in the inferior angle and contiguous part of the medial border and in the medial border. A variable area of the upper part of the glenoid cavity, usually the upper third, is ossified from the subcoracoid centre; it unites with the rest of the bone in the fourteenth year in the female and the seventeenth year in the male. A horseshoe-shaped epiphysis appears for the rim of the lower part of the glenoid cavity; thicker at its peripheral than at its central margin, it converts the flat glenoid cavity of the child into the gently concave fossa of the adult. The base of the acromion is formed by an extension from the spine; the rest of the acromion is ossified from two centres that unite and then join the extension from the spine. The various epiphyses of the scapula have all joined the bone by about the twentieth year.

Ligaments

The intrinsic scapular ligaments are strengthening ligaments (coraco-acromial ligament) and bounding ligaments (superior transverse scapular or suprascapular ligament, inferior transverse scapular or spinoglenoid ligament, and the variable glenocoracoid ligament).

Coraco-acromial ligament The coraco-acromial ligament is a strong triangular band between the coracoid process and acromion. It is attached apically to the acromion anterior to the articular surface for the clavicle, and by its base along the whole lateral border of the coracoid. Together with the coracoid process and acromion, it completes an arch above the humeral head. It may be composed of two strong marginal bands with a thinner centre; when pectoralis minor is inserted into the humeral capsule instead of the coracoid process, which happens occasionally, its tendon passes between the bands. The subacromial bursa facilitates movement between the coraco-acromial arch and the subjacent supraspinatus and shoulder joint, functioning as a secondary synovial articulation. When the coraco-acromial ligament is cut, it is impossible to appose the two cut surfaces afterwards: this suggests there is resting tension in the ligament, which forms a 'tension band' between the acromial and coracoid processes of the scapula, so 'pre-tensioning' both processes against the distracting forces of deltoid and trapezius, and pectoralis minor and the conjoined short head of biceps brachii and coracobrachialis, respectively.

Superior transverse scapular (suprascapular) ligament The superior transverse scapular (suprascapular) ligament converts the scapular notch into a foramen; it is sometimes ossified. A flat fasciculus, it narrows towards its attachments to the base of the coracoid process, blending with the lower fibres of the conoid ligament, and to the medial side of the scapular notch. The suprascapular nerve traverses the foramen, and the suprascapular vessels cross above the ligament.

Inferior transverse scapular (spinoglenoid) ligament When present, the inferior transverse scapular ligament is a membranous ligament that may stretch from the lateral border of the spine of the scapula to the glenoid margin (see Fig. 49.33). It forms an arch over the branches of the suprascapular nerve and vessels entering the infraspinous fossa to supply infraspinatus.

Humerus

The humerus, the longest and largest bone in the upper limb, has expanded ends and a shaft (Figs 49.11–49.12). The spheroidal humeral head forms an enarthrodial articulation with the glenoid fossa of the scapula. The lesser tubercle projects from the front of the shaft, close to the head, and is limited on its lateral side by the well-marked groove, the intertubercular sulcus, by which it is separated from the greater tubercle. The distal end is adapted to the forearm bones at the elbow joint and carries the medial and lateral epicondyles with the articular surfaces for the radius and ulna between them. The axis between the epicondyles is the inter-epicondylar axis.

The shaft of the human (and primate) humerus is relatively *medially* rotated with respect to the humeral head, compared with quadripedal ancestors; this gives the characteristically greater range of *external* rotation at the glenohumeral joint than that obtaining in other species. This is reflected in the spiroidal architecture of the adult humeral medullary cavity, the arrangement and relationship of the posterior compartment of brachial muscles and the radial nerve, and the disposition to long spiral fractures caused by external twisting forces.

With the arm by the side in the anatomical position, and with the medial and lateral epicondyles in the same (frontal) plane (i.e. the inter-epicondylar axis is in the frontal plane), the humeral *head* is rotated posteriorly at an angle averaging 15–20° in European cadaveric specimens (Boileau and Walch 1997). Since the glenoid fossa of the scapula faces anterolaterally, the humerus is not rotated posteriorly relative to the scapula in the anatomical position. It is important to remember this position of the bone when movements of the arm and forearm are considered; movements are recorded relative to the trunk (starting in the anatomical position) or relative to the scapula, and it is important to define which method is in use.

Proximal end

The proximal end of the humerus consists of the head, anatomical neck, and the greater and lesser tubercles. It joins the shaft at an ill-defined 'surgical neck', which is closely related on its medial side to the axillary nerve and posterior circumflex humeral artery (see Figs 49.22, 49.31, 49.33). The proximal end of the humerus makes up the upper fifth of the length of the bone.

Head

The head of the humerus forms rather less than half a spheroid; in sectional profile, it is spheroidal (strictly, ovoidal) (see Fig. 49.12). Its

The primordial scapula migrates caudally to its usual position at a level between the second and seventh ribs by the end of the embryonic period (53–58 postfertilization days). With further development, the scapula alters shape. Initially, the horizontal diameter exceeds the vertical but the ratio gradually decreases until mature dimensions are reached, an adaptation thought to provide upright hominids with increased range, and therefore freedom of use, of the upper limb. Avian gene-deletion studies have shed light on the development of the scapula. Scapular body development appears to be controlled by the *Emx2* gene, also expressed in the developing mesonephros. The development of the acromion and the spine of the scapula are controlled by the *Pax1* gene, and glenoid and coracoid development is controlled by the *Hoxc6* gene (Huang et al 2000), one of the homeobox genes responsible for somite differentiation and development; development of the glenoid and coracoid appears likely to be more intimately related to the development of the upper limb bud as a whole. The development of the scapular body appears to be independent of that of the processes and glenoid region. Adult scapulae may show a line of fusion across the body and spine of the scapula, suggesting that the primordia of the processes (including the glenoid) and the primordium of the body migrate towards each other; since the trapezius is derived from branchial arch mesoderm it would appear that the development of the spine of the scapula and acromion and trapezius are intimately related, but separate from the body. This hypothesis is supported by the observation that; in the condition of congenital undescended scapular syndrome (Sprengel deformity), the development of the scapular body is altered, and there is intramuscular ossification of variable parts of the medial scapulospinal muscles; the development of the processes (including the glenoid) is unaffected (Dhir and Lambert 2014; Dhir et al 2018). Since the medial border of the scapula develops from the dermomyotomes of somites 17–24 (see above) any vertebral anomalies at this level may result in tethering of scapular structures to the cervical spine, sometimes by an abnormal omovertebral tether (fibrous, chondral, or osseous), that prevents the upper border of the scapula descending to its usual position.

The suprascapular nerve may be entrapped by the ligament if this is thickened or ossified and this may cause the syndrome of neurostenalgia, a typical pain of unremitting burning or aching nature, due to stenosis or distortion of the nerve trunk by extrinsic compression. Weakness of supraspinatus and infraspinatus may subsequently occur. Surgical release of the ligament is often helpful; this may be undertaken by open or arthroscopic surgical exposure and division of the ligament.

A ganglion (an outpouching of the synovial membrane of the glenohumeral joint) may occur immediately behind and above the posterosuperior corner of the glenoid fossa; this can compress the branch of the suprascapular nerve that supplies infraspinatus as it courses around the lateral aspect of the spine of the scapula under the inferior scapular ligament. Since the nerve cannot move aside (it is 'held' under the ligament), it can be readily distorted; there is characteristic severe pain, followed by specific atrophy of infraspinatus. Decompression of the ganglion and division of the ligament are curative in the early stage of this syndrome. An intraneural ganglion may arise from the articular branch of the suprascapular nerve; muscular pain and atrophy would be expected to be more rapid than in the case of the synovial ganglion (Spinner et al 2006).

smooth articular surface is covered with hyaline cartilage that is thicker centrally. When the arm is at rest by the side, it is directed medially, backwards and upwards to articulate with the glenoid cavity of the scapula. The humeral articular surface is much more extensive than the glenoid cavity, which means that only a portion of it is in contact with the cavity in any one position of the arm.

Anatomical neck

The anatomical neck of the humerus immediately adjoins the margin of the head, forming a slight constriction that is least obvious next to the greater tubercle. A slight roughness indicates the line of capsular attachment of the shoulder joint, other than at the intertubercular sulcus, where the long tendon of biceps brachii emerges. Medially, the capsular attachment diverges from the anatomical neck and descends 1 cm or more on to the shaft.

Lesser tubercle

The lesser tubercle is anterior to and just distal to the anatomical neck. It is palpable through the thickness of deltoid about 3 cm below the anterior edge of the acromion. It can be distinguished from the coracoid by rotation of the humerus under the palpating finger; the lesser tubercle slips away from the examining finger, the tip of the coracoid does not. The lateral edge of the lesser tubercle is sharp and forms the medial border of the intertubercular sulcus. Subscapularis is attached to the lesser tubercle (see Fig. 49.11A). The transverse ligament of the shoulder (transverse humeral ligament) is attached to the upper aspect of the lateral margin of the tubercle.

Greater tubercle

The greater tubercle is the most lateral part of the proximal end of the humerus and projects beyond the lateral border of the acromion. Its posterosuperior aspect, near the anatomical neck, bears three smooth, flattened impressions for the attachment of supraspinatus (uppermost), infraspinatus (middle) and teres minor (lowest and placed on the posterior surface of the tubercle) (see Fig. 49.11). The attachments of subscapularis and teres minor are not confined to their respective tubercles, but extend for varying distances on to the adjacent metaphysis. The projecting lateral surface of the tubercle presents numerous vascular foramina and is covered by deltoid, producing the normal rounded contour of the shoulder. A part of the subacromial bursa may cover the upper part of this area and separate it from deltoid. The intertubercular sulcus (bicipital groove) lies between the tubercles. It contains the long tendon of biceps, its synovial sheath, and an ascending branch from the anterior circumflex humeral artery. The rough lateral lip of the groove is marked by the bilaminar tendon of pectoralis major, and its medial lip by the tendon and muscular insertion of teres major. The floor of the groove provides attachment for a frequent upward extension of the tendon of pectoralis major, and for the tendon of latissimus dorsi more caudally (Dancker 2013).

Shaft

The shaft of the humerus is almost cylindrical in its proximal half. Distal to the deltoid tuberosity, it is equilaterally triangular in cross-section, flaring out into a broad isosceles triangular cross-section just above the elbow joint. It can be readily palpated laterally and medially, but the muscles of the anterior and posterior compartments obscure the bone to palpation anteriorly and posteriorly. It has three surfaces and three borders, which are only distinct towards the elbow joint. The shaft comprises the middle three-fifths of the humerus.

Surfaces

The posterior surface, between the medial and lateral borders, is broad, flat and convex distally. The medial head of triceps is attached to the posterior surface over an elongated triangular area, the apex of which is placed on the medial part of the bone above the level of the lower limit of insertion of teres major. The area widens below and covers the whole surface almost down to the lower end of the bone. The lateral head of triceps is attached to a ridge, sometimes rough, that descends obliquely and laterally above the attachment for the medial head. Above triceps, the axillary nerve and the posterior circumflex humeral vessels wind around the bone on the deep surface of deltoid. Below the attachment of the lateral head of triceps, but above the attachment of the medial head, a shallow groove runs from the upper medial aspect of the surface downwards and laterally towards the lateral border; it contains the radial nerve and its branches, and the profunda brachii vessels.

The anterolateral surface is bounded by the anterior and lateral borders, and is smooth and featureless in its upper part, which is covered by deltoid. About, or a little above, the middle of this surface, deltoid is attached to the deltoid tubercle. Further distally, the surface gives origin to the lateral fibres of brachialis, which extend upwards into the floor of the lower end of the groove for the radial nerve (see Fig. 49.11). The nerve perforates the lateral intermuscular septum close to the bone at the level of the junction of the upper three-fifths and lower two-fifths of the humerus, and enters the anterior compartment of the arm close to the anterolateral surface, between brachialis medially and brachioradialis laterally.

The anteromedial surface is bounded by the anterior and medial borders. Below the intertubercular sulcus, the rest of the upper half of the surface is smooth and devoid of muscular attachment; its lower half is occupied by the medial part of brachialis (see Fig. 49.11A). Coracobrachialis is attached to a long rough strip in the middle third of the medial border, posterior to the brachial neurovascular sheath, which lies in close relation to the humerus in the middle third of this surface. The humeral head of pronator teres is attached to a narrow area close to the lowest part of the medial supracondylar ridge; the ridge itself gives attachment to the medial intermuscular septum of the arm.

A little below its midpoint, the nutrient foramen, which is directed downwards, opens close to the medial border. A hook-shaped process of bone, the supracondylar process, ranging from 2 to 20 mm in length, occasionally projects from the anteromedial surface of the shaft, approximately 5 cm proximal to the medial epicondyle. It is curved downwards and forwards, and its pointed apex is connected to the medial border, just above the epicondyle, by a fibrous band, to which part of pronator teres is attached. The foramen completed by this fibrous band usually transmits the median nerve and brachial artery, but sometimes encloses only the nerve, or the nerve plus the ulnar artery (in cases of high division of the brachial artery). A groove that lodges the artery and nerve is usually found posterior to the process.

Anterior border

The anterior border starts on the front of the greater tubercle and runs downwards almost to the lower end of the bone. Its proximal third forms the lateral lip of the intertubercular sulcus and is roughened for muscular attachments. The succeeding portion is also roughened and forms the anterior limit of the deltoid tubercle; the lower half of the border is smooth and rounded.

Lateral border

The lateral border is most conspicuous at the lower end of the bone, where it is thickened to form the lateral supracondylar ridge, and its sharp edge is roughened along its anterior aspect. In its middle and upper thirds, the border is barely discernible, but in a well-marked bone it can be traced upwards to the posterior surface of the greater tubercle. A little above its middle, it is marked by a V-shaped, roughened area: the deltoid tubercle. The limbs of the V are broad; the groove for the radial nerve runs downwards and laterally behind the posterior limb and fades away on the lower part of the anterolateral surface. The lateral intermuscular septum is attached to the lateral border, and is a condensation of the fascia over the lower part of deltoid and the neighbouring brachialis, forming a septum between the anterior and posterior muscular compartments. The septum is most obvious in the lower three-fifths of the arm, and is perforated by the radial nerve and accompanying vessels.

Medial border

The medial border, although rounded, can be identified without difficulty in the lower half of the shaft, where it becomes the medial supracondylar ridge. In its proximal third, the medial border is indistinct until it broadens out to form a triangular area. The lateral border of this area forms the medial lip of the intertubercular sulcus, and the medial border runs upwards as the calcar humerale to the anatomical neck, where it is roughened, with vascular apertures, and forms the area of attachment of the inferior part of the shoulder capsule. In its middle third, the medial border is interrupted by a wide, shallow groove, the radial (spiral) groove that crosses the bone obliquely, passing downwards and forwards from its posterior to its anterior surface.

Fractures of the humeral shaft

Humeral shaft fractures are common; the pattern of the fracture and the displacement of the fragments depend on the force of injury and on the level at which the bone is broken. If there is wide displacement at the time of fracture, closely associated nerves and vessels are at risk of direct injury. Nerves that are 'fixed' in relation to the bone and attached septa are at further risk of indirect injury by stretching or, later, by the callus of bone healing. (For a discussion of radial nerve injury and fractures of the humeral shaft, see Lambert (2005).)

Distal end

The distal end of the humerus is described in Chapter 50.

Ossification

The proximal humerus and shaft are ossified from four centres: one each in the shaft, head, greater and lesser tubercles (**Fig. 49.13**). The centre for the shaft appears near its middle in stages 21–22 (50–55 postfertilization days) and gradually extends towards the ends. Most growth occurs at the distal end of the bone. Ossification beginning in the head has been reported between 4 and 6 postnatal months; the greater tubercle starts to ossify during the first year in females and second year in males; the lesser tubercle begins to ossify at about the fifth year.

By the sixth year, the centres for the head and tubercles have joined to form a single large epiphysis, hollowed out on its inferior surface to adapt to the conical upper end of the metaphysis. This macroscopic topography provides for mechanical stability in the physis during growth, although rotational stability is still relatively poor; adolescent proximal humeral physial fracture-separations are commonly unstable in rotation. The proximal humeral epiphysis fuses with the shaft of the humerus at about the thirteenth or fourteenth year in females, beginning on the medial aspect of the physial line, and between the fourteenth to sixteenth year in males.

JOINTS

Sternoclavicular joint

The sternoclavicular joint is a synovial sellar (saddle, or hyperbolic paraboloid) joint with an intra-articular fibrocartilaginous disc. It is the only skeletal articulation between the upper limb and the axial skeleton (Sewell et al 2013).

Articulating surfaces The articulating surfaces are the sternal end of the clavicle and the clavicular notch of the sternum, together with the adjacent superior surface of the first costal cartilage (Fig. 49.14). The larger clavicular articular surface is covered by fibrocartilage, which is thicker than the fibrocartilaginous lamina on the sternum. The joint is convex vertically but slightly concave anteroposteriorly, and is therefore sellar; the clavicular notch of the sternum is reciprocally curved but the two surfaces are not fully congruent. An articular disc completely divides the joint.

Fibrous capsule The capsule is thickened anteriorly and posteriorly, but superiorly and especially inferiorly, it is little more than loose areolar tissue.

Ligaments There are two sets of associated ligaments. The intrinsic ligaments are the anterior and posterior sternoclavicular ligaments; the extrinsic ligaments are the midline interclavicular ligament and the costoclavicular ligaments on each side.

Anterior sternoclavicular ligament The anterior sternoclavicular ligament is broad and attached above to the anterosuperior aspect of the sternal end of the clavicle. It passes inferomedially to the upper anterior aspect of the manubrium, spreading on to the first costal cartilage.

Posterior sternoclavicular ligament The posterior sternoclavicular ligament is a weaker band posterior to the joint. It descends inferomedially from the posterior aspect of the sternal end of the clavicle to the posterior aspect of the upper manubrium.

Interclavicular ligament The interclavicular ligament is continuous above with the deep cervical fascia. It unites the superior aspect of the sternal ends of both clavicles; some fibres are attached to the superior manubrial margin.

Costoclavicular ligament The costoclavicular ligament is like an inverted cone, but short and flattened. It has anterior and posterior laminae that are attached to the upper surface of the first rib and costal cartilage, and ascends to the margins of an impression on the inferior clavicular surface at its medial end. Fibres of the anterior lamina ascend laterally and those of the posterior lamina (which are shorter) ascend medially (see Fig. 49.14). They fuse laterally and are closely related to the attachments of subclavius, particularly the tendon of origin; it can be hard to distinguish the lateral border of the ligament from the tendon. The ligament merges medially with the capsule. It can be ossified in older adults, particularly females. A few deep fibres of pectoralis major attach to the external surface of the ligament, adjacent first rib, first costal cartilage and manubrium sterni.

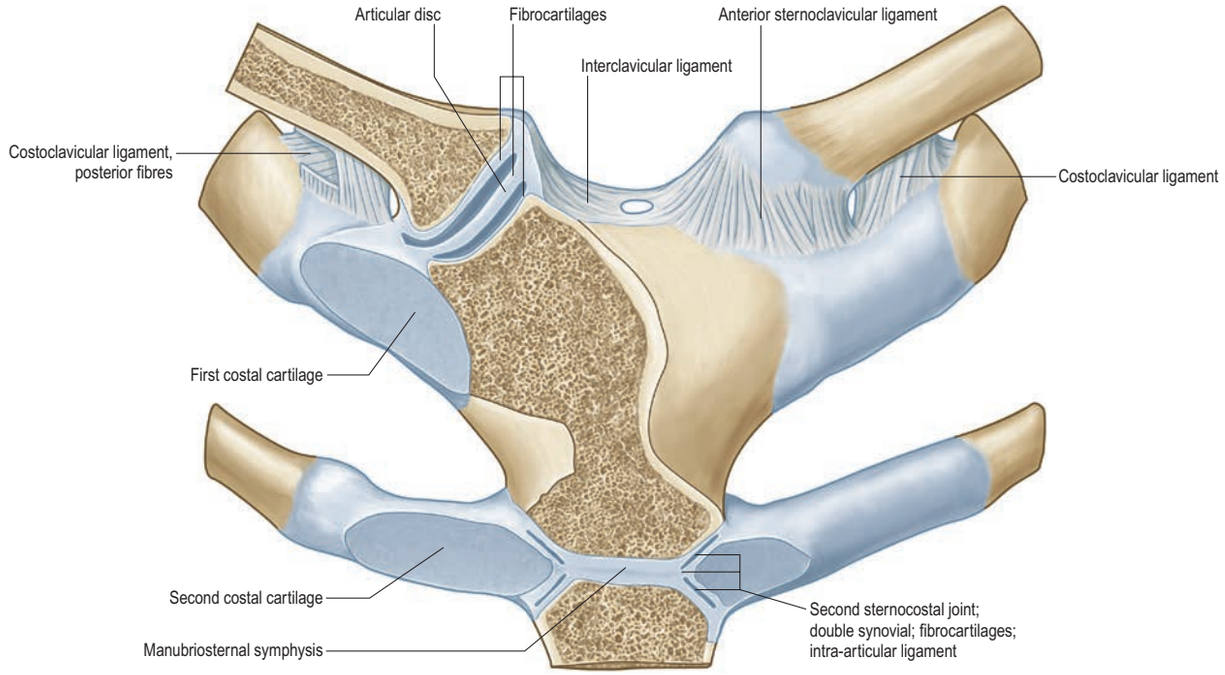

Fig. 49.14 The sternoclavicular joints, anterior aspect. The joint on the left side is intact and the joint on the right side is shown in coronal section.

Articular disc The fibrocartilaginous articular disc divides the cavity of the joint into two compartments between the sternal and clavicular surfaces. It is attached above to the posterosuperior border of the articular surface of the clavicle, below to the first costal cartilage near its sternal junction, and by the rest of its circumference to the capsule, and therefore adapts to the contour of the clavicular surface. It is thicker peripherally, especially superoposteriorly and inferomedially; the central part of the disc may be perforated in later life.

Vascular supply The sternoclavicular joint is supplied by branches from the internal thoracic and suprascapular arteries.

Innervation The sternoclavicular joint is innervated superficially by branches from the medial supraclavicular nerve and deeply by the nerve to subclavius.

Factors maintaining stability There is almost no bony articular congruence at the sternoclavicular joint. However, the strength of its associated ligaments and the articular disc produce durable stability. These factors make sternoclavicular joint dislocation rare; fracture of the clavicular shaft is far more common for the same force directed along the clavicle. (See Sewell et al (2013) for a review of the mechanisms and treatment of sternoclavicular instability.)

Movements The capsule around the clavicular attachment is more lax. Movements between the clavicle and the disc are more extensive than those between the disc and sternum. The sellar shape of the articular surfaces permits translation or gliding in approximately anteroposterior and vertical planes, with rotation about the long axis of the clavicle. Close-packing coincides with maximum posterior rotation associated with full scapular rotation, i.e. in high elevation of the arm above shoulder height.

In this position, the tension developed in the anterior sternoclavicular ligament and anterior component of the costoclavicular ligament causes the clavicle to undergo an obligatory posterior translation. It also acts as a check-rein on further rotation and displacement, so protecting the relatively weaker posterior sternoclavicular ligament from overload. Although the function of subclavius is unknown, a consideration of the simple biomechanics of forceful elevation of the arm above shoulder height suggests that this muscle has an important role in decelerating the elevating arm, so protecting the medial 'clavicular–costal–sternal' ligamentous structures from recurrent stretching that is likely to accelerate degeneration and injury. The common innervation of the sternoclavicular joint (the deep afferent–mechanoceptor system) and subclavius suggests an intimate functional relationship between these structures. In daily activities, in which the upper limb is used largely in front of the trunk, the sternal end of the clavicle glides on the sternal facet about the fulcrum provided by the costoclavicular ligament. All joints in which polyaxial gliding occurs, producing shear forces (rotation with translation), possess either intra-articular synovial bursae or intra-articular fibrocartilaginous discs; the latter degenerate over time, producing characteristic exophytic degenerative arthritis. In this context, it is interesting that degeneration of the sternoclavicular joint and ossification of the costoclavicular ligaments (claviculocostal synostosis) are almost exclusively found in females above the age of 50 years.

Acromioclavicular joint

The acromioclavicular joint is a synovial plane joint and has an intra-articular fibrocartilaginous disc.

Articulating surfaces The articulating surfaces are between the acromial end of the clavicle and the medial acromial margin (Fig. 49.15). The joint is approximately plane but either surface may be slightly convex, the other usually being reciprocally concave: both surfaces are covered by fibrocartilage. It may appear incongruent at rest. The clavicular surface is a narrow, oval area that faces laterally or inferolaterally and overlaps a corresponding facet on the medial acromial border. The long axis is anteroposterior (Colegate-Stone et al 2010).

Fibrous capsule The capsule completely surrounds the articular margins. It is lined by synovial membrane and is strengthened superiorly by the acromioclavicular ligament and the fibres of the attachment of trapezius, posteriorly by the fibres of attachment of trapezius, and anteriorly by the fibres of attachment of deltoid. The inferior capsule is often incomplete in later life.

Ligaments There are two sets of associated ligaments. The intrinsic ligaments are the acromioclavicular ligaments; the extrinsic ligaments are the coracoclavicular ligaments.

Acromioclavicular ligaments The superior acromioclavicular ligament is quadrilateral. It extends between the upper aspects of the lateral end of the clavicle and the adjoining acromion. Its parallel fibres interlace with the aponeuroses of trapezius and deltoid. The inferior acromioclavicular ligament is thin, and often perforated in later life; it extends between the inferior surface of the lateral end of the clavicle and the adjoining acromion. It provides attachment for the intra-articular disc when this is present and complete.

Coracoclavicular ligament The coracoclavicular ligament connects the clavicle and the coracoid process of the scapula. Though separate from the acromioclavicular joint, it is an efficient and important accessory ligament because it helps to maintain the apposition of the acromion to the clavicle, and so contributes to the suspension mechanism of the scapula (see above). The trapezoid and conoid parts of the ligament,

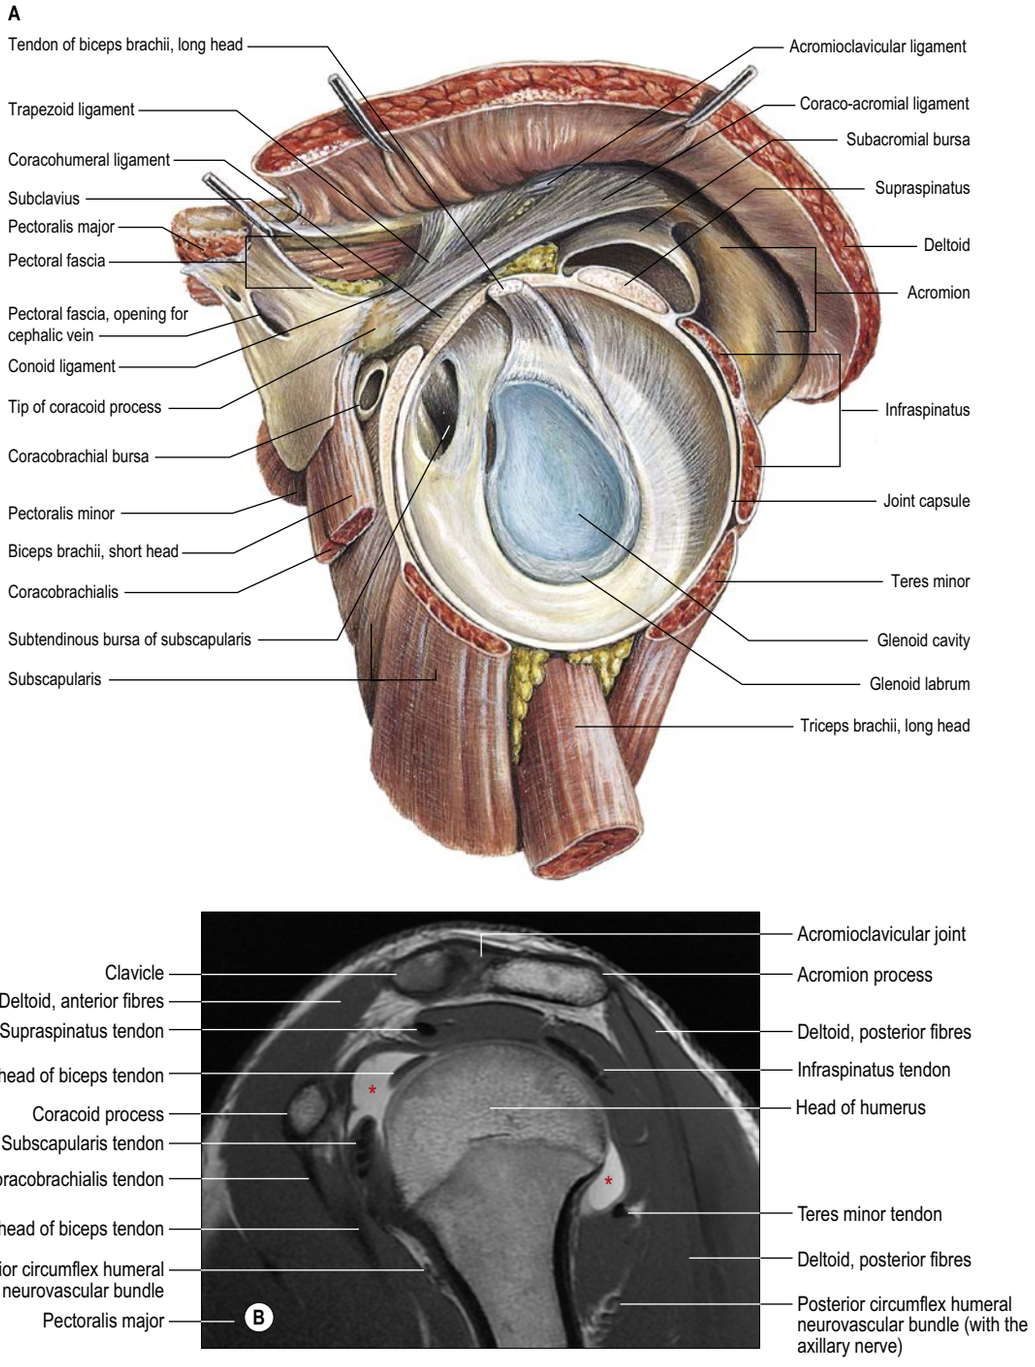

Fig. 49.15 **A**, The interior of the left shoulder joint, anterolateral aspect. **B**, Sagittal T1-weighted MR arthrogram of the left shoulder, viewed from the left. Contrast medium is injected into the joint before the acquisition, and then shows up as bright fluid within the distended joint capsule (*). (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

usually separated by fat or, frequently, by a bursa, connect the posterior (more horizontal) part of the coracoid process and the lateral end of the subclavian groove of the clavicle (Fig. 49.16): these adjacent areas may even be covered by cartilage to form a coracoclavicular joint.

The trapezoid part is anterolateral and is broad, thin and quadrilateral, ascending slightly from the upper coracoid surface to the trapezoid line on the inferior clavicular surface. Its anterior border is free, and its posterior border is joined to the conoid part, forming an angle that projects backwards and upwards. Quadrilateral ligaments twist when the adjoined bones rotate with respect to each other, and as they twist, the apposed surfaces must approach each other; such ligaments, therefore, act to oppose excessive rotation of the adjoining bones.

The conoid part is posteromedial and is a dense, almost vertical, triangular or conical band. Its broader base is attached superiorly to the conoid tubercle of the clavicle; its inferior apex is attached posteromedially to the dorsal surface and root of the coracoid process immediately lateral to the scapular notch, and is contiguous with the superior transverse scapular ligament. Conical ligaments are constructed to oppose distraction; the conoid ligament, therefore, helps to keep the coracoid and the clavicle closely apposed. If the trapezoid ligament is disrupted, the conoid ligament forms a vertical fulcrum around which the coracoid can rotate under the clavicle, particularly if the acromioclavicular ligaments are also disrupted. This is the anatomical basis for the spectrum of acromioclavicular joint dislocation.

Articular disc The articular disc is a complete fibrocartilaginous partition in juvenile and adolescent joints, creating medial and lateral compartments; over time, the centre of the disc perforates, and in adults (more than 20 years old), it is often incomplete inferiorly.

Vascular supply The acromioclavicular joint receives its arterial supply from branches of the suprascapular and thoraco-acromial arteries.

Innervation The acromioclavicular joint is innervated by branches from the suprascapular and lateral pectoral nerves. It has been suggested that the density of nociceptors is greatest in the inferior acromioclavicular ligament and capsule.

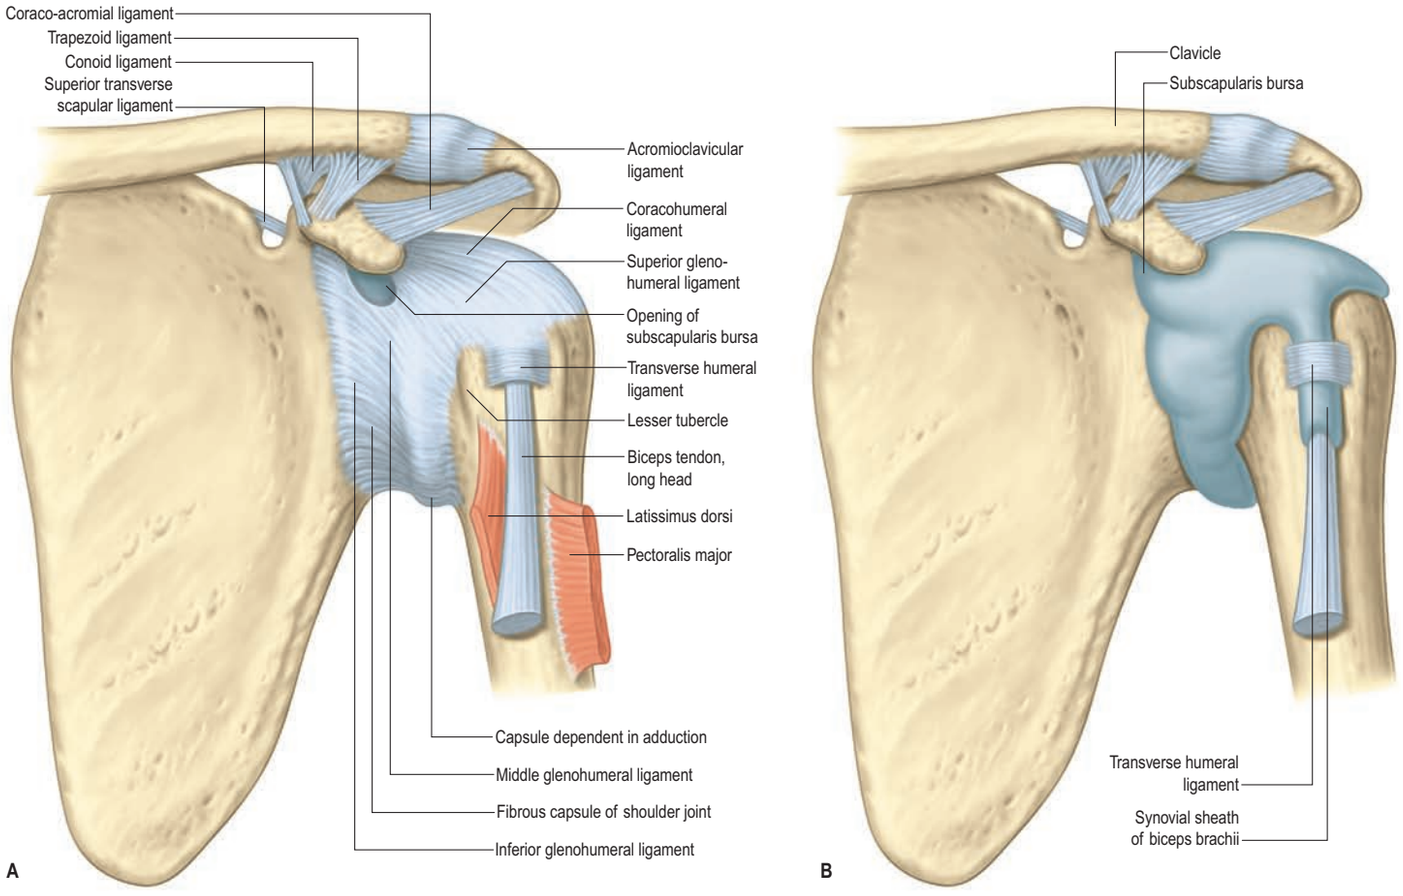

Fig. 49.16 **A**, The ligaments associated with the left shoulder, anterior aspect. **B**, A deeper view, showing the subscapularis bursa.

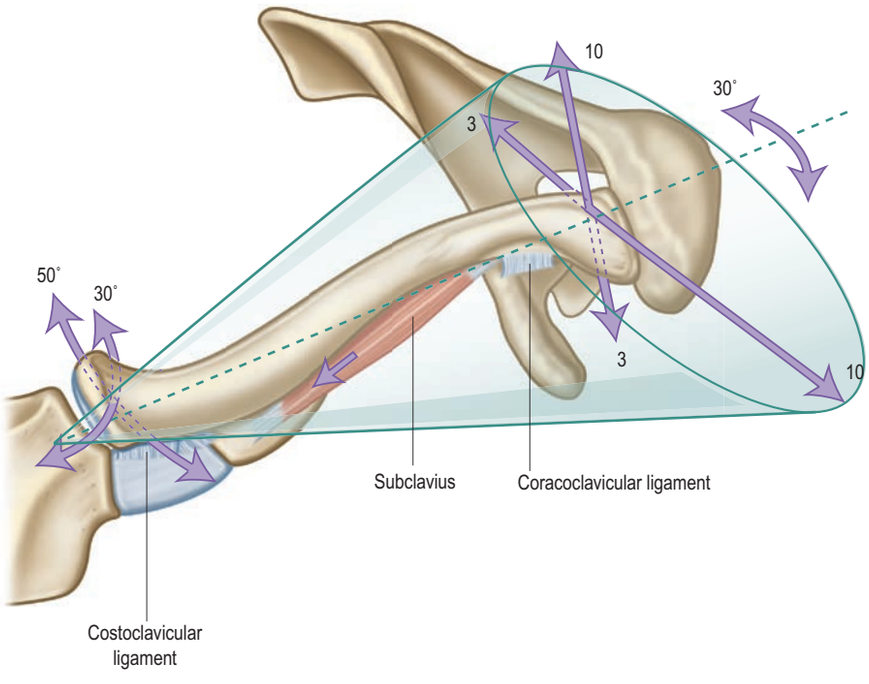

Fig. 49.17 Clavicular motion about the medial fulcrum of the costoclavicular ligaments immediately lateral to the sternoclavicular joint. The motion of the lateral end of the clavicle is limited by the motion available in the sternoclavicular joint, but based on an extra-articular fulcrum. The movements of the medial end of the clavicle at the sternoclavicular joint are therefore translations or gliding motions: the articular surfaces are configured for this type of motion. The lateral (acromial) end of the clavicle describes an asymmetric conical path during motion of the upper extremity. The maximal range of rotation of the clavicle (subtended by the sternoclavicular joint) is 30°; the maximal range of rotation of the scapula (sternoclavicular and acromioclavicular joints combined) is about 60° with respect to the sternum. The scapula is suspended from the distal clavicle at the acromioclavicular joint, which can be considered as the true joint (the cavity bounded by the acromioclavicular capsule and ligaments); it is also part of an extended articulation that comprises the true joint and the coracoclavicular suspensory ligaments. Arguably, the ligaments might be better defined as the claviculocoracoid ligaments, to acknowledge their role as the spiroid fulcrum around which the body of the scapula, and therefore the glenoid fossa, rotate during protraction and retraction of the scapula. The action of subclavius is to resist upward displacement of the distal clavicle, or to decelerate the clavicle moving into elevation. Linear measurements are given in centimetres.

Factors maintaining stability The acromioclavicular ligaments provide the greatest resistance to anteroposterior displacement of the acromioclavicular joint, while the coracoclavicular ligaments resist rotation and vertical translation of the joint.

Movements Movements at the joint complement those of the sternoclavicular joint (Figs 49.17–49.20). The sternal end of the clavicle is robustly supported by strong ligaments, and a similar, but less robust, arrangement of ligaments suspends the scapula from the lateral end of the bone. The motion of the acromioclavicular joint is limited by its small surface area and the articular capsule.

Movements at the scapulothoracic joint

The sternoclavicular and the acromioclavicular joints, in combination with the fascial space between the scapula and underlying chest wall, are known collectively as the scapulothoracic articulation. Scapular movements on the thoracic wall are facilitated by loose areolar tissue between subscapularis and serratus anterior, and between serratus anterior and the chest wall; the latter gliding plane is the scapulothoracic joint. It is a virtual space. There may be a bursa between the superior angle of the scapula and the dorsal aspect of the second rib.

The three long nerves innervating the scapulothoracic 'joint', i.e. accessory, long thoracic and dorsal scapular, innervate the three major muscle groups of scapulothoracic motion, namely: trapezius, serratus anterior and the medial scapular stabilizing muscles (levator scapulae and the rhomboids).

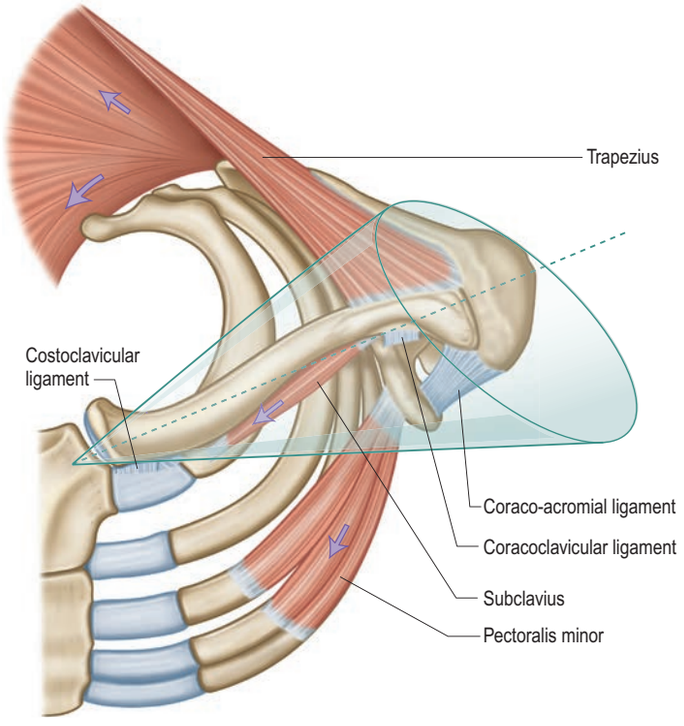

Fig. 49.18 The distal clavicle is moved by trapezius, which has an extensive attachment along the spine of the scapula and the medial aspect of the distal third of the clavicle. The antagonist of trapezial power is pectoralis minor, which, rarely, has an extension or slip of tendon that joins the coraco-acromial ligament. The latter acts as a tension band between the 'outriggers' of the acromion and coracoid. If surgically divided, the cut surfaces of the coraco-acromial ligament cannot be readily reapposed, suggesting a mechanical role in pre-tensioning the acromion and coracoid against the pull of trapezius. Shortening or tightness of pectoralis minor will create fixed protraction of the scapula, which then rotates ventrally around the chest wall. As a consequence, the acromion tilts and the space between it and the cranial surface of the rotator cuff below (the subacromial space) diminishes, creating the conditions in which forceful coaptation of the apposed surface of the rotator cuff and the coraco-acromial ligament may occur. This is the painful condition of 'impingement'.

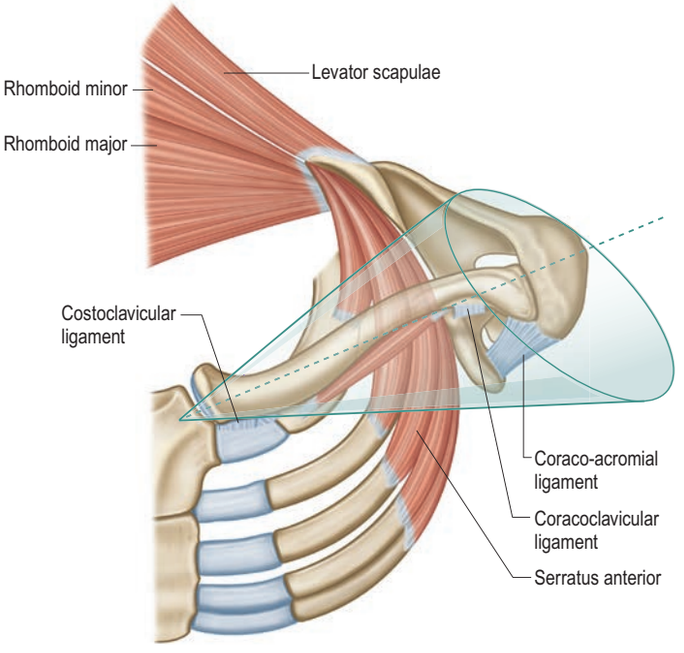

Fig. 49.19 Motion of the medial border of the scapula is governed by the opposing actions of the medial parascapular group (levator scapulae and rhomboids minor and major) and the scapulothoracic group (serratus anterior), causing retraction and protraction, respectively.

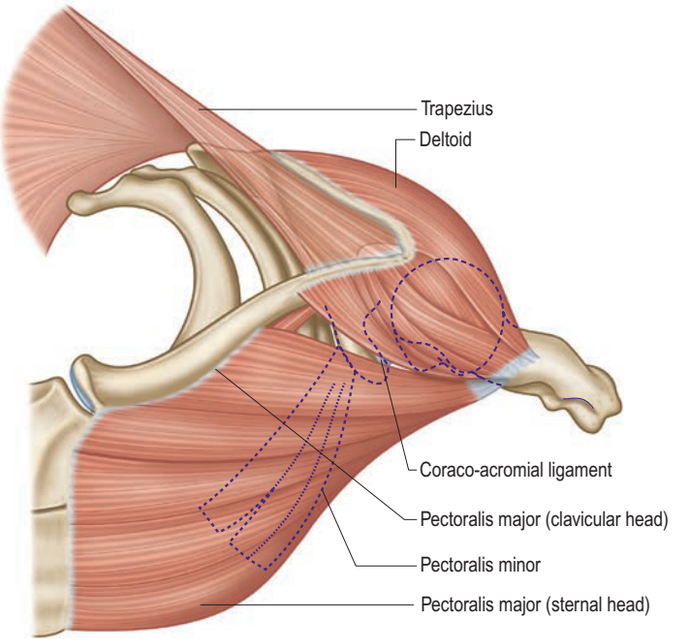

Fig. 49.20 The closely related humeral attachments of pectoralis major and deltoid (between one-third and one-half of the way down the shaft of the bone) enable the pectoralis major–deltoid muscular envelope to move the elbow, forearm and hand in space, using the shoulder as a fulcrum for effective delivery of power through a wide range of motion from in front of the trunk to behind. The relative coarseness of these muscles underlies their ability to produce great torque in upper-extremity motion; motion generated by these muscles is 'fine-tuned' by the rotator cuff working concordantly with the outer envelope (each segment or part of the rotator cuff can be said to have an equivalent segment or part in the outer envelope of muscles; this pattern is considered as a force-couple generating stable motion of the humerus on the scapula at the glenoid).

The following account should be read together with the description of movements of the glenohumeral joint. It is important to bear in mind that the purpose of scapular motion is the appropriate positioning of the glenohumeral joint in space, and the purpose of scapular stability is to provide a foundation for glenohumeral motion.

Elevation and depression

Scapular elevation, as in 'shrugging the shoulders', is generated by trapezius acting on the lateral clavicle, acromion and spine of the scapula. If levator scapulae is less active, the scapula rotates laterally (i.e. the inferior angle protracts around the chest wall), with dorsal rotation at the acromioclavicular joint; this is resisted by the rhomboid muscles and controlled by pectoralis minor. If levator scapulae is more active, then the scapula ascends with less rotation. The sternal end of the clavicle, rotating about an anteroposterior axis through the bone above the medial attachment of the costoclavicular ligament, slides down over the articular disc. This is resisted by subclavius and by tension in the costoclavicular ligament and sternoclavicular joint capsule. In scapular depression, ventral rotation occurs at the acromioclavicular joint, and the clavicle slides up on the disc at the sternoclavicular joint. The movements are checked by the cervical fibres of trapezius, the interclavicular and superior sternoclavicular ligaments and the articular disc. Usually, gravity alone is sufficient; when necessary, the lowest part of serratus anterior and pectoralis minor are active depressors.

Protraction and retraction

Protraction (forward movement) round the thoracic wall occurs in pushing, thrusting and reaching movements, usually with some lateral rotation. The acromion advances over the clavicular facet to the limit, and the shoulder is simultaneously advanced by forward movement of the lateral end of the clavicle and posterior translation of its sternal end over the sternal facet, carrying the disc with it. Pectoralis major, together with the anterior sternoclavicular ligament and posterior lamina of the costoclavicular ligament, check backward slide of the sternal end. Serratus anterior and pectoralis minor are prime movers and maintain continuous apposition of the scapula, especially its medial border, in smooth gliding on the thoracic wall, with the rhomboid muscles controlling the rate and

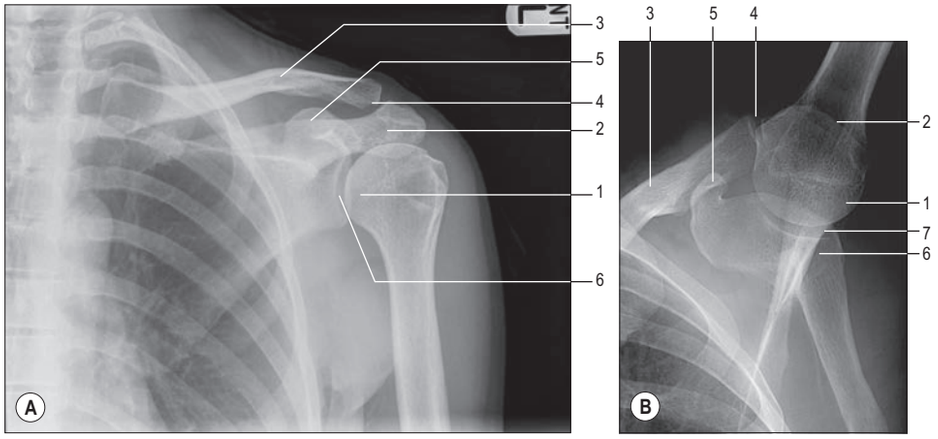

Fig. 49.21 Radiographs of the left shoulder of an 18-year-old female. **A**, Anteroposterior view. **B**, Axillary view with the arm abducted. Key: 1, head of humerus; 2, acromion; 3, clavicle; 4, acromioclavicular joint; 5, coracoid process; 6, glenoid fossa; 7, glenohumeral articulation.

range of motion. The upper part of latissimus dorsi also acts like a strap across the inferior scapular angle in protraction and lateral rotation.

In scapular retraction, i.e. bracing back the shoulders, these movements are reversed and checked at the sternoclavicular joint by the posterior sternoclavicular ligament and anterior lamina of the costoclavicular ligament. Trapezius (horizontal and lower fibres) and the rhomboids are prime movers, while the subclavius and pectoralis minor, enveloped within the clavi-coraco-axillary fascia, appear to decelerate the elevating limb.

Lateral and medial rotation

Lateral (upward) rotation of the scapula increases the range of humeral elevation by turning the glenoid cavity to face almost directly up, e.g. when raising the arm above the head. This movement is always associated with humeral elevation and rotation at the glenohumeral joint, and with protraction of the scapula. Scapular rotation requires movement at both sternoclavicular and acromioclavicular joints; the sternoclavicular joint permits elevation of the lateral end of the clavicle, a movement that is almost complete when the arm is abducted to 90°. The acromioclavicular joint moves in the first 30° of abduction, when the conoid ligament becomes taut, and is subsequently accompanied by clavicular rotation at the sternoclavicular joint around the longitudinal axis of the bone. The medial end is depressed further as the lateral end continues to rise. Some acromioclavicular movement also occurs in the final stages of humeral abduction. Trapezius (cervical fibres) and serratus anterior (the lower part) are prime movers, with the rhomboids providing resistance to motion.

Medial (downward) rotation is usually effected by gravity; gradual active lengthening of trapezius and serratus anterior is sufficient to control it. When more force is needed, levator scapulae, the rhomboids and, in the initial stages, pectoralis minor are prime movers in returning the scapula to a position of rest.

Glenohumeral (shoulder) joint

The glenohumeral joint is a synovial multiaxial spheroidal joint between the roughly hemispherical head of the humerus and the shallow glenoid fossa of the scapula (**Fig. 49.21**). It is the most mobile joint in the body and the most frequently dislocated. Its anatomy is a compromise between the requirements for motion and stability; both depend on the surrounding muscular and soft tissue envelope more than on the shape and surface area of the articulating surfaces.

The humeral head is held to the concave glenoid fossa by the compressive action of the rotator cuff muscles; the stabilizing mechanism of the glenohumeral joint is one of concavity compression. The rotator cuff muscles are attached to the proximal humerus through a musculotendinous envelope (see below), the deep surface of which fuses with the lateral part of the articular fibrous capsule. The humeral head is then contained in a spherical space bounded medially by the glenoid fossa and elsewhere by the deep surface of the fibrous capsule, a form of osseofibrous acetabulum. The walls of this 'acetabulum' (i.e. the rotator cuff muscles and tendons) are contained within a roughly spherical space bounded by the coracoid anteriorly; the coraco-acromial ligament anterosuperiorly; the acromion and spine of the scapula posteriorly, posterosuperiorly and posterolaterally; and the deep surface of deltoid anterolaterally and laterally. This arrangement creates two gliding planes, one internal (the glenohumeral articular gliding plane) and one external (the subcoracoid–subacromial–subdeltoid plane); the latter is continuous with the plane under the scapula (the scapulothoracic gliding plane). Gliding is facilitated by the synovial lined cavities of the glenohumeral joint and the subcoracoid, subacromial and subdeltoid bursae, which are nearly always contiguous. Infection, inflammation and injury commonly cause adhesions and fibrosis (with subsequent contracture) in these planes; restriction of motion follows, specific to the site and extent of adhesion. The surfaces of both gliding planes are extensive and fibrosis is consequently very restricting.

Articulating surfaces The articular surfaces are reciprocally curved and are correctly termed ovoids. The surface area of the humeral convexity is approximately four times that of the glenoid concavity, which means that only a small portion of the head opposes the glenoid in any position (**Figs 49.22–49.23**). The radius of curvature of the glenoid fossa in the coronal plane is greater than that of the humeral head, and is deepened by a fibrocartilaginous rim, the glenoid labrum (see Fig. 49.15). Both articular surfaces are covered by hyaline cartilage, thickest centrally and thinner peripherally over the humerus, and *vice versa* over the glenoid cavity. In most positions, their curvatures are not fully congruent and the joint is loose-packed; close-packing (full congruence) is probably only reached with the humerus abducted and laterally rotated.

Glenoid labrum The glenoid labrum is a fibrocartilaginous rim around the glenoid fossa. Anteriorly, it is triangular in section; posteriorly, it is more ovoid; while inferiorly, it may be flattened and almost deficient. It varies in size and thickness. The attachment to the edge of the glenoid fossa is secure superiorly where it blends with the anterior and posterior fasciculi of the long tendon of biceps (Vangsness et al 1994), less secure posteriorly, but relatively more secure anteroinferiorly (Bankart 1923). There may be an aperture between the free deep edge of the labrum and the anterior glenoid rim above the midpoint of the fossa. In slightly less than one-fifth of normal shoulders, there may be no anterior labrum, in which case its place is taken by a cord-like middle glenohumeral ligament. The labrum may be hypoplastic or absent in patients with collagen deficiency but with normal shoulder function (hypermobility syndrome); these shoulders are not necessarily unstable. The labrum deepens the glenoid cavity and so may assist in stabilizing the humeral head on the fossa, although the mechanism of this function remains uncertain. It may protect the bone and probably assists lubrication.

Fibrous capsule A fibrous capsule envelops the joint (see Figs 49.16, 49.22). It is attached medially to the glenoid neck at a variable distance from the glenoid labrum, so forming recesses anterior and posterior to the scapular neck; it includes the supraglenoid tubercle, to which the long head of biceps attaches, and which is therefore intracapsular. Laterally, it is attached to the anatomical neck of the humerus, i.e. near the articular margin, exceptinferomedially, where it descends more than 1 cm on the calcar humerale. The fibres of the capsule are orientated in a spiral fashion, so that, in elevation of the arm, the capsule tightens, so bringing the articular surfaces into closer apposition and contributing to the concavity compression. In some individuals, a deeper band of fibres orientated in a reverse obliquity to the main capsular fibres passes from the region of the lesser tubercle to the lower part of the anterior rim of the glenoid fossa. This is the anterior oblique band; its contribution to stability is uncertain.

(A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

The lateral part of the external surface of the fibrous capsule is blended with the tendons of supraspinatus (superiorly), infraspinatus and teres minor (posteriorly), subscapularis (anteriorly) and by the tendon of the long head of triceps at the infraglenoid tubercle (inferiorly). The rotator interval is a medially based, triangular area of uncovered capsule between the superior edge of subscapularis and the anterior edge of supraspinatus, with the base of the coracoid as the medial boundary of the interval. It is reinforced by the coracohumeral ligament, the superior glenohumeral ligament, and fibres from the supraspinatus tendon laterally. The axillary nerve and posterior circumflex humeral vessels are separated from the inferior capsule by the inferior border of subscapularis. The capsule is least supported inferiorly, and subjected to the greatest strain in full abduction, when it is stretched tightly across the humeral head. It is supported in this position by the proximal part of the long head of triceps and the broad bulk of teres major.

There are two openings in the capsule: below the coracoid process, connecting the joint cavity to a bursa that may envelop the upper border of the tendon of subscapularis (anteriorly); and between the humeral tubercles, allowing passage of the long tendon of biceps and its synovial sheath.

Ligaments The ligaments associated with the glenohumeral joint are the glenohumeral (superior, middle and inferior), coracohumeral and

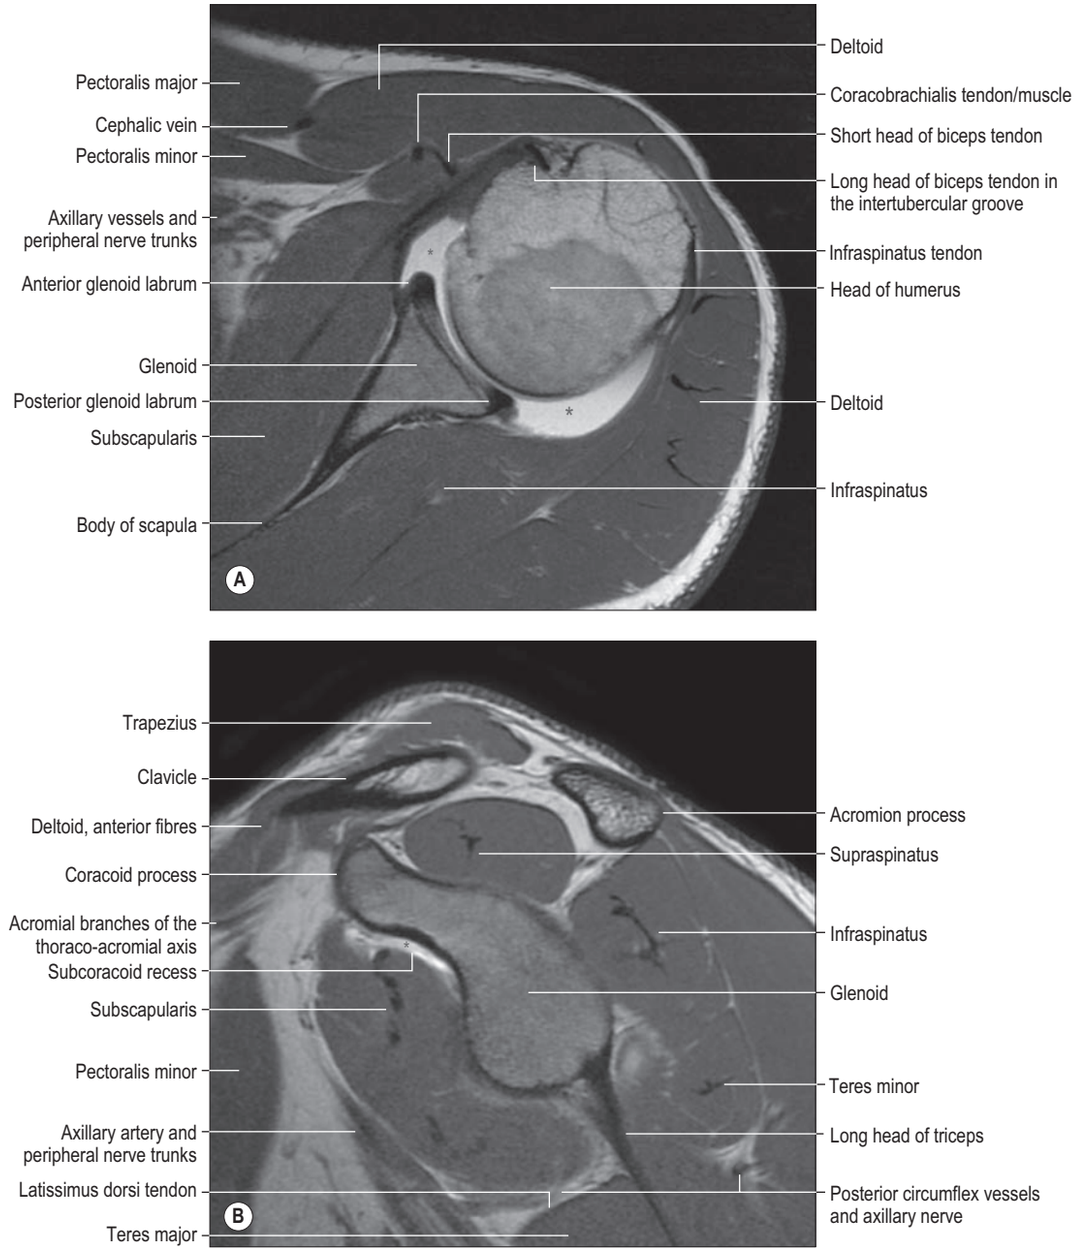

Fig. 49.23 A magnetic resonance arthrogram of the shoulder. **A**, Axial T1-weighted MRI of the left shoulder through the mid-level of the glenohumeral joint. Contrast medium is injected into the joint before the acquisition, and then shows up as bright fluid within the distended joint capsule (*). **B**, Sagittal T1-weighted MRI of the shoulder through the mid-level of the glenohumeral joint. Contrast medium is injected into the joint before the acquisition, and then shows up as bright fluid within the distended joint capsule (*).

transverse humeral. A ligament only restricts a specific motion of a joint when discrete parts of the ligament become tight; this only occurs at the limits of a specific motion of the joint when the ligament acts as a 'check-rein'. For movements that lie within the limit of motion, ligaments have no mechanical role. Mechanoreceptors and nociceptors are clustered at each end of the ligaments, more on the glenoid side than the humeral side (Halata and Baumann 2008). The capsule, ligaments and labrum contain the deep afferent innervation of the glenohumeral joint and therefore contribute to stability of the joint through facilitation of the rotator cuff activity within the normal range of human shoulder motion.

Glenohumeral ligaments Three glenohumeral ligaments, only visible from within the joint, reinforce the capsule anteriorly and inferiorly (**Fig. 49.24**). The superior glenohumeral ligament passes from the supraglenoid tubercle, just anterior to the origin of the long head of biceps, to the humerus at the fovea capitis, near the proximal tip of the lesser tubercle on the medial ridge of the intertubercular sulcus. It forms an anterior cover around the long head of biceps and is part of the rotator interval. Together with the coracohumeral ligament, it is an important stabilizer in the inferior direction, helping to keep the humeral head suspended (the coracohumeral ligament is more robust than the superior glenohumeral ligament).

The middle glenohumeral ligament arises from a wide attachment below the superior glenohumeral ligament, along the anterior glenoid margin as far as the inferior third of the rim, and passes obliquely inferolaterally, enlarging as it does so, to attach to the lesser tubercle deep to the tendon of subscapularis, with which it blends. The width and thickness of this ligament may be as much as 2 cm and 4 mm, respectively. It provides anterior stability between 45° and 60° of abduction in the scapular plane. However, 30% of individuals may not have a middle glenohumeral ligament; these individuals are not more likely to have unstable shoulders. It may be thickened and cord-like in the Buford complex (a congenital glenoidal labrum variant), again with no apparent disadvantage for stability.

The thicker and longer inferior glenohumeral ligament complex is a hammock-like structure with anchor points on the anterior and posterior sides of the glenoid. It arises from the anterior, middle and posterior margins of the glenoid labrum, below the epiphysial line, and passes anteroinferiorly to the inferior and medial aspects of the neck of the humerus. The anterior, superior edge of the inferior ligament is thickened as the anterior band; there is an equivalent, but not so robust, thickening of the posterior capsule: the posterior band. Between the two bands is a region of thin capsule known as the axillary pouch. (For further details, consult Burkart and Debski (2002), Di Giacomo et al (2008).)

Fig. 49.24 A sagittal MR arthrogram of the shoulder of a 28-year-old male. The glenohumeral joint has been distended by intra-articular injection of contrast medium: the glenohumeral ligaments are clearly outlined.

Coracohumeral ligament The coracohumeral ligament is attached to the dorsolateral base of the coracoid process and extends as two bands, which blend with the capsule, to the greater and lesser tubercles (see Fig. 49.16). Portions of the coracohumeral ligament form a tunnel for the biceps tendon on the anterior side of the joint. The rotator interval is reinforced by the coracohumeral ligament. It also blends inferiorly with the superior glenohumeral ligament. The ligament tightens in external rotation of the glenohumeral joint.

Transverse humeral ligament The transverse humeral ligament is a broad band that passes between the humeral tubercles, and is attached superior to the epiphysial line (see Fig. 49.16). It converts the intertubercular sulcus into a canal, and acts as a retinaculum for the long tendon of biceps.

Synovial membrane The synovial membrane lines the capsule and covers parts of the anatomical neck. The long tendon of biceps brachii traverses the joint in a synovial sheath that continues into the intertubercular sulcus as far as the surgical neck of the humerus (see Figs 49.16B, 49.22A). The intra-articular bicipital sheath may be connected to the articular surface of the superior capsule above by a mesotenon, which may be incomplete, presenting as one or several strands. This arrangement can only be the case if the biceps tendon was originally an extra-articular structure and invaginated, with its synovial sheath, into the glenohumeral joint as the upper limb rotated into external rotation relative to the trunk during development.

Bursae Many bursae adjoin the shoulder joint (see Figs 49.15–49.16). They are usually found between the tendon of subscapularis and the capsule, communicating with the joint between the superior and middle glenohumeral ligaments; on the superior acromial aspect; between the coracoid process and capsule; between teres major and the long head of triceps; and anterior and posterior to the tendon of latissimus dorsi. The subacromial bursa, between deltoid and the capsule, does not communicate with the joint cavity but is prolonged under the acromion and coraco-acromial ligament, and between them and supraspinatus: it appears to be attached, together with the subdeltoid fascia, to the acromion. Bursae sometimes occur behind coracobrachialis and between the tendon of infraspinatus and the capsule, occasionally opening into the joint.

Vascular supply The glenohumeral joint is supplied by branches from the anterior and posterior circumflex humeral, suprascapular and circumflex scapular vessels.

Innervation The glenohumeral joint is innervated mainly from the posterior cord of the brachial plexus through the subscapular nerves. The capsule is supplied by the suprascapular nerve (posterior and superior parts), axillary nerve (anteroinferior) and the lateral pectoral nerve (anterosuperior, including the rotator interval capsule).

Factors maintaining stability The articulation between the relatively large humeral head and the shallow glenoid fossa allows a wide range of movement but is a challenge for the stability of the joint.

Movements at the glenohumeral joint

The shoulder is capable of any combination of swing and spin over a range far wider than that of any other joint in the body. Flexion–extension, abduction–adduction, and medial (internal) and lateral (external) rotation all occur at the shoulder. A combination of all of these results in circumduction, which is not a useful movement to record in clinical practice. Although most movement of the shoulder occurs at the glenohumeral joint, the scapulothoracic articulation contributes to overall shoulder movement in all directions, including lateral rotation.

Muscles producing movements The muscles that produce movements at the glenohumeral joint are principally the scapulohumeral and thoracobrachial muscles: deltoid, pectoralis major and latissimus dorsi, assisted by coracobrachialis. The translating effect of these muscles on the shoulder joint is counteracted by the rotator cuff, a group of short muscles (subscapularis, supraspinatus, infraspinatus and teres minor), including teres major, that are attached closer to the joint, and that centre the head of the humerus in the glenoid fossa through the entire range of motion.

Flexion Flexion is carried out by pectoralis major (clavicular part), deltoid (anterior fibres) and coracobrachialis, assisted by biceps. The sternocostal part of pectoralis major is a major force in flexion forwards to the coronal plane from full extension.

Extension Extension is carried out by deltoid (posterior fibres) and teres major, from the dependent position. When the fully flexed arm is extended against resistance, latissimus dorsi and the sternocostal part of pectoralis major act powerfully until the arm reaches the coronal plane.

Abduction Abduction is carried out by supraspinatus and deltoid. The effect of deltoid is mainly upward and, unless opposed, this would displace the humerus upwards. Subscapularis, supraspinatus, infraspinatus and teres minor exert a centralizing force and so apply a balancing force; together with deltoid, they constitute a 'couple' to produce abduction in the scapular plane.

Medial rotation Medial rotation is carried out by pectoralis major, deltoid (anterior fibres), latissimus dorsi, teres major and, with the arm pendant, subscapularis.

Lateral rotation Lateral rotation is carried out by infraspinatus, deltoid (posterior fibres) and teres minor. Lateral rotation is important for clearance of the greater tubercle and its associated tissues as it passes under the coraco-acromial arch during elevation of the arm.

Glenohumeral joint dislocation

The glenohumeral joint is the most frequently dislocated joint in the body. Most dislocations are anterior, and occur when the forearm is forced backwards into greater lateral (external) rotation when it is in abduction, lateral rotation and extension. A dislocated shoulder loses its normal contour because the humeral head is displaced anterior to the glenoid rim and, sometimes, under the coracoid, which means that the acromion process, rather than the greater tubercle, becomes the most lateral bony structure, giving the shoulder a 'squared-off' appearance.

MUSCLES

The shoulder girdle and shoulder joint musculature are arranged in layered, functional groups (**Table 49.1**). The muscles of the shoulder girdle may suspend or move the scapula; these functions are

In the anatomical analysis of shoulder movements, it is usual to relate humeral movement to the scapula, rather than to conventional anatomical planes. However, in clinical practice, movements *are* related to the conventional anatomical planes. When the arm hangs at rest, the glenoid fossa faces almost equally forwards and laterally, and the humeral capitular and scapular (topographical) axes correspond, although the humerus, relative to the anatomical position, is medially rotated. With the humerus in the anatomical position, i.e. with the inter-epicondylar axis in the frontal plane, the humeral head axis is posteriorly directed, in line with the axis of the scapula.

Using the anatomical description, flexion carries the arm anteromedially on an axis through the humeral head orthogonal to the glenoid fossa at its centre. Abduction and adduction occur in a vertical plane orthogonal to that of flexion–extension and the axis is horizontal, through the humeral head and parallel with the glenoid plane. Pure abduction raises the arm anterolaterally in the plane of the scapula. However, when referred to the trunk, flexion and extension occur in the paramedian plane, and abduction and adduction occur in the coronal plane. In this sense, raising the arm vertically from flexion or raising it from abduction are both accompanied by humeral rotation in opposite directions. Whether 'scapular' or any other plane of abduction is described, these are selections from an infinite series. In scapular abduction, points on the humeral surface pursue vertical cords, but in rotation, they are horizontal. In 'pure' flexion–extension, in a plane orthogonal to the scapula, the axis of movement and the notional 'mechanical axis' are regarded as projected from the centre of the glenoid cavity.

Glenohumeral abduction is about 120° or more (see Fig. 49.21B). Abduction may reach 180° after thoracoscapular arthrodesis for facioscapulohumeral dystrophy (Copeland and Howard 1978). Abduction is restricted to about 45° after glenohumeral arthrodesis. Some 60° of further abduction occurs at the sterno- and acromioclavicular articulations, and contralateral vertebral flexion also aids in bringing the arm to the vertical. During active elevation, movements at the glenohumeral and acromioclavicular joints are simultaneous, except in the initial few degrees, when most, often all, movement is glenohumeral. For every 15° of elevation, glenohumeral movement is said to be 10° and scapular movement 5°, but this ratio is not linear throughout the range of motion. During the initial stages of abduction, the entire rotator cuff counteracts the strong upward component of the pull of deltoid, which would otherwise cause the humeral head to slide up the glenoid surface; the additive turning moments exerted by the combined deltoid and supraspinatus force-couple may then abduct the arm. Deltoid also acts with the other elements of the rotator cuff, according to the position of the arm in space, to maintain rotation, flexion and extension of the arm. It is important to consider the synergistic relation between the rotator cuff and deltoid as a continuum in which the rotator cuff muscles act to provide a stable base on which deltoid can work effectively, whatever the position of the arm.

In flexion, the humerus swings at right-angles to the scapular plane, and scapular rotation cannot increase the elevation (120°) that is obtainable in full flexion. If the fully flexed humerus is also abducted, elevation increases *pro rata* until, when the humerus reaches the scapular plane, i.e. when true abduction is reached, 180° of elevation becomes possible. In medial or lateral rotation, the humerus revolves about one-quarter of a circle around a vertical axis; the range is greatest when the arm is pendant, and least when it is vertical. When the rotational range at the glenohumeral joint is assessed, the forearm should be flexed to a right-angle at the elbow in order to prevent the effects of superadded pronation or supination in the pendant limb. In circumduction, which is a succession of the foregoing movements, the distal end of the humerus describes the base of a cone with its apex at the humeral head. This glenohumeral movement may be greatly increased by scapular movements, e.g. in acts of slinging objects with force.

The peculiar relation of the long head of biceps brachii to the shoulder joint may serve several purposes. By its connection with both the shoulder and elbow, the muscle harmonizes their actions as an elastic connection during all upper limb movements. It helps to prevent the humeral head impinging on the acromion when deltoid contracts and also to steady it in movements of the arm. In paralysis or absence (i.e. in rotator cuff tendon tears) of supraspinatus, the long head of biceps may also help initiate abduction of the arm, particularly when the humerus is laterally rotated.

The axillary nerve and vessels may be injured during dislocation or, more commonly, during inexpert attempts at relocation, particularly in older patients. This can lead to an inability to maintain abduction of the shoulder as a result of paralysis of deltoid. If, after relocation of the joint, the patient cannot *initiate* elevation (abduction) from the pendant position, then there may be an associated rotator cuff rupture and/or suprascapular nerve lesion. If the patient can initiate, but cannot maintain, abduction beyond 15°, then deltoid palsy should be suspected. Patients, particularly the elderly, can have a rotator cuff rupture and an axillary nerve palsy causing deltoid paralysis; it can be difficult to distinguish between the two. There may also be an area of hypoaesthesia or anaesthesia over the distal part of the muscle (sometimes referred to as the 'regimental badge patch' of skin; see Fig. 49.2), reflecting loss of function in the upper lateral cutaneous nerve of the arm (a branch of the axillary nerve), as well as venous occlusive changes (swelling) in the limb. After more violent dislocation, younger patients may have deltoid paralysis and an intact, but stretched, rotator cuff or partial tearing of the tendons, with a suprascapular nerve injury; these patients may have unexpected pain in the supraspinous fossa with weakness of infraspinatus (lateral rotation), as well as the anticipated anterior shoulder pain. Posterior dislocation is rare and typically occurs when violent movements produce marked medial rotation and adduction, e.g. in epileptic seizures or electric shock. The upper limb is held in fixed medial rotation, and external rotation is impossible to perform.

TABLE 49.1 The relationship between functional muscle grouping and actions of the pectoral girdle*

Functional group	Specific muscles	Action
Occipitospinoscapular	Trapezius	Scapular suspension Position and motion of the acromioclavicular joint in relation to the thorax and (neur) axis Deceleration of the lateral clavicle during motion
Thoracoscapular	Pectoralis minor	
Spinoclavicular	Trapezius	
Thoracoclavicular	Subclavius	
Thoracoscapular (medial border)	Levator scapulae Rhomboid minor Rhomboid major Serratus anterior Serratus posterior superior Serratus posterior inferior	Scapular motion Position and motion of the glenohumeral joint in relation to the thorax and (neur)axis
Thoracohumeral	Pectoralis major Latissimus dorsi	Thoracobrachial motion Position of the arm
Scapulohumeral	Deltoid Coracobrachialis Biceps brachii (short head)	
	Teres minor Infraspinatus Supraspinatus Subscapularis Teres major	Concavity compression of the glenohumeral joint
	Triceps brachii (long head) Biceps brachii (long head)	Coordination of shoulder and elbow motion

*As a principle, a muscle will act on a motion segment to alter the position of the distal extent of that segment in space. As an example, deltoid acts on the shoulder joint but its effect is to move the distal extent of the humerus, i.e. the elbow.

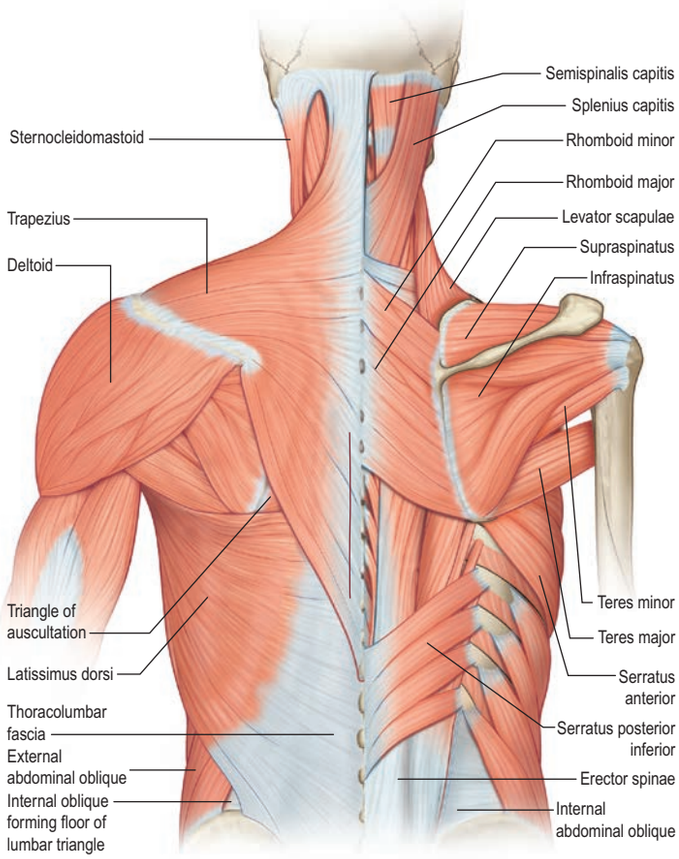

Fig. 49.25 The muscles of the back and shoulder girdles. Superficial muscles are shown on the left. Deeper muscles, revealed after excision of deltoid, latissimus dorsi and trapezius, are shown on the right.

interdependent. The muscles of the shoulder joint may stabilize the joint, move the arm on the stable shoulder joint, or coordinate shoulder and elbow movement; these functions are also interdependent. The closer a muscle is to the centre of motion of the joint on which it acts, the greater its effect on the stability of that joint at rest and during motion. The further away from the centre of motion, the greater the effect of the resultant muscular vector on translation of the joint surfaces. As an example, both subscapularis and pectoralis major generate medial rotation of the glenohumeral joint; subscapularis contributes to concavity compression at the glenohumeral joint (i.e. stability), while pectoralis major causes anterior displacement into flexion and adduction in the absence of subscapularis; when these muscles are working synergistically, the arm is both stabilized at the glenohumeral joint, and flexed and adducted.

The clinical examination of the shoulder girdle muscles is demonstrated in Video 48.1.

Muscles of scapular suspension

Trapezius acts on the spine of the scapula, acromion and lateral clavicle to rotate the acromioclavicular joint upwards and dorsally; movement is guided and limited by the length and shape of the clavicle. Pectoralis minor acts to control the position of the coracoid as trapezius acts on the scapula, while subclavius acts to control clavicular elevation and rotation. These muscles act on the processes of the scapula, while the coraco-acromial ligament acts as a tension band between the processes. Disruption of the continuity of this arrangement (fracture of the clavicle or coracoid, or dislocation of the acromioclavicular joint) will have a profound effect on scapular suspension.

Trapezius

Trapezius is derived from head paraxial mesenchyme with neural crest connective tissue, rather than from the dermomyotomes of lower somites, and is therefore unique among shoulder girdle muscles. It is attached to the spine of the scapula and acromion, segments of the scapula for which development is encoded by a single gene (Dhir et al, 2018).

Attachments Trapezius is a flat, triangular muscle that extends over the back of the neck and upper thorax (Fig. 49.25). The paired trapezius muscles form a diamond shape, from which the name is derived. On either side, the muscle is attached to the medial third of the superior nuchal line, external occipital protuberance, ligamentum nuchae, and apices of the spinous processes and their supraspinous ligaments from C7 to T12. The occipital attachment is by a fibrous lamina, which is also adherent to the skin. The spinal attachment is by a broad triangular aponeurosis from the sixth cervical to the third thoracic vertebrae, and by short tendinous fibres below this.

Superior fibres descend, inferior fibres ascend, and the fibres between them are directed horizontally; all converge laterally on the scapula. The superior fibres are attached to the posterior border of the lateral third of the clavicle; the middle fibres to the medial acromial margin and superior lip of the crest of the scapular spine; and the inferior fibres pass into an aponeurosis that glides over a smooth triangular surface at the medial end of the scapular spine and is attached to a tubercle at its lateral apex.

Variants The clavicular attachment of trapezius varies in extent, sometimes reaching mid-clavicle, and occasionally blending with sternocleidomastoid. The vertebral attachment sometimes stops at the eighth thoracic spine. The occipital attachment may be absent. Cervical and dorsal parts are occasionally separate. The inferior part may be hypoplastic or absent.

Vascular supply The upper third of trapezius is supplied by a transverse muscular branch that arises from the occipital artery at the level of the mastoid process. It enters the muscle on its deep surface and gives off several musculocutaneous perforators to the overlying skin. The middle portion of trapezius, together with an area of overlying skin, is supplied by the superficial cervical artery or by a superficial branch of the transverse cervical artery, via musculocutaneous perforators. The lower third of trapezius is supplied by a muscular branch from the dorsal scapular artery, passing medial to the medial border of the scapula. It reaches the deep surface of the muscle either by piercing the rhomboids or by passing between rhomboids major and minor at the level of the base of the spine of the scapula. It anastomoses with the medial and lateral perforating branches of the posterior intercostal arteries.

Innervation Trapezius is innervated by the accessory nerve (see Chs 35 and 48 for more details). Sensory (proprioceptive) branches are derived from the third and fourth cervical ventral rami.

Actions Trapezius cooperates with other muscles in steadying the scapula, controlling it during movements of the arm and maintaining

the level and poise of the shoulder. Electromyographic activity is minimal in the unloaded arm, and heavy loads can be suspended with only a small contribution from the upper part; it is the lower part of the muscle that resists lateral rotation of the scapula under load. Acting with levator scapulae, the upper fibres elevate the scapula and, with it, the point of the shoulder; acting with serratus anterior, the lower fibres of trapezius protract and rotate the scapula medially (upwards) so that the arm can be raised above the head; acting with the rhomboids, it retracts the scapula, bracing the shoulder. With the shoulder fixed, trapezius may bend the head and neck backwards and laterally. Trapezius, pectoralis minor, levator scapulae, rhomboids and serratus anterior combine to produce a variety of scapular rotations see below.

If the muscle is denervated, the functions of trapezius cannot be substituted readily by muscle transfer; its unique suite of complex actions suggest that it should rarely, if ever, be used as a muscle for transfer elsewhere.

Testing The upper fibres of trapezius are palpated while the shoulder is shrugged against resistance (see Video 48.1). The lower fibres are palpated during scapular retraction. A better discriminative test is as follows: the hand is brought by medial rotation to the small of the back and the patient is asked to maintain it firmly in this position while the examiner tries to pull the hand off the back. The lower fibres of the trapezius are activated to hold the scapular spine horizontal. Failure to do so implies paresis or paralysis of trapezius, but this must be distinguished from congenital hypoplasia of the lower fibres of the muscle.

Trapezius palsy results in a characteristic posture: the shoulder is tilted laterally and forwards, the acromioclavicular joint is lowered, the superior pole of the scapula is rotated upwards and the inferior pole is displaced medially and, usually, away from the chest wall. This distinguishes trapezius palsy from that of serratus anterior, in which the entire medial border of the scapula tends to elevate away from the chest wall (so-called 'winging'). The scapula is displaced upwards and towards the spine. The altered posture and disordered motion of the scapula create distortion (narrowing and elongation) of the cervico-axillary sheath and its contents; symptoms of reduced venous return, lymphatic obstruction and disturbed neural perfusion (pain, paraesthesiae, dysaesthesiae) are almost universal.

Pectoralis minor

Attachments Pectoralis minor is a thin, triangular muscle lying posterior (deep) to pectoralis major (see Figs 49.26, 49.47). It arises from the upper margins and outer surfaces of the third to fifth ribs (frequently, second to fourth), near their cartilages, and from the fascia over the adjoining external intercostal muscles. Its fibres ascend laterally under cover of pectoralis major, converging in a flat tendon that is attached to the medial border and upper surface of the coracoid process of the scapula. Part or all of the tendon may appear to cross the coracoid process into the coraco-acromial ligament.

Variants Slips of the muscle are sometimes separated and vary in number and level. In rare cases, one passes from the first rib to the coracoid (pectoralis minimus). The costal attachments can be second to fifth ribs; third to fifth; second to fourth; or third to fourth. The muscle may be present or absent when pectoralis major is absent (in Poland's syndrome).

Relations Pectoralis major, the lateral pectoral nerve and pectoral branches of the thoraco-acromial artery are anterior. The ribs, external intercostals, serratus anterior, the axilla, axillary vessels, lymphatics and brachial plexus are all posterior. The upper border of pectoralis minor is separated from the clavicle by a triangular gap filled by the clavipectoral fascia, behind which are the axillary vessels, lymphatics and nerves. The lateral thoracic artery follows the lower border of the muscle. The medial pectoral nerves pierce and partly supply the muscle.

Vascular supply Pectoralis minor is supplied by pectoral and deltoid branches of the thoraco-acromial and superior and lateral thoracic arteries.

Innervation Pectoralis minor is innervated by branches of the medial and lateral pectoral nerves (fifth, sixth, seventh and eighth cervical and first thoracic ventral rami).

Actions Pectoralis minor assists serratus anterior in drawing the scapula forwards around the chest wall. With levator scapulae and the rhomboids, it rotates the scapula, depressing the point of the shoulder. It resists scapular rotation caused by trapezius. Both pectoral muscles are electromyographically quiescent in normal inspiration, but are active in forced inspiration.

Subclavius

Attachments Subclavius is a long, asymmetric triangular muscle between the clavicle and the first rib (Fig. 49.26). It arises from the junction of the first rib and its costal cartilage by a thick tendon, prolonged at its inferior margin and anterior to the costoclavicular ligament. It passes upwards and laterally to attach by direct muscular fibres into a groove on the undersurface of the middle third of the clavicle; the lower and most lateral fibres are the longest. Subclavius may be attached to the coracoid process or the upper border of the scapula as well as, or instead of, the clavicle.

Relations Posteriorly, subclavius is separated from the first rib by the subclavian vessels and brachial plexus; anteriorly, it is separated from pectoralis major by the anterior lamina of the clavipectoral fascia. The suprascapular artery, which has a variable pattern, descends behind the muscle, passing between it and omohyoid anteriorly and the subclavian vessels posteriorly; the artery, therefore, has a close relationship to the posterior surface of the clavicle, a feature that makes it susceptible to injury during clavicular fracture and surgical fixation.

Vascular supply Subclavius is supplied by the clavicular branch of the thoraco-acromial artery and the suprascapular artery.

Innervation Subclavius is supplied by the nerve to subclavius (fifth and sixth cervical ventral rami). It seems reasonable to assume that a muscle, however apparently insubstantial, that has a unique, solitary nerve supply must have an important function; subclavius is no exception (see above and below).

Actions Subclavius resists accelerated elevation and rotation of the clavicle during elevation of the shoulder girdle, and may help to close-pack the medial end of the clavicle against the articular disc of the sternoclavicular joint for greater stability under load. It is inaccessible to palpation and difficult to investigate by electromyography. Incidentally, it 'protects' the subclavian vessels and brachial plexus that lie behind it.

Muscles of scapular motion

Levator scapulae

Attachments Levator scapulae is a slender muscle attached by tendinous slips to the transverse processes of the atlas and axis, and to the posterior tubercles of the transverse processes of the third and fourth cervical vertebrae (see Figs 35.6, 49.25–49.26). It descends diagonally to attach to the medial scapular border between its superior angle and the triangular smooth surface at the medial end of the scapular spine.

Variants Levator scapulae varies considerably in its vertebral attachments and the extent to which it separates into slips. There may be accessory attachments to the mastoid process, occipital bone, first or second rib, the scaleni, trapezius and the serratus muscles.

Vascular supply Levator scapulae receives its arterial supply mainly from the transverse cervical and ascending cervical arteries. The vertebral extremity of the muscle is supplied by branches from the vertebral artery.

Innervation Levator scapulae is innervated directly by branches of the third and fourth cervical spinal nerves, and from the fifth cervical nerve via the dorsal scapular nerve.

Actions Levator scapulae elevates the superior angle of the scapula. If unopposed, this causes a lateral rotation of the scapula. With the cervical vertebral column fixed, levator scapulae acts with trapezius to elevate the scapula or to sustain a weight carried on the shoulder; with the shoulder fixed, the muscle inclines the neck to the same side.

Rhomboid minor

Attachments Rhomboid minor is a small, cylindrical muscle. It runs from the lower ligamentum nuchae and the spines of the seventh cervical and first thoracic vertebrae to the base of a smooth triangular surface at the medial end of the spine of the scapula, where dorsal and ventral layers enclose the inferior border of levator scapulae (see Fig. 49.25). The dorsal layer of rhomboid minor is attached to the rim of the triangular surface, dorsolateral to and below levator scapulae. The ventral layer is strong and wide, extending 2–3 cm medial to and below levator scapulae; here, the fasciae of rhomboid minor and serratus anterior are fused. Rhomboid minor is usually separate from rhomboid major, but the muscles overlap and are occasionally united.

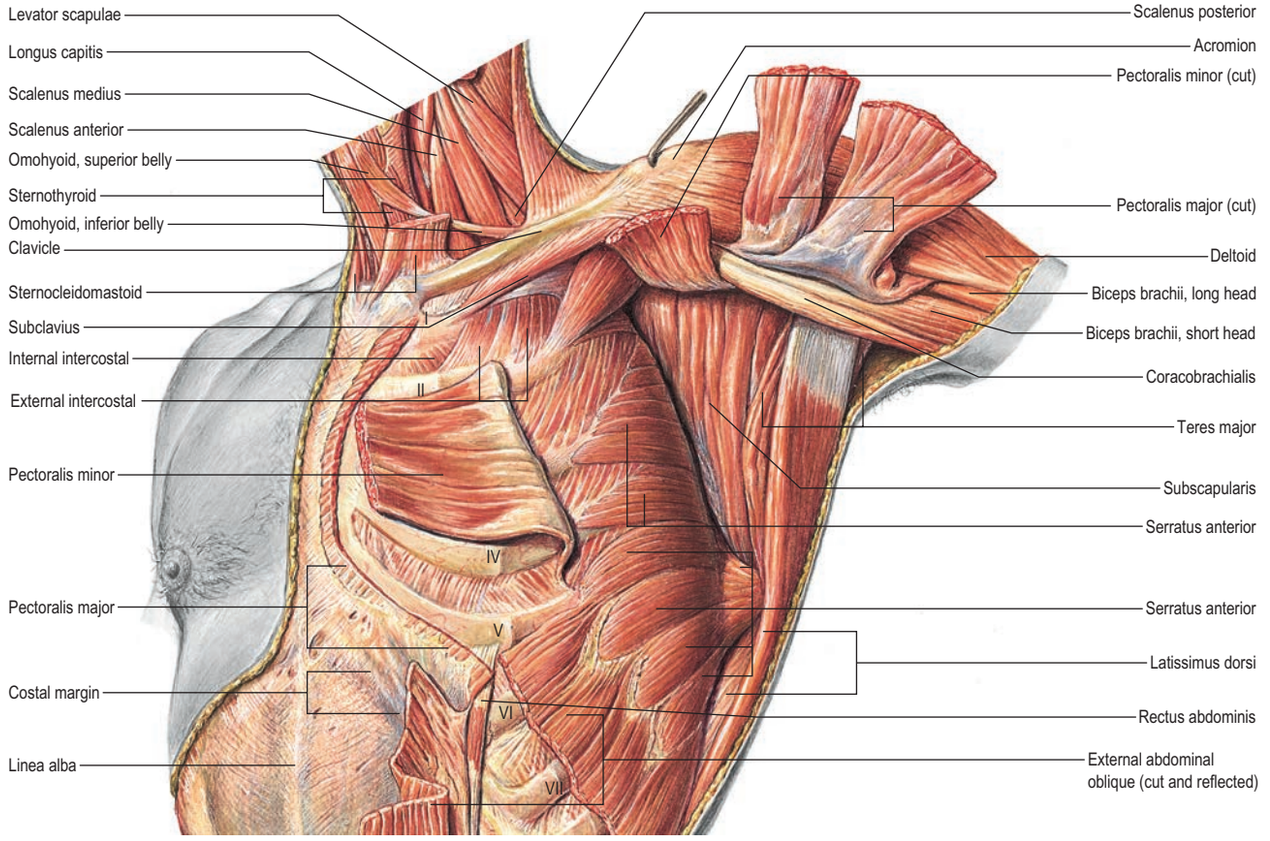

Fig. 49.26 The deep muscles of the chest and left shoulder girdle, anterior aspect. Roman numerals refer to costal cartilages. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Variants There is some variability in the vertebral and scapular attachments of rhomboids major and minor. A slip of muscle may extend from the upper border of rhomboid minor to reach the occipital bone (rhomboid occipitalis).

Rhomboid major

Attachments Rhomboid major is a quadrilateral sheet of muscle that arises by tendinous fibres from the spines and supraspinous ligaments of the second to fifth thoracic vertebrae, and descends laterally to the medial border of the scapula between the root of the spine and the inferior angle (see Fig. 49.25). Most of its fibres usually end in a tendinous band between these two points, joined to the medial border by a thin membrane. Occasionally, this is incomplete, in which case some muscular fibres are attached directly into the scapula. The attachments of rhomboid major (and also those of rhomboid minor, levator scapulae and serratus anterior) may be more extensive, with 'folds' or extensions passing to both dorsal and costal aspects of the scapula adjacent to its medial margin.

Vascular supply of the rhomboids Rhomboids major and minor are supplied by the dorsal scapular artery or the deep branch of the transverse cervical artery and by dorsal perforating branches from the upper five or six posterior intercostal arteries.

Innervation of the rhomboids Rhomboids major and minor are innervated by a branch of the dorsal scapular nerve (fourth and fifth cervical ventral rami).

Actions of the rhomboids Both rhomboid major and rhomboid minor retract the medial border of the scapula superiorly and medially, and are used in retraction of the shoulders.

Testing of the rhomboids Rhomboids major and minor can be palpated deep to trapezius on bracing the shoulder back against resistance with the arm in elevation at shoulder level.

Serratus anterior

Attachments Serratus anterior is a large muscular sheet that curves around the thorax. It arises from an extensive costal attachment and inserts on the scapula (see Figs 49.25–49.26). Fleshy digitations arise anteriorly from the outer surfaces and superior borders of the upper eight to ten ribs, and from fasciae that cover the intervening intercostal muscles. The line of origin of the muscle is long and slightly curved, and passes inferolaterally around the thorax. There are three parts: the upper fibres arise from the first and second ribs and intercostal fascia, the middle fibres arise from the third to sixth ribs, and the lower fibres interdigitate with the upper five slips of external oblique. The muscle follows the contour of the chest wall closely, reaching the medial border of the scapula anterior to subscapularis. The first (uppermost) digitation encloses, and is attached to, a triangular area of both the costal and the dorsal surfaces of the superior scapular angle. The next two or three digitations form a triangular sheet that is attached to the costal surface along almost its entire medial border. The lower four or five digitations converge to be attached by musculotendinous fibres to a triangular impression on the costal surface of the inferior angle; they enclose the inferior angle and are also attached to a smaller triangular part of its dorsal surface near its tip.

Variants Digitations may be absent, particularly the first and eighth, and sometimes also the intermediate part. Serratus anterior may be partly fused with levator scapulae, adjacent external intercostals or external oblique.

Vascular supply Serratus anterior is supplied by superior and lateral thoracic arteries, and by branches from the thoracodorsal artery before (occasionally, after) it divides in latissimus dorsi.

Innervation Serratus anterior is innervated by the long thoracic nerve (fifth, sixth and seventh cervical ventral rami), which descends on the external surface of the muscle.

Actions With pectoralis minor, serratus anterior protracts (draws forwards) the scapula, as a prime mover in all reaching and pushing movements. The upper part, with levator scapulae and the upper fibres of trapezius, suspends the scapula; only slight activity is sufficient to support the unloaded arm. The more extensive lower insertion pulls the inferior scapular angle forwards around the thorax, assisting trapezius in upward rotation of the bone, an action that is essential to raising the arm above the head. In the initial stages of abduction, serratus anterior helps other muscles to fix the scapula, so that deltoid acts effectively on the humerus and not the scapula. While deltoid is raising the arm to a right-angle with the scapula,

serratus anterior and trapezius are simultaneously rotating the scapula; the combination allows the arm to be raised to the vertical. To effect this upward rotation of the scapula, forward pull on the inferior angle by the lower digitations of serratus anterior is coupled with an upward and medial pull on the lateral end of the clavicle and acromion by the upper fibres of trapezius, and a downward pull on the base of the scapular spine by the lower fibres of trapezius. Conversely, slow downward scapular rotation, assisted by gravity, is achieved by controlled lengthening of these muscles. More powerful downward rotation requires balanced contraction of the upper fibres of serratus anterior, levator scapulae, rhomboids, pectoralis minor and the middle part of trapezius. When weights are carried in front of the body, serratus anterior prevents backward rotation of the scapula. Electromyography shows that serratus anterior is not active in normal human respiration. This may not apply to laboured respiration, e.g. when asthmatics and athletes may be observed to fix the scapula by grasping a rail or other support.

Testing The muscular digitations of serratus anterior can be seen and felt when the outstretched hand pushes against resistance.

When serratus anterior is paralysed, the medial border of the scapula, and especially its lower angle, stand out prominently. The arm cannot be raised fully. Pushing is ineffective; indeed, attempts to do so produce further projection, known as 'winging' of the scapula (Streit et al 2012; see Fig. 49.39).

Serratus posterior superior

Serratus posterior superior is described on page 1008.

Serratus posterior inferior

Serratus posterior inferior is described on page 1008 (see Fig. 49.25).

Muscles of thoracobrachial motion

The large muscles from the trunk to the arm, and from the scapula to the arm, act on the shoulder joint. Pectoralis major and latissimus dorsi are attached to the metaphysis of the humerus below the centre of rotation of the joint, while deltoid and coracobrachialis are attached to the midpoint of the diaphysis or shaft, some way from the centre of rotation of the shoulder joint. These four muscles move the arm in relation to the shoulder joint, so that, although they act through the shoulder joint, their role is to position the elbow joint (and, thus, the hand) in space. The continuous sheet of muscle that is pectoralis major and deltoid positions the elbow through a wide, asymmetrical, conical range of motion from adduction across the trunk with medial rotation, through flexion, abduction and external rotation, into extension at the shoulder. The cervical spinal segmental levels at which this range of movement is represented, C5 and C6, give rise to the anterior division innervation to pectoralis major (thus, pre-axial or predominantly flexor muscles) and the posterior division innervation (thus, post-axial or predominantly extensor muscles) to deltoid. Similarly, coracobrachialis (a flexor and adductor of the abducted arm) is innervated through the anterior division of C5, C6 and (predominantly) C7 segmental levels, while latissimus dorsi is innervated through the posterior division of C6, C7 and C8 (predominantly C7). These are examples of the *movements* of a joint, rather than individual muscles, being subserved in a biologically efficient manner by the minimum number of spinal segmental levels required to achieve the aim of positioning the elbow in space, while maintaining subtlety in effect.

Pectoralis major

Attachments Pectoralis major is a thick, fan-shaped muscle. It arises from the anterior surface of the sternal half of the clavicle (clavicular head); half the breadth of the anterior surface of the sternum down to the level of the sixth or seventh costal cartilage (sternal head); the first to the seventh costal cartilages (first and seventh often omitted); the sternal end of the sixth rib; and the aponeurosis of external oblique (rectus head) (**Fig. 49.27**). The clavicular fibres are usually separated from the sternal fibres by a slight cleft. The muscle converges to a flat tendon, approximately 5 cm wide, that is attached to the lateral lip of the intertubercular sulcus of the humerus. The tendon is bilaminar. The thicker anterior lamina is formed by fibres from the manubrium, joined superficially by clavicular fibres and deeply by fibres from the sternal margin and the second to fifth costal cartilages. Clavicular fibres may be prolonged into the tendon of deltoid. The posterior lamina receives fibres from the sixth (and, often, seventh) costal cartilages, sixth rib, sternum, and aponeurosis of external oblique. Costal fibres join the lamina without twisting. Fibres from the sternum and aponeurosis curve around the lower border, turning successively behind those above them, which means that this part of the muscle is twisted so that the fibres that are lowest at their medial origin are highest at their attachment on the humerus. The posterior lamina reaches higher on the humerus than the anterior, and gives off an expansion that covers the intertubercular sulcus and blends with the capsular ligament of the shoulder joint. An expansion from the deepest part of the lamina lines the intertubercular sulcus at its linear insertion; another expansion descends from its lower border into the deep fascia of the upper arm.

The rounded lower border of pectoralis major forms the anterior axillary fold and becomes conspicuous in abduction against resistance.

Variants The abdominal slip from the aponeurosis of external oblique is sometimes absent. The number of costal attachments and the extent to which the clavicular and costal parts are separated vary. Right and left muscles may decussate across the sternum. A superficial vertical slip, or slips, may ascend from the lower costal cartilages and rectus sheath to blend with sternocleidomastoid or to attach to the upper sternum or costal cartilages. This is sternalis (rectus sternalis).

Relations Skin, superficial fascia, platysma, medial and intermediate supraclavicular nerves, breast tissue and deep fascia are all anterior. The sternum, ribs and costal cartilages, clavipectoral fascia, subclavius, pectoralis minor, serratus anterior, external intercostal muscles and membranes are all posterior. Pectoralis major forms the superficial layer of the anterior axillary wall, and hence lies anterior to the axillary vessels and nerves and the upper parts of biceps brachii and coracobrachialis. Its upper border is separated from deltoid by the infraclavicular fossa, which contains the cephalic vein and deltoid branch of the thoracoacromial artery. Pectoralis major is separated from latissimus dorsi on the medial axillary wall but the two muscles converge as they approach the lateral axillary wall; the floor of the intertubercular sulcus lies between their attachments.

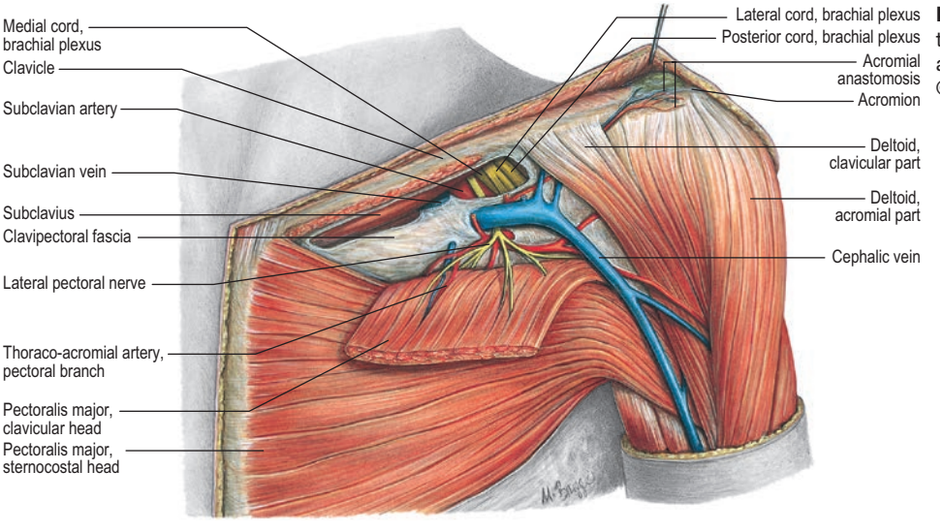

Fig. 49.27 The left deltopectoral groove, dissected to show the clavipectoral fascia and thoracoacromial axis. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Vascular supply Pectoralis major is supplied by one dominant vascular pedicle from the pectoral branch of the thoraco-acromial axis, supplemented by several smaller secondary segmental vessels from the deltoid and clavicular branches of the thoraco-acromial axis, and perforating branches of the internal thoracic arteries and superior and lateral thoracic arteries.

Innervation Pectoralis major is supplied through the medial and lateral pectoral nerves. Fibres for the clavicular part are derived from the fifth and sixth cervical ventral rami; those for the sternocostal part are derived from the seventh and eighth cervical ventral rami and first thoracic ventral ramus.

Actions The two parts of pectoralis major can act separately or together. The whole muscle assists adduction and medial rotation of the humerus against resistance. It swings the extended arm forwards and medially, its clavicular part acting with the anterior fibres of deltoid and coracobrachialis; the sternocostal part is relaxed. The opposite movement is usually aided by gravity. When it is resisted, the sternocostal part acts together with latissimus dorsi, teres major and the posterior fibres of deltoid; the clavicular part is relaxed. With the raised arms fixed, e.g. gripping a branch, the same combination of muscles draws the trunk up and forwards. Pectoralis major is active in deep inspiration.

Testing To test the clavicular head, the abducted arm is flexed against resistance. To test the sternocostal head, the arm is adducted against resistance.

Poland's syndrome

Available with the *Gray's Anatomy* e-book

Chondro-epitrochlearis Chondro-epitrochlearis is a rare extra 'head' of pectoralis major, arising deep to the sternal and rectus components of that muscle from the anterior aspect of the fifth, sixth and seventh ribs and their costal cartilages, and in the same plane as pectoralis minor.

Deltoid

Attachments Deltoid is a thick, curved triangle of muscle. It arises from the anterior border and superior surface of the lateral third of the clavicle, the lateral margin and superior surface of the acromion, and the lower edge of the crest of the scapular spine (other than its smooth, medial, triangular surface) (see Figs 49.25, 49.27). The fibres converge inferiorly to a short, substantial tendon that has an extensive attachment which envelops the deltoid tubercle on the lateral aspect of the midshaft of the humerus. Anterior and posterior fibres converge directly to this tendon. The intermediate part is multipennate; four intramuscular septa descend from the acromion to interdigitate with three septa ascending from the deltoid tubercle. The septa are connected by short muscle fibres that provide powerful traction (Leijnse et al 2008). The fasciculi are large, producing a coarse longitudinal striation. The muscle surrounds the glenohumeral articulation on all sides, except inferomedially, giving the shoulder its rounded profile. In contraction, its borders are easily seen and felt. The tendon gives off an expansion into the brachial deep fascia that may reach the forearm.

Variants Deltoid may fuse with pectoralis major or may receive additional slips from trapezius, the infraspinous fascia or the lateral scapular border. Teres minor shares a common innervation and could be considered as a fourth, posteroinferior part of deltoid.

Relations The skin, superficial and deep fasciae, platysma, lateral supraclavicular and upper lateral brachial cutaneous nerves are all superficial. The coracoid process, coraco-acromial ligament, subacromial bursa, tendons of pectoralis minor, coracobrachialis, both heads of biceps brachii, pectoralis major, subscapularis, supraspinatus, infraspinatus, teres minor, long and lateral heads of triceps, circumflex humeral vessels, axillary nerve, and the surgical neck and upper shaft of the humerus, including both tubercles, are all deep. The anterior border of deltoid is separated from pectoralis major proximally by the infraclavicular fossa, which contains the cephalic vein and deltoid branches of the thoraco-acromial artery; distally, these muscles are in contact. The posterior border of deltoid overlies infraspinatus and triceps.

Vascular supply Deltoid is supplied by acromial and deltoid branches of the thoraco-acromial artery; the anterior and posterior circumflex humeral arteries; subscapular artery; and the deltoid branch of profunda brachii.

Innervation Deltoid is innervated by the axillary nerve (fifth and sixth cervical ventral rami).

Actions The deltoid moves the upper limb around the centre of rotation of the glenohumeral joint. Different parts of the muscle can act independently, as well as together. Anterior fibres assist pectoralis major in drawing the arm forwards and rotating it medially. Posterior fibres act as external rotators, and act with latissimus dorsi and teres major in drawing the arm backwards (into extension). The posterior fibres of deltoid provide up to 80% of the external rotation power of the arm when elevated into the plane of the scapula. The multipennate, acromial, part of deltoid is a strong abductor; aided by supraspinatus, it abducts the arm until the inferior joint capsule is tight. Movement takes place in the plane of the body of the scapula, which is the only way that scapular rotation can be fully effective in raising the arm above the head. In true abduction, acromial fibres contract strongly, while clavicular and posterior fibres prevent departure from the plane of motion. In the early stages of abduction, traction on the humerus by deltoid would displace the arm upward, but the humeral head is prevented from translating upward by the synergistic centralizing effect of the rotator cuff muscles (supraspinatus, subscapularis, infraspinatus and teres minor). Electromyography suggests that deltoid contributes little to unresisted medial (internal) or lateral (external) rotation but confirms that it takes part in most other shoulder movements, particularly when resisted, for instance when lifting a weight.

Testing Deltoid can be seen and felt to contract when the arm is abducted against resistance in the scapular plane. Since this motion can also be achieved by supraspinatus, a more specific test for the activity of deltoid is to assess extension against resistance with the arm in 30° abduction in the scapular plane: this reduces the confounding effect of latissimus dorsi and triceps as extensors of the adducted arm. Subtle weakness can be determined using the deltoid lag sign (Hertel et al 1998).

Coracobrachialis

Coracobrachialis is the most medial of the three anterior compartment muscles of the arm. It has a common origin with the short head of biceps brachii. In turn, the short head of biceps shares a common distal attachment with the long head of biceps. The three anterior compartment muscles, therefore, form a single functional group that brings the supinated hand into flexion and medial rotation, towards the face.

Attachments Coracobrachialis arises from a muscular origin on the deep surface of the apex of the coracoid process, deep to the tendon of the short head of biceps brachii, and by muscular fibres from the proximal 5–10 cm of this tendon. It ends on an impression, 3–5 cm in length, midway along the medial border of the humeral shaft between the attachments of the medial head of triceps and brachialis (**Fig. 49.28**), and opposite the insertion of deltoid. Accessory slips may be attached to the lesser tubercle, medial epicondyle or medial intermuscular septum.

Relations Coracobrachialis forms an inconspicuous rounded ridge on the upper medial side of the arm; pulsation of the brachial artery can be felt and often seen in the depression behind it. The muscle is perforated and supplied by the musculocutaneous nerve. Anteriorly, it is related to pectoralis major above and, at its humeral insertion, to the brachial vessels and median nerve, which cross it. The tendons of subscapularis, latissimus dorsi, teres major, the medial head of triceps, the humerus and the circumflex humeral vessels are all posterior. The third part of the axillary artery and proximal parts of the median and musculocutaneous nerves are first medial and become posterior further distally; they may be partially obscured by the muscle if it is bulky. Biceps brachii and brachialis are lateral.

Vascular supply One or more branches from the axillary artery pass deep to the lateral root of the median nerve and the musculocutaneous nerve to reach the deep surface of coracobrachialis. Branches from the anterior circumflex humeral artery supply the deep surface of the muscle. The artery accompanying the musculocutaneous nerve sends a recurrent branch to the coracoid attachment and gives off a series of branches to coracobrachialis during its intramuscular course. Accessory branches from the thoraco-acromial artery supply the superficial part of coracobrachialis.

Innervation Coracobrachialis is innervated by the musculocutaneous nerve (fifth, sixth and seventh cervical ventral rami), the motor nerve to the anterior (flexor) compartment of the upper arm.

Actions Deltoid and coracobrachialis insert into the humerus approximately opposite each other. Coracobrachialis acts as an antagonist to

Poland's syndrome is a rare congenital anomaly, in which there is hypoplasia of the thoracic chest wall muscles and ipsilateral hypoplasia of the arm and hand. It occurs in approximately 1 : 50,000 live births. The major clinical feature is absence of the sternocostal head of pectoralis major and all of pectoralis minor. In addition, there may be hypoplasia of latissimus dorsi, serratus anterior, external oblique, supraspinatus, infraspinatus, deltoid and the intercostal muscles, and hypoplasia of the hemithorax and ribs. Hypoplasia affecting the arm ranges from syndactyly to symbrachydactyly and ectrodactyly. The second, third and fourth fingers are the most affected; the wrist, forearm, upper arm and scapula are variably involved. There may be ipsilateral breast hypoplasia and absent nipple–areolar complex.

The aetiology is unclear. Rib primordia are seen from stage 15 (35–36 postfertilization days) extending laterally and ventrally into hypaxial muscle sheets in the developing chest wall: anomalous vertebral development and other causes of pectoral aplasia would be initiated before this time. It has been suggested that the musculoskeletal anomalies reflect interruption of the early embryonic blood supply in the subclavian and vertebral arteries and/or their branches, during or around the sixth week of development (stages 15–17), the so-called subclavian artery supply disruption sequence (SASDS) (Bavinck and Weaver 1986).

The muscle has an extensive attachment to the lateral crest of the intertubercular sulcus, the medial intermuscular septum and the medial epicondylar ridge. It is innervated by branches of the lateral pectoral nerve that perforate pectoralis minor or pass to the muscle in the plane between pectoralis minor and major. It is noted as a pterygium deep to the anterior axillary wall with a sharply defined inferior border in the axilla, made more noticeable by flexion and medial rotation against resistance with the arm elevated into the scapular plane. With the arm in the elevated position, contraction of the muscle causes a retropulsion of the glenohumeral joint, a rare cause of posterior glenohumeral instability.

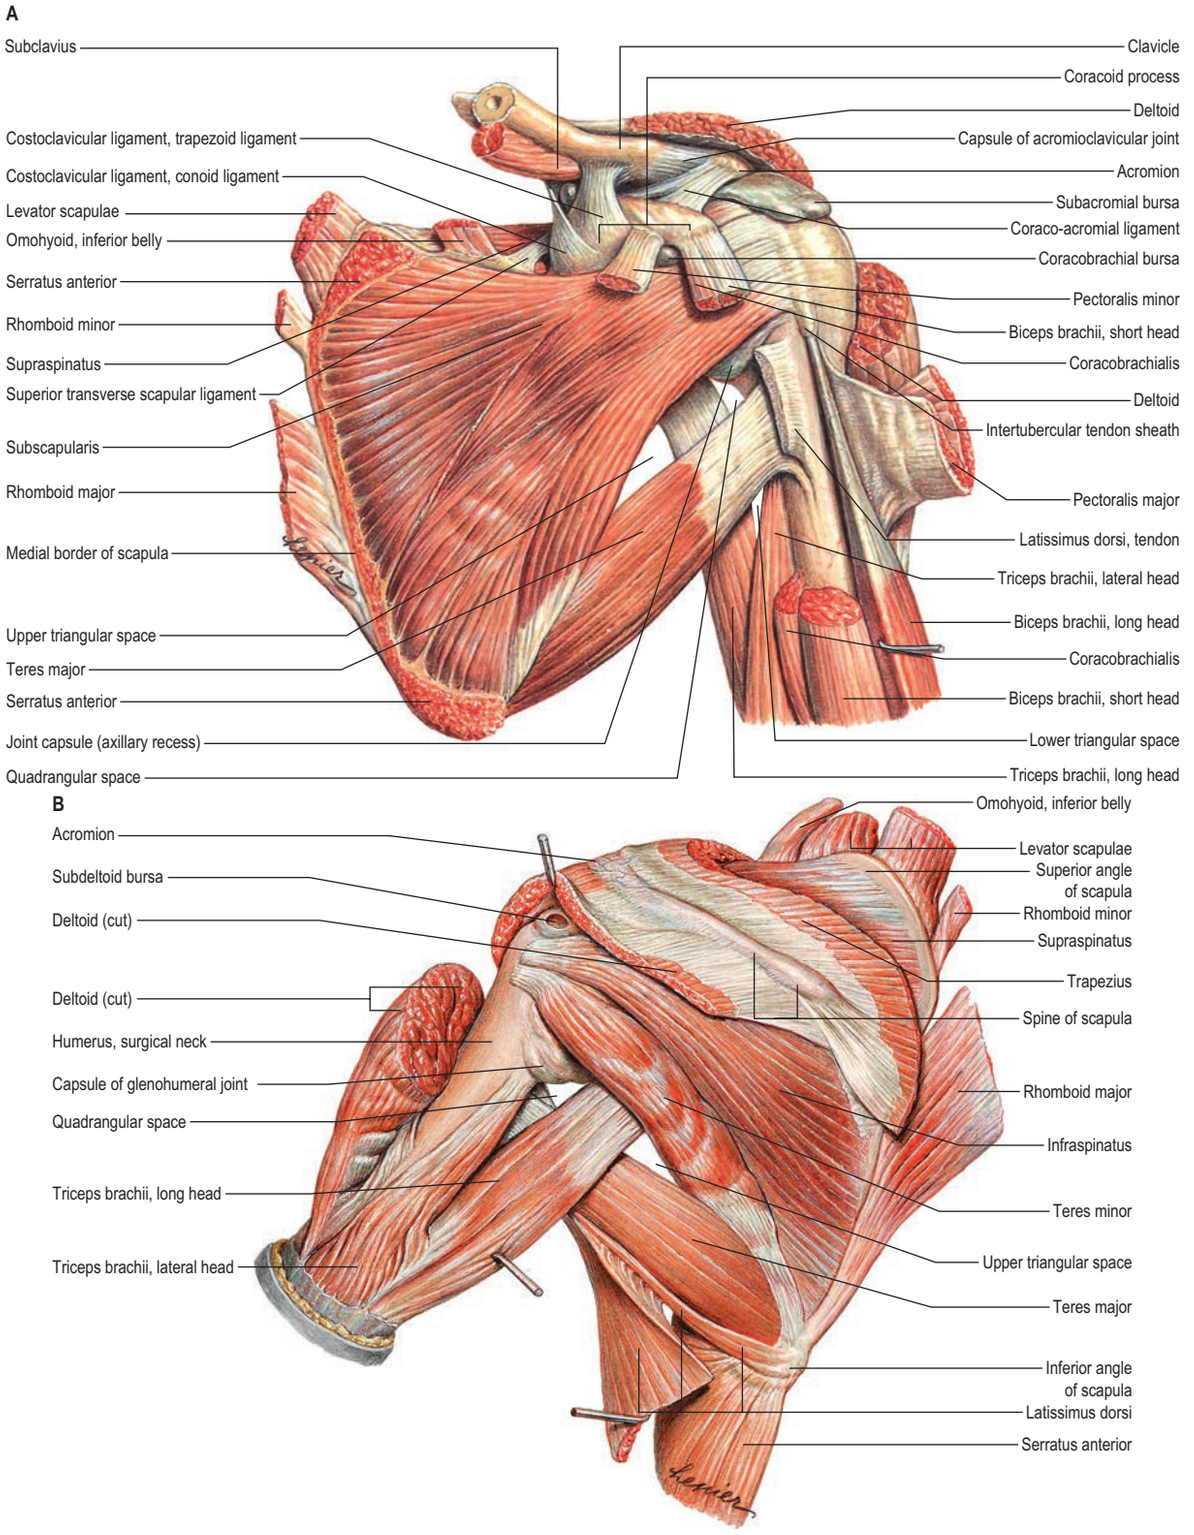

Fig. 49.28 The deep muscles of the left shoulder girdle. **A**, The anterior aspect after removal of the superficial muscles. **B**, Posterior aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

the action of deltoid, particularly when the arm is in abduction and extension; it flexes the arm forwards and medially. In abduction, it acts with the anterior fibres of deltoid to resist departure from the plane of motion.

Testing Coracobrachialis can be tested by palpating its fibres during adduction and medial rotation of the flexed shoulder against resistance. Alternatively, the muscle can be palpated during forceful depression of the elbow against resistance or with the arm by the side.

Latissimus dorsi

Attachments Latissimus dorsi is a large, flat, triangular muscle that sweeps over the lumbar region and lower thorax, and converges to a narrow tendon (see Fig. 49.25). It arises by tendinous fibres from the spines of the lower six thoracic vertebrae anterior to trapezius; from the posterior layer of thoracolumbar fascia, by which it is attached to the spines and supraspinous ligaments of the lumbar and sacral vertebrae; and from the posterior part of the iliac crest. It also springs by muscular fibres from the posterior part (outer lip) of the iliac crest lateral to erector spinae, and by fleshy slips from the three or four lower ribs, interdigitating with external oblique (see Fig. 60.2). From this extensive attachment, fibres pass laterally with different degrees of obliquity (the upper fibres are nearly horizontal, the middle oblique and the lower almost vertical), to form a sheet 12 or 13 mm thick that overlaps the inferior scapular angle, and may attach to it. The muscle curves around the inferolateral border of teres major to gain its anterior surface and ends as a flattened

tendon, up to 7 cm long, anterior to the tendon of teres major. It is attached to the floor of the intertubercular sulcus of the humerus with an expansion to the deep fascia (Dancker 2013). The attachment extends higher on the humerus than that of teres major. As the muscle curves round teres major, the fasciculi rotate around each other, so that fibres that originate lowest at the midline insert highest on the humerus, and fibres that originate highest at the midline insert lowest on the humerus. A bursa sometimes occurs between the muscle and the inferior scapular angle. The tendons of latissimus dorsi and teres major are united at their lower borders but separated by a bursa near their humeral attachments.

