Secondary prevention refers to the treatment of subclinical cardiomyopathy detected by elevated biomarkers or strain imaging. Cardinale et al. showed that the use of enalapril, in patients determined to be high-risk based on troponin I levels, prevented anthracycline-mediated cardiomyopathy (Cardinale et al., 2006). In another study, β-blockers improved LV systolic function in the cancer patients who developed subclinical cardiomyopathy detected by a decline in global longitudinal strain >11%(Negishi et al., 2014).

Dexrazoxane

Dexrazoxane, an intravenous iron chelating agent, is approved by the FDA as a cardioprotective agent in patients receiving anthracyclines (Hensley et al., 2009). This drug also inhibits the production of anthracycline-bound DNA–Top2 complexes (Sawyer et al., 2010; Hahn et al., 2014). The American Society of Clinical Oncology suggests restricting this medication to the adult patients with metastatic breast carcinoma who received >300 mg/m (Siegel et al., 2015) of anthracyclines and may benefit with additional dose of anthracyclines (Hensley et al., 2009). In one study involving adult cancer patients receiving anthracyclines, the use of dexrazoxane reduced the risk of HF and the rate of cardiac events (Kalam and Marwick, 2013; Marty et al., 2006). In another study involving pediatric patients with Hodgkin's disease, dexrazoxane increased the risk of secondary cancer (Tebbi et al., 2007). But this finding could not be confirmed in other studies (Lipshultz et al., 2007; Hellmann, 1996).

Statins

In addition to their lipid lowering action, statins also have cardioprotective effects mediated by their pleiotropic properties (Acar et al., 2011). In a small randomized study involving 40 patients receiving anthracyclines, the use of atorvastatin was associated with a lower rate of LVEF decline <50% (Acar et al., 2011). In a retrospective observational study involving 628 patients, statins significantly reduced the incidence of HF (Seicean et al., 2012). Further studies are needed to study the efficacy of statins for the prevention of CTMC.

Surveillance and Management of CTMC

Current surveillance protocols have been developed by expert consensus. One strategy involves risk stratification of patients based on cancer-related and cardiovascular risk factors (Herrmann et al., 2014). Baseline transthoracic echocardiogram with strain should be obtained before chemotherapy. Although the role of biomarkers is not well defined, monitoring of biomarkers is suggested (Herrmann et al., 2014). The timing and frequency of follow-up and serial imaging is institution-specific but should be individualized based on the patient-related risk factors and chemotherapy regimen (Hamo et al., 2016).

The Canadian Trastuzumab Working group suggests that LV function be assessed pretreatment and every 3 months for the duration of trastuzumab therapy with more frequent and closer monitoring for the patients determined to be high risk (Mackey et al., 2008). The FDA suggests holding trastuzumab for a minimum of 4 weeks if LVEF decreases $\geq$16% from baseline level or if LVEF drops by $\geq$10% from baseline to a value below normal. Trastuzumab can be restarted if the LVEF increases to normal in 4–8 weeks and the overall reduction from pretreatment level is $\leq$15% (FDA Drug Label, 2010).

Guidelines for discontinuation of anthracyclines are not clearly delineated (Herrmann et al., 2014). It is generally suggested that doxorubicin be stopped if the patient develops symptomatic HF (FDA Drug Label for DOXIL-doxorubicin hydrochloride injection s, liposomal, n.d.). In one study, a decline in LVEF >4% after a cumulative dose of 200 mg/m (Siegel et al., 2015) of doxorubicin has been shown to predict future anthracycline-mediated cardiomyopathy (Nousiainen et al., 2002). Surveillance imaging is recommended every 6 months for 1 year after completion of chemotherapy. In patients considered high risk, reevaluation at 3 months after completion of chemotherapy is suggested (Herrmann et al., 2014).

Treatment of patients who develop LV dysfunction and symptomatic CTMC should be according to AHA/ACC HF guidelines (Hamo et al., 2016).

Heart Failure Therapies for End-Stage CTMC

Conventional advanced HF therapies such as cardiac resynchronization therapy, mechanical circulatory devices, and orthotopic heart transplantation may be beneficial for end-stage chemotherapy-mediated cardiomyopathy (Hamo et al., 2016). In a small observational study involving patients with doxorubicin-mediated cardiomyopathy, cardiac resynchronization therapy improved symptoms and echocardiographic parameters to the same degree as seen in other nonischemic cardiomyopathy patients (Rickard et al., 2010). Otherwise, there is limited data regarding the benefit of cardiac resynchronization therapy in cancer patients. The results of the ongoing Multicenter Automated Defibrillator Implantation Trial—Chemotherapy-Induced Cardiomyopathy (MADIT-CHIC; Clinical Trial Registration No. NCT02154721) are eagerly awaited (Multicenter Automatic Defibrillator Implantation Trial, 2016).

Mechanical support devices are available as bridge-to-transplantation as well as destination therapy (Mukku et al., 2016). The patients with CTMC who receive LV assist devices have 1-, 2- and 3-year survival rates of 73%, 63%, and 47%, respectively (Mukku et al., 2016). Evaluation of the right ventricle before LV assist device implantation is extremely important, as these patients have an increased risk of right ventricular dysfunction. Not surprisingly, these patients are more likely to need right ventricular assist devices (Oliveira et al., 2014).

The number of patients with CTMC referred for orthotopic heart transplantation is steadily increasing (Oliveira et al., 2012). Patients with CTMC make up 0.8%–2.5% of all heart transplant recipients (Mukku et al., 2016). When compared to other nonischemic cardiomyopathy patients, CTMC patients had lower rates of rejection but higher rates of infection and malignancy in the first year after transplantation (Oliveira et al., 2012). However, overall survival was similar in both patient cohorts (Oliveira et al., 2012).

Conclusion

With improvements in cancer treatments and better survival, early detection and management of cardiomyopathy has become increasingly important. The first step is the risk stratification of cancer patients with prior cardiovascular conditions or known cardiac risk factors. These patients require regular imaging depending on their individual risk. Patients who develop asymptomatic LV dysfunction or overt HF require adjustment or interruption of chemotherapy. The goal is to detect and treat cardiomyopathy at an early stage so that life-saving cancer therapies can be administered without interruption (Fig. 5).

Introduction

A syndrome rather than a distinct diagnosis, with many potential pathways to developing cardiac dysfunction, heart failure (HF) is a diverse condition that is difficult to characterize from the individual to societal level. Consequently, it would be a mistake to assume that the characteristics and burden of HF will be the same from one country and population to the next. This is particularly true when considering the likely differences between countries with diverse socio-demographic, socio-economic, and disease profiles. Currently, HF is largely defined by how it presents in high-income countries, with research gravitating toward relatively younger cohorts with a predominance of affected men with coronary artery disease. For example, in the seminal PARADIGM Trial cohort (mean age 64 years) nearly 80% were men and 60% had an ischemic cardiomyopathy (McMurray et al., 2014). The consequence of this imbalance is a paucity of data to describe the burden and risk factors of HF from a low- to middle-income country (LMIC) perspective. Data from the Global Burden of Disease studies (1990–2000) reported 235 contributors to global death; none of which were HF (Lozano et al., 2012). However, HF was included as a nonfatal health outcome and as a key indicator of population health. Accordingly, the majority of deaths primarily due to HF are documented as such (Goldacre et al., 2005).

Global Burden and Risk Factors of HF

Worldwide, population health is likely to vary markedly due to the wide spectrum of ethnic and cultural communities whose health and welfare are influenced by a broad range of socio-economic factors. As will be described later, the distribution and characteristics of HF reflects this. Overall, however, it is estimated there are approximately 26 million cases of HF globally at any one time (Ambrosy et al., 2014).

There are a number of conditions that confer a high risk for developing cardiac dysfunction and then HF; the two most common conditions being coronary artery disease (most closely linked to ischemic cardiomyopathy and subsequent HFrEF) and uncontrolled hypertension (most closely linked to hypertrophic cardiomyopathy and HFpEF). As the pattern of HF has evolved over the past 20–30 years, numerous reviews have focused on its risk factors/antecedents from high-income countries (Killip, 1985; Mendez and Cowie, 2001). Notably, Khatibzadeh and colleagues published a systematic review focusing on the numerous risk factors for HF from a global perspective (Khatibzadeh et al., 2013). They found that more than 50% of HF patients in Western, Eastern, and Central Europe presented with ischemic heart disease compared to 30%–40% in East Asia, Asia Pacific, Latin America, and the

Caribbean. Alternatively, in sub-Saharan Africa, ischemic heart disease was found in only 10% of HF cases. Significantly, hypertension was the most consistent risk factor for HF among all regions (≥17% crude prevalence). On an age and sex-adjusted basis, hypertension was most common in sub-Saharan Africa (33%, range 30%–36%), and Central and Eastern Europe (35%, range 33%–37%). Rheumatic heart disease was more prevalent in East Asia (34%) and sub-Saharan Africa (14%). Dilated and restrictive cardiomyopathy was most common in sub-Saharan Africa (adjusted prevalence 26%, range 23%–29%), Latin America, and the Caribbean (20%, range 17%–23%), as well as in high-income countries in Asia Pacific (17%, range 13%–21%). Beyond these broad trends, there are relatively less common forms of HF (in the developed world) that are or have been endemic to certain parts of the developing world; including HF linked to endomyocardial fibrosis, Chagas disease, peripartum cardiomyopathy (PPCM), and HIV cardiomyopathy (Keates et al., 2017).

Gaps in HF Research in Low- to Middle-Income Countries

Population health data from many regions of the world are scarce, particularly that focusing on the differences of HF between urban and rural populations and the evolution of risk factors contributing to the syndrome over time. Overall, specific factors contributing to the spectrum of cardiomyopathies leading to HF are underreported. This reflects a shortage of resources and diagnostic capabilities, with many historical reports on HF based on clinical diagnoses in the absence of echocardiography. Paradoxically, surveillance for HF is especially poor in those communities most at risk of developing HF, particularly where communicable causes of cardiomyopathy are common. Generally, right HF/pulmonary hypertension is poorly documented and there is a paucity of detailed description of the subtypes of valvular heart disease (such as the various manifestations of rheumatic heart disease). Additionally, congenital heart disease is usually categorized with "other causes contributing to HF" and represents an under-researched contributor to the syndrome. (Van Der Linde et al., 2011).

HF in Low- to Middle-Income Regions

The regions that predominantly contain LMICs are: sub-Saharan Africa, Latin America and the Caribbean, Middle East and North Africa, Europe and Central Asia, East Asia and Pacific, and South Asia (The World Bank, 2017). However, it is important to note that there are high-income countries nested within these regions, as well as particularly disadvantaged populations nested in the high-income countries (e.g., Indigenous Australians) in whom HF more closely resembles that found in the developing world.

Sub-Saharan Africa

Countries within sub-Saharan Africa (**Fig. 1**), barring Seychelles, are largely defined as low-to-middle income (The World Bank, 2017). In this region, as in other parts of the developing world there is a critical lack of effective interventions, such as gold-standard pharmacotherapy, management programs, and invasive procedures/devices. Consequently, there is a critical need for new research investigating the progression, pathogenesis, and prognosis of HF within Africa (Keates et al., 2017).

Fig. 1 The sub-Saharan Africa Region.

Burden of heart failure

Acute decompensated HF is the most common primary diagnosis for patients admitted to hospital with heart disease in sub-Saharan Africa (Kraus et al., 2015; Sliwa et al., 2008; Damasceno et al., 2012). Recent data from the INTER-CHF Registry prospectively characterized the contemporary sociodemographic, clinical variables, HF risk factors, and treatment in patients with acute HF in several LMICs across different regions of the world (Dokainish et al., 2015); revealing important interregional differences in the process. Notably, HF patients in sub-Saharan Africa were more likely to present as NYHA Class III/IV and least likely to be prescribed a beta-blocker. Moreover, they were markedly younger (mean age of 53 years versus 69–72 years) than their Western counterparts and more likely to be female (Crespo-Leiro et al., 2016; Adams et al., 2005). Typically, therefore, HF strikes Africans in what should be the prime, and most productive years of their lives.

Risk factors of heart failure

In the THESUS-HF registry including 1006 acute HF patients from nine sub-Saharan African countries, the most forms of HF were hypertensive heart disease/cardiomyopathy (45%), dilated cardiomyopathy (18%), and rheumatic heart disease (14%) (Damasceno et al., 2012). Earlier reports published between 1957 and 2005 provide evidence of an evolving transition from communicable (excluding the emergence of HIV cardiomyopathy) to more noncommunicable forms of heart disease and HF (Mayosi, 2007). Accordingly, within the INTER-CHF cohort, the most common causes of HF were hypertensive or ischemic cardiomyopathy, while the contribution of rheumatic heart disease was relatively low. The high incidence of hypertension and increased recognition of ischemic heart disease (still relatively low when compared to other regions of the world) as causes of HF have also been observed in other single-center studies (e.g., the Heart of Soweto Study) (Stewart et al., 2008).

Major forms of HF in sub-Saharan Africa

For patients in sub-Saharan Africa, hypertension is considered to be a distinct biological entity (Drazner, 2011). Not only is hypertension especially prevalent (particularly in urban communities (Sanderson et al., 1995)), it is often more aggressive (Adams et al., 2005) and more resistant to treatment (Addo et al., 2007), typically resulting in HF. In the Heart of Soweto study (Stewart et al., 2011), case presentations were dominantly women (54%) with 42% presenting with a secondary diagnosis of hypertension. Among the latter, hypertensive HF (57%, mean age 60 ± 14 years) was the most common manifestation of underlying hypertension.

Dilated cardiomyopathy (including the idiopathic form) contributed to 20% of HF patients captured by the THESUS-HF registry (Damasceno et al., 2012). Familial dilated cardiomyopathy cases are consistently reported to present at a younger age (mean 26 years old) compared with idiopathic dilated cardiomyopathy (39 years old) (Ntusi et al., 2011). It has long been assumed (based on the volume of reports) that PPCM is particularly prevalent among African women. The recent EROP registry examined the characteristics of PPCM among 500 women from a range of ethnic backgrounds and from all continents (Sliwa et al., 2017). As in previous studies (Gentry et al., 2010; Brar et al., 2007), there were marked differences in socio-economic background and ethnicity of cases. However, timing and mode of presentation remained relatively similar overall. There appeared to be a higher incidence of PPCM in sub-Saharan Africa and Asia compared to Europe. This may, in part, be explained by a higher prevalence of preexisting cardiomyopathy (28% vs. 10%) in African and Asian patients. (Elkayam et al., 2001). Bromocriptine therapy, a prolactin-inhibitor, has emerged as a promising therapeutic strategy for the treatment of PPCM (Elkayam and Goland, 2010; Hilfiker-Kleiner et al., 2017).

The clinical spectrum of HF within sub-Saharan Africa is further broadened by cardiac complications relating to HIV/AIDS and its therapy (Sliwa et al., 2008). A prospective study on 243 asymptomatic HIV patients (Chong et al., 2003) from Zambia reported 29% of patients presenting with major cardiac abnormalities relating to HIV were commonly associated with increased incidence of HF (Soliman et al., 2011). In the Heart of Soweto study, 24% of patients with HIV-associated cardiomyopathy had asymptomatic left ventricular dysfunction (Sliwa et al., 2012). HIV-associated cardiomyopathy leads to a rapid progression of mortality in patients who are not treated with HAART (Asanuma and Kitakaze, 2011). Many HIV-positive patients in sub-Saharan Africa now have access to HAART which, by itself may have adverse cardiovascular effects (Thienemann et al., 2013).

In the Heart of Soweto study, 36% of the cases were diagnosed with rheumatic heart disease (Sliwa et al., 2010), many presenting with late-stage disease and associated valvular HF. As in other African cohorts (Bloomfield et al., 2013), a small proportion of HF cases in Soweto were associated with tuberculosis/pericardial disease compared to a relatively high number of cases with right HF/pulmonary hypertension (Sliwa et al., 2010). In the poorer regions of Central and Eastern parts of Africa in particular, endomyocardial fibrosis occurs in endemic and a major cause of HF (Bloomfield et al., 2013) (**Fig. 2**).

Middle East and North Africa

The entire region of the Middle East and North Africa comprises LMICs: specifically, Algeria, Arab Republic, Djibouti, Egypt, Iran, Iraq, Jordan, Lebanon, Libya, Morocco, Syrian Arab Republic, Tunisia, West Bank and Gaza, and Yemen Republic (**Fig. 3**; The World Bank, 2017).

Burden of heart failure

To our knowledge, there are no reliable data to describe the characteristics and burden of HF in Northern Africa. However, there are a number of tertiary hospitals, outcome studies derived from LMICs in the Middle East (Al-Shamiri, 2013). A study based on a highly equipped tertiary center in Saudi Arabia, found that the in-hospital mortality was 5.3% among those presenting with acute HF,

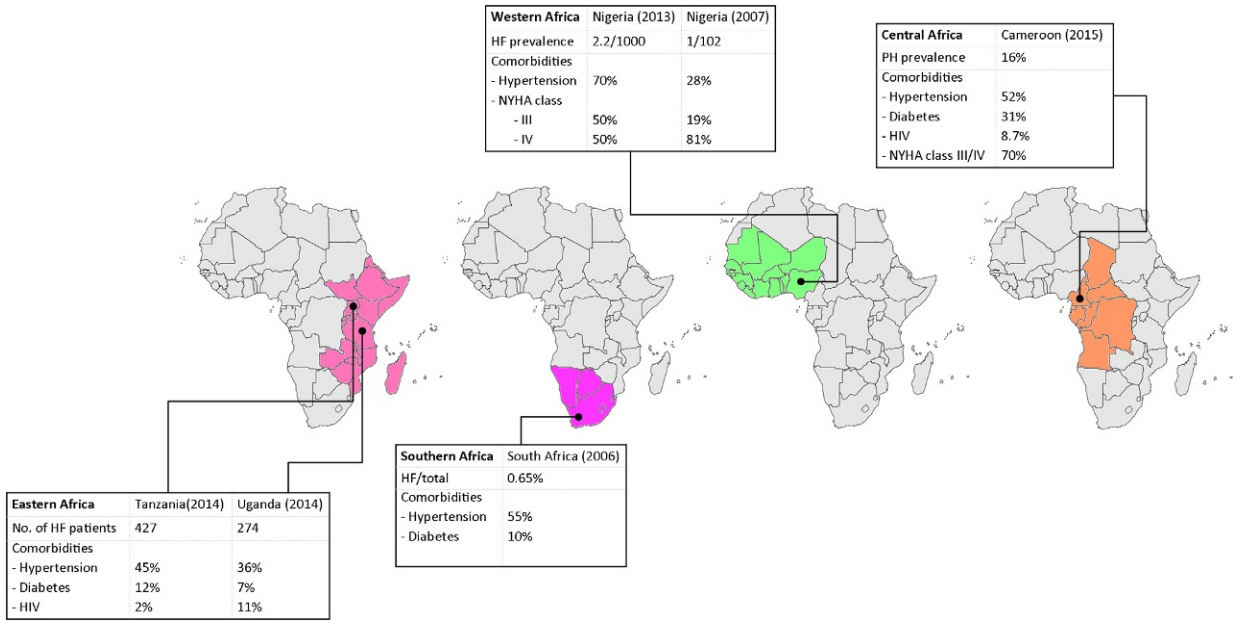

Fig. 2 Characteristics of primary HF hospitalizations across sub-Saharan Africa. *PH*, pulmonary hypertension. *Western Africa* data from PPCM cases. *Central Africa* data based on PH/right HF cases. Data from Tanzania (Makubi et al., 2014), Uganda (Okello et al., 2014), South Africa (Stewart et al., 2008), Nigeria (Akinwusi et al., 2013; Isezuo and Abubakar, 2007), and Cameroon. (Dzekem et al., 2015).

Fig. 3 The Middle East and North Africa Region.

increasing to 7.5% at 30 days (Alhabib et al., 2011). An equivalent study in Yemen showed a higher mortality rate of 9% (Bahaj, 2010). Broadly consistent with these data, a study focusing on in-hospital mortality associated with HF in the Middle East (1991–2010) found a reduction in mortality rates (in both men and women) from 8.4% to 4.8% during this period (Al Suwaidi et al., 2012).

Risk factors of heart failure

Many studies have examined the different risk factors of HF in the Middle East and North Africa region. The INTER-CHF study found the most common risk factor being ischemic cardiomyopathy (50%), followed by idiopathic dilated cardiomyopathy (19%),

hypertensive heart disease (10%), and rheumatic valvular heart disease (Dokainish et al., 2016). However, in Yemen and Oman, hypertensive heart disease was found to be the most common risk factor (25%) with idiopathic dilated cardiomyopathy (11%) being responsible for a relatively small proportion of HF cases. (Ibrahim, 2003) Of note, compared to the Middle East overall, in Egypt the relative contribution of valvular disease to HF is markedly higher (Al-Shamiri, 2013).

Europe and Central Asia

Within Europe and Central Asia, 36% of countries are considered as LMI. As shown in Fig. 4, these countries include: Armenia, Albania, Azerbaijan, Belarus, Bosnia and Herzegovina, Bulgaria, Georgia, Kazakhstan, Kosovo, Kyrgyz Republic, Macedonia, Moldova, Montenegro, Romania, Russia, Serbia, Tajikistan, Turkey, Turkmenistan, Ukraine, and Uzbekistan.

Burden of heart failure

The HAPPY study found that in Turkey, the crude prevalence of HF was 2.9% in 2012; a higher prevalence than many other Western countries despite its relatively younger population (Degertekin et al., 2012). A study of recurrent HF admissions across 20 cities of the Russian Federation found that the rehospitalization rate was 31% during the first 30 days following an acute HF admission of 31% (falling to 10% between 180 and 360 days). In-patient case fatality was 9%; increasing to 13% and 43% at 30-days and 12 months postdischarge, respectively (Arutyunov et al., 2015). As in other LMICs, however, there is a paucity of HF management programs designed to optimize treatment and outcome in affected individuals. However, a prospective observational study of this strategy conducted in Eastern Europe and focusing on patients with HFrEF showed that this strategy not only increased the prescription of beta-blockers (7%–81%) and ACE inhibitors (18%–93%) but reduced emergency department presentations and hospitalizations by 41% and 53%, respectively (Hebert et al., 2011).

Risk factors of heart failure

There is limited data for the risk factors of HF in the LMICs of Europe and Central Asia. However, the PROTECT trial, conducted in 17 countries (including North America (15%), Europe (52%), Israel (16%), and Argentina (3%)), investigated regional differences in acute HF (Mentz et al., 2014). Among European cases, hypertension, ischemic heart disease, and atrial fibrillation (58%–65%) were the most prevalent risk factors for HF; a similar pattern being observed in the RUS-HFR Study in Russia (Sitnikova et al., 2015).

Latin America and the Caribbean

Latin America and the Caribbean are relatively diverse from a socio-economic perspective with a number of high-income countries (38% of the region). LMICs in the region comprise Haiti, Bolivia, El Salvador, Guatemala, Honduras, Nicaragua, Argentina, Belize, Brazil, Colombia, Costa Rica, Cuba, Dominica, Dominican Republic, Ecuador, Grenada, Guyana, Jamaica, Mexico, Panama, Paraguay, Peru, St. Lucia, St. Vincent and the Grenadines, Suriname, and Venezuela (Fig. 5; The World Bank, 2017).

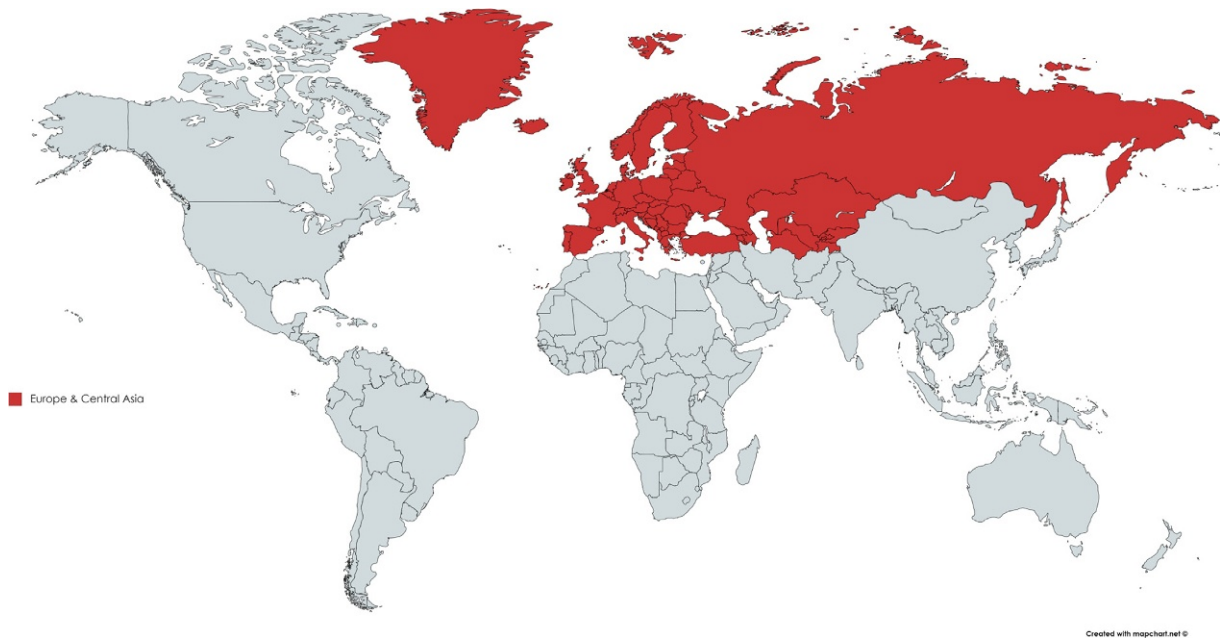

Fig. 4 The Europe and Central Asia Region.

Fig. 5 The Latin America and Caribbean Region.

Burden of heart failure

Although the main cause of hospitalization (based on available data) in the region is reportedly HF (Bocchi, 2013), there is a relative lack of data to describe the burden of disease imposed by the syndrome. However, the SEADE Foundation in São Paulo, Brazil found that HF and its contributory risk factors accounted for just over 6% of all deaths in that country (Chen et al., 2011). As with many parts of the globe, viable epidemiological data for HF are often restricted to inpatients and outpatients receiving ambulatory care in tertiary hospitals (Chen et al., 2011). In Argentina, among a cohort of hospitalized elderly patients, HFpEF was predominant in women (Giorgi et al., 2008). A study conducted in Brazil from 1999 to 2005, found a decreasing pattern in mortality rates due to HF; however, this was not the case for patients aged $\geq$80 years (Gaui et al., 2010). The Brazilian Ministry of Health (DATASUS) reported that from the total number of hospitalizations in 2007 from cardiovascular disease, 39% were due to HF, with a mean stay of 5.8 days and inpatient case fatality 7% (Bocchi, 2013), and a diagnosis of HF being a marker of high inpatient case fatality within the broader Brazilian patients population (Silva et al., 2009). In rural areas of Brazil, HFpEF was diagnosed in almost 50% of patients (being dominant in women) while HFrEF was dominant in men (Balieiro et al., 2009).

Risk factors of heart failure

The EVEREST Study (Gheorghiade et al., 2012) and the Eplerenone Post-AMI Heart Failure Efficacy and Survival Study (Pitt et al., 2003) compared North and South America data on the causes and outcome in patients with acute and chronic HF. The EVEREST study examined the characteristics of HF patients from Eastern Europe ($N=1619$), North America ($N=1251$), South America ($n=699$), and Western Europe ($n=564$). With a mean overall age of 62.2 years, the study determined that HF patients in South America were significantly younger compared to the other regions and had markedly different risk factor profiles (see **Fig. 6**), with less myocardial ischemia in the South American cohort. Differences were also noted in the use of pharmacological therapy with South American patients being prescribed proportionately more ACE-inhibitors (93% vs. 75%), aldosterone blockers (65% vs. 35%), however, North Americans were prescribed more beta-blockers (78% vs. 56%). Some differences (such as cardiovascular interventions, severity of the diseases, and drug use) appear to be associated with low socio-economic status.

Consistent with the above data, as in other parts of the world, there is evidence of epidemiological transition (Yusuf et al., 2001), with a clear rise in coronary artery disease due to an increasing prevalence of its risk factors (such as diabetes, obesity, aging population, and hypertension). Accordingly, ischemic cardiomyopathy is now attributed to be a major cause of HF in Latin America (Cubillos-Garzon et al., 2004). However, infectious diseases (such as rheumatic heart disease and Chagas disease) still remain common and also contribute substantially to the burden of HF in this region (Bocchi, 2013).

In a historic Brazilian report, 903 hospitalized cases (medium age 52 years) with a diagnosis of HF in a tertiary center, found that the most common risk factors were ischemic cardiomyopathy (33%), idiopathic cardiomyopathy (26%), valvular heart disease (22%), hypertensive heart disease (7%), and Chagas disease (6%) (Barretto et al., 1998), the findings of which are broadly supported by other studies in the region (Mangini et al., 2008). On a similar historical basis, a study in Argentina in 1993 showed that there was a slightly higher prevalence of hypertensive heart disease compared to ischemic cardiomyopathy (32% vs. 29%)

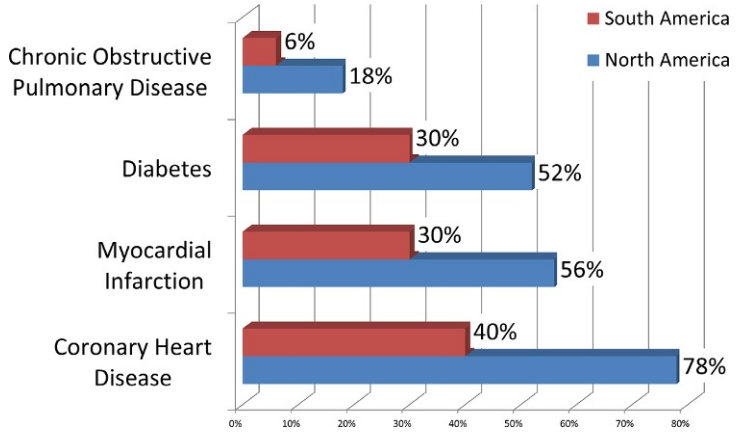

Fig. 6 Comparison of South versus North American HF Trial cohorts (Gheorghiade et al., 2012; Pitt et al., 2003).

Fig. 7 The East Asia and Pacific Region.

(Perna et al., 2006); these findings being supported by findings from the more contemporary Brazilian Evaluation of Levosimendan Infusion Efficacy multicenter study (Bocchi et al., 2003; Bocchi et al., 2008b). Among outpatients in a Brazilian cohort in the 1990s, idiopathic cardiomyopathy was present in 37%, Chagas disease in 20%, ischemic cardiomyopathy in 17%, and hypertensive heart disease, 14% (Freitas et al., 2005). The GESICA Study (Argentina) (Doval et al., 1994), REMADHF Study (Brazil) (Bocchi et al., 2008a), and a study in Mexico (Mendez et al., 2007) reported a prevalence of ischemic cardiomyopathy ranging from 22% to 47% followed by hypertensive and valvular heart disease. The GESICA and RAMADHF studies found that Chagas disease to be a major cause of HF with a prevalence ranging from 10% to 28%. Notably, there has been a significant decline in infected individuals in Latin America from around 16–18 million in the early 1990s to 10–12 million in the early 2000s due to disease control programs (Acquatella, 2007; Celermajer et al., 2012).

East Asia and Pacific

As with other parts of the developing world, it is difficult to report on the burden of HF and its risk factors in this region due a reliable epidemiological data. The LMICs within this region are: American Samoa, Cambodia, China, Federated States of Micronesia, Fiji, Indonesia, Kiribati, Korea, Laos, Malaysia, Marshall Islands, Mongolia, Myanmar, Palau, Papua New Guinea, Philippines, Samoa, Solomon Islands, Thailand, Timor-Leste, Tonga, Tuvalu, Vanuatu, and Vietnam (Fig. 7; The World Bank, 2017).

Burden of heart failure

As indicated, the challenge of reporting the burden of HF in the LMICs of Asia is highlighted by the limited number of reports available for this region. Interestingly, the number of hospitalized, de novo patients diagnosed with HF appears to be higher in Korea compared to other LMICs in this region, whilst Malaysia has reported the highest prevalence of HF (6.7%) in this region (Hung et al., 2000). Overall, a similar median length of hospital stay has been reported in most Asian-based registries examining the characteristics of HF admissions: the KorAHF Registry (Korea) reported 8 days (Lee et al., 2014), and the ADHERE International Study (including Australia, Hong Kong, Indonesia, Malaysia, Philippines, Singapore, Taiwan, and Thailand) reported 6 days (Atherton et al., 2012). However, a study conducted in China reported a median hospital stay of 22 days in the year 2000 (Wang et al., 2014). The KorAHF Registry reported a 30-day and 180-day all-cause mortality rate of 1.2% and 9.2% and an HF readmission rate of 6% and 24%, respectively (Lee et al., 2014).

Risk factors of heart failure

In Malaysia and Taiwan, the proportion of HF cases attributable to ischemic cardiomyopathy ranges from 25% to 47% (Tseng, 2011; Chong et al., 2003; Tsutsui et al., 2007), with hypertensive heart disease being the least common risk factor in Malaysia (19%) (Tseng, 2011). Valvular heart disease has been reported to be a relatively low risk factor of HF (compared to other LMICs) in East Asia (15%–35%) (Chong et al., 2003). Alternatively, atrial fibrillation (21%–42%) and diabetes (12%–36%) have been found to be relatively common in HF patients in the region (Tsutsui et al., 2007; Chong et al., 2003; Tseng, 2011).

South Asia

South Asia is considered to be the most populous and the most densely populated geographical region in the world. The entire region of South Asia is considered to comprise LMICs: Afghanistan, Nepal, Bangladesh, Bhutan, India, Pakistan, Sri Lanka, and Maldives (Fig. 8).

Burden of heart failure

Data describing the burden of HF are inherently unreliable for South Asia. Consequently, many figures are projected from Western Countries. For example, it is known that HF is predominant in the elderly; therefore the burden of HF is likely to increase with the progressing aging of the region with the projected increase in people aged older than 60 years from 133 million in 2011 to 494 million in 2051 (Pillai and Ganapathi, 2013). Pais and colleagues estimated the prevalence of HF in India to be 1.9% based on the rates from the United States (Pais and Xavier, 2011). If these rates are applied to the 2011 population of India and the entire South Asian region, the number of patients with HF is projected to be 22.7 million and 30 million, respectively (Pillai and Ganapathi, 2013). A prospective study was conducted in 2013 to determine the clinical outcomes of patients with HF in Sri Lanka. Of the patients studied, 60% were found to be de novo HF cases with a mean hospital stay of 5.5 days (Matthias and Ekanayaka, 2013).

Fig. 8 The South Asia Region.

Risk factors of heart failure

The Sri Lanka study discussed earlier found the three most common HF risk factors to be acute ischemic cardiomyopathy (37%), anemia (41%), and respiratory disease (10%) (Matthias and Ekanayaka, 2013). The predominance (up to 77% of HFrEF cases) of ischemic cardiomyopathy in Pakistan has been confirmed by a number of other studies (Pillai and Ganapathi, 2013). Ischemic cardiomyopathy is also reported to be the most common contributor to HF in South Asians living in Pakistan (Jafary et al., 2007), Nepal (Dubey et al., 2012), and India (Vora et al., 2017), as well as South Asian migrants in countries outside the region (Galasko et al., 2005; Chong et al., 2003). Emerging infectious diseases have also been found to contribute to the burden of HF. For example, 4% of patients in the leptospirosis outbreak in Sri Lanka were complicated by the syndrome (Agampodi et al., 2011). Additionally, rare cardiomyopathies have also been noted in specific regions such as endomyocardial fibrosis in India (Sivasankaran, 2009).

Indigenous Populations Within High-Income Countries

Any commentary on the burden of HF would be remiss without some consideration of Indigenous populations living in high-income countries. For example, in Australia the life expectancy of Aboriginal people is over a decade less than that of non-Aboriginal people, with 70% of the gap attributable to noncommunicable diseases (Mcgrady et al., 2012). More consistent with HF in LMICs, Indigenous Australians presenting with de novo HF are relatively young (mean age around 50 years), comprise more women, with markedly higher age-adjusted incidence rates compared to the rest of the (high-income) Australian population (Mcgrady et al., 2012). In New Zealand, Sopoago and colleagues (Sopoaga et al., 2010) found that Mäori people were six times more likely to be admitted to the hospital with a cardiomyopathy and four to five times more likely to present with rheumatic heart disease. These disparities were observed in earlier research (data period 1988–98) where HF case fatality was almost nine times higher in Mäori men aged 45–64 years than their non-Mäori counterparts, with similar patterns in women (Atherton et al., 2012; **Fig. 9**).

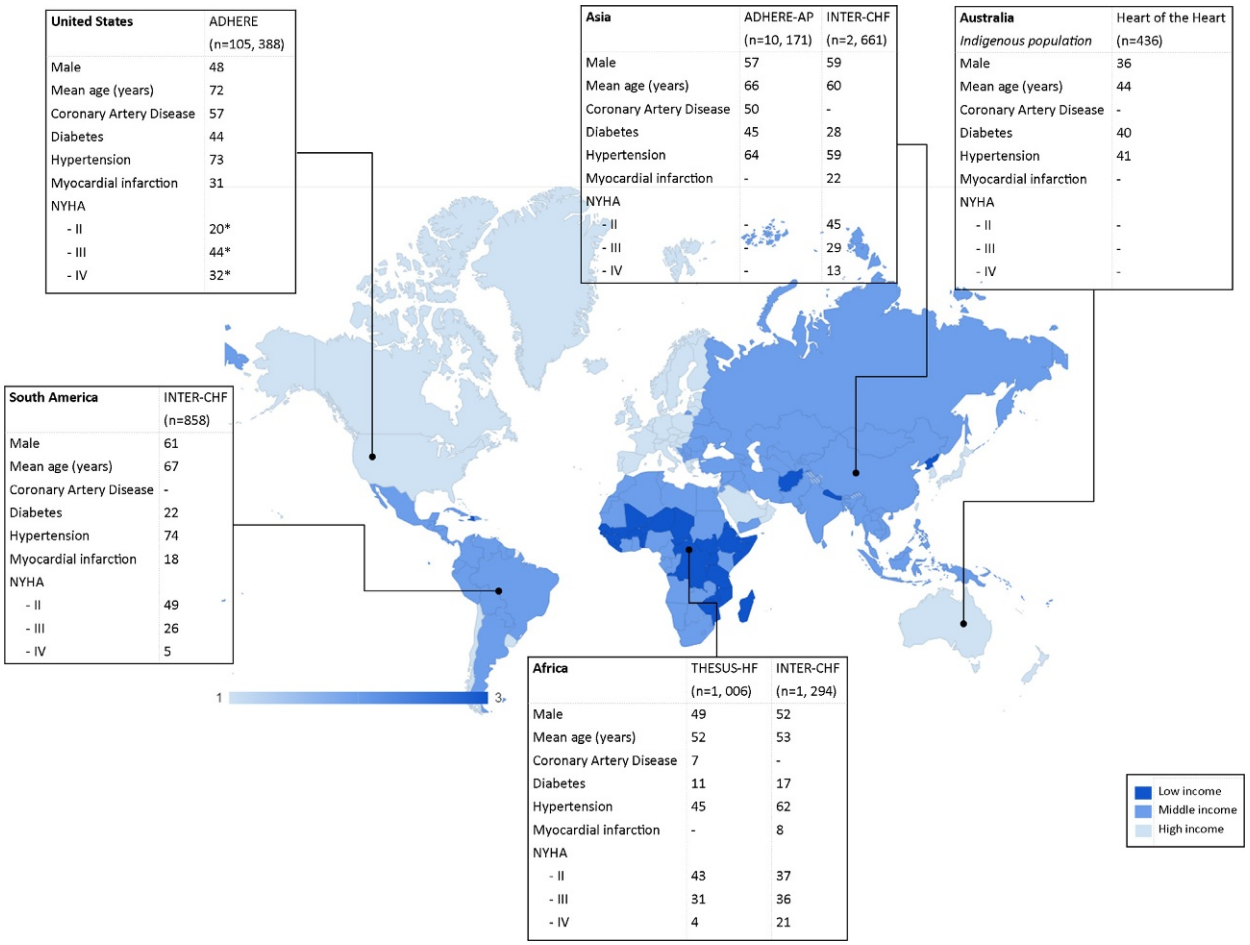

Fig. 9 Regional differences in the pattern of HF: insights from large-scale studies.

Key Considerations

HF poses an increasing problem for global healthcare systems, with current epidemiologic data in the different regions of the world remaining poorly described. An international approach that includes ethnically diverse populations of all ages and genders is urgently needed. Because so much information is missing, current guidelines developed by different societies in high-income countries may not be readily extrapolated to the developing world setting.

Future research investigating risk factors/antecedents for HF in community-based settings, across several world regions, is urgently needed. However, such studies are costly and as a result rarely receive full support. INTER-CHF, a longitudinal case study in LMICs, is one such study and described significant regional variability in sociodemographic factors, clinical characteristics, risk factors, and treatments of HF in several regions of the world. Studies such as these highlight the proportion of patients lacking appropriate care and treatment for HF. Further research of this nature may indicate opportunities for prevention and HF intervention studies that specifically target strategies to reduce the rapidly evolving burden of HF in the developing world.

Key Issues

- There is little to no evidence to describe the prevalence and incidence of HF in developing countries.
- Presentation of HF occurs at a much younger age (mean age 53–67 years) in developing countries. This is in contrast to developed countries where HF is increasingly a condition that affects the elderly (mean age 70–72 years).
- Nonischemic causes of HF (hypertensive heart disease, rheumatic heart disease, and dilated cardiomyopathy) account for around two-thirds of cases in sub-Saharan Africa, but ischemic cardiomyopathy is likely to be an increasing cause of HF in the future.
- Indigenous populations in developed countries have similar HF profiles to those living in developing countries.
- In the developing world, many forms of HF are highly preventable. Future research should address strategies which cost-effectively historically high levels of obesity, diabetes and hypertension.

MESA	Multi-Ethnic Study of Atherosclerosis
MI	Myocardial infarction
TTR	Transthyretin gene

In this section, we review the epidemiology, standard and novel risk factors contributing to congestive heart failure (CHF) in African Americans (AA) and Hispanic Americans (HA). We discuss the most common comorbidities and genetic dispositions that play a role in the physiology and management of disease in these groups.

Heart Failure in African Americans

Epidemiology of Heart Failure in African Americans

Heart failure (HF) affects 5.7 million adults in the United States annually (Mozaffarian et al., 2016). The annual incidence of HF events per 1000 in the population for AA men between the age of 65 and 74 years and between the age of 75 and 84 years are 16.9 and 25.5, respectively. For AA women, the rates are 14.2 and 25.5, respectively (Go et al., 2014). In the Atherosclerosis Risk in Communities (ARIC) Study, age-adjusted incidence rates per 1000 person-years were 8.1 in AA women, 6.0 in AA men, 3.4 for white women, and 6.0 in white men (Go et al., 2014). Compared to non-Hispanic whites, AA have a higher burden of CHF incidence, morbidity, and mortality that is incompletely explained by standard cardiovascular disease (CVD) risk factors. In the Multi-Ethnic Study of Atherosclerosis (MESA), AA had the highest proportion of CHF not preceded by a myocardial infarction (MI) (Bahrami et al., 2008). Additionally, CHF appears to affect AA at younger ages. In the ARIC Study, AA had a higher incidence of CHF at age less than 75 and a higher five-year mortality rate than non-Hispanic whites (Loehr et al., 2008). In the Coronary Artery Risk Development in Young Adults (CARDIA) Study, CHF before the age of 50 years was far more common in AA compared to whites (Bibbins-Domingo et al., 2009).

Risk Factors for Heart Failure in African Americans

Understanding the risk factors for CHF in AA is imperative as it gives the insight to aid in prevention. Traditional risk factors (most of which are modifiable) for CHF include coronary heart disease (CHD), cigarette smoking, hypertension, obesity, age, and diabetes (He et al., 2001). In the Health, Aging, and Body Composition (ABC) Heart Study, a higher proportion of CHF was attributable to modifiable risk factors in AA compared to whites (68% vs. 49%; 6 of 8 risk factors had at least a 5% higher attributable risk in AA compared to whites). Such data suggests a unique opportunity for targeting lifestyle and other modifiable risk factors in AA to lower the burden of CHF (Sharma et al., 2014).

Hypertension

Hypertension is of particular importance as a risk factor for CHF in AA. AA have the highest prevalence rates of hypertension globally (Sharma et al., 2014). In the National Health and Nutrition Examination Survey from 1999 to 2000, AA compared to white Americans had a higher prevalence of hypertension at 41.4% and developed hypertension at a younger age (Hertz et al., 2005). AA were also less likely to reach blood pressure goal (Hertz et al., 2005; Randolph et al., 2016). In MESA, AA had a higher risk of incident HF that was thought to be related to the prevalence of risk factors, particularly hypertension (Bahrami et al., 2008). In the AA community-based cohort followed by the Jackson Heart Study (JHS), every 10 mmHg increase in blood pressure was associated with a higher risk of CHF (Randolph et al., 2016). In the Health ABC study, uncontrolled blood pressure (BP) generated the highest population attributable risk (PAR) for the development of HF (30.9%) (Go et al., 2014). Hypertension has been strongly associated with incident HF, and blood pressure treatment strategies have demonstrated efficacy to prevent HF. In the Systolic Hypertension in the Elderly Program of over 4700 participants aged above 60 years or more with systolic hypertension, antihypertensive therapy including a low-dose diuretic exerted a strong protective effect in preventing HF. In the Hypertension in the Very Elderly Trial, treatment of elderly (>80 years of age) participants with indapamide with or without the angiotensin converting enzyme inhibitor perindopril lowered the mean blood pressure by 15/6 mmHg and resulted in a 64% reduction in the rate of HF at 2 years. Based on these data, treatment of hypertension particularly in aged individuals is associated with reduced HF. However, less is known about specific therapies in AA.

The specific mechanisms by which hypertension leads to CHF is not completely understood (Sharma et al., 2014). AA who develop HF tend to have uncontrolled hypertension (Sharma et al., 2014). One theory is that hypertension leads to ventricular remodeling and subsequent changes in structure and left ventricular (LV) systolic function that predisposes this group to higher rates of HF (Sharma et al., 2014). Indeed, the majority of AA with CHF have HF with reduced ejection fraction (EF) HF with preserved ejection fraction (HFPEF) compared to HFPEF (Sharma et al., 2014).

Obesity

Obesity has been associated with both LV dysfunction and incident HF in a number of ethnic groups (Krishnamoorthy et al., 2016; Kenchaiah et al., 2002). Excess weight causes increase in both blood volume (preload) and blood pressure (afterload) that lead to the structural and functional changes preceding clinical HF (Hall et al., 2015; Eaton et al., 2016). Obesity may also lead to HF through coexisting risk factors that commonly accompany it including hypertension, diabetes, ischemic heart disease, inflammation, and renal dysfunction. AA have high rates of obesity which may, in part, contribute to the excess burden of HF in this group. Specifically, obesity may contribute to HFPEF, which is the predominant type of HF observed in AA cohort studies (Gupta et al., 2013). For example, obesity has been implicated as a key player in HFPEF for AA women (Eaton et al., 2016). Approximately 26% of the attributable risk for HFPEF in a multiracial cohort of postmenopausal women was related to obesity. In the study, obesity was

found to be a more potent risk factor for AA women compared to white women. In a follow-up study of National Health and Nutrition Examination Survey 1 from 2001, obesity was associated with 1.3 relative risk of incident HF and a population attributable risk of 9.0% (He et al., 2001). AA represented 14% of the study group. In the JHS, among obese and morbidly obese participants, for every 1 kg/m^2 increase in body mass index (BMI), there was a 5% increase in the risk of prevalent HF (Krishnamoorthy et al., 2016).

Diabetes

Diabetes is also a strong contributor to the development of CHF in AA (Zhao et al., 2014). Every 1% increase in Hemoglobin A1C (HbA1c) was associated with 6% increase in the risk of HF in over 17,000 AA (Zhao et al., 2014). In MESA, 21% of AA participants with CHF had diabetes and further diabetes significantly contributed to the higher incidence of HF in AA (Bahrami et al., 2008). In the I-Preserve trial (Irbesartan in Heart Failure With Preserved Ejection Fraction), patients with HFPEF and diabetes had more signs of congestion, worse quality of life, higher N-terminal pro-B-type natriuretic peptide levels, and overall poorer prognoses (hazard ratio (HR) 1.75 for death or HF hospitalization) compared with those without diabetes. The mechanisms by which diabetes leads to the development of HF are not completely understood but are likely multifactorial. In addition to increasing the risk of ischemic heart disease, metabolic factors appear to play an important role. Altered substrate metabolism, myocardial lipotoxicity, oxidative stress, mitochondrial dysfunction, cardiac fibrosis, and apoptosis leading to impaired cardiac function (diastolic and systolic) are likely contributors to diabetic cardiomyopathy and HF. Given the high rates and overlap of diabetes and obesity in AA, further study of their effects on impaired cardiac function and HF is warranted.

Left ventricular hypertrophy

Left ventricular hypertrophy (LVH) poses a significant risk for CHF in AA. This is concerning because multiple investigations have shown that the prevalence and incidence of LVH are greater in AA compared to white Americans (He et al., 2001), and this disparity does not appear to be completely explained by risk factor burden alone (Drazner et al., 2005; East et al., 2004). In Health ABC, LVH by electrocardiography was a significant risk factor for incident HF in AA and this risk was independent of hypertension. In the JHS, after adjusting for clinical risk factors, an increase in echocardiographic left ventricular mass (LVM) over 8 years was associated with incident CVD defined as CHD, stroke, HF, and intermittent claudication (Fox et al., 2015).

Further, echocardiographic LV geometry appears to contribute to HF type which has prognostic implications. Those individuals with HFPEF tend to have the more concentric form of hypertrophy with thicker ventricular walls and LV diastolic dysfunction (Sharma et al., 2014). Alternatively, those with HFREF more commonly present with the eccentric form of hypertrophy. HFPEF comprise at least 50% of those with CHF in the population. AA and white Americans are equally affected by HFPEF despite the higher burden of risk factors predisposing to the HFPEF phenotype seen in AA (Sharma et al., 2014). In one recent study, survival among those with symptomatic HF improved over time in patients with HFREF but not in those with HFPEF and diastolic dysfunction was shown to be predictive of death among asymptomatic patients (Go et al., 2014).

Coronary heart disease

Although AA have higher rates of nonischemic cardiomyopathies compared to white Americans, CHD still incurs a highly significant risk for CHF in AA (Sharma et al., 2014; Coughlin et al., 1993). In the Health ABC study, AA participants were more likely than white participants to develop HF and CHD (PAR of 29.5% in blacks vs. PAR of 23.9% in whites) had among the highest population attributable risk for HF in both races (Go et al., 2014). CHD events are often followed by cardiac remodeling that result in the development of CHF. First noted in hearts post-MI and later identified in dilated cardiomyopathies including those due to myocarditis, cardiac remodeling is characterized by progressive increase in the LV chamber size, thinning of the ventricular walls, and transformation of the LV geometry to a more eccentric, spherical-shaped heart (Pfeffer et al., 1988; Florea et al., 1999). These changes are associated with a reduction in systolic function and subsequent development of CHF.

Comorbidities Associated With Heart Failure in African Americans

Pulmonary disease

Despite existing data supporting pulmonary disease as a significant comorbidity associated with CHF in predominantly or exclusively non-Hispanic white populations, there is limited data available in large AA cohorts. In MESA, pulmonary hyperinflation was associated with increased LVM on MRI (Smith et al., 2013). In a recent MESA report, subclinical lung disease was associated with reduced LV end-diastolic volume and stroke volume on magnetic resonance imaging (MRI), potentially due to increased LV stiffness and increased LV end-diastolic pressure (as a result of increased pulmonary vascular resistance due to hypoxia, hypercapnia, and endothelial damage) (Aaron et al., 2017).

These findings were further supported by a recent Framingham study where investigators showed the importance of noncardiac major organ system dysfunction in predicting incident CHF events. After adjusting for HF risk factors, cardiac systolic and diastolic function, lower ratio of forced expiratory volume (FEV1) to forced vital capacity (FVC), was associated with a 30% increased risk of CHF. Specifically, FEV1/FVC was associated with HFpEF (Lam et al., 2011). Further research is needed to identify the extent to which pulmonary disease plays a role in CHF in AA.

Chronic kidney disease

AA are disproportionately affected by both chronic kidney disease (CKD) and CHF. In the Health ABC Study, lower estimated glomerular filtration rate (eGFR) and higher cystatin C levels were associated with incident HF in both AA and whites; however, the magnitude was greater for AA compared to whites (HR 1.76 vs. 1.19 respectively) (Bibbins-Domingo et al., 2006). Hypertension, diabetes, and obesity, all higher in AA, are major risk factors for both CKD and CHF. The high prevalence of the apolipoprotein (APOL1) alleles which are present in approximately 13% of AA, significantly increases the rate of renal decline and CKD (Grams et al., 2016). As renal injury and dysfunction worsen, there is augmented renal sodium and water reabsorption and subsequently elevated blood pressure (Hall et al., 2014). This increase in BP further exacerbates renal dysfunction in addition to having detrimental effects on the heart including increased LVM. In the JHS, increased LVM was associated with estimated GFR decline and end-stage renal disease in AA (Hall et al., 2015). In a pooled analysis of three large longitudinal cohort studies, CKD was independently associated with an increased risk of HF (HR 2.3) and to a similar degree as CHD. This risk was 3.5-fold higher in AA compared to whites (Bansal et al., 2017). In patients with chronic HF, every 10 mL/min/1.73 m^2 decrease in eGFR was associated with a 10% increased risk of CVD death or HF hospitalization (Damman et al., 2017). While renal dysfunction has been implicated in the causal pathway for HF, cardiorenal interactions are increasingly recognized to contribute to overall health. Specifically, several cardiorenal syndromes have been defined (Udani and Koyner, 2010). CKD also sometimes confounds the treatment pathway for HF patients. For example, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers have significant mortality benefits in patients with HF with HFrEF (Pfeffer et al., 2003). However, these drugs can sometimes increase serum creatinine and may prevent their administration to patients with the underlying renal disease.

Atrial fibrillation

Atrial fibrillation (AF) and HF are increasingly prevalent, closely interrelated, and share many risk factors (Kotecha and Piccini, 2015). AF incidence is predicted to double over the next 20 years (Colilla et al., 2013). In a global registry of patients with AF, 33% of paroxysmal, 44% of persistent, and 56% of permanent AF patients had HF symptoms (Chiang et al., 2012). Common shared risk factors for AF and HF include hypertension, age, male sex, and obesity. However, AA have 41% lower adjusted risk of AF compared to whites despite a higher prevalence of many traditional AF risk factors (Alonso et al., 2009). The lower risk in AA may be related to less left atrial dilation or genetic differences compared to whites (Dewland et al., 2016; Marcus et al., 2010). In AA, echocardiographic measures including LV diameter, left atrial dimension, LVM index (LVMI), and reduced EF (<50%) were associated with higher AF risk in the ARIC Study. AF can be either a cause or an effect of HF (Bekwelem et al., 2014; Anter et al., 2009). Potential mechanisms by which AF may lead to the development or progression of HF include (1) increased resting heart rate/shorter diastolic filling time, (2) atrioventricular dyssynchrony, and (3) reduced effective atrial contraction. In patients with sinus rhythm, conversion to AF was associated with reduced peak oxygen consumption, increased mitral and tricuspid regurgitation, reduced cardiac index, and worsened NYHA functional class (Pozzoli et al., 1998). Despite a lower burden of AF in AA compared to whites, the risk of incident HF was twice as high in AA in the ARIC Study over a follow-up period of 20 years (Magnani et al., 2016).

Aging

CHF is primarily a disease process of the elderly with 50% of HF diagnoses and 90% of HF deaths occurring in those over 70 years of age (Strait and Lakatta, 2012). Although aging itself may not directly cause HF, diseases associated with aging (ischemic heart disease, valvular dysfunction, etc.) contribute to this increased HF prevalence. As treatment strategies for these diseases have improved (i.e., percutaneous coronary and valve interventions), patients with these predisposing conditions are living longer albeit with some degree of cardiac dysfunction. Some factors associated with aging that exacerbate or contribute to the pathogenesis of HF include diastolic dysfunction, impaired renal function, and arterial stiffness.

APOL1 risk alleles are associated with exaggerated age-related nephron loss which may accelerate normal age-related kidney dysfunction thereby augmenting the renin–angiotensin–aldosterone system, increasing salt-sensitivity, and sodium and water retention—all factors which can lead to or exacerbate HF (Hoy et al., 2015). Similarly to whites, diastolic dysfunction measured by reduced tissue Doppler velocities and diastolic parameters reflecting less LV compliance was significantly associated with future HF in a population of AA with hypertension and CKD (Peterson et al., 2013). Overall, aging is a multifactorial process that is associated with a number of pathogenic factors which contribute to HF.

Arterial stiffness/endothelial function

Arterial stiffness is an early predictor of hypertension, a major risk factor for HF. The underlying mechanism may be related to increased oxidative stress, decreased nitric oxide availability, exaggerated vasoconstrictor response, and attenuated responsiveness to vasodilators and nitric oxide (Sharma et al., 2014). AA race is a significant predictor of impaired microvascular vasodilatory function, greater large arterial wave reflections, and stiffness even after adjusting for traditional CVD risk factors (Morris et al., 2013). In the ARIC Study, arterial elasticity was associated with greater LVMI and higher LV filling pressures (measured by E/e′ ratio) in AA but not in whites suggesting that AA are more sensitive to increased afterload as a stimulus for LV structural and functional remodeling—both precursors to HF (Fernandes-Silva et al., 2017).

Genetics and Heart Failure in African Americans

Existing evidence indicates that disparity in the development of HF and response to some medications (Rotimi et al., 2013) may partly be due to the influence of genetic polymorphisms present at a slightly higher frequency in certain ethnic groups (McNamara, 2004; McNamara et al., 2009). While it is understood that human populations are similar at the DNA level, insights gleaned from advances in high-throughput genomics have shown that genetic differences between ancestral and ethnic groups may have important evolutionary and medical relevance (Rotimi et al., 2013). Our understanding of such differences will facilitate treatments tailored to specific patients according to their genetic features.

Of the genes previously reported to be associated with risk of HF in AA are regarded as potential candidates for targeted therapy (Sharma et al., 2014). G protein and transthyretin gene (*TTR*) have been the most studied. Polymorphism C→T at nucleotide 825 (C825T) in exon 10 of the β3 subunit of pertussis toxin-sensitive G-type protein is more frequent in individuals of African ancestry. Several epidemiologic studies have reported a significant association of the 825 T allele with increased risk of hypertension; obesity, and LVH (Siffert, 2000). Additionally, C825T polymorphism has been proposed as a genetic marker for arteriosclerosis (Hanon et al., 2002) and clinical trials are being conducted. In the AA HF trial (A-HeFT), McNamara and colleagues found that the effectiveness of fixed-dose hydralazine/isosorbide dinitrate was enhanced in AA patients who were *GNB3* 825 T homozygotes compared with 825C allele carriers (McNamara et al., 2014).

The V122I variant in the *TTR* gene has been implicated in cardiac amyloidosis and occurs in 3%–4% of AA. In one autopsy study, more than one-fourth of AA with cardiac amyloidosis were heterozygous for the V122I allele (Buxbaum and Ruberg, 2017). Quarta et al. (2015) reported that the V122I transthyretin variant was associated with increased risk of incident HF and worse systolic and diastolic function among AA in the ARIC study followed over two decades.

In recent genome-wide association studies (GWAS), loci associated with incident HF in AA have been identified. Some of these loci have been replicated while others have not, so their biological significance is less clear. In the Cohorts for Heart and Aging Research in Genomic Epidemiology consortium, Smith et al. (2010) discovered that the *LRIG3* gene (encoding leucine-rich repeats and immunoglobulin-like domains) was associated with increased risk of incident HF in individuals of African ancestry only. Functional work on this gene has yet to be conducted. Other GWAS studies involving B-type natriuretic peptide (BNP), a blood biomarker that serves as a diagnostic tool for HF, led to the identification of *KLKB1* and *NPPB* genes in the general population of AA (Musani et al., 2015). In a separate GWAS, Fox et al. (2013) found in a meta-analysis of four AA cohorts, common genetic variants associated with cardiac structure and function.

Most of these genetic findings for HF in AA are preliminary and further investigation is warranted. Indeed, a move from GWAS (or hypothesis generating studies) to prospective validation may be necessary, particularly for trials such as A-HeFT. While further exploration to identify the contribution of genetics to HF is warranted, as of now, the existing literature suggests that genetic influences are limited relative to traditional and sociocultural risk factors known to contribute substantially impact ethnic differences in disease occurrence.

Relation of Biomarkers to Heart Failure in African Americans

Multiple blood biomarkers have shown to be independently associated with cardiac remodeling and incident CVD (including CHF) in AA substantiating the theory that multiple biological pathways influence LV structure and outcomes in this group. In the JHS, investigators found that there was a significant and positive relation of aldosterone–renin ratio (ARR), BNP pathway, and homeostasis model assessment of insulin resistance (HOMAIR) to LV geometry (unpublished data). In a recent study, MESA investigators found that elevated NT-proBNP and high sensitivity troponin T were predictive of incident HFPEF with no significant interaction between race/ethnicity and these risk factors (Silverman et al., 2016). In other analysis in the JHS, BNP was the only biomarker retained in a prediction model for all CVD after incorporating standard risk factors, biomarkers, and subclinical disease markers in the risk prediction model. BNP relation to all CVD incidence was thought to be most likely due to the use of CHF in the definition of all CVD outcomes (Fox et al., 2016). The natriuretic peptide pathway is involved in a number of aspects of CVD physiology that accounts for its strong predictive value for CHF and CVD. These include (1) salt and fluid balance, (2) cardiac and vascular structure and function, (3) BP control, and (4) inhibition of the renin–angiotensin–aldosterone system (Fox et al., 2016; Martinez-Rumayor et al., 2008; Woodard and Rosado, 2008).

Risk Models for Heart Failure in African Americans

Several risk models have been developed and later validated in minority populations for CHD and stroke by Framingham Heart Study, ARIC Study, and CHS investigators. These models appear to perform well in the AA population (Lumley et al., 2002; Wolf et al., 1991; Wilson et al., 1998; Chambless et al., 2003, 2004). Health ABC Study (Butler et al., 2008) and the ARIC study (Agarwal et al., 2012) investigators have also developed CHF prediction scores using common clinical variables to predict incident HF risk. The ARIC study model included middle-aged white adults and AA adults, whereas in the Health ABC Study, the cohort tested was elderly, and approximately 40% of participants were AA (Fox et al., 2016). In a more recent study conducted in JHS, investigators developed multiple models in a community-based cohort of AA to predict general CVD risk (defined as CHF in combination with CHD, stroke, angina, and claudication) incorporating standard risk factors, blood biomarkers, and subclinical disease markers.

These models were validated in two external AA groups. Investigators found that biomarkers added minimal incremental improvement in discrimination beyond a model with only standard risk factors (Fox et al., 2016). Adding subclinical measures to traditional risk factors (both ankle–brachial index alone and with echo LV ejection fraction and LVM), significantly enhanced the predictive usefulness of the risk model (Fox et al., 2016). In the same investigation, the Framingham Risk Score and American College of Cardiology/American Heart Association risk algorithms worked well for all CVD in the Jackson cohort compared to models generated within the Jackson cohort utilizing all three tiers suggesting that there may not be a need for a unique risk calculator in AA (Fox et al., 2016).

Heart Failure in Hispanics/Latinos

The US Hispanic/Latino population is the single largest and one of the fastest growing ethnic minorities in the United States (US) (The United States Census Bureau, n.d.). The US Census Bureau projects that this subgroup of the population will more than double, from 53.3 million in 2012 to 128.8 million in 2060. Consequently, by the end of that period, nearly one in three US residents would be Hispanic, up from about one in six today. Further, while the non-Hispanic Whites population over the age of 65 years is expected to grow by 83% between 2000 and 2030, Hispanics of this same age group are projected to grow by 328% (The United States Census Bureau, n.d.). Thus, the public health impact of HF among the Hispanic population may be magnified. A sizeable proportion of this population has major CVD risk factors (Rodriguez et al., 2014). Compared to non-Hispanic Whites, Hispanics/Latinos have a higher prevalence of uncontrolled blood pressure, obesity, diabetes, and dyslipidemia (Daviglus et al., 2012; Dominguez et al., 2015).

With respect to HF, few studies that have specifically examined Hispanics/Latinos in the US found that Hispanics/Latinos have a higher incidence of HF compared to non-Hispanic Whites and that Hispanics/Latinos present with HF are younger with more comorbidities and a lower LV ejection fraction (Bahrami et al., 2008; Rodriguez et al., 2014; Vivo et al., 2009). In the Echocardiographic Study of Hispanic/Latinos (ECHO-SOL), an echocardiographic ancillary study of The Hispanic Community Health Study/Study of Latinos (HCHS/SOL), about half of the 1818 middle-aged and older Hispanic/Latinos adults had cardiac dysfunction, yet fewer than 1 in 20 participants knew they had a problem (Mehta et al., 2016). In the ECHO-SOL community-based sample, half were obese; half had high blood pressure; two-third had diabetes; two-third reported low levels of physical activity; and a fifth were current smokers (Mehta et al., 2016). Every unit increase in waist–hip ratio was significantly associated with 0.27% lower ejection fraction (Allison et al., 2015). Prediabetes and diabetes were associated with significantly reduced ejection fraction and a 36%–90% higher odds for diastolic dysfunction among the same community-based cohort Hispanic/Latinos (Demmer et al., 2016).

In MESA, Hispanics/Latinos were at high risk of developing HF, higher than non-Hispanic Whites and Chinese Americans and second only to AA who had the highest risk. Hispanics with HF are more likely to be underinsured and target doses of the angiotensin-converting enzyme inhibitor/angiotensin receptor blocker were reached in a lower percentage of Hispanic persons when compared with AA persons (Hebert et al., 2010). Hispanics/Latinos are least likely to have an assessment of LV ejection fraction and to be discharged from angiotensin-converting enzyme inhibitor treatment compared with non-Hispanic white patients and AA (Cohen et al., 2010). In addition, Hispanics/Latinos have higher rates of HF hospitalizations (Brown et al., 2005) and readmissions for HF (Alexander et al., 1999) but have lower in-hospital (Brown et al., 2005) and short-term mortality (Alexander et al., 1999). Rather than an indicator of advanced disease, HF hospitalization may be a marker of the first encounter with the health care system due to poor access to outpatient care among Hispanics/Latinos. Furthermore, community-based studies have found that Hispanics/Latinos have worse diastolic function and higher LV stiffness compared to estimates in non-Hispanic Whites (Mehta et al., 2016; Russo et al., 2010).

Unfortunately, most of these data, have been drawn from selective populations or subgroup analyses and may not accurately represent the clinical characteristics and outcomes of Hispanics/Latinos with HF. Hispanics/Latinos in the US represent a relatively young demographic such that the future public health burden of clinical HF as this population ages is potentially currently being underestimated. There is a need for further research with an adequate representation of Hispanic/Latino patients in HF registries and trials.

TGF-β	Transforming growth factor *beta*

Introduction

The prevalence of Heart failure (HF) in United States is 2.2%, and it is expected to rise to almost 3% by 2030 (Writing Group Members et al., 2016; Heidenreich et al., 2013). HF syndrome is diagnosed in 0.7% of persons 45–55 years of age but may be 8.5% in those >70 years (Redfield et al., 2003). Between 1979 and 2004 hospitalizations in United States, HF-related diagnoses tripled and currently HF is considered the most common reason for hospitalization in individuals >65 years of age in high-income countries. Practically, 80% of all HF patients are >65 years of age with an annual likelihood of hospital admission of 35% which may ascend to 75% if 5 comorbidities are present (Braunwald, 2015; Fang et al., 2008). In high-income countries, evidence-based treatments have improved the survival of HF patients, but at the same time national health systems have to spent 2% of the entire health budget for the management of HF (Ziaeian and Fonarow, 2016).

Concurrent data from USA and European registries show that overall age-adjusted prevalence of HF tends to stabilize ore even decrease in women, nevertheless the number of HF patients is paradoxically increasing worldwide (Vos et al., 2012; Ziaeian and Fonarow, 2016; Zhao et al., 2015). A global improvement in standards of nutrition, hygiene, housing availability, medical care, and general living conditions has dramatically increased life expectancy in previously considered low or medium income countries. Meanwhile a western-like way of life in these populations has increased the perseverance of obesity, hypertension, and diabetes (Braunwald, 2015; Zhao et al., 2015). As a result, similarly to what was observed in westernized societies, the previous decays, the cause of death is shifting from infection, inflammatory, and nutrition-related diseases observed in younger ages to cardiovascular

degenerating conditions diagnosed in elderly populations. HF syndrome is currently a global pandemic of the elderly, placing a heavy burden in healthcare providers and affecting the long-term planning of national health systems (Ziaeian and Fonarow, 2016; Vos et al., 2012; Zhao et al., 2015).

Age-Related Changes of the Myocardium and Aorta

Cellular Level

In the elderly population HF syndrome may be regarded as a downstream evolution of the "normal" deterioration of the myocardium. Collagen deposition plays a key role in cardiac aging. Fibroblasts are stimulated by multiple signaling hormones and control the secretion of fibronectin collagen and laminin in the extracellular matrix. The content of the extracellular matrix is also regulated by matrix metalloproteinase and their inhibitors (matrix metalloproteinase-2, −7, −9, tissue inhibitor of metalloproteinases-1, −2, −4). (Fig. 1) Individuals without cardiovascular disease show an age-related increase of metalloproteinase paralleling left ventricular (LV) concentric remodeling and diastolic dysfunction (Bonnema et al., 2007). In the Framingham study tissue inhibitor of metalloproteinases-1 levels increased proportionally with age and was associated with increased ventricular dimensions and wall thickness even after adjustment for age (Sundstrom et al., 2004). Of particular interest in the process of myocardial aging is the Transforming growth factor beta (TGF-β) signaling pathway which mediates phenotypic transformation of fibroblasts to myofibroblasts (Dobaczewski et al., 2011). Brooks and Conrad showed that TGF-b (1) heterozygous mutant mice exhibit less age-related myocardial fibrosis than normal mice (Brooks and Conrad, 2000). TGF-β is also activated with high levels of reactive oxygen species which tend to increase in the aging myocardium (Cucoranu et al., 2005). Titin, a giant protein of the sarcomere, can also modulate passive LV stiffness in the elderly population. Indeed, inadequate phosphorylation of titin and altered isoform composition was found in a model of old dogs with diastolic dysfunction when compared to a normal younger group (Hamdani et al., 2013).

The link of systemic inflammation and fibrosis in the elderly population has also been confirmed in many studies. Age is associated with increased markers of inflammation (e.g., Tumor necrosis factor-α, Interleukin-6, Interleukin-18, Monocyte chemoattractant protein-1, Vascular cell adhesion molecule 1) even after correction for cardiovascular disease (Miles et al., 2008). (Fig. 1) Even in the absence of a specific disease, this phenomenon is attributed to accumulation of multiple comorbidities that lead to a constant systemic inflammation state. Inflammation, in turn, imposes oxidative stress in the microvascular endothelium and leads to a pathophysiologic cascade: reduction of bioavailability of nitric oxide of the inflamed endothelium, decrease in cyclic guanosine monophosphate levels, decrease in protein kinase G activity, acceleration of the inflammation process via the subendothelial migration of leukocytes, hypophosphorylation of titin, increase of collagen deposition and ultimately fibrosis, and hypertrophy via the accelerated action of endothelin 1 and angiotensin II (Paulus and Tschope, 2013) (Fig. 1).

Mitochondrial DNA deletions and mitochondrial protein oxidation also are linked with cardiac aging. Studies have shown that homozygous mitochondrial polymerase γ (Polgm/m) knock-in mice have signs of premature aging such as cardiac enlargement

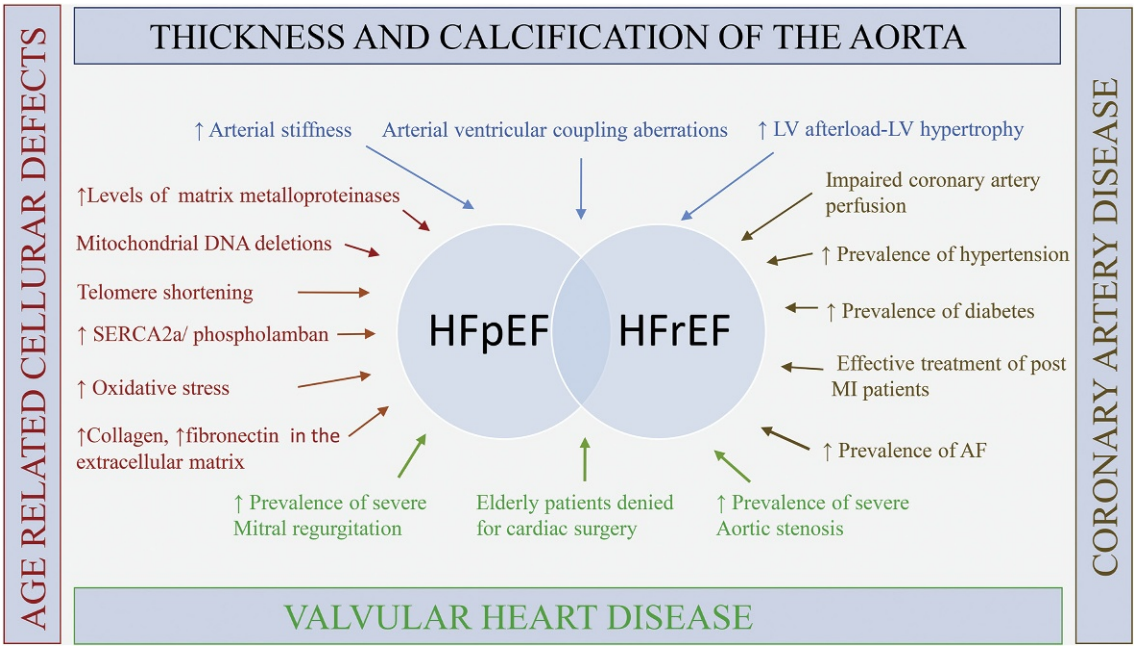

Fig. 1 Multiple parameters are implicated in the pathophysiology of heart failure in the elderly.

(Trifunovic et al., 2004). Additionally, other animal models demonstrated that the natural process of macroautophagy which disposes of dysfunctional mitochondria may decline with age (Taneike et al., 2010). Telomere shortening may further impair mitochondrial function and induce apoptosis (**Fig. 1**).

Various other pathophysiological mechanisms that are implicated in this "normal" aging course have only recently been appraised. Amyloid is a rare underestimated infiltrative disease that causes of HF mainly in older men (70 years) and is associated with a poor 5-year survival of 35.7% (Connors et al., 2016). It is estimated that 25% of the population aged >80 years have amyloid deposits of the cardiac muscle. Contemporary data show that the prevalence of wild-type familial transthyretin (TTR) amyloidosis is 13% among HF patients ≥60 years diagnosed with HF with preserved ejection fraction (HFpEF) (Gonzalez-Lopez et al., 2015).

The role of miRNA in the process of aging is also noteworthy. It was demonstrated that genetic deletion of miR-34a that regulate the expression of numerous gene pathways may ameliorate age-related myocardial apoptosis (Boon et al., 2013). Additionally, the role of protein SMP30 has been recently investigated. There is evidence that levels of SMP30 may fall by 40% with age in animal models, while SMP30 knockout mice have severe cardiac remodeling and dysfunction (Misaka et al., 2013).

Cardiac function and structure

The abovementioned age-related changes of fibrosis and endothelial dysfunction promote cardiac diastolic function through the development of a stiff myocyte. Meanwhile, a different age-related pathophysiological mechanism of impaired active diastolic relaxation has been proposed. In the normal cardiac cell phosphorylation of phospholamban increases the affinity of sarcoplasmic/endoplasmic reticulum Ca2+ ATPase (SERCA) for Ca, augmenting SERCA pump activity and consequently increasing Ca reuptake in the myocardial cell at the phase of active diastolic relaxation (**Fig. 1**). However, progressive age is associated with a decrease of SERCA levels and an increase of SERCA2a/phospholamban ratio (Cain et al., 1998). In support of this concept, animal models have shown that improvement of SERCA2a/phospholamban ratio through the gene transfer of the SERCA2a protein may restore cardiac diastolic function (Schmidt et al., 2000). Furthermore, age-induced elevated oxidative stress may directly damage the SERCA channel. In addition to that, deterioration of responsiveness to beta adrenergic stimulation may also lead to diminished phosporilization of phospholamban (Lancel et al., 2010). Alteration in Ca handling may also prolong the action potential and predispose to arrhythmias.

Undoubtedly, abnormal diastolic function is the hallmark of the aging myocardium. Diastolic dysfunction increases proportionally with age and may be prevalent in 50% of patents >80 years (Dannenberg et al., 1989). Older individuals exhibit an increase in the isovolumic relaxation time and a lower proportion of total diastolic filling. The atrial contraction contributes significantly to LV filling which, given time, results in atrial enlargement. As a result, a decrease in mitral E/A ratio is observed. In fact, elderly normal individuals exhibit similar LV filling patterns with younger patients (40–60 years) with mild diastolic dysfunction (Dalen et al., 2010).

Although diastolic dysfunction in elderly HF group is well documented, there are paradoxically no obvious significant age-related changes in LV structure. In registry of 765 autopsies the mean values for LV wall dimensions did not change significantly with age, with the exception of ventricular septum which was marked thicker in the elderly (Kitzman et al., 1988). According to Laplace's law, isolated septal hypertrophy in the elderly may result from chronic wall tensions developed in this area owing to the large septal diameter of the LV. In line with these results cardiac magnetic resonance studies of 336 healthy adults even showed a small reduction of LV mass with age (Hees et al., 2002). Also, there was no significant increase in LV mass with age in the Framingham Heart study among nonobese, nonhypertensive volunteers without a history of cardiovascular disease (Dannenberg et al., 1989).

Nonetheless, the overall architecture of cardiac muscle in the elderly may be ultimately affected. Healthy volunteers show a decline in the longitudinal strain and a correspondent raise in the circumferential strain in order to compensate for loss of systolic function. Radial strain and LV ejection fraction (LVEF) on the other hand tend to remain steady with progressive age (Sun et al., 2013).

Changes in LV systolic and diastolic function are more obvious in the healthy elderly during exercise and are associated with a reduced rise in stoke volume. A relationship of abnormal early relaxation and LV filling pattern with age was noticed in early studies. Older age is also related to impaired autonomic modulation and chronotropic incompetence that prevents the heart from adapting to demands during exercise, that is increase in heart rate, myocardial contractility and diastolic relaxation. Indeed, the maximum volume of oxygen during exercise declines with advancing age by 50% from age 20 to 80 years (Fleg et al., 2005).

HFpEF Phenotype

The HPpEF phenotype primarily affects the elderly population. In community-based studies HFpEF is reported only in 1% of women and 0% of men 25–49 years of age and rises to 8%–10% in women and 4%–6% in men aged ≥80 years (Brouwers et al., 2013). Although in the past decays HFpEF was considered as a transitory stage to HF with reduced ejection fraction (HFrEF) nowadays it is regarded as a distinct HF disease with distinct LV remodeling, cellular and interstitial characteristics. HFpEF patients exhibit increased myocardial total collagen and collagen I expression, which relates to the severity of diastolic dysfunction (Kasner et al., 2011). Dyspneic symptoms are attributed to inherent age-related changes such as LV diastolic dysfunction, atrial dysfunction, vascular stiffening, and endothelial dysfunction combined with proinflammatory coexisting conditions and noncardiovascular comorbidities. Symptomatic elderly HFpEF patients as compared with elderly healthy volunteers with preserved LVEF exhibit impaired echocardiography markers of diastolic and systolic function (mitral annular velocities and radial and longitudinal systolic strain), at rest which also fail to raise normally during exercise (Tan et al., 2009). Although concomitant comorbidities may

accelerate LV diastolic dysfunction, to date it is not clear what exactly shifts diastolic dysfunction from an asymptomatic state to the development of dyspneic symptoms. Specific echocardiography markers including E/e ratio < 14, Valsalva maneuver decrease in E/A by 50%, pulmonary vein Ar duration > mitral A duration by 30 msec, are indicative of significant diastolic dysfunction independent of age (Yamakado et al., 1997; Nagueh et al., 2016).

HFpEF patients have equally poor long-term mortality as compared with their HFrEF counterparts which age-related comorbidities can partly only explain (Mohammed et al., 2012). The definition of normal or near-normal LVEF among elderly patients presenting with HF symptoms is of paramount importance because the classical medical HFrEF therapy does not have any effect on clinical symptoms or long-term mortality. Patients with LVEF <50% but ≥40% are considered a distinct group with intermediate age values (Farmakis et al., 2016). There is currently an area of uncertainty regarding treatment options in HF patients with intermediate LVEF values.

Arterial Stiffness

Cardiac afterload is increased with aging vasculature. In young normal individuals the proximal aorta is rich in elastin while distal branches are progressively stiffer (**Fig. 1**). The elastic proximal aorta expands to accommodate stoke volume and acts as an aortic reservoir in order to ensure blood flow in diastole. Pulse wave reflections travel backward toward the heart during late systole and early diastole, increasing favorably diastolic pressure and therefore improving coronary perfusion. Aging dramatically increases intima-medial layer thickness calcification and endothelial function of large vessels (Elliott and McGrath, 1994). This is considered a result of chronic repeated local injuries and the ensuing inflammatory process. The formation of irreversible advanced glycation end products is also implicated in this course. The whole process is accelerated in the presence of risk factors including hypertension, chronic kidney disease, and diabetes (Paulus and Tschope, 2013). As a result, the aorta becomes more stiff leading to a pathophysiological cascade. In the elderly the reflected waves reach the ascending aorta much earlier in late systole. There is consequently an increase in systolic pressure and a decrease in diastolic pressure, which in turn impairs coronary perfusion and predisposes to ischemia. Moreover, aortic stiffness imposes an increased afterload which absorbs the mechanical energy developed by LV and accelerates LV hypertrophy. Augmentation index and pulse wave velocity are extensively studied markers of aortic stiffness which increase significantly with advancing age and seem to be independently related to long-term cardiovascular outcome (Mitchell et al., 2004; Najjar et al., 2008).

Coronary Artery Disease and Associated Risk Factors

The prevalence of risk factors predisposing to LV diastolic dysfunction and coronary artery disease (CAD) rises with age paralleling the increase in HF incidence: HF risk rises by twofold in patients with systolic blood pressure >160 mm Hg or diastolic blood pressure >100 mm Hg (Lloyd-Jones et al., 2002). As well as increasing the risk for CAD, hypertension promotes HF syndrome though elevated oxidative stress, microvascular inflammation, and myocardial afterload excess (Paulus and Tschope, 2013). In industrialized countries, elderly patients are also more likely to suffer from diabetes with a peak at age 60–74 (17.6%) and has a slightly lower prevalence (14.9%) in persons >75 years (Sloan et al., 2008). Diabetes may predispose to HF though various pathophysiological mechanisms including microvasculopathy, myocardial hypertrophy, fibrosis, and consequent LV systolic dysfunction, and also through atherosclerotic and thrombotic mechanisms (**Fig. 1**).

The effective invasive and medical treatment of myocardial infarction (MI) has also decreased the mortality of post MI patients and plays a central role in the occurrence of HF in the elderly. In a large cohort of patients >65 years of age hospitalized for MI in Canada there was a 28% reduction mortality between 1994 and 2000. Almost 2/3 of included patients developed HF during this follow-up (Ezekowitz et al., 2009). In the Framingham Heart Study the HF incidence following diagnosis of MI increased from 19.6% between 1970 and 1979 to 21.5% between 1980 and 1989 and to 33.9% between 1990 and 1999 (Velagaleti et al., 2008). In another registry of 2596 post MI patients, survival rates of post MI-related HF improved significantly between 1990 and 2010 (Gerber et al., 2016).

At the same time a different dynamic is observed: awareness of hypertension tents to improve overtime and so does the appropriate medical control of hypertension (Yoon et al., 2010). Also statin use is becoming more common and guideline-recommended LDL targets are more regularly achieved (Mann et al., 2008). Smoking habit has also shown a significant global reduction from 41.2% in men and 10.6% in women in 1980 to 31.1% and 6.2% in 2012 respectively, with a striper decline in the last decay (Ng et al., 2014). This trend may finally prove to delay onset of CAD or even ameliorate the burden of HF in Westernized countries.

Heart Valve Disease

Degenerative valvular heart disease is another underestimated cause of HF in high-income countries. Data from the Framingham study suggest that 7%–8% of HF can be attributed to heart valve disease (Kannel, 2000). Autopsy studies have shown that subendothelial thickening of the aortic valve may begin in early adulthood; however, significant aortic calcification, and loss of extensibility of aortic valve, is a disease of the elderly (Kuusisto et al., 2005). In The Framingham study severe aortic stenosis may rise from 2% in individuals between 70 and 80 years to 3%–9% in those >80 years of age (Singh et al., 1999). Additionally, more than moderate mitral regurgitation is present in 11.2% of men over 80 years of age while it is rarely documented in men or women

younger than 50 years. Similarly, degenerative or rheumatic aortic regurgitation may be present in up to 2.3% of individuals >70 years old but is hardly ever documented in ages <50 years (Singh et al., 1999). Moderate or more tricuspid regurgitation was also found in 1.5% of men and 5.6% of women 70–83 years whereas it was rare in younger age groups. Although in the past tricuspid valvulopathy was considered benign, it has recently shown to be relate to worst survival even in patients with normal ventricular function and without pulmonary hypertension. In a 10-year follow-up study of 353 elderly patients (mean age 70 years), free of structural valve disease or significant comorbidities, severe tricuspid regurgitation conferred a higher mortality risk independently of age (Topilsky et al., 2014).

It should be also pointed out that in clinical practice older age is a common reason why otherwise eligible elderly patients are denied for cardiac surgery (Iung et al., 2005). This in turn may increase further the burden of HF in the elderly population (**Fig. 1**).

Clinical profile

The clinical profile of elderly HF patients is drawn from the comparison of age groups from national and international registries and also from negative medical and interventional studies. Different age cut-offs have been used to define the elderly among various studies. Ages <64 old are commonly considered "young," ages between 65 and 74 "middle old," ages 75–84 "old" and ages >85 years are typically considered "oldest old." In the Acute decompensated heart failure syndromes (ATTEND) registry 26.5% of patents <65 years suffered from dilated cardiomyopathy as opposed to 3.3% in the >85-year cohort (Mizuno et al., 2016). Older patients as opposed to younger patients are also more likely to have a normal LVFE upon presentation and higher rates of valvular disease (Mogensen et al., 2011). They are also more commonly women, hypertensive, nondiabetic with a higher prevalence of atrial fibrillation (Herrero-Puente et al., 2012; Komajda et al., 2009; Metra et al., 2015a,b; Fonarow et al., 2009; Mahjoub et al., 2008; Pulignano et al., 2002; Mizuno et al., 2016) (**Table 1**). The prevalence of CAD and atrial fibrillation shows a relative decline after 80 years of age. Additionally, the proportion of diabetes and smoking may also be considerably lower in the "oldest old" subgroups. On the whole, very elderly HFpEF patients tend to show a marked reduction cardiac comorbidity as compared with their younger counterparts. This is probably a result of the highest mortality associated with these risk factors but may also be attributed to the ill-defined medical history and diagnostic defects in the elderly (Mogensen et al., 2011; Stein et al., 2012). Interestingly, atrial fibrillation is less prevalent in very elderly patients with HFrEF but is still prominent in the "old" HFpEF subgroup. Renal dysfunction is also pronounced in the HFrEF "oldest old" group but to a much lesser extent than in the HFpEF "oldest old" group (Stein et al., 2012).

It has been shown that 40% of patients >65 years hospitalized with HF have ≥5 noncardiac comorbidities (Braunstein et al., 2003). Noncardiac comorbidities including stoke, chronic pulmonary disease, and peripheral vascular disease may show a decline >85 years of age although there are discrepancies between studies. In contrast, anemia, myxedema, dementia rheumatic disease, and cancer are more pronounced in the "oldest old" cohorts (Mogensen et al., 2011; Stein et al., 2012; Metra et al., 2015b; Fonarow et al., 2009; Komajda et al., 2009).

It should be emphasized that in multinational registries patients presenting to outpatients' clinics tend to be older (77–81 years) as compared to those presenting to hospital emergency settings (70–73 years) (Mebazaa et al., 2015). Accordingly, the profile of HF patients may differ in keeping with the studied population (hospital vs. outpatient setting, acute HF vs. chronic HF patients, HFpEF vs. HFrEF patients).

Initial Diagnosis and Management

Common precipitating reasons for exacerbation of HF in the elderly include infection (40%) ischemia (17%), excessive water and salt intake (9.2%), hypertension, tachyarrhythmia, noncompliance with medication, and intravenous fluid intake (Taylor et al., 2012). Elderly HF patients are most likely to be admitted to the hospital after an initial evaluation in the emergency department; however this decision is usually influenced by multiple cumulative conditions that may not be directly related to HF (Ezekowitz et al., 2008). There is commonly an overlap of HF signs and symptoms with other common diseases in the elderly. For example, dyspnea may be commonly related to pneumonia or chronic obstructive pulmonary disease (COPD), asthma, and anemia. Also peripheral edema may be a result of chronic venous insufficiency, lymphedema. Moreover, cognitive impairment, confusion, loss of appetite, or delirium may be attributed to concomitant infection or acute neurological conditions. Elderly patients may also deliberately lower the levels of their daily physical activity and mask HF symptoms or, on the other hand, they may attribute dyspnea to normal aging.

Usually, a more dramatic initial clinical picture with tachypnea and lower oxygen saturation is reported in the elderly (Herrero-Puente et al., 2012; Metra et al., 2015a,b). Rales and elevated jugular venous pressure on initial presentation may be more common in elderly versus younger patients (Fonarow et al., 2009). However frequent evaluated signs and symptoms including orthopnea, paroxysmal nocturnal dyspnea, and jugular venous pressure may not be sufficiently sensitive and specific in the elderly (Ekundayo et al., 2009) (**Table 2**). Also, rales may not be present on auscultation and classic signs of pulmonary congestion may not be found in chest radiography (Collins et al., 2006). Nonspecific age-related changes are also frequent in chest radiography (e.g., emphysema) and the cardiothoracic ratio may be difficult to assess.

Atypical presentation in emergency ward entails a comprehensive biomarker workup. Laboratory findings namely creatinine and troponin are commonly higher in elderly patients when compared to younger AHF patient groups (Mahjoub et al., 2008; Metra et al., 2015a; Gustafsson et al., 2004; Herrero-Puente et al., 2012; Komajda et al., 2009). In lack of specific electrocardiography findings and symptoms, minor troponin elevation may reflect impaired renal function, elevated cardiac pressures, impaired oxygen

Table 2 Profile and practical considerations in elderly acute heart failure patients

Demographics	Women (60%), Hypertensive (40%), Nonobese, Nondiabetic (80%), Atrial fibrillation (40%), Coronary artery disease (45%)	Anticipate hypertensive HF and "vascular-type" HF, Anticipate de novo heart failure on the acute setting
Clinical presentation	↑Rales, ↑Jugular venous pressure, ↓Oxygen saturation, ↓Peripheral edema, Infection, ↑bleeding risk	Exclude alternative diagnosis, e.g., COPD pneumonia, anemia, cognitive dysfunction Use BNP and/or NTproBNP to confirm diagnosis, consider measuring, procalcitonin Acknowledge increased bleeding risk with anticoagulation therapy (and NOACs)
Laboratory findings	↑Creatinine, ↑Troponin, ↑Natriuretic Peptides	Calculate glomerular filtration rate Monitor electrolytes (hyperkalemia) Consider ST2 measurement for prognosis
Echocardiography	Preserved systolic function, Increased left atrial dimensions	Evaluate less age-dependent variables including E/e′ >14, Valsalva maneuver decrease E/A $\geq 50\%$, vein Ar duration $>$ mitral A duration by 30 msec. Consider using contrast agents
Comorbidities	Stoke (20%), Peripheral vascular disease (15%), Anemia (20%), Frailty (50%)	Consider HF diagnosis in internal medicine wards, ICU, and geriatric departments—evaluate by a specialist cardiologist Reduce polypharmacy—Consider stopping medication without effect in quality of life (e.g., statins) Screen for depression Evaluate frailty Acknowledge highest risk of surgery than predicted
Highest risk	Very elderly, Confusion, Shock, ↑Troponin, Infection, Diabetes, Renal dysfunction, Frail	Discuss do not resuscitate order Consider palliative care and hospice Talk openly about end of life matters
Medical Treatment	Lower doses of ACE/ARBS beta-blockers and MRAs	Be alert for digoxin toxicity signs Dissemination of HF treatment guidelines in ICU/internal medicine doctors
Device-Based Therapy	Questionable efficacy of ICD	Make individualized decisions for ICD and left ventricular assist devices

ACE, Angiotensin converting enzyme inhibitor; *ARBs*, Angiotensin II receptor blockers; *BNP*, Brain natriuretic peptide; *COPD*, chronic obstructive pulmonary disease; *MRA*, mineralocorticoid receptor antagonist.

supply endothelial dysfunction, and myocardial apoptosis. Natriuretic peptide levels are also commonly reported higher in acute HF elderly patients and the associated "gray zone" values for diagnosis of HF in the emergency department may have to be modified (Metra et al., 2015a; Fonarow et al., 2009) (**Table 2**). Particularly for B Natriuretic peptide (BNP) the exclusion cut-off for HF diagnosis may be adjusted to 250 pg/mL and the confirmatory cut-off to 600 pg/mL. For NTproBNP the gray zone values may be 1750–6000 pg/ML. Soluble ST2 values are less age dependent but their diagnostic efficiency for HF is limited. However, a value >35 ng/mL is clinically relevant and provides independent critical prognostic information (Parikh et al., 2016). Measurement of procalcitonin may also aid in the triage of elderly dyspnoeic elderly patients. In a recent study of patients presenting with dyspnea in the emergency department a high (≥0.10 ng/mL) versus low (<10 ng/mL) value of procalcitonin was more common in elderly patents (72.7 vs. 62.7 years, respectively) and could adequately discriminate pneumonia from heart failure even in the subgroup with the lowest clinical probability of microbial infection. (Alba et al., 2016) (**Table 2**).

Noninvasive ventilation in the emergency department is less frequent in the elderly (Metra et al., 2015a,b; Herrero-Puente et al., 2012). Studies also report a lower rate of cardiac catheterization interventions in elderly acute HF patients (Komajda et al., 2009; Pulignano et al., 2002; Biagi et al., 2011). Elderly as opposed to younger acute HF patients are also considerably less likely to undergo an echocardiogram during hospitalization (Herrero-Puente et al., 2012; Komajda et al., 2009).

Echocardiography workup in the elderly is additionally limited owing to poor acoustic window; therefore contrast agents may be needed for the definition of the endocardial LV border and the diagnosis of apical thrombus. Computed tomography coronary angiography may not be an ideal choice for the elderly with chest pain owing to the severe coronary artery calcification and associated blooming artifacts (de Agustin et al., 2013).

Regarding their hospital stay, elderly HF patients are less likely to be hospitalized in the cardiac units and are commonly referred to internal medicine and geriatric wards (Komajda et al., 2009; Metra et al., 2015b; Mahjoub et al., 2008). Patients admitted in internal medicine departments are less likely to be treated with evidence-based medication and undergo fewer invasive and noninvasive procedures (Di Lenarda et al., 2003; Biagi et al., 2011).

Outcomes and Prognosis

Hospital length of stay usually depends on country-specific policies and economic factors and data regarding the elderly HF population are diverge. For example, in the Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE HF) registry in United States there was no significant difference in the length of hospitalization between elderly (≥75 years) and younger (<75 years) patients (5.6 vs. 5.8 days, respectively) (Fonarow et al., 2009). In contrast, in the Value of Endothelin Receptor Inhibition with Tezosentan in Acute heart failure Study (VERITAS) multinational trial elderly patients ≥72 years had a mean 1.15 longer in hospital stay (Metra et al., 2015a).

Progressing age corresponds within hospital and long-term mortality in all registries and studies. Older (≥75 years) as compared to younger HF patients have a twofold increase in hospital mortality (4.9% vs. 2.4%) (Fonarow et al., 2010) (**Table 1**). Accordingly, the Euro Heart Failure Survey I reported 13% inhospitable mortality in participants ≥80 years versus 5% in patients <80 years (Komajda et al., 2007). Accumulating data from well-designed trials also show a median survival of 20 months for ≥85 years AHF patens versus 50 months for those <85 years (Mogensen et al., 2011). After a long 6-year follow-up of the prophylaxis for thromboembolism in critical care trial (PROTECT) there was a 17% increase of mortality per 5 year increase in age. In all studies age itself confers a significantly higher mortality and morbidity risk both in the older and younger AHF subgroups.

The mortality of elderly HF patients is largely driven by concomitant cardiac and noncardiac comorbidities. Diabetes, tricuspid regurgitation, and renal dysfunction are associated with a poor survival in all HF patients but may confer a worse impact in the younger groups (Mogensen et al., 2011; Stein et al., 2012; Metra et al., 2015a). On the contrary atrial fibrillation, COPD, and mitral regurgitation are more elderly-specific prognosticators. Another interesting finding is that although elderly patients tend to have a lower body mass index (BMI), the mortality benefit of a higher BMI is confined to patients >75 years (Shah et al., 2014).

Many age-specific differences can be explained by the predominance of the "vascular-type," HF in the elderly where, primarily, severe diastolic dysfunction aortic stiffness and noncardiac comorbidities affect outcome. In younger HF patients high systolic blood pressure on evaluation is related with a favorable outcome; nonetheless this effect is attenuated in the elderly. Anemia may have a better prognostic impact for younger patients, in whom it probably indicates a state of higher inflammation and fluid retention (Metra et al., 2015a; van der Meer et al., 2013; Komajda et al., 2009). Natriuretic peptides and troponin elevation are predictors of morality in both age groups; however albumin levels are determinants of mortality mostly in the elderly (Metra et al., 2015a).

Self-care problems and confinement to bed may also account for the high mortality rates in the elderly (Komajda et al., 2009). Poor health literacy, that is the poor capacity to read and understand basic health vocabulary and medical services (including follow-up appointments, medication use, etc.), is another suggested explanation of the ominous prognosis of this frail group (Wu et al., 2016). Another range of less-studied socioeconomic parameters such as ignorance of HF symptoms, housing stability, transportation, distance to hospital, and social support may be responsible for the poor outlook of the elderly in the developing world (Hawkins et al., 2012).

Medical Treatment

Large-scale registries in United States, Europe, and Japan and a large number of smaller studies unanimously agree that life prolonging agents such as Angiotensin converting enzyme inhibitors, (ACEI) Angiotensin II receptor blockers (ARBs), beta-blockers,

and mineralocorticoid receptor antagonists (MRAs) are commonly under-prescribed and under-dosed in elderly as opposed to younger patients (Mogensen et al., 2011; Stein et al., 2012; Metra et al., 2015b; Fonarow et al., 2009; Komajda et al., 2009) (**Table 1**). This may be explained by the high prevalence of associated side effects of neurohormone blocking agents like orthostatic hypotension bradyarrhythmias and renal dysfunction that are common in the elderly. Another proposed explanation is the ineffective dissemination of HF guidelines among medical specialties treating the HF patient, especially in internal medicine and geriatric wards. However, the principal reason for the under prescription of these agents is the skepticism regarding their effectiveness in the elderly. Metabolism and pharmacokinetics of these medications may vary in very elderly populations with lower body mass, different water content, multiple noncardiac comorbidities (e.g., renal, hepatic dysfunction), polypharmacy, and subsequent drug–drug interactions. In fact, early large-scale randomized trials commonly avoided including very elderly patients. For example, in the "effect of enalapril on survival in patients with reduced LV ejection fractions and congestive heart failure" (SOLVED) trial only 8 patients were older than 80 years of age (1991). Also in the "Randomized ALdactone Evaluation Study" (RALES) trial only 9% of included population was older than 80 years of age (Pitt et al., 1999). Likewise, in the "metoprolol CR/XL randomized intervention trial in congestive heart failure" (MERIT-HF) trial beta-blockers improved the outcome of HF patients but none of the participants was older than 81 years (1999). However, in successive studies metoprolol proved to retain its effectives even in HFrEF patients >75 year of age (Deedwania et al., 2004). Also in the OPTIMIZE HF registry administration of beta-blockers proved clinically effective with regard to mortality and rehospitalization outcome in the elderly (Hernandez et al., 2009). In line with these findings, prescription of neurohormonal blocking agents was associated with a better mid-term outcome in the EHFS II registry (Komajda et al., 2009).

Studies and registries demonstrate that digitalis is also more commonly prescribed in elderly compared to younger HF patients (Komajda et al., 2007; Fonarow et al., 2009; Mogensen et al., 2011). However in the "Digitalis Investigation Group" (DIG) trial digoxin demonstrated only a minor readmission benefit and only 5% of included HF patients were >80 years (1997). Caution is recommended with the use of digoxin because of its narrow therapeutic window. Physicians have to be alert for signs of toxicity including nausea, dizziness, and blurred vision (**Table 2**). Also bradycardia or ventricular tachycardia may occur especially in cases with concomitant renal dysfunction and electrolyte imbalance which are not uncommon in the elderly.

Sacubitril Valsartan is currently considered the biggest breakthrough in the treatment of HFrEF after decays of futile research with other agents. It is recommended for NYHA III–IV patients with LVEF ≤35% that are already treated with ACEI or ARBs. The drug combines the neuroblocking benefits of valsartan with the encashment of the positive effects of the endogenous natriuretic peptide system. In the "Prospective comparison of ARNI with ACEI to Determine Impact on Global Mortality and morbidity in Heart Failure" (PRADIGM-HF) clinical trial the benefits of the agent were consistent among all age groups and there was no more significant hypotension, renal impairment, or hyperkalemia in the elderly. Ongoing studies are testing its potential use for HFpEF patents, where currently medical treatment remains symptomatic and empirical.

Advanced Invasive Therapies in the Elderly

CRT and ICD

Although almost 30% of all Cardiac resynchronization (CRT) with defibrillators (CRT-D) CRTs in Europe are implanted in patients >75 years of age, elderly patients were not commonly included in large randomized CRT trials. A recent analysis from a single center showed that LV remodeling and overall mortality benefits from CRT were consistent among 70, 70–79, and ≥80 age groups at 20-months follow-up (Verbrugge et al., 2013). At a longer term follow-up of 7 years of "The Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy" (MADIT-CRT) trial mortality benefits were consistent in all (<60, 60–74, and ≥75 years) age groups (Thomas et al., 2016). In addition to this, more studies have shown that cardiac resynchronization therapy reduces the need for hospitalization and outpatients care but becomes cost-effective only after approximately 4 years from implantation (Linde et al., 2011). The cost and effectiveness OF ICD should be carefully balanced. Currently, CRT guidelines require CRT candidates with a life expectancy of at least 1 year.

Implantable cardioverter defibrillators (ICD) are recommended in elderly patients that meet appropriate criteria. Elderly patients receive equally appropriate device shocks as compared with younger age groups (Yung et al., 2013). In a study of 84 octogenarians ICD implantation proved safe and effective at 5-year follow-up; however, in other studies the effectiveness was not clear after adjustment for comorbidities (Mezu et al., 2011; Strimel et al., 2011). It should be also acknowledged that ICD therapy may be cost-effective if the patient lives more than 7 years, that is almost the life of one battery; nonetheless, median survival in elderly >75 years HF patients hardly ever surpasses 5 years (Hohnloser et al., 2004). In addition to this, in a large Danish nationwide registry 72% of elderly patients treated with IDC for primary prevention did not have any utilization of their device prior to death (Ruwald et al., 2016). Moreover, in a trial of 1116 patients with nonischemic HF randomized to ICD or medical treatment, prophylactic implantation of ICD showed a survival benefit only in younger ages (Kober et al., 2016). There are also concerns that patients with HF and nondialysis-dependent severe chronic kidney disease may not benefit from ICD impanation (Singh et al., 2014).

Pump failure, renal failure, and severe noncardiac comorbidities rather than malignant arrhythmias seem to be the main drivers in mortality in the elderly. This raises several ethical and practical concerns. For example, there is no clear recommendation for replacing the ICD generator in elderly patients that do not any more meet the criteria for ICD implantation, that is patients who did not experience appropriate shocks and/or their LVEF has drastically improved >35%. This subgroup may account for 26% of

patients where the device needs replacement (Kini et al., 2014). Also it is reasonable that all elderly ICD candidates understand the function of the device and anticipate shocks. As a matter of practicality being able to provide informed consent is a minimum prerequisite for ICD implantation in many centers, nonetheless witnessed informed consent is also practiced in cases with cognitive dysfunction.

Mechanical Circulatory Support

It is estimated that among 300 million USA residents there are 200,000–250,000 Class IIIb–IV HF patients. Taking under account that the average age of HF hospitalized patient is 75 years and that many centers are reluctant to consider patients >70 years for heart transplantation (only 1% of transplant patients are >70 years of age) we can acknowledge a rapidly escalating number of potential Left ventricular assist device (LVAD) candidates among the elderly, mainly for a destination therapy (Miller and Guglin, 2013; Mancini and Colombo, 2015).

In addition to that, exclusion criteria for LVAD are less strict than transplantation criteria and do not apply to a large pool of HF patients with advanced age: end-organ dysfunction, intolerance to anticoagulation, increased pulmonary vascular resistance, significant right ventricular dysfunction, and comorbidities including malignancy, significant pulmonary, renal disease, significant obesity, mental illness or alcohol and drug dependences (Mancini and Colombo, 2015). Some studies have linked older age with worse short-term prognosis, however other studies have shown that the survival of patients >70 years was comparable with 65–70 and only modestly inferior to patients 50–64 years (Kilic et al., 2013; Adamson et al., 2011). Apparently poorer clinical status, right ventricular dysfunction, comorbidities including renal failure and diabetes, and a history of cardiac surgery are related to worst outcome (Kirklin et al., 2013). Younger age is however paradoxically associated with higher incidence of pump thrombosis during follow-up which is a finding that needs further confirmation (Kirklin et al., 2015). Psychosocial evaluation of elderly patients before implantation is crucial. Elderly patients with LVAD can suffer severe cognitive impairment or even, given time, become ineligible candidates for heart transplantation (Kirklin et al., 2015).

Transcatheter Interventions

Elderly patients with valvular disease who would be considered nonoperable in previous decays may undergo a plethora of valve repair and valve replacement procedures that do not require the aid of cardiopulmonary bypass. The option of transcatheter aortic valve implantation for elderly patients suffering from symptomatic severe aortic stenosis and with a high risk for conventional surgery is very well documented. Transcatheter valve impanation is also an option for otherwise nonoperable high-risk HF patients with failing bioprosthesic valves in the aorta, mitral, and tricuspid positions (Bapat and Asrress, 2014).

For elderly HF patients with severe mitral regurgitation who are deemed at excessive risk for conventional surgery the role of self-expanding bioprostheses through trans—apical access is coming to front. Such therapeutic options are the Tiara™ TAMI system (Neovasc Inc., Richmond, BC, Canada) and the and CardiAQ™ transcatheter mitral valve implantation system (CardiAQ Valve Technologies, Inc., Irvine, CA, United States) that preclude the need for cardiopulmonary bypass. Initial experience with these systems is very promising (Cheung and Banai, 2016). Mitraclip (Abbott Vascular, part of Abbott Laboratories; Santa Clara, California) is also a therapeutic option for high-risk patients with severe primary and secondary mitral regurgitation which improves LV remodeling and functional status in >75 and ≤75 years old patients (Scandura et al., 2016). Initial experience of Mitralign percutaneous tricuspid valve annuloplasty system for severe functional mitral regurgitation is also promising (Nickenig et al., 2016). For patients with significant functional tricuspid regurgitation and high predicted surgical risk the catheter-guided Trialign device (Mitralign, Inc., Boston, MA, United States) may reduce tricuspid annulus dimensions and improve HF symptoms. Moreover, the transcatheter interatrial shunt device (IASD, Corvia Medical, Tewkesbury, MA, United States) creates an iatrogenic left-to-right atrial shunt device that attenuates excessive exercise-induced left atrial pressures. In an initial single arm trial of HFpEF patients (mean age 69 ± 8 years) the device improved functional capacity and quality of life at 6-month follow-up (Hasenfuss et al., 2016). This is of particularly importance for old HFpEF patients where medical treatment options are scarce.

Frailty

Frailty is documented in up to 50% of HF patients in large registries and influences outcome of HF patients independently of concomitant comorbidities (Afilalo et al., 2014). Advance HF and frailty are therefore distinct entities, although they may share common pathways including increased inflammatory state (C Reactive Protein, Interleukin 1, Tumor necrosis factor a), impaired cortisone regulation, decreased testosterone levels, insulin resistance, skeletal muscle atrophy, and hypercatabolic state. According to the contemporary school of thought the frail phenotype HF patient is more vulnerable to stressors which may trigger decompensation at a lower threshold (Afilalo et al., 2014). Moreover, frail patients exhibit higher functional decline and may require a longer recovery time.

It is clear that frailty sets a therapeutic limit to contemporary costly invasive treatment of HF. A study that used Fried and Walston's definition of frailty among CRT recipients showed that the frail phenotype was four times more likely to have HF decompensation at 1-year follow-up (Dominguez-Rodriguez et al., 2015). Another single center study used a 31-component deficit index and defined 62% of LVAD candidates as frail. At 2-year follow-up those in the highest tertile had almost 40% higher mortality rates compared to 16% at the lowest tertile. Frailty was associated with mortality even after correction for other risk confounders

Table 3 Fried frailty scale

1. Weight loss	Unintentional weight loss of $\geq$4.5 kg (10 lbs) or $\geq$5% of the previous year
2. Weakness	Grip strength of the dominant hand with a Jamar hand-held handgrip strength dynamometer (maximum value of three attempts) Positive at lowest quartile based in gender/body/mass index
3. Self-reported exhaustion	How often in the past week: 1. did you feel that everything you did was an effort? 2. you could not get going? Positive if at least one condition positive $\geq$3 days
4. Slowness	Time to walk 4.57 m (15 ft) at usual pace Positive according to height/gender cut-offs
5. Low activity	Evaluation of 18 activities from the Minnesota Leisure Time Physical Activity Questionnaire that links calorie expenditure to activity. Positive if kilocalorie expenditure in men $<$383 kcal/wk and in women $<$270 kcal/wk.

Nonfrail (score 0), prefrail (score 1–2), frail (score 3–5).

A. and Cardiovascular Health Study Collaborative Research Group (2001). Frailty in older adults: Evidence for a phenotype. *The Journals of Gerontology Series A, Biological Sciences and Medical Science*, **56,** M146–M156.

(Dunlay et al., 2014). In a similar study, weak grip strength weight was predictive of length of stay after LVAD implantation. Surprisingly, handgrip strength increased significantly post-LVAD (Yost and Bhat, 2017).

It is frequently unclear if symptoms fatigue and end-organ dysfunction of elderly HF patients are a result of an "instinct" frailty or a consequence of pump failure and therefore can be partially reversed after improvement of stroke volume and pulmonary capillary wedge pressure with invasive treatments. Specific comorbidities including chronic lung disease, dementia, disabling stoke, peripheral vascular disease, cirrhosis, osteoporosis, severe arthritis, and cancer may be linked more to an "irreversible" frailty phenotype. The fried scale is the most citied method in the bibliography to define frailty (Fried et al., 2001) (**Table 3**). Alternatively, single-component measurements such as 5-m gait speed or handgrip are used because of their simplicity (Pulignano et al., 2016). Given the increasingly aging global population and the economic constrains in most health systems there is currently an unmet need for simple, validated frailty indices in elderly CRT and LVAD candidates. So far, however, there are no specific recommendations for screening of frailty by guideline committee providers.

Palliative Care

For patients who are excluded from LVAD and heart transplant there comes a time where the focus of care shifts from prolonging their life to improving the quality of their remaining life with emotional, psychosocial, and spiritual support. Dyspnea, pain, and other distressing symptoms may require high doses of diuretics, benzodiazepines, and opioids. On the other hand, satins, aspirin, or even first-line drugs may be stopped. At this phase, patients may also wish to discuss "do-not-resuscitate" order or disable their ICD.

However, prognosis of end-stage HF patients is not always easy and reliable. Physicians treating the terminal stage HF patient are also reluctant to talk about palliative care and patients tend to overestimate their life expectancy. Health care providers point out the need for awareness availability and accessibility of palliative care in HF. This option cannot be reserved for patients facing imminent death but at an earlier phase where patients are able to participate in decision-making. Currently, in United Kingdom only a 7% proportion of HF patients were registered for palliative care as opposed to a 48% of cancer patients. Also 72% of registered HF palliative care patients were $\geq$80 years of age whereas only 3% were younger than 60 years (Gadoud et al., 2014). Similarly on the other side of the Atlantic, only 13% of patients receiving hospice care had a primary HF diagnosis; however an increasing trend is observed.

Cost for medical systems

In high-income countries more than 80% of patients are $>$ than 60 years. In United States the number of patients with HF is expected to rise from 5.8 to 8.5 million by 2030. The total HF financial cost in 2012 was estimated 31$ billion and may rise as 70$ billion in 2030 (Ziaeian and Fonarow, 2016; Heidenreich et al., 2013). HF-related hospitalizations are also projected to rise by 50% by the year 2030. Almost 2% total budgets are spent for HF in high-income countries including United States, Germany, and Sweden and more than half of the medical cost concerns interventions and repeated hospitalizations at the time nearing death.

Age per se may not be related with high HF expenditures in high-income countries. Instead hospitalization in urban and teaching hospitals and advanced invasive procedures increase expenditures (Ziaeian et al., 2015). However, advanced disease managed programs and Natriuretic Peptide guided therapy are less effective in the elderly especially when comorbidities are prevalent (Sanders-van Wijk et al., 2013).

At present almost 86% of universal HF spending concerns high-income countries and regards only 16% of global HF patients, while there is few information about the HF financial cost in developing countries (Ziaeian and Fonarow, 2016).

Limitations of Our Global Perspective

Unfortunately, although several studies have compared elderly versus younger population in high-income countries to date there are no such direct comparisons for middle and low-income countries. Inevitably assumptions are made based on registries carried out in westernized communities. This is partly justified because a global shift toward a westernized lifestyle is observed. Indeed, in earlier decades data from acute HF registries in Africa and Asia had shown a high prevalence of hypertension (45%) and rheumatic heart disease (14%) with ischemic heart disease consistently reported less than 10% (Damasceno et al., 2012). However in the "INTERnational Congestive Heart Failure" (INTER-CHF) study ischemic heart disease was a leading cause (20%) of HF in Africa (Dokainish et al., 2016). Similarly, a shift toward ischemic etiology of HF over hypertension and valvular etiology is noted in Asian countries as compared with registries in previous decays (Ziaeian and Fonarow, 2016) (**Table 4**).

However, an actual direct extrapolation of data from high-income countries may not be entirely appropriate. Patients in registries from developing countries are considerably younger (**Tables 4** and **5**). There are significant regional dissimilarities with regard to HF etiology as for example patients from Middle East and South America tend to be more obese and suffer more commonly from diabetes compared to African and Asian patients. Also rheumatic fever is almost extinct from developed countries; however almost 470,000 new cases are expected worldwide, the majority of which occur in low income African countries (Essop and Nkomo, 2005). Chagas disease accounts for 3.8% of heart failure cases in South America and is associated with high mortality in younger age groups. There are also dissimilarities with respect to clinical presentation as in the "Asian Sudden Cardiac Death in

Table 4 Clinical presentation according to the region in the INTER-CHF study (Dokainish et al., 2016)

Years 2012–14	*INTER-CHF Africa*	*INTER-CHF Middle East*	*INTER-CHF South America*	*INTER-CHF Asia*

ACE, Angiotensin converting enzyme inhibitors; *ARBs*, Angiotensin II receptor blockers; *BMI*, body mass index (kg/m^2); *CAD*, coronary artery disease pulmonary disease; *HFpEF*, heart failure with preserved ejection fraction; *MI*, myocardial infarction; *MRA*, mineralocorticoid receptor antagonist.

Table 5 Profile of HF patients with LVEF $\leq$40% in the Asian sudden death heart failure registry (Lam et al., 2016)

Years 2012–15	*High income*	*Middle income*	*Low income*
Mean age	62.6	57.7	57.3[a]
Number	2247	1212	1817
BMI	24.8	25.1	24.9
Male	78.3	80.4	76.5[b]
Hypertension	59.7	54.9	40.2[a,b]
Diabetes	46.2	36	36.1[a]
CAD	58.8	49.5	48.5
LVEF	27	28	28[a]
NYHA II–IV	27	40	41[a,b]
ACE/ARBs	76.6	66.9	79.4[a,b]
B-blocker	86.1	83	66.5[a,b]
MRAs	54.5	70	58.8[a,b]
Diuretics	82.3	83.2	79.3[a,b]

[a]$P < 0.005$ vs. high income.

[b]$P < 0.005$ vs. middle income.

Income level was defined according to World Health Organization as lower in Indonesia, Philippines, India; middle in China, Thailand, Malaysia and higher in Singapore, Hong Kong, Taiwan, South Korea, and Japan.

ACE, Angiotensin converting enzyme inhibitors; *ARBs*, Angiotensin II receptor blockers; *BMI*, body mass index (kg/m^2); *CAD*, coronary artery disease; *LVEF*, left ventricular ejection fraction; *MRA*, mineralocorticoid receptor antagonist.

Heart Failure" (ASIAN-HF) registry 27% patients from high-income countries were in NYHA III or IV compared to 40% and 41% in middle and low income countries, respectively (**Table 4**). Also an initial dramatic clinical presentation with orthopnea, pulmonary rales, and S3 is more common in lower income countries (Lam et al., 2016). It is also a fact that patients in low-income countries commonly have no health or medication insurance (e.g., >70% in Africa) and are subsequently derived from any costly treatment. Indeed, only 6.1% of HF patients from low income countries receive a ICD, pacemaker, or CRT compared to 14.6% and 20.8% of middle and high-income countries, respectively (Lam et al., 2016).

Another point of concern is that in the developing world registries are carried in centers located in urban-elite territories and results may not be generalizable in the broader population. Patients are usually included in primary care and diagnostic criteria of HF are commonly unspecified. Even well-designed HFs are registries executed in low income countries acknowledge several weaknesses: Paradoxically more patients are lost at follow-up in urban areas as compared to rural areas. At the same time a lower rate of major cardiovascular events is documented in urban as opposed to rural areas (Yusuf et al., 2014). Ongoing world HF registries are expected to show a global perspective of this complex issue and indicate county-specific measures to improve the survival and quality of life of elderly HF patients (Filippatos et al., 2015).

Areas of Uncertainty—Future Directions

There are still open issues regarding the diagnosis and management of this frail group. The role of novel biomarkers (ST2, adrenomedullin) for diagnosis and prognosis remains uncertain. Also specific cut-offs of natriuretic peptides in the elderly are also lacking. A multimarker approach could be more appropriate in older HF patients; however its cost and effectiveness need to be validated. There is also currently a gap of evidence regarding specific cut-offs in echocardiography to define severe diastolic dysfunction in the octogenarians and nonagenarians. Measurements of arterial stiffness can also be integrated in the diagnostic workup; however exact recommendations are lacking.

Accurate prognosis is critical in the elderly owing to financial limitations of advanced treatments but so far validated prognostic scores have included only a low proportion of very elderly patients. For example the mean age was 63.3 years in "The N-terminal ProBNP Investigation of Dyspnea in the Emergency Department" (PRIDE) score and 65 years in the "Seattle Heart Failure Model" (SHFM) (Mozaffarian et al., 2007; Baggish et al., 2006). To date there are also few studies and registries with long (>2 years) follow-up of elderly HF patients.

There is also an unmet need to represent more elderly patients in large-scale trials of new therapeutic agents. For instance, a prespecified percentage (e.g., 30%) of included patients could be older than 75 years of age with also a predetermined minimum number of comorbidities. Treatment goals may also be modified, emphasizing on improvement of quality of life. To date there is also no universally accepted frailty scores that can overcome socioeconomic barriers among the evaluated populations.

Another high priority unsolved issue is the lack of evidence-based medical treatment in the prevalent HFrEF phenotype in the elderly. The heterogeneous pathophysiology of HFrEF is currently in the center of intensive research in a genetic, cellular, and clinical level. So far a plethora of pharmaceutical agents have failed to improve mortality in this group. Sacubitril valsartan and serelaxin, a natural vasodilator, are promising new agents but large-scale trials are still pending (Filippatos et al., 2014).

HF in the elderly is a health concern that transcends national borders. There is a clear need for a better global perspective that will aid country and region-specific interventions regarding prevention, diagnosis, and treatment in the elderly, especially in socioeconomically disadvantaged countries (Teo et al., 2013). Long-term medical planning can accordingly be tailored in keeping with realistic expectations. Global and country-specific dissemination of HF guidelines is also crucial to assert evidence-based treatments and quality of care.

Introduction

Heart failure (HF) is a syndrome caused by many etiologies which share the common phenotype of volume overload and poor end-organ perfusion. It affects an estimated 23 million people worldwide (Roger, 2013) and its prevalence and incidence are expected to rise due to longer life expectancy, especially increased longevity in those patients who have risk factors for the development of HF, e.g., coronary artery disease, hypertension, diabetes mellitus, and obesity (Roger, 2013). In the United States, there are an estimated 6 million people with the diagnosis of HF. It is projected that by 2030, there will be 8 million people with HF and that the cost of caring for HF patients will rise from $31 billion to $80 billion (Heidenreich et al., 2013).

Goals of HF management are to improve survival, prevent worsening symptoms, and reduce risk for hospital admission. To accomplish these goals, many centers now have developed disease management programs specific to HF. Although the monitoring technologies used might be very different among programs, the basic structure is the same—a system by which changes in the patient's clinical status are directly communicated to a dedicated provider team that respond to these changes with the intent of preventing hospital admission and maintaining quality of life (QOL) for these patients.

Selecting the most clinically effective and cost-effective means of optimizing management remains a challenge for clinicians. Many monitoring systems have been studied, ranging from the creation of specialty care teams to implantation of invasive devices purely for the purpose of HF monitoring. The purpose of this review is to better understand the evidence (or in some cases lack of evidence) behind the modalities that have been created and studied for monitoring the HF patient. It is hoped that after reviewing the pros and cons of each approach, the provider can then decide which approaches are best suited for their programs and patients.

Goals of Heart Failure Monitoring

Based on the Seattle HF Model, combined use of ACE inhibitors, β-blockers, mineralocorticoid receptor antagonists, and defibrillators, was predicted to decrease morbidity and mortality for systolic heart failure (HFrEF) patients by an absolute 25% over the past 2 decades (Levy et al., 2006). However, although programs targeted at improving compliance with guideline directed medical therapy (GDMT) for HF, such as "Get with the Guidelines—Heart Failure"(AHA) and the tracking of HF Discharge Instructions by CMS, have resulted in the majority of HF patients being treated appropriately with evidence-based, goal-directed medical therapy, recent studies show that this has resulted in not only marginal decreases in mortality (Barker et al., 2006; Curtis et al., 2008), but also no change and possible worse readmission rates (Heidenreich et al., 2010; Dharmarajan et al., 2013; Kociol et al., 2012). For diastolic HF (HFpEF) patients, readmission and mortality rates remain unchanged and comparable to HFrEF (Meta-analysis Global Group in Chronic Heart Failure (MAGGIC), 2012). Annually there are 1 million hospitalizations for HF in the United States with 30-day readmission rates in the 25% range. Cost for HF care remains the highest of all medical conditions (Roger, 2013).

Regardless of cause and acuity, HF admissions are heralded by volume overload (Gheorghiade et al., 2013). Hence, the universal goal of HF monitoring is to detect subclinical volume overload and intervene as early as possible to prevent readmission. Clearly reducing the number of hospitalized days improves QOL for the HF patient. However, decongestion brings other benefits (besides preventing readmission) to the HF patient. There is evidence that suggests achieving and maintaining normovolemia improve QOL and survival and prevent damage to other organ systems.

Achieving normovolemia correlates with further improved QOL in HF patients. A study of ambulatory HF patients who were listed for transplantation and who underwent afterload reduction and diuresis to achieve a pulmonary capillary wedge pressure of <15 demonstrated significant improvements in all aspects of exercise functional capacity as measured by cardiopulmonary exercise stress test (Stevenson et al., 1995). In another study patients with elevated filling pressures but no clinical findings of congestive HF were hospitalized, had a pulmonary artery catheter (PAC) placed, and were diuresed to normovolemia. Patients reported significant subjective improvement in symptoms after diuresis (Androne et al., 2004; Chomsky et al., 1997) which correlated with significant improvement in objective measurements in exercise duration, minute ventilation, lactate levels, and Borg dyspnea scores (Chomsky et al., 1997). Secondary end points of the ESCAPE trial, a randomized, controlled trial comparing HF therapy guided by clinical assessment alone versus with a PAC, included changes in functional and HF quality of life measures: 6-min walk test, cardiopulmonary stress test, Minnesota Living with HF questionnaire (validated measurement of QOL), and time trade-off score (quantification of how many months of life out of 24 months patient would trade to feel better). Results showed a trend for more improvement in the group randomized to PAC at 1 month in all of the measures with time trade-off showing the greatest improvement, a significant result that was sustained for 6 months (Binanay et al., 2005). These findings were attributed to greater reduction in filling pressures in the PAC study group. Validating these findings is a post hoc analysis of the ESCAPE trial subjects who received a PAC and had reduction of wedge pressure to <16 mmHg and right atrial pressure to <8 mmHg. Percent reduction in wedge pressure after therapy correlated with improvement in measurements of QOL and functional capacity which included dyspnea during activity, global assessment, worst symptom score, 6-min walk test, and Minnesota Living with HF questionnaire (Rogers et al., 2006).

Volume status may predict mortality in HF patients. Stevenson et al. (1990) showed that the inability to achieve pulmonary capillary wedge pressure of <16 mmHg without causing hemodynamic compromise during treatment of acute decompensated systolic HF is associated with worse prognosis (38% 1-year survival versus 83%, $p = 0.0001$). Another *post hoc* analysis of patients in the ESCAPE trial who received a PAC found elevated filling pressures (wedge and right atrial pressures) after PAC-directed diuresis to be the only hemodynamic parameters significantly associated with adverse outcomes (Cooper et al., 2016). In a prospective, observational study of nonedematous ambulatory HF patients, hypervolemia as measured by blood volume analysis was found in 65% of the study group. Mortality, defined as either death or urgent transplantation, was significantly higher in the hypervolemia group than the normovolemia/hypovolemia group (39% 1-year event rate versus 0%, $p < 0.01$) (Androne et al., 2004).

Another important negative consequence of chronically elevated filling pressures in the HF patient is the downstream development of significant pathology in the liver, pulmonary vasculature, and right ventricle, each of which can increase the mortality of HF patients and also render them ineligible for advanced therapies such as left ventricular assist device implantation and/or cardiac transplantation.

Cardiac hepatopathy can be both acute and chronic. "Acute cardiogenic liver injury" is seen in the context of cardiogenic shock. Patients have elevated alkaline phosphatase and significantly elevated transaminases which correlate histologically with ischemic injury—necrosis surrounding central veins due to hypoxia. Studies of patients with HF and acute cardiogenic liver injury found that elevated right-sided or venous filling pressures highly correlated with ischemic injury but hypotension and low cardiac output did not (Seeto et al., 2000; Henrion et al., 1994). Thirty day and 180 day mortalities for HF patients with acute liver injury are high at 17.6% and 31.6%, respectively (Nikolaou et al., 2013). "Congestive hepatopathy" is an often subclinical process secondary to chronic hepatic congestion, decreased hepatic blood flow, and decreased arterial oxygen saturation (Giallourakis et al., 2002). Histopathology can show various stages from sinusoidal fenestrae enlargement early in the course of the disease to necrosis, fibrosis, and cirrhosis (Samsky et al., 2013). The association of both acute cardiogenic liver injury and congestive hepatopathy with venous congestion suggests that treatment of the venous congestion may be preventative. Indeed there are histological reports of disease regression, hepatic regeneration, and even fibrotic resolution in patients with cardiac hepatopathy after HF has been successfully treated (Rosenberg, 2004).

Secondary pulmonary hypertension is also a consequence of chronic congestion. Left untreated, left-sided heart failure results in elevated filling pressures, chronic pulmonary edema, and subsequent remodeling of the pulmonary vasculature, eventually resulting in fixed pulmonary arterial hypertension (Delgado et al., 2005). Chronically elevated pulmonary arterial pressures result in right ventricular failure. Hence the common saying, "the most common cause of right heart failure is left heart failure." Fixed pulmonary hypertension is a contraindication to heart transplant because the donor right ventricle is unable to meet the sudden increased workload (Mehra et al., 2006; Stadnick and Ignaszewski, 2010). In advanced heart failure, low right ventricular ejection fraction independently predicts functional capacity and mortality (Di Salvo et al., 1995). Severe right ventricular failure is a major cause of morbidity and mortality following implantation of a left ventricular assist device and therefore considered a contraindication (Khazanie and Rogers, 2011). In the absence of significant right ventricular failure, chronic decongestion after implantation of a left ventricular assist device has been reported to result in reversal of pulmonary hypertension such that patients later become eligible for heart transplantation (Mikus et al., 2011; Etz et al., 2007; Zimpfer et al., 2007). This suggests that both secondary pulmonary hypertension and right heart failure are avoidable secondary consequences of chronic congestion and again emphasize the importance of HF monitoring.

Noninvasive Monitoring

Team-Based Care

Both the American Heart Association and European Society of Cardiology guidelines recommend a team-based approach in the care of heart failure patients (Yancy et al., 2013a; McMurray et al., 2012). There have been many small randomized-controlled

studies comparing usual care to team-based care and the majority of the studies demonstrate significant decrease in both heart failure and all-cause readmissions (McAlister et al., 2001; Sochalski et al., 2009). One limitation of these studies is considerable variability among the studies in how team-based care is defined. A meta-analysis and systematic review of these randomized-controlled trials both came to the same conclusion—that the most effective team-based care approach utilizes a multidisciplinary team with enhanced access to in-person visits either at home or in the clinic (McAlister et al., 2001; Sochalski et al., 2009). Multidisciplinary teams reduced mortality by 25%, HF hospitalizations by 26%, and all-cause hospitalizations by 19%(McAlister et al., 2001).

Monitoring the HF patient at the office or at a home visit has significant limitations. In the office the provider determines volume status based on the patient's history and physical examination findings. Accurate assessment is limited by a number of factors shown in various studies, including lack of sensitivity of physical signs for estimating hemodynamics in HF (Stevenson and Perloff, 1989), lack of symptoms in HF patients who are volume overloaded by objective measurements (Androne et al., 2004; Chomsky et al., 1997), and inability by many clinicians to accurately estimate central venous pressures on exam (Davison and Cannon, 1974; Brennan et al., 2007; Sinisalo et al., 2007). Home visits also require resources that are limited, especially so in the current economic climate.

Currently the vast majority of HF patients are being monitored by what is probably the most noninvasive, and affordable monitoring technology—the bathroom scale (Glasgow et al., 2002). Daily weights are either routinely called to the team by the patient or called in when changes in weight meet certain parameters defined by the provider team so that the team can provide timely intervention (Glasgow et al., 2002). This type of monitoring is known as structured telephone support. Weight-based monitoring has been highly criticized. One study shows that only 14% of patients with HF weight themselves daily (Moser et al., 2005). The Fluid Accumulation Status Trial (FAST) showed a sensitivity of only 22.5% for daily weight monitoring in predicting a HF hospitalization (Abraham et al., 2011a) and this finding is supported by two other studies that showed changes in weights do not reliably predict changes in filling pressures (Abraham et al., 2011a; Yu et al., 2005; Bourge et al., 2008). Several metaanalyses of randomized, controlled trials performed by the same research team over the past decade repeatedly demonstrate reduced rates of rehospitalizations for HF patients followed by multidisciplinary teams with structured telephone support (Clark et al., 2007; Inglis et al., 2011; Inglis et al., 2015), suggesting that the scale, when used in certain settings, can be beneficial.

With the advent of technology and the need to remotely monitor large numbers of HF patients, telemonitoring has recently evolved from the structured telephone support to use of electronic equipment provided to the patient (i.e., scale, automated blood pressure cuff, etc.) which collects daily symptoms as well as weight, heart rate, and blood pressure and transmits this data to the care team via digital/broadband/satellite/wireless/blue-tooth. Whereas earlier meta-analyses and randomized-controlled trials concluded that telemonitoring was effective at reducing both HF and all-cause admissions (Dharmarajan et al., 2013; Inglis et al., 2011), two larger randomized, controlled studies later demonstrated a neutral effect (Chaudhry et al., 2010; Mortara et al., 2009) with resultant controversy in the HF community regarding the benefits of telemonitoring. More recently the results of several metaanalyses regarded as highly comprehensive (Inglis et al., 2015; Klersy et al., 2009; Polisena et al., 2010) suggest that telemonitoring is effective, reducing HF related hospitalizations by 7%–48% and all-cause mortality by 17%–47%.

Serum Biomarkers

Numerous serum biomarkers have been validated for the prognostication of HF, and include those involved in myocyte stretch (e.g., natriuretic peptides, ST2, GDF-15), myocyte necrosis (e.g., troponins, CKMB), systemic inflammation (e.g., CRP, TNF-alpha), oxidative stress (e.g., oxidized LDLs), extracellular matrix turnover (e.g., MMPs, galectin-3), and neurohormones (e.g., renin, angiotensin II, aldosterone, norepinephrine). However, data regarding their serial use in HF monitoring to prevent events remains weak. Pertinent criteria for a useful biomarker in the monitoring of HF patients include: (a) be easily measured with high analytical precision (Januzzi et al., 2015); (b) be measurable at a reasonable cost on short notice (Morrow and de Lemos, 2007); (c) have low biological variation (Januzzi et al., 2015); (d) should reflect important pathophysiologic processes involved in HF presence and progression without recapitulating clinical information that is already available (Januzzi et al., 2015); and (e) respond to a therapeutic modification that results in an improvement of clinical outcomes (Bohm et al., 2011). The most promising category of biomarkers for use in serial HF monitoring, which will be discussed in this review, are those upregulated during myocyte stress—BNP, NT-proBNP, MR-proANP, sST2, and GDF-15.

Brain natriuretic peptide (BNP) is a 32-amino acid protein secreted by the cardiac ventricles in response to volume overload and ventricular stretch. Its inactive metabolite, NT-proBNP, has been validated as a surrogate marker that accurately reflects BNP activity (Wu, 2006; Costello-Boerrigter et al., 2006; Goetze et al., 2006). Henceforth, for simplicity, BNP and NT-proBNP will both be referred to simply as BNP in the rest of this review. BNP assays became almost universally available at hospitals and outpatient laboratories after studies showed that normal BNP levels reliably exclude the diagnosis of heart failure (Chomsky et al., 1997; Goetze et al., 2006; Morrison et al., 2002). Elevated BNP levels are associated with worse outcomes and are useful for risk stratification. For every 100 ng/L increase in BNP level, there is a corresponding 35% relative increase in the risk of death (Doust et al., 2005). Treatment with each of the GDMT medications for heart failure (ACE inhibitors, ARBs, MRAs, β-blockers, and decongestion with diuretics) has been shown to result in a decrease in BNP level (Yoshimura et al., 2002; Ferreira et al., 2001; Murdoch et al., 1999; Latini et al., 2002; Tsutamoto et al., 2001). The use of BNP to guide uptitration of GDMT has been studied extensively in randomized trials and the vast majority of the studies report results of patients being on higher doses of GDMT with

significantly reduced mortality (Berger et al., 2010; Troughton et al., 2000; Pfisterer et al., 2009; Jourdain et al., 2007; Januzzi et al., 2011). The results of one study showed no difference in outcomes between patients randomized to BNP-guided therapy versus intensive clinical management where providers were instructed to aggressively uptitrate medical therapy based on current guidelines, suggesting that it was the instructions provided to uptitrate GDMT that resulted in the benefit and that measuring BNP levels is unnecessary (Lainchbury et al., 2009).

The results of the same randomized trials cited previously (Berger et al., 2010; Troughton et al., 2000; Pfisterer et al., 2009; Jourdain et al., 2007; Januzzi et al., 2011; Lainchbury et al., 2009) inconsistently reported specifically on the outcome of decreasing HF hospitalizations because HF hospitalization in the studies usually constituted part of the primary outcome and was not necessarily analyzed separately. Four of the randomized studies did analyze HF hospitalizations as a separate endpoint and found that the BNP-guided groups had significantly fewer HF hospitalizations (Berger et al., 2010; Troughton et al., 2000; Pfisterer et al., 2009; Lainchbury et al., 2009). The findings of these studies are supported by a recent metaanalysis showing that BNP-guided treatment significantly decreased the risk of HF hospitalizations (Xin et al., 2015). At the time of this writing the utility of serial BNP measurements to monitor HF patients with the purpose of reducing hospitalization is thought to be beneficial but not definitely established, rendering it a Class IIb in the 2013 ACC/AHA guideline for the management of HF (Yancy et al., 2013b).

Discordant clinical findings may be explained by the biological characteristics of BNP. Baseline BNP and NT-proBNP levels are known to be higher in the elderly, higher in females, and lower in the morbidly obese and in patients with HFpEF. Two studies show that BNP-guided therapy has been shown to be not beneficial in patients over the age of 75(Pfisterer et al., 2009; Lainchbury et al., 2009). BNP has also been shown to have a high biological variation of 92%, meaning that in the same healthy subjects there was 92% change from baseline in the absence of significant clinical instability (Wu et al., 2013). These highly variable biological characteristics of BNP challenge its reliability as a biomarker for monitoring HF.

Atrial natriuretic peptide (ANP) was the first natriuretic peptide described in heart failure but was not able to be assayed due to analytical instability. ANP also has an inactive metabolite called midregional (MR) proANP, which is much more stable and can be assayed. A large prospective study demonstrated MR-proANP is noninferior to BNP for the diagnosis of HF in patients presenting to the emergency room with dyspnea (Maisel et al., 2010). Checking MR-proANP when BNP levels are nondiagnostic appeared to be useful in obese patients (whose BNP levels might be falsely low) (Maisel et al., 2010). However, MR-proANP levels were not able to predict rehospitalization or visits to the emergency room (Maisel et al., 2010). A small, prospective, cohort study looking at the value of following MR-proANP serially showed that changes in levels of >30% were significantly and proportionally associated with increased risk for poor outcome. The risk for poor outcome was further significantly increased when MR-proANP was combined with cardiac troponin T levels (Miller et al., 2012). More studies are needed to determine the utility of MR-proANP in the monitoring and management of HF.

ST2 is a member of the interleukin (IL)-1 receptor family whose production is stimulated by myocardial strain. There are two forms of ST2—membrane bound (ST2L) and soluble (sST2). sST2 has low biological variability of only 30% making it a desirable biomarker to study. The activating ligand for ST2 is IL-33 which promotes antihypertrophic, antifibrotic, and antiapoptotic activity through ST2L which is believed to result in antiremodeling of the myocardium (Seki et al., 2009; Kakkar and Lee, 2008). *In vitro* sST2 is believed to block the effects of circulating IL-33 thereby promoting hypertrophy, fibrosis, and apoptosis, i.e., cardiac remodeling (Kakkar and Lee, 2008). In accordance with these findings, studies of HF patients show a significant relationship between sST2 concentrations and the presence of left ventricular adverse remodeling, diastolic dysfunction, and poor right ventricular function (Daniels et al., 2010; Shah et al., 2009). Elevated sST2 levels should predict worse outcomes and this was demonstrated in three large clinical studies (Broch et al., 2012; Gaggin et al., 2014; Anand et al., 2014). sST2 levels appear to decrease in response to treatment with β-blockers and valsartan (Gaggin et al., 2014; Anand et al., 2014) and combination treatment with ACE inhibitors, ARBs, MRAs, and β-blockers appear to correlate with lower sST2 levels (Januzzi et al., 2015). Patients with high baseline sST2 levels who were titrated to higher β-blocker doses were at lower risk for cardiovascular events than those with the same sST2 levels on lower β-blocker doses and uptitrating β-blockers in patients with low baseline sST2 levels resulted in much lower reduction in risk (Gaggin et al., 2014), suggesting sST2 levels might be useful in guiding GDMT. However, the results of one study suggest that decreased sST2 levels are not associated with a reduced risk of events, challenging its usefulness as a biomarker for HF monitoring (Anand et al., 2014). A randomized, controlled study is needed to test the hypothesis that sST2 monitoring is helpful in the management of HF.

Growth differentiation factor (GDF)-15 is a member of the transforming growth factor-β superfamily which plays critical roles in cardiovascular development and repair. *In vitro* and *in vivo* studies show that GDF-15 is produced by myocytes in response to mechanical stretch, neurohormonal stimulation, ischemia, and proinflammatory cytokines (Kempf et al., 2006; Frank et al., 2008; Xu et al., 2006). Like many other biomarkers studied in HF, higher GDF-15 levels are associated with worse prognosis and higher mortality (Gaggin et al., 2014; Kempf et al., 2007; Wang et al., 2010; Lok et al., 2013). Research about the role of GDF-15 in HF monitoring is still in the preliminary stages as only two studies have evaluated the role of serial GDF-15 levels. Anand et al. (2010) analyzed serial measurements of GDF-15 in heart failure patients and their results suggested that increases in GDF-15 levels were independently associated with mortality and morbidity. Interestingly, treatment with valsartan did not result in a significant change in GDF-15 levels in this study, challenging its usefulness as a HF biomarker (Anand et al., 2010). Likewise Cotter et al. (2015) reported that changes in GDF-15 levels but not baseline GDF-15 levels, predicted adverse outcomes, suggesting that serial monitoring of GDF-15 could be helpful in HF. However like Anand et al. (2010), they also reported findings suggesting GDF-15 levels may not change in response to therapy. The degree of dyspnea or dyspnea relief was not associated with baseline GDF-15 levels nor with changes in GDF-15 levels (Cotter et al., 2015).

Although validated for use in diagnosis and prognosis, appropriate use of biomarkers in monitoring and treating HF remains undefined. The use of biomarkers is certainly desirable due to its minimally invasive and cost-effective nature. It is unlikely that a single biomarker will be identified that can be used in the diagnosis, prognosis, monitoring, and treatment of all HF patients. More likely studies of patterns of biomarkers either via proteomics or genomics will generate more personalized diagnosis and treatment algorithms.

Minimally Invasive Monitoring

Blood Volume Analysis

Blood volume analysis (BVA) is a minimally invasive means of measuring intravascular volume status. The test is available commercially, and qualifies for both Medicare and third party payer reimbursement. A large bore IV is placed in the patient and albumin radiolabelled with Iodine-131 is injected into the patient by a trained technician. This is followed by a twelve minute waiting period to allow the radiolabeled albumin to redistribute, then five blood samples are drawn, one every six minutes. The patient's height, weight, and gender are used to calculate ideal blood volume. Total blood volume, red cell volume, and plasma volume are determined from the redistribution of the radiolabelled albumin as measured from the five blood samples. The final report provides both the number of milliliters and percent volume difference from ideal plasma volume. The accuracy of BVA has been validated against pulmonary arterial catheter measurements with good correlation (Androne et al., 2004). Hypervolemia in HF patients as determined by BVA is associated with high mortality and morbidity (39% event rate at 1 year) (Androne et al., 2004). The converse has also been demonstrated: normo- or hypo-volemia in HF patients as determined by BVA is associated with excellent survival of 100% up to 1000 days of follow up (Androne et al., 2004). This method has also been studied in HF patients with anemia and can reliably separate the truly anemic patient from a patient appearing to have anemia, but in fact has low hemoglobin due to hemodilution from being hypervolemic (Androne et al., 2004). BVA has not been studied in the context of longitudinal monitoring nor whether intervention based on its results reduces mortality or morbidity. Because BVA is minimally invasive and can be performed on both inpatients and outpatients with results available in 90 min, further studies validating its utility in HF monitoring are warranted.

Intrathoracic Impedance

Although technically considered invasive, monitoring of intrathoracic impedance utilizes the equipment of defibrillator or pacemaker devices which are implanted primarily for benefits unrelated to HF hospitalization and therefore this modality adds no additional "invasive" risk to the patient. Therefore I have included review of these devices under the category of being minimally invasive.

Intrathoracic impedance is measured by the amount of time it takes for the right ventricular lead to send an electrical current to the implanted pulse generator. Pulmonary edema results in decreased intrathoracic impedance, the measurement of which can be included as a part of certain permanent pacemakers (PPM), implantable cardioverter-defibrillators (ICD) and cardiac resynchronization therapy devices (CRT) and the devices can be programmed to report and alarm for abnormal parameters as frequently as daily if desired by the clinician. An inverse correlation between intrathoracic impedance and pulmonary capillary wedge pressure and between intrathoracic impedance and net fluid loss during hospitalization for acute decompensated HF has been established (Yu et al., 2005), suggesting that measuring and monitoring thoracic impedance might be helpful in the management of HF.

Many small prospective, observational studies have been conducted to determine how best to use the information provided by these devices, especially intrathoracic impedance, to predict a HF hospitalization. Results from these studies are highly variable with sensitivities ranging between 20% and 92% for intrathoracic impedance in predicting HF events (Abraham et al., 2011a; Yu et al., 2005; Vollmann et al., 2007; Heist et al., 2014; Forleo et al., 2013; Maines et al., 2011; Conraads et al., 2011; Soga et al., 2011). Two prospective, observational studies investigated alternative impedance vectors and algorithms. DEFEAT-PE (Detect Fluid Early from Intrathoracic Impedance Monitoring) showed low sensitivities for all the different impedance algorithms ranging 20%–30% for HF events (Heist et al., 2014). The other study by Forleo et al. looking at only biventricular defibrillators with multivector impedance monitoring capabilities reported a sensitivity of 61.5% which was similar to the sensitivities reported by many other studies which used the standard right ventricular lead to pulse generator vector (Forleo et al., 2013). In one prospective, observational trial with an unmatched cohort control group, rate of HF hospitalizations or emergency room admissions was 56% lower in the group whose intrathoracic impedance was being measured and followed, again suggesting that monitoring thoracic impedance should be beneficial (Molon et al., 2014).

In contrast, the randomized, controlled trials of intrathoracic impedance have not shown improved outcomes with respect to mortality and rehospitalization. In the LIMIT-CHF (Lung Impedance Monitoring in Treatment of Chronic Heart Failure) study, eighty patients were randomized to either intrathoracic impedance alarm turned on with instructions to increase diuretics for 1 week following an alarm or control (usual care with alarm turned off) (Domenichini et al., 2016). There was no significant difference in HF hospitalization between the two groups. The study found only nonsignificant reductions in time until event diagnosis and time from event to clinical decision. The MORE-CARE (Monitoring Resynchronization Devices and Cardiac Patients) study randomized 8965 patients receiving CRT-D devices to remote device checks which included thoracic impedance versus standard care. Again there was no difference between the two groups in the primary endpoint which included death,

cardiovascular, and device-related hospitalizations (Boriani et al., 2016). The CONNECT (Clinical Evaluation of Remote Notification to Reduce Time to Clinical Decision) study randomized almost 2000 patients after device implantation to either standard care or remote monitoring for 15 months (Cleland et al., 2010). Lead impedance was only one of many data points transmitted. There was no difference in rate of hospitalizations, but did show decrease in median time from event to clinical decision, fewer clinic visits per patient per year, and reduction in the average duration of hospitalizations in the remote monitoring group, all of which were statistically significant.

Much interest remains in determining how best to use these devices in HF monitoring. The PARTNERS-HF (Program to Access and Review Trending Information and Evaluate Correlation to Symptoms in Patients with Heart Failure) study is another prospective, observational study which combined intrathoracic impedance with other measurements—atrial fibrillation duration, rapid ventricular rate during atrial fibrillation, high fluid index, low patient activity, heart rate variability, low CRT pacing, or implantable cardioverter-defibrillator shocks. Having two or more abnormal measurements had a 5.5-fold increased risk of HF hospitalization with pulmonary signs or symptoms within the next month (hazard ratio: 5.5, 95% confidence interval: 3.4–8.8, $p < 0.0001$) (Whellan et al., 2010). PARTNERS-HF is provocative in that it suggests that all device-related parameters, rather than just intrathoracic impedance, should be studied in a randomized, controlled trial. However, CONNECT was a large randomized, controlled trial looking at many of the same measurements and did not demonstrate a benefit in the intervention group with respect to decreasing HF hospitalization.

Several study design and clinical factors were mentioned or alluded to in the aforementioned studies on intrathoracic impedance that may have confounded the results: (1) studying change in intrathoracic impedance from baseline as opposed to an absolute impedance threshold for all patients; (2) studying the same device and leads; (3) obtaining measurements at the same specified time interval after device implantation for all patients; (4) understanding and selecting a specified time interval after device implantation when impedance and lead are considered stabilized; and (5) establishing a standard "euvolemic" impedance at the start of the study when the patient has been objectively determined to be euvolemic.

In patients who qualify for implantation of these devices based on ACC/AHA guidelines, inclusion of this capability does not add risk to the procedure and so expert consensus endorses use of device monitoring in these patients (Wilkoff et al., 2008).

Invasive Monitoring

The latest monitoring technology involves implantation of devices solely for the purpose of hemodynamic monitoring some of which are accompanied by medication management protocols determined by the provider team. In recent years three devices have been developed and tested. Only one of the three devices received FDA approval. All three devices are reviewed in the following, because the trials, tribulations, and processes of each trial illustrate the challenges of studying the applicability of devices in complex diseases such as HF.

Right Ventricular Pressure Monitor

In the normal heart the right ventricular end-diastolic pressure is equal to the pulmonary artery end-diastolic pressure, which is also equal to the pulmonary capillary wedge pressure and the left atrial pressure. Utilizing this concept, an implantable right ventricular pressure monitoring lead called the Chronicle device was developed to continuously measure right ventricular pressures, heart rate, and body temperature. Similar to a pacemaker the device has a generator and a modified unipolar pacemaker lead. The initial pilot study of this device was observational and demonstrated that RVSP increased 4 ± 2 days prior to HF hospitalizations. During the second phase of the pilot study, data was made available to clinical providers for clinical decision making. Hospitalizations during this phase were decreased by 57% ($p < 0.01$) (Adamson et al., 2003). COMPASS-HF (Chronicle Offers Management to Patients with Advanced Signs and Symptoms of Heart Failure), a prospective, randomized clinical trial, compared using hemodynamic data from the Chronicle device to usual care in 274 patients (Bourge et al., 2008). The study showed a nonsignificant 21% reduction in the Chronicle group compared to the usual care control group in the primary efficacy endpoint of reduction in HF events, which included hospitalizations, emergency room, or urgent care visits requiring intravenous diuretic therapy. Weaknesses of the trial included being underpowered for the primary endpoint, having an event rate that was lower than anticipated in the control group, and failure by clinicians to adequately lower filling pressures or titrate medications. Usefulness of the Chronicle device in reducing filling pressures in order to prevent HF events was considered inadequately tested and its utility at this time remains uncertain.

Left Atrial Pressure Monitor

HeartPOD is a device developed to directly measure left atrial pressure. The device consists of a subcutaneously implanted case containing a coil antenna and a sensor lead that is placed in the left atrium through a transseptal puncture. Unique to this device is a handheld "patient advisor module" which when held over the implanted antenna, powers the sensor, receives and transmits left atrial pressure, body temperature, and intracardiac electrocardiogram to the care team. The patient advisor module displays the left atrial pressure to the patient with reminders about physician-directed, individualized medication strategies based on the

readings which encouraged independent patient self-management. HeartPOD was evaluated in the HOMEOSTASIS (hemodynamically Guided Home Self-Therapy in Severe Heart Failure Patients) study in which all 40 patients who had either NYHA class III or IV HF received the device (Ritzema et al., 2010). For the first 3 months both providers and patients were blinded to the hemodynamic and continued with usual care. After 3 months hemodynamic data became available to both the providers and the patients and individualized therapy instructions guided by these pressures were provided to the patients. Results showed significantly improved hemodynamics, survival, and event-free survival. The positive findings warranted further evaluation in a randomized, controlled trial called LAPTOP-HF (Left Atrial Pressure Monitoring to Optimize HF Therapy). Unfortunately LAPTOP-HF was terminated early by the Data and Safety Monitoring Board in June 2014 due to a high number of implant-related complications related to transseptal catheterization. In failure there is always opportunity, and LAPTOP-HF was the first randomized, controlled HF device trial to provide defined treatment guidelines which likely contributed to the success of the pilot trial. More importantly the study highlighted the importance of balancing the risk of invasive devices with the benefits of the information.

