If the histopathological results prove negative, the morbidity associated with axillary dissection can be avoided. Where metastases to the axillary nodal group are found, axillary completion dissection or radiotherapy is offered. The majority of sentinel nodes are found in the low axilla (level 1) (see Fig. 53.24). Higher-level 'skip' nodes are involved in 5–10% of cases. Occasionally, the sentinel node is identified in an extra-axillary position, either within the breast parenchyma as an intramammary lymph node, or as a parasternal (internal thoracic) lymph node or in the lesser supraclavicular fossa.

The breast is innervated with sensory and sympathetic motor fibres by the anterior and lateral cutaneous branches of the fourth to sixth intercostal nerves. The nipple is supplied from the anterior branch of the lateral cutaneous branch of the fourth intercostal nerve, which forms an extensive plexus within the nipple, its fibres terminating close to the epithelium as free endings, Meissner corpuscles and Merkel disc endings. These are essential for signalling suckling to the central nervous system. Secretory activities of the gland are largely controlled by ovarian and neurohypophysial hormones rather than by efferent motor fibres. The areola has fewer sensory endings.

Regional anaesthesia is a valuable component of multimodal analgesia. Localized nerve blocks reduce both acute and chronic postsurgical pain, thereby enhancing recovery. Pectoral nerve blocks are attractive alternatives to paravertebral and thoracic epidural blocks for breast surgery due to their simplicity and minimal complications (Versyck et al 2017). The majority of pectoral (Pecs) blocks are performed under general anaesthetic and ultrasound guidance. The Pecs I block targets the medial and lateral pectoral nerves located in the fascial plane between pectoralis major and minor. The Pecs II block can be used in addition to Pecs I to extend coverage to the axilla and serratus anterior area by blocking the intercostobrachial nerve, the third to the sixth intercostal nerves (including their lateral cutaneous branches) and the long thoracic nerve. The anaesthetic agent is directed between pectoralis minor and serratus anterior, in the plane deep to the fascia covering serratus anterior. These blocks provide consistent effective regional analgesia, reducing postoperative pain and the need for opioid pain relief. Serratus blocks were developed to extend analgesia to the lateral thorax from the second to ninth intercostal nerves and have been used for both postsurgical breast and thoracotomy pain. Injection of local anaesthetic is directed both superficial and deep to serratus anterior: the spread of the anaesthetic in the fascial planes eliminates the need for multiple injections to target each intercostal nerve.

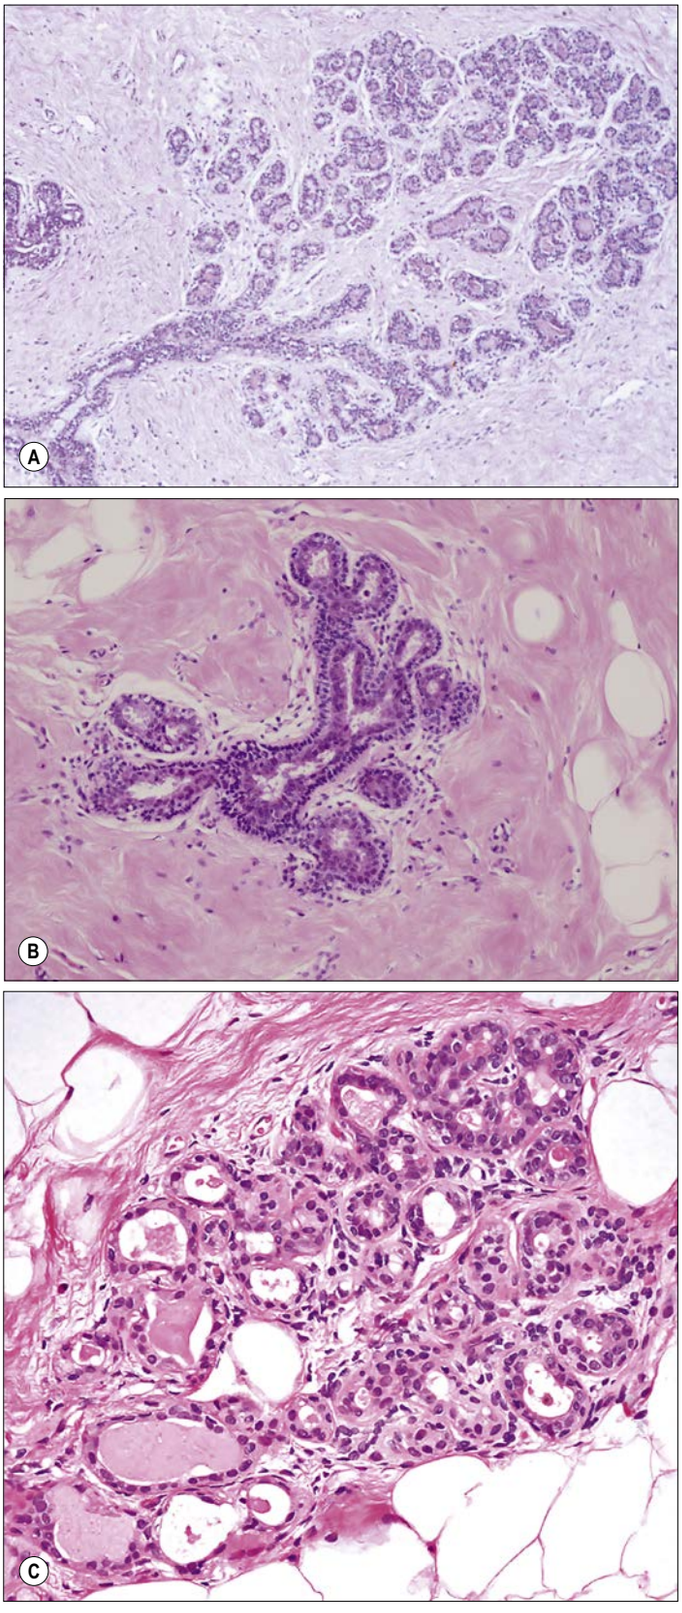

Fig. 53.25 A, A glandular lobule surrounded by collagenous interlobular connective tissue in the mature resting breast. A terminal duct (bottom left) branches extensively to terminate in rudimentary alveoli. **B**, Section through a large duct, surrounded by its smaller lobular branches, embedded in fibrocollagenous connective tissue. The ducts are lined by columnar epithelium enclosed by a prominent layer of myoepithelial cells, giving the appearance of a bilayered lining. **C**, Rudimentary alveoli shown at higher magnification, surrounded by fibrous and adipose connective tissue. (A, With permission from Young B, Heath JW 2000 Wheater's Functional Histology. Edinburgh: Churchill Livingstone. B, Courtesy of Mr Peter Helliwell, Department of Histopathology, Royal Cornwall Hospitals Trust, UK. C, Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

sometimes block the duct apertures in the non-pregnant breast. The ducts are slightly expanded at the base of the nipple, and there is considerable variation in duct diameter throughout the breast (Cooper 1840). The ductal system expands as it fills with milk during lactation, dilating even further to accommodate milk flow at milk ejection (Ramsay et al 2005). Each lactiferous duct is connected to a complex system of ducts and lobules, surrounded by connective tissue stroma, collectively forming a lobe of the breast (see Fig. 53.23B). Lobes vary in size, shape and depth. A single lobe may comprise from as little as 1% to as much as a 25% of the entire breast. Vestigial lobes have been identified and are composed of long ducts running deep into the breast with very few or no branches or glandular tissue. The presence of these lobes suggests a competitive process of ductal expansion and in part explains the observation of fewer functional lobes during lactation (Going and Moffat 2004). Whilst ducts can be intertwined, there is no evidence of anastomotic connections between lobes. Lobules consist of the portions of the glands that have secretory potential: their structure varies according to hormonal status. In the mature resting breast, each lobule consists of a cluster of blind-ended, branched ductules (**Fig. 53.25C**).

Internally, the nipple is composed mostly of collagenous dense connective tissue and contains numerous elastic fibres that wrinkle the overlying skin (see Fig. 53.23C–D). Deep to the nipple and areola, bundles of smooth muscle cells are arranged radially and circumferentially within the connective tissue and are thought to be remnants of the panniculus carnosus, a thin striated muscle layer attached to the deep surface of the skin, seen in other mammals. Their contraction, induced by cold or tactile stimuli (e.g. in suckling), causes erection of the nipple and wrinkling of the surrounding areola.

Development

The epithelial–mesenchymal interactions that give rise to the glandular tissue of the breast in both sexes can first be seen in Carnegie stages 16–17, when two ventral bands of thickened ectoderm, the mammary ridges (crests) or milk lines, extend from the axilla to the inguinal region (see Fig. 53.27). Invagination of the thoracic primary mammary buds as multiple longitudinal ducts occurs by stage 20, and the remaining mammary line involutes. Ductal epithelial branches subsequently develop, penetrating the mesenchyme at around stage 23.

The thoracic ectodermal ingrowths branch into 15–20 solid buds of ectoderm that will become the lactiferous ducts and their associated lobules and alveoli in the fully formed gland (**Fig. 53.26**). They are surrounded by somatopleuric mesenchyme that forms the connective tissue, fat and vasculature that is invaded by the nerves to the breast. Continued cell proliferation, elongation and further branching produce the alveoli and define the duct system. Nipple formation begins during stage 23, primitive ducts (mammary sprouts) develop from postmenstrual week 15, and canalization occurs at about postmenstrual week 24. During postmenstrual weeks 33–40, the ducts become canalized and the epidermis at the point of original development of the gland forms a small mammary pit, into which the lactiferous ducts open. Perinatally, the nipple is formed by mesenchymal proliferation. Should this process fail, the ducts open into shallow pits. Rarely, the nipple may not develop (athelia), an occurrence more commonly observed in accessory breast tissue.

Accessory breast tissue and nipples

Polymastia (supernumerary breasts) and polythelia (supernumerary nipples) may develop in males and females anywhere along the length of the mammary ridges (milk lines) (**Fig. 53.27**). Conversely, breast tissue may not develop at all (amastia), or there may be nipple development but no breast tissue (amazia). Supernumerary breast development occurs in most cases in the thoracic region, just inferior to the normal breast (90%), but may also occur in the axillary (5%) and abdominal regions (5%) and even on the medial thigh. Polythelia occurs along the same mammary line but no underlying glandular tissue develops. This condition is rare in females but is more common in males, in whom the accessory nipple may be mistaken for a mole.

Congenital inversion of nipple

Available with the *Gray's Anatomy* e-book

Under hormonal influence type 1 lobules (~11 alveolar buds) progress to type 2 (~47 alveolar buds) and type 3 lobules (~80 alveolar buds) that are larger in size consisting of a greater number of alveolar buds, reaching type 4 (the fully differentiated functional lobule) during lactation (Russo and Russo 2004). Greater numbers of type 1 lobules are observed in nulliparous women. However, in parous women with breast cancer more type 1 lobules and fewer type 3 lobules have been observed compared to parous women without breast cancer.

At birth the breasts have reached a similar developmental stage in both sexes, and the combination of fetal prolactin and maternal oestrogen may give rise to transient hyperplasia and neonatal galactorrhoea (the secretion of witch's milk). In males the breasts normally remain undeveloped whereas in females at puberty, in late pregnancy and during the period of lactation, they undergo further hormone-dependent developmental changes. The female breast is a unique organ in that it remains in a rudimentary (i.e. fetal) form until puberty, at which time its development continues under the influence of sex hormones. The adult form is reached in late adolescence, after which the breast is able to progress to a fully functioning milk-producing organ following pregnancy and childbirth. After the menopause the breast involutes into a predominantly fatty organ with reduced ductal-glandular parenchyma. Congenital inversion of the nipples occurs rarely in the female population and is almost always bilateral. The majority of the cases are umbilicated, i.e. the nipple can be easily pulled forwards from its depressed position underneath the areolar surface. The condition is thought to be due to failure of proliferation of the mesenchymal tissue which then fails to push the nipple out. The remaining cases are due to invagination of the nipple. Apart from psychological implications, inversion of the nipple may cause recurrent mastitis and difficulty with breast feeding: the anomaly may be corrected surgically.

Age-related changes

Prepuberty

The neonatal breast contains rudimentary lactiferous ducts but no alveoli. Until puberty, little branching of the ducts occurs, and any mammary enlargement is symmetric and reflects the growth of fibrous stroma and fat.

Puberty

In the postpubertal female the ducts elongate and become branched on stimulation by ovarian oestrogens. The ends of the branches form solid spheroidal masses of granular polyhedral cells, the potential alveoli. Oestrogens also promote adipocyte differentiation from mesenchymal cells in the interlobular stroma, and breast volume enlargement at puberty is mainly a consequence of lipid accumulation by these adipocytes.

From puberty onwards, externally recognizable breast development (thelarche) can be divided into five separate phases (Fig. 53.28): elevation of the breast bud (phase I); glandular subareolar tissue is present and both the nipple and breast project from the chest wall as a single mass (phase II); the areola increases in diameter and becomes pigmented, and there is proliferation of palpable breast tissue (phase

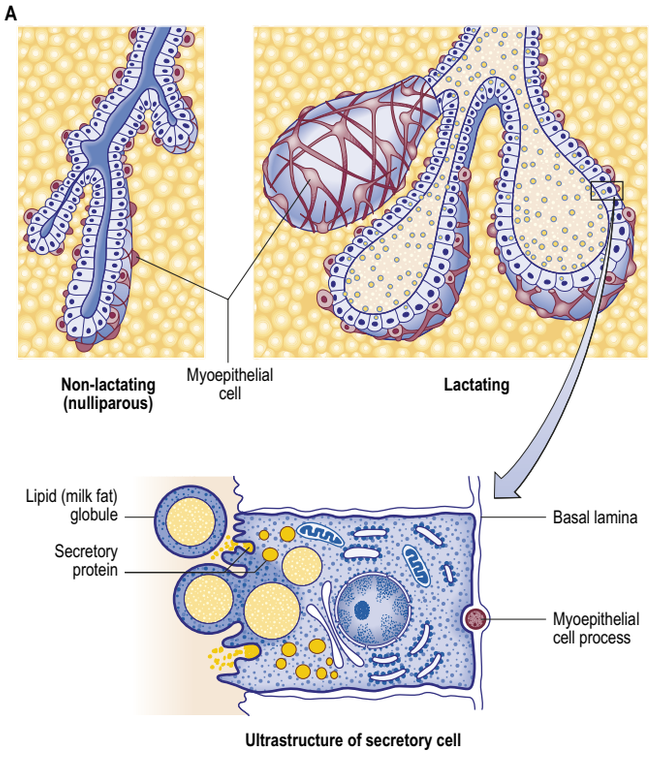

Fig. 53.29 The microstructure of breast epithelium. **A**, Note that the myoepithelial cell process is actually about half the relative size of that shown in the lower diagram. **B**, The peripheral part of a lactating breast lobule. The alveolar lumina contain milk secretion. Milk protein appears as eosinophilic material in the lumen and milk fat as pale cytoplasmic vacuoles in the secreted milk and in the alveolar epithelial cytoplasm. (B, Courtesy of Mr Peter Helliwell, Department of Histopathology, Royal Cornwall Hospitals Trust, UK)

III); further pigmentation and enlargement occur in the areola, so that the nipple and areola form a secondary mass anterior to the main part of the breast (phase IV); and a smooth contour to the breast develops (phase V).

Changes during the menstrual cycle

Changes occur in the breast tissues in the menstrual cycle. In the follicular phase (days 3–14) the stroma becomes less dense. Various changes, including luminal expansion, take place in the ducts, and there are occasional mitoses but no secretion. In the luteal phase (days 15–28) there is a progressive increase in stromal density and the ducts have an open lumen that contains secretion, associated with flattening of the epithelial cells. Cell proliferation is maximal on day 26 and thereafter the ductal system undergoes reduction; epithelial cell apoptosis is greatest on day 28 of the cycle. There are also changes in blood flow, greatest at mid-cycle, and an increase in the water content of the stroma in the second half of the menstrual cycle.

Postmenopausal

A decline in ovarian function triggers progressive atrophy of lobules and ducts after the menopause, and there is fatty replacement of glandular breast tissue. A few ducts and atrophic lobules may remain, the stroma becomes less cellular and collagenous fibres decrease. The amount of adipose tissue varies widely between individuals, as does the volume of glandular tissue, which is typically increased with the administration of hormone replacement therapy.

Changes associated with pregnancy and lactation

Pregnancy

As the output of oestrogen and progesterone, produced first by the corpus luteum and later by the placenta, increases during pregnancy, the intralobular ductal epithelium proliferates and the cells increase in size: the number and length of the ductal branches therefore increase. Alveoli develop at their termini and expand as their cells and lumina fill with newly synthesized and secreted milk. The myoepithelial cells, which are initially spindle-shaped, become highly branched stellate cells, especially around the alveoli. Adjacent myoepithelial cells intermesh to form a basket-like network around the alveoli and ducts, interposed between the basal lamina and the luminal cells (see Fig. 2.3). Their cytoplasm contains actin and myosin filaments, and they are contractile (see Fig. 2.4). Typically there is a concomitant reduction in adipose tissue in the stroma. The numbers of lymphocytes, including plasma cells, and eosinophils increase greatly. Blood flow through the breast increases to approximately double that of the non-pregnant state. Secretory activity in the alveolar cells rises progressively in the latter half of pregnancy. In late pregnancy, and for a few days after parturition, their product is different from later milk and is known as colostrum, characteristically low in lipid but rich in protein and immunoglobulins. Proliferation of the glandular breast parenchyma results in an overall increase in breast size through gestation.

Lactation

True milk secretion begins a few days after parturition as a result of a reduction in circulating oestrogen and progesterone, a change that appears to stimulate production of prolactin by the anterior lobe of the pituitary gland. Milk distends the alveoli so that the cells flatten as secretion increases (see Fig. 53.23B; **Fig. 53.29**). The alveolar cell cytoplasm accumulates membrane-bound granules of casein and other milk proteins and these are released from the apical plasma membrane by membrane fusion (merocrine secretion; see Fig. 2.6). Lipid vacuoles are formed directly in the apical cytoplasm as small lipid droplets that fuse with each other to create large 'milk vacuoles' up to 10 µm across. These are released as intact lipid droplets with a thin surround of apical plasma membrane and adjacent cytoplasm (apocrine secretion; see Fig. 2.6). Hormonal stimulation by oxytocin causes myoepithelial cells to contract and expel alveolar secretions into the ductal system in readiness for suckling. After the onset of lactation there is a gradual reduction in the numbers of lymphocytes and eosinophils in the stroma, although plasma cells continue to synthesize immunoglobulin A (IgA) for secretion into the milk. Alveolar cells take up IgA synthesized by adjacent plasma cells by endocytosis at their basal surfaces and secrete it apically, as dimers complexed to the epithelial secretory component.

Post lactation

Lactation may continue for several years. Whenever it finishes, the secretory tissue undergoes some involution but the ducts and alveoli never return completely to the pre-pregnant state. Two major processes are responsible for the regression of the alveolar–ductal system: a reduction in epithelial cell size and a reduction in cell numbers mediated via apoptosis. Gradually, the breast tissue reverts to its resting state. If another pregnancy occurs, the resting glandular tissue is reactivated and the process outlined above recurs. Up to the age of about 50 years, increasing amounts of elastic tissue tend to be laid down around vessels and ducts (elastosis), and in the stroma: elastosis does not normally continue into later life.

Mammary stem cells

Available with the *Gray's Anatomy* e-book

Postpartum mammary stem cells (MaSC) differ from other adult stem cells because they are likely to be involved in organ homeostasis and in postnatal development of the gland through each menstrual and reproductive cycle. Hormonal changes during puberty have been shown to drive ductal development through proliferation of MaSC in the terminal end buds (TEBs) in mice (Scheele et al 2017). TEBs consist of two layers, the cap cells that form the outer layer and differentiate into basal cells, and the body cells that form the inner layer and are precursors of luminal epithelial cells. TEBs are well characterized in rodents and are assumed to be analogous to terminal ductal lobular units (TDLUs) in humans, although their location at the periphery of ductal trees is the only confirmed shared feature.

Genetic lineage-tracing techniques in mice show that postpartum MaSC acting during puberty are unipotent (Davis et al 2016, Van Keymeulen et al 2017), although a small body of evidence suggests that some cells may also be bipotent or multipotent (Rios et al 2014, Wang et al 2018). It is currently unclear whether unipotent stem cells are the sole influential drivers of ductal elongation and alveologenesis during puberty in humans or during pregnancy in either humans or mice.

Together with unipotent stem cells responsible for the development and growth of the mammary epithelium, a population of cells may exist that act as multipotent stem cells under certain conditions (facultative or potential stem cells). These cells may be quiescent in the resting state and undetected by lineage tracing studies, and may only be recruited for regeneration in times of stress or exposure to a different microenvironment. Normal mammary cells may be transformed into bipotent stem cells when transplanted *ex vivo* into mice with cleared mammary fat pads (Stingl et al 2006).

Another unique population of cells seemingly involved in mammary gland remodelling are parity-induced mammary epithelial cells (PI-MEC): they have been identified in the ductal periphery and seemingly persist for multiple pregnancy–lactation cycles. PI-MECs only contribute to a luminal lineage that is hormone-receptor negative. The contribution of more than a single unipotent MaSC to the development of an alveolus during pregnancy or lactation confirms that a population of lineage-restricted MaSCs contribute to the functional mammary gland.

Rapid technological advances in the area of stem cell biology are providing a deeper understanding of stem cell dynamics integral to normal breast development and breast cancer (Lloyd-Lewis et al 2017). However, much of the research in mammary development is carried out in the mouse: species differences between mice and humans, particularly with respect to the architecture of the mammary gland, stroma and hormonal milieu, mean that experimental results should be interpreted with caution.

Histological changes are fibrosis and subsequent hyalinization. Ductal elements are usually present but lobular development is inconspicuous. The aetiology in the majority of cases is idiopathic. Broadly speaking, causes may be either physiological, reflecting imbalances of sex hormones in neonates, at puberty and in senescence, or pathological, reflecting hypogonadal or hyperoestrogenic states. Acquired causes include metabolic imbalances, endocrine and neoplastic conditions, and drug-induced gynaecomastia. In the adult male, unilateral gynaecomastia should be investigated to exclude male breast cancer.

Thoracocentesis is essential in the assessment of pleural effusion. A chest radiograph will confirm the location and extent of the effusion and clinical examination will identify the best position for aspiration, the posterior mid-scapular line being a common site. The skin of the desired intercostal space is cleaned and anaesthetized, and the aspiration needle is inserted at the inferior margin of the space because the main intercostal vessels run in the superior region of the space. After appropriate local analgesia has been applied, the needle is carefully advanced in a perpendicular direction through the fascial and muscular layers of the thoracic wall, until it passes through the parietal pleura and enters the pleural cavity (see Fig. 53.17). More complex or small effusions should be aspirated under ultrasound guidance.

Needle thoracocentesis is performed when a life-threatening tension pneumothorax is suspected. A needle is inserted into the second intercostal space in the mid-clavicular line on the affected side. A sudden escape of air is heard when the needle enters the parietal pleura. A thoracostomy followed by chest drain insertion must subsequently be performed within the revised triangle of safety after this procedure.

The site for thoracostomy and chest drain insertion is usually the fourth (ideally) or fifth intercostal space, between the mid and anterior axillary lines (revised triangle of safety). A thoracostomy is performed via a 2 cm horizontal skin incision, followed by blunt dissection (often using a clamp) through the subcutaneous tissues to the superior border of the inferior rib of the space, then through the intercostal muscles. The parietal pleura is penetrated with the tip of a clamp, and a gloved finger inserted into the pleural cavity to release pleural adhesions (pleural sweep). The chest drain tube is then inserted into the pleural cavity and attached to an underwater sealed container placed below the level of the lungs; the fluid level should rise and fall in the tube with ventilation.

Pericardiocentesis is performed to aspirate a pericardial effusion or, in an emergency, to decompress a cardiac tamponade, where pressure from blood in the pericardial space prevents the heart chambers from filling during the cardiac cycle, seriously impairing cardiac output. Rapid and extensive bleeds often clot and therefore limit the success of this procedure.

Pericardiocentesis is performed in either the fifth or sixth left intercostal space near the sternum (to avoid the more laterally located internal thoracic vessels) or 1–2 cm to the left of the angle between the junction of the xiphoid process and left costal arch. In the latter case, the needle is introduced and advanced at 45° to the skin, and directed superiorly and posteriorly towards the inferior angle of the left scapula until it enters the pericardial cavity.

Male breast

The male breast remains rudimentary throughout life. It is formed of small ducts (without lobules or alveoli) or solid cellular cords and a little supporting fibroadipose tissue (Ellis et al 1993). Slight temporary enlargement may occur in the newborn, reflecting the influence of maternal hormones, and again at puberty. The areola is well developed, although limited in area, and the nipple is relatively small. Normally the ducts do not extend beyond the areola in a male breast, although glandular tissue can be more extensive.

Gynaecomastia

Gynaecomastia is a benign proliferation of subareolar breast tissue in the male. It may be unilateral or bilateral and of varying severity (Simon et al 1973) and symptomatology. Pain or tenderness, thought to be due to accumulation of fluid in the glandular ducts, may be a presenting feature.

Thoracotomy incisions may be posterolateral or anterolateral, or involve a transverse thoracosternotomy.

Posterolateral incision A posterolateral incision is most commonly used in thoracic surgery for unilateral pulmonary resections, bullectomy, unilateral lung volume reduction surgery, chest wall resection and oesophageal surgery (Fry 2000). The patient is placed in a lateral decubitus position with adequate support of the elbow, axilla and knee with padding. The standard approach is via an incision from the anterior axillary line, which curves about 4 cm inferior to the inferior angle (tip) of the scapula and then vertically between the posterior midline and medial border of the scapula. The incision is usually extended to the level of the spine of the scapula. Overall, the incision forms an S-shape following the fifth intercostal space. The sixth or seventh intercostal space is used in oesophageal surgery.

The inferior portions of trapezius and latissimus dorsi are divided. Serratus anterior is retracted, and may be divided in a high (superior) thoracotomy. The costal muscle and pleura are dissected along the inferior margin of the intercostal space to avoid damaging the neurovascular bundle. The intercostal space should be spread slowly to avoid rib fracture: a small section of the posterior part of the rib may be removed to reduce the risk of fracture, particularly in patients older than 40 years. This technique provides good access to the thoracic contents; the main complication is postoperative pain as a consequence of intraoperative musculoskeletal traction, rib fracture and damage to the intercostal nerves.

Anterolateral incision The patient is placed in the supine position, with their arms by their sides. A roll is placed vertically under the back and hips in order to raise the operative side by approximately 45°. The incision is from the mid-axillary line over the fifth intercostal space along the inframammary skin fold, and curves superiorly parasternally. The pectoral muscles are divided, and subsequent access to the thorax is similar to that used in the posterolateral approach: access is limited, and may be improved by dividing costal cartilages.

'Clam shell' The transverse thoracosternotomy ('clam shell' incision) provides excellent exposure to both sides of the thoracic cavity and is therefore used in bilateral lung transplantation and in lung volume reduction surgery with bilateral lung resections. The patient is placed in the supine position with a roll vertically along the upper thoracic spine. Bilateral anterolateral incisions are made along the fifth intercostal space (or inframammary fold), and the sternum is transected. This allows the part of the thorax superior to the incision to be displaced upwards with a rib-spreader, hence the name 'clam shell'. The main disadvantage of the clam shell procedure is the need to transect the sternum; even after careful repair with sternal wires, there is a risk of sternal instability. This incision (in the fourth or fifth intercostal space) is also used for emergency access to the thorax in cases of loss of cardiac output from cardiac tamponade often resulting from penetrating trauma; spontaneous return of cardiac output may result from the rapid resolution of a tamponade and haemostasis.

Sternotomy is commonly needed in cardiac surgery. The patient is placed in the supine position with both arms extended by their side. A vertical incision is made in the midline (median plane) from the jugular (suprasternal) notch to a point just inferior to the xiphoid process, the tissues around the manubrium of the sternum and the xiphoid process are mobilized, and the pectoral fascia in the midline is incised. The sternum is divided equally and its two left and right halves retracted; it is subsequently closed using interosseous wire sutures.

The patient is placed in the lateral decubitus position, with arms abducted at 90° and supported on an arm rest. The incision is based along the desired intercostal space: for upper thoracic access, this is the second or third intercostal space. Latissimus dorsi is elevated and retracted, whereas serratus anterior is divided in the direction of its fibres. The anterior aspect of serratus anterior is divided to expose the intercostal muscles, which are divided in turn. Although the overall size of the incision is limited, it provides good access to the upper thorax. Postoperative pain is less than with some other approaches, but the long thoracic nerve may be damaged if serratus anterior is divided too posteriorly. The nerve is commonly located in the region between the mid and posterior axillary lines (Ebraheim et al 1998).

Occasionally, video-assisted thoracoscopic surgery is required to assess the mediastinum. The thoracoscope is usually introduced via the fifth intercostal space in the mid-clavicular line, with additional ports at the third and sixth intercostal spaces to assess the anterior mediastinum. To assess the posterior mediastinum, the thoracoscope is inserted into the seventh intercostal space in the mid-clavicular line.

The 12-lead ECG provides three-dimensional information on the electrical activity of the heart. The limb leads provide information about the electrical activity in the frontal plane and are placed on the left and right wrists and the left foot; the right foot acts as a neutral grounding point. The chest leads provide information about the electrical activity in the horizontal plane and are placed as follows: V1, right fourth intercostal space, parasternal position; V2, left fourth intercostal space, parasternal position; V3, midpoint of V2 and V4 on the left; V4, fifth intercostal space, mid-clavicular line on the left; V5, fifth intercostal space, anterior axillary line on the left; and V6, fifth intercostal space, mid-axillary line on the left.

CHAPTER
54

Pleura, lungs, trachea and bronchi

The lungs are the essential organs of respiration and are responsible for the exchange of oxygen and carbon dioxide in the blood. The functional anatomy of the thorax and respiratory diaphragm facilitates this complex process. Acting together, the muscles of respiration and the diaphragm increase the intrathoracic volume, creating a negative pressure within the pleural space that causes air influx and lung expansion (Ch. 55). The resultant reduction in intra-alveolar pressure prompts the flow of air down the pressure gradient, through the upper respiratory tract, trachea, bronchi and bronchioles, and finally into the alveoli, where gaseous exchange occurs. Conversely, a decrease in the intrathoracic volume increases intra-alveolar pressure, causing the expiration of air. The combined expiratory movements of the thorax and abdomen do not clear the lung of its gas with each breath; the presence of a large residual volume of gas minimizes the degree to which each new inspiration of air can affect the composition of gas in diffusion exchange with the blood (Lambertsen 1980). Besides efficient oxygen diffusion from alveolar air to blood, the lungs must also provide an inefficient carbon dioxide transfer, thus maintaining a stable carbon dioxide blood and tissue pressure, much higher (38–42 mmHg) than that in the atmosphere. Maintenance of critical homeostasis for carbon dioxide pressure is of greater importance than precise control of oxygen because so many essential electrical and metabolic functions depend on the hydrogen ion concentration [H^+] of the fluids in which these functions are carried out.

The process of breathing exposes the lung to noxious agents, including gases, dust particles, bacteria and viruses, and to dehydration and temperature extremes. The mucous barrier (including its cellular and immunoglobulin factors), the mucociliary escalator, branching pattern of the airways and the cough reflex are all anatomical defences against these insults. Studies of trends of particle deposition in children and young adults have shown that pulmonary deposition fractions are highest in infants who are at greatest risk from exposure to airborne particulate matter (Asgharian et al 2004). Respiratory function may be compromised by either anatomical defects such as chest wall abnormalities, or by paralysis of respiratory muscles or regional pain. Similarly, ultrastructural abnormalities, such as ciliary dysfunction (as seen in Kartagener's syndrome), lead to recurrent respiratory infections and airway damage.

PLEURA

Each lung is covered by a double-layered serous membrane, the parietal and visceral pleura, arranged as a closed, invaginated sac. The visceral pleura adheres closely to the lung surface and follows the interlobar fissures, separately covering each lobe of the lung. In the region of the lung hilum, the visceral pleura lifts off the mediastinal surface of the lung, and continues along the lung root for a short distance before folding back (reflecting) on itself to continue as the mediastinal parietal pleura (**Fig. 54.1**). The parietal pleura covers the lateral mediastinal margins (forming its lateral boundary), most of the respiratory diaphragm and the corresponding half of the thoracic wall.

The pleural cavity represents the potential space between the parietal and visceral pleura. It incorporates an intervening thin film of pleural fluid that allows close sliding contact between the two layers during all phases of respiration. The pleural fluid has a high daily turnover: fluid is produced at 0.01–0.02 ml/kg/h and is continuously absorbed to maintain a pleural fluid level of 0.1–0.2 ml/kg. Fluid movement and absorption are supported by a balance between plasmatic and pleural (hydrostatic and oncotic) pressures and thoracic lymphatic drainage. Pleural effusions occur when the mechanisms that normally resorb the fluid are destabilized.

The negative pressure developed in the pleural cavity during inspiration is the result of the opposing outward pull of the chest wall and the inward elastic recoil of the lung. Any change in the elasticity of these structures or accumulation of fluid or air within the pleural cavity will alter respiratory activity either regionally or globally. Inter-regional disparities in ventilation normally exist as a result of local differences in thoracic expansion and position-related, gravity-dependent gradients in pleural pressure, and are reflected as regional inequalities in gas exchange.

The right and left pleural sacs are separate compartments. Their parietal layers touch posterior to the superior half of the body of the sternum at the anterior junction line (see Fig. 53.4B), and come close to each other, or may touch, posterior to the oesophagus and level with the bodies of the third to fifth thoracic vertebrae at the posterior junctional line. Both lines are visible on radiographs and/or cross-sectional imaging (see Fig. 56.20); changes in the appearance of either line can indicate pathology. More inferiorly, the descending aorta (on the left) and azygos vein (on the right) demarcate the medial extent of the posterior parts of the pleural sacs. Cardiac asymmetry dictates that the left pleural cavity may sometimes be smaller. Transudates accumulate earlier and more often within the larger right pleural cavity.

Some of the folded portions of the pleura at its sites of reflection or recess (e.g. retrosternal, interlobar fissures and the azygo-oesophageal recess), or regions of contact between the left and right pleural cavity (e.g. anterior/posterior junctional lines) are the only parts of normal pleura that can be visualized radiologically. Demonstration of significant pleural shadowing in any other region usually implies pathological pleural abnormality. At direct inspection of the pleural cavity, as during thoracoscopy, both the parietal and visceral pleura appear translucent; the underlying thoracic muscles and blood vessels are visible beneath the parietal pleura, and the lung and subpleural vascular network are visible beneath the visceral pleura, rendering the latter grey and variegated in appearance.

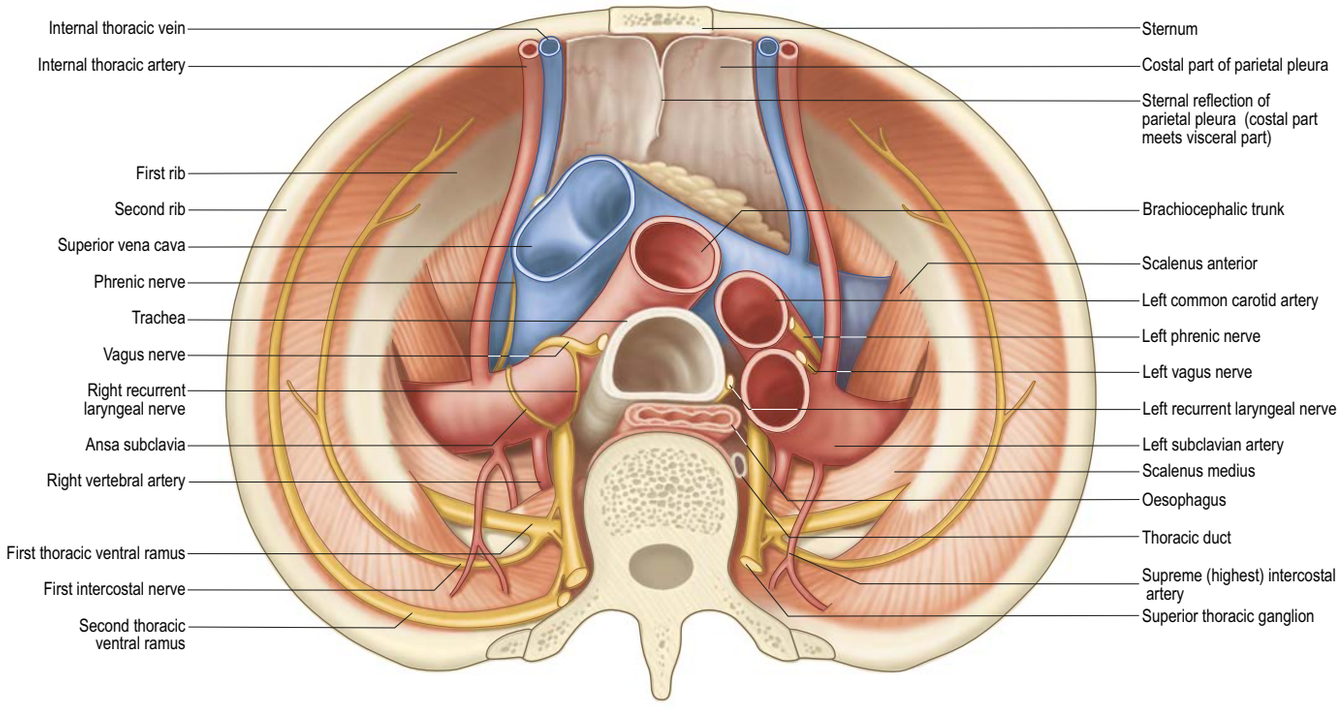

Fig. 54.2 An inferior view of structures related superiorly to the cervical pleura and suprapleural membrane (both have been removed).

Parietal pleura

Although continuous, different regions of parietal pleura are customarily distinguished by name according to the region they contact. The costal (costovertebral) part lines the internal surface of the thoracic wall and the lateral aspects of the vertebral bodies and intervening intervertebral discs; the diaphragmatic part covers the superior (thoracic) surface of the respiratory diaphragm; the cervical part (pleural dome) covers the inferior surface of the suprapleural membrane (in the region of the lung apex); and the mediastinal part covers the structures between the lungs and within the mediastinum, and forms the lateral border of the mediastinum. The surface markings of the parietal pleura are described in Chapter 52.

Costal part

The costal part of the parietal pleura lines the sternum, the lateral margins of the vertebral bodies and intervening intervertebral discs, the ribs and transversus thoracis and the intercostal muscles. External to the pleura, and located within the extrapleural space is the endothoracic fascia, a thin layer of loose connective tissue analogous to the transversalis fascia of the abdominal wall. Anteriorly, the costal pleura begins posterior to the sternum, where it is continuous with the mediastinal pleura along a line extending inferomedially, from posterior to the sternoclavicular joint to posterior to the sternal angle in the midline (see Fig. 53.4B). From here, the right and left costal pleurae descend in contact with each other to the level of the fourth costal cartilage and then diverge. On the right side, the pleura descends almost vertically to reach the posterior aspect of the xiphisternal joint, while on the left it diverges laterally and descends at a distance of 3–5 cm from the sternal margin to the anterior end of the sixth rib, forming the cardiac notch (pericardial triangle). On each side, the costal parietal pleura passes laterally, lining the internal surfaces of the costal cartilages, ribs, transversus thoracis and intercostal muscles. Posteriorly, it passes over the sympathetic trunk and its ganglia and splanchnic branches to reach the lateral sides of the vertebral bodies and intervertebral discs, where it again is continuous with the mediastinal pleura. Superior to the first rib, the costal pleura is continuous with the cervical pleura; inferiorly, it becomes continuous with the diaphragmatic pleura along a line that differs slightly on the two sides. On the right, the line of costodiaphragmatic reflection (junction) begins posterior to the xiphoid process, passes posterior to the seventh costal cartilage to reach the eighth rib in the midclavicular line and the tenth rib in the mid-axillary line, then the twelfth rib (approximately level with the superior border of the spinous process of the twelfth thoracic vertebra) adjacent to the vertebral column. On the left, the line initially follows the sixth costal cartilage but then follows a course similar to that on the right. In neonates and young children, the domes of the respiratory diaphragm are lower and flatter, reducing the angle of this point of reflection.

Diaphragmatic part

The diaphragmatic part of the parietal pleura covers most of the superior (thoracic) surface of the respiratory diaphragm where it is tightly attached to the phrenicopleural fascia, a continuation of the endothoracic fascia. It is continuous with the costal pleura around the periphery of the diaphragm, and within the costodiaphragmatic recess, and with the mediastinal pleura medially.

Cervical part

The cervical part of the parietal pleura is the continuation of the costal pleura over the apex of the lung and inferior to the suprapleural membrane, conforming tightly to both. It ascends medially from the internal border of the first rib to the apex of the lung, and then descends lateral to the trachea to become the mediastinal pleura. As a result of the obliquity of the first rib, the cervical pleura extends 3–4 cm superior to the first costal cartilage, up to or above the level of the neck of the first rib, reaching as high as the body of the seventh cervical vertebra (see Figs 54.1, 52.5). The cervical pleura is strengthened by the suprapleural membrane (Sibson's fascia), a thickening of the endothoracic fascia that is attached anteriorly to the internal border of the first rib and posteriorly to the anterior border of the transverse process of the seventh cervical vertebra. Scalenus minimus, when present, extends from the anterior border of the transverse process of the fifth, sixth and/or seventh cervical vertebra to the inner border of the first rib behind the subclavian groove, the cervical pleura and the suprapleural membrane (which it tenses). The cervical pleura and suprapleural membrane are related to the supraclavicular part of the brachial plexus, the stellate (cervicothoracic) ganglion and the vertebral vessels; the subclavian artery passes laterally in a groove located anterior to the most superior level of the membrane (Fig. 54.2).

Mediastinal part

The mediastinal part of the parietal pleura represents the lateral boundary of the mediastinum and forms a continuous covering above the level of the hilum of the lung, from the sternum anteriorly to the vertebral column posteriorly. On the right, it covers the right brachiocephalic vein, upper part of the superior vena cava, terminal part of the azygos vein, right phrenic and vagus nerves, trachea and oesophagus (see Figs 55.10A, 56.7A). On the left it covers the aortic arch, left phrenic and vagus nerves, left brachiocephalic and left superior intercostal veins,

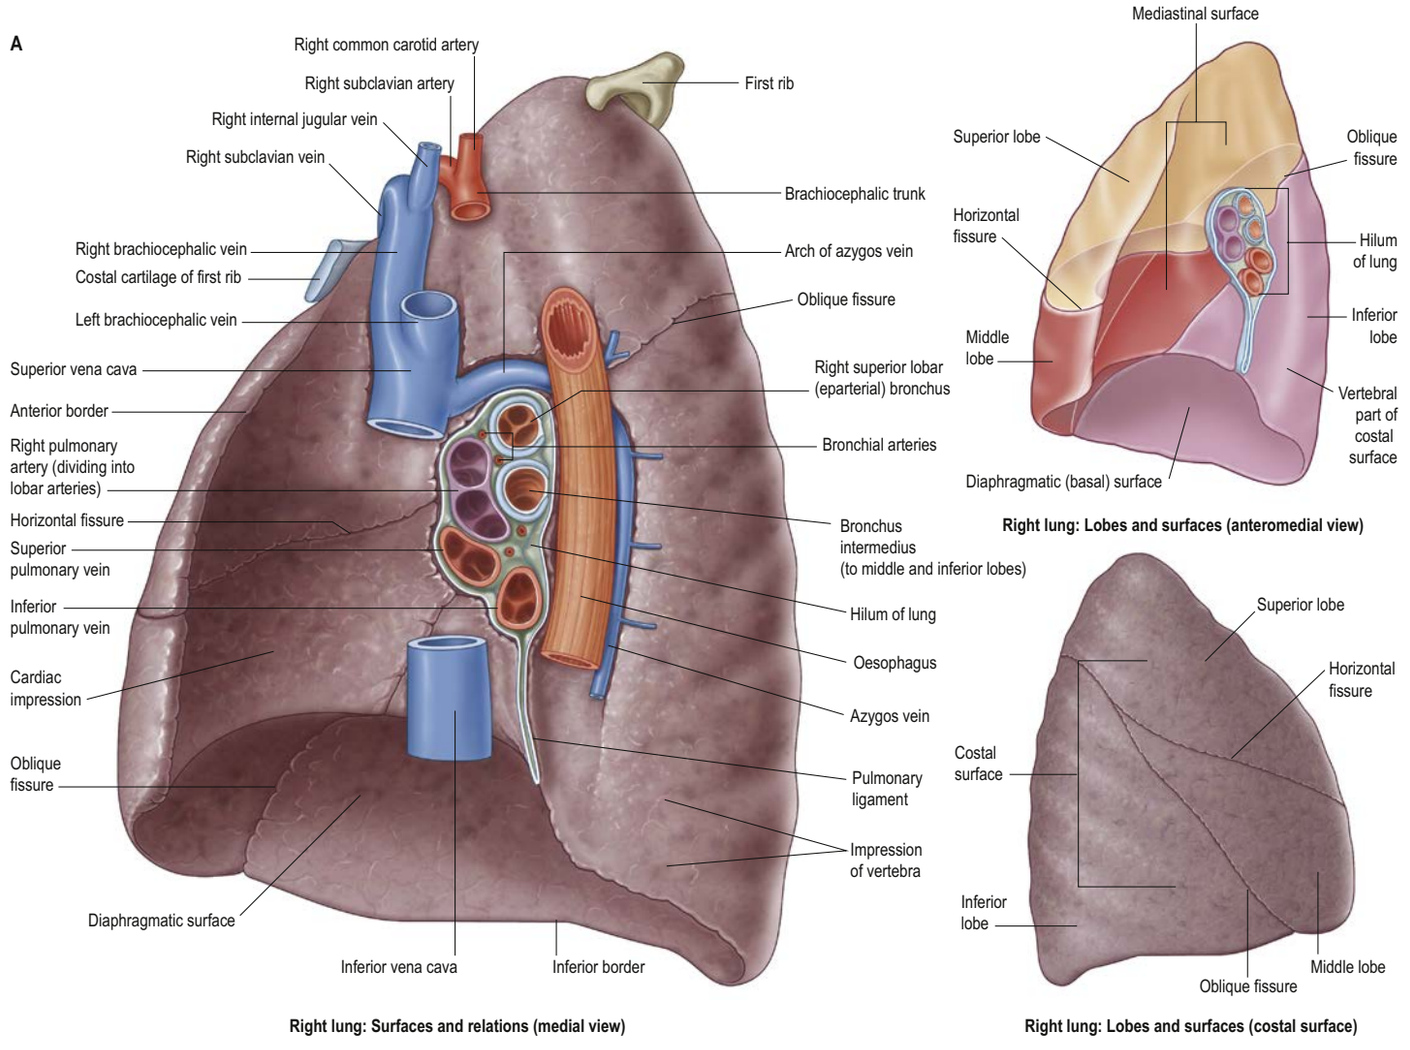

Fig. 54.3 The costal, mediastinal and diaphragmatic (basal) surfaces, and the mediastinal relations of the right (**A**) and left (**B**) lungs.

left common carotid and subclavian arteries, thoracic duct and oesophagus. At the root of the lung, it turns laterally to form a tube (sleeve) that encloses the structures passing to the lung hilum (see Fig. 54.1) and is continuous with the visceral pleura.

Visceral pleura

The visceral (pulmonary) part of the parietal pleura is adherent to the lung over all external surfaces, including those in the fissures, except at the hilum of the lung and along a line descending from this, that marks the formation and attachment of the pulmonary ligament (see Fig. 54.1; **Fig. 54.3**).

Pulmonary ligament

The pulmonary ligament, a thin almost vertically aligned double-layered fold of pleura, extends inferiorly from the region of the lung hilum and root. It passes between the mediastinal surface of the lung, where it joins the visceral pleura, and the lateral aspect of the mediastinum in the region of the oesophagus, where it joins the mediastinal part of the parietal pleura (see Figs 54.1, 54.3). It is continuous superiorly with the pleura around the lung hilum and root. Inferiorly, the two layers of pleura join, ending in a free sickle-shaped contour.

Parietal pleural recesses

The parietal pleura extends considerably beyond the inferior border of the lung but not as far as the attachment of the respiratory diaphragm, which means that the diaphragm is in contact with the costal cartilages and intercostal muscles below the line of pleural reflection from the thoracic wall to the diaphragm. In quiet inspiration, the inferior margin of the lung does not reach the point of parietal pleural reflection and the costal and diaphragmatic parts of the pleura are separated by a narrow slit, the costodiaphragmatic recess; the lower limit of the lung is normally about 5 cm superior to the lowest point of the recess. A similar costomediastinal recess exists between the mediastinum and the posterior surfaces of the sternum and costal cartilages, where the thin anterior margin of the lung projects toward the line of pleural reflection. The extent of this recess, the anterior costomediastinal line of pleural reflection, and the position of the anterior margin of the lung, exhibit individual variation.

The parietal pleural recesses allow the proportionate inspiratory expansion of the lungs with minimal friction. The same thin layer of pleural fluid within the recesses separates the costal and diaphragmatic parts of the parietal pleura during expiration, or the parietal pleura from the intervening visceral pleura during inspiration. Pleural adhesions and air or fluid accumulation limit this mechanism to a variable degree.

The inferior border of the costodiaphragmatic recess is an important consideration in surgical approaches to the kidney. The superior pole of the kidney crosses the twelfth rib and sometimes also the eleventh rib, which means that part of each kidney is associated with the parietal pleural reflection within the costodiaphragmatic recess. The parietal pleura may be damaged by flank incisions passing below the twelfth rib, but is more likely when rib resection is required during nephrectomy.

The aortico-oesophageal and azygo-oesophageal recesses project medially between the aorta and oesophagus on the left side and the azygos vein and oesophagus on the right side (see Fig. 56.7A).

Vascular supply and lymphatic drainage

The costal part of the parietal pleura is supplied by branches from the intercostal and internal thoracic arteries; the mediastinal part by

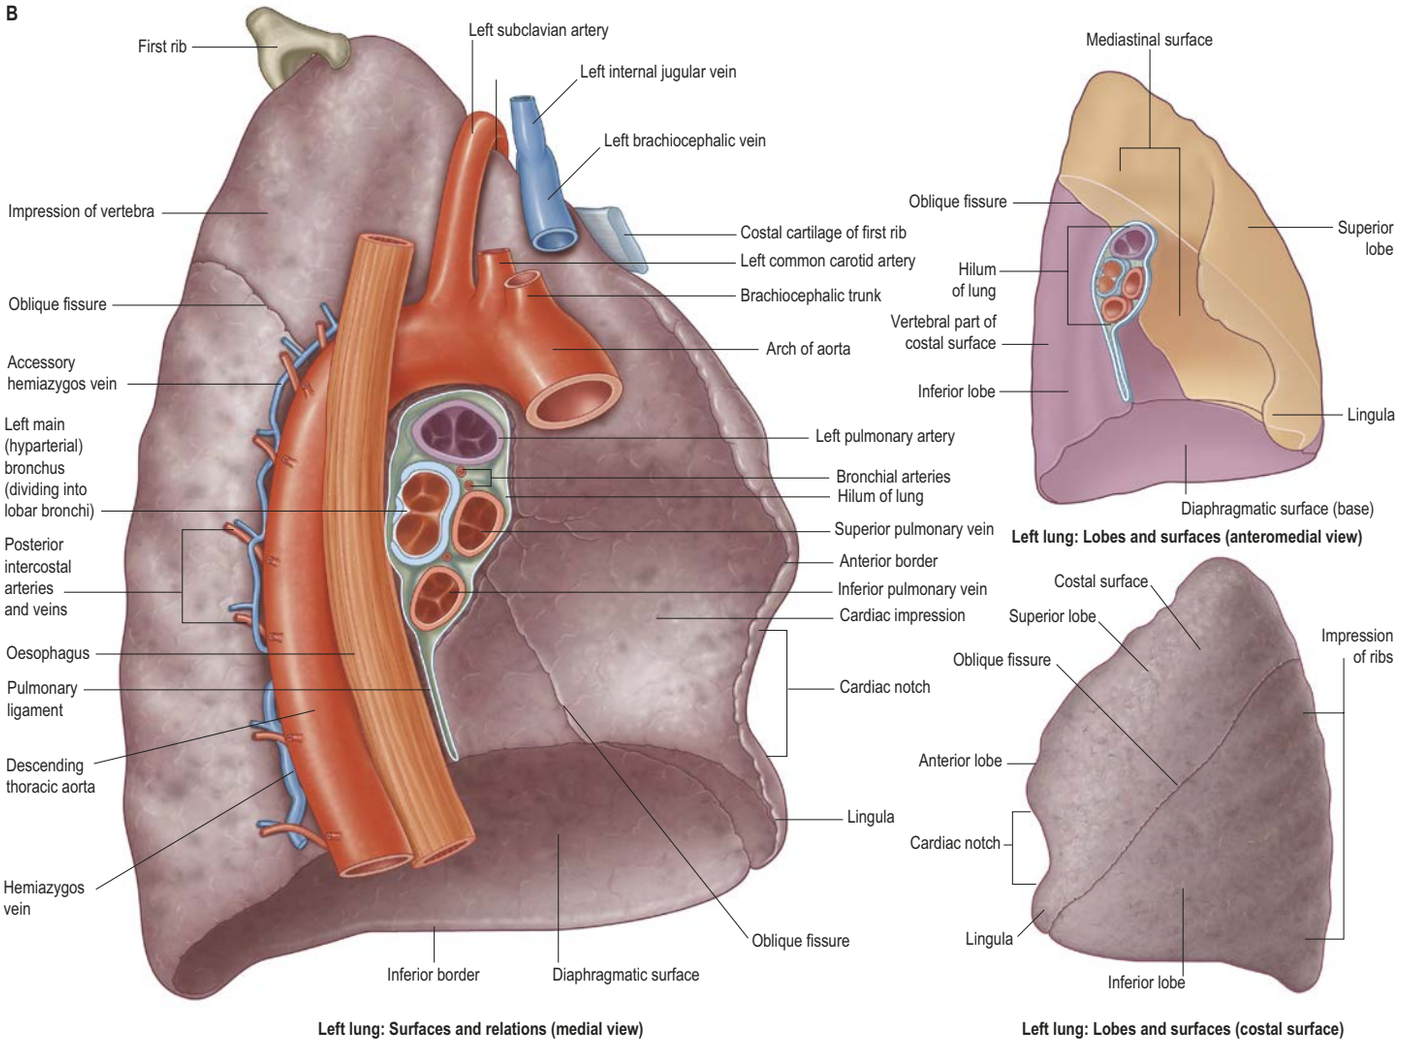

Fig. 54.3 Continued.

branches from the bronchial, superior phrenic, internal thoracic and mediastinal arteries; the cervical part by branches from the subclavian artery; and the diaphragmatic part by the superficial part of the diaphragmatic microcirculation. Veins draining the parietal pleura join the thoracic wall veins, eventually draining into the superior vena cava mainly via the azygos system (see Fig. 56.2). Lymph from the costal part of the parietal pleura drains into the parasternal nodes anteriorly and intercostal nodes posteriorly, while that from the diaphragmatic pleura drains into the mediastinal, parasternal, para-aortic (phrenic) and coeliac nodes (see Figs 56.4A, 56.5).

The visceral pleura forms an integral part of the lung and, accordingly, its arterial supply and venous drainage are provided by the bronchial vessels. The bronchial arteries at the hilum form a circle, surrounding the main bronchus, and pleural branches from this anulus supply the visceral pleura covering the mediastinum, interlobar and apical surfaces of the lung, and part of the diaphragmatic (base) surface. The visceral pleura is drained by pulmonary veins, apart from an area around the hilum that drains into bronchial veins. The lymphatic drainage of the visceral pleura is initially via the subpleural lymphatic plexus. Lymph can pass via segmental or intersegmental lymphatic pathways, and sometimes via peribronchial lymphatic pathways; the exact pattern of drainage varies depending on lobe, segment, side and individual (Fourdrain et al 2018).

Innervation

The costal and peripheral regions of the diaphragmatic parietal pleurae are innervated by intercostal nerves. The mediastinal and central regions of the diaphragmatic parietal pleurae are innervated by the phrenic nerves (C3–C5). Irritation of the intercostal nerves causes pain that is referred to the similarly innervated part of the thoracic or abdominal wall, whereas irritation of the central diaphragmatic pleura causes pain that is referred to the lower neck and shoulder tip, i.e. to the C3 and C4 dermatomes of the affected side.

Pneumothorax

A breach of the parietal or visceral pleura (e.g. in chest wall injury) may lead to the accumulation of air within the pleural cavity (pneumothorax). Fluid (hydrothorax), blood (haemothorax) and, rarely, lymph (chylothorax) can also accumulate in this space. Pneumothoraces may occur spontaneously (rupture of emphysematous bullae, or subpleural 'blebs' typically in tall, asthenic males) or following rib fracture or penetrating trauma.

Microstructure

The smooth pleural surface consists of a single layer of flat mesothelial (serosal) cells separated from an underlying lamina propria of loose connective tissue by a basal lamina. Ultrastructurally, pleural and peritoneal mesothelial cells are similar in having a highly folded basal plasma membrane, in that their adjacent cell surfaces interdigitate and are joined by desmosomes, and in that their luminal surfaces bear numerous microvilli and some cilia. Cytoplasmic pinocytotic vesicles are common. The connective tissue covers the entire pulmonary surface; it extends from the hilum along the bronchial tree and accompanying blood vessels within the substance of the lung and divides the lung into numerous small polyhedral lobules, each of which receives a terminal bronchiole and arteriole, venules, lymphatics and nerves. Lobules vary in size; the superficial ones are the largest, visible as polygonal areas 5–15 mm across.

Occasionally, a valve-like effect occurs, so that air enters the pleural cavity during inspiration (due to the presence of a negative pressure) but cannot escape in expiration. This may result in a 'tension pneumothorax', which can be life-threatening and should be suspected whenever there are unilateral decreased breath sounds, hypotension, jugular venous distension and contralateral tracheal deviation (due to mediastinal shift). A tension pneumothorax requires immediate decompression. This may be carried out using a wide-bore needle; or a decompression cannula apparatus, inserted into the second intercostal space in the midclavicular line; or via a thoracostomy with an incision made through the fourth or fifth intercostal space between the anterior and mid-axillary lines followed by digital insertion to breach the parietal pleura and sweep away pleural adhesions (Fitzgerald et al 2008), followed by tube insertion for longer-term drainage.

Fluid collection in the pleural cavity may be due to congestive cardiac failure, hypoalbuminaemia or inflammatory, infective or neoplastic conditions. A developing pleural effusion causes obliteration of the costodiaphragmatic recess, where a lateral fluid meniscus is often visible from a non-loculated effusion on a frontal chest radiograph. Drainage of the fluid and subsequent analysis are required for diagnostic purposes. Where there is a collection of purulence (empyema) or blood, pleural cavity drainage is essential for therapeutic purposes. Ultrasonography is useful in assessing the size and characteristics of an effusion, such as the presence of loculation and debris and can demonstrate underlying consolidated lung. Computed tomography (CT) is used to assess the underlying lung parenchyma, endobronchium and mediastinal lymph nodes.

LUNGS

The lungs are the organs of respiration. They are situated on either side of the heart and other mediastinal structures and occupy most of the thoracic cavity. Each lung is free to move in its pleural cavity, except at the hilum and pulmonary ligament, where it is attached to the mediastinum. When removed from the thorax, a fresh normal lung is spongy, can float in water, and crepitates when handled because of the air within its alveoli. It is also highly elastic and so retracts on removal from the thorax. Its surface is smooth and shiny, and is divided by fine, dark lines into numerous small polyhedral lobules, each crossed by numerous finer lines, indicating the areas of contact between its most peripheral lobules and the visceral pleural surface.

In proportion to body stature, the lungs are heavier in males than in females (Thurlbeck 1982). At post mortem examination, the adult right lung usually weighs 340 g (142–835 g) in females and 445 g (185–967 g) in males; the adult left lung weighs 299 g (108–736 g) in females and 395 g (186–885 g) in males (Molina and DiMaio 2012, 2015). A fetal lung pair at 40 weeks post fertilization weighs 51 ± 16 g (Archie et al 2006). Lung volume, air volume and pulmonary tissue volume all increase linearly with body length (Rao et al 2010).

Pulmonary surface features

Each lung roughly resembles a halved cone and has an apex, base, distinct anterior and inferior borders and three outer facing surfaces (costal, diaphragmatic (base), mediastinal) (see Fig. 54.3). A posterior border is sometimes defined, although it is often rounded and relatively indistinct. During post mortem examination of preserved tissue each lung bears the impression of neighbouring structures that the lung was pressed against through the pleural coverings in life.

Apex

The apex, the rounded upper limit of the lung, extends above the superior thoracic aperture where it contacts the cervical pleura, and is covered in turn by the suprapleural membrane. As a consequence of the obliquity of the aperture, the apex rises 3–4 cm above the level of the first costal cartilage. The highest point of the apex is up to 2 cm above the medial third of the clavicle, at or above the neck of the first rib, and level with the body of the seventh cervical or first thoracic vertebra, or the intervening intervertebral disc; it sits in the root of the neck (see Fig. 35.18). Some consider the apex to be an intrathoracic structure when it does not rise above the neck of the first rib. The subclavian artery arches superolaterally over the suprapleural membrane and grooves the anterior surface of the membrane and lung apex just below its highest point, separating it from scalenus anterior (see Fig. 54.2). The cervicothoracic (stellate) sympathetic ganglion, ventral ramus of the first thoracic spinal nerve and supreme intercostal artery all lie posterior to the lung apex. Scalenus medius is lateral and the brachiocephalic trunk, right brachiocephalic vein and trachea are adjacent to the medial surface of the apex of the right lung. The left subclavian artery and left brachiocephalic vein are adjacent to the medial surface of the left lung apex.

Diaphragmatic surface (base)

The diaphragmatic surface (base) of the lung, when static, is semilunar and concave, moulded on the superior surface of the respiratory diaphragm, which separates each lung from the corresponding lobe of the liver, and the left lung from the gastric fundus and spleen. Since the respiratory diaphragm extends higher on the right than on the left, the concavity is deeper on the base of the right lung. Posterolaterally, the diaphragmatic surface has a more tapered shape that projects a little into the costodiaphragmatic recess. The change in diaphragmatic surface shape and relations is best viewed with inspiration/expiration radiographs, or with a ventilation CT series.

Costal surface

The costal surface of the lung is smooth and convex, and its shape is adapted to that of the thoracic wall, which is vertically deeper posteriorly. It is in contact with the costal pleura; in lung specimens that have been preserved *in situ*, this surface exhibits grooves that correspond with the overlying ribs, a situation similar to the hyperinflated lungs of patients with asthma. The vertebral part of the costal surface faces, and is impressed by, the anterolateral margins of the thoracic vertebrae and intervening intervertebral discs, posterior intercostal vessels and splanchnic nerves. Some consider the vertebral surface of the lung separate to the costal part.

Mediastinal surface

The mediastinal surface of the lung is deeply concave because it is adapted to the heart at the cardiac impression: the impression is much larger and deeper on the left lung where the heart projects more to the left of the median sagittal plane. The hilum of the lung, posterosuperior to this concavity, is the area where various structures of the lung root enter or leave the lung. The lung root and hilum are surrounded by a sleeve of pleura that extends inferiorly, posterior to the cardiac impression, as the pulmonary ligament. The mediastinal surface and vertebral part of the costal surface are sometimes collectively termed the medial surface (border) of the lung.

Other impressions on the lung surface

Cadaveric lungs that have been preserved *in situ* can show a number of other impressions that indicate their relations with surrounding structures, especially on the mediastinal surface (see Fig. 54.3). All these impressions reflect the intimate relationship between the lungs and adjacent mediastinal structures and offer a good perspective on surgical approaches or considerations, either from the anterior or posterior aspect of the corresponding pleural cavity.

Pulmonary borders

The inferior border of the lung is thin and sharp where the diaphragmatic and costal surfaces extend into the costodiaphragmatic recess and meet, and more rounded medially where the diaphragmatic and mediastinal surfaces meet (see Fig. 54.3). The surface anatomy of the inferior border of the lung is described in Chapter 52 (see Figs 52.5–52.6). The respiratory diaphragm rises more superiorly on the right to accommodate the liver, which means that the right lung is vertically shorter (by about 2–3 cm) than the left. However, cardiac asymmetry means that the right lung is broader, and has a greater capacity and weight than the left. Although not obvious, the posterior border separates the costal surface from the mediastinal surface and corresponds to the region of the lung adjacent to the heads of the ribs. It has no recognizable markings and is represented by a rounded region where the costal and vertebral surfaces of the lung meet. The thin, sharp, anterior border of the lung overlaps the pericardium (see Fig. 54.7). On the right it corresponds closely to the costomediastinal line of pleural reflection and is almost vertical. On the left it approaches the same line posterior to the sternum and superior to the fourth costal cartilage; inferior to this point it shows a variably shaped cardiac notch, the edge of which passes laterally for about 3.5 cm before curving inferomedially to the level of the sixth costal cartilage, about 4 cm from the midline. This region of the left lung does not reach the line of parietal pleural reflection (see Fig. 52.5) and so the fibrous pericardium is covered only by a double layer of parietal pleura (over the area of superficial cardiac dullness). Observations during surgery suggest that the line of pleural reflection, the anterior pulmonary margin and the costomediastinal pleural recess are all variable.

Pulmonary fissures and lobes

Left lung

The left lung is commonly divided into superior and inferior lobes by an oblique fissure that extends from the costal to the mediastinal surfaces, superior and inferior to the hilum (see Fig. 54.3B). When observing the surface of the lung, this fissure begins on the medial surface at the posterosuperior part of the hilum, near the pulmonary artery; ascends obliquely and posteriorly to cross the posterior border of the lung about 6 cm below the apex; next descends anteriorly across the costal surface, to reach the inferior border almost at its anterior limit; and finally ascends posteriorly on the mediastinal surface to the inferior part of the hilum. The surface and positional anatomy of the lung fissures is described in Chapter 52. The extent of completeness and/or orientation of the left oblique fissure is variable (Wantanabe 2016a); for example, the left oblique fissure is atypical (incomplete or absent) in 18% (Medlar 1947) to 73% (Yamashita 1978) of cases. The additional presence of a left horizontal fissure is a normal, occasional variant. Incomplete separation of the lobes and identification of the completeness of the fissures are important prior to lobectomy because individuals with incomplete fissures are more prone to develop postoperative air leaks and may require further procedures, such as stapling and pericardial sleeves.

The superior lobe lies anterosuperior to the oblique fissure and includes the apex, anterior border and much of the costal and most of the mediastinal surfaces of the lung. A small process, the lingula, is

On the mediastinal surface of the right lung (see Fig. 54.3A), the cardiac impression is related to the anterior surface of the right auricle, the anterolateral surface of the right atrium and partially to the anterior surface of the right ventricle. A wide groove ascends anterior to the hilum for the superior vena cava, the terminal portion of the right brachiocephalic vein and the right subclavian vein. Posteriorly, this groove is joined by a deep sulcus that arches forwards immediately superior to the hilum and is occupied by the azygos vein. The right side of the oesophagus makes a shallow vertical groove posterior to the hilum and the pulmonary ligament, and posterior to this is a vertical groove for the azygos vein. Towards the respiratory diaphragm it inclines left and leaves the right lung, and therefore does not reach the lower limit of this surface. Posteroinferiorly, the cardiac impression is confluent with a short, wide groove adapted to the inferior vena cava. Between the lung apex and the groove for the arch of the azygos vein, the trachea and right vagus nerve are close to the lung but do not mark it.

On the mediastinal surface of the left lung (see Fig. 54.3B), the cardiac impression is related to the anterolateral surface of the left ventricle and left auricle. The anterior surface of the conus arteriosus and adjoining part of the right ventricle are related to the lung as it ascends anterior to the hilum to accommodate the pulmonary trunk. A large groove arches over the hilum, and descends behind both it and the pulmonary ligament, corresponding to the aortic arch and descending thoracic aorta. From its summit, a narrower groove ascends to the apex for the left subclavian artery. Posterior to this, and superior to the aortic groove, the lung is impressed by the oesophagus (with potential contribution from the thoracic duct as it passes along the posterolateral surface of the oesophagus). Anterior to the groove for the subclavian artery there is a faint linear depression for the left brachiocephalic vein. Inferiorly, the oesophagus may create a groove posterior to the lower end of the pulmonary ligament.

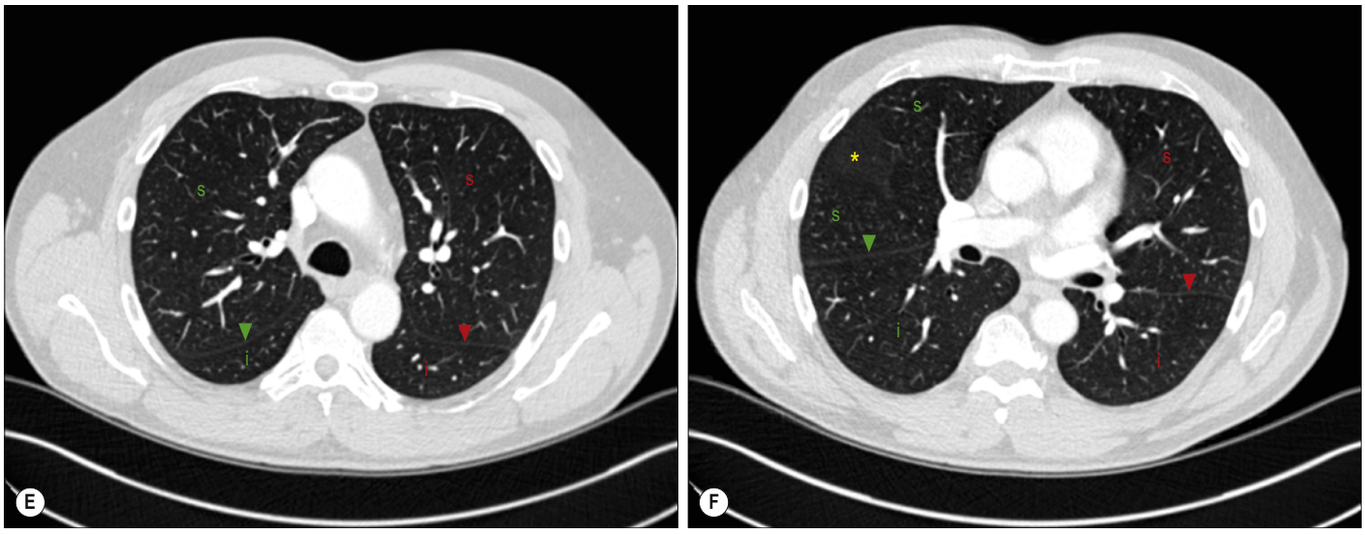

Fig. 54.4 E, Axial CT of the chest with intravenous contrast medium at the level of the lower trachea viewed with lung window settings, with arrowheads showing the right (green) and left (red) oblique fissures. Key: i, inferior lobe; s, superior lobe. **F**, Axial CT of the chest with intravenous contrast medium just inferior to the level of the carina viewed with lung window settings, with arrowheads marking the right (green) and left (red) oblique fissures and the yellow * marking the horizontal fissure in the plane of imaging. Key: i, inferior lobe; s, superior lobe. (A–D; G–J, *continued online*)

usually present at the inferior end of the cardiac notch. The larger inferior lobe lies posterior and inferior to the fissure and contributes almost the whole of the diaphragmatic surface, much of the costal surface and most of the posterior border and vertebral surface of the left lung.

Right lung

The right lung is divided commonly into superior, middle and inferior lobes by its oblique and horizontal fissures (see Fig. 54.3A). The oblique fissure separates the inferior from the superior and middle lobes, and although less vertical is similar in position on the lung surface to the left oblique fissure (described above). The surface and positional anatomy of the lung fissures is described in Chapter 52. On the surface of the lung, the right oblique fissure follows almost the same course as the left oblique fissure. A range of variation in the degree of completeness and/or orientation of the fissures is reported (Wantanabe 2016a). For example, the right oblique fissure is atypical (incomplete to absent) in 30% (Medlar 1947) to 71% (Yamashita 1978) of cases, whereas the right horizontal fissure is atypical in 62% (Medlar 1947) to 88% (Raasch et al 1982) of cases. The horizontal fissure is usually visible on a frontal chest radiograph and the oblique fissure is usually visible on a lateral radiograph and on a high-resolution CT scan as a curvilinear band passing from the lateral aspect of the costal surface to the hilum (Fig. 54.4). The smaller middle lobe is wedged between the superior and inferior lobes, and forms the inferior part of the anterior border, the anterior part of the inferior border and the associated part of the anteriorly located costal surface of the lung (see Fig. 54.7). The azygos vein may sometimes course in a more lateral position, within a four-layered pleural septum within the superior lobe, creating an 'azygos lobe'. This is not a true lobe, but a separated portion of the superior lobe that lacks its own bronchi, arteries or veins. The condition represents an incidental finding on chest radiographs or CT scans, with no associated morbidity; it may be confused with a pulmonary nodule, and loculated effusions may appear in the fissure. Accessory fissures may separate either the medial basal segment (Twining's line) or the superior segment from the remainder of the inferior lobe.

TRACHEA AND BRONCHI

Trachea

The adult trachea is a 10–11 cm long tube with cervical and thoracic parts. It is formed of cartilage and fibromuscular membrane and lined internally by mucosa. It descends from the cricoid cartilage of the larynx at the level of the body of the sixth (female) or seventh (male) cervical vertebra and divides into right and left main bronchi typically inferior to the sternal plane by 1–3 cm, and level with the body of the fifth or sixth thoracic vertebra or the T5–T6 intervertebral disc (see Fig. 52.7). It is located approximately in the midline sagittal plane but its point of bifurcation is usually a little to the right. In children less than 5 years of age a chest radiograph may demonstrate the trachea to appear to sharply deviate laterally to the right (buckle) at or just superior to the superior thoracic aperture and is considered a normal variant (Lee et al 2012). The variable position of the trachea in children makes it unreliable as an indicator of the presence of a right-sided aortic arch on a chest radiograph (Strife et al 1989).

The anterior and lateral surfaces of the trachea consist of 16–20 superimposed incomplete horseshoe-shaped 'rings' of hyaline cartilage and intervening anular ligaments formed from fibroelastic tissue that allows tracheal elongation during inspiration or neck movement (extension). During deep inspiration the tracheal bifurcation reaches the level of the body of the sixth thoracic vertebra. In children, the tracheal cartilages retain a high degree of elasticity that is often lost in adults: during full neck extension the length of the trachea increases by 0.95 ± 0.43 cm in a child (Jin-Hee et al 2005).

The posterior membranous wall is a flat, fibromuscular structure containing smooth muscle (trachealis). During the first postnatal year of life, tracheal diameter does not exceed 4 mm. Mean transverse diameter is greater than anteroposterior diameter up to the age of 6 years, after which the two diameters are nearly equal (Griscom and Wohl 1986). During later childhood, tracheal diameter in millimetres is approximately equal to age in years. The external transverse diameter is typically 2 cm in adult males and 1.5 cm in adult females. The lumen is about 12 mm in diameter in live adults but increases as a result of relaxation of the smooth muscle post mortem. The transverse shape of the lumen is variable, especially in the later decades of life, and it may be round, lunate or flattened. The trachea is funnel-shaped in neonates, when the upper end is wider than the lower end and gradually becomes cylindrical with increasing age. At bronchoscopy, the posterior membranous wall of the trachea bulges into the lumen and this is exaggerated during expiration and coughing. The distal end of the trachea is visible as a concave spur. A tracheal bronchus may occasionally arise, mainly from the right aspect of the trachea around 2 cm superior to the carina, as either a supernumerary lobar or apical bronchus, or a displaced apical or superior lobar (porcine) bronchus (Wantanabe 2016b). This occurs more commonly in males and may be associated with axial skeletal anomalies. A tracheal bronchus was noted in 2.4% of children undergoing bronchoscopy for respiratory symptoms (Wong et al 1999).

Relations of the cervical part of the trachea

Anterior relations

The cervical part of the trachea is covered anteriorly by skin and the intervening superficial and deep cervical fasciae, and the suprasternal space. It is crossed by the jugular venous arch and overlapped by sternohyoid and sternothyroid. The second to fourth tracheal cartilages are crossed by the isthmus of the thyroid gland, above which an anastomosis connects the two superior thyroid arteries; the pretracheal fascia, inferior thyroid veins, thymic remnants (in adults) and the thyroid ima artery (when present) are all anteroinferior. In children, the thymus (especially the left lobe) may extend anterior to the trachea to the level of the thyroid gland and the brachiocephalic trunk crosses obliquely in front of the trachea at, or a little above, the upper border of the manubrium; the left brachiocephalic vein may also rise a little above this level. An enlarged thyroid gland may cover the cervical part of the

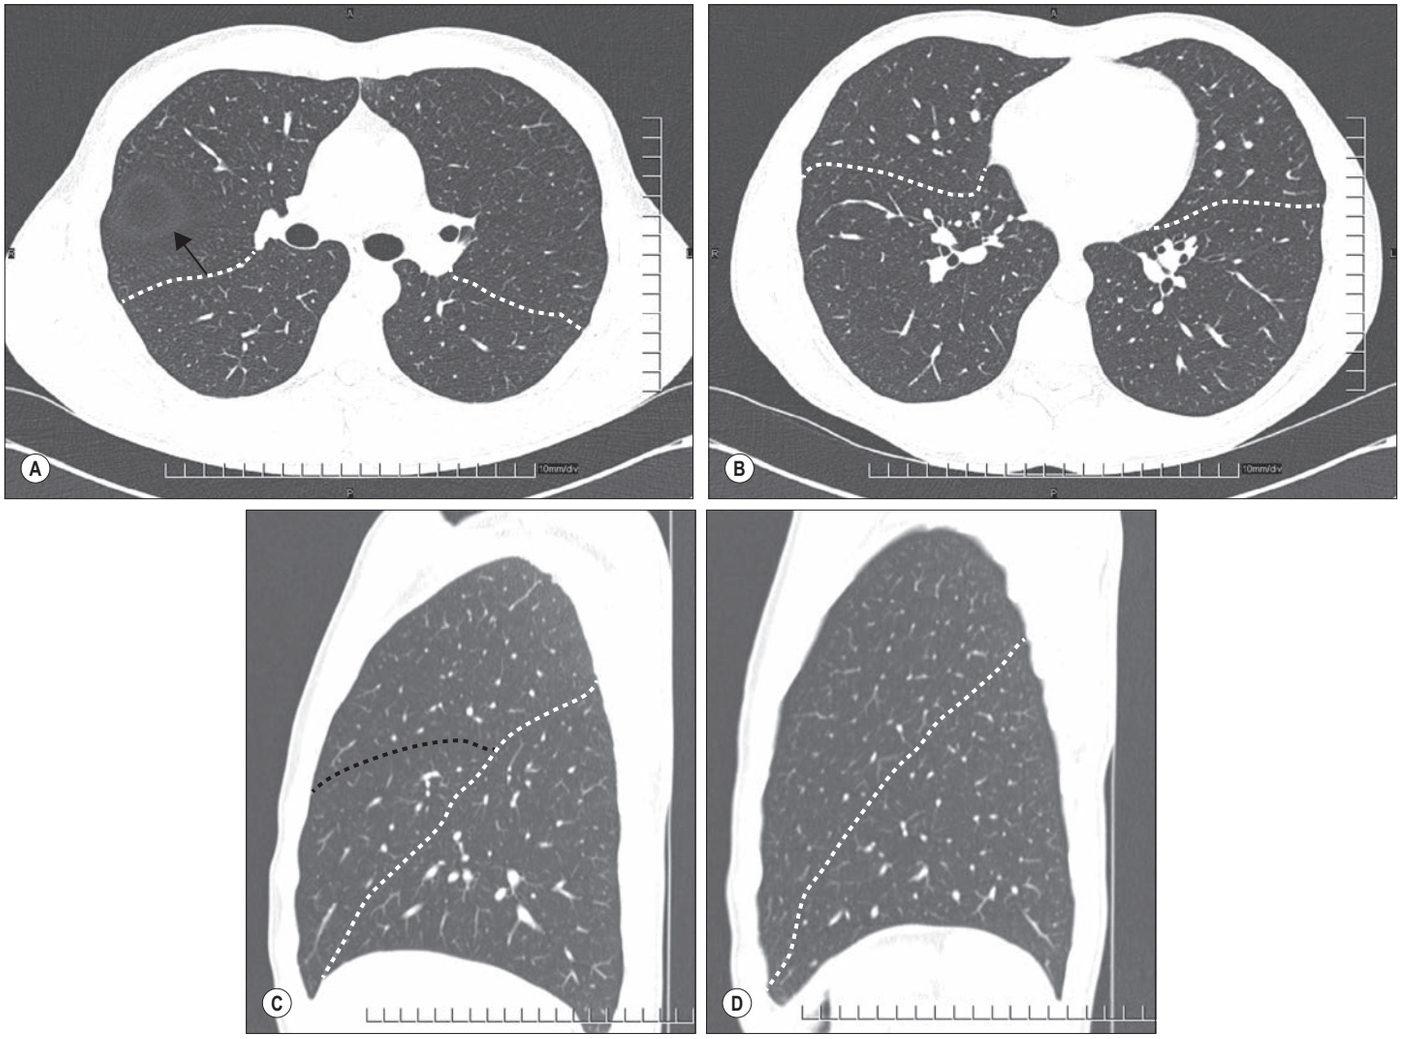

Fig. 54.4 **A**, An axial CT of the chest through the lungs inferior to the carina, demonstrating the left and right oblique fissures (white dashed lines). The circular avascular area anterior to the right oblique fissure and surrounded by a halo of white (arrow) is due to the horizontal fissure: in this individual the fissure is slightly domed and passes through the plane of the section. **B**, An axial section through the lungs at the mid-left atrial level, demonstrating the left and right oblique fissures (white dashed lines) as they pass more anteriorly and separate the inferior lobes from the superior (left lung) and middle (right lung) lobes. **C**, A sagittal section through the right lung, demonstrating the oblique (white dashed line) and horizontal fissures (black dashed line). **D**, A sagittal section through the left lung, demonstrating the oblique fissure (white dashed line).

trachea and reach the superior mediastinum, usually anterior to the left brachiocephalic vein.

Obstruction of the upper airways, craniofacial trauma and neck cancers (especially laryngeal), in either the acute or the chronic setting, require a tracheostomy. This is the creation of a hole (stoma) in the anterior aspect of the trachea that can serve either independently or as a site for an indwelling tube allowing the spontaneous or mechanical ventilation of the patient. The procedure usually involves incising the second and third tracheal cartilages and may be performed surgically or percutaneously (Ciaglia et al 1985, Griggs et al 1990). Surgical approaches are via a horizontal or vertical incision, about 2–3 cm in length, made midway between the jugular (suprasternal) notch and the thyroid cartilage; platysma, sternohyoid and then sternothyroid are separated along the midline to expose the trachea. Alternatively, in some cases, particularly in an emergency, the lumen of the larynx can be accessed directly via incision of the cricothyroid membrane (cricothyroidotomy).

Posterior relations

The cervical part of the oesophagus is the main posterior relation of the cervical trachea, separating it from the vertebral column and the prevertebral fascia.

Lateral relations

The paired lobes of the thyroid gland, that commonly descend to the level of the fifth or sixth tracheal cartilage, and the common carotid and inferior thyroid arteries, are all lateral relations. The thyroid gland is covered in a fascial capsule, an extension of the pretracheal fascia. This capsule condenses posteriorly to form the suspensory ligament of the thyroid gland (Berry) which is connected firmly to the trachea at the posterior margin of the adjacent cartilage rings, and blends with the posterior membranous wall. The recurrent laryngeal nerves ascend on each side, in or near the tracheo-oesophageal groove. The posterior suspensory ligament and the nearby terminal branches of the inferior thyroid artery are important landmarks for intraoperative identification of the recurrent laryngeal nerve.

Relations of the thoracic part of the trachea

Anterior relations

As it descends through the superior mediastinum, the thoracic trachea lies posterior to the manubrium of the sternum, the inferior attachments of sternohyoid and sternothyroid the remnants of the thymus and the inferior thyroid veins. In children the thymus sits anterior to the trachea. The brachiocephalic trunk and left common carotid artery come to lie on the right and left of the trachea, respectively, as they diverge superiorly into the neck. Inferiorly, the aortic arch, brachiocephalic trunk, left common carotid artery, left brachiocephalic vein, deep part of the cardiac plexus and upper and lower pretracheal lymph nodes are all anterior to the trachea.

Posterior relations

The oesophagus, with its venous and neural plexuses, is posterior to the trachea and separates it from the vertebral column. The close relation of these two tubular structures forms a trachea–oesophageal groove on either side. The retrotracheal lymph nodes sit between the trachea and oesophagus from the superior thoracic aperture to the level of the carina of the trachea (see Fig. 54.12B).

Lateral relations

Laterally and on the right are the right lung with its pleural coverings and cavity, right vagus nerve, right brachiocephalic vein, superior vena cava and azygos vein. On the left are the arch of the aorta, left common carotid and left subclavian arteries. The left recurrent laryngeal nerve is initially situated between the trachea and aortic arch, and then lies within or just anterior to the tracheo-oesophageal groove.

The trachea and oesophagus can be compressed (or even eroded) by vascular rings resulting from abnormal formation of the aorta and its branches, such as a double aortic arch, right aortic arch, aberrant right subclavian artery, double ductus arteriosus or persistence of the fifth aortic arch (Ch. 20).

Right main bronchus and subdivisions

The right main (principal) bronchus is approximately 2.5 cm long, and is wider, shorter and more vertical than the left (**Figs 54.5–54.6**). These differences explain why inhaled foreign bodies enter the right main bronchus more often than the left. This is more common in children, who may present with breathlessness, unilateral wheeze or recurrent aspirations, and a chest radiograph may show air trapping in the affected lobe. The right main bronchus gives rise to its first branch, the superior lobar bronchus (or eparterial bronchus, since it arises superior to the pulmonary artery), then enters the right lung opposite the bodies of the fifth to the seventh thoracic vertebrae. The azygos vein arches over it to join the superior vena cava; the surface position of the junction (0.6–2 cm inferior to the sternal plane) is an approximate marker for the superior extent of the hilum of the lung (see Table 52.2). The right pulmonary artery lies at first inferior, then anterior to the right main bronchus (see Fig. 54.13). After giving off the superior lobar bronchus, which arises posterior or posterosuperior to the right pulmonary artery, the right main bronchus continues as the bronchus intermedius and crosses the posterior aspect of the artery, enters the pulmonary hilum posteroinferiorly, and divides into the middle and inferior lobar bronchi (or hyparterial bronchi, since they arise inferior to the pulmonary artery).

Normal variants in the bronchial anatomy are occasionally seen and consist of either displaced or supernumerary airways (Ghaye et al 2001), or bridging and braided bronchi (Wantanabe 2016a).

Right superior lobar bronchus

The right superior lobar bronchus arises from the lateral aspect of the main bronchus and runs superolaterally to enter the hilum of the lung. About 1 cm from its origin it divides into three segmental bronchi: apical, posterior and anterior.

Segmental bronchi

The apical segmental bronchus continues superolaterally towards the apex of the lung, which it supplies, and divides near its origin into apical and anterior branches. The posterior segmental bronchus serves the posteroinferior part of the superior lobe, passes posterolaterally and slightly superiorly, and soon divides into a lateral and a posterior branch. The anterior segmental bronchus runs anteroinferiorly to supply the remainder of the superior lobe and divides near its origin into a lateral and anterior branch of equal size.

Bronchus intermedius

The bronchus intermedius is the continuation of the right main bronchus distal to the branching of the right superior lobar bronchus. It courses in a similar direction to the right main bronchus, but with a slight rightward deviation. It is slightly flattened, typically 1 cm wide and 2.5 cm long, and gives rise to the right middle and lower lobar bronchi, and sometimes to an additional variant, the subsuperior segmental bronchus (see below).

Right middle lobar bronchus

The right middle lobar bronchus usually branches from the bronchus intermedius about 2 cm below the superior lobar bronchus and descends anterolaterally.

Segmental bronchi

The right middle lobar bronchus soon divides into lateral and medial segmental bronchi that are distributed to the homonymous segments of the middle lobe.

Right inferior lobar bronchus

The right inferior lobar bronchus is the continuation of the bronchus intermedius beyond the origin of the right middle lobar bronchus.

Segmental bronchus anatomy

At or a little below its origin from the bronchus intermedius, the right inferior lobar bronchus commonly gives off a large superior (apical) segmental bronchus posteriorly that runs to the upper part of the inferior lobe, and then divides into medial, superior and lateral branches; the medial and superior usually arise from a common stem. After giving off the superior segmental bronchus, the right inferior lobar bronchus descends posterolaterally. The medial basal segmental bronchus branches from its anteromedial aspect and runs inferomedially to serve a small region below the hilum. The inferior lobar bronchus continues inferolaterally and divides into an anterior basal segmental bronchus that descends anteriorly and a trunk that soon divides into a lateral basal segmental bronchus that descends laterally and a posterior basal segmental bronchus that descends posteriorly. In more than half of all right lungs, a subsuperior (subapical) segmental bronchus arises posteriorly

Anomalies include a common origin of the right superior and middle lobar bronchi; an accessory cardiac bronchus; a right lower lobar bronchus that may arise from the left main stem bronchus; and an oesophageal bronchus. These anatomical variants are largely asymptomatic, occasionally causing haemoptysis, recurrent infection and bronchiectasis. Congenital bronchial atresia is associated with a bronchocele and emphysematous changes in the peripheral lung fields (Wang et al 2012). Left bronchial isomerism, characterized by two hyparterial bronchi and two bilobed lungs, and right bronchial isomerism, characterized by two eparterial bronchi and two trilobed lungs, may be features of the heterotaxy syndrome, which may include congenital cardiac, liver, stomach, intestinal and splenic abnormalities (Wantanabe 2016a).

Lung lobation and the morphology of the tracheobronchial tree can predict the atrial situs. In *situs solitus*, the right main bronchus is short and eparterial (its branch for the right superior lobe lies over the second branch of the right pulmonary artery) and the left main bronchus is longer and hyparterial (it courses underneath the left pulmonary artery). A bilobed left lung and a trilobed right lung are typical in *situs solitus*. In *situs inversus*, there is a mirror imaging of the disposition seen in *situs solitus*. In *situs ambiguus*, the bronchi and lungs can display either a bilateral right morphology with bilateral trilobed lungs and bilateral eparterial bronchi (heterotaxy syndrome: incomplete or inappropriate lateralization of the thoracic and abdominal viscera, and asplenia) or a bilateral left morphology with bilateral bilobed lungs and bilateral hyparterial bronchi (heterotaxy syndrome and polysplenia) (Van Praagh et al 1992).

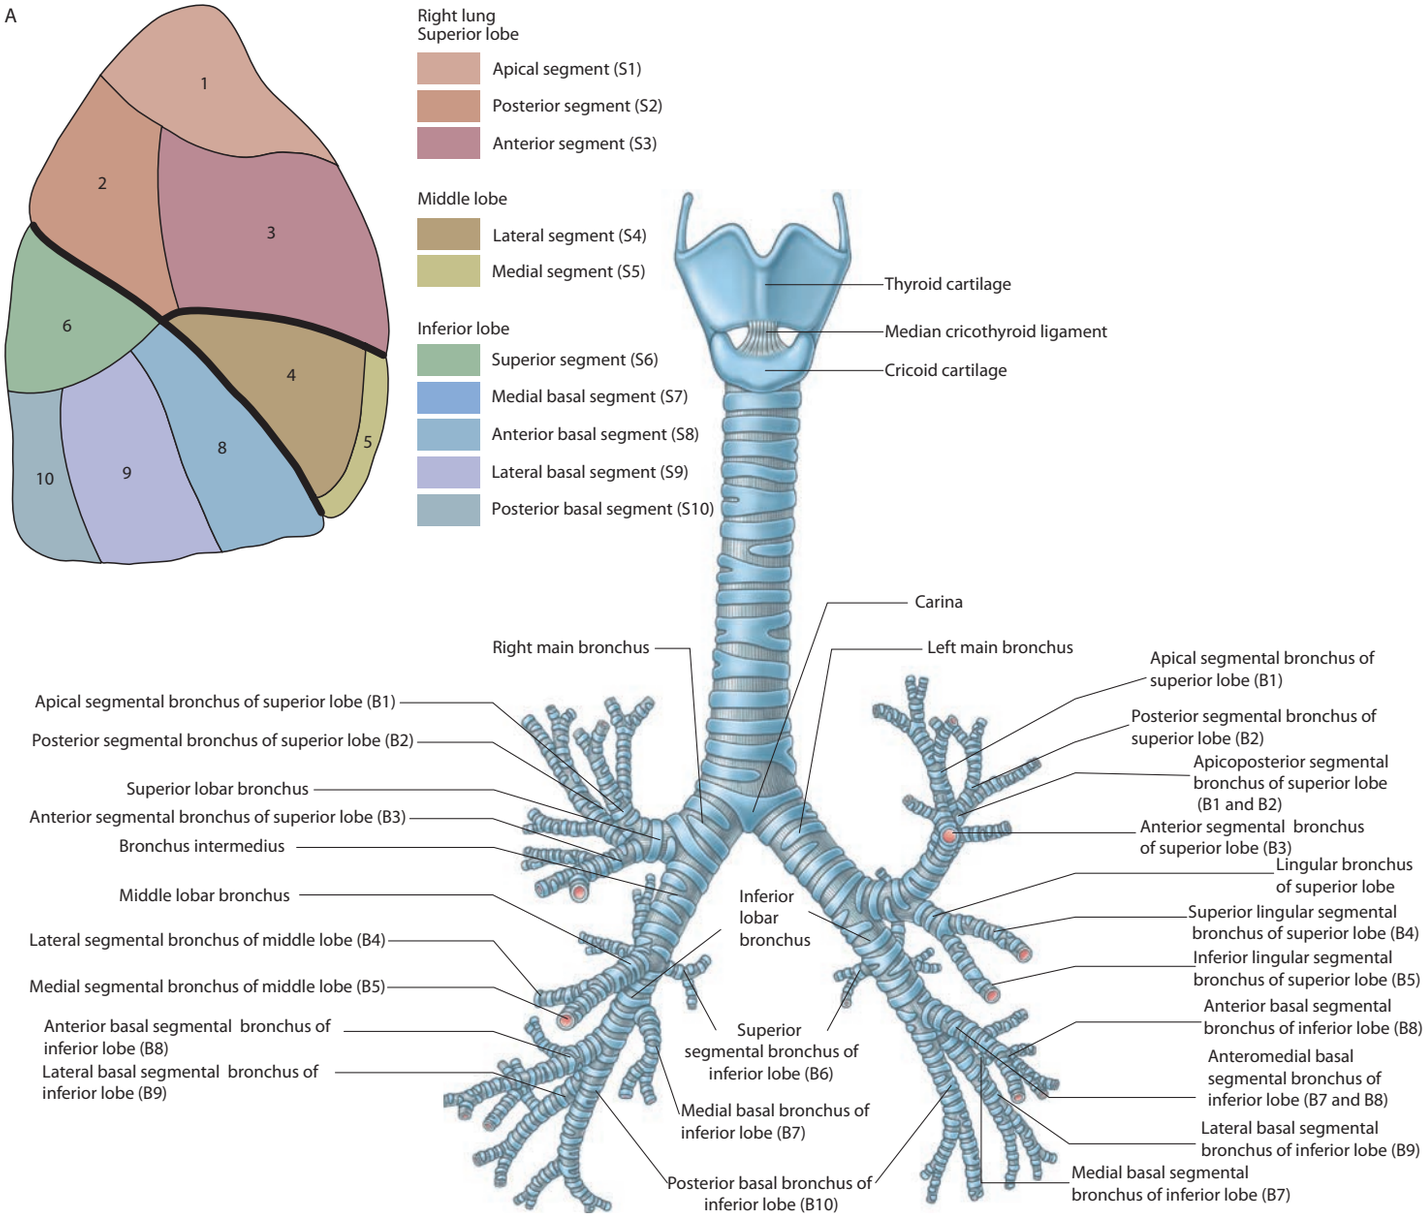

Fig. 54.5 A, The cartilages of the larynx, trachea and bronchi (anterior view), and the bronchopulmonary segments on the costal surface of the right lung. The bronchopulmonary segment (S) and segmental bronchus (B) labels are shown in brackets. In the left lung, segments S1 and S2, and S7 and S8, may be fused. (Redrawn from an original figure drawn from a metal cast made by the late Lord Russell Brock, GKT School of Medicine, London.) (B, *continued online.*)

from the bronchus intermedius or the right inferior lobar bronchus 1–3 cm below the superior segmental bronchus and is distributed to the region of lung between the superior and posterior basal segments.

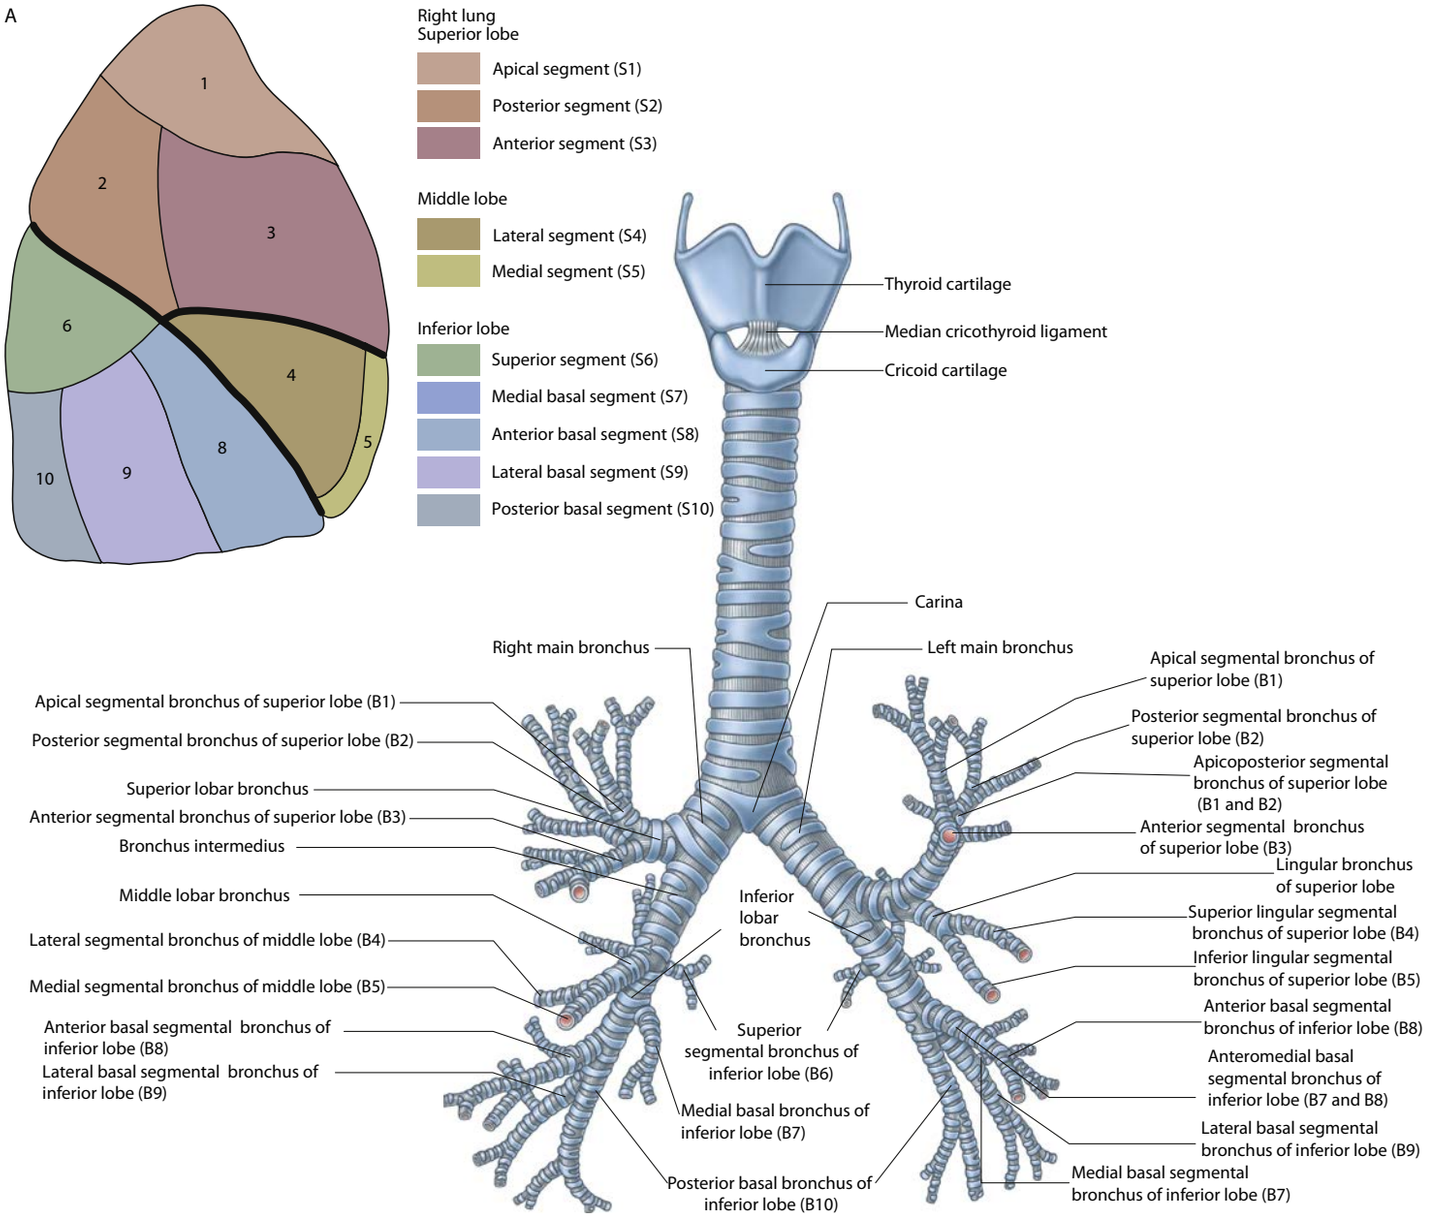
Left main bronchus and subdivisions

The left main (principal) bronchus is narrower, less vertical and twice as long (approximately 5 cm) as the right main bronchus (see Figs 54.5–54.6). Passing to the left, inferior to the aortic arch, it crosses anterior to the oesophagus, thoracic duct and descending thoracic aorta; the left pulmonary artery is at first anterior and then superior to it, at which point it may be termed the hyparterial bronchus. The left main bronchus enters the hilum of the left lung at the level of the bodies of the sixth to the seventh thoracic vertebrae and divides into the left superior and inferior lobar bronchi.

Left superior lobar bronchus

The left superior lobar bronchus arises from the anterolateral aspect of the left main bronchus. It curves laterally for a short distance and then divides into two branches (superior and inferior divisions). These branches are equivalent to the superior and middle lobar bronchial branches of the right main bronchus, except that the absence of a left middle lobe means that both are distributed to the left superior lobe.

Segmental bronchi



The superior division of the left superior lobar bronchus ascends 1 cm, gives off an anterior segmental bronchus and continues a further 1 cm as the apicoposterior segmental bronchus, which then divides into apical and posterior branches. The apical, posterior and anterior segmental bronchi are largely distributed as they are in the right superior lobe. The inferior division descends anterolaterally to the anteroinferior part of the left superior lobe (the lingula) and forms the lingular (common lingular) bronchus, which divides into superior and inferior lingular segmental bronchi. This is different from the pattern in the right middle lobe, where the corresponding distribution in the right middle lobe is to lateral and medial segments (see Fig. 54.7).

Left inferior lobar bronchus

The left inferior lobar bronchus descends posterolaterally and divides to supply the segmental territories of the left lung similar to those of the right lung.

Segmental bronchi

The superior (apical) segmental bronchus arises from the posterior surface of the inferior lobar bronchus posteriorly, about 1 cm from its origin. The anteromedial basal segmental bronchus arises anteriorly

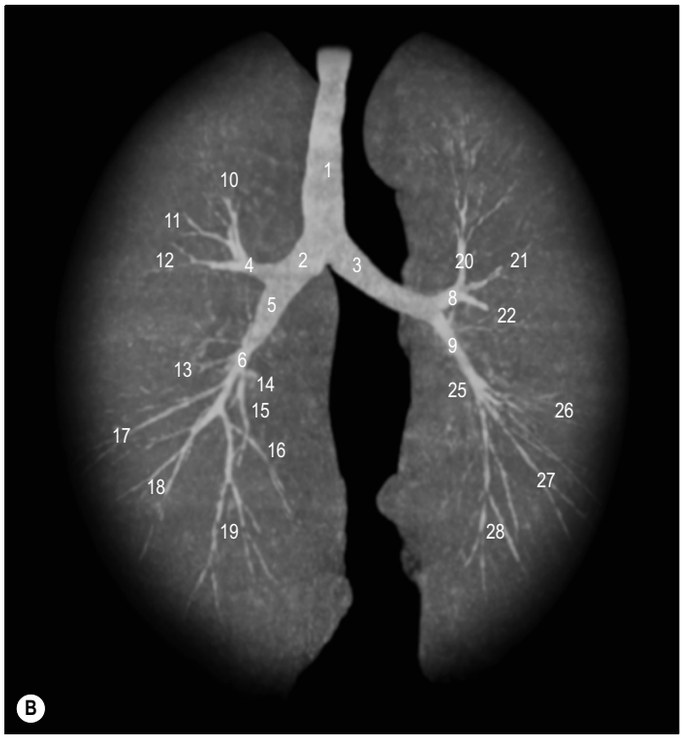


Fig. 54.5 A, The cartilages of the larynx, trachea and bronchi (anterior view), and the bronchopulmonary segments on the costal surface of the right lung. The bronchopulmonary segment (S) and segmental bronchus (B) labels are shown in brackets. Fig. 54.6 A, A bronchogram showing the branching pattern of the trachea and bronchi of the right lung, in a slightly oblique, anteroposterior view. In this procedure, a radiopaque contrast medium has been introduced into the respiratory tract to coat the walls of the respiratory passages. For identification of the major branches, compare with Figs 54.5B, 54.13. **B–E,** Lung window CT images demonstrating branching of lobar and segmental bronchi from the level of the carina **(B)** to the bifurcation of the right middle lobar bronchus (E). (F–O, *continued online.*)

after a further 1–2 cm and branches into the anterior and medial basal segmental bronchi, and the continuing stem of the inferior lobar bronchus soon divides into lateral and posterior basal segmental bronchi. The anterior basal segmental bronchus is an occasional independent branch of the inferior lobar bronchus, and a subsuperior (subapical) segmental bronchus occasionally arises posteriorly from the left inferior lobar bronchus.

Bronchopulmonary segments

The left and right main bronchi divide into lobar bronchi that subsequently divide into segmental bronchi (see Fig. 54.5). A segmental bronchus supplies a structurally separate and functionally independent unit of lung tissue called a bronchopulmonary segment (**Figs 54.7–54.8**). Each segment is a separate respiratory unit that is surrounded by connective tissue that is continuous with the visceral pleura. The vascular and lymphatic arrangements of the segments are described on page 1030. The bronchopulmonary segments are named and numbered (S1–S10) according to their supplying segmental bronchus (B1–B10). Although a relatively common pattern of segmentation can be identified (**Table 54.1**), there is often variability in the number and arrangement of the segments (Wantanabe 2016a). The arrangement of bronchopulmonary segments permit the resection of abscesses and localized primary lung malignancy, whilst retaining the normal functioning parts of the lung.

Secondary pulmonary lobules

Progressive subdivisions of the bronchi occur within each bronchopulmonary segment, and the bronchi become increasingly narrow (see Fig. 54.11). All intrapulmonary bronchi are kept patent by cartilaginous plates that decline in size and number, and finally disappear when bronchi become bronchioles (less than 1 mm in diameter). The secondary lobule is the smallest macroscopic subsection of the peripheral lung and is bounded by connective tissue septa of uneven size and shape. It consists of three to six terminal bronchioles, the latter being the most peripheral bronchioles that do not have alveoli in their walls. Distal to each terminal bronchiole is an acinus, the functional unit of the lung for gas exchange. It consists of 3–4 orders of respiratory bronchioles, each leading to 3–8 orders of alveolar ducts: the walls of the ducts consist of alveolar sacs or the mouths of alveoli. The primary lobule is a subunit of the secondary pulmonary lobule and is the part of the lung distal to the respiratory bronchiole.

Cartilaginous support

The trachea and extrapulmonary bronchi contain a framework of incomplete rings of hyaline cartilage united by fibrous tissue and smooth muscle (**Fig. 54.9**). Intrapulmonary bronchi contain discontinuous plates or islands of hyaline cartilage in their walls (see Figs 54.5, 54.11).

Tracheal cartilages

Each of the 16–20 tracheal cartilages measures about 4 mm in height and 1 mm in thickness, appearing thicker in the middle part: the external surface is flat and the internal aspect is slightly convex. The cartilages encompass the anterior two-thirds of the trachea, the posterior third is the membranous (posterior) wall consisting of fibro-elastic and muscular tissue. Tracheal cartilage loses elasticity and calcifies in older age

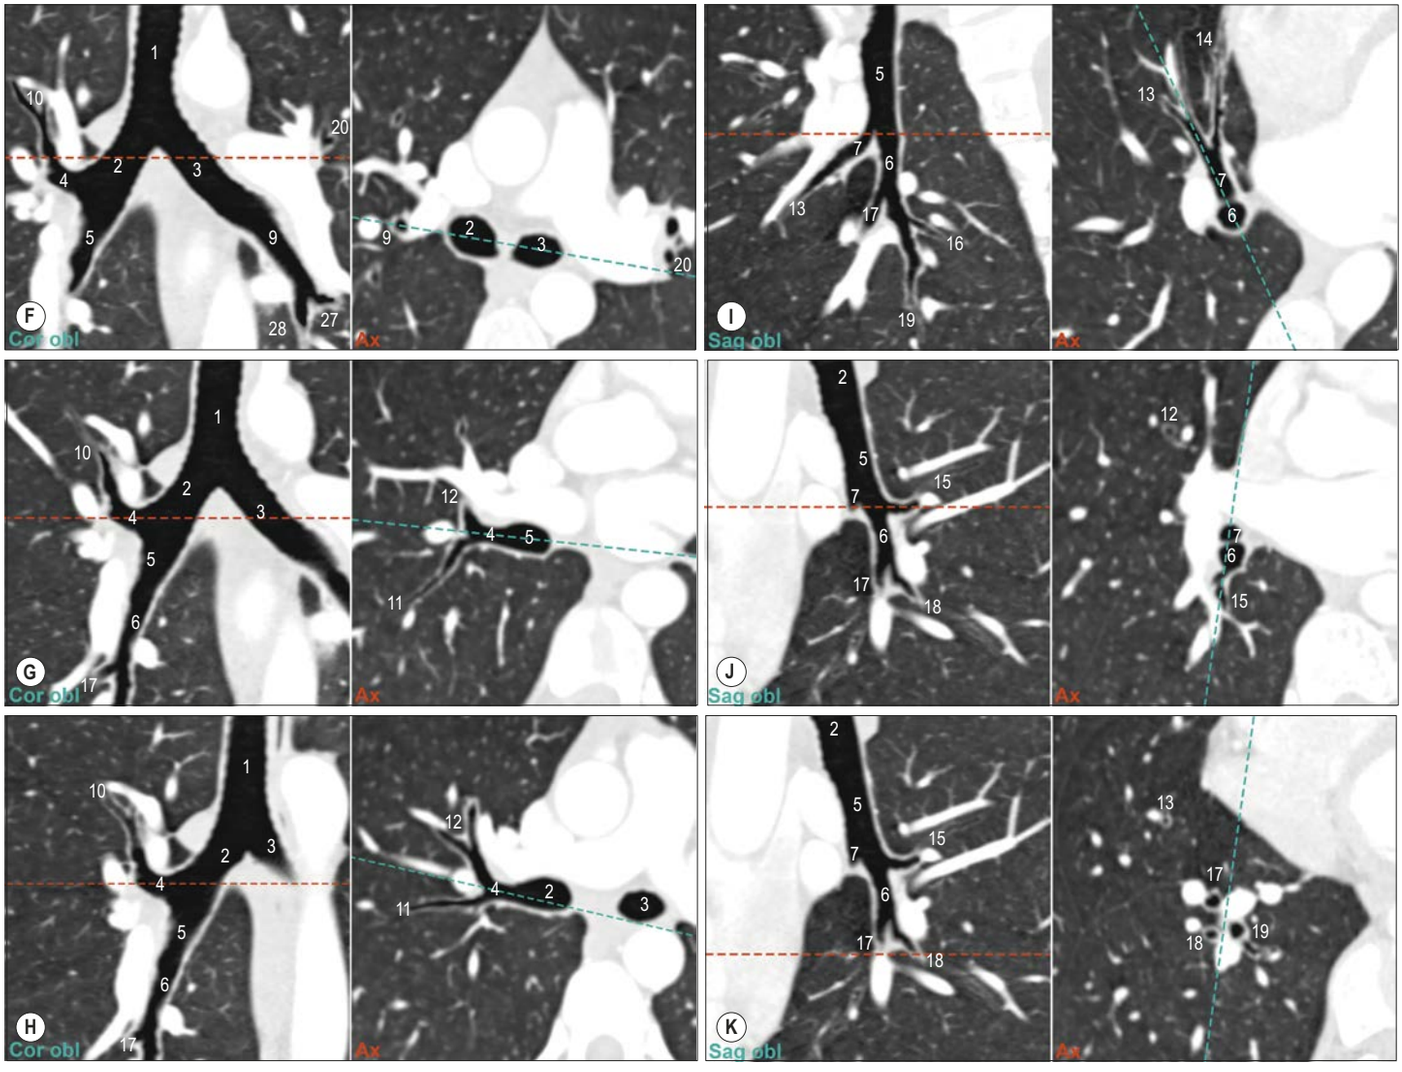

Fig. 54.6 A, A bronchogram showing the branching pattern of the trachea and bronchi of the right lung, in a slightly oblique, anteroposterior view. In this procedure, a radiopaque contrast medium has been introduced into the respiratory tract to coat the walls of the respiratory passages. For identification of the major branches, compare with Figs 54.5B, 54.13. **B–E**, Lung window CT images demonstrating branching of lobar and segmental bronchi from the level of the carina (**B**) to the bifurcation of the right middle lobar bronchus **(E). TABLE 54.1 Bronchopulmonary segments

	Right lung	Left lung
Superior lobe	S1, apical; S2, posterior; S3, anterior	S1, apical; S2, posterior; S3, anterior; S4, superior lingular; S5, inferior lingular; (S1 and S2 may be fused)
Middle lobe	S4, lateral; S5, medial	–
Inferior lobe	S6, superior (apical); S7, medial basal; S8, anterior basal; S9, lateral basal; S10, posterior basal	S6, superior (apical); S7, medial basal; S8, anterior basal; S9, lateral basal; S10, posterior basal; (S7 and S8 may be fused)

and adjacent cartilages may variously fuse. The first and the last two cartilages are more conspicuous, the first being the thickest (see Fig. 54.5) and the last merging into the incomplete rings at the origin of the left and right main bronchus. The tracheal bifurcation is marked by a cartilaginous spur, the carina.

Bronchial cartilages

Cartilaginous plates mainly surround the dorsal aspect of the lobar bronchi. They become more irregular and form progressively less of the bronchial walls in intrapulmonary bronchi and disappear in the bronchioles (see Fig. 54.11).

Vascular supply, lymphatic drainage and innervation

Trachea

The trachea is supplied mainly by branches of the inferior thyroid arteries, which anastomose with ascending branches of the bronchial arteries. Veins draining the trachea end in the inferior thyroid venous plexus. The lymph vessels pass to the pretracheal, retrotracheal and upper and lower paratracheal lymph nodes (Ch. 56, see Figs 54.12, 56.4A, Table 56.1).

Bronchi

Bronchial arteries

The bronchial arteries supply oxygenated blood and nutrition to the bronchi and connective tissue of the lungs and also supply the oesophagus (**Figs 54.10–54.11**). They are commonly derived from the proximal part of the descending thoracic aorta either directly or indirectly, travel and branch with the bronchi, and terminate around the level of the respiratory bronchioles. They anastomose with the branches of the pulmonary arteries, and together supply the visceral pleura of the lung.

Most commonly there is one right and two left bronchial arteries, although various combinations are possible, for example, two right and two left or two right and one left artery. The normal single right bronchial artery has a variable origin, usually arising as a common trunk with the right third posterior intercostal artery (a branch of the descending thoracic aorta), sometimes from the superior left bronchial artery or from various right intercostal arteries. There are normally two left bronchial arteries (superior and inferior) that branch separately from the descending thoracic aorta, although these may be singular and may also give rise to a right bronchial artery. Uncommon origins for the bronchial arteries include the abdominal aorta or the inferior phrenic, coronary, subclavian or internal thoracic arteries, or the brachiocephalic or thyrocervical trunks. A review of branching patterns and origins is presented by Akgun et al (2016).

The bronchial arteries accompany the bronchial tree and supply bronchial glands, the walls of the bronchi and larger pulmonary vessels. The bronchial branches form a capillary plexus in the muscular tunic of the air passages that supports a second mucosal plexus that communicates with branches of the pulmonary artery and drains into the pulmonary veins. Other arterial branches ramify in interlobular loose connective tissue and most end in either deep or superficial bronchial veins; some also ramify on the surface of the lung, forming subpleural capillary plexuses. The bronchopulmonary arterial anastomoses in the walls of the smaller bronchi and in the visceral pleura may be more numerous in the neonate and are subsequently obliterated.

In addition to the usual three main bronchial arteries, smaller bronchial branches arise from the descending thoracic aorta; some may travel through the pulmonary ligament and bleed during inferior lobectomy. The bronchial arteries are typically enlarged and tortuous in chronic pulmonary thromboembolic hypertension. They are not usually reconnected following lung transplantation. Aneurysms of a bronchial artery may mimic aortic aneurysms.

Bronchial veins

There are usually two bronchial veins on each side that drain blood from larger bronchi and hilar region structures. They form two distinct systems. Deep bronchial veins commence as intrapulmonary bronchiolar plexuses that communicate freely with the pulmonary veins and eventually join a single trunk that ends in a main pulmonary vein or in the left atrium. Superficial bronchial veins drain extrapulmonary bronchi, visceral pleura and the hilar lymph nodes. They also communicate with the pulmonary veins and end in the azygos vein on the right, and in the left superior intercostal or the accessory hemiazygos vein on the left. Much of the blood supplied by the bronchial arteries is returned via the pulmonary veins rather than the bronchial veins. The main bronchial arteries and veins run on the dorsal aspect of the extrapulmonary bronchi.

Lymphatic drainage

The pulmonary lymphatics originate in superficial and deep plexuses that start at the bronchioles: the walls of the alveoli and the alveolar ducts have no lymph vessels. The superficial plexus lies deep to the visceral pleura and its efferents pass around the margins of the lung and its fissures, eventually reaching the bronchopulmonary (hilar) nodes (**Fig. 54.12**). The deep lymphatics originate at bronchiolar level and follow the divisions of the bronchial tree and pulmonary vessels to the lung hilum, ending in the same nodes as the superficial plexus. In larger bronchi, the deep plexus has submucosal and peribronchial parts, but in smaller bronchi there is only a single plexus that extends to the bronchioles. Lymph node groups (stations) sit alongside the bronchi and are classified according to their location, specifically, subsegmental, segmental, lobar and hilar (Rusch et al 2009). Lymph from the hilar nodes drains into subcarinal (inferior tracheobronchial) and lower paratracheal (superior tracheobronchial) node groups.