Latissimus dorsi and teres major together form the posterior axillary fold. When the arm is adducted against resistance, this fold is accentuated, and the whole inferolateral border of latissimus dorsi can be traced to its attachment to the iliac crest. The radial nerve and the branch or branches it supplies to the medial head of triceps are close anterior relations of the tendon of the latissimus dorsi, 3–5 cm medial to the shaft of the humerus, before the radial nerve traverses the lower triangular space and passes into the posterior compartment of the arm (see quadrangular and triangular spaces below).

The lower, lateral margin of latissimus dorsi is usually separated from the posterior border of external oblique by the lumbar triangle. The base of this small triangle is the iliac crest and its floor the internal oblique; it should not be confused with the triangle of auscultation, medial to the scapula, which is bounded above by trapezius, below by latissimus dorsi and laterally by the medial border of the scapula. Part of rhomboid major is exposed in the triangle. If the scapulae are drawn forwards, by folding the arms across the chest, and the trunk is bent forwards, parts of the sixth and seventh ribs and the interspace between them (overlying the apex of the lower pulmonary lobe) become subcutaneous.

Variants Latissimus dorsi commonly receives some additional fibres from the scapula as it crosses the inferior scapular angle. A muscular axillary arch, 7–10 cm in length and 5–15 mm in breadth, may sometimes be present; it crosses from the edge of latissimus dorsi, midway in the posterior fold, and passes anterior to the axillary vessels and nerves to join the tendons of pectoralis major, coracobrachialis or the fascia over biceps brachii. The vertebral and costal attachments of latissimus dorsi may be reduced or, in rare cases, increased. A fibrous slip usually passes from the tendon, near its humeral insertion, to the long head of triceps.

Vascular supply Latissimus dorsi is supplied by a single dominant vascular pedicle, the thoracodorsal artery, itself a continuation of the subscapular artery. The thoracodorsal artery and its accompanying venae comitantes enter the muscle at a single neurovascular hilum on its costal surface, 6–12 cm from the subscapular artery and 1–4 cm medial to the lateral border of the muscle. The artery gives off up to three large branches to serratus anterior before dividing at, or even before, the neurovascular hilum for latissimus dorsi. The basic pattern of branching is a bifurcation into lateral and medial branches. The larger lateral branch follows a course parallel to, and 1–4 cm from, the upper border of the muscle; the smaller branch diverges at an angle of 45° and travels medially. In a small number of cases, the artery trifurcates. This usually yields a small recurrent branch that returns to supply the proximal part of the muscle but, in some cases, it provides a third major branch that supplies the distal part of the muscle. Occasionally, the lateral branch gives off a further collateral to serratus anterior. The major branches give off 5–9 longitudinal branches that travel distally, parallel with the muscle fibres. Musculocutaneous perforators arising from these vessels supply the overlying skin.

In addition to the dominant vascular pedicle, latissimus dorsi is supplied inferiorly by several smaller, secondary, segmental vascular pedicles. These are dorsal perforating arteries derived from the ninth, tenth and eleventh posterior intercostal arteries and the first, second and third lumbar arteries. They all enter the muscle on its deep surface and anastomose within the muscle with branches of the thoracodorsal artery.

Innervation Latissimus dorsi is supplied by the thoracodorsal nerve, from the posterior cord of the brachial plexus (sixth, seventh and eighth cervical ventral rami, predominantly from the seventh cervical ventral ramus). This nerve runs in the neurovascular pedicle and divides approximately 1.5 cm proximal to the point of bifurcation or trifurcation of the thoracodorsal artery. The neural and vascular branches travel together and so the pattern of branching of the nerve follows that of the artery closely.

Actions Latissimus dorsi is active in adduction, extension and, especially, in medial rotation of the humerus. Humeral adduction and extension are most powerful when the initial position of the arm is one of partial abduction or flexion, or a combination of the two. With the sternocostal part of pectoralis major and teres major, it adducts the raised arm against resistance. When the arms are raised above the head, as in climbing, it pulls the trunk upwards and forwards. It takes part in all violent expiratory efforts, such as coughing or sneezing; this is readily confirmed by palpation. Electromyography suggests that latissimus dorsi aids deep inspiration, but it is also active towards the end of forcible expiration, e.g. when blowing a sustained note on a musical instrument. When the arm is elevated, the stretched fibres of latissimus dorsi press on the inferior scapular angle (to which it may also be attached), keeping it in contact with the chest wall. Despite this range of actions, surgical transposition of the muscle does not appear to produce any serious measurable restrictions of normal activity.

Testing Latissimus dorsi is palpated on the lateral chest wall when the abducted arm is adducted against resistance, and can be felt to contract during coughing. The rounded muscular posterior wall of the axilla is formed by teres major, not latissimus dorsi.

Muscles of concavity compression

The function of the rotator cuff muscles is to generate a concavity compressive force in all positions of the arm at the shoulder. The term 'rotator cuff' is conventionally taken to mean the tendinous parts of the four rotator cuff muscles: subscapularis, supraspinatus, infraspinatus and teres minor. Since teres minor, parts of infraspinatus and most of subscapularis do not have tendons, this use of the term excludes important parts of the rotator cuff apparatus. In this description, the term 'rotator cuff' will be used to define the entire musculotendinous apparatus that centralizes the humeral head on the glenoid. The tendons of the rotator cuff will be referred to specifically.

It is maintained that the inferior capsule of the glenohumeral joint is exposed as a weak part of the capsule, and so predisposed to injury (dislocation). However, in elevation of the arm above 90°, the bulk of teres major forms a muscular buttress to the lower part of the joint and, in this position, clearly draws the humeral head into the glenoid, i.e. it has a centralizing effect. Teres major is a part of the centralizing function of the rotator cuff, and should be considered together with the conventional definition of the rotator cuff.

The mechanism of the rotator cuff has been likened to that of the fibrous 'endoskeleton' of the heart, in which the muscular chambers are constructed around the fibrous architecture of the valvular system, and muscle contraction is centralized on this fibrous support. The muscles of the rotator cuff are attached to their tendons in a similar manner: the fibrous architecture of the tendons provides a framework for the action of the rotator cuff so that it always generates a centralizing force on the glenoid (Gagey et al 1993).

The muscles of the rotator cuff combine in three groups (subscapularis and teres major, supraspinatus and infraspinatus, and teres minor) by virtue of their innervation. Subscapularis and teres major are innervated through the subscapular nerves (C5–7, posterior division, posterior cord); supraspinatus and infraspinatus by the suprascapular nerve (C5, C6, upper trunk); and teres minor by the axillary nerve (C5, C6, posterior division, posterior cord). The common origin of their innervation suggests a common final action, namely the generation of the centralizing compression force. In functional terms, supraspinatus and infraspinatus can be considered as one muscle on the grounds that they have the same innervation and the same vascular supply; their attachment to the scapula is a continuum broken only by the spine of scapula for the attachment of trapezius; and their actions are complementary.

Supraspinatus

Attachments Supraspinatus arises from the medial two-thirds of the supraspinous fossa and from the supraspinous fascia (see Fig. 49.28B). The fibres converge, under the acromion, into a thick tendon that passes obliquely through the muscle, crosses above the humeral head, and is attached to the highest facet of the greater tubercle of the humerus. The tendon has a posterior, flatter, component closer to the facet of attachment. The anterior, obliquely directed fibres of supraspinatus are inserted into the anterior aspect of the thick tendon; the more parallel posterior fibres are inserted into both the thick tendon and the flatter component. The thick tendon is contiguous with the transverse humeral and coracohumeral ligaments and forms an anterior pillar to the posterosuperior part of the rotator cuff. The deep surface of the tendon blends into the articular capsule over its distal 1 cm. Fibrocartilage has been described at the tendinous insertion, as in other tendons attached to epiphysial bone.

Vascular supply Supraspinatus is supplied by the suprascapular and dorsal scapular arteries.

Innervation Supraspinatus is innervated by the suprascapular nerve (fifth and sixth cervical ventral rami).

Actions The conventional view is that supraspinatus initiates abduction of the shoulder and assists deltoid in abduction thereafter. However, there is evidence that both supraspinatus and deltoid are involved throughout the range of abduction, including initiation of the movement. In complete axillary nerve lesions (complete, irreversible deltoid palsy), supraspinatus, acting with other cuff muscles, can initiate, regulate, achieve and maintain full abduction of the arm (although endurance is limited). If supraspinatus is detached, torn or paralysed, and deltoid is also paralysed, investigation and surgical exploration and repair of damaged rotator cuff tendon, muscle or nerve supply is considered important. With a functioning rotator cuff but a compromised deltoid (usually due to axillary nerve palsy) the arm is functionally adept and useful while lacking in endurance. In contrast, when the rotator cuff is functionally compromised (whether due to injury or denervation) but deltoid is normal, arm function is potentially poor because stability of the joint is adversely compromised and deltoid cannot readily function to overcome this disability, unless the diameter of the humeral head is sufficiently great to provide a form of 'pulley' for the (enhanced) action of the deltoid. Supraspinatus helps to stabilize the head of the humerus in the glenoid fossa during movements of the glenohumeral joint and when the arm is dependent, even when moderately loaded, supraspinatus assists deltoid in preventing downward displacement of the humerus.

Testing It is extremely difficult to palpate supraspinatus unless trapezius is thin. The tendon of supraspinatus is separated from the coraco-acromial ligament, acromion and deltoid by the large subacromial bursa; when this is inflamed, abduction of the shoulder joint is painful. The tendon is the most frequently torn element of the musculotendinous cuff around the shoulder joint.

Infraspinatus

Attachments Infraspinatus is a thick, triangular muscle that occupies most of the infraspinous fossa (see Fig. 49.28B). It arises by muscular fibres from the medial two-thirds of the fossa, by tendinous fibres from ridges on its surface and from the deep surface of the infraspinous fascia, by which it is separated from teres major and minor. Its fibres converge to a tendon that glides under the lateral border of the spine of the scapula, and then passes across the posterior aspect of the capsule of the shoulder joint to be attached to the middle facet on the greater tubercle of the humerus. The tendon fuses with that of supraspinatus immediately lateral to the thick lateral margin of the spine of the scapula; the fibres of the tendon decussate so that fibres of infraspinatus can be traced to the facet for supraspinatus, and vice versa (Mochizuki et al 2008). The tendon is sometimes separated from the capsule by a bursa that may communicate with the joint cavity. The tendon is flattened, but is thickened in several places, reinforcing its posterior aspect as it attaches to the middle facet. From this region, fibres passing orthogonally within the deeper substance of the tendon of infraspinatus pass forwards into supraspinatus, then pass across the rotator interval to subscapularis. This band of fibres is termed the 'cable' (Burkhart et al 1993), and it provides the mechanical link between the posterosuperior and anterior parts of the rotator cuff, thus ensuring that there is intrinsic coordination of the rotator cuff mechanism. The muscular part of infraspinatus is attached directly to the middle facet on the greater tubercle and is sometimes fused with teres minor laterally; their tendons are usually separable closer to the joint capsule.

Vascular supply Infraspinatus is supplied by the suprascapular and circumflex scapular arteries.

Innervation Infraspinatus is innervated by the suprascapular nerve (fifth and sixth cervical ventral rami).

Actions Infraspinatus is a lateral rotator of the humerus. Together with supraspinatus, subscapularis and teres minor, it helps to stabilize the head of the humerus in the glenoid fossa during shoulder movements.

Teres minor

Attachments Teres minor is a narrow, elongated muscle that arises from the upper two-thirds of a flattened strip on the dorsal surface of the scapula adjoining its lateral border, and from two aponeurotic laminae that separate it from infraspinatus and teres major (see Fig. 49.28B). It runs upwards and laterally. The upper fibres end in a short tendon (which may be absent), attached to the lowest facet on the greater tubercle of the humerus. The lower fibres are attached directly into the humerus distal to this facet and above the origin of the lateral head of triceps. The tendon passes across, and blends with, the lower posterior surface of the capsule of the shoulder joint. Teres minor may be fused with infraspinatus.

Vascular supply Teres minor is supplied by the circumflex scapular artery, which pierces the origin of the muscle as it turns upwards in the infraspinous fossa, and by the posterior circumflex humeral artery.

Innervation Teres minor is innervated by a branch of the axillary nerve that is given off the main trunk as it enters the quadrangular space (fifth and sixth cervical ventral rami).

Actions Teres minor acts as a lateral rotator and weak adductor of the humerus with the arm pendant. Together with supraspinatus, infraspinatus, subscapularis and teres major, it helps to stabilize the head of the humerus in the glenoid fossa during shoulder movements.

Subscapularis

Attachments Subscapularis is a bulky, triangular muscle that fills the subscapular fossa (see Figs 49.26, 49.28A). In its medial two-thirds, the fibres are attached to the periosteum of the costal surface of the scapula. Other fibres arise from tendinous intramuscular septa, attached to ridges on the bone, and from the aponeurosis that covers the muscle and separates it from teres major and the long head of triceps. The fibres converge laterally into a broad tendon above, which has a thickened, rounded upper margin, and is attached to the lesser tubercle of the humerus and the anterior part of the articular capsule, with a wide direct muscular attachment to the lower part of the lesser tubercle. The tendon is separated from the neck of the scapula by the large subscapular bursa, which may communicate with the shoulder joint.

Variation is unusual. A separate inferior slip (subscapularis accessorius) may pass from the lateral border of the scapula to the glenohumeral capsule or to the periosteum medial to the intertubercular sulcus of the humerus, and should be distinguished from the true infraglenoid muscle (Staniek and Brenner 2012).

Relations Subscapularis forms much of the posterior axillary wall. Its anterior surface is apposed inferomedially to serratus anterior, the axillary vessels, brachial plexus and subscapular vessels and nerves, and superolaterally to coracobrachialis and biceps. Its posterior surface is attached to the scapula and glenohumeral capsule. Its lower border contacts teres major and latissimus dorsi. Its upper border is contiguous with the capsule of the rotator interval; at the most lateral extent of the interval, the long tendon of biceps passes lateral to the attachment of subscapularis, covered by the transverse humeral ligament.

Vascular supply Subscapularis is supplied by small branches from the suprascapular, axillary and subscapular arteries.

Innervation Subscapularis is innervated by the upper and lower subscapular nerves (fifth and sixth cervical ventral rami, posterior cord).

Actions Subscapularis is a medial rotator of the humerus. Together with supraspinatus, infraspinatus, teres minor and teres major, it helps to stabilize the head of the humerus in the glenoid fossa during shoulder movements.

The attachment of teres major lies in direct continuity with the attachment of subscapularis on the lesser tubercle. The muscles lie in virtually the same plane as they approach the humerus, they share a similar innervation from the posterior cord of the brachial plexus, and perform the same actions. Like the spinati, subscapularis and teres major might be considered as a functional unit.

Teres major

Attachments Teres major is a large, thick, ovoid muscle that arises from the oval area on the dorsal surface of the inferior scapular angle, and from the fibrous septa interposed between the muscle and teres minor and infraspinatus (see Fig. 49.28A). Its fibres ascend laterally and end in a short, flat tendon, 2–5 cm long, attached to the medial lip of the intertubercular sulcus of the humerus. The tendon lies behind that of latissimus dorsi, from which it is separated by a bursa; the tendons are united along their lower borders for a short distance but are readily separated.

Variants Teres major may be fused with the scapular part of latissimus dorsi, and may send a slip to join the long head of triceps or the brachial fascia.

Vascular supply Teres major is supplied by the thoracodorsal branch of the subscapular artery on its way to latissimus dorsi and by the posterior circumflex humeral artery (Dancker 2013).

Innervation Teres major is innervated by the lower subscapular nerve (fifth, sixth and seventh cervical ventral rami).

Actions Despite its name, teres major has a nerve supply and action that is distinct from teres minor. Teres major draws the humerus backwards and rotates it medially. Electromyographic studies are equivocal about its major role in movement, but its involvement as a contributor to static posture and arm-swinging is not contested. In the elevated arm, teres major both supports the inferior glenohumeral joint capsule and humeral head, and centralizes the humeral head on the cavity of the glenoid, and thus, in functional terms, it is a rotator cuff muscle.

Testing Teres major can be palpated in the posterior axillary fold during adduction of the humerus against resistance.

Rotator cuff disease

The subacromial space is defined inferiorly by the superior surface of the rotator cuff (supraspinatus and the anterior part of infraspinatus); superiorly by the anterior edge and inferior surface of the anterior third of the acromion, the coraco-acromial ligament and the acromioclavicular joint, collectively forming the coraco-acromial arch; posteriorly by the posterior wall of the subacromial bursa. It is occupied by the subacromial bursa, lined by synovial membrane and extending anterolaterally under deltoid as the subdeltoid bursa, which facilitates movement of the rotator cuff under the coraco-acromial arch. The upper surface of the rotator cuff normally impinges, without symptoms, under the coraco-acromial arch when the humerus is abducted, flexed and medially rotated.

If the upper surface of the rotator cuff is damaged, or the bursa is thickened or inflamed, or the undersurface of the coraco-acromial arch is rough, then the impingement can become abrasive, producing the painful 'impingement syndrome'.

Muscles that coordinate shoulder and elbow motion

The muscles of the upper arm are coracobrachialis, which acts only on the shoulder joint; biceps brachii and triceps, which cross both shoulder and elbow joints; and brachialis, which acts only at the elbow joint. Coracobrachialis is described on page 915.

Anterior compartment of the arm

Biceps brachii

Attachments Biceps brachii derives its name from its two proximally attached 'heads' (see Figs 49.15–49.16, 49.26, 49.28A). The short head arises by a thick, flattened tendon from the apex of the coracoid, superficial to the muscular origin of coracobrachialis. The long head starts within the capsule of the shoulder joint as a long narrow, oval tendon running from the supraglenoid tubercle of the scapula at the apex of the glenoidal cavity, where it is variably continuous with the glenoidal labrum. The tendon of the long head is enclosed in a double tubular synovial sheath which may persist as a mesotenon. It arches over the humeral head, in close apposition to it, emerges from the joint under the transverse humeral ligament, and descends in the intertubercular sulcus, where it is retained by the transverse humeral ligament and a fibrous expansion from the tendon of pectoralis major.

The two tendons lead into elongated bellies that, although closely applied, can be separated to within 7 cm or so of the elbow joint. At this joint, they end in a flattened tendon that is attached to the rough posterior area of the radial tuberosity, separated by a bursa from the smooth anterior area of the tuberosity. As the tendon approaches the radius, it spirals so that its anterior surface becomes lateral before being applied to the tuberosity. The tendon has a broad medial expansion, the bicipital aponeurosis, which descends medially across the brachial artery and fuses with the deep fascia over the origins of the flexor muscles of the forearm (Fig. 49.29). The tendon can be split without difficulty as far as the tuberosity: it can thus be confirmed that its anterior and posterior layers receive fibres from the short and long heads, respectively.

Occasionally, a third head arises from the superomedial part of brachialis and is attached to the bicipital aponeurosis and medial side of the tendon of insertion. It usually lies behind the brachial artery but it may consist of two slips that descend in front of and behind the artery. Less often, other slips may spring from the lateral aspect of the humerus or intertubercular sulcus.

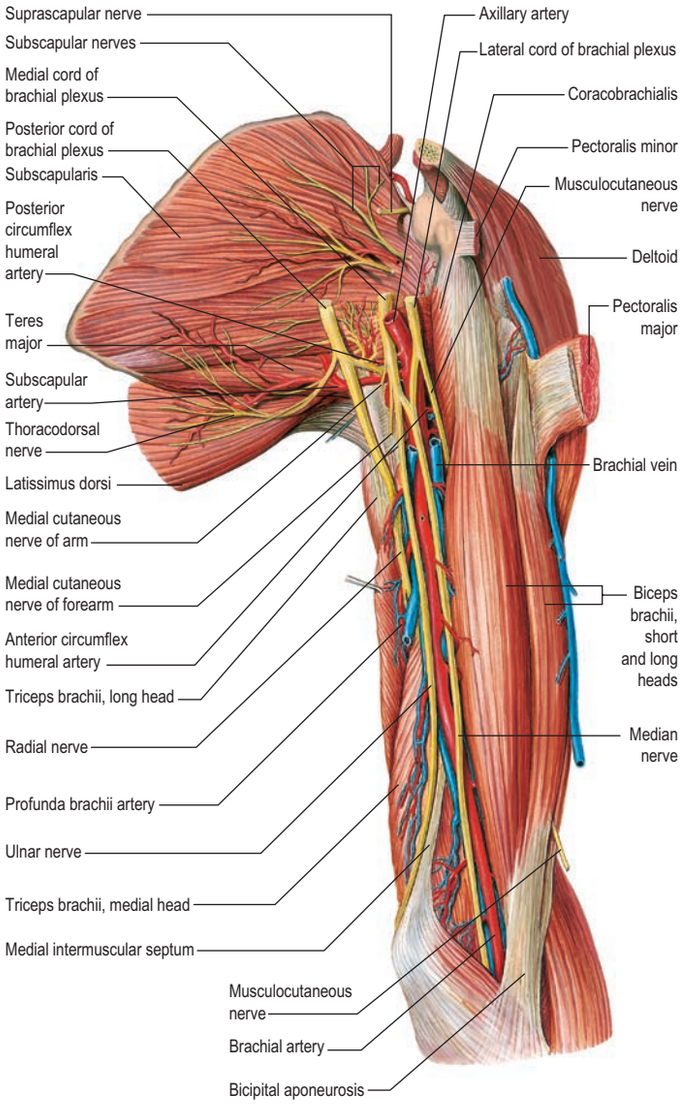

Fig. 49.29 The muscles, vessels and nerves of the left upper arm, anterior aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Relations Biceps is overlapped proximally by pectoralis major and deltoid. Distally, it is covered only by fasciae and skin, and it forms a conspicuous elevation on the front of the arm. Its long head passes through the shoulder joint; its short head is anterior to the joint. Distally, it lies anterior to brachialis, the musculocutaneous nerve and supinator. Its medial border touches coracobrachialis and overlaps the brachial vessels and median nerve and its lateral border is related to deltoid and brachioradialis.

Vascular supply Biceps brachii is typically supplied by up to eight vessels originating from the brachial artery in the middle third of the arm. These vessels pass laterally, posterior to the median nerve, and divide into ascending and descending branches just before reaching the deep surface of the muscle. Smaller branches arise from the anterior circumflex humeral artery and the deltoid branch of the acromial division of the thoraco-acromial axis.

The arterial supply to biceps brachii is very variable: the main arterial supply may originate from the superior or inferior ulnar collateral arteries, subscapular artery, axillary artery, ulnar or radial arteries (in cases of proximal bifurcation of the brachial artery) or the profunda brachii artery. There is often a single large pedicle that accompanies the nerve to biceps: injury to the muscle and musculocutaneous nerve at this level in the arm commonly results in a fibrotic, atonic muscle with distal sensory dysfunction.

Pain is generated during abduction of the arm in the scapular plane and typically an arc of pain is experienced between 60° and 120° of elevation, the so-called 'impingement arc'. Rotator cuff disease is a painful condition with many causes and severe or chronic impingement of the rotator cuff tendons on the undersurface of the coraco-acromial arch is often a significant factor. The supraspinatus tendon is anatomically affected most by the impingement, which coincides with an area of reduced vascularity in this tendon. When associated with a tendinopathy from age-related degenerative changes within the tendon, impingement may be associated with partial or complete tears of the cuff. Clinically, it causes tenderness over the anterior portion of the acromion in addition to the 'painful arc',

Innervation Biceps brachii is innervated by the musculocutaneous nerve (fifth and sixth cervical ventral rami); separate, often segmental, branches pass to each belly.

Actions Biceps brachii is a powerful supinator, especially in rapid or resisted movements. It flexes the elbow, most effectively, with the forearm supinated, and acts, to a slight extent, as a flexor of the shoulder joint. The long head helps to check upward translation of the humeral head during contraction of deltoid, in synergy with the action of the rotator cuff. Via the bicipital aponeurosis, it is attached to the posterior border of the ulna, the distal end of which is drawn medially in supination. When the elbow is flexed against resistance, the tendon of insertion and bicipital aponeurosis become conspicuous.

Testing With the forearm supinated, biceps brachii can be tested by palpating its fibres during elbow flexion against resistance.

Brachialis

Attachments Brachialis arises from the lower half of the anterior surface of the shaft of the humerus, starting on either side of the insertion of deltoid, and extending distally to within 2.5 cm of the cubital articular surface. It also arises from the intermuscular septa, more from the medial than the lateral, since it is separated distally from the lateral intermuscular septum by brachioradialis and extensor carpi radialis longus. Its fibres converge to a thick, broad tendon that is attached to the ulnar tuberosity and to a rough impression on the anterior aspect of the coronoid.

Brachialis may be divided into two or more parts. It may be fused with brachioradialis, pronator teres or biceps and it may send a tendinous slip to the radius or to the bicipital aponeurosis.

Relations Biceps brachii, the brachial vessels and the musculocutaneous and median nerves are anterior (Fig. 49.30). The humerus and the capsule of the elbow joint are posterior. Pronator teres and the medial intermuscular septum, which separates it from triceps and the ulnar nerve, are medial. The radial nerve, radial recurrent and radial collateral arteries, brachioradialis and extensor carpi radialis longus are all lateral.

Vascular supply The blood supply to brachialis typically consists of two main arteries (superior and inferior), supplemented by a system of accessory arteries. The superior main artery originates from the brachial artery distal to the site of origin of the superior ulnar collateral artery and travels laterally to enter the anterior surface of the upper third of the muscle. The inferior main artery originates either from the superior ulnar collateral artery or directly from the brachial artery, and enters the mid-portion of the muscle. The accessory arteries are small and variable in number, origin and course. They can arise from the brachial artery, the superior and inferior ulnar collateral arteries, or the profunda brachii artery. The fact that brachialis has a greater vascular supply than biceps brachii suggests that its metabolic demands are greater: brachialis is the prime flexor of the forearm at the elbow, while biceps has more subtle actions on the shoulder and elbow, coordinating the two joints while positioning the hand in space.

Innervation The musculocutaneous nerve (fifth and sixth cervical ventral rami)) supplies a large medial part of the muscle and the radial nerve (seventh cervical ventral ramus) often, but variably, supplies a small lateral part (Oberlin et al 1994).

Action Brachialis is a flexor of the elbow joint with the forearm either prone or supine, whether or not the movement is resisted.

Testing Brachialis can be tested by palpating its fibres during elbow flexion against resistance.

Posterior compartment of the arm

Triceps

Attachments Triceps fills most of the extensor compartment of the upper arm (see Figs 49.28–49.30). It has three heads (long, lateral and medial), from which it takes its name.

The long head arises by a flattened tendon from the infraglenoid tubercle of the scapula, blending above with the inferior part of the glenohumeral capsule. Its muscular fibres descend medial to the lateral head and superficial to the medial head, and join them to form a common tendon. The lateral head arises by a flattened tendon from a narrow, linear, oblique ridge on the posterior surface of the humeral shaft, and from the lateral intermuscular septum. The origin on the humerus ascends with varying obliquity from its lateral border above the radial groove and behind the deltoid tuberosity to the surgical neck medial to the insertion of teres minor. These fibres also converge to the common tendon. The medial head, which is overlapped posteriorly by the lateral and long heads, has a particularly extensive origin. It is attached to the entire posterior surface of the humeral shaft, below the radial groove from the insertion of teres major to within 2.5 cm of the trochlea; the medial border of the humerus; the medial intermuscular septum; and the lower part of the lateral intermuscular septum. Some muscular fibres reach the olecranon directly; the rest converge to the common tendon (Keener et al 2010). Some fibres from the medial head are attached to the posterior capsule of the elbow joint as articularis cubiti.

The tendon of triceps begins near the middle of the muscle. It is formed of two laminae that are organized in a similar manner to that of the tendon of gastrocnemius and soleus in the posterior compartment of the leg. In the distal half of the superficial part of the muscle, the superficial lamina forms an aponeurotic layer to which the deep fascia of the arm is adherent; the deeper lamina is more vertical. After receiving the muscle fibres, the two laminae unite above the elbow and are attached, for the most part, to the upper surface of the olecranon. On the lateral side, a band of fibres continues down over anconeus to blend with the antebrachial fascia.

Relations The long head of triceps descends between teres minor and major, dividing the wedge-shaped interval between them and the humerus into triangular and quadrangular spaces (see Fig. 49.28). The lateral head of triceps forms an elevation, parallel and medial to the posterior border of deltoid, that stands out prominently when the elbow is actively extended. The mass that lies medial to it, and that disappears under deltoid, is the long head.

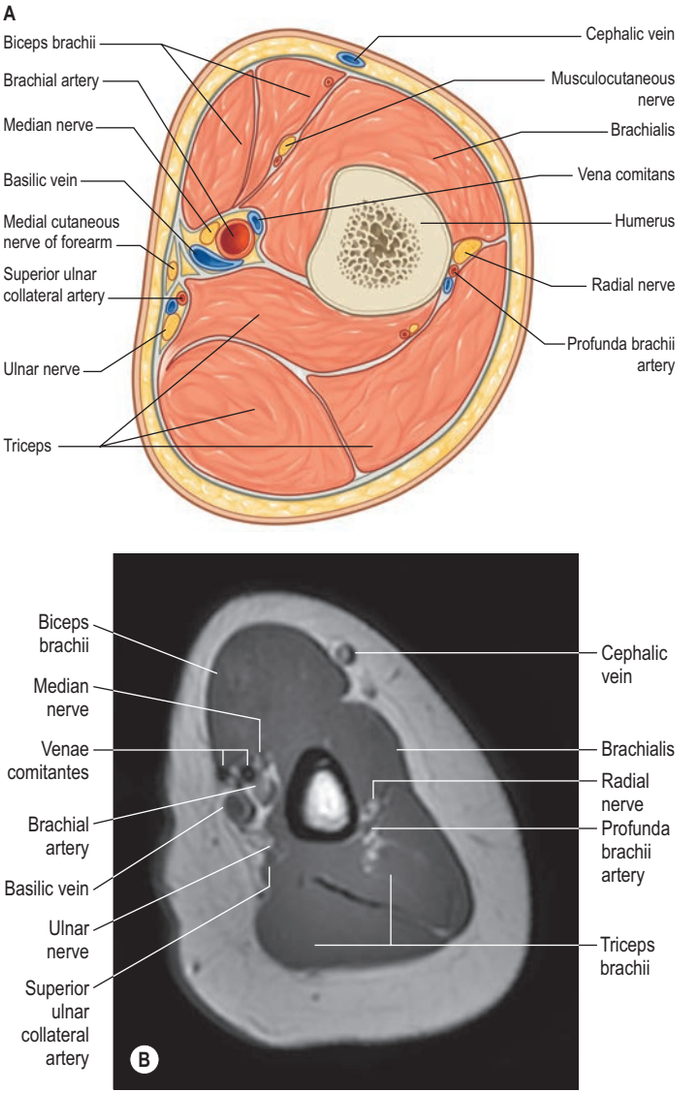

Fig. 49.30 A, A transverse section through the left arm, a little below the middle of the shaft of the humerus. **B**, An axial T1-weighted MRI at a similar level.

Lowering the hand under the influence of gravity by extension at the elbow calls for controlled lengthening of biceps brachii. This is an example of a habitual movement in which muscle tension increases despite increasing length. (This is 'eccentric' loading of a muscle; during such loading, the muscle–tendon junction is at greater risk of rupture. 'Concentric' loading occurs when the muscle shortens as tension increases.) As the hand descends and the elbow extends, the vertical through the centre of gravity of the forearm is carried further from the fulcrum of movement and therefore the turning moment exerted by the load increases and must be matched by an increase in the moment exerted by the muscle.

Vascular supply The blood supply to triceps is derived mainly from the profunda brachii artery and the superior ulnar collateral artery, with an accessory supply from the posterior circumflex humeral artery. The medial head of triceps is supplied on its anterior surface by two or three branches from the superior ulnar collateral artery. The posterior surface is supplied by a large proximal branch from the profunda brachii artery that passes medially anterior to the radial nerve. The long head of triceps is supplied on its anterior surface by two arteries, one arising from the axillary artery anterior to the tendon of latissimus dorsi and the other arising from either the brachial artery or the superior ulnar collateral artery. The posterior surface receives a recurrent branch from the posterior circumflex humeral artery immediately after it has passed through the quadrangular space. The lateral surface receives a number of small branches from the profunda brachii artery in its distal portion. The lateral head of triceps is primarily supplied by branches of the profunda brachii artery, with an additional supply from a branch of the posterior circumflex humeral artery.

Innervation Triceps is innervated by branches from the radial nerve (sixth cervical ventral ramus, lateral head; seventh cervical ventral ramus, long head; eighth cervical ventral ramus, medial head). There are separate branches for each head.

Actions Triceps is the major extensor of the forearm at the elbow joint. The medial head is active in all forms of extension, whereas the lateral and long heads are minimally active, except in extension against resistance, as in thrusting or pushing or supporting body weight on the hands with the elbows semi-flexed. When the flexed arm is extended at the shoulder joint, the long head may assist in drawing back and adducting the humerus to the thorax. The long head supports the lower part of the capsule of the shoulder joint, especially when the arm is raised. Articularis cubiti probably draws up the posterior part of the capsule of the elbow joint during extension of the forearm. In forceful supination of the semi-flexed forearm, involving contraction of both supinator and biceps brachii, triceps contracts synergistically to maintain the semi-flexed position.

Testing Triceps can be tested by palpating its fibres during elbow extension against resistance.

Quadrangular and triangular spaces

The quadrangular space (quadrilateral space; foramen of Velpeau) is more a horizontal cleft or tunnel than a vertical space. It has defined boundaries. Anteriorly, the space is bounded by subscapularis, the capsule of the shoulder joint and teres minor superiorly, teres major inferiorly, the long head of triceps medially and the surgical neck of the humerus laterally. Posteriorly, the quadrangular space is bounded above by teres minor. The axillary nerve and the posterior circumflex humeral artery and vein pass obliquely through the space (see Figs 49.33, 49.47).

There are two triangular spaces (see Figs 49.28, 49.47). The upper triangular space is bounded above by subscapularis anteriorly, teres minor posteriorly, teres major inferiorly and the long head of triceps laterally. The circumflex scapular vessels pass through this space. The lower triangular space (the triangular interval) is bounded above by subscapularis anteriorly, teres major posteriorly, the long head of triceps medially and the humerus laterally. The radial nerve and the profunda brachii vessels pass through this space.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

Dorsal scapular artery

In the majority of cases, the dorsal scapular artery arises from the third, or less often the second, part of the subclavian artery. It passes laterally through the trunks of the brachial plexus in front of scalenus medius and then deep to levator scapulae to reach the superior scapular angle. Here, it descends with the dorsal scapular nerve under the rhomboids along the medial border of the scapula to the inferior angle. It supplies the rhomboids, latissimus dorsi and the inferior portion of trapezius and the skin over the inferomedial aspect of trapezius via musculocutaneous perforators. It anastomoses with the suprascapular and subscapular arteries and with posterior branches of some posterior intercostal arteries. It sends a small branch to scalenus anterior; sometimes, this arises directly from the subclavian artery.

Variants About one-third of the superficial cervical and dorsal scapular arteries arise as a common vessel, the transverse cervical artery, from the thyrocervical trunk, which then divides into a superficial and a deep branch (superficial cervical and dorsal scapular arteries, respectively) (see Figs 33.1A, 49.31). In this case, the dorsal scapular artery arises near the superior border of the scapula; it passes laterally, anterior to the brachial plexus and then posterior to levator scapulae.

Suprascapular artery

The suprascapular artery usually arises from the thyrocervical trunk of the subclavian artery, although it may arise from the third part of the subclavian artery. It first descends laterally across scalenus anterior and the phrenic nerve, posterior to the internal jugular vein and sternocleidomastoid, then crosses anterior to the subclavian artery and brachial plexus, posterior and parallel with the clavicle, subclavius and the inferior belly of omohyoid, to reach the superior border of the scapula. Here, it passes above (sometimes, under) the superior transverse ligament, separating it from the suprascapular nerve, and enters the supraspinous fossa (**Fig. 49.31**; see Fig. 49.33), where it lies on the bone, and

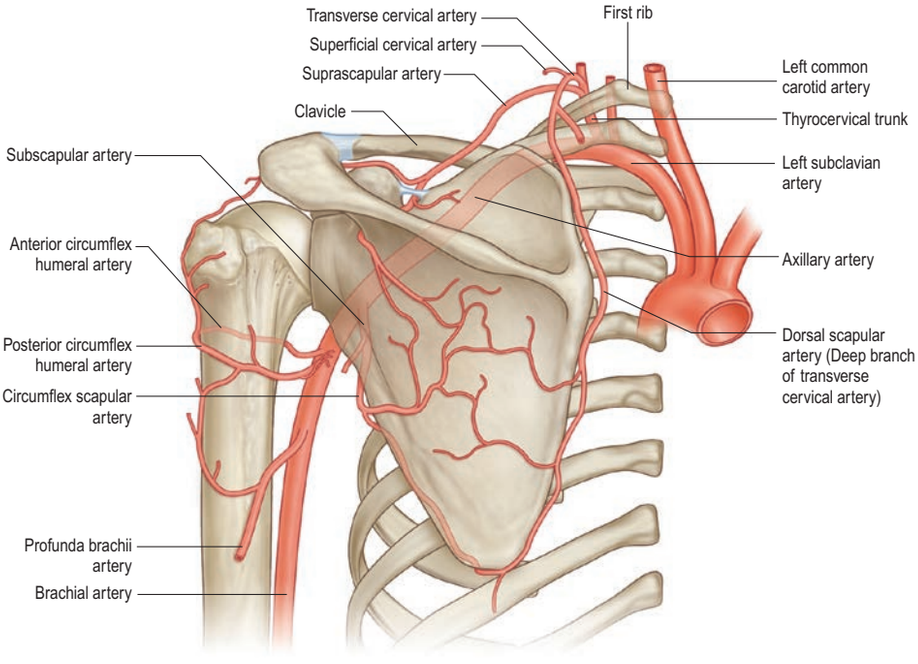

Fig. 49.31 The scapular anastomosis, left side. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

supplies supraspinatus. It descends behind the scapular neck, and passes through the spinoglenoid notch deep to the inferior transverse ligament to gain the deep surface of infraspinatus, where it anastomoses with the circumflex scapular and deep branch of the transverse cervical artery. Its muscular branches supply sternocleidomastoid, subclavius and infraspinatus. It also gives off a suprasternal branch that crosses the sternal end of the clavicle to supply the skin of the upper thorax, and an acromial branch that pierces trapezius to supply the skin over the shoulder. This last branch anastomoses with the thoraco-acromial and posterior circumflex humeral arteries.

As the suprascapular artery passes over the superior transverse ligament, it gives off a branch that enters the subscapular fossa beneath subscapularis and anastomoses with the subscapular artery and the deep branch of the transverse cervical artery. It also supplies the acromioclavicular and glenohumeral joints, the clavicle and the scapula.

Angiomyosomes

Supraclavicular artery

This small vessel arises from either the transverse cervical or superficial cervical artery. It pierces the deep fascia just superior to the clavicle and anterior to trapezius, and supplies an area of skin over the lateral end of the clavicle.

Axillary artery

The axillary artery, a continuation of the subclavian artery, begins at the outer border of the first rib and ends nominally at the inferior border of teres major, where it becomes the brachial artery (see Fig. 49.31). Its direction varies with the position of the limb; it is almost straight when the arm is raised at right-angles, concave upwards when the arm is elevated above this level, and convex upwards and laterally when the arm is by the side (**Fig. 49.32**). At first deep, it subsequently becomes superficial, when it is covered only by the skin and fasciae. Pectoralis minor crosses it and so divides it into three parts, which are proximal, posterior and distal to the muscle.

Relations of the first part

The skin, superficial fascia, platysma, supraclavicular nerves, deep fascia, clavicular fibres of pectoralis major and the clavipectoral fascia, lateral pectoral nerve and the loop of communication between the lateral and medial pectoral nerves, and the thoraco-acromial and cephalic veins are all anterior. The first intercostal space and external intercostal, first and second digitations of serratus anterior, long thoracic and medial pectoral nerves, and the medial cord of the brachial plexus are all posterior. The posterior cord of the brachial plexus is lateral and the axillary vein is anteromedial. The first part is enclosed with the axillary vein and brachial plexus in a fibrous axillary sheath, which is continuous with the prevertebral layer of the deep cervical fascia.

Relations of the second part

The skin, superficial and deep fascia, and pectoralis major and minor are all anterior. The posterior cord of the brachial plexus and the areolar tissue between it and subscapularis are posterior. The axillary vein is medial, separated from the artery by the medial cord of the brachial plexus and the medial pectoral nerve. The lateral cord of the brachial plexus is lateral, separating the artery from coracobrachialis. The cords of the brachial plexus thus surround the second part on three sides, with the dispositions implied by their names, and separate it from the vein and adjacent muscles.

Relations of the third part

Pectoralis major and, distal to the muscle, skin and fasciae are anterior. The lower part of subscapularis and the tendons of latissimus dorsi and teres major are posterior. Coracobrachialis is lateral and the axillary vein is medial. Branches of the brachial plexus are arranged as follows: laterally, the lateral root and then trunk of the median nerve and, for a short distance, the musculocutaneous nerve; medially, the medial cutaneous nerve of the forearm between the axillary artery and vein anteriorly, and the ulnar nerve between these vessels posteriorly; anteriorly, the medial root of the median nerve; and posteriorly, the radial and axillary nerves, the latter only to the distal border of subscapularis. The dispositions of the branches of the brachial plexus around the axillary artery have, therefore, altered: there has been a rotation such that the nerves derived from the lateral cord are now more anterior, those from the medial cord more posterior, and those of the posterior cord come to lie more laterally.

Variants

The branches of the axillary artery exhibit considerable variation. An alar thoracic artery, often from the second part, may supply fat and lymph nodes in the axilla. The lateral thoracic artery may be absent, in which case it is replaced by lateral perforating branches of the intercostal arteries; alternatively, it may become, or give off, a direct cutaneous vessel (named the superficial thoracic artery by some sources) that supplies the skin over the lateral border of pectoralis major. In up to one-third of cases, the subscapular artery can arise from a common trunk with the posterior circumflex humeral artery. Occasionally, the subscapular, circumflex humeral and profunda brachii arteries arise in common, and in this case, branches of the brachial plexus surround this common vessel instead of the axillary artery. The posterior circumflex humeral artery may arise from the profunda brachii artery and pass back below teres major, instead of passing through the quadrangular space. Sometimes, the axillary artery divides into radial and ulnar arteries (anomalous 'high division'), and is, occasionally, the source of the anterior interosseous artery.

Angiomyosomes

Branches

The branches of the axillary artery are one from the first part (superior thoracic), two from the second part (thoraco-acromial, lateral thoracic)

Fig. 49.32 Axillary angiograms. **A**, View with the arm by the side. **B**, View with the arm elevated.

Two branches of the subclavian artery perfuse the dorsal scapular suspension and medial motion muscles (the dorsal scapular artery), the posterosuperior rotator cuff muscles (the suprascapular artery) and the clavicle. These vessels correspond to the equivalent innervation for the same muscles. In this sense, innervation and angiomyotomes correspond. Pain afferents from the muscles, mostly small, unmyelinated axons, travel in the nerves. Ischaemic ('fatigue-related') pain from these three groups of dorsal muscles is felt as a diffuse, burning sensation in the same region as the vascular supply, without radiation or referral, and without respite during rest for a characteristic period, somewhat equivalent to the period over which the symptoms of a chronic ischaemic muscular compartment syndrome may resolve. The suprascapular artery supplies a muscular compartment that is contained in a well-defined and relatively restricting fascia; it is, therefore, not a surprise that the ischaemic ('fatigue-related') pain generated in this compartment may present earlier and be more persistent than elsewhere in muscles less well contained by fascial sheaths.

The axillary artery supplies the muscles of the ventral compartments of the shoulder, including the pectoral–deltoid muscle sheet, the scapulohumeral muscles (other than the posterosuperior rotator cuff) and the shoulder joint, including the scapula (with the serratus muscles) and proximal humerus. Its terminal branch, the brachial artery, supplies the muscles of the anterior compartment of the arm (for the branches of the brachial artery at the elbow and in the forearm, see Ch. 50). The profunda brachii artery, the major proximal branch of the brachial artery, supplies the muscles of the posterior compartment of the arm and the shaft of the humerus.

and three from the third part (subscapular, anterior and posterior circumflex humeral) (see Fig. 49.47).

Superior thoracic artery

The superior thoracic artery is a small vessel that arises from the first part of the axillary artery near the lower border of subclavius; it sometimes arises from the thoraco-acromial artery (see Fig. 49.47). It runs anteromedially above the medial border of pectoralis minor, then passes between it and pectoralis major to gain the thoracic wall. It supplies these muscles and the thoracic wall, and anastomoses with the internal thoracic and upper intercostal arteries.

Thoraco-acromial (acromiothoracic) artery

The thoraco-acromial artery is a short branch that arises from the second part of the axillary artery (see Figs 49.27, 49.47). It is initially overlapped by pectoralis minor, skirting its medial border; it next pierces the clavipectoral fascia and divides into pectoral, acromial, clavicular and deltoid branches, which supply pectoralis major and minor, an area of skin over the clavipectoral fascia, and the anterior portion of deltoid.

Pectoral branch The pectoral branch is the largest branch. It descends between the pectoral muscles, gives a branch to pectoralis minor, and then continues on the deep surface of pectoralis major. It enters the muscle and anastomoses with the intercostal branches of the internal thoracic and lateral thoracic arteries. It gives off perforating branches to the breast, and musculocutaneous perforators to the skin over pectoralis major.

Acromial branch The acromial branch crosses the coracoid process under deltoid, which it supplies, then pierces the muscle and ends on the acromion. It anastomoses with branches of the suprascapular artery, the deltoid branch of the thoraco-acromial artery and the posterior circumflex humeral arteries.

Clavicular branch The clavicular branch ascends medially between the clavicular part of pectoralis major and the clavipectoral fascia. It supplies the sternoclavicular joint and subclavius.

Deltoid branch The deltoid branch often arises with the acromial branch. It crosses pectoralis minor to accompany the cephalic vein between pectoralis major and deltoid, and supplies both muscles.

Lateral thoracic artery

The lateral thoracic artery arises from the second part of the axillary artery. Following the lateral border of pectoralis minor, it passes to the deep surface of pectoralis major as far distally as the fifth intercostal space (see Fig. 49.45). It supplies serratus anterior and the pectoral muscles, the axillary lymph nodes and subscapularis. It anastomoses with the internal thoracic, subscapular and intercostal arteries, and with the pectoral branch of the thoraco-acromial artery. In females, it is large and has lateral mammary branches, which curve round the lateral border of pectoralis major to the breast. In both males and females, it gives off cutaneous branches that pass around the lateral border of pectoralis major to supply the skin in this region.

Subscapular artery

The subscapular artery is the largest branch of the axillary artery (see Figs 49.31, 49.47). It usually arises from the third part of the axillary artery at the distal (inferior) border of subscapularis, which it follows to the inferior scapular angle where it anastomoses with the lateral thoracic and intercostal arteries and the deep branch of the transverse cervical artery. It supplies adjacent muscles and the thoracic wall. It is accompanied distally by the nerve to latissimus dorsi. Approximately 4 cm from its origin, the subscapular artery divides into the circumflex scapular and thoracodorsal arteries.

Circumflex scapular artery

The circumflex scapular artery, the larger of the two terminal branches of the subscapular artery, curves backwards around the lateral border of the scapula, traversing a triangular space between subscapularis above, teres major below and the long head of the triceps laterally (see Fig. 49.33). It enters the infraspinous fossa under teres minor and then divides. One branch (infrascapular) enters the subscapular fossa deep to subscapularis, and anastomoses with the suprascapular and dorsal scapular arteries (or deep branch of the transverse cervical artery). The other branch continues along the lateral border of the scapula between teres major and minor, then, dorsal to the inferior angle, anastomoses with the dorsal scapular artery. Small branches supply the posterior part of deltoid and the long head of triceps, and anastomose with an ascending branch of the profunda brachii artery.

Thoracodorsal artery The other terminal branch of the subscapular artery, the thoracodorsal artery, follows the lateral margin of the scapula, posterior to the lateral thoracic artery, between latissimus dorsi and serratus anterior. Before entering the deep surface of latissimus dorsi, it supplies teres major and the intercostals, and sends one or two branches to serratus anterior. It enters latissimus dorsi muscle with the thoracodorsal nerve; this constitutes the principal neurovascular pedicle to the muscle. It provides numerous musculocutaneous perforators that supply the skin over the superior part of latissimus dorsi. The intramuscular portion of the artery anastomoses with intercostal arteries and lumbar perforating arteries.

Anterior circumflex humeral artery

The anterior circumflex humeral artery arises from the lateral side of the axillary artery at the distal border of subscapularis (see Fig. 49.31). It runs horizontally behind coracobrachialis and the short head of biceps, anterior to the surgical neck of the humerus. Reaching the intertubercular sulcus, it sends an ascending branch to supply the humeral head and shoulder joint (Brooks et al 1993), continues laterally under the long head of biceps and deltoid, and anastomoses with the posterior circumflex humeral artery.

Posterior circumflex humeral artery

The posterior circumflex humeral artery is larger than the anterior (see Fig. 49.31). It branches from the third part of the axillary artery at the distal border of subscapularis and runs backwards with the axillary nerve through a quadrangular space bounded by subscapularis, the capsule of the shoulder joint and teres minor above, teres major below, the long head of triceps medially, and the surgical neck of the humerus laterally (see Fig. 49.22B). It curves round the humeral neck and supplies the shoulder joint, deltoid, teres major and minor, and long and lateral heads of triceps (Gerber et al 1990). It gives off a descending branch that anastomoses with the deltoid branch of the profunda brachii artery and with the anterior circumflex humeral and acromial branches of the suprascapular and thoraco-acromial arteries.

Potential vascular anastomoses around the shoulder girdle: clinical relevance

Available with the *Gray's Anatomy* e-book

Brachial artery

The brachial artery is a continuation of the axillary artery. It begins at the distal (inferior) border of the tendon of teres major and ends about a centimetre distal to the elbow joint (at the level of the neck of the radius) by dividing into the radial and ulnar arteries (see Figs 49.33, 49.44, 50.21–50.22). At first, it is medial to the humerus, but gradually spirals anterior to it until it lies midway between the humeral epicondyles. Its pulsation can be felt throughout the arm.

Relations

The brachial artery is wholly superficial, covered anteriorly only by skin and superficial and deep fasciae. The bicipital aponeurosis crosses it anteriorly at the elbow, separating it from the median cubital vein; the median nerve crosses it lateromedially near the distal attachment of coracobrachialis. Posterior to the artery are the long head of triceps, separated initially by the radial nerve and profunda brachii artery, and then successively by the medial head of triceps, the attachment of coracobrachialis and brachialis. Proximally, the median nerve and coracobrachialis lie laterally and the medial cutaneous nerve of the forearm and ulnar nerve lie medially. Distally, biceps brachii overlaps the artery laterally and the median nerve and basilic vein lie medially. The artery is accompanied by two venae comitantes, connected by transverse and oblique branches. At the elbow, the brachial artery sinks deeply into the triangular intermuscular cubital fossa and its further course is described in Chapter 50 and Chapter 81.

Variants

The brachial artery, with the median nerve, may diverge from the medial border of biceps brachii and descend towards the medial humeral epicondyle, usually behind a supracondylar process from which a fibrous arch crosses the artery, and which then runs behind or through pronator teres to the elbow. Occasionally, the artery divides proximally into two trunks that reunite. Frequently, it divides more proximally than usual into radial, ulnar and common interosseous arteries. Most often, the radial branches arise proximally,

Two significant cutaneous branches arise from the circumflex scapular artery as it emerges through the upper triangular space. The superior, or horizontal, branch is a direct cutaneous artery that passes medially at the level of the deep fascia parallel with the spine of the scapula and supplies a band of skin overlying the spine of the scapula. The lower branch (parascapular branch) is also a direct cutaneous vessel that passes in an inferomedial direction, again at the level of the deep fascia, and supplies an area of skin overlying the lateral border of the scapula. Both of these cutaneous vessels provide the anatomical basis of skin flaps that can be surgically raised in this region (scapular flap based on the horizontal branch and parascapular flap based on the lower, parascapular branch) to reconstruct areas of missing tissue elsewhere in the body.

The potential vascular anastomoses around the shoulder girdle are numerous, which means that collateral perfusion of the upper limb is possible in occlusion of the axillary artery or vein. In acute occlusion of the axillary artery, these potential anastomoses are not reliable and clinicians should not rely on anastomotic perfusion of the acutely ischaemic limb. The axillary artery is most 'at risk' of occlusion as a result of intimal separation and dissection in its second part, behind pectoralis minor, an injury associated with infraclavicular brachial plexus traction lesions (Birch 2011). Although magnetic resonance imaging with angiography is recommended for the diagnosis of the poorly perfused limb after distraction trauma, the site of intimal rupture is so consistent as to make urgent surgical exploration without imaging a reasonable clinical decision.

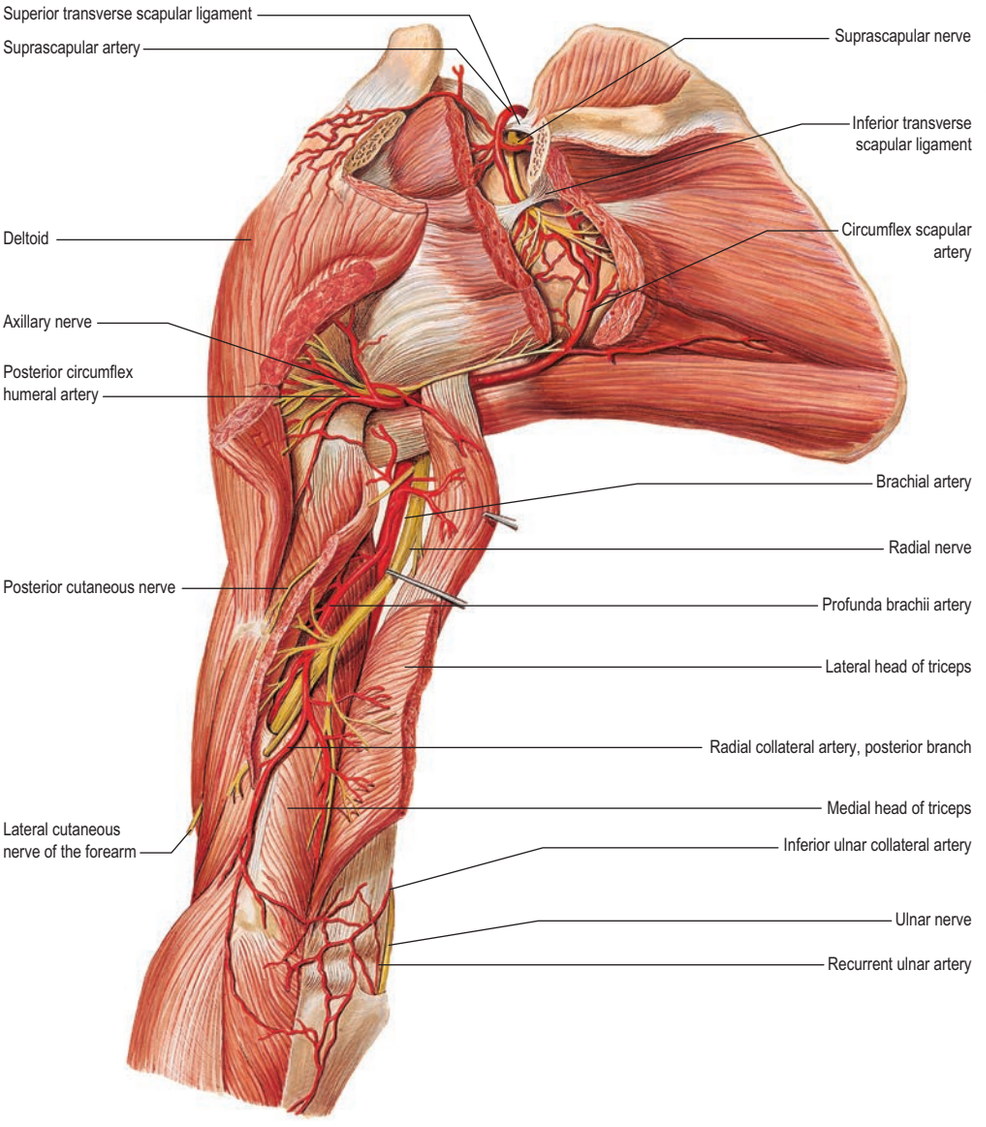

Fig. 49.33 Muscles, vessels and nerves of the left upper arm, posterior aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

leaving a common trunk for the ulnar and common interosseous arteries. Sometimes, the ulnar artery arises proximally and the radial and common interosseous arteries form the other division, or the common interosseous may also arise proximally. Slender vasa aberrantia may connect the brachial artery to the axillary artery or to one of the forearm arteries, usually the radial. The brachial artery may be crossed by muscular or tendinous slips from coracobrachialis, biceps brachii, brachialis or pronator teres. Rarely, the median nerve crosses posterior, rather than anterior, to the brachial artery near the insertion of coracobrachialis.

Branches

The branches of the brachial artery are the profunda brachii, nutrient, superior, middle and inferior ulnar collateral, deltoid, muscular, radial and ulnar arteries.

Profunda brachii artery The profunda brachii artery (Fig. 49.33; see Fig. 49.31) is a large branch from the posteromedial aspect of the brachial artery, distal to teres major. It follows the radial nerve closely, at first posteriorly between the long and medial heads of triceps, then in the spiral groove covered by the lateral head of triceps. It supplies muscular branches, and the nutrient artery of the humerus, and finally divides into terminal radial and middle collateral branches. The radial collateral branch pierces the lateral intermuscular septum to reach the anterior aspect of the epicondyle of the humerus in the groove between brachioradialis and brachialis, and takes part in the anastomosis around the elbow. The middle collateral branch runs posterior to the septum and epicondyle.

The profunda brachii may originate from a common origin with the posterior circumflex humeral artery, from the axillary artery proximal to the tendon of latissimus dorsi, or from the distal portion of the axillary artery.

Middle collateral (posterior descending) branch The middle collateral artery is the larger terminal branch of the profunda brachii artery. It arises posterior to the humerus and descends along the posterior surface of the lateral intermuscular septum to the elbow. Proximally, the artery lies between brachialis (anteriorly) and the lateral head of triceps (posteriorly). Distally, it lies between brachioradialis (anteriorly) and the lateral head of triceps (posteriorly). It may pierce the deep fascia and become cutaneous, or remain deep to the fascia, forming an arch with the inferior ulnar collateral artery proximal to the olecranon fossa before anastomosing with the interosseous recurrent artery behind the lateral epicondyle; it gives off about five small fasciocutaneous perforators and often has a small branch that accompanies the nerve to anconeus.

Radial collateral (anterior descending) branch The radial collateral artery accompanies the radial nerve through the lateral intermuscular septum, descending between brachialis and brachioradialis anterior to the lateral epicondyle and anastomosing with the radial recurrent artery. It supplies brachialis, brachioradialis, the radial nerve and a few fasciocutaneous perforators.

Nutrient artery of humerus The nutrient artery of the humerus arises near the mid-level of the upper arm and enters the nutrient canal near the attachment of coracobrachialis, posterior to the deltoid tuberosity; it is directed distally.

Superior ulnar collateral artery The superior ulnar collateral artery arises a little distal to the mid-level of the upper arm, usually from the brachial artery (see Fig. 48.3), but often as a branch from the profunda brachii. It accompanies the ulnar nerve, piercing the medial intermuscular septum to descend in the posterior compartment and supply the medial head of triceps. It passes between the medial epicondyle and olecranon, ending deep to flexor carpi ulnaris by anastomosing with

the posterior ulnar recurrent and inferior collateral arteries. A branch sometimes passes anterior to the medial epicondyle and anastomoses with the anterior ulnar recurrent artery.

Middle ulnar collateral artery If present, the middle ulnar collateral artery arises from the brachial artery between the superior and inferior ulnar collateral arteries. It passes anterior to the medial epicondyle, anastomoses with the anterior ulnar recurrent artery, supplies triceps and sends small fasciocutaneous perforators to the skin.

Inferior ulnar collateral (supratrochlear) artery The inferior ulnar collateral artery begins approximately 5 cm proximal to the elbow. It passes medially between the median nerve and brachialis, pierces the medial intermuscular septum and curls round the humerus between triceps and bone (see Figs 48.3, 49.33). It forms an arch proximal to the olecranon fossa with the middle collateral branch of the profunda brachii artery. As it lies on brachialis, it gives off branches that descend anterior to the medial epicondyle to anastomose with the anterior ulnar recurrent artery. Behind the epicondyle, a branch anastomoses with the superior ulnar collateral and posterior ulnar recurrent arteries.

Muscular branches Muscular branches are distributed to coracobrachialis, biceps and brachialis.

Deltoid (ascending) branch The deltoid branch ascends between the lateral and long heads of triceps, and anastomoses with a descending branch of the posterior circumflex humeral artery.

Radial and ulnar arteries The radial and ulnar arteries are described in detail on pages 951 and 951, respectively. For an account of the anastomosis about the elbow, see page 952.

Veins

The deep veins have numerous anastomoses with each other and with the superficial veins.

Axillary vein

The axillary vein is the continuation of the basilic vein (see Fig. 48.4). It begins at the lower border of teres major and ascends to the outer border of the first rib, where it becomes the subclavian vein. It is joined by the brachial vein near subscapularis, and by the cephalic vein near its costal end; other tributaries follow the axillary arterial branches. It lies medial to the axillary artery, which it partly overlaps. The medial pectoral nerve, medial cord of the brachial plexus, ulnar nerve and medial cutaneous nerve of the forearm lie between the artery and the vein. The medial cutaneous nerve of the arm is medial to the vein; the lateral group of axillary lymph nodes is posteromedial. There are a pair of valves near the distal end of the vein, and valves near the ends of the cephalic and subscapular veins.

Subclavian vein

The subclavian vein is a continuation of the axillary vein (see Fig. 48.4). It extends from the outer border of the first rib to the medial border of scalenus anterior, where it joins the internal jugular to form the brachiocephalic vein. The clavicle and subclavius are anterior; the subclavian artery is posterosuperior, separated by scalenus anterior and the phrenic nerve; and the first rib and pleura are inferior. The vein usually has a pair of valves about 2 cm from its end. Its tributaries are the external jugular, dorsal scapular and (sometimes) anterior jugular veins, and, occasionally, a small branch from the cephalic vein that ascends anterior to the clavicle. At its junction with the internal jugular vein, the left subclavian receives the thoracic duct, and the right subclavian vein receives the right lymphatic duct (see Fig. 35.16).

Brachial veins

The brachial veins flank the brachial artery, as venae comitantes with tributaries similar to the arterial branches; they join the axillary vein near the lower margin of subscapularis. The medial branch often joins the basilic vein before it becomes the axillary vein.

Superficial veins

The cephalic vein ascends anterior to the elbow, superficial to a groove between brachioradialis and biceps brachii, crosses superficial to the lateral cutaneous nerve of the forearm, and ascends lateral to biceps and between pectoralis major and deltoid, where it adjoins the deltoid branch of the thoraco-acromial artery (Fig. 49.34). It enters the infraclavicular fossa, passes posterior to the clavicular head of pectoralis major, pierces the clavipectoral fascia, crosses the axillary artery and joins the axillary vein just below clavicular level. It may connect with the external jugular vein by a branch anterior to the clavicle. The median cubital vein is sometimes large, transferring most blood from the cephalic to the basilic vein; when this occurs, the proximal cephalic vein is either absent or much diminished.

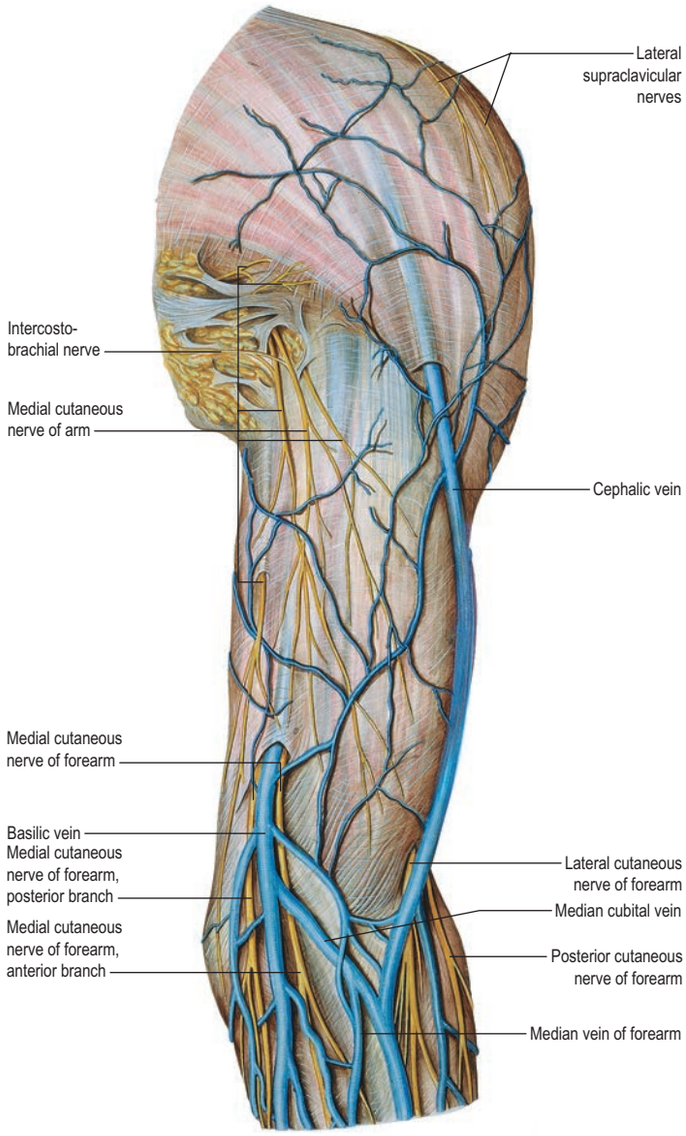

Fig. 49.34 The superficial veins and nerves, left arm, anterior (flexor) aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Lymphatic drainage

Lymphatics follow the usual pattern, in that superficial lymphatics follow the veins, and deep lymphatics follow the arteries (see Fig. 49.45).

INNERVATION

Brachial plexus

For an overview of the brachial plexus, see Chapter 48 and Figs 48.6–48.7.

In the axilla, the lateral and posterior cords of the brachial plexus are anterior and lateral to the first part of the axillary artery, respectively, and the medial cord is behind the artery. The cords assume their appropriate relations around the second part of the artery, deep to pectoralis major. In the lower axilla, the cords divide into nerves that supply the

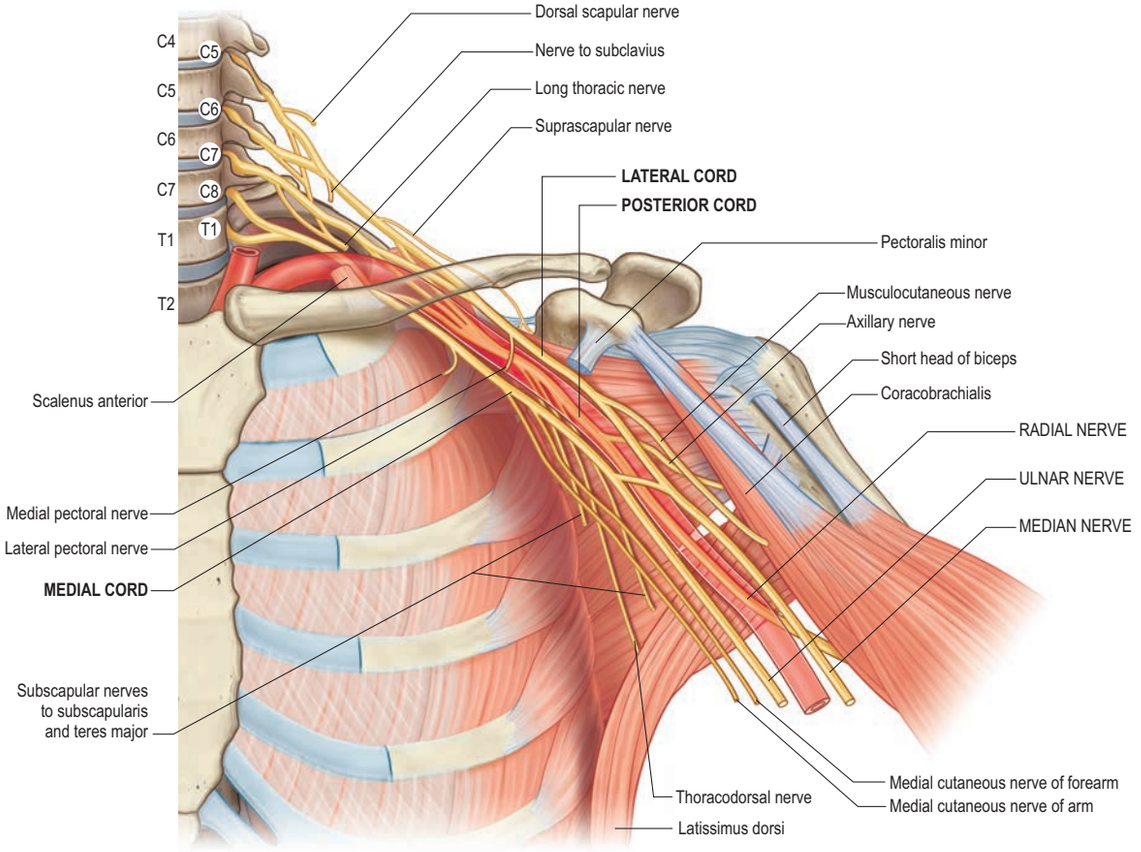

Fig. 49.35 The brachial plexus and its major branches. The axillary artery, shown in red outline, runs anterior to the radial nerve. The vertebral levels are labelled C4–T2; the spinal nerves are labelled C5–T1 (white circles).

upper limb (Fig. 49.35). Other than the medial root of the median nerve, these nerves are related to the third part of the artery in the same way as their cords are related to the second part, i.e. branches of the lateral cord are lateral to the artery, branches of the medial cord are medial, and branches of the posterior cord are posterior.

Suprascapular nerve

The suprascapular nerve is a large branch of the upper trunk (fifth and sixth cervical ventral rami) (see Figs 35.17, 49.35). It runs laterally, deep to trapezius and omohyoid, and enters the supraspinous fossa through the suprascapular notch inferior to the superior transverse scapular ligament. It runs deep to supraspinatus and supplies it. It curves round the lateral border of the spine of the scapula with the suprascapular artery to reach the infraspinous fossa, where it gives two branches to infraspinatus and articular rami to the shoulder and acromioclavicular joints. The suprascapular nerve rarely has a cutaneous branch: when present, it pierces deltoid close to the tip of the acromion and supplies the skin of the proximal third of the arm within the territory of the axillary nerve.

Lateral pectoral nerve

The lateral pectoral nerve (fifth and sixth cervical ventral rami) is larger than the medial, and may arise either from the anterior divisions of the upper and middle trunks, or by a single branch from the lateral cord, just above or deep to the clavicle. It crosses anterior to the axillary artery and vein, pierces the clavipectoral fascia and supplies the deep surface of pectoralis major. It sends a branch to the medial pectoral nerve, forming a loop in front of the first part of the axillary artery to supply some fibres to pectoralis minor.

Medial pectoral nerve

The medial pectoral nerve (eighth cervical ventral ramus and first thoracic ventral ramus) branches from the medial cord while the latter lies posterior to the axillary artery and curves forwards between the axillary artery and vein. Anterior to the artery, it joins a ramus of the lateral pectoral nerve and enters the deep surface of pectoralis minor, which it supplies. Two or three branches pierce pectoralis minor and others may pass round its inferior border to end in pectoralis major.

Upper (superior) subscapular nerve

The superior subscapular nerve is smaller than the inferior. It arises from the posterior cord (fifth and sixth cervical ventral rami), enters subscapularis at a high level, and is frequently double.

Lower (inferior) subscapular nerve

The inferior subscapular nerve arises from the posterior cord (fifth and sixth cervical ventral rami). It supplies the lower part of subscapularis and ends in teres major, which is sometimes supplied by a separate branch.

Thoracodorsal nerve

The thoracodorsal nerve arises from the posterior cord (sixth, seventh and eighth cervical ventral rami) between the subscapular nerves. It accompanies the subscapular artery along the posterior axillary wall and supplies latissimus dorsi, reaching its distal border (see Fig. 49.29).

Axillary nerve

The axillary nerve arises from the posterior cord (fifth and sixth cervical ventral rami) (see Figs 49.33, 49.35, 48.8). Initially it is lateral to the radial nerve, posterior to the axillary artery and anterior to subscapularis. At the lower border of subscapularis, it curves back inferior to the humeroscapular articular capsule and, together with the posterior circumflex humeral vessels, traverses a quadrangular space bounded above by subscapularis (anteriorly) and teres minor (posteriorly), below by teres major, medially by the long head of triceps, and laterally by the surgical neck of the humerus. It divides in the space into anterior and posterior branches. The anterior branch curves round the neck of the humerus with the posterior circumflex humeral vessels, deep to deltoid, to reach the anterior part of the muscle. At the level of the anterior border of the acromion, the nerve often consists of two or more thin filaments that supply the anterior deltoid; it gives off a few small cutaneous branches that pierce deltoid and ramify in the skin over its lower part. The posterior branch courses medially and posteriorly along the attachment of the lateral head of triceps, inferior to the glenoid rim. It usually lies medial to the anterior branch in the quadrangular space. It

gives off the nerve to teres minor and the upper lateral cutaneous nerve of the arm at the lateral edge of the attachment of the long head of triceps. The nerve to teres minor enters the muscle on its inferior surface. The posterior branch frequently supplies the posterior aspect of deltoid, usually via a separate branch from the main stem, but occasionally from the superior lateral cutaneous nerve of the arm. However, the posterior part of deltoid has a more consistent supply from the anterior branch of the axillary nerve, which should be remembered when performing a posterior deltoid-splitting approach to the shoulder. The upper lateral cutaneous nerve of the arm pierces the deep fascia at the medial border of the posterior aspect of deltoid, and supplies the skin over the lower part of deltoid and the upper part of the long head of triceps. The posterior branch is intimately related to the inferior aspects of the glenoid and shoulder joint capsule. There is often an enlargement or pseudoganglion on the branch to teres minor. The axillary trunk supplies a branch to the shoulder joint below subscapularis.

Injuries to the shoulder girdle involving the accessory, long thoracic, axillary and suprascapular nerves

Available with the *Gray's Anatomy* e-book

Musculocutaneous nerve

The musculocutaneous nerve arises from the lateral cord (fifth, sixth and seventh cervical ventral rami), opposite the lower border of pectoralis minor (**Fig. 49.44**; see Figs 48.13, 49.45). It pierces coracobrachialis a variable distance below the tip of the coracoid process and then descends laterally between biceps brachii and brachialis to the lateral side of the arm. The first branch, to coracobrachialis, may pass into the muscle no more than 2 cm distal to the tip of the coracoid; fibres from the seventh cervical ventral ramus may branch directly from the lateral cord. Branches to biceps brachii and brachialis leave after the musculocutaneous nerve has pierced coracobrachialis. There are usually two branches to brachialis, and the lower branch also supplies the anterior aspect of the elbow joint. The nerve to biceps brachii is consistently accompanied by a vascular pedicle. The nerve now inclines lateral and deep, into the plane between brachialis posteriorly and biceps anteriorly, where it supplies a small branch to the humerus that enters the shaft with the nutrient artery. Below the branches to brachialis, the musculocutaneous nerve continues as the lateral cutaneous nerve of the forearm.

The musculocutaneous nerve has frequent variations. It may run behind coracobrachialis or adhere for some distance to the median nerve and pass behind biceps brachii. Some fibres of the median nerve may run in the musculocutaneous nerve, leaving it to join their proper trunk; less frequently, the reverse occurs, and the median nerve sends a branch to the musculocutaneous nerve. Occasionally, the musculocutaneous nerve also supplies pronator teres and may replace radial branches to the dorsal surface of the thumb.

Medial cutaneous nerve of the arm

The medial cutaneous nerve of the arm (eighth cervical and first thoracic ventral rami) is the smallest and most medial branch of the brachial plexus, arising from the medial cord (see Fig. 49.35). It crosses the axilla, either anterior or posterior to the axillary vein, then passes medial to the axillary vein, communicates with the intercostobrachial nerve, and descends medial to the brachial artery and basilic vein. It pierces the deep fascia at the midpoint of the upper arm to supply the skin over the medial aspect of the distal third of the upper arm (see Fig. 49.34). It connects with the posterior branch of the medial cutaneous nerve of the forearm. Sometimes, the medial cutaneous nerve of the arm and the intercostobrachial nerve are connected in a plexiform manner in the axilla. The intercostobrachial nerve may be large and reinforced by part of the lateral cutaneous branch of the third intercostal nerve. In these cases, it replaces the medial cutaneous nerve of the arm and receives a connection representing the latter from the brachial plexus (occasionally, this connection is absent).

Medial cutaneous nerve of the forearm

The medial cutaneous nerve of the forearm comes from the medial cord (first thoracic ventral ramus) (see Fig. 49.34). It lies initially between the axillary artery and vein, and gives off a ramus that pierces the deep fascia to supply the skin over the biceps, almost to the elbow. The nerve descends medial to the brachial artery, pierces the deep fascia with the basilic vein midway in the arm, and divides into anterior and posterior branches. Its further course is described in Chapter 50 and Chapter 81.

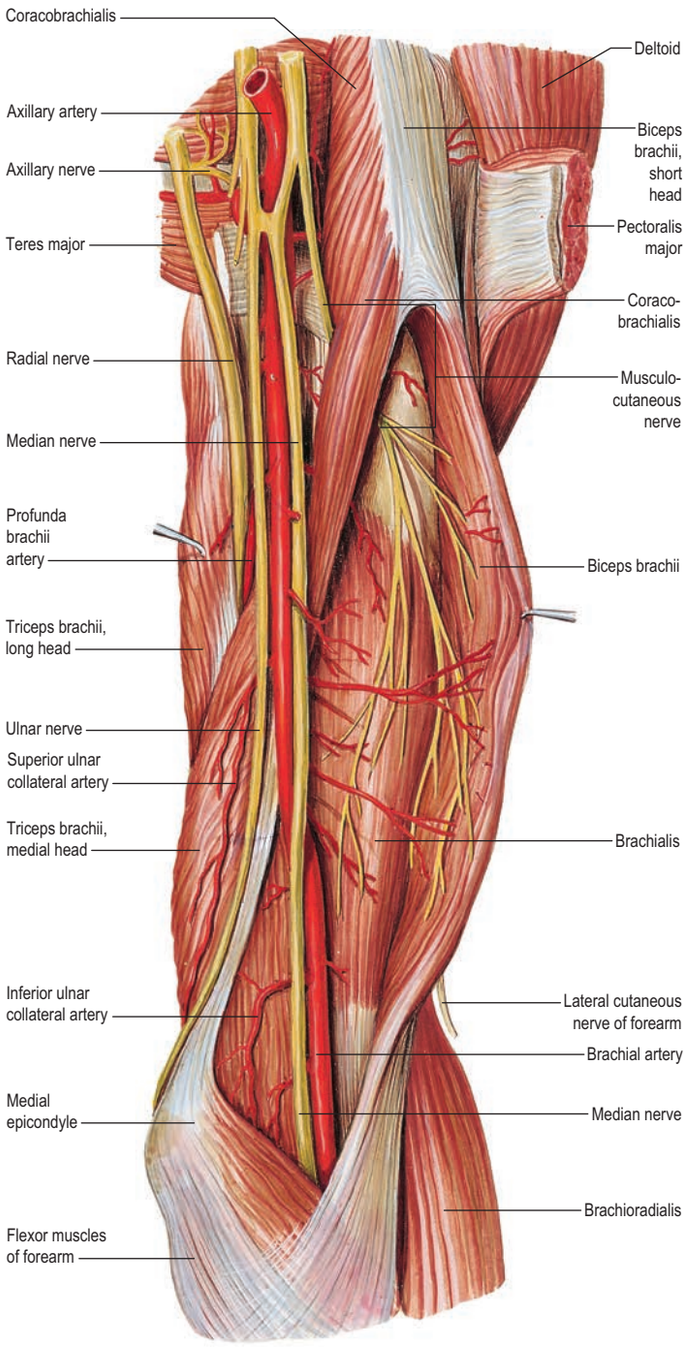

Fig. 49.44 The left upper arm dissected to show the musculocutaneous nerve. Note also the changing relationship of the brachial artery and median nerve. Anterior aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Median nerve

The median nerve has two roots from the lateral cord (fifth, sixth and seventh cervical ventral rami) and medial cord (eighth cervical and first thoracic ventral rami), which embrace the third part of the axillary artery and unite anterior or lateral to it (see Figs 49.29, 49.35, 49.44, 48.7, 48.10). Some fibres from the seventh cervical ventral ramus often leave the lateral root in the lower part of the axilla. They pass distomedially posterior to the medial root, and usually anterior to the axillary artery, to join the ulnar nerve. Clinically, they are believed to be mainly motor and to supply flexor carpi ulnaris. The median nerve gives off vascular branches to the brachial artery. If the lateral root is small, the musculocutaneous nerve (fifth, sixth and seventh cervical ventral rami) connects with the median nerve in the arm. The further course of the median nerve is described in Chapter 50 and Chapter 81.

Serious mistakes are most common in the diagnosis of severe injuries about the shoulder girdle: diagnosis of injuries to the accessory, long thoracic, axillary and suprascapular nerves is by no means straightforward. Precise but elementary clinical examination is reliable: delay before diagnosis is therefore inexplicable. Matters are not helped by the persistence with which incorrect and discredited ideas about what muscles do continue to be taught. Many nerve injuries in this region are painful and, too often, a patient is passed to a pain clinic without a diagnosis.

Inferior scapulohumeral angle (ISHA)

Assessing the inferior scapulohumeral angle (ISHA) informs the clinician about function at the thoracoscapular and shoulder joints (**Fig. 49.36**). The ISHA is subtended by the long axis of the humerus and the lateral border of the scapula; the apex of the angle is centred over the glenohumeral joint. Stiffness of the joints is detected by measuring *passive* range, which is normally between 170° and 180°. The excursion between the humerus and the scapula in a healthy adult is between 130° and 140°, i.e. the difference between the ISHA at rest and in full elevation. It is important to remember that full elevation is possible after successful thoracoscapular arthrodesis in scapulohumeral dystrophy (Copeland and Howard 1978). This range of movement occurs at the shoulder joints, mainly the glenohumeral joint, with some involvement of the acromioclavicular and sternoclavicular joints. Successful glenohumeral arthrodesis enables a range of elevation of 30–40°, provided by the thoracoscapular joint.

Accessory nerve

The integrity of the accessory nerve is fundamental to thoracoscapular function and essential for scapulohumeral rhythm. The nerve is usually divided at the apex of the posterior triangle, usually by surgeons, and is a crippling injury. Typically, there is immediate pain, then dropping of the shoulder and a remarkable loss of function. The average ISHA is about 50°. The pain is characteristic: often severe, deep-seated, dull, constant and boring in nature, and felt around the scapula and the posterior aspect of the neck and shoulder. The posture of the scapula is also characteristic: because of the loss of the great suspensory muscle, trapezius, the scapula drops down and away from the spinal column (**Fig. 49.37**). There is often winging of the scapula, easily distinguished from that caused by paralysis of serratus anterior by the posture of the scapula (**Fig. 49.38**). The nerve appears to be relatively immune to the harmful effects of delayed repair, even as late as 4 years after injury, with early relief of pain long before there is reinnervation of muscle (Camp and Birch 2011).

Long thoracic nerve

The long thoracic nerve is frequently injured during operations around the first rib, in the posterior triangle and in the axilla, and by misplaced intercostal drains. It is particularly susceptible to involvement in neuralgic amyotrophy. Serratus palsy is usual in preganglionic injury to C5, C6 and C7. Pain and loss of function are usual and are only slightly less than those seen after accessory nerve palsy. The signs are characteristic. The active ISHA is, on average, 130°; this is the only nerve lesion in which the active ISHA actually exceeds the total range of active abduction. The scapula is pulled upwards and towards the spine by the unopposed action of trapezius (**Fig. 49.39**), an action that is increased by the weight of the limb, which contributes to the winging and is most notable in protraction.

Dislocation of the shoulder: the suprascapular and axillary nerves

Although most nerve lesions in uncomplicated anterior dislocations are benign, it is well to remember the risk to adjacent vessels, more so in high-energy transfer injuries, in older patients and in those with peripheral vascular disease. The consequences of delay in treatment are severe. It is very hard to examine muscles in a patient with a fracture-dislocation of the shoulder. Sensory loss is inconsistent. Consider, for example, a patient after successful reduction of a dislocated shoulder, whose arm is supported in a sling. There are three simple tests: initiation of abduction shows that the suprascapular nerve is intact and that the rotator cuff is not ruptured; abnormal sensibility in the skin over deltoid indicates a lesion of the axillary nerve; and gentle extension of the shoulder on the part of the patient, supported as it is in a sling, means that the examiner can palpate activity in the posterior fibres of deltoid (**Figs 49.40–49.41**).

The diagnosis of nerve injury is by no means straightforward. All too often, rupture of the axillary nerve is not recognized until deltoid is atrophied, long past the ideal time for repair. The widely held view that deltoid is the abductor of the shoulder is erroneous. Deltoid provides power and stamina, and abduction is initiated and maintained by the suprascapular nerve, acting through supra- and infraspinatus, their tendons and attachments. Disruption of any component of this abductor mechanism interferes with or precludes abduction. Wynn Parry (1981) treated 145 patients in whom paralysis was confined to deltoid. The range of abduction was full or nearly so, and a system of training enabled most patients to return to full military duties. He wrote: 'It must be stressed that these movements providing full abduction and elevation are not trick movements, in the sense usually associated with this word; all the muscles involved normally help to abduct the shoulder. The scapulohumeral rhythm is quite normal and in the later stages of re-education the patient does not even need to rotate the humerus externally to initiate movement.' Seddon (1975) was a little more cautious, finding abduction to about 155° was more usual. The ISHA is diminished by about 20° in uncomplicated ruptures of the axillary nerve when there is no stiffness of the shoulder.

Axillary nerve

The axillary nerve innervates deltoid. Although a good range of elevation is usually maintained by an intact abductor mechanism, strength and stamina are greatly reduced. Early diagnosis of rupture of the axillary

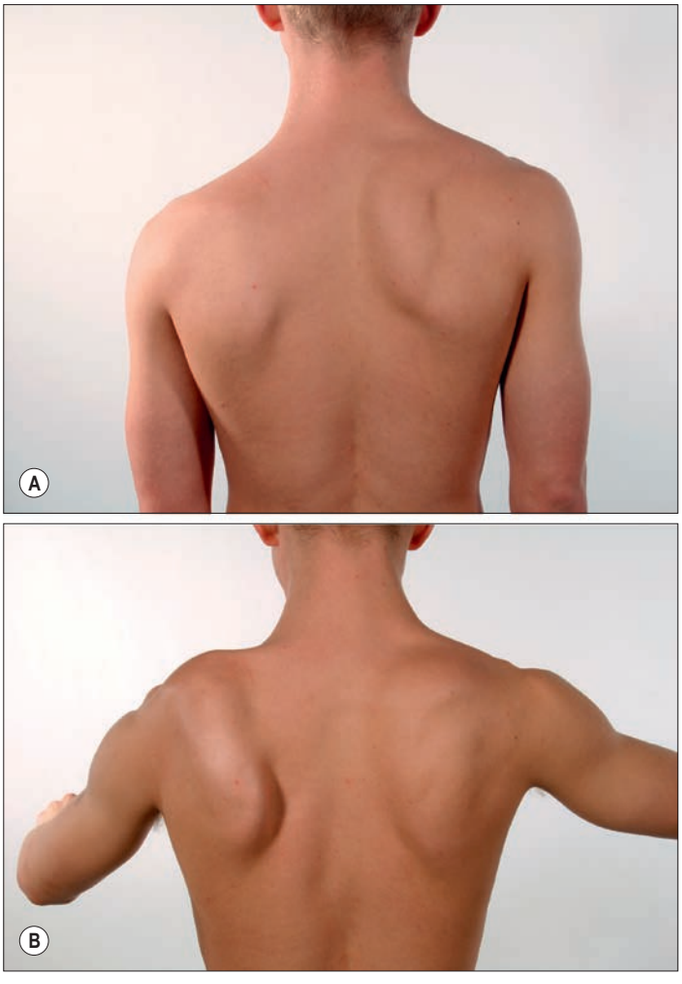

Fig. 49.38 A left accessory nerve palsy. Scapular winging, without prominence of the lower fibres of trapezius, in a case where there is some early recovery into the upper fibres after repair of the accessory nerve. **A**, At rest, the scapula is displaced downwards and away from the spine. **B**, Arm abducted. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

nerve can prove difficult; the nerve is deeply seated, which means that Tinel's sign is rarely detectable. Active movement is restricted by pain and by the restraint of any sling. The loss of sensation varies and there may not be complete anaesthesia. Patients with an intact suprascapular nerve and an intact rotator cuff are able to initiate abduction and many can fully elevate the arm, or nearly so. The power of forward flexion and of abduction is reduced to, at most, 30–40% of normal, whereas extension, with the shoulder at 90° of abduction, is 10% or less. One useful test is to palpate the posterior third of deltoid with the fingers and ask the patient to move the elbow gently backwards. It should be possible to detect activity in the muscle when the arm is supported in a sling or by the examiner's arm.

Suprascapular nerve

The suprascapular nerve is essential for abduction and lateral rotation at the glenohumeral joint. When the nerve or the rotator cuff is torn, or both are injured, the ISHA is so reduced that the patient is unable to move the arm away from the body. At rest, the head of the humerus drops inferiorly and migrates proximally in attempted abduction (see Fig. 49.41). In isolated cuff tears, the ISHA opens to about 30° or even more. In isolated axillary palsy, the ISHA is sometimes normal, or, more often, reduced by about 20° (**Figs 49.42–49.43**).

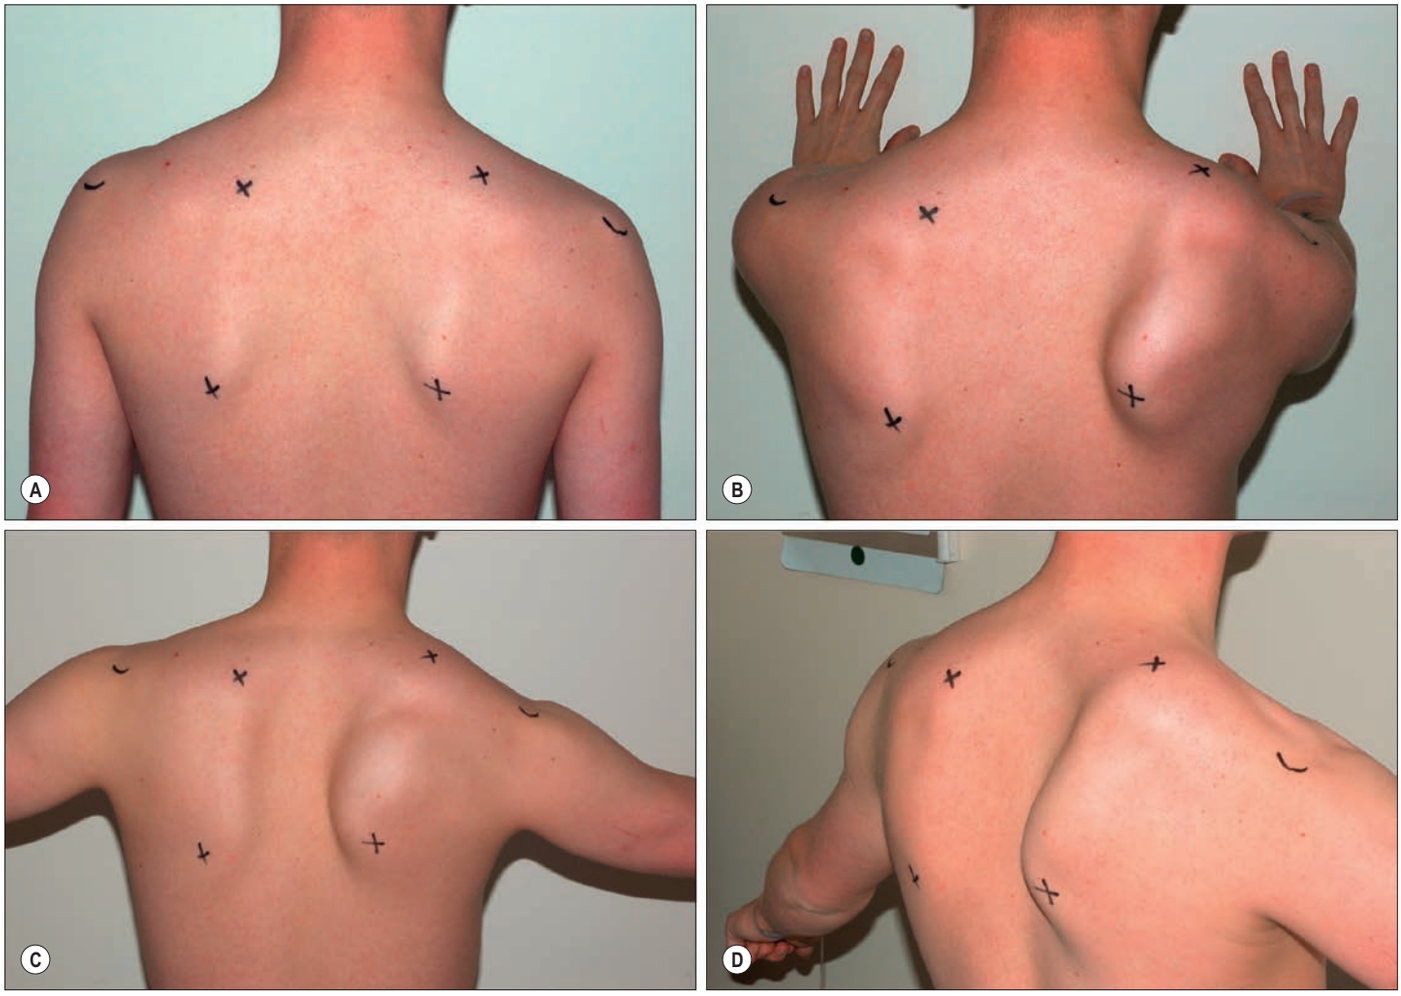

Fig. 49.39 Scapular winging in long thoracic nerve palsy. This is easily distinguishable from the winging provoked by accessory nerve palsy by the position of the scapula, which is drawn upwards and towards the spine by the unopposed action of trapezius, levator scapulae and the rhomboids. **A**, Arms at rest. **B**, Hands pressed against the wall. **C**, Attempted abduction. **D**, Oblique view. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

Fig. 49.40 Initiation of abduction, with opening of the active inferior scapulohumeral angle (ISHA), was the first sign of recovery into supraspinatus after repair of the suprascapular nerve. The lesion of the axillary nerve was irreparable. **A**, At rest. **B**, Attempted abduction. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

Fig. 49.41 Rupture of the rotator cuff, with lesions of the suprascapular and axillary nerves from fracture-dislocation of the shoulder. **A,** The range of elevation at the right shoulder in a 74-year-old man, in whom there was clear evidence of recovery for both of the nerves. **B–C**, This shipwright held on to a cable to rescue a man from the River Thames. The weight of the man and the force of the current were such that he felt the muscles tearing in his right shoulder; then he felt the head of the humerus pulling out from the socket and his arm went dead. Both nerves were recovering. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

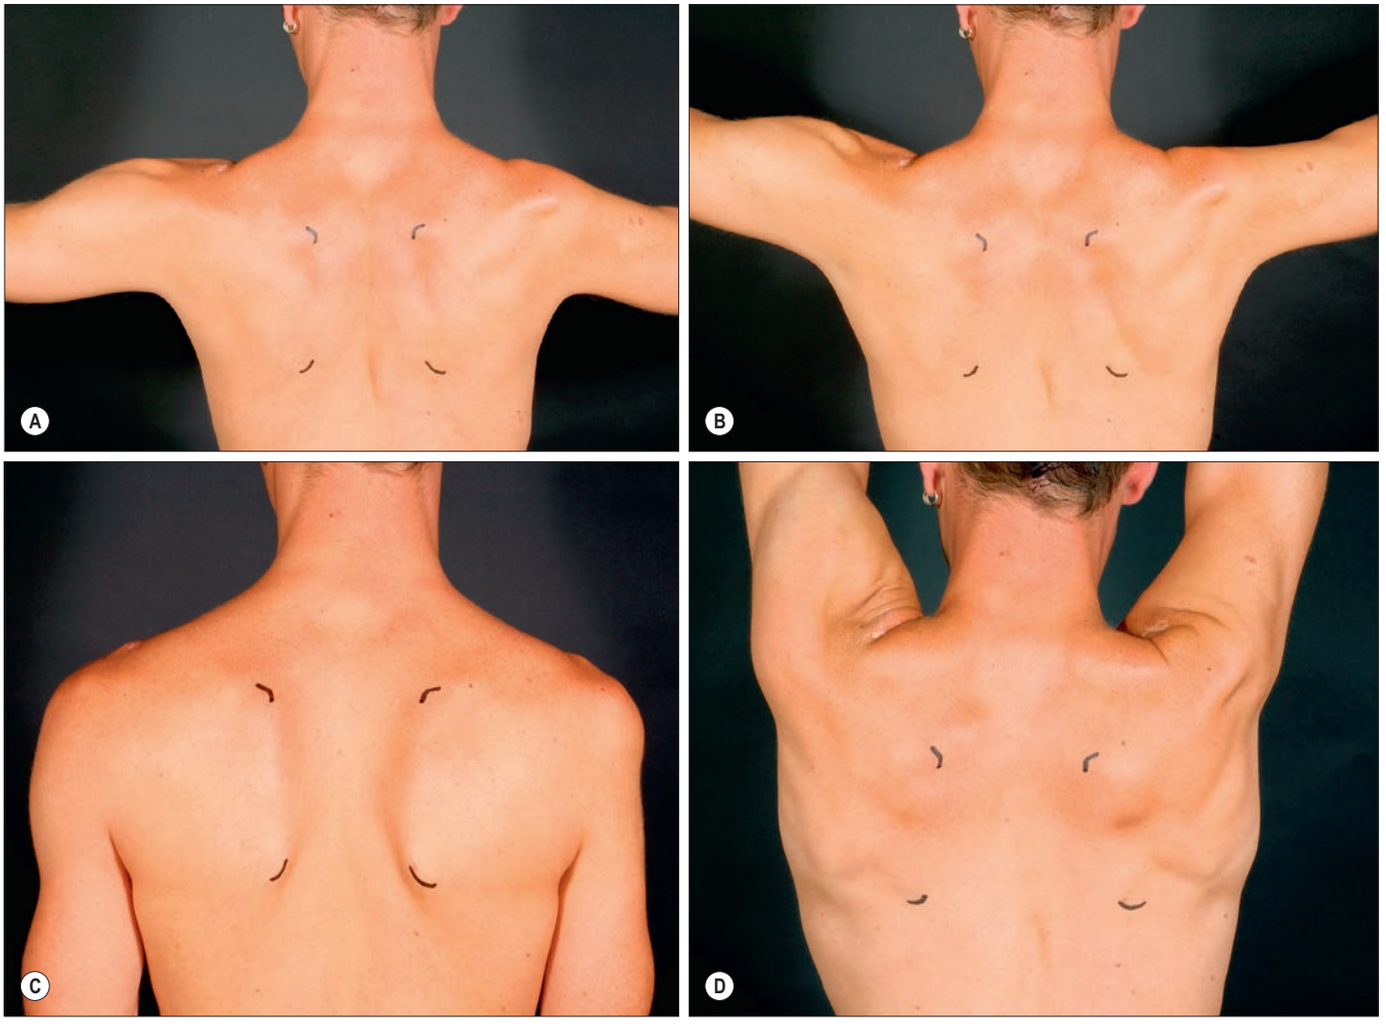

Fig. 49.42 A-D, Movement of the scapula in a case of rupture of the right axillary nerve. **D**, The active inferior scapulohumeral angle (ISHA) on the side of the injury is reduced by 20°, showing that 20° of the range of elevation is provided by extra movement at the thoracoscapular joint. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

Note the activity in the clavicular head of pectoralis major in **C**. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed, 2011. Springer-Verlag, London.)

Ulnar nerve

The ulnar nerve arises from the medial cord (eighth cervical and first thoracic ventral rami) but often receives fibres from the seventh cervical ventral ramus. It usually has no branches in the arm, but occasionally may give a branch to the medial head of triceps (see Figs 49.29, 49.35, 49.44, 48.12). The nerve runs distally through the axilla, medial to the axillary artery and between it and the vein, and continues distally medial to the brachial artery as far as the mid-arm. Here, it pierces the medial intermuscular septum, inclining medially as it descends anterior to the medial head of triceps to the interval between the medial epicondyle and the olecranon. The further course of the ulnar nerve is described in Chapter 50 and Chapter 81.

Radial nerve

The radial nerve is the largest branch of the brachial plexus. It arises from the posterior cord (fifth, sixth, seventh and eighth cervical ventral rami, and occasionally the first thoracic ventral ramus) (see Figs 49.33, 49.35, 49.45, 48.9) and descends behind the third part of the axillary artery and the upper part of the brachial artery, anterior to subscapularis above and the tendons of latissimus dorsi and teres major below, giving branches to the medial head of triceps at this level. With the profunda brachii artery, it inclines dorsally, passing through the lower triangular space below the lower border of teres major, between the long head of triceps and the humerus. Here, it supplies the long head of triceps and gives rise to the posterior cutaneous nerve of the arm, which supplies the skin along the posterior surface of the upper arm. It then spirals obliquely across the back of the humerus, lying posterior to the uppermost fibres of the medial head of triceps, which separate the nerve from the bone in the first part of the spiral groove. It gives off a muscular branch to the lateral head of triceps and a branch that passes through the medial head of triceps to innervate anconeus. On reaching the lateral side of the humerus, the radial nerve pierces the lateral intermuscular septum to enter the anterior compartment of the arm. The further course of the radial nerve is described in Chapter 50 and Chapter 81.

The branches of the radial nerve in the upper arm are: muscular, cutaneous, articular, superficial terminal and posterior interosseous.

Muscular branches

Muscular branches supply triceps, anconeus, brachioradialis, extensor carpi radialis longus and brachialis in medial, posterior and lateral groups. Medial muscular branches arise from the radial nerve on the medial side of the arm and supply the medial and long heads of triceps. The branch to the medial head is a long, slender filament that lies close to the ulnar nerve as far as the distal third of the arm, and is often termed the ulnar collateral nerve. A large posterior muscular branch arises from the nerve as it lies in the humeral groove and divides to supply the medial and lateral heads of triceps and anconeus. The branch to anconeus is a long nerve that descends in the medial head of triceps and partially supplies it; the nerve is accompanied by the middle collateral branch of the profunda brachii artery and passes behind the elbow joint to end in anconeus. Lateral muscular branches arise anterior to the lateral intermuscular septum and supply the lateral part of brachialis, brachioradialis and extensor carpi radialis longus.

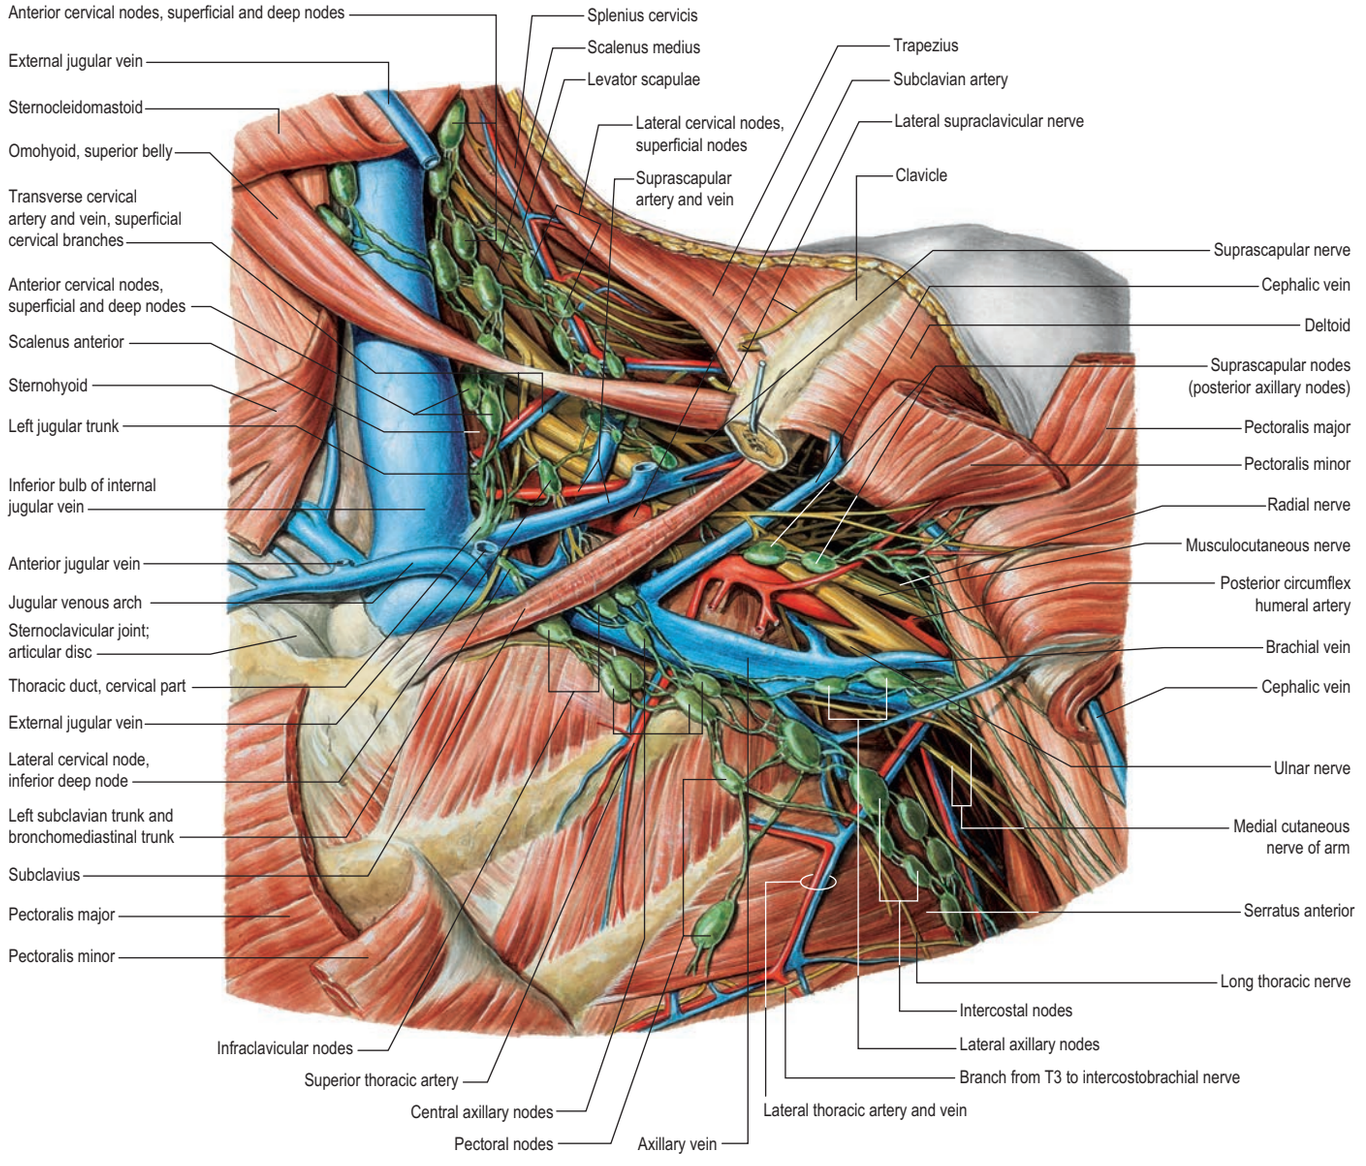

Fig. 49.45 The left axillary fossa and the deep aspect of the thoracic inlet, anterior aspect. The clavicle has been partially removed and the pectoral muscles have been reflected. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

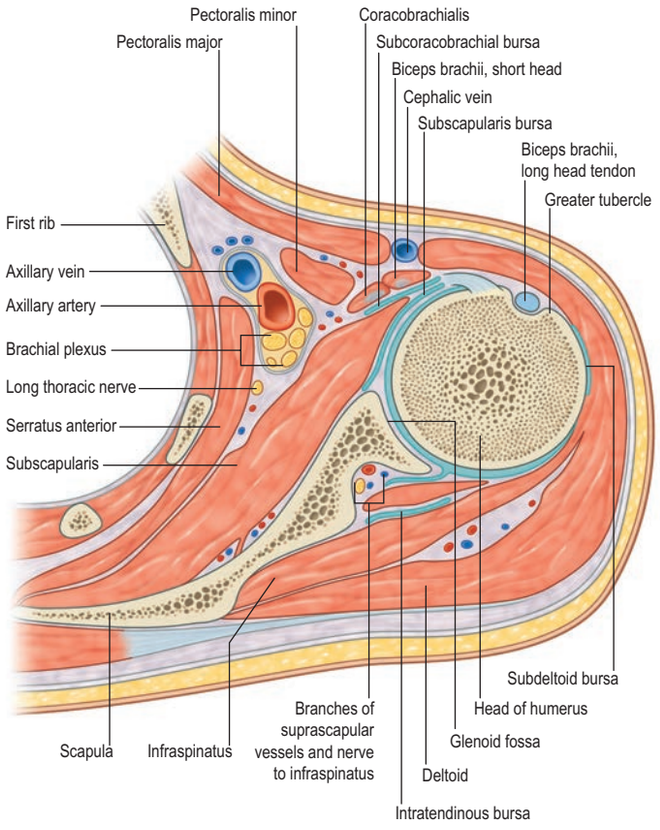

Fig. 49.46 A transverse section through the left shoulder joint and axilla, viewed from below.

Cutaneous branches

Cutaneous branches are the posterior and lower lateral cutaneous nerves of the arm and the posterior cutaneous nerve of the forearm.

Posterior cutaneous nerve of the arm. The small posterior cutaneous nerve of the arm arises in the axilla and passes medially to supply the skin on the dorsal surface of the arm nearly as far as the olecranon. It crosses posterior to, and communicates with, the intercostobrachial nerve.

Lower lateral cutaneous nerve of the arm. The lower lateral cutaneous nerve of the arm perforates the lateral head of triceps distal to the deltoid tuberosity, passes to the front of the elbow close to the cephalic vein, and supplies the skin of the lateral part of the lower half of the arm.

Posterior cutaneous nerve of the forearm. The posterior cutaneous nerve of the forearm arises with the lower lateral cutaneous nerve of the arm. Perforating the lateral head of triceps, it descends first lateral in the arm, then along the dorsum of the forearm to the wrist, supplying the skin in its course. Near its termination it joins dorsal branches of the lateral cutaneous nerve of the forearm.

AXILLA

Boundaries

The axilla is a pyramidal region between the upper thoracic wall and the arm (Figs 49.45–49.46; see Fig. 49.35). Its blunt apex continues into the root of the neck (cervico-axillary canal) between the external border of the first rib, superior border of the scapula, posterior surface of the clavicle, and the medial aspect of the coracoid process. Its triangular base, which is virtual, can be imagined as facing downwards; it is broad at the chest and narrow at the arm, and corresponds to the skin and a thick layer of axillary fascia between the inferior borders of pectoralis

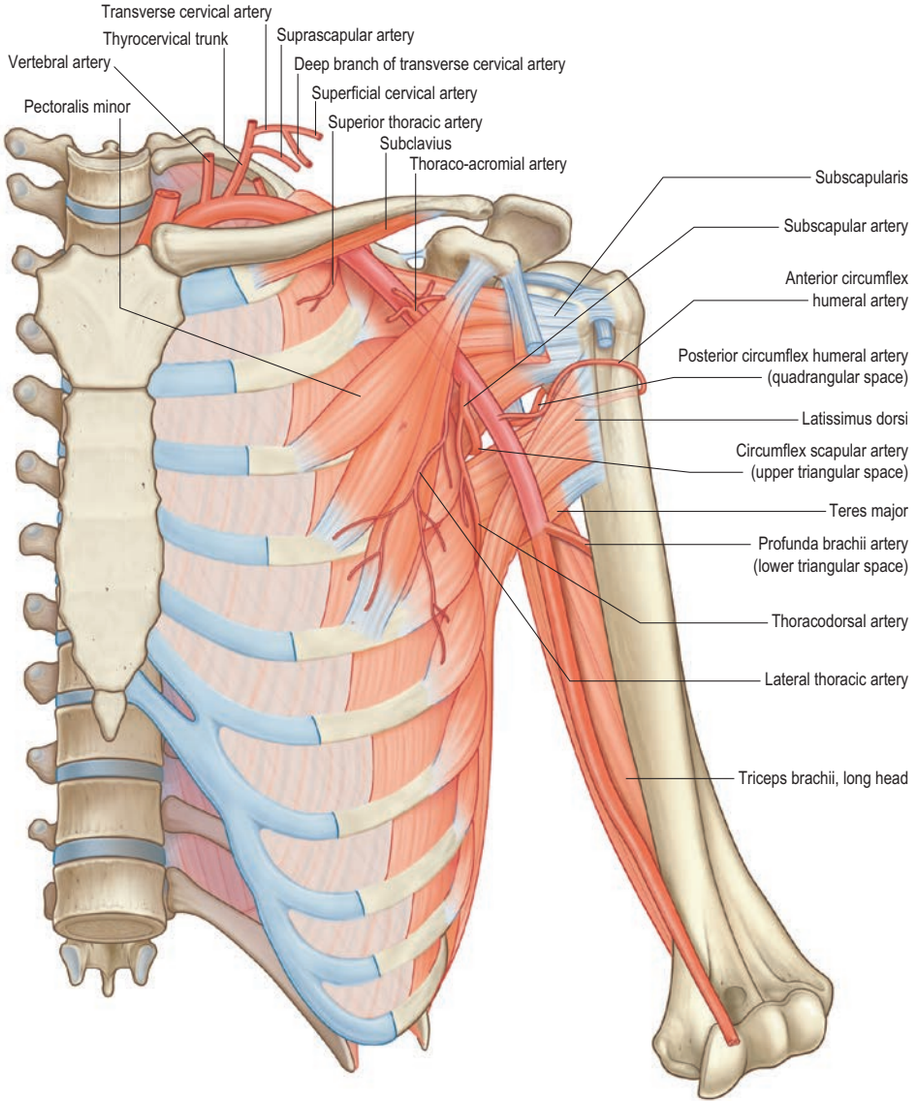

Fig. 49.47 The left axillary artery and its branches. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

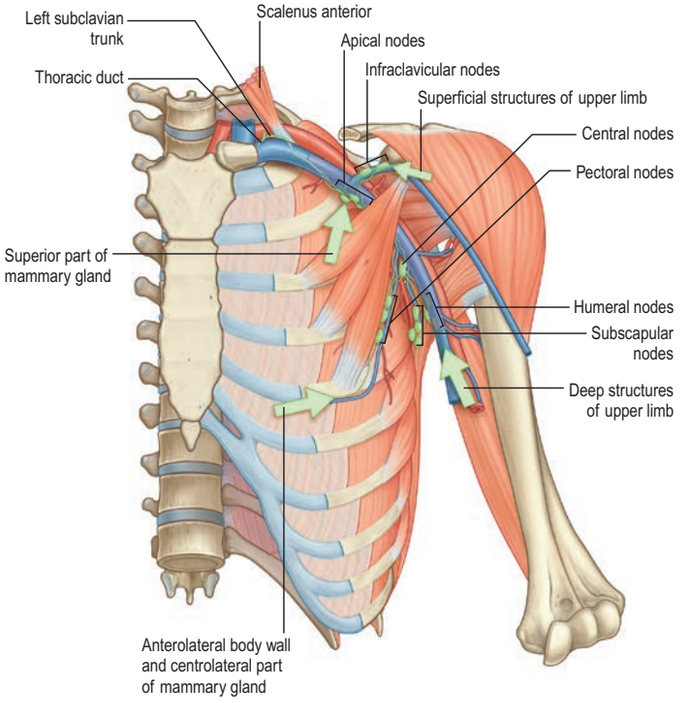

Fig. 49.48 Lymph nodes and vessels associated with the left axilla. Arrows indicate the direction of flow. (With permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

major anteriorly and latissimus dorsi posteriorly. It is convex upwards, conforming to the concavity of the armpit.

The anterior wall is formed by pectorales major and minor, the former covering the whole wall, and the latter its intermediate cranial part, with a clear fascial plane between the two muscles. The interval between the upper border of pectoralis minor and the clavicle is occupied by the clavipectoral fascia (see Fig. 49.27). The posterior wall is formed by subscapularis superiorly and teres major and latissimus dorsi inferiorly. The medial 'wall' is convex laterally and is composed of the first four ribs and their associated intercostal muscles, together with the upper part of serratus anterior. The anterior and posterior walls converge laterally; the 'wall' is narrow and consists of the humeral intertubercular sulcus. The lateral angle lodges coracobrachialis and biceps.

Contents

The axilla contains the axillary vessels, the infraclavicular part of the brachial plexus and its branches, lateral branches of some intercostal nerves, many lymph nodes and vessels, loose adipose areolar tissue and, in many instances, the 'axillary tail' of the breast. The axillary vessels and brachial plexus run from the apex to the base along the lateral wall, nearer to the anterior wall; the axillary vein is anteromedial to the artery. The obliquity of the upper ribs means that the neurovascular bundle, after it emerges from behind the clavicle, crosses the first intercostal space, and so its relations are different at upper and lower levels. Thoracic branches of the axillary artery are in contact with the pectoral muscles. The lateral thoracic artery reaches the thoracic wall along the lateral margin of pectoralis minor. Subscapular vessels descend on the posterior wall at the lower margin of subscapularis. The subscapular and thoracodorsal nerves cross the anterior surface of latissimus dorsi at different inclinations. Circumflex scapular vessels wind round the lateral border of the scapula; posterior circumflex humeral vessels and the axillary nerve curve back and laterally around the surgical neck of the humerus (Fig. 49.47; see Fig. 49.31).

No large vessel lies on the medial 'wall', which is crossed proximally only by small branches of the superior thoracic artery. The long thoracic nerve descends on serratus anterior and the intercostobrachial nerve perforates the upper anterior part of this wall, crossing the axilla to its lateral 'wall'.

Axillary lymph nodes

There are between 20 and 30 axillary nodes, divided into five not wholly distinct groups, namely, lateral, anterior (pectoral), posterior (subscapular), central and apical (see Fig. 53.24). Four of the groups are intermediary and only the apical group is terminal. Collectively, they drain the entire upper limb, breast and trunk above the umbilicus.

The lateral group of four to six nodes is posteromedial to the axillary vein; its afferents drain the whole limb, except the vessels that accompany the cephalic vein (**Fig. 49.48**; see Figs 49.45, 53.24). Efferent vessels pass partly to the central and apical axillary groups, and partly to the inferior deep cervical nodes. The anterior group of four or five nodes spreads along the inferior border of pectoralis minor near the lateral thoracic vessels. Their afferents drain the skin and muscles of the supraumbilical anterolateral body wall and breast, and their efferents pass partly to the central and partly to the apical axillary nodes. The posterior group of six or seven nodes lie on the inferior margin of the posterior axillary wall, along the subscapular vessels. Their afferents drain the skin and superficial muscles of the inferior posterior region of the neck and the dorsal aspect of the trunk down to the iliac crest, and their efferents pass to the apical and central axillary nodes. A central group of three or four large nodes embedded in axillary fat receives afferents from all preceding groups, and their efferents drain to the apical nodes. An apical group of six to twelve nodes is partly posterior to the superior part of pectoralis minor and partly above its superior border, extending to the apex of the axilla medial to the axillary vein. The only direct territorial afferents are those that accompany the cephalic vein and/or some that drain the upper peripheral region of the breast; the group drains all the other axillary nodes. Their efferents unite as the subclavian trunk and drain directly to either the jugulosubclavian venous junction, the subclavian vein, the jugular lymphatic trunk or (occasionally) to a right lymphatic duct; the left trunk usually ends in the thoracic duct (see Fig. 35.16). A few efferents from apical nodes usually reach the inferior deep cervical nodes. One or two infraclavicular nodes appear beside the cephalic vein in the groove between pectoralis major and deltoid, just inferior to the clavicle. Their efferents pass through the clavipectoral fascia to the apical axillary nodes. Occasionally, some pass anterior to the clavicle to the inferior deep cervical (supraclavicular) nodes.

CHAPTER
50

Elbow and forearm

SKIN AND SOFT TISSUES

Skin

Cutaneous vascular supply

The skin of the elbow and forearm receives its blood supply from muscle perforators, fasciocutaneous networks and direct cutaneous vessels. The skin of the anterolateral cubital fossa is supplied by muscle perforators arising from the radial collateral and radial recurrent arteries. The skin of the medial cubital fossa receives branches from an anastomosis between the inferior ulnar collateral and the ulnar recurrent arteries. Small direct cutaneous vessels spring from the brachial artery. The skin of the posterolateral aspect of the elbow is supplied by branches of the posterior interosseous recurrent artery and a rich plexus of collateral and anastomosing arteries. The skin of the posteromedial aspect is supplied by branches of the superior and inferior ulnar collateral arteries and the posterior ulnar recurrent artery feeding into the plexus.

The skin of the anterior forearm is supplied by fasciocutaneous perforators; the largest is the inferior cubital artery, which arises from the radial artery at the distal apex of the cubital fossa and extends to midway down the forearm. Fasciocutaneous perforators from the radial artery supply the lateral two-thirds of the anterior surface of the forearm (see Fig. 48.5). The vessels pass in the intermuscular septa between brachioradialis and flexor carpi radialis, and between flexor carpi radialis and flexor digitorum superficialis. Fasciocutaneous perforators from the ulnar artery supply skin over the ulnar side of the anterior forearm and the medial quarter of the posterior forearm from the cubital fossa to the wrist. A small contribution comes from musculocutaneous perforators that pass through brachioradialis and flexor carpi ulnaris.