Pulmonary Arterial Pressure Monitor

Recently a wireless pulmonary arterial pressure monitoring system called CardioMEMS has been developed and tested. The CardioMEMS device is a small 15×2 mm capacitor that is coil and pressure sensitive without leads and batteries (**Fig. 1**). It is placed in the pulmonary artery by right heart catheterization. The device is powered by electromagnetic coupling from external antennae placed on the back of the patient during readings. When powered, pressure data is collected and transferred wirelessly to a secure website managed by the care team. The CardioMEMS device was validated against the PAC and echocardiogram in a pilot study of 12 HF patients and found to be accurate (Verdejo et al., 2007). Its usefulness was studied in the CardioMEMS Heart Sensor Allows Monitoring of Pressure to Improve Outcomes in NYHA class III Heart Failure Patients (CHAMPION) trial (Abraham et al., 2011b). Five-hundred and fifty patients with NYHA class III HF received the CardioMEMS device. Half were managed using data from the device and the other half randomized to routine usual care. Results of the study showed significantly fewer HF hospitalizations in the CardioMEMS group when compared to the routine care control group (28% risk reduction, $p = 0.0002$). A post hoc analysis of CHAMPION study subjects with HFpEF (LVEF $\geq$ 40%) showed a 46% lower rate of HF hospitalization in the CardioMEMS group when compared with the control group (Adamson et al., 2014). There was a very low complication rate in the CHAMPION trial which was comparable to the reported complication rate of a right heart catheterization. The main differences (and strengths) of this study when compared with prior studies of implanted hemodynamic monitors were the mandated pressure targets and treatment protocols, which were lacking in COMPASS-HF but may have been the main contributing factor to the success of HOMEOSTASIS. A major weakness of the trial design is its inability to separate the contribution of the device data from the contribution of the strict hemodynamic targets and management protocol.

Conclusions

Goals of HF monitoring are to reduce hospitalizations, improve QOL, decrease mortality, and prevent secondary end-organ damage. Management of HF is challenging due to geographical barriers, socioeconomic factors, and available resources. Current research evidence identifies the following four interventions as the most effective at reducing HF hospitalization—the multidisciplinary care team, structured telephone support, telemonitoring, and the CardioMEMS device. The metaanalyses and research trials of these four interventions included HFpEF patients and therefore it is reasonable to assume that the results are applicable to all HF patients. The vast majority of the studies published on BVA, biomarkers, and intrathoracic impedance were studies of HFrEF patients. More investigation is needed to establish their roles (if any) in HF monitoring, especially in the HFpEF population.

Introduction

Heart failure with preserved ejection fraction (HFpEF) is a heterogeneous phenotype that is the product of multiple physiologic and anatomic factors that result in symptoms of heart failure in the setting of normal or near normal systolic function. Exercise intolerance is a nearly universal hallmark feature. It is estimated that nearly 50% of heart failure patients have preserved ejection fractions and that survival is similar to heart failure with reduced ejection fraction (HFrEF) with a fifty percent survival rate at 5 years (Borlaug and Paulus, 2012). Although somewhat lower, the mortality of patients with HFpEF at 3 years approaches that of patients with HFrEF (23.4% vs. 26.3% respectively) (MAGGIC, 2012). In the MAGGIC analysis, patients with HFpEF as compared to those with HFrEF were older (mean age 71 years vs. 66 years), were more often female (50% vs. 28%), more often had a history of hypertension (51% vs. 41%) and atrial fibrillation (27% vs. 18%). They less often had ischemic disease (43% vs. 59%) (MAGGIC, 2012). Risk factors include hypertension with I-PRESERVE and TOPCAT trials reporting a prevalence of 88% and 91%, respectively (Shah et al., 2013; McMurray et al., 2008). Female gender and age greater than 65 years constitute further risk factors (Lekavich et al., 2015). Diabetes and obesity, components of the metabolic syndrome, also seem to be emerging as potential risk factors (Le Winter and Meyer, 2013). In general, HFpEF patients more often die of noncardiovascular and nonheart failure causes than HFrEF (Campbell and McMurray, 2014). Again from MAGGIC, patients with HFpEF had lower risk of cardiovascular death than those with HFrEF with an adjusted HR 0.55 (MAGGIC, 2012). With prevalence estimates projecting an increase of 1% per year (Borlaug and Paulus, 2012), the proportion of patients with heart failure who have preserved ejection fractions will continue to increase.

Pathophysiology

This is a multifactorial process with many proposed pathways and areas of emerging interest and research. The various pathophysiologic pathways that are postulated to promote HFpEF will be discussed.

One area of thought is that there is abnormal systemic vasorelaxation and increased ventricular stiffening which leads to increased filling pressures despite a preserved EF.

Often these patients show concentric LV remodeling, reduced LV passive compliance, and slowed or incomplete relaxation (Borlaug and Paulus, 2012). This contributing factor is highlighted by the fact that diastolic dysfunction is a criteria for diagnosis according to the European diagnostic guidelines. Another potential area of pathology is inflammation. Risk factors such as diabetes and obesity lead to a proinflammatory state which can influence the myocardium to become fibrotic (Le Winter and Meyer, 2013). A recent study that evaluated biomarker levels of HFpEF and HFrEF patients revealed that HFpEF patients have serum markers that are more consistent with inflammation and fibrosis compared to that of HFrEF patients that had upregulation of myocardial stress and injury pathways (Sanders-van Wijk et al., 2015).

At a cellular level, there is hypophosphorylation of protein kinase A and G on cardiac titin which help to modulate stiffness and relaxation, as well as titin isoform modulations leading to isoforms with higher passive stiffness. Additionally, there has been shown to be abnormal calcium handling in the sarcoplasmic reticulum. This is particularly evident during low levels of myocyte stimulation at rates of 100–110 per minute, which would equate to heart rates of 100–110 per minute (Le Winter and Meyer, 2013). This observation may help explain some of the profound exercise intolerance that is observed in this patient population. This is likely secondary to the reduced myocardial relaxation rates resulting in decreased LV stroke volume especially at higher heart rates. This is the opposite of normal myocardium which increases relaxation at higher stimulation rates to allow for active ventricular relaxation and low pressure filling (Borlaug et al., 2006).

Regarding the extracellular matrix, there is an excess of collagen Type 1 which is due to down regulation of matrix metalloproteinases (MMP) which are responsible for collagen degradation. This is in contrast to dilated cardiomyopathy patients who have been found to have an upregulation of MMP leading to increased collagen matrix degradation (Borlaug et al., 2006) and decreased

ventricular thickness. For these reasons, there is an inherent increase in ventricular and vascular stiffening in HFpEF patients. Interestingly, in the HFpEF myocardium, the Starling curve is shifted up and right because of the decrease in LV filling volume and increase in LV pressure. This leads to very large blood pressure fluctuations based on changes in preload and afterload (Borlaug et al., 2006). The high blood pressure that results during exercise further impairs LV filling leading to decreased cardiac output and exercise intolerance. There is also evidence that myocardial energy reserve may be a factor. Myocardial phosphorus MR spectroscopy shows lower creatine phosphate/adenosine triphosphate ratio compared to controls indicating a lower energy reserve (Borlaug et al., 2006). As LV relaxation is an active process, an energy starved tissue may not be able to effectively relax during times of higher demand.

Presenting Symptoms and Exercise Dysfunction

Exercise time, peak workload, peak VO_2, ventilatory threshold VO_2, and percent predicted peak VO_2 were impaired in HFpEF compared to controls. Effort and dyspnea scores were higher in HFpEF at matched submaximal workloads indicating greater perceived difficulty with exercise. Borlaug et al. found limitations in chronotropic, contractile, endothelial, and vascular reserve resulting in impaired ventricular–arterial coupling during exercise. Interestingly, despite a "preserved EF," contractile reserve is impaired in HFpEF patients compared to matched controls. Because of the abnormal vasorelaxation and blunted contractile reserve, ventricular–arterial coupling is impaired with exercise (Borlaug et al., 2010). Also worth noting is the reduction in cardiac index (1.25 in HFpEF vs. 2.02 in healthy controls) due to impaired chronotropy even when controlling for beta blocker therapy. Inappropriate heart rate recovery following exercise and inappropriate heart rate decrease in response to baroreflex stimulation was also demonstrated in this study, which implies impaired autonomic tone (Borlaug et al., 2010). Interestingly, compared to matched controls, there was no difference in pulmonary blood volumes with exercise, thus calling into question the theory that impaired diastology and resultant necessary high filling pressures leads to increased pulmonary volume which leads to dyspnea. Surprisingly, change in end diastolic volume with exercise was similar to age matched controls. In a study which evaluated response to nitroprusside, an exaggerated blood pressure drop was noted in HFpEF patients. Conversely, HFrEF patients experienced a significant increase in stroke volume and cardiac output suggesting that a decrease in afterload is most beneficial to HFrEF patients and that HFpEF patients rely more on ventricular filling for stroke volume, as decreased preload also had an effect here (Schwartzenberg et al., 2012). In HFpEF patients, increased contractility results in a higher end systolic elastance (Ees) compared to controls resulting an exaggerated blood pressure response to exercise as mentioned earlier with the Starling curve shift. Additionally, it has been shown that HFpEF Ea/Ees ratios are generally nearly 0.5 indicating near maximal efficiency along the pressure volume loop (Ea = effective arterial elastance) (Schwartzenberg et al., 2012). This fact is demonstrated by the observation that even slight variations in either preload or afterload will lead to exaggerated variations in systemic arterial pressures. Arterial pressure variations, increased myocardial energy demands and impaired myocardial energy reserve likely all contribute to impaired exercise capacity in patients with HFpEF (Kawaguchi et al., 2003).

Diagnosis

Universally accepted diagnostic criteria for HFpEF remain undefined. However, there are currently four proposed diagnostic frameworks that are used for clinical identification of HFpEF. Initially, in 1998 the European Work Group proposed a framework, including signs or symptoms of heart failure, normal to mildly reduced systolic function, and evidence of diastolic dysfunction which included both echocardiogram and invasive cardiac catheterization measurements (European Study Group on Diastolic Heart Failure, 1998). Vasan and Levy (2000) described a tiered diagnostic approach using possible, probable, and definite categories based on signs or symptoms of heart failure, presence of normal >50% EF within 72 h of heart failure episode, and cardiac catheterization for definite diagnosis of LV diastolic dysfunction (Vasan and Levy, 2000). After much debate about the utility of measuring diastolic dysfunction, a third set of diagnostic criteria appeared making clinical evidence of heart failure and normal LVEF and chamber size essential, and LV hypertrophy, LA enlargement, and echocardiogram, or cardiac catheterization evidence of diastolic dysfunction optional/confirmatory (Yturralde and Gaasch, 2005). The European Society of Cardiology has perhaps the most comprehensive set of diagnostic guidelines, and states that in addition to clinical symptoms of heart failure one must have LVEF $\geq$50%, evidence of diastolic dysfunction as defined by: elevated left ventricular end diastolic pressure (LVEDP) >16 mmHg, pulmonary capillary wedge pressure >12 mmHg, $E/e' > 15$, mitral flow velocity Doppler signal showing E/A ratio <0.5 + deceleration time (DT) >280 ms, LA size >40 mL/m^2 or LV mass >149 g/m^2 for men or >122 g/m^2 for women (Paulus et al., 2007). Of note, the presence of LV mass criteria which places focus on the role of hypertension in pathophysiology. ACCF/ACC defines HFpEF with 3 criteria: clinical signs or symptoms of HF, evidence of preserved or normal LVEF $\geq$50%, and evidence of abnormal LV diastolic dysfunction that can be determined by Doppler echocardiography or cardiac catheterization (Yancy et al., 2013). While there is a proposed definition, there are no sanctioned diagnostic criteria from the ACC. This highlights the difficulty in clinically diagnosing these patients as evidence by the multiple competing diagnoses that must be excluded before arriving at an HFpEF diagnosis (Fig. 1).

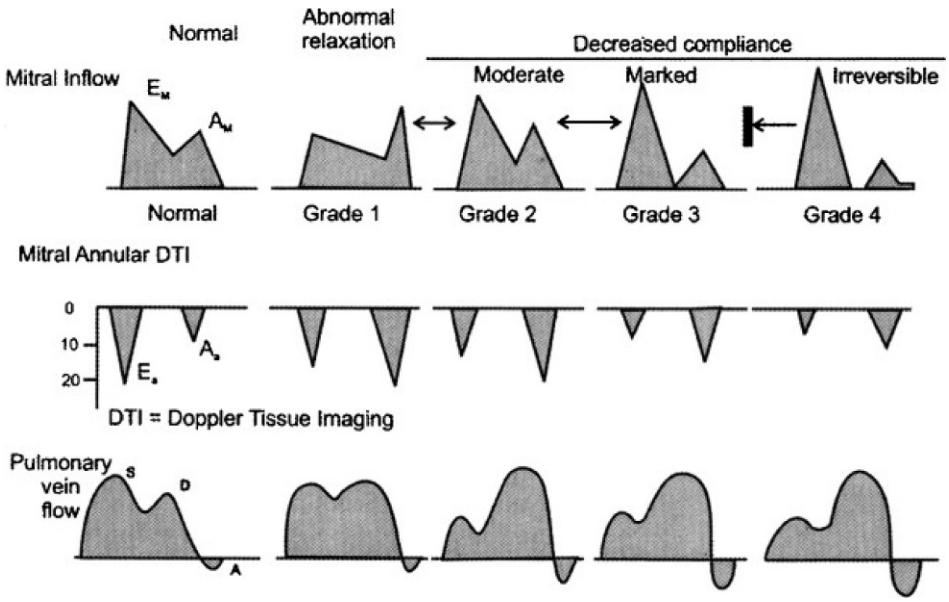

Fig. 1 Schematic representation of mitral inflow, mitral annular Doppler tissue imaging, and pulmonary vein flow in various stages of diastolic dysfunction. Diastolic heart failure and left ventricular diastolic dysfunction: What we know, and what we don't know! *International Journal of Cardiology* **115**(3), 284–292.

Management

The lack of universally accepted diagnostic criteria has confounded the design of clinical trials. The heterogonous nature of patients with HFpEF implies different pathophysiologic mechanisms, risk factors, and natural disease history among this broad group of patients. Often, EF cutoffs of 40%–55% are used although the American Society of Echocardiography (ASE) defines a normal EF as 55% or greater (Lang et al., 2015). This makes universal management guidelines based on randomized trials impossible. This is demonstrated in a recent analysis of the TOPCAT trial patients where evaluation based on EF subgroups in increments of 5% was undertaken. Within each subset, there were differences amongst sex, with males having a lower EF than females even among this "preserved ejection fraction" group. Additionally, the presence of coronary artery disease was lower in patients with higher EF which suggests that patients in EF groups <50% may more frequently have ischemic heart disease. With specific regard to TOPCAT, ultimately with subgroup analysis, patients with an EF ≥ 60% derived minimal benefit from spironolactone therapy and patients toward the lower end of the EF scale (cutoff 45%) derived some benefit from spironolactone (Solomon et al., 2016). This suggests that there are likely different pathophysiologic mechanisms at play with even just minor changes in ejection fraction. Again pointing out perhaps why large-scale trials have been ineffective in identifying potential therapeutic targets.

There are three notable large-scale trials directed toward HFpEF management:

CHARM-Preserved–In the CHARM-preserved trial, the primary outcome of cardiovascular (CV) mortality or admission for worsening congestive heart failure (CHF) was analyzed. Patients were NYHA Class II–IV, had had CV admission for any reason, and LVEF >40%. They were randomized to placebo or candesartan (uptitrated dose to 32 mg/day). There was a boarderline significant trend ($P=0.051$) toward favorable outcomes in candesartan groups for both CV mortality and CHF hospitalizations after adjustment for covariates. There was a significant reduction in CHF hospitalizations in the candesartan group. Note however the LVEF cutoff for this study is 40% which many would argue is too low to meet the accepted definition of HfpEF (Yusuf et al., 2003).

NEAT-HFpEF—evaluated patients with an EF of ≥ 50% and objective heart failure evidence, previous hospitalization for heart failure with radiographic evidence of pulmonary congestion, elevated left ventricular end diastolic pressure at rest (≥ 15 mmHg) or elevated pulmonary capillary wedge pressure at rest (≥ 20 mmHg) or with exercise (≥ 25 mmHg), an elevated level of N-terminal pro-brain natriuretic peptide (NT-proBNP) (>400 pg per milliliter) or brain natriuretic peptide (BNP) (>200 pg per milliliter) or Doppler echocardiographic evidence of diastolic dysfunction. The target dose was 120 mg isosorbide mononitrate. Interestingly, patients were less active on nitrates than placebo (all doses), had lower 6 min walk scores, and had lower quality of life scores along with unfavorable trends in proBNP levels (Redfield et al., 2015). As we have just discussed the mechanism by which slight alterations in preload affect have drastic effects on both stroke volume and blood pressure, this result is not surprising.

TOPCAT was a multicenter trial evaluating the use of spironolactone in patients ≥ 50 years of age with LVEF ≥ 45% and a heart failure hospitalization within 12 months defined according to predefined signs and symptoms. Interestingly, there was no requirement for evidence for diastolic dysfunction in these patients. There was no difference found in primary outcomes of death from CV causes, aborted cardiac arrest, or hospitalization from heart failure. However, the rate of hospitalization for any cause,

including repeat hospitalizations, was reduced in spironolactone patients (394 vs. 475, 6.8 vs. 8.3 per 100 person-years) (Pitt et al., 2014).

Recently, the ACC/AHA/HFSA updated their recommendations regarding HFpEF. It remains a Class I indication to manage hypertension to a systolic target of <130 along with use of diuretics for symptom relief. There is a new Class IIb recommendation to use aldosterone antagonists in patients with an EF ≥ 45% if they meet certain criteria (elevated BNP or HF admission within 1 year, estimated glomerular filtration rate >30 and creatinine <2.5 mg/dL, potassium <5.0 mEq/L) to reduce hospitalizations. There is now a Class III recommendation for routine use of nitrates or phosphodiesterase-5 inhibitors in this patient population (Yancy et al., 2017). To date, there are no randomized controlled trials to show that there are any agents which reduce mortality in HFpEF; thus most therapies are directed at symptoms and risk factor modifications. With regard to atrial fibrillation, a common comorbidity, it is suggested that in HFpEF patients, nondihydropyridine calcium channel blockers may be used with better effect for rate control than beta blockers (Yancy et al., 2013).

Besides the fact that limited to absent diagnostic criteria exists, there are no reliable prognostic or diagnostic biomarkers as such as BNP or NT-proBNP are for HFrEF patients. A recent evaluation did find that significant prognostic markers in HFpEF patients among this particular cohort were: high sensitivity troponin, soluble interleukin-like receptor 1, blood urea nitrogen, soluble fms-like tyrosine kinase, and N-terminal pro-brain natriuretic peptide in regard to both overall and hospital free 18-month survival. These biomarkers were also found to be expressed in HFrEF without any difference in prognostic significance between the two presentations with the exception for Cystatin-C which was less of prognostic value compared to HFrEF. Interestingly, NT proBNP was only significantly useful if practitioners guided their therapy based on symptoms, not NT proBNP levels. A different set of prognostic factors was significantly expressed more in HFrEF patients implying that there are likely several overlapping pathways in both forms of heart failure though some pathways are expressed more than others among the two classifications. In the future these biomarkers may have important therapeutic implications as well as risk stratification possibilities (Sanders-van Wijk et al., 2015).

Conclusion

HFpEF is a growing phenotype of heart failure patients and we are learning more about its pathophysiology. Diagnostic criteria that are reliable and validated are still lacking making therapeutic targets difficult to attain. Until that time, management of risk factors remains the best hope for treating these patients.

Introduction

Cardiovascular disease remains the leading cause of death worldwide despite current advancements in therapy (Mozaffarian et al., 2016). The morbidity and mortality of ischemic heart disease, the most common type of heart disease, have been greatly reduced by advances in pharmacological and surgical interventions aimed at salvaging viable myocardium. However, these approaches do not prevent the deleterious ventricular remodeling that occurs after myocardial infarction (MI), which can eventually lead to heart failure (HF). The only available option to cure end-stage HF is heart transplantation, which is hampered by low donor availability and issues with long-term immunosuppression. Given the limited options to treat HF, there is a great need for novel therapeutics to slow or even prevent cardiac remodeling and HF.

The paucity of therapies for cardiac disease is in part due to the fact that the heart was considered a terminally differentiated organ without regenerative potential. The landmark discovery of multipotent cardiac stem cells (CSCs), expressing c-kit (CD117), that can give rise to myocytes, smooth muscle, and endothelial cells within the heart, reframed this vital organ as one with self-regenerative capacity (Beltrami et al., 2003). This observation spurred enthusiasm for therapeutic approaches to enhance the innate regenerative capacity of the damaged heart. Stem cells, which are defined by their ability to proliferate and self-renew as well as differentiate into lineages of specialized cell types, have emerged as an exciting new therapy for regenerating the billions of cells that are lost or damaged in cardiac disease.

The first study to evaluate the regenerative capacity of transplanted stem cells in damaged myocardium was performed in 1992 (Marelli et al., 1992). Satellite cells (skeletal muscle stem cells) were implanted into canine hearts following cryoinjury of the myocardium in hopes that these cells would directly differentiate into new cardiomyocytes. Unfortunately, these cells did not produce any clear indication of regeneration. Over the past 20 years, preclinical, translational, and clinical studies have provided strong evidence that stem cells can prevent cardiac remodeling and stimulate repair and replacement of damaged myocardium. Because not all cell types have produced positive results, the search for the most beneficial cell-based therapy continues. The ideal stem cell for the treatment of cardiac disease is one that is readily available, can home (localize) to and survive in damaged myocardium, and can either directly or indirectly repair damaged myocardium. Numerous candidate stem cell types have been examined for their potential benefit, however, given the vast differences between animal models of cardiac disease and actual patients, the ultimate test of stem cell efficacy must be carried out in clinical trials. In this chapter, we will discuss several types of cells utilized in clinical trials and provide future perspectives for stem cell therapy in cardiac disease (**Table 1**).

Table 1 Cell types utilized for cardiac regeneration therapy

Cell type	*Source*	*Common markers*	*Advantages*	*Disadvantages*	*Clinical trials*
Skeletal myoblasts	Muscle biopsy	CD56+	Autologous resistance to ischemia	Do not differentiate into cardiomyocytes ventricular arrhythmias	Phase II
Bone marrow mononuclear cells	Bone marrow	CD117+, CD34+	Extensive clinical background paracrine effects safety profile	Minimal direct myocardial regeneration low engraftment	Phase III
Mesenchymal stem cells	Bone marrow adipose tissue Wharton's jelly and cord blood	CD105+, CD117+, CD45−	Autologous and allogeneic paracrine effects antiinflammatory effects safety profile	Weak cardiomyocyte differentiation low engraftment	Phase III
Endothelial progenitor cells	Bone marrow blood	CD34+, CD133+	Vasculogenesis	Weak cardiomyocyte differentiation low engraftment	Phase III
Cardiac stem cells	Cardiac biopsy	c-kit+, CD45−,	Differentiate into all cardiac lineages	Questionable cardiomyocyte commitment	Phase II
Embryonic stem cells	Embryo	Oct4+, Nanong+, SSEA4+	Pluripotent	Immunosuppression ethical and legal issues teratoma formation	Phase I
Induced pluripotent stem cells	Somatic cells	Oct4+, Nanong +, SSEA4 +	Pluripotent autologous readily obtained	Teratoma formation low maturity	Preclinical stage

Therapeutic Stem Cells

Mechanism of Action

The search for the ideal cell-based therapy has focused on harnessing two major mechanisms for cardiac repair: direct stem cell differentiation into new cardiomyocytes and stem cell stimulation of endogenous cardiac repair mechanisms. Multipotent stem cells such as mesenchymal stem cells (MSCs) can engraft and differentiate into new cardiomyocytes (Quevedo et al., 2009), although there are conflicting results as to degree to which these cells actually differentiate and the maturity of the new cardiomyocytes, and this mechanism may play only a limited role in the therapeutic capacity of these cells in vivo (Silva et al., 2005). MSCs also secrete numerous factors that act in a paracrine manner to promote survival and proliferation of resident cardiomyocytes, stimulate endogenous CSCs, induce angiogenesis, and moderate the damage caused by inflammatory cells and fibroblasts (Golpanian et al., 2016). Finally, MSCs have also been shown to recruit endogenous c-kit + CSCs via cell–cell interactions and enhance their differentiation into cardiomyocytes (Hatzistergos et al., 2010). Indeed, the mechanism by which stem cells prevent and even reverse cardiac remodeling is complex and multifaceted, involving both direct differentiation and modulation of endogenous repair mechanisms including stimulation of endogenous stem cell populations (**Fig. 1**).

Cell Types

Endogenous stem cells are found in virtually every tissue, and initial research in stem cell therapy for cardiac disease focused on multipotent stem cells derived from adult tissues. Given the vast medical experience in harvesting and expanding cells from bone marrow, many studies have examined bone marrow-derived stem cells. Bone marrow contains a heterogeneous population of progenitor cells that includes MSCs, endothelial progenitor cells (EPCs), and hematopoietic stem cells. Clinical trials have examined both fractionated bone marrow, where each stem cell type is isolated and tested individually, or unfractionated bone marrow, where all bone marrow-derived mononuclear cells (BMMNCs) are administered together (Bianco et al., 2001; Lambers and Kume, 2016). The abundant source of diverse stem cells and their ease of isolation have made bone marrow an attractive cell source, and bone marrow-derived stem cells have been utilized for more cardiac regenerative research than any other stem cells to date (Nguyen et al., 2016). Stem cells derived from other adult tissues including peripheral blood and adipose (fat) tissue have also been applied to clinical trials for cardiac disease (Houtgraaf et al., 2012).

Other cells such as induced pluripotent stem cells (iPSCs) and embryonic stem cells (ESCs) are attractive as therapeutics because of their greater capacity to differentiate into new cell types, including cardiomyocytes. Compared to multipotent bone marrow-derived stem cells identified above, ESCs and iPSCs are pluripotent (i.e., they can develop into any type of cell of the body except for extra-embryonic tissue). Pluripotent cells possess a vast potential for differentiation and proliferation. However, the therapeutic application of these cells is hampered by the risk of tumor formation, such as teratomas and teratocarcinomas, and the observation in preclinical studies that these cells fail to fully mature in vivo (Sun and Nunes, 2017; Hamel et al., 2017). Ethical concerns are also associated with the use of human ESCs since these cells are isolated from preimplantation embryos. Together, these issues have limited the therapeutic use of ESCs.

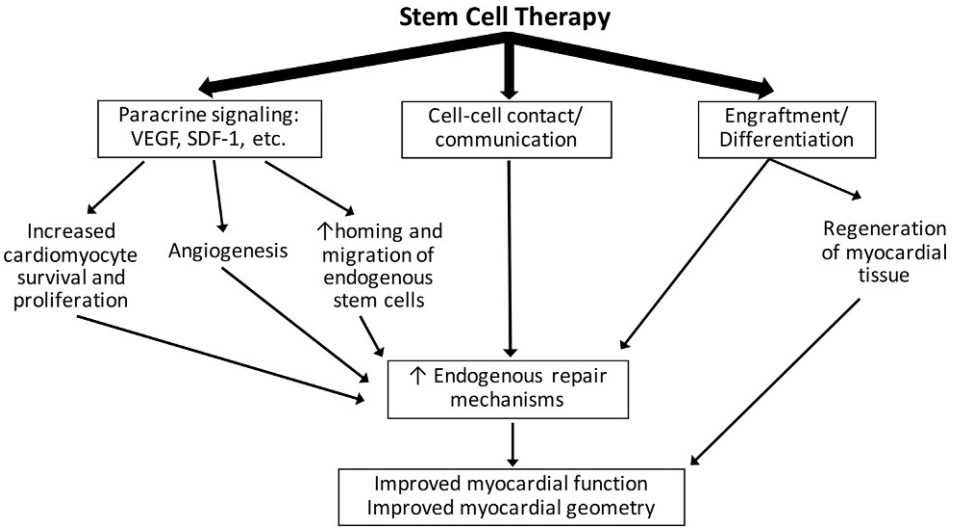

Fig. 1 Mechanisms of action of stem cell therapy for cardiac disease. Stem cells lead to improved cardiac structure and function by reversing myocardial remodeling. This occurs through a multifaceted process involving both direct repair via engraftment differentiation of the transplanted stem cells and indirect stimulation of endogenous repair mechanisms through paracrine signaling and cell–cell interactions. MSCs, in particular, can stimulate neoangiogenesis, migration of endogenous cells, and cardiomyocyte survival via paracrine signaling. They secrete secreting cytokines and growth factors including vascular endothelial growth factor (VEGF), and stromal cell-derived factor-1 (SDF-1) among others. Adapted from Karantalis, V., Balkan, W., Schulman, I. H., Hatzistergos, K. E. and Hare, J. M. (2012). Cell-based therapy for prevention and reversal of myocardial remodeling. *American Journal of Physiology. Heart and Circulatory Physiology* **303**, H256–H270, with permission from the publisher.

Another type of pluripotent cell was introduced in 2006 when Dr. Shinya Yamanaka demonstrated that adding genes that encode four specific transcription factors converts terminally differentiated adult cells into iPSCs (Takahashi and Yamanaka, 2006). This technique holds great promise for the field because iPSCs can be propagated indefinitely and can be induced to differentiate into a wide variety of cell types, including cardiomyocytes. For this momentous discovery, Dr. Yamanaka and Sir John Gurdon were awarded the 2012 Nobel Prize. iPSCs appear to offer many of the same advantages of ESCs without the ethical issues. However, similar to ESCs, iPSCs have the potential for tumor formation and immune incompatibility between donors and recipients (Medvedev et al., 2010). Despite these issues, iPSCs remain promising and exciting therapeutic candidates for regenerating the damaged heart and are being studied extensively in preparation for future clinical use.

Autologous Versus Allogeneic Stem Cells

One area of controversy in stem cell therapy is the source of the cells, either autologous or allogeneic. Some studies have used stem cells isolated from the patient's own tissue (autologous cells), while others advocate the use of stem cells from healthy donors (allogeneic cells). Despite the potential risk of cell rejection by the recipient, allogeneic cells offer the possibility of an effective, off-the-shelf therapeutic. Autologous cells must be harvested from the donor and expanded in culture, and the number and quality of the cells obtained are often dependent on the health status of the donor. In contrast, allogeneic cells, particularly if obtained from young, healthy donors, produce better outcomes than autologous cells (Cogle et al., 2014; Poglajen and Vrtovec, 2015). Clinical trials comparing autologous and allogeneic stem cells in cardiac disease suggest that allogeneic cells provide greater benefit to patients (Hare et al., 2012, 2017; Premer et al., 2015a).

Methods of Delivery

In addition to the cell type, the dosage, the timing (either in the acute phase or chronic phase of cardiac disease), and delivery method are all important practical considerations in determining the ideal cell-based therapy. Currently, four main cell delivery has been employed, two that require catheter access, intracoronary (arterial and venous) and transendocardial delivery, and two that do not require catheterization, epicardial and intravenous delivery (**Fig. 2**). Intracoronary delivery involves the injection of the cells into the coronary vessels that perfuse the heart tissue, but requires the stem cells to transmigrate across the blood vessel wall to reach the myocardium. Transendocardial delivery employs a small needle at the end of the catheter to directly inject the cells into the ventricular myocardium and serves to concentrate the cells into specific areas surrounding the infarcted area (scar) following MI. Epicardial injections are delivered to the outside of the heart accessed via surgery, while intravenous injection can involve either stem cell infusion into the coronary veins or the peripheral vasculature. While there are advantages and disadvantages to each strategy, there remains no definitive evidence of the superiority of one method over another; however, a recent meta-analysis suggests that for MSCs, transendocardial delivery provided the most favorable results (Kanelidis et al., 2017).

Bone Marrow-Derived Mononuclear Cells

Supported by the vast clinical experience in bone marrow transplant medicine, BMMNCs were the first stem cells to be incorporated into treatment for heart disease. BMMNCs are comprised of multiple progenitor cells and are isolated from bone marrow aspirates from the pelvis. The cells are then expanded in culture and delivered to the recipient patient, usually as autologous transplants. In 2002, the first randomized placebo-controlled trial using BMMNCs for heart disease was performed to evaluate their efficacy after intracoronary infusion in patients who had suffered an acute myocardial infarction (AMI) (Assmus et al., 2002). The initial beneficial effects of these cells were hypothesized to be from modulation of postinfarction left ventricle (LV) remodeling, and the 5-year follow-up results demonstrated, modest but sustained improvement of left ventricular ejection fraction (LVEF) (Leistner et al., 2011). This early, small trial highlighted the potential therapeutic benefits of the cells, and several subsequent trials have been done in both acute and chronic ischemic cardiac disease. Unfortunately, BMMNC treatment has failed to show consistent results across multiple studies.

BMMNCs were first tested as therapeutics after AMI in hopes that cell delivery in the early stage of ischemic cardiac disease would attenuate cell death, scar formation, and the development of ischemic HF. Strauer et al. were the first to show that intracoronary infusion of BMMNCs for AMI improves cardiac perfusion and function (Strauer et al., 2002). Additional benefits, including improved LVEF, regional wall motion, and reduced end systolic volume (ESV) have also been seen (Assmus et al., 2002; Fernandez-Aviles et al., 2004). The "Myocardial Regeneration by Intracoronary Infusion of Selected Population of Stem Cells in Acute Myocardial Infarction" (REGENT, NCT00316381) trial compared fractionated BMMNCs to CD34+/CXCR4+ (fractionated) bone marrow-derived cells and placebo in patients with AMI and impaired LVEF. Treatment was delivered by intracoronary injection. Neither cell treatment produced improvements compared to controls (Tendera et al., 2009). In the "Bone Marrow Transfer to Enhance ST-Elevation Infarct Regeneration" (BOOST trial, NCT00224536) intracoronary delivery of BMMNCs after AMI resulted in a significant improvement in LVEF at 6 months compared to placebo (Wollert et al., 2004); however, there were no long-term benefits noted at the 18-months follow-up (Meyer et al., 2006). While these cells have consistently proven to be safe, multiple studies have failed to show a conclusive benefit in both short and long-term follow-up. In fact, a recent meta-analysis investigating 2732 patients found no differences in mortality or major adverse cardiac events (MACE) associated with BMMNC therapy compared to controls and no differences in LVEF or New York Heart Association (NYHA) class in short-term follow-up. The authors concluded that there was inadequate evidence of a positive effect of cell therapy in the acute setting. A significant limitation of this meta-analysis was its lack of power, given the small sample size of each trial (Fisher et al., 2015). The absence of a consistent benefit of BMMNCs may be secondary to the proinflammatory environment of an acute insult, but such an environment is hostile to all cell types, including BMMNCs. Given the small size and inconsistent results of these phase I and II trials, it remains unclear if BMMNCs truly provide a benefit for acute MI.

Two clinical trials have been conducted to determine the optimal timing of delivery of BMMNCs following MI. The "Transplantation in Myocardial Infarction Evaluation" (TIME, NCT00684021) study was published in 2013 and compared the

effects of intracoronary cell delivery versus placebo at 3 and 7 days after ST-segment elevation MI in 120 patients (Traverse et al., 2012). The Late TIME trial (NCT00684060) randomized 87 patients to receive autologous BMMNCs versus placebo 2–3 weeks after PCI for MI (Traverse et al., 2011). In both studies, there were no significant improvements at 6 months follow-up in LVEF or regional wall motion compared to placebo. Taken together, these negative studies provide further evidence that BMMNCs therapy may not be efficacious in the setting of AMI. The "Effect of Intracoronary Reinfusion of Bone Marrow-derived Mononuclear Cells on All Cause Mortality in Acute Myocardial Infarction" (BAMI, NCT01569178), a Phase III European multicenter placebo-controlled trial with a projected enrollment of 3000 patients, will be appropriately powered and could provide definitive conclusions as to the therapeutic efficacy of BMMNCs for AMI (Mathur et al., 2017).

Similar to the AMI setting, autologous BMMNCs have produced mixed results in chronic ischemic HF (Taylor et al., 2016). The safety of transendocardial injection of BMMNCs was first established by Perin et al. who observed no periprocedural events upon injection of cells in patients with chronic ischemic cardiomyopathy (ICM). The cell-treated patients also experienced significant improvements in perfusion and contractility in viable areas of the myocardium (Perin et al., 2003, 2004). Similarly, subjects in a trial with chronic ischemia experienced enhanced myocardial perfusion and cardiac function 3 months after transendocardial BMMNC injection (Tse et al., 2003). The "Transplantation of Progenitor Cells and Regeneration Enhancement in Acute Myocardial Infarction" TOPCARE-CHD (NCT00289822) study reported reductions in probrain natriuretic peptide and proatrial natriuretic peptide (both of which are elevated in HF) at 3 months following intracoronary injection of BMMNCs in subjects with ischemic HF (Assmus et al., 2007). However, others have reported conflicting results. While BMMNC treatment in patients with ischemic HF did improve angina symptoms and quality of life scores, cell treatment failed to significantly increase myocardial perfusion and functional capacity as assessed by myocardial oxygen consumption (MVO_2) and LVEF (Perin et al., 2011). Interestingly, upon secondary analysis, subjects <60 years of age had higher levels of mesenchymal progenitor cells in their BMMNC population and experienced improved MVO_2 as compared to controls (Perin et al., 2011). The larger "Effectiveness of Stem Cell Treatment for Adults with Ischemic Cardiomyopathy" (FOCUS-Study, NCT00824005) trial did not meet its functional end points by failing to show improvements in LVEF, MVO_2, or perfusion 6 months after transendocardial stem cell injection. However, on posthoc analysis, an increase was observed in LVEF, left ventricular end systolic volume (LVESV), and MVO_2 max in patients with higher levels of $CD19^+$ B cells, $CD11b^+$ monocytes, $CD31^{dim}$ subsets, CXCR4+ migratory cells and lower levels of $CD31^{bright}$ lymphocytes in their bone-marrow profile at baseline (Perin et al., 2012; Taylor et al., 2016). The differences in patient response based on age and the types of progenitor cells present in their harvested bone marrow highlight the greater efficacy specific cells types and cells harvested from younger patients. Finally, the recent "Retrograde Delivery of Autologous Bone Marrow in Patients With Heart Failure" (REVIVE, NCT01299324) trial evaluated the effects of BMMNCs delivered via retrograde coronary sinus injection, in ischemic and nonischemic HF subjects. This trial showed that cell delivery was safe and although not all secondary endpoints were met, LVEF was improved in both groups and the end systolic diameter was decreased in the nonischemic HF group (Patel et al., 2015).

Given the discrepancy between conditions, delivery method and follow-up in these studies, there are a number of variables that could be modified in an effort to enhance the efficacy of future BMMNC trials. In the AMI setting, cell therapy has overall produced little or no lasting improvements in cardiac structure and function, possibly due to poor stem cell survival in the inflammatory milieu of the AMI tissue. Cell therapy may be more efficacious if injected once the acute inflammatory response has waned but before deleterious post-MI remodeling has become irreversible. Once the untoward effects of HF have set in, secondary analysis of trials in the chronic setting has shown us that patient age may influence the functional efficacy of autologous BMMNCs. The reduced effectiveness of cells from older individuals suggests that allogeneic cells may be more beneficial than their autologous counterparts, although potential issues related to immune tolerance may need to be addressed.

Further research on BMMNC therapy has focused on identifying the most effective, fractionated subpopulation of progenitor cells. Murray et al. found that one constituent of BMMNCs, hematopoietic stem cells, do not readily acquire a cardiac phenotype following MI (Murry et al., 2004), suggesting their weak regenerative capacity. In contrast, specific nonhematopoietic subtypes of BMMNCs such as MSCs and EPCs provide significant contributions to regeneration. MSCs have been extensively studied based on their relative ease of isolation, immunomodulatory properties, potential as an allogeneic cell therapeutic, secretion of paracrine factors, and the ability, albeit at low frequency, to engraft and differentiate into cardiomyocytes and vascular components (Hatzistergos et al., 2010). EPCs produce endothelial cells that line the inner surface of vessels and EPC function correlates with cardiac function (Munzel et al., 2008). In clinical trials, EPCs improve myocardial perfusion (Quyyumi et al., 2011) and symptoms related to refractory angina (Henry et al., 2016).

Mesenchymal Stem Cells

Multiple trials utilizing BMMNCs have not produced consistent positive findings, leading to a search for a more therapeutically potent cell. Bone marrow-derived mesenchymal stem cells (BMMSCs) comprise approximately 0.1%–0.05% of BMMNCs and were first reported in 1970 (Friedenstein et al., 1970). MSCs are defined by their ability to adhere to plastic, expression of the cell surface markers CD105, CD73, and CD90, the absence or very low levels of several other specific markers including CD34 and CD45, and the ability to differentiate into osteogenic, adipogenic, and chondrogenic lineages in vitro (Dominici et al., 2006). MSCs are found in multiple tissue types, including bone marrow, heart, umbilical cord, and adipose tissue (Golpanian et al., 2016). These cells are ideal candidates for cardiac therapy because they are easy to isolate from these various tissues, are true multipotent stem cells, and are immunotolerant and immunosuppressive, eliciting virtually no rejection response from the recipient when delivered as an

allogeneic product (Hare et al., 2012, 2017). As a cell therapy for the cardiac disease, MSCs display greater clinical efficacy compared to BMMNCs (Heldman et al., 2014).

This improved benefit of MSCs in cardiac regeneration is likely related to the factors they secrete, which act locally on nearby cells (paracrine effect). These paracrine factors promote immunomodulation, neovascularization, and remodeling of the extracellular matrix leading to reduced scar size (Karantalis et al., 2012; Sanina and Hare, 2015; Williams and Hare, 2011). MSCs secrete numerous factors including vascular endothelial growth factor (VEGF) (Wang et al., 2014), angiopoetin-1 (Kalinina et al., 2015), fibroblast growth factor (FGF) (Wang et al., 2014), interleukin (IL)-1 and IL-6 (Jaimes et al., 2017), stromal cell-derived factor 1 (SDF1) (Ghadge et al., 2011), and insulin-like growth factors I and II (Cheng et al., 1998). Other effects are mediated by cell-to-cell contact and direct differentiation. MSCs have been evaluated in several clinical trials for their safety and feasibility in acute and chronic heart diseases.

Bone marrow-derived mesenchymal stem cells

In 2004, Chen et al. investigated the effect of autologous BMMSCs delivered by intracoronary injection in patients with AMI. Cells were delivered approximately 18 days after the initial percutaneous stent procedure. This study showed improvement in LVEF, systolic and diastolic LV volumes, and perfusion defects compared to placebo. These improvements were maintained at 6 months follow-up (Chen et al., 2004). Hare et al. demonstrated the safety and efficacy of allogeneic MSC therapy for AMI in a phase I clinical trial. This double blinded, placebo-controlled study showed that MSCs from young, healthy donors significantly improved forced expiratory volumes (FEV1), LV end diastolic volume, LV function, and reduced ventricular arrhythmias at 12 months compared to placebo (Hare et al., 2009). In a phase I/II clinical trial, Chullikana et al. confirmed that allogeneic MSCs are safe (Chullikana et al., 2015). They assessed markers of inflammation and rejection of the allogeneic cells by evaluating lymphocyte markers (CD3, CD4, CD8) and serum proinflammatory cytokines levels such as IL-1, TNF-α, and interferon-γ, but observed no evidence of immunologic response, further supporting the safety of allogeneic MSC therapy.

The promising results seen in the acute phase of ischemic heart disease encouraged the application of MSC therapy to chronic disease. In 2006, Chen et al. evaluated the effect of autologous BMMSCs in patients with chronic ICM. The results of this trial demonstrated a significant decrease in perfusion defect from baseline to 12 months and patient functional capacity, as indicated by the 6-minute walk test, Minnesota Living with Heart Failure Questionnaire (MLHFQ) score, and NYHA classification improved after 3 months compared to placebo (Chen et al., 2006). The double blinded, randomized "Bone Marrow-Derived Mesenchymal Stromal Cell Treatment in Patients with Severe Ischaemic Heart Failure" (MSC-HFNCT00644410) trial compared intramyocardial injection of placebo versus autologous BMMSCs in patients with severe ischemic HF. In this trial, cell-treated patients exhibited significantly improved LVESV, stroke volume, myocardial mass, and LVEF compared to placebo. Despite these changes in cardiac volumes and pump function, overall patient functional parameters did not show a significant improvement (Mathiasen et al., 2015). The "Transendocardial Autologous Cells (hMSC or hBMC) in Ischemic Heart Failure Trial" (TAC-HFT, NCT00768066) was a randomized, double-blind, placebo-controlled trial that evaluated the safety and efficacy of autologous BMMSCs as compared to BMMNCs and placebo (Heldman et al., 2014). This clinical trial was the first to directly compare two different cell types delivered via transendocardial injection into patients with chronic ICM. Patients treated with both cell types showed a significant improvement in the MLHFQ score; however, 6-minute walk distance, regional cardiac contractility, cardiac strain, and scar size were improved only in the BMMSC group (**Fig. 3**). This study was the first to provide evidence that BMMSCs produce greater effects on cardiac remodeling, scar size reduction, and functional parameters when compared to BMMNCs. The PROMETHEUS trial (NCT00587990) examined the efficacy of autologous BMMSCs delivered via epicardial injection in ICM patients undergoing coronary artery bypass graft (CABG) surgery. This trial showed that areas of the heart receiving BMMSCs exhibited significant improvements in functional and structural parameters that in turn drive improvement in global LV function (Karantalis et al., 2014).

MSCs are immunotolerant (do not promote immune rejection) because they lack major histocompatibility complex class II antigens and are also immunosuppressive. These properties make them favorable candidates for allogeneic transplantation, as they are less likely to be identified and destroyed by the recipient's immune system (Karantalis et al., 2015a). The Comparison of Allogeneic versus Autologous Bone Marrow-Derived Mesenchymal Stem Cells Delivered by Transendocardial Injection in Patients with Ischemic Cardiomyopathy (The POSEIDON Randomized Trial: NCT01087996) was the first to compare three different doses (20 million, 100 million, and 200 million) of both autologous and allogeneic MSCs injected in a transendocardial fashion in patients with ICM. This trial demonstrated that both cell types were equally safe. Allogeneic and autologous cells alike decreased scar size and improved the sphericity index (a measure of LV dilation, which is increased in HF). The allogeneic group improved the LV end diastolic volume while the autologous group did not. Conversely, the autologous group improved in the 6-minute walk test and the MLHFQ, while the allogeneic group remained unchanged. Interestingly, the 20 million group produced the greatest improvement in EF and LV volume as compared to the others, which demonstrates an inverse dose response, a rather common finding in cardiac cell-based therapy (Hare et al., 2012; Suncion et al., 2014; Tompkins et al., 2017). A subanalysis from this study showed that unlike autologous BMMSCs, allogeneic cells improved EPC proliferation and flow-mediated vasodilation, two parameters that are impaired in HF; indicating improved functioning of endothelial cells (Premer et al., 2015b).

While the vast majority of studies examining the benefits of stem cell therapy for cardiac disease have focused on acute and chronic ischemic HF, nonischemic dilated cardiomyopathy (NIDCM), remains a challenging and widespread disease with no cure except heart transplant. Recent studies have begun to assess the effect of stem cell therapy on patients with NIDCM. A case report published in 2011 documented that the intracoronary infusion of autologous MSCs in an 11-year-old boy with progressive dilated cardiomyopathy was safe and improved the patient's clinical condition including improvements in NYHA functional class, paroxysmal nocturnal dyspnea, and reduced the hospitalization rate (Zeinaloo et al., 2011).

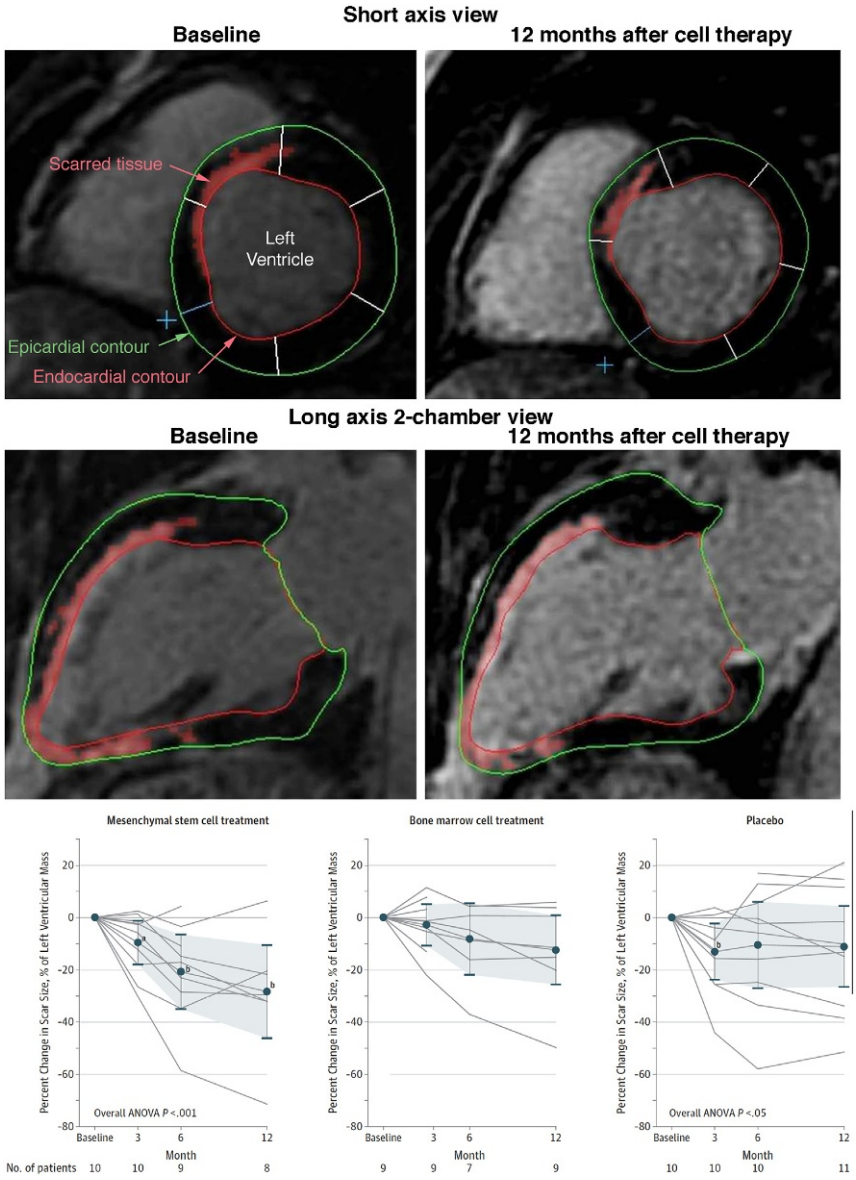

Fig. 3 Chronological change of scar evaluated by cardiac magnetic resonance imaging. Short-axis and long-axis two-chamber views of the heart, with delayed tissue enhancement depicting scar tissue (*pink*). Twelve months after injection of mesenchymal stem cells, scar mass was reduced in a patient from the TAC-HFT trial. Scar mass as a percentage of left ventricular mass was reduced in the MSC-treated and placebo groups. Reproduced from Heldman, A. W., Difede, D. L., Fishman, J. E., Zambrano, J. P., Trachtenberg, B. H., Karantalis, V., Mushtaq, M., Williams, A. R., Suncion, V. Y., Mcniece, I. K., Ghersin, E., Soto, V., Lopera, G., Miki, R., Willens, H., Hendel, R., Mitrani, R., Pattany, P., Feigenbaum, G., Oskouei, B., Byrnes, J., Lowery, M. H., Sierra, J., Pujol, M. V., Delgado, C., Gonzalez, P. J., Rodriguez, J. E., Bagno, L. L., Rouy, D., Altman, P., Foo, C. W., Da Silva, J., Anderson, E., Schwarz, R., Mendizabal, A. and Hare, J. M. (2014). Transendocardial mesenchymal stem cells and mononuclear bone marrow cells for ischemic cardiomyopathy: The TAC-HFT randomized trial. *JAMA* **311**, 62–73, with permission of the publisher.

The recent "Percutaneous Stem Cell Injection Delivery Effects On Neomyogenesis in Dilated Cardiomyopathy Trial" (POSEIDON-DCM trial, #NCT01392625), a counterpart to the POSEIDON trial in ICM patients, compared transendocardial delivery of allogeneic and autologous BMMSCs in an NIDCM population and demonstrated the safety of both cell types. Allogeneic BMMSCs produced greater improvements in cardiac function, performance (6-minute walk distance, MLHFQ), endothelial function, and FEV1 than autologous MSCs (Hare et al., 2017) (**Fig. 4**). These changes were accompanied by reductions in the proinflammatory serum immune marker TNF–α. Interestingly, allogeneic cell treatment also led to a systemic decrease in exhausted (poorly functional) T-cells (important mediators of adaptive immunity) as well as an increase in %Switch Memory B-cells (a predictive biomarker of antibody response to pathogens) (Hare et al., 2017). Butler et al. evaluated the benefits of allogeneic "ischemia tolerant" MCSs (grown in hypoxic conditions) delivered intravenously to NIDCM patients. This single-blinded, controlled, crossover study showed that cell treatment produced improvements in the 6-minute walk distance, Kansas City Cardiomyopathy Questionnaire scores and serum immune cells (CD3+, CD4+, and natural killer cells). In addition, there was no difference in rehospitalization or adverse effects up to 90-days posttreatment compared to the control group (Butler et al., 2016).

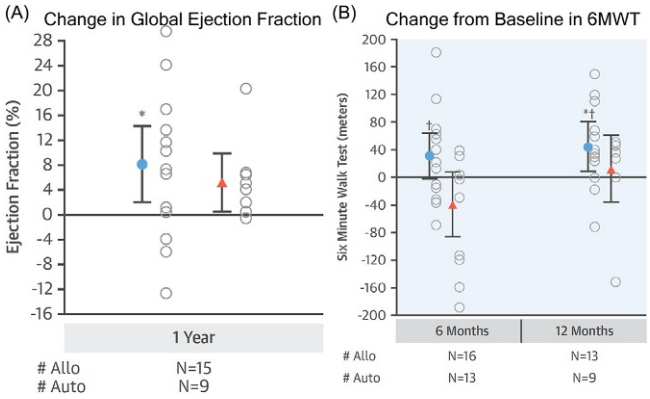

Fig. 4 Allogeneic MSCs demonstrate superior efficacy for treating NIDCM. Twelve months after treatment with MSCS, NIDCM patients from the POSEIDON-DCM trial showed improved (A) EF and (B) 6MWD. These improvements were superior in the allogeneic MSC-treated (*blue circles*) compared to autologous MSC treated (*red triangles*) patients. Adapted from Hare, J. M., Difede, D. L., Rieger, A. C., Florea, V., Landin, A. M., El-Khorazaty, J., Khan, A., Mushtaq, M., Lowery, M. H., Byrnes, J. J., Hendel, R. C., Cohen, M. G., Alfonso, C. E., Valasaki, K., Pujol, M. E., Anderson, E., Mendizabal, A., Mitrani, R. and Heldman, A. W. (2017). Randomized comparison of allogeneic versus autologous mesenchymal stem cells for nonischemic dilated cardiomyopathy: POSEIDON-DCM trial. *Journal of the American College of Cardiology* **69**, 526–537, with permission from the publisher.

Adipose-derived mesenchymal stem cells

While BMMSC isolation requires aspiration of bone marrow from the pelvis, adipose-derived mesenchymal stem cells (AdMSCs) can be isolated from biopsies of fat tissue. The safety and efficacy of AdMSCs for ICM were first assessed in "A Randomized Clinical Trial of AdiPOse-derived Stem ceLLs in the Treatment of Patients With ST-elevation myOcardial Infarction-the APOLLO trial" (NCT00442806) in which AdMSCs were delivered via an intracoronary route to patients with ICM. This randomized, double-blind, placebo-controlled, phase I/IIa trial established the safety of AdMSCs, as well as their ability to induce significant reductions in scar size and improve myocardial perfusion (Houtgraaf et al., 2012). Additional phase II clinical studies, including ADVANCE (NCT01216995) and AMICI (NCT01781390), where AdMSCs were used to treat AMI, have not reported their results.

Endothelial Progenitor Cells

Another stem cell constituent of BMMNCs, EPCs have also garnered interest as a potential therapeutic for cardiovascular disease. EPCs are CD34+ mononuclear cells that can be isolated from bone marrow or peripheral blood. CD34 is a cell surface marker primarily expressed on the surface of endothelial, hematopoietic, and vascular cells (Asahara et al., 1997). Cell populations enriched for CD34+ promote neovascularization and restore microcirculation in ischemic limb and ischemic myocardial models more effectively than unselected mononuclear cells (Kawamoto et al., 2006). EPCs, because of their ability to induce angiogenesis and modify endothelial function, were first tested in the setting of angina (chest pain secondary to inadequate blood flow to the myocardium) and their use was expanded to both ICM and NIDCM.

Bone marrow-derived EPCs

Initial studies utilizing EPCs as a therapy for heart disease demonstrated that peripheral blood or bone marrow-derived CD34+ cells can improve clinical outcomes in patients with refractory angina, including the incidence of MI, the frequency of angina episodes, and exercise tolerance. Losordo et al. demonstrated that intramyocardial injection of autologous EPCs is safe, feasible, significantly decreased weekly angina frequency, and improved exercise tolerance in patients with Canadian Cardiovascular Society (CCS) class III–IV angina at enrollment compared to placebo (Losordo et al., 2007). EPC therapy also increased myocardial perfusion, but notably, these improvements were more pronounced with lower doses of EPCs (Losordo et al., 2011). A similar study showed that autologous bone marrow-derived EPCs reduced angina frequency and nitroglycerin use per week, and increased exercise tolerance time and CCS angina class in patients with intractable angina (Wang et al., 2010). The larger phase III RENEW trial (NCT01508910) examined intramyocardial EPC delivery for angina, but was terminated prior to completion due to financial issues; however, the midterm results were consistent with observations from previous trials (Povsic et al., 2016).

While EPCs have produced beneficial effects in patients with refractory angina, they have also shown promise as therapeutics for both ischemic and nonischemic cardiomyopathies. The potential benefits of EPC therapy in HF were investigated by transplanting autologous CD34+ cells into patients with ICM and an LVEF $\leq$ 35%, during CABG surgery. Cell treatment elicited significant improvement in LVEF at 1, 3, and 6 months compared to the CABG only group (Patel et al., 2005). The multicenter, randomized placebo-controlled REGENT trial (NCT00316381) compared nonselected BMMNCs with selected CD34+/CXCR4+ EPCs (Tendera et al., 2009). As described above, the cell therapy provided no benefit to patients with AMI compared to placebo after 6 months.

EPCs induce modest improvements in LVEF when administered to patients with ICM and their effects on patients with NIDCM have been even more impressive. In a study by Vrtovec et al., 110 patients were randomized to receive autologous EPC treatment or

placebo control (Vrtovec et al., 2013). In this study, EPCs were mobilized by granulocyte colony-stimulating factor and injected into the coronary artery supplying cardiac segments with the greatest perfusion defect (limited blood supply). After 1 and 5 years, the cell treated group showed a significant improvement in LVEF, 6-minute walk distance, and long-term survival (Vrtovec et al., 2013). In a later study, this group also demonstrated that transendocardial CD34+ cell therapy is ineffective for NIDCM patients with diabetes mellitus (Vrtovec et al., 2016). Treatment increased LVEF and decreased N-terminal probrain natriuretic peptide levels in the insulin-resistant and non-insulin-resistant groups, but not in the diabetes mellitus group at 6-months posttreatment (Vrtovec et al., 2016).

Circulating EPCs

EPCs travel through the circulatory system, and endogenous bone marrow-derived CD34+ EPCs are actually mobilized to the peripheral circulation during the natural history of AMI. Moreover, the degree of mobilization has been correlated with improved outcomes after MI, which spurred the hypothesis that circulating EPCs may be beneficial in the acute phase of the ischemic cardiac disease (Quyyumi et al., 2016). Therefore, circulating progenitor cells have been studied as a treatment for cardiac repair in several trials. In the "Transplantation Of Progenitor Cells And Regeneration Enhancement in Acute Myocardial Infarction" (TOPCARE-AMI) trial (Schachinger et al., 2004), intracoronary injection of peripherally-derived circulating progenitor cells improved global LVEF and LVESV after 4 months. At 1-year follow-up, imaging analysis showed improved LVEF, scar size, and LV hypertrophy in the cell-treated group. In a randomized, placebo-controlled study of intracoronary EPC delivery in patients after recanalization of chronic coronary occlusion, EPC treatment produced increased coronary flow reserve, reduced infarct size, and increased LVEF in the treatment group at 3 months posttreatment (Erbs et al., 2005). Despite these initial promising results, a study comparing circulating progenitor cells to BMMNCs in patients with stable ischemic heart disease showed that bone marrow-derived cells were superior to circulating progenitor cells (Assmus et al., 2006). Global LVEF and regional contractility assessed at 3 months posttreatment were significantly increased in the bone marrow group only, but not in the circulating progenitor cell group (Assmus et al., 2006).

Bone marrow-derived CD133+ EPCs

In addition to CD34, CD133, a prominin 5 transmembrane glycoprotein 1, is coexpressed in a substantial number of hematopoietic cells with potent hematopoietic and angiogenic capacities (Quirici et al., 2001; Reyes et al., 2002). Injection of bone marrow-derived CD133+ cells into the infarct zone during CABG resulted in significant improvements in LV end diastolic volume, LVEF, and local perfusion in the stem cell-treated infarct area at 12 days posttreatment relative to baseline (Stamm et al., 2004). Another study investigating the safety and efficacy of intracoronary administered CD133+ cells into a patient with AMI (Bartunek et al., 2005) demonstrated feasibility but was associated with increased incidence of coronary events (Bartunek et al., 2005). In the "Safety and Efficacy of Autologous Endothelial Progenitor Cell CD133 for Therapeutic Angiogenesis" trial (PROGENITOR, NCT00694642) (Jimenez-Quevedo et al., 2014), a phase I/II, multicenter, single-blinded and randomized trial, patients with refractory angina were treated with granulocyte-colony-stimulating factor and randomized to receive CD133+ cells or no treatment. Although the findings supported the feasibility and safety of transendocardial injection of CD133+ cells into patients with refractory angina, the trial did not meet its primary endpoints of reducing cardiovascular death, nonfatal MI, ischemic stroke, need for revascularization, and procedure-related complications. However, there was a significant improvement in the number of angina episodes per month and angina functional class in the cell treatment group, but not in the controls.

Cardiac Stem Cells

Until recently, the heart was considered a postmitotic organ, incapable of regeneration, thus limiting the available options for therapeutics for cardiac disease. The discovery of a CSC population within the adult heart in spurred interest in using these stem cells as a novel cell-based therapeutic for regenerating damaged myocardium (Beltrami et al., 2003). CSCs are crucial components of the heart's endogenous repair machinery and are characterized by the expression of the cell surface marker, c-kit (CD117).

The regenerative ability of endogenous adult CSCs has been questioned and a murine study suggests that adult c-kit+ cells play little if any role in cardiomyocyte regeneration (van Berlo et al., 2014). Other murine studies indicate that c-kit+ cells can play an important role in cardiomyogenesis (Hatzistergos et al., 2015, 2016). Administration of c-kit+ CSCs following ICM in mice (Fransioli et al., 2008) and swine (Bolli et al., 2013; Kulandavelu et al., 2016; Tang et al., 2016; Williams et al., 2013) show that these cells promote significant improvements in cardiac function and structure. The therapeutic efficacy of c-kit+ CSCs in humans was first assessed in the setting of chronic ICM. In phase I "Cardiac Stem Cell Infusion in Patients with Ischemic Cardiomyopathy" (SCIPIO, NCT00474461) trial, autologous CSCs were harvested from the right atrial appendage of patients with severe HF undergoing CABG. The cells were expanded and readministered via intracoronary infusion 3–4 months later. Compared to placebo, the CSC-treated group had significant increases in LVEF at 4-months posttherapy. Moreover, the CSC group exhibited improvements in scar size, regional contractility, and HF symptoms (Bolli et al., 2011). The "Cardiosphere-Derived Autologous Stem Cells to Reverse Ventricular Dysfunction" (CADUCEUS, NCT00893360) trial evaluated the effectiveness of intracoronary delivery of cardiosphere-derived autologous stem cells in patients with ICM. Cardiospheres are a small population of cells isolated from biopsied heart tissue that spontaneously forms clusters comprised of heterogeneous cells, and are characterized by multiple markers, including CD105+, c-kit+, CD90+, CD34+, and CD31+. Despite the lack of improvements in LVEF in the cell-treated group, there was a significant reduction in scar mass, as well as an increase in viable myocardium and contractility at the 6-months follow-up (Makkar et al., 2012). Trials to enhance the potency of CSCs are ongoing. The "Combination of Mesenchymal and C-kit+ Cardiac Stem Cells as Regenerative Therapy for Heart Failure" trial (CONCERT-HF, NCT02501811) is designed to

test if the potency of CSCs is enhanced by combining them with MSCs. This landmark multicenter trial plans to enrol more than 100 patients and is based on results of preclinical studies in swine models of MI where the combination of autologous MSCs and CSCs produced greater effects than single cell types alone (Karantalis et al., 2015b; Williams et al., 2013).

Skeletal Myoblasts

Skeletal myoblasts were one of the first generation stem cell therapies to be studied, and the first to be utilized in a dog model of cardiac injury (Marelli et al., 1992). These cells have high proliferative capacity and resistance to ischemia and it was thought that their ability to promote recovery from muscle injury would translate to the heart. The 2008 MAGIC trial was the first randomized study of myoblast transplantation in ICM patients. Cells were administered via intramyocardial injection during open heart surgery, but they failed to produce significant increases of LVEF compared to placebo. Furthermore, the myoblasts did not integrate into the myocardium and in some cases, actually caused ventricular arrhythmias (Menasche et al., 2008). In contrast, the smaller (23 patients) "Study to Assess the Efficacy and Safety of Transplanting Autologous Skeletal Myoblasts, Into Infarcted Heart, Using a Catheter Delivery System" (CAuSMIC, NCT00626314) trial showed that transendocardial injection of skeletal myoblasts was safe, improved functional class and reversed ventricular remodeling (Dib et al., 2009). However, the skeletal lineage commitment of myoblasts appears to prevent these cells from becoming cardiomyocytes. This, coupled with their potential to induce arrhythmias, has limited their clinical applicability.

Pluripotent Stem Cells

Pluripotent stem cells (ESCs, iPSCs) are described in more detail in another chapter, but will be discussed briefly here. These cells can transform into virtually any adult cell and have superior proliferation capacities compared to MSCs and EPCs. There are some caveats to their use in therapeutic applications, as they have the potential to form teratomas and can instigate immune reactions, which hinders their advancement to clinical use. Differentiating pluripotent stem cells into cardiomyocytes prior to infusion should limit the generation of teratomas and expand their clinical applicability; however, there is a risk for arrhythmia because these cells can remain immature following engraftment (Behfar et al., 2007). Riegler et al. showed that human ESC-derived cardiomyocytes survive long-term in a rat model of ICM without teratoma formation. However, this long-term survival was not accompanied by cardiac functional improvements (Riegler et al., 2015). Functional improvements were observed when human ESC-derived cardiomyocytes were introduced into a macaque model of AMI (Chong et al., 2014) (**Fig. 5**), again with no teratoma generation. These findings paved the way for a phase I clinical trial investigating ESC-derived cardiac progenitor cells embedded into a fibrin scaffold and surgically delivered onto the infarct area for patients with ICM. A case report of a single patient who received this treatment reported LVEF recovery and improved symptoms without adverse events (Menasche et al., 2015).

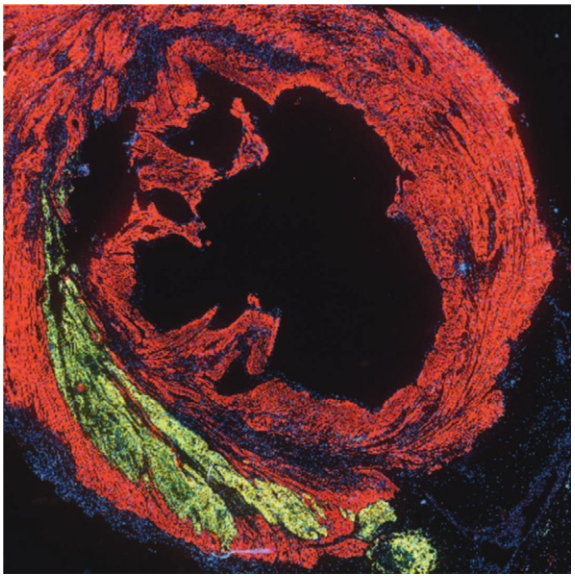

Fig. 5 hESC induced cardiomyocytes transplanted into infarcted macaque heart. Confocal immunofluorescence of a macaque heart subjected to myocardial infarct and transplantation of hESC-CMs. This image was taken 14 days after stem cell injection. hESC-CMs coexpressing GFP can be seen embedded in the *dark* infarcted region. Alpha-actin, staining in cardiomyocytes, is shown in *red*. Reproduced from Chong, J. J., Yang, X., Don, C. W., Minami, E., Liu, Y. W., Weyers, J. J., Mahoney, W. M., Van Biber, B., Cook, S. M., Palpant, N. J., Gantz, J. A., Fugate, J. A., Muskheli, V., Gough, G. M., Vogel, K. W., Astley, C. A., Hotchkiss, C. E., Baldessari, A., Pabon, L., Reinecke, H., Gill, E. A., Nelson, V., Kiem, H. P., Laflamme, M. A. and Murry, C. E. (2014). Human embryonic-stem-cell-derived cardiomyocytes regenerate non-human primate hearts. *Nature* **510**, 273–277, with permission from the publisher.

Similar to ESCs, iPSCs require effective positive selection (cardiomyocyte differentiation and purification) and negative selection (to avoid teratoma formation) for clinical application. While this approach may prove effective, the immature nature of iPSC-derived cardiomyocytes (iPSC-CMs), like that for ESC-derived cardiomyocytes, currently presents a hurdle. iPSC-CMs are mechanically and electrophysiologically immature, resembling fetal cardiac tissue and techniques to further mature them for clinical use are needed (Csobonyeiova et al., 2015). Nevertheless, extensive research and an increasing number of preclinical and clinical studies should improve the safety and efficacy of iPSCs and iPSC-derived cells in cardiac cell-based therapies. In fact, one group in Japan has evaluated surgical engraftment of bioengineered sheets of myocardium derived from autologous iPSCs into damaged hearts in animal models, and this method is currently undergoing investigation in phase II clinical trial in Japan (Sawa, 2017).

Stem Cell Modification and Other Approaches

An alternative approach to augment stem cell therapy is the pretreatment of cells to enhance their therapeutic potency. There are several strategies, such as pretreatment of cells with growth factors (Bartunek et al., 2013), in vitro exposure to hypoxia (Bellio et al., 2016), genetic modulation (Samse et al., 2016; Kulandavelu et al., 2016; Quijada et al., 2012), and specific cell phenotype selection (Tendera et al., 2009). Because CSCs must be isolated through surgery or cardiac biopsy, both of which are invasive and carry some risk, several preclinical studies have sought to modify MSCs to make them more like CSCs. Treatment with a "cardiac cocktail" of several growth factors and other bioactive agents can successfully trigger MSCs toward a lineage-specified cardiac phenotype, or so-called cardiopoietic stem cells and these cells, and these cells demonstrated beneficial effects on damaged myocardium in an animal model (Behfar et al., 2010). Cardiopoietic stem cells have since been translated into clinical trials. One such study is the "Cardiopoietic stem Cell therapy in heart failure" (C-CURE, NCT00810238) multicenter, randomized trial that the safety and efficacy of transendocardial injection of cardiopoietic stem cells for IHF (Bartunek et al., 2013).There were no adverse events or systemic toxicity associated with these cardiopoietic stem cells. Moreover, at 6 months significant improvements in LVEF, ESV, and 6-minute walk test were seen in the cell pretreated group compared to standard of care alone. These promising results led to a phase III, sham-controlled multicenter trial, the Safety and Efficacy of Autologous Cardiopoietic Cell for Treatment of Ischemic Heart Failure trial (CHART-1) (NCT01768702), which examined the efficacy of cardiopoietic stem cells from autologous BMMSCs in IHF. At 39 weeks, compared to placebo, cell therapy failed to show improvements in the primary efficacy endpoint, which was a composite of mortality, worsening HF, MLHFQ, LVESV, and LVEF (Bartunek et al., 2017). Further analysis revealed a subpopulation of patients with severe heart enlargement (LVEDV 200–370) that did significantly improve in the primary endpoint.

Another interesting alternative approach to next generation stem cell therapy is the direct reprogramming of somatic cells into cardiomyocytes using a cocktail of transcription factors in vivo. By circumventing the pluripotent state, there is a decreased risk of teratoma formation and immune rejection. Although this method has shown promising results in murine studies, it has not been successfully replicated in human somatic cells. Transduction efficiencies are low, and generated cardiomyocytes are immature. The safety and efficacy of these manipulated cells have yet to be established in a large animal preclinical models (Cambria et al., 2016).

Conclusions and Future Perspectives for Stem Cell Therapeutics

Over the last 10–15 years of clinical trials involving stem cell therapies for cardiac disease, there have been both failures and remarkable breakthroughs that move the field forward. While not every study has proven successful, multiple studies have demonstrated that that stem cell therapy is remarkably safe. Preclinical and clinical trials to date have addressed many questions, but there is still uncertainty as to which stem cell type, source, combination, modification, delivery, etc. is the most effective for which type of cardiac regeneration, and which symptoms will respond to which treatment. Of the stem cells extensively tested, MSCs appear to be superior for short-term efficacy, and are the ideal cell type for allogeneic transplant because of their immunotolerant status. Despite promising preclinical data, the newer trials assessing the efficacy of MSCs modified to achieve a cardiac phenotype have shown the little benefit of these cells, highlighting the importance of clinical trials in this field. The next phase of studies will likely focus on enhancing the recipient tissue environment, improving cell delivery and engraftment, and optimizing the timing of cell administration. Studies to date indicate that it is highly unlikely that the injection of a single, unmodified cell type can reverse the entirety of the cardiac damage. Cell combinations, genetic manipulation, preconditioning, embedding cells within matrices have all produced improvements but it is unlikely that these approaches alone will replace the injured myocardium; treatment must also activate endogenous cells within the myocardium to promote healing.

Development of the "optimal treatment" is ongoing, but novel technologies continue to raise and answer questions. Phase III clinical trials including "Efficacy and Safety of Allogeneic Mesenchymal Precursor Cells (Rexlemestrocel-L) for the Treatment of Heart Failure" (DREAM HF-1, NCT02032004) and BAMI, (NCT01569178) are starting to recruit large populations of patients. Results of these large trials will hopefully answer critical questions about the efficacy of allogeneic MSCs and BMMNCs to further shape the direction of cell-based therapies in the near future.

Introduction

The age of thoracic organ transplant began in the 1960s, as years of research led to the first transplants. In 1967, the first heart was successfully transplanted in South Africa by Christiaan Barnard (Barnard, 1967). Prior to that, in 1963, the first lung transplant was performed at the University of Mississippi (Hardy et al., 1963). After these two landmark events, another important transplantation happened—the first heart–lung transplant. In 1981, the team at Stanford successfully transplanted a 45-year old female with the first heart–lung bloc. The patient had the primary diagnosis of primary pulmonary hypertension (Reitz et al., 1982).

Heart–lung transplants provide an opportunity to treat patients with end-stage cardiac and end-stage pulmonary disease. According to the International Society of Heart and Lung Transplant, nearly 3400 adult heart–lung transplants have been completed to date, and currently, about 65 are completed per year. Estimated median survival for heart–lung transplant patients is 3.3 years, with a condition survival, meaning survival if they reached the 1 year mark, of 10.3 years, based on data obtained in 2014 (Yusen et al., 2016). The top diagnosis leading to heart–lung transplant has remained congenital heart disease, with roughly 35% of patients receiving heart–lung transplants having this diagnosis. The other top indications to transplant include pulmonary artery hypertension (27%) and cystic fibrosis (13%). Other diagnoses compromise 5% or fewer transplants (Yusen et al., 2016). As results have improved, the total number of transplants has increased; however, total volume remains limited by donor availability and the improved success of double lung transplants.

Patient Selection

With the improvement and success of a double-lung transplant, the growth of heart–lung transplant has peaked; however, there still exists a role in a select patient population. The process for evaluation of heart–lung transplant begins with the diagnosis of end-stage heart and end-stage lung disease. Typically a right heart catheterization will be the final determinant, demonstrating right atrial pressures >15, indicating severe right heart failure. At that point, the patient would not be a candidate for a double lung transplant, but rather for a heart–lung bloc.

As with all operations, determining good surgical candidacy is an important factor. Evaluating laboratory values including kidney function, liver function, coagulation, lipid panels, hemoglobin A1c, and thyroid function all factor into the decision of whether the potential recipient can undergo an operation. Another value checked is the panel reactive antibody (PRA). This number is a value score associated with the number of antibodies a person has. The higher the PRA, the higher the number of antibodies a patient possesses. A patient with a high PRA requires a more specific donor in order to prevent acute rejection. If a patient's PRA is greater than 25%, a prospective crossmatch is obtained in order to prevent hyperacute rejection.

The final decision to list a patient is determined by the local transplant committee. In the case of heart–lung transplants, patients are listed according to their lung allocation score (LAS), the scoring system used in determining placement for lung transplants. The higher a patient's LAS, the higher the rank the patient occupies on the transplant list.

Contraindications to transplantation do exist. Relative contraindications include age >65, diabetes, HIV, and active hepatitis B or C. Absolute contraindications include active malignancy, active infection, active drug or alcohol use, and active cigarette smoking.

Donor Preservation

Prior to going to the operating room, the donor's organ systems are maintained in order to preserve end organ function. In situations involving a donor heart, attention is paid to reducing cardiac workload and oxygen consumption. Often this goal

can be difficult due to neurogenic shock and the requirement for pressor agents to maintain a mean arterial pressure above 60. Additionally, if the lungs are being matched, volume status is critical to prevent pulmonary edema in both the donor as well as ultimately in the recipient. Tidal volumes are kept at 6–8 cc/kg and FiO_2 is maintained as low as possible to prevent oxygen toxicity. Often times, atelectasis can occur and recruitment breaths will be necessary in the operating room.

Donor Operation

Upon arrival to the donor hospital, the operating team should review all necessary paperwork, including history and physical examination, brain death summary, and necessary laboratory work. In addition, for heart–lung transplant, the echocardiogram, chest X-ray, and if applicable, the chest CT should be reviewed. In the operating room, a bronchoscope with suction should be available to visually evaluate the lungs.

The patient is brought to the operating room by the home hospital's anesthesia team and organ donation nurses. Once positioned, the bronchoscopy can be performed, ensuring no major anatomical abnormalities that might prevent transplantation, inspecting the airways for signs of aspiration, and providing any necessary pulmonary toilet.

The patient is then prepped with chlorhexidine from the chin through the groins and draped in order to perform a full sternotomy and laparotomy. Following median sternotomy, the sternal retractor is placed and the pleural spaces are opened in order to visually inspect the lungs. At this time, some advocate for ligating the pulmonary ligament bilaterally to facilitate mobilization. Each lung is evaluated for pulmonary contusion or other abnormalities. Recruitment breaths are then given, in order to recruit all atelectatic segments of the lung.

Upon completing the lung evaluation, the heart can be evaluated in the standard fashion. The pericardium is opened and incised as superiorly as possible, and inferiorly to the diaphragm. Visual inspection of the heart is performed, after which, the surgeon should manually trace the coronary arteries to ensure no significant disease.

Once confirmed that the heart also is acceptable, additional dissection is performed to prepare the heart–lung bloc. The superior vena cava (SVC) is separated from the right pulmonary artery and the inferior vena cava is released from the posterior pericardium. The trachea is mobilized as high as possible, to the larynx if able, and released posteriorly from esophageal attachments. Limited dissection is performed on the lateral trachea to preserve blood supply to what will be the new anastomosis and surrounding mediastinal tissue is left en bloc.

Once all transplant teams are ready, the patient is prepared for crossclamp and explant of organs. Typically at this time, 30,000 units of heparin are administered. Prostaglandins are then injected either intravenously or directly into the pulmonary artery to promote pulmonary vasculature vasodilation. It is not uncommon for this step to also lower systemic blood pressure. Pulmonary artery cannulation is then performed proximal to the bifurcation, and a cardioplegia needle is inserted into the ascending aorta. Additionally, the left atrial appendage is snared using a Satinsky clamp and the tip is ligated. The appendage will later be used to vent the left side of the heart. After 3 minutes following heparinization, crossclamps are then applied. The SVC is snared or tied off, the inferior vena cava is cut, and the left atrial appendage is vented. Ice and cold slush are placed on the heart and in both plural spaces, and pool tip suction is used to remove blood from the field. At this time, the cardioplegia and pulmoplegia lines should be opened and running freely. Once all fluid is given, anesthesia is asked to give one final breath and to hold it. The endotracheal tube is retracted and the trachea is stapled with the lungs moderately inflated. A 15-blade knife is used to make a clean cut across the trachea. The inferior vena cava is fully divided, and then the SVC and ascending aorta are divided as high as possible. If the pulmonary ligaments were not previously ligated, they must be now in order to fully mobilize and then remove the heart–lung bloc.

Once removed, the heart–lung bloc is inspected on the back table for any intracardiac abnormities that would require repair. They are packaged in cold fluid, either saline or University of Wisconsin (UW), a series of two sterile bags, and then a plastic container. The container is placed in one final bag and then a cooler for transport.

Recipient Operation

When a probable donor is found, the recipient will be called in from home. The standard preoperative routine of shaving, chlorhexidine wipes, etc. will be performed in the hospital prior to arrival in the operative room. Once transplant is confirmed, the patient will receive initial immunosuppressive therapy with mycophenolate mofetil (MMF) and/or a calcineurin inhibitor.

The patient then proceeds to the operating room. The patient is positioned supinely. Anesthesia is induced and the patient is intubated. The decision of single or double-lumen endotracheal tube is institution dependent. Standard monitoring lines are present, including arterial line, central venous line with Swan–Ganz catheter. Ultimately, the Swan will need to be retracted during the implantation.

Surgical approaches for the heart–lung transplant include the preferred median sternotomy or bilateral anterolateral thoracotomies, or the clamshell incision. The surgical approach is typically dependent on the extent of adhesions to be encountered in the pleural spaces. Patients with prior lung surgeries or severe inflammatory lung processes would benefit from a clamshell incision in order to control bleeding from adhesions.

After entering the chest, the operation begins by isolating and snaring the hilar vasculature outside the pericardium. As this area is dissected, special care is taken to preserve the phrenic nerves. Pedicles are created on each side roughly 3 cm in width. Posterior to the pedicle, the pericardium is excised to facilitate placement of the donor organs.

Following hilar dissections, the vena cava and the ascending aorta are dissected and encircled with snares. The patient is placed on cardiopulmonary bypass using a high aortic cannulation stitch and bicaval venous cannulation. The cardiopulmonary bypass circuit typically has a white blood cell filter to prevent host cells from entering the soon-to-be implanted graft.

The trachea, typically approached between the SVC and the innominate artery, is encircled roughly five rings above the carina. While dissecting the posterior aspect, the vagus nerves, traveling along the esophagus, must be preserved.

The recipient organs are then sequentially removed, starting with the heart. The lungs are then removed, first by stapling the vasculature and finally stapling across each bronchus. Special care is given to the left pulmonary artery, where a segment is left in the recipient near the ligamentum. This remnant preserves the left recurrent laryngeal nerve.

After preparation on the back table, the heart–lung block is ready to be implanted. The block is first inserted by placing the right lung under the phrenic pedicle, and then the left lung under the left pedicle. While there is no standard procedure to sew the anastomoses, the preferred order begins with the trachea. The endotracheal tube is retracted back, and using a 15-blade, the trachea is cut. Once the anastomosis, sewn with 4–0 nonabsorbable monofilament, is complete, the lungs can be ventilated in order to recruit alveoli and prevent on-going atelectasis. This area will be difficult to inspect for hemostasis once all remaining structures are sewn in place. It is therefore imperative to ensure this area will not bleed once perfusion is resumed.

The remaining structures are then sewn—the inferior vena cava, then SVC, and finally the aorta. Special care must be taken while sewing the cava in place in order to prevent strictures, which can impair cardiac filling. By using a donor superior vena cuff, the AV node should be preserved. Prior to sewing the aortic anastomosis, the heart can begin to fill and deair. Following its completion, cardioplegia is reattached and suction is placed on the aortic root to deair and prevent embolic complications.

Once all anastomoses are complete and the patient is ready to be weaned from cardiopulmonary bypass, 500–1000 mg of methylprednisone is given. It is imperative that the patient received the full dose prior to reperfusion of the grafts, that is—release of the aortic cross clamp. Atrial and ventricular pacing wires are placed, the heart is defibrillated if needed, and isoproterenol is started to keep the heart rate between 90 and 110. Depending on pulmonary arterial pressures and right heart function, inhaled epoprostenol or nitrous oxide may be needed. The chest is closed in standard fashion once hemostasis in ensured, and the patient is transported to the intensive care unit intubated.

Acute Postoperative Management

The postoperative management of a heart–lung transplant patient incorporates aspects of both a heart transplant and lung transplant. Key management points in the acute setting involve fluid management, ventilator weaning, and maintenance of cardiac output. These three tenants are intricately involved and after a heart–lung transplant can be opposing forces, as the support for heart transplant patient and lung transplant patient can be opposites regarding fluid resuscitation. The patient should return to the intensive care unit intubated, which he or she will remain for roughly 24 hours. The pacing wires are plugged in and set on a backup rate of 90. Chest tubes are placed to suction, and a full set of postoperative labs are sent.

The fluid management of a heart–lung transplant patient is a delicate balance. Heart transplants are aggressively resuscitated to maintain a central venous pressure, or CVP, around 8–10. Often multiple liters of fluid are required as the time spent on cardiopulmonary bypass increases the body's inflammatory response. Conversely, lung transplants are often time kept "dry," indicating minimal fluid resuscitation in order to prevent pulmonary edema. Thus, in postheart–lung transplants, fluid is judiciously managed. Vasoactive medications, specifically norepinephrine and vasopressin, will be used to support blood pressure while maintaining a CVP around 8. Phenylephrine, due to is alpha-agonist activity, has a great effect on pulmonary vascular bed constriction, and therefore is not the first line after a lung or heart–lung transplant.

Over the first 24 hours, the ventilator is weaned to minimal settings first, and then toward extubation after the stability of the patient is verified. While oxygen is essential to life, higher than normal levels can be detrimental to postoperative transplanted lung. Daily chest X-rays are used to track the status of pulmonary edema and monitor for some of the first signs of graft dysfunction. Additionally, bronchoscopies are performed to assist in airway clearance immediately post operation and to evaluate suture lines for dehiscence and stricture. At least one bronchoscopy is performed prior to extubation. Once the patient is extubated, the aggressive pulmonary toilet is employed to encourage airway clearance and lung expansion.

Essential to any postcardiac surgery, patient is the maintenance of cardiac output, usually though inotropes and fluid. Due to the stiffness of the transplanted heart, increased heart rate is the primary method used to increase output. Posttransplant patients are kept between 90 and 110 in the initial postoperative period until the new heart can relax and its diastolic function improves. Additionally, inotropes are used to support contractility as the new heart acclimates to its new anatomic and physiologic environment.

Immunosuppression is a key component of acute posttransplant management. Treatment begins concurrently with the patient coming off cardiopulmonary bypass, as the patient is dosed with 500–1000 mg of methylprednisone. Methylprednisone is redosed on the day of surgery at 125 mg every 8 hours for three doses. Following the three doses, methylprednisone, or oral prednisone, is dosed at 1 mg/kg/day, and then tapered depending on the transplant center's protocol and patient specific needs. MMF therapy also begins at this time, with 1500 mg dosed every 12 hours.

At this point, further immunosuppressive management depends on the patient's renal function, the presence of allosensitivity, and/or primary graft dysfunction. If the patient is not experiencing any acute kidney injury or failure, a calcineurin inhibitor is started at a low dose, 1–2 mg twice a day, with monitoring of daily trough levels. If the patient is having renal dysfunction, induction therapy with an antithymocyte globulin is started. Typically, it is dosed at 1.5 mg/kg. Center-specific monitoring of white blood cells, platelets, and/or CD3 counts are used to determine continued dosing strategy. Ultimately, the plan would be to resume using a calcineurin inhibitor within 7–14 days posttransplant.

The first posttransplant milestone is the initial biopsy to assess for rejection. Depending on institutional schedules, the first biopsy is typically done between postop days 5 and 7. Research has shown that a biopsy sample from the bronchial graft is more predictive of rejection than a sample from the endo- and myocardium of the right ventricle (Sibley et al., 1993). Thus biopsies are typically just taken from the lung. Ultimately, this lowers the risk of tricuspid disease in the transplanted heart, as the valve is not disturbed and the cords and papillary muscles are left intact. Pacing wires are routinely kept in place until after this first biopsy in the event of rejection and graft dysfunction. Provided no signs of rejection, the wires can then be removed.

Acute Complications

The acute postoperative time period is crucial in the heart–lung transplant patient as different types of complications and setbacks can occur, including technical, medical, rejection, and primary dysfunction. Technical or surgical complications are similar to those experienced in other heart and or lung operations. Bleeding, tamponade, hemothorax, etc. that result in reoperation or exploration of the transplant patient can negatively affect outcomes and can prolong hospital courses. As mentioned above in the operation section, there are particular areas to examine carefully during the implant due to their limited accessibility once the heart–lung block is in place. Examination of all sutures lines and areas of adhesions ensuring hemostasis will help prevent bleeding complications.

Acute medical complications postheart–lung transplantation typically center around fluid management. The delicate balance of fluid typically places the patient on a continuum from renal failure (too little volume) to severe pulmonary edema (too much volume). Most patients will be managed with a "dry" mentality, providing just enough fluid to maintain adequate cardiac output, tolerating a minor acute kidney injury in the process. Even if that injury progresses to acute kidney failure, given recovery time and a period of dialysis, renal function can return, provided baseline function was normal. Additionally, if a patient gets too "wet," or fluid overloaded, diuresis can help relieve the volume burden while positive pressure ventilation can maintain oxygenation in the interim.

The most feared acute complications are acute rejection and graft dysfunction. Prevention of rejection begins as the patient arrives at the hospital. As detailed earlier, patients receive initial therapy prior to the operating room. Patients also receive corticosteroids prior to reperfusion of the transplanted grafts. These treatments are done to reduce leukocyte activity reducing the possibility of a hyperacute rejection. The first assessment for rejection typically happens between posttransplant day 5 and 7, and involves biopsies of the transplanted lungs. Further antirejection medication adjustments occur following the biopsy results.

Despite these treatments, optimal preservation techniques, and short ischemic times, patients can still experience primary graft dysfunction. Studies have reported primary graft dysfunction at 10%–15% (Date et al., 1996). For transplanted hearts, this process can manifest as right heart failure or global heart failure. Supportive inotropes, or even extracorporeal membrane oxygenation (ECMO), might be necessary during the acute postoperative period. For transplanted lungs, graft dysfunction manifests as impaired oxygenation and ventilation. The patient will develop high peak pressures, indicating stiff, noncompliant, and poorly functioning lungs. Treatment typically involves delayed extubation, keeping the patient as dry as possible, and limiting ventilator trauma through oxygen and pressure. If severe enough, ECMO must be considered to support the patient in the acute postoperative period. In the case of a heart–lung transplant, graft dysfunction can manifest in one or both grafts. Mortality for primary graft failure can be as high as 60% (Christie et al., 1998). Invasive monitoring and frequent review of laboratory values, every 4–6 hours immediate to posttransplant, help to detect early signs of dysfunction.

Posttransplant Care

The major tenants of posttransplant care focus on management of immunosuppressive medication, infection prevents, and monitoring for rejection or failure of the transplanted grafts. Each institution will have specific drugs and tailored regimens, but the main principles of balancing too much suppression, leading to infections and possible malignancy, and too little suppression, leading to graft rejection, are balanced and monitored. Living near the transplant center and having regular clinic visits help in close monitoring and good outcomes. As detailed earlier, current median survival is 3.3 years, but if a patient survives the first year, the median survival jumps to 10.3 years (Yusen et al., 2016).

Infection prevention is essential to posttransplant care, and as soon as a patient is stable after surgery prophylaxis is initiated. Depending on the cytomegalovirus, or CMV, the status of the recipient and donor, ganciclovir will be prescribed. Systemic antifungal prophylaxis, such as voriconazole, may be given while in the hospital. Typically, antifungal mouthwash is prescribed to prevent oral thrush or a *Candida* infection. Another important agent to prevent is *Pneumocystis* species, for which Bactrim, or trimethoprim-sulfamethoxazole, is given.

Each institution will develop a schedule, or routine for biopsies and monitoring for rejection. Additionally, other studies such as echocardiograms, heart catheterizations, and pulmonary function tests help to track the function of the transplanted grafts. Chronic rejection takes the form of accelerated coronary artery disease in the heart and bronchiolitis obliterans in the transplanted lungs. Immunosuppression regimens can be adjusted at the first signs of rejection. Various interventions of medication may temporize the disease progression; however, the only true curative treatment is retransplant.

Introduction

Pregnancy produces a unique physiologic state that adapts to meet the hemodynamic and metabolic needs of the growing fetal-placental circulation. In this context, the maternal cardiovascular system undergoes a series of dynamic changes, culminating in an increased plasma volume, increased cardiac output (CO), and decreased systemic vascular resistance (SVR). These changes serve to ensure adequate delivery of oxygenated blood to peripheral tissues and the fetus. Maternal physiologic adaptations, coordinated by a complex neurohormonal cascade, drive structural and functional changes. Failure of the maternal cardiovascular system to appropriately adapt to the metabolic demands of pregnancy can unmask preexisting heart disease, resulting in maternal and fetal morbidity and mortality. Given that cardiovascular diseases are the number one cause of maternal mortality in the United States (Pregnancy Mortality Surveillance System | Pregnancy | Reproductive Health | CDC, 2017), a thorough understanding of the normal cardiovascular changes induced by pregnancy is necessary to diagnose and manage cardiovascular disease, or, stated simply, "normal must be known before abnormalities can be detected" (Dieckmann et al., 1934). This module will examine the hemodynamic changes in pregnancy during the growth of the fetus (antepartum), through labor (peripartum), and after delivery (postpartum).

Antepartum

The hemodynamic changes of pregnancy, characterized by an early decrease in SVR and mean arterial pressure (MAP), coupled with an increase in CO and glomerular filtration rate (GFR), begin in the embryonic period, before they are functionally necessary and prior to maturation of the utero-placental unit (Duvekot et al., 1993; Clapp et al., 1988; Robson et al., 1989). Indeed, the same changes can be seen after ovulation in nonpregnant women; during the mid-luteal phase of the menstrual cycle, women experience a decrease in SVR, with a commensurate increase in left ventricular chamber size, stroke volume, and CO (Chapman et al., 1997; Veille et al., 1986). Early initiation of these changes are mediated by several circulating hormones that increase in concentration during pregnancy, including chorionic gonadotropin, estradiol, and progesterone, all of which bind to receptors located in vascular endothelium and smooth muscle (Veille et al., 1986; Clapp and Capeless, 1997; McGill, 1989). Furthermore, animal studies suggest a role for increased nitric oxide (NO) synthesis in systemic vasodilation and reduction in vascular resistance (Deng et al., 1996).

Preload

Venous compliance and blood volume are principal determinants of preload and can be altered without direct modification of the myocardium. Dating to the early 19th century, obstetricians observed a substantial increase in circulating volume as a normal physiologic process, driven primarily through increased plasma volume and erythrocyte mass (Miller et al., 1915). These changes serve to increase the available supply of hemoglobin and other vital nutrients to the growing fetus. In fact, successful fetal growth appears to rely, in part, on appropriate expansion of plasma volume, as evidenced by the positive correlation between plasma volume and birth weight (Pirani et al., 1973).

Plasma volume increases progressively (**Fig. 1**) (Peck and Arias, 1979) from early pregnancy, peaks between 28 and 34 weeks, and then plateaus as the pregnancy approaches term (Salas et al., 2006; Metcalfe et al., 1981). The initial phase, starting in the first trimester, occurs rapidly, with only gradual volume expansion in the third trimester. A larger plasma volume is necessary to support a larger fetus or multigravida state; consequently, inadequate volume expansion is related to vascular pregnancy complications,

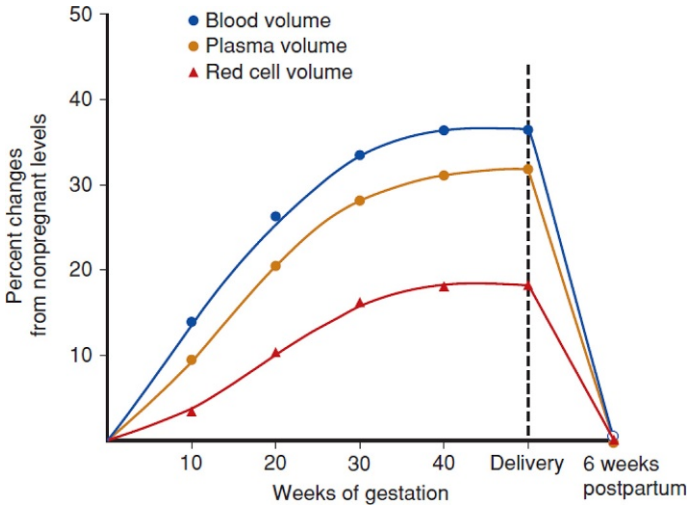

Fig. 1 Blood, plasma, and red cell volume during pregnancy. Reproduced with permission from Peck, T. M. and Arias, F. (1979). Hematologic changes associated with pregnancy. *Clinical Obstetrics and Gynecology* **22**, 785.

including intrauterine growth restriction, preeclampsia, and fetal demise (Hytten, 1986; Gallery et al., 1979). Plasma volume increases 30%–50% above nonpregnant values, with a range from 20% to 100% in individual women (Pritchard, 1965; Sanghavi and Rutherford, 2014; Paidas and Hossain, 2010). To this end, changes begin as early as week 6 of gestation, prior to full development of the fetal-placental circulation (Chapman et al., 1998), an effect related to systemic vasodilation and increased renal perfusion caused by persistence of the corpus luteum (Chapman et al., 1997; Van Beek et al., 1996). The luteal body produces the hormone relaxin at high concentrations during early gestation. Relaxin mediates increased renal perfusion, peripheral vasodilation, and plasma volume expansion via activation of the NO pathway (Deng et al., 1996; Conrad and Novak, 2004). Further, plasma volume expansion occurs between weeks 7 and 12 of the first trimester through the placental production of progesterone and estrogen, both of which have vasodilatory effects (Kristiansson and Wang, 2001; Bernstein et al., 2001). Stimulation of estrogen receptors present in the vascular endothelium exerts a direct vasodilatory effect via prostacyclin and NO synthesis (Tostes et al., 2003). The decreased effective arterial blood volume, in turn, leads to compensatory sodium retention and volume expansion through activation of the renin-angiotensin-aldosterone system (RAAS) (Salas et al., 2006; Longo, 1983). Additionally, the presence of the utero-placental circulation, which acts as an arteriovenous shunt, prompts further volume expansion. The rate of expansion peaks during the second trimester, with a slower, but continued increase until approximately week 32, after which the volume typically stabilizes until term. This increase in circulating volume causes, as would be expected, an increase in the atrial natriuretic peptide (ANP) via concomitant atrial enlargement (Chapman et al., 1998).

Along with expansion in plasma volume, erythrocyte mass (i.e., the number of circulating red blood cells) increases by 20%–30% during pregnancy (Paidas and Hossain, 2010; Longo, 1983; Means, 2013). Erythrocyte production is driven primarily by erythropoietin, which binds selectively to associated receptors on red-cell progenitors in the bone marrow. In the nonpregnant adult, erythropoietin production is promoted via sensed hypoxemia and red cell hemoglobin concentration. In order to increase red blood cell mass during pregnancy despite normoxic conditions, human placental lactogen (hPL) serves as a potent hematopoietic stimulant to drive erythrocyte production. hPL augments erythrocytosis via enhanced sensitivity to erythropoietin, increased iron incorporation, and direct effects on red-cell progenitors (Jepson and Lowenstein, 1968; Berczi and Nagy, 1991). Pregnancy-related erythrocytosis is further potentiated by progesterone, uteroferrin, and prolactin via the JAK/STAT pathways, which act in concert to prompt the differentiation, proliferation, and survival of nascent red blood cells (Watowich, 2011; Soares et al., 2007; Bazer et al., 1991). This increase in red cell mass, however, can be inhibited by conditions that limit the resources required for erythrocyte production, such as iron or copper deficiency (Rodak et al., 2007; Langston, 2015). Notably, plasma volume increases to a greater degree than red cell mass, resulting in a relative, physiologic anemia of pregnancy. This dilutional anemia typically produces a 1–2 g/dL drop in hemoglobin concentration, with hemoglobin concentration as low as 11 mg/dL considered normal (Cunningham et al., 2013). Hemoglobin levels reach a nadir in the late second trimester and subsequently stabilize until delivery.

In sum, a primary decrease in SVR, in concert with the early hormonal changes described above, prompt a 30%–50% increase in plasma volume, accompanied by a 20%–30% increase in red blood cell mass to meet the increased maternal metabolic needs of pregnancy. Despite the increased circulating volume, pulmonary capillary pressure and central venous pressure remain within the normal range (Clark et al., 1989).

Afterload

A hallmark of the hemodynamic changes of pregnancy is a decrease in SVR through vasodilation, with a commensurate decrease in blood pressure. The drop in SVR begins at approximately week 5 of pregnancy, under the influence of a persistent luteal body. This

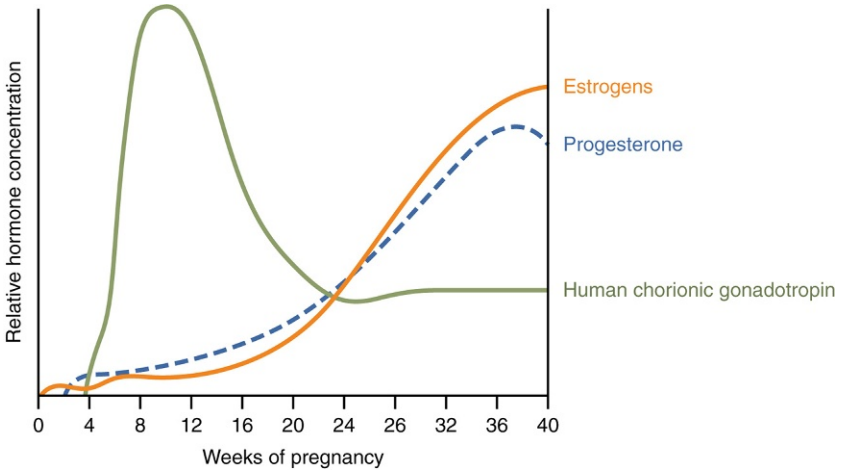

Fig. 2 Concentrations of various sex hormones throughout pregnancy. Reproduced under the Creative Commons License from OpenStax, Maternal Changes During Pregnancy, Labor, and Birth. OpenStax CNX. Jun 4, 2013 http://cnx.org/contents/f068080a-4376-4d88-a150-33e105a4cad8@3.

process continues until week 32 of pregnancy, at which time the vascular resistance normally plateaus until term. SVR decreases, in part, as a result of several circulating hormones (**Fig. 2**) (Cheung and Lafayette, 2013), including relaxin, prostacyclin, estrogen, and progesterone, which serve at various levels to increase the activity of the NO, a common final pathway in the vasodilation of pregnancy (Sladek et al., 1997).

Relaxin, produced in high levels by the corpus luteum, enacts both rapid and persistent vasodilation. The rapid, more pronounced vasodilatory response to relaxin begins with G-protein-dependent phosphorylation of nitric oxide synthase, prompting NO production and subsequent relaxation of vascular smooth muscle (Conrad and Emerging, 2011). NO stimulates cyclic guanosine monophosphate (cGMP) production, which reduces intracellular calcium concentration, thereby inhibiting smooth muscle contraction. The persistent, though less dramatic, sustained vasodilatory response to relaxin occurs by increased production of arterial gelatinases, which hydrolyze endothelin to an active form that further activates the NO pathway (Conrad, 2016). Serelaxin, a recombinant form of human relaxin-2, is currently being investigated as a potential therapeutic agent in acute heart failure, though recent phase III trial data suggests that it does not reduce cardiovascular death at six months when added to standard therapy (Tietjens and Teerlink, 2015; Novartis provides update on Phase III study of RLX030 (serelaxin) in patients with acute heart failure | Novartis, 2017).

Early studies of vascular tone in pregnancy described the role of eicosanoids in this process, including prostacyclin (PGI2), a potent vasodilator and inhibitor of platelet aggregation, and thromboxane (TXA2), a vasoconstrictor which can potentiate platelet aggregation (Myatt and Elder, 1977; Mitchell et al., 1978; Walsh, 2004). Arachidonic acid is converted to prostaglandin and thromboxane via the constitutive cyclooxygenase (COX-1) and inducible COX-2 enzymes (Fitzpatrick, 2004). Prostacyclin synthase in the vascular endothelium produces PGI2, which can then act in a paracrine manner to exert its vasodilatory effect. In the pregnant female, PGI2 production is augmented by the placenta, uterine vessels, amnion, chorion, and decidua (Walsh, 2004). As a result of the increased synthesis of PGI2 in comparison to its counterpart, TXA2, systemic vasodilation is potentiated throughout pregnancy. Alterations in the prostacyclin-thromboxane balance, particularly with decreased placental PGI2 production, have thus been implicated in the pathogenesis of preeclampsia (Weiner et al., 1989; Ylikorkala et al., 1981). Clinical trials of low-dose aspirin, an inhibitor of TXA2 synthesis, aimed at preventing preeclampsia in at risk women have yielded promising results (CLASP Collaborative Group, 1994; Sibai et al., 1993; Schiff et al., 1989), prompting the current recommendation to prescribe aspirin 81 mg for women considered to be at high risk for preeclampsia (LeFevre and U.S. Preventive Services Task Force, 2014).

Estrogen acts through several different mechanisms to cause vasodilation and subsequent volume expansion. Dehydroepiandrosterone sulfate (DHEA-S), produced by the maternal and fetal adrenal glands, is converted to estrogen in the placenta, accounting for the progressive increase in the concentration of this sex hormone during pregnancy (Manabe et al., 1999). Activation of the traditional isoforms of the estrogen receptor (ERα, ERβ), in addition to the G protein-coupled estrogen receptor (GPER), increased NO synthase activity, cGMP production, and caused vasodilation of the systemic and uterine circulation (Maliqueo et al., 2016; Tropea et al., 2015; Rosenfeld et al., 1996). Estrogen further causes vasodilation by stimulation of PGI2 synthesis via upregulation of COX-1 expression (Maliqueo et al., 2016). In a similar manner to estrogen, progesterone increases NOS activity, PGI2 production as mechanisms to promote vasodilation. Progesterone also directly decreases intracellular calcium concentrations to achieve the same effect (Maliqueo et al., 2016).

Plasma renin activity also rises considerably in pregnancy (Wilson et al., 1980). The RAAS is primarily thought to exert vasoconstrictive effects. However, during pregnancy, estrogen alters the dynamics of the RAAS, favoring its vasodilatory effects, sodium retention, and volume expansion (O'Donnell et al., 2014). Activation of angiotensin converting enzyme isoform 2 (ACE2) yields angiotensin-(1–7) (ang-(1–7)), a component of vasodilatory arm of the RAAS (Valdes et al., 2009). Ang-(1–7), via the Mas receptor, once again increases nitric oxide synthase activity and thus vasodilation (Sampaio et al., 2007). Additionally, angiotensin II acts via the angiotensin II type 2 receptor (AT2R) to promote vasodilation (Widdop et al., 2002).

The sum of these pathways is a primary reduction in SVR, which, in turn, prompts nonosmotic release of arginine vasopressin and further activation of RAAS due to a sensed decrease in effective arterial blood volume. These processes result in increased sodium and water retention, and thus, volume expansion (Schrier, 1988). In animal models, failure of these pathways is hypothesized as a potential cause of poor maternal/fetal outcomes, due to sustained systemic hypertension, preeclampsia, prevention of the normal renal vasodilation, and proteinuria (Deng et al., 1996).

Blood Pressure

The result of these changes in volume and vascular tone results in decrease in systemic blood pressure, though to a lesser degree than the significant decrease in peripheral vascular resistance (**Table 1**) (Ouzounian, 2012). This is because the effect of systemic vasodilation on blood pressure is partly ameliorated by an increase in CO. Diastolic pressure typically decreases to a greater extent (5–10 mmHg), than systolic blood pressure, (2–3 mmHg) (Head et al., 2009). Measureable mean arterial blood pressure changes begin at week 6 of pregnancy, dropping to a nadir between weeks 16 and 20. Blood pressure subsequently begins to rise again, approaching prepregnancy levels at term (Hall et al., 2011; Moutquin et al., 1985).

Heart rate

With the decreased SVR and increased circulating volume, heart rate increases throughout pregnancy in order to maintain adequate CO, reaching its peak near term. Heart rate increases up to 25% (approximately 10–20 beats per minute) above prepregnancy values, starting as early as week 5 of gestation and continuing into the late third trimester (Sanghavi and Rutherford, 2014; Mahendru et al., 2014; Rubler et al., 1977).

Stroke volume

Increases in stroke volume also begin as early as week 6 of pregnancy, reaching a peak near week 32, and remaining stable until delivery (Clapp and Capeless, 1997). The increased preload, in addition to the increased ventricular wall muscle mass, result in augmented myocardial contractility.

Cardiac Output

As early as 1932, Grollman and colleagues concluded that CO increased during pregnancy, approximately 50% above baseline levels (Grollman, 1932; Gilson et al., 1997). CO rises to a peak of greater than 6 L/min at 32 weeks, then declines slightly until term, though still to a value greater than the prepregnancy baseline (Mabie et al., 1994; Hennessy et al., 1996). The initial increase in total CO results from augmented stroke volume, with the later increase in CO occurring secondary to elevation in heart rate (**Fig. 3**) (Liu and Arany, 2014), combined with the aforementioned decrease in SVR. Notably, the difference in arterial-venous oxygen content narrows during early pregnancy, suggesting that the increase in supply, during the normal pregnancy, exceeds demand (Conrad and Novak, 2004).

CO is also position dependent, given the mass effect of the gravid uterus on the inferior vena cava (IVC) and aorta. When supine, the uterus compresses the IVC, decreasing venous return to the heart and thus reducing CO. In fact, near term (38–40 weeks), there can be an increase in CO of 25% when moving from the supine to left lateral decubitus position, with associated increase in left-ventricular end-diastolic pressure (Gilson et al., 1997; Secher et al., 1979; Kundra et al., 2012; Armstrong et al., 2011; Lange et al., 1988). Recent analysis on cardiac parameters with left lateral tilt, as assessed by magnetic resonance imaging, suggests an increase in CO, stroke volume, and end-diastolic diameters of both ventricles (Rossi et al., 2011). Additionally, there is a differential distribution of blood flow and CO during pregnancy (**Table 2**) (Ouzounian, 2012); the gravid uterus can receive 17% of total output, compared to 2% in nonpregnant states (Thaler et al., 1990; Konje et al., 2001). This may result in reduced relative output to skeletal muscle and the splanchnic bed (Palmer et al., 1992). Renal blood flow increases enough to up to 70%, with a resultant

Table 1 Circulatory changes during normal pregnancy

Table 2 Changes in regional blood flow during normal pregnancy

Organ	*Change*	*Comments*
Uterus	Increased	Increase from 50 mL/min at 10 wk to 1200 mL/min at term
Kidneys	Increased	30%–80% increase with 50% increase in GFR. Returns to nonpregnant state at term
Extremities	Increased	Flow to hands greater than flow to feet
Skin	Increased	Results in warm skin, clammy hands, nasal congestion
Liver	Unchanged	—
Brain	Unchanged	—
Breast	Increased	May cause flow murmurs

Reproduced with permission from Ouzounian, J. G. (2012). Physiologic changes during normal pregnancy and delivery. *Cardiology Clinics* **30**, 317–329.

increase in the GFR by 50% (Thornburg et al., 2000). In fact, the positional variation in CO due to aortocaval compression makes it such that maternal resuscitation is more effective if the mother is in the left lateral position (Tan and Tan, 2013).

Anatomic Changes and Echocardiography

The noted changes in plasma volume, vascular resistance, and CO result in distinctive cardiac remodeling during normal pregnancy. As volume expands during pregnancy, all the four cardiac chambers increase in size to accommodate this physiologic state (Liu and Arany, 2014). The relative impact of this volume is greater on the right, with an up to 20% increase in right atrial and ventricular sizes, compared to an approximate increase of 10% in the left-sided chambers (Ain et al., 2012). This chamber dilation also results in dilation of the valve annulus, causing clinically insignificant tricuspid or mitral valve regurgitation in up to a third of pregnant women. Ventricular remodeling may occur, along with other anatomic changes to the heart as a result of the loading conditions. As a result of increased wall stress, eccentric hypertrophy occurs, resulting in progressive increase in left ventricular mass of, peaking at 15%–25% above prepregnancy levels at term (Robson et al., 1989; Geva et al., 1997; Simmons et al., 2002). Left ventricular end-diastolic dimension also increases, without a significant change in ventricular filling pressure, pulmonary artery pressure, or pulmonary capillary wedge pressure, as noted by both echocardiography and cardiac catheterization (Clark et al., 1989; Bader et al., 1955; Estensen et al., 2013). Notably, cardiac remodeling during pregnancy appears similar to the changes seen in athletes (Simmons et al., 2002). These physiologic changes to the structure of the heart are typically well tolerated, without significant morbidity, mortality, or long-term negative effects on cardiac function (Li et al., 2012).

Echocardiography reveals no significant change in ejection fraction during normal pregnancy (Katz et al., 1978), though the elevated CO can be noted via Doppler echocardiography (Vered et al., 1991). Additionally, as pregnancy progresses, functional multivalvular regurgitation may be noted in a majority of women due to the aforementioned annular dilatation. Reflecting relatively greater increase in right-sided chamber size, physiologic valvular regurgitation of the tricuspid and pulmonic valves is noted more frequently than mitral regurgitation (Campos et al., 1993). Aortic regurgitation is not a normal finding in pregnancy (Campos et al., 1993; Dennis, 2011). Finally, a trace to small pericardial effusion may be noted in up to 40% of pregnant women, typically resolving after delivery (Haiat and Halphen, 1984; Ristic et al., 2003). In twin pregnancies, these changes are more pronounced, with a particular increase in heart rate, CO, and atrial size (Robson et al., 1987a). New research with speckle-tracking will provide further insights regarding the noninvasive evaluation of maternal cardiac function during pregnancy (Cong et al., 2015).

Electrocardiogram

These anatomic changes, in combination with the expansion of the gravid uterus and elevation of the diaphragm, result in anterior and leftward displacement of the heart, which prompts changes on the electrocardiogram (Vårtun et al., 2015). The culmination of the various cardiovascular changes of pregnancy can yield an increased sinus rate, left axis deviation, nonspecific ST-T changes, T-wave inversion, and increased atrial/ventricular ectopy (Wenger et al., 1964; Schwartz and Schamroth, 1979; Carruth et al., 1981). Additionally, there is an increase in the prevalence of supraventricular tachyarrhythmias, potentially driven by physiologic atrial enlargement (Adamson and Nelson-Piercy, 2007).

Physical Exam

The physical examination in pregnancy reflects the physiologic state of hypervolemia, with its associated changes in CO, chamber size, and blood pressure. Resulting from the increased circulating volume, we see increases in the level of jugular venous pulsation and a systolic flow murmur (often along the left sternal border). Pedal edema is often present, caused by elevated hydrostatic pressure in the venous system and a relative decrease in albumin concentration. Changes in the cardiac chambers can result in a loud first heart sound (S1), a split second heart sound (S2), and even a third heart sound (S3), in addition to a laterally displaced point of maximal impulse. Furthermore, with the aforementioned increase in annular diameter, systolic murmurs associated with valvular regurgitation are common. Coincident with this hyperdynamic state, tachycardia and bounding peripheral pulses can also be noted (Goodlin et al., 1983). With increased blood flow to peripheral tissues, nasal congestion may be noted and the extremities can be warm and erythematous. Consequently, mammary blood flow also increases, causing superficial vasodilation and a continuous murmur known as the mammary souffle (Tabatznik et al., 1960).

Delivery/Postpartum

The hemodynamic changes of pregnancy serve to provide adequate supply of oxygen and nutrients for the mother and maturing fetus. At delivery, these changes are further augmented by the uterine contractions, driven by increased sympathetic tone, and mobilization of extravascular tissue. These events result in elevated heart rate, higher stroke volume, and thus increased CO, both at baseline and during contractions. In the first stage, CO can increase up to 15%, with an additional 50% increase in the second stage of labor. Consequently, blood pressure also rises transiently during this time (Robson et al., 1987b). CO peaks immediately postdelivery, due to autotransfusion from the placenta and relief of aortocaval compression, resulting in a significantly increased venous return. Within 1 h of delivery, however, CO returns to prelabor levels via reduction in heart rate, stroke volume, and blood pressure (Soma-Pillay et al., 2016). The return to prepregnancy hemodynamics, however, takes more time (Ruys et al., 2013). CO begins to drop further in the first 24 h, returning to baseline at 6–8 weeks postdelivery. Notably, ANP and brain natriuretic peptide (BNP), both elevated as a result of the elevated circulating volume of pregnancy, help mediate postpartum diuresis and a return to prepregnancy volume status by 6 weeks postpartum (Peck and Arias, 1979; Ouzounian, 2012). Vascular resistance and blood pressure require up to 12 weeks to return to normal, and cardiac chamber size by echo can be enlarged for up to 24 weeks. Notably, our recent research suggests that these changes in heart structure and function may not revert completely to prepregnancy homeostasis, may accumulate with each successive pregnancy, and be detectable in midlife on cardiac MRI (Parikh et al., 2012).

However, these changes may persist beyond a year and are potentiated by subsequent pregnancies (Clapp and Capeless, 1997). Given the complex hemodynamic and anatomic effects of pregnancy on the cardiovascular system, clinical history, physical examination, and diagnostic testing must be considered with these changes in mind.

Introduction

Historically relegated the "underdog" ventricle, a status perhaps bolstered by seminal work in the 1940s and 1950s supporting cardiac output preservation even in the face of complete right ventricular cauterization (Kagan, 1952; Starr et al., 1943), the right ventricle (RV), and right heart, has leapt in repute and respect as it has humbled us with its importance in functional capacity and prognosis in congenital heart disease, pulmonary arterial hypertension, myocardial infarction, and heart failure (D'Alonzo et al., 1991; Di Salvo et al., 1995; Gavazzi et al., 1997; Ghio et al., 2001). In this article, we summarize salient features of RV anatomy and physiology, review important hemodynamic concepts of the right heart in health and apply these concepts in major disease states, and review right heart hemodynamic assessment by both invasive and noninvasive approaches.

RV Anatomy

Located immediately behind the sternum and most anteriorly situated, the RV is demarcated by the tricuspid valve and pulmonary valves. The RV can be divided into tripartite components: (1) inlet (tricuspid valve, chordae tendineae, and papillary muscles); (2) apical trabeculated myocardium; and (3) smooth outlet region. This classification approach lends itself clinically relevant particularly in congenital heart disease where one or more of the components may be absent (Goor and Lillehei, 1975; Ho and Nihoyannopoulos, 2006). Hallmark differences between the left ventricle (LV) and RV are shown in **Table 1**. Importantly, the RV myocardial two-layer fiber orientation dictates its contraction pattern; the outer circumferential fibers contribute toward inward movement compared to the longitudinal fibers at the endocardial level promoting longitudinal motion. This longitudinal shortening of the RV myocytes at the endocardial level lends insight into why longitudinal measures of RV systolic function, particularly via echocardiography, are robust in RV function assessment.

Normal Right Heart Hemodynamic Concepts

RV Preload

The primary function of the right heart, specifically RV, is to receive all the blood returning from the periphery (venous return) and to pump into the pulmonary circulation with the rate of venous return dictated by peripheral resistance. Due to the low-pressure, highly

Table 1 Key differentiating features of RV compared to LV

Embryologic	Second heart field (RV, portions of atria, outflow tract, interatrial septum, cardiac conduction system) First heart field (LV, atrioventricular canal, portions of atria)
Myocyte fiber orientation	RV—2 layers (outer – oblique/circumferential, inner – longitudinal) LV—3 layers (outer – oblique, middle – circumferential, inner – longitudinal)
Morphologic differences	(1) Hinge point of septal leaflet is more apical in relation to anterior mitral valve leaflet (2) Greater than 2 papillary muscles (3) Coarse apical trabeculations (4) Presence of moderator band in RV (5) Trileaflet configuration of tricuspid valve with septal papillary attachments
Shape	Triangular when viewed from side; crescent-shaped in cross-section
Size	RV mass is 1/6th of LV; slightly larger end-diastolic volume than LV; thinner than LV
Perfusion	Infundibulum and anterior RV receive more constant arterial supply (conal artery) from right coronary artery; coronary artery dominance impacts vascularization of inferior/diaphragmatic wall and inferior septum; left coronary artery supplies the free wall of the RV adjacent to the anterior portion of septum and apical RV

compliant pulmonary circuit the RV pumps the same stroke volume of the LV but at one-fourth of the stroke work (Anastasiadis, 2015). Hemodynamic studies by Pinky and colleagues (Pinsky, 2014) evaluating the effect of positive end-expiratory pressure on RV function showed that RA transmural pressure (or RV filling pressure) has no relationship on RV end-diastolic volume, supporting the concept that the RV operates under its unstressed volume; thus RA pressure should not be equated to RV preload (Pinsky, 2014; Tyberg et al., 1986). A clinically important fact, RA pressure should be not used to predict volume responsiveness (Shippy et al., 1984) but can help predict impending RV failure when ongoing fluid resuscitation results in no cardiac output increase and an abrupt increase in RA pressure is seen (Jardin et al., 1985). A corollary finding is if RV volume does impact RA pressure it is in the setting of an abnormal RV (RV hypertrophy, RV diastolic dysfunction, or RV over-distension) (Pinsky, 2014).

RV Afterload

While the right and left ventricles circulate the same blood volume, the pulmonary circulation is notably one of low-resistance, only one-sixth of the systemic circulation, and utilizes one-fifth of energy of the left ventricle (Lammers et al., 2012). This high-flow, low-pressure system of the right heart requires efficient ventricular-vascular coupling. In its purest sense, RV afterload is the RV wall stress that occurs during RV ejection. With its small ventricular radius and constant wall thickness during ejection, the largest contributor to RV wall stress is the RV pressure during ejection. However, the RV pressure during ejection is complex and composed of four main components: (1) resistance to blood flow during steady state; (2) compliance (the blood storage capacity of the pulmonary system); (3) arterial wave reflections that occur as a result of pulsatile blood flow; and (4) blood inertance during RV ejection (Tedford, 2014). The most comprehensive method for RV vascular load assessment, taking into account all four components, is pulmonary artery input impedance (with application of Fourier transformation which separated pressure and flow signals into their respective sums of harmonic oscillations) classically described in 1965 (Milnor et al., 1969). However, pulmonary impedance is both difficult to measure and interpret; simpler models, such as the 3-element Windkessel models, (extending original work in a two-element model by Frank (1899)) have been applied to the arterial circulation. The three-element model, resistance, capacitance, and impedance, is a lumped model of the entire systemic arterial tree to define the total load on the heart (Westerhof et al., 2010). In physiologic terms, resistance (due to dependence on vessel diameter) is quantified by small arteries, arterioles, and capillaries as the pulmonary vascular resistance (PVR)—a static, steady-state resistance. Compliance, representing the storage capacity of all arteries and arterioles with the largest contribution usually from the proximal elastic conduit arteries, takes into consideration the pulsatile load in the system. However, in the pulmonary tree, the total compliance is distributed throughout the arterial tree with the main, right, and left PA only contributing to 15%–20% of the pulmonary compliance (Saouti et al., 2009). Characteristic impedance (Z_c) of the proximal pulmonary artery accounts for the fact that blood must be accelerated in early ejection and into a compliant artery; thus blood mass, pulmonary artery diameter, and wave speed components are utilized (Tedford, 2014; Westerhof et al., 2010; Saouti et al., 2010).

Relationship of RV to Load

The heart pumps at near maximal efficiency and maximal power. Whether it maintains at this operational level depends on both its cardiac and arterial state, that is, ventriculo-arterial coupling. The RV adapts to increased vascular load by enhancing "coupling" to maintain flow (Vonk Noordegraaf et al., 2017). This coupling concept is best depicted by constructing RV pressure-volume (P-V) loops for a single cardiac cycle with the four sides of the loop denoting: (1) isovolumetric contraction; (2) ejection; (3) isovolumetric relaxation; (4) filling. The loop demarcates boundaries on the end-systolic pressure-volume relationship (ESPVR) and end-diastolic pressure–volume relationship (EDPVR). Relatively linear, ESPVR slope is *RV* end-systolic elastance (E_{es}) which represents RV contractility (muscular properties and muscle hypertrophy) with the intercept volume-axis V_o. The *pulmonary* arterial elastance (E_a), generated at the end-diastolic volume axis extending to the intersection of the ESPVR at the end-systolic pressure–volume point

of the RV P-V loop, represents RV afterload (often simplistically, PVR). EDPVR, a nonlinear parameter, represents diastolic properties and can characterize two characteristics: (1) diastolic stiffness (represented by the change in pressure divided by the change in volume on any given point on the EDPVR curve); (2) ventricular capacitance (the ventricular volume at any given pressure) (Vonk Noordegraaf et al., 2017; Burkhoff et al., 2015). Ventriculo-arterial coupling can be defined as the ratio of RV elastance to pulmonary elastance (E_{es}/E_a). RV mechanical work and oxygen consumption is most optimal when this ratio is between 0.5 and 2.0 (Burkhoff and Sagawa, 1986; Sunagawa et al., 1985; Kuehne et al., 2004; Sagawa, 1988). **Fig. 1** depicts a normal RV P-V loop with changes in E_a and E_{es} with changes in afterload, preload, and RV contractility.

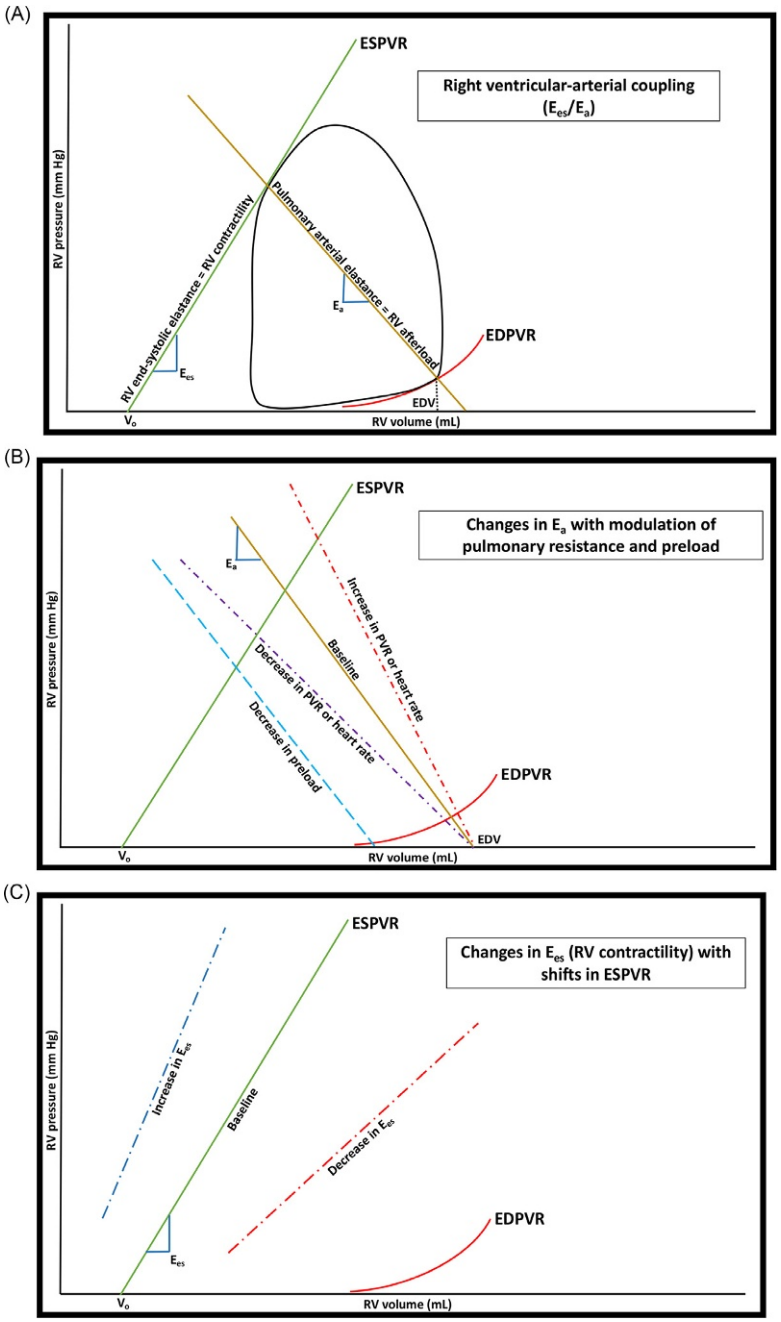

Fig. 1 Overview of pressure-volume loops and RV-arterial coupling. (A) Normal pressure-volume loop depicting ESPVR, EDPVR, E_a, and E_{es}. Right ventricular-arterial coupling relationship is E_{es}/E_a. (B) E_a slope is altered with changes in resistance and volume; ESPVR and EDPVR are static assuming no other changes are occurring with the heart. (C) Changes in contractility of RV are reflected with ESPVR shifts; leftward-upward with increase in contractility; downward-rightward with decrease in contractility. Modified from Burkhoff, D., Sayer, G., Doshi, D., Uriel, N. (2015). Hemodynamics of mechanical circulatory support. *Journal of the American College of Cardiology* 66, 2663–2674, with permission from Elsevier.

Pressure Proportionality in the Right Heart

Compared to the 50% increase in systemic vascular resistance in hypertension, PVR may increase by a factor of 4 or more in the pulmonary circuit (Handoko et al., 2016; London et al., 1987). Accordingly, the pulmonary arterial pressure will increase and interestingly (and likely underappreciated), the pulmonary arterial (PA) systolic and diastolic pressures are proportional to the mean pulmonary pressures (Chemla et al., 2004; Syyed et al., 2008) even across a wide range of increased PVRs with and without elevated pulmonary capillary wedge pressure (PCWP) (Handoko et al., 2016). Reliable calculations of mean and diastolic pressures estimated from invasive or echocardiography-derived PA systolic pressures (sPAP) are as follows: diastolic pulmonary pressure (dPAP) = 0.36 × sPAP; mean PAP (mPAP) = 0.61 × sPAP; pulmonary pulse pressure (PP) = 0.6 × sPAP (Handoko et al., 2016).

Resistance and Compliance: An Inverse Relationship in the Pulmonary Circuit

The source of compliance is a major difference between the pulmonary and systemic arterial systems. Compliance in the pulmonary system is distributed over the entire arterial system (which is dependent on the number of peripheral vessels which is ~8-10 times more compared to the systemic arterial system where 80% of compliance is located in the thoracic-abdominal aorta) (Kind et al., 2011). Due to this difference, pulmonary resistance and compliance pulmonary resistance and compliance are inextricably related in the pulmonary system. Originally described in 1971 (Reuben, 1971), the hyperbolic relationship between PVR and pulmonary compliance has been further studied in pulmonary hypertension (PAH) and chronic thromboembolic pulmonary hypertension (CTEPH) (Saouti et al., 2009; Lankhaar et al., 2008; Lankhaar et al., 2006). In addition, the impact of elevated PCWP shifts this hyperbolic relationship downward-leftward; thus, elevated filling pressures may augment pulmonary pulsatile load leading to lower compliance for any given PVR (Tedford et al., 2012). **Fig. 2** depicts this hyperbolic relationship between PVR and pulmonary compliance.

Ventricular Interdependence

The impact of size, shape, and compliance of one ventricle on the performance of the other ventricle via mechanical interactions is called interventricular dependence (Feneley et al., 1985), a critical concept in the pathophysiology of right heart dysfunction. Three main components contribute to ventricular interdependence: (1) the interventricular septum; (2) the pericardium; (3) the muscular fiber continuity between the RV and LV; the contribution of each of this components varies by phase in cardiac cycle. Unquestionably, diastolic ventricular interaction is paramount; seminal hemodynamic studies have shown that increasing RV volume shifts the LV EDPVR upward and leftward (i.e., less compliance) and reciprocally, as LV volume increases, a similar upward-leftward of the EDPVR curve is seen in the RV. This relationship was similarly shown with independent loading of a ventricle (with a fixed volume) resulting in similar upward-leftward shift of the EDPVR of the contralateral ventricle (Bemis et al., 1974; Elzinga et al., 1974;

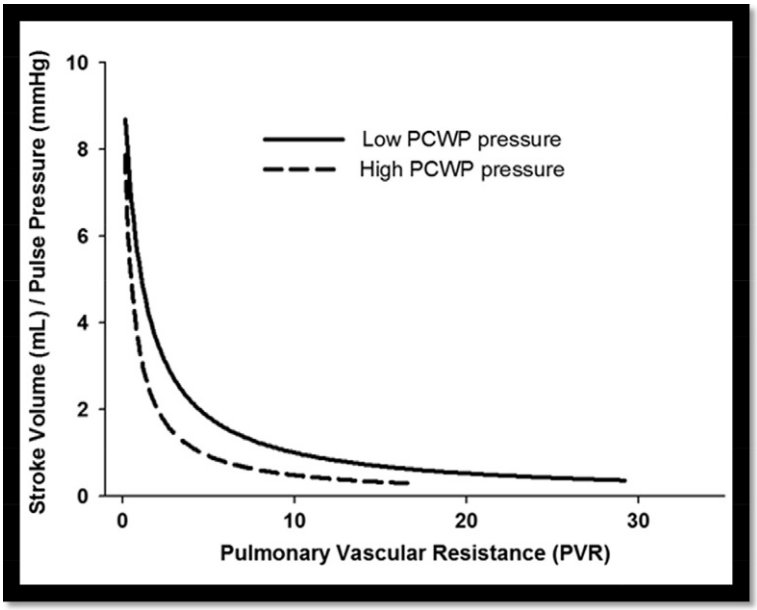

Fig. 2 Hyperbolic relationship between pulmonary vascular resistance and pulmonary compliance (represented by stroke volume/pulse pressure) with interaction with left ventricular filling pressures (represented by PCWP). *PCWP*, pulmonary capillary wedge pressure. Adopted from Tedford, R. J. (2014). Determinants of right ventricular afterload (2013 Grover Conference series). *Pulmonary Circulation* 4, 211–219.

Laks et al., 1967; Santamore et al., 1976; Taylor et al., 1967). These have significant clinical consequences: decreased distensibility (with the shift of the EDPVR upward-leftward), LV preload decline, increase in LV end-diastolic pressure, and lowering of cardiac output (Haddad et al., 2008a). Impaired LV filling can be related to: (1) parallel interaction—leftward bowing of the septum into the LV or (2) series interaction—decreased LV filling due to lower RV stroke volume (Gan et al., 2006). The septum and pericardium are both important in diastolic ventricular interdependence and the presence of the pericardium enhances the proportion of mechanical contribution of the septum to ventricular interdependence (Slinker and Glantz, 1986). However, the pericardium may be less vital in systolic interdependence (Feneley et al., 1985; Santamore and Dell'Italia, 1998). The interventricular septum mediates the major contribution to systolic interdependence; animal studies show LV contraction contributes to 20%–40% of the RV systolic pressure and volume outflow (Santamore and Dell'Italia, 1998; Damiano et al., 1991) and without RV dilation, the septum can maintain circulatory stability even in the setting of an inert RV patch or RV scarring (Hoffman et al., 1994).

Invasive Right Heart Hemodynamic Assessment

Invasive measurements via Swan-Ganz catheterization continue to be the mainstay in assessment of right heart hemodynamics in clinical practice. Variables of interest with normal ranges are displayed in **Table 2**.

Definitions of Pulmonary Hypertension

Pulmonary hypertension (PH) is defined as a mPAP $\geq$ 25 mmHg at rest (Hoeper et al., 2013). PH can be divided into two main subtypes: (1) precapillary PH (mPAP $\geq$ 25 mmHg and PCWP $\leq$ 15 mmHg); and (2) postcapillary PH (mPAP $\geq$ 25 mmHg and PCWP $\geq$ 15 mmHg (Hoeper et al., 2013; Galie et al., 2016). Precapillary PH includes the clinical groups pulmonary arterial hypertension (PAH) (precapillary PH criteria in addition to PVR > 3 WU in the absence of other etiologies), PH due to lung disease, chronic thromboembolic PH, and PH due to other/multifactorial mechanisms. Postcapillary PH includes PH secondary to left heart disease and PH due to other/multifactorial mechanisms (Galie et al., 2016). Pulmonary vascular resistance (PVR) is calculated taking mPAP-PCWP/cardiac output. PVR > 3 WU is part of the hemodynamic definition for PAH (McLaughlin et al., 2009). Importantly, patients with left heart disease can have additional classification by evaluating the trans-pulmonary gradient (TPG) or diastolic pressure gradient (DPG). TPG, the difference between mPAP-PCWP, has been used to define "passive" PH (TPG < 12 mmHg) vs. "reactive" PH (TPG $\geq$ 12 mmHg) (Galie et al., 2009). Some studies have proposed that TPG is influenced by mechanisms that impact mPAP including resistance, cardiac output, compliance, and left heart filling pressures (Naeije et al., 2013; Provencher et al., 2008; Vachiery et al., 2013) and advise the use of the DPG (end-diastolic pressure (dPAP)—PCWP) to determine pulmonary vascular disease (Naeije et al., 2013; Provencher et al., 2008). In most patients, the DPG lies between 1 and 3 mmHg, and even with patients with left heart disease (excluding shunts) the DPG $\leq$ 5 mmHg (Naeije et al., 2013; Vachiery et al., 2013). A DPG < 7 mmHg (and/or PVR $\leq$ 3 WU) can be classified as isolated postcapillary PH compared to combined post- and precapillary PH is defined with a DPG $\geq$ 7 mmHg (and/or PVR $\geq$ 3 WU) (Galie et al., 2016). Recently, Handoko and colleagues (Handoko et al., 2016) conducted an elegant hemodynamic study with 1054 patients comprised of patients without PH, patients with elevated mPAP and low PCWP, and patients with elevated mPAP and elevated PCWP. The conclusions of this study implied that dPAP and mPAP depend equally on PCWP (with PCWP between 1 and 31 mmHg) and both depend similarly on CO, and

Table 2 Normal right heart catheterization hemodynamics

Right atrium (RAP)	
Mean pressure	0–6 mmHg
Right ventricle (RV)	
Peak-systolic pressure	18–24 mmHg
End-diastolic pressure	0–6 mmHg
Pulmonary artery	
Mean pressure (mPAP)	11–20 mmHg
Peak-systolic pressure (sPAP)	18–28 mmHg
End-diastolic pressure (dPAP)	6–15 mmHg
Pulmonary capillary wedge pressure (PCWP)	
Mean pressure	8–12 mmHg
Resistance [(mPAP-PCWP)/cardiac output)]	
Pulmonary vascular resistance	<2 WU (40–160 dynes*s/cm^5)
Cardiac index (cardiac output/BSA)	2.8–4.2 L/min/m^2
Trans-pulmonary gradient (mPAP-PCWP)	<12 mmHg
Diastolic pressure gradient (DPG)	1–3 mmHg
RV stroke work index (RVSWI)	580–735 mmHg $\times$ mL/m^2
Pulmonary compliance (PAC)	3.8–12 mL/mmHg
Pulmonary artery pulsatility index (PAPi)	>1.85

there were no significant advantages to using DPG vs TPG (Handoko et al., 2016). At this time, however, there is still insufficient data in determining the best variable to predict outcomes in PH with left heart disease.

Hemodynamic Approach for Assessment of RV Performance

The utilization of several hemodynamic parameters is helpful in assessing right heart function and performance. Noninvasive cardiac imaging, particularly echocardiography and cardiac magnetic resonance imaging, have a critical role in assessment of RV performance via structural information of right heart volumes, contraction and motion, myocardial disease, in addition to hemodynamic assessments that can be applied in a more frequent manner for clinical monitoring. However, the gold standard assessment for measuring absolute intracavitary pressures still lies in the invasive assessment, particularly when guiding more advanced therapies in right heart management. It must be acknowledged that noninvasive hemodynamic evaluations that can target the hemodynamic parameters listed below are either currently available or being developed and while may prognosticate, are beyond the scope of this review. We will reserve the majority of our description of the RV performance assessment to an invasive assessment but will include essential noninvasive measurements that aid in this evaluation. Much of our evaluation of RV performance has been gleaned from the mechanical support literature, particularly with studies evaluating RV failure post left ventricular assist device (LVAD) implantation and determining risk factors/predictors for poor RV outcomes. No single parameter has been absolutely consistent across studies, but important parameters are highlighted below.

RA Pressure

An elevated right atrial pressure can herald significant RV dysfunction. RA pressures >15 mmHg are predictive of RV failure in the mechanical circulatory support (MCS) literature (Atluri et al., 2013; Dang et al., 2006). An elevated RAP/PCWP ratio (greater than 0.63) has been shown to be predictive of RV failure in patients receiving LVAD (Kormos et al., 2010).

RV Stroke Work Index

RV stroke work index (RVSWI) provides a quantitative measure of the ability of the RV to generate pressure and flow incorporating both hemodynamics and right ventricular function and serves as a measure of RV contractility. The calculation for the formula is as follows:

$$\text{RVSWI}\ \left(\text{mmHg}\times\text{mL/m}^2\right)=\left[\text{mPAP}\ \left(\text{mmHg}\right)-\text{RAP}\ \left(\text{mmHg}\right)\right]\times\text{SV}\ \left(\text{mL}\right)/\text{BSA}\ \left(\text{m}^2\right)$$

To convert to g/m^2/beat multiply by the density of mercury factor of 0.0136 to the equation. *SV*, stroke volume; *BSA*, body surface area.

Several studies have shown that RVSWI can predict mortality and length of hospitalization following lung transplantation (Armstrong et al., 2013), predict right ventricular failure prompting RV assist device post-LVAD implantation (Fitzpatrick et al., 2008), and predict duration of inotropic therapy for RV failure post-MCS therapy (Schenk et al., 2006). RVSWI < 300–600 mmHg × mL/m^2 (Starr et al., 1943) generally portends worse RV performance (Ochiai et al., 2002).

Pulmonary Compliance

Pulmonary compliance (PAC) is an attribute in the pulmonary system that, in simple terms, can be defined as a change in lumen area for a given change in pressure. Compliance calculation allows the characterization of all the pulmonary vasculature to accommodate blood in systole and release in diastole and is a measure of arterial distensibility. Calculation of pulmonary compliance via hemodynamic measurements using stroke volume and pulmonary pulse pressure has been validated (Lankhaar et al., 2006; Stergiopulos et al., 1999; Stergiopulos et al., 1995) with prognosis in HF (Dupont et al., 2012). Calculation of pulmonary compliance allows calculation of the pulsatile load (in addition to resistive load) contribution to afterload in the pulmonary circulation (Ghio et al., 2015). Pulmonary compliance, thus, can be defined with the following formula:

$$\text{PAC}\ \left(\text{mL/mmHg}\right)=\text{SV}\ \left(\text{mL}\right)/\text{pulmonary artery pulse pressure}\ \left(\text{mmHg}\right)$$

Pulmonary artery pulse pressure = sPAP (mmHg) − dPAP (mmHg)

Pulmonary Vascular Resistance

PVR, a major component of RV afterload, contributes significantly to RV dysfunction and has been shown to be a powerful predictor of RV failure early postoperative following LVAD implantation with increasing weight with increasing quartile of PVR (Drakos et al., 2010). Calculation of PVR is as follows:

$$\text{PVR}\ \left(\text{Wood's unit}\right)=\left[\text{mPAP}\ \left(\text{mmHg}\right)-\text{PCWP}\ \left(\text{mmHg}\right)\right]/\text{CO}\ \left(\text{L/min}\right)$$

To convert to dynes*s/cm^5, multiple above equation by 80.

Pulmonary Artery and Ventricular Elastance (Right Heart Ventriculo-Arterial Coupling)

Ventriculo-arterial coupling quantification usually requires complex invasive measurements with specialized, conductance catheters and varying loading conditions which often precludes its application in clinical practice (Sunagawa et al., 1985; Chantler et al., 2008; Sanz et al., 2012). Single-beat methods have been described and validated by multiple studies with the following derived equations (Sunagawa et al., 1985; Chantler et al., 2008; Sanz et al., 2012).

$$\text{RV elastance} = E_{es}\ (\text{mmHg/mL/m}^2) = \text{mPAP}\ (\text{mmHg})/\text{end} - \text{systolic volume}\ (\text{mL})^*$$
$$\text{Pulmonary arterial elastance}\ (\text{mmHg/mL/m}^2) = E_a = [\text{mPAP}\ (\text{mmHg}) - \text{PCWP}\ (\text{mmHg})]/\text{stroke volume}\ (\text{mL})^*$$
$$\text{Ventriculo} - \text{arterial coupling} = E_{es}/E_a$$

With borderline pulmonary hypertension, end-systolic pressure (numerator in elastance equation) is best estimated using sPAP instead of mPAP (Vanderpool et al., 2015).

Pulmonary Artery Pulsatility Index

Pulmonary artery pulsatility index (PAPi) is a novel hemodynamic index described by Kapur et al. (Korabathina et al., 2012) as a tool to predict RV dysfunction and need for RV support following acute myocardial infarction. PAPi also predicted RV failure and need for RV support after LVAD implantation (Kang et al., 2016; Morine et al., 2016). PAPi has not been studied in other populations of RV failure and requires additional study for generalizability.

$$\text{PAPi} = [\text{sPAP}\ (\text{mmHg}) - \text{dPAP}\ (\text{mmHg})]/\text{RAP}\ (\text{mmHg})$$

Structural/Functional Considerations by Noninvasive Evaluation

From an imaging perspective, a comprehensive RV assessment for structure and function should include the following parameters: (1) RV shape and architecture; (2) RV volume; (3) RV hypertrophy and mass; (4) RV contractility; (5) ventricular interdependence. Echocardiography remains the first-line imaging modality for RV assessment, particularly due to its versatility and accessibility. Cardiac magnetic resonance imaging (CMR) has been becoming more utilized as an informative and vital tool in RV evaluation. RV volume is most accurately characterized by CMR. Ideally, a contractility index would be a parameter independent of loading conditions, sensitive to inotropic conditions, independent of cardiac size and mass, and with clinical utility (Carabello, 2002). Several indices of RV contractility have been applied widely; however, many do not meet these ideal conditions and may be imperfect in reflecting contractility. Lastly, assessment of ventricular interdependence can be evaluated by the flattening of the interventricular septum (D-shaped left ventricle) during the cardiac cycle. RV volume overload is present if the septal flattening is evident only during diastole; flattening throughout the cardiac cycle with prominence in end systole heralds RV pressure overload. Selected parameters of RV structure, volume, contractility, and interventricular dependence with normal values are shown in **Table 3**.

Right Heart Hemodynamics in Disease States

RV adaptation to disease and pathology is complex and is dependent on a multitude of factors. The most three most vital factors include: (1) the type and severity of right heart injury or stress; (2) time course (acute vs. chronic); (3) time of onset of the disease (newborn, pediatric, or adult years) (Haddad et al., 2008b). RV ventricular failure has been defined as a complex clinical syndrome (with cardinal symptoms including exercise limitations and fluid retention) as a consequence of the RV's inability to maintain flow output to match metabolic needs and consequent increase in right heart filling pressures (Naeije and Manes, 2014; Vonk-Noordegraaf et al., 2013). Most pathophysiologic states that contribute to RV failure include pressure overload, volume overload, combination of pressure-volume overload, and intrinsic RV failure in the absence of pulmonary hypertension (e.g., myocardial infarction). **Table 4** reviews mechanisms and specific causes of right heart failure.

Pressure Overload

When the RV is faced with a sudden increase in afterload, cardiac output is preserved via two proposed mechanisms: (1) increase in RV end-diastolic volume via Starling's law of the heart can be applied to beat-to-beat changes in preload and afterload; and (2) a homeometric contractile adaptation described by Anrep's law of the heart (de Vroomen et al., 2000; von Anrep, 1912). In the setting of chronic pulmonary hypertension, the highest wall stress initially is believed to develop in the pulmonary infundibulum, the RV region that develops the earliest evidence of hypertrophy (Naeije and Manes, 2014). Over time, infundibular hypertrophy with normal RA pressures extends to generalized RV hypertrophy with sustained elevated RA pressures with eventual progression to RV dilation similar to end-stage LV failure (Pinsky, 2016). The transition point from adaptive compensatory remodeling (concentric hypertrophy with preservation of systolic and diastolic function, preserved E_{es}/E_a coupling) to maladaptive remodeling resulting in decrease in contractility, eccentric hypertrophy, with dilation is not completely understood but likely the result of mismatch in

Table 3 Selected parameters of RV structure, volume, interventricular dependence, and contractility

Characteristic	*Criteria*	*Significance*
RV volume	>101 mL/m^2 (CMR)	Volume overloaded
RV mass	>32 g/m^2 in females (CMR)	Pressure overloaded—concentric hypertrophy
	>36 g/m^2 in males (Maceira et al., 2006) (CMR)	Volume overloaded—eccentric hypertrophy
	RV wall thickness >5 mm (Lang et al., 2015) (TTE)	
Ventricular interdependence-D-shaped LV	Eccentricity index >1 (Ryan et al., 1985)	RV pressure or volume overload
		Diastolic D-shaped LV supports volume overload; systolic D-shaped LV supports pressure overload
TAPSE	<1.7 cm (Lang et al., 2015)	Decreased contractility/systolic function
		Prognostic value
RVEF	$<61\pm7\%$ (48%–74%) (Maceira et al., 2006) (CMR)	Decreased contractility
RV myocardial performance index	>0.54 (via tissue Doppler) (Lang et al., 2015) (TTE)	Decreased RV global function
		Prognostic value
	>0.43 (via pulse-wave) (TTE)	

CMR, cardiac magnetic resonance; *TTE*, transthoracic echocardiography.

Table 4 Mechanisms and specific causes of right heart failure

Pressure overload
Left-sided heart failure (most common cause)
Pulmonary embolism (common)
Other causes of PH
RV outflow tract obstruction
Peripheral pulmonary stenosis
Double-chambered RV
Systemic RV
Volume overload
Tricuspid regurgitation
Pulmonary regurgitation
Atrial septal defect
Anomalous pulmonary venous return
Sinus of Valsalva rupture into RA
Coronary artery fistula to RA or RV
Carcinoid syndrome
Rheumatic valvulitis
Ischemia and infarction
RV myocardial infarction
Ischemia contributing to RV dysfunction in congenital heart disease and RV overload states (particularly pressure overload)
Intrinsic myocardial process
Cardiomyopathy and heart failure
Arrhythmogenic RV dysplasia
Sepsis
Inflow limitation
Tricuspid stenosis
Superior vena cava stenosis
Complex congenital defect
Ebstein's anomaly
Tetralogy of Fallot
Transposition of the great arteries
Double-outlet RV with mitral atresia
Pericardial disease
Constrictive pericarditis

RA, right atrium; *RV*, right ventricle; *PH*, pulmonary hypertension.

Reproduced from Haddad, F., Doyle, R., Murphy, D. J., Hunt, S. A. (2008). Right ventricular function in cardiovascular disease, part II: Pathophysiology, clinical importance, and management of right ventricular failure. Circulation 117, 1717–1731. With permission from Wolters Kluwer Health, Inc.

myocardial oxygen demand and perfusion, oxidative stress, inflammation, apoptosis, mitochondrial dysfunction, and pathologic neurohormonal signaling (Naeije and Manes, 2014; Vonk-Noordegraaf et al., 2013). How the RV adapts is impacted by the type of original insult (e.g., Eisenmenger syndrome often exhibits adaptive remodeling with RVF only very late in disease course vs. PAH with connective tissue or idiopathic PAH with maladaptive remodeling often early and progressive) (Campo et al., 2010; Chung et al., 2010). Many studies have evaluated RV-arterial coupling in a variety of PH models and RV failure is evident once RV function and afterload lose equilibrium.