Free anastomoses between the two superficial and deep plexuses are found only at the hilum and also peripherally, where small but dilatable channels connect superficial and deep lymphatic vessels: these connections direct lymph from the deep to the superficial channels when outflow from deep vessels is obstructed by pulmonary disease. There is a tendency for lymph vessels from the superior lobes to pass to the lower paratracheal (superior tracheobronchial) nodes, and those from the inferior lobes to pass to the subcarinal (inferior tracheobronchial) nodes. However, lymphatic vessels of adjoining lobes connect deep in the fissures which means that these connections are not exclusive. At the level of pulmonary lobation, the arrangement of lymphatic vessels follows the central artery of a lobule and its peripheral veins. Lymphoid aggregations, non-follicular in appearance, occur in peribronchial sites and in 'placoid' formations deep to the visceral pleura.

Innervation

The autonomic nervous system (either by direct axonal innervation or circulating neurotransmitter) controls many aspects of airway function, including regulation of airway smooth muscle tone, mucus secretion from submucosal glands and surface epithelial goblet cells, vascular permeability and blood flow (Belvisi 2002).

The trachea and bronchi are innervated by branches of the vagus nerves, recurrent laryngeal nerves and sympathetic trunks via the anterior and posterior pulmonary plexuses. The plexuses are interconnected and lie anterior and posterior to the structures of the lung root and hilum (see Figs 56.6–56.7, 57.61). The anterior plexus is small and is formed by branches from the vagus nerves and sympathetic cervical cardiac nerves via connections with the superficial cardiac plexus. The left and right posterior pulmonary plexuses are formed by the branches of the vagus nerves, and sympathetic cardiac branches from the second to fifth or sixth thoracic sympathetic ganglia. The left posterior plexus also receives branches from the left recurrent laryngeal nerve. Further details of the pulmonary plexuses are given in the description of the cardiac plexuses on page 1094. Branches of the plexuses enter the lung as networks that travel along successive branches of the bronchi and the pulmonary and bronchial vessels as far as the visceral pleura.

Fig. 54.9 A micrograph of the trachea of a child, sectioned transversely. An incomplete cartilage ring (C) is joined posteriorly by muscular tissue (M). Seromucous submucosal glands (S) are concentrated in this region and between adjacent cartilages. Note the thyroid gland tissue (T) surrounding the left, anterior and right sides of the trachea. (With permission from Stevens A, Lowe JS 1996 Human Histology, 2nd ed. London: Mosby.)

Some degree of mixing of blood between bronchial and pulmonary circulations and through small cardiac veins (venae cordis minimae or Thebesian veins) draining into the left ventricle normally occurs. A small degree of shunt, i.e. perfusion without ventilation, appears as normal and is usually 2–4%. Cardiac malformations with right-to-left flow, pulmonary arteriovenous malformations, congenital diaphragmatic herniae or pulmonary embolism cause more important shunting that is refractory to the administration of pure oxygen.

Efferent preganglionic parasympathetic nerves from the vagus nerve synapse on small ganglia within the walls of the tracheobronchial tree, likely acting as sites of integration and/or modulation of the input from extrinsic nerves or permitting local control of aspects of airway function by local reflex mechanisms. The predominant contractile innervation of airway smooth muscle is parasympathetic cholinergic, while the primary relaxant innervation of the airways is non-cholinergic (parasympathetic nerves containing nitric oxide synthase and vasoactive intestinal peptide). These parasympathetic nerves are anatomically and physiologically distinct and differentially regulated by reflexes. Stimulation of cholinergic nerves also results in mucus secretion and bronchial vasodilation. Sympathetic-adrenergic nerves play little, if any, role in directly regulating smooth muscle tone in the human airways, although they may control constriction of tracheobronchial blood vessels. Circulating noradrenaline (norepinephrine) can bring about bronchodilation through activation of β-adrenergic receptors in the airways. Extrapulmonary afferents may modulate neurally mediated regulation of airway smooth muscle tone (Canning and Fischer 2001).

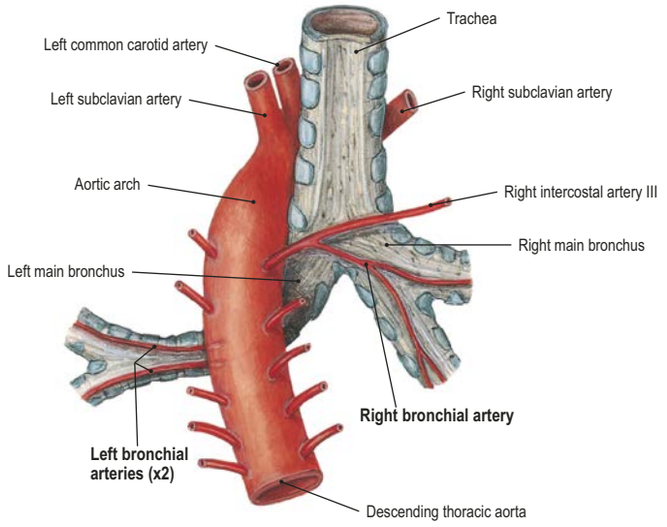

Fig. 54.10 The common pattern of origin of the bronchial arteries from the descending thoracic aorta (posterior view).

Lung root and hilum

The lung root connects the mediastinal surface of the lung to the heart and trachea, and is formed by a group of structures that enter or leave the lung hilum including the main bronchus, or its lobar branches, pulmonary artery, two pulmonary veins, bronchial vessels, a pulmonary autonomic plexus, lymph vessels, hilar (bronchopulmonary) lymph nodes and loose connective tissue, all enveloped by a double-layered sleeve of pleura (a visceral and a parietal layer) (see Figs 54.3, 54.13). The lung roots commonly lie opposite the bodies of the fifth to seventh thoracic vertebrae. The phrenic nerve, pericardiacophrenic vessels and anterior pulmonary plexus are common anterior relations of the left and right lung roots, the vagus nerve and posterior pulmonary plexus are common posterior relations and the pulmonary ligament is a common inferior relation.

Left hilum

The hilum of the left lung and the closely associated lung root are situated inferior to the aortic arch and anterior to the descending thoracic aorta. Usually, the order of structures at the hilum, from superior to inferior, is the pulmonary artery, left main (hyparterial) bronchus and inferior pulmonary vein (see Fig. 54.3B). The superior pulmonary vein is often the most anterior structure at the hilum, sitting anterior to the left main bronchus. The pulmonary artery is longer on the left side and may have branched before entering the hilum: each of its branches from the hilum to the oblique fissure must be identified in pulmonary resections.

Right hilum

The hilum of the right lung and the closely associated lung root are situated posterior to the superior vena cava and the fibrous pericardium covering the right atrium and inferior to the terminal (arching) part of the azygos vein. Usually the superior lobar (eparterial) bronchus is the most superior structure, with the bronchus intermedius located immediately inferior; the superior and inferior pulmonary veins are the most anterior (or anteroinferior) and inferior structures, respectively; and the pulmonary artery is anterior to the bronchi and may be either posterior and/or superior to the superior pulmonary vein (see Fig. 54.3A). One or two pulmonary arteries may be present at the hilum, depending on where the right pulmonary artery branches: when two are present their arrangement is commonly superior–inferior.

Pulmonary vascular supply and drainage

The lungs have two functionally distinct circulatory pathways. Pulmonary arteries convey systemic deoxygenated blood to the alveolar walls and pulmonary veins drain oxygenated blood back to the left atrium for systemic distribution by the left ventricle. The much smaller bronchial arteries, derived from the systemic circulation, provide oxygenated blood to lung tissues that do not have close access to atmospheric oxygen, i.e. those of the bronchi and larger bronchioles (see Fig. 54.10).

The pulmonary trunk bifurcates into right and left pulmonary arteries, each of which approaches the respective lung hilum via the lung root (**Fig. 54.13**). Each pulmonary artery divides into branches that accompany the segmental and subsegmental bronchi, mostly in a posterolateral position. The pulmonary capillaries form single-layered, thin-walled plexuses immediately outside the epithelium in the walls and septa of the alveoli and alveolar sacs (see Fig. 54.11). Pulmonary veins, two from each lung, drain the pulmonary capillaries; their rootlets coalesce into larger and more freely communicating veins that traverse the lung, for the most part independently of the pulmonary arteries and bronchi. Near the lung hilum, the pulmonary vessels accompany the main bronchial division, the veins lying anteromedial and the arteries posterolateral to the bronchi. This is not the case in the bronchopulmonary segments, where a segmental bronchus, its branches and associated arteries occupy a central position, whereas the many tributaries of the pulmonary veins run between segments, serving adjacent segments (which therefore drain into more than one vein). Some veins also lie beneath the visceral pleura, including the pleura in the interlobar fissures. It follows from this that a bronchopulmonary segment is not a complete vascular unit with an individual bronchus, artery and vein. During resection of segments, it is apparent that the planes between them are not avascular but are crossed by pulmonary veins and sometimes by branches of arteries. This relationship of bronchi, arteries and veins exhibits considerable variation, veins are the most variable and arteries are more variable than bronchi.

Pulmonary arteries

The right pulmonary artery divides into two large branches posterior to the superior vena cava, or immediately lateral to its right side (see Fig. 54.13). This intimate relationship facilitates the cavopulmonary anastomosis (the Glenn shunt) conceived to bypass the defective right heart chambers in various congenital cardiac disorders. A lymph node usually lies adjacent to the bifurcation. The smaller branch to the superior lobe usually divides again, supplying the majority of that lobe. The inferior branch descends anterior to the bronchus intermedius and posterior to the superior pulmonary vein. It provides a small recurrent branch to the superior lobe, and then, at the point where the horizontal fissure meets the oblique fissure, it gives off the branch to the middle lobe anteriorly, and a branch to the superior segment of the inferior lobe posteriorly. It then continues a short distance before dividing to supply the rest of the inferior lobe segments.

The left pulmonary artery emerges from under the concavity of the aortic arch and descends anterior to the descending thoracic aorta to enter the oblique fissure. The ligamentum arteriosum passes between the superior aspect of the left pulmonary artery and the proximal descending thoracic aorta; the aorta is relatively fixed in position by the ligament, and so may be ruptured in this region in cases of major trauma associated with rapid deceleration. The left recurrent laryngeal nerve branches from the left vagus nerve, passes inferior to the aortic arch to the left of the ligamentum arteriosum, and then courses superiorly posterior to the aortic arch; it is a close relation of the superior part of the left lung root and hilum, where it may be compressed or invaded by lung tumour. The branches of the left pulmonary artery are variable (Sivrikoz 2016). The first and largest branch is usually given off to the anterior segment of the left superior lobe. Before reaching the oblique fissure, the artery gives off a variable number of other branches to the superior lobe; it usually supplies a large branch to the superior segment of the inferior lobe as it enters the fissure. Lingular branches arise within the fissure, and the rest of the lower lobe is supplied by many varied branching patterns. It was a surgical aphorism of the late Lord Brock that when performing a left upper lobectomy, 'there was always one more branch of the pulmonary artery than you thought!'

Pulmonary sequestration

When a portion of lung exists without the appropriate bronchial and vascular connections, it is usually supplied by the systemic vasculature (descending thoracic or abdominal aorta or one of its branches) and drains into either the atria, superior vena cava or azygos venous system (Clements 1999) (**Figs 54.14–54.15**).

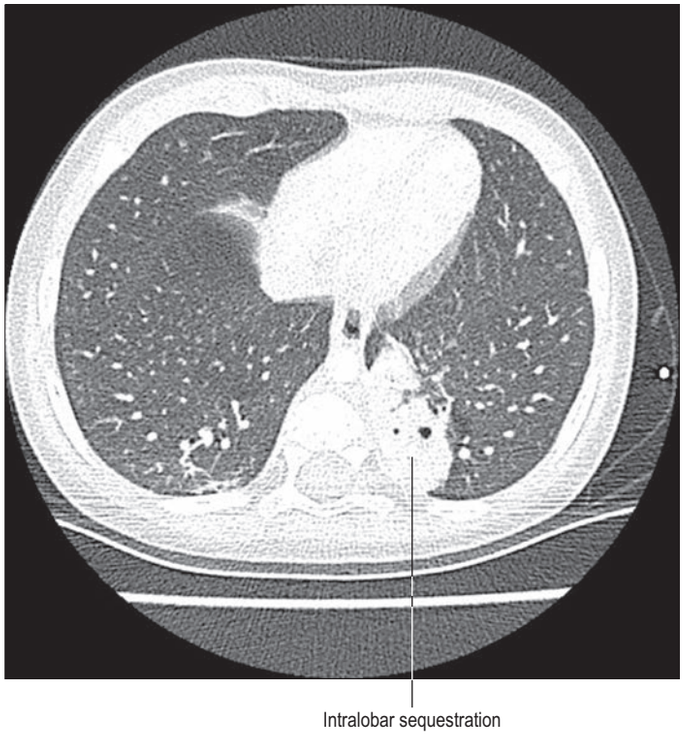

Fig. 54.14 A CT of the chest (lung windowed, axial view) showing an intralobar sequestration in the left inferior lobe of the lung in a 15-month-old girl. (Courtesy of Mr Hany Gabra and Mr Jonathan Goring, Great North Children's Hospital, Newcastle upon Tyne, UK.)

(Courtesy of Mr Hany Gabra and Mr Jonathan Goring, Great North Children's Hospital, Newcastle upon Tyne, UK.)

Unilateral absence of a pulmonary artery is a rare congenital anomaly characterized by normal lung volume and anatomy at birth. Revascularization before the age of 6 months avoids the development of lung hypoplasia (Alison et al 2011). The left pulmonary artery sling is a congenital anomaly where the left pulmonary artery arises from the right pulmonary artery, travels posteriorly over the right main bronchus and then passes between the trachea and oesophagus: it is associated with significant tracheobronchial stenosis (Zhong et al 2010).

Extralobar pulmonary sequestration segments are covered by visceral pleura and usually found below the left inferior lobe, whereas intralobar anomalies are usually embedded in normal lung, classically, in the posterior basal segment of the left inferior lobe. Extralobar pulmonary sequestration is normally asymptomatic but often associated with other congenital anomalies such as pulmonary hypoplasia, congenital diaphragmatic hernia, congenital cystic adenomatoid malformation and congenital heart disorders (Stocker et al 1978, Kravitz 1994). A fistula into the oesophagus may also develop. Consideration of differential diagnoses that include mediastinal or pulmonary tumours is mandatory.

A thrombus that has developed in the deep venous system (usually in the lower limb or pelvis) may embolize and travel in the right side of the circulation through the right atrium and right ventricle and lodge in the pulmonary vasculature. The clinical abnormalities observed depend on the size of the embolus and on the number and frequency of embolic episodes. Large emboli may lodge in branches of the main pulmonary artery and cause right ventricular dysfunction and hypoxia, representing a medical emergency. Smaller emboli may lodge in segmental pulmonary arteries and cause pleuritic chest pain, shortness of breath and haemoptysis, although the clinical picture is rarely pathognomonic. Pulmonary emboli cause a ventilation–perfusion ratio mismatch that can have serious physiological implications leading to a significant reduction in the oxygenation of blood. Ventilation–perfusion scans with radiolabelled xenon and technetium usually demonstrate segmental abnormalities in perfusion with normal ventilation in the corresponding regions. Pulmonary emboli may also be evaluated by contrast-enhanced spiral CT or pulmonary angiograms and appear as filling defects. Repetitive embolization may eventually lead to a dramatic reduction of the pulmonary vascular bed and chronic cor pulmonale. Thrombolysis, anticoagulation or inferior vena caval filters prevent progression or recurrence of embolism. A clot may also traverse a patent foramen ovale and lodge in the arterial system (paradoxical embolism), most severely in the cerebral circulation resulting in stroke (Kent and Thaler 2011).

The variable incorporation of the primitive pulmonary vein into the left atrium during development (Ch. 13) means that the number of main pulmonary veins may differ. Pulmonary vein atresia is a rare congenital anomaly (Kozak et al 2011). The left atrium is the heart chamber most posterior and median in position, and so the length of the left and right pulmonary veins is relatively equal, unlike the arteries and bronchi, where there are obvious left–right differences in length. The terminal parts of the pulmonary veins are surrounded by atrial myocardium; these areas represent potential accessory re-entrant circuits responsible for the initiation or maintenance of supraventricular tachycardias or atrial fibrillation and may be percutaneously ablated.

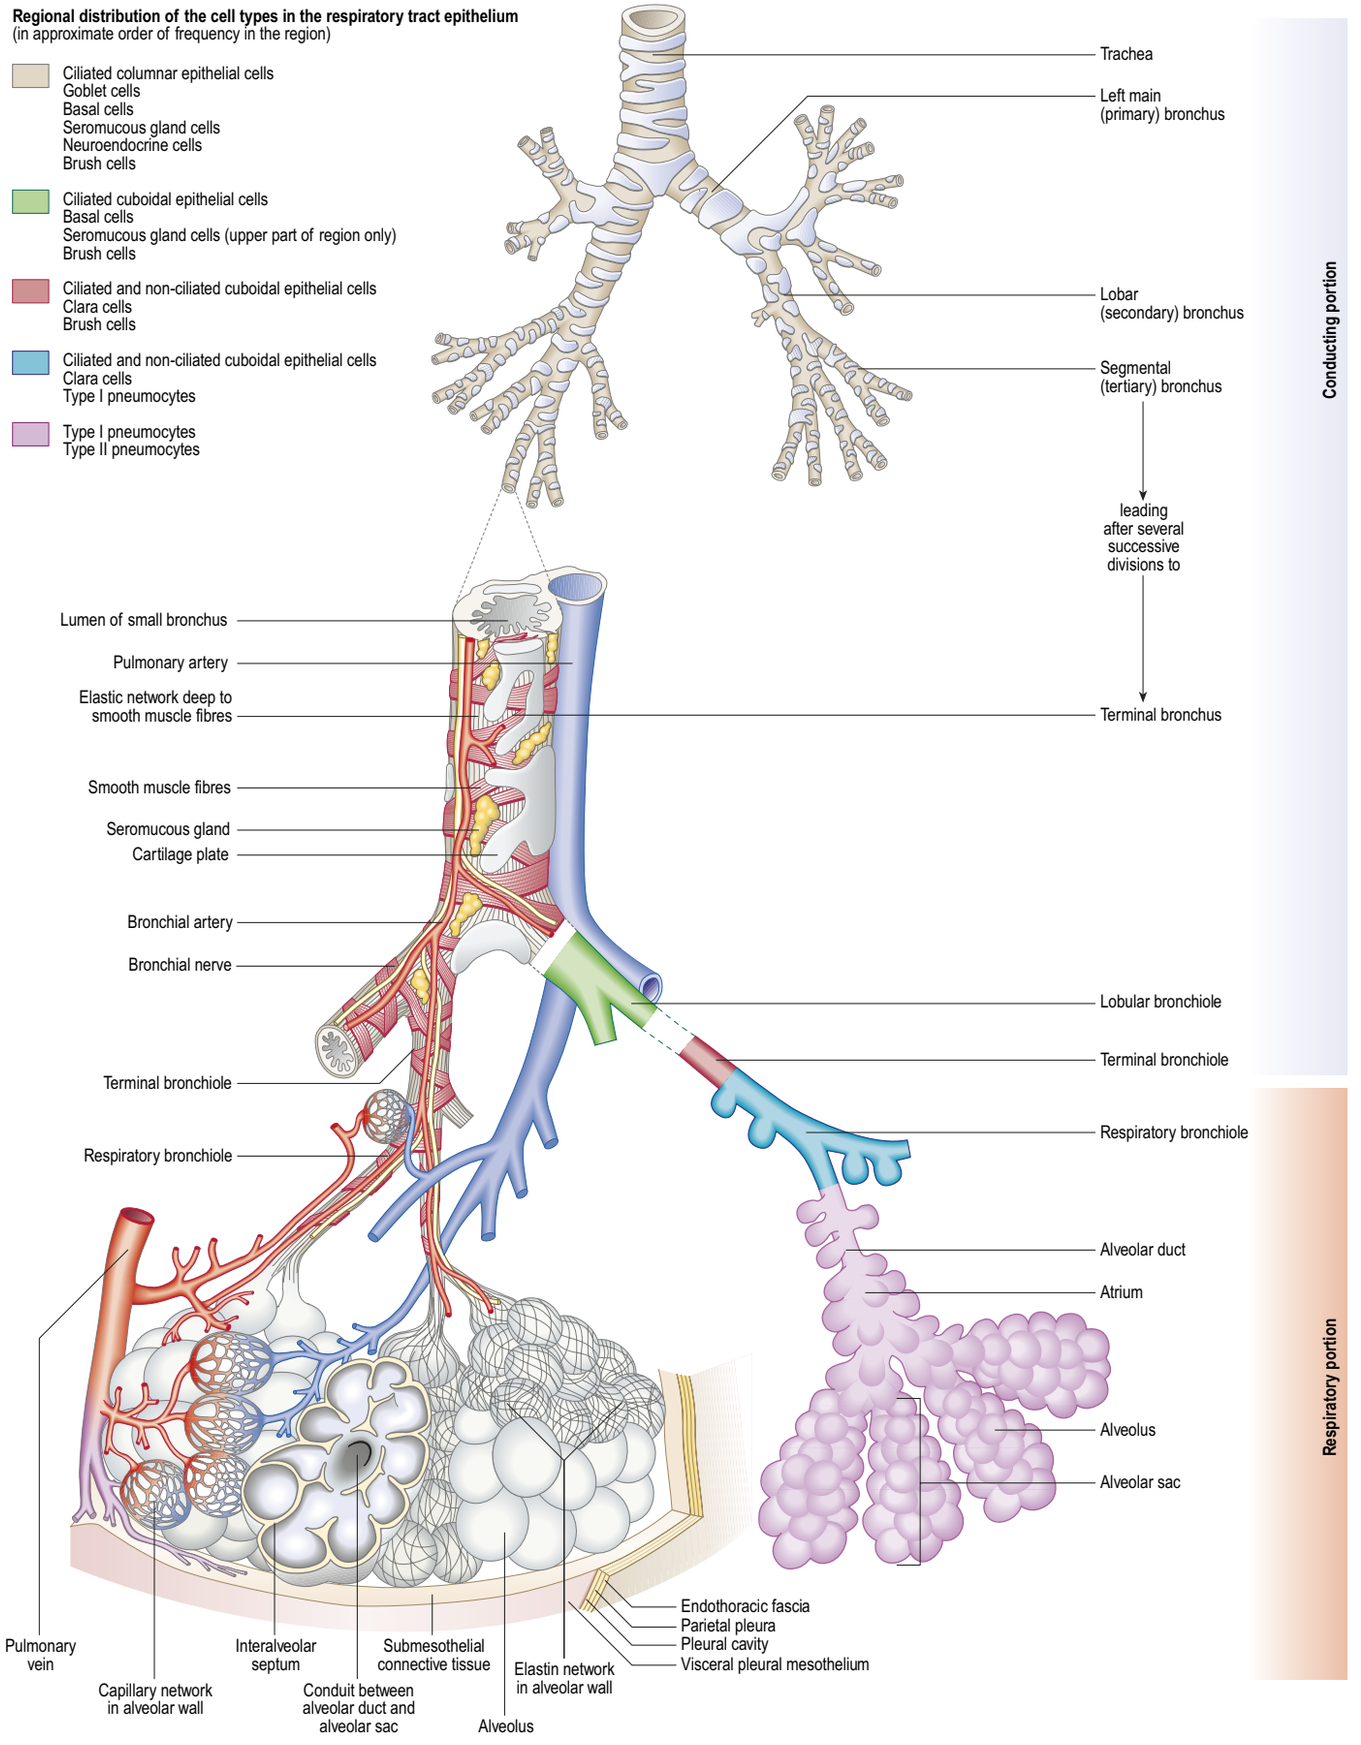

Fig. 54.11 The respiratory tree and its arterial blood supply and venous drainage. The distribution of the different epithelial cells is shown. Blue is used for vessels that contain deoxygenated blood, and red for vessels that contain oxygenated blood. The deep lymphatic plexus (not shown) accompanies the bronchial artery and nerve to the bronchioles but does not reach the alveolar duct or beyond.

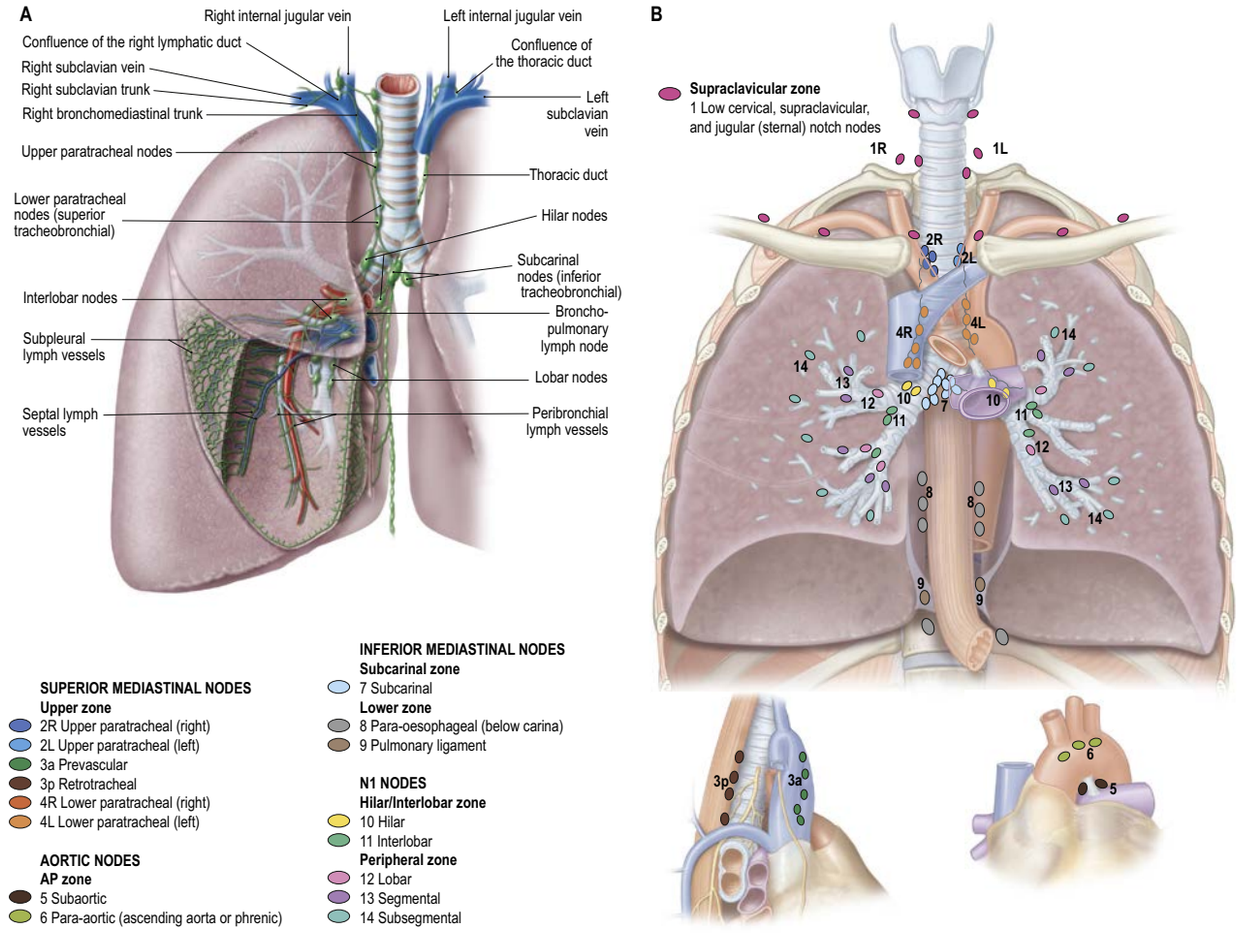

Fig. 54.12 Lymphatic vessels, pathways and nodes (zones and stations) of the lung and tracheobronchial tree. **A**, The peribronchial and the subpleural and septal systems drain via different routes and converge in lymph nodes at the lung hilum. **B**, The lymph node groups of the lung, trachea and mediastinum, arranged as stations and zones. Pulmonary veins

There are usually four pulmonary veins, two from each lung. They originate from capillary networks in the alveolar walls and return oxygenated blood to the left atrium: they are devoid of valves. All the main tributaries of the pulmonary veins receive smaller tributaries, both intra- and intersegmental. By serial junctions, tributaries ultimately form a single lobar trunk (one for each lobe). Usually, there are three trunks in the right lung and two in the left: variations reflect the lobar arrangement of an individual. The right middle and superior lobar veins usually unite so that two veins, superior and inferior, leave each lung at the hilum: the superior pulmonary vein is anteroinferior to the pulmonary artery, and the inferior pulmonary vein is the most inferior hilar structure and is also slightly posterior (see Fig. 54.3). The right superior pulmonary vein is formed by the union of apical, anterior and posterior veins (draining the superior lobe) with a middle lobar vein formed by lateral and medial tributaries. The right inferior pulmonary vein is formed in the hilar region by the union of superior (apical) and common basal veins from the inferior lobe. The union of superior and inferior basal tributaries forms the common basal vein. Occasionally, the three right lobar veins remain separate. The right superior pulmonary vein passes posterior to the superior vena cava, and the inferior passes posterior to the right atrium.

The left superior pulmonary vein is formed by the union of apicoposterior, anterior and lingular veins. The left inferior pulmonary vein is formed by the union of the superior (apical) and common basal veins, the latter formed by the union of the superior and inferior basal veins. Both left superior and inferior pulmonary veins pass anterior to the descending thoracic aorta. Sometimes, the two left pulmonary veins form a single trunk, or they may be augmented by an accessory lobar vein from each lobe that unite to form a third left pulmonary vein.

The right and left pulmonary veins pass through the pericardia and open separately in the posterosuperior aspect of the left atrium (see Fig. 57.4B). Their terminations are separated medially by the oblique pericardial sinus, and laterally by smaller and variable pulmonary venous pericardial recesses that are directed superomedially.

Pulmonary defensive mechanisms

The respiratory tract presents a huge surface area that is vulnerable to desiccation, freezing, microbial invasion and the mechanical and chemical effects of inhaled particles. Inhaled air is humidified mainly in the upper respiratory tract, where it passes, with some turbulence, over the nasal and buccopharyngeal mucosae (Ch. 39). The secretions of the various glands of the tracheobronchial tree also help to prevent desiccation. Goblet cells secrete sulphated acid mucins; cells in mucous glands beneath the epithelial surface contain mainly carboxylated mucins, particularly those associated with sialic acid, although sulphated groups also occur; cells of serous glands contain neutral mucins. Goblet cells respond mainly to local irritation, while tubular glands, both mucous and serous, are predominantly under neural and hormonal control. Excessive or altered secretions may

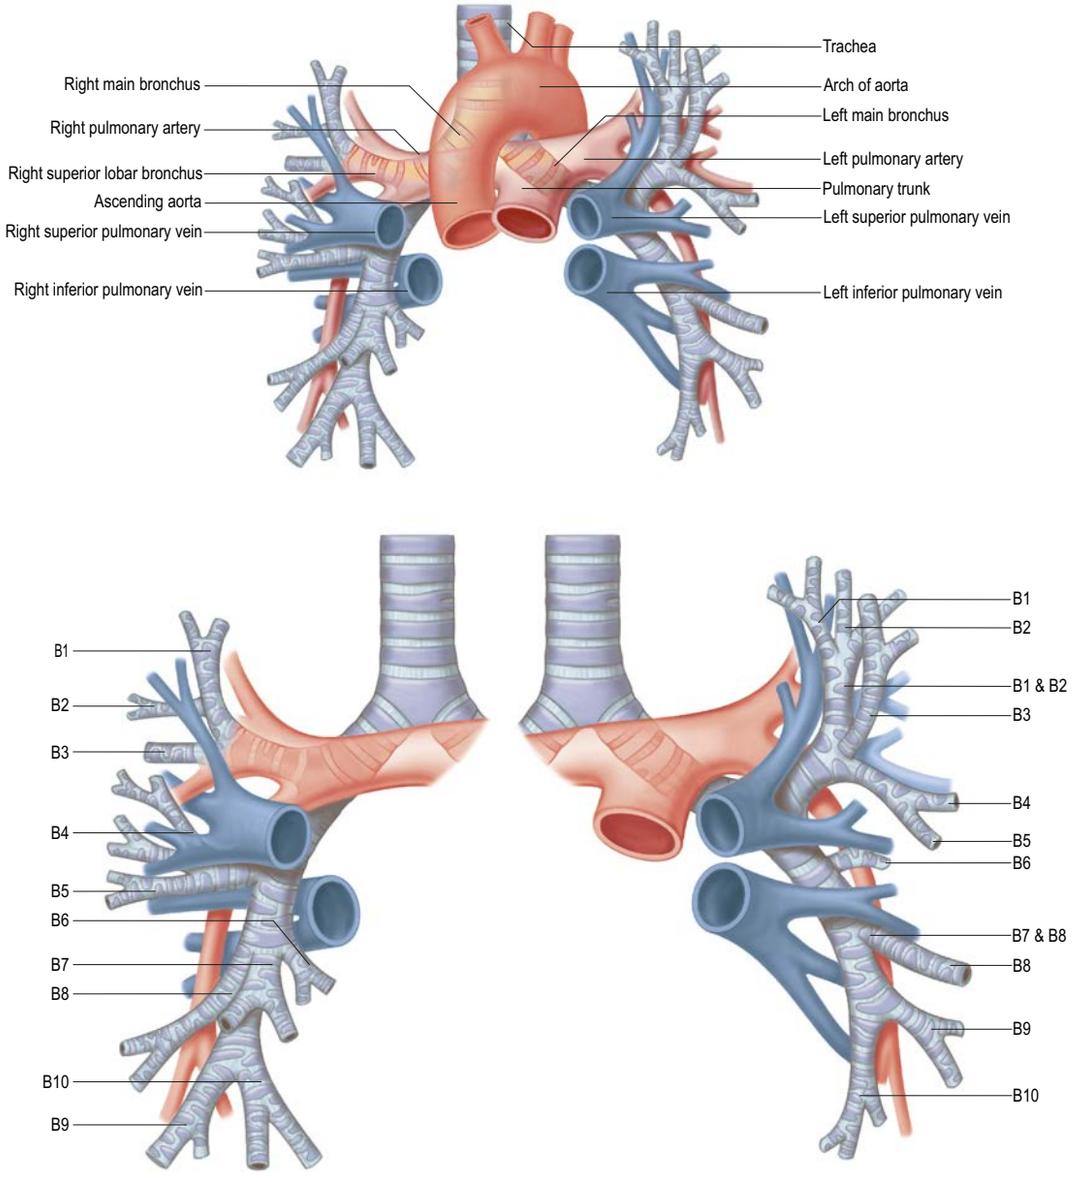

Fig. 54.13 The relationship between the central airways and the pulmonary vessels. The alphanumeric labels in the lower figure denote the numbers of the segmental bronchi supplying the corresponding bronchopulmonary segments.

obstruct the flow of air. Antibacterial and antiviral substances, e.g. lysozyme, IgA antibodies and possibly interferon, also appear in the secreted fluid.

Inhaled particles may be cleared by the cough reflex (see below) or removed via the mucociliary rejection current. Cilia sweep the fluid overlying the surfaces of bronchioles, bronchi and trachea upwards at 1 cm/min, and much of the inhaled matter trapped in the viscous fluid may be removed in this way. Particles small enough to reach the alveoli may be removed by alveolar phagocytes. Alveolar epithelium is continually replaced: the lifespan of alveolar squamous cells is approximately 3 weeks, and that of alveolar phagocytes is 4 days.

Numerous lymphoid nodules occur in the bronchial lining, providing foci for the production of lymphocytes and providing local immunological protection against infection both by cell-mediated (T-cell) activities, and by the production of immunoglobulins (mainly IgA) from B cells that are passed onto gland cells for secretion to the epithelial surface.

Anatomy of coughing

Under normal conditions, coughing is an important defensive reflex. It enhances clearance of secretions and particulates from the airways and protects from aspiration of foreign materials (occurring as a consequence of aspiration or inhalation of particulate matter, pathogens, accumulated secretions, postnasal drip, inflammation and mediators associated with inflammation). In some conditions coughing may become excessive, non-productive and potentially harmful to the airway mucosa.

The mechanical events of a cough can be divided into three phases. An initial deep inhalation generates the volume necessary for an effective cough and is followed by a compression phase, when forceful contraction of the muscles of the chest wall, respiratory diaphragm and abdominal wall against a closed glottis results in a rapid rise in intrathoracic pressure. Subsequent glottal opening causes a rapid peak expiratory airflow that dislodges and expels mucus from the airways and this forceful airway compression produces the coughing sound.

Microstructure of the conducting airways

The conducting airways are lined internally by a mucosa (see Fig. 2.16), and the epithelium lies on a thin connective tissue lamina propria. External to this is a submucosa, also composed of connective tissue that contains airway smooth muscle, glands, cartilage plates (depending on the level in the respiratory tree), vessels, lymphoid tissue and nerves. Cartilage is present from the trachea to the smallest bronchi but is absent (by definition) from bronchioles (see Fig. 54.9).

Epithelium

The epithelia of the trachea, bronchi and bronchioles are generally similar although the numbers of different cell types vary according to location. The extrapulmonary and larger intrapulmonary passages are lined with respiratory epithelium, which is pseudostratified and predominantly ciliated, and contains interspersed mucus-secreting goblet cells (see Fig. 2.2D). There are fewer cilia in terminal and respiratory bronchioles, and the cells are reduced in height to low columnar or cuboidal. The epithelium of smaller bronchi and bronchioles is folded into conspicuous longitudinal ridges that accommodate changes in luminal diameter (see Figs 54.11, 54.17). The epithelium in the respiratory bronchioles progressively reduces in height towards the alveoli, and is eventually composed of cuboidal, non-ciliated cells. Lateral pouches lined with squamous cells in the walls of the respiratory bronchioles provide an accessory respiratory surface.

Six distinct types of cell have been described in the conducting airways, namely: ciliated columnar, goblet, Clara, basal, brush and neuroendocrine (see Fig. 54.11). Lymphocytes and mast cells migrate into the epithelium from the underlying connective tissue.

Microstructure of respiratory surfaces

Thin-walled respiratory surfaces (alveoli) are distributed as isolated patches within the walls of respiratory bronchioles and as tube-like alveolar ducts and balloon-like alveolar sacs that contain groups of adjacent alveoli (see Fig. 54.11).

Alveolar area

Each human lung contains approximately 300–500 million alveoli, giving a total surface area of 70–100 m^2. These values vary considerably between normal young individuals and the differences become more marked with age and as a consequence of degenerative changes. The number of alveoli increases from approximately 10 million at birth to the adult value, mainly in the first 8 years of life; thereafter, the increase in lung volume is achieved through augmentation of alveolar volume (Narayanan et al 2013). Their diameter when inflated varies with lung position, being greatest in superior regions because of the increased gravitational pressure at the lung base. Although the lung enlarges in all directions during inspiration, most of the change in volume appears to be due to the lengthening and expansion of the alveolar ducts and increase in the size of the openings into the air sacs, whereas the inspiratory change in the volume of the gas-conducting system is insignificant. The combined alveolar and capillary surface area for gaseous exchange is 60–80 m^2 surface and the capillary blood transit time at rest is 0.75 seconds, halving with exercise.

Alveolar structure

The alveoli are thin-walled pouches that lie in a delicate connective tissue containing a network of capillaries (**Figs 54.18–54.19**). Since the walls are extremely thin, they present a minimal barrier to gaseous exchange between the atmosphere and the blood in the capillaries. Adjacent alveoli are frequently in close contact, the intervening connective tissue forming the central part of an interalveolar septum. Alveolar macrophages are present within the alveolar lumen and migrate over the epithelial surface.

Interalveolar septum

The alveolar lining epithelium varies in thickness; extensive areas are as little as 0.05 μm thick (see Fig. 54.19). The epithelium lies on a basal lamina that is fused with the basal lamina surrounding the adjacent capillaries in the thin portions of a septum. The total barrier to diffusion between air and blood in these thin portions may be as little as 0.2 μm. The thick portions of a septum contain connective tissue elements, including elastic and collagen type III fibres, resident and migratory cells (see Fig. 54.18).

Alveolar epithelial cells (pneumocytes)

The alveolar epithelium is a mosaic of type I and II pneumocytes. Type I pneumocytes are simple squamous epithelial cells and form over 90% of the alveolar area. In histological sections they are characterized by the protrusion of their nuclei from the alveolar surface. Their basal laminae fuse with that of the adjacent capillary endothelium to form the thin portions of interalveolar septa. Their thin cytoplasm (0.05–0.2 μm) facilitates gaseous diffusion between the lumen of the alveolus and its capillaries. The edges of adjacent cells overlap and are joined by tight junctions, creating a strict diffusion barrier between the alveolar surface and underlying tissues. Together with a similar endothelial barrier, this arrangement limits the movement of fluid from blood and interstitial spaces into the alveolar lumen (the blood–air barrier). If damaged, type I pneumocytes, which do not divide, are replaced by type II pneumocytes, which proliferate and differentiate into type I pneumocytes.

The smaller type II cells are often more numerous than type I pneumocytes, but they contribute less than 10% of the alveolar surface area. In histological sections they are characterized by a brush-border projection from the alveolar surface. In the human lung, they are often associated with interalveolar pores of Kohn. Their cytoplasm contains numerous characteristic secretory lamellar bodies consisting of concentric whorls of phospholipid-rich membrane, the precursors of alveolar surfactant, which they can recycle (see Fig. 54.19C).

Interalveolar pores of Kohn

Interalveolar pores of Kohn are small pores lined by epithelium (usually type II pneumocytes), that cross interalveolar septa to link adjacent alveolar airspaces. Humans have up to seven pores per alveolus, ranging in size from 2 to 13 μm. These small passages may sustain the flow of air in the event of blockage of one of the alveolar ducts and also provide routes of migration for alveolar macrophages, bacteria and viruses.

Alveolar macrophages

Alveolar macrophages are derived from circulating monocyte precursors (see Fig. 4.12). They originate in haemopoietic tissue in the bone marrow, migrate into the alveolar lumen from adjacent blood vessels and connective tissue, and 'wander' about on the epithelial surfaces. They clear the respiratory spaces of inhaled particles that are small enough to reach the alveoli (hence their alternative name of 'dust cells'; see Fig. 4.13). Most of them migrate with their phagocytosed load to the bronchioles, where they are swept into the mucociliary rejection current and removed from the lung. Others migrate through the epithelium of the alveoli into the lymphatics that drain the connective tissue of the lung, and so pass into lymphoid tissue around the pulmonary lobules. Under normal conditions, alveolar macrophages have a granular cytoplasm because they contain phagocytosed particles; in smokers, the particles have a characteristic appearance and are called 'tar bodies'. When actively phagocytic, macrophages release proteases: if antiproteases such as α_1-antitrypsin that are normally present in the alveolar lining are deficient, macrophage activity may damage the lung. Alveolar macrophages are involved in the turnover of surfactant.

Alveolar macrophages can be recovered from sputum and are of diagnostic importance if they appear abnormal. For instance, whenever

Coughing is initiated when mechanically and chemically sensitive vagal afferents that innervate the airways from the upper respiratory tract to the terminal bronchioles and lung parenchyma are activated (Morice and Geppetti 2004, Canning et al 2014). Data from experimental studies suggest that the receptors innervated by these afferents may be broadly divided into three groups: slowly (SAR) and rapidly (RAR) adapting stretch receptors and bronchopulmonary unmyelinated C fibres (see below). The vagal afferents terminate centrally in largely non-overlapping regions of the caudal half of the nucleus tractus solitarius. Second-order neurones from this nucleus terminate on respiratory-related regions of the pons, medulla and spinal cord. Efferent impulses travel via the vagus, phrenic and spinal motor nerves to the inspiratory and expiratory muscles, larynx, respiratory diaphragm and abdominal wall muscles. Airway receptors in the external acoustic meatuses (external auditory canals), tympanic membranes, paranasal sinuses, pharynx, respiratory diaphragm, pleura, pericardium and stomach are probably mechanoreceptors, stimulated by triggers such as touch or displacement (Polverino et al 2012).

The specific pattern of a cough depends on the site and type of stimulation. Mechanical laryngeal stimulation results in immediate expiratory stimulation (sometimes termed the expiratory reflex), protecting the airway from aspiration; stimulation distal to the larynx causes a more prominent inspiratory phase to generate the airflow necessary to remove the stimulus.

During vigorous coughing, intrathoracic pressures may reach 300 mmHg (with an abrupt rise in pleural pressure from 6.5 to 13 kPa) and expiratory velocities approach 500 miles per hour (Ford et al 2007). While these pressures and velocities are responsible for the beneficial effects of cough on mucus clearance, they are also the cause of many of the complications of cough, including exhaustion, self-consciousness, insomnia, headache, dizziness, musculoskeletal pain, hoarseness, excessive perspiration, urinary incontinence and cough-induced multiple rib fractures.

Lesions that compress the upper airway, including arteriovenous malformations and retrotracheal masses, may present with chronic cough. Cough can also be a symptom of tracheobronchomalacia, which results from the loss of rigid support of the large airways and inspiratory collapse, usually seen in conjunction with obstructive lung disease in patients with a history of tobacco smoking. Chronic dry cough may be caused by irritation of the external acoustic meatus by impacted foreign bodies or cerumen (Jegoux et al 2002). The aetiology of the 'ear-cough' (otorespiratory reflex) is related to stimulation of the auricular branch of the vagus nerve (Arnold's nerve) (Feldman and Woodworth 1993). Holmes–Adie syndrome is a rare cause of coughing when autonomic dysfunction affects the vagus nerve. Patients present with anisocoria, abnormal deep tendon reflexes and patchy areas of hyperhidrosis or anhidrosis (Kimber et al 1998).

Differences among several sites from which cough stimuli can originate may result in variations in the sounds and patterns of coughing. Laryngeal stimulation produces a choking type of cough without a preceding inspiration. Inadequate mucociliary clearance mechanisms (as in bronchiectasis or cystic fibrosis) may produce a pattern of coughing with less violent acceleration of air and a sequence of interrupted expirations without any intervening inspiration.

Since cough is an important defensive reflex required to maintain the health of the lungs, individuals who do not cough effectively are at risk of atelectasis, recurrent pneumonia and chronic airways disease from aspiration and retention of secretions. Many disorders can impair the ability to cough effectively and this may result in persistent cough. The elderly, the newborn, lung transplant recipients and patients with paralysis or neuromuscular disorders have a poorly developed and/or compromised cough reflex and are rendered highly susceptible to infective and aspiration pneumonia (Polverino et al 2012). Patients with paralysis or neuromuscular disorders (including rib fractures) and chest wall anomalies may not generate the flows necessary for effective clearance of secretions due to defective 'pump' mechanisms. Individuals with reduced function of the abdominal wall musculature are particularly at risk of ineffective cough. Individuals with laryngeal disorders (e.g. vocal fold paresis or paralysis), including those with tracheostomies, may not achieve sufficient laryngeal closure to generate the increased intrathoracic pressures necessary for an effective cough.

RARs are dynamic receptors that respond to changes in airway mechanical properties (e.g. diameter, length and interstitial pressures). Functional studies of RARs suggest that they terminate within or beneath the epithelium mainly of the intrapulmonary airway (Widdicombe 2003). They may be differentiated from other airway afferents by their rapid adaptation (in 1–2 seconds) to sustained lung inflation (Schelegle and Green 2001). RARs are sporadically active throughout the respiratory cycle, activated by the dynamic mechanical forces that accompany lung inflation and deflation, and become more active as the rate and volume of lung inflation increase. Their activation initiates reflex bronchospasm and mucus secretion through parasympathetic pathways.

SARs are found mostly in alveoli and bronchioles. They are highly sensitive to the mechanical forces that act on the lung during breathing. Their activity increases during inspiration and peaks just prior to the initiation of expiration; they are thought to be the afferent fibres involved in the Hering–Breuer reflex, which terminates inspiration and initiates expiration when the lungs are adequately inflated. SARs appear to terminate primarily in the intrapulmonary airways. Their activation results in the central inhibition of respiration and the inhibition of the cholinergic drive to the airways, leading to decreased phrenic nerve activity and decreased airway smooth muscle tone (Canning et al 2001).

The majority of afferent nerves innervating the airways and lungs are unmyelinated C fibres, similar to the unmyelinated somatic sensory nerves that innervate the skin, skeletal muscle, joints and bones and that respond to noxious chemical and mechanical stimuli. In addition to their slow conduction velocity (<2 m/s), airway vagal afferent C fibres are distinguished from RARs and SARs by their relative insensitivity to mechanical stimulation and lung inflation. They are generally quiescent throughout the respiratory cycle (Lee and Pisarri 2001).

Bronchoscopy allows the direct visualization of the vocal folds (cords), trachea and major airways as far as the first division of the subsegmental airway. Occasionally, bronchoscopy can also provide some information about structures adjacent to the airways, e.g. significant subcarinal lymphadenopathy can cause splaying or widening of the carina. Bronchoscopy enables the acquisition of samples (e.g. bronchial lavage, bronchial brushings, bronchial and transbronchial biopsies); provides information about staging in lung cancer; facilitates therapeutic procedures (e.g. foreign body removal, ablation of tumours and insertion of airway stents). The information obtained by volume CT scanning can be reconstructed to provide three-dimensional images that can be used to create endobronchial views (virtual bronchoscopy, Fig. 54.16) or to demonstrate the pulmonary arteries.

Ciliated columnar cells

Ciliated columnar cells are the driving force of the mucociliary rejection current (escalator) in the bronchial tree. They vary from low to tall columnar, each cell has up to 300 cilia projecting from its apical surface. The cilia extend into a watery fluid secreted by serous cells of the submucosal glands, but their tips are in contact with a more superficial layer of thicker mucus secreted by surface goblet cells and mucous cells in the submucosal glands. The rate of ciliary beating is usually 12–16 per second; mechanical stimulation of the epithelial surface and inflammatory mediators increase the rate. In addition to tight junctions, which seal the apical intercellular space from the airway lumen, the ciliated cells are coupled by gap junctions that allow a change in rate of beating to spread from stimulated cells to their neighbours (probably via calcium signalling) so that their metachronal coordination remains intact. Primary ciliary dyskinesia is a ciliary abnormality inherited as an autosomal recessive disorder and may be a feature of Kartagener's syndrome (a combination of bronchiectasis, sinusitis and situs inversus).

Goblet cells

Goblet cells are present from the trachea (6000–7000 per mm^2) to the smaller bronchi but are normally absent from bronchioles. Their apical regions are full of large secretory vacuoles filled with mucinogen. When the epithelium is irritated, e.g. by tobacco smoke, the overall number of goblet cells increases, and they extend into the bronchioles.

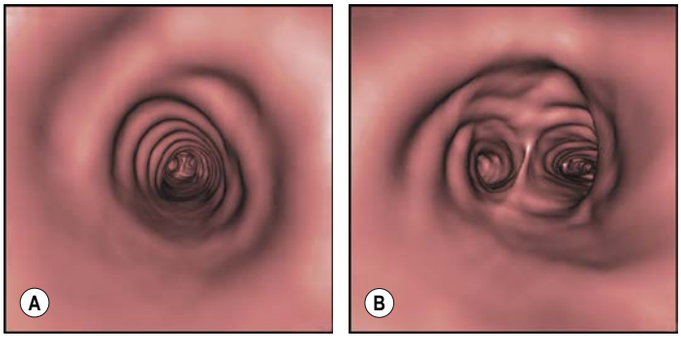

Fig. 54.16 A virtual CT bronchoscopic view obtained by planar reconstruction of spiral CT. **A**, Left main bronchus. **B**, Carina. (Courtesy of GE Medical Systems.)

Clara cells

Clara cells are cuboidal, non-ciliated cells with apices that bulge into each lumen. They contain numerous electron-dense secretory granules and lysosomes. Clara cells produce surfactant lipoprotein and thus share functional similarities with the type II alveolar cell of the pulmonary alveoli, although their secretory granules differ in structure and composition.

Basal cells

Basal cells are small, rounded cells that occur in parts of the airway lined by pseudostratified respiratory epithelium; they are mitotic stem cells for other epithelial cell types. Basal cells contact the basal lamina and are most frequent in the larger conducting passages.

Brush cells

Brush cells are slender, non-ciliated cells with characteristically long, stiff apical microvilli, hence their name. Although infrequent, they are present throughout all parts of the conducting airway passages, including the respiratory epithelium of the nasopharynx. They are in contact with afferent nerve fibres basally and are presumed to have a sensory receptor function.

Neuroendocrine cells

Neuroendocrine cells (dense-core, small granule or Kulchitsky cells) are found mainly in the basal part of the epithelium. They have a rounded shape and the cytoplasm basal to their nuclei contains numerous small, dense-cored vesicles, approximately 150 nm in diameter. They form part of the dispersed neuroendocrine system of amine precursor uptake and decarboxylation (APUD) cells (Ch. 3). Most numerous in fetal lungs, their number decreases dramatically after birth and there appears to be little further change in their frequency during adult life, although they may proliferate in certain pulmonary diseases.

Lymphocytes

T lymphocytes, derived from mucosa-associated lymphoid tissue (MALT), occur within the epithelium throughout the conducting airway tissues, particularly in the extrapulmonary portion. They are concerned with the immune surveillance of the epithelium. Clusters of lymphocytes sometimes lie beneath non-ciliated epithelial cells of the microfold (M-cell) type.

Mast cells

Mast cells are present within the basal regions of the epithelium. They resemble connective tissue mast cells, and their cytoplasmic histamine-containing granules are released in response to irritants, including inhaled allergens.

Tubuloacinar, seromucous glands are present in the submucosa of the trachea and bronchi and, to a lesser extent, in the larger bronchioles. They contain separate mucous and serous cells and are an important source of the mucus at the surface of the ciliated respiratory epithelium. Their secretions include mucins; bacteriostatic substances such as lysozyme and lactoferrin; secretory antibodies (immunoglobulin A (IgA)) produced by plasma cells in the submucosal connective tissue; and protease inhibitors (e.g. α_1-antitrypsin), important for neutralizing leukocyte-derived proteases in the respiratory tract, particularly elastase. Deficiency of α_1-antitrypsin causes chronic obstructive pulmonary disease, by inducing panacinar emphysema and bronchiectasis. The secretory acini and tubules are surrounded by myoepithelial cells innervated by autonomic axons.

Broad, longitudinal bands of elastin within the submucosa follow the course of the respiratory tree and connect with the elastin networks of the interalveolar septa (**Fig. 54.17**, see Fig. 54.11). This elastic framework is a vital mechanical element of the lung and is responsible for elastic recoil during expiration.

In the trachea and extrapulmonary bronchi, smooth muscle is mainly confined to the posterior, non-cartilaginous part of the tracheal tube (see Fig. 54.9). Along the entire intrapulmonary bronchial tree, smooth muscle forms two opposed helical tracts that become thinner and finally disappear at the level of the alveoli (see Fig. 54.11). The tone of these muscle fibres is under nervous and hormonal control; groups of muscle cells are coupled by gap junctions to spread excitation within fascicles. Muscle cell contraction narrows the airway, while relaxation permits bronchodilation. Some tone normally exists in the muscular bands, which relax slightly during inspiration and contract during expiration, so assisting the tidal flow of air. Abnormal contraction may be caused by circulating smooth muscle stimulants or by local release of excitants such as 5-HT (5-hydroxytryptamine, serotonin), histamine and leukotrienes, causing bronchospasm. Numerous mast cells are present in the connective tissue of the respiratory tree, especially towards the bronchioles.

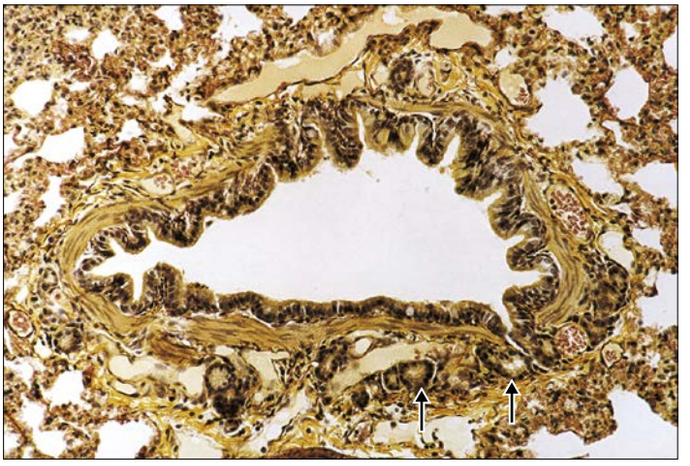

Fig. 54.17 A large bronchiole stained for elastin (black), showing smooth muscle in the bronchiolar wall and a few small seromucous glands (arrows).

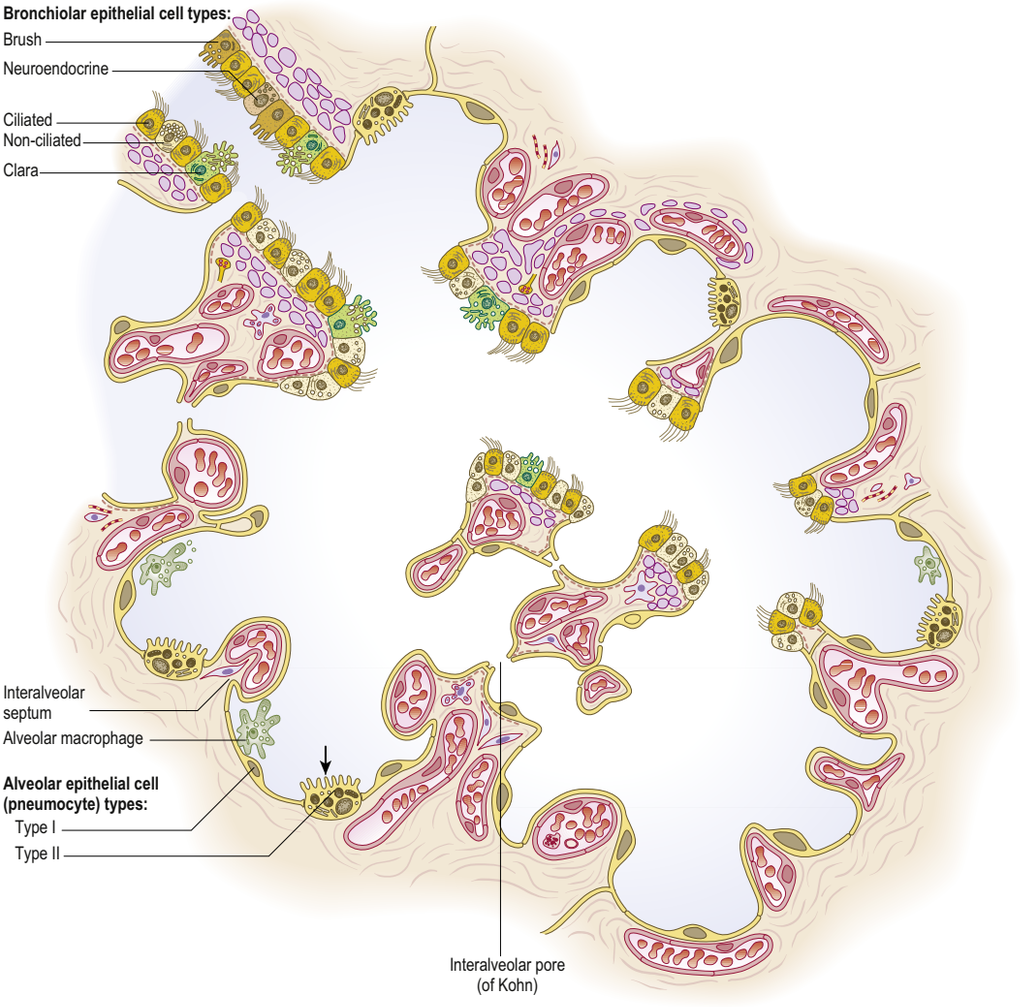

Fig. 54.18 The respiratory portion of the lung and its cell types. Type I pneumocytes have a large surface area and form much of the alveolar wall, but can be less numerous than type II pneumocytes, which have a larger, more distinct nucleus and protrude into the alveolar space (black arrow). The alveolar surface cytoplasm of each type II pneumocyte has clusters of surfactant-containing secretory vesicles, the release of which gives the cell membrane an irregular appearance histologically.

erythrocytes leak from pulmonary capillaries, the macrophages that engulf the extravasated cells become brick-red and are detectable in 'rusty' sputum. They are typical of congestive heart failure and often termed 'heart-failure cells'. Macrophages that migrate back into the connective tissue of the lung settle in patches that are visible beneath the visceral pleura, e.g. carbon-filled cells give the lungs a mottled appearance. However, if the inhaled particles are abrasive or chemically active, they may elude macrophage removal and damage the respiratory surface, producing fibrosis and a concomitant reduction in the respiratory area. This occurs in many industrial diseases, e.g. pneumoconiosis caused by coal dust, or asbestosis, where the long thin fibres of asbestos can cause considerable damage and may trigger fatal mesothelioma in the pleural lining.

Pulmonary surfactant

The alveolar surface is normally covered by a film of pulmonary surfactant, a complex mixture mainly of phospholipids (particularly dipalmitoylphosphatidylcholine and phosphatidylglycerol), with some protein and neutral lipid. Surfactant is stored in lamellar bodies and secreted in the form of tubular myelin (unrelated to myelin of the nervous system) by type II pneumocytes. It is recycled by type II pneumocytes or cleared (i.e. phagocytosed) by alveolar macrophages. Clara cells of the bronchiolar epithelium are thought to secrete surfactant of a different composition.

Surface tension at the alveolar surface is very high because the alveoli are minute and spherical, features that oppose expansion during inspiration and tend to collapse the alveoli in expiration. The detergent-like properties of pulmonary surfactant greatly reduce the surface tension and make ventilation of the alveoli much more efficient. As the volume of an alveolus alternatively increases and decreases, so does its surface area. With a fixed amount of surfactant in the alveolar film, the relative concentration of surfactant increases on exhalation. The fortunate result is a decrease in collapsing tendency as the alveolar volume decreases, stabilizing the alveolus and overcoming the tendency of small gas spaces to obliterate.

CHAPTER
55

Respiratory diaphragm and phrenic nerves

The respiratory diaphragm is a domed musculofibrous sheet, approximately 2–4 mm thick that separates the thoracic and abdominopelvic cavities (Fig. 55.1). The superior surface of the respiratory diaphragm is mainly convex and forms the floor of the thoracic cavity. It is covered by a layer of phrenicopleural fascia, a continuation of the endothoracic fascia, covered in turn by a layer of diaphragmatic parietal pleura, except in the region inferior to the heart, which is covered by a layer of parietal serous pericardium. The concave inferior surface of the respiratory diaphragm forms the roof of the abdominopelvic cavity and is mostly covered by a layer of diaphragmatic fascia, a continuation of the transversalis fascia, which is then covered by a layer of parietal peritoneum. The position of the domes or cupulae of the respiratory diaphragm is variable and may be altered by body position, ventilatory phase, thoracic cavity morphology, height and body mass. Conditions resulting in lung over-inflation, e.g. emphysema, cause diaphragmatic depression or flattening. Usually, after forced expiration, the right dome is level with the fourth costal cartilage anteriorly, whereas the left dome lies approximately one costal cartilage level lower. At end tidal inspiration in the supine position, the domes of the diaphragm descend to sit at the level of the fifth intercostal space anteriorly on the right and sixth rib on the left. On a posteroanterior (PA) chest radiograph at full inspiration, the highest point of the right hemidiaphragm is located at the anterior end of the sixth rib, or at the posterior end of the tenth rib; the left hemidiaphragm is normally 1.5–2.5 cm lower (see Fig. 56.17A). Unilateral paralysis may be seen as a raised hemidiaphragm on a chest radiograph, but this sign may be inconsistent.

In the erect position the amount of respiratory diaphragmatic excursion is approximately 1–2 cm during quiet breathing and 5–7 cm during deep breathing; all movements are slightly greater in males compared to females (Boussuges et al 2009, Jung et al 2014). The diaphragm lies more superiorly in the supine compared to the erect position. In the lateral decubitus position the lowermost gravity-dependent dome of the diaphragm sits at a higher level than the uppermost dome; this results in greater diaphragmatic muscle displacement, and therefore ventilation, on the gravity-dependent side (Froese 2006).

ATTACHMENTS AND COMPONENTS

The respiratory diaphragm consists of a central tendinous portion, the central tendon, and a muscular peripheral portion. The muscle fibres arise from the circumference of the inferior thoracic aperture and converge to an attachment to the central tendon; the posterior and lateral attachments are therefore located relatively inferior to the

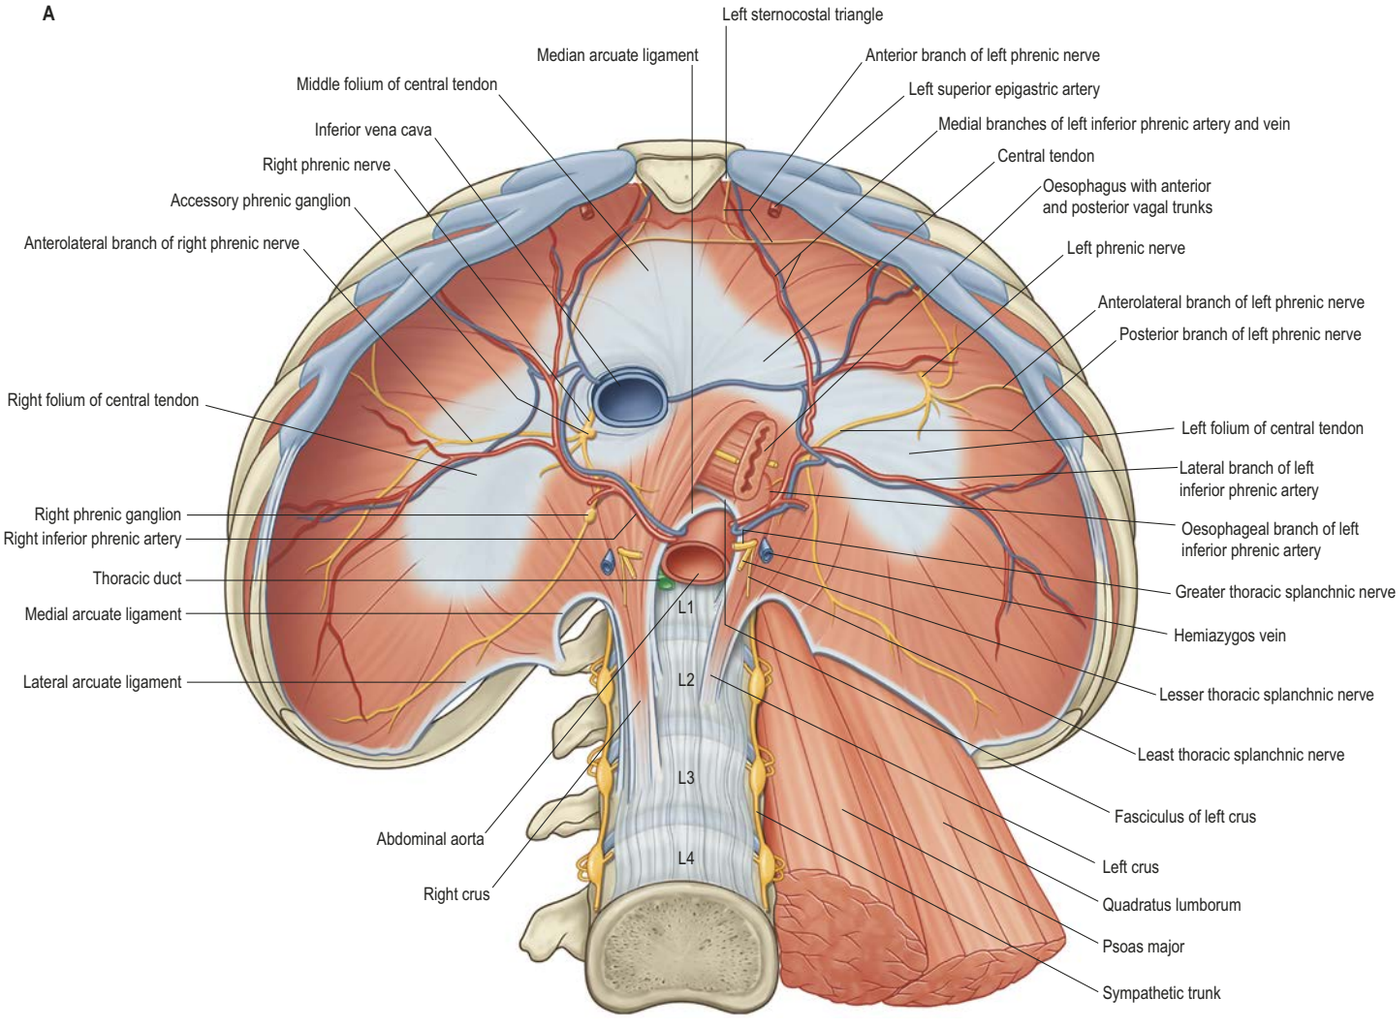

Fig. 55.1 A, Inferior view of the abdominal surface of the respiratory diaphragm.

Movement of the respiratory and pelvic diaphragms is often complementary. Magnetic resonance imaging has shown the respiratory and pelvic diaphragms to move symmetrically during normal respiration and other physiological processes: as the respiratory diaphragm descends during inspiration, the pelvic floor also descends in response to the change in intra-abdominal pressure. These changes assist with supporting the trunk and maintaining urinary continence during respiration and coughing (Talasz et al 2011).

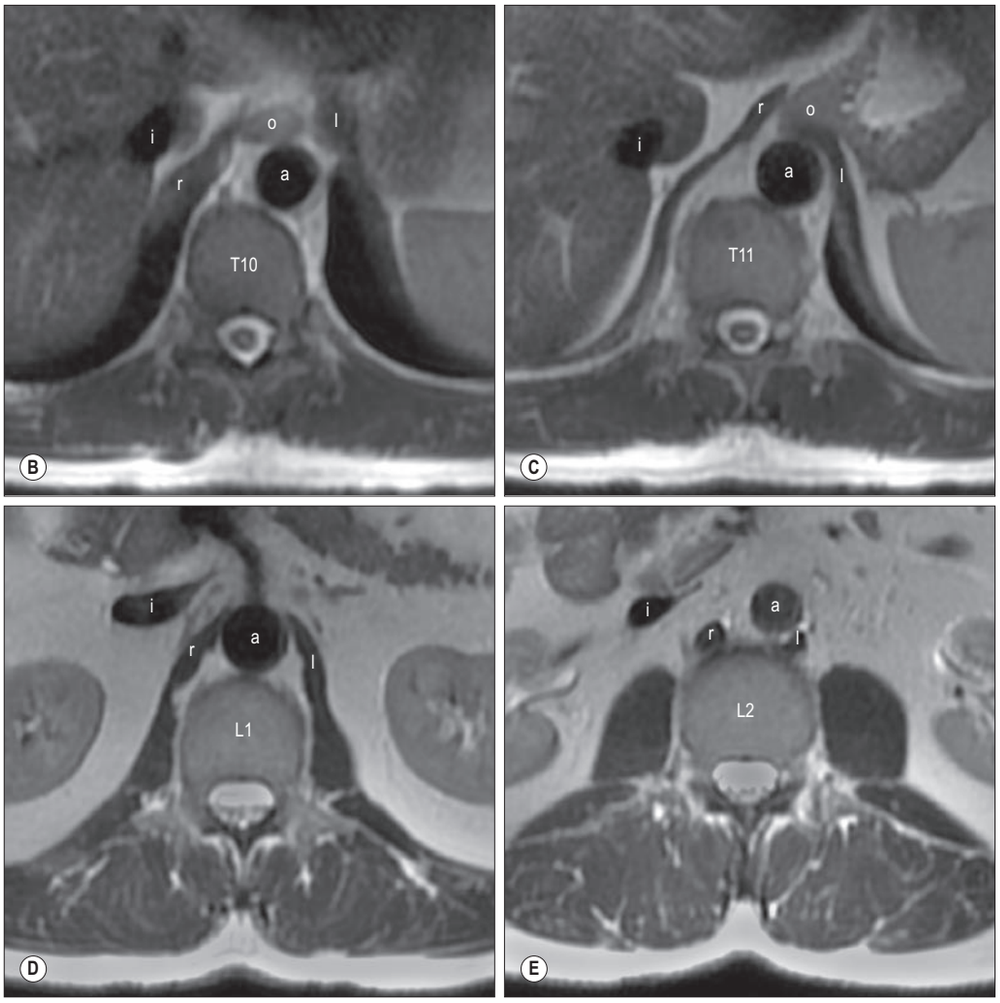

Fig. 55.1, cont'd B–E, Axial T2-weighted MRI images through the upper abdomen showing the posterior diaphragmatic attachments and hiatuses from superior to inferior. Key: a, aorta; i, inferior vena cava; l, left crus of respiratory diaphragm; o, oesophagus; r, right crus of respiratory diaphragm. (A, With permission from Drake RL, Vogl AW, Mitchell AWN (eds) Gray's Anatomy for Students, 3rd ed. Elsevier, Churchill Livingstone. Copyright 2015.)

anterior attachments (**Fig. 55.2**) (du Plessis et al 2015). The muscle can be considered in three parts, sternal, costal and lumbar. The sternal part is the smallest and varies in size and presence, it may be a broad and continuous band or may be absent (du Plessis et al 2015). It commonly arises as two muscular strips from the posterior surfaces of the rectus sheath and the xiphoid process, near its apex. On each side, the costal part arises from the internal surfaces and superior margins of the lower six costal cartilages and their adjoining ribs, and interdigitates with transversus abdominis (see Fig. 53.15A) (Sun et al 2016).

The lumbar part arises from two aponeurotic arches, the medial and lateral arcuate ligaments (Haller's or the lumbocostal arches), and asymmetrically from the more superiorly located lumbar vertebral bodies via the left and right crura. The medial arcuate ligament covers the upper part of psoas major. Medially, it is continuous with the lateral tendinous margin of the corresponding crus and is attached to the side of the first or second lumbar vertebral body. Laterally, it is fixed to the anterior aspect of the transverse process of the first lumbar vertebra. The lateral arcuate ligament covers and arches across quadratus lumborum, attaching medially to the anterior aspect of the transverse process of the first lumbar vertebra, and laterally to the inferior margin of the midpoint of the twelfth rib (Sun et al 2016).

The crura are tendinous at their attachments to the lumbar vertebrae and blend with the anterior longitudinal ligament (see Fig. 55.1). The broader and longer right crus arises from the anterolateral surfaces of the bodies and intervertebral discs of the superior three lumbar vertebrae. The left crus arises from the corresponding parts of the superior two lumbar vertebrae and intervertebral disc. The medial tendinous margins of the crura meet in the midline to form the median arcuate ligament, an often poorly defined tendinous arch that crosses anterior to the aorta at the level of the body of the twelfth thoracic vertebra (range, vertebral body of T10–L1). The crura vary greatly in length, thickness and the ratio of muscle to tendon (du Plessis et al 2015, Sun et al 2016).

The muscle fibres of the sternal, costal and lumbar parts of the respiratory diaphragm converge into the central tendon. Fibres from the xiphoid process are short, run almost horizontally and are occasionally aponeurotic. Fibres originating from the medial and lateral arcuate ligaments, and particularly the osteochondral surfaces of the ribs, are much longer. They arise almost vertically at first and then curve towards their central attachment. The right crus is commonly divided into three bundles of fibres (medial, middle and lateral), whereas the left crus is divided into two (medial and lateral) (Botros et al 1990). Muscle fibres from the crura diverge, the most lateral fibres pass more laterally as they ascend to the central tendon. Medial fibres of the right crus ascend and loop around the oesophagus where it passes through the diaphragm at the oesophageal hiatus; the more superficial fibres form the left margin, and the deeper fibres form the right margin of the hiatus. Multiple different patterns of crural muscle fibre arrangement may occur around the oesophageal hiatus (Loukas et al 2008a). Sometimes, a fleshy fasciculus from the medial side of the left crus crosses the aorta and runs obliquely through the fibres of the right crus towards the caval foramen; this fasciculus does not normally pass around the oesophageal hiatus on the right side.

The central tendon of the respiratory diaphragm is a thin but strong aponeurosis of closely interwoven fibres situated near the centre of the muscle. In the anteroposterior plane, it sits closer to the anterior thoracic wall, which means that the posterior muscle fibres are longer than the anterior fibres (**Fig. 55.3**). The central region of the central tendon lies immediately inferior to the pericardium, with which it partially blends. This region consists of four diagonal bands of fibres that fan out from a thick central node; from here, compressed tendinous strands decussate anterior to the oesophagus and to the left side of the inferior vena cava.

The central tendon is classically described as being trifoliate (cloverleaf) in shape, with middle, right and left folia. The middle folium projects anteriorly and is an equilateral triangle in shape, with the apex

The right and left sternocostal triangles (of Morgagni) are openings in the anterior part of the diaphragmatic muscle, between the sternal and costal parts (Downey 2011). They are covered by connective tissue and are the conduits by which the internal thoracic vessels access the anterior abdominal wall. A retrosternal (parasternal) hernia can pass through the triangles: it is more common on the right side and often congenital, which may reflect a deficit of muscle fibres in this region.

The lumbocostal triangle (of Bochdalek) represents a developmental defect resulting from an incomplete formation of the pleuroperitoneal membrane. When present, it is located in the posterolateral diaphragm between the lumbar and costal parts, superior to the lateral arcuate ligament. The lumbocostal triangle is devoid of muscle fibres, covered only by the diaphragmatic parietal pleura superiorly and parietal peritoneum inferiorly (Downey 2011), and is the most common route for congenital diaphragmatic herniation.

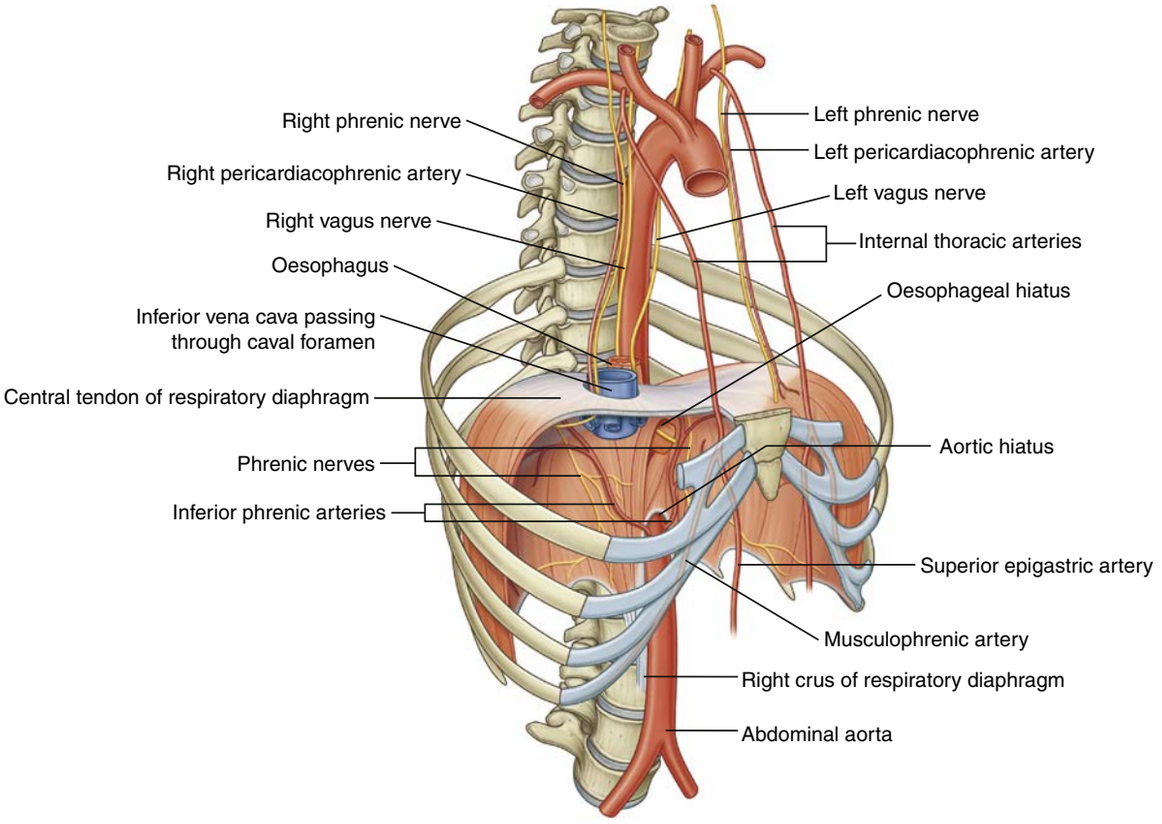

Fig. 55.2 The respiratory diaphragm with attachments, openings and arterial blood and nerve supply. (With permission from Drake RL, Vogl AW, Mitchell AWN (eds) Gray's Anatomy for Students, 3rd ed. Elsevier, Churchill Livingstone. Copyright 2015.)

directed towards the xiphoid process. The right and left folia are tongue-shaped and similar in length, although the left may be narrower; both curve posterolaterally to form a V-shape that spans the midline. The size and shape of the folia and the ratio of diaphragmatic muscle to tendon varies between individuals, the most common arrangement being a V-shaped central tendon and a 10–15% muscle to tendon ratio (du Plessis et al 2015). The muscle to tendon ratio can vary disproportionately, such that larger respiratory diaphragms may have a small central tendon, and smaller diaphragms may have a large central tendon and a relatively small amount of muscle.

PROFILE AND RELATIONS

The superior surface of the respiratory diaphragm is covered by three separate serous membranes. On each side, the diaphragmatic parietal pleura separates it from the base of the corresponding lung. Centrally, the parietal pericardium separates mainly the middle folium of the central tendon from the inferior surface of the heart. The middle folium is almost flat and extends more to the left than the right. From an anterior view, the smooth convex domes or cupulae of the left and right sides of the diaphragm rise above the middle folium: the right cupula is higher and slightly broader than the left. Most of the inferior surface of the diaphragm is covered by diaphragmatic fascia and parietal peritoneum. The right cupula conforms to the convex surface of the right lobe of the liver, right kidney and right suprarenal gland; the left cupula conforms to the surface of the left lobe of the liver, gastric fundus, spleen, left kidney and left suprarenal gland. Given the differences in their profiles and anatomical relationships, clinical descriptions of the respiratory diaphragm should always reference a specific side.

Ultrasound imaging Ultrasound examination of the posterior and lateral aspects of the respiratory diaphragm is best undertaken with the patient in the supine position, to limit veiling by other organs and reducing the risk of misdiagnosis due to underlying pulmonary pathologies. The respiratory diaphragm is typically identified by its curved morphology, deep location and specific echotexture. It is visualized as a thin, muscular hypoechoic line wedged between two hyperechoic layers consisting of parietal peritoneum and pleura (Fig. 55.4). During inspiration, the hypoechoic line thickens as the muscle contracts, making it more visible. An atrophic diaphragm may be suspected when the thickness of this line does not change during inspiration. The left side of the diaphragm often poses more of a challenge in visualization (Sarwal et al 2013).

OPENINGS

A number of structures pass between the thorax and abdomen via openings (apertures) in the respiratory diaphragm. There are three large openings, for the aorta, oesophagus and inferior vena cava, and a number of smaller openings (see Figs 55.1A, 55.3).

The aortic hiatus transmits the aorta, thoracic duct, lymphatic trunks from the lower posterior thoracic wall and, sometimes, the azygos and hemiazygos veins. It is the most posteroinferior of the openings, and is commonly found at the level of the superior half of the body of the twelfth thoracic vertebra (range, vertebral body of T10 to L1), slightly to the left of the midline. It is an osseo-aponeurotic opening bordered by the diaphragmatic crura laterally, the vertebral column and anterior longitudinal ligament posteriorly and the median arcuate ligament anteriorly; the aorta therefore normally passes posterior to the diaphragmatic musculature and as such is not affected by its contraction (Nason et al 2012). Occasionally, some tendinous fibres from the medial parts of the crura also pass posterior to the aorta, converting the osseo-aponeurotic hiatus into an aponeurotic fibrous ring.

The oesophageal hiatus transmits the oesophagus, anterior and posterior vagal trunks, gastric nerves, oesophageal branches of the left gastric vessels and lymphatic vessels. It is commonly located level with the inferior half of the body of the eleventh thoracic vertebra (range, vertebral body of T9 to L1–L2 intervertebral disc), anterosuperior to, and to the left of, the aortic hiatus. The elliptical hiatus has a slightly oblique long axis, and is bounded by muscle fibres that originate from the medial part of the right crus and cross the midline, forming a tunnel approximately 2.5 cm long that accommodates the distal part of the oesophagus. The outermost fibres run in a craniocaudal direction, and the innermost fibres are arranged circumferentially. There is no direct continuity between the oesophageal wall and the muscle around the oesophageal hiatus. The fascia on the inferior surface of the diaphragm, rich in elastic fibres, is continuous with the transversalis fascia and extends superiorly into the oesophageal hiatus in the shape of a flattened cone to blend with the oesophageal wall 2–3 cm superior to the gastro-oesophageal (squamocolumnar) junction. Some of its elastic fibres penetrate to the submucosa of the oesophagus. This

The diaphragm is connected to closely related organs by various connective tissue formations known as ligaments. Within the thoracic cavity, the inferior pulmonary ligament, a double-layered fold of parietal pleura, connects the inferior part of the hilum and root of the lung and the mediastinal surface of the inferior lobe of the lung to the diaphragm. The phrenico-oesophageal ligament, formed from peri-oesophageal areolar tissue, connects the diaphragm to the oesophagus as it passes through the oesophageal hiatus. Within the abdominopelvic cavity, a number of peritoneal formations form a series of supportive ligaments. The falciform ligament connects the anterior surface of the liver to the diaphragm and rectus sheath. The right and left coronary and triangular ligaments pass to the diaphragmatic surface of the liver forming the boundaries of the bare area of the liver. The phrenicosplenic and phrenicocolic ligaments connect the diaphragm to the spleen and splenic flexure of the colon, respectively. The suspensory muscle of the duodenum (ligament of Treitz) is formed from a series of muscular bands that originate from the left crus and connect to the duodenojejunal flexure (Bordoni and Zanier 2013).

peri-oesophageal areolar tissue forms the phrenico-oesophageal ligament, that connects the oesophagus flexibly to the diaphragm, thus permitting freedom of movement during swallowing and ventilation while synchronously limiting superior oesophageal displacement.

The caval foramen transmits the inferior vena cava, which adheres to its margins, and branches of the right phrenic nerve (see Fig. 55.1A). It is the most superior of the three large openings, and lies approximately level with the superior part of the body of the eleventh thoracic vertebra (range, T8–T9 intervertebral disc to the body of the twelfth thoracic vertebra). Quadrilateral in shape with aponeurotic margins, it is located at the junction of the right folium of the central tendon with the central part. During inspiration, dilation of the caval foramen, combined with increased intra-abdominal pressure, increases cardiac venous return (Nason et al 2012).

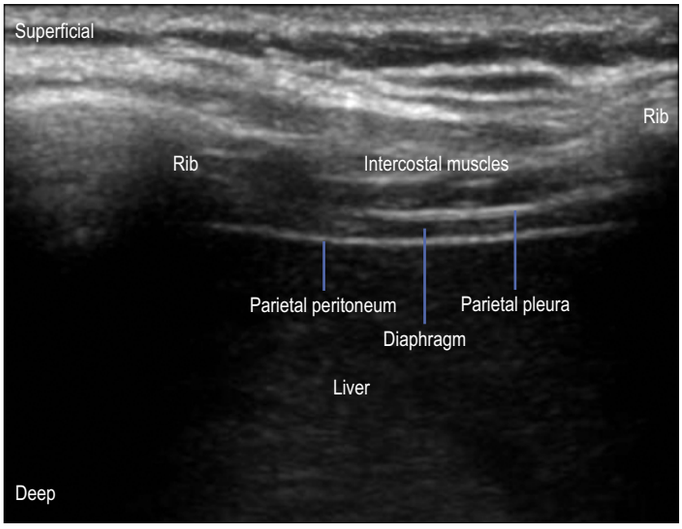

Fig. 55.4 Ultrasound of the respiratory diaphragm at the level of the eighth left intercostal space in the midaxillary line. The diaphragm is visualized as a hypoechoic (dark) line sitting between two hyperechoic (light) layers consisting of the parietal peritoneum and the parietal pleura. (With permission from Naicker J and van Tonder DJ, Department of Anatomy, University of Pretoria.)

Two smaller openings within each crus transmit the greater and lesser thoracic splanchnic nerves. The ganglionated sympathetic trunks usually enter the abdominal cavity posterior to the respiratory diaphragm, deep to the medial arcuate ligaments. There are frequently openings for small veins in the central tendon.

On each side of the respiratory diaphragm, small areas of muscle may be replaced by areolar tissue. The superior epigastric branch of the internal thoracic artery and some lymph vessels from the abdominal wall and convex surface of the liver pass through an area of areolar tissue covering the sternocostal triangle (between the sternal and costal attachments of the respiratory diaphragm). An inconstant area of areolar tissue between the costal attachment and the fibres that originate from the lateral arcuate ligament may be all that separates the diaphragmatic parietal pleura from the posterosuperior surface of the kidney. Additional smaller fascial spaces may be found throughout the lateral aspects of the domes of the diaphragm without evidence of vascular penetration. Although these spaces are found on both the left and right sides, they appear to be more numerous on the left (du Plessis et al 2015).

Oesophageal reflux Reflux of gastric contents into the oesophagus, with risk of pulmonary aspiration, is normally prevented by the specialized smooth muscle of the inferior oesophageal wall and the encircling crural muscle fibres forming a physiological barrier at the gastro-oesophageal junction. The diaphragm acts as a 'physiological' sphincter to prevent gastro-oesophageal reflux by constricting during inspiration (Nason et al 2012) (see also Ch. 63).

Hiatus hernia Deep inspiration followed by closure of the glottis and contraction of the muscles of the abdominal and thoracic walls provides additional power to all expulsive efforts including sneezing, coughing, laughing, crying, urination, defecation, vomiting and uterine fetal expulsion. The resulting increase in intra-abdominopelvic pressure can also be used to provide an anteriorly located pneumatic support to the vertebral column when lifting heavy objects. Repeated mechanical stress may eventually compromise the integrity of the oesophageal hiatus, leading to widening of the muscular hiatal tunnel. Concomitant laxity of the phrenico-oesophageal ligament allows the gastro-oesophageal junction to migrate into the posterior mediastinum, a condition that is normally termed a sliding (type I) hiatus hernia. Sliding hernias are typically acquired in the fifth decade of life, and are found in more than 50% of patients with gastro-oesophageal reflux. This reflux induces tonic contraction of the longitudinal oesophageal muscle, further exacerbating the hiatus hernia.

Congenital hernia Congenital respiratory diaphragmatic defects may cause abdominal organs, usually the stomach and/or the small bowel, colon, liver and spleen, to herniate through the diaphragm into the thoracic cavity; they are described in Chapter 20.

Herniation of the stomach into the thoracic cavity adjacent to the oesophagus is termed a para-oesophageal (type II) hiatus hernia. There are three distinct types: II, III and IV. Type II refers to a herniated stomach with normal positioning of the gastro-oesophageal junction. Type III, a 'mixed' hernia, refers to both a herniated stomach and a sliding-type hernia. Type IV refers to a hernia in which more than one-third of the stomach is herniated into the thoracic cavity. Para-oesophageal herniae can be diagnosed with barium swallow, CT or endoscopy (Daugherty et al 2017).

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

The rich arterial supply of the respiratory diaphragm is derived from anastomoses between the lower five intercostal and the subcostal arteries, the superior and inferior phrenic arteries and the pericardiacophrenic and musculophrenic arteries (Ch. 53).

Intercostal and subcostal arteries

The lower five intercostal and the subcostal arteries supply the costal margins of the respiratory diaphragm (Ch. 53).

Pericardiacophrenic and musculophrenic arteries

Available with the *Gray's Anatomy* e-book

Inferior phrenic arteries

The major arterial supply to the diaphragm is derived from the right and left inferior phrenic arteries, which usually arise either independently or as a common trunk from the coeliac trunk or the abdominal aorta (see Figs 55.1–55.2; **Fig. 55.5**). Less commonly, the right inferior phrenic artery arises from the right renal artery, the left gastric artery or the hepatic artery proper, and the left inferior phrenic artery arises from the left or right renal artery, the left gastric artery or the proper hepatic artery (Loukas et al 2005a, Tubbs et al 2016).

The arteries ascend anterolateral to the diaphragmatic crura, near the medial border of each suprarenal gland. The left inferior phrenic artery passes posterior to the oesophagus, and the right passes posterior to the inferior vena cava. Both arteries then run anteriorly; the left passes along the left side of the oesophageal hiatus and the right passes along the right side of the caval foramen. They both divide into medial and lateral branches near the posterior border of the central tendon. The medial branches curve anteriorly to anastomose with each other anterior to the central tendon, and with the musculophrenic and pericardiacophrenic arteries, when present. The lateral branches approach the thoracic wall and anastomose with the musculophrenic arteries and the lower posterior intercostal arteries. The left inferior phrenic artery sends ascending branches to the distal oesophagus, and the lateral branch of the right inferior phrenic artery supplies the inferior vena cava.

Superior phrenic arteries

The left and right superior phrenic arteries supply the superior surface of the diaphragm (**Figs 55.6–55.7**). They most commonly arise from either the descending thoracic aorta or the proximal segment of the tenth intercostal artery before it enters the intercostal space. The right artery (and less commonly the left) may arise from the distal segment of the tenth intercostal artery (Loukas et al 2007).

Veins

Phrenic veins

The superior surface of the respiratory diaphragm is drained by tributaries of the musculophrenic and pericardiacophrenic veins that run alongside the corresponding arteries. The inferior surface of the diaphragm is drained by tributaries of the right and left inferior phrenic veins that usually drain into the inferior vena cava inferior to the diaphragm (**Fig. 55.8** see Figs 55.1, 61.12). The right inferior phrenic vein may drain into the right hepatic vein or the inferior vena cava superior to the diaphragm; the left inferior phrenic vein may drain into the left suprarenal vein, the left renal vein, the left hepatic vein or, rarely, both the left suprarenal renal vein and the inferior vena cava (Loukas et al 2005b).

Lymphatic drainage

The respiratory diaphragm is drained by anterior, middle and posterior groups of lymph nodes that lie on its superior surface and that also drain the superior portion of the liver, the gastro-oesophageal junction and the inferior surface of the diaphragm. Lymph also drains anterosuperiorly to the parasternal and anterior mediastinal nodes, and posterosuperiorly to the posterior mediastinal and brachiocephalic nodes.

INNERVATION

The right and left phrenic nerves supply motor fibres to the muscle of the respiratory diaphragm and sensory fibres to the central parts of the diaphragm (C3, C4, C5) (**Fig. 55.9**). The lower six or seven intercostal nerves supply sensory fibres to the peripheral parts of the diaphragm. The fibres of the right crus of the diaphragm divide and pass to the right and left sides of the oesophagus and are innervated by both the right and left phrenic nerves.

Phrenic nerve

The left and right phrenic nerves are mixed somatic sensory and motor nerves that provide the sole motor supply to the respective hemidiaphragm. Each is derived mostly from the ipsilateral ventral ramus of the fourth cervical spinal nerve, with contributions from the ipsilateral

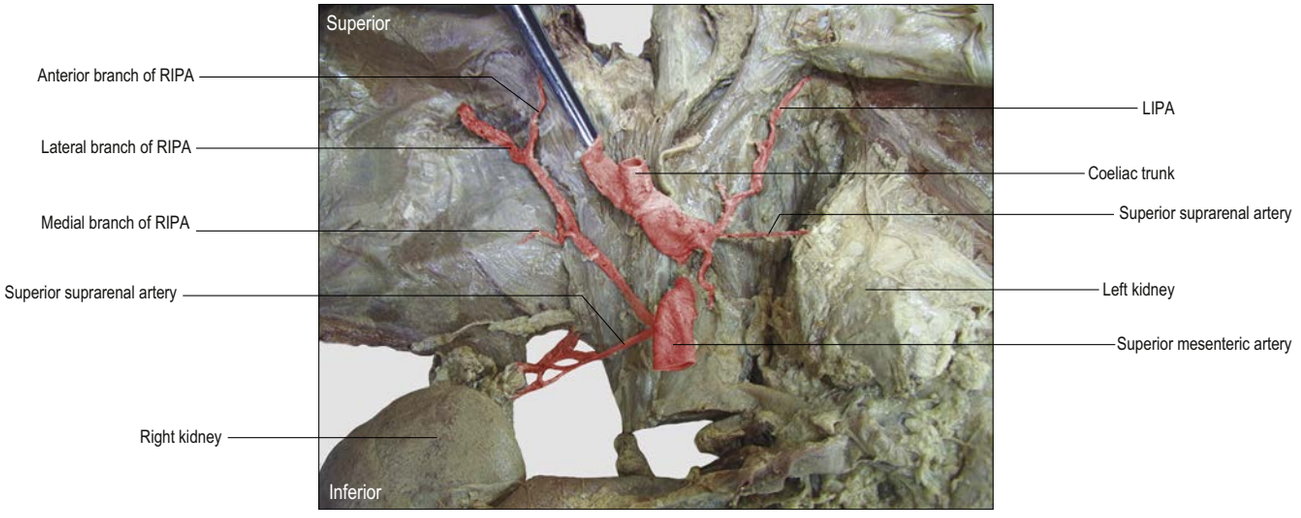

Fig. 55.5 A cadaveric dissection (anterior view) showing the origin and course of the right (RIPA) and left (LIPA) inferior phrenic arteries. The right inferior phrenic artery arises from the superior mesenteric artery (SMA), and the left inferior phrenic artery arises from the coeliac trunk. (With permission from Loukas M, Hullett J, Wagner T 2005 Clinical anatomy of the inferior phrenic artery. Clin Anat 18(5):357–65.)

Eventration is a focal bulge, usually located in the anteromedial segment of the muscular portion of the diaphragm. It is most often caused by a congenital thinning of the diaphragmatic muscle: such regions are covered by a thin fibroelastic connective tissue that stretches over time: eventration may be mistaken for a diaphragmatic hernia.

Eventration may be congenital or acquired as a result of pathological processes, including malignancy, trauma, infection and obesity. On X-ray imaging, the affected region appears as an elevated hump on a hemidiaphragm with an otherwise normal contour; there is often a sharp transition between the area of eventration and the surrounding normal diaphragm. The elevation becomes more pronounced with increased abdominal pressure and is typically found on the left; the affected part shows diminished or paradoxical movement during inspiratory 'sniff' testing while the posterior aspect of the ipsilateral dome acts normally (Nason et al 2012). Eventration and hemidiaphragmatic paralysis are differentiated by the amount of diaphragm involved: specifically, eventration involves only a part of a hemidiaphragm. Management is usually conservative but more aggressive treatment might be warranted should the patient become symptomatic, e.g. worsening dyspnoea, chronic atelectasis or recurrent pneumonia (Daugherty et al 2017).

Closed or penetrating thoraco-abdominal injuries may result in rupture or laceration of the diaphragm. With closed injuries and diaphragmatic rupture, abdominal contents may herniate into the thorax. CT imaging with planar reformation should be the primary mode of investigation (Shanmuganathan et al 2000): magnetic resonance imaging is usually performed when other imaging modalities have produced equivocal findings. Early operative repair is recommended because untreated cases may develop gastrointestinal obstruction or perforation. Patients with penetrating injuries may require additional assessment by thoracoscopy (Lowdermilk and Naunheim 2000).

In up to 25% of individuals, the median arcuate ligament lies inferior to its normal position, and anterior to the coeliac trunk. When this occurs, the coeliac trunk may become compressed and arch downward, leading to mesenteric angina and aneurysms in the pancreaticoduodenal arteries as a consequence of collateral flow. Most patients will present with postprandial pain, nausea and often vomiting, and many will avoid eating, resulting in significant weight loss. During expiration, concurrent movement of the abdominal aorta and the median arcuate ligament compresses the coeliac trunk; the position, angle and vertebral level of origin of the coeliac trunk are additional aetiological factors. Diagnosis is based mainly on the exclusion of other causes, e.g. compression of the vessel as a result of fibrotic or neoplastic changes in the sympathetic coeliac plexus and coeliac ganglion, as well as atherosclerotic changes in the coeliac trunk. Definitive diagnosis can only be made with multiple imaging modalities (Horton et al 2005).

The pericardiacophrenic and musculophrenic arteries originate from the internal thoracic artery (see Figs 55.2, 55.9): both are conventionally included in the description of the arterial supply of the diaphragm, but the extent to which these two arteries actually supply the diaphragm is uncertain. Studies have often failed to trace the phrenic branches of the pericardiacophrenic artery to the surface of the diaphragm, possibly because the vessels are too small to be detected angiographically (Loukas et al 2008b).

During liver resection, failure to control excessive bleeding from the hepatic veins impairs patient outcome and prognosis: correctly identifying and clamping the hepatic veins is therefore essential. The right inferior phrenic vein can be used to help to identify the hepatic veins because it usually drains into the inferior vena cava just cranial to the confluence of the hepatic veins into the inferior vena cava (see Fig. 55.8): tracing its course therefore allows a surgeon to visualize, encircle and clamp the hepatic veins prior to mobilization of the liver (Torzilli et al 2006).

ventral rami of the third and fifth cervical spinal nerves (see Figs 35.17–35.18). The course of the cervical part of the phrenic nerves is described on page 596 in Chapter 35. Within the thoracic cavity, the phrenic nerves descend anterior to the lung root and hilum, between the fibrous pericardium and mediastinal parietal pleura, accompanied by the pericardiacophrenic vessels. Each phrenic nerve supplies sensory branches to the mediastinal pleura, fibrous pericardium and parietal layer of serous pericardium. The right and left phrenic nerves differ in their intrathoracic relationships (Rajanna 1947).

Right phrenic nerve

The right phrenic nerve is shorter and more vertical than the left. At the root of the neck it is separated from the second part of the right subclavian artery by scalenus anterior (**Fig. 55.10A**). It then passes inferomedially through the superior thoracic aperture between the first part of the right subclavian artery and the right subclavian vein. Occasionally, the right or left phrenic nerves may pass anterior to, or through the anterior wall of, the respective subclavian vein (Paraskevas et al 2011). Around the level of the first rib or the first costal cartilage, the right phrenic nerve crosses the right internal thoracic artery either superiorly between the artery and the first rib, or inferiorly, pressed against the artery by the apex of the right lung and its covering pleura (Owens et al 1994). The nerve continues to descend, passing immediately lateral to the right brachiocephalic vein, the superior vena cava, the fibrous pericardium covering the right side of the right atrium and the inferior vena cava. It branches just superior to, or at the level of, the diaphragm.

Left phrenic nerve

At the root of the neck, the left phrenic nerve commonly leaves the medial border of scalenus anterior and passes anterior to the first part of the left subclavian artery and posterior to the left subclavian vein and the thoracic duct (**Fig. 55.10B**). Sometimes the right and left phrenic nerves are symmetric in their cervical course, in which case the left phrenic nerve is initially separated from the second part of the left subclavian artery by scalenus anterior. After passing through the superior thoracic aperture the left phrenic nerve crosses the left internal thoracic artery, most commonly superiorly, around the level of the first rib or the first costal cartilage (Owens et al 1994). It descends across the medial aspect of the apex of the left lung and its pleural covering to pass between the left common carotid and left subclavian arteries. The nerve then descends anteromedially and passes anterior and close to the left vagus nerve while in the region superior to the aortic arch and posterior to the left brachiocephalic vein. It continues inferiorly, passing anterior to the left superior intercostal vein, the aortic arch and the left lung root and hilum, after which it passes inferolaterally and to the left, over the fibrous pericardium covering the left atrium and left ventricle (see Fig. 55.9). As it passes over the fibrous pericardium, the left phrenic nerve is located more anterior than the right phrenic nerve and is therefore at greater risk of damage during the placement of surgical incisions to access the pericardial cavity.

Diaphragmatic relationships The right phrenic nerve passes through the central tendon of the respiratory diaphragm, either via the caval foramen or just lateral to it. The left phrenic nerve passes through the muscular part of the diaphragm anterior to the central tendon, just lateral to the fibrous pericardium covering the left pulmonary border of the heart, and posterior to the cardiac apex (see Fig. 55.9). At or slightly superior to the diaphragm each phrenic nerve supplies fine branches to the parietal pleura covering the central part of the respiratory diaphragm. Typically, the trunk of each nerve then divides into three branches (anterior or sternal, anterolateral and posterior) as it passes through the diaphragm (see Fig. 55.1A). The main branches may be submerged in diaphragmatic muscle or lie inferior to it. They supply motor fibres to the muscle and sensory fibres to the peritoneum and pleura covering the central part of the diaphragm. They also relay proprioceptive fibres from the musculature. The anterior (sternal) branch runs anteromedially towards the sternum and connects with its contralateral counterpart. The anterolateral branch runs to the lateral folia of the central tendon. The short posterior branch divides into a posterolateral ramus that passes posterior to the left or right folia of the central tendon and a posterior ramus that supplies the crura of the diaphragm. The posterolateral and posterior crural branches may arise separately from the phrenic nerve.

The phrenic nerves also relay proprioceptive information; the right phrenic nerve supplies the part of the right crus that lies to the right of the oesophagus, and the left phrenic nerve supplies the left crus and the part of the right crus that lies on the left of the oesophagus.

Phrenic ganglia The right phrenic nerve continues its course inferior to the diaphragm and frequently connects to the right phrenic ganglion. An additional, smaller, right accessory phrenic ganglion is sometimes located proximally along the phrenic nerve, close to its exit from the caval foramen (see **Fig. 55.1A**). The right phrenic ganglion has plexiform communications with the coeliac and aorticorenal ganglia and with the right suprarenal gland (**Fig. 55.11**). A left phrenic ganglion is less commonly seen; when present, it exhibits plexiform communications to several autonomic ganglia. Both phrenic nerves and ganglia are closely related to the diaphragmatic crura, therefore sutures for crural approximation in the repair of hiatal hernia must be placed superior to the ganglia in order to avoid iatrogenic injuries to the autonomic supply of the diaphragm and abdomen (Loukas et al 2016).

Lesions of the phrenic nerve An appreciation of the location of the main branches of the phrenic nerves is important to avoid iatrogenic surgical damage. Radial incisions in the diaphragm, passing from the costal margin toward the oesophageal hiatus, can lead to diaphragmatic paralysis, especially if made lateral to the point at which the phrenic nerve pierces the diaphragm, whereas thoraco-abdominal incisions in a circumferential manner in the periphery of the diaphragm do not involve any significant branches of the phrenic nerves and preserve diaphragmatic function. Similarly, incisions of the central part of the central tendon are relatively safe.

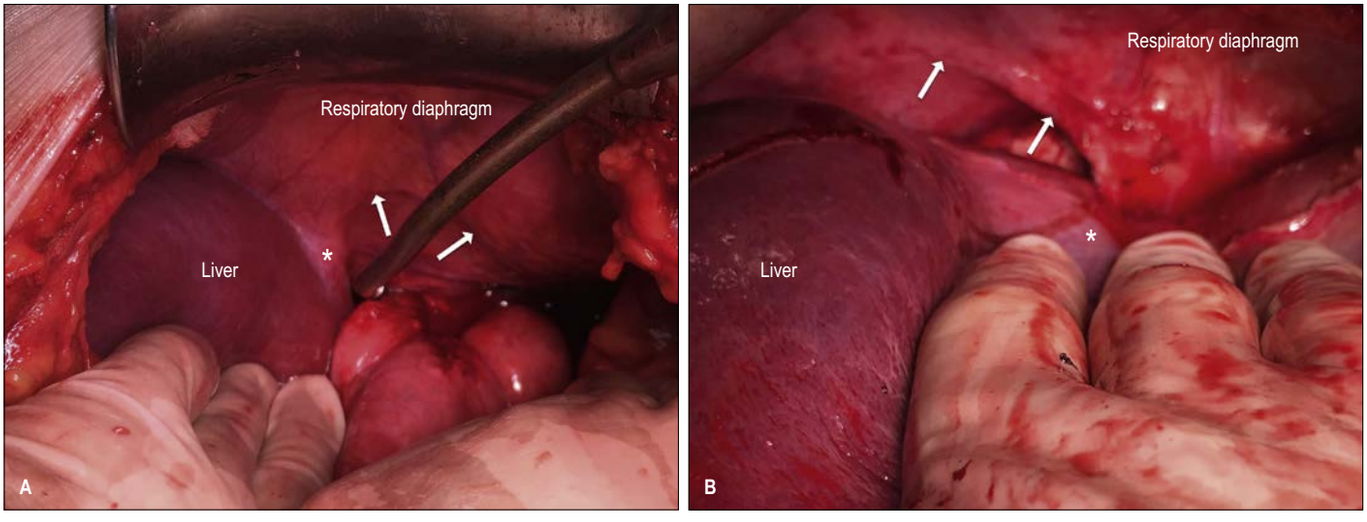

Fig. 55.8 Intraoperative inferior view of the respiratory diaphragm. With the liver retracted, the left inferior phrenic vein (**A**) and the right inferior phrenic vein (**B**) (both indicated by white arrows) can be used as landmarks, when followed to their terminations, to aid identification of the hepatic veins and inferior vena cava (*) during liver surgery. (Courtesy of Dr HJ Pretorius, Department of Surgery, Steve Biko Academic Hospital, Pretoria, South Africa.)

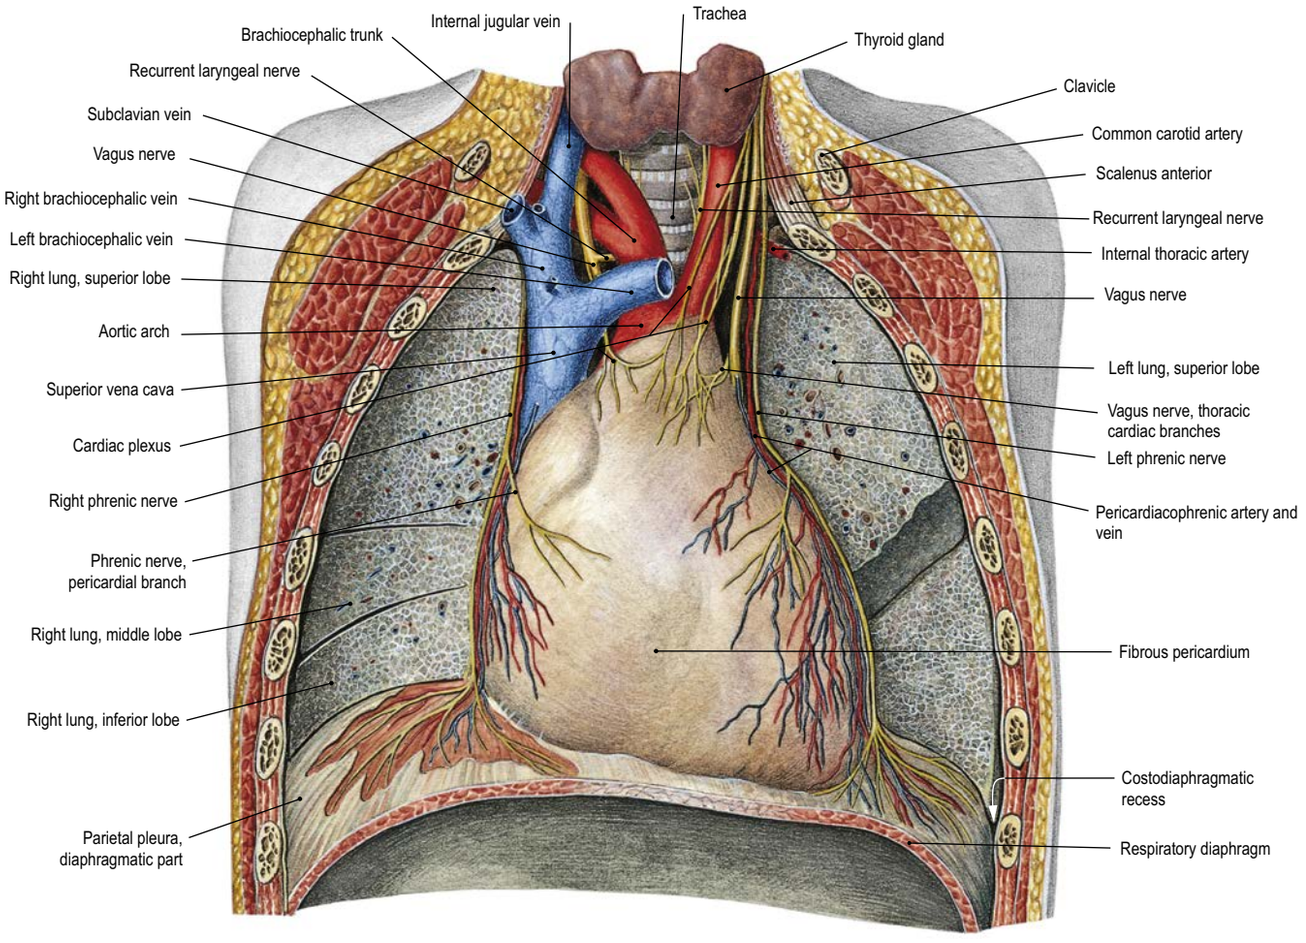

Fig. 55.9 The course and distribution of the right and left phrenic nerves within the thoracic cavity. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Division of the phrenic nerve in the neck completely paralyses the corresponding half of the diaphragm, which subsequently atrophies. If an accessory phrenic nerve exists, section or crushing of the main nerve as it lies on scalenus anterior will not produce complete paralysis. The phrenic nerve may be involved in traumatic lesions of the upper brachial plexus. Cardiac surgery is one of the most common iatrogenic causes of phrenic nerve injury, especially when cold saline slush for myocardial preservation is instilled. The phrenic nerve may also be damaged during surgery for tumours of the lung or mediastinum, traumatic childbirth or radiation therapy, or by infections such as poliomyelitis (Nason et al 2012). Respiratory muscle weakness of rapid onset is a feature of Guillain–Barré syndrome.

Phrenic nerve damage leads to paradoxical movement of the diaphragm that is best observed fluoroscopically, with the patient first in the upright position (diaphragm unloaded), and then supine with a small weight on the abdomen (diaphragm loaded). Diaphragmatic paralysis can also be assessed by ultrasound examination, using an inhalation 'sniff' manoeuvre.

Referred pain Diaphragmatic irritation or pain is frequently felt at the tip of the shoulder, reflecting the common spinal nerve root origins of the phrenic and supraclavicular nerves (the ventral rami of the third and fourth cervical spinal nerves). It usually occurs when there is inflammation of the diaphragmatic parietal pleura, e.g. in basal pneumonia, pleural effusions, malignant disease, or irritation of the diaphragmatic parietal peritoneum, e.g. in pneumoperitoneum or subphrenic abscess, where involuntary diaphragmatic contraction (hiccups) may also occur.

Accessory phrenic nerve

The accessory phrenic nerve is described on page 596.

ANATOMY OF BREATHING

Breathing is a highly coordinated abdominal and thoracic process. The respiratory diaphragm is the main muscle of inspiration, responsible for approximately two-thirds of the volume of air intake during quiet breathing in healthy humans. Contraction of the external and internal intercostal muscles during inspiration and expiration varies with the superior-to-inferior position of an intercostal space and the position of the intercostal muscle within a given intercostal space. For example, the external intercostal muscles in the dorsal region of the more superiorly located intercostal spaces are mainly active during inspiration, whereas those in the ventral region of the more inferiorly located intercostal spaces are mainly active during expiration (De Troyer et al 2005).

Increasing the vertical, transverse and anteroposterior dimensions of the thoracic cavity increases the volume of the pleural cavity: the resulting decrease in pressure within the pleural cavity creates a pressure gradient that draws air at atmospheric pressure into the lungs. During expiration, the diaphragm relaxes and is moved superiorly by the intra-abdominal viscera and increased intra-abdominal pressure produced by contraction of the muscles of the anterior abdominal wall. Air is expelled from the lungs and the elastic recoil of the lung creates a sub-atmospheric pressure that returns the lateral and anteroposterior dimensions of the thorax to normal (De Troyer and Estenne 1988, Celli 1998). During inspiration, the most inferior ribs are fixed and contraction of the diaphragm draws the central tendon inferiorly, minimally altering diaphragmatic curvature. The cupulae of the diaphragm move inferiorly and slightly anteriorly, almost parallel to their original positions. The associated inferior displacement of the abdominal viscera is permitted by the extensibility of the abdominal wall, but the limit of this extensibility is soon reached. The central tendon, its further motion prevented by the abdominal viscera, becomes a fixed point from which the fibres of the diaphragm continue to contract. This causes the second

The 'gold standard' for assessment of phrenic nerve and diaphragm function is electrical or magnetic stimulation of the phrenic nerve with recording of the compound muscle action potential and/or the transdiaphragmatic pressure. Electrical stimulation of the diaphragm, by 'pacing' of one or both phrenic nerves, has been used with some success in infants with congenital central alveolar hypoventilatory syndrome ('Ondine's curse') and in patients with high cervical lesions of the spinal cord, where the diaphragm is paralysed but the lower motor neurones are intact. Electrodes are placed adjacent to the nerves, sometimes in the neck but more usually in the chest, and a ventilatory rhythm is established by stimuli delivered by an implanted device. As this is a non-physiological way of recruiting the muscle, the fibres must be 'conditioned' during the initial period of stimulation, so that they acquire the necessary resistance to fatigue.