The skin of the distal third of the lateral forearm is supplied by the terminal perforating branches of the anterior interosseous artery. The central half of the posterior surface of the forearm, from the lateral edge of extensor digitorum, just below the lateral epicondyle of the humerus, to the wrist, is supplied by fasciocutaneous perforators from the posterior interosseous artery that pass along the intermuscular fascia between extensor carpi ulnaris and extensor digiti minimi.

Cutaneous innervation

A small area of skin anterolateral to the elbow is supplied by the lateral cutaneous nerve of the arm. The skin overlying the posterior aspect of the elbow is innervated by the posterior cutaneous nerve of the arm and proximal branches of the posterior cutaneous nerve of the forearm. The lateral cutaneous nerve of the forearm innervates the skin of the anterior half and radial posterior quarter of the forearm. The medial cutaneous nerve of the forearm supplies the skin overlying most of the elbow, the ulnar half of the anterior forearm and the ulnar quarter of the posterior forearm (**Fig. 50.1** and p. 956).

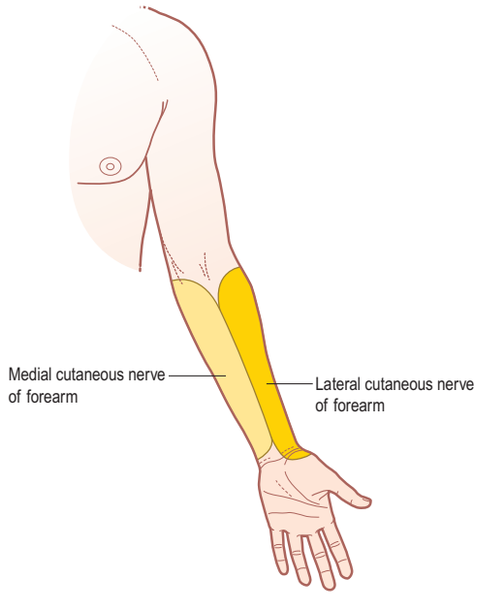

Fig. 50.1 Sensory loss or disturbance after complete section of the medial and lateral cutaneous nerves of the forearm.

Soft tissues

Cubital fossa

The cubital fossa is a triangular depression in the anterior aspect of the upper forearm (see Fig. 48.53) (Macchi et al 2014). It is bounded proximally by the epicondylar line, medially by the lateral margin of pronator teres, and laterally by the medial face of brachioradialis; it is bisected by the tendon of biceps brachii. The deep fascia of the forearm forms its roof. It is continuous with the deep fascia of the anterior arm, attached to the medial and lateral humeral epicondyles and augmented by the bicipital aponeurosis, which sweeps across the medial and inferior part of the fossa to the fascia over the superficial flexor muscles. Supinator and brachialis lie in the floor of the fossa. From medial to lateral, the basilic, median cubital and cephalic veins lie in the superficial fascia. Branches of the medial cutaneous nerve of the forearm are closely related to the basilic vein. The lateral cutaneous nerve of the forearm runs down alongside the lateral edge of the tendon of biceps brachii. Deep to the deep fascia, and from medial to lateral, are the median nerve and the brachial artery, the latter inclining from the medial side of the arm to pass down the fossa close to the midline. The radial and ulnar arteries, with their accompanying veins, originate in the lower part of the fossa. The radial nerve enters the fossa laterally in the groove between brachioradialis and brachialis, and divides into the superficial radial and posterior interosseous nerves above the humero-radial joint. The superficial radial nerve continues down the forearm under cover of brachioradialis.

Compartments of the forearm

The deep fascia, the interosseous membrane and the fibrous intermuscular septa, some of which pass between the deep fascia and bone, divide the forearm into compartments. These include the superficial and deep flexor (anterior) compartments, the extensor (posterior) compartment, and a proximolateral compartment that includes brachioradialis and extensors carpi radialis longus and brevis (the mobile wad) (**Fig. 50.2**). The dense sheath of the antebrachial fascia (the deep fascia of the forearm) is continuous above with the brachial fascia. It is attached to the olecranon, the posterior border of the ulna, and the lateral and medial epicondyles. The fascia is thicker posteriorly and in the lower forearm. It is strengthened above by tendinous fibres from biceps and triceps. Near the wrist, two localized thickenings, the flexor and extensor retinacula, retain the digital tendons in position (Ch. 51). From its deep surface, septa pass between muscles, providing areas of additional attachment. Muscles arise from its inner aspect in the upper forearm. Vessels and nerves pass through apertures in the fascia; a large aperture anterior to the elbow transmits a venous communication between superficial and deep veins.

BONES

Humerus

Distal end of humerus

The distal end of the humerus is a modified condyle; it is wider transversely and has articular and non-articular parts (Figs 50.3–50.4). The articular part is curved forwards, so that its anterior and posterior surfaces lie in front of the corresponding surfaces of the shaft. It articulates with the radius and the ulna at the elbow joint, and is divided by a faint groove into a lateral capitulum and a medial trochlea.

The capitulum is a rounded, convex projection, considerably less than half a sphere, which covers the anterior and inferior surfaces of the lateral part of the condyle of the humerus but does not extend on to its posterior surface. It articulates with the discoid head of the radius, which lies in contact with its inferior surface in full extension of the elbow but slides on to its anterior surface during flexion. The groove of the trochlea winds backwards and laterally from the anterior to the posterior surface of the bone, and is wider, deeper and more symmetrical posteriorly. Anteriorly, the medial flange of the pulley is longer than the lateral, and the surface adjoining its projecting medial margin is convex to accommodate itself to the medial part of the upper surface of the coronoid process of the ulna. These asymmetries entail varying angulation between the humeral and ulnar axes, together with some conjunct rotation. The non-articular part of the condyle includes the medial and lateral epicondyles, and the olecranon, coronoid and radial fossae.

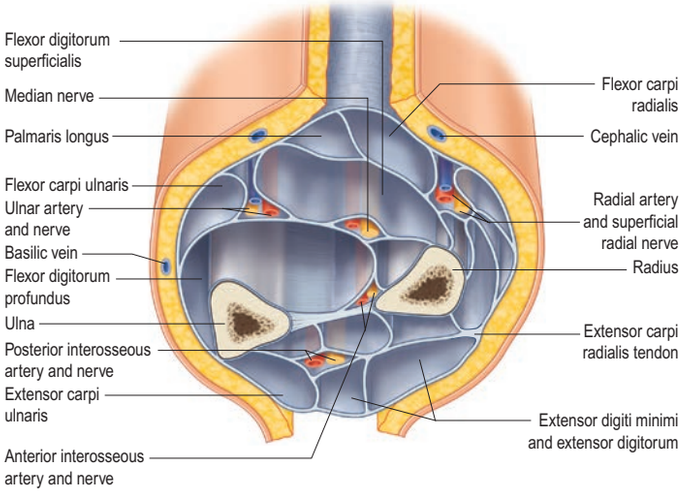

Fig. 50.2 The compartments of the forearm. A cross-section through the upper third of the left forearm.

Trochlea

The trochlea is a pulley-shaped surface that covers the anterior, inferior and posterior surfaces of the condyle of the humerus medially and articulates with the trochlear notch (greater sigmoid notch) of the ulna. On its lateral side, it is separated from the capitulum by a faint groove; its medial margin projects distally beyond the rest of the bone. When the elbow is extended, the inferior and posterior aspects of the trochlea are in contact with the ulna but, as the joint is flexed, the trochlear notch slides on to the anterior aspect so that its posterior aspect is then left uncovered (Giannicola et al 2015). The downward projection of the medial edge of the trochlea is the principal factor in determining the degree of angulation between the long axis of the humerus and the long axis of the supinated forearm when the elbow is extended.

Medial epicondyle

The medial border of the humerus ends by turning slightly backwards as the medial epicondyle, which forms a conspicuous, blunt projection on the medial side of the condyle. It is subcutaneous and usually visible, especially in passive flexion of the elbow. Its posterior surface is smooth and is crossed by the ulnar nerve, which lies in a shallow sulcus as it enters the forearm. The nerve can be felt and rolled against the bone here; if jarred against the epicondyle, a characteristic tingling sensation results. The lower part of the anterior surface of the medial epicondyle is marked by the attachment of the superficial group of forearm flexors: they arise from the epiphysis for the epicondyle but are entirely extracapsular. A capsular condensation, the ulnar collateral ligament of the elbow, is attached to the medial epicondyle medial to the attachments of these tendons.

Lateral epicondyle

The lateral border of the humerus ends at the lateral epicondyle; its lower portion constitutes the lateral supracondylar ridge. The lateral

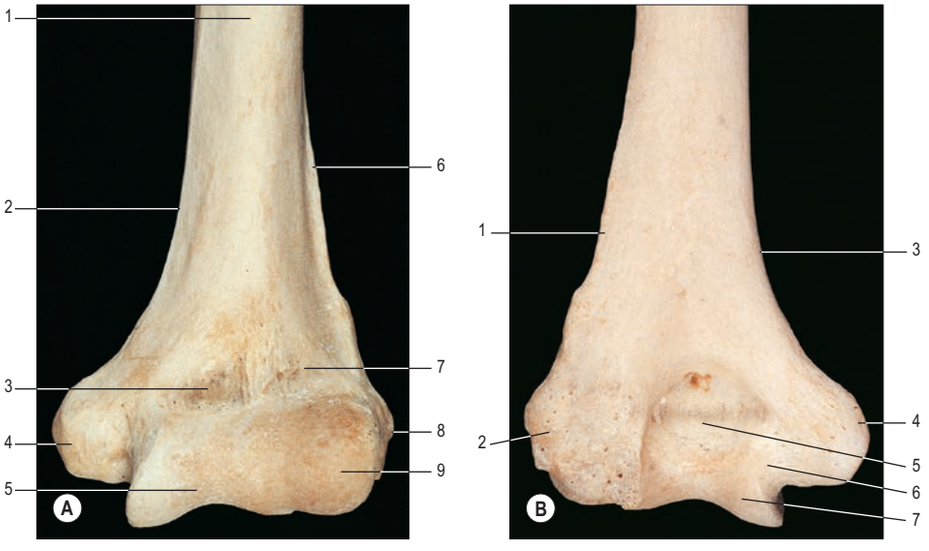

Fig. 50.3 **A**, Anterior aspect of the distal end of the left humerus. Key: 1, shaft; 2, medial supracondylar ridge; 3, coronoid fossa; 4, medial epicondyle; 5, trochlea; 6, lateral supracondylar ridge; 7, radial fossa; 8, lateral epicondyle; 9, capitulum. **B**, Posterior aspect of the distal end of the left humerus. Key: 1, lateral supracondylar ridge; 2, lateral epicondyle; 3, medial supracondylar ridge; 4, medial epicondyle; 5, olecranon fossa; 6, sulcus for ulnar nerve; 7, trochlea.

epicondyle occupies the lateral part of the non-articular portion of the condyle but does not project beyond the lateral supracondylar ridge. It turns slightly forwards, unlike the medial epicondyle, which turns slightly backwards. Its lateral and anterior surfaces show a well-marked impression for the tendons of the superficial group of the extensor muscles of the forearm (see Fig. 49.11A), which arise from the lateral side of the lower humeral epiphysis; like the flexor tendons, they are extracapsular. The posterior surface, which is very slightly convex, is easily felt in a depression visible behind the extended elbow. A small area on the posterior surface gives origin to anconeus. A small tubercle is readily palpable on the lateral epicondyle. The lateral ligamentous complex, a capsular condensation attached to the lateral epicondyle, is immediately anterior and inferior to this tubercle, deep to the origins of the common tendon (see later).

Olecranon, coronoid and radial fossae

The olecranon fossa is a deep hollow on the posterior surface of the condyle, immediately above the trochlea, that lodges the tip of the olecranon of the ulna when the elbow is extended. The floor of the fossa is always thin and may be partially deficient. A similar but smaller hollow, the coronoid fossa, lies immediately above the trochlea on the anterior surface of the condyle and accommodates the anterior margin of the coronoid process of the ulna during flexion of the elbow. A very slight depression, the radial fossa, lies above the capitulum on the lateral side of the coronoid fossa and is related to the margin of the head of the radius in full flexion of the elbow.

Ossification

The distal humerus ossifies as follows. During the first year, ossification begins in the capitulum and extends medially to form the main part of the articular surface. The centre for the medial part of the trochlea appears in the ninth year in females and tenth year in males. Ossification begins in the medial epicondyle in the fourth year in females and the sixth in males, and in the lateral epicondyle in about the twelfth year. The centre for the medial epicondyle forms a separate epiphysis, which is entirely extracapsular, on the posteromedial aspect of the epicondyle. It is separated from the rest of the lower epiphysis by a downgrowth from the shaft, with which it becomes continuous at about the twentieth year. The centres for the lateral epicondyle, capitulum and trochlea coalesce around puberty, and the composite epiphysis consolidates with the shaft in the fourteenth year in females and sixteenth in males.

Radius

The radius is the lateral bone of the forearm (Figs 50.5–50.7). It has expanded proximal and distal ends, the distal being much the broader. The shaft widens rapidly towards its distal end, and is convex laterally and concave anteriorly in its distal part. The radius articulates with the humeral capitulum, the lateral surface of the lateral ridge of the trochlea, the ulna and the carpus.

Proximal radius

The proximal radius includes a head, neck and tuberosity. The head is discoid, its proximal surface a shallow cup for articulation with the humeral capitulum. Its smooth articular periphery is vertically deepest medially, where it contacts the ulnar radial notch. The posterior surface of the radial head is palpable on the posterolateral aspect of the extended elbow. The head overhangs the neck, which is the circumferential constriction immediately below it, particularly laterally. The tuberosity is distal to the medial part of the neck; posteriorly, it is rough, whereas anteriorly, it is usually smooth.

Radial shaft

The radial shaft has a lateral convexity and is triangular in cross-section. The interosseous border is sharp, except proximally, near the tuberosity, and distally, where the interosseous border is the posterior margin of a small, elongated, triangular area, proximal to the ulnar notch. These two areas form the medial surface of the radial shaft. The interosseous membrane is attached to the distal three-quarters of the radial shaft, and connects the radius to the ulna. The anterior surface, between anterior and interosseous borders, is concave transversely and shows a distal anterior curvature. There is a proximally directed nutrient foramen and canal near the midpoint of the shaft. The posterior surface of the shaft, between the interosseous and posterior borders, is largely flat but may be slightly hollow proximally. The lateral surface is gently convex. A finely irregular oval area occurs near the midshaft; further distally, the surface is smooth.

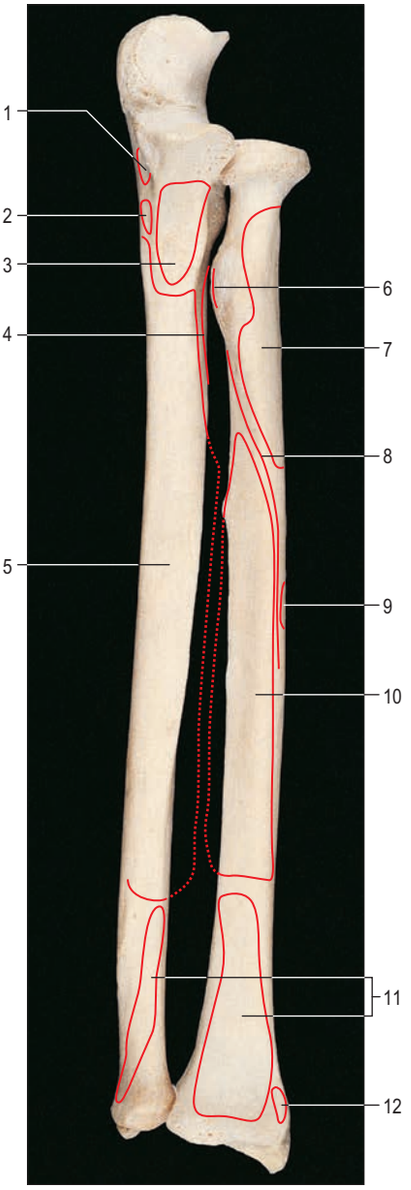

Fig. 50.5 Articulated radius and ulna: anterior view, showing muscle attachments. Note that the hatched lines denote extension of muscular attachments on to the interosseous membrane. Key: 1, flexor digitorum superficialis; 2, pronator teres (ulnar head); 3, brachialis; 4, supinator; 5, flexor digitorum profundus; 6, biceps; 7, supinator; 8, flexor digitorum superficialis (oblique line); 9, pronator teres; 10, flexor pollicis longus; 11, pronator quadratus; 12, brachioradialis.

Distal radius

The distal end of the radius (Fig. 50.8) is the widest part and is four-sided in section. The lateral surface is slightly rough, projecting distally as the radial styloid process. The smooth carpal articular surface is divided by a ridge into medial and lateral areas. The medial distal radial articular surface (lunate fossa) is quadrangular, whereas the lateral part of the articular surface (scaphoid fossa) is triangular and curves on to the styloid process. The anterior surface of the distal radius is a thick, palpable, prominent ridge 2 cm proximal to the thenar eminence. The medial surface is the ulnar notch, which is smooth and anteroposteriorly concave for articulation with the head of the ulna. The posterior surface has a palpable dorsal tubercle (Lister's tubercle), limited medially by an oblique groove and in line with the cleft between the index and middle fingers. Lateral to the tubercle is a wide, shallow groove, divided by a vertical ridge.

Muscular, ligamentous and articular attachments

The proximal articular surface of the radial head and its circumference are covered by hyaline cartilage. The upper rim fits the groove between the capitulum and trochlea and enters the radial fossa in flexion. The articular circumference articulates with the ulnar radial notch and anular ligament, within which it rotates in pronation and supination. The radial

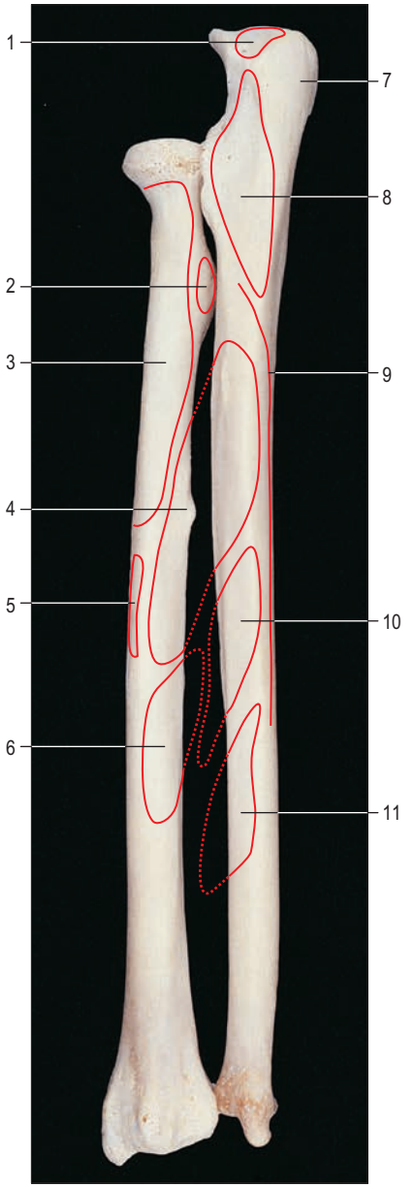

Fig. 50.6 Articulated radius and ulna: posterior view, showing muscle attachments. Compare with Fig 51.20A.

neck is enclosed by the narrower distal part of the ligament, from which it is separated by a synovial protrusion from the superior radio-ulnar joint. The posterior area of the tuberosity is marked by the tendon of biceps brachii, which is separated from a smooth anterior area by a bursa. The oblique cord of the interosseous membrane is attached just distal to the bursa.

Flexor digitorum superficialis is attached to the proximal anterior surface of the radius by a thin, wide head. Flexor pollicis longus has an extensive attachment to the proximal two-thirds of the anterior surface of the radial shaft, overlying the nutrient foramen. Pronator quadratus is attached to the distal quarter of the anterior radial shaft; a small, triangular area proximal to the ulnar notch gives attachment to the deepest part of the muscle. Pronator teres is attached to a rough area near the midpoint of the lateral surface of the radial shaft, at its maximal curvature. Proximally, supinator is attached to a long, V-shaped area on the lateral surface of the shaft. Distal to pronator teres, the lateral surface is covered by tendons of brachioradialis, extensor carpi radialis longus and brevis. On the posterior surface, abductor pollicis longus is attached proximally, and extensor pollicis brevis more distally. The remaining surface is devoid of attachments and covered by the long and short extensors of the thumb. The lateral surface, proximal to the styloid process, receives the attachment of brachioradialis and is crossed obliquely, downwards and forwards, by the tendons of abductor pollicis longus and extensor pollicis brevis. The radial styloid process projects beyond that of the ulna, its apex covered by the tendons of abductor pollicis longus and extensor pollicis brevis. The lateral radiocarpal ligament is attached to its tip, and the palmar radiocarpal ligament is attached to the terminal ridge on the anterior surface of the lower end. The base of the triangular articular disc of the inferior radio-ulnar joint is attached to a smooth ridge distal to the ulnar notch. A narrow protrusion of synovial membrane extends proximally from the ulnar notch, anterior to the lower end of the interosseous membrane. The lateral part of the carpal articular surface articulates with the scaphoid, and the medial part with the lateral part of the lunate. In full adduction, the proximal surface of the lunate is wholly in contact with the radius.

The radial dorsal tubercle receives a slip from the extensor retinaculum and is grooved medially by the tendon of extensor pollicis longus. The wide groove lateral to the tubercle contains the tendons of extensor carpi radialis longus laterally and extensor carpi radialis brevis medially, together with their synovial sheaths. Medially, the dorsal surface is grooved by the tendons of extensor digitorum, separated from the bone by the tendons of extensor indicis and the posterior interosseous nerve. The dorsal radiocarpal ligament is attached to the distal margin of this surface.

Vascular supply

The radius is supplied by branches of the radial, ulnar and anterior and posterior interosseous arteries through multiple metaphysial nutrient foramina. Usually, there is one nutrient diaphysial foramen located on the anterior surface of the bone, which is directed proximally towards the elbow. A network of small fascioperiosteal and musculoperiosteal vessels arise from the compartmental vessels and reach the bone via its septal and muscular attachments.

The dorsal metaphysis of the distal radius is richly supplied (Fig. 50.9A). Branches connect the anterior interosseous artery proximally to the dorsal carpal arch distally. These pass through the fourth and fifth extensor compartments of the wrist and provide metaphysial nutrient arteries. Intercompartmental vessels send nutrient arteries to the radius through the retinaculum between the first and second dorsal compartments, and the second and third dorsal compartments. These vessels originate from the radial artery and anterior interosseous arteries, respectively, and anastomose with the dorsal carpal arch.

Ossification

The radius ossifies from three centres. One appears centrally in the shaft in embryonic stage 23, and the others appear in each end (see Figs 49.13, 50.12). Ossification begins in the distal epiphysis towards the end of the first postnatal year and in the proximal epiphysis during the fourth year in females and the fifth year in males. The proximal epiphysis unites with the shaft in the fourteenth year in females and seventeenth year in males, and the distal epiphysis unites with the shaft in the seventeenth and nineteenth years, respectively. A fourth centre sometimes appears in the tuberosity at about the fourteenth or fifteenth year.

Ulna

The ulna is medial to the radius in the supinated forearm. Its proximal end is a massive hook, concave forwards, that articulates with the distal humerus (Figs 50.10–50.11). The lateral border of the shaft is a sharp interosseous crest to which the interosseous membrane is attached. The bone diminishes progressively from its proximal mass throughout almost its whole length, but, at its distal end, expands into a small, rounded head and styloid process. The shaft is triangular in cross-section proximally, and almost cylindrical distally. Along its whole length, the ulna is slightly convex posteriorly. Mediolaterally, its profile is sinuous; the proximal half has a slight curvature that is concave laterally and the distal half a curvature that is concave medially.

Proximal ulna

The proximal end of the ulna has large olecranon and coronoid processes, and trochlear and radial notches that articulate with the humerus and radius, respectively. The olecranon process is more proximal and is bent forwards at its summit like a beak that enters the olecranon fossa of the humerus in extension. Its posterior surface is smooth, triangular and subcutaneous, and its proximal border underlies the 'point' of the elbow. In extension, it can be felt near a line joining the humeral epicondyles, but in flexion, it descends, so that the three osseous points form an isosceles triangle. The relationship between the plane of the dorsal surface of the olecranon and the ulnar shaft, known as the proximal ulna dorsal angulation (PUDA, average 5.7º) is variable. In some individuals, the olecranon plane is flexed, in some it is extended and in some the dorsal surface of the olecranon and the shaft of the ulna are in the same plane:

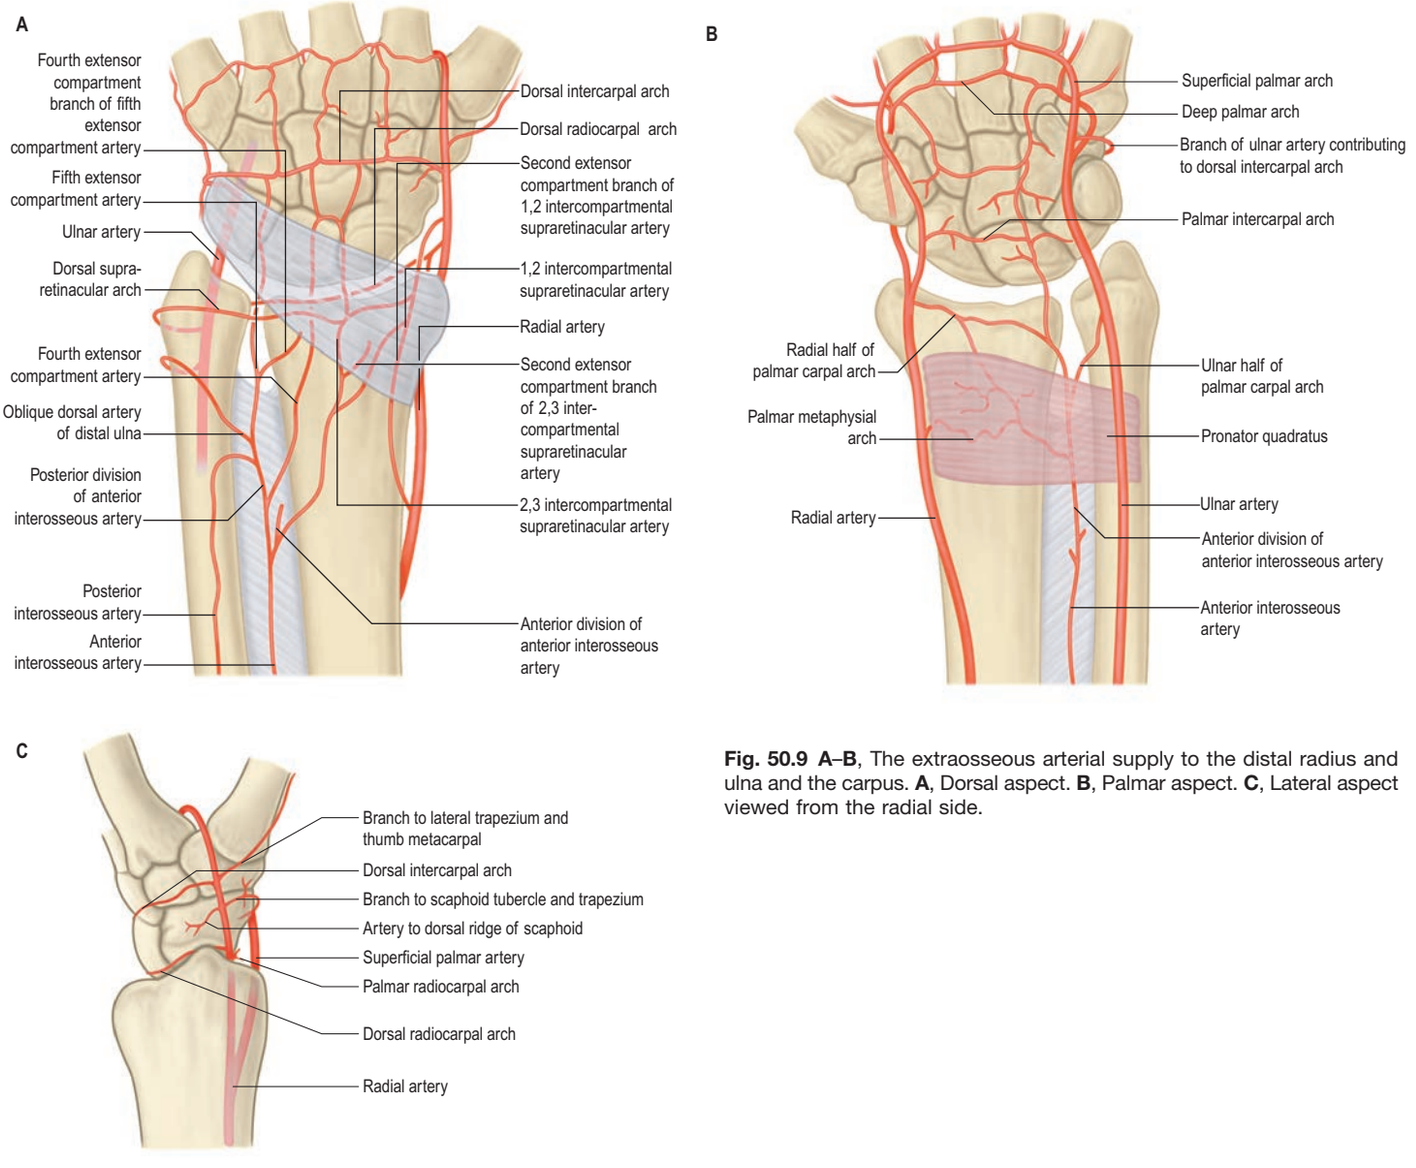

Fig. 50.9 A–B, The extraosseous arterial supply to the distal radius and ulna and the carpus. **A**, Dorsal aspect. **B**, Palmar aspect. **C**, Lateral aspect viewed from the radial side.

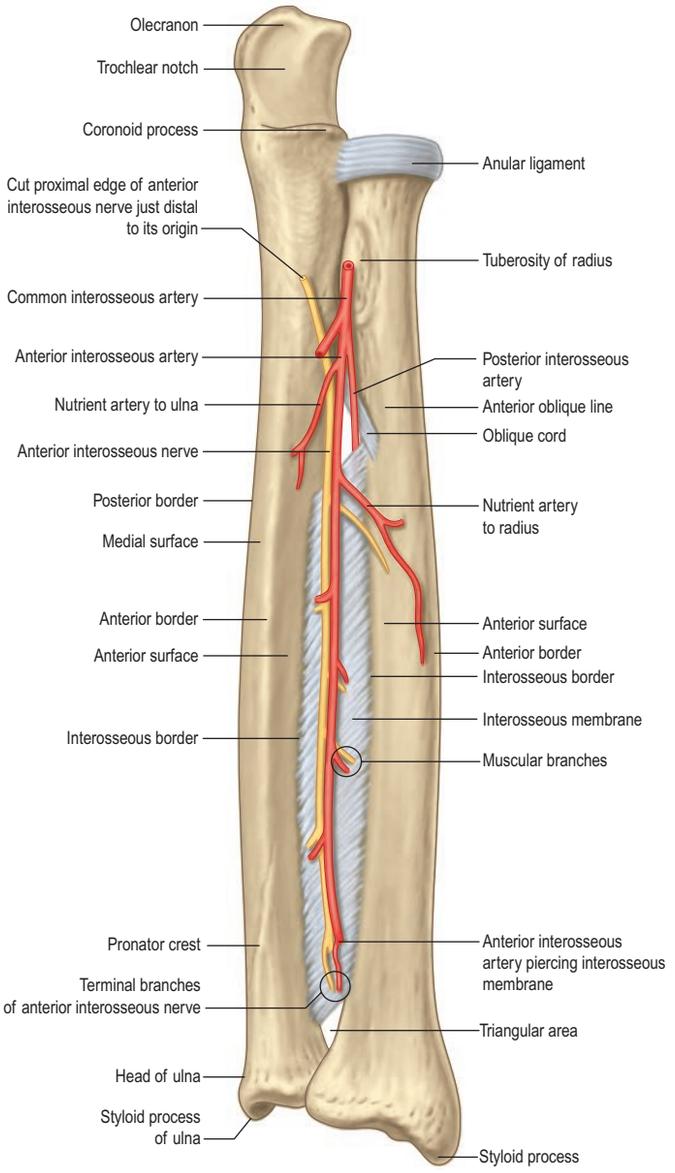

Fig. 50.10 Anterior aspect of the interosseous membrane and oblique cord of the forearm: the membrane and cord are syndesmoses.

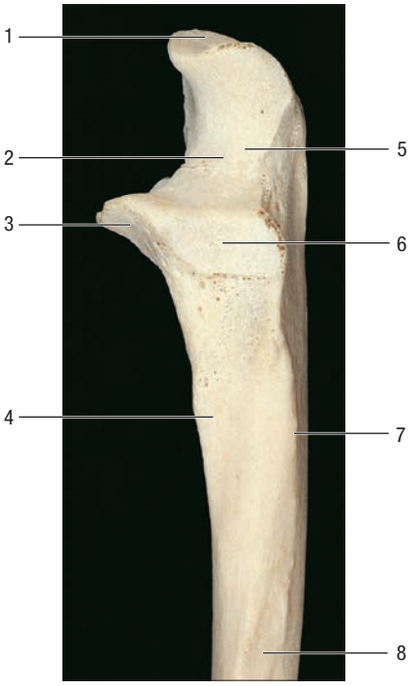

Fig. 50.11 The proximal end of the left ulna: lateral view. Key: 1, olecranon; 2, non-articular strip in trochlear notch; 3, coronoid process; 4, tuberosity; 5, trochlear notch; 6, radial notch; 7, supinator crest; 8, shaft.

these differences may explain some of the variability in the range of extension of the normal elbow (Rouleau et al 2010).

The anterior, articular surface of the olecranon forms the proximal area of the trochlear notch. Its base is slightly constricted where it joins the shaft and is the narrowest part of the proximal ulna. The coronoid process projects anteriorly distal to the olecranon. Its proximal aspect forms the distal wall of the trochlear notch and possesses two facets, the anterolateral facet which articulates with the lateral ridge of the trochlea and the anteromedial facet which articulates with the medial ridge. On the lateral surface, distal to the trochlear notch, a shallow, smooth, oval radial notch articulates with the radial head. Distal to the radial notch, the surface is hollow to accommodate the radial tuberosity during pronation and supination. The anterior surface of the coronoid is triangular. Its distal part is the tuberosity of the ulna and its medial border is sharp and bears the small sublime tubercle proximally for insertion of the anterior band of the medial ligament.

The trochlear notch articulates with the trochlea of the humerus. It is constricted at the junction of the olecranon and coronoid processes, where their articular surfaces may be separated by a narrow, rough, non-articular strip. A smooth ridge, adapted to the groove on the humeral trochlea, divides the notch into medial and lateral parts. The medial fits into the trochlear flange. The radial notch, an oval or oblong proximal depression on the lateral aspect of the coronoid process, articulates with the periphery of the radial head and is separated from the trochlear notch by a smooth ridge.

Ulnar shaft

The ulnar shaft is triangular in cross-section in its proximal three-quarters, but distally is almost cylindrical (see Figs 50.31–50.32). It has anterior, posterior and medial surfaces and interosseous, posterior and anterior borders. The interosseous border is a conspicuous lateral crest in its middle half. Proximally, it becomes the supinator crest, which is continuous with the posterior border of a depression distal to the radial notch. Distally, it disappears. The rounded anterior border starts medial to the ulnar tuberosity, descends backwards, and is usually traceable to the base of the styloid process. The posterior border, also rounded, descends from the apex of the posterior aspect of the olecranon, and curves laterally to reach the styloid process. It is palpable throughout its length in a longitudinal furrow, most obvious when the elbow is fully flexed.

The anterior surface, between the interosseous and anterior borders, is longitudinally grooved, sometimes deeply (see Fig. 50.10). Proximal to its midpoint, a proximally directed nutrient foramen admits a branch of the anterior interosseous artery. Distally, it is crossed obliquely by a rough, variable prominence, descending from the interosseous to the anterior border. The medial surface, between the anterior and posterior borders, is transversely convex and smooth. The posterior surface, between the posterior and interosseous borders, is divided into three areas. The most proximal is limited by a sometimes faint, oblique line that ascends laterally from the junction of the middle and upper thirds of the posterior border to the posterior end of the radial notch. The region distal to this line is divided into a larger medial and narrower lateral strip by a vertical ridge, which is usually distinct only in its proximal three-quarters.

Distal ulna

The distal end of the ulna is slightly expanded and has a head and styloid process. The head is palpable and visible in pronation on the posteromedial aspect of the wrist. Its lateral convex articular surface fits the radial ulnar notch. Its smooth distal surface is separated from the carpus by an articular disc, the apex of which is attached to a rough area between the articular surface and styloid process. The ulnar styloid process is a short, round, posterolateral projection of the distal end of the ulna, palpable in supination about 1 cm proximal to the plane of the radial styloid. A posterior vertical groove is present between the head and styloid process.

Muscular, ligamentous and articular attachments

The capsule of the elbow joint is attached to the proximal, anterior surface of the olecranon, and the tendon of triceps is attached to its rough posterior two-thirds; the capsule and tendon may be separated by a bursa. The medial surface of the olecranon is marked proximally

by the attachment of the posterior and oblique bands of the ulnar collateral ligament and by the ulnar part of flexor carpi ulnaris. The smooth area distal to this is the most proximal attachment of flexor digitorum profundus. Anconeus is attached to the lateral surface of the olecranon and the adjoining posterior surface of the ulnar shaft as far as its oblique line. The posterior surface of the ulna is separated from the skin by a subcutaneous bursa.

Brachialis is attached to the anterior surface of the coronoid process, including the ulnar tuberosity. The oblique and anterior bands of the ulnar collateral ligament and the distal part of the humero-ulnar slip of flexor digitorum superficialis are attached to a small tubercle at the proximal end of the medial border. Further distally, the margin of the coronoid process provides attachment for the ulnar head of pronator teres. An ulnar head of flexor pollicis longus may be attached to the lateral or, more rarely, the medial, border of the coronoid process. Fibres of flexor digitorum profundus are attached to its medial surface. The anular ligament is attached to the anterior rim of the radial notch and, posteriorly, to a ridge at, or just behind, the posterior margin of the notch. The depressed area distal to the notch is limited behind by the supinator crest, and both provide attachment for supinator.

The olecranon area of the trochlear notch is usually divided into three areas. The most medial faces anteromedially, and is grooved to fit the medial flange of the humeral trochlea, with which it makes increasing contact during flexion. A flat intermediate area fits the lateral flange. The most lateral area is a narrow strip that abuts the trochlea in extension. The articular surface is narrower than the base of the olecranon; non-articular areas are related to the synovial processes. The coronoid area of the trochlear notch is also divided; its medial and lateral areas correspond to the medial and intermediate areas of the olecranon. The medial is the deeper, and conforms to the convex medial trochlear flange and is essential for elbow stability. The medial and anterior parts of the capsular ligament are attached to its medial and anterior borders.

The deep fascia of the forearm is attached to the subcutaneous posterior border, which also provides an attachment for the aponeurosis of flexor digitorum profundus in its proximal three-quarters, for flexor carpi ulnaris in its proximal half, and for extensor carpi ulnaris in its middle third. These three muscles are attached to the posterior border through a common blended aponeurosis. The interosseous membrane is attached along the interosseous border, except for a short length proximally.

Flexor digitorum profundus is attached to the proximal three-quarters of the anterior border and medial surface, arising medial to the coronoid process and olecranon. The rough strip across the distal fourth of the anterior surface provides part of the bony attachment for pronator quadratus. Anconeus is attached to the posterior surface proximal to the oblique line and lateral to the olecranon. The narrow strip between the interosseous border and vertical ridge gives rise to the attachment of three deep muscles: abductor pollicis longus arises from the proximal quarter, extensor pollicis longus from the succeeding quarter (sometimes a ridge is interposed between them), and extensor indicis from the third quarter. Extensor carpi ulnaris covers the broad strip medial to the vertical ridge and its tendon grooves the posterior aspect of the distal end of the ulna.

Vascular supply

The ulna receives its vascular supply from branches of the radial, ulnar, anterior and posterior interosseous arteries via multiple metaphysial nutrient foramina. Usually one, but occasionally two, major nutrient diaphysial foramina are located on the anterior surface of the bone, directed proximally towards the elbow. A network of small fascioperiosteal and musculoperiosteal branches given off from the compartmental vessels reaches the bone via septal and muscular attachments.

Ossification

The ulna ossifies from four main centres: one each in the shaft and distal end, and two in the olecranon (see Fig. 49.13; **Fig. 50.12**). Ossification begins in the midshaft in embryonic stages 22 and 23 and extends rapidly. A centre appears in the distal end in the fifth year in females and sixth year in males, and extends into the styloid process. The distal olecranon is ossified as an extension from the shaft, the remainder from two centres, one for the proximal trochlear surface and the other for a thin, scale-like proximal epiphysis on its summit. The proximal epiphysis appears in the ninth year in females and eleventh year in males, and the whole proximal epiphysis has usually joined the shaft by the fourteenth year in females and sixteenth year in males. The distal epiphysis usually unites with the shaft in the seventeenth year in females and eighteenth year in males. Together with the distal humerus, the proximal ulna ossifies in a sequential manner; skeletal maturity may be assessed by observations of elbow radiographs.

JOINTS

The elbow joint acts as a platform for the forearm and hand. The humero-ulnar and humero-radial (radiocapitellar) joints form a complex hinge.

The humero-ulnar joint is continuous with pivot joints between the distal humerus and proximal radius, and between the proximal radius and ulna (**Figs 50.13–50.16**). There is a high degree of congruity between the deep trochlea of the humerus and the large trochlear notch of the ulna. This stable arrangement is enhanced by strong ulnar (medial) and radial (lateral) collateral ligaments and, in full extension, by the anterior capsule. An arc of 150° of flexion and extension is possible. The configuration of the humero-ulnar joint, between the trochlea and the trochlear notch of the ulna and the distal prolongation of the medial edge of the trochlear pulley, tilts the ulna, forming a 'carrying angle' (approximately 14° in females and 11° in males) between the longitudinal axes of the humerus and ulna when the elbow is fully extended and supinated. These axes become aligned in full flexion as a result of the spiral morphology of the trochlea. The humero-radial joint, in conjunction with synchronous movements at the proximal and distal radio-ulnar joints that are aided by minor contributions from the radiocarpal and carpal joints, allows 180° of pronation and supination of the forearm.

Humero-ulnar and humero-radial joints

The humero-ulnar joint is a complex hinge joint and is continuous with two pivot joints between the distal humerus and proximal radius, and

between the proximal radius and ulna (see Figs 50.13–50.16). There is a high degree of congruity between the deep trochlea of the humerus and the large trochlear notch of the ulna. This stable arrangement is enhanced by strong ulnar (medial) and radial (lateral) collateral ligaments and, in full extension, by the anterior capsule. An arc of 150° of flexion and extension is possible. A range of 180° of pronation and supination is achieved by synchronous movements at the proximal and distal radio-ulnar joints, aided by minor contributions from the radio-carpal and carpal joints.

Articulating surfaces The distal humerus has two distinct articulating surfaces: the trochlea and the capitulum (see Fig. 50.3). The shape of the trochlea is asymmetrical, with a longer medial flange. It is widest posteriorly in the adult. The joint line lies 2 cm distal to the interepicondylar line and is tilted inferomedially. The flexion–extension arc of elbow movement is not that of a simple hinge. Different parts of the distal humerus are in contact with the corresponding articular surface of the proximal ulna throughout the range of movement; in full extension of the elbow, a medial segment of the distal humerus is not in contact with the ulna, whereas in full flexion, a lateral segment is not in contact.

The surface of the trochlear notch has an asymmetrical sellar surface that allows some rotation during swing in the flexion–extension plane. It is predominantly concave in the transverse plane, but convex in the anteroposterior plane. There is a 'bare area' devoid of hyaline cartilage between the olecranon and coronoid areas of the trochlear notch that is covered by fibrofatty tissue and synovium. The humeral capitulum is reciprocally convex with the concavity of the articulating surface of the radial head. The more prominent medial rim of the radial head sits in the groove between the capitulum and trochlea. Contact between the capitulum and radial head is maximal with the elbow in mid-flexion and the forearm in mid-pronation.

Fibrous capsule The fibrous capsule is broad and thin anteriorly. It is attached proximally to the anterior surfaces of the medial epicondyle and humerus above the coronoid and radial fossa, and distally to the edge of the ulnar coronoid process and anular ligament. It may be

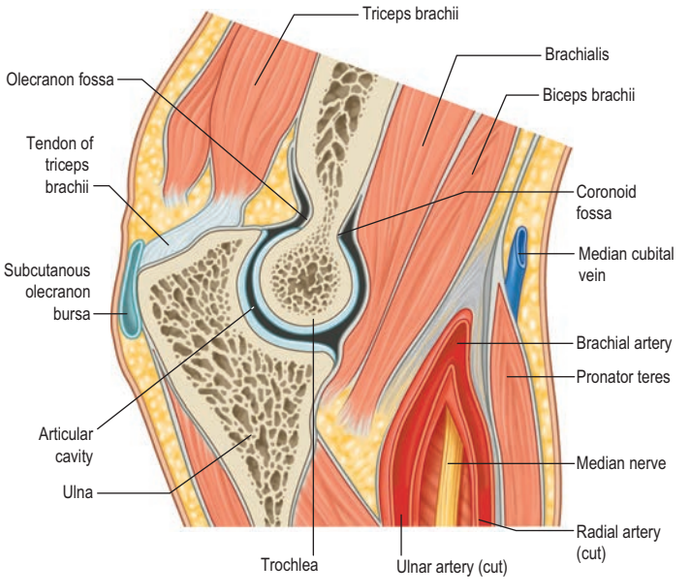

Fig. 50.15 A sagittal section through the left elbow joint: medial aspect. The synovial membrane is shown in blue. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

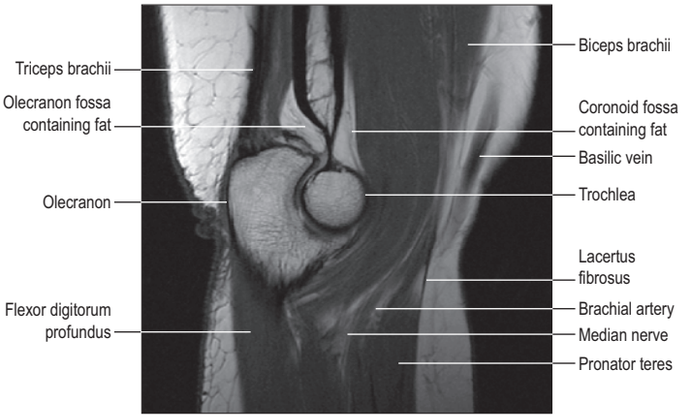

Fig. 50.16 Sagittal proton density weighted MRI through the left elbow joint.

augmented by fibres from brachialis and blends into the ulnar collateral ligament medially and the radial collateral ligament laterally. Posteriorly, the capsule is even thinner and is related to the tendon of triceps and anconeus. It is attached proximally to the superoposterior aspect of the humeral capitulum, the posterior aspect of the medial epicondyle and the olecranon fossa. Only the lowest part of the olecranon fossa is devoid of a capsular attachment. Inferomedially, it reaches the superior and lateral margins of the olecranon and is laterally continuous with the superior radio-ulnar capsule deep to the anular ligament. The olecranon bursa lies between the capsule of the elbow and the insertion of triceps. Inflammation caused by pressure, friction or infection of the bursa can result in marked swelling and limitation in elbow function.

Ligaments The humero-radio-ulnar articulations have ulnar (medial) and radial (lateral) collateral ligamentous complexes (see Fig. 50.13).

Ulnar collateral ligamentous complex The ulnar (medial) collateral ligament complex is triangular and consists of thick anterior, posterior and inferior bands connected by thinner tissue. The strongest and stiffest anterior band is attached by its apex to the anterior aspect of the medial epicondyle midway between the medial trochlea and the apex of the medial epicondyle and by its broader base to a proximal sublime tubercle on the medial margin of the coronoid. The anterior band is taut throughout most of the range of flexion and contributes to the stability of the joint. The posterior band of the ulnar collateral ligament is also triangular in shape; its apex is attached to the back of the medial epicondyle and its distal attachment is the medial margin of the olecranon. The posterior band becomes taut between 90° and full flexion of the elbow. Connecting these two thick bands is a less sturdy inferior oblique band that runs between the olecranon and coronoid processes, converting a depression on the medial margin of the trochlear notch into a foramen, through which the intracapsular fat pad is continuous with the extracapsular fat medial to the joint. The ulnar collateral ligament of the elbow lies beneath triceps, flexor carpi ulnaris, the ulnar nerve and the attachment of flexor digitorum superficialis as it extends from the medial epicondyle to the medial coronoid border.

Radial collateral ligamentous complex The capsule on the lateral aspect of the elbow has interconnecting thickenings that form a broad sling between the humerus and ulna around the radial head. The radial (lateral) collateral ligamentous complex is divided into four elements, the radial collateral ligament, anular ligament, lateral ulnar collateral ligament and posterolateral ligament (Camp et al 2018). The radial collateral ligament is attached low on the lateral epicondyle anterior and inferior to a small tubercle on the lateral epicondyle and inserts distally into the anular ligament which wraps around the radial head from the anterior rim of the radial notch of the ulna to the supinator crest. Proximally, the radial collateral ligament is continuous with the lateral ulnar collateral ligament that arises from the inferior aspect of the tubercle on the lateral epicondyle and inserts into the supinator crest and often gives rise to accessory fibres that cross the anular ligament distally. The posterolateral ligament is more proximal still and extends onto the posterior aspect of the capitulum, creating a hammock behind the radial head that limits dorsal translation (Edwards et al 2018). The posterolateral ligament blends with the bony attachments of supinator and extensor carpi radialis brevis. It is taut throughout most of the range of flexion of the elbow and contributes to the stability of the joint.

Synovial membrane The synovial membrane extends from the articular margins of the humerus and lines the coronoid, radial and olecranon fossae, the flat medial surface of the trochlea, the deep surface of the elbow capsule and the distal part of the anular ligament. A crescentic synovial fold projecting between the proximal radius and ulna contains extrasynovial fat and forms the division between the humero-ulnar and humero-radial joints.

There are three other fat pads between the capsule and synovium; the largest is in the olecranon fossa, where it is pushed into the fossa by triceps during flexion of the elbow. The two other fat pads are in the coronoid and radial fossae, and are pushed into these fossae by brachialis on extension of the elbow. Smaller fat pads covered by synovium project into the joint at the trochlear notch and also cover non-articular areas of bone.

Vascular supply The articular arteries of the elbow are derived from numerous small periarticular anastomoses around the joint (see Fig. 50.29). Of particular note is the blood supply to the radial head, an intracapsular structure supplied by vessels arising from the radial recurrent artery that travels retrogradely up the surface of the bare area of the bone and fans out to supply the whole radial head (Yamaguchi et al 1997).

Innervation The elbow joint is innervated by filaments arising from all of the main nerves supplying the upper limb, except the axillary nerve. The ulnar posterior part is supplied by the ulnar nerve and the medial cutaneous nerve of the forearm; the ulnar anterior part is supplied by the median and musculocutaneous nerves. The radial nerve is the sole supplier of the radial posterior part, and the radial anterior part is innervated by both radial and musculocutaneous nerves (de Kesel et al 2012).

Proximal radio-ulnar joint

The proximal radio-ulnar joint is a uniaxial pivot joint (**Fig. 50.17**).

Articulating surfaces Articulating surfaces include the articulation between the circumference of the radial head and the fibro-osseous ring of the ulnar radial notch and anular ligament.

Fibrous capsule The fibrous capsule of the proximal radio-ulnar joint is continuous with that of the elbow and is attached to the anular ligament.

Ligaments The proximal radio-ulnar joint has anular and quadrate ligaments.

Anular ligament The anular ligament is the principal stabilizer of the joint. It is a strong composite band that winds around four-fifths of the

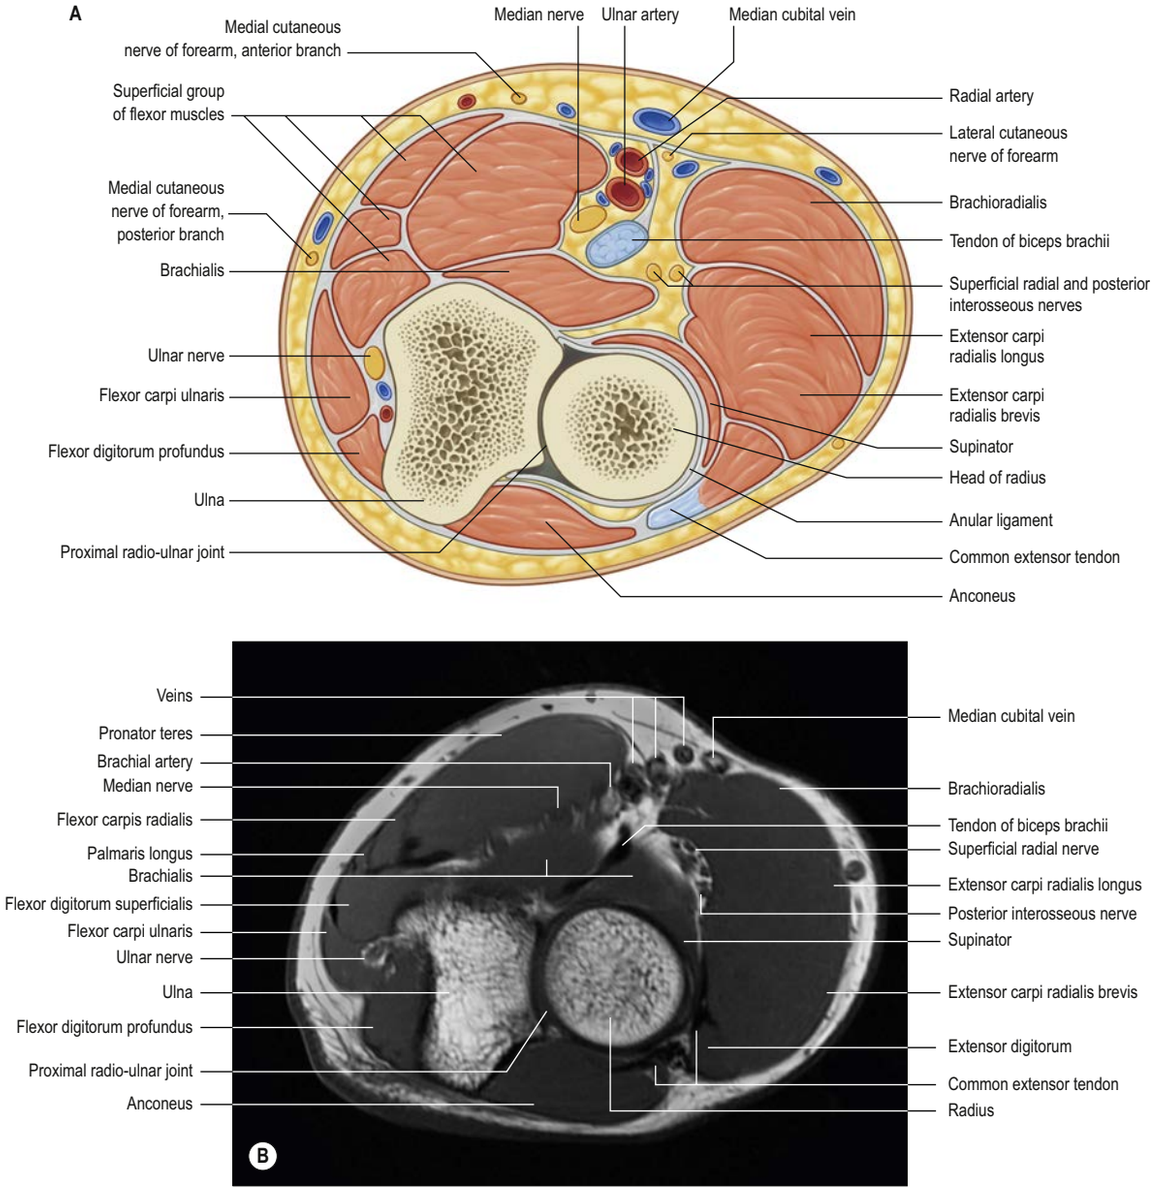

Fig. 50.17 The proximal left radio-ulnar joint. **A**, Transverse section. **B**, Axial T1-weighted MRI at the level of the proximal radio-ulnar joint.

radial head and holds it against the radial notch of the ulna. It is attached to the anterior margin of the notch. The ligament is wider posteriorly, where it may be composed of several bands. It is attached to a rough ridge at or behind the posterior margin of the notch. Some bands may diverge and attach superiorly to the lateral margin of the trochlear notch, or inferiorly to the supinator crest. Proximally, the anular ligament blends into the joint capsule, except posteriorly where the capsule is deep to the ligament. Distally, the anular ligament gives off a few fibres, which pass over the synovial membrane to attach to the radial neck. The superficial surface of the anular ligament blends into the radial collateral ligament and provides an attachment for a part of supinator. The deep surface of the anular ligament is lined with a thin layer of cartilage where it is in contact with the radial head. Distally, there is a synovial membrane that is reflected up on to the radial neck. The anconeus and the interosseous recurrent artery lie behind the ligament.

Quadrate ligament The quadrate ligament is a much thinner and more fibrous structure than the anular ligament. It runs between the radial neck and the upper part of the supinator fossa of the ulna, and is taut throughout pronation and supination. It lies over the synovial membrane on the distal surface of the joint.

Synovial membrane The synovial membrane of the proximal radio-ulnar joint is continuous with that of the elbow joint, forming one continuous synovial cavity. It attaches to the joint margins, lining the capsule and anular ligament. The quadrate ligament prevents herniation of the synovial membrane between the free edges of the anular ligament.

Vascular supply The vascular supply of the proximal radio-ulnar joint is derived from a rich periarticular anastomotic plexus (**Fig. 50.18**; see Fig. 50.19).

Innervation The proximal radio-ulnar joint is innervated by small branches arising from the musculocutaneous, median, radial and ulnar nerves.

Radio-ulnar syndesmoses

The radial and ulnar shafts are connected by two syndesmoses, an oblique cord and an interosseous membrane.

Oblique cord

The oblique cord is a small, inconstant, flat fascial band on the deep head of supinator (see Fig. 50.10). It extends from the lateral side of the ulnar tuberosity to the radius a little distal to its tuberosity. Its fibres are at right-angles to those in the interosseous membrane. Its functional significance is unclear.

Interosseous membrane

The interosseous membrane is a broad, thin, collagenous structure (see Fig. 50.10). Its fibres slant distomedially between the interosseous borders of the radius and ulna, and its distal part is attached to the posterior

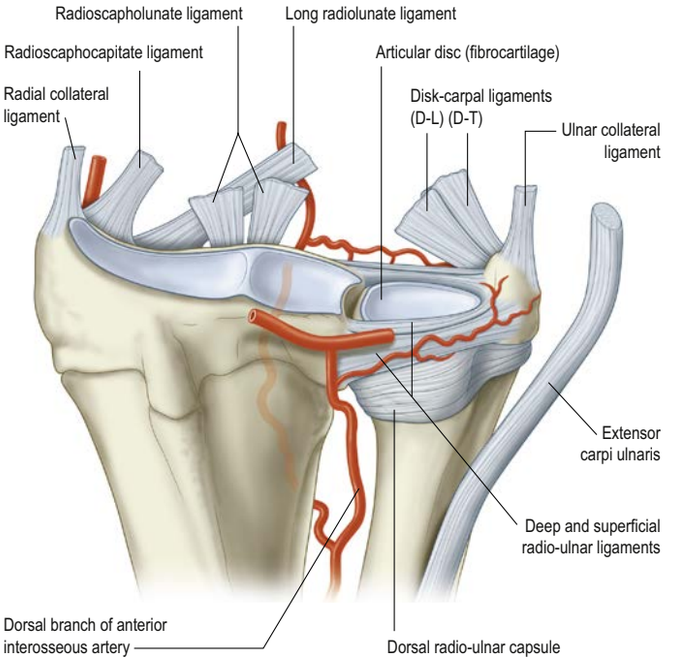

Fig. 50.18 The prime intrinsic stabilizer of the distal radio-ulnar joint is the triangular fibrocartilage. The triangular fibrocartilage complex consists of superficial and deep radio-ulnar fibres, the two disc carpal ligaments (disc–lunate (D–L) and disc–triquetral (D–T)), and the central articular disc. The articular disc is responsible for transferring load from the medial carpus to the pole of the distal ulna. The vascularized, peripheral radio-ulnar ligaments are nourished by dorsal and palmar branches of the posterior interosseous artery and are responsible for guiding the radiocarpal unit around the seat of the ulna. (Redrawn with permission from Kleinmann WB 2010 Stability of the distal radioulnar joint: biomechanics, pathophysiology, physical diagnosis and restoration of function. In: Slutsky DJ (ed) Principle and Practice of Wrist Surgery. Philadelphia: Saunders; Ch. 5, pp. 41–45.)

division of the radial shaft. Two or three posterior bands occasionally descend distolaterally across the other fibres. The membrane is deficient proximally, starting 2 or 3 cm distal to the radial tuberosity, and broadest at midlevel. An oval aperture near its distal margin conducts the anterior interosseous vessels to the back of the forearm. The posterior interosseous vessels pass through a gap between its proximal border and the oblique cord.

The membrane provides attachments for the deep forearm muscles. Anteriorly, in its proximal three-quarters, it is related laterally to flexor pollicis longus and medially to flexor digitorum profundus; between them, it is related to the anterior interosseous vessels and nerve. In its distal quarter, it is related to pronator quadratus. Its posterior relations are supinator, abductor pollicis longus, extensors pollicis brevis, longus and indicis, and, near the carpus, the anterior interosseous artery and posterior interosseous nerve.

The interosseous membrane consists of several parts, the most important of which is the central band originally described by Hotchkiss et al (1989). This probably acts in conjunction with the radial head to restrain the radius from proximal migration and to stabilize the forearm. Previously described as being at its most taut in almost every position of rotation of the forearm, it now appears to maintain the same tension throughout pronation and supination. Noda et al (2009) have described four other subsidiary portions. The distal oblique band has fibres that arise from the ulna and incline distally and laterally; they are attached to the radius just proximal to the distal radio-ulnar joint and contribute to the anteroposterior stability of the joint.

Distal radio-ulnar joint

The distal radio-ulnar joint is a uniaxial pivot joint.

Articulating surfaces The articulating surfaces are between the convex distal head of the ulna and the concave ulnar notch of the radius; they are connected by an articular disc.

Fibrous capsule The fibrous capsule is thicker anteriorly and posteriorly, and more lax proximally.

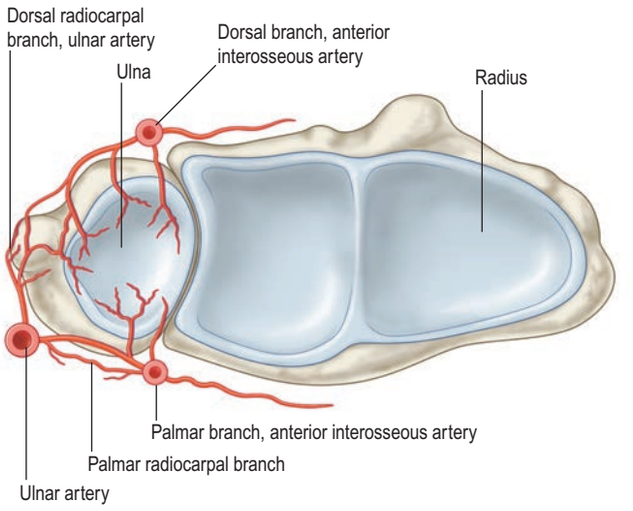

Fig. 50.19 The arterial anatomy of the triangular fibrocartilage complex. (Redrawn with permission from Thiru-Pathi RG, Ferlic DC, Clayton M et al 1986 Arterial anatomy of the triangular fibrocartilage of the wrist and its surgical significance. J Hand Surgery [Am] 11:258–63.)

Triangular fibrocartilage complex and distal radio-ulnar ligaments The triangular fibrocartilage complex (TFCC) is a ligamentous and cartilaginous structure that suspends the distal radius and ulnar carpus from the distal ulna. It stabilizes the ulnocarpal and radio-ulnar joints, transmits and distributes load from the carpus to the ulna, and facilitates complex movements at the wrist. By definition, it is made up of the triangular fibrocartilage proper (the articular disc), meniscus homologue (the ulnocarpal meniscus), ulnar collateral ligament, dorsal and palmar radio-ulnar ligaments, floor of extensor carpi ulnaris subsheath, and the ulnolunate and ulnotriquetral ligaments. The triangular fibrocartilage proper is a biconcave body composed of chondroid fibrocartilage that extends across the dome of the ulnar head, ranging in thickness between 2 and 5 mm. The meniscal homologue is a broad expansion of loose connective tissue that runs from the articular disc to the ulnar styloid and the surrounding joint capsule; it is not a major contributor to the structural integrity of the triangular fibrocartilage complex.

The triangular fibrocartilage complex is attached to the ulnar aspect of the lunate fossa of the radius. Medially, it is inserted into the head of the ulna and the base of the ulnar styloid. Here, it is joined by fibres from the ulnar part of the ulnar styloid (the ulnar collateral ligament); thus thickened, it attaches to the lunotriquetral interosseous ligament, triquetrum, hamate and base of the fifth metacarpal. A constant perforation just distal to the level of the ulnar styloid leads to the prestyloid recess. The dorsal and palmar (volar) aspects of the triangular fibrocartilage complex are thickened to form the dorsal and palmar radio-ulnar ligaments, which are attached to the dorsal and palmar ulnar corners of the distal radius and to the fovea of the ulnar head at the base of the ulnar styloid (Palmer and Werner 1981, Pacek and Buterbaugh 2015).

The triangular fibrocartilage complex receives its blood supply from the ulnar artery via its palmar and dorsal radiocarpal branches, the dorsal branch of the anterior interosseous artery and the palmar branch of the anterior interosseous artery. Only the outer 15–20% of the disc is vascularized; the rest is avascular (Thiru-Pathi et al 1986, Bednar et al 1991) (**Fig. 50.19**).

The triangular fibrocartilage complex acts as a cushion for the ulnar carpus, preventing ulnocarpal abutment and overloading of the ulna in ulnar deviation. It is a major stabilizer of the distal radio-ulnar joint. Degenerative perforation of the triangular fibrocartilage complex becomes more common with age and is a constant finding after the age of 50 years (Mikić 1978).

Synovial membrane The synovial membrane lines the capsule and forms a sacciform recess in front of the distal part of the interosseous membrane.

Vascular supply The arterial supply of the distal radio-ulnar joint is derived from the palmar and dorsal branches of the anterior interosseous artery, reinforced by the posterior interosseous and ulnar arteries.

Innervation The distal radio-ulnar joint is innervated by branches of the anterior and posterior interosseous nerves.

Movements at the humero-ulnar, humero-radial and proximal and distal radio-ulnar joints

The main movements that occur at the humero-ulnar, humero-radial and proximal and distal radio-ulnar joints are flexion, extension, supination and pronation.

Flexion and extension

The elbow joint has relatively stable semi-congruent articular surfaces that are assisted by strong static and dynamic stabilizers, and which allow a flexion–extension arc of approximately 150°. When the elbow is extended and supinated, the forearm forms a 'carrying angle' with the humerus of approximately 17°; the absolute angle varies from individual to individual. It exists because the medial edge of the trochlear projects distally by 6 mm and because the superior articular surface of the coronoid is oblique. The carrying angle is not present in flexion when the humerus and ulna are in the same plane. With the arm adducted and the elbow flexed, the little finger meets the clavicle. If the humerus is rotated laterally, the little finger reaches the anterior shoulder. Pronation of the extended forearm masks the carrying angle by lining up the arm, forearm and hand.

Accessory movements

Availatble with the *Gray's Anatomy* e-book

Pronation and supination

Movements at the humero-radial, proximal and distal radio-ulnar joints pronate and supinate the hand. In pronation, the radius turns anteromedially and obliquely across the ulna. Its proximal end remains lateral to the ulna while its distal end lies medially and the interosseous membrane becomes spiralled. In supination, the radius returns to its former position lateral and parallel to the ulna and the interosseous membrane becomes unspiralled. The hand can be turned through 140–150° with the elbow extended; this can be increased to nearly 360° by humeral rotation and movements of the scapula. Power is greater in supination, a fact that has affected the design of nuts, bolts and screws, which are tightened by supination in the right-handed.

Stability of the distal radio-ulnar joint

With the wrist in neutral extension and deviation, the main axis for transmission of force from the hand to the forearm passes through the head of the capitate, then through the scapholunate ligament and finally into the distal radius. Loading is transferred to the triangular fibrocartilage complex and distal ulna in ulnar deviation. The joint is stabilized by extrinsic and intrinsic structures.

Extrinsic stabilizers Extrinsic stabilizers include the tendon of extensor carpi ulnaris, pronator quadratus, the distal oblique band of the interosseous membrane and the sheath of the sixth dorsal compartment, which overlies extensor carpi ulnaris (Spinner and Kaplan 1970).

Intrinsic stabilizers Intrinsic stabilizers are stronger than extrinsic stabilizers and include the radio-ulnar capsule and the dorsal and palmar radio-ulnar ligaments. The dorsal and palmar radio-ulnar ligaments contain superficial and deep components. The superficial layers insert on to the ulnar styloid. The stronger, deep layers insert more laterally into the fovea adjacent to the articular surface of the pole of the distal ulna (Kleinmann 2010).

Muscles producing movement

Flexion. Movement is produced by brachialis, biceps brachii and brachioradialis. In slow flexion or its maintenance against gravity, brachialis and biceps are principally involved, even for light loads. With increasing speed and activity, brachioradialis is increasingly prominent; its attachments determine that it acts most effectively in mid-pronation. Against resistance, pronator teres, longus and brevis, flexors carpi radialis and ulnaris, and extensor carpi radialis may contribute.

Extension Movement is produced by triceps, anconeus and gravity.

Pronation Pronator quadratus is aided in rapid movement and against resistance by pronator teres. Gravity also assists.

Supination Movement is produced by supinator, in slow unresisted movement and extension, assisted by biceps in fast movements in flexion, especially when resisted.

MUSCLES OF THE FOREARM

There is some anatomical segregation by function of muscles that cross the elbow. Most of those that arise medially pass to the flexor aspect of the wrist, or stabilize or move the ulnar column of the carpus and the ulnar side of the hand. Those that arise laterally pass to the lateral column of the forearm and carpus, and to the extensor aspect of the wrist. The muscles that act on the thumb have a wide origin: the extensor and abductor muscles arise from the entire width of the interosseous membrane. Rotator muscles, such as supinator, pronator teres and pronator quadratus, pass between the radius and ulna, crossing the longitudinal axis of the forearm.

Anterior compartment

The anterior compartment contains the flexor muscles of the forearm. These are arranged in superficial and deep groups.

Superficial flexor compartment

Muscles of the superficial flexor compartment are pronator teres, flexor carpi radialis, palmaris longus, flexor digitorum superficialis and flexor carpi ulnaris.

Pronator teres

Attachments Pronator teres arises from two heads. The humeral origin of pronator teres is the larger and more superficial. It arises at the medial supracondylar ridge just proximal to the medial epicondyle from the common tendon of origin of the flexor muscles, from the intermuscular septum between it and flexor carpi radialis, and from the antebrachial fascia (see Fig. 50.6, **Figs 50.20–50.22**). The smaller ulnar head arises from the medial side of the coronoid process of the ulna, distal to the attachment of flexor digitorum superficialis, and joins the humeral head at an acute angle. This ulnar coronoid attachment may be absent in some individuals. The muscle passes obliquely across the forearm to end in a flat tendon that is attached to a rough area midway along the lateral surface of the radial shaft at the apex of its lateral curve (see Fig. 50.25). Accessory slips may arise from a supracondylar process of the humerus, if present, or from biceps, brachialis or the medial intermuscular septum.

Relations The median nerve usually enters the forearm between the two heads of pronator teres, separated from the ulnar artery by the ulnar head. The lateral border of pronator teres is the medial margin of the cubital fossa (see Fig. 48.53). Proximally, the medial border of pronator teres is related to the lateral aspect of flexor carpi radialis. Pronator teres is anterior to flexor digitorum superficialis.

Vascular supply The humeral head of pronator teres is supplied by the inferior ulnar collateral and anterior ulnar recurrent arteries. The ulnar head is supplied by the common interosseous artery, the mid portion of the muscle belly by direct branches from the ulnar artery, and the radial insertion by the radial artery.

Innervation Pronator teres is innervated by the median nerve, sixth and seventh cervical ventral rami.

Actions Pronator teres pronates the forearm by rotating the radius medially on the ulna. It is a weak flexor of the elbow joint.

Testing Pronator teres is tested by palpating its contracting fibres during pronation against resistance. The tendon of pronator teres is chiefly responsible for the symptoms of golfer's elbow or medial epicondylosis.

Flexor carpi radialis

Attachments Flexor carpi radialis arises from the common flexor origin on the medial epicondyle, the antebrachial fascia and from the adjacent intermuscular septa (see Fig. 49.11A). Its fusiform muscular belly converges in the mid-forearm into a long tendon that passes within a synovial sheath through a lateral canal, formed by the flexor retinaculum above and a groove on the trapezium beneath. It inserts on the palmar surface of the base of the second metacarpal and sends a slip to the third metacarpal. These distal attachments lie beneath the oblique head of adductor

The surface topography of the humero-ulnar joint permits some rotation of the ulna against the humerus. The radius acts as a mobile strut within the forearm, such that rotation of the distal radius around the ulna carries the radiocarpal joint, wrist and hand into pronation or supination. The medial side of the head of the radius is longer than the lateral side; this eccentric morphology causes a cam effect during rotation of the proximal radio-ulnar joint. The radius is suspended by the interosseous membrane from the ulna, which is the fixed structure in the forearm.

The interosseous membrane contributes to longitudinal stability by virtue of its oblique course from the radius proximally to the ulna distally. It appears to maintain the same tension throughout pronation and supination (Ekenstam et al 1984). If the membrane is disrupted, as in an Essex–Lopresti injury (fracture of the head of the radius, disruption of the interosseous membrane and dislocation of the distal radio-ulnar joint), the radius will migrate proximally; persistent radio-ulnar dissociation causes a complex instability of the forearm (Hotchkiss et al 1989). Correction of the fixed deformity of the forearm commonly seen in untreated cases of spastic cerebral palsy or birth lesions of the brachial plexus usually requires release of the membrane because it has become relatively shortened. Pronator quadratus and supinator protect the interosseous membrane, to some extent, during forced, rapid rotation of the forearm by 'paying out' eccentrically, thereby reducing the load applied across the membrane.

The elbow is stabilized by the intrinsic shape of the joint and by its ligaments and muscles. The trochlear pulley is deeply seated within the trochlear notch, while the olecranon provides anteroposterior stability. Anterior stability in the sagittal plane is enhanced by the joint capsule, biceps, brachialis and the bicipital aponeurosis; posterior stability is enhanced by the triceps tendon and aponeurosis.

The radial and ulnar collateral ligaments are key to stability in the coronal plane. Resistance to varus strain comes from the radial ligament complex, of which the posterior band is the most important. Resistance to valgus strain is provided by the ulnar collateral ligament complex, of which the anterior band is the most important. If the head of the radius is lost, an intact ulnar collateral ligament maintains stability of the elbow. If the ligament is disrupted, the ulna drifts into valgus, there is rotational instability and the trochlea is damaged. Stability of the radius is enhanced by anconeus and by the muscles arising from the lateral aspect of the distal humerus. Muscles that arise from the medial epicondyle contribute to stability of the ulna. Muscles that act across the elbow have a shunting effect, creating articular joint reaction compression forces that contribute to close-packing (the position of a joint in which the greatest stability is achieved for the least expended effort). The humero-ulnar joint is most closely packed and, therefore, most resistant to fatigue in flexion and supination.

The flexion–extension arc of the elbow is accompanied by some rotation; the ulna is slightly pronated in extension and supinated in flexion. In full extension, the radial head can be palpated posteriorly because the radial facet is larger than the capitulum. The excursion of the radial head in extension is limited by tension in the posterolateral ligament, by the muscles anterior to the joint and by the tip of the olecranon entering the olecranon fossa. In flexion, the rim of the radial head enters the radial fossa and the tip of the coronoid process enters the coronoid fossa. Flexion is principally limited by the apposition of soft tissues.

Accessory movements include anterior and posterior translation of the radial head on the ulnar radial notch, and of the ulnar head on the radial ulnar notch.

Accessory movements of the human elbow are minimal and facilitate the movements described above. The ulna rotates slightly at the elbow and allows a few degrees of abduction and adduction. The radial head exhibits a little anteroposterior translation on the capitulum when it moves on the ulnar radial notch and the anular ligament moves back and forth; this occurs maximally with the elbow in 90° of flexion.

Rotation of the forearm occurs between the head of the radius and the radial notch of the ulna proximally and the articulation of the head of the ulna and trochlear (sigmoid) notch. These proximal and distal radio-ulnar joints are pivot-type synovial joints; they act as a unit, permitting stable rotary motion (pronation 61–66°, supination 70–77°). During rotation, the distal radius moves around the head of the ulna. The axis for pronation and supination is often represented as a line through the centre of the radial head proximally and the ulnar attachment of the articular disc distally. This represents the axis of movement of the radius relative to the ulna but this does not remain stationary. The radial head rotates in the fibro-osseous ring; its distal lower end and articular disc swing round the head of the ulna. Rotation of the radial head occurs on the humeral capitulum. As the forearm moves from full pronation into supination, the ulna translocates medially by 9–10 mm, so that the axis of rotation shifts but still passes through the head of the ulna. In addition, the trochlear notch changes its position of contact with the ulnar head, lying dorsal proximally in pronation and palmar distally in supination. The distal end of the ulna is not stationary during these movements; it moves along a curved course, posterolaterally in pronation and anteromedially in supination. The axis of movement, as defined above, is therefore displaced laterally in pronation and medially in supination. Hence, the axis for pronation and supination of the forearm and hand passes between the bones at both the proximal and distal radio-ulnar joints when ulnar movement is marked, but through the centres of the radial head and ulnar styloid when it is minimal. The axis may be extended along any digit, depending on whether the distal end of the ulna is medially or laterally displaced. The hand will rotate further than the forearm because of the sliding–rotatory movement that occurs between the carpal bones and the bases of the metacarpals, and, to a very minor degree, at the radiocarpal joint.

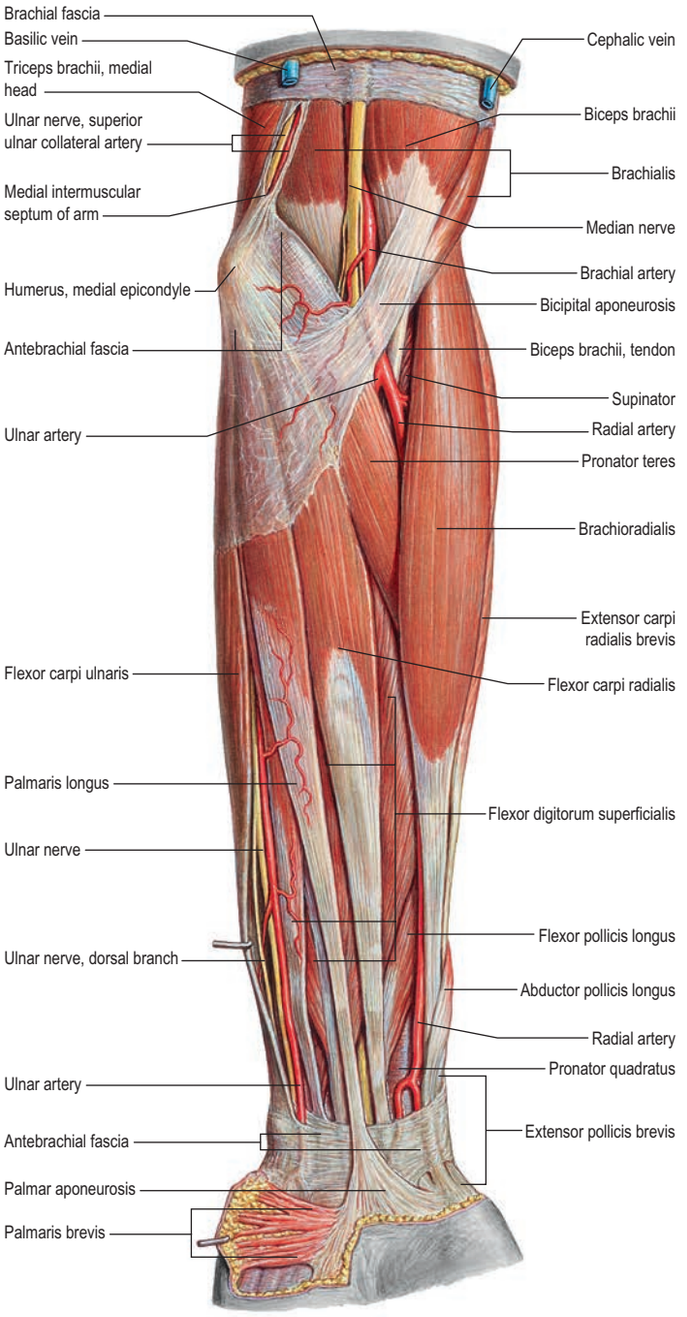

Fig. 50.20 The superficial flexor muscles of the left forearm. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

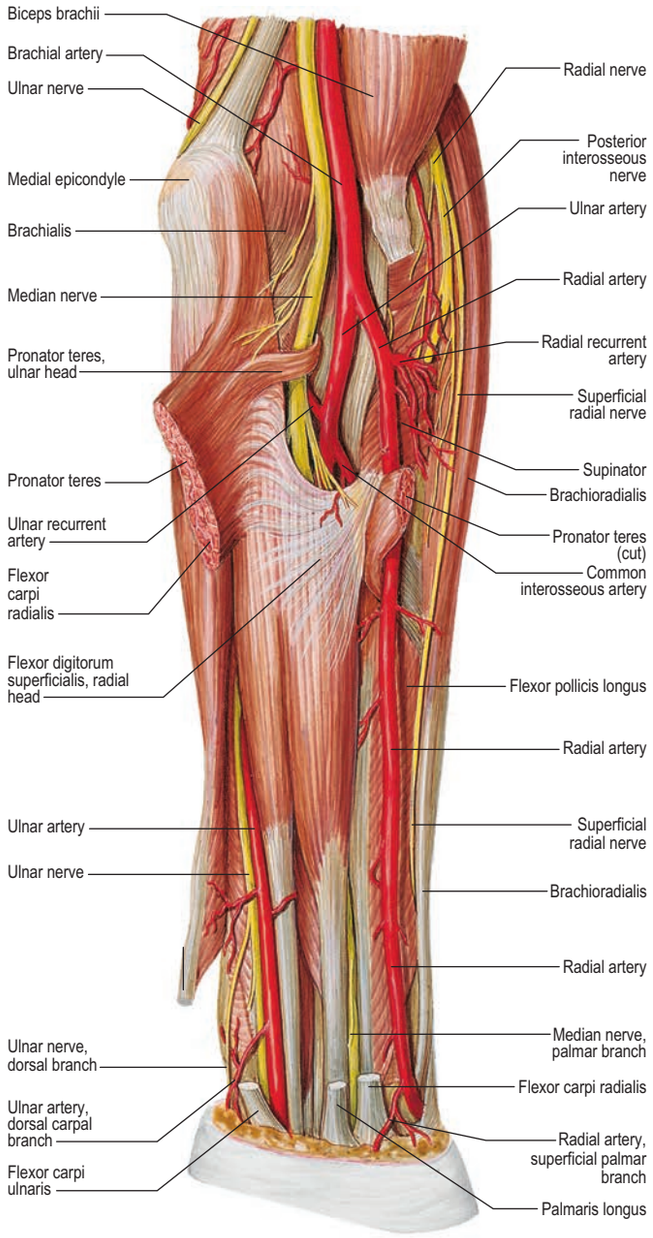

Fig. 50.21 The deep flexor muscles of the left forearm. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

pollicis. Rarely, the muscle may be absent. There may be accessory slips from the biceps tendon, bicipital aponeurosis, coronoid process or radius. Distally, it may also be attached to the flexor retinaculum, trapezium or fourth metacarpal.

Relations At its origin, flexor carpi radialis lies medial to pronator teres. In the lower part of the forearm, the radial artery lies between the tendon of flexor carpi radialis and the tendon of brachioradialis; the radial pulse may be palpated proximal to the wrist between these two tendons.

Vascular supply Flexor carpi radialis is supplied by a single dominant proximal pedicle and several distal minor pedicles. The dominant pedicle is formed by a branch that arises from either the anterior or the posterior ulnar recurrent artery. The posterior ulnar recurrent artery passes deep to pronator teres to enter the deep surface of flexor carpi radialis; from here, it divides into a small ascending branch and a larger descending branch. The distal minor pedicles supplying flexor carpi radialis are six to eight branches from the radial artery that enter the muscle on the anterolateral side.

Innervation Flexor carpi radialis is innervated by the median nerve, sixth and seventh cervical ventral rami.

Actions Flexor carpi radialis is a wrist flexor. It acts with flexor carpi ulnaris to effect balanced wrist flexion, and in concert with the radial extensors of the wrist to achieve balanced abduction of the hand.

Testing Flexor carpi radialis is tested by palpating its contracting fibres during flexion of the wrist against resistance.

Flexor digitorum superficialis

Attachments Flexor digitorum superficialis is the largest of the superficial flexors, and arises by two heads (see Figs 49.11A, 50.20–50.21). The humero-ulnar head arises from the medial epicondyle of the humerus via the common flexor origin, the anterior band of the ulnar collateral ligament, adjacent intermuscular septa, and from the medial side of the coronoid process proximal to the ulnar origin of pronator teres. The radial head, a thin sheet of muscle, arises from the anterior radial border between the radial tuberosity and the insertion of pronator teres. The median nerve and ulnar artery descend between the heads. The muscle usually separates into two strata, directed to digits two to five. The superficial stratum, joined laterally by the radial head, divides into two tendons for the middle and ring fingers. The deep stratum gives off a

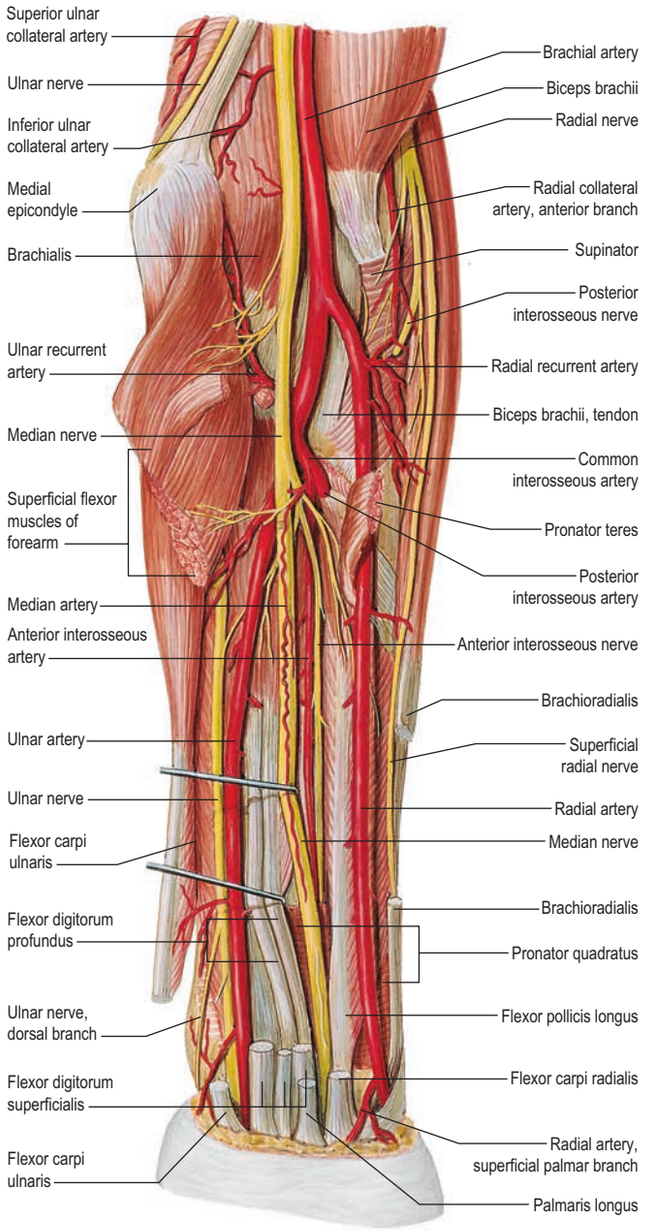

Fig. 50.22 The deep flexor aspect of the left forearm. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

muscular slip to join the superficial fibres directed to the ring finger, and ends in two tendons for the index and little fingers. As the tendons pass behind the flexor retinaculum, they are arranged in pairs; the superficial pair passes to the middle and ring fingers, the deep pair to the index and little fingers. The four tendons diverge distal to the carpal tunnel. Each passes towards a finger superficial to the corresponding tendon of flexor digitorum profundus. The two tendons for each finger enter the digital flexor sheath at the metacarpophalangeal joint. The superficialis tendon splits into two bundles that pass around the profundus to lie posteriorly, and then reunite to insert into the anterior surface of the middle phalanx. Some fibres interchange from one bundle to another.

An intermediate tendon is always found in the central branching area of the muscle belly and is an important landmark in deep dissection; it may be confused with the median nerve. The radial head of flexor digitorum superficialis may be absent and the muscular slip from the deep stratum may provide most or all of the fibres acting on the index finger. The fibres associated with the little finger may be absent, in which case they are replaced by a separate slip from the ulna, flexor retinaculum or palmar fascia. Variations occur in the arrangement of the tendons.

Relations Flexor digitorum superficialis runs deep to pronator teres and flexor carpi radialis. The median nerve and ulnar artery descend between the heads of flexor digitorum superficialis, and the nerve continues distally deep to the muscle.

Vascular supply The humeral head of flexor digitorum superficialis is supplied by the anterior ulnar recurrent artery. The main body of the muscle is supplied on its anterior surface by three or four branches from both the ulnar and the radial arteries. The posterior surface is supplied by the ulnar artery and median artery, and the lateral surface by additional branches from the radial artery.

Innervation Flexor digitorum superficialis is innervated by the median nerve, eighth cervical ventral ramus and first thoracic ventral ramus.

Actions Flexor digitorum superficialis is a flexor of all the joints over which it passes, i.e. the wrist, metacarpophalangeal and proximal interphalangeal joints; its precise action depends on which other muscles are acting. It has independent muscle slips to all four fingers, and is therefore able to flex the proximal interphalangeal joints individually, unlike flexor digitorum profundus, which has a muscle group common to the middle, ring and little fingers.

Testing The independent action of flexor digitorum superficialis for a particular finger is tested by flexing that digit while holding the three other fingers in full extension. This eliminates any simultaneous contraction of the flexor digitorum profundus that might flex the digit.

Palmaris longus

Attachments Palmaris longus arises from the medial epicondyle of the humerus via the common flexor origin and from adjacent intermuscular septa and deep fascia. It is a slender, fusiform muscle that runs medial to flexor carpi radialis (see Figs 49.11A, 50.20, 50.32). It becomes tendinous in the mid-forearm, and the long tendon passes anterior (superficial) to the flexor retinaculum. A few fibres leave the tendon and interweave with the transverse fibres of the retinaculum but most of the tendon passes distally. As the tendon crosses the retinaculum, it broadens out to become a flat sheet that becomes incorporated into the palmar aponeurosis. Palmaris longus is occasionally absent on one or both sides.

Relations Palmaris longus runs distally, flanked by flexor carpi radialis and flexor carpi ulnaris, and superficial to flexor digitorum superficialis. The median nerve at the wrist lies partly under the cover of the tendon of palmaris longus and partly between the tendons of palmaris longus and flexor carpi radialis.

Vascular supply The muscle belly of palmaris longus is supplied by a small branch from the anterior ulnar recurrent artery. A contribution is sometimes made by the median artery, if this is well developed.

Innervation Palmaris longus is innervated by the median nerve, seventh and eighth cervical ventral rami.

Actions Palmaris longus is a weak wrist flexor. Through its insertion in the palmar aponeurosis, it also acts as an anchor for the skin and fascia of the hand against horizontal shearing forces.

Testing If the wrist is flexed against resistance, the taut tendon of palmaris longus will be seen in the midline of the flexor wrist crease as the tendon passes superficial to the flexor retinaculum. When testing palmaris longus, it helps to oppose the thumb to the middle fingertip at the same time as the wrist is flexed, in order to make palmaris stand out.

Flexor carpi ulnaris

Attachments Flexor carpi ulnaris is the most medial of the superficial forearm flexors (see Figs 50.20, 50.31–50.32). It arises by two heads, humeral and ulnar, connected by a tendinous arch (arcuate ligament of Osborne). The smaller humeral head arises from the medial epicondyle via the common flexor origin (see Fig. 49.11A). The ulnar head has an extensive origin from the medial margin of the olecranon and proximal two-thirds of the posterior border of the ulna (from an aponeurosis shared with extensor carpi ulnaris and flexor digitorum profundus) and from the intermuscular septum between it and flexor digitorum superficialis (see Fig. 50.6). Occasionally, there is a slip from the coronoid process. A thick tendon forms along its anterolateral border in its distal half. The tendon is attached to the pisiform, and from here it is prolonged to the hamate and fifth metacarpal by pisohamate and pisometacarpal ligaments. The attachment to the flexor retinaculum and the fourth or fifth metacarpal bones is sometimes substantial.

Relations Flexor carpi ulnaris is the most medial of the forearm flexors and forms the bulk of the soft tissue cover of the medial aspect of the ulna. The ulnar nerve and posterior ulnar recurrent artery pass under

the tendinous arch between its humeral and ulnar heads. Ulnar vessels and nerve lie lateral to its tendon in the distal forearm.

Vascular supply The main arterial supply of flexor carpi ulnaris is derived from three pedicles. The proximal pedicle arises from a branch of the posterior ulnar recurrent artery as it passes between the humeral and ulnar heads. The middle pedicle arises from the ulnar artery and enters the muscle at the junction of the upper and middle thirds. The distal pedicles arise from the ulnar artery and enter the muscle at the musculotendinous junction. Flexor carpi ulnaris also receives a small supply near its origin from the inferior ulnar collateral artery.

Innervation Flexor carpi ulnaris is innervated by the ulnar nerve, seventh and eighth cervical ventral rami and first thoracic ventral ramus.

Actions Flexor carpi ulnaris is a powerful flexor and also adductor (ulnar deviation) of the wrist. When it acts with flexor carpi radialis, balanced wrist flexion is achieved. When it acts with extensor carpi ulnaris, balanced adduction occurs.

Testing Flexor carpi ulnaris is tested by palpating its tendon while the wrist is flexed against resistance, or by palpating the tendon while the patient abducts the little finger against resistance. The muscle synergistically stabilizes the pisiform, giving abductor digiti minimi a stable origin.

Deep flexor compartment

The muscles of the deep flexor compartment are flexor digitorum profundus, flexor pollicis longus and pronator quadratus (see Fig. 50.22).

Flexor digitorum profundus

Attachments Flexor digitorum profundus arises deep to the superficial flexors from the proximal three-quarters of the anterior and medial surfaces of the ulna (see Figs 50.5–50.6, 50.22). It embraces the attachment of brachialis above and extends distally almost to pronator quadratus. It also arises from a depression on the medial side of the coronoid process, from the proximal three-quarters of the posterior ulnar border by an aponeurosis that it shares with flexor and extensor carpi ulnaris, and from the anterior surface of the ulnar half of the interosseous membrane. The muscle ends in four tendons that run deep to the tendons of flexor digitorum superficialis and the flexor retinaculum. The part of the muscle that acts on the index finger is usually distinct throughout, while the tendons for the other fingers are interconnected by areolar tissue and tendinous slips as far as the palm. Anterior to their proximal phalanges, the tendons pass through the tendons of flexor digitorum superficialis to insert on the palmar surfaces of the bases of the distal phalanges. The tendons of the profundus undergo fascicular rearrangement as they pass through those of superficialis. Flexor digitorum profundus may be joined by accessory slips from the radius (which act on the index finger), flexor superficialis, flexor pollicis longus, the medial epicondyle or the coronoid process.

Relations Flexor digitorum profundus forms most of the surface elevation medial to the palpable posterior ulnar border. In the forearm, the median nerve runs on the anterior surface of its lateral aspect. In the palm, the lumbricals are attached to its tendons.

Vascular supply The origin of flexor digitorum profundus is supplied by the inferior ulnar collateral and ulnar recurrent arteries. The proximal part is supplied by one or two branches from either the ulnar or the common interosseous artery. The distal part is supplied by a series of branches from the ulnar artery, the anterior interosseous artery and the median artery.

Innervation The medial part of flexor digitorum profundus, i.e. the muscle bellies to the little and ring fingers, is innervated by the ulnar nerve. The lateral part, i.e. the muscle bellies to the middle and index fingers, is innervated by the anterior interosseous branch of the median nerve, eighth cervical ventral ramus and first thoracic ventral ramus.

Actions Flexor digitorum profundus flexes the distal interphalangeal joints of the fingers. It is also capable of flexing any or all of the joints over which it passes and therefore has a role in coordinated finger flexion. The index finger tendon is usually capable of independent function, whereas the other three work together.

Testing Flexor digitorum profundus is tested by flexing the distal interphalangeal joint while holding the proximal interphalangeal joint in extension.

Flexor pollicis longus

Attachments Flexor pollicis longus arises from the grooved anterior surface of the radius, and extends from below its tuberosity to the upper attachment of pronator quadratus (see Fig. 50.5, 50.21–50.22). It also arises from the adjacent interosseous membrane and, frequently, by a variable slip from the lateral, or more rarely the medial, border of the coronoid process, or from the medial epicondyle of the humerus. The muscle ends in a flattened tendon that passes behind the flexor retinaculum, between opponens pollicis and the oblique head of adductor pollicis, to enter a synovial sheath. It inserts on the palmar surface of the base of the distal phalanx of the thumb.

Flexor pollicis longus can sometimes be connected to flexor digitorum superficialis or profundus, or pronator teres. The interosseous attachment, and, indeed, the whole muscle, may be absent. Anomalous tendon slips from the flexor pollicis longus to flexor digitorum profundus are common.

Relations Flexor pollicis longus runs lateral to flexor digitorum profundus. The anterior interosseous nerve and vessels descend on the interosseous membrane between these muscles.

Vascular supply The medial half of flexor pollicis longus is supplied by the anterior interosseous artery. The lateral half is supplied by branches of the radial artery. The median artery may contribute if it is well developed.

Innervation Flexor pollicis longus is innervated by the anterior interosseous branch of the median nerve, seventh and eighth cervical ventral rami.

Actions Flexor pollicis longus principally flexes the phalanges of the thumb. It also flexes the carpometacarpal joint of the thumb, especially if the more distal joints are stiff or fused.

Testing Flexor pollicis longus is tested by flexing the interphalangeal joint of the thumb against resistance.

Pronator quadratus

Attachments Pronator quadratus is a flat, quadrilateral muscle that extends across the front of the distal parts of the radius and ulna (see Fig. 50.5). It arises from the oblique ridge on the anterior surface of the shaft of the ulna, the medial part of this surface and a strong aponeurosis that covers the medial third of the muscle. The fibres pass laterally and distally to the distal quarter of the anterior border and surface of the shaft of the radius (see Fig. 51.31). Deeper fibres insert into the triangular area above the ulnar notch of the radius.

Vascular supply Pronator quadratus receives its main arterial supply from the anterior interosseous artery as it passes through the interosseous membrane.

Innervation Pronator quadratus is innervated by the median nerve, seventh and eighth cervical ventral rami.

Actions Pronator quadratus is a pronator of the forearm and dynamic stabilizer of the distal radio-ulnar joint (DRUJ). The deeper fibres oppose separation of the distal ends of the radius and ulna when axial load is transmitted through the carpus.

Testing Pronator quadratus is tested by pronation of the forearm against resistance while the wrist finger flexors are relaxed. The simultaneous contraction of pronator teres makes it difficult to test the independent action of pronator quadratus.

Posterior compartment

The posterior compartment contains the extensor muscles of the forearm, brachioradialis and supinator. The superficial posterior muscles include anconeus, brachioradialis, extensor carpi radialis longus, extensor carpi radialis brevis, extensor digitorum, extensor digiti minimi and extensor carpi ulnaris. The deep posterior group of muscles includes supinator, abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus and extensor indicis.

Superficial extensor compartment

Brachioradialis

Attachments Brachioradialis is the most superficial muscle along the radial side of the forearm and forms the lateral border of the cubital

fossa (see Figs 50.22, 50.25). It arises from the proximal two-thirds of the lateral supracondylar ridge of the humerus and the anterior surface of the lateral intermuscular septum (see Figs 49.11A, 50.5). The muscle fibres end above mid-forearm level in a flat tendon that is inserted on the lateral side of the distal end of the radius, just proximal to the styloid process. This attachment may be more proximal; the muscle may fuse proximally with brachialis and the tendon may, occasionally, divide into two or three separately attached slips. In rare instances, it is double or absent.

Relations The radial nerve and the anastomosis between the profunda brachii artery and the radial recurrent artery lie in the groove between brachioradialis and brachialis, anterior to the lateral intermuscular septum. The tendon is crossed near its distal end by the tendons of abductor pollicis longus and extensor pollicis brevis. The radial artery is on its ulnar (medial) side. The superficial radial nerve emerges from between brachioradialis and extensor carpi radialis brevis to run superficially over the tendon of extensor carpi radialis brevis and extensor pollicis brevis, and then superficial to the extensor retinaculum.

Vascular supply Brachioradialis is supplied by branches of the radial recurrent artery that pierce the posteromedial surface of the muscle. It also receives branches from the radial collateral branch of the profunda brachii and directly from the radial artery in the distal part of the muscle.

Innervation Brachioradialis is innervated by the radial nerve, fifth and sixth cervical ventral rami.

Actions Brachioradialis is a powerful flexor of the elbow, acting most strongly with the forearm in mid-pronation. It is minimally active in slow flexion or with the forearm supine, but generates a powerful burst of activity in both flexion and extension when movement is rapid. Under these conditions, it develops a pronounced transarticular component of its force that helps to stabilize the elbow joint by balancing the centrifugal force of rapid swings in either direction.

Testing Brachioradialis can be seen and felt when the semi-pronated forearm is flexed against resistance.

Extensor carpi radialis longus

Attachments Extensor carpi radialis longus arises from the distal third of the lateral supracondylar ridge of the humerus and the front of the lateral intermuscular septum (see Fig. 49.11A). Some fibres join from the common tendon of origin of the forearm extensors. The muscle belly ends at the junction of the proximal and middle thirds of the forearm in a flat tendon that runs along the lateral surface of the radius, deep to abductor pollicis longus and extensor pollicis brevis. The tendon passes deep to the dorsal carpal ligament in a radial groove behind the styloid process alongside extensor carpi radialis brevis. Just before it is inserted on the radial side of the dorsal surface of the base of the second metacarpal, the tendon is crossed obliquely by the tendon of extensor pollicis longus. It may send slips to the first or third metacarpal bones and contributes to the intermetacarpal ligaments.

Relations Extensor carpi radialis longus runs alongside brachioradialis and is partly overlapped by it.

Vascular supply Extensor carpi radialis longus receives its principal arterial supply from a single branch of the radial recurrent artery. Additional blood supply comes from branches of the radial collateral branch of the profunda brachii and directly from the radial artery in the distal part of the muscle.

Innervation Extensor carpi radialis longus is innervated by the radial nerve, sixth and seventh cervical ventral rami.

Actions Extensor carpi radialis longus acts as an extensor and abductor of the wrist and midcarpal joints.

Testing The muscle belly and tendon of extensor carpi radialis longus can be palpated when the wrist is extended and abducted against resistance with the forearm pronated.

Extensor carpi radialis brevis

Attachments Extensor carpi radialis brevis arises from the lateral epicondyle of the humerus by a common tendon shared with extensor digitorum, extensor digiti minimi and extensor carpi ulnaris, the radial collateral ligament of the elbow joint, a strong aponeurosis that covers its surface, and adjacent intermuscular septa. The muscle belly ends at mid-forearm in a flat tendon that closely accompanies that of extensor carpi radialis longus to the wrist. The tendon passes under the extensor retinaculum, is crossed by the tendon of extensor pollicis longus, and is attached to the dorsal surface of the base of the third metacarpal on its radial side, distal to its styloid process, and on adjoining parts of the base of the second metacarpal. The tendons of both extensor carpi radialis longus and brevis share a common synovial sheath; they may split into slips that are variably attached to the second and third metacarpal bones. The muscles themselves may be united or may exchange muscular slips.

Relations Extensor carpi radialis brevis is shorter than extensor carpi radialis longus and is covered by it. The tendon passes deep to abductor pollicis longus and extensor pollicis brevis in the distal third of the forearm, then under the extensor retinaculum, where it lies in a shallow groove on the back of the radius, medial to the tendon of extensor carpi radialis longus, and separated from it by a low ridge.

Vascular supply Extensor carpi radialis brevis receives its arterial supply principally from two pedicles: a single branch from the radial recurrent artery, and a branch of the radial artery that arises about one-third of the way down the forearm. There is an additional blood supply proximally from branches from the radial collateral branch of the profunda brachii.

Innervation Extensor carpi radialis brevis is innervated by a branch from the radial nerve or from the posterior interosseous nerve, seventh and eighth cervical ventral rami. The branch to extensor carpi radialis brevis arises before the nerve enters the arcade of Frohse.

Actions Extensor carpi radialis brevis is the prime dorsiflexor of the wrist. It acts with extensor carpi radialis longus as an extensor and abductor of the wrist and mid-carpal joints. It acts in synergism with the finger flexors when making a fist.

Testing The muscle belly and tendon of extensor carpi radialis brevis can be palpated when the wrist is extended and abducted against resistance with the forearm pronated.

'Mobile wad' of Henry

Available with the *Gray's Anatomy* e-book

Extensor digitorum

Attachments. Extensor digitorum arises from the lateral epicondyle of the humerus via the common extensor tendon, the adjacent intermuscular septa and the antebrachial fascia (see Fig. 49.11A). The muscle belly divides in the distal third of the forearm into four tendons, which pass in a common synovial sheath with the tendon of extensor indicis through a tunnel under the extensor retinaculum. The tendons diverge on the dorsum of the hand, one to each finger. The tendon to the index finger is accompanied by extensor indicis, which lies ulnar (medial) to it. On the dorsum of the hand, adjacent tendons are linked by three variable intertendinous connections (juncturae tendinae), which are inclined distally and radially (see Figs 50.23, 51.11). The digital attachments enter a fibrous expansion on the dorsum of the proximal phalanges, to which lumbrical, interosseous and digital extensor tendons all contribute.

The tendons of extensor digitorum may be variably deficient. More commonly, they are doubled, or even tripled, in one or more digits: most often, the index finger or the middle finger. Occasionally, a slip of tendon passes to the thumb. The arrangement of the intertendinous connections on the dorsum of the hand is highly variable. The medial connection is strong and pulls the tendon of the little finger towards that of the ring finger, whereas the connection between the middle two tendons is weak and may be absent.

Relations The extensor tendon to the index finger lies radial (lateral) to the tendon of extensor indicis. The extensor tendon to the little finger lies radial (lateral) to the tendon of extensor digiti minimi.

Vascular supply The proximal third of extensor digitorum is supplied by branches from the radial recurrent artery, and the distal two-thirds are supplied by branches from the posterior interosseous artery. The very distal portion is supplied by a perforating branch from the anterior interosseous artery that passes through the interosseous membrane.

Innervation Extensor digitorum is innervated by the posterior interosseous nerve (seventh and eighth cervical ventral rami).

Actions Extensor digitorum can extend any or all of the joints over which it passes: wrist, metacarpophalangeal, and proximal and distal

Henry (1957) described a 'mobile wad' of three muscles, brachioradialis and the extensors carpi radialis longus and brevis, which are visible and palpable below the lateral epicondyle of the humerus, lying on the lateral aspect of the radius. The wad is tethered by a fan-shaped leash of vessels derived from the radial artery (the radial recurrent artery) that has to be released before the muscles can be fully mobilized. Its anterior and posterior margins are used to define the surgical approaches to the radius and to discover planes of cleavage. The anterior margin is used to define the anterior approach (of Henry) to the radius and can be extended down to the wrist at the level of the insertion of brachioradialis. This requires detachment of supinator from the radius, taking care not to damage the posterior interosseous nerve. More distally, pronator teres is released. This approach is particularly useful for plating fractures of the radius. The posterior margin is used to expose the posterior aspect of the forearm (posterior approach of Thompson) and, if need be, the posterior interosseous nerve, which, in any event, should be protected; unlike the anterior approach, this approach cannot be extended.

interphalangeal joints (the latter two via the extensor expansion of the digits). When acting on the metacarpophalangeal joints, extensor digitorum tends to spread the digits apart because of the different axes of the individual joints imposed by the transverse arch of the hand. The intertendinous bands stabilize the individual tendons as they cross the dorsum of the hand and permit some extension when a tendon has been divided in the metacarpal segment. The extent to which this occurs depends on the presence and orientation of the juncturae tendinae.

Testing The tendons of extensor digitorum can be readily felt, and usually seen, when the fingers are extended against resistance and the forearm is pronated.

Extensor digiti minimi

Attachments Extensor digiti minimi is medial to, and usually covered by, extensor digitorum; proximally, the bellies of these two muscles may be connected and indistinct from each other, whereas, in the mid-forearm, extensor digiti minimi is clearly discernible as a slender muscle (Fig. 50.23). It arises from the common extensor tendon by a thin, tendinous slip and adjacent intermuscular septa, and frequently has an additional origin from the antebrachial fascia. It forms a long tendon that constitutes the fifth dorsal compartment as it proceeds beneath the extensor retinaculum. Distal to the retinaculum, the tendon typically splits into two, and the lateral slip is joined by a tendon from extensor digitorum. All three tendons are attached to the dorsal digital expansion of the fifth digit; there may be a slip to the fourth digit. Extensor digiti minimi is rarely absent but, sometimes, it is fused with extensor digitorum.

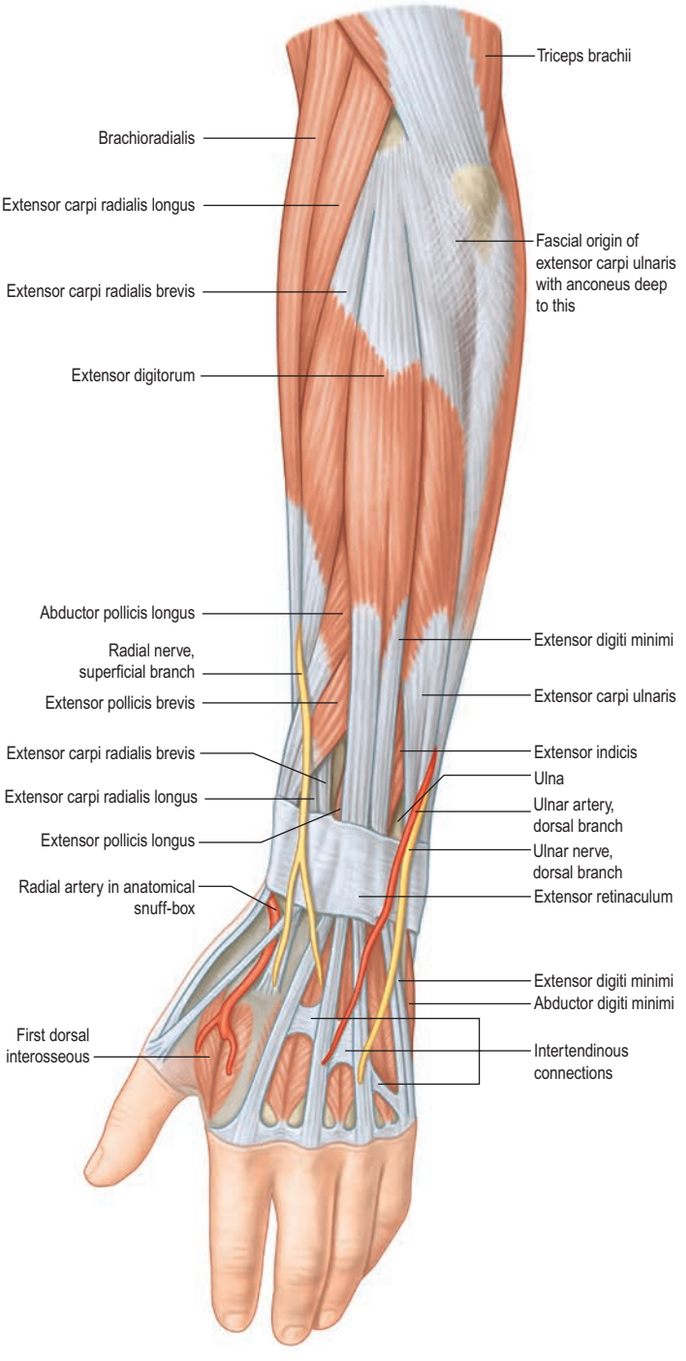

Fig. 50.23 The superficial extensor muscles of the left forearm.

Relations The tendon of extensor digiti minimi lies ulnar (medial) to the common extensor tendon to the little finger. The dorsal branch of the ulnar artery and the dorsal branch of the ulnar nerve pass superficial to the extensor retinaculum and cross the tendon of extensor digiti minimi as it lies beneath the retinaculum.

Vascular supply Extensor digiti minimi is supplied by branches from the radial recurrent and posterior interosseous arteries, and by terminal branches from the anterior interosseous artery after it has pierced the interosseous membrane.

Innervation Extensor digiti minimi is innervated by the posterior interosseous nerve (seventh and eighth cervical ventral rami).

Actions Extensor digiti minimi can extend any of the joints of the little finger, or contribute to wrist extension. It permits extension of the little finger independently of the other digits, even in extremes of ulnar or radial wrist deviation.

Testing Extensor digiti minimi is tested by extending the little finger while holding the remaining fingers flexed at the metacarpophalangeal joints; this eliminates any simultaneous contraction of extensor digitorum.

Extensor carpi ulnaris

Attachments Extensor carpi ulnaris arises from the lateral epicondyle (where it forms the most medial part of the common extensor origin), the posterior border of the ulna (by an aponeurosis shared with flexor carpi ulnaris and flexor digitorum profundus) and overlying fascia (see Fig. 50.6). It runs between extensor digiti minimi and anconeus proximally, and extensor digiti minimi and flexor carpi ulnaris in the mid-forearm (see Figs 50.31–50.32). It forms a tendon in the distal third of the forearm that slides in a groove between the head and the styloid process of the ulna. It forms the content of the sixth dorsal compartment as it runs under the extensor retinaculum and is attached to a tubercle on the medial side of the base of the fifth metacarpal.

Vascular supply Proximally, extensor carpi ulnaris receives branches from the radial recurrent artery. Distally, it is supplied by several branches from the posterior interosseous artery.

Innervation Extensor carpi ulnaris is innervated by the posterior interosseous nerve (seventh and eighth cervical ventral rami).

Actions Extensor carpi ulnaris works synergistically with extensors carpi radialis longus and brevis and the digital flexors to effect balanced wrist extension, enabling a power grip with a clenched fist. It also acts with flexor carpi ulnaris to adduct the hand.

Testing The tendon can be felt lateral to the groove that overlies the posterior subcutaneous border of the ulna when the wrist is adducted against resistance.

Anconeus

Attachments Anconeus is a short, triangular muscle posterior to the elbow joint, partially and variably blended with triceps or extensor carpi ulnaris (Fig. 50.24). It arises by a separate tendon from the posterior surface of the lateral epicondyle of the humerus, proximal to the common extensor tendon. The tendon lies beneath the muscle belly of extensor carpi radialis longus. The muscle fibres run obliquely and medially towards the ulna, covering the posterior aspect of the anular ligament, and are attached to the lateral aspect of the olecranon and proximal quarter of the posterior surface of the shaft of the ulna.

An accessory muscle, anconeus epitrochlearis, may be present in up to one-third of individuals and has been reported to be an occasional cause of cubital tunnel syndrome (Grewal et al 2019).

Vascular supply Anconeus is supplied by branches of the posterior interosseous recurrent artery. A small number of musculocutaneous perforators reach the skin overlying the muscle.

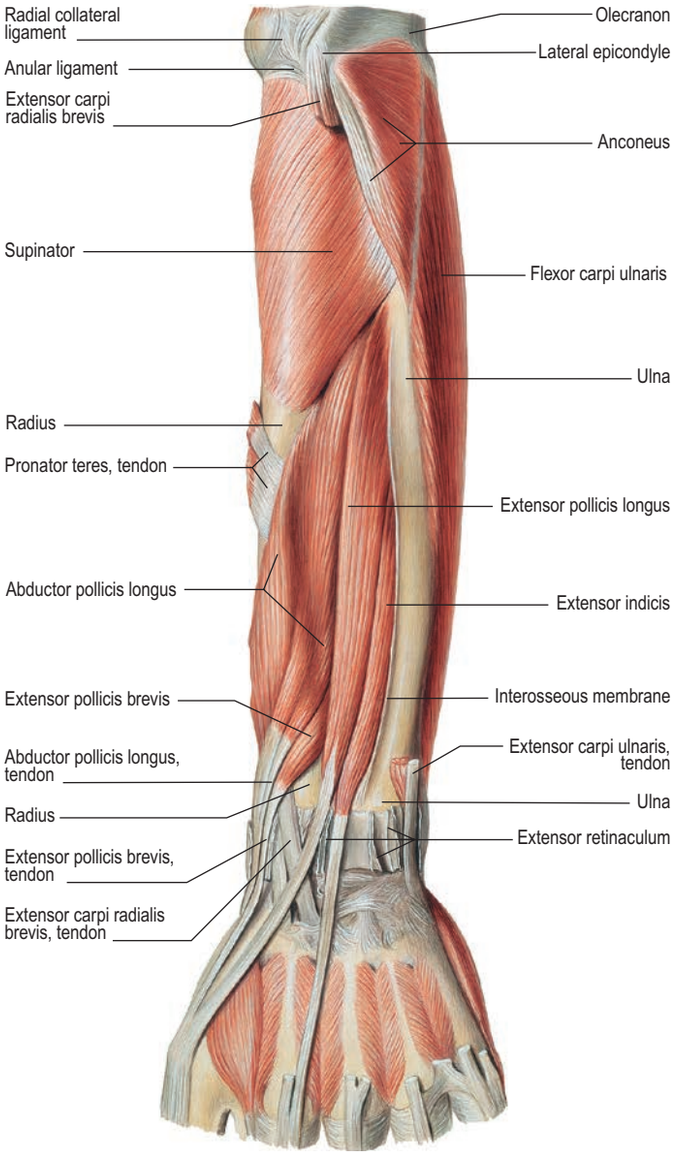

Fig. 50.24 The deep extensor muscles of the forearm. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Innervation Anconeus is innervated by the radial nerve (sixth, seventh and eighth cervical ventral rami).

Actions Anconeus is an extensor of the elbow. Its principal function is not fully understood but it may control ulnar abduction in pronation, which is necessary if the forearm is to turn over the hand without translating it medially. In this way, a tool can be revolved 'on the spot' or it can be swept through an arc.

Deep extensor compartment

The five deep forearm extensor muscles are abductor pollicis longus, extensor pollicis longus and extensor pollicis brevis (all of which act on the thumb), extensor indicis and supinator. Apart from supinator, the other four deep forearm extensors all arise from the bones of the forearm and do not, therefore, act on the elbow.

Abductor pollicis longus

Attachments Abductor pollicis longus arises in part from the posterior surface of the shaft of the ulna, just distal to the insertion of anconeus, and from the adjoining interosseous membrane (see Fig. 50.6). The muscle runs obliquely in a lateral and distal direction from an apex formed by anconeus and supinator, and is joined by fibres that arise from the middle third of the posterior surface of the radius distal to the attachment of supinator (see Fig. 50.24). As it proceeds distally, abductor pollicis longus becomes more superficial in the forearm, where it is visible as an oblique elevation. The muscle fibres form a tendon just proximal to the wrist. The tendon runs in a groove on the lateral side of the distal end of the radius, accompanied by the tendon of extensor pollicis brevis. It runs under the extensor retinaculum in the first dorsal compartment. It usually splits into two slips; one is attached to the radial side of the first metacarpal base, and the other is attached to the trapezium. Slips from the tendon may continue into opponens pollicis or abductor pollicis brevis. Occasionally, the muscle itself may be wholly or partially divided.

Relations Abductor pollicis longus runs on the radial aspect of extensor pollicis longus. The posterior interosseous nerve runs over the belly of abductor pollicis longus with the accompanying posterior interosseous artery; the nerve runs to the border of abductor pollicis longus and then dives between the muscles bellies of abductor pollicis longus and extensor pollicis longus at the apex of their divergence.

Vascular supply Abductor pollicis longus is supplied proximally by a lateral branch from the posterior interosseous artery. Distally, it is supplied on the medial side by a perforating branch from the anterior interosseous artery.

Innervation Abductor pollicis longus is innervated by the posterior interosseous nerve (seventh and eighth cervical ventral rami).

Actions Abductor pollicis longus abducts the metacarpal of the thumb. It is the prime radial abductor of the thumb. It also acts to abduct the wrist. With abductor pollicis brevis, it effects palmar abduction.

Testing The tendon of abductor pollicis longus can be seen and felt at the radial aspect of the anatomical snuff-box when the thumb and wrist are abducted against resistance at the carpometacarpal joint.

Extensor pollicis longus

Attachments Extensor pollicis longus arises from the lateral part of the middle third of the posterior surface of the shaft of the ulna below abductor pollicis longus and from the adjacent interosseous membrane. It partly overlies the proximal attachment of the smaller extensor pollicis brevis (see Fig. 50.24). The tendon is formed just proximal to the wrist and passes through the third compartment of the extensor retinaculum in a narrow, oblique groove on the back of the distal end of the radius. It turns around a bony fulcrum, Lister's tubercle, which changes its line of pull from that of the forearm to that of the thumb, and is attached to the base of the distal phalanx of the thumb. The sides of the tendon are joined on the dorsum of the proximal phalanx by expansions from the tendon of abductor pollicis brevis laterally and from the first palmar interosseous and adductor pollicis medially.