Volume Overload

Congenital heart disease and valvular disease (congenital/acquired) often have substantial volume loads on the RV; the three most common lesions associated with RV volume overload are tricuspid regurgitation, atrial septal defects, and pulmonic regurgitation. The RV is known to have better adaptation mechanisms to volume overload than pressure overload. Eccentric hypertrophy is the initial adaptive response of the RV to chronic volume overload; cardiomyocytes lengthen by increasing sarcomeres in series and increasing myofibrils, capillary supply, and mitochondria (Apostolakis and Konstantinides, 2012). Initially, the hypertrophic response maintains coupling, but over time and with progressive insults, ventriculo-arterial uncoupling is seen. In addition, progressive RV hypertrophy outstrips the underlying capillary bed capacity, tricuspid annular dilation with secondary tricuspid regurgitation creates a vicious cycle of worsening volume overload, and RV dilation creates leftward septal shift leading to impairment in LV filling. Over many decades, cardiac dysfunction and heart failure can ensue (Apostolakis and Konstantinides, 2012).

Conclusion

Right heart health, previously undervalued, has been recognized as an important predictor of survival and functional capacity. Deepening our foundation of the basic physiology and hemodynamics of this unique system aids us in our efforts to target and understand RV disease while developing effective therapeutics in right heart failure.

Introduction

Chronic heart failure (CHF) is a clinical syndrome in which structural and functional cardiac abnormalities induce an impairment of cardiac output or an increase of intracardiac pressures at rest or during stress, resulting in typical symptoms (e.g., ankle swelling, fatigue, dyspnea) or signs (peripheral edema, pulmonary crackles, or elevated jugular venous pressure) (Ponikowski et al., 2016; Yancy et al., 2016). In the last few decades, cardiovascular disease (CVD) mortality rates have dropped dramatically by about two-third in high-income countries (Nabel and Braunwald, 2012). Nevertheless, among the CVDs, CHF represents an unfortunate exception to such encouraging trend, showing a 5-year mortality that is still approximately 50%, even worse than many cancers (Askoxylakis et al., 2010; Braunwald, 2013). In the last few years, the so-called model of neurohormonal activation has been used to provide mechanistic basis of the natural progression of CHF. According to such a model, the overactivity of neurohormone pathways, that is, the renin–angiotensin–aldosterone or the adrenergic system, in the first stages of the disease, plays a compensatory role, but soon becomes in itself responsible for the worsening and progression of CHF, triggering a vicious circle leading to further and following deleterious increase of neurohormonal action (Braunwald, 2013; Mann, 1999). Based on this model, to counteract the neurohormonal activation, a therapeutic approach aimed at blocking the activated pathways has been postulated and implemented through the current guidelines (beta-blockers, ACE-I/ARBs, aldosterone receptor blockers) (Cole et al., 2014). However, since apparently CHF progress at a certain point independent of neurohormonal status, some limitations on the full effectiveness of the proposed therapy have been postulated. In particular, the obstacle to fully antagonize the overactivated hormonal pathways with the available drugs and the presence of alternative escaping metabolic pathways, such as the action of myocardial chimases for the conversion of angiotensin I in angiotensin II, have partially nullified the neurohormonal model. Thus, the uncertainty regarding the comprehension of all the mechanisms behind the pathogenesis of CHF has lead the way to the search of alternative approaches, capable of improving patient survival and relieving his/her symptoms. Increasing evidences suggest that, rather than the increase of the pathways regulated by the neurohormonal overactivity in itself, might be the loss of balance between the activation of these catabolic pathways and the impairment of a set of anabolic hormonal stimuli to characterize the progression of the disease. Reduction in the activity of anabolic hormones can be due to either reduction of their circulating plasma levels (e.g., growth hormone (GH) and its tissue effector insulin-like growth factor-1 (IGF-1), thyroid hormone (TH), anabolic steroids) or inhibition of their intracellular signaling pathways (i.e., GH resistance, insulin signaling impairment, resulting in insulin resistance (IR)) (Broglio et al., 2000; Suskin et al., 2000; Kontoleon et al., 2003; Pingitore et al., 2005; Doehner et al., 2005; Jankowska et al., 2006). Such a novel approach, rooted in the downregulation of many hormonal pathways, can be defined the hormonal-metabolic model and considers the CHF as a multiple hormonal deficiency syndrome (MHDS) (Saccà, 2009; Arcopinto et al., 2015a,b; Salzano et al., 2016). The deficiency of the action of a given hormone can be associated with reduced functional capacity of the heart and is an independent risk factor for poor clinical outcome (Niebauer et al., 1998; Iervasi et al., 2003; Doehner et al., 2005; Marra et al., 2012, 2016; Arcopinto et al., 2015a, 2017). Strikingly, the deficiency in the anabolic pathway sustained by the impairment of multiple hormones has been associated with even worst impaired cardiovascular performance and poor prognosis in CHF (Jankowska et al., 2006).

GH/IGF-1 Axis

GH and IGF-1 have an indispensable role in preserving cardiac performance and morphology in adulthood (Saccà and Fazio, 1996; Saccà, 1999). Activation of GH/IGF-1 pathway promotes a myocardial profile characterized by preserved capillary density, absence of fibrosis, and changes of calcium regulatory proteins, all factors playing a role in the protection against ischemia–reperfusion and mechanical stretching (Cittadini et al., 1996; Stromer et al., 2006; Bruel and Oxlund, 1999). In addition, GH/IGF-1 stimulation induces reduction of apoptosis and release of endothelial nitric oxide, resulting in vasodilation (Cittadini et al., 1997; Saetrum

 https://doi.org/10.1016/B978-0-12-809657-4.64122-4

Opgaard and Wang, 2005; Boger, 1998; Merola et al., 1996; Napoli et al., 2002, 2003). In particular, IGF-1 but not GH, through calcium sensitization of the myofilaments, increases myocardial contractility, a downstream mechanism not associated with arrhythmias (Cittadini et al., 1998). Moreover, GH increases skeletal muscle protein content suggesting an additional role in improving CHF by contrasting the consequences of skeletal muscle cachexia (Napoli et al., 1995). IGF-1 administration in preclinical studies induces an increase in the size of cardiomyocytes and in the expression of mRNAs for actin, myosin light chain 2, and troponin associated with the reduction in apoptosis (Ito et al., 1993; Ren, 2002).

GH deficiency (GHD) is present in more than one-third of patients with CHF (Cittadini et al., 2009; Broglio et al., 2000). Many mechanisms might be involved in the reduced activity of GH/IGF-1 axis in CHF: reduced GH secretion or peripheral resistance to its action, hypothalamic somatostatin hyperactivity, drug interference, poor nutritional status, or increased circulating and tissue levels of inflammatory cytokines (Broglio et al., 1999, 2000; Cicoira et al., 2003; Climent et al., 2007; Saccà et al., 2003; Mann, 1999; Colao, 2008).

In the general population, GHD is associated with increased cardiovascular mortality and the coexistence of many factors might trigger this increase (Rosen and Bengtsson, 1990). GHD patients show impaired cardiac performance, increased peripheral vascular resistance, and reduced exercise capacity (Saccà, 1997) and the degree of severity of the deficiency appears to be a major determinant of cardiac impairment (Colao et al., 2004). Recently, we have shown that the presence of GHD in patients with CHF identifies a subgroup with worse clinical status and increased all-cause mortality, higher depression scores, impaired quality of life, presence of left ventricular (LV) remodeling, lower physical performance, and increased NT-proBNP levels (Arcopinto et al., 2017). Larger LV volumes with elevated wall stress, as well as higher filling pressures, and impairment of right ventricle function characterize patients with CHF and GHD. In addition, at similar values at anaerobic threshold, these patients demonstrated a worse cardiopulmonary performance with significantly lower peak VO_2 and reduced ventilatory efficiency.

The data regarding the effects of perturbations in circulating plasma levels of IGF-1 are less consistent. In the general population, a low level of IGF-1 is predictive of cardiovascular mortality, ischemic heart disease, and CHF (Juul et al., 2002; Vasan et al., 2003; Laughlin et al., 2004). In the population of patients with CHF, IGF-1 levels have been found decreased, normal, or even increased when compared with healthy controls (Anker et al., 2001; Al-Obaidi et al., 2001; Anwar et al., 2002; Andreassen et al., 2009). Several studies show that low levels of IGF-1 associate with poor outcome, greater neurohormonal activation and cytokine activation, reduced skeletal muscle performance, and endothelial dysfunction (Niebauer et al., 1998; Napoli et al., 2002; Petretta et al., 2007). Recently, our group demonstrated that IGF-1 circulating plasma levels are predictors of all-cause mortality in CHF patients (Arcopinto et al., 2015a,b). Given the inconsistency of the data about circulating levels of IGF-1 in the population with CHF, there is no agreement on which one can be the best marker of GH/IGF-1 axis activity. Rather than isolated IGF-1 levels, the IGF-1/GH ratio relates to survival in CHF patients (Petretta et al., 2007). Watanabe showed that the IGF-1/IGF-binding protein-3 ratio is associated with increased rate of all-cause mortality, cardiac death, and a composite outcome of cardiac death and rehospitalization in a population of CHF patients (Watanabe et al., 2010).

Experimental studies in animal models of postischemic heart failure have reported beneficial effects of treatments with GH, or GH-releasing peptide, on cardiac function, peripheral vascular resistance, and survival (Yang et al., 1995; Duerr et al., 1996; Ryoke et al., 1999). Early treatment of large myocardial infarction with GH attenuates pathologic LV remodeling and improves LV function (Cittadini et al., 2009). Since the nineties, many studies have focused on the effect of GH treatment in patients with CHF: the results have not been always consistent (Fazio et al., 1996; Frustaci et al., 1996; Isgaard et al., 1998; Osterziel et al., 1998; Genth-Zotz et al., 1999; Jose et al., 1999; Spallarossa et al., 1999; Perrot et al., 2001; Smit et al., 2001; Napoli et al., 2002; Acevedo et al., 2003; Adamopoulos et al., 2003; Cittadini et al., 2003).

Le Corvoisier and colleagues, in an elegant meta-analysis summarizing the findings, show that GH treatment improves several relevant cardiovascular parameters in patients with CHF; in particular, they reported an increase in LV ejection fraction (LVEF) and a reduction in systemic vascular resistance (Le Corvoisier et al., 2007). Moreover, a long-term modification in cardiac morphology (reduction of LV diastolic diameter and an increase in LV wall thickness) was demonstrated. Tritos et al., in another meta-analysis, illustrated that treatment with GH resulted in an increase of exercise duration, maximum oxygen uptake, LVEF, cardiac output, and improvement in systemic vascular resistance and NYHA class level (Tritos and Danias, 2008).

The inconsistency of the results obtained from different trials on GH treatment of patients with CHF might be explained by differences in duration of treatment, target, or dosage. Recently, the concept has emerged that the GH/IGF-1 patient profile might prejudice the response to the treatment with GH. Therefore, patient selection is extremely relevant to obtain the hoped-for results. In particular, GHD appears to be the condition needed to get the best response in CHF patients. In a randomized, single-blind, controlled trial, we studied the relevance of GHD on the effects of GH replacement therapy in patients with CHF. After 6 months of treatment, GH replacement therapy increased LVEF, peak oxygen uptake, exercise duration and flow-mediated vasodilation, and improved the quality of life score. Furthermore, GH administration decreased circulating N-terminal pro-brain natriuretic peptide levels (Cittadini et al., 2009). On these premises, we extended the study with a 4-year follow up. After 4 years, the GH replacement therapy induced the significant reductions of both LV end-diastolic and end-systolic volume indexes, circumferential wall stress, and an increase in LVEF, suggesting the activation of the reverse remodeling of the LV. Although the result did not reach statistical significance, GH treatment improved remarkably the peak VO_2. Finally, the combination of death from any cause and hospitalization due to CHF worsening was sensibly reduced by the treatment with GH in this group of patients with CHF, although hard clinical endpoints were not the purpose of the study (Cittadini et al., 2013).

TNF-α, interleukin-6, and other proinflammatory cytokines increased levels have also been associated with poorer prognosis in patients with CHF. GH therapy has shown to normalize the circulating levels of TNF-α andinterleukin-6 (Adamopoulos

et al., 2002). Consistently, the levels of soluble adhesion molecules, granulocyte-macrophage colony-stimulating factor, and macrophage chemoattractant protein-1 were also affected by GH administration (Acevedo et al., 2003), suggesting an immunomodulatory role for GH therapy in CHF.

Androgens

The role of anabolic steroids on cardiovascular system and skeletal muscle is well recognized. Testosterone is the primary androgen in the adulthood and some evidences have linked its levels to the risk of CVDs (Khaw et al., 2007). Consistently, male gender is an independent risk factor of atherosclerosis (Criqui, 1986). Furthermore, several evidences, in vivo and in vitro, suggested that androgens exert adverse effects on the cardiovascular risk factor profile and induce the development of atherosclerosis (Muller et al., 2003; Dubey et al., 2002; Adams et al., 1995; McCrohon et al., 1999; Ng et al., 2003). Several clinical studies have shown that low levels of androgens associates with increased carotid intima-media thickness in middle-aged and elderly men (Mäkinen et al., 2005; Muller et al., 2003) and risk of CVDs and all-cause mortality (Haring et al., 2010; Laughlin et al., 2008; Malkin et al., 2010a).

Dehydroepiandrosterone (DHEA) and its sulfate ester (DHEA-S), produced mainly by the adrenal glands, are the most abundant androgens in humans. Although DHEA-S derives mainly from the conversion to testosterone in peripheral tissues, direct actions on the cardiovascular system (Komesaroff, 2008) and association with cardiovascular variables have also been shown (Tivesten et al., 2014).

Testosterone exerts its effects through genomic and nongenomic actions and testosterone receptors (TR) are present in cardiomyocytes, where their stimulation induces protein synthesis and cell hypertrophy (Marsh et al., 1998) and regulates myocardial contractility, through a mechanism involving L-type Ca^{2+} channel, the Na^{2+}/Ca^{2+} exchanger, b1-adrenoceptors, and myosin heavy chain subunits (Golden et al., 2003, 2004). TR are present also in endothelial and vascular smooth muscle cells, where testosterone decreases the intracellular Ca^{2+} flux through interaction with voltage-operated calcium and potassium channels (Liu et al., 2003). Moreover, the endogenous testosterone/TR system exerts a protective action on the angiotensin II-induced vascular remodeling by inhibiting the gene expression for the components of NADPH oxidase, resulting in control of superoxide production and reduction in the activation of JNK and TGF-beta-Smad signaling pathways (Ikeda et al., 2009).

In healthy males, the decline in androgens levels with aging contributes to sarcopenia, visceral adiposity deposition, and osteopenia. The physiologic phenomenon of andropause is characterized by a decrease in serum testosterone level of about 3.5 ng/dL per year starting from the forth decade of life (Lapauw et al., 2008). Even circulating DHEA-S levels shows an age-dependent decline starting at the age of about 25 years (Kaufman and Vermeulen, 2005). However, it must be said that the criterion for testosterone deficiency is not widely accepted, although is often considered when morning total testosterone level drops below 300 mg/dL in two or more occasions in presence of consistent symptoms and signs (Bhasin et al., 2010). However, signs and symptoms of testosterone deficiency blend with those of common comorbidities making uncertain the identification of reliable testosterone deficiency in elderly. Nowadays, the annual incidence of hypogonadal levels of testosterone in men is 20% in people 60 or older and 30% in 70 or older (Harman et al., 2001).

Epidemiological studies demonstrated that testosterone deficiency in old men associates with increased risk of death (Haring et al., 2010; Laughlin et al., 2008) and low serum testosterone levels might be used as a marker of poor survival (Haring et al., 2010).

In patients with CHF syndrome, 25% of patients have low plasma levels of testosterone (Anker et al., 1997; Moriyama et al., 2000; Kontoleon et al., 2003; Malkin et al., 2009) and such reduction might well be involved in the impairment of skeletal muscle function and exercise tolerance (Iellamo et al., 2010a) and contributes to the poor survival (Pugh et al., 2004; Malkin et al., 2010b; Volterrani et al., 2012). In addition, reduced serum levels of DHEA-S predict all-cause and cardiovascular mortality in elderly (Ohlsson et al., 2010).

The concept that testosterone deficiency affects cardiac function encouraged studies on the effects of testosterone replacement in CHF. In an experimental model of CHF, testosterone treatment induced physiological cardiac growth without increase in markers of hypertrophy or accumulation of collagen (Nahrendorf et al., 2003). In animal model of ischemia–reperfusion injury, testosterone administration preserved cardiomyocytes by activating ATP-sensitive K channels and upregulating cardiac alpha(1)-adrenoceptors (Tsang et al., 2008). Compared with placebo, in 12 male patients with CHF, a single dose of testosterone (60 mg orally) induced a decrease in peripheral vascular resistance and after-load, associated with higher cardiac output (Pugh et al., 2002).

In a following double-blind, placebo-controlled study, the same group showed that intramuscular testosterone therapy (100 mg every 2 weeks for 12 weeks) in 20 male patients with CHF increased the 6-min walking distance and improved the Minnesota Living with Heart Failure Questionnaire (Pugh et al., 2004). These promising results prompted a robust randomized, double-blind, placebo-controlled trial on the effects of testosterone replacement therapy in unselected CHF patients (Malkin et al., 2006). In such a study, 76 men with CHF were randomly assigned to receive either testosterone (5 mg/day administered by an adhesive skin patch) or placebo for 12 months. In the group treated with the hormone, an increase in serum testosterone level by 40% was observed. Despite testosterone did not modify LV morphology or function, a significant increase in shuttle walk distance and dominant handgrip strength was observed. Moreover, the clinical severity of CHF improved as demonstrated by the shift of at least one New York Heart Association class for 35% of patients treated with testosterone versus 8% of patients receiving placebo. Since the functional improvement recorded during testosterone treatment was not associated with any relevant change in heart function or morphology, an hypothetical positive effect of testosterone on skeletal muscle could be invoked to justify the improvement in

patient performance. On the other hand, the involvement of peripheral mechanisms in the maintenance and progression of CHF is so relevant that the possibility that testosterone may act through such mechanisms does not undermine the potential importance of its use.

A few years ago, in a double-blind, randomized, placebo-controlled study, 70 elderly patients with CHF were treated for 12 weeks with very long acting intramuscular testosterone. The data from this trial showed that peak VO_2 and ventilatory efficiency, as assessed by the VE/VCO_2 slope, improved significantly. In addition, the beneficial effects of testosterone therapy were confirmed by improvement in IR and the slowdown of skeletal muscle deterioration, in particular in large, weight-bearing muscles, as demonstrated by the increase in quadriceps maximal voluntary contraction. The deterioration of skeletal muscle strength in elderly patients with CHF is a relevant phenomenon capable of bringing about early fatigue and limiting exercise tolerance (Caminiti et al., 2009). More recently, 50 male CHF patients recruited in a RCT receiving intramuscular long-acting androgen injection once every 4 weeks for 12 weeks confirmed the previous finding (Mirdamadi et al., 2014). The effects of testosterone (intramuscular testosterone 6×100 mg in 12 weeks) have been studied also during a rehabilitation program in male patients with CHF and low testosterone status. After 24 supervised sessions of mixed exercise, an improvement in peak oxygen consumption, leg strength, and response to quality of life questionnaire was demonstrated in the patients treated with testosterone (Stout et al., 2012).

The decline of androgen levels with aging is a phenomenon detectable also in women. Such consideration prompted a study involving 36 female patients with CHF, treated with either transdermal testosterone (300 mg patch, applied twice/week) or placebo for 6 months (Iellamo et al., 2010b). At the end of the study, treated patients displayed an improvement in 6-min walking distance and peak oxygen consumption and a reduction of IR.

Taken together, the studies looking at the effects of testosterone administration did not show changes in the size or function of heart ventricles. However, they invariably exhibited an improvement in cardiovascular performance and muscular strength, supporting the hypothesis that the action of testosterone might be mediated through peripheral mechanisms involved in the pathogenesis of CHF, that is, improvement in skeletal muscle or vascular function, rather than on the heart function in itself.

Insulin Action

The existence of an intimate link between diabetes and CHF has been apparent for many years. Since the first data from the Framingham heart study were published, the fact that among diabetic patients there is a large prevalence of patients with CHF and that CHF patients have an increased risk of being diabetic appeared clear. In addition to the increased risk of CVDs, diabetic patients show abnormalities in the metabolism of the heart able to induce a condition of cardiomyopathy independent of atherosclerosis, hypertension, and coronary artery disease: the so-called diabetic cardiomyopathy. In the last few years, the concept emerged that the mechanisms behind the development of diabetic cardiomyopathy are quite complex. In particular, among the defects critically present in diabetes and potentially responsible for heart damage, IR has emerged forcefully. On the other hand, IR can be present in patients with CHF independent from diabetes and recent data prove that, roughly, one-third of patients with CHF are insulin resistant and almost half have diabetes or IR (Suskin et al., 2000). Furthermore, IR does not appear to be a simple bystander, but plays an active role in the development and prognosis of the disease. In particular, in a population of elderly people, the presence of IR, as measured by hyperinsulinemic euglycemic clamp study, independently of obesity, showed to be a powerful predictor of CHF (Ingelsson et al., 2005). IR correlates with the severity of CHF when categorized by the 6-min walking distance or VO_{2max} (Swan et al., 1997; Suskin et al., 2000). Finally, and more importantly, the presence of IR is strictly associated with poor prognosis in patients with CHF (Doehner et al., 2005). On the other hand, it has been experimentally demonstrated in animals that once CHF is established, IR can rapidly develop or worsen in the heart and skeletal muscle (Nikolaidis et al., 2004). Many different mechanism can potentially be evoked to explain the onset or worsening of IR in patients with CHF, such as endothelial dysfunction, skeletal muscle loss, cytokines surge, sympathetic nervous system overactivity, FFA elevation, physical inactivity, etc., likely induced by the impaired hemodynamic. With regard to the mechanisms dangerously triggered by IR and responsible of the worsening of CHF performance and prognosis, a few hypothesis can be proposed. Under normal circumstances, heart metabolism is very flexible and myocardiocytes are capable of switching from FFA to glucose utilization according to the metabolic and energetic needs and the different age (Witteless and Fowler, 2008; Iozzo et al., 2010). When CHF develops, heart metabolism switches from a preferential FFA oxidation to the more convenient glucose uptake (Huss and Kelly, 2005; Witteless and Fowler, 2008). Preferential glucose oxidation under the circumstances supports a favorable energetic profile, allowing the production of ATP and other high-energy substrates with lower oxygen consumption (Huss and Kelly, 2005). Unfortunately, when IR is present, heart metabolism becomes less agile and capable of utilizing glucose, and cardiomyocytes are compelled to an unfavorable inflexibility with the preferential use of FFA to produce energy (Witteless and Fowler, 2008). On the assumption that IR represents a relevant player in the maintenance and progression of CHF, the aim of the therapy of the disease should be to counteract IR. Life style interventions, a pharmacologic approach, or both can oppose IR. The life style interventions, pillars of the treatment of IR in the general population, are weight control and physical activity. Unfortunately, in patients with CHF both approaches have pitfalls. Weight control or reduction must be weighed against the risk of cachexia, a frequent and serious complication of CHF. On the other hand, physical activity is of limited use, given the difficulty that CHF patients have in this regard. Several different drugs, used for the treatment of diabetes, are capable of improving IR. First, the insulin sensitizers thiazolidinediones are drugs directly addressing IR. Although the treatment with glitazones has shown some interesting results (Masoudi et al., 2005), they are contraindicated in patients with CHF and diabetes for the increased paradoxical risk of inducing or worsening CHF (Gerstein et al., 2006). Metformin, first choice drug for the

treatment of diabetes, has been for long time contraindicated in patients with CHF for the potential risk of lactic acidosis enhanced by the tissue ischemia present in CHF. However, in an experimental model of CHF, metformin, but not rosiglitazone, improves cardiac function and performance very powerfully (Cittadini et al., 2012). Recently, a critical analysis of the data available in the literature has clearly indicated that the use of metformin was not associated with an increased risk of lactic acidosis (Masoudi et al., 2005) and associated with the improvement of many functional parameters (Wong et al., 2012). Therefore, metformin has become the drug of choice in patients with diabetes and reduced EF (Ponikowski et al., 2016). Recently, the field of diabetes has been flooded with a series of new and promising drugs. A series of drugs act by increasing the plasma activity of glucagon-like peptide-1 (GLP-1). Native GLP-1 cannot be routinely used for treatment because of its short half-life (less than 2 min) and the need of parenteral administration. However, GLP-1 administration under experimental circumstances has provided promising results in the field of CHF. In dogs with CHF, GLP-1 administration improved LV function (Nikolaidis et al., 2004). In 12 patients with severe CHF, with or without diabetes, continuous subcutaneous administration of GLP-1 for 5 weeks improved LVEF, VO_{2max}, 6-min walking distance, and the response to a QoL questionnaire (Sokos et al., 2006). The mechanisms responsible for the striking improvement in these patients are unclear. However, it has been hypothesized that improvement of IR might have played a role. Given the short half-life of native GLP-1, increase in the activity of GLP-1 can be achieved through two different approaches. Dipeptidyl-peptidase IV inhibitors (DPP-IVi) or GLP-1 agonists act by increasing the GLP-1 activity, by either inhibiting the enzyme DPP-IV, responsible of the degradation of endogenous GLP-1 and in so doing increasing the level of endogenous GLP-1, or providing a GLP-1 analog resistant to the action of the DPP-IV, respectively. Three recent randomized clinical trials of cardiovascular safety, involving more than 36,000 patients with diabetes, half of them treated with DPP-IVi, have been completed (Scirica et al., 2013; White et al., 2013; Green et al., 2015). Although CHF was not the focus of the three trials, surprising observations have been made. In the SAVOR-TIMI trial (Scirica et al., 2013), an unexpected statistically significant increase in the number of patients hospitalized for heart failure was reported for the group treated with saxagliptin. In the EXAMINE trial (White et al., 2013), the treatment with alogliptin showed a 19%, although nonsignificant, increase in the incidence of hospitalization for CHF in the 2700 patients treated with the drug. Finally, in the TECOS trial (Green et al., 2015), no signal of increase in CHF hospitalization was observed treating the patients with sitagliptin. However, the safety data collected in the real world practice suggest that this family of drug is generally safe to use, but certainly, the hopes of improving the burden of CHF have been neglected. With regard to the data relative to the GLP-1 agonists, three RCT have been published so far (Pfeffer et al., 2015; Marso et al., 2016a,b)). In these trials, the diabetic patients did not show any change in CHF hospitalization due to the treatment with lixisenatide, liraglutide, or semaglutide, respectively. However, the effects of liraglutide, a long-acting analog of GLP-1 administered once a day, on heart performance and patient safety in patients with CHF have been investigated (Jorsal et al., 2017). In this study, 241 CHF patients, with (74 patients) or without diabetes, were treated with either liraglutide (122 patients) or placebo in a randomized, double-blinded, placebo-controlled, multicentre trial. Primary end-point of the study was changed in LVEF. At the end of the 24 weeks of treatment, LVEF improved more in the placebo group than in the liraglutide arm, although the difference did not reach statistical significance (LVEF: −0%–8% active vs. placebo group). Unfortunately, serious cardiac adverse events were more frequent with liraglutide than placebo ($P=0.04$). In a similar, but smaller and open label, trial, albiglutide was tested versus placebo (Lepore et al., 2016). In this study also, GLP-1 analog failed to improve ventricular function in patients with CHF. Extremely interesting data have been recently provided by the diabetic patients treated with empagliflozin in the EMPA-REG OUTCOME trial were (Zinman et al., 2015). Empagliflozin is the first drug of the family of the inhibitors of sodium glucose cotransporter 2 (SGLT2i) to complete the cardiovascular safety trial required by the FDA to approve the drug in the United States. Other drugs with the same mechanism of action, dapagliflozin and canagliflozin, are currently being studied in similar CV safety trials. The administration of gliflozins induces the reduction of blood glucose concentration by increasing the loss of glucose with the urine. Such reduction removes the impact of glucose mass effect on the cells, improving IR and glucose transport (Rossetti et al., 1987; Napoli et al., 1995). During the EMPA-REG OUTCOME trial, diabetic patients treated with the empagliflozin, in addition to reduction in all-cause and CVD mortality, showed a significant reduction in hospitalization for CHF. Similarly, in a recent large real world study recruiting 300,000 diabetic patients, dapagliflozin, empagliflozin, and canagliflozin induced a reduction in death or hospitalization for HF (Kosibord et al., 2017). The relevant mechanisms behind such reduction are unclear and many of them have been invoked: changes in substrate (i.e., butyrate, glucose), hormones (i.e., glucagon), changes in the intracellular metabolism, or reduction in IR might be implicated. However, the diuretic effect of the gliflozins must be kept in mind when data on hospitalization are analyzed, since diuresis per se may improve the hemodynamic in patients with CHF.

Thyroid Hormone

The importance of the TH role in the regulation of cardiovascular function has been clear for many years. TH perturbations, as in hypo- or hyperthyroidism, have a potent impact on the cardiovascular apparatus, involving both the regulation of heart rhythm and function. TH exerts its powerful intracellular effects through genomic and nongenomic mechanisms. The action of TH on heart function might be divided in a direct action on cardiac structure and an indirect action mediated by the very potent effects the TH have, both acutely (Napoli et al., 2007) and chronically (Napoli et al., 2001; Napoli et al., 2010) on the vessel wall. The effects on cardiac structure are mediated through the expression of proteins involved in many different ways in the contractile response of the ventricles (Iervasi et al., 2003). On the other hand, the effects observed on the peripheral circulation have a potent effects on hemodynamic and, consequently, on cardiac function. The implications of TH action on heart function can be easily evaluated by

looking at the effects that hypo- or hyperthyroidism have on hemodynamic. In particular, thyroid diseases are associated with changes in cardiac output, contractility, and vascular resistance. On the other hand, the treatment of these diseases, if quickly started, before irreversible changes have taken place, is rapidly followed by the restoration of normal cardiovascular functions (Klein and Danzi, 2007; Napoli et al., 2010). The levels of circulating TH must be maintained in a pretty narrow normal range, as suggested by the fact that either elevation or decrease of TH is followed by increased cardiovascular mortality (Biondi et al., 1999; Iervasi et al., 2007). Treatment with low dose of oral (0.1 mg/day of T4) of CHF patients has led to an increase in LVEF and improvement in exercise tolerance (Moruzzi et al., 1996). T3 administration induces an increase in cardiac output in few hours (Malik et al., 1999; Hamilton et al., 1998; Pingitore et al., 2008). On the other hand, T3 has potent and rapid activity on the vessel wall and is capable of improving endothelial function when infused intra-arterially in healthy volunteers (Napoli et al., 2007). In addition to the obvious hemodynamic effect of heart function and structure, the improvement of endothelial function with T3 administration has important implication in CHF, since a better perfusion of peripheral tissue, including skeletal muscle, might potentially improve exercise tolerance.

Conclusions

In the last few years, the hypothesis that CHF is a clinical syndrome characterized by an imbalance between catabolic and anabolic pathways has prepotently emerged. Such imbalance is sustained by the neurohormonal activation from one side and MHDS on the other side. Reduction in the activity of GH/IGF-1 axis, androgens, insulin, and TH is associated with the clinical worsening of CHF. More importantly, the correction of these defects is followed by significant clinical improvements. On the basis of these observations, new trials focusing on the identification and treatment of multiple hormonal deficiencies in CHF patients should be supported. Meanwhile the MHDS should be routinely searched in the patients with CHF and a consistent treatment evaluated.

Introduction

Hypertensive heart disease (HHD) can be defined as the response of the heart to the afterload imposed on the left ventricle by the progressively increasing arterial pressure and total peripheral resistance that entails hypertension (Frohlich et al., 1992). HHD is characterized by increased left ventricular (LV) mass leading to left ventricular hypertrophy (LVH). In fact, hypertension-induced LVH consists of a constellation of genetic, structural and functional alterations of cardiac tissue that allow its differentiation as a separate entity (Lip et al., 2000). LVH is associated with alterations of cardiac contractility and relaxation, abnormalities of myocardial perfusion, and disturbances of cardiac rhythm in hypertensive patients. In addition, LVH is an independent risk factor related to cardiovascular complications in these patients.

Diagnostic methods to detect LVH in the routine clinical setting include electrocardiography and echocardiography, although novel biochemical and imaging tools are being developed to help diagnose and treat patients in a personalized manner. A number of studies have established that reduction of LV mass is attained with effective antihypertensive treatment and that reversal of LVH and its underlying mechanisms decreases the occurrence of adverse cardiovascular events in hypertensive patients. However, there is still room for further improvement because it is now appreciated that treated hypertensive patients in which LVH regresses still have considerable cardiovascular risk (Struthers, 2013). On the other hand, due to the aging of the population and the increase in the prevalence of hypertension and related comorbidities, HHD remains a major socioeconomic problem. Therefore, there is an important need for physicians to recognize this entity, understand its pathophysiology, and be aware of the available treatment options.

Pathophysiological Aspects

Physically, in conditions of pressure overload due to systemic hypertension, the left ventricle undergoes hypertrophic growth, which is characterized by the thickening of the LV wall and the augmentation of LV mass, thus resulting in concentric LVH. This is as predicted by the law of Laplace. Functionally, this early LVH is a compensatory process that helps the heart in sustaining cardiac output despite increased afterload imposed by systemic hypertension (Frohlich et al., 2011). However, this process is only an initial "adaptive" response to biomechanical stress associated with hemodynamic load; chronic exposure to the stress eventually leads to impaired inotropic (contraction)/lusitropic (relaxation) function which, in many cases, progresses to congestive heart failure (HF). This "maladaptive" evolution is intimately linked to the underlying histological changes of the cardiomyocyte and noncardiomyocyte components of the myocardium that result in its structural remodeling (**Fig. 1**) (Knöll et al., 2011).

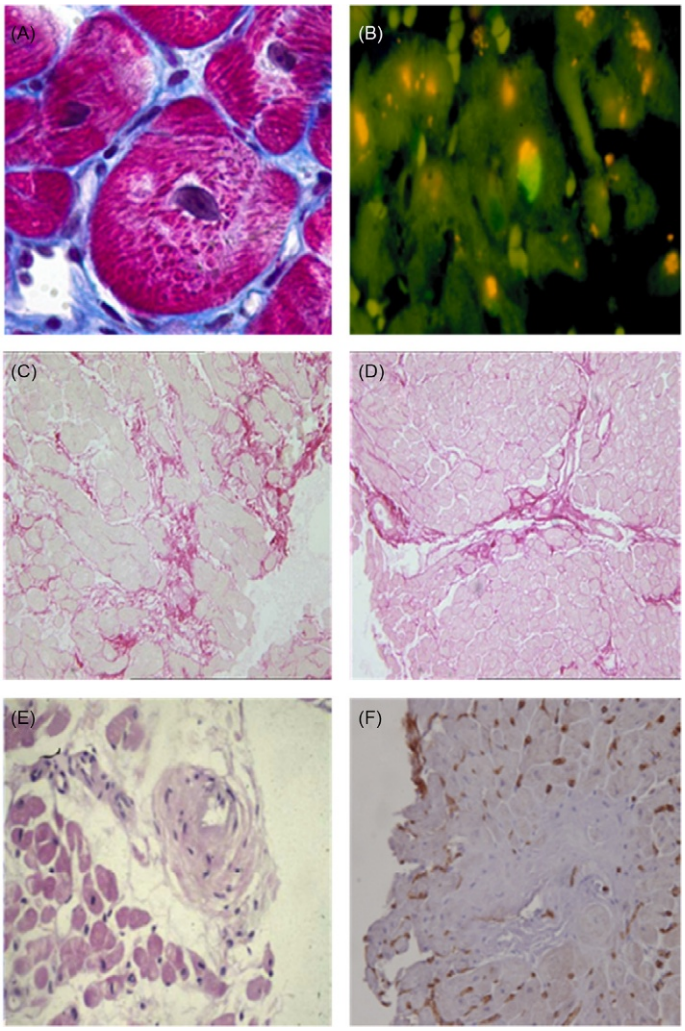

Fig. 1 Main microscopic lesions found in the hypertensive myocardium: (A) view of a transversely enlarged cardiomyocyte (Masson's trichrome staining, magnification 100 ×); (B) a cardiomyocyte exhibiting apoptotic appearance (TUNEL, magnification 100 ×); (C) excessive interstitial collagen deposition (picro-sirius red staining, magnification 20 ×); (D) perivascular fibrosis (picro-sirius red staining, magnification 20 ×); (E) an intramyocardial artery presenting wall thickening and lumen narrowing (Masson's trichrome staining, magnification 20 ×); (F) capillary rarefaction (von Willebrand staining, magnification 20 ×).

Cardiomyocyte Lesions

As mentioned before, the response of the cardiomyocyte to pressure overload must not be considered simply as an adaptive compensation, as it has critical detrimental consequences (Frohlich et al., 2011).

Hypertrophy

The primary mechanism by which the heart reduces the stress on the LV wall imposed by pressure overload is the hypertrophic growth of cardiomyocytes. This entails the stimulation of intracellular signaling cascades that activate gene expression and promotes protein synthesis, protein stability, or both, with consequent increases in protein content and in the size and organization of force-generating units (sarcomeres). This, in turn, leads to increased size of individual cardiomyocytes with resulting augmentation in LV mass and thus LVH (Sugden and Clerk, 1998). Although it is unclear how the mechanical stretch of cardiomyocytes is transduced across the cell membrane, it probably involves stretch-sensitive ion channels, a Na^+/H^+ exchanger, integrins and integrin-interacting molecules as well as other internal and membrane-bound stretch sensors, in a complex network that links the extracellular matrix, the cytoskeleton, the sarcomere, calcium (Ca^{2+})-handling proteins, and the nucleus (Clerk et al., 2007).

The changes in genetic expression characteristic of the cardiomyocyte hypertrophic response involve reexpression of a fetal gene program, as well as repression of postdevelopmental genes (**Table 1**) (Barry et al., 2008; Kuwahara et al., 2012). The long-held views are that, in response to pressure overload, these morphological and genetic changes are positive and serve to restore cardiac

Table 1 Genes whose expression is altered during cardiomyocyte hypertrophy

Activated genes
β-Myosin heavy chain
Fetal isoforms of contractile proteins (skeletal α-actin and β-myosin heavy chain)
Fetal type cardiac ion channels (hyperpolarization activated cyclic nucleotide-gated channel and T-type Ca^{2+} channel)
IVS3A form of calcium channel
α3-Subunit of Na^+, K^+-ATPase
B subunit of creatine kinase
Atrial and brain natriuretic peptides
Switch from fatty acid oxidation to glycolysis genes
Lactate dehydrogenase M subunits
Genes directing cardiomyocyte lengthening
Smooth muscle genes (smooth muscle α-actin and SM22α)
Inhibited genes
α-Myosin heavy chain
Calcium ATPase of sarcoplasmic reticulum (SERCA2)
β_1-Adrenergic receptors
M_2 muscarinic receptors
Early transient K^+ current, I_{to}
Myoglobin
N2BA titin isoform

muscle economy and counteract myocardial dysfunction. However, blunting of cardiomyocyte hypertrophy and attenuation of the fetal gene reexpression do not necessarily result in immediate LV dysfunction or HF despite the pressure overload. Therefore, genetic reprogramming associated with cardiomyocyte hypertrophy may no longer be considered as an adaptive process (Meijs et al., 2007). Moreover, the detailed analysis of the genetic changes that accompany cardiomyocyte hypertrophy indicates that they translate into derangements in energy metabolism, contractile cycle and excitation–contraction coupling, cytoskeleton and membrane properties. These changes determine mechanical dysfunction which, in turn, provides the basis for cardiomyocyte malfunction, which is associated with LVH and predisposes the ventricle to diastolic and/or systolic dysfunction (Dhalla et al., 2009).

Death

The death of cardiomyocytes by apoptosis is abnormally increased in patients with HHD with HF (González et al., 2006). Cardiomyocyte apoptosis has been proposed to occur as a result of an imbalance between the factors that induce or block apoptosis. In this sense, inducers of cardiomyocyte apoptosis (e.g., mechanical stretching and angiotensin II) predominate over suppressors (e.g., agonists of the gp130/LIFR survival pathway) in arterial hypertension (Fortuño et al., 2001).

Apoptosis of cardiomyocytes may contribute to the development of LV dysfunction/failure through three different pathways. First, apoptosis may be one mechanism involved in the loss of contractile mass and function of the hypertensive myocardium, as association of increased cardiomyocyte apoptosis with diminished cardiomyocyte number has been found in hypertensive patients (González et al., 2006). Second, some mechanisms that are activated during the apoptotic process may also interfere with the function of viable cardiomyocytes before death (Narula et al., 2001). For instance, caspase-3 cleaves cardiac myofibrillar proteins, resulting in an impaired force/Ca^{2+} relationship and myofibrillar ATPase activity. Also, the release of cytochrome *C* from mitochondria during apoptosis may impair oxidative phosphorylation and ATP production, thus leading to energetic compromise and functional impairment. Third, in addition to contributing to histological remodeling of the myocardium, cardiomyocyte apoptosis may also contribute to geometric remodeling of the LV chamber. In fact, severe cardiomyocyte apoptosis may lead to side-to-side slippage of cells, mural thinning, and chamber dilatation. This wall restructuring secondary to severe cardiomyocyte apoptosis may create an irreversible state of the myocardium, facilitating progressive dilatation and the continuous deterioration of LV hemodynamics and performance with time (Chandrashekhar, 2005).

It is important to point out that, although apoptosis is a hallmark of HHD, in the response to any given cardiac injury various modalities of cell death are stimulated, as they are interconnected by common cellular pathways at multiple points (Whelan et al., 2010). For instance, autophagy is activated during hypertensive LVH, serving to maintain cellular homeostasis. Excessive autophagy eliminates, however, essential cellular elements and possibly provokes cardiomyocyte death, which contributes to myocardial remodeling (Wang et al., 2010).

Noncardiomyocyte Lesions

It has become evident in the last 25 years that in addition to lesions involving the cardiomyocytes, changes in the extracellular matrix and the microvasculature are also key components of the structural remodeling of the myocardium and have a profound detrimental impact on the overall cardiac function, thus contributing to the development of HHD.

Myocardial fibrosis

Myocardial fibrosis is the exaggerated accumulation of extracellular matrix, namely collagen type I fibers, within the interstitium and surrounding intramural coronary arteries and arterioles in the myocardium. This excess of myocardial collagen present in hypertensive LVH is the result of the combination of several alterations (Berk et al., 2007): (i) increased procollagen synthesis by fibroblasts and phenotypically transformed fibroblast-like cells or myofibroblasts; (ii) increased extracellular conversion of procollagen into microfibril-forming collagen by specific proteinases; (iii) increased spontaneous microfibril assembly to form fibrils; (iv) enhanced cross-linking of fibrils to form fibers by the action of lysyl oxidases (LOX); and (v) unchanged or even decreased fiber degradation by matrix metalloproteinases (MMPs).

Fibrosis might contribute to the structural and clinical alterations of HHD through diverse mechanisms. First, there is a connection between fibrosis and LV dysfunction (Brower et al., 2006). The accumulation of collagen fibers compromises the rate of relaxation, diastolic suction, and passive stiffness, thereby contributing to impaired diastolic function. In addition, continued accumulation of collagen fibers, together with changes in their spatial orientation, further impairs diastolic filling. These changes further compromise cardiomyocyte contraction and myocardial force development thus impairing systolic performance. Second, the impaired coronary flow reserve associated with LVH might be related to, among others, perivascular fibrosis (Schwartzkopff et al., 1993). In fact, the amount of perivascular collagen has been correlated inversely with coronary flow reserve in patients with LVH (Dai et al., 2012). Third, the increased deposition of fibrotic tissue which occurs in association with hypertension and LVH, results in diffusion problems in a situation in which oxygen and nutritional demands are increased (Frohlich, 2001). Finally, interstitial fibrosis may also contribute to ventricular arrhythmias in hypertension (McLenachan and Dargie, 1990). Thus, hypertensive patients with dysrhythmias exhibit higher values of LV mass and myocardial collagen than patients without arrhythmias, despite the finding that the ejection fraction and the frequency of coronary vessels with significant stenosis may be similar in the two groups of patients. Fibrosis induces conduction abnormalities thereby promoting local reentry arrhythmias. Moreover, whereas the key role of ectopic foci in pulmonary veins, which may trigger atrial fibrillation, has been recognized, atrial fibrosis has been identified as the main mechanism for atrial fibrillation (Boldt et al., 2004). This suggests that atrial fibrosis in hypertensive patients (namely those with chronic HF) may promote more widespread changes in the myocardial collagen matrix.

It is worth mentioning that the alterations in the quantity (namely amount of type I collagen) and quality (namely the degree of cross-linking of the fibers) of the myocardial collagen matrix also may influence adversely the clinical outcome in patients with HHD. For instance, it has been shown that whereas increased collagen type I cross-linking is associated per se with HF hospitalization in patients with HHD and HF (López et al., 2016), the coincidence of increased collagen type I cross-linking with severe collagen type I deposition is associated with HF hospitalization and mortality (cardiovascular and all-cause) (Ravassa et al., 2017).

Microvascular alterations

The hypertensive myocardium is characterized by multiple structural alterations in the small intramyocardial vessels (Feihl et al., 2008). On the one hand, hyperplasia or hypertrophy, and altered vascular smooth muscle cellular alignment may promote encroachment of the tunica media into the lumen, thereby causing both increased medial thickness/lumen ratio and reduced maximal cross-sectional area of intramyocardial arteries. On the other hand, vascular density in LVH becomes relatively decreased. This seems to result from capillary rarefaction or inadequate vascular growth in response to increasing muscle mass. These microcirculatory alterations, together with perivascular fibrosis, contribute to decreased coronary flow reserve (CFR) of patients with HHD (Kelm and Strauer, 2004). In fact, there is an association between decreased CFR and LV systolic and diastolic dysfunction in HHD during stress maneuvers (Galderisi et al., 2002; Ikonomidis et al., 2012; Kozàkovà et al., 2003).

Recently, the role of coronary microvascular endothelial inflammation in HF with preserved ejection fraction (HFpEF), in the context of systemic conditions such as hypertension, has been highlighted (Paulus and Tschöpe, 2013). Coronary microvascular endothelial inflammation would decrease the bioavailability of nitric oxide and cyclic guanosine monophosphate content, resulting in decreasing cardiomyocyte protein kinase G (PKG) activity. Thus low PKG activity may promote cardiomyocyte hypertrophy, hypophosphorylation of the cytoskeletal protein titin, stimulation of fibroblast differentiation into myofibroblasts with high fibrogenic activity, and increased myocardial stiffness. This sequence of events suggests that coronary microvascular endothelial inflammation may be responsible for myocardial remodeling in HFpEF of hypertensive etiology. This idea was recently supported by the demonstration that CFR was abnormally reduced in hypertensive patients with LVH and patients with HFpEF of hypertensive etiology (Kato et al., 2016). Of interest, reduced CFR was found to be associated with microvascular endothelial activation in HFpEF patients (Franssen et al., 2016).

Clinical Aspects

HHD evolves progressively along two consecutive phases, one subclinical in which elements of myocardial remodeling may be present but do not result in altered clinical parameters, and one clinically overt in which remodeling causes signs, symptoms, and a clinical profile of HF (Drazner, 2011). HHD is a multifactorial disease: whereas several factors linked to genetics, gender and lifestyle will determine the initial hemodynamic and nonhemodynamic damage of the left ventricle in the hypertensive patient, other factors related to ageing and comorbidities (e.g., diabetes, obesity, and chronic kidney disease) will influence the subclinical evolution of HHD (**Fig. 2**).

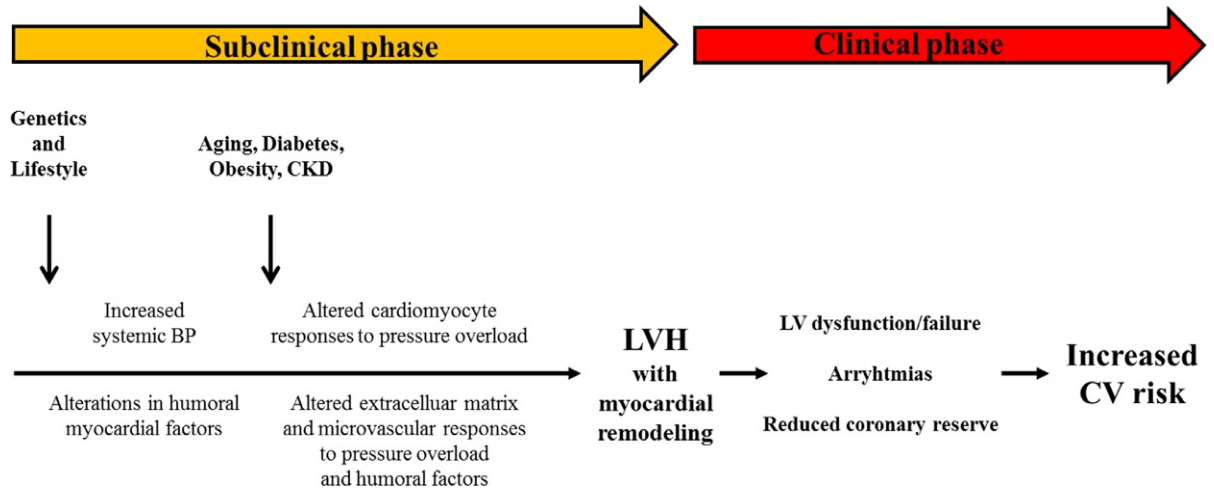

Fig. 2 Phases of the hypertensive heart disease continuum. *BP*, Blood pressure; *CKD*, chronic kidney disease; *LVH*, left ventricular hypertrophy; *CV*, cardiovascular.

Clinical Manifestations

Most patients with HHD, although at risk, are asymptomatic. However, dyspnea, edema, angina, palpitations, syncope, and sudden death can be present when complications occur. In fact, epidemiological studies have suggested that hypertension is the most common etiological factor for chronic congestive HF, being present in 50% of cases. Besides alterations of LV myocardium characteristic of HHD, hypertension may itself result in HF as a consequence of underlying coronary artery disease and arrhythmias, such as atrial fibrillation.

Unlike HF caused by coronary artery disease, in which HF progresses after a discrete event (myocardial ischemia or infarction) that damages the heart muscle, LV dysfunction/failure in the patient with HHD may progress gradually from the stage of compensated LVH with subclinical LV dysfunction to clinically overt HF (Drazner, 2011). It is worth mentioning that it has been estimated that among 30%–45% of hypertensive patients with HF present diastolic dysfunction, but normal systolic function (i.e., HFpEF). In addition, hypertensive patients with LVH may have symptoms and electrocardiographic signs of myocardial ischemia in the absence of atherosclerosis of epicardial vessels due to a combination of microvascular disease and diminished CFR (Preik et al., 2003). On the other hand, ventricular arrhythmias, atrial fibrillation, and sudden cardiac death are more prevalent in patients with hypertension and LVH than in those hypertensive patients without hypertrophy or in normotensive individuals (Yiu and Tse, 2008).

Diagnosis, Prevention, and Treatment

The classical physical findings in patients with HHD are related to the presence of LVH and include a sustained, enlarged, and displaced outside the midclavicular line apical impulse and an S_4 gallop best heard in the left lateral decubitus position.

The two most common tools used to confirm the diagnosis of LVH are the electrocardiogram (Schillaci et al., 2012) and the echocardiogram (Marwick et al., 2015) (**Table 2**). Beyond the diagnosis of LVH, the electrocardiogram provides unique information on rhythm disturbances, PR and QT intervals, whereas the echocardiogram supplies precise information about LV wall thickness (and thus on the geometric pattern of LVH), LV function, wall motion abnormalities, and left atrial size. Each provides different performance for diagnosis of LVH, with the electrocardiogram being more specific (95% vs. 84%) but much less sensitive (50% vs. 88%) than the echocardiogram. The echocardiographic determination of the cardiac architecture with the use of LV mass and relative wall thickness data allows for the identification of three LV geometry patterns (concentric hypertrophy, eccentric hypertrophy, concentric remodeling) with clear implications regarding prognosis (Marwick et al., 2015). In fact, concentric LVH carries the highest risk and eccentric LVH an intermediate risk, whereas concentric remodeling is associated with a smaller, albeit important risk (Koren et al., 1991).

The first step in HHD prevention is the control of blood pressure by the control of predisposing factors and, of course, the use of antihypertensive therapies (Pfeffer, 2017). Clinical studies have consistently shown that blood pressure reduction is a fundamental strategy to prevent LVH in patients with arterial hypertension (Georgiopoulou et al., 2010). However, there may be differences on risk-reduction effectiveness among the available antihypertensive therapies (Georgiopoulou et al., 2010; Sciarretta et al., 2011), which may be linked to the different ability of the drugs to interfere with myocardial remodeling.

Antihypertensive drugs are, in fact, effective in reducing LV mass. One meta-analysis including 80 double-blind, randomized controlled trials with 146 active treatment arms and 17 placebo arms showed that after adjustment for treatment duration and change in diastolic pressure, there was a significant difference among medication classes in decreasing LV mass (Klingbeil et al., 2003). The decreased LV mass indexed by body surface area or LV mass index induced by the different classes was as follows: AT_1

Table 2 Electrocardiographic and echocardiographic diagnostic criteria for left ventricular hypertrophy

Electrocardiogram[a]
Sokolow-Lyon index
$S_{V1} + (R_{V5}$ or $R_{V6}) > 3.5$ mV
$R_{aVL} > 1.1$ mV
Cornell voltage criteria
$S_{V3} + R_{aVl} \geq 2.8$ mV (for men)
$S_{V3} + R_{aVl} \geq 2.0$ mV (for women)
Cornell voltage-duration product
QRS duration × Cornell voltage >2436 mm × ms
QRS duration × sum of voltages in all 12 leads >17,472 mm × ms
Romhilt-Estes point score system (LVH is diagnosed if 5 points are computed)
Any limb lead R wave or S wave ≥2.0 mV: 3 points
S_{V1} or $S_{V2} \geq 3.0$ mV: 3 points
R_{V5} to $R_{V6} \geq 3.0$ mV: 3 points
ST-T wave abnormality (no digitalis therapy): 3 points
ST-T wave abnormality (digitalis therapy): 1 point
P terminal force in V_1 >40 mV-ms: 3 points
Left axis deviation: 2 points
Intrinsicoid deflection in V_5 or $V_6 \geq 50$ ms: 1 point
Echocardiogram[b]
Indexed left ventricular mass (left ventricular mass:body surface area)
Men >115 g/m^2
Women >95 g/m^2
Indexed left ventricular mass (left ventricular mass: [height])$^{2.7}$
Men >48 g/m$^{2.7}$
Women >44 g/m$^{2.7}$
Relative wall thickness (2 × posterior left ventricular wall thickness): left ventricular diameter in diastole) ≥0.42

[a]Schillaci et al. (2012).
[b]Marwick et al. (2015).

receptor blockers>calcium antagonists>ACE inhibitors>diuretics>beta-blockers. In paired comparisons, AT_1 receptor blockers, ACE inhibitors, and calcium antagonists were more effective at reducing LV mass index than diuretics and beta-blockers.

Additional strategies, such as selective denervation of the renal sympathetic nerves to lower blood pressure, have also been shown to significantly reduce LV mass and improve diastolic function in patients with resistant hypertension (Brandt et al., 2012). It is worth to note that patients who did not respond hemodynamically to renal denervation did show LVH regression, supporting the notion of renal denervation effects on LVH independent of blood pressure.

Impact on Public Health

The impact of HHD on public health is undeniable (Ambrosy et al., 2014; Pfeffer, 2017). First, LVH is highly prevalent in hypertensive patients, as assessed either by electrocardiogram (Cuspidi et al., 2012a) or by echocardiography (Cuspidi et al., 2012b), with an average of 40%–45%. Second, considered as a categorical variable, LVH significantly and independently increases the risk of HF and other cardiac (e.g., coronary artery disease, arrhythmias, sudden death) and noncardiac (e.g., stroke) complications, as shown by data from the Framingham study (Levy et al., 1990). Third, recent evidence challenge the notion that blood pressure control by antihypertensive treatment completely prevents HHD-associated risk. It is classically admitted that cardiovascular risk decreases significantly in hypertensive patients in whom LVH regresses with antihypertensive treatment compared to patients in whom LVH persists, in spite of similar hemodynamic effectiveness of the treatment (Devereux et al., 2004). However, a meta-regression analysis of 14 studies in 12,809 hypertensive patients failed to demonstrate a continuous relationship between treatment-induced LVH changes and the occurrence of cardiovascular events (namely, myocardial infarction and new onset HF) (Constanzo et al., 2013). Moreover, a study conducted in 763 hypertensive patients followed up for an average of 12 years showed that the progression of LV mass with respect to the baseline value had a predictive value for cardiovascular events independent of the initial measurement and course of the office blood pressure (Gosse et al., 2012).

Current Challenges

Although current management of HHD is still focused on controlling blood pressure and reducing the increased LV mass (Schiattarella and Hill, 2015), it must be remarked that the impact of currently available antihypertensive agents on myocardial remodeling may not be optimal (**Table 3**). This may in part be due to the lack of personalized diagnosis and therapy in HHD.

Table 3 Clinical evidence-based hemodynamic and cardiac effects of antihypertensive agents

Pharmacological class	*Decrease of blood pressure*	*Reduction of LV mass*	*Repair of remodeling lesions*[a]
Alpha-blockers	Yes	Mild	Unknown
Beta-blockers	Yes	Mild–moderate	Apparently not
Calcium antagonists	Yes	Moderate	Apparently not
Diuretics	Yes	Mild	Proven for torasemide[b]
Aldosterone antagonists	Yes	Mild–moderate	Proven for spironolactone[c]
Direct renin inhibitors	Yes	Marked	Unknown
Angiotensin converting enzyme inhibitors	Yes	Marked	Proven for lisinopril[d]
Angiotensin receptor blockers	Yes	Marked	Proven for losartan[e]
Angiotensin receptor blocker and neprilysin inhibitor	Yes	Unknown	Unknown

LV, left ventricular.

[a]Refers to some of the lesions (namely, fibrosis).

[c]Izawa et al. (2005).

[d]Brilla et al. (2000).

[e]Díez et al. (2002).

Therefore, additional strategies aimed at specific diagnosis by noninvasive biochemical (González et al., 2009) or imaging (Hoey et al., 2014) techniques, as well as individually tailored therapeutic repair (González et al., 2011) of the microscopic changes responsible for hypertensive myocardial remodeling are needed.

Search for Patients Predisposed to LVH and LV Dysfunction

Emerging evidence indicates that identification of subsets of patients with a common denominator may help select a therapeutic approach. For instance, 24 h monitoring of blood pressure may help identify those hypertensive patients highly predisposed to develop LVH (i.e., patients with early morning pressure rise or with a nondipping profile) and therefore more prone to benefit from the ability of some antihypertensive drugs to prevent it (Kawano et al., 2008).

LV mass is a highly complex phenotype influenced by interacting effects of multiple hemodynamic and nonhemodynamic factors, including genetic factors. Identification of genes influencing LV mass may enhance the detection of those patients requiring early treatment. In this regard, a meta-analysis of case–control and association studies has shown that the D allele of the insertion/deletion (I/D) polymorphism of the angiotensin converting enzyme (ACE) gene behaved as a marker of future LVH in untreated hypertensive patients (Kuznetsova et al., 2000).

Finally, novel diagnostic tools, such as quantification of the myocardial strain by speckle-tracking echocardiography, may help shed light in the cardiac dysfunction of patients with HFpEF (Saito et al., 2016), providing clues for specific preventive and therapeutic approaches of this growing clinical entity.

Noninvasive Diagnosis of Myocardial Remodeling

The noninvasive assessment of the histological alterations that underlie HHD is key to personalized diagnosis and treatment. On the one hand, novel imaging tools are key contributors of diagnosis of myocardial remodeling. Cardiac magnetic resonance imaging (CMR) not only can measure LV mass and dimensions more accurately than conventional echocardiographic techniques (Hoey et al., 2014; Janardhanan and Kramer, 2011), but it is also a promising technique for characterizing the myocardial composition, particularly with the analysis of T1 mapping and late gadolinium enhancement areas in the myocardium may represent fibrotic regions (Janardhanan and Kramer, 2011). In addition, CMR is rapidly evolving with the introduction of an increasing number of high-affinity molecular probes potentially useful to monitoring specific alterations in the myocardium such as apoptosis (i.e., using ^{99m}Tc-labeled annexin A5 that binds to apoptotic cardiomyocytes) and collagen synthesis (i.e., using ^{99m}Tc-labeled peptides that bind to activated fibroblasts) (Chun et al., 2008).

On the other hand, the identification of biochemical markers of potential usefulness for clinical management of cardiac diseases is emerging as a very active field (González et al., 2009). Regarding biochemical markers related to cardiomyocyte alterations, plasma concentration of CT-1 has been correlated with LV mass in untreated hypertensive patients (González et al., 2009), suggesting that plasma CT-1 may be a potential marker for assessment of cardiomyocyte hypertrophy and LVH in hypertensive patients. In addition, the decrease of plasma CT-1 induced by antihypertensive treatment is associated with the reduction of LV mass in patients with LVH (González et al., 2009), suggesting that this cytokine may be useful to assess ability of antihypertensive drugs to reduce cardiomyocyte growth and decrease LV mass. Moreover, CT-1 is associated with myocardial systolic dysfunction in asymptomatic hypertensive patients (Ravassa et al., 2013), indicating that CT-1 may also provide information regarding the clinical impact of myocardial remodeling. Regarding biochemical markers related to myocardial fibrosis, diverse studies indicate that they are promising tools to assess this aspect of myocardial remodeling in hypertensive patients (González et al., 2009; López et al., 2015). Clinical data indicate that the serum levels of the carboxy-terminal propeptide of procollagen type I (PICP), excised from the

procollagen molecule in its maturation process, is a marker of the amount of collagen in the myocardium (González et al., 2009; López et al., 2015). In addition, a recent work indicates that the circulating levels of the carboxyl-terminal telopeptide of collagen type I, normalized by circulating MMP-1 levels, may be indicative of the degree of cross-linking of myocardial collagen (López et al., 2016; Ravassa et al., 2017). As mentioned before, not only do these biomarkers help diagnose by giving evidence of the remodeling that takes place in the myocardium, but they may also provide information about hospitalization or death risk (López et al., 2016; Ravassa et al., 2017) and may even influence therapeutic approaches (Díez et al., 2002; López et al., 2007, 2015).

Another aspect of myocardial remodeling that may benefit from noninvasive diagnosis is the coronary microcirculation (Paulus and Tschöpe, 2013). Although research so far has focused mainly in coronary artery disease, novel imaging techniques may clarify the role of altered cardiac microcirculation in HHD (Camici et al., 2015).

Antiremodeling Strategies

Available experimental and clinical data suggest that the goal of repairing myocardial remodeling is also achievable in HHD using available antihypertensive agents (**Table 3**). For instance, in patients with HHD, ACE inhibition reduced myocardial fibrosis, irrespective of blood pressure and LV mass reduction, and was accompanied by improved LV diastolic function (Brilla et al., 2000). In addition, despite similar antihypertensive and antihypertrophic efficacy, the AT_1 receptor blocker losartan, but not the calcium channel blocker amlodipine, reduced cardiomyocyte apoptosis (González et al., 2002) and myocardial fibrosis (Díez et al., 2002) in patients with HHD. Reduction of myocardial fibrosis by the AT_1 blocker was associated with decreased LV chamber stiffness and the improvement of diastolic filling in hypertensive patients (Díez et al., 2002).

Since the action of most of the reviewed antihypertensive therapies on myocardial remodeling is limited, the attention has been recently turned to the potential of targeting specific intracellular events (González et al., 2011). Hypothetically, these novel therapeutic interventions could be directed to the following aspects: first, to block the detrimental intracellular mechanisms activated in mechanical stress-triggered cardiomyocyte hypertrophic response (e.g., kinases such as Rho-kinase, and phosphatases such as calcineurin). Second, to prevent inhibition of "negative" signaling modulators and interacting proteins that are repressed in such conditions (e.g., increasing the availability and actions of cyclic GMP). Third, to take advantage of beneficial mechanisms inherent in the mechanical stress-triggered cardiomyocyte hypertrophic response (e.g., via enhancement of important aspects of the IGF1/PI3K/Akt pathway like angiogenesis). Fourth, to block the deleterious modulation that pathological stresses impose on protein synthesis (e.g., through regulation of HDACs or sets of microRNAs). Fifth, to prevent mitochondrial oxidative stress (e.g., through mitochondrial targeted small molecules and peptides). Sixth, to preserve functioning cardiomyocytes (e.g., through the inhibition of the process of apoptosis and/or preservation of cell survival mechanisms). Seventh, to regenerate lost cardiomyocytes (e.g., using stem cell therapy). Eighth, to restore the normal turnover of collagen network (e.g., inhibiting exaggerated collagen synthesis and deposition at nonphysiological localizations).

Two examples may illustrate the mentioned possibilities. First, experimental data in mice show that the systemic administration of the mitochondrial targeted antioxidant peptide SS-31 ameliorated angiotensin II-induced LVH, diastolic dysfunction, myocardial apoptosis, and fibrosis in these animals, despite the absence of blood pressure-lowering effect (Dai et al., 2011). SS-31 reduced also angiotensin II-induced mitochondrial reactive oxygen species and oxidative damage, as well as mitochondrial biogenesis in cardiac cells. Second, circulating miRNA-21 is increased in hypertensive patients, as well as in the experimental model of HHD of the spontaneously hypertensive rat (SHR). MiR-21 targeting in SHR normalized mitochondrial cytochrome-*b* expression and oxidative stress, which resulted in attenuated blood pressure, cardiomyocyte hypertrophy, and myocardial fibrosis (Li et al., 2016).

Conclusion

HHD begins with the hypertrophic response of cardiomyocytes to increased hemodynamic load. The increase in LV wall thickness normalizes increased wall stress and, therefore, LVH is initially beneficial. However, sustained and progressive load, that is accompanied by the activation of humoral factors, is associated with additional responses of the cardiomyocyte and noncardiomyocyte compartments of the myocardium that result in its structural remodeling and the deleterious long-term consequences on myocardial function, electrical activity, and perfusion that significantly increase the morbidity and mortality in hypertensive patients with LVH. A detailed understanding of the complexities underlying these responses will aid in the development of novel diagnostic and therapeutic approaches aimed to prevent or minimize their deleterious impact on the heart of the hypertensive patient in a tailored, effective, and safe manner. This knowledge is also critical due to the increasing prevalence of HHD and its risk factors, and taking on account its social and economic burden (Ambrosy et al., 2014; Pfeffer, 2017).

Introduction

Hypertrophic cardiomyopathy (HCM) is a common genetic cardiovascular disorder affecting 1 in 500 of the general population. While historically it was viewed as a rare condition associated with excess mortality, in the current era with contemporary management strategies the majority of patients will achieve normal or near-normal life expectancy (Maron et al., 2015). Despite this, HCM remains one of the most common causes of sudden cardiac death (SCD) in young people and athletes.

An increase in left ventricular wall thickness or hypertrophy (LVH), in the absence of coexistent cardiac or systemic conditions which could result in LVH (such as hypertension and aortic valve stenosis), is central to the diagnosis. This increase in wall thickness can involve virtually any segment of the left or less frequently the right ventricular myocardium. On a microscopic level there is evidence of myocyte disarray, patchy myocardial fibrosis or scarring, and abnormalities of the small intramural blood vessels.

Genetic Basis of the Disease

HCM is typically inherited in an autosomal dominant pattern, whereby each offspring of an affected individual has a 50% chance of inheriting a pathogenic mutation. Most cases are caused by a mutation in the genes coding for the sarcomere proteins, with over 80% of cases arising from a mutation in either the MYH7 (myosin heavy chain) or MYBPC3 (myosin binding protein C) genes. However, in some cases the disease can result from a sporadic mutation in one of these genes.

Pathophysiology

Diastolic and systolic function

The presence of LVH, myocardial disarray, and fibrosis results in an increase in left ventricular stiffness. This adversely affects myocardial relaxation and diastolic function, leading to an increase in intracavitary pressures in both the left ventricle (LV) and left atrium (LA). In a small subset of patients (<15%) the presence of significant myocardial fibrosis can result in a progression to systolic dysfunction (burnt-out HCM), characterized by progressing wall thinning and chamber dilatation.

Obstruction

Intracavitary and left ventricular outflow tract obstruction (LVOTO) is seen in up to 70% of patients, either at rest or with provocation such as exercise. The pattern of hypertrophy of the LV often determines whether obstruction will arise and is typically seen in patients with classic asymmetric LVH affecting the basal interventricular septum.

Myocardial ischaemia

Myocardial ischaemia in patients with HCM can arise from several causes, including disease of the large epicardial coronary arteries as well as a supply–demand mismatch due to significant LVH. However, even in the absence of epicardial coronary artery disease, abnormalities of the small intramural vessels are noted, resulting in microvascular dysfunction.

Arrhythmias

Chronic increases in LV and LA pressure secondary to diastolic dysfunction and LVOTO result in progressive LA dilatation, and increase the risk of supraventricular arrhythmia. Atrial fibrillation occurs in up to 20% of patients with HCM, and carries with it an increased risk of stroke and thromboembolic events. Myocardial fibrosis and disarray serve as a substrate for ventricular arrhythmia, which carries with it an increased risk of SCD. While nonsustained ventricular tachycardia (NSVT) is seen in 15%–20% of patients on ambulatory ECG monitoring, sustained VT is less common.

Autonomic dysfunction

Autonomic dysfunction can be demonstrated in up to a third of patients with HCM, and typically manifests as an abnormal blood pressure response to exercise (i.e., an inability to augment systolic blood pressure appropriately). The underlying mechanism is an inappropriate firing of stretch-sensitive mechanoreceptors in the LV myocardium, resulting in exaggerated drops in systemic vascular resistance. In addition, these abnormalities of vascular control can result in episodes of presyncope or syncope.

Clinical Presentation

Patients with HCM may present with symptoms, or may be identified after the incidental finding of abnormalities on an ECG or echocardiogram performed for other reasons. In the current era of family screening a significant number of cases are diagnosed in asymptomatic family members of an affected individual.

Up to 50% of patients with a confirmed diagnosis of HCM are either asymptomatic or present with minimal symptomatic limitations. Shortness of breath and chest discomfort are common, predominantly as a result of underlying diastolic dysfunction and LVOTO. Chest pain may present as typical angina or may be atypical. In patients with LVOTO, symptoms are typically worse after a heavy meal (postprandial exacerbation). Dizziness and syncope may occur at rest or on exertion, and arrhythmia and dynamic LVOTO are important causes. Palpitations are not uncommon, and may signify underlying episodes of atrial fibrillation of ventricular arrhythmia.

Investigations and Diagnosis

The diagnosis of HCM centers around the identification of unexplained LVH.

Clinical examination

The classic findings on clinical examination are shown in **Fig. 1**.

Electrocardiography (ECG)

A 12-lead ECG is often used as a screening tool for HCM, and is abnormal in up to 95% of patients. Classic ECG abnormalities include the presence of LVH by voltage criteria, widespread Q waves, and repolarization abnormalities. Diffuse and giant ($>$10 mm) T-wave inversion is a distinctive pattern seen in patients with apical hypertrophy. Ambulatory ECG monitoring plays a vital role not only in the investigation of symptoms of palpitations but also for the identification of patients at risk for SCD (nonsustained ventricular tachycardia) and stroke (paroxysmal atrial fibrillation) (**Fig. 2**).

Imaging

Transthoracic echocardiography (TTE) is the mainstay of diagnosis, allowing direct assessment not only of LV wall thickness but also assessment of LVOTO, concomitant mitral valve disease and dysfunction, and the assessment of diastolic and systolic function. The diagnosis hinges on the presence of a wall thickness of $>$15 mm in any myocardial segment, or in the paediatric population $\geq$2 standard deviations above the mean (Z-score) after correction for age and body surface area (Nagueh et al., 2011). While the classic description is of asymmetric hypertrophy involving the interventricular septum, hypertrophy can be concentric or involve the apical segments of the ventricle preferentially. LVOTO is present in over two-thirds of patients, occurring under resting conditions in 30% of cases, and provocable in a further 40% (Maron et al., 2006). Mitral regurgitation is seen frequently in patients with obstruction due to systolic anterior motion of the mitral valve, with a typically posteriorly directed jet into the LA (**Fig. 3**). However, intrinsic structural abnormalities of the mitral valve and subvalvular apparatus frequently coexist in patients with HCM, and further contribute to the degree of mitral regurgitation. Diastolic dysfunction, LVOTO, and mitral regurgitation all result in progressive LA dilation.

Cardiac magnetic resonance imaging (CMR) adds valuable additional information to the diagnostic work-up of patients with presumed or confirmed HCM (Nagueh et al., 2011). It is particularly helpful in patients with suboptimal TTE image quality, and in patients in whom the ECG is strikingly abnormal and the diagnosis is suspected but TTE is equivocal. CMR provides superior

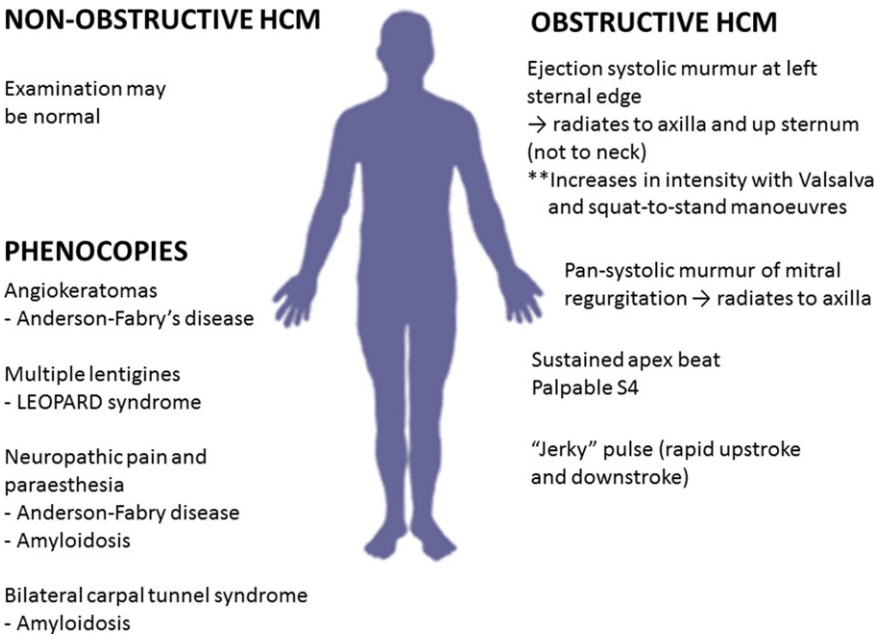

Fig. 1 The classic findings on clinical examination in patients with hypertrophic cardiomyopathy. Most abnormalities on examination are related to the presence of left ventricular outflow tract obstruction and associated mitral regurgitation. Some of the "red flags" which may point to an alternative diagnosis or disease "phenocopy" are shown as well, and highlight the importance of a complete clinical examination.

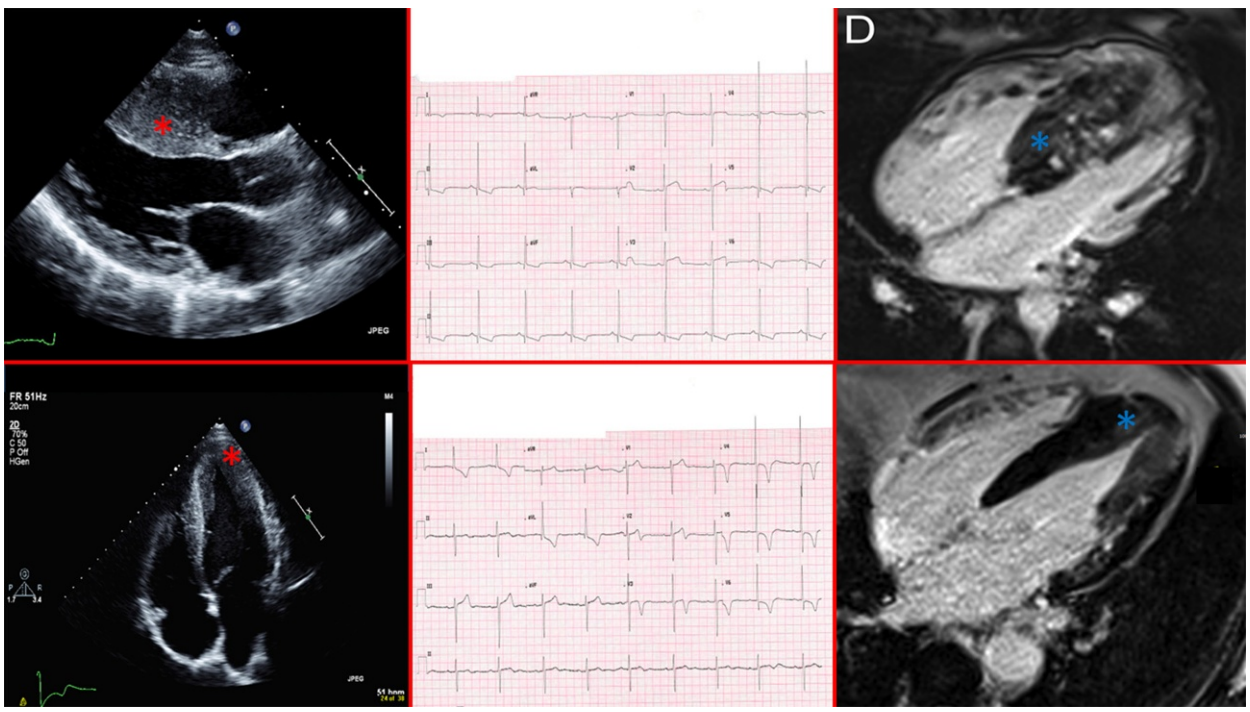

Fig. 2 The classic imaging findings on ECG and imaging are shown in a patient with asymmetric septal hypertrophy (*upper panel*) and apical hypertrophy (*lower panel*). *Upper panel*—the marked septal hypertrophy is noted (*red asterisk*), along with LVH and repolarization abnormalities on the ECG (ST segment and T-wave changes). The CMR image demonstrates the presence of extensive myocardial fibrosis in the hypertrophied segments (*blue asterisk*). *Lower panel*—hypertrophy is confined to the apical segments of the left ventricle (*red asterisk*), with the classic giant negative T-waves seen on ECG. In this patient, myocardial fibrosis is again seen in the hypertrophied segments of the LV apex (*blue asterisk*).

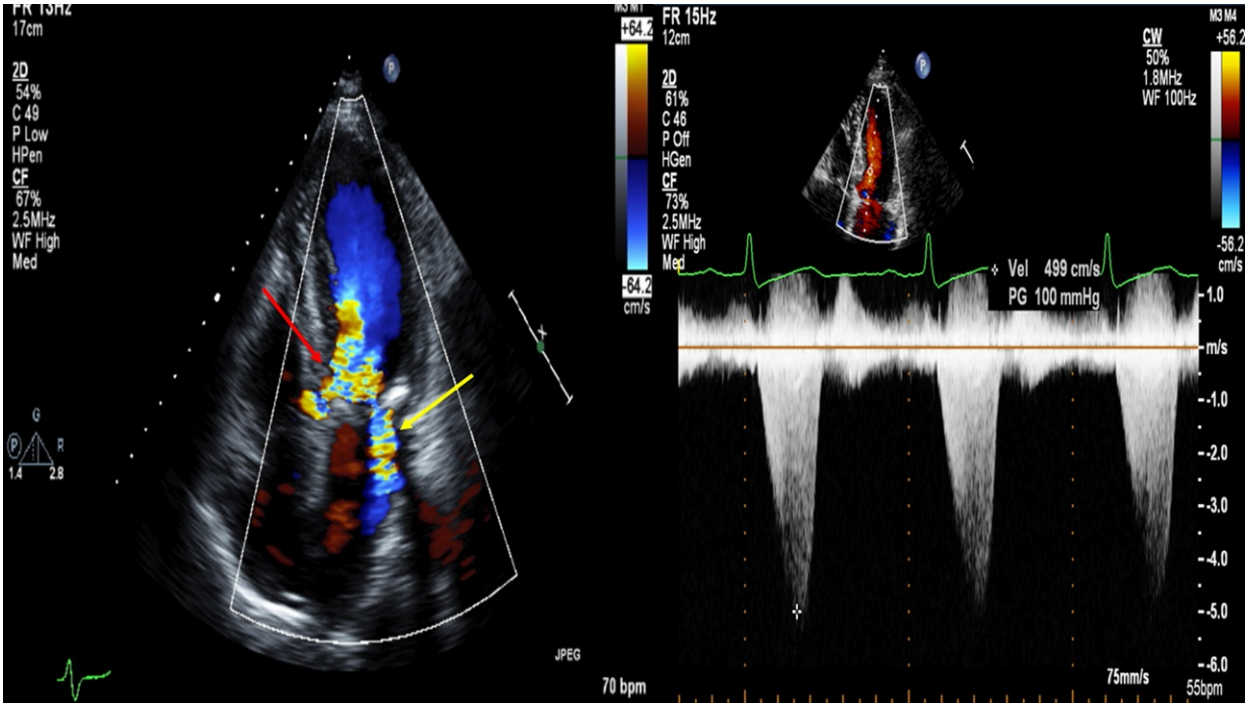

Fig. 3 On color flow imaging on transthoracic echocardiography there is marked turbulence of blood flow in the left ventricular outflow tract (*red arrow*), along with a posteriorly directed jet of mitral regurgitation (*yellow arrow*). A cursor is placed across the outflow tract and using continuous wave Doppler an outflow tract gradient of 100 mmHg can be recorded, indicating severe outflow tract obstruction under resting conditions.

delineation of apical hypertrophy and allows identification of apical infarction and aneurysm formation. Gadolinium contrast agents allow identification of underlying myocardial scar and fibrosis, the pattern and degree of which may often alert the clinician to the possible presence of a "mimic" or phenocopy of HCM such as cardiac amyloidosis or Anderson-Fabry disease. The degree of myocardial fibrosis may relate to risk of development of heart failure, arrhythmia, and SCD (Fig. 2).

Exercise testing

Exercise testing allows objective assessment of exercise capacity, blood pressure response to exercise, and exercise-induced arrhythmia. When combined with TTE, it can identify patients with provocable LVOTO.

Ischaemic testing

Exercise ECG and functional testing such as myocardial perfusion scanning and stress echocardiography are not sensitive markers of underlying epicardial coronary artery disease, given that inducible ischaemia and ECG changes may occur in the absence of significant stenosis of an epicardial coronary artery. CT coronary angiography is most useful in those cases in whom a low likelihood of coronary artery disease (CAD) exists, but in the presence of traditional risk factors for CAD and an intermediate to high likelihood of CAD coronary angiography is preferred.

Differential Diagnosis

The presence of LVH does not always represent a pathological response, and can represent a physiological or compensatory response to high levels of athletic training. However, the presence of LVH represents a pathologic response to hemodynamic loading of the ventricle in cases such as systemic hypertension and aortic stenosis. Unexplained LVH can also occur in a range of systemic and genetic disorders, most notably lysosomal and glycogen storage disorders such as Anderson-Fabry disease and Danon disease. Infiltrative disorders such as cardiac amyloidosis, mitochondrial disorders, and genetic syndromes such as Noonan syndrome account for a small percentage of cases. Accurate identification of the underlying cause of unexplained LVH is important to guide appropriate therapy.

In patients in whom a "mimic" or phenocopy of HCM is suspected, a routine panel of blood tests to assess renal and liver function, full blood count, plasma BNP, and troponin should be performed. Impaired renal function and proteinuria may be seen in systemic amyloidosis and Anderson-Fabry disease, whereas liver tests and serum creatine phosphokinase may be abnormal in mitochondrial and glycogen storage disorders. In cases of suspected amyloidosis, serum and urine protein electrophoresis are mandatory. Assessment of plasma/leucocyte alpha galactosidase A activity should be performed in all men aged >30 years, and in

any case where Anderson-Fabry disease is clinically suspected. Enzyme levels are often within the normal range in affected females and genetic testing is necessary to confirm the diagnosis (Elliott et al., 2014).

Disease Course and Progression

While the majority of patients have minimal or no symptoms, and follow a benign and stable clinical course, in some cases progressive congestive heart failure or sudden cardiac death may occur. Progressive symptoms, secondary to diastolic dysfunction, LVOT obstruction, mitral regurgitation, or development of left ventricular systolic dysfunction, may occur and significantly impact quality of life (Fig. 4).

Three distinctive modes of death have been demonstrated in patients with HCM, with an overall annual mortality of <1%/year: (1) sudden and unexpected, (2) progressive heart failure, and (3) ischemic stroke secondary to atrial fibrillation (Maron et al., 2000).

Clinical Management

The clinical management of patients with HCM focuses on the treatment of symptoms, assessment and reduction of risk of SCD, and screening of at-risk family members either clinically or with cascade genetic testing.

Pharmacologic

The treatment of symptoms is determined by the presence or absence of LVOTO (Fig. 5), and beta-blocker and calcium-channel blockers remain the mainstay of first-line therapy, titrating up to a maximum tolerated dose. Fig. 5 demonstrates a schematic for the management of patients. In patients with obstruction who remain symptomatic despite the use of first-line agents, Disopyramide can be added as second-line therapy. Given its potential to result in QT prolongation, initiation should be performed under close cardiac and ECG monitoring. Attention should also focus on optimizing antihypertensive therapy in patients with concomitant systemic hypertension, as vasodilator agents such as angiotensin receptor inhibitors and alpha-blockers can aggravate outflow tract obstruction.

In the absence of LVOTO, oral diuretics can be added after a calcium-channel blocker or beta-blocker to control symptoms of dyspnoea.

Intervention

When symptoms related to ongoing LVOTO persist despite pharmacological therapy, as is the case in up to one-third of patients, interventional strategies may become necessary to improve quality of life. This may take the form of surgical septal myectomy, with resection of muscle from the basal and mid-interventricular septum, with or without concomitant coronary artery bypass grafting and mitral valve surgery. Septal myectomy can safely be performed in expert centers with extremely low rates of morbidity and mortality. Alternatively, alcohol septal ablation, performed through a percutaneous approach, involves injection of ethanol into a septal perforator vessel identified as supplying the myocardium of the hypertrophied basal interventricular septum. This creates an area of infarction with subsequent healing and thinning of the myocardium over a 6-12-month period. Dual-chamber pacing is an alternative for those patients who have an unacceptably high risk for either of the above interventional procedures. However, the benefit from pacing is usually modest compared with myectomy and alcohol ablation (Fig. 5).

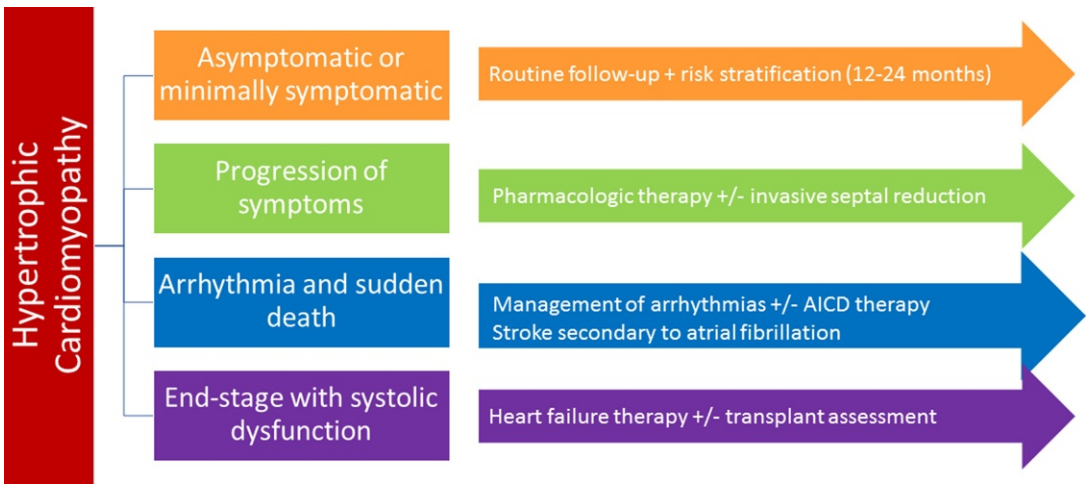

Fig. 4 Patients may progress along one of several disease courses, and may in fact be affected by various complications of the disease (such as progressive heart failure and arrhythmia).

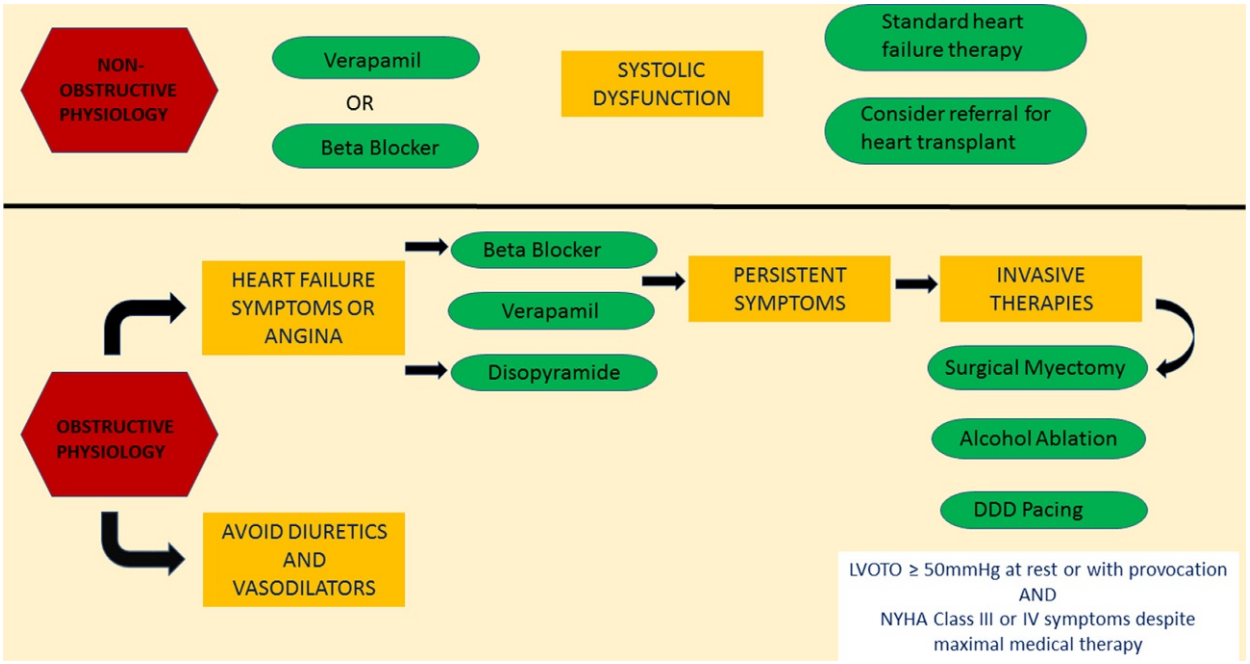

Fig. 5 An algorithm for the symptomatic treatment of HCM, stratified by the presence or absence of left ventricular outflow tract obstruction. The mainstay of therapy remains beta-blocker and calcium-channel blocker therapy. Invasive septal reduction therapies are reserved for those patients with medically refractory symptoms and significant outflow tract gradients either at rest or with provocation.

Risk stratification

SCD remains the most devastating complication of the disease, and is often the first presentation. Implantation of an automated implantable cardioverter defibrillator (AICD) can offer protection from SCD in patients deemed to be at higher risk.

An AICD should be implanted in any patient who has survived an aborted SCD or experienced a high-grade ventricular arrhythmia due to the increased risk of recurrence (up to 10%/year).

The challenge remains identifying patients at high risk of SCD and reassuring those at low risk, while also factoring in the risk–benefit of lifelong AICD therapy with its associated complications.

Established risk factors include: (1) a family history of sudden death, (2) a maximum wall thickness $\geq$30 mm, (3) one or more recent unexplained syncopal episodes, and (4) the presence of NSVT (especially in patients younger <30 years). Other SCD risk factors or modifiers of risk include: (1) an abnormal blood pressure response to exercise, (2) LVOTO, (3) the presence of significant myocardial fibrosis on CMR, and (4) the presence of an apical aneurysm (Gersh et al., 2011). The decision to implant an AICD cannot be solely determined by a checklist of risk factors, which can both over- or underestimate the risk in an individual patient, but integrated with the clinical assessment of the physician and the wishes of the patient.

Family screening

Family screening, either clinical (ECG and echocardiography) or genetic (if a pathogenic mutation has been identified in the family), should be offered to all first-degree relatives after appropriate counseling about the potential implications of a positive test.

PREFACE

The burden of cardiovascular disease is growing across the globe as the leading noncommunicable cause of morbidity and mortality. This is despite outstanding research that has improved our understanding of cardiovascular biology, the determinants of disease, and development of new therapies. We are optimistic that the next generation of scientists and clinicians will further these efforts and ultimately bring about changes that will reduce risk and improve outcomes for patients worldwide. We have assembled this encyclopedia with the explicit intent to provide this generation with easy access to past and current wisdom, with the hope that this helps to accelerate innovation in cardiovascular medicine.

This encyclopedia represents both a dream and a labor of love. The dream is to create a scientific compendium that recognizes that the methods and tools used to access and study the scientific literature have changed, with a burgeoning impact of digital technology—the so-called pocket book encyclopedia that is accessible on a smart phone fitting into medical overalls, and that can also be read as a textbook at a desk! These changes in the access of publications have been accompanied by the evolving need for studying different aspects of biology and disease as stand-alone chapters not necessarily read sequentially. Furthermore, as editors we recognize the fundamental importance of conveying knowledge through brilliantly illustrated texts that are profusely embedded with links to key references. The critical importance to use multimedia tools and to provide downloadable slides for educational purposes is reflected in this encyclopedia. Additionally, we want to ensure the feasibility of updating text, figures, and other reading material iteratively even after a publication date, recognizing the rapid advent of information and huge strides made in cardiovascular medicine every day. Thus, this work represents the end of the beginning of a live text that will metamorphose over time, being guided by the rapid strides and advances in both cardiovascular medicine and publication science.

Overall, we conceptualized this work as providing broad coverage of science and also serving the expansive needs of a readership that is quite diverse, that is, encompassing medical students, residents, fellows, and postdoctoral scientists interested in cardiovascular medicine. We hope the labor of love of an outstanding team of editors and a stellar group of authors is readily evident to the broad readership we have targeted.

Assembling this compendium had many challenges. Early on we made the choice to cover the broad range of cardiovascular biology, pathophysiology, epidemiology, and treatment of disease. We sought to assure equal coverage to foundational cardiovascular cellular and molecular biology as well as state-of-the-art treatments. Covering the breadth inevitably led to some overlap between some chapters, and yet we certainly have some residual gaps. We hope to have the opportunity to fill these gaps in future editions. There is also inevitable variation in the style and scope of articles in this multiauthor publication. We and the section editors felt it was more important to allow our expert authors freedom in how they chose to present their topic.

We invite feedback on how this encyclopedia can be improved as a resource for trainees worldwide. Undoubtedly, as noted above, there are gaps in content areas that need to be bridged in future iterations of this encyclopedia. We look forward to hearing from and listening to our readership about how the text can be better organized or better compiled to serve their scholarship better in future years.

This project was made possible through the hard work of many people from across the globe. We were pleased to have section editors and authors from around the world. Drs. Kessler and Schunkert, renowned cardiologists with an outstanding record of accomplishment in genetic research, have compiled a series of chapters on genetics and genomics. Dr. Baliga, a distinguished cardiologist and educator, has conceptualized a tour de force of chapters that capture all aspects of the heart failure syndrome, whereas Dr. DiSalvo, a master clinician and educator, has synthesized a fine tapestry of chapters focusing on diagnostic testing with key sections on cardiac imaging, interventions, and device therapy. Dr. Raj, an outstanding clinical investigator and

electrophysiologist, brought together an exemplary collection of chapters that offer coverage of a broad spectrum of topics in cardiac electrophysiology. Drs. Major and Liaw, both highly accomplished basic scientists and educators, were instrumental in identifying topics of fundamental importance to the field of cardiovascular biology and medicine. Dr. Lenihan, a pioneering clinical scientist and outstanding cardiologist, brought together a special set of articles that represent interactions between cardiovascular and other fields of medicine. Dr. Gale, a celebrated cardiologist with expertise in comparative effectiveness research and clinical cardiology, offers a series of stellar chapters underscoring various aspects of the pathogenesis and management of atherosclerotic cardiovascular disease. Dr. Kokubo, a leading preventive cardiologist with specialization in cardiovascular epidemiology, has orchestrated state-of-the-art chapters on cardiovascular epidemiology.

We would like to thank our colleagues at Elsevier who provided steadfast support of an exemplary nature throughout this long journey. Last but not the least, the editors would like to thank their families, their mentors, and their respective institutions for the constant encouragement, advice, and support over the years.

Introduction

While the rate of significant valvular heart disease is rising worldwide as the population ages, moderate to severe mitral regurgitation continues to be the most prevalent form of severe valvular disease in developed countries (Nkomo et al., 2006; Coffey et al., 2016; Iung et al., 2003; Shu et al., 2016). The exact prevalence of this disease is difficult to identify due to regional and temporal heterogeneity in the definition of severe valvular regurgitation as well as referral bias for echocardiography in clinical studies. In the Framingham Offspring Study, mild or greater mitral regurgitation was present in 19% of participants receiving screening echocardiograms (Coffey et al., 2016). Pooled prospective cohort studies of community-dwelling individuals assessed with echocardiography suggest that mitral regurgitation is present in 1.7% of the population, including 9.3% of individuals $\geq$75-years old (Nkomo et al., 2006). The prevalence of moderate or greater mitral regurgitation rises with age and appears to have a male predominance in 60%–75% of cases in surgical series (Nkomo et al., 2006). In an African-American cohort older than age 50, 0.7% of individuals had moderate or more severe mitral regurgitation (Coffey et al., 2016). Mitral regurgitation is associated with larger left ventricular diastolic and left atrial diameters compared to individuals without valvular heart disease (Nkomo et al., 2006). Given that mitral regurgitation is a heterogeneous entity, occurring either due to primary abnormalities with the valve or valvular apparatus or secondary abnormalities due to dysfunction in the left atrium or ventricle, the exact prevalence of mitral regurgitation depends on its etiology and definition of severity. For example, while mitral valve prolapse has a population prevalence of 2.4% (Freed et al., 1999), the majority of these individuals have trivial to mild regurgitation. In the setting of cardiomyopathy, up to 49% have mild to moderate mitral regurgitation and 24% have severe mitral regurgitation (Coffey et al., 2016).

Etiologies of Mitral Valve Disease

Mitral regurgitation can result from a variety of derangements affecting any portion of the valvular apparatus. Mitral regurgitation is generally classified as either primary (i.e., organic) due to an abnormality with the valvular leaflets or secondary (i.e. functional), which is typically caused by an abnormality of the atrium or ventricle. Though the terminology has changed over time, ischemic mitral regurgitation is often inappropriately used to refer to functional mitral regurgitation due to ischemic remodeling of the left ventricle. Properly described, ischemic mitral regurgitation represents a type of functional mitral regurgitation due to tethering and apical displacement of the posteromedial papillary muscle in the setting of myocardial infarction. This prevents full excursion of the inferolateral left ventricular wall and annular dilation from progressive volume overload.

While mitral regurgitation may be classified by the presence of valvular leaflet involvement, it may also be classified by functional derangement. A commonly used functional classification is that produced by Alain Carpentier, stratifying mitral

pathologies into Type I denoting normal leaflet motion, Type II denoting increased leaflet motion, and Type III denoting restricted leaflet motion (Carpentier, 1983).

Primary Mitral Regurgitation

Primary mitral regurgitation is due to dysfunction of the valvular tissue and is associated with a number of pathologies that can affect different parts of the valvular apparatus (Table 1).

Table 1 Causes of primary mitral regurgitation

Mitral annulus
Mitral annular calcification
Idiopathic
Rheumatic fever
Chronic kidney disease
Hyperparathyroidism

Infective endocarditis
Pannus or thrombus formation
Bioprosthetic valve degeneration
Immobilized ball/disc in mechanical prosthesis
Paravalvular Leak
Ring or strut fracture

Mitral Valve Prolapse

The most common cause of primary mitral regurgitation in developed countries is mitral valve prolapse, also known as degenerative valvular disease. Mitral valve prolapse is common, with an estimated prevalence of 2.4% in the general population (Nkomo et al., 2006; Coffey et al., 2016; Iung et al., 2003; Freed et al., 1999). More recently, recognition of the mitral valve's saddle-shaped three-dimensional structure has led to improved specificity of diagnosis, and therefore current estimates of disease prevalence are lower (Freed et al., 1999; Levine et al., 1988). Current criteria for diagnosis requires superior displacement of the mitral valve leaflets more than 2 mm from the annular plane during systole in the parasternal long-axis or the apical three chamber views on echocardiography (Nishimura et al., 2017). Mitral valve prolapse may be further delineated into classic disease with maximal thickening of the leaflets greater than 5 mm during diastasis and nonclassical with maximal thickness less than 5 mm (Freed et al., 1999). The majority of these individuals have mild mitral regurgitation; one series demonstrated that only 7% of patients with classic prolapse and no patients with nonclassic prolapse had severe mitral regurgitation (Freed et al., 1999). Nevertheless, mitral valve prolapse is the leading cause of isolated mitral regurgitation as well as regurgitation requiring surgery (Delling and Vasan, 2014). This is due in part to the propensity for papillary muscle or chordal rupture from the structural weakening by myxomatous degeneration seen in this disease, which can lead to sudden and severe mitral regurgitation due to a flail leaflet (**Figs. 1** and **2**). Patients with mitral valve prolapse have high rates of reported chest pain and dyspnea approximating 11%–15%, and while subjects with this disease are

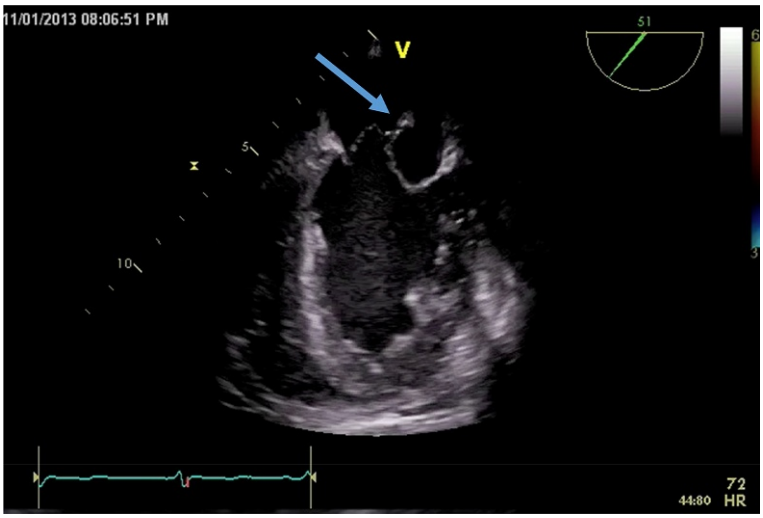

Fig. 1 Transesophageal echocardiogram of flail leaflet. This transesophageal echocardiogram in the mid-esophageal position demonstrates a portion of a torn papillary muscle head (*arrow*), which prolapses into the left atrium during systole, in a patient with mitral valve prolapse. The anterior mitral valve leaflet bows into the left atrium, indicating a flail leaflet. The patient had severe mitral regurgitation as a result.

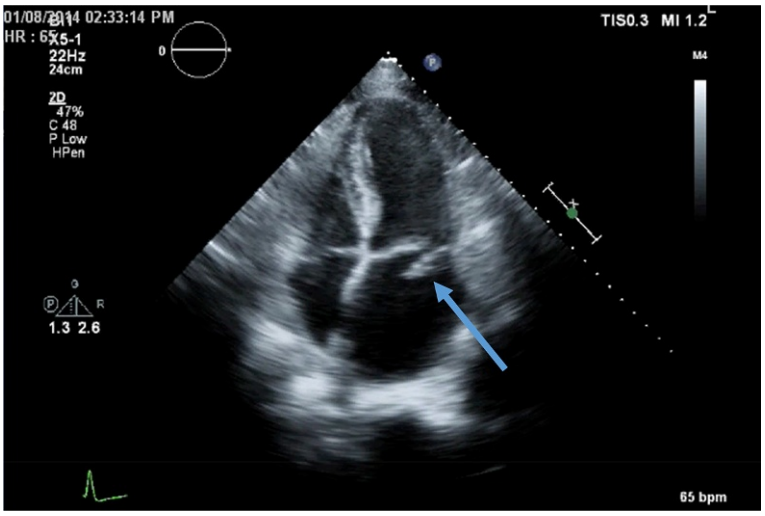

Fig. 2 Transthoracic echocardiogram of flail mitral valve leaflet. This transthoracic echocardiogram image of the mitral valve in the apical four chamber view, demonstrates a flail posterior leaflet (*arrow*), bowing into the left atrium in a patient with mitral valve prolapse and chordal rupture. Both anterior and posterior mitral valve leaflets are thickened consistent with the patient's known diagnosis of Barlow's syndrome. Of note, the left atrium appears enlarged consistent with increased left atrial pressure from mitral regurgitation. The patient had severe mitral regurgitation and required valvular repair.

overall leaner than those without prolapse, their rates of having heart failure, atrial fibrillation, cerebrovascular disease, and syncope are similar to the general population (Freed et al., 1999). Furthermore, while there has been concern that mitral valve prolapse may be associated with ventricular arrhythmias and sudden death, this risk is isolated to those with prolapse and severe mitral regurgitation with left ventricular dysfunction (Freed et al., 1999). Mitral valve prolapse is associated with two distinct valvular phenotypes, Barlow's syndrome representing extensive bileaflet involvement, and fibroelastic deficiency, representing isolated disease and prolapse of the P2 segment of the mitral valve (Delling and Vasan, 2014).

Rheumatic Heart Disease

Other notable etiologies of primary mitral regurgitation are rheumatic heart disease and endocarditis, which respectively, represent 14.2% and 3.5%of all mitral regurgitation cases in one study on population prevalence (Iung et al., 2003). Worldwide, rheumatic heart disease is the second most common etiology of mitral regurgitation (Iung et al., 2003). With recurrent streptococcal infection, autoimmune destruction with resultant thickening and calcification of the valvular commissures leading to mitral stenosis and regurgitation can occur. Involvement of the subvalvular apparatus with chordal thickening and shortening is seen with progressive rheumatic involvement, and this is primarily associated with mitral regurgitation rather than stenosis (**Fig. 3**) (Guilherme et al., 2004). Rheumatic heart disease may affect the aortic and tricuspid valves in addition to the mitral valve and rarely can affect the pulmonic valve (Guilherme et al., 2004).

Endocarditis

Vegetations on the mitral valve may be due to infectious or noninfectious causes and can lead to regurgitation by causing poor coaptation of leaflets, or perforation of paravalvular tissue leading to chordal rupture (**Fig. 4**). Fistulization caused by abscess formation can also lead to paravalvular regurgitation. Mitral valve endocarditis is increasingly common in elderly patients and those with indwelling lines and hemodialysis catheters, though the increasing prevalence of injecting drug use may alter these epidemiologic trends (Wurcel et al., 2016). Endocarditis may also affect prosthetic valves in the mitral position leading to valvular dysfunction and regurgitation. Mitral regurgitation is commonly seen with mechanical mitral valve prostheses but generally is mild in severity with centrally located regurgitant flow. Any paravalvular or more significant regurgitation seen with mitral valve prostheses should be considered pathologic and prompt work-up for endocarditis in the appropriate clinical setting.

Secondary Mitral Regurgitation

Secondary mitral regurgitation, also known as functional mitral regurgitation, may be caused by any abnormality leading to atrial or ventricular dilation as well as disease of the subvalvular apparatus (**Table 2**). Coronary artery disease and myocardial ischemia and/or infarction commonly contribute to secondary mitral regurgitation. With regional dysfunction of the inferolateral wall, particularly in the setting of ischemia, tethering of the posteromedial papillary muscle leads to insufficient anterior excursion of the posterior mitral valve leaflet, malcoaptation, and significant mitral regurgitation. While transient ischemia may cause myocardial stunning with failure of inferolateral wall thickening and subsequent intermittent mitral regurgitation, this typically resolves with

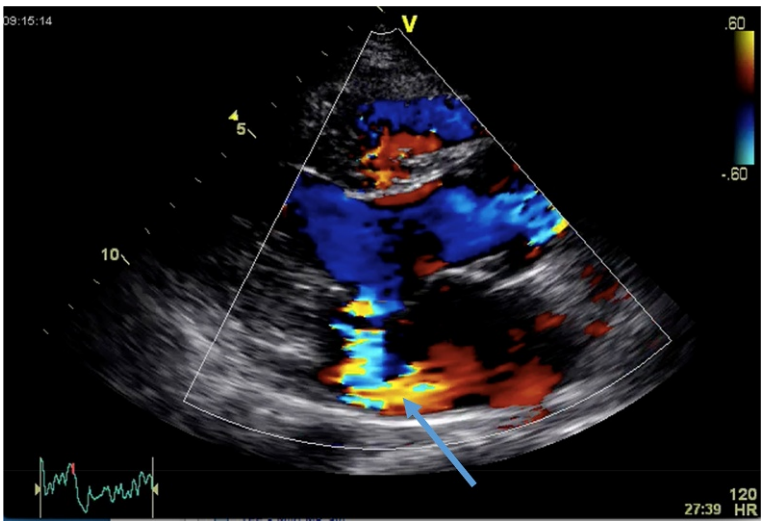

Fig. 3 Rheumatic mitral valve disease causing mitral regurgitaiton. This transthoracic echocardiographic image of the parasternal long axis-view demonstrates a patient with rheumatic mitral valve disease with shortening of the subvalvular apparatus, causing retraction of the posterior leaflet and a posteriorly directed jet of moderate mitral regurgitation (*arrow*).

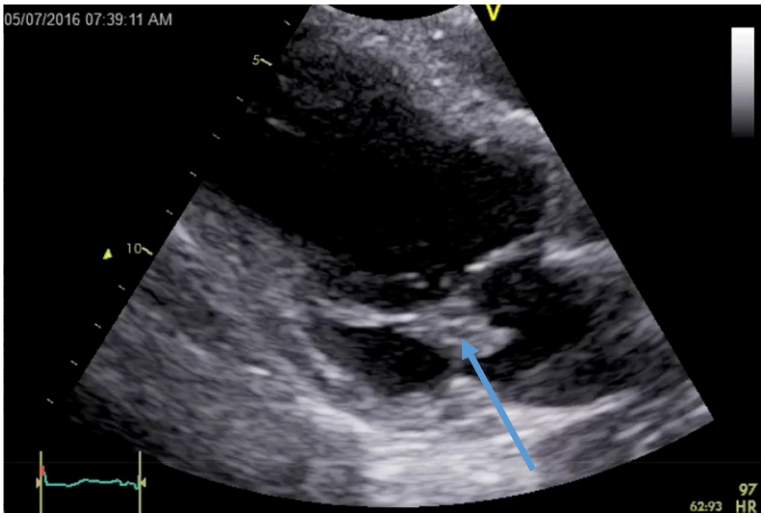

Fig. 4 Transthoracic echocardiogram of patient with infective endocarditis. This zoomed parasternal long-axis view of a transthoracic echocardiogram in a patient with suspected infective endocarditis demonstrates a large vegetation attached to the posterior mitral valve (*arrow*). Consistent with the behavior of valvular vegetations, the apparent echodense mass is present on the left atrial side of the valve.

Table 2 Causes of secondary mitral regurgitation

Mitral annulus dilatation
Myxomatous mitral valve disease
Dilated cardiomyopathy
Connective tissue disorders
Left atrial enlargement
Atrial fibrillation
Congestive heart failure (systolic and diastolic)
Left ventricular abnormalities
Dilated cardiomyopathy (left ventricular dilatation)
Coronary artery disease (focal wall motional abnormalities or papillary muscle dysfunction)
Left ventricular aneurysm
Right ventricular pacing (left ventricular dysychrony)

improvement in myocardial perfusion. In contrast, infarction of inferolateral wall leads to persistent mitral regurgitation. Additionally, ischemia, infarction, or infiltration may lead to papillary muscle rupture causing a flail mitral valve leaflet and significant mitral regurgitation.

Ventricular dilation from either ischemic or nonischemic cardiomyopathies frequently results in secondary mitral regurgitation. In one series, any mitral regurgitation was present in 73% of those with cardiomyopathy with up to 24% having severe secondary mitral regurgitation (Di Salvo et al., 2010). In secondary mitral regurgitation due to ventricular dilation, resulting apical and lateral papillary muscle displacement can lead to tenting and poor coaptation of the mitral leaflets (Fig. 5). Additionally, the increased volume loading of the left atrium in this setting may lead to further ventricular remodeling with annular enlargement, thus worsening coaptation and resulting in more regurgitation over time. Mitral regurgitation may also be caused by atrial dilation in the setting of atrial disease or long-standing atrial arrhythmias with remodeling.

Outcomes of individuals with secondary mitral regurgitation are difficult to distinguish from their underlying comorbidities, but evidence suggests a worse prognosis compared to individuals without mitral regurgitation (Di Salvo et al., 2010). While chordal-sparing mitral valve replacement is typically preferred to mitral valve repair in individuals with severe symptomatic mitral regurgitation, the overall benefit of surgery in this setting is unclear. The emergence of transcatheter therapies may improve outcomes for patients with severe mitral regurgitation who are not candidates for cardiac surgery, but further study is needed to determine the optimal population who would derive the most benefit from these technologies (Nishimura et al., 2017).

Natural History and Outcomes Associated With Mitral Regurgitation

Individuals with significant mitral regurgitation due to primary mitral valve disease are at risk for adverse outcomes in the presence of symptoms (David et al., 2013; Lamas et al., 1997a; Ling et al., 1996; Suri et al., 2008; Grigioni et al., 2001), atrial fibrillation (Suri et al., 2008), pulmonary hypertension (Marechaux et al., 2011; Patel et al., 2014), or depressed left ventricular systolic function

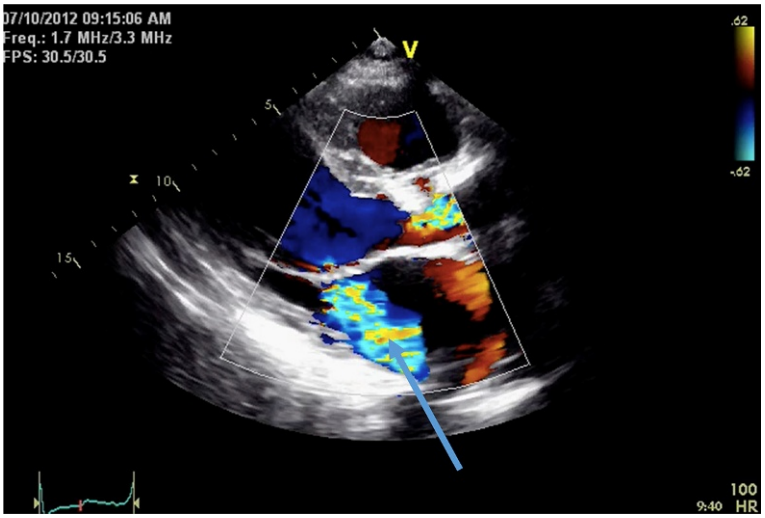

Fig. 5 Transthoracic echocardiogram of severe secondary mitral regurgitation. This parasternal long-axis view of a transthoracic echocardiogram in a patient with a dilated cardiomyopathy demonstrates apical displacement of the mitral valve leaflets (*tenting*) and poor coaptation leading to a centrally directed jet of mitral regurgitation (*arrow*).

(Enriquez-Sarano et al., 1994). However, data on outcomes of individuals with asymptomatic severe mitral regurgitation are more heterogeneous. Sarano et al. demonstrated that asymptomatic individuals with primary mitral regurgitation and an effective orifice area (EOA) of at least 40 mm^2 had a five-year survival less than expected by census estimates and a nearly five-fold increased risk of death from cardiac causes (Enriquez-Sarano et al., 2005). In the cohort of 232 patients who underwent cardiac surgery in this study, there was a 72% reduction in mortality suggesting a role for early surgery in severe asymptomatic patients with primary mitral valve disease.

Secondary mitral regurgitation following myocardial infarction is also associated with poor outcomes. In the Survival and Ventricular Enlargement study, individuals with any degree of mitral regurgitation shortly after myocardial infarction were at a two-fold risk of cardiovascular death at 3.5 years of follow-up (Lamas et al., 1997b). The degree of mitral regurgitation has been shown to be associated with long-term mortality and cardiac mortality risk at 5 years after myocardial infarction (Grigioni et al., 2001). The role of surgery in secondary mitral regurgitation is less clear. Retrospective data suggest that mitral valve surgery for individuals with advanced heart failure is both safe and efficacious with significant improvements in left ventricular ejection fraction, left ventricular volumes, and improvement in functional class and quality of life (Di Salvo et al., 2010). However, limited clinical trial data from the Cardiothoracic Surgical Trials Network do not clearly suggest a benefit to the addition of mitral valve repair in individuals with moderate or greater mitral regurgitation undergoing concomitant coronary artery bypass grafting at one year (Smith et al., 2014). Specifically, though the presence of moderate to severe mitral regurgitation was less common in the mitral repair cohort, there were no differences in adverse cardiac or cerebrovascular events, deaths, readmissions, functional status, or quality of life at one year (Smith et al., 2014). Whether or not subgroups of individuals may benefit from surgical or percutaneous treatment of mitral valve disease is a subject of ongoing research. Additionally, therapy directed toward management of heart failure such as cardiac resynchronization therapy may impact the natural history of functional or ischemic mitral regurgitation in this setting (Di Salvo et al., 2010; Auricchio et al., 2011). The optimal criteria for defining severe secondary mitral regurgitation has also been controversial, with some data suggesting worsened outcomes at a lower EOA compared with primary mitral regurgitation (Nishimura et al., 2017; Uretsky et al., 2015; Grayburn et al., 2014).

Imaging of Mitral Valvular Disease

While computed tomography, cardiac magnetic resonance imaging, and myocardial perfusion imaging have increasingly important roles in the evaluation and management of patients with significant mitral regurgitation, echocardiography remains the most pervasive modality for identifying the presence and severity of mitral regurgitation, as well as providing guidance for subsequent interventions.

Trans-Thoracic Echocardiography

The most common imaging modality used to identify mitral regurgitation is trans-thoracic echocardiography (TTE). Two-dimensional imaging or M-mode may identify abnormalities in left ventricular global or regional systolic function, atrial size

and function, and abnormalities with the mitral valve or valvular apparatus, including valvular vegetations, congenital abnormalities, and commissural thickening, which may indicate the likely etiology for regurgitation. Furthermore, color Doppler echocardiography permits detection of the mitral regurgitation jet, assessment of jet direction, and evaluation of the severity of disease including jet area and vena contracta (**Fig. 6**). Continuous and pulse wave Doppler may be used to calculate several markers of degree of regurgitation such as EOA, regurgitant fraction, and regurgitant volume. Additionally, examination of flow patterns may reveal alterations consistent with severe disease such as blunting or reversal of systolic flow in the pulmonary veins or significant pulmonary hypertension (**Fig. 7**). Stress echocardiography using TTE can additionally identify patients with inducible pulmonary hypertension with exercise, stress-induced ischemic mitral regurgitation, and latent left ventricular systolic dysfunction (Nishimura et al., 2017). Echocardiography can suggest concomitant valvular lesions, mitral stenosis, and underlying problems with left ventricular filling that may contribute to regurgitant severity. While evaluation of regional or global changes in left ventricular deformation using tissue Doppler or speckle-tracking strain imaging holds promise for better defining subclinical left ventricular dysfunction, lack of intervendor standardization on normal values for strain has impaired more widespread adoption of this technology (Collier et al., 2017). Furthermore, while 3D echocardiography has been shown to more accurately define left

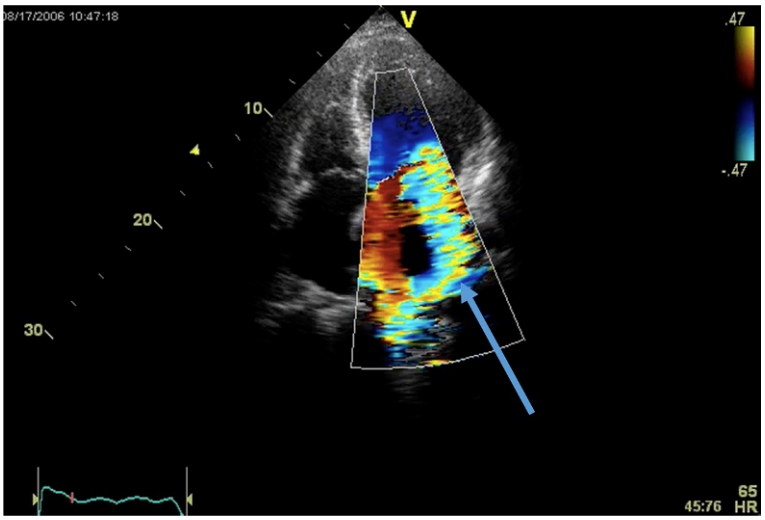

Fig. 6 Color flow doppler representation of severe mitral regurgitation. This zoomed-out apical four chamber view of a transthoracic echocardiogram in a patient with an underlying cardiomyopathy demonstrates severe functional mitral regurgitation (*arrow*) directed into the right pulmonary veins. The jet of mitral regurgitation has a large area on color flow Doppler and extends to the back wall of the left atrium, suggesting a large degree of regurgitant volume.

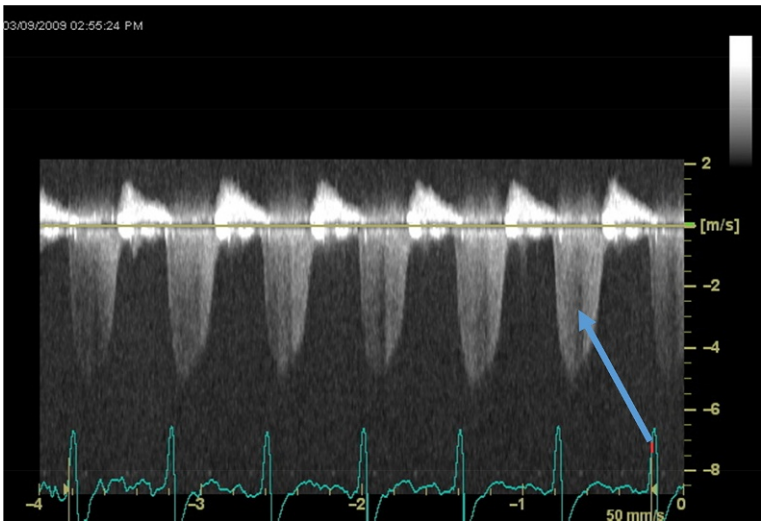

Fig. 7 Continuous wave Doppler of mitral regurgitation. This continuous wave spectral Doppler image of a patient with mitral regurgitation demonstrates high velocity flow during systole consistent with mitral regurgitation (*arrow*). Both the density and shape of the continuous wave jet can be used to help quantify the severity of mitral regurgitation. Moreover, the peak velocity and integral of the observed velocities is used in the calculation of the effective regurgitant orifice using the PISA method.

ventricular ejection fraction compared to 2D echocardiography and thus may predict impairment in left ventricular ejection at an early disease stage, there has not been widespread adoption of this technology for TTE use at the current time (Zoghbi et al., 2017).

Quantitation of Mitral Regurgitation Severity

TTE may also be used to define the severity of mitral regurgitation through several complimentary methods (**Table 3**) (Zoghbi et al., 2017). Both morphologic characteristics of the valve and chambers and quantitative methods are used to define disease severity, as no single metric is perfectly sensitive and specific for defining significant mitral regurgitation (Zoghbi et al., 2017). Assessment of the volumetric degree of regurgitation is possible by approximating the effective regurgitant orifice size using the vena contracta, the smallest diameter of the regurgitant jet as visualized by color Doppler. The vena contracta is best measured in zoomed views perpendicular to the axis of regurgitation in order to maximize axial resolution and is independent of flow rate and driving pressures. It can be used to accurately quantify eccentric jets that may be miscategorized as less severe through other methods. However, this estimate may underestimate regurgitant severity in the presence of multiple jets or regurgitation that does not extend the duration of systole. Furthermore, using the vena contracta requires adequate imaging of flow convergence region, which may be impossible in patients with suboptimal images. 3D measures of the vena contracta are rapidly emerging as an alternative metric for defining MR severity and may identify severe functional MR in cases where the flow convergence method may underestimate the ERO area. Yet, currently utilization and analysis of 3D echo images are cumbersome and subject to similar limitations as 2D measurements. Another tool to quantify MR, the color jet area, is measured in apical zoomed views using color Doppler, either in isolation or as a ratio of jet area to left atrial area. The jet area is easy to measure but is dependent on hemodynamics and other technical variables such as the Nyquist limit. For these reasons it has been shown to be imprecise in multiple studies, particularly in the presence of nonholosystolic MR or eccentric jets.

Quantitation of the regurgitant volume is possible by calculation of the difference between stroke volume through the mitral valve and stroke volume through the left ventricular outflow tract (i.e., forward stroke volume). This technique is valid in the presence of multiple and eccentric jets and has been validated against cardiovascular magnetic resonance for quantitative definition of lesion severity; however, it is lengthy for routine use in clinical practice and involves multiple measurements with potential for compounding measurement error. Additionally, it is inaccurate in the setting of combined mitral and aortic regurgitation. Owing to these difficulties, echocardiographic calculation of regurgitant volume is not routinely used in practice to define lesion severity. The flow convergence method is more commonly utilized to quantitate MR severity. This technique relies on the principle of conservation of mass, namely that the volume of blood entering the regurgitant orifice is the same as the regurgitant volume. In principle, the regurgitant flow can be quantified by taking the product of the aliasing velocity and the volume of a hemisphere whose radius is defined by the proximal isovelocity surface area (PISA). This is determined by lowering the color Doppler baseline in the direction of the regurgitant jet and measuring the radius as the vertical distance from the point of flow convergence to the edge of the hemispheric isovelocity shell (**Fig. 8**). The ERO area is then further defined as the ratio of the regurgitant flow rate and peak systolic velocity of the mitral regurgitant jet as measured by continuous wave Doppler at the same time in the cardiac cycle as the PISA. This method has been shown to be accurate and reproducible at defining ERO area and regurgitant volume and is strongly associated with adverse outcomes in degenerative and functional mitral regurgitation. While this method is commonly used in

Table 3 Assessing the severity of mitral regurgitation[a]

Parameter	*Mild*	*Moderate*	*Severe*
Structural parameters			
Left atrial size	Normal	Normal or dilated	Usually Dilated
Left ventricular size	Normal	Normal or dilated	Usually Dilated
Mitral leaflets/support apparatus	Normal or abnormal	Normal or abnormal	Abnormal structure/flail leaflet/ruptured papillary muscle
Doppler parameters			
Color flow jet area	Small, central jet (<4 cm^2 or $<20\%$ of left atrial area)		Large central jet (>10 cm^2 or $>40\%$ of left atrial area)
Mitral inflow (pulsed wave)	Dominant A wave	Variable	Dominant E wave (usually ≥ 1.2 m/s)
Jet density and contour (continuous wave)	Incomplete or faint; parabolic	Dense; usually parabolic	Dense; early-peaking, triangular
Pulmonary vein flow	Systolic dominance	Systolic blunting	Systolic flow reversal
Quantitative parameters			
Vena contracta width (cm)	<0.3	0.3–0.69	≥ 0.7
Regurgitant volume (mL/beat)	<30	30–59	≥ 60
Regurgitant fraction (%)	<30	30–49	≥ 50
Effective regurgitant orifice area (cm^2)	<0.20	0.20–0.39	≥ 0.40

[a]Adapted from Zoghbi WA, Enriquez-sarano M, Foster E, et al. Recommendations for evaluation of the severity of native valvular regurgitation with two-dimensional and Doppler echocardiography. Journal of the American Society of Echocardiography 2003;16(7):777–802.

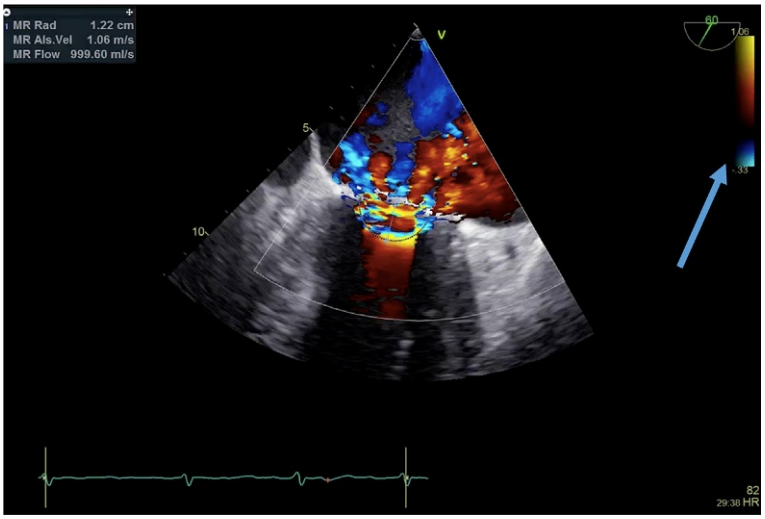

Fig. 8 PISA calculation of mitral regurgitation severity on transesophageal echocardiogram. This transesophageal echocardiographic image in the mid-esophageal position demonstrates calculation of the radius of the PISA shell to determine mitral regurgitation severity. Note that the aliasing velocity has been altered (*arrow*) to exclude low velocity flows from the calculation of the PISA radius.

research applications for defining MR severity, it may not be accurate in the setting of multiple or eccentric jets. Due to errors in measuring the PISA radius, it may also misclassify the severity of MR in patients with very large or small PISA radii.

Other ancillary findings on echocardiography may support a diagnosis of significant mitral regurgitation. For example, using pulsed wave Doppler at the mitral valve leaflet tips, one can define the velocity of blood flow during myocardial filling. A velocity of blood flow during early diastole (E-wave velocity) ≥ 1.2 m/s is sensitive for the diagnosis of severe mitral regurgitation and a pattern of filling that predominates in late diastole virtually excludes it. However, an elevated E-wave velocity is not specific for severe mitral regurgitation and depends on other physiologic parameters including left ventricular relaxation and filling pressures. Severe mitral regurgitation on continuous wave Doppler generally has a triangular contour with an early peak velocity denoting a large regurgitant pressure wave and has a density higher than mild mitral regurgitation due to the increased number of red blood cells scattering the ultrasound signal, though these findings are not quantitative and may be influenced by other technical factors such as gain settings and jet direction. Finally, evaluation of blunting or reversal of flow in the pulmonary veins using a pulse wave Doppler sample volume placed 1 cm distal to the ostium of the pulmonary vein, may identify significant mitral regurgitation due to the elevation in left atrial pressures and blunting or reversal of left atrial filling during systole. Additionally, demonstration of flow reversal in multiple pulmonary veins is specific for severe mitral regurgitation and a normal pulmonary vein pattern excludes severe mitral regurgitation. However, regurgitant jet flow directly into the pulmonary vein may alter the ability to discern increased left atrial pressure and systolic blunting may be seen in multiple other etiologies in which left atrial pressure is elevated.

Owing to the difficulty of any single modality for defining significant mitral regurgitation, current guidelines by the American Society of Echocardiography suggest that regurgitant lesions should satisfy 4 or more specific criteria for either mild or severe mitral regurgitation to fall into those respective classification groups (Zoghbi et al., 2017). For cases in which 2–3 criteria are met, assessment of the ERO area is recommended to better define mitral regurgitation grade. When TTE quality is poor or quantitative parameters are indeterminate or discordant with the clinical presentation, either transesophageal echocardiography or cardiovascular magnetic resonance is reasonable to obtain to better evaluate regurgitant severity.

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) may be used to define the presence, severity, and etiology of mitral regurgitation. Additionally, TEE may have particular utility in those with poor transthoracic echocardiographic windows to better define the mechanism of mitral regurgitation and for presurgical planning prior to intervention on the mitral valve. The mitral valve is best visualized at the mid-esophageal level with the ability to identify specific scallops at particular scan angles acquired. Since TEE allows for adjustment of the scan angle of the piezoelectric crystals, the mitral valve and surrounding structures may be interrogated from multiple vantage points, thus providing a comprehensive assessment of valvular and perivalvular pathology. The left pulmonary veins may be identified by turning the transducer laterally and angulating it superiorly from zero degrees. The right pulmonary veins are best identified in the 90 degrees imaging plane turning the tranducer toward the patient's right side. Visualization of the pulmonary veins allows for pulse wave Doppler interrogation of the pulmonary venous flow to evaluate for blunting or systolic reversal. Additionally, the mitral valve may be viewed in short axis through retroflexion of the TEE probe in the transgastric position to assist in identifying the particular scallops involved. The subvalvular structures of the mitral valve are well visualized in the transgastric position at 90 degrees rotation. All of the techniques previously mentioned for evaluation of mitral

regurgitation severity are available with TEE. Moreover, owing to the higher frequency of the TEE probes and the shallower depth of imaging, axial resolution is improved compared with trans-thoracic imaging and thus the anatomy and etiology of mitral regurgitation is better defined. Furthermore, while mitral annular calcification and other abnormalities may cause acoustic shadowing on transthoracic imaging and lead to inaccurate conclusions on the presence or severity of mitral regurgitation, the ability to acquire near-field images of the left atrium with TEE allows for more accurate identification of the presence of mitral regurgitation.

Role of 3D Imaging in Mitral Regurgitation

Another advantage of TEE relative to other imaging techniques is the ability to perform real-time 3D imaging. In 3D imaging, a three-dimensional matrix array of piezoelectric crystals acquires a pyramidal sector that permits evaluation of depth along the scan plane. Full 3D left ventricular volumes may be acquired with TEE using multibeat acquisition and respiratory gating, allowing accurate quantification of the left ventricular chamber sizes and ejection fraction. Full volume acquisition may also be used to define the right ventricular ejection fraction and function, which is suboptimally evaluated using 2D imaging due to the complex geometric assumptions of the right ventricle. Furthermore, 3D "zoom mode" is now routinely used to visualize the mitral valve from the top-down (i.e., "surgeon's" perspective), which may assist in the identification of valvular pathology, affected scallops, and presence/sizing of masses (Fig. 9). This view may be used in preoperative planning to assess the likelihood of successful mitral valve repair in the setting of severe degenerative mitral regurgitation. "Zoom mode" 3D imaging improves temporal resolution at the cost of spatial resolution and sector size, and thus the evaluation of regurgitant jets using 3D color Doppler is currently limited by frame rate. However, further advancements in 3D technology may improve the accuracy of MR quantification in the future. Simultaneous biplane and multi-plane images may be acquired to evaluate a structure of interest in multiple orthogonal planes, assisting with procedural guidance and improving with accurate quantitation. Additionally, 3D imaging, particularly "zoom mode" and "multiplane" imaging, can be used for intraoperative and intraprocedural guidance of mitral valve interventions. Intraoperative TEE can be used to verify the preoperative diagnosis, guide placement of cardioplegia and bypass cannulae as well as pulmonary artery catheters, and to assess for immediate complications of the procedure or any residual mitral regurgitation after valve repair or replacement. With the advent of the edge-to-edge percutaneous mitral valve repair technique (e.g., MitraClip) and the development of transcatheter mitral valve replacement, use of TEE and especially 3D TEE are likely to play a larger role in the management and outcomes of patients undergoing structural procedures on the mitral valve. As with transthoracic and 2D imaging, 3D TEE requires adequate imaging windows and lack of acoustic shadowing to optimally visualize structures of interest and thus must be interpreted within the context of the imaging study.

Conclusions

With the aging of the population, rates of significant valvular heart disease including mitral regurgitation are likely to increase. Noninvasive cardiac imaging, particularly echocardiography, provides an essential tool for clinicians to diagnose and manage patients with mitral regurgitation. The role of echocardiography is likely to expand even further with improvements in 3D and strain imaging as well as the increasing role of structural interventions in treating mitral regurgitation.

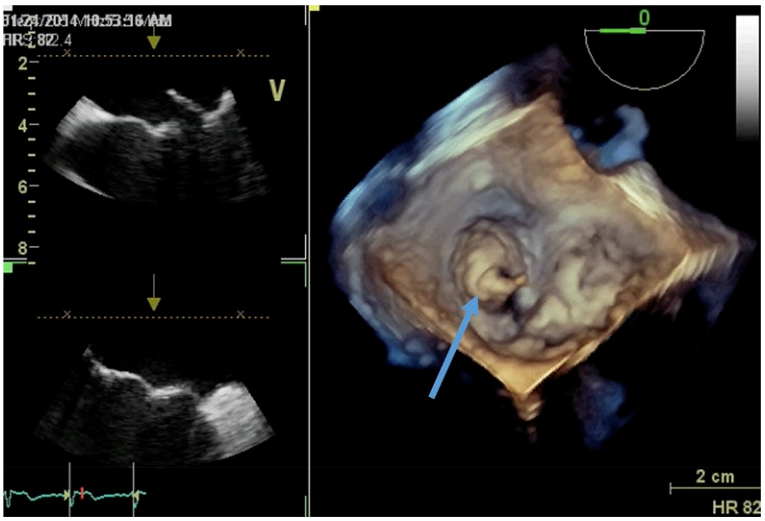

Fig. 9 Three-dimensional echocardiography of mitral valve. This transesophageal image demonstrates biplane (*left*) and live 3D volume rendered images of the mitral valve in a patient with mitral valve prolapse and a flail P3 scallop (*arrow*). The patient was found to have severe mitral regurgitation.

Introduction

Cardiovascular disease is the primary cause of overall mortality and morbidity in the western population (Nabel and Braunwald, 2012; Fuster and Mearns, 2009; Heidenreich et al., 2011). As such, there is a constant effort to establish biomarkers and develop tools in order to improve disease prevention and management.

Owing to new technological advancements in computed tomography (CT) technology leading to the introduction of multi-detector row computed tomography (MDCT) and improved temporal and spatial resolution, imaging of the beating heart became feasible in clinical practice. As a result, coronary CT angiography (CCTA) and MDCT of the aorta became the noninvasive modalities of choice for the assessment of cardiovascular disease (De Cecco et al., 2014a; Agarwal et al., 2009; Wadgaonkar et al., 2015; Shaw et al., 2012).

However, CCTA is primarily a tool for the anatomical assessment of coronary artery disease (CAD), rather than functional consequences of the disease. CT technology is improving and it is now possible to assess myocardial perfusion using technologies such as static single-energy CT myocardial perfusion imaging (CTMPI) as well as the hemodynamic significance of a coronary artery stenosis using technologies such as CCTA-derived fractional flow reserve (CT-FFR) and transluminal attenuation gradient (TAG). As a result of these advancements, CCTA could transition from a robust tool for the morphological assessment of CAD into a comprehensive modality providing additional functional information and thus better guiding patient management.

This article will present an overview of the current state-of-the-art cardiovascular CT techniques and applications and a discussion of new technology and future possibilities in cardiovascular CT imaging.

CT of the Heart

Technical Considerations

Spatial and temporal resolution

CT technology requires a very high level of spatial resolution in order to visualize the coronary arteries, which measure only a few millimeters in diameter, and even smaller features, such as plaque and stenosis. Since spatial resolution depends on both the number of detectors and the slice width, 64 or higher slice scanners using collimated slice width of 0.5, 0.6, or 0.625 mm were used to achieve appropriate isotropic resolution to visualize the coronary arteries. In routine clinical practice, the resolution for cardiac imaging is $0.5 \times 0.5 \times 0.5$ mm^3, which allows for smooth, low-noise images adequate enough to evaluate the heart's anatomy, bypass grafts, and coronary arteries. However, this spatial resolution is still not optimal for coronary artery assessment in the context of heavy calcifications where calcium blooming prevents a reliable assessment of vessel lumen due to the overestimation of stenosis (Vanhecke et al., 2011). Another challenge associated with this resolution is stent patency and in-stent restenosis assessment (Maintz et al., 2009), which seems to improve with the use of third-generation dual-source scanners (Gassenmaier et al., 2014; Mangold et al., 2016a) and iterative reconstruction (Geyer et al., 2015).

Further improvement in spatial resolution is crucial, but a decrease in image noise and an increase in image quality usually go hand in hand with higher radiation dose levels. However, this problem might be solved with the use of novel reconstruction algorithms, such as iterative reconstruction, which have been shown to substantially increase image sharpness and counteract a noise increase while reducing radiation dose (Mangold et al., 2016b).

Because the heart is in constant motion, a high temporal resolution (i.e. acquisition time per image) is needed in order to achieve high image quality; the faster the scan time, the better the visualization of cardiac and coronary anatomy. Modern 64- and 128-slice CT scanners can achieve gantry rotation times as low as 0.27 s resulting in temporal resolution as low as 135 milliseconds. This is sufficient to attain high image quality in patients with a regular heartbeat and normal to low heart rate. It becomes more challenging, however, when patients have elevated heart rates or sustained arrhythmia (Mangold et al., 2016b). Algorithmic approaches to correct motion artifacts have also been proposed (Apfaltrer et al., 2013; Fuchs et al., 2014).

Nevertheless, a temporal resolution of 50 milliseconds is required for optimal heart scans with high image quality, particularly in patients with irregular heart rates (Leschka et al., 2006). The introduction of the dual-source CT (DSCT) system featuring two X-ray tubes coupled with two detectors positioned at a 90-degree angle has led to great improvements in temporal resolution (Flohr et al., 2006). As a result, gantry rotation times were reduced to 83, 75, and 66 milliseconds with first-, second-, and third-generation DSCT systems, respectively (McCollough et al., 2008). Several clinical studies have, in fact, shown that reliable CCTA could be achieved using DSCT, even without heart rate control (Scheffel et al., 2006; Matt et al., 2007; Ropers et al., 2007; Weustink et al., 2009; Li et al., 2014; Yang et al., 2015; Nance et al., 2011). While most recent DSCT scanners have 192 slices, other vendors pursue the strategy of enhancing temporal resolution by building CT hardware with up to 640 slices. Thus, full cardiac coverage can be achieved within one heartbeat.

Electrocardiogram (ECG)-gating

An important consideration in heart imaging is phase-consistent acquisitions in order to capture the heart in both the systolic and diastolic phase. In order to achieve that goal, ECG-gated acquisitions must be performed. There are two techniques for ECG- gating: retrospective and prospective gating.

Generally, retrospective gating has been the more popular technique. Using this technique, the heart is continuously scanned throughout the entire cardiac cycle while the scanner table is moving and the patient's ECG is simultaneously recorded. Once the acquisition is completed, the data is analyzed retrospectively using the patient's ECG as a guide to select the data within the corresponding heart phase. This data is then used for phase-consistent image reconstructions of the heart. The main advantages of this technique are the ability to retrospectively perform reconstruction in any cardiac phase, minimizing imaging artifacts, and the ability to evaluate cardiac function given the multiphase acquisition. The main drawback remains the associated high radiation dose due to continuous irradiation during the cardiac cycle.

With the advent of newer CT systems, prospective ECG-gating has been proposed as an alternative to retrospective gating. With this technique, the patient's ECG is used to trigger the start of the acquisition, without table movement, at a user-determined distance from an R wave. Only the region of the heart aligned with the detectors will be scanned. Once the acquisition is completed, the scanner moves the table to the next position in order to scan the next part of the heart, and the process repeats. Because the acquisition only occurs in the selected phase, as opposed to continuously throughout the cardiac cycle, radiation dose is minimized (Stolzmann et al., 2008; Earls et al., 2008; Arnoldi et al., 2009). Consequently, functional evaluation and changing the reconstruction phase in order to reduce artifacts are not possible with this technique. Moreover, acquisition becomes more challenging in patients with irregular rhythms or elevated heart rates.

Radiation dose

Radiation dose in CT is an important source of concern for the medical community and the general public (Brenner and Hall, 2007; Einstein et al., 2007). A multicenter study demonstrated that radiation dose from cardiac CT varied from 5 to 30 mSv with an average dose of 12 mSv (Hausleiter et al., 2009). With the increased use of cardiac imaging, there have been efforts to establish radiation dose reduction techniques.

While there are many methods to reduce radiation, the choice of ECG-gating method is most important in determining radiation dose reduction. As mentioned above, prospective ECG-gating only requires irradiation during a specific interval of the cardiac cycle; thus, radiation dose can be reduced to 1–4 mSv using this technique (Ohnesorge et al., 2000). In a meta-analysis of 20 studies comparing prospective and retrospective ECG-triggering, the pooled effective dose was 3.5 mSv with prospectively triggered scans compared to 12 mSv using retrospective scanning (Menke et al., 2013). These results were confirmed by the PROTECTION III trial in which a radiation level of 3.5 mSv was achieved with prospective scanning as opposed to 11.2 mSv with retrospective ECG-gating. Consequently, prospective ECG-triggering is preferred in the reduction of radiation dose, particularly in patients with low, steady heart rates. Studies also demonstrated the ability to reach radiation doses lower than 1 mSv using ECG-triggered high-pitch scanning with DSCT (Neefjes et al., 2011; Yin et al., 2013). Again, however, this technique is particularly useful in patients with low to moderate, regular heartbeats.

Another approach to reducing radiation is low kV imaging. Because iodine contrast is increased at low kV levels, it is possible to maintain a good contrast-to-noise ratio (CNR) while lowering radiation dose. Studies have shown the ability to reduce radiation dose with 100 and 80 kV scanning protocols while maintaining image quality (Hausleiter et al., 2010; Cao et al., 2014). These techniques are particularly useful in small- to moderate-sized patients, as low kV scanning is associated with high noise levels in obese patients. Novel scanning systems are capable of providing diagnostic scans with reduced tube voltages (70 and 80 kV), resulting in a reduction of radiation dose by 49%–68% without compromising image quality, even in obese patients. In a recent study, the combination of high pitch with low kV scanning was able to reduce radiation dose to as low as 0.44 mSv (Meyer et al., 2014).

Radiation dose can be further decreased by using iterative reconstruction. With iterative reconstruction, a correction loop is introduced to the reconstruction process resulting in improved resolution in high contrast regions and noise reduction in low contrast areas, which are prerequisites for radiation dose reduction (Thibault et al., 2007). This becomes particularly useful when combined with other dose reduction techniques to achieve considerable dose reductions (Yin et al., 2013; Stehli et al., 2014; Layritz et al., 2014; Chen et al., 2013). In one study, the combination of low kV, high pitch scanning with iterative reconstruction resulted in a radiation dose as low as 0.06 mSv (Schuhbaeck et al., 2013). In addition to achieving lower radiation dose levels, the use of iterative reconstruction was found to improve image quality and diagnostic accuracy (Spears et al., 2014).

Calcium Scoring

Background

Risk prediction for CAD is based on the Framingham Risk Score (FRS), which takes into account classic cardiovascular risk factors such as age, sex, hypertension, hyperlipidemia, diabetes mellitus, and tobacco use (Wilson et al., 1998). Although FRS was found to be accurate (Wilson et al., 1998), the tool did not account for some CAD risk factors (Greenland et al., 2010). Consequently, new techniques to better stratify risk were sought out, particularly for patients in the intermediate (10%–20% 10-year risk) and low risk groups.

By improving image quality and reducing motion artifacts, MDCT made it possible to capture high quality images of the beating heart and coronary arteries in fine detail, including small calcium deposits in the artery walls. Because calcium deposits are readily detectable by X-ray-based imaging and are a direct sign of subclinical atherosclerotic disease (Rumberger et al., 1995), this tool quickly became of interest to clinicians as a new means of predicting CAD risk.

Technique

Coronary Artery Calcium Scoring (CACS) is a noncontrast CT study usually performed on a MDCT scanner. Calcium deposits in coronary artery walls can then be visualized (**Fig. 1**). The overall calcium burden is calculated and a calcium score called the Agatston score is generated based on the Agatston formula (Agatston et al., 1990). A growing body of literature has found this score to be an independent predictor of CAD and major adverse cardiac events (MACE) (Kondos et al., 2003), allowing clinicians to better stratify patients into appropriate risk groups based on their scores, (**Tables 1** and **2**) and thus better guide management.

Clinical relevance

Several studies have established the effectiveness of CACS in predicting the risk of future cardiac events, particularly in asymptomatic patients with intermediate risk based on FRS (Detrano et al., 2008; Greenland et al., 2004; van Kempen et al., 2011; Vogler et al., 2013; Becker et al., 2005). As a result, CACS was incorporated into the guidelines for risk assessment of asymptomatic patients with an intermediate 10-year risk (based on the FRS), effectively improving risk stratification and helping guide patient management (Greenland et al., 2007; Taylor et al., 2010). A CAC score of 0 was also associated with a very low risk (<1%) of cardiac event in patients presenting with atypical chest pain (Haberl et al., 2001; Georgiou et al., 2001). As a result, CACS was proposed as a tool to exclude significant stenosis in low-risk patients presenting with atypical chest pain (Oudkerk et al., 2008).

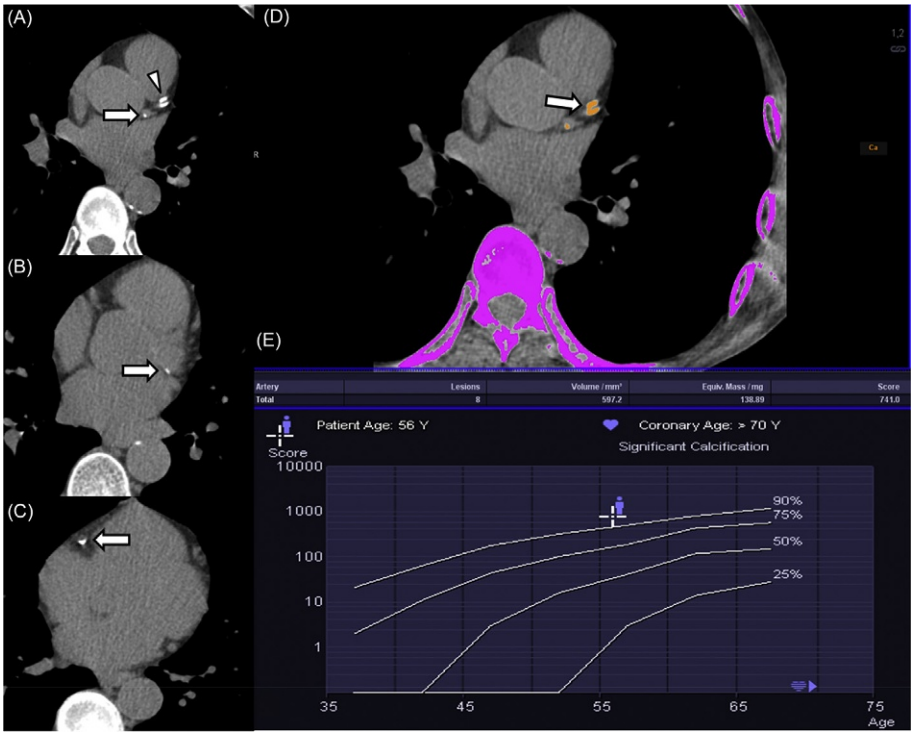

Fig. 1 A 59-year-old male with dyslipidemia and hypertension received a Coronary Artery Calcium Scoring (CACS) scan. (A) Axial noncontrast image of the heart showing a calcified plaque in the left main (*arrow*) and left anterior descending (*arrowhead*) coronary arteries. (B) Axial noncontrast image of the heart showing a small calcified plaque of the circumflex coronary artery (*arrow*). (C) Axial noncontrast image of the heart showing a calcified plaque of the right coronary artery (*arrow*). (D) The Agatston method was used to calculate a calcium score of 741. (E) Age-specific percentile curves show that the patient's CACS is in the 95th percentile for his age group.

Table 1 Relative risk ratio of coronary heart disease (CHD) based on calcium score

Calcium score	*Relative risk ratio*
1–112	1.9
100–400	4.3
400–1000	7.2
>1000	10.8

Table 2 Annual coronary heart disease (CHD) and myocardial infarction (MI) rate based on calcium score

Calcium score	*Annual CHD/MI rate*
0	0.40%
300–399	2.80%
400–1000	4.60%
>1000	7.10%

Limitations

The most important concern regarding CACS scanning is radiation exposure. Studies show variable radiation exposure from CACS scans ranging from 0.8 to 10.5 mSv with a mean dose of 3.1 mSv (Kim et al., 2009). While these values are relatively low, they still raise questions of a possible increased risk of radiation-induced cancer. While there is no direct evidence of radiation-induced cancer, there is still controversy regarding this topic (Huda et al., 2010). One study estimated an increased risk of radiation-induced cancer, particularly breast and lung cancer, as well as leukemia; estimated risk was higher for women and decreased with increasing age at screening (Kim et al., 2009). However, risk of death related to radiation-induced cancer is still relatively low compared to everyday risks and should not prevent patients from receiving necessary tests, especially since heart disease remains the primary cause of death overall (Meinel et al., 2014a). In addition, as CT technology continues to improve, radiation dose is further reduced

(Marwan et al., 2013; McQuiston et al., 2016). Innovative techniques, such as tin prefiltration of the X-ray beam at 100 kV instead of the standard 120 kV, have been demonstrated as effective in reducing radiation dose to the submillisievert level for CACS (Tesche et al., 2017).