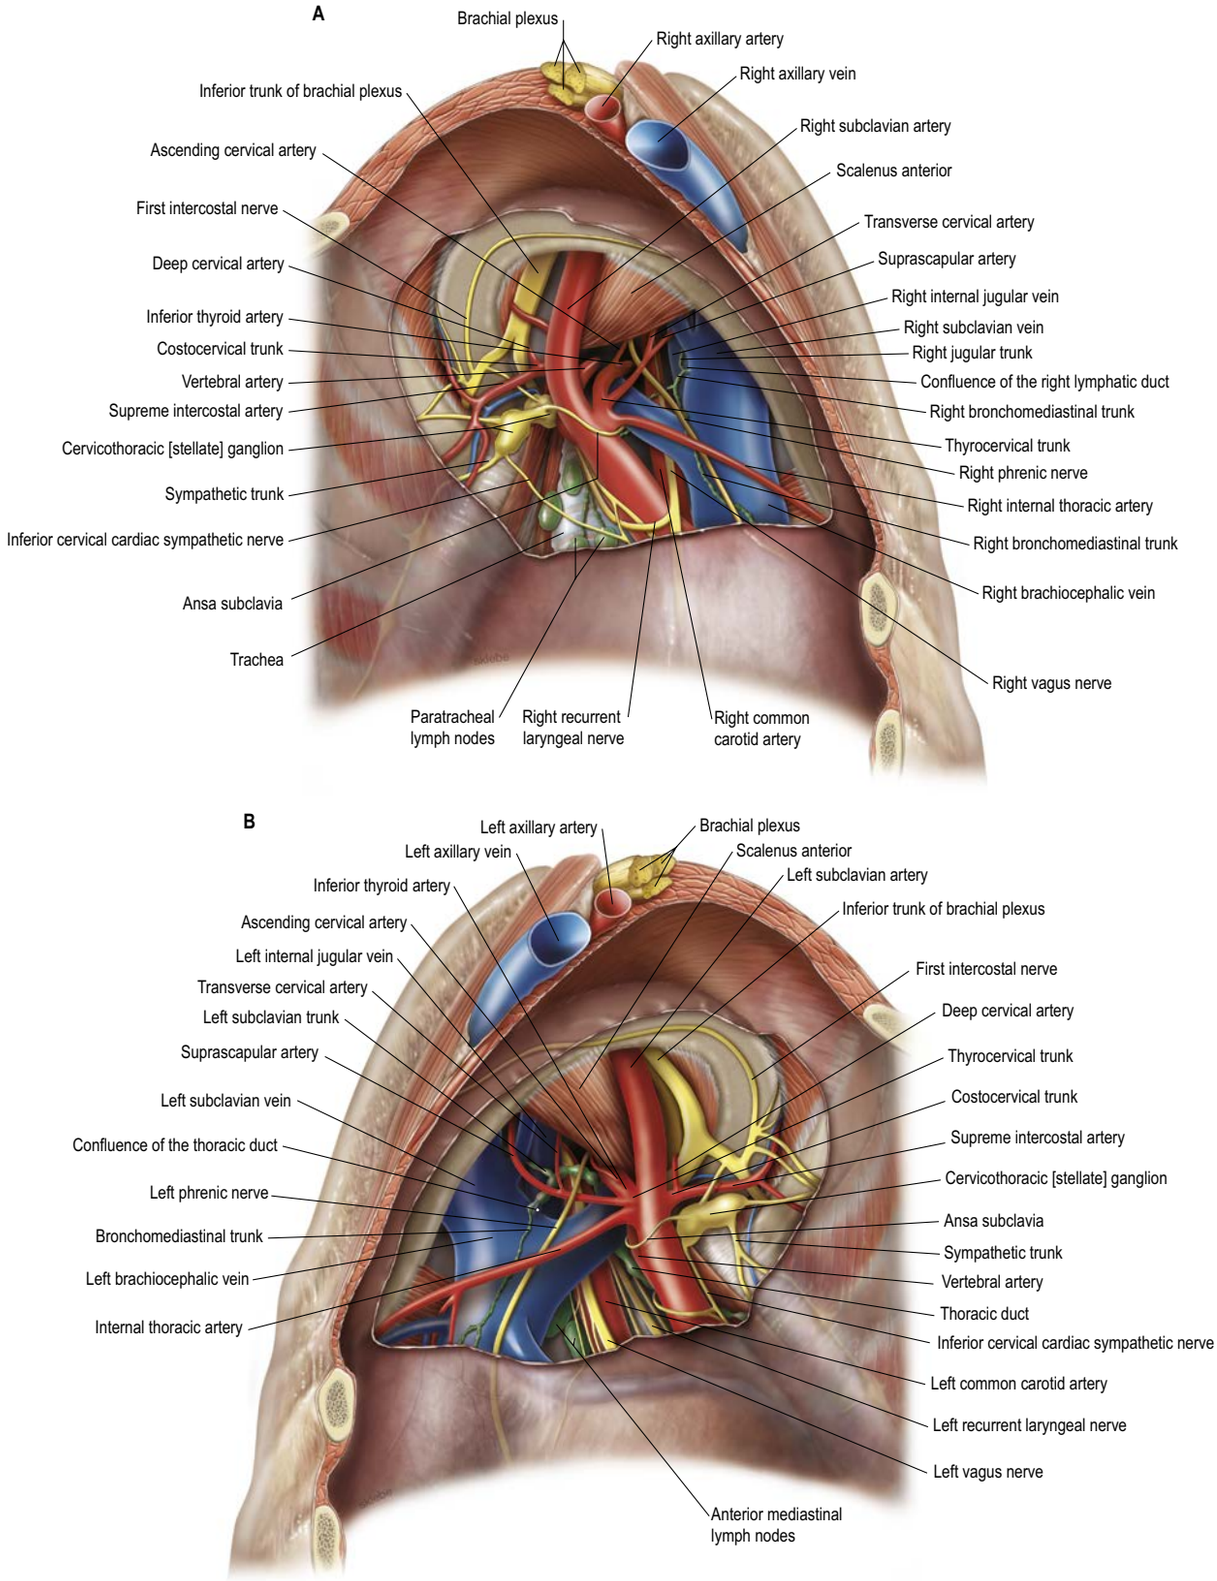

Fig. 55.10 The course and anatomical relations of the phrenic nerves in the superior thoracic aperture and superior thorax. **A**, Right side showing the right phrenic nerve. **B**, Left side showing the left phrenic nerve. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

to tenth ribs to be elevated and the inferior portions of the ribs to be turned outwards as a result of direct transmission of pressure through the costal attachments of the diaphragm (zone of apposition) (Fig. 55.12). During inspiration, the bodies of the ribs move superiorly and laterally, increasing the transverse dimensions of the thoracic cavity in the same manner as a bucket handle swinging outwards. This effect is most evident in the seventh to tenth ribs. Movements at the costovertebral joints cause elevation of the anterior ends of the ribs that push the body of the sternum and the upper ribs anteriorly in a 'pump handle' movement; this effect is most evident in second to sixth ribs, and increases the anteroposterior dimension of the thorax. The right cupula of the diaphragm, which lies over the liver, has a greater resistance to overcome than the left, which lies over the stomach; consequently the right crus and the muscle fibres of the right side of the diaphragm are more substantial than those of the left. The balance between descent of the diaphragm, protrusion of the abdominal wall

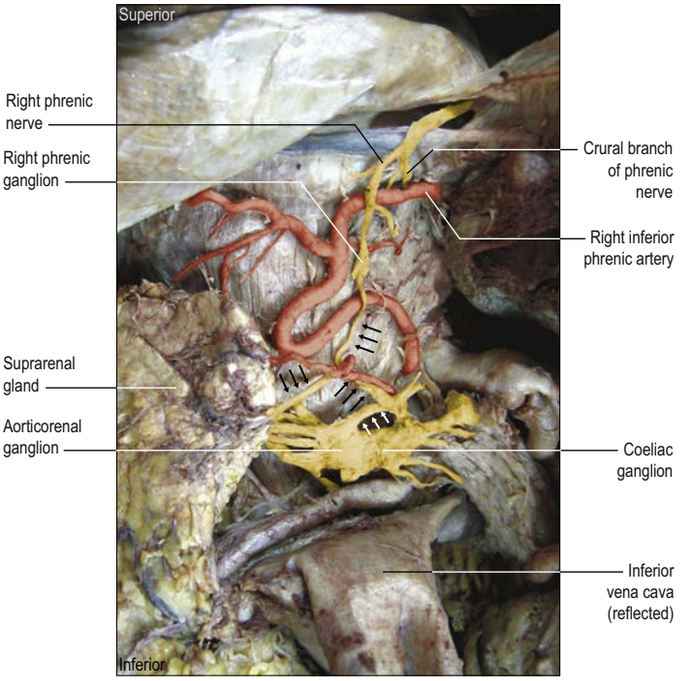

Fig. 55.11 A cadaveric dissection showing a right phrenic ganglion close to the right inferior phrenic artery and right diaphragmatic crus with plexiform communications to the coeliac ganglion, aorticorenal ganglion and suprarenal gland (arrows). The inferior vena cava has been reflected inferiorly. (With permission from Loukas M, Du Plessis M, Louis RG Jr et al 2016 The subdiaphragmatic part of the phrenic nerve – morphometry and connections to the autonomic ganglia. Clin Anat 29:120–8.)

('abdominal breathing') and elevation of the ribs ('thoracic breathing') varies between individuals and with the phase and depth of ventilation, the degree of distension of the stomach and intestines, and the size of the liver. The thoracic element is usually more evident in females, but increases in both sexes during deep inspiration.

The role of the abdominal wall in breathing is often underestimated. If the anterolateral abdominal wall connected the pelvic rim rigidly to the costal margins, inspiration would be impossible because the diaphragm could not descend (the abdominal contents would be incompressible), and the ribs could not rise (the connections to the pelvis would be inextensible). During normal breathing, the abdominal wall relaxes as the diaphragm contracts. It is possible to oppose this motion by tensing the abdomen, as in the 'beach posture' adopted to exaggerate the size of the chest. In this case, the abdominal contents fix the central tendon of the diaphragm, so that it raises the ribcage as it contracts, thus widening the gap between the ribs and the pelvic rim.

The ventilatory muscles must also work during sleep, when the pharyngeal muscles relax and upper airway resistance increases. In some individuals, particularly those with obesity, this relaxation can lead to periodic apnoea and marked hypoxia during sleep, implying that the pharyngeal muscles play an important ventilatory role in waking life. Although ventilatory muscles rarely tire in normal life, they do fatigue when placed under abnormal loads, e.g. in chronic obstructive pulmonary disease.

The primary role of the intercostal muscles is to stiffen the chest wall, preventing paradoxical motion during inspiratory diaphragmatic descent. This becomes most obvious immediately after high spinal cord injury, when there is flaccid paralysis of the entire trunk and only the diaphragm remains functional.

An observational study reporting the relationship of the left and right phrenic nerve with their respective internal thoracic arteries in the superior thoracic cavity.

The position of the respiratory diaphragm within the thoracic cavity varies with posture. It is highest (most superior) when the body is supine, when it performs the greatest range of ventilatory movements with normal breathing. When the body is erect, the diaphragm is located at a more inferior level and its ventilatory movements become smaller; when sitting, the diaphragm is at its most inferior level and its ventilatory movements are at their smallest. When the body is horizontal and on one side (lateral decubitus), the two halves of the diaphragm are positioned and move differently. The uppermost half sinks to a lower level than that seen when sitting, and moves little with ventilation. The lower half rises to a higher level in the thoracic cavity than it does even in the supine position, and its ventilatory excursions are considerably greater (Froese 2006). Changes in the position of the diaphragm with alterations in posture explain why patients with severe dyspnoea are most comfortable, and least short of breath, when sitting with the trunk upright.

In quiet breathing, the range of diaphragmatic excursion is about 1–2 cm, increasing to 5–7 cm during deep breathing (Boussuges et al 2009, Jung et al 2014). Following a forced inspiration, e.g. when breathing is partially obstructed, the right cupula of the diaphragm may descend to approximately the level of the body of the eleventh thoracic vertebra, while the left cupula may reach the level of the body of the twelfth thoracic vertebra. After forced expiration, the right cupula of the diaphragm is level anteriorly with the fourth costal cartilage, laterally with the fifth, sixth and seventh ribs, and posteriorly with the eighth rib; the left cupula is normally located more inferiorly by about one intercostal space, rib or costal cartilage.

The different pulmonary regions do not all move equally during ventilation. In quiet ventilation, the juxtahilar part of the lung moves minimally, the middle region moves only slightly and the superficial costal regions of the lung expand the most. The mediastinal surface, posterior border and apex move less because they are related to less movable structures. The diaphragmatic and costomediastinal regions expand most of all. Most of the volumetric change during ventilation occurs in the alveoli.

In a healthy adult with a vital capacity of 4.5 L, approximately 3 L is accounted for by diaphragmatic excursion. Immediately after high spinal cord injury, the vital capacity decreases to about 300 ml, even though the diaphragm is moving maximally, because the paradoxical incursion of the flaccid intercostal muscles results in a 2.7 L loss. After several weeks the paralysis usually becomes spastic, stiffening the chest wall, and the vital capacity increases towards its phrenic limit of about 3 litres. In the same way, high spinal cord injury reveals the role of the abdomen in inspiration and expiration. The abdominal musculature plays a major role in active expiration in humans. During the flaccid stage of high spinal cord paralysis, the only mechanisms available for returning the relaxed diaphragm into the thorax on expiration are passive recoil of the lungs and chest wall, and the weight of the abdominal viscera. The latter is the most important and operates only when an affected patient is lying down. If the patient is sat up or raised into an upright position, exhalation is impossible; trussing the abdomen with an elastic binder may be helpful. When the post injury paralysis becomes spastic, the stiff abdominal wall opposes inspiration.

CHAPTER 56

Mediastinum

The mediastinum is the visceral compartment between the two lungs and includes the mediastinal part of the parietal pleura. It is commonly defined as the region between the two pleural sacs, bounded laterally by the mediastinal parietal pleura, anteriorly by the sternum and posteriorly by the thoracic vertebral column, and extending vertically from the superior thoracic aperture (thoracic inlet) to the respiratory diaphragm (see Fig. 52.1). It communicates freely with the neck spaces and with the extraperitoneal, extrapleural and epidural spaces. Beyond each lung hilum, the mediastinum merges into the lung interstitium, incorporating the bronchial tree with its accompanying neurovascular bundles and the pulmonary vasculature.

The posterior mediastinal boundary is longer than the anterior as a result of the oblique orientation of the superior thoracic aperture and the posteroinferior curvature of the respiratory diaphragm. With respect to the median plane (midline), the mediastinum appears asymmetric.

The mediastinum is divided into superior and inferior mediastina by the sternal plane, which passes horizontally from the manubriosternal joint to intersect the vertebral column from the fourth to the superior half of the fifth thoracic vertebral body (Mirjalili et al 2012). This boundary is sometimes defined as a fixed plane passing from the manubriosternal joint to the inferior limit of the fourth thoracic vertebral body (**Fig. 56.1**). The inferior mediastinum is subdivided into anterior, middle and posterior parts.

Detailed accounts of mediastinal contents are included with descriptions of the respiratory viscera (Ch. 54), heart (Ch. 57) and great vessels (Ch. 58).

SUBDIVISIONS OF THE MEDIASTINUM

Superior mediastinum

The superior mediastinum lies between the manubrium of the sternum anteriorly and the bodies of the upper four or five thoracic vertebrae and the intervening intervertebral discs posteriorly. It is bounded laterally by the mediastinal parietal pleurae (see Fig. 56.1). The reflections of the left and right costal parietal pleura onto the superior mediastinum each follow a line that passes from the sternoclavicular joint in an inferomedial direction, to meet each other in the midline posterior to the sternal angle (see Fig. 53.4B). The resultant triangular space on the posterior surface of the manubrium of the sternum and between the lines of pleural reflection is occupied by the thymus or its remnants. The superior mediastinum contains the trachea, oesophagus, aortic arch, brachiocephalic trunk, left common carotid and subclavian arteries (the vertebral artery sometimes arises from the aortic arch between them), the internal thoracic arteries, the supreme intercostal, left superior intercostal, accessory hemiazygos, internal thoracic and inferior thyroid veins, and numerous lymph nodes, including those of the para-aortic, upper paratracheal, retrotracheal and prevascular groups (stations). Laterally, the superior mediastinal structures have the appearance of being 'shrink-wrapped' by the tightly applied mediastinal parietal pleura. The superior mediastinum transmits the sympathetic trunks, the sympathetic and parasympathetic cardiac nerves, the phrenic nerves laterally, the vagus nerves medially and the left recurrent laryngeal nerve. The terminal part of the thoracic duct emerges from the posterior aspect of the aortic arch and oesophagus, and passes superiorly between the left subclavian and left common carotid arteries to enter the neck (see Fig. 56.7B). The left and right brachiocephalic veins join to form the superior vena cava. The origins of sternothyroid and sternohyoid are attached to the posterior surface of the manubrium of the sternum. An enlarged thyroid gland may extend inferiorly between the manubrium and the brachiocephalic veins; its surgical excision requires care due to possible venous adherence. The origins of longus colli (inferior oblique and vertical intermediate portions) are the deepest contents of the superior mediastinum.

Inferior mediastinum

Anterior mediastinum

The anterior mediastinum lies between the sternal body and fibrous pericardium (see Fig. 56.1). It narrows above the level of the fourth

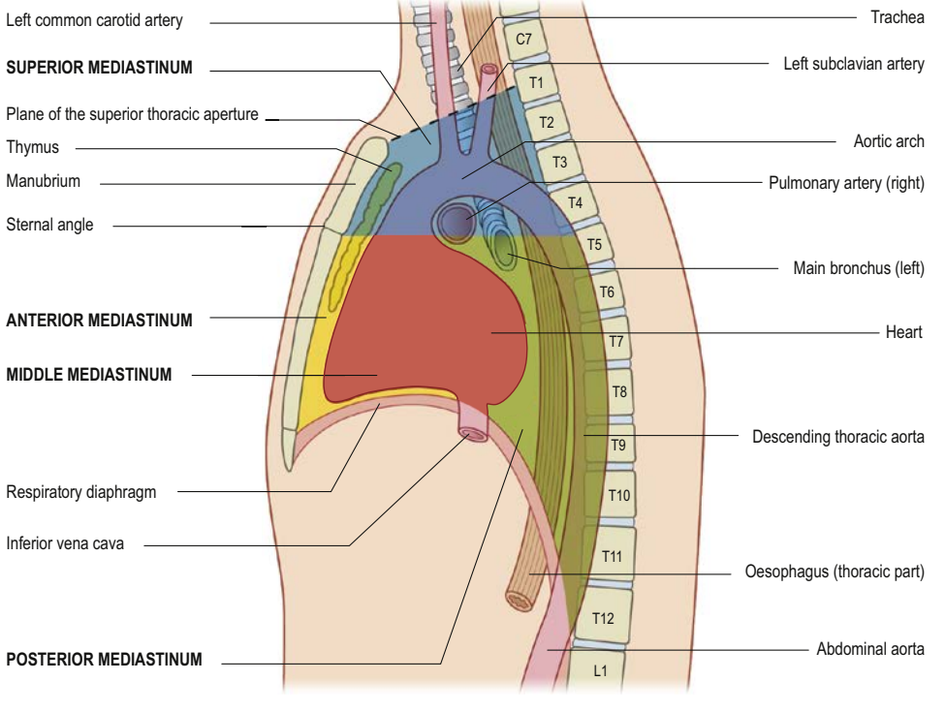

Fig. 56.1 Divisions of the mediastinum.

costal cartilages where the lines of pleural reflection converge (see Fig. 53.4B), and contains a variable amount of adipose tissue, loose connective tissue, sternopericardial ligaments, a few lymph nodes, the mediastinal branches of the internal thoracic artery, and sometimes part of the thymus gland or its remnants. The paired sternocostal triangles (of Morgagni) are openings between the sternal and costal attachments of the respiratory diaphragm: they are filled with areolar tissue and crossed by the superior epigastric vessels and by some lymph vessels from the abdominal wall and liver. A retrosternal hernia may pass through the triangles. The pericardium and the heart are routinely approached by either a complete or partial median sternotomy. The sternopericardial ligaments and the pleural reflections are easily separated by blunt dissection. In case of pericardial tamponade, the pericardial cavity can be drained through a left parasternal or subxiphoid approach, normally without entering the pleural cavity.

Middle mediastinum

The middle mediastinum is the broadest part of the inferior mediastinum (see Fig. 56.1) and contains the pericardia, heart and ascending aorta, the intrapericardial (inferior) half of the superior vena cava (receiving the azygos vein posteriorly), the tracheal bifurcation and main bronchi, the pulmonary trunk, right and left pulmonary arteries and veins, phrenic nerves, the deep part of the cardiac plexus and the subcarinal and lower paratracheal (tracheobronchial) lymph nodes. The short thoracic part of the inferior vena cava, both the extra- and intrapericardial segments, extends between the caval foramen of the respiratory diaphragm, through which it passes, and its termination in the right atrium. The structures forming the root of the lung converge at the hilum of the lung. The mediastinal part of the parietal pleura forms the lateral boundary of the middle mediastinum and is continuous with the visceral pleura at the level of the root of the lung and pulmonary ligament; the parietal pleura folds back (reflects) on itself to continue as the visceral pleura. The fibrous pericardium lies on, and is fused with, the middle folium of the central tendon of the respiratory diaphragm (see Fig. 55.3A).

Posterior mediastinum

The posterior mediastinum is the longest and narrowest part of the inferior mediastinum (see Fig. 56.1). It is bounded anteriorly by the tracheal bifurcation, fibrous pericardium and pulmonary vessels, and posteriorly by the bodies of the fourth or fifth to the twelfth thoracic vertebrae, and the intervening intervertebral discs. Numerous structures pass freely between the superior and posterior mediastina. The curved posterior third of the median (midline) region of the respiratory diaphragm constitutes the anteroinferior limit of the posterior mediastinum. Two pleural recesses, the aortico-oesophageal and azygo-oesophageal, project medially between the aorta and oesophagus on the left side and the azygos vein and oesophagus on the right side (see Fig. 56.7).

The posterior mediastinum contains the descending thoracic aorta (on the left side of the vertebral column), the oesophagus (median, but positioned anterior to the aorta inferiorly) and, more posteriorly, the azygos and hemiazygos venous systems, the thoracic duct, prevertebral and para-oesophageal lymph nodes, right and left sympathetic trunks and associated ganglia, and thoracic splanchnic nerves. The vagal trunks are located adjacent to the oesophagus; the anterior trunk is constituted mainly from the left vagus nerve and the posterior mainly from the right vagus nerve. The descending thoracic aorta gives off the intercostal arteries (see Fig. 52.3) and the largest anterior segmental medullary artery, the 'great radicular artery of Adamkiewicz' (Yoshioka et al 2003) (see Fig. 47.11).

There are communications between the posterior mediastinum and the abdomen either through, or posterior to, the respiratory diaphragm (Ch. 55). The oesophageal hiatus at the level of the body of the eleventh thoracic vertebra (conventionally reported as at the level of the body of the tenth thoracic vertebra), transmits the oesophagus, anterior and posterior vagal trunks, gastric nerves and oesophageal branches of the left gastric artery. The aortic hiatus at the level of the body of the twelfth thoracic vertebra transmits the aorta, thoracic duct and occasionally the azygos and hemiazygos vein. Apertures within the diaphragmatic crura transmit the thoracic splanchnic nerves; apertures deep to the medial arcuate ligament transmit the sympathetic trunks; minute openings in the central tendon of the respiratory diaphragm transmit small veins. All openings represent potential communication sites for suppurative or neoplastic processes.

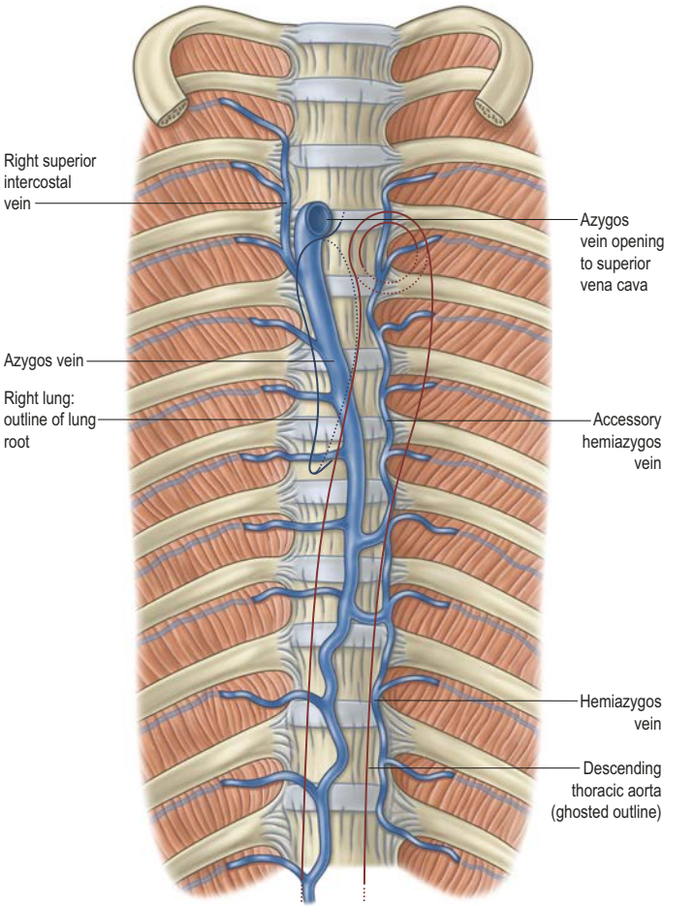

Fig. 56.2 A typical arrangement of the intrathoracic azygos, hemiazygos and accessory hemiazygos veins. Outlines of the root of the right lung and descending thoracic aorta are included for positional reference.

Mediastinal communications with the neck

Pathways exist between the oral cavity and the mediastinum via the parapharyngeal space and along other fascial planes/spaces of the neck. The parapharyngeal space is more likely to be infected than any of the other potential tissue spaces in the head and neck. It communicates with the retropharyngeal and pretracheal spaces, eventually reaching the superior mediastinum and then the inferior mediastinum (Chs 35, 37, 40). The planes between the buccopharyngeal, alar and prevertebral fasciae, the retropharyngeal and danger spaces, respectively, are a highway for the spread of air and gastric contents between the neck and mediastinum after oesophageal injury (Wind and Valentine 2013). The carotid sheath, containing the carotid arteries, internal jugular veins and vagus nerves, represents another potential route of communication.

Vascular supply and lymphatic drainage

The mediastinum contains the great vessels (ascending aorta, aortic arch and its branches, descending thoracic aorta, superior vena cava and the thoracic part of the inferior vena cava), the pulmonary arteries and veins, the internal thoracic and posterior intercostal arteries and veins, the azygos and hemiazygos venous systems, and the thoracic duct.

Great vessels of the superior mediastinum

The ascending aorta, aortic arch and its branches, descending thoracic aorta, pulmonary trunk and superior vena cava are described in Chapter 58.

Azygos venous system

Azygos vein

The azygos vein has a variable origin at or below the level of the renal veins (**Figs 56.2–56.3**; see Fig. 56.14B). When present, the azygos lumbar vein ascends anterior to the bodies of the upper lumbar vertebrae and passes either posterior to, or through, the right diaphragmatic

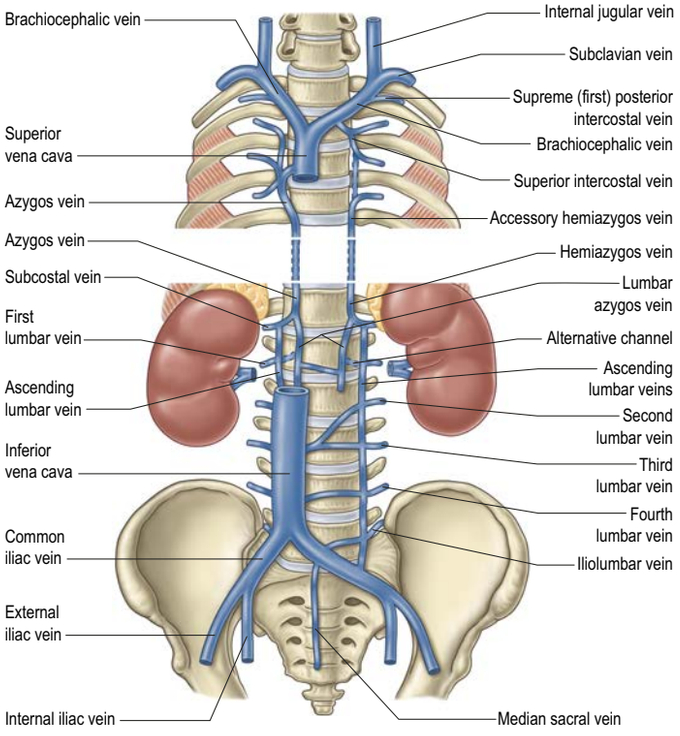

Fig. 56.3 The azygos venous system and its tributaries and connections.

crus or traverses the aortic hiatus to the right of the cisterna chyli. Anterior to the body of the twelfth thoracic vertebra, it is joined by a venous trunk, formed by the union of the right ascending lumbar and subcostal veins, to form the azygos vein. In the absence of a lumbar azygos vein, this common venous trunk continues as the azygos vein. The azygos vein passes to the right, posterior to the right crus of the respiratory diaphragm, and ascends in the posterior mediastinum to the level of the body of the fourth thoracic vertebra, where it arches anteriorly, superior to the right lung hilum and root, and joins the posterior aspect of the superior vena cava, just superior to the point where it passes into the pericardium.

In its course, the azygos vein lies anterior to the anterior longitudinal ligament covering the bodies of the lower eight thoracic vertebrae and the intervening intervertebral discs, and the right posterior intercostal arteries. Right lateral relations include the right sympathetic trunk and associated ganglia, the right greater thoracic splanchnic nerve, the right lung and parietal pleura. Left lateral relations include the thoracic duct, descending thoracic aorta and, where the vein arches anteriorly, the oesophagus, trachea and right vagus nerve. Aortic pulsations may assist venous return in the azygos and hemiazygos veins, although only a small and variable number of imperfect valves are present. Inferiorly, the azygos vein lies posterior to the oesophagus, from which it is separated by a right-sided pleural recess, the azygo-oesophageal recess. There are age-related differences in the appearance of the contour of this recess on computed tomography (CT); the recess is dextroconvex below the age of 6 years, non-concave (equally divided between straight and convex) between 6 and 12 years of age and concave, as seen in adults, after the age of 12 years of age (Miller et al 1993).

The major tributaries of the azygos vein are the right intercostal veins (excluding the right supreme (first) intercostal vein that drains into the right brachiocephalic vein), the right superior intercostal vein (usually formed by the union of the second to fourth intercostal veins), the right ascending lumbar and subcostal veins, mediastinal, oesophageal, superior phrenic, pericardial and right bronchial veins, and the hemiazygos and accessory hemiazygos veins.

Numerous anastomoses exist between the tributaries and the main trunks of the azygos, hemiazygos and accessory hemiazygos veins, the inferior vena cava and the vertebral venous plexuses. These allow for alternate drainage pathways in case of segmental agenesis ('interruption') or thrombosis of the inferior vena cava.

Hemiazygos vein

The hemiazygos vein represents the left-sided equivalent of the more inferior part of the azygos vein. It originates in a similar fashion, from the union of the left lumbar ascending and subcostal veins, but exhibits greater variability, and may also connect with the left renal vein via the equivalent of the lumbar azygos vein. The hemiazygos vein crosses the midline anterior to the body of the eighth or ninth thoracic vertebra, passing posterior to the descending thoracic aorta and oesophagus, and either anterior or posterior to the thoracic duct, to join the azygos vein (see Figs 56.2, 56.5B). It receives mediastinal, oesophageal and the ninth to eleventh left posterior intercostal veins.

Accessory hemiazygos vein

The accessory hemiazygos vein functions as the left-sided mirror image of the superior portion of the azygos vein. It drains the left fifth to eighth posterior intercostal veins and occasionally the left bronchial veins, and usually crosses the midline anterior to the body of the seventh thoracic vertebra to join the azygos vein. The supreme (first) left posterior intercostal vein drains directly into the left brachiocephalic vein, while the second to the fourth may connect indirectly to the accessory hemiazygos vein via the left superior intercostal vein (see Fig. 56.7). The accessory hemiazygos vein typically joins the azygos vein directly, but it can join the hemiazygos vein before draining into the azygos vein. One or more prevertebral transversal anastomoses can be present.

Variations of the azygos venous system

The origin, course, tributaries, anastomoses and termination of the azygos system of veins are all highly variable (Loukas and Tubbs 2016). The arrangement shown in **Fig. 56.2** represents the most common pattern with a right-sided azygos vein. The left-sided hemiazygos vein can be absent or underdeveloped, allowing direct drainage of the left intercostal veins into the azygos vein and/or the termination of the accessory hemiazygos vein into the left brachiocephalic vein either directly or by joining the left superior intercostal vein. In such cases, the azygos vein is located in a median position. In cases of common cardinal or anterior cardinal vein malformation, the azygos vein may enter the right atrium, right brachiocephalic vein or right subclavian vein rather than joining the superior vena cava.

Internal thoracic arteries and veins

The internal thoracic vessels are described in Chapter 53.

Pulmonary arteries and veins

The pulmonary vessels are described in Chapter 54.

Posterior intercostal arteries and veins

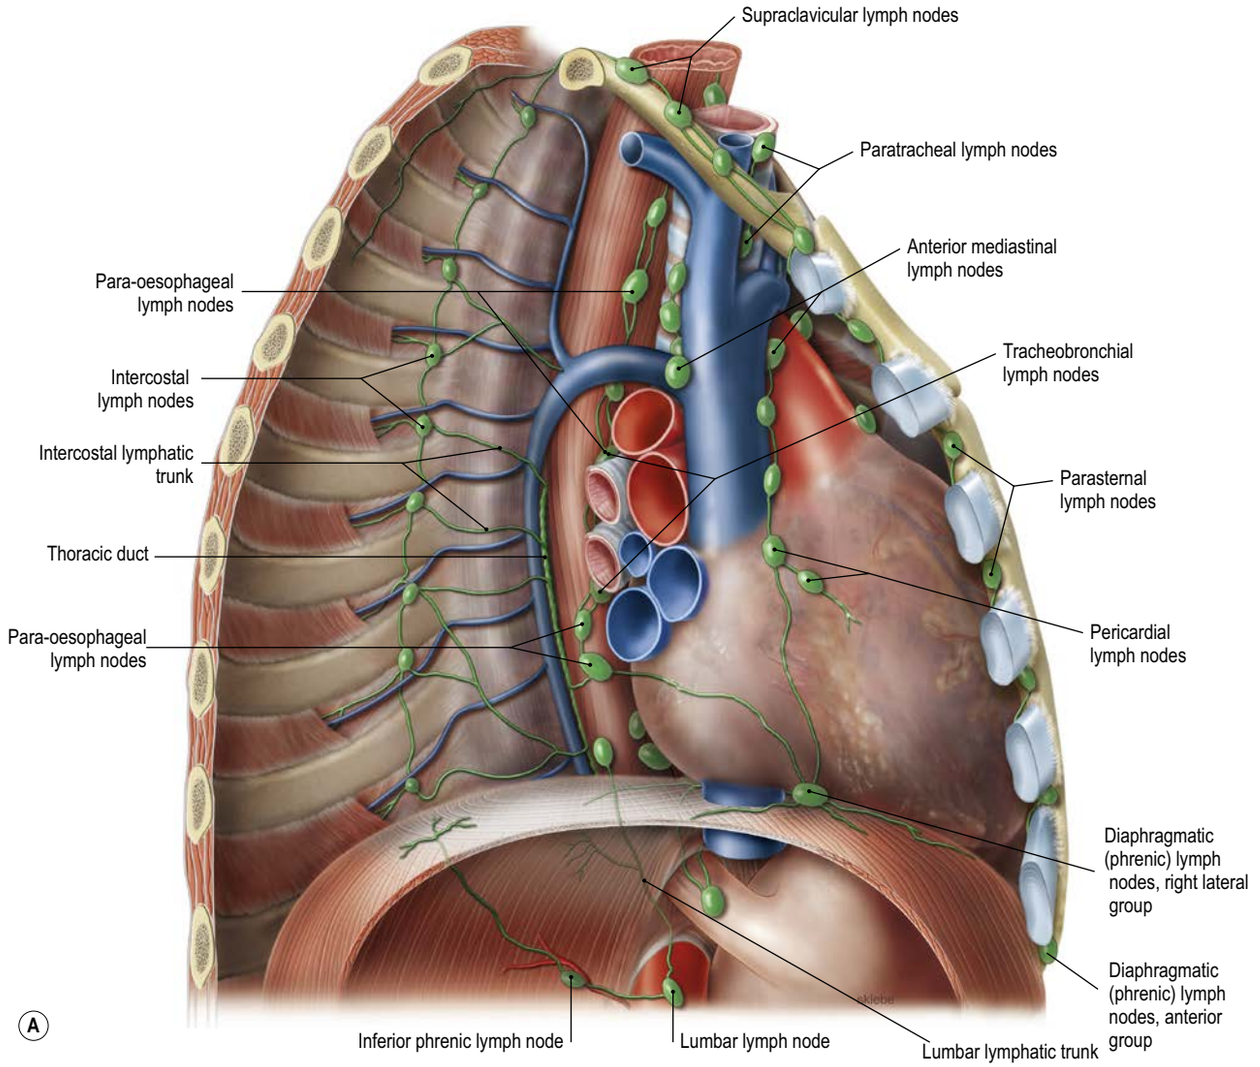
The posterior intercostal veins accompany their arteries in 11 pairs; they are described in Chapter 53.

Mediastinal lymph nodes

There are multiple groups of lymph nodes throughout the mediastinum. Conventionally they have been named according to the nearest mediastinal viscera or structure (which they often drain): parietal node groups drain the thoracic wall and visceral groups drain the thoracic viscera (**Fig. 56.4A**). However, this naming system implies that the mediastinal node groups are separate and distinct, whereas in reality they are part of a continuum. To better reflect their regional disposition, and for the purposes of cancer staging and management, mediastinal lymph node groups are best categorized into regional lymph node stations and zones (Rusch et al 2009) (see Fig. 54.12B, **Fig. 56.4B**, **Table 56.1**).

Pulmonary nodes within the lung parenchyma are continuous with the bronchopulmonary node groups (in order, these include subsegmental, segmental, lobar, interlobar and hilar nodes) (see Figs 56.4B, 54.12). Bronchopulmonary node groups are continuous with subcarinal (inferior tracheobronchial) nodes located inferior to the tracheal bifurcation and the lower paratracheal (superior tracheobronchial) nodes. In turn, these groups are continuous with the upper paratracheal groups of nodes that drain the lungs, bronchi, the thoracic part of the trachea, heart, pericardium and also receive efferent vessels from prevertebral nodes that receive lymph from the posterior respiratory diaphragm, thoracic oesophagus and intercostal lymph nodes. Efferent vessels ascend on the trachea to unite with efferents from the parasternal and brachiocephalic nodes to become the right and left bronchomediastinal trunks. The right trunk may occasionally join a right lymphatic duct or another right-sided lymph trunk, and the left trunk may join the thoracic duct, but usually they open independently in or near the ipsilateral junction of the internal jugular and subclavian vein (see Fig. 35.16).

Mediastinoscopy



In congenital interruption of the inferior vena cava or acquired thrombosis, the azygos system provides an alternative pathway for venous drainage. A higher than usual azygos arch may travel over the apical region of the right superior lobe within an accessory azygos fissure, covered by four pleural layers (two parietal and two visceral), and isolate a portion of the superior lobe of the right lung medially: the 'azygos lobe' (Loukas and Tubbs 2016). If present, the azygos fissure can be identified on chest radiograph as a fine radiopaque line. The azygos vein located within the azygos fissure often presents as a lung 'pseudonodule' on a chest radiograph; it is typically comma-shaped and should not be confused with a more rounded appearance of early lung carcinoma or metastasis.

Metastatic involvement of mediastinal lymph nodes has important prognostic implications and influences the choice of treatment (Mountain and Dresler 1997, Rusch et al 2009). The staging system for lung cancer classifies node involvement using a nodal descriptor (N-'Stage'), where N0 indicates no regional lymph node metastases; N1 indicates involvement of ipsilateral peribronchial or hilar lymph nodes and intrapulmonary nodes; N2 indicates involvement of ipsilateral mediastinal and/or subcarinal nodes; and N3 indicates involvement of contralateral mediastinal or hilar nodes, and ipsilateral or contralateral scalene or supraclavicular nodes/scalene nodes (Goldstraw et al 2016, Chansky et al 2017, Lim et al 2018).

The decision to proceed with mediastinoscopic biopsy depends on whether suitable nodal stations (zones) seem involved on CT scanning and whether there is a history of prior neck and mediastinal surgical procedures. Complications of mediastinoscopy include haemorrhage, iatrogenic injury to the trachea or left recurrent laryngeal nerve and pneumothorax. Mediastinoscopy can be performed with video-assisted or direct optic visualization. A transverse incision is made at the level of the jugular (suprasternal) notch; sternohyoid and sternothyroid muscles within the superficial lamina of deep cervical fascia are retracted; the deep lamina of the deep cervical fascia is incised. The pretracheal plane is dissected and a space is created between the anterior aspect of the trachea and the brachiocephalic trunk inferior to the carina and along both sides of the trachea and main bronchi. This space facilitates biopsy of the upper paratracheal 2R and 2L stations, the right lower paratracheal 4R station and higher nodes from the left lower paratracheal 4L station superior to the aortic arch (see Fig. 54.12B; Table 56.1). The anterior part of subcarinal station 7 and bilateral hilar stations 10R and 10L may be accessible but are technically challenging. Lymph nodes can be sampled or removed entirely for histological evaluation.

The anterior part of the superior mediastinum is more difficult to assess by mediastinoscopy and usually requires an anterior mediastinotomy (Chamberlain procedure). This is performed to biopsy nodes from the more inferior aspect of the left lower paratracheal 4L station, subaortic station 5, para-aortic station 6 and subcarinal station 7, and also facilitates anterior mediastinal mass biopsy. Endobronchial ultrasound can be performed to biopsy lymph nodes in stations 1–4, 7 and 10–12, using fine needle aspiration through the tracheal or bronchial walls. In a similar way, transoesophageal ultrasound may help during biopsy of subcarinal station 7, para-oesophageal station 8 and pulmonary ligament station 9 nodes.

A video demonstrating lymph node dissection via mediastinoscopy can be seen in Rami-Porta (2012). A video demonstrating mediastinal lymph node dissection via tracheo-oesophageal mediastinoscopy can be seen in Turner (2010).

TABLE 56.1 Classification of regional mediastinal lymph nodes into regional lymph node stations/zones (for detail see Rusch et al 2009)

Nodes	Zone	Station	
	Supraclavicular	1	Low cervical, supraclavicular and sternal (jugular) notch
Superior mediastinal	Upper	2R	Upper paratracheal (right)
		2L	Upper paratracheal (left)
		3a	Prevascular
		3p	Retrotracheal
		4R	Lower paratracheal (right)
		4L	Lower paratracheal (left)
Aortic	Aorticopulmonary	5	Subaortic
		6	Para-aortic (ascending aorta or phrenic)
Inferior mediastinal	Subcarinal	7	Subcarinal
	Lower	8	Para-oesophageal (below carina)
		9	Pulmonary ligament
N1	Hilar/interlobar	10	Hilar
		11	Interlobar
	Peripheral	12	Lobar
		13	Segmental
		14	Subsegmental

THORACIC DUCT

The thoracic duct conveys the lymph from the majority of the entire body back to the venous circulation, except lymph from the right part of the head, neck and heart, right upper limb, parts of the left and right lung and part of the convex surface of the liver. It usually originates anterior to the body of the first or second lumbar vertebra, where the intestinal and two lumbar lymphatic trunks join to form the cisterna chyli. Both the thoracic duct and the cisterna chyli are variable in their origin, course and length; the latter is even more variable in width and shape than the thoracic duct (Song 2016). From the superior aspect of the cisterna chyli, the thoracic duct passes through the aortic hiatus and enters the posterior mediastinum, lying to the right of the midline, between the descending thoracic aorta and the azygos vein, up to the level of the body of the fifth or sixth thoracic vertebra, where it typically passes to the left, over the vertebral column and posterior to the oesophagus (see Fig. 56.7B). It may branch or even have duplicate trunks that eventually form a single thoracic duct (Song 2016). It continues superiorly, first posterior to the aortic arch adjacent to the left side of the oesophagus, then posterior to the left subclavian artery in the superior mediastinum. It subsequently arches over the left subclavian artery and descends anteriorly to empty into the venous circulation in the region of the left internal jugular and subclavian veins, either at their very confluence or in proximity, or sometimes into the left brachiocephalic vein (**Fig. 56.5**). In the space between longus colli, scalenus anterior and the suprapleural membrane, the duct usually arches 3–4 cm superior to the clavicle, crossing anterior to the vertebral vessels, the left sympathetic trunk, the vertebral sympathetic ganglion, the left thyrocervical trunk and the left phrenic nerve. The course and position of the thoracic duct determines the location of the effusion seen with duct injury or obstruction.

Two thoracic ducts are sometimes present within the mediastinum and may terminate in veins on their respective side of the body. Occasionally a single thoracic duct may empty into right-sided venous structures, a disposition that is more frequent in individuals with an aberrant right subclavian artery originating from the distal aortic arch and ascending posterior to the oesophagus.

The thoracic duct is commonly 36–45 cm in length, its external diameter varies according to region (Song 2016). When present as a single channel it is 5–8 mm in diameter at its origin, narrows to 2–3 mm at mid-thoracic level and then widens again at its termination: the diameter may fluctuate with lymph flow rate (Smith et al 2013). Alternatively, the thoracic duct may divide into two or three branches that eventually reunite or drain into both the left and right venous systems. The duct appears sinuous and has valves throughout its length; a bicuspid valve at its termination may prevent the backflow of blood. As it passes through the mediastinum, the thoracic duct also receives non-chylous lymph from tributaries that drain regions of the pulmonary

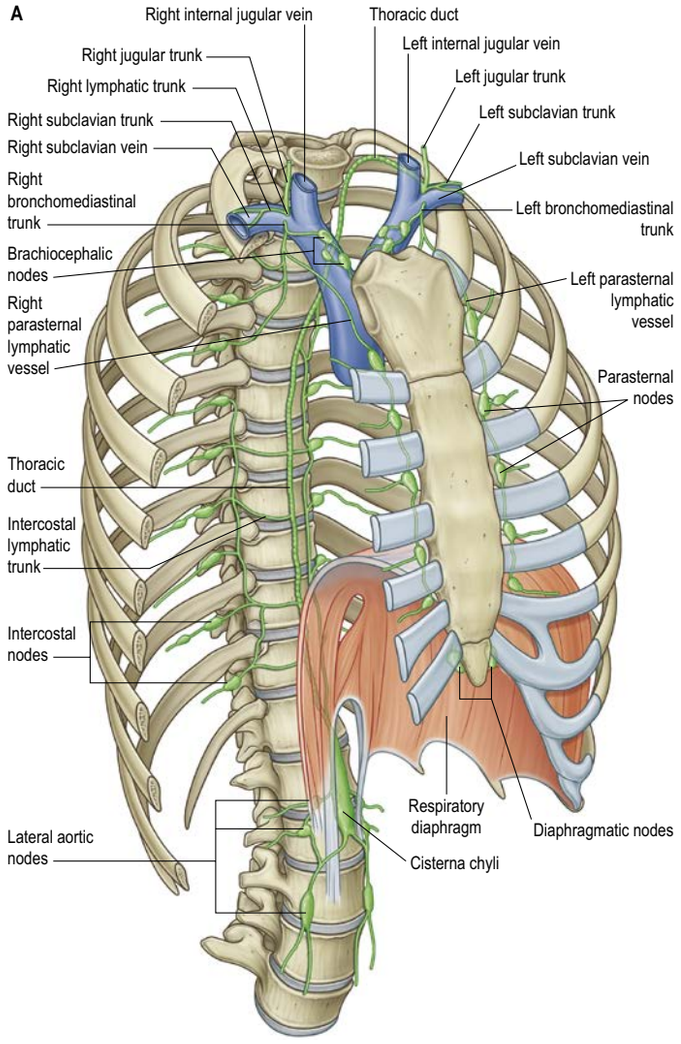

Fig. 56.5 The thoracic and right lymphatic ducts, and their tributaries. **A**, Major lymph nodes and vessels of the thoracic wall, and the termination of the lymphatic trunks. (B, *continued online*)

parenchyma and parietal pleura. The sum of these sources accounts for a total lymphatic flow through the thoracic duct of 1500–2400 ml per day in proportion to the dietary intake of fat, particularly long-chain triglycerides.

Tributaries of the thoracic duct

Some tributaries of the thoracic duct may terminate directly in the venous system. There are numerous anastomoses between visceral, parietal, limb and mammary lymphatics, as is apparent from observed multiple patterns of dissemination of cancer cells (see Figs 56.4–56.5). As well as the cisterna chyli and its tributaries, bilateral ascending lumbar lymphatic trunks from the upper lateral aortic (abdominal part) nodes pierce the corresponding diaphragmatic crus and eventually join the thoracic duct in the posterior mediastinum. The inferior six or seven intercostal lymphatic trunks from the corresponding bilateral intercostal nodes descend to terminate in the duct, either directly or by variable common trunks. The left upper intercostal lymphatics may join the cervical portion of the duct or the subclavian trunk. The left subclavian trunk usually joins the thoracic duct but may open independently into the left subclavian vein. These mediastinal trunks provide lymph drainage paths to the thoracic duct from the convex diaphragmatic aspect of the liver, the respiratory diaphragm, the pericardium, heart and oesophagus; many possess terminal bicuspid valves. The left bronchomediastinal trunk occasionally joins the thoracic duct but usually has an independent venous termination. The left jugular trunk usually joins the thoracic duct but may open independently into the left internal jugular vein (see Fig. 35.16).

Injury during oesophageal surgery

Available with the *Gray's Anatomy* e-book

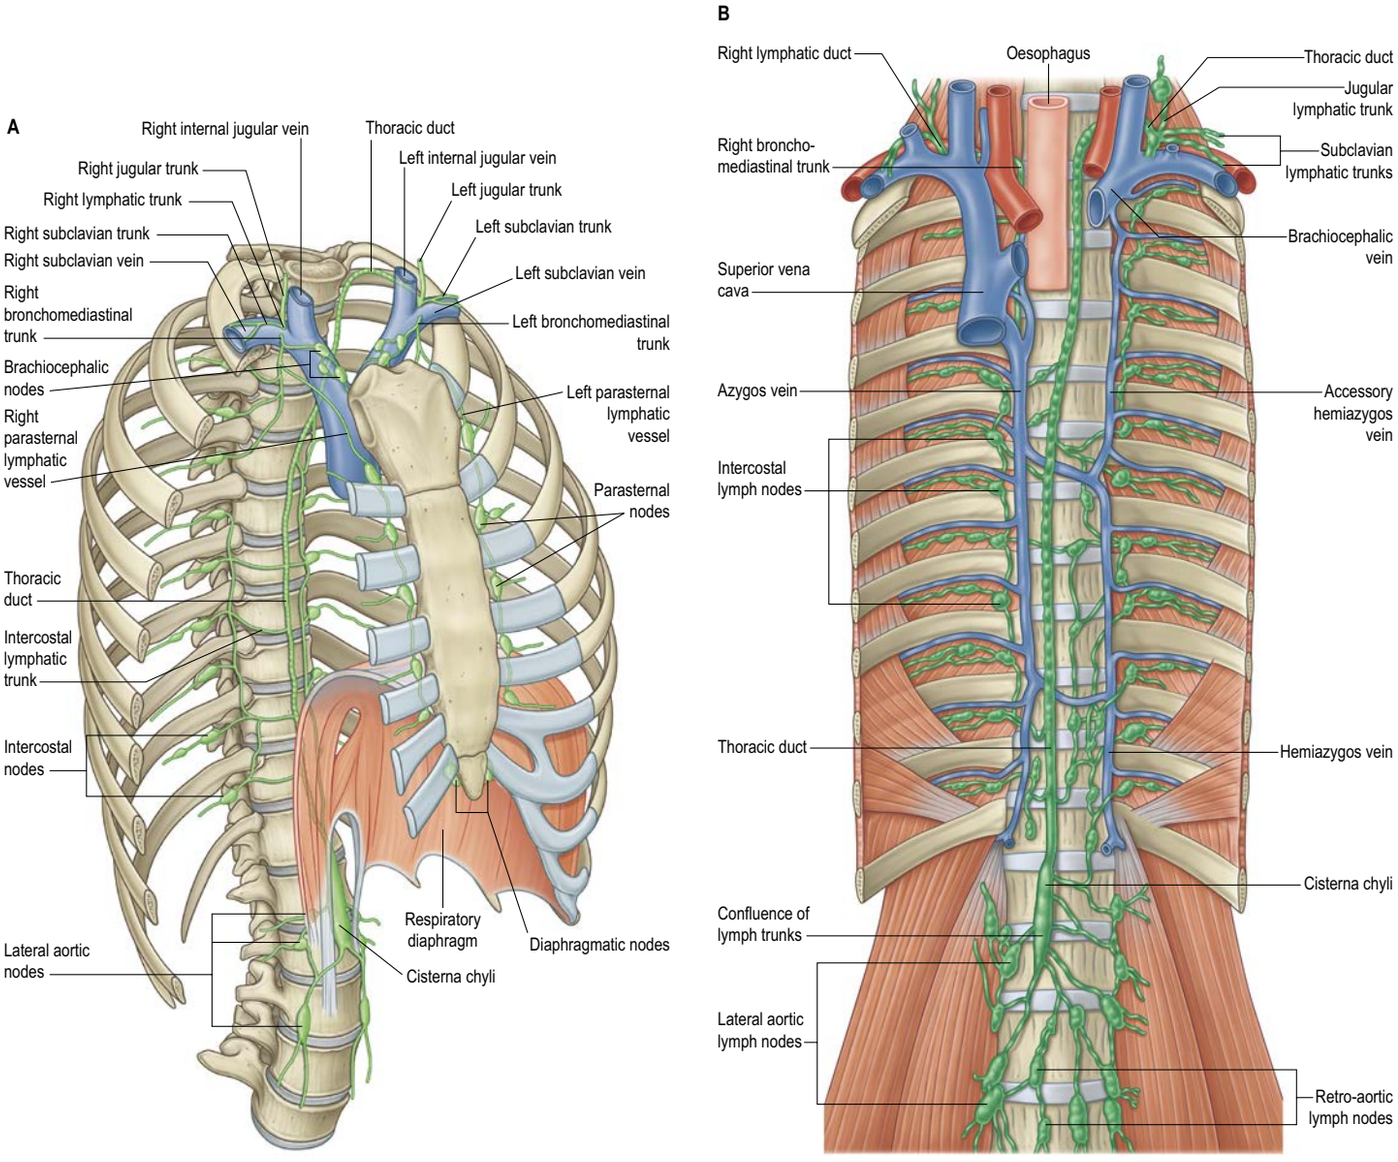

Fig. 56.5 The thoracic and right lymphatic ducts, and their tributaries. **A**, Major lymph nodes and vessels of the thoracic wall, and the termination of the lymphatic trunks. **B**, Anterior view with the major proximal vascular relations *in situ*. Note that the accessory hemiazygos vein is crossing the median plane lower and the hemiazygos higher than typically found. (A, Adapted with permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2015.)

The thoracic duct crosses the mediastinum at, or at about, the level of the body of the fifth thoracic vertebra which means that lymphatic injury or obstruction above or below this level results in a left- or right-sided pleural effusion (chylothorax), respectively (Doerr et al 2001). Anomalies and sites of injury to the duct are identified by lymphangiography, with or without post-procedure CT scanning, or lymphoscintigraphy. Lymphangiography is performed after bilateral localization of pedal lymphatics with a subcutaneous injection of methylene blue, followed by a minor surgical procedure to cannulate the lymphatic vessels, and injection of Lipiodol contrast agent. Conventional X-ray and CT imaging (without intravenous contrast) are then undertaken. Lymphangiography can identify areas of chyle leakage and lymphangiectasia in the majority of patients (Deso et al 2012).

Ligation of the thoracic duct via thoracoscopic surgery can be seen in Devulapalli (2016).

The variable origin, course and length of the thoracic duct, coupled with a failure to identify it during surgery, may lead to inadvertent incision or transection, particularly during trans-hiatal and thoracoscopic oesophageal surgery, with an incidence of 0.2–3% (Wemyss-Holden et al 2001). Thoracic duct laceration is a potentially life-threatening complication; mortality rates are higher with conservative management but remain elevated even after surgical ligation. Rupture of the thoracic duct leads to leakage of chyle, which is rich in lipid, protein, T lymphocytes (ranging from 400 to 6800 cells/μl), immunoglobulins and fat-soluble vitamins, and hence a progressive nutritional and immune deficit develops. Postoperative chylous effusions are usually the result of damage to ductal tributaries rather than to the duct itself, and are usually self-limiting. The greater incidence of injury with trans-hiatal resection may be attributable to shear forces exerted around the region of the duct during the mobilization of the distal oesophagus, whereas the limited field of view probably contributes to the greater incidence of thoracic duct injury during thoracoscopic surgery. Injury should be suspected in the postoperative period if there is either an enlarging mediastinal silhouette on serial chest radiographs or a significant drainage of milky looking fluid from chest or abdominal drains. An electrophoretic confirmation of the presence of chylomicrons in the pleural fluid is diagnostic amongst other tests. The thoracic duct may be injured during the left cervical approach for the exposure of the vertebral and subclavian arteries or the cervicothoracic (stellate) sympathetic ganglion. However, deliberate ligation of the duct at this level represents an accepted surgical manoeuvre with no particular consequences.

RIGHT LYMPHATIC TRUNK

The right lymphatic trunk has a variable anatomy (see Figs 56.5, 35.16). Its three main tributaries, the right jugular, subclavian and bronchomediastinal trunks, often empty separately into either the right internal jugular and/or subclavian veins. In up to 20% of individuals, they may aggregate to form the right lymphatic trunk that is usually 5–10 mm in length. The terminal portions of the right lymphatic trunk and of the thoracic duct are concealed by the scalene fat pad, rendering them more vulnerable during surgery.

AUTONOMIC NERVOUS SYSTEM

The thoracic autonomic nervous system consists of the right and left sympathetic trunks and associated ganglia, the vagus nerves, and the cardiac, pulmonary and oesophageal plexuses. The cardiac plexus is described in Chapter 57, the pulmonary plexus in Chapter 54, and the oesophageal plexus is described below.

Thoracic sympathetic trunk

The thoracic sympathetic trunks have ganglia that are almost equal in number to those of the thoracic spinal nerves (usually 11, occasionally 12, rarely 10 or 13), with which they are associated (**Figs 56.6–56.7**). Almost always, the first thoracic ganglion is fused with the inferior cervical ganglion, forming the cervicothoracic (stellate) ganglion; occasionally, the second thoracic ganglion is included in this fusion (Irwin et al 2016). The thoracic ganglia sit posterior to the costal part of the parietal pleura and except for the second and lowest two or three, they lie anterior to the heads of the ribs. The second thoracic sympathetic ganglion is commonly located in the second intercostal space, and the lowest two or three thoracic ganglia lie lateral to the bodies of the correspondingly numbered vertebrae. Inferiorly, the thoracic sympathetic trunks pass posterior to the medial arcuate ligament or through the ipsilateral diaphragmatic crus to become the lumbar sympathetic trunks.

The ganglia are relatively small and interconnected by intervening segments of the trunk. The classic description is that two or more rami communicantes, white (myelinated, preganglionic) and grey (unmyelinated, postganglionic), connect each ganglion with its corresponding spinal nerve, the white rami connecting with the spinal nerve distal to the grey. Variation in this pattern is common, especially at the upper thoracic levels and symmetry is rarely seen. Additional ascending and descending rami communicantes may emerge from the second (54% and 46%, respectively), third (6% and 25%) and fourth ganglia (5% and 8%) (Cho et al 2005). Occasionally, a grey and a white ramus fuse to form a 'mixed' ramus. An intrathoracic ramus may join the second intercostal nerve to the ventral ramus of the first thoracic spinal nerve proximal to the point where the latter sends a large branch to the brachial plexus (Kuntz 1927). This intrathoracic nerve of Kuntz is thought to carry sympathetic nerve fibres to the brachial plexus without passing through the sympathetic trunk and has been held responsible for the recurrence of symptoms following surgical sympathectomy. The anatomical variation exhibited by the rami communicantes and the location of the second sympathetic ganglion may also contribute to post-surgical symptom recurrence.

The medial branches from the upper five thoracic ganglia are very small and may supply nerve fibres in a retrograde manner to the thoracic parts of the aorta and its branches as they pass to the cardiac plexuses (Kawashima 2011). Rami of the second to fifth or sixth ganglia enter the posterior pulmonary plexus. Small branches from the pulmonary and cardiac nerves pass to the oesophagus and trachea. The larger medial branches from the lower seven ganglia supply the descending thoracic aorta and then unite to form the greater, lesser and least thoracic splanchnic nerves. The thoracic splanchnic nerves are variable in origin and presence (Irwin et al 2016); the greater thoracic splanchnic nerve is always present, the lesser is usually present and the least is often absent. A fourth (accessory) thoracic splanchnic nerve has been described.

The greater thoracic splanchnic nerve consists mainly of myelinated preganglionic efferent and visceral afferent nerve fibres. It is usually described as being formed by branches from the fifth to ninth or tenth thoracic sympathetic ganglia, but most commonly it originates from the seventh to the ninth thoracic sympathetic ganglia. Its roots vary in number from three to ten. It descends obliquely along the vertebral bodies and intervening intervertebral discs, sends branches to the descending thoracic aorta, and perforates the ipsilateral diaphragmatic crus to terminate mainly in the coeliac but also in the aorticorenal ganglion and suprarenal (adrenal) gland. A thoracic splanchnic ganglion is present on the nerve opposite the body of the eleventh or twelfth thoracic vertebra in most individuals. The lesser thoracic splanchnic nerve is formed commonly by rami of the ninth and tenth thoracic sympathetic ganglia (range, ninth to twelfth). It pierces the respiratory diaphragm with the greater thoracic splanchnic nerve, which it may join, and terminates in the aorticorenal ganglion. The least thoracic splanchnic nerve (or renal nerve) from the lowest thoracic sympathetic ganglion enters the abdomen with the sympathetic trunk and terminates in the renal plexus. Some nerve fibres from the greater thoracic splanchnic and vagus nerves form a fine web-like thoracic aortic plexus.

Thoracic sympathectomy

Endoscopic thoracic sympathectomy (ETS) is a surgical procedure used to relieve the symptoms of craniofacial, palmar or axillary hyperhidrosis, facial blushing and Raynaud's disease with digital ulcers.

Vagus nerve in the mediastinum

The vagus nerve contains branchiomotor, general visceral afferent and preganglionic parasympathetic nerve fibres. The proportion of efferent parasympathetic nerve fibres in the vagus nerve varies at different levels but is small relative to its sensory and sensorimotor content. The branchiomotor fibres arise from neurones in the nucleus ambiguus in the medulla oblongata and are distributed to the constrictor muscles of the pharynx and the intrinsic muscles of the larynx. The general visceral afferent fibres carry sensation from thoracic and abdominal viscera and from aortic arch baroreceptors and chemoreceptors and end in the caudal part of the nucleus solitarius of the medulla oblongata. The preganglionic parasympathetic nerves arise from cell bodies in the vagal dorsal nucleus in the medulla oblongata, travel in the nerve and in its pulmonary, cardiac, oesophageal, gastric and intestinal branches and synapse in minute ganglia in the visceral walls (see Fig. 56.6) (Mussa and Verberne 2013). Pulmonary branches contain axons that synapse in ganglia of the pulmonary plexuses: they are motor (bronchoconstrictor) to the circular non-striated muscle fibres of the bronchi and bronchioles (and therefore bring about bronchoconstriction), and secretomotor to the mucous glands of the respiratory epithelium. Cardiac branches join the cardiac plexuses and synapse in ganglia that are distributed freely over both atria in the subepicardial tissue. Postganglionic fibres are distributed to the atria and the atrioventricular bundle and are concentrated around the sinuatrial and, to a lesser extent, the atrioventricular nodes (Ch. 57). Cardiac branches slow the heart rate and diminish the force of contraction and may indirectly influence ventricular muscle via their effect on the atrioventricular node. The direct postganglionic parasympathetic innervation of the ventricles is sparse. The smaller branches of the coronary arteries are innervated mainly by parasympathetic vagal neurones, whereas the larger arteries are innervated mainly by sympathetic neurones.

Right vagus nerve

The right vagus nerve descends posterior to the right internal jugular vein in the neck and crosses anterior to the first part of the right subclavian artery to enter the thorax; the ansa subclavia is lateral, and the phrenic nerve is further lateral (see Fig. 55.10A). After giving off the right recurrent laryngeal nerve, it descends through the superior mediastinum, at first posterior to the right brachiocephalic vein, and then lateral to the trachea and posteromedial to the superior vena cava. Superiorly, the right mediastinal part of the parietal pleura and superior lobe of the right lung are lateral; inferiorly, the azygos vein and its arching terminal portion separate the right vagus nerve from the mediastinal parietal pleura (see Fig. 56.7A). The nerve next passes posterior to the right main bronchus and lies on the posterior aspect of the right lung root/hilum. Here, it gives off posterior bronchial branches that unite

ETS may be beneficial to ameliorate cerebral vascularization in patients with moyamoya disease and to treat migraine, hyperactive bronchial states, long QT syndrome, causalgic pain, erythromelalgia, Buerger's disease, Prinzmetal's angina, and chronic non-infectious rhinitis. ETS is also effective in frostbite injury, especially if performed within 36–72 hours of cold exposure.

The operation involves making tiny incisions posterior to the anterior axillary (pectoral) fold in the axilla, and insufflating a small amount of carbon dioxide into the thoracic cavity to allow access with a modified thoracoscope. In the treatment of facial blushing, it is sufficient to divide the nerve fibres that run superiorly from the second thoracic ganglion over the neck of the second rib, leaving the second ganglion almost intact. Treatment of palmar hyperhidrosis requires ablation thermocoagulation of the sympathetic trunk over the necks of the third and fourth ribs, taking care to avoid any spreading of thermal energy along the trunk in order to avoid damaging the more superior stellate ganglion (see Horner's syndrome below). The risk of compensatory sweating is greatly reduced, though not completely excluded, by limiting the number of ganglia treated to an absolute minimum. As an additional procedure, dividing the inconstant sympathetic pathways (nerve of Kuntz, ascending or descending additional rami communicantes) on the second, third and fourth ribs may improve surgical outcomes. The effect is immediately evident: the patient awakes from anaesthesia with dry, warm hands. In many cases, even hyperhidrosis of the feet improves, but the underlying anatomical and physiological mechanisms are not yet properly understood (Gofeld and Faclier 2006). Surgical complications are rare; Horner's syndrome is of most concern, and is caused by damage to the stellate ganglion and interruption of the sympathetic nerve fibres from the ventral rami of spinal nerves C8–T1 that ascend around the arteries supplying the head and neck (see Fig. 35.18). Side-effects include compensatory sweating (ranging from barely noticeable to profuse) in other locations of the body during exercise or from exposure to high temperatures in up to 70% of patients. Compensatory sweating is severe in 5% of patients, and may be more frequent in those with axillary hyperhidrosis when two more inferior ganglia have to be divided: for this reason, some surgeons do not now consider isolated axillary hyperhidrosis as an indication for this procedure. Gustatory or olfactory sweating may also occur in up to one-third of patients but is rarely considered a problem. Other documented side-effects are the inability to raise the heart rate during increased physical strain/load: in some cases, this has led to decreased ability to perform work and daily activities. Patients can also experience an uncomfortable sensation of not being able to control their body temperature.

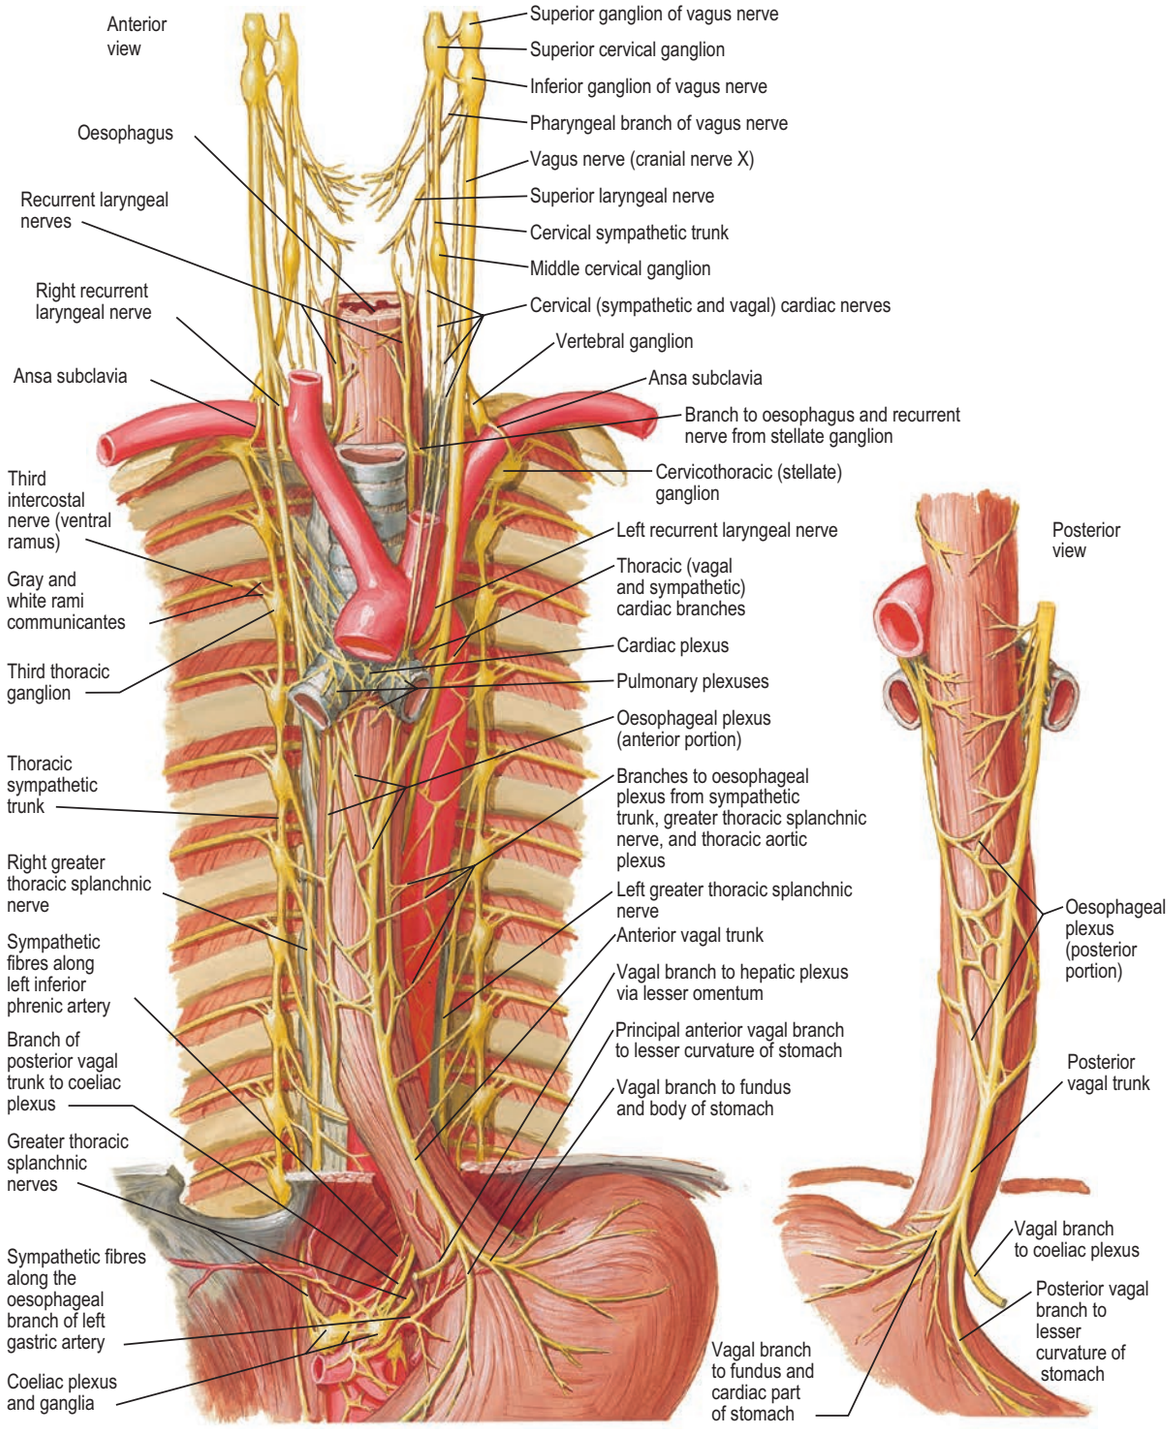

Fig. 56.6 The thoracic autonomic nervous system. (Adapted with permission from Netter FH Atlas of Human Anatomy, 7th ed. Elsevier. Copyright 2019.)

with rami from the second to fifth/sixth thoracic sympathetic ganglia to form the right posterior pulmonary plexus. Two or three branches descend from the inferior part of this plexus on the posterior aspect of the oesophagus to join a left vagal branch and form the posterior oesophageal plexus. The posterior vagal trunk, containing nerve fibres from both vagus nerves, leaves the plexus and passes inferiorly on the posterior surface of the oesophagus, entering the abdomen by passing through the oesophageal hiatus in the respiratory diaphragm (see Fig. 55.6).

Left vagus nerve

The left vagus nerve enters the thorax posterior to the left brachiocephalic vein, between the left common carotid artery (anterior) and left subclavian artery (posterior) (see Fig. 55.10B). It descends through the superior mediastinum, crosses the left side of the aortic arch, gives off the left recurrent laryngeal nerve and then passes posterior to the left lung root/hilum (see Fig. 56.7B). Superior to the aortic arch, it is crossed anterolaterally by the left phrenic nerve, and on the aortic arch, it is crossed laterally by the left superior intercostal vein and sometimes by a continuation of the accessory hemiazygos vein. Posterior to the hilum of the left lung, the left vagus nerve gives off posterior bronchial branches that unite with rami of the second to fourth thoracic sympathetic ganglia to form the left posterior pulmonary plexus. Two or three branches descend anteriorly on the oesophagus and join with one or more rami from the right posterior pulmonary plexus to form the anterior oesophageal plexus. The anterior vagal trunk, containing nerve fibres from both vagus nerves, passes inferiorly on the anterior surface of the oesophagus and enters the abdomen through the oesophageal hiatus in the

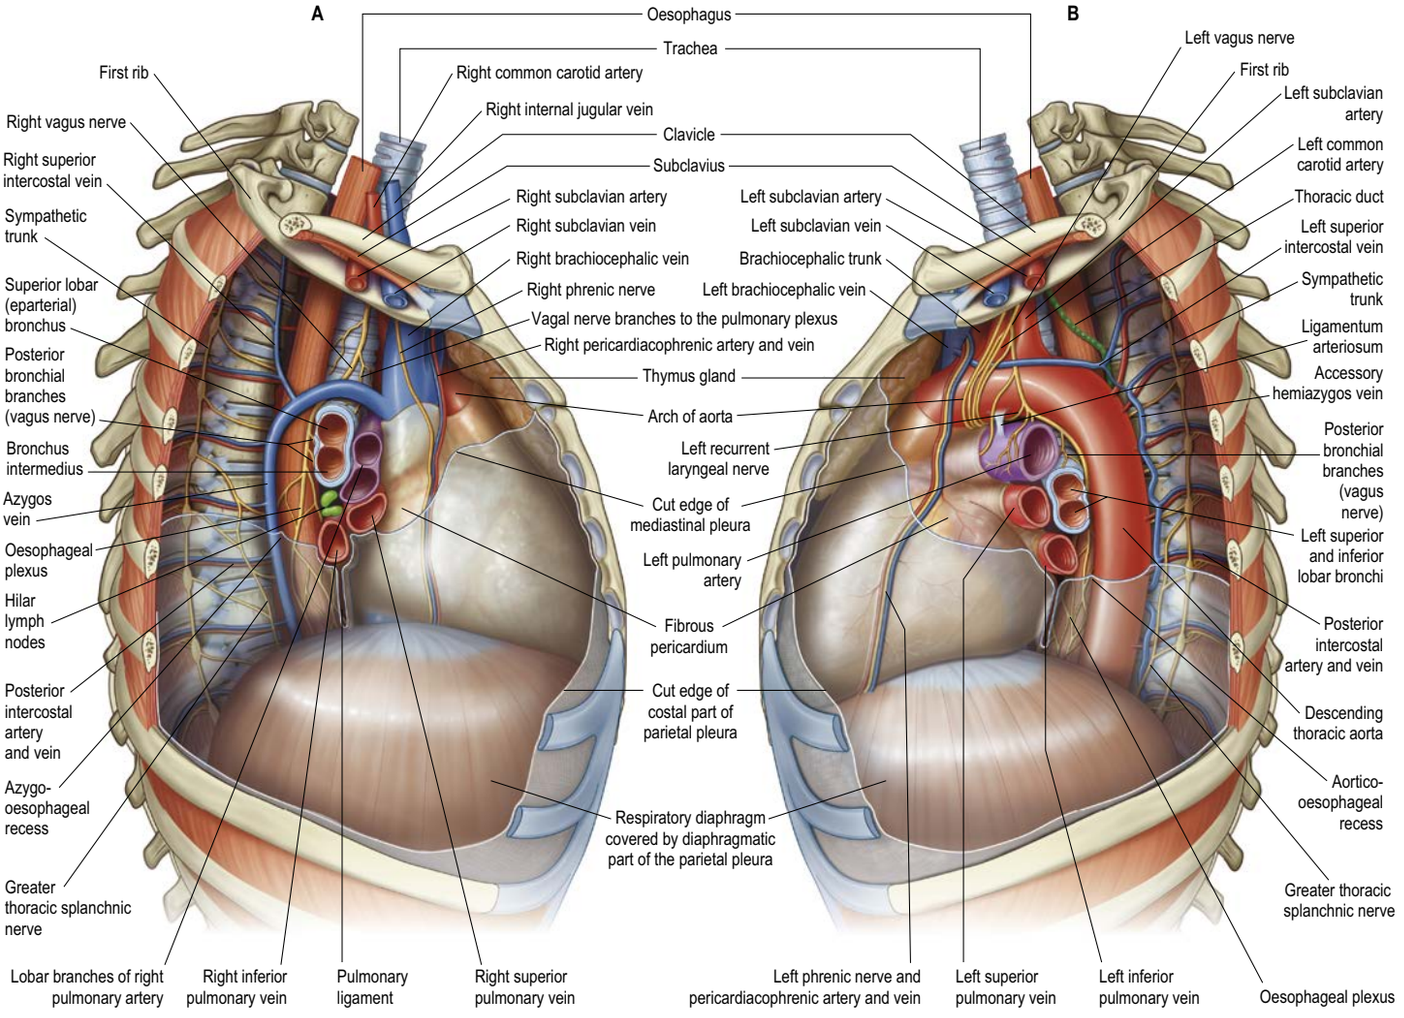

Fig. 56.7 The mediastinum. **A**, Right lateral aspect. **B**, Left lateral aspect. (Adapted with permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2015.)

respiratory diaphragm (see Fig. 56.6). Numerous branches from the anterior vagal and left sympathetic trunks are distributed to the descending thoracic aorta. This pathway transmits the typical intense, excruciating pain of an intramural aortic haematoma from aortic dissection or laceration.

THYMUS

The thymus and the bone marrow are the two primary lymphoid organs. The thymus is an encapsulated soft organ that is typically bilobed; the two lobes are joined in the midline by connective tissue that merges with the capsule of each lobe (**Figs 56.8–56.9**). It can also be a single lobe, or tri-lobed, or X-shaped. Capsular tissue may have adhesions to the fibrous pericardium, which is thinner superiorly and so may easily tear or require a limited pericardotomy during thymectomy. The thymus is visible on CT and MRI just anterior to the ascending aorta and inferior to the left brachiocephalic vein. CT attenuation in younger individuals is homogeneous, being greater than that of the chest wall and cardiac muscles below the age of 1 year, and similar to that of these muscles after the age of 1 year (Sklair-Levy et al 2000): the decline in CT attenuation with age is secondary to fatty infiltration. The signal intensity with MRI on T2-weighted images is similar to or greater than that of adipose tissue.

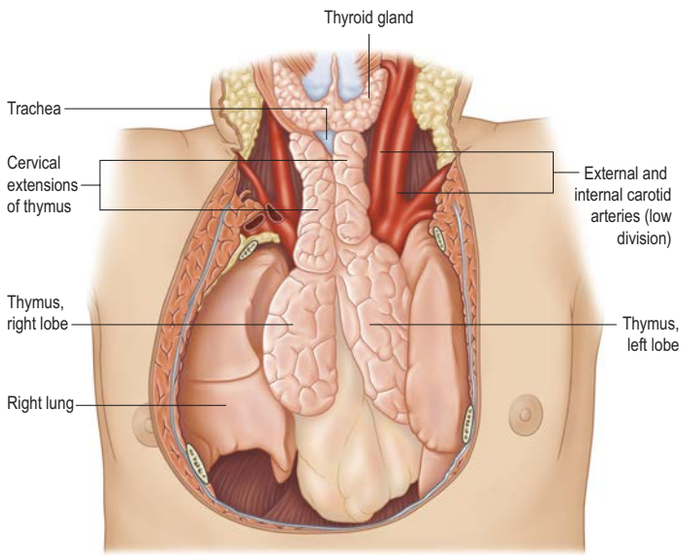

Fig. 56.8 The neonatal thymus.

Relations

The thymus is largest in the early part of life, particularly around puberty, although it persists actively into old age despite considerable fibrofatty degeneration that sometimes obscures the existence of persistent thymic tissue. The greater part of the thymus lies in the anterior mediastinum and the anterior part of the superior mediastinum: its inferior aspect reaches the level of the fourth costal cartilages. In some children, the thymus has been described as encircling the left brachiocephalic vein (Han et al 1989). Superiorly, thymic extensions into the neck are common, reflecting its bilateral embryonic origins from the third pharyngeal pouch (see Fig. 17.19). The superior poles join at, and extend above, the level of the jugular notch of the manubrium of

Fig. 56.9 A, A thymus from a 9-year-old female (left) and one from an 80-year-old male (right). Note the fibrofatty infiltration of the older thymus. (Courtesy of Professor M Kendall) (B–E, *continued online*.)

the sternum. The left pole usually extends higher and is seen first, sitting posterior to the infrahyoid muscles of the anterior neck during the initial stages of transcervical thymectomy. It sometimes reaches the inferior poles of the thyroid gland or even higher, and is connected to the thyroid gland by the thyrothymic ligament. Its shape conforms to that of adjacent structures. Inferiorly, the right lobe lies between the right side of the ascending aorta and the right lung, anterior to the superior cava. Anteriorly lie sternohyoid and sternothyroid muscles, superficial layer of deep cervical fascia, the manubrium of the sternum, the internal thoracic vessels and upper three costal cartilages. The mediastinal parts of the parietal pleurae lie laterally and the phrenic nerves can lie anterolateral and inferior; both structures can be injured during thymectomy. Posteriorly, the thymus is in contact with the vessels of the superior mediastinum (the left brachiocephalic vein and the inferior thyroid veins are usually partly embedded in the gland), the superior part of the thoracic trachea and the fibrous pericardium covering the anterior cardiac surface (right atrium and ventricle). Thoracic surgeons performing thymectomy must be aware of the anatomical variation in which the upper poles may lie posterior to the left brachiocephalic vein.

Additional thymic tissue is often found scattered around the thymus or in a range of ectopic locations: this is of importance when thymectomy is necessary (Jaretzki 1997, Varga 2016). The inferior parathyroid glands may be located within the thymus, reflecting their common origin from the third pharyngeal pouch. During development the thymus descends through the neck to the mediastinum and so ectopic thymic tissue/nodules may be found in a range of cervical or mediastinal locations, for example, lying near the trachea or oesophagus; within mediastinal adipose tissue; in the aorticopulmonary region; posterior to the brachiocephalic veins; posterior to the hyoid bone; rarely, near the carotid bifurcation/vessels. Ectopic intrathyroidal thymic tissue has been reported in children (Segni et al 2011).

Vascular supply and lymphatic drainage

Arteries

Thymic branches originating from the internal thoracic, inferior and sometimes superior, thyroid arteries supply the thymus and the surrounding mediastinal connective tissue. Since no definite hilum exists, the arterial branches travel either along the interlobar septa before entering the thymus at the junction of the cortex and medulla, or they reach the thymic tissue directly through the capsule.

Veins

Thymic veins drain to the left brachiocephalic, internal thoracic and inferior thyroid veins, and occasionally directly into the superior vena cava (see Fig. 58.1). One or more veins often emerge medially from each lobe of the thymus to form a common trunk that opens into the left brachiocephalic vein: they require careful ligation during thymectomy.

Lymphatic drainage

The thymus has no afferent lymphatics. Efferent lymphatics arise from the medulla and corticomedullary junction, drain through the extravascular spaces, accompany the supplying arteries and veins, and end in the brachiocephalic, paratracheal and subcarinal (tracheobronchial) and parasternal lymph nodes.

Innervation

The thymus is innervated from the sympathetic trunks via the cervicothoracic (stellate) ganglia or ansa subclavia and from the vagus nerves. Branches from the phrenic nerve and the inferior root of the ansa cervicalis are distributed mainly to the capsule. The two lobes are innervated separately through their dorsal, lateral and medial aspects. During development and before its descent into the thorax, the thymus is innervated by branches of the vagus nerves in the neck. After its descent, the thymus receives sympathetic innervation via nerve fibres that travel along the vessels that supply the gland: postganglionic sympathetic terminations branch radially and form a plexus with the vagal nerve fibres at the corticomedullary junction.

Microstructure

The thymus is responsible for the provision of thymus-processed (T) lymphocytes to the entire body, and provides a unique microenvironment in which thymocytes (T-cell precursors) undergo development, differentiation and clonal expansion to deliver the exquisitely specific T-cell response, simultaneously acquiring immune tolerance to the body's own components. These steps involve intimate interactions between thymocytes, mainly epithelial and antigen-presenting cells and biomolecular factors in the thymic environment. The thymus is also part of the neuroimmunological and neuroendocrine axes of the body, influenced by and influencing the products of these axes. Its activity therefore varies throughout life under the influence of different physiological states, disease conditions and chemical insults, such as hormones, drugs and pollutants. The thymus appears to be most active between the ages of 3 and 6 months, when the highest total number of thymocytes is present (Weerkamp et al 2005).

General architecture

It is useful to consider the embryological origins of the thymus in order to understand its cellular organization. It is derived from a number of sources, including epithelial derivatives of the third pharyngeal pouches, mesenchyme, haemolymphoid cells and vascular tissue. In section, the thymus can be seen to consist of an outer cortex of densely packed cortical thymocytes (T-cell precursors) and an inner medulla with fewer medullary thymocytes (**Fig. 56.10**). Both thymic lobes have a loose, fibrous connective tissue capsule, from which septa penetrate to the junction of the cortex and medulla, and partially separate the irregular lobules, which are each 0.5–2.0 mm in diameter (see Fig. 56.12). The connective tissue septa form a route of entry and exit for blood vessels and nerves, and carry efferent lymphatics. Most migrant cells enter or leave the thymus by this route. In each lobule, the cortex is composed of a superficial subcapsular cortex (a narrow band of cells immediately beneath the capsule) and a more extensive main cortex. The central medulla of both thymic lobes is continuous from one lobule to the next.

Epithelial framework

Unlike other lymphoid structures, in which the supportive framework is chiefly composed of reticular fibres, the thymus contains a network of interconnected epithelial reticular cells (see Fig. 56.10) that create an appropriate microenvironment, by cell-to-cell contact and the release of paracrine factors, in which thymocytes develop and mature into T lymphocyte cells. Although differing in morphology, all the epithelial reticular (nurse) cells of the thymus share a common origin from pharyngeal endoderm. They vary in size and shape, according to their positions within the thymus. Typically, they have pale, oval nuclei, an eosinophilic cytoplasm and intercellular desmosomal attachments. Intermediate filament bundles of cytokeratin lie within their cytoplasm. The subcapsular cells form a continuous external lining to the thymus, following its lobulated profile, ensheathing the

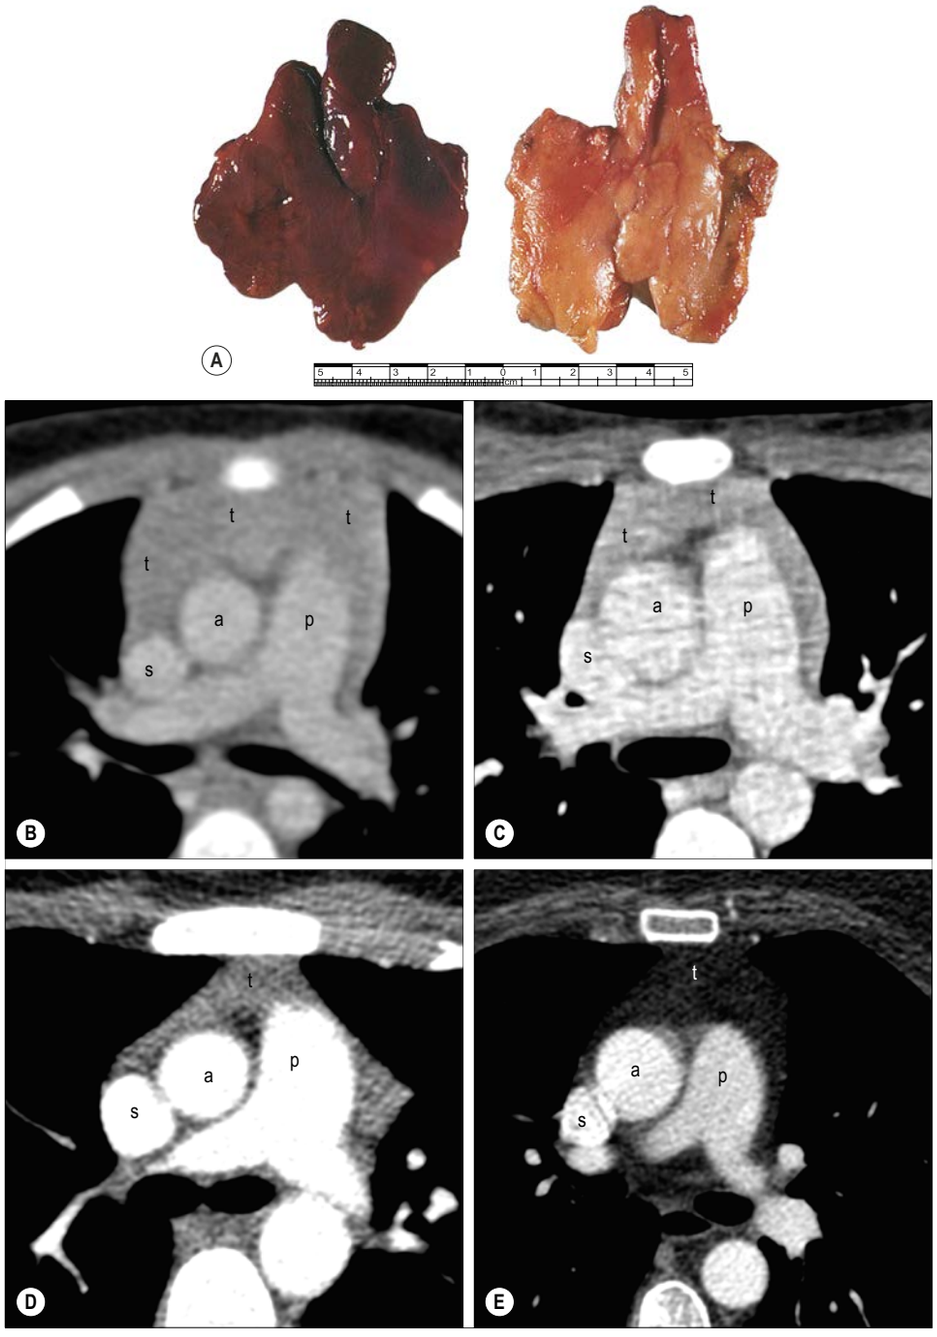

Fig. 56.9 A, Thymus glands from a 9-year-old female (left) and from an 80-year-old male (right). Note the fibrofatty infiltration of the older thymus. **B–E**, CT images of the chest with contrast medium showing the thymus in the anterior mediastinum in (**B**) a 10-month-old, (**C**) a 7-year-old, (**D**) a 17-year-old and (**E**) a 52-year-old. Notice how the thymus (t) reduces in volume relative to the great vessels with age (images are not to the same scale) and is then replaced by fatty material by late adulthood. Key: a, ascending aorta; p, pulmonary trunk; s, superior vena cava. (A, Courtesy of Professor M Kendall.)

The roles of the nervous system and other neuroendocrine elements in the overall biology of the thymus remain little understood. Many of the autonomic nerves most likely have a vasomotor effect, but other terminal branches (at least in rodents) ramify among the cells of the thymus, particularly the medulla, suggesting that they may have other roles. Innervation is complete by the onset of thymic function. The medulla contains a number of different types of non-lymphoid cells, including cells positive for vasoactive intestinal polypeptide and acetylcholinesterase, large non-myoid cells, and cells containing oxytocin, vasopressin and neurophysin, possibly of neural crest origin.

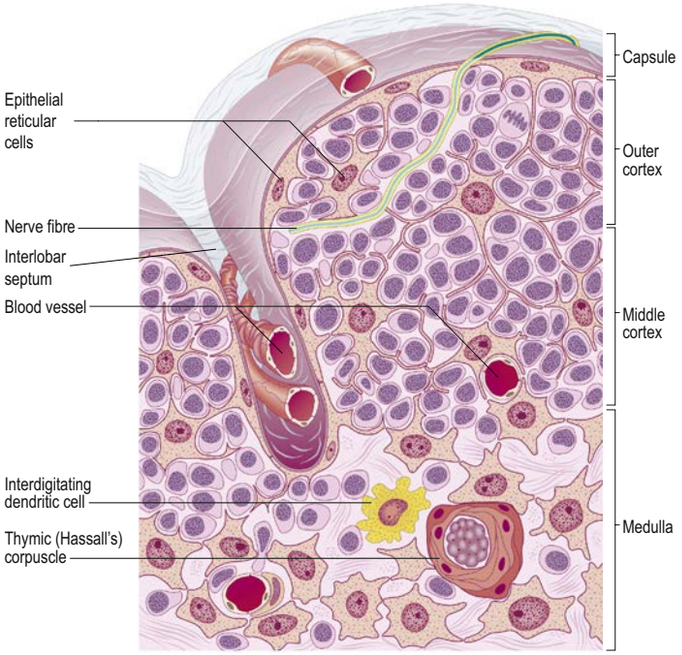

Fig. 56.10 Thymic structure and cellular organization, showing an interlobular septum, the cortical circulation and thymocytes within an epithelial framework.

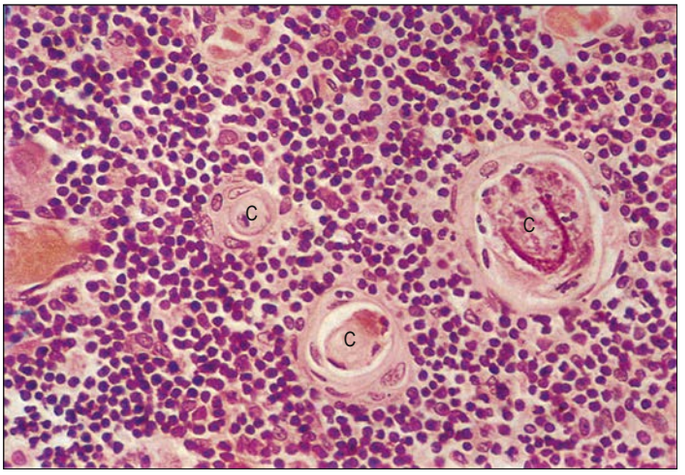

Fig. 56.11 The medulla of a neonatal thymus, showing three concentric thymic corpuscles (C) of varying degrees of maturity, surrounded by closely packed lymphocytes and a few epithelial reticular cells with larger nuclei.

penetrating vessels, and contributing to the blood–thymus barrier. Other cortical epithelial reticular cells form a loose mesh of long cytoplasmic processes, whereas medullary epithelial reticular cells tend to form more solid cords and thymic (Hassall's) corpuscles. Lymphocytes lie within the interstices of the mesh or between the cords. Large thymic epithelial reticular cells may be associated with around 50 or more thymocytes.

Thymic corpuscles are whorls of flattened, concentrically layered cells, 30–100 μm in diameter that characterize the thymic medulla (see Fig. 56.10; **Fig. 56.11**). Originating prenatally, and increasing in number throughout life, they perhaps remove dying thymocytes (their centres are eosinophilic and partly keratinized, and often contain cellular debris). Corpuscles with a similar appearance have been described in the palatine tonsil. For further reading, see Raica et al (2006), Asghar et al (2012).

Other non-lymphocytic thymic cells

The thymus also contains cells of the myeloid, fibroblastic and myoid lineages. Myeloid lineage cells include monocytes at the corticomedullary junction; mature macrophages throughout, but particularly in the cortex; and interdigitating dendritic (antigen-presenting) cells at the corticomedullary junction and in the medulla. Some dendritic cells are of lymphoid rather than myeloid origin (see Fig. 4.12). Fibroblasts are found in the capsule, perivascular spaces and medulla but are infrequent in the cortex, except in the involute thymus. Myoid cells, which are relatively rare, are situated mainly in the medulla and at the corticomedullary junction. They are large, rounded cells possessing a central nucleus surrounded by irregularly arranged bundles of myofilaments; their function is unknown, although it has been suggested that their contractions might aid the movement of lymphoid cells across or out of the thymus.

Thymocytes

The cortex is densely packed with small cortical thymocytes (presumptive T cells, see Ch. 4). They occupy the interstices of the epithelial reticulum, which they largely obscure in histological sections, and form 90% of the total weight of the neonatal thymus. A distinct subcapsular zone houses the thymic stem cells and lymphoblasts undergoing mitotic division. The first stem cells to enter the thymus in the embryo come from the yolk sac and liver during their haemopoietic phases. During later developmental periods, it is probable that all thymic lymphocytes originate in the bone marrow before passing in the blood stream to the thymus.

Thymocytes undergo mitosis in all cortical zones as the differentiating T cells mature, gradually moving deeper into the cortex (**Fig. 56.12**). The processes of thymocyte development and maturation to generate T cells depend on the microenvironment provided by epithelial cells, dendritic cells, macrophages and fibroblasts. T cells that either fail to recognize self-MHC (histocompatibility) molecules, or that recognize self-antigens, die by apoptosis in order to achieve functional immune reactivity and maintain self-tolerance, respectively. Over 95% of cortical thymocytes die within the thymus, and the surviving T cells migrate through the walls of high endothelial venules and efferent lymphatics to enter the circulation and populate secondary lymphoid tissues.

Microcirculation

Cortex

The pattern of blood flow differs in the cortex and medulla. Major blood vessels enter the gland at the corticomedullary junction and pass within each lobe, giving off small capillaries to the cortex and larger vessels to the medulla. Most cortical capillaries loop around at different depths in the cortex and join venules at the corticomedullary junction; some continue through the cortex and join larger capsular venules that leave the thymus. Sheaths of thymic epithelial reticular cells forming the blood–thymus barrier lie between the narrow perivascular space of the smaller cortical capillaries and cortical thymocytes (Henry et al 1992). This perivascular space sometimes contains pericytes and, rarely, neurones.

Medulla

Medullary blood vessels are not as well protected by epithelial cells, and those of the corticomedullary junction are only partially ensheathed, usually on their cortical aspect. Medullary vessels are variable in size and some have short lengths of cuboidal endothelium similar to those in lymph nodes and mucosa-associated lymphoid tissue (MALT).

Development

The embryology and prenatal development of the thymus are described in Chapter 17.

Thymic changes during postnatal life

At birth, the thymus is most often bilobar and is 4–6 cm long, 2.5–5 cm wide and 1 cm thick. The bulkiest part of the gland at this age is located immediately above the base of the heart where it covers the left and right phrenic nerves laterally: protection of these nerves is mandatory during paediatric cardiac surgery. The left lobe is longer and thicker than the right lobe in full-term neonates (Varga et al 2011). During childhood, the thymus narrows and lengthens and the cervical portion becomes less noticeable.

The thymus is largest relative to body mass at birth, weighing 10–15 g. It is typically larger in boys than girls at 6 months of age (Garly et al 2008). Studies of thymic mass after sudden death have recorded a wide variation at all ages, but the general pattern is that, after increasing

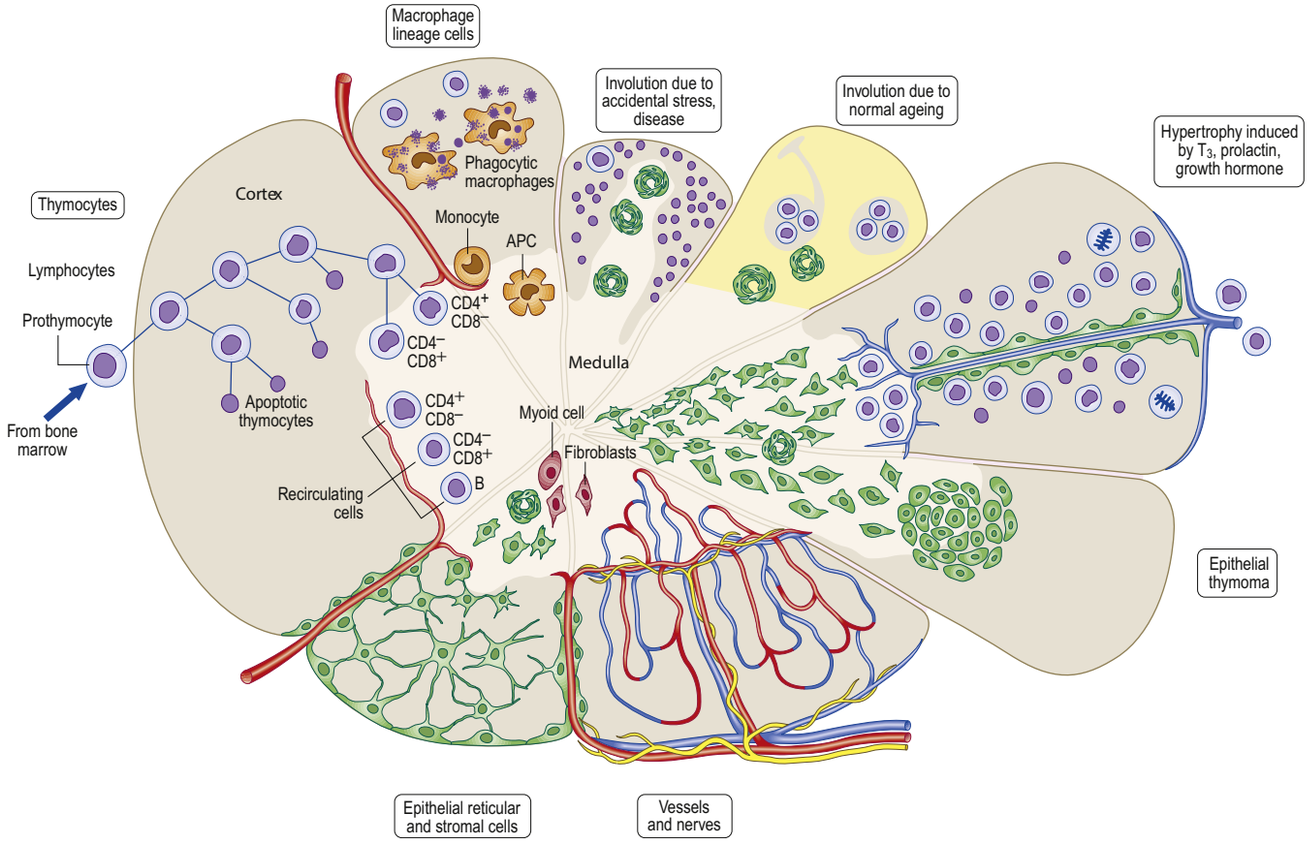

Fig. 56.12 The microscopic organization of the thymus at various stages of life and under different conditions. Abbreviations: APC, antigen-presenting cell; T_3, tri-iodothyronine hormone.

in the first year of life, the mean mass remains fairly constant at 20 g until the sixth decade, when a reduction occurs. At birth, individual adipocytes are present in connective tissue septa, and increased numbers are found within the cortex in the second and third decades of life. Fatty infiltration is usually complete by the fourth decade, when only the medulla and small patches of associated cortex are spared. This process is independent of body mass index (BMI).

In children, the gland is more pyramidal in shape and firmer than in later life, when the amount of lymphoid tissue is greatly reduced. In the fresh state, it is deep red, reflecting its rich vascularity (see Fig. 56.9). With age, it becomes thinner, greyer and increasingly infiltrated by yellow adipose tissue. Each of the two lobes is partially divided by the ingrowth of shallow septa, so that, superficially, the gland appears lobulated. As fatty atrophy proceeds, this lobulation becomes more distinct. In older adults the thymus may be distinguished from the surrounding mediastinal adipose tissue only by the presence of its capsule. However, even greatly atrophied glands usually contain perivascular areas of persistent lymphoid tissue. Thymocyte production and differentiation persist throughout life, and thymic T cells continue to populate peripheral lymphoid tissue, blood and lymph.

Congenital anomalies of the thymus

Undescended thymus, accessory thymic bodies and rare cysts of the third pharyngeal pouch are usually of no clinical significance in isolation. Patients with thymic agenesis, aplasia and hypoplasia, as in severe combined immune deficiency disease (SCID), have reduced lymphocyte numbers, and early death from infection is common. Most cases are familial, with autosomal recessive genes. Thymic aplasia is commonly associated with DiGeorge syndrome and deletion of chromosome 22q11.2 and is thought to be a consequence of insufficient neural crest cell migration into the third pharyngeal pouch. In young children, a large normal thymus may press on the trachea, causing episodes of ventilatory stridor. This condition must be differentiated from other congenital conditions such as vascular rings and slings that require surgical correction.

OESOPHAGUS

The oesophagus is a muscular tube, between 20 and 25 cm long in the adult (Kaisha Otsianyi et al 2011), that connects the pharynx to the stomach (see Figs 56.6, 56.16; **Figs 56.13–56.14**). It starts in the neck, level with the lower border of the cricoid cartilage (i.e. level with the body of the sixth cervical vertebra in females and the body of the seventh cervical vertebra in males). It descends largely anterior to the vertebral column through the superior and posterior mediastina, passes through the oesophageal hiatus in the respiratory diaphragm level with the superior half of the body of the eleventh thoracic vertebra (range, the body of the ninth thoracic vertebra to L1–L2 intervertebral disc) and ends at the gastric cardiac orifice, to the left of the midline, posterior to the left seventh costal cartilage and level with the body of the eleventh thoracic vertebra (range, superior half of the body of the tenth thoracic vertebra to L1–L2 intervertebral disc).

Generally vertical in its course, the oesophagus normally displays two shallow curves. Starting in the median plane, it inclines to the left as far as the inferior neck, gradually returns to the median plane near the body of the fifth thoracic vertebra, then deviates leftwards again at the body of the seventh thoracic vertebra before passing through the respiratory diaphragm. The oesophagus also deviates in the sagittal plane as it follows the cervicothoracic vertebral lordosis. Further inferiorly, it is pushed slightly to the right by the descending thoracic aorta before resuming its leftward course towards the oesophageal hiatus. It is the second narrowest part of the alimentary tract (the narrowest is the vermiform appendix) and is constricted at multiple points along its course, that are measured relative to the incisor teeth during oesophagoscopy. The constriction points are at its origin, where it is surrounded by cricopharyngeus (15 cm from the incisor teeth); where it is crossed anteriorly by the aortic arch (23 cm from the incisor teeth), and by the left main bronchus (28 cm from the incisor teeth); and as it passes through the respiratory diaphragm (40 cm from the incisor teeth). In

The thymus is essential for the normal development of lymphoid tissues during neonatal and early postnatal life. Thymectomy during this period results in hypoplasia of the peripheral lymphoid organs, wasting and an inability to mount an effective immune response, and is ultimately fatal. By the onset of puberty, when the main lymphoid tissues are fully developed, thymectomy is less debilitating, but effective responses to novel antigens are reduced.

Thymectomy is commonly performed for myasthenia gravis, usually after referral from a neurologist. The most beneficial effects of thymectomy are seen in myasthenic females who present with systemic muscular weakness; controversial operative groups include the elderly and those with isolated ocular symptoms.

Thymectomy is performed through a transcervical approach or a sternotomy, the choice of approach depending on the size and disposition of the diseased gland. The cervical approach involves a transverse incision that includes the sternal heads of both sternocleidomastoids, permitting good access to the substernal region (plane). Sternothyroid and sternohyoid are separated and the superior poles of the thymus are identified immediately deep to these muscles. A safe pre-thymic plane is created by blunt dissection just posterior to the sternum, facilitating subsequent mobilization of the gland. The mediastinal great vessels and the thymic vessels must be carefully identified. The thymic veins are selectively ligated and divided, especially those draining directly into the superior vena cava or the left brachiocephalic vein. The smaller arterial branches from the internal thoracic arteries are usually dealt with using electrocautery, care being taken to avoid injury to the phrenic nerves (patients are generally not given a paralytic agent during anaesthesia, so that the phrenic nerves can be identified intraoperatively). The thymus generally remains completely encapsulated and is separated without difficulty from the pericardium (occasionally, adhesions necessitate a limited pericardiectomy). Further inferiorly, a gentle push on the great vessels allows direct visualization into the interval between the aorta and pulmonary trunk to enable complete removal of the thymus in this vicinity. In most cases the thymus is removed completely with both upper and lower poles intact. Careful inspection of the remaining tissue in the mediastinum is performed to identify any possible anatomical anomalies that might result in retained thymic tissue after the operation. The most common anomaly is the unanticipated location of the upper poles of the thymus behind the left brachiocephalic vein. The interval between the aortic arch and pulmonary trunk is also a common location for thymic tissue and this area is sometimes difficult to expose with a transcervical approach. Any suspicious foci of adipose tissue in the mediastinum are removed, and, if necessary, sent for frozen section to ascertain whether or not they contain thymic tissue.

Thymic tumours may compress the trachea, oesophagus and large veins in the neck, causing hoarseness, cough, dysphagia and venous engorgement of the head and neck. Thymomas tend to have a heterogeneous signal intensity on MRI, often developing in one lobe of the thymus without affecting the other. Many affected patients also have myasthenia gravis or other autoimmune conditions. Myasthenia gravis, a chronic autoimmune disease of adults, presents as a diminution in power of repetitive contraction in certain voluntary muscles. Although there may be more than one condition with these signs, myasthenia gravis is essentially an autoimmune disease in which acetylcholine receptor proteins of neuromuscular junctions are attacked by autoantibodies. Muscles commonly involved are levator palpebrae superioris, leading to ptosis, and the extraocular muscles, leading to diplopia. Other muscles in the face, jaw, neck and limbs may be involved, and in severe cases, the ventilatory muscles are compromised. For further reading see Wolfe et al 2016.

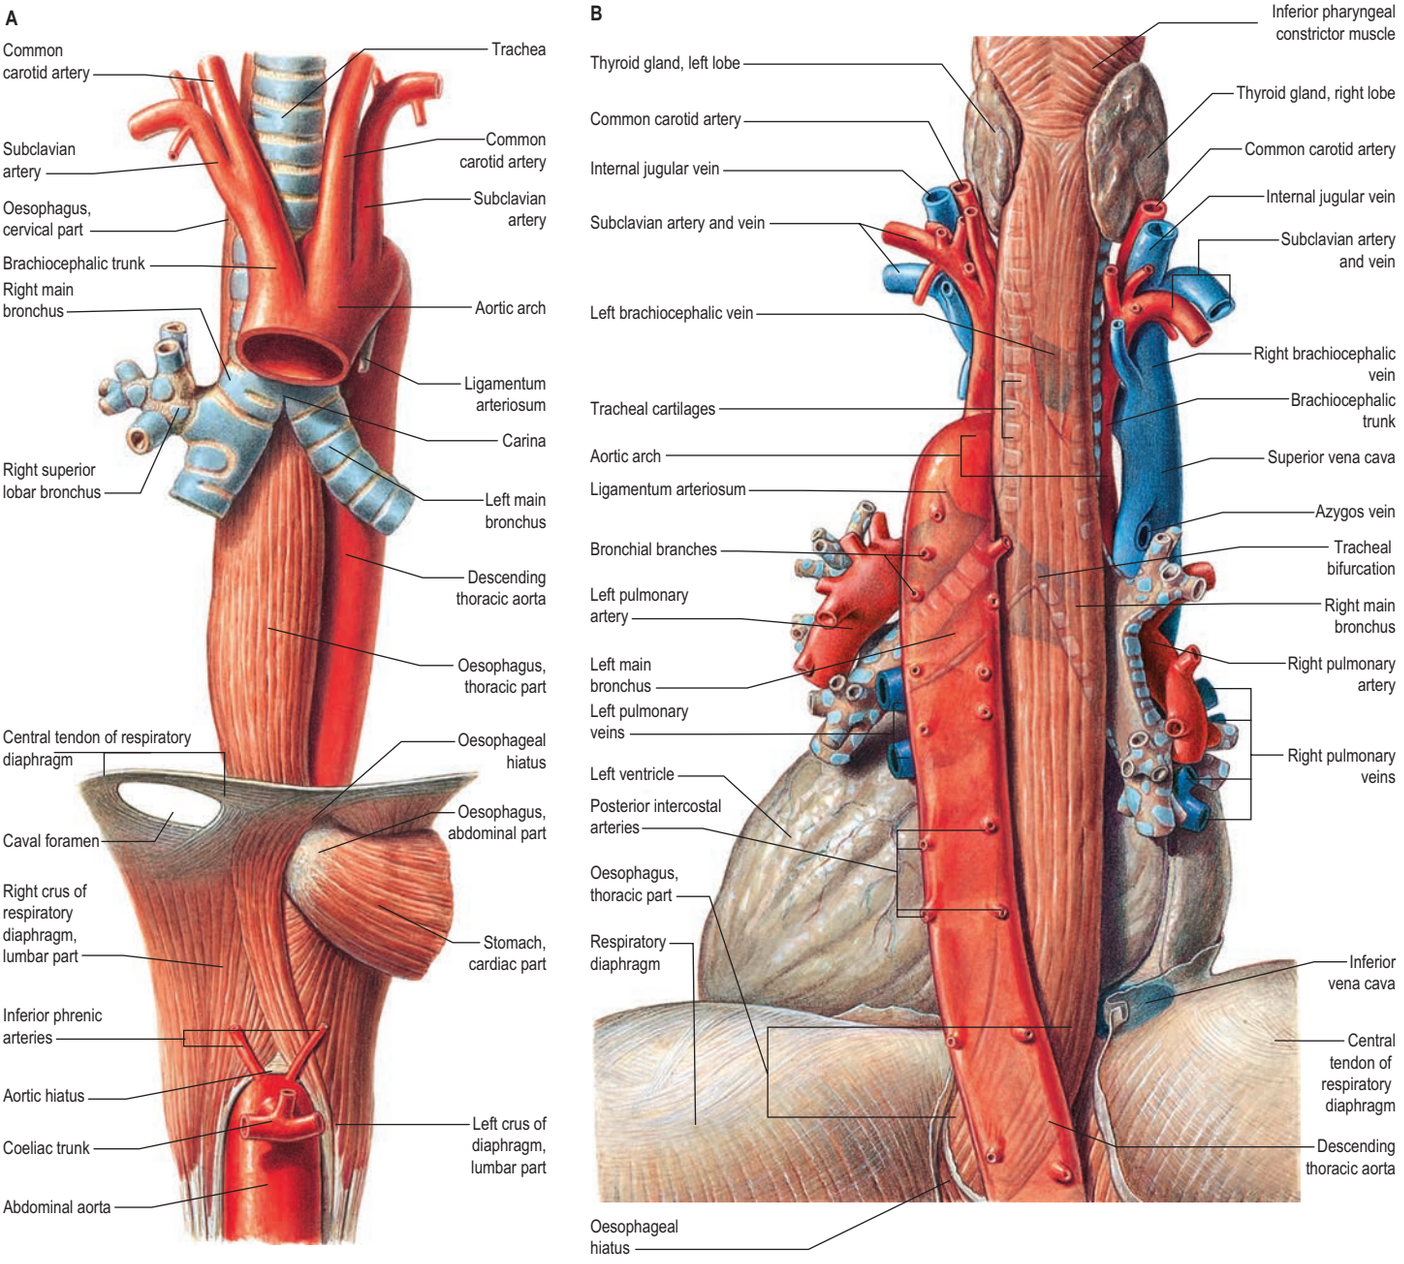

Fig. 56.13 The oesophagus and its mediastinal relations. **A**, Anterior view. **B**, Posterior view. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

children, the length of the oesophagus is best correlated with height (Yang et al 2005).

Cervical oesophagus

The cervical portion of the oesophagus is located posterior to the trachea, to which it is attached by loose connective tissue. The recurrent laryngeal nerves ascend on each side in or near the tracheo-oesophageal groove. Posteriorly are the vertebral column, longus colli, the anterior longitudinal ligament and the prevertebral layer of cervical fascia. Laterally, on each side, are the common carotid arteries and the posterior part of the thyroid gland. In the inferior neck, where the oesophagus deviates to the left, it sits closer to the left carotid sheath and thyroid gland than the right; the thoracic duct ascends for a short distance along its left side (see Figs 56.5B, 56.7B).

Thoracic oesophagus

The thoracic oesophagus (see Figs 56.13–56.14) is situated a little to the left of the midline in the superior mediastinum, between the trachea and the vertebral column. It passes posterior and to the right of the aortic arch to descend in the posterior mediastinum along the right side of the descending thoracic aorta. Inferiorly, as it inclines left, the thoracic oesophagus crosses anterior to the descending thoracic aorta and enters the abdomen through the respiratory diaphragm level with the superior half of the body of the eleventh thoracic vertebra (conventionally reported as level with the body of the tenth thoracic vertebra). As it descends, its immediate anterior relations successively are the trachea, tracheal bifurcation, right pulmonary artery, left main bronchus, fibrous pericardium (separating it from the left atrium) and the respiratory diaphragm. Posteriorly, it is related to the vertebral column, longus colli, right posterior intercostal arteries, thoracic duct, azygos vein and the terminal parts of the hemiazygos and accessory hemiazygos veins, and, near the diaphragm, the descending thoracic aorta. Two recesses in the pleural cavity track along the left and right sides of the oesophagus: the aortico-oesophageal recess lies on the left side between the oesophagus anteriorly and the descending thoracic aorta posteriorly and the azygo-oesophageal recess lies on the right side between the oesophagus anteriorly and the azygos vein and vertebral column posteriorly (see Fig. 56.7).