Relations Extensor pollicis longus runs between abductor pollicis longus and extensor indicis in the forearm. The posterior interosseous artery runs over its muscle belly. After passing around Lister's tubercle, the tendon of extensor pollicis longus crosses the tendons of extensor carpi radialis brevis and longus obliquely.

Vascular supply Extensor pollicis longus is supplied on its superficial surface by branches from the posterior interosseous artery, and on its deep surface by perforating branches from the anterior interosseous artery.

Innervation Extensor pollicis longus is innervated by the posterior interosseous nerve (seventh and eighth cervical ventral rami).

Actions Extensor pollicis longus extends the distal phalanx of the thumb. Acting in association with extensor pollicis brevis and abductor pollicis longus, it extends the proximal phalanx and the metacarpal. In continued action, as a consequence of the obliquity of its tendon, extensor pollicis longus adducts the extended thumb and rotates it laterally. It is a weak extensor of the wrist.

Testing The tendon of extensor pollicis longus can be palpated at the ulnar border of the anatomical snuff-box when the thumb is extended at the interphalangeal joint against resistance. When the thumb is opposed and adducted, abductor pollicis brevis can extend the interphalangeal joint of the thumb, mimicking the action of extensor pollicis longus.

Extensor pollicis brevis

Attachments Extensor pollicis brevis arises from the posterior surface of the radius distal to abductor pollicis longus and from the adjacent interosseous membrane (see Fig. 50.6). It runs between abductor pollicis longus and extensor pollicis longus. The tendon is attached to the base of the proximal phalanx of the thumb and, commonly, has an additional

attachment to the base of the distal phalanx, usually through a fasciculus that joins the tendon of extensor pollicis longus. Extensor pollicis brevis may be absent or fused completely with abductor pollicis longus.

Relations Extensor pollicis brevis is ulnar (medial) to, and closely connected with, abductor pollicis longus. In the distal forearm, the two muscles emerge between extensor carpi radialis brevis and extensor digitorum, and pass obliquely across the tendons of extensors carpi radialis brevis and longus (see Fig. 50.24). They cover the distal part of brachioradialis, and pass through the most lateral compartment of the extensor retinaculum in a single synovial sheath, sharing a groove in the distal radius. Ultimately, they cross, superficial to the radial styloid process and radial artery, to reach the dorsolateral base of the proximal phalanx of the thumb.

Vascular supply Extensor pollicis brevis is supplied from branches from the posterior interosseous artery, together with perforating branches from the anterior interosseous artery.

Innervation Extensor pollicis brevis is innervated by the posterior interosseous nerve (seventh and eighth cervical ventral rami).

Actions Extensor pollicis brevis extends the proximal phalanx and metacarpal of the thumb.

Testing The tendon of extensor pollicis brevis can be felt at the radial border of the anatomical snuff-box, lying medial to the tendon of abductor pollicis longus, when the metacarpophalangeal joint of the thumb is extended against resistance.

Extensor indicis

Attachments Extensor indicis is a narrow muscle that lies medial and parallel to extensor pollicis longus (see Fig. 50.24). It arises from the posterior surface of the ulna distal to extensor pollicis longus and the adjacent interosseous membrane. The tendon is formed just proximal to the wrist and passes under the extensor retinaculum in a common compartment with the tendons of extensor digitorum (see Fig. 51.11). Opposite the head of the second metacarpal, it joins the ulnar side of the tendon of extensor digitorum that serves the index finger. Extensor indicis occasionally sends accessory slips to the extensor tendons of other digits. Its tendon may be interrupted on the dorsum of the hand by an additional muscle belly (extensor indicis brevis manus) (Georgiev et al 2018).

Relations The posterior interosseous artery passes over the muscle belly of extensor indicis. On the dorsum of the hand, the tendon of extensor indicis lies on the ulnar aspect of the tendon of extensor digitorum to the index finger.

Vascular supply Extensor indicis is supplied on its superficial surface by branches from the posterior interosseous artery, and on its deep surface by perforating branches from the anterior interosseous artery.

Innervation Extensor indicis is innervated by the posterior interosseous nerve (seventh and eighth cervical ventral rami).

Actions Extensor indicis extends the index finger independently of the other digits. It is a weak extensor of the wrist.

Testing Extensor indicis is tested by extending the index finger while holding the remaining fingers flexed at the metacarpophalangeal joints in order to eliminate the effects of any simultaneous contraction of extensor digitorum.

Supinator

Attachments Supinator is a wide muscle that surrounds the proximal third of the radius. It has superficial and deep layers The two parts arise together, the superficial by tendinous fibres, and the deep by muscular fibres, from the lateral epicondyle of the humerus; the radial collateral ligament of the elbow joint; the anular ligament of the superior radio-ulnar joint; the supinator crest of the ulna and the posterior part of the triangular depression in front of it; and an aponeurosis that covers the muscle (see Figs 50.5–50.6; **Figs 50.25–50.26**). Supinator is attached distally to the lateral surface of the proximal third of the radius, down to the insertion of pronator teres. The radial attachment extends onto the anterior and posterior surfaces between the anterior oblique line and the fainter posterior oblique 'ridge'. Supinator is subject to frequent variation; small parts have acquired individual names, e.g. lateral and medial tensors of the anular ligament (Paraskevas and Ioannidis 2011).

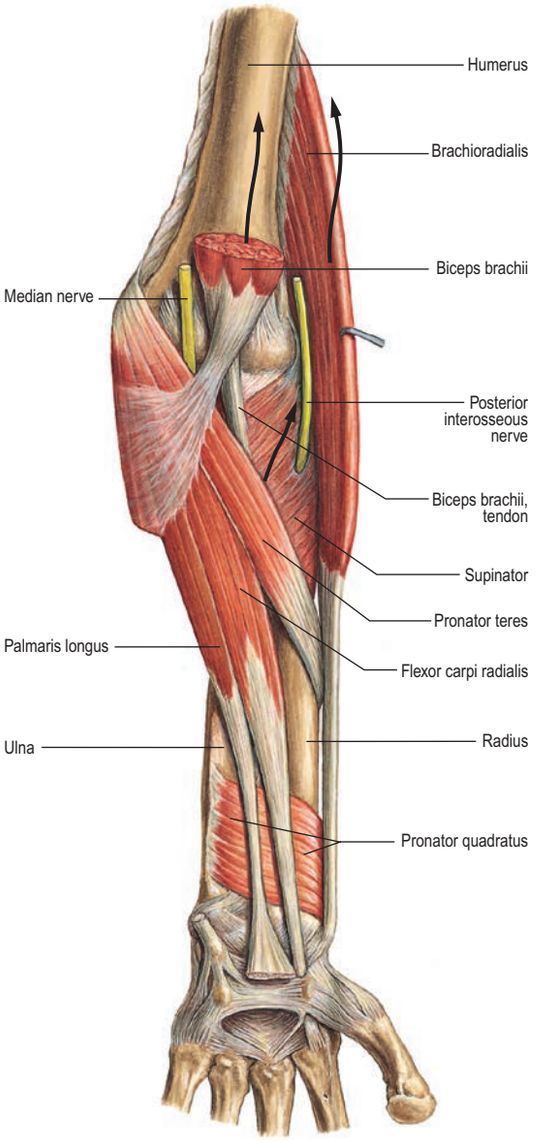

Fig. 50.25 The supinated forearm. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Relations Supinator emerges under the lower border of anconeus and is related to abductor pollicis longus at its inferior medial border. Extensor carpi radialis brevis and longus pass over its radial aspect. The posterior interosseous nerve enters the forearm by passing between its superficial and deep heads.

Vascular supply The superficial part of supinator is supplied by branches from the radial recurrent artery. The deep part of supinator is supplied by branches from the posterior interosseous artery and the posterior interosseous recurrent artery.

Innervation Supinator is innervated by the posterior interosseous nerve (sixth and seventh cervical ventral rami).

Actions Supinator rotates the radius to bring the palm to face anteriorly. It acts alone in slow, unopposed supination, and together with biceps brachii in fast or forceful supination. An object, which potentially may be heavy, is often picked up with the forearm initially pronated. The more powerful supinator lifts the object against gravity; rotation is often combined with increasing elbow flexion in order to bring the object towards the eyes.

Testing Supinator lies too deep to be palpated. It may be assessed by supinating the forearm against resistance with the elbow extended, on the grounds that biceps brachii is inactive on supination when the elbow is fully extended.

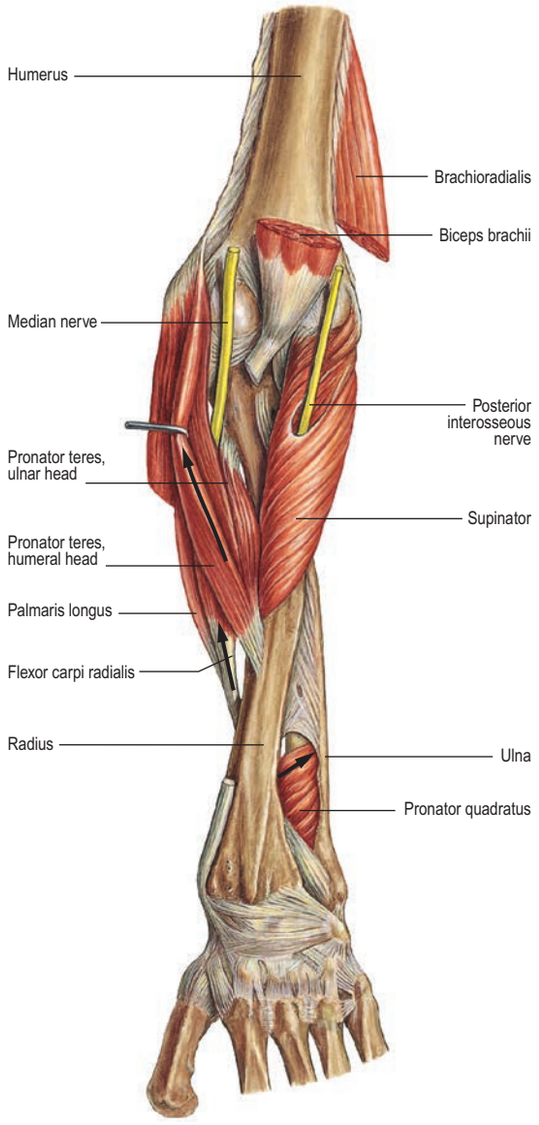

Fig. 50.26 The pronated forearm. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Compartment syndrome of the forearm

Available with the *Gray's Anatomy* e-book

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

Brachial artery

The brachial artery is medial in the arm but moves towards the midline, medial to the tendon of biceps brachii and deep to the bicipital aponeurosis. The latter separates the artery from the anterior structures, namely: the skin, superficial fascia and the median cubital vein. Posteriorly, brachialis separates it from the elbow joint. The median nerve passes close to the medial side of the artery. The artery divides into its terminal branches, the radial and ulnar arteries, at the level of the radial neck (Fig. 50.27).

Radial artery

The radial artery is smaller than the ulnar artery, yet appears a more direct continuation of the brachial artery (see Figs 50.21–50.22). It passes deep to brachioradialis and gives off the radial recurrent artery before continuing into the forearm. It descends along the lateral side of the forearm, accompanied by paired venae comitantes, from the medial side of the neck of the radius to the wrist. The artery is medial to the radial shaft proximally, and anterior to it distally. Proximally, it is overlapped anteriorly by the belly of brachioradialis, but elsewhere in its course it is covered only by the skin and superficial and deep fasciae. Its posterior relations in the forearm are, successively, the tendon of biceps, supinator, the distal attachment of pronator teres, the radial head of flexor digitorum superficialis, flexor pollicis longus, pronator quadratus and the lower end of the radius (where its pulsation is most accessible). Brachioradialis is lateral to the artery throughout its length. Pronator teres is medial to the proximal part of the artery, and the tendon of flexor carpi radialis is medial to the distal portion. The superficial radial nerve lies lateral to the middle third of the radial artery; multiple branches from the artery supply the nerve throughout its length.

The radial artery may occasionally arise from a continuation of a superficial brachial artery, or as a high proximal division of an otherwise normal brachial artery. It can give rise to the common interosseous artery.

Branches in the forearm

Radial recurrent artery The radial recurrent artery is given off by the radial artery just distal to the elbow joint (see Figs 50.21–50.22, 50.27). It passes between the superficial radial nerve and the posterior interosseous nerve before ascending beneath brachioradialis, anterior to supinator and brachialis. It supplies these muscles and then anastomoses with the radial collateral branch of the profunda brachii artery. The radial recurrent artery also gives branches to extensor carpi radialis longus, extensor digitorum, extensor digiti minimi and extensor carpi ulnaris. Its cutaneous branches are described on page 932.

Muscular branches Muscular branches are distributed to the muscles on the radial side of the forearm. Direct branches from the radial artery supply the radial insertion of pronator teres, the anterolateral aspect of flexor carpi radialis, the lateral surface of flexor digitorum superficialis, the lateral half of flexor pollicis longus, and the distal sections of extensor carpi radialis longus and extensor carpi radialis brevis.

Ulnar artery

The ulnar artery arises from the brachial artery just distal to the flexion crease of the elbow at the level of the radial neck, and reaches the medial side of the forearm in its upper third (see Figs 50.21–50.22). It is larger than the radial artery and is accompanied throughout its length by venae comitantes. In the forearm, the ulnar artery initially lies on brachialis

A compartment syndrome exists where increased pressure in an osseofascial compartment leads to decreased perfusion of the contents of the compartment. In the forearm, this commonly occurs as a result of trauma, external pressure, burns, arterial injury or post-ischaemic swelling. The resultant increase in interstitial pressure causes vascular occlusion and myoneural ischaemia. The patient presents with pain that is disproportionate to the severity of the injury and which is provoked or markedly increased by passive extension of the fingers. There may also be reduced sensation or paraesthesiae in the affected hand. If a compartment syndrome is suspected, compartment pressure measurements may be indicated, but, in unequivocal cases, the definitive treatment is emergency fasciotomies of the forearm. The absolute intracompartmental pressure threshold for decompression is the subject of debate: an absolute value of 30 mmHg is generally accepted, although some authorities prefer a figure that comes within 30 mmHg of diastolic pressure. The pressure in each compartment should be measured separately.

Incisions to decompress the flexor compartment (Ronel et al 2004) run from the medial epicondyle and curve down the anterior aspect of the forearm, ending on the radial side of flexor carpi ulnaris; from here, they may be extended distally to decompress the carpal tunnel, if necessary. The bicipital aponeurosis (lacertus fibrosus) is routinely released to decompress the median nerve. After retraction of the superficial flexors, the fascia over the deep muscles of the forearm may be incised over its full length. Both median and ulnar nerves should be inspected to ensure that their decompression is complete. The mobile wad and dorsal compartment are decompressed through a straight longitudinal incision that starts just distal to the lateral epicondyle; this is deepened through the plane between extensor digitorum and extensor carpi radialis brevis, and ends over the midline of the wrist. In both cases, the wounds are left open and dressed, and only closed when circumstances permit.

Failure to decompress a compartment syndrome promptly may lead to Volkmann's ischaemic contracture with severe loss of function in the affected forearm and hand. Subsequent amputation is not unknown.

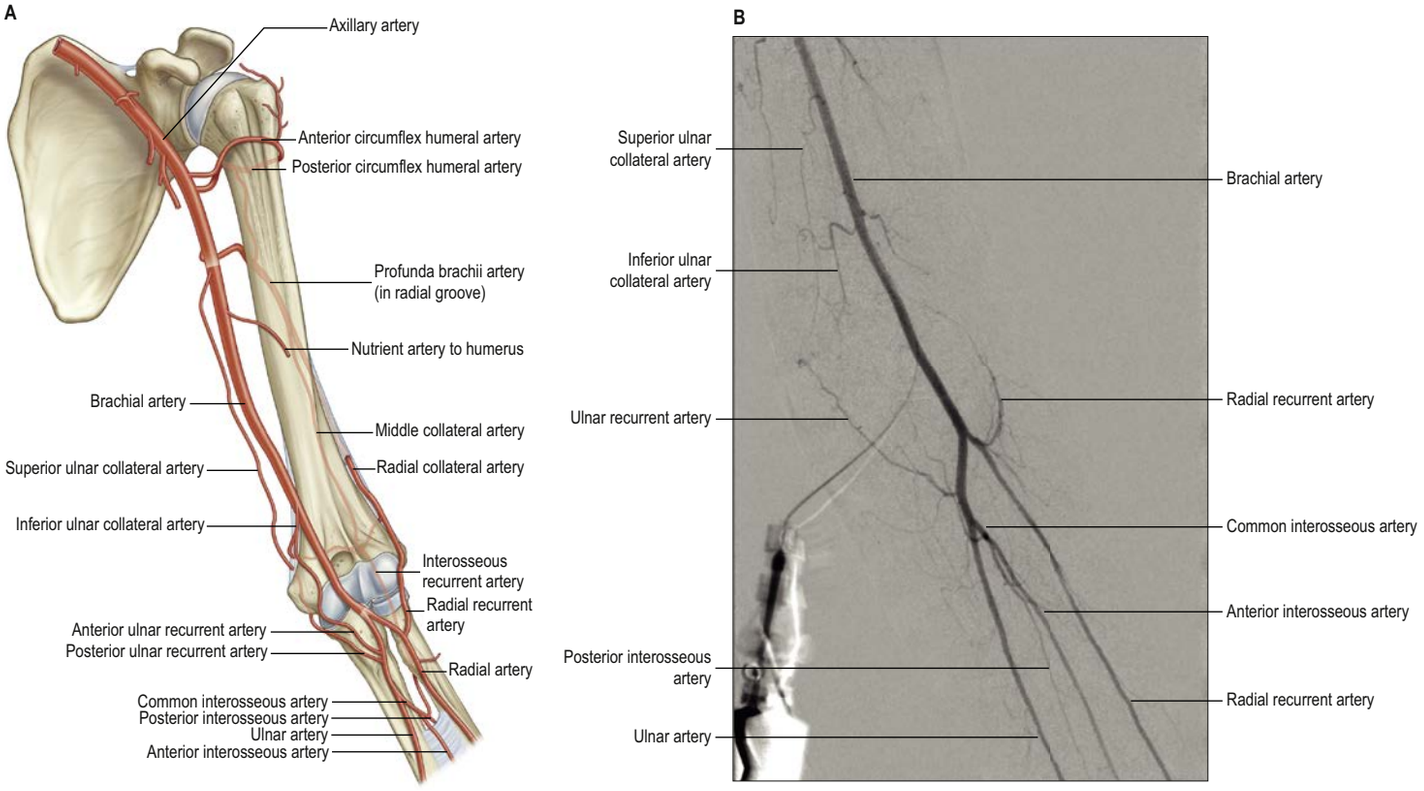

Fig. 50.27 **A**, Arterial anastomoses around the left elbow joint, anterior aspect. **B**, Digital subtraction angiogram of the left brachial to forearm arteries, injected via a catheter in the distal left brachial artery. The catheter and syringe filled with contrast medium (bottom left) cast a 'shadow' because they have moved between the initial subtraction mask and the acquisition run.

before passing deep to pronator teres, flexor carpi radialis, palmaris longus and flexor digitorum superficialis. It then lies on flexor digitorum profundus, between flexor carpi ulnaris and flexor digitorum superficialis, and is covered by the skin and superficial and deep fasciae. The artery crosses the flexor retinaculum, lateral to the ulnar nerve and pisiform bone, to enter the hand. The median nerve is a medial relation for approximately 2.5 cm distal to the elbow, and then crosses the artery, from which it is separated by the ulnar head of pronator teres. The ulnar nerve lies medial to the distal two-thirds of the artery, which supplies the nerve throughout its length; the palmar cutaneous branch of the ulnar nerve descends along the ulnar artery to reach the hand.

The ulnar artery may arise above the elbow, when it can lie superficial to the forearm flexors under the deep fascia; only rarely is it subcutaneous. When this occurs, the brachial artery supplies the common interosseous and the ulnar recurrent arteries.

Branches in the forearm

Anterior ulnar recurrent artery The anterior ulnar recurrent artery arises from the ulnar artery distal to the elbow and close to the origin of the ulnar artery itself. It ascends between brachialis and pronator teres, which it supplies, then anastomoses with the inferior ulnar collateral artery anterior to the medial epicondyle (see Fig. 50.27A). It limits distal extension of the medial Hotchkiss approach to the coronoid process.

Posterior ulnar recurrent artery The posterior ulnar recurrent artery arises from the ulnar artery distal to the anterior ulnar recurrent artery, passes dorsomedially between flexor digitorum profundus and flexor digitorum superficialis, and ascends between the posterior aspect of the medial epicondyle and the olecranon. It is deep to flexor carpi ulnaris, ascending between its heads with the ulnar nerve. It supplies flexor digitorum profundus, flexor digitorum superficialis, flexor carpi ulnaris, the ulnar nerve, underlying bone and the elbow joint, and anastomoses with the ulnar collateral artery and interosseous recurrent artery. The posterior ulnar recurrent artery and ulnar nerve are both vulnerable to injury behind the medial epicondyle (**Figs 50.28–50.29**).

Common interosseous artery The common interosseous artery is a short branch of the ulnar artery (see Figs 50.10, 50.22). It arises just distal to the radial tuberosity and passes back to the proximal border of the interosseous membrane, where it divides into the anterior and posterior interosseous arteries. Occasionally, the common interosseous artery is a branch of the radial artery.

Anterior interosseous artery The anterior interosseous artery arises from the common interosseous artery and descends on the anterior aspect of the interosseous membrane with the anterior interosseous branch of the median nerve (see Figs 50.10, 50.22, 50.27, 50.32). It is overlapped by contiguous sides of flexor digitorum profundus and flexor pollicis longus. Shortly after its origin, it usually gives off a slender median artery. This accompanies and supplies the median nerve as far as the palm, where it may join the superficial palmar arch or end as one or two palmar digital arteries. The median artery can also arise from the ulnar or the common interosseous artery. Muscular and nutrient branches from the anterior interosseous artery pierce the interosseous membrane to supply deep extensor muscles and the radius and ulna, respectively. A branch descends deep to pronator quadratus before piercing the interosseous membrane to join the anterior 'carpal' arch.

The anterior interosseous artery leaves the anterior compartment by piercing the interosseous membrane proximal to pronator quadratus. It anastomoses with the posterior interosseous artery in the posterior compartment of the forearm, and travels through a tunnel under the extensor retinaculum with the tendons of the digital extensors before joining the dorsal carpal arch. Three small cutaneous perforating branches supply the skin over the lower lateral border of the forearm.

Posterior interosseous artery The posterior interosseous artery arises from the common interosseous artery and is usually smaller than the anterior interosseous artery (see Figs 50.10, 50.27A). It passes dorsally between the oblique cord and proximal border of the interosseous membrane, and then between supinator and abductor pollicis longus. It descends deep in the groove between extensor carpi ulnaris and the extensor digiti minimi component of extensor digitorum. While in the groove, it gives rise to multiple muscular branches that supply these muscles and fasciocutaneous perforators that travel in the intermuscular septum between extensor carpi ulnaris and extensor digiti minimi. The posterior interosseous artery accompanies the deep branch of the radial nerve (posterior interosseous nerve) on abductor pollicis longus. Distally, it anastomoses with the terminal part of the anterior interosseous artery and the dorsal carpal arch.

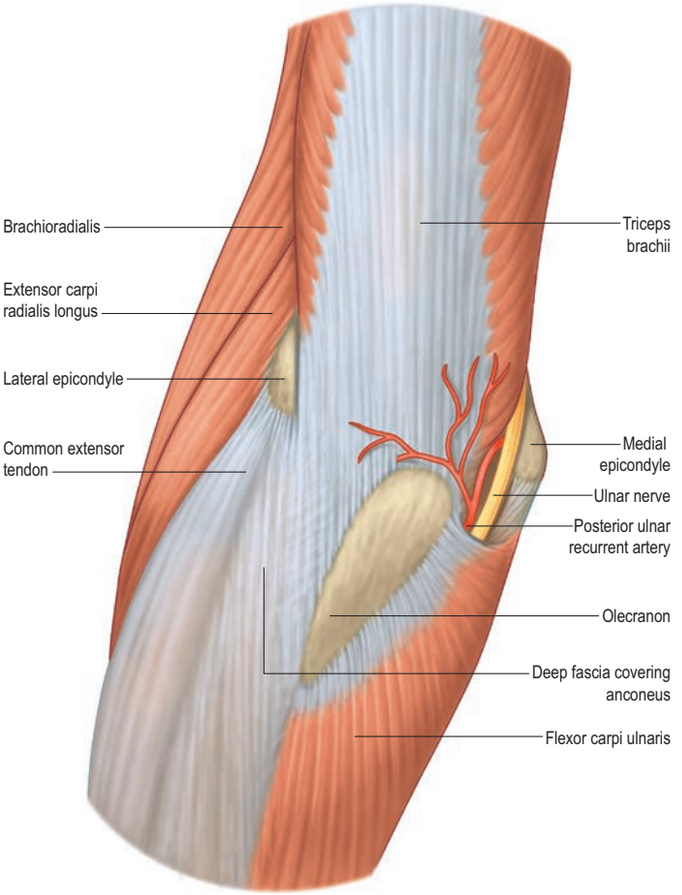

Fig. 50.28 The posterior aspect of the left elbow: superficial structures.

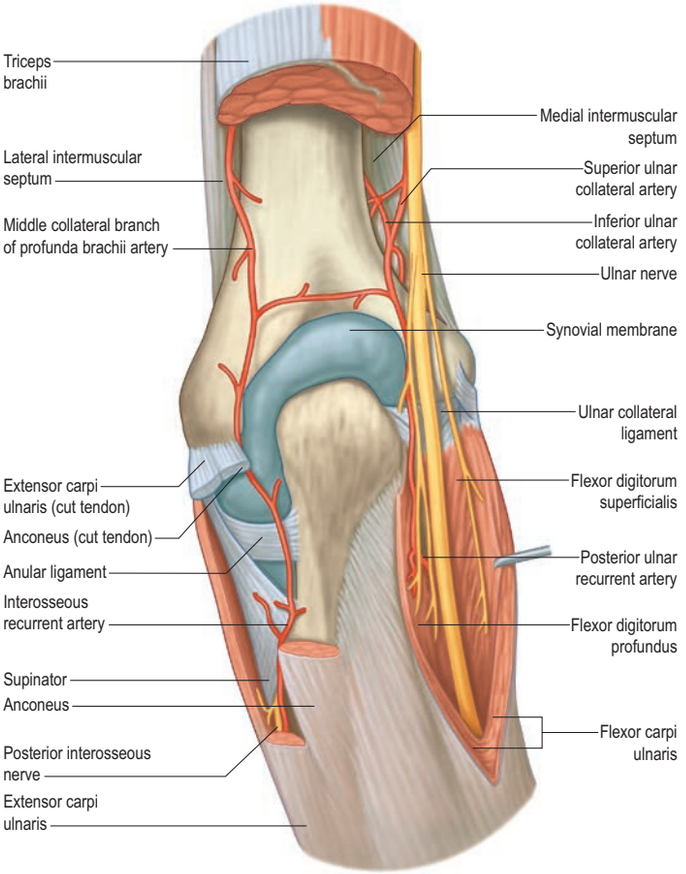

Fig. 50.29 The posterior aspect of the left elbow region: deep structures.

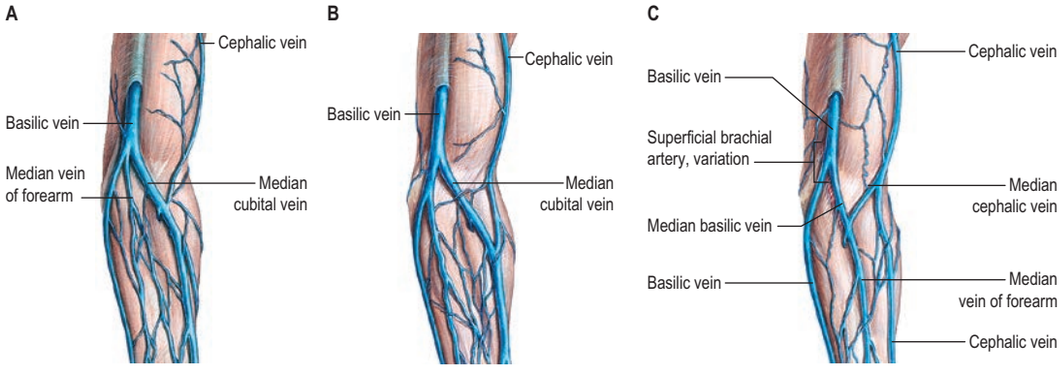

Fig. 50.30 A–C, Variations in the superficial veins of the left cubital fossa. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Sometimes, the posterior interosseous artery disappears halfway down the forearm, in which case the anterior interosseous artery pierces the interosseous membrane more proximally to anastomose with it. Occasionally, the two vessels do not anastomose.

Posterior interosseous recurrent artery The posterior interosseous recurrent artery leaves the posterior interosseous artery near its origin and ascends between the lateral epicondyle and olecranon, either on or through supinator, and deep to anconeus. It anastomoses with the middle collateral branch of the profunda brachii artery, posterior ulnar recurrent artery and ulnar collateral artery. Occasionally, the artery is absent. Its cutaneous branches are described on page 932.

Collateral circulation at the elbow

The collateral circulation at the elbow is more robust than that at the knee. Alternative pathways include the profunda brachii artery, which accompanies the radial nerve through the lateral intermuscular septum to become the radial collateral artery. The superior ulnar collateral artery accompanies the ulnar nerve: in the adult, it may be as wide as 1.5 mm at its origin; hence its regular use as the artery to a free vascularized ulnar nerve graft. The inferior ulnar collateral artery is regularly seen during medial approaches to the elbow as a vessel that pierces the intermuscular septum to curl around the humerus between triceps and bone. On occasion, there is a substantial artery running with the median nerve. These vessels anastomose with recurrent branches from the ulnar and radial arteries to form a network that may maintain perfusion of the hand and the extensor muscles in cases where the brachial artery has been divided in the lower third of the arm (when there is no associated fracture or dislocation). Collateral circulation will diminish or cease altogether if the ulnar or radial nerve is entrapped within the fracture or compressed by haematoma (Blakey et al 2009, Birch 2011).

Veins

Deep veins

Venae comitantes run with the radial and ulnar arteries to drain the deep and superficial palmar venous arches, respectively. They unite near the elbow as paired brachial veins. The radial veins are smaller and receive the deep dorsal veins of the hand. The ulnar veins are larger and drain the deep palmar venous arch. They connect with superficial veins near the wrist and receive the venae comitantes of the anterior and posterior interosseous arteries near the elbow. A large branch connects them to the median cubital vein.

Superficial veins

Cephalic vein

The cephalic vein usually forms over the anatomical snuff-box on the radial side of the wrist from the radial end of the dorsal venous plexus (see Figs 48.4, 51.3). It curves proximally around the radial side of the forearm, receiving tributaries from both radial and ulnar aspects of the forearm. Distal to the elbow, a branch, the median cubital vein, diverges proximomedially to reach the basilic vein. The median cubital vein is joined by a branch from the deep veins (**Fig. 50.30**). The further course of the cephalic vein is described in Chapter 49 and Chapter 81.

Accessory cephalic vein The accessory cephalic vein may arise either from a dorsal forearm plexus or from the ulnar side of the dorsal venous network in the hand. It joins the cephalic vein distal to the elbow. A large oblique vein often connects the basilic and cephalic veins dorsally in the forearm.

Basilic vein

The basilic vein arises medially in the dorsal venous network of the hand (see Figs 48.4, 51.3). It ascends posteromedially in the forearm, inclining forwards to the anterior surface distal to the elbow, where it is joined by the median cubital vein. It then ascends superficially between biceps and pronator teres, and is crossed by filaments of the medial cutaneous nerve of the forearm that pass both superficial and deep to the vein. The basilic vein continues as the axillary vein from the lower border of teres major (Ch. 49 and Ch. 81).

Median vein

The median vein of the forearm drains the superficial palmar venous plexus and ascends through the anterior part of the forearm to join either the basilic or the median cubital vein (see Figs 49.34, 50.30). It may divide distal to the elbow to join both veins.

Lymphatic drainage

One or two supratrochlear nodes are superficial to the deep fascia proximal to the medial epicondyle and medial to the basilic vein; their efferents accompany the vein to join the deep lymph vessels. Small, isolated nodes sometimes occur along the radial, ulnar and interosseous vessels, in the cubital fossa near the bifurcation of the brachial artery, or in the arm medial to the brachial vessels.

Innervation

Median nerve

In the cubital fossa, the median nerve lies medial to the brachial artery, deep to the bicipital aponeurosis and anterior to brachialis. It usually enters the forearm between the heads of pronator teres, although, occasionally, it may pass posterior to both heads of the muscle, or it may pass through its humeral head (**Fig. 50.31**; see Figs 50.21–50.22). The nerve crosses to the lateral side of the ulnar artery, from which it is separated by the deep head of pronator teres, passes behind a tendinous bridge between the humero-ulnar and radial heads of flexor digitorum superficialis, and descends through the forearm posterior and adherent to flexor digitorum superficialis and anterior to flexor digitorum profundus. It is accompanied by the median branch of the anterior interosseous artery. The first branch of the median nerve to pronator teres arises 2–3 cm above the medial epicondyle. A second branch, or leash of branches, arises at the level of the tip of the medial epicondyle and innervates palmaris longus, flexor carpi radialis and flexor digitorum superficialis. About 5 cm proximal to the flexor retinaculum, the median nerve emerges from behind the lateral edge of flexor digitorum superficialis, and becomes superficial just proximal to the wrist. Here, it lies between the tendons of flexor digitorum superficialis and flexor carpi radialis, projecting laterally from beneath the tendon of palmaris longus. It then passes deep to the flexor retinaculum into the palm.

Branches in the forearm

Anterior interosseous nerve

The anterior interosseous nerve arises from the posterior aspect of the median nerve between the two heads of pronator teres, just distal to the branches to the superficial forearm flexors and proximal tendinous

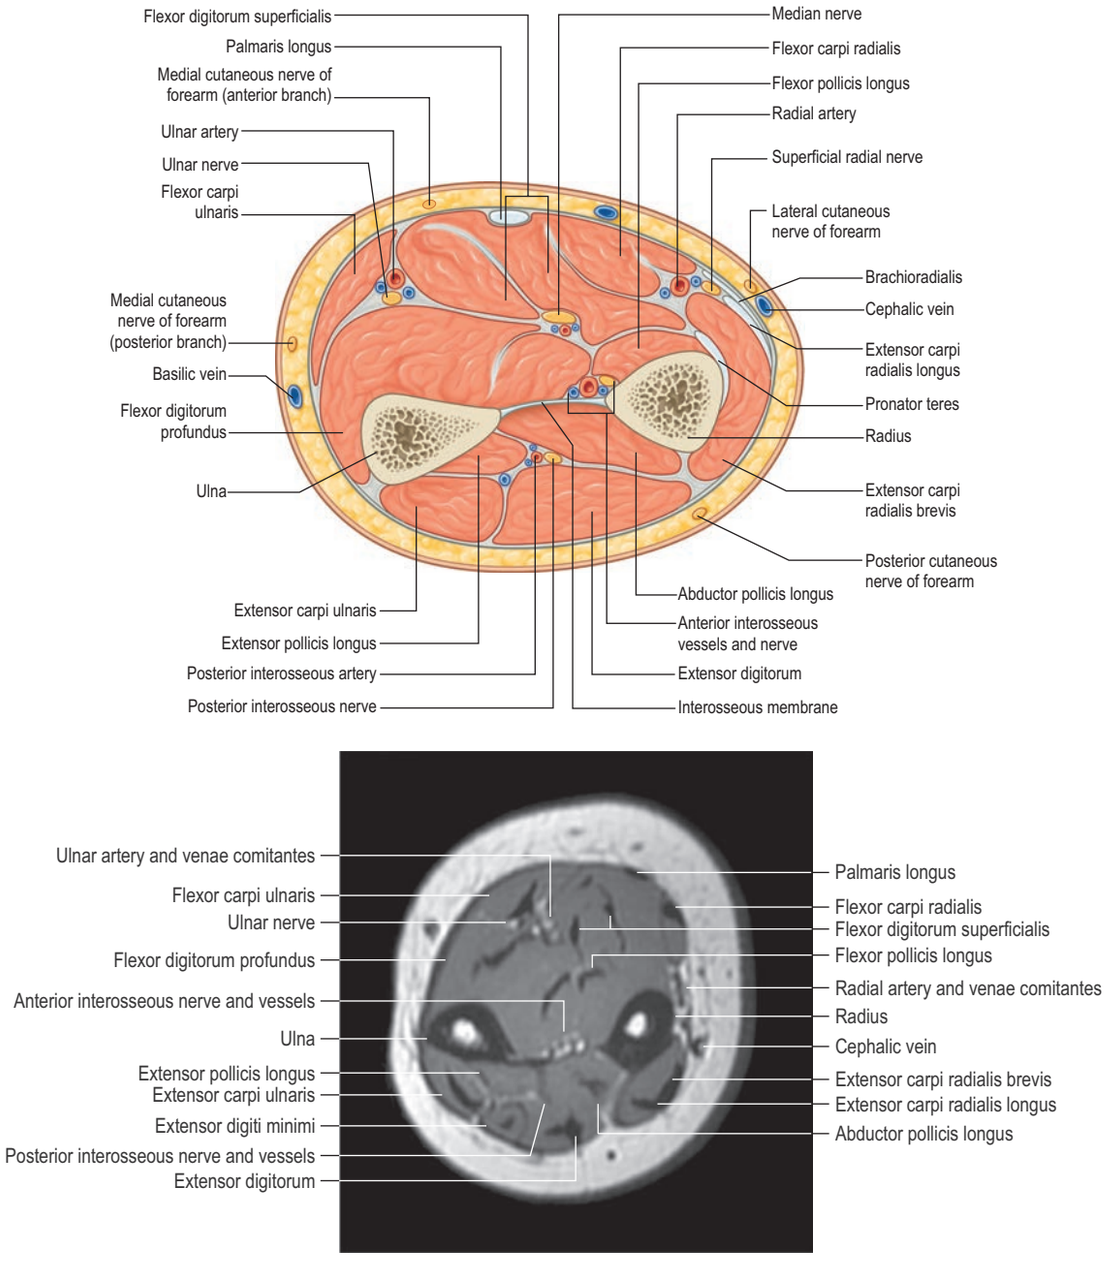

Fig. 50.32 **A**, Transverse section through the middle of the left forearm. **B**, Axial T1-weighted MRI at the mid-level of the supine forearm, oriented as in **A**.

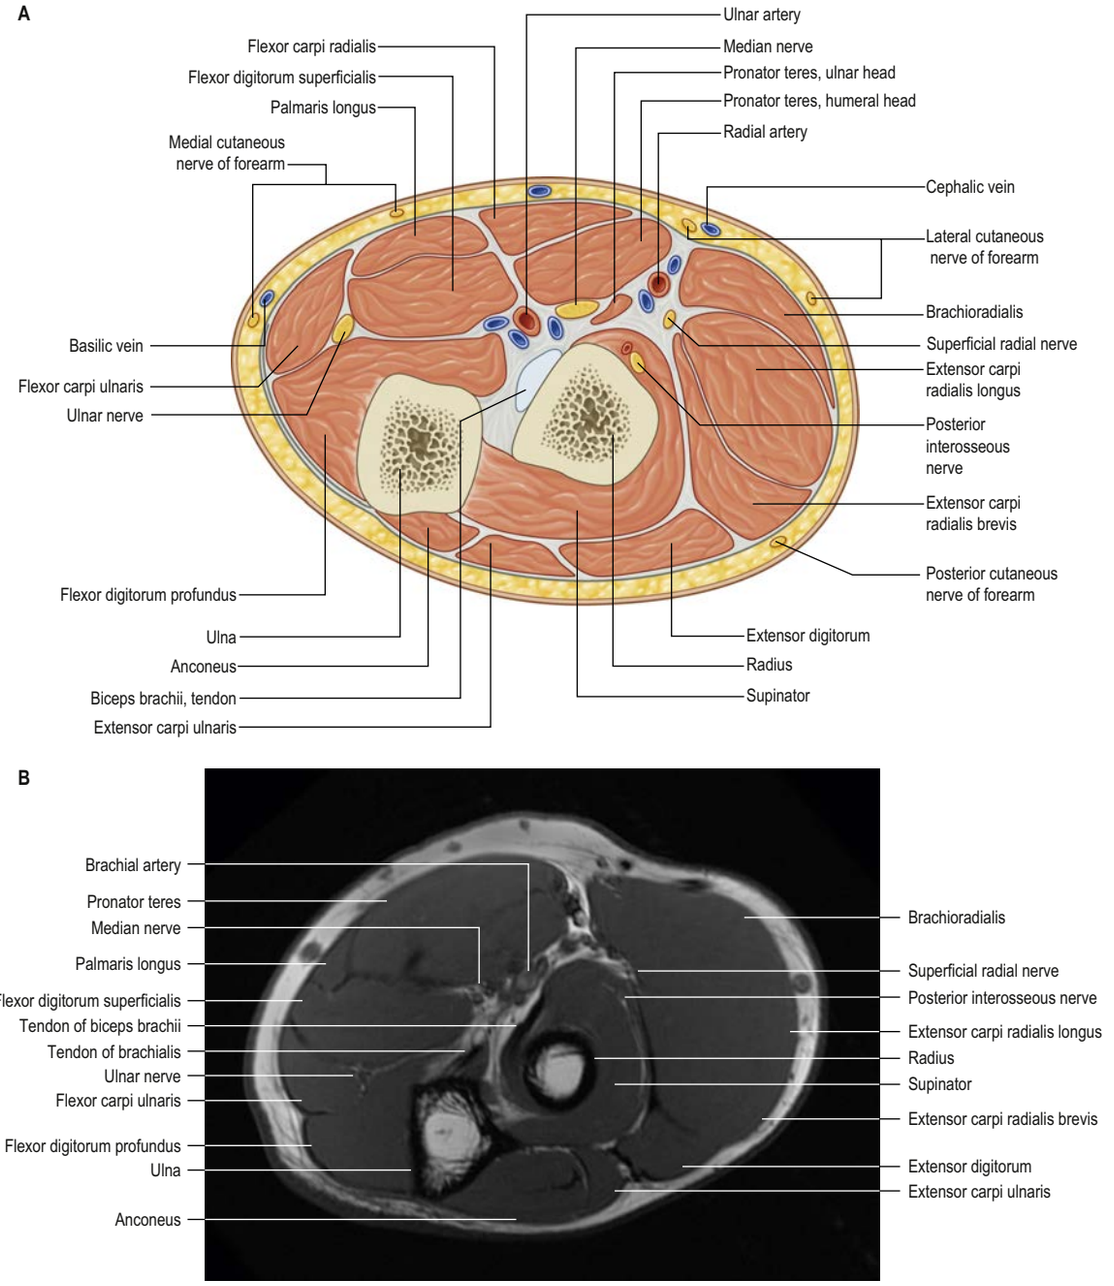

Fig. 50.31 **A**, Transverse section through the left forearm at the level of the radial tuberosity: proximal aspect. **B**, Axial T1-weighted MRI through the left forearm at the level of the radial tuberosity, oriented as in **A**.

arch of flexor digitorum superficialis (see Figs 50.10, 50.22). It descends with the anterior interosseous artery anterior to the interosseous membrane, between and deep to flexor pollicis longus and flexor digitorum profundus (Fig. 50.32), supplying flexor pollicis longus and the lateral part of flexor digitorum profundus (to the index and middle fingers). Terminally, the anterior interosseous nerve lies posterior to pronator quadratus, which it supplies via its deep surface. It also supplies articular branches to the distal radio-ulnar, radiocarpal and carpal joints.

Palmar cutaneous branch

The palmar cutaneous branch starts about 3 cm proximal to the flexor retinaculum. It runs in a small tunnel in the sheath of flexor carpi radialis before piercing the deep fascia, where it divides into lateral branches that supply the thenar skin and connect with the lateral cutaneous nerve of the forearm. Medial branches supply the central palmar skin and connect with the palmar cutaneous branch of the ulnar nerve (see Figs 48.11, 50.21).

Muscular branches

Muscular branches are given off near the elbow to all the superficial flexor muscles except flexor carpi ulnaris. The branch to the part of flexor digitorum superficialis that serves the index finger is given off near the mid-forearm and may be derived from the anterior interosseous nerve. The median nerve is palpable in the anterior aspect of the elbow, deep to the bicipital aponeurosis. It is closely related to the brachial artery in the anterior aspect of the elbow, where it courses anterior to brachialis and medial to the artery.

Median nerve compression

The median nerve may be compressed at four sites in the elbow and forearm. The most proximal is the ligament of Struthers, where, if the median nerve is accompanied by the brachial artery, vascular symptoms and signs may also be present. More distally, it may become entrapped by a thickened bicipital aponeurosis. The other sites of compression are between the superficial and deep heads of pronator teres, and the proximal fibrous arch of flexor digitorum superficialis.

Martin–Gruber nerve connection.

Available with the *Gray's Anatomy* -book

Ulnar nerve

The ulnar nerve passes behind the medial epicondyle in a groove where it is easily palpable (see Figs 50.29, 48.12). It runs through the cubital tunnel, between the capsule of the humero-ulnar joint and the overlying arcuate ligament of Osborne joining the two heads of flexor carpi

Patients essentially present with one of two syndromes. The anterior interosseous nerve syndrome presents as a failure of pinch grip due to weakness of flexor pollicis longus and the radial portion of flexor or digitorum profundus. This reduces the flexion power of the interphalangeal joint of the thumb and the distal interphalangeal joint of the index finger. The pronator syndrome presents with symptoms and signs that mimic carpal tunnel syndrome. Patients present with pain and altered sensation in the radial three and a half fingers of the hand that are aggravated by activity. However, a Tinel's sign will be positive over the proximal forearm, and sensation over the thenar eminence may be diminished, because the palmar cutaneous branch of the nerve arises above the carpal tunnel. The clinical presentation may vary in the presence of a Martin–Gruber anastomosis (Rodriguez-Niedenführ et al 2002).

Most patients will respond to non-operative treatment but those who fail to do so usually respond well to surgical decompression. Exploration and decompression should address all the potential areas of compression.

A motor communicating branch between the median and ulnar nerves in the forearm occurs in approximately one-quarter of patients. The most common variant has a branch passing from the anterior interosseous to the ulnar nerve. A number of patterns have been described where branches pass between flexors digitorum superficialis and profundus, deep to the ulnar artery, to join the ulnar nerve; such branches may explain the variations in innervation of the intrinsic muscles.

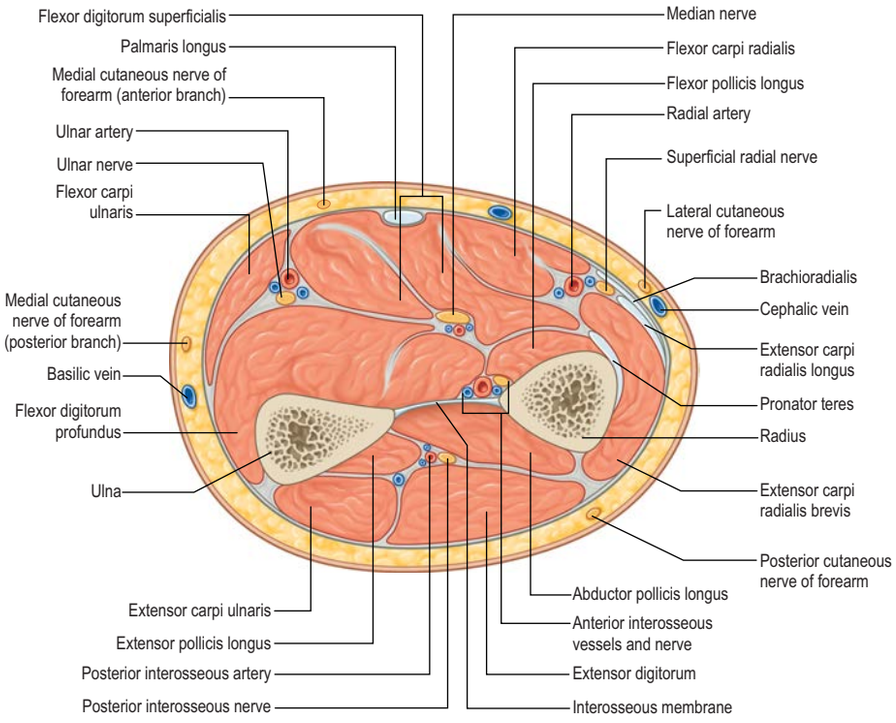

Fig. 50.32 A, Transverse section through the middle of the left forearm. (B, *continued online*).

ulnaris. It gives off articular branches to the elbow as it lies between the medial epicondyle and the olecranon. In some individuals an accessory muscle, the anconeus epitrochlearis is found superficial to the cubital retinaculum connecting the medial epicondyle to the olecranon (Grewal et al 2019). The ulnar nerve enters the forearm between the two heads of flexor carpi ulnaris, which it supplies by two neurovascular pedicles, one arising just distal to the cubital tunnel and one in the forearm: it is superficial to the posterior and oblique parts of the ulnar collateral ligament and deep to the tough deep fascia of flexor carpi ulnaris (Osborne's fascia).

The ulnar nerve descends on the medial side of the forearm on flexor digitorum profundus (see Fig. 50.32). Proximally, it is covered by flexor carpi ulnaris; its distal half lies lateral to the muscle and is covered only by skin and fasciae. In the upper third of the forearm, the nerve is distant from the ulnar artery but, more distally, it comes to lie close to the medial side of the artery. About 5 cm proximal to the wrist, it gives off the dorsal cutaneous branch. At the wrist, the ulnar nerve passes under the superficial part of the flexor retinaculum (in Guyon's canal) and divides into superficial and deep branches (see Fig. 51.10).

Branches in the forearm

Muscular branches

There are two main muscular branches of the ulnar nerve in the forearm. They arise near the elbow and supply flexor carpi ulnaris and the medial half of flexor digitorum profundus.

Dorsal branch

The dorsal branch of the ulnar nerve continues distally and dorsally, deep to flexor carpi ulnaris. It perforates the deep fascia and descends along the medial side of the back of the wrist and hand. Its further course is described in Chapter 51 and Chapter 80.

Palmar cutaneous branch

The palmar cutaneous branch of the ulnar nerve arises in mid-forearm, descends on the ulnar artery, which it supplies, and then perforates the deep fascia. It communicates with the palmar branch of the median nerve and ends in the palmar skin. It sometimes supplies palmaris brevis. Its further course is described in Chapter 51 and Chapter 80.

Ulnar nerve compression

The ulnar nerve may be compressed by the arcade of Struthers at the level of the medial intermuscular septum; at the level of the flexor/pronator aponeurosis as it enters the forearm between the heads of flexor carpi ulnaris; or deep to the deep fascia of flexor carpi ulnaris which exhibits tough condensations extending up to 9 cm from the medial epicondyle (Siemionow et al 2007). The nerve is most often compressed at the level of the cubital tunnel by the Osborne's arcuate ligament; this is the most common nerve compression syndrome after that of the median nerve in the carpal tunnel.

Radial nerve

The radial nerve at the elbow lies in the deep groove between brachialis medially and brachioradialis and extensor carpi radialis longus laterally (see Fig. 50.21). The nerve to brachioradialis arises about three fingers'-breadths proximal to the lateral epicondyle; the nerve to extensor carpi radialis longus about one finger's-breadth more distal; and the nerve to extensor carpi radialis brevis about one finger's-breadth above the epicondyle. These branches arise from the main radial nerve as it runs between brachialis and brachioradialis. The nerve may be palpable at this level. The radial nerve divides into the posterior interosseous and superficial radial nerves anterior to the elbow at the level of the tip of the lateral epicondyle. Another branch to extensor carpi radialis brevis is usually given off here. There is some variation in the level at which branches of the radial nerve arise from the main trunk in different individuals. Branches to extensor carpi radialis brevis and supinator may arise from the main trunk of the radial nerve or from the proximal part of the posterior interosseous nerve, but almost invariably above the arcade of Frohse.

Branches in the forearm

Superficial radial nerve

The superficial radial nerve descends from the lateral epicondyle anterolaterally in the proximal two-thirds of the forearm, initially lying on supinator, lateral to the radial artery and behind brachioradialis. In the middle third of the forearm, it lies behind brachioradialis, close to the lateral side of the artery. It runs anterior to pronator teres, the radial head of flexor digitorum superficialis and flexor pollicis longus, and usually leaves the artery 7 cm proximal to the wrist and passes deep to the tendon of brachioradialis. It curves round the lateral side of the radius as it descends, pierces the deep fascia and divides into five, sometimes four, dorsal digital nerves. On the dorsum of the hand, it usually communicates with the posterior and lateral cutaneous nerves of the forearm.

Posterior interosseous nerve

The posterior interosseous nerve is the deep terminal branch of the radial nerve (see Figs 48.9, 50.21, 50.29). It reaches the back of the forearm by passing round the lateral aspect of the radius between the two heads of supinator (see Figs 50.25–50.26). It supplies supinator both before entering the muscle and as it passes through it. As it emerges from supinator posteriorly, the nerve gives off three short branches to

The cross-sectional area of the cubital tunnel has been shown to narrow by almost 55% in full flexion. Ultrasound studies have suggested that the ratio of the cross-sectional area of radial nerve: cubital tunnel is most strongly linked to reduced conduction velocity (Yoon et al 2007). Combining elbow flexion with direct pressure over the cubital tunnel for 60 seconds will elicit symptoms in most affected patients (Novak et al 1994). Other contributory factors are previous trauma, especially supracondylar and medial epicondyle fractures in childhood, valgus instability of the elbow in athletes involved in throwing sports, and degenerative disease.

The most reliable treatment for patients who fail to respond to non-surgical remedies is a simple release of the cubital tunnel. The release should be complete and include release of Osborne's ligament and the deep fascia of flexor carpi ulnaris; care should be taken to avoid damage to branches of the medial cutaneous nerve of the forearm that usually cross the line of incision approximately 2 cm above the medial epicondyle and a mean 3.1 cm distal to the medial epicondyle in all patients (Lowe et al 2004). Anconeus epitrochlearis should be excised if present because it is a potential cause for recurrent symptoms. The ulnar nerve should not be circumferentially denuded of its retinaculum because this contains its intrinsic blood supply. Transposition of the nerve should be reserved for cases of persistent subluxation or of failure of a simple release to achieve symptomatic relief. This is relatively unusual and is said to occur in only 7% of cases.

The ulnar nerve is a mixed nerve and so patients may present with sensory or motor symptoms or a combination of the two, sometimes with additional physical signs of autonomic disturbance. There may be tenderness and a positive Tinel's sign over the nerve at the point of compression. Numbness and paraesthesiae occur early, followed, in more severe cases, by weakness of power grip and, ultimately, atrophy of the lumbricals and interossei with clawing of ring and little fingers.

extensor digitorum, extensor digiti minimi and extensor carpi ulnaris, and two longer branches, a medial branch to extensor pollicis longus and extensor indicis, and a lateral branch that supplies abductor pollicis longus and extensor pollicis brevis. The nerve at first lies between the superficial and deep extensor muscles, but at the distal border of extensor pollicis brevis, it passes deep to extensor pollicis longus and, diminished to a fine thread, descends on the interosseous membrane to the dorsum of the carpus. Filaments arising from its flattened termination supply the carpal ligaments and articulations. Articular branches from the posterior interosseous nerve supply carpal, distal radio-ulnar and some intercarpal and intermetacarpal joints. Digital branches supply the metacarpophalangeal and proximal interphalangeal joints.

The distal portion of the nerve lies in a separate fascial sheath in the radial, deep, aspect of the fourth dorsal compartment of the extensor retinaculum of the wrist, where it is located deep to extensor digitorum and extensor indicis.

Radial nerve compression

Radial nerve compression may occur at several sites in the elbow and forearm. The most proximal of these is within the radial tunnel, which starts where the deep branch of the radial nerve lies over the radiohumeral joint and ends at the point where the deep branch becomes the posterior interosseous nerve at the distal border of supinator. At the level of the radial head, the nerve may be compressed by fibrous bands. More distally, it has been suggested that branches of the radial recurrent artery may compress the posterior interosseous nerve. Other sites of compression are the tendinous edge of the deep surface of extensor carpi radialis brevis and the point at which the nerve passes under the arcade of Frohse and between the two heads of supinator. Rarely, the nerve can be compressed at the level of the distal border of supinator.

Lateral cutaneous nerve of the forearm

The lateral cutaneous nerve of the forearm is the cutaneous division of the musculocutaneous nerve. It lies between biceps brachii and brachialis, inclining from the medial to the lateral side, then passes through the cubital fossa lateral to the tendon of biceps brachii and deep to the cephalic vein and descends along the radial border of the forearm to the wrist (see Figs 49.33–49.34, 50.31–50.32). It supplies the skin of the anterolateral surface of the forearm (see Fig. 50.1) and connects with the posterior cutaneous nerve of the forearm and the terminal branch of the radial nerve by branches that pass around the radial border of the forearm. Its trunk gives rise to a slender recurrent branch that extends along the cephalic vein as far as the middle third of the upper arm, distributing filaments to the skin over the distal third of the anterolateral surface of the upper arm close to the vein. At the wrist joint, the lateral cutaneous nerve of the forearm is anterior to the radial artery. It gives off filaments that pierce the deep fascia and accompany the artery to the dorsum of the carpus. The nerve then passes to the base of the thenar eminence, where it ends in cutaneous rami, some of which connect with the terminal branch of the radial nerve and the palmar cutaneous branch of the median nerve.

Medial cutaneous nerve of the forearm

The medial cutaneous nerve of the forearm has already divided into anterior and posterior branches before it enters the forearm (see Figs 49.34, 50.31–50.32). The larger anterior branch usually passes anterior to, or occasionally behind, the median cubital vein, and descends anteromedially in the forearm to supply the skin as far as the wrist. It curves round to the dorsum of the forearm, descending on its medial border to the wrist, supplying the skin (see Fig. 50.1). It connects with the medial cutaneous nerve of the arm, the posterior cutaneous nerve of the forearm, and the dorsal branch of the ulnar nerve.

Posterior cutaneous nerve of the forearm

The posterior cutaneous nerve of the forearm passes along the dorsum of the forearm to the wrist (see Figs 49.34, 50.31–50.32). It supplies the central forearm skin along its course and, near its termination, joins the dorsal branches of the lateral cutaneous nerve of the forearm.

Birch R 2011 Surgical Disorders of the Peripheral Nerves, 2nd ed. London: Springer-Verlag.
An account of the current state-of-the-art practice of diagnosis and management of surgical lesions of the peripheral nerves, including the brachial plexus.

Patients present with one of two syndromes: the radial tunnel syndrome, in which the presentation is that of pain along the lateral border of the elbow and upper forearm (Roles and Maudsley 1972), or the posterior interosseous nerve syndrome, which presents with motor weakness in the distribution of the nerve particularly affecting the extensors digitorum and carpi ulnaris. Primary treatment is non-operative and involves the avoidance of activities that cause pain, aided by appropriate splintage. In resistant cases, surgical decompression may be necessary. A complete release of all potential areas of compression is essential.

The elbow is a notorious site for nerve injuries, especially in children. The close proximity of all the major nerve trunks to bone makes them vulnerable. The ulnar nerve is particularly at risk in elbow dislocation, especially when the medial epicondyle is displaced into the joint. All three nerves are at risk of displacement into a dislocated joint. The posterior interosseous and radial nerves are particularly at risk from a Monteggia fracture-dislocation. Any nerve may become entrapped within a fracture, e.g. the median nerve is often accompanied by the brachial artery in cases of supracondylar fracture. Pain that persists, or worsens, after reduction of a fracture suggests impending critical ischaemia, continuing irritation of the nerve, or both. The nerves are at risk during operations or other medical interventions, particularly so when normal anatomical planes are distorted by haematoma, fibrosis or bone fragments.

Fractures of the shaft of the radius and ulna are commonly displaced, reflecting not only the violence required to cause such injury but also the pull of the forearm muscles that may accentuate displacement of the fracture fragments. Open fractures or penetrating injuries to the forearm may be associated with nerve and vessel injury. Compartment syndrome can occur. Monitoring of compartment pressures and careful neurological examination are required.

Fracture-dislocations of the forearm

Monteggia, Galeazzi and Essex–Lopresti injuries are common combinations of high energy forearm fractures associated with accompanying soft tissue injury.

Monteggia fracture-dislocation

A Monteggia fracture-dislocation injury is a fracture of the proximal ulna with dislocation of the radial head. The interosseous membrane and the triangular fibrocartilage complex remain largely intact, which means that anatomical reduction of the ulnar fracture will usually restore congruity of the radiocapitellar and proximal radio-ulnar joints. The most common type of Monteggia fracture, type 1 (anterior dislocation), occurs when falling onto an outstretched arm hyperextends the elbow (**Fig. 50.33**). The forearm is in neutral to mid-pronation, biceps brachii resists the hyperextension, the anular and quadrate ligaments rupture under the bending force, and the radial head dislocates. Compressive load then transfers to the ulnar diaphysis, which fails in tension in an oblique fracture. Type II (posterior dislocation) involves longitudinal force directed up the forearm with the elbow in a flexed position. The ulnar cortex fails first before rupture of the ulnar collateral ligament complex and posterior dislocation of the radial head. Four subtypes of this injury pattern have been identified, based on the location and force direction through the ulnar fracture (Jupiter et al 1991). Type III Monteggia injuries result in lateral or anterolateral dislocation of the radial head, associated with a metaphysial fracture of the proximal ulna. Type IV Monteggia injuries result in an anterior dislocation of the radial head and a fracture through the proximal third of both the radius and the ulna. The mechanism of injury is similar to that seen in type I injuries but the anteriorly directed force of the distal ulnar fragment, combined with the biceps resistance force, causes a fracture through the proximal radius. There is poor inter-observer agreement in classifiying these injuries. It is most useful to consider them as apex anterior ulna fracture with an intact dislocated radial head, or apex posterior ulna fracture with a fractured radial head. The apex posterior injuries have a worse prognosis (Ring 2013).

Galeazzi fracture-dislocation

A Galeazzi injury is a fracture at the junction of the middle and distal thirds of the radius, associated with disruption of the distal radio-ulnar joint (**Fig. 50.34**). The injury occurs when the forearm is axially loaded and fully pronated. The radius fractures first, force transmission continues along the interosseous membrane to the distal ulna, the triangular fibrocartilage complex is disrupted and the ulnar head dislocates. The ulnar styloid can also be fractured in this injury (Galeazzi 1934).

Fig. 50.33 Type 1 Monteggia fracture with anterior dislocation of the radial head (arrow).

Fig. 50.34 Galeazzi fracture-dislocation.

Essex–Lopresti injury

Essex–Lopresti injury is a radio-ulnar dissociation injury, usually caused by a fall on to an outstretched hand that involves a fracture of the radial head, force transmission between the radius and ulna, and disruption of the central condensation of the interosseous membrane and the distal radio-ulnar joint. The radius migrates proximally relative to the ulna (Chow and Leung 2010).

Traumatic elbow instability

Posterolateral rotatory pattern instability and dislocation of the elbow, with or without associated fracture of the radial head and coronoid, are the three general patterns of traumatic elbow instability (Ring 2010). Posterolateral rotatory pattern instability is an injury of the capsule and ligaments that progresses from lateral to medial with a posterolateral rotatory mechanism (O'Driscoll et al 1992). It usually occurs as the result of a fall onto an outstretched hand that creates a valgus, axial posterolateral rotatory force. The ulna and forearm supinate away from the distal humerus and a posterior dislocation of the elbow occurs (**Fig. 50.35**). As the elbow dislocates posteriorly, the radial head and coronoid impact on the distal humerus, where either can fracture; the anterior band of the ulnar collateral ligament is the last structure to be disrupted. Varus posteromedial rotational pattern instability and anteromedial coronoid facet fractures occur when a fall on to an outstretched hand produces a varus, axial posteromedial force through the elbow. The anteromedial facet of the coronoid is fractured and the lateral ligament complex may be injured or the olecranon may be fractured. Anterior olecranon fracture-dislocations occur as a result of direct violence to the flexed elbow. The mechanism of posterior olecranon fracture dislocation is less certain; it occurs more commonly in osteopenic bone.

Wrist and hand

CHAPTER 51

SKIN AND SOFT TISSUES

Skin

Dorsal skin versus palmar skin

The dorsal skin is thin, mobile and frequently hirsute over the proximal phalanges and the ulnar aspect of the dorsum of the hand. The skin of the palm and the palmar surface of the digits is thick and hairless, with a well-defined stratum lucidum and a higher density of nerve endings and eccrine sweat glands, but no sebaceous glands. The skin on the dorsum is visible to others and has aesthetic relevance whereas the palmar skin has more functional relevance.

Skin creases and fingerprints

Flexure lines crease the skin of the flexor surfaces of the wrist and hand (Fig. 51.1) where they are anchored to the deep fascia. Less regular, mainly transverse, creases cross the dorsal aspect of the carpal, metacarpophalangeal and interphalangeal joints. The dorsal creases are more prominent in extension; the loose skin becomes stretched in flexion. (For a general review of 'skin lines', see Chapter 7.) Three anterior transverse lines usually cross the wrist. The proximal line marks the proximal limit of the flexor synovial sheaths, the intermediate line overlies the radiocarpal joint, and a distal line marks the proximal border of the flexor retinaculum.

In the palm, a curved radial longitudinal line bounds the thenar eminence, ending close to the distal wrist crease. Proximal and distal transverse lines ascend medially across the palm. The proximal line begins at the distal end of the thenar crease and runs obliquely to the middle of the hypothenar eminence across the shafts of the metacarpals. The distal palmar crease begins at or near the cleft between the index and middle finger, and curves across the palm over the necks of the metacarpals from the middle finger to little finger. In the ring and little finger the crease is just proximal to the underlying metacarpophalangeal joint.

The second to fifth digits have proximal, middle and distal sets of transverse lines. The proximal, often double, lies at the level of the distal margin of the webspace, approximately half way along the underlying proximal phalanx. The middle creases are usually double, the proximal line lying directly over the proximal interphalangeal joint. The distal lines are usually single, and lie proximal to the distal interphalangeal joints. The metacarpophalangeal joint of the thumb is crossed by a crease that starts on the radial side and ends in the web space level with the base of the proximal phalanx. There is a second, shorter, crease, usually 1 cm distal to this line. Two creases cross the interphalangeal joint of the thumb (see Fig. 51.1).

'Fingerprints' are striations that are unique to each individual and particularly well developed at sites of grip, namely the pulps of the fingers and thumb together with the base of the hypothenar eminence.

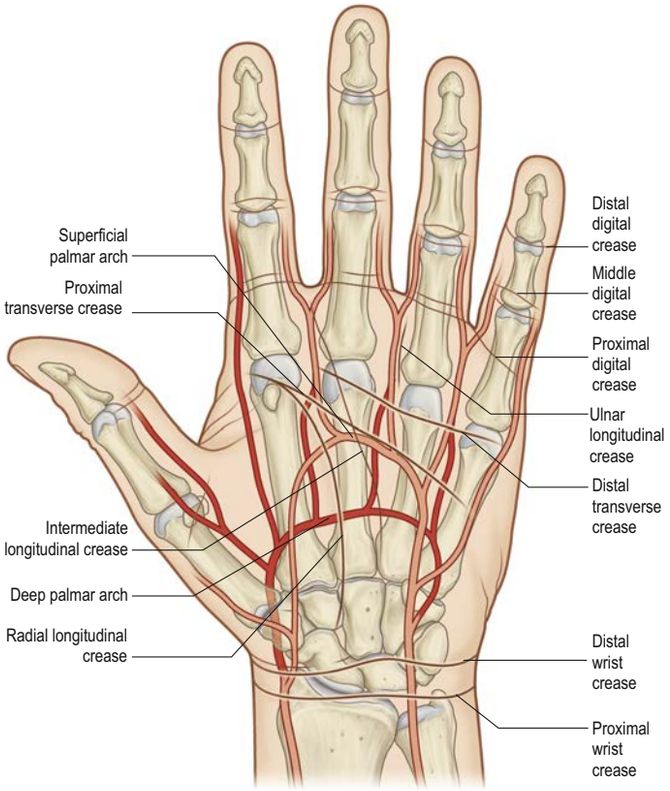

Fig. 51.1 The relation of the skin flexure lines and palmar arterial arches to the bones of the left hand. (Adapted from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Cutaneous vascular supply

The skin of the palmar aspect of the wrist is supplied by branches from the superficial palmar branch of the radial artery, the ulnar artery and, occasionally, the median artery (Fig. 51.2). The skin over the thenar eminence is supplied by small perforating branches from the superficial palmar branch of the radial artery and the princeps pollicis. The skin over the hypothenar eminence is supplied by perforating branches from the ulnar artery, some of which pass through palmaris brevis. The rest of the palm is supplied by branches from the common palmar digital arteries that pierce the palmar aponeurosis, and branches from the radialis indicis artery. The palmar digital skin is supplied by branches from each digital artery. In the distal phalanx, the two digital arteries typically form an H-shaped anastomosis, from which cutaneous perforators fan out within the pulp. Deep digital veins accompanying the digital arteries are usually very small and frequently absent. Superficial palmar veins tend to pass dorsally and drain into the larger superficial dorsal venous system (Fig. 51.3).

The dorsal skin of the wrist is supplied by branches from an arterial plexus which lies over the extensor retinaculum and is formed by branches of the radial artery, including its dorsal carpal branch, the dorsal carpal branch of the ulnar artery, and the anterior and posterior interosseous arteries. The blood supply to the dorsum of the hand arises from longitudinal rows of four or five branches from each of the dorsal metacarpal arteries, which usually arise either directly from the radial artery or from the dorsal carpal arch. At the level of the neck of the metacarpals, where the second, third and fourth dorsal metacarpal arteries communicate with branches from the corresponding common palmar digital arteries, a large cutaneous perforating branch passes proximally to supply an area of skin as far as the dorsal aspect of the wrist.

The blood supply to the dorsum of the fingers arises proximally from the terminal branches of the dorsal metacarpal arteries, (supplying a region as far distally as the proximal interphalangeal joint) as well as from dorsal branches of the palmar digital arteries that are given off at the level of each phalanx (Fig. 51.4). At the level of the distal phalanx, the cutaneous supply comes from three dorsal arcades: a superficial arcade over the base of the distal phalanx, and two distal subungual arcades (Fig. 51.5). The skin of the dorsum of the thumb is supplied by longitudinal axial branches of the princeps pollicis and dorsal branches from the palmar digital arteries.

Degloving injuries of the hand and wrist

A degloving injury is one in which the skin is avulsed from its underlying structures, often leaving the entire musculoskeletal unit of the hand

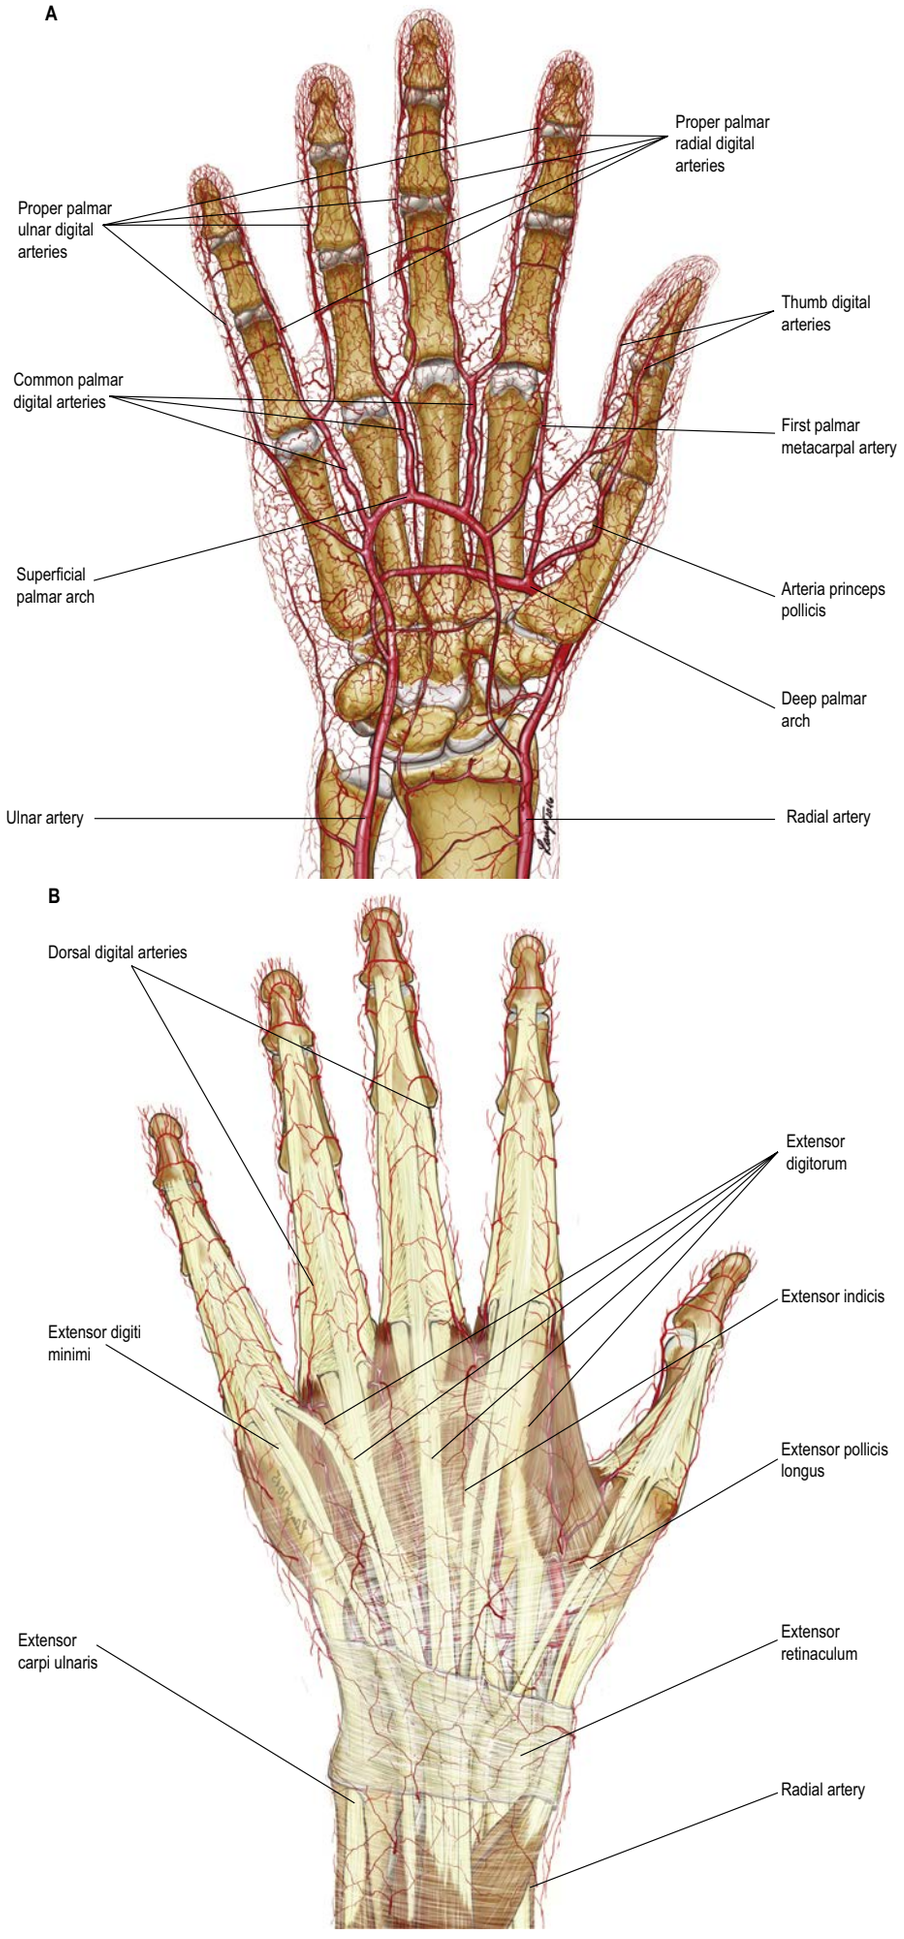

Fig. 51.2 **A**, The blood supply to the palmar (volar) skin of the right wrist and hand. **B**, The blood supply to the dorsum of the left hand. (Copyright Martin Langer.)

Treatment of these injuries depends on their extent (Krishnamoorthy and Karthikeyan 2011). In complete avulsion, restoration of the tissue and microvascular anastomosis is called replantation. Where the skin remains attached but is devascularized, restoration of the blood supply by anastomosis is called revascularization. Because the traction injury may extend over a considerable distance, large sections of vessel may need to be excised: the judicious use of vein grafts is essential. If neither of these procedures is feasible, the avulsed skin may be defatted and reapplied to the affected part, where it effectively acts as a split skin graft. If none of these techniques is practicable, primary amputation may have to be considered. Subsequently, reconstruction may be by split-skin graft, skin/fasciocutaneous flap or free flap. The decision whether to reconstruct or to amputate is multifactorial and depends not just on the injury but on the medical, psychological and social situation of the patient.

intact, thereby permitting the patient to mobilize the 'naked' finger fully. These injuries occur as the result of a low velocity traction force being applied to the affected part. The plane of cleavage is through the subcutaneous tissues, leaving the underlying structures essentially intact. These injuries may occur if the hand is caught in industrial machinery, typically between rollers or in a conveyor belt.

The most common manifestation is the 'ring avulsion injury', when a ring is caught and the finger rapidly pulled away (Bamba et al 2018). The degloving may be complete or partial. Complete avulsion is rare, whereas avulsion of the skin of all or part of the finger is relatively common. Urbaniak et al (1981) grouped ring avulsion injuries into three classes: those in which the blood supply is intact (class I); those in which the blood supply is compromised (class II); and those in which digits are either completely degloved or amputated (class III). While these represent injuries of increasing severity, the avulsion force required to achieve them does not occur in a linear manner (Kupfer et al 1999). The longitudinal force applied to a finger causes a traction injury to the blood vessels, which may extend over a considerable distance. The crushing element of a degloving injury may cause skin necrosis and thrombosis of the underlying vessels (Brooks et al 2007).

Basic skin flaps in reconstruction

Available with the *Gray's Anatomy* e-book

Cutaneous innervation

The skin of the anterior aspect of the wrist is innervated by the terminal branches of the lateral and medial cutaneous nerves of the

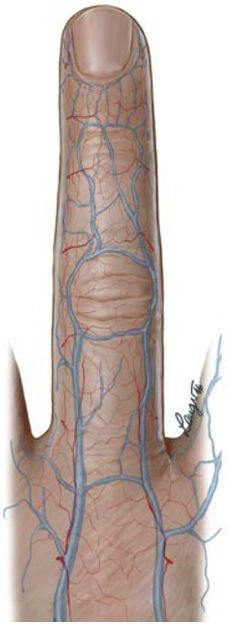

Fig. 51.4 Cutaneous arterial supply and venous drainage for the dorsum of the finger. (Copyright Martin Langer.)

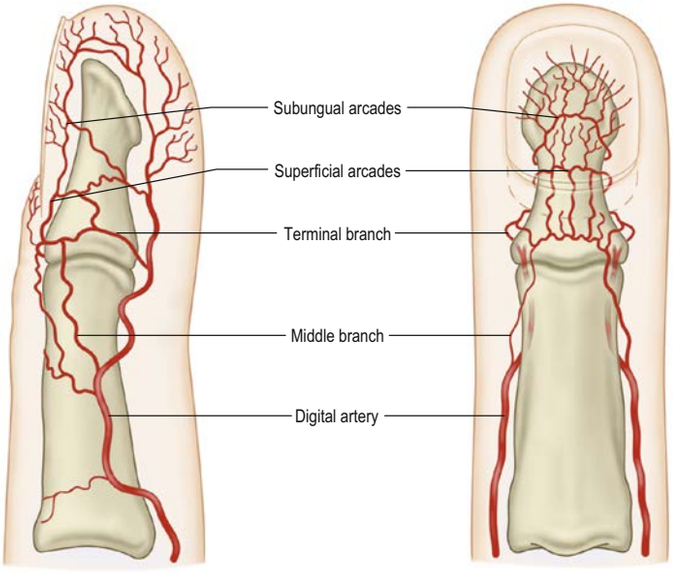

Fig. 51.5 Terminal vascular arcades over the distal phalanx. (With permission from Flint MH 1956 Some observations on the vascular supply of the nail bed and terminal segments of the fingers. BJPS 8:186–95.)

The pedicled groin flap used to be regarded as the workhorse flap for reconstruction of the hand. Swelling due to the dependent position of the hand, and the need for a second operation, coupled with the social stigma associated with the position of the hand, has led to it falling out of favour.

Regional and free flaps have gradually replaced the pedicled groin flap. Numerous different types of regional and free flaps have been used to cover soft tissue defects in the hand, based on the principle that the hand has a reliable vascular anatomy. The anatomical basis can be a named artery to which a free flap is attached (e.g. toe to thumb transfer), a naked vessel that can be rotated with a paddle of skin (e.g. the radial forearm and dorsal intermetacarpal artery flaps), or a skin flap based on a reliable subcutaneous blood supply (e.g. the cross-finger flap).

The radial forearm flap was originally described by surgeons from the Shenyang Military Hospital in 1978 and was consequently known as the 'Chinese flap'. It can be used as a free flap or as a reversed pedicled fasciocutaneous island flap to cover soft tissue defects of the ipsilateral hand. Its blood supply is based on septocutaneous perforators that arise from the distal part of the radial artery and supply the skin on the radial side of the lower forearm; these tend to become more sparse proximally. Venous drainage is by the venae comitantes and superficial subcutaneous veins.

The ulnar forearm flap is a fasciocutaneous flap based on the ulnar artery distal to its common interosseous branch. A variant on this flap based on the ascending branch of the dorsal ulnar artery was described by Becker and Gilbert (1988). It has the disadvantage of a short pedicle but is useful for achieving cover of defects of the proximal and ulnar side of the palm. For each of these flaps, the patency of the other vessel must be confirmed by the clinical 'Allen occlusive test' wherein both radial and ulnar arteries are occluded by digital pressure at the wrist then the ulnar or radial artery is released: perfusion of the hand indicates adequate residual flow in the other artery. This test is now supplemented by Doppler ultrasonography and angiography.

The posterior interosseous island flap, distally based on the dorsal carpal arterial arch via the anastomoses between the posterior and anterior interosseous arteries just lateral to the head of the ulna (Costa et al 2007), was introduced by Zancolli and Angrigiani in 1985 (Zancolli and Angrigiani 1988). Its principal advantages are that it spares both of the major arteries of the forearm and is a good match for the skin colour and texture of the dorsum of the hand. Care must be taken to avoid injury to the adjacent posterior interosseous nerve when harvesting the flap. Doppler studies should be carried out preoperatively to ensure the presence and positioning of the anastomoses between the posterior and anterior interosseous arteries. It has been claimed that most defects of the hand can be treated using this flap; its particular advantage is in the treatment of hand injuries with severe accompanying vascular damage.

The anatomical distribution of the first dorsal metacarpal artery allows a flap of skin over the dorsum of the proximal phalanx of the index finger to be raised on the artery and its accompanying venae comitantes. This flap is particularly useful under certain circumstances for reconstruction of the thumb following injury. The distribution of the second, third and fourth dorsal metacarpal arteries allows the surgical elevation of flaps of dorsal skin based either proximally, on the dorsal metacarpal arteries proper, or distally, on their direct cutaneous branches. These flaps may be used for reconstructing areas of missing tissue elsewhere in the hand. The dorsal cutaneous branch of the ulnar artery is constant and can support a flap of skin on the medial aspect of the distal forearm just proximal to the wrist; it is useful in the reconstruction of areas of missing skin in this region.

Anatomical studies that define the cutaneous vascularity of the hand provide the scientific foundations of new skin flap techniques. These can then be added to the surgeon's armamentarium when faced with soft tissue loss in the upper extremity (Moschella et al 1996, Moschella and Cordova 2006, Hierner et al 2016).

forearm. The skin of the palm is innervated by the palmar branches of the ulnar and median nerves. The skin of the radial aspect of the dorsum of the wrist and hand, as well as the dorsal aspect of the radial three and a half digits as far distally as the nail beds, is innervated by the dorsal digital nerves (the terminal branches of the radial nerve) (**Fig. 51.6**). The palmar skin of the thumb, index and middle fingers and the radial aspect of the ring finger is innervated by the median nerve, while that of the little finger and the ulnar side of the ring finger is innervated by the ulnar nerve (**Figs 51.7–51.8**). Between two and five dorsal digital nerves supply each digit. The skin of the ulnar aspect of the dorsum of the wrist and hand, and the dorsal aspect of the ulnar one and a half digits as far distally as the nail beds, is innervated by dorsal digital branches of the dorsal branch of the ulnar nerve. The skin of the dorsum of the middle and distal phalanges is innervated by dorsal branches of the palmar digital nerves (**Fig. 51.9**).

Nail apparatus

The nail apparatus is described in Chapter 7 (see Fig. 7.27) (Zook 1981).

It comprises the nail plate beneath which lie the germinal and sterile matrix. The tissue to the side of the nail plate is the paronychium. The nail is enveloped proximally by the nail fold, the roof of which is formed by skin and is known as the nail wall. The thin membrane beyond the roof onto the nail is the eponychium. The skin just beyond the nail plate is the hyponychium.

Soft tissues

Flexor retinaculum

The flexor retinaculum (see Fig. 51.27) is a strong, fibrous band that crosses the front of the carpus and converts its anterior concavity into the carpal tunnel which conveys the flexor tendons of the digits and the median nerve. The retinaculum is short and broad, measuring 2.5–3 cm in both dimensions. It is attached medially to the pisiform and the hook of the hamate. Laterally, it splits into superficial and deep laminae. The superficial lamina is attached to the tubercles of the scaphoid and trapezium. The deep lamina is attached to the medial lip of the groove on the trapezium. Together with this groove, the two laminae form a tunnel, lined by a synovial sheath, that contains the tendon of flexor carpi radialis. The retinaculum is crossed superficially by the ulnar vessels and nerve, immediately radial to the pisiform, and by the palmar cutaneous branches of the median and ulnar nerves (see Fig. 51.27). A slender band of fascia, the superficial part of the flexor retinaculum, bridges the ulnar neurovascular bundle and is attached to the radial side of the pisiform, forming a tunnel (Guyon's canal), which is the occasional site of ulnar nerve entrapment (**Fig. 51.10**). The tendons of palmaris longus and flexor carpi ulnaris are partly attached to the anterior surface of the retinaculum. Distally, some of the intrinsic muscles of the thumb and little finger are attached to the retinaculum. The retinaculum mimimizes the flexion torque that the long finger flexors transmit at the radiocarpal joint.

Guyon's canal Guyon's canal is a fibro-osseous canal, approximately 4 cm long in the adult, on the anteromedial aspect of the wrist (see Fig. 51.10). Its roof is formed by the superficial part of the flexor retinaculum and palmaris brevis. Its floor is formed by the transverse carpal and pisohamate ligaments and, more distally, by flexor digiti minimi. The ulnar side is bounded by flexor carpi ulnaris, the pisiform bone and abductor digiti minimi, and the radial side by the extrinsic flexor tendons, the transverse carpal ligament and the hook of the hamate. The fibrous arcade at the origin of the hypothenar muscles lies distally.

The canal transmits the ulnar nerve and artery, together with occasional venae comitantes. The ulnar nerve divides within it at the level of the hook of the hamate into a deep motor branch that passes deeply and radially around the medial and then the distal edge of the hook of hamate, and a superficial sensory branch that passes distally and ulnarwards. Depending on the site, motor, sensory or both components can be affected by compression: if the nerve is compressed proximally, both modalities will be affected, whereas, distal to the bifurcation, either the sensory or motor branch will be compromised.

Variations in the branching of the ulnar nerve may occur. The most common variant is its trifurcation into three branches (deep and two superficial) in about a third of cases, and varying innervation of the abductor digiti minimi.

Extensor retinaculum

The extensor retinaculum is a strong, fibrous band which extends obliquely across the back of the wrist (**Fig. 51.11**). It prevents 'bowstringing' of the long digital extensor tendons across the wrist joint, minimizing the torque that these tendons transmit to the radiocarpal joint as the fingers extend. It is attached laterally to the anterior border of the radius, then passes medially to blend into the fascia overlying the ulnar side of the distal forearm and carpus and into the anteromedial surfaces of the pisiform and triquetrum. As the retinaculum passes across the wrist, it is connected to vertical ridges that are attached to the back of the radius, creating separate compartments for abductor pollicis longus–extensor pollicis brevis, extensor carpi radialis longus–extensor carpi radialis brevis, extensor pollicis longus, extensor digitorum–extensor indicis, and extensor digiti minimi. Extensor carpi ulnaris has a separate sub-sheath attached only to the back of the head of the ulna (there would be no rotation if it were in continuity with the other extensors which are bound to the radius by the retinaculum).

Palmar fascial complex

The palmar fascia is a three-dimensional ligamentous system consisting of longitudinal, transverse and vertical fibres (**Fig. 51.12**).

Longitudinal fibre system

The longitudinal fibres run distally beyond the tendon of palmaris longus (if present) or the flexor retinaculum of the wrist (if palmaris longus is not present) to fan out across the whole width of the central third of the palm, producing four well-defined longitudinal bundles anterior to the metacarpals of the index, middle, ring and little fingers. This is known as the superficial palmar aponeurosis. A less well-defined bundle passes to the thumb. Distal to the transverse fibres of the palmar aponeurosis, the longitudinal fibres pass in three layers (McGrouther 1982). The most superficial longitudinal fibres (layer 1) are inserted superficially into the skin of the distal palm between the distal palmar crease and the proximal digital crease. Some superficial fibres pass distally into the palmar midline of the digit. Deeper longitudinal fibres (layer 2) pass deep to the natatory ligament and neurovascular bundles into the skin at the apex of the web space and into the fingers themselves, where they are continuous with Cleland's ligaments and the lateral digital sheet on either side. Deeper still, the longitudinal fibres in layer 3 perforate the deep transverse metacarpal ligament to pass around the sides of the metacarpophalangeal joint and attach to the metacarpal and proximal phalanx, and extensor tendon.

Transverse fibre system

The transverse fibre system consists of the superficial transverse metacarpal (natatory) ligament, the transverse fibres of the palmar aponeurosis and the deep transverse metacarpal ligament.

Superficial transverse metacarpal ligament (natatory ligament)

The fibres of the superficial transverse metacarpal ligament cross the apex of the web skin and extend into each digit to blend with the lateral digital sheet. They limit the separation of adjacent fingers and support the skin in the web space. Fibres on the ulnar side of the little finger surround the insertion of abductor digiti minimi. Fibres on the radial side of the index finger form the distal commissural ligament (of Grapow) which passes proximally to meet the fascia in front of the thumb metacarpal.

Transverse fibres of the palmar aponeurosis

The transverse fibres of the palmar aponeurosis (Skoog fibres) form the deepest layer of the palmar fascia. They lie proximal to the distal palmar crease in a band approximately 2 cm wide, interconnecting the anterior fibres of the flexor tendon sheaths with the fasciae over the thenar and hypothenar muscles. The extension to the first ray forms the proximal commissural ligament.

CHAPTER 51

Deep transverse metacarpal ligament

The strong fibres of the deep transverse metacarpal ligament lie deep to the palmar aponeurosis and flexor sheaths, and are attached to the adjacent edges of the volar plates of the metacarpal heads of the little, ring, middle and index fingers. The ulnar edge of the little finger intermetacarpal ligament is attached to abductor digiti minimi; the radial edge of the index finger intermetacarpal ligament is attached to the first dorsal interosseous.

Vertical fibre system

The vertical fibres (of Grapow) are more delicate. They pass from the dermis, between the longitudinal and transverse fibres, to the fibrous flexor sheaths and the metacarpals. They are concentrated on either side of the palmar skin creases, as well as the thenar and hypothenar eminences. The vertical septa of Legueu and Juvara (Bilderback and Rayan 2004) pass from the transverse fibres of the palmar aponeurosis to the underlying deep transverse metacarpal ligament, forming compartments that contain the flexor tendons and the lumbricals and neurovascular bundles.

Digital fascial complex

The superficial fascia within a finger is fibrofatty in its palmar and dorsal aspects, but becomes condensed laterally into the lateral digital sheet. The flexor sheath is a well-defined thickening of the fascia (discussed in detail on page 975). Cleland's ligaments extend from the sides of the proximal interphalangeal joints, pass transversely and dorsal to the neurovascular bundles to insert into the lateral digital sheet (see Fig. 51.12D–E) (Zwanenburg et al 2014). Grayson's ligaments are more delicate and may even be discontinuous: they pass palmarwards from the lateral sides of the phalanges to pass over the midline of the flexor sheath to insert in the skin of the opposite side (see Fig. 51.12D–E). The retrovascular cord (of Thomine) is very flimsy in health. The oblique retinacular ligament (ORL) of Landsmeer (Adkinson et al 2014) is an inconsistent anatomical structure with tenuous fibres that connect the flexor sheath attachment to bone proximal to the proximal interphalangeal joint into the lateral band of the extensor tendon alongside the middle phalanx and into the base of the distal phalanx.

Functions of the fascia of the hand

The fascial continuum of the hand performs a number of different, but interrelated, functions, such as channelling structures in transit between the forearm and the digits transmitting loads; and anchoring, binding and tethering structures. It has a complex nerve supply suggesting a proprioceptive function (Stecco et al 2018).

Digital and palmar spaces

There are many potential spaces within the hand, often with ill-defined margins. The nail fold is a 'U-shaped' space made up of the eponychium and the lateral nail fold. The pulp space in the apex and palmar pulp space of the fingertip are formed by the fibrous attachments of the distal phalanx to the digital pulp skin. The synovial flexor tendon sheaths are described on pages 975 and 976. The web space is bounded distally by the skin and natatory ligament, by the deep transverse metacarpal ligament posteriorly, and by the deep attachments of the palmar fascia, together with their lateral attachments to the tendon sheaths, proximally. The lumbrical canal transmits the lumbricals as they pass dorsally, palmar to the deep transverse metacarpal ligament and radial to the metacarpophalangeal joint; the interosseous canal transmits the interossei as they pass dorsal to the deep transverse metacarpal ligament to one side or other of the metacarpophalangeal joint. The deep palmar space is a complex, three-dimensional space, limited proximally by the carpal tunnel. It lies deep to the palmar aponeurosis, between the radial and ulnar condensations of vertical fibres that connect the palmar aponeurosis to the thenar and hypothenar eminences. Partitions that pass deeply from the longitudinal bands of the palmar aponeurosis form eight narrow compartments; four contain the digital flexor tendons and four contain the lumbricals and the neurovascular bundles.

BONES

The skeleton of the hand comprises the carpus, metacarpus and the phalanges.

Carpus

The carpus contains eight bones: four each in proximal and distal rows (Figs 51.13–51.15). In radial to ulnar order, the scaphoid, lunate, triquetrum and pisiform make up the proximal row, and the trapezium, trapezoid, capitate and hamate make up the distal row. The pisiform articulates with the palmar surface of the triquetrum. The other three proximal bones form an arch that is convex proximally, and which articulates with the distal surface of the radius and central articular disc of the triangular fibrocartilage complex. The distal concavity of the arch articulates with the capitate and hamate.

The dorsal carpal surface is convex. The palmar surface forms a deeply concave carpal groove, accentuated by the palmar projection of the radial and ulnar borders. The ulnar projection is formed by the pisiform and the hook (hamulus) of the hamate. The pisiform is at the proximal border of the hypothenar eminence, on the ulnar side of the palm, and it is easily felt in front of the triquetrum. The hamulus is concave in a radial direction; its tip is palpable 2.5 cm distal and 1 cm radial to the pisiform, in line with the radial border of the ring finger. The radial border of the carpal groove is formed by the tubercles of the scaphoid and trapezium. The former is distal on the anterior scaphoid surface and palpable (sometimes also visible) as a small medial knob at the proximal border of the palmar thenar eminence, radial to the tendon of flexor carpi radialis. The tubercle of the trapezium is a vertically rounded ridge on the anterior surface of the bone, slightly hollow medially and just distal and radial to the scaphoid tubercle. The scaphoid can be moved passively into extension by direct backward pressure onto the scaphoid tubercle. The carpal groove is converted into an osseofibrous carpal tunnel by the flexor retinaculum which is attached to its margins: the tunnel transmits flexor tendons and the median nerve into the hand. The retinaculum strengthens the carpus and augments flexor efficiency. Ligaments are attached to the palmar and dorsal surfaces of all of the carpal bones, interconnecting the bones with each other and also to the radius, ulna and metacarpals.

Individual carpal bones

Scaphoid

The scaphoid is the largest element in the proximal carpal row (see Fig. 51.15A). It has a long axis that is distal, radial and palmar in

The vertical septa act as spacers between the tendons and neurovascular bundles of the individual digital rays. Where tendons change direction around a concave surface, the channels are thickened. The flexor tendon sheaths, flexor retinaculum and extensor retinaculum act as sheaths or pulleys to prevent bow-stringing of the tendons .

At points where compressive loading is applied to the hand, such as the finger pulp and palm, loculi of fat act as shock absorbers. The loculi are contained within defined fibrous boundaries, which means that the shape, but not the volume, of each loculus can change. The compliance or deformability of the boundaries determines the amount of shock absorption. The palm also contains much larger fibrous compartments between skin and skeleton that transmit muscles, tendons and other structures. The honeycomb pattern of these compartments constitutes the palmar shock absorption system. The soft, padded parts of the hand are able to conform to the contours of objects that are grasped which allows better interpretation of sensation and better grip. The hand must also resist tensile loading. Tendons and ligaments are particularly suitable for resisting such forces but many other parts of the fascial continuum, such as the anchorage system of the palm, also play a major role in resisting 'pulling' forces.

Whilst the thin hair-bearing skin on the dorsum has considerable excursion on flexion and extension, the thick palmar skin is retained by fascial ligaments that allow the hand to flex while retaining the skin in position. The palmar creases have been described as skin 'joints'. Fascial anchors may be vertical (perpendicular to the palm), as in the mid-palm, where scattered vertical fibres run from the dermis down into the depths of the hand; horizontal (in the plane of the palm); or oblique to the skin surface. As the hand grips an object, the skin creases constrain each intervening cushion of fat to provide a secure conforming grip; adhesion is further improved by sweating of the palmar skin.

The insertion of the longitudinal (pretendinous) fibres of the palmar aponeurosis is an example of a well-developed horizontal anchorage system. The most superficial longitudinal fibres insert into the dermis of the distal palm. This arrangement resists horizontal shearing force in gripping tasks, such as holding a hammer, where it prevents distal skin slippage or degloving of the palm during use. The characteristic blisters on the palms of those unaccustomed to such use map out the sites of the skin anchorage points. This anchorage system can be demonstrated by flexing the palm until the skin of the distal palm folds loosely. An attempt to pull the loose skin distally will reveal the anchoring longitudinal fibres of the palmar aponeurosis. Oblique anchors occur in the fingers where Cleland's ligaments tether the skin of the proximal and middle segments of the digits to the region of the proximal interphalangeal joints.

Binding

Transversely orientated fascial structures help to maintain the transverse arch of the hand by 'binding' the underlying skeletal structures or the tendon sheaths.

Limiting or tethering

Joint motion is limited not only by the action of its ligaments but also, in some cases, by skin tightness. Skin in the interdigital webs is reinforced by the natatory ligaments in the fingers and by the commissural ligament in the thumb, which resist stretch. The volar plates of the metacarpophalangeal and interphalangeal joints limit hyperextension. The deep transverse intermetacarpal ligaments prevent splaying (abduction from the axis of the third metacarpal).

Since the oblique retinacular ligament of Landsmeer runs from an attachment anterior to the axis of the proximal interphalangeal joint to an insertion posterior to the axis of the distal interphalangeal joint, it causes obligatory extension of the distal interphalangeal joint when the proximal interphalangeal joint extends – a 'tenodesis' effect.

Lubrication

There are many other gliding planes, e.g. between periosteum and the extensor apparatus, and between the extensor apparatus and the skin, on the dorsum of the digits. The flexor tendon sheaths are lined by synovium: the extensor tendons are also invested in a synovial gliding plane. Biomechanical studies of tendons gliding within their sheaths have emphasized the importance of avoiding extreme postures of a joint, which increase the friction between tendon and pulley, as well as the need to establish a smooth, well-lubricated tendon surface after repair. Increased friction within a tendon sheath may, in part, explain the cause of spontaneous rupture of extensor pollicis longus because the gliding resistance of the tendon has been shown to be significantly higher than that of other tendons (An 2007).

Vascular protection and pumping action

The blood vessels of the palm are surrounded by a cuff of tough fascia or by a fatty pad. When the hand is compressed, as in gripping, these relatively incompressible fascial structures protect the predominantly palmar arterial inflow into the hand to some extent. By contrast, large capacitance veins on the dorsum of the hand lie in gliding skin, surrounded by loose areolar tissue which allows the veins to dilate. However, when the hand grips firmly, the skin tightens, so expressing the venous blood.

Framework for muscle attachments

The fascial framework can be visualized as a harness by which muscles can act on the underlying skeleton: many of the small muscles of the hand are attached to it, at least in part. The metacarpophalangeal joint is moved by a ring of fascial and ligamentous structures that surrounds the joint and to which tendons are attached.

The cause of Dupuytren's disease remains unknown. Many theories have been postulated. Geographical variations in incidence suggest a genetic cause, but it is not a monoclonal process (Chansky et al 1999) and at least nine genetic loci have been implicated in its development (Dolmans et al 2011). Environmental risk factors include alcohol consumption, smoking, diabetes, manual work and vibration exposure, and possibly the ingestion of anticonvulsants (Descatha et al 2011). In the proliferative stage of the disease, there is considerable myofibroblast activity, which may be the result of upregulation of the musculo-aponeurotic fibrosarcoma oncogene homologue B (*MafB*), found in the diseased cord tissue (Lee et al 2006). Mechanical stimuli subsequently cause the alignment of myofibroblasts along the lines of traction, which are later replaced by collagen. These collagenous cords cause the flexion contractures that characterize the disease. Treatment of Dupuytren's disease includes suppressing myofibroblast turnover with radiotherapy; dividing the cord (fasciotomy) with a percutaneous needle or an enzyme (collagenase); surgically removing the cord (fasciectomy), which can include removal of the overlying involved skin (dermofasciectomy), and replacement with disease-free skin from elsewhere (skin autograft) .

The pattern of contracture is determined by the anatomy of the basic constituents of the palmar and digital fasciae. The physiological 'bands' formed by the healthy palmar fascia are replaced by pathological 'cords' of diseased tissue. The pretendinous bands that constitute the superficial layer (layer 1) of the palmar aponeurosis are most frequently involved. The development of nodules that tether the skin to the deep fascia usually precedes cord formation. Contracture of the pretendinous cords causes flexion of the metacarpophalangeal joints. Shortening of the vertical fibres causes skin pits. Involvement of the natatory ligament restricts abduction of the fingers. The transverse metacarpal fibres are never contracted and are a useful surgical landmark in the palm because the neurovascular bundle runs deep to them. The vertical fibres can become very thickened but do not contract: they form a dense barrier between the flexor tendons and the neurovascular bundle.

The pretendinous cord in the palm extends into a finger as a central cord that lies superficially in the midline. The lateral digital sheet gives rise to a lateral cord that is attached to the skin or flexor tendon sheath near Grayson's ligament, causing a flexion contracture of the proximal interphalangeal joint and, sometimes, displacing the digital neurovascular bundle medially. Spiral cords arise from the pretendinous band in layer 1 of the palmar fascia and pass deeper through layer 2 to become attached to the middle phalanx by Grayson's ligament. They are so named because they spiral round the neurovascular bundle, displacing it proximally, palmarwards and towards the midline as contracture increases, rendering it vulnerable to injury during fasciectomy (McFarlane 1974).

The ulnar side of the little finger often develops a dense cord (Barton's 'abductor cord') that runs from the medial edge of the insertion of abductor digiti minimi, through the lateral digital sheet and onto the anteromedial surface of the flexor sheath at the level of the A3 pulley. This causes a pronounced flexion contracture of the proximal interphalangeal joint and must be fully removed to achieve a successful and durable correction.

The distal interphalangeal joint is uncommonly involved because the palmar aponeurosis usually peters out beyond the sides of the middle phalanx. Nevertheless, a thin tight cord on one or other side of the digit can occur, causing a combined contracture of the proximal and distal interphalangeal joints. Distal interphalangeal joint hyperextension can occur in association with a severe prolonged contracture of the proximal interphalangeal joint, with secondary attrition of the central slip, soft tissue contractures and boutonnière deformity. Some authors have suggested that this deformity occurs because Dupuytren's disease affects the oblique retinacular ligament (Littler 1967).

The spaces of the hand form predictable sites of infection and also limit its spread. Infections in the digit can occur in the nail fold (paronychia); the distal pulp (a felon); and the flexor sheaths. The flexor synovial sheath of the thumb and the little finger often connect in the palm (see Fig. 51.27C) such that an infection in one can spread to the other causing a 'horseshoe abscess'. Deep infections in the palm are not usually confined to any particular space; the infection may be inoculated by direct penetration but more often occurs from a primary infection in the web space or flexor sheath.

An abscess in any of the digital or palmar spaces should always be drained. An understanding of the anatomy is crucial to successful surgical treatment. Incisions should, wherever possible, follow the line of the flexion creases and adhere to the principles of extensile exposure. A felon is drained with a midlateral incision or midline incision avoiding the neurovascular bundle and spreading apart the taut vertical septa. A web space infection is drained with a longitudinal incision that allows extensile exposure of the web space and the lumbrical-interosseous canals, also avoiding a web contracture that would follow a transverse incision. A thenar space abscess is drained through a palmar incision: the motor and palmar cutaneous branches of the median nerve are very vulnerable to iatrogenic damage (Birch 2011). The mid-palmar space is best approached through a combination of a transverse distal palmar incision with an oblique longitudinal extension (McDonald et al 2011), although alternative incisions can be employed, based on the location and size of the collection. Hypothenar space infections are very rare and tend to be confined by the hypothenar fascia, resulting in swelling of the ulnar side of the hand with some flexion and adduction of the little finger. These lesions are of less clinical consequence than other palmar collections because there is no direct communication with the two other major palmar spaces and hence the long flexors of the fingers and lumbricals are not involved. They may be drained by an incision along the ulnar border of the space without significant risk of damage to underlying structures. The flexor sheath is drained by a transverse or oblique incision over the flexion crease of the distal interphalangeal joint and another over the distal palmar (metacarpophalangeal) joint crease.

There are 10 identifiable muscle compartments in the hand: four contain each of the dorsal interossei; three contain the palmar interossei; three contain the thenar, hypothenar and adductor compartments. Any or all of these compartments may be injured by a rise in intracompartmental pressure caused by bleeding, blast, burn, crush, ischaemia–reperfusion and by injection, whether of therapeutic substances at low pressure or of industrial agents at high pressure. This rise in pressure prevents venous inflow then capillary (low pressure) inflow. Arterial (high pressure) inflow persists which causes yet more congestion; this compounds the rise in compartment pressure and the condition deteriorates. The tissues then become ischaemic, causing transient impairment then permanent necrosis. The hand will be extremely painful, usually with tingling and weakness due to nerve ischaemia. It becomes increasingly swollen. On examination, the tissues are tense; passive movement of the fingers is very painful due to stretching of the ischaemic muscles. There will be reduced sensitivity in the territory of the nerves passing through the compartment. Intra-compartmental pressure measurements should be taken; the means by which this is done is not critical (Ortiz and Berger 1998) but it should not delay emergency surgery if the diagnosis is reasonably suspected.

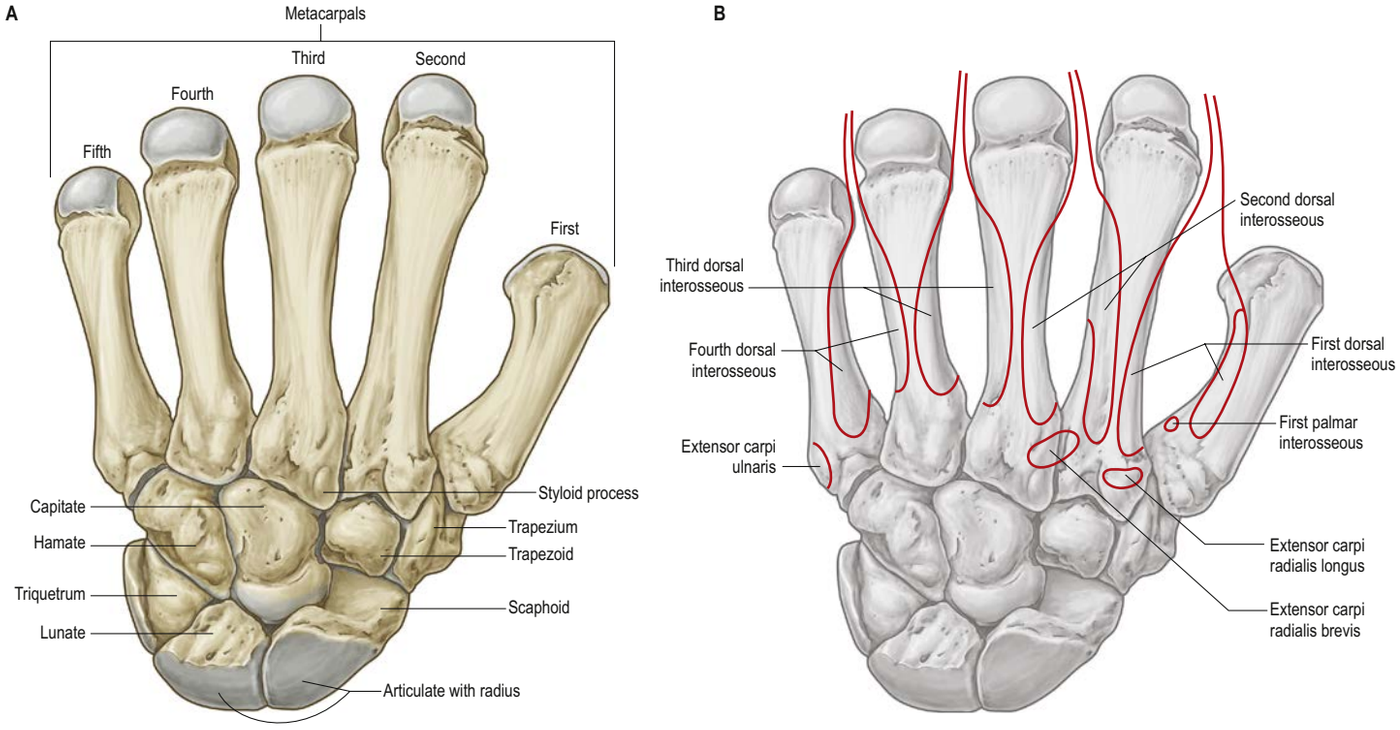

Fig. 51.14 **A**, The carpals and metacarpals of the left hand: dorsal aspect. **B**, Sites of muscle attachments.

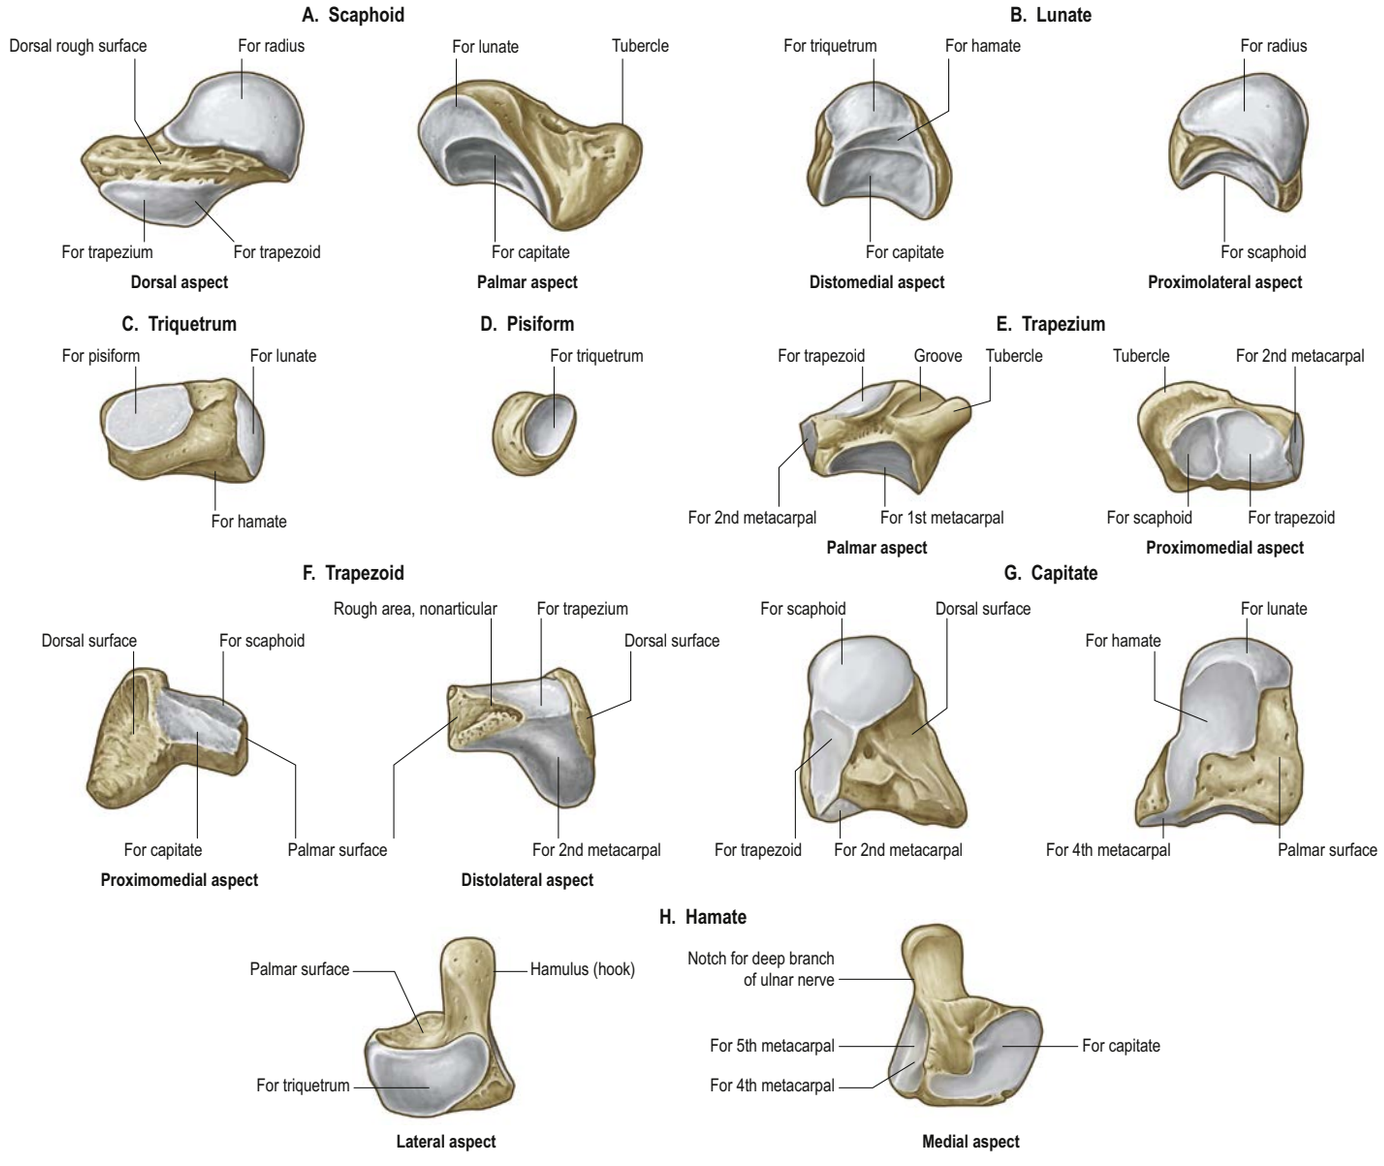

Fig. 51.15 Disarticulated carpal bones.

direction. A round tubercle on the distolateral part of its palmar surface is directed anterolaterally, and provides an attachment for the flexor retinaculum and abductor pollicis brevis; it is crossed by the tendon of flexor carpi radialis. The rough dorsal surface is slightly grooved, narrower than the palmar, and pierced by small nutrient foramina, which are often restricted to the distal half. The radial collateral ligament is attached to the lateral surface, which is also narrow and rough. The remaining 42% of the surfaces are all articular. The radial (proximal) surface is convex, proximal and directed proximolaterally; the lunate surface is flat and semilunar, and faces medially; the capitate surface is large, concave, distal and directed distomedially. The surface for the trapezium and trapezoid is continuous, convex and distal.

The blood supply of the scaphoid is derived from two sources (Gelberman and Menon 1980). Its dorsal ridge is penetrated by the dorsal scaphoid artery and by branches of the styloid artery. Its distal pole receives vessels from the palmar carpal artery or, in its absence, from branches of the superficial palmar artery (Oehmke et al 2009) or the first dorsal metacarpal artery. Variation in this pattern is not uncommon. The proximal pole is circumferentially devoid of periosteum and therefore has no arterial supply: it relies on intraosseous flow from the dorsal and distal supply, which is disrupted in a fracture through the waist of the scaphoid.

Scaphoid bone fractures

Available with the *Gray's Anatomy* e-book

Lunate

The lunate is approximately semilunar and articulates between the scaphoid and triquetrum in the proximal carpal row (see Fig. 51.15B). Its rough palmar surface, almost triangular, is larger and wider than the rough dorsal surface. Its smooth convex proximal surface articulates with the radius and the articular disc of the distal radio-ulnar joint. Its narrow lateral surface bears a flat semilunar facet for the scaphoid. The medial surface, which is almost square, articulates with the triquetrum and is separated from the distal surface by a curved ridge, usually somewhat concave for articulation with the edge of the hamate in adduction. The distal surface is deeply concave to fit the medial part of the head of the capitate. Its articulation with the hamate varies: in the type 1 lunate (35–55%) there is no articulation with the hamate, whereas in the type II lunate (45–65%), the medial facet articulates with the hamate (Viegas 1990). The blood supply relies on variable palmar (volar) and dorsal arteries that may or may not anastomose within the bone.

Kienböck's disease

Available with the *Gray's Anatomy* e-book

Triquetrum

The triquetrum is somewhat pyramidal. Its distal palmar surface bears an oval isolated facet for articulation with the pisiform. Its medial and dorsal surfaces are confluent (see Fig. 51.15C). The dorsal surface is marked by the strong ligamentous attachments of the ulnocarpal, dorsal intercarpal and radiolunate ligaments and is marked distally by the attachment of the ulnar collateral ligament, but is smooth proximally to match the articular disc of the triangular fibrocartilage complex. The lateral and distal, hamate, surface is concavo-convex, broad proximally and narrow distally. The lateral and proximal, lunate, surface is almost square.

Pisiform

The pisiform is a sesamoid bone within the tendon of flexor carpi ulnaris that increases the flexion torque applied by the muscle. It is shaped like a pea, with a distolateral long axis (see Fig. 51.15D). It bears a dorsal flat articular facet for the triquetrum. The tendon of flexor carpi ulnaris and its distal continuations, the pisometacarpal and pisohamate ligaments, are all attached to the palmar non-articular area. The deep motor branch of the ulnar nerve runs on its radial side.

Trapezium

The trapezium has a tubercle and groove on its rough palmar surface (see Fig. 51.15E). The tendon of flexor carpi radialis passes dorsomedial to the tubercle which acts as a pulley to prevent flexor carpi radialis from bowstringing palmarwards on flexion. Two layers of the flexor retinaculum are attached to its margins. The tubercle is obscured by the thenar muscles attached to it (opponens pollicis, flexor pollicis brevis and abductor pollicis brevis) (see Fig. 51.13B). The elongated, rough dorsal surface is related to the radial artery. The large lateral surface is rough for attachment of the radial collateral ligament and capsular ligament of the carpometacarpal joint of the thumb. A large sellar surface faces distolaterally and articulates with the base of the first metacarpal. Most distally, it projects between the bases of the first and second metacarpals and carries a small, quadrilateral, distomedially directed facet that articulates with the base of the second metacarpal. The large medial surface is gently concave for articulation with the trapezoid. The proximal surface is a small, slightly concave facet for articulation with the scaphoid. Its ridge, or 'summit', fits the concavity of the base of the first metacarpal, and extends in a palmar and lateral direction, at an angle of approximately 60° with the plane of the second and third metacarpals. Abduction and adduction occur in the plane of the ridge, which is shorter than the corresponding metacarpal groove. Their contours vary reciprocally: they are more curved near the base of the second metacarpal, whereas the radius of curvature is longer further away from this site. The two surfaces are not completely congruent, and the area of close contact probably moves towards the palm in adduction and dorsally in abduction. While the axis of flexion/extension passes through the trapezium, the axis for adduction/abduction is in the metacarpal base. Flexion is accompanied by medial rotation, and extension by lateral rotation.

Trapezoid

The trapezoid is small and irregular. It has a rough palmar surface that is narrower and smaller than its rough dorsal surface (see Fig. 51.15F). The distal surface, which articulates with the grooved base of the second metacarpal, is triangular, convex transversely and concave at right-angles to this. The medial surface articulates by a concave facet with the distal part of the capitate, the lateral surface articulates with the trapezium, and the proximal surface articulates with the scaphoid.

Capitate

The capitate is the central and largest carpal bone. It articulates with the base of the third metacarpal via its triangular distal concavo-convex surface (see Fig. 51.15G). Its lateral border is a concave strip for articulation with the medial side of the base of the second metacarpal. Its dorsomedial angle usually bears a facet for articulation with the base of the fourth metacarpal. The head projects into the concavity formed by the lunate and scaphoid, the proximal surface articulates with the lunate, and the lateral surface with the scaphoid. The facets for the scaphoid and trapezoid, though usually continuous on the distolateral surface, may be separated by a rough interval. The medial surface bears a large facet for articulation with the hamate, which is deeper proximally where it is partly non-articular. Palmar and dorsal surfaces are roughened for carpal ligaments, the dorsal being the larger.