Coronary CT Angiography

Background

CAD and its complications, such as MI, heart failure and stroke, are the leading cause of mortality and morbidity worldwide (Go et al., 2013). There are continual efforts to improve the management of this disease and develop effective preventive strategies to decrease its prevalence in the general population and avoid its potentially fatal complications.

Over the past decades, invasive coronary angiography (ICA) has been the gold standard for visualization of the coronary arteries. However, this is an invasive procedure and can result in complications, albeit rarely (Zanzonico et al., 2006). Most patients receive ICA for diagnostic rather than therapeutic purposes (Maier et al., 2006). MDCT, owing to its higher spatial and temporal resolution, can capture images of the beating heart. The higher temporal resolution compensates for the heartbeat and respiratory motion while higher spatial resolution makes way for higher quality acquisitions. As a result, MDCT was quickly considered a possible alternative to ICA for noninvasive CAD diagnosis (De Cecco et al., 2014a; Achenbach and Daniel, 2001).

Technique

Capturing the heart with the fewest possible motion artifacts and highest possible image quality was not possible until the introduction of 64-slice MDCT systems, which are now a prerequisite for CCTA in clinical practice (Leschka et al., 2006).

CCTA is an ECG-gated, contrast-enhanced scan allowing the visualization of the coronary artery lumen and arterial wall. This tool has many clinical applications, the most important of which are myocardial ischemia and infarction detection, stenosis visualization, and atherosclerotic plaque detection and characterization (**Figs. 2–4**). Other applications are also now feasible: preinterventional planning for cardiac surgery or interventional cardiology, stent patency evaluation, heart failure evaluation, follow-up after heart transplant and coronary artery bypass graft surgery, and imaging of congenital heart disease in pediatric patients (Baumann et al., 2015a; Meinel et al., 2015).

Clinical relevance

Several studies comparing CCTA to gold standard ICA have shown the former's reliability and accuracy in detecting significant coronary artery stenosis (>50% narrowing of the vessel lumen) (Li et al., 2013, 2014; Menke et al., 2013; von Ballmoos et al., 2011; Salavati et al., 2012). The results for sensitivity and specificity ranged from 93% to 99% and 86% to 89.6%, respectively, translating to a negative predictive value (NPV) of 95%–100%. Furthermore, CCTA excludes CAD with a high degree of certainty.

Moreover, studies have already demonstrated the short-term prognostic value of this technique; a meta-analysis demonstrated that the presence of significant stenosis on CCTA was associated with a 10-fold increased risk of MACE, whereas any CAD increased

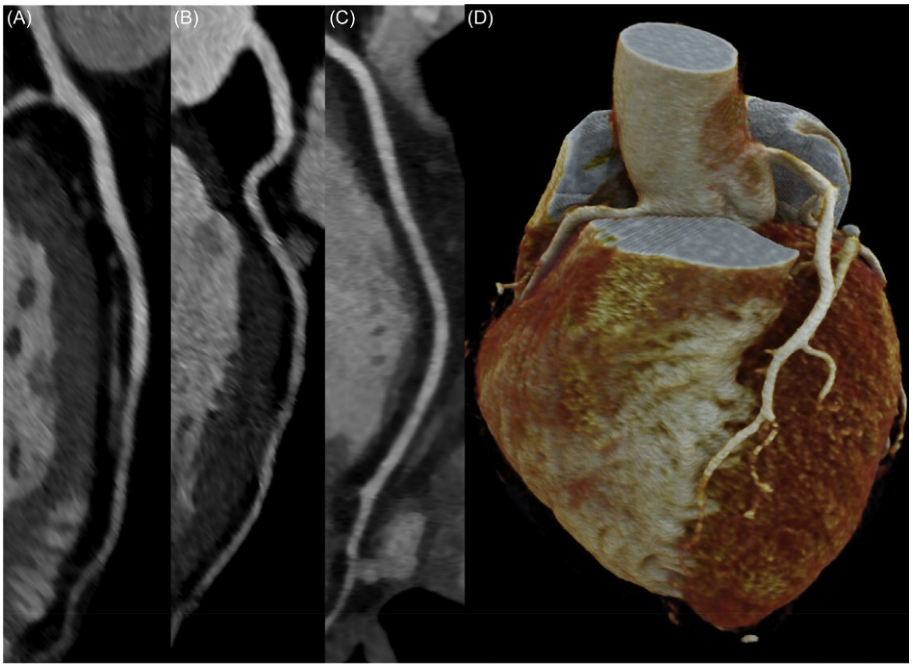

Fig. 2 Coronary CT angiography in a 48-year-old male presenting with chest pain. Curved multiplanar views of the (A) left anterior descending, (B) circumflex, and (C) right coronary artery. (D) Cinematic Rendering (Siemens Healthineers, not intended for clinical use) reconstruction of the heart.

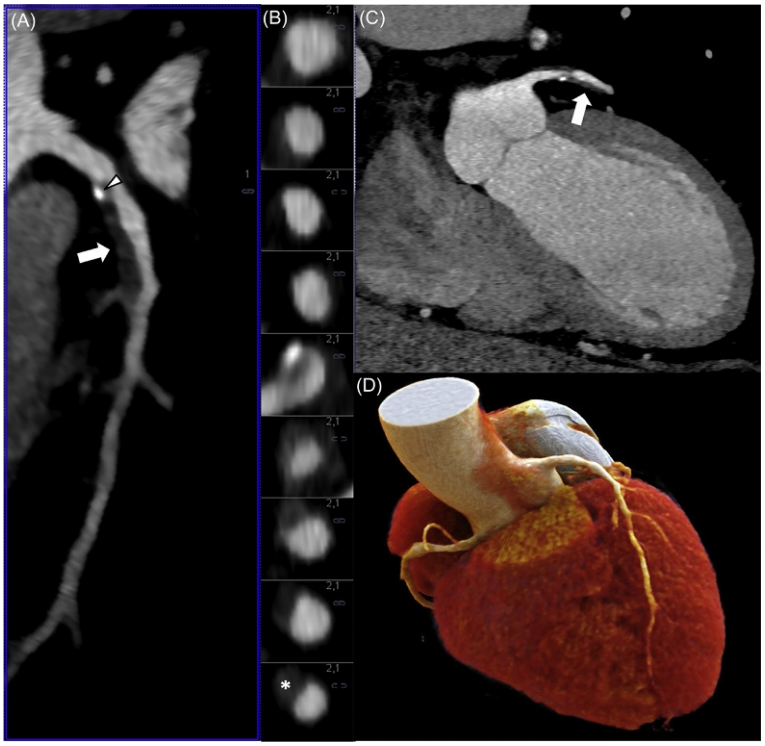

Fig. 3 A 65-year-old male with hypertension, diabetes mellitus, and a history of smoking presenting with exertional chest pain. A triple rule-out study was performed. (A) Curved multiplanar reconstruction of the left anterior descending (LAD) coronary artery shows a mixed calcified (*arrowhead*) and noncalcified (*arrow*) plaque. (B) Successive cross-sectional images of the LAD show the plaque causing moderate stenosis of the lumen (*asterisk*). the risk of MACE 4.5-fold (Bamberg et al., 2011a). More recently, long-term studies have shown an increased risk of MACE when CAD is detected on CCTA. In a cohort of 1584 patients followed for a median of 5.6 years, Hadamitzky et al. showed a 1.1% risk of MACE with obstructive CAD (Hadamitzky et al., 2013). Another study following 218 patients for a median of 6.9 years reported annual MACE rates of 2.7% and 6.0% for nonobstructive and obstructive CAD, respectively (Dougoud et al., 2014). Based on this evidence, CCTA has become an appropriate initial test for the evaluation of patients with stable angina and an intermediate to high risk of CAD, particularly in the setting of equivocal ECG and blood test results (Wolk et al., 2014).

Based on several clinical trials proving that CCTA can safely exclude CAD in the acute chest pain setting (Litt et al., 2012; Hoffmann et al., 2012), this modality is an important test in the workup of patients with chest pain in the emergency setting, particularly if they have low to intermediate risk of CAD, as it allows for quick and safe triage of patients (Taylor et al., 2010). Furthermore, triple rule-out studies, which consist of ECG-gated contrast-enhanced scans of the coronary arteries, pulmonary arteries, and aorta are now commonly performed in the acute chest pain setting to look for three common and potentially fatal causes of chest pain (CAD, pulmonary embolism, and aortic dissection) in one comprehensive test (White et al., 2005).

Left ventricular function assessment is a crucial part in managing patients with CAD (White et al., 1987). Some studies have demonstrated the superiority of CT over echocardiography, scintigraphy, and left ventriculography for this assessment (Yamamuro et al., 2005; Dewey et al., 2006; Sugeng et al., 2006). Furthermore, it has been shown that most novel CT scanners have approached the accuracy of cardiac MR (CMR) in assessing left ventricular function (Busch et al., 2008; van der Vleuten et al., 2009; Bastarrika et al., 2008a). However, echocardiography and CMR remain more popular for the primary assessment of cardiac function (Busch et al., 2008; van der Vleuten et al., 2009; Bastarrika et al., 2008b). Left ventricle function analysis with CT is currently performed in clinical practice when a patient is scanned with the retrospective ECG-gating technique since, as mentioned earlier, this technique contains data acquired throughout the cardiac cycle, which can be reconstructed to derive global parameters of ventricular function (**Fig. 5**). Moreover, multiphasic CT acquisitions have also been shown to detect wall motion abnormalities, an important consequence of CAD (Dirksen et al., 2005; Fischbach et al., 2007; Wu et al., 2008).

CCTA is now considered an important tool in the evaluation and management of patients with ischemic heart disease (De Cecco et al., 2014a). However, there remains controversy over the appropriate use of this technique; specific indications and guidelines are still being developed.

Limitations

It is necessary to acknowledge the minor concerns that are considered risks associated with CCTA: contraindications for iodinated contrast agent in cases of known allergy, hyperthyroidism, or renal impairment, and the inherent burden of ionizing radiation from CT. Effective dose values vary greatly depending on the acquisition technique. An average of 12 mSv has been reported for

Fig. 4 A 58-year-old male presenting with chest pain; he had an occluded left anterior descending artery. A stent was placed and a post-stent coronary computed tomography angiography (CCTA) was performed. (A) Axial section of the heart showing an area of hypodensity (*arrow*) in the apex consistent with myocardial infarction. (B) Sagittal section of the heart displaying the infarct (*arrowhead*) as well as myocardial thinning (*arrow*). (C) Multiplanar reconstruction of the left anterior descending artery showing the patent stent (*arrow*) and a noncalcified plaque (*arrowhead*).

retrospective ECG-gating, whereas the average falls to 3.5 mSv with prospective gating (De Cecco et al., 2014a; Menke et al., 2013). Novel scanning techniques such as dual-energy high-pitch acquisitions have reduced radiation doses to 1.5 mSv for CCTA (Yin et al., 2013), and a recent study managed to reduce radiation dose by 90% using a non-ECG-gated high pitch acquisition CT angiography (CTA) of the whole aorta (Zhang et al., 2016).

While techniques to further reduce radiation are continually investigated, it is worth mentioning that data regarding radiation-induced cancer is scarce (Meinel et al., 2014a). It is estimated that for a radiation dose of 10 mSv, the lifetime risk of developing a fatal cancer due to radiation is 1 in 2000, with an increased risk in younger, healthier patients and women, and a lower risk in older patients and men (Meinel et al., 2014a). Additionally, image quality of CCTA can be greatly hampered by artifacts, reducing diagnostic accuracy.

CTA of the Great Vessels

Carotid arteries

Atherosclerosis is a systemic inflammatory and multivessel disease (Libby et al., 2011). Consequently, assessment of the carotid arteries for the presence of atherosclerotic plaques beyond the coronary arteries is critical. Indeed, carotid artery atherosclerosis is a major cause of cerebrovascular events, which are themselves a major cause of morbidity and mortality (Barnett et al., 2000), highlighting the importance of evaluation of the carotids for efficient disease prevention.

Following the improved image resolution and faster acquisition times, CTA became a robust and reliable test for imaging of the carotid arteries (**Fig. 6**). Using this technique, Koelemay et al. found a sensitivity and specificity for carotid stenosis of 97% and 99%, respectively (Koelemay et al., 2004). Additionally, some studies reported CTA as accurate in detecting signs of plaque vulnerability such as ulcerations (Saba et al., 2007), large lipid cores, and plaque hemorrhage (Wintermark et al., 2008).

(D) Cinematic Rendering reconstruction of the head and neck vessels displaying the three-dimensional anatomy of the neck vessels.

Aorta

The ability to scan the whole aorta and branches from the carotid to the iliac arteries in a single breath hold has made CTA the better tool to evaluate the aorta and its runoffs, replacing invasive angiography as the gold standard (Prokop, 2000; Hayter et al., 2006).

CTA is very accurate in detecting many aortic anomalies such as aneurysms (Hartnell, 2001) and dissections (Shiga et al., 2006), which are important causes of morbidity and mortality (Figs. 7 and 8). Atherosclerosis and calcifications, which were found to be

predictors of stroke and CAD (Song et al., 2016; Amarenco et al., 1994; Rohani et al., 2005), stenosis, congenital anomalies, and wall thickening, as seen in inflammatory diseases, are also visualized by CTA (**Fig. 9**). Furthermore, CTA is used to assess posttreatment progression and complications such as restenosis, endoleak, and thrombosis (**Fig. 10**).

Future Directions

Plaque characterization

In the natural evolution of atherosclerosis, plaques can become vulnerable, that is more prone to rupture, when they have a thin fibrous cap and a large lipid-rich core (Little, 1990; Renker et al., 2015; Kolodgie et al., 2004). It has been shown that the compositional characteristics of atherosclerotic plaques can be more predictive of MACE than the degree of stenosis (Bittencourt et al., 2014). As a result, plaque composition analysis has become an increasingly important aspect of better risk stratification in cardiac imaging. The introduction of 64-slice scanners has allowed accurate plaque characterization; plaques are usually classified as calcified (density higher than 400 Hounsfield units (HU)) or noncalcified (density between 0 and 150 HU) (Rasouli et al., 2006). Noncalcified plaques can be further subcategorized into fibrous and lipid-rich plaques with a density of less than 60 HU (Nance et al., 2012; Becker et al., 2003). Several studies have shown the accuracy of CCTA in detecting plaque components with invasive vascular ultrasound (IVUS) as the reference standard (Voros et al., 2011; Gao et al., 2011). Particularly, Obaid et al. found that there was favorable diagnostic accuracy in the detection of calcified, necrotic, and fibro-lipidic components using plaque maps derived from plaque attenuation (Obaid et al., 2013) (**Fig. 11**).

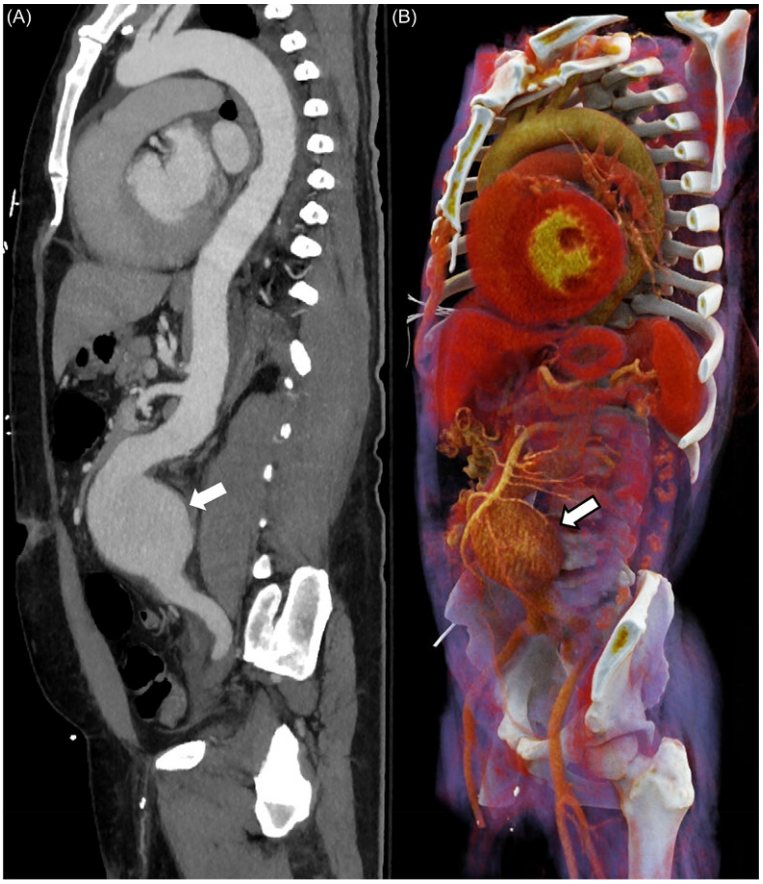

Fig. 8 CT angiography in a 62-year-old male presenting with abdominal pain. (A) Sagittal and (B) Cinematic Rendering reconstructions of the aorta showing a massive infrarenal aneurysm (*arrow*).

Novel CT systems have the potential to further characterize plaque composition (Ohnesorge et al., 2005). Several vulnerable plaque features can be detected by CCTA, most notably the napkin-ring sign. The napkin-ring sign is identified as a region of low attenuation surrounded by a ring of high attenuation, which is thought to represent a necrotic core surrounded by a fibrous cap (Maurovich-Horvat et al., 2010) (**Fig. 12**). CCTA also detects other important signs of vulnerable plaque: spotty calcifications (⊠3 mm calcifications surrounded by noncalcified plaque) (van Velzen et al., 2011), low-attenuation plaque (density = 30–60 HU), and positive remodeling, defined as an enlargement of both the vessel lumen and arterial wall seen in early atherosclerosis. These features were detected by CCTA with good correlation when compared to IVUS ($r = 0.94$, $P < 0.001$), as reported by Nakazato et al. (Nakazato et al., 2013). Moreover, these signs were independently associated with cardiac events (Puchner et al., 2014). Specifically, spotty calcifications detected on CCTA were associated with plaque progression and culprit lesions (Kataoka et al., 2012). Low-density plaques, positive remodeling, and spotty calcifications were all signs present in culprit lesions when compared with nonculprit lesions (Benedek et al., 2013). Additionally, Otsuka et al. found that the presence of the napkin-ring sign on CCTA had a high predictive value for MACE that was independent of other risk factors (Otsuka et al., 2013). More recently, Tesche et al. found that CCTA-derived markers such as the remodeling index and the napkin-ring sign were predictive of MACE, achieving the highest predictive values when combined with FRS (Tesche et al., 2016a). However, limited spatial and temporal resolution poses a challenge to identifying thin-capped fibroatheromas and lipid-rich necrotic cores, both important markers of plaque vulnerability, which could potentially cause high-risk lesions to go unnoticed (Obaid et al., 2013). Concomitantly to software and hardware technology improvements, plaque characterization approaches are evolving, which could play a more important role in stratifying patients and lead to better treatment management.

Dual-energy CT (DECT)

In DECT image acquisition, patients are scanned at two different kilovoltage (kV) levels: usually a low level of 80–90 kV and a high level of 140–150 kV (Ruzsics et al., 2008). The underlying consideration is that different materials show specific attenuation characteristics depending on the applied tube voltage. Whereas traditional single-energy CT depends only on the measured density (HU) of materials that are penetrated by the CT X-ray beam, DECT allows for the identification and differentiation of tissues and molecules such as calcium, iodine, and uric acid. Depending on vendor-specific systems, this can be achieved either with a dual-source dual-detector setup (Kang et al., 2010) or with a single-source rapidly switching between low and high kV (Matsumoto et al., 2011). While there remain concerns about the radiation dose associated with CCTA, DECT allows for the subtraction of iodine from

Fig. 9 CT angiography in a 26-year-old female presenting with joint pain and fever. (A, B) Axial and (C) curved multiplanar reconstructions of the aorta showing thickening of the aortic wall (*arrows* and *arrowhead*) consistent with Takayasu's disease.

contrast-enhanced images, resulting in so-called virtual noncontrast images (**Fig. 13**). To date, these reconstructions cannot fully replace true unenhanced images because of low image quality (De Cecco et al., 2013); although it has been shown that they have comparable diagnostic accuracy in clinical scenarios such as active bleeding detection (Sun et al., 2015). Despite the relatively low image quality, these reconstructions hold great promise as an ancillary diagnostic image set, reducing radiation dose by almost 50% (Sun et al., 2013). Due to its ability for material decomposition, DECT could also somewhat improve plaque characterization even though preliminary results have been inconsistent (Barreto et al., 2008; Tanami et al., 2010; Henzler et al., 2011). Another promising DECT approach in angiography consists of the reconstruction of the so-called monoenergetic images (Albrecht et al., 2016a,b), sometimes referred to as monochromatic images (**Fig. 14**). Since image noise usually increases with lower kV levels, it is not possible to take full advantage of the increased contrast in the image. Monoenergetic DECT reconstructions combine the benefits of the simultaneous datasets: the high contrast of the low energy series with the low noise of high energy series (Grant et al., 2014). Thus, various authors demonstrated tremendous increases in quantitative image quality indices such as CNR and signal to noise ratio (SNR) in virtual monoenergetic CTA (Albrecht et al., 2016a,b; Beeres et al., 2016). Notably, the highest objective image quality of these monoenergetic images at 40 keV did not coincide with the highest qualitative, sometimes referred to as "subjective," image quality at keV levels ranging from 50 to 70 keV (Albrecht et al., 2016a,b; Beeres et al., 2016). Several authors suggested that virtual monoenergetic imaging could allow for distinct reductions in contrast media volume (Chung et al., 2015; Clark et al., 2015). More importantly, DECT has the ability to assess myocardial perfusion (Vliegenthart et al., 2012a), an important element in CAD risk assessment as discussed later in the review.

CT-myocardial perfusion

While CCTA has been accepted as a modality to assess CAD in patients with intermediate risk (Taylor et al., 2010), it is mainly used as a tool for anatomical and morphological assessments as it is not accurate in predicting ischemia (Stolzmann et al., 2010; Mouden and Ottervanger, 2009). However, determining which lesions reduce myocardial perfusion is important for a comprehensive anatomical and functional evaluation of CAD with CCTA and helps to better guide coronary intervention. CTMPI allows for the assessment of functional and morphological parameters in a single scan.

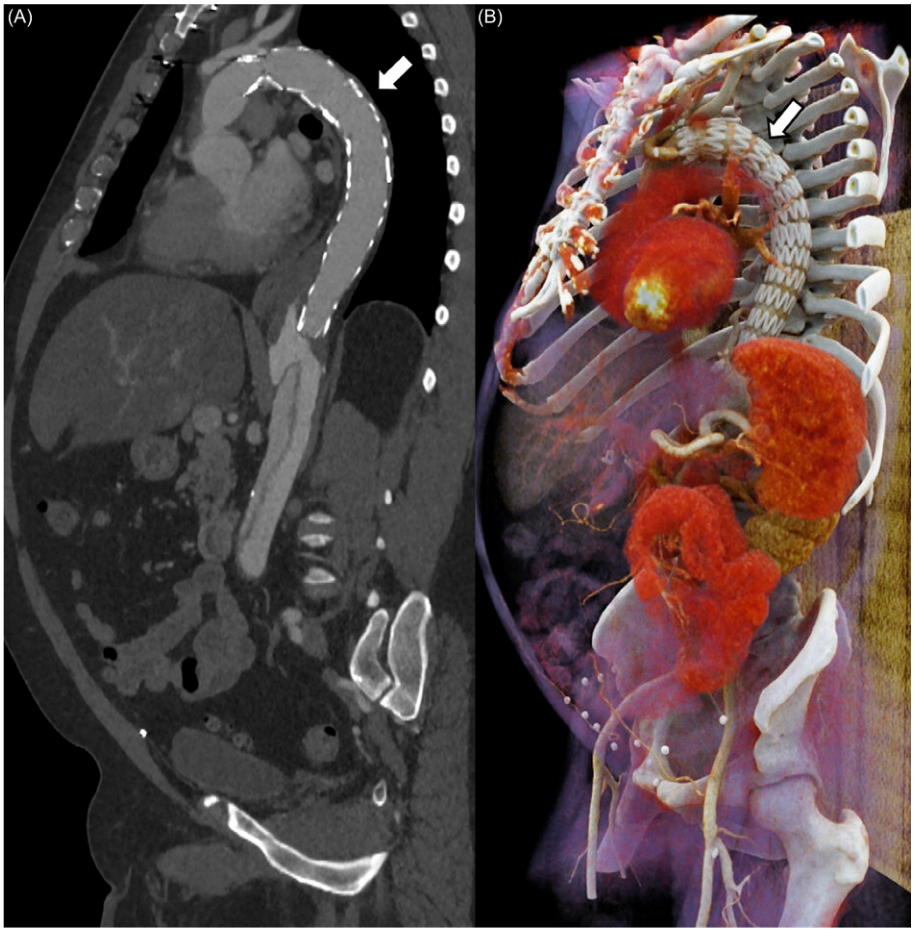

Fig. 10 CT angiography in a 68-year-old female post thoracic aorta dissection repair. (A) Sagittal and (B) Cinematic Rendering reconstructions of the aorta showing a stent in the thoracic aorta (*arrow*).

Myocardial perfusion is based on the distribution of iodinated contrast material during its first pass through the myocardium. Since the distribution of the contrast material is determined by the arterial blood supply, myocardial perfusion defects can be identified as hypo-attenuating areas containing reduced amounts of contrast material (George et al., 2006). There are different approaches for CT evaluation of myocardial perfusion: static myocardial perfusion, which can be further categorized into single-energy-CTMPI (SE-CTMPI) and dual-energy-CTMPI (DE-CTMPI), and dynamic CTMPI (dCTMPI).

Static CT perfusion allows for a visual, qualitative assessment of a single snapshot of contrast attenuation (**Fig. 15**). The snapshot encompasses the entire left ventricle and is acquired during early first-pass enhancement. In order to detect early differences in contrast uptake, it is crucial that the acquisition is performed during peak enhancement of the coronary arteries (Bischoff et al., 2013). Because the same parameters and datasets are used for static myocardial perfusion as for the morphological assessment of the coronary arteries, theoretically, any scanner capable of CCTA can be used and no additional acquisitions are needed for the perfusion evaluation at rest (Vliegenthart et al., 2012b; Nagao et al., 2008). Myocardial perfusion is evaluated by visual assessment of contrast enhancement, preferably in multiphase reconstructions, to better discriminate between true defects, which persist throughout the cardiac cycle, and artifacts only visible during a single cardiac phase (Vliegenthart et al., 2012b). SE-CTMPI has been widely investigated and most studies have shown high sensitivity and specificity for the detection of hemodynamically significant lesions compared with single photon emission computed tomography (SPECT) or SPECT with ICA (Cury et al., 2010, 2011; George et al., 2009, 2012; Kachenoura et al., 2009; Blankstein et al., 2009; Rocha-Filho et al., 2010; Ko et al., 2012a; Nasis et al., 2013; Osawa et al., 2014; Rochitte et al., 2014; Feuchtner et al., 2011). Sensitivity ranged from 50% to 96% and specificity from 68% to 98%, translating to a NPV and PPV of 79%–98% and 55%–94%, respectively. However, the main drawback is that the timing of the acquisition is crucial; missing the peak attenuation could greatly reduce diagnostic accuracy (Bischoff et al., 2013). Performing data acquisition in consecutive regions of the heart during different cardiac cycles results in heterogeneous contrast uptake, which hinders perfusion assessment.

Additionally, DE-CTMPI is based on a dual-simultaneous image acquisition at only one time point. DE-CTMPI merges datasets from both energy spectra allowing for the generation of a color-coded iodine distribution map where iodine concentration is

Fig. 11 Coronary CT angiography in a 58-year-old male presenting with chest pain. (A) Curved multiplanar and (B) axial images of the heart showing the plaque segmentations for plaque analysis. (C) A graph is generated showing the volume, size, and ratio of each plaque component.

normalized to areas of normal myocardial perfusion (**Fig. 16**). This iodine concentration is an indicator of myocardial perfusion and thus, myocardial blood pool can be quantified based on the amount of iodine per voxel (Koonce et al., 2014). Several studies have already demonstrated the good accuracy of DE-CTMPI in detecting hemodynamically significant CAD at rest and stress (Kim et al., 2014; Ko et al., 2011, 2012b, 2014a,b; Ruzsics et al., 2009; Wang et al., 2011; Weininger et al., 2012; Delgado et al., 2013; Delgado Sanchez-Gracian et al., 2016). De Cecco and colleagues showed a significant increase in specificity from 33% to 67% when DE-CTMPI was added to CCTA, as compared with ICA (De Cecco et al., 2014b). Moreover, studies have reported the reclassification of perfusion defects using DE-CTMPI; almost half of the defects classified as reversible with SPECT were reclassified as fixed with DE-CTMPI (Vliegenthart et al., 2012b; Wang et al., 2011; Meinel et al., 2014b). In addition to the limitations of SE-CTMPI, an additional drawback of DE-CTMPI is the nonstandardized iodine distribution maps, which make perfusion assessment highly user-dependent.

dCTMPI requires whole heart coverage and great temporal resolution to sample the heart multiple times during the first pass of the contrast agent. Currently, only MDCT scanners with 256 or 320 detector rows or second-generation DSCT scanners with shuttle mode are capable of dCTMPI (Weininger et al., 2012; Hsiao et al., 2010; Bastarrika et al., 2010a,b). The main advantage of the dynamic technique is the ability to perform an objective quantitative evaluation of myocardial perfusion through quantification of myocardial blood flow and myocardial blood volume (So et al., 2012; Rossi et al., 2014) (**Fig. 17**). Several studies have already demonstrated the good accuracy of dCTMPI compared with cardiac MRI (Weininger et al., 2012; Bastarrika et al., 2010a; Bamberg et al., 2014), SPECT (Weininger et al., 2012), SPECT plus ICA (Ho et al., 2010; Wang et al., 2012), and invasive fractional flow reserve (FFR) (Rossi et al., 2014; Ho et al., 2010; Bamberg et al., 2011b; Greif et al., 2013; Huber et al., 2013). The respective sensitivity and specificity ranged from 76% to 100% and 74% to 100%, which translates to a NPV and PPV of 82%–100% and 48%–100%, respectively. Since dCTMPI requires multiple acquisitions in shuttle mode, this technique is inherently associated with substantially increased radiation dose levels in comparison with traditional CCTA. This distinctly increased dose of ionizing radiation is the primary drawback of this technique, limiting its adoption into clinical routine. Presently, the use of dCTMPI is limited to research studies and academic centers.

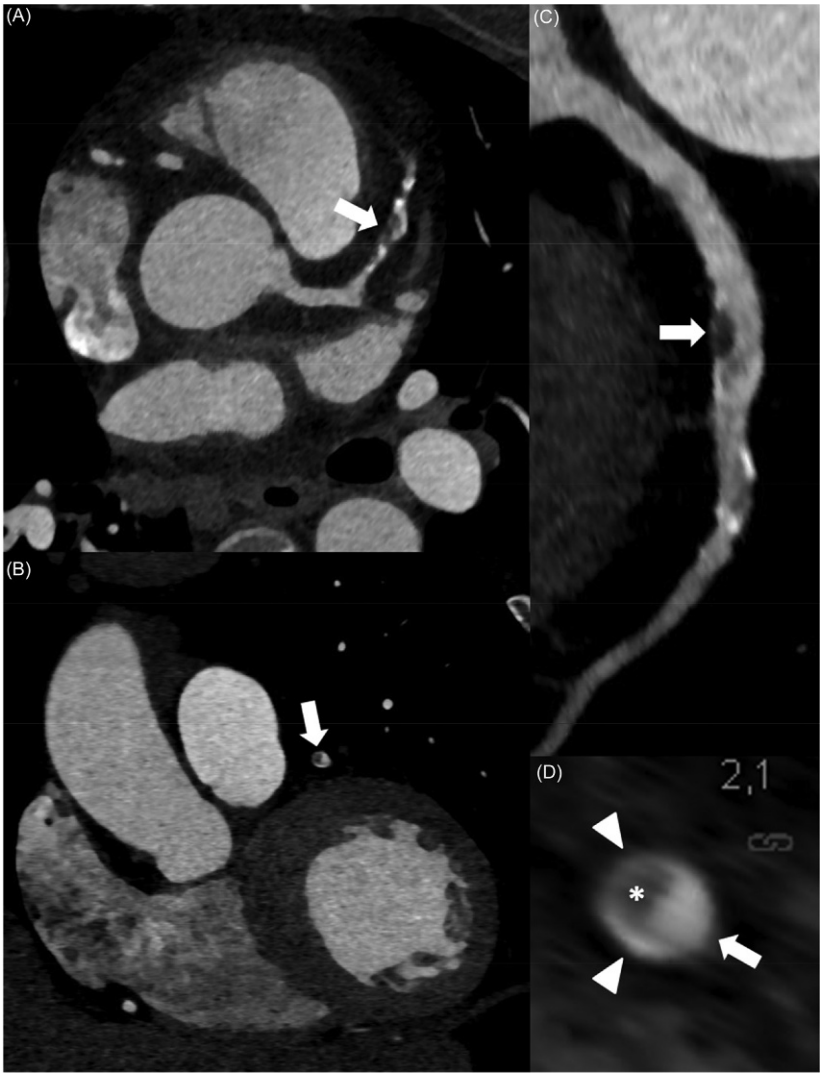

Fig. 12 Coronary CT angiography in a 67-year-old female presenting with chest pain. CT-FFR

The evaluation of FFR with ICA provides important information regarding the hemodynamic significance of CAD (Patel et al., 2012). However, even though this technique is currently the reference standard, its invasive nature makes it an impractical choice for the general evaluation of CAD (Pijls and Sels, 2012). Third-generation DSCT scanners have vastly improved the temporal and spatial resolution of standard CCTA. These improvements have resulted in improved lumen definition and plaque characterization throughout the coronary tree. These advancements in CT technology allow the calculation of noninvasive CT-derived FFR values through the application of computational fluid dynamics to standard CCTA datasets (Kim et al., 2010). While CCTA has been shown to have high sensitivity and NPV in excluding significant CAD, its specificity and PPV for detecting ischemia-causing disease are low (Min et al., 2013). As a result, the ability to add physiologic information through CT-FFR to the anatomical datasets of CCTA has high clinical relevance.

The feasibility of CT-FFR with standard CCTA has been demonstrated (Leipsic et al., 2014) (**Fig. 18**). Recent studies have shown CT-FFR to be a highly accurate technique for the diagnosis of hemodynamically significant stenosis when compared with invasive FFR (Norgaard et al., 2014; Tesche et al., 2016b; Wang et al., 2015; Baumann et al., 2015b). Moreover, adding CT-FFR to CCTA was found to significantly improve diagnostic accuracy for hemodynamically significant CAD (Renker et al., 2014). A recent meta-analysis showed that CT-FFR improved specificity when combined with CCTA, without altering sensitivity for the detection of hemodynamically significant lesions (Baumann et al., 2016). One benefit of CT-FFR is that it is based on the standard CCTA data, meaning it does not require additional acquisitions or radiation exposure. However, CT-FFR still requires time-consuming, off-site computation in super-computer core laboratories, a problem that could be solved with more novel computational algorithms, which seem feasible in an on-site manner (Baumann et al., 2015b; Renker et al., 2014).

Transluminal attenuation gradient (TAG)

TAG is a novel postprocessing technique that provides functional information in the context of CAD. TAG is defined as the gradient of contrast opacification along the coronary artery (Stuijfzand et al., 2014). It has already been shown that TAG correlates well with ICA and adding TAG to CCTA provides incremental value for the detection of hemodynamically significant CAD (Wong et al., 2013;

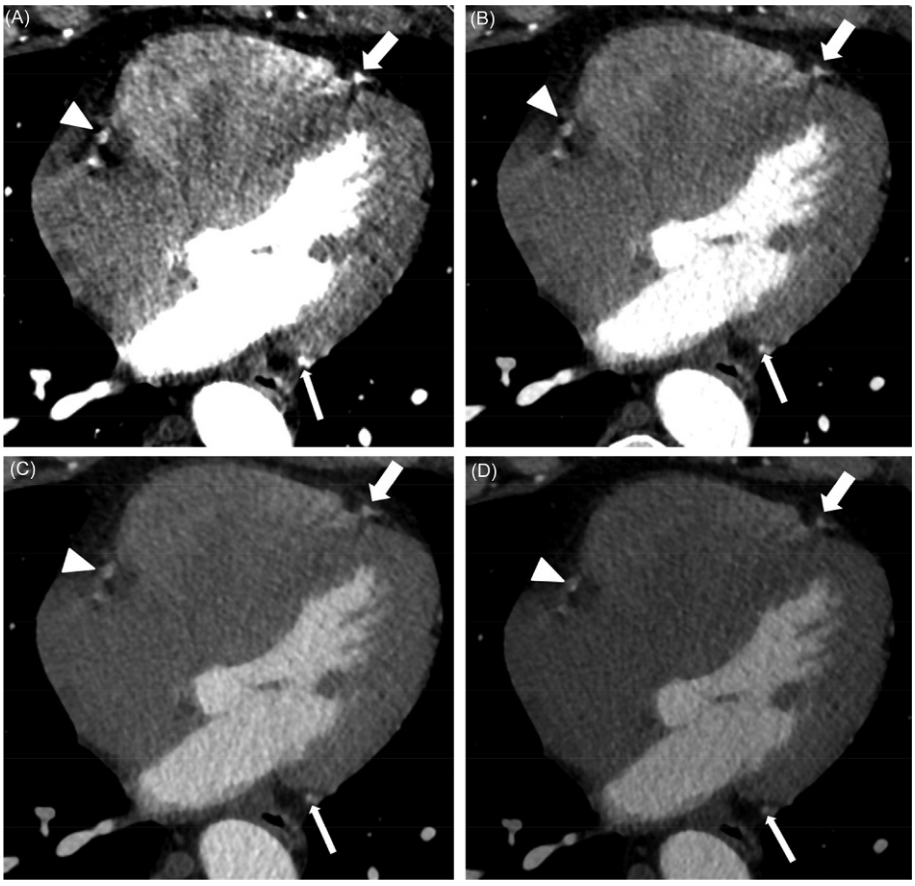

Fig. 14 Dual-energy coronary CT angiography in a 64-year-old male presenting with chest pain. (C) Dual energy CT myocardial perfusion in rest phase showing a normal myocardial perfusion. (D) Dual energy CT myocardial perfusion in stress phase showing reduced perfusion in the apical and lateral walls (*arrows*).

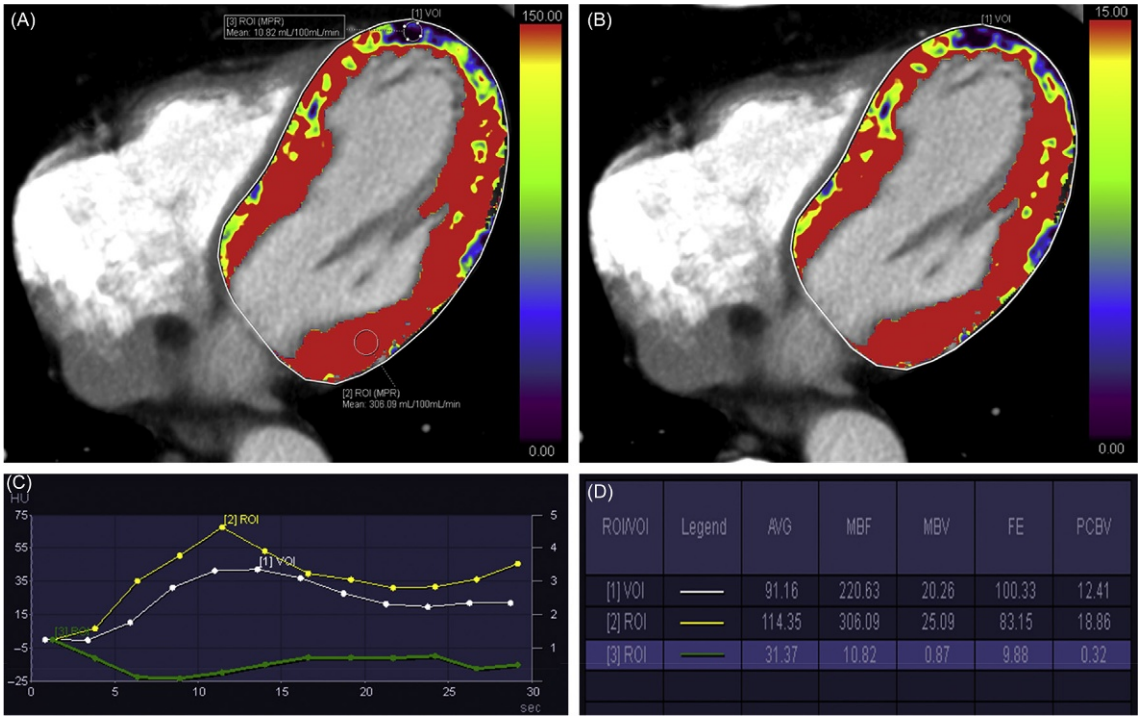

Fig. 17 Dynamic CT myocardial perfusion in a 72-year-old male presenting with chest pain. (A) Myocardial blood flow and (B) myocardial blood volume showing a diminished perfusion in the apical wall. (C) Time attenuation curves and (D) quantitative perfusion values can also be generated.

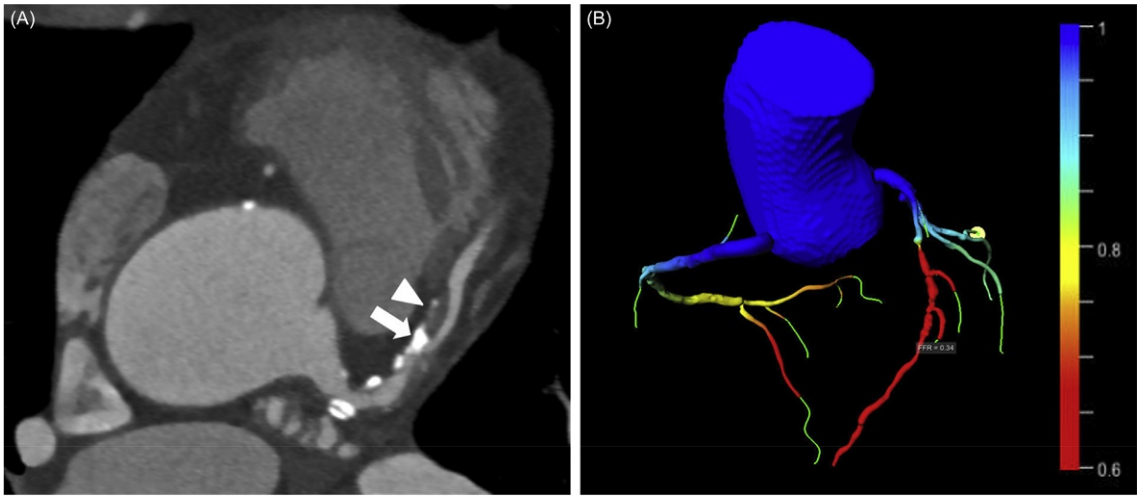

Fig. 18 Coronary computed tomography angiography (CCTA)-derived fractional flow reserve (CT-FFR) in a 58-year-old male presenting with chest pain and shortness of breath. (A) Axial view of the heart showing extensive coronary artery disease of the left anterior descending (LAD) with both calcified (*arrow*) and noncalcified (*arrowhead*) plaques resulting in severe stenosis of the vessel. (B) CT-FFR of the same patient showing markedly reduced blood flow in the LAD with an FFR value of 0.34.

Ko et al., 2016). As with CT-FFR, TAG can be achieved with standard CCTA acquisitions without requiring additional scans or increasing radiation exposure. Further studies are needed to confirm the utility of TAG in routine clinical practice.

Conclusion

Cardiovascular imaging plays an increasingly important role in the clinical diagnosis and management of cardiovascular diseases. As scientific evidence continues to build, guidelines for appropriate indications will evolve, ensuring appropriate use and cost-effectiveness.

As CT technology improves, new applications for cardiovascular CT are being explored, widening the scope of this modality from simple morphologic assessment to comprehensive evaluation of cardiac anatomy, function, and perfusion.

Introduction

Assessment of cardiac structure and function is the foundation of cardiac imaging, and the echocardiographic examination specifically has this role at its core. Echocardiography is a noninvasive modality and is the most commonly used method of cardiac imaging. It has the distinctive capability of providing real-time images of the heart, is low risk, does not confer radiation to the patient, is portable, and is widely available. As a result, echocardiography is a valuable diagnostic test to evaluate the cardiovascular system and assess physiologic function in a variety of diseases. It provides reliable structural, functional, and hemodynamic information, making an impact in clinical cardiology and is a valuable tool for cardiovascular research.

Left Ventricle

General

Since the inception of echocardiography, this technology has been used in the evaluation of the left ventricle (LV). Assessment of the left ventricle is an integral part of every echocardiogram and defining its structure and function is often the primary indication for the examination. Evaluation of ventricular function offers important prognostic information and guidance for clinical management of the patient. Echocardiography conveys both qualitative and quantitative measures of left ventricular function, and there are a variety of parameters which provide insight into cardiovascular physiology and disease pathology. Assessment of the LV has improved as the technology has evolved to include functions such as strain imaging and three-dimensional (3D) echocardiography; however two-dimensional (2D) echocardiography remains the primary tool for quantification and evaluation of the left ventricular structure and function.

Shape

The shape of the left ventricle is normally comprised of a relatively symmetric short axes and a long axis taken from the base at the mitral annulus to the apex. The basal portion of the ventricle is shaped similar to a cylinder making the minor-axis views appear circular. The apical portion in the long-axis views appears somewhat rounded, giving it the shape of a hemiellipse. Various assumptions about the shape of the left ventricle are made in order to calculate the size and volumes, most of which require geometric simplifications, introducing some degree of error. As technology has progressed from single-plane imaging, to 2D echocardiography and later 3D techniques, the accuracy and reproducibility in determination of the left ventricular shape, size, and function has improved as the number of assumptions is reduced. One method to quantify LV shape is the sphericity index although it is not commonly used in a clinical setting. This ratio is expressed as the left ventricular long-axis length divided by the diameter and a ratio of less than 1.5:1 typically implies pathologic remodeling (Tischler et al., 1993; Douglas et al., 1989).

Size

Linear dimensions

Left ventricular size is most commonly measured as linear dimensions and volumes of the LV cavity (**Table 1**). These are typically gained from measurements of the endocardium at end-diastole and end-systole, allowing wall thickness and global LV function to be calculated using these parameters. Historically, M-mode measurements in the parasternal long-axis view of the heart have been used to obtain these linear dimensions. The aim is to identify the endocardium through the short (minor) axis of the left ventricle at the tips of the mitral leaflets. This angle-dependent practice is significantly limited, however, by off-axis orientations of the ultrasound beam relative to the left ventricular surface, introducing error into the calculations. Further, M-mode, which measures the LV in only one region, has a limited ability to recognize segmental wall motion abnormalities which may lead to over or underestimation of the overall left ventricular size and function. The strength of M-mode is its high-quality temporal resolution which is valuable in timing of cardiac events.

The pursuit of more consistent and accurate measurements of cardiac size and function led to the development of 2D echocardiography (Picard et al., 2008). This technology allows a more comprehensive view of the cardiac structures compared with the single-dimension measurements made by M-mode. 2D echocardiography can be utilized to guide the M-mode to assure a more perpendicular orientation of the ultrasound beam to the long axis of the LV for measurement, or to directly measure the left ventricular endocardium on still-frames at end-diastole and end-systole of the 2D image (Lang et al., 2015) (**Fig. 1**). The recommended technique is to perform this measurement in the parasternal short-axis view at the level of the chordae, using the blood–tissue interface to delineate the points of measurement (Lang et al., 2006).

Volumes

Left ventricular volumes can be measured using 2D or 3D echocardiography. These techniques reduce inherent errors from the geometrical assumptions that are employed for volume calculations derived from linear dimensions. 2D echocardiographic (2DE)-derived volumes rely on endocardial border tracing during end-systole and end-diastole in multiple tomographic planes. The recommended transthoracic echo (TTE) planes for these volumetric tracings are the apical four-chamber and apical two-chamber views of the left ventricle. In order to obtain more accurate volumetric measurements, care must be taken to maximize the LV area obtained by the echo while avoiding foreshortening in order to include the apex of the left ventricle for tracing. Another prerequisite to minimizing errors in volume measurements includes ensuring adequate endocardial border

Table 1 Normal values for echocardiographic parameter of LV size and function

	Male	*Female*
Parameter	*Mean ± SD*	*Mean ± SD*
LV internal dimension

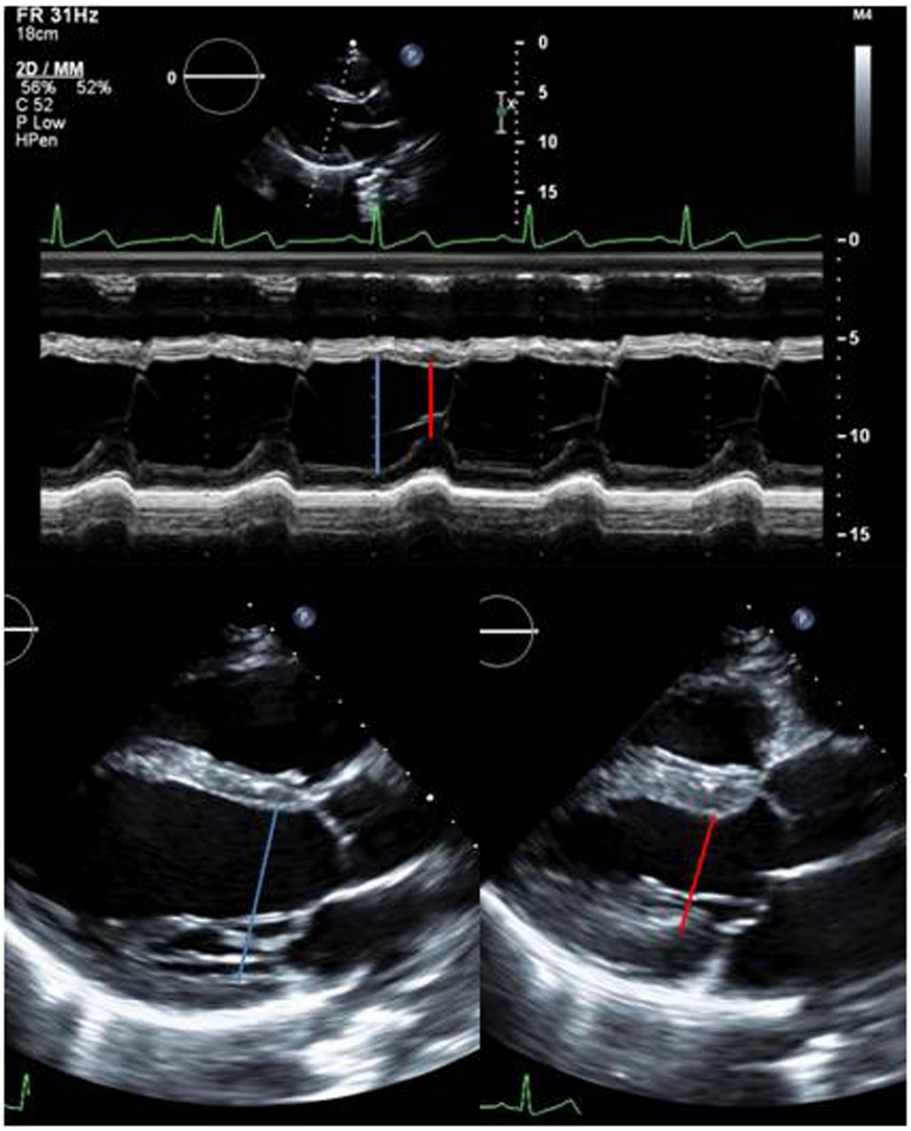

Fig. 1 LV internal linear dimensions. Acquired in the parasternal long-axis view, LV internal dimensions must be obtained perpendicular to the long axis and measured at the level of the mitral valve leaflet tips. Top panel shows 2D-guided M-mode measurements at end-diastole and end-systole. Bottom panel shows corresponding measurements made on still-frame 2D-echo.

definition within the LV cavity. When there is a need to improve image quality to enhance endocardial demarcation, echo contrast agents should be used. This is especially important when two or more adjacent endocardial segments are not well visualized (Mulvagh et al., 2008; Lang et al., 2015).

The most robust and commonly used practical method for 2DE volume calculation is the biplane method of disks. This method applies Simpson's rule, which states that the "volume of a large figure can be calculated from the sum of the volumes of a series of smaller, similar figures." (Vuille and Weyman, 1994) This method is currently recommended by a consensus of experts as it corrects for shape distortions and reduces geometric assumptions of the LV shape compared with alternative 2DE methods (**Table 1**). First, it requires tracing of the left ventricular cavity in the apical four-chamber and apical two-chamber views at end-systole and end-diastole (**Fig. 2**). This area is subsequently rendered into a series of stacked disks of equal height, whose volumes are added together from base to apex, producing LV volumes at end-systole and end-diastole using the formula volume $= (\pi/4)\sum_{i=1}^{20}(a_i b_i)(L/20)$. Another option for determining volume is the area–length method, which assumes the base of the LV is shaped as a cylinder and the apex is an ellipsoid, making the LV a "bullet shape." This is performed by measuring the length of the left ventricle from base to apex in the apical four-chamber view and cross-sectional area of the mid-LV by planimetry in the parasternal short-axis view (**Fig. 3**) and applying the formula volume $= 5/6(AL)$ (Lang et al., 2005, 2015).

Because 2D echocardiography remains a tomographic technique, volume calculations necessitate geometric assumptions regarding the left ventricle. In contrast, 3D echocardiography does not require geometric assumptions, is unaffected by

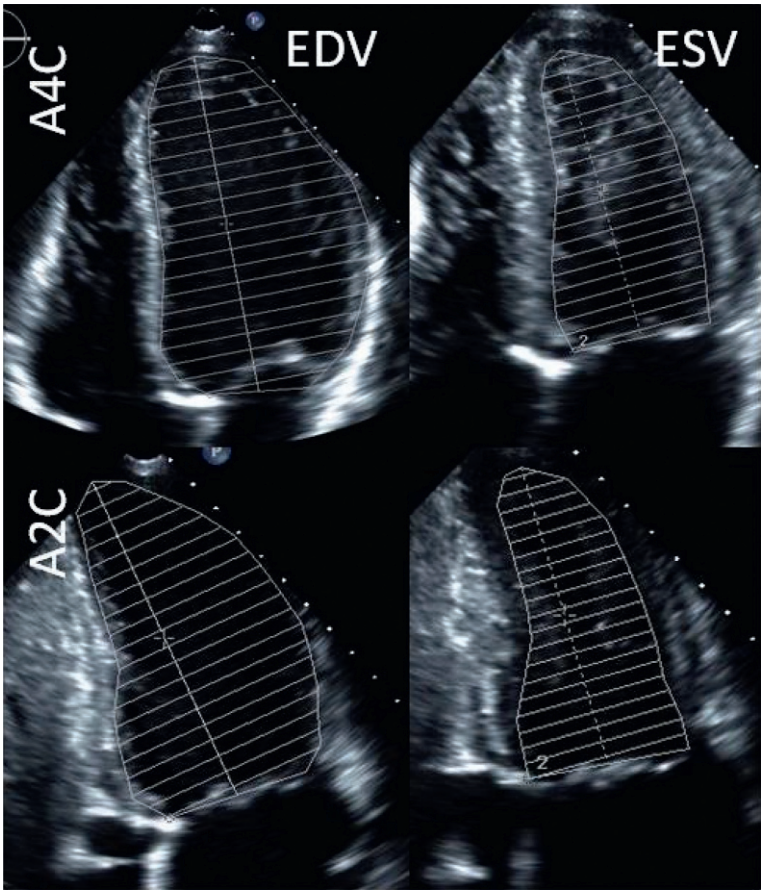

Fig. 2 LV method of disk summation. Volume measurements are made by tracing the blood–tissue interface in the apical four and apical two-chamber views, at end-diastole and end-systole. The shape is closed by a virtual line made across the level of the mitral valve annulus. *A4C*, apical four-chamber; *A2C*, apical two-chamber; *EDV,* end-diastolic volume; *ESV*, end-systolic volume.

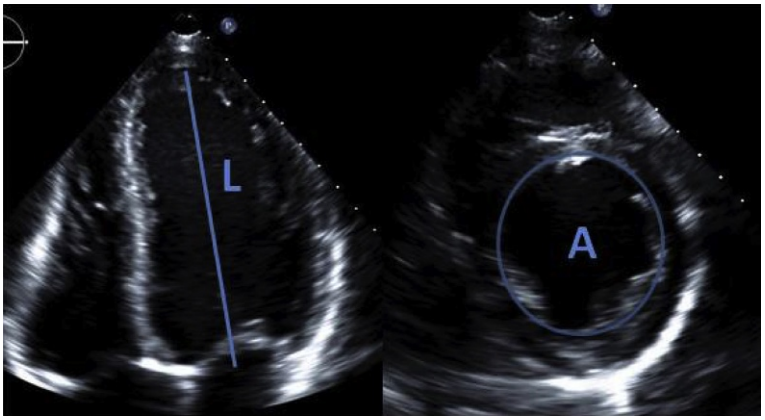

Fig. 3 LV area–length volumetric method. Volume is determined by measuring the length of the left ventricle in the apical four-chamber view and the area of the mid-level of the left ventricle in the parasternal short-axis view, using specific assumptions regarding LV shape. *L*, length; *A*, area.

foreshortening, and has demonstrated improved accuracy and precision compared with alternate imaging modalities in assessing the LV volumes (Dorosz et al., 2012). 3D echocardiographic data is transferred to a workstation, allowing the volume to be calculated offline (Fig. 4). One method directly adds the volumes of the voxels, or 3D volume elements, that are enclosed by the LV endocardial borders. Another technique utilizes the disc summation method, adding component 3D volumes after identifying the LV borders. The major drawbacks of 3D-derived volumes include a dependency on high-quality 2D echo acquisition and its lower temporal resolution, which may limit accurate identification of end-systole and end-diastole (Lang et al., 2015).

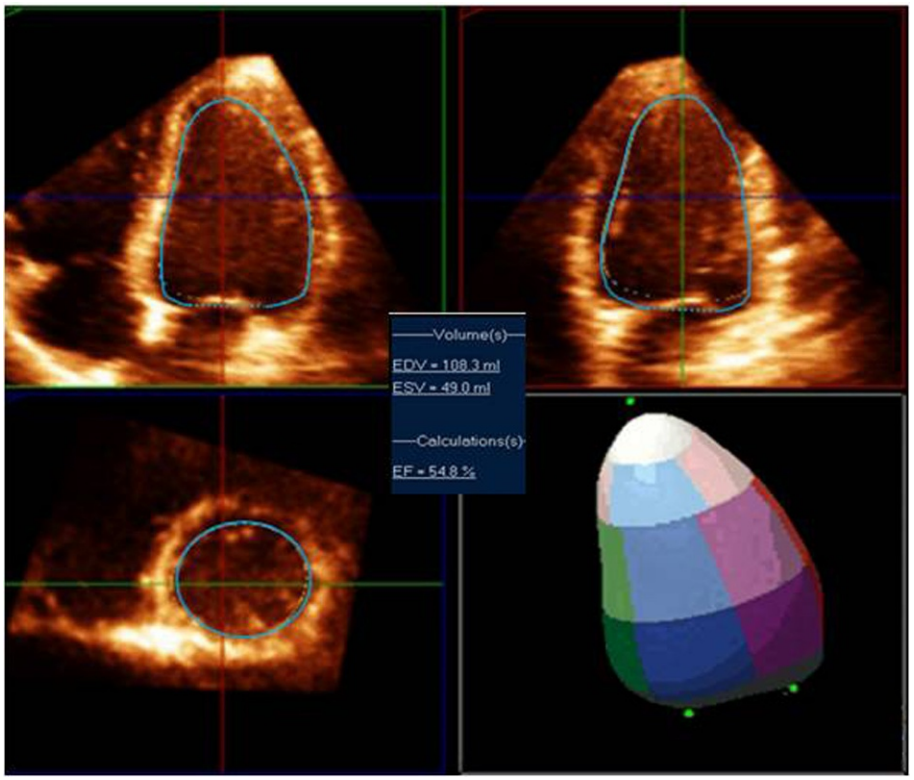

Fig. 4 Three-dimensional Echocardiography. From a 3-dimensional echo data set of the left ventricle (LV) the endocardium can be traced (*top left*, *top right*, and *bottom left panels*) to obtain the LV volume throughout the cardiac cycle and derive the EF. The LV endocardium can be divided according to the 17-segment model (*bottom right panel*). *EDV*, end-diastolic volume; *ESV*, end-systolic volume; *EF*, ejection fraction.

Systolic Function

Fractional shortening

In addition to assessing wall thickness and determination of LV internal dimensions during systole and diastole, linear dimensions supply the information necessary to compute endocardial fractional shortening of the left ventricle. Fractional shortening is a simple measurement for determining the global LV function and can be derived from linear measurements made on 2D imaging or 2D-guided M-mode. As previously mentioned, using linear measurements to derive global LV function can be problematic in the presence of regional wall motion abnormalities. If these abnormalities are located in the area where the measurements are performed they may lead to underestimation of the global LV function because the rest of the ventricle may be normal. In contrast, if the measurements are made in a normal region, for example, the base of the LV, and the mid or apical LV is hypokinetic or akinetic, it could lead to overestimation of the global function. In the absence of regional abnormalities, fractional shortening may provide simple and useful information to the clinician and in research studies. However, in patients with wall motion abnormalities or diseases that distort the LV shape, volumetric measurements provide a more accurate assessment of the global function. The merits of the fractional shortening method include its simplicity, reproducibility, and ease of use to gather data in large populations.

Ejection fraction

Ejection fraction (EF) is the percentage of blood volume ejected in each cardiac cycle and is a representation of LV systolic performance. It is calculated from the end-diastolic and end-systolic volumes of the left ventricle. The formula for calculating EF is:

$$\mathrm{EF} = \frac{(\mathrm{EDV} - \mathrm{ESV})}{\mathrm{EDV}}$$

where EF is ejection fraction, EDV is end-diastolic volume, and ESV is end-systolic volume. Note that the difference between the end-diastolic volume and end-systolic volume is the stroke volume. See **Table 2** for the normal and abnormal ranges of EF.

The left ventricular volume measurements may be obtained from 2D echo or 3D echo, as discussed previously. The current recommendation for assessment of the EF is to use the biplane method of disk summation. In echocardiograms with sufficiently high-quality imaging, 3D echo-based volume can be used to calculate the EF. Studies of 3D echo have shown that it is more accurate and reproducible than 2D echo measures of EF when compared with reference standards. This most likely reflects the fact that no geometric assumptions about the LV shape are required.

Table 2 LV EF reference ranges and severity partitions using 2D echocardiography

	Male				*Female*			
	Normal	*Mildly abnormal*	*Moderately abnormal*	*Severely abnormal*	*Normal*	*Mildly abnormal*	*Moderately abnormal*	*Severely abnormal*
LV EF (%)	52–72	41–51	30–40	<30	54–74	41–53	30–40	<30

LV EF, Left ventricular ejection fraction.

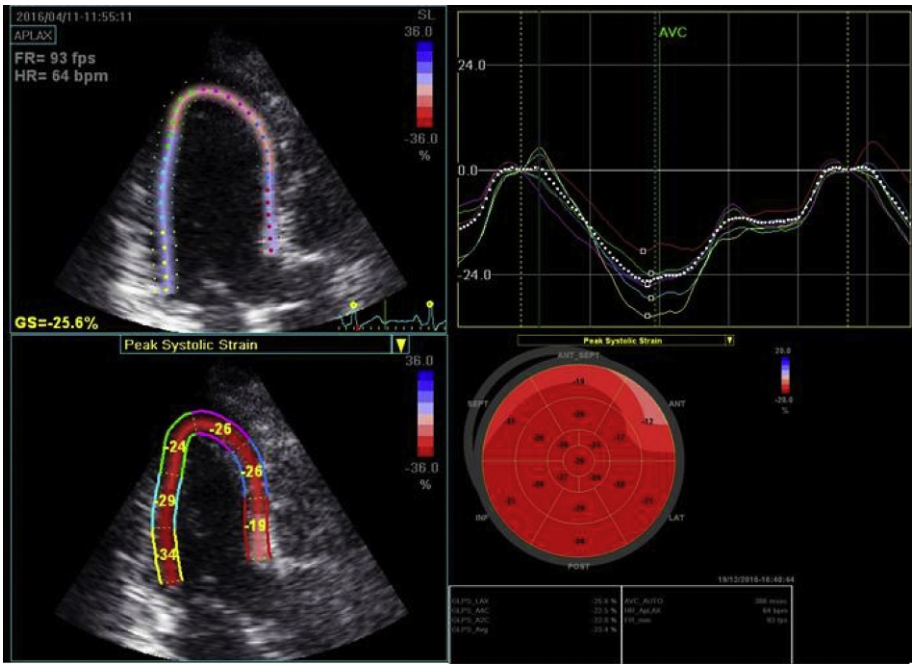

Fig. 5 Strain Imaging. The left ventricle is traced (*top left panel*) and then processed by the strain software algorithm, assigning values (*bottom left panel*). Each endocardial segment is tracked throughout the cardiac cycle and the percent strain is plotted over time (*top right panel*). Once all 17 segments are traced and processed, an average global longitudinal strain can be calculated and a bull's eye plot containing values of all the segments can be displayed (*bottom right panel*).

Strain

Myocardial strain can be determined by echocardiography (Fig. 5). This measure of myocardial deformation can be assessed in longitudinal, radial, or circumferential axes. Lagrangian strain refers to the change in length of an object compared with its baseline length. Longitudinal strain (LS) is the most commonly used strain-based assessment of the left ventricular global function. With echocardiography, this is often performed using "speckle-tracking," software that allows the ultrasound system to track the motion of features in the heart by using the naturally occurring speckle pattern in the myocardium when imaged by ultrasound. These specular reflectors are unique patterns (analogous to a fingerprint) that remain relatively stable from frame to frame during echocardiography, allowing their position to be tracked throughout the cardiac cycle thus allowing measurement of relative lengths of myocardial segments. The change in length between these myocardial features is quantified from end-diastole and end-systole. LS is then calculated as:

$$\text{LS}\ (\%) = \frac{(\text{MLs} - \text{MLd})}{\text{MLd}},$$

where LS is longitudinal strain, MLs is myocardial length at end-systole, and MLd is at end-diastole. Myocardial length in the longitudinal axis in systole is smaller than in diastole, making LS a negative number. More negative LS (a higher number in absolute terms) represents more robust ventricular function. This is consistent since a smaller end-systolic measurement and a larger end-diastolic measurement will produce a higher absolute difference.

Global longitudinal strain (GLS) is an average of the strain calculations across the left ventricle. 2D echo-derived GLS has been shown to have some incremental benefits over LV EF in various conditions because of its reproducible nature and ability to identify subclinical myocardial dysfunction (in the setting of normal EF). Quantitation of circumferential strain at the base and apex of the LV can be used to measure the twist or torsion of the ventricle. Assessment of the timing of peak radial strain can be used to evaluate the synchrony of myocardial thickening and is often used to identify candidates for Cardiac Resynchronization Therapy in heart failure or to assess response to such therapy. Current applications of strain echocardiography include monitoring of patients receiving chemotherapy with potentially cardiotoxic effects and in cardiac amyloid. Currently one of the limitations of this technique is the difference in normal values among different echocardiography machines marketed by different vendors and different software versions on a particular echocardiography machine; however a peak GLS in the range of −20% or higher (in absolute numbers) is considered to be normal (Mor-Avi et al., 2011; Lang et al., 2015).

Regional LV Function

For purposes of assessment of regional LV function, the ventricle is divided into segments. For all cardiac imaging modalities a 17-segment model has been developed. The 17th segment is a cap at the LV apex. This segment is used to describe a perfusion pattern, but since it does not extend from epicardium to endocardium, it is not used to describe wall motion. Thus for echocardiographic indications a 16-segment model without the apical cap is often used (Fig. 6). The typical pattern of myocardial perfusion for each coronary artery can be overlaid on this segmentation (Fig. 7).

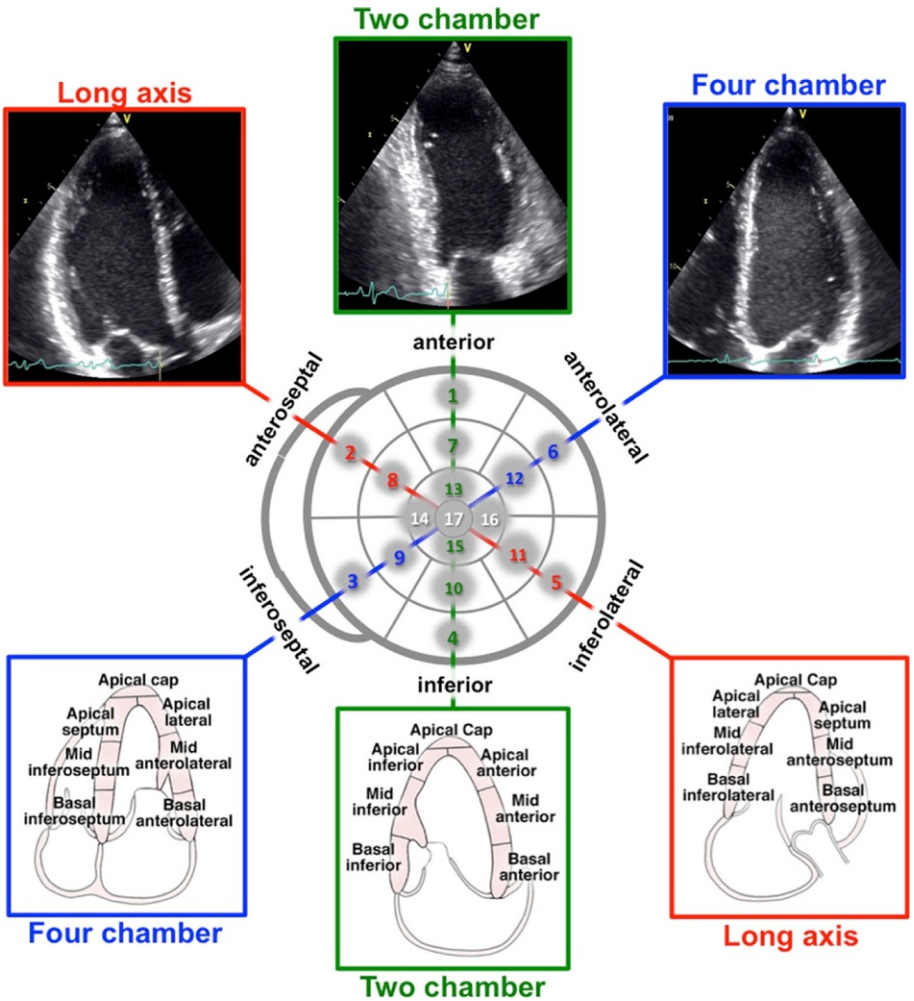

Fig. 6 17-segment model and its correlated echocardiographic territory. Orientation of apical four-chamber (A4C), apical two-chamber (A2C), and apical long-axis (ALX) views in relation to the bull's-eye display of the left ventricular segments (*center*). Visual assessment of the left ventricular regional wall motion is typically a semiquantitative method. This method utilizes an estimation of endocardial motion and wall thickening of each segment of the left ventricle. Each segment should be analyzed individually, in multiple views and a score assigned based on this analysis. The recommended scoring system is: normal or hyperkinetic = 1, hypokinetic = 2, akinetic = 3, dyskinetic or aneurysmal = 4. The LV wall motion score index is the average score for each segment, calculated as the total summed score divided by the number of segments, with a higher value indicating more diseased segments in terms of quantity and/or severity.

Most commonly, regional wall motion abnormalities represented by these segments are due to coronary artery disease and are notable for decreased systolic thickening. However, conditions such as sarcoidosis, myocarditis, and stress-induced (Takotsubo) cardiomyopathy may cause regional dysfunction in the absence of flow-limiting epicardial coronary disease. Wall motion abnormalities of the interventricular septum with normal wall thickening intact may be caused by cardiac pacing of the right ventricle, left bundle branch block, following cardiac surgery, or right ventricular volume overload.

LV Mass

LV mass can be calculated using linear dimensions (from M-mode or 2D echo), 2D-based formulas using area, or 3D echo. In each calculation, measurements are performed at end-diastole. Additionally, all of these methods are designed to calculate the volume of the LV myocardium and are then converted to mass by multiplying it by 1.04 g/mL or 1.05 g/mL, the density of the myocardium. Each method has its advantages and limitations. Studies show that calculating LV mass using linear dimensions is simple and quick and has the most established prognostic benefit (Armstrong et al., 2012; Lang et al., 2015). The linear method formula, also known as the "cube formula," is:

$$\text{LV mass} = 0.8 \times 1.04 \times \left[(\text{IVS} + \text{LVID} + \text{PWT})^3 - \text{LVID}^3\right] + 0.6\,\text{g}$$

where IVS is the interventricular septum thickness, LVID is LV internal diameter, and PWT is the posterior wall thickness, all taken from the parasternal imaging location (Fig. 8).

However, similar to utilizing linear dimensions in measuring LV size, this method comes with important limitations. The linear formula assumes the LV thickness is the same throughout the LV. If the LV is measured by M-mode and the ultrasound beam is obliquely directed then this exaggerates small errors because overestimation of the LV wall thickness will be cubed. Thus if this method is used it is best to use 2D-directed M-mode to ensure on-axis, accurate wall thickness and cavity measurements.

There are two commonly used 2DE-based methods of determining LV mass; the truncated ellipsoid method and the area-length method. Both derive the myocardial volume by subtraction of the internal LV volume from the total epicardial volume. This remainder (the volume of the LV walls without the cavity) is then multiplied by the density of the myocardium, providing the LV mass (Fig. 8). Both of these methods are subject to less geometric assumptions than the linear method and can correct for some distortions in the shape of the LV; however they are more time-consuming and rely on higher-quality imaging. The two formulas are shown here:

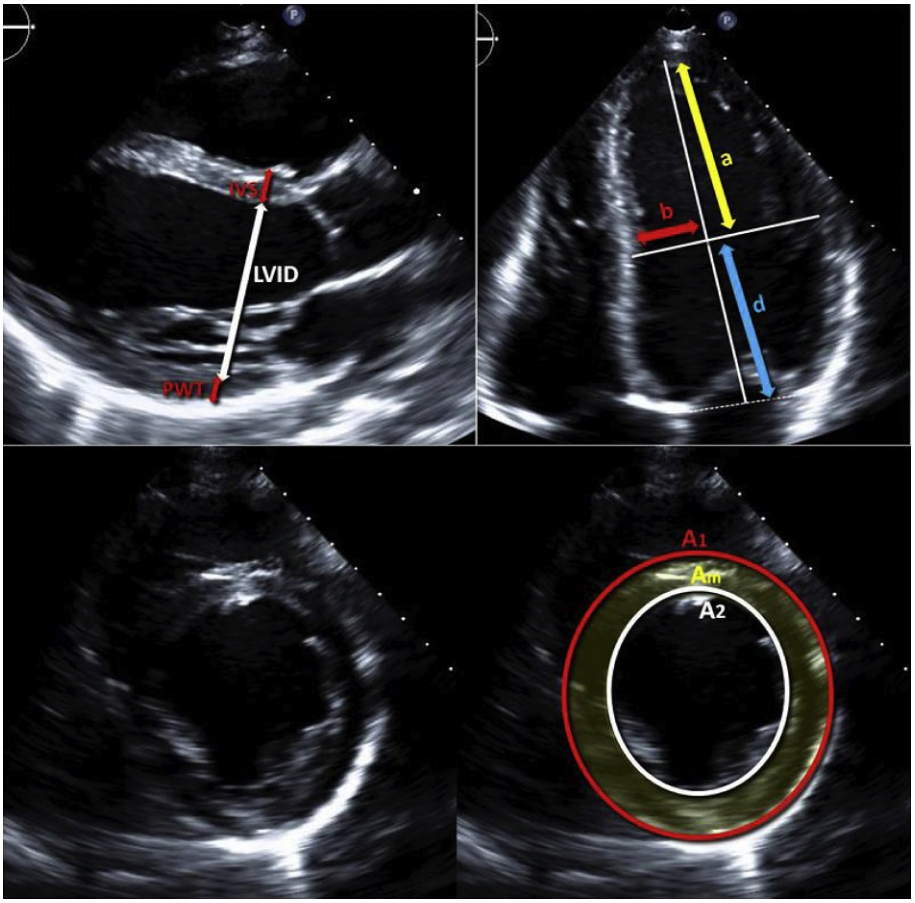

Fig. 8 LV mass assessment by 2D echocardiography. *Top left:* Linear dimensions used in the cube formula; *IVS*, interventricular septum; *LVID*, left ventricular internal dimension (diastole); *PWT*, posterior wall thickness. *Top right:* Dimensions needed for 2D echo-based formulas (see text). *Bottom row:* Parasternal short-axis view at the mid-LV level, needed for the area-length method. Bottom right depicts the areas at this level: *A*1, epicardial area; *A*2, endocardial area; *Am*, myocardial area as defined by subtracting *A*2 from *A*1.

Truncated ellipsoid:

$$\text{LV mass} = 1.05\pi\left\{(b+t)^2 \times \left[{}^2\!/_3(a+t) + d - d^3/3(a+t)^2\right] - b^2 \times \left[2a/3 + d - d^3/3a^2\right]\right\}$$

where a is the distance from the minor axis to the endocardium at the LV apex, b is the LV minor radius, d is the distance from the minor axis to the mitral valve plane, and t is the mean wall thickness.

Area-length:

$$\text{LV mass} = 1.05\pi\left\{\left[{}^5\!/_6 A1(a+d+t)\right] - \left[{}^5\!/_6 A2(a+d)\right]\right\}$$

where $A1$ is the epicardial cross-sectional area and $A2$ is the endocardial cross-sectional area. These are complex calculations that can be performed by the software of the ultrasound machine once the variables have been entered.

3D echocardiography provides a direct measurement without geometrical assumptions and is more accurate and reproducible than other methods. However, this is a newer modality, is not as widely available, and relies on high-quality imaging. Once the LV epicardial and endocardial surfaces are defined the myocardial volume is calculated similar to the method described earlier for 3D LV volume by quantitating the voxels within the prescribed region.

Regardless of the technique employed to determine LV mass, it is important to consider that there is variability between them and thus the same measurement approach should be used to assess a patient over time. Current guidelines have established the normal values for LV mass, when indexed to body surface area, as less than 95 g/m^2 for women and less than 115 g/m^2 for men.

Once LV mass has been determined, relative wall thickness (RWT) is computed with the formula:

$$\text{RWT} = (2 \times \text{PWT})/(\text{LVIDd})$$

where PWT is posterior wall thickness and LVID is LV internal dimension at end-diastole. LV mass together with relative wall thickness allows the classification of various patterns of LV hypertrophy and remodeling. These include concentric hypertrophy

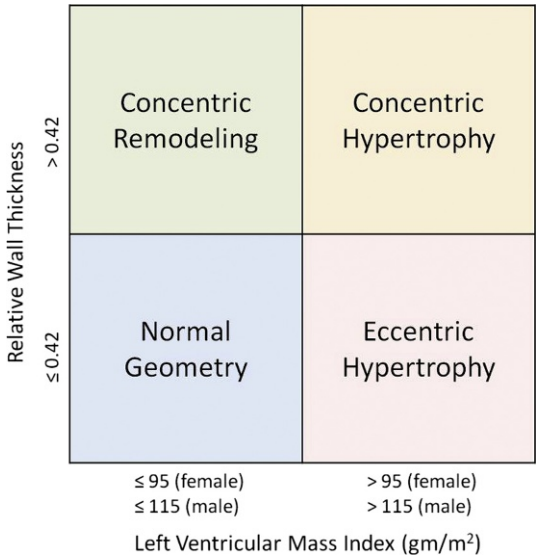

Fig. 9 Relative wall thickness (RWT) versus LV mass index. Patients with normal LV mass and normal RWT have normal geometry (bottom left panel). Patients with normal LV mass and increased RWT have concentric remodeling (top left panel). Patients with increased LV mass can have either eccentric hypertrophy (normal RWT, bottom right panel) or concentric hypertrophy (increased RWT, top right panel).

(RWT > 0.42) as you may see in patients with hypertension; eccentric hypertrophy (RWT < 0.42), commonly seen in cases of dilated cardiomyopathy; or concentric remodeling in the case of athletes with a normal LV mass and a RWT > 0.42. Fig. 9 illustrates these classifications determined by LV mass and RWT.

LV diastolic function

LV diastolic function can be assessed by echocardiography in several ways. Normal LV diastolic function is noted by normal LV diastolic pressure and relaxation indices. It is determined by both passive elastic properties of the heart and active relaxation properties. Disorders of LV filling are associated with increased LV diastolic pressure, and this can occur as a disorder of filling, relaxation, or a reduction in compliance (increased stiffness) of the LV.

There are many indirect measures of LV diastolic function by echocardiography. For example, an increased LA dimension or volume can occur in the setting of increased LV diastolic pressure. This measure has prognostic value. Increased LV wall thickness is often associated with a reduced rate of LV relaxation or increased stiffness both of which can lead to increased LV diastolic pressure. Doppler measures of pulmonary venous blood flow velocity can also be utilized to infer relative LA pressure and thus in the absence of mitral valve disease, the LV diastolic pressure. With increasing LA pressure the pulmonary venous systolic forward flow velocities are reduced and the normal duration of the reversed flow during atrial contraction is increased. Pulmonary venous Doppler is not specific for elevated LA pressure as there are other factors that can influence its pattern. In fact, healthy young adults without elevated LA pressure may demonstrate this reversal in the normal systolic to diastolic velocity ratio. Thus the pulmonary venous Doppler measure is used as a supporting index but not in isolation to assess diastolic function.

Doppler of the mitral valve, both the transmitral inflow velocity patterns and the mitral annular velocities, are the key echocardiographic measures to assess diastolic function. The transmitral Doppler filling pattern reflects differences in the LA and LV pressure during diastole. The peak velocity of the passive filling portion of transmitral flow (E wave) and its velocity decay (deceleration time) can be used to identify elevations in LA pressure and whether such are due to a delay in LV relaxation (long deceleration time) or a decrease in LV compliance (short deceleration time). The ratio of the peak velocity of the passive filling phase (E wave) to the early diastolic annular peak velocity (é) correlates with mean LA pressure in some conditions.

Algorithms have been developed to classify grades of diastolic function and dysfunction (Redfield et al., 2003; Nagueh et al., 2009; Nagueh et al., 2016). In addition, the assessment of diastolic function by echocardiography in unique populations such as in the presence of atrial fibrillation, hypertrophic cardiomyopathy, reduced LV systolic function, and heart block can be challenging, but various cutoff values for echocardiographic parameters have been established (Nagueh et al., 2016). Elastic and relaxation properties of the myocardium change with aging, and this can make the discrimination of normal from abnormal findings challenging in the elderly population. Diastolic myocardial strain assessment by echocardiography is now being investigated as a method for quantitation of LV diastolic function.

Right Ventricle

General

Much of the attention in echocardiography is focused on the assessment of the left ventricle; however the right ventricle often plays a key role in the well-being of the patient. In patients presenting with signs and symptoms of cardiopulmonary disease, a thorough evaluation of the right ventricle (RV) is crucial as it is strongly associated with clinical outcomes in several diverse diseases and after some cardiac procedures. This comes with unique obstacles and challenges as many of the standard echocardiographic views are oriented with respect to the left ventricle. An assessment of the right ventricle focuses on many of the same goals as its counterpart on the left, including an evaluation of its shape, size, function, and mass.

Shape

The crescent shape of the right ventricle makes it a complex chamber to study. It is composed of three regions: the trabecular apex, the outflow tract including the subpulmonary infundibulum, and a smooth muscular inflow region which serves as the body of the ventricle. One cannot image all of these regions in a single, 2D image plane. This makes quantification of the RV size and function especially challenging because of the difficulty obtaining reliable and consistent imaging planes for analysis and the many assumptions used to estimate function from the images. Advances in 3D echocardiography, however, have led to improved accuracy in assessing the right ventricle.

Size

Linear

The size of the right ventricle is a marker of prognosis in many patients. Dilation of the right ventricle occurs in response to volume and/or pressure overload or in cases of RV failure. Studies have shown that increased RV diameter and increased RV to LV end-diastolic ratios predict survival in patients with chronic lung disease and acute pulmonary embolism, respectively (Burgess et al., 2002; Fremont et al., 2008; Rudski et al., 2010; Mendes et al., 1994).

Visual assessment of the right ventricle alone has been shown to have significant limitations in accuracy and interobserver variability (Ling et al., 2012). Therefore, it is essential to quantify the RV dimensions to accurately interpret the size and function of this chamber. Due to the complexities in RV anatomy and its variable appearance in the standard left ventricular-centric echo imaging view, it can be challenging to perform accurate and consistent assessments of this structure. Right ventricular measurements are best approached from an apical four-chamber view, focused on the RV (**Fig. 10**). The LV apex should be seen in the view to avoid foreshortening, with the largest RV basal diameter displayed for calculations (**Fig. 11**). According to the current guidelines, the normal linear dimensions for the RV are a basal diameter of 25–41 mm, a mid-ventricular diameter of 19–35 mm, and a longitudinal diameter of 59–83 mm.(Lang et al., 2015).

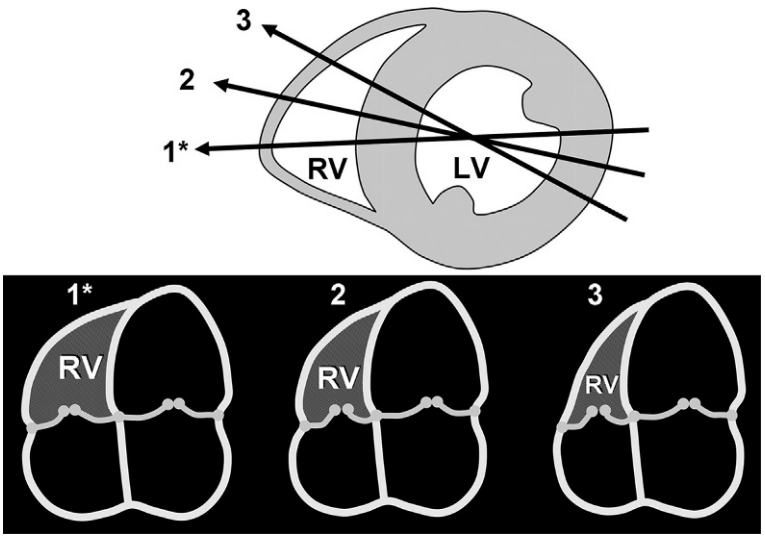

Fig. 10 RV-focused view. Diagram of the apical four-chamber view focusing on the right ventricle (RV). *Top image* shows how the plane of the ultrasound beam can be directed in multiple ways through the RV resulting in different dimensions. *Bottom panel* depicts corresponding images using the same ultrasound imaging planes. The illustration labeled *1** represents the recommended RV-focused view. Reproduced with permission from Rudski, L. G., Lai, W. W., Afilalo, J., Hua, L., Handschumacher, M. D., Chandrasekaran, K., Solomon, S. D., Louie, E. K., Schiller, N. B. (2010). Guidelines for the echocardiographic assessment of the right heart in adults: A report from the American Society of Echocardiography endorsed by the European Association of Echocardiography, a registered branch of the European Society of Cardiology, and the Canadian Society of Echocardiography. *Journal of the American Society of Echocardiography* **23**, 685–713; quiz 786–788.

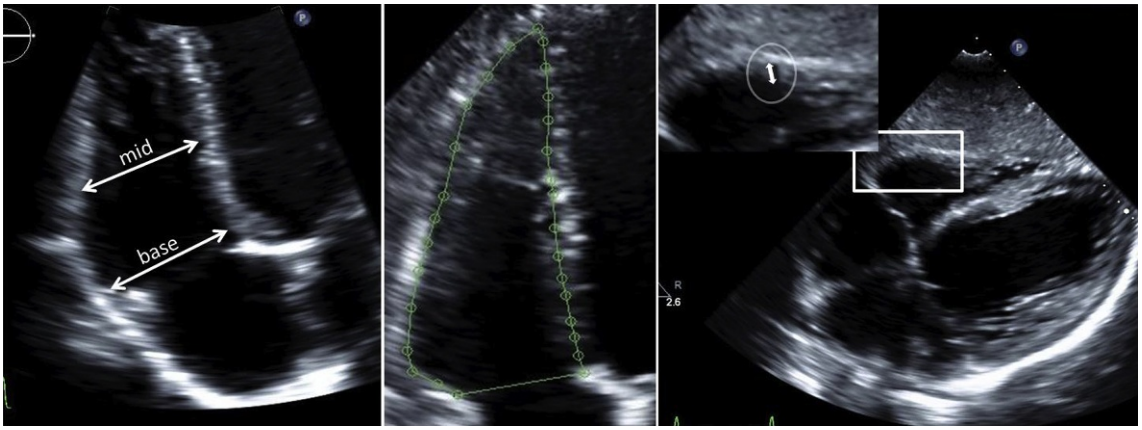

Fig. 11 Right ventricular size and thickness. *Left panel:* RV linear dimensions in the apical four-chamber RV-focused view at end-diastole. *Base*, maximal dimension in the basal third of the ventricle; *mid*, mid-cavity dimension in the middle third of the ventricle. *Middle panel:* Manual tracing of RV endocardial border to determine area measurement. *Right panel:* measurement of RV free wall thickness in subcostal view at end-diastole. Measurement of wall thickness should be made at the point that the tricuspid valve tip would be if it were maximally open.

Volume and Volumetric Estimations of RV Function

2DE estimations of RV volume include area-length methods, disk summation methods, and other methods. However, due to the complexity of estimating RV volumes in 2D echocardiography, recent guidelines recommend against these methods. RV EFs are calculated using the formula (end-diastolic volume–end-systolic volume)/end-diastolic volume. When used in the past, the normal value was reported as an RV EF above 44% (Lang et al., 2015; Rudski et al., 2010).

3D echocardiography provides significant advantages over 2D echo in regard to RV volume estimation. Although it is limited by image quality or incomplete visualization of the entire chamber in severely enlarged right ventricles, it delivers more accurate assessments of the end-diastolic and end-systolic volumes of the right ventricle. 3D echo supplies improved test-retest variability when compared to 2DE measurements of the right ventricle. Both 2D and 3D methods tend to underestimate these volumes compared with cardiac MRI because echo methods tend to exclude the RV endocardial trabeculations from the enclosed volume but MRI includes these structures in the enclosed volume (Jenkins et al., 2007; Gopal et al., 2007). Current guidelines suggest that in laboratories with 3D echocardiography experience, disk summation by 3D echo may be used to report EFs, and it may further be used for serial volume and EF determinations. Using this method, the median reference value for RV end-diastolic volume is 91 mL with a range of 61–150 mL representing the 5th-95th percentile. The median RV end-systolic volume is 35 mL with an equivalent range of 16–62 mL. The median reference value for RV EF using this method is 62%, with a range of 47%–77% representing the 5th-95th percentile (Lang et al., 2015; Rudski et al., 2010).

Nonvolumetric Assessments of RV Function

The assessment of RV systolic function is in some ways more challenging than the left ventricle. There are methods to judge global function, including RV EF (see above), fractional area change (FAC), RV dP/dt, and the myocardial performance index (MPI). As with the left ventricle, there are also methods for interpreting regional RV function, including strain imaging, Doppler-derived systolic annular velocities (S′), and tricuspid annular plane systolic excursion (TAPSE). Not all of these indices of RV function require visualization of the RV endocardial border. Each method has limitations and must be interpreted within the context of the overall study including the other indices measured. At least one quantitative measure of RV function should be incorporated into routine interpretations of echocardiograms. Normal reference values for and images portraying these methods are seen in **Table 3** and **Fig. 12**, respectively.

The RV fractional area change represents the difference in the RV area between diastole and systole, normalized to diastole and expressed as a percentage. The formula is:

$$\text{RV FAC} = (\text{end} - \text{diastolic area} - \text{end systolic area})/\text{end} - \text{diastolic area} \times 100.$$

At both end-diastole and end-systole the RV endocardial border is traced in an apical 4-chamber view, with the trabeculations, papillary muscles, and moderator band included within this area. The lower limit of normal RV function by FAC is 35% (Lang et al., 2015; Rudski et al., 2010).

RV dP/dt refers to the rate of pressure rise in the ventricles (change in pressure/change in time) and has been validated as an index of ventricular systolic function. Using the tricuspid regurgitant signal by continuous wave Doppler, one calculates the time it takes as the pressure changes, which is measured via the simplified Bernoulli equation ($4\ V^2$) at velocities in the ascending limb of the TR

Table 3 Reference values for RV function parameters

Parameter	*Normal threshold*
Fractional area change (%)	≥35
Three3-dimensional EF (%)	≥45
TAPSE (mm)	≥17
Global longitudinal strain (%)	≥−20 (larger absolute number)
Pulsed doppler Sé (cm/s)	≥9.5
RV dP/dt (mm Hg/s)	≥400
Pulsed doppler MPI	<0.43
Tissue doppler MPI	<0.54

signal. Commonly, this is measured by determining the time it takes for the TR signal to increase in velocity from 1 to 2 m/s. This is a difference of 12 mm Hg of pressure (16–4 mm Hg), and this is divided by time (in seconds) between the two velocities to calculate mean dP/dt. Abnormal RV dP/dt is considered less than 400 mm Hg/s (Rudski et al., 2010). This echo measure differs from invasively derived dP/dt obtained in the cardiac catheterization laboratory. Invasive hemodynamics provide an instantaneous, peak dP/dt, as opposed to a mean dP/dt derived via echocardiography.

The MPI, also called the RV Index of Myocardial Performance (RIMP) or Tei index, is a calculation of the ratio of time that the ventricle spends in ejection of blood. The formula is:

$$\text{RIMP} = (\text{IVRT} + \text{IVCT})/\text{ET}$$

where IVRT is the isovolumetric relaxation time, IVCT is the isovolumetric contraction time, and ET is the ejection time. Another way to calculate it is:

$$\text{RIMP} = (\text{TCO} - \text{ET})/\text{ET}$$

where *TCO* is the duration of time the tricuspid valve is closed (which encompasses IVRT, IVCT, and ET). The time measurements of these variables can be done using pulsed wave Doppler or tissue Doppler. One must be sure that the heartbeats used for time measurements have similar R-R intervals. More time spent in ejection relative to isovolumetric phases signifies better RV function, thus lower values for the RIMP are normal. RIMP < 0.43 by PW Doppler and < 0.54 by tissue Doppler imply normal RV function. This measurement is load dependent and is not reliable in conditions associated with elevated RA pressure (Lang et al., 2015; Rudski et al., 2010).

The TAPSE method is a relatively simple technique used to assess RV longitudinal performance. To perform this measurement, an M-mode cursor is aligned through the lateral tricuspid annulus in the apical four-chamber view and one measures the amount of longitudinal motion of the annular plane in systole. TAPSE < 17 mm suggests RV dysfunction, and it is correlated with parameters such as radionuclide angiography, RV EF, and FAC (Kaul et al., 1984; Miller et al., 2004). It has limitations including the assumption that the basal segment is representative of global RV function. It is angle dependent, as the base to apex motion of the RV must be along the path of the M-mode line. Thus any translational motion of the heart in another direction will reduce the accuracy of this measurement.

Doppler tissue imaging, which assesses the velocity of the annulus as it moves during the cardiac cycle, can provide a reliable and reproducible measurement, similar in methodology to the TAPSE. Here, the pulsed Doppler sample volume is placed in the lateral tricuspid annulus in the apical four-chamber view. The Sé wave is observed moving toward the transducer in systole, and its peak velocity is easily measured. The limitations are similar to that of TAPSE, and it also has been correlated with methods such as radionuclide angiography. A free wall-derived Sé velocity >9.5 cm/s suggests normal RV function (Lang et al., 2015; Rudski et al., 2010).

RV strain and strain rate can be used to assess global and regional RV systolic function. It can be measured by Doppler or tissue tracking. Measurement of Doppler strain is angle dependent, which is not present with speckle-tracking echocardiography (STE). Since it may be difficult to orient the heart in the echocardiographic image such that the RV free wall motion is parallel to the Doppler interrogation line STE is preferred. RV GLS, an average of the three segments of the RV free wall and septum or the free wall segments alone, is typically used to describe function. As with the LV strain, limitations of this technique include the variation in values among vendors and software versions, thus requiring different reference points for normal values for different echo machines or software versions. However a peak GLS in the range of -20% or higher (in absolute value) is likely normal regardless of vendor or software version. Because of the need for further studies to provide additional data, no definitive reference ranges for strain-derived normal function are recommended in current guidelines (Lang et al., 2015).

Right Ventricular and Pulmonary Pressures

Right ventricular systolic pressure (RVSP), often used as a surrogate for pulmonary arterial systolic pressure (PASP), can be estimated relatively easily utilizing Doppler profiles in echocardiography. Using this for estimation of PASP, however, only applies if there is no obstruction between the right ventricle and the pulmonary artery. The peak RV–RA pressure gradient is derived by applying the simplified Bernoulli equation to the peak tricuspid regurgitant jet velocity. The RA pressure is then added to this value to determine RVSP. The right atrial pressure is estimated from the inferior vena cava (IVC) diameter and its response to respiration as described later in the section dedicated to the right atrium. Because the Doppler velocity measurement is angle dependent, however, one could underestimate the true peak TR velocity and RVSP. Therefore, it is recommended that this tricuspid regurgitant (TR) Doppler velocity be measured from several echocardiographic windows and to use the highest velocity for measurement. This measurement cannot be used in some patients with an inadequate TR jet for measuring the velocity, seen as an incomplete, or cut off, Doppler profile. Injection of agitated saline often improves the Doppler profile in these cases (Himelman et al., 1989). In patients with very severe tricuspid regurgitation (TR), the Doppler profile may be shortened as well due to early equalization of the RV–RA gradient and again should not be used in these cases as it may underestimate the true RVSP. This is also true when there is a large tricuspid valve regurgitant orifice as the regurgitant flow may be laminar rather than turbulent, in which case the simplified Bernoulli equation may not apply.

Pulmonary arterial diastolic pressure (PADP) can be similarly estimated using the velocity of the end-diastolic pulmonary regurgitant jet. Using the modified Bernoulli equation $\text{PADP} = 4(\text{EDPR})^2 + \text{RA pressure}$, where EDPR is the end-diastolic pulmonary regurgitant velocity allows this estimation to be performed. The mean PA pressure (MPAP) can be calculated using the PASP and PADP via the formula $\text{MPAP} = 1/3(\text{PASP}) + 2/3(\text{PADP})$. Alternatively, the MPAP can be calculated using the pulmonary acceleration time (AT) using the equation:

$$\text{MPAP} = 79 - (0.45 \times \text{AT})$$

where AT is the time in milliseconds from the onset of ejection to peak systolic velocity, measured using pulsed wave Doppler of the pulmonary artery in systole. Generally, a shorter AT represents a higher pulmonary vascular resistance and therefore higher PA pressure. This formula is especially useful when the Doppler signal from the TR jet is inadequate or cannot be obtained. Its use is limited to cases of normal heart rates, however, because it depends on the timing of pulmonary ejection and can be erroneous at high or low heart rates.

Mass

Right ventricular wall thickness is determined by measuring the width of the RV free wall by M-mode or 2D echo. RV hypertrophy, often the result of increased right ventricular systolic pressure, can be due to various infiltrative and hypertrophic cardiomyopathies, as well as pulmonic valve stenosis or elevated pulmonary pressure. The current guidelines recommend that RV free wall thickness be measured at end-diastole from the subcostal or left parasternal view of the heart, about where the tip of the anterior tricuspid leaflet would be when fully open and parallel to the RV wall (**Fig. 11**). A normal RV wall thickness should be 5 mm or less. Care should be taken to exclude trabeculae, papillary muscles, and epicardial fat, which would erroneously increase the measurement (Rudski et al., 2010; Lang et al., 2015).

Left Atrium

The left atrium (LA) has three principal roles in the function of the heart. It acts as a contractile pump during atrial contraction, it is a reservoir for pulmonary venous blood during ventricular systole, and it is a conduit for blood to pass into the left ventricle during diastole (Rosca et al., 2011). In the absence of mitral stenosis, the left atrium dilates in response to increased pressure, ultimately causing LA dysfunction. This may lead to atrial fibrillation, thrombus formation, and stroke. LA enlargement confers higher risks in many situations including postmyocardial infarction, in diabetics, and in patients with dilated cardiomyopathy (Rosca et al., 2011; Lonborg et al., 2013; Kim et al., 2008; Modena et al., 1997; Poulsen et al., 2013).

Anatomy and Shape

From the perspective of blood flow, the left atrium begins at the pulmonary veno-atrial junction of the four pulmonary veins and ends at the mitral annulus where the blood passes through to the left ventricle. It is a relatively smooth-walled structure with a finger-like compartment known as the left atrial appendage attached to the anterolateral aspect of the left atrial body. This appendage plays an important role, as it is the area most likely to develop thrombus in LA mechanical dysfunction such as in atrial arrhythmias. For this reason it is often amputated or ligated during cardiac surgery or via percutaneously delivered left atrial appendage closure devices to decrease the risk of thromboembolism and stroke in patients who cannot tolerate anticoagulation. On the septal wall of the left atrium is the foramen ovale, a fetal remnant of the area where blood flow was able to pass through between the left and right atrium before birth when the fetus received oxygenated blood from the mother instead of its own pulmonary circulation. In approximately 25% of the population, there is a remaining connection between the left and right atria, called a patent foramen ovale. Atrial septal defects due to congenital anomalies in other areas of the septum may also occur, although less commonly.

Size

Left atrial size can be determined using linear dimensions, area, and volume measurements. By convention LA size is determined at ventricular end-systole, before the mitral valve opens, when the atrium is at its largest. The anteroposterior (AP) dimension is the most commonly used linear determination of LA size because it is the LA dimension with the lowest intrameasurement variability. It is performed in the parasternal long-axis view, using 2D echocardiography or 2D-guided M-mode (**Fig. 13**). It is easy to perform and is reproducible; however the single dimension measurement may not accurately represent left atrial size. The upper reference values for this method are 40 mm in males and 38 mm in females, as seen in **Table 4** (Lang et al., 2015).

The area of the left atrium can be obtained via planimetry in the apical four and apical two-chamber views. This tracing should be along the inner border of the LA, excluding the inlet of the pulmonary veins and the area between the mitral valve annulus and the mitral valve leaflets. This is more representative of LA size than the AP diameter; however this method makes the assumption of a symmetric atrial shape.

Current guidelines recommend assessment of left atrial size using volumetric measurements, which require fewer geometric assumptions. Left atrial volumes reflect both the extent and the chronic nature of elevated left-sided pressures. Specifically, the biplane disk summation method is recommended, using the apical four-chamber and apical two-chamber views of the left atrium. Similar to the modified Simpson's method used in measuring LV volume, here the LA volume is calculated by adding the volume of a stack of cylinders of equal height (**Fig. 13**). The area–length method of volumetric calculation can also be used; however it is not the preferred method. The upper reference limit for 2D echo-derived LA volume is 34 mL/m^2 as seen in **Table 4** (Lang et al., 2015). In experienced echo labs, newer techniques using 3D data sets may be used. They are more accurate than 2D methods as they include no geometric assumptions. However, limited data on reference values are currently available.

Right Atrium

The right atrium (RA) has the same three primary functions as the LA: acting as a reservoir for systemic venous return (analogous to pulmonary venous return to the LA), acting as a conduit for blood to flow through the tricuspid valve in early diastole, and active RV filling via atrial contraction during late ventricular diastole. The RA is primarily imaged in the apical four-chamber view in transthoracic imaging, and thus 2D assessments are limited by lack of standard orthogonal imaging planes. Compared with the left atrium, there are significantly less data regarding right atrial size, normative reference values, and its importance to patient outcomes (Lang et al., 2015; Rudski et al., 2010).

Size

The right atrial size can be measured by linear dimensions, area, or volume. These are performed at ventricular end-systole, when the right atrium is at its largest. Conventionally, the right atrium should be measured from an apical four-chamber view in which both

Table 5 Normal RA size from 2D echocardiography

Parameter	*Male*	*Female*
RA minor axis/BSA (cm/m^2)	1.9 ± 0.3	1.9 ± 0.3

A., Kuznetsova, T., Lancellotti, P., Muraru, D., Picard, M. H., Rietzschel, E. R., Rudski, L., Spencer, K. T., Tsang, W., Voigt, J. U. (2015). Recommendations for cardiac chamber quantification by echocardiography in adults: An update from the American Society of Echocardiography and the European Association of Cardiovascular Imaging. *Journal of the American Society of Echocardiography* **28**, 1–39 e14.

the mitral and tricuspid valves and largest medial–lateral annular dimensions are visualized. Linear dimensions include major (superior RA wall to bisector of tricuspid annular dimension) and minor (lateral wall to interatrial septum) axes. Mean and standard deviation for RA major and minor axes are listed in **Table 5**.

Current guidelines recommend using volume to calculate RA size, either by area–length or disk summation methods. Similar to calculating area, the RA is traced in the four-chamber view. A single-plane area–length measurement of the RA can be performed using this formula:

$$8/3\pi\left[(A)^2/L\right]$$

where A is the area defined by the tracing and L is the superior–inferior length of the atrium. The disk summation method is similar to that mentioned in previous sections; however in this case only uses a single plane with the assumption of a symmetrical cavity shape (**Fig. 14**). The mean and standard deviations for 2D echo-derived RA volume are listed in **Table 5** (Lang et al., 2015). 3D data sets may be used to calculate more accurate RA volume; however, this is not routinely performed in clinical echo labs.

RA Pressure

Right atrial pressure is commonly estimated in echocardiography using the IVC diameter and its response to respiration. Combining these two parameters allows a simplified method for estimating a reasonable RA pressure in many patients. The IVC diameter should be measured about 1–2 cm from the caval–atrial junction (**Fig. 15**). An IVC diameter of ≤2.1 cm that collapses >50% with a sniff supports an estimated RA pressure of 3 mm Hg (range, 0–5 mm Hg). An IVC diameter of >2.1 cm that collapses <50% with a sniff supports an estimated RA pressure of 15 mm Hg (range, 10–20 mm Hg). Cases that are indeterminate due to discrepant findings between IVC size and its response to a sniff suggest an estimated RA pressure of 8 mm Hg (range, 5–10 mm Hg). This method allows individualized echo-specific factors to be taken into account in assigning an RA pressure, which is preferable to assuming a fixed RA pressure across all patients regardless of what the imaging signals (Rudski et al., 2010).

Aortic Root

The aortic root is well visualized in the parasternal long-axis TTE view. This structure includes the aortic valve annulus, aortic leaflets, the sinuses of Valsalva, and the sinotubular junction (STJ), which lead to the tubular portions of the ascending aorta. The aortic annulus is a virtual ring (not a true anatomic structure) defined by joining the basal attachments of the three aortic valve leaflets. This measurement is important in sizing aortic valve replacements, especially in transcatheter aortic valve replacements (TAVR). This measurement may be challenging by transthoracic echocardiography and often requires measurements by transesophageal echocardiography or computed tomography allowing cross-sectional dimensions, perimeter, and area measurements. By TTE a linear anteroposterior measurement should be made in mid-systole when the aortic leaflets are maximally opened and the annulus is at its largest. It is measured in the parasternal long-axis view from inner edge to inner edge (I–I) between the hinge point of the right coronary cusp anteriorly and the fibrous trigone between the left and noncoronary cusps, seen posteriorly (**Fig. 16**).

The other aortic root measurements, including the sinuses of Valsalva, the STJ, and the proximal ascending aorta, should be made at end-diastole, perpendicular to the long axis of the aorta (**Fig. 16**). By 2D echocardiography, these measurements are made from leading edge to leading edge (L–L); however it is important to note that other modalities such as CT and MRI use other conventions. Echocardiography has not adopted these other conventions because the normative values are reported using the L–L standard. Some institutions utilize an inner edge to inner edge measurement convention, especially if this is being used to calculate flow such as stroke volume. See **Table 6** and **Fig. 17** for aortic root sizing reference values.

Introduction

The immune system fulfils an important sensory function in the detection of circumstances requiring immune-mediated response, repair, or regeneration. The importance of immune cell activation in the contexts of infection, inflammation, and injury repair is well established. Prominent features of an inflammatory response typically include increased production and mobilization of white blood cells. Less is known, however, about the extent to which the immune system contributes to tissue health at homeostasis.

Immune cells govern tissue homeostasis and debris management during physiologic cell turnover, but these roles are subclinical and thus may remain undetected by clinically relevant outcome measures such as elevation in white blood cell counts in the peripheral blood stream.

Homeostasis in the Adult Heart

At homeostasis, resident tissue macrophages are present within the myocardium and facilitate the clearance of apoptotic cardiomyocytes during normal cell turnover. While there is heterogeneity in macrophage subsets, basic functions of macrophages include sampling of the environment by phagocytosis and endocytosis, receptor and antigen presentation, and production of secretory factors that can modulate the immune response. Macrophages also contribute to immune quiescence at steady state by depleting chemotactic proteins, such as integrins and selectins, which mediate leukocyte infiltration. Macrophages contribute to angiogenic balance at homeostasis by interacting with endothelial cells both by direct contact and by secretion of pro- or anti-angiogenic paracrine factors. In vitro study of cultured macrophages has led to characterization of a proinflammatory phenotype, defined by the production of proinflammatory cytokines, and an antiinflammatory phenotype, defined by production of antiinflammatory factors. In vivo macrophage phenotype classification is more complex, however, and is best understood as a spectrum of macrophage phenotype and function determined by multiple environmental factors. Of note, resident cardiac tissue macrophages can also contribute to fibrosis at steady state by activation of fibroblasts, a process that increases with age. In general, macrophages proliferate locally during steady state to replenish the resident cardiac macrophage population. While resident cardiac macrophages are the predominant immune cell subset observed in the adult heart at homeostasis, small numbers of resident mast cells, dendritic cells, and lymphocytes are also present.

Innate Immunity in the Heart at Homeostasis

In addition to the role of tissue macrophages in efficiently clearing cell debris caused by cell turnover, pattern-recognition receptors (PRRs) expressed on innate immune cells also contribute to maintenance of homeostasis. PRRs, including toll-like receptors (TLRs), recognize pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs), and they also play a role in mediation of sterile inflammation, as in the case of ischemia–reperfusion injury. PRRs can lead to activation of inflammatory signaling pathways, such as those mediated by nuclear factor-κB (NFκB). Subsets of PRRs, including nucleotide-binding oligomerization domain (NOD)-like receptors, can also initiate assembly of inflammasomes, which are cytosolic complexes that trigger production of proinflammatory cytokines interleukin (IL)-1β and IL-18.

Adaptive Immunity in the Heart at Homeostasis

Regulatory T (T_{Reg}) cells, characterized by $CD4^+CD25^+FOXP3^+$ cell surface marker expression, are a subset of helper T cells that contribute to maintenance of homeostasis and tolerance in the heart. T_{Reg} cells suppress effector T cells by contact-dependent and contact-independent mechanisms. Loss or disruption of T_{Reg} function is associated with the development of chronic inflammation and autoimmunity. T_{Reg} cells also produce the inhibitory cytokines transforming growth factor β (TGFβ) and IL-10, which contribute to their immunosuppressive profile. While modulation of T_{Reg} cell number or function may theoretically be an attractive therapeutic approach to diseases characterized by an excessive immune response, T_{Reg} cell therapies are only in the very early stages of development.

Immune Contributions During Injury and Repair

Ischemic injury is a predominant cause of myocardial injury, resulting in necrosis-dependent release of intracellular components and other DAMPs. Ischemia and ischemia–reperfusion injury cause mast cell degranulation and activation of endothelial cells, both of which contribute to a proinflammatory amplification loop mediated by histamine, tumor necrosis factor alpha (TNFα), complement activation, reactive oxygen species (ROS), and IL-1β. Increased production of proinflammatory cytokines and chemokines leads to the recruitment of neutrophils and exogenous monocytes and macrophages (Frangogiannis, 2014). The temporal course of CD45 positive immune cell infiltration into the heart following injury by surgically induced myocardial infarction in mice is demonstrated in Fig. 1. Most experimental knowledge about the time course of immune cell contribution following infarction is derived from mouse models due to the limited resources available to study these time-dependent changes in large animal models.

Neutrophil infiltration peaks at 24 hours after myocardial infarction in mice, resulting in widespread phagocytosis of tissue debris, neutrophil degranulation, and release of proinflammatory cytokines and factors. Subsequent monocyte and macrophage recruitment is largely dependent on neutrophil-derived chemokine (C-C motif) ligand 2 (CCL2, also known as monocyte chemotactic protein 1 (MCP-1)), and typically peaks at 3–5 days after injury, with a proinflammatory subset predominating at day 3 and an antiinflammatory subset predominating later, at 5–7 days following injury (Nahrendorf et al., 2007). Despite limitations of macrophage subset classification, resident cardiac tissue macrophages are generally considered to more closely

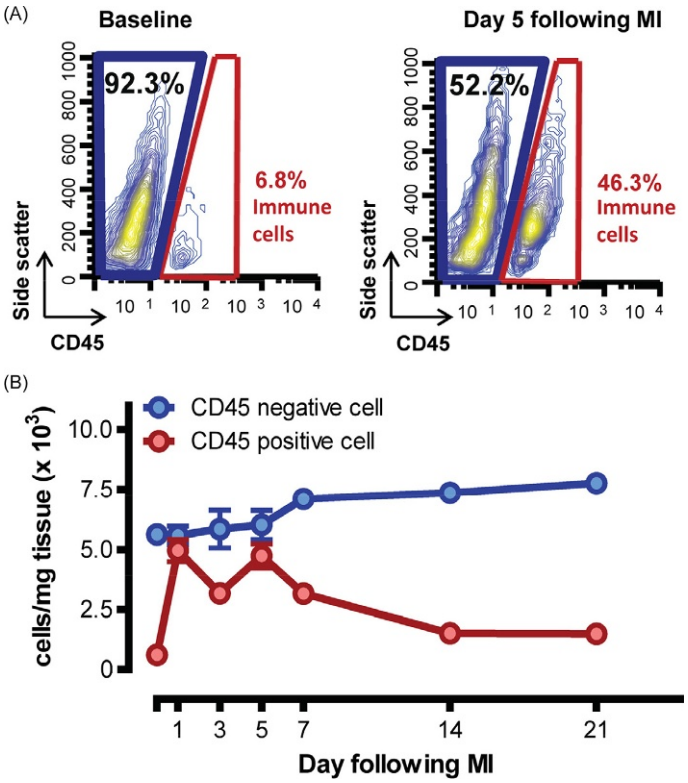

Fig. 1 Infiltration of CD45 positive immune cells into the heart following myocardial infarction (MI). (A) Flow cytometric analysis of cell suspensions derived from whole heart tissue prior to (baseline) and at day 5 following myocardial infarction induced by ligation of the left coronary artery. CD45 was used as a pan-leukocyte marker. (B) Temporal course of changes in CD45 positive and negative cell counts following myocardial infarction as demonstrated by cells per mg of tissue.

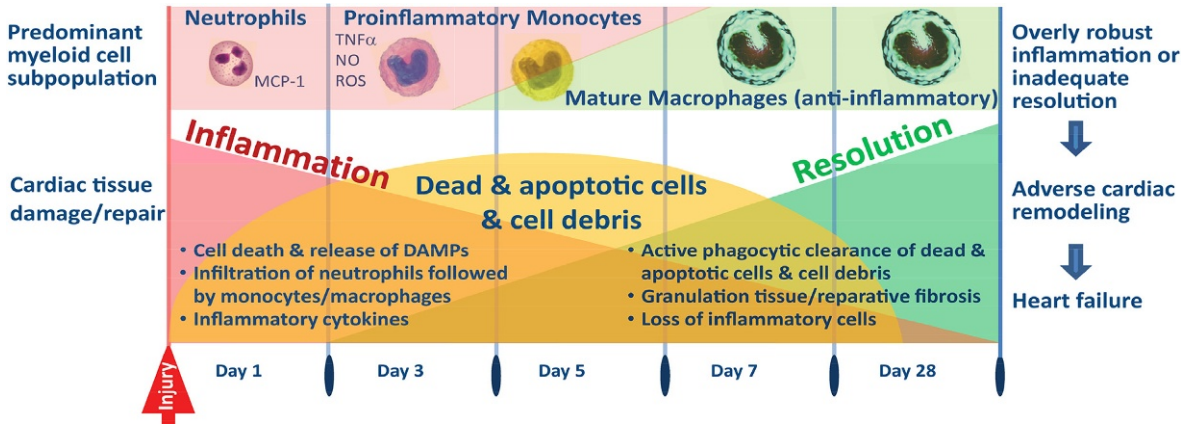

Fig. 2 Schematic overview of the temporal course of acute cardiac tissue damage and repair following myocardial injury. There are two major phases following myocardial injury due to infarction, an early inflammation phase and a subsequent resolution phase. An appropriate balance between these two phases is required for optimal repair. In the inflammation phase, high cytokine production leads to rapid neutrophil influx, followed by proinflammatory monocytes, and the level of dead and apoptotic cells is high. During the resolution phase, maturation of antiinflammatory macrophages corresponds to phagocytic clearance and reparative fibrosis. Over time, excessive inflammation or inability to adequately resolve it during the resolution phase can both contribute to adverse cardiac remodeling and structural changes in the heart that can lead to heart failure. *MCP-1*, monocyte chemotactic protein 1; *TNFα*, tumor necrosis factor alpha; *NO*, nitric oxide; *ROS*, reactive oxygen species.

resemble the antiinflammatory phenotype, whereas blood-derived infiltrating monocytes are considered to be the predominant source of proinflammatory macrophages in the first few days after injury and antiinflammatory macrophages by day 7 (Pinto et al., 2014). Synthesis of highly vascularized connective tissue, referred to as granulation tissue, then gives rise to the final stage of repair characterized by fibroblast activation and reparative myocardial fibrosis. Following resolution of injury, the macrophage population is replenished by local proliferation. A summary of this process is shown in Fig. 2.

Although neutrophils and monocytes/macrophages predominate in the two major phases of myocardial remodeling, other immune cells also play a role in cardiac remodeling after injury. Local perivascular mast cell degranulation is an important source of inflammatory mediators. Mast cells also contribute to fibroblast and vascular cell activation during injury repair. After injury caused by myocardial infarction, both B and T cells are recruited to the injured myocardium. Mouse models have demonstrated that B lymphocytes contribute to myocardial recruitment of proinflammatory monocytes, and that depletion of B cells attenuates the extent of myocardial damage induced by proinflammatory monocytes (Zouggari et al., 2013). B cell depletion is thus a promising potential therapeutic approach for further exploration. T cell contribution to myocardial remodeling has been studied more extensively and is covered in the following sections.

T Cell Role in Repair Following Injury

T cell programming in the thymus assists in creating a population of T cells that can distinguish between self and nonself, a process critical for ensuring that foreign pathogens are appropriately targeted but host tissue is not. Despite this tightly controlled process, antigenic cross-reactivity and other pitfalls of this process can result in T cells that inappropriately attack host tissue, also known as autoimmunity. In the context of host tissue damage, such as myocardial infarction, there is widespread release and exposure of intracellular antigens that can result in T cell sensing of host tissue damage and subsequent T cell activation by costimulatory signals mediated by other cell surface receptors. There are many T cell subsets, typically defined by cell surface marker expression and associated with different stages of T cell development and activation. This section will focus on CD4+ T helper cells and CD8+ cytotoxic T cells. During differentiation, T helper cells are generally shunted toward one of the two major subsets of effector T cells, proinflammatory Th1, or antiinflammatory Th2 cells, as determined by the cytokine milieu. A third subset of T helper cells, $CD4^+CD25^+FOXP3^+$ T_{Reg} cells, are also commonly considered to be antiinflammatory, in part by inhibiting the proinflammatory Th1 response. One limitation of current knowledge is that analysis of T cell subpopulations in the peripheral blood, the most common source for human T cell subset analysis, does not accurately reflect T cell subpopulations in tissue. A related limitation is that while human tissue biopsies of myocardium or draining lymph nodes would be ideal, such invasive samples are difficult to obtain.

Contribution of T cell subsets to cardiac repair

Following myocardial infarction, there is T helper cell activation and proliferation in lymph nodes draining from the heart. The process of activation and infiltration of expanded T helper cells into the myocardium can take a few days and may not peak until day 7 following myocardial infarction in mouse models. T helper cell infiltration is characterized by a predominance of proinflammatory Th1 cells along with a smaller subset of T_{Reg} cells. Once present, proinflammatory Th1 cells appear to contribute to the differentiation of infiltrating monocytes. Absence of $CD4^+$ T cells is associated with a poor outcome following myocardial infarction, suggesting a beneficial role in this context. In contrast, experimental models have established that $CD4^+$ T cells have a detrimental effect in the setting of myocardial ischemia–reperfusion injury, which is mediated mainly through production of interferon gamma (IFNγ) (Yang et al., 2006). The role of $CD8^+$ T cytotoxic cells following myocardial infarction has not yet been clearly established and depletion of $CD8^+$ cells does not yield a significant difference in infarct size in mouse models of myocardial infarction. However, a small subset of angiotensin 2 receptor positive CD8+ T cells present in the peri-infarct zone can produce the antiinflammatory cytokine IL-10. Intramyocardial transplantation of these cells decreases infarct size, suggesting a cardioprotective role following injury (Curato et al., 2010). One common mechanism involved in switching T cells from deleterious to beneficial activation is related to adenosinergic signaling. Myocardial hypoxia raises the extracellular concentration of adenosine from submicromolar to several tens of micromolar, which induces activation of A2 adenosine receptors on T cells. Stimulation of A2 adenosine receptors results in the inhibition of Th1 cytokines, including TNFα and IFNγ, ROS and cytotoxic T cell activity. In addition, adenosine, acting via A2A receptors, elicits production of brain-derived neurotrophic factor, a growth factor with cardioprotective properties, from both $CD4^+$ and $CD8^+$ lymphocytes. $CD8^+$ T cells are also presumably implicated in the activation of T helper cells by presentation of autoantigens on major histocompatibility complex (MHC)-II molecules following myocardial damage, but further work is needed to determine the identity of these autoantigens. Of note, age-related decreases in T cell diversity and expansion of clonal $CD8^+$ memory T cells may contribute to immunosenescence, characterized by decreased adaptive immunity, increased frequency and severity of disease, and presence of chronic inflammation in the elderly (Hoffmann and Spyridopoulos, 2015).

T_{Reg} contribution to cardiac repair

T_{Reg} cells are generally considered to be beneficial following myocardial infarction by inhibiting excessive inflammation and to be protective in heart failure by limiting fibrosis. Molecular mechanisms involved in T_{Reg} cell-dependent inhibition of inflammation include secretion of antiinflammatory factors such as TGFβ and IL-10. T_{Reg} cells constantly express cytotoxic T lymphocyte-associated molecule-4 (CTLA-4) which is a powerful negative regulator of T cell activation. Inhibition of the Th1 response by T_{Reg} cells prevents lymphocyte-induced secondary myocardial tissue damage. The coordinated action of two ectonucleotidases, CD39 and CD73, expressed on T_{Reg} results in the generation of adenosine from adenosine triphosphate (ATP), released from apoptotic and dying cardiomyocytes. The endogenous purine nucleoside adenosine is a potent immunosuppressive and proangiogenic agent, which also contributes to T_{Reg} cell-mediated cardiac repair after myocardial ischemic injury.

Dendritic Cell Role in Repair Following Injury

Dendritic cells are professional antigen-presenting cells that reside in lymphatic tissue and in the heart. Dendritic cells are markedly increased in the infarcted and border zone myocardium after ischemic injury, and they are activated by endogenous toxins such as molecules released from necrotic cells. Upon activation, dendritic cells migrate to secondary lymphoid organs, where they stimulate the clonal expansion and differentiation of effector T cells. Homing of activated T cells into the injured tissue may further amplify local inflammation. The increase in the proinflammatory Th1/Th2 balance is documented in patients with acute myocardial infarction, and it is associated with left ventricular dilation and systolic dysfunction. The presence of autoimmunity to cardiac myosin, actin, and troponin is associated with adverse clinical outcomes after myocardial infarction. Lymphocytes obtained from rats following myocardial infarction can injure normal cardiomyocytes in vitro, and adoptive transfer of splenic lymphocytes from animals after myocardial infarction results in induction of heart failure. Experiments in animal models have also demonstrated that activated and self-antigen loaded dendritic cells induce myocarditis and heart failure in susceptible mice. The exact mechanisms for the induction of autoimmunity and its contribution to myocardial injury require further investigation, but growing evidence indicates that dendritic cells may have a significant role in the excessive inflammatory response after myocardial infarction. However, treatment of dendritic cells with troponin I and IL-37, an inhibitor of innate and adaptive immunity, can induce a semimature tolerogenic phenotype which alleviates adverse cardiac remodeling following myocardial infarction (Zhu et al., 2016). Tolerogenic dendritic cells are characterized by lower levels of MHC-II and CD40 expression, decreased proinflammatory cytokine production, and increased antiinflammatory IL-10 production. Following myocardial infarction, adoptive transfer of tolerogenic dendritic cells increases T_{Reg} cell number, decreases myocardial immune cell infiltration, decreases fibrosis, and improves cardiac functional outcomes.

Inflammatory Cardiomyopathies

Inflammatory cardiomyopathy refers to heart muscle inflammation characterized by the influx of immune cells and the production of cytokines which can cause pain, alterations in blood flow, functional changes, and tissue destruction. This section focuses primarily on the pathophysiology and clinical manifestations of inflammatory cardiomyopathies in humans. For a summary of small animal models of cardiomyopathies, we refer readers to a recent review by Camacho et al. (2016).

Myocarditis

Myocarditis is a heterogeneous group of conditions encompassing infectious and noninfectious etiologies as well as unknown etiologies. There are many known causes of myocarditis, and the most common of these will be discussed here.

Viral myocarditis

Common viruses reported to cause myocarditis include enterovirus, adenovirus, influenza viruses, human herpes virus-6 (HHV-6), Epstein-Barr-virus, cytomegalovirus, hepatitis C virus, and parvovirus B19. For a comprehensive listing of all viruses known to cause myocarditis, we refer readers to a 2013 Position Statement on myocarditis prepared by the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases (Caforio et al., 2013). Diagnosis is typically confirmed by positive Polymerase chain reaction (PCR) amplification of viral genetic material.

The natural progression of viral myocarditis typically involves an initial period where viral replication is occurring intracellularly. Infection may be subclinical at this stage. This is followed, 2–4 weeks later, by an immune response with contributions from both antibody and cell-mediated immune mechanisms. The antibody response may have autoimmune features, including cross-reactivity of antibodies against viral antigens with host cardiac tissue or host cardiac tissue damage leading to exposure of self-antigens leading to an immune response. The next phase in the progression of viral myocarditis involves either (1) resolution and functional improvement or (2) chronic inflammation and/or impairment leading to dilated cardiomyopathy.

Nonviral infectious myocarditis

Nonviral infectious myocarditis can occur in the setting of a number of different bacterial (including rickettsial and spirochetal), protazoal, mycotic, or helminthic infections. While an exhaustive list of causative infectious agents is beyond the scope of this article, it is important to note that myocarditis is a heterogeneous clinical entity that encompasses inflammation caused by a wide variety of triggers, many of which have distinct impacts on disease progression and prognosis despite shared myocardial inflammatory pathway endpoints such as arrhythmias or heart failure.

Lymphocytic and giant cell granulomatous myocarditis

Both lymphocytic and giant cell granulomatous myocarditis involve significant infiltration of immune cells into the myocardium, with subsequent inflammation-mediated myocardial damage. Both entities are believed to be triggered by infectious myocarditis.

Lymphocytic myocarditis

Lymphocytic myocarditis is typically characterized by new onset of heart failure in the setting of systemic viral infection. Biopsy reveals predominant lymphocytic infiltrates into the myocardium. Notably, granulomas are not typically present, which can aid in distinguishing it histologically from other types of inflammatory myocarditis.

Giant cell granulomatous myocarditis

Giant cell granulomatous myocarditis is a rare and often fatal form of myocarditis characterized by the presence of infiltrating immune cells, multinucleated giant cells, granulomas, myocyte hypertrophy, necrosis, and interstitial fibrosis on histopathological analysis. Treatment may require immunosuppressive agents, such as cyclosporine, cardiac device implantation, and heart transplantation. Common complications, which may be due in part to treatment, include renal failure, ventricular arrhythmias, and heart failure.

Drug-induced myocarditis

Drug-induced myocarditis is a form of hypersensitivity reaction that can occur in response to a wide variety of different medications. This category includes drug rash with eosinophilia and systemic symptoms (DRESS)-associated myocarditis. Two common classes of instigating drugs include aromatic anticonvulsants and sulfonamides. Several other drugs implicated in the development of DRESS-associated myocarditis include allopurinol, calcium channel blockers, nonsteroidal antiinflammatory drugs (NSAIDs), antiretrovirals, angiotensin-converting enzyme inhibitors, diuretics, inotropes, and other types of antibiotics and antifungal agents. Additional clinical features might include fever, swelling, lymphadenopathy, rash, chest pain, hemodynamic instability, hepatitis, nephritis, interstitial pneumonitis, and atypical lymphocytosis. Myocarditis can occur early or late in the clinical course, and is characterized by infiltration of eosinophils and lymphocytes, which can be patchy and may not be adequately captured by endomyocardial biopsy. In severe cases, progression to acute necrotizing eosinophilic myocarditis results in cardiomyocyte necrosis and extensive tissue damage. Prompt cessation of the offending drug and immunosuppressive therapy are typically required for optimal treatment outcome, although the reaction can sometimes progress to multiorgan failure and death, even after discontinuation of the inciting medication. Standard heart failure medications, including diuretics and angiotensin-converting enzyme inhibitors (provided that neither was implicated as the cause of the drug-induced myocarditis), and beta-blockers can be helpful in some cases. In fulminant myocarditis with heart failure refractive to therapy, ventricular assist devices (VAD) can be life-saving. While eosinophils are a prominent feature of drug-induced myocarditis, it is important to note that there are several other nondrug-related etiologies of hypereosinophilic syndromes, such as neoplasm, familial, and idiopathic, which can also result in eosinophilic myocarditis.

Idiopathic inflammatory cardiomyopathy

Idiopathic inflammatory cardiomyopathy is primarily a diagnosis of exclusion, in which all established causes of inflammatory cardiomyopathy have been ruled out. This is also referred to as virus-negative inflammatory cardiomyopathy, even though the etiology may still be due to a virus that was not specifically tested for. Furthermore, the ability of viruses to mutate and recombine indicates that diagnostic capabilities may never be fully at pace with viral evolution.

Myocarditis diagnosis and therapy

Suspected myocarditis may be evaluated by detailed clinical history, electrocardiography, echocardiography, and cardiac MRI (magnetic resonance imaging). While histopathological analysis of an invasive endomyocardial biopsy has historically been required to definitively confirm the diagnosis, this is falling out of favor with advancements in cardiac MRI. The clinical presentation of myocarditis might include chest pain, heart failure, or symptoms relating to arrhythmia, but it is important to emphasize that the clinical spectrum of myocarditis spans from subclinical disease to fulminant disease with associated heart failure and life-threatening ventricular arrhythmias. In some cases, sudden cardiac death may be the first overt clinical manifestation of the disease, as determined on postmortem analysis. When endomyocardial biopsy is performed, the specimens should be analyzed for evidence of infectious agents, which may include PCR analysis for the detection of cardiotropic viruses. Blood specimens may also be screened for evidence of autoantibodies, such as those targeting membrane proteins, mitochondrial proteins, or structural proteins. Therapy options are dependent on the determined etiology of the inflammation and may include immunosuppressive therapy, appropriate antimicrobial therapy as applicable, and the placement of implantable cardioverter defibrillators (ICD) or VAD, in the case of severe systolic failure, as indicated. Spontaneous functional improvement or even full recovery may be observed in the weeks following diagnosis, so this should be factored into decision-making about treatment, and some therapeutic interventions may be delayed for 3–6 months when appropriate to do so in order to gauge the extent of the predicted recovery. Given the clinical heterogeneity of this disease, it has been proposed that patients be classified according to risk level as low, intermediate, or high risk, and that these designations might help guide diagnostic decisions as well as therapeutic management (Sinagra et al., 2016). Due to the complexity of the disease, however, these decisions must often be made on a case-by-case level.

Sepsis-Induced Myocardial Dysfunction

Sepsis is a clinical syndrome comprised of a dysregulated systemic inflammatory response that can quickly progress to multiple organ dysfunction syndrome and death. Septic patients may be at high risk for myocardial dysfunction due to the primary cause of

sepsis, such as the direct effect of an infectious agent, or due to the secondary effects of the systemic inflammatory response. Postulated contributing factors include circulating toxins, cytokines, complement activation, apoptosis, mitochondrial damage, catecholamine storm, and metabolic derangements, such as severe acidosis. Myocardial dysfunction in this setting is typically characterized by global myocardial systolic and diastolic dysfunction, or Takotsubo cardiomyopathy with apical akinesis and ballooning being the most classic manifestation.

Cardiac Sarcoidosis

Cardiac sarcoidosis is characterized by infiltrating noncaseating granulomas with associated inflammation and scar formation, leading to ventricular dysrhythmias, sudden cardiac death, atrioventricular conduction block, and development of heart failure. Cardiac MRI and PET–CT (positron emission tomography–computed tomography) are the current preferred modalities for the diagnosis of cardiac sarcoidosis, in part because the sensitivity of endomyocardial biopsy is relatively low due to the patchy nature of the disease. There is no curative treatment, as the cause is poorly understood and the disease process is quite unpredictable, but systemic immunosuppressive therapy has been observed to produce some benefit in limiting active disease and improving left ventricular function, which fits with the contemporary belief that there is a significant immune-mediated component to the disease. Sarcoidosis is typically a systemic illness with the potential to affect nearly any organ system, with mortality highest from pulmonary or cardiac involvement.

Dilated Cardiomyopathies

The clinical categorization of dilated cardiomyopathies includes a polymorphic spectrum of disorders characterized by ventricular dilation and functional impairment in the absence of hypertensive, ischemic, valvular, or congenital heart disease. In essence, patients with inflammatory cardiomyopathy may develop dilated cardiomyopathy, but not all patients with dilated cardiomyopathy have inflammatory cardiomyopathy. The term nonischemic cardiomyopathy encompasses the range of dilated cardiomyopathies due to several different nonischemic causes, such as doxorubicin, alcohol, familial, or viral, among others. Nonischemic cardiomyopathy is the underlying diagnosis leading to heart transplant in 64% of patients in the 18–39 age group, according to the Registry of the International Society for Heart and Lung Transplantation (Lund et al., 2016).

Diagnosis of Cardiomyopathies

Given the relatively recent and rapidly evolving interdisciplinary field of immune mechanisms in cardiac physiology, it is not surprising that there is a lack of consensus on the classification or management of immune-mediated cardiomyopathies. Much of the progress in this field has been forged by nonevidence-based expert opinion on best practices for the diagnosis, classification, and management of this heterogenous group of disorders. One major hindrance to progress in this area is the limited availability of human tissue from endomyocardial biopsies which might allow for more patient-tailored therapies.

Current Therapeutics for Inflammatory Cardiomyopathy

Specific treatment of inflammatory cardiomyopathy is partially dependent on the etiology, but management may also include general therapies common to all causes. These include therapy for heart failure, primary and secondary prophylaxis for arrhythmias, and anticoagulation when indicated. In cases refractory to optimal medical therapy, mechanical support and ultimately transplantation may be indicated. NSAIDs have no demonstrated benefit in the treatment of inflammatory cardiomyopathy and often increase mortality risk. Alcohol and smoking should generally be avoided, and exercise should also be avoided during acute myocarditis. Given the high prevalence of autoantibodies present in certain types of myocarditis, apheresis has been proposed as a possible therapy. Apheresis involves an extracorporeal circuit to separate whole blood into cells and plasma, with removal of antibodies from the plasma and reintroduction of treated plasma and cells into the body. Small initial clinical studies have been very promising, demonstrating improvement in left ventricular ejection fraction, but large randomized controlled studies have not yet been completed to determine if there is a clear benefit to this form of therapy.

Autoimmune Mechanisms

While a moderate amount of inflammation in an acute setting is beneficial for wound healing, a dysregulated inflammatory response can produce an array of chronic inflammatory or autoimmune diseases. Many autoimmune diseases are associated with greatly increased risk of adverse cardiovascular events. The etiology of autoimmune disorders is broad and may include genetic and epigenetic factors, environmental, infectious, and other as yet undiscovered factors.

Determination of Autoimmune Etiology of Myocarditis

In autoimmune myocarditis, autoantibodies may or may not be present and they may or may not be pathogenic. Autoantibodies may be present as a biomarker of disease, or they may be absent, as in cell-mediated autoimmune diseases. In some cases,

myocarditis may be presumed to be of autoimmune etiology when all other known causes are ruled out. In addition, evidence from mouse models suggests that some individuals may be genetically predisposed to autoimmune myocarditis based on MHC genes or other non-MHC genes (Caforio et al., 2013).

Autoimmune Myocarditis

The connection between infection and autoimmune disease processes is well established. Viral myocarditis, for example, is considered to be a common triggering factor for the development of autoimmune myocarditis. Several theories exist for the mechanism by which infection leads to autoimmunity. Molecular mimicry describes the phenomenon by which there is accidental cross-reactivity between foreign antigens and self-antigens. The cryptic antigen theory posits that hidden antigens are exposed or released by tissue damage. The adjuvant effect describes an immune-boosting effect, which may result in activation of preexisting autoreactive immune cells. The dual T cell receptors theory suggests that two different T cell receptors on a single T cell cause dual reactivity to both foreign and self-antigens, leading to autoimmunity in the setting of infection. Of note, existing theories do not provide a good explanation for observed sex differences in the prevalence of many autoimmune conditions. Unlike most autoimmune diseases that more commonly affect women, autoimmune myocarditis rates are higher in males than in females, and males typically experience a higher rate of progression to dilated cardiomyopathy. While the mechanism for progression from viral myocarditis or autoimmune myocarditis to dilated cardiomyopathy is not well understood, there are some characteristic and overlapping features of immune mechanisms leading to resolution or pathology that are summarized in **Fig. 3**.

Secondary Cardiac Manifestations of Systemic Autoimmune Diseases

Atherosclerosis is a systemic inflammatory condition characterized by lipid and immune cell deposition in vessel walls. There are overlapping features of atherosclerosis and autoimmune disease, and patients with autoimmune diseases often have accelerated atherosclerotic progression. Adverse cardiac outcomes in patients with systemic autoimmune disease are likely due to a combination of traditional and nontraditional risk factors, such as the presence of autoantibodies, genetic polymorphisms, and chronic inflammatory status. The systemic autoimmune disease category includes patients with spondyloarthropathies such as psoriatic arthritis and ankylosing spondylitis, who have accelerated rates of atherosclerotic cardiovascular disease and higher rates of cardiovascular mortality. Patients with systemic sclerotic diseases, which can result in vascular and myocardial fibrosis, also experience accelerated cardiovascular disease. Common adverse manifestations of cardiac fibrosis associated with systemic sclerotic diseases include coronary artery disease, arrhythmias, and left ventricular diastolic dysfunction. Cardiac manifestations of antiphospholipid syndrome, a known prothrombotic state, include increased thrombotic events, coronary artery disease, and valvular sclerosis due to immune complex deposition.

Systemic lupus erythematosus is a common systemic autoimmune disease that most commonly affects young women and is associated with substantially increased rates of cardiovascular mortality. Cardiac manifestations of the disease may include coronary artery disease and increased myocardial infarction rates. Rheumatoid arthritis, an autoimmune joint disease with systemic manifestations, is also associated with increased cardiovascular mortality rates, most often due to inflammation promoting coronary artery disease. Of note, sudden cardiac death is more common in these patients than in the general population due to subclinical ischemic heart disease.

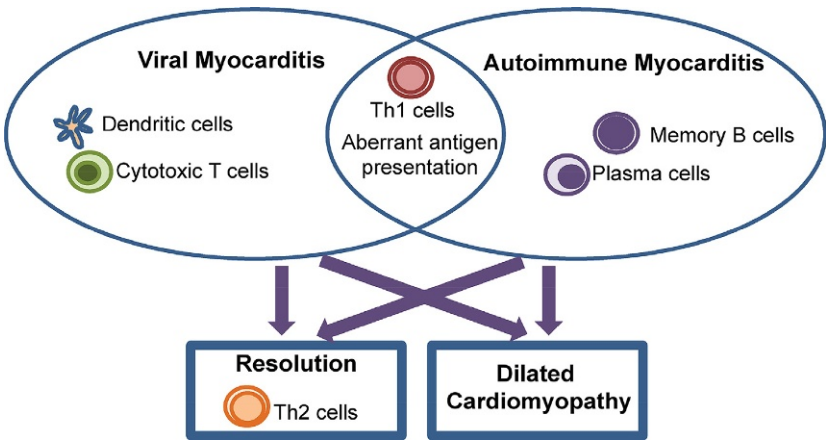

Fig. 3 Schematic overview of predominant immune cell types and overlapping immune mechanisms leading from viral myocarditis or autoimmune myocarditis to resolution or dilated cardiomyopathy. In viral myocarditis, antigen-presenting dendritic cells activate cytotoxic T cells favoring a proinflammatory Th1 response. In contrast, autoimmune myocarditis is primarily B cell-mediated, with contributions from both memory B cells and antibody-secreting plasma cells which also favor a proinflammatory Th1 response. Common immune mechanisms of both viral and autoimmune myocarditis include a proinflammatory Th1 shift and aberrant antigen presentation mediating host tissue destruction and progression to dilated cardiomyopathy. Antiinflammatory Th2 cells, however, can assist in driving the balance back toward resolution of inflammation.

Postpericardiotomy Syndrome

Open heart surgery, device implantation, or other forms of cardiac manipulation or trauma can lead to postpericardiotomy syndrome, an aseptic inflammatory response characterized by fever, pericarditis, and the potential for pleural effusions. It can occur in the weeks or months following cardiac injury, and is generally considered to be an autoimmune phenomenon triggered by exposure of cardiac antigens. Evidence for an autoimmune etiology includes the presence of autoantibodies and immune complexes and the absence of alternative known causes for the fever or other clinical manifestations of the syndrome, which might include leukocytosis, elevated erythrocyte sedimentation rate and C-reactive protein (CRP), new or worsening chest pain, or pleuritic chest pain. As with some other types of autoimmune syndromes, there is evidence that a common viral infection could be a trigger for development of autoimmunity in the postcardiac injury setting. Treatment includes NSAIDs, steroid, and colchicine. Progression to constrictive pericarditis or tamponade may require pericardiocentesis. Of interest, the neutrophil to lymphocyte ratio is reportedly higher in postoperative patients with postpericardiotomy syndrome than in postoperative patients without it, suggesting that it may be useful as a predictive biomarker in this setting (Sevuk et al., 2016). The neutrophil to lymphocyte ratio is a systemic inflammatory marker that correlates with poor prognosis in several cardiovascular conditions. It is also associated with other types of autoimmune conditions.

Cardiac Transplant Rejection

Following heart transplantation, immunosuppresive therapy greatly prolongs graft survival by reducing the incidence and severity of cellular and antibody-mediated rejection. As cardiac transplant and the pathophysiology of transplant rejection will be covered elsewhere in this encyclopedia, this topic will not be covered here. For a review of immune mechanisms in solid organ transplantation, we recommend one by Wood et al. (2012).

Immune Mechanisms in Pediatric Cardiovascular Disease

In contrast to adult patients, heart disease in the pediatric population is more likely to be due to nonischemic causes, including structural, infectious, and inflammatory etiologies.

Kawasaki Disease

Kawasaki Disease is an acute febrile systemic vasculitis of unclear etiology that can occur in early childhood. Epidemiological evidence of epidemics, community outbreaks, and seasonality suggests an infectious cause yet there is no evidence of person-to-person transmission. Genetic factors are believed to contribute as the incidence is highest in East Asia and among family members, but twin studies suggest that environmental factors are weighted more heavily than genetic predisposition. Many microbes or microbe-derived PAMPs are believed to cause Kawasaki disease by causing production and release of DAMPs from host cells, which then activate PRRs on endothelial cells and immune cells. PRR activation subsequently leads to inflammasome activation, as suggested by the characteristic increase in IL-1β levels, and production of chemokines, which attract neutrophils and monocytes/macrophages, with neutrophils predominating early in the blood and macrophages subsequently comprising the majority of infiltrated immune cells. Kawasaki disease is thus felt to be primarily mediated by the innate immune system. While the acquired immune system may play a minor role in disease pathogenesis, animal models suggest that the innate immune system can cause vasculitis even in experimental models lacking an acquired immune system. Kawasaki disease primarily affects the coronary arteries and can lead to coronary artery abnormalities in up to one third of patients if untreated. Other potential cardiac complications include cardiomyopathy, myocardial infarction, heart failure, and arrhythmias. The main treatment is intravenous immunoglobulin (IVIG) therapy and aspirin, and early diagnosis and treatment are both critical for achieving optimal therapeutic outcome. Although the disease is typically self-limited and treatment significantly lowers the risk, persistent coronary artery abnormalities such as aneurysms can also lead to increased risk of myocardial infarction, thrombus, and sudden cardiac death much later in life. Despite therapy, Kawasaki disease is the most common cause of acquired heart disease in children.

ABO-Incompatible Heart Transplantation

Children under 2 years of age are able to tolerate heart transplant from a donor with a different ABO blood type, a phenomenon mediated by the immaturity of the immune system in this young age group. ABO-incompatible transplantation takes advantage of the impaired ability to develop antibodies to polysaccharide antigens in the first 24 months of life. This is also what makes these young children particularly susceptible to severe infections caused by certain polysaccharide-encapsulated bacteria, such as Streptococcus pneumoniae, Neisseria meningitidis, and Haemophilus influenzae type B. At this early stage, the immune system is also able to develop long-term tolerance of the foreign polysaccharide antigens resulting from an incompatible transplant thus yielding outcomes that are equivalent to ABO-compatible transplants.

Immune Mechanisms in Heart Failure

Heart failure, characterized by impairment of pump function, is a common end pathway for various causes of myocardial injury. Our discussion will focus specifically on immune contributions to heart failure. While the role of the immune system in several types of cardiac injury has been well described, less is known about ongoing immune and inflammatory contributions in chronic heart failure trajectory. A summary of factors contributing to progression to heart failure is shown in Fig. 4.

Proinflammatory Cytokines

Several circulating proinflammatory cytokines tend to be elevated in chronic heart failure patients, regardless of the etiology. These include TNFα, IL-1β, and IL-6, galectin-3, TNF receptor 1, and TNF receptor 2 (Dick and Epelman, 2016). Despite strong evidence of systemic inflammation in chronic heart failure, clinical trials of steroid-based therapies targeting systemic inflammation have been largely unsuccessful. Animal studies of therapies targeting TNFα were initially very promising and demonstrated both worsening of heart failure with exogenously administered TNFα and improvement with TNFα-targeting antibodies. More specifically, TNFα is critically involved in the development of cardiac hypertrophy, fibrosis, and apoptosis of cardiomyocytes, all of which contribute to the progression of heart failure. These studies led to the initiation of several large clinical trials which, taken together, failed to demonstrate clinically significant improvement with TNFα blockade and instead revealed adverse cardiac outcomes associated with high dose therapy. In brief, the Randomized Etanercept North American Strategy to Study Antagonism of Cytokines (RENAISSANCE) and the Research into Etanercept Cytokine Antagonism in Ventricular Dysfunction (RECOVER) studies both involved treatment with the soluble TNFα receptor fusion protein etanercept and showed no benefit in heart failure (Coletta et al., 2002). The Randomized Etanercept Worldwide Evaluation (RENEWAL) trial combined and analyzed a large subset of patients from the RENAISSANCE and RECOVER trials and came to similar conclusions about the lack of effectiveness of TNFα blockade in chronic heart failure (Mann et al., 2004). The anti-TNFα in congestive heart failure (ATTACH) trial, involving treatment with the chimeric TNFα neutralizing antibody infliximab, also failed to demonstrate improvement in clinical status and adversely affected the clinical status of moderate-to-severe chronic heart failure patients at high doses (Chung et al., 2003). More recently, the TNFα pathway has been linked to cardioprotection in ischemia–reperfusion injury by facilitating mitochondrial autophagy, a conserved lysosomal degradative pathway for damaged mitochondria which might otherwise trigger cell death. Mitochondrial autophagy is mediated by TNF receptor-associated factor-2 (TRAF2) a scaffolding protein and downstream effector of TNF (Yang et al., 2015).

Autoantibodies and Heart Failure

The observance of autoantibodies in heart failure is common, even in patients with a nonimmune-mediated primary etiology for heart failure, such as ischemia, hypertension, structural, or mechanical causes. Autoantibodies associated with heart failure and cardiac dysfunction include antibodies against the β1 receptor, the M2 muscarinic receptor, mitochondria, myosin, cardiac troponin I, cardiac actin, NA/K ATPase, and several other proteins and intracellular components. Not surprisingly, these same types of autoantibodies can also be observed in the absence of heart failure, and it is as yet unclear whether autoantibodies play a causative

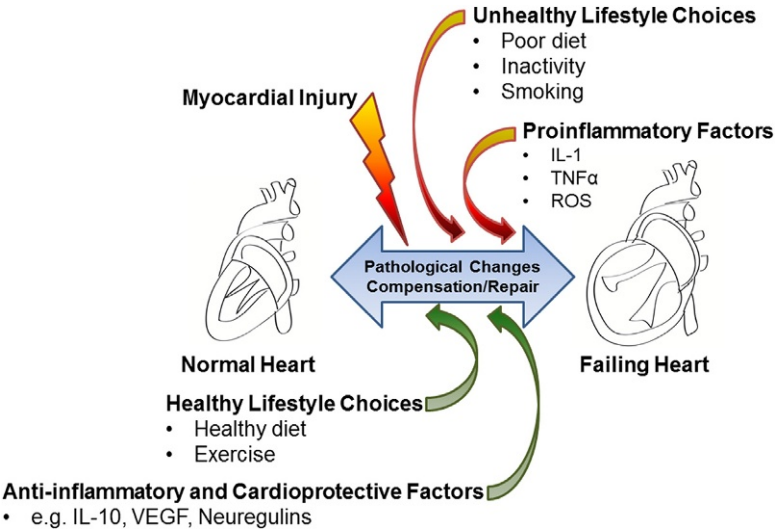

Fig. 4 Schematic overview of factors contributing to progression to heart failure. Following myocardial injury, unhealthy lifestyle choices and proinflammatory factors can expedite the progression to heart failure. In contrast, healthy lifestyle choices, antiinflammatory and cardioprotective factors can slow or reverse heart failure progression.

role in the progression of heart failure. Potential therapies for autoantibody removal include administration of IVIG and immunoadsorption with subsequent immunoglobulin substitution, although the mechanistic evidence supporting both of these therapeutic options is still very limited (Ohlow et al., 2017).

Systemic Inflammation and Cardiovascular Disease

Cardiac inflammation can be categorized as primary, in which the heart is the main organ involved, but it can also be categorized as secondary, in which heart involvement is a feature of more extensive involvement in one or more other organs. This section will address common causes of systemic inflammation leading to secondary cardiac involvement.

Atherosclerosis and Systemic Inflammation

Chronic inflammation can contribute to endothelial damage, which is often described as an initiating event in the development of atherosclerosis. Endothelial damage can be caused by an array of factors including hypertension, smoking, hypercholesterolemia, hyperglycemia, and aging. Once damaged, there is upregulation of endothelial adhesion molecules, recruitment and infiltration of leukocytes, low-density lipoprotein oxidation, inflammatory cell activation, and vascular smooth muscle cell proliferation and migration. Immune-mediated mechanisms of atherosclerosis have been extensively reviewed in the literature and are thus not a focus of this article. For a comprehensive review of this topic, including an update on clinical trials with currently available therapeutics, we recommend a review by Nus and Mallat (2016).