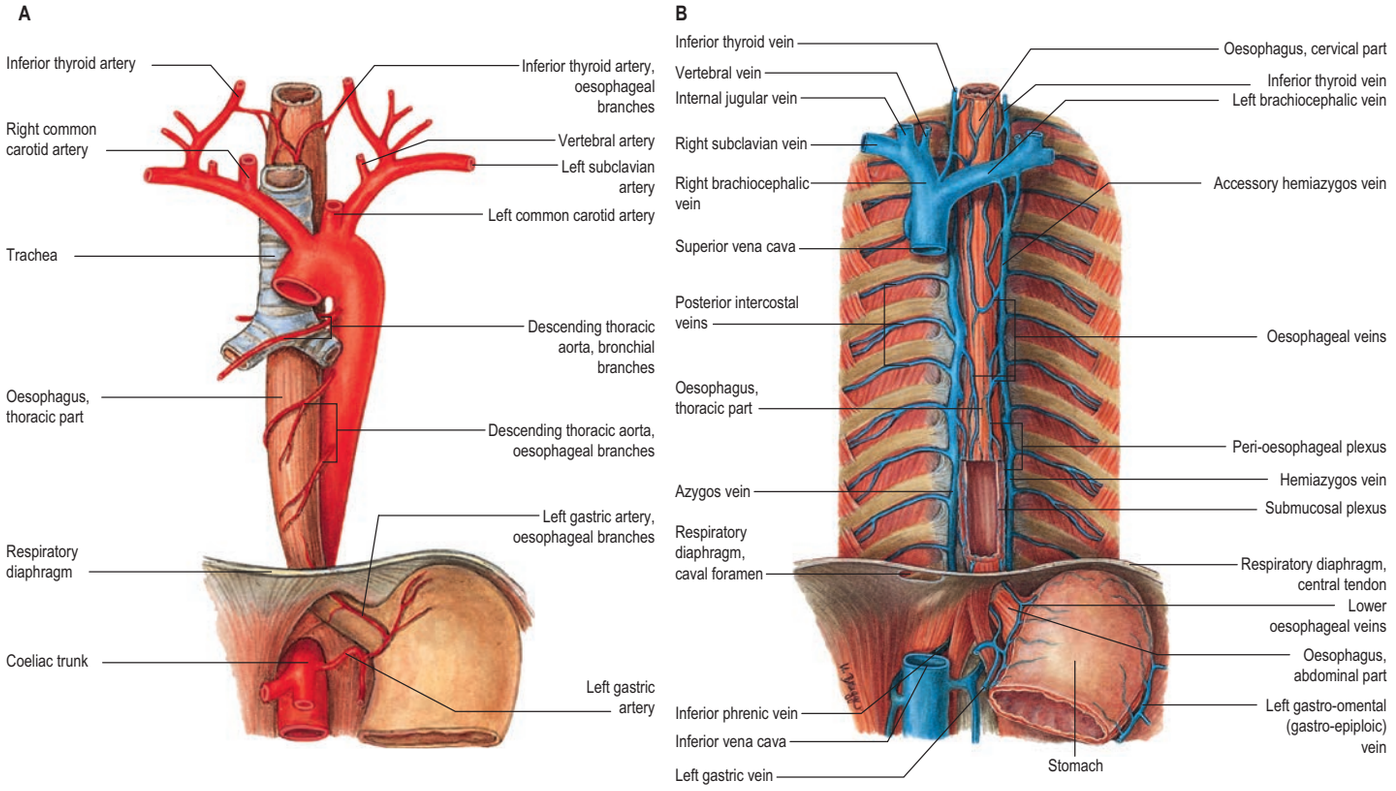

Fig. 56.14 The oesophagus, anterior view. **A**, Arterial blood supply. **B**, Venous drainage. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

In the superior mediastinum, left lateral relations include the terminal part of the aortic arch, left subclavian artery, thoracic duct, left mediastinal parietal pleura and the left recurrent laryngeal nerve. In the posterior mediastinum, left lateral relations include the descending thoracic aorta and, just before the oesophagus passes through the respiratory diaphragm, the left mediastinal parietal pleura. Right lateral relations include the right mediastinal parietal pleura and the azygos vein, as it arches anteriorly above the right main bronchus to join the superior vena cava. Inferior to the root of the lung, the vagus nerves descend in contact with the oesophagus, the right vagus becomes mainly posterior and the left vagus is anterior. The vagi subsequently unite to form a plexus around the oesophagus that gives origin inferiorly to the anterior and posterior vagal trunks (see Fig. 56.6). Low in the posterior mediastinum, the thoracic duct is posterior and to the right of the oesophagus, whereas at higher levels, the duct is posterior, crossing to the left of the oesophagus at about the level of the body of the fifth thoracic vertebra and then ascending on the left side of the oesophagus.

To the right of the oesophagus, just above the respiratory diaphragm, a small, serous infracardiac bursa may be present, representing the detached apex of the right pneumatoenteric recess.

The close relationship between the oesophagus, the heart and the thoracic aorta constitutes the anatomical basis of transoesophageal cardiovascular and aortic ultrasonography.

Vascular supply and lymphatic drainage

Arteries

The cervical oesophagus is supplied by the inferior thyroid artery and the thoracic oesophagus is supplied by bronchial and oesophageal branches of the descending thoracic aorta (see Fig. 56.14A). Four or five oesophageal branches arise from the anterior surface of the aorta and descend obliquely to the oesophagus, where they form a vascular chain that anastomoses above with the oesophageal branches of the inferior thyroid arteries, and below with ascending branches from the left inferior phrenic (see Fig. 56.13A) and left gastric arteries. Extensive devascularization of the oesophagus, as occurs in dissection of the descending thoracic aorta, may cause acute oesophageal necrosis (van der Wal-Visscher et al 2011).

Veins

Blood from the oesophagus drains into a superficial submucosal plexus (see Fig. 56.15A) that drains into a peri-oesophageal venous plexus from which the oesophageal veins arise. Veins from the thoracic oesophagus drain into the superior vena cava predominantly via the azygos venous system and, to a lesser extent, via the intercostal and bronchial veins (see Fig. 56.14B). Veins from the cervical oesophagus drain into the inferior thyroid veins.

The left gastric vein, which drains via the portal venous system, ascends along the lesser curvature of the stomach to the oesophageal opening in the respiratory diaphragm, where it receives several lower oesophageal veins: this is one of the sites of porto-caval (porto-systemic) venous anastomoses where variceal formation can occur in portal hypertension.

Oesophageal varices

Cirrhosis or fibrosis of the liver affects the vascular tree within the liver, resulting in a decrease of hepatic vascular compliance, and a likely increased vascular tone reflecting a reduction in endothelial vasodilators such as nitric oxide. The portal vascular resistance increases, leading to the formation of a collateral circulation. Porto-systemic shunting of blood occurs between the left gastric and lower oesophageal veins, largely as the result of the dilation of pre-existing channels.

Varices in the distal oesophagus are easily visible at endoscopy because they are situated superficially in the lamina propria. The blood from the superficial veins drains into a superficial venous plexus, then into a deeper intrinsic venous plexus and finally into the peri-oesophageal veins via perforating veins. Bidirectional flow is normally possible in this region, a phenomenon that accommodates pressure changes during breathing and Valsalva manoeuvres. However, in portal hypertension, the valves within the perforating vessels become incompetent and blood flow is retrograde, causing dilation (varices) of the deep intrinsic veins. The greater pressure within this region enlarges the varices, which may lead to rapid and life-threatening bleeding. Treatment is directed towards controlling the formation of a collateral circulation and the obliteration of varices that are susceptible to bleeding. This is achieved by paravariceal endoscopic injection of a sclerosant, causing obliteration of the varices as a result of thrombus formation. Fibrosis is also induced within the mucosa, which reduces the formation of new

collateral vessels. Alternatively, rubber bands may be applied in an attempt to ligate the varices. Bleeding from varices is associated with a mortality rate of 25%, reflecting the problems of recurring hemorrhage and underlying comorbidity.

Lymphatic drainage

The oesophagus has an extensive, longitudinally continuous submucosal lymphatic system within which flow may be bidirectional: this is pertinent to lymphatic spread in oesophageal carcinoma. Efferent vessels from the cervical oesophagus drain to the deep cervical nodes either directly or through the paratracheal nodes. Vessels from the cervical oesophagus drain to para-oesophageal, deep cervical and supraclavicular nodes; those from the thoracic oesophagus drain directly to the thoracic duct or to paratracheal, retrotracheal, subcarinal and right recurrent laryngeal nodes; and those from the abdominal oesophagus drain to the nodes associated with the left gastric artery or other arteries originating from the coeliac trunk, including those associated with the lesser curvature of the stomach (Wang et al 2018).

Innervation

The upper oesophagus is supplied by the branches of the recurrent laryngeal nerve and by postganglionic sympathetic fibres that reach it by travelling along the inferior thyroid arteries. The lower oesophagus is supplied by the oesophageal plexus, a wide-meshed autonomic network that surrounds the oesophagus below the level of the roots of the lungs, and contains a mixture of parasympathetic and sympathetic nerve fibres (see Fig. 56.6).

Motor nerve fibres to the striated and smooth muscle of the oesophageal wall travel in the vagus nerve. Axons from branchiomotor neuronal cell bodies in the nucleus ambiguus travel via the recurrent laryngeal nerves and supply cricopharyngeus and the striated muscle of the upper third of the oesophagus. Axons from parasympathetic neuronal cell bodies in the dorsal nucleus of the vagus nerve pass through the oesophageal plexus and supply the smooth muscle that makes up the lower two-thirds of the oesophagus, after synapsing locally in the oesophageal wall. Other branches are given off by the vagus nerve as it travels through the mediastinum and pass directly to the oesophagus. The vagus also carries secretomotor fibres to mucous glands in the oesophageal mucosa and muscular and mucosal afferent (sensory) fibres that are thought to terminate mainly in the nucleus of the solitary tract.

Vasomotor sympathetic nerve fibres destined for the oesophagus arise from the upper 4–6 thoracic spinal nerves and associated spinal cord segments. Those from the upper thoracic ganglia pass to the middle and inferior cervical ganglia, where they synapse: postganglionic fibres innervate the vessels of the cervical and upper thoracic oesophagus. Those from the lower thoracic ganglia pass either directly to the oesophageal plexus or to the coeliac ganglion (via the greater thoracic splanchnic nerve), where they synapse: postganglionic fibres innervate the distal oesophagus. Visceral afferent fibres travel within the sympathetic nerve bundles to terminate within the upper thoracic spinal cord. This region of the spinal cord also receives visceral afferent fibres from the heart, which means that it is sometimes difficult to distinguish between pain of oesophageal and cardiac origin.

Microstructure

The tissues forming the thoracic oesophageal wall, from the lumen outwards, are the mucosa (consisting of epithelium, lamina propria and muscularis mucosae), submucosa, muscularis externa (consisting of inner circular and outer longitudinal muscle) and adventitia (Fig. 56.15A).

Mucosa

The mucosa is thick. At the gastro-oesophageal junction, a jagged boundary line separates the greyish-pink-coloured smooth oesophageal mucosa from the reddish-pink-coloured gastric mucosa, the latter covered by minute bulges and depressions. Throughout its length, the oesophageal lumen is marked by deep longitudinal grooves and ridges, which flatten (reduce) when the lumen is distended.

Epithelium

The epithelium is non-keratinized, stratified squamous and is continuous with that of the oropharynx. In humans this protective layer is 300–500 μm thick and is not affected by oesophageal distension. The boundary between the oesophageal epithelium and its lamina propria is distinct but markedly uneven because tall connective tissue papillae invaginate the epithelial base, helping to anchor the epithelium to underlying tissues (Fig. 56.15B). These papillae are permanent structures, are unaffected by oesophageal distension, and are rich in blood vessels and nerve fibres. At the base of the epithelium there is a basal lamina to which epithelial cells are attached by hemidesmosomes, an arrangement that also occurs in the oral mucosa.

Oesophageal epithelium is similar to other stratified squamous epithelia and so can be divided into a basal layer of proliferating cells, a parabasal layer of cells undergoing terminal differentiation and a flattened layer of superficial cells or squames that retain their nuclei. The most superficial strata of cells contain a few keratohyalin granules, in addition to keratin filaments. The epithelial cell population is constantly renewed by mitosis in the cuboidal basal and deepest parabasal cells: as the cells migrate towards the lumen, they become progressively polygonal and then more flattened and are eventually desquamated at the epithelial surface. This sequence of events normally takes 2–3 weeks, and is markedly slower than in the stomach and intestine.

The epithelium is an effective protection against mechanical injury during swallowing because of its thickness and the presence of mucus at its surface. However, protection is limited by repeated exposure to the strongly acidic, protease-rich secretions of the stomach, as occurs abnormally during reflux. Failure of the lower oesophageal sphincter allows reflux and results in ulceration and fibrosis, accompanied by dysphagia/odynophagia, with possible epithelial metaplasia (see Commentary 1.3) to a gastric-like mucosa (Barrett's mucosa), or to more overt neoplastic changes.

Dendritic cells Dendritic (Langerhans) cells are present in the oesophageal epithelium. They resemble those found in the epidermis and perform similar antigen-processing and antigen-presenting roles, that are important in immunostimulation of naïve T cells and mucosal defence (Ch. 4).

Lamina propria

The oesophageal lamina propria contains scattered groups of mucosa-associated lymphoid tissue (MALT), especially prominent near the gastro-oesophageal junction. Small tubular mucous glands occur in this region and also at the oesophago-pharyngeal junction.

Muscularis mucosae

The muscularis mucosae is composed mainly of longitudinal smooth muscle and forms a thin sheet near the epithelium, following its contours closely. It may be absent or represented only by sparse, scattered bundles at the pharyngeal end of the oesophagus, but becomes progressively thicker distally. The longitudinal orientation of its cells changes to a more plexiform arrangement near the gastro-oesophageal junction. The ducts of the oesophageal glands pierce the muscularis mucosae.

Submucosa

The submucosa loosely connects the mucosa and the muscularis externa, penetrating the longitudinal ridges of the oesophageal lumen. It contains larger blood vessels, nerves and mucous glands. Its elastic fibres aid closure of the oesophageal lumen after peristaltic dilation.

Oesophageal glands

Groups of small tubulo-acinar oesophageal glands lie mainly in the submucosa, each sending a single long duct through the intervening layers into the lumen. They are composed mostly of mucous cells; some serous cells that secrete lysozyme are also present. Close to the pharynx and stomach, the glands are simpler in form and restricted to the lamina propria of the mucosa (not the submucosa). The mucosal mucous glands of the abdominal oesophagus closely resemble the gastric cardiac glands, and are therefore named oesophageal cardiac glands.

Muscularis externa

The muscularis externa is up to 300 μm thick, and consists of an outer longitudinal and inner circular layer of muscle that is typical

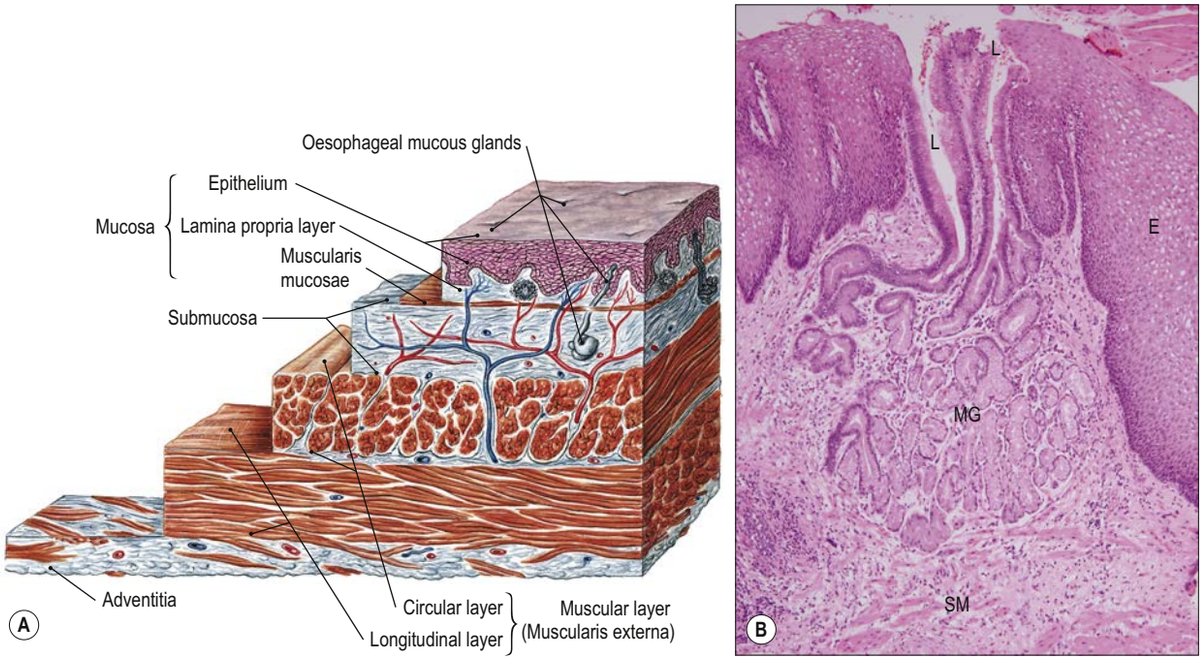

Fig. 56.15 Structure of the oesophageal wall. **A**, Main layers from the epithelium to the adventitia. **B**, Section through the wall of a human oesophagus, showing the superficial stratified squamous epithelium (E) lining the lumen (top), supported by a thin lamina propria and an indistinct muscularis mucosae at this level. The submucosa (SM) contains oesophageal mucous glands (MG, centre field) that secrete a thin mucus into the oesophageal lumen via a short duct. The duct has been sectioned through part of its wall in this specimen, so the duct lumen (L) appears duplicated. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

of the intestine. The thicker longitudinal layer exists as a continuous coat of fibres that extends almost the entire length of the oesophagus, except posterosuperiorly, 3–4 cm inferior to the cricoid cartilage, where it diverges as two fascicles that ascend obliquely and anteriorly, passing deep to the lower border of the inferior constrictor, and ending in a tendon that is attached superiorly to the posterior ridge of the cricoid lamina (Fig. 56.16). The V-shaped space between these fascicles is filled by the circular oesophageal muscle fibres, thinly covered inferiorly by decussating longitudinal fibres and superiorly by the cricopharyngeal part of the inferior constrictor.

In the upper third of the oesophagus, the muscularis externa is formed by skeletal muscle; in the middle third, smooth muscle fascicles intermingle with striated muscle; and the lower third contains only smooth muscle. This transition between striated and smooth muscle is reflected in the innervation pattern of the oesophagus.

Oesophageal diverticula

Portions of the oesophagus may expand secondary to increased intraluminal pressure, adhesion of nearby inflamed tissues, or muscle motility disorders. True oesophageal diverticula occur in two locations, either the subdiaphragmatic or parabronchial part of the oesophagus (Watanabe 2016). Superiorly, diverticula may form in the posterior wall of the distal laryngopharynx, through the interval between the inferior pharyngeal constrictor and cricopharyngeus (Zencker's diverticulum or pharyngeal pouch); it could be argued that they are not true oesophageal diverticula even though they are often classed as such.

Development

The development of the oesophagus is described in Chapter 21.

Tracheo-oesophageal fistula

Tracheo-oesophageal fistula is described in Chapter 20.

Oesophageal sphincteric mechanisms

Radiological studies show that swallowed food stops momentarily in the gastric end of the oesophagus, before entering the stomach, suggesting the presence of a sphincter at this point. In the past, controversy surrounded the reason for this observation because only slight thickening of the muscle coat has been found in humans. There is now ample physiological and clinical evidence that closure depends on two major mechanisms. The more important of these is the lower oesophageal sphincter, a specialized zone of circular smooth muscle surrounding the oesophagus as it traverses the respiratory diaphragm and for much of its short abdominal course. This region of the oesophagus is maintained under tonic contraction, except during swallowing, when it relaxes briefly to admit ingesta to the stomach, and during vomiting. Intramural plexuses of the enteric nervous system and the neural release of nitric oxide contribute to its relaxation. The second mechanism is a functional external sphincter provided by the right crus of the respiratory diaphragm (see Fig. 55.1), which encircles the oesophagus as it passes into the abdomen and is attached to it by the phrenico-oesophageal ligament. Fluoroscopy, electromyography and manometry have shown that its muscular fibres contract around the oesophagus during inspiration and when

Accessory slips of smooth muscle sometimes pass between the oesophagus and left mediastinal parietal pleura (pleuro-oesophageal muscle) (Bilge et al 2013) or the left main bronchus (broncho-oesophageal muscle), trachea, fibrous pericardium or descending thoracic aorta (see Fig. 56.16). They may act to equilibrate the normal physiological changes in position, shape and dimensions of the various organs between which they extend during swallowing (Watanabe 2016). Superiorly, the circular muscle fibres blend posteriorly with the cricopharyngeal part of the inferior pharyngeal constrictor, and anteriorly, the uppermost fibres are attached to the lateral margins of the tendon of the two longitudinal muscle bundles (fasciculi) of the oesophagus. Inferiorly, the circular muscle fibres are continuous with the oblique layer of muscle fibres in the stomach wall.

Oesophagoscopy, a component of superior digestive endoscopic examination, may be indicated in patients with persistent non-cardiac chest pain, dysphagia, odynophagia (painful swallowing) or symptoms of reflux that include nocturnal cough. The endoscope is passed orally under direct vision with the patient in a lateral decubitus position, with or without sedation, and manoeuvred into the oesophageal inlet when the patient is asked to swallow; once through, the endoscope is advanced slowly under direct vision. The mucosa normally appears whitish-pink in colour, changing to red at the squamocolumnar junction (Z line) near the oesophageal hiatus in the respiratory diaphragm. Cranial displacement of the Z line by more than 2 cm is indicative of a hiatus hernia. There may be slight extrinsic compression by the aortic arch and the left main bronchus (see Fig. 56.19).

Endoscopic transoesophageal ultrasound permits assessment of the oesophageal wall and para-oesophageal structures, such as lymph nodes and the heart and thoracic aorta. Numerous surgical and percutaneous cardiovascular procedures are guided by transoesophageal echocardiography. The technique is more sensitive than CT in detecting mediastinal nodal metastases, allowing those less than 10 mm in size to be assessed. Normal lymph nodes cannot be identified easily by endoscopic ultrasound because they have the same echogenic characteristics as surrounding tissue; a hypoechoic or inhomogeneous echo portrayal on ultrasound is considered more suspicious of malignancy. Endoscopic ultrasound-guided fine needle aspiration allows accurate diagnosis for para-oesophageal nodes. Transbronchial fine needle aspiration is an alternative approach for sampling mediastinal or paratracheal nodes, guided by CT or positron emission tomography (PET) CT findings.

The majority of oesophageal ruptures are iatrogenic and occur during the instrumentation of the oesophagus during simple endoscopy, endoscopic intervention including dilation, and nasogastric tube placement. Other causes are barotrauma, foreign bodies and oesophageal carcinoma. Barotrauma occurs with intense retching and vomiting that may cause longitudinal tearing in the posterior wall of the thoracic oesophagus (Boerhaave's syndrome). Locations of oesophageal perforation are 60% thoracic, 25% cervical and 15% abdominal. Perforation in the cervical oesophagus occurs in the posterior wall, where it is at its thinnest, often corresponding to an area of mucosa with minimal muscular covering bordered by the pharyngeal inferior constrictor and cricopharyngeus (see Fig. 56.16). Mortality from oesophageal perforations is 20% and results from mediastinitis and necrotizing infection. Presenting symptoms include thoracic pain, odynophagia, haematemesis, subacute surgical emphysema, tachycardia, breathlessness and, in advanced cases, septic shock. Diagnosis and repair within 24 hours is associated with a better prognosis and a mortality rate of between 10% and 15%, whereas late diagnosis has a much greater mortality rate. For a perforation in the upper two-thirds of the thoracic oesophagus, a right thoracotomy in the fifth or sixth intercostal space is performed. The lower third of the oesophagus is approached through a left thoracotomy in the sixth or seventh intercostal space. The perforation is closed in layers after any necrotic tissue has been debrided.

A double-contrast barium swallow with fluoroscopy enables anatomical and functional assessment of the oesophagus (see Fig. 56.19). A standard examination involves the patient swallowing a barium solution and gas granules, and images are taken in the erect, supine and prone recumbent positions. The upright posture fully dilates the oesophagus and is useful in evaluating any constrictions. The narrow tubular lumen of the oesophagus is normally indented slightly by the aortic arch and the left main bronchus. The supine view allows better evaluation of any motor dysfunction and varices, and moving into the prone position provokes underlying gastro-oesophageal reflux. Both repeating single digital images and cine loops of fluoroscopy can be obtained. The fluoroscopic images demonstrate defective opening of the pharyngeal (upper) oesophageal sphincter and the nature of the contractions in the body of the oesophagus. The lower oesophageal sphincter can be assessed in achalasia. Other abnormalities, such as hiatal hernia and areas of narrowing or dilation of the oesophagus, can be demonstrated. Mucosal relief images are obtained once the bulk of the contrast media has passed into the stomach, and this provides fine mucosal detail. Cross-sectional imaging is usually used for the preoperative planning and staging of oesophageal tumours, and is of value in radiotherapy planning.

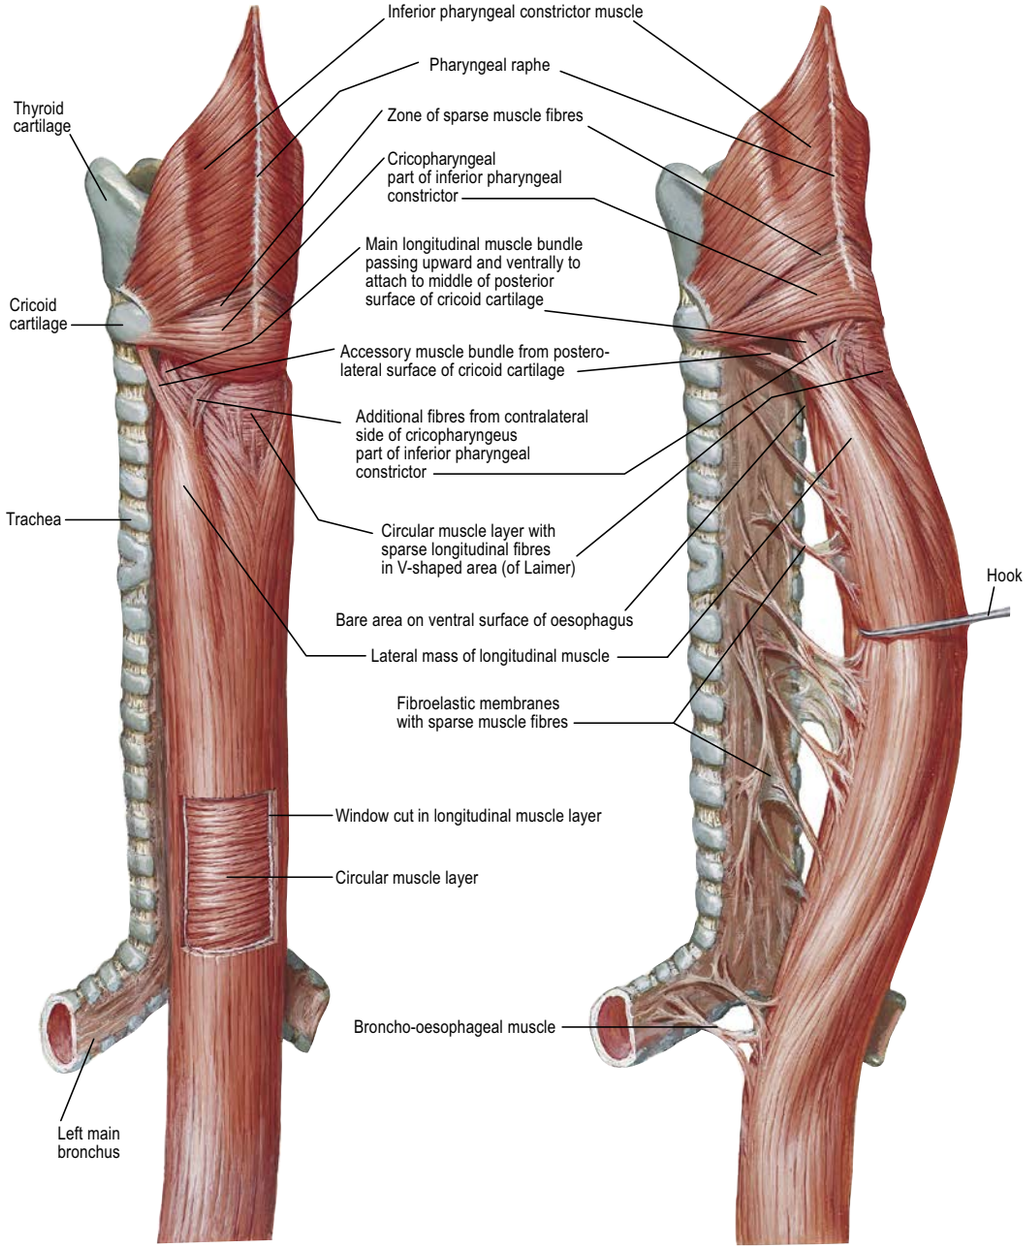

Fig. 56.16 Musculature of the distal pharynx and oesophagus, showing accessory muscle bundles. (Adapted with permission from Netter FH Atlas of Human Anatomy, 7th ed. Elsevier. Copyright 2019.)

intra-abdominal pressure is increased, thus helping to prevent gastro-oesophageal reflux, even when the lower oesophageal sphincter is inhibited experimentally with atropine. The relative importance of these two agents in the prevention of oesophageal reflux is still a matter for debate. Clinically, there is a good correlation between this condition and lower oesophageal sphincter dysfunction in some cases, whereas in others failure of the respiratory diaphragmatic component, as seen in hiatus hernia, appears to be a major factor. The anatomical configuration of the gastro-oesophageal junction may also play some part in these processes.

Swallowing

The oesophageal phase of swallowing is described in Chapter 40.

Vomiting

In the initial phase of vomiting, the lower oesophageal sphincter and peri-oesophageal crural muscle fibres simultaneously relax and rapid diaphragmatic and abdominal muscular contraction commences, increasing intra-abdominal pressure.

Oesophageal dysmotility

Oesophageal dysmotility encompasses disorders of the upper and lower oesophageal sphincters (see gastro-oesophageal reflux in Chapter 63), congenital anomalies such as atresia, and achalasia. Upper oesophageal sphincter dysfunction is usually neurological; often brainstem disease impairs relaxation of cricopharyngeus with resultant dysphagia and aspiration as demonstrated by videofluoroscopy.

Achalasia of the cardia is a primary motor disorder of the oesophagus in which there is failure of relaxation of the lower oesophageal sphincter and loss of peristalsis in the oesophagus as a consequence of degeneration of myenteric plexus neurones. Dysphagia, regurgitation of undigested food and retrosternal chest pain result and a posteroanterior chest radiograph may show dilation of the oesophagus and retention of food products as a mottled, double-contoured mediastinal widening. Barium swallow shows a classic 'bird-beak' appearance as a result of failure of relaxation of the lower oesophageal sphincter and an absence of peristalsis. Oesophageal pressure manometry demonstrates absent or impaired relaxation of the lower oesophageal sphincter. Treatment options are endoscopic pneumatic balloon dilation or laparoscopic cardiomyotomy (Heller's myotomy). Alternatively, intrasphincteric

injection of botulinum toxin may be offered in frail patients and confers lower morbidity and mortality.

Diffuse oesophageal spasm may present with dysphagia and chest pain. It is characterized by abnormal oesophageal contractions on barium swallow, and produces simultaneous segmental contractions that obliterate the oesophageal lumen to produce a 'corkscrew oesophagus'. Manometry also demonstrates these tetanic contractions. Non-specific oesophageal motility disorder occurs with ageing (presbyoesophagus) and is characterized by a decreased incidence of normal or even absent peristalsis after swallowing, often accompanied by repetitive tertiary contractions and failure of relaxation of the lower oesophageal sphincter. Oesophageal dysmotility is also seen in scleroderma and other connective tissue diseases where atrophic smooth muscle is replaced by fibrous tissue in the submucosa and lamina propria.

Gastro-oesophageal reflux

Gastro-oesophageal reflux is described in Chapter 63.

Hiatus hernia

Hiatus hernia is described in Chapter 55.

MEDIASTINAL IMAGING

Mediastinal structures may be viewed using X-ray, CT and MRI.

Normal mediastinal contours on a frontal chest radiograph

In the posteroanterior (PA) chest radiograph, the X-ray beam enters the posterior thoracic wall and exits the anterior thoracic wall during a full inspiratory breath-hold. The patient stands and flexes and partly abducts the arms over the radiographic detector; this protracts the scapulae and depresses the medial ends of the clavicles to clear the peripheral lung fields and lung apices, respectively. In this view, the heart and large blood vessels appear as the 'mediastinal silhouette' (Fig. 56.17A). Forming its left border, from superior to inferior, are the aortic arch ('aortic knuckle') sometimes with the left superior intercostal vein visible upon it ('aortic nipple'), left pulmonary artery and left ventricle. The descending thoracic aorta is projected as a continuous left paravertebral border to the respiratory diaphragm. The right border is delineated by structures containing deoxygenated blood: from superior to inferior are the right brachiocephalic vein, superior vena cava, right atrium and thoracic inferior vena cava. The right paratracheal stripe (up to 3 mm wide) is seen with the oval silhouette of the azygos vein arching anteriorly at its lower margin. In paediatric patients it is normal for the right lobe of the thymus to show as an opaque rightward triangular extension (thymic sail sign) (Fig. 56.17B). This appearance should not be confused with right upper lobe pneumonia.

An accessory lung fissure, the azygos fissure, is seen in 0.5% of posteroanterior chest radiographs, extending from the lung apex to the right tracheobronchial angle. The width of the azygos vein as it arches anteriorly to join the superior vena cava should be no more than 5 mm, but may measure up to 10 mm in the third trimester of pregnancy reflecting a physiological blood volume increase and the fact that flow through the inferior vena cava may be diminished as a result of compression by the uterus, with compensatory drainage through the azygos system. Congenital inferior vena cava interruption at the respiratory diaphragm or acquired inferior vena cava thrombosis also enlarge the azygos vein.

Dilation or displacement of any of these structures accentuates the normal bulges on the borders of the mediastinal silhouette; for example, an enlarged left auricle caused by mitral valve stenosis is seen between the left pulmonary artery and left ventricle. Pulmonary vessels associated with the roots of the lungs form the hilar contours. Superiorly, the anterior junctional line (representing the apposition of the left and right pleural cavities and lungs in the supracardiac region in the median plane), and inferiorly, the posterior junctional line (representing the apposition of the parietal pleura and pleural cavities posterior to the oesophagus), are sometimes visible. The azygo-oesophageal line (representing the medial border of the right lung in the azygo-oesophageal recess (see Fig. 56.7A)), can also sometimes be seen. The paraspinal lines are visible parallel to the right and left margins of the thoracic vertebral column.

Key: 1, trachea; 2, wall of right trachea (paratracheal stripe); 3, right brachiocephalic vein; 4, azygos vein; 5, superior vena cava; 6, right atrium (right pulmonary surface of the heart); 7, aortic arch; 8, left pulmonary artery; 9, left ventricle (left pulmonary surface of the heart). **B**, An anteroposterior radiograph of a paediatric thorax showing the normal 'thymic sail sign' (arrows). (With permission from Epelman M 2017 Fundamentals of Pediatric Imaging. Elsevier. Copyright 2017.)

Normal mediastinal contours on a lateral chest radiograph

On a lateral view, the cardiac silhouette in the middle mediastinum is seen above the anterior, horizontal part of the respiratory diaphragm (Fig. 56.18). The nomenclature of the cardiac chambers reflects their pre-rotational embryonic state: the right ventricle and left atrium form the anterior and posterior cardiac contours, respectively. Posteriorly, both the descending thoracic aorta and the oesophagus in the posterior mediastinum may be seen; the oesophagus can be visualized with swallowed air or barium on a chest radiograph or fluoroscopically in the barium swallow examination (Fig. 56.19). The compressive effect on the oesophagus of a dilated left atrium is readily identified during barium swallow. Superiorly, the less dense trachea and main bronchi are recognizable, the

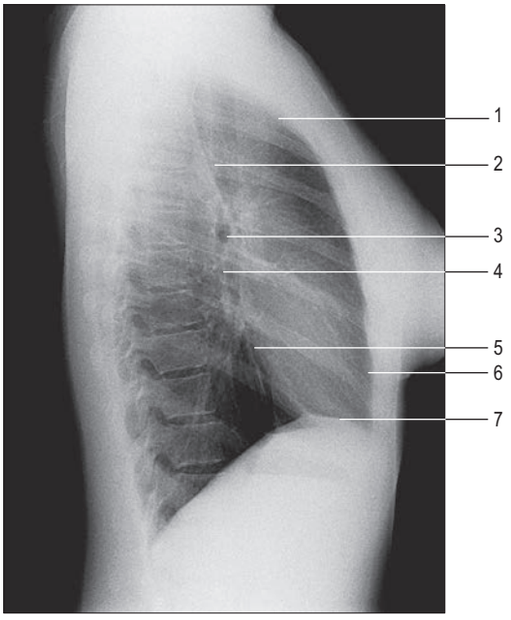

Fig. 56.18 A lateral radiograph of the adult female thorax. Key: 1, retrosternal line (fat); 2, posterior tracheal line; 3, right main bronchus; 4, bronchus intermedius; 5, left atrium; 6, right ventricle; 7, respiratory diaphragm (horizontal part).

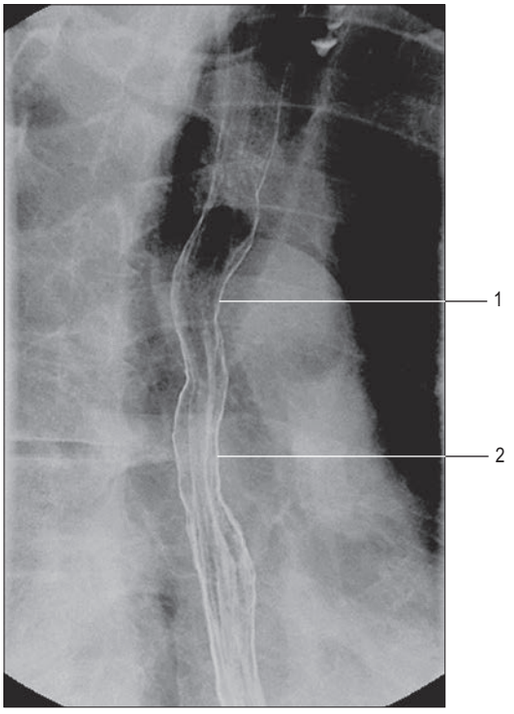

Fig. 56.19 An oblique radiograph of the thorax during barium swallow. Key: 1, indentation from aortic arch; 2, indentation from left main bronchus.

left main bronchus appearing almost circular, seen end-on due to its more horizontal orientation. The oesophagus is directly posterior to the trachea, and the adjacent anterior oesophageal and posterior tracheal walls appear as the posterior paratracheal line, seen in the majority of lateral radiographs and normally less than 5 mm wide.

The aortic arch and its main branches, anterior to the trachea, produce faint shadows in the superior mediastinum. The brachiocephalic veins are visible as an extrapleural bulge directly posterior to the manubrium. Retrosternal lung should always be seen; if it is absent, this raises a strong suspicion of a superior mediastinal tumour or lymphadenopathy. The thoracic part of the inferior vena cava is visible in the majority of patients as it drains into the right atrium.

CT and MRI of the mediastinal spaces

CT provides excellent mediastinal delineation (Figs 56.20–56.21), with intravenous contrast enhancement enabling normal anatomy to be distinguished from pathological lymph nodes and tumours. The hilar, pretracheal, subcarinal, right paratracheal, posterior tracheal and subaortic stations are common sites of lymph node metastases in lung cancer.

The pretracheal space, as seen on CT, is bordered by the trachea posteriorly, the superior vena cava and right brachiocephalic vein anteriorly, and the descending thoracic aorta and superior aortic recess of the transverse pericardial sinus to the left. The subaortic node station (located in the aortopulmonary window/interval) is located between the aortic arch superiorly, the left pulmonary artery inferiorly, the trachea medially and the left lung laterally. The right paratracheal space is between the right lung and the trachea on its anterolateral aspect; the posterior tracheal space is between the lung and the posterolateral aspect of the trachea; and the subcarinal space inferior to the carina is bounded by the main bronchi. On the right, the azygo-oesophageal recess (see Fig. 56.7A) is located posterior to the subcarinal space and on the left side is the oesophagus. All these areas are in direct continuity with each other and are inspected during transcervical mediastinoscopy.

The junctional areas are where the right and left lungs approach and often contact each other at the median plane. The anterior junction lies between the great vessels posteriorly, the posterior surface of the sternum and adjacent thoracic wall anteriorly, and the lungs laterally, specifically in the region where the left brachiocephalic vein, superiorly located mediastinal nodes, thymus and phrenic nerves are located. The posterior junction is an area posterior to the trachea and is where the pleurae-covered lungs appose. The paraspinal area (thoracic paravertebral space) lies between the lateral margins of the vertebral column and the pleurae covering the lungs and contains the intercostal vessels, the ganglionated sympathetic trunk and small lymph nodes surrounded by adipose tissue. The retrocrural space, between the diaphragmatic crura and vertebral bodies, is traversed by the descending thoracic aorta, azygos venous system, thoracic duct, intercostal arteries, sympathetic trunks and sympathetic thoracic splanchnic nerves.

CHAPTER
57

Heart

PERICARDIUM

The pericardium contains the heart and the juxtacardiac parts of its great vessels (**Fig. 57.1**). It consists of two parts, the fibrous and the serous pericardia, arranged in three layers with a normal combined thickness of 1–2 mm, as seen on cross-sectional imaging (**Figs 57.2–57.3**). The fibrous pericardium is a closed sac made of tough connective tissue, completely surrounding but unattached to the heart (see Fig. 56.7). It develops through a sequential process of cavitation of the embryonic body wall by expansion of the secondary pleural cavity; its lateral walls are thus covered by the mediastinal part of the parietal pleura. The serous pericardium consists of two layers: the inner, visceral layer adheres to the heart and forms its outer, epicardial, covering and the outer, parietal layer adheres to the internal surface of the fibrous pericardium (Rodriguez and Tan 2017a). Except at their points of reflection, the two serous pericardial membranes are separated by a narrow space, the pericardial cavity, which contains a thin film of fluid that provides complete separation between the heart and its surroundings, allowing freedom of cardiac motion and shape change.

Many functions have been attributed to the pericardium. These include facilitating intrathoracic cardiac stability (via the sternopericardial ligaments and the fusion of the fibrous pericardium with the central diaphragmatic tendon and adventitia of the great vessels); reducing friction between the heart and the mediastinal structures; limiting cardiac distension and chamber dilation and so preventing hypertrophy; ensuring uniform cardiac distribution of pericardial cavity hydrostatic pressure, preventing ventriculoatrial regurgitations under increased ventricular end-diastolic pressure; forming a barrier to the spread of infection; facilitating atrial filling by promoting negative pericardial pressure during ventricular systole; and, in association with the pleural fluid, forming a system that automatically applies compensating hydrostatic pressures to the cardiac periphery when accelerating forces act.

Fibrous and serous pericardium

Fibrous pericardium

The fibrous pericardium is a roughly conical, compact, covering composed mainly of three collagen layers, cross-woven at 120° to each other; this arrangement limits stretch and ensures a physical barrier to disease. Three anchor points, superior, inferior and anterior, secure the pericardium and help maintain the normal intrathoracic cardiac disposition. The pericardium is continuous superiorly with the adventitia of the great vessels and the pretracheal fascia, inferiorly it is attached to the central diaphragmatic tendon and a small adjacent muscular area to its left, and anteriorly it is attached to the posterior sternal surface via the superior and inferior sternopericardial ligaments (the extent of these ligaments is variable, and the superior is often undetectable).

Anteriorly, the fibrous pericardium is almost completely separated from the thoracic wall by the costomediastinal recess of the parietal pleura and the lungs during inspiration (see Fig. 53.4B). However, in a small area posterior to the lower left half of the body of the sternum and the sternal ends of left fourth and fifth costal cartilages, the pericardium is in direct contact with the thoracic wall, and, until it regresses during early adulthood, the inferior extent of the thymus is anterior to the superior part of the pericardium. The main bronchi, oesophagus, descending thoracic aorta and posterior parts of the mediastinal surface of both lungs are all posterior relations. Laterally, the mediastinal parts of the parietal pleurae cover the mediastinal surfaces of the lungs. The phrenic nerve and pericardiacophrenic vasculature descend on each side between the fibrous pericardium and mediastinal part of the parietal pleura (see Fig. 56.7). Inferiorly, the pericardium is separated from the liver and gastric fundus by the respiratory diaphragm and the diaphragmatic fascia and parietal peritoneum covering its inferior (abdominal) surface. The ascending aorta, superior vena cava and the pulmonary arteries and veins all receive extensions of the fibrous pericardium; the inferior vena cava traverses the central tendon of the diaphragm and so has no such covering.

Serous pericardium

The serous pericardium forms the closed pericardial cavity (sac) within the fibrous pericardium. It has visceral and parietal layers. The parietal layer lines the internal surface of the fibrous pericardium. The visceral layer, or epicardium, covers the heart and great vessels, and at specific points folds back on itself (reflects) to become continuous with the parietal layer (see Fig. 57.1). The visceral layer of serous pericardium is a single layer composed of ciliated mesothelial cells supported on a thin subserosal layer of connective tissue rich in elastic fibres. The serosal cilia increase the surface area for fluid production and resorption, and reduce friction between the opposing pericardial layers. The visceral layer blends with interstitial myocardial tissue. The cardiac subserosal layer contains fat, especially along the ventricular side of the atrioventricular and interventricular sulci (grooves) and the inferior cardiac border. The main coronary vessels and their larger branches are embedded in this fat; the amount is related to the general extent of body fat and gradually increases with age. The anterior cardiophrenic angles typically possess increased epipericardial fat, which can be mistakenly identified as an abnormal mass on imaging (Rodriguez and Tan 2017b). The amount of epicardial adipose tissue may be a cardiometabolic risk factor, with increasing thickness linked to metabolic syndrome and diabetes mellitus. A significant correlation has been demonstrated between obesity in children and the thickness of this fat layer (Ozdemir et al 2010).

Pericardial reflections and sinuses The points of reflection of the serous pericardium around the great veins and arteries of the heart are arranged as two complex pericardial tubes that enclose the ascending aorta and pulmonary trunk and the venae cavae and four pulmonary veins. The perivenous tube is an inverted J in shape: the recess of its inner curve, located posterior to the left atrium and between the left and right superior pulmonary veins, is termed the oblique pericardial sinus. The transverse pericardial sinus is a passage between the two pericardial tubes (see Figs 57.1, 57.24): the ascending aorta and pulmonary trunk are anterior (**Fig. 57.4A,C**), and the atria and their great veins and the superior vena cava are posterior (**Fig. 57.4B,D**).

Pericardial cavity and fluid

The pericardial cavity is the space between the parietal and visceral layers of the serous pericardium. It surrounds the proximal part of the great vessels and the majority of the heart. Part of the cavity extends between the left atrium and descending thoracic aorta. The pericardial cavity in adult humans normally contains 20–60 ml (average 15–35 ml) of fluid (serous plasma ultrafiltrate) (Vogiatzidis et al 2015).

Vascular supply and lymphatic drainage

Approximately 80% of the pericardial blood supply is derived from the right and left internal thoracic arteries by way of the pericardiacophrenic arteries. Inferiorly, the pericardium is supplied by small branches from the intercostal and superior phrenic arteries. The posterior part of the pericardium is supplied from small mediastinal branches that are derived either directly from the descending thoracic aorta or from its oesophageal or bronchial branches. Venous drainage is through tributaries of the azygos venous system, internal thoracic and superior phrenic veins.

Cardiac lymphatics play a crucial role in cardiac function, such as maintaining fluid balance, removal of extravasated proteins and transport of immune cells (Vuorio et al 2016). The developed lymphatic network of the heart traverses all its layers, including those of the atria and ventricles and extends to the mitral valve. Most lymph drainage of the pericardium is to the thoracic and the right lymphatic ducts; upper

The arrangement of the oblique and transverse pericardial sinuses and of the main part of the pericardial cavity is influenced by the development of complex three-dimensional pericardial recesses between adjacent structures, grouped according to the position of their entrances (mouths) (see Fig. 57.1). The postcaval recess projects from the main pericardial cavity towards the left behind the atrial termination of the superior vena cava: it is limited superiorly by the right pulmonary artery and inferiorly by the right superior pulmonary vein, its entrance facing superolaterally and to the right. The right and left pulmonary venous recesses each project superomedially on the posterior surface of the left atrium, between the superior and inferior pulmonary veins on each side, indenting the side walls of the oblique pericardial sinus. The left pulmonary recess has an entrance under the fold of the oblique vein of the left atrium and passes to the left between the inferior aspect of the left pulmonary artery and the superior border of the left superior pulmonary vein. The right pulmonary recess lies between the inferior surface of the proximal part of the right pulmonary artery and the superior border of the left atrium. The superior aortic recess ascends from the transverse pericardial sinus, initially posterior to, and then to the right of, the ascending aorta, ending around the level of the sternal angle. The inferior aortic recess also extends from the transverse pericardial sinus, descending from a superiorly located entrance to run between the inferior part of the ascending aorta and the right atrium.

A triangular fold of serous pericardium reflected from the left pulmonary artery to the inferiorly located left superior pulmonary vein marks the site of the left common cardinal vein during development. It contains a fibrous ligament, a remnant of the left common cardinal vein (left duct of Cuvier) that is usually obliterated during development. This ligament descends anterior to the hilum of the left lung from the superior part of the left superior intercostal vein to the posterior surface of the left atrium, where it is continuous with the oblique vein of the left atrium. The left common cardinal vein may persist sometimes as a left superior vena cava: when present, it replaces the oblique vein of the left atrium and empties into the right atrium through the coronary sinus. When both common cardinal veins persist as a double superior vena cava, the transverse anastomosis between them that normally forms the left brachiocephalic vein may be small or absent. A left superior vena cava is normally joined by the left superior intercostal vein. Knowledge of these recesses and sinuses is important in the avoidance of misdiagnosis of lymphadenopathy or aortic dissection, and in surgical control of the great vessels.

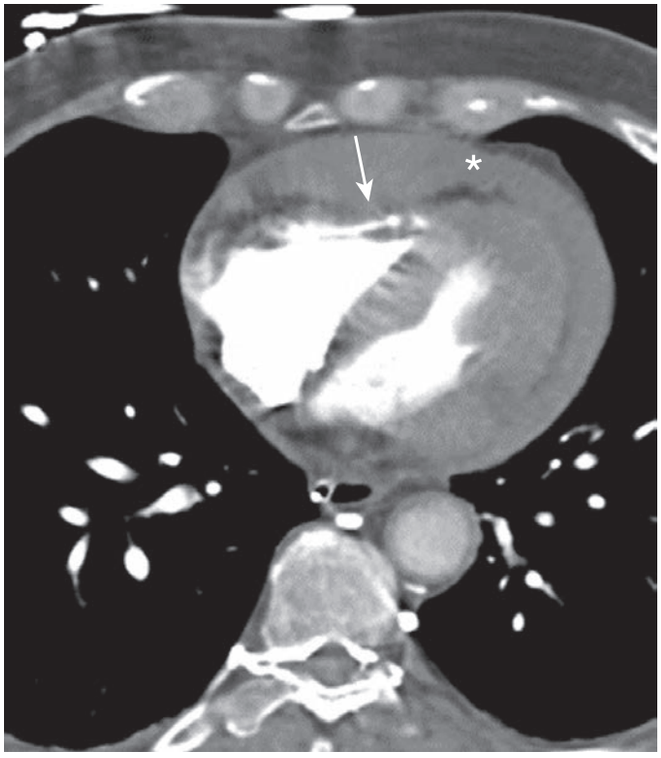

Fig. 57.5 Acute cardiac tamponade in a 22-year-old patient following a motor vehicle collision. Axial multidetector row CT images demonstrate an extensive high attenuation pericardial effusion indicative of haemopericardium (asterisk) and notching (partial collapse) of the anterior (sternocostal) wall of the right ventricle (arrow). (With permission from Raptis DA, Bhalla S 2018 Computed tomographic imaging of cardiac trauma. Radiologic Clinics of North America 57: 201–212.)

Cardiac tamponade is external compression of the heart, usually caused by accumulation of fluid in the pericardial cavity (pericardial effusion) (Fig. 57.5). This causes compression of the right atrium, reducing venous return and therefore reducing cardiac output. It may be secondary to trauma, proximal extension of a dissecting aortic aneurysm, cardiac surgery or central venous catheter insertion. A patient with cardiac tamponade will develop hypotension, chest tightness, dyspnoea and, possibly, a form of cardiogenic shock. The typical signs of a cardiac tamponade include three elements (Beck's triad): a small quiet heart (due to fluid within the pericardial cavity), falling atrial pressure (decreased stroke volume) and rising jugular venous pressure (impaired cardiac venous return). Emergency treatment involves first relieving the tamponade by percutaneous pericardial aspiration (pericardiocentesis), possibly followed by surgery to address the underlying cause. The volume of fluid may not be proportional to the degree of physiological circulatory impairment. A rapid increase in fluid volume within the pericardial cavity is more likely to cause cardiac tamponade than an increase that accumulates over a longer period of time. Echocardiography is an important tool for diagnosis and guiding subsequent percutaneous pericardial aspiration. Surgery is via a subxiphoid incision or a left anterior thoracotomy.

Pericardiocentesis is the aspiration of fluid from the pericardial cavity in cases of cardiac tamponade and for relief of symptomatic pericardial effusion. It can also be used for the diagnosis of neoplastic effusions and purulent pericarditis, and for introducing cytolytic agents into the pericardial cavity. Ultrasound-guided parasternal pericardiocentesis has become the preferred elective procedure. With acute traumatic cardiac tamponade, the subxiphoid approach is used; aspiration of as little as 10–20 ml of blood may greatly increase cardiac output. The parasternal approach with ultrasound guidance provides the most controlled approach to pericardiocentesis, and avoids injury to structures such as the respiratory diaphragm and phrenic nerve. Apical and abdominal approaches may also be used (Fig. 57.6). Pericardiocentesis is likely to be ineffective in cases of substantial haemorrhage into the pericardial cavity because of haemostasis and clot formation: in an emergency situation, a thoracotomy (often bilateral 'clamshell') and surgical opening of the pericardial cavity with clearance of the clot and occlusion of the source of the bleed can result in return of spontaneous circulation (ROSC).

Congenital anomalies of the pericardium include pericardial cysts and diverticula, and absence of the pericardium.

Pericardial cysts and diverticula

Pericardial cysts are congenital and form when a portion of pericardium is pinched off during early development. They are encapsulated with no pericardial communication, are most often incidental, and are located at the right cardiophrenic angle or sulcus, where they present as a well-defined ovoid expansion of the right inferolateral cardiac border on a chest X-ray; a thin-walled and sharply defined, usually round or elliptical, object with fluid attenuation on CT; and a homogeneous high signal object on fluid-sensitive MRI sequences (Fig. 57.7).

A pericardial diverticulum is a rare condition where a herniation through a defect in the parietal layer of serous pericardium communicates with the pericardial cavity. It typically occurs at the same place as a pericardial cyst and should be suspected when a complete wall cannot be identified in all parts of the mass (expansion).

Congenital absence of the pericardium

Congenital absence of the pericardium is rare: it encompasses defects ranging from a small foramen to absence of the entire fibrous sac. The majority of defects occur on the left side but can be located anywhere in the pericardium, and are three times more common in males. Failure of pericardial development may be a consequence of premature atrophy of the cardinal vein and hence poor nourishment of the left pleuropericardial membrane. The most common defect is complete absence of the left side of the pericardium. When this occurs, lung tissue is interposed between the pulmonary trunk and ascending aorta. Bulging of the left atrial auricle through the defect will cause ischaemic necrosis and compression of the left coronary artery, and a rotation of the heart to the left. Complete absence of the pericardium is usually asymptomatic. Partial defects may cause complications such as herniation of cardiac structures (Fig. 57.8).

Congenital pericardial defects are associated with other congenital abnormalities such as bronchogenic cysts, ventricular and atrial septal defects, patent ductus arteriosus, mitral stenosis, bicuspid aortic valve, pulmonary arteriovenous malformations, diaphragmatic hernia, midline closure defects or bronchopulmonary sequestration (Hutchison 2009). Pentalogy of Cantrell is a rare congenital abnormality consisting of absence of the diaphragmatic portion of the pericardium; midline closure defects, including sternal and abdominal wall defects; anterior diaphragmatic defect; and congenital heart defects.

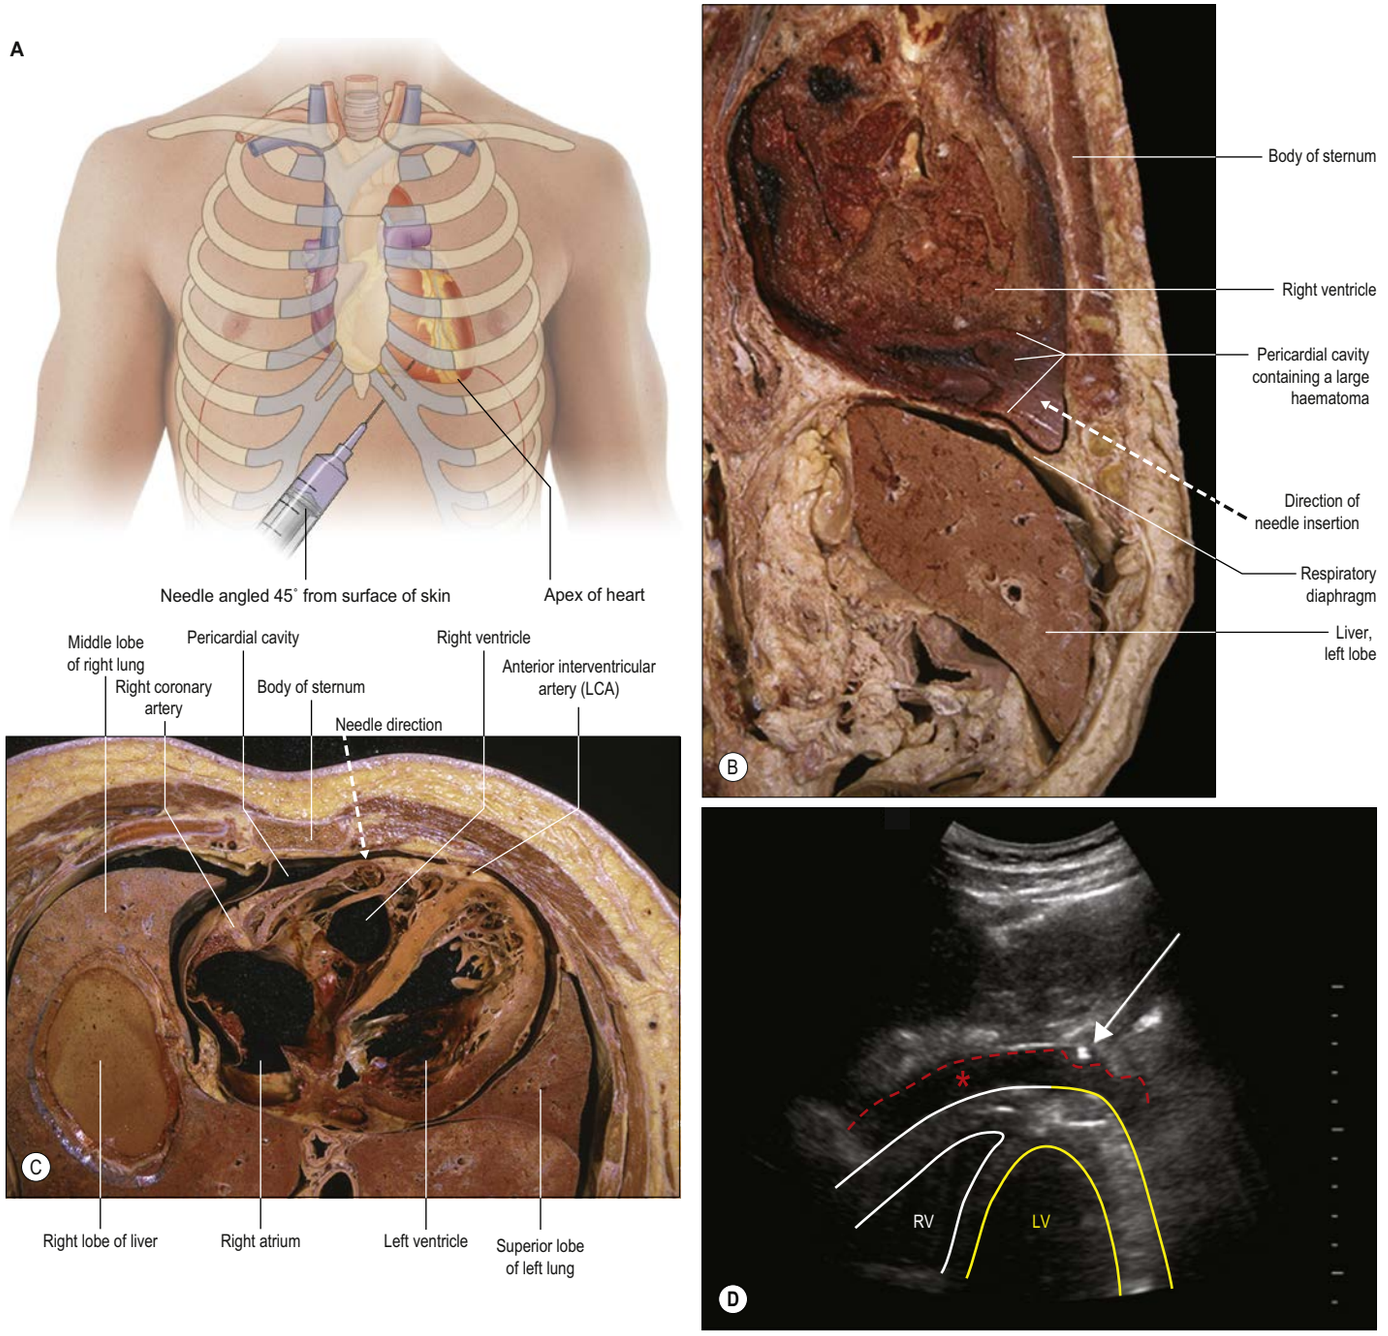

Fig. 57.6 A, The subxiphoid approach in pericardiocentesis. The needle is inserted into the angle between the xiphisternum and the left costal margin (arch) at about 45° to the anatomical transverse plane. **B**, A sagittal section in the median plane of a cadaver. The broken arrow shows the direction of the pericardiocentesis needle. **C**, An axial section through the lower part of the thorax to show the relationships of the pericardial cavity with adjacent structures. The broken arrow shows the direction of the pericardiocentesis needle. **D**, Bedside cardiac ultrasound performed in a 62-year-old man, demonstrating a large pericardial effusion consistent with cardiac tamponade (red asterisk). The broken red line shows the extended pericardial cavity. An 18-gauge 9 cm (3.5 inch) needle was attached to a 60 ml syringe and advanced between the xiphoid process and left costal margin at a 45° angle, directed towards the left shoulder (arrow). The white line demarcates the borders of the right ventricular wall (apical region) and right ventricular cavity (RV) at the cardiac apex; the yellow line depicts the left ventricular wall (apical region) and left ventricular cavity (LV). Abbreviation: LCA, branch of left coronary artery. (With permission from Loukas M, Walters A, Boon JM et al 2012 Pericardiocentesis: a clinical anatomy review. Clin Anat 25:872–81.)

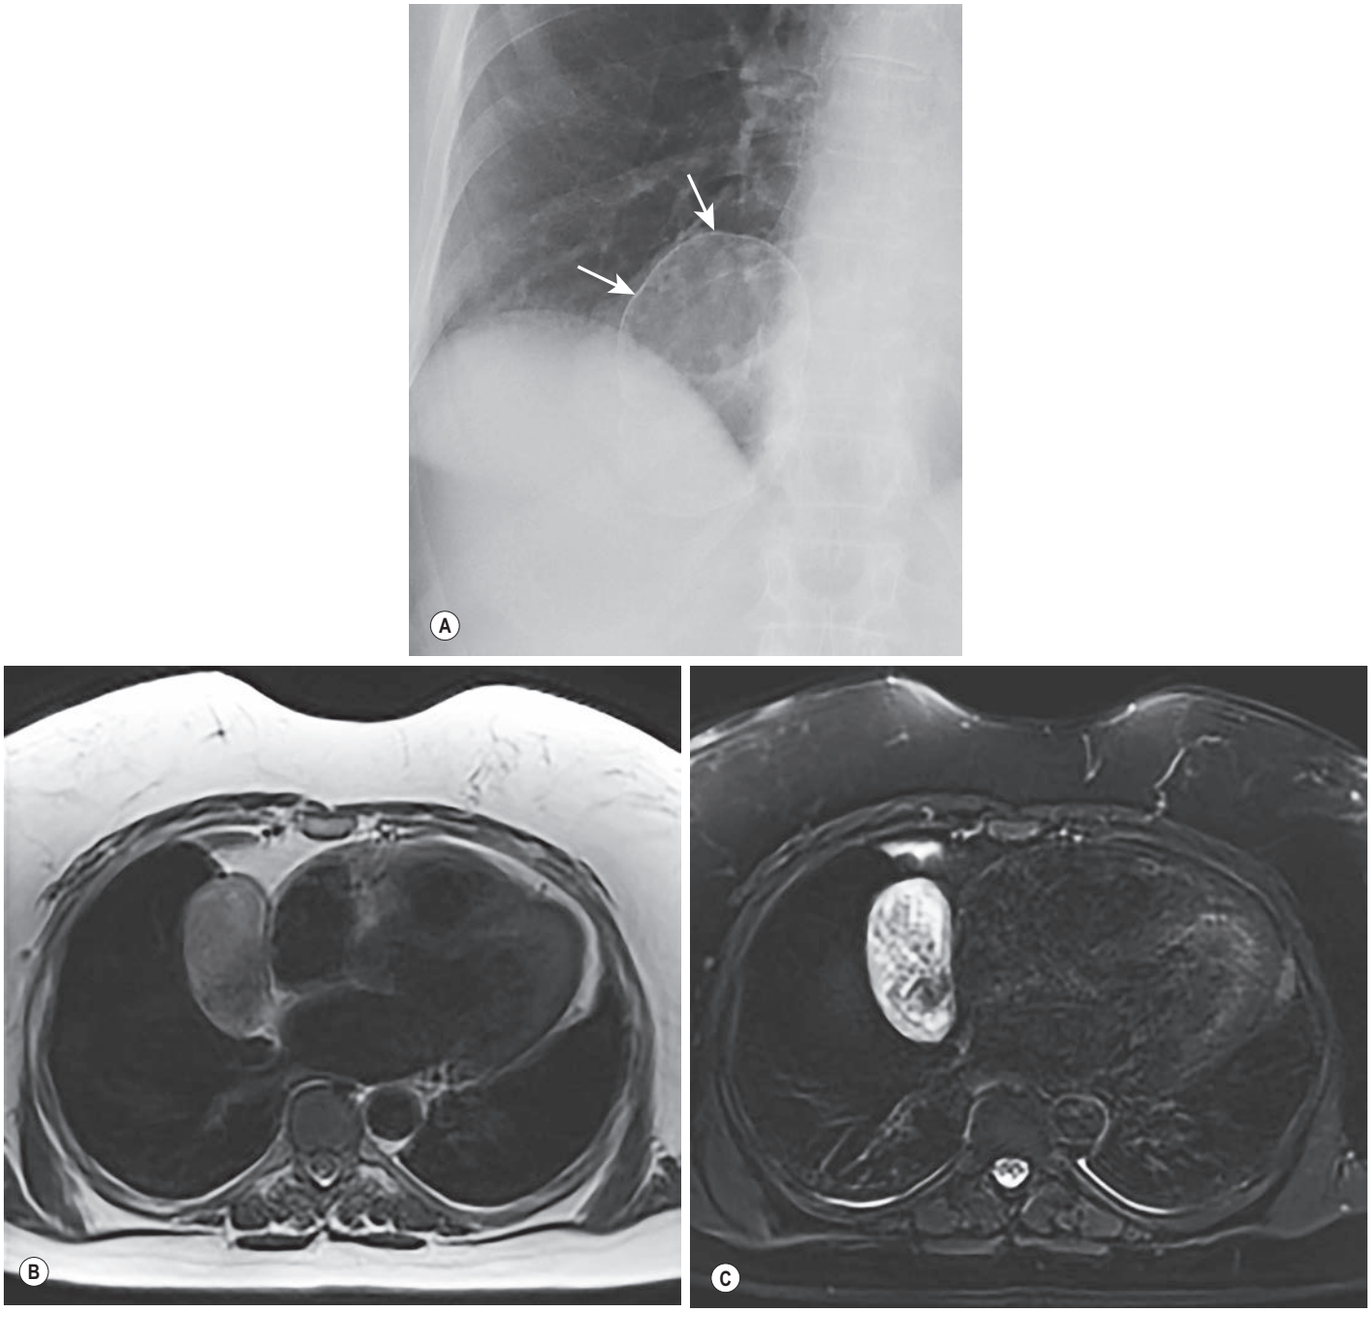

Fig. 57.7 TThe X-ray and MRI appearances of a pericardial cyst in two patients. Pericardial cysts most commonly occur on the right side and are asymptomatic. **A**, A posteroanterior (PA) chest X-ray showing a right-sided calcified pericardial cyst (white arrows). A rim-like calcification identifies the structure containing the calcification as cystic or saccular. **B, C,** MRI imaging (B, T2 weighted; C, T2 fat saturated) showing a fluid signal cystic lesion directly abutting the pericardium along the right pulmonary surface of the heart. (A, with permission from Herring W 2020 Recognizing abnormal calcifications and their causes. In: Learning Radiology: Recognizing the Basics. 4th ed. Elsevier.)

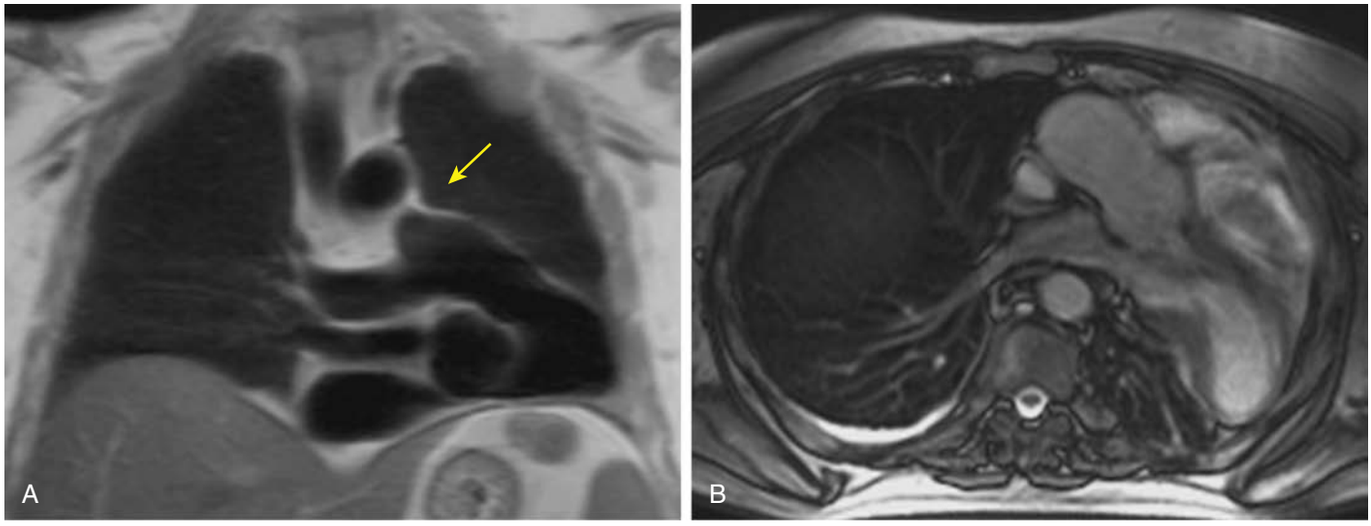

Fig. 57.8 Congenital absence of the pericardium. Coronal T1-weighted (**A**) and axial T2-weighted (**B**) cardiac magnetic resonance images showing pronounced left-sided rotation and displacement of the heart, filling the anterior portion of the left hemithorax. Pericardial absence can be difficult to visualize and is indicated by the abnormal location of the heart in the absence of other predisposing factors, and sometimes by the presence of lung tissue between the aortic arch and left atrium (yellow arrow). (With permission from Kim M-Y, Fairbairn T 2013 Complete congenital absence of the pericardium: an incidental finding. J Cardiol Cases 8: 148-150.)

mediastinal (e.g., para-aortic, subaortic, retrotracheal, prevascular) and parasternal internal thoracic lymph nodal groups also receive efferents (see Fig. 54.12B). There are two layers of pericardial lymphatic vessels, contacting and surrounding the parietal pericardium and also within the fat and loose areolar tissue. The anterior (sternocostal) part of the pericardium either drains laterally towards the phrenic nerves as they enter the diaphragm (lateral group of diaphragmatic nodes, superior phrenic nodes), or travels along the ventral border of the pericardium to enter the prepericardial lymph nodes located at the pericardio-diaphragmatic junction. Drainage from the lateral pericardium is more variable. Inferiorly, it drains towards the phrenic nerves and the pericardiacophrenic vessels as they reach the respiratory diaphragm, and includes the lateral pericardial nodes; superiorly, it drains into the tracheobronchial (subcarinal) and paratracheal lymph nodes. The posterior pericardium, including the posterior aspect of the associated dome of the respiratory diaphragm and extending as far as the pulmonary veins, drains superiorly to the superior and inferior tracheobronchial (upper and lower paratracheal, and subcarinal) lymph nodes. The portion of the pericardium that adheres to the diaphragm drains via short channels to the lymph nodes at the right border of the caval foramen in the central diaphragmatic tendon.

Lymphangiogenesis, the formation of new lymphatic vessels, is beneficial in delaying atherosclerotic plaque formation in coronary arteries. In patients with myocardial infarction, lymphangiogenesis is therapeutic during the healing process, reflecting its ability to reduce fluid retention and aid the clearance of inflammatory cells within the cardiac tissues.

Innervation

Pain from the parietal layer of serous pericardium is mainly transmitted by the left and right phrenic nerves. Pain from the visceral layer of serous pericardium is transmitted along visceral afferent fibres that travel via sympathetic nerves that arise from the cervical, upper thoracic and stellate ganglia and travel to the aortic and cardiac plexuses. The pericardium is also innervated by vagal fibres via the oesophageal plexus and left recurrent laryngeal nerve (see Fig. 57.61). Pericardial pain (somatic) is typically sharp, severe and substernal, often exacerbated when lying in the supine or left lateral position and relieved by leaning forwards; it occasionally radiates to the superior border of trapezius.

HEART

The heart has a complicated, spiral, three-dimensional structure that is markedly skewed (rotated) relative to the planes of the body. Historically, established anatomical orientation terms that have been applied to the heart were based on early embryological development before axial rotation of the heart tube (i.e. left and right sides). This, together with the traditional study of isolated whole or dissected hearts outside the body, hinders the intuitive understanding of the descriptive relations of *in vivo* and surface anatomy. The following description emphasizes such difficulties in order to circumvent certain misconceptions, before proceeding to an account of more detailed structure. The oblique position of the heart in the thorax may be conceptualized by comparing it to a deformed pyramid, with the base facing posteriorly and to the right, and the apex anteriorly and to the left. A line from the apex to the approximate centre of the base projected posterolaterally emerges near the right scapular line. Some surfaces of the cardiac 'pyramid' are flat and others relatively convex. The surfaces merge along rather ill-defined borders. Precise definitions of surfaces and intervening borders are therefore difficult. In the account that follows, terms from *Terminologia Anatomica* (2019) are used and more generally used terms from clinical practice are given as alternatives.

The heart is described as having a base and apex; its surfaces are designated as anterior (sternocostal), inferior (diaphragmatic), and right and left pulmonary (Fig. 57.9). Its borders are termed upper, inferior (acute margin or border), right and left (obtuse margin or border). The right pulmonary surface is sometimes referred to as a border, despite its extent. Although the heart is placed obliquely in the thorax, the atrial and ventricular septal structures are virtually in line, and inclined anteriorly and to the left at around 45° to the sagittal plane. The planes of the mitral and tricuspid valves are near vertical and not precisely co-planar; they are broadly at right-angles to the septal plane. The right atrium, therefore, is not only to the right, but also anterior and inferior to the left atrium, and it is partly anterior to the left ventricle. The right ventricle forms most of

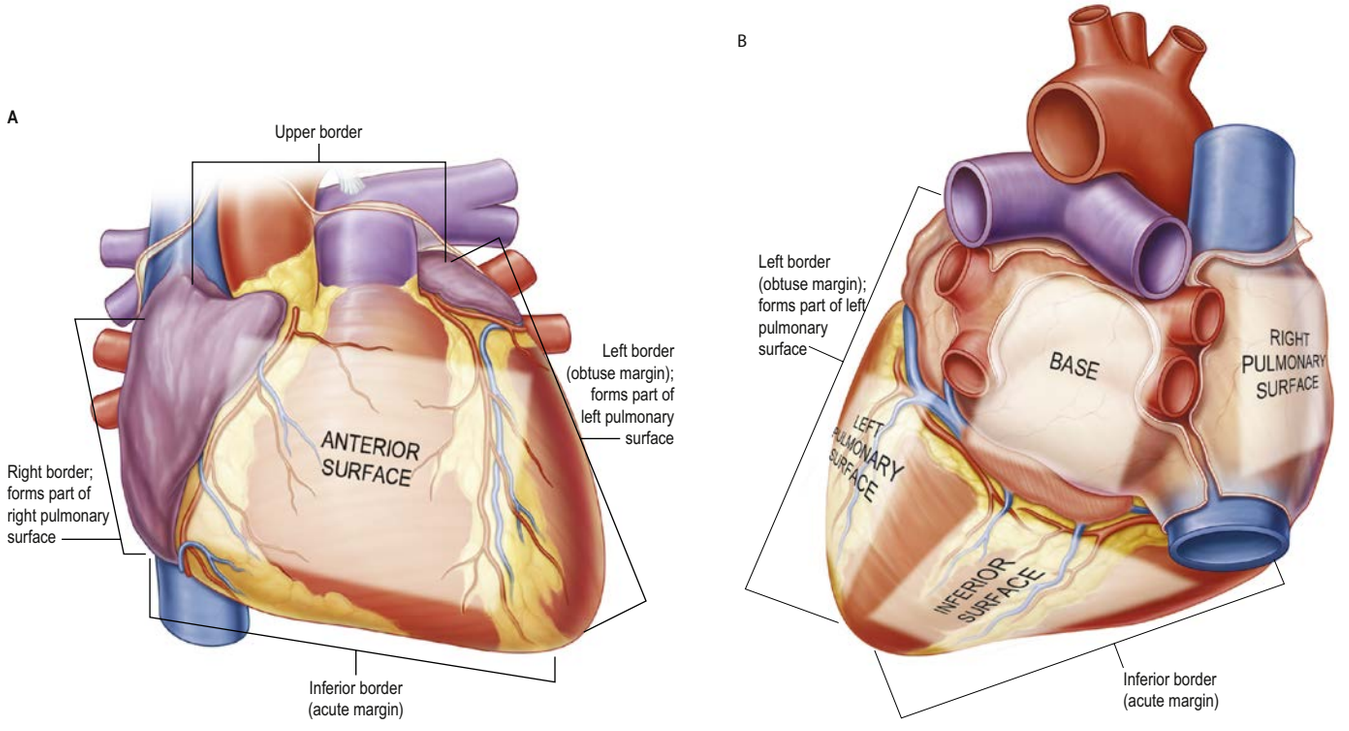

Fig. 57.9 The surfaces and borders of the heart. **A**, View of the anterior surface. **B**, View of the basal, inferior and pulmonary surfaces. (Adapted from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2015.)

CHAPTER 57

the anterior aspect of the ventricular mass (see Fig. 57.1B). Only its inferior end lies to the right of the left ventricle, while its upper extremity, supporting the pulmonary valve, is to the left of the left ventricle and superior to the level of the aortic valve (**Fig. 57.10**). The left atrium forms most of the posterior aspect of the heart, whereas the left ventricle is only prominent inferiorly, running along the left border to reach the cardiac apex. Each atrium is essentially to the right of and posterior to its respective ventricle. These general dispositions are of the greatest importance in planning or interpreting radiographs, CT and MRI studies, cardiac angiograms and echocardiograms (see Fig. 57.32).

The right heart (right-sided chambers), while forming the right border and pulmonary surface, follows a gentle curve and also covers most of the anterior aspect of the left heart (except for a left-sided strip of the left border that includes the cardiac apex). Thus, the right heart forms the largest part of the anterior surface, its outflow tract ascending until it terminates on the left side of the outflow tract from the left ventricle. The sites of the tricuspid and pulmonary valves are widely separated and on different planes, and the sectionally crescentic flat cavity of the right ventricle splays out between them (see Figs 57.18B, 57.27A). Conversely, the left heart (except the left-sided strip mentioned above) is largely posterior in position and, when viewed from the front (anteriorly), is obscured by the chambers of the right heart. The inlet to the left ventricle, which contains the mitral valve, is very close to its outlet (the aortic valve), the two being embraced by the wide tract linking the inlet and outlet parts of the right ventricle (see Fig. 57.36). The planes of the left ventricular orifices, although relatively inclined, are more nearly co-planar than those of the right (see Fig. 57.19). The left ventricular cavity is narrow and conical, and its tip sits within the cardiac apex.

Structures within the heart should be described relative to the bodily coordinates rather than to the heart itself, i.e. they should be described like the rest of the body when viewed in the anatomical position: it is important to appreciate that the diaphragmatic surface is inferior, and the left atrium is posterior (**Fig. 57.11**).

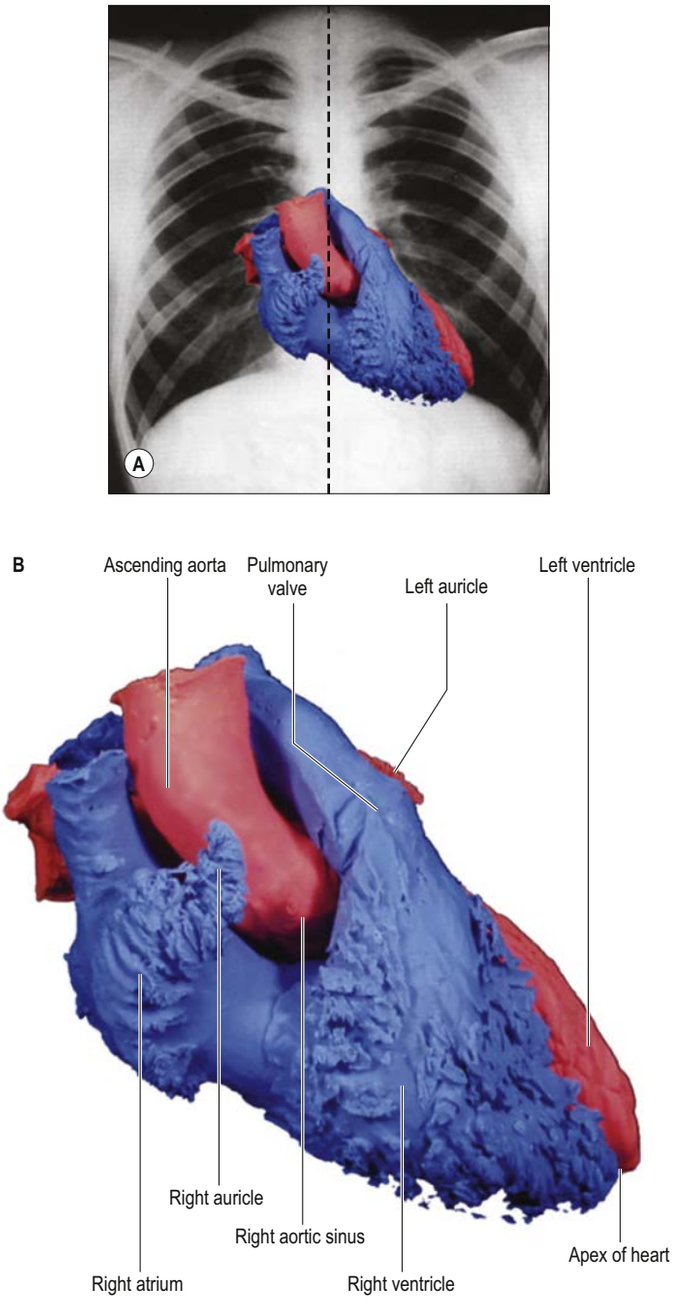

Fig. 57.10 A cast of the right (blue) and left (red) chambers of the heart. **A**, The cast superimposed on a normal posteroanterior (PA) chest radiograph. The black dashed line indicates the median plane. The long axis of the heart extends from the right shoulder towards the left hypochondrium. The adult heart is usually positioned within the mediastinum such that about one-third is to the right of the median plane and two-thirds to the left. **B**, The cast enlarged to show the chambers that form the various borders of the frontal cardiac silhouette. (With permission from Anderson R, Loukas M. 2009 The importance of attitudinally appropriate description of cardiac anatomy. Clin Anat 22:47–51.)

General organization

The heart is a fused pair of valve-containing muscular pumps circulating blood in series through systemic (left heart) and pulmonary (right

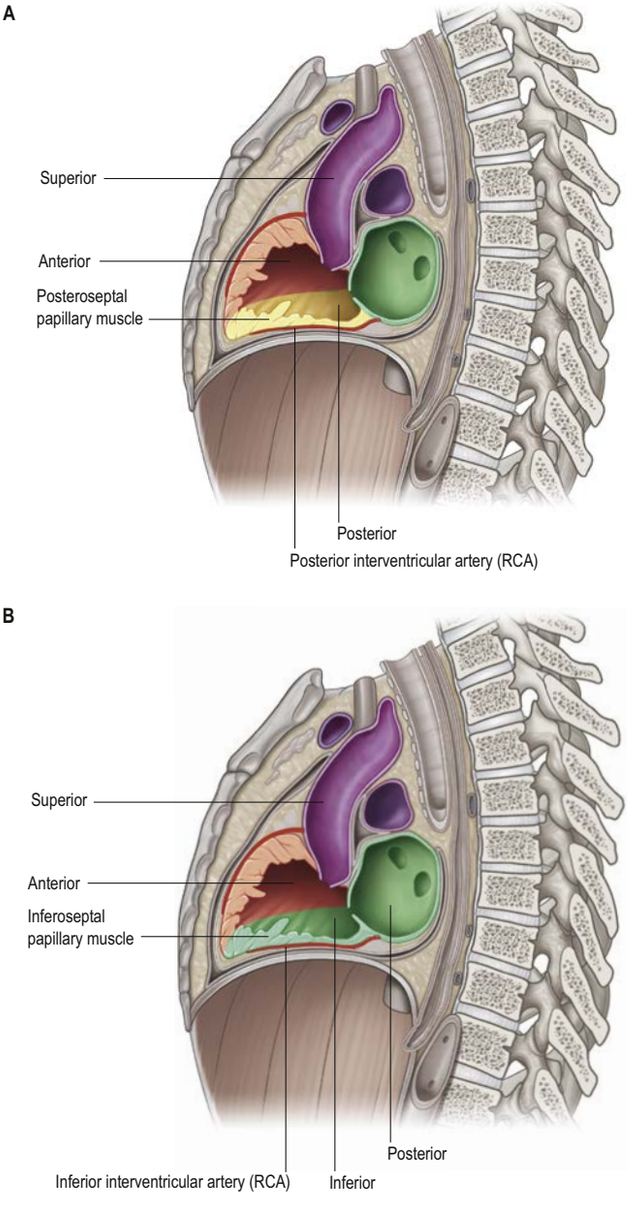

Fig. 57.11 The fundamental differences between describing the heart according to (**A**) the conventional or (**B**) the attitudinally correct, orientation. Abbreviation: RCA, branch of right coronary artery. (With permission from Anderson R, Spicer D, Hlavacek A et al 2013 Describing the cardiac parts – attitudinally appropriate nomenclature. J Cardiovasc Transl Res 6:118–23.)

A typical example of not applying this concept is the posterior interventricular artery. In cardiological and older anatomical texts, this artery is described as being posterior and descending, whereas three-dimensional reconstruction of cross-sectional imaging of adults clearly demonstrates that the artery occupies the inferior interventricular sulcus on the inferior surface of the heart, and is not posterior to the anterior interventricular artery: it can be described as posterior and descending only when using the 'Valentine' position, with the heart removed from the body and positioned standing on its apex (Mori et al 2019). In life, the posterior interventricular sulcus is situated inferiorly rather than posteriorly: blockage of the inferior (posterior) interventricular artery can produce inferior myocardial infarction. Another example is the papillary muscles that support the leaflets of the mitral valve. These were conventionally described as being anterolateral and posteroseptal, reflecting the fact that the heart was placed on its apex (Valentine position) in order to describe its component parts. However, when examined in left anterior oblique orientation, the posteroseptal muscle is anterior and inferior to its partner, despite the fact that the latter is conventionally described as anterolateral (see Figs 57.4, 57.9, 57.10, 57.27A).

heart) circulations (see Fig. 57.4). The fibromuscular framework and conduction tissues of these physiologically separate pumps are structurally interwoven. Despite the functional disposition in series, the two pumps are topographically described in parallel. Of the four cardiac chambers, the two atria receive venous blood and serve as weakly contractile reservoirs for final filling of the two ventricles, which then provide the powerful expulsive contraction that forces blood into the main arterial trunks.

The right heart starts at the right atrium, which receives the superior and inferior venae cavae and the main myocardial venous inflow via the coronary sinus. The systemic venous blood traverses the right atrioventricular orifice, guarded by the tricuspid (right atrioventricular) valve, to enter the inlet part of the right ventricle. Contraction of the ventricle, particularly its apical trabecular part, closes the tricuspid valve and, with increasing pressure, ejects the blood through the muscular right ventricular outflow tract into the pulmonary trunk and then through the relatively low-resistance pulmonary vascular bed. Many structural features of the right heart, including its overall geometry, myocardial architecture and the construction and relative strengths of the tricuspid and pulmonary valves, accord with this low resistance and comparatively low changes in pressure.

The left heart starts at the left atrium, which receives all the pulmonary inflow of oxygenated blood and some coronary venous inflow. It contracts to fill the left ventricle through the left atrioventricular orifice, guarded by its mitral (left atrioventricular) valve. Left ventricular contraction rapidly increases the pressure in the apical trabecular part, closing the mitral valve and opening the aortic valve, enabling the ventricle to eject via the left ventricular outflow tract into the aortic sinuses, ascending aorta, and the entire systemic arterial tree, including the coronary arteries. This vast vascular bed presents a high peripheral resistance that, with large metabolic demands (especially the sustained requirements of the cerebral tissues), explains the relatively massive structural organization of the left heart. The ejection phase of the left ventricle is shorter than that of the right but its fluctuations in pressure are much greater. The heart is, therefore, a functionally and structurally asymmetric pair of combined pumps in which both ventricles are designed to deliver the same volume with each contraction into two very different resistive series circulations.

Cardiac size, shape and external features

The heart is a hollow, fibromuscular organ of a somewhat conical or pyramidal form, with a base, apex and a series of surfaces and borders (margins) (see Fig. 57.9). Enclosed in the pericardium, it occupies the middle mediastinum between the lungs and their pleural coverings (see Fig. 57.1). It is placed obliquely behind the body of the sternum, adjoining costal cartilages and ribs, and the intervening intercostal muscles. Approximately one-third of its mass lies to the right of the midline. An average adult heart is 12 cm from base to apex, 8–9 cm at its broadest transverse diameter and 6 cm from anterior to posterior. Its weight varies from 280 to 340 g (average 300 g) in males and from 230 to 280 g (average 250 g) in females. Cardiac weight is 0.45% of body weight in males and 0.40% in females. The difference in weight between males and females appears after the age of 12 years (Kortelainen 1997). Adult weight is achieved between the ages of 17 and 20 years. The heart reaches 50% of its adult dimensions at birth, 75% by 5 years and 90% by 12 years (Nidorf et al 1992).

Sulci on the cardiac surface

The division of the heart into four chambers produces boundaries that are visible externally as sulci (grooves). Some are deep and obvious and contain prominent structures. Others are less distinct or barely perceptible, and are sometimes obscured, in part, by the major structures that cross or traverse them.

The extensive interatrial sulcus (of Waterston) separates the two atria. The lateral limits are defined by the borders of the atria. The atrioventricular (coronary) sulcus separates the atria from the ventricles and contains the main parts of the right and circumflex coronary arteries. It descends obliquely to the right on the anterior (sternocostal) surface, separating the right atrium and its auricle (appendage) from the obliquely oriented right margin of the right ventricle and its conus arteriosus (infundibulum). Superiorly, it is obliterated by the crossing of the pulmonary trunk, and posterior to this, the ascending aorta from which the coronary arteries originate. Continuing to the left, the atrioventricular sulcus curves around the left border (obtuse margin) and descends to the right, separating the atrial base from the inferior surface of the ventricles (see Fig. 57.4). This inferior part of the atrioventricular sulcus then curves around the inferior border (acute margin) at its lower right end to become confluent with the anterior part of the sulcus. The inferior part of the sulcus sits slightly to the left of the anterior part. A section of the heart through the plane of the atrioventricular sulcus is at about 45° to the sagittal plane and at a variable angle to the transverse and coronal planes. It approximately traverses the lines of attachment of the atrioventricular valves and, even less precisely, those of the aortic and pulmonary valves. A line at right-angles to the centre of this plane will descend anteriorly and leftwards to the cardiac apex. Internally, the ventricles are separated by the interventricular septum; its margins correspond to the anterior and inferior interventricular sulci. The anterior sulcus, seen on the anterior cardiac surface, is near and almost parallel to the left border (obtuse margin). On the inferior surface, the inferior interventricular sulcus is closer to the midpoint of the ventricular mass. The interventricular sulci extend from the atrioventricular sulcus to the notch of the cardiac apex on the inferior border (acute margin), the latter a little to the right of the cardiac apex (see Fig. 57.24).

Cardiac base, apex, surfaces and borders

Posterior surface (base) of the heart The true cardiac base is somewhat quadrilateral, with curved lateral extensions (see Fig. 57.9). It faces posteriorly and to the right, separated from the bodies of the thoracic vertebrae (fifth to eighth when supine, sixth to ninth in the erect position) and their intervening intervertebral discs by the pericardium, right pulmonary veins, oesophagus, azygos venous system, thoracic duct and descending thoracic aorta. It is formed mainly by the left atrium, and only partly by the posterior part of the right atrium (see Fig. 57.4B). It extends superiorly to the bifurcation of the pulmonary trunk and inferiorly to the inferior part of the atrioventricular sulcus, which contains the coronary sinus and coronary arterial branches. It is limited to the right and left by the rounded surfaces of the corresponding atria. The junction of the atrioventricular, interatrial and inferior interventricular sulci is termed the cardiac crux. Two pulmonary veins on each side open into the left atrial part of the base, whereas the superior and the inferior venae cavae open into the respective parts of the right atrial basal region (see Fig. 57.4B). The area of the left atrial wall between the openings of right and left pulmonary veins forms the anterior wall of the oblique pericardial sinus (see Fig. 57.1). This description of the anatomical base reflects the usual position of the heart in the thorax. Some confusion is produced by other current usages of the term 'base', often applied to the segment of the atrioventricular and ventriculoarterial junctions seen after dissections through the atrioventricular sulcus. This area is better termed the base of the ventricles. In clinical practice, auscultation in or near the parasternal parts of the second intercostal spaces is often described as occurring at the 'clinical base', to make a distinction with the 'clinical apex'. Such descriptions, while less than perfect anatomically, are likely to persist.

Anatomical apex of the heart (cardiac apex) The apex of the conical left ventricle is directed anteroinferiorly and to the left and is overlapped by the left lung and its covering pleurae. The apex is located most commonly behind the fifth left rib, fifth left intercostal space or the sixth left rib, near or a little medial to the mid-clavicular line (a line located 8–9 cm lateral to the midline).

Anterior (sternocostal) surface of the heart Facing anteriorly and superiorly, the anterior surface has an acute rightward and a more gradual leftward convexity (see Fig. 57.1B; **Fig. 57.12**). It consists of an atrial region superior and to the right, and a ventricular region inferior and to the left of the atrioventricular sulcus. The atrial region is occupied almost entirely by the right atrium. The left atrium is largely hidden by the ascending aorta and pulmonary trunk: only a small part of the left atrial auricle projects forwards to the left of the pulmonary trunk. Of the ventricular region, about one-third is made up by the left and two-thirds by the right ventricle. The site of the interventricular septum between them is indicated by the anterior interventricular sulcus. The anterior surface is separated by the pericardium from the body of the sternum, the sternocostal muscles, the third to sixth costal cartilages and the intervening intercostal muscles. Because of the bulge of the heart to the left, more of this surface is behind the left costal cartilages than those on the right. It is also covered by the pleural membranes and the thin anterior borders of the lungs, except for a triangular area at the cardiac notch of the left lung. The lungs and their pleural coverings vary in their extent of cardiac overlap during breathing and between individuals.

Inferior (diaphragmatic) surface of the heart Largely horizontal, the inferior surface of the heart gently slopes anteroinferiorly towards

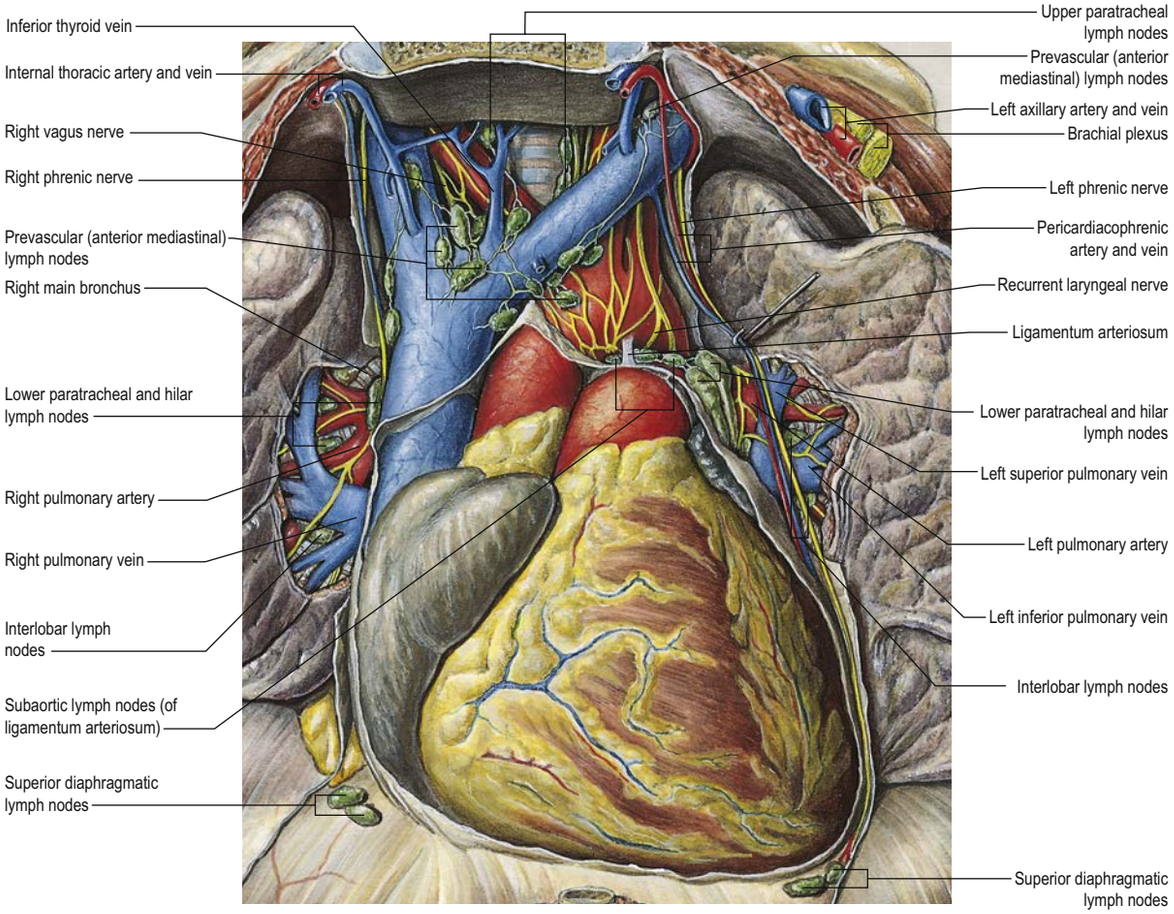

Fig. 57.12 The heart, great vessels and the lungs *in situ*. The manubrium of the sternum has been retracted cranially, the thymus has been completely removed and the pericardium has been partially removed. The hilum of the lung has been dissected to expose the hilar, subaortic, para-aortic and hilar lymph nodes. (With permission from Waschke J, Paulsen F (eds) Sobotta Atlas of Human Anatomy, 15th ed. Elsevier, Urban & Fischer. Copyright 2013.)

the cardiac apex (see Figs 57.4B,D, 57.9). It is formed by the ventricles (primarily the left) and rests mainly on the central tendon but also, apically, on a small area of the left muscular part of the diaphragm. It is separated from the anatomical base of the heart by the atrioventricular sulcus, and is traversed obliquely by the inferior interventricular sulcus.

Left (pulmonary) surface of the heart Facing posterosuperiorly to the left, the left pulmonary surface consists almost entirely of the left border (obtuse margin) of the left ventricle; a small part of the left atrium and its auricle contribute superiorly. Convex and widest superiorly, where it is crossed by the atrioventricular sulcus, it narrows as it passes towards the cardiac apex. It is separated by the pericardium from the left phrenic nerve and pericardiacophrenic vasculature, and from the pleura covering the cardiac notch of the left lung.

Right (pulmonary) surface of the heart The right pulmonary surface is rounded and formed by the right atrial wall. It is separated by the pericardium from the pleura covering the mediastinal surface of the right lung, and from the right phrenic nerve and pericardiacophrenic vasculature. Its convexity merges inferiorly into the short intrathoracic part of the inferior vena cava and superiorly into the superior vena cava. The sulcus terminalis is a prominent landmark separating the systemic atrial venous sinus from the auricle; it curves approximately along the junction of the anterior and right surfaces, corresponding to the position of the crista terminalis.

Upper border of the heart The upper border is atrial, mainly the left atrium. Anterior to it are the ascending aorta and the pulmonary trunk (see Figs 57.1, 57.4B). At its right lateral extremity, the superior vena cava enters the right atrium.

Right border of the heart Corresponding to the right atrium, the profile of the right border is slightly convex to the right.

Inferior border of the heart Also known as the acute margin of the heart, the inferior border is sharp, thin and nearly horizontal. It extends from the inferior limit of the right border to the cardiac apex and is formed mainly by the right ventricle, with a small contribution from the left ventricle near the cardiac apex.

Left border of the heart Also known as the obtuse margin, the left border separates the anterior and left pulmonary surfaces. It is round and mainly formed by the left ventricle but, to a slight extent superiorly, is formed by the left atrial auricle. It descends obliquely, convex to the left, from the left atrial auricle to the cardiac apex.

Right atrium

General and external features

The right atrium is both anterior and to the right of the left atrium, and extends inferior to it (see Fig. 57.4A–D). Its walls form the right superior part of the anterior surface, the convex right (pulmonary) surface and a small part of the right side of the anatomical base. The superior vena cava opens into its roof, and the inferior vena cava into its inferoposterior part. The auricle is an extensive muscular pouch that projects anteriorly to overlap the right side of the ascending aorta: it is a broad, triangular, pyramidal structure and has a wide junction with the systemic venous part of the atrium. The junction between the venous part (sinus venosus) and the atrium proper is marked externally by the shallow sulcus terminalis running between the right sides of the openings of the two venae cavae. Internally, the sulcus terminalis corresponds to the crista terminalis, the site of origin of the extensive pectinate muscles that arise serially at right-angles from the crista and extend anterolaterally along the internal surface of the right atrial auricle. Posteriorly, the vertical interatrial sulcus passes inferiorly to the cardiac crux. Anteriorly, the right atrium is related to the anterior part of the mediastinal surface of the right lung, from which it is separated by pleura and pericardium. Laterally, the atrium is also related to the mediastinal surface of the right lung, but anterior to its hilum, and separated from the lung by the pleura, right phrenic nerve, pericardiacophrenic vessels and pericardium. Posteriorly and to the left, the interatrial septum and the surrounding infolded atrial walls separate the atria; this infolding is indicated by an extensive interatrial sulcus. Posteriorly and to the right are the right pulmonary veins. Medially are the ascending aorta and, to a limited extent, the pulmonary trunk and its bifurcation.

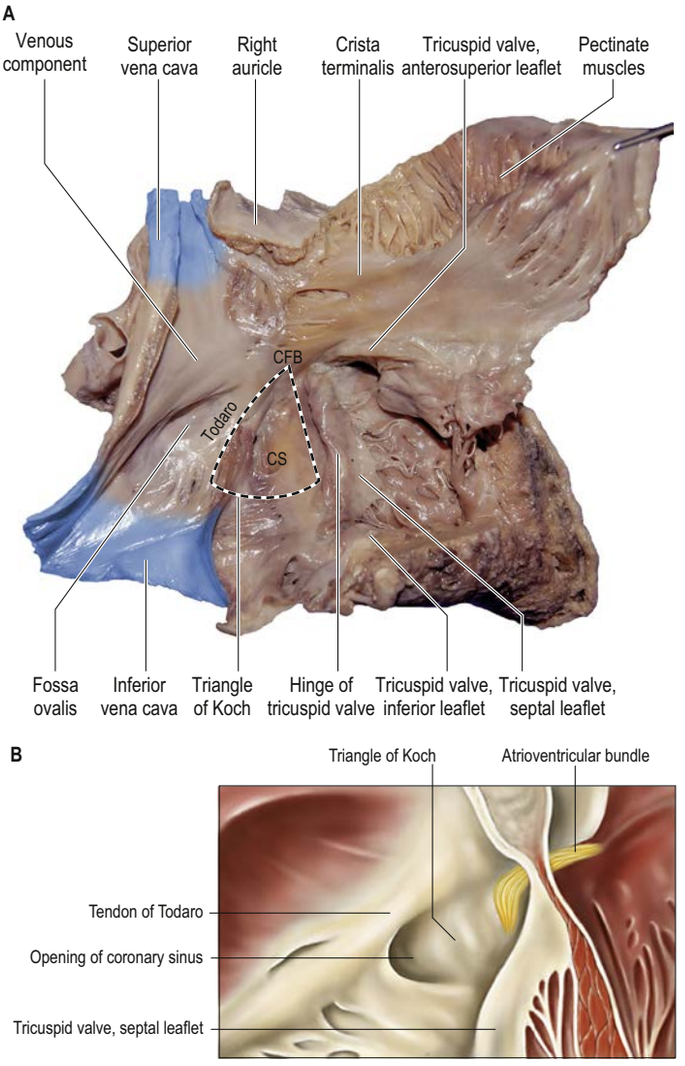

Fig. 57.14 A, The internal features of the right atrium. The superior and inferior venae cavae have been dissected, exposing the systemic venous part of the right atrium and the fossa ovalis. The dotted line indicates the triangle of Koch, demarcated by the opening of the coronary sinus (CS) and its valve (Thebesian valve); the anterior extension of the valve of the inferior vena cava (Eustachian), the tendon of Todaro (or tendon of the inferior pyramidal space), to the central fibrous body (CFB); and the septal leaflet of the tricuspid valve. **B**, The triangle of Koch marking the location of the atrioventricular node. (A, Image courtesy of Professor M Loukas.)

Internal features

The internal surface of the right atrium can be divided into three regions: the smooth-walled systemic venous part, located posteriorly, leads anteriorly to the vestibule of the tricuspid valve and to the atrial auricle (Figs 57.13–57.14). The wall of the vestibule is smooth but its junction with the auricle is ridged all around the atrioventricular junction by pectinate muscles. The smooth-walled systemic venous sinus receives the openings of the superior and inferior venae cavae and the coronary sinus.

The superior vena cava returns blood from the head, neck and upper limbs through an orifice that faces anteroinferiorly and has no valve; it also receives blood from the thoracic wall and the oesophagus via the azygos system (see Fig. 56.3).

The inferior vena cava is larger in diameter than the superior. It drains blood from all structures below and including the respiratory diaphragm into the lowest part of the atrium near the interatrial septum. Anterior to its orifice, and passing around its left margin toward the limbus (rim) of the fossa ovalis, is the flap-like valve of the inferior vena cava (Eustachian valve), a triangular fold of endocardium of varying size that encloses a few muscular fibres (see Fig. 57.13; Fig. 57.15). It is usually a fibrous or fibromuscular flap. When traced inferiorly, it forms the Eustachian ridge, and is continuous with the valve of the coronary sinus (Thebesian valve). The Eustachian ridge borders the coronary sinus and the fossa ovalis. The anterior extension of the valve of the inferior vena cava is seen as a fibrous strand, the tendon of Todaro (inferior pyramidal space), which forms part of the border of the

Elsevier, Urban & Fischer. Copyright 2013.)

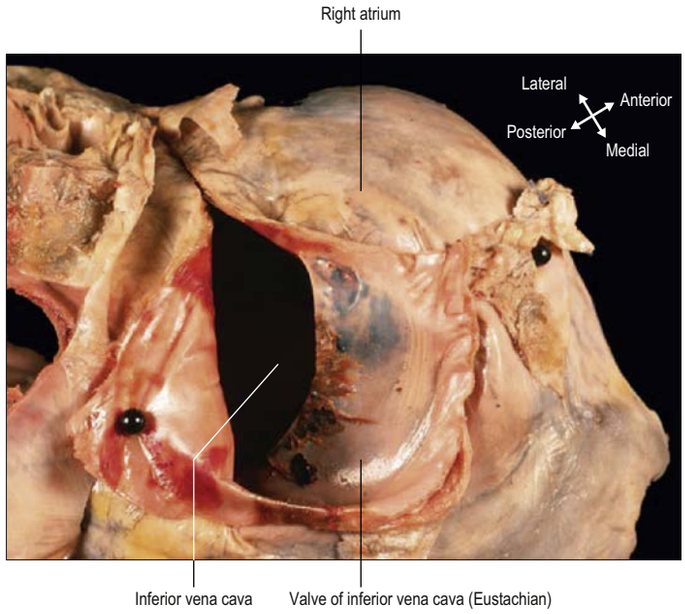

Fig. 57.15 An inferior view of a cadaveric heart, demonstrating an unusually large valve of the inferior vena cava (Eustachian valve) occupying the majority of the lumen of the inferior vena cava. (With permission from Loukas M, Sullivan A, Tubbs R et al 2010. Chiari's network: review of the literature. Surg Radiol Anat 32:895–901.)

triangle of Koch, itself the anatomical landmark of the atrioventricular node. The lateral part of the valve of the inferior vena cava becomes continuous with the inferior end of the crista teminalis. The valve of the inferior vena cava is large during fetal life, when it serves to direct richly oxygenated blood (from the placenta) toward and through the foramen ovale of the interatrial septum and into the left atrium. The valve varies markedly in size in postnatal life, is sometimes cribriform or filamentous, and is often absent.

Occasionally, a reticulated network, Chiari's network, originates from the valve of the inferior vena cava and connects to different parts of the right atrium, including the coronary sinus. It is the result of incomplete resorption of the right valve of the embryonic sinus venosus (**Fig. 57.16**). Often clinically insignificant, Chiari's network has been associated with the pathogenesis of thromboembolic disease, endocarditis, arrhythmias, cardiac flow obstructions, heart murmurs, infective endocarditis, cardiac tumours and entrapment of catheters on percutaneous intervention.

The prominent sub-Thebesian recess is located anterior to the valve of the inferior vena cava and posteroinferior to the opening of the coronary sinus (see Fig. 57.18). The area extending from the valve of the inferior vena cava to the vestibule of the tricuspid valve, inferior to the opening of the coronary sinus (the cavotricuspid isthmus), is the target of catheter-directed ablation procedures, which are the treatment of choice for atrial flutter (Sánchez-Quintana et al 2013).

The coronary sinus opens into the systemic venous part of the right atrium between the orifice of the inferior vena cava, the fossa ovalis and the vestibule of the tricuspid valve (see Figs 57.13–57.14). It is often guarded by a thin, semicircular Thebesian valve (valve of the coronary sinus) that covers the lower part of the orifice. The upper limb of this valve joins the valve of the inferior vena cava and its muscular extension, the Eustachian ridge. It also joins a tendinous structure (tendon of Todaro or tendon of the inferior pyramidal space) running from this commissure into the sinus septum between the coronary sinus and the fossa ovalis. The tendon of Todaro runs forwards to insert into the central fibrous body and forms one of the borders of the triangle of Koch (triangle of the atrioventricular node). The opening of the coronary sinus forms a prominent landmark in the right atrium. The coronary sinus itself lies within the posterior and inferior parts of the atrioventricular sulcus (see Figs 57.4B,D,E) and is the conduit for the return of most of the venous blood from the heart, although some veins drain directly into the atrial chambers. The coronary sinus starts at the confluence of the oblique vein of the left atrium and the great cardiac vein, and receives the middle and small cardiac veins close to its junction with the right atrium. Several small venous openings, draining the smallest cardiac (Thebesian) veins, are found scattered around the atrial walls. They return a small fraction of blood from the heart, and are most numerous on the septal aspect. The anterior cardiac veins and, sometimes, the right marginal vein may enter the atrium through larger openings.

The right atrium and its auricle are separated from the systemic venous part by the crista terminalis, a smooth, C-shaped muscular ridge that originates from the upper part of the septal surface, passes anterior to the orifice of the superior vena cava and then skirts the right margin of the inner atrium to reach the right side of the orifice of the inferior vena cava. It marks the site of the right venous valve of the embryonic heart, corresponding externally to the sulcus terminalis. The sinu-atrial node is located in the superior part of the sulcus (groove), inferolateral to the orifice of the superior vena cava (see Fig. 57.13). The mean length of the crista terminalis is 51±9 mm and its thickness from epicardium to endocardium at the junction of the superior vena cava with the posterior atrial wall is 5.5 ±1.3 mm. The multiple raised parallel ridges of the pectinate muscles extend anterolaterally from the crista terminalis, reaching into the right auricle where they form several trabeculations. The largest and most prominent pectinate muscle, the taenia sagittalis (second crest or septum spurium), forms the bridge of the sulcus terminalis internally. The septal wall is dominated by the fossa ovalis, an oval depression superior and normally to the left of the orifice of the inferior vena cava. Its floor is the primary atrial septum (septum primum). The limbus (rim) of the fossa ovalis is prominent. Often said to represent the edge of the septum secundum, in reality the muscular borders of the fossa are no more than infoldings of the atrial walls, incorporating extracardiac adipose tissue. The limbus is most distinct anterosuperior to the fossa, and is usually deficient inferiorly. Some hearts display an excessive amount of extracardiac adipose tissue within the fold, markedly elevating the superior limbus of the fossa and forming the intervenous tubercle of Lower (interatrial fold of the inferior vena cava). A small slit-shaped passageway is sometimes found at the superior margin of the fossa ovalis. It ascends beneath the limbus, between it and the valve of the foramen ovale, to communicate with the left atrium, and represents failure of obliteration of the fetal foramen ovale, which remains patent or probe-patent in up to one-third of all normal hearts. Anteroinferiorly in the right atrium the large, oval vestibule leads to the right atrioventricular (tricuspid) orifice. A triangular zone, the triangle of Koch (triangle of the atrioventricular node), is present between the attachment of the septal leaflet of the tricuspid valve, the anteromedial margin of the opening of the coronary sinus (and its valve), and the palpable round, collagenous subendocardial tendon of Todaro (see Figs 57.13–57.14). Koch's triangle is a landmark of surgical importance since it contains the atrioventricular node and its atrial connections. Anterosuperior to the insertion of the tendon of Todaro, the septal wall is formed by the atrioventricular part of the membranous septum, which intervenes between the vestibule of the right atrium and the subaortic outlet of the left ventricle (**Fig. 57.17**). The bulging atrial wall anterosuperior to the membranous septum, the aortic mound (torus aorticus), marks the location of the non-adjacent aortic sinus with its enclosed aortic valvular leaflet.

Right ventricle

The right ventricle extends from the right atrioventricular (tricuspid) orifice nearly to the cardiac apex. It then ascends to the left to become the conus arteriosus (infundibulum) reaching the pulmonary orifice and supporting the leaflets of the pulmonary valve. Topographically, the ventricle possesses an inlet part that supports and surrounds the tricuspid (right atrioventricular) valve; a coarsely trabeculated apical part; and a muscular outlet (conus arteriosus or infundibulum) that surrounds the attachments of the pulmonary valve leaflets.

External features

The convex anterosuperior surface of the right ventricle makes up a large part of the anterior surface of the heart, and is separated from the thoracic wall by the fibrous and serous pericardium (see Figs 57.1B, 57.2–57.3). The left costomediastinal recess of parietal pleura and, to a lesser extent, the anterior border of the left lung are interposed superiorly and to the left. The inferior surface is flat and is related mainly (with the interposition of the serous pericardium) to the central tendon and a small adjoining muscular part of the respiratory diaphragm. The left and posterior wall is formed by the interventricular septum, slightly curved and bulging into the right ventricle so that, in sections across the cardiac axis, the outline of the right ventricle is crescentic (see Fig. 57.27). The wall of the right ventricle is relatively thin (3–5 mm), the ratio of the thickness of the right : left ventricular walls usually being 1 : 3.

Internal features

The inlet and outlet parts of the right ventricle, supporting and surrounding the leaflets of the tricuspid and pulmonary valves, respectively, are separated in the roof of the ventricle by the prominent supraventricular crest (**Fig. 57.18**). The crest is made up predominantly by the inner heart curvature, bounded on the epicardial aspect by the rightward margin of the transverse pericardial sinus. The crest is a thick, muscular, highly arched structure, extending obliquely anteriorly and to the right from a septal limb high on the interventricular septal wall to a mural or parietal limb on the anterolateral right ventricular wall. The posterolateral aspect of the crest provides the principal attachment for the anterosuperior leaflet of the tricuspid valve. The septal limb of the crest is embraced by the septal limbs of the septomarginal trabeculation (moderator band). The inlet and outlet parts of the ventricle extend apically into and from the prominent coarsely trabeculated part of the ventricle. The inlet part itself is also trabeculated, whereas the outlet part has predominantly smooth walls, albeit with septoparietal trabeculations anteriorly. The trabeculated appearance is produced by a myriad of endocardial lined, irregular muscular ridges and protrusions collectively known as trabeculae carneae. These protrusions and intervening grooves impart great variation in ventricular wall thickness; the protrusions vary in extent from slight ridges to trabeculations, fixed at both ends but otherwise free. Other conspicuous protrusions are the papillary muscles, which are inserted at one end on to the ventricular wall and are continuous at the other end with collagenous cords, the chordae tendineae (tendinous cords), inserted on the free edge of the tricuspid valvular leaflets. One protrusion in the right ventricle, the septomarginal trabecula, is particularly prominent, originating as one or more limbs from the upper two-thirds of the interventricular septum, from the supraventricular crest to the ventricular apex. Towards the ventricular apex, it supports the anterior papillary muscle of the tricuspid valve and, from this point, crosses to the parietal (anterior) wall of the ventricle. The septomarginal trabecula is often termed the moderator band, a name reflecting an earlier idea that it prevented overdistension of the

ventricle. The role of the septomarginal trabecula as part of the conduction system of the heart involves carrying the right branch of the atrioventricular bundle, as conduction cardiomyocytes move towards the apex of the ventricle before entering the anterior papillary muscle. The septomarginal trabecula may be any combination of short or long and thick or thin: it is occasionally absent. A further series of prominent trabeculations, the septoparietal trabeculations, extend from the anterior surface of the septomarginal trabecula and run on to the parietal ventricular wall. The smooth-walled outflow tract (conus arteriosus or infundibulum), ascends to the left, superior to the septoparietal trabeculations and inferior to the arch of the supraventricular crest to the pulmonary orifice (Spicer and Anderson 2013).

Tricuspid (right atrioventricular) valve

The atrioventricular valvular complex of both ventricles consists of an orifice and its associated anulus, leaflets, supporting chordae tendineae of various types and papillary muscles. Harmonious interplay of these components, together with the myocardial mass, depends on the conduction tissues and mechanical cohesion provided by the cardiac skeleton. All parts change substantially in position, shape, angulation and dimensions during the cardiac cycle (see Fig. 57.20).