Hamate

The hamate is cuneiform and bears an unciform hamulus (hook) that projects from the distal part of its rough palmar surface (see Fig. 51.15H). The hamulus is curved with a lateral concavity and its tip inclines laterally, contributing to the medial wall of the carpal tunnel. The tendon of flexor digitorum profundus to the little finger passes directly radial to the hamulus which acts as a pulley because the origin of this tendon is more radial than its insertion. The flexor retinaculum is attached to the apex of the hamulus. Distally, on the base of the hamulus, a slight transverse groove may be in contact with the terminal deep branch of the ulnar nerve. The remaining palmar surface, like the dorsal, is roughened for the attachment of ligaments. A faint ridge divides the distal surface into a smaller lateral facet that articulates with the base of the fourth metacarpal, and a medial facet for articulation with the base of the fifth. The proximal surface, the thin margin of the wedge, sometimes bears a narrow facet that contacts a reciprocal facet on the lunate. The medial surface is a broad strip, convex proximally, concave distally, that articulates with the triquetrum; distally, a narrow medial strip is non-articular. The lateral surface articulates with the capitate by a facet covering all but its distal palmar angle.

Ossification

Each carpal bone is ossified from one centre (**Fig. 51.16A–D**). Most are cartilaginous at birth, although ossification may have started in the capitate and hamate. The triquetrum begins to ossify in the third

year and the lunate, scaphoid, trapezium and trapezoid begin to ossify in either the fourth year (females) or the fifth year (males). The pisiform begins to ossify in the ninth or tenth year (females) and in the twelfth year (males). The order varies according to sex, nutrition and, possibly, race. Occasionally, an os centrale occurs between the scaphoid, trapezoid and capitate bones and usually fuses with the scaphoid. Lunate and triquetral elements may occasionally fuse. Other fusions and accessory ossicles have also been described (Vaz and Trippia 2018).

Metacarpus

The metacarpus consists of five metacarpals, conventionally numbered in radio-ulnar order. These are small long bones, with a distal head, shaft and expanded base. The rounded heads articulate with the proximal phalanges. The articular surfaces of the head are convex, although less so transversely, and extend further on the palmar surfaces, especially at their margins. From a distal perspective the metacarpal head has a trapezoidal shape and is broader on its palmar aspect than its dorsal. The knuckles are produced by the metacarpal heads. The metacarpal bases articulate with the distal carpal row and with each other. The shafts have longitudinally concave palmar surfaces, which form hollows for the palmar muscles. Their dorsal surfaces bear a distal triangular area, which is continued proximally as a round ridge. These surfaces are palpable proximal to the knuckles.

The medial four metacarpals gently diverge proximodistally. The first metacarpal is more anterior and rotated medially on its axis through 90°, so that its morphologically dorsal surface is lateral, its radial border palmar, its palmar surface medial, and its ulnar border dorsal. Hence, the thumb flexes medially across the palm and can be rotated into opposition with each finger. Opposition is important in manual dexterity and depends on pronation of the thumb carpometacarpal joint and flexion-supination of the little finger carpometacarpal joint. When an object is grasped, the fingers and thumb encircle it from opposite sides, greatly increasing the power and precision of the grip.

Individual metacarpals

First metacarpal

The first metacarpal is shorter and thicker than the other metacarpals (**Fig. 51.17A**). Its dorsal (lateral) surface can be felt to face laterally; its long axis diverges distolaterally from its neighbour. The shaft is flattened, dorsally broad and transversely convex. The palmar (medial) surface is longitudinally concave and divided by a ridge into a larger lateral (anterior) and smaller medial (posterior) part. Opponens pollicis is attached to the radial border and adjoining palmar surface: the first dorsal interosseous muscle (radial head) is attached to its ulnar border and adjacent palmar surface. The base is concavo-convex and articulates with the trapezium. Abductor pollicis longus is attached on its lateral (palmar) side, the first palmar interosseous muscle to its ulnar side. The head is less convex than in other metacarpals and is transversely broad. Sesamoid bones glide on radial and ulnar articular eminences on its palmar aspect.

Second metacarpal

The second metacarpal has the longest shaft and largest base (**Fig. 51.17B**). The latter is grooved in a dorsopalmar direction for articulation with the trapezoid. Medial to the groove, a deep ridge articulates with the capitate; laterally, nearer the dorsal surface of the base, there is a quadrilateral facet for articulation with the trapezium, and just dorsal to this facet, a rough impression marks the attachment of extensor carpi radialis longus. On the palmar surface, a small tubercle or ridge receives flexor carpi radialis. The medial side of the base articulates with that of the third metacarpal by a long facet, centrally narrowed. The shaft is prismatic in section and longitudinally curved, convex dorsally, concave towards the palm. Its dorsal surface is distally broad but proximally narrows to a ridge that is covered by extensor tendons of the index finger. Its converging borders begin at the tubercles, one on each side of its head for the attachment of collateral ligaments. Proximally, the lateral surface inclines dorsally for the ulnar head of the first dorsal interosseous. The medial surface inclines similarly, and is divided by a faint ridge into a palmar strip for attachment of the second palmar interosseous, and a dorsal strip for attachment of the radial head of the second dorsal interosseous.

Third metacarpal

The third metacarpal has a short styloid process which projects proximally from the radial side of the dorsal surface (**Fig. 51.17C**). Its base articulates with the capitate by a facet which is anteriorly convex but dorsally concave where it invades the styloid process on the lateral aspect of its base. A strip-like facet, constricted centrally, articulates with the bases of the second metacarpal (laterally) and the fourth metacarpal (medially), the latter by two oval facets. The palmar facet may be absent: less frequently, the facets are connected proximally by a narrow bridge. The palmar surface of the base receives a slip from the tendon of flexor carpi radialis: extensor carpi radialis brevis is attached to its dorsal surface, beyond the styloid process. The shaft resembles that of the second metacarpal. The ulnar head of the second dorsal interosseous muscle is attached to its lateral surface; the radial head of the third dorsal interosseous is attached to its medial surface, and the transverse head of adductor pollicis to the intervening palmar ridge in its distal two-thirds. Its dorsal surface is covered by the extensor tendon.

Fourth metacarpal

The fourth metacarpal is shorter and thinner than the second and third (**Fig. 51.17D**). On its base, it displays two lateral oval facets for articulation with the base of the third metacarpal; the dorsal is usually larger and proximally in contact with the capitate. A single medial elongated facet is for articulation with the base of the fifth metacarpal. The quadrangular proximal surface articulates with the hamate; it is anteriorly convex and dorsally concave. The shaft is like the second, but a faint ridge on its lateral surface separates the attachments of the third palmar interosseous and the ulnar head of the third dorsal interosseous. The radial head of the fourth dorsal interosseous is attached to the medial surface.

Fifth metacarpal

The fifth metacarpal (**Fig. 51.17E**) differs in its medial basal surface, which is non-articular and bears a tubercle for extensor carpi ulnaris. The lateral basal surface is a facet, transversely concave, convex from palm to dorsum, for articulation with the hamate. A lateral strip articulates with the base of the fourth metacarpal. The shaft bears a triangular dorsal area that almost reaches the base; the lateral surface inclines dorsally only at its proximal end. Opponens digiti minimi is attached to the medial surface. The lateral surface is divided by a ridge, which is sometimes sharp, into a palmar strip for the attachment of the fourth palmar interosseous and a dorsal strip for the ulnar part of the fourth dorsal interosseous.

Ossification

Each metacarpal ossifies from a primary centre for the shaft and a secondary centre that is in the base of the first metacarpal and in the heads of the other four (**Fig. 51.18**).

Ossification begins in the midshaft about postmenstrual week 11. Centres for the second to fifth metacarpal heads appear in that order in the second year in females, and between 1½ to 2½ years in males. They unite with the shafts about the fifteenth or sixteenth year in females, and the eighteenth or nineteenth in males. The first metacarpal base begins to ossify late in the second year in females, early in the third year in males, uniting before the fifteenth year in females and seventeenth in males. Sometimes, the styloid process of the third metacarpal is a separate ossicle. The thumb metacarpal ossifies like a phalanx, and some authorities therefore consider that the thumb skeleton consists of three phalanges. Others believe that the distal phalanx represents fused middle and distal phalanges, a condition occasionally observed in the fifth toe. When the thumb has three phalanges, the metacarpal has a distal and a proximal epiphysis. It occasionally bifurcates distally. When it does, the medial branch has no distal epiphysis and bears two phalanges, while the lateral branch shows a distal epiphysis, and three phalanges. The existence of only a distal metacarpal epiphysis may be associated with a greater range of movement at the metacarpophalangeal joint. In the thumb, the carpometacarpal joint has the wider range, and the first metacarpal has a basal epiphysis. A distal epiphysis may appear in the first, and a proximal epiphysis in the second, metacarpal.

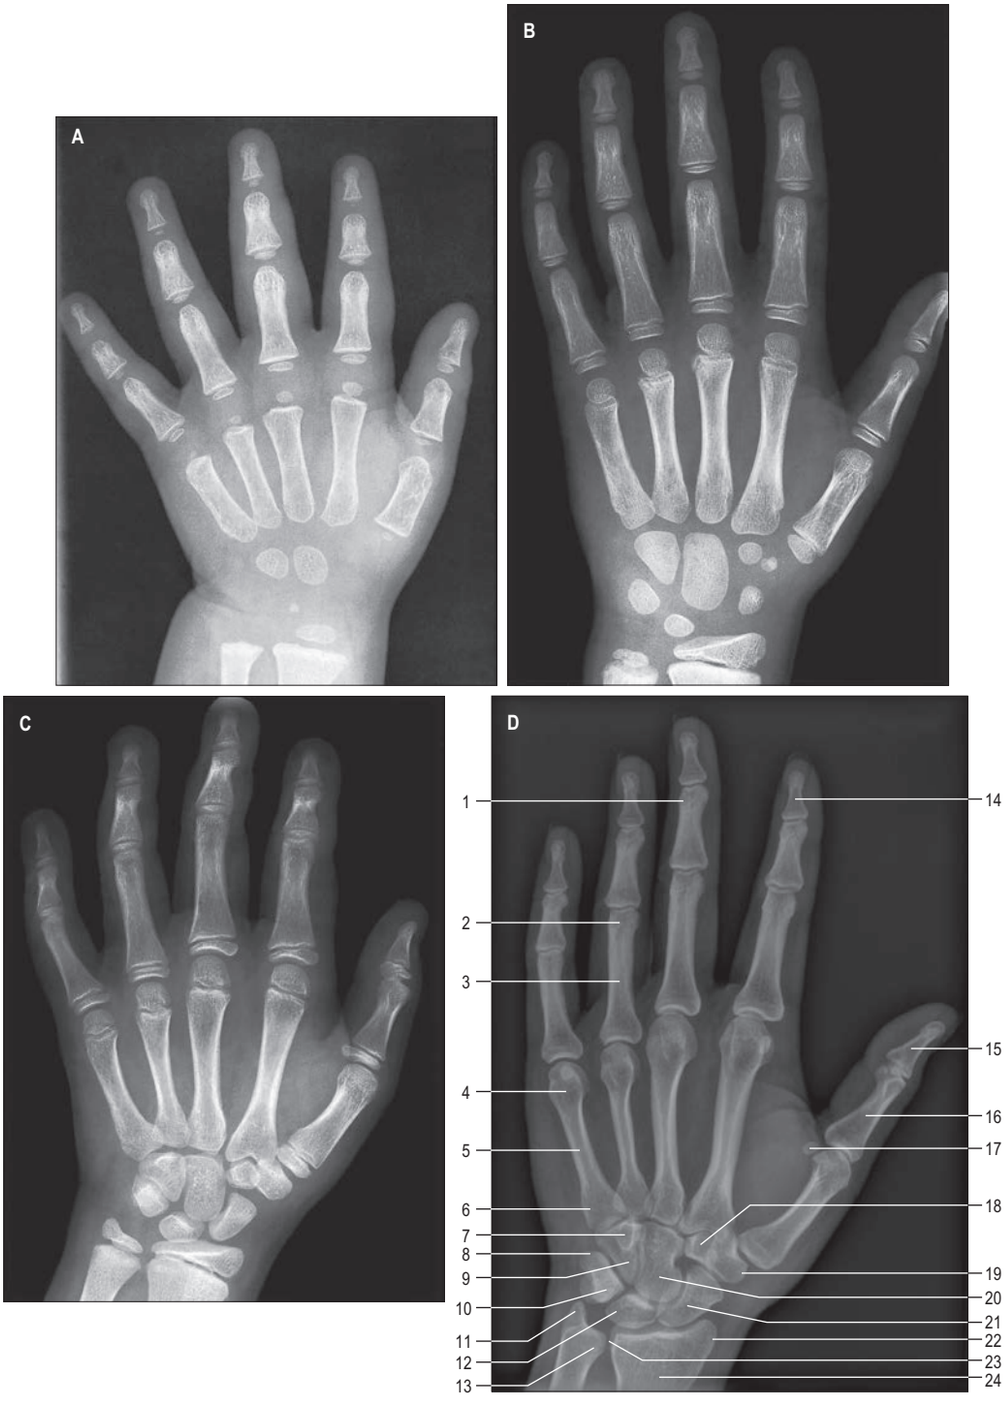

Fig. 51.16 A-D, Radiographs of hands illustrating maturing ossification from infant to adult, dorsopalmar projection. **A,** Male, 2½ years: note the early stages of ossification in the epiphyses at the proximal ends of the phalanges and first metacarpal; the distal ends of the remaining metacarpals and radius; and for the capitate, hamate and lunate. The centre for the lunate is typically preceded by the centre for the triquetrum. **B,** Male, 6½ years: note the more advanced state of the centres of ossification that are already visible in **A,** and the appearance of additional centres in the distal ulnar epiphysis and in the triquetrum, scaphoid, trapezium and trapezoid. **C,** Female, 11 years: compare the maturing ossification with that seen in **A** and **B**. Note the addition of the pisiform. **D,** Adult. Key: 1, head of middle phalanx of middle finger; 2, head of proximal phalanx of ring finger; 3, shaft of proximal phalanx of ring finger; 4, head of fifth metacarpal; 5, shaft of fifth metacarpal; 6, base of fifth metacarpal; 7, hook of hamate; 8, triquetrum; 9, hamate; 10, pisiform; 11, styloid process of ulna; 12, lunate; 13, head of ulna; 14, distal phalanx of index finger; 15, distal phalanx of thumb; 16, proximal phalanx of thumb; 17, sesamoid bone; 18, trapezoid; 19, trapezium; 20, capitate; 21, scaphoid; 22, styloid process of radius; 23, distal radio-ulnar joint; 24, radius.

The scaphoid is the most frequently fractured carpal bone (Kawamura and Chung 2008, Oka and Moritomo 2018), typically as a result of a fall on to the outstretched hand in a young adult male. The fracture most commonly occurs at the waist of the bone, probably because, on impact, the scaphoid folds into flexion over the taut radioscaphocapitate ligament. Distal tubercle fractures occur as a result of avulsions by the attached radial collateral ligament. Proximal fractures are the result of avulsion by the scapholunate ligament. Compson (1998), in a study of the true, rather than the radiological, anatomy of scaphoid fractures, identified three distinct fracture patterns: transverse through the 'surgical waist'; oblique (45° to the surgical waist) in the plane of the dorsal sulcus; and through the proximal pole. A fractured scaphoid is prone to non-union because of its anatomy. Since it is largely covered by articular cartilage, the surface area for arterial inflow is limited. There is no arterial inflow through the scapholunate ligament proximally; the blood supply enters distally, which means that a fracture through the

waist or more proximally will cut off the blood supply to the proximal pole. However, it has been argued that an inadequate blood supply is unlikely to be the cause of scaphoid non-union after fracture (Oehmke et al 2009, Sendher and Ladd 2013).

Kienböck's disease, first described in 1910, is avascular necrosis of the lunate. Its aetiology remains unclear but is thought to be associated with an impaired arterial blood supply. Variations in the vascular anatomy may render an individual at increased risk of osteonecrosis. Up to eight small vessels usually enter both the dorsal and the palmar aspects of the bone, three on the dorsal surface and five on the palmar; they divide into smaller branches within the bone. Obstruction of the venous outflow may also lead to osteonecrosis. Extrinsic, nonvascular aetiological factors include trauma, steroid use and mechanical factors such as negative ulnar variance or variations in carpal osseous morphology that affect loading of the lunate.

While patients generally present with pain and stiffness of the wrist, these symptoms correlate poorly with the radiological findings and, indeed, patients may be asymptomatic. The natural history of the disease is variable; some progress and others do not. In the earliest stage, radiographs are normal and only an MRI can detect the disease. In later stages, the lunate becomes sclerotic and then collapses, the relative height of the lunate to the capitate diminishing from the usual ratio of 0.54. (For further reading, see Cross and Matullo (2014).)

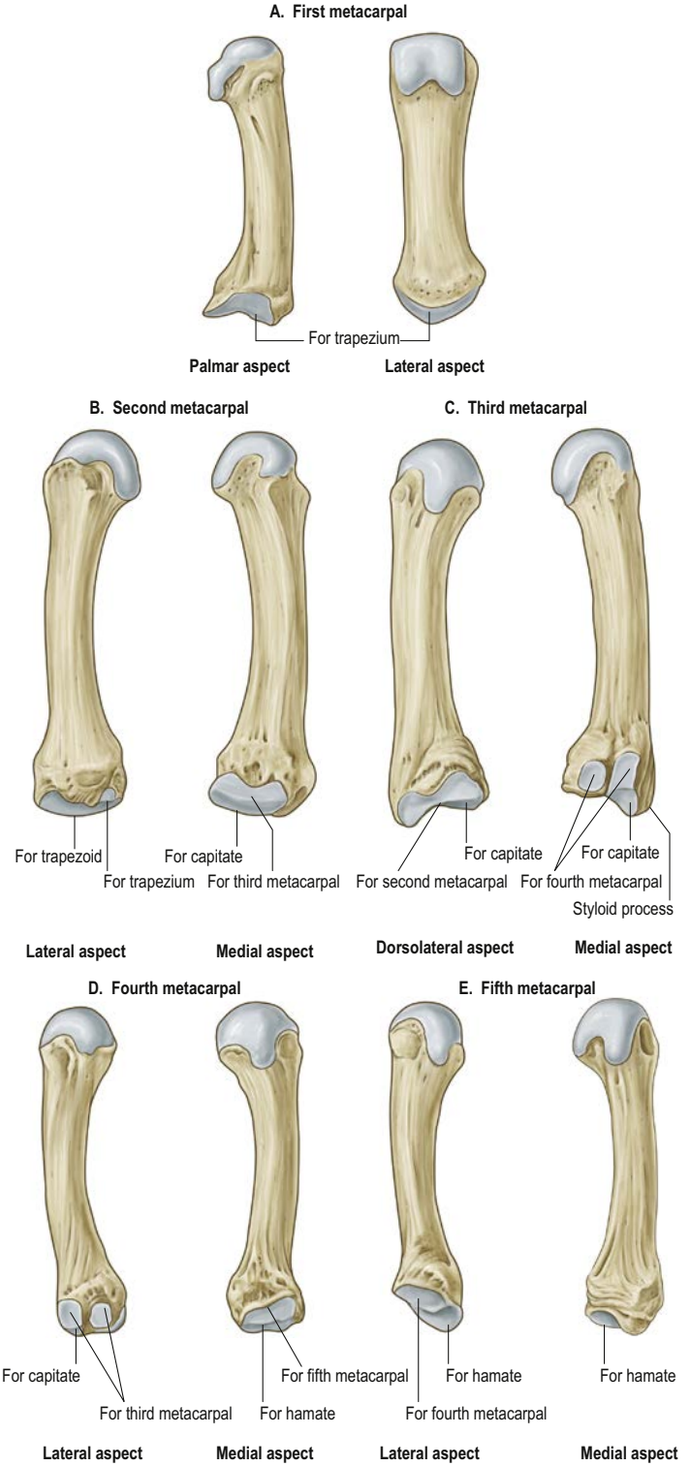

Fig. 51.17 Disarticulated metacarpal bones.

Phalanges

There are 14 phalanges, three in each finger and two in the thumb (see Fig. 51.18). Each has a head, shaft and proximal base. The shaft tapers distally, its dorsal surface transversely convex. The palmar surface is transversely flat but gently concave anteriorly in its long axis. The bases of the proximal phalanges carry concave, oval facets adapted to the metacarpal heads. Their own heads have a midline dorsal–palmar groove and encroach more on to the palmar surfaces. The bases of the middle phalanges carry two concave facets separated by a smooth ridge, conforming to the heads of the proximal phalanges and a dorsal lip to receive the central slip of the extensor tendon. The bases of the distal phalanges are adapted to the shallow midline groove of the middle phalangeal heads. A dorsal lip receives the conjoined extensor tendon and a palmar lip receives the flexor digitorum profundus tendon. The heads of the distal phalanges are non-articular and carry a rough, crescentic palmar tuberosity, to which the pulps of the fingertips are attached. The flatter dorsal surface is roughened to attach the nail matrix.

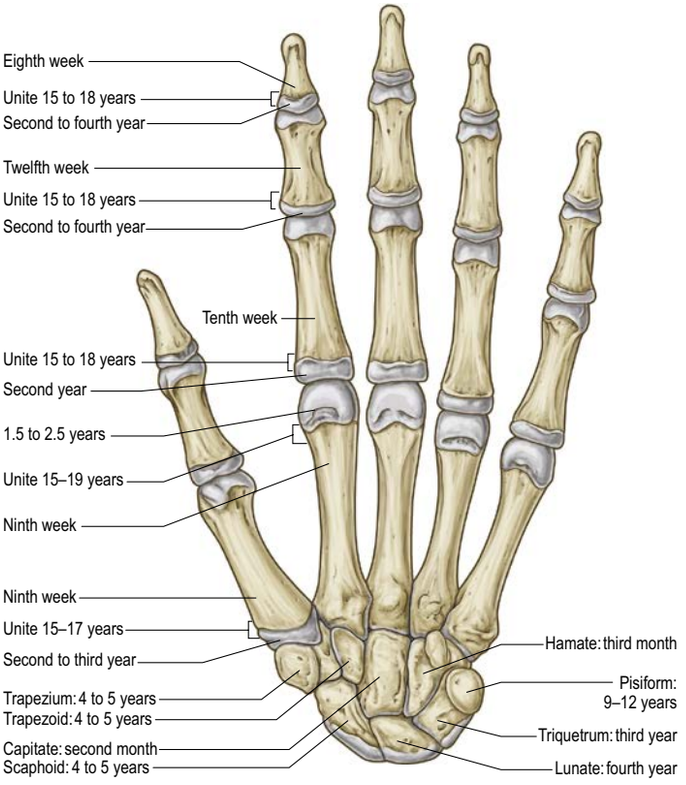

Fig. 51.18 The approximate dates of ossification of the individual bones of the hand and their epiphyses.

Articular ligaments and numerous muscles are attached to the phalanges. The tendon of flexor digitorum profundus is attached to the palmar aspect of the base of the distal phalanx and the tendon of extensor digitorum to its dorsal surface. The tendon of flexor digitorum superficialis is attached to the anterolateral surface of the middle phalanx, and the central slip of the extensor mechanism into the base dorsally. The fibrous flexor sheath is attached to the sides of the proximal and middle phalanx. The dorsal interosseous is attached to the base of the proximal phalanx laterally or medially.

The phalanges of the little finger and the thumb differ. Abductor digiti minimi and flexor digiti minimi are attached to the medial side of the base of the proximal phalanx of the little finger. The tendon of extensor pollicis brevis is attached to the dorsolateral corner of the base of the proximal phalanx. The oblique and transverse heads of adductor pollicis, sometimes conjoined with the first palmar interosseous (medially), are attached to the anteromedial corner of the base of the proximal phalanx of the thumb.

Ossification

Phalanges are ossified from a primary centre for the shaft and a proximal epiphysial centre (see Fig. 51.18). Ossification begins prenatally in the shafts as follows: distal phalanges after postmenstrual week 10, proximal phalanges after postmenstrual weeks 11–12 and middle phalanges after postmenstrual week 14. Epiphysial centres appear in proximal phalanges early in the second year (females), or later in the same year (males), and in middle and distal phalanges in the second year (females), or third or fourth year (males). All epiphyses unite about the fifteenth to sixteenth year (females), and seventeenth to eighteenth year (males).

JOINTS

Radiocarpal joint

Articulating surfaces The radiocarpal joint is a synovial, biaxial and ellipsoid joint formed by articulation of the distal end of the radius and the articular disc of the triangular fibrocartilage (which overlies the ulnar head) with the scaphoid, lunate, triquetrum and their interposed ligaments (Figs 51.19–51.20). In the neutral position of the wrist, only the scaphoid and lunate are in contact with the radius and articular disc; the triquetrum comes into apposition with the disc only in full adduction of the wrist joint. The radial articular surface and distal discal surface form an almost elliptical, concave surface with a transverse long axis. The radial surface is bisected by an anteroposterior low ridge into two concavities to receive the reciprocal convex surface

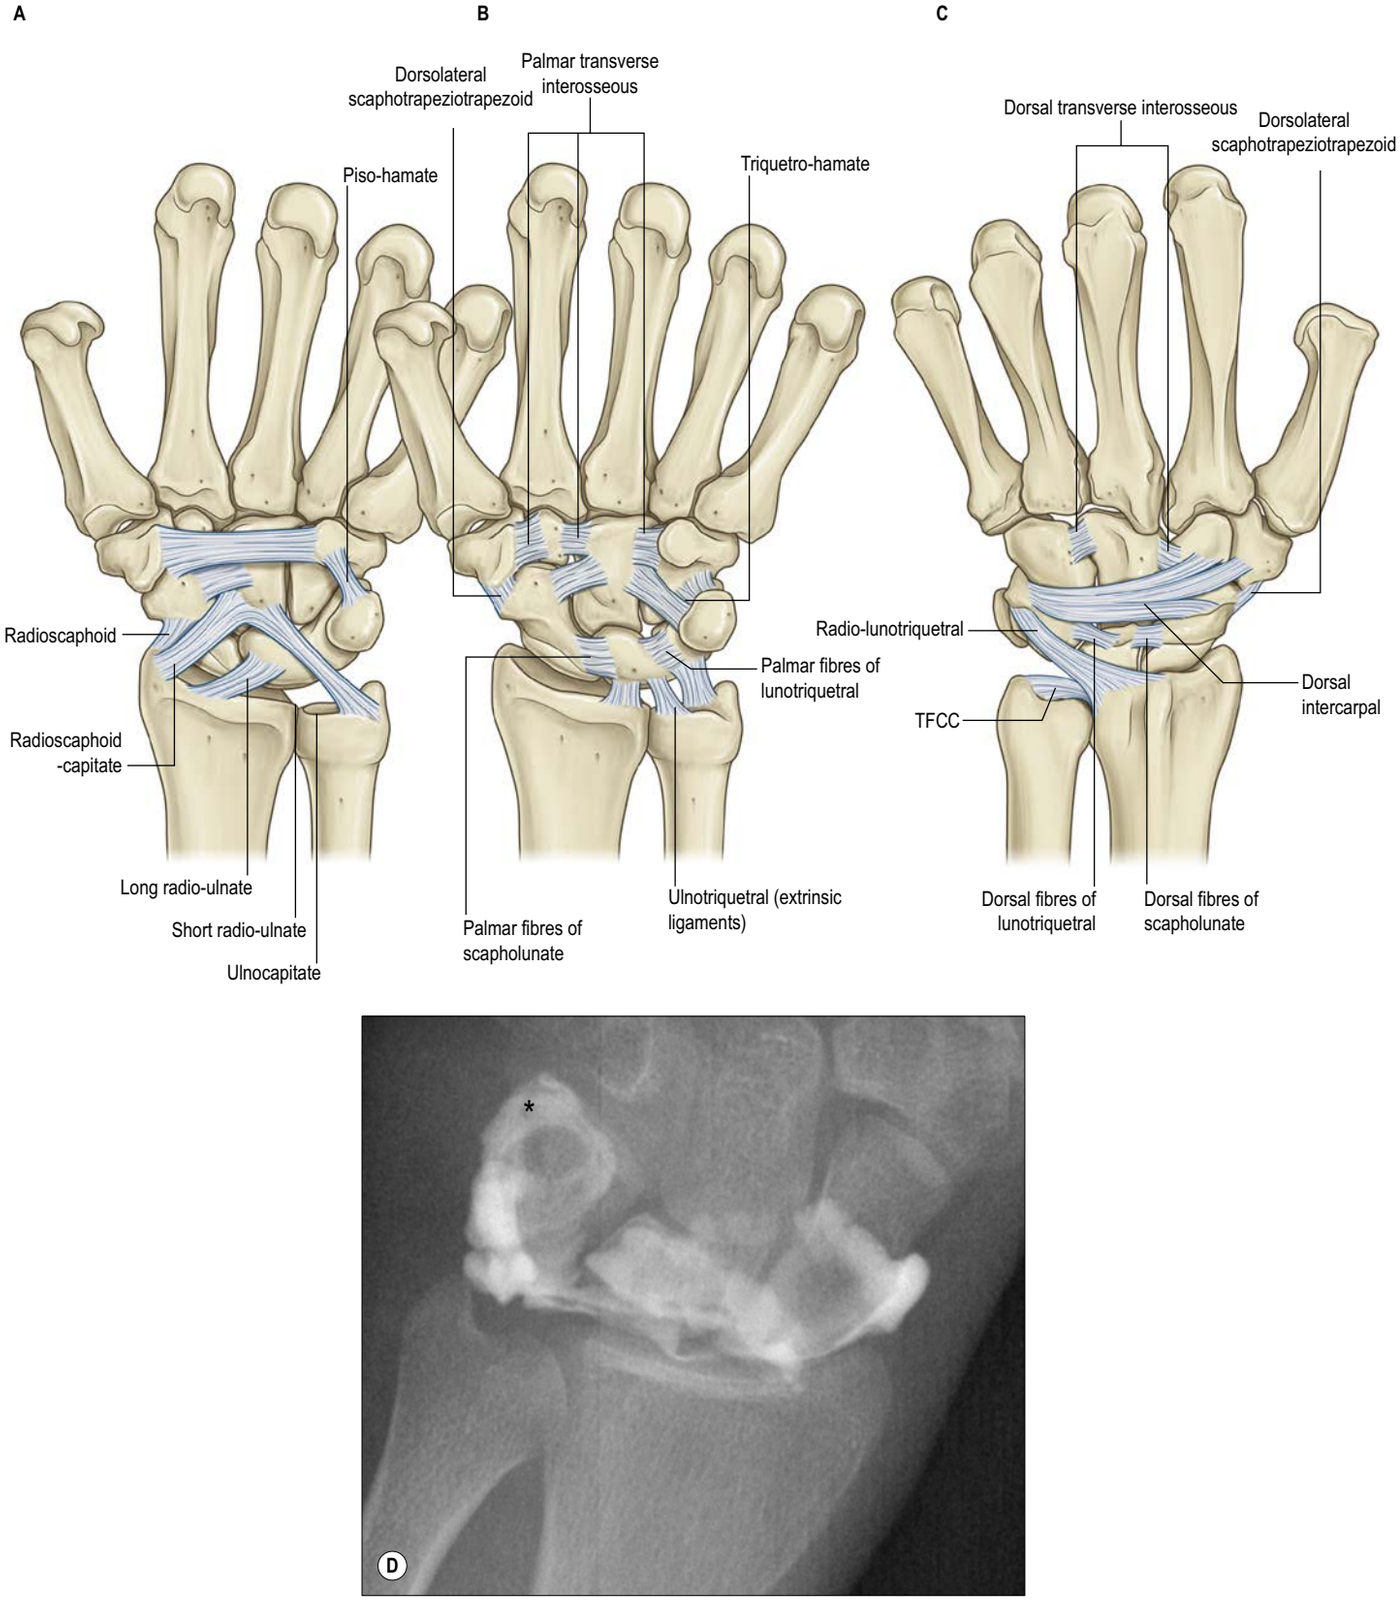

Fig. 51.19 The joints and ligaments of the left wrist. **A**, Palmar aspect: extrinsic ligaments. **B**, Palmar aspect: intrinsic ligaments. **C**, Dorsal aspect. Key: TFCC, triangular fibrocartilage complex. **D**, A fluoroscopic arthrogram of the radiocarpal joint. Contrast medium (white) has been injected into the joint space from the dorsal aspect and has remained within the radiocarpal joint, indicating that the scapholunate ligament, lunotriquetral ligament, and triangular fibrocartilage disc are intact. Some normal extension is seen into the pisotriquetral recess at the ulnar aspect of the joint (*).

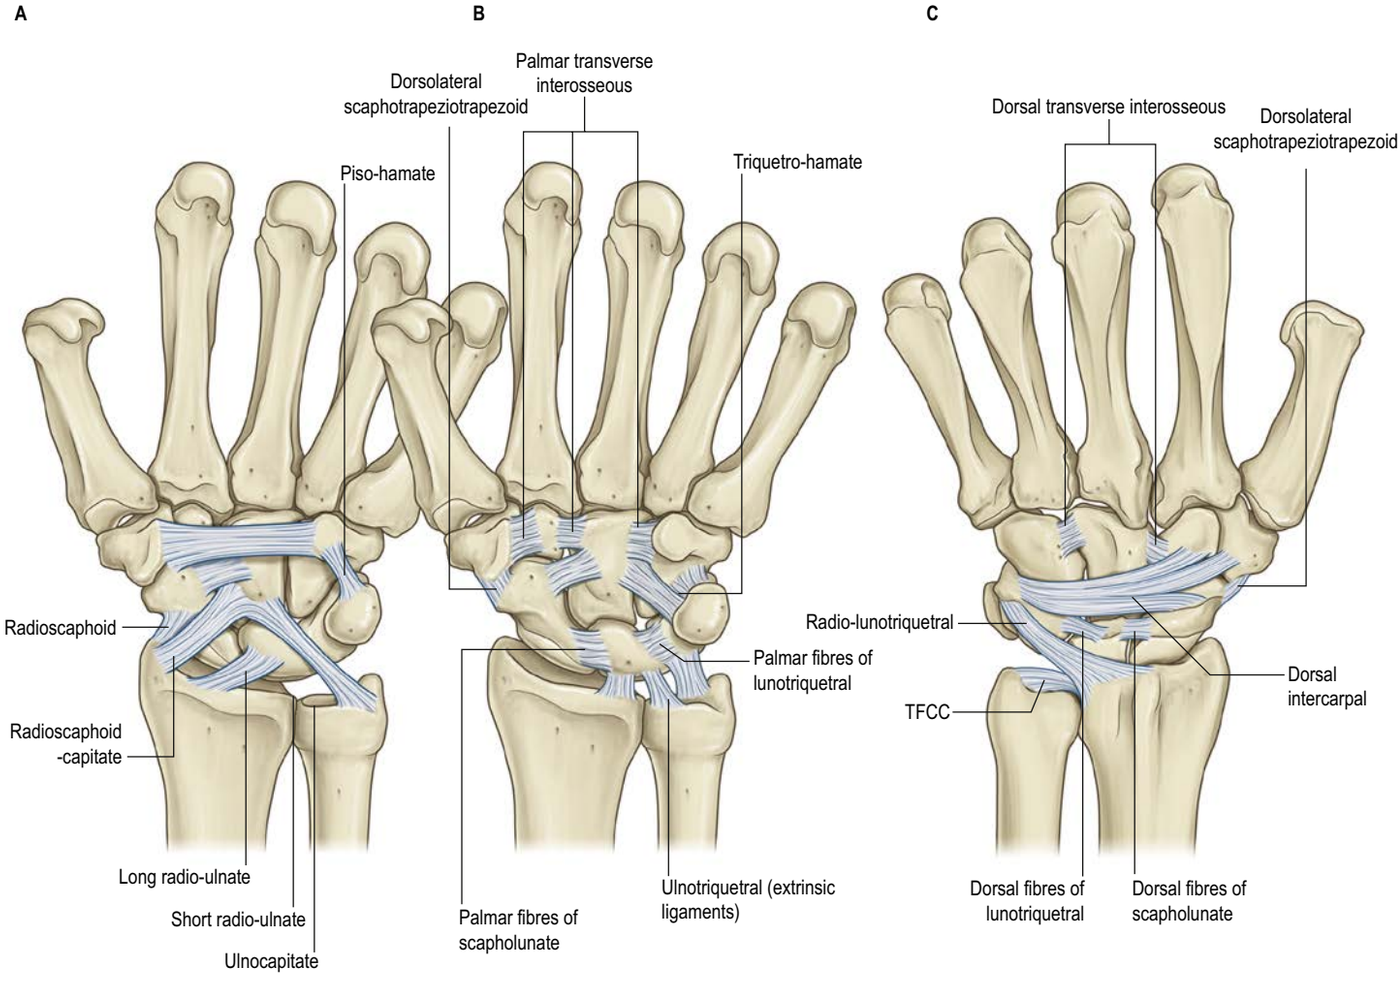

Fig. 51.19 The joints and ligaments of the left wrist. **A**, Palmar aspect: extrinsic ligaments. **B**, Palmar aspect: intrinsic ligaments. **C**, Dorsal aspect. Key: TFCC, triangular fibrocartilage complex. (D, *continued online*)

of the scaphoid and lunate. The proximal articular surfaces of the scaphoid, lunate and triquetrum and their interosseous ligaments form a smooth convex surface that is received into the proximal concavity.

Fibrous capsule The fibrous capsule is an agglomeration of collagenous tissue which includes several more defined and thus named ligaments (see below). It is lined by a synovial membrane which is usually separate from that of the distal radio-ulnar and intercarpal joints. A prestyloid recess (recessus sacciformis) lies anteroradial to the styloid process of the ulna.

Synovial membrane The synovial membrane lines the fibrous capsule.

Muscles producing movement Movements accompany those of the intercarpal and midcarpal joints, and are described on page 969.

Carpal joints

The intercarpal joints connect the carpal bones. Their articular surfaces are saddle-shaped, flat, ellipsoid or spheroidal. The carpal bones are connected by an extensive array of ligaments, not all of which are specifically named. The flexor retinaculum is an accessory intercarpal ligament which connects the scaphoid and triquetrum to the hamate and pisiform.

Joints of the proximal carpal row

Joints of the proximal carpal row are between the scaphoid, lunate and triquetrum. In addition, the pisiform articulates with the palmar surface of the triquetrum at a small, oval, almost flat, synovial pisotriquetral joint. A thin capsule surrounds the joint. The synovial cavity is usually separate but may communicate with that of the radiocarpal joint.

Joints of the distal carpal row

Joints of the distal carpal row are between the trapezium, trapezoid, capitate and hamate. There is little movement at these joints.

Midcarpal joint

The midcarpal joint, between the scaphoid, lunate and triquetrum (proximally), and trapezium, trapezoid, capitate and hamate (distally), is a compound articulation that may be divided descriptively into medial and lateral parts. Throughout most of the medial compartment, the convexity formed by the head of the capitate and hamate articulates with a reciprocal concavity formed by the scaphoid, lunate and much of the triquetrum. However, most medially, the curvatures are reversed, forming a compound sellar joint. In the lateral compartment, the trapezium and trapezoid articulate with the scaphoid, forming a second planosellar compound articulation.

Carpal synovial membrane The extensive carpal synovial membrane lines an irregular articular cavity. Its proximal part is between the distal surfaces of the scaphoid, lunate and triquetrum, and the proximal surfaces of the distal carpal row. It has three distal prolongations between the four bones of the second row. The prolongation between the trapezium and trapezoid and/or between the trapezoid and capitate is often continuous with corresponding carpometacarpal joints, either from the second to the fifth, or from the second and third only. In the latter case, the joint between the hamate and fourth and fifth metacarpals has a separate synovial membrane. Synovial cavities of carpometacarpal joints are prolonged slightly between the metacarpal bases. The synovial joint between the pisiform and triquetrum is usually isolated.

Wrist ligaments

The distal radio-ulnar joint and triangular fibrocartilage complex are described on page 942.

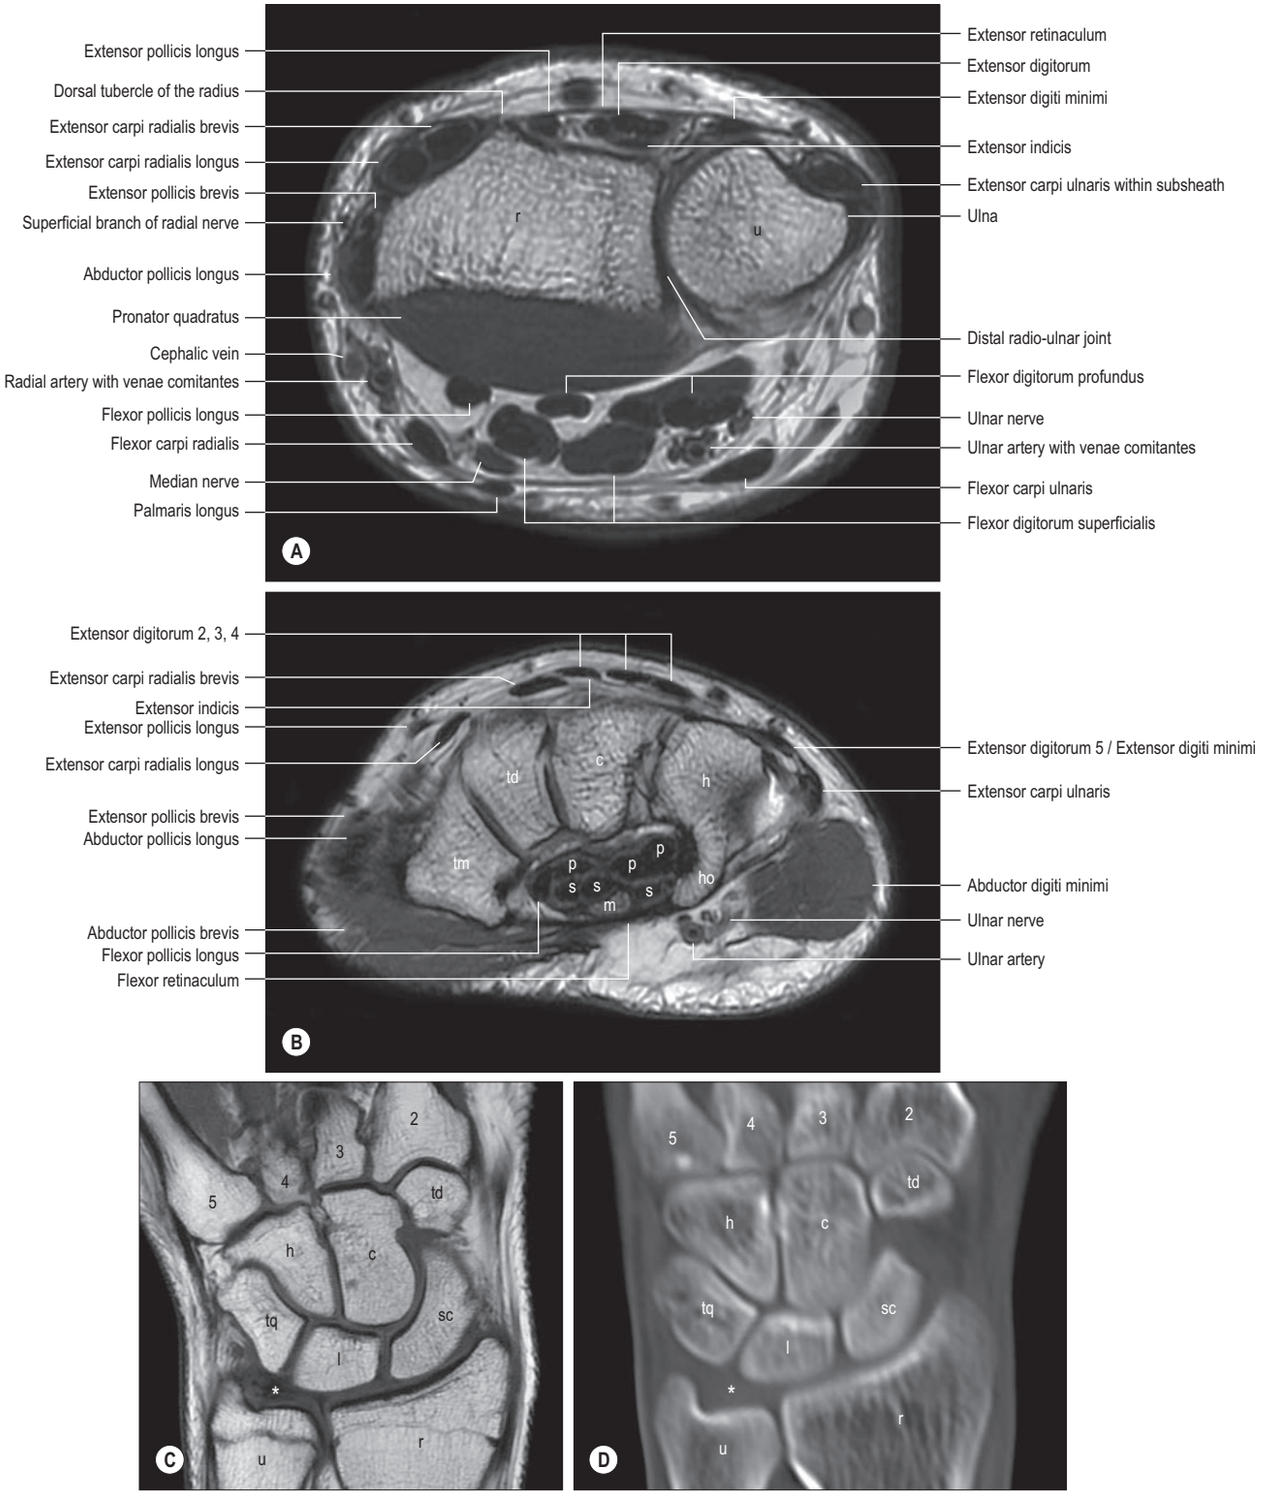

Fig. 51.20 A–B, Axial T2-weighted MRI images of the prone wrist: **A**, at the level of the distal radio-ulnar joint; **B**, at the distal aspect of the carpal tunnel. **C**, Coronal T1-weighted MRI and **D** mean intensity projection CT slab, through the wrist of two different individuals. Key: r, radius; c, capitate; h, hamate; ho, hook of hamate; m, median nerve; p, flexor digitorum profundus; s, flexor digitorum superficialis; td, trapezoid; tm, trapezium; l, lunate, sc, scaphoid; tq, triquetrum; u, ulna; *, triangular fibrocartilagenous disc. The metacarpal bases are appropriately numbered.

The wrist ligaments can be divided into intra-articular and extra-articular ligaments. The intra-articular ligaments can be further divided into intrinsic and extrinsic ligaments. The *extra-articular* ligaments comprise the flexor retinaculum, extensor retinaculum and the pisohamate ligament. The *intrinsic* ligaments connect the bones within the carpus. The *extrinsic* ligaments are condensations of the joint capsule that connect the carpus to the forearm; they tend to be longer than the intrinsic ligaments and are approximately one-third as strong. The deeper surfaces of some of the extrinsic ligaments and the superficial surfaces of some of the intrinsic ligaments are identifiable at wrist arthroscopy.

Wrist ligaments are conventionally named for the bones to which they attach from proximal to distal and from radial to ulnar, e.g. the radioscaphocapitate ligament passes between the radius, scaphoid and capitate.

Extrinsic ligaments

The extrinsic ligaments are best considered as two distinct groups, palmar extrinsic carpal ligaments and the dorsal extrinsic carpal ligaments. These individual ligaments work together as a ligamentous complex with the intrinsics to stabilize the wrist.

Extrinsic palmar carpal ligaments

There are three palmar extrinsic ligaments which arise from the radius and three from the ulna. From radial to ulnar they are: the radioscaphocapitate (RSC), long radiolunate and short radiolunate (long and short

RL), ulnolunate (UL), ulnocapitate (UC) and ulnotriquetral UT (Berger 1997, Feipel and Rooze 1999).

When the synovial lining of the carpal tunnel is dissected away, two V-shaped ligamentous bands are visible with their apices lying distally (see Fig. 51.19A). This V-shaped ligamentous complex is termed the arcuate ligament. It is formed by the twin insertions of the radioscaphocapitate and ulnocapitate ligaments to the capitate in the distal carpal row.

Radioscaphocapitate ligament The radioscaphocapitate ligament originates from the radial styloid and the palmar lip of the radius, and has three parts. The radial part inserts onto the lateral aspect of the waist of the scaphoid (radioscaphoid ligament). The middle part continues as part of the distal 'V' and inserts onto the distal pole of the scaphoid. The ulnar part passes over the proximal pole of the scaphoid towards the mid-carpus to insert into the capitate, meeting with the fibres that originate from the ulnar side of the triangular fibrocartilage complex (ulnocapitate ligament) to form the arcuate ligament over the palmar aspect of the capitate. There is a discrete interval (the space of Poirier) between the inferior margin of the arcuate ligament and the palmar surface of the lunate. It is through this area of relative weakness that lunate dislocations may occur (Jones and Kakar 2012). The radioscaphocapitate ligament forms a fulcrum over which the scaphoid waist rotates in wrist movement.

Long radiolunate ligament The long radiolunate ligament (long RL) arises adjacent to the radioscaphocapitate ligament on the palmar lip of the radius, passes over and supports the proximal pole of the scaphoid, and inserts into the palmar surface of the lunate. It is discrete from the radioscaphocapitate ligament, from which it is separated by the interligamentous sulcus (see Video 51.1) continuous with the space of Poirier.

The long RL resists distal and ulnar translation of the lunate and is a current area of interest in the study of scapholunate instability.

Ligament of Testut The radioscapholunate ligament is covered by a thick synovial fold that is frequently referred to as the ligament of Testut. It is not a true ligament, more a conduit for nerves and blood vessels. It is a visible landmark during wrist arthroscopy connecting the anterior lip of the radius and the scapholunate interval.

Short radiolunate ligament The short radiolunate ligament arises from the palmar lip of the lunate fossa of the radius and passes directly to the radial border of the lunate just radial to the ulnolunate ligament.

Ulnolunate ligament The ulnolunate ligament originates from the palmar aspect of the triangular fibrocartilage complex (TFC) and inserts on to the palmar distal lip of the lunate adjacent to the short radiolunate ligament.

Ulnotriquetral ligament The ulnotriquetral ligament arises from the palmar aspect of the ulna, inserts into the medial aspect of the triquetrum, and continues distally to a further attachment to the medial aspect of the hamate.

Ulnocapitate ligament The ulnocapitate ligament passes from the ulnar fovea and proximal radio-ulnar ligament of the TFC and inserts into the ulnar border of the capitate. This ligament partially overlies the other ulnar carpal ligaments. Together they form the ulnar contributions to the arcuate ligament complex.

Extrinsic dorsal carpal ligaments

The dorsal wrist ligaments are comparatively thin and are reinforced by the floor and septa of the fibrous tunnels for the six dorsal compartments.

Dorsal radiolunotriquetral ligament The dorsal radiolunotriquetral ligament, also known as the dorsal radiocarpal (DRC) ligament, is the only dorsal ligament that attaches the radius to the carpus. It is formed of superficial and deep components. The superficial part connects the radius and triquetrum, and the deep part connects the radius, lunate and triquetrum. The wide superficial component arises from the dorsal margin of the distal radius and courses ulnarwards to insert on the dorsal edge of the triquetrum. The deep component takes a narrower origin from the ulnar aspect of the distal dorsal radius and passes in an ulnar direction to attach to part of the lunotriquetral articulation and the intrinsic lunotriquetral ligament.

Intrinsic ligaments

The intrinsic ligaments of the wrist are only attached to carpal bones (see Fig. 51.19A–C). They are stronger and shorter than the extrinsic ligaments and are connected with the extrinsic ligament complexes by interdigitating fibres. The intrinsic ligaments are subdivided into ligaments that connect the carpal bones of the proximal and distal rows, respectively, and ligaments that connect the rows by crossing over the midcarpal joint.

Proximal row interosseous ligaments The scapholunate ligament acts as the primary stabilizer of the scapholunate joint. In the sagittal plane, it is an approximate horseshoe-shape with palmar (volar), proximal and dorsal components.

The scapholunate ligament contains short transverse fibres that connect the dorsal aspect of the scaphoid to the lunate and more obliquely orientated fibres which connect the palmar aspects. The stronger and tighter dorsal component of the ligament acts as a hinge permitting just 20° of motion between the scaphoid and the lunate. The ligament continues in its proximal section as an interosseous membrane and is easily visualized from the radiocarpal joint at arthroscopy.

The lunotriquetral ligament has similar dorsal proximal and palmar (volar) components, but the fibres of the palmar component are the thickest and strongest. The interosseous membranous component of the scapholunate and lunotriquetral ligaments separate the midcarpal from the radiocarpal joint spaces. Leaking of dye from one of these joint spaces into the other during an arthrogram denotes a tear of one of these ligaments.

Distal row interosseous ligaments The strong interosseous ligaments of the distal row connect and stabilize the capitate, hamate, trapezium and trapezoid. They have superficial and deep components, and, unlike the ligaments of the proximal row, are seldom torn.

Palmar midcarpal ligaments The scaphotrapezial, the scaphotrapezoidal (STm) and the scaphocapitate ligaments constitute the scaphotrapeziotrapezoid ligament complex (STT). They serve to stabilize the triscaphe joint. The triquetrohamate ligament has both palmar (volar) and dorsal components and functions to resist flexion between the hamate and triquetrum. The triquetrocapitate ligament is a palmar (volar) structure that indirectly stabilizes the lunate through its contribution to the ulnar limb of the arcuate ligament.

Dorsal midcarpal ligaments The dorsal intercarpal ligament helps to stabilize the proximal carpal row. It consistently arises from the dorsal tubercle of the triquetrum. Its radial insertion is more variable but may include almost all the lunate and scaphoid, and about half of the trapezoid and trapezium. The ligament forms the floor of the fourth and fifth extensor compartments.

Arthroscopy of the wrist and hand

See **Video 51.1**.

Arthroscopy of the wrist joint allows inspection of articular surfaces and ligaments, identification of pathology and altered kinematics, and therapeutic manoeuvres using scissors, rongeurs, sutures and cautery. Wrist arthroscopy may be carried out through various anatomically defined 'portals' which allow access between the tendons and neurovascular structures into the midcarpal and radiocarpal joints.

Movements and loading of the wrist joint

Movements of the wrist (carpal kinematics)

See **Video 51.2**.

The wrist joint consists of a series of complex articulations between the eight carpal bones, the two forearm bones and the five metacarpals of the hand. The function of the wrist is to allow the hand to function independent of the position of forearm rotation. In order to do this, it needs to function as a universal joint. Our understanding of the exact mechanism by which it does this is developing as new techniques for imaging and tracking carpal movement become available. Despite the progress in imaging and kinematic measurement techniques, no past or present concept of carpal mechanics adequately explains the complex behaviour of the carpus (Rainbow et al 2015).

Flexion–extension The movements at the radiocarpal and intercarpal joints are considered together. The range of movement varies between individuals; the approximate ranges of active movement are flexion (85°), extension (85°), adduction (ulnar deviation) (45°), abduction (radial deviation) (15°). The range of flexion is greater at the radiocarpal joint, while in extension there is more movement at the midcarpal

Some portals are, as de Smet (2002) has described, 'frighteningly' close to key anatomical structures. Consequently, only the skin should be incised when establishing a portal, and the remaining dissection should be carried out with narrow blunt artery forceps to spread aside the neurovascular structures and tendons with subsequent penetration of the capsule using a blunt probe.

Dorsal radiocarpal portals The dorsal radiocarpal portals are named according to their relationship to the extensor tendon compartments (1–2, 3–4, 4–5, 6–R, 6–U) with 6–R and –U describing a portal radial or ulnar to the sixth compartment which transmits the extensor carpi ulnaris tendon. The 1–2 portal is usually avoided because of the proximity of the radial artery which lies just 3 mm (range 1–5 mm) radially: the branches of the superficial radial nerve are similarly adjacent (range 1–6 mm) (Abrams et al 1994). The 3–4 portal is normally used as the main viewing portal and the 4–5 or 6–R portal for instrumentation. The dorsal cutaneous branch of the ulnar nerve lies within 2.5 mm of the 6–R portal). The articular surfaces of the scaphoid and lunate are seen distally, linked by the scapholunate ligament. Proximally, the triangular fibrocartilage complex may be viewed.

Dorsal midcarpal portals The radial midcarpal portal (MCR) is used to view the scaphocapitate joint, scaphotrapezoid joint and scapholunate joint. The ulnar midcarpal portal (MCU) is used for viewing the hamate, triquetrum and lunotriquetral joint.

Volar portals Volar portals (radial, VR, midcarpal, VMC and ulnar, VU) are not commonly used because of their proximity to nerves and arteries. They allow a view of the dorsal capsule, the dorsal radiocarpal ligament and the palmar subregions of the scapholunate and lunotriquetral interosseous ligaments. Use of the volar radial portal carries with it the potential for damage to flexor carpi radialis, the palmar cutaneous branch of the median nerve and the lateral cutaneous nerve of the forearm, all of which can run close to, but not within 3 mm of, the portal. The volar ulnar portal lies more than 5 mm away from the ulnar neurovascular bundle, provided the entry point in the capsule is deep to the ulnar edge of the profundus tendons (Slutsky 2002).

The above description fits with the convenient consideration of wrist motion in the traditional orthogonal anatomical directions (flexion, extension, ulnar). However, in reality few if any functional tasks occur within these planes. Most day-to-day activities require simultaneous coupled movements. Fisk noted that many functional activities such as 'casting a fly, throwing a dart or conducting an orchestra' occur along an arc from extension and radial deviation to flexion and ulnar deviation (Fisk 1970). This observation led Palmer to coin the term 'dart thrower's motion' (Palmer 1985). During the 'dart-throwing' movement almost no movement occurs within the proximal row and the motion occurs almost entirely at the distal row of the carpus (Werner 2004). It is believed that this coupled wrist motion combined with an upright stance allowed early hominid species to begin using tools and throwing objects purposefully (Rohde et al 2010).

The lack of movement between the bones of the proximal carpal row during the dart thrower's movement has clinical implications for both surgical treatment of wrist arthritis and rehabilitation following injury or surgery of the proximal carpal row. Preservation of this oblique plane when carrying out a partial wrist fusion for arthritis potentially results in more natural wrist kinematics, as has been shown by the improved functional outcome in 3-corner fusion when compared to 4-corner fusion (Singh et al 2015). Traditionally, prolonged immobilization has been part of the routine rehabilitation of injuries or surgery to the proximal carpal row such as for fractures of the scaphoid and reconstruction of the scapholunate ligament. However, with the knowledge that the proximal row undergoes little movement during the dart thrower's movement it seems logical to allow early rehabilitation exercises provided they occur in this plane (Rohde et al 2010). Radiolunate fusion, a procedure used for conditions such as radiolunate arthritis and radiocarpal instability, incurs surprisingly little loss of functional wrist movement.

Movement of the carpus was originally quantified by measuring carpal bone length in static radiographs while the wrist was moved in orthogonal anatomical planes. From these observations two models emerged. Destot described a *row* or *rigid body* theory wherein the carpus was felt to move simply as proximal and distal rows (Destot 1926). According to this view, during the composite movement of wrist flexion and extension, approximately two-thirds of movement occurs at the radiocarpal joint and one-third at the midcarpal joint. Navarro described a model in which the carpus was believed to move in radial, central and ulnar *columns* more than it did in rows (Navarro 1921). This theory was modified (Taleisnik 1976) to incorporate the specific stabilizing role of the scaphoid as it bridges the proximal and distal rows. Further studies have suggested that carpal movement may display characteristics of both these models in varying proportions. The degree to which a wrist displays column-like or row-like behaviour depends on the bony architecture and ligamentous laxity (Craigen and Stanley 1995, Garcia-Elias 1995). An attempt to provide a unifying theory of carpal kinematics describes a stable central column with the triquetrum serving as an anchor to prevent ulnar translation, and the scaphoid functioning as a supporting lateral column (Sandow et al 2014). This concept of a central column based on the radiolunate articulation is at variance with other kinematic studies which have shown 60% load transmission through the radio-scaphoid joint (Ulrich et al 1999): the theory remains to be validated through a full range of motion, particularly within the dart thrower's plane (Rainbow et al 2015). With regards to carpal kinematics, it seems sage to recall the words of the statistician George Box, who said 'all models are wrong, but some are useful'.

Flexor carpi ulnaris is stronger than extensor carpi ulnaris, which, in turn, is stronger than extensors carpi radialis longus and brevis, and flexor carpi radialis. The other muscles are all weaker. It is for this reason that these muscles tend to be selected for the major tendon transfers around the wrist (Brand 1985). During flexion and extension, flexor carpi radialis, flexor carpi ulnaris and extensor carpi radialis brevis have a greater excursion than extensor carpi radialis longus and extensor carpi ulnaris. During radial and ulnar deviation, extensor carpi radialis longus and extensor carpi ulnaris have a greater excursion, whereas that of flexor carpi radialis is relatively small. The axes of rotation for flexion/extension and radial/ulnar deviation intersect at a point in the proximal part of the capitate bone. Flexor carpi radialis and flexor carpi ulnaris are most efficient in flexion, extensor carpi radialis brevis in extension, extensor carpi radialis longus in radial deviation and extensor carpi ulnaris in ulnar deviation.

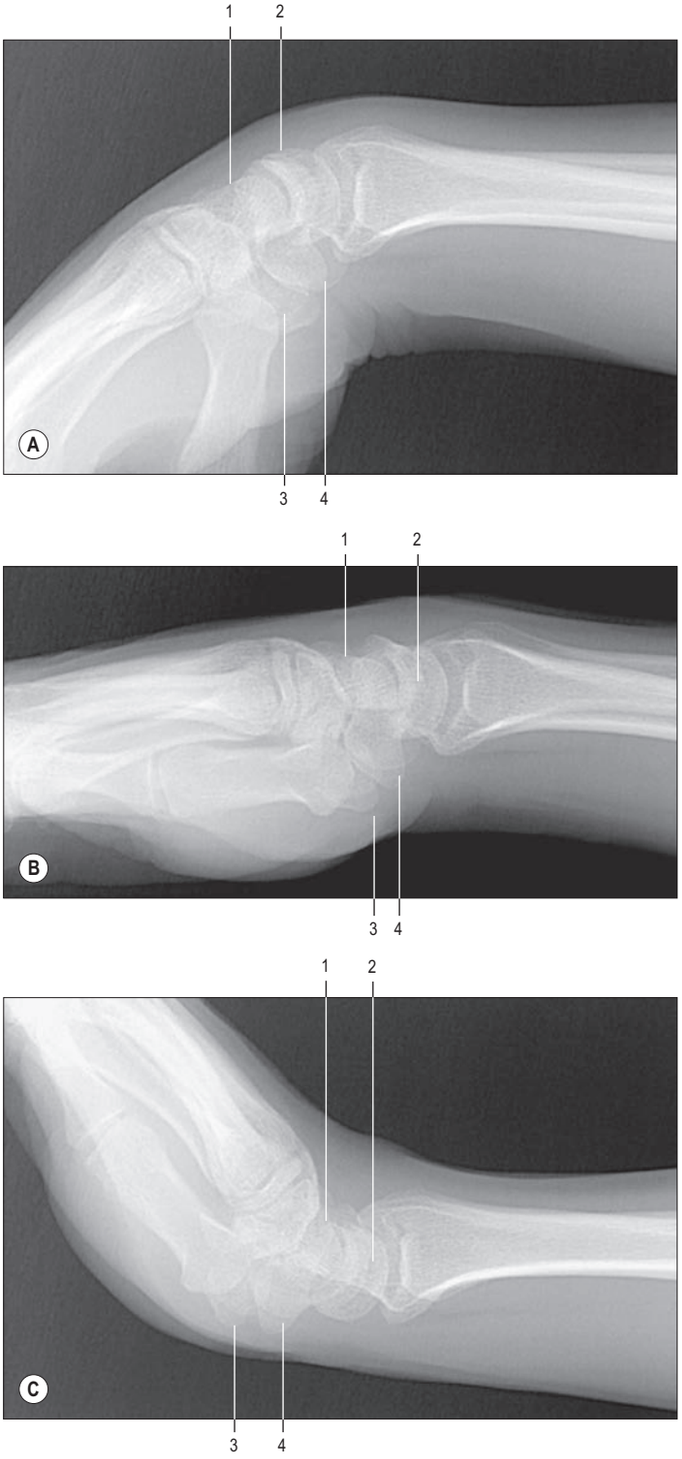

Fig. 51.21 **A**, A radiograph of the hand and wrist in full flexion: lateral aspect. Compare with **B**, and note the relative positions of the capitate and lunate, and the lunate and radius. **B**, A radiograph of the hand and wrist: lateral aspect. The long axes of the third metacarpal, capitate and lunate are, approximately, in line with the long axis of the radius. Note the relative positions of the capitate and lunate, and the lunate and radius. **C**, A radiograph of the hand and wrist in full extension: lateral aspect. Compare with **B** and note the alterations in the relative positions of the capitate and lunate, and the lunate and the radius. Key: 1, capitate; 2, lunate; 3, tubercle of the trapezium; 4, tubercle of the scaphoid.

joint (Fig. 51.21). Hence, the proximal surfaces extend further posteriorly on the lunate and scaphoid bones. These movements are influenced by antagonistic muscles, and therefore the range of flexion is perceptibly diminished when the fingers are flexed, due to increased tension in the extensors. Only when the joints are forced to the limits of flexion or extension with the digits relaxed are the dorsal or palmar ligaments fully stretched. During extension of the wrist, the distal carpal bones rotate into extension with slight radial deviation.

Adduction and abduction Most ulnar adduction occurs at the radiocarpal joint. The lunate articulates with both the radius and articular disc when the hand is in the midposition but, in adduction, it articulates solely with the radius, and the triquetrum now comes into contact with the articular disc (Fig. 51.22A). Much of the proximal articular surface of the scaphoid becomes subcapsular beneath the radial collateral ligament and forms a smooth, convex, palpable prominence in the floor of the 'anatomical snuff-box'. Radial abduction from the neutral position occurs at the midcarpal joint. A radiograph of the radially deviated hand shows that the capitate rotates round an anteroposterior axis so that its head passes medially and the hamate conforms to this; the distance between the lunate and the apex of the hamate is increased (Fig. 51.22B). The scaphoid rotates around a transverse axis, and its proximal articular surface moves ulnarwards so that the entire scaphoid now articulates solely with the radius. Movements are limited by the carpal collateral ligaments.

Dart thrower's motion

Available with the *Gray's Anatomy* e-book

Proximal and distal carpal row The proximal row (scaphoid, lunate and triquetrum) is an intercalated segment; no tendons insert onto the bones of the row. It is inherently unstable and controlled by specific retaining and gliding ligaments. Its relative position is determined by the dimensions of the space between the radius, triangular fibrocartilage complex and ulna on one side, and the rigid distal carpal row on the other. The proximal carpal row is subject to two opposing moments: the scaphoid straddles the proximal and distal rows and tends to rotate the proximal row into flexion under axial load and radial deviation. At the same time, there is a force tending to extend the proximal row, which is initiated by the distal row and transmitted via the midcarpal ligaments to the triquetrum. Stability of the midcarpal joint is thus ensured during both movement and loading. The distal carpal row (trapezium, trapezoid, capitate and hamate) can be regarded as one rigid structure. The scaphoid bridges the proximal and distal carpal rows and provides a functional couple between the two.

Muscles producing movements

Flexion Flexor carpi radialis, flexor carpi ulnaris and palmaris longus produce flexion, assisted by flexor digitorum superficialis, flexor digitorum profundus and flexor pollicis longus.

Extension Extensor carpi radialis longus, extensors carpi radialis brevis and ulnaris, assisted by extensors digitorum, digiti minimi, indicis and pollicis longus. With the forearm supinated, extensor carpi ulnaris is a pure extensor with no ulnar deviation moment.

Adduction (ulnar deviation) Flexor and extensor carpi ulnaris produce adduction. With the forearm pronated, extensor carpi ulnaris is a pure ulnar deviator with no extension moment.

Abduction (radial deviation) Flexor carpi radialis, extensors carpi radialis longus and brevis, with abductor pollicis longus and extensor pollicis brevis.

Loading of the wrist (carpal kinetics)

Axial loading, i.e. load or force applied along a line parallel to the long bones of the arm, occurs in clenching the fist. In most activities, loading is multiplanar with a combination of vectors of force. Grasping an object whilst lifting it against gravity with the elbow in flexion causes transverse and axial loading (Horii et al 1993).

Force transmission

Radiocarpal and ulnocarpal joints

The radiocarpal and ulnocarpal articulations involve the scaphoid and lunate fossae of the radius and the facet formed by the distal aspect of the triangular fibrocartilage complex. The scaphoid fossa contributes 43%, the lunate fossa 46% and the triangular fibrocartilage complex 11% of the total area of this articulating surface. Under resting conditions, about 20% of the surface area of the combined radiocarpal and ulnocarpal joint abuts the proximal carpal row. Greater contact is seen in forearm supination, radial deviation and dorsiflexion of the wrist. Lesser contact occurs in forearm pronation, ulnar deviation and palmar flexion of the wrist. Axial loading increases the contact area to a maximum of about 40%. Force across the joint also varies with the position of the forearm and the degree of wrist flexion. For a given load in wrist-neutral position, 50% of force passes across the scaphoid fossa,

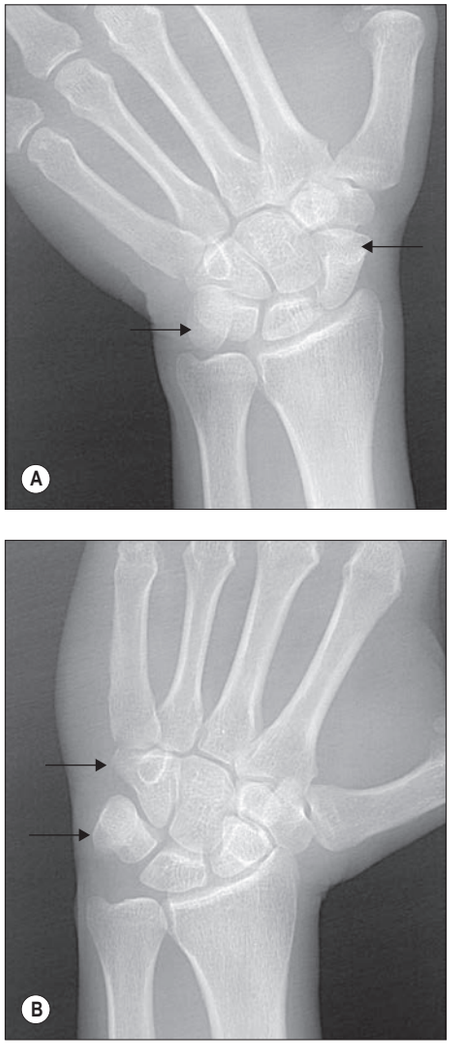

Fig. 51.22 A, A radiograph of the hand in full adduction (ulnar deviation): dorsopalmar projection. The arrows point to the scaphoid on the radial side and to the pisiform on the ulnar side. Compare with **B** and observe that the movements occur at both the radiocarpal and intercarpal joints. **B**, A radiograph of the same hand in full abduction (radial deviation). The arrows point to the hamate and pisiform. Compare with **A** and note that: the scaphoid and lunate have passed medially (ulnarly) so that the latter articulates to a large extent with the articular disc of the distal radio-ulnar joint; the pisiform is now widely separated from the styloid process of the ulna; the scaphoid, having rotated round a transverse axis, is much foreshortened; the apex of the hamate has been thrust away from the lunate by the rotation of the capitate around an anteroposterior axis; a gap has opened up between the distal portions of the hamate and triquetrum; and the long axes of the capitate and lunate are now almost in the same straight line.

35% through the lunate fossa and 15% across the triangular fibrocartilage complex. With a power grip, there is slight ulnar deviation and the proportion of force passing across the scaphoid and lunate fossae reverses.

Midcarpal joint

With the wrist in neutral position, 50–60% of a given load is transmitted from the distal row through the capitate to the scaphoid and lunate. Up to 30% of the load is transmitted via the scaphotrapeziotrapezoid joint and up to 20% via the hamate–triquetral joint.

Distal radio-ulnar joint (DRUJ)

See Chapter 50.

Power grip

In power grip, the wrist is positioned in mid-dorsiflexion and slight ulnar tilt. Force is transmitted from the hand and wrist via the radiocarpal joint and triangular fibrocartilage complex to both bones of the forearm, through the elbow joint to the humerus, and from there, via the glenohumeral joint, to the pectoral girdle. Dynamic muscle action accounts for transmission of a large part of the force; a smaller proportion is transmitted through the osseoligamentous structures. The distribution of force between the radius and ulna varies dynamically and depends on the absolute value of load, degree of forearm rotation and position of the carpus relative to the forearm.

Carpal instability

See **Video 51.3**.

The upper limb has evolved to facilitate the placing of the hand in space for prehension, but mobility of the hand on the forearm has evolved at the expense of stability. A wrist is said to be kinetically unstable when it cannot bear physiological loads without giving way or causing injury, and to be kinematically unstable when it exhibits sudden changes in carpal alignment during movement, manifest as a 'clunk' as one or more of the carpal bones move abnormally with respect to the others. Stability of the various joints, so that the bones maintain normal anatomical relations with respect to each other throughout the normal range of motion, is essential for physiological load transmission. Disruption of this complex system leads to pain, loss of function and, in time, degeneration of the articular surfaces.

Carpometacarpal joints

Carpometacarpal joint of the thumb

Articulating surfaces The carpometacarpal joint of the thumb (basal joint of the thumb) is a sellar joint between the first metacarpal base and trapezium. Its extensive articular surfaces and their topology ensure that the joint enjoys a wide mobility. Its curved saddle shape, as if designed for a 'scoliotic horse' (Kuczynski 1975), allows the metacarpal base to slide into flexion and pronation as the pulp of the thumb opposes the digits.

Ligaments The first metacarpal and trapezium are connected by lateral, anterior and posterior ligaments and a fibrous capsule. The broad lateral ligament runs from the lateral surface of the trapezium to the radial side of the metacarpal base. The palmar and dorsal ligaments are oblique bands that converge to the ulnar side of the metacarpal base from the palmar and dorsal surfaces of the trapezium, respectively.

Synovial membrane The synovial membrane lines the joint capsule and is separate from it.

Joint movements Except at its initiation, flexion is accompanied by pronation (medial rotation) of the thumb metacarpal, whilst pronation necessitates flexion. This linkage of movements is due largely to the shape of the articular surfaces and to the obliquity of the dorsal ligament (which, when taut, anchors the ulnar side of the metacarpal base while its radial side continues to move). Contraction of flexor pollicis brevis, assisted by opponens pollicis, produces medial rotation with flexion; combined with abduction, this opposes the thumb pulp to the pulps of the slightly flexed fingers. Full extension of the thumb metacarpal entails slight supination (lateral rotation), attributable to the saddle shape of the joint and to the action of the palmar ligament (similar to that of the dorsal ligament in flexion) (Edmunds 2011, Ladd et al 2013).

Muscles producing movements

Flexion Flexor pollicis brevis and opponens pollicis, aided by flexor pollicis longus which continues the flexion moment when the other joints of the thumb are flexed.

Extension Abductor pollicis longus and extensors pollicis brevis and longus.

Abduction Abductors pollicis brevis and longus.

Adduction Adductor pollicis and extensor pollicis longus.

Opposition Opposition describes the action of bringing the pulp of the thumb across the palm to appose the pulps of the digits. Abductor pollicis brevis abducts the thumb whilst opponens pollicis and flexor pollicis brevis simultaneously flex and pronate (medially rotate) the abducted thumb. Interpulpal pressure, generated by digital grasping, is increased by adductor pollicis and flexor pollicis longus.

Retroposition Retroposition describes elevating the pulp of the thumb into extension and ulnar adduction dorsal to the plane of the palm. Extensor pollicis longus uniquely provides this movement.

Some degree of carpal instability may occur as part of inherent hypermobility in affected individuals. More commonly it occurs after acute rupture or chronic attenuation of intrinsic and extrinsic carpal ligaments, which may be detected either clinically or radiologically as malalignment of the carpal bones. In clinical practice, certain patterns of instability predominate.

Garcia-Elias described a kinetic theory of carpal stability that states that the neutral posture of the lunate is preserved by balancing the flexion moment of the scaphoid with the extension moment of the triquetrum (Garcia-Elias 1997). When axially loaded, these rotational forces increase. If the interosseous scapholunate ligament is disrupted then the extension moment of the triquetrum remains unopposed leading to an extended position of the lunate. This is referred to as dorsal intercalated segment instability (DISI). In the absence of the luno-triquetral ligament the scaphoid flexion moment loses its antagonistic extension moment from the triquetrum and the lunate adopts a flexed posture: this is termed volar intercalated segment instability (VISI).

Circumduction Extensors, abductors, flexors and adductors acting consecutively in this, or reverse, order.

Second to fifth carpometacarpal joints

The second to fifth carpometacarpal joints are synovial ellipsoid joints between the carpus and second to fifth metacarpals. Although widely classed as plane, they have curved articular surfaces that are often of complex saddle shape. The bones are united by articular capsules and by dorsal, palmar and interosseous ligaments.

Ligaments The dorsal ligaments are the strongest, and connect the dorsal surfaces of the carpals and metacarpals. The second metacarpal has two ligaments, from the trapezium and trapezoid; the third has two, from the trapezoid and capitate; the fourth has two, from the capitate and hamate; and the fifth has a single band from the hamate, which is continuous with a similar palmar ligament, forming an incomplete capsule. The palmar ligaments are similar, except that the third metacarpal has three: a lateral from the trapezium, superficial to the tendon sheath of flexor carpi radialis, an intermediate from the capitate, and a medial from the hamate. The interosseous ligaments consist of two short, thick, fibrous bands. They are limited to one part of the carpometacarpal articulation and connect contiguous distal margins of the capitate and hamate with adjacent surfaces of the third and fourth metacarpals; they may be united proximally.

Synovial membranes The synovial membranes are often continuous with those of the intercarpal joints. Occasionally, the joint between the hamate and fourth and fifth metacarpals has a separate synovial cavity, bounded laterally by the medial interosseous ligament and its extensions to the palmar and dorsal parts of the capsule.

Muscles producing movements The second to fifth carpometacarpal joints exhibit an increasing range of movement, progressing from the radial to the ulnar side. Thus, there is little mobility at the base of the index ray but considerable mobility at the base of the small finger ray, which facilitates 'cupping' of the palm of the hand. Compressive forces between the metacarpals and the distal carpal row are estimated to be upwards of ten times the forces at the tips of the fingers during 'pinch' or 'chuck' grip.

Slight gliding movements are effected by the long flexor and extensor muscles of the digits.

Intermetacarpal joints

Articulating surfaces The second to fifth metacarpal bases articulate reciprocally by small cartilage-covered facets connected by dorsal, palmar and interosseous ligaments.

Fibrous capsule The intermetacarpal joints have fibrous capsules.

Ligaments The dorsal and palmar ligaments pass transversely from bone to bone. The interosseous ligaments connect contiguous surfaces just distal to their articular facets.

Synovial membranes The synovial membranes are continuous with those of the carpometacarpal articulations.

Movements at the carpometacarpal joints The fifth metacarpal is the most mobile and the second and third are the least mobile. These variations are easily demonstrated by opposing each digit to the thumb over the centre of the palm. While the majority of movement is in the thumb, the carpometacarpal joint of the little finger flexes, abducts and pronates (laterally rotates). Less movement occurs at the carpometacarpal joint of the ring finger and essentially none occurs at the middle and index (Tucker and Titley 2002).

Movements at the intermetacarpal joints Movements at the intermetacarpal articulations vary. There is very slight gliding movement in flexion–extension in the index–middle joint and slightly more glide in the middle–ring joint. There is more glide and some rotation during pronation and supination generated at the carpometacarpal joint in the ring–little joint and slight rotation in the little finger.

Muscles producing movements The extrinsic (i.e. forearm-derived) and intrinsic (i.e. palm-derived) flexors and extensors of the second to fifth digits move the carpometacarpal and intermetacarpal joints.

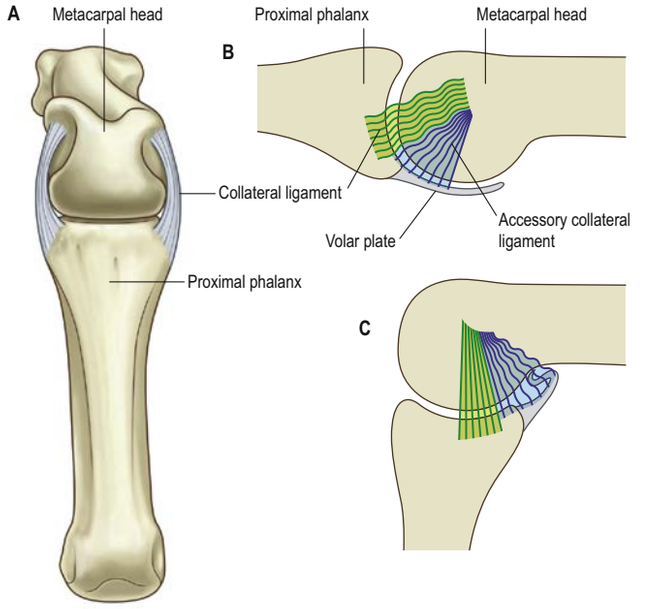

Fig. 51.23 The metacarpal head is narrower on its dorsal surface than its palmar surface (**A**), which means that the collateral ligament is loose in extension (**B**) but tight in flexion (**C**).

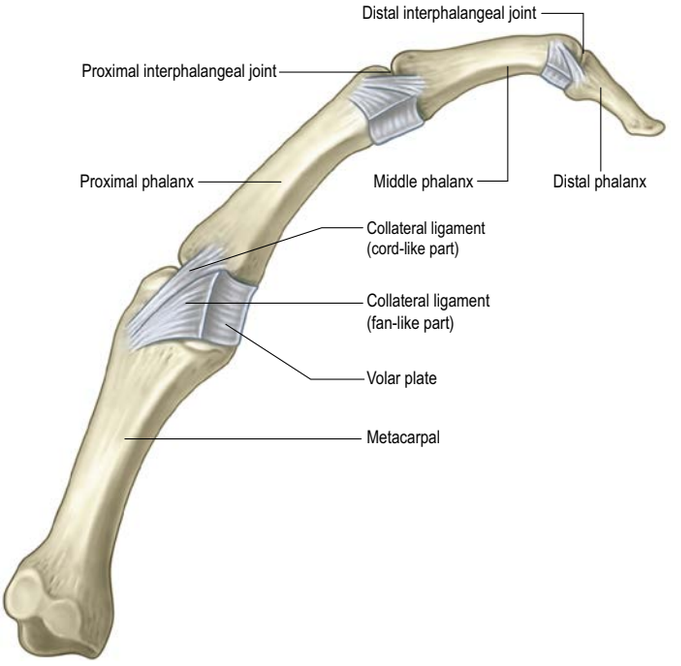

Fig. 51.24 The metacarpophalangeal and digital joints of the left third finger: medial aspect.

Metacarpophalangeal joints

The metacarpal heads are incongruous with the shallow concavities on the phalangeal bases; they are not regularly convex but are partially divided on their palmar aspects and, thus, almost bicondylar. The dorsal width of the metacarpal head is about two-thirds of its palmar width, which means that the joint is lax in the coronal plane in extension yet taut in flexion (compared with the proximal interphalangeal joint which is taut throughout its range) (Fig. 51.23).

Fibrous capsule The metacarpophalangeal joints all have fibrous capsules.

Ligaments Each metacarpophalangeal joint has a palmar and two collateral ligaments.

Palmar ligaments The palmar ligaments (volar plates) are thick, dense and fibrocartilaginous. They are attached quite loosely to the metacarpal neck proximally and firmly to the base of the proximal phalanx distally (Fig. 51.24). The deep transverse metacarpal ligaments extend

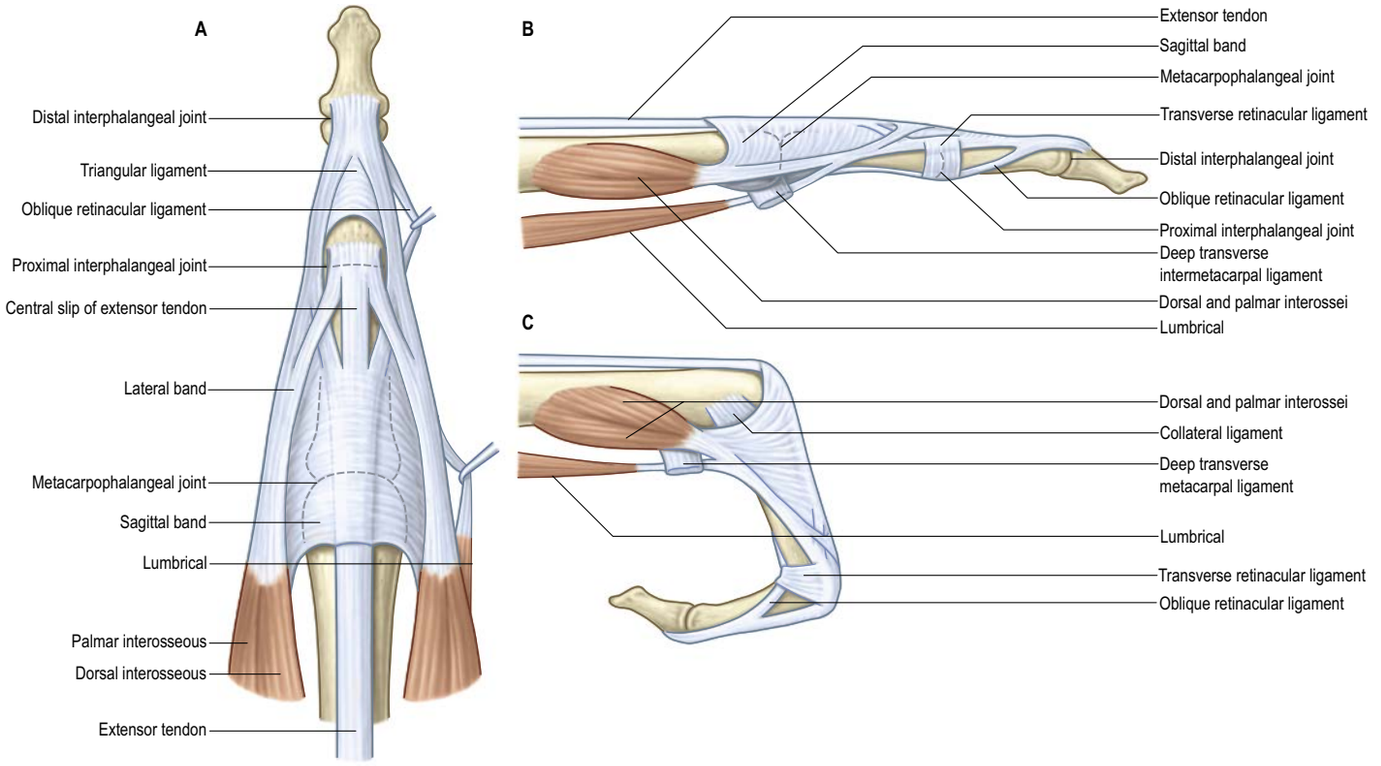

Fig. 51.25 The extensor mechanism of the finger. **A**, Dorsal view. **B**, Lateral view. **C**, Lateral view in flexion.

between the palmar plates from the ulnar side of the second metacarpal head to the radial side of the fifth metacarpal head. The collateral ligaments arise from the posterior tubercle on the lateral aspect of the metacarpal heads and insert into the palmar portion of the lateral aspect of the base of the proximal phalanges. The palmar aspects are grooved for the flexor tendons. The A1 component of the flexor tendon sheath is attached to the edge of the ligament and the associated attachment of the collateral ligament, but is not attached to the metacarpal. The deep surface of the volar plate increases the articular contact area for the metacarpal heads.

Deep transverse metacarpal ligaments The deep transverse metacarpal ligaments are three short, wide, flat bands that connect the palmar ligaments of the second to fifth metacarpophalangeal joints. They are related anteriorly to the lumbricals and digital vessels and nerves, and posteriorly to the interossei. The vertical fibres of the palmar aponeurosis (septa of Legueu and Juvara) join their palmar surfaces. On both sides of the third and fourth metacarpophalangeal joints, but only the ulnar side of the second and radial side of the fifth joints, the transverse (sagittal) bands of the extensor hood join the deep transverse metacarpal ligaments. The lumbricals and the phalangeal attachments of the dorsal interossei lie anterior to this band; the remaining attachments of the dorsal and palmar interossei are posterior to it (**Fig. 51.25**).

Collateral ligaments The collateral ligaments are attached proximally to the posterior tubercle and an adjacent pit on the side of the metacarpal neck. Two components pass distally. The more dorsal fibres form a cord-like band that is attached to the side of the palmar corner of the base of the proximal phalanx, blending with the insertion of the volar plate. The more palmar fibres spread distally and anteriorly to form a fan that can fold up like a concertina as the metacarpophalangeal joint flexes (see Fig. 51.23). The radial collateral ligament of the index finger is strongest because it must resist ulnar deviation when the thumb opposes the index finger. Because the metacarpal head is narrow dorsally and wider anteriorly, the collateral ligaments are tight only in full flexion but loose in extension.

Synovial membrane The metacarpophalangeal joints are lined by a synovial membrane.

Joint movements

Digits These include flexion, extension, adduction, abduction, circumduction and limited rotation. Rotation accompanies flexion–extension, e.g. when the finger flexes and rotates to place its tip near the centre of the palm. The range of rotation is frequently increased as a result of the resistance of a grasped object. Active flexion is 90° or more and is greater in the little finger than in the index. The range of extension depends on whether it is active or passive: the former is limited by the resistance of the antagonistic muscles, the latter is significantly greater because the volar plate offers little resistance. (This contrasts with the thumb–metacarpophalangeal joint and all the proximal interphalangeal joints, in which a rigid volar plate prevents hyperextension, so that passive and active extension are equal.) Passive extension is greater in the little finger than in the index. The range can be even greater in those with generally lax joints. The trapezoidal shape of the metacarpal heads means that the collateral ligament allows no ulnar or radial deviation of the proximal phalanx when the joint is fully flexed, but allows the fingers to move through about 20° in each direction when the joints are extended.

Slight supination (lateral rotation) accompanies digital flexion of the middle, ring and little fingers. Flexion of the index finger may be accompanied by little or no pronation. These movements allow the digits to cup around an object such that the thumb pulp can appose the middle–ring pulp as the sides of these touch each other whilst the edge of the index and little fingers touch the sides of the thumb pulp.

Thumb The metacarpophalangeal joint of the thumb has a flexion–extension range of approximately 60°, with minimal extension. The latter is prevented by a stout volar plate. There is minimal rotation and no abduction or adduction.

Accessory movements Anteroposterior translation of the phalanx on the metacarpal and distraction.

Muscles producing movements

Flexion In the fingers, flexion is produced by flexors digitorum superficialis and profundus, assisted by the lumbricals, interossei and flexor digiti minimi brevis (in the little finger). In the thumb, flexor pollicis longus flexes the thumb. Flexor pollicis brevis, abductor pollicis brevis and adductor pollicis flex the metacarpophalangeal joint through attachments to their respective tubercles at the anteromedial and anterolateral base of the proximal phalanx, and through the extensor hood overlying the dorsum of the base of the proximal phalanx.

Extension In the digits, extension is produced by extensor digitorum, assisted in the second and fifth digits by extensor indicis and extensor digiti minimi, respectively; in the thumb, extensors pollicis longus and brevis.

Adduction In extended fingers, adduction towards the middle finger is produced by the palmar interossei, enabled by a lax collateral ligament.

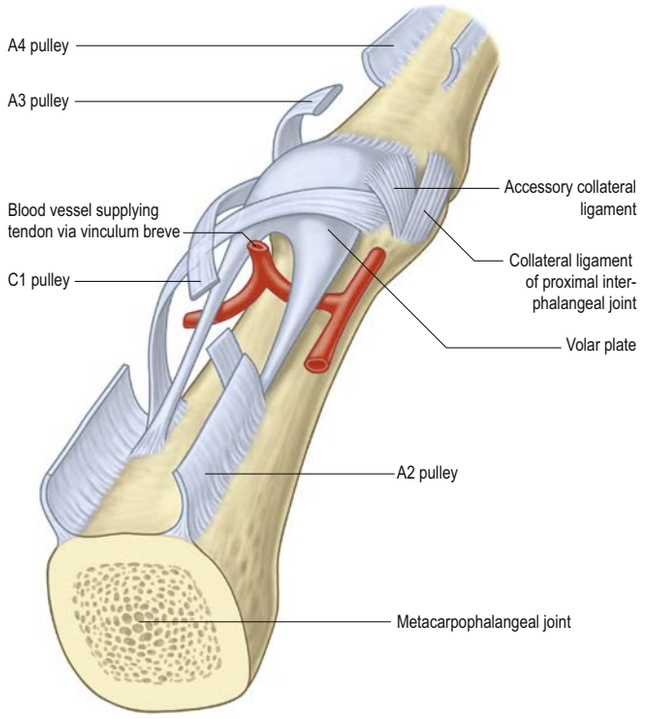

Fig. 51.26 The anatomy of the volar plate at a proximal interphalangeal joint. The blood vessel supplying the flexor tendons via the vincula brevum is shown; the mesentery forming the vinculum has been omitted.

In flexion, adduction is prevented by a taut collateral ligament. In the thumb, very limited metacarpophalangeal adduction is possible because of constraint by the radial collateral ligament.

Abduction In extended fingers, abduction from the axis of the middle finger is produced by the dorsal interossei and abductor digiti minimi. There is no abduction when the metacarpophalangeal joint is flexed because of tightening of the collateral ligament. When the fingers are flexed at the interphalangeal joints, active abduction at the metacarpophalangeal joints is possible. In the thumb, there is minimal or no abduction at the metacarpophalangeal joint because of the constraint of the ulnar collateral ligament. Abduction, if it occurs, is provided by abductor pollicis brevis.

Gamekeeper's thumb and skier's thumb

Available with the *Gray's Anatomy* e-book

Interphalangeal joints

The interphalangeal joints are uniaxial hinge joints.

Fibrous capsule Each interphalangeal joint has a fibrous capsule.

Ligaments The proximal interphalangeal joint is stable in all positions. Stability is conferred by a palmar ligament (the volar plate) and two collateral ligaments (**Fig. 51.26**; see Figs 51.23, 51.24) in addition to the flexor sheath, which is inserted not only into the side of the volar plate but also into the base and neck of the proximal phalanx, so conferring additional stability to the volar plate. There is a different arrangement in the metacarpophalangeal joint, where the sheath is inserted into the volar plate and the base of the proximal phalanx but not into the metacarpal.

Palmar ligament (volar plate) The volar plate of the proximal interphalangeal joint constitutes the floor of the interphalangeal joint. In the joint itself, the distal end of the volar plate is thickened laterally where it is firmly attached to the base of the middle phalanx at the position of the true attachment of the collateral ligament. Centrally, it is more delicate and blends with the volar periosteum of the middle phalanx. Proximally, the volar plate is also very delicate in its central portion, but it is thickened laterally to form the 'check rein ligaments' that are attached to the periosteum of the proximal phalanx, beyond the walls of the A2 pulley component of the fibrous flexor sheath. Nutrient branches of the digital arteries pass underneath these check ligaments to reach the vincula (see Fig. 51.26). The A3 pulley is attached to the edge of the volar plate, together with the accessory part of the collateral ligament.

Collateral ligaments The cord-like proper collateral ligaments pass from the dorsal half of the lateral aspect of the neck of the proximal phalanx to the lateral palmar corner of the base of the adjacent proximal phalanx, where they are incorporated into the insertion of the A3 pulley and volar plate. They remain taut throughout flexion and extension in contrast to the collateral ligaments of the metacarpophalangeal joint, which are taut in flexion but lax in extension. In the proximal interphalangeal joint, a fan-like accessory collateral ligament arises in continuity from the palmar edge of the main ligament and passes in a palmar direction to attach to the volar plate: it folds like a concertina on flexion. The accessory collateral ligament and check rein ligament are not found in the distal interphalangeal joint (Slattery et al 2014).

Synovial membrane Each interphalangeal joint has a synovial lining.

Factors maintaining stability Stability is conferred by the articular contours of the joint surfaces and the proper collateral ligaments (Allison 2005). The flexor and extensor tendons provide secondary stabilization. Stability against hyperextension of the proximal interphalangeal joint is enhanced by the three-dimensional box arrangement that is produced by the collateral ligament–volar plate complex.

Joint movements Flexion and extension are active movements at the interphalangeal joints. Their range is greater at the proximal joints. Flexion is considerable, whereas extension is limited by tension of the digital flexors and terminated by tension in the palmar ligaments. Flexion and extension are accompanied by slight rotation: during flexion, this turns the digital pulps into slight supination to face the opposed thumb: an opposite rotation occurs during extension.

Accessory movements Limited rotation, abduction, adduction and anteroposterior translation permit the fingers to adapt to the shapes of gripped objects and help to protect against stresses and strains.

Muscles producing movements

Flexion Flexion is produced by flexors digitorum superficialis and profundus at the proximal interphalangeal joints, flexor digitorum profundus at the distal interphalangeal joints and flexor pollicis longus at the interphalangeal joint of the thumb.

Extension Extension of the interphalangeal joint of the thumb is produced by extensor pollicis longus and by the combined pull of abductor pollicis brevis, flexor pollicis brevis and abductor pollicis through the extensor expansion (which simultaneously flexes the metacarpophalangeal joint). This supplementary action allows extension of the interphalangeal joint of the thumb even if extensor pollicis longus or the radial nerve are divided. Extension of the interphalangeal joints of the digits is achieved though the complex extensor mechanism with contributions from the central tendon (extensors digitorum, digiti minimi and indicis) and the lateral bands that draw from the lumbricals and interossei. Extension occurs simultaneously in both joints in digits 2–5. Simultaneous flexion at the metacarpophalangeal joints and extension at the interphalangeal joints of a digit are essential for the fine movements of writing, drawing, threading a needle, etc. The lumbricals and interossei are primary agents in flexing the metacarpophalangeal joints and also in extending the interphalangeal joints through their attachments to the dorsal digital expansions.

Vascular supply of the joints of the wrist and hand

The radiocarpal joint is supplied by branches of the anterior interosseous artery, anterior and posterior carpal branches of the radial and ulnar arteries, palmar and dorsal metacarpal arteries, and recurrent rami of the deep palmar arch. The carpal joints are supplied by the posterior

The ulnar collateral ligament of the metacarpophalangeal joint of the thumb may be avulsed from its distal attachment to the base of the proximal phalanx by a combination of forced extension and radial deviation of the joint. Chronic attritional tears of this ligament are traditionally reported to occur in gamekeepers from wringing the necks of pheasants. Acute injuries typically occur in skiers who fall onto an outstretched hand while having the strap of a ski pole wrapped around the thumb, or if the thumb is caught in the snow (or the grid of an artificial slope). The ligament may be avulsed directly from the bone or with a pyramidal fragment of bone. The fragment also includes the insertion of the volar plate, flexor sheath and part of adductor pollicis. The ulnar collateral ligament is normally covered by the aponeurotic fibres of the tendon of adductor pollicis. Following avulsion, the proximal end can become superficially displaced around the proximal free edge of the aponeurotic insertion of adductor pollicis. This is termed a Stener lesion (Mattox et al 2015). The soft tissue interposition prevents the ends of the avulsed ligament from healing. The presence of a Stener lesion is indicated clinically if there is more than 30° of radial laxity when stressing the metacarpophalangeal joint in 40° of flexion. If the joint is assessed in extension, then the lateral fibres of the volar plate may contribute significantly to the lateral stability of the joint and give a false impression of stability. Surgical repair requires division of the aponeurotic fibres of adductor pollicis to expose the insertion, followed by reattachment of the avulsed ligament to its attachment in the anteromedial corner of the proximal phalanx. Postoperative rehabilitation requires early movement of the interphalangeal joint of the thumb, otherwise the adductor aponeurosis will adhere to the repair and prevent flexion of the tip. The ulnar collateral ligament is isometric, i.e. the same length in flexion and extension. Consequently, early movement of the metacarpophalangeal joint will prevent adherence of the repair to the side of the joint, which would otherwise limit movement.

The comparable injury to the radial collateral ligament is less common. It is caused by sudden, forced adduction of the metacarpophalangeal joint as the result of a fall or during ball games. The ligament may be ruptured in its mid-substance or avulsed from either bony attachment, usually the distal. A Stener lesion does not occur because the aponeurosis of abductor pollicis brevis is closely apposed to the joint and thus does not provide the space.

The oblique retinacular ligament of Landsmeer (see Fig. 51.25) runs from an attachment anterior to the axis of the proximal interphalangeal joint to an insertion posterior to the axis of the distal interphalangeal joint. This ligament is inconsistent (Adkinson et al 2014), but when present causes a dynamic tenodesis with obligatory extension of the distal interphalangeal joint when the proximal interphalangeal joint extends.

Mallet finger deformity is caused by laceration, traumatic rupture or an avulsion fracture of the distal extensor tendon to the terminal phalanx of the finger. It is usually caused by forced flexion of the distal phalanx of the finger or laceration of the tendon. A closed rupture is usually painless. The patient is unable to extend the distal interphalangeal joint actively, but it can be extended passively. As time passes, the residual extensor mechanism is pulled proximally by the intrinsic tone, which increases the torque across the dorsum of the interphalangeal joint, causing a secondary swan neck deformity.

Swan neck deformity is caused by hyperextension of the proximal interphalangeal joint, together with flexion of the distal interphalangeal joint and occurs as a result of an imbalance between the component parts of the extensor and flexor mechanism: it may be related to problems at the metacarpophalangeal, proximal interphalangeal and distal interphalangeal joints. The deformity can be caused by a number of factors: erosion of the volar plate of the proximal interphalangeal joint by synovitis, so that the joint can hyperextend; rupture of flexor digitorum superficialis from rheumatoid disease or laceration; intrinsic muscle tightness (spasm, ulnar drift, palmar subluxation of the proximal phalanx on the metacarpal head); mallet finger, where the extensor mechanism moves proximally because it is unconstrained by the distal insertion into the distal phalanx, conferring an increased extensor moment to the base of the middle phalanx.

A boutonnière deformity is a flexion deformity of the proximal interphalangeal joint with hyperextension of the distal interphalangeal joint. It reflects an imbalance between tension in the central slip and the lateral bands of the extensor mechanism following failure of the central slip. This can occur as a result of acute division or chronic attrition. Initially, the proximal interphalangeal joint still extends because the lateral bands are intact, but in time the dorsal triangular ligament becomes attenuated, allowing the lateral bands of the extensor tendon to migrate in a volar direction and the head of the proximal phalanx to migrate dorsally: the extensor mechanism then exerts a flexion force at the proximal interphalangeal joint. The terminal part of the extensor mechanism still runs dorsal to the axis of the distal interphalangeal joint but is relatively tightened due to anterior subluxation of the lateral bands, causing hyperextension at the distal interphalangeal joint. Initially, the deformity is passively correctable, but, with time, the soft tissues around the joint contract and a fixed deformity results.

carpal branches of the radial and ulnar arteries, and by the anterior interosseous artery. The carpometacarpal joint of the thumb receives its blood supply from the radial artery and its first dorsal metacarpal branch. The second to fifth carpometacarpal joints are supplied by the posterior carpal branches of the radial and ulnar arteries, by twigs from the anterior interosseous artery, and from the palmar digital arteries. The metacarpophalangeal joints receive their blood supply from the dorsal and palmar metacarpal arteries, the arteria princeps pollicis and the arteria radialis indicis. The interphalangeal joints are supplied by branches from the palmar digital arteries (see Fig. 51.2A).

Innervation of the joints of the wrist

The radiocarpal joint is innervated by the anterior interosseous nerve, posterior interosseous nerves and lateral antebrachial cutaneous nerves with contributions from the median, ulnar and radial nerves. The palmar cutaneous branch of the median nerve, the deep branch of the ulnar nerve, the superficial branch of the radial nerve and the dorsal branch of the ulnar nerve also innervate the capsule (Van de Pol et al 2006). The ulnar corner of the wrist and triangular cartilage is innervated by the dorsal cutaneous branch of the ulnar nerve, medial antebrachial cutaneous nerve and ulnar nerve. Occasionally it receives fibres from the anterior and posterior interosseous nerves (LaPorte et al 2014). These appear to be pure afferent nerves innervating mechanoreceptor endings (there are an average of 10 in each dorsal radiocarpal ligament) (Tomita et al 2007). Golgi organs, Pacinian corpuscles, Ruffini endings and free nerve endings are found in the palmar radiocarpal ligaments (Petrie et al 1997). The apparently uneven distribution of these receptors throughout the ligaments suggests as yet unspecified functional adaptations.

Innervation of the joints of each digit

The second to fifth carpometacarpal joints are innervated by branches of the ulnar nerve, the anterior interosseous nerve and the superficial radial and dorsal ulnar nerves. The metacarpophalangeal joints are innervated by twigs from the palmar digital branches of the median and ulnar nerve, the deep terminal branch of the ulnar nerve and the posterior interosseous nerve. The interphalangeal joints of the fingers are innervated by one branch, occasionally two, from the palmar digital branches of the median nerve (to the thumb, index, middle and ring fingers), and the ulnar nerve (to the ring and little fingers). The dorsal cutaneous nerves rarely provide innervation (Pastrana et al 2019).

Innervation of the joints of the thumb

The carpometacarpal joint of the thumb is innervated by branches from the lateral antebrachial cutaneous nerve, the palmar cutaneous branch of the median nerve and, less commonly, the superficial radial nerve (Tuffaha et al 2018). The interphalangeal joint of the thumb is innervated by a palmar capsular branch from the radial and ulnar digital nerve as well as a branch from each of the dorsal radial nerve terminal branches (Zaidenberg et al 2018).

MUSCLES

Extrinsic long flexors and extensors

The extrinsic long flexors and extensors are described on pages 942 to 950. The flexor and extensor retinacula are described on page 958.

Long flexor tendon apparatus

Flexor tendon sheaths

The fibrous sheaths of the flexor tendons are specialized parts of the palmar fascia. Each finger and the thumb have an osseo-aponeurotic tunnel that extends from the neck of the metacarpal to the distal phalanx. The proximal border is well defined, lying just beneath the distal palmar crease of the little, ring and middle fingers at the level of the neck of the metacarpal. The sheath consists of arcuate fibres that arch anteriorly over bone, tendons (where the sheath is required to be stiff) and the centres of joints (where a bucket-handle of arcuate fibres is a mechanically favourable arrangement). By contrast, where the sheath is required to fold to permit joint flexion, it consists of cruciate fibres. These fibrous sheaths are lined by a thin synovial membrane that provides a sealed lubrication system containing synovial fluid. The synovial membrane extends from the distal phalanx to mid-palm in the case of the index, middle and ring fingers, and further proximally in the case of the little finger (**Fig. 51.27C**). The sheaths around the thumb and little finger are continuous with the flexor sheaths in front of the wrist. The parietal synovial membrane is reflected on to the surface of the flexor tendon, forming a visceral synovium.

A standard nomenclature for the anular (A) and cruciform (C) pulleys is used. The usual pattern is as follows (**Fig. 51.27A–B**). The A1 pulley is situated anterior to the palmar cartilaginous plate of the metacarpophalangeal joint and may extend over the proximal part of the proximal phalanx. The A2 overlies the middle third of the proximal phalanx. It is the strongest pulley and arises from well-defined longitudinal ridges on the palmar aspect of the phalanx. Its distal edge is well developed. A pouch or recess of synovium extends superficial to the free edge of the pulley fibres so that the free edge forms a lip protruding into the synovial space. A3 is a narrow pulley lying palmar to the proximal interphalangeal joint. A4 overlies the middle third of the middle phalanx, and A5 overlies the distal interphalangeal joint. The cruciate fibres are numbered in a slightly different manner. C0 is palmar to the metacarpophalangeal joint. There are two cruciate zones, C1 and C2, at the proximal interphalangeal joint, and they lie just proximal and distal, respectively, to A3. At the distal interphalangeal joint, there is one pronounced cruciate system, C3, which lies between A4 and A5. Variations occur frequently. During flexion, the cruciate fibres become orientated more transversely in the digits, and the edges of adjacent anular pulleys approximate so that they form, in full flexion, a continuous tunnel of transversely orientated fibres. Surgically, the most important pulleys that prevent bowstringing of the flexor tendons are the A2 and A4 pulleys.

In the thumb, there are three constant pulleys: two anular and one oblique (**Fig. 51.28**). The A1 pulley is located at the metacarpophalangeal joint. The oblique pulley is located over the mid-portion of the proximal phalanx and its fibres pass from the ulnar aspect proximally to the radial aspect dorsally. The A2 pulley is thinner than the A1 pulley and is situated just proximal to the interphalangeal joint. The oblique pulley is the most important pulley in the thumb for maintaining the action of flexor pollicis longus.

Synovial sheaths of the carpal flexor tendons

Two synovial sheaths envelop the flexor tendons as they traverse the carpal tunnel: one for flexors digitorum superficialis and profundus, the other for flexor pollicis longus. These sheaths typically extend into the forearm for 2.5 cm proximal to the flexor retinaculum and, occasionally, communicate with each other deep to it. The sheath surrounding the tendons of the flexors digitorum reaches about halfway along the metacarpals, where it ends in blind diverticula around the tendons to the index, middle and ring fingers (see Fig. 51.27B). The sheath is prolonged around the tendons to the little finger and is usually continuous with their digital synovial sheath. The sheath of flexor pollicis longus, which is usually separate, is continued along the thumb as far as the insertion of the tendon (see Fig. 51.28).

Vincula

The phenomenon of tendon gliding within a fibrous sheath requires a very specialized arrangement of the vascular supply. Folds of synovial membrane, vincula brevia and longa, each containing a loose plexus of fascial fibres, carry blood vessels to the tendons at certain defined points (**Fig. 51.29**). Vincula brevia are attached to the deep surfaces of the tendons near to their insertions. There are two in each finger, one attaches flexor digitorum profundus to the region of the distal interphalangeal joint, and a more proximal vinculum lies deep to flexor digitorum superficialis at the proximal interphalangeal joint. Vincula longa are filiform: two are usually attached to each superficial tendon and one to each deep tendon.

Trigger finger

Available with the *Gray's Anatomy* e-book

Synovial sheaths of the carpal extensor tendons

Six tunnels deep to the extensor retinaculum transmit the extensor tendons, each containing a synovial sheath (**Fig. 51.30**). Each tunnel has an annotation from I to VI (1 to 6, first to sixth). The tendons of abductor pollicis longus and extensor pollicis brevis lie in a tunnel (compartment I) on the lateral side of the styloid process of the radius;

Precise knowledge of the nerve supply to the joints of the wrist and hand allows the surgeon to remove the afferent nerve supply in various conditions. This may effectively remove pain and avoid the alternative of joint excision, fusion or replacement, each of which has substantial disadvantages.

Trigger finger is a stenosing tenovaginosis of uncertain aetiology. The opening of the fibrous flexor sheaths of the fingers thickens to form a distinct palpable, often tender, nodule in the palm beneath the distal transverse palmar crease. This inhibits the normal excursion of the flexor tendons, causing the finger to lock down into flexion at all three joints. The corresponding extensor muscle is insufficiently powerful to extend the affected finger, so the patient does this passively, accompanied by a painful snap. As time passes the proximal interphalangeal joint develops a contracture. Treatment frequently requires corticosteroid injection or surgical division of the A1 pulley of the flexor sheath to relieve the stricture.

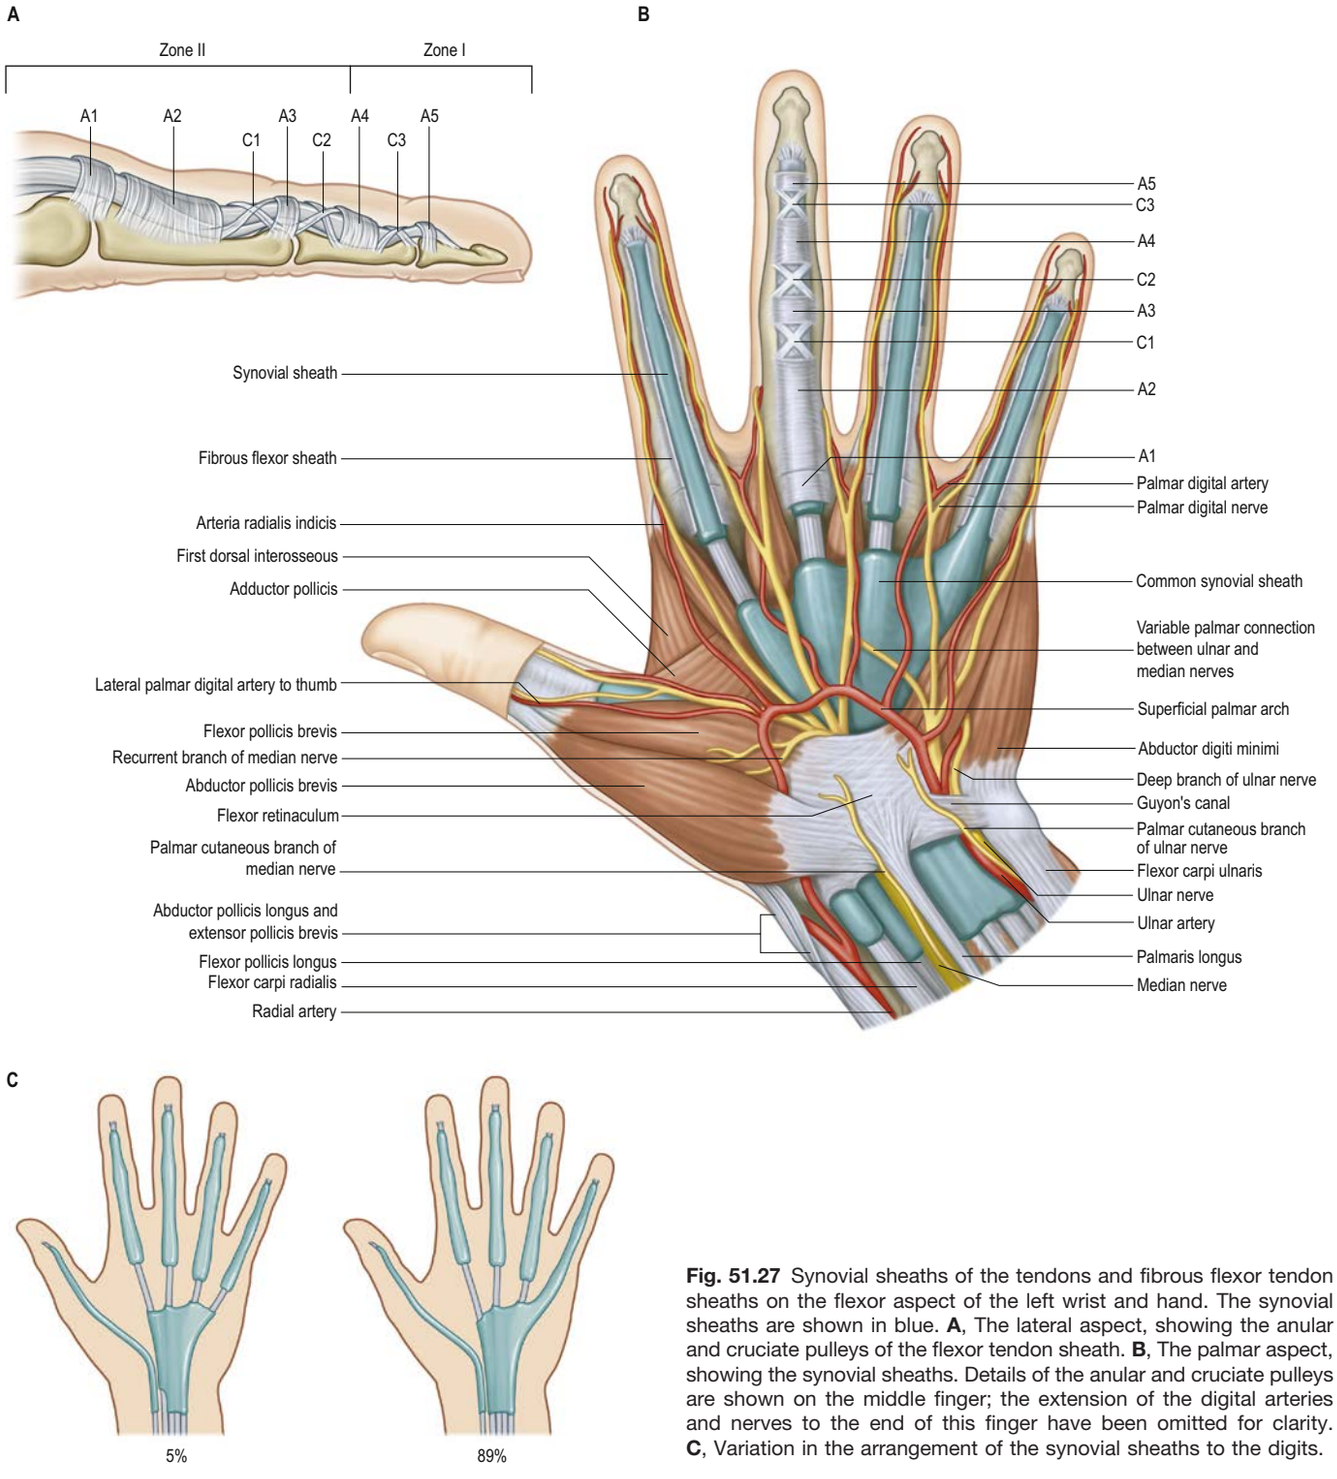

Fig. 51.27 Synovial sheaths of the tendons and fibrous flexor tendon sheaths on the flexor aspect of the left wrist and hand. The synovial sheaths are shown in blue. **A**, The lateral aspect, showing the anular and cruciate pulleys of the flexor tendon sheath. **B**, The palmar aspect, showing the synovial sheaths. Details of the anular and cruciate pulleys are shown on the middle finger; the extension of the digital arteries and nerves to the end of this finger have been omitted for clarity. **C**, Variation in the arrangement of the synovial sheaths to the digits.

there may be a separate synovial sheath for each, or the tendon of the abductor may be double. The floor of the sheath is formed by the insertion of brachioradialis. The tendons of extensors carpi radialis longus and brevis lie dorsomedial to the styloid process (compartment II); the tendon of extensor pollicis longus lies on the medial side of the dorsal (Lister's) tubercle of the radius (compartment III); the tendons of extensors digitorum and indicis lie in a tunnel on the medial side of the tubercle (compartment IV); the tendon of extensor digiti minimi lies dorsal to the distal radio-ulnar joint (compartment V); the tendon of extensor carpi ulnaris lies between the head and the styloid process of the ulna in a narrow groove (compartment VI). The tendon sheaths of abductor pollicis longus, extensors pollicis brevis and longus, extensors carpi radialis longus and brevis and extensor carpi ulnaris stop immediately proximal to the bases of the metacarpals, while those of extensors digitorum, indicis and digiti minimi are sometimes prolonged a little more distally along the metacarpus. The sheaths of compartments I–V are separated by vertical pillars that connect the dorsum of the distal radius and the extensor retinaculum. Compartment VI (containing extensor carpi ulnaris) has a separate subsheath that is not in continuity with the extensor retinaculum, an arrangement that allows rotation of the distal radio-ulnar joint that would not otherwise be possible if the rigid retinaculum linked compartments V and VI.

De Quervain's tenovaginitis

Available with the *Gray's Anatomy* e-book

De Quervain's tenovaginitis is a stenosing tenovaginosis of unknown aetiology that occurs in the first dorsal compartment at the level of the radial styloid. It involves the common extensor sheath containing the tendons of abductor pollicis longus and extensor pollicis brevis. There is palpable thickening of the tendon sheath with painful limitation of active extension and passive flexion of the thumb. Treatment may involve splinting, corticosteroid injection or surgery to divide the thickened sheath. The sheath is divided longitudinally along its dorsal attachment. This reduces the chance of 'bowstringing' of the abductor tendons on wrist flexion by retaining some pulley function. The surgeon must seek for a second and sometimes even third separate sheath within the first compartment. Care must be taken to avoid the immediately adjacent superficial radial nerve.

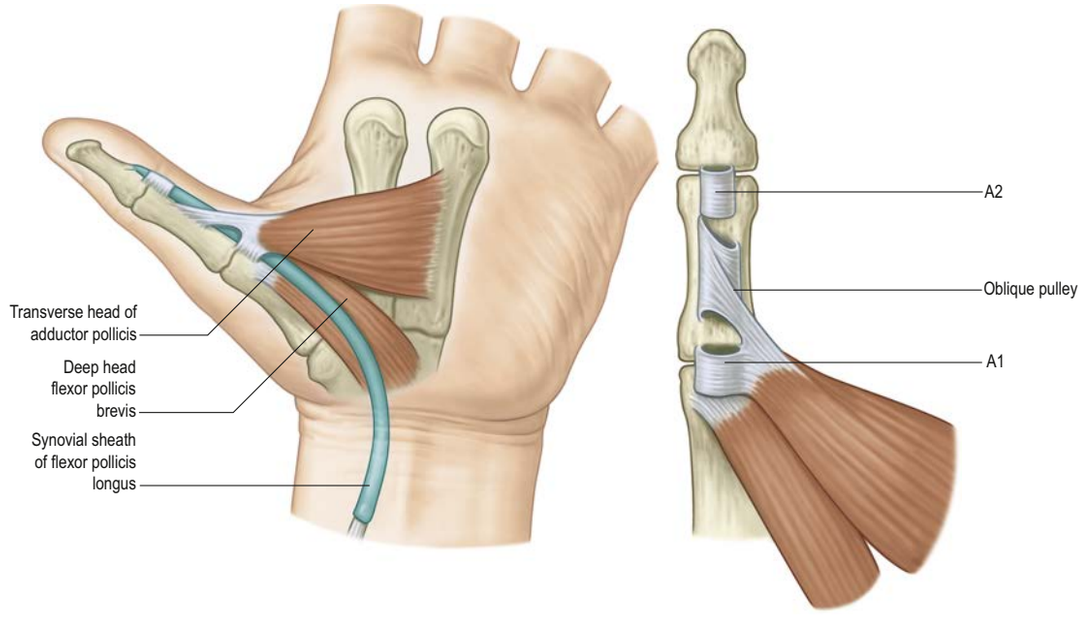

Fig. 51.28 The flexor sheath of the left thumb, showing the anular and oblique pulleys. (From Doyle JR, Blythe WF 1977 Anatomy of the flexor tendon sheath and pulleys of the thumb. J Hand Surg Am 2:149–51. With permission from the American Society for Surgery of the Hand.)