Circadian Contributions to Systemic Inflammatory Profile

Circadian rhythms are set by a combination of endogenous factors and external cues processed by the brain's suprachiasmatic nucleus. The vasculature also demonstrates evidence of circadian gene expression that can be maintained even in the absence of light and dark cues in experimental mouse models. Evidence from animal models demonstrates that disruption of circadian rhythms can contribute to progression of atherosclerosis, metabolic impairments, and systemic inflammation. Evidence from human studies has established higher rates of myocardial infarction, obesity, diabetes, and stroke in shift workers with disrupted circadian rhythms. It has thus been suggested that lack of sleep and/or dysregulation of circadian rhythms be considered as a cardiovascular risk factor. There are currently few mechanistic studies addressing molecular basis for circadian disruption on cardiometabolic profile, and this is an interesting area for future research.

Infection, Microbiota, and Systemic Inflammation

In addition to the previously described increases in cardiovascular mortality due to classic noninfectious systemic inflammatory conditions, such as rheumatoid arthritis, systemic lupus erythematosus, psoriasis, spondyloarthropathies, and systemic sclerotic diseases, several infectious causes of systemic inflammation have also been connected with increased cardiovascular mortality.

Human immunodeficiency virus

HIV infection can lead to chronic systemic inflammation with associated increases in adverse cardiovascular events. HIV patients have higher levels of lipopolysaccharide-induced endotoxemia, increased monocyte activation, and accelerated progression of atherosclerosis such that coronary artery disease development is earlier and more severe in this population. Evidence from clinical studies in HIV patients indicates that this population is at higher risk for subclinical or asymptomatic coronary artery disease. Plaques in HIV-infected patients are also more likely to be unstable, leading to increased incidence of rupture. With the success of antiretroviral therapies transforming HIV infection from a fatal illness to a manageable chronic disease, effective overall disease management requires increasing attention devoted to comorbidities such as cardiovascular disease. Given the increased risk for subclinical coronary artery disease, further research is needed about screening and management of cardiovascular risk in HIV positive patients.

CRP and systemic inflammation

CRP is a nonspecific marker of inflammation that is associated with increased cardiovascular mortality. CRP is elevated in many inflammatory conditions ranging from infection to atherosclerosis to autoimmune diseases. While it is well established that inflammation is associated with cardiovascular disease, further research is needed to determine causality and molecular mechanisms. Several ongoing clinical trials have been designed to address these important questions.

Emerging theory on gut and oral microbiome, inflammation, and cardiovascular risk

There is emerging acceptance that the gut microbiome contributes to overall cardiovascular health. Gut microbiota aid in digestion, contribute to the development of the immune system, and produce metabolites that regulate lipid profiles, glucose management, and adipose tissue storage. Recent estimates suggest that the human colon contains 3.9×10^{13} bacteria in an approximate 1:1 ratio

with the total number of cells in the human body (Sender et al., 2016). While bacteria reside throughout the body, the majority are contained in the colon. Strong evidence supports the interconnectedness of the gut microbiome with obesity, metabolic syndrome, hypertension, inflammatory status, and cardiovascular risk. Animal model development and human clinical studies are ongoing to determine mechanisms by which alterations in the gut microbiome can decrease cardiovascular risk. For example, vaccination with bacterial outer membrane proteins from common gut bacteria enhances adaptive immunity, alters intestinal flora composition, decreases atherosclerotic plaque immune cell infiltration, and promotes an antiinflammatory macrophage phenotype in an apolipoprotein E-null mouse model (Saita et al., 2016). Therapeutic interventions to alter the human gut microbiome are still in development and include prebiotics or probiotics, dietary alterations, targeted metabolic drug therapy, and fecal microbiota transplantation (Koopen et al., 2016). The oral microbiome is also likely to contribute to cardiovascular health. In humans, meta-analysis of clinical studies thus far indicates that periodontitis is strongly associated with hypertension, with the highest odds ratio observed with severe periodontitis (Martin-Cabezas et al., 2016). While the association between the gut and oral microbiome and cardiovascular risk is well established, further research is needed to elucidate biological mechanisms, confirm the intermediary role of systemic inflammation, and prove causality.

Conclusion

The topic of immune mechanisms in cardiac physiology is best understood in the wider context of immune mechanisms contributing to homeostasis. This perspective accommodates the vast field of emerging research on host microbiome contributions to cardiovascular risk factors such as obesity, metabolic syndrome, high blood pressure, and chronic inflammatory conditions. It highlights the benefit of expansion of interdisciplinary inquiry into the mechanisms by which the immune system and cardiometabolism are interconnected. Acceptance of the broader role of the immune system in homeostasis also encourages new advances in the mechanistic understanding of the development of autoimmunity following injury or infection.

Introduction

Atherosclerosis is a chronic process triggered by accumulation of cholesterol-containing low density lipoprotein (LDL) particles in the arterial wall (Hansson, 2005; Libby et al., 2011). The notion of atherosclerosis as an inflammatory disease has emerged based on observations of immune activation and inflammatory signaling in human atherosclerotic lesions, inflammatory biomarkers as independent risk factors for cardiovascular events, and an LDL-induced immune activation. The understanding of immune-mediated mechanisms of atherosclerosis may be crucial for the development of antiinflammatory therapies for atherosclerosis (Bäck and Hansson, 2015).

The initiating vascular inflammation may be promoted by several of the classical cardiovascular risk factors, such as hyperlipidemia, hypertension, diabetes, and cigarette smoking. Biomechanical factors, including the switch from a laminar to a turbulent flow at for example arterial caliber changes and bifurcations, may determine the predilection sites for atherosclerosis development (Bäck et al., 2013). At those locations, a combinatorial expression of endothelial adhesion molecules and leukocyte integrins and selectins mediate the recruitment of myeloid or lymphoid cell to initiate atherosclerosis development. The presence of retained LDL together with activated leukocytes marks that the atherosclerotic lesion is emerging, which is depicted in **Fig. 1** and further discussed in the following sections.

As the atherosclerotic plaque develops, smooth muscle cells (SMCs) and collagen form a cap to protect the lipid and inflammatory content from contact with the blood. Degradation of this fibrous cap surrounding the core of a coronary atherosclerotic lesion induces plaque rupture provoking acute thrombosis (Hansson et al., 2015) as depicted in **Fig. 2**. Destabilization of the atherosclerotic lesion and plaque rupture are stimulated by a number of inflammatory mediators and proteolytic enzymes (Ketelhuth and Bäck, 2011), which are released by the inflammatory cells within the lesion (**Fig. 2**).

Innate Immunity: Recognizing the Danger

Monocytes represent the most numerous white blood cells recruited into atherosclerotic plaques. Once resident in the arterial wall, they differentiate into tissue macrophages under the influence of mediators locally formed in the forming atherosclerotic lesions (**Fig. 1**). The retained and modified LDL (**Fig. 1**), for example oxidized forms of LDL (oxLDL), may serve as an initiating stimulus for inflammatory reactions, by being recognized as a danger-associated-molecular-pattern (DAMP) by specific pattern recognition, such as toll-like receptors (TLRs) (Edfeldt et al., 2002; Lundberg et al., 2013). Today at least 10 TLRs have been identified, some localizing to the cell surface (e.g., TLR4, TLR2) others found intracellularly (e.g., TLR3, TLR7) across the endosome membrane. Whereas TLR4 and TLR2 activation is detrimental in atherosclerosis, TLR7 has recently been assigned antiinflammatory properties by suppressing proinflammatory responses in macrophages (Koltsida et al., 2013; Salagianni et al., 2012). The translational implications of those findings are reinforced by the observation that TLR7 transcript levels in atherosclerotic lesions are associated with an improved outcome after vascular surgery (Karadimou et al., 2017), which will be further discussed below.

In addition to LDL, endogenous alarmins, also named as warning signals, are released into extracellular milieu during inflammation and tissue damage. Extracellular heat shock proteins, high mobility group box protein-1 and S100 proteins (Wick et al., 2014; Oesterle and Bowman, 2015; Harris et al., 2012), along with LDL particles and other alarmins, represent an important element of danger signals that promote inflammation associated with atherosclerosis.

Macrophages referred to as classically activated or M1 macrophages will sustain the inflammatory response and induce tissue damage. In contrast, the alternatively activated, or M2, macrophages secrete antiinflammatory mediators and may promote tissue repair and healing (Bäck et al., 2015) by means of a resolution of inflammation (*cf.* infra).

The uptake of lipoprotein particles will induce the conversion of macrophages into foam cells, a pathogenic process that results in the microscopic appearance of lipid-laden macrophages, which is a characteristic of the atherosclerotic lesion. The oxLDL uptake

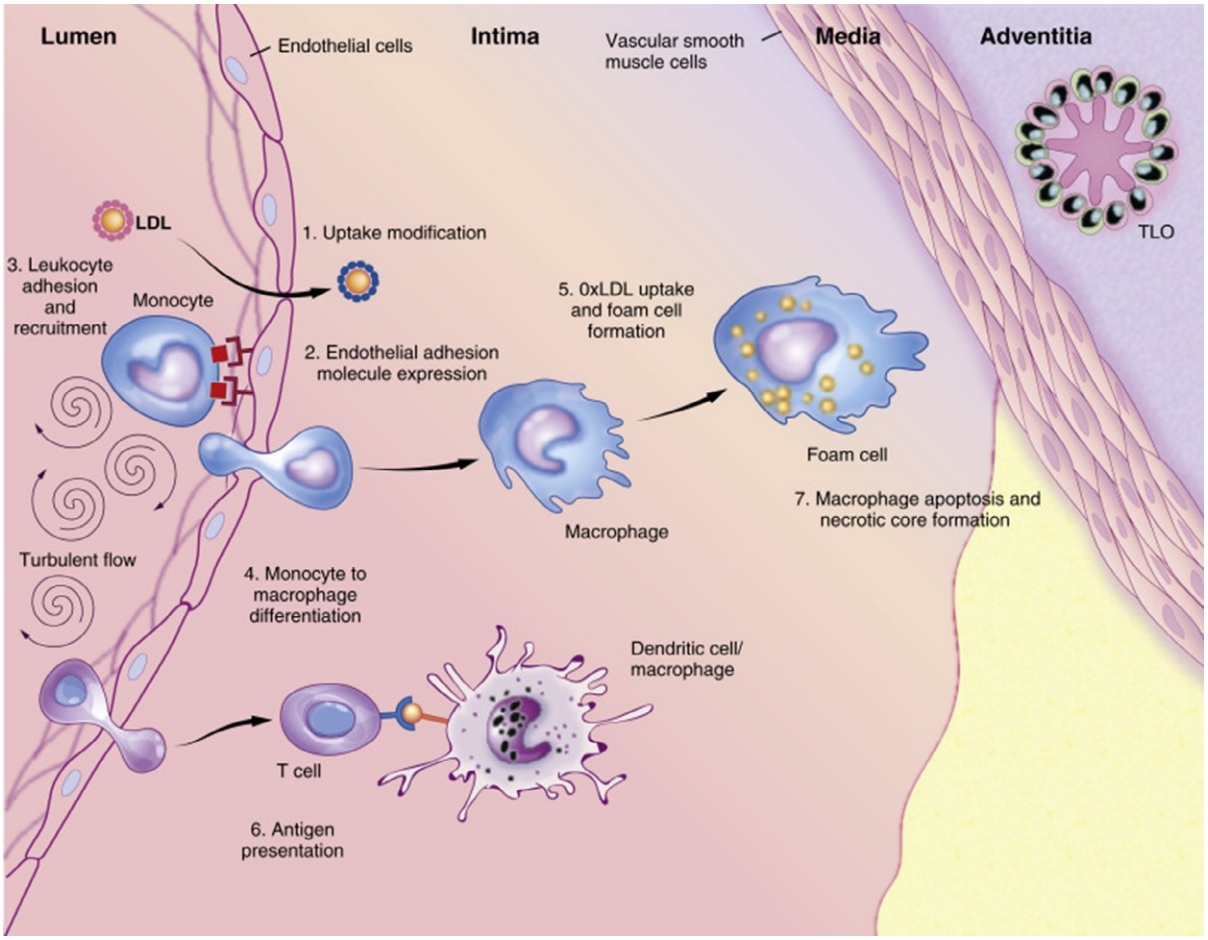

Fig. 1 Immune-mediated mechanisms of atherosclerosis. (1) Low density lipoprotein (LDL) is retained in the vascular wall, where it is modified by oxidation. (2) Oxidized LDL (oxLDL) stimulates endothelial cells to express adhesion molecules, which (3) induces leukocyte adhesion and recruitment. (4) Infiltrating monocytes differentiate into macrophages that (5) take up oxLDL and become foam cells. (6) Dendritic cells and macrophages present antigens to lymphocytes. (7) Macrophage death, for example by apoptosis, creates a lipid-filled necrotic core. Note also the presence of mast cells within the lesion. Tertiary lymphoid organs (TLO) in the adventitia are also depicted (see text for details). Reprinted from Chronic Coronary Artery Disease edited by Lemos and Omland. Bäck and Hansson, Basic Mechanisms of Atherosclerosis, pp. 45–54, 2018 with permission from Elsevier.

initiates several pathways of inflammation in the macrophage. Recently it was shown that oxLDL bound within immune complexes has even more potent effect, leading to activation of the inflammasome (Rhoads et al., 2017). In addition, the internalization of oxLDL by macrophages can lead also to antigen presentation and the consequential activation of the adaptive immune system (Nicoletti et al., 1999).

Macrophage death, for example by apoptosis, creates a lipid-filled necrotic core within the atherosclerotic lesion (**Fig. 1**). Under normal conditions, apoptotic cells are cleared by a specific phagocytosis process, termed efferocytosis, which is an essential response for normal steady state (Serhan, 2014). The defective clearance of lipid-laden apoptotic macrophages in the atherosclerotic lesion further enhances the necrotic core formation.

Also mast cells are present in human atherosclerotic lesions (**Fig. 1**), and may derive from mast cell precursors recruited to the lesions either by means of adventitial vasa vasorum or migration from the lumen toward the arterial intima (Shi et al., 2015). Activation of lesion mast cells by for example immune complexes, LPS, and complement (Lappalainen et al., 2011) results in the release of chemokines, cytokines, and lipid mediators (Dichlberger et al., 2014), which may participate in the atherosclerosis progression, as well as several proteases involved in plaque instability (Kovanen, 2007).

Adaptive Immunity: Fine Tuning the Immune Reaction

T- and B-cells are the major cells involved in adaptive immunity. In conjunction with the innate immune system, the responses of T- and B-cells are essential for the elimination of infectious and toxic agents. The adaptive immune system has the ability to recognize and recall specific responses against foreign and self-antigens. Maladaptive immune responses to self-molecules can lead to the

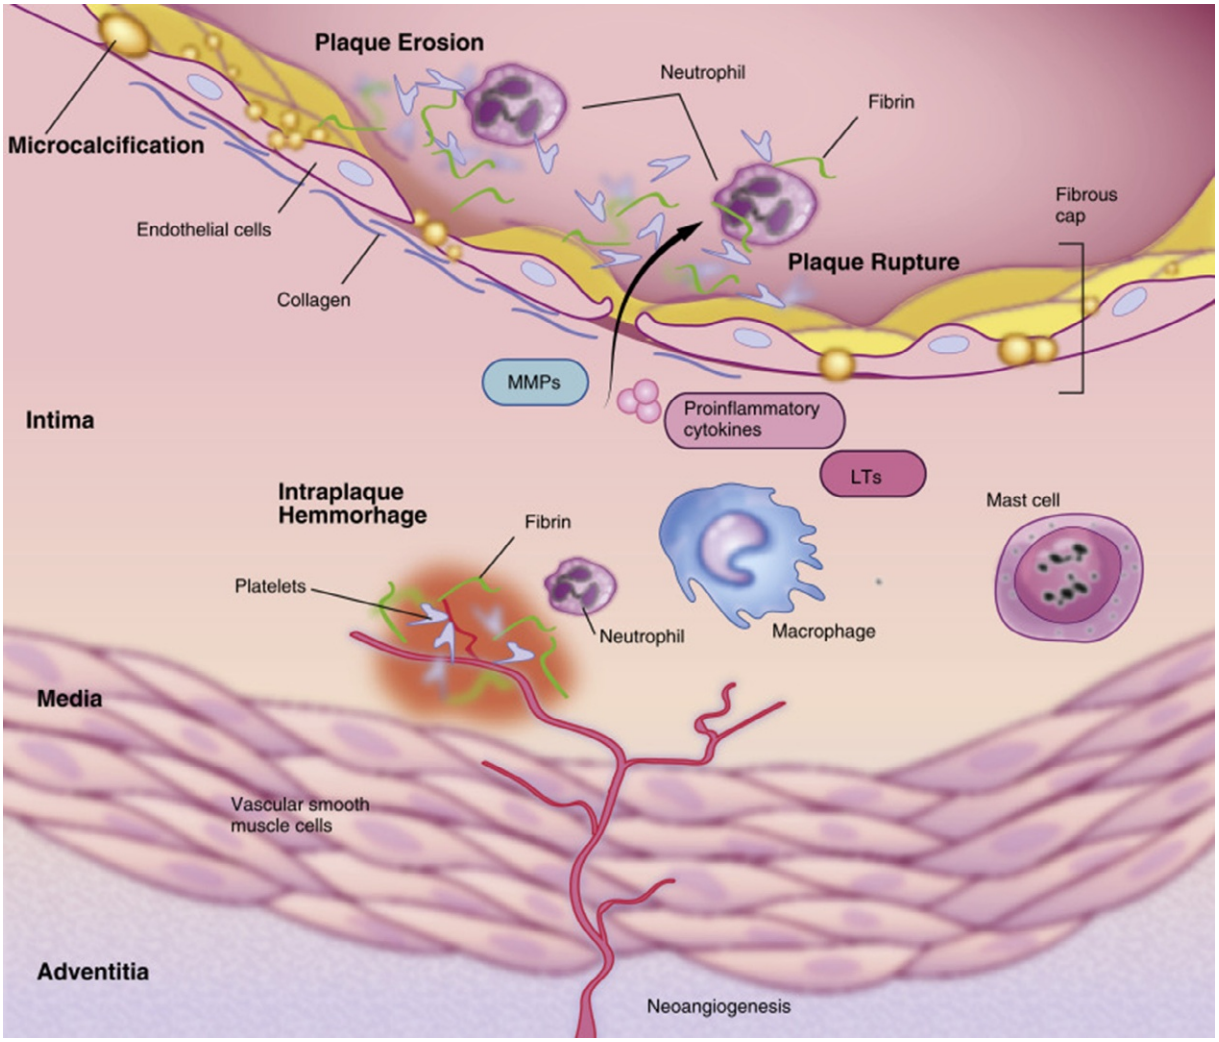

Fig. 2 The vulnerable plaque. The fibrous cap, containing mainly smooth muscle cells and collagen, protects the lipid- and inflammatory content of the atherosclerotic lesion from contact with the blood. In plaque erosion, endothelial cells detach and the exposure of the subendothelial matrix will lead to neutrophil activation and thrombus formation. Degradation of this fibrous cap surrounding the core of a coronary atherosclerotic lesion induces plaque rupture provoking acute thrombosis and vessel occlusion. Hypoxia and growth factors contributes to neo-angiogenesis within the atherosclerotic lesions, which is the source of intraplaque hemorrhage, another important characteristic of vulnerable plaques. *LTs*, *leukotrienes*; *MMPs*, *matrix metalloproteinases*. development of autoimmune diseases. Indeed, the chronic inflammation in atherosclerosis shares many features with autoimmune disorders. For instance, mice that carry global defects in adaptive immunity due to recombinase-activating gene or SCID (severe combined immunodeficiency) defects are much less prone to develop atherosclerotic lesions, even on a hypercholesterolemic background while animals defective in specific components of adaptive immunity display characteristic changes in disease development and lesion formation (Dansky et al., 1997; Zhou et al., 2000; Hansson and Hermansson, 2011). Adoptive transfer of CD4+ T-cells from the autoimmune mouse model for SLE can actually accelerate atherosclerosis in LDLr−/− mice (Wilhelm et al., 2015). However, atherosclerosis differs in two important aspects: atherosclerosis is much more abundant than any of the autoimmune diseases, and it does not show linkage to any specific HLA haplotype. Instead, several different HLA types appear to be permissive. In atherosclerosis, autoimmune responses have been identified that recognize LDL particles and their molecular components (Stemme et al., 1995; Binder et al., 2003; Hermansson et al., 2010). Such T- and B-cell responses to LDL have been shown to be pathogenically important and may also offer new opportunities for cardiovascular therapy (Bäck and Hansson, 2015).

T- and B-cells have been identified in human atherosclerotic lesions as well as in animal models of disease. In experimental models, $CD4^+$ T-cells interact with antigen-presenting cells in the vessel wall, leading to their activation, proliferation, and secretion of cytokines such as IFNγ and TNF (Koltsova et al., 2012). While most B-cells are usually found in the adventitial layer of the arterial wall, in tertiary lymphoid organs (TLOs; **Fig. 1**), T-cells can account for up to 10% of all cells in human plaques. T helper 1 $CD4^+$ (Th1) cells are the most abundant T-cell population in the plaque (Jonasson et al., 1986). However, other T helper cells, for example

Th2 and Th17, as well as regulatory T-cells (Tregs), TCR$\gamma\delta^+$ T-cells, and NKT cells have been described in plaques (Ketelhuth and Hansson, 2011).

Most T-cell subtypes have been implicated in the modulation of experimental atherosclerosis. Indeed, Th1 and Tregs play major opposite roles in the disease, being pro- and antiatherogenic, respectively (Ketelhuth and Hansson, 2016; Klingenberg et al., 2013). In addition to influencing plaque inflammatory burden, pro- and antiatherogenic T-cells can influence plaque stability by affecting the differentiation of SMCs and collagen production, and the release of proteases (Ketelhuth and Bäck, 2011; Gisterå et al., 2013). For example, Th17 and IL-17A have been recently implicated in the regulation of collagen production and thickening of fibrous cap (Gisterå et al., 2013). However, the role of Th17 cells in atherosclerosis remains unclear since they have been implicated in acceleration (van Es et al., 2009; Butcher et al., 2012; Erbel et al., 2009; Gao et al., 2010; Smith et al., 2010) and deceleration (Taleb et al., 2009; Danzaki et al., 2012) of disease.

The natural killer T (NKT) cell type that recognizes lipid antigen rather than protein-derived peptides has been implicated as a proatherogenic cell population. Thus, defects in lipid antigen presentation to NKT cells lead to reduced atherosclerosis, whereas NKT cell activation with exogenous ligands accelerates disease development (Tupin et al., 2004; Nakai et al., 2004; Major et al., 2004; van Puijvelde et al., 2009; Kyriakakis et al., 2010). These effects likely depend on NKT cell populations in the liver as well as in the artery wall.

Antibodies to LDL components and other disease-associated antigens such as heat shock protein-60 show correlations with disease development. Therefore, it was a surprise when two groups reported that B cells play a protective role in atherosclerosis (Caligiuri et al., 2002; Major et al., 2002). Although several additional studies have confirmed that B-cells have atheroprotective properties, their role in disease remains controversial. While the elimination of the majority of B-cells accelerates atherosclerosis, the depletion of certain B2 cell types, for example $CD20^+$ (Ait-Oufella et al., 2010) or $BAFFR^+$ (B cell-activating factor receptor)(Sage et al., 2012), is atheroprotective. These results suggest that similar to T-cells, different B-cell subtypes can convey a protective or deleterious role in atherosclerosis (Ketelhuth and Hansson, 2016).

Considering the pathophysiological roles, the specificity, and the long-lasting characteristics of their responses, the modulation of T- and B-cell responses is an attractive target for the development of novel therapies for CVD (Ketelhuth et al., 2013; Ketelhuth and Hansson, 2016; Bäck and Hansson, 2015). This offers the possibility to trigger long-lasting T- and B-cells, including Tregs, regulatory B-cells (Bregs), and B-1 cells, that can provide antiatherogenic immunity while leaving the general host defense untouched. There are several experimental studies supporting this notion, which needs to be further investigated and validated in humans. One particularly attractive option would be to increase the number of IL-10 producing B cells that reside within the aortic lymph nodes. It is possible that this population may respond directly to atherosclerotic plaque formation (Strom et al., 2015). Conversely, reducing other B cell populations that exacerbate atherosclerosis, such as those that produce GMCSF (Hilgendorf et al., 2014), could also provide a therapeutic avenue. It may appear to be a crude approach to generally target immune populations outside of their disease specific function. However, it should be noted that broad anti-B cell therapy has achieved substantial clinical success with regard to autoimmune disease.

Immunomodulatory therapies against atherosclerosis are under investigation by several groups worldwide (Bäck and Hansson, 2015). In animal models, different vaccination protocols against disease-related antigens, for example oxLDL, Apolipoprotein B-100, HSP65, have shown atheroprotective effects (Palinski et al., 1995; Ameli et al., 1996; George et al., 1998; Zhou et al., 2001). ApoB100 epitopes recognized by circulating autoantibodies in patients and healthy individuals (Fredrikson et al., 2003a) have been shown to reduce vascular inflammation and protect against atherosclerosis (Schiopu et al., 2004, 2007; Strom et al., 2007; Fredrikson et al., 2003b; Klingenberg et al., 2010; Fredrikson et al., 2008; Herbin et al., 2012; Wigren et al., 2011). Atheroprotection has been demonstrated using murine ApoB100-derived T-cell epitopes (Tse et al., 2013), and recently human ApoB100-derived atheroprotective T-cell epitopes have also been identified (Gistera et al., 2017). Notably, the latter study showed that ApoB100 epitopes are predicted to bind several HLA haplotypes, suggesting a large proportion of the world population has the potential to mount T-cell responses against these when used in a vaccine.

Different mechanisms have been proposed for explaining the efficacy of vaccines in mitigating vascular inflammation and plaque development, including the induction of antigen-specific Tregs and antibody-mediated effects, for example, neutralization of oxLDL and the diminishment of its deleterious effects on macrophages and vascular cells, inhibition of scavenger receptor-mediated uptake of oxLDL by foam cells, and Fc-mediated inhibition of macrophage activation (Ketelhuth and Hansson, 2016; Gistera et al., 2017).

Humoral Immunity: The Remote Control

Antibodies are capable of recognizing a broad range of potentially dangerous molecules, including reactivity against modified versions of self. This recognition of altered-self is believed to have important functions in protecting mammals from atherosclerosis formation. The first line of humoral defense is provided by something termed “natural immunity” in this case provided by germline encoded antibodies that are produced in the absence of antigen, but can also be increased in titers following antigenic stimulation. IgM Antibodies that recognize phosphocholine when present in oxLDL are thought to help in the clearance of both oxLDL and apoptotic cell bodies (Shaw et al., 2000), which can accumulate in the atherosclerotic plaque. Antibodies also recognize many other pro-atherosclerotic antigens, especially the neo-epitopes produced during covalent bond formation between the lipid and proteins present in LDL, and also potential danger sequences present in the apolipoproteins themselves (Ketelhuth et al., 2011).

Direct evidence that antibodies can comprehensively reduce or even prevent plaque formation has not been forthcoming, but a number of observations suggest that humoral immunity may provide a pathway to ameliorating atherosclerosis. First, either transfer of total IgM or intravenous injection of immunoglobulins (ivIG) can reduce atherosclerosis in animal models (Cesena et al., 2012; Nicoletti et al., 1998). Second, increasing the concentrations of antibodies with the T15 idiotype, which recognizes phosphocholine, can also reduce the extent of atherosclerosis plaque formation under certain defined conditions (Binder et al., 2003; Faria-Neto et al., 2006), although targeted deletion of an immunoglobulin gene segment that is critical for antiphosphocholine responses following acute infection or immunization does not affect atherosclerosis development (Centa et al., 2016). Similarly, immunization of atherosclerosis susceptible mammals with either phosphocholine or oxLDL reduces the subsequent extent of the disease (Steinberg and Witztum, 2010). This has led to more refined searches to allow for the cloning of antibodies that recognized oxLDL, with some limited success in hindering atherosclerosis development (Schiopu et al., 2007; Tsimikas et al., 2011). It is highly likely that full "neutralization" of oxLDL, recognized as a dangerous moiety by the immune system, will require multiple antibody specificities acting in concert and perhaps through multiple effector systems, including complement and FC receptor-mediated responses. As a final note of caution, antibodies have also been suspected of having pathogenic functions in atherosclerosis, and inhibition of this putative promoting effect may also be a fruitful approach in future therapeutics.

Neural Immune Programming: The Spleen as a Router

Recent discoveries in immunology and neuroscience show that the immune system in addition is regulated by neural reflexes (Olofsson et al., 2012). These insights have spawned clinical trials that use nerve stimulators to treat inflammatory disease. The human study populations to date are small, but the reports are promising and show reduced inflammatory disease activity after activation of an implanted vagus nerve stimulator (Koopman et al., 2016; Bonaz et al., 2016). If rigorous, large-scale clinical trials confirm the efficacy of implanted vagus nerve stimulators, it is conceivable that nerve stimulation could be approved for routine clinical use in treatment of select conditions characterized by excessive inflammation (Tracey, 2015).

The inflammatory reflex, in which the vagus nerve plays a key role, is one of many reflex circuits that control cytokine release and immune cell activity (Andersson and Tracey, 2012). The detailed mapping of this circuit has been important for the emerging understanding of reflex control of inflammation and as a basis for clinical trials of vagus nerve stimulation for treatment of inflammatory diseases. In this reflex circuit, proinflammatory cytokines such as IL-1β trigger sensory activity in the vagus nerve (Watkins et al., 1995; Niijima, 1996). Efferent signals travel through the vagus nerve to the celiac ganglion where the splenic nerve arises. Activation of the vagus nerve gives rise to a cascade of events involving release of norepinephrine by the splenic nerve. Norepinephrine promotes a subset of splenic T-cells, denoted T_{ChAT}, to release acetylcholine, which acts on macrophage cholinergic receptors to reduce release of proinflammatory cytokines, including TNF (Olofsson et al., 2012). Recent reports link components of this pathway to the regulation of blood pressure and potentially to development of hypertension (Olofsson et al., 2016; Carnevale et al., 2016), and suggest that the neural control of the immune system needs to be considered in the development of cardiovascular disease where inflammation is involved, including hypertension and atherosclerosis (Harrison et al., 2011; Libby et al., 2009).

Lipid Mediators: Accelerating and Resolving Inflammation

Activated immune cells are an important source for the production of bioactive lipid mediators from polyunsaturated fatty acids (PUFAs) at all stages of atherosclerosis (**Figs. 1** and **2**). For example, prostaglandins and thromboxanes, which originate from cyclooxygenase (COX) metabolism of phospholipid-derived arachidonic acid, play well-recognized roles in the atherosclerosis process (Gabrielsen et al., 2010; Capra et al., 2014). The use of low-dose aspirin in cardiovascular prevention relies on its irreversible inhibition of COX-1 in platelets, which lack the ability to resynthesize COX enzymes, leading to a selective inhibition of platelet pro-aggregatory TXA_2 formation (Capra et al., 2014). In contrast, the use of COX-2 selective inhibitors has been associated with an increased cardiovascular risk (see Bäck et al. (2012) and references therein).

Arachidonic acid also serves as a substrate for the lipoxygenase (LO) enzymes leading to the formation of lipid mediators that transduce specific signaling patterns in atherosclerotic lesions. Leukotrienes (LTs) act on specific receptors, BLT and CysLT receptors (Bäck et al., 2011), respectively, to transduce several proinflammatory effects with implications for atherosclerosis development, such as leukocyte recruitment and activation, SMC proliferation, endothelial dysfunction (Bäck and Hansson, 2006), and plaque rupture (Bäck, 2009). Interestingly, anti-LTs that are in clinical use for the treatment of asthma and allergic rhinitis have been associated with a reduced risk of recurrent cardiovascular events in retrospective analysis (Ingelsson et al., 2012), further underlining the therapeutic potential for targeting immune-mediated mechanisms in atherosclerosis (Bäck and Hansson, 2015).

In addition to the formation of proinflammatory LTs, LO metabolism of both the omega-6 PUFA arachidonic acid and omega-3 PUFAs participate in the formation of antiinflammatory lipid mediators, such as lipoxins och resolvins (Serhan, 2014). In addition to dampening the immune response, these lipid mediators also actively promote the resolution of inflammation (Serhan, 2014). For example, lipoxins and resolvins stimulate efferocytosis (Serhan, 2014; Petri et al., 2015a), which is an important mechanism for the resolution of inflammation and may serve to decrease the necrotic core formation in atherosclerosis (*cf.* supra and **Fig. 1**).

The opposing effects of the lipid mediators, being either proinflammatory or pro-resolving, taken together with their potent effects in experimental atherosclerosis (Ketelhuth et al., 2015; Petri et al., 2017), indicate that the balance between the two classes of

mediators may be crucial for either stimulating or repressing the immune response in atherosclerosis. Indeed, the expression of their respective receptors is differentially regulated in monocytes (Petri et al., 2015b), suggesting that the composition of the proinflammatory milieu in the atherosclerotic lesion may be decisive to determine if lipid mediator signaling is either proinflammatory or pro-resolving. Furthermore a disturbed lipid mediator balance with prevailing leukotriene over resolvin production can be used as a biomarker of nonresolving inflammation in the context of subclinical atherosclerosis (Thul et al., 2017).

Carotid Endarterectomy Studies: Observing Immune Responses in Human Atherosclerosis

As mentioned above, inflammatory pathways are involved throughout the different stages of atherosclerosis, from early onset (**Fig. 1**) to final ischemic events (**Fig. 2**). However, it is not clear how local immune responses may lead to the life threatening condition of plaque rupture in patients with severe atherosclerosis. Mouse models are very useful to study progression and early phases of atherosclerosis have thereby helped identifying several key factors and immune cells. However, regarding the later stages in human disease we still lack really robust animal models.

Larger cohorts of patients or healthy controls can be used to investigate genetic markers and other measurable parameters using blood samples that are easy to collect. To get a more detailed picture of disease processes one needs to analyze the affected tissue, not only a blood sample. Vascular tissue samples, even very minute, from patient undergoing operations have proved to be very useful not only for immunohistochemistry analysis but also in the growing field of molecular biology analysis. The ability to do large-scale analysis on RNA, DNA, and protein levels have opened new possibilities.

Functional genomic studies have been used in medicine research since the beginning of 2000. The methodologies are developing fast and today these studies use large-scale analysis to get molecular data on pathological processes all the way from gene to RNA to protein. One of the earliest methods introduced was transcript profiling. This type of methods can on a chip analyze mRNA from 20,000 genes in one sample, giving information on which genes are activated or silenced—generating a transcript profile, also called transcriptome, for a given sample.

To be able to study mechanisms within the atherosclerotic plaque on a molecular level, bio-banks have been built of plaques removed under carotid endarterectomy (CEA), also including from each patient. In the prospective BiKE—Biobank of Karolinska Carotid Endarterectomies, the atherosclerotic plaque and circulating leukocytes are collected for mRNA isolation and transcript profiling, thereby building a database of present transcripts in diseased tissue and in circulating leukocytes in relation to the clinical data of the patients (Folkersen et al., 2009, 2012; Perisic et al., 2016; Gabrielsen et al., 2010). The composition and biology of the carotid plaque is assumed to be representative of other plaques found in other parts of the vascular tree, such as coronary arteries. By means of such analysis, specific pathways of both innate and adaptive immunity have been identified. For example receptors and cytokines controlling response in T lymphocytes (Gisterå et al., 2013) and lipid-carrying proteins boosting macrophage-driven inflammation (Agardh et al., 2011), respectively, have been identified. Finally, postsurgical follow-up after CEA can be monitored in order to determine the prognostic valve of a specific transcript profile in the removed atherosclerotic plaque on future cardiovascular events. Using the latter approach, TLR7 was identified as a positive prognostic marker in patients with severe atherosclerosis (Karadimou et al., 2017). Taken together, atherosclerotic plaque biobanks allow a unique translational tool for the search for immune controlling treatments of atherosclerosis in the future (Bäck and Hansson, 2015).

Summary and Conclusions

The immune response in atherosclerosis can be triggered by several known cardiovascular risk factors that initiate the vascular inflammation. The retention and modification of LDL and its recognition as danger signal and antigen triggers both an innate and adaptive immune activation, which is regulated by a number of mediators and also by neural reflexes. As with all immune-mediated mechanisms, the context must also be taken into consideration. For example, how immune reactions in secondary lymphoid organs impact atherosclerotic plaque progression in relation to the local immune responses in the form of tertiary lymphoid organs located in the adventitia and juxtaposed to fulminant atherosclerotic lesions.

The study of the immune-mediated mechanisms of atherosclerosis requires adequate experimental in vitro and in vivo models, as well as observational studies in atherosclerotic patients and high-throughput molecular analysis of human atherosclerotic lesions to determine key pathways. In terms of antiinflammatory treatments in atherosclerosis, we emphasize targeting pattern recognition and/or T- and B- cell responses, as well as immunomodulation by pro- and antiinflammatory lipid mediators, vagus nerve stimulation, antibodies, and vaccines.

Pathophysiology

Pacemakers are the only available ambulatory therapy to treat patients with a slow heart rhythm. The origin of the slow heart rhythm can be either situated on the level of the sinus node or the AV node. It is clinically important to make this distinction because bradycardia caused by AV-node problems could be associated with an increased risk in sudden cardiac death, while sinus node disease is a symptomatic problem without an increased mortality (Kastor, 1975a,b; Shaw et al., 1980, 1985). As such pacing for AV-nodal problems can be life saving, while pacing for sinus node disease is a symptomatic treatment. Bradycardia at sinus node level can manifest itself as a problem of the sinus node, with intermittent sinus arrest or sinus bradycardia. It can also be due to a problem in the junction between the atrium and the sinus node: sino atrial block. Problems of the sinus node are often a sign of generalized atrial myopathy presenting with on the one side bradycardia from the sinus node and the other side atrial tachyarrhythmia (atrial fibrillation, atrial flutter, and ectopic atrial tachycardia). This mixed presentation with slow and fast heart rhythm problems is called brady-tachy syndrome (John and Kumar, 2016). In assessing bradycardia originating from the AV node, it is important to distinguish nodal from infranodal problems. Infranodal conduction disease, situated below the bundle of his, is associated with an increased risk of sudden cardiac death. A second-degree AV block type II, a third-degree AV block, or the presence of severe conduction disturbances with a broad QRS are suspect for an infranodal origin of the problem. This suspicion can be proven by the documentation of a prolonged HV interval on an invasive diagnostic electrophysiological study (Kastor, 1975a,b).

In the majority of patients, the underlying problem is aging or ischemia-dependent fibrosis. This results in the fact that pacemakers are used mainly in the elderly population with implantation at the age of 75–80 years (Greenspon et al., 2012). Due to the fact that the underlying pathophysiological process is identical there is a large overlap between AV-nodal and sinus node problems in 30 up to 50% of the patients in this age group. If patients present with bradycardia at a younger age a more thorough diagnostic approach is warranted. In that case structural or genetic arrhythmogenic heart disease (in particular A/VSD and SCN5a or HCN mutations) or systemic disease (in particular sarcoidosis, amyloidosis, hypothyroidism, HLAB27 associated spondylitis) or extrinsic problems (as increased vagal tone due to endurance sports, infectious disease (in particular Lyme and peri/myocarditis) and medication (ab)use) should be ruled out.

Indications for Pacing

Although there is a clear difference in the approach between the European and North American guidelines in this paragraph, the 2012 ACC/AHA/HRS guidelines and the 2013 ESC guidelines are compared (Epstein et al., 2013; Brignole et al., 2013). The ACC/AHA/HRS guidelines use a traditional approach dividing the indications according to the pathophysiological mechanism (sinus node disease vs. AV block), while the ESC considers the indications by their clinical presentation, distinguishing permanent bradycardia from intermittent bradycardia. While the North-American guidelines provide detailed indications for every possible clinical diagnosis, the European Society of Cardiology gives broader advice, resulting in clearly less statements. For both documents it is clear that most of the guidelines are based on expert consensus. In view of the (patho)physiological obvious effect of the treatment and the lack of pharmacological alternative large randomized clinical trials were historically never undertaken and seem in most recognized indications unethical to set-up (**Table 1**).

Table 1 International guidelines ESC vs. AHA/ACC/HRS

	AHA/ACC/HRS	*Level*	*ESC*	*Level*
Indications for pacing				
Sinus node disease	SND with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms	IC	When symptoms can clearly be attributed to bradycardia	IB
	Symptomatic chronotropic incompetence	IC	SND who have the documentation of symptomatic bradycardia due to sinus arrest or sinus atrial block	IB
	Symptomatic sinus bradycardia that results from required drug therapy for medical conditions	IC		
	SND with heart rate less than 40 bpm when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented	IIaC	When symptoms are likely to be due to bradycardia, even if the evidence is not conclusive	IIbC
	Syncope of unexplained origin when clinically significant abnormalities of sinus node function are discovered or provoked in electrophysiological studies	IIaC	With history of syncope and documentation of asymptomatic pauses >6 s due to sinus arrest, sinus-atrial block or AV block	IIaC
	In minimally symptomatic patients with chronic heart rate less than 40 bpm while awake	IIbC		
AV block	Third-degree and advanced second-degree AV block at any anatomic level associated with bradycardia with symptoms (including heart failure) or ventricular arrhythmias presumed to be due to AV block	IC	Third- or second-degree type 2 AV block irrespective of symptoms	IC
	Third-degree and advanced second-degree AV block at any anatomic level associated with arrhythmias and other medical conditions that require drug therapy that results in symptomatic bradycardia	IC		
	Third-degree and advanced second-degree AV block at any anatomic level in awake, symptom-free patients in sinus rhythm, with documented periods of asystole greater than or equal to 3.0 s (86) or any escape rate less than 40 bpm, or with an escape rhythm that is below the AV node	IC	Asymptomatic pauses > 6 s due to sinus arrest, sinus-atrial block or AV block	IIaC
	Third-degree and advanced second-degree AV block at any anatomic level in awake, symptom-free patients with AF and bradycardia with 1 or more pauses of at least 5 seconds or longer	IC		
	Third-degree and advanced second-degree AV block at any anatomic level associated with postoperative AV block that is not expected to resolve after cardiac surgery	IC	High degree or complete AV block after cardiac surgery and TAVI. A period of clinical observation up to 7 days is indicated in order to assess whether the rhythm disturbance is transient and resolves. However, in case of complete AV block with low rate of escape rhythm this observation period can be shortened since resolution is unlikely	
	Third-degree and advanced second-degree AV block at any anatomic level associated with neuromuscular diseases with AV block, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy, with or without symptoms	IB		
	Second-degree AV block with associated symptomatic bradycardia regardless of type or site of block	IB		
	Asymptomatic persistent third-degree AV block at any anatomic site with average awake ventricular rates of 40 bpm or faster if cardiomegaly or LV dysfunction is present or if the site of block is below the AV node	IB		
	Second- or third-degree AV block during exercise in the absence of myocardial ischemia	IC		
	Asymptomatic type II second-degree AV block occursing with a wide QRS, including isolated right bundle-branch block	IC		

(*Continued*)

Table 1 International guidelines ESC vs. AHA/ACC/HRS (Continued)

	AHA/ACC/HRS	*Level*	*ESC*	*Level*
	Advanced second-degree AV block or intermittent third-degree AV block	IB	Intermittent/paroxysmal intrinsic third- or second-degree AV block.	IC
	For type II second-degree AV block	IB		
	Persistent third-degree AV block with an escape rate greater than 40 bpm in asymptomatic adult patients without cardiomegaly	IIaC		
	Asymptomatic second-degree AV block at intra- or infra-His levels found at electrophysiological study	IIaB	Second-degree type I AV block which causes symptoms or is found to be located at intra- or infra-His levels at EPS	IIaC
	First- or second-degree AV block with symptoms similar to those of pacemaker syndrome or hemodynamic compromise	IIaB		
	Asymptomatic type II second-degree AV block with a narrow QRS	IIaB		
	For neuromuscular diseases such as myotonic muscular dystrophy , Erb dystrophy (limb-girdle muscular dystrophy) , and peroneal muscular atrophy with any degree of AV block (including first-degree AV block), with or without symptoms, because there may be unpredictable progression of AV conduction disease	IIbB		
	For AV block in the setting of drug use and/or drug toxicity when the block is expected to recur even after the drug is withdrawn	IIb		
Conduction disturbances	For alternating bundle-branch block	IC	In patients with alternating BBB with or without symptoms	IC
	Bifascicular block with for syncope not demonstrated to be due to AV block when other likely causes have been excluded, specifically ventricular tachycardia (VT)	IIaB	In selected patients with unexplained syncope, BBB and non diagnostic investigations	IIbB
	Bifascicular block and an incidental finding at electrophysiological study of a markedly prolonged HV interval ($\geq$ 100 ms) or non-physiological pacing induced infra-His block in asymptomatic patients	IIaB	in patients with syncope, BBB and positive EPS defined as HV interval of $\geq$70 ms, or second- or third-degree His-Purkinje block demonstrated during incremental atrial pacing or with pharmacological challenge	IB
	In the setting of neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with bifascicular block or any fascicular block, with or without symptom	IIbC		
Contra-indications for pacing				
Sinus node disease	SND in asymptomatic patients	IIIC	SND which is asymptomatic or due to reversible causes	IIIC
	SND in patients for whom the symptoms suggestive of bradycardia have been clearly documented to occur in the absence of bradycardia	IIIC	In patients with unexplained syncope without evidence of bradycardia or conduction disturbance	IIIC
	SND with symptomatic bradycardia due to nonessential drug therapy	IIICC	In reversible causes of bradycardia	IIIC
AV block	Asymptomatic first-degree AV block	IIIB	AV block which is due to reversible causes	IIIC
	Asymptomatic type I second-degree AV block at the supra-His (AV node) level or that which is not known to be intra- or infra-Hisian	IIIC		
	AV block that is expected to resolve and is unlikely to recur (100) (e.g., drug toxicity, Lyme disease, or transient increases in vagal tone or during hypoxia in sleep apnea syndrome in the absence of symptoms)	IIIB		
Conduction disturbances	Fascicular block without AV block or symptoms	IIIB	Asymptomatic BBB	IIIB
	Fascicular block with first-degree AV block without symptoms	IIIB		

Recommendation: I, is indicated; IIa, is reasonable; IIb, may be considered; III, not indicated.

Evidence: B, data derived from a single randomized clinical trial or large non-randomized studies; C, Consensus of opinion of experts and/ or small studies, retrospective studies, registries.

Sinus Node Disease

In sinus node disease, a clear relation between symptoms and bradycardia should be demonstrated in most cases to warrant PM implantation. A PM however is reasonable if a patient presented with syncope and if sinus node dysfunction can be demonstrated on an electrophysiological study or by severe bradycardia on ECG monitoring. The ESC guidelines put forward an asymptomatic pause >6 s as a cut-off in this case, while the ACC/AHA/HRS guidelines leave more room for interpretation and mention the presence of clinically significant abnormalities of sinus node function without specific rate of pause cut-off. Another demonstration of a somewhat more liberal position on the indication of PM for sinus node disease in the North-American guidelines is the fact that implantation may be considered in minimally symptomatic patients with chronic heart rate less than 40 bpm while awake.

AV Block

Symptomatic AV block of second degree or higher at any location is generally accepted as an indication for PM implantation. Asymptomatic AV block located to an infranodal location, either by electrocardiographic characteristics (second-degree AV block type II or third-degree AV block) or confirmed on an invasive electrophysiological study are also uniformly accepted as indication for PM implantation. In case of an asymptomatic second-degree AV block or higher the ESC guidelines ask for the documentation of a pause >6 s, while the ACC/AHA/HRS guidelines state a pause >3 s in sinus rhythm or 5 s in atrial fibrillation is sufficient to warrant the implantation of a PM.

Conduction Disturbances

Since conduction disturbances are an electrocardiographic manifestation of infranodal disease, a combination of any second-degree AV block with conduction disturbances is considered an indication for the implantation of a PM. Asymptomatic alternating bundle branch block is also a clear PM indication. Finally, in case of syncope in patients with severe conduction disturbances on the surface ECG and either the exclusion of other causes or the demonstration of prolonged infranodal conduction on an invasive electrophysiological study, the implantation of a PM is indicated.

Choice of Device

It has been clearly shown that addition of leads adds significantly to the procedural risk of device implantations (Poole et al., 2010). It is therefore of utmost importance to choose the right hardware at the initial implantation: single-chamber pacemaker, dual-chamber pacemaker, and cardiac resynchronization pacemaker (**Fig. 1**).

This hardware can be programmed in different pacing modes. The pacing modes are described by a four-letter abbreviation. The first letter describes where the PM stimulates the heart (V = ventricle; A = atrium; D = dual). The second letter describes where the PM senses (V = ventricle; A = atrium; D = dual). The third letter describes what the PM does when it senses an intrinsic heartbeat (I = inhibit; T = trigger; D = dual). The fourth letter describes if the PM is programmed in a rate responsive mode (R = rate response). In this case the PM estimates the metabolic need of the patient using build in sensors and automatically increases the heart rate in case of a higher metabolic need. The most commonly used PM programming for single-chamber PMs is AAI (atrial based) or VVI (ventricular based) and DDD in dual-chamber or cardiac resynchronization PMs.

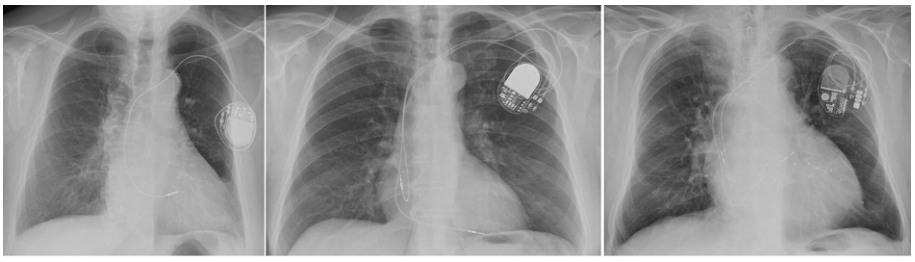

Fig. 1 Chest radiography of the different types of devices.

Single- vs. Dual-Chamber Pacing

It was presumed that physiologic AV sequential dual-chamber pacing (AAI or DDD) would have clear clinical advantages over single-chamber ventricular pacing (VVI). Initial results of Andersen et al. comparing single-chamber atrial (AAI) with single-chamber ventricular (VVI) pacing in 225 patients with sinus node disease showed a significant decrease in atrial fibrillation, stroke, and mortality (Andersen et al., 1994). The PASE trial moreover showed that quality of life was significantly better with physiologic pacing (Lamas et al., 1998). These results set the path for three large randomized clinical trials: CTOPP, MOST, and UKpace (Connolly et al., 2000; Lamas et al., 2002; Toff et al., 1997). The outcome was disappointing. The main results of these seminal trials are summarized in **Table 2**. None of the trials could show a mortality benefit of dual-chamber pacing, not even with an extended follow-up up to 6.4 years (Kerr et al., 2004). The individual patient data of these trials were bundled in one meta-analysis (Healey et al., 2006). There was statistical heterogeneity among the results of the individual trials. This meta-analysis confirmed that there was no effect on mortality (HR 0.95 (0.87–1.03); $P=0.19$) or heart failure (HR 0.89; (0.77–1.03); $P=0.15$) with physiologic pacing. There was however a significant reduction in atrial fibrillation (HR 0.80 (0.72–0.89); $P<0.001$) leading to a borderline significant reduction in stroke (HR 0.81 (0.67–0.99); $P=0.035$). There was no clear evidence that patients with sinus node disease would benefit more than patients with AV block. So compared with single-chamber ventricular pacing (VVI), dual-chamber physiologic pacing (AAI or DDD) does not improve survival or reduce heart failure, but it decreases the risk for atrial fibrillation and possibly stroke.

To further elucidate the perceived difference between the early positive experience with single-chamber atrial pacing (AAI) versus the disappointing results with mainly dual-chamber pacing (DDD) in these trials the DANPACE trial randomized 1415 patients with sinus node disease between AAIR and DDDR pacing (Nielsen et al., 2011). The primary endpoint was all-cause mortality. Secondary endpoints were similar as in the previous discussed trials and included atrial fibrillation, stroke, heart failure, but also the need for re-intervention. There was no difference in mortality (HR 1.06 (0.88–1.29); $P=0.53$). Surprisingly paroxysmal atrial fibrillation was increased with AAIR pacing (HR 1.27 (1.03–1.56); $P=0.024$). AAIR pacing was also associated with a significant increased necessity for re-intervention (HR 1.99 (1.53–2.59); $P=0.001$). There was no difference in the incidence of permanent atrial fibrillation, stroke, and heart failure between AAIR and DDDR. So DANPACE did not show a difference in all-cause mortality between AAIR and DDDR, but single-chamber atrial pacing was associated with an increased risk for paroxysmal atrial fibrillation and reoperation. The authors conclude that their findings support the routine use of DDDR pacing in patients with sinus node disease.

Dual-Chamber Pacing vs. Cardiac Resynchronization Therapy

Cardiac resynchronization therapy (CRT) has undoubtedly proven in patients with heart failure and severe conduction disturbances (LBBB and QRS >130 ms or all BBB and QRS >150 ms) that remain symptomatic despite adequate drug treatment, that is, increases quality of life, exercise capacity, and left ventricular ejection fraction and decreases hospitalizations for heart failure and mortality (Ponikowski et al., 2016).

This positive impact of CRT has fuelled the idea that CRT might replace dual-chamber pacing for a broader range of indications, which led to several randomized trials to broaden the indication of CRT to regular bradycardia-related indications for pacing. These focus on AV block-related indications, leading to a high necessity of possible detrimental right ventricular pacing.

In the small PREVENT-HF trial, 108 patients with AV block and expected high ($\geq$80%) pacing percentage were randomized between DDD and CRT pacing (Stockburger et al., 2011). The primary endpoint was echocardiographic remodeling as assessed by change in LV end-diastolic volume after 1 year. Secondary endpoints were other echocardiographic parameters but also a combination of heart failure-related events and cardiovascular hospitalizations. This trial however showed no significant difference in any of the predefined primary or secondary endpoints.

Despite these negative results the authors found their results encouraging and informative for the design of subsequent larger trials with a higher statistical power.

The larger BLOCK-HF trial randomized 691 patients with AV block and a left ventricular ejection fraction of 50% or less (Curtis et al., 2013). All patients received a CRT-P, but were programmed either to DDD or CRT pacing. The primary endpoint was all-cause mortality, heart failure requiring intravenous therapy, or increase $\geq$15% in the left ventricular end-systolic volume index. The average follow-up was just over 3 years. Patients programmed to CRT had a significantly lower incidence of the primary endpoint (HR 0.74 (0.60–0.90)). In a prespecified analysis, BLOCK-HF also examined functional outcomes, including quality of life (Curtis et al., 2016). CRT patients showed greater improvement in NYHA functional class, quality of life, and clinical composite score. Implantation was unsuccessful in 5.5% of patients (51/918) and CRT-related complications occurred in 6.4% of randomized patients. For patients with AV block and a left ventricular function <50%, in BLOCK-HF CRT not only reduces the risk of heart failure and mortality, but also leads to functional improvement. This however comes at the cost of an increased complication rate. Finally it is important to point out that 30% of patients in BLOCK-HF had an ejection fraction <35% and as such had a guideline-based indication for CRT (**Table 3**).

Another large trial BIOPACE randomized 1810 patients with AV block to DDD or CRT to determine if CRT could prevent the deleterious effects of RV pacing. The first results were presented in 2014, but the study has not been published (Blanc, 2014; Funck et al., 2006, 2014). During a follow-up of 5.6 years there was no difference in the composite primary endpoint of mortality and heart failure hospitalization. Up to 14% of CRT implants were unsuccessful in this study. The positive results of BLOCK-HF could not be confirmed by this first analysis of BIOPACE, but because the investigators saw a trend in favor of CRT (HR 0.87; $P=0.08$) to our knowledge the follow-up was extended. Although it seems attractive and there are some encouraging results, a preventive role of CRT to avoid the development of heart failure in patients with a conventional bradycardia-related PM indication remains controversial. The guidelines for now do not recommend routine use of CRT in AV block patients with an expected high percentage of right ventricular pacing, but certainly in patients with a decreased left ventricular function the advantages of a one-stage approach should be weighed against the possibility of upgrading in a second intervention.

Choice of Programming

AV Delay Management

The disappointing results of the trials comparing single chamber ventricular pacing with more physiologic atrial-based pacing raised the question if right ventricular pacing might be detrimental. This hypothesis gained evidence by a post hoc analysis of the CTOPP

Table 3 Complication rate of the different types of implantations in clinical trials

Trial	*VVI*	*DDD*	*CRT*
CTOPP	3.8%	9.0%

trial that evaluated if pacemaker-dependent patients, defined as having an unpaced heart rhythm ≤60 bpm, could have an increased benefit from physiological pacing compared with nonpacemaker-dependent patients, defined as having an unpaced heart rhythm >60 bpm (Tang et al., 2001). This analysis confirmed that the unpaced heart rhythm had an important influence on how pacing mode selection affected mortality. Also in MOST the effect of right ventricular pacing induced desynchronization was studied (Sweeney et al., 2003). This analysis revealed that patients were more frequently paced in the right ventricle in the DDD group compared with the VVI group (90% vs. 58%, $P=0.001$). The percentage of right ventricular pacing was a strongly associated with the risk for heart failure hospitalization and atrial fibrillation in both groups. Finally a defibrillator trial (The dual-chamber and VVI implantable defibrillator (DAVID) trial) in 506 patients (without a bradycardia-related PM indication) prospectively demonstrated a worse outcome of the composite endpoint of death or hospitalization for heart failure (HR 1.61 (1.06–2.44)) with DDDR at 70 bpm compared with VVI backup pacing at 40 bpm (Wilkoff et al., 2002). Pacing was more frequent in the DDDR group and the percentage RV pacing was correlated with the primary endpoint. In a subanalysis, the cut-off of right ventricular pacing resulting in the best prediction of endpoints was 40%, with patients with ≤40% pacing in DDDR having an equal outcome as patients in the VVI group (Sharma et al., 2005).

This notion that right ventricular pacing has harmful effects on ventricular function led to the development of different AV delay management (AVM) algorithms in modern pacemakers, developed to minimize right ventricular pacing. These algorithms are either based on prolongation of the AV delay or on AAI pacing with monitoring of the ventricular response and the possibility to switch from AAI to DDD pacing at the occurrence of second-degree AV block.

Several studies evaluated the effect of AVM. The SAVE PACE trial randomized 1065 patients with sinus node disease (Sweeney et al., 2007). The primary endpoint time to persistent atrial fibrillation developed in 12.7% in the conventional DDD pacing and 7.9% with AVM (HR 0.60 (0.41–0.88); $P=0.009$). The median percentage of ventricular pacing was significantly lower (9.1% vs. 99.0%) with AVM. These positive results could however not be confirmed in several more recent trials. The MINERVA trial randomized 1166 patients with tachy-brady syndrome, to conventional DDD pacing, AVM with or without atrial preventive pacing algorithms (Boriani et al., 2014). A combined endpoint of death, cardiovascular hospitalizations, or permanent AF, after 2 years of follow-up occurred in 26.5% with conventional pacing, 19.9% with AVM with atrial preventive pacing algorithms, and 21.4% with AVM only. Compared with conventional DDDR pacing, this was significant for the combination of AVM with atrial preventive pacing algorithms (HR=0.74 (0.55–0.9); $P=0.04$), but not for AVM only (HR 0.89 (0.77–1.03); $P=0.125$). The PREFER MVP trial compared DDD with and without AVM (Botto et al., 2014). A total of 605 patients were randomized, but no significant differences in the primary endpoint or cardiovascular hospitalization nor the secondary endpoint of atrial fibrillation were found, despite a clear reduction in right ventricular pacing percentage (5% vs. 86%; $P<0.001$). The ANSWER trial enrolled 650 patients between conventional DDD and AVM. AVM led to a significant decrease ventricular pacing (11.5% vs. 93.6%; $P<0.001$). No significant difference was found in the co-primary composite of hospitalization for HF, AF, or cardioversion (HR 0.78 (0.48–1.25); $P=0.30$), nor in the individual components. There was however a slightly significant reduction in the secondary combined endpoint of cardiac death or heart failure hospitalization (HR 0.49 (0.27–0.90); $P=0.02$).

The mixed results of these trials have to be interpreted carefully because they included different patient populations and the programming of the AV delay in conventional DDD was not uniform. It is clear that AVM decrease the percentage of right ventricular pacing and that this might reduce the risk for atrial fibrillation and heart failure, but the mixed results together with the previously discussed DANPACE trial make a strategy of avoiding right ventricular stimulation and allowing very long AV intervals highly controversial. Currently the optimal AVM strategy to optimize clinical outcomes remains unknown. Use of these algorithms may be not appropriate in patients in whom atrial pacing leads to a long first-degree AV block. How long is too long however is a matter of debate. The optimal AV delay varies individually, but varies up to 250 ms, a cut-off proposed also in HRS/ACCF Expert Consensus Statement on Pacemaker Device and Mode Selection (Strohmer et al., 2004; Gillis et al., 2012).

Rate Responsive Pacing

Patients with sinus node disease commonly have problems to adapt their heart rate to exercise. Antiarrhythmic drugs often exacerbate this chronotropic incompetence. All current PMs are equipped with sensor to estimate the metabolic need of the patients. These sensors are mainly based on three principles: motion detection, estimation of the respiratory rate, or estimation of the contractile force of the ventricle. The PMs have auto-adaptive software that can increase the paced rate in case of a higher metabolic demand. This rate adaptive pacing was used in most of the patients included in the trials comparing VVI/R with DDD/R pacing.

Over the short term, a benefit of rate adaptive pacing on exercise tolerance is reported, but the long-term benefit is the subject of debate (Abi-Samra et al., 2013; Coman et al., 2008; Duff et al., 2003; Lamas et al., 2007).

The large ADEPT trail was a single-blind randomized controlled trial comparing dual-chamber with rate-modulated dual-chamber pacing with the purpose to determine whether dual-chamber rate-modulated pacing improves quality of life (Lamas et al., 2007). The randomized patient cohort included 872 patients of which 64% had sinus node disease. Patients with DDDR reached a higher peak heart rate during exercise test at 6 months (DDD 113.3 ± 19.6 vs. DDD 101.1 ± 21.1; $P<.0001$), however total exercise time was not different. At 1 year, there were no significant differences in any quality-of-life assessment.

It is also not clear if any sensor technology has advantage over the other. This was tested in the MOST trial. In a selection of 1245 patients with three sensors (accelerometer, piezoelectric, and blended (ventilation rate and accelerometer)) the clinical characteristics and quality of life were followed during the trial (Shukla et al., 2005). A limitation is that since there was no randomization the clinical characteristics of the patients were not equally distributed. After a follow-up of almost 3 years mortality, heart failure hospitalization, atrial fibrillation, and the combined endpoint of mortality and stroke were not different between the sensor types, even after adjustment for baseline differences. Patients with blended sensors had worse physical function and quality of life. However, a selection bias cannot be ruled out. The most sophisticated sensors could have been used in the sickest patients.

Therefore rate adaptive pacing is recommended only for patients with symptomatic chronotropic incompetence and should be re-assessed every visit (Gillis et al., 2012). There seems no evidence one type of sensor is absolutely better than another, however there is some logic in using devices with two types of sensor in the more difficult patients to allow more means of fine-tuning.

Clinical Implications

When you consider implanting a device first make sure there is no indication for an implantable defibrillator (ICD) or CRT by taking into account the left ventricular ejection fraction, QRS-width, and the co-morbidity of the patient. In case of a left ventricular ejection fraction <35% or between 35% and 40% with nonsustained VT on monitoring there could be an indication for an ICD. In case of a left ventricular ejection fraction <35% and the intrinsic QRS width is broader 130 ms or the patient will be continuously paced, there could be an indication for CRT. As discussed previously if the EF is between 35% and 50% and you expect continuous right ventricular pacing in a patient with a good life expectancy the BLOCK-HF trial suggests that CRT might be an option as well.

If you decide to implant a PM you can use the algorithm of Fig. 2 as guidance. If the underlying rhythm is either permanent atrial fibrillation or there is a history of recurrent atrial arrhythmia treated with a rate control strategy, a single-chamber pacemaker is indicated. In case of symptomatic chronotropic incompetence, this should be programmed in VVIR, in the other case programming in VVI is sufficient. In case of sinus rhythm or recurrent atrial arrhythmia treated with a rhythm control

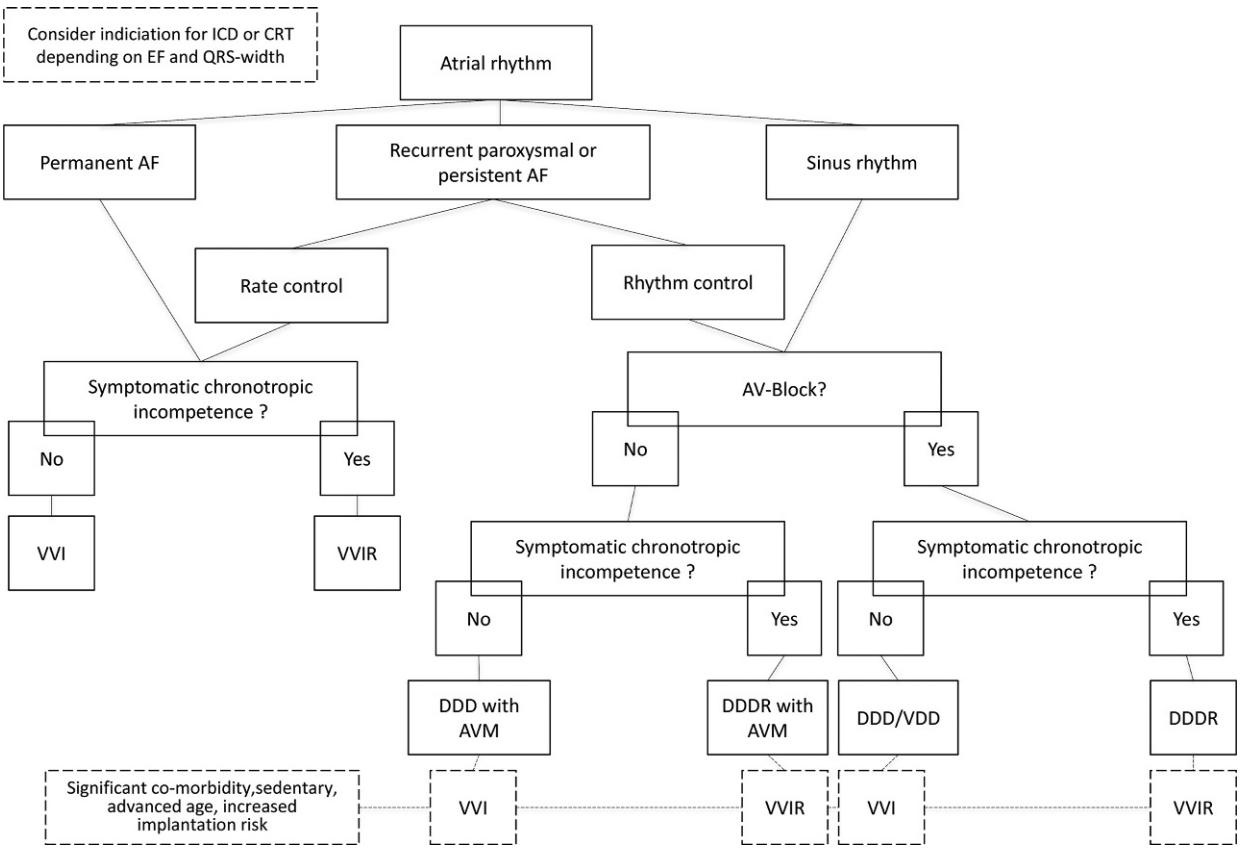

Fig. 2 Clinical decision algorithm.

strategy, a dual-chamber pacemaker is indicated. If there is underlying AV block depending on the presence of concomitant sinus node disease, the best programming is DDD (normal sinus node function) or DDDR (symptomatic chronotropic incompetence). If there is no problem with AV nodal conduction DDD or DDDR with AVM to minimize right ventricular pacing is indicated. In case of frail elderly sedentary patients or increased implantation risk (e.g., patients on hemodialysis, re-implantation post infection, and venous obstruction) cross over to single-chamber pacing always seems warranted in view of the equal mortality between both options.

Introduction to iPSCs

Pluripotency is the ability to give rise to all cell types that comprise the organism (except placental cells, which necessitates totipotency) with unlimited potential for self-renewal. Embryonic stem cells have this innate characteristic, but over the past 10 years, scientists have unraveled a mechanism to coax fully differentiated somatic cells back to their precursor states.

The origins of induced pluripotent stem cells (iPSCs) began with Yamanaka and his team in 2006, who identified four crucial transcription factors, *Sox2*, *Oct4*, *Klf4*, *and c-Myc*, that were necessary and sufficient to induce pluripotency from murine fibroblasts, in turn generating the first set of iPSCs (Takahashi et al., 2006). Within a year of their discovery, Yamanaka had successfully generated iPSCs from primary human somatic cells (Takahashi et al., 2007).

These versatile cells have the added benefit of being manipulated and propagated without the ethical concerns surrounding the use of embryonic stem cells. The notion of isolating human cells from anywhere in the body, then reconditioning them to a more primitive, labile state, and, finally, diverting them to a new lineage provide ample opportunity to study diseases with tropisms for specific cell types as well as detecting underlying molecular markers of disease.

The potential of hiPSCs is immense, but the technology is still far from perfect, with several prominent barriers before they can be routinely integrated into human clinical trials. In 2014, the first iPSC clinical trial led by Dr. Takahashi involved transplantation of patient-derived retinal pigment epithelial cells (RPC) to treat age-related macular degeneration (Kimbrel and Lanza, 2015). However, the trial was put on hiatus in 2015 after the discovery of six genetic mutations in the first patient's iPSCs with concern for tumorigenesis prior to transplantation into a second patient (Trounson and DeWitt, 2016). In June 2016, the trials were given the green light to resume after further investigations and regulatory changes (Scudellari, 2016).

The utility of iPSCs stems from their in vitro versatility and in vivo applicability. They serve as excellent models of heritable and inducible disease states, functional platforms for gene-editing innovation (especially in the wake of CRISPR-Cas9 technology), and are safe surrogates for drug testing that help bridge the translational divide from bench to bedside.

The Role of iPSCs in Cardiovascular Research

Heart disease is the leading cause of death in the United States (Roth et al., 2015). Because cardiac myocytes have severely limited capacity for regeneration and self-renewal, dying cardiomyocytes (CMs) due to ischemic injury or aging are replaced by scar tissue, leading to worsening heart function and ultimately death (Chin and Murry, 2012). A smaller subset of heart diseases involves inherited conditions in which typically young patient populations present with potentially fatal arrhythmias or heart failure (Watkins et al., 2011). For many with advanced heart failure, there is no definitive treatment besides heart transplantation. While early enthusiasm for human iPSCs involved their potential in cell therapies for heart diseases, these efforts are still years away from human trials. By contrast, human iPSCs have already had a major impact in the study of human heart diseases (Karakikes et al., 2014).

Traditionally, the study of human heart diseases has been hampered by the extremely limited access to live human heart tissues. Moreover, while animal models have been extremely helpful, they have important species differences, and CMs isolated from adult animals are highly catabolic (Louch et al., 2011), making them less than ideal as an in vitro model. Therefore, there has been tremendous interest and effort in developing patient-specific iPSC-derived cardiomyocytes (hiPSC-CMs) as an in vitro platform to study human heart diseases.

Generating Cardiomyocytes From Human iPSCs

There are a number of differentiation protocols for generating CMs from human iPSCs. For instance, Kattman et al. found that robust differentiation of hiPSCs to CMs depended on conditions that recapitulated key commitment points in embryonic heart development (Kattman et al., 2011). This initially involved modulation of Activin A/TGF-beta superfamily signaling, which in turn modulated the Wnt signaling pathway (Wang et al., 2014b). Today, the most widely utilized cardiac induction protocols involve sequential activation and inhibition of the canonical Wnt signaling pathway (Lian et al., 2013; Burridge et al., 2014). With the use of small molecule Wnt pathway modulators, chemical defined media, and metabolic selection (Burridge et al., 2014), highly purified populations of hiPSC-derived cardiomyocytes (hiPSC-CMs) can now be routinely generated in large quantities from virtually all iPSC lines.

Despite rapid advances in the field, a major hurdle remains the immaturity of hiPSC- CMs. For instance, hiPSC-CMs generated by most methods are small and circular, and express the fetal isoform of troponin (Yang et al., 2014). Moreover, hiPSC-CMs often display weak contractile properties and are unable to respond appropriately to adrenergic stimulation. This contrasts with adult CMs, which are larger and rod-shaped, and exhibit robust contraction and cell shortening (Lundy et al., 2013). Therefore, a number of approaches involving tissue engineering, biomaterials, mechanical loading, and electric stimulation have been utilized to promote hiPSC-CM maturation (Yang et al., 2014; Chun et al., 2015). Recently, Feaster et al found that hiPSC-CMs plated on an undiluted Matrigel of at least 0.4 mm in thickness, termed a "Matrigel Mattress," elongated into a rod-like shape and exhibited robust cell shortening, a phenomenon that was not observed previously (**Fig. 1**) (Feaster et al., 2015). In addition, hiPSC-CMs plated on the Matrigel Mattress adopted more mature characteristics and exhibited contractile properties akin to acutely isolated rabbit and mouse CMs. Moreover, these Mattress hiPSC-CMs exhibited the intracellular calcium handling and electrophysiological properties similar to that of adult CMs, and expressed mature CM molecular markers with reduced fetal markers. Innovations such as these toward the development of hiPSC-CM models that faithfully recapitulate characteristics of native human adult CMs represent a significant step toward utilizing these cells as a valuable platform for human heart disease modeling, drug testing, and regenerative therapies (**Fig. 2**).

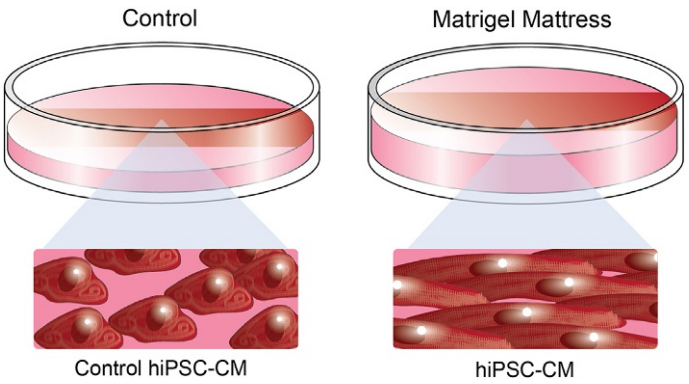

Fig. 1 hiPSC-CMs plated on the Matrigel Mattress recapitulates adult cardiomyocyte properties. Seeding of hiPSC-CMs on undiluted Matrigel promotes elongation and contractile shortening when compared to hiPSC-CMs plated using standard substrate (control).

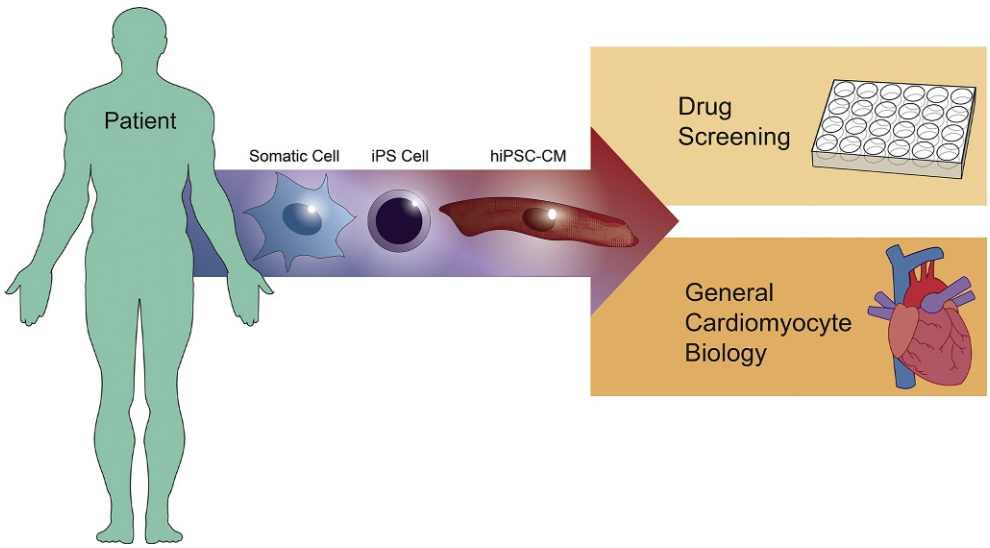

Fig. 2 Patient-derived iPSCs enable in vitro and in vivo applications of hiPSC-CMs in drug discovery and cardiomyocyte biology. HiPSCs can be generated from human somatic cells. HiPSCs can be differentiated into hiPSC-CMs for drug discovery for toxicity and drug efficacy. HiPSC-CMs can also be used for disease modeling and general cardiomyocyte physiology.

Modeling Human Diseases With iPSC-Derived Cardiomyocytes

Among the earliest efforts to use patient-specific iPSC-derived CMs involved the study of inherited arrhythmias caused by specific gene mutations. In one such condition named congenital long QT syndrome, patients present with markedly prolonged QT intervals on electrocardiograms and delayed repolarization, which predisposes them to sudden cardiac death from ventricular tachyarrhythmias such as *torsades de pointes* (Roden, 2008). For instance, CMs derived from a patient with type-1 long QT syndrome (LQTS1), associated with a mutation in the *KCNQ1*, which encodes a subunit of the voltage-gated potassium channel involved in action potential termination, recapitulated the electrophysiological features of the disorder, including the diminution in I(Ks) potassium current and susceptibility to catecholamine-induced tachyarrhythmia (Moretti et al., 2010). Similarly, hiPSC-CMs from patients with type-2 long QT syndrome (LQTS2), associated with a mutation in KCNH2, which encodes another voltage-gated potassium channel, recapitulated the electrical derangements, including propensity for early–after depolarization triggered arrhythmias that is aggravated by potassium-channel blockers (Itzhaki et al., 2011).

In addition, hiPSC-CMs from patients with familial hypertrophic cardiomyopathy (HCM), an autosomal-dominant disorder of the cardiac sarcomere associated with left ventricular wall thickening and predisposition to arrhythmias and sudden cardiac death, recapitulated many of the hallmarks of HCM in vitro (Lan et al., 2013). Patient-specific hiPSC-CMs carrying the missense mutation in the *MYH7* gene, encoding the beta-myosin heavy chain, exhibited cellular hypertrophy, sarcomere disarray, contractile arrhythmias, and abnormal calcium handling. Furthermore, the team investigated the role of calcium dysregulation in the progression of disease and found that treating these CMs with calcium inhibition significantly mitigated the disease phenotype and reduced electrophysiological irregularities.

Patient-derived iPSC-CMs have been used to model familial dilated cardiomyopathy (DCM), in which the heart chamber becomes enlarged along with the loss of contractile function. For instance, Sun et al. demonstrated that hiPSC-CMs from patients with a point mutation in the gene encoding sarcomeric protein troponin T exhibited altered calcium regulation, decreased contractility, and abnormal sarcomere structure (Sun et al., 2012). Interestingly, just as seen in DCM patients, beta-adrenergic stimulation of mutant hiPSC-CMs exacerbated these abnormalities, while beta-adrenergic blockade improved cardiac function. Recently, Hinson et al. generated hiPSCs from familial DCM patients with a titin-truncating variant, which as a group is thought to be the most common genetic cause of DCM, and demonstrated poor sarcomere contractile performance in their engineered microtissue model (Hinson et al., 2015). Besides these studies, patient-derived hiPSCs have provided important pathophysiologic insights into many other inherited heart diseases, including the mitochondrial cardiomyopathy of Barth syndrome (Wang et al., 2014a), the metabolic derangements of arrhythmogenic right ventricular cardiomyopathy (Kim et al., 2013), abnormal TGF-β signaling in left ventricular noncompaction cardiomyopathy (Kodo et al., 2016), and aberrant AMP-activated kinase signaling in PRKAG2 cardiomyopathy (Hinson et al., 2016), just to name a few.

Drug Discovery, Efficacy, and Toxicity in Cardiovascular Medicine

Drug discovery is an integral aspect of translational medicine that applies basic science understanding of disease physiology to pharmaceutical outcomes. In the broadest sense, there are two major routes for drug discovery—phenotypic and target-based screening (Swinney and Anthony, 2011). Phenotypic screening involves evaluating the effects of a candidate molecule on phenotypes of a biological system. For millennia, this was the primary route of drug discovery that relied on serendipitous observations. With advances in cellular and molecular technologies, target-based screening, which entails high-throughput screens for hits that modulate a target, came to the forefront. The compounds that perturbed the target of interest would then be further evaluated for desired effects in in vitro and in vivo studies. While target-based screening has been the dominant paradigm for decades, in recent years, there has been a revival in phenotypic screening (Wagner, 2016). The iPSC technology dovetails nicely with this trend.

The versatility of iPSCs has already proven fruitful in evaluating potential cardiovascular therapeutics. Catecholaminergic polymorphic ventricular tachycardia (CPVT) is an inherited rhythm disorder characterized by potentially fatal ventricular arrhythmias that manifest during high adrenergic, or stressful, states in otherwise healthy adults with structurally normal hearts. The disease is caused by autosomal-dominant mutations in *RYR2*, which encodes the cardiac ryanodine receptor (CPVT-1), or by recessive mutations in calsequestrin, a calcium-binding protein in the sarcoplasmic reticulum (CPVT-2) (Napolitano et al., 1993). Both are sarcoplasmic reticulum proteins that control CM contractility by regulating calcium cycling within the CM, and mutations that disrupt them result in the loss of calcium regulation, reduced myocyte electrical stability, and a predisposition to ventricular tachyarrhythmias under catecholaminergic states. Jung et al. discovered that Dantrolene, a muscle relaxant that binds to ryanodine receptors and inhibits calcium release from the sarcoplasmic reticulum, reduced the arrhythmogenic potential of CPVT-1 iPSC CMs harboring a mutation in the *RYR2* gene (Jung et al., 2012). In the hiPSC-CM model of LQTS2 mentioned above, the calcium channel blocker Nifedipine and the potassium channel opener Pinacidil markedly reduced early–after depolarizations, correcting the underlying pathology that predisposes these patients to life-threatening arrhythmias (Itzhaki et al., 2011).

While it is important to recognize the potential of hiPSC-CMs on guiding cardiovascular drug discovery and contributing to proof-of-principle models for certain monogenic disorders, it is also important to acknowledge current limitations. Many in vitro experiments are conducted in controlled, single, immature CM settings and do not take into consideration the multicellular and organ system interactions that would be present on an organismal level. The single cell cardiac models may not adequately reproduce the contractile dynamics observed in mice or human hearts experiencing daily alterations in the level of adrenergic innervation and suppression (Garbern et al., 2013). Technical variability that arises during differentiation may also mask true pathologic differences among CMs and blur the lines between medication efficacy and individual variation, especially in sporadic diseases that have poorly characterized baselines.

Drug development is a highly risky and costly endeavor. Unforeseen adverse outcomes, especially during late-stage clinical trials, can derail a multibillion dollar effort. Certain medications, especially cytotoxic chemotherapeutic agents with a proclivity for accumulating in metabolically active tissues, are notorious for contributing to heart disease and heart failure. For example, many cancer survivors previously treated with anthracyclines such as Doxorubicin go on to develop heart failure. Burridge et al. used hiPSC-CMs from breast cancer patients who developed cardiomyopathy following Doxorubicin therapy to demonstrate that patient-derived hiPSC-CMs reproducibly elicited Doxorubicin-induced injury responses, including decreased cellular viability and increased production of reactive oxygen species, in contrast to healthy control cells (Burridge et al., 2016). Tyrosine kinase inhibitors (TKIs) are another class of anticancer agents that have also been implicated in cardiovascular toxicities, including arrhythmias and heart failure. Using hiPSC-CMs, hiPSC-derived endothelial cells, and hiPSC-derived cardiac fibroblasts, Sharma et al. carried out a high-throughput screen of FDA-approved TKIs and found that VEGFR2/PDGFR-inhibiting TKIs were associated with cardiotoxicity in this model (Sharma et al., 2017). Interestingly, they also identified insulin and insulin-like growth factor (IGF) signaling as cardioprotective signaling mechanisms that could alleviate TKI-mediated cardiotoxicity. Thus, in addition to modeling disease phenotypes, hiPSC-CMs also serve as effective platforms for investigating collateral effects of novel therapeutic compounds.

The most feared, though rare, cardiotoxicity of a drug is QT prolongation, which may progress to potentially fatal *torsades de pointes* (Fermini and Fossa, 2003). The drug-induced QT prolongation is typically brought about by inhibition of delayed rectifier potassium channels, the alpha subunit of which is encoded by the hERG/KCNH2 gene, which causes LQT2 (Yu et al., 2015). Several drugs, which cause QT prolongation/*torsades de pointes*, have been withdrawn from the market, while others have garnered black box warnings, which preclude use by many patients who would otherwise benefit from these medications.

Presently, assays involving whole heart specimens or tissue slices as well as animal testing are the gold standard in industry testing prior to human clinical trials. Early screening of cardiotoxicity is still heavily reliant upon single channel hERG models expressed within cell lines such as Chinese hamster oocytes (CHO) or human epithelial kidney cells (HEK). The screening of proarrhythmic drug effects can be simulated through patch-clamp trials, which involve electrophysiological measurements of current passing through hERG channel before and after the additional of the compound being tested (Yao et al., 2008).

Implementation of hiPSC-CMs to assess cardiotoxicity of drugs offers several potential benefits. In principle, cells from patients who developed drug-induced arrhythmias may provide a greater sensitivity for detecting potential proarrhythmic drugs as well as greater negative predictive value. Several groups have now developed an iPSC-based approach using a panel of cells from subjects with a range of susceptibility to drug challenge, including those with extremely low or high changes in cardiac repolarization in response to Sotalol challenge (Stillitano et al., 2017) as well subjects with specific inherited cardiomyopathies, such as LQTS and familial HCM (Liang et al., 2013). These studies showed that hiPSC-CMs from healthy and diseased patients exhibited different susceptibilities to cardiotoxic drugs and their use accurately modeled drug-induced proarrhythmic responses compared to the traditional hERG inhibition assay.

Precision Medicine and Personalized Therapies

While much of the focus has been on the deployment of hiPSCs for modeling heart diseases and for screening and testing new drugs, the application of hiPSCs in cell replacement therapy remains an exciting, albeit formidable, next frontier. Generation of virtually any cell or tissue type from hiPSCs on a large scale seems well within the horizon, and the use of healthy hiPSC-derived tissues to replace those lost or injured has tremendous medical implications. Currently, the only definitive therapy for end-stage heart failure is heart transplantation (Katz et al., 2015). However, given the dearth of available donor hearts and the extraordinary skills and resources required, transplantation cannot hope to meet the ever-growing demand. In this light, autologous, or patient-specific, hiPSC-CM may 1 day serve as an alternative to orthotopic heart transplantation. Recent studies involving the transplantation of hiPSC-CMs encapsulated in hydrogel or in cardiac "patches" or sheets have shown promise in rodent models (Wang et al., 2015; Wendel et al., 2015; Kawamura et al., 2012). In these studies, hiPSC-CM transplantation tissue engraftment significantly improved cardiac function and reduced left ventricular remodeling. However, it is worth noting that the long-term survival of these transplanted cells was very small, despite still being able to be detected after 8 weeks (Kawamura et al., 2012). Recently, Shiba et al. carried out an allogeneic transplant of MHC-matched primate iPSC-CMs into the heart of monkeys that were subjected to myocardial infarction (Shiba et al., 2016). The iPSC-treated monkeys had improved cardiac function at 4- and 12-week of transplantation, and grafted cells survived for 12 weeks, showing electric coupling to the host CMs. Similarly, Murry and colleagues

introduced human embryonic stem cell–derived cardiomyocytes (hESC-CMs) via intramyocardial injection to monkeys that were subjected to myocardial ischemia–reperfusion injury. The donor cells had complete electrical coupling to the recipient primate hearts and significantly remuscularized the infarcted monkey hearts (Chong et al., 2014). In contrast to small animal studies, nonfatal ventricular arrhythmias are noted in the primate studies, indicating that additional efforts are needed to minimize posttransplant arrhythmic complications.

These myocardial cell transplantation experiments, particularly those in primates, provide proofs-of-principle that much of the logistic challenges of cell manufacturing and delivery can be overcome. Nevertheless, the long-term durability of engraftment and beneficial effects remain unknown and continue to be an ongoing challenge. Allogeneic cell transplants or tissue grafts will carry the attendant risk of rejection despite optimal immunosuppression. Given this concern, autologous hiPSCs may become a mainstay of truly personalized therapy for regenerating myocardium. However, even autologous hiPSCs, from epigenetic and genetic changes incurred during reprogramming and culturing, have been found to incite an immune response that could lead to rejection (Scheiner et al., 2014).

Until the effectiveness of generating and maintaining hiPSCs improves to the point where the associated costs are greatly reduced, the use of allogeneic donor hiPSCs on multiple patients with immunosuppression may be more practical. With recent revolution in the CRISPR/Cas9 gene-editing technology, it may soon be possible to design a universal donor hiPSC line with modified human leukocyte antigen (HLA) genes that can overcome the immune (Riolobos et al., 2013).

In January of 2016, President Obama announced the Precision Medicine Initiative (PMI), the fundamental goal of which is to develop preventative and treatment regimens that account for phenotypic variations within the general population. Individual genetic composition and environmental differences can account for variations in responsiveness among individuals to disease therapies. The PMI strives to identify these interindividual discrepancies in order to develop patient-specific treatments. In principle, patient-derived hiPSCs offer an unlimited source of cells and tissues with patient-specific disease susceptibilities and treatment responses, which may better predict a patient's individual response in the clinical setting (Karakikes et al., 2015).

Future Directions

Although iPSCs have tremendous potential in the field of personalized and regenerative medicine, there are currently a number of obstacles to their widespread use in the clinic. Concerns regarding mutagenesis and tumorigenic potential of hiPSCs must be thoroughly addressed (Ghosh et al., 2011). An obvious solution is to fully differentiate iPSCs into tissue cells prior to transplantation, but even then, there still exists more than a trivial risk of transformation of trace undifferentiated iPSCs into malignant cells or teratomas. In addition, since each of the reprogramming factors Oct4, Sox2, Klf4, and c-Myc is associated with oncogenesis (Kumar et al., 2012; Lundberg et al., 2016; Yu et al., 2011; Miller et al., 2012), research is ongoing to identify induction factors that are less carcinogenic, to streamline the number of factors required to achieve pluripotency, and to develop ways to completely eliminate exogenous DNA once the somatic cell has been reprogrammed (Medvedev et al., 2010). Low efficiency and slowness of the reprogramming process are other hurdles to a widespread implementation of the iPSC technology (Medvedev et al., 2010). In this light, several recent studies have shown that the use of small molecules that alter epigenetics through the modulation of histone methyltransferases, or histone deacetylases, can significantly increase reprogramming efficiency (Shi et al., 2008; Huangfu et al., 2008). Given the breathtakingly rapid advances in cellular reprogramming, directed differentiation, and genomic editing (Hajjar and Hulot, 2014), there is little doubt that these hurdles can be overcome in the near future. In summary, human iPSCs and hiPSC-CMs offer an unprecedented window to human heart disease pathogenesis and individualized response to therapy as well as the opportunity for transformative new therapies.

Introduction

Infective endocarditis (IE) is the infection of the endocardial surface of the heart, native valves, prosthetic valves, and indwelling cardiac devices. IE can result in injury to multiple organ systems of the body and is associated with high mortality and morbidity unless treated early and properly. IE was described as early as 16th century. In 1885, Sir William Osler described this disease as malignant endocarditis in Gulstonian lectures. (Osler, 1885) Since that time the pattern of this disease has continuously changed.

Epidemiology

Incidence

IE is a rare disease with annual incidence of about 3–11 patients per 100,000 population (Murdoch et al., 2009; Duval et al., 2012; Hoen et al., 2002; Pant et al., 2015). The incidence of IE has changed over the years. The incidence of IE from 1988 to 1990 in Philadelphia metropolitan area was approximately 11.6 cases per 100,000 person-years (Berlin et al., 1995). Between 2000 and 2011, the incidence of IE in the United States increased from 11 per 100,000 population to 15 per 100,000 population (Pant et al., 2015).

Risk Factors

The risk factors for the disease vary worldwide. Access to healthcare, living conditions, migration of population, development of antibiotics, and advances in therapy has created ever changing epidemiology of IE. The epidemiology in low and high income countries was similar during the early antibiotic age and has changed since then (Yew and Murdoch, 2012). In developing countries, rheumatic heart disease (RHD) still remains as the major risk factor and is responsible for about two-thirds of the cases (Yew and Murdoch, 2012). RHD is predominantly caused by group A streptococcus from a preceding respiratory infection and patients are typically younger. In the developed countries, RHD contributes to <5% cases, and the most common heart disease associated with IE is degenerative valve disease (Murdoch et al., 2009). Prosthetic valve was a predisposing condition in 22.2% of the patients with IE, while implanted devices such as permanent pacemakers and implantable cardioverter-defibrillators (ICD) were implicated in 11% of the cases (Murdoch et al., 2009). Other predisposing causes of IE are congenital heart disease, intravenous drug use, diabetes, and cancer.

Age

The mean age of patients with IE has also changed significantly overtime. Historic data from John Hopkins Hospital showed the median age of patients with IE was <30 years in 1926 (Thayer, 1926). Patients with IE appear to be older in recent times, with the average age of patients was >70 years in 2001–2006, compared to mid-40s during the early 1980s (Correa de Sa et al., 2010).

This change in age at which IE presents is due to falling incidence of RHD in the economically developed world. RHD seen mostly in developing or undeveloped countries occurs primarily in younger age group, but even in those countries the incidence of degenerative valve disease is rising with increases in life expectancy.

Hospital acquired IE

Healthcare acquired IE accounts for 25%–30% of contemporary cohorts (Murdoch et al., 2009). Increase in the use of chronic indwelling intravenous lines and invasive procedures has led to increase in rates of staphylococcal bacteremia, which is a risk factor for IE (Lyytikäinen et al., 2005). Prosthetic valves and indwelling cardiac devices such as permanent pacemakers, ICD can also be a nidus for infection within the heart. As the rate of implantation of these devices increases, the burden of IE increases (Voigt et al., 2006; Greenspon et al., 2011). In a recent study of 2781 patients with definite IE, 20% of patients had a prosthetic valve and 7% of the patients had a cardiac device (Murdoch et al., 2009).

Congenital heart disease

Increased survival rate of patients with congenital heart disease has resulted in increases in IE in this population (Day et al., 2009). The overall incidence of IE in adults with congenital heart disease is 11 per 10,000 person-years (Verheugt et al., 2011). The most common conditions associated with IE among children with cyanotic congenital heart disease are endocardial cushion defect and left-sided lesions (Rushani et al., 2013). Cardiac surgery within 6 months of birth is associated with 5-fold increased risk for IE (Rushani et al., 2013). IE risk appears to be reduced after repair that leaves no residual shunt or prosthetic material, and the highest risk during follow up is found in patients with left-sided outflow obstruction (Morris et al., 1998). In the cohort mentioned earlier (Murdoch et al., 2009), congenital heart disease accounted for 12% of all patients with definite IE.

Other risk factors

Other risk factors include intravenous drug use, which results in blood stream seeding of skin flora and other contaminated organisms from the materials used for injection. Also, injection of particulate matter (e.g., talc, which may be present in drug solutions or introduced by intravenous injection of talc containing drugs intended for oral use) may cause valvular endothelial damage predisposing to infection. Poor dentition and dental infection are also thought of as risk factors for IE (Lockhart et al., 2009).

Microbiology

As the spectrum of risk factors has changed overtime, the microbiology has also changed. Staphylococcus and Streptococcus bacteria still account for majority of cases, although the proportion of these two organisms varies by region.

The increase in healthcare-associated IE has resulted in an increase in the incidence of *Staphylococcus aureus* (Federspiel et al., 2012) and coagulase-negative staphylococci (Duval et al., 2012) associated with IE. *Staphylococcus aureus* is the most common cause of IE in developed countries accounting for 30% of the cases (Murdoch et al., 2009; Selton-Suty et al., 2012).

Coagulase-negative Staphylococci are ubiquitous skin commensals and can colonize indwelling lines and devices. They are the most common cause of early prosthetic valve IE (López et al., 2007) and frequently noted in hospital-acquired native valve IE (Chu et al., 2008). These organisms are associated with biofilm production, high rates of abscess formation, and multiantibiotic resistance (Chu et al., 2009).

Enterococcus is now the third leading cause of IE (Pericas et al., 2015). It accounts for about 10% of cases of IE (Murdoch et al., 2009). Some recent data suggest that the frequency of Enterococcal IE is actually increasing, attributed to rise in hospital-associated infections caused by these organisms. Enterococcus spp. cause as much as 30% of hospital-acquired cases of IE (Giannitsioti et al., 2007). Two main species of Enteroccocus species *Enterococcus faecalis* and *Enterococcus faecium* account for most cases of IE in humans, *Enterococcus faecalis*, can cause both native valve and prosthetic valve IE in the elderly or chronically ill patients, and the vast majority of this species are still responsive to penicillin. On the other hand, *Enterococcus faecium* poses significant clinical challenge, and most clinical isolates in the United States are resistant to ampicillin and vancomycin. (Nigo et al., 2014)

With the decline in RHD, the proportion of *Streptococcus viridans* as a cause of IE has declined in developed countries (Duval et al., 2012), although it still remains the most common cause in developing and underdeveloped countries (Yew and Murdoch, 2012).

Other rare causes of IE are fastidious bacteria, zoonotic bacteria and fungi (Cahill and Prendergast, 2016), which are usually associated with healthcare (Morpeth et al., 2007; Baddley et al., 2008). These rare organisms vary significantly with geographical, epidemiological, and risk factors. Fastidious organisms include the HACEK bacteria (*Haemophilus*, *Aggregatibacter*, *Cardiobacterium*, *Eikenella corrodens*, *Kingella*), which account for about 3% of cases (Das et al., 1997; Fournier et al., 2010). Zoonotic IE is caused by *Coxiella burnetii* (*livestock contact*, *tick borne*), *Brucella* spp. (livestock, unpasteurized dailry products), *Bartonella henselae* (*cats*), and *Chlamydia psittaci* (*parrots*, *pigeons*). Other rare causes include Gram-negative bacteria (such as *Acinetobacter* spp., *Pseudomonas aeruginosa*), *Legionella* spp., *Mycoplasma* spp., and *Tropheryma whippelii* (Cahill and Prendergast, 2016; Holland et al., 2016; Brouqui and Raoult, 2001). Fungal endocarditis, usually caused by *Candida* or *Aspergillus*, is rare but is seen in patients with prosthetic valves who are immunosuppressed (Baddley et al., 2008).

About 10% of the cases have "blood culture negative" IE (Holland et al., 2016), most of which are due to patient receiving antibiotics before the culture. Fastidious organisms are difficult to isolate with traditional techniques. Specialized methods such as serological testing, histological examination, and polymerase chain reaction (PCR) using blood or valve biopsies can suggest a causative pathogen in up to 75% of these cases (Fournier et al., 2010).

Clinical Features

Clinical presentation of IE is often nonspecific, and this disease should be suspected in anyone presenting with fever with risk factors for IE. It can also present with complications arising from IE, especially stroke and systemic embolism. About 80%–90% of cases of IE have fever (Murdoch et al., 2009; Duval et al., 2012; Cahill and Prendergast, 2016). New murmur and worsening of a known murmur are reported in 48% and 20% of cases, respectively (Hoen and Duval, 2013). Less common presentations include hematuria (25% of cases), splenomegaly (11%), and splinter hemorrhages (8%). Janeway lesions, Roth's spots, and conjunctival hemorrhage are rare, presenting in 5% of cases. (Richet et al., 2008). Septic emboli can affect any organ system in the body and can present in several ways.

Cardiac manifestations include perforation of a valve leaflet or rupture of the papillary muscle, chordae tendineae, or the interventricular septum. Perivalvular abscesses and conduction abnormalities may result, especially with IE due to *Staphylococcus aureus*. Also, myocardial infarctions may occur as an embolic complication, especially in aortic-valve IE (Holland et al., 2016).

Neurologic manifestations arise most frequently due to cerebral emboli, clinically apparent in about 20%–30% of the people (Holland et al., 2016). The incidence of stroke in IE is 4.82 cases per 1,000 patient-days during the first week and declines quickly after initiation of antibiotics (Dickerman et al., 2007). Other complications include mycotic aneurysms formation, which tend to arise at bifurcation points, most commonly in the cerebral vessels, although almost any vascular bed can be affected.

Renal manifestations include infarction from a septic emboli, abscess, and immune complex glomerulonephritis. Renal biopsies performed during active IE are consistently abnormal, even if clinical renal disease is absent (Morel-Maroger et al., 1972).

Pulmonary manifestations include formation of septic pulmonary emboli from showering of emboli from the vegetation, which is more common in tricuspid valve IE. Pneumonia, pleural effusions, or empyema often accompany septic pulmonary emboli.

Other manifestations include petechiae, cutaneous infarcts, Osler's nodes (arteriolar intimal proliferation with extension to venules and capillaries), Janeway lesions (caused by septic emboli), and Roth spots in their eyes (immunological phenomena presenting as retinal hemorrhages with a pale centre). Also, direct bacteremic seeding of the eye may occur, causing endophthalmitis. Splenic infarcts may also be clinically occult, although splenic abscesses may develop which presents with pain, fever, and leukocytosis. Splenomegaly is found in about 10% of patients with IE (Murdoch et al., 2009) in the developed world, possibly due to prolonged immunological response.

Any patient with unexplained sepsis should be evaluated for IE, regardless of presentation. *Staphylococcus aureus* bacteremia is associated with IE in 25%–30% of cases, and all cases with *Staphylococcus aureus* bacteremia should undergo echocardiography (Fowler et al., 1997; Joseph et al., 2013).

Diagnosis

The diagnosis of IE is usually based on a combination of clinical, microbiologic, and echocardiographic findings. Any patient presenting with IE should undergo evaluation of risk factors such as previous IE, presence of prosthetic valve, valvular or congenital heart disease, intravenous drug use, indwelling intravenous lines and cardiac devices, immunosuppression, or a recent dental or surgical procedure. The Duke criteria have sensitivity and specificity of more than 80% and can aid in diagnosis along with clinical judgment (**Table 1**) (Li et al., 2000). According to the modified Duke criteria, definite IE is defined by pathologically proven IE or fulfillment of the clinical criteria (either two major criteria or one major and three minor criteria or five minor criteria) (Li et al., 2000). Possible IE is defined by either one major and one minor criteria or three minor criteria. Rejected IE is defined by firm alternative diagnosis, resolution of IE symptoms with antibiotic therapy for $\leq$4 days, no pathological evidence of IE at surgery or autopsy with antibiotic therapy for $\leq$4 days, or patient does not meet clinical criteria for possible IE (Li et al., 2000).

Identification of the microorganism with blood culture remains the mainstay in microbiological diagnosis. Three sets of blood cultures can identify organisms in 96%–98% of the cases and should be obtained before starting antibiotics (Lee et al., 2007). As mentioned earlier, 10% of the patients may have negative blood cultures. If blood cultures are negative for 5 days, risk factor-driven testing should be performed. Serological testing for coxiella, bartonella, brucella, mycoplasma, legionella, and chlamydia should be undertaken (Gould et al., 2012).

In blood culture-negative cases, molecular techniques may be helpful to identify the organism if the excised valve tissue is available. Broad range PCR combined with sequencing can identify specific organism (Goldenberger et al., 1997; Vondracek et al., 2011), and this can be helpful in patients with prior antibiotic exposure and with organisms difficult to culture. PCR combined with electrospray ionization mass spectrometry has been used recently to detect and characterize the amplified DNA and offers the possibility of direct detection of the organism from the tissue (Brinkman et al., 2013).

Routine laboratory investigations are usually nonspecific. Elevated inflammatory markers are detected in two-thirds of cases, and leukocytosis and anemia are noted in about half the cases (Murdoch et al., 2009; Crawford and Durack, 2003). Urinalysis may show

Table 1 Modified Duke clinical criteria for diagnosis of IE.

Major criteria

1. Positive blood cultures for one of the following:
   A. Typical microorganisms consistent with IE from two separate blood cultures:
   Staphylococcus aureus, Viridans streptococci, *Streptococcus gallolyticus*, HACEK organisms, Community-acquired enterococci, in the absence of a primary focus.
   B. Persistently positive blood culture for microorganisms consistent with IE:
      - At least two positive blood cultures from blood samples drawn >12 h apart
      - Three or a majority of ≥4 separate blood cultures positive >1 h apart
   C. Single positive blood culture for *Coxiella burnetii* or antiphase I IgG antibody titer >1:800
2. Evidence of endocardial involvement (one of the following):
   A. Echocardiogram positive for IE:
   Findings of oscillating intracardiac mass attached on a valve or on supporting structures, in the path of regurgitant jets, or on implanted material, in the absence of an alternative anatomic explanation) OR Abscess OR New partial dehiscence of prosthetic valve
   B. New valvular regurgitation

Minor criteria

1. Predisposing conditions such as intravenous drug use or presence of a predisposing heart condition
2. Fever: Temperature ≥38.0°C (100.4° F)
3. Vascular phenomena: Major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, or Janeway lesions
4. Immunologic phenomena: Glomerulonephritis, Osler nodes, Roth spots, or rheumatoid factor
5. Microbiologic evidence: Positive blood cultures that do not meet major criteria or serologic evidence of active infection with organism consistent with IE

Reproduced with permission from Oxford University Press: Li, J. S., Sexton, D. J., Mick, N., et al. (2000). *Clinical Infectious Diseases* 30, 633.

microscopic hematuria and occasionally red cell casts or pyuria (Cahill and Prendergast, 2016). New conduction abnormalities noted in EKG are suggestive of paravalvular or myocardial extension of IE (Meine et al., 2001).

Echocardiography plays a crucial role in the diagnosis of IE, detecting complications, assessing severity of lesions, and assessing underlying heart function. Transthoracic echocardiography (TTE) has 75% sensitivity and more than 90% specificity for detection of a vegetation (Habib et al., 2010). TTE is better than transesophageal echocardiography (TEE) for identifying prosthetic aortic valve abscess and to determine the hemodynamic consequences of valvular dysfunction (Hoen and Duval, 2013) (**Fig. 1**). TEE is recommended if the results of TTE are equivocal or negative and if there is high clinical suspicion for IE. TEE has higher sensitivity (more than 90%) compared to TTE and is superior in detection of complications such as abscess, leaflet perforation, and pseudoaneurysm, and should be done for most cases, even when the diagnosis of IE is already established by TTE (De Castro et al., 2000). A normal TEE favors ruling out IE; however it should be repeated in 7–10 days if clinical suspicion remains high. TEE should also be repeated if a complication is suspected and at the completion of therapy. In suspected cardiac device infection, TEE is the investigation of choice. Three-dimensional echocardiography is especially useful in assessment of paravalvular regurgitation, paravalvular abscess, valve perforation, and dehiscence and is helpful if providing a surgical view to aid in the surgical planning (Bruun et al., 2014) (**Fig. 2** and **3**).

There are few studies, which assess the utility of Cardiac CT, cardiac MRI, and ^{18}F-fluorodesoxyglucose (^{18}F-FDG) PET-CT in diagnosis of IE. Cardiac CT is useful in patients with extensive calcifications, perivalvular abscess, pseudoanuerysms, and also in prosthetic valve IE, which can produce acoustic shadowing in echocardiography; however, TEE is superior to CT in detecting smaller vegetations and valvular perforations. Cardiac CT is also useful in assessment of coronary anatomy before valve surgery, when cardiac catheterization carries a risk of producing septic embolism. Cardiac MRI has sensitivity of about 85% compared to

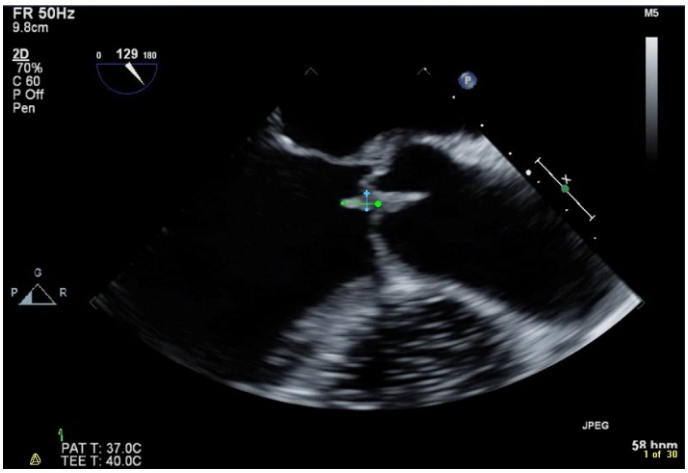

Fig. 1 TEE image of aortic valve vegetation. Differential diagnosis involves Lambl's excrescences/fibrous strands, tumor, or thrombi. Together clinical and echocardiographic characteristic often helps clinch accurate diagnosis and guide therapy.

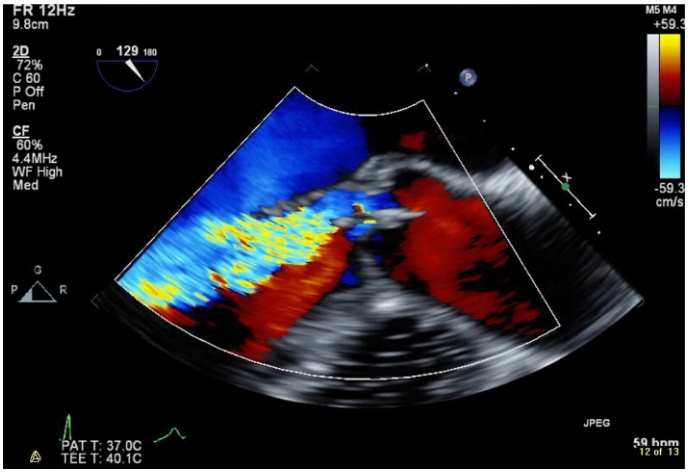

Fig. 2 TEE image showing valve perforation from aortic valve infective endocarditis. Valve perforation appears as an interruption in the tissue continuity (2-D echo) and often leads to eccentric regurgitation jet (color doppler).

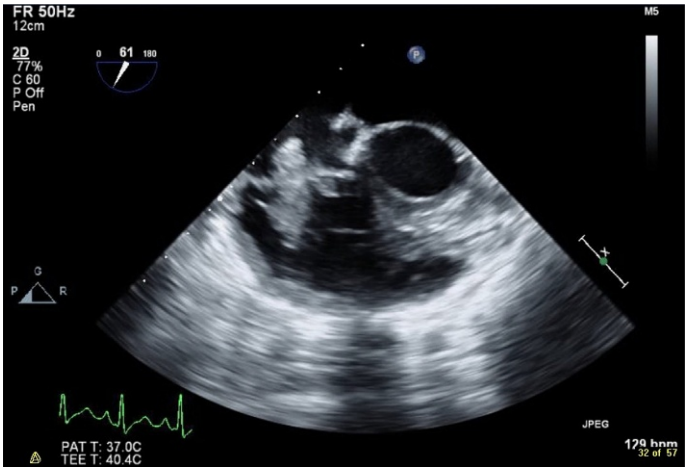

Fig. 3 TEE image shoeing tricuspid valve infective endocarditis. Usually occurs in intravenous drug users, device, or catheter. Valve destruction leading to significant tricuspid regurgitation and septic emboli to lungs are common complications and may lead to right heart failure.

echocardiography in detecting IE. Late gadolinium enhancement was noted in the perivalvular tissue in 43% of patients suggesting perivalvular extension even before abscess or fistula developed (Wong et al., 2016). Few reports have shown utility of ^{18}F-FDG PET-CT in diagnosis, mostly in prosthetic valve IE, even in some cases with negative TEE (Dickerman et al., 2007; Duval et al., 2012). An abnormal FDG uptake in PET-CT around a prosthetic valve, when added to the modified Duke criteria as a new major criterion, increases the sensitivity of diagnosis at admission from 70% to 97% (Wong et al., 2016). Its utility in native valve IE may be limited.

Management

Management of patient with IE should involve a multidisciplinary team comprising of cardiologists, cardiac surgeons, and infectious disease experts. Recent international working group recommendations emphasized the importance of the team approach (Chambers et al., 2014), and it has been shown that the team approach decreases 1-year mortality from 18.5% to 8.2% in IE (Botelho-Nevers et al., 2009). The cornerstone in treatment of IE includes prolonged antibiotic therapy to eradicate the causative organism and early surgery when indicated.

Antibiotic Therapy

Empiric antibiotics should be initiated as soon as the cultures are obtained. Empirical antibiotic regimens for native valve IE and prosthetic valve IE are based on established guidelines (Baddour et al., 2015) which are updated regularly. Choice of empiric therapy should depend on the most likely suspected pathogens. Ideal empiric therapy should cover Staphylococci (including

methicillin resistant, when suspected), Streptococci, and Enterococci. Vancomycin is an appropriate choice for initial therapy for most patients, and antibiotic regimen can be modified base on culture results, resistance patterns, infection severity, and the presence of prosthetic valves. It is reasonable to obtain repeat blood cultures 24–48 h apart until bacteremia resolves (Baddour et al., 2015). Duration of therapy depends on the pathogen, site of valvular infection, complications, and native or prosthetic valves. Duration of therapy should be counted from the first day of negative blood cultures. When valve replacement is performed, duration of antibiotics should remain the same as the duration of native valve IE, not prosthetic valve IE (Hoen and Duval, 2013).

Most viridans group Streptococci are highly penicillin susceptible. AHA guidelines recommend aqueous crystalline penicillin G or ceftriaxone for 4 weeks for viridans and bovis strains of Streptococci IE. The duration can be reduced to 2 weeks if combination therapy is used with gentamycin plus either aqueous crystalline penicillin G or ceftriaxone (Baddour et al., 2015). For viridans and bovis strains of Streptococci relatively resistant to penicillin G (defined by AHA as MIC >0.12 mcg/mL and <0.5 mcg/mL), the recommendation is aqueous penicillin G for 4 weeks with gentamycin added to the first 2 weeks of therapy. Ceftriaxone can be used as monotherapy if susceptible. Vancomycin is a reasonable alternative for patients with beta lactam allergy (Baddour et al., 2015).

Enterococcus exhibits narrow spectrum of susceptibility. Whenever the strain exhibit high level of resistance to gentamycin, it should be used in combination with other antibiotics. The AHA guidelines recommend that *Enterococcus faecalis* with typical low-level penicillin resistance should be treated with combination therapy with penicillin/ampicillin plus gentamicin for 4–6 weeks, or ceftriaxone plus ampicillin for 6 weeks, and for beta lactam allergic patients, vancomycin plus gentamicin for 6 weeks. Vancomycin-resistant enterococcal IE is rare and is treated with linezolid (Falagas et al., 2006) and daptomycin (Kullar et al., 2013) for more than 6 weeks (Baddour et al., 2015).

Staphylococcal endocarditis treatment is dependent on multiple factors including susceptibility, and type and location of the valve. Treatment for native valve IE due to methicillin-susceptible *Staphylococcus aureus* consists of a semisynthetic penicillin, such as nafcillin or oxacillin or flucloxacillin for 6 weeks. Gentamycin is not indicated for Staphylococcal native valve IE as there is no evidence of clinical benefit and there is a risk of nephrotoxicity (Cosgrove et al., 2009). Native valve IE due to methicillin-resistant *Staphylococcus aureus* (MRSA) and coagulase-negative staphylococci should be treated with vancomycin for 6 weeks.

Other organisms like HACEK organisms are treated with ceftriaxone, ampicillin (if organism is susceptible), or ciprofloxacin for 4 weeks (Baddour et al., 2015). Fungal IE is rare and outcomes are poor. Treatment of fungal IE consists of antifungal therapy and valve replacement. After initial therapy with amphotericin or an echinocandin, indefinite azole therapy is recommended, especially when valve surgery is not performed (Cornely et al., 2012).

Culture-negative IE is difficult to manage. Apart from patients receiving antibiotics before culture and inadequate microbiological technique, the most common cause of culture negativity is fastidious organisms. Empiric therapy should cover both Gram-positive and Gram-negative organisms. According to AHA guidelines (Baddour et al., 2015), in patient with acute clinical presentation (days), initial empiric therapy should include vancomycin and cefepime. For patient with subacute presentation (weeks), initial therapy should include vancomycin and ampicillin–sulbactam. This regimen can be modified for individual patient circumstances.

Prosthetic valve infective endocarditis (PVIE) is a serious infection which can occur early or late after surgery (**Fig. 4**). Most common pathogens in early PVIE are *Staphylococcus aureus* and coagulase-negative staphylococci, while streptococci and *Staphylococcus aureus* are frequently encountered in late PVIE (Wang et al., 2007). No randomized-controlled trials have assessed the optimal duration of antibiotics for PVIE. AHA guidelines recommend PVIE should be treated with bactericidal agents against the isolated microorganism for at least 6 weeks. Implantable device (pacemakers and defibrillators) infection can occur with or without associated valvular IE and the complete device and lead explanation is recommended (Baddour et al., 2010).

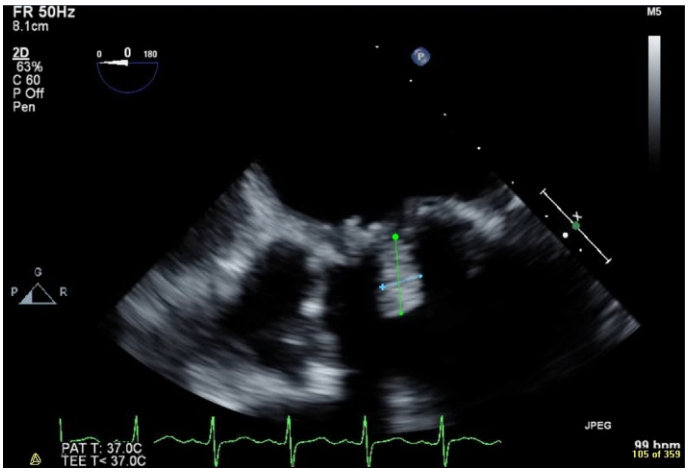

Fig. 4 TEE image showing Infective endocarditis of prosthetic mitral valve. Prosthetic valve endocarditis is a life-threatening condition and is associated with poor prognosis. It is difficult to detect on transthoracic echo, and TEE is indicated if there is clinical suspicion. Suture material or patch may mimic prosthetic valve endocarditis.

Surgery

The rate of early valve repair or replacement has increased over the last 30 years to about 50% (Murdoch et al., 2009). Main indications for early surgery include valve dysfunction leading to heart failure, paravalvular extension of the infection, uncontrolled or persistent infection, and prevention of embolism (Baddour et al., 2015). The criteria for prevention of emboli include patients presenting with recurrent emboli and persistent or enlarging vegetations despite appropriate antibiotic therapy or mobile vegetations >10 mm associated with severe valve regurgitation or involvement of anterior mitral leaflet (Joseph et al., 2013). Surgery is not contraindicated after ischemic stroke as long as cerebral hemorrhage has been ruled out by cerebral imaging (Habib et al., 2009).

Despite advances in diagnosis and management in recent year, the mortality rate for IE patients still remain high at around 15%–20% (Murdoch et al., 2009).

Prevention

Use of antibiotic prophylaxis for prevention of IE is based on expert opinion rather than data from clinical trials. The 2007 AHA guideline for the prevention of IE made major revisions to the previous 1997 AHA guidelines. The new guidelines recommend antibiotic prophylaxis only for patients who have a prosthetic valve, a history of IE, or unrepaired cyanotic congenital heart disease and who are planning to undergo an invasive dental procedure. Prophylaxis is no longer recommended for gastrointestinal or genitourinary procedures (Wilson et al., 2007).

Background

Inflammatory aortitis is a term which encompasses a number of disease processes of both infectious and noninfectious etiology. Quite literally, aortitis means inflammation of the aorta. While aortic inflammation may occur in response to any injury, including trauma, the most well-described causes are infectious in nature or secondary to underlying vasculitis, such as giant cell arteritis (GCA) and Takayasu arteritis (TA). Aortitis can cause aortic dilatation, resulting in aortic valve insufficiency and it has become an uncommon but increasingly recognized cause of abdominal aortic aneurysms and dissections. In addition, it can also cause fibrous thickening and ostial stenosis of major aortic branches. This can lead to end-organ ischemia with important clinical complications.

Inflammatory aortitis is a rare, but potentially life-threatening disorder with a highly variable clinical presentation (Gornik and Creager, 2008).

Epidemiology

The epidemiology of aortitis is poorly classified (Gornik and Creager, 2008). In the United States and Europe, the incidence of inflammatory aortitis is said to be 1–3 new cases per year per one million populations. This number is likely higher as many cases are incidentally identified at the time of histopathologic examination following surgery for aortic aneurysms, suggesting that many cases go unreported.

The most common causes of inflammatory aortitis have been well described (**Table 1**). Giant cell arteritis (GCA) is the most common form of vasculitis among elderly with a reported yearly incidence of 18.8 cases per 100,000 adult males aged 50 or older and this is said to be two-fold higher among females (Espitia et al., 2016; Hall et al., 1985). Worldwide, the greatest prevalence of vasculitis is among Asians. One survey of Japanese hospitals determined an incidence of 1 case per million children per year. Another study conducted in Japan in 1984 identified 20 cases per million population and by 2000 Takayasu arteritis (TA) there was a 2.5-fold increase in prevalence (Vanoli et al., 2005).

To this day, the prognosis for inflammatory aortitis is difficult to predict; however survival rates for vasculitis have been well described with the major predictors of death being vasculitis-related end-organ sequelae, aortic aneurysm, dissection, and a progressive course.

Pathophysiology

Inflammatory aortitis is a pathologic term for inflammation of the aortic wall of various etiologies with similar, nonspecific pathologic, radiologic, and clinical features. A standardized classification system has yet to be adopted. Several classification systems have been published, including one by the Society for Cardiovascular Pathology and the Association for European Cardiovascular Pathology. This classification breaks inflammatory aortitis into three categories including atherosclerosis, atherosclerosis with excessive inflammation, and aortitis/periaortitis (Ladich et al., 2016). This classification is not helpful clinically as many cases are thought to be idiopathic and only become apparent after pathologic evaluation of an excised specimen (Rojo-Leyva et al., 2000). Practically, the entity may be simply classified as infectious or noninfectious (Bossone et al., 2015).

Table 1 Common causes of inflammatory aortitis

(1) Inflammatory, likely auto-immune
  (A) Large vessel vasculitides
    a. Giant cell or temporal arteritis
    b. Rheumatoid Associated
    c. Systemic lupus Associated
    d. Takayasu's Arteritis
    e. Spondyloarthropathy associated
  (B) Other vasculitides
    a. Anca Positive vasculitides
      i. Granulomatosis with polyangitis, formerly known as Wegener's granulomatosis
      ii. Polyarteritis nodosa or panarteritis nodosa
    b. Behcet's disease
    c. Relapsing polychondritis
    d. Cogan syndrome
  (C) Isolated aortitis
    a. Ormond disease, or idiopathic retroperitoneal fibrosis
    b. Inflammatory abdominal aortic aneurysms
    c. Idiopathic isolated aortitis
(2) Infectious aortitis
  (A) Bacterial
    a. Salmonella
    b. Streptococcal
    c. Staphylococcal
    d. Neisseria gonorrhea
  (B) Mycobacterial (Tuberculosis)
  (C) Syphilitic
  (D) Fungi
    a. Aspergillosis
    b. Mucormycosis
  (E) Viruses
    a. Hepatitis B and C
    b. Herpes
    c. Varicella zoster
(3) Iatrogenic aortitis
  a. Post implantation syndrome

Infectious Aortitis

While less common than noninfectious inflammatory aortitis, the possibility of infectious aortitis must always be considered. A number of organisms have been described to be associated with infectious aortitis, most commonly *Staphylococcus*, *Streptococcus*, and *Salmonella*. Tuberculous aortitis, although uncommon in the Western world, is a common organism seen in aortitis in underdeveloped countries (Foote et al., 2005a). Other infectious agents that have been described include *Neisseria* (gonorrhea), *Rickettsia* (Rocky Mountain Spotted Fever), spirochetes (syphilis), fungi (*aspergillosis*, *mucormycosis*), and viruses (hepatitis B and C, herpes, varicella-zoster) (Gornik and Creager, 2008).

Regardless of infectious etiology, the pathophysiology is similar. Typically, involved aorta has underlying baseline pathologic changes, such as atherosclerosis or aneurysmal degeneration. The infectious agent seeds via the vasa vasorum, either through direct seeding from infected adjacent tissue, hematogenous spread during sepsis, infectious endocarditis producing septic emboli, or an underlying immunocompromised state (Foote et al., 2005a).

Noninfectious Aortitis

As described previously, the most common cause of inflammatory aortitis is vasculitis, the two most common being giant cell arteritis (GCA) and Takayasu's arteritis (TA) (Loricera et al., 2014). GCA primarily involves arteries of the head such as temporal and ophthalmic arteries, and TA primarily involves aortic arch and great vessels. Although considered two separate clinical entities with differing arterial involvement, there is significant overlap at the pathologic level. Both cause cellular infiltrate of the intima, media, and adventitia causing arterial wall thickening and both can have granuloma formation and multinucleated giant cells, making their histologic appearances indistinguishable (Kumar et al., 2010). Both can cause an inflammatory aortitis, which confers increased risk for both thoracic and abdominal aneurysms and aortic dissection (AD). Of the two vasculitides, GCA more commonly results in dissection and/or rupture (Tavora and Burke, 2006). Although many theories have been postulated including a cell-mediated autoimmune process and genetic predisposition, the pathogenesis of GCA and TA remains to be elucidated (Gravanis, 2000).

Another less common cause of noninfectious aortitis is idiopathic isolated aortitis. Idiopathic isolated aortitis is a disease process characterized by giant cell or lymphoplasmacytic inflammation of the aorta. While this phenomenon may involve the entire aorta, it most commonly involves the ascending aorta and accounts for 2% to 4% of ascending aortic aneurysms (Warrington and Cooper, 2010). Although rare, these disorders are unique as they are limited to the aorta and peri-aortic tissue. The primary histopathologic findings include patchy necrosis of the aortic media as well as inflammatory cellular infiltrate, which may include multinucleated giant cells, again making it difficult to distinguish from other vasculitides. While it has been postulated to be associated with IgG4-related systemic disease, the underlying pathophysiology is still poorly understood (Venkata et al., 2012).

In addition to vasculitis and idiopathic isolated aortitis, rheumatologic disorders (rheumatoid arthritis, systemic lupus erythematosus) have also been implicated in this phenomenon. While stenosing lesions are more common among patients with TA, dilatations or aneurysms of the aorta are a more common pattern among patients with rheumatic disease and aortic involvement. Both the thoracic and/or abdominal aorta may be involved and it can present in a variety of specific and nonspecific forms of aortitis. Because of this, there is a diverse clinical presentation representing both aneurysmal as well as ischemic symptoms in addition to the constitutional symptoms seen in rheumatic diseases. With thoracic aortic involvement, once may see aortic valve incompetence and heart failure, while involvement of the abdominal aorta may lead to leak, rupture, or thrombus formation and thromboemboli. While much less common and not well described, there should be a high index of suspicion of inflammatory aortitis in patients with rheumatic disease with new unexplained aortic regurgitation, arterial embolic events, or pain distribution concerning for aortic involvement (Slobodin et al., 2006).

With the advent of endovascular repair of abdominal aortic aneurysms (AAA), a newer phenomenon of noninfectious inflammatory aortitis has surfaced known as postimplantation syndrome (PIS). This poorly understood syndrome is a clinical and biochemical expression of an inflammatory response following EVAR. The incidence varies depending on literature quoted and is said to be as high as 60%. Nearly one-third of patients undergoing EVAR will suffer from PIS. It presents as a systemic inflammatory response induced by implantation of endoprosthesis. It was first described in 1999 with fever and leukocytosis following EVAR. Although many postulated mechanisms exist, the leading theory implicates manipulation of aneurysm leading to activating of the leukocyte response and cytokine release. PIS is frequently well tolerated and thought to be a benign process; however its impact on long-term outcomes is still unknown (Arnaoutoglou et al., 2015).

Presentation

The clinical presentation of inflammatory aortitis varies significantly and can range from asymptomatic to aortic insufficiency with acute aortic syndromes (Guard et al., 1995; Nuenninghoff et al., 2003). The underlying cause of aortitis and concomitant manifestations determine presentation. This can make diagnosis difficult as both infectious and noninfectious causes have nonspecific signs and symptoms.

Inflammatory aortitis causes inflammation of the aorta which can lead to aortic dilatation. This can occur at any level of the aorta. When it involves the proximal aorta, symptoms can be related to aortic valvular insufficiency and regurgitation or thoracic aortic dissection. More distally in the abdominal aorta this more commonly manifests as aneurysm formation. Inflammation may also cause fibrous thickening and ostial narrowing of major aortic branches. This is common in Takayasu arteritis, giving it the classic name "pulseless disease" with absence of peripheral pulses and lower arm blood pressures and arm fatigue (**Fig. 1**).

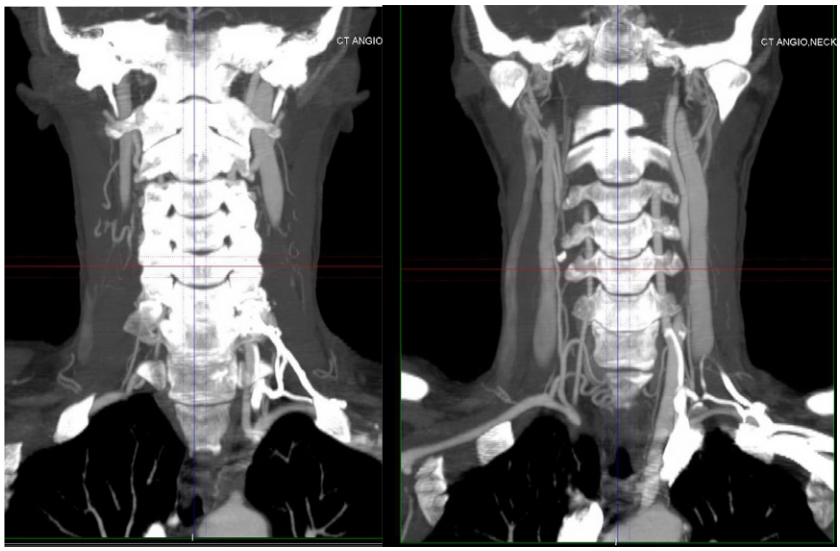

Fig. 1 CT angiogram of patient with Takayasu's Arteritis, demonstrating occluded left subclavian artery, occluded brachiocephalic artery, and occluded right common carotid.

Many other manifestations may occur depending on the vascular beds involved. They can range from claudication if involving lower extremity, ocular disturbances if involving retinal vessels, neurologic deficits if involving intra- or extracranial cerebrovascular beds, and others (Bossone et al., 2015). Systemic clinical manifestations include constitutional symptoms such as fevers, chills, weight loss, and general malaise. Aortitis may also be completely asymptomatic and discovered incidentally on imaging for other purposes or seen on autopsy.

Differential Diagnosis

Clinicians must maintain a high index of suspicion for inflammatory aortitis, especially in patients with nonspecific inflammatory manifestations.

Infectious Aortitis

Before the era of antibiotics, infective endocarditis from organisms such as *group A Streptococci*, *Streptococcus pneumoniae*, or *Haemophilus influenza* was the most common cause of infectious aortitis. Currently, a diverse number of bacteria and fungi have been associated with infectious aortitis, most commonly *Salmonella* species and *Staphylococcus aureus* (Foote et al., 2005b). Although less common, other infectious diseases, including syphilis, tuberculosis and mycosis, should be considered as well if infectious etiology is suspected. It is also important to keep in mind that even after treatment of infectious source, patients may still have sequelae of the inflammatory process (Fabio et al., 2006).

Infectious aortitis generally presents in older patients often with preexisting aortic pathology (e.g., abdominal aortic aneurysm). It often presents with back or abdominal pain as well as constitutional symptoms. Bacteremia may or may not be present. Imaging should be performed early to exclude possible infectious aortitis as it may lead to mycotic aneurysms and subsequent rupture with high rate of mortality.

Noninfectious Aortitis

Various noninfectious causes have been identified, including systemic vasculitides (e.g., polyarteritis nodosa), granulomatous diseases [e.g., giant cell (temporal) arteritis and Takayasu arteritis], rheumatologic diseases (e.g., systemic lupus erythematosus and ankylosing spondylitis), as well as idiopathic and they can all manifest with aortic lesions.

Giant cell arteritis (GCA) or temporal arteritis often has a nonspecific presentation. Common symptoms include headache, polymyalgia rheumatic, scalp tenderness, jaw claudication, and visual changes in addition to abnormal temporal artery biopsy and elevated inflammatory markers. There have been associations made between GCA and aortic aneurysms, particularly thoracic aortic aneurysms (Laco et al., 2011).

Takayasu arteritis is a less common disorder associated with inflammatory aortitis. It has a predilection for younger women. Versus GCA which presents with more nonspecific symptoms, Takayasu arteritis more often presents with arterial occlusive disease of the aorta, aortic arch and large vessel branches (most commonly subclavian, innominate, renal, and carotid arteries). It has often been called "pulseless disease" due to occlusive disease of subclavian arteritis demonstrating pulseless upper extremities. Many present with associated large vessel manifestations, such as renovascular hypertension and lower extremity claudication. Like giant cell arteritis there have been associations made between Takayasu arteritis and aortic aneurysm, however versus GCA which more often involves the thoracic aorta, Takayasu more often involves the abdominal aorta. Takayasu arteritis may also present with nonspecific symptoms and elevated inflammatory markers.

Although less common, rheumatologic disorders can be associated with inflammatory aortitis. This should be suspected when there is evidence of vasculitis in setting of underlying rheumatologic disorders such as in younger patients with longstanding rheumatologic diseases (e.g., ankylosing spondylitis).

Idiopathic isolated aortitis can present with symptoms associated with aortic inflammation but is more often discovered incidentally on pathology for aortic procedures. Idiopathic isolated aortitis can present with nonspecific symptoms as well as elevated inflammatory markers, similar to GCA and Takayasu arteritis (Miller et al., 2006).

Evaluation

Whenever there is suspicion for inflammatory aortitis on clinical findings, imaging is warranted as missing the diagnosis can be associated with high morbidity and mortality.

Initial evaluation should include basic labs. These include a measurement of inflammatory markers, erythrocyte sedimentation rate (ESR), and c-reactive protein (CRP), which are often times elevated above normal limits complete blood count, which may demonstrate leukocytosis, kidney, and liver function tests, which may be elevated if there is end organ malperfusion, and blood cultures, which may be positive in setting of an infectious etiology. If rheumatologic cause is suspected, a rheumatologic panel should also be considered (e.g., anti-nuclear antibodies (ANA), anti-neutrophil cytoplasmic antibodies (ANCA) and rheumatoid

factor (RF)). If infectious etiologies are suspected, plasma protein derivative (PPD) and RPR-VDRL should also be done to rule out tuberculosis and syphilis.

Several imaging modalities are available and there continue to be emerging studies that show promise for diagnosis in the future. Although angiography has traditionally been the gold standard for diagnosis of inflammatory aortitis, advances in less-invasive imaging techniques have led to its replacement. Noninvasive angiographic imaging, including Computed tomography with iodinated contrast (CTA), and magnetic resonance angiography (MRA) are now widely available, allow for rapid identification or exclusion of aortic pathology, and adequately visualize surrounding structures.

CTA allows for assessment of stenotic lesions in aorta and large arterial branches as well as presence and extent of aneurysms or dissections. CTA is useful for long-term follow-up of patients with aortitis or treated for aortitis and for surveillance of known aneurysms. It is also useful for assessing extent of calcification. Its primary limitation is the requirement of iodinated contrast in patients with renal insufficiency or allergy to iodinate contrast as well as need for radiation exposure.

MRA with gadolinium contrast has emerged as a noninvasive imaging modality for inflammatory aortitis, particularly those associated with GCA and Takayasu arteritis. It allows for detailed assessment and characterization of aortic involvement, areas of active aortic inflammation as well as wall edema or wall thickening. One benefit of MRA over CTA is lack of radiation exposure and iodinated contrast. One limitation of MRA with gadolinium is the risk of nephrogenic systemic sclerosis in patients with renal dysfunction.

Positron emission tomography (PET) scanning is yet another imaging modality that can discern vascular inflammation; however it has limited availability and its utility in diagnosis is still under investigation.

Treatment

Once the diagnosis has been established, approach to treatment depends on the underlying etiology and presence of associated ischemic or aneurysmal complications. The spectrum of therapy varies from immediate treatment to chronic management and long-term surveillance.

When infectious aortitis has been diagnosed, treating the underlying infectious source is essential. Initial treatment includes intravenous antibiotics with broad spectrum antimicrobial coverage for the most common organisms, including staphylococcal species and gram negative rods. Once the organism has been identified, the antibiotic coverage should be narrowed appropriately. If aortic involvement is diagnosed (e.g., mycotic aneurysm), antimicrobial therapy alone is insufficient and surgical debridement is required; however despite surgical management, the mortality rate remains high largely due to aortic rupture at time of presentation. Muller et al. reported an operative mortality rate of 36%, which related to a rupture rate of 85 (Muller et al., 2001). While several surgical approaches have been described including aggressive debridement and extra-anatomic bypass, aortoiliac reconstruction with cryopreserved arterial homograft or rifampin-soaked dacron and a neoaortoliliac system (NAIS) with aortoiliac reconstruction using the deep venous system of the lower extremities for mycotic abdominal aortic aneurysms, there is no established optimal surgical management as an infected field puts any reconstruction at high risk of breakdown. Dubois et al. compared extra-anatomic reconstruction with in situ repair. In-hospital mortality rate was 22.7%, 50% in the extra-anatomic reconstruction group and 18.9% in the in situ repair group (Dubois et al., 2010).

For inflammatory aortitis associated with systemic vasculitis or rheumatologic disorders, immunosuppressive therapy with glucocorticoids is the primary mode of treatment in the active phase (Chan et al., 2001; Hunder et al., 1975). The recommended initial dose of glucocorticoid therapy is 60 mg/day for GCA and 1 mg/kg/day for Takayasu arteritis (Salvarani et al., 2002; Kerr et al., 1994; Koening and Langford, 2008). Intravenous glucocorticoids are recommended when visual symptoms are present in GCA and in any patients with symptomatic aortitis. Duration of treatment must be tailored to each individual patient's condition and disease activity and tapering is required to reduce severe side effects.

Despite glucocorticoid therapy, relapse rates remain high, especially in GCA and Takayasu arteritis, and steroid-related adverse effects are not insignificant. While there have been several studies investigating potential steroid-sparing regimens for immunosuppression, including monoclonal antibodies and antitumor necrosis factor agents, steroid therapy remains the superior treatment.

For idiopathic isolated aortitis, treatment is not well established and surgical versus immunosuppressive therapy should be considered on a case-to-case basis.

When deciding the appropriate surgical management, several factors need to be taken into account. It is preferable for inflammation of the aorta to be treated with immunosuppressive therapy and patients to be in quiescent state as evidenced by lack of constitutional symptoms and normal inflammatory markers prior to surgery. There is a large body of evidence that demonstrates improved patency rates of surgery when patients are not in an active inflammatory state. Open vascular reconstruction has been the standard treatment for inflammatory aortitis, although endovascular techniques have been employed with some success (Zehr et al., 2005; Engelke et al., 2002; Baril et al., 2006). Endovascular surgery has the advantage of avoiding a large surgical procedure as well as reducing extensive manipulation of inflamed aortic tissue; however there is yet to be a randomized controlled trial comparing surgical versus endovascular management of inflammatory aortitis and this is an area that deserves further investigation especially with the advent of improved endovascular techniques and lower profile systems.

Introduction

Heart failure (HF) is a complex condition characterized by periods of exacerbations and stability, and often with an overall progressive decline, resulting in deterioration of quality of life, worsening of symptoms, and functional limitation. Patients with HF struggle with physical symptoms including dyspnea, fatigue, and edema, as well as emotional symptoms such as depression and anxiety.

As a result, patients with HF often have frequent hospitalizations especially with progression of their disease severity. Currently there are almost 6 million people with HF in the United States, with 3 million HF-related hospitalizations per year and an associated cost of 40 billion dollars (Norton et al., 2011).

As the disease progresses, patients with advanced HF have limited options including cardiac transplantation, permanent mechanical circulatory support, home inotropes, and hospice care. These patients with end-stage HF are refractory to conventional HF drug and device therapy and are classified under the American College of Cardiology Foundation/American Heart Association (ACCF/AHA) Guideline for the management of HF as stage D HF. Many patients may not be candidates for a heart transplant or left ventricular assist device (LVAD) or may not want to avail of these therapies. These patients with poor quality of life scores often choose to improve their quality of life over longevity. Intermittent or continuous use of inotropic therapy is an option that may be advantageous in this setting (Kraai et al., 2013; Fruhwald et al., 2016).

For the patient with advanced HF, inotropic therapy may be beneficially used in several different scenarios (**Table 1**). Inotropes may be used in acute settings such as acute cardiogenic shock (CS) with or without multiorgan failure, or as a "bridge" to transplantation or LVAD implantation. Inotropes may also be used as a palliative "destination therapy" measure in patients with end-stage HF to improve their functional capacity and quality of life.

Inotropes and Their Pharmacology

Inotropic agents improve myocardial contractility through a variety of mechanisms. Each agent impacts the systemic and pulmonary vasculature differently leading to characteristic hemodynamic effects. Furthermore, the metabolism and side effect profile of each agent differ. A thorough knowledge of both biologic effects and available outcomes data are needed to guide optimum clinical use. **Table 2** compares different inotrope characteristics and **Table 3** offers a practical approach to the use of one inotrope over the others.

Milrinone

Milrinone is a bipyridine derivative that indirectly increases intracellular cyclic adenosine monophosphate (cAMP) via inhibition of phosphodiesterase-III, the enzyme responsible for hydrolytic cAMP breakdown. Increased intracellular cAMP, the secondary messenger of the beta agonist system, leads to increased intracellular calcium via phosphorylation of substances responsible for calcium handling. Milrinone is also thought to have additional direct effects on calcium channel activity, vascular cAMP, and

[b]PVR = pulmonary vascular resistance

perhaps cGMP, which may explain its slightly different impact on chronotropy and vascular relaxation compared with dobutamine (Hess, 1996).

Milrinone decreases systemic and pulmonary vascular resistances (PVR), decreases left and right ventricular (RV) filling pressures, and increases cardiac output without increasing myocardial oxygen consumption (Grose et al., 1986). Electrophysiologic changes associated with milrinone use include increased conduction through the atrioventricular (AV) node and decreased atrial refractoriness (Tisdale et al., 1995a).

Beta receptor downregulation, common in chronic HF (Bristow, 1993), reduces the inotropic efficacy of beta-agonists, but does not diminish the efficacy of milrinone. Likewise, milrinone remains efficacious in patients previously or concomitantly receiving beta-blockers (Travill et al., 1994). Furthermore, milrinone enhances the effects of both endogenous and exogenous catecholamines, which also increase cAMP through first messenger beta-adrenergic stimulation (Honerjäger, 1991).

Milrinone is approved for administration via a continuous intravenous drip, however inhaled delivery forms are being studied (Haglund et al., 2015). Current ACC/AHA guidelines recommend against initiation bolus dosing (Yancy et al., 2013), which has

been associated with hypotension (Baruch et al., 2001). The recommended maintenance dose is between 0.125 and 0.75 mcg/kg/min. The onset of action is approximately 5–15 min, although full hemodynamic impact may take hours (Baruch et al., 2001).

Unlikely dobutamine, tachyphylaxis is not exhibited with milrinone. Milrinone is renally excreted, largely via active tubular secretion in an unchanged drug form. Only minor hepatic metabolism takes place and dose adjustments for hepatic impairment are not necessary. The elimination half-life in HF patients is about between 2 and 3 h, although this may be prolonged in patients with renal insufficiency (Rocci and Wilson, 1987). The elimination half-life in patients undergoing continuous venovenous hemofiltration is approximately 20 h (Taniguchi et al., 2000). Conservative dosing strategies should be considered in patients with kidney disease.

The most common serious side effects are arrhythmias and hypotension. Ventricular premature contractions and nonsustained ventricular tachycardia are not uncommon during short-term milrinone use, however sustained ventricular tachycardia or ventricular fibrillation typically occur in about 1%–3% with short-term use. Supraventricular tachycardia occurs in about 4% of patients, worsening control of atrial fibrillation is not unusual. Headache has been reported in up to 3% of patients. Due to the drugs prolonged half-life, hypotension or arrhythmias may persist even after discontinuation, particularly in patients with renal insuffiency. Uncommon side effects include thrombocytopenia, tremor, elevated liver function tests, rash, and allergic reactions. Concomitant use of riociguat may enhance hypotensive effects and should be used with caution and monitored closely. Concomitant use of furosemide is common but the two drugs have a notable Y-site administration incompatibility and administration through the same IV line should be avoided (Lexicomp, 2016). Milrinone may be associated with increased costs in the current healthcare system compared with other inotropic agents (Hauptman et al., 2006).

Dobutamine

Dobutamine is a synthetic catecholamine that exists as a racemic mixture. FDA approved for clinical use in 1978, dobutamine has served as the most commonly employed inotrope for several decades. At typical doses, the predominant hemodynamic effects of increased contractility and mild peripheral vasodilation are due to a strong affinity for the beta-1 and beta-2 receptors, which are bound in a 3:1 ratio (Overgaard and Dzavík, 2008). The negative enantiomer of the racemic mixture leads to vasoconstriction via alpha-1 antagonism, however at usual doses this appears to be more than counterbalanced by beta-2 stimulation leading to a mild net reduction in systemic vascular resistance. At doses greater than 15 mcg/kg/min, vasoconstriction becomes more prominent leading to increased systemic vascular resistance (Ruffolo, 1987). PVR response is variable, but overall a mild decrease can be expected within the lower dose range, while moderate to high doses result in little appreciable PVR change (Kerbaul et al., 2004; Bradford et al., 2000; Romson et al., 1999).

Unlike milrinone, dobutamine is known to increase myocardial oxygen consumption (Grose et al., 1986). Also tachyphylaxis occurs with infusions greater than 48 h. Electrophysiologic changes associated with dobutamine include increased sinoatrial node automaticity and decreased atrial and AV node refractoriness as well as decreased AV node conduction time (Tisdale et al., 1995a).

Patients taking chronic beta-blocker therapy may have an attenuated response to dobutamine until the beta-blocker has been metabolized. Limited data, in compensated individuals, suggests that concomitant dobutamine and metoprolol administration can lead to a favorable but blunted hemodynamic response. Concomitant dobutamine and carvedilol does not result in favorable hemodynamics and is associated with elevated filling pressures, mean pulmonary artery pressure, systemic vascular resistance, and PVR (Metra et al., 2002).

The manufacturer recommended starting dose is 0.5–1 mcg/kg/min, however initiation at 2.5 mcg/kg/min is commonly employed. Current ACC/AHA guidelines recommend a maintenance dose between 2.5–20 mcg/kg/min. Onset of action is between 1 and 10 min, with peak effect in 10–20 min. Unlike milrinone, dobutamine has an extremely short elimination half-life of 2 min and no dose adjustments are necessary in patients with kidney disease. The predominant route of metabolism is tissue methylation via catechol-*O*-methyltransferase (COMT) and monoamine oxidase (MAO), as well as hepatic conjugation (Yan et al., 2002). Caution should be exercised in patients concurrently receiving MAO inhibitors or tricyclic antidepressants, as paradoxical, prolonged hypertensive episodes may result. Notable drug interactions leading to exaggerated hypertensive reactions also include linezolid and atomoxetine.

Arrhythmias are the major life-threatening side effects of dobutamine. Ventricular ectopy is observed in at least 5% of patients during short-term use. Dose-dependent sinus tachycardia is common and approximately 10% of adult patients in clinical studies have a rate increases of 30 beats/minute or more. Increased frequency of atrial fibrillation and worsening control over ventricular response are not uncommon. Headache is reported in 1%–3% of patients. Less common side effects include hypotension, dyspnea, paresthesias, thrombocytopenia, nausea, and leg cramps. Fever can occur in 1%–3% of patients, while infrequent peripheral eosinophilia and rash have also been reported. Rare allergic reactions ranging from mild bronchospasm to anaphylaxis can ensue due to the sulfite component of drug preparation (Lexicomp Online Dobutamine, 2016). Although thought rare, about 2%–8% of patients receiving prolonged dobutamine infusions while waitlisted for heart transplant have evidence of eosinophilic myocarditis on explantation (Takkenberg et al., 2004; Yoshizawa et al., 2013).

Dopamine

Dopamine, the immediate precursor to norepinephrine, is an endogenous catecholamine that exhibits dose-dependent physiologic effects. Dopamine activate dopaminergic receptors leading to naturiesis and vasodilation of the renal arteries, as well as the

mesenteric, coronary, and cerebral beds (Cheung and Barrington, 199). Doses of <2.5 mcg/kg/min are thought to activate dopaminergic receptors and doses in this range are commonly referred to as "renal-dosed dopamine." Controversy exists as to the legitimacy of renal-dosed dosing strategies (Denton et al., 1996), particularly given the neutral results of ROSE AHF (Renal Optimization Strategies Evaluation in Acute Heart Failure), a randomized trial in which 2mcg/kg/min of dopamine failed to increase urine output, preserve renal function, or improve clinical outcomes against placebo or neseritide (Chen et al., 2013).

Conversely, a recent meta-analysis of trials using variable dopamine doses <5 mcg/kg/min suggests efficacy in preventing renal deterioration (Xing et al., 2016). With increasing doses of dopamine from 1 to 10 mcg/kg/min, renal artery cross-sectional area continues to increase and renal vascular resistance progressively decreases (Elkayam et al., 2008). HF patients may require dopamine doses greater than 2.5 mcg/kg/min to achieve favorable renal changes (Ungar et al., 2004), however the impact of improved cardiac index with these doses confounds attributable benefit.

At intermediate doses, beta-adrenergic inotropic effects are thought to predominate, while at higher doses (>10 mcg/kg/min) alpha-adrenergic vasoconstrictor effects increase. Dopamine improves cardiac index and mean arterial blood pressure, but at the expense of a greater increase in heart rate compared with dobutamine (Stoner et al., 1977). Also dopamine does not effectively decrease filling pressures and at higher doses may actually increase left ventricular end diastolic pressure (Francis et al., 1982). Dopamine has a variable impact on PVR and at low to intermediate doses PVR is largely unaffected in patients with cardiomyopathy (Stoner et al., 1977) as well as pulmonary hypertension (Holloway et al., 1975). Dopamine does however increase the pulmonary vascular resistance/systemic vascular resistance (PVR/SVR) ratio to a greater extent than other inoconstrictors (Barrington et al., 1995). Electrophysiologic changes associated with dopamine include dose-related sinus tachycardia, increases automaticity in Purkinje fibers, and at high doses reduced atrial repolarization and action potential durations. Arrhythmias associated with dopamine occur at lower inotropic doses than dobutamine-associated arrhythmias (Tisdale et al., 1995b).

Dopamine is typically begun at 2 mcg/kg/min (base on ideal body weight) and uptitrated to desired hemodynamic effect. ACC/AHA guidelines recommend a maximum dose of 15 mcg/kg/min although the manufacturer label maximum dose is 50 mcg/kg/min. Ideally the drug should be administered into a large vein via central line to prevent the possibility of extravasation. The onset of action is between 1 and 5 min and the elimination half-life is 2 min. Dopamine is metabolized in the liver, kidney, and plasma primarily by MAO as well as COMT. No dose adjustments are necessary in renal or hepatic disease. Like dobutamine, caution should be exercised in patients concurrently receiving MAO inhibitors or tricyclic antidepressants, as prolonged hypertension may result. Notable drug interactions leading to exaggerated hypertensive reactions also include linezolid, atomoxetine, hyaluronidase, serotonin norepinephrine reuptake inhibitors, or ergot derivatives.