Tricuspid valvular orifice

The tricuspid valvular orifice is best seen from the right atrial aspect. It measures, on average, 11.4 cm in circumference in males and 10.8 cm in females. There is a clear line of transition from the atrial wall or interatrial septum to the lines of attachment of the valvular leaflets. Its margins are not precisely in a single plane. It is almost vertical but at 45° to the sagittal plane and slightly inclined to the vertical, such that it faces (on its ventricular aspect) anterolaterally to the left and somewhat inferiorly (**Fig. 57.19**). Roughly triangular, its margins are described as anterosuperior, inferior and septal, corresponding to the lines of attachment of the valvular leaflets. The connective tissues around the orifice of the atrioventricular valves separate the atrial and ventricular myocardial masses completely, except at the point of penetration of the atrioventricular bundle; they vary in density and disposition around the circumference of the valvular orifice. Extending from the right fibrous trigone of the central fibrous body is a pair of fila coronaria (curved, tapered, prong-like subendocardial tendons), which partly encircle the circumference of the right atrioventricular orifice (see Fig. 57.22). The latter is completed by more tenuous, deformable fibroblastic sulcal areolar tissue. Although the extent of cardiac fibrous tissue varies with sex and age, the tissue within the atrioventricular junction around the tricuspid orifice is always less robust than similar elements found at the attachments of the mitral valve. The topographical attachment of the free valvular leaflets in the tricuspid valve does not wholly correspond to the internal level of attachment of the fibrous core of the valvular leaflets to the junctional atrioventricular connective tissue. The line of attachment of the leaflets is best seen when the heart is examined grossly, and is more readily discerned clinically.

Tricuspid valvular leaflets

When they are closed, it is usually possible to distinguish the three leaflets in the tricuspid valve on the basis of the zones of apposition between them. The leaflets are located anterosuperiorly, septally and inferiorly, corresponding to the respectively named marginal sectors of the atrioventricular orifice (see Fig. 57.21A). The inferior leaflet is often described as being posterior, but when assessed in the attitudinally correct anatomical position, the leaflet is positioned inferiorly (Anderson and Loukas 2009). Each leaflet is a reduplication of endocardium enclosing a collagenous core, continuous on its free margin and ventricular aspect with diverging fascicles of chordae tendineae, and confluent with the anular connective tissue at the inserted margin.

In passing from the free margin to the inserted margin, all leaflets of the atrioventricular valves display rough, clear and basal zones. The rough zone is relatively thick, opaque and uneven on its ventricular aspect where most chordae tendineae are attached; its atrial aspect contacts the comparable surface of the adjacent leaflets during full valve closure. The clear zone is smooth and translucent, receives few chordae tendineae and has a thinner, fibrous core. The basal zone, extending 2–3 mm from the circumferential attachment (inserted margin) of the leaflets, is thicker (because of increased connective tissue), vascularized and innervated, and contains the insertions of the atrial myocardium. The anterosuperior leaflet is the largest part of the tricuspid valve and has a semicircular shape. It is attached mainly to the atrioventricular junction on the posterolateral aspect of the supraventricular crest, extending along its septal limb to the membranous septum ending at the anteroseptal commissure. One or more notches often indent its free margin. The attachment of the septal leaflet passes from the inferoseptal commissure on the inferior ventricular wall across the muscular septum, then angling across the membranous septum to the anteroseptal commissure. The septal leaflet defines one of the borders of the triangle of Koch, thereby aiding location of the atrioventricular node at the apex of this triangle, and ensuring avoidance during tricuspid valve surgery (see Figs 57.13–57.14, 57.22). The inferior leaflet is wholly mural in attachment and guards the inferior surface of the atrioventricular junction, its limits being the inferoseptal and anteroinferior commissures. The zone of apposition between the septal and the anterosuperior leaflets is supported by the septal papillary muscle of the conus arteriosus.

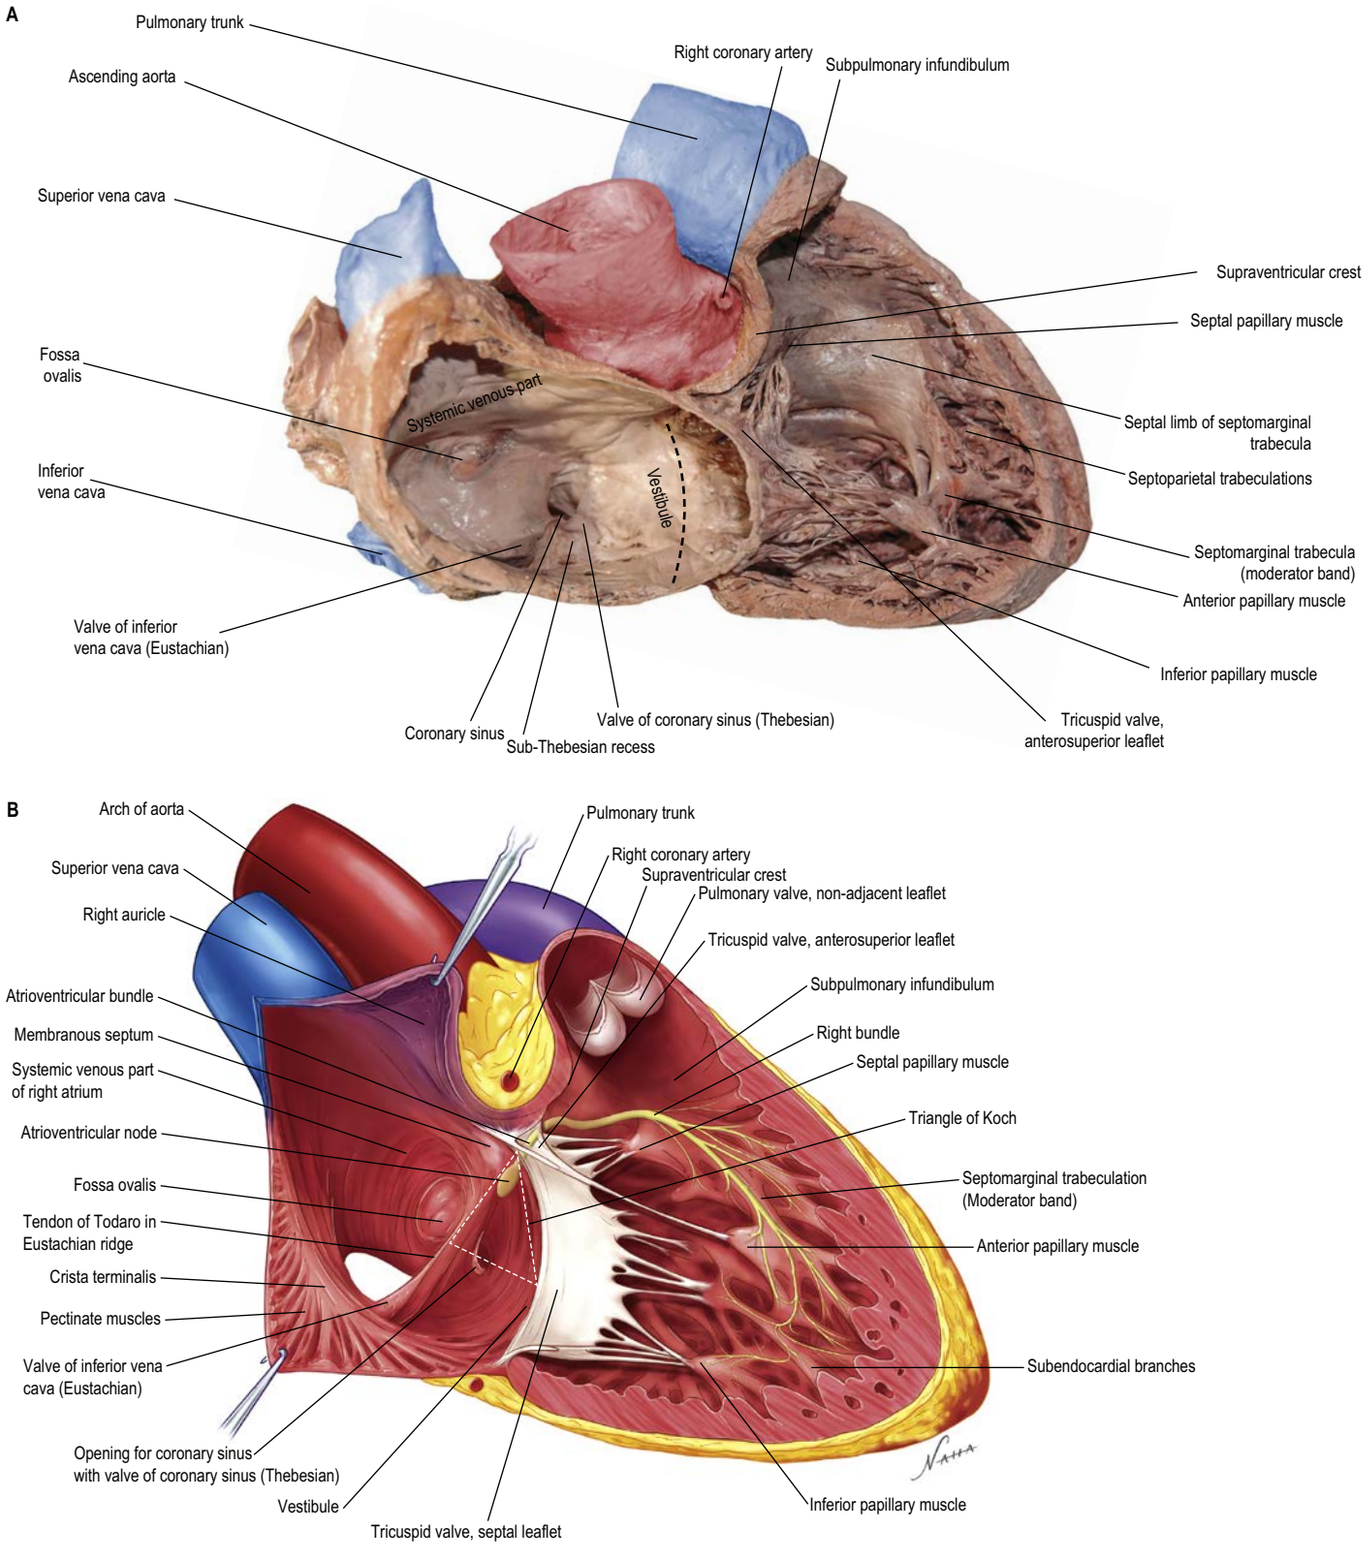

Fig. 57.18 Internal features of the right atrium and ventricle shown (**A**) in a cadaveric heart and (**B**) an illustration showing the atrioventricular node, atrioventricular bundle and right bundle, viewed via a 'window dissection' (prepared by removing the anterosuperior wall of the right atrium and ventricle). The valve of the inferior vena cava (Eustachian) separates the inferior vena cava from the sub-Thebesian recess. The valve of the coronary sinus (Thebesian) guards the entry into the coronary sinus. The smooth circumferential area of atrial wall that surrounds the orifice of the tricuspid valve is the vestibule. Note the location of the supraventricular crest and septomarginal trabeculation. The body of the septomarginal trabeculation (moderator band) continues as a muscular band to the anterior papillary muscle and the parietal wall of the right ventricle. Conduction tissue accompanies fine trabeculae carneae and false chordae. (Image courtesy of Professor M Loukas.) See Fig. 57.36 for the left-sided conduction system.

Opening of the tricuspid valve

Despite its name, the tricuspid valve acts more like a bicuspid valve because its smallest septal leaflet is fixed between the atrial and ventricular septa. The remainder of the tricuspid anulus is muscular. The anulus of the tricuspid valve is less fibrous than the anulus of the mitral valve, which presumably accounts for the low occurrence of degenerative calcifications seen on the tricuspid valve (Saremi et al 2017). During diastole, the anulus dilates with right ventricular relaxation and the large anterosuperior and inferior leaflets move away from the plane of the anulus into the right ventricle. During systole, the anulus constricts as the right ventricle contracts and the two major leaflets move like sails about a relatively immobile septal leaflet and the septum itself (Fig. 57.20).

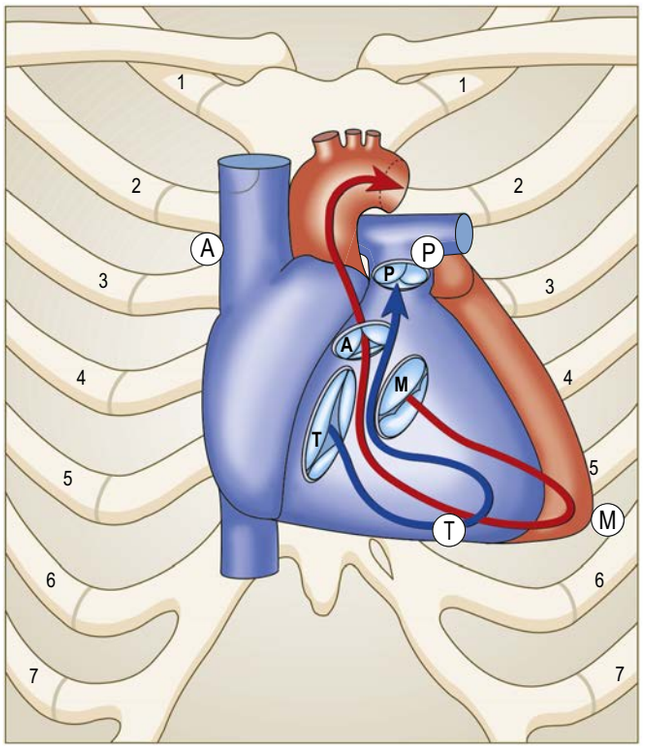

Fig. 57.19 The relationship between the anterior thoracic wall and valves of the heart. The right heart is blue, the blue arrow denotes the inflow and outflow channels of the right ventricle; the left heart is treated similarly in red. The positions, planes and relative sizes of the cardiac valves are shown. The position of the letters A, P, T and M (in a white circle) indicate the aortic, pulmonary, tricuspid and mitral auscultation areas of clinical practice, respectively. Note that, for the purpose of illustration, the orifices of the aortic, mitral and tricuspid valves are shown with some separation between them, whereas, in reality, the leaflets of the three valves are in fibrous continuity (see Fig. 57.22).

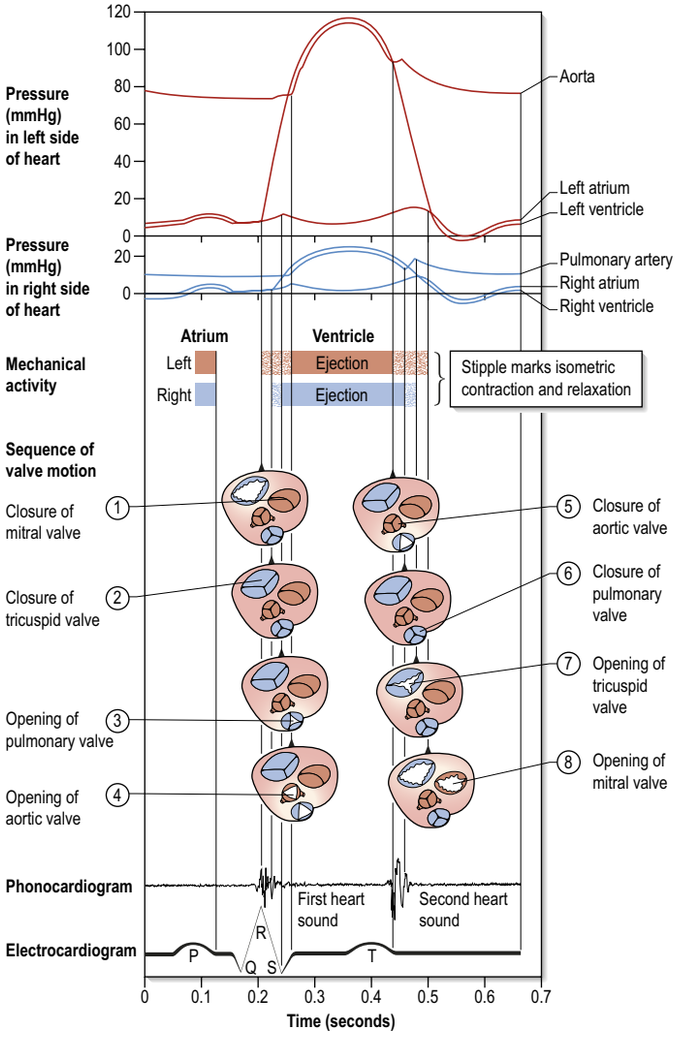

Fig. 57.20 A summary of some of the principal events that occur in the cardiac cycle. Systole begins at the onset of the first heart sound (see phonocardiogram) and ends at the onset of the second heart sound, when diastole begins, and this cycle repeats itself.

Tricuspid valvular chordae tendineae

The chordae tendineae are fibrous collagenous structures that support the leaflets of the atrioventricular valves. In about one-third of hearts, false chordae connect the papillary muscles to each other or to the ventricular wall or septum, or pass directly between points on the wall or septum, or both. Their numbers and dimensions in the right ventricle vary: approximately 40% of these false cords contain conduction cardiomyocytes.

The true chordae usually arise from small projections on the tips or margins of the apical third of papillary muscles, but may sometimes arise from the papillary muscle bases or directly from the ventricular walls and septum. They are attached to various parts of the ventricular aspects or the free margins of the valvular leaflets. True chordae are classified into first-, second- and third-order types, according to the distance of the attachment from the margins of the leaflets, but this classification has little functional or morphological merit. Fan-shaped chordae have a short stem from which branches radiate to attach to the free margins or ventricular aspect of the zones of apposition between leaflets and to the ends of adjacent leaflets. Rough-zone chordae arise from a single stem that usually splits into three parts that attach to the free margin, the ventricular aspect of the rough zone and to some intermediate points on the leaflet, respectively. Free-edge chordae are single, thread-like and often long, passing from either the apex or the base of a papillary muscle into a marginal attachment, usually near the midpoint of a leaflet or to one of the scallops on its free edge. Deep chordae pass beyond the free margins and, branching to various extents, reach the more peripheral rough zone or even the clear zone. Basal chordae are round or ribbon-like, long and slender, or short and muscular; they arise from the smooth or trabeculated ventricular wall and are attached to the inserted margin (basal part) of a leaflet.

Papillary muscles

The two major papillary muscles in the right ventricle are located in anterior and inferior positions. A third, smaller septal muscle lies medially, together with several smaller, variable muscles attached to the interventricular septum. The anterior papillary muscle is the largest, its base arising from the right anterolateral ventricular wall inferior to the anteroinferior commissure between the anterosuperior and inferior valvular leaflets, also blending with the right side of the septomarginal trabecula. The inferior papillary muscle, often bifid or trifid, arises from the myocardium inferior to the inferoseptal valvular commissure. The septal papillary muscle of the conus (muscle of Lancisi) is almost always present and is the most superior and largest of the small septal papillary muscles. It arises from the posterior septal limb of the septomarginal trabeculation and locates the right bundle branch within the right ventricle. All the major papillary muscles supply chordae to adjacent parts of the valvular leaflets they support (see Figs 57.17–57.18). A feature of the right ventricle is that the septal leaflet is tethered by individual chordae tendineae directly to the interventricular septum; such septal insertions are never seen in the left ventricle. When closed, the three leaflets fit snugly together, the pattern of the zones of apposition confirming the trifoliate arrangement of the tricuspid valve.

Pulmonary valve

The pulmonary valve, guarding the outflow from the right ventricle, sits at the top of the conus arteriosus (infundibulum) and is situated at some distance from the other three cardiac valves (see Fig. 57.19; **Figs 57.21–57.22**). Its plane of orientation faces superiorly to the left and slightly posteriorly. It has three semilunar leaflets, attached by convex edges partly to the infundibular wall of the right ventricle and partly to the origin of the pulmonary trunk. The line of attachments is curved, rising at the periphery of each leaflet near their zones of apposition (the commissures) and reaching the sinutubular junction of the pulmonary trunk, in a manner similar to that of the aortic valve (**Fig. 57.23**). Removal of the leaflets reveals that the fibrous semilunar attachments enclose three crescents of infundibular musculature within the pulmonary sinuses, whereas three roughly triangular segments of arterial wall are incorporated within the ventricular outflow tract beneath the apex of each commissure at the point of attachment. Thus there is no proper

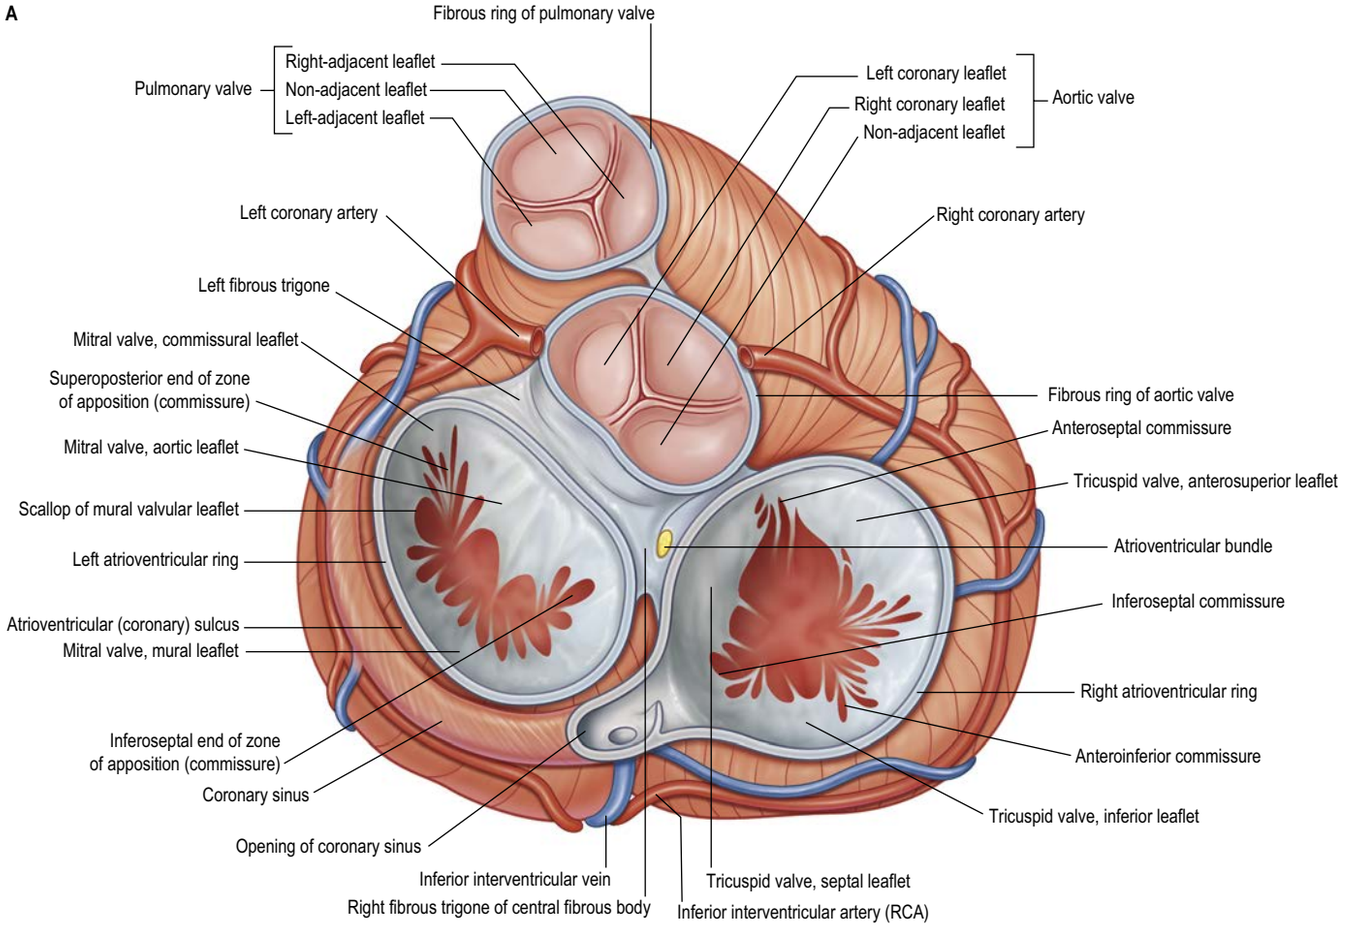

Fig. 57.21 A, The atrioventricular valvular entrance (base) of the ventricles, after removal of the atria and the pericardium, exposing the coronary arteries and cardiac veins. Contrast the planes and positions of the aortic and pulmonary valves, and with Fig. 57.22. Abbreviations: RCA, branch of right coronary artery. (Adapted from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2015.) (B, *continued online*)

circular 'anulus' supporting the leaflets of the valve, and the fibrous semilunar attachment is an essential requisite for snug closure of the nodules and lunules of the semilunar leaflets during ventricular diastole.

It is difficult to name the leaflets and corresponding sinuses of the pulmonary valve and trunk precisely according to the coordinates of the body because the valvular orifice is obliquely positioned. The convention of referring to the leaflets as anterior, posterior and septal is based on their fetal position: in the adult, the leaflets become anterior, right and left, respectively. Each leaflet is an endocardial fold with a variably developed intervening fibrous core that traverses both the free edge and the semilunar-shaped inserted margin. The latter is particularly thickened at its deepest central part (the nadir) of the base (inserted margin) of each leaflet, and therefore never forms a simple complete fibrous ring. The free margin of each leaflet contains a central localized collagenous thickening, the nodule of the semilunar leaflet (nodule of Arantius). Perforations within the leaflets close to the free margin and near the commissures are frequently present and are of no functional significance. Each semilunar leaflet is contained within one of the three sinuses of the pulmonary trunk.

Opening of the pulmonary valve

During diastole, all three leaflets of the pulmonary valve are tightly apposed (see Fig. 57.20). The pulmonary valve is difficult to visualize at echocardiography; atrial systole may help by causing a slight posterior movement of the valve leaflets. The pulmonary valve opens passively during ventricular systole and closes rapidly at the end of systole.

Left atrium

General, external and internal features

Although smaller in volume than the right, the left atrium has thicker walls (3 mm on average). It possesses a venous part that receives the right and left superior and inferior pulmonary veins, a vestibule and an auricle. Its cavity and walls are formed largely by the proximal parts of the primordial pulmonary veins that are incorporated into the atrial wall during development. The atrial auricle is a remnant of the initial atrial component of the primary heart tube (Ch. 13). The left atrium is roughly cuboidal, extending posterior to the right atrium and separated from it by the obliquely positioned interatrial septum. The right atrium is therefore anterolateral to the right part of the left atrium. The left part is covered anteriorly by the intraepicardial part of the pulmonary trunk and ascending aorta, and part of the intervening transverse pericardial sinus. Anteroinferiorly, and to the left, it adjoins the base of the left ventricle at the orifice of the mitral (left atrioventricular) valve. Its approximately quadrangular posterior wall forms most of the anatomical base of the heart, receives the terminations of (usually) two pulmonary veins from both the left and right lungs, and forms the anterior wall of the oblique pericardial sinus (see Fig. 57.1). This surface, with the atrial roof, ends on the right side at the shallow vertical interatrial sulcus that descends to the cardiac crux (see Figs 57.4B,E).

The left atrial auricle (appendage) is characteristically longer, narrower and more hooked than the right, and is a finger-like extension with more deeply indented margins (see Fig. 57.1; **Fig. 57.24**). It is constricted at its junction with the body of the atrium and all its contained pectinate muscles are smaller than their right-sided counterparts. The left atrium lacks a crista terminalis, and the muscle bundles in the auricle are arranged in a whorl-like fashion rather than being in an array. The tip of the auricle has a variable position, often lying over the pulmonary trunk and anterior interventricular branch of the left coronary artery, and pointing towards the ascending aorta. Its narrow morphology predisposes it to being a site for thrombus formation, especially in cases of atrial fibrillation.

The four pulmonary veins (left and right, superior and inferior) open into the superior part of the left and right posterolateral surfaces of the left atrium, two on each side (see Figs 57.1, 57.4B,E). This arrangement is present in 20–60% of studied subjects. Additional supernumerary or accessory pulmonary veins may be present (Hassani and Saremi 2017). A common variation includes the presence of a short or long left common venous trunk and multiple pulmonary veins on

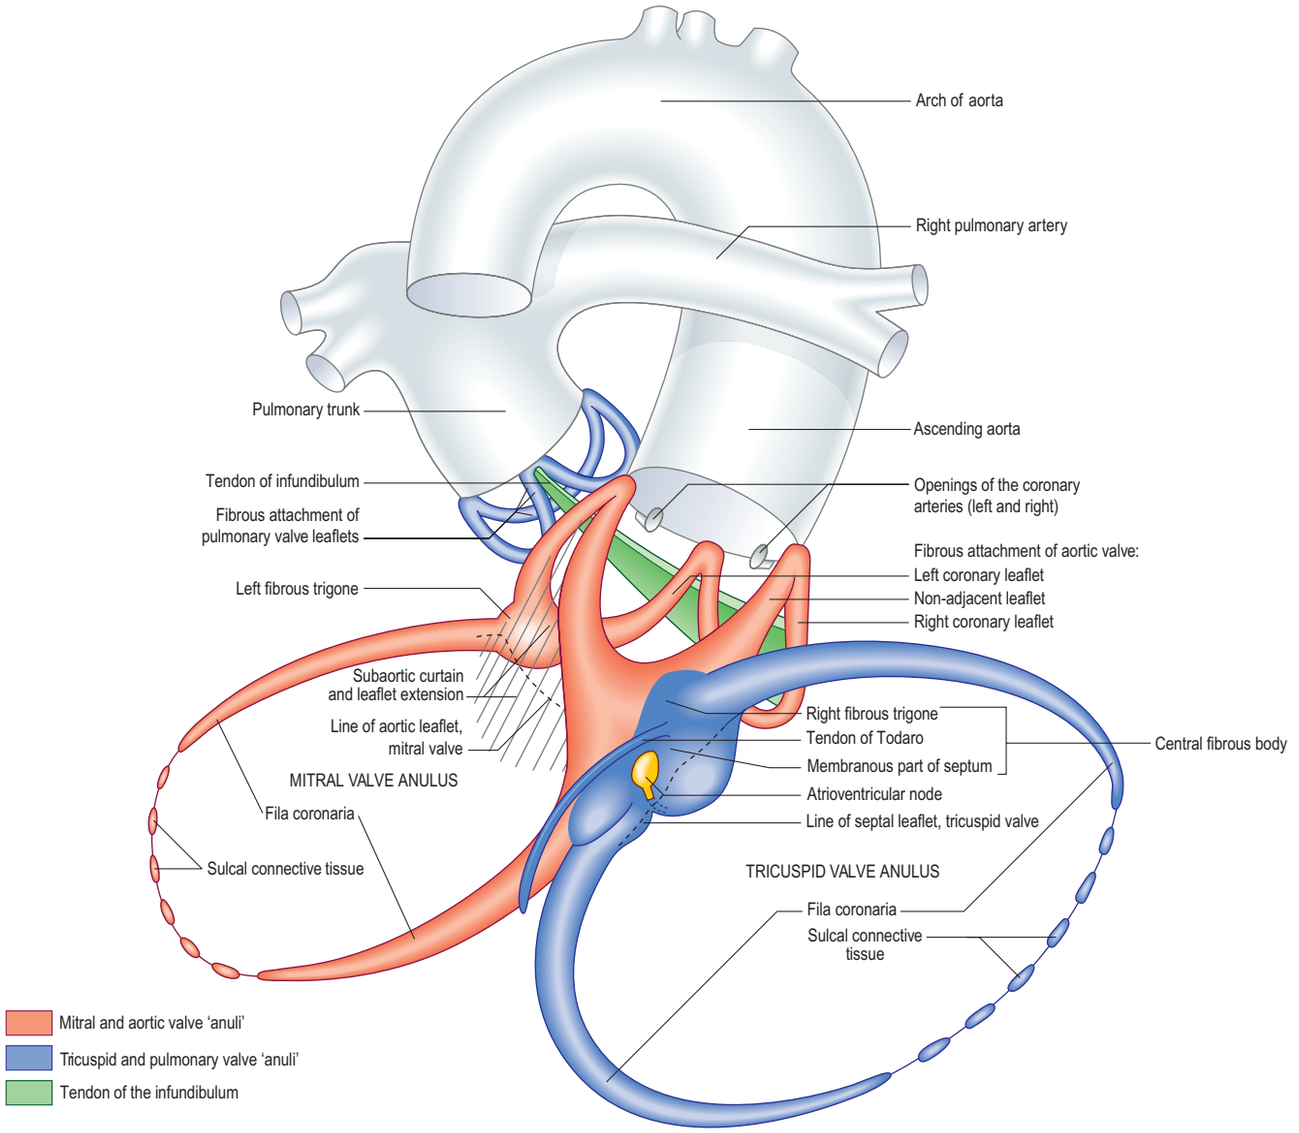

Fig. 57.22 Principal elements of the fibrous skeleton of the heart. For clarity, the view is from the right posterosuperior aspect. Perspective causes the pulmonary anulus to appear smaller than the aortic anulus, whereas, in fact, the reverse is the case. (Copyright of The Royal College of Surgeons of England. Reproduced with permission.)

the right (Fig. 57.25). The right superior and inferior pulmonary veins travel posterior to the respective vena cava. The orifices of the veins at their point of entry are smooth and oval. Interpulmonary ridges are usually present between ipsilateral orifices; the most prominent is located between the openings of the left auricle and left superior pulmonary vein. The ridges are infoldings of the left atrial wall and contain adipose tissue, atrial arteries and nerve bundles. At the site of the pericardial reflection, the atrial musculature extends into the pulmonary veins, forming myocardial sleeves that are thickest in the inferior wall of the superior pulmonary veins and the superior walls of the inferior pulmonary veins. They lie external to the venous tunica media and internal to the epicardium/adventitia. The myocardial sleeves, especially those of the superior veins, are often the site of focal electrical activity that initiates atrial fibrillation. Atrial myocardial bridges and crossing strands are often present, connecting the left superior and inferior pulmonary veins.

Several epicardial fat pads on the pulmonary venous part of the left atrium house the superior left, posterolateral, left inferior and posteromedial ganglionated cardiac intrinsic nerve plexuses (typically four). The smallest cardiac veins (venae cordis minimae) return blood directly from the myocardium to the left atrial cavity. The left atrial aspect of the interatrial septum has a characteristically rough appearance, bounded by a crescentic, superiorly concave ridge that marks the site of the fetal foramen ovale. The left-sided atrial septal pouch is a variant of the interatrial septum that carries a high association with cryptogenic strokes (Hołda and Koziej 2018). The vestibule is the smooth circumferential area of atrial wall that surrounds the orifice of the mitral valve (see Fig. 57.25; **Fig. 57.26**). The musculature that makes up the posteroinferior aspect of the left lateral wall of the atria, between the opening of the left inferior pulmonary vein or common left pulmonary vein, and the mitral valve anulus is known as the left atrial (mitral) isthmus. In this area, the vestibule of the left atrium directly faces the great cardiac vein, coronary sinus and the circumflex branch of the left coronary artery.

Left ventricle

General and external features

The left ventricle is constructed in accordance with its role as a powerful pump for the high-pressured systemic arterial circulation. Variously described as half-ellipsoid or cone-shaped, it is longer and narrower than the right ventricle, extending from its base in the plane of the atrioventricular sulcus to the cardiac apex. Its long axis descends anteriorly and to the left. In transverse section, at right-angles to the long axis, its cavity is oval or nearly circular, with walls three times thicker (8–12 mm) than those of the right ventricle (Fig. 57.27). It forms part of the anterior, left pulmonary and inferior cardiac surfaces. Except where obscured by the ascending aorta and pulmonary trunk, the base of the ventricular cone is superficially separated from the left atrium by part of the atrioventricular sulcus with the coronary sinus passing along its posterior and inferior aspect (see Fig. 57.4B,E). The anterior and inferior interventricular sulci indicate the lines of mural attachment of the ventricular septum and the limits of the ventricular territories. The anterior surface of the ventricle curves bluntly into its left pulmonary surface at the left border (obtuse margin) (see Figs 57.1B, 57.9).

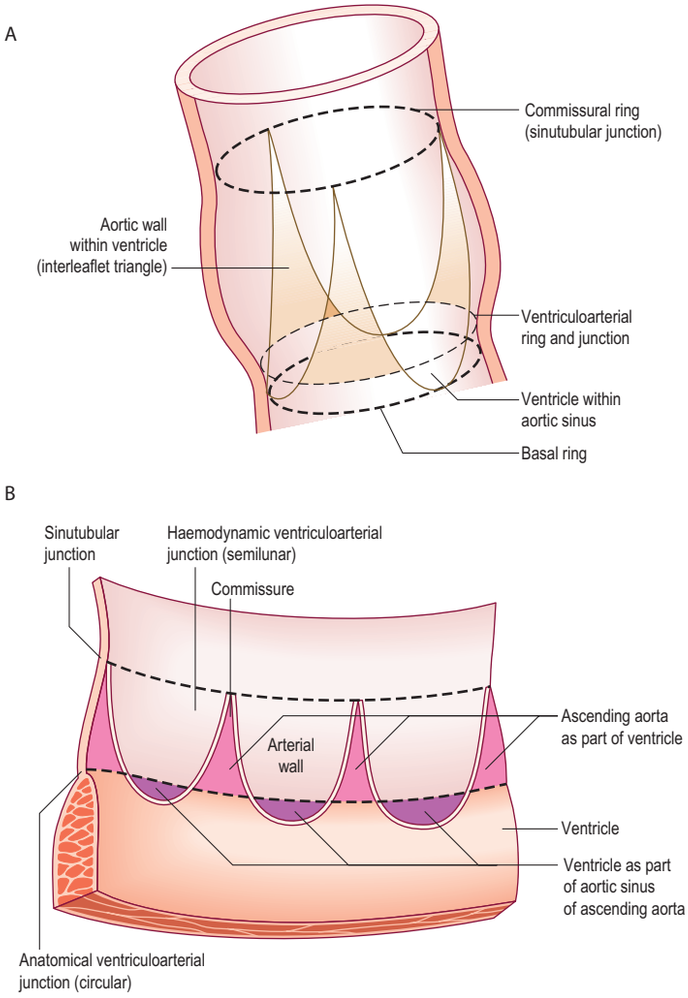

Fig. 57.23 A, The structure of the aortic root is best conceptualized in terms of a three-pronged coronet; there are at least three rings within this coronet but none supports the entirety of the attachments of the valvular leaflets (compare with **C**). **B**, The aortic valvular leaflets have been resected at their attachment to the aortic wall. Note the relationship of the leaflet insertions and the ventriculoarterial junction. **C**, The root of the aorta has been cut open and distended, in order to show the insertion of the semilunar leaflets. Note the zone of fibrous continuity between the leaflets of the aortic and mitral valves and their relationship to the fibrous trigones, and the semilunar attachment of the leaflets (compare with **B**). (Redrawn with permission, courtesy of Professor RH Anderson, Institute of Child Health, University College, London.)

The cross-sectional shape of the left ventricle changes from elliptical in the neonatal period to the round adult shape later in infancy (Azancot et al 1983). The effect of obesity on the heart is apparent as early as the second year of life. Obese children at 2 years of age may have a greater left ventricular mass compared with normal weight controls (de Jonge et al 2011).

Internal features

The left ventricle has an inlet part guarded by the mitral (left atrioventricular) valve, an outlet part guarded by the aortic valve and an apical trabecular part. The left atrioventricular orifice admits left atrial blood during diastole, the flow being directed towards the cardiac apex (**Fig. 57.28**; see Fig. 57.36). After closure of the mitral valvular leaflets and throughout the ejection phase of systole, blood is expelled from the cardiac apex through the aortic orifice. In contrast to the orifices within the right ventricle, those of the left ventricle are in close contact: fibrous continuity between leaflets of the aortic and mitral valves forms the subaortic curtain (see Fig. 57.22). The inlet and outlet turn sharply round this fibrous curtain (**Fig. 57.29**). The anteromedial wall is the muscular interventricular septum: its convexity completes the circular cross-section of the left ventricle (see Fig. 57.27). Towards the aortic orifice, the septum becomes the thin and collagenous membranous part of the interventricular septum, an oval or round area below and confluent with the right fibrous trigone (triangle) that separates the right and the non-adjacent leaflets of the aortic valve (see Figs 57.22, 57.30). Between the inferior limits of the free margins of the leaflets of the mitral valve and the ventricular apex, the muscular walls exhibit deeper, finer and more intricate trabeculae carneae (fine apical trabeculae carneae) than those of the right ventricle: they are more developed nearer the apex, and become smoother as the superior aspect of the interventricular septal surface is reached.

Hypertrophy of heart muscle

Available with the *Gray's Anatomy* e-book

Mitral (left atrioventricular) valve

The general description of the component parts of the tricuspid valve (see p. 1076) also applies to the mitral valve; it has an orifice with a supporting anulus, valvular leaflets and varying arrangements of chordae tendineae and papillary muscles.

Mitral valvular orifice

The mitral orifice, smaller than the tricuspid orifice, is a well-defined transitional zone between the left atrial wall and the inserted margin of the mitral valvular leaflet bases. It measures, on average, 9.0 cm in circumference in males and 7.2 cm in females. The approximately oval orifice is almost vertical and at 45° to the sagittal plane in diastole, but with a slight anterior tilt. Its ventricular aspect faces anterolaterally to the left and a little inferiorly towards the left ventricular apex (see Fig. 57.19). It is almost co-planar with the tricuspid orifice but posterosuperior to it, whereas it is posteroinferior and slightly to the left of the aortic orifice. The mitral, tricuspid and aortic orifices are intimately connected at the site of the central fibrous body (see Fig. 57.22). When the mitral valve leaflets close, they form a single zone of coaptation that should be termed the commissure: clinicians usually recognized the two ends of the zone as commissures. The anulus of the valve is not a simple fibrous ring but is made up of fibrocollagenous elements of varying consistency, from which the fibrous core of each leaflet take origin; the variable consistency is essential to allow the major changes in anular shape and dimensions during the cardiac cycle that are needed for optimal valvular efficiency. The area of the anulus increases linearly with body surface area in children and young adults (Poutanen et al 2006). The anulus is strongest at the internal aspects of the left and right fibrous trigones. Extending from these structures, the anterior and posterior fila coronaria (curved, tapered, fibrous, prong-like subendocardial tendons) partly encircle the orifice at the atrioventricular junction (see Fig. 57.22). Between the tips of the fila coronaria, the atrial and ventricular myocardial masses are separated by a more irregular sheet of deformable fibroelastic connective tissue. Spanning anteriorly between the fibrous trigones, the fibrous core of the central part of the aortic leaflet of the mitral valve is a continuation of the fibrous subaortic curtain that descends from the adjacent halves of the left and non-adjacent (non-coronary) valve leaflets (see Fig. 57.22, 57.29).

Mitral valvular leaflets

The mitral valvular leaflets have long been described as paired structures. The name 'bicuspid valve' is explicit but erroneous as a descriptor because the leaflets are not cuspid, or 'peaked', in form.

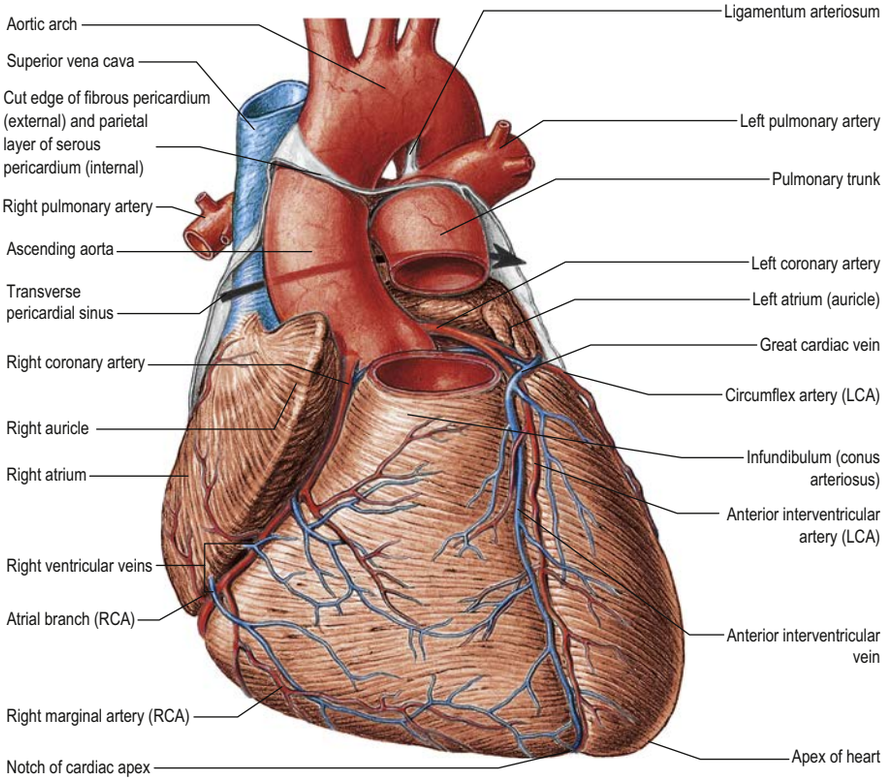

Fig. 57.24 The anterior (sternocostal) surface of the heart, with the initial part of the pulmonary trunk removed. Abbreviations: RCA, branch of right coronary artery; LCA, branch of left coronary artery. (With permission from Waschke J, Paulsen F (eds) Sobotta Atlas of Human Anatomy, 15th ed. Elsevier, Urban & Fischer. Copyright 2013.)

Hypertrophic cardiomyopathy is characterized by myocardial wall thickening, with a disproportionate thickening of the interventricular septum in comparison with the posterior wall. Echocardiography accurately assesses the degree of thickening and its effect on systolic function, such as dynamic left ventricular outflow obstruction, systolic anterior motion of the aortic leaflet of the mitral and mid-systolic closure of the aortic valve. There may also be a degree of diastolic dysfunction. Serial short-axis gradient echo MRI allows accurate measurement of wall thickness and is particularly useful in assessing apically confined hypertrophy. There are a number of histological changes, including cardiomyocytic disarray with replacement fibrosis and collagenous component expansion. Treatment is usually medical, except for refractory cases and when the left ventricular outflow tract obstruction has a gradient of greater than 50 mmHg. Ventricular septal myotomy and myectomy are performed in such cases. Catheter alcohol septal ablation has been introduced as a non-surgical alternative. A number of patients may also require implantation of cardiac defibrillators to prevent sudden cardiac death.

The heart of an athletic individual may physiologically hypertrophy but in a uniform fashion, and thickness decreases on deconditioning. In contrast, hypertrophic cardiomyopathy reveals asymmetric patterns of left ventricular hypertrophy, often with sharp segmental transitions, left atrial enlargement and unusual electrocardiographic patterns. There is an autosomal dominant inheritance pattern of abnormalities in genes coding for myocardial proteins associated with hypertrophic cardiomyopathy. Individuals with mutations of the β-MHC (major histocompatibility complex) gene usually develop the classic form of hypertrophy, whereas those with mutations of the cardiac troponin T gene generally have only mild or clinically undetectable hypertrophy. Rare forms of hypertrophy include localized left ventricular apical hypertrophy as a result of mutations of the cardiac troponin I gene, and isolated mid-cavity hypertrophy caused by mutations of cardiac actin and MLC (myosin light chain) genes.

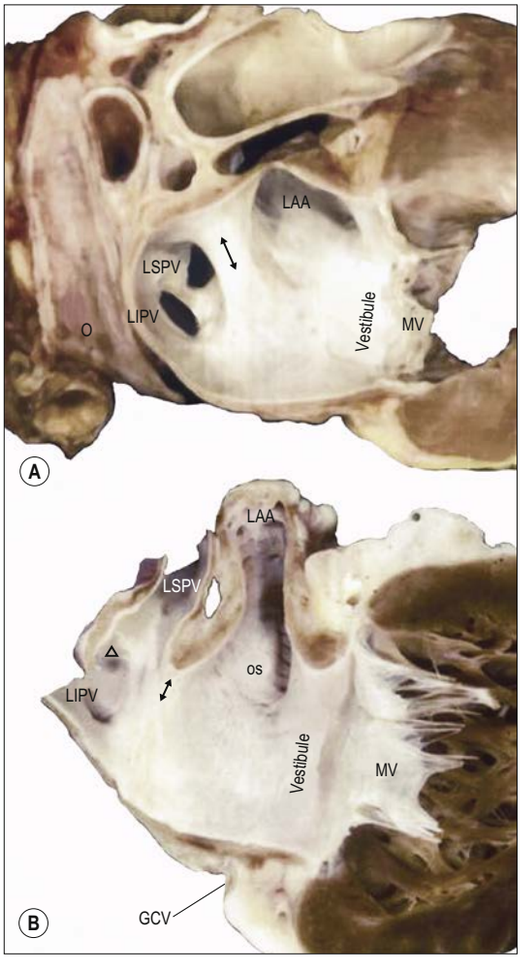

Fig. 57.25 Sagittal sections through a cadaveric heart showing the left side of the left atrium. **A**, The oesophagus (O) passing posterior to the posterior left atrial wall and a broad left-lateral ridge (double-headed arrow). The left superior (LSPV) and left inferior (LIPV) pulmonary veins enter the left atrium via a short common stem. Other abbreviations: LAA, left atrial auricle; MV, mitral valve. **B**, The section passes through the os (opening) of the left atrial auricle and the infolding of the ridge. The triangle indicates the carina or interpulmonary ridge between the left superior and inferior pulmonary veins. The great cardiac vein (GCV) runs inferior to the left atrial wall. A small accessory (commissural) leaflet is almost always found between the two major leaflets (aortic and mural) and so the mitral valve is better described as a continuous veil that is attached around the entire circumference of the mitral orifice. The free edge of the mural and aortic leaflets normally bear several indentations that create a scalloped edge. Two indentations are sufficiently deep and regular to be defined as the ends of the solitary and oblique zone of apposition or the commissures of the valve. These inferoseptal (anteromedial) and superoposterior (posterolateral) extremities of the solitary zone of apposition may be regarded as two independent commissures.

The original designations of anterior and posterior for the valve leaflets are somewhat misleading because of the obliquity of the valve, and the terms aortic and mural leaflet, respectively, are now preferred. When the valve is laid open, the aortic leaflet (anterior, septal, 'greater' or anteromedial) is seen to guard one-third of the circumference of the orifice and to be semicircular or triangular, with few or no free marginal indentations or scallops. Its fibrous core (lamina fibrosa) is continuous on the outflow aspect, beyond the margins of the fibrous subaortic curtain, with the right and left fibrous trigones (see Figs 57.17, 57.21, 57.23C). Between the trigones, it is continuous with the fibrous subaortic curtain itself and, beyond the trigones, with the roots of the filia coronaria (see Fig. 57.22). The leaflet has a deep crescentic rough zone that receives various chordae tendineae. The ridge limiting the outer margin of the rough zone indicates the maximal extent of surface contact with the mural leaflet in full closure. A clear zone is seen between the rough zone and the valvular anulus; it is devoid of attachments of chordae, although its fibrous core carries extensions from chordae attached in the rough zone. The aortic leaflet has no basal zone and continues into the subaortic curtain. Hinging on its anular attachment, and continuous with the subaortic curtain, it is critically placed between the inlet and the outlet of the ventricle. During passive ventricular filling and atrial systole, its smooth atrial surface is important in directing a smooth flow of blood towards the body and apex of the ventricle. After the onset of ventricular systole and closure of the mitral valve, the ventricular aspect of its clear zone merges into the smooth surface of the subaortic curtain, which, with the remaining fibrous walls of the subvalvular aortic vestibule, forms the smooth boundaries of the outlet part of the ventricle.

Also shown are the continuity of the subaortic curtain with connection to the aortic leaflet of the mitral valve, the openings of the left and right coronary arteries, and the spatial relationship of the aortic orifice to the pulmonary orifice and left ventricle. Abbreviation: LCA, branch of left coronary artery. (With permission from Waschke J, Paulsen F (eds) Sobotta Atlas of Human Anatomy, 15th ed. Elsevier, Urban & Fischer. Copyright 2013.)

The mural leaflet (posterior, ventricular, 'smaller' or posterolateral) usually has two or more minor indentations on its free margin that form scallops. Lack of definition of the major intervalvular commissures has led to disagreement and confusion concerning the territorial extent of this leaflet and the possible existence of accessory scallops. Examination of the valve in the closed position reveals that the mural leaflet may conveniently be regarded as comprising all the valvular tissue posterior to the inferoseptal (anterolateral) and superomedial (posteromedial) ends of the major zone of apposition with the aortic leaflet. Thus defined, it has a wider attachment to the anulus than does the aortic leaflet and guards two-thirds of the circumferential attachments. In most cases indentations usually divide the mural leaflet into

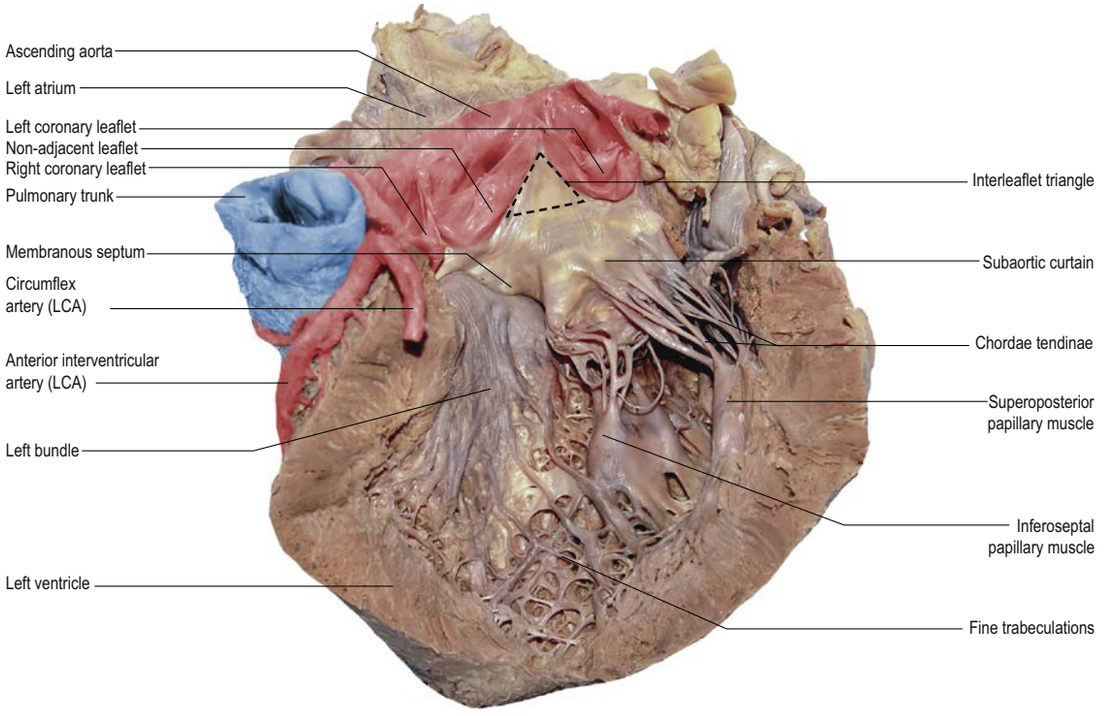

Fig. 57.30 Internal features of the left ventricle, aortic sinus and ascending aorta of a cadaveric heart. Transection of the aorta at the level of the sinutubular junction shows the closed leaflets of the aortic valve and the supporting sinuses named according to the origin of the coronary arteries (left coronary, right coronary and non-adjacent). However, these terms may be ambiguous if the coronary arteries arise in variable locations, whereas the terms of right, left and non-adjacent aortic sinus avoid this issue. Note the inter-leaflet triangles, membranous septum and fibrous continuity between the aorta and mitral valve. Abbreviation: LCA, branch of left coronary artery. (Image courtesy of Professor M Loukas.)

a relatively large middle scallop and smaller lateral and septal commissural scallops. Each scallop has a crescentic opaque rough zone, receiving on its ventricular aspect the attachments of the chordae that define the area of valvular apposition in full closure. From the rough zone to within 2–3 mm of its anular attachment, there is a membranous clear zone devoid of chordae. The basal 2–3 mm is thick and vascular, and receives basal chordae. The ratio of rough to clear zone in the aortic leaflet is 0.6 and in the middle scallop of the mural leaflet is 1.4. Much more of the mural leaflet is in apposition with the aortic leaflet during closure of the mitral valve.

Opening of the mitral valve

At the onset of diastole, opening is passive but rapid, the valvular leaflets parting and projecting into the ventricle as left atrial pressure exceeds left ventricular diastolic pressure (see Fig. 57.20). Passive ventricular filling proceeds as atrial blood pours to the apex, directed by the hanging aortic valvular leaflet. The leaflets begin to float passively together, hingeing on their anular attachments and partially occluding the ventricular inlet. Atrial systole now occurs, forcing blood apically and causing re-opening of the leaflets. As maximal filling is achieved, the leaflets again float rapidly together. Closure is followed by ventricular systole, which starts in the papillary muscles and continues rapidly as a general contraction of the walls and septum.

Mitral valvular chordae tendineae (tendinous cords)

The chordae tendineae of the mitral valve resemble those supporting the tricuspid valve (**Fig. 57.30**; see Fig. 57.29). False chordae are also irregularly distributed as in the right ventricle. They are single or multiple, thin, fibrous or fibromuscular structures that traverse the cavity of the left ventricle and have no connection with the valvular leaflets. They occur commonly in the left ventricle and often cross the subaortic outflow. Histologically, false chordae sometimes contain extensions from the ventricular conducting tissues; these left ventricular bands are often identified on echocardiography. It has been suggested that false chordae produce premature ventricular contractions and may be the cause of functional heart murmurs or innocent murmurs in children and young adults.

True mitral valve chordae may be divided into four types: interleaflet (commissural), rough zone (including the special strut chordae), cleft and basal chordae. Most true chordae divide into branches from a single stem soon after their origin from the apical third of a papillary muscle, or proceed as single chordae that each divide into several branches near their attachment. Basal chordae, in contrast, are solitary structures passing from the ventricular wall to the mural leaflet and are supported by their own miniature papillary muscles. There is such marked variation between the arrangement of the chordae (Gunnal et al 2015) that any detailed classification loses much of its clinical significance. Suffice it to say that, in the majority of hearts, the chordae support the free margins of the valvular leaflets, together with varying degrees of their ventricular aspects and bases, and there is some evidence to suggest that those leaflets with unsupported free edges become prone to prolapse in later life.

Papillary muscles

The two papillary muscles supporting the leaflets of the mitral valve vary in length and width, and may be bifid. The superoposterior muscle arises from the mural myocardium forming part of the anterior cardiac surface, and the inferoseptal muscle from the mural myocardium forming the inferior cardiac surface (see Figs 57.27, 57.28). Chordae tendineae arise mostly from the tip and apical third of each muscle but sometimes take origin near their base. The chordae from each papillary muscle diverge and are attached to corresponding areas of closure (apposition) on both valvular leaflets.

Aortic root

The aortic root, the anatomical bridge between the left ventricle and ascending aorta, consists of the aortic valvular leaflets supported by the aortic sinuses (of Valsalva), and the inter-leaflet triangles interposed between their basal attachments (inserted margin). As such, it is relatively long, but because of the semilunar attachment of the leaflets, it has no discrete proximal border. It is limited distally by the sinutubular junction, which is the only circular or anular structure located within the aortic root (see Figs 57.23, 57.30). The essential feature is the semilunar attachments of the valve leaflets; the lines of their point of hingeing cross the anatomical ventriculoarterial junction, marking a transition from the myocardium of the left ventricle to the fibroelastic tissue of the aortic sinuses (**Fig. 57.31**). The muscular portion of the aortic root is roughly half of its circumference. Descriptions of the aortic root over the years have included erroneous accounts of a valve anulus. Although echocardiographers used to describe this proximal

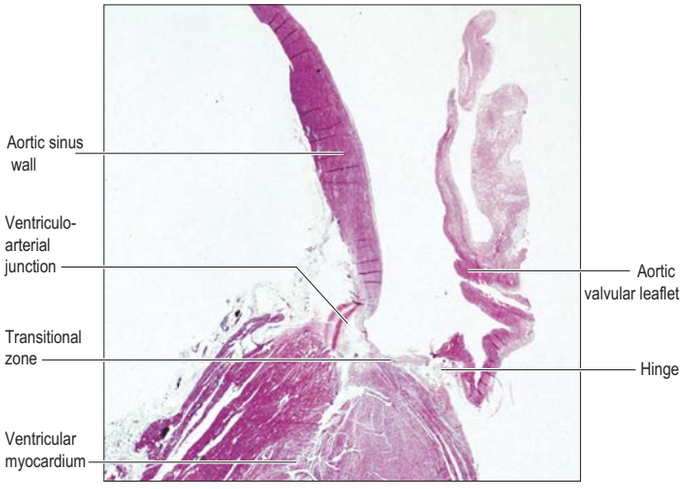

Fig. 57.31 A histological section through an aortic sinus demonstrating ventricular muscle supporting the transition from the fibroelastic wall of the sinus to the tissues of the valvular leaflet. The transitional area is anchored to the ventricular muscle. The hinge of the leaflet is located below the level of the ventriculoarterial junction. Importantly, there is no evidence of a ring-like structure in the form of an anulus supporting the hinge of the leaflet within the ventricle. The muscular tissue of the ventricle is stained pink; fibrous tissue, which would show up as a characteristic light colour with this stain, is absent. Haematoxylin and eosin stain. (Courtesy of Diane E Spicer.)

Coordinated contraction of the papillary muscles increases the tension in the chordae and promotes joining of the corresponding points on opposing leaflets, preventing their eversion. With general mural and septal excitation and contraction, left ventricular pressure increases rapidly. The leaflets 'balloon' towards the atrial cavity, and the atrial aspects of the rough zones come into maximal contact. Precise papillary contraction, and increasing tension in the chordae tendinae, continue to prevent valvular eversion and maintain valvular competence. The orifices and the leaflets of both the left and right atrioventricular valves undergo considerable changes in position, form and area during a cardiac cycle. Both valves move anteriorly and to the left during systole, and reverse their motion in diastole. The mitral valve reduces the area of its orifice (anulus) by as much as 40% during systole; its shape changes from circular to crescentic at the height of systole, the anular attachment of its aortic leaflet being the concavity of the crescent. The attachment of its mural leaflet, although remaining convex, contracts towards the anterior cardiac surface. The smooth left ventricular outflow tract (aortic vestibule) terminates at the leaflets of the aortic valve. Although stronger in construction, the aortic valve resembles the pulmonary valve (see Figs 57.21, 57.23, 57.29) in possessing three semilunar leaflets, supported within the three aortic sinuses (of Valsalva). Although the aortic valve, like the pulmonary valve, is often described as possessing an anulus in continuity with the fibrous skeleton, there is no complete collagenous ring that supports the attachments of the leaflets. As with the pulmonary valve, the anatomy of the aortic valve is dominated by the fibrous semilunar leaflet attachment (see Fig. 57.23C).

border in terms of an anulus, examination of cross-sections of the left ventricular outflow tract has never found any circular anatomical boundary or a distinct boundary of any kind (Loukas et al 2014a). There are at least two rings within the aortic root, attached in semilunar fashion from the sinutubular junction to a basal ventricular attachment, and neither serves to support the aortic valvular leaflets. Two of the leaflets are partially supported by muscle, and the third has an exclusively fibrous attachment. The root acts as a bridging structure not only anatomically, separating the myocardial and arterial parts of the left ventricular pathway, but also functionally because its proximal and distal parts can withstand considerable changes in ventricular and arterial pressures.

Aortic valve leaflets

Three sets of names are used to describe the aortic leaflets. Posterior, right and left refer to their embryonic positions before full cardiac rotation has occurred (Ch. 13). Names based on their approximate positions in maturity are anterior, left posterior and right posterior, respectively. Widespread clinical terminology, which links the leaflets and sinuses to the origins of the coronary arteries, has replaced anterior, left and right posterior leaflets with right coronary, left coronary and non-adjacent (non-coronary) leaflets, respectively. The non-coronary leaflet is more accurately termed the non-adjacent leaflet, since the associated aortic sinus may give rise (rarely) to a coronary artery that is consistently situated adjacent to the root of the pulmonary trunk. These clinical terms are preferable because they are simple and unambiguous.

The aortic valve leaflets are attached in part to the aortic wall and in part to adjacent supporting ventricular structures. The arrangement is more complicated than in the pulmonary valve because parts of the leaflets also take origin from the fibrous subaortic curtain, and are continuous with the aortic leaflet of the mitral valve (see Fig. 57.29). This fibrous area of continuity is thickened at its two ends to form the right and left fibrous trigones (see Figs 57.21, 57.22). The semilunar attachments of the aortic valve incorporate segments of ventricular tissue within the bases of two of the aortic sinuses that give rise to the coronary arteries. The aortic sinuses are named according to the aortic valvular leaflet with which they are associated (see Figs 57.23C, 57.29).

The semilunar attachments incorporate three triangular areas of aortic wall within the apex of the left ventricular outflow tract. They are interposed between the aortic sinuses and separate the cavity of the left ventricle from the pericardial cavity. Removal of the trigones in an otherwise intact heart is instructive in demonstrating the relationships of the aortic valve, which, justifiably, may be considered as the keystone of the heart. The first triangle, between the non-adjacent and left coronary leaflets, has a base continuous inferiorly with the fibrous subaortic curtain (see Figs 57.22, 57.30). The second triangle, between the right coronary and non-adjacent leaflets, has the membranous parts of the interventricular septum as its base. It faces the right ventricle, whereas its apex is directed towards the transverse pericardial sinus posterior to the origin of the right coronary artery. The third triangle, between the left and right coronary leaflets, has its base on the muscular interventricular septum and its apex directed to the plane of the space between the aortic wall and the free-standing sleeve of right ventricular infundibular musculature that supports the leaflets of the pulmonary valve. Although the basal attachments (inserted margins) of each aortic valvular leaflet are thickened and collagenous at their ventricular origins, the leaflets lack a continuous circular collagenous support and valvular function depends primarily upon the semilunar attachments of the leaflets.

The leaflets are endocardial folds with a central fibrous core covered by subendothelial fibroelastic tissue on its aortic and ventricular aspects. With the valve half open, each is equivalent to just greater than one-quarter of a sphere; an approximate hemisphere is completed when this is viewed in conjunction with the corresponding aortic sinus. Each leaflet has a thick basal border that is deeply concave on its aortic aspect, and a horizontal free margin that is only slightly thickened, except at its midpoint, where an aggregation of fibroelastic tissue on the ventricular aspect forms the nodule of the semilunar leaflet (Arantius). The nodule extends bilaterally along the central part of the inferior border of the lunule. The crescent-shaped zone of apposition (lunule), on the ventricular surface of the leaflet, extends along its free edge and up to one-third of its depth (see Fig. 57.29). Parts of the lunule are relatively thin and may be fenestrated, particularly in older adults; fenestrations are inconsequential if located above the line of valve closure. The aortic surface of each leaflet is rougher than its ventricular aspect.

Aortic sinuses (of Valsalva)

The three aortic sinuses (right, left and non-adjacent) are more prominent than those in the pulmonary trunk. The upper limit of each sinus reaches considerably beyond the level of the free border of each aortic valvular leaflet and forms a well-defined circumferential sinutubular ridge on the aortic inner surface, just above the aortic valvular leaflets (see Figs 57.23C, 57.29). Coronary arteries usually open near this ridge within the upper part of the sinus, but may be markedly variable in their origin. The walls of the sinuses are largely collagenous near the attachment of the leaflets but the amount of lamellated elastic tissue increases with distance from the region of attachment. At the midlevel of each sinus, its wall is about half the thickness of the supravalvular aortic wall and less than one-quarter of the thickness of the sinutubular ridge. At this level, the mean luminal diameter at the commencement of the aortic root is much larger than that of the ascending aorta; these details are functionally significant in the mechanism of aortic valvular motion. For example, a linear relationship between the diameter of the aortic sinus and the square root of body surface area has been described in children (Kaiser et al 2008).

Opening of the aortic valve

During diastole, the closed aortic valve supports an aortic column of blood at high but slowly diminishing pressure (see Fig. 57.20). Each sinus and its valvular leaflet form a hemispherical chamber. The three nodules of the semilunar leaflets are apposed and the free margins and lunular parts of the adjacent leaflets are tightly apposed on their ventricular aspects. From the aortic aspect, the closed valve is triradiate, with three pairs of closely compressed lunules radiating from the nodules to their peripheral commissural attachments at the sinutubular junction (see Figs 57.21, 57.29). As ventricular systolic pressure increases, it exceeds aortic pressure and the valve is opened passively.

The fibrous wall of the sinuses nearest the aortic vestibule is almost inextensible but, more superiorly, the wall is fibroelastic. Under left ventricular ejection pressure, the radius of this region increases by about 16% in systole, as the commissures move apart to form a fully open triangular orifice. The free margins of the leaflets then become almost straight lines between their peripheral attachments. However, they do not flatten against the sinus walls, even at maximal systolic pressure, which is probably an important factor in their subsequent closure. During ejection, most blood enters the ascending aorta but some enters the sinuses, forming vortices that help to maintain the triangular mid-position of the leaflet during ventricular systole and also probably initiate their approximation at the end of systole. Tight and full closure occurs with the rapid decrease in ventricular pressure in diastole. Commissures narrow, nodules appose and the valve reassumes its triradiate form. Experiments indicate that 4% of ejected blood regurgitates through a valve with normal aortic sinuses, whereas 23% regurgitates through a valve without them. The normal structure of the aortic sinuses also promotes non-turbulent flow into the coronary arteries.

Echocardiography

Available with the *Gray's Anatomy* e-book

Connective tissue and fibrous skeleton of the heart

From epicardium to endocardium and from the orifices of the great veins to the roots of the arterial trunks, the intercellular spaces between contractile and conduction elements are permeated by connective tissue. The amount of connective tissue varies greatly in arrangement and form in different locations. Most of the fibrous tissue network of the heart is condensed at the atrioventricular junctions. The network assists in anchoring the valve leaflets to the ventricular masses and is crucial for the propagation of electrical conduction because it insulates the atrial chambers from the ventricular mass, other than at the site of the atrioventricular node. Over much of the heart, a fine layer of areolar tissue found beneath the mesothelium of the visceral part of the serous pericardium (epicardium) accumulates subepicardial fat, concentrated along the inferior border (acute margin), the atrioventricular and interventricular sulci, and their side channels. The coronary vessels and their main branches are embedded in this fat; the amount of fat increases with age. The endocardium also lies on a fine areolar tissue rich in elastic fibres. Fibrocellular components of these subepicardial and subendocardial

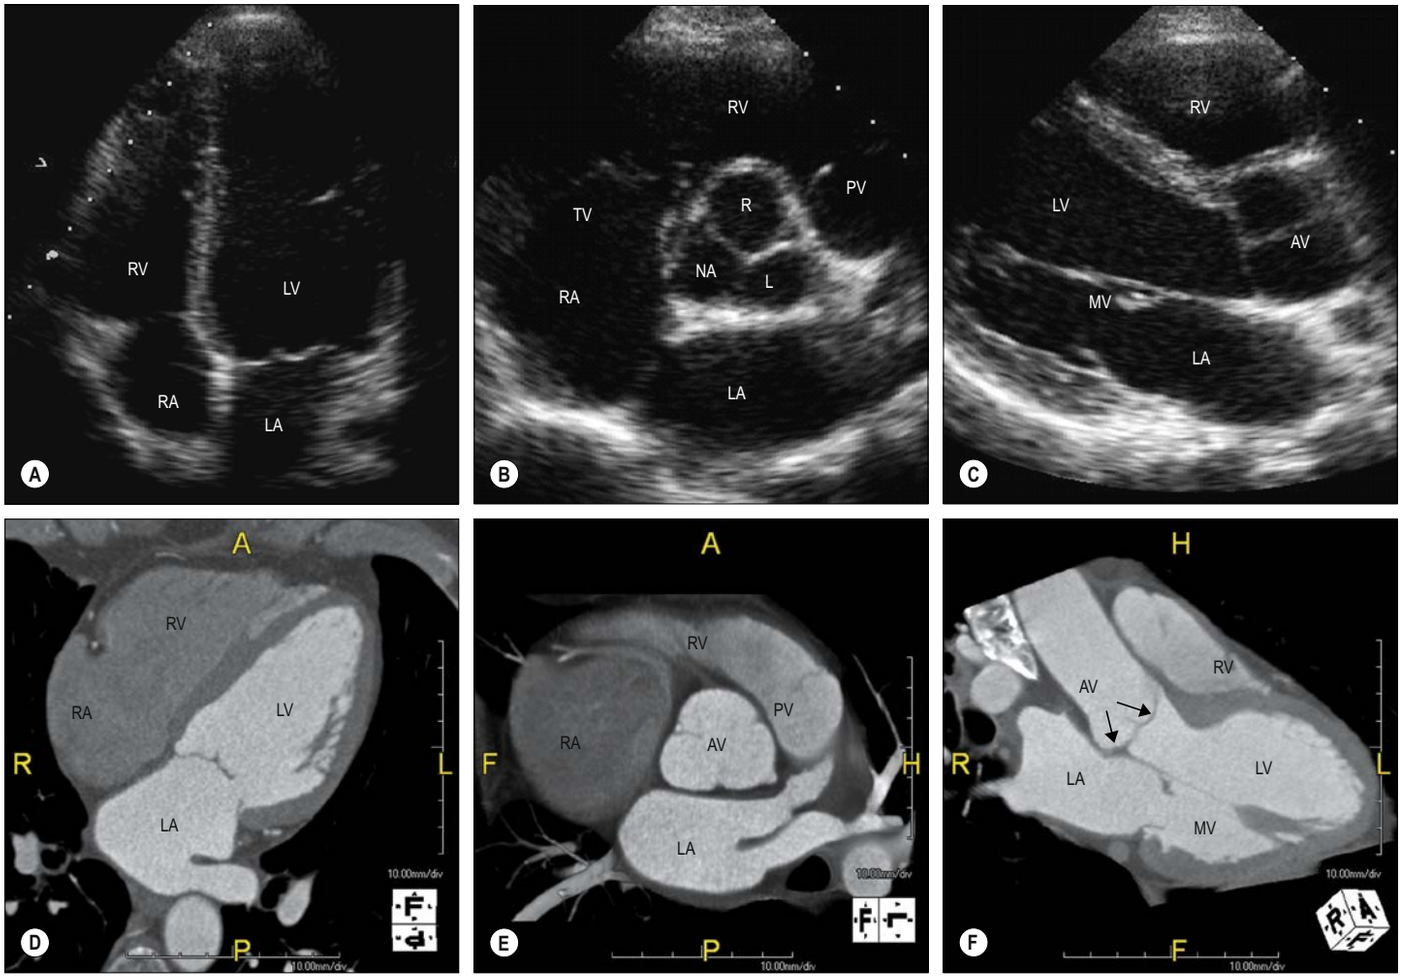

Fig. 57.32 Sectional cardiac anatomy shown by transthoracic echocardiography and CT. **A**, Four-chamber view. **B**, Short-axis view at aortic valve level. Note three aortic valvular leaflets (right, left and non-adjacent) and the central position of the aorta. **C**, Parasternal long-axis view. **D–F**, Corresponding images by CT. Note the different orientation compared with transthoracic echocardiography (looked at from below, foot to head). Abbreviations: A, anterior; AV, aortic valve; F, foot; H, head; L, left; LA, left atrium; LV, left ventricle; MV; mitral valve; NA, non-adjacent; P, posterior; PV, pulmonary valve; R, right; RA, right atrium; RV, right ventricle; TV, tricuspid valve. Echocardiography allows a detailed assessment of the functional anatomy of the heart. The gross anatomy of the heart can be evaluated by two-dimensional echocardiography in the parasternal, apical, suprasternal and subcostal positions (**Fig. 57.32**). The standardized planes used are long-axis, short-axis and four-chamber. The long-axis view is obtained by placing the ultrasound transducer in the left apicosternal position and provides detailed images of the left ventricle, ascending aorta, left atrium, and mitral and aortic valves (Fig. 57.32C). Angling the beam towards the right also allows assessment of the right atrium, right ventricle and tricuspid valves. Rotating the transducer by 90° in the clockwise direction produces the short-axis view, which allows assessment of the left ventricle, papillary muscles, chordae tendineae and mitral valve leaflets (Fig. 57.32B). The four-chamber view demonstrates the ventricles, atria, and mitral and tricuspid valves (Fig. 57.32A). Rotation of the transducer allows two-chamber views of the heart and more detailed assessment of the ascending aorta and aortic valve leaflets. Cardiac MRI and CT provide similar information on cardiac structure and function (see Figs 57.2, 57.35A–B), together with complementary information on great vessels (Fig. 57.32D–F) and other extracardiac intrathoracic structures.

layers blend on their mural aspects with the endomysial and perimysial connective tissue on the myocardium. Each cardiac myocyte is invested by a delicate endomysium composed of fine reticular, collagen and elastin fibres embedded in ground substance. This matrix is lacking only at desmosomal and gap junctional contacts of intercalated discs. Similar arrangements apply to ventricular conduction myocytes and their extensive working myocardial contacts. The connective tissue matrix itself is interconnected laterally to form bundles, strands or sheets of macroscopic proportions showing a complex geometric pattern. Surrounding and attaching to larger myocardial bundles are stronger perimysial condensations. The overall pattern is described in terms of struts and weaves. Despite its importance, the myocardial matrix cannot be grossly dissected.

Running at the ventricular base is a complex framework of dense collagen with membranous, tendinous and fibroareolar extensions, intimately related to atrioventricular valves and the aortic orifice. The structure as a whole is sufficiently distinct to be termed the fibrous skeleton of the heart. Although it is often stated that all four valves are contained within this skeleton, this is not the case. The leaflets of the pulmonary valve are supported on a free-standing sleeve of right ventricular infundibulum (conus arteriosus) that can easily be removed from the heart without disturbing either the fibrous skeleton or the left ventricle. Moreover, the fibrous skeleton of the heart does not incorporate the entirety of the atrioventricular and arterial anuli. Much of the insulation between the atrial and ventricular chambers is provided by the fibroadipose tissues within the atrioventricular sulci. There is some collagenous tissue in the mitral valvular anulus, but it is not always continuous with the fibrous structure. The tricuspid valvular anulus is almost exclusively composed of fibroadipose tissue. The only true fibrous part of the tricuspid anulus is where the valvular leaflets are attached to the central fibrous body (Saremi et al 2017). Another point of confusion is the idea that the fibrous skeleton provides the support for the cardiac valves. In reality, it is the overall structure of the atrioventricular junctions that supports the mitral and tricuspid valves, whereas the arterial valves are hinged within the valvular sinuses. The fibrous skeleton is strongest at the central fibrous body, which is the junction of the aortic, mitral and tricuspid valves (see Figs 57.21–57.22). Two pairs of curved, tapering, collagenous, fila coronaria extend from the central fibrous body. They are stronger on the left, where they pass partially around the mitral and tricuspid orifices. These orifices are almost co-planar and incline to face the cardiac apex. In contrast, the aortic valve faces superiorly, lying anterosuperior and to the right of the mitral orifice. Two of the leaflets of the aortic valve (left coronary and non-adjacent) are in fibrous continuity with the aortic leaflet of the mitral valve; this subaortic curtain is also an integral part of the fibrous skeleton (see Figs 57.21–57.23C). The two ends of the fibrous curtain are strengthened as the right and left fibrous trigones, which are the strongest parts of the skeleton. The right trigone and the membranous septum constitute the central fibrous body, which is penetrated by the atrioventricular bundle (His). The membranous septum is crossed on its right aspect by the attachment of the tricuspid valve leaflets, dividing the septum into atrioventricular and interventricular parts.

The aortic root is central within the fibrous skeleton and is often described in terms of an anulus integrated within the fibrous skeleton (Anderson et al 2013). However, as with the pulmonary valve, the structure of the aortic root corresponds to the triple fibrous semilunar attachments of its valvular leaflets. Within this complex circumferential zone, three crucially important triangular areas separate, on the ventricular aspect, the aortic sinuses that house the valvular leaflets (see Fig. 57.23). Collectively, the three interleaflet triangles can be conceptualized in terms of a three-pointed coronet; their triangular apices correspond to the tips of the valvular commissures and their walls, significantly thinner than those of the aortic sinuses, consist variously of collagen or admixed muscle strands and fibroelastic tissue. They form the subvalvular extensions of the aortic vestibule. The first triangle is the interval between the non-adjacent and left coronary sinuses/leaflets that is filled with the deformable subaortic curtain. The second triangle between the non-adjacent and right coronary sinuses/leaflets is continuous with the anterior surface of the membranous septum. The third triangle, between the two coronary aortic sinuses/leaflets, is filled with loose fibroelastic tissue and separates the extension of the subaortic root from the wall of the free-standing subpulmonary infundibulum. The pulmonary valve possesses no fibrous continuity with the other three valves; however, in few cases a small fibrous band, known as the tendon of the conus, extends between the aortic and pulmonary valvar sinuses (Saremi et al 2017). Previously this was thought to be the location of the tendon of the infundibulum (conal ligament) (Loukas et al 2007); in mouse hearts, the ligament is found at the level of the sinutubular junctions at the site of initial fusion of the distal outflow cushions. The line of proximal fusion is the longitudinal raphe sometimes seen in the muscular subpulmonary infundibulum.

Similar fibrous triangles separate the sinuses of the pulmonary trunk but they are significantly less robust. Use of the terms mitral and tricuspid anuli implies that the atrioventricular valves are supported by discrete circular fibrous rings, when, in reality, the valves are D-shaped structures integrally attached at the atrioventricular junctions. It is therefore inaccurate to consider these valvular orifices as circular. Rather, the straight edge of the 'D'-shaped mitral valve represents a fibrous continuity between the aortic leaflet and the aortic root, and the remainder supports the mural leaflet. The straight edge of the 'D'-shaped tricuspid valve represents the attachment of the septal leaflet, marking the inferior border of the triangle of Koch, and the remainder supports the anterosuperior and inferior leaflets. The attachments of the atrioventricular valves are not simple, rigid collagenous structures but dynamic, deformable lines that vary greatly at different peripheral points and change considerably with each phase of the cardiac cycle, and with increasing age. The tricuspid valvular leaflet attachments are even less robust than those of the mitral valve. At several sites, only fibroareolar tissue separates the atrial and ventricular muscular masses.

The fibroadipose tissue of the fibrous skeleton provides electrical insulation between the atrial and ventricular walls, ensuring electrophysiological discontinuity between the atrial and ventricular myocardial masses, with the atrioventricular conduction axis being the only muscular structure crossing the plane of insulation (Saremi et al 2017). It also provides direct attachment for the myocardium and for fibrous tissue throughout the heart as a support matrix for a three-dimensional meshwork of cardiomyocytes.

Congenital cardiac malformations

Congenital malformations of the heart are common and amount to about 25% of all congenital anomalies. Their incidence is estimated at 8 per 1000 live births, however, they are found in up to 2% of stillbirths. Only a small proportion of the anomalies are directly attributable to genetic or environmental factors and the majority are the result of multifactorial events.

Conduction tissues

The cells of cardiac muscle differ from those of skeletal muscle in having the inherent ability to contract and relax spontaneously. This myogenic rhythm is shown by small pieces of cardiac tissue, and even isolated myocytes. Ventricular cells contract and relax at a lower frequency than atrial cells, but in the intact heart, both are synchronized to a more rapid rhythm, generated by pacemaker tissue in the sinuatrial and atrioventricular nodes and conveyed by a system of specialist conduction fibres in the atrioventricular conduction axis and the ventricular conducting pathways (Purkinje cells). For an account of excitation–contraction coupling in cardiac muscle, see Chapter 6.

The anatomical arrangement of these tissues is described in the context of the heart. Here, consideration is restricted to the cells that make up the impulse-generating and conduction system. All are modified cardiac cells. Three types within a continuum of morphology may be distinguished from normal working cells: nodal cells, transitional cells and Purkinje cardiomyocytes.

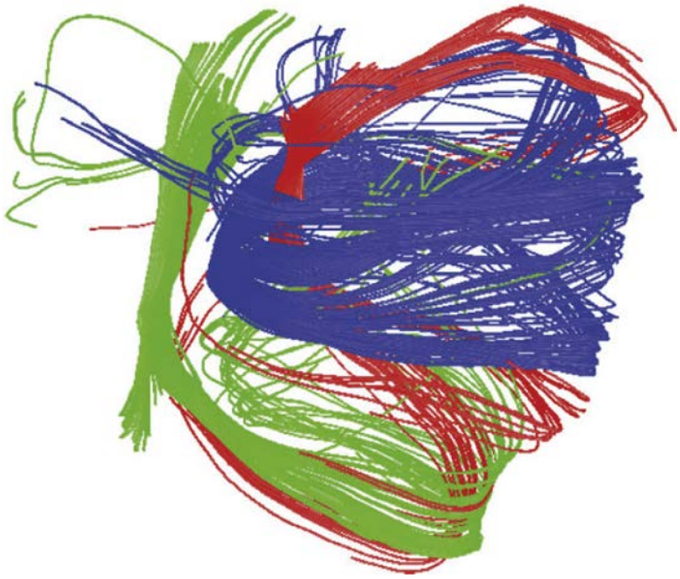

Fig. 57.33 Myocyte alignment in a cadaveric porcine heart acquired via diffusion tensor MRI and subsequent reconstruction. The tracks are created from the first eigenvectors and represent the alignment of the aggregated myocytes. This technique enables the identification of reproducible tracks, or pathways, through the myocardium that connect remote end and epicardial regions by means of simultaneous changes in helical and intrusion angles. (With permission from Anderson R, Smerup M, Sanchez-Quintana D et al 2009 The three-dimensional arrangement of the myocytes in the ventricular walls. Clin Anat 22:64–76.)

The microstructure of cardiac muscle is described in detail in Chapter 6. Diffusion tensor imaging, as well as microcomputed tomography, demonstrates the three-dimensional mesh of ventricular myocytes within a supporting matrix of fibrous tissue (Anderson et al 2018). One population is aligned so that the long axis of the aggregated cells is tangential to the epicardial and endocardial borders, albeit with marked variation in the angulation relative to the ventricular equator. Correlation with measurements taken using force probes shows that these myocytes produce the major unloading of the blood during ventricular systole. A second population is aligned at angles of up to 40° from the epicardium towards the endocardium and produces auxotonic forces during the cardiac cycle. Up to 40% of the cardiomyocyte chains in the ventricle are found to have a partially transmural alignment, which deviates from the prevailing tangential orientation of cardiomyocytes within the ventricles (Lunkenheimer et al 2018). The three-dimensional arrangement of the mesh as demonstrated in MRI of the porcine heart also mediates the realignment of cardiomyocytes that must take place during ventricular contraction and accounts for the extent of systolic mural thickening (Fig. 57.33).

The finding that the number of cardiomyocytes in the left ventricle increases between the first and the twentieth year of life suggests that children may be able to regenerate myocardium (Mollova et al 2013).

The most severe positional anomaly is an extrathoracic heart (ectopia cordis), where the heart usually projects to the surface through the lower thoracic and upper abdominal wall, remaining covered, in most instances, by the fibrous pericardium, and usually accompanied by herniation of the abdominal contents. A reversal in cardiac shape and position (mirror image) occurs predominantly in the right hemithorax (dextroposition). The cardiac apex may be directed to the right instead of the left (dextrocardia); this arrangement may be part of situs inversus, in which the heart, great vessels and thoraco-abdominal organs all occupy mirror-imaged positions. The heart may also be right-sided in Kartagener's syndrome (a subgroup of ciliary dyskinesias).

More usually, an abnormal location of the heart occurs in cases of isomerism, in which both sides of the thorax, including the main bronchi and the atrial auricles, retain features of either morphological right- or left-sidedness. Isomerism is also commonly associated with the anomalous arrangement of the abdominal organs: right isomerism with absence of the spleen (asplenia) and left isomerism with multiple spleens (polysplenia). Intracardiac anatomy in cases of isomerism is almost universally abnormal, and there are a range of heart defects (usually simpler in left and more complex in right isomerism).

These intrathoracic abnormal arrangements, with or without abdominal anomalies, often first manifest themselves incidentally following chest radiography. Reversal of normal anatomy has obvious clinical implications, a typical example being a patient with mirror-image arrangements and appendicitis, who presents with an acute left lower quadrant pain.

Most congenital heart anomalies can be detected during antenatal ultrasound screening (Fig. 57.34). Neonates with severe congenital heart disease may present with tachypnoea, difficulty in feeding, cyanosis and/or cardiovascular collapse, and there may be audible murmurs on auscultation. The vast majority of anomalies may be detected by postnatal echocardiography; in a very few cases, cardiac catheterization and direct measurements of pressure, oxygen saturations and angiography may be required.

Acyanotic cardiac defects are the result of either left-to-right cardiac shunting through heart defects (intra- or extracardiac) or of obstruction. Left-to-right shunting leads to an increased workload and stress on the heart and the lungs as a consequence of increased pulmonary blood flow and increased pulmonary venous return. Depending on the location of the shunt and the magnitude of left-to-right shunting, patients are at risk of developing pulmonary arterial hypertension unless timely corrective surgery is undertaken. Examples of defects leading to left-to-right shunting are simple atrial or ventricular septal defects or patent ductus arteriosus, or more complex atrioventricular septal defects, and/or a combination of any of these defects with abnormal atrioventricular or ventriculoarterial connections (e.g. a double-outlet right ventricle, where more than 50% of both the ascending aorta and the pulmonary trunk originate from the right ventricle). Obstructive lesions may involve the atrioventricular or arterial valves (e.g., stenosis), or narrow vessels (e.g., coarctation of the aorta or interrupted aortic arch). Depending on the level and severity of the obstruction, clinical presentations range from an asymptomatic heart murmur (common) to cardiovascular collapse (uncommon). Treatment in all cases is directed towards normalizing heart workload, systemic and pulmonary blood flow and cardiac output, and may be surgical and/or catheter-based.

Cyanotic cardiac defects may be attributable to a right-to-left intra- or extracardiac shunt or to a severe reduction in pulmonary blood flow. They may be caused by simple lesions such as severe pulmonary stenosis with an atrial septal defect and right-to-left shunting; Ebstein's malformation; moderate lesions, including Fallot's tetralogy, in which there is a ventricular septal defect, right ventricular outflow obstruction, right ventricular hypertrophy and an overriding aorta (the ascending aorta sits over an interventricular septal defect); or more complex lesions, including transposition of the great arteries (Fig. 57.35; Chs 13, 58), common arterial trunk and tricuspid and pulmonary atresia (often in the setting of hypoplastic right ventricle and functionally univentricular physiology). Totally anomalous pulmonary venous connection also results in cyanosis. Neonates with severe cyanotic congenital heart defects may be dependent on the patency of the ductus arteriosus; early diagnosis, treatment with intravenous prostaglandin infusion to delay ductus arteriosus closure and timely transfer to a tertiary centre for more definitive therapy is key to survival and good long-term outcomes. Major advances in the diagnosis and management of infants with congenital cardiac malformations in recent years have resulted in an increased number of adolescents and adults with palliated or repaired, but not cured, congenital heart disease. This is an area that poses multiple challenges to both cardiovascular and other medical disciplines.

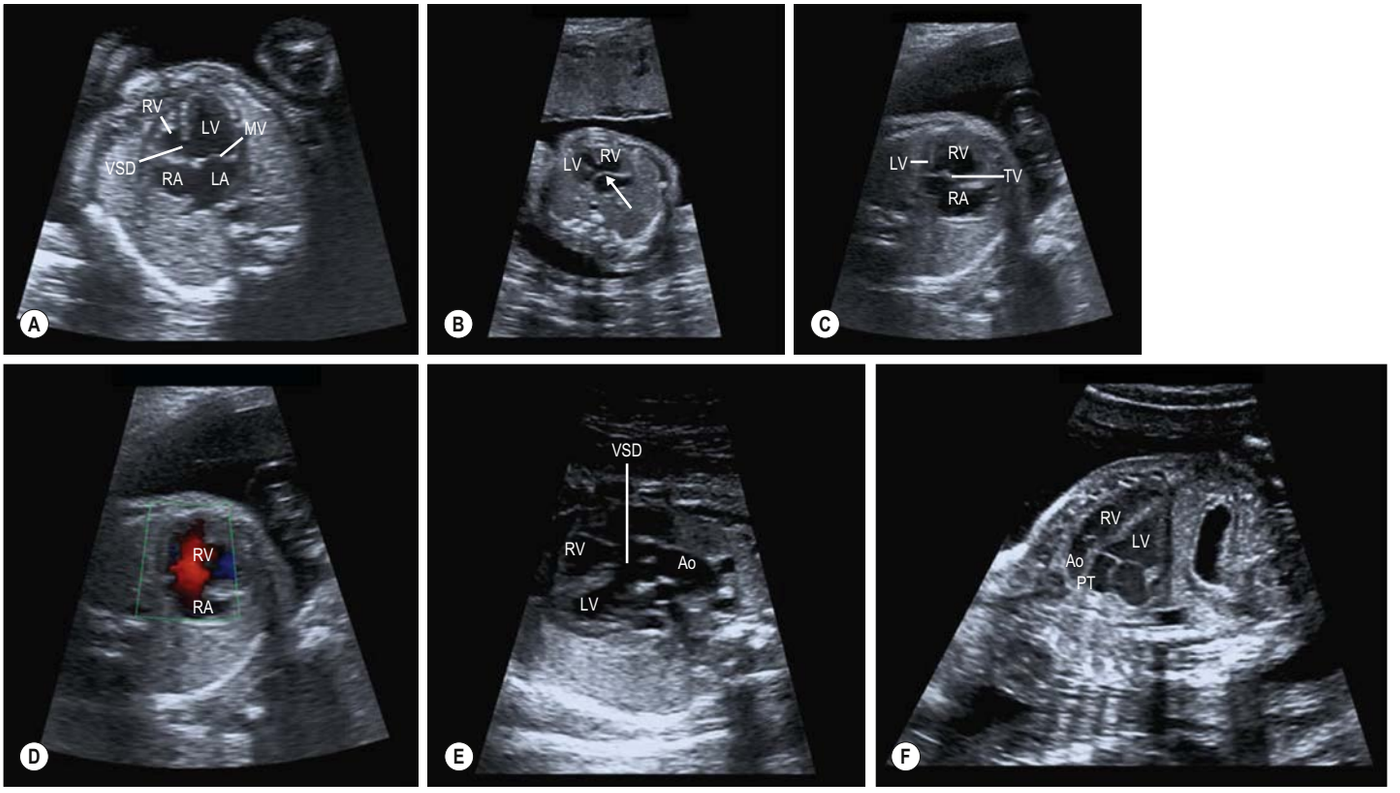

Fig. 57.34 Ultrasound imaging of fetal cardiac defects. **A**, Tricuspid atresia (postmenstrual week 21). A four-chamber view showing a large left ventricle and a hypoplastic right ventricle. The mitral valve is seen; no tricuspid valve is identified. There is an associated ventricular septal defect. **B**, An atrioventricular septal defect (postmenstrual week 20). A common atrioventricular valve (arrow) is associated with a defect in the atrioventricular septum. **C**, Hypoplastic left heart syndrome (postmenstrual week 32). This four-chamber view shows a large right atrium, right ventricle and tricuspid valve. There is a hypoplastic left ventricle; no mitral valve is identified. **D**, Hypoplastic left heart syndrome (postmenstrual week 32). This four-chamber view shows colour flow from right atrium to right ventricle across the tricuspid valve; no mitral valve is identified and there is no flow in the left side of the heart. **E**, Tetralogy of Fallot (postmenstrual week 33). The ascending aorta sits over (overrides) a ventricular septal defect. **F**, Transposition of the great arteries (vessels) (postmenstrual week 21). The ascending aorta and pulmonary trunk arise from the right ventricle and left ventricle, respectively, in a parallel orientation. Abbreviations: Ao, ascending aorta; LA, left atrium; LV, left ventricle; MV, mitral valve; PT, pulmonary trunk; RA, right atrium; RV, right ventricle; TV, tricuspid valve; VSD, ventricular septal defect. (Courtesy of Gurleen Sharland, Evelina London Children's Hospital.)

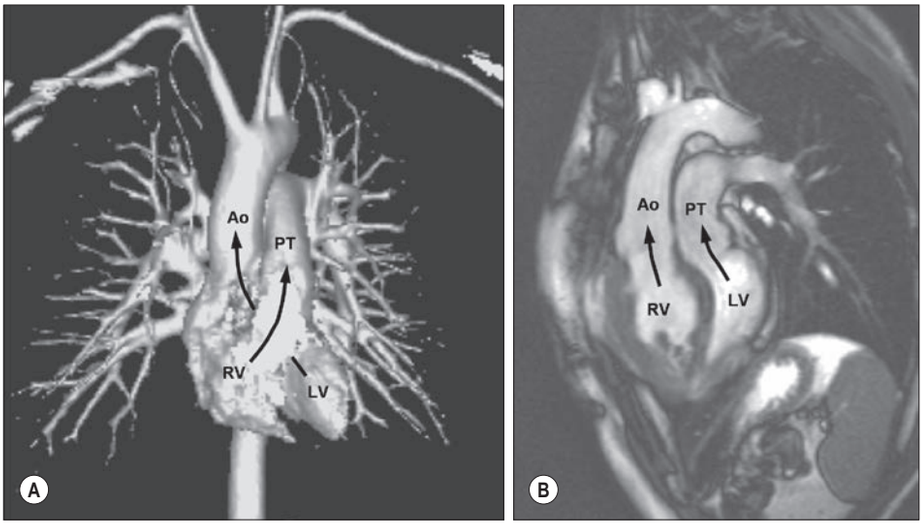

Fig. 57.35 Cardiac magnetic resonance angiography of a normal heart and a heart with transposition of the great vessels. **A**, Patient with a normal heart. Note the crossed relationship of the great arteries; the aorta arises from the left ventricle and runs to the right and posterior to the pulmonary trunk (at its origin) and towards the head. The pulmonary trunk arises from the right ventricle, anterior to the ascending aorta (at its origin), and crosses over and then runs to the left of the ascending aorta and then posteriorly towards the back (where it bifurcates into the right and left pulmonary arteries at the inferior surface (concavity) of the aortic arch). **B**, Patient with transposition of the great vessels (arteries). Note the parallel or side-by-side relationship of the great vessels and loss of their normal crossed relationship. The aorta runs anteriorly and arises from the right ventricle. The hypertrophied right ventricle supports the systemic circulation, and the ventricular septum bows from right to left. Abbreviations: Ao, ascending aorta; LV, left ventricle; PT, pulmonary trunk; RV, right ventricle. (Courtesy of Dr Philip Kilner, Royal Brompton Hospital, London.)

Overview of the conduction system

Of all the cells in the heart, those of the sinuatrial node generate the most rapid rhythm, and therefore function as the cardiac pacemaker. The impulse, believed to be generated in the nodal cells, is transmitted over preferentially conducting pathways to right and left atria, and to the atrioventricular node. At the atrioventricular node, the impulse is delayed by 40 ms, allowing the atria to eject their contents fully before commencement of ventricular contraction, and also placing an upper limit on the frequency of signals that can be transmitted to the ventricles. The transitional cells interpose between the atrial cardiomyocytes and the nodal cells. There is no transition in humans between the node and the penetrating bundle, and the cells are virtually identical. Here they become continuous with cells of the ventricular system. Often described as Purkinje cells, these cells in the human heart are barely larger than working ventricular cardiomyocytes. Conduction of the impulse is rapid in the bundle and its branches (2–3 m/s, compared to 0.6 m/s in normal myocardium). The cardiac impulse therefore arrives at the cardiac apex before spreading through the ventricular walls, producing a properly coordinated ventricular ejection. The human heart beats ceaselessly at an average of 70 cycles every minute for many decades, maintaining perfusion of pulmonary and systemic tissues. The rate and stroke volume fluctuate in response to prevailing physiological demands. The principal events in a cardiac cycle (valvular, phonocardiogram, electrocardiogram, pressure and mechanical) are summarized in Fig. 57.20.

Cardiac efficiency depends on precise timing of the operation in interdependent structures. Passive diastolic filling of the atria and ventricles is followed by atrial systole, stimulated by discharge from the sinuatrial node, which completes ventricular filling. Excitation and contraction of the atria must be synchronous and finish before ventricular contraction; this is effected by a delay in the conduction of excitation from atria to ventricles. Thereafter, ventricular contraction proceeds in a precise manner. The atrioventricular valves are closed by ventricular systole, which must occur prior to closure; ventricular activation must therefore precede valvular closure, which spreads from the ventricular apices towards the outflow tracts and orifices.

Cardiac contraction originates unequivocally in specialized cardiomyocytes, but neural influences are important in adapting the intrinsic cardiac rhythm to functional demands from the entire body. All cardiomyocytes are excitable. They display autonomous rhythmic depolarization and repolarization of their cell membranes, conduction of waves of excitation via gap junctions to adjacent cardiomyocytes, and excitation–contraction coupling to their actomyosin complexes. These properties are developed to different degrees in different sites and in different types of cardiomyocyte (Ch. 6). The rate of depolarization and repolarization is slowest in the ventricular myocardium, intermediate in the atrial muscle, and fastest in the myocytes of the sinuatrial node. The latter override those generating slower rhythms and, in the normal heart, are the locus for the rhythmic initiation of cardiac cycles. Conversely, conduction velocity is slow in nodal myocytes, intermediate in the general population of working cardiac myocytes, and fastest in the myocytes of the ventricular conduction system.

The nodes and networks of the specialized myocardial cells constitute the cardiac conduction system (see Fig. 57.18B; **Figs 57.36–57.37**). The parts of this system are the sinuatrial and atrioventricular nodes, the atrioventricular bundle with its left and right bundle branches, and the subendocardial plexus of ventricular conduction cells (Purkinje cells). The main pacemaker rhythm of the heart (sinus rhythm) is generated within the system but is influenced by autonomic nerves. It is transmitted specifically from atria to ventricles via the atrioventricular node and bundle. The spread of excitation is very rapid but not instantaneous. Different parts of the ventricles are excited at slightly different times, with important functional consequences. Failure of the conduction system will not block cardiac contraction but the system will become poorly coordinated. The rhythm will be slower because it originates from a spontaneous (myogenic) activity in the working cardiac myocytes or in a subsidiary pacemaker

in a more distal part of the diseased or disrupted conduction system. There are no specialized internodal and interatrial conduction pathways; the excitation emanating from the sinuatrial node spreads to the atrial musculature and to the atrioventricular node through ordinary working atrial myocardium. The geometric arrangement of fibres along well-organized atrial muscle bundles (e.g., the terminal crest, the limbus of the fossa ovalis and the interatrial (Bachmann's) bundle) provide a pathway for a marginally more rapid conduction than elsewhere within the atrium.

Sinuatrial node

In the majority of hearts, the sinuatrial node is a cigar-shaped structure, 8–25 mm long, located in the right atrium at the junction between the embryonic sinus venosus (venous) part and the primitive (proper) atrial part (see Figs 57.13, 57.37). In hearts over 65 years of age, a layer of connective or fatty tissue between the subendocardium and the body of the node may sometimes render it visible macroscopically. Extending on the right from the crest of the right auricle, the node typically courses posteroinferiorly into the upper part of the sulcus terminalis; in about 10% of hearts it extends in horseshoe fashion across the crest of the auricle. Nodal tissue does not occupy the full thickness of the right atrial wall from epicardium to endocardium, but is as a wedge of specialized subepicardial tissue within the sulcus terminalis. Its location is consistently marked by a large central artery originating equally from either the proximal part of the right coronary artery or the circumflex branch of the left coronary artery. Nodal cells are grouped circumferentially around the sinuatrial nodal artery, packed within a dense matrix of connective tissue as interlacing strands of myocytes. Histologically they are smaller, paler and more empty-looking than working atrial myocardial cells, being 5–10 μm in their greatest diameter, with a large central nucleus. Their pale appearance is attributable to the sparsity of organelles; myofibrils are few and irregularly arranged, and there is no proper sarcotubular system with little glycogen.

The sinuatrial node is described as having a head, body and tail, from which 5–8 short digitations of nodal tissue radiate towards the superior vena cava, subepicardium and crista terminalis, penetrating the working atrial myocardium (**Figs 57.38–57.39**). At the nodal periphery, nodal cells intermingle with slender, fusiform, transitional linking cells that are part of a heterogeneous cellular group intermediate in appearance between nodal cells and normal working atrial myocytes. The extent of nodal tissue can be mapped using molecular markers (Monfredi et al 2010). There are no autonomic ganglion cells within the node, although many border it anteriorly and posteriorly. Nerve fibres are present but do not appear to contact the nodal myocytes.

Paranodal area

A paranodal area within the crista terminalis, between the cells of the sinuatrial node and the working atrial cardiomyocytes, and possessing properties of both nodal and atrial tissues, has been identified (Molenaar et al 2011). Its precise function remains to be determined, but computer simulations suggest that it is an integral part of normal atrial activation and may play a role in pacemaking.

Internodal atrial myocardium

Specialized pathways have been alleged to connect the sinuatrial and atrioventricular nodes, but there is no evidence that tracts insulated from the working myocardium, as occurs in the ventricular conduction pathways, exist within the atrial walls. The impulse generated by the sinuatrial node is conducted more rapidly via the long axis of the atrial muscle bundles than it is transversely. The main pathways for conduction towards the atrioventricular node are the crista terminalis and the limbus of the fossa ovalis. Conduction to the left atrium is preferentially through the interatrial (Bachmann's) bundle; additional pathways occur through the limbus of the fossa ovalis and through the muscular connections between the walls of the coronary sinus and left atrium. During development, the walls of the sinus venosus (systemic venous part) are exclusively composed of primary myocardium. Although pathways within these walls may be identified in prenatal stages, primary myocardium is slowly conducting, which means that these pathways do not represent areas of preferentially rapid conduction.

Atrioventricular node

The atrioventricular node is an oblique, half-oval atrial structure, located within the atrial part of the muscular atrioventricular septum and separated from the ventricular musculature by the insulating tissues of the atrioventricular (coronary) sulcus (see Figs 57.18B, 57.21–57.22). Its anatomical landmarks are the boundaries of the triangle of Koch, specifically; the attachment of the septal leaflet of the tricuspid valve, the opening of the coronary sinus and the tendon of Todaro (inferior pyramidal space). The atrial aspect of the node is convex and overlain by atrial myocardium. Its left margin is concave and abuts on to the superior aspect of the central fibrous body. The basal end projects into the atrial muscle and the anteroinferior end enters the central fibrous body to become the penetrating atrioventricular bundle.

The node consists of both compact and transitional zones pervaded by an irregular collagenous reticulum that enmeshes the myocytes (**Fig. 57.40**). The compact zone consists of frequently stratified, interlocking nodal cells. Cells from the right and left atrial walls and the interatrial septum feed directly into the compact zone. The transitional zone envelops the compact portion of the node and consists of elongated transitional cells, intermediate in morphology and function between compact nodal cells and working atrial cardiomyocytes.

Extensions of nodal cardiomyocytes run in the direction of the coronary sinus along the tricuspid anulus (the putative slow pathway); in the anterior portion of the triangle of Koch near the compact portion of the atrioventricular node (the putative fast pathway); and in the direction of the mitral anulus (the left atrial extension) (Mani and Pavri 2014). In both sinuatrial and atrioventricular nodes, the intercellular contacts between nodal cells, and between nodal and transitional cells, are much less specialized than the intercalated discs between normal cardiac cells (Ch. 6). A sparsity of gap junctions is consistent with the absence from these areas of connexin-43 (a major protein component of mammalian gap junctions), and probably accounts for the observed difficulty in exciting these cells via adjacent cells. The atrioventricular delay may owe much to this relative non-excitability, which appears to disturb the spread of potential thereby delaying propagation; the narrow diameter of the transitional cells may also contribute to conduction delay.

The arterial supply to the atrioventricular node is from a characteristic vessel that originates from the dominant coronary artery at the cardiac crux. Autonomic ganglia are present between the node and the coronary sinus.

Atrioventricular bundle

The atrioventricular bundle (of His) is the direct continuation of the atrioventricular node and becomes oval, quadrangular or triangular in transverse sectional profile as it enters the central fibrous body (see Figs 57.18B, 57.36). It traverses the central fibrous body and branches into right and left bundles on the crest of the muscular interventricular septum; the branching tract is sandwiched between the muscular and the membranous parts of the septum.

The right bundle is a narrow, discrete, rounded group of fascicles that courses at first within the myocardium and then subendocardially towards the ventricular apex, entering the septomarginal trabeculation to reach the anterior papillary muscle. It has few branches to the ventricular walls in its septal course. At the origin of the anterior papillary muscle, it divides extensively into fine subendocardial fascicles that diverge, first embracing the papillary muscle, then recurving subendocardially for distribution to the remaining ventricular walls.

The left bundle and its subdivision show variability in position, size and structure (Cabrera et al 2020). The bundle commonly arises as numerous fine, intermingling fascicles that leave the left margin of the branching bundle through most of its course along the crest of the muscular interventricular septum, where it meets the membranous part of the septum. These fascicles form a flattened sheet down the smooth left ventricular septal surface that diverges apically and subendocardially across the left ventricular aspect of the interventricular septum, commonly (although not always) trifurcating into anterior, septal and posterior divisions (see Figs 57.23C, 57.30). Fine branches leave the sheets, forming subendocardial networks, which first surround the papillary muscles and then curve back subendocardially to be distributed to all parts of the ventricle. The principal branches of the bundle are insulated from the surrounding myocardium by sheaths of connective tissue.

Functional contacts between conduction and working ventricular myocytes become numerous only in the subendocardial terminal ramifications. Hence, papillary muscles contract first, followed by a wave of excitation and an ensuing contraction that travels from the apex of the ventricle to the arterial outflow tract. Because the network of conducting branches is subendocardial, muscular excitation proceeds from endocardium to epicardium.

Immunohistochemical staining of the developing heart indicates that the precursors of the atrioventricular conduction system arise from a ring of slow conducting primary myocardium within the atrioventricular junction and outflow tracts (see Fig. 13.11). The definitive atrioventricular node forms in the dorsal part of the interventricular ring and is continuous with the first part of the atrioventricular bundle; the segment of the interventricular ring that encircles the developing left ventricular outflow tract involutes. As the ventricles grow and expand on each side of the muscular ventricular septum, cells on the dorsal part of the crest and on the luminal surface of the septum differentiate into the fast-conducting Purkinje fibres and bundle branches of the atrioventricular bundle. The ventral parts largely disappear, the persisting segment within the ventricles extends along the septum beyond the branching atrioventricular bundle and forms a dead-end tract.

Wolff–Parkinson–White syndrome is caused by abnormal small strands of otherwise unremarkable ventricular myocardium that run through the insulating fibroareolar tissue of the atrioventricular sulcus, connecting the atrial and ventricular myocardial masses at some point around the atrioventricular junctions.

Temporary pacing wires are usually inserted by cannulation of either the internal jugular or subclavian veins; the latter approach carries a slightly greater risk of a pneumothorax because of the proximity of the pleural membranes, pleural cavity and lung. Other potential risks are brachial plexus injury if the entry site is too posterior, and thoracic duct injury if the left subclavian vein is cannulated. The most common location for permanent pacemaker devices is subcutaneously on the anterior thoracic wall. Access to the chambers and endocardium of the right heart is gained via the cephalic vein within the deltopectoral groove.

Intracardiac electrocardiography and electrophysiology are used to assess cardiac conduction and rhythm abnormalities. A catheter is inserted via the femoral, subclavian or internal jugular veins using a guidewire technique. Fluoroscopy, echocardiography and, more recently, cardiac magnetic resonance are used to guide accurate placement of the catheters to the appropriate position. The sites of study are the high right atrium (for assessing the atrioventricular bundle and right bundle branch) and the coronary sinus (for evaluating atrioventricular junctional arrhythmias and accessory pathways). The multipolar electrodes provide detailed electro-anatomical mapping of the sequence of excitation from the atria, atrioventricular junction and ventricles. The origin of supraventricular arrhythmias, ventricular tachycardias, accessory conduction pathways and re-entrant pathways can be identified and used to guide radiofrequency ablation.

In the past, there was an anatomical basis for the majority of presenting congenital conduction abnormalities: they were the product of either accessory pathways or conduction tissue dysgenesis at any point from the atrioventricular node to the atrioventricular bundle. Today, conduction abnormalities are increasingly likely to relate to long-standing haemodynamic problems and/or the effects of previous surgery for patients with congenital heart defects. This reflects the fact that, although surgery for most of these defects has been available for the past four decades, surgery itself has not been curative; more often than not, patients develop conduction abnormalities and arrhythmia from surgical scars that cause haemodynamic problems such as chamber dilation and/or hypertrophy. Occasionally, conduction abnormalities are caused by tumours such as multifocal Purkinje cell tumours, or benign congenital polycystic tumours of the atrioventricular node.

Vascular supply and lymphatic drainage

Coronary arteries

The right coronary artery arises from the right aortic sinus and the left coronary artery from the left aortic sinus of the proximal ascending aorta (see Figs 57.21, 57.23; **Fig. 57.41**); the level of the opening of each artery is variable. The two arteries form an oblique inverted crown (hence their name) within the atrioventricular sulcus. They also form a variable and often insignificant anastomosis (in the non-pathological state) via marginal and interventricular loops that intersect at the cardiac apex. The main arteries and major branches are usually subepicardial, but those in the atrioventricular and interventricular sulci are often deeply sited, and occasionally hidden by or embedded in overlapping myocardium (myocardial bridging) (see Fig. 57.53). The left or right coronary artery is classed as being dominant if it gives off the inferior interventricular branch, which supplies the inferior part of the ventricular septum and often part of the inferolateral wall of the left ventricle. The right coronary artery is dominant in around 60% of hearts. Anastomoses between right and left coronary arteries are abundant in the fetus but are much reduced by one year of age. Anastomoses providing collateral circulation may become prominent in conditions of chronic hypoxia and in coronary artery disease. An additional collateral circulation is provided by small branches from mediastinal, pericardial and bronchial vessels.

Normal coronary arterial calibre, based on arterial casts or angiogram measurements, ranges between 1.5 and 5.5 mm. The calibre of the left origin exceeds the right in 60% of hearts, the right being larger in 17%, and both vessels being of approximately equal calibre in 23%. The external diameter of the left coronary artery increases from 2.1 mm at the age of 1 year to 3.3 mm at the age of 15 years (Pesonen et al 1991) and the diameters of the coronary arteries may increase up to the 30th year. A significant association has been found between the diameters of the right and left coronary arteries at 0 (birth), 1 and 6 months of age and birth weight, height and body surface area (Karagol et al 2012).

A wide range of coronary artery anomalies or variants may occur, and are categorized according to the origin (connection), course, area of termination of the artery, or the presence of anastomoses, bridging, fistula or atresia (Muresian 2016) (Commentary 7.2).

Right coronary artery

The right coronary artery arises from the right aortic sinus; its opening is usually below the sinutubular junction (see Fig. 57.23). The artery is usually single, although up to four openings have been observed, reflecting the independent origins of the conal, sinuatrial nodal and ventricular arteries (**Figs 57.42–57.43**). The right coronary artery passes at first anteriorly and slightly to the right between the right atrial auricle and pulmonary trunk. On reaching the atrioventricular sulcus, it descends almost vertically to the right side of the inferior cardiac border, curving around it into the inferior part of the sulcus in which it passes towards the cardiac crux (the junction of the atrioventricular, interatrial and interventricular sulci) (see Fig. 57.4B). The artery ends a little to the left of the crux, often by anastomosing with the circumflex branch of the left coronary artery. The right coronary artery may end near the right cardiac border, between this and the crux, or more often it reaches the left border, replacing the more distal part of the circumflex artery. Its branches supply the right and variable parts of the left chambers and atrioventricular septum. Usually, the first branch is the conal branch of the right coronary artery (Loukas et al 2014b). This vessel arises independently from the right aortic sinus in approximately 33% of hearts and is sometimes termed the third coronary artery, but this is an inappropriate term because a similarly named vessel arises from the left coronary circulation. The conal branch of the right coronary artery branches anteroinferiorly over the conus arteriosus (infundibulum) and over the superior aspect of the right ventricle, sometimes anastomosing with a similar branch from the anterior interventricular (left anterior descending) artery to form Vieussens arterial ring, an inconstant anastomosis around the right ventricular outflow tract that may provide an important collateral circulation in cases of arterial occlusion (**Figs 57.44–57.45**) (Loukas et al 2009).

The first segment of the right coronary artery (between its origin and the right side of the inferior cardiac margin) gives off anterior atrial and ventricular branches that diverge widely. The ventricular arteries arise at almost 90° from the right coronary artery, an arrangement that is in marked contrast to the more acutely angled origins of the ventricular branches of the left coronary artery. The anterior ventricular branches, usually two or three, ramify towards the cardiac apex, but they rarely reach the apex unless the right marginal artery is included within this group. The right marginal artery is greater in calibre than the other anterior ventricular arteries and reaches the cardiac apex in most hearts. When it is very large, there may be no additional anterior ventricular branch. Two, sometimes three, small inferior ventricular branches, arise from the second segment of the right coronary artery between the right side of the inferior cardiac margin and cardiac crux to supply the inferior aspect of the right ventricle. Their size is inversely proportional to that of the right marginal artery, which usually extends to the inferior cardiac surface. On approaching the cardiac crux, the right coronary artery normally produces up to three inferior interventricular branches (occasionally none). The actual inferior interventricular artery sits within the interventricular sulcus, and may be flanked either to the right or left, or on both sides, by these parallel branches. When these flanking vessels exist, branches of the inferior interventricular artery are small and sparse. The inferior interventricular artery is occasionally replaced by a branch of the left coronary artery. Although the atrial branches of the right coronary artery are sometimes described as part of anterior, lateral (right or marginal) and posterior groups, they are usually small single vessels, 1 mm in diameter (**Figs 57.46–57.48**). The right anterior and lateral branches (occasionally double, and very rarely triple) mainly supply the right atrium. The posterior branch is usually single and supplies both atria.

The artery of the sinuatrial node is an atrial branch distributed largely to right atrial myocardium. Its origin is variable: most commonly, it arises as the first atrial branch of the right coronary artery, less often from its right lateral atrial branch, and least often from its inferior atrioventricular part. It may sometimes originate from the circumflex branch of the left coronary artery. It usually passes posteriorly in the groove between the right atrial auricle and ascending aorta, and branches around the junction of the superior vena cava and right atrium, typically as an arterial loop from which small branches supply the right atrium. A large branch, the ramus cristae terminalis, traverses and supplies the sinuatrial node: it would seem more appropriate to name this branch the nodal artery, given that the vessel currently bearing this name is predominantly atrial in distribution.

Interventricular septal branches of the right coronary artery are relatively short and leave the inferior interventricular branch to perforate and supply the inferior part (about one-third) of the interventricular septum. They are numerous but do not usually reach the apical region of the septum. The largest interventricular septal artery, usually the first branch, commonly arises from the inverted loop said to characterize the right coronary artery at the crux and it almost always supplies the atrioventricular node. Small, recurrent atrioventricular branches originate from the ventricular branches of the right coronary artery as they cross the atrioventricular sulcus and supply adjacent atrial myocardium.

Left coronary artery

The left coronary artery is usually larger in calibre than the right. It supplies a greater volume of myocardium, including almost all of the left ventricle and atrium, and most of the interventricular septum (see Fig. 57.42; **Figs 57.49–57.51**). In hearts with right dominance, the right coronary artery supplies a variable amount of the inferior region of the left ventricle (see Fig. 57.41A–C).