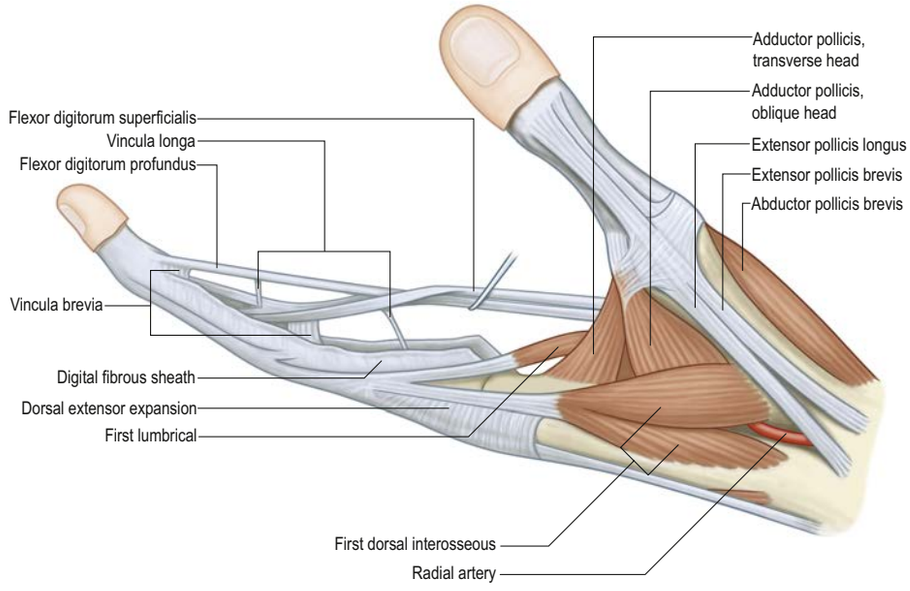

Fig. 51.29 The tendons and vincula tendina of the index finger and the muscles in the first intermetacarpal space of the left hand: lateral aspect.

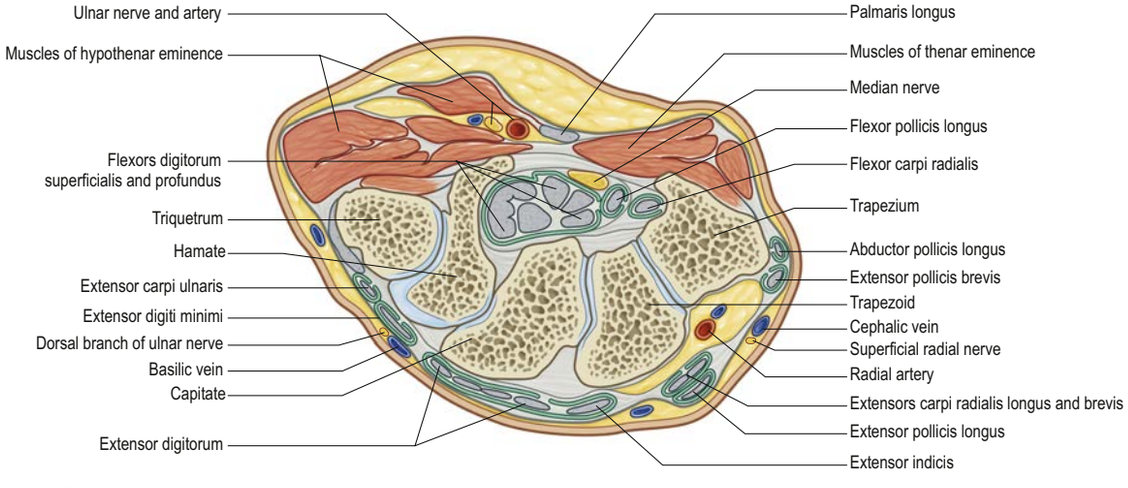

Fig. 51.30 A transverse section through the left wrist at the level of the distal row of the carpus, showing the muscle tendons (in grey) and their synovial sheaths (in green).

Extensor tendon apparatus

The extensor digitorum tendons emerge through the fourth dorsal compartment onto the dorsum of the hand, where they are joined together distally by a varying pattern of oblique interconnections, the juncturae tendinae. These typically pass in a distal direction from middle finger to index finger, and from ring finger to middle and little fingers. Proximal lacerations to the middle finger extensor tendon may result in only partial loss of extension because of these tendinous interconnections. There is considerable variability in the arrangement of the extensors over the back of the hand. There are usually two tendons to the middle and ring fingers, whereas the tendon to the little finger may be absent and replaced with a junctura tendinum from the ring finger.

At the level of the metacarpophalangeal joint, each extensor tendon is held in a central position over the dorsum of the joint by a flat, fibrous extensor expansion (see Fig. 51.25). The expansion extends on to the dorsum of the proximal phalanx of each digit, forming a movable hood that moves distally when the metacarpophalangeal joint is flexed, and proximally when it is extended. Each extensor tendon blends with the extensor expansion along its central axis and is separated from the metacarpophalangeal joint by a small bursa. The expansion is triangular in shape, with its base proximal. It receives the conjoined tendons of the interosseous and lumbrical muscles and is almost translucent between its margins and the tendon of extensor digitorum. Transverse fibres (the sagittal bands) pass to the volar plate and transverse metacarpal ligaments, separating the phalangeal attachment of the dorsal interosseous from the rest of the muscle, and the palmar interosseous from the lumbrical muscle. The margins of the extensor expansions are thickened on the radial side by the tendons of the lumbrical and interosseous muscles, and on the ulnar side either by the tendon of an interosseous alone or, in the case of the fifth digit, by abductor digiti minimi.

The tendons of the interossei join the extensor expansion at the level of the proximal portion of the proximal phalanx, while the tendons of the lumbricals join the extensor mechanism further distally at the midportion of the proximal phalanx. Their line of pull is anterior to the axis of rotation at the metacarpophalangeal joint, but dorsal to the axis of rotation at the proximal interphalangeal joint. The extensor mechanism trifurcates into a central slip and two lateral bands just proximal to the proximal interphalangeal joint. The central slip receives a contribution from the tendons of the lumbricals and interossei via the lateral bands. Similarly, some fibres from the central region pass to each lateral band, producing a criss-cross arrangement of fibres. The central slip attaches to the base of the middle phalanx, while the lateral bands continue distally; they eventually fuse together and insert into the distal phalanx. The tension in the central slip and the lateral bands varies as the finger moves between flexion and extension and plays a crucial role in coordinating synchronous activity between the proximal and distal interphalangeal joints.

The transverse and oblique retinacular ligaments of Landsmeer connect the fibrous flexor sheath to the extensor apparatus. The transverse retinacular ligament passes from the A3 pulley of the fibrous flexor sheath at the level of the proximal interphalangeal joint to the lateral border of the lateral extensor band. The oblique retinacular ligament lies deep to the transverse retinacular ligament. It originates from the lateral aspect of the proximal phalanx and flexor sheath (A2 pulley) and passes volar to the axis of rotation of the proximal interphalangeal joint, but in a dorsal and distal direction, to insert into the terminal extensor tendon.

Sagittal band movement

See **Video 51.4**.

Sagittal band injury

Available with the *Gray's Anatomy* e-book

Intrinsic muscles of the hand

The intrinsic muscles of the hand are organized into three groups plus a superficial muscle. The thenar muscles are flexor pollicis brevis, abductor pollicis brevis, opponens pollicis and adductor pollicis. The hypothenar muscles are abductor digiti minimi, flexor digiti minimi brevis and opponens digiti minimi. The interossei and lumbricals act on the fingers. Palmaris brevis is a superficial muscle that lies beneath the ulnar palmar skin.

Flexor pollicis brevis

Attachments Flexor pollicis brevis lies medial to abductor pollicis brevis (**Fig. 51.31**). It has superficial and deep parts. The superficial head arises from the distal border of the flexor retinaculum and the distal part of the tubercle of the trapezium, and passes along the radial side of the tendon of flexor pollicis longus. It is attached by a tendon that contains a sesamoid bone to the radial side of the base of the proximal phalanx of the thumb. The deep part arises from the trapezoid and capitate bones and from the palmar ligaments of the distal row of carpal bone, and passes deep to the tendon of flexor pollicis longus. It unites with the superficial head on the sesamoid bone and base of the first phalanx. The superficial head is frequently blended with opponens pollicis. The deep head varies considerably in size and may even be absent.

Relations Flexor pollicis brevis lies superficial in the thenar eminence and is distal to abductor pollicis brevis. It is crossed by the motor branch of the median nerve.

Actions Flexor pollicis brevis flexes the metacarpophalangeal joint.

Testing Flexor pollicis brevis is palpated whilst flexing the metacarpophalangeal joint, with the interphalangeal joint fully extended, to appose the pulp of the thumb against the pulp of the middle finger.

Abductor pollicis brevis

Attachments Abductor pollicis brevis is a thin, subcutaneous muscle in the proximolateral part of the thenar eminence (see Figs 51.13, 51.27). It arises mainly from the flexor retinaculum, but a few fibres spring from the tubercles of the scaphoid bone and trapezium and from the tendon of abductor pollicis longus. Its medial fibres are attached by a thin, flat tendon to the radial side of the base of the proximal phalanx of the thumb, and its lateral fibres join the dorsal digital expansion of the thumb. The muscle may receive accessory slips from the long and short extensors of the thumb, opponens pollicis, or the styloid process of the radius.

Relations Abductor pollicis brevis lies proximomedial to flexor pollicis brevis in the superficial part of the thenar eminence.

Actions Abductor pollicis brevis draws the thumb ventrally in a plane at right-angles to the palm of the hand (abduction).

Testing The subject abducts the thumb at right-angles to the palm against resistance; the muscle can be seen and felt.

Opponens pollicis

Attachments Opponens pollicis lies deep to abductor pollicis brevis (see Figs 51.13, 51.29, 51.31). It arises from the tubercle of the trapezium and the flexor retinaculum, and is attached to the whole length of the lateral border and the adjoining lateral half of the palmar surface of the metacarpal of the thumb. It does not insert into the proximal phalanx or the extensor expansion.

Relations Opponens pollicis lies deep between the other two muscles of the thenar eminence and is revealed only when they are retracted.

Actions Opponens pollicis flexes the metacarpal of the thumb and stabilizes the trapeziometacarpal joint.

Testing The subject touches the base of the little finger against resistance.

Adductor pollicis

Attachments Adductor pollicis arises by oblique and transverse heads (see Figs 51.13, 51.31). The oblique head is attached to the capitate bone, the bases of the second and third metacarpals, the palmar ligaments of the carpus, and the sheath of the tendon of flexor carpi radialis. Most of the fibres converge into a tendon (containing a sesamoid bone) that unites with the tendon of the transverse head and is attached to the ulnar side of the base of the proximal phalanx of the thumb. The most superficial fibres from the dorsal aspect pass into the medial side of the dorsal digital expansion of the thumb. The transverse head is the deepest of the muscles of the thumb; it is triangular and arises from the distal two-thirds of the palmar surface of the third metacarpal. The fibres converge to be attached, with the oblique head and the first palmar interosseous, to the base of the proximal phalanx of the thumb. The two parts of the adductor vary in relative size and degree of connection.

Injuries to the sagittal bands, from natural degeneration or a direct blow, can lead to subluxation of the extensor tendon. The radial sagittal band is usually affected. The tendon then passes anterior to the axis of the metacarpophalangeal joint, causing flexion and abduction of the proximal phalanx on the metacarpal. Secondary tightness of the opposite sagittal band and underlying collateral ligament promptly follows.

Treatment involves immediate splinting to extend the metacarpophalangeal joint whilst keeping the proximal joint mobile. This reduces the sagittal band and allows healing. An alternative, particularly when there is secondary tightness of the opposite sagittal band, is surgical reconstruction.

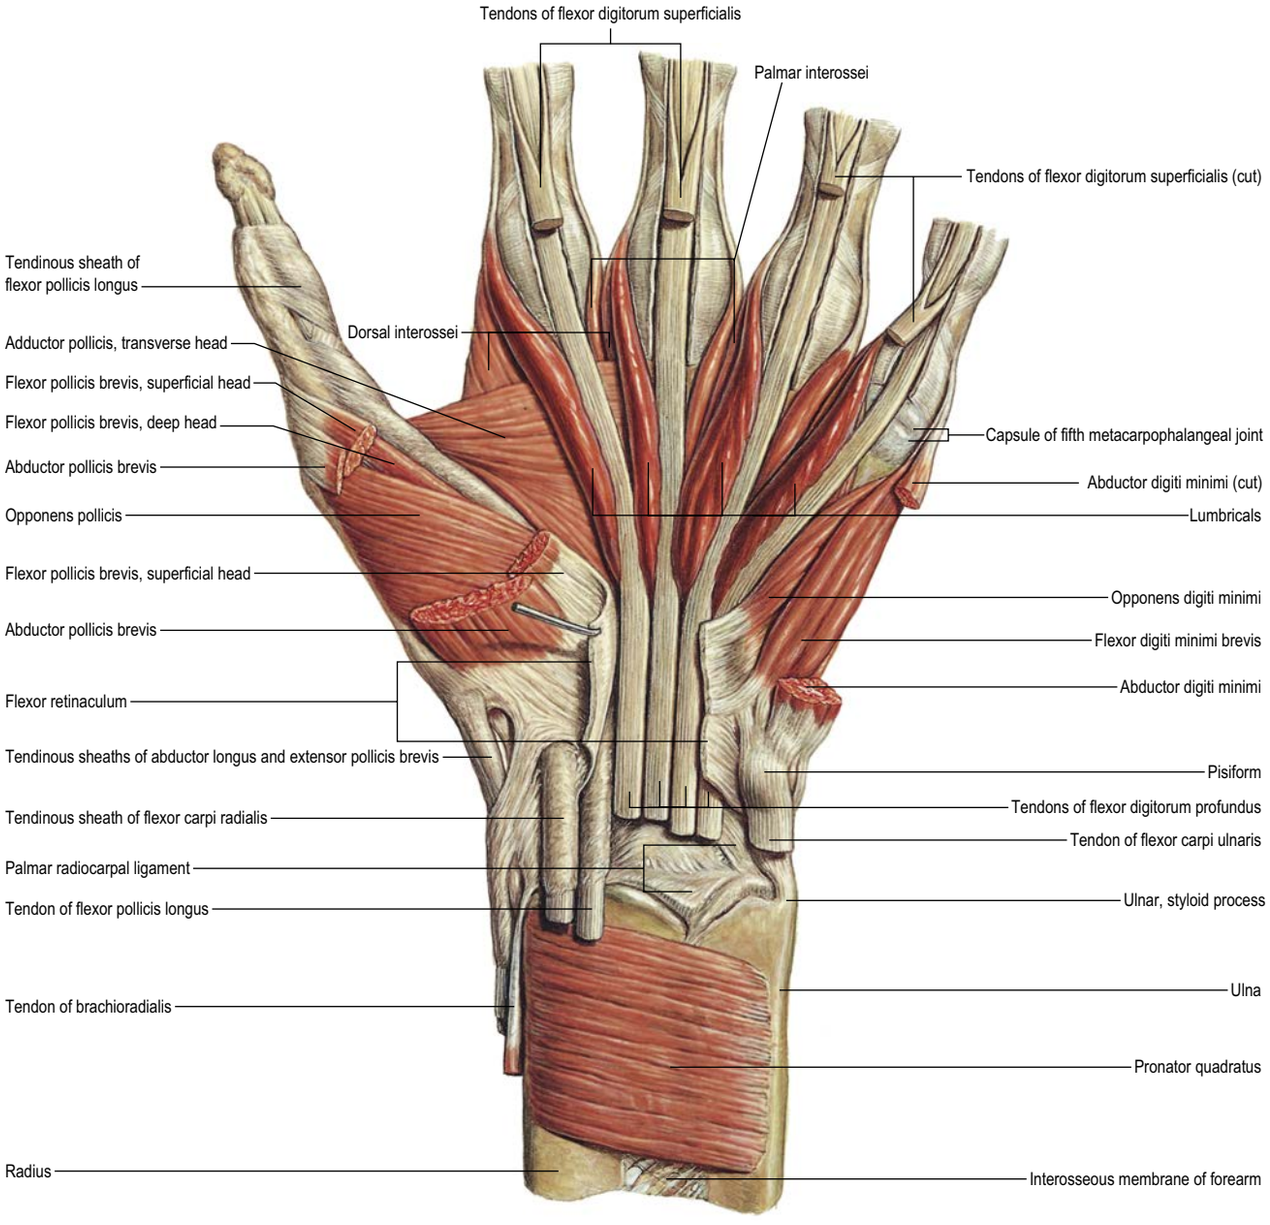

Fig. 51.31 The muscles of the left hand. The deep layer is shown after cutting the flexor retinaculum and partial removal of several superficial muscles: palmar aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Relations The deep palmar arch and the deep branch of the ulnar nerve pass between the two heads of the muscle. Anteriorly, adductor pollicis is crossed by the flexor tendons of the index finger and their sheath and the first lumbrical, and is overlapped by flexor pollicis brevis. Posteriorly, it abuts against the first dorsal interosseous muscle: together, these muscles form the mass of the first web space of the hand.

Actions Adductor pollicis is the largest and most powerful of the intrinsic muscles and acts to approximate the thumb to the palm of the hand. It acts optimally when the abducted, rotated and flexed thumb is opposed to the fingers in gripping.

Testing The subject adducts the thumb at right-angles to the palm against resistance.

Abductor digiti minimi

Attachments Abductor digiti minimi arises from the pisiform bone, the tendon of flexor carpi ulnaris and the pisohamate ligament (see Figs 51.13, 51.27, 51.31). It ends in a flat tendon that divides into two slips: one is attached to the ulnar side of the base of the proximal phalanx of the little finger, and the other to the ulnar border of the dorsal digital expansion of extensor digiti minimi. The muscle may have two or three slips and may be fused with flexor digiti minimi brevis. An additional slip may arise from the flexor retinaculum, antebrachial fascia, or tendons of palmaris longus or flexor carpi ulnaris, and may be partly attached to the fifth metacarpal by a slip from the pisiform.

Relations Abductor digiti minimi lies along the ulnar border of flexor digiti minimi brevis and overlies opponens digiti minimi.

Actions Abductor digiti minimi abducts the little finger away from the fourth, e.g. in the habitual spreading of the digits when they are extended. Abduction is also possible when digits 2–4 are tightly adducted in flexion or extension.

Testing The little finger is abducted against resistance.

Flexor digiti minimi brevis

Attachments Flexor digiti minimi brevis arises from the convex surface of the hook of the hamate and the palmar surface of the flexor retinaculum, and inserts into the ulnar side of the base of the proximal phalanx of the little finger with abductor digiti minimi (see Fig. 51.31). It may be absent, or fused with the abductor, and it may attach to the distal end of the fifth metacarpal by a muscular slip.

Relations Flexor digiti minimi brevis lies lateral to the abductor. Its origin is separated from that of the abductor by the deep branches of the ulnar artery and nerve.

Actions Flexor digiti minimi brevis produces flexion of the little finger at its metacarpophalangeal joint, together with some lateral rotation.

Testing The subject flexes the metacarpophalangeal joint of the little finger against resistance with the interphalangeal joints in extension.

Opponens digiti minimi

Attachments Opponens digiti minimi is a triangular muscle lying under cover of the flexor and abductor (see Figs 51.13, 51.31). It arises from the convexity of the hook of the hamate and the contiguous portion of the flexor retinaculum, and inserts along the whole length of the ulnar margin of the fifth metacarpal and the adjacent palmar surface. The muscle is often divided into two lamellae by the deep branches of the ulnar artery and nerve. It blends to a variable degree with its neighbours.

Relations Opponens digiti minimi lies on the ulnar margin and adjacent palmar surface of the fifth metacarpal, overlapped by, and often partly fused with, the other two muscles of the hypothenar eminence.

Actions Opponens digiti minimi flexes the fifth metacarpal, drawing it forwards and rotating it laterally at the carpometacarpal joint; this deepens the hollow of the palm. These actions, together with flexion and some lateral rotation at the metacarpophalangeal and interphalangeal joints, bring the digit into opposition with the thumb.

Testing The subject opposes the tip of the little finger to the tip of the thumb with the interphalangeal joints of the little finger in extension.

Palmaris brevis

Attachments Palmaris brevis is a thin, quadrilateral muscle lying beneath the skin of the ulnar side of the palm (see Fig. 51.12A). It arises from the flexor retinaculum and the medial border of the central part of the palmar aponeurosis and is attached to the dermis on the ulnar border of the hand.

Relations Palmaris brevis is superficial to the ulnar artery and the superficial terminal branch of the ulnar nerve.

Actions Palmaris brevis wrinkles the skin on the ulnar side of the palm of the hand and deepens the hollow of the palm by accentuating the hypothenar eminence.

Testing The subject opposes the thumb to the little finger; the skin on the ulnar side of the palm is seen to pucker.

Interossei

The interossei occupy the intervals between the metacarpals and are divided into a palmar and a dorsal set.

Palmar interossei

Attachments Palmar interossei are smaller than dorsal interossei and lie on the palmar surfaces of the metacarpals rather than between them (**Fig. 51.32**; see Fig. 51.13). The middle finger has no palmar interosseous; the remaining digits have palmar interossei on their aspects that face the middle finger. The first is often rudimentary and is not described by all anatomists. When present, it arises from the ulnar side of the palmar surface of the base of the first metacarpal and the trapezium; it is inserted into the ulnar sesamoid and from here, it passes to the phalanx and, usually, also into the dorsal digital expansion. It may be considered to be the most lateral head of the oblique component of adductor pollicis. The second palmar interosseous arises from the ulnar side of the second metacarpal and is inserted into the same side of the digital expansion of the index finger. The third arises from the radial side of the fourth metacarpal and is inserted together with the third lumbrical. The fourth arises from the radial side of the fifth metacarpal and is attached with the fourth lumbrical and to the base of the proximal phalanx. The attachment of these muscles to the dorsal digital expansions (see Figs 51.25, 51.29) stabilizes the extensor tendons on the convex heads of the metacarpals during flexion and extension at the metacarpophalangeal joints. The interossei show little variation in their arrangement; occasionally they may be duplicated.

Relations The first palmar interosseous lies anterior to the lateral head of the first dorsal interosseous and is overlapped anteriorly by the oblique head of adductor pollicis that also crosses anterior to the second palmar interosseous. The third and fourth are overlapped by the long flexor tendons of the ring and little finger, respectively, within their flexor sheaths.

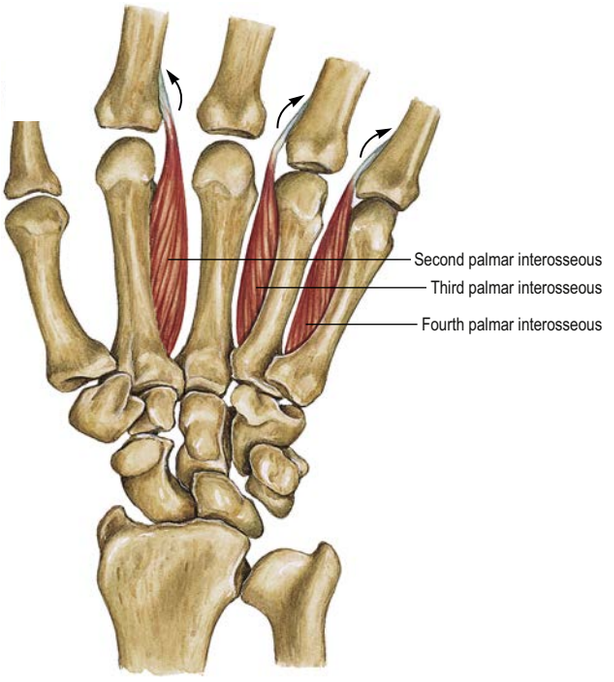

Fig. 51.32 The palmar interossei of the left hand: palmar aspect. Note that there is no first palmar interosseous in this specimen. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Actions Palmar interossei adduct the fingers towards the longitudinal axis of the middle finger when the metacarpophalangeal joints are extended. This action is facilitated by the laxity of the collateral ligaments in extension (because the dorsal width of the metacarpal head is less than its palmar width). Interossei have a considerable cross-sectional area and, therefore, contribute significantly to metacarpophalangeal joint flexion and interphalangeal extension. When the interossei are paralysed, the grip strength of the hand is reduced and the arc of finger motion is abnormal, with a tendency for the fingers to claw. Each interosseous also rotates the digit at the metacarpophalangeal joint. Generally, this is not obvious because interossei act in pairs, but it may occur where one interosseous is deficient as a result of injury or congenital deformity.

Testing The subject adducts the index ring and little fingers against resistance.

Dorsal interossei

Attachments Dorsal interossei consist of four bipennate muscles, each arising from the adjacent sides of two metacarpals, but more extensively from the metacarpal of the finger into which the muscle passes (**Fig. 51.33**). They insert on the bases of the proximal phalanges and separately into the dorsal digital expansions (see Fig. 51.25). There is a narrow triangular interval between the double origin of each of these muscles; the radial artery passes through the first of these intervals, and a perforating branch from the deep palmar arch passes through each of the others. The first and largest muscle is sometimes called abductor indicis and is attached to the radial side of the proximal phalanx of the index finger and to the capsule of the adjoining metacarpophalangeal joint. The second and third are attached to the radial and ulnar sides of the middle finger, respectively. Whereas the second generally reaches the digital expansion and the proximal phalanx, the third usually extends only to the digital expansion. The fourth may be wholly attached to the digital expansion, but it often sends an additional slip to the proximal phalanx.

Relations The first dorsal interosseous abuts anteriorly with adductor pollicis. The other dorsal interossei occupy the spaces between the second and the fifth metacarpals.

Actions Dorsal interossei abduct and externally rotate the fingers away from the longitudinal axis of the middle finger. This allows cupping of

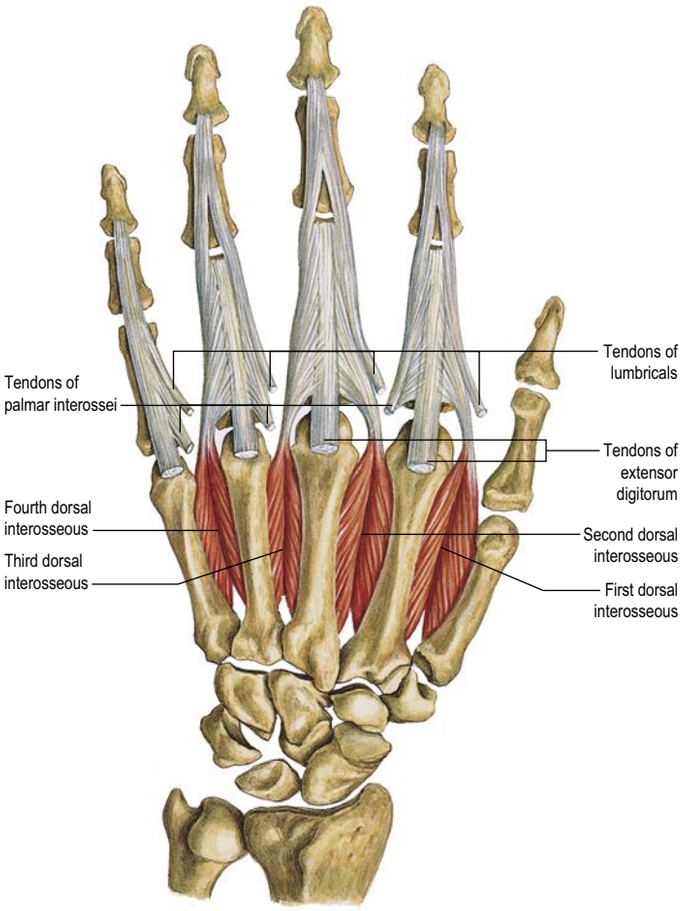

Fig. 51.33 The dorsal interossei of the left hand: dorsal aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

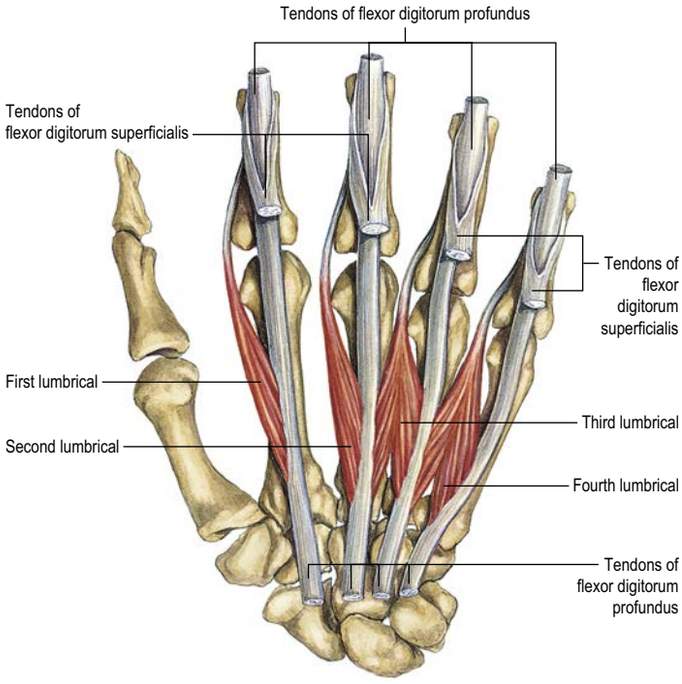

Fig. 51.34 The lumbricals of the left hand: palmar aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

the hand through the distal transverse metacarpal arch around an object such as a ball.

Testing The subject abducts the index, middle and ring fingers against resistance. The first dorsal interosseous is tested with the subject's fingers and palm flat on the table and the subject tries to abduct the index finger against the examiner's resistance. The muscle belly can be felt and seen.

Lumbricals

Attachments The four small lumbrical muscles arise from the tendons of flexor digitorum profundus (**Fig. 51.34**; see Fig. 51.31). The first and second are unipennate muscles and arise from the radial sides and palmar surfaces of the tendons of the index and middle fingers, respectively. The third arises from the adjacent sides of the tendons of the middle and ring fingers, and the fourth from the adjoining sides of the tendons of the ring and little fingers; both are bipennate muscles. Each passes to the radial side of the corresponding finger and is attached to the lateral margin of the dorsal digital expansion of extensor digitorum covering the dorsal surface of the finger. The lumbrical is distal to the interosseous and attached to the extensor retinaculum at a greater angle. Variations in the attachments of the lumbricals are common (Parminder 2013). Any of them may be unipennate or bipennate. When they are bipennate, the two heads arise from adjoining tendons of flexor digitorum profundus, and, in the case of the first lumbrical, from the tendon of flexor pollicis longus. Accessory lumbrical slips may be attached to an adjacent tendon of flexor digitorum superficialis.

Actions

See **Video 51.5**.

Lumbricals arise from flexor tendons and insert into the extensor apparatus. Since both attachments are mobile, they have the potential for producing movement at either. The action on the extensor apparatus extends both interphalangeal joints in a coordinated manner. The mode of action at the metacarpophalangeal joints is disputed, but if there is a flexor action, it is weaker than that of the interossei. Because of the more distal insertion into the expansion, the lumbricals can still extend the interphalangeal joints with the metacarpophalangeal joints flexed, whereas the interossei cannot. The effect on the flexor digitorum profundus attachment is to pull the tendon distally. The combined action on both origin and insertion is, therefore, to weaken the tone of flexor digitorum profundus and augment the extension tone. Pinching the index finger against the thumb without a lumbrical would result in a nail-to-nail contact; the addition of the lumbrical increases the interphalangeal joint extension and results in pulp-to-pulp pinch. Lumbricals contain many muscle spindles and have a long fibre length and it is therefore reasonable to assume that they play a role in proprioception.

The intrinsic muscles of the fingers, the interossei and lumbricals combined, have an important role in advancing metacarpophalangeal joint flexion yet inhibiting interphalangeal joint flexion when grip is initiated. This allows the fingers to form a hemisphere to hold an item such as a ball or a stick. In the absence of this accessory function, the long flexors would pull the interphalangeal joints into flexion too early which would hook the tips of the fingers and obstruct the space in front of the phalanges into which the ball would sit.

Testing Lumbricals cannot be tested in isolation but only as the lumbrical–interosseous muscle complex. The examiner asks the subject to hold the metacarpophalangeal joint of the finger in full flexion whilst fully extending the interphalangeal joints. An inability to do this causes the finger to assume a 'clawed' posture wherein the metacarpophalangeal joint extends and the interphalangeal joints flex. Tightness of the intrinsic muscles is assessed by the Bunnell test the metacarpophalangeal joint is held extended by the examiner and the proximal interphalangeal joint is passively flexed. An inability to flex the latter indicates that the intrinsic muscle is foreshortened.

Vascular supply to the intrinsic muscles of the hand

Flexor pollicis brevis is supplied by the superficial palmar branch of the radial artery, and branches from the princeps pollicis artery and radialis indicis artery. Abductor pollicis brevis is supplied by the superficial palmar branch of the radial artery and, often, by an independent branch directly from the radial artery lying on the radial aspect of the thumb. Opponens pollicis is supplied by the superficial palmar branch of the radial artery and by branches from the first palmar metacarpal artery (when present), arteria princeps pollicis, arteria radialis indicis and the deep palmar arch. Adductor pollicis is supplied by the arteria princeps pollicis and arteria radialis indicis (sometimes combined as the first palmar metacarpal artery) and by branches from the deep palmar arch. Abductor digiti minimi and flexor digiti minimi brevis are supplied by the deep palmar branch of the ulnar artery and branches from the ulnar end of the superficial palmar arch; the medial border of the little finger

is supplied by the palmar digital artery. Opponens digiti minimi is supplied by the deep palmar branch of the ulnar artery and branches from the medial end of the deep palmar arch. Palmaris brevis is supplied by branches from the ulnar end of the superficial palmar arch. The palmar interossei are supplied by branches from the deep palmar arch, arteria princeps pollicis, arteria radialis indicis, palmar metacarpal arteries, proximal and distal perforating arteries, and common and proper digital (palmar) arteries. The dorsal interossei are supplied by the dorsal metacarpal arteries (first to fourth), palmar metacarpal arteries (second to fourth), radial artery (first), arteria princeps pollicis, arteria radialis indicis, three perforating branches from the deep palmar arch (proximal perforating arteries) and three distal perforating branches. Their tendons are supplied by branches from the common and proper palmar digital arteries and the dorsal digital arteries.

The first and second lumbricals are supplied by the first and second dorsal metacarpal and dorsal digital arteries. The third and fourth lumbricals are supplied by the second and third common palmar digital arteries, and the third and fourth dorsal digital arteries and their anastomoses with the palmar digital arteries.

Innervation of the intrinsic muscles of the hand

The superficial head of flexor pollicis brevis is usually innervated by the recurrent motor branch of the median nerve, and the deep head by the deep branch of the ulnar nerve; variation is common. Abductor pollicis brevis is innervated by the recurrent motor branch of the median nerve and is the only thenar muscle that is constantly supplied by the median nerve. Opponens pollicis is innervated by the lateral terminal branch of the median nerve and, commonly, by a branch of the deep terminal branch of the ulnar nerve. Adductor pollicis, abductor digiti minimi, flexor digiti minimi brevis, opponens digiti minimi and all the interossei are innervated by the deep branch of the ulnar nerve; the first dorsal interosseous and adductor pollicis are supplied by its most distal portion. Palmaris brevis is innervated by the superficial branch of the ulnar nerve. The first and second lumbricals are innervated by the median nerve, and the third and fourth lumbricals by the deep terminal branch of the ulnar nerve. The third lumbrical frequently receives a supply from the median nerve. The first and second lumbricals are, occasionally, innervated by the deep terminal branch of the ulnar nerve.

MOVEMENTS OF THE HAND

The apparently simple human functions of closing the hand to grasp an object, or opening the palm to release it, are, in reality, tasks of considerable mechanical complexity, requiring the simultaneous contraction of many individual muscles. The isolated action of a single muscle may be inferred from the positions of its origin and insertion, and the estimated line of action (usually, the centre line of the muscle) in relation to the axes of all the joints traversed by the muscle and its tendon. The limb can be regarded as a chain of joints crossed by muscles. If it is known which muscles are active, then the reason why one joint moves and others do not is a matter of simple mechanical relationships. For example, flexor pollicis longus is considered to have a major role as a flexor of the interphalangeal joint of the thumb. However, the position of its tendon relative to more proximal joints in the limb gives it the potential for producing flexion at the metacarpophalangeal joint and also at the trapeziometacarpal and wrist joints. In the living subject, the actual motion that takes place depends on which other muscle groups are acting as antagonists, and so the potential for movement must be considered for each joint in the chain in turn. Potential flexion at the wrist by flexor pollicis longus is generally balanced by wrist extensors and flexion at the trapeziometacarpal joint is balanced by abductor pollicis longus. Flexor pollicis longus will then have an action as a flexor of the metacarpophalangeal and interphalangeal joints only.

The factor that determines whether one or both of two joints will move is the turning moment at each. The greater the perpendicular distance from the line of muscle or tendon pull to the axis of the joint, the stronger is the turning effect of the muscle at the joint, but the smaller the range of joint motion that can be produced. In the case of flexor pollicis longus, the tendon is situated further from the axis of the metacarpophalangeal joint than from the axis of the interphalangeal joint; it will, therefore, tend to produce flexion preferentially at the metacarpophalangeal joint, unless that joint is restrained by extensor pollicis brevis. In this way, different postures of the thumb can be produced by the interplay of flexor and extensor forces. These simple guiding principles should provide an understanding of muscle action in the hand that is sufficient for most purposes.

In considering the role of a particular muscle, there is a tendency to concentrate on motion. Indeed, many muscles are named on the basis of the movements that they generate, although others, often those whose actions are the most difficult to interpret, are described according to their morphology or situation. A more important function may be the nature of the force generated. For example, although flexor pollicis longus flexes the thumb, a large range of flexion is actually required in only a few activities, such as grasping a narrow bar in the palm. In most pinch and manipulative tasks, the role of the thumb is to apply isometric force, which it does with such precision that it is possible to pick up an egg and neither crush nor drop it. Thus, for much of the time, flexor pollicis longus behaves as an extremely sophisticated mechanism for the application of force, in which contraction and proprioception are equally important.

The anatomical position of the hand (palm flat and pointing anteriorly, forearm supinated) is a convenient standard for studying structural relationships. The hand in the relaxed (anaesthetized) position adopts a posture of partial flexion and mid-supination/pronation (the reader can verify this by relaxing completely and observing forearm and hand position).

VASCULAR SUPPLY

Arteries

Anastomoses occur between the radial and ulnar arteries at the wrist (via the palmar and dorsal carpal arches) and in the hand (via the superficial and deep palmar arches), and between their digital and metacarpal branches (**Figs 51.35, 51.36**) (Wong and Higgins 2015).

Radial artery

At the wrist, the radial artery passes on to the dorsal aspect of the carpus between the lateral carpal ligament and the tendons of abductor pollicis longus and extensor pollicis brevis (**Fig. 51.37**). It crosses the scaphoid bone and trapezium (in the anatomical snuff-box), where again, its pulsation is obvious; as it passes between the heads of the first dorsal interosseous, it is crossed by the tendon of extensor pollicis longus. Between the thumb extensors, it is crossed by the start of the cephalic vein and the branches of the radial nerve that pass to the thumb and index finger. Occasionally, it gives off a distal superficial dorsal branch that crosses the radial extensor tendons at the wrist, together with the superficial radial nerve. Branches of the lateral cutaneous nerve of the forearm run along its distal part as it curves round the carpus.

In the hand, the radial artery passes through the first interosseous space between the heads of the first dorsal interosseous and crosses the palm. At first, it lies deep to the oblique head of adductor pollicis and then passes between its oblique and transverse heads or through the transverse head. At the fifth metacarpal base, it anastomoses with the deep branch of the ulnar artery, completing the deep palmar arch (see Fig. 51.36).

Palmar carpal branch The palmar carpal branch arises near the distal border of pronator quadratus (see Fig. 50.9B). It crosses the anterior surface of the distal end of the radius, near the palmar carpal surface, and passes medially to anastomose behind the long flexor tendons with the palmar carpal branch of the ulnar artery. This transverse anastomosis is joined by longitudinal branches from the anterior interosseous artery and recurrent branches from the deep palmar arch, forming a cruciate palmar radiocarpal arch that supplies the carpal articulations and bones by descending branches.

Closing the hand

Whilst the fingers flex in gripping, grasping or making a fist, there are subtle differences in hand posture in these various activities. The basic mechanisms of hand closure will be described before special grips are considered.

As the digits flex, the wrist usually extends (dorsiflexes) at the same time. The involvement of the long digital flexors in this movement will be considered first, followed by an analysis of the role of the wrist.

Role of the long digital flexors

Flexor digitorum superficialis acts principally to flex the proximal interphalangeal joints, through its insertions into the middle phalanges. However, in each digit, it also has an action on the metacarpophalangeal joint because the tendon passes anterior to that joint. The muscle has the potential to produce flexion at the wrist for the same reason. The fact that each tendon arises from an individual muscle slip allows the clinician to test one finger at a time. The reader can verify this by attempting to flex each digit individually while using the other hand to keep the distal interphalangeal joints of the remaining fingers in extension. This test is frequently used in clinical practice and is useful for the middle and ring fingers, where flexion of one finger alone must be attributed to flexor digitorum superficialis. The index finger, however, has its own profundus musculotendinous unit and may, therefore, move independently under the action of this tendon. Many individuals cannot flex the proximal interphalangeal joint of the little finger alone, usually because of linkage between the tendons of the ring and little finger flexor digitorum superficialis, but occasionally because superficialis is deficient. Most individuals can flex the metacarpophalangeal joint of the little finger using flexor digiti minimi.

Flexor digitorum profundus is the only flexor of the distal interphalangeal joint. It also contributes, together with superficialis, to flexion at the proximal interphalangeal and metacarpophalangeal joints. These two long flexors (sometimes called extrinsic flexors because the muscle bellies are outside the hand) can be considered to act together to flex the fingers.

Role of the intrinsic muscles of the hand

The action of the long flexors alone would wind up the interphalangeal joints before the metacarpophalangeal joints, and the fingers would not move in a normal arc of flexion. This is precisely what happens in an ulnar nerve paralysis, in which the interossei and lumbricals are not functioning. These small (intrinsic) muscles have been described earlier in terms of their individual actions. For their role in coordinated activity, it is sufficient to appreciate that their contribution changes the arc produced by the long flexors, increasing flexion at the metacarpophalangeal joint and reducing flexion at the proximal and distal interphalangeal joints. All three joints are then angulated to the same degree and the fingers form a normal arc of flexion. As the finger flexes, the long extensor tendons (extensor digitorum, extensor indicis and extensor digiti minimi) aid the process by relaxing and allowing the extensor apparatus to glide distally on the dorsum of the phalanges.

Role of the wrist

As the fingers wind up to make a fist, the wrist tends to extend, particularly when force is applied. This extension has a marked effect on the excursion of the long flexor tendons. On its own, digital flexion requires the long tendons to move proximally in their sheaths and the flexor muscles in the forearm would shorten. The maximum excursion possible in flexor digitorum superficialis and flexor digitorum profundus is approximately 7 cm. Extension of the wrist tends to produce a lengthening of these muscles, which, in normal use, is almost enough to balance the shortening due to finger flexion; the net effect is a very slight shortening (approximately 1 cm) of the long flexors in the forearm. The wrist can, therefore, be seen as a mechanism for maximizing force because it allows the fingers to flex while maintaining the resting length of the extrinsic muscles near to the peak of the force–length curve. It is, of course, possible to wind up the fingers with the wrist held in a neutral position but the grip is somewhat weaker. With the wrist in full flexion, it is not possible to flex the fingers fully as there is insufficient excursion of the muscle unit.

Flexion of the fingers on gripping tends to result in a distal excursion of the long extensors. However, this tendency is counteracted by dorsiflexion of the wrist. The net effect is a very small proximal excursion of the long extensor tendons on gripping, mirroring the effect on the flexor surface. If the movement of the wrist is exaggerated so that the wrist is a little flexed on opening the hand, and fully dorsiflexed on closing it, the net excursion of long flexors and extensors is zero, i.e. this whole movement sequence can be completed with the forearm flexor and extensor muscles contracting isometrically.

The reader can observe the relationship between digits and wrist by performing the following manoeuvre. The wrist is held in a relaxed, mid-supinated position, with the elbow flexed at 90°. If the forearm is now rotated into pronation, the wrist will fall into flexion and the fingers will automatically extend. If the forearm is rotated into supination, the wrist will extend and the fingers flex. The finger movements compensate for the wrist movements and are entirely automatic; they are made without the need for any excursion of forearm flexor or extensor tendons. This test, the wrist tenodesis test, is a useful way of

examining the limb for tendon injury. The pointing finger (which does not move with wrist motion) 'points to' a tendon injury.

Making a tight fist

It is possible to observe and to palpate the muscle groups that are active in making a tight fist. Flexor digitorum profundus and flexor digitorum superficialis are active, and flexor carpi ulnaris contracts strongly, as do the wrist extensors. Palpation of the long digital extensors on the dorsum of the wrist, the first dorsal interosseous in the thumb web, and of the other interossei and the thenar and hypothenar muscles, will confirm that all these muscles are contracting. As a firm fist is swung forwards in anger, brachioradialis stands out; at the moment of impact, virtually every muscle in the limb is active.

Role of the arches of the hand

The hand has *stable* elements and *mobile* elements (Tubiana et al 1996). The distal row of the carpus together with the second and third carpometacarpal joints are stable and rigid. The fourth and especially the fifth carpometacarpal joints, the thumb ray and the phalangeal joints are mobile. This allows the hand to form adaptable arches on gripping. The transverse carpal arch, formed by the carpal bones, is rigid. The metacarpal arch, between the metacarpal heads of the index and little finger, allows the ulnar side of the palm to curve into supination, by movement at the fourth and fifth carpometacarpal joints. The longitudinal arch, along the axis of a metacarpal and its phalanges, allows the finger to flex around an object. The thumb forms two important oblique arches, one between the tip of the thumb through the thumb–index web to the pulp of the index finger, the other from the pulp of the thumb, along the thumb ray, across the palm and along the front of the little finger to its pulp. As the fingers flex into the palm, the combined alignment and mobility of the involved joint surfaces bring all the finger tips to a focal point over the scaphoid tubercle. This also increases the security of grip of small items such as a golf ball.

Opening the hand

The hand is opened from its relaxed balanced posture, e.g. when stretching out to reach an object. This motion is made up of extension of the distal interphalangeal, proximal interphalangeal and metacarpophalangeal joints together with retroposition and extension of the thumb. As the fingers extend they tend to abduct and rotate outwards from the axis of the middle finger. The hand is provided with an ingenious mechanism that allows this to happen. The laws of mechanics would suggest that one motor would be required for every joint in a chain, together with some sort of controlling mechanism to ensure that the chain of joints moved together in a coordinated fashion. In the hand, this is achieved through an extensor apparatus that minimizes the number of motors required for movement by allowing the muscles to act on more than one joint, and by linking different levels in the mechanism so that the arc of motion is controlled.

The tendons of extensor digitorum run distally over the metacarpal heads, forming the major component of the extensor apparatus. Extensor digitorum has no insertion into the proximal phalanx and, therefore, exerts its extensor action on the metacarpophalangeal joint indirectly through more distal insertions. The first point of insertion is at the base of the middle phalanx (known as the 'central slip'). Acting at this insertion alone, extensor digitorum can extend both metacarpophalangeal and proximal interphalangeal joints together. The interossei are also active in hand opening, since they extend both the proximal and interphalangeal joints through the lateral bands. There is, therefore, a range of possibilities. At one extreme, with no contribution from the interossei, the long extensor will exert all of its action at the metacarpophalangeal joint; this leads to full extension, and even hyperextension, while the proximal interphalangeal joint remains flexed (the typical 'intrinsic minus', or claw hand, of ulnar nerve paralysis). At the other extreme, when the intrinsics act strongly together with extensor digitorum, the proximal interphalangeal joint will extend completely while the metacarpophalangeal joint remains flexed ('intrinsic plus' hand). Thus, the hand possesses, in the proximal part of the extensor apparatus, a variable mechanism that allows different amounts of relative metacarpophalangeal or proximal interphalangeal joint motion.

In contrast, the more distal part of the extensor apparatus acts as an automatic or fixed mechanism that determines that the two interphalangeal joints, proximal and distal, will move together. The lateral slips of the extensor apparatus arise from extensor digitorum and pass distally on either side of the central slip and thus over the proximal interphalangeal joint; being further lateral, they are nearer the joint axis because the dorsal surface curves away on each side. A helpful analogy that has been suggested for this arrangement is to consider it as two pulleys of different size on one axle. The central slip can be regarded as a cord that passes over the larger wheel, and each lateral slip as a cord that passes over the smaller wheel. Since these latter pulleys are smaller, there is less longitudinal excursion for a given rotation of the wheel, and this allows some of the excursion to be used for another function, namely: extension at the distal joint. There is an additional mechanism by which the lateral slips move laterally during flexion of the proximal interphalangeal joint. The effect of this lateral movement is to reduce further the distance between the lateral slips and the joint axis, thereby reducing the amount of excursion at the proximal interphalangeal joint still more and allowing more excursion at the distal joint. When the hand flexes, this mechanical linkage system allows both interphalangeal joints to flex together in a coordinated way.

The extensor expansion also receives contributions from the interossei and lumbricals, which approach the digits from the webs and join the corresponding expansion in the proximal segment of the digit. These muscles can, therefore, act on the extensor apparatus at two levels: they can extend the proximal interphalangeal joint through fibres that radiate towards the central slip, and they can act on the distal interphalangeal joint through fibres that join the lateral slip.

The oblique retinacular ligament also passively aids synchronized extension by linking the terminal extensor fibres at the level of the distal interphalangeal joint with the flexor sheath just proximal to the proximal interphalangeal joint. This tightens with extension of the proximal interphalangeal joint causing obligatory passive extension of the distal interphalangeal joint. The presence of this structure can be confirmed by noting the marked resistance when passively flexing the distal joint with the proximal interphalangeal joint held passively extended, which resistance disappears if the proximal joint is flexed.

Apart from the components of the extensor expansion that are concerned with joint function, the whole structure requires additional anchorage (see Fig. 51.25). The transversely lying triangular ligament just distal to the insertion of the central slip prevents the lateral bands from subluxating too far outwards and palmarwards when the proximal interphalangeal joint flexes. Following a central slip rupture, this triangular ligament becomes attenuated, causing the lateral bands to slide outward and forwards until they pass anterior to the axis of the joint acting as flexor and causing the boutonnière deformity.

As the expansion glides backwards and forwards, the transverse fibres move like bucket handles. Smooth gliding layers are required under the expansion and retinacular ligaments to allow motion to occur without friction.

See **Video 51.6**.

The thumb does not easily assume the classical anatomical position. Therefore, the normal descriptive anatomical terms, i.e. anterior, posterior, medial and lateral, do not readily apply. The terms 'palmar', 'dorsal', 'ulnar' and 'radial' have been adopted in clinical practice.

An opposable thumb requires a different system of control from the other digits. Since the metacarpal is much more mobile than in the digits, muscles are needed to control the extra freedom of movement. The basic active movements are flexion–extension, abduction–adduction, rotation and circumduction. In the resting position of the first metacarpal, flexion and extension are parallel with the palmar plane, and abduction and adduction occur at right-angles to this.

Flexion and extension should be confined to motion at the interphalangeal or metacarpophalangeal joints). Palmar abduction (in which the first metacarpal moves away from the second at right-angles to the plane of the palm, and radial abduction in which the first metacarpal moves away from the second with the thumb in the plane of the palm, occur at the carpometacarpal joint. The opposite of radial abduction is ulnar adduction, or transpalmar adduction, in which the thumb crosses the palm towards its ulnar border. In clinical practice, the term adduction is generally used without qualification. Circumduction describes the angular motion of the first metacarpal, solely at the carpometacarpal joint, from a position of maximal radial abduction in the plane of the palm towards the ulnar border of the hand, maintaining the widest possible angle between the first and second metacarpals. Lateral inclinations of the first phalanx maximize the extent of excursion of the circumduction arc. Opposition is a composite position of the thumb (achieved by palmar abduction, flexion and pronation of the first metacarpal, with slight radial deviation and flexion of the metacarpophalangeal joint and slight flexion of the interphalangeal joint) such that the pulp of the thumb opposes the pulp of a digit with the nail of the thumb parallel to the palm (Bunnell 1938). Retroposition restores the hand from opposition, lifting the thumb backwards from the plane of the palm.

Rotary movements occur during circumduction. The simple angular movements described above combine with rotation about the long axis of the metacarpal shaft. In opposition, the shaft must rotate medially into

pronation. In retroposition, the thumb must rotate laterally into supination. Axial rotation of the thumb metacarpal is produced by muscle activity (which moves the thumb through its arc of circumduction); the geometry of the articular surfaces of the trapeziometacarpal joint; and tensile forces in the ligaments (which combine with forces exerted by the muscles of opposition and retroposition to produce axial rotation). The stability of the first metacarpal is greatest after complete pronation in the position of full opposition, when the tension in the ligaments, muscular contraction and joint congruence combine to maximal effect.

Position of rest

The hand has a well-recognized position of rest, with the wrist in extension and the digits in some degree of flexion. The precise position of the thumb in the position of rest is variable. Typically, it is considered as the midpoint between maximal palmar abduction and maximal retroposition. In this position, the carpometacarpal joint lies at about 20° of radial abduction and 30° of palmar abduction; the metacarpophalangeal joint lies at about 40° of flexion and the interphalangeal joint at about 20° of flexion.

Grips

See **Video 51.7**.

From the position of rest, the tip of the thumb can approach the radial aspect of the fingers without incurring axial rotation because the palmar and dorsal trapeziometacarpal ligaments remain relaxed (see below). From different positions of the arc of circumduction, numerous different types of pinch grip are possible. In clinical practice, these have been classified into two main types: tip pinch and lateral (or key) pinch. Many forces contribute to these configurations.

The thumb is activated by monoarticular muscles (abductor pollicis longus and opponens pollicis), biarticular muscles (extensor pollicis brevis, adductor pollicis, abductor pollicis brevis and flexor pollicis brevis) and polyarticular muscles (extensor pollicis longus and flexor pollicis longus). It appears, however, that even a monoarticular muscle can change posture in all three joints by altering the overall balance of forces and it is, therefore, very difficult to attribute function to the individual intrinsic muscles. However, the thumb muscles do seem to provide two broad functions. They position the metacarpal, an activity automatically accompanied by rotation, and also control the axial stability of the skeleton of the thumb.

The thumb muscles may be classified into those used for retroposition, opposition and pinch grip.

Retroposition muscles

The muscles that bring about retroposition are extensor pollicis longus, extensor pollicis brevis and abductor pollicis longus. As the thumb moves into retroposition, automatic axial rotation produces supination of the first metacarpal. This is produced by the off-axis action of two parallel, but oppositely directed, forces: one exerted by extensors pollicis longus and brevis, and the other by abductor pollicis longus and the anterior oblique carpometacarpal ligament.

In the absence of extensor pollicis longus (from rupture, laceration or paralysis) the thumb cannot be retroposed. Only this muscle has the moment to elevate the thumb behind the plane of the palm.

Opposition muscles

A succession of activity occurs in the thenar muscles during the movement of opposition. Three subgroups of radial (abductor pollicis longus and extensor pollicis brevis), central (abductor pollicis brevis and opponens pollicis) and ulnar (flexor pollicis brevis) muscles are involved. These forces act simultaneously but with different intensities, depending on the situation of the thumb. As the thumb moves into opposition, there is automatic axial rotation of the first metacarpal shaft to produce pronation. This is produced by the paired action of oppositely directed forces: the opposition muscles provide one force, and the posterior oblique carpometacarpal ligament provides the other.

Pinch grip muscles

Pinch grip is mainly conferred by flexor pollicis longus and adductor pollicis. The former flexes the interphalangeal and metacarpophalangeal joints. The adductor pollicis adducts the thumb and, through the extensor expansion, counteracts excessive interphalangeal joint flexion from flexor pollicis longus. The proximal phalanx is stabilized from translating dorsally in pinch by the volar plate and by the extensor hood (which is actively contracted by the adductor pollicis and flexor pollicis brevis). The abductor pollicis longus also contracts firmly, locking the base of the metacarpal into a stable position of abduction and compression against the trapezium. The index finger is stabilized by the first dorsal interosseous which is, necessarily, the strongest of all the intrinsic muscles. With the index metacarpophalangeal joint fully flexed, the radial collateral ligament is taut and imparts additional static stability.

The wrist and hand may be paralysed by many conditions that affect the brain spinal cord, brachial plexus or peripheral nervous system. The aetiology can be traumatic, infective (such as poliomyelitis and leprosy), vascular, inflammatory or congenital. Each of these will cause different patterns of paralysis and contracture.

The main deformities from cerebral palsy are pronation of the forearm, flexion of the wrist and fingers, and flexion–adduction of the thumb (thumb in palm deformity). Flexion–adduction deformity of the thumb reflects an imbalance between its intrinsic and extrinsic musculature – principally powered by adductor pollicis, the first dorsal interosseous, flexor pollicis brevis and abductor pollicis brevis – which produces flexion, adduction and lateral rotation of the carpometacarpal joint, flexion and lateral rotation of the metacarpophalangeal joint and flexion of the interphalangeal joint. In an attempt to counteract this, the patient tends to hold the wrist in extreme flexion and ulnar deviation (Matev 1963). Surgery for the hand in cerebral palsy aims to optimize the ability to grasp and release objects and abduct the thumb to improve hand span. It is important to note that any procedure that improves one of these functions may well compromise the others.

In leprosy, the intrinsic muscles of the hand are paralysed. The metacarpophalangeal joints have no primary flexor but retain the powerful extensor digitorum. Extensor digitorum relies on a single muscle belly to extend the metacarpophalangeal joints and the proximal and the distal interphalangeal joints. In order to permit interphalangeal joint flexion with metacarpophalangeal joint extension (hook grip) there needs to be some ‘slack’ in the tendons distal to the metacarpophalangeal joints when extensor digitorum is contracted: the intrinsic muscles are responsible for trimming this slack in order to extend the interphalangeal joints fully. Absence of the intrinsic muscles results in four main disabilities: the fingers cannot be extended fully at the interphalangeal joints; abduction and adduction of the digits are lost; when grasping an object, flexion begins at the terminal joints, closing the fingers on themselves rather than on the palm; and the effective part of the finger becomes the tip and nail rather than the pulp (Brand 1958).

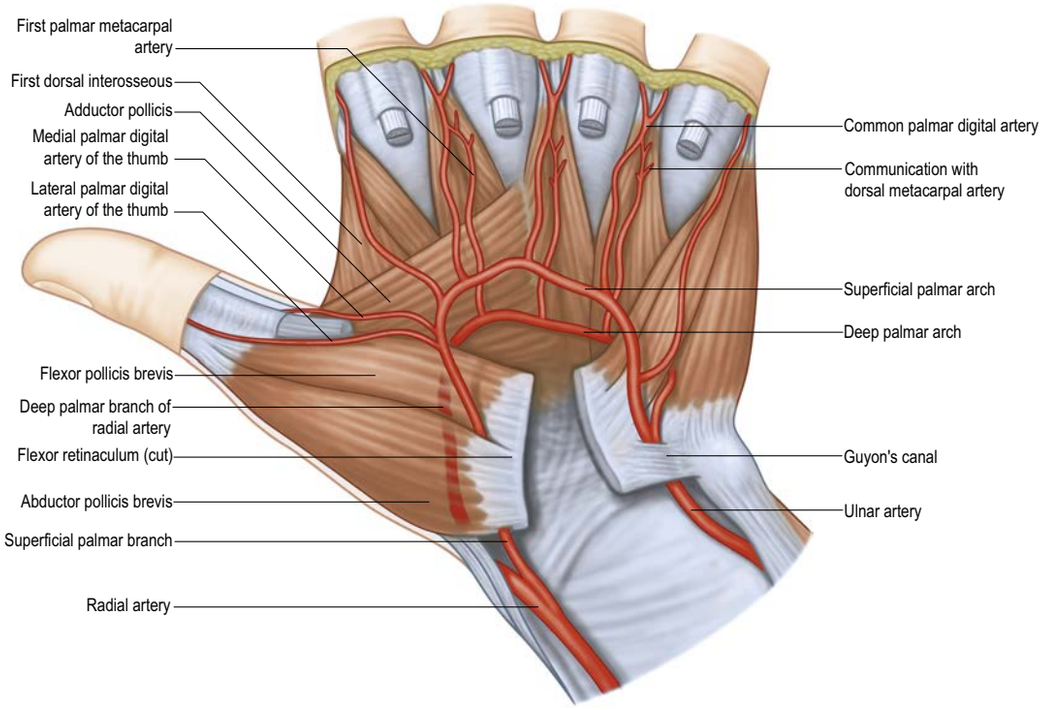

Fig. 51.36 The deep palmar arch and its branches. Note that the palmar digital arteries to the thumb have a separate origin from the superficial palmar arch in this specimen (as sometimes occurs). The arteria princeps pollicis is absent in this specimen.

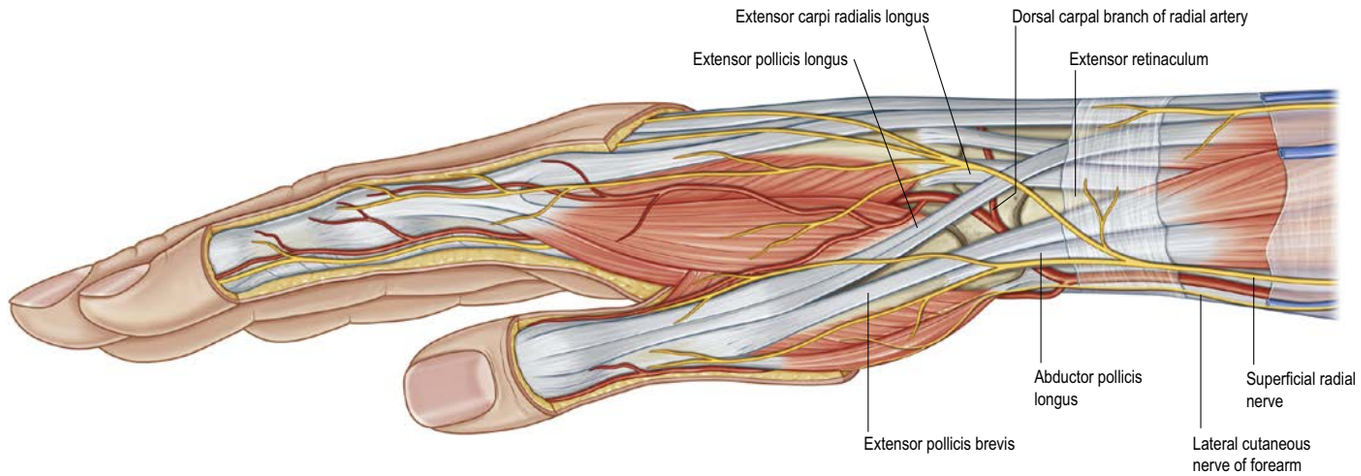

Fig. 51.37 The radial side of the hand. Note the course of the terminal branches of the superficial radial nerve and the lateral cutaneous nerve of the forearm. (Courtesy of Rolfe Birch, all rights reserved. Published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed. 2011. Springer-Verlag, London.)

Superficial palmar branch The superficial palmar branch arises from the radial artery just before it curves round the carpus. It passes through, and occasionally over, the thenar muscles, which it supplies, and usually anastomoses with the end of the ulnar artery to complete a superficial palmar arch (see Fig. 51.36). The superficial arch is complete in about 80% of cases (Zarzecki et al 2018).

Dorsal carpal branch The dorsal carpal branch arises deep to the tendons of the thumb extensors. It runs medially across the dorsal carpal surface under the tendons and anastomoses with the ulnar dorsal carpal branch, and also with the anterior and posterior interosseous arteries, to form a dorsal radiocarpal arch (see Figs 50.9A, 50.9C). The carpal arches are both close to bone and supply the distal epiphysial parts of the radius and ulna. Three dorsal metacarpal arteries descend from the dorsal intercarpal arch on the second to fourth dorsal interossei, and bifurcate into dorsal digital branches to supply the adjacent sides of all four fingers.

First dorsal metacarpal artery The first dorsal metacarpal artery arises from the radial artery just before it passes between the heads of the first dorsal interosseous. It divides, almost at once, into two branches that supply the adjacent sides of the thumb and index finger as far distally as the proximal interphalangeal joint. The radial side of the thumb receives a branch direct from the radial artery proper. In most cases, the first dorsal metacarpal artery follows a fascial course overlying the first dorsal interosseous and parallel to the second metacarpal. Occasionally, it may follow an intramuscular course. Distally, it anastomoses with the dorsal branches of the radiopalmar digital artery of the index finger over the proximal phalanx.

Second, third and fourth dorsal metacarpal arteries The second to fourth dorsal metacarpal arteries arise from the dorsal carpal arch. Near their origins, they anastomose with the deep palmar arch by proximal perforating arteries and, near their bifurcation, with dorsal perforating branches from the palmar metacarpal arteries that pass between the metacarpal necks. They also anastomose distally at the level of the web spaces with dorsal perforating branches from the palmar digital arteries from the superficial palmar arch. The third and fourth dorsal metacarpal arteries are much smaller than the first and second. Cutaneous branches from the dorsal metacarpal arteries supply the dorsal skin as far distally as the proximal interphalangeal joint. At the level of the neck of the second, third and fourth metacarpals, a direct cutaneous branch is given off that passes proximally and supplies an area of skin between the two adjacent metacarpals (see Fig. 51.2B).

Arteria princeps pollicis The arteria princeps pollicis (Miletin et al 2017) arises from the radial artery as it turns into the palm to form the deep palmar arch. It descends on the palmar aspect of the first

metacarpal under the oblique head of adductor pollicis lateral to the first palmar interosseous. At the base of the proximal phalanx, deep to the tendon of flexor pollicis longus, the artery divides into two branches that appear between the medial and lateral attachments of the oblique head of adductor pollicis and run along both sides of the thumb. On the palmar surface of the distal phalanx, the branches form a pollicial arch that supplies the skin and subcutaneous tissue. The arteria princeps pollicis is the usual nutrient of supply to the first metacarpal.

Arteria radialis indicis The arteria radialis indicis is often a proximal branch of the arteria princeps pollicis, or may arise from the superficial arch or from the first dorsal metacarpal artery, or may combine with the arteria princeps pollicis to form the first palmar metacarpal artery. It descends between the first dorsal interosseous and transverse head of adductor pollicis, and runs along the lateral side of the index finger to its tip (see Fig. 51.36). It anastomoses with the index medial digital artery and with the arteria princeps pollicis and the superficial palmar arch at the distal border of the transverse head of adductor pollicis.

Deep palmar arch The deep palmar arch is formed by anastomosis of the end of the radial artery with the deep palmar branch of the ulnar artery (see Fig. 51.35G, 51.36). It crosses the bases of the metacarpals and interossei, covered by the oblique head of adductor pollicis, the tendons of the digital flexors and the lumbricals. In its concavity, running laterally, is the deep branch of the ulnar nerve. The deep palmar arch is incomplete in about 5% (Zarzecki et al 2018).

Palmar metacarpal artery The three palmar metacarpal arteries run distally from the convexity of the deep palmar arch on the interossei of the second to fourth spaces, and join the common digital branches of the superficial arch at the digital clefts (see Fig. 51.36). They supply nutrient branches to the medial four metacarpals.

Perforating branches Three perforating branches from the deep palmar arch cross the second to fourth interosseous spaces between the heads of the corresponding dorsal interossei and anastomose with the dorsal metacarpal arteries.

Recurrent branches Recurrent branches ascend proximally from the deep palmar arch anterior to the carpus to supply the carpal bones and intercarpal articulations. They end in the palmar carpal arch.

Ulnar artery

At the wrist, the ulnar artery (see Fig. 51.10) is covered by skin, fascia and palmaris brevis. It lies between the superficial and main parts of the flexor retinaculum, lateral to the ulnar nerve and pisiform.

Dorsal cutaneous branch A constant dorso-ulnar perforator vessel is given off distally. It arises 2–5 cm proximal to the pisiform and accompanies the dorsal cutaneous branch of the ulnar nerve. It emerges between flexor carpi ulnaris and extensor carpi ulnaris.

Palmar carpal branch The palmar carpal branch crosses the distal ulna deep to the tendons of flexor digitorum profundus and anastomoses with the palmar carpal branch of the radial artery to make a palmar radiocarpal arch.

Dorsal carpal branch The dorsal carpal branch arises just proximal to the pisiform. It curves deep to the tendon of flexor carpi ulnaris to reach the carpal dorsum, which it crosses laterally beneath the extensor tendons. It anastomoses with the dorsal carpal branch of the radial artery to complete the dorsal carpal arch. Near its origin, it sends a small digital branch along the ulnar side of the fifth metacarpal to supply the medial side of the dorsal surface of the fifth finger.

Deep palmar branch The deep palmar branch is often double. It passes between abductor and flexor digiti minimi, through or deep to opponens digiti minimi, and anastomoses with the radial artery, completing the deep palmar arch. The deep palmar branch accompanies the deep branch of the ulnar nerve.

Superficial palmar arch

The superficial palmar arch is an anastomosis fed mainly by the ulnar artery (see Figs 51.2A, 51.10, 51.36). The latter enters the palm with the ulnar nerve, anterior to the flexor retinaculum and lateral to the pisiform. It passes medial to the hook of the hamate, then curves laterally to form an arch that is convex distally and level with a transverse line through the distal border of the fully extended base of the thumb. About one-third of superficial palmar arches are formed by the ulnar artery alone, a further third are completed by the superficial palmar branch of the radial artery, and a third by the arteria radialis indicis, or a branch of either arteria princeps pollicis or the median artery. The superficial palmar arch is covered by palmaris brevis and the palmar aponeurosis, and it is superficial to flexor digiti minimi, branches of the median nerve and the tendons of the long flexors and the lumbricals.

Common and proper palmar digital arteries Three common palmar digital arteries arise from the convexity of the superficial palmar arch (see Figs 51.2A, 51.36). They pass distally on the second to fourth lumbricals, each joined by a corresponding palmar metacarpal artery from the deep palmar arch, and divide into two proper palmar digital arteries. These run along the contiguous sides of all four fingers, dorsal to the digital nerves, between Grayson's and Cleland's ligaments, anastomosing in the subcutaneous tissue of the fingertips and near the interphalangeal joints. Each digital artery has two dorsal branches that anastomose with the dorsal digital arteries and supply the soft parts dorsal to the middle and distal phalanges, including the matrices of the nails (see Fig. 51.2B). The palmar digital artery for the medial side of the little finger leaves the arch under palmaris brevis. Palmar digital arteries supply the metacarpophalangeal and interphalangeal joints and nutrient rami to the phalanges. They are the main digital supply because the dorsal digital arteries are minute. The origins of the palmar digital arteries of the thumb are quite variable. Both may arise from a single arteria princeps pollicis or they may arise separately from the superficial palmar arch. The ulnar digital artery may arise from the first dorsal metacarpal artery.

The terminal branches of the digital arteries contribute to a number of vascular arcades that provide a rich vascular supply for the distal elements of each digit (see Figs 51.2A, 51.5). Three distal phalangeal dorsal arterial arcades anastomose with each other and with those from the other side of the digit. The superficial arcade occurs at the level of the proximal nail fold and is supplied primarily by a dorsal branch from the palmar digital artery, which is given off at the level of the middle phalanx. The proximal subungual arcade is at the level of the lunula and is supplied by a terminal branch of the digital artery, which passes dorsally. The distal subungual arcade occurs more distally in the nail bed. It is supplied by a dorsal vessel that emerges from the point of confluence of the 'H'-shaped anastomosis between the terminal portions of both digital arteries, and passes from volar to dorsal aspect of the digit under the interosseous ligament connecting the proximal and distal parts of the distal phalanx.

Variations The ulnar and radial arteries to the hand may occasionally be supplemented by a median artery that contributes to, or supplies, the superficial palmar arch and by the anterior interosseous artery, which may make a contribution to the deep palmar arch. The median artery may persist in two different forms, palmar and antebrachial (Rodriguez-Niedenführ et al 1999). The palmar type arises from the junction of the ulnar artery and its common interosseous trunk; it is long and large, and reaches the palm, usually ending as the first or second common digital artery, or both. The antebrachial type is slender and short, usually arising from the anterior interosseous artery and finishing in the forearm. These variations are seen in about 20% of individuals and tend to be unilateral. Ulnar artery dominance in all digits is rare, complete radial artery dominance has been described in 28% of hands (Kleinert et al 1989).

Glomus tumours

Available with the *Gray's Anatomy* e-book

Veins

Superficial veins of the hand

Dorsal and palmar digital veins Dorsal digital veins pass along the sides of the fingers, joined by oblique branches (see Fig. 51.4). They unite from the adjacent sides of the digits into three dorsal metacarpal veins that form a dorsal venous network over the metacarpus (see Fig. 51.3). This is joined laterally by a dorsal digital vein from the radial side of the index finger and both dorsal digital veins of the thumb, and is prolonged proximally as the cephalic vein. Medially, a dorsal digital vein from the ulnar side of the little finger joins the network, which ultimately drains proximally into the basilic vein. A vein often connects

Glomus tumours are very painful tumours of the glomus bodies (small arteriovenous anastomoses involved in the regulation of peripheral skin temperature control (see Fig. 6.16)). They are often tiny and sometimes difficult to identify. These tumours typically occur in the proximal nail fold/subungual regions of the fingertips in association with the dorsal digital arterial arcades, although they can occur anywhere. They are diagnosed by exquisite point tenderness over the swelling, with reduction of tenderness when the finger is exsanguinated.

the central parts of the network to the cephalic vein near the mid-forearm. Palmar digital veins connect to their dorsal counterparts by oblique veins that pass between metacarpal heads. They also drain to a plexus superficial to the palmar aponeurosis, extending over both thenar and hypothenar regions. The venous drainage of the hand is predominantly dorsal: flexion and extension of the digits compresses the veins within the tight dorsal skin envelope, promoting venous return.

Deep veins of the hand

Superior and deep palmar venous arches Superficial and deep palmar venous arches accompany their arterial counterparts and receive correspondingly named tributaries; common palmar digital veins drain to the superficial arch and palmar metacarpal veins join the deep arch.

Palmar and dorsal metacarpal veins Deep veins accompanying the dorsal metacarpal arteries receive perforating tributaries from the palmar metacarpal veins and end in the radial veins and the dorsal venous network over the metacarpus. This network is joined laterally by a dorsal digital vein from the radial side of the index finger and by both digital veins of the thumb, and is prolonged proximally as the cephalic vein.

Cephalic vein The cephalic vein forms over the anatomical snuff-box from the radial extremity of the dorsal venous plexus and runs proximally over the distal lateral aspect of the radius, where it is easily visible. Its further course is described in Chapters 49, 50 and 81.

INNERVATION

Median nerve

The median nerve just proximal to the flexor retinaculum is lateral and superficial to the tendons of flexor digitorum superficialis and lies between the tendons of flexor carpi radialis and palmaris longus (see Fig. 51.30). It passes under the retinaculum in the 'carpal tunnel', where it may be compressed in carpal tunnel syndrome. Distal to the retinaculum, the nerve enlarges and flattens, and usually divides into five or six branches; the mode and level of division are variable. Within the carpal tunnel and hand, the median nerve has been shown to glide by up to 3 mm, depending on the position of the elbow and the attitude of the forearm in pronation or supination (Echigo et al 2008). The greatest longitudinal excursion of the median nerve (15.5 mm) is seen just proximal to the carpal tunnel; similar excursion of the ulnar nerve has been recorded as 14.8 mm in cadavers (Wilgis and Murphy 1986).

Muscular branch (motor or recurrent branch)

The muscular branch is short and thick, and arises from the lateral side of the nerve; it may be the first palmar branch or a terminal branch that arises level with the digital branches. It runs laterally, just distal to the flexor retinaculum and with a slight recurrent curve beneath the part of the palmar aponeurosis covering the thenar muscles (see Fig. 51.27B). It turns round the distal border of the retinaculum to lie superficial to flexor pollicis brevis, which it usually supplies, and either continues superficial to the muscle or traverses it. It gives a branch to abductor pollicis brevis that enters the medial edge of the muscle, and then passes deep to it to supply opponens pollicis, entering its medial edge. Its terminal part occasionally gives a branch to the first dorsal interosseous, and may be its sole or partial supply. The muscular branch may arise in the carpal tunnel and pierce the flexor retinaculum. Anomalies of the median nerve occur in approximately 10% of patients undergoing a carpal tunnel release. These branches usually arise from the ulnar side of the nerve and may be motor or sensory. (For further reading see Wynter and Dissabandara 2018.)

Palmar cutaneous nerve

This branch emerges from the radial side of the median nerve 3.5 cm to 6 cm proximal to the flexion increase of the wrist flexion. It runs distally alongside the ulnar edge of the sheath of flexor carpi radialis, radial and deep to palmaris longus to enter the palm either through or superficial to the flexor retinaculum (Fig. 51.27B). It usually ends in medial and lateral terminal branches to supply a patch of skin over and just beyond the anterior surface of the palm overlying the scaphoid tubercle and anterior aspect of the thumb carpometacarpal joint (Hobbs et al 1990, daSilva et al 1996).

Palmar digital branches

The median nerve usually divides into four or five digital branches. It often divides first into a lateral ramus, providing digital branches to the thumb and the radial side of the index finger, and a medial ramus, supplying digital branches to adjacent sides of the index, middle and ring fingers. Other modes of termination can occur.

Digital branches are commonly arranged as follows. They pass distally, deep to the superficial palmar arch and its digital vessels, at first anterior to the tendons of the long flexors. Two proper palmar digital nerves, sometimes from a common stem, pass to the sides of the thumb; the nerve supplying its radial side crosses in front of the tendon of flexor pollicis longus. The proper palmar digital nerve to the lateral side of the index finger also supplies the first lumbrical. Two common palmar digital nerves pass distally between the tendons of the long flexors. The lateral divides in the distal palm into two proper palmar digital nerves that traverse adjacent sides of the index and middle finger. The medial divides into two proper palmar digital nerves that supply adjacent sides of the middle and ring fingers. The lateral common digital nerve supplies the second lumbrical, and the medial receives a communicating twig from the common palmar digital branch of the ulnar nerve and may supply the third lumbrical. In the distal part of the palm, the digital arteries pass deeply between the divisions of the digital nerves; the nerves lie anterior to the arteries on the sides of the digits. The median nerve usually supplies palmar cutaneous digital branches to the radial three and a half digits (thumb, index, middle and the lateral side of the ring); sometimes, the radial side of the ring finger is supplied by the ulnar nerve. Occasionally, there is a communicating branch between the common digital nerve to the middle and ring fingers (derived from the median nerve) and the common digital nerve to the ring and little fingers (derived from the ulnar nerve); this may explain variations in sensory patterns that do not conform to the classic pattern.

The proper palmar digital nerves pass along the medial side of the index finger and both sides of the middle and the lateral side of the ring finger. They enter these digits in fat between slips of the palmar aponeurosis. Together with the lumbricals and palmar digital arteries, they pass dorsal to the superficial transverse metacarpal ligament and ventral to the deep transverse metacarpal ligament. In the digits, the nerves run distally beside the long flexor tendons (outside their fibrous sheaths), level with the anterior phalangeal surfaces and anterior to the digital arteries, between Grayson's and Cleland's ligaments. Each nerve gives off several branches to the skin on the front and sides of the digit and sends branches to the metacarpophalangeal and interphalangeal joints.

The digital nerves supply the fibrous sheaths of the long flexor tendons, blood vessels (vasomotor) and sweat glands (sudomotor). Distal to the base of the distal phalanx, each digital nerve gives off a branch that passes dorsally to the nail bed (see Fig. 51.9). The main nerve frequently trifurcates to supply the pulp and skin of the terminal part of the digit. Distal to the base of the proximal phalanx, each proper digital nerve also gives off a dorsal branch to supply the skin over the back of the middle and distal phalanges. The proper palmar digital nerves to the thumb and the lateral side of the index finger emerge with the tendons of the long flexors from under the lateral edge of the palmar aponeurosis. They are arranged in the digits as described above, except that, in the thumb, small distal branches supply the skin on the back of the distal phalanx only.

Other branches

In addition to the branches of the median nerve described above, variable vasomotor branches supply the radial and ulnar arteries and their branches. Some of the intercarpal, carpometacarpal and intermetacarpal joints are said to be supplied by the median nerve or its anterior interosseous branch; the precise details are uncertain.

Carpal tunnel syndrome

Carpal tunnel syndrome is the most common entrapment mononeuropathy. It is caused by compression of the median nerve as it passes through the fibro-osseous tunnel beneath the flexor retinaculum (see Fig. 51.38).

Carpal tunnel syndrome is usually idiopathic, however, certain diagnoses may predispose to the condition. The carpal tunnel may be narrowed by arthritic changes in the wrist joint, by thickening of the synovium (especially in rheumatoid disease), by soft tissue thickening, as may occur in myxoedema and acromegaly; it is associated with diabetes, oedema, obesity, pregnancy and vibration. The association with repetitive use and computing is controversial and has probably been overestimated. Normally, the median nerve slides smoothly in and out of the carpal tunnel during flexion and extension of the wrist, but when the nerve is compressed this sliding is restricted by traction which

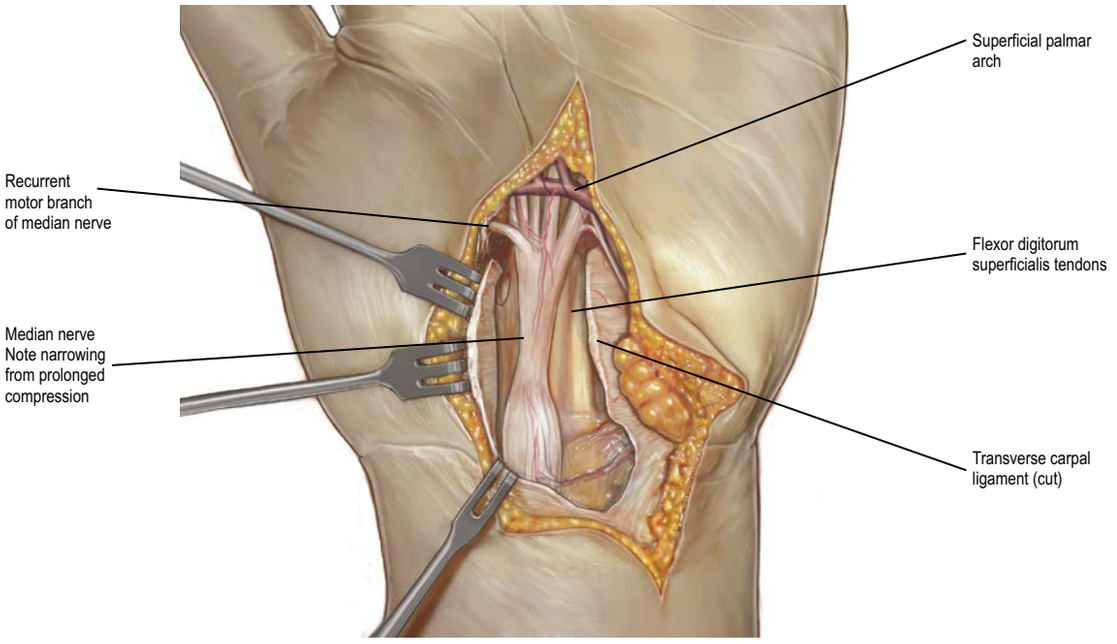

Fig. 51.38 Carpal tunnel syndrome, left wrist, flexor aspect: the flexor retinaculum has been divided, exposing the median nerve. (Copyright Martin Langer.)

aggravates the conduction block. Typically, the syndrome produces painful paraesthesia and numbness in the thumb, index, middle and medial side of the ring fingers, which is worse at night and on manoeuvres such as holding a book or telephone. The palmar branch of the median nerve is spared because it does not pass through the carpal tunnel. With time, the compression leads to wasting and weakness of abductor pollicis brevis and loss of sweating in the cutaneous territory of the median nerve, sparing the patch overlying the scaphoid tubercle and palmar side of the carpometacarpal joint which is supplied by the palmar cutaneous nerve. Treatment depends on the cause. If present just at night, due to involuntary flexion of the wrist (which increase pressure in the carpal canal) then a splint may suffice. If the syndrome is of recent onset, especially in association with pregnancy or synovial thickening, then a steroid injection can be curative. For more persistent symptoms, and especially if there is evidence of axonal failure (numbness, loss of sweating, wasting of abductor pollicis brevis) then surgery is recommended. This involves dividing the flexor retinaculum (**Fig. 51.38**). The most common hazards of decompression are inadequate decompression because of failure to divide the most distal or most proximal part of the flexor retinaculum, damage to the motor branch causing weakness, or palmar cutaneous branch or one or more terminal sensory branches causing scar tenderness and a patch of numbness and damage to the superficial palmar arch causing a haematoma.

Anatomical anomalies of the median nerve in the carpal tunnel are very common (Henry et al 2015) and occur in up to 12% of hands. The most common are variations in the course of the recurrent motor branch in relation to the flexor retinaculum. These may be transligamentous (11.3%), subligamentous (13.5%%) or extraligamentous (75.2%). Damage may also occur to the palmar cutaneous branch of the median nerve and to the superficial connections between the median and ulnar nerves (Martin et al 1996) (the so-called Berrettini branch, division of which will leave the patient with numbness in the middle and ring fingers). Stancić et al (1999) noted that this connection was present in 81% of dissected hands and proposed that it should be regarded as a normal anatomical finding.

Median nerve division at the wrist

Median nerve division at the wrist leads to paralysis of the lumbricals to the index and middle fingers and of the thenar muscles (apart from flexor pollicis brevis and adductor pollicis), as well as loss of sensation to the thumb, index, middle and radial half of the ring fingers (see Fig. 51.7). The thenar muscles waste, and the adductor pollicis, which is no longer antagonized by flexor pollicis brevis and opponens pollicis, produces an adducted posture of the thumb. Division of the median nerve distal to the origin of its palmar cutaneous branch, which arises somewhere between 3.5 and 6 cm proximal to the proximal edge of the flexor retinaculum and the distal transverse wrist crease, will leave the branch intact to supply the skin over the thenar eminence and radial side of the proximal part of the hand. Careful clinical examination of the sensibility of the skin in this region should help to clarify the level of the lesion. High division of the nerve (Ch. 50) will, as with compressive lesions at this level, result in weakness of pronation of the forearm, radial flexion of the wrist and the lateral two fingers.

Ulnar nerve

At the wrist, the ulnar nerve passes under the superficial part of the flexor retinaculum (in Guyon's canal) with the ulnar artery, and divides into superficial and deep terminal branches (see Fig. 51.10).

Dorsal branch

The dorsal branch arises approximately 5 cm proximal to the wrist (see Fig. 50.9). It passes distally and dorsally, deep to flexor carpi ulnaris, perforates the deep fascia, descends along the medial side of the back of the wrist and hand, and then divides into two, or often three, dorsal digital nerves. The first supplies the medial side of the little finger; the second, the adjacent sides of the little and ring fingers; while the third, when present, supplies adjoining sides of the ring and middle fingers. The latter may be replaced, wholly or partially, by a branch of the radial nerve, which communicates with it on the dorsum of the hand (see Fig. 51.9). In the little finger, the dorsal digital nerves extend only to the base of the distal phalanx; in the ring finger, they extend only to the base of the middle phalanx. The most distal parts of the little finger and of the ulnar side of the ring finger are supplied by dorsal branches of the proper palmar digital branches of the ulnar nerve. The most distal part of the lateral side of the ring finger is supplied by dorsal branches of the proper palmar digital branch of the median nerve.

Superficial and deep terminal branches

Superficial terminal branch

The superficial terminal branch supplies palmaris brevis and the medial palmar skin. It divides into two palmar digital nerves. One supplies the medial side of the little finger. The other (a common palmar digital nerve) sends a branch to the median nerve and divides into two proper digital nerves to supply the adjoining sides of the little and ring fingers. The proper digital branches within the digit are distributed like those derived from the median nerve.

Deep terminal branch

The deep terminal branch accompanies the deep branch of the ulnar artery as it passes between abductor digiti minimi and flexor digiti minimi, and then perforates opponens digiti minimi to follow the deep palmar arch dorsal to the flexor tendons (see Fig. 51.27B). At its origin, it supplies the three short muscles of the little finger. As it crosses the hand, it supplies the interossei and the third and fourth lumbricals. It

The ulnar nerve can be compressed as it passes through Guyon's canal at the wrist.

Causes of compression at this site include a ganglion from the pisotriquetral joint, prolonged compression from a cyclist's handlebars, hook of hamate fracture, and proximity of aberrant or accessory muscles. The symptoms depend on the precise level at which the ulnar nerve and its branches are compressed. Altered sensation is noted in the palmar aspect of the little and ulnar half of the ring fingers; sensation on the ulnar aspect of the dorsum of the hand is normal due to preservation of the dorsal cutaneous branch. If the motor branch fibres are affected, there is weakness and wasting of the intrinsic muscles of the hand supplied by the ulnar nerve, with clawing posture in severe compression. Weakness of adductor pollicis and the first dorsal interosseous substantially degrades pinch strength: if a slip of paper is held in the key pinch position between the pulp of the thumb and the radial side of the index proximal interphalangeal joint, the tip of the thumb involuntarily flexes as flexor pollicis longus contracts to compensate for the absent adductor pollicis and first dorsal interosseous (Froment's sign).

Surgical treatment involves decompression of the nerve by division of the roof of Guyon's canal and removal of any causative lesion, such as a ganglion. Ulnar tunnel syndrome can be difficult to distinguish from more proximal causes of ulnar nerve compression, of which the most common is entrapment of the nerve in the cubital canal at the elbow. In this condition, sensory changes would include the dorsoulnar aspect of the hand and motor changes would involve flexor carpi ulnaris and flexor digitorum profundus to the little and ring fingers. Clawing is less apparent with a more proximal failure of the ulnar nerve (the 'ulnar paradox') because flexor digitorum profundus also fails so there is less flexion force to expose the absent extensor moment of the paralysed intrinsics.

In the absence of obvious clinical indicators, an unpleasant tingling sensation (Tinel sign) over the site of compression, electrophysiological studies and MRI scans may aid diagnosis.

Ulnar nerve division at the wrist paralyses all the intrinsic muscles of the hand (apart from the radial two lumbricals, abductor pollicis brevis, and part of flexor pollicis brevis and opponens pollicis). The intrinsic muscle action of flexing the metacarpophalangeal joint and extending the interphalangeal joints is lost. The unopposed action of the long extensors and flexors of the fingers causes clawing, with extension of the metacarpophalangeal joints and flexion of the interphalangeal joints. (See section 'The paralysed hand' for explanation of why clawing occurs in the intrinsic minus hand.) The clawing is less intense in the index and middle fingers because their lumbricals are supplied by the median nerve.

There is sensory loss over the little finger and the ulnar half of the ring finger. The skin over the ulnar aspect of the dorsum of the hand is spared because the dorsal branch of the ulnar nerve is given off approximately 5 cm proximal to the wrist joint. A combined median and ulnar nerve palsy at the wrist results in a full claw hand with thenar and hypothenar flattening and thumb adduction and flexion (a simian hand).

The wrist joint is identified between the distal ends of the radius and ulna, and the proximal row of the carpus, on flexion and extension of the wrist. The line of the wrist joint corresponds to a line, convex superiorly, joining the radial and ulnar styloid processes. Its position is also marked by the proximal of the two transverse anterior wrist creases (see Fig. 48.54A). The radial styloid process normally sits 1 cm distal to the ulnar styloid process.

When the forearm is pronated, the head of the ulna forms a rounded surface elevation on the medial side of the posterior aspect of the wrist (see Figs 48.53C, 48.54B), and the ulnar styloid process projects distally from its posteromedial aspect. The radial styloid process projects inferiorly from the distal radius along the lateral aspect of the wrist. The posterior aspect of the lower end of the radius is partly obscured by the extensor tendons but is palpable. The prominent dorsal radial (Lister's) tubercle is both visible and palpable, and aligns with the web space between digits 2 and 3. The tendon of extensor pollicis longus in extensor compartment 3 sits medial to the tubercle, and the tendons of extensors carpi radialis longus and brevis sit lateral to the tubercle in compartment 2.

Four of the carpal bones are palpable. The pisiform is both visible and palpable on the palmar aspect of the medial wrist at the base of the hypothenar eminence. It is often overlain by the distal wrist crease. It can be moved over the articular surface of the triquetrum when the wrist is passively flexed. The hook of the hamate lies approximately 2.5 cm distal to the pisiform, in line with the ulnar border of the ring finger. It can be felt on deep palpation, and the superficial division of the ulnar nerve can be rolled from side to side over the tip of the hook. The tubercle of the scaphoid is situated at the base of the thenar eminence, in line with the tendon of flexor carpi radialis and, in many individuals, forms a small, visible elevation. Immediately distal to it, but covered by the muscles of the thenar eminence, the tubercle of the trapezium can be identified on deep palpation.

Proximal to the wrist creases, the prominent tendon of flexor carpi radialis can be seen and palpated when the wrist is flexed against resistance (see Fig. 48.54A). The radial artery lies on its lateral side and crosses the anterior margin of the expanded distal end of the radius, where it is palpable. It then passes posteriorly, deep to the tendons of abductor pollicis longus and extensor pollicis brevis, and enters the anatomical snuff-box, where its pulsations are palpable (see Fig. 48.54C).

Palpation lateral to flexor carpi radialis, 5–6 cm proximal to the wrist crease, reveals the muscle belly of flexor pollicis longus (flexing and extending the thumb will confirm that the examining finger is correctly placed). The area on the medial (ulnar) side of flexor carpi radialis tendon is packed with functionally important structures. The median nerve is either covered by, or situated just radial to, the tendon of palmaris longus. The latter can be identified by gently pinching the tips of the digits together and partially flexing the wrist (see Fig. 48.54A). Near to the wrist, the median nerve lies very close to the skin and can, therefore, be injured by relatively superficial lacerations. When palmaris longus is absent, only a thin covering of subcutaneous fat and deep fascia separate skin and nerve. The four tendons of flexor digitorum superficialis lie deep to the median nerve; the tendons to the middle and ring fingers lie anterior to those for the index and little fingers as they pass deep to the flexor retinaculum, and can be felt and usually seen to move during finger flexion/extension. Deeper still are the tendons of flexor digitorum profundus. The broad tendon of flexor carpi ulnaris is easily palpated passing to the pisiform on the ulnar side of the anterior wrist; the ulnar nerve, artery and venae comitantes lie along its lateral (radial) edge. Any sharp injury that cuts through the tendon usually has enough energy to sever the ulnar neurovascular bundle.

When the thumb is fully extended, the depression of the anatomical snuff-box is seen on the lateral aspect of the wrist immediately distal to the radial styloid process. The snuff-box is bounded on its anterolateral (radial) side by the tendons of abductor pollicis longus (laterally) and extensor pollicis brevis (immediately dorsomedial), and on its posteromedial/ulnar side by the tendon of extensor pollicis longus. Running a finger along extensor pollicis brevis enables palpation of the superficial radial nerve, which can be rolled from side to side on the tendon. The cephalic vein passes through the roof of the snuff-box, where it is visible and palpable, and the pulsation of the radial artery can be palpated deeply on its floor. Three bones are palpable distal to the radial styloid process along the floor of the anatomical snuff-box: the convex, ovoid proximal articular surface of the scaphoid (best palpated during alternating wrist abduction/adduction), the radial aspect of the trapezium and the expanded base of the first metacarpal. The first carpometacarpal joint forms a palpable depression distal to the trapezium.

The tendons located within the six extensor compartments of the wrist are subcutaneous and palpable (see Fig. 48.54B). Compartment I (containing abductor pollicis longus and extensor pollicis brevis) sits over the lateral radius. Regional tenderness to palpation occurs in de Quervain's tenosynovitis. Compartment II is bounded laterally by the radial styloid and medially by Lister's tubercle. The tendons of extensors carpi radialis longus and brevis in this compartment can be identified on the dorso-radial carpus when the fist is clenched and relaxed. Compartment III (containing extensor pollicis longus) is palpable to the medial side of Lister's tubercle: the tendon of extensor pollicis longus is palpable if the thumb pulp is actively retroposed behind the plane of the palm. Compartment IV (containing extensors digitorum and indicis) sits between the ulnar head and compartment III: the tendons of extensor digitorum are visible and palpable on the dorsum of the hand with the fingers fully extended. Compartment V (containing extensor digiti minimi) overlies the distal radio-ulnar joint. Compartment VI (containing extensor carpi ulnaris) overlies the dorso-ulnar corner of the ulnar head: the tendon of extensor carpi ulnaris is palpable distal to the ulnar styloid as it crosses the wrist, with the wrist in resisted extension and supination or pronation and adduction. The first dorsal interosseous forms a visible fleshy mass on the lateral part of the dorsal hand between the index finger and thumb, especially whilst abducting the index finger against resistance.

The palmar skin is marked by a number of creases but they are of little value as points of reference (see Fig. 51.1). Transverse skin creases cross the palmar aspect of the fingers in three places: the most proximal crease sits at the junction of the digit with the palm and lies approximately 2 cm distal to the metacarpophalangeal joint; the intermediate

crease sits opposite the proximal interphalangeal joint; and the distal crease sits just proximal to the distal interphalangeal joint.

The first metacarpal is both visible and palpable on the dorsolateral hand; its dorsal aspect forms the lateral border of the hand. The fleshy elevation of the thenar eminence, produced by abductor and flexor pollicis brevis overlying opponens pollicis, is located on the lateral palm. The less prominent hypothenar eminence is located on the medial palm and is formed by the comparable muscles of the little finger. The medial aspect of the hypothenar eminence forms the medial border of the hand.

The dorsal aspects of the trapezium and of each of the metacarpals are partially palpable around the margins of the corresponding extensor tendons. The heads of the metacarpals form the prominences of the knuckles and are most obvious during digit flexion. On the dorsal hand, the metacarpophalangeal joint line forms a palpable depression either side of the digital extensor tendon: alternating digit flexion/extension aids identification. The joint can be aspirated/injected from this perspective. Palpation distal to the metacarpal head reveals the flared base of the corresponding proximal phalanx. The interphalangeal joints are palpable on the dorsal aspect of a flexed digit just distal to the prominences formed by the heads of the proximal and middle phalanges.

The flexor retinaculum, and therefore the surface position of the carpal tunnel, can be mapped according to its palpable bony attachments. Its distal border is concave inferiorly and is marked by a curved line that joins the tubercle of the trapezium to the hook of the hamate. Its proximal border is marked by a curved line, concave superiorly, which joins the tubercle of the scaphoid to the pisiform. Flexion of the wrist produces a number of transverse skin creases (usually two, sometimes three) at the wrist. The dominant, most distal, wrist crease normally sits distal to the lunate and overlies pisiform and the proximal edge of the flexor retinaculum. The carpal tunnel passes distal to this crease for 2.5–3 cm.

The position of the superficial palmar arterial arch is indicated by a horizontal line approximately 4 cm long, drawn at the level of the fully extended and partially abducted thumb. A horizontal line, approximately 4 cm long and running from a point just distal to the hook of the hamate, indicates the position of the deep palmar arterial arch, which is located approximately 1 cm proximal to the superficial arch. The digital neurovascular bundles pass along the medial and lateral sides of the dorsal and palmar (volar) surfaces of the digits, and can be anaesthetized in these positions via the web space.

ends by supplying adductor pollicis, the first dorsal interosseous and, usually, flexor pollicis brevis.

The medial part of flexor digitorum profundus is supplied by the ulnar nerve, as are the third and fourth lumbricals, which are connected with the tendons of this part of the muscle. Similarly, the lateral part of flexor digitorum profundus and the first and second lumbricals are supplied by the median nerve. The third lumbrical is often supplied by both nerves. The deep terminal branch gives branches to some intercarpal, carpometacarpal and intermetacarpal joints; precise details are uncertain. Vasomotor branches, arising in the forearm and hand, supply the ulnar and palmar arteries.

Radial nerve

Branches of the superficial branch of the radial nerve reach the hand by curving around the wrist over the tendons of abductor pollicis longus and extensor pollicis brevis, and dividing into dorsal digital nerves (see Fig. 51.37). They usually communicate with the posterior and lateral cutaneous nerves of the forearm on the dorsum of the hand.

Dorsal digital nerves

There are usually four or five small dorsal digital nerves (see Fig. 51.9). The first supplies the skin of the radial side of the thumb and the adjoining thenar eminence, and communicates with branches of the lateral cutaneous nerve of the forearm. The second supplies the medial side of the thumb; the third, the lateral side of the index finger; the fourth, the adjoining sides of the index and middle fingers. The fifth communicates with a ramus of the dorsal branch of the ulnar nerve and supplies the adjoining sides of the middle and ring fingers, where it is frequently replaced by the dorsal branch of the ulnar nerve. The digital nerves of the thumb reach only to the root of the nail; those in the index finger, midway along the middle phalanx; and those to the middle and the lateral part of the ring finger may reach no further than the proximal interphalangeal joints. The remaining distal dorsal areas of the skin in these digits are typically supplied by palmar digital branches of the median and ulnar nerves. However, the superficial terminal branch of the radial nerve may supply the whole dorsum of the hand.

COMMENTARY
6.1

Nerve biomechanics

Kimberly S. Topp

Peripheral nerves are subject to physical forces as a result of body position and movement. Nonetheless, the biomechanical properties of these nerves permit continued electrical signalling when faced with reasonable physical demands. For example, when an individual moves from a standing to a sitting position, the sciatic nerve lengthens as it crosses the posterior aspect of the hip joint, its cross-sectional shape becomes elliptical and narrowed, and endoneurial fluid is forced proximally and distally away from the site of compression. The sciatic nerve glides proximally in the thigh towards the flexing hip joint and away from the knee joint (Topp and Boyd 2006).

When a nerve bed is elongated across a moving joint, the nerve is placed under longitudinal tension. The biomechanical response of that nerve may be documented in a load–elongation curve, measured in Newtons per millimetre (Haftek 1970). To enable comparisons to be made between nerves, the load–elongation curve may be translated into a stress–strain curve. Stress is defined as the intensity of force per unit cross-sectional area, and is reported in N/m^2 or MPa (Pascal). Strain is defined as the ratio of change in length to the original length, and is often reported as a percentage.

Three distinct regions are seen in nerve load–elongation or stress–strain curves (**Fig. 6.1.1**). In the initial 'toe' region of the curve, application of very little tensile load or stress results in significant elongation or strain. In the 'linear behaviour' region, there is a correlation between the applied load or stress and the elongation or strain. In the 'plastic' region of the curve, minimal load or stress results in mechanical failure and discontinuity of nerve structures.

Several structural features of peripheral nerves may be related to segments of the stress–strain curve, and these features may vary between nerves requiring functional adaptation. Nerve *in situ* is under tension: the transition between the 'toe' region and the 'linear behaviour' region of the curve corresponds roughly with the *in situ* strain (Kwan et al 1992).

The elasticity seen in the initial part of the stress–strain curve is due to structures that make up visible, periodic light–dark bands that were initially described by, and named after, Felix Fontana (Fontana 1781). These bands vary in their angulation, width, spacing and periodicity. Studies of rat sciatic nerve using Fourier analysis have shown a linear relationship between increasing nerve strain and decreasing band frequency and axonal undulations (Love et al 2013). *In vivo* microdissection studies coupled with computer modelling suggest that layers of perineurial cells are possibly responsible for the short-wavelength, large-amplitude bands and that wavy spiralling nerve fibres in the endoneurium are responsible for the long-wavelength, small-amplitude bands (Merolli et al 2012), the two patterns merging to form the visible bands of Fontana. In a recent study, however, the nerves of *Trembler-J* mice, a model of Charcot–Marie–Tooth disease, were found to have altered bands of Fontana, resulting solely from unusually long, sinuous axons moving out of phase (Power et al 2015). Increasing strain in the 'linear behaviour' region of the stress–strain curve causes the bands of Fontana to disappear (Pourmand et al 1994). An illustration of functional adaptation is seen in a study of nerves in the feeding pouch of the rorqual whale (Lillie et al 2017). These highly extensible nerves demonstrate straightening of nerve fibres and connective tissues internal to the thick epineurium at the transition from 'toe' region to 'linear behaviour' region of the stress–strain curve. Further lengthening is achieved through unfolding of the thick, elastin-laden epineurium, a feature that differs from other nerves in less mobile regions of this animal (Vogl et al 2017).

Anatomical features are also known to contribute to the 'linear behaviour' region of the stress–strain curve. The slope of this region is termed Young's modulus of elasticity, or stiffness in the case of the load–elongation curve. A steep slope indicates that the nerve is stiff: significant tensile force results in only a modest change in length. The modulus of elasticity or stiffness of an acellular nerve is comparable to that of fresh nerve, indicating that connective tissue fibres contribute to stiffness (Borschel et al 2003, Zilic et al 2016). Endoneurial fluid and the perineurial sheath that encloses the fluid compartment also contribute to stiffness. When a nerve is elongated, it undergoes transverse contraction (Walbeehm et al 2004): the reduction in cross-sectional area increases pressure in the endoneurial compartment and, consequently, stiffness of the nerve (Millesi et al 1995). As one might predict, nerve roots, which lack a perineurial sheath, demonstrate less stiffness than a peripheral nerve (Beel et al 1986). The differing biomechanical properties of nerve roots and nerves were investigated in a study of the neonatal brachial plexus (Singh et al 2018). There was less stiffness in the plexus roots, trunks and cords, compared to nerve branches or to the more frequently studied tibial nerve. External features, such as nerve branching, entering/exiting blood vessels, and paraneural tissue connections, resist elongation of the nerve in its nerve bed, and increase *in situ* nerve stiffness (Millesi et al 1995, Foran et al 2018).

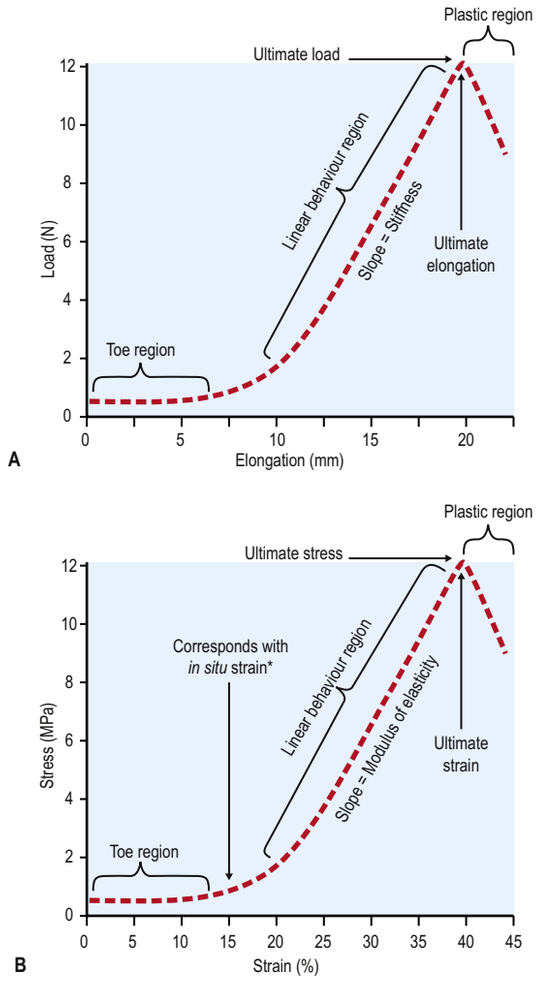

Fig. 6.1.1 Typical load–elongation (**A**) and stress–strain curves (**B**) for a peripheral nerve. The transition between the toe region and the linear region in the stress–strain curve (asterisk) has been shown to correspond approximately with the strain *in situ*. The slope of the stress–strain curve is called the modulus of elasticity and represents the stiffness of the nerve, as seen in the load–elongation curve. If the slope is steep, then the nerve has more stiffness and is less compliant to elongation. If the slope is less steep, then the nerve has less stiffness and is more compliant to elongation. Once the nerve has reached ultimate strain, the structural integrity of the nerve is overcome and the deformation is termed 'plastic' or 'permanent'. (From Topp KS, Boyd BS 2006 Structure and biomechanics of peripheral nerves: nerve responses to physical stresses and implications for physical therapist practice. Phys Ther 86:92–109.)

In the 'plastic' region of the stress–strain curve, increasing longitudinal stress causes non-recoverable elongation and structural integrity is lost. The force per unit cross-sectional area at the point of mechanical failure is termed ultimate stress and occurs at ultimate strain. At this point, a nerve behaves like a viscous material (Haftek 1970). The velocity and direction of the applied load influence the result: dynamic loads are more likely than quasistatic loads to result in nerve rupture (Mahan et al 2018). Additionally, nerve damage is more likely to occur at lower strains with forces applied along the long axis of the nerve when compared to forces applied orthogonally, and forces applied orthogonally result in rupture at nerve branch points (Mahan et al 2018). Along the stress–strain curve, structures within the nerve become impaired in a hierarchical fashion. With increasing tensile load, there is first sliding and loss of tenuous connections in the interface between the layer of inner perineurial cells and the sheath of outer perineurial cells and associated epineurial tissues (Tillett et al 2004, Georgeu et al 2005). With continued load, the core of nerve fibres and inner perineurial cell layers is disrupted and function is impaired or lost: ultimately, the sheath of outer perineurial and epineurial tissues ruptures. Given that acellular nerve is of significantly lower tensile strength and ultimate strain than fresh nerve (Borschel et al 2003), the perineurial cell layer should be appreciated for its ability to withstand stress. Although definitive anatomical studies are lacking, it is likely that microscopic disruptions of perineurial cell–cell connections occur with increasing stress along the 'linear behaviour' region of the stress–strain curve, long before ultimate strain is reached.

Nerve is best described as a viscoelastic tissue because its bio-mechanical properties are time-dependent. In response to fixed tension over time, nerve demonstrates creep or elongation (Grewal et al 1996). Slow elongation allows for higher ultimate strain (Haftek 1970, Rydevik et al 1990). When stretched to a fixed length over time, nerve exhibits stress relaxation or a reduction in tension (Wall et al 1991, Driscoll et al 2002).

Returning to the example of the sciatic nerve, during movement from standing to sitting, the nerve bed is elongated posterior to the hip as forward movement of the trunk causes flexion at the hip joint. The sciatic nerve is exposed to tensile load or stress with resultant elongation or strain, the magnitude of which is greatest near the moving joint. Adjusting to these forces, segments of the nerve converge towards the flexing hip joint, with minimal motion in distant segments (Topp and Boyd 2006). Endoneurial pressure resists transverse contraction. When the seated posture is assumed and maintained, the nerve undergoes stress-relaxation – until the next change in position.

COMMENTARY

6.2

The anatomy and variation of the coracoid attachment of the subclavius muscle and its relation to the clavi-coraco-axillary aponeurosis

Simon Lambert

The classic descriptions of the gross anatomy of the subclavius muscle in humans agree that it originates at the junction of the first rib and first costal cartilage immediately lateral to the costoclavicular ligament (Cave 1961), and inserts into the subclavian groove on the inferior surface of the clavicle, limited laterally by the conoid tubercle and terminating between the coracoclavicular ligaments. Additional, variable, insertions onto the coracoid process have also been noted. In one description, the lateral part of subclavius was separated into a superomedial part inserted, as usual, onto the inferior surface of the clavicle and an inferolateral part inserted onto the root of the coracoid process in 12 (16.8%) of 72 cases (Mori 1964). Several anatomical variations (largely duplications) have been reported (Le Double 1897, Georgiev and Jelev 2009, Ozcakar et al 2010, Yun et al 2018), of which the subclavius posticus appears to be the commonest (Cogar et al 2015). This aberrant muscle may play a role in more proximal neurogenic thoracic outlet syndromes (Hasan and Romeo 2001, Ozcakar et al 2010, Piyawinijwong and Sirisathira 2010, Muellner et al 2015), as well as being of relevance to cannulation of the subclavian vein (Kawagishi et al 2016) and venous occlusion syndromes (McCleery et al 1951, Lusskin et al 1967).

During a surgical anatomy programme conducted at the Division of Clinical and Functional Anatomy at the Medical University of Innsbruck in 2017 it was noted that, in many dissections, additional fibrous structures contiguous with, and extending from, the epimysial fascia of subclavius were inserted into the base, medial margin and tip of the coracoid process. This suggested, first, that anatomical variations of the insertion of subclavius onto the coracoid are more common than previously reported, and second, that the function of subclavius is more subtle than simply that of stabilizing the clavicle at the sternoclavicular joint (SCJ) as previously thought (Reis et al 1979).

In a series of subsequent dissections of 52 adult shoulders, the anatomy of the *origin* of subclavius was constant and there were no additional medial musculotendinous attachments. However, 23% of the specimens had some form of variation in the anatomy of the *muscular* part of subclavius. These included an *additional* muscular belly (i.e. a duplication rather than a substitution anomaly) inserting into the superior border of the scapula adjacent to the origin of omohyoid, consistent with the previously described subclavius posticus (two specimens); an additional muscular insertion to the clavicle (i.e. subclavius appeared to be bicipital) (seven specimens); the muscular part of subclavius extending directly to the body of the coracoid process; an additional muscular insertion at the base of the coracoid process; and an additional muscular insertion onto the glenohumeral joint capsule. Subclavius was perforated in one specimen by a venous plexus, but no other anomalies of the subclavian vein were noted in this, or other, cases.

Conversely, the anatomy of the coracoid *insertion* fibres was highly variable. Three shoulders did not have any extension to the coracoid process. In the other shoulders (94%) subclavius had a lateral extension that took one of three basic forms: a single strong cord-like band (37%); a planar twisted sheet-like structure attached along the medial side of the base of the coracoid process and extending to the body of the process, *discrete from the clavipectoral fascia* (32%); and a small, thin cord-like structure (24%). In two specimens, the cord-like structure was duplicated with one band passing deeply to the base of the coracoid process. The small fibrous extensions were often multiple, suggesting that they were a derivative form of a (perforated) planar sheet. Whatever their configuration, the fibrous structures comprised shiny, parallel-orientated fibres, resembling an aponeurosis.

There was a clear gender difference in the form of the aponeurosis, but no side difference. In male specimens there were thick cord-like structures in 14/24 (58%) dissections and a twisted sheet form in 11/24 (46%) dissections. In female specimens cord-like structures were present in 9/28 (32%), and a twisted sheet structure in 5/28 (18%).

The mean length of the insertion of subclavius into the subclavian groove was relatively constant, occupying, as a ratio of the clavicular length, approximately 38% (male) to 41% (female) of the inferior surface of the clavicle. However, there was a wide range of actual lengths of the insertion into the groove, varying up to 4.5 cm in total length. The form of the aponeurotic extension (robust cord, small cord, or twisted sheet) did not correlate with a particular range of lengths of the insertion of subclavius into the clavicle. The most lateral point of insertion of subclavius into the clavicle was further from the muscular origin the longer the overall clavicular insertion into the groove, but there was no correlation with the form of the aponeurotic extension: this also held true for the coracoid insertion of the aponeurosis (when one was present).

The nerve to subclavius was identified and dissected in 44 of 52 specimens, while the artery was seen in only 19 of 52 dissections. The nerve entered the muscle belly at a mean of 50% of the length of the muscle (from its origin) in the right specimens in females, and at a mean of 54% in the left specimens, while in the males the nerve entered the muscle at a mean of 59% of the muscle length on the right, and 54% on the left. These observations concur with those of Jeon et al (2018), where the artery to subclavius could be defined as it entered the muscle with the nerve.

The anatomy of subclavius and its *intrinsic* tendon structure have been elucidated by Cave and Warwick Brown (1952), who acknowledged the prior contribution of French anatomists to the description of the muscle and its relations. Their description corresponds to the structures seen in this series of dissections as the aponeurosis of extension of the subclavius fascia in its various forms, but discrete from the clavipectoral fascia. Testut (1904) illustrated the anatomy of subclavius in relation to the 'clavi-coraco-axillary aponeurosis'. A fascinating illustration in his text shows the tip of the coracoid process held within this extensive aponeurosis, which extended from the clavicle deep to pectoralis major to the upper part of the humerus, enveloping subclavius, pectoralis minor, coracobrachialis and the short head of biceps brachii from superiorly to inferolaterally. The coracoid process is thus suspended from the clavicle, and the trajectory of coracoid motion guided by the muscles enveloped by the clavipectoral fascia.

The strong cord-like form described here would appear to be an extension of the pars paramuscularis and forms a strong, concave inferior border to the musculo-aponeurotic structure bridging the first rib, the clavicle and the coracoid process. Importantly, this structure therefore bridges two joints (the sternoclavicular and scapulo- (acromio-) clavicular joints). The tendinous border is relatively inelastic, although deformable. This suggests that subclavius might actually function to pre-tension the pars paramuscularis and aponeurosis of extension, contributing to the control of the motion of the distal clavicle as an antagonist of the primary scapular motion muscles. A corollary to this suggestion is that the *functional* anatomy of subclavius might be better 'viewed' from the perspective of the clavicle (with the coracoid below it) rather than from the perspective of the observer (who sees the coracoid with the clavicle above it, and so presumes the function of subclavius is to limit movement at the sternoclavicular joint in relation to elevation, and pro-retraction, of the scapula). The nomenclature of the

origin and insertion of subclavius persuades the observer that the muscle acts *on* the clavicle. However, the fact that the nerve to subclavius enters midway along its length *suggests* that the muscle contracts towards its centre. If this is so, then the muscle acts with the clavicle as its origin or base, and inserts onto its own robust tendinous border, attached medially to the first rib, and laterally to the coracoid and/or into the clavi-coraco-axillary aponeurosis in order to brace (pre-tension) the upper part of that aponeurosis during movement of the upper limb.

Subclavius and its lateral aponeurotic extension therefore form the superior element of a 'functional system' that contributes to the control of the position of the scapula in relation to the thorax (i.e. at the scapulothoracic 'joint') in a manner synonymous with all other articulations (i.e. there are at least two articulating surfaces whose relative movement is generated by muscular action, the range, arc and trajectory of which are determined by capsular or, in the case of the scapulothoracic joint, aponeurotic, restraints).

Our study in Innsbruck found the aponeurotic extension to be more common than previously documented (Mori 1964). If only the strong cord-like lateral fibrous extension is considered, then the frequency of that form in our series remains greater (35%) than previously described in a Japanese series (Mori 1964). We considered the twisted planar sheet-like aponeurosis, present in 31% of specimens, to be a variant (possibly an archetype) of this lateral extension, and not simply a fascial septum from the clavipectoral fascia. It is unclear why there should be a gender difference in the form of the lateral extension.

The function of subclavius in humans has been assumed to be that of stabilizing the sternoclavicular and acromioclavicular joints (Reis et al 1979). However, evidence suggests that muscle functions to regulate the output of kinetic energy in movement of the upper extremity rather than as a primary stabilizer of either the sternoclavicular or acromioclavicular joint. That the nerve to subclavius serves no other muscle suggests that subclavius has, or had, an important role in efficient brachiation, the modern equivalent being of overhead (sport-related) movements. Extending the muscle through a strong aponeurosis to the coracoid process (and so the scapula) would enhance this function.

COMMENTARY 6.3

Instability of the shoulder – a neurological disease

Simon Lambert

This commentary addresses glenohumeral instability (GHI), although the analysis of stability and its perturbation, and the system of classification described, is applicable to all articulations in which the experience of symptomatic abnormal motion (the clinical syndrome of instability) is reported by a patient.

Stability: definition

Stability of any articulation (defined as asymptomatic normal mechanical behaviour at rest and in motion) depends on the retention of structural integrity, intact neural control systems (afferent, efferent and neuromuscular connectivity), and the absence of strain exceeding the yield point for the whole system. For the glenohumeral joint (GHJ) stability is therefore the product of a functionally (not necessarily anatomically) intact rotator cuff, competent capsular and labral structures, a sufficient surface arc (or surface area) of contact between humeral head and glenoid, and an intact neuromuscular system comprising central and peripheral connections, with functioning mechanoreceptors clustered in the capsule and labrum, and in the tendons of the rotator cuff (RC) and long head of biceps (LHBT).

The essence of stability and the stability equation

Motion about the centroid of rotation and 'containment' of the humeral head on the size-mismatched glenoid is the result of concavity compression, generated by the centralizing joint reaction force (CJRF) of the rotator cuff (including LHBT), and the generation of negative intra-articular pressure, facilitated by the conformity of the glenoid/labral surface. Rotator cuff competence is a function of centrally driven activation via feed-forward systems, and the strength and inertia of the cuff muscles. Shoulder joint position sense and motion are the products of right parietal cortical programming (the parietal reach region), and visual, vestibular and cervical afferent inputs: it appears that visual cues are more important than hand position in determining the control of shoulder motion. Maintenance of this activity is achieved through feedback mechanisms derived through mechanoreceptors in the capsular and labral structures, rotator cuff tendons and muscles, and the surfaces of the shoulder gliding planes (the acromio-coraco-deltoid-scapulothoracic space, and the glenohumeral joint space), and affected by the inertia of the rotator cuff tendino-fibrous 'skeleton' and muscles, and fascial and cutaneous afferents. The relationship between the dominant factors in creating stability in the GHJ can be illustrated by a simple diagram (**Fig. 6.3.1**), and described by an equation:

$$CJRF = RC^{a} + SAC^{b} + CLMNS^{c} + NS^{d}$$

(where *CJRF* is the centralizing joint reaction force, and the elements *RC* = rotator cuff, *SAC* = surface arc (area) of contact, *CLMNS* = capsulolabral mechano-nociceptive system, *NS* = central and peripheral neural control system elements, and a–d are factors describing the weight of each element in the overall mechanism of stability for that individual at a specific point in time).