Arrhythmias are the major life-threatening side effect of dopamine. Dose-dependent sinus tachycardia is common, although paradoxical bradycardia can also occur. Arrhythmias including atrial fibrillation as well as ventricular arrhythmias are not uncommon. QRS widening may be observed with low dose dopamine. Increased intraocular pressure and mydriasis have been reported. Contraindications to use include known hypersensitivity to sulfites or known pheochromocytoma. Extravasation of dopamine leads to tissue necrosis with the potential for gangrene. If extravasation occurs, immediately stop infusion and disconnect line while leaving the vascular catheter in place. Then gently aspirate through the catheter before removing it. Elevate the arm and apply a dry, warm compress. Quickly infiltrate the area with 5–10 mg of phentolamine diluted in 10–15 cc of normal saline using a fine hypodermic needle, alternatively topical nitroglycerin ointment or diluted terbutaline can be used (Lexicomp Online Dopamine, 2016).

Levosimendan

Levosimendan is a calcium-sensitizing drug that is currently approved for use in Europe and South America, but remains investigational in the United States. All conventional inotropes increase intracellular calcium leading to increased inotropy as well as potential unwanted toxicity related to calcium overload (Allen et al., 1985; Hove-Madsen et al., 2004). Levosimendan does not cause increased intracellular calcium and instead cause increased myofibrillar calcium responsiveness. The drug selective binds to calcium-saturated cardiac troponin, which enhances the sensitivity of the myofilament and facilitates actin–myosin cross-bridge formation (Sorsa et al., 2004). Additional mechanisms of action include opening of adenosine triphosphate dependent-potassium (K^{ATP}) channels on the sarcolemma of the vasculature smooth muscle cells and cardiac myocyte mitochondria. K^{ATP} channel activation in the vascular smooth muscles leads to arterial (Yokoshiki et al., 1997) and venous (Pataricza et al., 2000) vasodilation, thus decreased preload and afterload, as well as coronary vasodilation (Kaheinen et al., 2001). Cardiac myocyte K^{ATP} channel activation is thought to protect against ischemia–reperfusion injury (Scheiermann et al., 2011).

Characteristic hemodynamic response includes dose-dependent increased stroke volume and heart rate, while decreasing systemic vascular resistance, mean pulmonary artery pressure, and left- and right-sided filling pressures. Compared with dobutamine, levosimendan produces a marginally greater increase in cardiac output but a significantly greater decrease in pulmonary capillary wedge pressure (Follath et al., 2002). These hemodynamic effects are achieved without any significant increase in myocardial energy consumption (Ukkonen et al., 2000). Levosimendan remains active in patients receiving beta-blocker therapy and may be considered to reverse the effect of beta-blockade induced hypotension with hypoperfusion (Ponikowski et al., 2016).

Levosimendan can be initiated with a loading dose of 6–12 mcg/kg over 10 min if the systolic blood pressure is >100 mmHg, followed by a maintenance infusion rate of 0.05–0.2 mcg/kg/min. If a loading dose is utilized effects are seen in minutes. No tachyphylaxis is observed with levosimendan use. The major route of elimination is via conjugation forming an inactive metabolite excreted in the urine and feces. However, a small but significant proportion of the drug undergoes reduction in the small

bowel and is further acetylated to an active metabolite (OR-1896). The active metabolite has an elimination half-life of up to 80 h, thus a degree of drug effect may be maintained for days after stopping the infusion. Significant heterogeneity in acetylation status exists in the population and could theoretically contribute to a differential duration of drug effect, although limited clinical studies to date have failed to demonstrate this phenomenon (Kivikko et al., 2011).

Hypotension is the major side effect of levosimendan use and may persist following infusion discontinuation. This is considered to be related to an initial bolus. Currently, it is recommended that a bolus be administered initially only if immediate effects are required and its systolic blood pressure is over 100 mmHg.

Although levosimendan does not lead to increased intracellular calcium overload, arrhythmias continue to be a significant side effect. In the SURVIVE (Survival of Patients With Acute Heart Failure in Need of Intravenous Inotropic Support) trial, levosimendan was actually associated with a significantly greater incidence of atrial fibrillation and a similar incidence of ventricular tachycardia compared with dobutamine (Mebazaa et al., 2007). Other common side effects include headache, nausea, and diarrhea.

An oral formulation of levosimendan has been evaluated in chronic advanced HF as a palliative measure. Early studies showed a reduction in NT-proBNP was recorded along with improvement in quality of life assessed by the Minnesota Living with Heart Failure quality of life score (Nieminen et al., 2008).

Digoxin

Digoxin can be considered a weak oral inotrope. Digoxin inhibits the sodium–potassium ATPase pump. This inhibition promotes sodium–calcium exchange, which increases the intracellular calcium concentration available for myofilament cross bridging (Gheorghiade et al., 2004). Digoxin may also have beneficial effects on baroreceptor sensitivity (Wang et al., 1990). Digoxin has been shown to improve symptoms and reduce hospitalizations, but it does not convey a mortality benefit in patients with chronic systolic HF (Group TDI, 1997). A level between 0.5 and 0.8 ng/mL is recommended, and levels greater than 1.2 ng/mL are associated with increased mortality rate. The use of digoxin therapy in HF is outside the scope of this article and will not be covered further.

Investigational Agents

Istaroxime is a novel intravenous agent with inotropic and lusitropic properties related to inhibition of Na/K adenosine triphosphatase (ATPase) and stimulation of sarcoplasmic reticulum calcium ATPase. The HORIZON-HF investigators demonstrated improvements in cardiac index, pulmonary capillary wedge pressure, blood pressure, heart rate, and end-diastolic volume in a phase 2 trial of patients hospitalized with decompensated heart failure (Gheorghiade et al., 2008). Istaroxime is currently being evaluated in another clinical trial (https://clinicaltrials.gov/ct2/show/NCT02617446). Gene therapy manipulating calcium cycling changes in the failing heart have been attempted. The sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase (SERCA2a) regulates cardiomyocyte contraction and relaxation via intracellular calcium transportation, and SERCA2a deficiency is associated with progression of myocardial dysfunction (Hasenfuss et al., 1994; Hasenfuss and Pieske, 2002). Although a pilot study of SERCA2a gene transfer showed promising findings (Zsebo et al., 2014), a subsequent randomized, phase 2b trial failed to show a reduction in heart failure events at 12 months. Further studies of gene transfer are currently ongoing.

Clinical Uses

Acute Decompensated HF or Chronic HF as Bridge to Other Therapies

Inotropic therapy should be considered in hospitalized patients with severely depressed cardiac output complicated by systemic hypoperfusion and end-organ dysfunction. The goal of inotropic therapy is to preserve end-organ function, while the acute precipitating insult is being corrected and/or until definitive therapy (coronary revascularization, mechanical circulatory support, heart transplantation) is undertaken (Yancy et al., 2013). Outside of this setting, inotrope use is associated with increased mortality (Abraham et al., 2005; Cuffe et al., 2002; Packer et al., 1991).

The survival impact of temporary inotrope use as a bridge to definitive therapy in patients in extremis with signs of hypoperfusion has never been adequately studied (Guglin and Kaufman, 2014), thus its impact in this setting is unknown but likely lifesaving. As such evidence is lacking, choice of inotropic agent in the setting of low-output HF is largely based upon desired hemodynamic effects. Milrinone causes relatively larger decreases in both systemic vascular resistance (Grose et al., 1986) and PVR (Eichhorn et al., 1987) than dobutamine. In cases of severe hypotension or vasoplegia, dobutamine may be preferable. Conversely, in cases of high systemic vascular resistance or PVR, milrinone may be more appropriate. Milrinone may also be preferable in patients recently taking beta-blockers or those suspected of beta-blocker induced low-output syndrome (Travill et al., 1994). Prolonged elimination half-life, particularly in the setting of renal dysfunction, may make milrinone a less attractive choice in patients with significant renal dysfunction and hemodynamic instability. Use of inotropic therapy in acute decompensated HF improves cardiac output and enhances diuresis by improving renal blood flow (Al-Hesayen and Parker, 2008). Literature documenting improved outcomes with inotropic therapy in acute cardiorenal syndrome is lacking (Shchekochikhin et al., 2013), nonetheless inotropic agents are commonly used in this setting. Although logical inotropic agent choices should be guided by patient and drug characteristics,

data from the Get With The Guidelines-Heart Failure Registry demonstrated that inotropic agent choice in the United States is largely attributable to institutional preference alone (Allen et al., 2014).

The OPTIME (Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure) trial of short-term milrinone use in acute decompensated HF patient without CS failed to show a benefit in days spent hospitalized for cardiovascular cause, short- to mid-term mortality, nor a composite of death or readmission. Milrinone use in this setting was however associated with increased rates of atrial arrhythmias and sustained hypotension requiring intervention (Cuffe et al., 2002). Subgroup analysis of the trial suggested those with ischemic cardiomyopathy had worse outcomes compared to placebo, while those with nonischemic cardiomyopathy may have a more favorable response to such therapy (Felker et al., 2003). Regardless of HF etiology, use of inotropes in patients without significantly depressed cardiac output and hypotension or impaired perfusion remains contraindicated by AHA/ACC HF guidelines (Yancy et al., 2013).

Compared to placebo, short-term use of levosimendan for acute decompensated HF with systolic blood pressure >90 mmHg was associated with improvements in symptoms but no mortality benefit in REVIVE II (Randomized Evaluation of Intravenous Levosimendan Efficacy). Also levosimendan use in this setting was associated with an increased incidence of hypotension and cardiac arrhythmias (Packer et al., 2013). The largest levosimendan trial, SURVIVE (Survival of Patients With Acute Heart Failure in Need of Intravenous Inotropic Support), randomized 1327 patients with acute decompensated HF and SBP>85 mmHg to short-term levosimendan versus dobutamine. Levosimendan failed to improve the primary outcome of all-cause mortality at 180 days and was associated with increased incidence of atrial fibrillation, headache, and hypokalemia (Mebazaa et al., 2007).

Levosimendan is currently being evaluated for use in decompensated and high-risk patients with severely reduced left ventricular ejection fraction undergoing cardiac surgery. Early data suggested benefit with preoperative use of levosimendan in patients with severely reduced LVEF undergoing cardiac surgery (Levin et al., 2012); however, a recent, larger randomized trial failed to demonstrate any benefit of preoperative use with regard to the incidence of short-term death, MI, dialysis, or need for mechanical assist device (Mehta et al., 2017). Likewise, postoperative use of levosimendan in patients with LV dysfunction following cardiac surgery also failed to improve short-term mortality, duration of mechanical ventilation, or length of stay compared to standard postoperative hemodynamic support (Kolte et al., 2014).

CS Complicating Acute Myocardial Infarction

Current revascularization strategies and adjunct medical therapy have led to a dramatic reduction in mortality from acute myocardial infarction (AMI) to as low as 3%–4% of cases. That said CS remains the leading cause of death from AMI, occurring in up to 10% of all myocardial infarctions (Kolte et al., 2014) and in-hospital mortality with current approaches may be as high 40%–50% (Goldberg et al., 2009). In the SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock) trial, emergency revascularization, as opposed to immediate medical stabilization, lead to reduced mortality rates at 6 and 12 months (Sleeper et al., 1999; Hochman et al., 2001), thus management should focus on immediate revascularization followed by adjunct therapy. Adjunct therapy for pump failure largely consists of temporary mechanical circulatory assist devices and intravenous vasoactive medications, including inotropes. Several studies have demonstrated improvements in end-organ function with the use of temporary mechanical support device, however none have demonstrated a survival advantage (Thiele et al., 2005, 2013; Seyfarth et al., 2008), thus inotropes remain a viable alternative or adjuvant to such devices. Strategies to reduce extension of the infarct area should be undertaken, yet both catecholaminergic and PDE inhibitors have been shown to induce cardiac myocyte cell death (Burniston et al., 2005; Garcia-Cazarin et al., 2008). Furthermore, vasoactive medications utilized in the peri-AMI period are likely to increase the incidence of ventricular arrhythmias.

Current ACC/AHA STEMI guidelines recommend individualized support with inotropes guided by invasive hemodynamic monitoring, but do not specify a preferred agent (O'Gara et al., 2013). These guidelines do however go on to comment that the use of dopamine may be associated with excess hazard (De Backer et al., 2010), and dopamine is contraindicated for use in the German-Austrian S3 Cardiogenic Shock guidelines (Werdan et al., 2012). Both recommendations were largely based on the results of the SOAP (Sepsis Occurrence in Acutely Ill Patients) II study, in which a subgroup analysis of CS revealed a higher rate of death, ascribed to a higher incidence of arrhythmic events, in patients treated with dopamine compared to norepinephrine (De Backer et al., 2010). Notably this was a subgroup analysis of a neutral trial involving predominantly septic shock patients. Furthermore, neither the etiology, nor the remaining therapy of CS was reported in this study. In contradistinction, the ESC 2012 STEMI guidelines make a IIa recommendation for the use of dopamine in STEMI patients with hypotension and hypoperfusion (Steg et al., 2012).

Dobutamine carries a IIa recommendation in the ESC 2012 STEMI guidelines (Steg et al., 2012) and is deemed the drug of choice in the German-Austrian C3 guidelines (Werdan et al., 2012) for intropic support in AMI complicated by CS. Although dobutamine has served as the inotrope of choice in this situation for several years, little prospective evidence exists, and no compelling evidence demonstrates the superiority of dobutamine over another agent. Furthermore, several authors (Overgaard and Dzavík, 2008; Khalid and Dhakam, 2008) have suggested a hemodynamic benefit of combined dobutamine and dopamine to improve hemodynamics and limit side effects, yet the source commonly cited for this practice is from a study of eight patients (Richard et al., 1983), thus an evidence base for this practice is severely limited. Nonetheless, dobutamine seems a well-suited agent for CS complicating AMI from a hemodynamic perspective and is the most commonly used inotrope worldwide in the management of CS (Allen et al., 2014).

In contrast to dobutamine, milrinone is associated with less tachycardia and does not increase myocardial oxygen consumption (Grose et al., 1986), which could theoretically provide a benefit in peri-MI care. However, cell death is not solely due to effects on myocardial oxygen consumption, and cAMP mediated increased intracellular calcium common to dobutamine and milrinone likely

plays a role in the activation of apoptosis (Opie, 1993). Systemic inflammatory response syndrome (SIRS) leading to lower than expected systemic vascular resistance has been described in a subset of patients suffering from CS following AMI (Kohsaka et al., 2005). Introduction of milrinone, known to have significant arterial vasodilatory effects, could be problematic in patients with a SIRS response. No large scale randomized, controlled trials have been performed to assess the utility of milrinone for use in CS complicating AMI. A meta-analysis of four small studies suggests that treatment with milrinone may be safe and effective for patients with CS following AMI (Tang et al., 2015). Subgroup analysis from the OPTIME CHF (Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure) study demonstrated increased need for short-term cardiovascular rehospitalization and an increased composite of death or rehospitalization in ischemic cardiomyopathy patients treated with milrinone (Felker et al., 2003). Importantly, this was not a trial of patients with CS, nor recent AMI. Furthermore this was a subgroup analysis of trial yielding neutral results, thus these findings are hypothesis generating at best. As it is unlikely that prospective trials with milrinone will be performed in the AMI setting, future registry data will likely help elucidate this drugs role in AMI complicated by CS.

Levosimendan improves myocardial contractility without increasing cAMP or intracellular calcium, thus provides potential biochemical advantages from a cellular perspective. RUSSLAN, a randomized, placebo-controlled trial of levosimendan in patients with left ventricular failure following AMI, use of the calcium-sensitizing drug lead to a significant decrease in both short- and mid-term survival (Moiseyev et al., 2002). Notable exclusion criteria for this trial included SBP<90 mmHg, thus unlikely a true CS population. Levosimendan was associated with improved 30-day survival compared with enoximone, a phosphodiesterase type III inhibitor, in a small randomized trial of refractory CS complicating AMI (Fuhrmann et al., 2008). Another very small trial failed to show a long-term survival benefit of levosimendan over dobutamine in patients with CS following PCI for AMI (Samimi-Fard et al., 2008). Registry data also failed to show a beneficial effect of levosimendan on mortality in patients with CS due to AMI (Omerovic et al., 2010). None the less, the ESC 2012 STEMI guidelines give levosimendan a IIb recommendation, citing particular usefulness in patients on chronic beta-blocker therapy (Steg et al., 2012).

A recent Cochrane Review of randomized controlled trials in patients with AMI complicated by CS concluded that at present there are no robust and convincing data to support a distinct superior inotropic or vasodilator drug to reduce mortality (Unverzagt et al., 2014). Therefore, pharmacologic support with inotropic agents for CS complicating AMI should be individualized and used as an adjunct to prompt revascularization with or without concomitant temporary mechanical support.

Inotropic Support of the Failing Right Heart

RV dysfunction may occur in isolation or in combination with left heart dysfunction. Isolated RV failure may occur due to primary pump failure as is seen in acute RV infarction or may fail secondary to elevated afterload from pulmonary vascular disease. Few clinical studies evaluating the performance of specific inotropes in the setting of primary RV failure have been performed, thus choice of inotropic agent is largely guided by pharmacologic properties and patient characteristics. In addition to the agent impact on contractility and ventriculo-arterial coupling, the PVR/SVR ratio is an important factor in determining RV performance and systemic perfusion.

At low doses, dobutamine leads to improved RV–pulmonary artery coupling via reduced PVR and increased RV contractility (Kerbaul et al., 2004). Dobutamine has been successfully used for RV failure in the setting of acute MI (Ferrario et al., 1994), pulmonary arterial hypertension (Sztrymf et al., 2010), and pulmonary hypertension in the setting of liver transplantation (Romson et al., 1999). RV failure-induced congestive hepatopathy or renal disease may be improved with dopamine therapy via splanchnic vasodilation (Sztrymf et al., 2010). At high doses, dopamine increases the PVR/SVR ratio, thus may be less effective as a primary inoconstrictor in the setting of RV failure with pulmonary hypertension and systemic hypoperfusion (Barrington et al., 1995). Similar to dobutamine, milrinone augments RV performance via increased contractility and decreased PVR. Milrinone decreases RV afterload to a greater extent than dobutamine (Eichhorn et al., 1987), thus many consider milrinone the inotrope of choice in patients with RV failure secondary to high pulmonary afterload (Price et al., 2010; Green and Givertz, 2012). The limiting factor for milrinone use is the drugs impact on systemic vascular resistance and subsequent hypotension, which often requires coadministration of a vasopressor. Vasopressin may be the ideal vasopressor in this setting as concomitant use with milrinone preserves a favorable PVR/SVR ratio compared with other agents (Jeon et al., 2006). Limited data with inhaled milrinone suggests favorable effects on RV afterload and intrapulmonary shunt fraction while avoiding systemic hypotension (Wang et al., 2009). Levosemindan is known to increase CO and decrease PVR in patients with left HF (Slawsky et al., 2000). Experimental data suggest that levosemindan improves RV–pulmonary artery coupling more effectively than dobutamine (Kerbaul et al., 2006). In patients with left ventricular dysfunction and pulmonary hypertension, levosimendan causes similar reductions in PVR and mean pulmonary artery pressure as milrinone. However, levosimendan causes more tachycardia and hypotension requiring norepinephrine than milrinone (Mishra et al., 2016).

Palliative Inotrope Use

Long-term, continuous intravenous inotropic support may be considered as palliative therapy for symptom control in select patients with stage D HF on optimal therapy who are not candidates for durable mechanical circulatory support or transplant (Yancy et al., 2013). A right heart catheterization documenting a favorable hemodynamic response is typically required for reimbursement. Medicare coverage requires the study be performed within 6 months prior to the initiation of home inotropic

therapy and a documented cardiac index $\leq$2.2 L/m/m^2 and/or pulmonary capillary wedge pressure $\geq$20 mmHg before inotrope infusion on maximum medical management and a $\geq$20% increase in CI and/or a $\geq$20% decrease in PCWP during inotrope infusion at the dose initially prescribed for home infusion. The median survival of patients on chronic continuous inotropic therapy is improved in the recent era to 9–18 months as compared to 3–6 months previously. This may be related to the higher use of guideline-based HF therapy including beta-blockers and presence of defibrillators (Hershberger et al., 2003; Hashim et al., 2015; Ginwalla, 2016).

Suitable candidates must understand the goals of palliation and have adequate caregiver support. Given the well-known arrhythmogenic potential of inotropic therapy, it is important to discuss patient preference for ongoing ICD therapy. Almost one-fifth of patients on chronic inotropic therapy will receive an appropriate ICD shock if the device remains activated (Acharya et al., 2016). Other issues include infection risk involved with a chronic indwelling intravenous catheter and availability of caregiver support. Assistance with dressing care and inotrope infusion bags changes is required. Also availability of community and hospice resources is important. Unfortunately, financial coverage for continuous inotropes is often limited if the patient transitions to hospice care.

Conclusion

Varying hemodynamic profiles and clinical scenarios require different inotropic strategies. Each agent causes a unique hemodynamic response and carries a slightly different side effect profile. Knowledge of both biologic effects and clinical outcomes data is required for effective inotropic use.

Case Report

A 34-year-old male patient was admitted to an external hospital with signs of acute heart failure. The patient's medical history was empty. Transthoracic echocardiogram (TTE) showed a highly reduced ejection fraction (EF <20%) with global hypokinesia (data not shown) and the patient underwent coronary angiography revealing no signs of coronary artery disease. Following angiography the patient deteriorated on the same day, went into cardiogenic shock, and was transferred to our hospital for further diagnostic work up and treatment. Upon arrival TTE showed a hypertrophic septal wall and a reduced left ventricular ejection fraction of 22%–25%. (Online **Video 1A**). The patient's respiratory and haemodynamic condition worsened and we stabilized his condition by means of extracorporeal life support (Extracorporeal membrane oxygenation (VA-ECMO)) the following day. On the basis of his clinical presentation and the TTE findings, the patient was felt to require further diagnostics and an endomyocardial biopsy (EMB) was performed the same day and we decided to initiate an immunosuppressive therapy with azathioprine (50 mg/12 h for 6 months) and methylprednisolone (1 mg/kg for 4 weeks) (Frustaci et al., 2009). EMB revealed eosinophilic myocarditis with markedly increased cytotoxic cells (**Fig. 1**). TTE after 5 days of immunosuppressive treatment showed an improved left ventricular systolic function (LVEF-35%) and we could take the patient off the extracorporeal life support (Online **Videos 1B**). TTE performed after 9 days and after one month showed a normalized left ventricular ejection fraction of 60% (Online **Video 1C**).

Introduction

Endomyocardial biopsy (EMB) is the technique of choice in the diagnosis of adults presenting with cardiomyopathy of unknown origin. The toxic, infectious, inflammatory, infiltrative, or autoimmune processes that cause cardiac dysfunction occur at a cellular level and no other diagnostic techniques can establish the nature of the etiological agent. In addition to detection of inflammation or viral genomes in the acute phase of myocarditis, EMB adds important prognostic information during the follow-up of patients that can influence therapeutic decisions (Caforio et al., 2013; Dominguez et al., 2016; Escher et al., 2016; Savvatis et al., 2015).

Indication and Recommendation

The 2007 American Heart Association/American College of Cardiology Foundation/European Society of Cardiology scientific statement on EMB limited its class I recommendations to unexplained new-onset heart failure of less than two weeks duration associated with hemodynamic compromise or unexplained new onset heart failure of two weeks to three months duration associated with a dilated left ventricle (LV) and new ventricular arrhythmias or conduction disturbances (Cooper et al., 2007). In a position statement from the ESC (Caforio et al., 2013), the recommendation for EMB was extended, including patients with a pseudo-infarct presentation after excluding coronary artery disease, myocarditis, and inflammatory cardiomyopathies, as well as for patients with rapidly advancing cardiomyopathy refractory to conventional therapy. Hence, an increasing number of patients can benefit from specific treatment. Moreover, recently the 2016 ESC Guidelines for the diagnosis and treatment of acute and chronic heart failure recommends EMB in patients with rapidly progressive heart failure despite standard therapy when there is a probability of a specific diagnosis which can be confirmed only in myocardial samples and specific therapy is available and effective (Ponikowski et al., 2016).

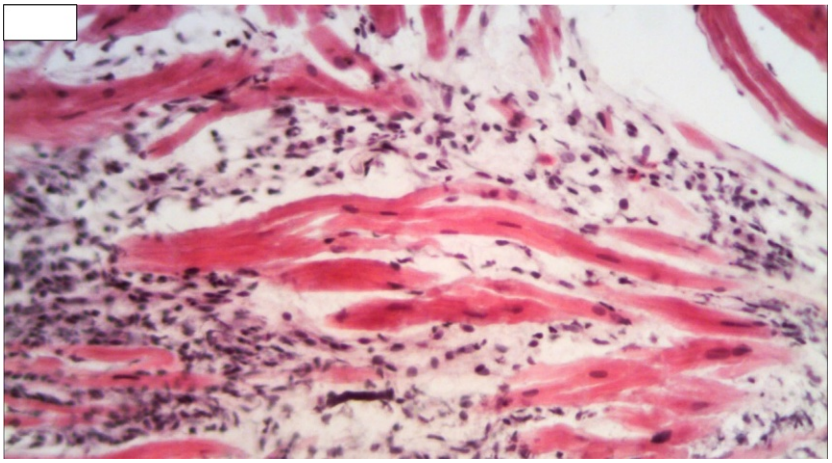

Fig. 1 Histological results of endomyocardial biopsy. H & E Stain. Histology revealed eosinophilic myocarditis with markedly increased eosinophilic invaded cytotoxic inflammatory cells (*red*: myocytes).

These changes respond to the more widespread availability of immunohistochemical and viral genome detection techniques, which improve the ability to detect the underlying cause of myocarditis.

Patient Preparation

EMB is performed in a supine position under local anesthesia. The patient must be monitored with 3-lead ECG, noninvasive blood pressure monitoring, and oxygen saturation. International normalized ratio (INR) of <1.5 is required before the EMB, and anticoagulation therapy should be discontinued 16 h before and 12 h after the procedure. Echocardiogram is recommended before and immediately after the procedure to exclude pericardial effusion. If possible, we recommend a 12–24 h telemetric observation after the procedure. Furthermore, we recommend an in-house transthoracic echocardiography prior to the biopsy to confirm the diagnosis of cardiomyopathy, estimation of the LV ejection fraction, LV hypertrophy, detection of altered myocardial texture and to rule out any obstacles for left ventricular EMB such as a diameter of the lateral LV wall <8 mm or noncompaction cardiomyopathy, LV thrombus, or relevant aortic valve stenosis.

Left Ventricular Versus Right Ventricular Endomyocardial Biopsy

The choice of the ventricular site for EMB is still widely discussed. Whereas some observe that diagnostic yield of LV EMB is superior to right ventricular (RV) EMB when routine immunohistochemistry and viral genome amplification are used in suspected LV myocarditis, more recent data state that both procedures are similar when assessing inflammation or viral genome in the myocardium (Chimenti and Frustaci, 2013). However, we recently showed that morphological changes such as interstitial fibrosis and cardiac collagen type I expression were more reliably found in LV EMB (Escher et al., 2014).

RV-EMB approached by right internal jugular or femoral vein and LV-EMB approached by the left or right femoral artery are commonly used and when performed by experienced operators, both right and left EMBs have very low complication rates. In a single center study that analyzed 3048 EMB in a nontransplant setting, risk of major complications including cardiac tamponade and AV block requiring permanent pacemaker implantation was 0.12% (Holzmann et al., 2008; Tschope et al., 2015). Chimenti et al. documented that over a 28-year period and over 4000 EMB procedures performed complications appeared in only 0.33% of patients who underwent LV-EMB (Chimenti and Frustaci, 2013).

We strongly believe that for this analysis not the localization but the number of taken EMBs is important to get a definite diagnosis and to reduce the sampling error.

Since we could demonstrate that at least morphological changes such as interstitial fibrosis and cardiac collagen type I expression were more reliably found in LV EMB, we perform routinely LV EMB especially in cases where a coronary angiogram is performed prior to LV biopsy to rule out relevant coronary artery disease as the underlying pathology for heart failure.

Access Site

When LV-EMB is performed, the femoral artery is usually the access site (Cooper et al., 2007; Yilmaz et al., 2010). The transfemoral site, however, is associated with bleeding complications form the access site and limited due to postprocedural immobilization.

The radial artery is increasingly used for diagnostic coronary angiography and percutaneous coronary interventions and has been recently recommended according to ESC guidelines. Lower direct costs, fewer vascular complications, better patient acceptance, and earlier ambulation are some of the direct benefits from using radial access (Schueler et al., 2013). When compared to the femoral approach, less vascular access site complications and reduced major bleeding have been reported (Jolly et al., 2011; Rao et al., 2008; Bertrand et al., 2010).

Access-site vascular complications in patients undergoing transradial coronary procedures are rare but may have relevant clinical consequences (Burzotta et al., 2013). Complications include spasm, occlusion or perforation of radial artery (RA), hematoma, pseudoaneurysm, arteriovenous fistula, and nerve injury (Kanei et al., 2011).

We previously showed that transradial LV-EMB is feasible (Schulz et al., 2015). We recently showed in 18 patients undergoing transradial LV-EMB that the success rate was 100%. There were no periprocedural cardiac complications. Immediate postprocedural ambulation could be achieved in all patients. Although radial artery pulse was confirmed by ultrasonic vascular Doppler after removal of the guide in 100% of the patients, 50% (9/18) of the patients showed occlusion of the radial artery (RAO) by duplex sonography proximal to the access site. 33% (3/9) of the patients in the RAO group and 11.1% (1/9) of the patients in the patent radial artery (RAP) group, respectively, experienced mild pain after the procedure in the right lower arm. Color Doppler ultrasonography of the right radial artery performed 24 h after the procedure revealed radial occlusion in 50% (9/18) of the patients. The diameter of the radial artery was significantly smaller in the RAO group ($P=0034$), and peak systolic velocity (PSV) of the right ulnar artery was significantly higher in the RAO group ($P=0.012$). Peak systolic velocity of the opposite radial artery was significantly lower in the RAO group ($P=0045$) (Kherad et al., 2016). Gender, diabetes, and radial artery inner diameter $\leq$2.5 mm are known predictors of RAO (Uhlemann et al., 2012) and we have shown that lower PSV of $<$50 cm/s is also associated with RAO and used these parameters to create the *B*erlin *RAD*ial Access *S*core, $BRAD_2$Score. The $BRAD_2$Score is the sum of the clinical parameters (age, gender, and diabetes) and the ultrasound-based parameters (Radial artery diameter and PSV), whereas the ultrasound parameters count twice to the overall sum. We postulate that with a clinical $BRAD_2$Score of 1 radial access can be performed without the risk of RAO and without an ultrasound evaluation of the radial artery. With a clinical $BRAD_2$Score of 2 we recommend ultrasound evaluation of the radial artery. With a remaining $BRAD_2$Score of 2 after ultrasound evaluation radial access can be performed, whereas with a $BRAD_2$Score of $>$2 after ultrasound evaluation we recommend alternative access sites. All patients with RAO had a $BRAD_2$ Score of $>$3. The $BRAD_2$Score might be a valuable novel tool to identify patients at risk for postprocedural occlusion of the radial artery and will be analyzed in a prospective study (**Table 1**).

Transradial Left Ventricular EMB

Following local anesthesia, a 6 F sheath (Radifocus Introducer II, 10 cm, Terumo, Japan) is introduced into the right radial artery. Following sheath introduction every patient receives 3000 IU unfractionated heparin and 5 mg verapamil i.a. to prevent radial artery occlusion or spasm. A 5 F pigtail catheter (Boston Scientific, USA) is then placed into the LV. A long J-wire (260 cm, 0.03500) is now advanced over the pigtail catheter into the LV to hold the ventricular position, the pigtail and the 6F radial sheath are removed, and a 7.5F sheathless multipurpose guiding catheter (MP1.0, Asahi Intecc, Japan) is introduced and its dilatator is removed as soon as the sheathless guiding catheter reaches the ascending aorta and carefully advanced over the wire into the LV cavity. The J-wire is now removed and a Y-connector (Copilot, Abbott Vascular, USA) is connected. The correct position of the guiding catheter tip is checked in 20 degree left anterior oblique (LAO) projection with the tip of the catheter pointing to the lateral LV wall. Once the positioning of the catheter is confirmed 6 mL of contrast agent are injected to visualize the distance of the tip to the lateral LV wall (**Fig. 2B**). The guiding catheter should not touch the wall. Prior to the biopsy, activated clotting time is checked (ACT: 200–250 s) to prevent thromboembolism during the procedure. After the bioptome forceps (B-18110; 1100 mm, 1.8 mm, Medizintechnik Meiners, Germany; **Fig. 3**) have been rinsed in water to prevent air embolism, they are inserted into the MP1.0 guiding catheter via the Y connector.

Table 1 Berlin RADial access score $BRAD_2$Score

Risk factors	*Points*
R Radial peak systolic velocity (PSV) $\leq$50 cm/s	2
A Age $\leq$ 50 years	1
D Diameter radial artery $\leq$2.6 mm	2
D Diabetes mellitus	1
S Sex (female)	1
$BRAD_2$Score 1 point → Radial access	
$BRAD_2$Score 2 points → Perform color-coded duplex ultrasonography (CCD)	
$BRAD_2$Score 2 points after CCD → Radial access	
$BRAD_2$Score $\geq$3 points → Nonradial access	

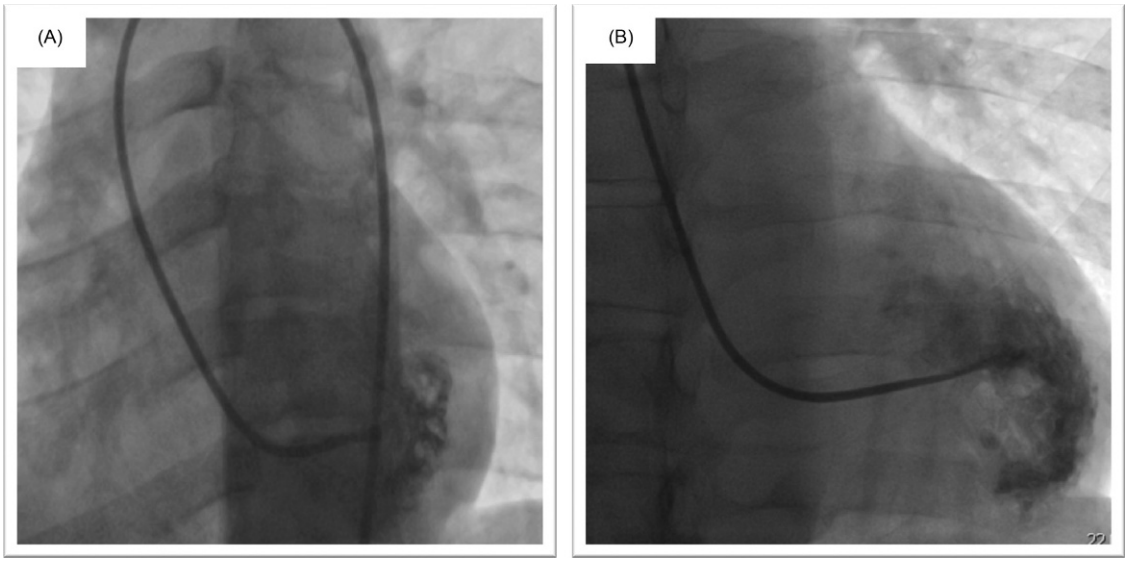

Fig. 2 LV angiography Fluoroscopy in LAO 20 degree view with injection of 6 mL contrast agent to visualize the position of the 7.5F MP-1 guiding catheter inside the left ventricle with the tip pointing to the lateral LV wall. 1A: Transfemoral approach. 1B: Transradial approach.

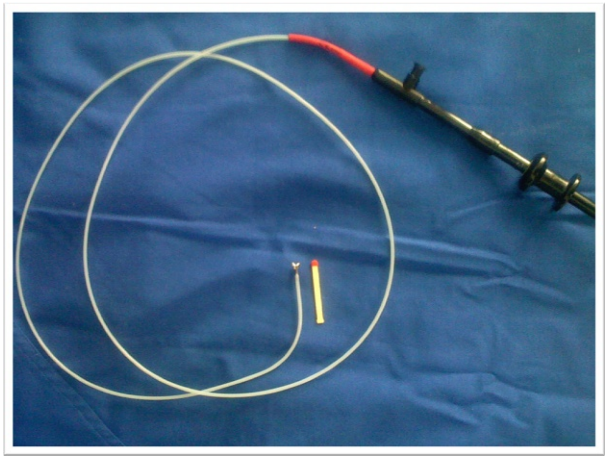

Fig. 3 Biotome (B-18110; 1100 mm, 1.8 mm, Medizintechnik Meiners, Germany).

There are a number of bioptomes available from different companies and they all differ in prize, the possibility of resterilization, and in stiffness and flexibility, respectively. We use a very flexible bioptome (B-18110, Medizintechnik Meiners, Germany). It has a 6F diameter and a length of 1100 mm. The 2 closed jaws have a total diameter of 1.8 mm, a length of 2.8 mm, and a volume of 4.5 mm^3. Compared with other bioptomes, it has a more flexible polytetrafluoroethylene (Teflon) tube instead of an inflexible steel spiral and smaller jaws.

The forceps of the bioptome are advanced under fluoroscopy close to the tip of the guiding catheter. The forceps are opened inside the guiding catheter and carefully advanced toward the lateral left ventricular wall. As soon as resistance is recorded or fluoroscopically seen, the jaws are closed and the forceps are immediately retracted into the guiding catheter (Online **video 2**). Upon completion of the procedure, the sheathless guiding catheter is removed and a vascular closure device (TR Band, Terumo, Japan) is applied for haemostasis. Each patient receives low-dose aspirin for 4 weeks to prevent embolisms from the area of biopsies.

Transfemoral Left Ventricular EMB

Following local anesthesia, an 8 F sheath (Radifocus Introducer II, 10 cm, Terumo, Japan) is introduced into the right or left femoral artery. Upon sheath introduction every patient receives 3000–4000 IU unfractionated heparin (ACT: 200–250 s). A 5 F pigtail catheter (Boston Scientific, USA) is now advanced into the LV. A long J-wire (260 cm, 0.03500) is advanced over the pigtail catheter to hold the ventricular position, the pigtail is removed, and an 8 F multipurpose guiding catheter with side holes

(MP1.0 SH, Medtronic, USA) is introduced, and the guiding catheter is carefully advanced over the wire into the LV cavity. The J-wire is now removed and a regular Y-connector (Copilot, Abbott Vascular, USA) is again connected. The following steps are identical to the transradial approach (Fig. 2A).

Upon completion of the procedure, the guiding catheter and the 8F sheath are removed and an 8F vascular closure device is applied for haemostasis. Each patient receives a low-dose aspirin prophylaxis for 4 weeks.

Transfemoral Right Ventricular EMB

For this access no heparinization or aspirin prophylaxis is recommended. Following local anesthesia, an 8F sheath (Arrow Flex, 30 cm, Tereflex, USA) is introduced into the right or left femoral vein. The left vein access might have an advantage in younger patients where the position of the heart is often steep. We use the described bioptome of Meiners (B-18110), which allows due to its flexibility, an easy modulation of the Teflon tube according to individual anatomy of the patient. In contrast to others, we do not use a guiding catheter under these conditions, which would destroy the flexibility of the tube and increase the perforation risk. Principally, we do not recommend a use of any stiff bioptomes for RV biopsies. Under fluoroscopic control at 0° right anterior oblique (RAO) projection the bioptome is advanced to the right atrium. After carful turning into the direction of the tricuspid valve it can be advanced into the RV. The ideal position of the bioptome in the RV has to be checked at 90 degree LAO (Fig. 4). It is not recommended to take RV biopsies at RAO views, since these views cannot exclude that the bioptome is still in the (large) right atrium or was introduced into the sinus coronaries. Before opening the forceps of the bioptome one should make sure that the bioptome is not touching the wall to prevent uncontrolled tissue damage. Usually a short backward move of the bioptome is enough to open the forceps in the cavum of the RV, followed by a new forward move with an opened forceps to the lower part of septal wall to get the biopsy. Taking biopsies at higher parts of the septum would increase the risk of AV blocks, especially in patients with established left bundle block. Upon completion of the procedure, the bioptome and the 8 F sheath are removed and haemostasis is established by manual compression for several minutes.

Tissue Analysis

On average 6–8 EMBs are necessary to be able to perform histology, immunohistology, and molecular analysis and to overcome the sampling error.

Light microscopic examination is routinely performed on formalin-fixed, Paraffin-embedded, and Tissue-Tek® (Sakura Finetek, USA)-embedded frozen tissues. Histology includes H&E-, EvG-, PAS-, and Azan-stained sections to evaluate tissue alterations such as fibrosis, scars, granulomas, pathological vascular conditions, infiltrative and storage diseases (e.g., amyloidosis, iron deposits, enhanced glycogen storage, M. Fabry), or distinct inflammatory cell infiltrates (lymphocytes, leukocytes, eosinophiles, monocytes, macrophages, giant cells), which may cause acute or chronic myocyte damage, myocytolysis or apoptosis and replacement fibrosis, in inflammatory cardiomyopathy and myocarditis (Dallas-Classification). Immunohistochemistry and digital morphometric analyses improve diagnostic sensitivity and allow a more quantitative and specific differentiation of, for example, amyloid subtypes

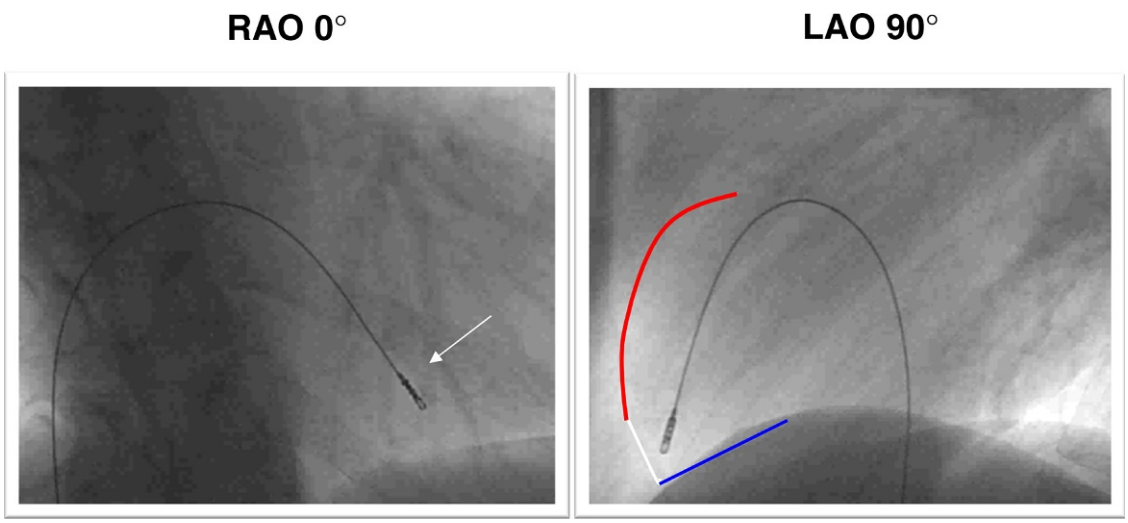

Fig. 4 RV angiography fluoroscopy in RAO 0 degree and LAO 90 degree view. Visualization of the position of the biotome within the right ventricle. *Red*: septum with increased risk of transient or permanent third degree or second degree type 2 AV Block; *White*: optimal position, *Blue*: free wall with increased risk of perforation.

(IgG λ or κ light chains) and of inflammatory infiltrates using monoclonal and polyclonal antibodies (including CD3, CD4, CD8, CD45R0, CD20 CD68/PGM1, HLA-DR. HLA-ABC, or cellular adhesion molecules) in frozen cryostat sections. Whereas the number of cellular infiltrates (lymphocytes, macrophages) is varying in different biopsies (sampling error), the expression of adhesion molecules (e.g., ICAM-1/2, VCAM-1) is more homogeneously distributed and indicates the global tissue activation. The introduction of these markers in routine biopsy diagnostics improves identification of inflammatory processes in myocardium even without on-site identification of infiltrative cellular foci. The timely presence of activated or cytotoxic lymphocytes and proinflammatory or antiinflammatory macrophages furthermore differentiates chronic active from healing inflammation (myocarditis) and thus may be used as a marker of autoimmune myocarditis where immunosuppression may be considered (Leone et al., 2012; Maisch et al., 2005).

Microbial genomes are determined, quantified, and sequenced using PCR-based methods. Depending on the two types of viral nucleic acids the isolation of DNA and RNA is performed in separate extraction procedures needing multiple biopsy specimen. The viral load is determined by quantitative PCR. The transcriptional activity of virus in myocardial tissue or peripheral blood cells is performed by nested RT-PCR and QPCR. These sensitive techniques detect the most common cardiotropic viruses such as enteroviruses, adenoviruses, erythrovirus, human herpesvirus 6, Epstein-Barr virus, and in the Far East also hepatitis C, in about 50%–60% of patients clinically presenting as myocarditis or DCMI. At present the clinical significance is, however, demonstrated for few viruses only (incl. entero/adenoviruses) (Bock et al., 2010; Caforio et al., 2007; Kuhl et al., 2012).

In order to exclude systemic infection, peripheral blood (one sample (5–10 mL) collected in EDTA or sodium citrate tubes) should be investigated in parallel with EMB (Leone et al., 2012; Caforio et al., 2007). The assessment of the viral replication status and parallel studies of the blood compartments (peripheral cells, plasma, serum) allows us to differentiate between acute and latent infections. This additional virus diagnostics allows us to identify subgroups of patients with viral persistence that might benefit from specific antiviral therapy strategies (Caforio et al., 2007; Kuhl et al., 2003, 2005, 2012, 2015; Magnani et al., 2006).

In general, genetic testing is unable to detect viral infections or inflammation in myocardium. In the future next-generation sequencing technology that reads out millions of sequence fragments within in a very short time will significantly improve the EMB-based diagnostics by parallel identification of pathological mutations in genomic DNA and the involved microbial genomes in one single biopsy sample. Treatment strategies for inflammatory cardiomyopathies have been recently summarized by Dominguez et al. (2016).

Conclusion

EMB is central in diagnosing suspected myocarditis, inflammatory cardiomyopathies, and rapidly advancing cardiomyopathy thereby allowing in many cases specific treatment of the underlying cause. Both right and LV EMBs, when performed by experienced operators, are safe and have very low complication rates.

Introduction

Approximately 6 million adults in the United States suffer from heart failure. Predictions have shown that from 2012 to 2030, the prevalence of heart failure will increase to more than 8 million people in the United States (1 in every 33) (Heidenreich et al., 2013). The clinical spectrum of heart failure encompasses a broad range of pathology and begins with an initial event such as acute myocardial infarction (AMI), progressive valvular heart disease, myocarditis, or onset of a primary dilated cardiomyopathy. Due to improvements in medical therapy, these patients can survive and may eventually develop chronic heart failure, which is characterized by neurohormonal activation, increased sympathetic tone, and maladaptive cardiac remodeling that unfortunately precipitate readmissions for heart failure and eventually lead to mortality. Low cardiac output and multi-organ hypoperfusion refractory to medical therapy are primary indications for the use of advanced therapies including durable mechanical circulatory support (MCS) devices, including surgically implanted left ventricular, right ventricular, or biventricular assist devices or cardiac transplantation.

In the United States, the number of patients receiving cardiac transplant has remained stable at approximately 2000–2500 per year. In contrast, based on data from the HeartMate-II and HeartWare bridge to transplant trials and the HeartMate-II destination therapy trial, the number of LVAD implants has increased to over 2500 implants in 2013 in the United States alone (Kirklin et al., 2015). According to registry data from the Interagency for Mechanically Assisted Circulatory Support (INTERMACS), there has been a reported increase in the use of LVADs for "destination therapy" and a decrease in their utilization as part of a "bridge to recovery" or "rescue" approach. This redirection of LVAD implantation away from unstable, high-risk INTERMACS categories (profiles 1 and 2) toward more stable candidates (profiles 3 and 4) is partially guided by data that demonstrated increased mortality after LVAD implantation for INTERMACS profiles 1 and 2 above the age of 65 and the increasing accessibility of nondurable MCS devices, which include temporary, percutaneously inserted devices without the need for surgery.

Supporting this trend of an increase in the use of acute device support, a recent analysis of the Nationwide Inpatient Sample from the Healthcare Cost and Utilization Project showed a 1511% increase in the implantation of nondurable MCS, including the TandemHeart (Cardiac Assist Inc.) and Impella (Abiomed Inc.), while there was no significant change in intra-aortic balloon pump (IABP) use between 2007 and 2011 compared with 2004–07 (Stretch et al., 2014). Use of the TandemHeart and Impella devices was associated with a reduction in the length of stay and cost for patients admitted with a diagnosis of congestive heart failure, but no change in their in-hospital mortality. The objective of this review is to describe the various options for acute, percutaneous MCS device therapy and the recent clinical trial data supporting their use for patients presenting with an ST-segment elevation myocardial infarction (STEMI), cardiogenic shock, and advanced heart failure.

Intra-aortic Balloon Pumps

The IABP is the most commonly used acute MCS device with over 50,000 implants per year in the United States alone (Cohen et al., 2003; Stone et al., 2003; Williams et al., 1982; Kern et al., 1993a,b). The IABP is a catheter-mounted balloon that inflates during diastole, thereby displacing blood volume in the descending aorta and increasing mean aortic pressure (Fig. 1). The IABP may assist in augmenting coronary perfusion during diastole. The IABP then deflates during systole, which creates a pressure sink that is then filled by blood from the left ventricle. The ideal hemodynamic effects from an IABP are increased diastolic aortic pressure, reduced aortic and LV systolic pressure, increased systemic mean arterial pressure, reduced LV diastolic volume and pressure, and increased coronary perfusion pressure. The magnitude of diastolic augmentation and systolic unloading can be determined from measurements from the IABP console tracing.

Previous studies have shown that the hemodynamic impact of balloon counterpulsation is primarily determined by four factors: (1) the magnitude of diastolic pressure augmentation, (2) the magnitude of reduced systolic pressure, (3) the magnitude of volume

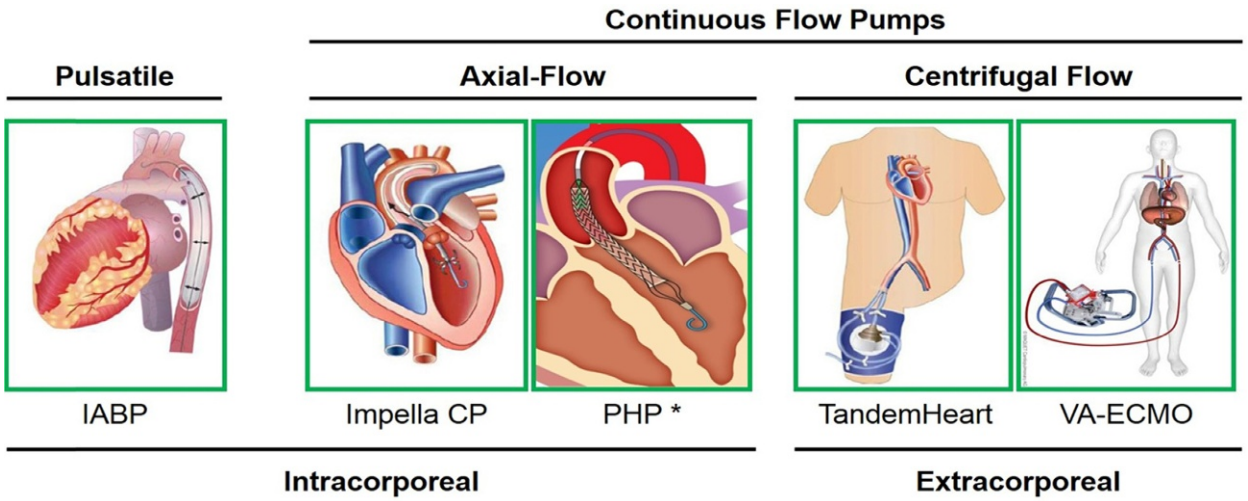

Fig. 1 Acute mechanical circulatory support device options for left-sided ventricular support.

displacement, and (4) the timing of balloon inflation and deflation (Kern et al., 1993b; Braunwald et al., 1958; Sarnoff et al., 1958a, b; Welch et al., 1958; Schreuder et al., 2005a,b). IABP balloon capacity ranges from 34 to 50 cm^3. Larger capacity IABPs potentially offer better hemodynamic support than standard 40 cm^3 IABPs (Kapur et al., 2015a). We recently reported that larger capacity, 50 cm^3 IABPs, provide greater diastolic augmentation and systolic unloading compared with the 40 cm^3 IABP in a retrospective analysis of IABP tracings from 52 consecutive patients. We further showed that the magnitude of systolic unloading correlates directly with the magnitude of diastolic augmentation and inversely with pulmonary artery occlusion pressure. These observations suggest that future clinical trials employing the 50 cm^3 IABPs may demonstrate better clinical outcomes than studies predominantly using the 40 cm^3 IABP.

Benefits of the IABP are its relative cost compared with other acute MCS devices, ease of insertion, and widespread familiarity among the interventional community. Major complications, including acute limb ischemia, severe bleeding, IABP failure or leak, or death directly related to IABP insertion, occurred at a frequency of 2.6% in 16,909 patient case records in the Benchmark Registry (Ferguson et al., 2001). Clinician expertise, sheathless insertion, and smaller IABPs are associated with decreased incidence of vascular complications (Eltchaninoff et al., 1993; Erdogan et al., 2006).

The data from multiple registries have traditionally been in favor of IABP usage (Stone et al., 2003; Abdel-Wahab et al., 2010; Curtis et al., 2012); however, recent studies attempting to identify optimal candidates for IABP support in high-risk percutaneous coronary intervention (PCI), acute MI, or cardiogenic shock have shown no significant benefit associated with elective IABP insertion. The Counterpulsation Reduces Infarct Size Acute Myocardial Infarction (CRISP-AMI) trial showed that IABP implantation immediately prior to revascularization for an anterior ST-elevation myocardial infarction did not reduce infarct size or improve short-term survival (Patel et al., 2011). The IABP-SHOCK II study suggested that not all patients presenting with an ACS with marginal blood pressures and clinical evidence of hypoperfusion benefit from IABP activation (Thiele et al., 2012). In HR-PCI patients, the PROTECT II study showed no difference in major adverse cardiovascular events between IABP and Impella 2.5 axial-flow catheter (O'Neill et al., 2012). The balloon pump-assisted coronary intervention study (BCIS)-1 also showed no reduction in short-term mortality with IABP insertion prior to HR-PCI; however, follow-up data suggested a possible long-term benefit up to 5 years after PCI (Perera et al., 2010, 2013). Recent analysis of trends for acute MCS use has reported an increase in the cost of hospital stays associated with IABP use (Stretch et al., 2014). No clinical studies have rigorously examined the clinical utility of IABP therapy in advanced heart failure.

The Impella Microaxial-Flow Catheter

The Impella devices are catheter-mounted microaxial-flow pumps that are deployed into the LV across the aortic valve via retrograde insertion (Fig. 1). Blood enters the pump though the left ventricle and is moved via a circulating impeller across the aortic valve into the ascending aorta. The Impella 2.5 LP and CP devices can be deployed percutaneously, while the Impella 5.0 device requires surgical vascular access through a conduit graft. In contrast to LV apical cannulation with durable MCS, transvalvular delivery may initially increase LV stroke work (LVSW) until the Impella pump is activated by inducing transient aortic insufficiency (Valgimigli et al., 2006). Remmelink and colleagues reported decreased LV end-diastolic pressure, but no change in LVSW, LV volumes, or cardiac output with maximal activation of the Impella 2.5 LP device in 11 patients presenting for high-risk coronary intervention (Remmelink et al., 2010). In 2007, Sauren et al. reported a 50% reduction in LVSW with a larger Impella prototype device that generated 3.8 LPM of flow in a preclinical model of acute LV injury (Sauren et al., 2007). Consistent with this observation, we recently reported that activation of the Impella CP device generated 3.1 LPM of flow and reduced LVSW by 32% in a bovine model of AMI (Kapur et al., 2015b).

The utility of the Impella 5.0 device has been examined in few studies. RECOVER-I was a prospective, single-arm feasibility study using the Impella 5.0 for postcardiotomy cardiogenic shock (Griffith et al., 2013). The device significantly improved cardiac index from 1.65 to 2.7 L/min/m^2 ($P < 0.01$) and mean arterial pressure (71–83 mmHg), while reducing pulmonary artery diastolic pressure (28–20 mmHg, $P < 0.01$). Ninety-three percent of patients survived to hospital discharge. A larger retrospective analysis of Impella use in cardiogenic shock included 37 of 47 total patients receiving an Impella 5.0 pump. In this study, 1-year survival was 71.8% for postcardiotomy cardiogenic shock and 42.9% for patients with shock complicating AMI or dilated cardiomyopathy (Lemaire et al., 2014).

The TandemHeart Left Atrial-to-Femoral Artery Centrifugal Pump

The TandemHeart device is an extracorporeal centrifugal flow pump that decreases left ventricular preload via bypassing oxygenated blood from the left atrium (LA) into the descending aorta via two cannulas: a 21Fr transseptal inflow cannula in the LA and an outflow cannula into the femoral artery (FA) (Fig. 1). The device can provide up to 3.0–5.0 L/min of flow via percutaneous application depending on the size of the outflow (arterial) cannula, which range between 15Fr and 19Fr (Kar et al., 2011). Prior reports have shown that the positioning of the outflow cannula affects the degree of LV unloading. Specifically, LA-to-ascending aortic bypass will increase LVSW, while LA-to-descending aortic bypass greatly reduces LVSW. By bypassing blood from the LA to the arterial system, the TH device increases pressure in the aorta (Burkhoff and Naidu, 2012). In the ascending aortic position, this increase in afterload limits the magnitude of LV unloading (Kono et al., 2003). In the descending aorta, the increase in afterload is diminished by retrograde perfusion of smaller, branching vessels including the mesenteric, renal, and great vessels of the aortic arch, thereby allowing for a reported 66% reduction in LVSW (Goldstein et al., 1994). Consistent with this study, we recently reported that activation of the TandemHeart pump at 5500 rpm with a 17Fr arterial cannula generates 3.1 LPM of flow and reduces LVSW by 38%, while maximal activation at 7500 rpm generates 4.4 LPM of flow and reduces LVSW by 67% in a bovine model of AMI (Kapur et al., 2015b). Unlike the Impella CP, the primary effect of the TandemHeart was a reduction in native LV stroke volume leading to reduced LVSW.

The safety and efficacy of the TandemHeart device compared with the IABP was clinically assessed in small multicenter randomized trials in which the TandemHeart significantly improved hemodynamic variables without any mortality benefit compared with IABP (Burkhoff et al., 2006; Thiele et al., 2005). The largest data series with TandemHeart was reported by Kar et al. who studied the effects of the TandemHeart in 117 patients with cardiogenic shock refractory to IABP and medical therapy (Kar et al., 2011). The TandemHeart increased mean arterial pressure, pulmonary capillary wedge pressure, mixed venous oxygen saturation, and end-organ perfusion. In this study of critically ill patients with advanced heart failure and shock, only 40.2% of patients died within 30 days after device implantation. An important meta-analysis of smaller studies evaluating these continuous flow devices for cardiogenic shock showed improved hemodynamic profiles with the use of the Impella and TandemHeart devices compared with IABP, yet there was no difference in short-term mortality (Cheng et al., 2009).

Venoarterial Extracorporeal Membrane Oxygenation

Venoarterial extracorporeal membrane oxygenation (VA-ECMO) is more commonly used to improve systemic oxygenation during cardiorespiratory collapse or biventricular failure. When deployed percutaneously, an extracorporeal centrifugal pump (i.e., TandemHeart, CentriMag, Rotaflow, or Biomedicus pumps) removes venous blood from the right atrium and circulates it through an oxygenator into an artery (most commonly the FA) (Fig. 1). As a result, VA-ECMO reduces right-sided ventricular volumes with a simultaneous increase in mean arterial pressure and both LV systolic and diastolic pressures. The potential risk of increased LV afterload may lead to progressive acute lung injury and thus lead to worse outcomes (Boulate et al., 2013). This increase in LV afterload or wall stress occurs in contrast to the Impella or TandemHeart devices since there is no direct unloading ("venting") of the LV with VA-ECMO. Several approaches to "vent" the LV include atrial septostomy, insertion of an Impella or IABP device, or the insertion of an additional venous cannula into the LA.

The majority of the clinical studies involving VA-ECMO in cardiogenic shock are for extracorporeal life support (ECLS) in cardiac arrest. These data suggest a possible benefit with VA-ECMO if "door-to-ECLS" times are shorter than 30 min, which has led to increasing interest in the application of VA-ECMO by specialized teams of first responders (Leick et al., 2013). A systematic review of the literature for the use of VA-ECMO identified 67 manuscripts published between 1966 and 2008 with a reported median survival of 41% (range, 13%–78%) for cardiogenic shock (Allen et al., 2011). The best median survival was associated with VA-ECMO for the indication of myocarditis (73%; range, 40%–83%).

Clinical Trial Data: Acute MCS in STEMI, Cardiogenic Shock, and Heart Failure

Strategies for enhancing cardioprotection in STEMI are limited (Schreuder et al., 2005b). Previous studies have shown that implantation of a cardiopulmonary bypass circuit reduces myocardial oxygen demand and has been associated with improved clinical outcomes and a reduction in infarct size in AMI complicated by cardiogenic shock (Kanter et al., 1982; Allen et al., 1993).

Based on these observations, studies involving the use of an IABP or catheter-mounted axial-flow pump prior to coronary occlusion, known as primary unloading, were found to be associated with reduced infarct size in preclinical models of AMI (Smalling et al., 1992; Achour et al., 2005; Meyns et al., 2003). We and others have previously reported that insertion of the TandemHeart left atrial-to-femoral artery bypass pump and thereby delaying coronary reperfusion by 30 min significantly decreased infarct size in a preclinical model of AMI (Kapur et al., 2013; Catinella et al., 1983). This preclinical study led to the TandemHeart to Reduce Infarct Size (TRIS) trial in the United States, which was later withdrawn prior to enrollment due to insufficient patient recruitment (Cardiac Assist, Inc., 2015).

Myocardial perfusion is influenced by multiple factors, including coronary perfusion pressure versus ventricular filling pressure and myocardial oxygen supply versus demand. The net effect of acute circulatory support may affect these factors in favor of optimal myocardial perfusion. We can also learn from our surgical colleagues, who often approach STEMI and shock management by first initiating cardiopulmonary bypass to unload both the right and left ventricles, followed by a period of time to harvest bypass conduits (during which time the culprit artery remains occluded), and ultimately reperfusion. Third, we know from a recent analysis of the USPELLA registry that implantation of an Impella device before PCI in STEMI and shock may improve survival (O'Neill et al., 2014). Based on these preclinical and clinical data, the Door-to-Unloading trial was initiated in the United States in early 2017 to study the concept of first unloading the LV before reperfusion in STEMI (Abiomed Inc., n.d.).

An unfortunate complication of AMI is the development of cardiogenic shock. In addition to the persistent problem of high mortality associated with AMI complicated by CS, the profile of patients with CS has changed over the past three decades to now include both AMI and a growing population of individuals with advanced heart failure.

While the IABP has been the cornerstone of management for AMI complicated by CS for several decades, the data indicate that IABP is not indicated for routine use in CS, but may be considered in select cases. The randomized, multicenter IABP-SHOCK-II trial is the largest study of IABP therapy in AMI complicated by CS to date. Compared with medical therapy alone, this study did not identify any improvement in 30-day mortality or after 12 months with IABP therapy (Thiele et al., 2012). Data from the SHOCK trial and registry indicate a nearly 60% rate of incomplete hemodynamic recovery after IABP insertion in CS complicating AMI with an increased associated mortality compared with responders (Hochman et al., 1999). The absence of a survival benefit and heterogeneous hemodynamic effects has dampened enthusiasm for the use of IABPs for CS.

A randomized clinical trial comparing the Impella 2.5 with IABP (ISAR-SHOCK) demonstrated a greater increase in cardiac index and MAP, a greater reduction in lactate, and a neutral effect on mortality with the Impella 2.5 (Seyfarth et al., 2008). The multicenter EUROSHOCK registry studied 120 patients receiving the Impella 2.5 for severe CS after failure of conventional therapy (Lauten et al., 2013). A reduction in lactate levels after device activation was observed after Impella 2.5 activation: however, cardiopulmonary resuscitation prior to Impella placement occurred in 41% of patients and 30-day mortality remained high. A more recent analysis of the USPella registry reported improved survival to hospital discharge with implantation of an Impella device immediately before compared with after coronary revascularization in AMI and cardiogenic shock. In this registry analysis, mean door-to-balloon time was delayed by 60 min in patients receiving the Impella device before versus after primary reperfusion (O'Neill et al., 2014). The recently published IMPella versus IABP reduces mortality in STEMI patients treated with primary PCI IN SEVERE and deep cardiogenic SHOCK (IMPRESS) trial (Ouweneel et al., 2017) and highlights the lack of benefit with the use of IABP or Impella device therapy for patients presenting with end-stage CS.

For patients with heart failure undergoing elective PCI, the PROTECT II study randomized patients to the Impella 2.5 LP or IABP before PCI (O'Neill et al., 2012). The trial was terminated early due to expected futility of the 30-day major adverse event primary endpoint. Subsequent analyses of the trial have shown potentially important benefits favoring Impella support associated with more complete revascularization and 90-day major adverse events.

Given the success of medical therapy in the advanced heart failure population with New York Heart Association class III and IV symptoms and the subsequent improvements in longevity for this sick cohort of patients, the role of device therapy in the road to recovery is more crucial than ever. Acute MCS options not only offer hemodynamic support but act as bridges to LVAD, transplant, recovery, and even as a bridge to decision, so patients presenting anywhere along the cardiogenic shock/heart failure spectrum may derive benefit. Future studies are needed to examine the effects of acute MCS device implantation on long-term patient survival and to potentially halt and reverse the progress of end-stage heart failure.

Introduction

The channelopathies are a group of rare inherited cardiac disorders characterized by a propensity for the development of life-threatening ventricular arrhythmias due to cardiac ionic channel dysfunction. They include long QT syndrome (LQTS), catecholaminergic polymorphic ventricular tachycardia (CPVT), Brugada syndrome (BrS), short QT syndrome (SQTS), and early repolarization syndrome (ERS). Idiopathic ventricular fibrillation (VF), as its name implies, is characterized by unexplained cardiac arrest (CA) and therefore is not truly a channelopathy but most probably a heterogeneous group of disorders sharing a final common pathway (i.e., VF). Nevertheless, in a minority of these cases an underlying genetic abnormality effecting ionic currents has been implicated and therefore it is included in this article.

As patients with channelopathies, with rare exceptions, have a structurally normal heart and do not have extra-cardiac manifestations, symptoms are almost exclusively arrhythmia related. When the arrhythmia is nonsustained and extremely short or occurs during sleep it may go unnoticed, however, if it is more prolonged it may result in loss of consciousness. In the case of sustained arrhythmia, resuscitated CA or sudden cardiac death (SCD) is the inevitable consequence. In some cases syncope may serve as a warning sign facilitating diagnosis and implementation of sudden death preventive measures. In others, however, SCD is the first symptom. It is this risk of a devastating event striking without warning in an otherwise healthy and frequently young individual that makes diagnosis, risk stratification, and treatment of patients with channelopathies most challenging. Genetic testing, which is useful for diagnoses of presymptomatic individuals, is therefore of special importance in these inherited disorders.

In this article we briefly review the clinical aspects of the various channelopathies and focus on their genetic background and the way genetic testing may be utilized in the clinical setting

Terminology note: For simplicity the term "mutation" in this article is used to denote pathogenic or likely pathogenic genetic variants.

General Approach to Genetic Testing for Channelopathies

Genetic testing may be used for four main indications: support of diagnosis, estimation of prognosis, personalized therapy, and family screening. The latter is the most robust indication for genetic testing in channelopathies (Ackerman et al., 2011).

Family screening—Whenever a pathogenic or likely pathogenic variant is found in a patient diagnosed with one of these syndromes, it is recommended that all first-degree family members be genetically screened in order to facilitate presymptomatic diagnosis and appropriate management. A word of caution is appropriate, though, in this context—in recent years we have become increasingly aware of the limitations of current knowledge in regard to classification of rare variants uncovered by genetic testing. The realization that some of the variants previously classified as pathogenic or likely pathogenic are not rare in large populations (and therefore unlikely to be truly pathogenic) and that many benign variants are also rare has raised the bar for robustness of evidence required for such classification (Richards et al., 2015). Re-evaluation of previously classified variants should therefore be considered depending on the clinical likelihood and details of the genetic variants found.

Evaluation of prognosis and personalized therapy—the use of genetic testing for these indications in channelopathies is still limited mainly to the classification of LQTS types. As LQTS type 1 (LQT1), 2, and 3 differ in their natural history and response to therapy, this genetic classification has an impact on management decisions (see below).

Support of diagnosis—in most cases, the diagnosis of a channelopathy should be made based on phenotype alone and genetic testing is reserved for the other indications (mainly family screening). Nevertheless, in some situations the clinical data does not

allow for a definite diagnosis to be made and the finding of a pathogenic variant may support the diagnosis and lead to change of management.

In recent years there has been a growing interest in the use of molecular autopsy for determination of the cause of SCD. As clinical data in these cases is frequently scarce genetic testing may offer important information leading to diagnosis. Indeed, a recent study demonstrated that pathogenic and likely pathogenic variants in genes associated with channelopathies (*KCNQ1*, *KCNH2*, *SCN5A*, or *RYR2*) were found in 3% and 6%, respectively, of unexplained SCD cases (Bagnall et al., 2016). A detailed discussion of the role of molecular autopsy in the era of next generation sequencing may be found elsewhere (Lahrouchi et al., 2016).

Long QT Syndrome

LQTS is characterized by prolongation of the QT interval and an increased risk for the development of a specific type of ventricular arrhythmia—torsades de pointes (TdP—Fig. 1). The extremely rare and highly lethal autosomal-recessive form of LQTS was first

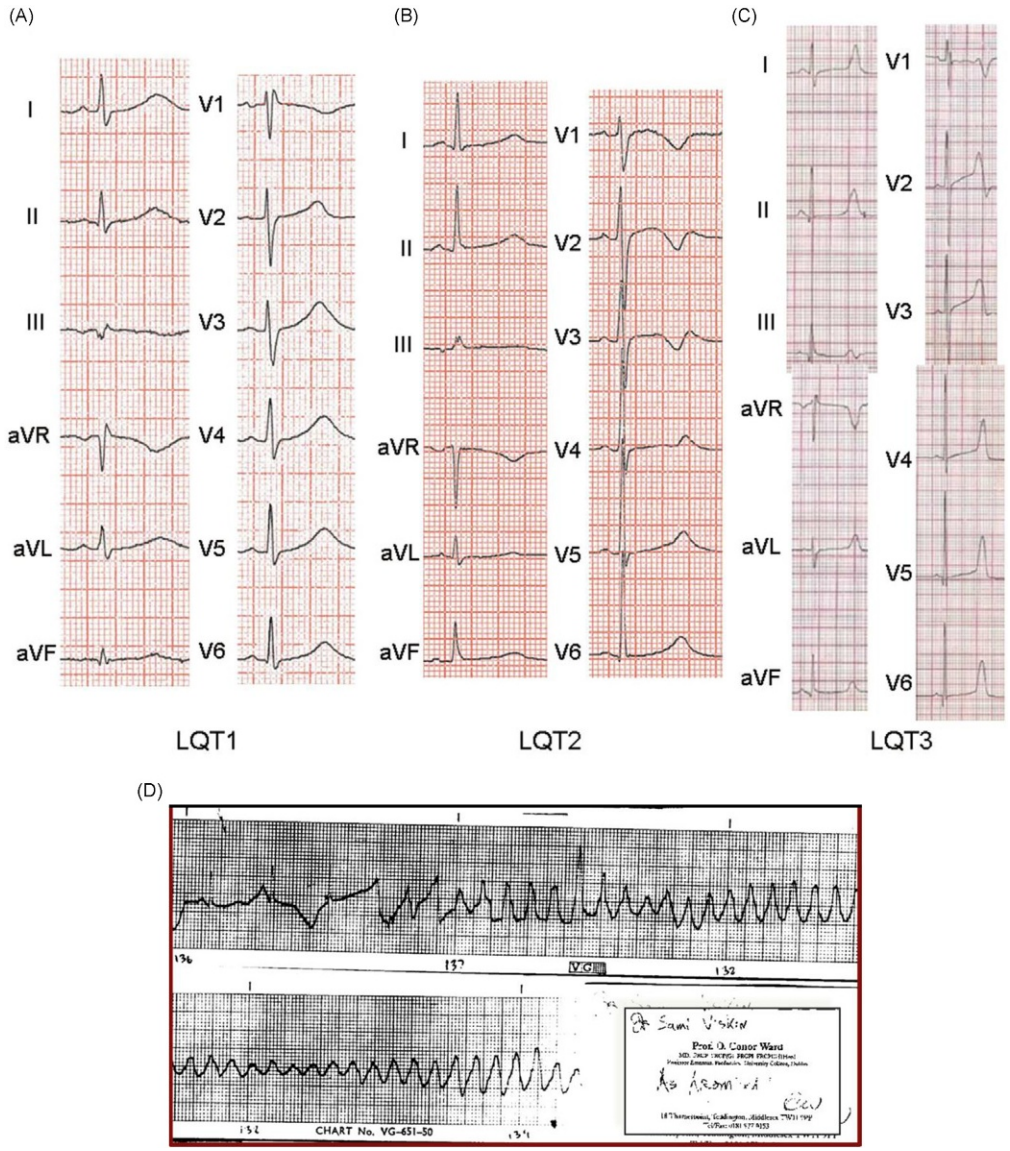

Fig. 1 Typical electrocardiographic patterns in long QT syndrome. (A) QT prolongation with typical broad-based T wave in LQT1. (B) QT prolongation with typical bifid T wave in LQT2. (C) QT prolongation with typical long ST-segment in LQT3. described in 1957 by Jervell and Lange-Nielsen (1957). This type also includes sensorineural deafness which is absent from the much more common autosomal dominant form described only a few years later by Romano et al. (1963) and then by Ward (1964).

Typically, symptoms (syncope or CA) develop during episodes of adrenergic stimulation. In LQTS type 1 (LQT1) common scenarios include exercise (especially swimming). In LQT2 sudden startling, particularly due to auditory stimulus (e.g., alarm clock), is a typical trigger for arrhythmias with higher risk during the postpartum period in female patients. In contrast, patients with the less common LQT3 are atypical in the sense that they tend to develop arrhythmias during rest.

Management includes lifestyle changes for avoidance of arrhythmogenic triggers (e.g., exercise, QT-prolonging drugs, hypokalemia) and drug therapy (mainly beta blockers). Left cardiac sympathetic denervation (LCSD) and implantable cardioverter defibrillators (ICDs) are used in higher risk patients.

Genetics of Congenital LQTS

To date, 15 genes have been associated with LQTS, the majority of which encode for subunits of cardiac ionic channels (**Table 1**). Mutations in these genes lead to perturbation of ionic currents which causes prolongation of the repolarization phase of the action potential and its surface ECG manifestation, the QT interval (**Fig. 1**). Differences in the degree of this prolongation between layers of the myocardium (i.e., transmural dispersion of repolarization) create a substrate predisposing for the development of TdP (Antzelevitch and Shimizu, 2002). Mutations in the *KCNQ1*, *KCNH2*, and *SCN5A* genes, responsible for LQTS type 1, 2, and 3, respectively, are found in 75%–80% of patients. Mutations in other genes are found in a small minority of patients while ≈15% remain genotype-negative.

KCNQ1 and *KCNH2* encode for the α-subunit of the slowly and rapidly activating delayed rectifier channels which are responsible for voltage-gated outward potassium currents (I_{Ks} and I_{Kr}, respectively). These are the major repolarization forces in the cardiomyocyte's action potential and therefore it is not surprising that loss-of-function mutations in these genes lead to QT prolongation. *KCNE1* and *KCNE2* encode for the β-subunits of these channels and mutations in these genes result in the less common LQT5 and LQT6, respectively (**Table 1**). Patients with Jervell-Lange-Nielsen syndrome are homozygous for mutations in *KCNQ1* or *KCNE1*.

SCN5A encodes for the α-subunit of the sodium channel, which is responsible for the inward sodium current (I_{Na}). This current is the main depolarization force; however, it has a late component which persists into the repolarization phases of the action potential. This late current ($I_{Na\text{-}L}$) opposes the repolarizing outward potassium currents but is normally very small. In LQT3, however, gain-of-function mutations augment the $I_{Na\text{-}L}$, thereby prolonging repolarization. Interestingly, loss-of-function mutations in this gene are the main genetic substrates in BrS (see below). Even more intriguing is the fact that some specific variants have been demonstrated in both LQT3 and BrS, suggesting that these variants' effect is variable and depends on yet poorly understood factors (Bezzina et al., 1999).

Table 1 Genes associated with long QT syndrome

Gene		*Protein*	*Effect on ionic current*	*% of index cases*
LQT1	*KCNQ1*	Potassium voltage-gated channel subfamily KQT member 1	$I_{Ks}\downarrow$	30–35
LQT2	*KCNH2*	Potassium voltage-gated channel subfamily H member 2 (hERG)	$I_{Kr}\downarrow$	25–30
LQT3	*SCN5A*	Sodium channel protein type 5 subunit alpha	$I_{Na}\uparrow$	5–10
LQT4[a]	*ANK2*	Ankyrin-2	Multiple (disrupts binding and assembly of membrane proteins)	Rare
LQT5	*KCNE1*	Potassium voltage-gated channel subfamily E member 1 (Mink)	$I_{Ks}\downarrow$	Rare
LQT6	*KCNE2*	Potassium voltage-gated channel subfamily E member 2 (MiRP1)	$I_{Kr}\downarrow$	Rare
LQT7[b]	*KCNJ2*	Inward rectifier potassium channel 2	$I_{K1}\downarrow$	Rare
LQT8[c]	*CACNA1C*	Voltage-dependent L-type calcium channel subunit alpha-1C	$I_{Ca\text{-}L}\uparrow$	Rare
LQT9	*CAV3*	Caveolin-3	$I_{Na}\uparrow$	Rare
LQT10	*SCN4B*	Sodium channel subunit beta-4	$I_{Na\text{-}L}\uparrow$	Rare
LQT11	*AKAP9*	A-kinase anchor protein 9 (Yotiao)	$I_{Ks}\downarrow$	Rare
LQT12	*SNTA1*	Alpha-1-syntrophin	$I_{Na}\uparrow$	Rare
LQT13	*KCNJ5*	G protein-activated inward rectifier potassium channel 4	$I_{K\text{-}ACh}\downarrow$	Rare
LQT14	*CALM1*	Calmodulin	Impaired Ca^{2+} binding	Rare
LQT15	*CALM2*	Calmodulin	Impaired Ca^{2+} binding	Rare

[a]Ankyrin B syndrome.
[b]Andersen-Tawil syndrome.
[c]Timothy syndrome.

Notable among the rest of the genes implicated in LQTS (**Table 1**) is *KCNJ2*. Mutations in this gene have been demonstrated to underlie Andersen-Tawil syndrome (LQT7). This syndrome differs from other types of LQTS by extra-cardiac symptoms (periodic paralysis and dysmorphic features), ventricular arrhythmias other than TdP and QT-U rather than QT prolongation (Zhang et al., 2005). These variances have led some experts to exclude Andersen-Tawil syndrome from the LQTS group.

Genotype-tailored management

As mentioned above, arrhythmogenic triggers differ between patients with mutations in *KCNQ1*, *KCNH2*, and *SCN5A* (leading to LQT1, LQT2, and LQT3, respectively). Accordingly, genetic results are incorporated into the clinical decision algorithm regarding lifestyle changes recommended for these patients: LQT1 patients are likely to receive stricter exercise restrictions while women with LQT2 may be followed more closely in the postpartum period. Furthermore, the impact of gender and age seems to be genotype dependent. In LQT1, boys have a higher risk of CA or SCD when compared to girls but after onset of adolescence this difference disappears (Costa et al., 2012). In LQT2, however, women were found to have a higher risk of CA/SCD up to the age of 40 (Migdalovich et al., 2011) and a higher risk of syncope in the peri- and postmenopausal period (Buber et al., 2011). These genotype-specific age and gender-dependent factors may be included in risk stratification schemes that guide therapy in LQTS.

Genotype may also have an impact on effectiveness of drug therapy in LQTS. The protective effect of BB is thought to be most robust in patients with LQT1. One study analyzed data of over 300 patients with LQT1 and LQT2 treated with BB (Priori et al., 2004). It demonstrated that 10% of LQT1 patients had cardiac events (mainly unexplained syncope), including 1% with CA, during 5 years of follow-up. In LQT2 patients, BB offered less protection with 23% having cardiac events, including 7% with CA. Of note, LQT1 patients in this study had shorter QTc intervals, an alternative explanation for their lower risk; however, genotype remained a predictor of cardiac events in treated patients on multivariable analysis. Furthermore, these results are in line with a previous smaller study demonstrating 19% and 36% cardiac event rate over a similar period of follow-up in LQT1 and LQT2, respectively (Moss et al., 2000).

Among patients with LQT1, patients with mutations demonstrated to have a negative-dominant effect had longer QT intervals and were at higher risk of cardiac events when compared to those with haploinsufficient mutations (Moss et al., 2007). Mutations effecting amino acids incorporated into the cytoplasmatic loops (C-loops) may also be at increased risk of CA or SCD. One study, including 860 LQT1 patients, demonstrated a 33% risk of these events up to the age of 40 in patients with C-loop mutations compared with <16% in patients with other mutations (Barsheshet et al., 2012). On BB, however, there was an 88% reduction in events in patients with C-loop mutations but a nonsignificant reduction of 18% in LQT1 patients with other mutations. These findings are possibly limited to female patients (Costa et al., 2012). In LQT2, missense mutations in the pore region of the hERG channel were associated with a higher risk of cardiac events (Shimizu et al., 2009), an observation that may be limited to male patients only (Migdalovich et al., 2011).

Based on studies which included a limited amount of LQT3 patients (28 in each study) (Moss et al., 2000; Priori et al., 2004) the protection derived from BB therapy in LQT3 was thought to be limited. However, a recent study, including 391 LQT3 patients, demonstrated otherwise with an 83% reduction in cardiac events in women with LQT3 (Wilde et al., 2016). Although no statistically significant benefit was demonstrated in men, this may have resulted from a lower event rate in the male subpopulation in this study.

Because of the unique pathophysiology in LQT3 (mutations leading to increase in $I_{Na\text{-}L}$) sodium channel blockers have been investigated for therapy of patients with this LQTS subtype. Indeed small studies have demonstrated benefit using mexiletine (Mazzanti et al., 2016) and ranolazine [ChorinCircEP16-pending] (Chorin et al., 2016). Studies using specific $I_{Na\text{-}L}$ blockers are currently under way [NCT02300558].

Genetics of Acquired LQTS

Acquired LQTS results from prolongation of repolarization due to factors other than pathogenic genetic variants. Common causes of acquired LQTS include drugs blocking the *KCNH2*-encoded hERG channel, hypokalemia, and bradyarrhythmias. In most cases, however, a single factor is insufficient for the development of significant QT prolongation and TdP (Zeltser et al., 2003). For symptoms to occur a combination of several factors is usually necessary, one of which may be genetic predisposition. Indeed, single nucleotide polymorphisms (SNP) in *SCN5A* (Ser1103Tyr) (Splawski et al., 2002), *KCNE1* (Asp85Asn) (Nishio et al., 2009; Kaab et al., 2012), and *KCNE2* (Thr8Ala & Gln9Glu) (Sesti et al., 2000; Abbott et al., 1999) have been associated with increased risk of acquired LQTS and TdP. The *SCN5A* and *KCNE1* variants were found to be polymorphisms in African and European populations, respectively. Both were demonstrated to be overrepresented in arrhythmia cases. The *KCNE2* variants are polymorphisms in European (Thr8Ala) and African (Gln9Glu) populations and were shown to induce sensitivity to the QT-prolonging effect of sulfamethoxazole (Thr8Ala) and clarithromycin (Gln9Glu). Thus, these SNPs may induce an effect which is insufficient for the development of congenital LQTS; however, they probably increase the risk for acquired LQTS and TdP if patients are exposed to other QT-prolonging factors.

Genetic Modifiers

As in many genetic syndromes patients with LQTS demonstrate a wide range of phenotypic severity. This is true not only for patients with different mutations but also within families harboring a single pathogenic variant. Unfortunately, the mechanisms influencing

severity of phenotype are poorly understood. Research in the past decade and a half uncovered multiple genetic variants that have been associated with longer QTc intervals and poorer prognosis in patients with LQTS. Most of these variants have been found in one of the LQTS-associated genes (Amin et al., 2012; Crotti et al., 2005; Makielski et al., 2003) (**Table 1**) but, similar to the abovementioned polymorphisms specifically associated with acquired LQTS, they are regarded as modifiers rather than truly pathogenic. The validity of these associations and their impact on clinical management of patients awaits further studies, however. For instance, a recent publication (Crotti et al., 2016) could not corroborate previous findings implicating SNPs in the 3′ untranslated region of *KCNQ1* as disease modifiers (Amin et al., 2012).

Perhaps surprisingly, the strongest evidence supporting genetic variants as modifiers of disease was found for polymorphisms in the *NOS1AP* gene, which encodes for nitric oxide synthase 1 adaptor protein. Multiple studies have demonstrated association of these polymorphisms with QT interval (Arking et al., 2006; Newton-Cheh et al., 2007; Aarnoudse et al., 2007) and prognosis in patient with LQTS (Crotti et al., 2009; Tomas et al., 2010). Other modifiers in genes not otherwise associated with LQTS have been suggested in *ADRA2C* and *ADRB1* (Schwartz et al., 2008).

Catecholaminergic Polymorphic Ventricular Tachycardia

Patients with CPVT usually present with recurrent syncope, CA, or SCD triggered by physical or emotional stress. Typically, patients develop symptoms during childhood although milder phenotypes presenting only later in life have been described (van der Werf et al., 2012; Priori et al., 2002; Hayashi et al., 2009) and may become increasingly recognized with expansion of genetic family screening. Unlike in other channelopathies patients with CPVT cannot be diagnosed based on ECG findings. Although sinus bradycardia (Postma et al., 2005) and prominent U waves (Aizawa et al., 2006) have been described in this disorder these findings are not diagnostic. The most helpful diagnostic tool is an exercise test, which typically demonstrates incremental ventricular arrhythmias with increased exercise. The typical arrhythmia characteristic of CPVT is bidirectional VT (**Fig. 2**) although it appears only in a minority of patients.

Management of CPVT includes avoidance of exercise and, if possible, emotional stress. Medical therapy includes BB and, in case this proves insufficient or intolerable, flecainide (van der Werf et al., 2011). LCSD (De Ferrari et al., 2015) and ICD implantation are utilized in higher risk patients.

Fig. 2 Typical bidirectional ventricular tachycardia in CPVT. Note the 180 degrees alternating axis change during tachycardia. Copied with permission from Leenhardt, A., Denjoy, I. and Guicheney, P. (2012). Catecholaminergic polymorphic ventricular tachycardia. *Circulation. Arrhythmia and Electrophysiology* **5**, 1044–1052.

Table 2 Genes associated with catecholaminergic polymorphic ventricular tachycardia

Gene	*Protein*	*% of index cases*
RYR2	Ryanodine receptor 2	65
CASQ2	Calsequestrin-2	2–5
TRDN	Triadin	Rare
CALM1	Calmodulin	Rare
CALM2	Calmodulin	Rare
CALM3	Calmodulin	Rare
TECRL	Trans-2,3-enoyl-CoA reductase-like	Rare

RYR2 is the only gene associated with CPVT that encodes for a protein directly incorporated into an ionic channel (the cardiac ryanodine receptor). All other genes encode for proteins that influence the function of the ryanodine receptor. Data on the association of the *TECRL* gene with CPVT is very preliminary.

In 2001 mutations in *RYR2* were identified as the culprits of CPVT in seven families demonstrating cosegregation with the disease (Priori et al., 2001; Laitinen et al., 2001). This gene, mutations in which are found in 65% of CPVT patients (**Table 2**), encodes for the cardiac ryanodine receptor, an ionic channel responsible for calcium flow from the sarcoplasmic reticulum into the cytosol. Gain-of-function mutations in *RYR2* result in a calcium leak during diastole which raises the cytosolic calcium levels. This increased calcium concentration activates the calcium–sodium exchanger leading to an inward sodium current and delayed-after-depolarizations triggering VT (Jiang et al., 2004). As the calcium leak is enhanced by β-sympathetic stimulation, it is not surprising that CPVT patients usually present with stress-induced arrhythmias. The majority of mutations in *RYR2* are found in three regions within the gene (Medeiros-Domingo et al., 2009) located in the N-terminus (amino acids 77–466), central domain (amino acids 2246–2534), and channel region (amino acids 3778–4959). This has led in the past to genetic testing focusing on these domains with optional testing for the rest of the gene in negative cases. However, with introduction of next generation sequencing and declining cost of genetic testing this approach has been largely replaced by a single tier approach of testing the whole gene.

The second gene that was discovered in CPVT is *CASQ2*, mutations in which are found in 2%–5% of CPVT patients. This gene encodes for calsequestrin which is responsible for calcium binding and storage within the sarcoplasmic reticulum and interacts with the ryanodine receptor. Its causality in CPVT was first described in seven families found to harbor a missense mutation cosegregating with the disease (Lahat et al., 2001). Although families with *CASQ2* mutations usually demonstrate an autosomal-recessive pattern of inheritance, an autosomal-dominant form was recently described (Gray et al., 2016).

Other genes associated with rare cases of CPVT are listed in **Table 2**. Patients with Andersen-Tawil syndrome (LQT7) and Ankyrin-B disease (LQT4) caused by mutations in *KCNJ2* and *ANK2*, respectively, may present with an atypical phenotype resembling CPVT (Kimura et al., 2012; Tester et al., 2006). Therefore, these genes should be considered in the evaluation of otherwise gene-negative CPVT cases (and are indeed included in many CPVT commercial genetic testing panels).

Like in other channelopathies, genotype–phenotype correlations in CVPT have been described. Patients with *CASQ2* (CPVT2) mutations are generally thought to express more severe disease than those with *RYR2* mutations (CPVT1). Within the CPVT1 group, patients with *RYR2* mutations located in the C-terminus channel-forming domain were demonstrated to have more nonsustained VT than those harboring mutations in the N-terminus (van der Werf et al., 2012). Nevertheless, these correlations have little impact on clinical management of patients, which is currently mainly phenotype-driven.

Brugada Syndrome

BrS is characterized by typical coved ST-segment elevation in the right precordial leads (type 1 Brugada pattern—**Fig. 3**). This pattern may be either spontaneous or induced by fever or drugs. Indeed, sodium channel blockers are used for diagnostic purposes in order to uncover a type 1 Brugada pattern in patients suspected of BrS who do spontaneously demonstrate this pattern. BrS is more common in males who typically develop symptoms during rest or sleep in their third to fifth decade of life.

Despite more than two decades of research the pathophysiology of BrS is still a matter of debate (Wilde et al., 2010). Some argue that BrS is primarily the result of transmural dispersion of repolarization in the right ventricle due to abnormal ionic repolarizing currents. Others argue that BrS is mainly a depolarization disorder with conduction delay and, possibly, subtle structural abnormalities of the right ventricular outflow tract being responsible for arrhythmogenesis.

Management of BrS is mainly dependent on ICD implantation for secondary prevention. ICDs may also be implanted for primary prevention in patients deemed to be at high risk, although methods for risk stratification remain a topic of heated debate (Adler et al., 2016). As fever and certain drugs may be arrhythmogenic, using antipyretics during febrile illness and avoiding drugs that may be deleterious is also important. Other management options include the use of pharmacological agents [e.g., quinidine (Belhassen et al., 2004; Hermida et al., 2004), isoproterenol (Maury et al., 2004)], and epicardial ablation of the right ventricular outflow tract (Nademanee et al., 2011).

The gene in which mutations are most commonly found and which has the most robust evidence associating it with the disease is *SCN5A*. Mutations in this gene, which encodes for the α-subunit of the cardiac sodium channel, cause loss of function with

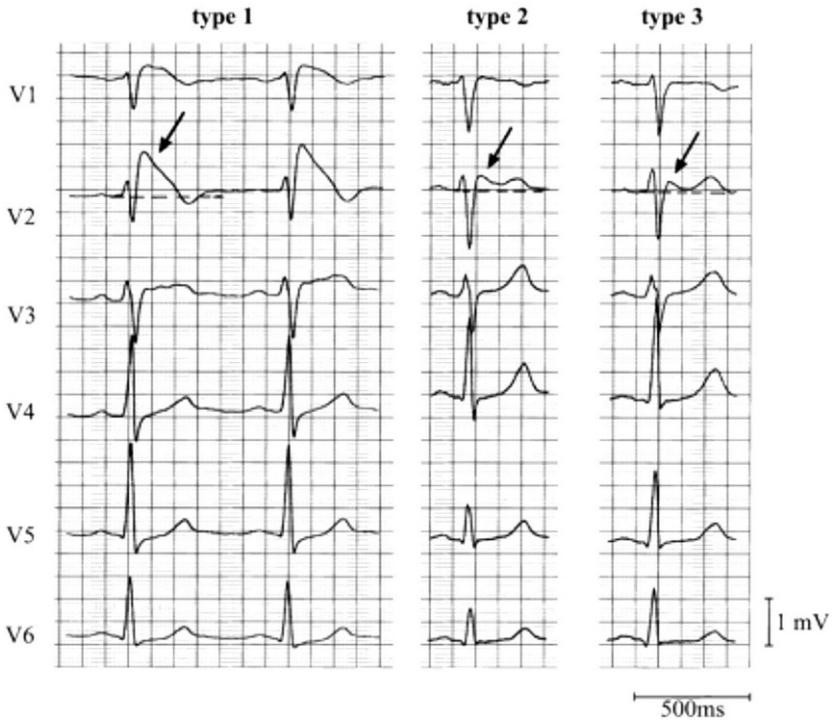

Fig. 3 Brugada ECG patterns. Type I pattern is defined as a coved ST-segment elevation in $\geq$2 mm in lead V1 or V2. Type II is defined as a saddle-back ST-segment elevation of $\geq$1 mm. Type III is defined as an ST-segment elevation $<$1 mm. Type II and III are suggestive of the diagnosis but only documentation of a type I pattern is regarded as diagnostic. Adapted from with permission from Brugada, P., Brugada, R. and Brugada, J. (2005). Should patients with an asymptomatic Brugada electrocardiogram undergo pharmacological and electrophysiological testing? *Circulation* **112**, 279–292; discussion 279–292.

reduced inward current and are found in up to 28% of patients. As mentioned above, gain-of-function mutations in this same gene are responsible for LQT3.

A specific mutation (Ala280Val) in *GPD1L* has been described in a large family of Italian descent and demonstrated cosegregation with phenotype (London et al., 2007). In vitro analysis demonstrated it reduces the inward sodium current (I_{Na}), possibly by impeding trafficking of the channel protein to the membrane. There is little information regarding the pathogenicity of other genetic variants in this gene.

Mutations in *CACNA1C* and *CACNB2b*, encoding for the α_1- and β_{2b}-subunits of the cardiac L-type calcium channel, have been associated with a phenotype consisting of Brugada pattern, a relatively short QT interval and SCD (Antzelevitch et al., 2007). Although supported by in vitro studies, cosegregation of genotype with phenotype was limited due to the small size of families studied.

Rare variants in *SCN10A* have been identified in 17% of patients in one study (Hu et al., 2014). However, subsequent studies comparing burden of rare variants in cases vs. controls casted doubt on whether variants in this gene contribute to disease in a significant percentage of BrS patients (Le Scouarnec et al., 2015; Behr et al., 2015).

The many other genes associated with BrS are listed in **Table 3**. Due to the limited available data supporting the pathogenicity of rare variants in these genes, interpretation of genetic testing utilizing large gene panels for BrS should be performed with extra care.

The use of genetic testing for risk stratification in BrS is currently limited. The presence of a mutation in *SCN5A* has not been associated with a different prognosis when compared with genotype-negative patients in large BrS cohorts (Probst et al., 2010; Conte et al., 2015). Truncating mutations in *SCN5A* and those found to cause a more significant reduction in the peak sodium current (I_{Na}) were associated with a higher risk of unexplained syncope and more pronounced conduction disease in one study (Meregalli et al., 2009). Recently, a SNP in *HEY2* has been associated with a protective effect against VF in BrS patients (Nakano et al., 2016); however, further studies are required for corroboration of this finding. Thus, our knowledge is currently insufficient for integration of genetic data into risk stratification algorithms in BrS.

Short QT Syndrome

SQTS is an extremely rare disorder described for the first time in 2000 (Gussak et al., 2000; Giustetto et al., 2011). It is characterized by a short QT interval (Fig. 4) and an increased risk for the development of atrial and ventricular arrhythmias. Patients are most

Table 3 Genes associated with Brugada syndrome

Gene	*Protein*	*Effect on ionic current*	*% of index cases*
SCN5A	Sodium channel protein type 5 subunit alpha	$I_{Na}\downarrow$	11–28
GPD1L	Glycerol-3-phosphate dehydrogenase 1-like protein	$I_{Na}\downarrow$	Rare
CACNA1C	Voltage-dependent L-type calcium channel subunit alpha-1C	$I_{Ca}\downarrow$	6.6
CACNB2b	Voltage-dependent L-type calcium channel subunit beta-2	$I_{Ca}\downarrow$	4.8
SCN1B	Sodium channel subunit beta-1	$I_{Na}\downarrow$	1.1
KCNE3	Potassium voltage-gated channel subfamily E member 3 (MiRP2)	$I_{to}\uparrow$	Rare
SCN3B	Sodium channel subunit beta-3	$I_{Na}\downarrow$	Rare
KCNJ8	ATP-sensitive inward rectifier potassium channel 8	$I_{K\text{-}ATP}\uparrow$	2
CACNA2D1	Voltage-dependent calcium channel subunit alpha-2/delta-1	$I_{Ca}\downarrow$	1.8
KCND3	Potassium voltage-gated channel subfamily D member 3	$I_{to}\uparrow$	Rare
RANGRF	Ran guanine nucleotide release factor	$I_{Na}\downarrow$	Rare
SLMAP	Sarcolemmal membrane-associated protein	$I_{Na}\downarrow$	Rare
ABCC9	ATP-binding cassette subfamily C member 9	$I_{K\text{-}ATP}\uparrow$	Rare
SCN2B	Sodium channel subunit beta-2	$I_{Na}\downarrow$	Rare
PKP2	Plakophilin-2	$I_{Na}\downarrow$	Rare
FGF12	Fibroblast growth factor 12	$I_{Na}\downarrow$	Rare
SCN10A	Sodium channel protein type 10 subunit alpha	$I_{Na}\downarrow$	5–16.7
HEY2	Hairy/enhancer-of-split related with YRPW motif protein 2	$I_{Na}\uparrow$	Rare
SEMA3A	Semaphorin-3A	$I_{to}\uparrow$	Rare

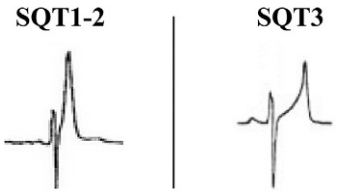

Fig. 4 Typical ECG patterns in short QT syndrome. Adapted with permission from Brugada, R., Hong, K., Dumaine, R., Cordeiro, J., Gaita, F., Borggrefe, M., Menendez, T. M., Brugada, J., Pollevick, G. D., Wolpert, C., Burashnikov, E., Matsuo, K., Wu, Y. S., Guerchicoff, A., Bianchi, F., Giustetto, C., Schimpf, R., Brugada, P. and Antzelevitch, C. (2004). Sudden death associated with short-QT syndrome linked to mutations in HERG. *Circulation* **109**, 30–35 and Priori, S. G., Pandit, S. V., Rivolta, I., Berenfeld, O., Ronchetti, E., Dhamoon, A., Napolitano, C., Anumonwo, J., DI Barletta, M. R., Gudapakkam, S., Bosi, G., Stramba-Badiale, M. and Jalife, J. (2005). A novel form of short QT syndrome (SQT3) is caused by a mutation in the KCNJ2 gene. *Circulation Research* **96**, 800–807.

Table 4 Genes associated with short QT syndrome

Gene	*Protein*	*Effect on ionic current*
KCNH2	Potassium voltage-gated channel subfamily H member 2 (hERG)	$I_{Kr}\uparrow$
KCNQ1	Potassium voltage-gated channel subfamily KQT member 1	$I_{Ks}\uparrow$
KCNJ2	Inward rectifier potassium channel 2	$I_{K1}\uparrow$
CACNA1A[a]	Voltage-dependent L-type calcium channel subunit alpha-1C	$I_{Ca}\downarrow$
CACNB2b[a]	Voltage-dependent L-type calcium channel subunit beta-2	$I_{Ca}\downarrow$

Due to the limited number of patients data regarding yield of genetic testing is scarce. See text for further discussion.

[a]This gene has been associated with a phenotype consisting of a Brugada pattern and a relatively short QT interval. A putative mutation has also been described in index cases from short QT cohorts.

commonly males and typically develop symptoms during sleep or rest in the second to fourth decade of life (Giustetto et al., 2011; Mazzanti et al., 2014). The diagnosis of SQTS can be a challenge and requires a high level of suspicion. A diagnostic score has been proposed as an aid for this matter (Gollob et al., 2011).

ICD implantation for secondary prevention is the mainstay of therapy. An ICD may also be considered for asymptomatic patients with family history of SCD (Priori et al., 2013). Pharmacological therapy with quinidine is an option in cases with recurrent ICD interventions.

The first mutations to be associated with SQTS were gain-of-function mutations in *KCNH2* (Brugada et al., 2004) and *KCNQ1* (Bellocq et al., 2004), the same genes in which loss-of-function mutations cause LQT2 and LQT1, respectively (**Table 4**). As a mirror image of LQTS, these mutations are thought to lead to abbreviated repolarization. Once more, it is differences between action potential duration in different layers of the myocardium that are thought to create the vulnerable substrate predisposing to arrhythmogenesis (Patel et al., 2010).

Other genes subsequently associated with SQTS are *KCNJ2*, encoding for the α-subunit of the inward rectifying potassium channel (I_{K1}) (Priori et al., 2005), *CACNA1C*, and *CACNB2b*. As mentioned in the previous section, the last two genes have been associated with an overlap syndrome which includes phenotype of both BrS and SQTS.

Data regarding prevalence of genetic findings in SQTS patients and phenotype–genotype correlations is limited by the small number of patients (the largest series include 53 (Giustetto et al., 2011) and 73 (Mazzanti et al., 2014) patients with only 17 and 45 genotyped index cases). In the larger of these series genetic testing was positive in 13% of patients with none of the genes implicated in more than 5% of patients. In three out of five gene-positive cases familial disease was found (the other two were de novo mutations) and demonstrated an autosomal dominant inheritance. According to the limited data available and in stark contrast to the findings in other channelopathies, families with a positive mutation demonstrated complete penetrance. Mutation carriers were found to have shorter QTc intervals when compared with gene-negative cases but this did not translate into more severe outcomes (Mazzanti et al., 2014).

Early Repolarization Syndrome

ERS is the most recent channelopathy described, first defined in a consensus paper only in 2013 (Priori et al., 2013). It is characterized by the finding of J-point elevation in two consecutive leads other than right precordial leads in a patient resuscitated from CA or the previous documentation of this finding in an SCD victim. Importantly, exclusion of all other reasons for J-point elevation or CA is imperative for diagnosis. Although this prerequisite is true for all channelopathies it is of special importance in ERS due to the relatively high prevalence of J-point elevation (3%–13%) in the general population (Adler and Gollob, 2015). For the same reason diagnosis of asymptomatic patients with ERS is especially difficult but may be suspected in family members of ERS patients or specific and rare clinical scenarios. Similar to the presentation in BrS and SQTS, patients are typically male presenting with symptoms during rest or sleep during their third to fifth decade of life (Haissaguerre et al., 2008; Rosso et al., 2008).

Because most ERS patients are diagnosed after developing symptoms, ICD implantation for secondary prevention is recommended in almost all patients. In the minority of patients with suspected ERS despite being asymptomatic, ICD implantation may be discussed on a case-by-case basis (Antzelevitch et al., 2016). Pharmacological therapy in ERS is similar to that in BrS, which is not surprising taking into account the similarities in patients' characteristics and suspected pathophysiology (Antzelevitch and Yan, 2015).

The molecular basis for ERS is thought to rely on augmentation of the physiological transmural gradient during early repolarization phases of the action potential. The main current responsible for this gradient is I_{to} (transient outward potassium current), which is more prominent in the epicardium than endocardium (Antzelevitch, 2013). It was therefore hypothesized that mutations causing augmentation of outward currents (e.g., I_{to}, I_{KATP}) or diminution of opposing inward currents (e.g., I_{Ca}, I_{Na}) may underlie the pathophysiology of ERS. Studies utilizing a candidate gene approach have indeed uncovered putative mutations in genes encoding for subunits of potassium, calcium, and sodium channels or proteins regulating their activity (**Table 5**). Importantly, however, robust data supporting the pathogenicity of these genetic variants and demonstrating cosegregation of genotype with phenotype is lacking. Furthermore, in a study describing four large families with ERS and multiple SCD cases, analysis of most of the genes associated thus far with ERS (*KCNJ8*, *SCN5A*, *CACNA1C*, *CACNB2*, and *CACNA2D1*) failed to uncover mutations in the probands of each family.

Idiopathic VF

Idiopathic VF is diagnosed in cases resuscitated from CA after exhaustive diagnostic tests have been unable to uncover the cause. As such it is not truly a syndrome but most probably a heterogeneous group consisting of multiple conditions. Nevertheless, many patients with idiopathic VF share common characteristics suggesting a possible common etiology. These include male gender, first presentation during sleep or rest in the third to fifth decade of life, and VF triggered by close-coupled premature ventricular complexes (PVC) (Viskin et al., 1997).

Table 5 Genes associated with early repolarization syndrome

Gene	*Protein*	*Effect on ionic current*	*% of index cases*
KCNJ8	ATP-sensitive inward rectifier potassium channel 8	$I_{K\text{-}ATP}\uparrow$	Rare
CACNA1C	Voltage-dependent L-type calcium channel subunit alpha-1C	$I_{Ca}\downarrow$	4
CACNB2b	Voltage-dependent L-type calcium channel subunit beta-2	$I_{Ca}\downarrow$	8
CACNA2D1	Voltage-dependent calcium channel subunit alpha-2/delta-1	$I_{Ca}\downarrow$	4
ABCC9	ATP-binding cassette subfamily C member 9	$I_{K\text{-}ATP}\uparrow$	Rare
SCN5A	Sodium channel protein type 5 subunit alpha	$I_{Na}\downarrow$	Rare
SCN10A	Sodium channel protein type 10 subunit alpha	$I_{Na}\downarrow$	Rare
KCND2[a]	Potassium voltage-gated channel subfamily D member 2	$I_{to}\uparrow$	Rare

[a]A putative mutation in this gene was found in a patient resuscitated from a cardiac arrest who was found to have large J waves in right precordial leads but not a typical Brugada pattern (i.e., does not answer the diagnostic criteria for Brugada syndrome or early repolarization syndrome).

Table 6 Genes associated with idiopathic ventricular fibrillation

Gene	*Protein*	*% of index cases*
DPP6[a]	Dipeptidyl aminopeptidase-like protein 6	Rare
CALM1	Calmodulin	Rare
ACTN2	Alpha-actinin-2	Rare
RYR2	Ryanodine receptor 2	Rare
IRX3	Iroquois-class homeodomain protein IRX-3	Rare

[a]Dutch founder mutation.

As all patients with idiopathic VF are symptomatic, ICD for secondary prevention is recommended in all. Therapy with quinidine may be considered in patients with frequent ICD shocks or in those who have a contraindication for an ICD (Priori et al., 2013). Ablation of PVCs may be considered in cases with frequent arrhythmias.

As most cases of idiopathic VF are sporadic genetic studies of this population are difficult. One large kindred from Holland, however, does demonstrate multiple cases of SCD and CA. In this kindred a risk haplotype including a variant upstream of the coding region of *DPP6* (c.1-340 C>T) has been identified (Alders et al., 2009). It is thought that this variant results in over-expression of the dipeptidyl peptidase-like protein-6 (DPP6) and subsequent increase in I_{to} which is modulated by it (Xiao et al., 2013).

Others genes that have been implicated with idiopathic VF are listed in **Table 6**. In all of these cases the genes have been found in single cases or small families. Furthermore, in most cases the phenotype has not been typical of idiopathic VF as described above and may be more concordant with an overlap syndrome or an atypical presentation of another syndrome. For instance, a rare variant in *ACTN2* was found in two families with short-coupled PVCs triggering VF; however, in some mutation carriers a variable phenotype including hypertrophic cardiomyopathy and left ventricular noncompaction was demonstrated (Bagnall et al., 2014). Thus, an arrhythmogenic cardiomyopathy rather than idiopathic VF may be the diagnosis in these families. In other studies mutations in *RYR2* were found in patients with CA but without exercise-induced arrhythmias (Cheung et al., 2014). Whether these patients should be best approached as atypical CPVT patients, idiopathic VF patients, or as a unique subset is not clear. Accordingly, the role of clinical genetic testing for rare variants in these genes in the setting of idiopathic VF remains to be elucidated.

Introduction

Cardiovascular disease is the leading cause of death in the United States accounting for 801,000 deaths annually, 2200 deaths daily, and a death every 40 s. It causes more deaths than all forms of cancer and chronic lower respiratory tract disease combined. Coronary artery disease (CAD) is the leading cause of and attributed for 45% of all cardiovascular deaths. Further, CAD accounts for 790,000 myocardial infarctions annually, approximately one every 40 s (**Table 1**). Typically, patients with ischemic cardiomyopathy have CAD with or without a past history of myocardial infarction. Ischemic cardiomyopathy is the leading cause for sudden cardiac death that affects 350,000 Americans annually. In this article, we will characterize the transition from CAD to ischemic cardiomyopathy and address its prevention, diagnosis, and management.

Ischemic cardiomyopathy is the most common etiology of heart failure (HF), a disease which affects 6 million patients today and is projected to affect 8 million patients by 2030 (Mozaffarian et al., 2016). In 13 multicenter HF treatment trials involving >20,000 patients, it was the underlying etiology of HF in nearly 70% of patients (Ghoerghiade and Bonow, 1998). Further, the presence of CAD is not only common in patients with HF with reduced ejection fraction (HFrEF), but also in patients with HF with preserved ejection fraction (HFpEF) (Lee et al., 2009; Owan et al., 2006). This is particularly relevant because ischemic cardiomyopathy represents a potentially treatable cause of HF. The importance of assessing CAD in HF is underscored by the observation that prognosis of patients with HF from ischemic cardiomyopathy is considerably worse than that of patients without ischemic cardiomyopathy, and is related to the angiographic severity of the CAD (Bart et al., 1997).

Progression of CAD to Ischemic Cardiomyopathy

There are multiple pathways to ischemic cardiomyopathy that include acute myocardial infarctions, silent ischemia, and recurrent small infarctions (**Fig. 1**). Changes in the myocardium in acute ischemia are dynamic and complex. The acute loss of myocardium results in an abrupt increase in loading conditions in the infarct border zone and the noninfarcted myocardium that triggers neurohormonal activation and a cascade of intracellular signaling processes which induce ventricular remodeling. Ischemia produces a rapid and massive surge in endogenous catecholamines with a deleterious effect on myocytes resulting in myocardial apoptosis, fibrosis, and arrhythmias. This neurohormonal activation and ventricular remodeling can lead to progressive deterioration of further viable myocardium. Ventricular dilation and hypertrophy may continue for weeks or months until the distending forces are counterbalanced by the strength of the collagen scar. The size, location, transmurality of the infarction, patency of the infarct-related artery, and degree of neurohormonal response determine this balance (Rouleau et al., 1993; Sutton and Sharpe, 2000; Warren et al., 1988). Accordingly, in the setting of acute ischemia, therapies are aimed at prompt revascularization to restore infarct-related artery patency and salvage of viable myocardium, as well as ameliorating the neurohormonal activation with the use of ACE inhibitors or angiotensin receptor blockers (ARB), beta-blockers, statins, and aldosterone antagonists. Patients who survive an acute myocardial infarction are at high risk of re-infarction and further loss of myocardial function. This further underscores the importance of risk factor modification to prevent recurrent ischemic events.

While revascularization significantly reduces mortality following acute myocardial infarction, left ventricular remodeling often occurs despite sustained patency of the infarct-related artery and preservation of regional and global left ventricular function (Bolognese et al., 2002) (**Fig. 2**). Sometimes the ischemic event can be asymptomatic or silent and contribute to the progression of left ventricular systolic and/or diastolic dysfunction leading to the development of clinical HF or arrhythmias. Myocardial

Table 1 Fact sheet on ischemic cardiomyopathy

- Cardiovascular disease affects 90 million Americans, accounting for 801,000 deaths annually
- Coronary artery disease is the leading cause of cardiovascular death
- Coronary artery disease leads to ischemic cardiomyopathy with or without myocardial infarction
- Ischemic cardiomyopathy is the leading cause of heart failure
- Ischemic cardiomyopathy is the leading cause of sudden cardiac death

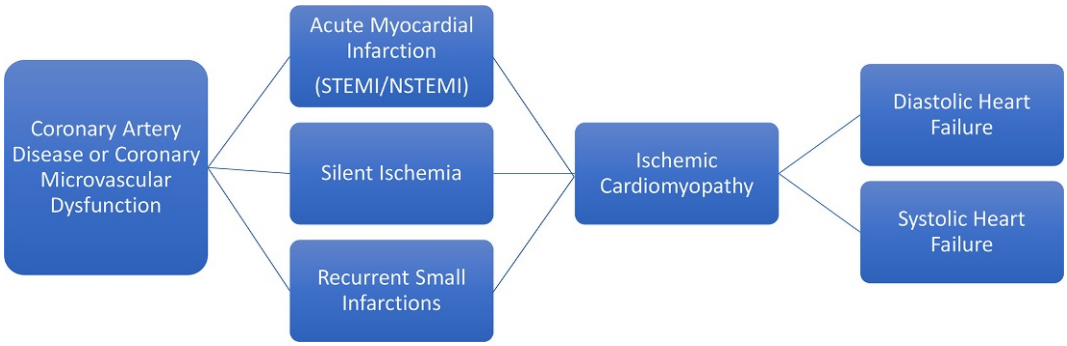

Fig. 1 Progression from coronary artery disease to ischemic cardiomyopathy and heart failure.

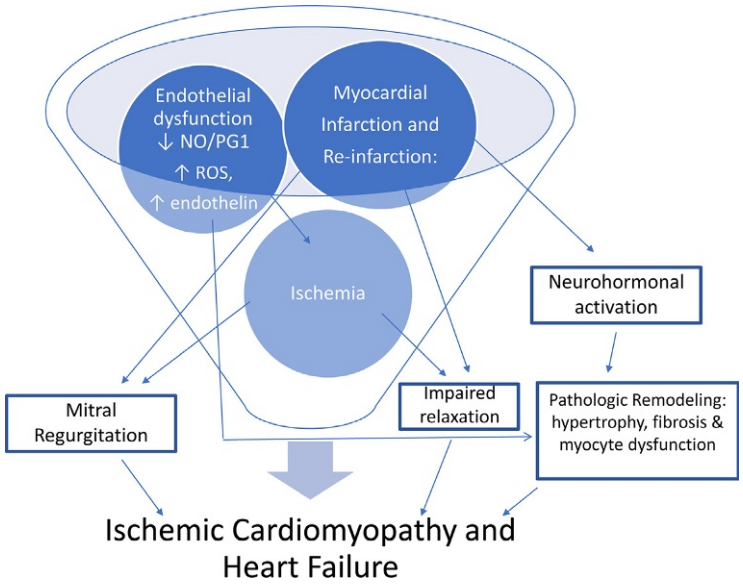

Fig. 2 Patho-biology of Ischemic cardiomyopathy and heart failure. (NO = nitric oxide; PG = prostaglandin; ROS = reactive oxygen species).

hibernation from chronic ischemia may also contribute to left ventricular dysfunction. Coronary microvascular dysfunction, in the absence of obstructive coronary disease, is frequently characterized by heightened sensitivity to vaso-constrictor stimuli and decreased vasodilator reserve, and can cause myocardial ischemia.

The presence and extent of CAD often determines the pace of development and progression of ischemic cardiomyopathy and HF. In a prospective study that longitudinally followed patients for 10 years, the cohort hospitalized for the first time due to HF had documented coronary disease in 25% of patients who developed HFpEF and in 39% of patients with HFrEF (Rusinaru et al., 2014). The vast majority of patients died of cardiovascular causes, and the proportion was comparable between HFpEF and HFrEF. In the presence of coronary disease, sudden cardiac death was the leading cause of death in HFpEF, while refractory HF was the most common cause among HFrEF patients. Coronary disease though was independently predictive of sudden death in both HFpEF and HFrEF and also showed an independent association with HF-related death and with acute myocardial infarction death (Rusinaru et al., 2014).

Mitral regurgitation is a common complication after myocardial infarction, particularly inferior wall infarction, due to changes in ventricular structure and function and often accompanies ischemic cardiomyopathy. Even mild mitral regurgitation after myocardial infarction carries an adverse prognosis and is an independent predictor of HF and death (Lamas et al., 1997; Salukhe et al., 2005). Further, in hemodynamically significant ischemic mitral regurgitation, the left ventricle dilates to preserve forward cardiac output, which in turn worsens mitral regurgitation due to tethering of the papillary muscles and sparks a viscous cycle that often leads to worsening HF.

Prevention of Ischemic Cardiomyopathy

Since patients with and at risk for coronary disease are likely to develop ischemic cardiomyopathy HF, clinicians should seek to control vascular and metabolic risk factors in such patients (Smith et al., 2011). Treatment of hypertension and dyslipidemia can significantly reduce the development and progression of coronary disease and should be controlled in accordance with contemporary guidelines. Long-term treatment of hypertension reduces the risk of HF development by approximately 50% (Kostis et al., 1997). Obesity, diabetes, tobacco use, unhealthy diet, physical inactivity, stress, known cardiotoxic agents, and systemic inflammation that may lead to or contribute to both HF and the progression of underlying coronary disease should be controlled or avoided or addressed.

Diagnostic Strategy in Ischemic Cardiomyopathy

Etiology of HF

Any patient who presents with HF should be evaluated for the presence of CAD. The 2013 ACC/AHA Heart Failure Guideline (**Tables 2–6**) supports seeking the etiology of HF by evaluating for ischemic disease either noninvasively or invasively (Yancy et al., 2013b). Surprisingly, a recent study analyzing the patterns of testing for CAD in patients with new-onset HF showed that only 17% of patients underwent testing for CAD during the index hospitalization and this increased to only 27% at 90 days (Doshi et al., 2016). This underutilization of coronary artery assessment in new-onset HF patients has significant treatment implications.

Given its widespread availability and lack of ionizing radiation, echocardiography is often preferred as the initial imaging diagnostic test in patients with or at risk for HF. Echocardiography should address whether the left ventricular ejection fraction is reduced or whether there are structural or focal wall motion abnormalities that could account for the patient's clinical presentation. Echocardiographic evaluation can also give the clinician insight into the degree and duration of myocardial damage if it is present.

Table 2 ACC/AHA guidelines for imaging in HF

Recommendations	*COR*	*LOE*
A 2-D echocardiogram with Doppler should be performed for initial evaluation of HF	I	C
Repeat measurement of EF is useful in patients with HF who have had a significant change in clinical status or received treatment that might affect cardiac function or for consideration of device therapy	I	C
Noninvasive imaging to detect myocardial ischemia and viability is reasonable in HF with CAD	IIa	C
Viability assessment is reasonable before revascularization in HF with CAD	IIa	B
MRI is reasonable when assessing myocardial scar	IIa	B
When ischemia may be contributing to HF, coronary angiography is reasonable	IIa	C

Table 3 ACC/AHA HFrEF medical therapy guidelines

Recommendations	*COR*	*LOE*
Diuretics for fluid retention	I	C
ACEI	I	A
ARB, if ACEI intolerant	I	A
ARB as alternative to ACEI	IIa	A
ARNI as an alternative to ACEI or ARB for NYHA II-III	I	B
Replacement of ACEI or ARB with ARI for symptomatic patients with NYHA II–III symptoms	I	B
Approved beta-blockers	I	A
Aldosterone antagonist for NYHA class II–IV	I	A
Combination of hydralazine-isosorbide dinitrate for patients who cannot receive ACEI or ARB	IIa	B
Combination of hydralazine-isosorbide dinitrate for African American patients with NYHA II–IV symptoms on GDMT	I	A
Digoxin	IIa	B
Ivabradine to decrease HF hospitalization in NYHA class II–III patients on GDMT (including beta-blocker) with NSR and resting HR $\geq$70 bpm	IIa	B

Table 4 ACC/AHA HFpEF therapy guidelines

Recommendations	*COR*	*LOE*
Blood pressure control according to published guidelines	I	B
Diuretics for volume retention	I	C
Coronary revascularization in patients with angina or demonstrable ischemia despite GDMT	IIa	C
Beta-blockers, ACEI, and ARBs for treatment of hypertension	IIa	C

Recommendations	*COR*	*LOE*
ICD therapy for primary prevention of SCD for LVEF $\leq$ 35%, NYHA II–III symptoms, at least 40 days post-MI, at least 3 months of GDMT	I	A
ICD therapy for primary prevention of SCD for LVEF $\leq$30%, NYHA I, at least 40 days post-MI, at least 3 months of GDMT	I	B
CRT therapy for LVEF $\leq$35%, sinus rhythm, LBBB with QRS $\geq$150 ms, NYHA II–IV symptoms on GDMT	I	A/B
CRT therapy for LVEF $\leq$35%, sinus rhythm, non-LBBB with QRS $\geq$150 ms, NYHA III–IV symptoms on GDMT	IIa	A
CRT therapy for LVEF $\leq$35%, sinus rhythm, non-LBBB with QRS $\geq$150 ms, NYHA II symptoms on GDMT	IIb	B
CRT therapy for LVEF $\leq$30%, sinus rhythm, non-LBBB with QRS $\geq$150 ms, NYHA I on GDMT	IIb	C
CRT therapy for LVEF $\leq$35%, sinus rhythm, LBBB with QRS 120–149 ms, NYHA II–IV symptoms on GDMT	IIa	B
CRT therapy for LVEF $\leq$35%, sinus rhythm, non-LBBB with QRS 120–149 ms, NYHA III–IV symptoms on GDMT	IIb	B

In the setting of an infarction of unclear duration, a thin and akinetic anterior ventricular wall would be managed differently than diffuse global dysfunction or a focal regional wall motion abnormality with normal ventricular thickness.

Assessment of Myocardial Ischemia and Viability

Once the diagnosis of CAD as an etiology of HF is suspected or established, the question then becomes whether further testing to evaluate the ischemic burden or degree of viability is indicated. Noninvasive imaging, such as stress nuclear imaging or stress echocardiography, to detect myocardial ischemia is recommended in patients who have symptoms, and are potentially eligible for revascularization. Exercise–redistribution–reinjection thallium scintigraphy and dobutamine and exercise stress echocardiography are safe, nonvinvasive, and accurate means of identifying viable myocardium and have been shown to predict contractile recovery after redistribution (Arnese et al., 1995; Dilsizian et al., 1990; Vanoverschelde et al., 1995). Additionally, positron emission tomography (PET) enhanced fluorine-18-labeled fluorodeoxyglucose (FDG) uptake in myocardial segments with impaired function and reduced blood flow is evidence of myocardial viability.

Cardiac magnetic resonance (CMR) is now established as a key noninvasive modality for the evaluation of patients with coronary disease. Late gadolinium enhancement (LGE) on CMR identifies infarcted or fibrotic tissue, whereas its absence indicates "viable" myocardium that exhibits a high potential for recovery after restoration of blood flow. LGE on CMR is the gold standard technique for myocardial infarct visualization in both acute and chronic MI and an accurate predictor of recovery of ventricular function after revascularization (Kim et al., 2000). Further, the presence of LGE has been associated with a higher incidence of major adverse cardiac events (MACE) and is an important prognostic indicator (Kwong et al., 2006).

While the results of the STICH (Surgical Treatment for Ischemic Heart Failure) trial cast doubt on the role of myocardial viability assessment to determine the mode of therapy, the presence of viable myocardium was associated with greater likelihood of survival in patients with CAD and left ventricular dysfunction (Bonow et al., 2011).

Coronary angiogram should be completed in all patients with a positive noninvasive study, or patients with obstructive coronary disease who are candidates for coronary revascularization. The utility of intervention can be determined either by effect on viable ischemic myocardium and contractile recovery or by treatment of angina.

Assessment of Coronary Microvascular Dysfunction

Coronary microvascular dysfunction is suspected when patients have angina and no obstructive coronary disease. Noninvasive studies, such as stress echocardiography or stress nuclear imaging, may be normal in these patients. However, CMR with LGE, PET, and myocardial contrast echocardiography may be useful in quantifying myocardial perfusion and coronary blood flow. There is no specific diagnostic test to directly visualize the coronary microvasculature. Coronary angiography with coronary vasoreactivity testing and measurement of coronary flow reserve should be considered in select patients with a high index of suspicion.

Treatment

In patients with ischemic cardiomyopathy and HF, a comprehensive management strategy that draws on all three components of evidence-based therapy is required. Care of the patient should include pharmacologic therapy, revascularization strategies, and assessment for electrophysiological device-based treatment.

Pharmacologic Therapy (Fig. 3)

In the past two decades, numerous clinical trials have examined the effects of medical therapy on clinical outcomes, including survival in patients with chronic HF. Though the majority of these clinical trials that have shaped guideline-directed medical therapy were performed considering HF as a homogenous disease process, the diagnosis of ischemic cardiomyopathy was generally well represented in these trials and subgroup analyses did demonstrate consistent benefit in patients with ischemic cardiomyopathy. Guideline-based medical therapy in HF is based upon whether the patient has HFrEF (LVEF $\leq$40%) or HFpEF (LVEF $\geq$50%), has symptoms, and the degree of functional limitation assessed subjectively by New York Heart Association (NYHA) Class.

Inhibition of the renin–angiotensin system with angiotensin-converting enzyme inhibitors (ACEI), ARB, or angiotensin receptor-neprilysin inhibition (ARNI) has emerged as the clinical strategy of choice for all patients with HFrEF to improve symptoms and functional class, reduce morbidity, risk of hospitalization, and mortality. ACEI or ARB are also recommended for postmyocardial infarction patients with HFrEF. In the SOLVD and SAVE trials, the ACEI enalapril and captopril not only reduced overall mortality in patients with coronary disease but also reduced the rate of nonfatal myocardial infarction and unstable angina (UA) (Pfeffer et al., 1992; Yusuf et al., 1992). In CHARM-Alternative trial, therapy with the ARB candesartan demonstrated a 23% reduction in the relative risk of cardiovascular mortality or hospital admission for HFrEF patients intolerant of ACEI, a reduction similar to that seen in SOLVD with enalapril (Granger et al., 2003). Recent results of the PARADIGM-HF trial showed that the ARNI valsartan–sacubitril was superior to ACEI enalapril in reducing the risk of death and hospitalizations for HF (McMurray et al., 2014).

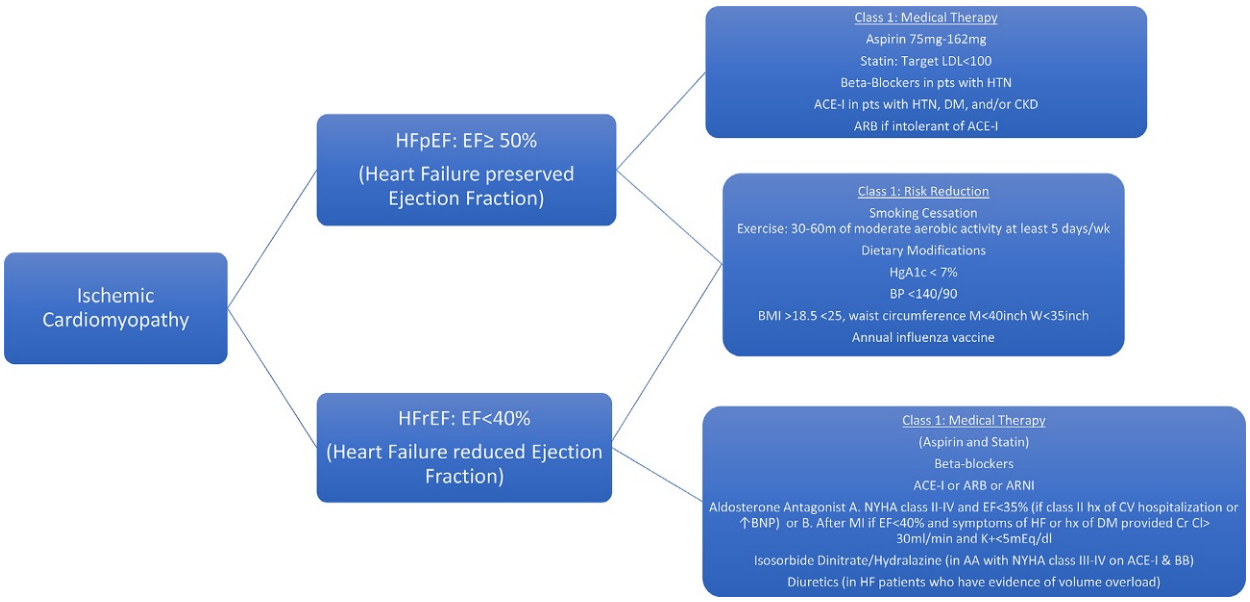

Fig. 3 Pharmacologic therapy.

Based on this data, in symptomatic HFrEF patients with NYHA class II or III symptoms who tolerate an ACEI or ARB, replacement by an ARNI is recommended to further reduce morbidity and mortality (Yancy et al., 2016). According to guidelines, treatment with ACEI and ARB is recommended to treat hypertension in patients with HFpEF. Further, the risk of hospitalization in HFpEF may be reduced by ARBs.

Beta-blockers are indicated in all patients recovering from UA and non-ST segment elevation myocardial infarction (NSTEMI) unless contraindicated and should be started within a few days of the event and continued indefinitely. In patients with ST segment elevation myocardial infarction (STEMI), oral beta-blocker therapy should be initiated in the first 24 h for patients who do not have signs of HF, evidence of a low-output state, increased risk for cardiogenic shock or other relative contraindications for beta blockade such as significant bradycardia. In all patients with a recent or remote history of myocardial infarction or acute coronary syndrome (ACS) and moderate or severely reduced EF (LVEF $\leq$35%), evidence-based beta-blockers (bisoprolol, or carvedilol, or sustained release metoprolol succinate) should be initiated and the daily dose gradually uptitrated. In HFrEF beta-blocker therapy is associated with a 34% relative risk reduction in mortality and a 41% relative risk reduction in HF hospitalizations (Dargie and Lechat, 1999; MERIT-HF Study Group, 1999; Packer et al., 1996, 2001). Beta-blockers have also been shown to improve survival by decreasing risk of re-infarction and ventricular tachyarrhythmia's in patients with preserved EF post-MI who are not at risk for cardiogenic shock (Beta Blocker Heart Attack Trial Research Group, 1983; ISIS Study Group, 1986). Beta-blockers are recommended for treatment of hypertension in HFpEF patients. However, they do not appear to increase exercise capacity or survival in HFpEF patients.

Aldosterone antagonists are recommended to reduce morbidity and mortality following an acute myocardial infarction in patients who have an LVEF of 40% or less who develop symptoms of HF based on the EPHESUS trial which showed a relative 15% reduction in mortality with this therapy (Bertram Pitt et al., 2003). Interestingly, the mortality benefit was primarily driven by a reduction in sudden cardiac death. Aldosterone antagonists are more widely recommended in HFrEF patients with an LVEF <35% with NYHA class II–IV HF to reduce morbidity and mortality based on the RALES and EMPHASIS-HF trials (B Pitt et al., 1999; Zannad et al., 2011). Aldosterone antagonism also decreases hospitalization risk and improves exercise capacity in HFpEF.

While initiating guideline-directed medical therapy is essential, it is as important to be fastidious and uptitrate to the recommended target dose or the highest tolerated dose in order to achieve maximal clinical benefit (Yancy et al., 2013a). Though ACEI, ARB, ARNI, aldosterone antagonists, and beta-blockers improve survival in HFrEF patients, they have not shown similar clinical benefit in HFpEF, even though HFpEF patients experience patterns of functional decline and morbidity that are similar to HFrEF. The differential response to these same therapies suggests that HFrEF and HFpEF are distinctly separate entities with fundamentally different pathophysiologies influenced by different factors in their natural history. In fact, ventricular remodeling in HFrEF is driven by loss of cardiomyocytes, while in HFpEF it is driven by comorbidities, proinflammatory markers, and vascular hyperemic responses. Improved understanding of pathogenesis and identification of new therapeutic targets are probably needed to achieve progress in the clinical outcomes of HFpEF patients.

The combination of hydralazine and isosorbide dinitrate is recommended in patients with HFrEF, who cannot tolerate ACEI or ARB or ARNI to reduce morbidity and mortality. In two trials that compared this vasodilator combination with an ACEI, the ACEI produced more favorable effects on survival and thus should be first line (Cohn et al., 1991; Fonarow et al., 1992). In African Americans with NYHA class III–IV HFrEF already receiving optimal therapy with ACEI or ARB, beta-blockers, and aldosterone antagonist, the addition of hydralazine and isosorbide dinitrate showed significant clinical benefit (Taylor et al., 2004). The particular benefit of this combination in African Americans was also demonstrated in a post-hoc retrospective analysis (Carson et al., 1999). There is no known benefit from the combination of hydralazine and isosorbide dinitrate in HFpEF.

Diuretics are recommended for fluid retention in both HFrEF and HFpEF. Digoxin reduces the need for hospitalization and improves symptoms but not survival in HFrEF (Cody, 1993; Group, 1997). Digoxin has no role in the treatment of HFpEF.

Statins should be used in all patients with a recent or remote history of myocardial infarction or ACS to prevent symptomatic HF and cardiovascular events. High intensity statin should be started or continued as first line therapy in women and men $\leq$75 years of age. In individuals >75 years of age, moderate or high intensity statin is appropriate.

In all patients with coronary disease, a daily aspirin dose of 81 mg (range, 75–100 mg) is recommended. For patients treated with a bare metal stent (BMS), the minimum duration of dual antiplatelet therapy (DAPT) with aspirin and $P2Y_{12}$ receptor inhibitor of 1 month is recommended. BMS is generally reserved for patients who cannot receive DAPT for more than 1 month for reasons of active bleeding, nonadherence to medical therapy, or planned surgery. The recommended minimum duration of DAPT in patients treated with a drug eluting stent is 6 months (Yancy et al., 2016).

Coronary Revascularization Strategies

Myocardial revascularization has been the topic of more randomized clinical trials than almost any other intervention over the past 5 decades and revascularization techniques have undergone continued advances. The timing of angiography and revascularization in ischemic cardiomyopathy should be based on patient risk profile. In both acute and stable CAD, patients should receive guideline-recommended medical treatment, due to its established benefits in terms of symptom relief and prognosis.

Based on extensive trial data, revascularization is recommended to improve survival in patients with (a) >50% left main disease (and ischemia or FFR $\leq$0.80 for stenosis <90%), (b) significant three-vessel disease, (c) significant two-vessel disease with proximal LAD disease, (d) two-vessel or three-vessel disease with stenosis >50% (and ischemia or FFR $\leq$0.80 for stenosis <90%) with impaired LV function (EF <40%), and (e) a large area of ischemia (>10% LV) (Kolh et al., 2014; Levine et al., 2011). Revascularization is recommended to improve symptoms in those patients with significant coronary stenosis in the presence of angina

unresponsive to medical therapy. Revascularization and medical therapy should be seen as complimentary, as the indications for revascularization include persistence of symptoms despite medical treatment.

In patients with stable ischemic heart disease, percutaneous coronary intervention (PCI) decreases angina and the extent of myocardial ischemia but has not shown a survival benefit. In the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial, an initial management strategy of optimal medical therapy alone compared with optimal medical therapy plus PCI among patients with stable ischemic heart disease found no significant difference between the treatment groups with respect to the composite primary end point of death from any cause or nonfatal MI or the secondary endpoint of hospitalization for ACS over a median follow-up period of 4.6 years (Boden and O'Rourke, 2007). During an extended follow-up of up to 15 years, with a median duration of 6.2 years, there was still no difference in survival between an initial strategy of PCI plus medical therapy and medical therapy alone in stable ischemic heart disease (Sedlis et al., 2015). However, freedom from angina was significantly greater in the PCI group at 1 year and 3 years. At 5 years there was a decreased need for additional revascularization in the PCI group, namely, 21% of the PCI group and 33% of the medical therapy received additional revascularization ($P < 0.001$). It is important to note that the severity of coronary disease in COURAGE was moderate and 70% of patients had no or mild ischemia, further, most patients had normal LV function. To date, The Medical, Angioplasty, or Surgery Study II (MASS II) trial is the only RCT comparing medical therapy with PCI (72% with BMS, 28% with balloon angioplasty alone) and with coronary artery bypass graft (CABG) (Hueb et al., 2010). This study compared the 10-year follow-up of PCI, CABG, and medical treatment in patients with multivessel CAD, stable angina, and preserved ventricular function and found that compared with CABG, medical therapy was associated with a significantly higher incidence of subsequent MI, a higher rate of additional revascularization, and a higher incidence of cardiac death. Compared with CABG, PCI was associated with an increased need for further revascularization, a higher incidence of myocardial infarction, and a 1.46-fold increased risk of combined events.

The 10-year outcomes of the STICH trial demonstrated a significant mortality benefit of revascularization with CABG surgery over optimal medical therapy for patients with ischemic cardiomyopathy with an EF of 35% or less and coronary disease amenable to CABG (Velazquez et al., 2016).

In the elective setting, myocardial revascularization is appropriate when the expected benefits exceed the risks of the procedure and should take into consideration coronary anatomy, patient preferences, age and comorbidities, and hospital/operator experience. Whether medical therapy, PCI, or CABG is preferred depends on the risk–benefit ratio of these treatment strategies and should be made as a multidisciplinary team aided by risk models that assess short-term and long-term outcomes.

By contrast, myocardial infarction and myocardial ischemia in the acute setting of ACSs are potentially life threatening and often leads to progressive ischemic cardiomyopathy and HF. In this setting, patients at highest risk (those with refractory angina, severe HF, cardiogenic shock, or life-threatening arrhythmias) should be considered for urgent (<2 h) coronary angiogram and timely intervention. In the management of ACS, there are no specific randomized controlled trials comparing PCI with CABG and the decision whether to perform CABG or PCI is left to the clinician's discretion. With the widespread use of fibrinolytic therapy or primary PCI in patients with STEMI, emergency CABG is generally reserved for patients with (1) left main and/or 3-vessel CAD with proximal LAD disease, (2) ongoing ischemia after successful or failed primary PCI, (3) coronary anatomy not amenable for PCI, (4) a mechanical complication of STEMI, and (5) cardiogenic shock (Hillis et al., 2011). In STEMI, PCI has been shown to increase survival (Patel et al., 2009). Similarly, in NSTEMI PCI has also shown to improve long-term survival by reducing early and late cardiac events (Bavry et al., 2006; Mehta et al., 2005).

Device Therapy

Patients who survive myocardial infarction are at increased risk for sudden death from cardiac causes, largely due to ventricular tachyarrhythmias. In this population and those with chronic ischemic heart disease, a marked reduction of the left ventricular ejection fraction is the most powerful of the known predictors of sudden cardiac death (Myerburg, 2008). The ACC/AHA guidelines recommend ICD therapy for primary prevention of sudden cardiac death in patients with ischemic heart disease at least 40 days post-MI with LVEF of 35% or less and NYHA class II or III symptoms on appropriate medical therapy who are expected to survive more than 1 year. For asymptomatic patients (NYHA class 1) with ischemic cardiomyopathy, the LVEF cut off for implantation of a primary prevention ICD decreases to 30%. MADIT-II (Multicenter Automatic Defibrillator Implantation II) showed a 31% relative risk reduction in all-cause mortality in patients post-MI with LVEF <30% receiving a prophylactic ICD compared with standard of care (Moss et al., 1996). It is not recommended that patients with NYHA class IV HF have an ICD implanted as they are more likely to die from pump failure than ventricular tachyarrhythmias. ICD is not indicated in patients with HFpEF.

HF progression is accompanied by substantial prolongation of the QRS interval, a marker used to define cardiac dyssynchrony, in approximately one-third of patients and is associated with worse outcomes (Young et al., 2003). Cardiac resynchronization therapy (CRT) is an important treatment for patients with HF and aims to restore contractile synchrony at the atrioventricular, interventricular, and intraventricular level. It is a class 1 indication that CRT be placed in patients who have an LVEF of 35% or less, who are in sinus rhythm, and have a left bundle branch block (LBBB) with a QRS duration of 150 ms or greater and NYHA class II, III, or ambulatory class IV symptoms despite optimal guideline-directed medical therapy (Yancy et al., 2013a). Improvement in survival with CRT is evident as early as the first 3 months of therapy and overall CRT has shown a reduction in all-cause mortality of 24%–36% (Bristow et al., 2004). Additionally, a number of studies have demonstrated that CRT results in an improvement in symptoms, exercise capacity, and peak oxygen consumption (Abraham et al., 2002; Saxon and Ellenbogen, 2003). CRT is not indicated in patients with HFpEF.

Advanced HF Treatment in Ischemic Cardiomyopathy

Despite the drugs, devices, and strategies described in the previous sections, a subset of patients with ischemic HF will continue to progress and develop persistently severe symptoms at rest or with minimal exertion. This group of patients with truly refractory HF has Stage D HF. In addition to severe symptoms, the European Society of Cardiology (ESC) has developed a definition of advanced HF with objective criteria that can be useful and include: (1) patients with episodes of fluid retention and/or reduced cardiac output at rest (peripheral hypoperfusion), severe cardiac dysfunction (LVEF <30% or restrictive mitral inflow, PCWP >16 mmHg and/or RAP >12 mmHg, elevated BNP or NT-proBNP), severe impairment of functional ability (inability to exercise or 6MWT <300 m or peak V02 <12–14 mL/kg/min), and HF hospitalization in the past 6 months despite attempts to optimize therapy (Metra et al., 2007). It is important to identify this group of individuals and refer them to a HF specialist to be evaluated for advanced treatment strategies, including mechanical circulatory support with a left ventricular assist device (LVAD), continuous inotropic infusions, cardiac transplantation, or end-of-life care, such as hospice.

While in many ways the treatment of ischemic and nonischemic advanced HF patients is similar, there are some considerations worth noting. Patients with ischemic cardiomyopathy often have comorbidities that are relative contraindications to mechanical circulatory support such as significant chronic kidney disease, diabetes with macro- or microvascular complications, or peripheral arterial disease. These comorbidities can increase procedural risk and may decrease quality of life after mechanical circulatory support. However, no data in the literature to date shows that there is a mortality difference between advanced HF patients with ischemic cardiomyopathy who receive LVADs versus those who have a nonischemic etiology. Continuous intravenous inotropic support is occasionally used in those patients with refractory stage D HF as a bridge to LVAD or cardiac transplantation, and is also considered as palliative therapy in those who are not eligible for either mechanical circulatory support or cardiac transplantation. In patients with ischemic HF, inotropic therapy is associated with significantly higher mortality from ventricular tachyarrhythmias when compared to nonischemic HF patients on inotropic therapy.

In a recent analysis of over 30,000 patients looking at whether or not survival on the heart transplant list depends on the underlying etiology of heart disease, patients with ischemic cardiomyopathy were not shown to be at higher risk of death while waiting transplantation when compared to other patients with dilated, hypertrophic, or valvular cardiomyopathy (Hsich et al., 2016).

Prognosis

The prognosis of patients with HF from ischemic cardiomyopathy is considerably worse than that of patients without coronary disease (Bart et al., 1997). Ischemic etiology from CAD often goes hand in hand with other comorbidities such as peripheral vascular disease and ischemic stroke as a risk factor for poor prognosis. In addition to being a risk factor for the development of HF, progression of ischemic heart disease adversely affects the outcomes of patients with established HF (Shindler et al., 1996). Targeting both HF treatment and prevention of progression of underlying coronary disease through healthy lifestyle habits and appropriate medical therapy remains critical.

Introduction

The heart and the kidneys are intimately related, and dysfunction of one organ often leads to dysfunction of the opposite organ. Concomitant dysfunction of the kidney and the heart was first described in 1868 by Moxon and is now termed cardiorenal syndrome (CRS) (Moxon, 1868). Since then, the definition, understanding, and treatment have grown significantly. However, despite nearly 150 years of research, many questions remain unanswered regarding the impact, underlying pathophysiology, and best approaches to the prevention and treatment for CRS.

The generally accepted definition for CRS stems from the National Heart, Lung, and Blood Institute's 2004 report that defined CRS as a condition in which therapy to relieve congestive symptoms of HF is limited by a decline in renal function as manifested by a reduction in glomerular filtration rate (GFR) (https://www.nhlbi.nih.gov/research/reports/2004-cardiorenal-hf-hd, accessed February 22, 2017). The Acute Dialysis Quality Initiative (ADQI) further defines CRS as a disorder of the heart and kidneys whereby acute or chronic dysfunction in one organ may induce acute or chronic dysfunction of the other (Davenport et al., 2010; Pinheiro da Silva and Vaz da Silva, 2016). CRS is subdivided into five distinct categories, which are described later in this article (Ronco et al., 2008). However, these categories are dynamic, and many patients will transition among the various categories of CRS. These transitions throughout one's disease course reflect the close interplay between the two organ systems (Damman et al., 2011).

Definitions

Acute Heart Failure

The nomenclature for acute heart failure is inconsistent throughout the literature and has been referred to as acute heart failure syndromes, acute decompensated heart failure (ADHF), acute decompensation of chronic heart failure, and others. Broadly speaking, acute heart failure refers to a syndrome of new onset or recurrence of symptoms and signs of heart failure requiring urgent or emergent therapy and resulting in seeking unscheduled care or hospitalization (Pinheiro da Silva and Vaz da Silva, 2016). However, acute heart failure can often times present in a more indolent course, with slow progression of symptoms leading to acute decompensation.

Chronic Heart Failure

Chronic heart failure is a clinical syndrome characterized by a combination of typical signs and symptoms in conjunction with objective evidence of structural or functional abnormalities of the heart (Pinheiro da Silva and Vaz da Silva, 2016). Heart failure ultimately results in the inability of the heart to deliver oxygen at a rate required to meet metabolic demands despite normal filling pressures (Pinheiro da Silva and Vaz da Silva, 2016). The classic signs and symptoms of heart failure are shown in **Tables 1–7**. Heart failure affects approximately 2%–3% of the worldwide population. However, age is an independent risk factor for heart failure, and its prevalence in patients older than 70 years is above 10% (Pinheiro da Silva and Vaz da Silva, 2016).

Table 1 Common signs and symptoms of heart failure

Symptoms	*Signs*
Orthopnea	S3 gallop
Dyspnea	Laterally displaced point of maximal impulse
Paroxysmal nocturnal dyspnea	Elevated jugular venous distention
Poor exercise tolerance	Hepatojugular reflex
Lower extremity edema	Hepatomegaly
Fatigue	Cardiac cachexia

Harrison's Internal Medicine (2015).

Table 2 Diagnostic criteria of heart failure

Heart failure reduced ejection fraction

1. Symptoms of heart failure
2. Signs of heart failure
3. Reduced LVEF $< 45\%$

Heart failure preserved ejection fraction

1. Symptoms of heart failure
2. Signs of heart failure
3. LVEF $> 45\%$
4. Relevant structural heart disease and/or diastolic dysfunction

Table 3 ACC/AHA heart failure classification

ACC/AHA stage		*NYHA functional classification*	
A	At risk for heart failure but without structural heart disease or HF symptoms		
B	Structural heart disease without signs or symptoms of HF	I	No limitations of physical activity
C	Structural heart disease with previous or current symptoms of HF	I	No limitations of physical activity
		II	Patients with cardiac disease resulting in slight limitation of physical activity, causing fatigue, palpitation, dyspnea, or angina. They are comfortable at rest
		III	Patients with cardiac disease resulting in marked limitation in of physical activity. Less than ordinary activities result in fatigue, palpitation, dyspnea, or angina
D	Refractory HF requiring specialized interventions	IV	Patients with cardiac disease resulting in inability to carry on any physical activity without discomfort. Symptoms may be present at rest

Table 4 Definition of CKD

Criteria for CKD (either of the following for > 3 months)	
Markers of kidney damage (1 or more)	Albuminuria
	Electrolyte disturbances from tubular disorders
	Urine sediment abnormalities
	Radiographic structural abnormalities
	History of renal transplantation
Decreased GFR	GFR $<$ 60 mL/min/1.73 m^2

Reproduced from Webster, A. C., Nagler, E. V., Morton, R. L. and Masson, P. (2017). Chronic kidney Disease. *Lancet* **389**, 1238–1252.

Table 5 Classification of CKD

Stage	*GFR, mL/min/1.73 m^2*
0	$\geq$90 with risk factors for CKD
1	$\geq$90 with evidence of kidney damage
2	60–89
3	30–59
4	15–29
5	$<$15

Table 6 Definitions and subtypes of cardiorenal syndrome

Cardiorenal syndrome	A disorder of the heart and the kidneys where acute or chronic dysfunction in one organ may induce acute or chronic dysfunction in the other organ
Cardiorenal syndrome type 1 (acute cardiorenal syndrome)	Acute worsening of cardiac function leading to acute kidney injury
Cardiorenal syndrome type 2 (chronic cardiorenal syndrome)	Chronic abnormalities in cardiac function causing progressive kidney damage
Cardiorenal syndrome type 3 (acute renocardiac syndrome)	Abrupt worsening in kidney function causing acute cardiac dysfunction
Cardiorenal syndrome type 4 (chronic renocardiac syndrome)	CKD contributing to decreased cardiac function and/or increased risk of cardiovascular events
Cardiorenal syndrome type 5 (secondary cardiorenal syndrome)	Systemic conditions contributing to both cardiac and renal dysfunction

Adapted from Ronco, C., Haapio, M., House, A. A., Anavekar, N. and Bellomo, R. (2008). Cardiorenal syndrome. *Journal of the American College of Cardiology 52*, 1527–1539.

Table 7 Categories of biomarkers and examples

Category	*Examples*
Functional markers	SCr, plasma/serum cystatin C
Upregulated proteins	Neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1 (KIM-1), Liver fatty acid-binding protein (L-FABP), interleukin-18 (IL-18)
Low-molecular-weight proteins	Urine cystatin C
Enzymes	Alpha-glutathione *s*-transferase and pi-glutathione *s*-transferase (α-GST), gammaglutanyl transpeptidase (GGT), alkaline phosphatase (AP), *N*-acetyl-b-D-glucosaminidase (NAG)

Adapted from de Geus, H. R., Betjes, M. G. and Bakker, J. (2012). Biomarkers for the prediction of acute kidney injury: a narrative review on current status and future challenges. *Clinical Kidney Journal* **5**, 102–108

There are two major classification systems of heart failure. The first is the American College of Cardiology/American Heart Association (ACC/AHA) Heart Failure staging approach, which focuses on the severity and progression of disease. The second major classification is the New York Heart Association Functional Classification, which emphasizes the functional burden of heart failure (Kasper, 2015).

Acute Kidney Injury

The definition of acute kidney injury (AKI) has evolved over time. The currently accepted definition is based on the KDIGO Acute Kidney Injury Work Group recommendations; a harmonization of prior RIFLE and AKIN criteria (Palevsky et al., 2013). KDIGO defines AKI as any of the following: increase in serum creatinine (SCr) by $\geq$0.3 mg/dl ($\geq$26.5 μmol/L) within 48 h; or increase in SCr to $\geq$1.5 times baseline, which is known or presumed to have occurred within the prior 7 days; or urine volume $<$0.5 ml/kg/h for 6 h (Kidney Disease: Improving Global Outcomes (KDIGO) Acute Kidney Injury Work Group, 2012). AKI represents a broad category of multiple different underlying pathologies. The presentation of AKI can range from asymptomatic to fatal derangements in one's electrolyte and fluid balance. AKI is a common diagnosis complicating an estimated 15% of hospital admissions and up to 60% in critically ill patients (Makris and Spanou, 2016). AKI is also an independent predictor of hospital admission mortality, particularly in the intensive care setting (Makris and Spanou, 2016).

Chronic Kidney Disease

Chronic kidney disease (CKD) is characterized by abnormalities in kidney structure or function or reduced GFR for greater than 3 months duration (Webster et al., 2017). CKD is a public health epidemic, affecting >10% of people aged 20 years or older in the United States, which equates to nearly than 20 million people (National Chronic Kidney Disease Fact Sheet, 2014). Worldwide, CKD affects approximately 8%–16% of the population, and the prevalence is increasing.