The left coronary artery arises from the left aortic sinus. The opening of the artery sometimes lies inferior to the margin of the valve leaflets and may be double, usually leading into the circumflex and anterior interventricular (left anterior descending) branches of the left coronary artery. Its initial portion, between its opening and first branches, varies in length from a few millimetres to a few centimetres. The artery lies between the pulmonary trunk and the left atrial auricle, emerging into the atrioventricular sulcus, where it turns left. This part is loosely embedded in subepicardial fat and usually has no branches, but may give off a small atrial branch and, rarely, the sinuatrial nodal artery. Upon reaching the atrioventricular sulcus, the left coronary artery divides into its two main branches: the circumflex and anterior interventricular arteries.

The anterior interventricular artery is commonly described as the continuation of the left coronary artery. It descends obliquely forwards and to the left in the interventricular sulcus (**Fig. 57.52**), sometimes deeply embedded in or crossed by myocardial tissue (myocardial bridges), and by the great cardiac vein and its tributaries.

Almost invariably, the anterior interventricular artery reaches the cardiac apex, where it terminates in around 33% of hearts. More frequently, it curves around the notch of the cardiac apex into the inferior interventricular sulcus and passes one-third to one-half of the way along its length, meeting the terminal parts of the inferior interventricular branches of the right coronary artery.

The anterior interventricular artery gives off right and left anterior ventricular and interventricular septal branches, and a variable number

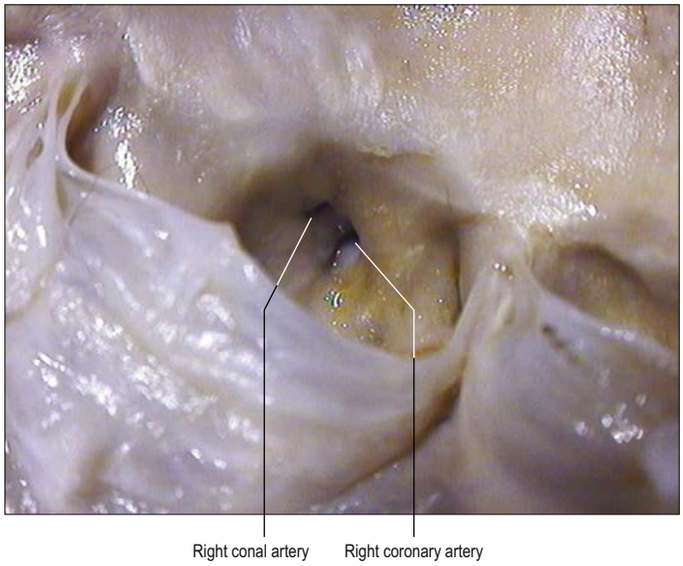

Fig. 57.43 The right coronary sinus, revealing the openings of both a right coronary artery and a right conal artery. (With permission from Loukas M, Sharma A, Blaak C 2013 The clinical anatomy of the coronary arteries. J Cardiovasc Transl Res 6:197–207.)

Congenital anomalies of the coronary arteries are found rarely in children. The two most common anomalies are coronary arteriovenous fistula and anomalous left coronary artery arising from the pulmonary trunk (Uysal et al 2014). Other congenital anomalies include ectopic origin of circumflex artery (normally a branch of the left coronary artery) from right coronary artery, single coronary artery arising from right aortic sinus, ectopic right coronary artery arising from the left aortic sinus, left or right coronary artery arising from the ascending aorta (Clemente et al 2010).

Myocardial bridges are reported to have a frequency varying from 0.5 to 40% when identified clinically and from 15 to 85% when found at autopsy (**Fig. 57.53**). The wide variation in frequency indicates that many bridges may be asymptomatic during life. The major clinical conditions produced by a myocardial bridge are cardiac ischaemia, atherosclerosis and sudden cardiac death. The incidence of atherosclerosis is increased when the right coronary artery is bridged. Although a relationship between myocardial bridges and sudden cardiac death has not been established, autopsy series have shown histological evidence of otherwise unexplained ischaemia in individuals with myocardial bridges; many died during exercise and had no other risk factors for coronary arterial disease.

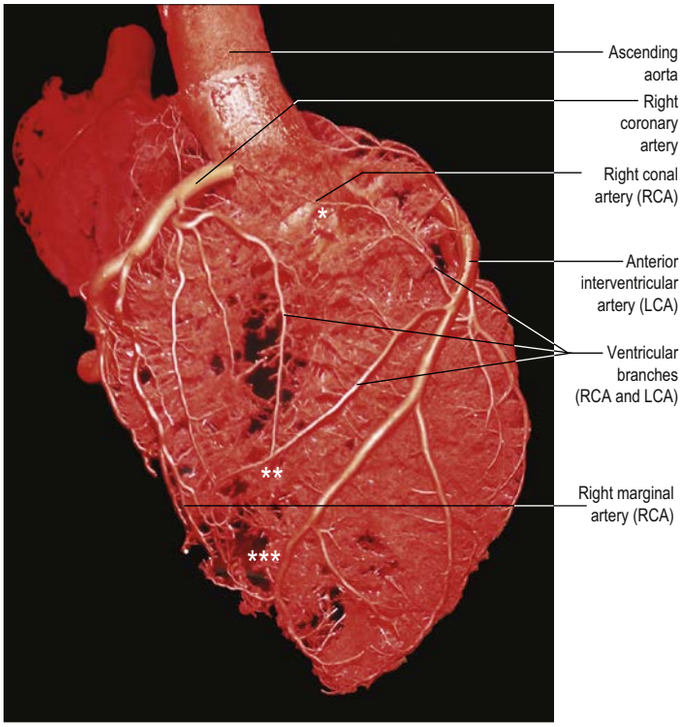

Fig. 57.44 A variation of the arterial ring (arterial circle or anulus) of Vieussens (*). This corrosion cast specimen shows the right conal artery, a branch of the right coronary artery, anastomosing with a proximal ventricular branch of the anterior interventricular artery. A second anastomosis (**) occurs between the ventricular branches of the right coronary and anterior interventricular arteries. Close to the apex, a third anastomosis (***) appears between the distal part of the anterior interventricular artery and branches of the marginal branch of the right coronary artery. Abbreviations: RCA, branch of right coronary artery; LCA, branch of left coronary artery. (With permission from Loukas M, Bilinsky S, Bilinsky E et al 2009 The clinical anatomy of the coronary collateral circulation. Clin Anat 22:146–60.)

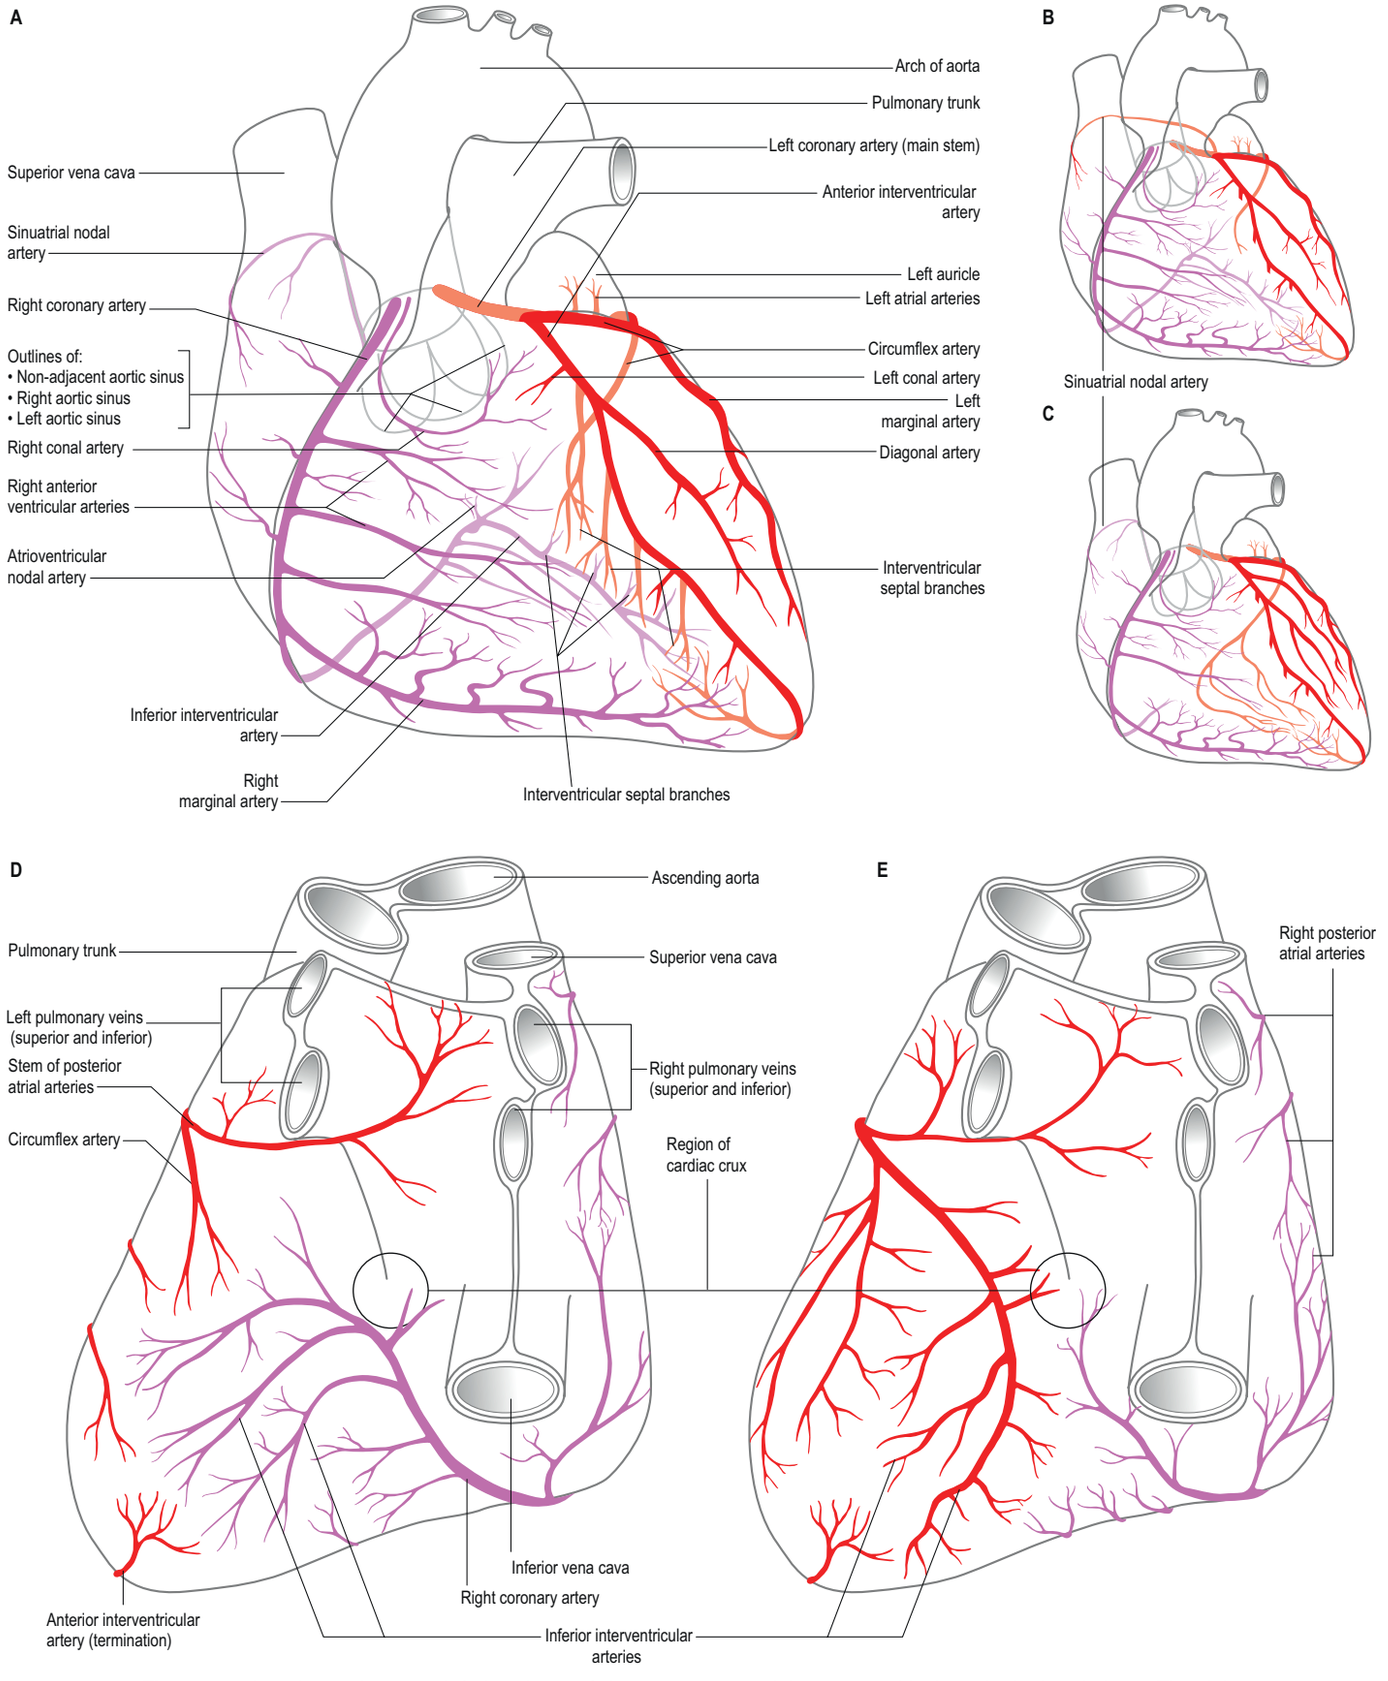

Fig. 57.41 Anterior and posteroinferior views of the coronary arterial system, with the principal variations. The right coronary arterial tree is shown in purple, the left in red. **A–C** (anterior view) show the posterior and inferior distribution in a paler shade. **A**, The most common arrangement. **B**, A common variation in the origin of the sinuatrial nodal artery. **C**, An example of left coronary artery dominance, also showing an uncommon origin of the sinuatrial nodal artery. **D–E** (posteroinferior view) show the right coronary arterial tree in purple and the left in red. **D**, An example of the more normal distribution in right coronary artery dominance. **E**, A less common form of left dominance. In views **D** and **E** the inferior (diaphragmatic) surface of the ventricular part of the heart has been artificially displaced and foreshortened to clarify the details of the inferior distribution of the coronary arteries.

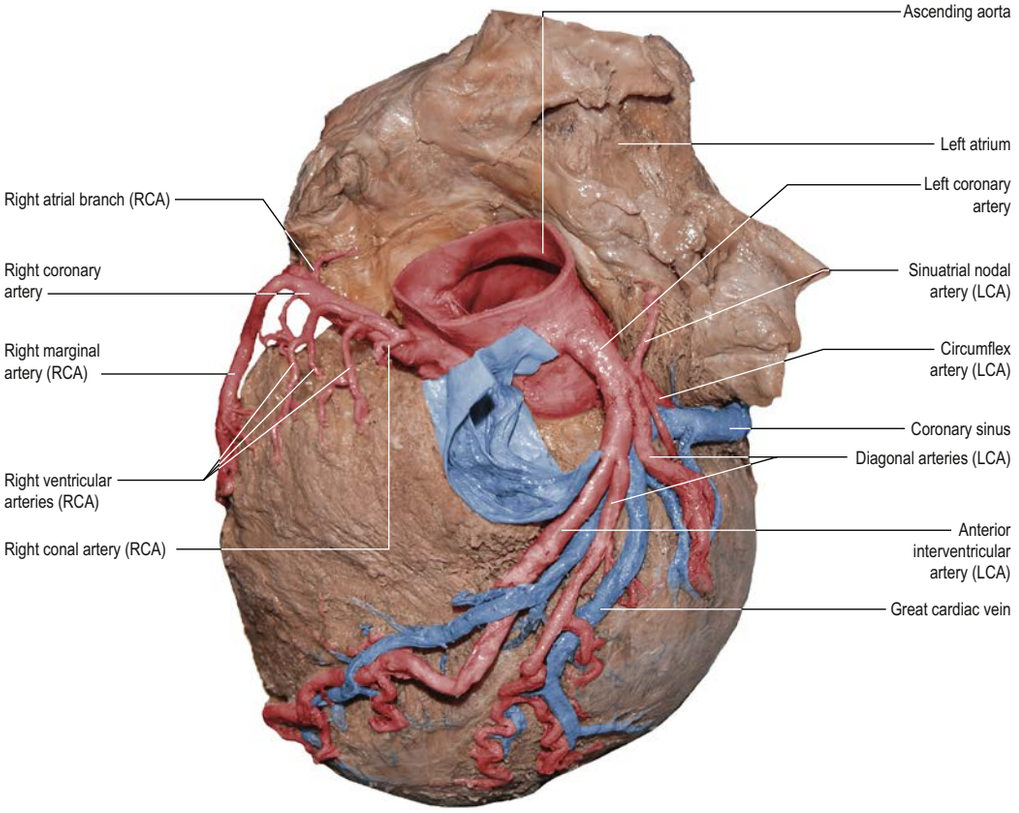

Fig. 57.42 A dissection of a cadaveric heart in which both coronary arteries have been exposed to reveal their branches to the right and left ventricles, respectively. Note how the great cardiac vein is intertwined around the anterior interventricular artery. Abbreviations: RCA, branch of right coronary artery; LCA, branch of left coronary artery. (Image courtesy of Professor M Loukas.)

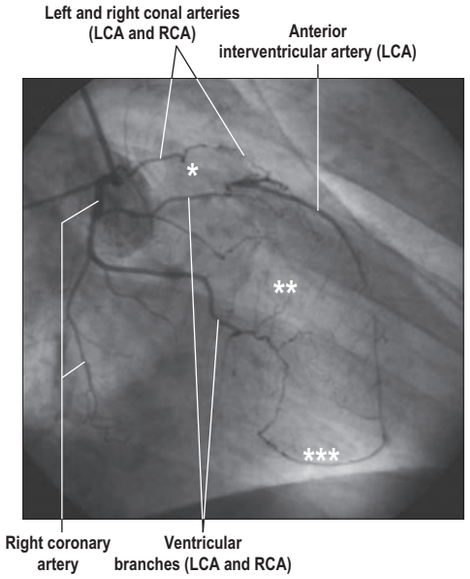

Fig. 57.45 A right coronary artery angiogram demonstrating three collateral arterial anastomoses. Across the area of the subpulmonary conus arteriosus, the right conal artery, a branch of the right coronary artery, anastomoses with the left conal artery, a branch of the anterior interventricular artery, to form the arterial ring of (arterial circle or anulus) of Vieussens (*). Ventricular branches of the right coronary artery anastomose with the proximal (**) and distal portions (***) of the anterior interventricular artery, forming two additional collateral pathways. As a result, there is contrast medium in the anterior interventricular artery. Abbreviations: RCA, branch of right coronary artery; LCA, branch of left coronary artery. (With permission from Loukas M, Bilinsky S, Bilinsky E et al 2009 The clinical anatomy of the coronary collateral circulation. Clin Anat 22:146–60.)

of corresponding posterior branches. Anterior right ventricular branches are small and rarely number more than one or two; the right ventricle is supplied almost entirely by the right coronary artery. Up to nine large left anterior ventricular arteries branch at acute angles from the anterior interventricular artery, crossing the anterior aspect of the left ventricle diagonally, with the largest reaching the rounded left (obtuse) cardiac border. One, termed the left diagonal artery, often dominates, sometimes arising separately from the left coronary artery, which then ends by trifurcation. It is reported in at least 33–50% of hearts, and may be doubled in around 20%. A small left conal artery frequently leaves the anterior interventricular artery near its origin, and anastomoses on the conus arteriosus with its counterpart from the right coronary artery and with the vasa vasorum of the pulmonary trunk and ascending aorta. The interventricular septal branches leave the anterior interventricular artery almost perpendicularly, and pass posteroinferiorly within the septum, usually supplying its anterior two-thirds. The first interventricular septal artery usually supplies the atrioventricular bundle at the point of its division into right and left bundles. Small inferiorly located interventricular septal branches from the same source supply the inferior third of the septum for a variable distance from the cardiac apex (Loukas et al 2009).

The circumflex branch of the left coronary artery, comparable to the anterior interventricular artery in calibre, curves leftwards in the atrioventricular sulcus, and continues around the left cardiac border into the posterior and then inferior part of the sulcus, terminating to the left of the cardiac crux in most hearts, although sometimes continuing as the inferior interventricular artery. Proximally, the left atrial auricle usually overlaps it. A large ventricular branch, the left marginal artery, normally arises from the left circumflex artery at a 90° angle and branches over the rounded left border, supplying much of the adjacent left ventricle, typically to its apex. Smaller anterior and inferior branches of the circumflex artery also supply the left ventricle. Anterior ventricular branches (from one to five, commonly two or three) course parallel to the diagonal artery when it is present, and replace it when it is absent. Inferior ventricular branches are smaller and fewer because the left ventricle is partly supplied by the inferior interventricular branch of the right coronary artery. When this artery is small or absent, it is accompanied or replaced by often doubled or tripled interventricular continuations of the circumflex artery.

The artery to the sinuatrial node is often derived from the first 1–2 cm of the circumflex artery after its origin from the left coronary artery (anterior circumflex segment) and less often from the remaining length of the circumflex artery. It passes over and supplies the left atrium, encircles the superior vena cava (similar to a right coronary sinuatrial nodal branch) and sends a large branch through the node; despite its name, it is predominantly atrial in distribution. The artery to the atrioventricular node, sometimes the terminal branch of the circumflex artery (20%), arises near the cardiac crux. When this occurs, the circumflex artery usually gives off the inferior interventricular artery, an example of left dominance.

Coronary arterial distribution

Details of coronary arterial distribution should be integrated into a concept of total cardiac supply. Most commonly, the right coronary artery supplies all of the right ventricle (except a narrow strip to the right of the anterior interventricular sulcus); a variable part of the

inferior aspect of the left ventricle; the inferior one-third of the interventricular septum; the right atrium and part of the left atrium; the conduction system as far as the proximal parts of the right and left bundles (branches of the atrioventricular bundle). Left coronary artery distribution is reciprocal and includes most of the left ventricle; a narrow strip of right ventricle; the anterior two-thirds of the interventricular septum; most of the left atrium. Variations in the coronary arterial system mainly affect the inferior aspect of the ventricles and reflect the relative dominance of coronary arterial supply (see Fig. 57.41). The term dominance is misleading because the left artery almost always supplies a greater volume of tissue than the right. In right dominance, the inferior interventricular artery is derived from the right coronary artery, and in left dominance it is derived from the left coronary artery. In the balanced pattern of supply, branches of both the left and right coronary arteries run in or near the inferior interventricular sulcus.

Less is known about variations in atrial supply because the small vessels involved are not easily preserved in the corrosion casts that are used for analysis. In more than 50% of individuals, the right atrium is supplied by the right coronary artery alone. More than 62% of left atria are supplied mainly by the left coronary artery, 27% by the right coronary artery (in each group a small accessory supply from the other coronary artery exists) and 11% are supplied almost equally by both arteries. Arterial supply to the sinuatrial and atrioventricular nodes also varies: the sinuatrial node is supplied more often by the right coronary artery and fewer than 10% of sinuatrial nodes receive a bilateral supply. The atrioventricular node is usually supplied by the right coronary artery.

Coronary anastomoses

Available with the *Gray's Anatomy* e-book

Extracardiac anastomoses

Extracardiac anastomoses connect various coronary arterial branches with other intrathoracic vessels, most commonly involving the bronchial and internal thoracic arteries (**Fig. 57.54**). To a much lesser degree, anastomoses between coronary arteries and pericardiacophrenic branches of the internal thoracic, anterior mediastinal, intercostal and oesophageal arteries also exist.

Coronary artery fistula

A coronary artery fistula is an abnormal connection that directly links one or more coronary arteries to a heart chamber or to major thoracic vessels without an interposed capillary bed.

Cardiac veins

The cardiac venous system is divided into two major parts. The greater system consists of large vessels that lie within the subepicardial myocardium and drain most of the outer myocardium. These veins extend over the myocardial surface and do not adhere to topographical borders, although the larger collecting vessels lie within the interventricular sulci before draining into the coronary sinus (see Fig. 57.4; **Fig. 57.59**). The intercommunicating parts of this system are the coronary sinus and its tributaries, the anterior cardiac venous system, and the ventricular septal and atrial veins. The coronary sinus and its tributaries return blood to the right atrium from the entire heart (including its septa), except for the anterior region of the right ventricle and small, variable parts of both atria and the left ventricle. The anterior cardiac veins drain an anterior region of the right ventricle; this expands to include a region around the right cardiac border when the right marginal vein joins this group.

The smaller system functions primarily to return venous blood from the inner myocardial walls into the right atrium and ventricle and, to a lesser extent, into the left atrium and sometimes the left ventricle. It contains the smallest cardiac (Thebesian) veins that drain the subendocardial myocardium either directly, via connecting intramural arteries and veins, or indirectly, via subendocardial sinusoidal spaces.

Variation in cardiac veins Attempts to categorize variations in cardiac venous circulation into types have not produced any accepted pattern. The coronary sinus may receive all the cardiac veins, except the smallest (Thebesian) veins, including the anterior cardiac veins, which may be reduced by diversion into the small cardiac vein and then to the coronary sinus.

Coronary sinus

Most cardiac veins drain into the wide coronary sinus, 2 or 3 cm long, lying in the inferior atrioventricular (coronary) sulcus between the left atrium and ventricle (see Fig. 57.4B,E). The sinus opens into the right atrium between the opening of the inferior vena cava and the right atrioventricular orifice. The opening may be guarded by the valve of the coronary sinus (Thebesian valve), a fold of endocardium (see Fig. 57.13); the fold may be absent or may cover completely the opening of the sinus. The tributaries of the coronary sinus are the great, small and middle cardiac veins, the inferior vein of the left ventricle and the oblique vein of the left atrium; all except the oblique vein have valves

Eur Heart J 11:275–9.)

Uncommonly, variants of coronary arteries may be present and are the second most common cause of sudden cardiac death in young athletes. Anomalous origins of the coronary artery, particularly from the contralateral aortic sinus, are the variant that is most commonly associated with sudden cardiac death. Other anomalies include left coronary artery origin from the pulmonary trunk, coronary fistula and left main stem atresia (Kastellanos et al 2018).

The cardiac collateral circulation represents a built-in system for coronary arterial bypass. The first few centimetres of the main stems of the left and right coronary arteries are devoid of anastomotic branches. Collateral channels are abundant further distally, exhibiting variable calibres and occupying numerous locations, allowing for bidirectional flow between most arteries. Approximately 30 different sites of collateral extramural vessels have been described, the most frequent being at the cardiac apex; the anterior aspect of the right ventricle; the inferior aspect of the left ventricle; the cardiac crux; the interatrial and interventricular sulci; between the sinuatrial nodal and other atrial vessels (see Figs 57.44–57.45). Anastomoses between branches of the coronary arteries, both subepicardial and myocardial, and between these arteries and extracardiac vessels (see Fig. 57.54) are of great clinical importance. Clinical studies suggest that anastomoses cannot rapidly provide collateral routes sufficient to circumvent sudden coronary obstruction. Nevertheless, it has long been established that anastomoses do occur, particularly between fine subepicardial branches, and they may increase during the life of an individual by both angiogenesis and arteriogenesis. The Vieussens arterial ring is a collateral vessel that crosses the conus arteriosus inferior to the pulmonary trunk, and provides an anastomosis between the conal branches of the right coronary artery and the anterior interventricular artery. The artery to the sinuatrial node commonly provides a communication between the proximal parts of the left and right coronary arteries. The apical collateral artery joins the interventricular arteries. The frequent enlargement of the first

TABLE 57.1 Patterns of cardiac collateral arteries

Grade	Description
0	Total absence of any collateral arteries
1	Poorly developed collateral arteries with no prominent distal channel visualized by angiography
2	Presence of moderate collateral arteries providing faint but delayed opacification of a prominent distal channel
3	Good collateral arteries giving clear opacification of a prominent distal channel
4	Excellent collateralization giving full and brisk opacification of prominent distal vessels

interventricular septal branch of the anterior interventricular artery, Kugel's anastomotic artery (arteria anastomotica auricularis magna), has been described as running between the proximal parts of the coronary arteries along the anterosuperior margin of the fossa ovalis to anastomose with the distal part of the right coronary artery. Clinical imaging (catheter angiography and colour Doppler ultrasound) has led to the development of a grading system to describe the overall pattern of cardiac collateral arteries (Table 57.1).

The posterior pericardium also receives a direct supply from the bronchial arteries: extracardiac coronary anastomoses involving bronchial arteries are typically found at the pericardial reflections, such as the points of entry of the superior and inferior venae cavae. The most common anastomoses are with the circumflex branch of the left coronary artery via the posterior pericardial reflections and reflect the close proximity of the bronchial arteries within the root of the lung. In pathological conditions, notably those resulting in pericardial adhesions, it is also possible for extracardiac anastomoses to develop through trans-pericardial vascularization. Extracardiac communications also exist with coronary atrial branches, especially the sinuatrial nodal artery. The effectiveness of any of these connections as collateral routes in coronary occlusion is not well quantified. Coronary arteriovenous anastomoses and numerous connections between the coronary circulation and cardiac cavities, producing so-called 'myocardial sinusoids' and 'arterioluminal vessels', have been reported, but their importance in coronary disease remains uncertain.

Coronary angiography may be performed by introducing a catheter through the femoral, radial or brachial artery. The femoral artery is punctured with a needle 3 cm below the inguinal ligament while the lower limb is held adducted and slightly externally rotated. The exact position is guided by palpation of the femoral arterial pulse, and the needle is inserted at an angle of 45° to the artery. After arterial puncture, a fine guidewire is inserted through the needle and fed into the artery. The catheter is then inserted over the guidewire and passed through the external and common iliac arteries into the abdominal aorta, then through the descending thoracic aorta, aortic arch and ascending aorta. The brachial or radial artery may be used for percutaneous access to the circulation. Once the catheter is located in the ascending aorta, a variety of guidewires may be used to enter the coronary vessels for selective arteriography and interventions. Angiography is performed with standard high osmolality contrast medium and cine-angiography. In selected patients, new-generation, low osmolality contrast medium may be used. All the coronary arteries are catheterized and visualized in a variety of views to obtain a full evaluation of their anatomy and to determine the location and degree of any stenosis (Figs 57.55–57.56). The opening of the left coronary artery arises from the left aortic sinus and is best viewed in the direct frontal and left anterior oblique projections. The right anterior oblique view is useful in demonstrating the diagonal and anterior interventricular branches of the left coronary artery. The right coronary artery originates from the right aortic sinus and is usually visualized in the right anterior oblique view. Pressure and oxygen saturations can be measured via the catheter; changes in pressure across valves allow the degree of stenosis to be measured. Coronary blood flow and relative flow reserve can also be calculated. Significant stenosis may be treated initially by balloon angioplasty followed by stent insertion. The balloon exerts pressure against the plaque in the arterial wall, fracturing and splitting the plaque. The splinting effect of the plaque and elastic recoil are reduced, resulting in an increase in the arterial lumen. Stent insertion reduces the rate of re-stenosis.

Atherosclerosis causing more than 60% stenosis of the terminal diameter of the coronary arteries is likely to cause significant reduction in myocardial perfusion. Patients with high-grade lesions, left main stem coronary artery or triple-vessel disease with impaired left ventricular function are usually considered for coronary artery bypass grafting. The common grafts that are used are the internal thoracic (mammary) and radial arteries. The left internal thoracic artery and radial artery grafts have a greater patency rate than saphenous vein grafts. Approximately 15% of saphenous vein grafts occlude in 1 year and, from then on, at an annual rate of 1–2% in the first 6 years and 4% thereafter; between 40% and 50% of saphenous vein grafts have occluded by 10 years, whereas only about 10% of left internal thoracic or radial artery grafts will have occluded over this time. The common surgical approach is via a midline sternotomy (Ch. 53). If the internal thoracic artery is used as a donor graft, it is divided distally (maintaining its proximal origin from the subclavian artery) and anastomosed to the coronary artery distal to the stenosis. If radial artery grafts are used, they must bridge the stenosis via both proximal and distal anastomoses. In selected cases, minimally invasive direct coronary artery bypass grafting is performed, but the approach is dependent on the vessel being grafted. The anterior approach, via a mini-thoracotomy through the left fourth intercostal space, is used for grafting the left anterior interventricular and diagonal arteries. The anterolateral approach, via an incision in the left third intercostal space from the mid-clavicular to anterior axillary lines, is used for grafting early marginal branches of the circumflex branch of the left coronary artery. The lateral approach, via a lateral thoracotomy measuring only 10 cm in size through the left fifth or sixth intercostal spaces, allows grafting of the circumflex vessels. Extrathoracic approaches that are occasionally used include the subxiphoid approach for the distal part of the right coronary artery and inferior interventricular artery. The vast majority of patients are treated with stent placement (Fig. 57.57). Port access surgery allows for full revascularization with cardiopulmonary bypass and obviates the need for midline sternotomy.

Coronary artery fistulae are rare (Fig. 57.58); those that arise from a coronary artery and then terminate in a chamber of the heart are known as coronary cameral fistulae, while those terminating in a vein are coronary arteriovenous fistulae. Fistulae may be congenital or may develop later in life. Congenital fistulae are more common and account for 50% of paediatric coronary vascular aberrations: they are believed to be derived from the smallest cardiac (Thebesian) veins. Acquired coronary artery fistulae are most commonly iatrogenic in aetiology but may also occur after traumatic injury. The most commonly seen are of the coronary cameral type, from the right coronary artery into the right side of the heart.

at their openings. Isolated absence of the coronary sinus has been reported, with coronary venous drainage into the pulmonary trunk (Ogawa et al 2013).

Great cardiac vein The great cardiac vein begins at the cardiac apex, and ascends in the anterior interventricular sulcus to the atrioventricular sulcus, which it follows, passing to the left and posteriorly to enter the coronary sinus at its origin. It receives tributaries from the left atrium and both ventricles, including the large left marginal vein that ascends the left (obtuse) border of the heart. It usually courses superior to the arterial branches. The valve of Vieussens normally sits at the opening of the great cardiac vein at its junction with the oblique vein of the left atrium (this junction often representing the start of the coronary sinus); smaller diminutive valves may occur. The valve of Vieussens can impede the passage of a catheter into the great cardiac vein.

Small cardiac vein The small cardiac vein lies in the anterior part of the inferior atrioventricular sulcus between the right atrium and ventricle, receiving blood from the inferior parts of each chamber and opening into the atrial end of the coronary sinus. The right marginal vein passes right, along (or near) the inferior cardiac border. It sometimes joins the small cardiac vein in the atrioventricular sulcus, although typically opens directly into the right atrium.

Middle cardiac vein The middle cardiac vein begins at the cardiac apex and runs posteriorly in the inferior interventricular sulcus to end in the coronary sinus near its atrial termination. The vein is also described as meeting the great cardiac vein at the cardiac apex, and so forming, with the coronary sinus, a complete venous circle.

Inferior vein of the left ventricle The inferior vein of the left ventricle (previously named the posterior vein of the left ventricle) lies on the inferior surface of the left ventricle, a little to the left of the middle cardiac vein. It usually opens into the middle of the coronary sinus, but may sometimes empty into the great cardiac vein. Rarely, the inferior vein of the left ventricle is absent, in which case the left marginal vein drains most of the left ventricular wall.

Oblique vein of the left atrium The diminutive oblique vein of the left atrium descends obliquely on the posterior aspect of the left atrium to join the coronary sinus. Its junction with the great cardiac vein marks the start of the coronary sinus and, often, the location of the valve of Vieussens. It is continuous above with the ligament of the left superior vena cava.

Left marginal vein

The left (obtuse) marginal vein courses over or near the left border of the heart, draining much of the left ventricular myocardium. It runs superficial to the marginal branch of the left coronary artery and usually drains into the great cardiac vein, although it may sometimes drain directly into the coronary sinus.

Anterior cardiac veins

The anterior cardiac veins drain the anterior part of the right ventricle. Usually two or three, and up to five, they ascend in subepicardial tissue to cross the anterior part of the atrioventricular sulcus, passing deep or superficial to the right coronary artery. They drain into the right atrium, near the atrioventricular sulcus, separately or in variable combinations, or may open into a subendocardial collecting channel.

Right marginal vein

The right marginal vein courses along the inferior (acute) border of the heart, draining adjacent parts of the right ventricle, and usually opens separately into the right atrium, although it may join the anterior cardiac veins or, less often, the coronary sinus. It is often grouped with the small cardiac veins, but it is larger in calibre, being comparable to or even wider than the anterior cardiac veins.

Smallest cardiac veins

The smallest cardiac (venae cordis minimae, Thebesian) veins open directly into all heart chambers. Their numbers and size are highly variable: vessels up to 2 mm in diameter open into the right atrium and vessels as small as 0.5 mm in diameter open into the right ventricle, all with valveless openings. Numerous smallest cardiac veins have been identified in the right atrium and ventricle but they are rarely found in the left side. Four types of smallest cardiac veins have been described. Venoluminal veins drain directly into the cardiac chambers; venosinusoidal veins drain into subendocardial sinusoids (which, in turn, drain into the cardiac chambers); arterioluminal veins connect small arteries and arterioles directly with the cardiac chambers; and arteriosinusoidal veins connect thin arteries or arterioles with subendocardial sinusoidal spaces.

Cardiac venous anastomoses

Widespread anastomoses occur at all levels of the cardiac venous circulation, on a scale exceeding that of the arteries and amounting to a venous plexus. Not only are adjacent veins often connected, but connections also exist between tributaries of the coronary sinus and those of the anterior cardiac veins. Abundant anastomoses occur at

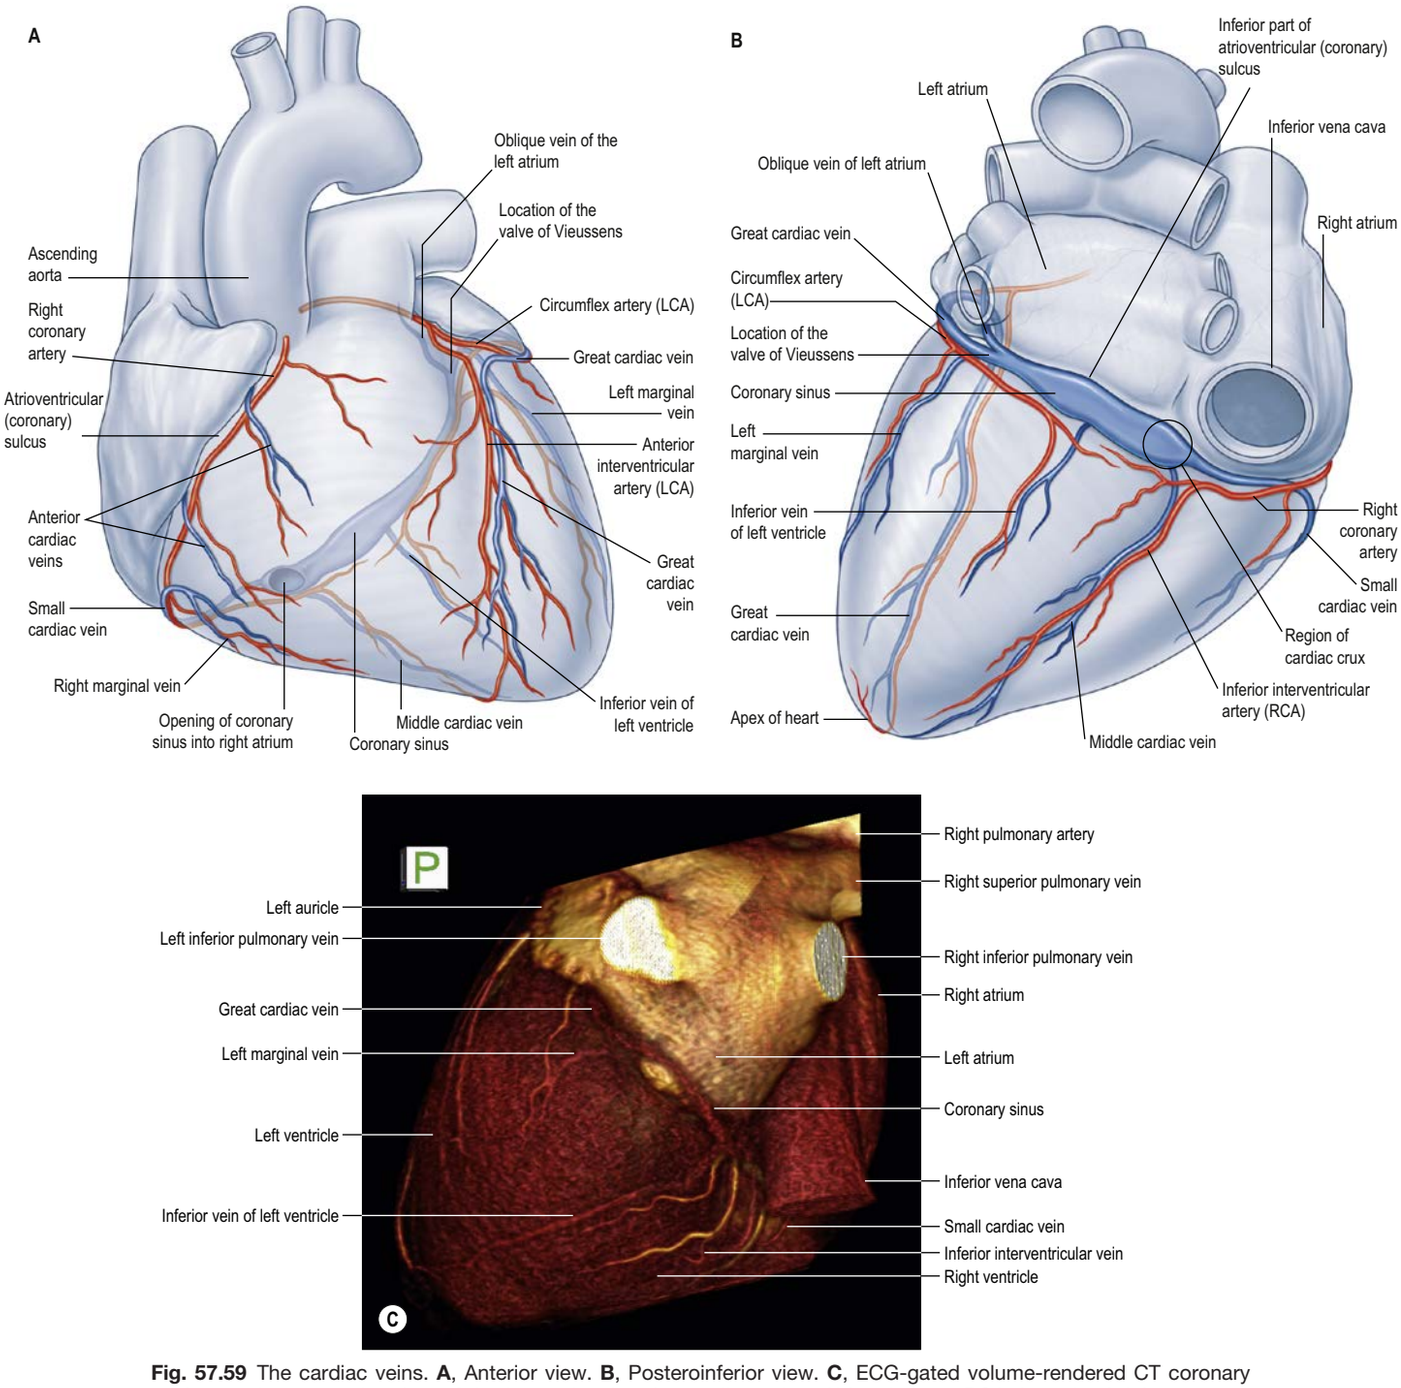

Fig. 57.59 The cardiac veins. **A**, Anterior view. **B**, Posteroinferior view. **C**, ECG-gated volume-rendered CT coronary angiogram in a posterior view of the heart showing the cardiac veins. Abbreviations: RCA, branch of right coronary artery; LCA, branch of left coronary artery. Fig. 57.60 The cardiac lymphatic system. (Adapted from from Loukas M, Shah S, Bhusnurmath S et al 2013 A general outline of the cardiac lymphatic system. In: Karunamuni G (ed) The Cardiac Lymphatic System. Springer Nature.)

the cardiac apex and its anterior and inferior aspects. Like the coronary arteries, cardiac veins are connected with extracardiac vessels, particularly the vasa vasorum of the large vessels that are continuous with the heart.

Lymphatic drainage of the heart

Cardiac lymphatic vessels form subendocardial, myocardial and subepicardial plexuses that play essential roles in myocardial fluid and immune cell homeostasis (Brakenhielm and Alitalo 2019). The valved lymphatic subepicardial precollector channels display very few lymphatic smooth muscle cells: lymph propulsion from the heart is largely dependent upon the rate and force of cardiac contractions and the duration of diastole, and passes from the subendocardial to the subepicardial plexuses. Efferent vessels from the subepicardial plexuses form the left (major) and right (minor) cardiac collecting trunks: their number, arrangement, course and destination and the terminology used to described them vary (e.g. Loukas et al 2013; Ratajska et al 2014). Generally, two or three left-sided trunks ascend the anterior interventricular sulcus, receiving vessels from both ventricles. On reaching the atrioventricular sulcus, they are joined by a large vessel from the inferior surface of the left ventricle that first ascends in the inferior interventricular sulcus and then turns along the atrioventricular sulcus. The vessel formed by this union, the left cardiac collecting trunk, ascends between the pulmonary trunk and the left atrium and usually ends in a subcarinal (inferior tracheobronchial) node. The right cardiac collecting trunk receives efferents from the right atrium and the right border and inferior surface of the right ventricle. It ascends in the atrioventricular sulcus, near the right coronary artery, and then anterior to the ascending aorta, and ends in a brachiocephalic or prevascular node, usually on the left (**Fig. 57.60**) (Loukas et al 2011).

Innervation

Initiation of the cardiac cycle is myogenic, originating in the sinuatrial node. It is harmonized in rate, force and output by autonomic nerves that innervate the sinuatrial nodal tissue and its digitations, coronary vessels and the working atrial and ventricular musculature. During development the autonomic cardiac neurones originate from cells of the neural crest, neurotrophic factors from nearby vasculature assist in the development and maintenance of these neurones (Hasan 2013). All cardiac branches of the vagus nerves (parasympathetic) and sympathetic trunk (except the cardiac branch of the superior cervical sympathetic ganglion, which is entirely efferent) contain both afferent and efferent fibres.

Sympathetic cardiac innervation

The postganglionic sympathetic fibres that modulate efferent neural responses to the cardiac tissues and cardiac function originate in the cervicothoracic (stellate) ganglion, with contributions from the cervical, vertebral and upper thoracic ganglia. The ganglia receive preganglionic sympathetic input from neurones originating in the intermediolateral column (nucleus) of the upper thoracic spinal cord (Goldberger et al 2019). Efferent postganglionic fibres pass to the cardiac plexus as the cervical and thoracic cardiac nerves (Kawashima 2005), and then travel with the coronary vasculature towards the endocardium. When stimulated, they release noradrenaline (norepinephrine) that activates beta-adrenergic receptors in the cardiac tissue (Linz et al 2014). The resultant effect is an increase in conduction speed in the atrioventricular node as well as increased heart rate and force of cardiac muscular contractions. Sympathetic innervation increases heart rate and dilates the coronary arteries, whereas parasympathetic vagal innervation has the opposite effect.

Baroreceptors (mechanoreceptors) located in the adventitia of the aortic wall and carotid sinus detect intra-arterial pressure changes. Afferent

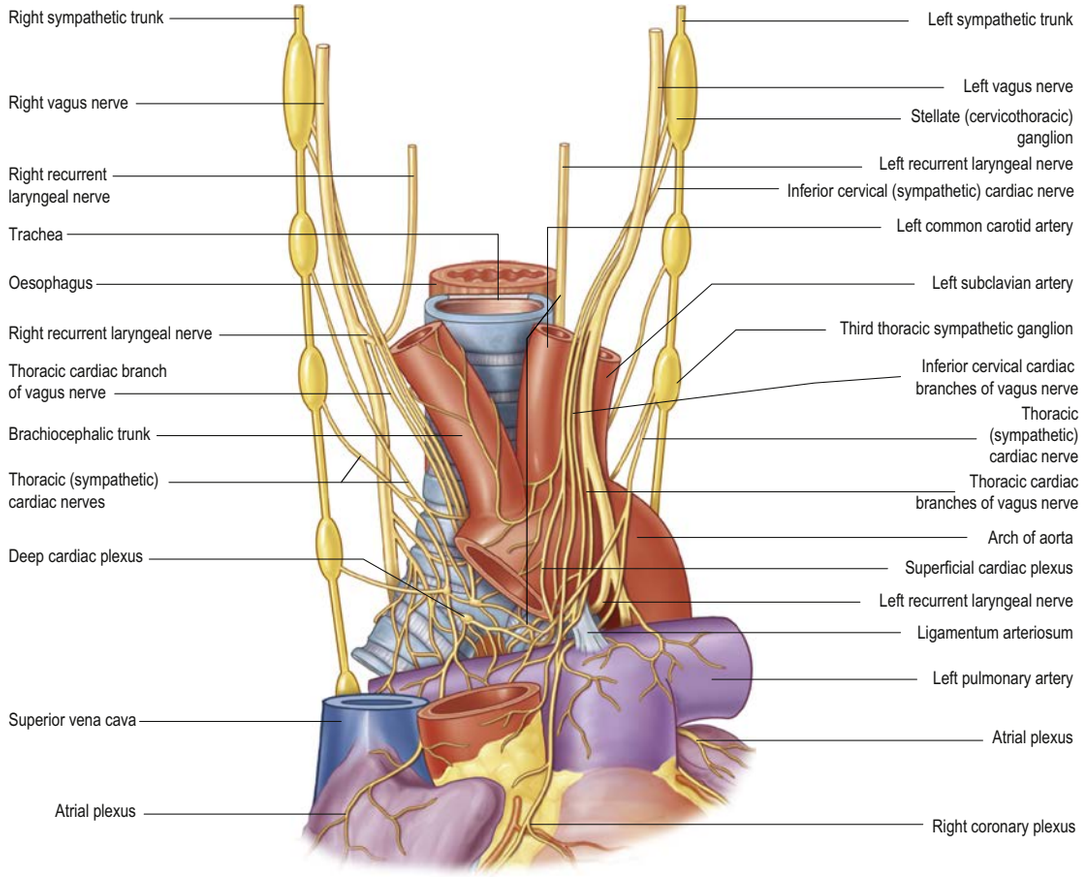

Fig. 57.61 The cardiac plexus and its source from the cervical branches of the vagus nerves and sympathetic trunks. Also seen are its extensions to the pulmonary, atrial and coronary plexuses. Note the numerous junctions between sympathetic and parasympathetic (vagal) branches that form the plexus.

input passes to the nuclei of the solitary tract in the medulla oblongata (Ch. 28) which in turn regulates sympathetic and parasympathetic output to the heart and modulates heart rate and blood pressure (Goldberger et al 2019). Evidence suggests that in addition to 'flight and fight' responses the sympathetic nervous system maintains cardiac function in resting states via specific neuro-cardiac junctions, such as the interface between sympathetic motor neurones and cardiomyocytes (Zaglia and Mongillo 2017). The sympathetic nervous system is overly active in patients with heart failure and certain therapies targeting this pathway have reduced mortality rates. Imaging of cardiac sympathetic innervation is important to determine prognosis of these treatments (Kobayashi et al 2017). For further reading see Chapter 6 and Coote and Chauhan (2016) and Jamali et al (2017).

Parasympathetic cardiac innervation

Parasympathetic innervation mainly slows heart rate and constricts the coronary arteries. Its effects are mediated by the cardiac branches of the vagus nerve, which divide into superior and inferior branches before entering the heart through the cardiac plexus (Goldberger et al 2019). Parasympathetic innervation of the cardiac musculature is mediated by cholinergic muscarinic receptors that function dissimilarly to those of the sympathetic adrenergic beta receptors (Linz et al 2014). Experimental evidence suggests that groups of vagal preganglionic neurones originating in the nucleus ambiguus and dorsal vagal nucleus control the heart rate and atrioventricular conductance (via their innervation of nodal tissue) and modulate the contractility and excitability of the ventricular myocardium (Gourine et al 2016).

Preganglionic cardiac parasympathetic axons arising from either the dorsal vagal nucleus or the nucleus ambiguus run in cervical cardiac branches of the vagus nerve to synapse in the cardiac plexuses and atrial walls. Intrinsic cardiac neurones are limited to the atria and interatrial septum, and are most numerous in the subepicardial connective tissue near the sinuatrial and atrioventricular nodes. There is evidence that these intrinsic ganglia are not simple nicotinic relays but may act as sites for integration of extrinsic nervous inputs and form complex circuits for the local neuronal control of the heart and perhaps even local reflexes. Postganglionic neurones distributed within discrete fat pads on the atrial surface can mediate cardiac function. The ganglion cells in a fat pad adjacent to the epicardium of the right pulmonary veins selectively mediate negative chronotropic effects whereas ganglion cells in a fat pad at the junction between the inferior aspect of the right atrium and the inferior vena cava mediate the slowing of atrioventricular conduction (Sánchez-Quintana et al 2014).

Cardiac plexus

Nearing the heart, the autonomic nerves form a mixed cardiac plexus, usually described in terms of a superficial part inferior to the aortic arch, lying between the arch and the right pulmonary artery, and a deep part between the aortic arch and the tracheal bifurcation. The cardiac plexus is also described with reference to regional names for its coronary, pulmonary, atrial and aortic extensions (**Fig. 57.61**). Ganglion cells are largely confined to the atrial tissues, with a preponderance adjacent to the sinuatrial node, but some may also be found within the heart along the branches of the plexuses. Their axons are considered to be largely, if not exclusively, postganglionic parasympathetic. Cholinergic and adrenergic fibres, arising in or passing through the cardiac plexus, are distributed most profusely to the sinuatrial and atrioventricular nodes; the supply to the atrial and ventricular myocardium is much less dense. Adrenergic fibres supply the coronary arteries and cardiac veins. Rich plexuses of nerves containing cholinesterase, adrenergic transmitters and other peptides, e.g. neuropeptide Y, are found in the subendocardial regions of all chambers and within the valvular leaflets.

Superficial (ventral) part of the cardiac plexus The superficial part of the cardiac plexus lies inferior to the aortic arch and anterior to the right pulmonary artery. It is formed by the cardiac branch of the left superior cervical sympathetic ganglion and the inferior of the two cervical cardiac branches of the left vagus nerve. A small cardiac ganglion is usually present in this plexus immediately below the aortic arch, to the right of the ligamentum arteriosum. This part of the cardiac plexus has connections with the deep part, the right coronary plexus and the left anterior pulmonary plexus.

Deep (dorsal) part of the cardiac plexus The deep part of the cardiac plexus lies anterior to the tracheal bifurcation, superior to the point of division of the pulmonary trunk and posterior to the aortic arch. It is formed by the cardiac branches of the cervical and upper thoracic sympathetic ganglia, the vagus and recurrent laryngeal nerves. The only cardiac nerves that do not join it are those that join the superficial part of the

plexus. The deep plexus consists of right and left halves, the right typically surrounding the brachiocephalic trunk, and the left surrounding the aortic arch. The more dorsal (deep) aspect is larger than its more ventral (superficial) aspect on both sides. Branches from the right half of the deep part of the cardiac plexus pass both anterior and posterior to the right pulmonary artery. Fibres passing anterior to the pulmonary artery are more numerous; they supply a few filaments to the right anterior pulmonary plexus before continuing onwards to form part of the right coronary plexus. Fibres passing posterior to the pulmonary artery supply a few filaments to the right atrium and then continue into the left coronary plexus. The left half of the deep part of the cardiac plexus is connected to the superficial part; it supplies filaments to the left atrium and left anterior pulmonary plexus, and forms much of the left coronary plexus.

Left coronary plexus The left coronary plexus is larger than the right and is formed mainly by the prolongation of the left half of the deep part of the cardiac plexus and a few fibres from the right half. It accompanies the left coronary artery to supply the left atrium and ventricle.

Right coronary plexus The right coronary plexus is formed from both superficial and deep parts of the cardiac plexus. It accompanies the right coronary artery to supply the right atrium and ventricle.

Atrial plexuses The atrial plexuses are derivatives of the right and left continuations of the cardiac plexus along the coronary arteries. Their fibres are distributed to the corresponding atria, overlapping those from the coronary plexuses.

Intrinsic cardiac nervous system

In addition to the peripheral autonomic innervation, the heart has an intrinsic nervous system, the ganglionic plexus, which regulates heart rate, atrial and ventricular refractoriness and contractility, and coronary blood flow. Ganglia of the plexus receive an extrinsic innervation and interact with the myocardium through various neurotransmitters. The intrinsic cardiac nervous system is a complex of distinct subplexuses located on the superior and posterior surfaces of the right and left atria, and the inferior and lateral aspects of the posterior surface of the left atrium and left pulmonary vein (Sánchez-Quintana et al 2014). It has been implicated in the pathophysiology of several conditions, including arrhythmias, heart failure and myocardial infarction (Wake and Brack 2016). Atrial fibrillation is initiated and maintained by the autonomic nervous system and may be corrected by transection of the parasympathetic and sympathetic afferent and efferent fibres in the ganglionated plexus in the epicardial fat pads through catheter ablation (Hanna and Shivkumar 2018).

Great vessels

CHAPTER 58

MAJOR BLOOD VESSELS

The major blood vessels of the thorax include the pulmonary trunk, the thoracic aorta and its branches, and the superior and inferior venae cavae and their tributaries (Fig. 58.1).

Arteries

Pulmonary trunk

The pulmonary trunk conveys deoxygenated blood from the right ventricle to the lungs (see Figs 57.4, 57.10). About 5 cm in length and 3 cm in diameter, it is the most anterior of the cardiac vessels and arises from the pulmonary anulus surrounding the subpulmonary conus arteriosus (infundibulum) at the base of the right ventricle, superior and to the left of the supraventricular crest. The pulmonary trunk inclines posterosuperiorly and divides into right and left pulmonary arteries, of almost equal size, at the level of the body of the sixth thoracic vertebra (range, bodies of the fourth to the eighth thoracic vertebrae), 2–3 cm inferior to the sternal plane (horizontal plane through the sternal angle) and inferior to the aortic arch to the left of the midline (see Tables 52.1–52.2). The bifurcation of the pulmonary trunk commonly lies anteroinferior and to the left of the tracheal bifurcation and the associated subcarinal (inferior tracheobronchial) lymph nodes and deep cardiac plexus. In the fetus, at the level of the tracheal bifurcation, the left pulmonary artery is connected to the aortic arch by the ductus arteriosus, the obliterated remnant of which forms the ligamentum arteriosum in the adult (Ch. 13).

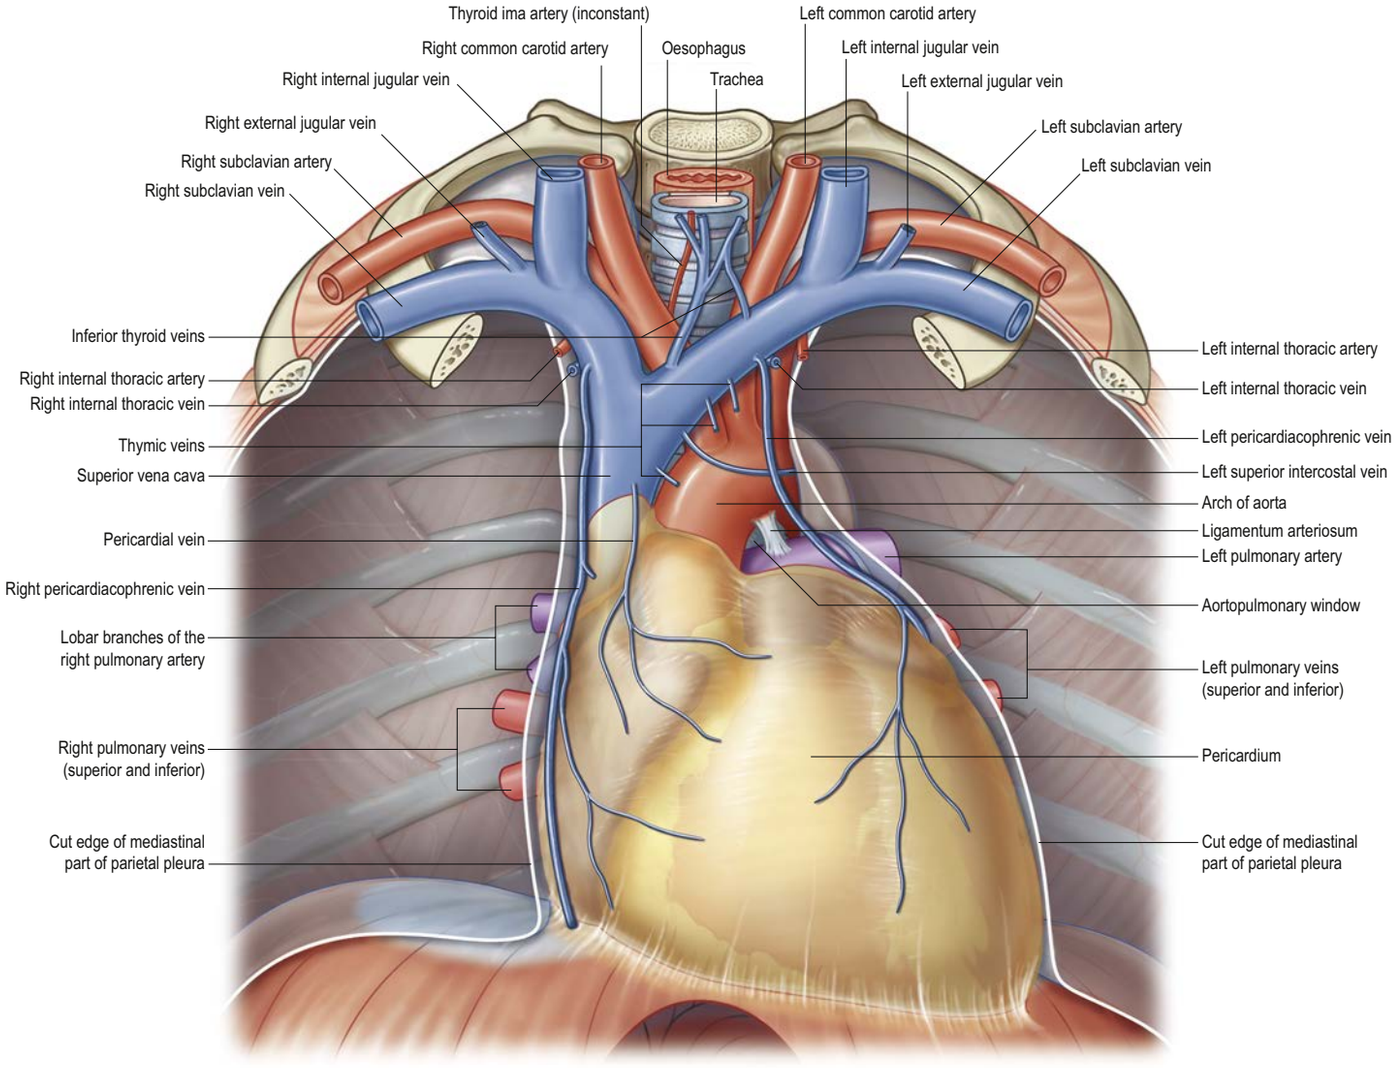

Fig. 58.1 The arteries and veins (great vessels) of the mediastinum and their branches/tributaries. (Adapted from Drake RL, Vogl AW, Mitchell A et al Gray's Atlas of Anatomy, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2015.)

Relations The pulmonary trunk is located entirely within the pericardium, enclosed with the ascending aorta in a common sheath of the visceral layer of serous pericardium (see Figs 57.1, 58.1). The fibrous pericardium gradually blends with and disappears within the adventitia of the pulmonary arteries. Anteriorly, it is separated from the sternal end of the left second intercostal space, and/or the third costal cartilage, by the pericardium, pleura, left lung and the superior part of transversus thoracis. Posterior relations of the proximal part near to its origin are the ascending aorta and left coronary artery, and superiorly, the left atrium. Moving superiorly, the ascending aorta spirals around the pulmonary trunk and comes to lie to the right of its more superior part. The atrial auricles and left and right coronary arteries lie on each side of its origin. The superficial cardiac plexus lies between the branching of the pulmonary trunk and the aortic arch (see Fig. 57.61). The tracheal bifurcation and subcarinal lymph nodes are superior and to the right (see Fig. 52.7).

Variations and congenital anomalies The pulmonary trunk is a relatively constant structure and there are minimal variations in healthy individuals. Congenital anomalies include pulmonary atresia and truncus arteriosus (common truncus).

Right and left pulmonary arteries

The pulmonary arteries are described in Chapter 54.

Thoracic aorta

Ascending aorta

The ascending aorta is typically about 5 cm in length. It originates at the base of the left ventricle, commonly level with the inferior border of the third left costal cartilage, and initially ascends whilst curving anteriorly and to the right. It passes from posterior to the left half of the sternum to become the aortic arch posterior to the right half of the inferior part of the manubrium of the sternum, or the manubriosternal joint (level with the right second costal cartilage), or the superior part of the right side of the sternal body (level with the right second intercostal space). In children, the diameter of the thoracic aorta correlates most closely with body surface area (Kervancioglu et al 2006, Kaiser et al 2008).

Relations The ascending aorta lies within the fibrous pericardium, enclosed in a tube of visceral serous pericardium together with the pulmonary trunk (see Figs 58.1, 57.1, 57.4). The conus arteriosus of the right ventricle, initial segment of the pulmonary trunk and right auricle are anterior to its lower part. Superiorly, it is separated from the sternum by the pericardium, the pleura and the anterior border of the right lung, loose areolar tissue and the thymus or its remnants. The left atrium, right pulmonary artery and right main bronchus are posterior. The superior vena cava (also partly posterior) and the right atrium are to the right. The left atrium and, more superiorly, the pulmonary trunk are to the left. At least two para-aortic bodies (aortopulmonary paraganglia) lie between the ascending aorta and the pulmonary trunk. Relative to the ascending aorta, the inferior para-aortic body is located on its anterior surface near to the heart, and the middle para-aortic body is located on its right side.

The aortopulmonary window is a space between the pulmonary trunk and aortic arch, bordered by the ascending aorta anteriorly, the descending aorta posteriorly, the mediastinal part of the parietal pleura laterally and the left main bronchus medially (Deutsch and Savides 2005) (see Fig. 58.1; **Fig. 58.4**). It contains lymph nodes, fatty tissue, the ligamentum arteriosum, the superficial cardiac plexus, cardiac nerves and the left recurrent laryngeal nerve.

Aortic arch

The aortic arch continues from the ascending aorta and lies mainly within the superior mediastinum (see Fig. 57.4A–C). Its origin, slightly to the right of the midline, is level typically with either the right first intercostal space, the second costal cartilage or the second intercostal space. The arch initially ascends obliquely and posteriorly to the left over the anterior surface of the trachea, and then posteriorly across its left side. It ascends superiorly to the midlevel of the manubrium of the sternum, and curves around the hilum of the left lung. Posteriorly it descends to the left of the body of the fourth thoracic vertebra: at around the level of the sternal plane, posterior to the second left sternocostal joint, it continues as the descending thoracic aorta. The concavity of the aortic arch may lie superior, on or inferior to the sternal plane: most commonly it is inferior to the plane (see Fig. 52.7, Tables 52.1–52.2).

The shadow of the aortic arch is easily identified in frontal chest radiographs, where it is seen as a rounded leftward projection (aortic knuckle) to the left of the manubrium of the sternum (see Fig. 56.17). The shadow of the adjacent left superior intercostal vein crossing its left side, from posterior to anterior, may form an additional small rounded shadow termed the 'aortic nipple'. The aortic arch is best visualized in left anterior oblique views on angiography and with equivalent computed tomography (CT) reconstruction planes, when the pulmonary trunk and its left branch will be seen inferiorly occupying the concavity of the arch.

The concavity of the aortic arch is the upper curved limit through which structures gain access to, or leave, the hilum of the left lung. The diameter of the aortic arch initially matches that of the ascending aorta but is significantly reduced distal to the origin of the three large branches to the head, neck and upper limbs. The aortic isthmus, a small stricture at the border of the aortic arch with the descending thoracic aorta, may be followed by a dilation; in the fetus, the isthmus lies between the origin of the left subclavian artery and the opening of the ductus arteriosus (Ch. 13).

Relations The left mediastinal part of the parietal pleura is located anterior and to the left of the aortic arch. Deep to the pleura, the arch is crossed, in anteroposterior order, by the left phrenic nerve, left lower cervical cardiac branch of the vagus nerve, left superior cervical cardiac branch(es) of the sympathetic trunk, the left thoracic cardiac branches of the vagus nerve, and the left vagus nerve (see Figs 56.6, 56.7B, 57.61). As the latter crosses the aortic arch, its recurrent laryngeal branch hooks inferior to the vessel, to the left posterior aspect of the ligamentum arteriosum, and then ascends on the right of the aortic arch. The left superior intercostal vein ascends obliquely anteriorly on the arch, anterolateral to the left vagus nerve and posteromedial to the left phrenic nerve and pericardiacophrenic vessels. The left lung and pleura separate all these structures from the thoracic wall. Posterior and to the right are the trachea and the deep cardiac plexus, the left recurrent laryngeal nerve, the oesophagus, thoracic duct and vertebral column. Superiorly, the brachiocephalic trunk, left common carotid and left subclavian arteries arise from its convexity (from right to left), and are crossed anteriorly near their origins by the left brachiocephalic vein. The branching of the pulmonary trunk (into pulmonary arteries), left main bronchus, ligamentum arteriosum, superficial cardiac plexus and the left recurrent laryngeal nerve are typically inferior.

Pneumomediastinum and aortic nipple

Available with the *Gray's Anatomy* e-book

Variations of the aortic arch The most superior level of the aortic arch is typically about 2.5 cm inferior to the jugular notch, although this may vary. It is located more superiorly, closer to the jugular notch, in infants and again in senescence when it is a result of vascular ectasia.

In a right-sided aortic arch, the aorta curves over the hilum of the right lung and descends to the right of the vertebral column: this is usually associated with transposition of the thoraco-abdominal viscera (situs inversus) (Akgun et al 2016). Less often, after arching over the hilum of the right lung, the descending thoracic aorta may pass posterior to the oesophagus to gain a left-sided position, and this is not accompanied by visceral transposition. The presence of a right-sided aortic arch is of relevance when planning the repair of oesophageal atresia in neonates.

The aorta may divide into ascending and descending trunks, the former dividing into three branches to supply the head and upper limbs. Alternatively, it may divide near its origin, producing a double aortic arch; the two branches soon reunite and the oesophagus and trachea usually pass through the interval between them. Entrapment of the oesophagus and/or trachea by a double aortic arch, or by aberrant great vessels (arteries), is referred to as a vascular ring.

Branches and variations From right to left, the brachiocephalic trunk, left common carotid and left subclavian arteries arise from the convex aspect of the aortic arch (see Figs 58.1, 57.4,). These vessels may branch from the beginning of the aortic arch or the superior part of the ascending aorta. The distance between their origins varies, the most frequent being apposition of the left common carotid artery to the brachiocephalic trunk. Multiple variants of their branching pattern have been observed; other branches may arise from the aortic arch, including the inferior thyroid, thyroidea ima, thymic, left coronary and bronchial arteries (Akgun et al 2016). The left vertebral artery may arise between the left common carotid and the left subclavian arteries (see Fig. 52.5B).

The coronary arteries usually originate from the aortic sinuses, but occasionally may arise from ectopic locations. Most commonly, an ectopic left coronary artery arises from the pulmonary trunk or one of its branches (Anomalous Left Coronary Artery from the Pulmonary Artery (ALCAPA) or Bland–White–Garland syndrome) (Fig. 58.2; Commentary 7.2). This potentially fatal condition requires urgent surgical correction because the myocardium is supplied with deoxygenated pulmonary blood instead of systemic blood (Loukas et al 2009). Infantile symptoms include pallor, fatigue, irritability, weak cry, cough, dyspnoea, and signs of ischaemia and cardiac failure precipitated during or after feeding, or during defecation or crying. The electrocardiogram may reveal deep narrow Q waves, left ventricular hypertrophy and left axis deviation. Radiologically, cardiomegaly is present with left ventricular and left atrial enlargement. Colour flow imaging can identify the anomalous origin of the left coronary artery. The pulmonary trunk may also give rise to the right coronary artery, the anterior interventricular branch of the left coronary artery, or even both coronary arteries. Typically, there is an extensive development of collateral vessels in the heart (Fig. 58.3).

Pulmonary atresia is caused by a complete obstruction of pulmonary outflow and may be due to an absence or defect of the pulmonary valvular leaflets. It is associated with a blind-ending pulmonary trunk that causes right ventricular hypoplasia. Reduced flow may render the pulmonary trunk atretic, small or even normal in size, making diagnosis challenging. A diminished pulmonary flow is supplied through a patent ductus arteriosus (Smith and McKay 2004), and a concomitant ventricular septal defect may permit outflow from the right ventricle. Surgical repair is necessary to allow adequate oxygenation of blood throughout the body.

In truncus arteriosus (common truncus), a single common arterial trunk exits the heart and subsequently divides into the pulmonary trunk and the ascending aorta. Early neonatal life is possible because there is usually a coexisting ventricular septal defect; expedited surgical repair is necessary to avoid congestive heart failure, failure to thrive and death.

Pneumomediastinum is an overarching term that describes the presence of air in the mediastinum. It may arise from a wide range of pathological conditions or physiological states, e.g. penetrating trauma, ruptured major airways or oesophagus, hyperventilation or distressed ventilation such as acute asthma, periparturition or diabetic ketoacidosis.

The aortic nipple is the radiographic term used to describe a lateral nipple-like projection located on the aortic knuckle. It corresponds to the end-on appearance of the left superior intercostal vein coursing anteriorly and is not observed in all individuals. It may be mistaken radiologically for lymphadenopathy or an intrapulmonary nodule or neoplasm. Despite their relative independence, the aortic nipple is defined by new contours in cases of pneumomediastinum, taking on an 'inverted aortic nipple' appearance (Fig. 58.5). In this position, the inverted aortic nipple

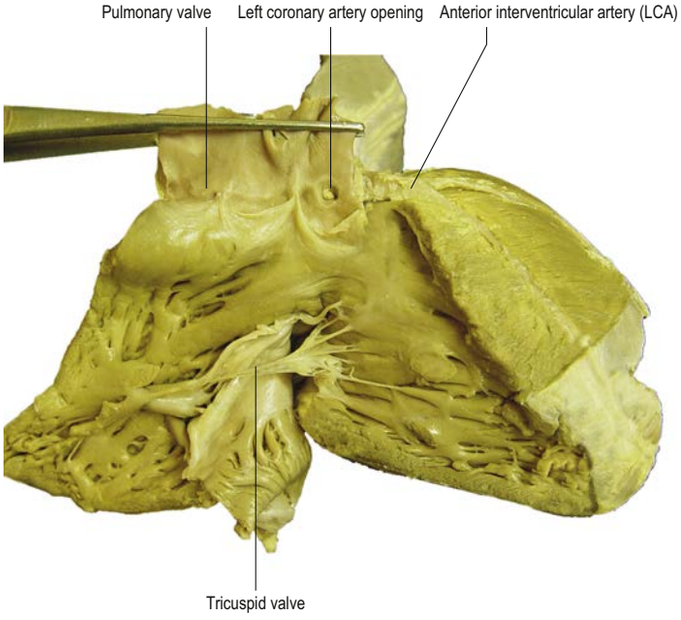

Fig. 58.2 A case of a left coronary artery arising from the pulmonary trunk (Bland–White–Garland syndrome). (Courtesy of Professor M Loukas. With permission from Loukas M, Groat C, Khangura R et al 2009 The normal and abnormal anatomy of the coronary arteries. Clin Anat 22:114–28.)

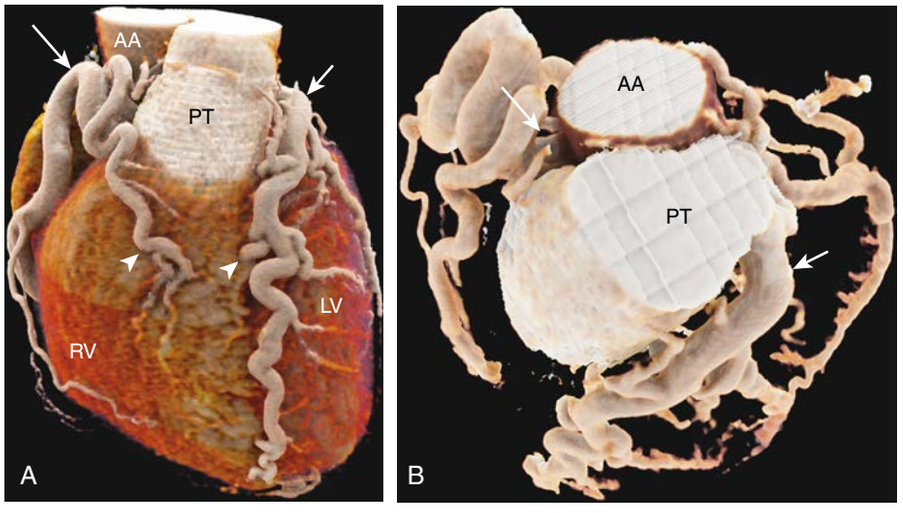

Fig. 58.3 **A-G**, Anomalous left coronary artery from the pulmonary artery (ALCAPA), also known as Bland–White–Garland syndrome, in an adult male. **A**, Anterior oblique volume rendered (VR) image shows dilated right (long arrow) and left (short arrow) coronary arteries with extensive hypertrophied collateral vessels (arrow heads). **B**, Top-down VR image shows a conventional origin of the right coronary artery (long arrow) from the ascending aorta and an aberrant origin of the left coronary artery from the pulmonary trunk (short arrow). **C**, Right lateral oblique view shows a large right coronary artery (long arrow) with dilated branches including a large conal branch (arrow head). **D**, Left lateral view shows the aberrant origin of the left coronary artery from the pulmonary trunk (short arrow) and dilated dilated anterior interventricular (white arrow head), circumflex arteries (black arrow head) and associated branch vessels. **E**, Anterior oblique VR image shows coronary arteries with heart chambers removed. Note the dilated right (long arrow) and left (short arrow) coronary arteries with extensive hypertrophied collateral vessels (arrow heads). **F**, Anterior oblique VR image of coronary arteries and myocardium shows dilated right (long arrow) and left (short arrow) coronary arteries and an extensive collateral supplying the left ventricle and interventricular septum (arrow heads). **G**, Inferior view showing large right coronary artery (long arrow) with multiple large collateral vessels supplying the inferior left ventricle (arrow heads). Abbreviations. AA, ascending aorta; PT, pulmonary artery; RA, right atrium; RV, right ventricle; LA, left atrium; LV, left ventricle.

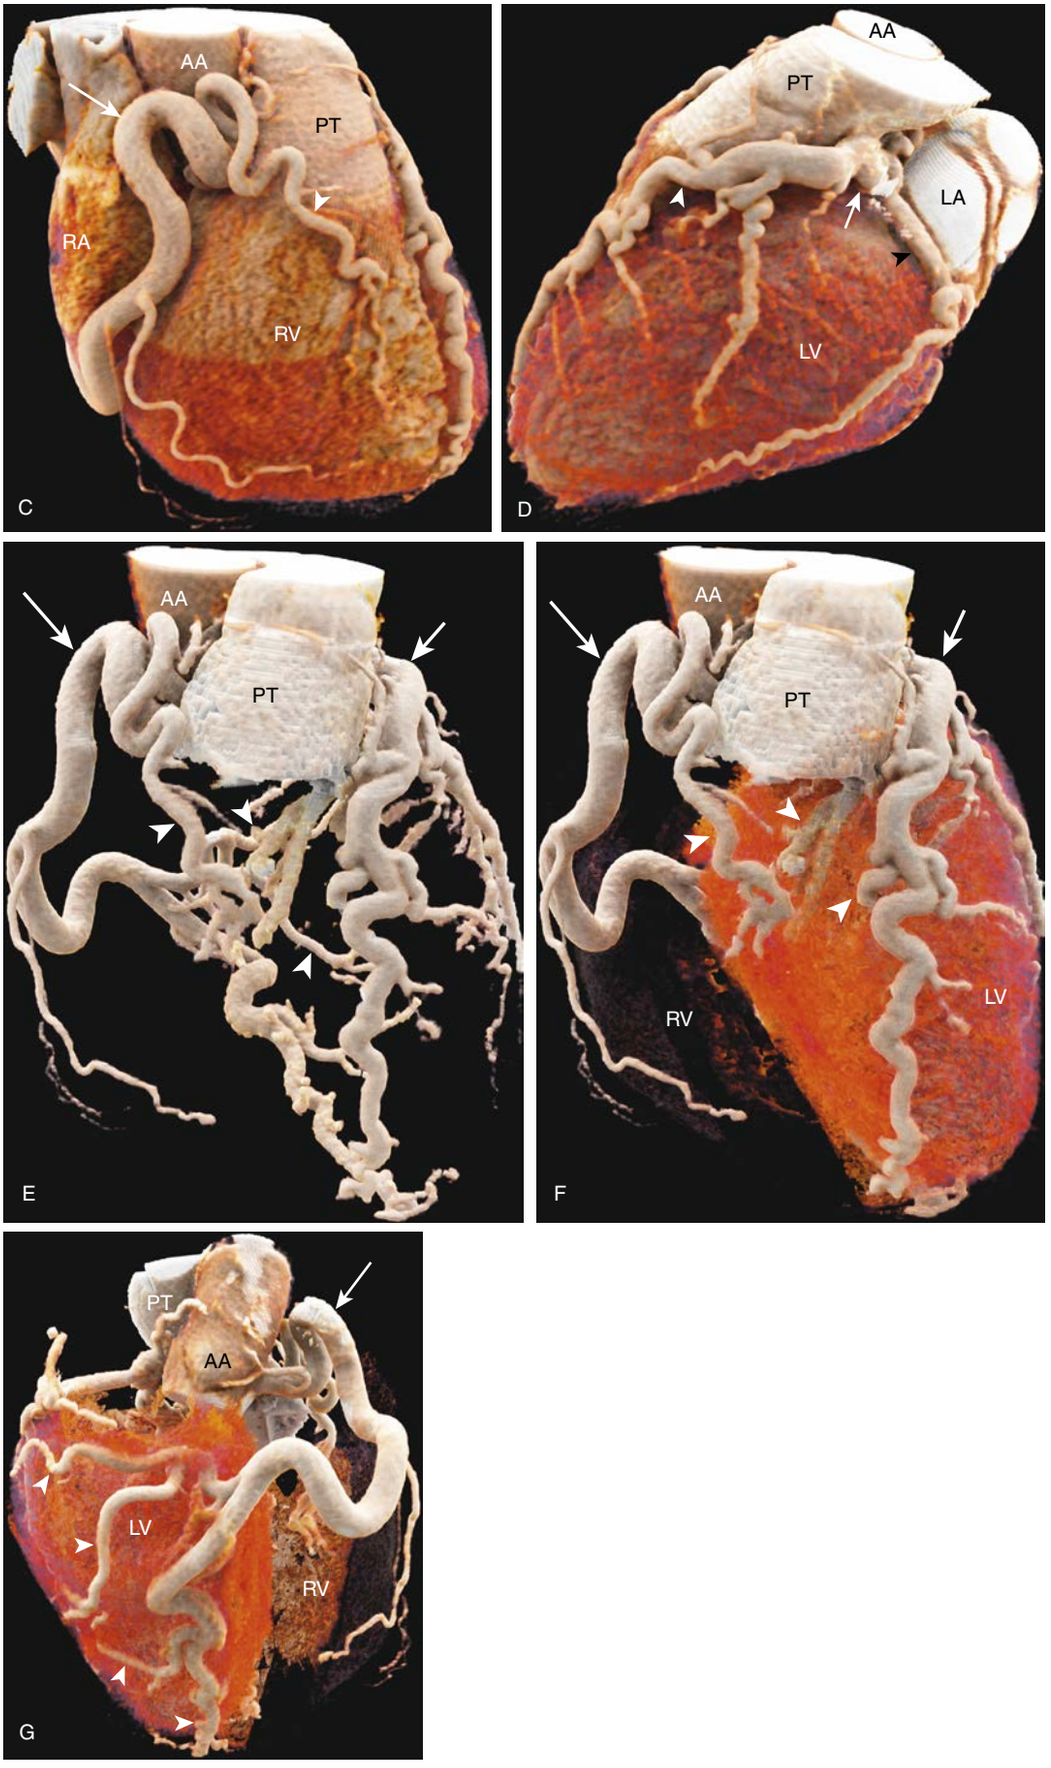

Fig. 58.3 cont'd

may facilitate radiographic discrimination of pneumomediastinum from similar conditions. The presence of a particularly prominent aortic nipple has also been shown to precede pathological conditions such as venous obstruction in the superior and inferior venae cavae or left brachiocephalic vein, and has been identified in conditions where venous flow through the left superior intercostal vein is increased (e.g. portal venous hypertension and certain congenital venous anomalies).

There are several variants of this arrangement. The most common are: when a right-sided aortic arch and the upper part of the descending thoracic aorta pass anterior to the oesophagus and trachea, and the ductus arteriosus passes posterior to the oesophagus into an aortic diverticulum; a right-sided aortic arch and the upper part of the descending thoracic aorta pass anteriorly, and the ductus arteriosus is inserted into the left subclavian artery arising as a fourth branch from the aortic arch; a left-sided descending thoracic aorta is attached to a left-sided ductus arteriosus anterior to the oesophagus, and a right-sided aortic arch passes posteriorly; the right superior part of the descending thoracic aorta wraps around the oesophagus and the ductus arteriosus is right-sided; the right upper part of the aorta wraps around the oesophagus and the ductus arteriosus is left-sided (Akgun et al 2016).

The left common carotid artery may arise from the brachiocephalic trunk, when it is known as a bovine arch (7%), although this does not represent the morphology seen in bovines. Rarely, the left common carotid and subclavian arteries may arise from a left brachiocephalic trunk or from the right common carotid artery, with the right subclavian artery arising separately (Akgun et al 2016). The right common carotid and subclavian arteries may arise separately, in which case the right subclavian artery often branches from the left part of the aortic arch distal to the left subclavian artery, and usually passes posterior to the oesophagus as an aberrant right subclavian artery (sometimes referred to as a lusoria artery). A diverticular outpouching (diverticulum of Kommerell) may be present at the origin of an aberrant left or right subclavian artery from a right or left aortic arch, respectively (**Fig. 58.6**). It can become aneurysmal and cause fatal haemorrhage during endoscopy and can form a vascular ring around the oesophagus and trachea, presenting in the neonate as a feeding disorder with failure to thrive.

Rare avian forms of branching have been reported. For example, the right common carotid and right subclavian arteries arise from the aortic arch, and the left common carotid and left subclavian arteries arise from the descending thoracic aorta (Akgun et al 2016). Alternatively, two common arterial trunks arise from the aortic arch, the right trunk branching into the left and right common carotid arteries, and the left trunk branching into the left and right subclavian arteries. Another rare order of the branching from the aortic arch is (from right to left): the right subclavian artery, left subclavian artery, followed by the right common carotid and left common carotid arteries, the latter two arising close together and almost forming a common carotid trunk.

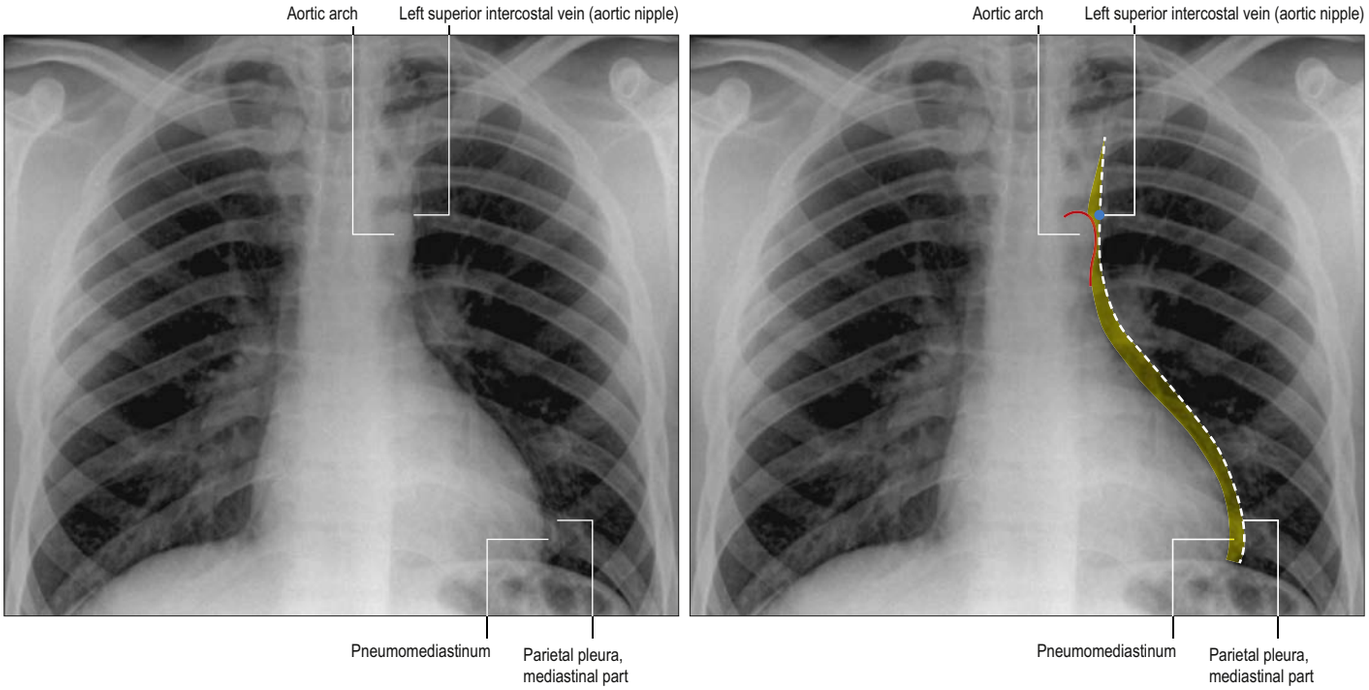

Fig. 58.5 A posteroanterior (PA) chest radiograph, showing the 'aortic nipple' appearance of the left superior intercostal vein (green dot) in a patient with pneumomediastinum. (Courtesy of Professor M Loukas. With permission from Walters A, Cassidy L, Muhleman M et al 2013 Pneumomediastinum and the aortic nipple: the clinical relevance of the left superior intercostal vein. Clin Anat 27:757–63.)

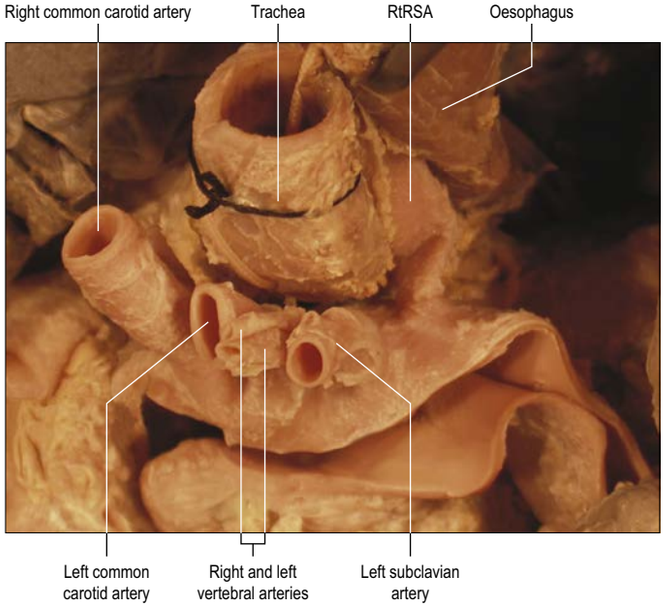

Fig. 58.6 A dissection showing a left aortic arch that gives rise to a common vertebral trunk (seen branching into the right and left vertebral arteries) and a retrotracheal aberrant right subclavian artery (RtRSA), also known as a lusoria artery. (Courtesy of Professor M Loukas with permission from Loukas M, Louis RG Jr, Gaspard J et al 2006 A retrotracheal right subclavian artery in association with a vertebral artery and thyroidea ima. Folia Morphol (Warsz) 65:236–41.)

The aortic arch may curve posterior to the oesophagus and trachea, instead of passing anteriorly, and may show variation in its branching. For example, another rare avian form reported is with both carotid arteries originating from the same common trunk, and a left subclavian artery originating from the aortic arch, while the right subclavian artery arises from the descending thoracic aorta. One or more of the ductus arteriosi may remain patent.

Very rarely, the external and internal carotid arteries arise separately from the aortic arch and the common carotid artery is absent on one or both sides, or both carotid arteries and one or both vertebral arteries can be separate branches. When a right aortic arch and descending thoracic aorta occur, the arrangement of its three branches is reversed and the common carotid arteries may have a single trunk. Other arteries may branch from it; most commonly, these are one or both bronchial arteries and the thyroidea ima artery.

Coarctation of the thoracic aorta The aortic lumen is occasionally partly or completely obliterated, either above (preductal or infantile type), opposite or just beyond (postductal or adult type), the entry of the ductus arteriosus. In the preductal type, the length of coarctation is variable, aortic arch hypoplasia is common and the left subclavian and even the brachiocephalic trunk may be involved. Severe forms of infantile coarctation and its extreme form (aortic interruption) may be patent ductus arteriosus-dependent, as there is no time for effective collateral circulation to develop. Prostaglandin infusion prior to transfer, and surgery at a tertiary centre, often provide a good mid- to long-term outlook for such infants.

The postductal type of coarctation has been attributed to abnormal extension of tissue of the ductus arteriosus into the aortic wall, stenosing both vessels as the duct contracts after birth. This form may permit years of normal life, allowing the development of an extensive collateral circulation to the aorta distal to the stenosis (Figs 58.7–58.8). High vascularity of the thoracic wall is important and clinically characteristic. Many arteries that arise indirectly from the aorta proximal to the region of coarctation anastomose with vessels that are connected to the aorta distal to the region of coarctation; these vessels form a bypass route and become greatly enlarged. Thus, in the thoracic wall, the thoraco-acromial, lateral thoracic and subscapular arteries (from the axillary artery), the suprascapular artery (from the subclavian artery) and the supreme intercostal artery (from the costocervical trunk) anastomose with other posterior intercostal arteries and the internal thoracic artery and its terminal branches (e.g. the musculophrenic artery) anastomose with many of the posterior intercostal arteries and the inferior epigastric arteries (from the external iliac artery). Posterior intercostal arteries are always involved, and enlargement of their dorsal branches may eventually groove (notch) the inferior margins of the ribs. The radiographic shadow of an enlarged left subclavian artery is also increased. Enlargement of the scapular vessels and anastomoses may lead to widespread interscapular pulsation which is palpated easily with the palm of the hand, and is sometimes heard on auscultation.

Para-aortic bodies

Para-aortic bodies (aortopulmonary paraganglia) belong to the branchiomeric category of paraganglia. They are chemoreceptors and respond to changes in arterial gas concentrations such as lowered pO_2, increased pCO_2 and increased hydrogen ion concentration. These microscopic structures occur in several locations within the thorax. Coronary paraganglia lie between the ascending aorta and pulmonary trunk, either anteriorly or posteriorly, adjacent to the proximal aorta (aortic root); pulmonary paraganglia lie in the groove between the ductus arteriosus and the pulmonary trunk; subclavian–supra-aortic paraganglia lie between either the right subclavian and right common carotid arteries, or the left subclavian and left common carotid arteries, or caudal to the left subclavian artery, adjacent to the aortic arch.

Rarely, tumours may arise within the para-aortic bodies (e.g. mediastinal paragangliomas that originate in the pulmonary trunk and aortic arch). Generally, these tumours are asymptomatic and are discovered incidentally, but they may occasionally lead to feelings of pressure and hoarseness (Rooke et al 2007).

Brachiocephalic trunk (brachiocephalic artery)

The brachiocephalic trunk, the largest diameter branch of the aortic arch, is 4–5 cm in length (see Figs 58.1, 57.4A–B). It arises from the convexity of the aortic arch posterior to the centre of the manubrium of the sternum, and ascends posterolaterally to the right, initially located anterior to the trachea, then on its right. It divides into the right common carotid and right subclavian arteries level with the superior border of the right sternoclavicular joint, or immediately superior to it. The brachiocephalic trunk and left common carotid artery may share a common origin (Osborn 1998).

Relations The anterior surface of the brachiocephalic trunk is separated from the manubrium of the sternum by sternohyoid and sternothyroid, thymic remnants, the left brachiocephalic and right inferior thyroid veins (crossing its root), and sometimes by the right cardiac branches (cervical and/or thoracic) of the vagus nerve. Posterior relations are the trachea (inferiorly) and the right mediastinal part of the parietal pleura (superiorly). The right vagus nerve is posterolateral (superiorly) and lateral to the trachea (inferiorly) (see Fig. 56.7A). On its right side are the right brachiocephalic vein and the upper part of the superior vena cava and mediastinal part of the parietal pleura, and on its left side are thymic remnants, the origin of the left common carotid artery, the inferior thyroid veins, the thyroidea ima artery (if present) and the trachea (superiorly).

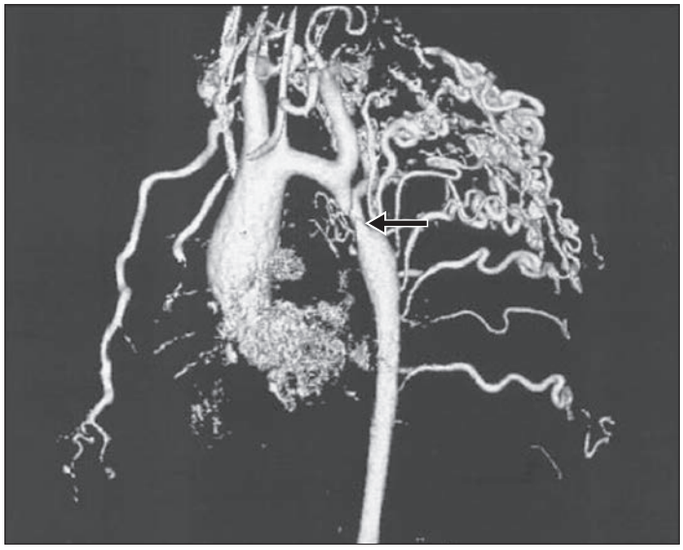

Fig. 58.7 A cardiac magnetic resonance (MR) angiogram showing three-dimensional reconstruction of a native aortic coarctation (arrow) in an adult with extensive collateral flow. Note the marked dilation of the left subclavian artery, supplying most of the collateral vessels, and mild hypoplasia of the aortic arch. (Courtesy of Dr Raad Mohiaddin, Royal Brompton Hospital, London.)

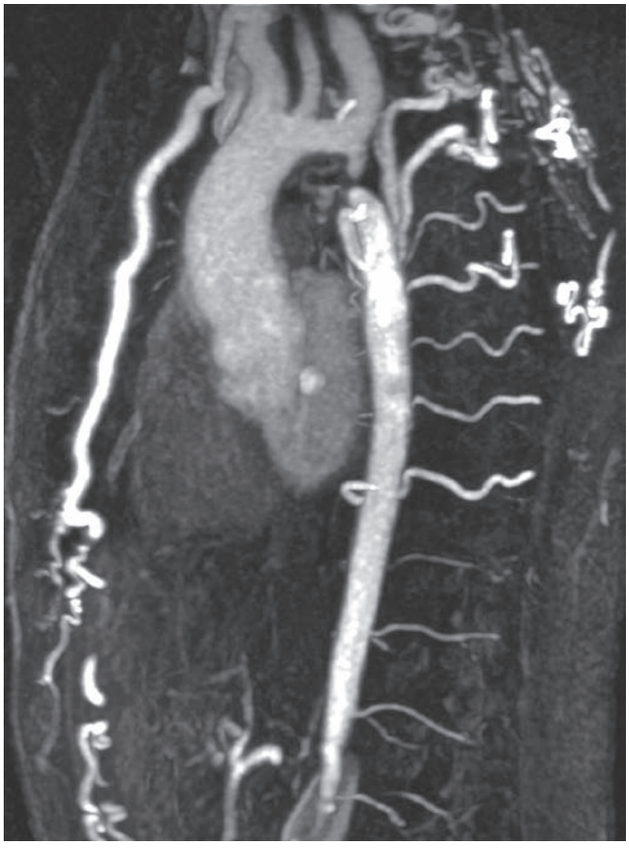

Fig. 58.8 MRA (sagittal oblique reconstruction) of a patient presenting with hypertension and femoral delay. There is a coarctation of the aorta just beyond the left subclavian artery and an extensive collateral circulation through intercostal and internal thoracic arteries. (With permission from Fattoni R, Lovato L 2015. The thoracic aorta: diagnostic aspects. In Grainger and Allison's Diagnostic Radiology. 553-590.)

Degeneration of the aortic tunica media and intimal dissection play a major role in the pathogenesis of aneurysms affecting the ascending aorta and aortic arch. Smooth muscle cells are lost and elastic fibres degenerate, producing cystic spaces in the media that then fill with mucoid material. The loss of these structural cells leads to weakening of the wall with progressive dilation. Ageing and hypertension are major predisposing factors to cystic medial degeneration and there is a strong link with cigarette smoking. Thoracic aortic aneurysms are categorized by their location. A particular pattern of aortic root involvement, anulo-aortic ectasia, is seen in Marfan syndrome (Baliga et al 2007). Descending aortic aneurysms are generally caused by atherosclerosis (90%) and the remainder result from mycotic disease or trauma.

Associations also exist between thoracic aortic aneurysm and other connective tissue diseases such as homocysteinuria and Ehlers–Danlos syndrome. A genetic relation is seen in familial thoracic aortic aneurysm syndrome (Baliga et al 2007). Rarely, aneurysms may occur as a result of Takayasu's arteritis, or infections within the aortic wall. Some aortic aneurysms are incidental findings on chest films or CT studies. Symptomatic cases present with breathlessness, unbearable chest and back pain, hoarse voice, cough and haemoptysis. Early diastolic murmurs caused by aortic regurgitation may be audible. Repair is carried out in patients with symptoms or fusiform dilation measuring more than 5 cm in diameter. Aneurysms may also occur in an aberrant right subclavian artery and may involve the diverticulum of Kommerell, leading to dysphagia and even tracheal compression. Inadvertent rupture may occur during endoscopy because of the retro-oesophageal location.

Aortic dissection occurs as a result of degeneration of the tunica media of the aortic wall and is associated with senescence, persistent hypertension or collagen vascular diseases such as Marfan syndrome. Many patients with aortic dissection have a pre-existing aneurysm. Other associations include aortic coarctation, Turner syndrome, cocaine abuse (<1%) and trauma during surgical procedures. There is a higher prevalence in males than females, but after 75 years of age there is no sex difference in prevalence (Baliga et al 2007). In a classic aortic dissection, an intimal tear may occur, producing a split into the tunica media that creates a false lumen (Fig. 58.9). If another tear occurs, connection can be made once again with the true lumen (double-barrel aorta). Additional aetiopathologies include penetrating atherosclerotic ulceration, where an atherosclerotic plaque ruptures into the aortic tunica media, and aortic intramural haematoma, where the vasa vasorum haemorrhage into the wall of the aorta (Baliga et al 2007).

Aortic dissections are classified as types I, II, IIIa and IIIb (DeBakey classification), or types A and B (Stanford classification). Dissections that include the aorta proximal to the left subclavian artery, with or without distal extension, are classified as type I, II or A. Type I involves up to the entire aorta (ascending, arch and descending), whereas type II involves the ascending aorta only. Dissections that are distal to the left subclavian artery are classified as type IIIa (extend to the respiratory diaphragm), IIIb (extend below the respiratory diaphragm) or B. These cases present acutely with severe retrosternal, neck or interscapular chest pain. Depending on the extent of the dissection, they may be associated with neurological signs, diarrhoea or leg weakness. Extension into the pericardium causes cardiac tamponade and circulatory collapse. Diagnosis is established by echocardiography and on contrast-enhanced CT or magnetic resonance imaging (MRI). Medical management is possible for descending aortic dissections, while surgical repair is essential for ascending aortic or aortic arch dissection.

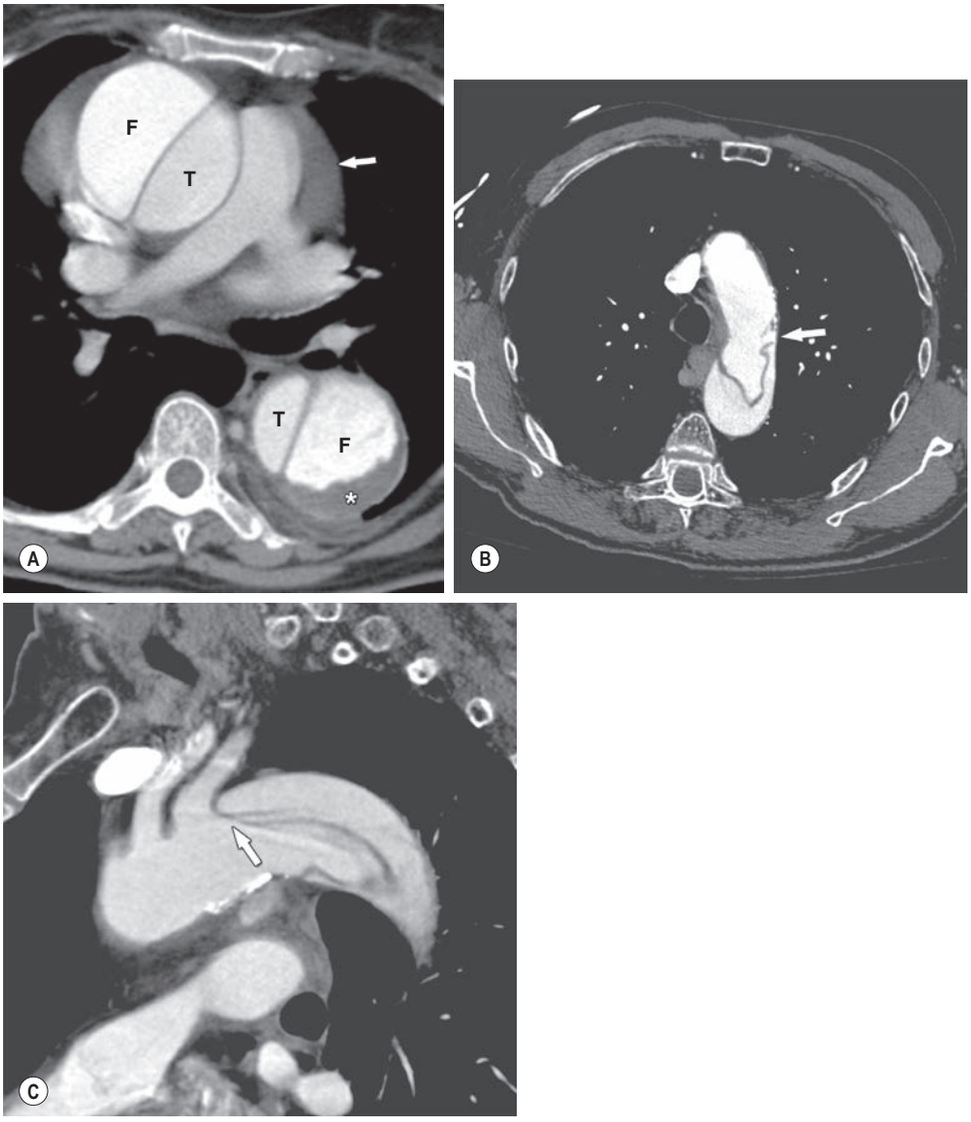

Fig. 58.9 A-C. Contrast enhanced CT images of thoracic aortic dissection, showing a double barrelled aortic lumen with true (T) and false (F) lumen. **A**, Stanford type A (axial section) aortic dissection including both the ascending aorta and descending thoracic aorta. A pericardial effusion (white arrow) is also present. **B**, Stanford type B aortic dissection (axial sections) showing the intimal defect (white arrow) and opening between the true and false lumina. **C**, Stanford type B aortic dissection (sagittal oblique section) showing the dissection flap (white arrow) originating immediately distal to the origin of the left subclavian artery. In Advanced Cardiac Imaging (Nieman K, Gaemperle O, Lancellotti P et al eds) Chapter 20, 661-705. Woodhead Publishing Series in Biomaterial, Elsevier.)

Branches The brachiocephalic trunk usually has only terminal branches, the right common carotid and right subclavian arteries. A thymic or bronchial branch, or a thyroidea ima artery (occasionally), can arise from it (see Fig. 58.1). The thyroidea ima artery is a small and inconstant artery that may arise from the aortic arch, brachiocephalic trunk, common carotid, subclavian, pericardiacophrenic or internal thoracic arteries; most commonly it arises from right-sided vessels (Tunali 2016, Yalcin 2016). It ascends on the trachea to the thyroid isthmus, where it terminates.

Descending thoracic aorta

The descending thoracic aorta is located within the posterior mediastinum (see Figs 52.3, 56.1, 56.6–56.7B, 56.13–56.14A, 56.20D–E). It is continuous with the aortic arch, beginning level with the lower border of the body of the fourth thoracic vertebra (typically at the sternal plane, although the level of this plane may vary), and ending anterior to the lower border of the body of the twelfth thoracic vertebra at the aortic hiatus, through which it passes. It is to the left of the vertebral column at its origin, and reaches the midline (median plane), anterior to the vertebral bodies, as it descends.

Relations Anterior to the descending thoracic aorta, from superior to inferior, are the hilum of the left lung, the pericardium separating it from the left atrium, the oesophagus and the lumbar part of the respiratory diaphragm. The vertebral column and accessory hemiazygos (superiorly) and hemiazygos (inferiorly) veins are posterior. To the right is the thoracic duct and the azygos vein, and inferiorly, to both the left and right sides, are the pleura-covered parts of the mediastinal surfaces of the respective lungs. The oesophagus with its associated plexus of nerves is closely related to the descending thoracic aorta: it is located to the right of the descending aorta in the upper thorax, anterior to it in the lower thorax, and anterolaterally to the left at the level of the respiratory diaphragm. Occasionally, the descending thoracic aorta traverses the respiratory diaphragm to the left and posterior to the oesophagus (Berdjas and Turina 2011).

Branches

The descending thoracic aorta provides visceral branches to the pericardium, lungs, bronchi and oesophagus, and parietal branches to the thoracic wall and vertebral column.

Pericardial branches A variable number of small vessels are distributed to the posterior aspect of the pericardium.

Bronchial arteries Bronchial arteries vary in number, size and origin. There is usually only one right bronchial artery that commonly arises from the right third posterior intercostal artery, but it may arise from the superior left bronchial artery, or various right posterior intercostal arteries. It runs posterior to the right main bronchus. The left bronchial arteries, usually two, arise from the descending thoracic aorta, near the body of the fifth or sixth thoracic vertebra, and run posterior to the left main bronchus. The bronchial arteries supply the pulmonary areolar tissue, bronchopulmonary lymph nodes, pericardium, visceral pleura and thoracic oesophagus (Ch. 54).

Oesophageal branches Two or three oesophageal arteries that arise either anteriorly or from the right side of the descending thoracic aorta supply the distal thoracic oesophagus (Norton et al 2008).

Mediastinal branches Numerous small vessels supply lymph nodes and areolar tissue in the posterior mediastinum.

Superior phrenic branches Superior phrenic arteries arise from the distal descending thoracic aorta and are distributed posteriorly to the superior (thoracic) surface of the respiratory diaphragm, anastomosing with the musculophrenic and pericardiacophrenic arteries (see Fig. 55.6).

Posterior intercostal arteries The posterior intercostal arteries and their branches are described in Chapter 53.

Subcostal arteries The subcostal arteries are the last paired branches of the descending thoracic aorta, arising in series with the posterior intercostal arteries and inferior to the twelfth ribs. Each runs laterally, anterior to the body of the twelfth thoracic vertebra and posterior to the thoracic splanchnic nerves, sympathetic trunk, costal part of the parietal pleura and lumbar part of the respiratory diaphragm. The right subcostal artery is also posterior to the thoracic duct and azygos vein, while the left is posterior to the hemiazygos vein. Each artery enters the abdomen at the lower border of the twelfth rib, accompanied by the twelfth thoracic (subcostal) nerve, lying posterior to the lateral arcuate ligament and kidney, and anterior to quadratus lumborum. The right artery courses posterior to the ascending colon, and the left courses posterior to the descending colon. The subcostal arteries pierce the aponeurosis of transversus abdominis to become more superficial, and continue toward the anterior midline in the plane between transversus abdominis and internal abdominal oblique; they anastomose with the superior epigastric, lower posterior intercostal and lumbar arteries. Each has a dorsal branch, distributed like those of the posterior intercostal arteries.

Aberrant artery (right dorsal aorta vestige) A small artery sometimes leaves the descending thoracic aorta from its right side near the origin of the right bronchial artery. It ascends to the right behind the trachea and oesophagus and may anastomose with the right supreme intercostal artery.

Aortic rupture in trauma Rupture of the ascending aorta is usually associated with a high immediate mortality (Baliga et al 2007). Blunt aortic rupture commonly occurs in road traffic accidents and has a 20% survival rate. There is usually a transverse tear involving the tunica intima and tunica media of the aortic wall; systemic circulatory pressure may cause the formation of a false aneurysm. Rupture of the isthmus region of the descending thoracic aorta is more common, probably because it marks the junction between the mobile and fixed parts of the aorta. Other sites include the ascending aorta proximal to the origin of the brachiocephalic trunk, the aortic arch and the abdominal aorta. Rupture is likely to be the result of a number of factors, including torsion, shear and stretching forces, possibly compounded by hydrostatic pressure.

Aortic atherosclerosis or calcification Echocardiography, particularly transoesophageal, allows detailed assessment of proximal aortic atherosclerosis implicated in systemic embolic events and strokes, and the extent of turbulent flow. MRI can allow accurate assessment of the composition and size of atherosclerotic plaques and flow dynamics, permitting assessment of the risk of plaque rupture and thrombus formation.

Subclavian arteries

Right subclavian artery

The right subclavian artery arises from the brachiocephalic trunk either posterior to the right sternoclavicular joint or immediately superior to it (level with the body of the second thoracic vertebra or T1–T2 intervertebral disc (Badshah et al 2017)) (see Fig. 52.3). It ascends superolaterally to the level of the first rib, where it is located posterior to both the sternal end of the clavicle and scalenus anterior; it has a minimal intrathoracic presence. The vessel then passes inferolaterally across the superior surface of the first rib, and at the external border of the rib becomes the right axillary artery (see Fig. 48.3).

Left subclavian artery

In the majority of individuals the left subclavian artery originates independently from the aortic arch after the origins of the brachiocephalic and left common carotid arteries (see Fig. 57.4). It ascends into the neck posterior to scalenus anterior, then passes inferolaterally towards the external border of the first rib, where it becomes the left axillary artery. A common origin occasionally exists between the left subclavian and vertebral arteries. Bilateral brachiocephalic trunks are rare: each divides into common carotid and subclavian arteries.

Relations In the thorax the left subclavian artery is related anteriorly to the left common carotid artery and left brachiocephalic vein (and sometimes the inferior thyroid vein), from which it is separated by the left vagus, cardiac and phrenic nerves (see Figs 56.6–56.7, 57.12). Sternothyroid and sternohyoid lie between the vessel and

the upper left aspect of the posterior surface of the manubrium of the sternum.

The mediastinal surface of the left lung and parietal pleura are lateral, and also encroach on its anterior and posterior surfaces. The trachea, left recurrent laryngeal nerve, oesophagus and thoracic duct are medial. When located immediately lateral to the oesophagus, the thoracic duct and longus colli are posterior.

Common carotid arteries

The right and left common carotid arteries differ in their length and origin. The right is exclusively cervical and arises from the brachiocephalic trunk posterior to the superior part of the right sternoclavicular joint, or immediately superior to the joint. The left originates directly from the aortic arch immediately posterolateral to the brachiocephalic trunk and therefore has both thoracic and cervical parts. The origin of the arteries may be variable; for example, both common carotid arteries may emerge from the brachiocephalic trunk (Panagouli et al 2018), separately from the aorta or from a common trunk (Akgun et al 2016).

Right common carotid artery

The right common carotid artery and its relations are described in Chapter 35.

Left common carotid artery

The left common carotid artery (see Figs 58.1, 35.8) ascends and enters the neck by passing through the superior thoracic aperture, posterior to the left sternoclavicular joint. Its thoracic part is 2.0–2.5 cm long. It lies initially anterior to the trachea, and moves to its left side as it ascends. The cervical course of the artery is described in Chapter 35.

Relations Sternohyoid and sternothyroid, the parietal pleura and the mediastinal surface of the left lung, the left brachiocephalic vein and the thymic remnants are anterior and separate the left common carotid artery from the manubrium of the sternum (Fig. 58.1). The trachea, left subclavian artery, left border of the oesophagus, left recurrent laryngeal nerve and thoracic duct are posterior. To the right are the inferior part of the brachiocephalic trunk and the trachea, inferior thyroid veins and thymic remains. To the left are the left vagus and phrenic nerves, and the parietal pleura and the mediastinal surface of the left lung.

Veins

Brachiocephalic veins

The right and left internal jugular and subclavian veins join to form the right and left brachiocephalic veins, respectively. The right and left brachiocephalic veins join to form the superior vena cava (see Figs 35.14, 52.5, 52.7, 57.12).

Right brachiocephalic vein

The right brachiocephalic vein is about 2.5 cm long. It is commonly formed posterior to the right sternoclavicular joint, although this may vary with study population (see Fig. 52.7). It descends almost vertically to join the left brachiocephalic vein, forming the superior vena cava posterior to the right second costal cartilage or first intercostal space and the associated part of the sternum. It is located anterolateral to the brachiocephalic trunk and right vagus nerve; the right pleura, phrenic nerve and internal thoracic artery are initially posterolateral, becoming lateral inferiorly (see Figs 35.14, 55.10A, 56.7A). Its tributaries are the right vertebral, right internal thoracic and right inferior thyroid veins, and sometimes the right supreme intercostal (first right posterior intercostal) vein.

Left brachiocephalic vein

The left brachiocephalic vein is about 6 cm long. It arises posterior to the left sternoclavicular joint, although this may vary with study population (see Fig. 52.7). It initially sits anterior to the cervical part of the parietal pleura, then descends obliquely and to the right, posterior to the superior half of the manubrium of the sternum, reaching the right second costal cartilage or first intercostal space and the associated part of the sternum where it joins the right brachiocephalic vein to form the superior vena cava (see Figs 58.1, 35.14, 57.12). It is separated from the left sternoclavicular joint and manubrium by sternohyoid and sternothyroid, the thymus or its remnants, and areolar tissue. Near its junction with the right brachiocephalic vein it is partly covered by the mediastinal part of the right parietal pleura. It crosses anterior to the left internal thoracic, left subclavian, left common carotid and brachiocephalic arteries, the left phrenic and left vagus nerves, and the trachea (see Fig. 55.10B). The aortic arch is normally inferior to it. Its tributaries are the left vertebral, left internal thoracic, left inferior thyroid and left superior intercostal veins, and sometimes the left supreme intercostal (first left posterior intercostal), thymic and left pericardiacophrenic veins.