The relative importance of each factor varies according to the individual case, but several points are common.

First, the anatomy of the rotator cuff is relatively invariant (although subscapularis can vary in the 'height' of its attachment to the lesser tuberosity). The number of muscle spindles (MS, predominantly *stretch* receptors) in rotator cuff muscles has been studied in marsupials and is approximately 1.5 times the number of Golgi tendon organs (GTO; predominantly *contraction* receptors) (Maass et al 2001a, 2001b). GTOs are situated predominantly in the musculotendinous junctions and at the regions of confluence between the tendon and capsule of the joint. Both muscle spindles and GTOs have large myelinated, fast conducting afferents. The GHJ will remain stable in the partial absence of medial capsulolabral structures (for instance after surgical release for frozen shoulder syndrome, or complete capsulotomy for total shoulder replacement), provided that the rotator cuff function is normal. Thus the dominant proprioceptive input for glenohumeral stability would appear to be from the muscles and the tendinous endoskeleton of the rotator cuff. The LHBT has a special role in linking rotator cuff activity, humeral head position and overall upper limb position, particularly in activities requiring optimal close-packing of the shoulder and elbow. Anomalies of the intra-articular tendon and isolated rupture of the tendon do not appear to contribute to humeral head instability, provided the closely associated components of the rotator cuff remain intact. By contrast, a rotator cuff rupture in an elderly patient presents as superior GHJ instability.

Second, the SAC can vary. Thus, segmental dysplasia of the glenoid, congenital glenoid version anomalies and humeral head defects (Broca or Hill–Sachs, and McLaughlin lesions) all contribute to a decrement in the SAC, which predisposes to failure of the CJRF vector to pass through the glenoid during all arcs of motion.

Third, the structure of the CLMNS can vary considerably. The labrum can be absent, hypoplastic, or dysplastic, and ligament anomalies are well recognized (and common) in subjects with no instability. The incidence of ligamentous anomalies in patients with atraumatic structural instability is the same as that in the general population: lax individuals do not appear to have a greater prevalence of anomalies of ligament morphology, although the molecular structure is clearly altered. The labrum contains numerous free nerve endings, with a frequency about ten times greater than any other corpuscular receptor type (Halata et al 1985), which are readily distorted by motion.

The number of corpuscular mechanoreceptors in the capsule of a marsupial is equivalent to that of muscle spindles, with about 87% being small lamellated corpuscles (rapid-response stretch signalling in a local region) having relatively smaller myelinated afferents than either MSs or GTOs. Pacinian corpuscles (rapid-response stretch signalling over a wider field) are found in the outer fibrous laminae of the capsule, predominantly in the axillary region, while Ruffini corpuscles, which are uncommon, are found in the dense fibrous layer of the capsule in the axilla, and the dermis of the skin. When articular afferents are stimulated in the cat shoulder there is a very short latency (3 ms) to contraction in biceps and deltoid, suggesting a monosynaptic reflex at spinal cord level (Knatt et al 1995). There therefore appears to exist a gradient of receptor speed, locality and density from within to without the joint. As is apparent from the preceding text, data is largely derived from non-human sources, but there is increasing clarity about the role of neural pathways in generating and maintaining shoulder joint stability (Myers and Lephart 2002). It is not known whether variations occur in the densities or function of mechanoreceptors in the capsule and labrum in patients with atraumatic structural and muscle-patterning.

Fourth, neural control systems are readily deranged, by central or peripheral neurological conditions: aberrant muscle activation or suppression contributes to GHJ instability (Gibson et al 2004), and diseases of the cerebellum and basal ganglia may present with shoulder instability, particularly of the scapulothoracic joint.

It is self-evident that we are not aware of our shoulder if it has not been injured or affected by a disease in some way, nor do we regard it during gestural and stereotactic activities. In other words, the presentation of our shoulder is unconscious: all activity is predicted, planned and executed without cognition. This lack of conscious awareness of the shoulder (or any other joint) seems likely to be a function of the entirety of the afferent data about the shoulder. Different combinations of afferent inputs must be produced during varying positions and actions involving the joint. However, providing the total afferent input remains within a range of normality for that joint at that particular time (as predicted by the purpose for which the joint action has been generated), there is no conscious awareness of the joint. If injured, there is awareness (i.e. a conscious, therefore cortical, event occurs, one usually signifying *potential* danger) and, if the injury is sufficient, what is clinically defined as 'apprehension' (i.e. a conscious, therefore cortical, event appreciated as a fear of *actual* danger) often accompanied by a reflex

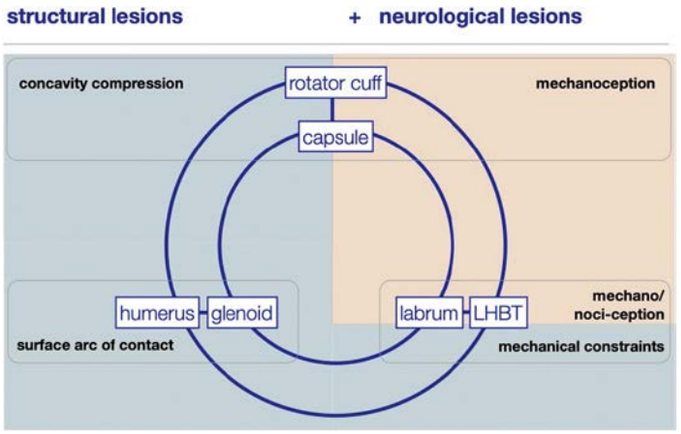

Fig. 6.3.1 Schematic of factors involved in generating stability in the glenohumeral joint. The inner (medial) system comprises the capsule, labrum and glenoid fossa, while the outer (lateral) system comprises the rotator cuff, long head of biceps tendon (LHBT) and the articular surface of the humerus. The LHBT forms a link between the two systems. All tissues contain mechanoceptors and nociceptors: the distribution of these in the human shoulder has been incompletely characterized. Key: grey indicates structural elements; ochre indicates non-structural (neural) elements.

activation of muscles of the shoulder girdle region. If the injury is more deleterious still, and tissue disruption of a critical 'amount' occurs, then pain will occur (in biological evolutionary terms, the incentive to remove oneself from the source of the injury). The central pathways of awareness, apprehension and pain are similar. The total afferent input from the shoulder joint has been changed in some way, and if there has been a disruption of tissues then that region of disruption will likely be de-afferented. A change in overall afferent input, either an absolute loss or an alteration in the ratio of inputs from the various sources, results in both cortical and spinal level reflex (protective) activity. Since the central nervous system works on the principle of inhibition, the 'permission' of spinal activity activating a shoulder girdle response ('apprehension') is produced by an inhibition of the normal inhibitory pathways of motor activation patterns. The individual becomes aware (now at cortical level) of actions, motions or positions of the arm in space which will both generate pain (through distortion of the injured afferent neural tissue) and unpleasant sensations perceived as potential or incipient displacement of the articular surfaces. Restoration of the afferent input, by the healing of the disrupted tissues (whether by natural means or by surgery) results in less pain and less apprehension. That some patients often remark that their shoulder 'feels' better immediately after restorative surgery (if undertaken soon after the injury) suggests that the afferent pathways from spinal level to cortical level remain intact and non-adapted. That other patients, also undergoing restorative surgery, particularly after recurrent episodes of dislocation or failed healing, take a long time to recover to the point of no apprehension suggests not only that re-afferentation is relatively less well organized and quantitatively diminished, but also that central re-adaptation has to occur. That rehabilitation programmes designed to restore stability take roughly the same period as programmes for integrating tendon transfers suggests similar central neural mechanisms are at work. Muscle-patterning instability, the so-called Stanmore type III instability (see below), is a large spectrum of disorders of shoulder stability, characterized by a lack of structural abnormalities, likely to be a failure (by inhibition) of the normal inhibitory pathways of muscle control.

The increased risk of a traumatic GHJ dislocation in the first-degree relatives of patients with traumatic (i.e. structural) GHJ instability suggests a predisposition to the condition, even where the structure of the joint was previously apparently normal. Whether this is located in the afferent, central, or efferent components of the neural control mechanisms is uncertain, but the part of the 'system' that could most readily be perturbed is the afferent, in terms of the number, density and distribution of mechanoreceptors.

Instability: a clinical definition

Instability is usefully defined as the condition of symptomatic abnormal motion of the joint. This universal definition combines the mechanistic view and the clinical perspective, and distinguishes the pathological state from the constitutional state of laxity, in which anatomical anomalies may exist, but do not necessarily cause impairment of function. Since it is a symptom, the term implies recognition (a cerebral cortical event) of the abnormal motion (a difference in position, motion direction or motion velocity has been identified by the patient): 'instability' cannot be determined by examining the shoulder under anaesthetic (EUA). Laxity (looseness) of the GHJ can be determined by EUA either by comparison of the perceived abnormal with the perceived normal side or by reference to what is considered a normal range of laxity for the population of which the patient is representative.

The relationship between the dominant factors in creating instability in the GHJ can be described by a second equation, derived from the first:

$$\text{Instability} = \left[RC^{a} + SAC^{b} + CLMNS^{c} + NS^{d}\right] P \,.\, t$$

where the elements *RC*, *SAC*, *CLMNS* and *NS* are as before (see above) and a–d are factors describing the weight of each element in the overall mechanism of instability for that individual at a specific point in time. *P* are patient-specific factors (occupational and sports, lifestyle, motivation in rehabilitation, etc.), and *t* represents the probability that pathology will evolve over time.

The pathologies causing instability comprise structural (*RC*, *SAC*) and non-structural (*NS*) elements. Many authors hold that the labrum has a structural role, particularly in anterior glenohumeral instability: by virtue of its content of noci-mechanoreceptor clusters and arborizations of free nerve endings, it clearly has a role in neural information loops and so also represents a non-structural stabilizing element. The structural elements may be developmentally abnormal, contain abnormal collagen, or acquire microtraumatic lesions over time (collectively defined as *atraumatic structural* elements) or damaged by extrinsic force (defined as *traumatic structural* elements). The non-structural elements can be developmentally abnormal (e.g. neuromuscular dyspraxias) or can be acquired over time as perturbations of neuromuscular control, particularly at periods of skeletal growth (Fig. 6.3.2).

The shoulder in hypermobility syndromes

Laxity (or 'looseness') is defined as asymptomatic motion in a shoulder through a range that would not be considered normal for the patient's age or gender. Laxity varies with age. Adolescents have a greater overall range of motion than adults, and stiffness (reduced compliance of rotator cuff and capsular tissues) increases with age. Shoulder laxity can exist as part of the generalized benign hypermobility syndromes, or as part of an upper limb dominant form of hypermobility, or in isolation. In the latter form, if one shoulder alone is affected then congenital bony architectural anomalies should be considered, whereas if bilateral isolated shoulder hypermobility is present then soft tissue anomalies are more prevalent.

Appropriate laxity

Normal soft tissue laxity is influenced by many factors such as oestrogen levels, the state of hydration and training. Laxity is very useful in certain circumstances (for instance during childbirth), so selective biological advantage might be conferred on those who develop appropriate laxity. Similarly, degenerative arthritis is uncommon in those who have loose shoulders, unless there are associated morphological anomalies of the glenoid or proximal humerus or inappropriate operations have been performed.

Inappropriate laxity, energy expenditure and the rotator cuff

Much greater energy expenditure is required to maintain shoulder stability in hyperlax shoulders, which means that persistent laxity does not confer a selective biological advantage, except in those whose daily activities, including sport, require laxity for best performance (e.g. dancers and swimmers). These individuals must train consistently to protect their shoulder connective tissues from overload: the capacity of the rotator cuff to generate a centralizing joint reaction force (to keep the humeral articular surface on the glenoid) is much less at the extreme ranges of motion. The musculature of the rotator cuff is specifically organized from deep to superficial so that the shortest muscle fibres (the deepest fibres) take origin at the most lateral extent of their scapular attachment, and insert into the capsule of the shoulder. These fibres contribute most to the centralizing or stabilizing function. The most superficial muscle fibres take origin more medially on the scapula and insert into the humerus

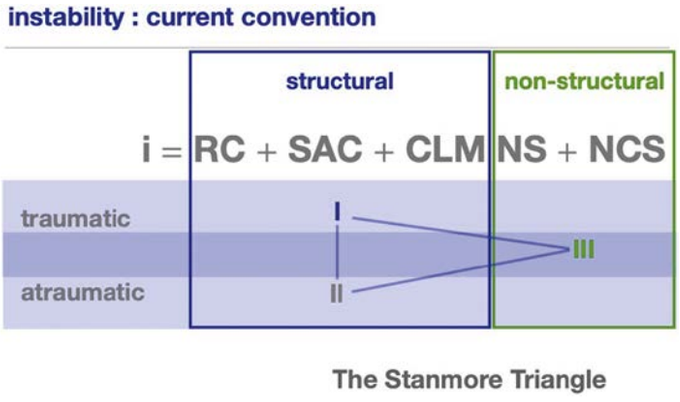

Fig. 6.3.2 Structural and non-structural elements of GHJ instability. These may be damaged (degenerative or traumatic, Stanmore type I), or underdeveloped (dysplastic or atraumatic, Stanmore type II). Note that 'non-structural' factors involved in generating instability may be damaged or dysplastic and are collectively brought under one group (Stanmore type III): this remains a weakness of the Stanmore system of classification of shoulder instability. Repeated 'sub-clinical' damage may occur, in structurally dysplastic or normal tissues, leading to instability through a mechanism involving repeated microtrauma. Abbreviations: CLMNS, capsulolabral mechano-nociceptive system; i, instability; NCS, central and peripheral neural control system elements; RC, rotator cuff; SAC, surface arc (area) of contact. (For further reading on the clinical syndromes of GHJ instability see Lambert 2007.)

lateral to the articular surface (on the tuberosities) through their tendons and by direct muscle insertions. These fibres contribute more to the initiation and control of motion of the shoulder. Each muscle fibre has a length at which it functions optimally and therefore each muscle, depending on the position of the shoulder, has a specific range of motion over which its constituent fibres contribute best to both stability and the control of motion. It follows that when the muscle fibres are at their shortest, at the extremes of range of motion, their effectiveness as both stabilizers and controllers of motion is suboptimal. At these positions the activity of the rotator cuff becomes very asymmetrical: the stability of the joint is less and the rapidity of response to motion diminished. Greater muscle bulk increases the inertia of the joint (its 'passive' resistance to displacement), so that training to increase muscle bulk will improve stability, but will conversely require greater energy expenditure. When training ceases, muscle tone diminishes and the joints are less protected. If, in addition, microtraumatic structural surface damage has occurred as a result of previous activity then the joint is at greater risk of degenerative change. The quality of proprioception is reduced in shoulders with hyperlaxity, instability and previous capsular trauma. Improvement in joint position and motion sense has been shown in trained shoulders, and after anterior capsular reconstruction in those with traumatic structural instability. It is not clear whether this is also the case for patients with atraumatic structural instability.

Group I (Traumatic structural instability)

The traumatic structural group includes the TUBS (Traumatic, Unilateral, Bankart lesion present [in the anterior instability type], Surgery usually indicated) group but also includes the posterior traumatic instability characterized by the McLaughlin or reversed Hill–Sachs lesion and posterior labral damage or locked posterior dislocation. Instability can thus be acute, recurrent or persistent (acute or chronic). Luxatio erecta is a specific version of anterior instability, usually of the more elderly, and may be associated with infraclavicular plexopathy, rotator cuff rupture and extensive bruising indicative of rupture of the humeral circumflex vessels. Surgical treatment is indicated for most patients in whom capsulolabral or rotator cuff disruption is evident: the choice and timing of open versus arthroscopic surgical techniques remains controversial.

Group II (Atraumatic structural instability)

In this group the incidence of ligamentous anomalies is the same as in the population of traumatic instabilities. The group contains the population defined as AMBRI (Atraumatic, often Multidirectional, often Bilateral, treated by Rehabilitation/physiotherapy). In the original definition of AMBRI, surgical treatment by inferior capsular shift is indicated if rehabilitation fails. However, this concept is flawed because some patients will possess some neuromuscular control aberration: surgery may fail because of the muscle-patterning behaviour (so-called type III instability) and patients may have a substantially greater probability of developing instability or post-capsulorrhaphy arthropathy if surgery is undertaken. The decision to operate should not be made on the basis of failed physiotherapy.

This group also contains a subgroup of individuals with benign hypermobility syndrome (of which Ehlers–Danlos syndrome is a variant), characterized by a Beighton score of greater than 5 out of a total possible 9 points. Hypermobility may be limited to the upper limbs. These patients may present with pain rather than overtly abnormal displacements and anterior atraumatic instability is less common than posterior atraumatic positional types. Posterior structural anomalies (including posterior glenoid dysplasia, excessive glenoid retroversion, glenoid hypoplasia, and medialized posterior capsular attachment) create an environment in which obligatory positional posterior displacement may occur during elevation of the arm in the sagittal plane. If abnormal, clinically obvious, muscle activation appears *at the onset* of this motion, then the diagnosis is modified to acknowledge the muscle-patterning: the case is group II/III (peripheral subtype). If the muscular activation occurs *during* the motion, and appears to be provoked by the position of the arm at the shoulder, then the diagnosis is still II/III but with the suffix (protective subtype). If there is no clinically or electrophysiologically proven aberrant muscle activation, then the condition is labelled II (positional subtype).

Scapular dyskinesis is common, and reflects the attempt by the scapular postural muscles to maintain scapulohumeral homeostasis. Serratus anterior can be suppressed in some cases: the aberrant muscle activity now affects the scapula primarily: this represents a scapulothoracic (STh) type III condition. Treatment consists of rehabilitation, avoidance of activities promoting the instability, pain management, and surgical intervention in selected cases. The variants of medially or laterally based inferior capsular shift with augmentation of dysplastic labral tissue are complemented in some cases of glenoid insufficiency by glenoid augmentation using autologous bone blocks (anteriorly and/or posteriorly), or glenoplasty (the Scott posterior glenoplasty, or posteroinferior segmental glenoplasty).

Group III (Muscle-patterning instability)

Muscle-patterning instability (MPI) consists of aberrant activation of large muscles identified by dynamic electromyography (latissimus dorsi, pectoralis major and anterior deltoid have been characterized thus far) and simultaneous suppression of the rotator cuff (infraspinatus has been characterized thus far: whether suppression of infraspinatus reflects suppression of the whole rotator cuff or specific suppression of infraspinatus is not yet clear). MPI can be clinically obvious, in polar group III, but may be occult, requiring dynamic electromyography (DEMG) for confirmation of the suspicion of the existence of MPI in the presentation (as in types II/III and III/II instabilities).

Demographic characteristics

Patients with abnormal muscular activation leading to 'pure' MPI appear to present in a trimodal distribution with peaks at 6, 14 and 20 years. The mean age at onset of symptoms is 14 years and the mean duration of symptoms before presentation is 8 years. In the under-10-year age group there are more girls (71% vs 47%), greater laxity (estimated with the Beighton score, 63% vs 29%), greater bilaterality (54% vs 42%) and fewer presenting with pain (17% vs 50%). As age increased, laxity decreased and pain increased. Bilaterality does not appear to be associated with gender, laxity or pain. Laxity is associated with gender but not pain or bilaterality. These observations suggest different aetiologies for the MPI in the three cohorts.

Bayley (2005) used DEMG in latissimus dorsi (LD), pectoralis major (PM), anterior deltoid (AD) and infraspinatus (IS) to evaluate the patterns of muscular activation in patients who clearly demonstrated, visibly or by palpation, apparently abnormal muscular activation immediately before and during dislocation of the glenohumeral joint in the outpatient clinic. These muscles were chosen because they were reliably accessible. Early pilot studies were expanded into a cohort study of over 1000 cases of GHI seen at the Royal National Orthopaedic Hospital, a tertiary referral centre, over a 22-year period (1981–2003), from which DEMG data were extracted. Muscle-patterning instability was diagnosed, clinically and/or electrophysiologically, in 494 shoulders of 386 patients (45% of the entire cohort of 1097 shoulders). In 44% the MP instability (MPI) affected both shoulders. The dominant arm was affected more often in right-handed patients, the non-dominant more often in left-handed patients. The central neurological basis for these differences

remains obscure. There were 323 shoulders with 'pure' MPI; 161 shoulders presented a mixed picture of MPI in addition to either traumatic or atraumatic structural causes for the instability.

The value of recognizing this form of instability is considerable given the success of specialist physiotherapy using biofeedback techniques rather than conventional therapy for retraining abnormal muscle activity: 76% of patients had either no change or a deterioration in their condition with conventional therapy (including conventional strengthening exercises) compared with 61% of patients overall achieving improvement in their condition with specialist therapy. The incidence of iatropathic arthropathy increases with inappropriate surgery in those with type III instability, but has not been reported in patients with type III instability who did not undergo surgery.

Dynamic electromyography

Given the limitation that only four muscles have been studied in depth, the evidence strongly suggests that these, and perhaps other, muscles are implicated in many cases of instability. Inappropriate activity in PM, LD and AD, with suppression of IS, appear either singly or as couples in the generation of instability in the shoulder with and without capsular collagen insufficiency. Whether suppression of IS reflects specific inappropriate inactivity in IS alone or reflects abnormal activation of the rotator cuff as a whole remains unknown. DEMG provides additional information about abnormal muscle activation or suppression in subtle muscle-patterning instability in which clinical examination has a low specificity and sensitivity. DEMG was found to be most useful in patients presenting with pain, glenohumeral capsular insufficiency and occult muscle-patterning, categorized as the interpolar group II/III. Given that a chance of a successful outcome for rehabilitation of patients with MPI (symptoms abolished or controlled) was diminished five-fold for anterior and 10-fold for posterior instability after inappropriate surgery in patients with MPI, it is clear that the identification of this specific cohort is important. These patients contribute to the failures of the AMBRI group after rehabilitation (if MPI has not been recognized). It is noteworthy that the pathology is not defined by direction but rather that the direction of instability is determined by the pathology.

Rehabilitation is the first mode of treatment used for MPI: there is usually a change in aberrant muscle activity within 6 months. Therapy has to continue for at least two years, possibly for cortical re-imprinting to be re-established. There is a 25% recurrence rate within two years, needing 'top-up' therapy, including in-patient treatment in which a multidisciplinary approach is favoured. The value of specific suppression of specific muscles by injection of botulinum toxin is unclear.

Multidirectional instability (MDI)

MDI is not a diagnosis but a symptom. Multidirectional *laxity* is assessed by examination under anaesthesia (EUA). It may be difficult to determine if a lax shoulder is centralized during EUA. An individual shoulder may have the same pathology (i.e. group I, II or III pathology) causing instability in each of more than one direction, or more than one pathology (e.g. group I in one direction, and group II/III in the other direction), thus distinguishing 'group I' MDI from 'complex' MDI. The underlying diagnoses of the different directions of instability are distinguishable by the history, clinical observations, arthroscopy and/or magnetic resonance imaging with arthrography, supplemented by dynamic electro-myography (DEMG) where necessary. Each pathology is treated separately, with rehabilitation of MPI elements taking priority.

Summary

Functional disturbance within the neurological pathways that control joint stability appears to be a fundamental component of the pathologies that lead to instability. Current understanding of the afferent 'field' for stability in the shoulder is poor. Inferences from non-human experimental animal studies have been illuminating but it is unclear how accurately they reflect the human condition. The ascending pathways and spinal level reflexes needed to maintain shoulder stability in humans are even less well characterized. The subcortical and cortical mechanisms of control of shoulder (and other joint) motion are better understood as a result of experimental animal studies, but the interrelated mechanisms of joint position and motion awareness (proprioception), apprehension and pain await clarification.

Mechanical insufficiency in the anatomical structures that comprise the shoulder may lead to dysfunction that presents as the syndrome of instability. Given the variability of these anatomical structures, it seems reasonable to suggest that the overall afferent 'field' of the shoulder (from cutaneous to capsular and osseous mechanoceptors) exerts a more significant influence on joint stability or its perturbation. The neurological deficit consequent on structural damage or degeneration, or inherent in poorly developed tissues, may be more important, and the restoration of a neurologically healed shoulder may be a more logical goal than one which is structurally intact but neurologically incompetent.

CHAPTER
52 Thorax: overview and surface anatomy

The thorax is the upper part of the trunk. It consists of an external musculoskeletal cage, the thoracic wall and an internal cavity that contains the heart, lungs, oesophagus, trachea and main bronchi, thymus, vagus and phrenic nerves, sympathetic trunks and ganglia, thoracic duct, lymph nodes, and major systemic and pulmonary vasculature (Fig. 52.1). Superiorly, the thoracic cavity communicates with the neck and the upper limbs via the superior thoracic aperture. Inferiorly, it is separated from the abdominal cavity by the respiratory diaphragm. The thoracic cage offers protection to some of the superiorly located abdominal viscera: the majority of the liver lies inferior to the right dome (cupula) of the respiratory diaphragm; the stomach, spleen and left lobe of the liver lie inferior to the left dome of the diaphragm; and the posterior surfaces of the suprarenal glands and kidneys contact the anteroinferior surface of the lumbar part of the diaphragm.

MUSCULOSKELETAL FRAMEWORK

Bones and joints

The thoracic cage consists of 12 thoracic vertebrae and the intervening intervertebral discs, 12 pairs of ribs and their anteriorly located costal cartilages, and the sternum (Fig. 52.2). When articulated, they form an irregularly shaped osseocartilaginous frame (see Fig. 53.8). Laterally, the outer surface of the thoracic cage is convex and is formed by the ribs; anteriorly, it is slightly convex and is formed by the sternum and the distal parts of the ribs and their costal cartilages. The costal cartilages of the first seven pairs of ribs are connected to the sternum at the sternocostal joints, the costal cartilages of the eighth to tenth ribs usually join the inferior border of the superiorly located costal cartilage at the interchondral joints, and the eleventh and twelfth (sometimes the tenth) ribs and their cartilage are free (floating) at their anterior ends and project into the musculature of the abdominal wall. The posterolateral curvature of the ribs, from their head (vertebral end) to their angle (see Fig. 53.9), produces a deep internal groove, the paravertebral gutter, located on either side of the vertebral column. The ribs and costal cartilages are separated by intercostal spaces, which are deeper anteriorly and between the more superiorly located ribs. Each space is occupied by two or three layers of flat muscles and their aponeuroses (membranes), neurovascular bundles and lymphatic channels.

The superior thoracic aperture (thoracic inlet) typically measures 5 cm anteroposteriorly and 10 cm transversely (see Fig. 52.1). It is bounded by the body of the first thoracic vertebra posteriorly, the internal (medial) borders of the left and right first ribs, and the superior border (jugular notch) of the manubrium of the sternum anteriorly. It slopes anteriorly and inferiorly from the vertebral column, so that the apex of the lung is located in the inferior neck, above the level of the first rib and the medial one-third of the clavicle, and level with the body of the seventh cervical or first thoracic vertebra, or the intervening C7–T1 intervertebral disc; structures that pass between the thorax and the upper limb therefore pass over the first rib and the suprapleural membrane covering the pleurae and lung apex.

The inferior thoracic aperture (thoracic outlet) is bordered posteriorly by the body of the twelfth thoracic vertebra, posterolaterally by the twelfth rib and its costal cartilage and the distal end of the eleventh rib and its costal cartilage, anterolaterally by the cartilaginous ends of the seventh to tenth ribs (which unite and ascend as the costal arch or margin), and anteriorly by the xiphoid process of the sternum (see Fig. 52.2). In adults the dimension of the transverse plane of the aperture is larger than the sagittal plane, and the aperture slopes obliquely inferiorly and posteriorly towards the vertebral column, so that the thoracic cavity is deeper posteriorly than anteriorly.

The sternum is formed from three parts (manubrium, body and xiphoid process) that articulate at the manubriosternal and xiphisternal joints. The sternal plane passes horizontally through the manubriosternal joint (sternal angle, angle of Louis) at the level of the second costal cartilage anteriorly, intersecting the vertebral column posteriorly in a region that extends from the body of the fourth thoracic vertebra to the superior half of the body of the fifth thoracic vertebra (Mirjalili et al 2012a). The sternal plane separates the superior mediastinum from the inferior mediastinum and can be used as a reference plane to position intrathoracic mediastinal structures.

Muscles

Intrinsic and extrinsic muscles

The intrinsic muscles of the chest wall are the intercostal muscles, subcostalis, transversus thoracis, levatores costarum and serratus posterior superior and inferior (see Figs 46.71, 53.15). Transversus thoracis may mimic pleural thickening on CT imaging: the uncommon variants, sternalis and rectus thoracis bifurcalis, are important clinically because they may mimic a focal density in medial breast craniocaudal mammograms and may be encountered during reconstructive surgery of the breast and chest wall.

The intercostal muscles are arranged in consecutive layers in each intercostal space and are named according to their positional relationship to each other, i.e. external, internal and innermost (see Fig. 53.17). All the intrinsic muscles except levatores costarum are innervated

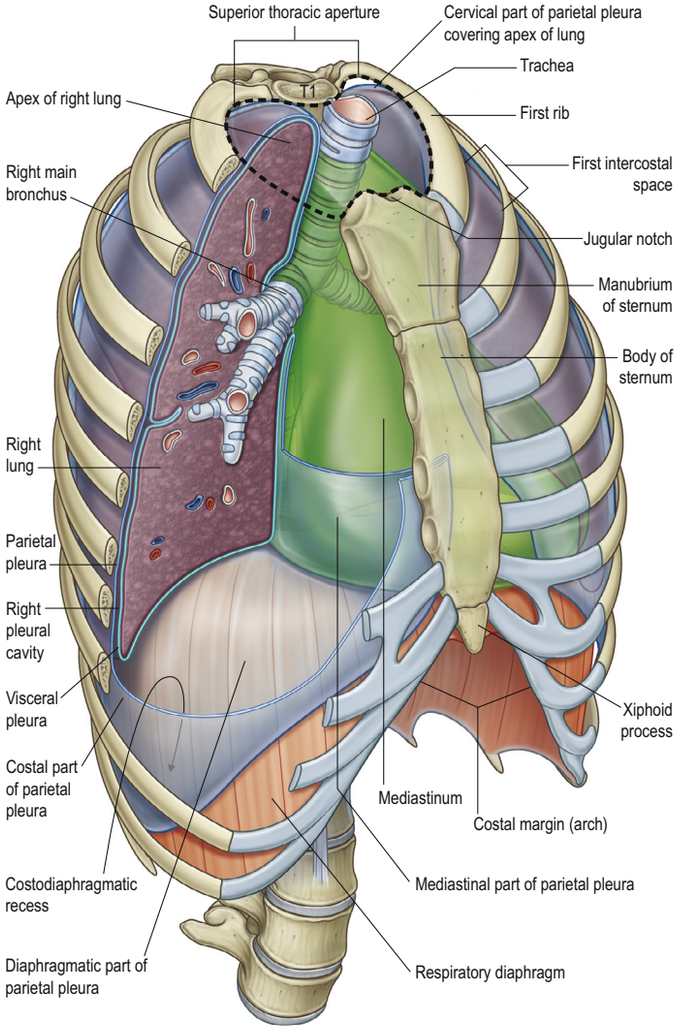

Fig. 52.1 The thoracic cage and thoracic cavity; showing the lungs, pleura, pleural cavity, diaphragm and mediastinum. (With permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2015.)

The shape, dimensions and proportions of the thoracic cage vary between individuals, particularly with age and sex (Joshua et al 2014). In an adult, the dimensions of the thoracic cavity change continuously with the movements of the ribs and diaphragm during respiration (Ch. 55) and also with distension of the abdominal viscera and movement of the vertebral column. In a normal healthy adult, both the thoracic cage and abdominal wall move outwards on inspiration and inwards on expiration. Changes to this pattern, including paradoxical movements, may be seen in respiratory disease (Goldman 1982). Thoracic capacity is less in females than it is in males, both absolutely and proportionately; in the female, the sternum is normally shorter and the thoracic inlet more oblique.

In neonates and young infants, the thoracic cage has the shape of a truncated cone and is relatively round in cross-section, the ribs have an almost horizontal alignment, and the domes of the respiratory diaphragm and sternal ends of the clavicles sit in a more superior position than is the case in older children and adults (Openshaw et al 1984). Thoracic expansion is consequently limited and contributes little to breathing, which is reliant on the respiratory diaphragm. In a neonate, diaphragmatic contraction during inspiration pulls the thoracic cage inwards and moves the abdomen outwards, the thoraco-abdominal paradox. The neonatal thoracic wall is highly compliant and is easily deformed. By 2 years of age, as standing and walking begin, adult thoracic proportions and geometry have developed. These include downward sloping ribs, an oval cross-sectional shape to the thoracic cage, and a more inferior position of the domes of the respiratory diaphragm and the sternal ends of the clavicles (Openshaw et al 1984, Joshua et al 2014). This means that the thorax is able to move outwards during inspiration and the thoraco-abdominal paradox diminishes until it is no longer observed.

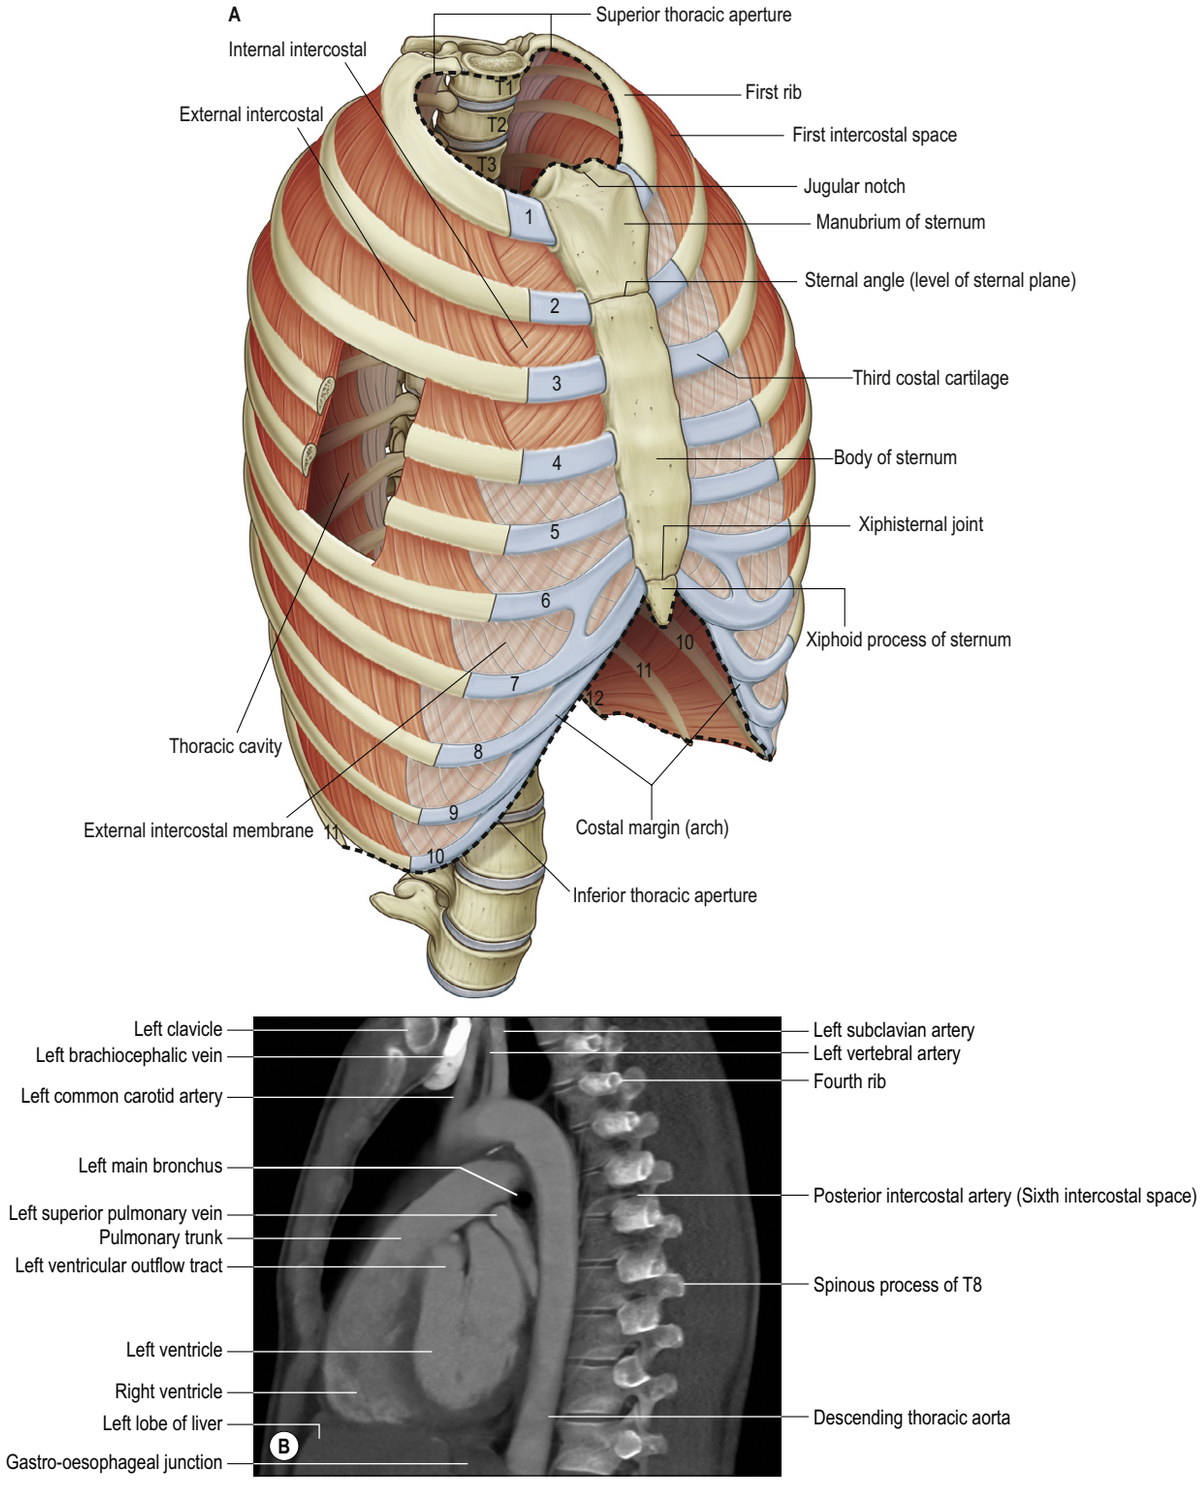

Fig. 52.2 **A**, The musculoskeletal components of the thoracic wall showing the superior and inferior thoracic apertures. The costal cartilages and ribs are labelled accordingly 1–12. The first three thoracic vertebrae are labelled T1–T3. **B**, Left sagittal CT volume-rendered slab showing the left posterior intercostal arteries arising from the thoracic aorta. Note the origin of the left vertebral artery from the arch of the aorta (for a description of this variant, see Tardieu et al 2017). segmentally by the intercostal nerves derived from the ventral rami of the thoracic nerves. Levatores costarum are innervated segmentally by lateral branches of the dorsal rami of the thoracic spinal nerves. The intrinsic muscles can elevate or depress a rib depending upon their location and are particularly active in forced (deep) breathing; some also help to stiffen the chest wall, thereby preventing paradoxical movement during inspiration and optimizing inspiratory/expiratory reserve volume.

The skeletal framework of the thoracic wall provides attachment sites for muscles associated functionally with the neck, back, upper limbs and abdomen. Some (e.g., scalenes, infrahyoid strap muscles, sternocleidomastoid, serratus anterior, pectoralis major and minor, external and internal abdominal obliques and rectus abdominis) may also function as accessory muscles of respiration; they are usually active only during forced breathing. Muscles with thoracic attachment are described in more detail in Chapters 35, 48 and 60.

Respiratory diaphragm

The respiratory diaphragm is a curved musculotendinous sheet attached to the circumference of the inferior thoracic aperture and the bodies of the superior two or three lumbar vertebrae. It forms the inferior boundary (floor) of the thoracic cavity and separates it from the abdominal cavity (Ch. 55). The diaphragm is relatively flat centrally, in the region inferior to the heart, and domed peripherally, rising higher on the right side than on the left, an asymmetry reflecting the differences in relative densities of the underlying abdominal viscera. From its most superior point on each side, the diaphragm slopes inferiorly to its peripheral costovertebral attachments. Posteriorly, the space between the diaphragm and the thoracic wall (costodiaphragmatic recess) is long and narrow. The position of the domes varies with body position; they are higher in the supine compared to the erect position. During quiet respiration in the erect position, diaphragmatic excursion is about 2 cm in both sexes, increasing to around 7 cm during deep breathing (Boussuges et al 2009); the range of excursion is often greater in men and may increase further whilst in the supine position (Takazakura et al 2004).

Diaphragmatic openings

The respiratory diaphragm is traversed by structures that pass between the thorax and abdomen, including the right and left vagus, phrenic, thoracic splanchnic and subcostal nerves, the thoracic duct, sympathetic trunks, right and left superior epigastric arteries (continuations of the internal thoracic arteries), and the azygos and hemiazygos veins. The inferior vena cava and oesophagus pass through the tendinous and muscular parts of the diaphragm, respectively (see Fig. 55.1). CT-based studies have shown the vertebral level at which they pass through the diaphragm is more inferior than reported conventionally.

THORACIC CAVITY

Fascia and spaces

The endothoracic fascia (parietal fascia of the thorax) is a mixture of tissue types including connective, adipose, lymphoid and smooth muscle. It lines the inner surface of the thoracic wall and the superior surface of the respiratory diaphragm, separating them from the respective region (part) of the parietal pleura. It is attached posteriorly to the periosteum of the thoracic vertebrae and becomes continuous with the thoracic prevertebral fascia; superiorly it forms the suprapleural membrane; inferiorly it is continuous with the endo-abdominal fascia via apertures in the respiratory diaphragm, e.g., the aortic hiatus (Dugan and Samson 1975).

Pleural cavities

The right and left pleural cavities are separate compartments within the thoracic cavity, located on either side of the mediastinum. Each surrounds a lung and its associated bronchial tree, vessels, nerves and lymphatics (Ch. 54). The walls are formed by a serous membrane, the pleura, arranged as a closed sac. Each cavity represents a potential space between the parietal and visceral pleura, two serous membranous layers that are continuous on the medial aspect of the lung root and pulmonary ligament at the pleural reflection. The outermost layer, the parietal pleura, lines the inner surface of the corresponding half of the thoracic wall, the superior surface of the ipsilateral hemidiaphragm and structures along the ipsilateral lateral side of the mediastinum. The parietal pleura covers part of the lung root, close to the hilum, then folds internally on itself to become continuous with the innermost layer, the visceral pleura, which adheres to the outer surface of the lobes of the lung, following the interlobar fissures. The two layers of pleura are in close contact throughout all phases of breathing, yet are able to slide freely over each other due to the presence of an intervening thin layer of serous fluid. The pleural cavity is maintained normally at a negative pressure by the inward elastic recoil of the lung and the outward pull of the thoracic wall. The lungs do not occupy the full extent of the pleural cavity during quiet breathing, but are free to move into recesses such as the costodiaphragmatic and costomediastinal recesses, during deep breathing.

Mediastinum

The mediastinum is a visceral compartment of the thoracic cavity, located within and adjacent to the median sagittal plane, between the right and left pleural cavities (see (Figs 52.1, 56.1): the mediastinal part of the parietal pleura forms its lateral boundaries. The mediastinum extends from the sternum anteriorly to the thoracic vertebral column posteriorly, and from the superior thoracic aperture superiorly to the respiratory diaphragm inferiorly. The sternal plane (which passes horizontally through the manubriosternal joint at the level of the second costal cartilage anteriorly, intersecting the vertebral column posteriorly in a region that extends from the body of the fourth thoracic vertebra to the superior half of the body of the fifth thoracic vertebra) is used to divide the mediastinum into superior and inferior parts. The sternal plane is sometimes defined as a fixed plane that passes from the manubriosternal joint to the most inferior part of the body of the fourth thoracic vertebra. Regional mediastinal content is reviewed in Ch. 56.

Superior mediastinum

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The skin of the thorax is supplied by direct cutaneous vessels and musculocutaneous perforators, which reach the skin primarily via the intercostal muscles, pectoralis major, latissimus dorsi and trapezius. The positions of the cutaneous vascular territories and their arterial supply guide the placement of free flap grafts for reconstructive surgery. Branches from the thoraco-acromial, lateral and superficial thoracic, internal thoracic, anterior and posterior intercostal, thoracodorsal, transverse cervical, dorsal scapular and circumflex scapular arteries are the major contributing vessels to the skin of the thoracic wall (see Figs 46.4, 53.1, 53.2).

The muscles of the thoracic wall receive their blood supply from the internal thoracic artery (either directly or via the musculophrenic artery), the supreme (highest) intercostal artery (from the costocervical trunk), the superior thoracic artery (from the axillary artery) and the descending thoracic aorta (via the posterior intercostal and subcostal arteries) (**Fig. 52.3**). The main anterior and posterior intercostal arteries pass around the superior aspect of each intercostal space, their anastomoses provide a potential route for collateral circulation in cases of aortic coarctation. Collateral branches of the intercostal arteries pass around the inferior aspect of each space. Additional contributions come from vessels that supply the proximal muscles of the upper limb, namely the suprascapular, superficial cervical, thoraco-acromial and subscapular arteries (see Fig. 46.4).

The detailed arterial supply of the thoracic viscera is described with the viscera.

Veins

The posterior intercostal veins and their collateral branches accompany their similarly named arterial counterparts in the superior and inferior aspect of each intercostal space (**Fig. 52.4**). The anterior intercostal veins are tributaries of the internal thoracic and musculophrenic veins; the internal thoracic veins drain into the ipsilateral brachiocephalic veins. The posterior intercostal veins drain directly or indirectly into the azygos vein on the right and the hemiazygos or accessory hemiazygos veins on the left. In some cases the veins from the upper two or three intercostal spaces on

More recent descriptions define the endothoracic fascia as the outermost connective tissue layer within the extrapleural space, a space situated between the parietal pleura and the inner surface of the thoracic wall and superior (thoracic) surface of the respiratory diaphragm (Santamarina et al 2017). The extrapleural space also contains a layer of adipose tissue in contact with the parietal pleura, loose connective tissue, vessels and lymphoid tissue. A range of pathologies may occur in this tissue plane, including liposarcoma, leiomyosarcoma, fibrosarcoma and lymphoma (Morelli et al 2007). An increased accumulation of extrapleural fat may be confused for pleural thickening on CT imaging (Im et al 1989).

The superficial subcutaneous fascia of the thorax, formed mainly by fat, is attached loosely to the skin and includes the breast tissue. Deeper fascial layers include those surrounding the muscles of the thoracic wall: some layers are dense and supportive, e.g. the clavipectoral fascia (Ch. 49) and the thoracolumbar fascia (Ch. 46).

The extrathoracic fascia is located posteriorly between the muscles that attach the scapula to the posterior thoracic wall and the underlying posterior thoracic wall (Latarjet and Juttin 1953). The extrafascial space is superficial to the extrathoracic fascia and is relatively sealed, whereas the subfascial space deep to the extrathoracic fascia communicates freely with the cervical region superiorly and with the lumbar region inferiorly.

The superior mediastinum lies between the manubrium of the sternum anteriorly and the anterior longitudinal ligament covering the bodies of the first four or five thoracic vertebrae and their intervening intervertebral discs posteriorly (depending upon the level at which the sternal plane intersects the vertebral column). It contains the lower ends of sternohyoid, sternothyroid and longus colli on each side; the aortic arch, brachiocephalic trunk and thoracic portions of the left common carotid and left subclavian arteries; the brachiocephalic veins and upper half of the superior vena cava; the supreme and superior intercostal veins; the vagus, cardiac, phrenic and left recurrent laryngeal nerves; and the trachea, oesophagus, thoracic duct, thymic remnants and lymph nodes (e.g. upper paratracheal, para-aortic, subaortic and prevascular nodes).

The inferior mediastinum, between the sternal plane and diaphragm, is divided into three parts: anterior, middle and posterior.

Anterior mediastinum The anterior mediastinum is primarily located on the left side where the point of reflection between the left costal and mediastinal part of the parietal pleura diverges from the median plane. It is bounded anteriorly by the sternum, laterally by the left and right mediastinal parietal pleura and posteriorly by the fibrous pericardium. It is approximately triangular in shape, being wider inferiorly, and may be absent above the level of the fourth costal cartilage if the left and right parietal pleural layers meet. Its anterior wall is formed mainly by the left transversus thoracis and the fifth to seventh left costal cartilages and intervening intercostal muscles. The anterior mediastinum contains loose areolar tissue, lymphatic vessels from the liver, thymic remnants (or fatty replacement), parasternal lymph nodes and mediastinal branches of the internal thoracic artery.

Middle mediastinum The middle mediastinum is the broadest part of the mediastinum. It contains the heart within the pericardial coverings and cavity; the ascending aorta; the inferior part of the superior vena cava with the azygos vein joining it; the tracheal bifurcation and right and left main bronchi; the pulmonary trunk dividing into the left and right pulmonary arteries; the right and left pulmonary veins (superior and inferior) and phrenic nerves; and hilar, subcarinal and lower paratracheal (tracheobronchial) lymph nodes.

Posterior mediastinum The posterior mediastinum is a relatively long and narrow space. It is bounded anteriorly by the fibrous pericardium, pulmonary vessels, tracheal bifurcation, left and right main bronchi and the posterior (or posterosuperior) surface of the respiratory diaphragm; posteriorly, depending on the level of the sternal plane, by the anterior longitudinal ligament covering the vertebral column from the bodies of the fourth or the superior half of the body of the fifth to the twelfth thoracic vertebrae and intervening intervertebral discs; and laterally by the mediastinal part of the parietal pleura. It contains multiple structures passing to/from the abdominal cavity and posterior thoracic wall including the descending thoracic aorta; the oesophagus and the anterior and posterior vagal trunks; the azygos venous system; the thoracic duct and lymph nodes (e.g., paraoesophageal and retrotracheal); the right and left sympathetic trunks and ganglia; and the left and right vagus nerves.

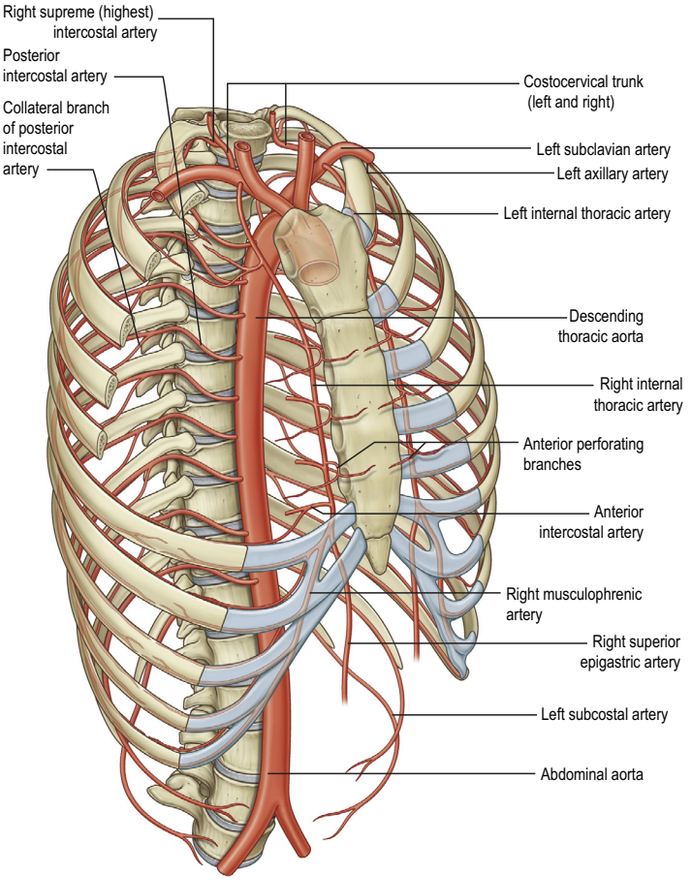

Fig. 52.3 The thoracic and abdominal aorta, and the arteries of the thoracic wall (With permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy, Elsevier, Churchill Livingstone. Copyright 2015.)

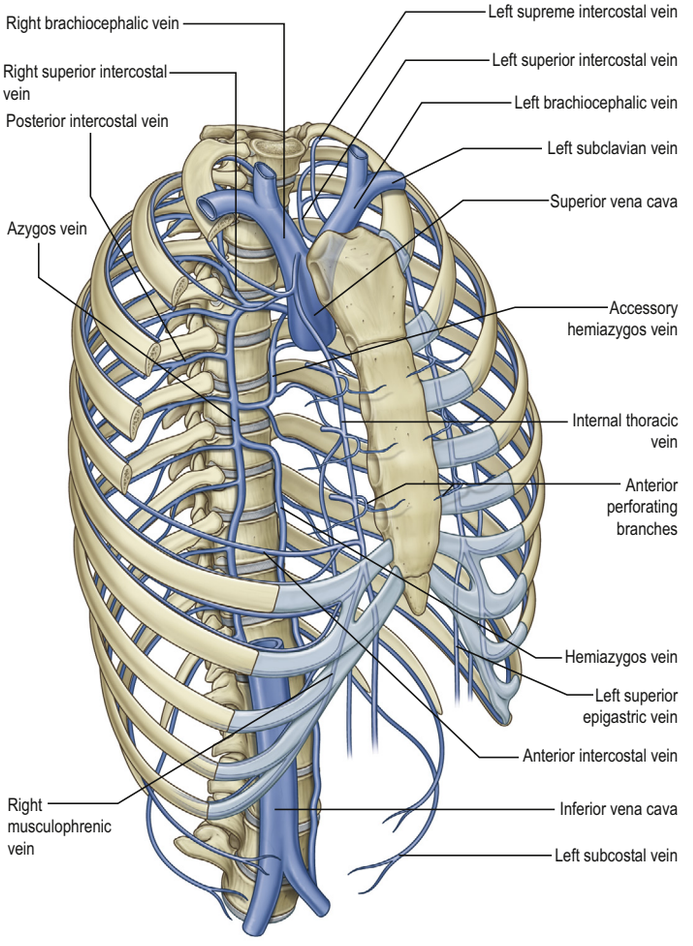

Fig. 52.4 Veins of the thoracic wall and the azygos venous system. (With permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2015.)

the left join and drain directly into the left brachiocephalic vein. The azygos venous network shows great variation in its formation, origin, course, tributaries, anastomoses and termination (Loukas and Tubbs 2016) (see Figs 56.2–56.3).

Lymphatic drainage

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (see Figs 46.5, 53.22), similarly lymphatic vessels from the breast tissue drain mainly to axillary nodes, with some passing initially to parasternal, interpectoral and supraclavicular nodes (see Fig. 53.24). The extent of drainage of the breast is of particular importance in metastatic breast cancer. Lymph vessels from deeper tissues of the thoracic walls drain mainly to the parasternal, intercostal and diaphragmatic nodes. Lymph from the thoracic viscera drains to consecutive node groups (stations) situated throughout the mediastinum (see Fig. 54.12).

INNERVATION

Thoracic spinal nerves

There are 12 pairs of thoracic spinal nerves. The ventral rami, unlike their cervical and lumbar counterparts, have retained a largely segmental distribution to the body wall (see Figs 24.10, 47.7, 53.3). The first to the eleventh intercostal nerves pass in the intercostal spaces between adjacent ribs, and the twelfth (subcostal nerve) passes inferior to the twelfth rib. Each is connected with an adjacent ganglion of the sympathetic trunk by pre- and postganglionic axons that form the white and grey rami communicantes, respectively (see Figs 24.13, 53.21). The majority of the intercostal nerves are distributed to the thoracic and, in the case of the more inferiorly located nerves, abdominal walls. The greater part of the first thoracic ventral ramus passes into the brachial plexus (see Fig. 48.6), together with variable proportions of the second and sometimes third thoracic ventral rami via the intercostobrachial nerves. The fourth to sixth intercostal nerves supply only the thoracic wall, whereas the seventh to eleventh nerves supply the thoracic and abdominal walls. The subcostal nerve is distributed to the abdominal wall and skin covering the superior part of the lateral aspect of the gluteal region and thigh. Communicating branches may link the intercostal nerves across the intercostal spaces posteriorly (see Fig. 56.6). The dorsal rami of the thoracic spinal nerves divide into medial and lateral branches that supply the intrinsic muscles of the back and the overlying postvertebral skin on a segmental basis (see Figs 46.3, 47.8).

The breast is mainly innervated by the anterior and lateral cutaneous branches of the fourth to sixth intercostal nerves. The nipple is innervated by a plexus formed primarily from cutaneous branches of the fourth intercostal nerve.

The supraclavicular branches of the cervical plexus (derived from the ventral ramus of the fourth cervical spinal nerve) innervate the skin over the clavicle and may communicate with the anterior cutaneous branches of the second thoracic ventral ramus.

Regional anaesthesia

Available with the *Gray's Anatomy* e-book

Autonomic innervation

The autonomic nervous system in the thorax consists of the left and right sympathetic trunks and left and right vagus nerves, and the cardiac, oesophageal and pulmonary plexuses (see Figs 56.6, 56.7).

Sympathetic trunks

The left and right thoracic sympathetic trunks and associated ganglia (commonly 11 in number) sit posterior to the costal part of the parietal pleura on either side of the vertebral column. The majority of the thoracic sympathetic ganglia lie anterior to the head of a rib; the first thoracic and inferior cervical ganglia are fused, and the inferior two or three thoracic ganglia are often located lateral to their correspondingly numbered vertebral bodies (see Fig. 56.6). A tumour of the superior

Regional anaesthesia may be used to alleviate the pain associated with rib fracture, thoracostomy, thoracotomy or breast surgery. Nerve blocks performed in the thoracic paravertebral space target the ventral rami of the thoracic spinal nerves (or the posterior intercostal nerves) as they travel through the fat-filled space (Bouman et al 2017). Various fascial plane blocks are used to target segmental and cutaneous branches of regional nerves as they pass through specific fascial planes or compartments (Elsharkawy et al 2018), for example, serratus anterior plane (Biswas et al 2018), pectoralis and serratus anterior plane (Pecs1 or Pecs2) and erector spinae plane blocks (Forero et al 2017). Anaesthetic agents are able to track through the fascial lined space or compartment into which they are injected: effective anaesthesia of multiple nerves can therefore be achieved via a single point of access.

pulmonary sulcus (apex of lung) may compress the ventral ramus of the first thoracic spinal nerve, the cervicothoracic ganglion or the sympathetic trunk (see Fig. 54.2) resulting in a loss of sympathetic innervation to the ipsilateral side of the head (Horner's syndrome) (Nikolaos et al 2014) and pain radiating to the medial aspect of the ipsilateral forearm (Bruzzi et al 2008).

Preganglionic sympathetic axons originate from neuronal somata in the intermediolateral nucleus (lateral horn) of the spinal cord from T1 to L2. They travel initially with the corresponding ventral roots (rami) and leave the latter as white rami communicantes to enter the adjacent sympathetic ganglion in the sympathetic trunk. Their targets vary; some synapse in the sympathetic ganglion that they enter, whereas others ascend or descend in the sympathetic trunk to synapse in cervical or lumbar ganglia, respectively. Many of the preganglionic axons that originate in the lower thoracic spinal segments (T5–T12) do not synapse locally but enter the abdominal cavity as the thoracic splanchnic nerves. These nerves pass through the posterior mediastinum and respiratory diaphragm to enter the abdominal cavity where they synapse either in prevertebral ganglia that surround the origin of the major visceral arteries arising from the abdominal aorta, e.g. the coeliac and superior mesenteric ganglia (Ch. 59), or around the medullary chromaffin cells of the suprarenal gland (Ch. 70). Axons destined for the cervical ganglia are mainly derived from preganglionic neurones in the first thoracic spinal nerve.

Vagus nerves in the thorax

Preganglionic parasympathetic axons arise from neuronal cell bodies in the dorsal motor nucleus of the vagus in the medulla oblongata. Those destined for the thoracic viscera travel in the pulmonary, cardiac and oesophageal branches of the vagus nerve (see Fig. 56.7) and synapse in minute ganglia in the walls of the target viscera. Axons travelling in cardiac branches join the cardiac plexuses and synapse in ganglia distributed over both atria, the interatrial septum and peri-nodal subepicardial tissue: when stimulated, they normally slow the cardiac cycle and constrict coronary arteries, although low level stimulation may increase heart rate (Ch. 57). Pulmonary branches contain axons that synapse in ganglia of the pulmonary plexuses; they are motor (broncho constrictor) to the circular non-striated muscle fibres of the bronchi and bronchioles, and secretomotor to the mucous glands of the respiratory epithelium.

Autonomic plexuses in the thorax

Cardiac plexus The cardiac plexus has a superficial component inferior to the aortic arch, lying between the arch and the pulmonary trunk, and a deep part between the aortic arch and tracheal bifurcation (Ch. 57, see Fig. 57.61).

Pulmonary plexus. The pulmonary plexuses are located both anterior and posterior to the hila of the lungs (Ch. 54 and see Fig. 56.7), and connect with the cardiac plexuses (Ch. 57).

Oesophageal plexus. The oesophageal plexus surrounds the oesophagus below the level of the hila of the lungs (Ch. 56, see Fig. 56.6).

SURFACE ANATOMY

Thoracic surface anatomy underpins proficient physical examination and clinical procedures such as thoracostomy, placing drains or catheters and siting surgical incisions. Previous cadaver-based descriptions of surface landmarks are now being revised based upon CT imaging of living subjects. These studies are demonstrating a wider range of variation in positional and surface anatomy than appears in the current anatomical literature (Hale et al 2010, Mirjalili et al 2012a, Keough et al 2016, Pak et al 2016, Shen et al 2016, Uzun et al 2016, Badshah et al 2017).

Skeletal landmarks

Anteriorly, the clavicle, sternoclavicular and acromioclavicular joints are palpable and visible in most individuals (**Fig. 52.5**). The sternum may be felt throughout its length in the midline; laterally it may be covered by pectoralis major. The jugular (suprasternal) notch is palpable in the midline at the superior border of the manubrium of the sternum and commonly sits horizontally level with the vertebral bodies of T2 or T3. The cartilaginous rings and lateral borders of the trachea are palpable immediately superior to the notch. The sternal angle (of Louis) is more pronounced in males than in females, and is palpable at the junction of the manubrium with the body of the sternum. It marks the level of the horizontal sternal plane and the medial ends of the second costal cartilages, and so offers a reference point at which to start counting ribs. In the majority of adults the sternal plane intersects the vertebral column in a region that extends from the vertebral body of T4 to the superior half of the vertebral body of T5. The xiphisternal joint and xiphoid process are palpable at the inferior end of the sternum; the joint usually lies at the level of the vertebral body of T9, although it may be slightly higher. The costal margin (arch) is palpable passing inferolaterally from either side of the xiphoid process of the sternum. Posteriorly, the free ends of the eleventh and twelfth ribs may be palpable. Tracing the twelfth rib superomedially aids identification of the spinous process of T12 (**Fig. 52.6**). In thin individuals, it is possible to palpate all ribs anteriorly, from the first to the costal margin, and laterally, from the fourth rib at the floor of the axilla to the costal margin. Posteriorly, the spinous processes of the thoracic vertebrae are palpable in the midline; the spinous process of T1 sits below that of C7 (vertebra prominens) and is often more prominent. The prominent and distinct angles of the ribs are palpable several centimetres lateral to the spinous processes of the vertebrae. The surface anatomy of the back is described in Chapter 46.

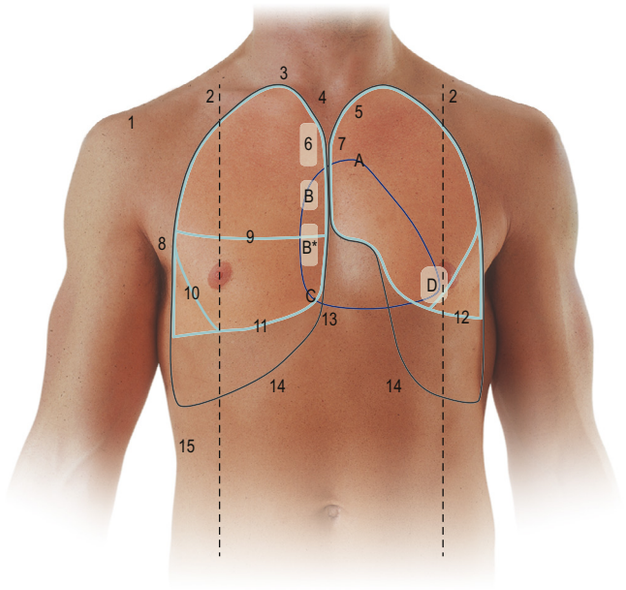

Fig. 52.5 Surface anatomy of the anterior thorax. Key: 1, right acromioclavicular joint; 2, clavicle and mid-clavicular line (dashed black); 3, apex of right lung, located posterior and 1–2 cm superior, to the medial one third of the clavicle; 4, jugular notch of the manubrium of sternum; 5, left sternoclavicular joint: marks the formation of the left brachiocephalic vein; 6, zone of formation of the superior vena cava: from the first to second costal cartilage level (white zone); 7, manubriosternal joint: marks the sternal plane and the second costal cartilage laterally; 8, pectoralis major and the anterior axillary fold; 9, horizontal fissure; 10, right oblique fissure; 11, lower anterior border of the right lung: typically, either at the sixth intercostal space or rib 7 in the mid-clavicular line; 12, lower anterior border of the left lung: typically, either at rib 5 or the fifth intercostal space in the mid-clavicular line; 13, xiphoid process; 14, costal margin (arch); 15, tenth costal cartilage; the lowest part of the costal margin. A–D and blue line: surface markings of the heart. A overlies the left second costal cartilage; B and B*, junction of superior vena cava with the right atrium; located posterior to the right third costal cartilage or intercostal space (white zone B) or posterior to the fourth to the fifth costal cartilage (white zone B*); C, right sixth costal cartilage; D, zone of location of the cardiac apex: commonly from the level of rib 5 to rib 6, and a mean of 8–9 cm from the midline.

Musculotendinous landmarks

In a lean, muscular subject, pectoralis major, the digitations of serratus anterior, latissimus dorsi, trapezius, external abdominal oblique and rectus abdominis are all visible and palpable. In females, the breasts may obscure part of the anterior thoracic wall.

The plexus has coronary, pulmonary, atrial and aortic extensions. The superficial (ventral) part is formed by the cardiac branch of the left superior cervical sympathetic ganglion and the inferior of the two cervical cardiac branches of the left vagus nerve. The deep (dorsal) part is formed by the cardiac branches of the cervical and upper thoracic sympathetic ganglia and of the vagus and recurrent laryngeal nerves. The only cardiac nerves that do not join it are those that join the superficial part of the plexus. Branches from the cardiac plexuses subsequently form the left and right coronary and atrial plexuses.

The posterior plexus provides the majority of the autonomic innervation to the lung and is formed by approximately 12 (range, 8–18) branches from the vagus nerve (Weijs et al 2015) and cardiac branches from the second to fifth (or sixth) thoracic sympathetic ganglia. The smaller anterior plexus is formed by 3 (range, 2–4) branches of the vagus nerve and cervical sympathetic cardiac nerves via the superficial and deep parts of the cardiac plexus. Branches of the recurrent laryngeal nerves form a plexus on the membranous posterior wall of the trachea; the plexus primarily innervates the trachea and proximal parts of the main bronchi, with branches to the oesophagus. Vagal nerve innervation is involved in the cough reflex, mucous production and control of bronchial diameter; inadvertent transection of the pulmonary vagal nerves during oesophagectomy may be related to the high incidence of postoperative pneumonia and pulmonary complications following oesophagectomy (Weijs et al 2017); preservation of vagal pulmonary branches is therefore desirable (Weijs et al 2016).

Preganglionic parasympathetic axons from the vagus and recurrent laryngeal nerves travel to ganglia in the oesophageal wall, either directly or through the oesophageal plexus and are motor to the smooth muscle in the lower oesophagus and secretomotor to mucous glands in the oesophageal mucosa. Vasomotor sympathetic axons arise from the first to sixth (sometimes fewer) thoracic segments of the spinal cord. Those passing from the more superior cord segments often synapse in the middle and inferior cervical sympathetic ganglia; their postganglionic axons are vasomotor to the vessels of the cervical and superior part of the thoracic oesophagus. Preganglionic axons from the fifth or sixth thoracic spinal cord segments pass directly to the oesophageal plexus or to the coeliac ganglion, where they synapse; postganglionic axons innervate the vessels of the distal oesophagus.

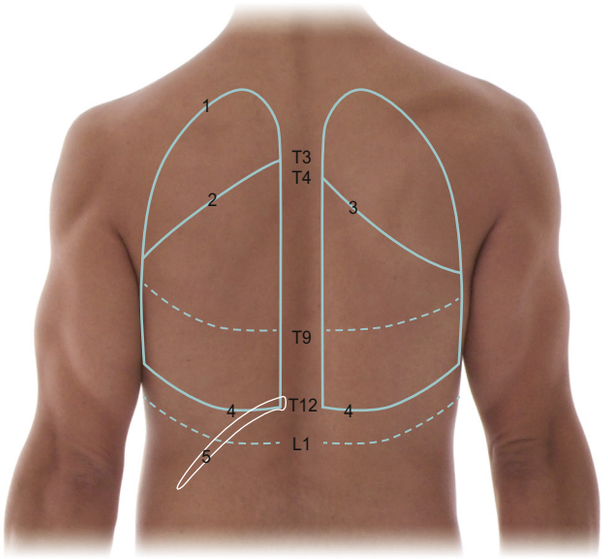

Fig. 52.6 Surface anatomy of the posterior thorax. The levels of the spinous processes of T3, T4, T9, T12 and L1 are indicated in the midline. Key: 1, border of the left lung; 2 and 3, oblique fissure of the lung: pass from the posterior part (neck) of rib 4 (level with the spinous process of T3) on the left side and the posterior part of rib 5 (level with the spinous process of T4) on the right side, to rib 6 in the mid-axillary line on both sides; 4, lower border of the lung, commonly located level with the vertebral body of T12, adjacent to the vertebral column at end tidal inspiration. Dashed blue lines indicate the range of levels for the lower border of the lung (from the vertebral bodies of T9 to L1); 5, rib 12: can be traced superomedially to aid identification of the spinous process of T12.

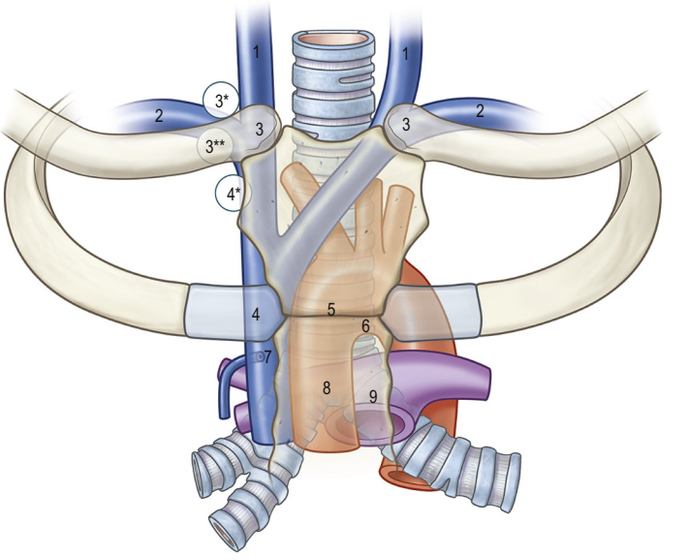

Fig. 52.7 Surface anatomy of the great vessels and tracheobronchial tree relative to bony landmarks. Key: 1, internal jugular vein; 2, subclavian vein; 3, formation of the brachiocephalic vein: commonly posterior to the sternoclavicular joint although this may vary with study population (e.g., 3* superolateral or 3** lateral to the sternoclavicular joint); 4, formation of the superior vena cava: commonly posterior to the right first or second costal cartilage or first intercostal space, although this position may vary with study population (e.g., 4*, posterior to the first costal cartilage); 5, manubriosternal joint (level of horizontal sternal plane); 6, concavity of the aortic arch, typically located inferior to the sternal plane, level with the vertebral body of T5; 7, azygos vein joining the superior vena cava, about 1 cm inferior to the sternal plane, level with the vertebral body of T5; 8, tracheal bifurcation, about 3 cm inferior to the sternal plane, level with the vertebral bodies of T5 or T6; 9, bifurcation of the pulmonary trunk, about 2–3 cm inferior to the sternal plane, level with the vertebral body of T6. (Redrawn with permission from Mirjalili S, Hale S, Buckenham T et al 2012 A reappraisal of adult thoracic surface anatomy. Clin Anat 25:827–34.)

Breast

In females the base of the breast is relatively constant in position; it extends vertically from the second or third rib to the sixth rib, and the associated costal cartilage, and horizontally from the lateral sternal border medially to around the mid-axillary line laterally. The tail of the breast extends towards the axilla along the inferolateral border of pectoralis major (anterior axillary fold) (see Figs 53.22–53.23). In adult females, the location of the nipple is dependent on the size and shape of the breasts: the pigmented areola surrounding the nipple also varies in size. In adult males the nipple is often located either in the fourth intercostal space or over the fifth rib in the mid-clavicular line, approximately 20 cm from the jugular notch and 18 cm from the mid-clavicular point (Beckenstein et al 1996). The position of the nipple should never be relied upon for accurate landmarking.

Intrathoracic viscera

The sternal plane represents the inferior border of the superior mediastinum. It is typically described as marking the position of the tracheal bifurcation, the concavity of the aortic arch and the point where the azygos vein joins the superior vena cava. CT-based studies show these major structures are more commonly located below the sternal plane, from the level of the vertebral body of T5 to the vertebral body of T6 (Mirjalili et al 2012a) (**Fig. 52.7**; **Tables 52.1–52.2**): sometimes the aortic arch may be located in or above the sternal plane (Uzun et al 2016, Badshah et al 2017). The pulmonary trunk bifurcation is commonly located about 2–3 cm inferior to the level of the sternal plane, around the level of the vertebral body of T6 (Keough et al 2016, Pak et al 2016, Shen et al 2016, Uzun et al 2016); it may be located more often at a higher level in females.

Heart

The surface projection of the cardiac borders on to the anterior thoracic wall, between four landmark points, forms a trapezoid. The area of cardiac dullness may be mapped out via percussion. The description below applies to an average adult with a normal heart; this may be modified by age, sex, stature, ventilation, the position of the diaphragm, posture and pathology.

The superior cardiac border is marked by a curved line joining the second left costal cartilage to the third right costal cartilage (each point about 1 cm lateral to the sternum) (see Fig. 52.5), the latter point representing the junction between the superior vena cava and right atrium. In some study populations this junction is located more commonly at the right third costal cartilage or third intercostal space level (Keough et al 2016, Pak et al 2016), whereas in others it is located at the fourth to the fifth right costal cartilage level (Mirjalili et al 2012a, Shen et al 2016). The right border is represented by a curved line joining the point marking the junction of the superior vena cava and right atrium with the sixth right costal cartilage, usually 1–2 cm lateral to the sternal edge. The inferior cardiac border runs leftwards from the sixth right costal cartilage to the cardiac apex, located approximately 8–9 cm lateral to the midline, commonly in the left fifth intercostal space or level with the fifth or sixth ribs (Mirjalili et al 2012a, Keough et al 2016, Pak et al 2016, Shen et al 2016), close to the mid-clavicular line. Clinicians vary considerably when locating the mid-clavicular line (Naylor et al 1987); a measurement from the midline is therefore preferred. The cardiac apex beat is usually palpable near the cardiac apex and represents the most inferolateral point at which cardiac pulsation is visible and palpable.

The left cardiac border gently curves superomedially from the cardiac apex to meet the second left costal cartilage approximately 1 cm from the left sternal edge. An oblique line joining the sternal end of the third left and sixth right costal cartilages represents the anterior part of the coronary (atrioventricular) sulcus, which separates the right atrium from the right ventricle. The projections of the cardiac valves, although in different planes, are sited along or close to this line (see Fig. 57.19). The orifice of the pulmonary valve is represented by an approximately horizontal 2.5 cm long line that lies over the superior border of the left third costal cartilage and the corresponding part of the left side of the sternum. The pulmonary trunk is delineated by two parallel lines drawn perpendicular to the ends of the pulmonary valve line, commonly up to the level of the left second intercostal space. The orifice of the aortic valve is located inferior and to the right of the orifice of the pulmonary valve, and is represented by a line approximately 2.5 cm long running inferolaterally and to the right from the medial end of the left third intercostal space. Two parallel lines, drawn perpendicular to the ends

TABLE 52.1 The level of key thoracic viscera relative to the sternal plane and vertebrae

	Mean position relative to sternal plane (range, cm)	Most common position/level (frequency % of 153 subjects studied)	Sex differences (95% CI)
Tracheal bifurcation	−3.1 cm (0 to −7.5)	T6 (46%) (range, inferior half of vertebral body of T4 to inferior half of vertebral body of T7)	1.3 cm higher in females (0.8–1.8 cm: p <0.001)
Aortic arch concavity	−1.1 cm (+2.8 to −4.8)	T5 (55%) (range, inferior half of vertebral body of T3 to inferior half of vertebral body of T6)	0.6 cm higher in females (0.1–1.1 cm: p = 0.01)
Azygos vein joining the superior vena cava	−2 cm (+1.3 to −6.4)	T5 (49%) (range, superior half of vertebral body of T4 to superior half of vertebral body of T7)	0.7 cm higher in females (0.3–1.2 cm: p = 0.001)
Pulmonary trunk bifurcation	Not reported	Superior half of vertebral body of T6 (28%) (range, T4–T5 to T7–T8 intervertebral discs)	No significant effect

Measurements relative to the sternal plane are shown as + (superior to the plane) and − (inferior to the plane). Adapted from Mirjalili S, Hale S, Buckenham T et al 2012a A reappraisal of adult thoracic surface anatomy. Clin Anat 25:827–34.

TABLE 52.2 The level of key thoracic viscera relative to the sternal plane and vertebrae. A comparison of four study populations

	Study reference	Mean position relative to sternal plane (range, cm)	Most common position/level (frequency) (range)
Tracheal bifurcation	1	−3.1 cm (0 to −7.5)	T6 (46%) (range, inferior half of vertebral body of T4 to inferior half of vertebral body of T7)
	2	−2.3 cm (+2 to −6)	T5 (40%); T6 (35%) (range, superior half of vertebral body of T4 to superior half of vertebral body of T7)
	3	−1.4 cm	Not reported
	4	Not reported	T5 (45%) (range, T3–T4 intervertebral disc to vertebral body of T7)
Aortic arch concavity	1	−1.1 cm (+2.8 to −4.8)	T5 (55%) (range, inferior half of vertebral body of T3 to inferior half of vertebral body of T6)
	2	−0.4 cm (+2.7 to −3.2)	T5 (33%) (range, inferior half of T3 to superior half of vertebral body of T6)
	4	Not reported	T4 (58%) (range, vertebral bodies of T3–T5)
Azygos vein joining the superior vena cava	1	−2 cm (+1.3 to −6.4)	T5 (49%) (range, superior half of vertebral body of T4 to superior half of vertebral body of T7)
	2	−1.4 cm (+2.7 to −4.3)	T5 (47%) (range,T3–T4 to T6–T7 intervertebral discs)
	3	− 0.6 cm (Not reported)	Not reported
Pulmonary trunk bifurcation	1	Not reported	T6 (28%) (range, T4–T5 to T7–8 intervertebral discs)
	2	−2.8 cm (+0.9 to −5.6)	T6 (37%) (range, T4–T5 intervertebral disc to inferior half of vertebral body of T7)
	3	−2 cm (Not reported)	Not reported
	4	Not reported	T6 (42%) (range, vertebral bodies of T4–T8)

Measurements relative to the sternal plane are shown as + (superior to the plane) and − (inferior to the plane). Adapted from (Study 1) Mirjalili S, Hale S, Buckenham T et al 2012a A reappraisal of adult thoracic surface anatomy. Clin Anat 25:827–34; (Study 2) Shen XH, Su BY, Liu JJ et al 2016 A reappraisal of adult thoracic and abdominal surface anatomy via CT scan in Chinese population. Clin Anat 29:165–74; (Study 3) Keough N, Mirjalili SA, Suleman FE et al 2016 The thoracic surface anatomy of adult black South Africans: a reappraisal from CT scans. Clin Anat 29:1018–24; (Study 4) Badshah M, Soames R, Ibrahim M et al 2017 Surface anatomy of major anatomical landmarks of the neck in an adult population: a CT evaluation of vertebral level. Clin Anat 30:781–7.

of the aortic valve line and slanting superolaterally towards the right side of the manubriosternal joint, delineate the location of the ascending aorta.

The orifice of the tricuspid valve is represented by a line approximately 4 cm long that starts near the midline just inferior to the level of the right fourth costal cartilage and passes down and slightly to the right. The centre of this line is level with the middle of the right fourth intercostal space. The orifice of the mitral valve is level with the left half of the sternum opposite the left fourth costal cartilage and is represented by a line approximately 3 cm long and descending to the right.

The direction of blood flow through a valve carries the valve sound with it, consequently the sites of cardiac valve auscultation do not correspond to the surface anatomy of the valves. Common sites at which to auscultate using a stethoscope are: the sternal end of the left second intercostal space (pulmonary area); the sternal end of the right second intercostal space (aortic area); near the cardiac apex in the fifth intercostal space (mitral area); and adjacent to the left lower sternal border, at the level of the fifth intercostal space (tricuspid area) (see Fig. 57.19).

Great vessels

Starting at the aortic valve (see above), the ascending aorta curves anteriorly, superiorly and to the right, and becomes the aortic arch posterior to the right half of the manubrium or the superior part of the right side of the sternal body, at the level of the right second costal cartilage or second intercostal space, respectively. The aortic arch lies mainly posterior to the manubrium of the sternum (see Fig. 52.7). The concavity of the arch is located commonly up to 1 cm inferior to the sternal plane (range, 2.7 cm superior to 4.8 cm inferior), approximately level with the superior half of the vertebral body of T5 (Mirjalili et al 2012a, Shen et al 2016), although it may be located in or superior to the sternal plane (Uzun et al 2016, Badshah et al 2017) (see Tables 52.1, 52.2). It then arches to the left within the superior mediastinum and descends such that the distal part of the arch protrudes just to the left of the manubrium around the level of the first intercostal space, where it is visible on thoracic X-ray (aortic knuckle). The brachiocephalic trunk arises approximately posterior to the centre point (or just to its left) of the manubrium and ascends toward the right sternoclavicular joint. The left and right brachiocephalic veins are commonly formed posterior to the sternoclavicular joints (Mirjalili et al 2012a); the right brachiocephalic vein descends almost vertically, whereas the left brachiocephalic vein passes inferiorly and to the right, posterior to the manubrium and across the midline. The position of formation of the brachiocephalic veins varies between study populations; for example, the right brachiocephalic vein may form lateral to the sternoclavicular joint (Shen et al 2016) or both brachiocephalic veins may form superolateral to the sternoclavicular joints (Keough et al 2016). According to conventional descriptions, the superior vena cava forms posterior to the right first costal cartilage. The majority of *in vivo* CT-based studies show it forms posterior to the right second costal cartilage or first intercostal space and the associated part of the manubrium (Mirjalili et al 2012a, Pak et al 2016, Shen et al 2016). The level of formation may be higher in females, children and younger adults, and in some adult study populations (Keough et al 2016). The position of the junction of the superior vena cava and right atrium is described above with the heart. The azygos vein joins the superior vena cava up to 2 cm inferior to the sternal plane at the level of the inferior part of the vertebral body of T5 (Mirjalili et al 2012a, Keough et al 2016, Shen et al 2016).

Lungs and pleural reflections

Anteriorly, the apex of the lung sits posterior, and up to 2 cm superior, to the medial one-third of the clavicle; posteriorly, it lies level with the vertebral body of C7 or T1, or the C7–T1 intervertebral disc (see Fig. 52.5). The surface markings of both the apex, costal surface and vertebral part of the lung correspond to those of the parietal pleura. Conventionally, the surface projection of the lower border of the lung is represented by a curved line that crosses the mid-clavicular line at the sixth rib, the mid-axillary line at the eighth rib, and is just lateral to the vertebral column at the tenth rib. CT data show this border, at the end of tidal inspiration, is located at the fifth rib or the fifth intercostal space on the left, or the sixth intercostal space or the seventh rib on the right, in the mid-clavicular line, and adjacent to the vertebral body of T12 posteriorly (range: vertebral bodies of T9–L1) (Mirjalili et al 2012a, Pak et al 2016, Shen et al 2016). In full expiration, the lower margin of the lung may rise 5 cm above the line of reflection of the parietal pleural within the costodiaphragmatic recess and may fully leave the retrosternal costomediastinal recess.

Trachea and bronchi

The trachea originates at the level of the inferior border of the cricoid cartilage, which usually sits at the level of the vertebral body of C7 (range, vertebral bodies of C5–T1) (Mirjalili et al 2012b). It passes inferiorly in the midline and bifurcates a mean of 1.4–3.1 cm inferior to the sternal plane, often level with the vertebral bodies of T5–T6 (Mirjalili et al 2012a, Shen et al 2016, Uzun et al 2016, Badshah et al 2017). The tracheal bifurcation may be more superior in location in females (Keough et al 2016). The trachea is palpable immediately superior to the jugular notch either by rolling one finger over its anterior surface or by defining its lateral borders with two fingers. A shift to one side indicates that the mediastinum has either been pulled over to that side by loss of lung volume, or pushed over by a pneumothorax or large pleural effusion. The level at which the trachea bifurcates appears to move inferiorly, on average, by a mean of 3 mm per decade.

Pulmonary fissures

The superior and inferior lobes of the left and right lung are normally separated by the oblique fissure; this is marked by a line that curves around the thoracic wall, from the posterior part (neck) of the fourth rib (level with the spinous process of T3) on the left side and the posterior part of the fifth rib (level with the spinous process of T4) on the right side, to the sixth rib in the mid-axillary line on both sides (Heřmanová et al 2012) (see Figs 52.5–52.6, 54.3). Continuing along the same trajectory of descent, the line marking the oblique fissure passes towards the inferior border of the lung near to the mid-clavicular line (i.e. 7–8 cm lateral to the anterior median plane), where it terminates. The lowest margin of the lung in the mid-clavicular line is located at the sixth intercostal space or the seventh rib on the right or at the fifth rib or the fifth intercostal space on the left (Mirjalili et al 2012a). As a convenient approximation, posteriorly the oblique fissure follows the medial border of the scapula when the upper limb is in full abduction. The left oblique fissure may be slightly more vertical than the right. The surface position of the pulmonary fissures show little change during inspiration and expiration (Heřmanová et al 2012).

The horizontal fissure lies between the superior and middle lobes of the right lung (see Figs 52.5, 54.3; **Fig. 52.8**). It extends from the right fourth costal cartilage at the right sternal border to intersect the oblique fissure, approximately in its middle one third. The right middle lobe may be projected on to the thoracic wall using three points: the fourth costal cartilage at the right sternal border (sternocostal joint), the fifth rib in the mid-axillary line and the sixth intercostal space or seventh rib in the mid-clavicular line. The superior lobe, and middle lobe on the right, lie anterior to the oblique fissure and are best examined from the anterior and lateral wall of the thorax. The inferior lobes lie posteriorly and should be examined via the posterior thoracic wall, below the level of the oblique fissure. The arrangement of the pulmonary fissures can vary widely (Wantanabe 2016).

Pleural margin and reflections

Starting in the midline at the sternal angle, the anterior line of reflection of the parietal pleura may be traced superiorly along a curved line that diverges from the midline and passes superiorly and laterally to the apex of the lung (see Fig. 52.5). The line lies 3–4 cm above the anterior end of the first rib; the surface marking is posterior, and up to 2 cm superior, to the medial one third (sternal end) of the clavicle. The right and left parietal pleurae are in contact retrosternally in the midline from the level of the second to the fourth costal cartilages, at which point they often diverge (see Fig. 53.4). Above this level and posterior to the manubrium the diverging lines of pleural reflection border a triangular shaped region which is occupied by the thymus, or its remnants. The pleura on the right descends almost vertically, often remaining near the midline, to the xiphoid process, whereas the pleura on the left deviates laterally by 3–5 cm and then passes inferolaterally to cross the anterior end of the sixth rib. This deviation produces an area, roughly triangular in shape (the pericardial triangle), between the heart and the sternum that is free of pleura; a needle puncture of the pericardium may be performed at this site and on the left lateral sternal edge with minimal risk of damaging the pleura.

The reflection of the parietal pleura (costal and diaphragmatic parts), forming the inferior limit of the costodiaphragmatic recess, may be followed around the chest wall along a line sitting just superior to the costal attachment of the respiratory diaphragm (see Fig. 52.1); passing from the sixth costal cartilage (sternocostal joint) lateral to the sternum, to the eighth rib in the mid-clavicular line, the tenth rib in the mid-axillary line and the twelfth rib, or just below, adjacent to the vertebral column. Viewed from posteriorly, the medial edges of the pleurae pass along a line joining the transverse processes of T12 to T2 on either side. The diaphragmatic part of the parietal pleura is fused to fascia on the superior (thoracic) surface of the respiratory diaphragm, with which it can be landmarked.

Respiratory diaphragm

The highest point of the dome of the respiratory diaphragm is commonly located level with the fifth intercostal space or the sixth rib on the right and the sixth rib or the sixth intercostal space on the left: these levels vary widely, from the fourth rib to the seventh intercostal space, and in some cases may even sit inferior to the costal margin (Mirjalili et al 2012a, Shen et al 2016). Conventionally, the inferior vena cava, oesophagus and descending thoracic aorta are said to traverse the respiratory diaphragm at the levels of the vertebral bodies of T8, T10 and T12, respectively. However, CT-based studies have shown that at end tidal inspiration, the inferior vena cava, oesophagus and aorta more commonly pass through the respiratory diaphragm at the levels of the vertebral bodies of T11 (sometimes T10) and T12, respectively (Mirjalili et al 2012a, Pak et al 2016, Shen et al 2016, Badshah et al 2017).

Paediatric thoracic surface anatomy

CT-based assessment of paediatric thoracic surface anatomy in subjects from birth to 12 years of age has shown that some structures are similar in position to those seen in adults, whereas others change position with increasing age (Tarr et al 2016, Fischer et al 2017).

Wantanabe K 2016 Lungs. In: Tubbs RS, Shoja MM, Loukas M (eds) Bergman's Comprehensive Encyclopedia of Human Anatomic Variation, 2nd ed. Hoboken: Wiley Blackwell; Ch. 102, pp. 1216–33.
Describes morphological variations of normal and supernumerary lung fissures and pulmonary sequestrations. Supernumerary fissures (e.g. superior accessory fissure, medial basal fissure, left horizontal fissure and azygos fissure) do not exist normally and form supernumerary lobes. Pulmonary sequestrations (regions of lung parenchyma that do not have a normal connection to the tracheobronchial tree) have an anomalous systemic blood supply.

The sternal angle in the majority of children from birth to 12 years of age is located level with the vertebral body of T4 (range, inferior half of the vertebral body of T1 to the inferior half of the vertebral body of T5), and the sternal plane marks the level at which the azygos vein joins the superior vena cava. Relative to the sternal plane, the concavity of the aortic arch is located approximately 0–5 mm inferior and the bifurcation of the trachea and pulmonary artery are located approximately 10–15 mm inferior. The cardiac apex is located close to the mid-clavicular line from birth to 12 years of age; specifically, it is located approximately 4 cm (0–1 year of age), 5 cm (1–4 years of age) and 6 cm (4–12 years of age) to the left of the midline. The cardiac apex is typically located posterior to the fifth intercostal space (range, fourth intercostal space to the sixth rib) from birth to 4 years of age and posterior to the fourth intercostal space or the fifth rib from 4 to 12 years of age. The highest (most superior) part of the dome of the respiratory diaphragm is commonly located at the level of the fifth rib or the fifth intercostal space on the right and the sixth rib or the fifth intercostal space on the left; the left dome is slightly lower than the right, and both domes are flatter in children compared to adults. On average, the respiratory diaphragm is traversed by the inferior vena cava, oesophagus and descending thoracic aorta at the levels of the vertebral bodies of T9, T10 and T11, respectively, although some variability occurs. The apex of the lung is commonly situated posterior to the medial one third of the clavicle across all age groups, although it is sometimes located more laterally, i.e. posterior to the middle one third of the clavicle, in younger children.

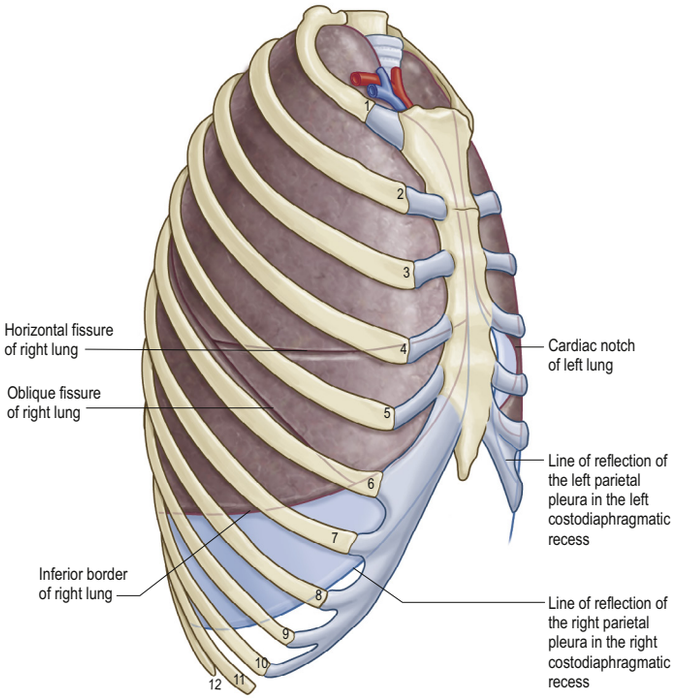

Fig. 52.8 The relations of the pleura, lungs and pulmonary fissures to the thoracic cage (right anterolateral view).

The right and left brachiocephalic veins are formed posterior to the ipsilateral sternal head of the clavicle in the majority of children from birth to 11 years of age (Tarr et al 2016). The vertebral level of the formation of the superior vena cava and the junction between the superior vena cava and right atrium are variable in position (Fischer et al 2017). The superior vena cava forms most commonly posterior to the second right costal cartilage in children from 0–3 years of age, and moves superiorly to sit posterior to the right first costal cartilage or right first intercostal space during subsequent growth. The junction between the superior vena cava and right atrium is commonly located posterior to the right fourth costal cartilage in children from birth to 3 years of age, moving superiorly to sit posterior to the right third costal cartilage or right third intercostal space during subsequent growth in childhood. In adults the junction is commonly located posterior to the right fourth costal cartilage.

Supernumerary fissures (e.g. superior accessory fissure, medial basal fissure, left horizontal fissure and azygos fissure) do not exist normally and form supernumerary lobes. Pulmonary sequestrations (regions of lung parenchyma that do not have a normal connection to the tracheobronchial tree) have an anomalous systemic blood supply.

Chapter 53 Chest wall and breast

The chest wall surrounds the thoracic cavity. It is formed by: an osseocartilaginous frame consisting normally of 12 pairs of ribs, which articulate with the 12 thoracic vertebrae posteriorly and (except for the last two or three pairs of ribs) with the sternum anteriorly, via their costal cartilages; intrinsic muscles and muscles that connect the chest wall with the upper limb and the vertebral column; overlying skin, fasciae and breast tissue; and numerous blood and lymphatic vessels and nerves that supply the components of the musculoskeletal frame.

SKIN AND FASCIA

Skin

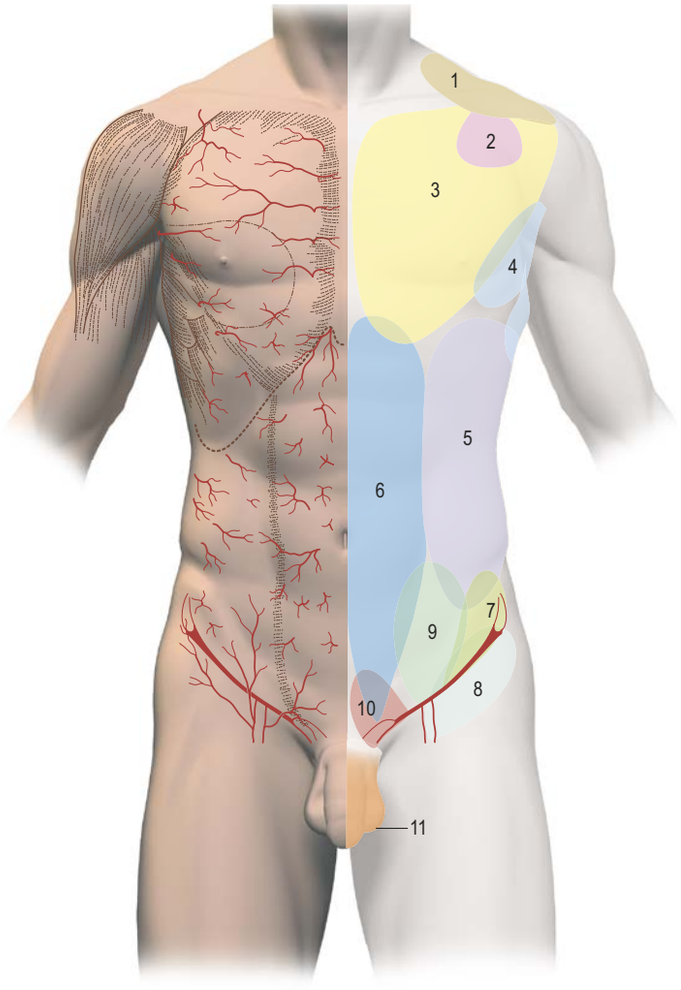
Vascular supply

Arteries

The skin of the thorax is supplied by a combination of direct cutaneous vessels and musculocutaneous perforators that reach the skin primarily via the intercostal muscles, pectoralis major, latissimus dorsi and trapezius. The major contributing vessels are branches from the thoracoacromial, lateral thoracic, superficial thoracic and internal thoracic, anterior and posterior intercostal, thoracodorsal, transverse cervical, dorsal scapular and circumflex scapular arteries (**Figs 53.1–53.2**; see Fig. 46.4).

The anterior aspect of the thoracic skin is supplied by branches of the thoraco-acromial artery, the internal thoracic arteries, perforating branches from the intercostal arteries and branches from the lateral thoracic and superficial thoracic arteries. The thoraco-acromial artery supplies the skin primarily via musculocutaneous perforators from its pectoral branch that reach the skin through pectoralis major. Direct cutaneous branches also arise from the acromial and deltoid branches. The internal thoracic artery sends direct perforating branches to the skin covering the first (superior) six intercostal spaces and associated costal cartilages, accompanied by the cutaneous branches of the anterior intercostal nerves. The branches reach the skin after passing through pectoralis major and travelling laterally in the subcutaneous fat as direct cutaneous vessels. The right internal thoracic artery is normally larger than the left and the perforator in the second intercostal space is usually the largest. The lateral aspect of the thoracic skin is supplied by the lateral thoracic and superficial thoracic arteries, lateral cutaneous branches of the intercostal arteries, and musculocutaneous branches of the thoracodorsal artery (via latissimus dorsi). The lateral thoracic artery gives off direct cutaneous branches to the lateral chest wall in addition to musculocutaneous branches that pass through pectoralis major. The posterior aspect of the thoracic skin is supplied by the medial and lateral dorsal cutaneous branches of the posterior intercostal arteries (via erector spinae and latissimus dorsi) (see Fig. 53.18); musculocutaneous perforating branches from the superficial cervical, transverse cervical and dorsal scapular arteries (via trapezius); musculocutaneous perforating branches from the thoracodorsal artery and the intercostal arteries (via latissimus dorsi); and direct cutaneous branches from the circumflex scapular artery.

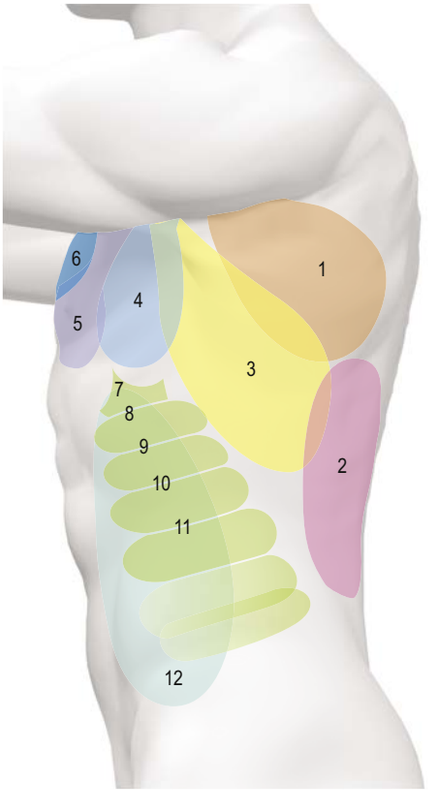
Veins



The intercostal veins accompany the similarly named arteries in the intercostal spaces (see Fig. 52.4). The small anterior intercostal veins are tributaries of the musculophrenic and internal thoracic veins, the latter draining into the ipsilateral brachiocephalic vein. The posterior intercostal veins drain directly or indirectly into the azygos vein on the right and the hemiazygos or accessory hemiazygos veins on the left. The azygos veins exhibit great variation in their origin, course, tributaries, anastomoses and termination (Ch. 56).

Lymphatic drainage

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (see Figs 53.22, 53.24, 46.5 and Ch. 49). Lymph vessels from the deeper tissues of the thoracic walls drain mainly to the parasternal, intercostal and diaphragmatic lymph nodes.



Innervation

The skin of the thorax is supplied by cutaneous branches of cervical and thoracic spinal nerves in consecutive overlapping curved zones; the upper zones are almost horizontal and the lower curve obliquely inferiorly

around the thoracic wall as they pass to the anterior midline (median plane). On the upper anterior aspect of the thorax, the areas innervated by the ventral rami of the third and fourth cervical nerves adjoin those innervated by the ventral rami of the second (and sometimes first) thoracic spinal nerves because the intervening thoracic spinal nerves are distributed to the upper limb (Ladak et al 2014) (**Fig. 53.3**). There is a similar but less extensive 'gap' in innervation on the upper posterior thoracic wall (see Fig. 47.8). Most of the skin covering the posterior thorax is supplied by the dorsal rami of the thoracic spinal nerves.

The ventral rami of the first to the eleventh thoracic spinal nerves pass into the correspondingly numbered intercostal space, give off a lateral cutaneous branch distal to the angle of the rib (that then divides into anterior and posterior rami) and terminate near the sternum as an anterior cutaneous branch (that divides into medial and lateral branches) (see Fig. 53.21).

Branches of the supraclavicular nerves, which originate from the ventral rami of the third and fourth cervical spinal nerves, supply the skin in the upper pectoral region. Most of the ventral ramus of the first thoracic spinal nerve joins the brachial plexus, apart from a small inferior branch that becomes the first intercostal nerve. The lateral cutaneous branch of the second intercostal nerve (intercostobrachial nerve) supplies the skin of the axilla, lateral chest and medial arm. It courses as either a single trunk or in a bifurcating pattern (Henry et al 2017): its variability puts it at increased risk of injury during breast-related surgery, potentially resulting in postoperative pain and paraesthesia. The ventral rami of the seventh to eleventh thoracic spinal nerves supply the skin of the thoracic wall as they pass anteriorly and inferiorly; they continue beyond the costal cartilages to supply the skin and subcutaneous tissues of the abdominal wall (see Fig. 60.5). The skin of the abdomen at the level of the umbilicus is supplied by the ventral ramus of the tenth thoracic spinal nerve. The subcostal nerve (ventral ramus of twelfth thoracic spinal nerve) follows the inferior border of the twelfth rib and supplies the skin of the lower abdominal wall.

Fascia

Superficial fascia

The superficial fascia consists primarily of fat and is only loosely attached to the skin, an arrangement that allows movement of the underlying structures. Small blood vessels and nerves perforate the superficial fascia to supply the skin. The breast lies within the superficial fascia, apart from a superolateral extension that pierces the deep fascia to form the axillary process (tail, tail of Spence) in the female.

Deep fascia

Clavipectoral fascia

The clavipectoral fascia is the cranial continuation of the deep lamina of the pectoral fascia and the medial continuation of the parietal layer of the subscapular bursal fascia. It extends between the clavicle and pectoralis minor, surrounds subclavius and extends medially to the first rib. It is described in detail in Chapter 49.

BONE AND CARTILAGE

The 12 thoracic vertebrae and associated intervertebral discs are described in detail in Chapter 46.

Sternum

The sternum is an elongated, flattened bone that forms the middle portion of the anterior thoracic wall. It consists of three parts, namely (from cranial to caudal): manubrium, body and xiphoid process (**Figs 53.4–53.5**) and articulates with the clavicles at the sternoclavicular

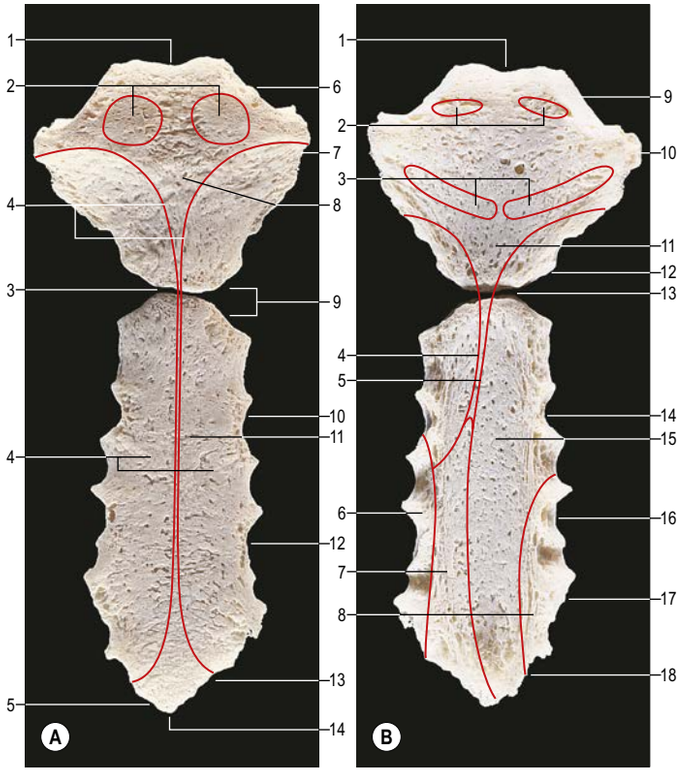

Fig. 53.4 The sternum, showing muscle attachments (red outline). **A**, Anterior aspect. Key: 1, jugular (suprasternal) notch; 2, attachment for sternocleidomastoid; 3, sternal angle and manubriosternal joint; 4, attachment for pectoralis major; 5, seventh costal notch; 6, clavicular notch; 7, first costal notch; 8, manubrium; 9, second costal notch; 10, third costal notch; 11, body of sternum; 12, fourth costal notch; 13, sixth costal notch; 14, xiphisternal joint. **B**, Posterior aspect. Fig. 53.5 The sternum, left lateral aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

joints and with the cartilages of the first seven pairs of ribs at the costosternal joints. Until puberty, the body consists of four intersegmental sternebrae. The average length of the adult sternum is 16.5 cm in males and 15.0 cm in females: the ratio between the length of the sternal manubrium and body differs between males and females. Sternal growth may continue beyond the third decade and possibly throughout life.

The sternum projects (slopes) anteroinferiorly from the jugular notch. Viewed as a whole, and due to the angulation of the manubriosternal joint, the majority of the anterior surface of the sternum appears vertically convex and the posterior surface appears vertically concave. Inferiorly and proximal to the xiphoid process, the shape transitions to become vertically concave on both anterior and posterior surfaces. The geometry of the individual parts of the sternum vary with surface and region (Lindner et al 2017, Chakravarthi et al 2018). The manubrium is the broadest part, at its joints (articulations) with the first costal cartilages. It narrows at the manubriosternal joint, gradually widens to its joints with the fifth costal cartilages, and then narrows to the xiphoid process. The sternum contains highly vascular trabecular bone enclosed by a compact layer that is thickest in the manubrium between the clavicular notches. Centrally, the bone is relatively lightly constructed; the trabeculae are thicker and wider laterally. The medullary cavity contains haematopoietic bone marrow. The sternum and its component parts may be variable in morphology, joint alignment and fusion, and can contain clefts or foramen (Tubbs and Wantanabe 2016).

Manubrium of sternum

The jugular notch (superior border) of the manubrium of the sternum commonly aligns with the bodies of the second to third thoracic vertebrae, and the inferior border with the bodies of the fourth to fifth thoracic vertebrae at the manubriosternal joint. It has an average length of 5.1 cm and forms up to 35% of the total sternal length. It has a somewhat quadrangular shape, being broad and thick superiorly and narrowing inferiorly to its junction with the sternal body. The anterior and posterior surfaces are smooth in appearance. The anterior surface is transversely convex and vertically concave in shape, whereas the posterior surface is both transversely and vertically concave. The superior border is thick in the sagittal plane and bears the jugular (suprasternal) notch in the midline between the left and right clavicular notches. The clavicular notches are directed superiorly, posteriorly and laterally for articulation with the sternal articular surface of the clavicles. Fibres of the interclavicular ligament attach to the jugular notch. The inferior border is oval and rough and carries a thin layer of hyaline cartilage for articulation with the sternal body. The lateral borders are marked at the widest part of the manubrium by a depression for the first costal cartilage (first costal notch), and, inferior to this depression, by a small articular demifacet that articulates with part of the second costal cartilage. The narrow curved lateral border descends medially between these facets. There is little accessory movement at the manubriosternal joint, although pressure on either the sternal body or manubrium close to the joint will produce slight angling of the two sections, particularly in younger individuals.

Unlike all the other sternocostal joints, the joint between the manubrium and the first costal cartilage is a fibrous synarthrosis. It lies about 1 cm below and 1 cm lateral to the sternal (medial) end of the clavicle and is difficult to palpate.

Body of sternum

The body of the sternum is located level with the bodies of the fourth or fifth to the ninth thoracic vertebrae. It is longer, narrower and thinner than the manubrium, and is broadest at its junction with the fifth costal cartilages. The anterior surface is vertically convex and transversely varies from convex to concave depending upon region. It faces slightly superiorly and usually bears three variable transverse ridges that mark the levels of fusion of its four sternebrae (see Fig. 53.6B). Sternal foramina, of varying size, form and completeness, may occur in up to 10% of the population in the body of the sternum (Chakravarthi et al 2018). The posterior surface is vertically concave and transversely convex in shape and bears three transverse lines. The oval superior border articulates with the inferior border of the manubrium at the level of the

manubriosternal joint (sternal angle) that commonly lies horizontally level with the inferior border of the body of the fourth thoracic vertebra, T4–T5 intervertebral disc or body of the fifth thoracic vertebra (the sternal plane), and is marked anteriorly and posteriorly by a transverse ridge and groove, respectively.

On each lateral border, at its superior angle and lateral to the manubriosternal joint, a small notch articulates with part of the second costal cartilage (see Figs 53.4–53.5). Inferiorly, four costal notches articulate with the third to sixth costal cartilages. The inferior angle bears a small facet, which, together with the xiphoid process, articulates with the seventh costal cartilage. Between these articular depressions are a series of curved bony edges that form the anterior limits of the associated intercostal spaces. The sternal body narrows from the fifth costal notch inferiorly to the xiphisternal joint, where it articulates with the xiphoid process.

Xiphoid process (xiphisternum)

The xiphoid process joins the inferior part of the sternal body at the xiphisternal joint, commonly level with the body of the ninth thoracic vertebra. It is the smallest and most variable part of the sternum, and may be broad and thin, pointed, bifid, triangular, perforated or curved (see Fig. 53.8). It sits in the epigastric region of the abdomen, therefore when elongated and curved anteriorly it may be mistaken for an epigastric mass, and when unusually long with a sharp bifid end it can damage the liver. The xiphoid process is cartilaginous during early life and is commonly ossified in adults. Costal notches located on the superolateral border, lateral to the xiphisternal joint, articulate with part of the seventh costal cartilages (see Fig. 53.5).

Muscle attachments The sternocostal head of pectoralis major and sternal head of sternocleidomastoid are attached to the anterior surface of the manubrium (see Fig. 53.4). Sternothyroid is attached to the posterior surface of the manubrium, opposite or just inferior to the first costal notch, and the most medial fibres of sternohyoid are attached superior to sternothyroid and level with the clavicular notch. The articular capsules of the sternocostal joints and sternocostal fibres of pectoralis major are attached to the anterior surface of the body of the sternum, and transversus thoracis (sternocostalis) is attached to the posterior surface. The external intercostal membranes are attached to the lateral borders of the body of the sternum between the costal notches. The most medial fibres of rectus abdominis and the aponeuroses of external and internal abdominal oblique are attached to the anterior surface of the xiphoid process. The linea alba is attached to its inferior end, and the aponeuroses of internal abdominal oblique and transversus abdominis are attached to its non-articular borders. Slips of the respiratory diaphragm are attached to its posterior surface, and posteriorly it is related to the liver.

Vascular supply The internal thoracic artery provides the main blood supply for the sternum via anterior and posterior networks of perforating arteries that directly penetrate the sternum at the level of each intercostal space. These networks are particularly well developed posteriorly and at the level of the fourth and fifth intercostal spaces.

The venous network is less developed. It is formed mainly by an inframedullary network of sinuses in the bone that drain via transcortical veins either into the peripheral sternal networks or the internal thoracic vein.

Innervation The manubrium is innervated by the anterior branch of the supraclavicular nerve and the anterior cutaneous branch of the first intercostal nerve, whereas the body of the sternum is innervated largely by anterior branches of the second to sixth intercostal nerves. The anterior (sternal) branch of the phrenic nerve arises within or immediately inferior to respiratory diaphragm and runs anteromedially to innervate the lower part of the body of the sternum and xiphoid process.

Ossification The sternum is formed by fusion of two cartilaginous sternal plates flanking the median plane. The arrangement and number of centres of ossification vary according to the level of completeness and time of fusion of the sternal plates, and according to the final width of the adult bone. Incomplete fusion leaves a sternal foramen (Tubbs and Wantanabe 2016). The manubrium is ossified from one to three centres that appear during postmenstrual weeks 17–20. The sternal body is formed from four sternebrae. The first and second sternebrae usually ossify from single centres that appear at about the same time (**Fig. 53.6A**). Centres in the third and fourth sternebrae are commonly paired, and appear during postmenstrual weeks 17–20 and 21–24, respectively; one of either pair may be delayed until after postmenstrual week 28, and the fourth sternebral centre may be absent. The xiphoid process begins to ossify in the third year or even later. In some sterna, all centres are single and median; in others, the manubrial centre is single and the sternebral centres are paired, symmetric or asymmetric. Union between the sternebral centres begins at puberty and proceeds from inferior to superior; by 25 years of age, they are all united (**Fig. 53.6B**).

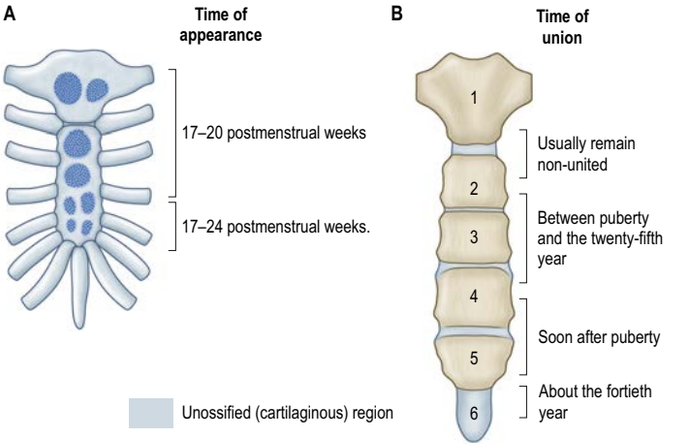

Fig. 53.6 The ossification of the sternum. **A**, Before birth. **B**, After birth.

Suprasternal ossicles, paired or single, sometimes occur. They may fuse to the manubrium or articulate posteriorly at the lateral border of the jugular notch. When well formed, they are pyramidal with an articular base. The ossicles are cartilaginous at birth and ossify during adolescence.

Pectus excavatum and carinatum

Available with the *Gray's Anatomy* e-book

Clavicle

The clavicle is described in Chapter 49.

Ribs

The ribs are 12 pairs of curved bony arches with elastic properties (as measured by their stress–strain relationship) (**Fig. 53.8**). Each consists of a highly vascular trabecular bone containing large amounts of red marrow, enclosed in a thin layer of compact bone. The ribs articulate posteriorly with the thoracic vertebral column and form the greater part of the thoracic skeleton. Their number may be increased by cervical or lumbar ribs or reduced by the absence of the twelfth pair. The first seven 'true' ribs connect directly to the costal notches of the sternum by costal cartilages, whilst the remaining inferior five 'false' ribs either join the costal cartilage (ribs 8–10) located immediately superior, or 'float' free at their anterior ends as relatively small and delicate structures tipped with cartilage (ribs 11 and 12). The tenth rib may also float; the incidence varies from 35% to 70%, depending on ancestry. The ribs change in their width, height and angulation with growth and/or age (Openshaw et al 1984, Joshua et al 2014, Casha et al 2015).

The ribs are separated by the intercostal spaces, which are deeper anteriorly and between the more superiorly located ribs. The latter are less oblique than the inferiorly located ribs; obliquity is maximal at the ninth rib. The ribs increase in length up to the seventh and thereafter decrease in length. In general, they decrease in height or breadth from superior to inferior; the upper ten are at their highest/broadest at their anterior ends. The first two and the last three ribs have special features, whereas the remainder show a typical form.

Typical rib

A typical rib has a shaft with anterior and posterior ends (**Fig. 53.9**). The anterior costal end has a small concave depression for articulation with the lateral end of its cartilage. The shaft has an external convexity and is grooved internally near its inferior border, which is sharp, whereas its superior border is rounded. The posterior vertebral end has a head, neck and tubercle. The head presents two articular facets, separated by a transversely oriented crest. The inferior and larger facet articulates with the body of the correspondingly numbered vertebra, its crest attaches to the superiorly located intervertebral disc and the smaller superior facet articulates with the body of the vertebra above. The neck

Pectus excavatum is the most common congenital deformity of the anterior thoracic wall and is more common in males than females. It is a depression of the sternum and costal cartilage that is sometimes referred to as cobbler's chest, sunken chest, the crevasse or funnel chest. The lower (inferior) costal cartilages and the body of the sternum are depressed and there is some asymmetric curving of the ribs posteriorly. There is often an abnormal posture with dorsal lordosis, sometimes with developing scoliosis. The deformity is found either at birth (1 in 400 live births) or early in life; in the majority of cases, the condition is visible by 1 year of age but may not develop until puberty. The aetiology is unknown but some cases are associated with connective tissue diseases, such as Marfan syndrome.

The clinical significance of pectus excavatum may vary considerably (**Fig. 53.7**). Severe defects can lead to cardiopulmonary dysfunction, including changes in cardiac anatomy due to compression of the right ventricle and left atrium between the sternum and thoracic vertebral column. Almost all patients will have some degree of cosmetic concern, while back and chest pain may occur. Evaluation of the deformity demands careful symptom assessment in addition to baseline radiological investigations (chest radiograph and computed tomography (CT)). Where there are physiological restrictions, lung function tests, electrocardiograms (ECGs), echocardiograms and MR-based strain imaging form part of the assessment before specialist clinicians can determine the safety of surgical intervention (Lollert et al 2018). A classification system based on morphology using CT scanning has been proposed (Park et al 2004) and is useful for standardizing the results of surgical correction of the different subtypes.

Mild defects causing aesthetic concerns may be improved with customized silicone implants (Masson et al 1970) or with soft tissue reconstructive procedures (Raab et al 2009), to camouflage the concavity. More severe defects often require correction of the underlying skeletal deformity. Several techniques have been described. Open resection procedures were pioneered by Ravitch in the 1950s and subsequently minimally invasive techniques have gained in popularity (Ravitch 1955, Nuss et al 1988). With the development of three-dimensional (3D) printers, simulated surgeries can now be performed using patient-specific 3D chest wall models, allowing higher precision in bar placement and the number required for the best surgical outcome (Matsuo et al 2018). Additionally, 3D printing of titanium plate and polyethylene implants has allowed for advances in patient implant customization and an increase in optimal surgical outcomes (Lin et al 2018).

Pectus carinatum, often called 'pigeon chest', is an overgrowth of cartilage that causes the sternum to protrude forwards. It is less common than pectus excavatum, accounting for 5–20% of anterior thoracic wall deformities: a quarter of cases are familial. The condition may occur as a solitary congenital anomaly or in association with other genetic disorders. Although present in early childhood, pectus carinatum usually progresses during adolescence and then remains unchanged throughout adulthood. In recent years treatment has gravitated towards minimally invasive or noninvasive methods of applying external pressure to the anterior chest wall to depress the sternum (Wells and Coonar 2018). Pectus carinatum occurs in three different ways, most commonly in pubertal males aged 11–14 years undergoing a growth spurt. Some parents report that their child's pectus seemingly popped up 'overnight'. The second most common occurrence is from birth, when it is evident in newborns as a rounded chest, becoming more prominent as the child reaches 2 or 3 years old. The least common occurrence is as an acquired condition after open heart surgery, when healing has been aberrant. Pectus carinatum may be associated with Turner, Marfan, Ehlers–Danlos, Morquio's, Noonan's, Sly's or multiple lentigines syndromes, trisomies 18 or 21, homocystinuria, osteogenesis imperfecta or scoliosis.

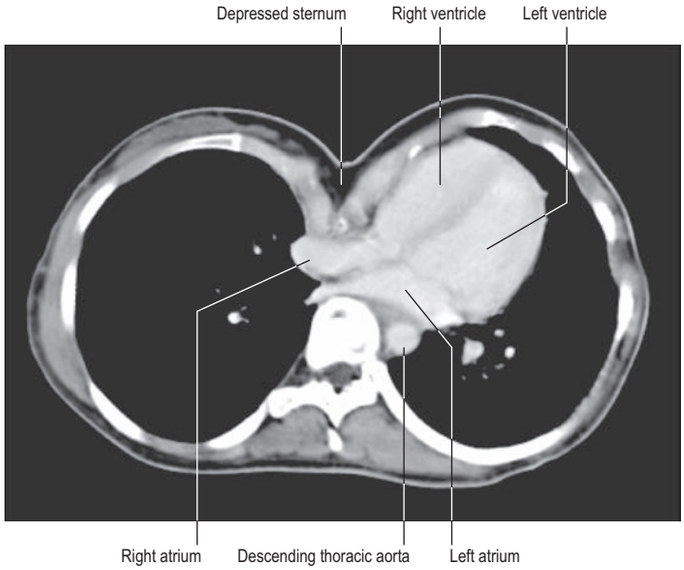

Fig. 53.7 Pectus excavatum (axial CT image), showing displacement and compression of mediastinal structures.