CKD is divided into stages, as shown later. The Kidney Disease Outcomes Quality Initiative (K/DOQI) classification system is uniformly utilized in defining not only the concept of CKD but also its subsequent classification the different stages of kidney dysfunction (National, 2002).

Cardiorenal Syndrome

The generally accepted definition for CRS stems from the National Heart, Lung, and Blood Institute's 2004 report that defined CRS as a condition in which therapy to relieve congestive symptoms of HF is limited by a decline in renal function as manifested by a reduction in GFR (https://www.nhlbi.nih.gov/research/reports/2004-cardiorenal-hf-hd, accessed February 22, 2017). The heart and the kidney have a unique ability to initiate and perpetuate injury to the opposite organ, as both organ systems rely upon each other and utilize common pathways including hemodynamics, neurohormonal and immunologic/biochemical pathways (Ronco et al., 2008).

CRS plays a significant role in the morbidity and mortality of patients with kidney and cardiac disease. CKD is disproportionally associated with heart failure. In the Acute Decompensated Heart Failure National Registry (ADHERE), CKD was reported in 30% of patients admitted to hospital for heart failure as compared with just over 10% in the general adult US population (Adams et al., 2005). This is clinically significant, as declining renal function and CKD stage, as defined by the K/DOQI classification system, is associated with increasing mortality in the heart failure population. Furthermore, the rate of decline in kidney function is a strong predictor of increased mortality in this population, independent of worsening heart failure and baseline kidney function. (Khan et al., 2006) Therefore, it is crucial to recognize, prevent, and treat both renal and cardiac dysfunction.

The CRS is divided into five distinct categories (Ronco et al., 2008). These categories are based upon the chronology of the affected organs and the acuity by which they have developed dysfunction. CRS type 1 is known as acute CRS, whereby acute cardiac dysfunction leads to AKI. CRS type 2 is also known as chronic CRS, where chronic cardiac dysfunction progressively causes renal dysfunction. CRS type 3, or acute renocardiac syndrome, is the syndrome by which acute renal dysfunction causes acute cardiac

dysfunction. CRS type 4, also known as chronic renocardiac syndrome, is the process by which CKD contributes to progressive cardiac dysfunction. Lastly, CRS type 5, or secondary CRS, is the process in which a systemic disease causes both cardiac and renal dysfunction. These distinct, though overlapping, syndromes are described below, along with their underlying pathophysiology and the basic approaches to treatment.

Types of CRS

Cardiorenal Syndrome Type 1 (Acute Cardiorenal Syndrome)

Cardiorenal syndrome type 1, or acute cardiorenal syndrome, is defined as acute heart failure, whether new onset or acute decompensation of chronic disease, causing AKI (Ronco et al., 2008). As above, heart failure and AKI are common hospital admission diagnoses. It is estimated that AKI occurs in over 70% of patients presenting to the hospital in cardiogenic shock (Jose et al., 2006). Moreover, AKI has shown to be a poor prognostic factor in patients with acute heart failure, particularly those related to acute coronary syndrome (Goldberg et al., 2005).

The underlying pathophysiology for acute cardiorenal syndrome is complex and equivocal. There are multiple components at play, which are described later in this article. The combination of alterations in hemodynamics, venous congestion, upregulation of renin–angiotensin–aldosterone system (RAAS), activation of the sympathetic nervous system, and the immune-mediated, pro-inflammatory state of acute heart failure and creation of reactive oxygen species from oxidative stress results in a cyclic deterioration of renal and cardiac function (Ronco et al., 2008). The management, as described later in this article, is targeted toward minimizing the deleterious effects of each of the proposed pathophysiological processes.

Cardiorenal Syndrome Type 2 (Chronic Cardiorenal Syndrome)

Cardiorenal syndrome type 2, or chronic cardiorenal syndrome, is defined as chronic abnormalities in cardiac function causing progressive kidney injury (Ronco et al., 2008). An estimated 25% of patients with the diagnosis of chronic heart failure also have a component of CKD (Hillege et al., 2006). Mortality significantly increases with even slight decreases in the GFR in patients with heart failure (McAlister et al., 2004). The pathophysiology of chronic cardiorenal syndrome is multifactorial. Chronic venous congestion plays a crucial role, decreasing effective renal perfusion. Chronic activation of renin–angiotensin–aldosterone pathway results in progressive cardiac dysfunction. The principles of treatment for chronic cardiorenal syndrome include optimization of hemodynamics and inhibition of the RAAS pathway, as described later.

Cardiorenal Syndrome Type 3 (Acute Renocardiac Syndrome)

Cardiorenal syndrome type 3 is defined as abrupt and primary worsening of renal function causing acute cardiac dysfunction (Ronco et al., 2008). Acute changes in renal function have multiple deleterious effects, which contribute to cardiac dysfunction. The Frank–Starling mechanism and the force–tension curve can best explain the hemodynamic effects from acute renal dysfunction. The Frank–Starling mechanism states that as venous return increase, ventricular filling, or end-diastolic volume, increases. The increase in end-diastolic volume results in myocyte and sarcomere stretching and resultant increase in stroke volume. However, the Frank–Starling curve is not linear, and the sarcomere can reach a point where further stretching does not result in an increase in stroke volume, and in patients with heart failure, stroke volume can actually decrease with further myocyte stretching. In patients with acute renal dysfunction, this becomes problematic as RAAS activation leads to sodium and water retention and increases in preload beyond what the cardiac myocytes can accommodate. The other component is explained by the force–tension curve, which describes the relationship between afterload and stroke volume. Afterload increases from acute renal dysfunction through the activation of the RAAS and the sympathetic nervous system. The increase in afterload results in decreases in stroke volume.

Other consequences of acute renal dysfunction can affect cardiac function. For example, electrolyte abnormalities can cause cardiac arrhythmias; nitrogenous waste accumulation can cause pericarditis; and acidemia from severe renal dysfunction is a cardiac depressant. Each of these mechanisms falls under the broad category of acute renocardiac syndrome (Ronco et al., 2008).

Cardiorenal Syndrome Type 4 (Chronic Renocardiac Syndrome)

Cardiorenal syndrome type 4, or chronic renocardiac syndrome, is defined as primary CKD results in cardiac dysfunction (Ronco et al., 2008). CKD is a complex disorder with numerous consequences, many of which affect cardiac function. Electrolyte disturbances, including hyperkalemia, calcium and phosphorus dysregulation, and academia, all affect cardiac function. CKD also activates RAAS pathway, which leads to hypertension, accelerated coronary artery disease, and cardiac remodeling (Ronco et al., 2008). Anemia is also a consequence of CKD, impairing oxygen delivery to cardiac muscle and impairs function (Jie et al., 2006). CKD is also known to cause hyperlipidemia, insulin resistance, endothelin dysfunction, vascular calcification, and accelerated atherosclerosis, all of which are risk factors for cardiac disease.

Slowing the progression of CKD and treating the cardiac risk factors from CKD is the hallmark of treatment for chronic renocardiac syndrome. Specific treatment strategies are discussed later in the article. In patients with ESRD and HF with reduced LVEF (<40%), correction of renal dysfunction has been shown to reduce cardiac comorbidities. Kidney transplantation can result in a considerable increase or even normalization of mean LVEF in a significant number of patients (Wali et al., 2005).

Cardiorenal Syndrome Type 5 (Secondary Cardiorenal Syndrome)

Cardiorenal syndrome type 5 is defined as combined cardiac and renal dysfunction secondary to an underlying acute or chronic systemic disease process. Multiple disease processes are known to cause both cardiac and renal dysfunction, including diabetes, systemic lupus erythematosus, sarcoidosis, and sepsis. The pathophysiology is largely dependent on the underlying systemic disease process.

The treatment for secondary cardiorenal syndrome depends on the underlying systemic disease. There is no common treatment strategy beside the (Ronco et al., 2008) avoidance of further cardiotoxic and nephrotoxic therapies.

Pathophysiology

Hemodynamics and Intra-Abdominal Pressure

Hemodynamics plays a crucial role in the pathogenesis of cardiorenal syndrome. Renal perfusion depends on the transrenal perfusion pressure, which is mean arterial pressure minus central venous pressure. Therefore, venous congestion as reflected in increases in CVP would result in decreased renal perfusion even in the setting of unchanged cardiac output (Gnanaraj et al., 2013). The initial theory was that decreased mean arterial pressure was the primary factor causing cardiorenal syndrome. However, studies have shown central venous pressure is the predominant factor causing renal dysfunction in CRS. The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial was the landmark study demonstrating that poor forward flow (mean arterial pressure) did not correlate with baseline creatinine but instead the only predictor was right atrial pressure (Nohria et al., 2008). Subsequent studies have further demonstrated this concept, including a 2009 study of patients with ADHF that concluded that in fact venous congestion, not cardiac output, was the most important hemodynamic factor causing worsening of renal function (Mullens et al., 2009).

Renal perfusion is also dependent on the intra-abdominal pressure (IAP). Renal blood flow is inversely correlated to IAP, and in patients with ADHD, IAP is elevated in up to 60% of patients. A normal IAP is usually 5–7 mmHg but can be affected by venous congestion, visceral edema, ascites, abdominal wall edema, gaseous distention of the bowel, urinary retention, and obesity. Intra-abdominal hypertension is defined as persistent IAP above 12 mmHg. In patients with ADHD, consideration of IAP is crucial to the understanding and management of CRS. In a study of 40 patients admitted for ADHF, elevated IAP (IAP (greater than or equal to) 8 mmHg) was seen in 24 (60%) of the patients and was associated with impaired kidney function (Mullens et al., 2008). One study showed that the greater the IAP was lowered, the more renal function improved, independent of hemodynamic changes.

Neurohormonal Activation

Hormonal activation contributes to further renal and cardiac dysfunction in cardiorenal syndrome. Venous congestion and renal vein distention activates mechanoreceptors and enhances local sympathetic renal nerve activity, leading to intrarenal vasoconstriction and a reduction in GFR (Kostreva et al., 1981; Haddy, 1956; Dilley et al., 1983). Activation of the RAAS also plays a critical role in cardiorenal syndrome. RAAS is activated in response to decreased renal perfusion from venous congestion (Schrier, 2006). RAAS activation has multiple consequences, including peripheral vasoconstriction, sodium and water reabsorption, cardiac remodeling, nonosmotic release of arginine–vasopressin (AVP), and other neuroendocrine hormones, such as endothelin, all of which further promote congestion and renal function (Gnanaraj et al., 2013). RAAS activation ultimately leads to further cardiac dysfunction via increasing afterload by peripheral vasoconstriction and further hypervolemia by sodium and water reabsorption.

Vasopressin and Hyponatremia

In the setting of heart failure, serum AVP increases. This increase has several effects that are deleterious to cardiac and renal function. AVP activated V1 receptors causing subsequent vasoconstriction, with increases afterload and further reduced renal perfusion pressure. However, activation of V2 receptors leads to free water retention leading to hyponatremia. The Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study with Tolvaptan (EVEREST) trial sought to determine if selective inhibition of V2 receptors using tolvaptan would allow for improved volume overload correction without the potential electrolyte abnormalities of other classic diuretics like loops diuretics. Unfortunately, the EVEREST trial showed no effect of oral tolvaptan on long-term mortality or heart-failure-related morbidity (Konstam et al., 2007).

Endothelin Activation and Inflammatory Effect

Venous congestion results in activation of vascular endothelium to promote inflammation, pro-oxidation, and vasoconstriction (Gimbrone et al., 2000). Pro-inflammatory cytokines like tumor necrosis factor and interleukin-6 are released during venous

congestion, which impair myocardial function and accelerate heart failure (Braunwald, 2008). Renin is also secreted in response to the pro-inflammatory state that, as above, promotes fluid retention and worsening venous congestion, impaired renal function, and progressive worsening of cardiac function (Sánchez-Lozada et al., 2003).

Biomarkers

Cardiac and renal biomarkers are an emerging landscape in the early detection of renal and cardiac dysfunction. The classic cardiac biomarker is brain natriuretic peptide (BNP). BNP correlates with pulmonary capillary wedge pressure and is frequently used in the diagnosis of heart failure. Some data suggest that BNP is an indirect marker for worsening renal function during the treatment of ADHF. However, in the setting of concomitant renal dysfunction, markers such as BNP and NT-proBNP are less accurate (Pfister et al., 2011; Hatamizadeh et al., 2013).

SCr is currently the gold standard with regard to identifying renal dysfunction. However, because a rise in SCr is a late manifestation of renal dysfunction, it has limited utility in the detection of and prevention of kidney disease early in the disease course. Significant research is ongoing investigating alternative markers to detect early renal dysfunction (de Geus et al., 2012).

Functional Markers

Serum creatinine

As mentioned earlier, SCr is the current gold standard for the detection of kidney injury. Creatinine is a degradation product of muscle cells and is filtered in the renal glomerulus. It is therefore a surrogate for glomerular filtration. Unfortunately, following an injurious event like AKI, the rise in SCr is slow and is hours to days after the initial renal insult. It therefore has limited use in the detection of early kidney dysfunction (de Geus et al., 2012; Waikar et al., 2009).

Plasma/serum cystatin C

Cystatin C is a nonglycosylated cysteine protease inhibitor, which is produced by all nucleated cells at a constant rate. It is excreted exclusively by glomerular filtration and metabolized by the proximal tubules. Serum levels of cystatin C are currently being investigated for early detection of glomerular filtration changes, with some evidence suggesting serum cystatin C is superior to SCr in the detection of minor changes in glomerular function (Dharnidharka et al., 2002).

Upregulated Proteins

Neutrophil gelatinase-associated lipocalin

Neutrophil gelatinase-associated lipocalin (NGAL) is a small protein linked to neutrophil gelatins in specific leukocyte granules (Borregaard et al., 1995). It is expressed in a variety of epithelial cells and is associated with antimicrobial defense (Goetz et al., 2002). In normal kidneys, NGAL expression is limited to the distal tubule and the collecting duct. However, in AKI, NGAL staining shows expression in the proximal tubules as well (Mori et al., 2005; Hvidberg et al., 2005). Studies show urine and serum NGAL are early predictors of AKI both in adult and children in either cardiac surgery or patients in the intensive care unit (Haase et al., 2009).

Kidney injury molecule-1 (KIM-1)

Kidney injury molecule-1 (KIM-1) is a type 1 transmembrane glycoprotein expressed by the dilated tubules in acute and chronic renal injury (Ichimura et al., 2008). The proposed function of KIM-1 is this protein is involved in the regenerative processes after epithelial injury and in the removal of dead cells in the tubular lumen through phagocytosis (Bailly et al., 2002; Bonventre, 2009). Several studies have investigated its clinical utility, with some evidence that detection has predictive value in the detection of acute kidney dysfunction (de Geus et al., 2012).

Liver fatty acid-binding protein

Fatty-acid-binding proteins are small, cytoplasmic proteins expressed in tissues with robust fatty acid metabolism. These proteins function to facilitate long-chain fatty acid transportation, regulation o gene expression and reduction of oxidative stress (de Geus et al., 2012). The liver fatty acid-binding protein (L-FABP) is a specific subtype with undetectable urinary levels in healthy individuals. The healthy proximal tubule internalized L-FABP via megalin-mediated endocytosis (Ferguson et al., 2010; Oyama et al., 2005). However, during an ischemic event, upregulation of L-FABP gene expression occurs, and with concomitant renal dysfunction, absorption, and internalization by the proximal tubule is impaired (Oyama et al., 2005; Yamamoto et al., 2007). Limited research has investigated urinary L-FABP levels in the detection of renal dysfunction, and further investigations are needed.

Interleukin-18

Interleukin-18 (IL-18) is an inflammatory cytokine that has proved to be an important mediator in the process of AKI in animal models. Several studies have investigated IL-18's predictive utility for detection of AKI, but further research is needed (de Geus et al., 2012).

Low-Molecular-Weight Proteins

Urine cystatin C

Cystatin C, as mentioned earlier, is a nonglycosylated cysteine protease inhibitor that is produced at a constant rate by all nucleated cells (de Geus et al., 2012). It is excreted via glomerular filtration and is completely metabolized by the proximal tubules (Herget-Rosenthal et al., 2007). Ongoing research is determining if measurement of urine cystatin C can be used to detect early proximal tubular injury. Unfortunately, several factors affect urine cystatin C, including albuminuria, which has limited its diagnostic utility or predictive value of AKI (Nejat et al., 2012).

Enzymes

Alpha-glutathione s-transferase and pi-glutathione s-transferase

Alpha-glutathione *s*-transferase (α-GST) and pi-glutathione *s*-transferase (π-GST) are two enzymes part of a large multigene family responsible for detoxification. These enzymes are not normally expressed or excreted in the urine (de Geus et al., 2012). During injury, α-GST is exclusively expressed in the proximal tubule, and π-GST is expressed in the distal tubule, both of which can be identified in urine during AKI (Harrison et al., 1989).

N-*acetyl*-b-*D*-*glucosaminidase*

N-acetyl-*b*-D-glucosaminidase (NAG) is a large liposomal enzyme produced in the renal tubules. Due to its size, it is impermeable to glomerular filtration, and urinary detection has been associated with tubular injury (de Geus et al., 2012). Measurement of urine NAG suggests tubular injury or increased liposomal activity. However, limited studies to date have examined the predictive value in early tubular injury.

Gammaglutanyl transpeptidase and alkaline phosphatase

Gammaglutanyl transpeptidase and alkaline phosphatase are enzymes expressed in the tubular brush border and are released into the urine during severe renal injury (de Geus et al., 2012). There are few studies investigating their clinical utility and predictive value for AKI.

Management of CRS

The cornerstone of the management of cardiorenal syndrome is based on the minimization of venous congestion. The most appropriate strategy to achieve venous decongestion has been extensively studied. Also, judicious inhibition of RAAS and avoidance of further cardiac or nephrotoxicity are crucial to the treatment of CRS. Emerging strategies continue to be investigated.

Anticipation and Prevention

Cardiorenal syndrome is a cyclic pathophysiological process, by which damage to one organ perpetuates damage to the opposite organ. Breaking this cycle is crucial in the prevention and treatment. Similarly, recognition and minimization of further renal or cardiac dysfunction is imperative. Early recognition of the signs and symptoms of CRS helps aid in preventing further dysfunction and can expedite appropriate treatment. Avoidance of further nephrotoxicity, including avoidance of contrast media and NSAIDs, helps prevent further renal dysfunction. Recognition of early satiety and anorexia as symptoms of splanchnic congestion and resistance to oral diuretics can allow early treatment implementation. Orthopnea, paroxysmal nocturnal dyspnea, and elevated jugular venous distention are all signs and symptoms of volume overload and useful in the diagnosis of heart failure and risk for CRS. Optimization of hemodynamics, including avoiding hypotension, can prevent further renal injury. Also, prevention of intra-abdominal hypertension, which, as above, can further perpetuate renal dysfunction, should be implemented. Strategies include preventing urinary retention, treating constipation, and keeping the head of the bed <30 degrees are all practical strategies to decreased IAP (von Haehling et al., 2013).

Minimization of Venous Congestion

Diuretics are the hallmark of venous decompression in patients with CRS. Administration of intravenous loop diuretics is the initial treatment approach (von Haehling et al., 2013). The Determining Optimal Dose and Duration of Diuretic Treatment in People with Acute HF (DOSE-AHF) trial compared patients receiving high doses of furosemide (2.5 times their usual home oral dose) with patients receiving lower doses (equal to home oral dose) and found to difference in the patient's SCr or prognosis (Felker et al., 2011). Provider preference and experience should be taken into account in the initial diuretic dosing in patients with volume overload and CRS. Intravenous diuretics should be administered due to poor oral absorption due to splanchnic congestion. A 2011 prospective, double-blind randomized study compared continuous intravenous loop diuretics with intermittent, bolus doses of loop diuretics and found no difference in renal function between the two groups (Felker et al., 2011). Long-acting loop diuretics, like torsemide, can be helpful in the management of CRS. Short-acting loop diuretics can cause neurohormonal activation from rebound sodium reabsorption. Long-acting loop diuretics may prevent this occurrence (Salvador et al., 2005).

A common problem in the management of venous congestion, particularly in patients who are not diuretic naive, is diuretic resistance. Several strategies have been proposed to facilitate overcoming diuretic resistance. The addition of thiazide-like diuretics or potassium sparing diuretics in patients who fail to respond to large doses of loop diuretics is a reasonable approach to prevent enhanced sodium reabsorption in the distal tubule (Dormans and Gerlag, 1996). The addition of a mineralocorticoid antagonist like spironolactone or eplerenone in patients with a left ventricular ejection fraction <35% is also a helpful approach to overcome diuretic resistance (van Vliet et al., 1993). Some small studies suggest these medications in high doses overcome diuretic resistance in patients with ADHF without a significant effect on SCr. However, larger, randomized studies are needed.

The addition of natriuretic peptides, for example, nesiritide, is also an effective approach to overcoming diuretic resistance. Nesiritide is a recombinant form of endogenous BNP (von Haehling et al., 2013). It has been shown to rapidly reduce cardiac filling pressure, increase cardiac output, promote diuresis and suppress RAAS, and release of norepinephrine (Cheng, 2002). Some data suggest improved dyspnea symptoms with no increase in mortality or renal dysfunction in patients treated with nesiritide with acute HF.

Neurohormonal Inhibition

Diuresis causes a reflex sympathetic overactivity and activation of the renin–angiotensin–aldosterone pathway. As mentioned previously, RAAS activation leads to sodium and fluid retention, vasoconstriction, and cardiac remodeling, all of which worsen cardiac and renal function. Targeting blockade with beta-blockers, angiotensin-converting-enzyme (ACE) inhibitors, and aldosterone receptor blockers (ARBs) are routinely used in the treatment of heart failure. ACE inhibitors and ARBs are also routinely used in the treatment of CKD and should be used judiciously in patients with CRS. Electrolyte abnormalities, particularly hyperkalemia in patients with CKD, should be closely monitored with ACE inhibitors and ARBs, which may limit their use (von Haehling et al., 2013).

The timing of introduction of beta-blockers, ACE inhibitors, and ARBs in patients with ADHF or worsening renal function is a debated topic. ACE-I and ARBs can make renal function worse in patients undergoing active diuresis, and careful attention to renal function and consideration of withholding in high-risk patients is a reasonable approach (Knight et al., 1999). Similarly, beta-blockade in patients with ADHF can lead to clinical decompensation, and cautious introduction is crucial (von Haehling et al., 2013).

Role of Inotropes

Inotropic medications increase cardiac contractility and were once thought to be useful in patients with cardiorenal syndrome. However, the use of these agents is now known to be associated with higher morbidity and mortality. Their use is now reserved for patients in shock or as a bridge to cardiac transplantation (Goldberg, 1989).

Low-dose continuous dopamine (2–5 mg/kg/min) is known to increase renal blood flow via activation of dopaminergic receptors and also inhibits aldosterone, promoting sodium excretion and diuresis (Goldberg, 1989). Unfortunately, studies comparing the use of dopamine with standard treatment have shown no significant benefit, and dopamine is not currently approved for treatment of heart failure. Further assessment will be available from the ROSE trial, which is an ongoing study investigating the safety and efficacy of adjuvant low-dose dopamine compared with low-dose nesiritide versus standard diuretic therapy in patients with CKD and ADHF (HF Network: ROSE Trial, n.d.).

Emerging Therapies

New, emerging therapies to treat CRS is an area of ongoing research. One area is combining hypertonic saline with furosemide to prevent rebound sodium reabsorption and promote effective diuresis. One study has shown shorter hospital stay, decreased BNP and lower readmission rates in patients with NYHA class IV HF when compared with IV diuretics alone (Paterna et al., 2005).

Relaxin is a peptide hormone that acts on nitric oxide pathways to promote systemic and renal vasodilation. The Efficacy and Safety of Relaxin for the Treatment of Acute HF (RELAX-AHF) trial is ongoing and should provide further information on the impact on congestion, renal dysfunction and overall outcomes in patients with acute decompensated HF (Ponikowski et al., 2012). Early data from the pre-RELAX trial show improvement in dyspnea and greater weight loss compared with smaller doses of diuretics and nitrates (Teerlink et al., 2009).

Hyponatremia is a common electrolyte complication in ADHF and volume overload. This is, in part, from the actions of AVP, which causes vasoconstriction and free water reabsorption via activation of V1 and V2 receptors, respectively. The EVEREST trial sought to compare the use of vasopressin antagonists, specifically V2 receptor antagonist tolvaptan. There was no effect on morbidity and mortality between the two groups, but patients receiving oral tolvaptan did report short-term symptom benefit and weight reduction with worsening renal function compared with their standard heart failure treatment regimen (Konstam et al., 2007).

Iron supplementation is another area of ongoing research in the treatment of ADHF and CRS. The triad of anemia, renal failure, and HF multiplies the mortality rate (Attanasio et al., 2012). The FAIR-HF study has recently shown that among 459 patients with stable chronic HF, those receiving intravenous ferric carboxymaltose were more likely to report an improvement in their quality of life after 24 weeks of follow-up than those receiving placebo (Anker et al., 2009).

Summary

Cardiorenal syndrome is a complex, intertwined, and cyclic interaction between the heart and the kidney that often necessitates the multidisciplinary approach of a cardiology, nephrologist, and critical care physicians. The pathophysiological processes that cause cardiorenal syndrome highlight the intimate nature of these two organ systems. Since the initial description in 1868, significant strides have been made in the understanding and ultimately treatment of cardiorenal syndrome. However, much is still unknown, and further investigations are needed to improve the morbidity and mortality associated with this complex interaction.

Complications With CIEDs 166
Device Performance 166
Conclusion 169
References 169

Cardiovascular implantable electronic devices (CIEDs) have undergone revolutionary changes in the last decade, resulting in widespread use globally for treatment of both bradyarrhythmias as well as tachyarrhythmias, in both primary and secondary prevention (Connolly et al., 2000; Moss et al., 1996; Moss et al., 2002; Bardy et al., 2005; The Antiarrhythmics versus Implantable Defibrillators (AVID) Investigators, 1997). Cardiac resynchronization therapy is also increasing in use as one of the most effective treatments for advanced heart failure, to prevent progressive heart failure and prevent mortality (Tang et al., 2010; Moss et al., 2009). Pacemakers were the first generation of CIEDs available for implantation in humans, as early as 1958. Implantable defibrillators in the current form (transvenous) have been available since 1997. As the absolute and relative numbers of the elderly population increase, so do the use of CIEDs.

CIEDs in most instances provide life-saving therapy. If a CIED malfunctions or there is a complication, this can result in significant morbidity and/or mortality. They are implanted in the vascular system, so that infection can become a deadly problem leading to infective bacterial endocarditis. If this occurs, complete system removal is required, this may be associated with a mortality risk. The weakest link in any CIED system is the transvenous lead, that is, subject to repeated stress that can result in fracture, insulation breakdown, or other malfunction. Removal of leads can also be fraught with significant morbidity, as laser lead extraction techniques, are often required. The following review deals with lead-related as well as lead extraction-related complications.

Complications With CIEDs

Device Performance

It is well known that there is an inherent failure rate with all devices, described in reliability engineering as the "bathtub curve" (Sohail et al., 2007). The majority of these causes of failure are addressed before devices are released to the market and are identified through bench testing, which occurs prior to in vivo use. Bench testing refers to rigorous experiments replicating how a device may behave in vivo and whether it can withstand such stressors as induced by cardiac motion, shoulder movement, interaction with the bloodstream and interaction with other intravascular devices. It is well known that the number of cardiac cycles averages 100,000 times per day, up to 3.5 billion times in a lifetime. Other interactions, such as metal ion oxidation were discovered after in vivo use, resulting in improvements in bench testing. Metal ion oxidation was found to occur with leads made with polyurethane as the outer conductor. These fluoropolymers can incur micro-damage during the manufacturing process, thereby increasing susceptibility to metal ion oxidation, which is an oxidative degradation resulting from interaction of the micro-damaged polyurethane with the bloodstream. A random failure rate of a device is an accepted failure rate, but occurs at a very low rate. Such random malfunctions are reported in the form of product performance reports that are required to be released by manufacturers at regular intervals, where any abnormalities in performance are reported to the manufacturer. These are published as rates, the denominator being the number of products sold worldwide. Once a device reaches its design lifetime, the rate of "wear out" failures is seen to accelerate. Device advisories are declared if and when the known rate of random failures is exceeded, or if a systematic device flaw has been detected that requires closer monitoring.

A CIED device consists of a battery (pulse generator) that is attached to one, two, or three leads. These leads are typically placed into the right atrium, right ventricle or into a branch in the coronary sinus, in cardiac resynchronization therapy (CRT) devices. Vascular access for these leads is obtained from the subclavian or axillary veins, or through a cut-down of the cephalic vein located in the deltopectoral groove. Once the lead is appropriately placed, it is attached to the battery, which is placed in a pocket that may be submuscular or within the prepectoral fascia. Complications may arise at any stage during the implant: access to the subclavian vein

 https://doi.org/10.1016/B978-0-12-809657-4.99790-4

may lead to a hemo/pneumothorax, cardiac perforation could occur from the leads once placed, coronary sinus dissection, bleeding with subsequent hematoma formation in the pocket, infection, atrial or ventricular arrhythmias. The intravascular ICD lead has always been the weakest link in the ICD system, and is associated with an increased risk of both early and late complications. Early postimplant, the majority of complications arise from lead dislodgement. Venous thrombosis, persistent pain at the site of the device, set screw dislodgement, development of a seroma, and superficial infection are other complications that may occur in the early (<30 days) peri-implant period.

Complications from initial ICD implants are not insignificant (2.5%–13%)(Tang et al., 2010; Krahn et al., 2011), increasing with complexity of device implant (single chamber < dual chamber < CRT). Initial pacemaker implants run a risk of complication of approximately 4%, primarily due to lead dislodgement (Sweeney et al., 2008). Most patients will require a pulse generator change in their lifetime due to battery depletion (typically 5–7 years for an ICD, 8–12 years for a pacemaker). In this circumstance, the major and minor complication rates are dramatically increased. These rates vary with the type of device (ICD, pacemaker, single versus dual chamber, cardiac resynchronization therapy (CRT)) and whether or not a lead revision is being performed concurrently (Poole et al., 2010). Major complications for a CRT upgrade or revision is as high as 18%, while the rates for ICDs and pacemakers were significantly lower (OR for ICD compared with pacemaker 2.38 $p = 0.004$; CRT versus pacemaker 3.68 $p < 0.001$). At the time of lead insertion, perforation of the lung or heart may occur. In a large, recent multinational study, pneumothorax occurred in 1.5% of ICD implants and cardiac perforation in a further 0.9% (**Table 1**) (Healey et al., 2010). In addition, early lead dislodgement, or loss of adequate lead sensing or pacing are among the most common device-related complications and can occur in 2%–5% of individuals; while late lead fracture or loss of function may occur in another 2%–3% of patients.

In addition to these common complications, there are other vascular complications such as deep venous thrombosis and compromise of dialysis access (**Table 1**). Transvenous ICD leads are also associated with a significant risk of developing tricuspid insufficiency (Baquero et al., 2015). Although this is often an echocardiographic finding, without evidence of right heart failure, existing studies have been too short in duration to adequately capture the potential consequences of this complication. Furthermore, there have not been any randomized trials to evaluate the effect of transvenous ICD leads on this outcome. All of these complications could be avoided (>75% reduction), if one eliminates the need to place a lead through the venous system and into the heart. There are additional common, early complications which are less directly related to the presence of a transvenous lead, including device-related infection, wound hematoma, death stroke, and myocardial infarction (**Table 1**) (Krahn et al., 2011; Healey et al., 2010).

Infectious complications and lead issues are the most concerning and the ones that are fraught with the greatest risk. Device infection, occurs in about 2% of all cases, and is a serious and potentially catastrophic consequence of these procedures (Gould and Krahn, 2006; Sohail et al., 2007; Klug et al., 2007). Device infection rates are increasing (Greenspon et al., 2011) and infection is more common in patients undergoing generator replacement or having more complex procedures where the infection risk is 2%–3%. Device Infection is costly as it is almost always managed with hospitalization with long courses of intravenous antibiotics (Gula et al., 2008; Paulin et al., 2008). System extraction is usually required and is associated with major complications (**Table 2**) (Byrd, 2007; Wilkoff et al., 2009; Wazni and Wilkoff, 2016). A 2008 study of 4.2 million device patients in the USA reported a cost of $146,000 per device system infection, and the risk of death associated with device infection in that study was 4.69% (Greenspon et al., 2011). The major risk factor for device infection is number of prior procedures on the pocket, so that minimizing repeated procedures, due to lead dislodgement, for example, is a major goal to prevent device infection. Given the significant issues surround device infection, there is a randomized clinical trial being conducted in Canada to try and improve outcomes (Prevention of Device Infection (PADIT) NCT01613092).

Lead issues provide an even greater level of complexity. Pacemaker lead failures can lead to loss of pacing which may be life-sustaining. ICD lead failures can lead to not only loss of pacing, but also inappropriate ICD shocks and/or ineffective treatment of

Table 1 Estimated incidence of complications due to pacemaker and ICD transvenous leads

Complication	*Estimated Rate*
Early avoidable, lead-related complications	
Pneumothorax/hemothorax (Healey et al., 2010; Armaganijan et al., 2012; Bernard et al., 2012)	1.5% (30 days)
Cardiac perforation, effusion, tamponade, pericarditis (Healey et al., 2010; Lee et al., 2010; Olde Nordkamp et al., 2016; Kleemann et al., 2007; Russo et al., 2015)	1.0%
Lead dislodgement, loss of sensing/pacing (Armaganijan et al., 2012; Lee et al., 2010; Olde Nordkamp et al., 2016; Kleemann et al., 2007; Russo et al., 2015)	3.0%
New, severe tricuspid insufficiency (Sadreddini et al., 2014)	3%
Ipsilateral upper extremity DVT	0.3%
Need to revise dialysis access	0.2%
Total	*9%*
Other early complications	
Death (Healey et al., 2010)	0.6%
Myocardial Infarction (Healey et al., 2010)	0.1%
Stroke (Healey et al., 2010)	0.2%
Significant wound hematoma (Healey et al., 2010)	2.3%
Device-related infection (Healey et al., 2010; Armaganijan et al., 2012)	1.3%

Table 2 Complications from laser lead extraction

Publication	*Number of leads*	*Major complications (%)*	*Procedural mortality (%)*
Byrd (2007)	2561	1.9	0.8
LExICon study (Wazni et al., 2010)	2405	1.4	0.28
Brunner et al. (2014)	5521	1.8	0.4
Epstein et al. (2013)	2274	0.82	0.31
Bongiorni et al. (2008)	2062	0.7	0.3

Table 3 Major complications: Lead extraction versus lead abandonment in two ICD lead advisories (Parkash et al., 2010, 2016)

	Lead abandonment		*Lead extraction*	
Lead advisory	*Major complications (%)*	*Death (%)*	*Major complications (%)*	*Death (%)*
Sprint Fidelis ($n=468$)	5	0.5	7.3	0.4
Riata ($n=496$)	5.2	0	18.6	1.2

Fig. 1 This demonstrates cable externalization due to inside-out abrasion in a Riata lead under advisory. This lead was removed by laser lead extraction. Courtesy of A. Krahn and R. Yee.

dangerous ventricular arrhythmias. Inappropriate diagnosis of lead failure can also lead to unnecessary lead replacement resulting in unnecessary morbidity or death. Transvenous lead design has had significant improvements over time, including the evolution of materials from silicone rubber to polyurethane, combinations of materials and the creation of copolymers such as Optim, which provides the benefits of silicone rubber (inert, biocompatible) and polyurethane (high tear strength) (Epstein et al., 2009). Lead-to-can insulation defects were previously primarily observed with abdominal implants. Silicone leads are highly durable but are known to have a lower tear strength and ultimate tensile strength than polyurethane. This property led to the development of protective sheaths using thinner coatings of materials with higher tensile and tear strength, to prevent degradation and abrasion.

Advisories affecting pacing or high voltage leads pose a very different clinical management scenario than those affecting the pulse generator alone. Revision of leads with or without a pulse generator change is known to confer an increased risk of complications, as reported in the REPLACE registry where it was associated with a risk as high as 18.7% (Poole et al., 2010). Lead *removal* is not easy to perform, as compared to generator *removal*, with significant morbidity and mortality associated with it; lead *addition* may also be wrought with difficulties, may also have long-term consequences of venous thrombosis, or obstruction, necessitating greater complexity if the need for extraction arises. The Canadian Heart Rhythm Society Device Committee has conducted two large cohort studies examining complications from lead revision due to a lead advisory (**Table 3**), the risks attributable to lead revision and lead extraction are shown in **Table 2** from each of these advisory cohorts (Parkash et al., 2010, 2016). If the lead was abandoned rather than removed, the risk of complications was significantly reduced in both advisory cohorts.

Use of lead extraction versus lead abandonment must take into account several factors including age and clinical status of the patient, comorbidities, number of leads in place, vascular issues and lead model and duration of lead implantation. The Riata lead advisory has proven to be an especially challenging lead to extract given the propensity of this lead to undergo inside-out insulation degradation, resulting in cable externalization, and "snow-plowing" of the lead during extraction attempts (**Fig. 1**) (Parkash and Bennett, 2016). In the case of a lead advisory, careful weighing of risks and benefits is required to prevent harm to patients. In certain

circumstances, such as device infection, total system removal may be unavoidable. Even in the case of infections, the use of laser lead extraction needs to be assessed carefully due to the possibility of life-threatening complications, including superior vena cava and/or right ventricular perforation. Most reports of complications due to laser lead extraction are from high-volume, experienced centers, hence their results may not extrapolate to all centers with this technology available (**Table 2**). Attempts to improve laser lead extraction are underway, with novel technology that may assist in prevention of these life-threatening complications.

Conclusion

Technology is advancing rapidly to eliminate some of the issues we are faced with respect to transvenous leads, however, there are significant limitations with leadless technology as well. Overall, the future is bright for leadless technology, but advances are required to ensure safety and efficacy for patients who require life-saving pacing or defibrillation therapy.

Left Ventricular Remodeling

Molecular Basis

Ventricular remodeling encompasses alterations in ventricular mass, shape, and geometry as a result of an increased hemodynamic load, neurohormonal activation, and genetic factors (Mann, 1999; Cohn et al., 2000). As a result of stressful stimuli, the failing myocardium undergoes cellular changes such as myocyte hypertrophy, decreased myocyte viability, fibroblast proliferation, increased collagen, and fibrosis. These effects manifest as changes in the geometry of the heart, leading to progressive ventricular dysfunction. Pressure and volume overload are the two major inciting stressors that trigger the left ventricular (LV) remodeling process. In the case of pressure overload conditions such as that seen in aortic stenosis or arterial hypertension, the left ventricle has a higher level of resistance to overcome during systole. In conditions where the LV is subjected to handling higher volumes during diastole as in aortic or mitral valve insufficiency, the LV diastolic wall stress increases. Regardless of the type of LV stressor, the consequence is an increase in size of the cardiac myocyte, which is termed LV hypertrophy (LVH). The underlying mechanism of these changes is thought to involve matrix–integrin interactions that are able to activate and/or modify a complex intracellular signaling pathway involving multiple kinases and transcription factors (Heineke and Molkentin, 2006). Intricately connected to this pathogenic process is the role of the renin-angiotensin-aldosterone system (RAAS), namely angiotensin II, which promotes fibroblast activation and potentiates maladaptive LV remodeling (Ahokas et al., 2003; Patel and Mehta, 2012). This chain of events is triggered by the mechanical deformation of cardiac myocytes that occurs with increased ventricular wall stress.

The pattern of LVH differs between that seen in pressure overload and volume overload states. In pressure overload states, there is a parallel addition of sarcomeres (the contractile elements of the myocyte) resulting in overall thickening of the LV, or concentric hypertrophy. Conversely, sarcomeres are added in series when volume overload is the primary LV stressor. This results in lengthening of the cardiac myocyte along with dilatation of the LV and is termed eccentric hypertrophy.

Neurohormonal activation plays a large role in disease progression and the remodeling process. Increasing ventricular wall stress activates the RAAS system, leading to myocardial hypertrophy. The increased level of angiotensin II and aldosterone further promote interstitial remodeling. Angiotensin II was found to increase DNA synthesis in myocardial fibroblasts and increase protein synthesis in both fibroblasts and myocytes. It mediates cell proliferation and growth in response to cellular stretch. In addition, Angiotensin II increases diffusion of growth factors into the myocardial interstitium. Angiotensin II has also been shown to elicit cytotoxic effects on cardiomyocytes leading to necrosis and fibrosis. Increased aldosterone production as a result of RAAS activation stimulates myocardial fibroblasts to synthesis collagen (Brilla et al., 1994). Additionally increased aldosterone has an effect on energy balance that leads to myocyte death (Sheehan and Seelig, 1984). Catecholamine activation also contributes to the process of remodeling.

Myocardial hypertrophy is stimulated by alpha-adrenergic stimulation. Chronic beta-adrenergic stimulation occurs in heart failure (HF) that overtime suppresses beta-adrenergic receptors and augments $G_i\alpha$ protein.

Additional vasoactive peptides such as endothelin, cytokines, and nitric oxide also influence remodeling. Endothelin exerts strong vasoconstrictive properties and is increased in HF. Blockade of endothelin production in animal models of HF has shown to slow the progression of HF. Tumor necrosis factor (TNF) and interleukins are cytokines produced by cells in response to stressful stimuli. Levels of TNF and interleukins are elevated in patients with HF. The elevation of these cytokines has been found to be associated with activation of RAAS. The SOLVD study found an inverse relationship between the increase in TNF and interleukins and clinical decline.

The cardiac myocyte is directly involved in the remodeling process. Cytoskeletal changes of the cardiac myocyte are associated with decreased contractile function in cardiac hypertrophy. In the early reversible stage of hypertrophy, cytoskeletal proteins accumulate to counteract increased myocyte stress. Mitochondria increase in number and decrease in size. As the stress continues, further changes take place that become irreversible. The loss of contractile material and proteins of the sarcomeric skeleton characterize this second stage. Concurrently, there is an increase in desmin and tubulin to compensate for the loss of cellular integrity. The result is a disorganized arrangement of the sarcomeres and disruption of Z bands leading to less effective contraction.

In the failing cardiomyocyte, excitation–contraction coupling is impaired. Normally, calcium influx into the myocyte triggers additional calcium release from the sarcoplasmic reticulum (SR). The released calcium then reenters the SR through the calcium ATPase, the SERCA2a. In diseased myocytes, SERCA2a number is reduced. This leads to high cytosolic calcium and low SR calcium, leading to decrease in calcium transit during contraction. Additionally, increased activity of calcium/calmodulin-dependent protein kinase II in HF leads to leaky ryanodine receptors, further worsening the decrease in calcium transient and contraction.

Another important change is in the phenotype of the failing myocyte. In normal conditions, the expression of myosin heavy chain (MHC) gene is predominantly α-MHC. α-MHC has high ATPase activity and promotes faster shortening velocity of cardiac myofibers. In HF, there is a return to fetal gene expression where α-MHC expression is downregulated and β-MHC is upregulated (Lowes et al., 1997). β-MHC has less ATPase activity and has been shown to correlate with the degree of cardiac hypertrophy.

Fibroblasts in the interstitial compartment modify the volume and composition of the extracellular matrix (ECM). Myocytes are tethered and supported by the connective tissue network formed from fibrillary collagen. Fibroblasts are responsible for the production and resorption of collagen. Fibroblasts are activated in response to ischemic stimuli. Stimulation leads to collagen synthesis and increased fibrosis with effects on ventricular size, structure, and stiffness (Hudlicka et al., 1992). Matrix metalloproteinases degrade ECM proteins and further contribute to ventricular remodeling.

LV Remodeling Effect on Heart Failure Clinical Outcomes

A key early prospective study assessed risk factors for mortality in 36 patients with dilated cardiomyopathy utilizing echocardiography data and demonstrated the significant clinical consequences of pathologic LV remodeling. The investigators found a statistically significant association between an increased degree of spherical LV geometry, as reflected by a higher ratio of short- to long-axis end-diastolic dimensions, and mortality (Douglas et al., 1989). Their other major finding was that smaller baseline LV end-diastolic short-axis dimensions conferred a survival advantage. This was substantiated in a later study assessing patients with decreased LV ejection fraction (LVEF) and symptomatic HF, where it was demonstrated that LV end-diastolic dimension (LVEDD) index was an independent predictor of survival (Lee et al., 1993). Echocardiographic parameters such as LV volume, mass, and ejection fraction have been found to be strong predictors of clinical outcomes (St John Sutton et al., 1997). Even in patients without prior myocardial infarction or HF, a large study consisting of 4744 patients, followed longitudinally over 11 years, found that increased LV end-diastolic and LV end-systolic dimensions were independent risk factors for developing HF (Vasan et al., 1997) with risk factor-adjusted hazard ratios (HR) of 1.47 (95% confidence interval [CI]: 1.25–1.73) and 1.43 (95% CI: 1.24–1.65), respectively (**Fig. 1**).

More recently, the predictive value of LV mass and size was further demonstrated in the Multi-Ethnic Study of Atherosclerosis (MESA) which included 5098 participants who underwent baseline cardiac MRI and followed for a median of 4 years (Bluemke et al., 2008). In this study, a strong association between increased LV mass and incident HF was demonstrated (**Fig. 2**). A later analysis also based on the MESA cohort found that participants with LV dilation (defined as LVEDD > 52 mm) had an increased risk for incident HF compared with those with normal LV size (HR: 2.4; 95% CI: 2.0–5.3) (Yeboah et al., 2014) (**Fig. 3**). Furthermore, a recent study retrospective cohort study (Phan et al., 2016) assessing the risk of sudden cardiac arrest (SCA) with distorted LV geometry in patients with LVEF ≤ 40% and without an implanted cardioverter-defibrillator found that eccentric LVH (elevated LV mass index and normal relative wall thickness (RWT)) was independently predictive of SCA (odds ratio [OR]: 2.15; 95% CI: 1.08–4.29).

Adverse LV remodeling has traditionally been classified as either concentric or eccentric LVH on the basis of increased RWT and LV mass as defined by the American Society of Echocardiography guidelines (Lang et al., 2015) (**Fig. 4** and **Table 1**). While this remains to be the most commonly used schema, a recent prospective analysis of 3,181 elderly participants with predominantly preserved LVEF and without previously diagnosed HF from the Cardiovascular Health Study assessed the prognostic implications of a novel LV geometry grading scheme (**Fig. 4**) that combines LV enlargement (defined as LVEDD > 56 mm), hypertrophy, and concentric remodeling in a sequential fashion (Zile et al., 2014). The incorporation of LV enlargement into this framework proved to be significant as an additive risk of incident HF and death was demonstrated when patients met criteria for both LV enlargement and hypertrophy. This study reaffirmed the prognostic importance of LV enlargement and hypertrophy for incident HF and mortality. Despite preserved LVEF in most of the participants, these alterations in LV structure were statistically significant predictors for both incident HF and death.

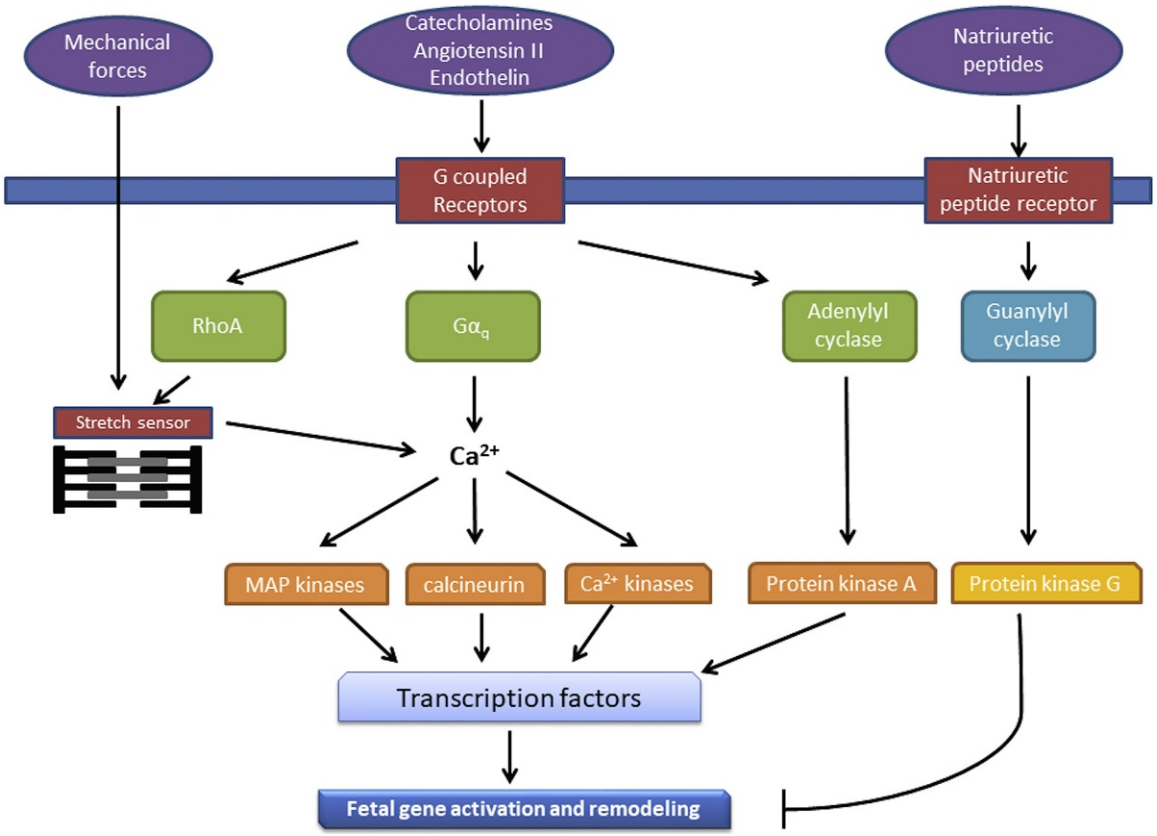

Fig. 1 Simplified diagram of pathways involved in LV remodeling. Mechanical stresses are sensed by stretch receptors and sarcomeric stretch-activated mechanisms. Neurohumoral stress mediators, such as catecholamines, angiotensin II, and endothelins, are sensed by membrane-bound receptors. These receptors signal through G proteins such as $G\alpha_q$, $G\alpha_x$, Rho proteins, and adenylyl cyclase. This affects calcium release and activates downstream phosphatases and kinases. Ca^{2+} kinases and MAP kinases play a role in cellular growth. Calcineurin acts as a key transducing phosphatase. Protein kinase A regulates myocyte contractility. Protein kinase G plays a role in anti-hypertrophy. The activation of these and other signals together affects downstream fetal gene activation and LV remodeling. Imaging Modalities for Assessing Ventricular Remodeling in HF

Transthoracic Echocardiography

Two-dimensional echocardiography

Echocardiography utilizes a transthoracic probe that emits ultrasound waves directed at cardiac structures that in turn reflect these ultrasound signals back to the probe. The computer within the ultrasound machine uses an algorithm to reconstruct images of the heart based on characteristics of the returning signal. In the clinical setting, two-dimensional (2D) transthoracic echocardiography (2DE) remains to be the predominant imaging modality for assessing ventricular structure and function in HF patients. It has the capability to provide valuable information on LV geometry and function while offering a high degree of safety, accessibility, and ease of use. Quantitative assessment of LV volumes, mass, geometry, and ejection fraction with 2DE allows clinicians to recognize the progression of adverse LV remodeling in HF patients (**Fig. 5** and **Table 1**). **Table 1** outlines the mathematical basis for these and other relevant parameters as recommended by the most recent American Society of Echocardiography guidelines (Lang et al., 2015). Limitations regarding the reproducibility and accuracy of serial measurements with conventional 2DE have been described on the basis of findings in a recent meta-analysis involving studies on echocardiographic surveillance in patients receiving cardiotoxic chemotherapy (Thavendiranathan et al., 2013).

Speckle-tracking echocardiography

More sensitive measurements can be obtained using newer techniques such as speckle-tracking echocardiography, which involves averaging of myocardial velocities in adjacent segments compared to a single measurement based on a single tracing using conventional 2DE (Sawaya et al., 2011). This allows for the calculation of myocardial strain which is defined as the change in length of a segment of myocardium divided by the segment's resting length and is based on quantitative data on global and regional myocardial deformation obtained on 2DE and the use of a computer algorithm (Amundsen et al., 2006). Strain imaging has been shown to detect early signs of LV remodeling in asymptomatic patients at risk for HF such as patients with diabetes and

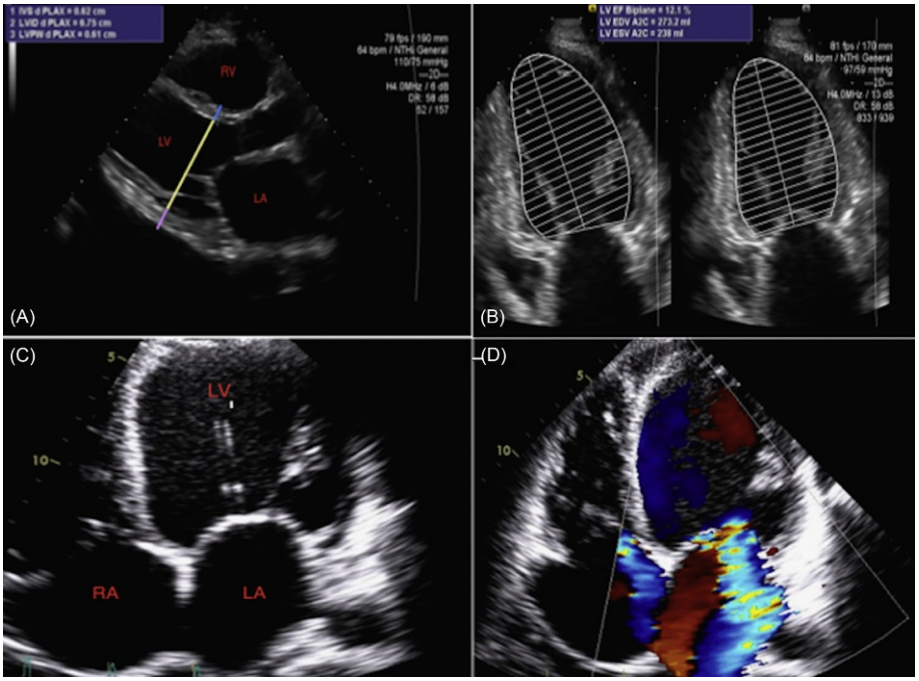

Fig. 5 Echocardiographic assessment of adverse LV remodeling. (A) Transthoracic echocardiogram of the parasternal long-axis view at end diastole showing severe LV dilation of a 58-year-old male with a history of HFrEF secondary to ischemic cardiomyopathy (*yellow line* = LV end-diastolic dimension, *blue line* = interventricular septal thickness, *purple line* = posterior wall thickness). This patient developed end-stage HF and successfully bridged to heart transplantation with home inotrope support 3 months after this study. (B) Apical two-chamber views at end diastole (left) and end systole (right) showing the traced endocardial borders for calculation of biplane LV systolic (238 mL) and diastolic (273.2 mL) volumes and LV ejection fraction (12.1%) in a 43-year-old male with advanced HFrEF secondary to idiopathic nonischemic cardiomyopathy (C) Apical 4-chamber view at end diastole of the same patient showing a severely dilated LV and severe biatrial enlargement. (D) Severe eccentric mitral regurgitation (MR) during systole detected with color flow Doppler in the same patient as in B and C. Secondary MR as seen in this patient is commonly observed in those with severely reduced LVEF and significant LV dilation because the distorted LV geometry with papillary muscle separation results in abnormal coaptation of the mitral valve leaflets and MR.

hypertension. In a prospective study involving 154 type 2 diabetic patients who were followed for 3 years, those with decreased longitudinal systolic strain at baseline were at higher risk of developing adverse LV remodeling (defined as the absence of a decrease in LV end-systolic volume over time and higher RWT) compared to patients with normal longitudinal systolic strain on speckle-tracking echocardiography (Ernande et al., 2014). A preclinical animal study assessing the changes in LV architecture and function associated with systemic hypertension found a striking link between decreased longitudinal myocardial strain and histologic patterns such as myocyte hypertrophy transmurally along with subendocardial fibrosis consistent with adverse LV remodeling (Ishizu et al., 2014). On the basis of their findings, the investigators concluded that longitudinal strain may serve as a surrogate of subendocardial fibrotic changes and may be useful for risk stratification of hypertensive HF.

Three-dimensional echocardiography

Real-time 3D echocardiographic (3DE) image acquisition is a newer imaging modality that is advantageous compared to conventional 2DE because no geometric assumptions are used and it has been shown to be more accurate (using cardiac magnetic resonance (CMR) as the reference standard) and reproducible in the assessment of ventricular chamber size and morphology (Jenkins et al., 2004). A later study calculated LV remodeling index (LVRI), defined as the 3DE-derived ratio between LV mass and LV end-diastolic volume, to describe various patterns of LV remodeling and found significantly lower values of LVRI in patients with dilated cardiomyopathy and significantly higher values in patients with hypertrophic cardiomyopathy (De Castro et al., 2007). Limitations of 3DE include image-quality dependence, lower volume of published data on reference values, and lower temporal resolution. However, 3DE appears to be a promising tool as part of multimodality cardiovascular (CV) imaging for the evaluation of LV remodeling.

Cardiac Magnetic Resonance

High-quality images of the heart can be obtained with CMR by utilizing a strong magnet, which is usually 1.5 or 3.0 Tesla (1 Tesla is equivalent to 20,000 times the strength of the earth's magnetic field). In addition to this main static magnetic field, the other main components of the CMR system are the magnet gradient coils along with radiofrequency transmitter and receiver coils. Gradient coils exist in three different axes and this accounts for the three-dimensionality of CMR. The gradient coils cause slight distortions in

the magnetic field by generating magnetic fields of varying strengths at a given position depending on which gradient coil is used. Positively charged protons mainly from water are aligned in the direction of the magnetic field when placed in the bore of the magnetic field. The transmitting radiofrequency coils act on these protons causing them to transition to a higher energy state. This is followed by a relaxation phase where the protons return to their baseline energy state. A signal is emitted during this relaxation phase that consists of two components, T1 and T2 relaxation. The magnetic gradients produced by the aforementioned gradient coils are applied across the cardiac structure of interest to localize the signals emitted during the relaxation phase. Differences in relaxation properties between extracellular fluid, blood, and different tissues account for the contrast in the final image. Of particular importance when using CMR in HF patients, regions of myocardial tissue that may have undergone adverse LV remodeling also have different relaxation properties compared to normal myocardial tissue. The radiofrequency receiver coil collects these signals that are then transformed into data ultimately used to create these images (**Fig. 6**). A more detailed discussion of the underlying physics and protocols involving CMR is outside the scope of this article but additional resources can be found in the Further Reading section at the end.

The high degree of spatial and temporal resolution, visualization of the endocardial border, and reproducibility provided by CMR have made it widely acknowledged as the reference imaging modality when quantifying LV dimensions, mass, and ejection fraction (Konstam et al., 2011). CMR has also emerged as the ideal noninvasive imaging choice in clinical trials investigating LV remodeling because fewer study participants are required as a result of its outstanding reproducibility and accuracy (Bellenger et al., 2000). The duration of a standard CMR study is roughly 45 minutes and scans are performed in a series of 5 to 15 second breath holds to optimize image quality. An important component of the standard CMR protocol worth noting is the use of intravenously administered gadolinium-based contrast agents to identify regions of myocardial fibrosis. The presence of late gadolinium enhancement (LGE) as seen in **Fig. 6F** accurately identifies the location and extent of myocardial scarring/fibrosis as evidenced by validation against histologic analysis (Kim et al., 1999). The significant clinical impact of CMR in HF patients was demonstrated in a prospective study involving 150 HF patients where 52% of patients had a change in management and 30% of patients had a new diagnosis on the basis of CMR findings (Abbasi et al., 2013). In total, the investigators found that CMR made a significant impact on diagnosis, management, and medical decision-making in 65% of HF patients. Furthermore, the presence of LGE on CMR was found to be a significant independent predictor of producing a significant clinical impact in a multivariable regression model (OR 6.72, 95% CI: 2.56–17.60, P = 0.0001).

In the HF patient population, signs of adverse LV remodeling represented mainly geometric distortions and presence of LGE on CMR as illustrated in **Fig. 6** provide powerful prognostic data on clinical outcomes. A prospective longitudinal study of 472 patients previously diagnosed with nonischemic dilated cardiomyopathy followed for a median of 5.3 years in the UK found that after

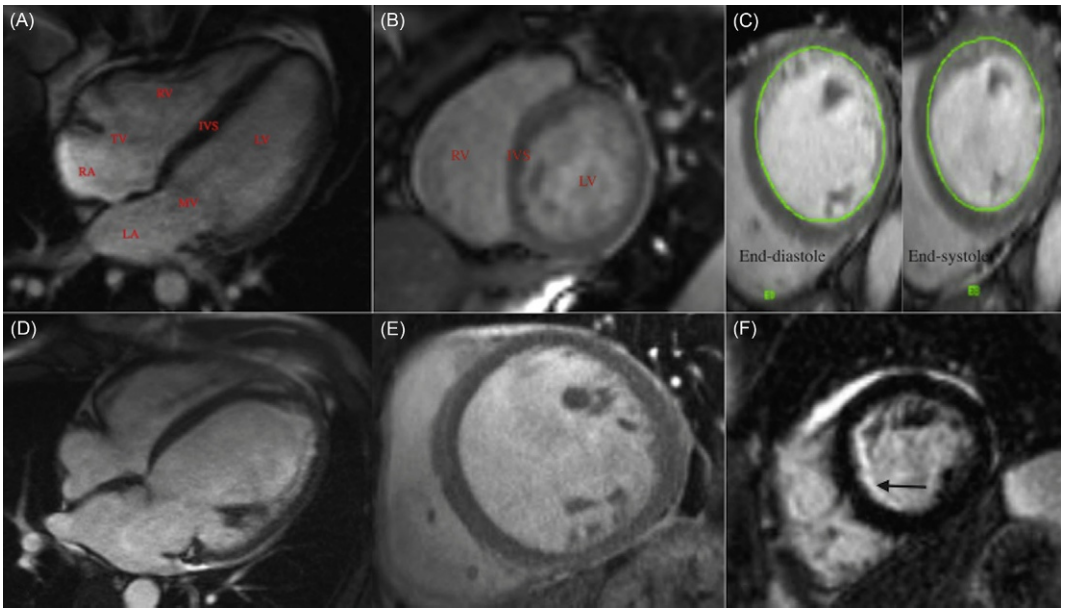

Fig. 6 Selected cardiac MR (CMR) images demonstrating LV remodeling in HF patients. (A) Single-slice four chamber CMR of a normal subject without HF. Note the high degree of soft tissue contrast that allows for clear visualization of intracardiac versus extracardiac structures. (B) End-diastolic short-axis view of a normal heart. (C) Accurate LV dimensions and LVEF can be obtained using contour drawing on short-axis CMR. (D) Significant LV remodeling demonstrated on this four chamber CMR view of a patient with chronic HFrEF. Here a more spherical LV architecture is seen compared to the ellipsoid shaped LV in image A. (E) CMR end-diastolic short-axis view demonstrating a severely dilated (LVEDD = 80 mm) failing LV (LVEF = 8.6%) in a 46 year old patient with significant history of alcohol abuse newly diagnosed with nonischemic cardiomyopathy. (F) Short-axis view using late gadolinium enhancement (LGE) during CMR study of a 64-year-old female cancer survivor with prior chemoradiation exposure presenting with progressive shortness of breath. Diffuse LGE at the mid-septal wall (*black arrow*) was demonstrated and correlates to myocardial fibrosis at this site secondary to a nonischemic etiology. *IVS*: interventricular septum; *LA*: left atrium; *LV*: left ventricle; *MV*: mitral valve; *RA*: right atrium; *RV*: right ventricle; *TV*: tricuspid valve.

adjustment for LVEF and other conventional risk factors, both the presence of fibrosis (HR: 2.43; 95% CI: 1.50–3.92; $P<.001$) and the extent of fibrosis (HR: 1.11; 95% CI: 1.06–1.16; $P<.001$) were independently and incrementally associated with all-cause mortality (Gulati et al., 2013). The presence of myocardial fibrosis was also independently associated with CV mortality or cardiac transplantation (HR: 3.22; 95% CI: 1.95–5.31; $P<.001$) as well as sudden cardiac death (SCD) or aborted SCD (HR: 4.61; 95% CI: 2.75–7.74; $P<.001$).

The high prognostic value of LGE on CMR in patients with nonischemic cardiomyopathy was further demonstrated in a meta-analysis where pooled data from nine studies (eight prospective, one retrospective design) comprising a total of 1488 patients were examined (Kuruvilla et al., 2014). The primary end points included all-cause mortality, HF hospitalization, and a composite end point of SCD or aborted SCD. Mean duration of follow-up was 30 months. Mean LVEF as determined with CMR was 37%. LGE was identified in 38% of patients and patients with LGE had increased overall mortality (OR: 3.27; 95% CI: 1.94–5.51; $P<0.00001$), HF hospitalization (OR: 2.91; 95% CI: 1.16–7.27; $P=0.02$), and SCD/aborted SCD (OR: 5.32; 95% CI: 3.45–8.20 $P<0.00001$) compared with those without LGE. Furthermore, the annualized event rates for mortality was higher in those with LGE at 4.7% versus 1.7% for LGE-negative patients ($P=0.01$), 5.03% versus 1.8% for HF hospitalization ($P=0.002$), and 6.0% versus 1.2% for SCD/aborted SCD ($P<0.001$).

Reversal of LV Remodeling

Role of Pharmacologic Therapy

Inhibitors of the RAAS

It has been well established that treatment with angiotensin-converting enzyme inhibitors (ACEi) and angiotensin receptor blockers (ARB) confers improved clinical outcomes and survival rates in HF patients with diminished LV systolic function (Group, 1987; Pfeffer et al., 1992). One of the earliest investigations of this was a substudy analysis as part of the SAVE trial (St John Sutton et al., 1994) that assessed whether captopril mitigates progression of LV enlargement in patients with LV dysfunction (defined as LVEF < 40%) after acute myocardial infarction (MI). In those patients who survived 1 year post MI, LV end-diastolic and end-systolic areas were smaller in the captopril than placebo group ($P=0.038$, $P=0.015$, respectively). Similar improvements in LV dimensions 1 year after MI were also seen in a substudy of the SOLVD trial (Konstam et al., 1992). Of note, the investigators found significant improvement of LV filling pressures as measured on cardiac catheterization and within roughly 2 weeks of enalapril discontinuation, blood pressure, and LV volumes increased to approximately baseline levels but remained below those of the placebo group. The authors concluded that ACEi therapy prevents progression of LV systolic dysfunction and LV dilation probably as a result from a combination of altered remodeling and sustained reduction in preload and afterload. An echocardiographic substudy of the Val-HeFT trial further demonstrated a statistically significant decline in LVEDD index and increase in LVEF after 18 months therapy with the ARB valsartan when added to a beta-blockers (BB) and/or ACEi (Wong et al., 2002). In this study, the valsartan-treated group had a demonstrable decrease in systolic blood pressure (i.e., decreased afterload) compared to placebo groups, which makes the degree of true reverse LV remodeling less clear. Another study further showed that the addition of the aldosterone receptor antagonist spironolactone to the ARB candesartan produced significant improvements in LVEF (35% vs. 26%, $P<0.01$) and reduction of LV end-diastolic volume index (LVEDVI) (121 mL/m^2 vs. 155 mL/m^2, $P=0.001$), LVESVI (88 mL/m^2 vs. 120 mL/m^2, $P<0.0005$), and LV mass index (81 g/m^2 vs. 93 g/m^2, $P=0.002$) in the combination group at 1 year (Chan et al., 2007). Reduction of collagen deposition in the myocardium in experimental HF models with the use of RAAS inhibitors is a possible mechanistic link to the evidence of reverse LV remodeling demonstrated in clinical trials (Liu et al., 1997; Milanez et al., 1997) (**Fig. 7**).

Beta-blockers

Three significant indicators of reversal of LV remodeling (RLVR) with metoprolol succinate were demonstrated in a substudy of 41 patients examined with CMR in the Metoprolol CR/XL Randomized Intervention Trial in HF (MERIT-HF) trial (Groenning et al., 2000): (1) a significant decrease in LVEDVI (150 mL/m^2 at baseline to 126 mL/m^2 after 6 months, P = 0.007), (2) a significant decline in LVESVI (107 to 81 mL/m^2, P = 0.001), and (3) LVEF increased in the metoprolol succinate group (29% to 37%, P = 0.005). A similar significant improvement in LV volumes and function assessed with CMR was demonstrated in a subgroup analysis of 34 patients with stable HF enrolled in the double-blind carvedilol versus placebo CHRISTMAS trial (Bellenger et al., 2004). Compared to placebo, treatment with carvedilol for 6 months significantly decreased LVESVI by nine units, LVEDVI by eight units, and increased LVEF by 3%. Carvedilol's efficacy in terms of contributing to LV reverse remodeling was further supported by Doughty et al. where a 5.8% increase in LVEF and 14 mL/m^2 decline in LVEDD index were observed after 12 months of carvedilol treatment (Doughty et al., 2004). Given carvedilol's inhibition of alpha-1 and beta-2 receptors in addition to beta-1 receptors, it is unclear whether the improvement in LV volumes with carvedilol therapy was a result of true intrinsic LV myocardial remodeling or due to improved LV loading conditions. Evidence of true RLVR occurring with carvedilol therapy was demonstrated by Loews et al. where LV mass decreased (276–247 g) as early as 4 months into carvedilol treatment and continued to decrease over a period of 12 months (Lowes et al., 1999). Improvement in the severity of mitral regurgitation and LV geometry, as manifested by a less spherical configuration, was also demonstrated with 4 months of carvedilol therapy. These changes were associated with an improvement in LVEF (21%–31%) and remained evident at 1-year follow-up. The value of CMR in predicting HF patients more likely to achieve some degree of RLVR with 6 months of BB therapy was demonstrated in a prospective study, where an inverse

relationship between the extent of transmural scarring (determined by LGE on CMR) and RLVR was identified (Bello et al., 2003). The investigators found that the amount of dysfunctional but viable myocardium by CMR was an independent predictor of the change in LVEF ($P=0.01$), mean wall motion score ($P=0.0007$), LVEDVI ($P=0.007$), and LVESVI ($P<0.0001$).

Novel pharmacologic agents for HF

Neprilysin is an endopeptidase that breaks down vasoactive peptides within the CV system such as natriuretic peptides, adrenomedullin, and bradykinin (Bayes-Genis et al., 2016). Cleavage of the molecules diminishes their net vasodilatory effect. This understanding of neprilysin's role in neurohormonal regulation in CV biology led to the pharmacologic development of neprilysin inhibitors as a potential treatment for chronic HF. Treatment with an angiotensin receptor-neprilysin inhibitor (ARNI) was shown to significantly reduce CV mortality and HF hospitalizations when compared to ACEi monotherapy among HFrEF (defined as LVEF $\leq$40% until 2010 at which point this was defined as LVEF $\leq$35%) patients in the 2014 PARADIGM-HF (McMurray et al., 2014). The effects of ARNI therapy on LV remodeling in the clinical setting remain largely unknown, but preclinical data has shown that 4-week treatment with the same ARNI used in PARADIGM-HF (LCZ696) attenuates cardiac remodeling and dysfunction after experimentally induced MI in rats (von Lueder et al., 2015). Statistically significant differences in echocardiographic parameters were noted in rats that underwent treatment with ARNI compared to the control group with higher LVEF (60 ± 2 vs. 47 ± 5%, lower LV end-diastolic diameter (9.7 ± 0.2 vs. 10.5 ± 0.3 mm), higher diastolic wall strain (0.23 ± 0.02 vs. 0.13 ± 0.02%), and circular strain (-9.8 ± 0.5 vs. -7.3 ± 0.5%). Compared to the control group, the treatment group was also found to have lower cardiac weights and significantly reduced levels of myocardial fibrosis, despite similar infarct size. Interestingly, the investigators found that the neprilysin inhibitor component of LCZ696, LBQ657, inhibited hypertrophy but not fibrosis. The ARB component of LCZ696 valsartan inhibited both hypertrophy and fibrosis.

Ivabradine is a newer agent that has been shown to reduce CV death and HF-related hospitalizations in patients with HFrEF and basal heart rates greater than 70 beats per minute while on BB therapy (Swedberg et al., 2010). It specifically inhibits the I_f current in the sinoatrial node by entering and binding to a site in the channel pore from the intracellular side (DiFrancesco and Camm, 2004). The SHIFT echocardiographic substudy (Tardif et al., 2011) of 411 patients found that ivabradine therapy led to a reduction in LVESVI compared to placebo (-7.0 ± 16.3 vs. -0.9 ± 17.1 mL/m^2; 95% CI: -8.8 to -2.7, $P<0.001$). LVESVI reduction with ivabradine use was also found to be independent of concomitant BB use, baseline LVEF, and etiology of HF.

The degree of LVESVI reduction correlated with the magnitude of CV risk reduction defined as the composite of CV mortality or hospitalization for progressive HF. Statistically significant improvements in LVEF and LVEDVI were also observed. The BEAUTIFUL echocardiographic substudy (Ceconi et al., 2011) also found a reduction in LVESVI along with a concomitant LVEF increase in ivabradine-treated HFrEF patients with stable CAD (defined as evidence of prior myocardial infarction, prior surgical or percutaneous coronary revascularization, or the presence of one or more major coronary arteries being narrowed by 50% or more on angiography) but failed to detect any significant differences in other echocardiographic parameters. They did demonstrate a clear link between the degree of ivabradine-induced heart rate reduction and reduction in LVESVI. On the basis of these clinical studies, there is evidence suggestive of ivabradine contributing to reversing adverse LV remodeling particularly in patients with ischemic cardiomyopathy.

Role of Device-Based Therapy

Cardiac resynchronization therapy

Patients with HF are commonly found to have concomitant abnormalities in their atrioventricular (AV) and intraventricular conduction pathways that correlate with the presence of left bundle branch block (LBBB) pattern on the electrocardiogram (ECG). These perturbations have been shown to be associated with a reduction in LV filling time compared to the right ventricular (RV) (Grines et al., 1989). The consequence of the delayed LV depolarization and ventricular diastolic imbalance is a dyssynchronous and inefficient pattern of ventricular contraction that contributes to progression of adverse LV remodeling. Cardiac resynchronization therapy (CRT) is defined as simultaneous pacing of both ventricles and its main therapeutic benefit in HF patients is derived from the reestablishment of coordinated interventricular contraction in addition to optimization of conduction within the LV and AV conduction.

On the basis of multiple randomized clinical trials, it is widely accepted that CRT decreases HF hospitalizations and mortality in HF patients who have a wide QRS complex, reduced LVEF, and New York Heart Association (NYHA) functional class I–IV (Moss et al., 2009; Linde et al., 2010; Tang et al., 2010). Its positive effect on halting and even reversing adverse LV remodeling has also been reported in multiple studies. For example, CRT duration of 6 months yielded significant decreases in LV mass, mitral regurgitation, LVEDVI, and LVESVI along with a 3.6% increased in LVEF compared with the control group in the MIRACLE trial (Abraham et al., 2002). A substudy analysis of the REVERSE trial further demonstrated a 68% reduction in mortality in patients who experienced a 15% or greater decrease in LVESVI after 6 months of CRT (Gold et al., 2015). The investigators found that improvement in other LV remodeling parameters such as LVEDVI and LVEF had a similar association with reduced mortality. When LV remodeling was assessed over 5 years in 419 patients in the REVERSE trial, sphericity index was used as a measure of distorted LV architecture (quantitatively derived based on LV shape at end diastole) and was found to be a predictor of death and HF hospitalization (St John Sutton et al., 2017). They also found the mean LV sphericity index to decline to its nadir within 1 year of CRT initiation. A decrease in LVESVI $>15\%$ with CRT occurred in 71% of patients over the 5-year follow-up period with a mean decrease of 22.8 mL/m^2 from baseline. Of note, the greatest decline in LVESVI (mean 18.3 mL/m^2) was observed over the first year of CRT initiation. Similar to prior studies, the decline in LVESVI with CRT was associated with an increase in LVEF compared to baseline (mean $33.2\pm12.7\%$ compared to $27.2\pm6.6\%$, $P<0.0001$) over the 5-year study period.

Predicting which patients respond to CRT (commonly defined as improvement in clinical HF symptoms and/or in LVEF and LV architecture on echocardiogram) has been an area of interest for researchers given the fact that approximately 30% of HF patients are clinical nonresponders to CRT. In addition to the diagnostic data obtained from CMR in HF patients, multiple studies have shown higher CRT failure rates when leads are placed in contact with scarred myocardium identified on CMR by the presence of LGE (White et al., 2006; Bilchick et al., 2014). A higher degree of baseline LV adverse remodeling determined on the basis of derangements in echocardiographic parameters described above and dyssynchrony as measured with CMR techniques have been shown to be reliable predictors of poor response to CRT (Bilchick et al., 2008; Carluccio et al., 2011).

One of the proposed mechanisms for RLVR with CRT is improved efficiency in the cardiomyocyte's cellular metabolism as was demonstrated by an increase in succinate-glutamate ratio, a marker of Krebs cycle activity, in patients undergoing CRT (Nemutlu et al., 2015). Studies have also suggested CRT partially reverses the derangements involving calcium handling in HF patients by inducing structural changes to the T-tubule apparatus, SR, ryanodine receptor, and voltage-gated calcium channels (Sachse et al., 2012). Another potential mechanism of CRT efficacy in RLVR is its ability to improve myofibril calcium sensitivity possible through phosphorylation and reactivation of glycogen synthase kinase-3β (Kirk et al., 2014).

Left ventricular assist device

A significant number of patients progress to end stage HF despite aggressive medical therapies. Implantation of a left ventricular assist device (LVAD) has been demonstrated to be effective in bridging these patients to cardiac transplantation (Miller et al., 2007). Furthermore, the REMATCH study expanded the use of LVADs as destination therapy for patients with end stage HF who are not candidates for cardiac transplantation (Rose et al., 2001). LVAD therapy affects two crucial aspects of pathologic LV remodeling. One, it is placed in parallel to the left ventricle, leading to unloading of pressure and volume, thus reducing both preload and afterload (Bellavia et al., 2017). And second, this unloading restores perfusion to critical organs leading to a decrease in pathologic neurohormonal activation (James et al., 1995). Patients who receive LVADs were found to have improved quality of life, functional status, and hemodynamics. Unfortunately, the long-term survival of patients with destination LVAD implantation remains low, and the use of LVADs as destination therapy remains limited.

Table 2 Mechanistic basis of reverse left ventricular remodeling with guideline-directed pharmacologic and device therapy for heart failure

Impairments in heart failure	*BB*	*ACEi/ARB*	*CRT*	*LVAD*
β-Adrenergic desensitization	↓	↓	↓	↓
Excitation-contraction coupling	↑	↑	↑	↑
Fetal gene expression	↓	↓	↓	↓
Myocyte hypertrophy	↓	↓	↓	↓
Myocyte apoptosis	↓	↓	↓	↓
MMP activation	↓	↓	↓	↓
Angiogenesis	↑	↑	↑	↓
Mitochondrial energetics	↑	↔	↑	↑
LV dilation	↓	↔[a]	↓	↓

Abbreviations. ACEi: angiotensin converting enzyme inhibitor, ARB: angiotensin receptor blocker, BB: beta-blocker, CRT: cardiac resynchronization therapy, LV: left ventricle, LVAD: left ventricular assist device, MMP: matrix metalloproteinase.
[a]Reflects ACEi/ARB effect of stabilizing LV size and preventing further dilation.
Adapted from Mann, D. L., Barger, P. M. and Burkhoff, D. (2012). Myocardial recovery and the failing heart: myth, magic, or molecular target?, *J Am Coll Cardiol*, 60(24), 2465–2472. https://doi.org/10.1016/j.jacc.2012.06.062.

LVADs reduce LV dilation by successfully unloading the LV. Immediate reduction in LV size after implantation has been demonstrated through transesophageal echocardiography (McCarthy et al., 1995). LV pressure–volume recordings have also confirmed lower LV volumes for equivalent pressure loads with LVAD support (Dandel et al., 2005). Moreover, patients with LVAD therapy also demonstrate improvement in ventricular contractile function. In a study by Maybaum et al., a third of patients with partial LVAD support were found to have an EF of greater than 40% at 30 days (Maybaum et al., 2007). Interestingly, the authors found that LVAD support up to 120 days resulted in a lower LVEF. Animal studies have found differential effects in mechanical unloading of normal versus failing hearts (James et al., 1995; Takaseya et al., 2004). Mechanical unloading of normal hearts led to a decrease in contractile function whereas improvement in myocardial contractility results from unloading of failing hearts (Kent et al., 1985; James et al., 1995; Takaseya et al., 2004). Further studies are needed to fully understand the effect of LVAD mechanical unloading on cardiac contractility.

LVADs have been show to help normalize the chronic maladaptive neurohormonal activation through improvement in hemodynamics. Decreased levels of angiotensin II, natriuretic peptide, and TNF-α have been observed after LVAD placement (James et al., 1995; Torre-Amione et al., 1999; Bruggink et al., 2006). Improvement in hypertrophy of the failing myocyte has been attributed to the mechanical unloading of the LV rather than changes in circulating systemic factors. Regression of hypertrophy is seen most prominently in the LV as compared to the RV (Barbone et al., 2001).

LVAD support also improves contractility through increased myocyte force. In vitro studies of myocytes obtained from patients with HF supported by LVAD as compared with patients without, the myocytes from LVAD patients had greater magnitude of shortening, faster time to peak contraction, and faster time to shortening (Dipla et al., 1998). Additional studies have demonstrated improved cardiac myocyte calcium handling and beta-adrenergic responsiveness contribute to in vivo improvements in cardiac function. Together, these studies suggest that the abnormalities seen in failing hearts are largely due to increased myocardial wall stress and abnormal neurohormonal activation. **Table 2** summarizes how each of these pharmacologic or device therapies impacts RLVR.

Right Ventricular Remodeling

Molecular Basis

Similar to LV remodeling, RV remodeling occurs at the structural, histological, and molecular level. RV remodeling and right-sided HF (RHF) have historically been understudied compared to left-sided HF (LHF) but RV function has been shown to be a significant predictor of outcomes in patients with LHF (Haddad et al., 2008). Similar to high afterload states (i.e., systemic arterial hypertension and aortic valve stenosis) triggering LV remodeling, pulmonary hypertension (PH) creates RV pressure overload. Left-sided cardiac abnormalities (i.e., LV systolic and/or diastolic dysfunction, mitral regurgitation) have been shown to be the most common cause of PH, being responsible for as many as 68% of PH cases (Strange et al., 2012). An important difference between RV and LV hypertrophy due to increased afterload is that RV enlargement occurs much earlier because the RV wall thickness is lower than the LV. It has also been shown that the transition to anaerobic metabolism appears to occur earlier in the pressure-loaded RV versus the pressure-loaded LV, resulting in an earlier decrease in net ATP production in the RV (Do et al., 1997). The increased RV wall stress results in reactionary RV hypertrophy and contractility to overcome the high afterload state. Maladaptive remodeling and ultimately RHF, however, ensues after prolonged RV wall stress.

In a swine PH model, investigators analyzed molecular and histologic differences between an RV that had undergone adaptive remodeling versus a failed RV. Decreased expression of RV SR Ca^{2+}-ATPase2a along with increased aldosterone levels was found in

the RV failure group (Aguero et al., 2014). Another important feature detected in the RV failure group was right ventriculoarterial uncoupling (reduced RV pump function despite increased RV contractility of the pressure-overloaded RV) using pressure–volume loop analysis. The progression from compensated RV remodeling to RV failure also appears to be closely involved with the transition from aerobic to anaerobic cellular metabolism due to mitochondrial dysfunction (Watts et al., 2010). When considering the relationship between the molecular basis of RV and LV remodeling, there is a high degree of overlap among them. Apoptosis, dysregulated angiogenesis with decreased capillary density, diminished oxidative capacity and direct cytotoxicity due to reactive oxidative stress, and neurohormonal activation involving RAAS and adrenergic signaling pathways have all been shown to occur with RV remodeling in a similar manner as LV remodeling (Voelkel et al., 2012). Key differences that have been described include myocardial RV-specific expression of phosphodiesterase type 5 (PDE5) in RV pressure-overload states thus making PDE5 inhibitors ideal pharmacologic agents for RV dysfunction (Nagendran et al., 2007). Preclinical investigation has also shown that a specific molecular pathway that is more prominent in RV remodeling is the Wnt pathway that is involved with kinase cascades which regulate cell migration, proliferation, and apoptosis (Urashima et al., 2008). In this experimental model, RV afterload stress was created with pulmonary artery constriction and compared to LV afterload-stressed myocardium. Wnt signaling was more active in the pressure-overloaded RV. Subtle differences in micro-RNA expression between RV and LV remodeling have also been demonstrated, with upregulation of four micro-RNAs (28, 34a, 93, and 148a) in RV hypertrophy/RHF that are downregulated or unchanged in LHF (Reddy et al., 2012).

Imaging Modalities to Assess the RV

Echocardiography is also the predominant imaging tool in assessing RV function and structure. Important prognostic parameters such as tricuspid annular plane systolic excursion, presence of pericardial effusion, RVEF, RV volumes, and RV mass can be obtained using echocardiography (Ghio et al., 2010). CMR has also become recognized as the gold standard in assessing RV function and is the most accurate and reproducible method for determining RV mass, volume with an interobserver variability <7% for the end-diastolic volume, <14% for the end-systolic volume, <7% for EF, and <20% for RV mass (Grothues et al., 2004). Another study identified CMR-derived RVEF as the most predictive parameter of clinical outcomes in patients undergoing PH-specific treatment (van de Veerdonk et al., 2011). This has been supported by a recent meta-analysis using a large sample ($n = 539$) from 21 different studies (Baggen et al., 2016). The significant prognostic value of LGE presence with CMR as seen in the LV has yet to be established in PH patients (McCann et al., 2005).

RV Reverse Remodeling

Currently approved therapy for PH includes PDE5 inhibitors (sildenafil, tadalafil), prostanoids (epoprostenol, iloprost, treprostinil), and endothelin-1 receptor antagonists (ambrisentan, bosentan). Use of these agents yields reverse RV remodeling that is predominantly a result of their afterload reducing and vasodilatory effects (Kerbaul et al., 2007; Holmboe et al., 2013). Recent experimental studies have also demonstrated reverse RV remodeling effects with the BBs carvedilol (Okumura et al. 2015) and bisoprolol (de Man et al. 2012). The proposed mechanism in the Okumura et al. study was that carvedilol reduces biventricular transforming growth factor-β1, connective tissue growth factor signaling, fibrosis, apoptosis and improved fibrosis and hemodynamics occurred despite persistent RV afterload. In the de Man et al. study histologic analysis revealed significantly less RV fibrosis and myocardial inflammation in bisoprolol-treated PH rats.

Introduction

Incidence and Prevalence

Heart failure continues to be a major public health concern in the United States, contributing to significant morbidity, mortality, and health care costs. An estimated 5.7 million American adults have heart failure, with this number expected to increase to over 8 million by 2030 (Heidenreich, et al., 2013). There is a 1 in 5 lifetime risk of developing heart failure for an adult 40 years of age (Lloyd-Jones et al., 2002). This places a tremendous burden on the health care system with heart failure costs in 2012 estimated to be $30.7 billion, of which 68% was attributable to direct medical costs (Heidenreich et al., 2013). By 2030 this is expected to increase 127% to $67.0 billion (Heidenreich et al., 2013).

For heart failure patients who are refractory to medical therapies, the only remaining therapeutic options are surgical. The ideal treatment is heart transplantation. However, this option is limited by the availability of organs and the strict criteria needed to be met to be a transplant candidate. Despite an increasing number of patients requiring heart transplantations, the number of transplants in North America has remained relatively stable over the past 20 years at approximately 2500 transplants per year (Lund et al., 2015). Therefore, with the aging population and increasing prevalence of heart failure, an alternative to heart transplantation is necessary. For end-stage heart failure patients who are either not a candidate for heart transplantation or cannot wait for a donor heart, mechanical circulatory support (MCS) with a left ventricular assist device (LVAD) can be lifesaving.

History of Mechanical Circulatory Support

The first use of MCS in open heart surgery was in 1953 when John Gibbon used a cardiopulmonary bypass machine to repair an atrial septal defect in an 18-year-old woman (Gibbon, 1954). This was followed by the development of temporary MCS systems for use in patients with low cardiac output after cardiac surgery (Liotta et al., 1963). In 1966, Michael DeBakey and colleagues implanted the first pneumatic paracorporeal pulsatile LVAD (DeBakey, 1971). Early generations of LVADs provided pulsatile flow and were pneumatically or electrically driven. Multiple variations on the pulsatile LVAD concept were developed during the 1980s and 1990s, including the first successful bridge-to-transplantation (BTT) LVAD implant of the Novacor Left Ventricular Assist

 https://doi.org/10.1016/B978-0-12-809657-4.99664-9

System (LVAS) by Phil Oyer in 1984 (Starnes et al., 1988). This device employed an electromechanically driven dual pusher-plate blood pump. However, probably the most successful of the first-generation LVADs was the Thoratec HeartMate XVE device. Variations of this device were initially approved for BTT, but the XVE ultimately became the first intracorporeal LVAD device for destination therapy (DT) after the landmark REMATCH (Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure) trial which compared LVAD therapy to optimal medical management (Rose, 2001). Despite the clinical advantages of LVAD therapy over medical management, these devices were limited by their large size, infectious complications, and limited durability.

The search for improved LVAD designs led to the development of the second-generation continuous flow pumps. Compared to the pulsatile pumps, these pumps are smaller in size, do not require valves, require less power, do not need a compliance chamber, and are less expensive. The most frequently used second-generation LVAD is the Heartmate II and was FDA approved for BTT in 2008 and for DT in 2010. The impeller of this axial-flow pump, which has a typical rotation rate of approximately 10,000 rpm, is both mechanically and magnetically positioned. This design improves its durability with an expected lifetime of at least five years.

The third-generation LVAD was designed as a radial centrifugal pump that propels blood using a spinning top with magnetic and hydraulic positioning inside a small chamber. Because there is no mechanical contact between the impeller and the chamber, minimal to no wear is expected, further improving the durability of the LVAD which is expected to last at least 10 years. With a further decrease in size, these LVADs are contained within the pericardium and can even be implanted without a sternotomy via bilateral thoracotomies (Schmitto et al., 2012). Two leading examples of this generation of LVADs are the HeartWare HVAD (HeartWare Inc., Framingham, MA, USA) and the HeartMate 3. Because of their reduced size, these pumps have also been used for right ventricular support, either as a standalone right ventricular assist device (RVAD) or in conjunction with a left-sided pump for biventricular failure. However, such application of these pumps is considered off-label use (Shehab et al., 2016).

In instances of biventricular failure, an LVAD alone may be inadequate. However, because of the large size of the earlier generation of LVADs, it was not possible to intracorporeally implant two pumps for biventricular support. In 1969, Denton Cooley and colleagues implanted the first total artificial heart, which was intended as a BTT (Cooley et al., 1969). In 1982, the JARVIK-7 TAH was implanted as DT by William DeVries (DeVries et al., 1984). This device was acquired by CardioWest, Inc, in 1992 and first implanted as a BTT in 1993. The CardioWest TAH was a pneumatically driven biventricular pulsatile pump implanted in the orthotopic position (Copeland et al., 2003). The modern version of this device is the Syncardia TAH, the only FDA approved TAH device currently in use.

Clinical Considerations

Heart Failure Management

The clinical syndrome of heart failure describes a constellation of signs and symptoms resulting from inadequate cardiac function. The traditional discussion of heart failure refers to heart failure associated with severe systolic dysfunction, or heart failure with reduced ejection fraction (HFrEF). However, heart failure can also be associated with normal systolic function, or heart failure with preserved ejection fraction (HFpEF). HFpEF is still not completely understood and ideal therapy is still undefined. However, in the context of MCS for heart failure, the discussion will focus on HFrEF.

Appropriate management of patients with heart failure requires close monitoring and an understanding of the severity of their disease and associated symptoms. To this end, classification systems have been developed to describe the severity of the heart failure. The two most commonly used classifications are the ACCF/AHA stages of heart failure, which emphasizes the development and progression of disease (Hunt, 2009) and the New York Heart Association (NYHA) functional classification, which focuses on exercise capacity and the symptomatic status of the patient. The ACCF/AHA stages represent a progression of disease wherein a patient advances through the stages but does not regress to earlier stages. However, a patient's NYHA functional class can change with time as the disease progresses or as the patient responds to therapy (**Table 1**).

The treatment of patients with heart failure is primarily dictated by the patient's disease etiology, symptoms, and heart failure state. As they progress through the stages of heart failure, patient therapies are escalated, beginning with risk factor management and then progressing to the use of a variety of heart failure medications (**Fig. 1**). Depending on the etiology and nature of their heart failure, they may also benefit from specific surgical intervention (coronary revascularization and valve surgery) and/or cardiac resynchronization therapy. This is followed by inotropic therapy, which may be temporary or chronic. However, as they advance to stage D heart failure with persistent NYHA class III or IV symptoms despite optimal therapy, or they become inotrope dependent, they are left with heart transplantation or MCS as their only remaining therapeutic options.

Stage D heart failure describes an advanced heart failure state that is associated with significant structural abnormalities of the heart and severe symptoms despite optimal therapy. Patients in this stage are faced with limited treatment options, elevated morbidity, and short survival. The selection of appropriate advanced therapeutic options is dictated by a number of factors. To aid in this discussion, a decision tree is provided in **Fig. 2**.

Terminology and Classifications

Among the wide range of MCS devices available, there are several categories of devices. The most fundamental distinction among these devices is whether they are temporary (nondurable) or permanent (durable). Nondurable MCS devices are meant for relatively

Table 1 Comparison of ACCF/AHA stages of HF and NYHA functional classifications (Yancy et al., 2013)

ACCF/AHA stages of HF	*NYHA functional classification*	
A. At high risk for HF but without structural heart disease or symptoms of HF	None	
B. Structural heart disease but without signs or symptoms of HF	I	No limitation of physical activity. Ordinary physical activity does not cause symptoms of HF
C. Structural heart disease with prior or current symptoms of HF	I	No limitation of physical activity. Ordinary physical activity does not cause symptoms of HF
	II	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in symptoms of HF
	III	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes symptoms of HF
	IV	Unable to carry on any physical activity without symptoms of HF, or symptoms of HF at rest
D. Refractory HF requiring specialized interventions	IV	Unable to carry on any physical activity without symptoms of HF, or symptoms of HF at rest

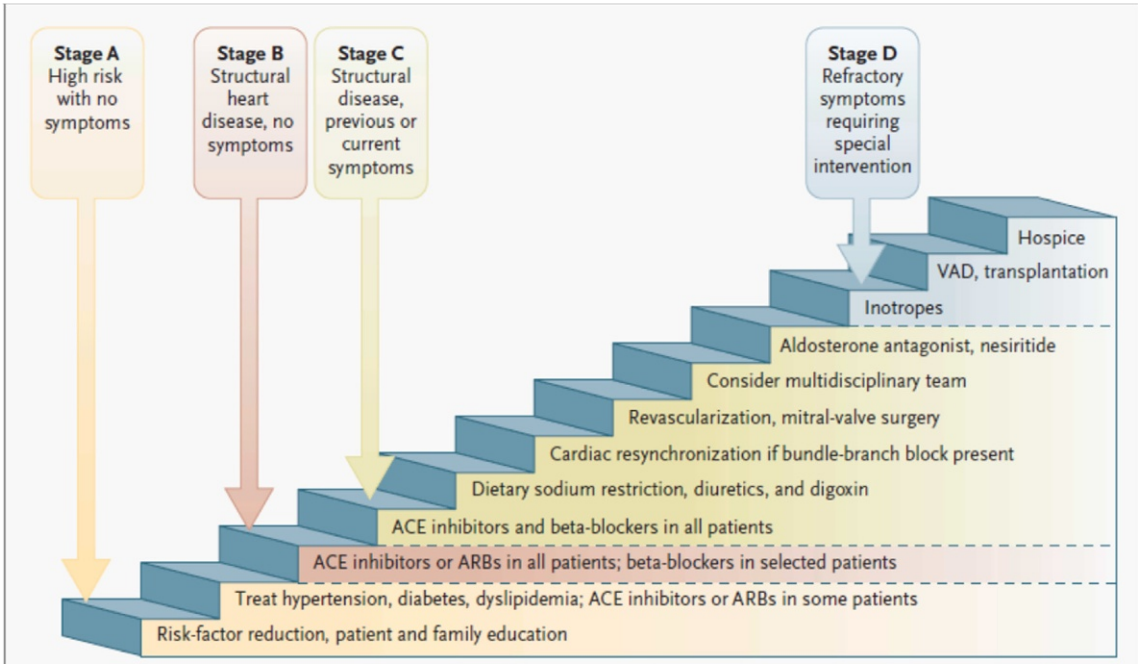

Fig. 1 Heart failure decision tree (Jessup and Brozena, 2003).

short term (days to weeks) use that is restricted to use in the hospital. These devices are typically employed for situations where the patient requires urgent or emergent hemodynamic support but are not yet candidates for heart transplantation or durable devices. A durable device is one that is implanted intracorporeally and meant for permanent or long-term use. Patients with these devices can be discharged from the hospital after recovery.

Another distinction that can be made between devices is whether they are centrally or peripherally inserted. For the most part, peripherally inserted devices are all nondurable devices. These devices can generally be inserted percutaneously via the femoral or axillary arteries, although some cases require surgical cut down for direct insertion into the artery. Centrally inserted devices are placed directly into the heart or associated vessels via a sternotomy or thoracotomy. All durable devices are centrally implanted; however, certain nondurable devices can or require central insertion as well. The advantage of peripherally inserted devices is the decreased invasiveness of the procedure, some of which can be carried out at the bedside. However, one of the primary limitations of any device inserted via the femoral artery is that the patient is bed bound and generally has to remain supine.

Devices can also be classified based on the type of support they provide. LVAD support the left heart, generally bypass the left heart. Typically, blood is diverted from the heart via the left atrium or left ventricle, go through the device, and return back into the aorta. Some devices, such as the Impella family of pumps, are placed across the aortic valve and pump the blood from the left ventricle to the ascending aorta. Similarly, RVAD bypass the right heart and take blood from the right atrium or some part of the

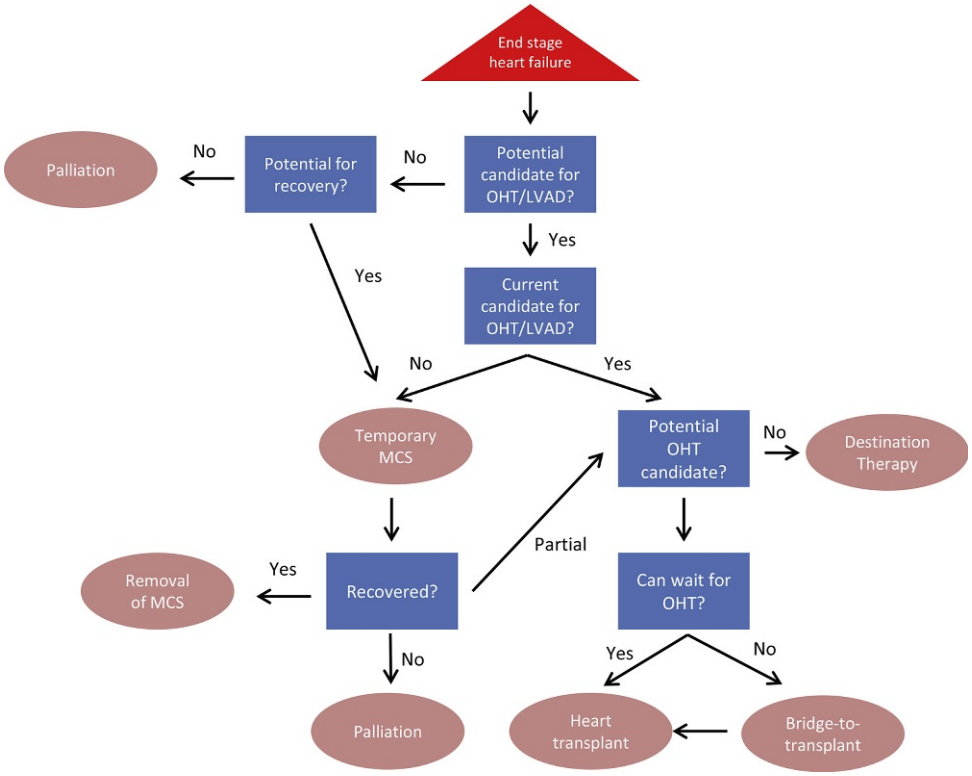

Fig. 2 Decision tree.

venous system, and return it to the pulmonary artery. Patients who have biventricular failure will either require both an LVAD and RVAD, or a total artificial heart (TAH). A TAH involves replacing both ventricles and provides pulsatile flow from the right and left atria to the pulmonary artery and aorta, respectively. An alternative to a TAH for biventricular support that is temporary and potentially percutaneous is Extracorporeal Membrane Oxygenation (ECMO). Here, the entire cardiopulmonary system is bypassed as blood is diverted from the right atrium or some part of the venous system to the arterial system. One other aspect that makes ECMO unique among MCS devices is that ECMO also includes an oxygenator, and can both oxygenate the blood and remove carbon dioxide.

Another important distinction that is made with MCS implantation is the intended purpose of the device. Devices that are meant for a patient who is a candidate for heart transplantation but is not able to wait long enough for the transplant are deemed to be for bridge-to-transplant (BTT). Those who are not candidates for heart transplant or do not want one, can have durable devices implanted for destination therapy (DT). BTT and DT are formal designations that are made prior to implanting any durable device. Sometimes, a patient may not be a transplant candidate at the time of implantation but has the potential to be one in the future. Such a patient can be implanted with a device with the intention of being a bridge-to-candidacy (BTC). Finally, a device can be implanted with an expectation of recovery or bridge to recovery (BTR). However, recovery is uncommon in patients implanted with durable devices. More commonly, recovery is seen in patients who need temporary support with a nondurable device for an acute problem.

Indications for MCS

Although the precise indications for nondurable versus durable MCS may differ, the main principles underlying the indications for MCS in general are the same. MCS is indicated in patients with advanced heart failure and/or cardiogenic shock who continue to have inadequate tissue perfusion despite optimal medical therapy. The International Society for Heart and Lung Transplantation (ISHLT) published guidelines for MCS in 2013 (**Table 2**) that outline recommendations for who should be considered for MCS (Feldman et al., 2013).

Decision Tree

Once a determination has been made that a patient requires MCS, a series of questions have to be answered to determine the ideal course of action (**Fig. 2**). And although the precise criteria and protocols involved in the decision making process may differ from institution to institution, the basic principles are universal. It is also important to note that having an indication for MCS does not necessarily make a patient a candidate for MCS.

Table 2 Recommendations for risk stratification for consideration of MCS (Feldman et al., 2013)

Class IIa

1. Long-term MCS for patients who are in acute cardiogenic shock should be reserved for the following:
   a. Patients whose ventricular function is deemed unrecoverable or unlikely to recover without long-term device support.
   b. Patients who are deemed too ill to maintain normal hemodynamics and vital organ function with temporary MCSDs, or who cannot be weaned from temporary MCSDs or inotropic support.
   c. Patients with the capacity for meaningful recovery of end-organ function and qualty of life.
   d. Patients without irreversible end-organ damage.

Level of evidence: C

2. Patients who are inotrope-dependent should be considered for MCS because they represent a group with high mortality with ongoing medical management.
   Level of evidence: B
3. Patients with end-stage systolic heart failure who do not fall into recommendations 1 and 2 above should undergo routine risk stratification at regular intervals to determine the need for and optimal timing of MCS. This determination may be aided by risk assessment calculators and cardiopulmonary stress testing.
   Level of evidence: C
4. Heart failure patients who are at high-risk for 1-year mortality using prognostic models should be referred for advanced therapy including heart transplant, or MCS (bridge to transplantation [BTT] or destination therapy [DT]) as appropriate.

1. One of first questions to answer is whether a potential candidate for MCS has a viable "exit strategy." The potential clinical outcomes for these patients (from best to worst) are recovery, heart transplantation, durable device implantation, or palliation. If the patient is not a potential candidate for either heart transplantation or durable device, then the next question is whether the patient has a reasonable potential for recovery. If he/she does not, then palliation may be the appropriate option. However, if there is a chance of meaningful recovery or transplant/durable MCS candidacy, then the patient may be offered a trial of temporary MCS.
2. If a patient is a potential heart transplant or durable device candidate, then they should be evaluated to see if they are currently a candidate for either therapy. If not, then they should be considered for temporary MCS with the hopes of either complete recovery (less likely), palliation if they do not have any meaningful recovery, or recovery to the point where they become candidates for heart transplantation or durable device implantation.
3. Patients who are current candidates for heart transplantation or durable device implantation should then be evaluated specifically for heart transplantation. If they are a candidate and are stable enough to wait for a suitable donor organ, then they can be listed for heart transplantation. If they are a candidate for transplantation but are not stable enough to wait for a donor heart, they can have a durable device implanted as BTT. Under certain circumstances, centrally cannulated extracorporeal pumps may also be appropriate for BTT. If they are not a candidate for transplantation, they can then have a durable device implanted as DT.

Nondurable Mechanical Circulatory Support

Clinical Considerations

Patients who require nondurable MCS generally fall under two categories. They may be patients with acute cardiogenic shock due to any one of a wide range of possible causes who require hemodynamic support despite maximal medical therapies. The other group of patients requiring nondurable MCS is those with stage D heart failure who are being considered for heart transplantation or durable MCS but need urgent support before they can be a candidate for these therapies. Various medical societies, including the ISHLT, the American Heart Association (AHA), and the Heart Failure Society of America (HFSA), have devised guidelines for when temporary MCS should be instituted (Kapur and Esposito, 2015).

ISHLT Mechanical Circulatory Support Guidelines 2012

- Class 1: Nondurable MCS indicated for acute decompensated heart failure failing maximal medical therapy, multi-organ failure, sepsis, or ventilator-dependent patients to optimize hemodynamics and evaluate status.
- Class 1: Right ventricular assist device is indicated for postoperative right ventricular failure refractory to maximal medical therapy after LV assist device implantation.

AHA Heart Failure Guidelines 2013

- Class 2A (level of evidence, B): Nondurable MCS is reasonable as a bridge to recovery or decision for carefully selected patients with heart failure and acute profound disease.

HFSA Heart Failure Guidelines 2010

- Urgent MCS is indicated for bridge to decision in unstable heart failure refractory to maximal medical therapy complicated by multi-organ dysfunction and with a relative contraindication to transplant or durable MCS.

Cardiogenic shock is typically characterized by severe refractory myocardial dysfunction that leads to inadequate tissue perfusion and progressive end-organ dysfunction in the setting of adequate preload. There is a wide range of causes of cardiogenic shock, many of which have specific medical or surgical treatments. However, sometimes the severity of their acute condition is such that they are either not candidates or cannot wait for these treatments (**Table 3**). These patients may be candidates for urgent or emergent nondurable MCS, allowing them to recover to the point where they can receive the definitive treatment they need, or even completely recover without needing further intervention.

Nondurable MCS Devices

Although the selection of nondurable MCS devices depends on a number of factors, they all have the common goals of (1) increasing vital organ perfusion, (2) augmenting coronary perfusion, and/or (3) reducing ventricular volume and filling pressures in order to reduce wall stress, stroke work, and myocardial oxygen consumption (Kapur and Esposito, 2015). The four most common percutaneous MCS devices that support the systemic circulation (as opposed to pulmonary circulation and right heart) are (1) the intra-aortic balloon pump (IABP), (2) extracorporeal membrane oxygenation (ECMO), (3) the Impella family of devices, and (4) the TandemHeart (**Fig. 3**). In addition to these peripherally placed devices, there are also centrally placed nondurable MCS devices.

Intraaortic balloon pump

IABP is a counterpulsation pump and is the most widely used nondurable MCS device. It can be considered the least invasive of the nondurable devices in that they can be placed percutaneously, at the bedside, and does not involve blood circulating through the device itself. It also has the advantage of being less expensive than other devices and relatively easy to insert. IABP comprises a double-lumen catheter mounted cylindrical polyethylene balloon that is inserted into the aorta and placed in the descending aorta just distal to the takeoff of the left subclavian artery. It is usually inserted percutaneously through a sheath placed via the femoral artery, although it has also been placed through the axillary artery (H'Doubler et al., 2000). The balloon is rapidly inflated and deflated using helium gas and is timed to inflate at the onset of cardiac diastole and deflate at the onset of systole. The timing is accomplished by synching the device with either the patient's electrocardiogram or direct arterial blood pressure. Inflation during diastole theoretically augments coronary perfusion by displacing blood volume in the descending aorta and increasing the mean aortic pressure. When the balloon deflates during systole, a vacuum effect is produced thereby decreasing afterload and augmenting cardiac output.

Table 3 Causes of cardiogenic shock (Hollenberg et al., 1999)

Acute myocardial infarction
Pump failure
Large infarction
Smaller infarction with preexisting left ventricular dysfunction
Infarction extension
Reinfarction
Infarction expansion
Mechanical complications
Acute mitral regurgitation caused by papillary muscle rupture
Ventricular septal defect
Free-wall rupture
Pericardial tamponade
Right ventricular infarction
Other conditions
End-stage cardiomyopathy
Myocarditis
Myocardial contusion
Prolonged cardiopulmonary bypass
Septic shock with severe myocardial depression
Left ventricular outflow tract obstruction
Aortic stenosis
Hypertrophic obstructive cardiomyopathy
Obstruction to left ventricular filling
Mitral stenosis
Left atrial myxoma
Acute mitral regurgitation (chordal rupture)
Acute aortic insufficiency

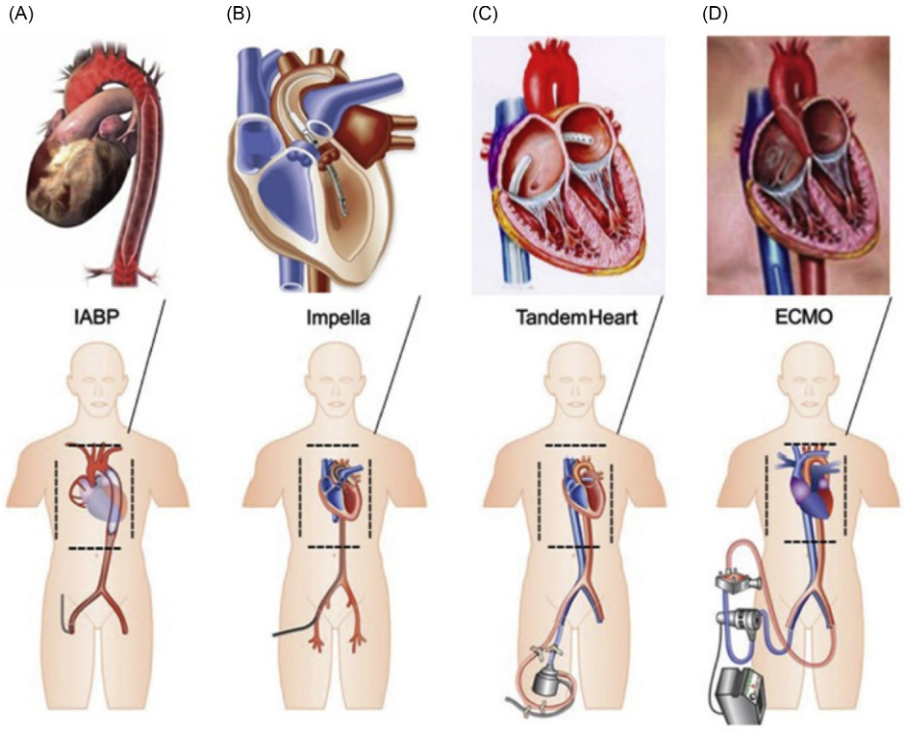

Fig. 3 Four most common percutaneous MCS devices that support the systemic circulation (Brown and Estep, 2016).

The standard balloon capacity is 40 cc, although the larger capacity 50 cc balloons potentially offer greater hemodynamic support (Kapur et al., 2015). The frequency of inflation can be adjusted with the 1:1 setting (inflation with every heart beat) being most common. As with all MCS devices, patients with IABPs should be anticoagulated, although this can be held on the 1:1 setting for brief periods of time should the clinical situation require such a measure. Caution should be taken in patients with severe peripheral arterial disease due to the risk of vascular complications and limb ischemia. Additionally, because afterload is increased during diastole, IABP is contraindicated in patients with more than mild aortic regurgitation. The risk of major complications including major limb ischemia, severe bleeding, balloon leak, and death directly due to insertion or leak has been reported to be 2.6% (Ferguson et al., 2001).

Impella circulatory support system

The Impella family of axial flow catheters (Abiomed, Danvers, MA) includes three devices of varying flow capacities to support the left heart and one for the right heart. These catheter-mounted devices use an axial flow pump containing an Archimedes screw impeller. The left-sided devices are placed in the left ventricle and are inserted in a retrograde fashion across the aortic valve, generating continuous blood flow from the left ventricle to the ascending aorta. Depending on the degree of hemodynamic support needed, there are three sizes to choose from: the Impella 2.5 provides up to 2.5 L/min of flow whereas the Impella CP provides up to 4 L/min of flow. The largest is the Impella 5.0 and can provide up to 5 L/min of flow. The 2.5 and CP devices can generally be inserted percutaneously via the femoral artery with an introducer sheath. The larger Impella 5.0 requires a surgical cut down and is frequently placed through the right axillary artery via a vascular graft, thus allowing the patient to sit up and even ambulate. The Impella is typically guided retrograde into the left ventricle with the use of fluoroscopy in the catheterization laboratory, although transesophageal echocardiography can also be used for positioning. Complications include vascular complications from the peripheral artery insertion, bleeding, ventricular arrhythmias, perforation from the catheter being placed too far into the left ventricle, and increased hemolysis, especially if the device is malpositioned.

The Impella provides hemodynamic support by unloading the left ventricle, with a resultant increase in mean arterial pressure, reduced myocardial oxygen demand, and reduced pulmonary capillary wedge pressure. ISAR-Shock (Efficacy Study of LV Assist Device to Treat Patients With Cardiogenic Shock) was a small randomized clinical trial comparing the Impella 2.5 to IABP in patients presenting with acute myocardial infarction and cardiogenic shock. In this study, the Impella 2.5 led to a greater improvement in cardiac index compared to the IABP (0.49 ± 0.46 L/min/m^2 for Impella 2.5 versus 0.11 ± 0.31 L/min/m^2 for the IABP; $P < .01$) (Seyfarth et al., 2008). In a multicenter, prospective, single-arm feasibility study (RECOVER I) of the Impella 5.0 for postcardiotomy cardiogenic shock, the device improved cardiac index from 1.65 to 2.7 L/min/m^2 $P = .0001$), mean arterial pressure from 71.4 to 83.1 mm Hg ($P = .01$), and decreased pulmonary artery diastolic pressure from 28.0 to 19.8 mmHg ($P < .0001$) (Griffith et al., 2013).

For right-sided support in the context of right ventricular failure, the Impella RP can be used. This pump can be inserted percutaneously via the femoral vein and can provide up to 4 L/min of flow. It is positioned with the inlet in the inferior vena cava and the outlet in the main pulmonary artery. This device can be used alone for right ventricular failure or in conjunction with left-sided support for biventricular failure.

TandemHeart

The TandemHeart device (Cardiac Assist, Inc; Pittsburgh, PA) is an extracorporeal centrifugal flow pump that can be placed percutaneously via the femoral artery and vein. A 21-Fr inflow cannula is inserted via the femoral vein, advanced into the right atrium and then the left atrium via transseptal puncture. Oxygenated blood is pumped by the continuous flow centrifugal pump to the descending aorta, which is inserted via the femoral artery using a 15-Fr to 19-Fr outflow cannula. The device can provide 3.0–5.0 L/min of flow, depending on the size of the arterial cannula, and serves to essentially bypass the left heart. The TandemHeart has been shown to increase cardiac output, unload the left ventricle, and decrease PCWP, central venous pressure, and pulmonary artery pressure, and reduce cardiac workload and oxygen demand (Kar et al., 2011; Burkhoff et al., 2006) In a meta-analysis of controlled trials comparing percutaneous Impella and TandemHeart devices to IABP, the percutaneous LVADs provided superior hemodynamic support, but was not associated with improved early survival (Cheng et al., 2009). Anticoagulation is required to prevent thrombotic complications. Complications include bleeding, pump thrombosis, limb ischemia, stroke, atrial perforation, and creation of atrial septal defects with an associated shunt.

Furthermore, by placing the inflow cannula in the right atrium, instead of the left atrium, and adding a membrane oxygenator to the circuit, the TandemHeart effectively becomes an ECMO circuit providing biventricular support. The TandemHeart can also be useful for right ventricular or biventricular failure. By positioning the inflow cannula in the right atrium and the outflow cannula in the pulmonary artery, inserted via a femoral vein and the right internal jugular vein, the pump bypasses the right heart and can serve as a right ventricular assist device, either as a stand-alone device or in conjunction with an LVAD (Kapur et al., 2013; Prutkin et al., 2008).

Extracorporeal membrane oxygenation

Extracorporeal support comes in two varieties. For patients who primarily require oxygenation support, the system can be set up as a veno-veno system (VV ECMO). VV ECMO requires a relatively normally functioning heart as it does not provide any systemic circulatory support. In this set up, the inflow cannula is placed in the inferior vena cava providing drainage of blood which is carried through a continuous flow pump and a membrane oxygenator for gas exchange. The oxygenated blood is then returned to the right atrium. The two cannulas are inserted via a combination of the two femoral veins and the right internal jugular vein. Alternatively, the Avalon bi-caval dual lumen catheter can be inserted via the right internal jugular vein. The dual-lumen cannula includes an inflow cannula with the tip inserted into the inferior vena cava and the outflow cannula that pumps oxygenated blood via side ports into the right atrium.

Unlike the VV ECMO system, the veno-arterial (VA ECMO) system provides total cardiopulmonary and biventricular support. In VA ECMO, the venous inflow cannula is placed via the femoral vein and/or the right internal jugular vein and advanced into the right atrium. More than one inflow cannula can be placed and Y-connected together if there is inadequate drainage. Cannula sizes range from 15 to 29 Fr. The deoxygenated blood is circulated through the centrifugal pump and a membrane oxygenator and then returned to the abdominal aorta via an arterial outflow cannula (ranging in size from 15 to 23 Fr), which is typically inserted via the femoral artery. Depending on the size of the cannulas, they can be inserted percutaneously or via surgical cut down. Like all other MCS devices, ECMO requires anticoagulation, although short periods without anticoagulation can be tolerated when necessary.

VA ECMO can provide flows of up to 6 L/min depending on the sizes of the inflow and outflow cannulas. VA ECMO is particularly useful in cases of cardiopulmonary failure or biventricular failure. The system effectively decompresses the cardiopulmonary system, reducing both the right and left ventricular volumes. This leads to not only an increase in mean arterial pressure but also an increase in both left ventricular systolic and diastolic pressures. This increase in LVEDP and PCWP has the potential risk of progressive acute lung injury. To alleviate this, LV decompression strategies can be employed, which include percutaneous options such as IABP, Impella, TandemHeart, and atrial septostomy. Surgical options include direct left ventricular apical cannulation and direct left atrial cannulation. Noninvasive options include inotropic support and reducing the VA ECMO flow. Based on a meta-analysis of VA ECMO treatment of cardiogenic shock or cardiac arrest, complications include major bleeding, lower extremity ischemia, compartment syndrome, and stroke (Cheng et al., 2014). Distal limb ischemia can occur, particularly with the use of large arterial cannulas. To minimize this risk, an antegrade sheath can be placed in the distal SFA connected to the arterial cannula to provide improved distal limb perfusion.

Centrally cannulated extracorporeal pumps

Central cannulation of extracorporeal pumps allows for a patient to be mobilized after implantation. These devices can generally also be used for longer periods of time compared to percutaneously placed devices. Additionally, these pumps are more versatile as they can be used for left, right, or bi-ventricular support. In patients who are candidates for heart transplantation, these devices can also be used as a bridge-to-transplantation. When used as an LVAD, the inflow cannula is placed in the left atrium, typically via the right superior pulmonary vein and the outflow cannula in the ascending aorta. The apex of the left ventricle can also be a cannulation site for the inflow cannula. For right ventricular support, the inflow cannula is placed in the right atrium with the

outflow cannula in the main pulmonary artery. The cannulas can be tunneled subcutaneously to exit the upper abdomen and connected to an external pump. With this configuration, the chest can be closed, allowing the patient to be mobilized postoperatively. Some currently available external pumps for this purpose include the CentriMag by Thoratec (formerly Levitronix) and the Thoratec paracorporeal ventricular assist device (PVAD).

Durable Mechanical Circulatory Support

Clinical Considerations

Even after a patient has been determined to have indications for a durable MCS device, careful consideration is required to determine if they are indeed good surgical candidates, what clinical treatment strategy should be employed, which devices should be implanted, and the ideal timing of the surgery.

Generally speaking, durable MCS is indicated in patients with stage D heart failure who have NYHA class III or IV symptoms. These are patients whose heart failure has led to severe circulatory compromise refractory to optimal medical therapy and thus requiring advanced therapy such as continuous inotropic therapy, heart transplantation, or MCS. Criteria for LVAD implantation include LVEF of less than 25%, systolic blood pressure $<$80 mm Hg, cardiac index $<$2.0 L/min/m^2, pulmonary capillary wedge pressure $>$20 mm Hg, and dependency on intra-aortic counterpulsation (Williams and Oz, 2001; Fitzpatrick et al., 2008). The Centers for Medicare and Medicaid Services have also developed an approved list of indications for LVAD support (**Box 1**).

Device strategy

The two primary payer-approved indications for MCS device implantation are as a bridge-to-transplant (BTT) and destination therapy (DT). A patient that is a candidate for heart transplantation but is clinically not stable enough to wait for a suitable donor heart would be implanted with a durable MCS as a BTT. These patients are usually listed as a heart transplant candidate and made inactive at the time of device implantation. They then wait to recover from surgery before being reactivated on the transplant list, typically at least three to six months after surgery. If a patient is not a heart transplant candidate, then they are implanted as DT, whereby the durable device is their definitive treatment. Sometimes patients may not be a candidate for heart transplantation at the time of evaluation but has the potential to become one after a durable device is implanted. These patients can be implanted with the subcategory designation of bridge-to-candidacy (BTC). Examples of BTC include patients who are too obese to be a heart transplant candidate but may become one once they have lost enough weight. Durable device implantation may allow them to exercise or get bariatric surgery to help them lose the weight they need to get off. Another typical example is a patient with elevated pulmonary artery pressures (PA), which may decrease after LVAD implantation, thus making the patient a heart transplant candidate. In rare instances, patients may be implanted with a durable MCS with the expectation or at least hope of recovery and eventual explantation of the device. Unfortunately, true bridge-to-recovery (BTR) implantations are not common due to the nature of end-stage heart failure.

Unfortunately, even when a patient has clear indications for durable MCS support, they may also have contraindications that make them ineligible for surgery. It is important to recognize these contraindications so that patients are not being placed at undue risk. The list of absolute and relative contraindications differs from program to program. However, general principles are universal. Examples of contraindications include major irreversible neurologic deficits, active or recent malignancy with poor prognosis, contraindications to anticoagulation, irreversible end-organ damage, and advanced age. The patient's overall fitness for surgery should be evaluated to ensure that they can tolerate the procedure and the postoperative recovery (**Box 2**).

INTERMACS

The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database collects outcomes on patients implanted with Food and Drug Administration (FDA)-approved durable MCS devices in the United States (Kirklin et al., 2015). Although the National Heart, Lung and Blood Institute (NHLBI) provides the primary funding and oversight of INTERMACS, this registry is a collaboration that includes not only the NHLBI but also the professional heart failure community, industry, and

Box 1 Centers for medicare and medicaid services—Approved indications for LVAD support

DT: FDA approved only for patients with NYHA class IV HF who are not candidates for heart transplant and:

1. Patients who have failed optimal medical therapy for at least 45 of the last 60 days or have been balloon pump dependent for 7 days or intravenous inotrope dependent for 14 days
2. LV ejection fraction less than 25%
3. Peak oxygen consumption of $\leq$14 mL/kg/min or unable to perform test

BTT

1. Use of an FDA-approved device, implanted according to FDA approval criteria, including NYHA class IV HF
2. Listed for transplant at the time of VAD implant

Data from Centers for Medicare & Medicaid Services. Decision memo for ventricular assist devices as destination therapy (CAG-00119 N).

Box 2 Selected contraindications for left ventricular assist device support

- Major irreversible neurologic deficits
- Active malignancy without reasonable intent for cure
- Inability to tolerate anticoagulation
- Active drug use, psychological instability, or noncompliance
- Nonreversible end-organ dysfunction, including end-stage renal disease and hepatic cirrhosis
- Pregnancy
- Advance age (center-dependent thresholds)
- Severe dementia
- Mechanical aortic valve or severe aortic insufficiency without surgical plan to address
- Severe RV dysfunction without options for RVAD support

Data from Feldman et al. (2013).

Table 4 INTERMACS level of limitation at time of implant (Stevenson et al., 2009)

Level	*Description*	*Time to MCS*
1	"Crashing and burning"—critical cardiogenic shock	Within hours
2	"Progressive decline"—inotrope dependence with continuing deterioration	Within a few days
3	"Stable but inotrope dependent"—describes clinical stability on mild-moderate doses of intravenous inotropes (patients stable on temporary circulatory support without inotropes are within this profile)	With a few weeks
4	"Recurrent advanced heart failure"—"recurrent" rather than "refractory" decompensation	Within a few months
5	"Exertion intolerant"—describes patients who are comfortable at rest but are intolerant of exercise	Variable
6	"Exertion limited"—a patient who is able to do some mild activity but fatigue results within a few minutes or any meaningful physical exercise	Variable
7	"Advanced NYHA 3"—describes patients who are clinically stable with a reasonable level of comfortable activity, despite history of previous decompensation that is not recent	Not a candidate for MCS

hospitals (Kirklin et al., 2015). One of their main goals is to use the extensive device and patient database to identify predictors of outcomes and risk factors for complications by stratifying device candidates. Because the timing of LVAD implantation with respect to the severity of the heart failure correlates with postoperative survival, proper patient selection is a critical factor in determining postoperative outcomes. INTERMACS stratifies patients into one of seven profiles or levels that describes the patient's severity and acuity (**Table 4**). Compared to higher levels (i.e., more stable), patients who are at lower levels (i.e., less stable) at the time of device implant have worse outcomes (Kirklin et al., 2015).

Outcomes

The landmark REMATCH (Randomized Evaluation of Congestive Heart Failure) trial was the first to compare survival outcomes of patients implanted with a durable MCS device and medical therapy (Rose et al., 2001; **Table 5**). This study randomized 129 patients with end-stage heart failure who were ineligible for cardiac transplantation to receive a HeartMate XVE (St. Jude Medical-Thoratec, Little Canada, Minnesota) LVAD or optimal medical management. The one year survival was 52% in the device group compared to only 25% in the medical therapy group ($P = .002$). However, the frequency of serious adverse events was 2.35 times higher in the device group compared to the medical-therapy group, with infection, bleeding, and device malfunction being the predominant complications. But despite these adverse events, the device group had a significantly improved quality of life at one year.

With the introduction of second- and third-generation LVADs, there have been great strides in LVAD outcomes since the first-generation XVE LVAD. One year survival has improved from 52% for the first-generation XVE to as high as 86% with third-generation LVADs (Aaronson et al., 2012).

MCS outcomes extend well beyond survival gains (Waqas and Cowger, 2016). LVAD support has demonstrated improvements in 6-minute walk distances, NYHA functional class, quality-of-life measures, and cardiac output (Aaronson et al., 2012; Starling et al., 2011; Rogers et al., 2017; Pagani et al., 2009; Slaughter et al., 2013).

Durable MCS Devices

HeartMate II

Although the first-generation LVADs, such as the XVE, paved the way for future generations of LVADs, these older models are now primarily of historical interest. The second-generation HeartMate II LVAD was FDA approved for BTT in 2008 and for DT in 2010. The device is implanted just below the heart and has a flexible inflow conduit that is attached to the apex of the left ventricle. Its size requires that it be implanted in the upper abdomen anterior to the peritoneum, which necessitates dividing the left diaphragm. The

outflow graft extends from the pump and is anastomosed to the ascending aorta. A percutaneously placed driveline connects the pump to an external controller. The pump itself consists of an axial-flow rotary pump containing a magnet and is driven by the electromotive force generated by the motor. The rotational speed of the pump is determined by the clinician but the actual pump output is pre- and after-load dependent. For a fixed pump speed, the pump flow is inversely related to the pressure gradient across the valve. The HeartMate II is continuous-flow LVAD and therefore patients typically have little to no pulsatility in their arterial waveform. Outcomes with the HeartMate II are significantly improved over the XVE with a 30-day operative mortality of 4% and a one-year Kaplan-Meier survival of 85% (Starling et al., 2011). The HeartMate II also provides significant functional improvements. Compared to a baseline where most patients had NYHA class IV symptoms, over 80% of patients had class I or II symptoms by 6 months, a finding that was sustained at 24 months (Rogers et al., 2010).

Third-generation LVADs

The HeartWare ventricular assist device (HVAD) is a third-generation LVAD and is a continuous flow pump. It was FDA approved for BTT in 2012. The device is small enough to be implanted directly into the left ventricular apex within the pericardial cavity. An outflow graft connects the pump to the ascending aorta. The titanium housing contains an elevated impeller that rotates utilizing magnetic and hydrodynamic forces. The driveline is tunneled subcutaneously and exits the upper abdomen on one side and connects the pump to the external controller. The small size of this pump has also led some surgeons to implant them via bilateral mini-thoracotomies, thus avoiding a sternotomy and making surgery during a subsequent heart transplant potentially easier in BTT patients (Schmitto et al., 2012). The ADVANCE clinical trial implanted 140 HVADs as BTT as an investigational device (Aaronson et al., 2012). Six-month success (survival, transplantation, recovery with LVAD explantation) was comparable between the HVAD and commercially available pumps at 90.7% versus 90.1% ($P < .001$ for noninferiority), respectively. At 6 months, median 6-minute walk distance and quality-of-life scores improved significantly as well. Because of its small size, the HVAD is particularly useful for smaller patients and in patients for whom a minimally invasive approach would be helpful.

The HeartMate III is also a third-generation continuous flow LVAD. It is currently under investigational use for BTT and DT. Similar to the HeartWare HVAD, it is implanted into the apex of the left ventricle within the pericardial cavity. The outflow graft is anastomosed to the ascending aorta and the driveline is tunneled subcutaneously and exits the upper abdomen to an external controller. The device has a magnetically levitated centrifugal pump. An additional feature of this pump is that it can generate pulsatile flow patterns which would theoretically reduce thrombosis formation. The MOMENTUM 3 trial (Multicenter Study of MagLev Technology in Patients Undergoing Mechanical Circulatory Support Therapy with HeartMate 3) compares the HeartMate III to the HeartMate II for advanced heart failure patients as BTT or DT (Mehra et al., 2017). Initial 6-month results are promising with the HeartMate III demonstrating a decrease in the primary end point (composite of survival free of disabling stroke or reoperation to replace or remove the device) of 86.2% compared to 76.8% for the HeartMate II (two-tailed $P = .04$ for superiority). There was no difference in rates of death or disabling stroke but reoperation for pump malfunction was less frequent and there were no pump thrombosis events with the HeartMate III.

Total artificial heart

Patients requiring biventricular MCS require two separate ventricular assist devices or a total artificial heart. Currently, there are no FDA approved durable RVAD devices, although the smaller third-generation LVADs have been used for this purpose (Shehab et al.,

2016). The SynCardia (Syncardia Systems, Inc. Tucson, AZ) total artificial heart (TAH) is the modern version of the CardioWest artificial heart from the 1990s. Unlike LVADs, the TAH provides biventricular support and is orthotopically implanted by replacing the native ventricles. It contains a pneumatically driven diaphragm pump containing valves. Two ventricular cannulas are tunneled subcutaneously and connect to an external drive system. It is available in two sizes, the original 70 cc version and the newer and smaller 50 cc version. The 70 cc temporary TAH (TAH-t) was FDA approved in 2004 for BTT for in-hospital use and is undergoing investigational studies for use as DT. The smaller 50 cc TAH is undergoing investigational studies for BTT use. In addition to the larger hospital driver, the Freedom Portable Driver is available for patients who are discharged home. In a prospective nonrandomized study of the TAH, 79% of the implanted patients survived despite 94% of the patients being INTERMACS level 1 (Copeland, 2014). Similarly matched historical control patients had a 46% survival ($P < .001$). The overall one-year survival was 80% for TAH patients compared to 31% for controls ($P < .001$).

Complications

While there have been significant improvements in patient survival with newer generation LVADs, these devices are unfortunately associated with a significant rate of complications. Freedom from major adverse events at 12 and 36 months is only 30% and 14%, respectively (Kirklin et al., 2013). The most common complication after LVAD implantation is bleeding. In the early postoperative period the reoperation rate for bleeding and the rate of blood transfusions of at least 2 units was 31% and 53%, respectively (Miller et al., 2007). During this early phase, postoperative bleeding may be due to number of factors, including diffuse coagulopathy, hemodilution, or consumption of coagulation factors, and the residual effects of antiplatelet therapies (Despotis et al., 2001). In the later period, bleeding is most commonly associated with the gastrointestinal (GI) tract. In addition to the chronic antiplatelet and anticoagulant therapy, this GI bleeding may also be due to an acquired von Willebrand syndrome secondary to mechanical damage within the pump.

Infection is another significant complication of LVAD therapy. This likely has much to do with the fact that the driveline allows for potential communication of external infectious hazards to the implanted device. The rate of infection is 7.3 events per patient year (EPPY) (Kirklin et al., 2015) and is associated with obesity, diabetes, malnutrition, younger age, and driveline trauma (John et al., 2014; Koval et al., 2014). Driveline infections may initially be treated with antibiotics but may also require surgical debridement. Infection involving the pump itself may require a device exchange, which is associated with increased morbidity and mortality (John et al., 2014).

Strokes are a potentially devastating complication of LVAD therapy, with a freedom from stroke rates of 89% at one year (Kirklin et al., 2013). They can be hemorrhagic or ischemic. Hemorrhagic strokes are likely associated with anticoagulation therapy and if severe enough or recurrent in nature, the anticoagulation goals may need to be reduced or event discontinued. However, this has to be balanced with the risk of thrombosis. Ischemic strokes, on the other hand, are likely related to thromboembolic events associated with pump thrombosis. Strokes are suspected based on clinical findings and confirmed with imagining by head CT and/or MRI, and are treated accordingly with the guidance of neurology. In hemorrhagic strokes, the degree of anticoagulation and antiplatelet therapy has to be weighed against the risk of device thrombosis.

LVADs require anticoagulation to prevent device thrombosis, a complication that had increased in HM II devices at 3 months post-implantation to 8.4% after 2011 compared to 2.2% before this date (Starling et al., 2011). The reason for this is not clear but may be multifactorial and include better recognition and diagnosis of the problem, modifications in anticoagulation intensity, and variable monitoring. The diagnosis of pump thrombosis involves a combination of clinical findings, laboratory assessments, device values, and imaging. Patients may present with symptoms of heart failure and hemoglobinuria. They may also have TIAs or strokes due to emboli from the pump. Pump thrombosis is associated with elevated power consumption with elevations in the power readings. Laboratory findings consistent with hemolysis can be expected and include an elevated lactate dehydrogenase and serum-free hemoglobin, and reduced haptoglobin and hemoglobin (Cowger et al., 2014). Echocardiography may show reduced unloading of the left ventricle by the LVAD that can be quantitatively demonstrated with a ramp protocol whereby the LV dimensions can be plotted against sequential increases in pump speed. A dampened decrease in LV dimensions is suggestive of pump thrombosis (Uriel et al., 2012). Initial management of pump thrombosis includes adequate anticoagulation and renal protection with IV fluids and sodium bicarbonate infusion. More aggressive measures include the use direct thrombin inhibitors or thrombolytics. If all this fails, the patient may require a surgical pump exchange.

Right ventricular (RV) failure is the Achilles heel of LVADs and is associated with poorer outcomes (Baumwol et al., 2011). Proper functioning of the LVAD requires adequate functioning of the right ventricle. RV failure can occur acutely in the OR at the time of implant, in the perioperative period, or even months after implantation. However, in a patient with known RV dysfunction, RV failure in the early perioperative period is of greatest concern. The published rates of acute RV failure ranges from 15% to 35% (Slaughter et al., 2009; Aaronson et al., 2012; Slaughter et al., 2013; Matthews et al., 2008). Careful preoperative assessment of RV function is critical and is primarily based on echocardiography and right heart catheterization. Aggressive volume management with diuretics and the use of pulmonary vasodilators and inotropes may be necessary to support the RV both preoperatively and postoperatively. If a patient has acute RV failure post-LVAD implantation, he/she may require temporary right-sided support with MCS. Off-label use of durable third generation LVADs has been reported for special circumstances (Shehab et al., 2016). Several risk scores have been published to assess the risk of RV failure after LVAD implantation. In a patient with significant biventricular failure at high risk of RV failure requiring MCS, a total artificial heart should be considered (Kasirajan et al., 2012).

Overview

Lesions causing left ventricular outflow obstruction typically result in acyanosis and adequate pulmonary blood flow. Characteristic lesions include aortic valve stenosis, coarctation of the aorta, and interrupted aortic arch. In the most extreme form of left-sided obstruction, hypoplastic left heart syndrome, cyanosis will occur resultant from intracardiac mixing at the atrial level.

Left-sided obstructive lesions result in a clinical presentation that correlates with the severity of obstruction. Those with significant obstruction may have an audible cardiac murmur, symptoms of congestive heart failure, and electrocardiographic changes consistent with myocardial hypertrophy or ischemia. This chapter focuses on the prevalence, physiology, clinical findings, and management of left-sided obstructive lesions including hypoplastic left heart syndrome.

Aortic Stenosis

There are three general classifications of aortic stenosis: below the level of the aortic valve (subvalvar or subaortic stenosis), at the level of the aortic valve (valvar aortic stenosis), and above the aortic valve (supravalvar aortic stenosis) (**Fig. 1**) (Park, 2014).

Valvar Aortic Stenosis

Definition and Prevalence

Obstruction to left ventricular outflow due to an abnormal aortic valve is termed valvar aortic stenosis (**Fig. 1B**) (Park, 2014). The reported incidence ranges from 0.16 to 0.38 per 1000 live births (Hoffman and Kaplan, 2002). A normal aortic valve has three

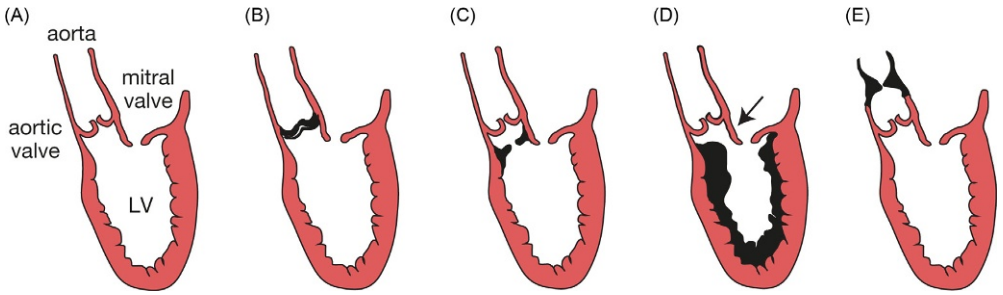

Fig. 1 Aortic stenosis subtypes. (A) Normal structure of left ventricle (LV) leading to the aorta, with the mitral valve and aortic valve indicated. (B) Valvar stenosis. (C) Discrete membranous subaortic stenosis. (D) Hypertrophic subaortic stenosis (*arrow indicates the anterior leaflet of the mitral valve*). (E) Supravalvar stenosis. Adapted from Park, M. K. (2014) Park's pediatric cardiology for practitioners (6th edn.). St. Louis: Mosby.

cusps or leaflets (termed tricuspid or trileaflet) and three commissures (termed tricommissural). As opposed to elderly patients, where stenosis is often due to a calcified and immobile trileaflet valve, young patients usually have a congenitally malformed, but noncalcified valve. Due to the abnormal valve development, the aortic valve can be unicuspid, bicuspid, tricuspid, or quadricuspid.

Physiology

Any obstruction to outflow results in an increased afterload on the left ventricle. This means the ventricle must generate an increase in pressure during systole proportional to the degree of obstruction to provide the required cardiac output. The effect the increased afterload has on the heart not only depends on the severity of the obstruction but also the timing of the stenosis. During fetal life, severe aortic valve stenosis will result in dilation and decreased contractility of the left ventricle followed by development of endocardial fibroelastosis. As the fetus matures to term, the growth of the left heart is below normal, and the fetus may develop hypoplastic left heart syndrome.

After birth upon closure of the ductus arteriosus, the left ventricle needs to support the entire systemic arterial circulation. If the degree of aortic valve stenosis is severe enough to result in the left heart being unable to support the systemic circulation, due to ventricular dysfunction and/or inadequate growth of the left heart, then the infant will develop cardiovascular collapse. In these circumstances when the systemic circulation is dependent on a patent ductus arteriosus, it is termed "critical" aortic stenosis. In keeping the ductus arteriosus patent, the right ventricle can support the systemic circulation.

Clinical Manifestations

If the degree of obstruction is not severe enough to interfere with the ability of the left ventricle to provide adequate systemic perfusion, a child may remain asymptomatic with normal growth and development. A heart murmur may be appreciated incidentally during a routine physical examination. Less commonly, a child with valvar aortic stenosis reports chest pain and exercise intolerance. A history of syncope in a child with aortic stenosis is a sign of clinically significant disease and is considered a high risk of sudden death.

The physical exam of a child may reveal weaker than normal peripheral pulses, a decreased pulse pressure, and a systolic thrill in the suprasternal notch. On auscultation, a systolic ejection click may precede the systolic ejection murmur. The heart murmur is normally loudest at the upper right sternal border with potential radiation to the neck. There is a delay in the timing of the aortic component of the second heart sound, since the duration of ventricular systole is in the direct proportion to the degree of stenosis, resulting in a narrowly split second heart sound. If the degree of stenosis is severe enough, the closure of the aortic valve may occur after the pulmonary valve, which is termed "reverse splitting."

Evaluation

Chest X-ray

A chest X-ray may reveal a prominent ascending aorta due to poststenotic dilation.

Electrocardiogram

Oftentimes, an electrocardiogram is normal in mild aortic valve stenosis. However, if the degree of obstruction is severe, changes such as left ventricular hypertrophy, T-wave changes, and/or ventricular ectopy may be present. In patients who remain asymptomatic with concerning findings or in those who want to participate in athletics, a stress test can be helpful. Significant obstruction can produce ST-segment and T-wave abnormalities during times of exercise.

Echocardiogram

The primary tool used to diagnose aortic valve stenosis is echocardiography. This imagining modality provides a detailed noninvasive assessment of the cardiac anatomy. The primary goals of the echocardiographic assessment include determining the severity of valve stenosis using Doppler interrogation; determining the morphology of the aortic valve; evaluating all left heart structures (determine if there are associated anomalies); and obtaining systemic ventricular dimensions, wall thickness, and function (Lai et al., 2015). The severity of valve stenosis is estimated by measuring the Doppler-derived maximum instantaneous and mean pressure decrease across the aortic valve. It is important to remember that these measurements are only valid if systemic ventricular function and cardiac output are normal.

Current guidelines define mild aortic valve stenosis as a peak velocity of 2.0–2.9 m/s or a mean pressure gradient of $<$20 mmHg. Moderate stenosis is defined as a peak velocity of 3.0–3.9 m/s or a mean pressure gradient of 20–39 mmHg. Severe stenosis is defined as a peak velocity of $>$4 m/s or a mean pressure gradient of $\geq$40 mmHg. In patients with decreased cardiac output, significant aortic stenosis can be present with lower peak flow velocities and pressure gradients. In these instances, an aortic valve area should be calculated to determine severity of stenosis (Feltes et al., 2011; Nishimura et al., 2014). An effective valve orifice of >1.4 cm^2 is considered mild aortic valve stenosis, 1.0–1.4 cm^2 is considered moderate aortic valve stenosis, and <1.0 cm^2 is considered severe aortic valve stenosis.

Cardiac catheterization

As the ability to accurately evaluate the severity of aortic valve stenosis using noninvasive diagnostic methods has improved greatly, the role of cardiac catheterization has become primarily one of therapeutic intervention.

Management

Valvar aortic stenosis is a difficult disease entity to treat, with repeated interventions often required, and necessitates lifelong follow-up as it is often progressive. Not counting infants in heart failure and/or those with "critical aortic valve stenosis," current recommendations for intervention are based on the published natural history studies (Keane et al., 1993). In many pediatric institutions, if the degree of aortic insufficiency is not significant, balloon valvotomy has become the initial intervention of choice. Current class I indications for aortic valvuloplasty include in a newborn with critical aortic stenosis or a child with depressed left ventricular systolic function regardless of valve gradient; children with a resting peak to peak systolic valve gradient of $\geq$50 mmHg; children with a resting peak systolic valve gradient of $\geq$40 mmHg if there are symptoms of angina, syncope, or ischemic ST-T wave changes at rest or with exercise. Although balloon valvuloplasty is considered an effective intervention, it is palliative and one must always be cautious about creating significant aortic valve regurgitation (Baim and Grossman, 2006; Warnes et al., 2008).

For infants with "critical" aortic stenosis, the main aspect of management is to ensure ductal patency as to allow for systemic and cerebral perfusion. Balloon aortic valvuloplasty is the primary method of treatment. Care is taken to avoid creating significant aortic valve insufficiency and/or injury to the mitral valve (Baim and Grossman, 2006).

Although not commonly performed for valvar aortic stenosis in children, surgical options include valvotomy and valve replacement. Valve replacement may consist of either a mechanical or bioprosthetic valve or with a pulmonary autograft (known as the Ross procedure) (Jonas, 2014).

Subvalvar Aortic Stenosis

Definition and Prevalence

Obstruction to left ventricular outflow from below the aortic valve is termed subaortic stenosis. The incidence of subvalvar aortic stenosis is 0.09 per 1000 live births and can occur either in isolation or in association with a multitude of other congenital heart defects (Kitchiner et al., 1994). These include but are not limited to ventricular septal defects (VSD), atrioventricular septal defect (AVSD), aortic valve stenosis, coarctation of the aorta, interrupted aortic arch (IAA), and double-chambered right ventricle.

There is variation in the morphologic types of subaortic obstruction. The most common type is due to a discrete, thin ridge, or membrane located beneath the aortic valve, known as discrete membranous subaortic stenosis (**Fig. 1C**) (Park, 2014). Due to the abnormal flow of blood through the obstruction, the aortic valve may be deformed, resulting in aortic valve insufficiency. It is important to remember that the abnormal obstructive tissue may not only involve the ventricular septum but can extend onto the anterior leaflet of the mitral valve. Although this type of obstruction is rare in neonates, significant progression is often noted in childhood.

Hypertrophic subaortic stenosis results from hypertrophy of the interventricular septum causing muscular obstruction of the ventricular outflow tract. This form of subaortic stenosis can often result in systolic anterior motion of the mitral valve (**Fig. 1D**) (Park, 2014).

Tunnel-type subaortic obstruction is characterized by a long-segment narrowing of the left ventricular outflow tract due to muscle. This type of stenosis often occurs early in life and is frequently associated with other left-sided obstructive lesions.

Subaortic obstruction is also seen in other congenital cardiac lesions such as interrupted aortic arch, which is often associated with posterior deviation of the infundibular septum, or complete atrioventricular septal defect, which may have accessory endocardial cushion tissue obstruct the left ventricular outflow tract.

Physiology

Although the development of subaortic stenosis is believed to be secondary to abnormal flow across the left ventricular outflow tract resulting in abnormal growth of tissue (either fibrous or muscular), the physiologic consequences may be like that of aortic valve stenosis as there is increased afterload on the left ventricle. Due to the obstruction, there is a compensatory ventricular hypertrophy to reduce the wall stress. Ventricular function is usually maintained; however, it can worsen overtime if the obstruction is not alleviated. Not only can the abnormal jet of flow across the subaortic region interfere with proper motion of the aortic valve, the fibrous tissue may extend onto the aortic valve leaflets and result in impaired functionality.

Clinical Manifestations

The physical exam of a child with subaortic stenosis will produce a crescendo–decrescendo systolic ejection murmur usually appreciated best at the left mid sternal border. There may be an additional blowing early diastolic murmur if significant aortic regurgitation is present. In severe cases, the peripheral pulses may be weak and delayed, and the left ventricular impulse is displaced and sustained.

Evaluation

Chest X-ray

Chest X-ray is often not diagnostic. If there is significant aortic regurgitation, cardiomegaly may be appreciated due to left ventricular dilation.

Electrocardiogram

Like aortic valve stenosis, an electrocardiogram may be normal in mild subvalvar stenosis. However, if the degree of obstruction is severe, changes such as left ventricular hypertrophy, T-wave changes, and/or ventricular ectopy may be present.

Echocardiogram

The primary tool used for diagnosis and assessment of disease severity is echocardiography. The primary goals of the echocardiographic examination include assessment of the severity of left ventricular outflow tract obstruction, determine the morphology of the outflow tract and the type of obstruction, and identify any associated anomalies. It is important to note that the severity of subaortic obstruction may be underestimated in cases of depressed left ventricular function or if there is a large, nonrestrictive ventricular septal defect (Lai et al., 2015).

Cardiac catheterization

Although cardiac catheterization will provide an accurate measurement of the systolic peak-to-peak gradient across the left ventricular outflow tract, this diagnostic tool is not used as much as echocardiography, which has become a reliable imaging modality and is noninvasive.

Management

As opposed to valvar aortic stenosis, subvalvar obstruction does not respond to balloon angioplasty. Therefore, surgical resection of the subvalvar membrane or fibrous ridge, or myectomy in patients with muscular or tunnel-like obstruction, is performed. However, due to the high rate of recurrence, the timing of surgical intervention can be controversial, particularly in the first decade of life. Subvalvar aortic obstruction tends to be progressive in most, and there is a risk of developing of aortic regurgitation (particularly if the mean echocardiographic Doppler gradient is >30 mmHg). Most recommend deferring surgery if the degree of obstruction is moderate or less (mean Doppler gradient <30 mmHg or peak instantaneous systolic gradient <50 mmHg) and there is no more than trivial aortic valve insufficiency. Consideration for surgery may be considered in those with lesser degree of obstruction if there is concomitant left ventricular dysfunction and/or significant aortic valve regurgitation. If a patient desires to become pregnant or participate in athletic activity, surgical intervention is considered in the setting of less significant obstruction. Although prevention of aortic valve insufficiency alone is not a criterion for surgical intervention, the development and progression of significant aortic valve insufficiency is commonly used as criteria for surgery (Warnes et al., 2008).

Supravalvar Aortic Stenosis

Definition and Prevalence

Obstruction to left ventricular outflow from above the aortic valve is termed supravalvar aortic stenosis (**Fig. 1E**) (Park). The incidence of supravalvar aortic stenosis is 0.05 per 1000 live births and can be associated with an abnormal aortic valve, coronary artery stenosis, coarctation of the aorta, and pulmonary artery stenosis (Kitchiner et al., 1994). It is commonly seen as a feature of Williams syndrome. Additionally, mutations in the ELN gene, which leads to a decrease in production of tropoelastin, are often seen in patients with supravalvar aortic stenosis (Health and Medicine).

Supravalvar aortic stenosis usually occurs at the sinotubular junction and is visualized as a discrete narrowing of the vessel lumen due to thickening of the aortic media. There is frequently prestenotic dilation of the sinuses of Valsalva, tethering of the aortic valve leaflets, and stenosis of the coronary ostia. There may be complete occlusion of the coronary ostia if a leaflet of the aortic valve adheres to the obstructing ridge of tissue. Additionally, there may be hypoplasia of downstream vascular structures such as the ascending aorta, aortic arch, and head and neck vessels.

Physiology

In general, the physiology is like that of valvar aortic stenosis as there is a hypertrophied left ventricle in the setting of significant stenosis. However, it is important to remember that due to the location of the narrowing above the aortic root, there is elevated systolic pressure proximal to the site of obstruction, which is believed to play a role in the development of coronary ostial stenosis. Therefore, as the demand from a hypertrophied ventricle increases, an inadequate degree of myocardial perfusion may result, particularly during periods of increased myocardial oxygen demand.