In children, the length and diameter of the left brachiocephalic vein are closely related to height; the diameter reaches adult dimensions at around 10–12 years of age (**Figs 58.10–58.11**)(Sanjeev and Karpawich 2006).

Superior vena cava

The superior vena cava returns blood to the heart from the tissues above the respiratory diaphragm. It is approximately 7 cm in length and is formed by the junction of the left and right brachiocephalic veins. According to conventional anatomical descriptions, the superior vena cava forms posterior to the right first costal cartilage. However, the majority of *in vivo* CT-based studies show that it forms posterior to the right second costal cartilage or first intercostal space and the associated part of the sternum. It descends vertically, being slightly convex to the right, and drains into the right atrium either posterior to the right third costal cartilage, or the third intercostal space, or the region posterior to the right fourth to fifth costal cartilages (see Fig. 52.5). Its inferior half is within the fibrous pericardium and it is covered anterolaterally by the visceral layer of serous pericardium (from which the retrocaval recess projects) (see Figs 57.1, 57.4A–B, 57.12). In children the length and diameter of the superior vena cava are closely related to height; the diameter reaches adult dimensions at around 10–12 years of age (see Figs 58.10–58.11) (Sanjeev and Karpawich 2006). The superior vena cava is valveless.

Relations The mediastinal surface of the right lung and parietal pleura are anterior, lateral and posterolateral, and the pericardium intervenes inferiorly; anteriorly these structures separate the superior vena cava from the right internal thoracic artery, transversus thoracis and the associated region of the anterior thoracic wall (see Figs 55.10A, 56.7A). The trachea and right vagus nerve are located posteromedially, and the hilum of the right lung is posterior. The right phrenic nerve is an immediate right lateral relation, the brachiocephalic trunk and ascending aorta sit to the left of the superior part, and the aorta sits anteromedial to the inferior part, of the superior vena cava (see Fig. 57.4A).

Tributaries Tributaries of the superior vena cava are the azygos vein and small veins from the pericardium and other mediastinal structures, e.g. the thymus (see Figs 56.7A, 58.1).

Superior vena cava obstruction Superior vena cava obstruction is characterized by headaches, facial and neck venous congestion, and oedema, reflecting impaired venous drainage of the head, neck and upper limbs, and of the collateral circulation, resulting in chest wall telangiectasia. Several of the symptoms may subside with recumbency, or may be aggravated by standing up (erect posture). The obstruction may be either partial or complete, and may occur suddenly or gradually. It is usually caused by mediastinally invasive right upper lobe primary bronchogenic carcinoma, metastatic involvement of the right paratracheal lymph nodes or non-Hodgkin lymphoma.

Haemorrhagic intrathoracic goitre, mediastinitis (either benign, malignant or fibrous), mediastinal haematoma, constrictive pericarditis, mediastinal cyst, thrombosis of the superior vena cava and sarcoidosis are less common aetiologies. Radiographic findings might include widening of the upper mediastinum on the frontal view or obliteration of the retrosternal space on the lateral view. Other correlative findings may include pulmonary or mediastinal masses, lymphadenopathy, an enlarged or obliterated azygos venous system, pleural effusion or rib notching. This is usually considered to be an oncological emergency and symptoms are often completely and promptly relieved by insertion of a vascular stent via the femoral vein or by radiotherapy to the affected region after a tissue diagnosis is established.

Variations of the brachiocephalic veins and superior vena cava The left and right brachiocephalic veins may enter the right atrium separately, the right vein descending like a normal superior vena cava. During embryological development, if the cardinal vein does not obliterate, it will persist as a left-sided superior vena cava. A left superior vena cava may have a slender connection with the right superior vena cava and subsequently cross the left side of the aortic arch to pass anterior to the hilum of the left lung before turning to enter the right atrium. It replaces the oblique vein of the left atrium (of Marshall) and coronary sinus, and receives all the normal tributaries of the coronary sinus. Other variations include drainage of the hemiazygos vein directly into the persistent left superior vena cava (Liu et al 2019). The left brachiocephalic vein sometimes projects above the manubrium (more frequently in childhood) and crosses the midline superior to the jugular notch, immediately anterior to the trachea. A left-sided superior vena cava may cause difficulties when placing a cardiac catheter, pacing or defibrillating electrodes because the angle between the left superior vena cava and the left subclavian vein is more acute than that normally found between the left subclavian and left brachiocephalic vein. Its calibre may also be smaller than that of the right. Even if insertion of a catheter into a left superior vena cava is possible, the angle at which the catheter enters the right atrium causes difficulty when attempting to place it into the right ventricle and pulmonary trunk; this generally leaves the catheter tip against the coronary sinus, making it difficult to obtain blood samples. In the majority of cases of persistent left superior venae cava, blood drains into the right atrium via the coronary sinus. When this does not happen, the coronary sinus is absent, and the persistent left superior vena cava drains directly into the right atrium. Cyanosis reflects a persistent right-to-left shunt and affected individuals have a higher risk for paradoxical embolism. Radiographically, there is a paramediastinal bulge anterior to the aortic arch. Electrocardiograms show a left P-wave axis. Diagnosis can be confirmed by cardiac catheterization and angiography. Persistent left superior vena cava may be associated with extracardiac conditions such as VACTERL association (vertebral defects, anal atresia, cardiac malformations, tracheo-oesophageal fistula with oesophageal atresia, radial and renal dysplasia, and limb anomalies); trisomy 21; 22q11; CHARGE association (coloboma, heart defects, choanal atresia, mental retardation, genital and ear anomalies); and 45 XO karyotype (Turner syndrome).

If the superior vena cava is duplicated, the right superior vena cava may drain into the right atrium and the left superior vena cava into the left atrium. Although double superior vena cava is largely asymptomatic, it is usually (along with a sole left-sided superior vena cava) associated with congenital cardiac anomalies, such as pulmonary stenosis, coarctation of the aorta, tetralogy of Fallot and atrial septal defects.

Inferior vena cava

The inferior vena cava returns blood to the heart from infradiaphragmatic tissues. It passes through the caval foramen of the respiratory diaphragm between the right folia and central area of the central tendon of the diaphragm at the level of the superior half of the body of the eleventh thoracic vertebra (see Fig. 55.1), and drains into the inferoposterior part of the right atrium (see Fig. 57.4B). The thoracic part is short, and is partly within and partly outside the pericardial sac. The extrapericardial part is separated from the mediastinal part of the parietal pleura and right lung by the right phrenic nerve and associated pericardiacophrenic vessels, and the intrapericardial part is covered, except posteriorly, by the visceral layer of serous pericardium (see Fig. 57.4E). The abdominal course of the inferior vena cava is described in Chapter 61.

Collateral venous channels In obstruction of the superior part of the inferior vena cava, the azygos and hemiazygos veins and vertebral venous plexuses are the main collateral channels that maintain venous circulation. They connect the superior and inferior venae cavae and communicate with the common iliac vein via the ascending lumbar veins and with multiple tributaries of the inferior vena cava.

Variations The inferior vena cava may be congenitally interrupted, duplicated, left-sided or even absent.

Embryologically, if the right subcardinal vein fails to anastomose with the hepatic sinusoids, the hepatic segment of the inferior vena cava fails to develop. When this occurs, the hemiazygos or azygos veins, both of which originate from the cranial supracardinal veins, return blood to the heart. Azygos continuation of the inferior vena cava, characterized by a prominent azygos vein, is a variant that the paediatric surgeon should be aware of when undertaking repair of oesophageal atresia and tracheo-oesophageal atresia in neonates. The azygos vein, which is commonly ligated and divided during this procedure, should be spared because ligation of this vessel in neonates with azygos continuation of the inferior vena cava leads to intraoperative circulatory collapse and death. Double inferior vena cava (right side usually dominant) is a result of the persistence of all or any segments of the subcardinal veins. One of the most common variations is a left-sided inferior vena cava, which is formed if the right supracardinal vein regresses and the left supracardinal vein persists (Spratt 2016). There may also be a duplication of the inferior vena cava, which typically occurs inferior to the level of the renal veins, and is the result of persistence of the left lumbar and thoracic supracardinal veins and left suprasubcardinal anastomosis as well as malformation of the right subcardinal–hepatic anastomosis. Abnormalities associated with duplication of the inferior vena cava include congenital heart disease, congenital absence of the right kidney, cloacal extrophy, renal ectopia with abdominal aneurysm, right retrocaval ureter, left retrocaval ureter and congenital absence of the iliac anastomosis, abnormal left upper limb drainage and transcaval ureter.

In situs inversus with dextrocardia, the inferior vena cava passes inferiorly along the left side instead of the right. In situs inversus with levocardia, the inferior vena cava remains on the right side. In situs ambiguus (heterotaxy) the major organs are arranged ambiguously within the body. Prominent azygos veins with interrupted inferior vena cava are associated with heterotaxy (Punn and Olson 2010). Situs ambiguus with polysplenia is associated with an absence of parts of the inferior vena cava on the right side (with continuation through the azygos or hemiazygos vein), transposition of the inferior vena cava to the left side, or duplication of the inferior vena cava with one on the right and one on the left. Situs inversus with asplenia is similar to that of polysplenia, in that the inferior vena cava may be absent with azygos continuation or with the inferior vena cava to the left of the midline. In situs inversus totalis, transposition of the inferior vena cava consists of a right-sided inferior vena cava. The inferior vena cava may have an abnormally high insertion into the right atrium.

Scimitar syndrome, a form of anomalous pulmonary venous drainage, occurs when there is an abnormal connection between the right pulmonary vein(s) and the inferior vena cava. This often involves hypoplasia of the pulmonary veins and the pulmonary trunk and arteries, as well as abnormal ipsilateral lung parenchyma. This creates a left-to-right shunt and increases the risk of right ventricular failure as a result of ventricular hypertrophy. Typical symptoms include respiratory insufficiency such as recurrent respiratory infections, heart failure, or pulmonary hypertension.

Congenital agenesis of the inferior vena cava may occur and may be completely asymptomatic because venous drainage of the lower limbs occurs through anastomosed channels of the azygos and hemiazygos veins. However, this condition may be associated with a higher risk for deep vein thrombosis.

Breast cancer

Donna Geddes, James Going

Breast cancer is a common disease, particularly in postmenopausal women (Fentiman 1993). Each year, in the United Kingdom, there are approximately 40,000 new cases diagnosed and 14,000 deaths. Male breast cancers constitute up to 1% of all mammary malignancies and may include tissue beyond the areolar boundary.

Breast cancers arise within the epithelia of lobules or ducts. As they increase in size and become invasive, they often lead to a fibrous stromal tissue reaction. Breast lumps may be classified as benign or malignant masses. More advanced malignant breast lumps (carcinomas) may have the clinical signs of infiltrating adjacent structures, leading to a hard and irregular mass with skin-tethering, muscle fixation, skin infiltration or oedema of the overlying skin (*peau d'orange*). Standard radiological imaging investigations of the breast include mammography and ultrasonography. Mammography is useful in detecting the presence of malignant masses as a stellate opacity with architectural distortion of the surrounding parenchyma. Preinvasive breast cancer, e.g. ductal carcinoma *in situ*, may appear as microcalcifications on the mammogram. An ultrasound scan of the breast is helpful to distinguish solid from cystic (fluid-filled) masses, and can also aid in the distinction of breast cancer from benign lumps by the different attenuation characteristics of the ultrasound waves and blood-flow patterns. Ultrasound may also be useful in guiding core biopsy.

A strong association between increased mammographic breast density and risk of breast cancer has been shown repeatedly. Breast density is assessed by mammograms where the appearance of the fibroglandular tissue is dense or white and the adipose tissue is less dense or grey. The fibroglandular tissue is comprised of epithelial cells, fibroblasts and connective tissue. Several scales of categorization of breast density have been devised. Wolfe was the first to introduce mammographic categorization of four mammographic patterns (Wolfe et al 1976a,1976b). Since then, in an effort to increase reproducibility of assessment of mammographic density, a number of methods have been devised comprising five or six categories. By the 1990s computerized measurements of mammograms were developed to calculate both total and percentage mammographic density. The computerized method has also been shown to be predictive of breast cancer risk. In general, there is high reproducibility and consistency between the scales, especially identification of women with high mammographic density (Garrido-Estepa et al 2010). Mammographic density appears to be influenced by a number of factors, including somatotype, BMI at 18 years of age, history of biopsy-confirmed benign breast disease (for both pre- and postmenopausal women) and hormone replacement therapy. It should be noted that premenopausal women's breasts are more mammographically dense due to the increased fraction of glandular and collagenous tissue present prior to postmenopausal involution. Given that the majority of breast malignancies are also radio-dense, this limits the effectiveness (as measured by the reduction in breast cancer mortality) of mammographic screening in premenopausal women. Breast cancer rates increase in 40- to 49-year-old women compared to those less than 40 years of age. These statistics may prompt clinicians to consider screening high-risk women and also incorporate supplementary imaging such as ultrasound or magnetic resonance imaging in those with high breast density.

Magnetic resonance imaging (MRI) is useful in diagnosis, particularly in women with younger, denser breasts, achieving higher sensitivity of breast cancer detection but with lower specificity. A cytological diagnosis of a breast lump can be achieved using fine-needle aspiration (FNA) to evaluate the cellular component of a lump. FNA is also useful to drain symptomatic breast cysts. A wide-bore needle biopsy is a procedure performed under local anaesthetic to obtain several pieces of specimen for a histological diagnosis with the tissue architecture maintained. This permits distinction between *in situ* and invasive cancer, and provides an indication of tumour subtype by evaluation of the pathological characteristics. Vacuum-assisted mammotome biopsies based on the wide-bore needle enable some benign and indeterminate lesions to be excised for full histological analysis and, in some patients, can avoid the need for conventional open surgery.

If a breast lump has to be surgically removed, the incision should be based, whenever possible, in the relaxed skin tension lines, for the best cosmetic results. In women with sizeable malignant lesions in whom breast conservation surgery is to be attempted, the skin incision should be planned with consideration of the possible requirement for a subsequent mastectomy if the margins of excision are incompletely excised by pathological criteria (Swanson et al 2002). Most women with single breast cancers of up to 4 cm in diameter are treated by breast conservation rather than mastectomy. This is a combination of surgery (tumour excision and sentinel node biopsy or clearance) together with external beam radiotherapy to minimize the risk of local recurrence. Patients with larger tumours are likely to be treated by mastectomy with axillary lymph node clearance. Neo-adjuvant endocrine or chemotherapy treatment prior to surgery may improve operability to allow breast conservation surgery of larger tumours.

During axillary dissection to clear the axillary lymph nodes, the long thoracic nerve (to serratus anterior), the thoracodorsal vessels, the thoracodorsal nerve (to latissimus dorsi), and the medial and lateral pectoral nerves are all identified and carefully preserved. The boundaries of the axillary dissection are the long thoracic nerve medially, the thoracodorsal vascular pedicle laterally and the axillary vein superiorly. The posterior limit of the dissection is the anterior (ventral) surface of subscapularis. The superomedial limit of a level 1 axillary dissection extends to the lateral (inferolateral) border of pectoralis minor at the apex of the axilla; a level 2 dissection extends to the medial (superomedial) border of pectoralis minor; and a level 3 dissection extends beyond the medial border until it reaches the point where the axilla is limited by the first rib (the latter is easily distinguished by its flat superior surface, easily palpable at surgery). Failure to preserve the long thoracic nerve will result in lifting of the medial border of the scapula (winging) from the posterior thoracic wall and a reduced scapula protraction. The intercostobrachial nerve is often sacrificed in an axillary lymph node clearance operation, and this may result in anaesthesia of a narrow strip of skin along the upper medial border of the ipsilateral arm.

Molecular breast cancer signatures

Mammary cell markers distinguish luminal from basal cells in the human breast. CK7, CK18 and Claudin-4 are expressed in luminal cells but not myopepithelial cells. CD10, SMA and p63 are expressed in myoepithelial cells but not luminal cells (Santagata and Ince 2014). Steroid hormone receptors are used in the classification of breast carcinomas. It remains clinically useful to classify carcinomas by the presence of the oestrogen receptor (ER+), progesterone receptor (PR+) and human epidermal growth factor receptor 2 (HER2+). Carcinomas not expressing any of these markers are referred to as triple-negative cancers (ER/PR/HER2−). Carcinomas expressing ER and PR are likely to respond to ER antagonists or aromatase inhibitors, blocking peripheral oestrogen production.

More recently, technological advances, including gene expression microarrays and next-generation sequencing, have emphasized the diversity and heterogeneity of breast cancer and greatly expanded knowledge of breast cancer biology. Breast cancer is driven by alterations in DNA and epigenetic changes that activate or suppress growth genes and high-throughput technologies have led to a more detailed identification of an array of subtypes that allow more targeted treatment of the cancer. For example, multiple genes can be tested that allow discrimination of luminal ER-positive tumours into subgroups that have better or worse prognosis. Similarly, basal-like cancers are typically triple-negative (although not all triple-negative breast cancers are basal-like) and display upregulation of basal cell genes. Basal-like cancers can be divided into four subtypes. One subtype, in particular, shows upregulation of androgen receptor and has a relatively good prognosis (Provenzano et al 2018). Using a combination or both clinical variables and molecular subtyping is more predictive than any single measure alone (Malhotra 2010).

Reconstructive surgery for breast cancer disease

Breast reconstruction may be performed at the time of mastectomy for breast cancer, or at a later stage (Serletti and Moran 2000). During a mastectomy where an immediate breast reconstruction is planned, the glandular breast tissue is removed either through a conventional mastectomy skin incision or in association with preservation of the native breast skin (skin-sparing mastectomy). Patient selection is important to minimize the risk of breast cancer recurrence in the skin of the reconstructed breast mound or associated lymph nodes. In an implant-based immediate breast reconstruction, a tissue expander is placed beneath the musculofascial plane consisting of pectoralis major, in continuity laterally under serratus anterior with the intervening fascia, and the abdominal fascia inferiorly. The lower fibres of the attachment of pectoralis major to the sixth rib need to be detached, otherwise the implant will be placed too high on the chest wall. The tissue expander has to stretch the potential space below this musculofascial plane to match the space created by the removed breast beneath the subcutaneous plane and the deep fascia overlying pectoralis major. The tissue expander is subsequently replaced by a silicone or saline breast implant.

The skin and volume component of the breast can also be replaced by the latissimus dorsi musculocutaneous flap, with or without an underlying silicone or saline breast implant. Latissimus dorsi and an overlying paddle of skin are raised on its dominant vascular pedicle: namely, the thoracodorsal vessels, which enter the muscle on its deep surface and send perforating branches through the muscle to the overlying skin. The flap is transferred in an arc from the posterior to the anterior thorax and fashioned to make a new breast. An implant may be required to provide additional volume replacement, in which case it is placed beneath the flap. The donor site defect on the back is directly sutured. In selected cases, this flap can be raised with additional superficial fascia and fat, to avoid the need for a silicone implant. This is known as the extended or autologous latissimus dorsi flap.

Women with a suitable abdominal panniculus may have breast reconstruction utilizing this tissue. Historically, this was achieved with a pedicled transverse rectus abdominis musculocutaneous (TRAM) flap based on the superior epigastric artery, where the skin and fat of the lower abdomen, attached to the rectus muscle, are transposed into the breast defect and shaped into a breast reconstruction.

The development of microvascular techniques over the past 30 years has seen an increase in the popularity of free tissue transfers, based on the inferior epigastric artery (often termed by surgeons the deep inferior epigastric artery), including muscle-sparing (MS-)TRAM flaps and deep inferior epigastric artery perforator (DIEP) flaps. These flaps require dissection of the blood vessels within rectus abdominis, rather than sacrifice of the entire muscle, and this aims to reduce donor site morbidity, including hernias and bulging. Radiological investigations (CT angiograms, MRI and duplex) are used to determine the calibre and position of cutaneous perforator vessels within these flaps to improve the accuracy of dissection and enhance surgical outcome (**Fig. 7.1.1**). Free TRAM and DIEP flap vessels are anastomosed to recipient vessels in the thoracic region; the internal thoracic or the thoracodorsal artery are used most frequently for this purpose.

Breast reconstruction using an autologous method, such as the extended latissimus dorsi, free MS-TRAM and DIEP flap, avoids the need for a silicone implant and has advantages in terms of producing a more natural appearance and achieving greater longevity of results. Free tissue transfers for breast reconstruction are also performed using buttock tissue (superior and inferior gluteal artery perforator flaps) and thigh tissue (transverse upper gracilis and anterolateral thigh flaps).

Breast reconstruction using autologous tissue

One of the earliest recorded breast reconstructions using latissimus dorsi, based on the thoracodorsal pedicle, was published by Tansini in 1906. The flap incorporated superficial fascia and a skin paddle attached to the muscle, and was used to replace part of the breast skin envelope that had been removed during the mastectomy. This form of breast reconstruction inexplicably fell out of regular use until the 1970s, when there was renewed interest in the latissimus dorsi musculocutaneous flap combined with silicone breast implants (Bostwick et al 1977, Schneider et al 1978) and improved definitions of the vascular supply and territory of the flap (McCraw et al 1977, Maxwell et al 1979).

Later in the twentieth century, further developments of this most versatile flap meant that breast reconstruction could be performed without a silicone implant. The so-called 'extended' flap (Hokin and Silfverskiold 1987) used autologous tissues exclusively; it was designed to satisfy an increasing demand for breast reconstruction in an era when silicone implants were under scrutiny because of safety fears and proposed links with autoimmune diseases. Further developments to maximize the volume available for autologous reconstructions of small to medium-sized breasts included harvesting larger skin paddles from the back and burying them beneath the breast skin envelope after de-epithelializing their surface (Papp et al 1988), and inclusion of additional fat pads in the back to increase flap volume (Delay et al 1998).

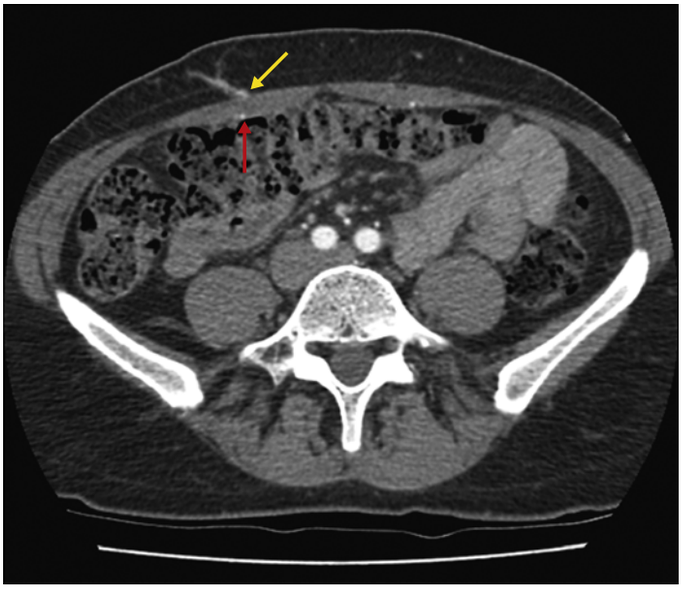

Fig. 7.1.1 A CT angiogram showing the deep inferior epigastric artery (red arrow) and a cutaneous perforating vessel (yellow arrow) emerging from the rectus sheath for MS-TRAM and DIEP flap reconstruction.

Despite the enhancements to the latissimus dorsi flap, the lower abdominal region provides a plentiful and more reliable source of tissue for reconstructive surgeons and also avoids the sometimes troublesome and often unsightly dorsal donor site wound. DIEP or MS-TRAM flaps are generally considered the first choice for breast reconstruction when the tissues are adequate.

The first description of lower abdominal tissues being used as a free flap appeared in 1979 (Holmstrom 1979), although at this time the pedicled TRAM flap was a far more popular choice for reconstruction. This was mainly because microvascular techniques were still in development and the required instruments and microscopes were not widely available. However, over the years, it became possible to achieve excellent, reliable results without the problems of fat necrosis and abdominal wall weakness associated with the pedicled version (Grotting et al 1989, Arnez et al 1991, Schusterman et al 1994). The TRAM flap particularly lends itself to microsurgical transfer on account of the characteristics of the supplying vessels (the inferior epigastric artery is 2.5–3 mm in diameter and its venae comitantes are 3 mm in diameter); the length of the pedicle (frequently up to 15 cm); and the large surface area of skin supplied by these vessels (see Fig. 53.1).

Further developments in dissection techniques, combined with a desire to reduce donor site morbidity, led to the first description of a 'perforator' flap based on the same vessels (Allen and Treece 1994). This is the DIEP flap, which captures the same soft tissue area of the abdomen for reconstruction, but attempts to avoid injury to rectus abdominis by dissecting the perforating vessels through the muscle rather than by sacrificing it. Some authors have identified fewer donor site bulges and herniae with DIEP flaps compared with TRAM flaps (Blondeel et al 1997), and it is for this reason that DIEP flaps are the preferred choice, if possible. However, the perforating vessels are not always anatomically favourable for allowing safe harvest of the flap. Many clinicians have adopted radiological studies (CT angiogram, duplex or MR angiogram) to determine the calibre and position of the vessels preoperatively for more accurate surgical planning (see Fig. 7.1.1).

COMMENTARY
7.2

Computed tomography coronary angiography (CTCA) of anomalous coronary vasculature

Julia Sun, Jonathan Weir-McCall

Invasive coronary angiography has long been used to map coronary arterial anatomy and associated disease. In this procedure, a contrast agent is instilled into a coronary artery via a catheter inserted into the opening (ostium) of that artery within an aortic sinus. The fluoroscopic images that are acquired have a high spatial and temporal resolution and are of benefit in patient diagnosis and treatment, but they are two-dimensional (2D). In marked contrast, computed tomography (CT) is a non-invasive imaging modality that can demonstrate the anatomy and relations of a region of interest in 3D.

Despite the benefits afforded by CT, the cross-sectional imaging community used to regard the heart as an 'object of mystery' because of the rapidity of its movements and the limited speed of the available technology. Recent advances in the temporal resolution of CT scanners and associated radiation dose have enabled the development of computed tomography coronary angiography (CTCA), which is able to capture motion-free, essentially 'freeze-frame', 3D images of the heart and coronary vasculature. Image quality can still be adversely affected by the presence of a tachycardia: in such cases image quality can be enhanced using a pharmacological intervention to reduce heart rate or by timing (gating) scans to end diastole or end systole, when the coronary arteries and associated cardiac structures show the least movement. The simplicity of image capture and quality improves as technology develops: the latest generation of CT scanners are now fast enough to acquire diagnostic images even in patients with tachycardia (Agliata et al 2019).

After volumetric dataset acquisition using CTCA, post-processing with 3D reconstruction tools such as volume rendering and multiplanar reformatting enables visualization of the course, origin and anatomical relationships of the coronary arteries to neighbouring structures in a level of detail unmatched by other modalities. A relatively new post-processing technique, cinematic rendering, provides striking photorealistic images from CTCA datasets (Dappa et al 2016). While standard volume rendering is able to demonstrate anatomy and anatomical relationships in three dimensions, the overall quality achieved with cinematic rendering is much higher (see Commentary I.4 and Fig. 7.2.7C–D for a comparison of standard 3D volume rendering of the coronary arteries with cinematic rendering).

Classification of coronary artery anomalies

While there is no universal definition for the division between coronary artery variants and anomalies, a simple, robust and commonly used threshold defines variants as differences occurring in >1% of the population, and anomalies as differences occurring in ≤1% of the population (Angelini 2002, 2007). Variants and anomalies may be asymptomatic and only of relevance during cardiac surgery or may cause chest pain, shortness of breath, or serious cardiovascular sequelae (Levin et al 1978, Frescura et al 1998). Coronary artery anomalies can be grouped into three broad categories: anomaly of origin and course; anomaly of intrinsic anatomy (absence, atresia or duplication); and anomaly of termination. Some anomalies are asymptomatic and discovered incidentally, whereas others require treatment for symptomatic relief or to ensure continued cardiac function. CTCA is an important clinical tool for the diagnosis and detailed mapping of anomalies and the addition of photorealistic cinematic rendering further enhances its quality and utility for surgical and procedural planning and research, especially in cases of complex aberrant anatomy.

An exhaustive list of all the documented coronary anomalies is not possible in a single article. The cases in this commentary demonstrate a mixture of both the most common and most serious anomalies and have been selected to highlight the sometimes extreme deviations from normal coronary artery anatomy that can occur. Many permit survival to adulthood, and although extremely rare, the physician should be aware of their existence in clinical practice.

Anomalies of origin and course

Anomalies of coronary artery origin and course are the most commonly encountered of the three categories of anomalous vessels. The left coronary artery, anterior interventricular branch or circumflex branch of the left coronary artery, or the right coronary artery, can all arise from ectopic positions, which include a non-conventional aortic sinus, the ascending aorta, pulmonary trunk or other coronary arteries. The proximal part of an anomalous coronary artery follows one of five paths (pre-pulmonic, retro-aortic, inter-arterial, trans-septal or retro-cardiac) to access its more usual distal course and designated perfusion territory (Fig. 7.2.1). The pre-pulmonic and retro-aortic paths pass anterior to the pulmonary trunk and posterior to the ascending aorta, respectively, whereas the inter-arterial path passes between the ascending aorta and pulmonary trunk. The trans-septal path is subpulmonic, traversing anteriorly and inferiorly through the myocardium of the interventricular septum; the retro-cardiac path passes around the heart within the atrioventricular (coronary) sulcus (Kim et al 2006).

Depending on their location and initial path, a proportion of anomalous coronary arteries are associated with functional ischaemia and are the second most common cause of sudden cardiac death among young athletes (Basso et al 2000). Anomalous vessels taking the inter-arterial path are most frequently associated with sudden cardiac death, perhaps due to the exercise-related expansion of the ascending aorta and pulmonary trunk and the consequent increase in angulation and decrease in luminal diameter of the anomalous vessel (Angelini et al 2006) (Fig. 7.2.2). Sudden cardiac death is more likely with an inter-arterial anomalous left coronary artery or anterior interventricular artery because of the larger volume of subtended myocardium at risk during an associated cardiac event (Moustafa et al 2008). Other paths are not commonly associated with haemodynamic compromise because they are not associated with luminal narrowing (Fig. 7.2.3), but their location may complicate surgery.

Single coronary artery

A single coronary artery is an anomaly in which only one coronary artery arises from an aortic sinus and supplies the entire heart (Fig. 7.2.4). A range of permutations of origin, course and distribution may occur, some of which can be classified into predefined groups (Lipton et al 1979). The left or right coronary artery may be singular and perfuse the entire heart, or the left coronary artery may arise ectopically from a relatively normal right coronary artery or *vice versa*. The proximal part of the ectopic artery may follow one of the five paths previously described to reach its normal course and territory (see Fig. 7.2.1). A single coronary artery may be associated with other congenital cardiac anomalies such as transposition of the great vessels, coronary artery fistulae, bicuspid aortic valve and the tetralogy of Fallot. The direction of blood flow in cases of a single coronary artery is normally anterograde or centrifugal (from larger central vessels to smaller peripheral vessels), whereas in left coronary artery atresia the direction of blood flow is partially retrograde or centripetal (from the smaller peripheral collateral vessels to one or more of the main left-sided arteries) (Musiani et al 1997). The vascular supply of the left ventricle when there is a single coronary artery is much better developed than it is in left coronary artery atresia, where the collateral vessels supplying the left ventricle are small (see Fig. 7.2.6).

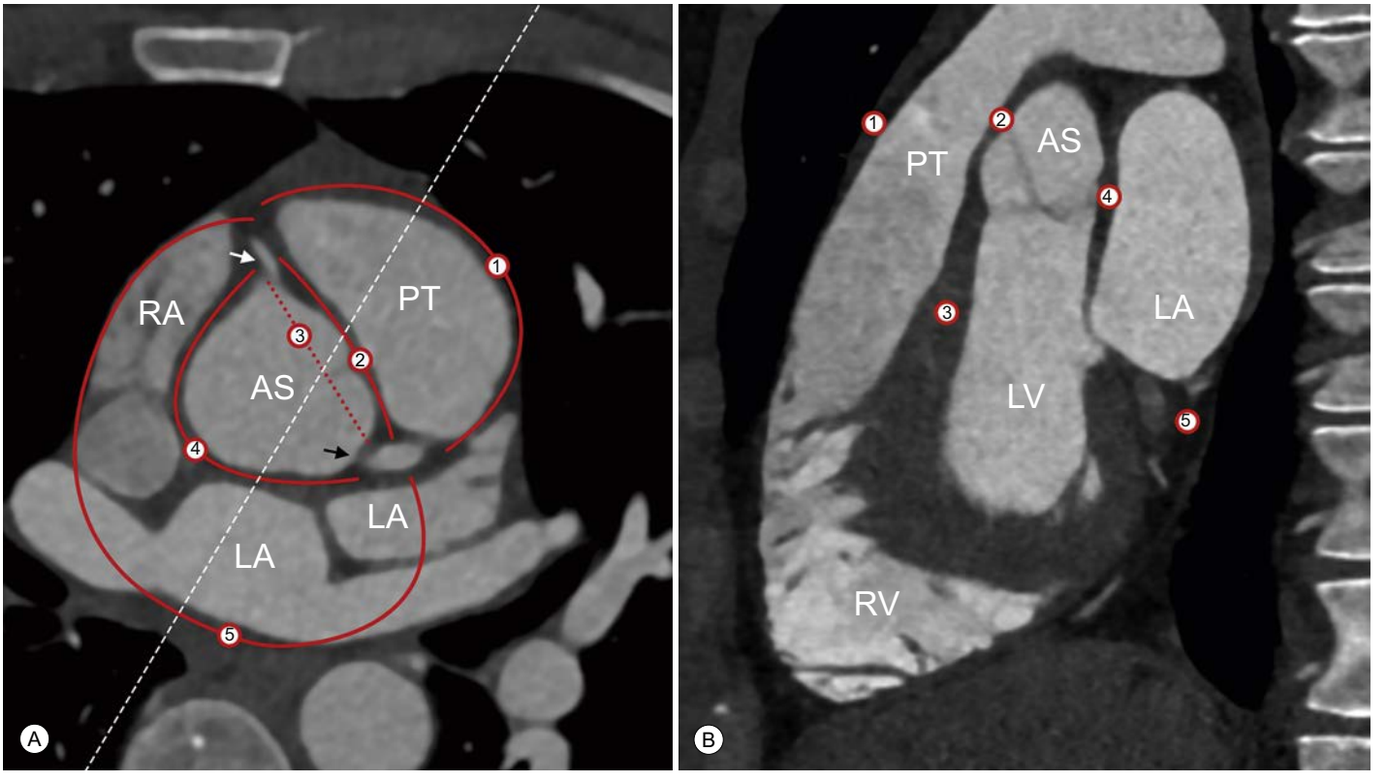

Fig. 7.2.1 CTCA showing the five paths along which the proximal part of an anomalous coronary artery may travel. The numbers 1–5 correspond to the five paths: 1, pre-pulmonic; 2, inter-arterial; 3, trans-septal; 4, retro-aortic; 5, retro-cardiac. **A**, Axial image at the level of the pulmonary trunk and origin of the left (black arrow) and right (white arrow) coronary arteries. The five paths are indicated by red lines. **B**, Sagittal oblique image (corresponding to the dashed white line in **A**) showing the position of the five paths relative to the great vessels and heart. Abbreviations: AS, aortic sinus; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle.

Anomalous origins from the pulmonary trunk

Anomalous coronary artery origin from the pulmonary trunk is one of the more haemodynamically significant coronary artery anomalies (Fig. 7.2.5). Either the left or right coronary artery or, uncommonly, both arteries may be involved. Cases where both coronary arteries arise from the pulmonary trunk are unlikely to survive beyond the first month of life without surgical intervention.

Anomalous origin of the right coronary artery from the pulmonary trunk (ARCAPA) and anomalous origin of left coronary artery from the pulmonary trunk/artery (ALCAPA or Bland–White–Garland syndrome) are rare (Pfannschmidt et al 1992, Williams et al 2006). ARCAPA is usually asymptomatic with no evidence of myocardial ischaemia. ALCAPA is of little relevance *in utero* where systemic (aortic) and pulmonary arterial pressures are equal, so that antegrade flow to the heart of similarly oxygenated blood occurs through both left and right coronary arteries. After birth, closure of the ductus arteriosus and a fall in pulmonary vascular resistance reduces pulmonary arterial pressure, which results in retrograde flow through the left coronary artery. Adequate perfusion of the territory of the left coronary artery becomes reliant on the development of a collateral circulation from the right coronary artery, which consequently dilates to accommodate the increased blood flow. The majority of patients with ALCAPA die during their first year of life, but occasionally patients with well-established collateral vessels may present later in life and are classified as having 'adult type' ALCAPA (Wesselhoeft et al 1968).

Anomalies of intrinsic anatomy

Hypoplasia or atresia of the ostium of a coronary artery within the aortic sinus can obstruct that artery at or near its origin and can result in a collateral circulation from the functional (normal) coronary artery developing to supply the affected territory (Fig. 7.2.6). Coronary ostial atresia is often associated with ischaemic manifestations (Musiani et al 1997). When the left coronary artery is affected, right-to-left collateralization occurs during the later stages of development, and is often insufficient to meet the oxygen requirements of the left ventricular myocardium. Atresia of the ostium or proximal part of a coronary artery may be accompanied or replaced by a fibrous connection spanning the gap between the aortic sinus and a more distal functional part of the affected coronary artery. The fibrous connection can pull on its points of attachment causing a focal distortion that may be visible as a beak-like projection on imaging. Single coronary artery anomalies are not characterized by a focal distortion of adjacent vessel walls because their developmental origin is different and no such fibrous remnant exists.

Anomalies of termination

An anomalous termination occurs when a coronary artery drains directly or via branches into a cardiac chamber, great vessel or other vascular structure, rather than into a capillary bed of the heart. Reported sites of abnormal termination include the right and left atria and ventricles, coronary venous system, pulmonary arteries and pulmonary veins. Fistulae terminating in the right heart chambers, pulmonary trunk or pulmonary arteries are the most common (Fig. 7.2.7). Depending on the position of origin and the vessel or chamber of termination, the affected vessel may become dilated or tortuous in response to increased blood flow and aneurysms may form (Fig. 7.2.8).

While most instances of coronary artery fistulae are congenital, some result from iatrogenic injury, infection or inflammatory disease. Larger coronary artery fistulae with significant intra-cardiac shunts are rare in adults: most are detected and repaired during childhood (Gowda et al 2006). Many are asymptomatic and identified incidentally on coronary angiography (Wilde and Watt 1980). Although the degree of left-to-right shunting of blood is usually very small and of little consequence, the presence of large or multiple left-to-right shunts could result in a right ventricular volume overload (Rittenhouse et al 1975). Multiple fistulae may form a complex network of shunts. A careful interrogation of conventional CTCA images can help identify fistulae within a tangled network of collateral vessels, some of which may initially be hidden from view on the 3D rendered images (Fig. 7.2.9): cinematic rendering can aid this task by depicting a more recognizable model of complex aberrant anatomy. The presence of fistulae can complicate surgical approaches to the heart; exact mapping of their anatomy and relations is required in such cases.

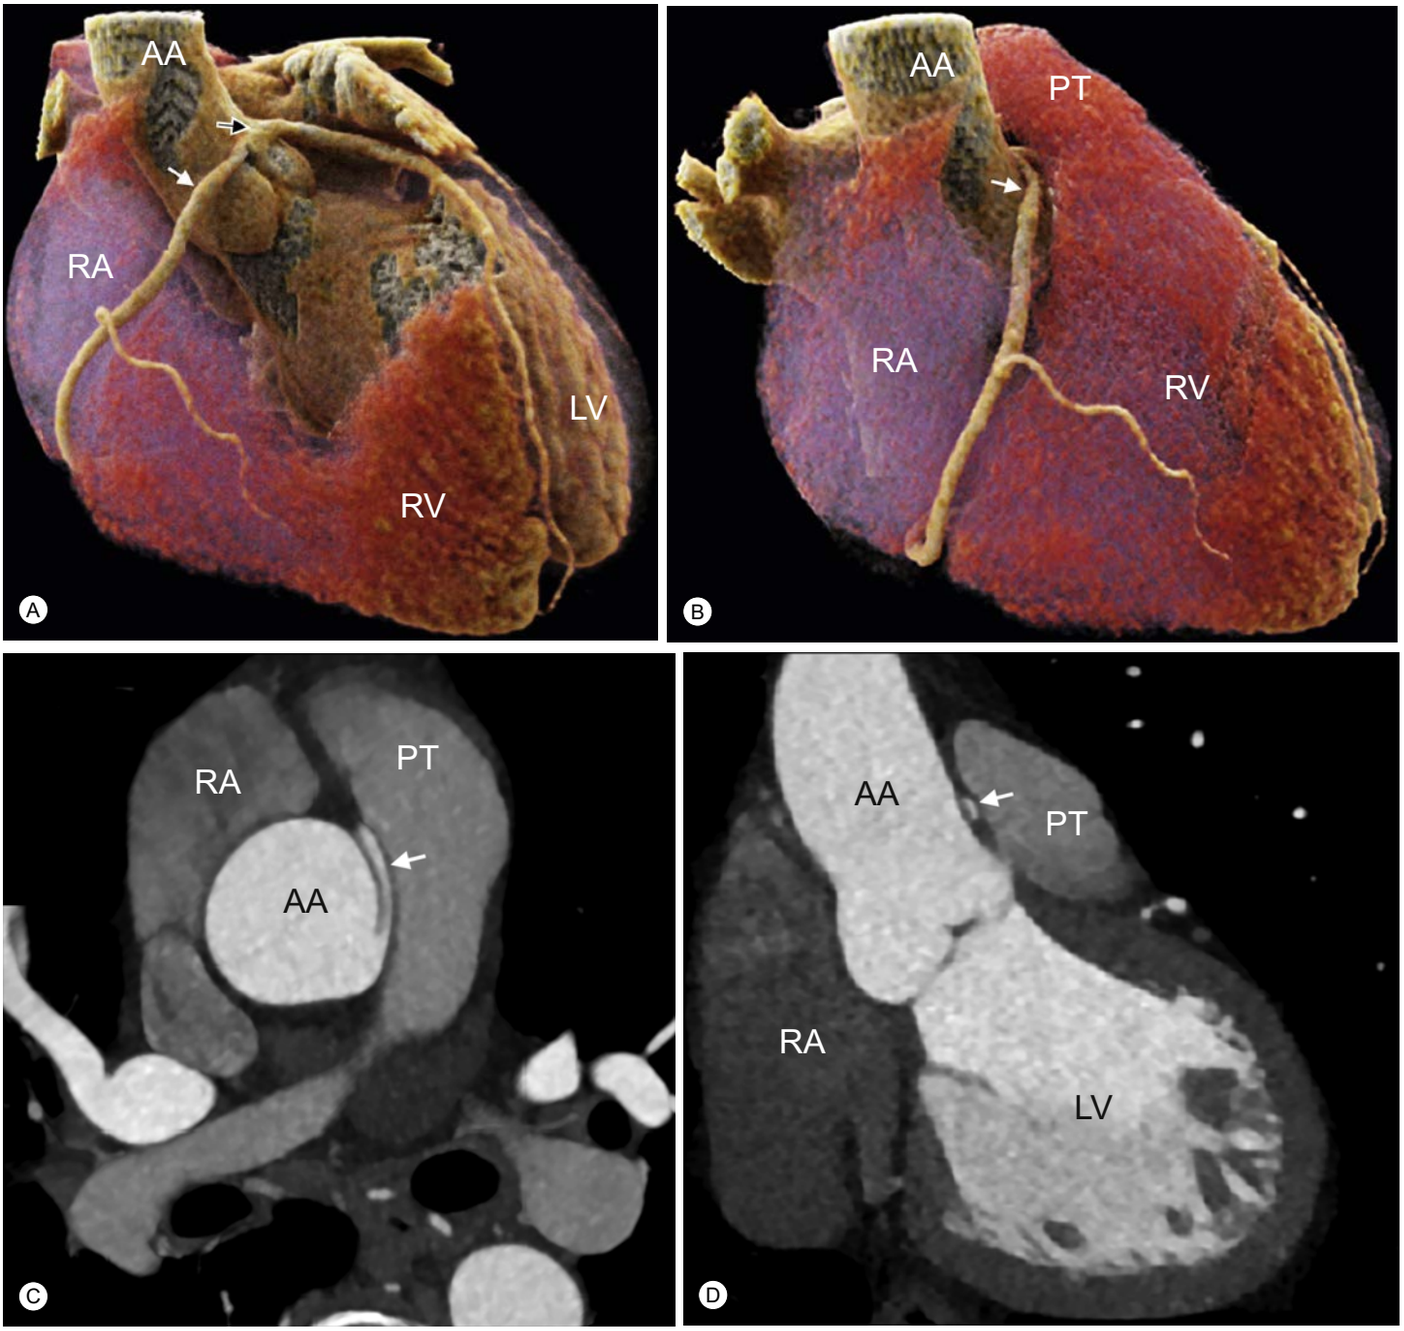

Fig. 7.2.2 CTCA showing an anomalous origin of the right coronary artery from the left aortic sinus and the inter-arterial course of its proximal part. **A**, Cinematic rendered image showing an anterior view with the right ventricle and pulmonary trunk removed to show the anomalous origin of the right coronary artery (white arrow) from the left aortic sinus adjacent to the left coronary artery (black arrow). **B**, Cinematic rendered image showing an anterior view of the right coronary artery (white arrow), with its proximal part passing through the interval between the ascending aorta and pulmonary trunk (inter-arterial path). **C**, Axial image showing the origin and proximal part (white arrow) of the right coronary artery passing between the ascending aorta and pulmonary trunk. **D**, Sagittal oblique image showing compression (note the oval-shaped lumen) of the inter-arterial part of the right coronary artery (white arrow). Abbreviations: AA, ascending aorta; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle.

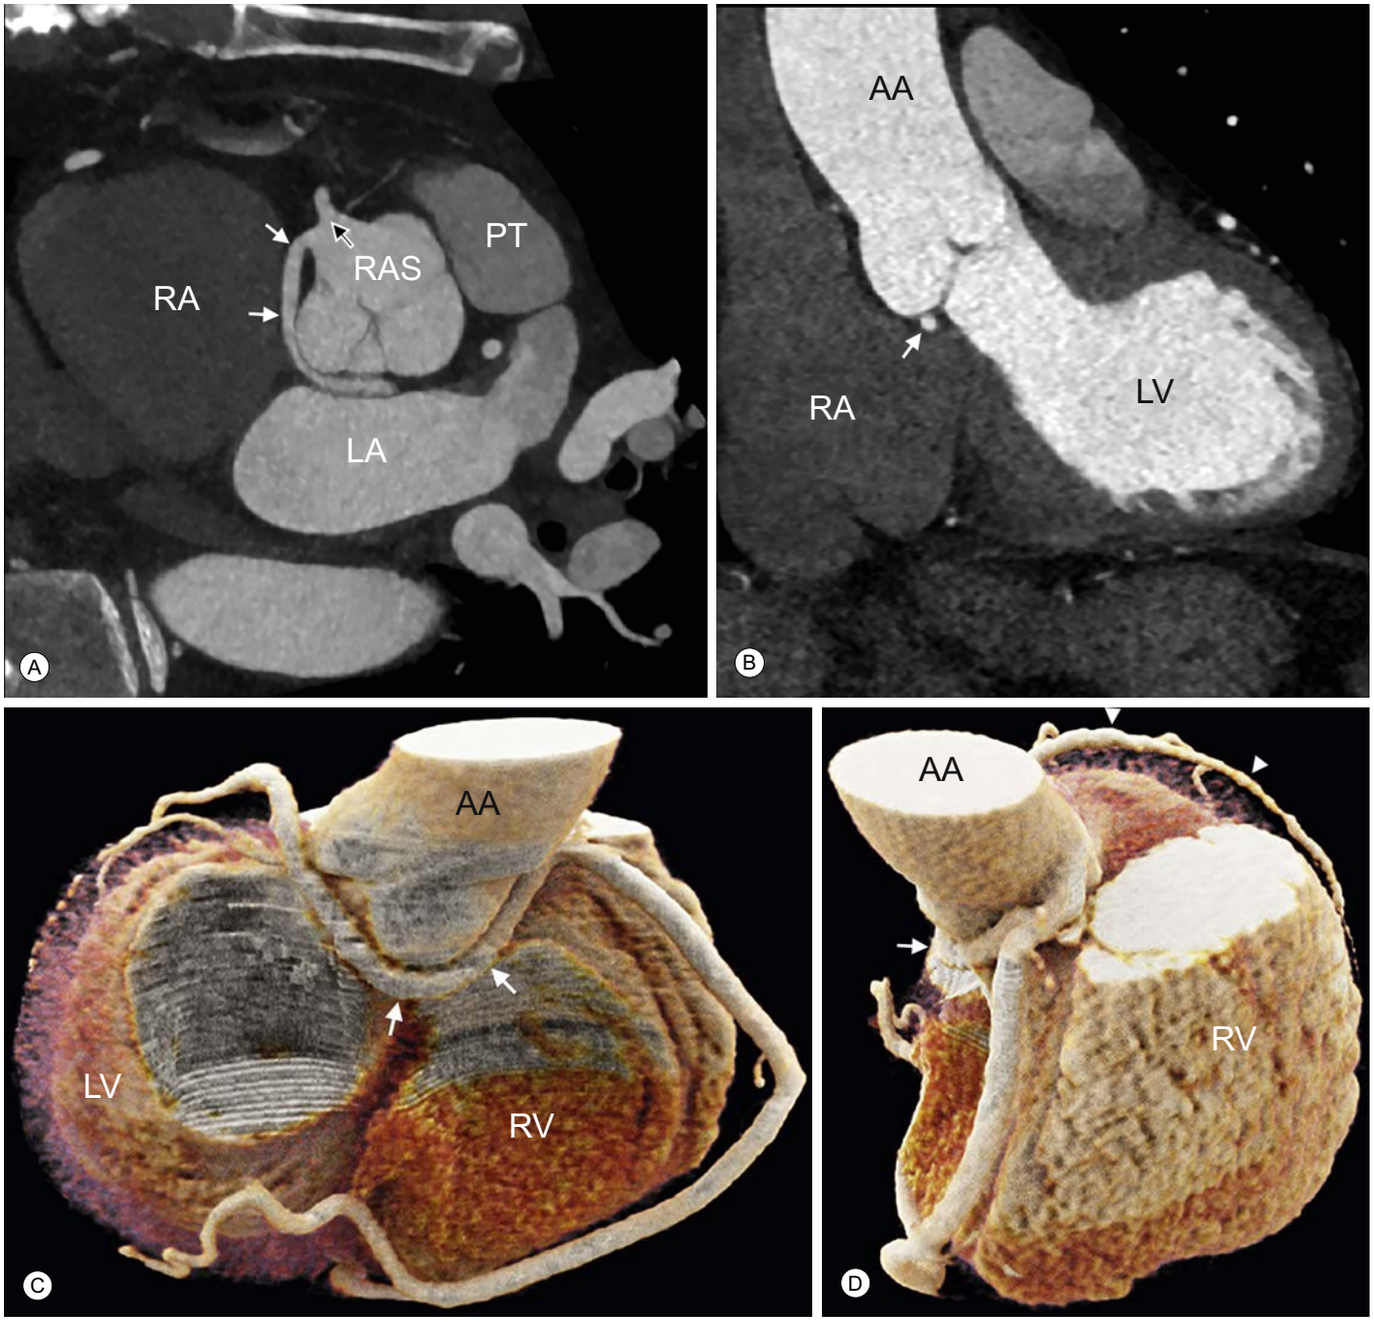

Fig. 7.2.3 CTCA showing an anomalous origin of the anterior interventricular artery and the retro-aortic course (posterior to the ascending aorta and anterior to the left atrium) of its proximal part. **A**, Axial image showing the anterior interventricular branch of the left coronary artery (white arrows) originating from the right aortic sinus, adjacent to a normal right coronary artery (black arrow), and the retro-aortic path of its proximal part. **B**, Sagittal oblique image showing the anterior interventricular artery passing posteriorly to take a retro-aortic path (white arrow). Note the relatively rounded lumen of the coronary artery indicating an absence of compression. **C** and **D**, Cinematic rendered images showing right posterolateral (**C**) and right anterolateral (**D**) views with both atria removed to reveal the retro-aortic course of the anterior interventricular artery (white arrows) and the conventional position of its more distal part in the anterior interventricular sulcus (white arrowheads). Abbreviations: AA, ascending aorta; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RAS, right aortic sinus; RV, right ventricle.

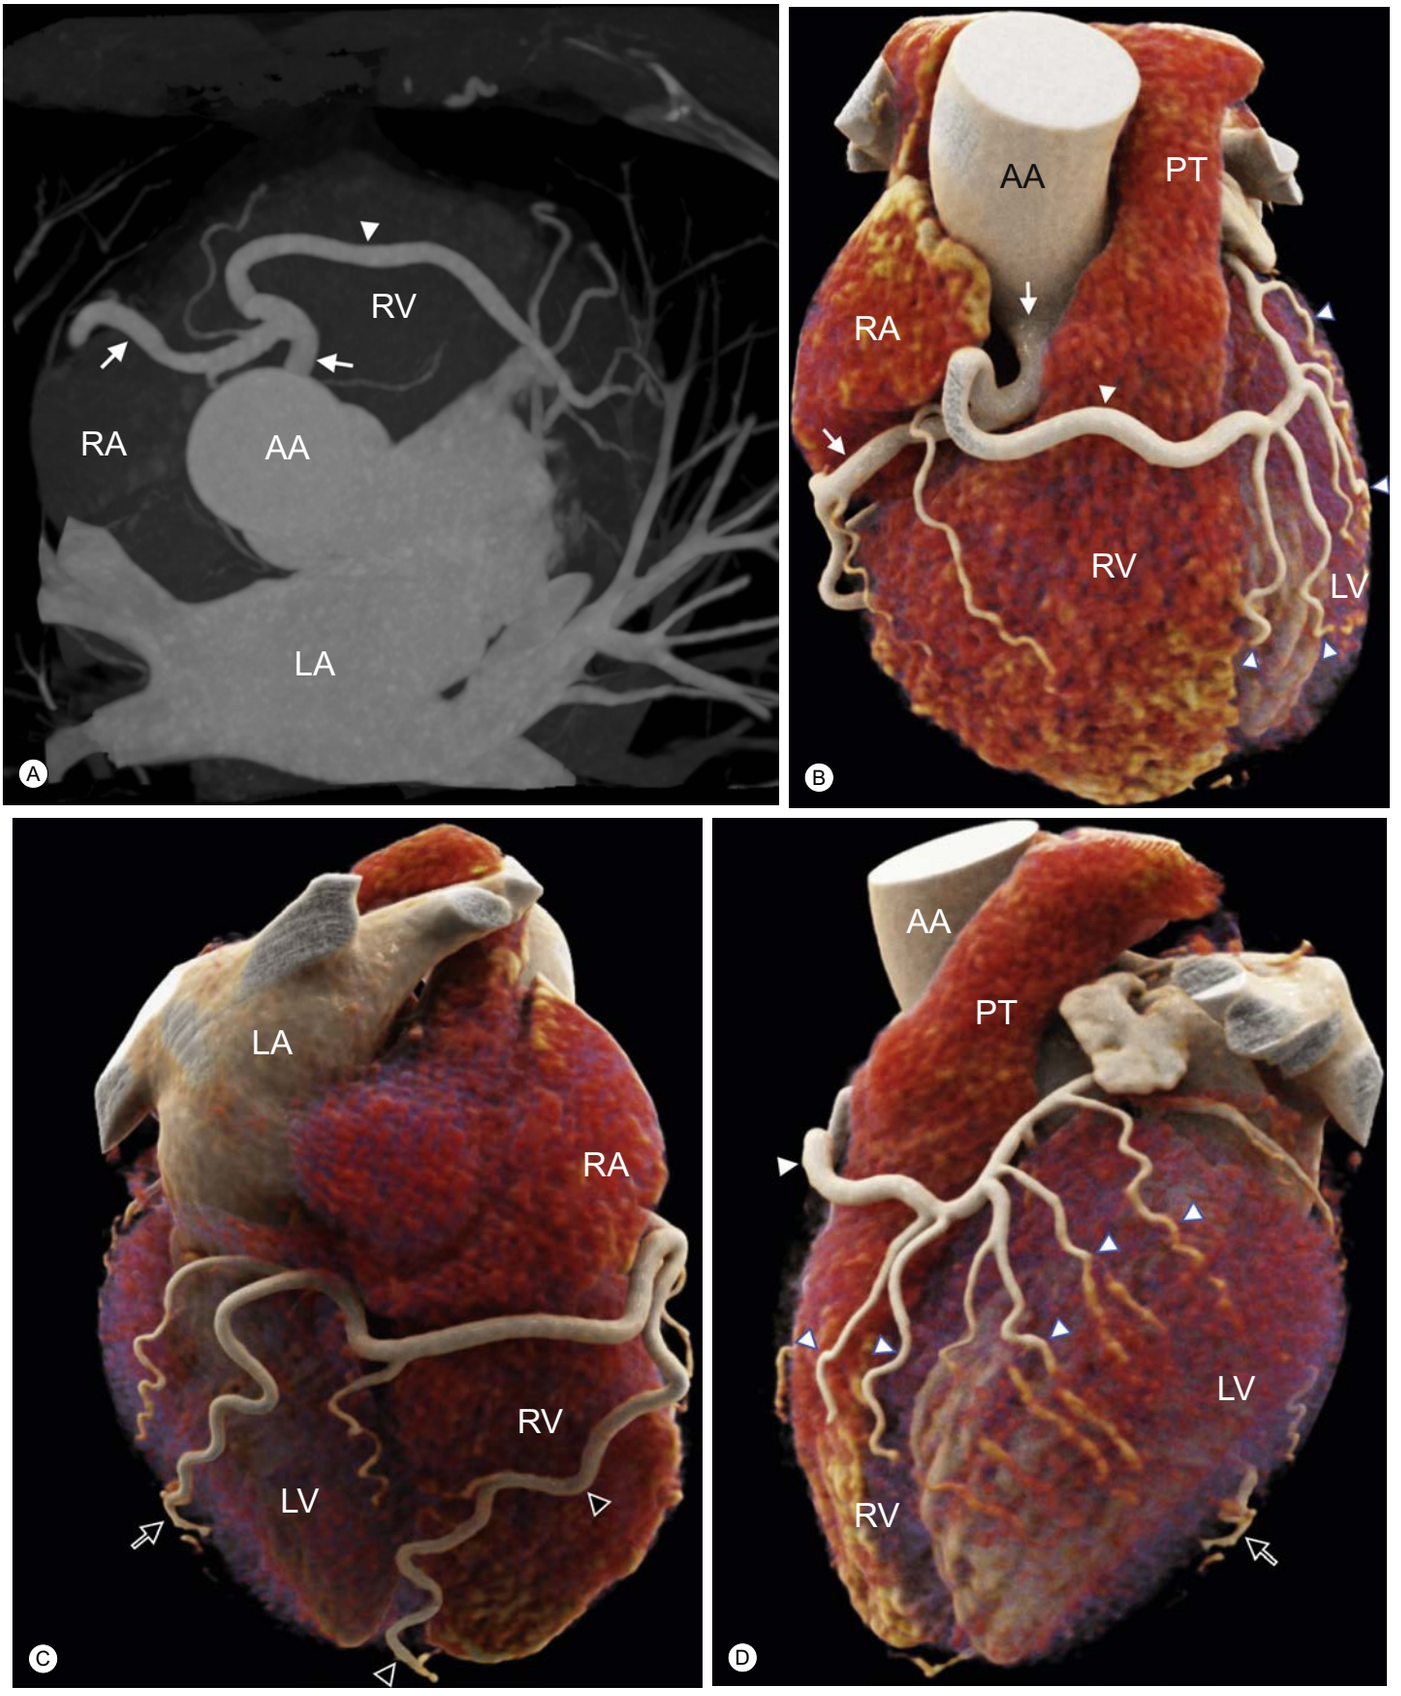

Fig. 7.2.4 CTCA showing a single right coronary artery (white arrows) arising from the right aortic sinus, with a dilated conal branch (white arrowheads) passing over the conus arteriosus to perfuse the left ventricle (white arrowheads with blue outline). The normal left coronary arterial system is absent. **A**, Maximum intensity projection (MIP) axial image at the level of the aortic sinuses. **B–D**, Cinematic rendered images showing right anterior (**B**), inferior (**C**) and left anterior (pulmonary surface) (**D**) views of the distribution of the single right coronary artery. The right coronary artery gives rise to a large inferior interventricular branch (black arrowheads) and a large posterolateral branch to the inferior and pulmonary surfaces of the left ventricle (black arrows), and multiple branches (arising from the conal branch) to the left pulmonary surface of the left ventricle (white arrowheads with blue outline). Abbreviations: AA, ascending aorta; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle.

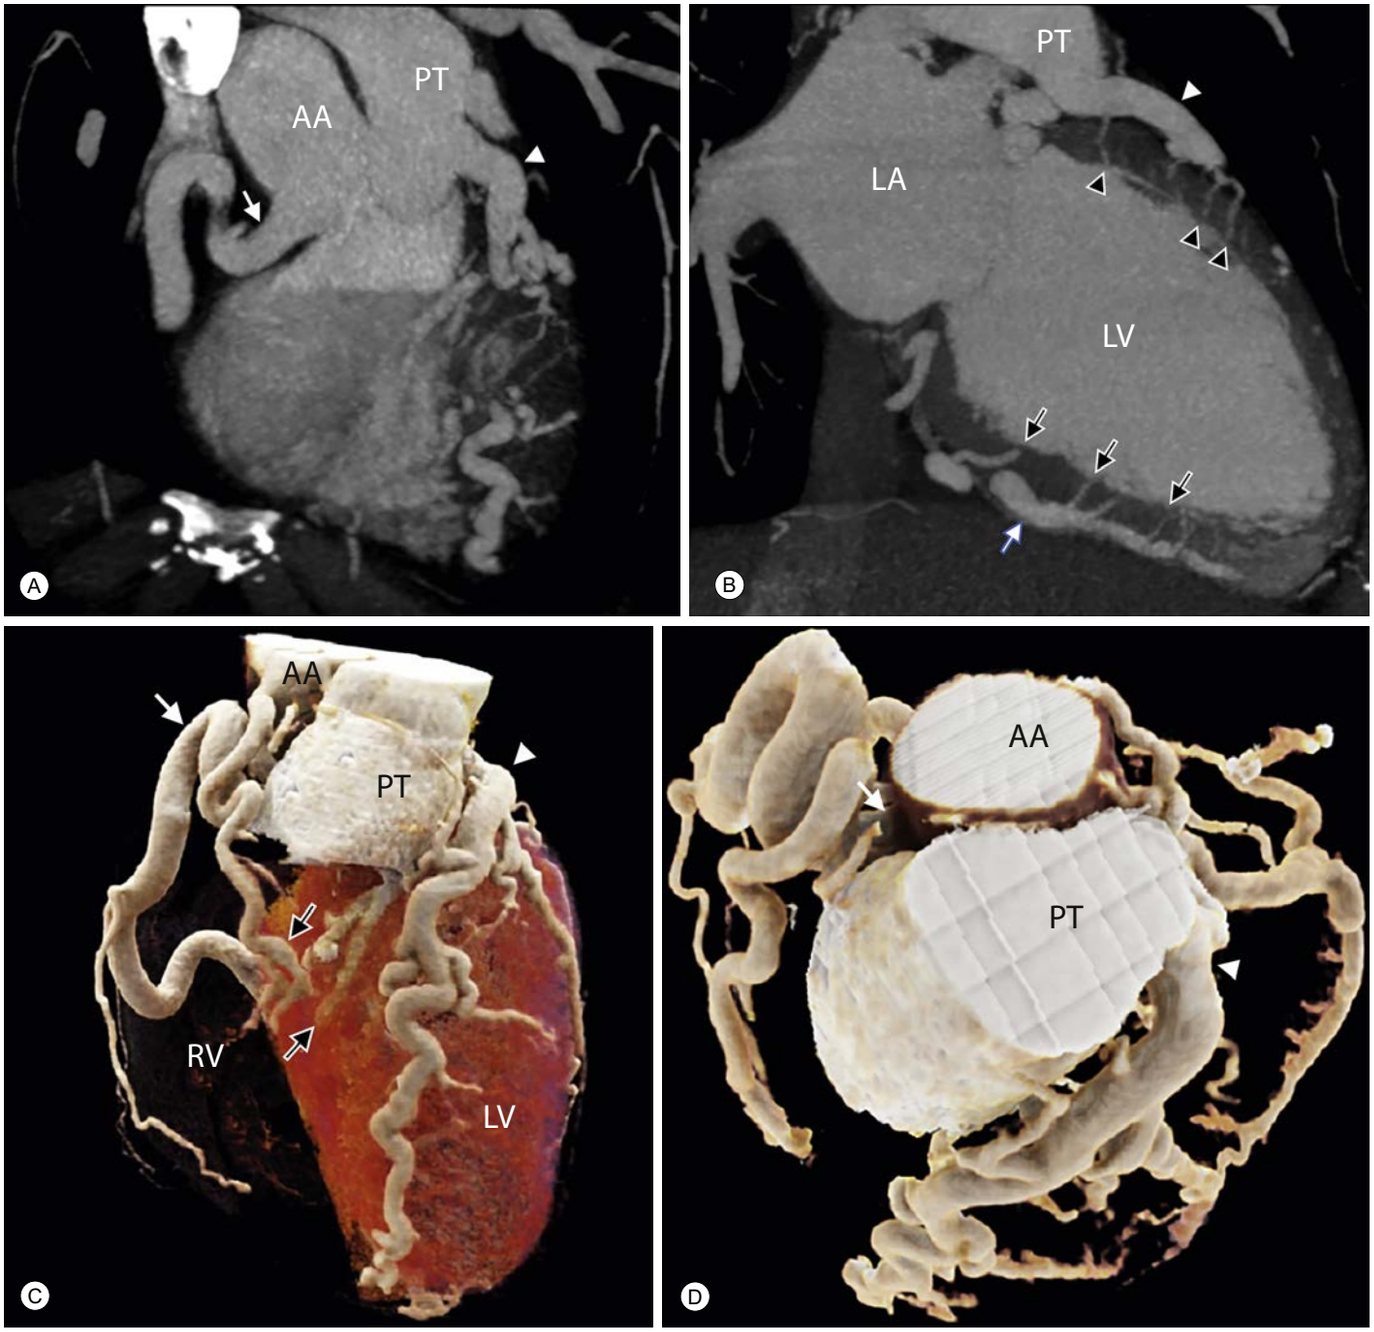

Fig. 7.2.5 CTCA showing an anomalous origin of the left coronary artery from the pulmonary trunk/artery (ALCAPA or Bland–Garland–White syndrome) in an adult male. The left and right coronary arteries are indicated by a white arrowhead and arrow, respectively. **A**, Maximum intensity projection (MIP) coronal image through the ascending aorta and pulmonary trunk showing a dilated right coronary artery arising from the right aortic sinus and a left coronary artery arising from the pulmonary trunk. **B**, Two-chamber long axis MIP view of the left atrium and left ventricle showing multiple enlarged collateral vessels (black arrows) branching from the inferior interventricular branch of the right coronary artery (white arrow with blue outline) to supply the inferior wall of the left ventricle. Enlarged collateral vessels from the anterior part of the left ventricular wall (black arrowheads) join and drain into the left coronary artery, which is continuous with the pulmonary trunk. **C**, Cinematic rendered image showing a left anterior view of the relationship between the coronary arteries and the left ventricular myocardium. Extensive hypertrophied collateral vessels (black arrows) supply the interventricular septum. The right ventricle is transparent. **D**, Top-down cinematic rendered image of the coronary arterial system with other cardiac anatomy removed. Abbreviations: AA, ascending aorta; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RV, right ventricle.

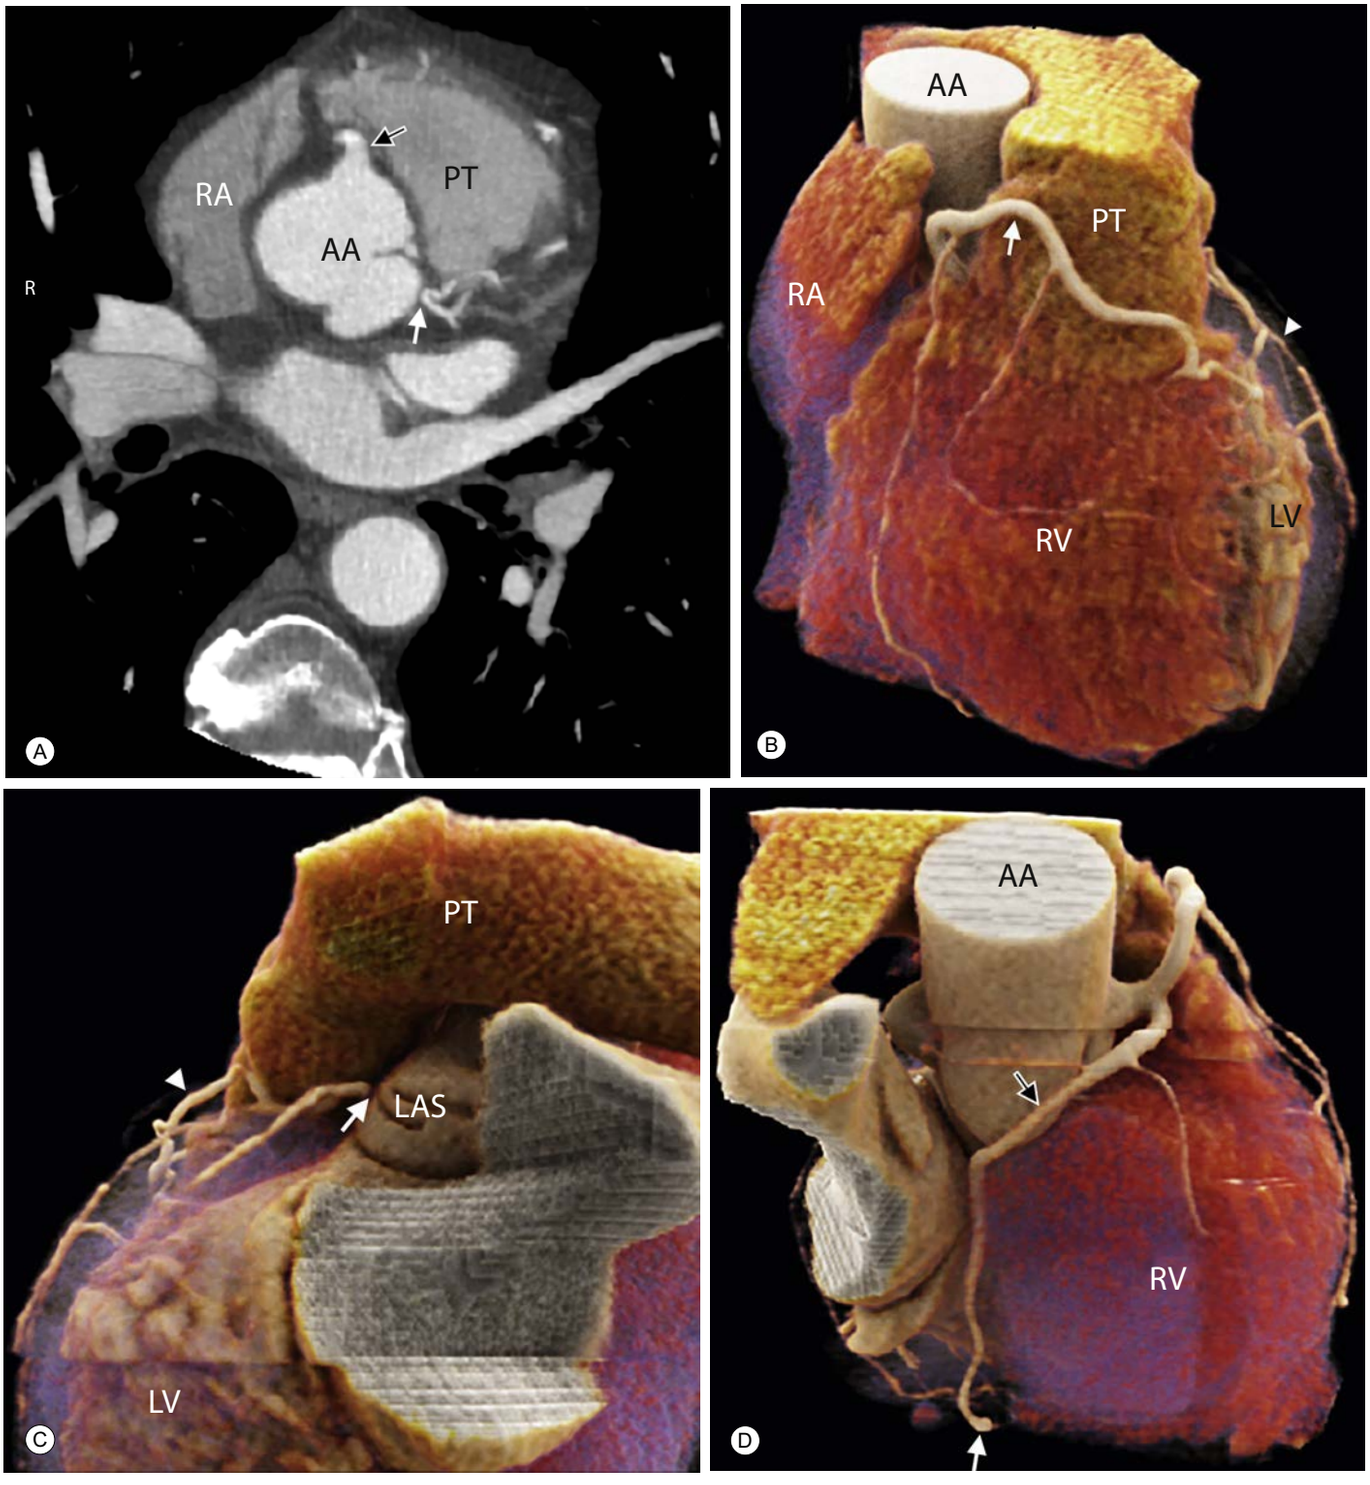

Fig. 7.2.6 CTCA showing atresia of the ostium (opening) of the left coronary artery. **A**, Axial image at level of the aortic sinuses showing a normal right coronary artery origin (black arrow) and atresia of the left coronary artery origin with no visible connection between the left aortic sinus and the small anterior interventricular artery (white arrow). **B–D**, Cinematic rendered images. **B**, Anterior view showing a dilated conal branch of the right coronary artery (white arrow) connecting to, and supplying the territory of, the anterior interventricular branch of the left coronary artery (white arrowhead). The coronary arteries supplying the left ventricular wall are small in calibre and insufficient to meet increases in myocardial demand. **C**, Close up of a posterior view with the left atrium partially removed showing a small anterior interventricular artery (white arrowhead) and a gap (white arrow) at the normal site of origin of the proximal left coronary artery from the left aortic sinus. **D**, Right lateral (pulmonary surface) view with both atria removed showing a vessel branching from the right coronary artery and taking a retro-aortic route (black arrow) to become continuous with the inferior interventricular artery (white arrow). Abbreviations: AA, ascending aorta; LAS, left aortic sinus; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle.

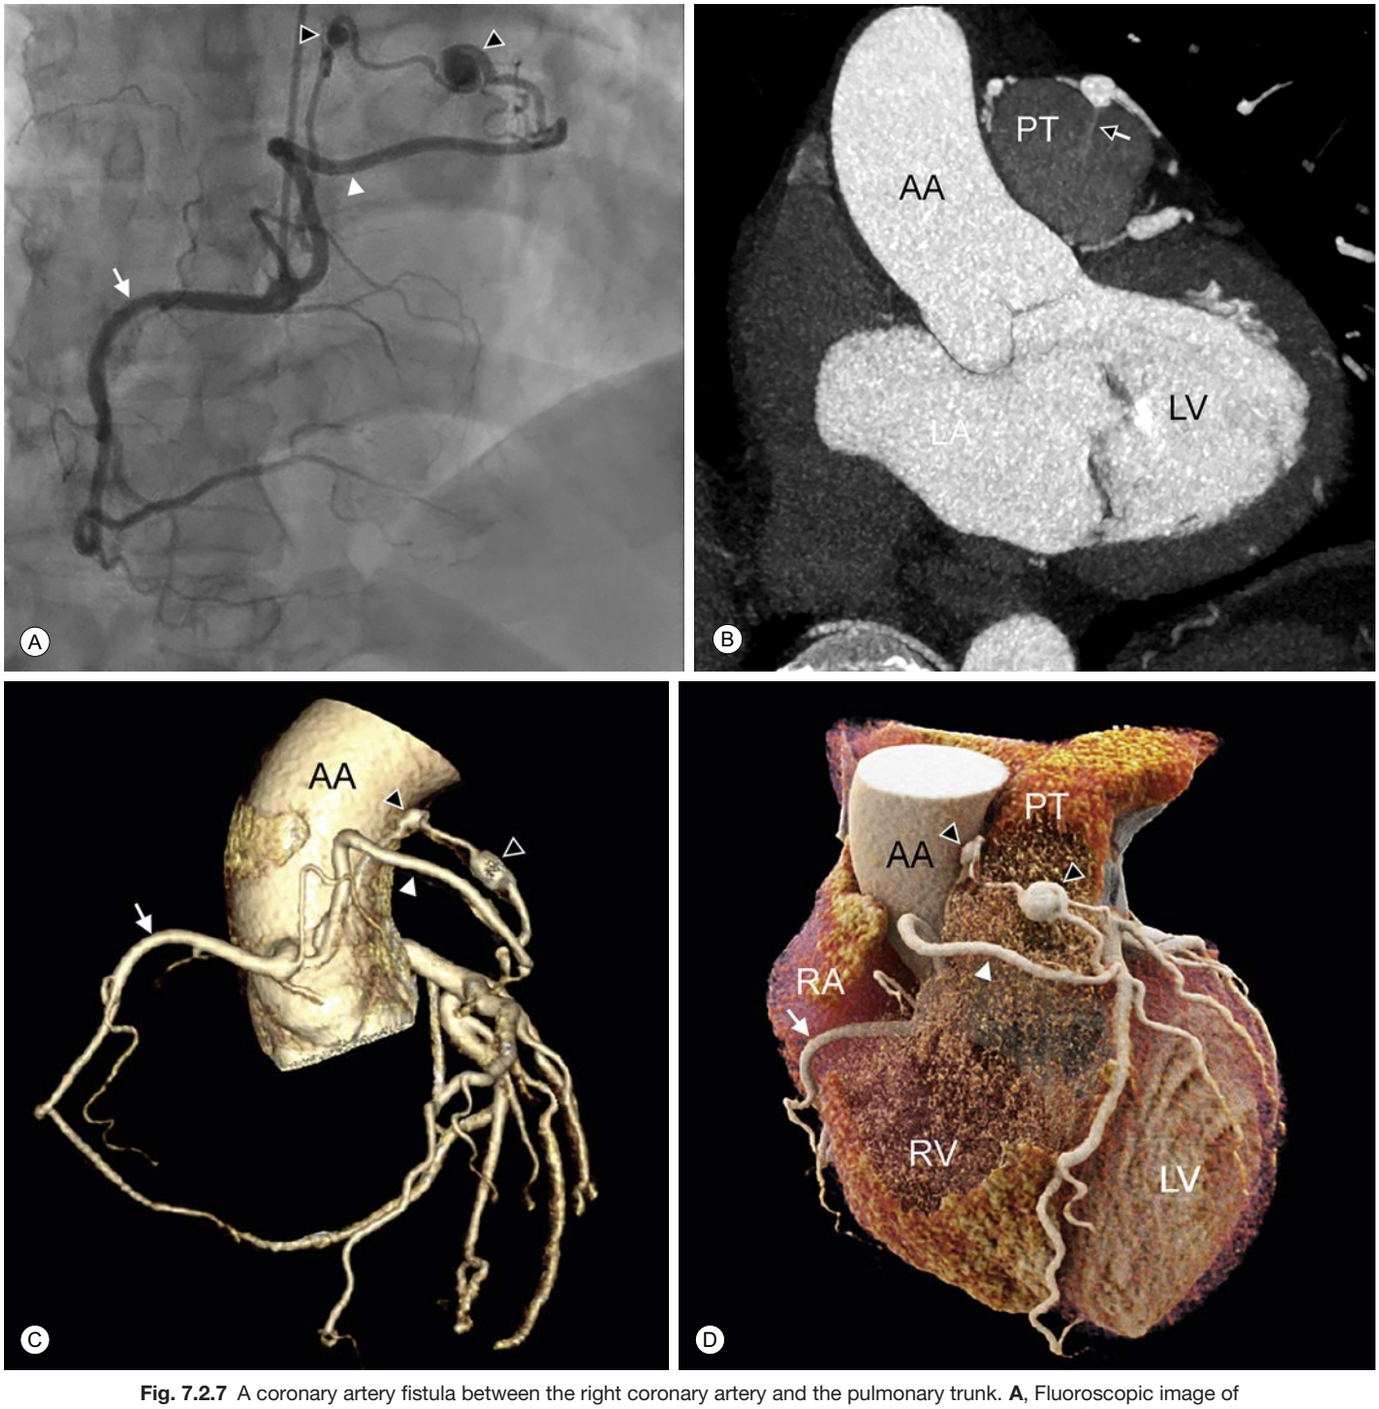

Fig. 7.2.7 A coronary artery fistula between the right coronary artery and the pulmonary trunk. **A**, Fluoroscopic image of a conventional invasive coronary artery angiogram showing an incidental finding of an aberrant vessel (white arrowhead) arising from the right coronary artery (white arrow). The aberrant vessel is wrapped around the pulmonary trunk and has two small aneurysms (black arrowheads). **B**, CTCA showing an oblique image centred on the larger of the two aneurysms. A tiny jet of contrast agent (black arrow) can be seen passing through a fistula between the aneurysm and pulmonary trunk. **C** and **D**, show similar lateral views of the heart enabling a comparison of 3D real time volumetric rendering (**C**) and cinematic rendering (**D**) of the coronary arterial system. Note the enhanced quality achieved using cinematic rendering. Abbreviations: AA, ascending aorta; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle.

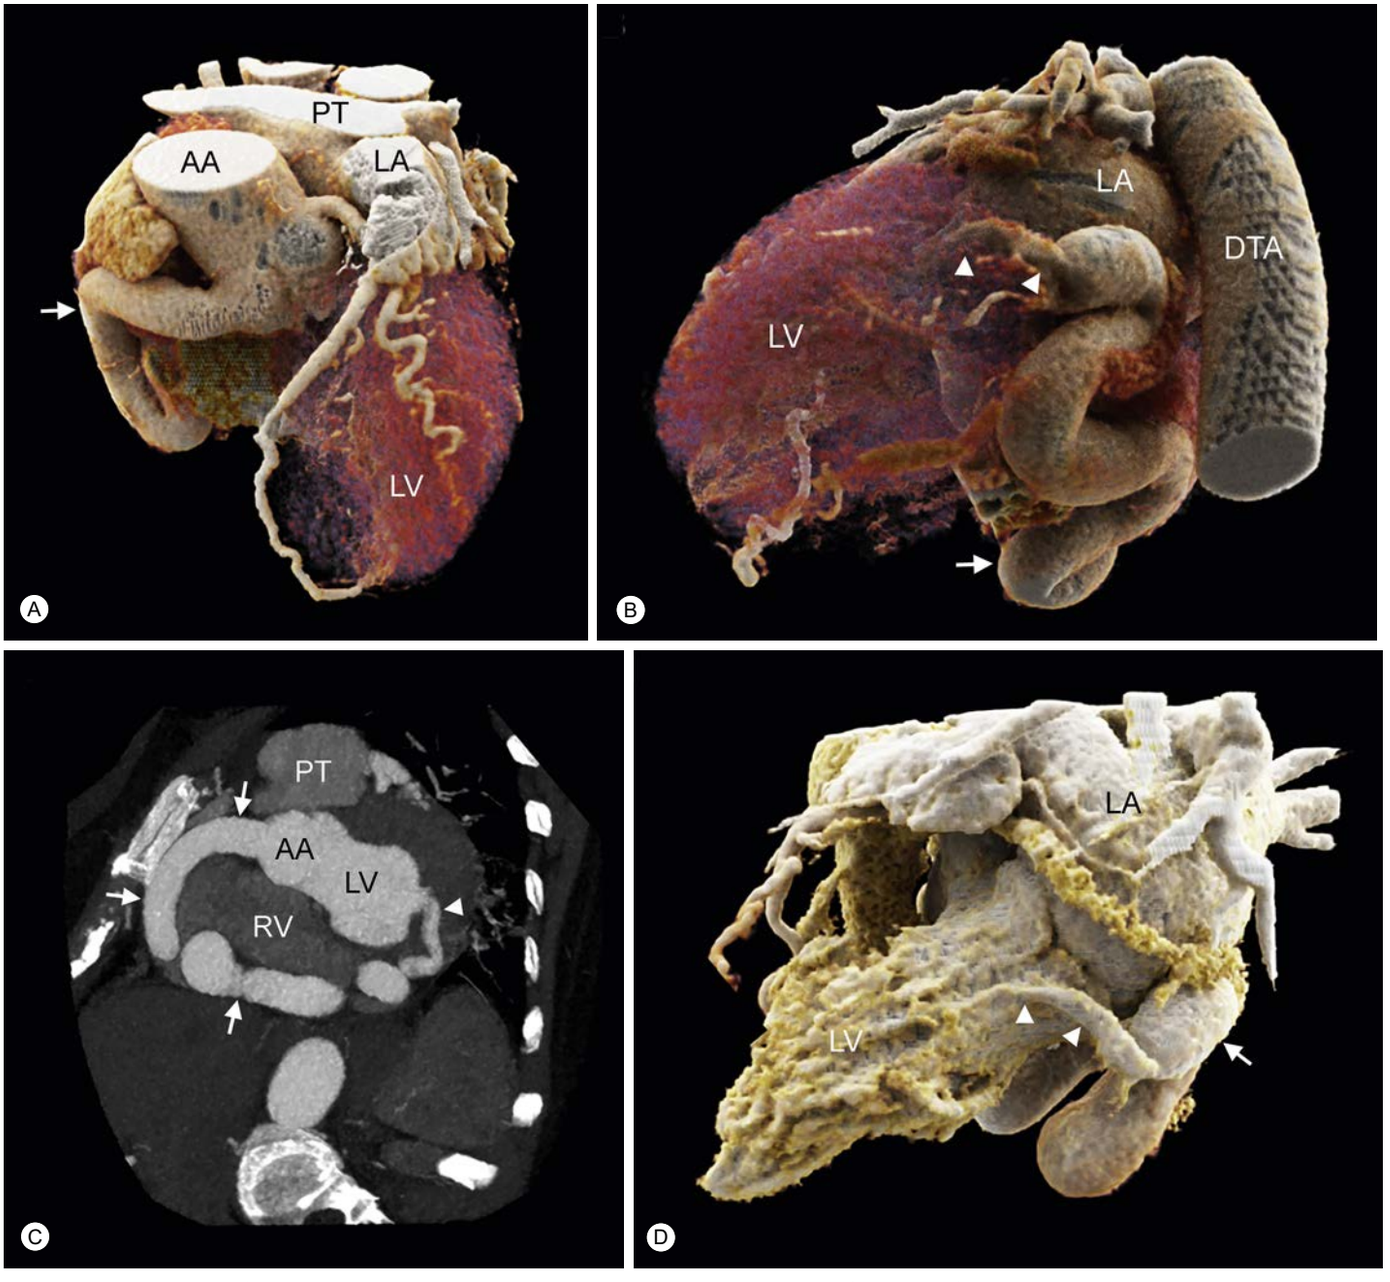

Fig. 7.2.8 CTCA of a coronary artery fistula showing the right coronary artery (white arrow) terminating in the left ventricle (white arrowhead). Cinematic rendered images showing **A**, left anterior and **B**, left inferolateral views of the course of the dilated right coronary artery as it travels around the atrioventricular (coronary) sulcus and enters the left ventricle through its inferior wall. **C**, Maximum intensity projection image showing an oblique view of a dilated right coronary artery passing from its origin to its insertion into the left ventricular chamber. **D**, Cinematic rendered image showing a left inferolateral view of the blood (contrast agent) within the cardiac chambers and coronary arteries: the myocardium has been removed. This image type provides a better visualization of the continuity of flow between the right coronary artery and left ventricle. Abbreviations: AA, ascending aorta; DTA, descending thoracic aorta; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RV, right ventricle.

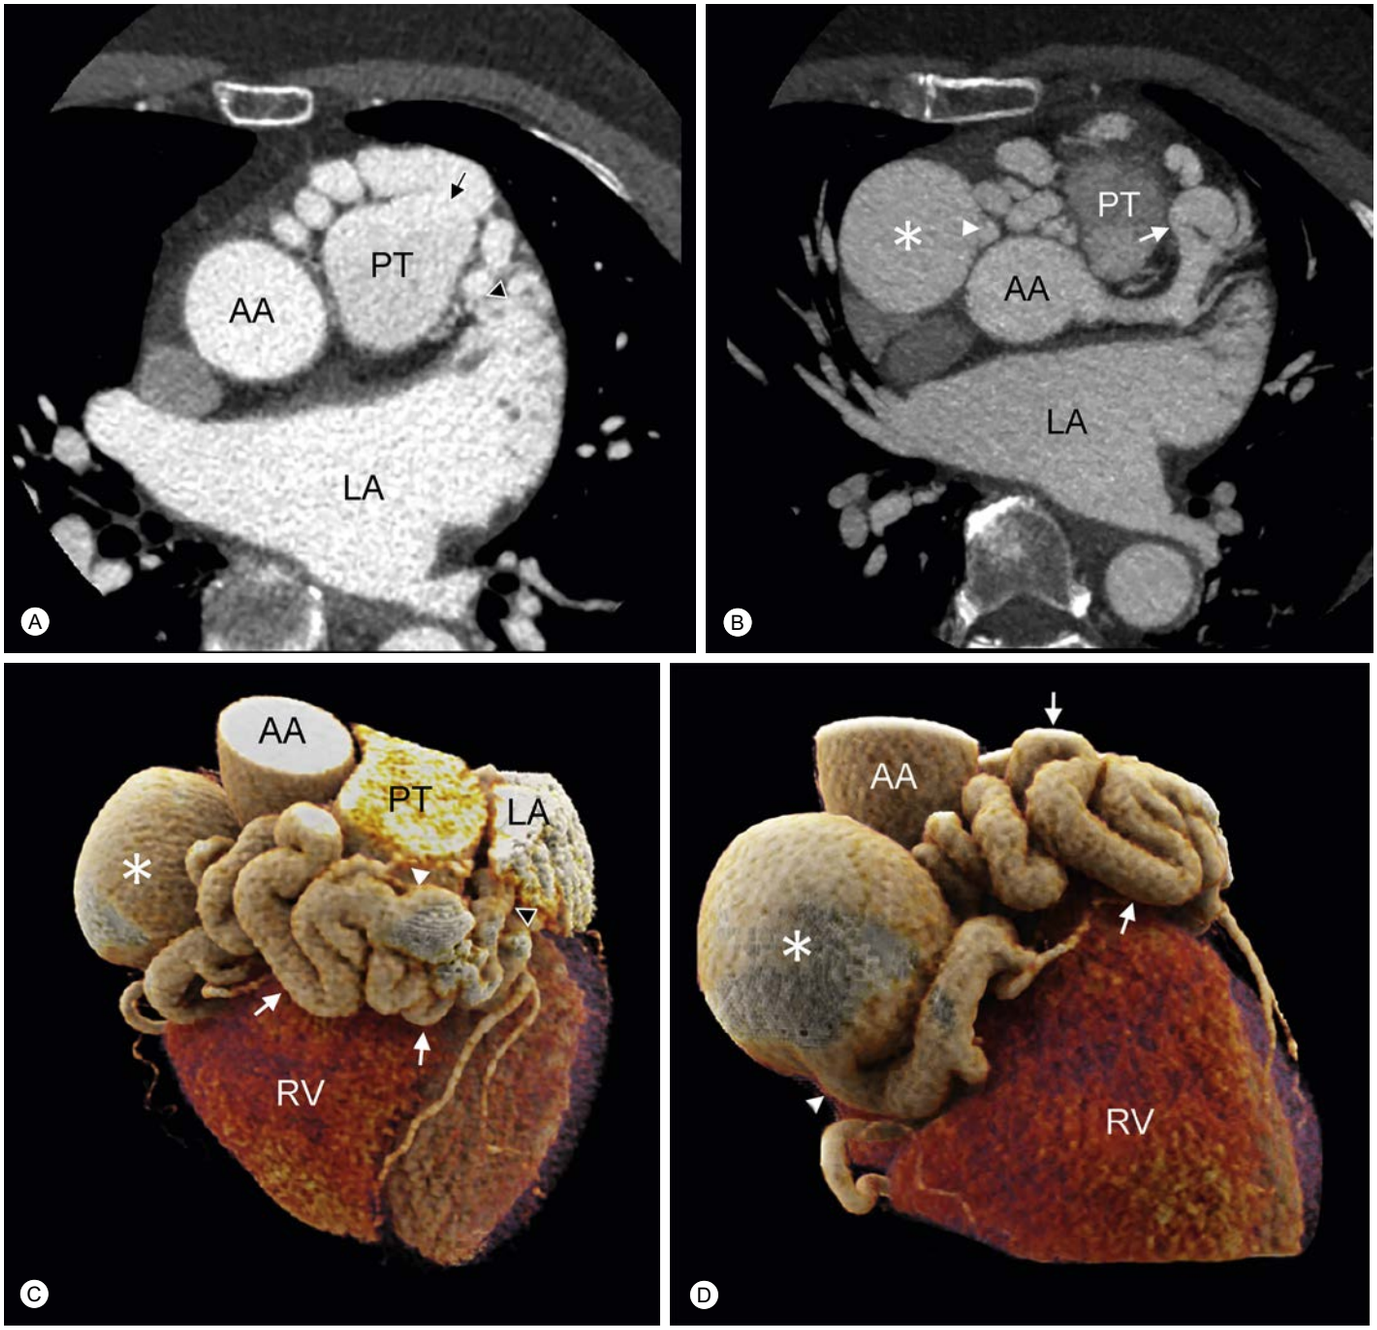

Fig. 7.2.9 CTCA showing complex coronary artery fistulae. **A**, Axial image at the level of the pulmonary trunk showing a complex network of dilated collateral coronary vessels with connections to the pulmonary trunk (black arrow) and left atrial auricle (black arrowhead). **B**, Axial image at the level of the aortic sinuses showing involvement of the anterior interventricular branch of the left coronary artery (white arrow), further complicated by an aneurysm of the right coronary artery (*) which also communicates with the collateral coronary vessels (white arrowhead). **C**, Cinematic rendered image showing an anterior view of the collateral vessels (white arrows) surrounding and in communication with the pulmonary trunk (white arrowhead) and left atrial auricle (black arrowhead). The aneurysm of the right coronary artery is again visible (*). **D**, Cinematic rendered image showing a posterior view of the right coronary artery aneurysm (*) in connection with a dilated right coronary artery (white arrow head). The superior connection with the collateral coronary vessels (white arrows at top of image) is hidden from view. Abbreviations: AA, ascending aorta; LA, left atrium; PT, pulmonary trunk; RV, right ventricle.

CHAPTER 59

Abdomen and pelvis: overview and surface anatomy

GENERAL STRUCTURE AND FUNCTION OF THE ABDOMINOPELVIC CAVITY

Although often considered separately, the abdomen and pelvis form the largest continuous visceral cavity in the body. Together, they provide multiple vital functions including: housing and protection of the digestive and urinary tracts and of the internal reproductive organs; a conduit for neurovascular communication between the thorax and lower limb; support and attachment for the external genitalia; access to and from the internal reproductive organs and urinary tract; assistance with physiological functions such as respiration, defecation and micturition; support for the vertebral column in weight-bearing, maintenance of posture and movement; and, in females, the ability to support gestation.

Musculoskeletal framework of the abdomen and pelvis

The walls of the abdominopelvic cavity consist of five lumbar vertebrae and their intervening intervertebral discs (lying in the posterior midline); the muscles of the anterior abdominal wall lying anteriorly (rectus abdominis) and anterolaterally (transversus abdominis, internal abdominal oblique and external abdominal oblique); the muscles of the posterior abdominal wall (psoas major, quadratus lumborum and the respiratory diaphragm); the bony 'basin' formed by the walls of the greater and lesser pelves; the muscles of the pelvic diaphragm and perineum lying inferiorly; and the respiratory diaphragm lying superiorly (**Fig. 59.1**). In addition, the superior aspect of the abdominal cavity gains protection from the inferior six ribs and their cartilages, even though these structures are technically part of the thoracic wall.

The muscles of the abdominal wall are important for movement of the trunk (flexion, extension and rotation). The anterolateral muscles in particular provide assistance with rotation of the thorax in relation to the pelvis (or vice versa if the thorax is fixed).

The abdominal cavity is somewhat kidney-shaped in horizontal cross-section owing to the posterior indentation of the vertebral column. In standing, the linea terminalis lies at an angle of about 55° to the horizontal such that the anterior superior iliac spines and pubic tubercles are in approximately the same coronal plane. The mean angle between the superior border of the first segment of the sacrum and the horizontal plane is about 40–45° (Woon et al 2013).

Thoracoabdominal interface

The respiratory diaphragm (diaphragm, thoracic diaphragm) constitutes the interface between the thoracic and abdominal cavities (Ch. 55). There are three principal pathways between the two cavities across the respiratory diaphragm: the caval foramen in the central tendon transmits the inferior vena cava and right phrenic nerve; the oesophageal hiatus, encircled by the right crus of the respiratory diaphragm, transmits the oesophagus, vagal trunks and vessels; and the aortic hiatus, posterior to the median arcuate ligament, transmits the aorta, thoracic duct and, usually, the azygos vein. The hemiazygos vein usually enters the thorax through the left crus of the respiratory diaphragm. Other lymphatics from the abdomen drain to the thorax alongside the inferior vena cava and via small vessels passing through and around the respiratory diaphragm. Thoracic splanchnic nerves reach the abdomen through the crura of the respiratory diaphragm and posterior to the medial arcuate ligaments, and the left phrenic nerve pierces the left side of the respiratory diaphragm. The subcostal vessels pass into the abdomen posterior to the lateral arcuate ligaments of the respiratory diaphragm. Anteriorly, the superior epigastric vessels pass between the costal and xiphoid process attachments, i.e. sternocostal foramen of the respiratory diaphragm. Neurovascular structures also cross between the thorax and abdomen within the subcutaneous tissues.

Pelvis–lower limb interface

The pelvis forms an integral part of the bony structure of both the abdominopelvic cavity and the lower limbs. It transmits the weight of the upright body and provides a stable platform for movement of the hip joint and bipedal locomotion. Its bony surfaces provide attachment sites for the muscles of the buttock and thigh (Ch. 77), the pelvic diaphragm and perineal membrane, the abdominal wall and lower back. The pelvis also transmits the neurovascular structures that supply the lower limb. There are four principal pathways between the pelvis and lower limb: the interval deep to the inguinal ligament anterior to the superior ramus of the pubis and ilium, which transmits the femoral neurovascular structures and lymphatics; the greater and lesser sciatic foramina, which transmit the gluteal vessels and nerves, sciatic nerve and internal pudendal vessels and pudendal nerve; and the obturator foramen, which transmits the obturator nerve, vessels and lymphatics. Autonomic nerves travel with the arterial supply to the lower limb and with the branches of the sacral plexus. Neurovascular structures also cross between the lower limb and pelvis within the subcutaneous tissues.

GENERAL ARRANGEMENT OF ABDOMINOPELVIC AUTONOMIC NERVES

What follows is a brief overview of the autonomic nervous system in the abdominopelvic region; descriptions of the neurovascular supply to individual organs are given in the relevant chapters. The autonomic supply to the abdominal and pelvic viscera is via the abdominopelvic part of the sympathetic trunk and the greater, lesser and least thoracic splanchnic nerves (sympathetic), and the vagus and pelvic splanchnic nerves (parasympathetic). There are numerous interconnections between plexuses and ganglia, particularly in the major plexuses around the abdominal aorta; hence, the descriptions tend to be simplifications based on the 'main' supply to each organ (**Fig. 59.2**). Details of the terminations of these fibres are given in the description of the general microstructure of the wall of the hollow viscera.

As a general rule, sympathetic neurones from the abdominopelvic autonomic plexuses inhibit visceral smooth muscle motility and glandular secretions, induce sphincter contraction and cause vasoconstriction. Parasympathetic stimulation leads to opposing effects. Visceral afferents also pass through these autonomic plexuses.

Sympathetic innervation

The cell bodies of neurones of the sympathetic supply of the abdomen and pelvis lie in the intermediolateral grey matter of the first to the twelfth thoracic and the first two lumbar spinal segments. Myelinated axons from these neurones travel in the ventral ramus of the spinal nerve of the same segmental level, leaving it via a white ramus communicans to enter a thoracic or lumbar ganglion. Visceral branches can exit at the same level or ascend or descend several levels in the sympathetic trunk before exiting; they leave the ganglia without synapsing and pass medially, giving rise to the paired greater, lesser and least thoracic splanchnic nerves and to the lumbar and sacral splanchnic nerves. Axons destined to supply somatic structures synapse in the sympathetic ganglion of the same level, and postganglionic, unmyelinated axons leave the ganglion as one or more grey rami communicantes to enter the spinal nerve of the same segmental level.

Greater thoracic splanchnic nerve

On each side, the greater thoracic splanchnic nerve is derived from the medial branches of the fifth to ninth thoracic ganglia. It gives off branches to the descending thoracic aorta and enters the abdomen through the fibres of the ipsilateral crus of the respiratory diaphragm, on which it descends anteroinferiorly. The main trunk of the nerve enters the superior aspect of the coeliac ganglion, where most of the

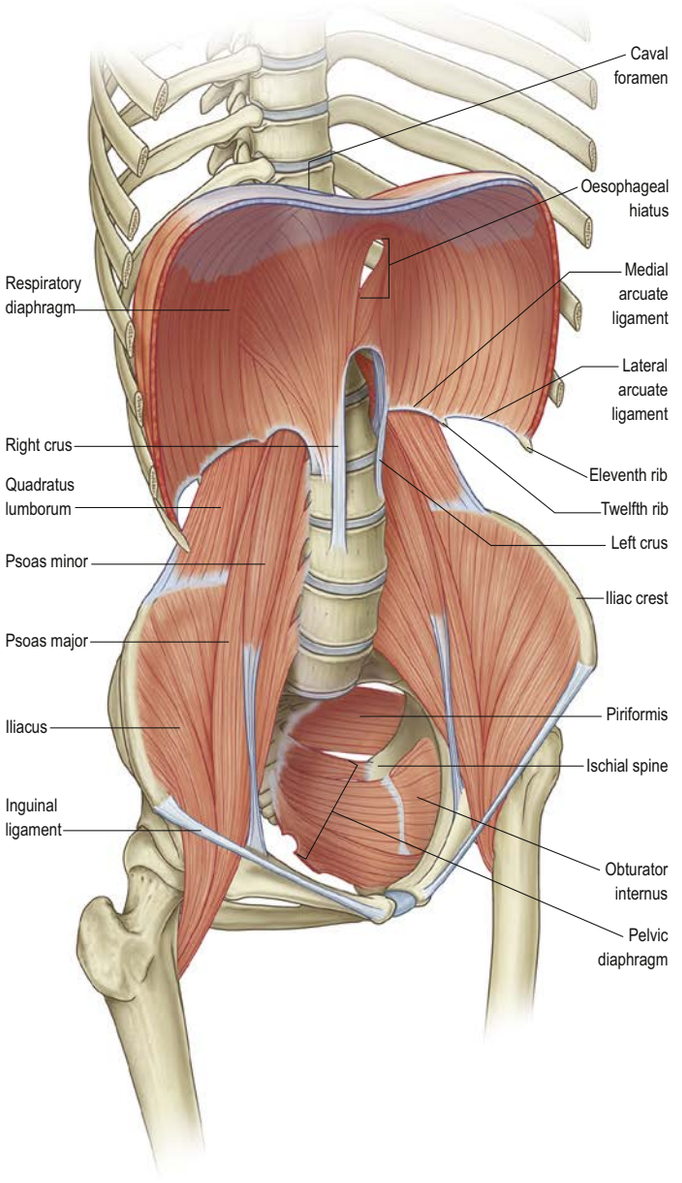

Fig. 59.1 The bony and muscular structures making up the abdominopelvic cavity. The anterolateral abdominal muscles have been removed for clarity.

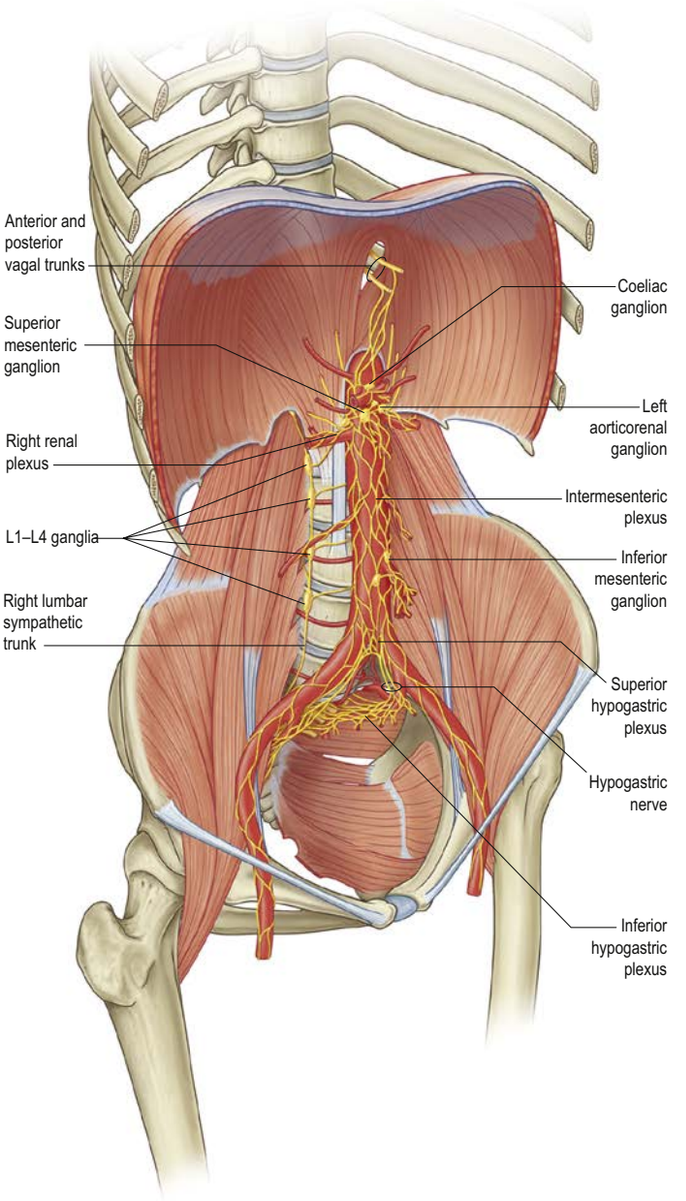

Fig. 59.2 The overall arrangement of the autonomic plexuses of the abdominal and pelvic viscera. The major ganglia are indicated and note their associated plexuses.

preganglionic fibres synapse (but not those destined for the medulla of the suprarenal gland).

Lesser thoracic splanchnic nerve

On each side, the lesser thoracic splanchnic nerve is derived from the medial branches of the tenth and eleventh (or ninth and tenth) thoracic ganglia. It enters the abdomen running through the most inferior fibres of the ipsilateral crus of the respiratory diaphragm or under the medial arcuate ligament, and then lies on the crus as it runs anteroinferiorly. The trunk of the nerve joins the aorticorenal ganglion and may give branches to the lateral aspect of the coeliac ganglion. It occasionally joins the greater and least thoracic splanchnic nerves as a single splanchnic nerve.

Least thoracic splanchnic nerve

On each side, the least thoracic splanchnic nerve is derived from the medial branches of the eleventh and/or twelfth thoracic ganglion. It enters the abdomen medial to the sympathetic trunk under the medial arcuate ligament of the respiratory diaphragm and runs inferiorly to join the renal plexus. The trunk of the nerve enters the aorticorenal ganglion and may give branches to the lateral aspect of the coeliac ganglion. It is sometimes part of the lesser thoracic splanchnic nerve, when it forms a twig that enters the renal plexus just below the aorticorenal ganglion.

The thoracic splanchnic nerves show considerable individual variation in their origin and distribution (Loukas et al 2010). For example, the greater thoracic splanchnic nerve can receive a contribution from the fourth or tenth thoracic ganglion of the sympathetic trunk or originate only from the sixth to ninth ganglia.

Lumbar sympathetic system

The lumbar part of each sympathetic trunk usually contains four ganglia lying on the anterolateral aspects of the lumbar vertebrae along the medial margin of psoas major (see Figs 59.2–59.4, 61.15) (Murata et al 2003). Superiorly, it is continuous with the thoracic part of the sympathetic trunk posterior to the medial arcuate ligament. Inferiorly, it passes posterior to the common iliac vessels and is continuous with the sacral part of the sympathetic trunk. On the right side, it lies posterior to the inferior vena cava; on the left, it is posterior to the lateral aortic nodes. It is anterior to most of the lumbar vessels but may pass posterior to some lumbar veins.

On each side, the first, second and sometimes the third lumbar ventral rami are connected to the lumbar part of the sympathetic trunk by white rami communicantes. All lumbar ventral rami are joined near their origins by long, slender, grey rami communicantes from the four lumbar ganglia. Their arrangement is irregular: one ganglion can give rami to two or three lumbar ventral rami, one lumbar ventral ramus can receive rami from two ganglia, or grey rami can leave the sympathetic trunk between ganglia (Murata et al 2003).

Somatic and vascular branches

Sympathetic nerve branches accompany the lumbar arteries round the sides of the vertebral bodies, medial to the fibrous arches to which psoas major is attached, to provide sympathetic innervation to the segmental distribution of the lumbar arteries. Branches from the lumbar ganglia

innervate the abdominal aorta and common, external and internal iliac arteries, forming delicate nerve plexuses that extend along the vessels. Other postganglionic sympathetic nerves to vessels and skin travel with somatic nerves. Thus, the femoral nerve carries vasoconstrictor sympathetic nerves to the femoral artery and its branches in the thigh, as well as sympathetic fibres in its cutaneous branches. Postganglionic fibres travelling with the obturator nerve supply the obturator artery and a variable patch of skin of the medial thigh. Sympathetic denervation of vessels in the lower limb can occur by removing or ablating the proximal three lumbar ganglia and intervening parts of the sympathetic trunk; this procedure can be useful for treating some varieties of vascular insufficiency of the lower limb.

Lumbar splanchnic nerves

Four lumbar splanchnic nerves pass as medial branches from the ganglia to join the coeliac, inferior mesenteric and superior hypogastric plexuses (see Fig. 59.4). The first lumbar splanchnic nerve, from the first ganglion of the lumbar part of the sympathetic trunk, gives branches to the coeliac, renal and inferior mesenteric plexuses. The second lumbar splanchnic nerve joins the inferior part of the intermesenteric or inferior mesenteric plexus. The third lumbar splanchnic nerve arises from the third or fourth ganglion and joins the superior hypogastric plexus. The fourth lumbar splanchnic nerve from the lowest ganglion joins the distal part of the superior hypogastric plexus, or the hypogastric nerve. It is important to note that lumbar splanchnic nerves contribute to the superior and inferior hypogastric plexuses and therefore to the innervation of the neck of the urinary bladder, ductus deferens and prostate, among other structures. Injury to these nerves, e.g. during aortoiliac surgery, can result in sexual dysfunction.

Pelvic sympathetic system

The sacral part of the sympathetic trunk usually consists of four or five ganglia located medial or anterior to the anterior sacral foramina posterior to the presacral fascia (Oh et al 2004). Occasionally, one or two coccygeal ganglia are present. The sacral part of the sympathetic trunk is continuous above with the lumbar part of the sympathetic trunk, and preganglionic fibres descend from the distal lumbar spinal cord segments via this route. The first sacral ganglion is the largest. Ganglia become progressively smaller in the caudal direction (Blaszczyk 1981). The sacral sympathetic trunk is often asymmetric, with absent or fused ganglia, and cross-communications between sides are frequent. Each ganglion sends at least one grey ramus communicans to its adjacent spinal nerve but up to 11 such branches from a single ganglion have been reported (Potts 1925).

The sacral part of the sympathetic trunk converges caudally to form a solitary retroperitoneal structure, the ganglion impar (ganglion of Walther), which lies at a variable level between the sacrococcygeal joint and the apex of the coccyx; it is occasionally paired, unilateral or absent (Oh et al 2004). It conveys sympathetic fibres to and nociceptive afferents from the perineum and terminal urogenital regions. Anaesthetic blockade of the ganglion impar can be used to treat intractable perineal pain carried by visceral afferent fibres in patients with pelvic cancers (Toshniwal et al 2007).

Somatic and vascular branches

Grey rami communicantes containing postganglionic sympathetic nerves pass from the pelvic sympathetic ganglia to the sacral and coccygeal spinal nerves. There are no white rami communicantes at this level. The postganglionic fibres are distributed via the sacral and coccygeal plexuses (Woon and Stringer 2014). Thus, sympathetic fibres in the tibial nerve are conveyed to the popliteal artery and its branches in the leg and foot, whilst those in the pudendal and superior and inferior gluteal nerves accompany these arteries to the perineum and buttocks, respectively. Small branches also travel with the median and lateral sacral arteries.

Sacral splanchnic nerves

Sacral splanchnic nerves pass directly from the ganglia of the sacral part of the sympathetic trunk to the inferior hypogastric plexus and, from there, to pelvic viscera; they usually arise from the first two sacral ganglia.

Parasympathetic innervation

The parasympathetic neurones innervating the abdomen and pelvis lie either in the posterior nucleus of the vagus nerve or in the intermediolateral grey matter of the second, third and fourth sacral spinal cord segments. Traditionally, the vagus nerves have been said to supply parasympathetic innervation to the abdominal viscera as far as the distal transverse colon, i.e. they supply derivatives of the foregut and midgut. Derivatives of the hindgut are supplied by parasympathetic fibres travelling via the pelvic splanchnic nerves (see below); the overlap between these two supplies is variable. The vagal trunks are derived from the oesophageal plexus and enter the abdomen via the oesophageal hiatus, closely related to the anterior and posterior walls of the abdominal part of the oesophagus (see Fig. 56.6). The anterior vagal trunk is mostly derived from the left vagus nerve and the posterior vagal trunk from the right vagus nerve. The nerves supply the abdominal part of the oesophagus and stomach directly. The anterior vagal trunk gives off a hepatic branch, which innervates the liver and its vasculature, including the gallbladder and bile ducts, and the other structures in the free edge of the lesser omentum (hepatoduodenal ligament). The posterior vagal trunk supplies branches to the coeliac plexus; these fibres frequently constitute the largest portion of the fibres contributing to the plexus. They arise directly from the posterior vagal trunk and from its gastric branch, and run posterior to the peritoneum, deep to the posterior wall of the superior part of the omental bursa, to reach the coeliac plexus. Their synaptic relays with postganglionic neurones are situated in the myenteric (Auerbach's) and submucosal (Meissner's) plexuses in the wall of the hollow viscera (see below).

Pelvic splanchnic nerves

Pelvic splanchnic nerves to the pelvic viscera travel in the ventral rami of the second, third and fourth sacral spinal nerves. They leave the nerves as they exit the anterior sacral foramina and pass in the presacral tissue as a fine network of branches that are distributed to three principal destinations. Most pass anterolaterally into the network of nerves that form the inferior hypogastric plexus; from there, they pass to the pelvic viscera. Some join directly with the hypogastric nerves and ascend out of the pelvis as far as the superior hypogastric plexus; from there they are distributed with branches of the inferior mesenteric artery (Ch. 65). A few run superolaterally in the presacral fascia, over the linea terminalis anterior to the left iliac vessels, and pass directly into the tissue of the retroperitoneum toward the sigmoid and descending colons. The pelvic splanchnic nerves are motor to the smooth muscle of the derivatives of the hindgut and wall of the urinary bladder, supply vasodilator fibres to the erectile tissues of the penis and clitoris, and are secretomotor to the derivatives of the hindgut.

An experimental study of the differential expression of transcription factors in embryonic mice argued that thoracic and sacral pools of preganglionic neurones share a common sympathetic identity and that the sacral autonomic outflow should therefore be regarded as sympathetic (Espinosa-Medina et al 2016). This controversial view has been challenged (Horn 2018).

Abdominopelvic autonomic plexuses and ganglia

The abdominopelvic autonomic plexuses are somewhat variable and often fuse or are closely interrelated. The following descriptions encompass their main features (**Figs 59.3–59.4**).

Coeliac plexus

The coeliac plexus is located at the level of the twelfth thoracic and first lumbar vertebrae. It is a dense network that unites the coeliac ganglia, and surrounds the coeliac trunk and the proximal superior mesenteric artery. It is posterior to the stomach and omental bursa and anterior to the crura of the respiratory diaphragm and the beginning of the abdominal aorta, and lies medial to the suprarenal glands. The plexus and ganglia receive the greater and lesser thoracic splanchnic nerves and branches from the vagal trunks. The plexus is in continuity with small branches along adjacent arteries and is connected to the phrenic, splenic, hepatic, superior mesenteric, suprarenal, renal and ovarian/testicular plexuses. Visceral afferent fibres in the coeliac plexus convey pain and other sensations from proximal abdominal viscera. Anaesthesia or ablation of these nerves (coeliac plexus blockade) is sometimes undertaken to treat medically intractable pain from pancreatic disorders.