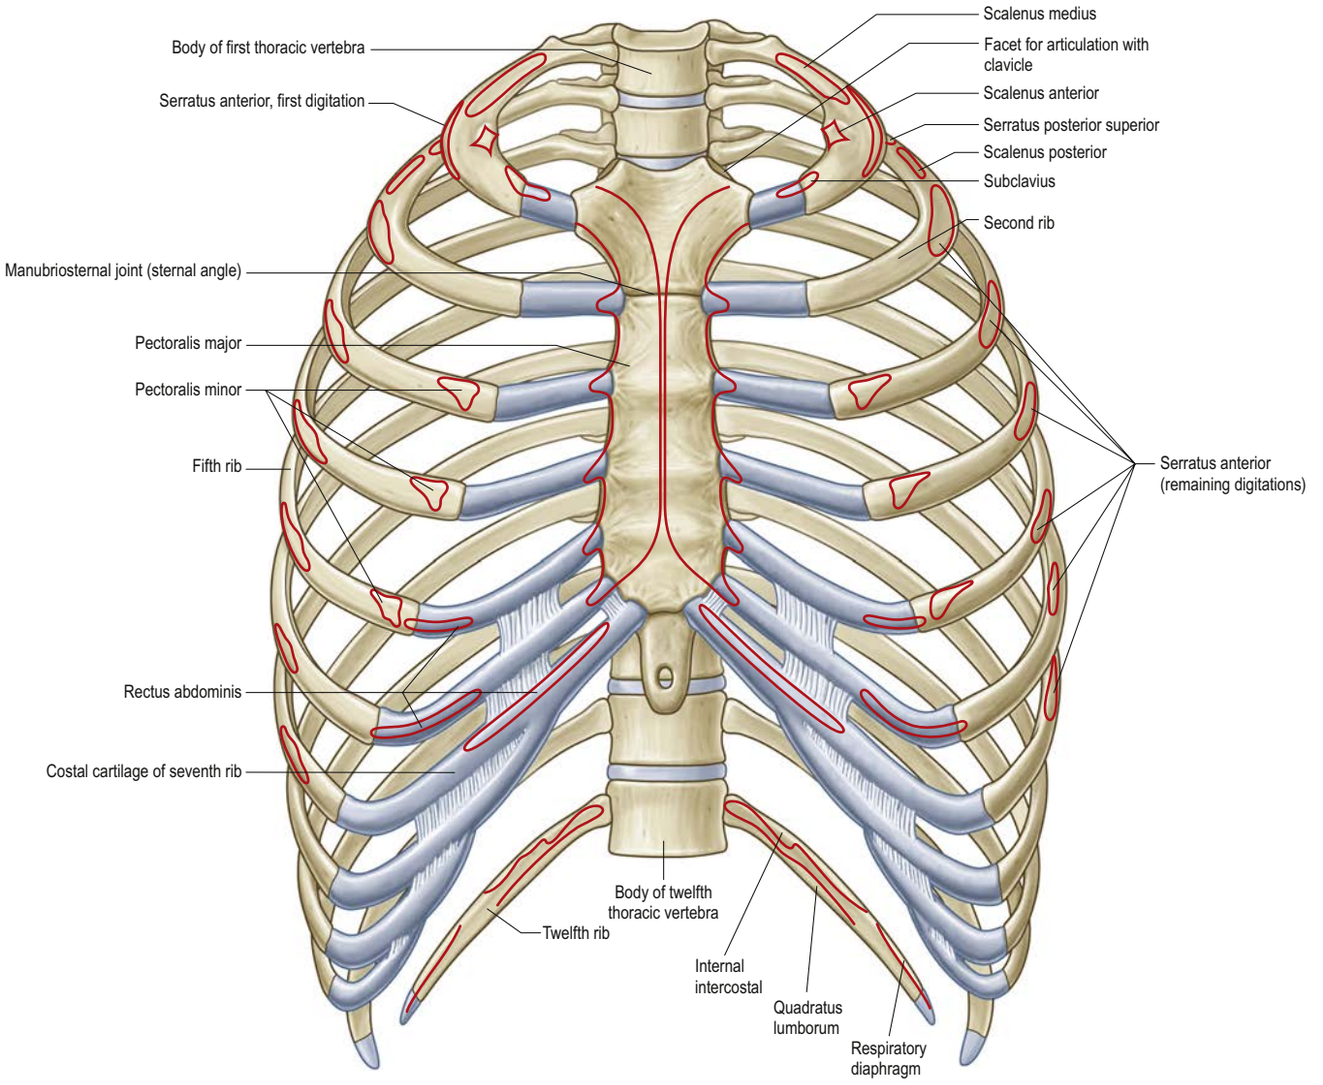

Fig. 53.8 The skeleton of the thorax, anterior aspect, showing muscle attachments (red outline).

is the flat part distal to the head and anterior to the transverse process of the correspondingly numbered thoracic vertebra. It is oblique and faces anterosuperiorly. Its posteroinferior surface is rough and pierced by foramina. Its superior border is sharp and formed by the crest of the neck, and its inferior border is rounded. The tubercle is located posteriorly between the neck and angle of the rib and is more prominent in the superiorly located ribs. It is divided into a medial articular area that bears a small oval facet for the transverse process of the correspondingly numbered thoracic vertebra, and a roughened lateral non-articular area for ligamentous attachment. The shaft is thin and flat, with external and internal surfaces, and superior and inferior borders. It is curved, bent at the angle of the rib, about 5–6 cm lateral to the tubercle, and twisted about its long axis. The smooth internal surface of the rib is marked by the costal groove, bounded inferiorly by the inferior border and which houses the intercostal neurovascular bundle (see Fig. 53.17). The superior border of the costal groove continues posteriorly as the inferior border of the neck of the rib, but terminates anteriorly at the junction of the middle and anterior thirds of the shaft: the groove is often absent anterior to this junction

Attachments and relations A radiate ligament is attached along the anterior border of the head of the rib and an intra-articular ligament is attached along its crest (see Fig. 53.11). The anterior surface of the head is related to costal parietal pleura and, in the more inferior ribs, to the sympathetic trunk and ganglia. The anterior surface of the neck of the rib is divided by a faint transverse ridge, for attachment of the internal intercostal membrane, and is continuous with the inner lip of the superior border of the shaft. The area superior to the ridge, which is more or less triangular, is separated from the membrane by fatty tissue and the area inferior to the ridge is smooth and covered by costal parietal pleura. The posterior surface of the neck gives attachment to the costotransverse ligament and contains vascular foramina. The superior costotransverse ligament is attached to the crest on the neck of the rib that extends laterally into the outer lip of the superior border of the shaft. The rounded inferior border of the neck of the rib continues laterally into the superior border of the costal groove, and gives attachment to the internal intercostal membrane. The articular facet on the tubercles of the first to the sixth ribs is convex and faces posteromedially. In the subsequent three or four ribs it is almost flat, and faces inferiorly, posteriorly and slightly medially. The lateral costotransverse ligament is attached to the non-articular area.

The ridge on the external surface of the shaft (near to the angle of the rib) gives attachment to an upward continuation of the thoracolumbar fascia and lateral fibres of iliocostalis thoracis. From the second to the tenth ribs, the distance between angle and tubercle of the rib increases. Medial to the angle, the external surface gives attachment to levator costae and is covered by erector spinae. Near the sternal end of this surface, an indistinct oblique line, the anterior 'angle' of the rib, separates the attachments of external abdominal oblique and serratus anterior (or latissimus dorsi, in the case of the ninth and tenth ribs). The internal intercostal muscle is attached to the costal groove on the internal surface, and separates the intercostal neurovascular bundle from the bone of the rib. At its vertebral end, the costal groove faces inferiorly. The shaft of the rib broadens posteriorly near the angle, and the costal groove reaches its internal surface. The innermost intercostal muscle is attached to the superior border of the costal groove; this attachment occasionally extends to the anterior quarter of the rib. The external intercostal muscle is attached to the sharp inferior border of the rib. The superior border of the rib has two lips posteriorly, an inner and an outer lip. The internal intercostal muscles and the innermost intercostal muscles are attached to the inner lip and the external intercostal muscle is attached to the outer lip.

Vascular supply and innervation Typical ribs receive their blood supply anteriorly via branches from the internal thoracic artery (first six intercostal spaces) or musculophrenic artery (subsequent spaces), and

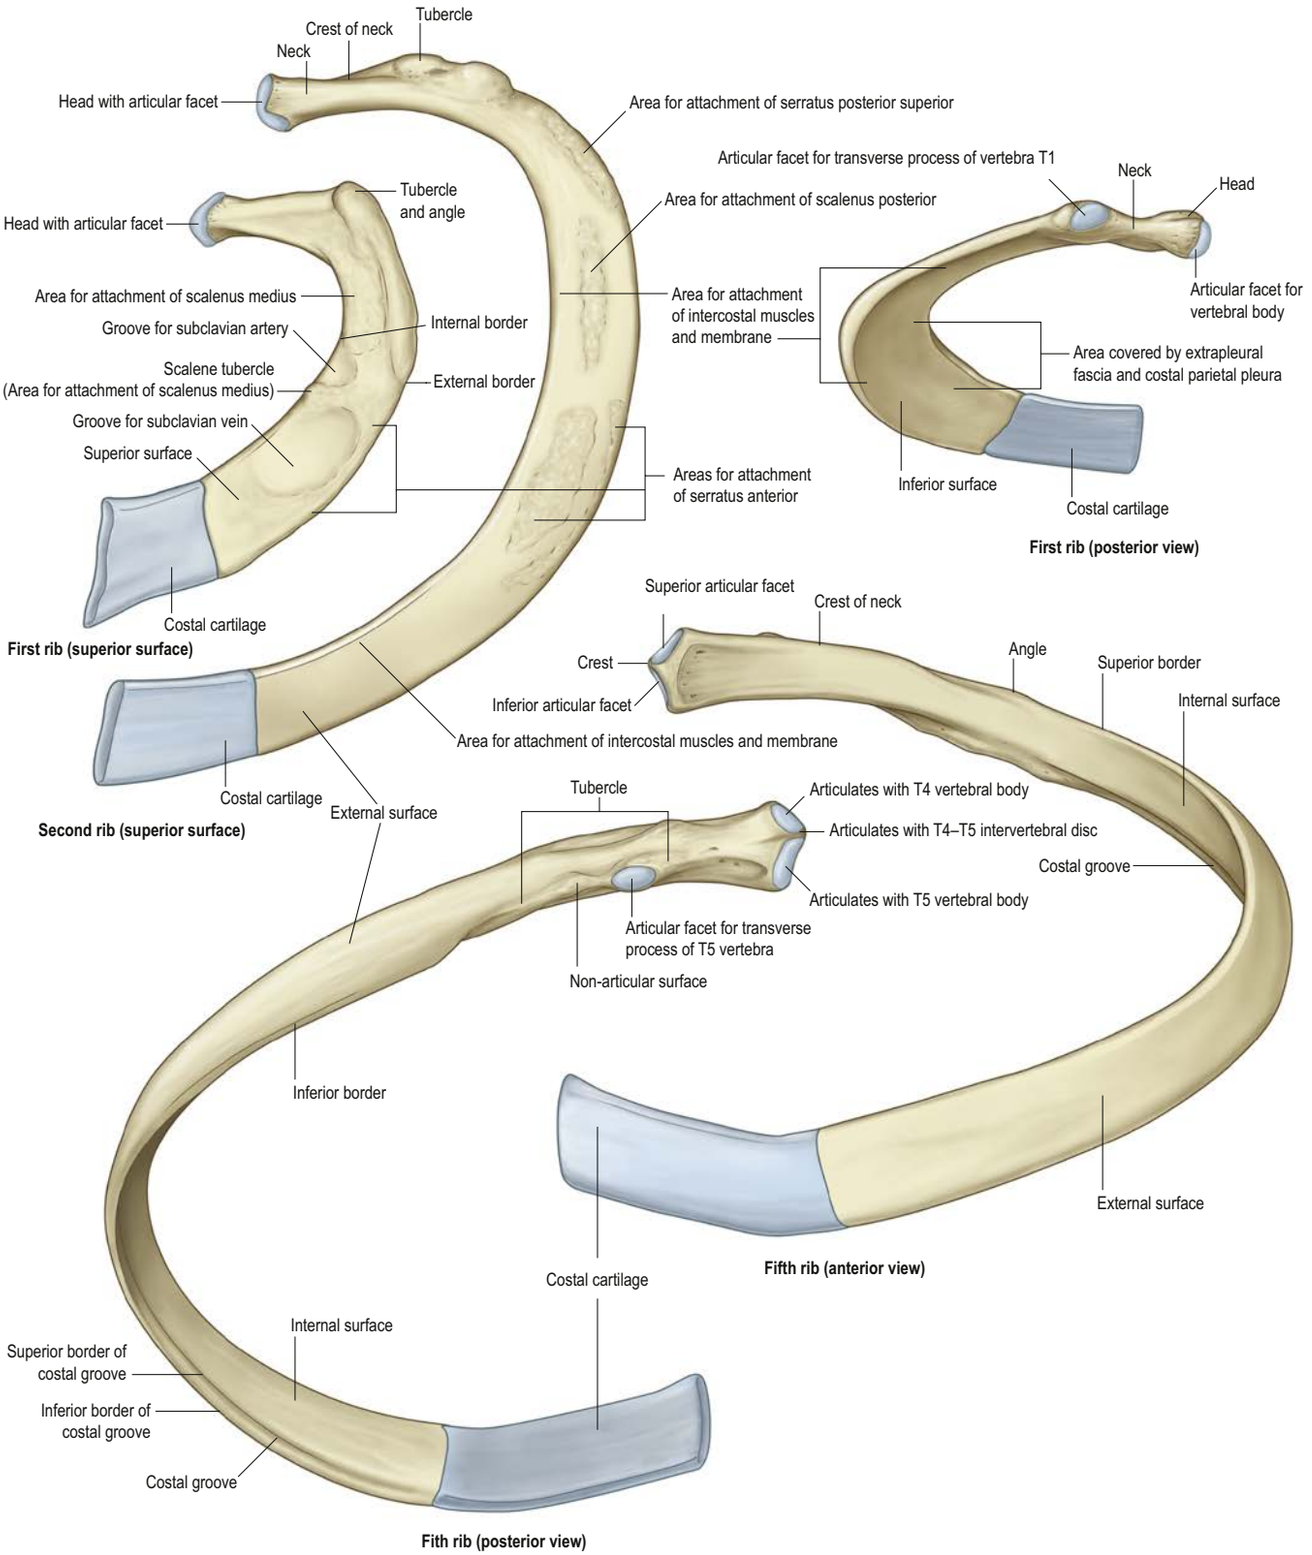

Fig. 53.9 Surface features of the left first, second and fifth rib. (With permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2015.)

posteriorly from posterior intercostal arteries derived directly from the descending thoracic aorta. Venous drainage is into the corresponding intercostal vein and subsequently into the azygos system or the brachiocephalic vein (see Fig. 52.4). Typical ribs are innervated segmentally by branches from their corresponding intercostal nerves.

Variant and accessory ribs

Ribs may be asymmetric, absent, fused, intrathoracic or accessory (Tubbs and Wantanabe 2016). Accessory (supernumerary) ribs may be in a cervical or lumbar location, lumbar being the most common but least problematic.

First rib

The first rib is broad and flat, has superior and inferior surfaces and internal and external borders, and is the most acutely curved and shortest of all the ribs (see Fig. 53.9). It slopes obliquely anteroinferiorly towards its sternal end, which is larger than that of any other rib. The obliquity of the first rib means that the lung apex and covering pleura project superior to the superior thoracic aperture and into the neck.

The head of the first rib is small and round, bears an almost circular facet that articulates with the body of the first thoracic vertebra, and is turned slightly inferiorly relative to the tubercle of the rib. The neck of the rib is rounded and ascends posterolaterally, and the tubercle is wide and prominent and directed superiorly and posteriorly. Medially, an

Cervical ribs arise from the seventh cervical vertebra, occur in up to 1% of the population, and are thought to result from mutations of *HOX* genes (Chang et al 2013). Their size varies from a simple epiphysis on the transverse process of the seventh cervical vertebra to, more commonly, a structure with a head, neck and tubercle. When a shaft is present, it is of variable length and extends anterolaterally into the posterior triangle of the neck, where it may end freely or join the first rib or its costal cartilage, or even the manubrium of the sternum. Long cervical ribs have relations similar to those of the first thoracic rib: the brachial plexus (usually lower trunk) and subclavian vessels are superior and may become compressed in the narrow angle between the rib and scalenus anterior. This anatomical relationship means that cervical ribs may first be revealed by neurovascular symptoms (thoracic outlet syndrome, see Ch. 48) including ipsilateral limb pain, numbness, weakness or cold intolerance, particularly when the cervical rib puts pressure on the ventral rami of the eighth cervical and first thoracic spinal nerves. The symptoms resulting from a cervical rib are unrelated to the relative sizes of its constituent parts (specifically osseous vs fibrous). A cervical rib (pleurapophysis) may show synostosis or diarthrosis with either the anterior (parapophysial) or posterior (diapophysial) 'roots' of the transverse process of the seventh cervical vertebra or, more usually, with both.

oval facet articulates with the transverse process of the first thoracic vertebra. The angle and tubercle of the first rib normally coincide. The inferior surface of the flattened shaft of the rib is smooth whereas the superior surface is crossed obliquely by two shallow grooves, separated by a slight ridge that usually terminates at the scalene tubercle (a small pointed projection located on the internal border of the rib to which scalenus anterior is attached). The groove anterior to the scalene tubercle forms a bed for the subclavian vein, and the rough area between this and the first costal cartilage gives attachment to the costoclavicular ligament and, even more anteriorly, to subclavius (see Fig. 53.8). The subclavian artery and (usually) the lower trunk of the brachial plexus pass in the groove posterior to the scalene tubercle. Posterior to the scalene tubercle, scalenus medius is attached as far as the tubercle/angle of the rib.

The superior half of the smooth inferior surface is covered by endothoracic fascia and costal parietal pleura, the inferior half is an attachment point for the intercostal muscles and membranes. The external border is convex, thick posteriorly and thin anteriorly. It is covered posteriorly by scalenus posterior descending to the second rib. The first digitation of serratus anterior is, in part, attached to it, lateral to the groove for the subclavian vein. The internal border is concave and thin, and the scalene tubercle is near its midpoint. The suprapleural membrane (Sibson's fascia), covering the cervical parietal pleura and lung apex, is attached to the internal border (Ch. 54).

Vascular supply and innervation The first rib is supplied by the internal thoracic and supreme intercostal arteries, drained by the supreme intercostal vein and innervated by the first intercostal nerve.

Ossification The first rib has a primary ossification centre for the shaft, and secondary ossification centres for the head of the rib and the tubercle.

Second rib

The second rib is about twice the length of the first and has a similar curvature. The non-articular area of its tubercle is small. The angle of the rib is small and near the tubercle. The shaft is not twisted but at the tubercle is superiorly convex. The external surface of the shaft is convex and at around the midpoint is marked by a raised roughened prominence for the attachments of the inferior halves of the first and the second digitation of serratus anterior (see Figs 53.8–53.9). Passing anteriorly from the angle of the rib, a distinct midline ridge divides the external (upper) surface into outer and inner parts: scalenus posterior and serratus posterior superior are attached to the ridge and to the outer part. The internal surface of the shaft is smooth and concave, faces inferomedially and has a relatively short costal groove along the posterior part of its inferior border. The superior half of the internal surface is covered by endothoracic fascia and costal parietal pleura, and the inferior half is an attachment point for the intercostal muscles and membranes.

Vascular supply and innervation The second rib is supplied by the internal thoracic and supreme intercostal arteries, drained via the superior intercostal vein into the brachiocephalic vein, and by the anterior intercostal veins into the internal thoracic vein, and innervated by branches of the second intercostal nerve.

Ossification The second rib is ossified from a primary ossification centre for the shaft, which appears near the angle late in postmenstrual weeks 5–8. The secondary centres for the head and articular and non-articular parts of the tubercle appear around puberty, uniting to the shaft soon after the age of 20 years.

Tenth, eleventh and twelfth ribs

The tenth rib has a single facet on its head that articulates with the superior border of the body of the tenth thoracic vertebra near the pedicle, and may also articulate with the T9–T10 intervertebral disc. The costal cartilages of the ninth and tenth ribs may be united anteriorly by a fibrous joint, although in up to 70% of subjects the tenth rib may be free, in which case its end appears pointed like the eleventh and twelfth ribs.

The eleventh and twelfth ribs each have one large articular facet on their heads but no necks or tubercles. Their anterior ends are pointed and tipped with hyaline cartilage. The eleventh rib has a slight angle and shallow costal groove whereas the twelfth rib has neither, is much shorter and slopes cranially at its vertebral end. The internal surfaces of both ribs face slightly superiorly, this being more apparent in the twelfth.

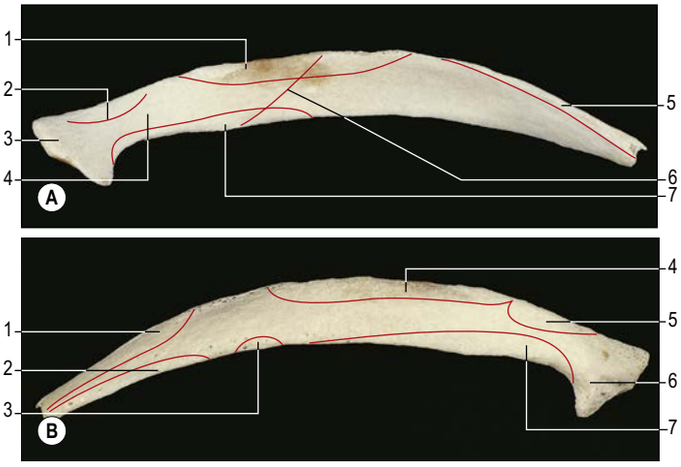

Fig. 53.10 The left twelfth rib, showing surface features, relations and muscle attachments (red outline). **A**, Internal (anterior) surface. Key: 1, attachment of internal intercostal muscle; 2, attachment of costotransverse ligament; 3, head of rib; 4, area covered by endothoracic fascia and costal part of parietal pleura; 5, attachment of respiratory diaphragm; 6, line of pleural reflection; 7, attachment of quadratus lumborum. **B**, External (posterior) surface. Key: 1, attachment of latissimus dorsi; 2, attachment of external abdominal oblique; 3, attachment of serratus posterior inferior; 4, attachment of external intercostal muscle; 5, attachment of levator costae; 6, head of rib; 7, attachment of erector spinae.

Numerous muscles and ligaments are attached to the twelfth rib (see Fig 53.8; **Fig. 53.10**). Quadratus lumborum and its anterior covering layer of thoracolumbar fascia are attached to the medial one-half to two-thirds of the inferior part of the anterior surface. The medial half of the internal surface is related to the costodiaphragmatic recess of the pleural cavity, approximately at the point where it is crossed by the lateral border of iliocostalis: the recess may extend inferior to the rib. The internal intercostal muscle (medially) and the respiratory diaphragm (laterally) are attached at or near the superior border. The inferior border and associated external surface give attachment to the middle layer of the thoracolumbar fascia and, lateral to quadratus lumborum, to the lateral arcuate ligament and posterior layer of the thoracolumbar fascia. The lumbocostal ligament is attached posteriorly, posterior to quadratus lumborum and normally close to the head of the twelfth rib (although it may extend more laterally): distally, the ligament is attached to the transverse processes of the first and second lumbar vertebrae and can be used to locate the subcostal nerve (Saker et al 2016). The lowest levator costae, longissimus thoracis and iliocostalis are all attached to the medial half of the external surface; serratus posterior inferior, latissimus dorsi and external abdominal oblique are attached to the lateral half of the external surface; the external intercostal muscle is attached along the central section of the superior part of the external surface. These attachments can vary; in particular, the attachments of the internal intercostal, levator costae and erector spinae merge and those of latissimus dorsi, the respiratory diaphragm and external abdominal oblique may reach the costal cartilage.

Vascular supply and innervation The tenth and eleventh ribs are supplied by the posterior intercostal arteries and by branches from the musculophrenic artery. The twelfth rib is supplied by the subcostal artery. Venous drainage is via the posterior intercostal and subcostal veins that drain into the azygos system and via the anterior intercostal veins (branches of the musculophrenic vein). The tenth and eleventh ribs are innervated by the corresponding intercostal nerve, and the twelfth rib is innervated by the subcostal nerve.

Ossification The tenth rib ossifies from a primary ossification centre in the shaft and secondary centres for the head and articular parts of the tubercle. The eleventh and twelfth ribs, without tubercles, both have two ossification centres.

Costal cartilages

The costal cartilages are the unossified anterior parts of the cartilaginous models from which the ribs develop. They are flat bars of hyaline cartilage that extend from the anterior ends of the ribs, and contribute greatly to thoracic mobility and elasticity (see Fig. 53.8). The upper seven pairs articulate with the sternum; the eighth to tenth articulate with the inferior border of the costal cartilage above; and the lowest

two have free, pointed ends located within the soft tissue of the abdominal wall (see Figs 53.14, 53.15B). The costal cartilages increase in length from the first to the seventh, and then decrease to the twelfth. They diminish in breadth/height from first to last, as do the intercostal spaces. They are broad at their articulation with the ribs and taper as they pass anteriorly and toward the midline. The first and second are of even breadth and the sixth to eighth enlarge where their margins are in contact. The first descends a little, the second is horizontal and the third ascends slightly; the others are angulated and incline superomedially towards the sternum or cartilage above, in a plane slightly anterior to their ribs.

Each costal cartilage has two surfaces, borders and ends. The external (anterior/anterosuperior) surface is convex. The sternoclavicular articular disc, costoclavicular ligament and subclavius are all attached to the external surface of the first costal cartilage, pectoralis major is attached to the medial ends of the first six costal cartilages, rectus abdominis to the fifth to seventh and others, including the costal cartilages forming the costal arch (margin) offer attachment sites for the muscles of the anterior abdominal wall. The internal (posterior/posteroinferior) surface is concave. Sternothyroid is attached to the internal surface of the first costal cartilage, transversus thoracis is attached to the second to seventh costal cartilages, and transversus abdominis is attached to the seventh to twelfth costal cartilages. The internal intercostal muscles and external intercostal membranes are attached to the concave superior and convex inferior borders. At around the point (apex) of maximum convexity of the inferior border of the sixth (sometimes the fifth) to ninth costal cartilages an inferiorly facing oblong articular facet articulates with a superiorly facing articular facet on the superior border of the cartilage below via a synovial interchondral joint. The lateral end of each cartilage articulates with its corresponding rib. The medial end of the first cartilage articulates with the manubrium of the sternum; the medial ends of the six succeeding cartilages are round and articulate with shallow costal notches on the lateral margins of the body of the sternum (and the manubrium in the case of the second); those of the eighth to tenth are pointed and articulate with the costal cartilage above; and those of the eleventh and twelfth are pointed and free. With the exceptions of the fibrous synarthrosis between the first rib and sternum, and the costal cartilages of the ninth and tenth ribs, all the articulations are synovial. Costal cartilages may undergo calcification with age (Middleham et al 2015).

Rib fractures

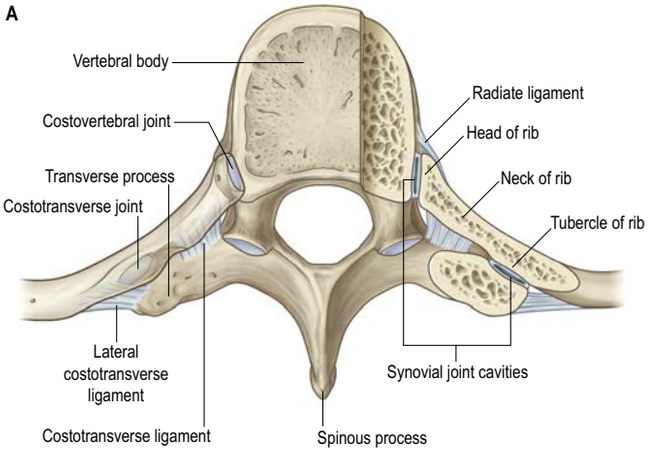

Fig. 53.12 A, Costovertebral and costotransverse joints, superior aspect. (B, *continued online*)

JOINTS

Manubriosternal joint

The manubriosternal joint lies between the manubrium and the body of the sternum approximately 7 cm below (inferior to) the jugular (suprasternal) notch of the manubrium. It is usually a symphysis but may be synovial, synchondrotic or synostotic. The bony surfaces are covered by hyaline cartilage and connected by a fibrocartilage that may ossify with increasing age. The central part of the disc is sometimes absorbed so that the joint appears synovial. Occasionally, in individuals over the age of 30 years, the manubrium appears to be joined to the body of the sternum by bone. However, the intervening cartilage may be only superficially ossified because ossification is not completed until late adult life. Early synostosis has been attributed to a persistent synchondrosis in place of a symphysis. In the newborn, union is by collagenous and elastic fibres, without chondrocytes.

Movements There is a small range of angulation between the longitudinal axes of the manubrium and the body of the sternum, and limited anteroposterior displacement. The powerful ligamentous attachments in this region mean that dislocation of the manubriosternal joint is rare, although it may be associated with high-energy trauma. Dislocation is most common when the joint is synovial, whereas synchondral and synosteal types typically fracture through the manubrium.

Xiphisternal joint

The joint between the xiphoid process and body of the sternum is a symphysis. It is usually transformed to a synostosis by the fortieth year but sometimes remains unchanged, even in older adults.

Sternoclavicular joint

The sternoclavicular joint is described in Chapter 49.

Costovertebral, sternocostal and interchondral joints

The heads of the ribs articulate with the bodies of the vertebrae at costovertebral joints; their necks and tubercles articulate with transverse processes at costotransverse joints.

Joints of the heads of the ribs

The head of a typical rib articulates with facets (often termed demifacets) on the margins of the bodies of adjacent thoracic vertebrae and with the intervening intervertebral disc (Figs 53.11–53.12). The first and tenth to twelfth ribs articulate with their corresponding vertebra alone by a simple synovial joint. For the second to ninth ribs, an intra-articular ligament bisects the joint, producing a double synovial compartment, so the joint is classified as both compound and complex. Often inaccurately described as a plane joint, the articular surfaces are

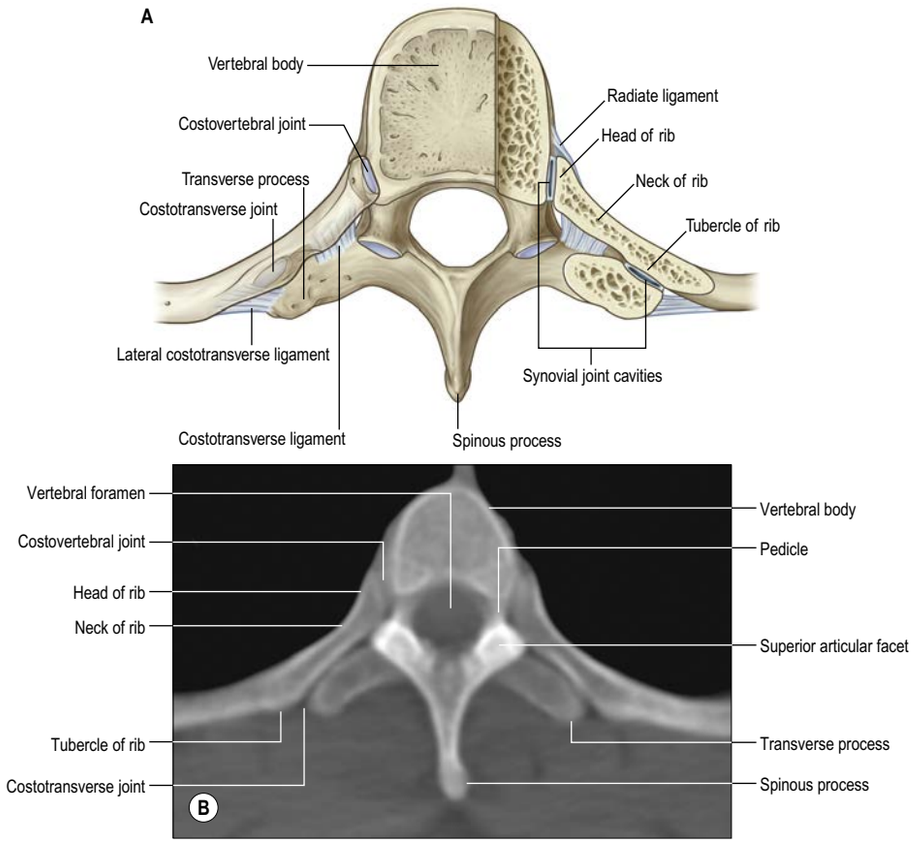

Fig. 53.12 **A**, Costovertebral and costotransverse joints, superior aspect. **B**, CT mean intensity projection slab through a typical rib and thoracic vertebra showing the typical arrangement of costotransverse and costovertebral joints. (A, Adapted from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2015.)

Despite their pliability, the ribs are much more frequently broken when compared to the sternum; the anterior and anterolateral portions of the middle to lower ribs are the most vulnerable. The elastic recoil of the ribs that articulate with and effectively suspend the sternum may explain the rarity of sternal fractures. Because traumatic stress is often the result of compression of the thorax, the usual site of fracture is just anterior to the angle of the rib, the weakest point of the bone, however direct impact may fracture a rib at any point. Nearly 10% of all patients admitted after blunt force thoracic trauma have one or more rib fractures. Morbidity and mortality increase as the number of fractured ribs increases (Tomas et al 2017): the ends of the broken bone may be driven inwards and potentially injure thoracic or upper abdominal viscera (Kasotakis et al 2017). The pain associated with rib fracture, particularly multiple rib fractures in older adults, can predispose to pneumonia by limiting normal airway protective mechanisms (e.g. cough).

slightly ovoid and the superior and inferior synovial articulations are obtusely angled to each other. The ligaments associated with the joints are capsular, radiate and intra-articular.

Fibrous capsule

A fibrous capsule connects the head of the rib to the circumference of the articular surface formed by an intervertebral disc and the demifacets of two adjacent vertebrae. Some of the superior fibres of the capsule traverse the intervertebral foramen to blend with the posterior aspect of the associated intervertebral disc. The posterior fibres are continuous with the costotransverse ligament.

Radiate ligaments

The radiate ligaments connect the anterior surface of the head of each rib, just distal to its articular surface, to the bodies of two articulating vertebrae and their intervening intervertebral disc. Superior fibres ascend to the body of the vertebra above, inferior fibres descend to the body of the vertebra below, and intermediate fibres, which are the shortest and least distinct, pass horizontally to the intervening intervertebral disc. The radiate ligament associated with the first rib is attached to the bodies of the seventh cervical and first thoracic vertebrae. The tenth to twelfth ribs articulate with single vertebral bodies and the radiate ligament is attached to the body of the corresponding vertebra and the body of the vertebra above.

Intra-articular ligament

The intra-articular ligament is a short flat band that joins the crest on the head of the rib, between the articular facets, to the intervertebral disc and so divides the synovial joint into two compartments. The ligament is absent from the first and tenth to twelfth costovertebral joints.

Costotransverse joints

The facet on the tubercle of a rib articulates with the costal facet on the transverse process of its corresponding vertebra (see Figs 53.11, 53.12). The eleventh and twelfth ribs lack this articulation. In the upper five or six joints, the articular surfaces are reciprocally curved; they are flatter in the joints located inferiorly (**Fig. 53.13**). The ligaments associated with the costotransverse joints are capsular, costotransverse, superior and lateral costotransverse, and accessory.

Fibrous capsule The fibrous capsule is thin, attached to articular peripheries and has a synovial lining.

Costotransverse ligament The costotransverse ligament fills the costotransverse foramen between the neck of a rib and the transverse process of its adjacent corresponding vertebra. Its numerous short fibres pass posteriorly from a rough area on the posterior surface of the neck of the rib to the anterior surface of the transverse process. A costotransverse ligament is rudimentary or absent in the eleventh and twelfth ribs.

Superior costotransverse ligament The superior costotransverse ligament has anterior and posterior layers. The anterior layer is attached between the crest on the neck of the rib and the inferior surface of the transverse process of the vertebra above, and blends laterally with the internal intercostal membrane; it is crossed by the intercostal vessels and nerve. The posterior layer is attached posteriorly on the neck of the rib, ascends posteromedially to the transverse process of the vertebra above, and blends laterally with the external intercostal muscle. The first rib has no superior costotransverse ligament. The inferior surface of the head, neck and sometimes the medial part of the shaft of the twelfth rib are connected to the transverse processes of the first and second lumbar vertebrae by the lumbocostal ligament.

Accessory ligament An accessory ligament is usually present. It lies medial to the superior costotransverse ligament, from which it is separated by the dorsal ramus of a thoracic spinal nerve and accompanying vessels. Its attachments are variable, but it usually passes from a depression medial to the tubercle of the rib to the inferior articular process and the base of the transverse process of the vertebra above.

Lateral costotransverse ligament The lateral costotransverse ligament is short, thick and strong. It passes obliquely from the apex of the transverse process of a vertebra to the rough non-articular part of the tubercle of the corresponding rib (see Figs 53.9, 53.12). The ligaments of the upper ribs appear to ascend from the transverse processes of the vertebrae, and are shorter and more oblique than those of the lower ribs, which appear to descend.

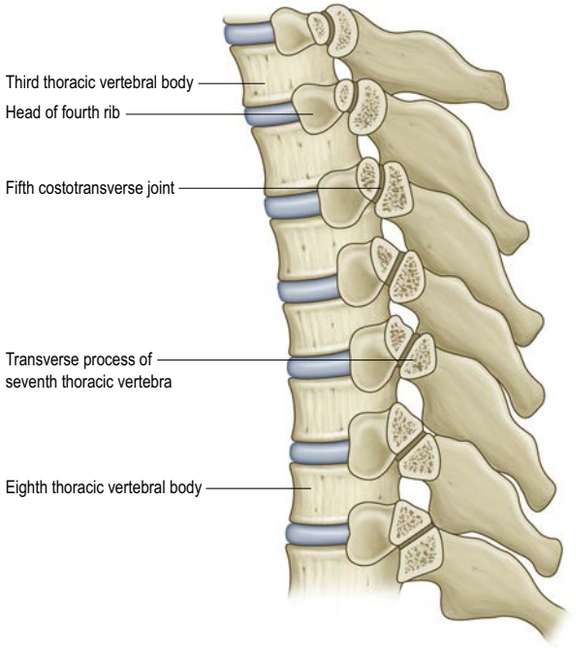

Fig. 53.13 A section through the third to the ninth costotransverse joints. Note the concave facets on the superiorly located vertebral transverse processes and the less curved facets on the inferiorly located vertebral transverse processes.

Movements The strong, tight radiate and intra-articular ligaments attached to the head of a rib only permit slight gliding at the costovertebral joints. Strong ligaments bind the necks and tubercles of the ribs to the transverse processes of the vertebrae and limit movements at the costotransverse joints to slight gliding, guided by the shape and direction of the articular surfaces (see Fig. 53.13). The facets on the tubercles of the first six ribs are oval and vertically convex, and fit corresponding concavities on the anterior surfaces of the transverse processes of the vertebrae; up and down movements of tubercles consequently involve rotation of the costal necks about their long axes. The facets on the tubercles of the seventh to tenth ribs are almost flat and face posteriorly, inferiorly and medially; the opposing articular surfaces are located on the superior aspects of the transverse processes, which means that when these tubercles move superiorly, they also move posteromedially. Both the costovertebral and costotransverse joints move simultaneously and in the same directions; the neck of a rib therefore moves as if at a single joint in which the costovertebral and costotransverse joints form its ends.

The main movement of the neck of each of the first six ribs is one of rotation about its long axis (a slight superior–inferior movement is also seen): a downward rotation of its anterior surface is therefore associated with depression, and an upward rotation with elevation, of the shaft and anterior end of the rib. The shape of the costotransverse joint in the seventh to tenth ribs means that the neck of the rib ascends posteromedially or descends anterolaterally, increasing or decreasing the infrasternal angle, respectively; slight rotation accompanies these movements.

Sternocostal joints

The costal cartilages articulate with small concavities (costal notches) on the lateral sternal borders at the sternocostal joints (**Fig. 53.14**). The first sternocostal joint is an unusual type of synarthrosis (fibrous joint) and is often inaccurately called a synchondrosis. The second to seventh sternocostal joints are synovial, although articular cavities are often absent, particularly in the lower joints. Fibrocartilage covers the articular surfaces and also unites the costal cartilages and the sternum in those joints where cavities are absent. The seventh sternocostal joint may be synovial or symphysial. Ligaments associated with the joints include capsular, radiate sternocostal, intra-articular and costoxiphoid.

Fibrous capsules Fibrous capsules surround the second to seventh sternocostal joints. They are thin, blended with the sternocostal ligaments, and strengthened superiorly and inferiorly by fibres that connect the costal cartilages to the sternum.

Radiate sternocostal ligaments The radiate sternocostal ligaments are broad, thin bands that radiate from the anterior and posterior

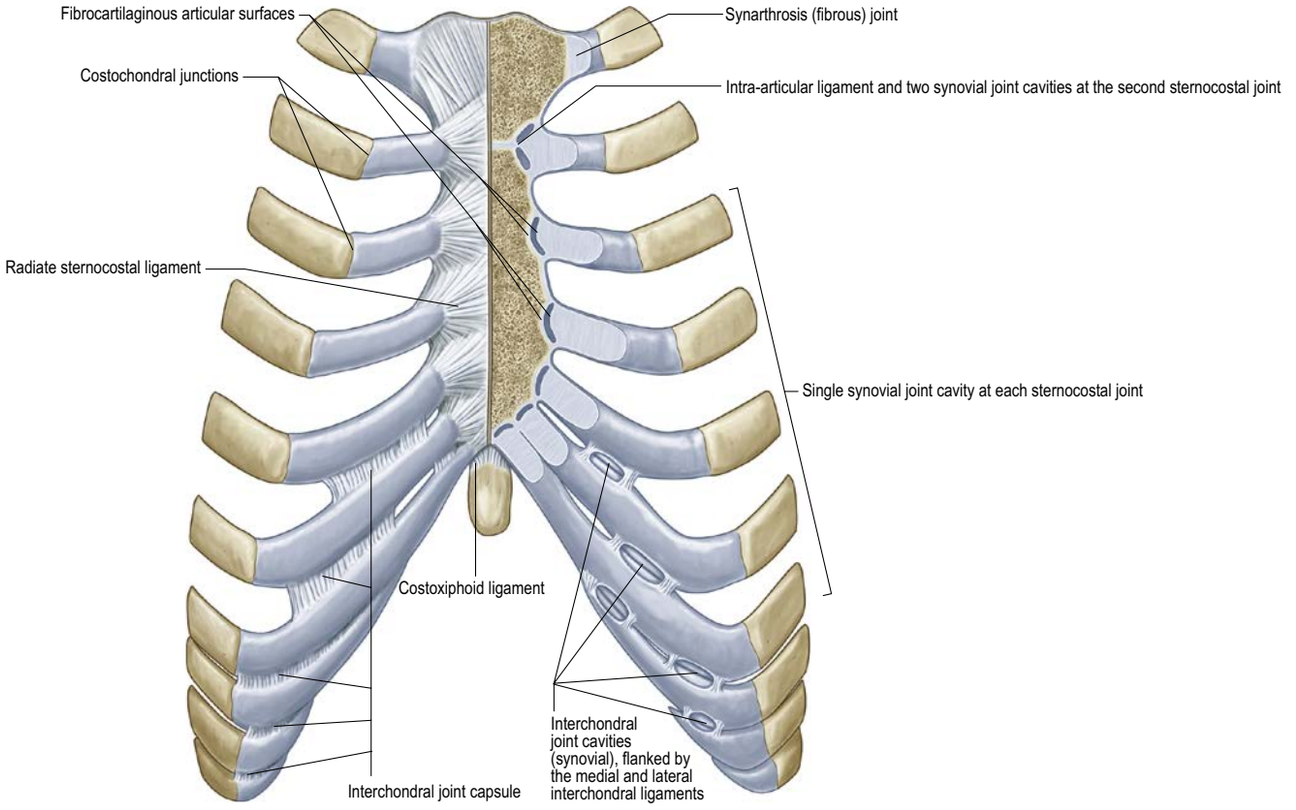

Fig. 53.14 Sternocostal and interchondral joints, anterior aspect.

surfaces of the sternal ends of the costal cartilages of the true ribs to the adjacent corresponding sternal surfaces. Their superficial fibres intermingle with adjacent ligaments superiorly and inferiorly, with those of the contralateral side and with tendinous fibres of pectoralis major. Collectively, these tissues form a thick fibrous membrane around the sternum that is more apparent inferiorly.

Intra-articular ligaments Intra-articular ligaments are constant only between the second costal cartilages and the manubriosternal joint. The ligament associated with the second costal cartilage extends from the costal cartilage to the fibrocartilage uniting the manubrium and sternal body, and is therefore intra-articular. Occasionally, the third costal cartilage is connected with the first and second sternal segments (sternebrae) by a similar ligament. Fibrocartilaginous strands may occur in the third to seventh joints. Articular cavities may be absent at any age.

Costoxiphoid ligaments Costoxiphoid ligaments connect the anterior and posterior surfaces of the seventh (and sometimes sixth) costal cartilage to the same surfaces of the xiphoid process. They vary in length and breadth, and the posterior is less distinct.

Movements Small gliding movements, sufficient for ventilation, occur at the sternocostal joints.

Interchondral joints

Adjoining borders of the sixth to ninth costal cartilages articulate by apposition of small oblong facets. Each articulation is enclosed in a thin fibrous capsule, lined by synovial membrane, with lateral and medial interchondral ligaments. Sometimes the fifth cartilage articulates inferiorly with the sixth; this connection is usually formed by ligamentous fibres. Articulation between the ninth and tenth cartilages is never synovial, often fibrous and sometimes absent.

Costochondral junctions

When artificially separated from its rib, a costal cartilage has a rounded lateral end that fits a reciprocal depression in the rib. Periosteum and perichondrium are continuous across the costochondral junctions and the collagen of the osseous and cartilaginous matrices blend. No movement occurs at costochondral junctions. Costochondritis is a common condition of unknown aetiology that presents as pain and tenderness of the costochondral or sternocostal joints due to involvement of cutaneous intercostal nerve branches; a prevalence of 30% has been reported amongst patients presenting to an emergency department with chest pain (Gregory et al 2002).

MUSCLES

The intrinsic muscles of the chest wall are the intercostals, subcostales, transversus thoracis, levatores costarum, serratus posterior superior and inferior and, occasionally, sternalis (**Figs 53.15–53.16**). Scapular muscles and muscles connecting the upper limb, chest wall and vertebrae, i.e. trapezius, latissimus dorsi, rhomboids major and minor, levator scapulae, pectorales major and minor, and subclavius, are described in Chapter 49.

Intrinsic chest wall muscles

Intercostal muscles

The intercostal muscles are thin, consist of muscular and tendinous fibres and are arranged in layers within each intercostal space. Their names are derived from their positional relationship to each other, i.e. the external, internal and innermost intercostals (**Fig. 53.17**). There are 11 pairs of external and internal intercostal muscles, the innermost intercostal has a variable presence.

External intercostals

The external intercostal muscles pass between adjacent ribs, from the tubercle of the rib, where they blend with the posterior layer of the superior costotransverse ligaments, almost to the costal cartilage, where each continues forwards to the sternum as an aponeurotic layer, the external intercostal membrane (see Fig. 53.18). Each muscle passes from the inferior border of one rib to the superior border of the rib below; their fibres are angled obliquely inferiorly and laterally in the posterior part of an intercostal space, inferiorly and anteriorly in the lateral part of the space and inferiorly and medially in the anterior part of the space. They do not quite reach the anterior ends of the rib in the first two or three spaces, and they extend to the free ends of the costal cartilages in the tenth and eleventh spaces. The external intercostals are thicker than the internal intercostals.

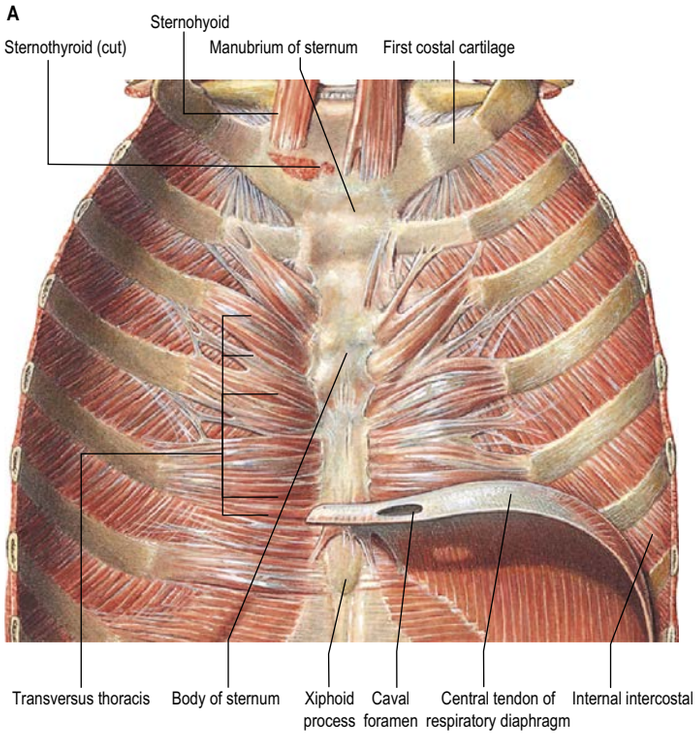

Fig. 53.15 Muscles of the thoracic wall. **A**, The left transversus thoracis, exposed and viewed from its posterior aspect. The inferior part of transversus thoracis is in contact with the superior part of transversus abdominis in the interval between the sternal and costal origins of the respiratory diaphragm. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.) (B–D, *continued online*)

Innervation The external intercostals are innervated by the adjacent intercostal nerves.

Internal intercostals The internal intercostals pass between adjacent ribs, from the lateral border of the sternum or the anterior limits of the costal cartilages of the 'false' ribs, to the angle of the rib, where each is replaced by an aponeurotic layer, the internal intercostal membrane, that is continuous posteriorly with the anterior layer of a superior costotransverse ligament, and anteriorly with the fascia between the internal and external intercostal muscles. The muscle is thickest anteriorly, in its intercartilaginous or parasternal part. Each muscle descends from the floor of a costal groove and adjacent costal cartilage, and inserts into the superior border of the rib below; the muscle fibres are directed obliquely, nearly at right-angles to those of the external intercostal muscles.

Innervation The internal intercostals are supplied by the adjacent intercostal nerves.

Innermost intercostals

The innermost intercostals were once regarded as internal laminae of the internal intercostal muscles, especially since fibres in the two layers coincide in direction. Each muscle is attached to the internal aspects of two adjoining ribs. They are insignificant, and sometimes absent, in the upper intercostal spaces but become progressively more substantial in the lower spaces, typically extending through the middle two quarters of the intercostal spaces. Posteriorly, the innermost intercostals, in those spaces where they are well developed, may come together with the corresponding subcostales (see Fig. 53.15B). The innermost intercostals are related internally to the endothoracic fascia and costal parietal pleura, and externally to the intercostal nerves and vessels.

Innervation The innermost intercostals are innervated by the adjacent intercostal nerves.

Actions Contraction of the intercostal muscles during inspiration and expiration varies according to the intercostal space in which they are located and the position of the muscles within that space (Ch. 55). The intercostal muscles contribute to rigidity of the thoracic wall, helping to maximize inspiratory and expiratory volumes.

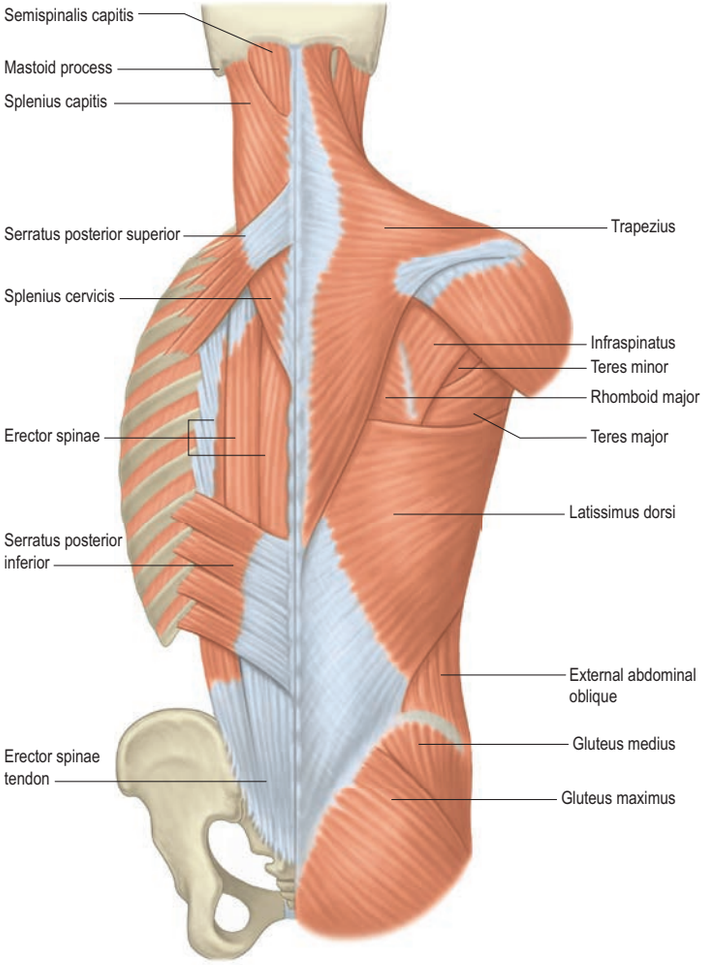

Fig. 53.16 Superficial (extrinsic) muscles of the back.

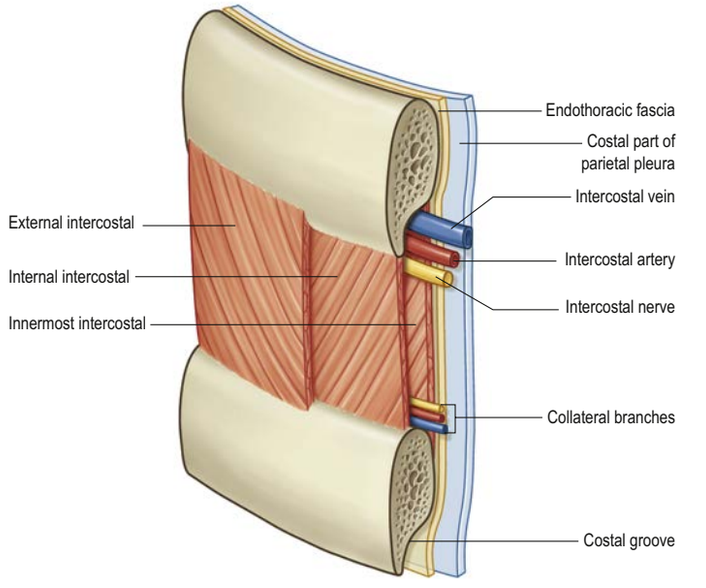

Fig. 53.17 A right intercostal space, external aspect, showing the position of the intercostal vessels and nerve and their collateral branches relative to the intercostal muscles, and the position of the endothoracic fascia and costal parietal pleura.

Transversus thoracis

Transversus thoracis spreads over the internal surface of the anterior thoracic wall (see Fig. 53.15A). It arises from the inferior half to inferior third of the posterior surface of the sternum, the xiphoid process and the sternal ends of the fifth (sometimes fourth) to seventh costal cartilages. The fibres diverge as separate slips that pass superiorly and laterally to the inferior borders and internal surfaces of the costal cartilages

The use of pectoral nerve block (Pecs) and serratus anterior plane block (SAPB) to provide analgesia and anaesthesia to the anterior and anterolateral chest wall to manage postsurgical thoracic pain is well documented. These blocks alone are often insufficient to fully block the territory of the anterior cutaneous nerves that innervate the anterior chest wall in the sternal and medial breast/pectoral regions, and often leave a patient with postoperative residual pain. Recent advances in fascial plane blocks have enabled more effective delivery of analgesia to these regions (Piraccini et al 2018). In a parasternal intercostal nerve block (PSI), local anaesthetic is injected between the fascial planes of pectoralis major and the external intercostal muscle, blocking the anterior branches of the intercostal nerves. In a parasternal block (PSB) local anaesthetic is injected in the region between the fascial planes of pectoralis major and the internal intercostal muscles, blocking the anterior branches of the second to seventh thoracic intercostal nerves. In a transversus thoracis plane block (TTP), local anaesthetic is injected between the fascial planes of the internal intercostal muscles and transversus thoracis. Compared to Pecs and SAPB, the PSI, PSB and TTP fascial plane blocks have been shown to decrease postsurgical opioid consumption, and provide long-lasting pain relief, including in the anterior thoracic wall (Versyck et al 2017).

of the second to sixth ribs. The inferiormost fibres are horizontal and are contiguous with the superiormost fibres of transversus abdominis; the intermediate fibres are oblique; and the superiormost are almost vertical. Transversus thoracis varies in its attachments, between individuals and on opposite sides of the same individual. Similar in arrangement to the innermost intercostals and subcostales, transversus thoracis separates the intercostal neurovascular bundle (and also the internal thoracic artery and vein) from the costal part of the parietal pleura.

Innervation Transversus thoracis is innervated by the adjacent intercostal nerves.

Action Transversus thoracis depresses the costal cartilages to which it is attached.

Subcostales

Subcostales consist of muscular and aponeurotic fasciculi and are usually better developed in the lower (inferior) part of the internal surface of the posterior thoracic wall (see Fig. 53.15B). Each passes inferomedially from the internal surface of a rib, near its angle, to the internal surface of the second or third rib below (inferior). Their fibres run parallel to those of the internal intercostals and, like the innermost intercostals, they lie between the intercostal neurovasculature and the endothoracic fascia and costal part of the parietal pleura.

Innervation The subcostales are innervated by the adjacent intercostal nerves.

Action Subcostales depress the ribs.

Levatores costarum

Levatores costarum are strong bundles of muscle fibres located on the external surface of the thoracic wall that arise from the tips of the transverse processes of the seventh cervical and first to eleventh thoracic vertebrae (see Fig. 53.15C). They pass obliquely inferolaterally, parallel with the posterior borders of the external intercostal muscles. Each is attached to the superior border and external surface of the rib located immediately inferior to the vertebra from which it takes origin, between the tubercle and the angle of the rib (levatores costarum breve). Each of the four lower levatores costarum divides into two fasciculi; one is attached as already described, and the other descends to attach to the second rib inferior to its vertebral origin (levatores costarum longi).

Innervation Levatores costarum are innervated by the lateral branches of the dorsal rami of the corresponding cervical or thoracic spinal nerves (commonly C8–T11).

Action Levatores costarum elevate the ribs but their role and importance in ventilation is disputed. From their costal attachments they may assist in rotation and lateral flexion of the vertebral column.

Serratus posterior superior

Serratus posterior superior (see Fig. 53.16) is a thin quadrilateral muscle, located on the superior part of the posterior thoracic wall. It arises by a thin aponeurosis from the inferior part of the nuchal ligament, the spinous processes of the seventh cervical and first (superior) two or three thoracic vertebrae, and the associated supraspinous ligaments. It passes inferiorly and laterally and ends in four digitations attached to the superior borders and external surfaces of the second to fifth ribs, just lateral to their angles. It is superficial to the thoracic part of the thoracolumbar fascia and deep to rhomboid minor and major. The number of digitations can vary from three to six, and the muscle may be absent. Regional pain has been reported over the location of the muscle in myofascial pain syndromes.

Innervation Serratus posterior superior is innervated by the second to fifth intercostal nerves.

Action The attachments of serratus posterior superior indicate that it could elevate the ribs, although its role in ventilation in humans is uncertain. It may have a greater role in proprioception related to thoracic movement.

Serratus posterior inferior

Serratus posterior inferior (see Fig. 53.16) is a thin, irregularly quadrilateral muscle located on the posterior trunk at the junction of the thoracic and lumbar regions. It arises from the spinous processes of the last (inferior) two thoracic and first (superior) two or three lumbar vertebrae and the associated supraspinous ligaments by a thin aponeurosis that blends with the lumbar part of the thoracolumbar fascia. It passes superolaterally and its four digitations pass into the inferior borders and external surfaces of the last (inferior) four ribs, just lateral to their angles. There may be fewer than four digitations and, in rare cases, the entire muscle may be absent.

Innervation Serratus posterior inferior is innervated by ventral rami of the ninth to twelfth thoracic spinal nerves.

Action The attachments of serratus posterior inferior indicate that it could depress the ribs, although its role in ventilation in humans is uncertain. It may have a greater role in proprioception related to thoracic movement.

Sternalis

Sternalis is an anatomical variation well known to anatomists but relatively unknown to clinicians and surgeons (Snosek et al 2014) (see Fig. 53.15D). The muscle appears as a parasternal mass deep to the superficial fascia of the anterior thoracic wall and superficial to the pectoral fascia overlying pectoralis major. It may be a cord-like, flat band or irregular and flame-like in shape, it may present with a single, double or triple-bellied arrangement (Dudgeon et al 2017). It is almost twice as common unilaterally, and occurs more often on the right side. Various attachment sites have been described, including the sternum, inferior border of the clavicle, sternocleidomastoid fascia, pectoralis major, and the upper ribs and their costal cartilages, all superiorly, and the lower ribs and their costal cartilages, pectoralis major, the rectus sheath and the aponeurosis of external abdominal oblique, all inferiorly. Attachments may be contralateral and bilateral sternalis muscles may join. Most documented variants are innervated by either the medial pectoral nerve or an intercostal nerve. The muscle occurs in about 8% of the general population, but there is great variation both within and between different geographic populations (Snosek and Loukas 2016). Its superficial location makes it an ideal candidate for utilization as a muscular flap in plastic reconstruction of the head and neck region. For more extensive thoracic wall defect repairs, external abdominal oblique can be utilized as a muscular flap (Wang et al 2018).

Mechanism of thoracic cage movement

Breathing involves changing the thoracic volume by altering the vertical, transverse and anteroposterior dimensions of the thorax. The anatomy of breathing is considered in Chapter 55.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE OF THE CHEST WALL

Arteries

Muscles of the thoracic wall receive their blood supply from branches of the subclavian and axillary arteries and the descending thoracic aorta (see Fig. 52.3). Additional contributions come from vessels that supply the proximal muscles of the upper limb including the suprascapular, superficial cervical, thoraco-acromial, lateral thoracic and subscapular arteries.

Internal thoracic artery

The internal thoracic (mammary) artery arises inferiorly from the first part of the subclavian artery, approximately 2 cm superior to the sternal end of the clavicle and opposite the root of the thyrocervical trunk (see Fig. 52.3). It descends posterior to the first six costal cartilages and intervening intercostal spaces, about 1 cm lateral to the lateral sternal border and divides at the level of the sixth intercostal space into musculophrenic and superior epigastric branches. The superior epigastric artery is described in Chapter 60.

Both the right and left internal thoracic arteries are used as standard in coronary artery bypass grafting (CABG), reflecting successful long-term outcomes. Variations are rare; when present, however, they must be imaged prior to harvesting for CABG. Morphologically abnormal internal thoracic arteries have been shown to supply major parts of the gastrointestinal tract (Mashhour et al 2018).

Relations From its origin, the internal thoracic artery descends anteromedially, passing posterior to the sternal end of the clavicle, the internal jugular and brachiocephalic veins, and the first costal cartilage. As it enters the thoracic cavity, the phrenic nerve crosses it obliquely from its lateral side either superiorly or inferiorly (Ch. 55). The artery then descends

The aetiology is unknown: sternalis may be an example of a much larger group of variations, including pectoralis minimus, pectoralis tertius, infraclavicularis and chondroepitrochlearis, that are thought to be caused by a disturbance of the normal processes of pectoral muscle development. In rare cases sternalis can become symptomatic, causing painful soft tissue swelling in the parasternal region (Gruber et al 2016). The relationship of sternalis to pectoralis major may cause a diagnostic dilemma during breast surgery, mammography, computed tomography and magnetic resonance imaging scans because its appearance mimics tumour pathology of the region. The mammographic appearance of sternalis is variable. Typically visible in the medial aspect of the breast on a craniocaudal (CC) mammogram, it appears as a small soft tissue density or mass abutting the thoracic wall. Its margins and shape are variable. Sternalis is not usually seen on standard mediolateral oblique or mediolateral views.

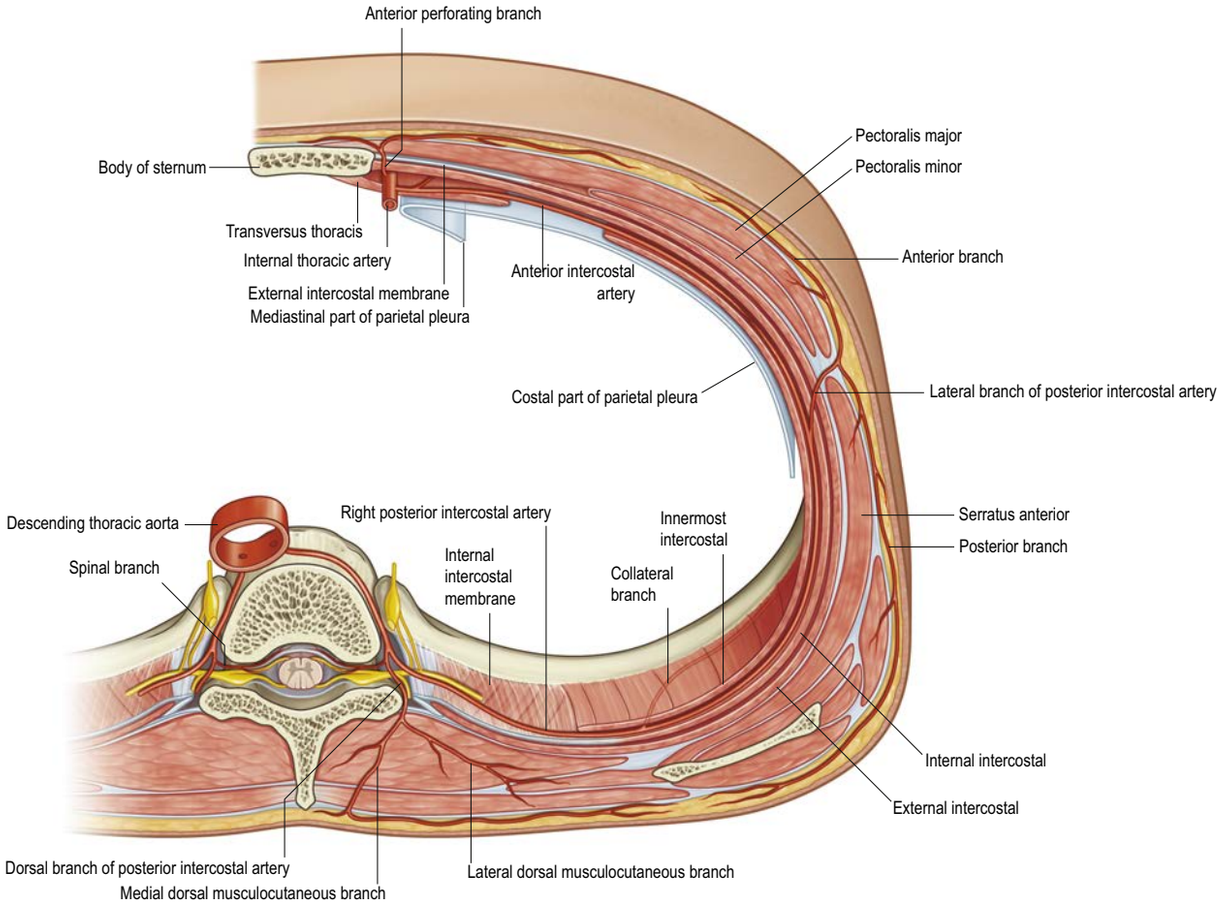

Fig. 53.18 A transverse section through an intercostal space, showing the course and branching of a typical intercostal artery. Collateral branches are shown.

almost vertically to its bifurcation, lying anterior to transversus thoracis and posterior to the first six costal cartilages, internal intercostals and terminations of the first six intercostal nerves. Down to the second or third cartilage it is separated from the costal parietal pleura and its associated endothoracic fascia by a strong layer of fascia, and below this by transversus thoracis (see Fig. 53.18). The artery is accompanied by the parasternal lymph nodes (see Fig. 56.4A) and by venae comitantes that unite at about the third costal cartilage into a single vein medial to the artery. Its intermediate branches are sternal, anterior intercostal and perforating.

Sternal branches Sternal branches are distributed to transversus thoracis, the periosteum of the posterior sternal surface and the sternal red bone marrow. These branches, together with small branches of the pericardiacophrenic artery, anastomose with branches of the posterior intercostal and bronchial arteries to form a subpleural mediastinal plexus.

Anterior intercostal branches Anterior intercostal arteries are distributed to the first six intercostal spaces. They usually arise from the internal thoracic artery as single vessels that promptly divide into two branches (anterior and collateral intercostal arteries) that pass laterally along the superior and inferior borders of each space and anastomose with the posterior intercostal arteries and their collateral branches (**Figs 53.17–53.18**). Occasionally, separate branches of the anterior intercostal artery pass to the intercostal space located superiorly and/or inferiorly, or the two branches of an anterior intercostal artery may arise separately from the internal thoracic artery. At first, the arteries lie between the endothoracic fascia and associated costal parietal pleura posteriorly, and the internal intercostals anteriorly. As they pass posteriorly within a space they lie between the innermost and internal intercostals. They supply the intercostal muscles and send branches through them to the pectoral muscles, breast and skin.

Perforating branches Perforating branches traverse the first five or six intercostal spaces with the anterior cutaneous branches of the corresponding intercostal nerves. They pierce and supply pectoralis major, and then curve laterally to become cutaneous vessels that supply the skin (see Figs 53.18, 52.3). These cutaneous vessels provide the anatomical basis for surgically raising the deltopectoral skin flap that is used for reconstructing areas of missing tissue in the head and neck. The second to fourth branches supply the breast and become enlarged during lactation (see Fig. 53.22).

Musculophrenic artery The musculophrenic artery passes inferolaterally posterior to the seventh to ninth costal cartilages, close to the costal arch, then traverses the respiratory diaphragm and terminates near the eleventh (last) intercostal space (see Figs 52.3, 55.2). It anastomoses with the inferior phrenic and tenth and eleventh posterior intercostal arteries and ascending branches of the deep circumflex iliac arteries. Two anterior intercostal arteries branch from it for each of the seventh to ninth intercostal spaces, and are distributed similarly to their counterparts in other intercostal spaces. The musculophrenic artery also supplies the inferior part of the pericardium and the abdominal muscles.

Clinical significance of the internal thoracic artery

Available with the *Gray's Anatomy* e-book

Supreme intercostal artery

The supreme (highest) intercostal artery arises from the costocervical trunk. It descends between the parietal pleura (and its associated endothoracic fascia), and the neck of the first and second ribs, and anastomoses with the third posterior intercostal artery. As it crosses the neck of the first rib, it lies medial to the ventral ramus of the first thoracic spinal nerve, and lateral to the stellate ganglion (see Fig. 55.10). In the first intercostal space it gives off the first posterior intercostal artery, which has a similar distribution to the more inferiorly located posterior intercostal arteries. It descends to become the second posterior intercostal artery, usually also joining a branch from the third. The artery is not constant, and is more common on the right: when absent, it is replaced by a direct branch from the thoracic aorta.

Posterior intercostal arteries

There are usually nine pairs of posterior intercostal arteries. They arise from the posterior aspect of the descending thoracic aorta and are

The internal thoracic artery has a number of clinical uses but perhaps most significant is that it is the vessel of choice for coronary artery bypass grafting. It has become a commonly selected recipient vessel for free flap transfers to the chest wall, principally for breast reconstruction (Ninković et al 1995), and has largely superseded the thoracodorsal vessels for this purpose. It is routinely accessed by removing a portion of the third costal cartilage (**Fig. 53.19**), although some surgeons prefer to dissect the vessels between the ribs, with a rib-sparing approach (Parrett et al 2008, Malata et al 2011) or even utilizing the anterior perforating branches as they pierce pectoralis major (Park et al 2003, Munhoz et al 2004). The anterior perforating branches form the vascular pedicles for fasciocutaneous flaps raised from the anterior chest wall that have been used for many decades in head and neck reconstruction (Bakamjian et al 1971, Neligan et al 2007). The superior epigastric artery is the main vascular pedicle for the superiorly based rectus abdominis flap, a muscle or myocutaneous flap useful in breast, sternal and chest wall reconstruction (Hartrampf et al 1982). During CT-guided lung and mediastinal biopsies, the internal thoracic vessels must be avoided; exsanguination has been reported following Tru-Cut needle trauma: the approach must be at least 2 cm lateral to the sternal margin. The vessels are not seen easily on non-contrast fluoroscopic CT images.

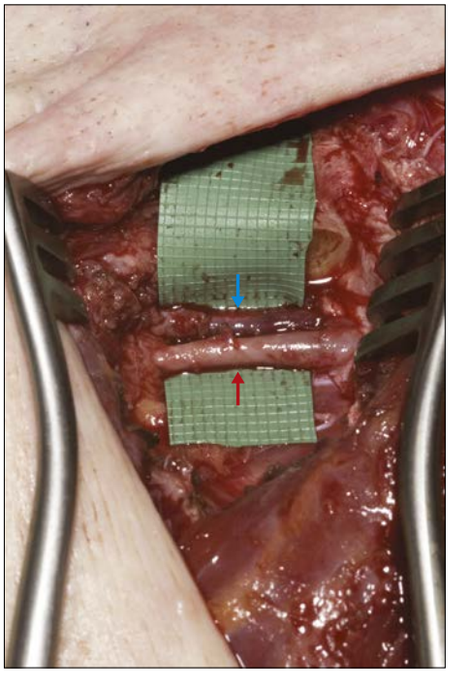

Fig. 53.19 The internal thoracic vessels prepared for micro-anastomosis beneath the third costal cartilage. The dissected internal thoracic artery (red arrow) and vein (blue arrow) are shown after removal of the right third costal cartilage. These vessels are divided to provide recipient blood supply for a free tissue transfer.

distributed to the third to eleventh intercostal spaces. The right posterior intercostal arteries are longer because the descending thoracic aorta deviates to the left (see Fig. 53.18): they cross the vertebral bodies posterior to the oesophagus, thoracic duct and azygos vein, and the parietal pleura covering the right lung. The left posterior intercostal arteries travel posteriorly across the vertebral bodies and are in contact with the parietal pleura covering the left lung; the first and second (branches of the supreme intercostal artery) are crossed by the left superior intercostal vein, and those located inferiorly are crossed by the hemiazygos and accessory hemiazygos veins. The sympathetic trunk and ganglia lie anterior to all of the arteries, and the thoracic splanchnic nerves are anterior to the more inferiorly located arteries.

Each artery crosses its intercostal space obliquely towards the angle of the rib above and continues forwards in its costal groove. It runs between the costal parietal pleura (and its associated endothoracic fascia), and the internal intercostal membrane as far as the angle of the rib, then passes between the internal and innermost intercostal muscles (see Fig. 53.17) and anastomoses with an anterior intercostal branch from either the internal thoracic or musculophrenic artery. Each artery is accompanied by a vein superiorly and a nerve inferiorly, except in the first three or four spaces, where the nerve is initially superior to the artery. The third posterior intercostal artery anastomoses with the supreme intercostal artery and may provide the major supply to the second intercostal space. The inferior two posterior intercostal arteries continue anteriorly into the abdominal wall, where they anastomose with the subcostal, superior epigastric and lumbar arteries (see Fig. 52.3). Each posterior intercostal artery has dorsal, collateral, muscular and cutaneous branches (see Fig. 53.18).

Dorsal branch Each dorsal branch passes posteriorly in the space between the necks of adjacent ribs (superiorly and inferiorly), the adjacent vertebral body (medially) and the superior costotransverse ligament (laterally) (see Fig. 53.11). Each dorsal branch gives off a spinal branch that enters the vertebral canal via the intervertebral foramen and supplies the vertebra, spinal cord and meninges, anastomosing with the spinal arteries located immediately superior, inferior and contralateral (see Fig. 53.18). It then divides into a medial and a lateral dorsal musculocutaneous branch; occasionally these arise separately from the posterior intercostal artery rather than from a common trunk. The medial branch crosses the transverse process of a vertebra with the medial branch of the dorsal ramus of a thoracic spinal nerve to supply spinalis, longissimus thoracis and an area of overlying skin. The lateral branch supplies longissimus thoracis and iliocostalis, and the medial aspects of latissimus dorsi and trapezius, in addition to an area of overlying skin (see Fig. 53.2).

Collateral intercostal branch A collateral intercostal branch arises near the angle of a rib and descends across the intercostal space to the superior border of the rib below, along which it courses to anastomose with its partner branch from the anterior intercostal branch of the internal thoracic or musculophrenic artery.

Muscular branches Muscular branches supply the intercostal and pectoral muscles and serratus anterior, and anastomose with the superior and lateral thoracic branches of the axillary artery. Mammary branches from the anterior intercostal vessels in the second to fourth spaces supply the pectoral muscles, breast tissue and covering skin, and enlarge during lactation.

Lateral cutaneous branch The lateral cutaneous branch arises in the posterior part of the intercostal space and travels anteriorly for a few centimetres with an accompanying vein and the lateral cutaneous branch of the accompanying intercostal nerve (see Fig. 53.21). This neurovascular bundle pierces the intercostal muscles and passes slightly inferiorly to emerge between the interdigitations of serratus anterior and external abdominal oblique. It divides into anterior and posterior branches that contribute to the blood supply of the skin of the lateral trunk (see Fig. 53.2); these vessels are less significant in the first three intercostal spaces.

Unnamed branches Unnamed branches supply tissues of the thoracic wall including the costal periosteum, bone and bone marrow of the ribs, tissues of the synovial and synarthrodial joints, and the parietal pleura and tissues of the extrapleural space.

Clinical significance of the posterior intercostal arteries

Available with the *Gray's Anatomy* e-book

Veins

Internal thoracic veins

The internal thoracic veins are formed by the union of the venae comitantes associated with the inferior half of the internal thoracic artery. Near the third costal cartilage, the veins unite and ascend medial to the artery to drain into the ipsilateral brachiocephalic vein. The internal thoracic veins have several valves. Their tributaries correspond to the branches of the internal thoracic artery and include the pericardiacophrenic veins, which run parallel to the phrenic nerves. The phrenic nerves are surrogate markers of the thymic border but are difficult to detect on CT: the pericardiacophrenic veins can therefore be used in their place as an important landmark when differentiating thymic versus non-thymic tumours (Ozawa et al 2018). The small anterior intercostal veins are tributaries of the internal thoracic and musculophrenic veins.

Left superior intercostal vein

The left superior intercostal vein drains the second and third (sometimes fourth) left posterior intercostal veins (see Fig. 56.7B). It ascends obliquely anteriorly across the left aspect of the aortic arch, lateral to the left vagus nerve and medial to the left phrenic nerve, to open into the left brachiocephalic vein. It usually receives the left bronchial veins and sometimes the left pericardiacophrenic vein, and connects inferiorly with the accessory hemiazygos vein. It may be seen on a chest X-ray as the 'aortic nipple', not to be confused with a small lung nodule.

Posterior intercostal veins

The eleven pairs of posterior intercostal veins accompany their respective arteries (see Fig. 52.4). Approaching the vertebral column, each vein receives a posterior tributary that returns blood from the dorsal musculature and skin and the external vertebral venous plexuses, and an intervertebral vein that drains the internal vertebral venous plexus. On both sides, the first posterior (supreme) intercostal vein ascends anterior to the neck of the first rib, then arches anteriorly, close to the lung apex to drain into the ipsilateral brachiocephalic or vertebral vein. On the right side, the second, third and often the fourth veins form a right superior intercostal vein that drains into the arch of the azygos vein. The more inferior intercostal spaces drain directly into the azygos vein. On the left side, the second, third and sometimes the fourth veins form a left superior intercostal vein. Veins from the fifth (sometimes fourth) to eighth intercostal spaces drain into the accessory hemiazygos vein, and veins from the ninth to the eleventh intercostal spaces drain into the hemiazygos vein; it should be remembered that the azygos system is highly variable.

Lymphatic drainage

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (see Figs 53.22, 46.5). Those superficial to trapezius and latissimus dorsi unite to form up to twelve trunks that end in the subscapular (posterior axillary) nodes. Those in the pectoral region, including vessels from the skin covering the periphery of the breast and its subareolar plexus, run back, collecting those superficial to serratus anterior, to reach the pectoral (anterior axillary) nodes. Vessels near the lateral sternal margin pass between the costal cartilages to the parasternal nodes and anastomose across the sternum, providing a route for contralateral nodal spread in medially located breast carcinoma. A few vessels from the upper pectoral region ascend over the clavicle to the inferior deep cervical nodes. Lymph from the deeper tissues of the thoracic walls drains mainly to the parasternal, intercostal or diaphragmatic (phrenic) nodes.

Parasternal (internal thoracic) nodes

There are four or five parasternal nodes along each internal thoracic artery at the anterior ends of the intercostal spaces. They drain afferents from the breast, deeper structures of the supra-umbilical anterior abdominal wall, the superior hepatic surface (through a small anterior group of nodes posterior to the xiphoid process) and deeper parts of the anterior thoracic wall. Their efferents usually unite with those from the paratracheal (tracheobronchial) and brachiocephalic (prevascular)

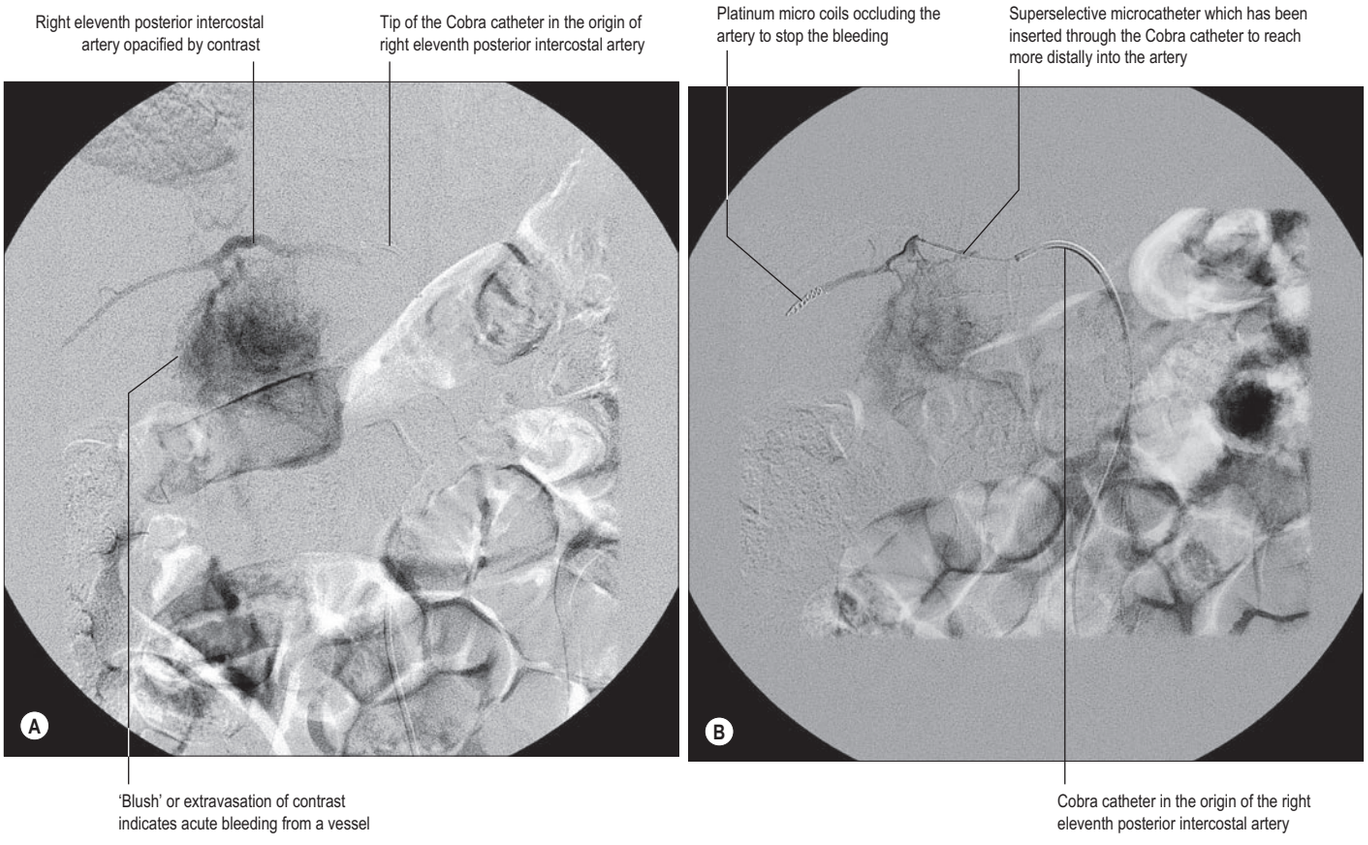

Fig. 53.20 A–B, Pre- and post-embolization images after selective catheterization of the right eleventh posterior intercostal artery.

Catheter embolization is an interventional radiology technique that can be used to block branches of the posterior intercostal arteries when they are bleeding, e.g. secondary to blunt trauma usually associated with rib fractures, or when there is an abnormality of the vertebra supplied by the dorsal branch of the posterior intercostal artery. In such cases, the posterior intercostal artery may be accessed by placing a catheter in the descending thoracic aorta, usually by puncturing the femoral artery in the femoral triangle. A smaller catheter (referred to as a superselective catheter) may then be placed in the posterior intercostal artery and embolic material (metallic coils or glue) is injected to block the artery. This can cause cessation of bleeding in cases of trauma and provide pain relief when, for example, the vertebral body is infiltrated with tumour (Fig. 53.20).

nodes to form the bronchomediastinal trunk (see Figs 54.12, 56.5). On either side, the bronchomediastinal trunk may either open directly into the jugulosubclavian junction; into either the internal jugular or subclavian vein near their junction; into the subclavian trunk; or into the lymphatic duct on the right or the thoracic duct on the left.

Intercostal nodes

Intercostal nodes occupy the intercostal spaces near the heads and necks of the ribs (see Fig. 56.4). They receive deep lymph vessels from the posterolateral aspects of the chest wall and breast, some of which are interrupted by small more laterally placed intercostal nodes. Efferent vessels from nodes in the lower intercostal spaces unite into a trunk that descends to the abdominal confluence of lymph trunks or to the thoracic duct. Efferent vessels from nodes in the left upper intercostal spaces end in the thoracic duct; those of the right upper intercostal spaces end in one of the right lymphatic trunks.

Diaphragmatic nodes

Located on the superior (thoracic) surface of the respiratory diaphragm, the diaphragmatic (phrenic) nodes are arranged in anterior, right lateral, left lateral and posterior groups (see Fig. 56.4A).

Anterior group The anterior group consists of two or three small nodes posterior to the base of the xiphoid process, draining the convex diaphragmatic surface of the liver, and one or two nodes on each side near the junction of the seventh rib and costal cartilage that receive anterior lymph vessels from the respiratory diaphragm. The anterior group drains to the parasternal nodes.

Lateral groups The lateral groups each contain two or three nodes and lie close to the point where the phrenic nerves enter the respiratory diaphragm. On the right, some nodes lie within the fibrous pericardium anterior to the intrathoracic part of the inferior vena cava. Their afferents drain the central part of the respiratory diaphragm; those on the right also drain the convex (diaphragmatic) surface of the liver, and their efferents pass to the para-oesophageal (posterior mediastinal), parasternal and brachiocephalic nodes.

Posterior group The posterior group consists of a few nodes that lie on the posterior aspect of the crura of the respiratory diaphragm and connect with the lateral and posterior aortic (prevertebral) and para-oesophageal (posterior mediastinal) nodes.

Lymphatic drainage of deeper tissues

Collecting vessels of the deeper thoracic tissues include lymphatics that drain the muscles attached to the ribs. Most end in axillary nodes but some from pectoralis major also drain to the parasternal nodes. Intercostal vessels drain the intercostal muscles, tissues of the extrapleural space (e.g. endothoracic fascia) and the costal parietal pleura; those from the anterior thoracic wall end in the parasternal nodes and their posterior counterparts drain to intercostal nodes.

Vessels from the respiratory diaphragm form a thoracic and an abdominal plexus, which anastomose freely, especially in areas covered by diaphragmatic parietal pleura and peritoneum, respectively. The thoracic plexus unites with lymph vessels draining the costal and mediastinal parts of the parietal pleura. Its efferents are: anterior, draining to the anterior diaphragmatic nodes near the junctions of the seventh rib and costal cartilage; middle, draining to nodes on the oesophagus (para-oesophageal) and around the intrathoracic part of the inferior vena cava (right lateral); and posterior, draining to nodes around the descending thoracic aorta at the point where it leaves the thorax. The abdominal plexus anastomoses with the hepatic lymphatics and peripherally with those of the subperitoneal tissue. Efferents from its right half pass to a group of nodes close to the right inferior phrenic artery, or in the right lateral aortic nodes. Those from the left half of the abdominal diaphragmatic plexus pass to the preaortic, lateral aortic and para-oesophageal nodes.

INNERVATION OF THE CHEST WALL

Thoracic ventral spinal rami

There are 12 pairs of ventral rami of the thoracic spinal nerves. The first 11 lie in the intercostal spaces, between the first to twelfth ribs (intercostal nerves) and the twelfth lies inferior to the twelfth rib (subcostal nerve). Each is connected with the adjacent sympathetic ganglion by grey and white rami communicantes; the grey ramus normally joins the nerve proximal to the point at which the white ramus leaves it (Fig. 53.21; see Fig. 56.6), although this pattern varies. Intercostal nerves are distributed primarily to the thoracic and abdominal walls. The first two nerves supply fibres to the upper limb in addition to their thoracic branches, the third to the sixth nerves supply only the thoracic wall, and the seventh to eleventh nerves supply both thoracic and abdominal walls. The twelfth (subcostal nerve) is distributed to the abdominal wall and skin covering the anterior aspect of the gluteal region. Communicating branches link the intercostal nerves posteriorly across the intercostal spaces (see Fig. 55.10), and the eighth to twelfth nerves communicate freely in the abdominal wall.

First to sixth thoracic ventral rami

The first thoracic ventral ramus divides unequally: a large branch ascends across the neck of the first rib, lateral to the supreme intercostal artery (see Fig. 55.10), to enter the brachial plexus, and a smaller branch (the first posterior intercostal nerve) runs in the first intercostal space and terminates as the anterior cutaneous branch. A lateral cutaneous branch pierces the chest wall anterior to serratus anterior and supplies the axillary skin; it may communicate with the intercostobrachial nerve and sometimes joins the medial cutaneous nerve of the arm. The first thoracic ventral ramus often receives a connecting branch from the second, which ascends anterior to the neck of the second rib.

The second to sixth thoracic ventral rami travel within their respective intercostal spaces inferior to the intercostal vessels (see Fig. 53.17). Posteriorly, they lie initially between the costal parietal pleura (and its associated endothoracic fascia), and the internal intercostal membrane, but more laterally they lie between the internal intercostals and subcostales and/or innermost intercostals. Near the sternum, they cross anterior to the internal thoracic vessels and transversus thoracis, pierce the internal intercostals, the external intercostal membrane and pectoralis major, and terminate as the anterior cutaneous branches of the intercostal nerves. The anterior cutaneous branch of the second intercostal nerve may be connected to the medial supraclavicular nerves of the cervical plexus. Branches from the sixth intercostal nerve supply abdominal skin immediately inferior to the apex of the costal arch (the infrasternal angle).

Branches Numerous slender muscular filaments supply the intercostals, serratus posterior superior and transversus thoracis. Anteriorly, some cross the costal cartilages to pass from one intercostal space to another. Each posterior intercostal nerve gives off a collateral and a lateral cutaneous branch before it reaches the angle of the adjoining ribs (see Fig. 53.21). The collateral branch follows the inferior border of the numerically corresponding intercostal space in the same intermuscular plane as the posterior intercostal nerve, which it may rejoin before it is distributed as an additional anterior cutaneous branch. The lateral cutaneous branch accompanies the main nerve for a short distance and then pierces the intercostal muscles obliquely. With the exception of the lateral cutaneous branches of the first and second intercostal nerves, each divides into anterior and posterior branches that subsequently pierce serratus anterior. The anterior branches pass anteriorly over the border of pectoralis major to supply the overlying skin; those from lateral branches of the fifth and sixth intercostal nerves also supply small motor branches to a variable number of upper digitations of external abdominal oblique. The posterior branches run posteriorly and supply the skin over the scapula and latissimus dorsi.

The lateral cutaneous branch of the second intercostal nerve is the intercostobrachial nerve (see Fig. 49.34). It crosses the axilla to reach the medial side of the arm and joins a branch of the medial cutaneous nerve of the arm. It then pierces the brachial (deep) fascia of the arm, and supplies the skin of the superior half of the posterior and medial aspects of the arm, communicating with the posterior brachial cutaneous branch of the radial nerve. Its size is in inverse proportion to the size of the medial cutaneous nerve of the arm. A second intercostobrachial nerve often branches from the anterior branch of the lateral cutaneous branch of the third intercostal nerve and sends fibres to the axilla and the medial side of the arm.

Seventh to eleventh thoracic ventral rami

The ventral rami of the seventh to eleventh thoracic spinal nerves follow a similar course to that as described above for the ventral rami of the second to sixth thoracic spinal nerves. They continue anteriorly from

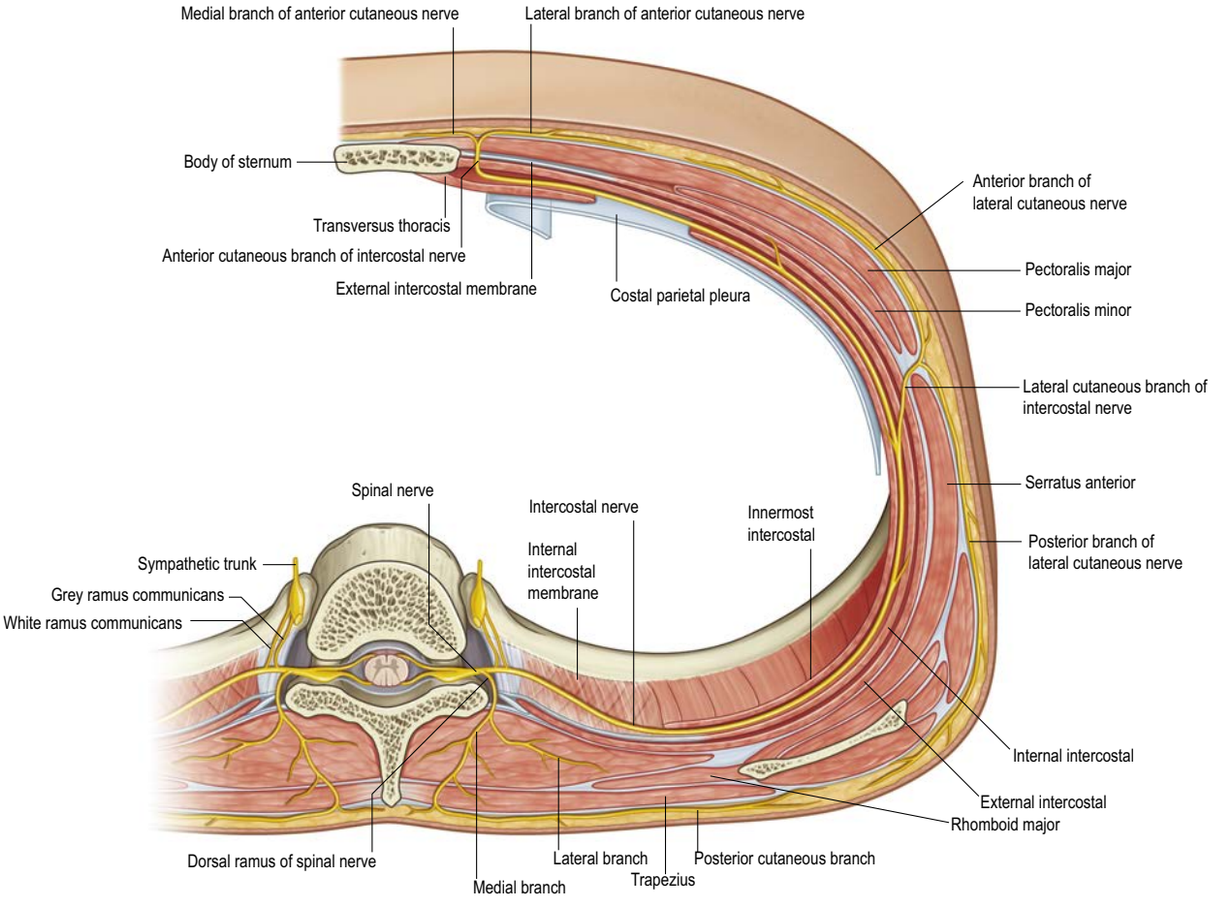

Fig. 53.21 A transverse section through an intercostal space, showing the course and branching of a typical intercostal nerve.

the intercostal spaces into the abdominal wall and their further course is described in Chapter 60.

Lesions of the intercostal nerves

Available with the *Gray's Anatomy* e-book

Twelfth thoracic ventral ramus (subcostal nerve)

The ventral ramus of the twelfth thoracic spinal nerve (subcostal nerve) is larger than the others and gives a communicating branch (dorsolumbar nerve) to the ventral ramus of the first lumbar spinal nerve. As with the intercostal nerves, it gives off a collateral branch and then accompanies the subcostal vessels along the inferior border of the twelfth rib, passing posterior to the lateral arcuate ligament and kidney, and anterior to the superior part of quadratus lumborum. It perforates the aponeurosis of transversus abdominis to pass forwards between it and internal abdominal oblique. It is distributed in the same manner as the lower intercostal nerves. The subcostal nerve connects with the iliohypogastric nerve of the lumbar plexus and sends a branch to pyramidalis. Its lateral cutaneous branch pierces the internal and external abdominal oblique muscles and supplies the lowest slip of the latter. It usually descends over the iliac crest about 5 cm posterior to the anterior superior iliac spine (see Fig. 60.5) and is distributed to the skin covering the anterior aspect of the gluteal region; some nerve fibres may reach as low as the greater trochanter of the femur. A transversalis fascia plane (TFP) block can improve the coverage of proximal surgical incisions used in hip surgery, because both the inferior branches of the subcostal nerve and the iliohypogastric nerve are anaesthetized.

Thoracic dorsal spinal rami

The dorsal rami of the thoracic spinal nerves pass posteriorly close to the vertebral zygapophysial (facet) joints and divide into medial and lateral branches (see Figs 53.21, 47.10). Their course and distribution are reviewed in Chapter 47. Briefly, the medial branch emerges between the joint and the medial edge of the superior costotransverse ligament and intertransverse muscle. The lateral branch runs laterally in the interval between the ligament and the muscle before turning posteriorly and inferiorly at the level of the costotransverse joint.

The medial branches of the first to sixth thoracic dorsal rami subsequently pass between and supply semispinalis thoracis and multifidus, then pierce the rhomboids and trapezius and reach the skin near the vertebral spines (see Figs 53.15C, 53.16): they descend for some distance close to the vertebral spines before reaching the skin (see Fig. 47.8). The medial branches of the seventh to twelfth thoracic dorsal rami are distributed mainly to multifidus and longissimus thoracis and occasionally give fibres to the skin covering the median region of the back.

The lateral branches increase in size from superior to inferior and run through or deep to longissimus thoracis to the interval between it and iliocostalis cervicis, supplying these muscles and levatores costarum. A variable number of the lateral branches of the upper thoracic dorsal rami may supply the skin. The lower five or six lateral branches give off cutaneous branches that pierce serratus posterior inferior and latissimus dorsi in line with the angles of the ribs. The lateral cutaneous branches descend by as much as four ribs before they become superficial, e.g. the branch of the twelfth thoracic ramus reaches the skin only a few centimetres superior to the iliac crest.

BREAST

The breasts form a secondary sexual feature of females and the milk produced is a source of protection and nutrition for the neonate and infant. In young adult females, each breast is a rounded eminence largely lying within the superficial fascia covering parts of the anterior and lateral thoracic walls but spreading laterally to a variable extent toward the midaxillary line (**Figs 53.22–53.23**). Breast shape and size varies with genetics, race and dietary factors and on the age, parity and menopausal status of the individual. Breasts may be hemispherical, conical, variably pendulous, piriform or thin and flattened. In the adult female, the base of the breast (its deep attached surface) extends vertically from the second or third to the sixth rib/costal cartilage, and in the transverse plane from the lateral sternal border medially to the mid-axillary line laterally. The axillary process (tail or tail of Spence) of the breast is an extension of the superolateral quadrant towards the

Slipping rib syndrome occurs with subluxation of the interchondral joints between the eighth to tenth rib costal cartilages. This may trap or impinge intercostal nerves, causing subsequent localized pain or referred abdominal pain (McMahon 2018). The dorsal cutaneous branch of an intercostal nerve can become entrapped as it penetrates the fascia of erector spinae, producing an area of numbness, usually with painful paraesthesia, that extends laterally from the posterior midline by about 10 cm, and is 10 cm in height (notalgia paraesthetica); the area between the medial border of the scapula and the spinous processes of the vertebrae is commonly affected. The anterior cutaneous branches of the intercostal nerves can also become entrapped as they penetrate the fascia of rectus abdominis, producing an area of numbness on the anterior abdominal wall, usually with painful paraesthesia, that extends from the anterior midline laterally by about 10 or 12 cm (rectus abdominis syndrome).

axilla along the inferolateral edge of pectoralis major; it may extend through the deep fascia toward the apex of the axilla.

Fascia

The complex fascial network that encases and shapes the breast has been variously described. According to Rehnke et al (2018), the glandular breast tissue is surrounded on its superficial and deep surfaces by anterior and posterior laminae, respectively, of superficial fascia and fat (see Fig. 53.23B). The fascial laminae and deep fascial system of the trunk interconnect around the perimeter of the breast via the circummammary ligament, a circular zone of adhesion traversed by nerves, blood vessels and lymphatic vessels. The breast lies on the deep pectoral fascia covering pectoralis major and serratus anterior superiorly, external abdominal oblique and its aponeurosis inferiorly as the latter forms the anterior wall of the rectus sheath, and the clavipectoral fascia laterally. Fibrous strands or sheets consisting of condensations of connective tissue extend between the posterior lamina of the superficial fascia and the dermis. These suspensory ligaments (retinacula or Cooper's ligaments) are often well developed in the superior parts of the breast and support the breast tissue, helping to minimize drooping. Loose connective tissue in the submammary space (between the posterior lamina of superficial fascia and the deep fascia of the trunk) allows the breast some degree of independent movement across the deep pectoral fascia. Advanced mammary carcinoma may cause tethering or fixation of the breast and its skin to the underlying musculature, resulting in indentation of the skin or breast movement upon contraction of pectoralis major. Occasionally, small projections of glandular tissue may pass through the deep fascia into the underlying muscle in normal subjects.

Nipple and areola

The nipple projects from the breast anteriorly (see Fig. 53.23). It may be cylindrical and rounded, hemispherical or flattened, depending on the effects of developmental, nervous or hormonal factors and external temperature on the erectile properties of the subareolar muscle of the nipple. The level of the nipple varies widely. In females, its site is dependent on the size and shape of the breasts; it often overlies the fourth intercostal space in prepubescent females. In the male, the nipple is usually sited in the fourth intercostal space in the mid-clavicular line, although this should not be relied upon when landmarking. In the young adult of either sex, the nipples are usually positioned 20–23 cm from the suprasternal notch in the mid-clavicular line and 19–23 cm apart in the horizontal plane. With increasing age, parity and weight, female breasts adopt an increasingly drooped shape and the position of the nipple descends to the level of the inframammary crease or below. In the nulliparous, the nipple is pink, light brown or darker, depending on the general melanization of the body. Occasionally, one or both nipples may not evert during prenatal development and remain permanently retracted (see below).

The skin covering the nipple and the surrounding areola (the disc of skin that circles the base of the nipple) has a convoluted surface. It contains numerous sweat and areolar (Montgomery's) glands that open directly onto the skin surface. The oily secretion of these specialized sebaceous glands acts as a protective lubricant and facilitates latching of the neonate during lactation; the glands are often visible in parous women, arranged circumferentially as small elevations, areolar (Montgomery's) tubercles, around the areola close to the margin. Other areolar glands, intermediate in structure between mammary and sweat glands, become enlarged in pregnancy and lactation as subcutaneous tubercles. The

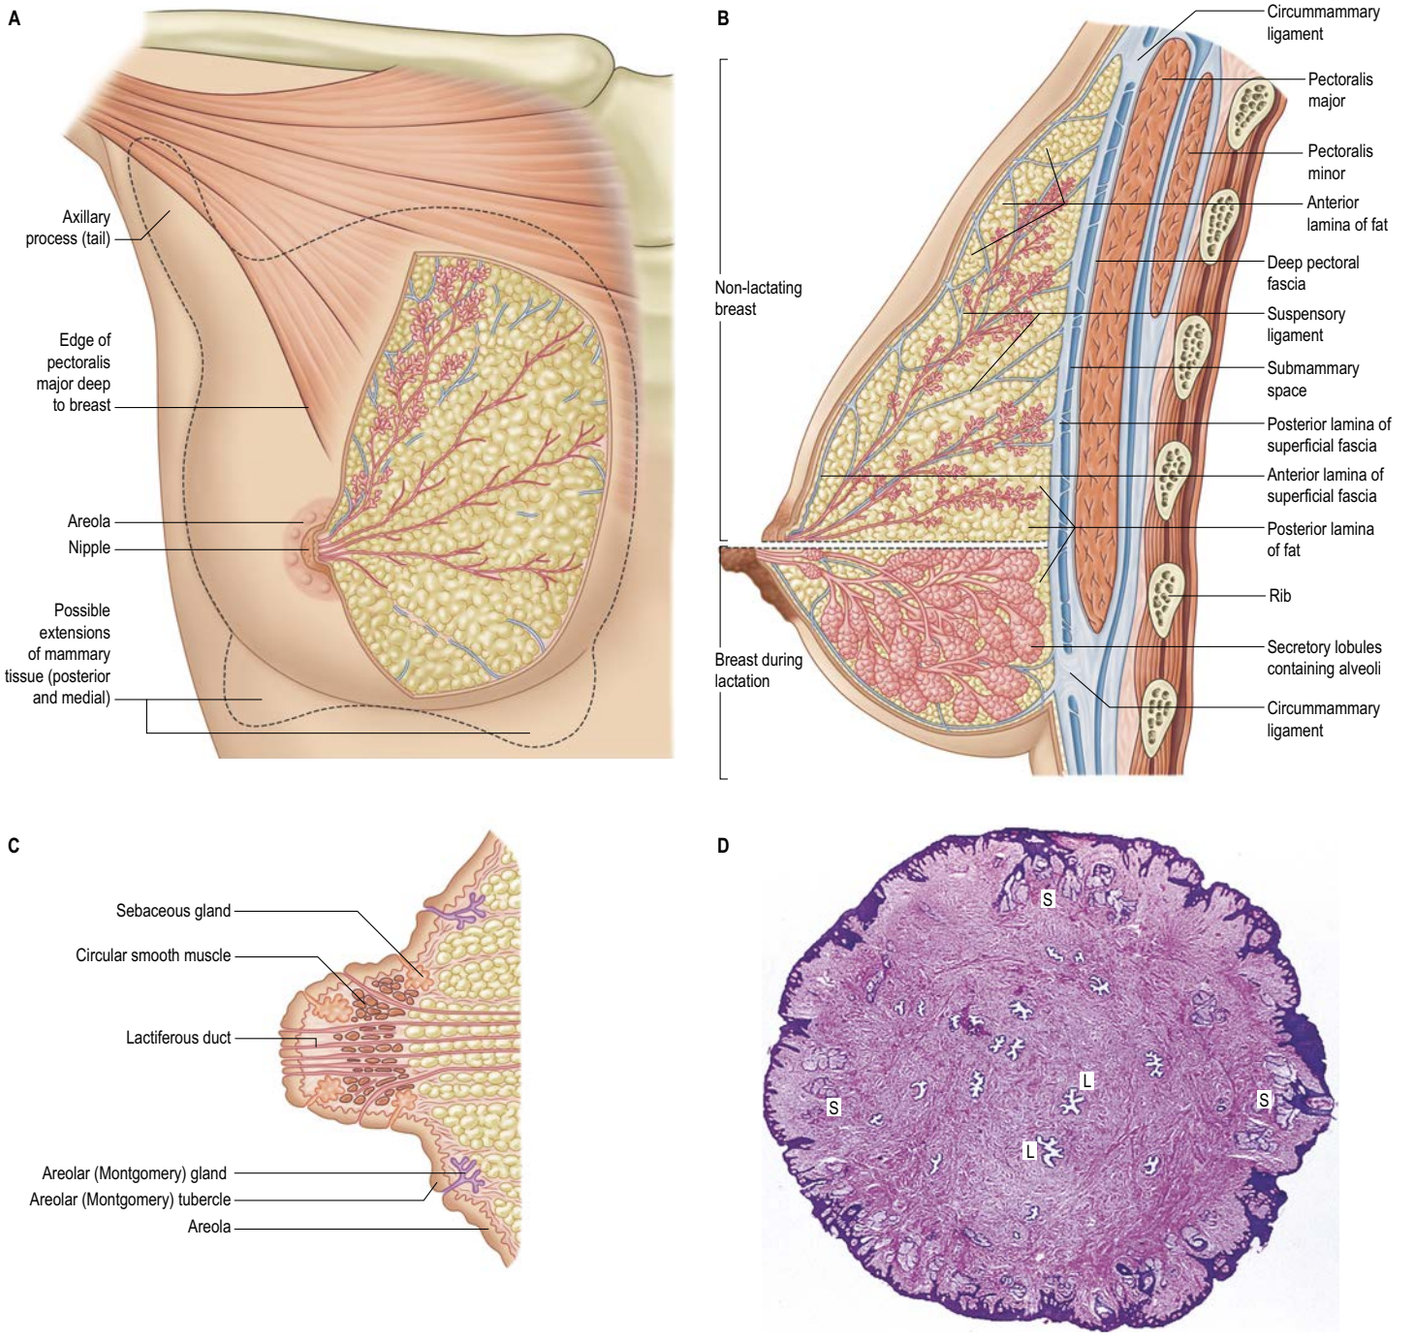

Fig. 53.23 **A**, The structure of the breast. **B**, Fascia of the breast and changes in the breast during lactation. **C**, A section of the nipple. **D**, A cross-section of the nipple. There is a corrugated layer of stratified squamous keratinized epithelium over the nipple surface; 20 or more lactiferous ducts (L) open on to the surface; sebaceous glands (S) are deep to the epidermis. (D, With permission from Dr JB Kerr, Monash University, from Kerr JB 1999 Atlas of Functional Histology. London: Mosby.)

sebaceous glands of the areola are not usually associated with hair follicles although scattered hairs may be present at the areolar margin. The skin of the nipple and areola is rich in melanocytes and is therefore typically darker than the skin covering the remainder of the breast; the areola increases in size and further darkening occurs during the second month of pregnancy and subsequently persists to a variable degree.

Soft tissue

The breasts are normally composed of up to 20 discrete lobes that contain ductal-glandular tissue consisting of branching ducts and terminal secretory lobules in a connective tissue stroma (see Fig. 53.23). Each lobe is derived by branching from one central lactiferous duct in the nipple. The terminal duct lobular unit (TDLU or lobule) is the functional milk secretory component of the breast. Histological evidence suggests premalignant epithelial proliferations originate from the TDLU; alternatively, a predisposition to malignant transformation may be present throughout an individual lobe ('sick lobe' hypothesis), creating an impression of multifocality. Although lobes are usually described as discrete territories, they intertwine in three dimensions, merge at their edges and cannot be distinguished during surgery. The interlobular connective tissue stroma is dense and fibrocollagenous, whereas intralobular connective tissue has a loose texture that allows the rapid expansion of secretory tissue during pregnancy (see Figs 53.23B, 53.29B). Elsewhere in the normal breast, fibrous tissue surrounds the ductal glandular components and extends to the skin and nipple, assisting the mechanical coherence of the breast. The interlobular stroma contains variable amounts of adipose tissue, which is responsible for much of the increase in breast size at puberty.

Vascular supply and lymphatic drainage

Arteries

The breasts are supplied by branches of the axillary, internal thoracic and some anterior intercostal arteries. The axillary artery supplies blood via the superior thoracic artery (if present), the pectoral branches of the thoraco-acromial artery, the lateral thoracic artery (via

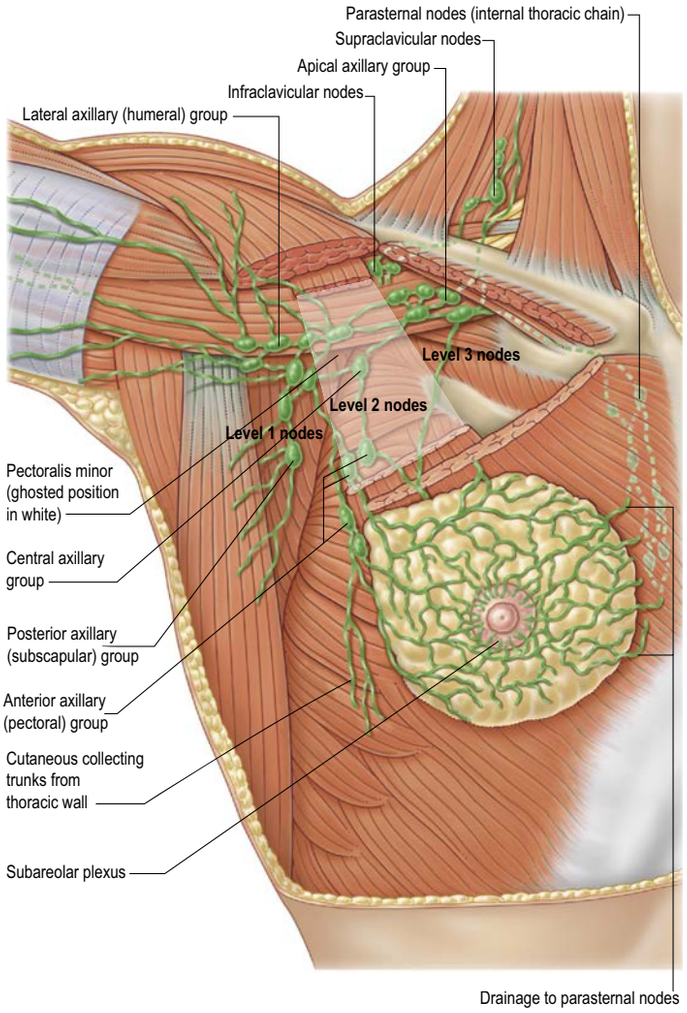

Fig. 53.24 Lymph vessels of the breast and the draining axillary nodes (level 1–3 shown) and supraclavicular nodal groups.

lateral mammary branches that curve around the lateral border of pectoralis major to supply the lateral aspect of the breast) and the subscapular artery. The internal thoracic artery supplies medial mammary branches to the anteromedial part of the breast. The second to fourth anterior intercostal arteries may supply perforating branches more laterally in the anterior thorax. The second perforating artery is usually the largest and supplies the superior region of the breast, the nipple, areola and adjacent breast tissue. Arteries access the body of the breast tissue via circumferential connections between deep and superficial fasciae.

Veins

Blood drains from the circular venous plexus around the areola and from the glandular tissue of the breast into the axillary, internal thoracic and intercostal veins via veins that accompany the corresponding arteries. Individual variation is common.

Lymphatic drainage

The lymphatic drainage of the breast is of great clinical significance because metastatic dissemination occurs principally by the lymphatic routes (the breasts are the site of malignant change in as many as 1 in 8 women; Commentary 7.1). The dominant lymphatic drainage of the breast is derived from the dermal network (Fig. 53.24). Breast lymphatics branch extensively; the smallest valveless superficial lymph capillaries (20–70 μm diameter) drain into larger lymph pre-collecting vessels (~300 μm diameter) that contain valves and smooth muscle. These pre-collectors unite to form a subcutaneous network between skin and breast tissue and drain almost always to at least one sentinel node, usually near the lateral border of pectoralis minor (Suami et al 2008). Lymphatic blockage through tumour occlusion may therefore result in reverse flow through the lymphatic channels, resulting in oedema. The direction of lymphatic flow within the breast parallels the major venous tributaries and enters the regional lymph nodes via an extensive periductal and perilobular network of lymphatic channels. Most of these lymphatics drain into the axillary group of regional lymph nodes either directly or through the subareolar lymphatic plexus (see Fig. 49.48). Dermal lymphatics also penetrate pectoralis major to join channels that drain the deeper parenchymal tissues, and then follow the vascular channels to terminate in the regional lymph nodes below the level of the clavicle.

Lymphatics from the left breast ultimately terminate in the thoracic duct and, subsequently, the left subclavian vein. On the right, the lymphatics ultimately drain into the right subclavian vein near its junction with the internal jugular vein. Part of the medial sides of the breasts drain to the parasternal nodes, lying along the internal thoracic vessels. These may anastomose across the sternum, providing a route for contralateral nodal spread in medially located breast carcinoma. Parasternal nodes and vessels may drain inferiorly via the superior and inferior epigastric lymphatic routes to the superficial and deep inguinal nodes in the femoral triangle.

Axillary nodes receive more than 75% of the lymph from the breast. There are 20–40 axillary nodes, grouped somewhat artificially as anterior (pectoral), posterior (subscapular), lateral (humeral), central and apical. Surgically, the nodes are described in relation to pectoralis minor; those lying lateral or inferior to pectoralis minor are the low nodes (level 1), those lying posterior to pectoralis minor are the middle group (level 2), and those lying between the superomedial (upper) border of pectoralis minor and the inferior (lower) border of the clavicle are the upper or apical axillary nodes (level 3) (see Fig. 53.24). There may be one or two interpectoral (Rotter's) nodes lying between pectoralis minor and major. Efferent vessels may pass directly from the breast around the anterior axillary border and through the axillary fascia to the anterior axillary (pectoral) lymph nodes; some may pass directly to the posterior axillary (subscapular) nodes. A few vessels pass from the superior part of the breast to the apical axillary nodes, sometimes interrupted by the infraclavicular nodes or by small, inconstant, interpectoral nodes. Most of the remainder drain to parasternal nodes from the medial and lateral parts of the breast and accompany perforating branches of the internal thoracic artery. Lymphatic vessels occasionally follow lateral cutaneous branches of the posterior intercostal arteries to the intercostal nodes (see Fig. 56.4A).

Axillary surgery in breast cancer

Axillary lymph node dissection may be performed for diagnostic and therapeutic reasons. The presence of metastases within axillary lymph nodes has strong prognostic significance and may influence decisions on adjuvant therapy. Axillary lymph node dissection can lead to chronic postoperative problems such as pain, seroma formation, reduced mobility of the upper limb, impaired sensation and lymphoedema.

Microstructure

The microstructure of breast tissue varies with age, time in the menstrual cycle, pregnancy and lactation. The following description relates to the mature, resting (non-lactating) breast. For most of their lengths, the ducts are lined by columnar epithelium (Fig. 53.25A–B). The bases of these cells are in close contact with numerous myoepithelial cells of ectodermal origin, similar to those of certain other glandular epithelia (see Figs 53.29A, 2.3, 2.4). Myoepithelial cells are so numerous that they form a distinct layer surrounding the ducts and presumptive alveoli, and give the epithelium a bilayer appearance.

Lactiferous ducts draining each lobe of the breast pass through the nipple and open on to its tip as up to 20 orifices. Close to their openings on the nipple, the stratified cuboidal epithelial lining of the lactiferous ducts is replaced by keratinized stratified squamous epithelium, continuous with the epidermis. Shed squames may

Nerves and lymph vessel in the axillary region must be considered as anatomical landmarks during surgery and carefully identified and preserved. Chronic neuropathic pain is a common consequence of surgery, with a prevalence of 25–60% (Jung et al 2003). Chronic pain exacerbates the stress associated with the already burdensome management of breast cancer and in many patients adversely impacts their daily life. Complete resection, stretch or compression of the lateral cutaneous branch of T2 (intercostobrachial nerve) may result in numbness or pain in the ipsilateral axilla, medial arm and upper anterior chest. Symptoms are more common and longer lasting when the origin of the nerve is injured as opposed to its peripheral branches (Jung et al 2003). Resection or compression of the long thoracic nerve, which passes inferior to the clavicle through the axillary sheath and then down the chest wall between the midaxillary and posterior axillary lines to innervate serratus anterior, can result in palsy (with scapular winging): shoulder pain may be exacerbated by shoulder instability and reduced abduction.

Lymphatic mapping with sentinel lymph node biopsy has become an important technique in the staging of patients with early breast cancer. Based upon the assumption that the majority of the lymphatic drainage of the breast occurs through the subareolar plexus (Suami et al 2009), a radiolabelled colloid is injected into either the subareolar tissue of the index quadrant of the breast or into the peritumoural and intradermal tissue overlying the primary breast cancer. At the time of surgery, a vital blue dye is injected after general anaesthesia is established. The combination of radioisotope and dye provides the most accurate means of localizing the sentinel node (Tanis et al 2001). The latter represents the first draining node within the axilla and is surgically removed for careful histopathological analysis to detect the presence of metastases. There is a 5–10% false-negative rate for this procedure that can be partly attributed to anatomical differences in lymphatic drainage (Tanis et al 2005, Suami et al 2008).