Clinical Manifestations

The physical exam will often reveal a basilar crescendo–decrescendo systolic ejection murmur with radiation to the suprasternal notch and may be associated with a thrill. There may be preferential flow into the right brachiocephalic artery, which results in a blood pressure and strength of pulse differential between the right and left upper extremities (known as the Coanda effect) (Lai et al., 2015; Eidem et al., 2015). A dynamic apical impulse may be present and there can be paradoxical splitting of the second heart sound. Additionally, these patients tend to display poor growth, exercise intolerance, and potentially angina with effort and/or syncope.

Evaluation

Chest X-ray

The chest X-ray is often normal, however left ventricular hypertrophy or a prominent aortic knob may be present.

Electrocardiogram

If the stenosis is significant, left ventricular hypertrophy and/or ischemic changes may be present.

Echocardiogram

The diagnosis of supravalvar aortic stenosis is usually confirmed by echocardiography. The aims of the echocardiogram include assessment of the aortic root, sinotubular junction, and aortic valve morphology, Doppler evaluation of the severity of stenosis, anatomic assessment of the aortic arch (including head and neck vessels), and functional assessment of the left ventricle. Magnetic resonance imaging with angiography can also be used and provides detail of the supravalvar obstruction and aortic arch anatomy (Lai et al., 2015; Eidem et al., 2015).

Cardiac catheterization

Cardiac catheterization may be performed, particularly if additional disease is suspected such as branch pulmonary artery stenosis. If there is severe bilateral outflow obstruction, catheterization is extremely high risk. As there is often coronary ostial stenosis, selective coronary angiography is high risk.

Management

Therapy for supravalvar aortic stenosis consists of surgical repair of the obstruction, regardless if it is discrete versus long-segment narrowing. The lesion does not reliably respond to balloon angioplasty, and stent placement has mixed results and is considered an inferior therapy. Current recommendations support operative repair for patients with a mean Doppler gradient or systolic peak-to-peak gradient ≥ 50 mmHg. Surgical repair is also recommended in those who have a lower gradient and are symptomatic, have left ventricular hypertrophy or systolic dysfunction, or who desire to become pregnant or engage in athletic activity (Warnes et al., 2008).

Current Topics in Aortic Stenosis

Understanding the development heart valve disease is an interesting area of research. Recently, efforts have been directed at the use of novel mass spectrometry techniques to evaluate lipid biology in heart valve tissues (Angel et al., 2016). Interventional research has focused on understanding the long-term outcomes of aortic valvuloplasty in pediatric patients with aortic stenosis (Awasthy et al., 2016). Others have focused on novel methods of monitoring and risk stratification of patients with aortic stenosis (Domanski et al., 2017).

Coarctation of the Aorta

Definition and Prevalence

Coarctation of the aorta is defined as a narrowing of the aorta, most typically in the descending aorta at the insertion point of the ductus arteriosus (referred to as juxtaductal, **Fig. 2**) (Townsend et al., 2016). It has been estimated to account for 4%–6% of all congenital heart disease (4 per 10,000 live births) (Reller et al., 2008; Hoffman and Kaplan, 2002). Coarctation of the aorta is associated with Turner syndrome and will occur in 5%–15% of girls with this syndrome (Eckhauser et al., 2015; Wong et al., 2014).

Physiology

In utero, coarctation has limited hemodynamic consequence as 60% of the cardiac output is via the ductus arteriosus. During transition, obstruction becomes increasingly problematic as the ductus closes from the pulmonary artery toward the aorta after birth (Rudolph, 2009; Johnson and Moller, 2014; Moller and Neal, 1981). Progression of obstruction to left ventricular outflow leads to increased pressure (afterload) in the left ventricle and ascending aorta. This stress on the left ventricle results in increased myocardial

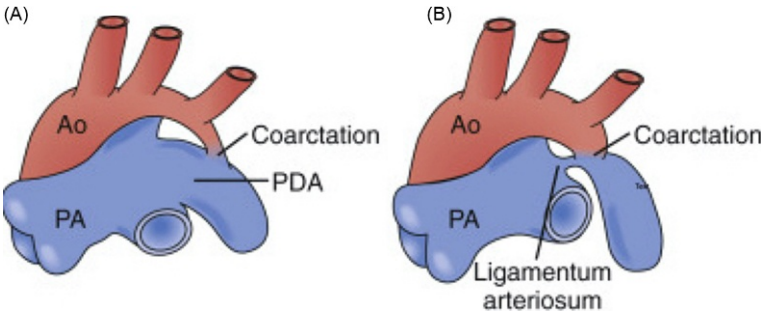

Fig. 2 Coarctation of the aorta (Ao). (A) Preductal aoarctation. (B) Juxtaductal coarctation. *PA*, Pulmonary artery; *PDA*, patent ductus arteriosus. Reprinted with permission from Townsend, C. M., Beauchamp, R. D., Evers, B. M. and Mattox, K. L. (2016). Sabiston textbook of surgery: The biological basis of modern surgical practice (20th edn.). Philadelphia, PA: Elsevier.

oxygen consumption as well as compensatory hypertrophy. In cases of severe obstruction in a neonate, compensatory hypertrophy may be inadequate. This, coupled with the inability of the neonate to augment myocardial contractility, can result in left ventricular failure (Johnson and Moller, 2014; Moller and Neal, 1981).

Coarctation of the aorta may also result in the formation of collateral vessels. In the setting of a pressure gradient across the aorta, blood vessels may enlarge and result in communications with the descending aorta as a means of bypassing the obstruction. Such collateral blood vessels aid in compensation and may mask the development of symptoms even in the setting of a significant coarctation (Moller and Neal, 1981).

Clinical Manifestations

Symptoms are directly related to the degree of obstruction and typically develop as the ductus arteriosus closes in the first several days of life. A majority will remain asymptomatic in childhood. However, 10% of patients will present in infancy with signs of failure (Moller and Neal, 1981; Johnson and Moller, 2014). Those with severe obstruction will have poor perfusion. Others may gradually develop symptoms of heart failure.

Physical exam findings also vary with the degree of obstruction. In the absence of cardiogenic shock, a blood pressure gradient may be noted with lower systolic pressure measured in the lower extremities when compared with the upper extremities. A systolic murmur may be audible; however, in infants with cardiogenic shock this may be absent.

A patient may elude diagnosis until presentation for other findings such as hypertension. If the hypertension is severe, there may be report of headaches and/or epistaxis, and the individual may be at risk for heart failure and dissection of the aorta.

Evaluation

Chest X-Ray

The chest X-ray findings correlate with the severity of obstruction. In asymptomatic children and young adults, the only findings may be rib notching and indentation of the aorta resulting in a "3" sign. In infants with severe obstruction and congestive heart failure, the chest X-ray will reveal cardiomegaly and pulmonary venous congestion (Park, 1996).

Electrocardiogram

The electrocardiogram will also vary with the severity of obstruction. The EKG may be normal. A rightward QRS axis or right bundle branch block may be present in symptomatic infants. Older children with coarctation may have evidence of left ventricular hypertrophy (Park, 1996).

Echocardiography

Echocardiography is the diagnostic test of choice for evaluation of coarctation given its noninvasive nature, ability to quantify obstruction, detect additional lesions, and provide follow-up after repair. In addition to identifying coarctation, echocardiography can be used to describe additional intracardiac findings that suggest arch obstruction including left ventricular obstruction, right or left ventricular hypertrophy, or ventricular dysfunction. Doppler evaluation will demonstrate flow acceleration proximal to the coarctation. With the addition of color Doppler, a turbulent flow pattern around the area of narrowing will be evident. Doppler evaluation can also be used to demonstrate an abnormal flow pattern in the descending aorta. Following arch repair, the echocardiogram can be used to monitor and quantify the presence and degree of residual obstruction (Eidem et al., 2015).

Cardiac catheterization

The use of cardiac catheterization is largely interventional as noninterventional methods of diagnosis, such as echocardiography, are quite accurate. Cardiac catheterization may be used for stent placement, balloon dilation of residual coarctation following repair, or evaluation of additional cardiac defects such as coronary abnormalities. The use of catheter-based interventions varies widely among institutions.

Management

Medical management

Infants with coarctation of the aorta and severe obstruction require medical management prior to surgical intervention. The goals of medical management are to maintain patency of the ductus arteriosus to ensure systemic cardiac output, support ventricular function, and address additional consequences of cardiac failure such as metabolic acidosis. Ductal patency is achieved with infusion of prostaglandin E1. Patients on prostaglandin infusion need to be monitored for the development of apnea and fever as the most common side effects. Support of ventricular function can be achieved with inotropes when necessary (Moller and Neal, 1981).

If an older child presents with hypertension and is discovered to have a coarctation, the hypertension should be controlled by medical therapy. Current recommendations advocate for intervention when the peak-to-peak gradient is $\geq$20 mmHg or in the presence of a significant coarctation with evidence of substantial collateral flow (Feltes et al., 2011).

Surgical intervention

Surgery remains the mainstay of intervention for coarctation of the aorta in infants and children. Societal guidelines recommend that surgical repair be performed as early as possible to avoid long-term complications (Warnes et al., 2008; Feltes et al., 2011; Silversides et al., 2010). Surgical approach varies widely from institution to institution. Options for surgical repair include resection with end-to-end anastomosis, subclavian flap aortoplasty, bypass graft placement across an area of coarctation, and prosthetic patch aortoplasty. Overall, the mortality for surgical repair is low (Warnes et al., 2008; Burch et al., 2009; Mery et al., 2015).

Percutaneous alternatives to surgery in older children and adolescents include balloon angioplasty or stent placement. Balloon angioplasty is the treatment of choice in patients, regardless of age, with recoarctation.

Current topics in coarctation of the aorta

At present, coarctation of the aorta remains the most common ductal-dependent lesion missed on neonatal screening. As such, ongoing research is being done to identify methods and tools to improving fetal diagnosis of the disease (Beattie et al., 2016). Additionally, methods of improving aortic arch dimensions in utero are ongoing (Zeng et al., 2016).

Interrupted Aortic Arch

Definition and Prevalence

Interrupted aortic arch (IAA) represents a rare, extreme form of coarctation of the aorta in which the aortic arch is atretic or absent (**Fig. 3**) (Eidem et al., 2015; Townsend et al., 2016). There are three types of IAA categorized by the location of the defect (Celoria and Patton, 1959):

1. Type A: interruption of the aorta occurs distal to the left subclavian artery (40%).
2. Type B: interruption of the aorta occurs between the left common carotid and the left subclavian artery (most common, >50%).
3. Type C: interruption of the aorta occurs proximal to the origin of the left common carotid artery (rare).

Interrupted aortic arch often occurs in association with other congenital heart defects such as patent ductus arteriosus (PDA), bicuspid aortic valve, atrial septal defect (ASD), ventricular septal defect (VSD), transposition of the great vessels, and truncus arteriosus. In almost every patient, a VSD and PDA are present (Moller and Neal, 1981; Johnson and Moller, 2014). DiGeorge syndrome is a commonly associated syndrome (Health and Medicine).

Physiology

The physiology of interrupted aortic arch is like that of coarctation of the aorta with a VSD. Left ventricular output is directed across the aortic valve, into the ascending aorta, and through the head and neck vessels. Additionally, left to right shunting occurs at the level of the VSD. Right ventricular output is directed across the pulmonary valve with a portion crossing the PDA and into the descending aorta.

Left to right shunting through the VSD is influenced by the pulmonary vascular resistance (PVR) and the degree of subaortic stenosis. As the PVR falls after birth, an increasing amount of blood flows through the VSD and into the pulmonary circulation. Subaortic stenosis results in increased resistance to left ventricular output and augments left to right shunting through the VSD. Finally, as the patent ductus arteriosus narrows, blood flow to the pulmonary bed is increased. It should be noted that, in the setting of an unrestrictive VSD, the pulmonary artery pressure and ascending aorta pressure will be equal.

Clinical Manifestations

The presentation of IAA is like that of other left-sided obstructive lesions. Many patients will develop symptoms of congestive heart failure in the first several weeks of life due to pulmonary overcirculation. If the ductus arteriosus constricts, there will be inadequate systemic perfusion and shock will ensue.

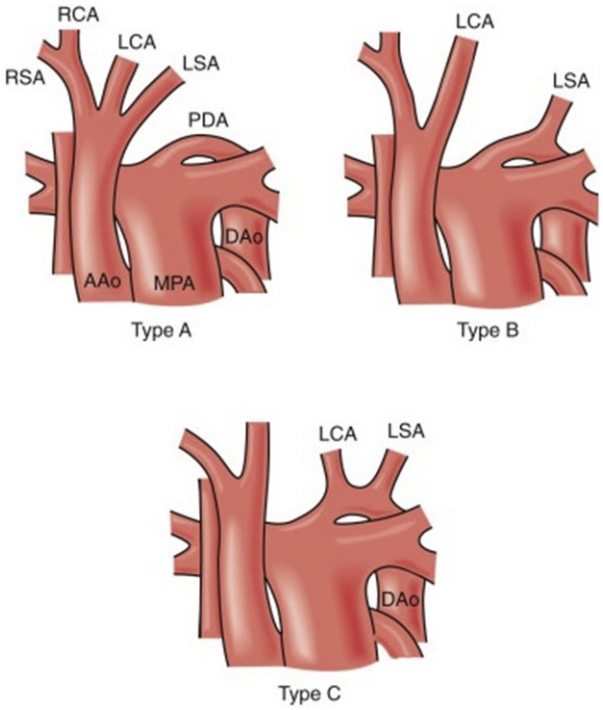

Fig. 3 Classification of interrupted aortic arch. *AAo*, Ascending aorta; *Dao*, descending aorta; *LCA*, left common carotid artery; *LSA*, left subclavian artery; *MPA*, main pulmonary artery; *RCA*, right common carotid artery; *RSA*, right subclavian artery. Reprinted with permission from Townsend, C. M., Beauchamp, R. D., Evers, B. M. and Mattox, K. L. (2016). Sabiston textbook of surgery: The biological basis of modern surgical practice (20th edn.). Philadelphia, PA: Elsevier.

The physical exam may reveal a blood pressure gradient from upper to lower extremities suggestive of progressive ductal closure. Differential cyanosis may be absent as a large VSD results in a large left to right shunt. In the case of Type B interrupted aortic arch with an anomalous right subclavian artery, all limb pulses may be absent. A strong carotid pulse may help differential IAA from aortic stenosis (Johnson and Moller, 2014; Moller and Neal, 1981).

Evaluation

Chest X-ray

The chest X-ray will reveal cardiomegaly, pulmonary vascular congestion, and pulmonary edema. In the case of DiGeorge Syndrome, an absent thymus results in a narrow mediastinum.

Electrocardiogram

The electrocardiogram demonstrates a normal to rightward axis. Right atrial and ventricular enlargement may be evident. Left ventricular hypertrophy may be evident in the setting of subaortic stenosis.

Echocardiogram

As with coarctation of the aorta, the goals of echocardiography include delineation of anatomy, quantification of cardiovascular function, operative planning, and postoperative follow-up. In the presence of a patent ductus arteriosus, the color Doppler pattern in the descending aorta may be normal with normal pulsatility by spectral Doppler. Following surgical repair, the echocardiogram can be used to identify and quantify the degree of residual obstruction (Eidem et al., 2015).

Cardiac catheterization

There currently are no percutaneous-based interventions that are indicated in an infant with IAA prior to surgical repair. If there is a postoperative narrowing of the repaired aortic arch, balloon angioplasty is often beneficial.

Management

Medical management

As with coarctation of the aorta, initial management focuses on maintaining/establishing ductal patency, ensuring adequate fluid resuscitation, and correcting metabolic derangements such as acidosis. This lesion is not compatible with life unless the ductus arteriosus is patent. Ductal patency is achieved with infusion of prostaglandin E1. Inotropes may be necessary for support of

ventricular function. To ensure adequate perfusion to the lower half of the body, strategies to increase the pulmonary vascular resistance are often employed (see HLHS section).

Surgical intervention

A variety of surgical interventions have been proposed for repair. As with coarctation of the aorta, the surgical approach will vary by institution. In general, the goals of surgical repair center on relieving left ventricular outflow obstruction, providing aortic continuity, and removing pulmonary over circulation (Jonas, 2014).

Current Topics in Interrupted Aortic Arch

Novel techniques for surgical intervention of IAA are continually evaluated (Wu et al., 2017; Kato et al., 2016). As with coarctation of the aorta, fetal detection can be challenging and ongoing efforts are being made to improve the tools and strategies for detection on IAA in the fetus (Axt-Fliedner et al., 2011).

Hypoplastic Left Heart Syndrome

Definition and Prevalence

Hypoplastic left heart syndrome (HLHS) is applied to underdeveloped mitral and/or aortic valves resulting in an inadequate left ventricle that is unable to support systemic circulation. The three major anatomic types of HLHS include mitral and aortic stenosis, mitral stenosis and aortic atresia, and mitral and aortic atresia (**Fig. 4**) (Davis et al., 2011). The aortic and mitral valves may be hypoplastic, atretic, or severely stenotic. Although the ascending aorta is also hypoplastic, it remains sufficient to supply coronary arterial blood flow. Oftentimes, the coronary arterial and brachiocephalic vessel flow is supplied in retrograde fashion via a patent ductus arteriosus (which is essential to survival). The incidence of HLHS is 266 per 1 million live births (Hoffman and Kaplan, 2002).

Physiology

Survival after birth is predicated on the ductus arteriosus remaining patent, meaning the right ventricle supplies both the pulmonary and systemic circulations. Even in cases with prograde aortic flow, it is insufficient to meet the demands of the systemic circulation. Therefore, the ratio of pulmonary to systemic blood flow is determined by the relative resistances of each vascular bed. There is a direct relationship between the volume of pulmonary blood flow and the systemic saturation. Meaning the more the pulmonary blood flow, the higher the systemic saturation, as the volume of oxygenated blood returning from the lungs is greater compared to the volume of deoxygenated systemic venous return from the body.

Immediately after birth, the ductus arteriosus is widely patent and does not restrict systemic blood flow. Although the aortic arch may be hypoplastic, if there is no constriction of the ductus, the aortic arch should be adequate to ensure proper coronary and

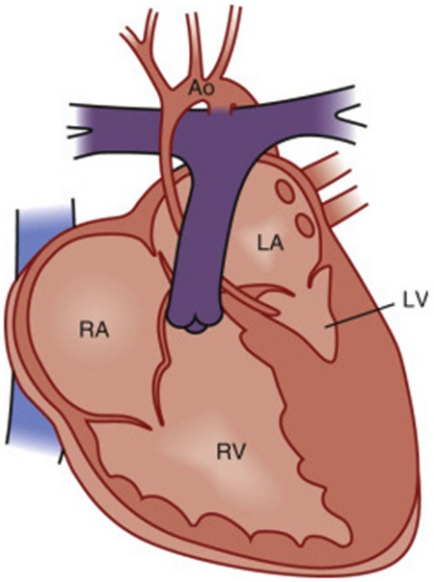

Fig. 4 Hypoplastic Left Heart Syndrome Reprinted with permission from Davis, P. J., Cladis, F. P. and Motoyama, E. K. (2011). Smith's anesthesia for infants and children (8th edn.). Philadelphia: Mosby

cerebral perfusion. Normally the descending aorta is of appropriate caliber, allowing for adequate systemic perfusion. Importantly, during the newborn period there is a normal elevation in pulmonary vascular resistance which naturally limits the quantity of pulmonary blood flow, often limiting pulmonary overcirculation.

Infants with HLHS become critically ill because of normal physiologic changes: closure of the ductus arteriosus and a decrease in the pulmonary vascular resistance. As the ductus becomes restrictive, the balance of blood flow favors the pulmonary vascular bed as the systemic vascular resistance increases. This occurs alongside the physiologic decrease in pulmonary resistance. Both changes decrease systemic output significantly leading to weak peripheral pulses, tachypnea, lethargy, metabolic acidosis, and cardiogenic shock. These profound changes occur in the setting of increased systemic oxygen saturation since there is an increase in pulmonary blood flow.

The physiologic changes on the right (systemic) ventricle are significant. As the ductus closes there is an increase in afterload, which results in a pressure load on the ventricle. The resultant increase in pulmonary blood flow results in a volume load on the ventricle as well. As the systemic output decreases, the coronary perfusion falls, resulting in decreased oxygen delivery to the organ at a time when metabolic demand increases. These changes lead to right ventricular dysfunction and dilation, which leads to worsening atrioventricular valve insufficiency, which further increases the volume load. Clinically these patients may present in respiratory distress (due to pulmonary overcirculation and elevated pulmonary venous/left atrial pressure), cardiogenic shock, metabolic acidosis, and end-organ failure (due to inadequate systemic output).

Inadequate systemic perfusion can develop in the setting of a widely patent and unobstructed ductus arteriosus. The right ventricle is volume loaded as it is pumping a more than normal volume of blood to adequately perfuse the systemic vascular bed. As mentioned previously, the relative flows to the pulmonary and systemic circuits are determined by the relative resistances. As the pulmonary vascular resistance decreases, the decrease in systemic blood flow is due to the right ventricle's inability to meet the metabolic demand of the systemic circuit as the pulmonary circuit becomes overcirculated. The increase in pulmonary blood flow results in a volume load to the left atrium and if there is obstruction to atrial egress (such as a restrictive atrial septal communication) then pulmonary venous hypertension develops. In response to the volume load, the right ventricle becomes dilated and the ventricular end-diastolic pressure increases. As the ventricular dilation worsens, tricuspid valve insufficiency develops, which further lessens cardiac output.

Clinical Manifestations

Clinically, an infant with HLHS appears to be healthy at birth. Oftentimes a heart murmur is not present. Shortly after birth, hour to days, the infant becomes pale, gray, tachypneic, develops feeding intolerance, and the peripheral pulses are weak or nonpalpable. Essentially, the infant is in cardiogenic shock with circulatory collapse.

Evaluation

Chest X-ray

Similarly, a chest X-ray is often nonspecific as well, potentially demonstrating cardiomegaly and/or increased pulmonary vascularity.

Electrocardiogram

An electrocardiogram is often not diagnostic. It may reveal low left-sided voltages and amplified right ventricular forces for a newborn.

Echocardiogram

The diagnosis of HLHS is made by echocardiography, either postnatally or more commonly prenatally by a fetal echocardiogram. The abnormal mitral and aortic valves with resultant left ventricle and ascending aorta hypoplasia should be definitively seen. Additionally, the patency of the atrial septum and ductus arteriosus, with retrograde flow visualized in the aortic arch, and ventricular function need to be adequately interrogated. Color Doppler interrogation is used to determine if a valve is atretic and to assess the competency of the tricuspid and pulmonary valves.

Cardiac catheterization

If there is either an intact or significantly restricted atrial septum resulting in hemodynamically significant left atrial hypertension, a cardiac catheterization is often necessary to create an atrial septal defect via balloon angioplasty or atrial septal stent placement. Otherwise, a catheterization is usually not required prior to initial surgical palliation.

Management

Medical management

The initial management of an infant with HLHS is aimed at maintaining a balance between pulmonary and systemic blood flow. After the airway is secured, if applicable, the infant with HLHS is started on prostaglandin E_1 to maintain ductal patency and ensure systemic perfusion. As the pulmonary vascular resistance decreases and pulmonary overcirculation (with systemic hypoperfusion)

ensues, medical management is required to increase pulmonary vascular resistance. Oftentimes, the infant will be intubated while minimizing the Fi02 to achieve controlled ventilation. The PC02 will be allowed to rise in order to increase pulmonary vascular resistance. The positive end-expiratory pressure may be increased as well to raise the total pulmonary resistance. Usually sedation is required as well to achieve this goal, as the intrinsic respiratory drive will increase the respiratory rate in response to an elevated PC02. Additionally, the use of vasoactive agents, such as dopamine and milrinone, will have beneficial effects on the contractility of the right ventricle and decrease systemic vascular resistance, both of which are physiologically beneficial to a patient with this anatomy.

As mentioned previously, there are patients with HLHS with a restrictive interatrial communication which result in clinically significant left atrial hypertension. Meaning that the severity of left atrial hypertension leads to a substantial reduction in pulmonary blood flow that results in inadequate oxygenation. In these cases, decreasing the degree of obstruction across the atrial level communication, usually by balloon atrial septostomy or stent placement, is necessary.

Surgical intervention

In general, there are three main aims in the surgical palliation of HLHS. It is important to note that the overall goal is surgical palliation and not surgical repair, as a patient with HLHS will not have a "normal" heart after the surgical interventions.

The first aim is to establish unobstructed systemic ventricular outflow to the systemic vascular bed. Meaning there is no obstruction between the right ventricle and the aorta. The second aim is to provide a stable and adequate source of pulmonary blood flow. The degree of pulmonary blood flow should be adequate but limited, as to protect the pulmonary vascular bed from overcirculation. The third aim is to ensure unobstructed pulmonary venous return.

The initial surgical procedure is referred to as a Norwood palliation (**Fig. 5**) (Davis et al., 2011). This procedure consists of creating an anastomosis between the proximal main pulmonary artery, the hypoplastic ascending aorta, and the aortic arch. The main pulmonary artery is transected at the distal end and oversewn. Pulmonary blood flow is most commonly ensured through a modified Blalock–Taussig shunt or a right ventricle to distal pulmonary artery shunt. In addition, the ductus arteriosus is ligated and if applicable, the atrial septum is opened. It is important to note that some centers advocate for primary cardiac transplantation rather than proceeding with staged surgical palliation. This initial surgical palliation not only allows for the infant to grow, but also adjust to the decrease in pulmonary vascular resistance without resulting in pulmonary overcirculation. The patency of the interatrial septum, reconstructed aortic arch, and branch pulmonary arteries along with the function of the right ventricle and competency of the tricuspid valve are all followed closely.

The second surgical palliation, a bidirectional Glenn shunt or a hemi-Fontan, is usually performed at 4–6 months of age (**Fig. 5**). With this surgical palliation, superior cava blood is directed to the pulmonary arteries. Prior to this surgery, a cardiac catheterization is performed for hemodynamic assessment and assess candidacy for proceeding with single-ventricle palliation. In addition, percutaneous intervention can be performed to address inefficiencies in the single ventricle physiology, such as clinically significant aorto-pulmonary and/or veno-venous collaterals.

The third and final surgical procedure is referred to as the Fontan operation (**Fig. 5**). There have been many modifications to the original procedure described in 1971 (Fontan and Baudet, 1971). Currently, the two most common techniques to achieve total cavopulmonary anastomosis are the lateral tunnel or extracardiac conduit (Driscoll, 2007; Feinstein et al., 2012). Oftentimes a

small communication (or fenestration) is created between venous pathway and the common atrium. Although there is a resultant mild systemic desaturation, this allows for decompression of the venous pathway while maintaining cardiac output.

Outcomes

Mortality is most notable following the first stage with overall 1-year mortality approaching 30% (Ohye et al., 2012). Mortality rates with stage II and III are low (McGuirk et al., 2006; d'Udekem et al., 2012). As more and more patients survive into adulthood, more attention is paid to long-term morbidity.

An important area of morbidity is neurodevelopmental outcomes (Fogel et al., 2016). Multiple studies have demonstrated that patients with HLHS are at risk for impaired neurodevelopmental outcomes, regardless of type of surgical intervention (Mahle et al., 2006; Tabbutt et al., 2008; Newburger et al., 2012; Goldberg et al., 2014; Marino et al., 2012). As such, these children require evaluation, monitoring, and early intervention for the suspected neurodevelopmental delays (Marino et al., 2012).

Current topics in hypoplastic left heart syndrome

Research in the field of hypoplastic left heart syndrome is varied. The development of the Pediatric Heart Network has resulted in completed studies regarding optimal surgical approach medical management, and the outcomes following the Fontan Procedure (Bradley, 2016). Others are focusing on improving our understanding of neurodevelopmental outcomes in these patients (Cheatham et al., 2015; Lloyd et al., 2016). Additional topics of interest include the use of ventricular assist devices in Fontan physiology, and stem cell therapy in single ventricle physiology (Imielski et al., 2017; Ishigami et al., 2017).

Conclusion

Obstruction to left ventricular outflow compromises a group of lesions that result in inadequate systemic perfusion. In certain instances, patency of the ductus arteriosus is crucial to survival until either surgical or percutaneous intervention is performed. Specific management will be determined based on the location and severity of the obstruction.

Introduction

Cardiovascular disease (CVD) is the number one cause of death worldwide. The increased prevalence and cost of treatment for CVD and associated risk factors have placed a huge economic burden on society. The primary cause of CVD is atherosclerosis (Bhatnagar et al., 2015), which is a lipoprotein-driven disease that involves vascular resident cells and immune cells. The complex interactions between those cells and various lipoproteins lead to plaque formation in large and medium-sized arteries (de Jager and Pasterkamp, 2013).

Atherosclerosis is initiated by the retention and accumulation of apolipoprotein B (apoB)-containing lipoproteins, mainly low density lipoprotein (LDL), in the intimal layer of arteries (Khalil et al., 2004). The dysmetabolism of lipids fuels atherogenesis (Gustafsson et al., 2007). As cholesterol influx exceeds its efflux, foam cells form, which serve as the building blocks of an atheroma. Atherosclerosis is also recognized as a chronic inflammatory disease in which a broad spectrum of inflammatory cytokines and chemokines participate. In the past decade, it has been revealed that immune cells participate in the interactions with the vascular resident tissue cells. Thereby, the immune system plays a crucial role in the development and progression of atherosclerotic plaques (Hansson and Hermansson, 2011). In this review, we summarized the current knowledge of the lipid-mediated mechanisms of atherosclerosis including metabolic perturbations, inflammation, and immune responses, and the interactions of these factors (Schaftenaar et al., 2016; Hansson, 2001).

Overview of Pathology of Atherosclerosis

When the risk factors for atherosclerosis were analyzed, both genetic and environmental components were revealed in epidemiological studies (Musunuru and Kathiresan, 2016). Among them, the abundance of atherogenic lipoproteins was found to be a prerequisite, and thus hypercholesterolemia plays a key role in the development of atherosclerosis. The increase of apoB-containing LDL and its accumulation in the arterial intima is sufficient for atherosclerosis to develop (Khalil et al., 2004). The interactions between hypercholesterolemia and other risk factors (e.g., smoking, hypertension, and diabetes) can further accelerate atherogenesis (McIntyre and Hazen, 2010).

Among the cells responding to LDL, monocytes and macrophages are essential in atherogenesis. During this process a series of changes occur in the vessel wall. After the endothelial cells are injured by turbulent blood flow or oxidized LDL (oxLDL), blood-derived inflammatory monocytes and other innate immune cells are recruited to the injured sites, adhere to the endothelial cells, and penetrate into the intima where monocyte-derived macrophages as well as the resident vascular smooth muscle cells (VSMCs) phagocytose lipids and become foam cells, which are the main components of the atherosclerotic plaque (Davidson and Rotondo, 2003). Morphologically speaking, there are continuous stages in the development of an atherosclerotic plaque, from the fatty streak formation resulting from intracellular lipid accumulation, to the visible intermediate lesion and atheroma formation, which is composed of an extracellular lipid core filled with an abundance of foam cells; these stages progress mainly by lipid addition (Subbotin, 2016). Then a fibroatheroma can be formed from single or multiple lipid cores with a fibrotic cap and increased VSMCs and collagen. The last stage in the development of a thrombosis usually comes from the disruption of complicated lesions, with the potential to result in hematoma and hemorrhage (Usman et al., 2015). Theoretically, atherosclerotic plaques can be classified into two types depending on their composition: the stable plaques which are less prone to thrombotic complications and the vulnerable plaques which are susceptible to rupture and complications. From an examination of more than 800 cases of sudden coronary death at autopsy, 55%–60% of them resulted from plaque rupture (Finn et al., 2010).

Lipoprotein Metabolism in Atherosclerosis

Based on the density, which is determined by the lipid to protein ratio in the lipoproteins, plasma lipoproteins are classified into five major categories: LDL, intermediate-density lipoproteins (IDL), high-density lipoproteins (HDL), very low density lipoproteins (VLDL), and chylomicrons. The larger the size is, the lower the density. Key components of these lipoprotein particles are apolipoproteins. Apolipoproteins are structural components of lipoprotein particles, cofactors for enzymes, and ligands for cell-surface receptors in lipid transport.

There are six major classes of apolipoproteins with several subclasses, that is, apoA (apo A-I/II/IV/V), apoB (apo B48/B100), apoC (apo C-I/II/III/IV), apoD, apoE, and apoH. These apolipoproteins can be classified into two major types. ApoB forms LDL particles and associates with lipid droplets irreversibly; thus it is called a nonexchangeable apolipoprotein (Plakkal Ayyappan et al., 2016). All other apolipoproteins form lipoprotein particles and associate with lipids reversibly, and thus are called exchangeable apolipoproteins. ApoB is the main apolipoprotein of LDL and is required for LDL formation and metabolism. ApoB exists in two isoforms: apolipoprotein B100 (apoB100), which is located on liver-derived VLDL, IDL, and LDL, and apoB48, which mainly resides on intestine-derived chylomicrons (Khalil et al., 2004). With the help of apoB, lipoproteins retained in the intima adhere to vessel walls by binding to proteoglycans in the extracellular matrix (ECM) during the pathogenesis of atherosclerosis. ApoA-I is the major protein component of HDL, and apoE is also found on some HDL particles (Feig et al., 2014). Since apoE has high affinity for LDL receptors (LDLR); defects in apoE result in experimental hyperlipoproteinemia, with accumulation of plasma cholesterol and triglycerides (TGs), the result of impaired clearance of VLDL and chylomicron remnants (Xu et al., 2016).

Metabolism of lipoproteins and apolipoproteins involves the process of synthesis, secretion, uptake, cholesterol transport, and reverse cholesterol transport (RCT), accomplished by multiple organs (Tall, 1998). The liver and intestine are major organs for synthesizing lipoproteins and apolipoproteins; the immune cells residing in these organs can assist in their synthesis and secretion. Lipoproteins can be taken up by many cell types through certain receptors; for example, LDL can be internalized by cells via LDLR. LDLR is a trans-membrane protein that diffuses freely within the cell membrane until binding to the membrane dynamic protein clathrin-coated pits. After the ligation of LDLR with LDL, the complex of LDL-LDLR and clathrin-coated pits can be brought into the cell through endocytosis. Similar to LDL, oxLDL can be internalized via the scavenger receptor B-3 (SR-B3, also named CD36) (Chistiakov et al., 2016). These LDL uptake receptors are essential in cellular cholesterol homeostasis; and a variety of mutations in the receptor genes have been suggested to contribute to dyslipidemia and increased plasma cholesterol. About 10 years ago an enzyme named proprotein convertase subtilisin kexin type 9 (PCSK9), which is synthesized along with LDLR, was demonstrated to act on LDLR and prevent it from being recycled back to the plasma membrane (Giunzioni and Tavori, 2015); instead, PCSK9 marks the LDLR for degradation in lysosomes. Antibodies that neutralize PCSK9 have become potent drugs that lower plasma cholesterol (Li and Li, 2015).

RCT is a process through which cholesterol is transported from nonhepatic peripheral tissues back to the liver (Jukema et al., 2004). It is mainly mediated by apoA-1-containing HDL and the ATP-binding cassette transporters (ABC), such as ABCA1 and ABCG1 (Feig et al., 2014). The cholesterol can be converted to cholesteryl ester (CE) by the enzyme lecithin-cholesterol acyltransferase in HDL particles and selectively taken up by the liver through SR-B1 or be transferred by CE transfer protein in exchange for TGs to other lipoproteins (such as LDL and VLDL), and these lipoproteins can then be taken up by the liver (Shao and Heinecke, 2009).

When investigating the metabolic functions of lipoproteins and apolipoproteins in mediating the pathogenesis of atherosclerosis, four kinds of lipids, LDL cholesterol, HDL cholesterol, lipoprotein(a) (Lp(a)), and TG are mainly considered (Aluganti Narasimhulu et al., 2016).

LDL Cholesterol

LDL cholesterol is generally referred to as bad cholesterol because it can be transported in LDL particles into the artery wall, initiating foam cell formation and atherogenesis (Segrest et al., 2001). This process seems to be self-accelerated, as the LDL-stimulated inflammatory cells can release cytokines to promote VSMC to secrete proteoglycans, thus increasing the affinity for LDL. In addition, engulfing of LDL enables macrophages to produce lipoprotein lipase (LPL) and thus further enhances LDL retention (Hasham and Pillarisetti, 2006; Rutledge et al., 1997).

After invading the endothelium, LDL becomes oxidized and/or aggregated. The formation of oxLDL is regulated by a complex set of biochemical reactions. Both necrotic cell debris and free radicals participate in these reactions in the endothelium (Khalil et al., 2004). Compared to the native LDL, the oxidized forms of LDL are more easily retained in the intima to be later recognized, engulfed, and accumulated by macrophages, forming foam cells and initiating inflammatory responses (Libby, 2002). In this process, oxLDL triggers VSMC to produce more proteoglycans and helps to retain more LDL in the arterial wall; while the retention of LDL leads to oxidative modification of LDL, forming a vicious cycle (Kiyan et al., 2014). OxLDL exerts a wide range of effects to activate various cell types and drive the development of atherosclerosis. As a ligand for the scavenger receptors on macrophages, oxLDL can be engulfed for foam cell formation and initiate the proinflammatory properties of macrophages (Boullier et al., 2001). Moreover, the degree of oxidation of LDL determines the differentiation of naïve macrophage to either an M1 or M2 phenotype (Seo et al., 2015). Minimally oxidized LDL induces the production of TNF-α and IL-12p40 in macrophages, indicating an M1 macrophage phenotype; while heavily oxidized LDL induces mannose receptor CD206 expression that indicates an M2 phenotype (Seo et al., 2015). OxLDL also affects the apoptosis of macrophages and plaque rupture (Hundal et al., 2001, 2003). OxLDL can also

induce VSMC proliferation, migration, and transition to a proinflammatory phenotype from a contractile smooth muscle phenotype (Chien et al., 2003; Zettler et al., 2003). For endothelial cell (EC), oxLDL enhances the expression of adhesive molecules such as VCAM-1 and the production of several chemokines (Takei et al., 2001).

Clinically, the increased plasma LDL cholesterol level is associated with increased incidence and severity of atherosclerosis (Plakkal Ayyappan et al., 2016). Significant elevation of oxLDL was observed in patients with acute coronary syndromes, while treatment with a statin drug markedly reduced its levels (Ramadan et al., 2009). Thus, the oxLDL levels are widely used to predict the development of atherosclerosis and other CVDs, based on the correlation between oxLDL levels and CVD outcome (Shimada et al., 2004). However, it is critical to note that oxLDL is highly heterogeneous, which suggests more complex functions of oxLDL in mediating the progression of atherosclerosis (Levitan et al., 2010).

HDL Cholesterol

HDL is the driving force of RCT, a process that removes excess cholesterol from cells in peripheral tissues (e.g., foam cells in arterial wall) to the liver (Ohashi et al., 2005). Therefore, HDL exerts strong protection against atherosclerosis and has a strong negative correlation with the risk of atherosclerotic CVD. Plasma level of cholesterol carried by HDL (HDL-C) reflects the availability of functional HDL (Rosenson et al., 2016; Ansell et al., 2005).

Functionally, HDL and lipid-poor apoAI promote the regression of atherosclerosis due to the antioxidant properties of their enzymatic and nonenzymatic components and the ability to remove normal and toxic lipid species from cells (Feig et al., 2014). HDL interferes with the oxidative modification of LDL and inhibits the biological activity of oxLDL. This is attributed to many antioxidative and antiinflammatory enzymes, such as paraoxonase 1 (PON1), an esterase carried on HDL that can degrade certain biologically active oxidized phospholipids (oxPL) (Shao and Heinecke, 2009). Another enzyme, myeloperoxidase (MPO), also contributes to the anti-atherogenic function of HDL. The functionality of HDL, conferred by these antioxidative and antiinflammatory components, is considered more important than the quantity of HDL in peripheral blood (Calabresi et al., 2015). HDL can also protect the arterial endothelium via nitric oxide synthase activation (Mineo and Shaul, 2003), and exert antiinflammatory effects through dampening toll-like receptor (TLR) signaling by modulating the content of plasma membrane cholesterol (De Nardo et al., 2014). Regarding the phenotypes of macrophages, HDL can decrease proinflammatory cytokine production and promote the differentiation of M2 macrophages. This is associated with the promotion of the phosphorylation of STAT6, an essential cell signaling pathway for M2 polarization (Sanson et al., 2013). Nevertheless, the anti-atherogenic functions of HDL may be compromised once HDL is trapped in the arterial wall or when modified in the context of kidney disease or diabetes.

Lipoprotein(a)

After being assembled at the hepatocyte cell membrane surface and released into the plasma, Lp(a) consists of two components: an LDL-like particle and apo(a). The latter is covalently bound to apoB of the LDL-like particle (Fless et al., 1985). However, unlike LDL, Lp(a) contains lower amounts of antioxidants and exhibits a high affinity to ECM and fibrin. Lp(a) contributes to the pathological processes of both atherogenesis and thrombogenesis, depending on Lp(a) plasma concentrations and the variable antifibrinolytic capacity of different apo(a) isoforms. Thus an increased plasma level of Lp(a) has been recognized as an independent risk factor for an atherothrombotic event (Kronenberg et al., 1996; Nordestgaard et al., 2010).

Lp(a) promotes the pathogenesis of both the early and advanced stages of atherosclerosis. Lp(a) is the major carrier in plasma of oxPL, which attracts inflammatory cells to infiltrate into arterial walls and promotes the proliferation of VSMCs (Bergmark et al., 2008). Lp(a) can also inhibit anti-atherogenic transforming growth factor-β (TGF-β) activation by impairing the synthesis of plasmin (Bogavac-Stanojevic et al., 2003). Since it usually is retained in the subendothelial space of the arterial wall, Lp(a) can stimulate endothelial cells to increase the expression of intercellular adhesion molecule-1, which promotes circulating monocyte adhesion to the arterial endothelium (Takami et al., 1998). Moreover, Lp(a) may also act as a potent chemoattractant for monocytes in a dose-dependent manner in the development of atherosclerosis (Syrovets et al., 1997). Based on these functions, plasma levels of Lp(a) can be used to predict the risk of early atherosclerosis in subjects with high LDL cholesterol levels, and it was found that this effect is independent of the size polymorphism of apo(a) because the distribution of apo(a) is similar in subjects with or without early atherosclerotic plaques (Kronenberg et al., 1999).

Lp(a) also promotes thrombogenesis (Lip et al., 1997). Because the structure of Lp(a) is similar to plasminogen and tissue plasminogen activator, it can competitively reduce fibrinolysis. In addition, Lp(a) can enhance the secretion of plasminogen activator inhibitor(PAI) (Rouy et al., 1991). Moreover, Lp(a) can enhance coagulation by inhibiting the effect of tissue factor pathway inhibitor (van der Stoep et al., 2014). Lp(a) is also observed to be involved in wound healing and tissue repair by interacting with the ECM in vascular wall.

Triglyceride

TG is an ester derived from glycerol and fatty acids. There are two different types of TG: saturated and unsaturated (Pundir and Narang, 2013). There is a renewed interest in investigating increased levels of TGs in atherogenesis in recent years. The intestine is the main location for TG metabolism (Mattson and Volpenhein, 1964). Bile salts are used to emulsify dietary TG and cholesterol in the intestinal lumen. This results in the enhanced uptake of TG. After uptake, TGs can be digested by lipases into free fatty acids

(FFA) and monoacylglycerides (MAG) in the intestinal lumen and absorbed into the enterocyte for the synthesis of new TG, phospholipid, and CE. Subsequently, the synthesized materials can be packaged into chylomicrons, secreted, and enter the lymphatic system.

Similar to both atherogenic apoB-containing lipoproteins and Lp(a) (Kimak and Solski, 2002), TG-rich remnant lipoproteins also promote atherothrombosis (Krauss, 1998a). It is known that high levels of TGs in the bloodstream have been linked to atherosclerosis, which is attributed to multiple mechanisms. TG can directly influence the development of atherosclerotic plaque, as TG-rich lipoproteins carry abundant cholesterol and thus promote foam cell formation (Krauss, 1998b). Because TGs can be degraded by most cells, while cholesterol cannot, cholesterol content of TG-rich lipoproteins is more likely to be the cause of atherosclerosis and CVD (Nordestgaard and Varbo, 2014). Besides cholesterol delivery, TG-rich lipoproteins could also promote atherosclerosis by inducing lipid toxicity (Goldberg et al., 2012). After lipolysis cholesterol in the TG-rich lipoproteins can be concentrated, and FFA and MAG are produced. This product is cytotoxic as demonstrated in vitro, as these lipids can promote cell death and local inflammatory injury, especially in the arterial wall where the lipoprotein-lipase activity at the surface of remnants is active (Liu and Czaja, 2013). TG-rich lipoproteins could also accelerate hypertriglyceridemia, because these lipoproteins contain apoCIII, which inhibits LPL and remnant uptake by the liver (Larsson et al., 2013). Moreover, an elevated TG level can result in increased plasma levels of thrombotic factors including the fibrinogen, PAI, and inflammatory mediators (McLaughlin et al., 2005).

Inflammation Caused by Dysfunctional Lipoprotein Metabolism in Atherosclerosis

During the pathogenesis of atherosclerosis, native LDL can be modified into oxLDL at early stages, and oxLDL is rapidly taken up by macrophages to generate foam cells. By exposure to the oxidative waste of vascular cells, LDL is mildly oxidized with the help of an enzyme called 12/15-lipoxygenase (LO), which is an important source of the reactive oxygen species in LDL oxidation (Huo et al., 2004). It is found that 12/15-LO is also an inducer for proinflammatory molecule production and thus promotes atherosclerosis. 12/15-LO induces the production of TNF-α, IL-6, and CCL2, and 12/15-LO deficiency exhibits diminished fatty streak formation and atherosclerotic lesions in mice (Wen et al., 2007). Therefore, there are multiple connections between the metabolic functions of lipids and cytokine-mediated inflammatory responses in atherosclerosis (Buckley and Ramji, 2015).

Abundant oxLDL generated in the context of hyperlipidemia accelerates cholesterol accumulation in macrophages and thereby provokes inflammation. The inflammatory responses to oxLDL include the activation of TLRs (Goldklang et al., 2012), inflammatory cell infiltration, inflammatory cytokine and chemokine production, and inflammasome activation. Subsequently, TLR-mediated inflammatory responses can decrease cholesterol efflux (Tall and Yvan-Charvet, 2015) and lead to increased cholesterol accumulation, resulting in a vicious cycle.

TLR signaling is a bridge from innate immune response and inflammation to atherogenesis, while the cholesterol-enriched atherogenic microenvironment augments the TLR signaling activation. For example, LPS-activated TLR4 signaling can be enhanced by plasma membrane cholesterol enrichment via promoting the formation of TLR4-MD2 and TLR4-CD14 complexes (Dauphinee and Karsan, 2006) and TLR-activated macrophage inflammatory responses can be suppressed by ABCA1 and ABCG1-mediated macrophage cholesterol efflux (Zhu et al., 2010).

The activation of TLRs and the uptake of oxLDL and phospholipids by macrophages result in the release of proinflammatory cytokines such as TNF-α, IL-1, IL-18, IL-6, IL-12, IL-15, and MCP-1, as well as some antiinflammatory cytokines including IL-10, IL-4, and TGF-β (Han and Boisvert, 2015). The proinflammatory cytokines could enhance inflammatory responses in vessels and further induce immune cell infiltration and exacerbate atherosclerosis (Aluganti Narasimhulu et al., 2016). Three of the most important proinflammatory cytokines are TNF-α, IL-1, and IL-6. TNF-α promotes the development of atherosclerosis at the early fatty streak stage. IL-1β is associated with inflammasome activation (Duewell et al., 2010), and IL-1 can stimulate VSMCs to produce IL-6 in atherosclerotic lesions (Ait-Oufella et al., 2011). However, the role of IL-6 in atherogenesis is still controversial, as the administration of exogenous IL-6 can increase the formation of fatty streaks in apoE$^{-/-}$ mice (Huber et al., 1999); however, IL-6$^{-/-}$apoE$^{-/-}$ mice showed elevated atherosclerosis and decreased leukocyte homing (Elhage et al., 2001). To some extent, these effects of cytokines are achieved by controlling lipid metabolism associated genes. For example, IL-6 downregulates scavenger receptor-A, IL-4 upregulates CD36, while TNF-α and TGF-β affect the expression of the lectin-like oxidized LDL receptor (LOX-1) (Minami et al., 2000).

In hyperlipidemia, the accumulated cholesterol crystals in macrophages can promote inflammasome activation during atherogenesis, while inflammasome activation can subsequently exert pro-atherogenic effects. On the one hand, the ligation of oxLDL with TLR4 or CD36 could provide a priming signal, while the phagocytosis of extracellular cholesterol crystals via CD36 could provide a second signal for inflammasome activation (Abderrazak et al., 2015). On the other hand, the inflammasome activation could further lead to the maturation and secretion of the proinflammatory cytokines IL-1β and IL-18 (Buckley and Ramji, 2015). Both of these cytokines are pro-atherogenic molecules. IL-1 initiates leukocyte adhesion to ECs and transmigration, and it can also provoke vascular tissue cells to produce other cytokines (Tsouknos et al., 2003), while IL-18 can increase lymphocyte infiltration.

Furthermore, the exposure of macrophages to the inflammation and oxidative stress within atherosclerotic lesions can also activate endoplasmic reticulum stress pathways and result in macrophage apoptosis and necrosis. With TNF-α and IL-1 stimulation, pentraxins such as C-reactive protein can be produced, and exert direct effects on leukocyte recruitment and cell apoptosis induction in the vessel wall (Buckley and Ramji, 2015).

Immune Responses to Lipids in Atherosclerosis

Over the past few decades, the roles of the immune system including both the innate immunocytes, such as monocytes, macrophage, mast cells, nature killer cells, and dendritic cells (CDs), and adaptive immunocytes including T cells and B cells, in the pathological process of atherosclerosis have been gradually revealed.

Native LDL does not trigger an immune response, unless oxPL or aldehyde-modified breakdown fragments of apoB expose neo-antigens, which break self-tolerance and induce inflammation (Matsuura et al., 2014). Cells of the innate immune system recognize and respond to pathogens in a generic and immediate way, but this defense is relatively transient. Their major functions are to recruit immune cells by producing cytokines and chemokines and activate the adaptive immune system through antigen presentation (Hansson and Hermansson, 2011). Atherosclerosis is now recognized as a disease associated with immune responses since antigen presentation occurs in atherosclerotic lesions.

It is believed that monocyte-derived macrophages are the main cellular component of an atheroma, and these cells are the major precursors of foam cells. OxLDL affects the migration of monocytes to the vascular wall by switching from CCR2 to CX3CR1 expression in a peroxisome proliferator-activated receptor-γ-dependent manner (Yu et al., 2015). After infiltrating the arterial wall, monocytes can differentiate into macrophages, ingest modified lipids, predominantly oxLDL, and then store them in lipid droplets (Plakkal Ayyappan et al., 2016). As short-lived phagocytic cells, neutrophils possess a variety of biological enzymes such as MPO and proteinases. The infiltration of these cells is recognized as a driving force for atherosclerotic lesion growth (Tiyerili et al., 2016). The infiltrated neutrophils are produced in bone marrow under the control of granulocyte colony stimulating factor and IL-23. Neutrophils express the G protein-coupled receptor CXCR4, whose ligand is CXCL12, and their interaction plays an essential role in neutrophil egress from bone marrow and migration to the atherosclerotic lesions (Bot et al., 2014). Mast cells and natural killer (NK) cells are both major effector cells in host defense responses and are also found to be involved in atherogenesis. The activated mast cells release abundant proinflammatory cytokines, proteolytic enzymes, growth factors, and vasoactive substances (Bot and Biessen, 2011). These molecules participate in altering lipid metabolism via affecting the cholesterol efflux mediated by apoE and apoAI, and they also modify lipoproteins and digest matrix components, thereby taking part in plaque formation and rupture. The NK cells were mainly found in the shoulder regions of the atherosclerotic plaques. An adoptive transfer experiment indicates that the deficiency of NK cells can result in dramatic reduction of atherosclerotic lesion formation (Selathurai et al., 2014).

As the professional antigen-presenting cells, DCs are essential in the initiation of immune responses to lipid antigens (e.g., oxLDL) in atherogenesis. DCs share phenotypic and functional properties with macrophages, which enables them to have the ability to phagocytize and present antigens (Manthey and Zernecke, 2011). DCs take up lipids via scavenger receptors and form a dendritic cell-like phenotype of foam cells, contributing to the development of atherosclerotic lesions. In the meantime, more importantly, the uptake of lipid antigens such as oxLDL and apoB100 results in DC maturation, migration, and antigen presentation to T cells in the draining lymph nodes, subsequently initiating the activation of subpopulations of T cells and B cells (Paulson et al., 2010; Hermansson et al., 2011). For example, after the intravenous injection of oxLDL or apoB100 coupled splenocytes, the Th1 polarization was dramatically enhanced in both WT and apoE$^{-/-}$ mice (Steinmetz et al., 2015). By contrast, if these lipid antigens including apoB100-derived peptides are recognized and presented to regulatory T cells, they will reduce the development and progression of atherosclerosis in mice (Herbin et al., 2012). These reports indicate that different subsets of T cells exert different functions in modulating atherogenesis even after having been exposed to similar lipid antigens.

Summary

Increased plasma LDL levels cause LDL entry into and accumulation in the arterial intima. After the modification by oxidation and aggregation, these lipoproteins can activate both the vascular resident tissue cells and immunocytes, driving pathogenic evolution of the plaque by forming lipid-loaded foam cells as well as releasing proinflammatory cytokines and chemokines. As the atherosclerotic lesion evolves, other immune inflammatory cells such as DCs, neutrophils, NKs, mast cells, T cells, and B cells are recruited by the chemokine and cytokine stimulation and also accumulate in the lesion area. The adaptive immunocytes like T cells and B cells recognize specific epitopes on lipid antigens presented by the innate immunocytes, leading to lymphocyte activation and secretion of cytokines and lipid antigen-specific antibodies. As a result, a positive feedback loop of inflammatory cell infiltration and foam cell formation further exacerbate the pathological process of atherogenesis.

Although the mechanisms of metabolism, inflammation, and immunity in lipid-mediated atherogenesis are discussed individually, these factors in the network cannot be separated. Many of the details in this network need to be investigated further, and questions must be raised such as: can we use our current knowledge of these mechanisms in atherosclerosis to prevent or treat this disease? Or will immunomodulation during atherogenesis be helpful to improve the treatment of atherosclerosis? Immunotherapies are attractive as a possible therapeutic approach for CVDs (Hermansson et al., 2011; Shah et al., 2004), although no such immunotherapy is clinically available today. The success in protective immunization with oxLDL as an immunogen in experimental models suggests that this might be a fruitful approach in humans. However, broadly acting immunosuppressants are unsuitable for this purpose; instead the development of more specific immunomodulators that act on the key mechanisms in the pathogenesis of atherosclerosis should be encouraged. We assert that, with the further understanding of the lipid-mediated mechanisms of atherogenesis, more promising therapeutic methods will be developed.

Introduction

Average life expectancy in ancient Greek and Roman times was 27 years in 200–300BC. By the year AD1900, it had increased to 47 years. Thus, life expectancy had increased by only 20 years during more than 2000 years. However, looking back to the end of the 20th century, life expectancy had increased by a further 30 years in a mere century as a consequence of the control of epidemic diseases, treatment of infections with antibiotics, vaccination, and improvements in food and environmental safety. Prolongation of life expectancy more recently has been due mostly to prevention of cardiovascular disease (CVD), and for many years plasma cholesterol has been recognized as one of its most important risk factors.

This article reviews aspects of lipids and CVD from the viewpoint of epidemiology, from the first epidemiologic studies to recent clinical trials.

The Dawn of Epidemiologic Studies on Lipids and CVD

The Framingham Heart Study: The Advent of CVD Risk Factors

The onset of prospective studies of cholesterol and CVD was heralded by "The Framingham Heart Study" (Dawber et al., 1951). It was planned in 1948, just after the end of World War II, when CVD accounted for 80% of total mortality in the United States. The National Heart Institute of the United States Public Health Service organized a large-scale prospective study in the town of Framingham, Massachusetts, with a population of 28,000, to consider measures for preventing a further increase in CVD complications. The study followed the causes of coronary heart disease (CHD) for the first time by epidemiology, which up to then had been a research method mostly for infectious diseases. The study contributed to a halving of the incidence of CVD in the United States during the following 30 years. The Framingham Offspring Study targeting the first participants and their children and spouses was initiated in 1971, the Omni study targeting minority races was started in 1994, and the Third-Generation Cohort targeting grandchildren of first participants was initiated in 2002. Moreover, in 2003 the New Offspring Spouse Cohort and the Second-Generation Omni Cohort were started. These studies are still in progress today.

In the Framingham Heart Study, 5070 subjects aged 35–64 years were followed for 30 years to examine the relation between candidate risk factors and the development of CHD. The results showed clearly that CHD incidence was strongly affected by systolic blood pressure (SBP), serum cholesterol concentration, and smoking habit (Stokes et al., 1987). In doing so, the study created the concept of "risk factors" and had a major impact on clinical practice for CVD prevention worldwide. The message that CVD might be preventable by risk factor control had a great and far-reaching impact. The outcome of the study has had a remarkable impact on life expectancy through prevention of CVD during the 20th century (Futterman and Lemberg, 2000).

"The Seven Countries Study," the First International Collaborative Study of CVD Epidemiology

The Seven Countries Study is a prospective study that began in 1957 (Verschuren et al., 1995). It targeted men aged 40–59 years in seven countries (United States, Finland, Yugoslavia, Greece, Italy, Netherlands, Japan), using a unified survey procedure. It was the pioneer of international collaborative studies that have identified associations between CHD incidence and lifestyle, especially dietary habits. One of the pioneering features of the study was the application of standardized food surveys, mostly using duplicate meals. The study confirmed that total cholesterol (TC) is related to CHD in a manner similar to that identified in the Framingham Heart Study and also showed that the association partly explained regional differences in CHD mortality, that is, CHD mortality was lowest in Japan where serum cholesterol levels were very low and was very high in the United States and Finland (Verschuren et al., 1995). Many associations with CHD and stroke were observed, including those of saturated fatty acid intake, smoking, and blood pressure. The follow-up was completed at the 25th year. Two similar studies are in progress in different parts of the world: the FINE Study in Finland, Italy, and the Netherlands, and the Tanushimaru Study in Japan.

"The Whitehall Study," Targeting Socioeconomic Status

The association between social class and health status has been one of the classic topics of social epidemiology. A number of studies have been undertaken to date. One of the most notable is the Whitehall Study in the United Kingdom. "The Whitehall I Study" commenced in 1967 with the aim of studying the association between socioeconomic status (SES) and all-cause mortality in 18,403 male civil servants working in public offices in London (Reid et al., 1974). An association between the occupation class of civil servants and their mortality risk was observed, with the risk being higher in lower class occupations than in higher class occupations. Men in the lowest class had a threefold greater all-cause mortality risk than men in higher grades during more than 10 years of follow-up (Marmot et al., 1984). "The Whitehall II Study," which began in 1985 and targeted 10,308 male and female civil servants aged 35–55 years (Marmot et al., 1991), was undertaken to explore the relations between SES, stress, and CVD. It found that mortality due to CHD had increased along with the rise in serum TC levels, and differences in CHD risk by SES were partly explained by differences in risk factor levels such as TC (Rose and Shipley, 1986; Whitty et al., 1999).

The Cohort Study of CVD in Asia (Hisayama Study)

The Hisayama Study is the oldest cohort study targeting CVD in Japan and might be the oldest in all Asian populations. Since 1961, an epidemiologic survey of CVD, of which the main target was stroke, has been performed in Hisayama town (approximate population 8400) in Fukuoka prefecture located in the western part of Japan (Kiyohara et al., 1989). The residents of Hisayama have almost the same age and occupational distribution as the national average and accordingly are almost a representative sample of the Japanese population. The justification for this study was uncertainty about the credibility of Japanese death certificates expressed by US researchers. According to the World Congress on Neurology in Rome in 1960 (Goldberg and Kurland, 1962), the annual mortality from stroke in Japan was the highest among 33 countries with reliable vital statistics. Moreover, when looking into stroke subtypes, intraparenchymal hemorrhage was conspicuously high in Japan. Goldberg and Kurland had questioned whether there were inaccuracies in the completion of death certificates by Japanese physicians. There was no evidence to refute this at the time. The Hisayama Study had started with the aim of clarifying the natural history of stroke of Japanese. In the initial data from the first follow-up population (autopsy rate 80%) in 1961, mortality due to intraparenchymal hemorrhage was high as expected, but 1.1-fold that of cerebral infarction. The study recruited residents aged 40 years or more from the town in the years 1961, 1974, 1988, and 2002, after which there was continuous follow-up. The initial endpoints were stroke and they have since been expanded to include cancer, diabetes, dementia, and others. As an example, one recent publication reported that increased risks of atherothrombotic cerebral infarction and CHD were observed with increasing low-density lipoprotein cholesterol (LDL-C) or non-high-density lipoprotein cholesterol (non-HDL-C) concentrations, each in a linear manner (Imamura et al., 2009; Imamura et al., 2014).

Subsequent to the Pioneer Studies

It has been shown that the incidence/mortality of CVD is associated with dyslipidemia, such as a raised serum TC level in cohort studies in many countries. Evidence provided by these studies has become the foundation for the National Cholesterol Education Program (NCEP)-Adult Treatment Panel III (ATP III) of the US National Institutes of Health, which provides guidelines for atherosclerotic disease prevention (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). This program developed the Framingham Score, which predicts the future development of CHD. In Japan, the Hisayama Risk Score was developed (Arima et al., 2009).

Advances in Cohort Studies and CVD Risk Assessment Worldwide

TC Cut-Off Points by Cohort Studies

In 1986, Stamler et al. reported the relationship between serum TC and CHD death rate in the Multiple Risk Factor Intervention Trial (MRFIT) (Stamler et al., 1986). In this study, 356,222 men aged 35–57 years who had no history of hospitalization for myocardial

infarction (MI) were recruited at 22 clinical centers in 18 US cities and then followed for 6 years. The relative risk (RR) of 6-year CHD mortality in the second to fifth quintiles of TC (182–202, 203–220, 221–244, and ≥245 mg/dL) were compared with that in the lowest quintile. The RR results were 1.29, 1.73, 2.21, and 3.42, respectively. These findings contributed to the determination of the criteria for TC levels in the US National Cholesterol Education Program. In the National Cholesterol Education Program Adult Treatment Panel II and III (NCEP-ATP II and III), a categorical high TC was defined as ≥240 mg/dL (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 1994, 2001), as subjects with such TC levels have almost twice the RR for CHD death as those with TC ≥200 mg/dL.

Risk Assessment for Future CVD Based on Cohort Studies

Since the dawn of CVD epidemiology, several cohort studies have identified multiple risk factors for CVD. These findings have given rise to the strategy of CVD prevention in populations at risk by the treatment of those with established risk factors. To this end, it is important to detect individuals who are at high risk owing to the magnitude of each risk factor and the combination of risk factors. In order to estimate individual CVD risk, risk assessment tools have been introduced. In 1998, the Framingham Risk Score for CHD in the United States was published (Wilson et al., 1998). Subsequently, the SCORE risk charts in Europe and the Pooled Cohort Equations validated by the 2013 ACC/AHA guidelines on the assessment of CVD in the United States were promulgated using a pooled dataset from several cohort studies (Conroy et al., 2003; Goff et al., 2014). In addition, several CVD risk assessment tools were developed in Asian countries (NIPPON DATA80 Research Group, 2006; Nishimura et al., 2014).

The American College of Cardiology (ACC) and American Heart Association (AHA) jointly published the 2013 ACC/AHA guidelines on the assessment of cardiovascular risk in collaboration with the National Heart, Lung, and Blood Institute (NHLBI) (Goff et al., 2014). The 2013 ACC/AHA guidelines were based on evidence from a systematic review and metaanalysis of relevant randomized controlled trials with the aim of reducing cardiovascular risk. As a consequence, statin therapy is now widely recommended for TC reduction. There are four major statin benefit groups: (1) atherosclerotic CVD (ASCVD; defined as history of acute coronary syndrome (ACS), MI, stroke, transient ischemic attack, or peripheral arterial disease), (2) LDL-C ≥190 mg/dL and age >21 years, (3) ages 40–75 years with diabetes and LDL-C 70–189 mg/dL without ASCVD, and (4) ages 40–75 years without ASCVD or diabetes and with LDL-C 70–189 mg/dL and estimated 10-year ASCVD risk ≥7.5%.

The 10-year ASCVD risk was defined as the risk of developing a first ASCVD event, nonfatal MI, CHD death, or fatal or nonfatal stroke, over a 10-year period among people with no history of ASCVD at the beginning of the period. The estimated 10-year risk of ASCVD was calculated using the new Pooled Cohort ASCVD Risk Equations. The pooled cohorts included the ARIC (Atherosclerosis Risk in Communities) study, the Cardiovascular Health Study, the CARDIA (Coronary Artery Risk Development in Young Adults) study, the Framingham Heart Study, and the Offspring Study cohorts, which are NHLBI-funded community-based cohorts. Participants were 24,626 non-Hispanic, Caucasian, and African-American women and men aged 40–79 years who were without a history of CVD, nonfatal MI, heart failure, stroke, percutaneous coronary intervention, coronary artery bypass surgery, and atrial fibrillation. The ASCVD risks were estimated using sex- and race-specific proportional hazards models that included the covariates of age, treated or untreated SBP, TC, HDL-C, current smoking status, and diabetes.

The ACC/AHA guidelines focus on statin therapy (high or moderate intensity) without the need for lipid monitoring ("fire and forget" approach) to assess therapeutic efficacy (Stone et al., 2014) and identifying the target population by means of the Pooled Cohort ASCVD Risk Equations.

Ten-year risk assessment of CVD using The SCORE risk chart was introduced in the 2016 ESC/EAS Guidelines for the Management of Dyslipidaemias (Catapano et al., 2016). This assessment was based on pooled data from 12 European cohort studies, which included 205,178 participants free of a history of CVD. The RRs of each risk factor for CVD were calculated using a cohort- and sex-stratified Weibull proportional model, with the covariates of age, SBP, TC, HDL-C, and smoking status. Risk estimates have been produced as charts for high- and low-risk regions of Europe.

The targeted approach for lipid management is mainly to reduce LDL-C. For patients with a *very* high total CVD risk, the targeted value is an LDL-C of 70 mg/dL. For subjects with a high total CVD risk, the goal is an LDL-C of 100 mg/dL. Among populations with moderate total CVD risk, the LDL-C goal is 115 mg/dL. Regardless of risk levels, at least a 50% reduction from baseline is recommended in the 2016 ESC/EAS Guidelines.

It can be seen that there is a clear difference in lipid management between the United States and Europe. The latter recommends treatment of the targeted population in order to reduce the value of cholesterol to a targeted value, that is, a "target-to-target" approach. They are both controversial approaches for the prevention CVD in clinical practice.

Investigating the Impact of Lipid Parameters on CVD in Asian Countries

Recently, many cohort studies have investigated the association between various lipid parameters and CVD in Asian countries. The Asia Pacific Cohort Studies Collaboration (APCSC) is a pooled analysis from prospective cohort studies in several Asian countries, Australia, and New Zealand (Asia Pacific Cohort Studies Collaboration, 2004). The inclusion criteria were as follows: (1) all participants were from Asia or the Pacific region (including Australia and New Zealand); (2) age, sex, and blood pressure of each individual had been measured at baseline; and (3) ≥5000 person-years of follow-up had been completed.

There are three representative studies that have shown the association between lipid parameters and CVD in the APCSC. It was reported that serum triglycerides (TG) were an important and independent predictor of CHD and stroke risk in the Asia-Pacific

region (Asia-Pacific Cohort Studies Collaboration, 2004). For this study, the APCSC analyzed data from 96,224 individuals (median follow-up period, 7.9 years) in 26 cohort studies. Participants in the highest 5th of TG (≥168 mg/dL) had a 70% greater risk of CHD death, an 80% greater risk of fatal or nonfatal CHD, and a 50% increased risk of fatal or nonfatal stroke when compared to participants in the lowest 5th of TG (≤62 mg/dL). On the other hand, Huxley et al. reported that an isolated low HDL-C was significantly associated with CHD in 220,060 individual data from the APCSC (Huxley et al., 2011). In that study, during 6.8 years of follow-up, participants with isolated low HDL-C had a 63% greater risk of CHD death relative to those with normal and high HDL-C level in Asians. Hirakawa et al. (2016) recently reported the impact of body mass index (BMI) on the associations of lipid parameters with CHD risk in the Asia-Pacific region by using data from the APCSC. The authors showed that the risk of CHD increased with increasing TC and with decreasing HDL-C independent of BMI. On the other hand, the impact of TG on CHD events significantly increased as BMI increased, and this effect was still evident after adjusting for TC and HDL-C.

In China, a multicenter prospective cohort study of cardiovascular risk factors in Chinese, the Chinese Multiprovincial Cohort Study (CMCS), was performed from 1992. Chinese subjects ($n=30,378$) aged 35–64 years and free of CVD participated. Ren et al. (2010) reported that a very low density density lipoprotein cholesterol (VLDL) level was significantly associated with an elevated 15-year CVD risk. After the CMCS, the China Cardiovascular Health Study and the China Multicenter Collaborative Study of Cardiovascular Epidemiology (ChinaMUCA) were conducted during 1998–2001. A total of 11,480 participants were followed in the ChinaMUCA study. Gu et al. (2015) reported that a higher non-HDL-C level was associated with an increase in CVD incidence in Chinese and had a similar effect on cardiovascular risk as LDL-C.

The Korea Medical Insurance Corporation (KMIC) Study was conducted in 1990. This study aimed to assess risk factors for ASCVD in Korean men and women and included more than 100,000 men and 50,000 women aged 35–59 years. Suh et al. (2001) reported that low-serum TC was not an independent risk factor for either intracerebral or subarachnoid hemorrhagic stroke in Korean men. In addition, Jee et al. (1999) have indicated that a low-cholesterol level did not protect against smoking-related ASCVD in Korean men. The Korea National Health and Nutrition Examination Survey (KNHANES) was established in 1998, and many reports concerning cardiovascular risk factors including lipid parameters have been published. KNHANES is a national surveillance system to assess the health and nutritional status of Koreans, and the surveys have been conducted by the Korea Centers for Disease Control and Prevention (KCDC) (Kweon et al., 2014). In this project, Lee et al. (2014) have reported the descriptive data in Korea, the age-standardized mean levels of serum cholesterol, and the prevalence, awareness, treatment, and control rates of high LDL-C levels according to age. Compared with elderly participants, significant proportions of young and middle-aged adults were unaware of their hypercholesterolemia and were not being treated with effective lipid-lowering medications.

Cohort studies for CVD risk including lipid parameters have been reported in several countries. However, there have not been sufficient studies to elucidate the differences between races, regions, or health behaviors. In light of these differences, future cohort studies are warranted to clarify more specific individual risks.

Evidence From Lipid-Lowering Clinical Trials

Clinical Trials of Primary Prevention

Before the advent of the 3-hydroxy-3-methylglutaryl–coenzyme A reductase inhibitors, also known as the stains, several lipid-lowering therapies had been evaluated in controlled clinical trials. LRC-CART (Lipid Research Clinics-Coronary Prevention Program) was the first trial that succeeded in the prevention of CHD by lipid-lowering therapy, using cholestyramine to reduce LDL-C (Lipid Research Clinics Program, 1984). The study was a double-blind randomized controlled trial (DB-RCT) with a placebo control. It included 3806 patients with no history of CHD and randomly assigned 1906 patients to cholestyramine (daily use: 24 g/day) and 1900 patients to a placebo. Both groups were recommended to take a moderate cholesterol-lowering diet. The primary outcome variable was the first occurrence of CHD death or nonfatal MI. During 7.4 years, 155 events (8.1%) of primary outcomes occurred in the cholestyramine arm and 187 events (9.8%) in the placebo arm. The estimated relative risk reduction (RRR) for the primary endpoint was 19% (90% confidence interval (CI): 3%–32%). However, the RRR for all-cause death was not statistically significant as deaths due to accidents and violence were greater in the cholestyramine arm.

Since their first market appearance in 1987, statins have been the most used lipid-lowering drugs. The first trial that tested a statin in the primary prevention of CHD was WOSCOPS (West of Scotland Coronary Prevention Study) (Shepherd et al., 1995). It was a DB-RCT and included 6595 men with hypercholesterolemia and no history of MI aged 45–64 years. Their mean TC was 7.0 ± 0.6 (standard deviation, SD) mmol/L. The subjects were randomly assigned to pravastatin (daily use: 40 mg each evening) or a placebo and followed for 4.9 years. In the pravastatin arm, serum TC and LDL-C were lowered 20% and 26%, respectively, at the end of the trial. The event numbers for the primary endpoint were 248 of 3293 in the placebo arm and 174 of 3302 in the pravastatin arm, corresponding to a 31% risk reduction (95% CI: 17%–43%, $P<0.001$). In addition, there was no difference in deaths due to non-CVD such as suicide, trauma, and cancer. Overall, a 22% reduction of total deaths was observed in the pravastatin arm (95% CI: 0%–40%, $P=0.051$). The WOSCOPS study was the first trial to show not only a preventive effect for primary CHD events but also no evidence for an increase in adverse events, which until then had been a concern about use of statins.

The AFCAPS/TexCAPS (Air Force/Texas Coronary Atherosclerosis Prevention Study) (Downs et al., 1998) evaluated the efficacy of lovastatin in a population that had no history of CHD and had normal serum TC (4.65–6.82 mmol/L) and LDL-C (3.36–4.91 mmol/L) levels but low HDL-C (≤1.16 mmol/L for men, ≤1.22 mmol/L for women). The study was a DB-RCT with placebo. The total number of subjects was 6605, who were divided into a lovastatin arm (daily use 20–40 mg, $n=3304$) and a

placebo arm ($n=3301$). The primary endpoint was a major CHD event defined by fatal or nonfatal MI, unstable angina, or sudden cardiac death. The mean follow-up period was 5.2 years. Lovastatin reduced LDL-C by 25% and increased HDL-C by 6% during follow-up. 116 major CHD events were observed in the lovastatin arm and 183 events in the placebo arm. The estimated RR for lovastatin vs. placebo was 0.63 (95% CI: 0.50–0.79, $P<0.001$). The results of this study suggested that lipid-lowering treatment with a statin may be beneficial even for subjects with low-serum HDL-C and normal TC/LDL-C levels.

The target of CARDS (Collaborative Atorvastatin Diabetes Study) (Colhoun et al., 2004) was patients with type 2 diabetes mellitus without high-serum LDL-C ($\leq$4.14 mmol/L). The participants also each had at least one of the following risk factors: retinopathy, albuminuria, current smoking, and hypertension. This DC-RCT with a placebo arm enrolled 2838 patients aged 40–75 years who had no previous history of CVD. They were randomly assigned to atorvastatin (daily use 10 mg, $n=1428$) or placebo ($n=1410$), and the primary endpoint was the first event, defined as acute CHD, coronary revascularization, or stroke. The trial was stopped 2 years earlier than expected because the early stopping rule for efficacy was adopted. At the end of the trial, 83 primary events had occurred in the atorvastatin arm (5.8%, 1.54 per 100 person-years at risk) and 127 events in the placebo arm (9.0%, 2.46 per 100 person-years at risk). The estimated RRR between the two arms was 37% (95% CI: −52 to −17), $P=0.001$). In addition, subgroup analyses showed risk reductions for both stroke and acute CHD.

These studies were performed in Western countries, where the incidences of CHD are relatively high. MEGA (Management of Elevated Cholesterol in the Primary Prevention Group of Adult Japanese) (Nakamura et al., 2006) was the first trial to evaluate the effectiveness of pravastatin for the primary prevention of CHD in Japan, where the incidence of CHD is low. This trial was based on the PROBE design (prospective, randomized, open-labeled, blinded study) and included 7832 patients with hypercholesterolemia (serum TC, 5.69–6.98 mmol/L) and no history of CHD or stroke. The primary endpoint was the first episode of CHD, defined as fatal or nonfatal MI, angina, cardiac sudden death, and coronary revascularization. The mean follow-up period was 5.3 years, and 3966 patients were assigned to the diet therapy arm and 3866 to the diet therapy plus pravastatin arm (daily use 10–20 mg). At the end of the trial, the reductions of serum TC and LDL-C were 2.1% and 3.2%, respectively, in the diet only arm and 11.5% and 18% in the diet plus pravastatin arm. For the primary endpoint, 66 events were observed in the diet plus pravastatin arm and 101 in the diet only arm. The estimated hazard ratio (HR) indicated that the diet plus pravastatin arm had significantly fewer CHD events (HR: 0.67, 95% CI: 0.49–0.91, $P=0.01$).

A metaanalysis of randomized control trials (RCTs), including the trials mentioned earlier, confirmed that statins prevented primary CVD (Taylor et al., 2013) (**Table 1**). Totally 20 to 30% relative risk reductions for CVD, CHD and stroke were observed in this metaanalysis.

The results of epidemiological studies have suggested that a high intake of long-chain n-3 fatty acids may reduce the risk of CVD events (Burr et al., 1989; Lemaitre et al., 2003). To test this hypothesis, the PROBE trial called JELIS (Japan EPA Lipid Intervention Study) was performed in Japan (Yokoyama et al., 2007), where consumption of fish is higher than in Western countries. The primary endpoint was a major coronary event, defined as sudden cardiac death, fatal or nonfatal MI, and other nonfatal events including unstable angina pectoris, angioplasty, stenting, or coronary artery bypass grafting. The participants were 18,645 patients with serum TC$\geq$6.5 mmol/L and were composed of a primary prevention group ($n=14,981$) and a secondary prevention group ($n=3664$). A total of 9326 patients were assigned to eicosapentaenoic acid (EPA) plus a statin (intervention arm), and 9319 patients were assigned to a statin only (control arm). The mean follow-up period was 4.6 years. At the end of the trial, there were 262 events (2.8%) in the intervention arm and 324 events (3.5%) in the control arm. The estimated HR for intervention vs. control was 0.81 (95% CI: 0.69–0.95, $P=0.011$). However, when the analysis was limited to primary prevention, there was no significant difference between the intervention and control groups (1.4% vs. 1.7%, respectively, $P=0.132$).

Clinical Trials of Secondary Prevention

The first DB-RCT trial that evaluated secondary prevention for CVD with a statin was 4S (Scandinavian Simvastatin Survival Study) (Scandinavian Simvastatin Survival Study group, 1994). The primary endpoint was all-cause death, and the secondary endpoint was a major CHD event (coronary death, nonfatal MI, resuscitated cardiac arrest, or definite silent MI confirmed by electrocardiogram). 4444 patients with hypercholesterolemia (serum TC 5.5–8.0 mmol/L) who had experienced angina pectoris or had suffered a MI were randomly assigned to simvastatin (daily use 20–40 mg, $n=2221$) or placebo ($n=2223$). The median follow-up period was 5.4 years. For the primary endpoint, 182 deaths (8%) were observed in the simvastatin arm and 256 deaths (12%) in the placebo arm. The estimated RR for total death in the simvastatin arm was 0.70 (95% CI: 0.58–0.85, $P=0.0003$). For the secondary endpoint,

Table 1 The results of the metaanalysis for primary prevention of CVDs

Endpoint	*No. of studies*	*No. of participants*	*Summary RR (95% CI)*
Total number of CVD events	9	23,805	0.75 (0.70–0.81)
Total number of CHD events	14	48,049	0.73 (0.67–0.80)
Total number of stroke events	10	40.295	0.78 (0.68–0.89)
Total mortality	13	48,060	0.86 (0.79–0.94)[a]

CVD, cardiovascular disease; *CHD*, coronary heart disease; *RR*, risk ratio; *CI*, confidence interval.
[a]Estimated as summary odds raio.

there were 431 events (19%) in the simvastatin arm and 622 (28%) in the placebo arm, demonstrating a significant risk reduction in the simvastatin arm (RR: 0.66, 95% CI: 0.59–0.75, $P<0.00001$).

The object of CARE (Cholesterol and Recurrent Events) (Sacks et al., 1996) was to investigate a secondary prevention effect using a statin in patients who had a history of MI and a normal serum profile. The primary endpoint was a fatal coronary event or nonfatal MI. This DB-RCT included 4159 patients, who were randomly assigned to pravastatin (daily use 40 mg/day, $n=2081$) or a placebo ($n=2078$). During a mean follow-up of 5 years, 212 events (10.2%) were observed in the pravastatin group and 274 events (13.2%) in the placebo group, corresponding to a RRR of 24% (95% CI: 9%–36%, $P=0.003$). However, in those patients with serum TC $\leq$ 3.2 mmol/L, pravastatin had not significantly prevented recurrent CHD events. On the other hand, additional posthoc analysis of CARE (Plehn et al., 1999) showed that pravastatin also reduced stroke and stroke or transient ischemic attack in patients with a history of MI.

A metaanalysis of the RCTs including 4S and CARE confirmed that statins were effective in the secondary prevention of CVD (Gutierrez et al., 2012) (**Table 2**). The estimated relative risk reductions were about 15% to 25% for CVD, CHD and stroke.

In contrast to the result in the primary prevention group of JELIS (Yokoyama et al., 2007), major secondary coronary events in the intervention arm were reduced by 19% relative to the control arm (intervention arm: 8.7%, control arm: 10.7%, $P=0.048$). The discrepancy between the results obtained for primary and secondary prevention suggests that the benefit of EPA treatment may be stronger for higher-risk individuals than it is for lower-risk ones.

Recently, new evidence was provided by IMPROVE-IT (Improved Reduction of Outcomes: Vytorin Efficacy International Trial) (Cannon et al., 2015). The participants of this DB-RCT were 18,144 patients who had been hospitalized because of ACS within the preceding 10 days. Their serum LDL-C levels were in the range of 1.3–2.6 mmol/L if receiving lipid-lowering therapy, or 1.3–3.2 mmol/L if not receiving such therapy. Both of these ranges were within guideline recommendations (Grundy et al., 2004; Perk et al., 2012). The trial compared the combination of simvastatin (40 mg/day) and ezetimibe (10 mg/day) with simvastatin alone (40 mg/day) for the secondary prevention of CVD events, defined as cardiovascular death, nonfatal MI, unstable angina requiring rehospitalization, coronary revascularization ($\geq$30 days after randomization), or nonfatal stroke. After the standard treatment for ACS, the participants were randomly assigned to a combination arm ($n=9067$) and a monotherapy arm ($n=9077$). The median follow-up period was 6 years. The median time-weighted average serum LDL-C level was 1.4 mmol/L in the combination group and 1.8 mmol/L in the monotherapy group ($P<0.001$). The Kaplan–Meier event rate for the primary endpoint was 32.7% (combination) versus 34.7% (monotherapy). The estimated absolute risk difference was 2.0%, and the HR was 0.936 (95% CI: 0.89–0.99, $P=0.016$). The rates of adverse events such as hepatic disorder, myopathy, and cancer were not different between the two arms. IMPROVE-IT was the first trial that supported the treatment concept "the lower, the better" for reducing CVD events by lowering serum LDL-C levels below guideline recommendations and showed the prevention effect for recurrent CVD events of adding another lipid-lowering drug to a statin.

Conclusions From Clinical Trials

The evidence that lipid-lowering therapies, especially statins, can reduce the risk of CVD events through reduction of serum lipid levels is now well established. However, the estimated risk reduction rates for CVD events were at most only 30%. Therefore, control of the residual risk by new therapies or treatment concepts is needed for greater prevention of CVD.

Traditional but Long-Standing Problems

Is HDL-C a Causal Protective Factor for CHD?

Serum HDL-C concentration has been known to be a protective factor for CHD since the first the epidemiologic report from the Tromsø heart-study (Miller et al., 1977). The principal mechanism postulated for the protective effect of HDL is reverse cholesterol transport, which opposes cholesterol accumulation in artery walls due to LDL-C deposition. This may show its protective effect only in the presence of a high-serum level of LDL-C. Recently, a large pooled analysis from Japan where mean LDL-C levels were lower than those of Westerners showed that isolated low HDL-C was not associated with an increased risk of CHD (Hirata et al., 2016).

The results of a large Mendelian randomization analysis reconfirmed the causal effect of LDL-C on CHD, but a causal association of HDL-C with CHD was less clear (Holmes et al., 2015). Among patients with ASCVD and normal LDL-C levels, there was no clinical benefit from addition of niacin to statin therapy, despite a significant increase in HDL-C (AIM-HIGH Investigators

Table 2 The results of the metaanalysis for secondary prevention of CVDs

Endpoint	*No. of studies*	*No. of participants*	*Summary RR (95% CI)*
Total number of CVD events	11	43,191	0.81 (0.78–0.85)
Total number of MI events	4	13,916	0.73 (0.65–0.81)
Total number of stroke events	7	27,746	0.84 (0.76–0.93)
Total mortality	5	19,059	0.81 (0.75–0.88)

CVD, cardiovascular disease; *MI*, myocardial infarction; *RR*, risk ratio; *CI*, confidence interval.

et al., 2011). Furthermore, a clinical trial using a cholesteryl ester transfer protein inhibitor failed to show a protective effect for CHD (Barter et al., 2007).

These findings indicate two possibilities. One is that a low HDL-C per se is not a risk factor for CHD but is instead a surrogate marker of metabolic syndrome with impaired glucose tolerance. The other is that it is not so much the serum level of HDL-C that matters for CHD but the antiatherosclerotic function of HDL particles. Accordingly, we need clinical trials or Mendelian randomization studies that focus on improvement of HDL function, in other words the quality of HDL. Further studies that provide such information are warranted.

Weak Association Between Hypercholesterolemia and Stroke

In contrast to the case of CAD, relatively little attention has been given to the relations between hypercholesterolemia and stroke, even though stroke has been the most common CVD in East Asia, the most populated region in the world (Ueshima et al., 2008). The majority of cohort studies in Japan have failed to demonstrate a positive relation between hypercholesterolemia and stroke (Tanaka and Okamura, 2012). Indeed, even in the Western populations, the relation between hypercholesterolemia and stroke is controversial and less clear. A positive association between TC and cerebral infarction was observed in the MRFIT trial in the United States (Iso et al., 1989) and in the Copenhagen City Heart Study in Europe. On the other hand, the ARIC Study did not find TC to be associated with the incidence of cerebral infarction. Hypercholesterolemia was associated only with nonlacunar, nonembolic stroke, in other words, atherothrombotic cerebral infarction (Kurth et al., 2007). A large metaanalysis of data from 61 prospective studies, most of which were carried out in the United States and Europe, showed the absence of independent positive associations between TC and ischemic and total stroke mortalities (Prospective Studies Collaboration, 2007). Consequently, the relation between hypercholesterolemia and cerebral infarction may be modified by the proportion of atherothrombotic cerebral infarctions in the populations surveyed.

On the other hand, recent RCTs using statins have shown substantial reductions in cerebral infarction (Mills et al., 2008; Vergouwen et al., 2008). However, caution is needed when interpreting the results of these trials. In the protocols of most clinical trials, the primary endpoint was CHD, and cerebral infarction was usually set as a secondary endpoint. To our knowledge, the Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) and the Japan Statin Treatment against Recurrent Stroke Trial (J-STARS) are only two trials that were designed with stroke as the primary endpoint (Amarenco et al., 2006; Hosomi et al., 2015). Although both found a protective effect of statins against stroke, the first study found a relatively small effect (16% risk reduction), and the second found a reduction of only atherothrombotic infarction occupying one-fourth of cerebral infarction. Furthermore, statins have pleiotropic effects, such as antiinflammatory actions, that may reduce atherosclerosis. This may be the reason why we observed a discrepancy between cohort studies and clinical trials, which to date has not been adequately explained, and which was not observed in relation to hypercholesterolemia and CHD, or to hypertension and stroke.

Low Blood Cholesterol and Noncoronary Mortality

In 1980, Japanese investigators reported that community dwellers with low-serum TC levels had a high risk of intraparenchymal hemorrhage (Ueshima et al., 1980). At the end of the 1980s, similar results were observed in the United States (Iso et al., 1989). In 1990, an NHLBI conference was held to discuss associations between low blood cholesterol and noncoronary mortality (Jacobs et al., 1992). Most of the inverse associations between cholesterol and noncoronary mortality, such as malignancy and chronic pulmonary diseases, were thought to be explained by latent preexisting disease, unconsidered confounding factors, and SES. The only concern expressed in the report was the possibility of a causal relationship between low TC and intraparenchymal hemorrhage. The associations between low TC levels and intraparenchymal hemorrhage in previous cohort studies were not rare findings, although they were scarcely observed in populations with a very low incidence of intraparenchymal hemorrhage such as the United States. Furthermore, even in a metaanalysis of clinical trials the results were controversial (Boekholdt et al., 2014; Cholesterol Treatment Trialists' (CTT) Collaboration (2015)). In SPARCL, intraparenchymal hemorrhage was more frequent in those treated with a statin, especially in those with a past history of hemorrhagic stroke or hypertension (Amarenco et al., 2006) although similar results were not observed in the J-SATARS trial (Hosomi et al., 2015).

The pathologic link between hypercholesterolemia and coronary artery disease is atherothrombosis, but that between hypercholesterolemia and intraparenchymal hemorrhage is angionecrosis in a penetrating arteriole, which is also the main focus of lacunar infarction (Konishi et al., 1990). Low blood cholesterol may causally induce angionecrosis although there is little experimental evidence. As another hypothesis, low blood cholesterol might reflect nutritional status, which might influence mortality rate after the event. An inverse association between low cholesterol and intraparenchymal hemorrhage seems to have been well documented when the endpoint was mortality (Tanaka and Okamura, 2012). Nevertheless, further experimental, clinical, and epidemiological studies are warranted to examine these hypotheses.

Introduction

Since its initial description by Jervell and Lange-Nielsen (1957) the congenital long QT syndrome (LQTS) has been the most investigated cardiac ion channelopathy. A prolonged QT interval in the surface electrocardiogram (ECG) is the *sine qua non* of the LQTS and is a surrogate measure of the ventricular action potential duration (APD). Congenital as well as acquired alterations in certain cardiac ion channels can affect their currents in such a way as to increase the APD and hence the QT interval. The inhomogeneous lengthening of the APD across the ventricular wall results in dispersion of APD, that is, of ventricular repolarization (VR). This together with the tendency of prolonged APD to be associated with oscillations at the plateau level, termed early afterdepolarizations (EADs), provides the substrate of ventricular tachyarrhythmia (VT) associated with LQTS, usually referred to as Torsade de Pointes (TdP) VT (El-Sherif and Turitto, 1999). The term was first coined by Dessertenne who described its ECG pattern of continuously changing morphology of the QRS complexes that seem to twist around an imaginary baseline (Dessertenne, 1966). The quasimusical term (**Fig. 1**) and the intriguing ECG pattern have caught the attention of electrophysiologists for years and have been, to some extent, a driving force behind the recent focused interest into the role of genetics and cardiac ion channel pathophysiology in cardiac arrhythmias (El-Sherif and Turitto, 1999).

Acquired LQTS is by far more prevalent than congenital LQTS. The vast majority of acquired LQTS is the result of adverse effect of drugs (Kannankeril et al., 2010) and/or electrolyte abnormalities (El-Sherif and Turitto, 2011) that interact in the majority of cases with the Human Ether-à-go-go-Related Gene (HERG) encoding the pore-forming subunits (Kv11.1) of the rapidly activating delayed rectifier current, I_{Kr}.

This article review the genetic, molecular, and phenotype characteristics of both congenital and acquired LQTS as well as current management strategies and future directions in the field.

ECG Characteristics of TdP

In an updated analysis of 150 different episodes of non-sustained VT obtained from 62 patients with the acquired LQTS (El-Sherif and Turitto, 1999), the arrhythmia ranged in length from 3 beats (the definition of nonsustained VT) up to 117 beats (**Fig. 2A**) with an average length of 16 ± 8 beats. The cycle length (CL) of these episodes ranged from 193 to 364 ms with an average of 279 ± 47 ms. The VT was frequently preceded by a variable period of bigeminal rhythm due to one or two premature ventricular beats coupled to the prolonged QT segment of the preceding basic beat (**Fig. 2**, panels A and C). This so called short-long cardiac sequence is seen in both the acquired and congenital LQTS, and the arrhythmogenic mechanism is related to increased dispersion of repolarization (DR).

Following termination of an episode of fast VT, it was not uncommon to see one or more ectopic beats of variable configuration occurring at much longer CL compared to that of the VT (see beats marked by stars in **Fig. 2**). The change in QRS configuration during VT can take several forms. During a very fast VT, periodic decrease in the amplitude of the entire QRS-T complex is seen with less distinct shifts in QRS axis (**Fig. 2A**). In VTs with slower rates, the classic twisting of the QRS axis from a predominantly positive to a predominantly negative configuration with a variable number of transitional complexes and vice versa is commonly seen (**Fig. 2B**). Sometimes, a polymorphic QRS configuration is seen without any of the two previously characteristic patterns (as verified in multiple simultaneous leads, **Fig. 2C**, middle recording). Different patterns can be seen in different VT episodes from the same patient (**Fig. 2C**).

Fig. 1 The daily utterance of the term "torsade" in French refers to different bakery items, including bread loaves with characteristic twisting configuration. The above card displays one advertisement for such products.

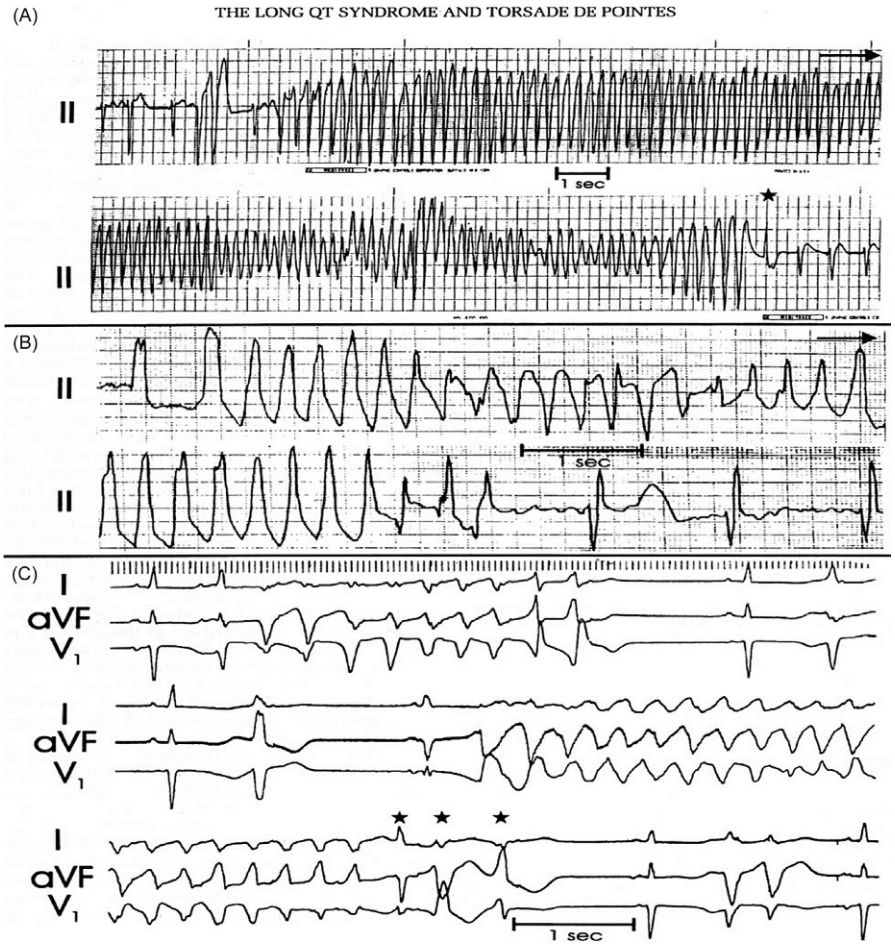

Fig. 2 Three electrocardiographic examples of acquired long QT syndrome (LQTS) and torsade de pointes (TdP). Panel A was obtained from a 23-year-old woman who had human immunodeficiency virus (HIV) positive and was receiving pentamidine. The patient was admitted with severe diarrhea and hypokalemia. Panel B was recorded from a 62-year-old man with hypertension and chronic atrial fibrillation who was receiving digoxin and hydrochlorothiazide and had a potassium level of 3.2 mEql. The TdP tachycardia developed 12 h after the patient received a total of four tablets of quinidine gluconate in an attempt to restore normal sinus rhythm. Panel C was obtained from a 64-year-old man who was receiving procainamide for suppression of very frequent ventricular premature complexes. N.B. pentamidine, quinidine, and procainamide are considered a group of drugs with high risk of drug-induced acquired QT syndrome and their use is currently curtailed. Reproduced with permission from El-Sherif N, Turitto G, Pace 1999;22:91–110.

QT/T Wave Alternans and TdP

It has long been known that tachycardia-dependent T wave alternans (TWA) occurs in patients with the congenital or acquired form of the LQTS and may presage the onset of TdP (Fig. 3).

In analysis of 1103 LQTS patients with QTc interval >0.44 s from the International LQTS Registry, TWA was recorded in 30 patients (Moss, 1995). The frequency of occurrence of TWA was directly proportional to the length of the QTc interval on the enrollment ECG. TWA occurred in one or more occasions during an average 4-year follow-up in 21% of the patients with QTc > 0.60 s, but in <0.2% of the patients with QTc <0.50 s. Patients with advanced forms of TWA (those with bidirectional beat-to-beat changes in T wave polarity; $n = 21$) were younger, had longer QTc values, had a higher incidence of complex VT, and were more likely to experience a cardiac event (syncope or cardiac arrest) than those with less advanced forms of TWA (those without bidirectional beat-to-beat changes in T wave polarity; $n = 9$).

Although overt TWA in the ECG is not common, in recent years, digital signal-processing techniques have made it possible to detect subtle degrees of TWA. This suggests that the phenomenon may be more prevalent than previously recognized and may represent an important marker of vulnerability to VT (Verrier et al., 2011). Interest in TWA is attributed to the hypothesis that it reflects a greater degree of underlying DR (Chinushi et al., 1998).

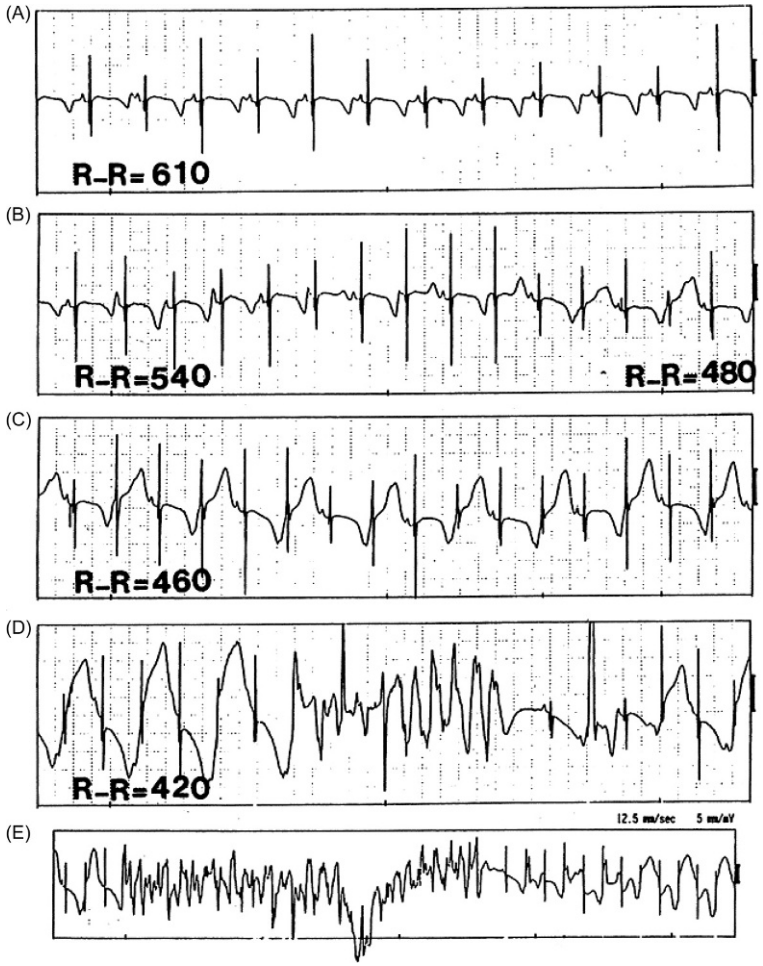

Fig. 3 Tachycardia-dependent QT alternans from a newborn baby with the Romano-Ward long QT syndrome (LQTS). The figure illustrates the development of TWA with gradual acceleration of the heart rate. At a cardiac cycle length (CL) of 610 ms (panel A), the QTU interval was 440–480 ms and TWA alternans was not discernible. Gradual shortening of the CL to 540 ms resulted in TWA alternans that became more prominent at shorter CLs (panels B and C). In panel D, on further shortening of the CL to 420 ms, TWA alternans was markedly exaggerated and was associated with the onset of nonsustained polymorphic ventricular tachycardia (VT) with a twisting QRS morphology characteristic of torsade de pointes (TdP). Panel E was recorded at reduced paper speed to illustrate the onset and termination of a longer run of TdP that was also associated with marked TWA alternans at a sinus CL of 420–440 ms. Reproduced with permission from Habbab MA, El-Sherif N, Pace 1992;15:916–931.

Genotype-Specific T-Wave Morphology

The ventricular myocardial action potential changes are based on the affected ion channels along with the distributive pattern of channels in the layers of the myocardium. Multiple ST-segment and T-wave morphologies associated with a particular genotype have been delineated (Zareba, 2006). Due to the small available sample sizes, this association has been restricted to the most common genotypes (LQT1, LQT2, and LQT3). Presence of broad-based T-waves in LQT1, low-amplitude T-waves in LQT2, and late-peaking T-waves in LQT3 was initially demonstrated by Moss et al. (1995). This association was demonstrated in-vitro, based on models affecting particular ion channels (Antzelevitch, 2003). Further delineation of the T-wave morphology was done by Zhang et al. using 284 LQTS carriers; demonstrating 10 typical patterns (4 LQT1, 4 LQT2, and 2 LQT3) (Zhang et al., 2000). In this study, LQT1 carriers demonstrated normal or broad-based T-wave pattern consistent with the homogenous action potential prolongation caused by affecting I_{Kr}. LQT2 carriers had a bifid T-wave pattern, thought to be a result of increased transmural dispersion due to greater increase in APD in the M cells of the myocardium compared to the endocardium or the epicardium. Due to the delay in opening of the sodium channels and hence phase 2 of the action potential, LQT3 patients had a late-peaked T-wave (Fig. 4).

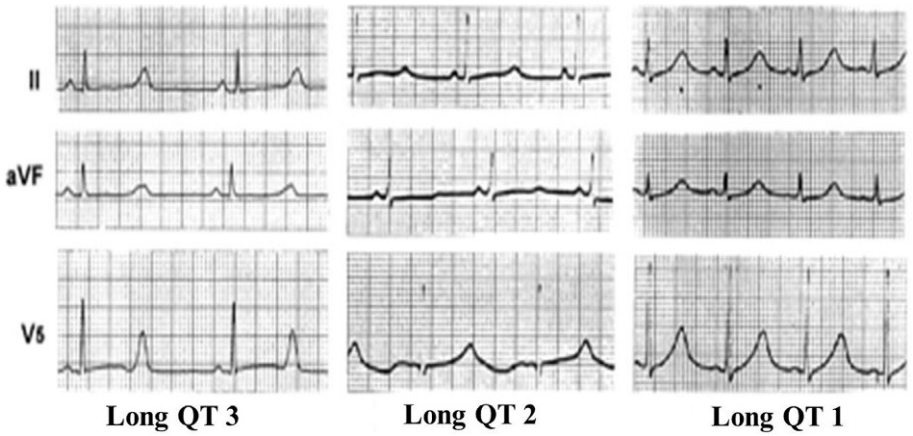

Fig. 4 Genotype-specific T-wave morphology of the common genotypes: LQT1 is characterized by broad-based T-waves; LQT2 by low-amplitude T-waves, and LQT3 by late-peaking T-waves. Reproduced with permission from Moss et al., Circulation 1995;92:2929–2934.

A Paradigm of TdP From Ion Channels to ECG

Figs. 5 and 6 are a composite that is intended to briefly summarize the correlation between the molecular mutation of an ion channel, the electrophysiological consequence, and the final phenotype presentation of LQTS. The gene selected encodes for the α subunit of the Na channel SCN5A whose mutation can result in LQT3, together with the *β* subunit of the channel, SCN4B, whose mutation results in LQT10 (Medeiros-Domingo et al., 2007). Over 200 different mutations of the SCN5A have been identified, the majority giving rise to LQT3. There is wide variation in the phenotypic presentation of different mutations. In general, mutations involving subunits results in a milder form of the disease as compared to mutations involving the pore forming region of the channel. An interesting aspect of the cardiac Na channel is that some mutations can result in different electrophysiological syndromes other than LQTS. This phenomenon is referred to as cardiac Na channel overlap syndrome (Remme et al., 2008). Certain mutations can result in Brugada syndrome, sick sinus syndrome, atrial stand still, atrial fibrillation, and cardiac conduction defects. Thus, although these syndromes were originally considered separate entities, various SCN5A-related arrhythmia syndromes are now known to display mixed phenotypes. This understanding could have an important impact on the management of cardiac ion channelopathies.

Fig. 5, panel A illustrates an ECG obtained from an infant with LQT3 that shows a nonsustained run of TdP. The first four beats of the recording are sinus rhythm and show the marked prolongation of the QT interval, the hall mark of the LQTS. Fig. 5, panel B is a diagrammatic illustration of the α subunit of the Na channel SCN5A and its β subunit, SCNB4.

Fig. 6, panels A–D illustrates the whole spectrum of the electrophysiological consequence of Na channel mutations causing LQT3. The panels represent data obtained from a surrogate model of LQT3 that faithfully reproduced the genetic counterpart. The model is created by the neurotoxin Anthopleurin-A (AP-A) (El-Sherif et al., 1988). Of interest, the experimental surrogate model of LQT3 anticipated the first description of the clinical LQT3 (Wang et al., 1995) by 7 years. Panel A illustrates the effect of ATXII on the behavior of single unitary Na channels. The control Na channel opens briefly, on average only once. In contrast, Na channels exposed to ATXII, a similar neurotoxin to AP-A, show long-lasting burst consisting of repetitive long openings interrupted by brief closures. The effects of ATXII on the Na channel (El-Sherif et al., 1992) are almost identical to the effects of the clinical mutations of the SCN5A a subunit on the function of the channel (Bennett et al., 1995). This abnormality of Na channel relaxation has the consequence of inducing consistent Na current during the plateau phase of the AP resulting in significant prolongation of the APD as shown in panel B. Panel B shows AP recordings from a Purkinje fiber and a mid-myocardial (M) fiber. Both fibers show marked prolongation of APD. The Purkinje fiber, in particular, shows the development of multiple oscillatory responses at the plateau level characteristic of EADs. Panel C shows the differential prolongation of APD of different myocardial fibers across the left ventricular wall. It illustrates AP recordings from an epicardial (EPI), mid-myocardial (M), and endocardial (END) myocardial fiber from a transmural slice from a canine left ventricular wall. Because of the different ionic constituents of different myocardial fibers, the drug results in differentially more marked prolongation of the M cell compared to EPI and END cells (Sicouri and Antzelevitch, 1995).

Panel D represents tridimensional activation maps of a 12-beat run of TdP from the in vivo canine surrogate AP-A model of LQT3 and helps to summarize the final electrophysiological mechanism of TdP in the LQTS. The first beat of a TdP is due to EAD-triggered beat from the subendocardial Purkinje network that acts on the transmural dispersion of myocardial repolarization to induce reentrant excitation in the form of circulating tridimensional wave fronts (the thick continuous line that traces the activation wave front from one beat to the next (El-Sherif et al., 1996). The twisting QRS pattern of the classic TdP is attributed in this example to transient bifurcation of a predominately single rotating wavefront into two separate simultaneous wave fronts rotating around the left and right ventricular cavities (El-Sherif et al., 1997).

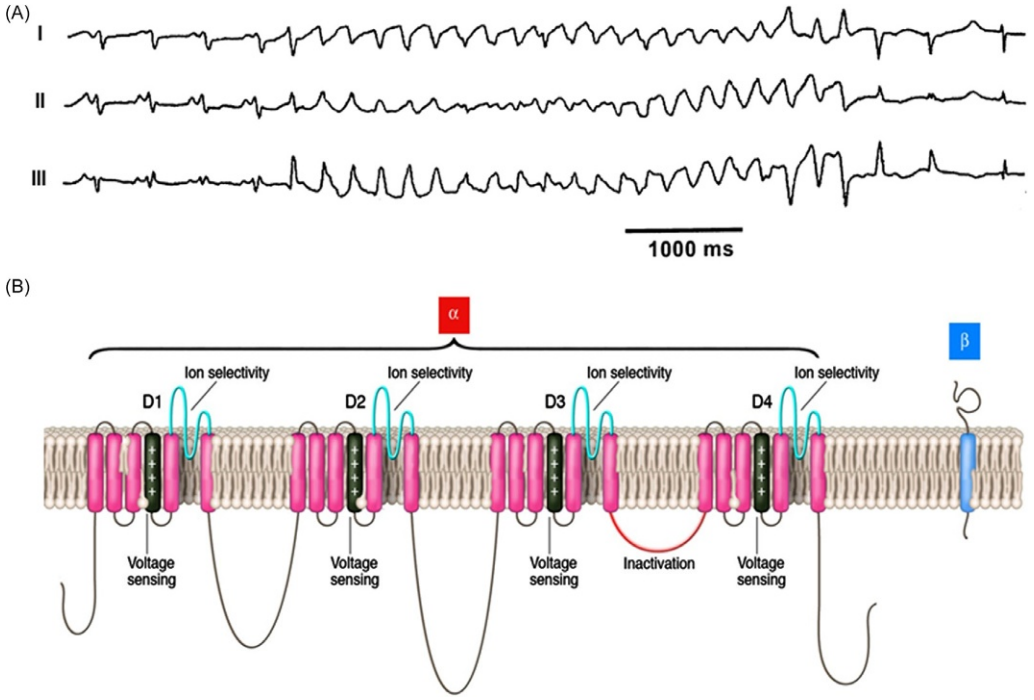

Fig. 5 (A) Electrocardiographic recording from an infant with LQT3. The first four beats are sinus showing prolonged QT interval followed by a nonsustained run of polymorphic ventricular tachycardia with the characteristic Torsade de Pointes pattern. (B) Diagrammatic presentation of the α subunit of the Na channel KCN5A whose mutation can result in LQT3, together with the β-subunit of the channel, SCN4B, whose mutation results in LQT10.

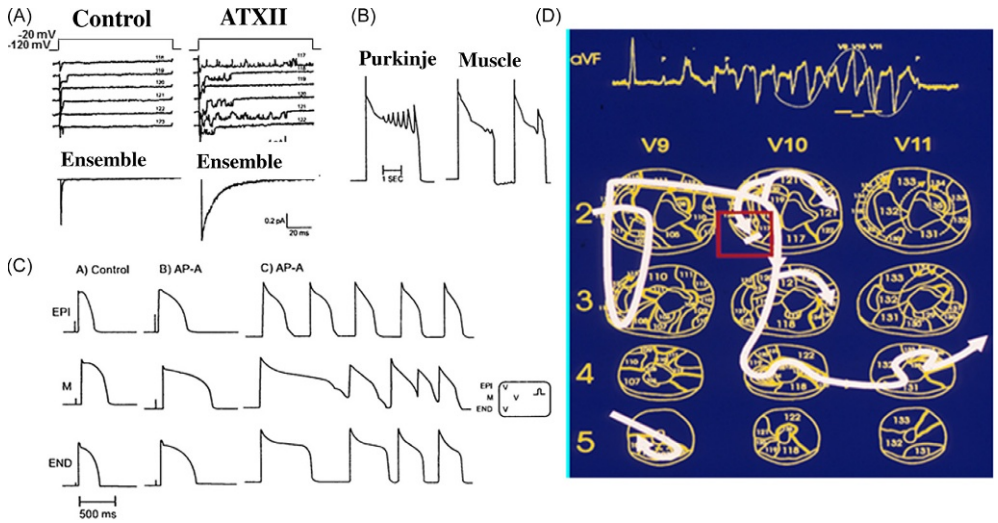

Fig. 6 Composite figure that illustrates the correlation between the specific molecular changes of the Na channel that result in LQT3, the electrophysiological consequence, and the final phenotype presentation of LQTS. (A) Cell-attached patch clamp recordings of the Na channel during control and following superfusion with ATXII. This neurotoxin faithfully reproduces the molecular changes associated with the clinical mutations of the Na channel in patients with LQT3. It illustrates sequential recordings of single Na channel current responses during depolarizing steps from −120 to −20 mV from rabbit cardiomyocytes. The left panel shows control recordings and the right panel shows recordings from a patch exposed to 100 nM of ATXII that resulted in long-lasting burst consisting of repetitive long opening interrupted by brief closures. The ensemble current from this patch shows markedly slowed relaxation. (B) Action potential recordings from a Purkinje fiber (PF) and a mid-myocardial (M) cell; both isolated from a 10-week-old puppy and placed in the same chamber perfused with 50 mg/L AP-A and stimulated at 3000 ms. The PF shows a series of early afterdepolarizations (EADs) that increased gradually in amplitude before final repolarization. (C) Simultaneous recordings from a subepicardial cell (EPI), M cell, and a subendocardial cell (END) from a transmural strip isolated from the left ventricle of a 12-week-old puppy and transfused with 50 mg/L AP-A and stimulated at 4000 ms. AP-A resulted in marked differential prolongation of the action potential of the M cell resulting in asynchronous activation in the preparation which is a substrate of reentrant excitation. (D) Illustration of cardiac tridimensional activation maps of a 12-beat run of TdP VT from the in vivo canine surrogate AP-A model of LQT3 and helps to summarize the final electrophysiological mechanism of the characteristic twisting QRS configuration of the TdP electrocardiogram in the LQTS.

Genotype of LQTS

Table 1 illustrates the heterogeneity of the genetic, molecular, and ionic basis of the congenital LQTS (Giudicessi and Ackerman, 2013). To date mutations of 16 different genes have been identified in patients clinically diagnosed with LQTS. Since approximately 20% of LQTS eludes genetic classification, this list is expected to grow. Loss of function of one of several potassium (K^+) channels, gain of function of the sodium (Na^+) and calcium (Ca^{2+}) channels are the three abnormalities that can result in prolongation of APD and LQTS. The three channels abnormal behavior can be traced to either gene mutations involving the channel protein itself or mutations of membrane structural proteins that can indirectly affect the function of the channel (El-Sherif and Boutjdir, 2015). LQT1, LQT2, and LQT3, account for an estimated 75%–85% of genotype-positive LQTS cases, while minor LQT syndromes account for less than 5%. LQT1 is due to loss of function of the KCNQ1 that encodes for I_{Ks} (Barhanin et al., 1996; Sanguinetti et al., 1996) LQT2 is due to loss of function of KCNH2 channel that encodes for I_{Kr} (Sanguinetti et al., 1995), while LQT3 is due to gain of function of SCN5A α subunit of the Na channel that encodes for I_{Na} (Wang et al., 1995).

Homozygous or compound heterozygous mutations of KCNQ1 or KCNE1 occurring in recessive form underlie the relatively rare Jervel and Lang-Nielsen syndrome (JLNS) (Splawski et al., 1997; Duggal et al., 1998).

Some LQTS types are associated with somatic and neurological changes in addition to prolongation of the LQT interval. Loss of function of the KCNJ2 gene which encodes the inward rectifier K channel Kir2.1 (I_{K1}) results in a syndrome termed Anderson–Tawil syndrome (ATS) or LQT7. In addition to a long QT interval, periodic paralysis and dysmorphic features are present (Andersen et al., 1971; Tawil et al., 1994) Similarly, gain of function of mutations in the CA CNA1C gene which encodes the L-Type Ca channel Ca_v

Table 1 Genetic basis of Long-QT syndrome and multisystem syndromes associated with QT prolongation

Gene *(genotype)*	*Locus*	*Protein*	*Functional effect*	*Mode of inheritance*	*Frequency*	*References*
Long QT syndrome (major)						
KCNQ1 (LQT1)	11p15.5	Kv7.1	Reduced I_{Ks}	AD; AR	30%–35%	Wang et al. (1995), Sanguinetti et al. (1996)

1.2 leads to immunodeficiency and Autism in addition to prolonged QT interval and is termed Timothy syndrome (TS) or LQT8 (Splawski et al., 2004; Splawski et al., 2005). JLNS results in severe congenital bilateral sensorineural hearing loss in addition to marked QT interval prolongation with very high risk of cardiac events (Splawski et al., 1997).

Examples of mutations of structural proteins that affect the function of ion channels are LQT4 due to mutations of ankyrin gene encoding the anchoring β subunit ANK2 that leads to intracellular Ca overload (Mohler et al., 2003). LQT9 due to mutations of CAV3, which encodes caveolin-3 that alters the biophysical properties of the Na channel (Vatta et al., 2006), and LQT11 due to mutations of an A-kinase-anchoring protein (AKAP9-Yotiao) that binds to KCNQ1, responsible for the most common LQT1 syndrome, and depresses the function of the channel by reducing the c-AMP-induced phosphorylation (Chen et al., 2007).

Genotype-Specific Triggers for Cardiac Events

Sympathetic activation caused by conditions such as physical exercise triggers the activation of IKs which results in shorter VR at fast heart rates, which prevents afterdepolarizations caused by β1-adrenergic stimulation. Patients with LQT1, who have diminished IKs, are prone to develop prolonged VR during exercise, whereas patients with LQT2 and LQT3 who have intact IKs are relatively protected against this phenomenon. This failure of the QT interval to adapt at faster heart rates results in a high risk for afterdepolarization which can culminate in TdP. In a study of 670 asymptomatic LQTS patients, Schwartz et al. demonstrated that the majority of LQT1 patient's lethal and nonlethal cardiac events were triggered by exercise or stress, especially swimming (Schwartz et al., 2001). LQT2 patients are exquisitely sensitive to sudden auditory stimuli which is thought to mimic a fright response resulting in an abrupt release of local catecholamines leading to EADs and resultant TdP (Schwartz et al., 2001; Wilde et al., 1999).

Women with LQT2 are also at higher risk for cardiac events in the postpartum period. This is thought to be multifactorial, which likely includes hormonal changes, sleep disruption, and the sudden auditory stimuli caused by the crying neonate (Khositseth et al., 2004). In contrast, LQT3 patients seem to be more prone for cardiac events during sleep; this is hypothesized to be secondary to amplification of the inward flow of Na+ at low heart rate when time spent at a negative potential is increased (Schwartz et al., 2001; Stramba-Badiale et al., 2000).

Genetic Modifiers of LQTS Risk

In the last several years it became obvious that LQTS shows incomplete penetrance and variable expressivity. In other words, different clinical phenotypes (sudden cardiac death (SCD), syncope, asymptomatic) are observed in family members carrying the same familial mutation, which may suggest the influence of multiple genetic and environmental factors affecting the pathophysiology of LQTS (Mizusawa et al., 2014). The discovery of common genetic variants that explain the heritable component of the human ECG, including the QT interval, generated the hypothesis that genetic modifiers may account for phenotypical variability in LQTS. In LQTS, variants in the coding regions of LQTS-related genes such as KCNE1 D85N (Nishio et al., 2009), KCNH2 K897T (Crotti et al., 2005), and SCNA5A H558R (Makielski et al., 2003) are known to influence the QT interval. Single-nucleotide polymorphisms (SNPs) in noncoding regions (intron, 3′UTR) of KCNQ1 are also reported as an important QT interval modifier (Duchatelet et al., 2013). Genome-wide association studies (GWAS) have revealed SNPs in nitric oxide synthase 1 adaptor protein gene (NOS1AP) as modulator of QT interval in LQTS patients (Tomas et al., 2010), as well as in the general population (Arking et al., 2006). However, despite the fact that multiple SNPs have been linked to QT interval duration, the clinical applications of any findings are limited by the small effect sizes conferred by SNPs and incomplete knowledge of their functional consequences. Nevertheless, there is continuing efforts to understand the complexity of genotype–phenotype relationship in LQTS.

Risk Stratification of Congenital LQTS

Both genotypic (e.g., LQTS genetic, intragenic, and mutation-specific subtype) and phenotypic (e.g., gender, QTc, and history of cardiac events) characteristics are used to guide the risk stratification, and ultimately the clinical management, of patients with congenital LQTS (**Fig. 7**) (Giudicessi and Ackerman, 2013). Those patients who harbor LQT1-causative mutations on >1 KCNQ1 allele (e.g., JLNS and AR-LQT1) (Schwartz et al., 2006; Goldenberg et al., 2006) have suffered ≥ 10 cardiac events before the age of 18 (Sauer et al., 2007) or have TS at highest risk ($\geq 80\%$) of suffering from one or more LQTS-associated cardiac events before the age of 40, including a high rate of sudden cardiac arrest/death. Those patients require aggressive clinical management, which often involves more invasive approaches such as left cardiac sympathetic denervation (LCSD), and/or use of the implantable cardioverter defibrillator (ICD).

Similarly, individuals with a QTc ≥ 550 ms regardless of LQTS genotype (Sauer et al., 2007), a QTc ≥ 500 ms with an LQT1, LQT2, or males with an LQT3 genotype (Priori et al., 2003), non-JLNS patients with LQTS-causative mutations on >1 major LQTS-susceptibility allele (e.g., compound heterozygosity or digenic heterozygosity) (Westenskow et al., 2004; Mullally et al., 2013), or individuals who have suffered ≥ 2 but <10 cardiac events before the age of 18 (Sauer et al., 2007) are at higher risk ($\geq 50\%$) for suffering an LQTS-associated cardiac event(s) before the age of 40 and often require a combination of medical, surgical, or device-related management.

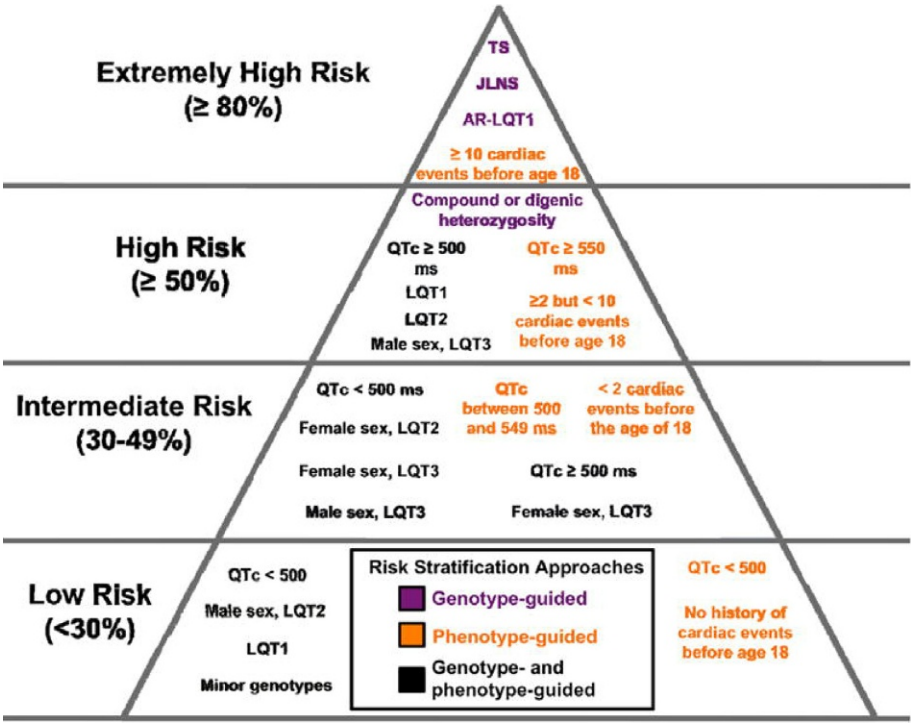

Fig. 7 Genotype- and phenotype-guided risk classification of long-QT syndrome patients: Risk groups have been defined based on the previously published probability of suffering a first or recurrent cardiac event (syncope, seizure, sudden cardiac arrest, or sudden cardiac death) before 40 years of age without appropriate therapeutic interventions. A probability of suffering a first cardiac event >80% defines the extremely high-risk group, >50% the high-risk group, between 30% and 49% as the intermediate-risk group, and below 30% as the lowest-risk group. Genotype-guided recommendations are indicated by purple text, phenotype-guided recommendations are indicated by orange text, and a combination of genotype- and phenotype-guided recommendations is indicated by black text within the figure. Reprinted with permission from Giudicessi JR, Ackerman MJ, Curr Probl cardiol, 2013;38(10):417–455.

Those individuals with a QTc between 500 and 549 ms regardless of genotype, females with major genotype-positive LQTS, male LQT3 patients with a QTc <500 ms, and any individual who has experienced <2 cardiac events before the age 18 are at intermediate risk for experiencing an LQTS-associated cardiac event(s) before the age of 40 and require some form of treatment, typically β-adrenergic blockers (Sauer et al., 2007; Priori et al., 2003).

Management of Congenital LQTS

Beta-blocker therapy is the first choice for LQTS. It dramatically decreases event rates from 0.97 to 0.31 events per patient per year (Moss et al., 2000). In addition to beta-blockers, there is a large number of adjuvant drugs that are tailored for a specific genetic abnormality (El-Sherif and Boutjdir, 2015). Patients who fail pharmacotherapy, patients with history of resuscitated cardiac arrest, and patients with J-LNS or TS are at particularly high risk and require other management modalities that is LCSD or the ICD. Besides medical treatment, life style modification is important, as well as meticulous avoidance of other drugs that can prolong the QT interval.

Detailed Pharmacotherapy in the LQTS

β-Blockers

β-Blockers are the main drugs of choice for LQTS irrespective of the genotype (Sauer et al., 2007; Moss et al., 2000). However, clinical data from the International Registry of LQTS found that β-blockers are more effective in preventing arrhythmias and SCD in LQT1 patients (81%) compared to LQT2 patients (59%) and LQT3 patients (50%) (Schwartz et al., 2001). This is due to the fact that arrhythmias in LQT1 patients are more frequently triggered by enhanced sympathetic stimulation. Despite β-blockers' efficacy in LQTS, a minority of patients remain symptomatic and in those patients additional therapeutic options like LCSD has been advocated (Schwartz et al., 2004). Alternatively, those patients may be candidates for the ICD. β-Blockers may be harmful in some patients with LQT3 if the heart rate is significantly slowed since bradycardia-dependent arrhythmias are more common in LQT3 patients.

Congenital LQTS in adults requires special risk stratification. A report from the International LQTS Registry has shown that the severity of LQTS in adulthood can be risk stratified with information regarding genotype, gender, QT duration, and history of cardiac events. β-Blockers effectively reduce but do not eliminate the risk of life-threatening cardiac events in congenital LQTS in adults (Sauer et al., 2007).

In a study including 382 LQT1 and LQT2 patients it was shown that not all β-blockers are equally effective (Chockalingam et al., 2012). In this regard, propranolol seems to be the most effective drug from this class, due to Na channel blocking action with limited effects on cardiac K channels. However, not only different properties on the various channels may influence the effectiveness of the β-blocker therapy, the precise location of a mutation in the underling gene and the specific type of resultant amino acid exchange has an impact on the effectiveness of the β-blocker therapy. For example, LQT1 patients with a missense mutation in a specific cytoplasmic loop region seem to benefit more from the β-blocker therapy than patients with other mutations (Barsheshet et al., 2012).

Pharmacotherapy in LQT2

Although LQT2 patients experience more life-threatening events under β-blocker therapy when compared with LQT1 patients, it still remains the first choice of therapy (Crotti et al., 2008). Analyzing 204 cardiac events of 634 genetically confirmed LQT2 patients from the US cohort of the International LQTS Registry, β-blocker therapy was associated with a pronounced reduction of exercise-triggered events but had a nonsignificant effect on the risk of arousal- and nonexercise/nonarousal events (Kim et al., 2010). Beside β-blockers, Na channel blockers such as mexiletine may also have a positive effect on the recurrence of cardiac events in LQT2 patients. In a small study of four LQT2 patients recurrent syncope and polymorphic VT occurred, although they received β-blocker therapy at full dose. An additional therapy with mexiletine resulted into a significant reduction in polymorphic VT and no syncope episodes occurred during follow-up (Ildarova et al., 2012).

Na Channel Blockers in LQT3 Patients

Since LQT3 syndrome is caused by gain of function due to delayed Na channel inactivation resulting in increased Na current during the plateau phase of AP, it comes to reason that Na channel blockers may be beneficial in LQT3 patients. Schwartz et al. demonstrated that a single oral dose of the Na channel blocker, mexiletine, administered to seven LQT3 patients with the AKPQ deletion produced significant shortening of the QTc interval within 4 h (Schwartz et al., 1995). Similar QTc shortening in LQT3 patients with the AKPQ deletion has been reported with lidocaine and tocainide (Rosero et al., 1997). Benhorin et al. reported QT shortening with flecainide in LQT3 patients with the D1790G mutation involving the SCN5A gene (Benhorin et al., 2000). Windle et al. showed normalization of the QTc interval with low doses of oral flecainide administered over 48 h in five patients with the AKPQ deletion (Windle et al., 2001). In vitro studies have shown that flecainide has high affinity for the Na channel protein and provides almost complete correction of the impaired inactivation associated with the AKPQ deletion (Nagatomo et al., 2000). Moss et al. have shown that chronic low-dose flecainide significantly shortens the QTc interval in LQT3 subjects with the AKPQ mutation with no major adverse drug effects, but the sample size was not large enough to evaluate the safety of flecainide therapy in patients with this mutation (Moss et al., 2005).

Several case reports describe that also phenytoin has antiarrhythmic effects in LQT3 patients (Vukmir and Stein, 1991). Phenytoin is thought to restore normal membrane responsiveness, to decrease basic sympathetic activity, to increase atrioventricular conduction velocity, and ventricular automaticity.

The Na channel inhibitor ranolazine was also shown to shorten the QT-interval effectively in five LQT3 patients (Moss et al., 2008). The underlying mechanism is the inhibition of late component of Na currents (predisposing indirectly to intracellular Ca overload) with only minimal effects on peak Na current during upstroke of the action potential.

Pharmacotherapy in LQT7 and LQT8

In patients with ATS (LQT7), β-blockers are often prescribed, although the International ATS Registry showed that in most cases the frequency of ventricular ectopy did not change (Tristani-Firouzi and Etheridge, 2010). A single case report indicated the efficacy of verapamil, by blocking voltage-dependent Ca channel, suppressing bidirectional ventricular tachycardia in a patient with ATS (Tristani-Firouzi and Etheridge, 2010). There is more convincing evidence of the efficacy of flecainide in ATS patients (Bokenkamp et al., 2007). The underlying antiarrhythmic action may result from flecainide's activation of I_{K1} as observed in ventricular myocytes (Caballero et al., 2010). However, in another case report flecainide was ineffective in a patient with genetically confirmed ATS, but after administration of amiodarone ventricular tachycardia was suppressed (Junker et al., 2002). In some cases the substitution of K and thereby increasing the serum K level to a high normal value may reduce the occurrence of ventricular arrhythmias and/or neurological features such as the episodic attacks of periodic paralyses (Sansone and Tawil, 2007).

Timothy syndrome (LQT8) is associated with a high mortality rate; therefore, if the diagnosis is confirmed, ICD implantation is the most important therapeutic approach. Although there are no specific data concerning antiarrhythmic therapy, β-blockers are used on the basis that they are generally effective in LQTS patients. However, mexiletine (Krause et al., 2011), verapamil (Jacobs et al., 2006), and ranolazine (Shah et al., 2012) have been proposed to shorten repolarization by directly or indirectly suppressing the L-type Ca channels and reduce the risk and burden of ventricular arrhythmias and ICD shocks.

K Supplement and K Channel Openers in LQTS

Currently 5 out of 15 LQTS are caused by mutations that result in reduction of net K current. Compton et al showed that administration of oral K to raise plasma concentration can reduce the QTc interval in patients with LQT2 (Compton et al., 1996). However, the long-term clinical efficacy of this approach is not clear. On the other hand, several experimental studies have shown the efficacy of K channel openers like nicorandil (Shimizu et al., 1998), and novel HERG current enhancers like RPR260243 (Kang et al., 2005) to shorten the QT interval in LQT1. The future role of this category of drugs in the clinical management of LQTS remains to be determined.

Drugs That Correct Trafficking Defects in LQTS

Transport of ion channel proteins through the secretory pathway involves a selective mechanism in which cargo molecules are concentrated into carrier vesicles. The importance of protein trafficking abnormalities is the recognition that this can be corrected. An early example was the observation that culturing cells expressing the key trafficking-deficient cystic fibrosis mutation AF 508 at reduced temperature could restore the cellular processing of CFTR protein and Cl transport (Lenhart et al., 2007). This has resulted in an intense search for chemical chaperones that can act as ligands to cause pharmacological correction of trafficking-deficient mutations. It is estimated that as little as a 10%–20% improvement in protein trafficking would ameliorate most of the clinical syndrome. Compared with a monogenetic defect in cystic fibrosis (1:2000) that occurs at a frequency similar to that in LQTS (1:2500), LQTS is a multigenetic syndrome, and probably because of the complexity of mechanisms and defects, industry interest in LQTS mechanism-specific drug development has been limited (Lenhart et al., 2007). However, recent studies have indicated that channel trafficking defects are common in LQT2 (Anderson et al., 2006), and therefore, pharmacological agents like thapsigargin (Delisle et al., 2003), and fexofenodine (Rajamani et al., 2002), or other trafficking rescue approaches are promising therapeutic rationales.

Left Cardiac Sympathetic Denervation

LCSD is a surgical procedure to denervate cardiac sympathetic innervation to the heart. It is indicated as an adjuvant therapy in patients who are refractory to b-blocker therapy. LCSD has been shown to significantly reduce cardiac events (Schwartz et al., 2004; Olde Nordkump et al., 2014). In patients with history of syncope, post-LCSD QTc <500 ms predicts efficacy of the procedure. However, those with persistent QTc prolongation (>500 ms) have a higher chance of SCD and are candidate for the ICD.

Implantable Cardioverter Defibrillator

The ICD is indicated in patients who have frequent syncopal episodes despite maximal pharmacotherapy and in those at high risk of recurrent cardiac arrest, for example, symptomatic infants <1 year of age or patients with JLNS.

Acquired LQTS

Acquired LQTS is by far more prevalent than congenital LQTS. The vast majority of acquired LQTS is the result of adverse effects of drugs that interact with the HERG gene encoding the pore-forming subunits (Kv11.1) of the rapidly activating delayed rectifier current, IKr (Kannankeril et al., 2010; Schwartz and Woosley, 2016). A recent report suggests that some drugs that block IKr and are known to cause TdP (dofetilide, E-4031, d-sotalol, thioridazine, and erythromycin) also increase the late sodium current, which may contribute to their proarrhythmic effect (Yang et al., 2014). Other causes of acquired LQTS include electrolyte abnormalities (hypokalemia, hypomagnesemia, and hypocalcemia), hypothyroidism, hypothermia, and marked bradycardia. Any of these factors can cause acquired LQTS or contribute to the risk of drug-induced LQTS.

In addition, there is recent evidence of the high prevalence of QTc interval prolongation in patients with anti-SSA/Ro antibody, autoimmune, and inflammatory diseases (Lazzerini et al., 2015; Boutjdir et al., 2016; Lazzerini et al., 2016). A recent report from this laboratory provided strong evidence for a pathogenic role of anti-SSA/Ro antibody in the development of QTc prolongation. Anti-Ro antibody from patients with autoimmune disease was shown to inhibit I_{Kr} by directly cross-reacting with the HERG channel likely at the pore region where homology between 52Ro antigen and HERG channel was demonstrated (Yue et al., 2015). In addition, an animal model of autoimmune-associated QTc prolongation was established, for the first time, whereby induction of anti-SSA/Ro antibodies by immunization resulted in QTc prolongation on the surface ECG (Yue et al., 2015).

Incidence of Drug-Induced LQTS

The overall incidence of drug-induced LQTS in a given population is difficult to estimate. One study estimated that between 5% and 7% of reports of VT, ventricular fibrillation, or SCD were in fact drug-induced LQTS and TdP (Molokhia et al., 2008). European

pharmacovigilance centers in Sweden, Germany, and Italy have found an annual reporting rate of drug-induced LQTS or TdP of approximately 0.8–1.2 per million person-years (Schwartz and Woosley, 2016; Molokhia et al., 2008). In an epidemiological study of drug-induced LQTS in Germany found the reporting rate for symptomatic acquired LQTS to be 2.5% per million person-years for men and 4.0% per million person-years for women, with 60% attributed to drugs (Sarganas et al., 2014).

QT prolongation is one of the most common reasons for drug withdrawal from the market despite the fact that these drugs may be beneficial for certain patients and not harmful in every patient (Niemeijer et al., 2015). Since 1989, 14 clinically important drugs have been removed from the market due to TdP (Ninan and Wertheimer, 2012), and development of an unknown number has been stopped due to concerns that these might pose a risk of causing QT prolongation and TdP (Schwartz and Woosley, 2016). In the 1990s, the US Food and Drug Administration (FDA) and the European Medicine Agency (EMA) began requiring routine preclinical and clinical testing to determine whether drugs have the potential to cause QT prolongation. Today, according to CredibleMeds website, which has become the standard reference for drug-induced TdP, marketed drugs are now recognized for their potential to cause TdP and another 72 to cause QT prolongation (Woosley and Romero, 2013).

Pharmacogenetics of Acquired LQTS

The susceptibility to acquired QT interval prolongation can be influenced by genetic variation (Mahida et al., 2013). This is supported by the fact that the heritability of QT interval duration in the general population (excluding congenital LQTS patients) is estimated to be around 35% (Hong et al., 2001; Newton-Cheh et al., 2005). Further, first-degree relatives of patients with congenital LQTS have a higher risk of drug-induced QT prolongation than nonrelated individuals (Kannankeril et al., 2005). In GWAS, a large number of genes associated with QT interval duration have been identified (Duchatelet et al., 2013; Pfeufer et al., 2009). The gene with the strongest signal related to QT interval duration is the NOS1AP, located on chromosome 1 (Pfeufer et al., 2009; Jamshidi et al., 2012), and inhibit L-type calcium channel and influence impulse propagation (Kapoor et al., 2014). Other finding from GWAS included polymorphisms within genes known to be mutated in congenital LQTS, genes associated with intracellular calcium handling, as well as genes previously not known to influence cardiac repolarization. In a recent study that compared 188 patients with drug-induced LQTS and more than 1000 patients with congenital LQTS found disease causing mutations in 28% of patients with drug-induced LQTS. Of interest, under basal conditions, the QTc of drug-induced patients (453 ± 39 ms) is significantly longer than that of control subjects (406 ± 26 ms).

It is important to consider pharmacogenetics of drug-induced LQTS as related to both *Pharmacokinetic* and *Pharmacodynamic* properties (Mahida et al., 2013). Pharmacokinetics constitute the effect of the body on the drug, which is usually categorized into effect on absorption, distribution, metabolism, and elimination of the drug. Pharmacokinetic genetic susceptibility is mainly characterized by variation in genes encoding drug-metabolizing cytochrome P450 or drug transporter like the P-glycoprotein. On the other hand, the pharmacodynamics component of genetic susceptibility is mainly characterized by genes known to be associated with QT prolongation in the general population and genes in which the causal mutations of congenital LQTS are located.

Ethnicity and Gender Differences in Drug-Induced LQTS

As ethnic differences ultimately reflect genetic variation, it is useful to study ethnicity with regard to susceptibility to drug-induced QT interval prolongation and TdP. However, the role of ethnic differences has not been well established in published studies on drug-induced QT interval prolongation. In 20 QT/QTc studies, only 10% of the total study population was African American and only 7% was Asian (Florian et al., 2011). Nevertheless, the frequency of polymorphisms in genes known from congenital LQTS had varying distribution among ethnic groups (Ackerman et al., 2004). African Americans had the highest risk of prolonged QT interval after acute overdose of QT-prolonging drugs while Hispanics had the lowest risk compared to all other ethnic groups (Manini et al., 2014).

Adult females have a longer QT interval, greater drug and bradycardia-induced QT prolongation, and approximately twofold greater incidence of cardiac arrhythmias (Drici and Clement, 2001). Several studies have shown female gender as a risk factor for TdP with drugs that suppress I_{Kr} (Makkar et al., 1993; Burke et al., 1997; Coker, 2009; Liu et al., 1998). These differences have been attributed most likely due to regulation of cardiac ion channels expression by sex steroids. For example, sex differences in QTc interval are not present at birth, but postpubertal women have longer baseline QTc interval than men (Goldberg et al., 1991). This change may be due to shortening of the male QT interval (Rautaharju et al., 1992). Further, the QTc interval of women is prolonged during pregnancy (Lechmanova et al., 2002). In fact, the definition of the upper limit of normal QTc interval is sex specific (440 ms in adult males and 460 ms in adult females).

The concept of reduced repolarization reserve in females compared to males has been used to explain sex differences in arrhythmia risk in LQTS (Roden, 2004). The reduced repolarization reserve of the female heart is attributed to lower repolarizing $K+$ currents. This difference was thought to be primarily due to testosterone-mediated increase in I_{Kr} and I_{K1} resulting in shorter APD and QTc interval in male hearts. However, recent experimental data that include, among others, estrogen upregulation of Ica-L by a classical genomic mechanism (Yang et al., 2012), may challenge the concept of repolarization reserve. Instead, Ca^{2+} homeostasis (Slama and Bett, 2014) and voltage-Ca^{2+} uncoupling (El-Sherif et al., 2017) may provide more attractive electrophysiological mechanisms for the increased vulnerability of female to drug-induced LQTS.

Future Directions and Concluding Remarks

There is increased recognition that a sizable minority of patients who are susceptible to VT and SCD, and who are usually young and have structurally normal heart have genetically inherited abnormality of the cardiac ion channels. This recognition has heightened interest in the diagnosis and management of this group of patients. Of all malignant channelopathies, the LQTs is the most widely investigated. Although some of the patients may receive the ICD, pharmacotherapy remains the first line of management for majority of patients. Looking ahead into the future, the role played by modifier genes in determining the phenotype along with studies on induced pluripotent stem cells (Savla et al., 2014) for treatment strategies will continue to enhance our understanding and help optimal management of those patients.

Although congenital LQTS continues to remain the domain of cardiologists, cardiac electrophysiologists, and specialized centers, the by far more frequent acquired drug-induced LQTS is the domain of all physicians and other members of the health care team who are required to make therapeutic decisions. To support better prescribing of medicines, clinical decision support systems to date have issued alerts that warn of potential harm from a prescribing decision (Schwartz and Woosley, 2016; Payne et al., 2015). However, the impact of these systems has been limited. Moving away from the use of alerts to signal prescribing errors, the concept of "medical autopilots" has been suggested as a preferred approach (Woosley et al., 2016). These programs will monitor the electronic medical record and send signals to guide prescribers toward decisions that result in maximum benefit and minimal risk of TdP.

Background

Despite major therapeutic advances, cardiovascular disease (CVD) remains the leading cause of morbidity and mortality in the United States and throughout the world. Older adults are particularly susceptible to CVD; prevalence extends to more than two-thirds of adults >60 years of age and to more than 85% of those aged ≥85 years (Writing Group Members et al., 2016). Of the 23.6 million adults that the American Heart Association predicts will die from CVD by 2030 (Writing Group Members et al., 2016), advanced age is leading mortality risk (Sahyoun et al., 2001). Moreover, risks of CVD-related hospitalizations, poor quality of life, functional decline, and other detrimental sequelae are also disproportionate in older adults. While numerous trials have focused on treatment and prevention of CVD in younger adults, care for elderly that best achieves survival as well as improved quality of life and function remains relatively uncertain (Forman et al., 2011). Despite a tradition of evidence-based CVD management, therapeutic choices for older candidates are commonly confounded by the presence of multimorbidity (i.e., concomitant cardiac and noncardiac comorbidities), as well as interrelated issues of polypharmacy, cognitive impairment, frailty, falls, functional decline, and other age-related complexities of care. In this chapter, we highlight the physiologic changes of aging and the intertwined issues of aging that both exacerbate CVD risks and transmute management considerations. Some of the many research opportunities to address these gaps will also be discussed.

Physiology of Cardiovascular Aging

While a comprehensive account of cardiovascular aging is beyond the scope of this chapter, **Table 1** provides an overview of characteristic age-related physiologic changes that fundamentally predispose to CVD. With rising age, distinctive changes within the vascular structure, myocardium, valvular apparatuses, and conduction system are common and have important implications on development of CVD (Lakatta and Levy, 2003a; Lakatta and Levy, 2003b; Lakatta, 2003). Aging itself is the foremost risk factor for CVD pathophysiology, and adults who survive into old age are fundamentally more vulnerable to CVD.

In the vascular system, deposition of calcium and collagen and loss of elastin fibers within the media of larger vessels contribute to increased stiffness, hypertrophy of vessel walls, and decreased arterial compliance in older adults (Fleg and Strait, 2012). In addition, the reduction of nitric oxide production and increases in angiotensin II have been associated with endothelial dysfunction, resulting in decreased coronary blood flow and reduction of flow-mediated vasodilation in exercising muscles. As a result of such structural and functional changes, arterial systolic pressure tends to increase (Lakatta, 1999). Even in older adults without clinical hypertension, systolic blood pressures may increase by as much as 20 mmHg between the ages of 60 and 80 (Lakatta and Levy, 2003a). Smaller arteries are also affected by increased lipid deposition, resulting in a more heterogeneous intimal layer which disrupts laminar flow, thereby increasing perfusion pressure (Pepe and Lakatta, 2005).

In the myocardium, an enhanced rate of cell degeneration due to oxidizing radicals and proliferation of interstitial fibrosis contribute to a significant loss of myocytes and increased myocardial stiffness (Olivetti et al., 1991). Although there is a reduction in the overall number of myocytes, the remaining myocytes are increased in their individual size (myocyte hypertrophy), which commonly results in mild thickening of the myocardium (Fleg and Strait, 2012; Hees et al., 2002). Deposition of amyloid, collagen content, lipofuscin, and fat in the myocardium also increases stiffening of ventricles in older adults (Folkow and Svanborg, 1993). These changes result in higher diastolic pressures in the left ventricle, at rest and particularly during exercise (Lakatta and Levy, 2003b; Folkow and Svanborg, 1993; Lakatta, 1994). Patterns of elevated diastolic pressures exacerbate susceptibility to heart failure (HF) with preserved ejection fraction (HFpEF), left atrial enlargement, as well as the development of atrial fibrillation.

Table 1 Age-associated physiologic changes in the cardiovascular system

System	*Physiologic changes*	*Clinical implications*
Vascular system	*Arterial wall*	● ↑↑ isolated systolic hypertension ● ↑ diastolic pressure until 6th decade ● ↓ diastolic pressure after 6th decade ● ↑ pulse pressure[b] ● ↑ cardiac workload ● ↓ renal function ● ↑ vascular encephalopathy ● ↑ in aorto-femoral pulse wave velocity ● ↑ atherosclerotic disease
	● ↑↑ arterial wall media thickness ● ↑↑↑ intimal medial thickness ● ↑ fraying of elastic fibers ● ↑↑ collagen content ● ↓↓↓ arterial dispensability ● ↑↑↑ arterial stiffness[a] ● *Endothelial function* ● ↓ vasodilation ● ↓ nitric oxide production ● ↑ angiotensin II signalling ● *Oxidative stress and inflammation* ● ↑ NADPH oxidase ● ↑ uncoupled nitric oxide synthase ● ↑ xanthine oxidase ● ↓ in anti-oxidant capacity	
Cardiac structure and function	*LV composition and mass*	Left ventricle
	● ↓↓ numbers of myocytes ● ↑↑ myocyte hypertrophy ● ↑ deposition of collagen, fibrous tissue, amyloid, and lipofuscin within connective tissue	● ↑ LV stiffness and fibrosis ● ↑↑ LV dysfunction and heart failure ● ↑↑ LV systolic and diastolic volumes ● ↑↑↑ in LV mass to volume ratio ● ↑↑ susceptibility to HFpEF [c] ● ↑↑ susceptibility to myocardial ischemia
	LV wall thickness, cavity size, and shape	*Left atrium*
	● ↑↑ myocardial thickness ● ↑↑ concentric LVH ● ↑ interventricular wall thickness ● ↑ spherical LV shape	● ↑ atrial size ● ↑ susceptibility to atrial fibrillation
	Left heart valves	*Left heart valves*
	● ↑ calcium deposition & collagen infiltration ● myxomatous degeneration ● fixation of valvular leaflets	● ↑aortic sclerosis and stenosis ● ↑ mitral annular calcification ● ↑ mitral and aortic regurgitation
	LV function	
	● ↓ early diastolic peak filling ● ↑ LV filling facilitated by atrial contraction ● ↑ late LV filling	
Cardiovascular physiology	*Response to exercise*	● ↑ pulmonary hypertension ● ↓ myocardial contractility ● ↓↓↓ functional independence ● ↓↓↓ quality of life ● ↓↓ muscle function
	● ↓ in VO2 max per kg weight at peak exercise ● inability to increase LVEDP during exercise ● ↑↑ sarcopenia ● ↓↓ body weight ● ↑↑ muscle fiber atrophy (fast twitch) ● ↑ intramuscular fat	

LV, left ventricle; *LVH*, left ventricular hypertrophy; *VO2*, oxygen consumptions; *LVEDP*, left ventricular end diastolic pressure; *HFpEF*, heart failure with preserved ejection fraction.
[a]Mainly large and medium sized arteries.
[b]Pulse pressure is defined as the difference between systolic and diastolic blood pressure, which is a potent predictor of cardiovascular events.
[c]Exacerbated by stress-induced tachycardia.

In the valvular apparatus, calcium deposition, collagen infiltration, and myxomatous degeneration are common, especially in the left heart (Cheitlin, 2003a). Though calcification alone rarely affects the function of the mitral or aortic valves, fibrosis can lead to hemodynamically significant stenosis (Cheitlin, 2003b). Fixation of valvular leaflets can also cause substantial valvular regurgitation (Hu et al., 2016; American College of Cardiology et al., 2006).

The conduction system can also be affected by collagen and elastin deposition, which can cause slower propagation of electric impulses and abnormalities in intraventricular conduction (Fleg and Strait, 2012; Folkow and Svanborg, 1993; Kistler et al., 2004). Degeneration of sinus node and pacemaker cells exacerbates risks of sick sinus syndrome as well as supraventricular and ventricular arrhythmia (Fleg and Strait, 2012).

Aging is also associated with important changes in organs outside the cardiovascular system including kidney function, pulmonary reserve, and hemostasis. These changes may also accelerate the development of CVD because of their many interactions with cardiovascular function (Senni et al., 2014; Shah et al., 2016).

Research Opportunities

Aging entails physiological steps that predispose to CVD. Research that distinguishes mechanisms of aging may also provide opportunities to modify these determinant pathways (North and Sinclair, 2012). The burgeoning field of Geroscience focuses on key cellular and subcellular pathways of aging that are potentially modifiable (Kennedy et al., 2014).

Geriatric Domains That Impact CVD Management

Many of the same physiologic processes that predispose to CVD in old age (e.g., increased inflammation, oxidative stress, and related changes in gene expression and mitochondrial function) also predispose to geriatric syndromes (**Table 2**) (Chaudhry et al., 2013). Whereas CVD pathophysiology is generally considered the primary determinant of cardiovascular instability in younger CVD patients, geriatric syndromes become progressively more likely to play a codominant role among older adults. Geriatric syndromes essentially entwine with CVD physiology and presentation, such that diagnosis, prognosis, and management are typically transformed.

Multimorbidity implies a situation in which two or more chronic conditions are active. Multimorbidity increases with age and is prevalent in more than 70% of adults age $\geq$75 years (Dunlay and Chamberlain, 2016). Whereas "evidence-based" CVD guidelines typically rely on investigations that selected study populations with few if any comorbidities, such evidence becomes less reliable when then applied to typical patients who usually have many concomitant diseases (Boyd et al., 2005). Thus, such "evidence-based" regimens become more likely to provoke interactions and/or management complexities that have not been studied.

Polypharmacy is common among older adults with multimorbidity as clinicians prescribe a group of evidence-based medications oriented to each disease, and which often result in a risky accumulation. Common scenarios include combined regimens for multiple pathologies with combinations that jeopardize hemodynamics and stability (e.g., medications for hypertension, heart failure [HF], atrial fibrillation in a context also including frailty, falls, and dehydration). Adverse drug reactions, poor adherence, and exorbitant costs are all more likely to occur among older CVD patients.