Coeliac and aorticorenal ganglia

The coeliac ganglia are irregular neural masses, measuring approximately 2 cm across, located between the origin of the coeliac trunk and superior mesenteric artery, medial to the suprarenal glands and anterior to the crura of the respiratory diaphragm (Zhang et al 2006). They vary in number, size, shape and precise location; there are often two, one on each side. The right ganglion is frequently posterior to the inferior vena cava, and the left ganglion often lies posterior to the origin of the splenic artery. The ipsilateral greater thoracic splanchnic nerve joins the superior part of each ganglion and the lesser thoracic splanchnic nerve joins the inferior part. The most inferior part of each ganglion usually forms a distinct

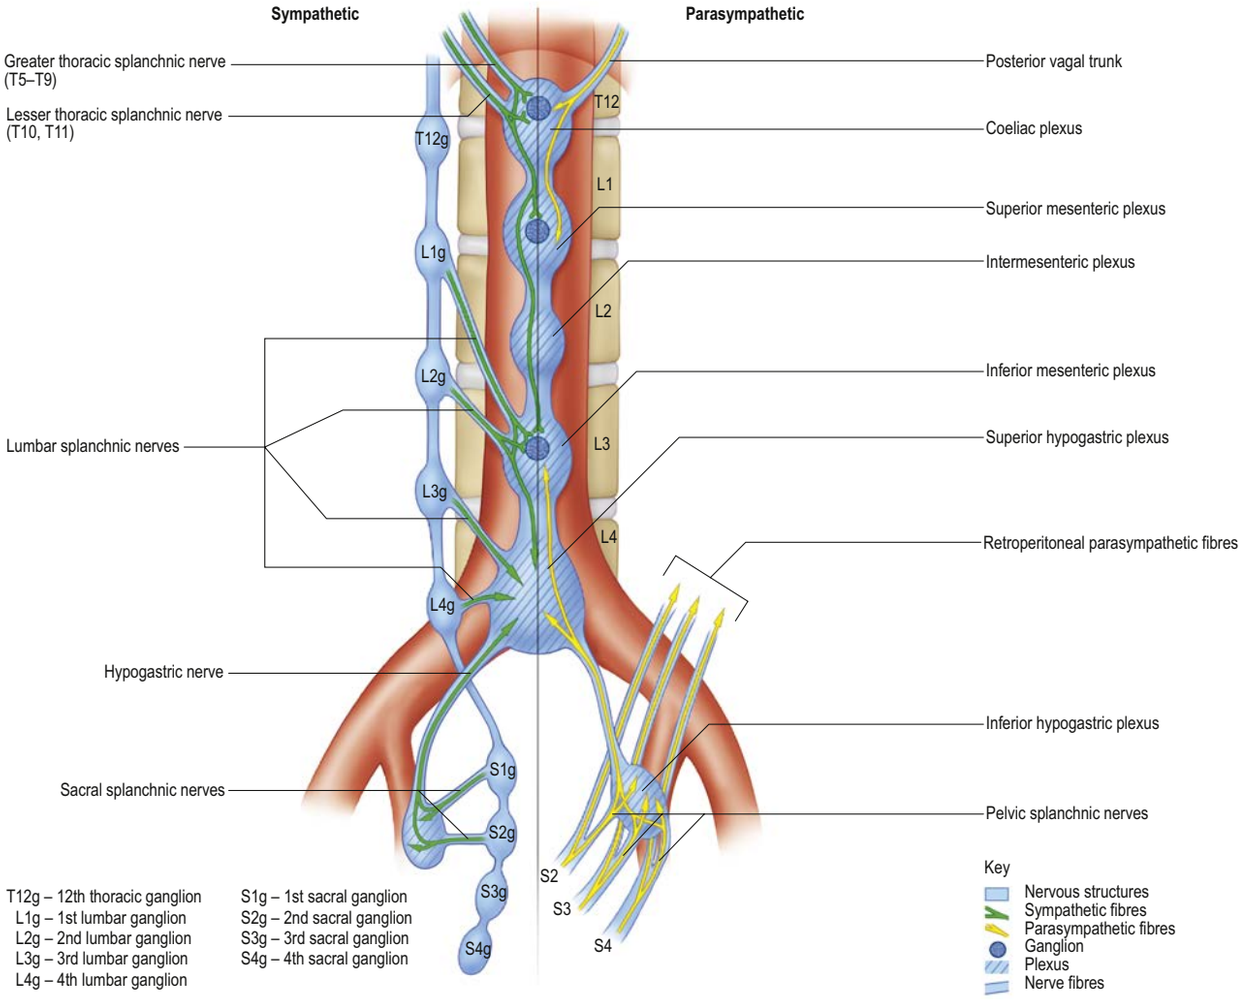

Fig. 59.3 The autonomic plexuses innervating the abdominal and pelvic viscera: schematic diagram.

subdivision, the aorticorenal ganglion, which receives the ipsilateral lesser splanchnic nerve and gives origin to most of the renal plexus.

Phrenic plexus

The phrenic plexus is a periarterial extension of the coeliac plexus around the right inferior phrenic artery, adjacent to the right crus of the respiratory diaphragm (Rusu 2006). It contains one or two phrenic ganglia and a definable nerve trunk that connects the coeliac plexus and phrenic nerve: the phrenic ganglion is probably sympathetic (Tubbs et al 2008). The phrenic plexus supplies branches to the suprarenal glands and the respiratory diaphragm.

Superior mesenteric plexus and ganglion

The superior mesenteric plexus lies in the pre-aortic connective tissue posterior to the pancreas, around the origin of the superior mesenteric artery. It is an inferior continuation of the coeliac plexus and includes branches from the posterior vagal trunk and coeliac plexus. Its branches accompany the superior mesenteric artery and its branches. The superior mesenteric ganglion lies superiorly in the plexus, usually above the origin of the superior mesenteric artery.

Intermesenteric plexus

Like other parts of the abdominal aortic autonomic plexus, the intermesenteric plexus is not a discrete structure but is part of a continuous periarterial nerve plexus connected to the ovarian/testicular, inferior mesenteric, iliac and superior hypogastric plexuses. It lies on the lateral and anterior aspects of the aorta, between the origins of the superior and inferior mesenteric arteries, and consists of numerous fine, interconnected nerve fibres and a few ganglia continuous superiorly with the superior mesenteric plexus and inferiorly with the superior hypogastric plexus. It is not well characterized but receives parasympathetic and sympathetic branches from the coeliac plexus and additional sympathetic contributions from the first and second lumbar splanchnic nerves.

Inferior mesenteric plexus

The inferior mesenteric plexus lies around the origin of the inferior mesenteric artery and is distributed along its branches. It is formed predominantly from the aortic plexus, supplemented by sympathetic fibres from the first and second lumbar splanchnic nerves and ascending pelvic parasympathetic fibres from the inferior hypogastric plexus (via the hypogastric nerves and superior hypogastric plexus). Disruption of the inferior mesenteric plexus alone rarely causes clinically significant disturbances of autonomic function.

Superior hypogastric plexus

The superior hypogastric plexus lies anterior to the aortic bifurcation, the left common iliac vein, median sacral vessels, fifth lumbar vertebral body and promontory of the sacrum, and between the common iliac arteries. It lies within extraperitoneal connective tissue in the midline, extending a little to the left. The breadth of the plexus and its constituent nerves varies; appearances range from a reticular-like arrangement to a band-like structure or one or two distinct nerve trunks (Paraskevas et al 2008). The medial attachment of the sigmoid mesocolon and superior limit of the mesorectum lie anterior to the distal part of the plexus, separated from it by a thin layer of loose connective tissue. The plexus is formed by branches from three main sources: the abdominal aortic plexus (sympathetic and parasympathetic), lumbar splanchnic nerves (sympathetic) and pelvic splanchnic nerves (parasympathetic), which ascend from the inferior hypogastric plexus via the right and left hypogastric nerves (Kraima et al 2015). Visceral sensory fibres also pass through the plexus. The hypogastric nerves lie in loose connective tissue just posterolateral to the proximal mesorectum and pass over the linea terminalis medial to the internal iliac vessels. The superior hypogastric plexus conveys branches to the inferior mesenteric plexus and to the ureteric, ovarian/testicular and common iliac nerve plexuses; additional small branches turn abruptly forwards into the proximal mesorectum to travel with the superior anorectal artery.

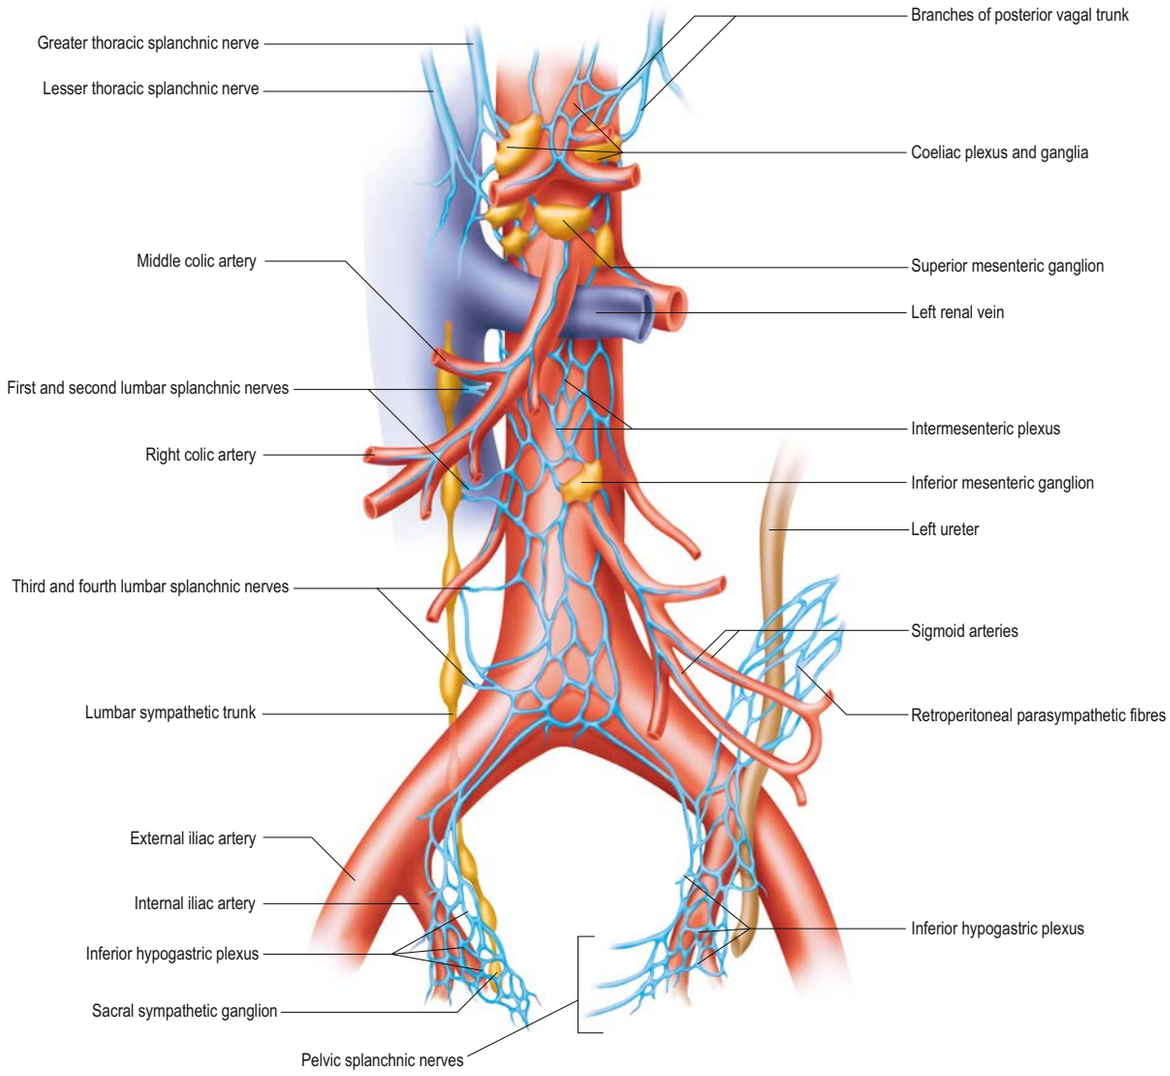

Fig. 59.4 The major autonomic plexuses of the abdomen and pelvis.

Inferior hypogastric plexus

The inferior hypogastric plexus lies in the thin extraperitoneal connective tissue on the pelvic side wall anterolateral to the mesorectum. The internal iliac vessels and the attachments of levator ani and obturator internus lie laterally, and the superior vesical and occluded part of the umbilical arteries superiorly. In males the inferior hypogastric plexus lies posterolaterally on either side of the seminal glands, prostate and the fundus of the urinary bladder (Röthlisberger et al 2018): the point where the ductus deferens crosses the ureter provides an approximate guide to the superior limit of the plexus (Mauroy et al 2003). The proximal border of the plexus lies beneath the peritoneum of the rectovesical pouch and is in contact with the lateral aspect of the fundus of the urinary bladder. The anterior border reaches the posterior aspect of the prostate; at its inferior limit, the cavernous nerves of the penis pass forwards to reach the posterolateral aspect of the prostate (see Fig. 73.8). In females, each plexus lies lateral to the cervix of the uterus, vaginal fornix and the fundus of the urinary bladder, often extending into the broad ligament of the uterus: the proximal limit of the plexus corresponds approximately to the level where the uterine artery crosses the ureter (Azaïs et al 2013).

The inferior hypogastric plexus is formed mainly from pelvic splanchnic (parasympathetic) and sacral splanchnic (sympathetic) branches; a smaller contribution is derived from sympathetic fibres (from the inferior lumbar ganglia) that descend into the plexus from the superior hypogastric plexus via the hypogastric nerves. It gives origin to a complex network of small pelvic branches that supply the pelvic viscera either directly or indirectly via periarterial plexuses. The branches of the inferior hypogastric plexus supply the ductus deferens, seminal glands, prostate, bulbo-urethral glands and penis in males; the ovary, uterine tubes, uterus, cervix of the uterus and vagina in females; and the urinary bladder and distal ureter in both sexes. The plexus plays a key role in continence and sexual function.

Hypogastric nerves The hypogastric nerves are usually paired nerve bundles but can consist instead of multiple filaments. They contain sympathetic fibres (mostly descending from the superior hypogastric plexus) and parasympathetic fibres (ascending from the inferior hypogastric plexus). The nerves run between the superior and inferior hypogastric plexuses on each side posterior to the presacral fascia medial to the internal iliac vessels and lateral to the anterior sacral foramina.

Other autonomic plexuses and ganglia

Additional plexuses are described for abdominopelvic viscera, such as the hepatic and ovarian/testicular plexuses. Each plexus tends to lie around the main arterial supply to the named organ, receive both sympathetic and parasympathetic fibres from one or more of the major autonomic plexuses, and contain at least one ganglion. Thus, autonomic ganglia supplying the testis are found around the origin of the testicular arteries from the abdominal aorta and have connections with the renal and intermesenteric plexuses and the first and second lumbar splanchnic nerves (Motoc et al 2010).

Para-aortic bodies

The para-aortic bodies (also known as paraganglia or, collectively, as the organ of Zuckerkandl) are collections of neural crest-derived chromaffin tissue found in close relation to the abdominal aortic plexus. They are relatively large in the fetus, reach a maximum size at around 3 years of age, and have usually regressed by adulthood. They are most commonly found as a pair of bodies lying anterolateral to the abdominal aorta in the region of the inferior mesenteric and superior hypogastric plexuses, but multiple smaller collections may be present. Occasionally they are found as high as the coeliac plexus or as low as the inferior hypogastric plexus in the pelvis, or can be close to the ganglia of the lumbar part of the sympathetic trunk. Rarely, scattered

cells that persist into adulthood can be the sites of paraganglioma (Subramanian and Maker 2006).

GENERAL ARRANGEMENT OF ABDOMINOPELVIC VASCULAR SUPPLY

The major vessels that occupy the peritoneal cavity and pelvis not only supply the viscera, retroperitoneal structures and much of the bony and soft tissue walls, but also course through the cavities en route to supplying the lower limbs. From the caval foramen and aortic hiatus in the respiratory diaphragm, the inferior vena cava and abdominal aorta follow the general parabolic shape of the lumbar spine (**Figs 59.5–59.6**).The individual parts of the aortoiliac and iliocaval systems are described in the relevant chapters.

Arterial supply to the gastrointestinal tract

The arterial supply to the gastrointestinal tract is derived from the large unpaired branches of the aorta, e.g. coeliac trunk, superior and inferior mesenteric arteries. Major variants in the origin of these arteries are uncommon (Ch. 61). Accessory or replaced branches to the abdominal viscera are more common. The inferior mesenteric artery almost always arises separately but replaced, accessory or anastomotic vessels can arise from the proximal superior mesenteric artery or its branches (Tubbs et al 2016).

The coeliac trunk and its branches supply foregut derivatives that extend from the distal oesophagus to the mid part of the descending part of the duodenum, together with associated viscera (e.g. liver, spleen and pancreas). The superior mesenteric artery supplies derivatives of the midgut, which extends from the mid descending duodenum to the distal third of the transverse colon (including jejunum, ileum, caecum, appendix, and ascending and transverse colons). The inferior mesenteric artery supplies the derivatives of the hindgut that extend from the distal transverse colon to the proximal anal canal. Even in the absence of accessory arteries, there are numerous anastomoses among these vascular territories. For example, anastomoses around the head of the pancreas and the duodenum are formed between the anterior and posterior superior pancreaticoduodenal arteries and the anterior and posterior inferior pancreaticoduodenal arteries, and between the posterior superior pancreaticoduodenal artery and jejunal arteries (Ch. 68). Anastomoses between the territories of the superior and inferior mesenteric arteries are less numerous; the most consistent is the marginal artery (Ch. 65).

Hepatic portal venous system

All portal venous systems connect two capillary beds. The hepatic portal system connects the capillary bed of the abdominal and pelvic parts of the gastrointestinal tract, from the abdominal part of the oesophagus to the distal anal canal, together with all derived organs other than the liver (i.e. the pancreas, gallbladder and spleen) and the hepatic sinusoidal 'capillary' bed (**Fig. 59.7**). The intrahepatic hepatic portal vein ramifies and ends in the hepatic sinusoids: blood drains from the sinusoids into central veins that converge to form the hepatic veins which drain into the inferior vena cava (Ch. 66). In fetal and early postnatal life, valves are demonstrable in tributaries of the hepatic

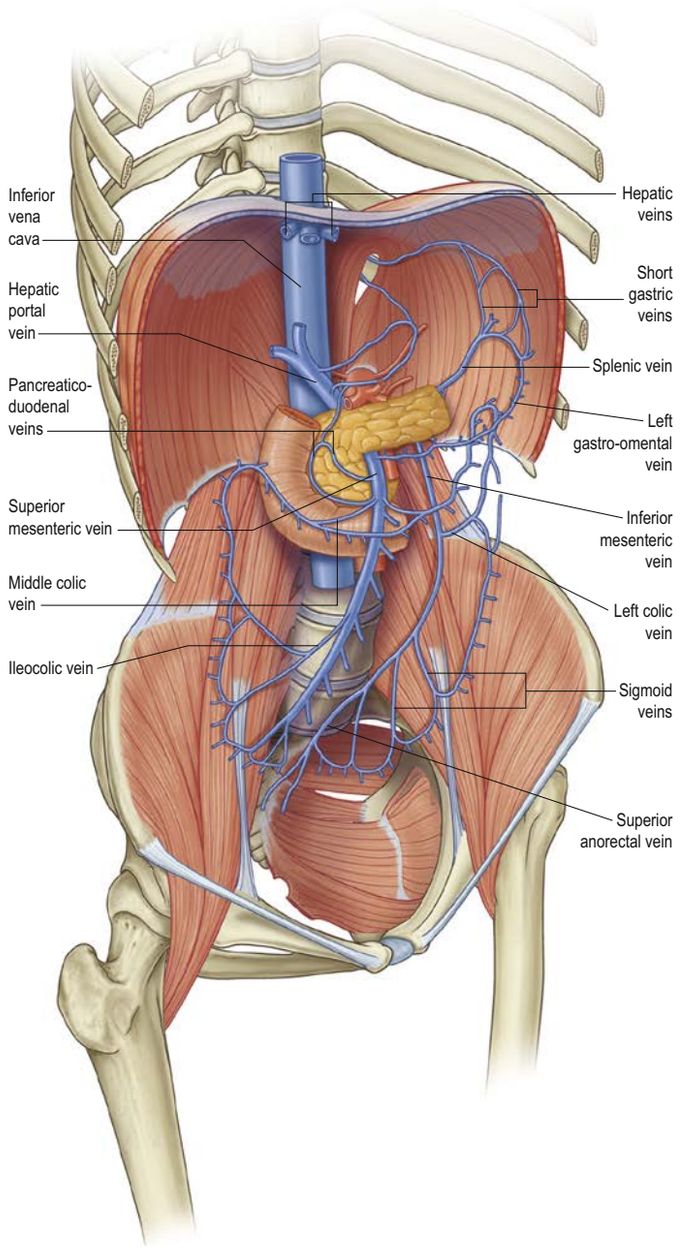

Fig. 59.7 The overall arrangement of the hepatic portal venous system draining various abdominal viscera.

portal vein but they usually atrophy with further maturation. There are no valves in the hepatic portal vein in adults.

Hepatic portal vein

The hepatic portal vein is formed from the convergence of the superior mesenteric and splenic veins posterior to the neck of the pancreas at the level of the first lumbar intervertebral disc (in the transpyloric plane) (see Fig. 59.7). It is approximately 8 cm long in the adult and ascends obliquely to the right posterior to the first part of the duodenum, the bile duct and gastroduodenal artery; at this point, it is directly anterior to the inferior vena cava. It enters the right border of the lesser omentum (i.e. hepatoduodenal ligament) and ascends anterior to the omental foramen to reach the right end of the porta hepatis, where it divides into right and left main branches, which accompany the corresponding branches of the hepatic artery into the liver. In the lesser omentum, the hepatic portal vein lies posterior to both the bile duct and the hepatic artery. It is surrounded by the hepatic plexus and accompanied by lymphatics and some lymph nodes.

Tributaries of the hepatic portal vein

The main extrahepatic tributaries of the hepatic portal vein are the left gastric vein and the posterior superior pancreaticoduodenal vein (Ch. 66). Within the liver, the left branch receives the remnant of the umbilical vein via the round ligament of the liver. Collateral pathways between the hepatic portal vein and the systemic venous system can become engorged (varices) as a result of portal hypertension which is most commonly due to cirrhosis of the liver (Pillai et al 2015).

GENERAL MICROSTRUCTURE OF THE WALL OF THE GASTROINTESTINAL TRACT

The wall of the gastrointestinal tract displays a common structural plan that is modified regionally to take account of local functional differences. The general microstructure is best appreciated by reference to the development of the gut (Ch. 21). Much of the alimentary canal originates as a tube of endoderm enclosed in splanchnopleuric mesoderm. Its external surface faces the embryonic coelom, and the endodermal lining forms the epithelium of the canal and also the secretory and ductal cells of various glands that secrete into the lumen, including the pancreas and liver. The splanchnopleuric mesoderm forms the connective tissue, muscle layers, blood vessels and lymphatics of the wall, and its external surface becomes the visceral mesothelium or serosa. There is no serosa surrounding the cervical and thoracic portions of the oesophagus, or below the point where the derivatives of the hindgut traverse the pelvic diaphragm; in these sites the digestive tract is surrounded by connective tissue adventitia. Neural elements invade the gut from neural crest tissue (Ch. 14). The smooth muscle of the muscularis externa layers of the digestive tract is supplemented with striated muscle at its beginning (from the pharyngeal arches) and end.

The mature wall of hollow abdominal viscera has four main layers: mucosa, submucosa, muscularis externa and serosa (Fig. 59.8). The mucosa (mucous membrane) is the innermost layer and is subdivided into a lining epithelium, an underlying lamina propria (a layer of loose connective tissue, where simple glands may also be found) and a thin layer of smooth muscle, the muscularis mucosae. The submucosa is a strong and highly vascularized layer of connective tissue, which, in some regions, contains glands with ducts to the luminal surface. The muscularis externa consists of inner circular and outer longitudinal layers of smooth muscle; an incomplete oblique muscle layer is present only in the stomach. The external surface is bounded by serosa or adventitia, depending on its position within the body.

Mucosa

Epithelium

The epithelium is the site of secretion and absorption and provides a defence against various threats, including microorganisms. Its protective function against mechanical, thermal and chemical injury is particularly evident in the oesophagus and anal canal, where it is thick, stratified and covered in mucus, which serves as a protective lubricant. At other sites the epithelium lining the gastrointestinal tract is single-layered, and either cuboidal (in glands) or columnar. It contains cells modified for absorption as well as various types of secretory cell.

The barrier function and selectivity of absorption depend on tight junctions over the entire epithelium. The surface area of the lumen available for secretion or absorption is increased by mucosal folds, crypts, villi and glands (see Fig. 59.8). Microvilli on the surfaces of individual absorptive cells amplify the area of apical plasma membrane in contact with the contents of the gastrointestinal tract. Some glands lie in the lamina propria and some in the submucosa; others (the liver and pancreas) are totally external to the wall of the gut. All of these glands drain into the lumen of the gastrointestinal tract. The epithelium also contains scattered neuroendocrine (enteroendocrine) cells.

Lamina propria

The lamina propria consists of compact connective tissue, often rich in elastin fibres, which supports the surface epithelium and contains

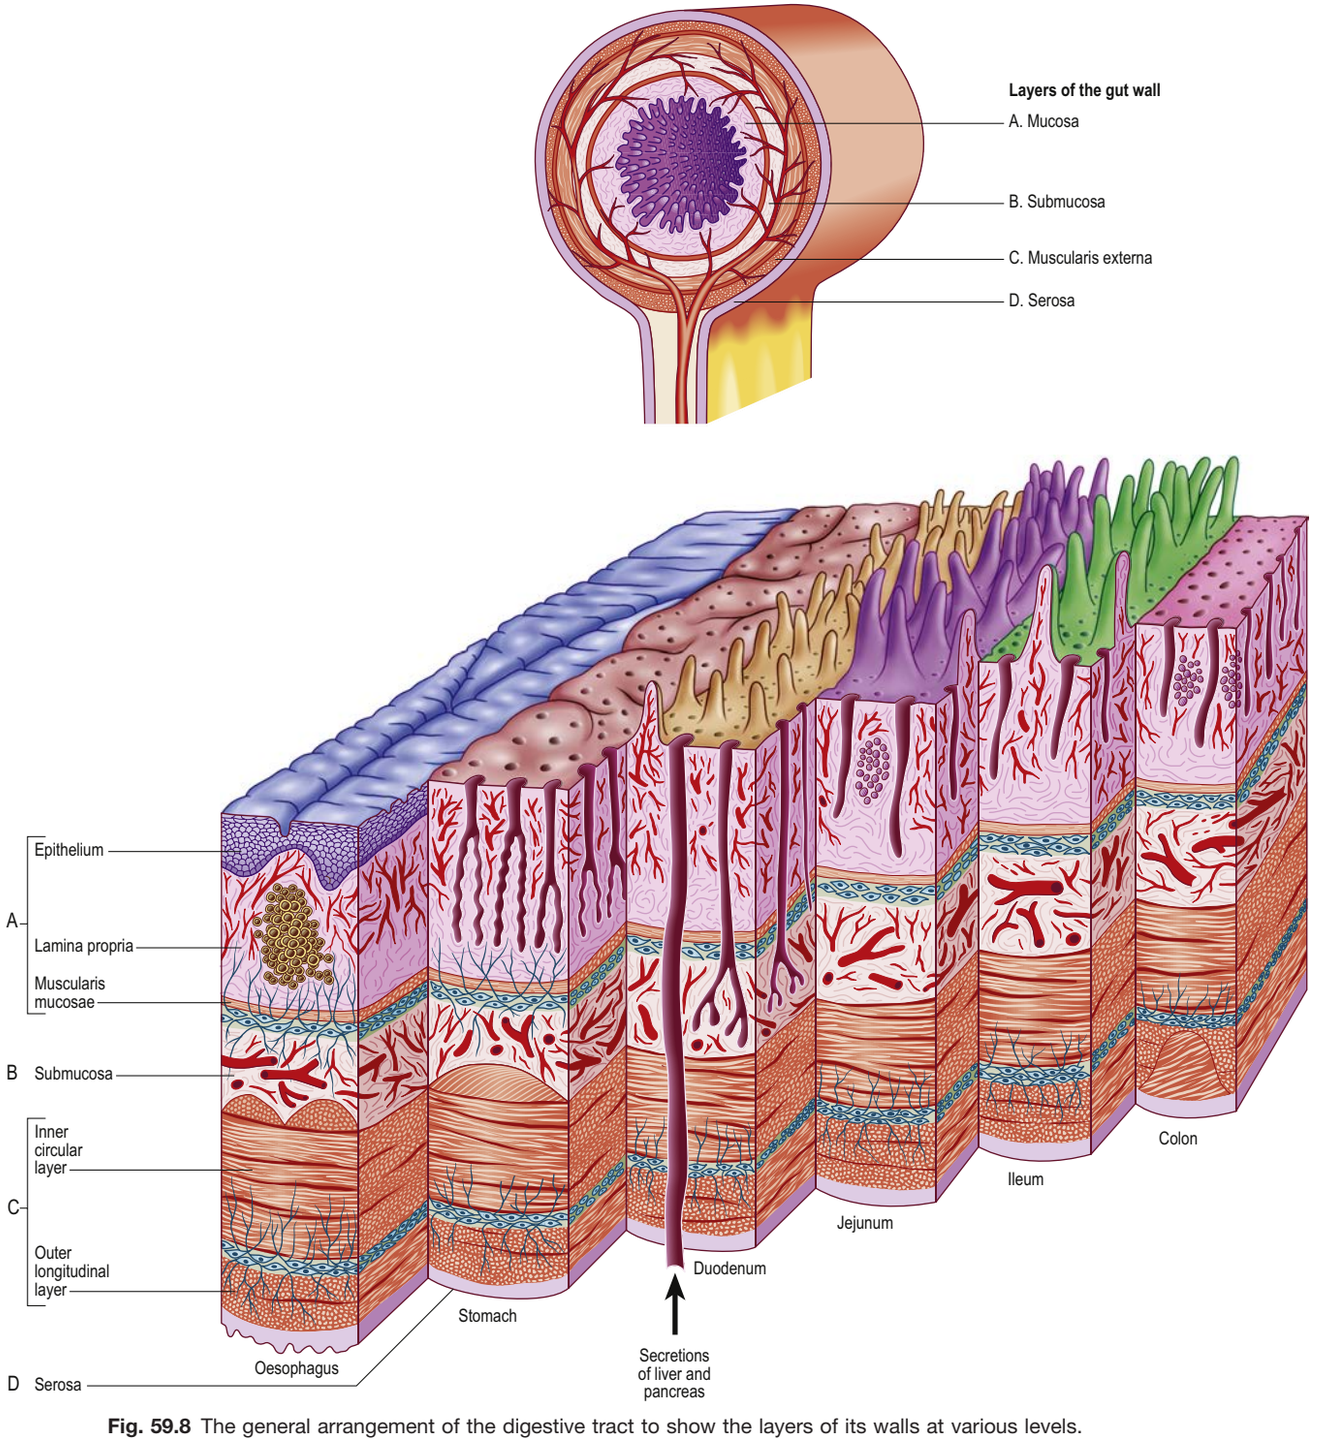

Fig. 59.8 The general arrangement of the digestive tract to show the layers of its walls at various levels.

nutrient vessels and lymphatics. Lymphoid follicles are present in many regions of the gastrointestinal tract, most notably in aggregated lymphoid nodules, particularly in the distal small intestine, e.g. Peyer's patches. Cells within the lamina propria are the source of growth factors that regulate cell turnover, differentiation and repair in the overlying epithelium.

Muscularis mucosae

The muscularis mucosae is particularly well developed in the oesophagus and the large intestine, especially in the terminal part of the rectum. In addition, single muscle cells originating from the muscularis mucosae are found inside the villi or between the tubular glands of the stomach and large intestine. By its contraction, the muscularis mucosae can alter the surface configuration of the mucosa locally, allowing it to adapt to the shapes and mechanical forces imposed by the contents of the lumen, and in the intestinal villi, promoting vascular exchange and lymphatic drainage.

Submucosa

The submucosa contains large bundles of collagen and is the strongest layer of the wall of the gastrointestinal tract. However, it is also pliable and deformable, and can therefore adjust to changes in the length and diameter of the wall of the hollow viscus. Its contained arterial network is relatively dense and supplies both the mucosa and the muscle coat. The submucosa extends into the rugae of the gastric wall, the plicae circulares (valves of Kerckring) of the small intestine (but not the villi), and the folds that project into the lumen of the colon and rectum.

Muscularis externa

The muscularis externa usually consists of distinct inner circular and outer longitudinal layers that create waves of peristalsis responsible for the movement of ingested material through the lumen of the hollow viscus. In the stomach, where movements are more complex, there is an incomplete oblique layer of muscle, internal to the other two layers. The circular muscle layer is thicker than the longitudinal muscle except in the colon, where the longitudinal muscle is condensed into three bands (taeniae coli).

The muscularis externa is composed almost exclusively of smooth muscle, except in the proximal oesophagus, where smooth muscle blends with striated muscle. Although the proximal oesophageal musculature resembles that of the pharynx, it is entirely under involuntary control. For most of its length, the smooth muscle of the wall of the gastrointestinal tract consists of ill-defined bundles of cells, typically visceral in type and somewhat larger than vascular smooth muscle cells. They are approximately 500 μm long, regardless of body size, and are electrically and mechanically coupled. Their fasciculi lack a perimysium but have sharp boundaries.

The arrangement of the musculature allows a segment of the gastrointestinal tract to undergo extensive changes in diameter (to virtual occlusion of the lumen) and length, although elongation is limited by the mesenteries. The coordinated activity of the two muscle layers produces a characteristic motor behaviour that is mainly propulsive and directed aborally (peristalsis), combined with a non-propulsive motor activity that either mixes the luminal contents, as occurs in the stomach, or partitions them, as occurs at the pyloric sphincter. The muscle maintains a constant volume, so that shortening of a segment of the wall of the hollow viscus is accompanied by thickening of the muscle layer.

Intestinal smooth muscle exhibits variable and changing degrees of contraction on which rhythmic (or phasic) contractions are superimposed. Slow waves of rhythmic electrical activity, driven by changes in membrane potentials in pacemaker cells (interstitial cells), spread throughout the thickness of the circular and longitudinal smooth muscle coats. After spreading circumferentially, slow waves can move in either oral or anal directions, causing segmental contraction. The distances of propagation and the patterns of this spontaneous activity differ among areas of the intestine. Neural regulation of slow and phasic contractions involves excitatory and inhibitory transmitters that are released from the myenteric plexus. This motor control is closely coordinated with mucosal absorption and secretion, and is mediated via intrinsic nerves in the submucous plexus. The peristaltic reflex occurs during passage of luminal contents down the intestine. It involves ascending contraction and descending relaxation; the sensory limb is mediated by sensory neurones that respond to either mucosal stimulation (intrinsic primary afferents) or muscle stretch (extrinsic afferents).

Interstitial cells

Interstitial cells of Cajal (ICCs) are found throughout the length of the gastrointestinal tract, where they lie in close contact with nerve terminals; they have numerous gap junctions with each other and with smooth muscle cells. Distinct networks are found in the myenteric plexus between the circular and longitudinal muscles. Looser arrangements exist within the individual muscle layers and the submucosa of the wall of the hollow viscera, and isolated or small groups of ICCs are also found in the subserosal region. ICCs originate from mesenchymal cells and resemble smooth muscle cells but have fewer contractile elements and their intermediate filaments contain vimentin rather than desmin. They are involved in generating pacemaker signals, propagating electrical slow wave activity, neuromuscular transmission, and mechanosensation (Sanders et al 2014). Defective ICC function has been implicated in a wide range of gastrointestinal motility disorders (Al-Shboul 2013) and in the development of gastrointestinal stromal tumours (Roggin and Posner 2012).

Cells with a similar morphology have been found in association with smooth muscle at many other sites such as the urethra, ductus deferens, prostate, urinary bladder, corpus cavernosum, ureter, uterine tube and uterus. They may act as electrical pacemakers in the urethra and ureter but their role at other sites is less certain (Drumm et al 2014).

Serosa and adventitia

A layer of connective tissue of variable thickness lies external to the muscularis externa. In many places it contains adipose tissue. Where the hollow viscera are covered by visceral peritoneum the external layer is a serosa, consisting of mesothelium overlying a thin layer of connective tissue. In extraperitoneal regions the surfaces of the gastrointestinal tract in contact with the peritoneum are covered by serosa, while other parts are covered by connective tissue that blends with the surrounding fasciae and is referred to as an adventitia.

Vascular plexuses

Vascular plexuses are present at various levels of the wall, especially in the submucosa and mucosa; they connect with vessels that supply the surrounding tissues or those entering through the mesentery, and accompany the ducts of outlying glands.

Innervation

The wall of the hollow viscera is densely innervated by both the enteric nervous system (intrinsic control) and the autonomic nervous system (extrinsic control). The latter is not essential for function, as evidenced by intestinal activity after transplantation of the extrinsically denervated part of the gastrointestinal tract. In contrast, neuropathies affecting the enteric nervous system, such as Hirschsprung's disease, are potentially life-threatening. For a detailed description of the enteric nervous system, see Furness et al (2014).

Extrinsic innervation

Extrinsic innervation of the gastrointestinal tract is from sympathetic, parasympathetic and visceral sensory nerves. The cell bodies of preganglionic parasympathetic axons are found in the dorsal nucleus of the vagus nerve in the medulla oblongata and in the second to fourth sacral segments of the spinal cord. Their main targets in the wall of the hollow viscera are the enteric neurones of the myenteric plexus. The vagus nerve plays a major role in oesophageal propulsion, gastric acid secretion and emptying of the stomach, gallbladder contraction and pancreatic exocrine secretion. Pelvic splanchnic nerves innervate the distal colon and rectum. Sympathetic neurones have their preganglionic cell bodies in the intermediolateral grey matter (lamina VII) of the thoracolumbar segments of the spinal cord; those destined for the smooth muscle of the wall of the hollow viscera mostly pass through the sympathetic trunk without synapsing and relay in prevertebral ganglia (coeliac, mesenteric and pelvic), whereas those mediating vasoconstriction synapse in the sympathetic trunk or prevertebral ganglia. Postganglionic sympathetic fibres are distributed with the branches of the coeliac trunk and mesenteric arteries to three principal targets: the myenteric and submucosal ganglia (causing inhibition), blood vessels (inducing vasoconstriction) and sphincter muscles (inducing contraction).

Visceral sensory fibres are distributed throughout the layers of the walls of the hollow viscera. They respond to various stimuli including excessive muscular contraction or distension, ischaemia and inflammation; their cell bodies are located in the inferior ganglion of the vagus nerve and in thoracic and lumbosacral spinal ganglia (visceral afferent

fibres that run with sympathetic efferent fibres). Their central projections reach the brain stem and spinal cord, respectively. Sensory fibres in the vagus nerve are more numerous in the derivatives of the foregut than those of the derivatives of the midgut and are concerned with physiological responses such as satiety, whereas pain and discomfort are mediated by spinal pathways.

Intrinsic innervation

The intrinsic innervation of the gastrointestinal tract is derived from enteric neurones distributed throughout its wall in thousands of small ganglia, each consisting of neuronal cell bodies supported by enteric glial cells; it is estimated that there are between 200 and 600 million neurones in the human enteric nervous system. Enteric neurones are derived from neural crest cells and innervate the hollow viscera from oesophagus to anus, together with the pancreas and bile ducts.

Most of the enteric neurones in the wall of the gastrointestinal tract are found in two ganglionated plexuses (**Fig. 59.9**). The most extensive of these is the myenteric (Auerbach's) plexus, which consists of a network of nerve fibres and small ganglia lying between the circular and longitudinal layers of the muscularis externa. It runs in continuity from the oesophagus to the anus. The submucosal (Meissner's) plexus has outer and inner components and is present throughout the intestines but is absent or minimal in the oesophagus and stomach (Nagy and Goldstein 2017).

Interconnecting, non-ganglionated nerve plexuses lie at various levels in the wall of the gastrointestinal tract, including the lamina propria (mucosal plexus); at the interface between the submucosa and muscularis externa; between the circular and longitudinal muscles (the non-ganglionated part of the myenteric plexus); and within the serosa.

Individual enteric neurones function in one of several ways: as afferent (sensory) nerves responding to mechanical and chemical stimuli; as efferent (motor) nerves innervating epithelial cells (influencing absorption, secretion and/or the release of hormones), smooth muscle (excitatory or inhibitory), arterioles (vasoconstriction or vasodilatation) and lymphoid tissue; or as interneurones that relay and integrate signals. Collectively, they are involved in a hierarchy of enteric reflexes that include local reflexes within the wall of the hollow viscera; reflexes mediated through prevertebral ganglia; and reflexes mediated through the central nervous system (the gut–brain axis). The functions of enteric neurones can be further modulated by local environmental factors, e.g. enteric glia, gut microbiota and feeding state, and by general factors in the host, e.g. the immune system, stress and disease (Brierley and Linden 2014). Pathological states become manifest by abnormal secretion, impaired absorption, disordered gastrointestinal motility and pain.

SURFACE ANATOMY OF THE ABDOMEN AND PELVIS

Abdominal planes and regions

For descriptive purposes, the abdomen can be divided into regions using a combination of horizontal and vertical planes that are based on skeletal landmarks. Cross-sectional imaging-based studies in adults have enabled traditional descriptions of abdominal surface anatomy to be validated or updated. The extent to which these surface projections can be extrapolated to neonates, infants and children is uncertain; some differences are inevitable given their different visceral and body proportions (Stringer and Mirjalili 2017). In this chapter, descriptions of the surface projections and vertebral level correlations with the positions of abdominal structures refer to the arrangement most commonly seen in adults. However, it is important to note that there is considerable inter-individual variation in surface anatomy, compounded by potential variations related to age, sex, posture, respiration, body shape and body mass (Mirjalili and Stringer 2012).

Vertical lines and planes

The midline (or median plane) passes through the xiphoid process and the pubic symphysis. There are two paramedian lines, left and right, passing from the midclavicular point to a point midway between the anterior superior iliac spine and the pubic symphysis (**Fig. 59.10A**). In the upper abdomen, this line approximates to the lateral border of rectus abdominis.

Horizontal lines and planes

Several horizontal reference planes have been defined but, with modern cross-sectional imaging, their clinical utility for positioning abdominal viscera has become limited. Nevertheless, they provide a guide as to the approximate relative positions of abdominal viscera with respect to vertebral levels and bony surface landmarks.

The xiphisternal joint most often lies in the same horizontal (axial) plane as the vertebral body of T9 (Mirjalili et al 2012b).

The transpyloric plane lies midway between the jugular (suprasternal) notch of the manubrium and the superior border of the pubic symphysis. This corresponds to a plane approximately midway between the xiphisternal joint and the umbilicus, or slightly below. In most individuals the plane intersects either the inferior half of the vertebral body of L1, the L1–L2 intervertebral disc, or the superior half of the vertebral body of L2 (range, inferior half of the vertebral body of T12 to inferior half of the vertebral body of L2); it sits more superiorly in males (range, inferior half of the vertebral body of L1 to L1–L2 intervertebral disc) than in

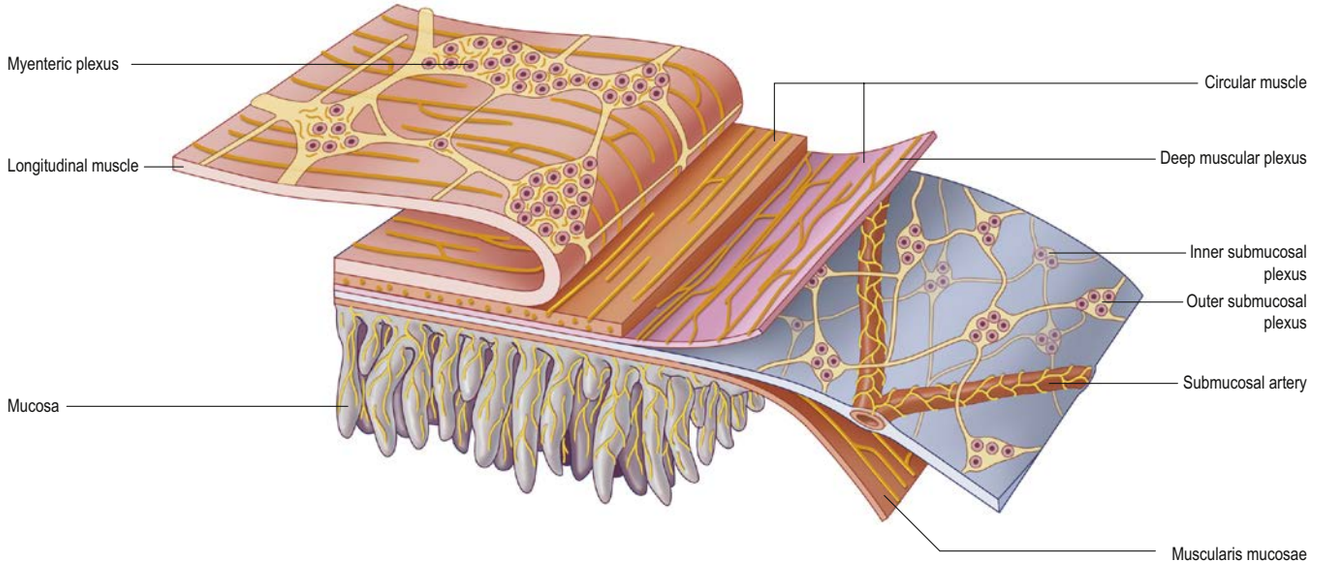

Fig. 59.9 The organization of the enteric nervous system in the small intestine. There are two ganglionated plexuses: the myenteric plexus between the longitudinal and circular layers of the external musculature, and the submucosal plexus (SMP), which has outer and inner components. Nerve fibre bundles connect the ganglia and form plexuses innervating the longitudinal muscle, circular muscle, muscularis mucosae, intrinsic arteries and mucosa. Axons of extrinsic origin also run in these nerve fibre bundles. There are also innervations of gastroenteropancreatic (GEP) endocrine cells and gut-associated lymphoid tissue (GALT), which are not shown here. (Redrawn from Furness JB. The enteric nervous system and neurogastroenterology. Nat Rev Gastroenterol Hepatol 2012;9:286–294. Reprinted with permission from Nature Publishing Group.)

Key: 1, right hypochondriac region; 2, epigastric region; 3, left hypochondriac region; 4, right lateral region; 5, umbilical region; 6, left lateral region; 7, right inguinal region; 8, hypogastric region; 9, left inguinal region; 10, paramedian (midclavicular to midinguinal) line; 11, subcostal plane; 12, intertubercular plane. **B**, Anterior abdominal wall landmarks. Key: 1, xiphoid process; 2, costal margin (arch); 3, tip of the ninth costal cartilage; 4, tendinous intersections of rectus abdominis; 5, umbilicus; 6, iliac crest; 7, anterior superior iliac spine; 8, linea semilunaris; 9, linea alba; 10, inguinal ligament; 11, pubic tubercle; 12, pubic crest; 13, pubic symphysis. **C**, The surface projection of the abdominal viscera. Key: 1, respiratory diaphragm position (black dashed line): superior-most aspect on the right level with fifth intercostal space and superior most aspect of left level with the sixth rib; 2, liver: mapped between three points: right sixth rib/intercostal space midclavicular line, left fifth intercostal space/sixth rib midclavicular line and right tenth costal cartilage midaxillary line; 3, zone of gastro-oesophageal junction position (white): mainly located (black X) posterior to left seventh costal cartilage, level with the vertebral body of T11; 4, transpyloric plane; 5, region of fundus of gallbladder position (white), usually on or below the transpyloric plane; 6, duodenum: four parts marked D1–D4; 7, semilunar line; 8, position of mesentery of the small intestine; 9, linea alba; 10, tendinous intersection of rectus abdominis; X, (green) duodenojejunal flexure at L1, arrows show range of locations (inferior half of the vertebral body of T11 to superior half of the vertebral body of L3). **D**, The surface position of the spleen and kidneys. Key: 1, spleen: sits deep to tenth to twelfth ribs with its long axis aligned with the eleventh rib (yellow arrows show range of locations); 2, kidney (black lines shown range of positions of the superior and inferior poles, and the common position of the hilum); 3, supracristal plane. (D, Derived with permission from Mirjalili SA, McFadden SL, Buckenham T et al 2012b A reappraisal of adult abdominal surface anatomy. Clin Anat 25:844–50.)

females (inferior half of the vertebral body of L2) (Mirjalili et al 2012a, Uzun et al 2016). Anteriorly, it intersects the costal margin (arch) at the ninth costal cartilage, where the semilunar line crosses, and where a distinct 'step' may be palpable. The following structures lie approximately within the transpyloric plane (Mirjalili et al 2012a, 2012b): the origin of the superior mesenteric artery; the origin of the hepatic portal vein (from the confluence of the superior mesenteric and splenic veins posterior to the neck of the pancreas); the hilum of the left kidney (the hilum of the right kidney may be slightly more inferior); the origin of the renal arteries; the level of the duodenojejunal flexure; and the termination (conus medullaris) of the spinal cord (Nasr 2017). The pylorus may be found in the transpyloric plane but is not a constant feature.

The subcostal plane is defined by a line that joins the lowest point of the costal arch on each side (usually, the tenth costal cartilage); it

most commonly intersects the vertebral body of L2 (range, T12–L1 intervertebral disc to superior half of the vertebral body of L3) (Mirjalili et al 2012a, Uzun et al 2016).

The supracristal plane (Tuffier's line) joins the most superior point of the iliac crest on each side. It serves as a useful landmark for the aortic bifurcation and when a lumbar puncture or spinal injection is performed, and usually lies at the level of the vertebral body or the spinous process of L4 or the L4–L5 intervertebral disc (Fig. 76.19) (Mirjalili et al 2012a, Pak et al 2016, Shen et al 2016, Uzun et al 2016).

The intertubercular plane joins the iliac tubercles and commonly lies at the level of the vertebral body of L5, near its proximal border. It is an approximate landmark for the origin of the inferior vena cava from the confluence of the left and right common iliac veins.

The plane of the pubic crest is in line with the superior border of the pubic symphysis. In supine individuals, this plane frequently intersects the head of the femur and the most inferior part of the coccyx (Mirjalili et al 2012a, Uzun et al 2016), but there are variations relating to the degree of lumbar lordosis, sacral inclination and pelvic tilt.

Abdominal regions

The abdomen can be divided into nine regions using the subcostal and intertubercular planes, and left and right midclavicular lines. Alternatively, the midclavicular line may be substituted for the paramedian plane, as defined previously (see Fig 59.10A). The nine regions are used in clinical practice for descriptive localization of a patient's pain or tenderness, or the position of a mass, and can be used to reference the position of abdominal viscera. From superior to inferior, the nine regions are: the epigastric region, flanked by the right and left hypochondriac regions; the umbilical region, flanked by the right and left lateral (flank) regions; and the hypogastric region, flanked by the right and left inguinal regions. In practice, these regions are often loosely defined without strict reference to their boundaries. An alternative system of description involves dividing the abdomen into quadrants using the median plane and a horizontal line passing through the umbilicus.

Anterior abdominal wall

Skeletal landmarks

The superior boundary of the anterior abdominal wall is formed by several clear landmarks (**Fig. 59.10B–C**). The xiphoid process is palpable inferior to the body of the sternum, in the midline. From here, the left and right costal arches can be felt passing inferolaterally from the seventh costal cartilage at the xiphisternal joint to the tenth costal cartilage. The distal border of the ninth costal cartilage can usually be defined as a distinct 'step' along the costal arch. The inferior part of the costal arch lies in the midaxillary line and is formed by the inferior margin of the tenth costal cartilage. Further palpation may reveal the distal ends of the eleventh and twelfth ribs, although these may be difficult to feel in the obese or if the ribs are short.

The inferior boundary of the anterior abdominal wall is formed, from lateral to medial, by the iliac crest, which descends to the anterior superior iliac spine; the inguinal ligament, which runs inferomedially to the pubic tubercle; and the pubic crest, which extends from the pubic tubercle laterally to the pubic symphysis in the midline. The pubic tubercle is palpable on the anterosuperior surface of the pubic bone approximately 2 cm lateral to the midline. The prominent tendon of adductor longus (best felt with the hip flexed, abducted and laterally rotated) attaches to the body of the pubis directly below the pubic tubercle, and can therefore be used to verify the position of the pubic tubercle.

The posterolateral boundary of the anterior abdominal wall is the midaxillary line.

Soft tissue landmarks

Umbilicus

The umbilicus is an obvious landmark with a relatively inconstant position. In the supine adult, it usually lies level with the vertebral body of L4 (range, L2–L3 intervertebral disc to superior half of the vertebral body of S1) (Mirjalili et al 2012b, Shen et al 2016). The umbilicus can lie at a more inferior level in children and the obese, and in adults in the erect position or with a distended anterior abdominal wall.

Rectus abdominis

In a thin, muscular individual, the tendinous intersections of rectus abdominis may be visible, especially when the muscle is tensed by lifting the head against resistance or by sitting up; the tendinous intersections are usually situated at the level of the umbilicus, the level of the xiphoid process and midway between these two points (see Fig. 59.10B–C).

Linea alba

The linea alba is usually visible only in thin, muscular individuals in the median plane. It is wider and more obvious above the umbilicus, and is less visible below this level (Ch. 60) (see Figs 59.10B–C, Fig. 60.2).

Semilunar line

The semilunar (Spigelian) line lies along the lateral margin of the rectus sheath and is visible as a shallow, curved groove in muscular individuals, particularly when the abdominal muscles are tensed, e.g. by sitting up from the lying position (Fig. 59.10B–C). It passes from the ninth costal cartilage to the pubic tubercle.

Midinguinal point

The midinguinal point is at the midpoint of a line between the pubic symphysis and the anterior superior iliac spine. In adults, it is the approximate surface marking of the femoral artery (located just inferior to the inguinal ligament) and the deep inguinal ring (located just superior to the inguinal ligament) (Hale et al 2010).

Inferior epigastric artery

The inferior epigastric artery lies along the medial border of the deep inguinal ring immediately above the inguinal ligament. Up to the level of the umbilicus, it follows a course that lies approximately 40% of the distance between the midline and a sagittal plane running through the anterior superior iliac spine (Epstein et al 2004). The surface anatomy of the artery is particularly important in laparoscopic surgery because trocar insertion may injure the vessel, causing a rectus sheath haematoma or intra-abdominal bleeding. The artery can be avoided if a trocar is inserted at least two-thirds of the distance along a horizontal line between the midline and a sagittal plane passing through the anterior superior iliac spine.

Superficial reflexes

Cremasteric reflex

Stroking the skin of the medial side of the thigh evokes a reflex contraction of cremaster, which elevates the ipsilateral testis. The reflex is mediated by the genitofemoral nerve (L1 and L2 ventral rami), although the afferent arc of the reflex may be via sensory fibres in the ilio-inguinal nerve. The reflex is usually absent if there is torsion of a testis.

Superficial abdominal reflex

Gently stroking each of the four quadrants of the anterior abdominal wall normally elicits a visible contraction of the ipsilateral abdominal wall muscles. Historically the reflex was used to help localize lesions in the spinal cord such as syringomyelia but is now of limited clinical significance because of the availability of neuroimaging and the difficulties of eliciting the reflex in multiparous women, the elderly and the obese (Fujimori et al 2010, Gosavi and Lo 2014).

Intra-abdominal viscera and respiratory diaphragm

The surface markings of the intra-abdominal viscera are variable and depend on age, sex, body habitus, nutritional state, phase of ventilation, body position and pathology. The availability of cross-sectional and ultrasound medical imaging of the abdominal viscera has reduced the need to rely on surface anatomy alone in clinical practice. Nevertheless, a sound knowledge of surface anatomy helps guide proficient physical and ultrasound-based examinations, invasive procedures such as lumbar puncture, and surgical approaches. The following descriptions should be regarded as the most common approximate markings in a healthy supine adult (Fig. 59.10C). The spinous processes of the lumbar vertebrae can be used to locate vertebral levels, the inferior part of the spinous process normally marking the level of the inferior part of the correspondingly numbered vertebral body or the intervertebral disc below.

Respiratory diaphragm

In the supine position at end-tidal inspiration the most superior part of the respiratory diaphragm is most frequently located level with the fifth intercostal space in the midclavicular line on the right and the sixth rib in the midclavicular line on the left, and ranges from the fourth intercostal space to below the costal arch (Mirjalili et al 2012c, Shen et al 2016) (Fig. 59.10C) (see Ch. 55 for further discussion of the respiratory diaphragm). These levels are approximate, not only because of

individual variation but also because respiratory diaphragmatic excursion in the erect position during quiet breathing is about 1–2 cm and increases to about 5–7 cm during deep breathing (Jung et al 2014, Boussuges et al 2009). The highest part of the respiratory diaphragm may reach as high as the fourth rib on maximal expiration.

Stomach

The gastro-oesophageal junction lies to the left of the midline, posterior to the left seventh costal cartilage, at the level of the vertebral body of T11 (range, superior half of the vertebral body of T10 to L1–L2 intervertebral disc), the level being more inferior in females and more superior in the obese (Mirjalili et al 2012b) (see Fig. 59.10C). The stomach lies in a curve normally within the left hypochondriac and epigastric regions, although it may lie as distally as the umbilical or hypogastric regions when distended. The epigastric region is the usual place to auscultate for a 'succussion splash' caused by gastric outlet obstruction or stasis, and is also the region in infants where a thickened pylorus, e.g. hypertrophic pyloric stenosis, is palpable.

Duodenum

The superior (first) part of the duodenum sits in, and sometimes ascends above, the transpyloric plane (vertebral body of L1); the descending (second) part usually lies just to the right of the midline, alongside the vertebral bodies of L2 and L3; the horizontal (third) part usually crosses the midline at the level of the vertebral body of L3; and the ascending (fourth) part ascends to the left of the vertebral body of L2, reaching the transpyloric plane in the region of the inferior half of the vertebral body of L1 (see Fig. 59.10C). The duodenojejunal flexure commonly sits level with the vertebral body of L1 (range, lower half of the vertebral body of T11 to superior half of the vertebral body of L3) (Mirjalili et al 2012b). In children from 0 to 11 years of age the duodenojejunal flexure is also commonly located level with the vertebral body of L1 (range, level with the vertebral bodies of T11 to L3) (Koch et al 2016), which is of clinical importance when assessing for duodenal or gut tube malrotation.

Small intestine and its mesentery

The attachment of the mesentery of the small intestine to the posterior abdominal wall passes obliquely inferiorly to the right, from a point just to the left of the vertebral body of L1 (the transpyloric plane) in men and the vertebral body of L2 (the subcostal plane) in women, towards the right iliac fossa.

Appendix

The appendix is located in the right lower quadrant of the abdomen but is highly variable in its length and position. Studies analysing barium enemas in supine adults have shown the position of the proximal appendix to be variably located and rarely precisely at McBurney's point (a point two-thirds of the way along a line drawn to join the anterior superior iliac spine to the umbilicus) (Naraynsingh et al 2002).

Liver

At the end of normal tidal inspiration, the inferior border of the liver extends along a line that passes from the right tenth costal cartilage in the midaxillary line to the left fifth intercostal space/sixth rib in the midclavicular line (see Fig. 59.10C). It may be palpable inferior to the costal arch in healthy adults on deep inspiration, especially near the median plane. The superior border of the liver follows a line that passes from the right fifth rib or intercostal space in the midclavicular line to the left fifth intercostal space or sixth rib in the midclavicular line, and can be mapped with the curved contour of the respiratory diaphragm (Mirjalili et al 2012c). This border curves slightly downwards at its centre and crosses the midline posterior to the xiphisternal joint. The right border of the liver is curved to the right and joins the superior and inferior right limits. The superior border of the liver can be defined by dullness to percussion when compared with the resonance of the lungs above.

Gallbladder

The fundus of the gallbladder is commonly identified in the transpyloric plane near the junction of the semilunar line with the costal arch (see Fig. 59.10C). Recent data have shown that the fundus of the gallbladder lies in the transpyloric plane in approximately one-third of supine individuals and below that plane in most others (Mirjalili et al 2012b, Uzun et al 2016).

Spleen

The spleen is traditionally described as sitting on the left posterolateral abdominal wall deep to the ninth to eleventh ribs. Recent data from supine individuals show that the spleen sits deep to the tenth to the twelfth ribs in 50% of subjects and deep to the ninth to eleventh ribs in 25%, with its long axis aligning most closely with either the eleventh or tenth rib, respectively (Mirjalili et al 2012b, Shen et al 2016, Pak et al 2016). It passes anterior to the midaxillary line in most subjects (**Fig. 59.10D**). The spleen extends from a point about 5 cm to the left of the midline at the level of the spinous process of T11 and extends about 3 cm anterior to the midaxillary line. In children the spleen is often in a more superior location, with its long axis aligning with the ninth or tenth rib (Subramaniam et al 2016).

Retroperitoneal viscera

The surface projections of the retroperitoneal viscera are reasonably reliable and may be used to guide clinical examination or identification of structures on radiological images.

Pancreas

The surface projection of the head of the pancreas lies within the concavity of the duodenum on the right side of the vertebral body of L2; the neck lies in the transpyloric plane, level with the L1-L2 intervertebral disc; the body passes obliquely superolaterally to the left towards the spleen; and the tail lies slightly above the transpyloric plane.

Kidney

On average, the right kidney lies 2 cm lower than the left, although the left kidney can sit lower than the right in about 10% of cases (Mirjalili et al 2012b). The vertebral limits of the left kidney are between the vertebral bodies of T12 and L3 or L4, while those for the right kidney are between the vertebral bodies of L1 and L4 (range, superior half of the vertebral body of T11 to inferior half of the vertebral body of L5) (see Fig. 59.10D). The superior poles of both kidneys lie anterior to the twelfth rib, and may also lie anterior to the eleventh rib in 30% (left) and 10% (right) of subjects. In adults in the supine position at end-tidal inspiration, the centres of the hila of the kidneys most commonly lie level with the L1-L2 intervertebral disc or the vertebral body of L2: the hilum of the right kidney is slightly lower than the hilum of the left kidney (Pak et al 2016, Shen et al 2016, Uzun et al 2016). It is important to note that both kidneys move vertically by a mean of approximately 2 cm during deep respiration and both can descend by several centimetres when moving from lying to standing (Schwartz et al 1994, Reiff et al 1999).

The inferior pole of the normal right kidney may occasionally be felt in thin individuals by bimanual palpation via the renal angle (twelfth rib and lateral border of erector spinae) on full inspiration. The centre of the hilum of the kidney is approximately 6 cm from the midline in males and 5 cm in females.

Ureter

The ureter descends on either side, about 5 or 6 cm from the midline, from approximately the level of the transpyloric plane (range, inferior half of the vertebral body of L1 to superior half of the vertebral body of L2): this origin is slightly lower on the right. Each ureter passes downwards just medial to the tips of the transverse processes of the lumbar vertebrae and, in the pelvis, curves medially to enter the fundus of the urinary bladder.

Abdominal aorta and branches

The abdominal aorta begins at the level of the vertebral body of T12 near the midline. It descends and bifurcates at the vertebral body of L4 (range, inferior half of the vertebral body of L3 to inferior half of the vertebral body of L5), usually just to the left of the midline and up to 3 cm caudal to the umbilicus (Mirjalili et al 2012b, Pak et al 2016, Shen et al 2016, Uzun et al 2016). The aortic bifurcation is also most commonly located level with the vertebral body of L4 in children from 0 to 11 years of age (Subramaniam et al 2016). The position of the aortic bifurcation is moved slightly proximally with an increased lumbar lordosis (Moussallem et al 2012). The pulsations of the abdominal aorta can be felt in a supine individual of lower body mass by pressing firmly and deeply in the midline, thereby compressing the aorta on to the bodies of the lumbar vertebrae.

Unpaired visceral arteries

The coeliac trunk arises from the abdominal aorta immediately after it enters the abdomen at the level of the vertebral body of T12; the superior mesenteric artery arises most commonly at the level of the vertebral body of L1, close to the transpyloric plane; and the inferior mesenteric

The length of the normal adult kidney, measured along its long axis, is approximately 11.5 cm in males and 11.0 cm in females (Hale et al 2010); the left kidney is a few millimetres longer than the right (Cheong et al 2007, Glodny et al 2009). There is a small reduction in kidney length beyond 50 years of age (Glodny et al 2009). Each kidney is approximately 5–6 cm wide. Both its longitudinal and transverse axes are slightly oblique, such that the superior pole of each kidney is nearer the midline and the hilum is more anterior than the lateral surface.

artery usually arises at the level of the vertebral body of L3 (Mirjalili et al 2012b, Pak et al 2016, Shen et al 2016, Uzun et al 2016). The level of origin of each of these arteries is similar in children from 0 to 11 years of age (Subramaniam et al 2016).

Renal arteries

The left and right renal arteries most commonly arise level with the inferior half of the vertebral body of L1, approximately in the transpyloric plane (range, inferior half of the vertebral body of L1 to the superior half of the vertebral body of L2) (Mirjalili et al 2012b, Pak et al 2016, Shen et al 2016). Similar observations have been made in children aged 0–11 years (Subramaniam et al 2016).

Iliac arteries

The surface projection of the common iliac artery corresponds to the superior third of a broad line, slightly convex laterally, joining the aortic bifurcation (see above) to a point midway between the anterior superior iliac spine and the pubic symphysis. The external iliac artery corresponds to the inferior two-thirds of this line.

Inferior vena cava

The inferior vena cava most commonly forms level with the vertebral body of L5 in the intertubercular plane (range, superior half of the vertebral body of L4 to the superior half of the vertebral body of S1) to the right of the midline (Mirjalili et al 2012b, Pak et al 2016, Shen et al 2016). It forms level with the vertebral body of L4 in children aged 0–3 years, and level with the vertebral body of L5 in children aged 4–11 years (Subramaniam et al 2016). The inferior vena cava was traditionally thought to leave the abdomen through the caval foramen of the respiratory diaphragm at the level of the vertebral body of T8. In some individuals this may hold true (Keough et al 2016), however more commonly, the caval foramen is located between the levels of the vertebral bodies of T10 and T11 (Mirjalili et al 2012b, Shen et al 2016, Pak et al 2016).

Pelvis

The posterior superior iliac spines lie commonly at the level of the vertebral body of S2 (range, the L5–S1 interspinous space to the spinous process of S3 along the median sacral crest) (McGaugh et al 2007); some individuals have a depression or dimple (sacroiliac fovea) in the overlying skin. This palpable bony landmark corresponds approximately to the termination of the spinal dural sac (Nasr 2017) and the middle of the sacroiliac joint. The second dorsal sacral foramen lies approximately 2–3 cm medial to the posterior superior iliac spine on each side at an angle of 45° (McGrath and Stringer 2011). The latter is potentially useful for locating the branches of the sacral dorsal rami in the treatment of medically refractory sacroiliac pain.

Sciatic nerve

The sciatic nerve leaves the pelvis approximately one-third of the way along a line between the posterior superior iliac spine and the ischial tuberosity and enters the thigh approximately half way between the greater trochanter of the femur and the ischial tuberosity (see Fig. 76.19) (Currin et al 2014). In children from 0 to 11 years of age, the sciatic nerve is located within the middle third of two reference lines; a line joining the posterior superior iliac spine to the ischial tuberosity, and a line joining the greater trochanter to the ischial tuberosity (Selkirk et al 2016).

Other surface landmarks for pelvic structures are described in Chapter 76.

COMMON CLINICAL PROCEDURES

Pneumoperitoneum for laparoscopy

A pneumoperitoneum is frequently established by accessing the peritoneal cavity just below the umbilicus. An incision through the linea alba allows access to the peritoneum at a point where there is relatively little extraperitoneal fat. Additional working ports are inserted through the anterior abdominal wall, avoiding major vessels such as the inferior epigastric artery.

Surgical incisions

Most surgical incisions are sited according to surgical imperatives rather than anatomical constraints. Access to the peritoneal cavity is usually gained by dividing or splitting muscles. Common approaches include the midline incision through the relatively avascular linea alba, the transverse suprapubic (Pfannenstiel) incision for pelvic procedures, and, in infants and children, the upper abdominal transverse incision. In recent years, progressively more abdominal surgery has been performed using laparoscopic procedures (minimally invasive or 'keyhole' surgery) utilizing, for example, the umbilicus.

Intestinal stomas (ileostomy, colostomy)

When possible, intestinal stomas are usually formed through transrectus (rectus abdominis) incisions. A cruciate incision is made in the anterior layer of the rectus sheath and the muscle fibres are split, avoiding injury to the epigastric vessels. This incision offers the advantage that fibres of rectus abdominis support the stoma, providing a dynamic, contractile surround that tends to reduce the risk of herniation occurring around the stoma.

Suprapubic catheterization

The urinary bladder can be accessed for short- or long-term catheterization through the anterior abdominal wall. As the urinary bladder fills, its superior aspect rises above the pubis and can be relatively easily accessed by a midline transcutaneous puncture through the most distal part of the linea alba.

Endoscopic surgery

Endoscopic surgery is a broad term that encompasses all types of surgery performed using flexible or rigid fibre-optic endoscopes inserted through natural body orifices or small surgical incisions. It overlaps with the field of minimally invasive surgery. The aim is to minimize or eliminate external incisions and hasten the patient's recovery, whilst providing optimum treatment of the pathology with an acceptably low risk of complications. In the abdomen and pelvis it includes therapeutic procedures performed using an endoscope inserted via the mouth (gastroscope or duodenoscope), anus (proctoscope, sigmoidoscope or colonoscope), urethra (cystoscope or ureteroscope) or vagina, or via small surgical incisions in the anterior or posterior abdominal wall (laparoscope and other endoscopic systems).

A refinement of the technique is natural orifice transluminal endoscopic surgery, in which abdominal operations are performed using an endoscope inserted through a natural orifice (e.g. mouth, anus, urethra) and then through an incision in the viscus that has been entered (e.g. stomach, urinary bladder, vagina). For example, pelvic and intra-abdominal contents can be accessed through the vagina via the recto-uterine pouch. Hysterectomy, oophorectomy, pelvic organ prolapse repair and incontinence surgery are commonly performed using transvaginal techniques. This approach avoids the morbidity of abdominal incision but there are risks of sciatic, femoral and common fibular nerve injury from prolonged surgery in the lithotomy position.

A further development of endoscopic minimally invasive surgery has been the introduction of robotically assisted surgery, which allows the surgeon to manipulate precision instruments from a console remote from the patient whilst viewing the operative field in three dimensions. The procedure is becoming increasingly common in procedures such as prostatectomy.

CHAPTER
60

Anterior abdominal wall

The anterior abdominal wall constitutes a curved hexagonal area defined superiorly by the costal arches (margins) and xiphisternal junction, laterally by the mid-axillary line, and inferiorly by an imaginary line running along the iliac crests, inguinal ligament and pubic symphysis. It is continuous with the posterior abdominal wall and paravertebral tissues, forming a flexible sheet of skin, muscle and connective tissue across the anterior and lateral aspects of the abdomen. It is also contiguous with the respiratory diaphragm and with the bony and myofascial structures of the thorax. These tissues form the complex structures of the myopectineal orifice and the inguinal canal, which connect the peritoneal cavity to the scrotum in males or to the labia majora in females. The anterior abdominal wall maintains the shape of the abdomen and aids in numerous physiological functions. However, its dysfunction is equally notable, as hernia repair remains the single most common type of operation performed by general surgeons.

SKIN AND SOFT TISSUE

The integument of the anterior abdominal wall comprises skin, soft tissues, lymphatic and vascular structures, and segmental nerves. The outer layer is formed from the skin and subcutaneous fat. The skin is non-specialized and variably hirsute, depending on sex and ancestry. All postpubertal individuals have some extension of the pubic hair on to the skin of the anterior abdominal wall, though this is commonly most pronounced in males, where the hair can extend to the umbilicus in a triangular pattern. The subcutaneous fat of the abdominal wall is highly variable in thickness, depending in part on sex and caloric intake.

Soft tissue

Superficial fascia

The superficial fascia of the abdominal wall lies between the dermis and the muscles, and is conventionally divided into a superficial fatty layer (Camper's fascia) and a membranous layer (Scarpa's fascia) deeper to this. In reality there are three layers, with a further layer of adipose tissue deep to the membranous layer (i.e. deep fatty layer) (Lancerotto et al 2011). These three layers are particularly well defined in the child; the membranous layer remains well defined in adults. Lying within the superficial fascial planes are adipose tissue, blood vessels, lymphatics, nerves and, in the inguinal region, superficial inguinal nodes.

Superficial fatty layer

The superficial fatty layer contains a variable amount of fat that is partitioned by fibrous septa connecting the dermis with the deeper membranous layer. Inferiorly it is continuous with the superficial fascia of the thigh, and medially it is continuous over the linea alba. In males this layer continues over the external genitalia, where it becomes thin and pale red and contains very little adipose tissue. In the scrotum it also contains the smooth muscle fibres of dartos. In females it continues from the hypogastric region of the abdomen into the labia majora and perineum.

Membranous layer

The membranous layer is a variably developed entity composed of connective tissue and elastic fibres. In the adult its thickness varies over the anterior abdominal wall, becoming thinner in the proximal abdomen (Lancerotto et al 2011). Measured histologically, it is between 0.5 and 1 mm thick but it appears thicker on computed tomography (Chopra et al 2011, Lancerotto et al 2011). It is loosely connected to the underlying aponeurosis of external abdominal oblique and the rectus sheath by oblique fibrous septa. Superiorly, it is continuous with the superficial fascia over the remainder of the trunk. In the midline it is adherent to the linea alba and pubic symphysis. Inferiorly, it fuses with the iliac crest, and extends superficial to the inguinal ligament and fuses with the fascia lata at the inguinal crease. In males it extends onto the dorsum of the penis, forming the fundiform ligament of the penis, and onto the scrotum where it becomes continuous with the membranous layer of the superficial fascia of the perineum (Colles' fascia). In females it continues into the labia majora and is continuous with the superficial fascia of the perineum.

In boys the testis can frequently be retracted out of the scrotum into the loose areolar tissue between the membranous layer of superficial fascia over the inguinal canal and the aponeurosis of external abdominal oblique.

Deep fatty layer

The thickness of the deep fatty layer is more variable than the superficial fatty layer. It is thin or absent where the membranous layer fuses with bony prominences and the linea alba, and can become markedly thick in some morbidly obese individuals. Its adipocytes show different metabolic activities from those in the superficial fatty layer (Chopra et al 2011). Liposuction preferentially removes this layer of fat with relative preservation of the superficial fatty layer in order to avoid skin dimpling and other skin contour irregularities (Markman and Barton 1987).

Transversalis fascia

The transversalis fascia is a thin layer of connective tissue lying between the deep surface of transversus abdominis and the extraperitoneal fat. It is part of the general layer of thin fascia between the peritoneum and the abdominal wall. Posteriorly, it fuses with the anterior layer of the thoracolumbar fascia; anteriorly, it forms a continuous sheet. Superiorly, it blends with the fascia covering the inferior surface of respiratory diaphragm. Inferiorly, it is continuous with the iliac and pelvic parietal fasciae. It is attached to the iliac crest between the origins of transversus abdominis and iliacus, and to the posterior margin of the inguinal ligament as a discrete thickening known as the iliopubic tract (Teoh et al 1999); it consists of transverse fibres that fan out laterally towards the anterior superior iliac spine to blend with the iliopsoas fascia and run medially to the pubic bone. The iliopubic tract is a landmark structure during laparoscopic inguinal hernia repair, although it is often incorrectly described as the inguinal ligament. Medial to the femoral sheath the transveralis fascia is fused to the pubis behind the conjoint aponeurosis (conjoint 'tendon'). An inferior extension of the fascia forms the anterior part of the femoral sheath. A further thickening of the transversalis fascia, the interfoveolar ligament, runs inferior to the inguinal ligament at the medial margin of the deep inguinal ring; it may contain muscle fibres.

The transversalis fascia continues as the internal spermatic fascia over the structures that pass through the deep inguinal ring (the testicular vessels and ductus deferens in males and the round ligament of the uterus in females).

Extraperitoneal connective tissue

The extraperitoneal connective tissue lying between the peritoneum and the fasciae lining the abdominal and pelvic cavities contains a variable amount of fat. This adipose tissue is the most common content of small congenital umbilical and epigastric hernias (see below). The fat is especially abundant on the posterior wall of the abdomen around the kidneys but scanty proximal to the iliac crest and in much of the pelvis. The inferior epigastric vessels themselves are contained within an envelope of fat as they travel from the external iliac vessels to rectus abdominis. This fat pad serves as an anatomical landmark during various types of abdominal hernia repairs. An abundance of fat in the extraperitoneal space also enables a peritoneal flap to be created easily: such a flap can be used to cover mesh during hernia surgery (a so-called extraperitoneal or 'pre-peritoneal' hernia repair). Areas with little fat, where the peritoneum and transversalis fascia are in direct contact with one another, are difficult to separate, commonly resulting in rents in the peritoneum that must be carefully repaired.

Vascular supply and lymphatic drainage

Understanding the blood supply of the anterior abdominal wall is critical when planning incisions, creating lipocutaneous or myofascial flaps or reconstructing the abdominal wall during ventral hernia repair (**Fig. 60.1**).

Superior epigastric artery and veins

The superior epigastric artery is a terminal branch of the internal thoracic artery. It arises at the level of the sixth costal cartilage and descends between the costal and sternal parts of the diaphragm, accompanied by two or more veins that drain to the internal thoracic vein (see Fig. 60.1; **Fig. 60.2**). The vessels pass anterior to the distal fibres of transversus thoracis and the proximal fibres of transversus abdominis before entering the rectus sheath, where they run inferiorly behind rectus abdominis. They anastomose with the inferior epigastric arteries within rectus abdominis in one of several potential branching patterns (Rozen et al 2008).

Vascular branches supply rectus abdominis itself and perforate the anterior layer of the rectus sheath to supply the abdominal skin and subcutaneous fat. These vessels generally penetrate rectus abdominis within a 10 cm circle around the umbilicus and are referred to clinically as 'periumbilical perforator' vessels. A branch given off in the proximal rectus sheath passes anterior to the xiphoid process of the sternum and anastomoses with a corresponding contralateral branch. This vessel can give rise to bleeding during surgical incisions that extend up to and alongside the xiphoid process. The superior epigastric artery also gives small branches to the anterior part of the diaphragm. On the right, small branches reach the falciform ligament, where they anastomose with branches from the hepatic artery.

Inferior epigastric artery and veins

The inferior epigastric artery (often referred to as the deep inferior epigastric artery in clinical practice in order to distinguish it from the superficial (inferior) epigastric artery) originates from the medial aspect of the external iliac artery just proximal to where the vessels pass deep to the inguinal ligament (see Figs 60.1–60.2; **Fig. 60.3**). Its accompanying veins, usually two, unite to form a single vein that drains into the external iliac vein (Rozen et al 2009). The vessel curves forwards in the extraperitoneal tissue and ascends obliquely along the medial margin of the deep inguinal ring. It lies posterior to the spermatic cord, separated from it by the transversalis fascia. It pierces the transversalis fascia and enters the posterior layer of the rectus sheath by passing anterior to the arcuate line.

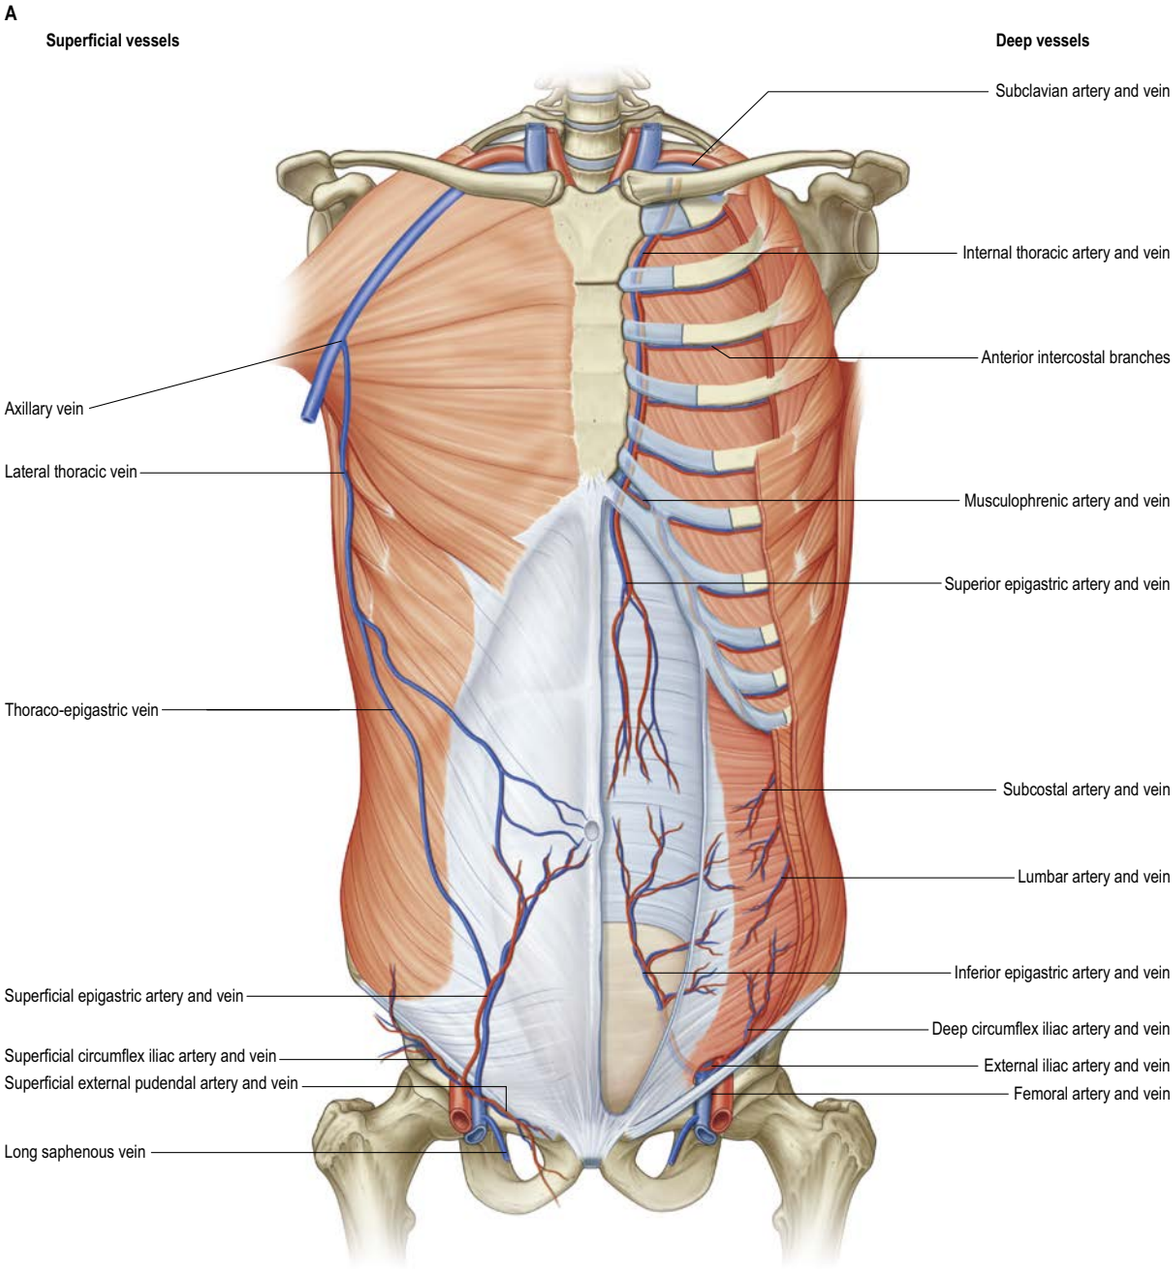

Fig. 60.1 A, The blood supply of the anterior abdominal wall. The left rectus abdominis has been removed to show the superior and inferior epigastric vessels. (B, *continued online*)

Surgical zones have been defined to better understand this vascular distribution. **Zone 1** is the central proximal abdomen. Superiorly, it receives blood supply from the superior epigastric artery, a branch of the internal thoracic artery. Inferiorly it is supplied by the inferior epigastric artery, a branch of the external iliac artery. As the superior and inferior epigastric arteries run posterior to rectus abdominis they supply musculocutaneous perforating vessels (the so-called periumbilical perforator vessels) to the overlying tissues. The superior and inferior epigastric arteries converge in the proximal umbilical region. **Zone 2** encompasses the hypogastric region distal to the arcuate line (semicircular line of Douglas). The area is supplied medially by superficial and deep branches of the inferior epigastric artery. Laterally, the blood supply arises from the superficial circumflex iliac artery as a branch of the femoral artery. **Zone 3** is the area proximal to the arcuate line and lateral to the semilunar line (linea semilunaris). It is perfused inferiorly by the deep circumflex iliac artery and superiorly by the musculophrenic artery, a branch of the internal thoracic artery.

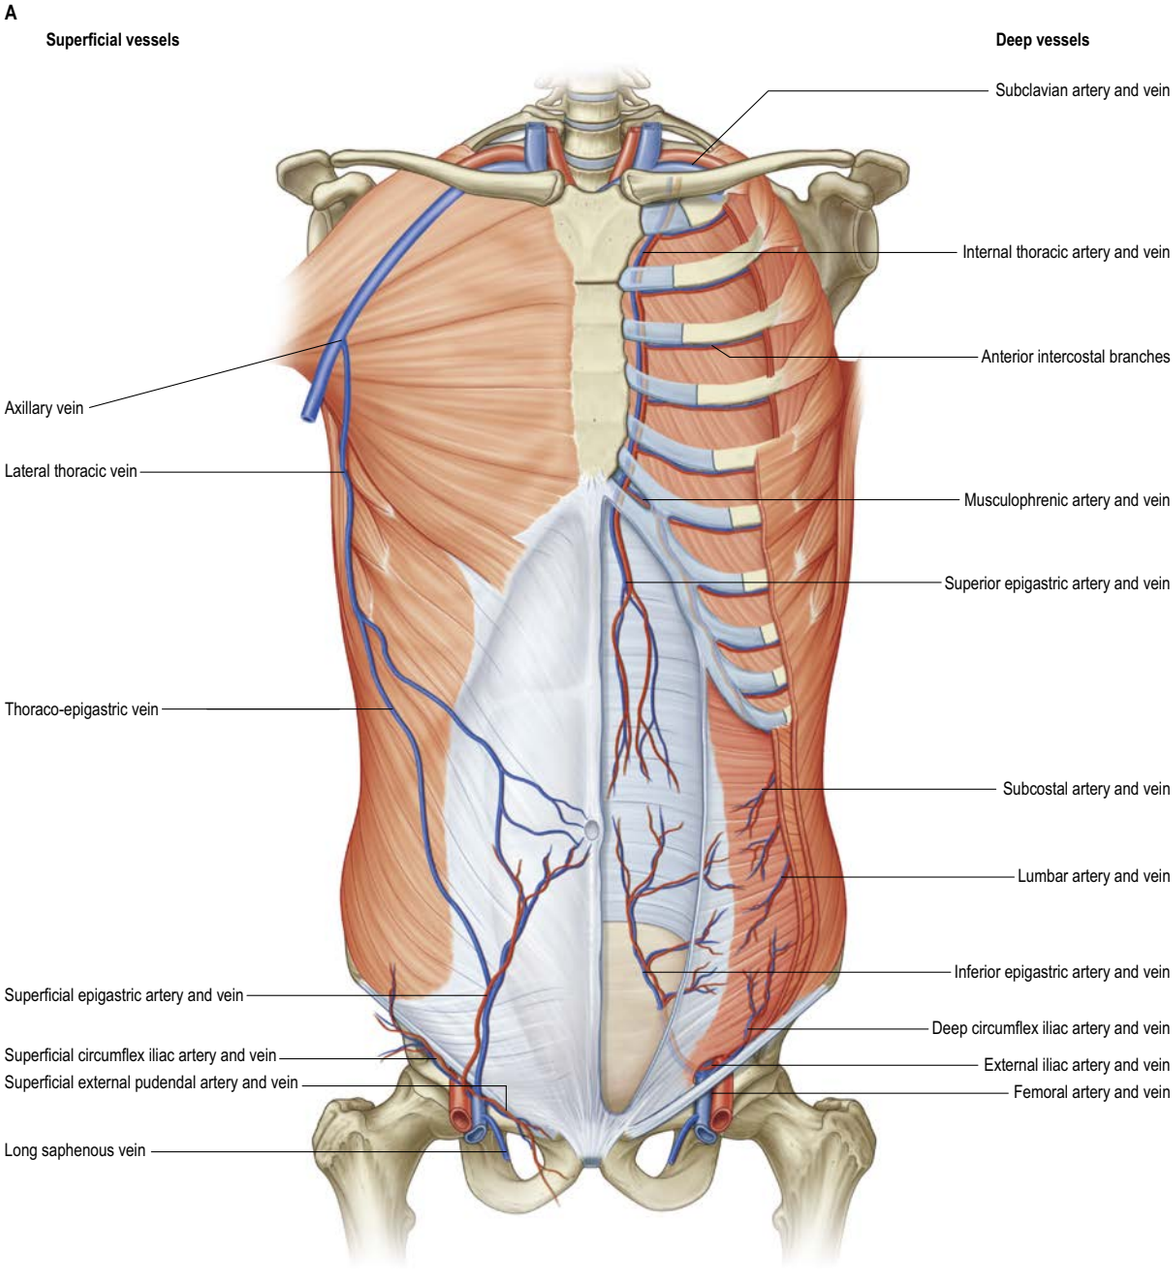

Fig. 60.1 A, The blood supply of the anterior abdominal wall. The left rectus abdominis has been removed to show the superior and inferior epigastric vessels.

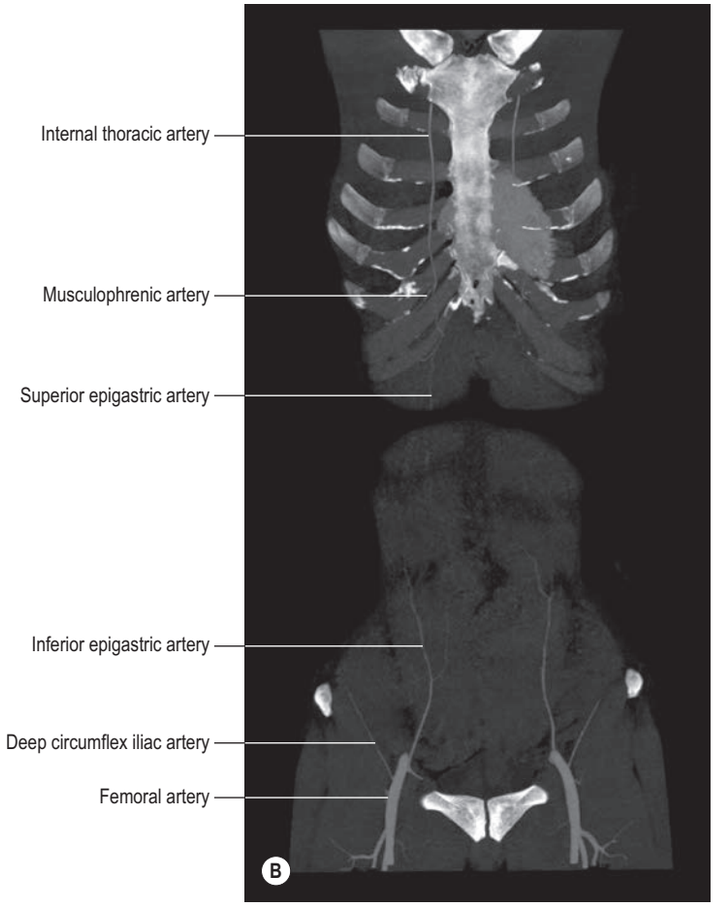

Fig. 60.1 cont'd B, Maximum intensity projection (MIP) coronal reconstruction slabs from a CT aortogram through the arterial supply of the upper and lower anterior abdominal walls. The sections are slightly oblique to each other in their coronal plane, and have been stitched together in order to show these vessels simultaneously.

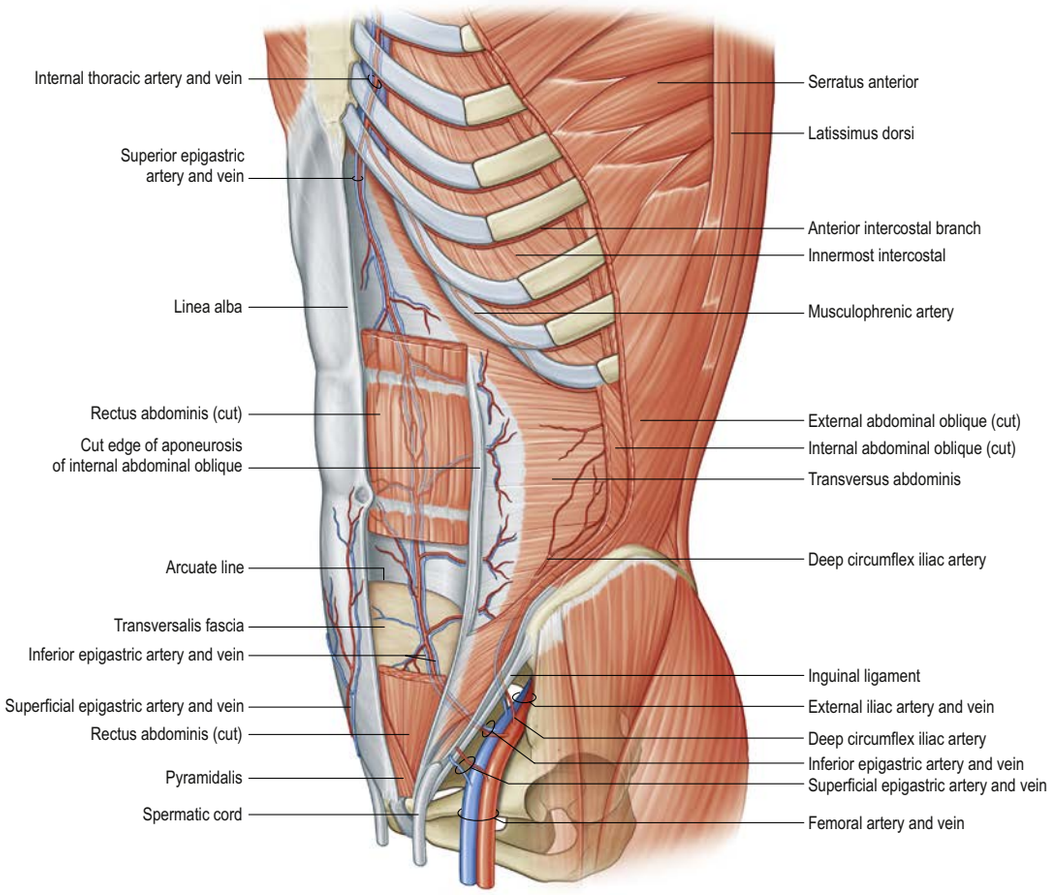

Fig. 60.2 The muscles and arterial supply of the anterolateral abdominal wall. Portions of the left rectus abdominis have been removed to show the superior and inferior epigastric vessels.

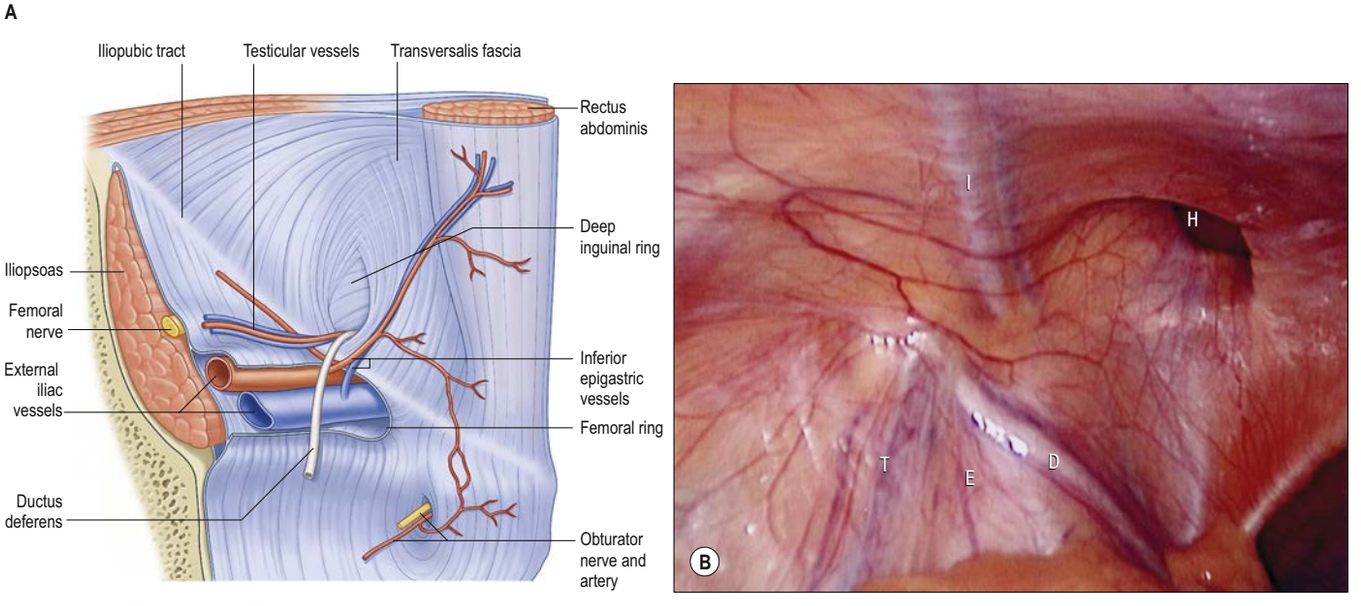

Fig. 60.3 A, The deep aspect of the distal part of the anterior abdominal wall of the left side. The femoral and deep inguinal rings are displayed, together with the vessels and other structures in relation to them and also the opening into the obturator canal. **B**, A laparoscopic view showing the parietal peritoneum covering the area. Abbreviations: D, ductus deferens; E, external iliac vessels; H, orifice of direct inguinal hernia; I, inferior epigastric vessels; T, testicular vessels. (B, With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.) (C, *continued online*)

In this part of its course it is visible through the parietal peritoneum of the anterior abdominal wall and with this covering forms the lateral umbilical fold. Disruption of the artery by surgical incisions (e.g. insertion of laparoscopic ports, surgical tacks or abdominal drains) can cause a haematoma, which can expand to considerable size because there is no adjacent tissue against which the bleeding can be tamponaded.

The inferior epigastric arteries ascend and anastomose with their superior counterparts as a single vessel in only about 30% of cases (El-Mrakby and Milner 2002). Branching into two vessels before anastomosing is the most common pattern, accounting for almost 60%, with a trifurcation in the remainder. The inferior epigastric arteries have an average diameter of approximately 3 mm at their origin, compared to an average diameter of 1.6 mm at the origin of the superior epigastric arteries, presumably explaining why the inferior epigastric arteries provide the 'dominant' blood supply to rectus abdominis. Preliminary ligation of the inferior epigastric artery is often performed when preparing a myocutaneous flap from the mid or lower rectus abdominis based on the superior epigastric artery; this encourages augmentation of the superior epigastric arterial supply.

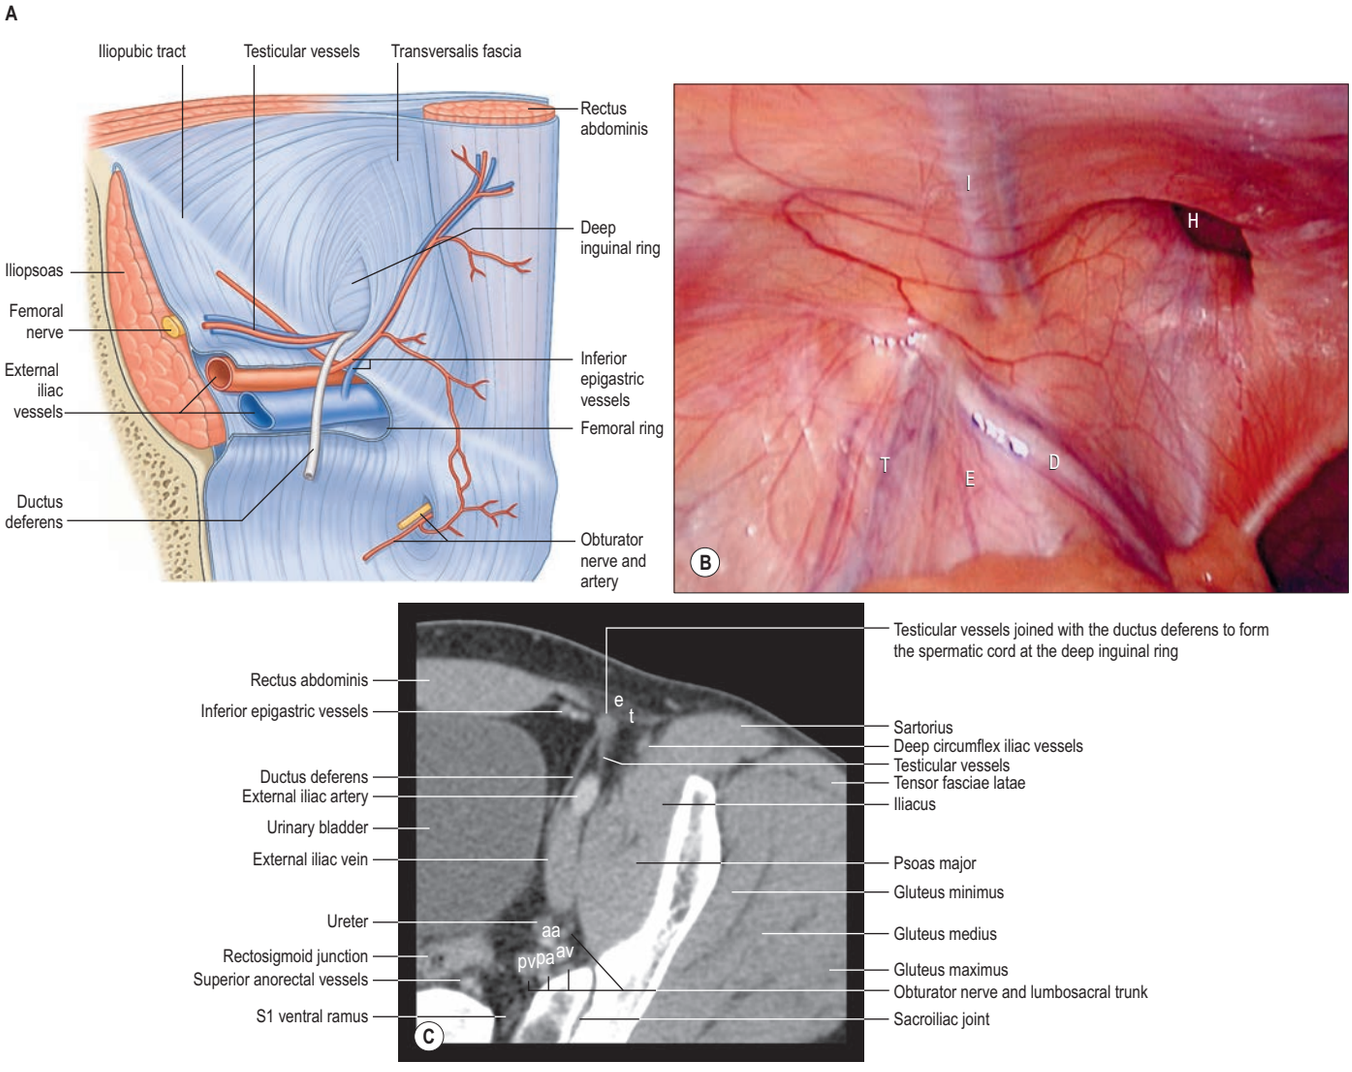

Fig. 60.3 A, The deep aspect of the distal part of the anterior abdominal wall of the left side. The femoral and deep inguinal rings are displayed, together with the vessels and other structures in relation to them and also the opening into the obturator canal. **B**, A laparoscopic view showing the parietal peritoneum covering the area. Abbreviations: D, ductus deferens; E, external iliac vessels; H, orifice of direct inguinal hernia; I, inferior epigastric vessels; T, testicular vessels. **C**, Slightly oblique axial CT with intravenous contrast medium showing the ductus deferens joining the testicular vessels at the deep inguinal ring to form the spermatic cord. Key: aa, anterior division of the internal iliac artery; av, anterior division of the internal iliac vein; e, external abdominal oblique fascia; pa, posterior division of the internal iliac artery; pv, posterior division of the internal iliac vein; t, transversalis fascia. (B, With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

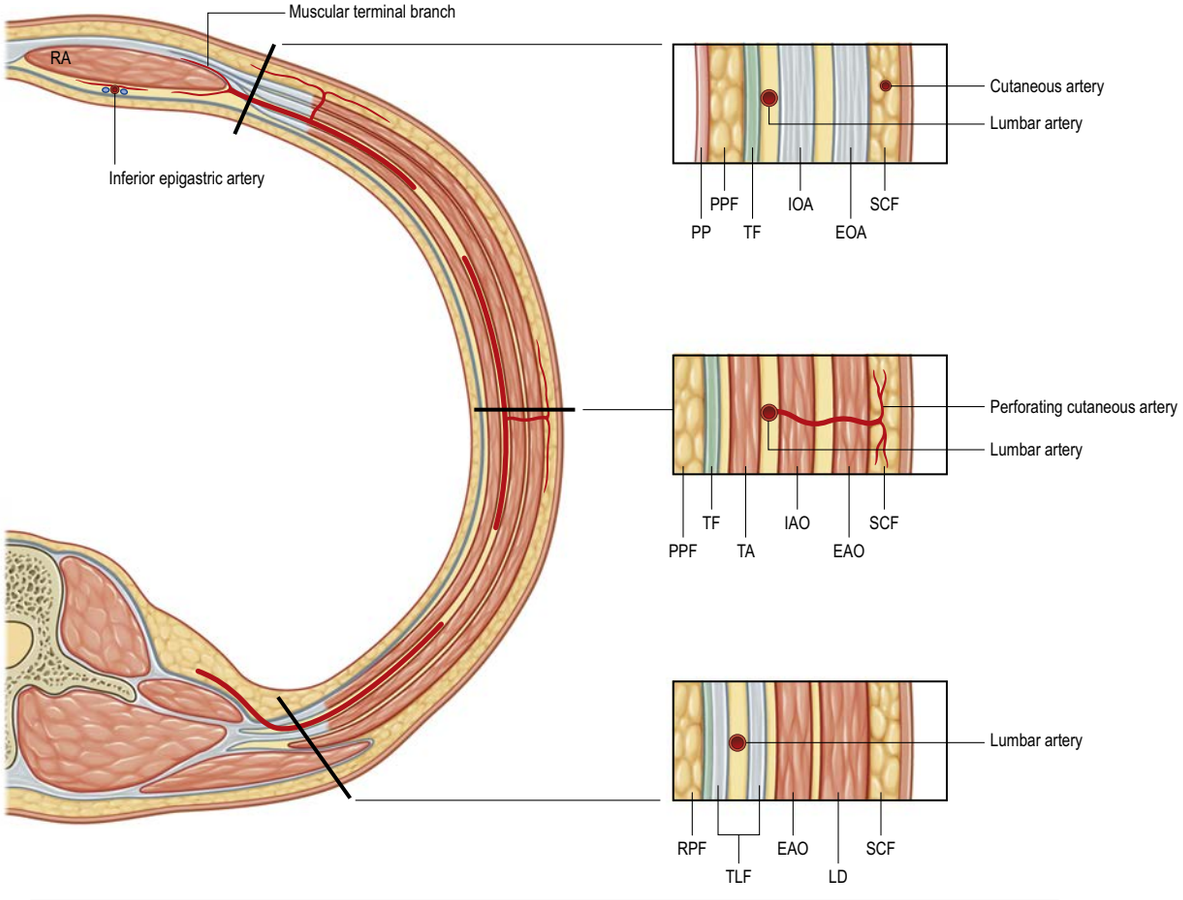
Branches of the inferior epigastric artery anastomose with branches of the superior epigastric artery within rectus abdominis at a variable level proximal to the umbilicus (Rozen et al 2008). Other branches anastomose with terminal branches of the distal five posterior intercostal, subcostal and lumbar arteries at the lateral border of the rectus sheath. Inferolaterally, branches anastomose with the deep circumflex iliac artery.

The ductus (vas) deferens in males or the round ligament of the uterus in females pass medially after hooking around the inferior epigastric artery at the deep inguinal ring. The inferior epigastric vessels form the lateral border of the inguinal triangle (Hesselbach's triangle). The boundaries of this anatomical region are seen during laparoscopic inguinal hernia repair: the inferior border of the triangle is formed by the iliopubic tract/inguinal ligament and the medial border by the lateral margin of rectus abdominis. Hernias occurring within the triangle are termed direct inguinal hernias.



The inferior epigastric artery also gives off the cremasteric artery, a pubic branch and muscular and cutaneous branches. The cremasteric artery accompanies the spermatic cord in males, supplies cremaster and other coverings of the cord and anastomoses with the testicular artery. In females the artery is small and accompanies the round ligament of the uterus. A pubic branch, near the femoral ring, descends posterior to the pubis and anastomoses with the pubic branch of the obturator artery. The pubic branch of the inferior epigastric artery can be larger than the obturator artery and supply most of the territory of the obturator artery in the thigh, in which case it is referred to as the aberrant obturator artery (Pai et al 2009). It lies close to the medial border of the femoral ring and can be injured during medial dissection of the ring in femoral hernia repair, laparoscopic inguinal hernia repair, or with pelvic fractures. Muscular branches supply the abdominal muscles and peritoneum and anastomose with the circumflex iliac and lumbar arteries. Cutaneous branches arise within rectus abdominis, and perforate the aponeurosis of external abdominal oblique to supply the overlying skin. They anastomose with branches of the superficial epigastric artery, contributing to the 'periumbilical perforator vessels'. These perforating vessels have been mapped in detail because they are particularly important in creating large lipocutaneous flaps on the abdominal wall: if this requires ligation of these vessels, the flap is at risk of necrosis (Rozen et al 2008).

Occasionally, the inferior epigastric artery arises from the femoral artery. It then ascends anterior to the femoral vein, passing deep to the inguinal ligament and into the abdominal cavity before following its usual abdominal course. Rarely it arises from the external iliac artery in common with an aberrant obturator artery or from the obturator artery itself.

The superior and inferior epigastric arteries are important sources of collateral blood flow between the internal thoracic artery, the external iliac artery and the lumbar vessels when aortic blood flow is compromised. Additionally, small tributaries of the inferior epigastric vein draining the skin around the umbilicus anastomose with terminal branches of the umbilical vein that drain into the liver via the falciform ligament. These portosystemic communications can dilate substantially in patients with portal hypertension, resulting in portal venous blood draining into the systemic circulation via the inferior epigastric veins. Back pressure to the level of the skin leads to a pattern of dilated, serpiginous superficial veins radiating out from the umbilicus, referred to as the 'caput medusae'.

Posterior intercostal, subcostal and lumbar arteries

In the paraspinal region, the tenth and eleventh posterior intercostal arteries, the subcostal artery and the lumbar arteries all pierce the posterior aponeurosis of transversus abdominis to enter the neurovascular plane of the abdominal wall running between transversus abdominis and internal abdominal oblique (**Fig. 60.4**). The arteries on either side run forwards, giving off muscular branches to the overlying internal and external abdominal obliques, before anastomosing with lateral branches of the superior and inferior epigastric arteries at the lateral border of the rectus sheath, just medial to the semilunar line (see Fig. 60.4). The location of these arteries is of clinical importance when myofascial flaps are created during anterior abdominal wall reconstruction, not because

EAO	External abdominal oblique	PP	Parietal peritoneum	SCF	Subcutaneous fat

LD	Latissimus dorsi				

Fig. 60.4 The arrangement of the anterolateral abdominal wall vessels at the level of the mid-abdomen.

of their vascular contributions but because of their accompanying nerves, which innervate rectus abdominis. Division of these nerves can result in a segmental denervation of portions of rectus abdominis and/or the lateral anterior abdominal wall musculature. Perforating vessels run vertically through the myofascial planes to supply the overlying skin and subcutaneous tissue. A small contribution to the supply of the distal abdominal muscles comes from branches of the deep circumflex iliac arteries.

The anterior abdominal wall is also supplied by branches of the femoral artery: namely, the superficial epigastric, superficial circumflex iliac and superficial external pudendal arteries, and by the deep circumflex iliac artery arising from the external iliac artery (see Fig. 76.4A).

Lymphatic drainage

The highest concentration of lymphatic vessels in the anterior abdominal wall is found in the dermis (Friedman et al 2015). Lymphatic vessels from the lumbar and gluteal regions run with the superficial circumflex iliac vessels, and those from the abdominal skin distal to the umbilicus run with the superficial epigastric vessels. Both drain into the superficial inguinal nodes. Lymphatic vessels from the proximal umbilical region drain to axillary and parasternal nodes. Enlargement of a lymph node in the umbilical region is rare but can herald an abdominal or pelvic malignancy.

The deep lymphatic vessels accompany the deeper arteries. Laterally, they run either with the lumbar arteries to drain into the lateral aortic nodes, or with the posterior intercostal and subcostal arteries to nodes in the posterior mediastinum. Lymphatics in the proximal anterior abdominal wall run with the superior epigastric vessels to parasternal nodes while those in the distal abdominal wall run with the deep circumflex iliac and inferior epigastric arteries to external iliac nodes. For further reading, see Tourani et al (2013).

Segmental nerves

The ventral rami of the sixth to eleventh intercostal nerves, the subcostal nerve (twelfth thoracic) and first lumbar nerve (iliohypogastric and ilio-inguinal nerves) innervate the muscles and skin of the anterior abdominal wall (Rozen et al 2008). The seventh to the twelfth thoracic ventral rami continue anteriorly into the abdominal wall (**Fig. 60.5**). Approaching the costal arch, the seventh to tenth intercostal nerves curve medially across the deep surface of the costal cartilages between the digitations of the respiratory diaphragm and transversus abdominis. The subcostal nerve often gives a branch to the first lumbar ventral ramus (dorsolumbar nerve), and in these cases therefore contributes to the lumbar plexus (Ch. 61). It accompanies the subcostal vessels along the inferior border of the twelfth rib, passing posterior to the lateral arcuate ligament and kidney, and anterior to the proximal part of quadratus lumborum.

All these segmental nerves run anteriorly within a thin layer of fascia in the neurovascular plane between transversus abdominis and internal abdominal oblique, where they branch and interconnect with adjacent nerves and give off branches to the lateral musculature (Rozen et al 2008). Cutaneous branches supply the skin of the lateral and anterior abdominal walls. The nerves enter the rectus sheath at its lateral margin by penetrating the posterior lamina of internal abdominal oblique and penetrating rectus abdominis on its posterior aspect. Here they give off muscular branches to rectus abdominis, transversus abdominis and pyramidalis, and cutaneous branches that pierce the anterior layer of the rectus sheath to supply overlying skin.

The ninth intercostal nerve supplies skin proximal to the umbilicus, the tenth intercostal nerve supplies skin that consistently includes the umbilicus, and the eleventh intercostal nerve supplies skin distal to the umbilicus (see Fig. 24.10; **Fig. 60.5**). The subcostal nerve supplies the skin over the anterior gluteal region just distal to the iliac crest and the skin of the distal abdomen and inguinal region (overlapping with the L1 dermatome in this

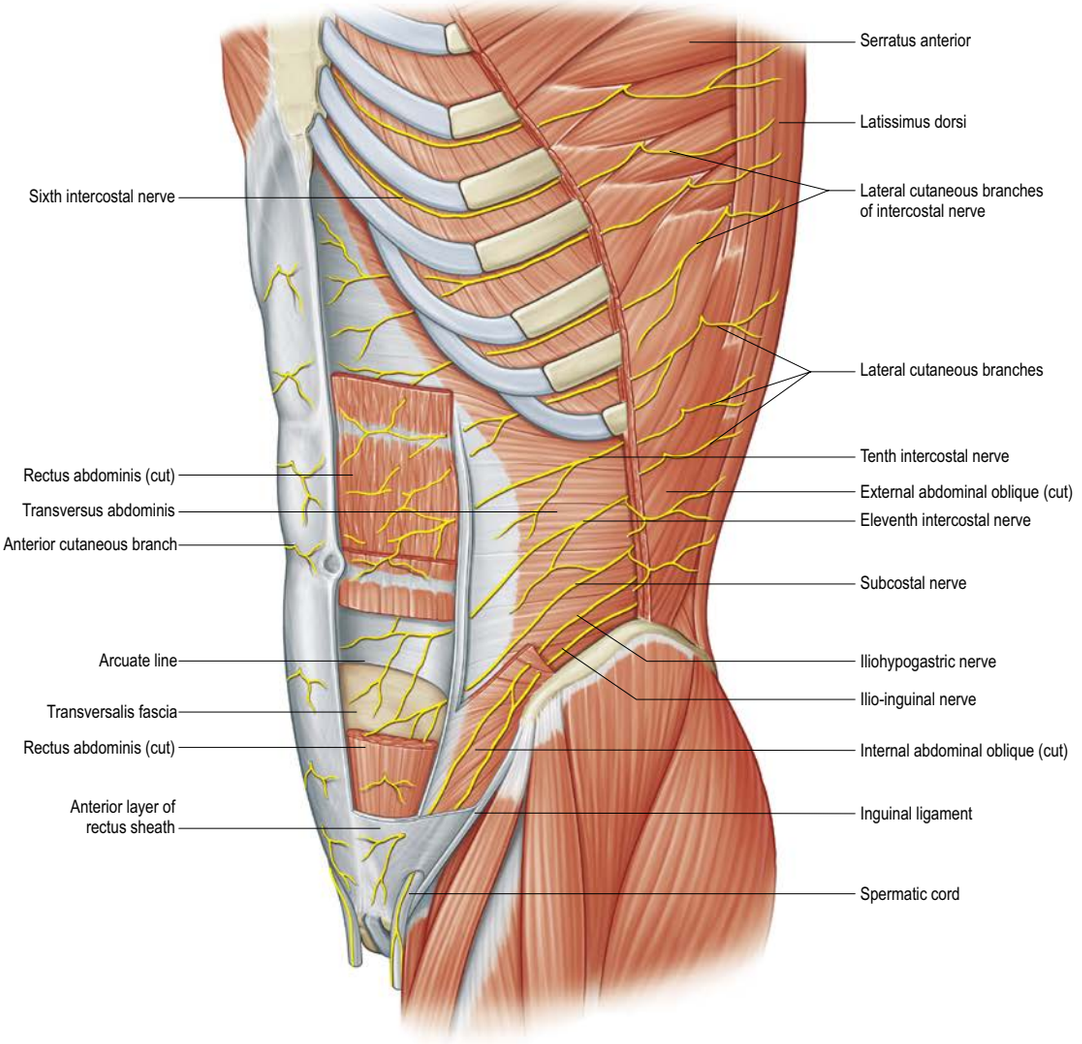

Fig. 60.5 The cutaneous branches of the distal intercostal and lumbar nerves. Portions of the muscles of the anterior abdominal wall have been removed, including most of the anterior layer of the rectus sheath and parts of rectus abdominis.

region) (Lee et al 2008). A typical dermatome map of the anterior abdominal wall is shown in Fig. 24.10. The inferior intercostal nerves and subcostal nerve also provide sensory fibres to the costal parts of the diaphragm and parietal peritoneum.

MUSCLES

Anterolateral muscles of the abdomen

Rectus abdominis, external and internal abdominal obliques, transversus abdominis and pyramidalis constitute the anterolateral abdominal musculature. They act together to perform a range of functions, some of which involve the generation of positive pressure within one or more body cavities. Although many of these activities can occur with no 'forced assistance', exhalation, defecation and micturition can be aided by the generation of positive intra-abdominal pressure. Parturition, coughing and vomiting always require such positive pressure. Under resting conditions, the tone developed within the muscles provides support for the abdominal viscera and retains the normal contour of the abdomen. The consequences of diminished muscular support can be seen in patients who have massive anterior abdominal wall hernias or congenital conditions such as 'prune belly syndrome' where there is deficiency or absence of these muscles.

Active contraction of the muscles is important for maintaining abdominal wall tone. The compression of the abdominal cavity required to increase intra-abdominal pressure is mainly effected by contraction of the respiratory diaphragm. The pelvic girdle, lumbar vertebrae and distal thorax provide rigidity to parts of the abdominal wall. During the generation of positive intra-abdominal pressure, the abdominal muscles hold the abdominal wall in a relatively fixed position rather than generating pressure directly: because most of the abdominal wall is muscular, the anterolateral abdominal wall muscles must contract synchronously to prevent displacement of the viscera.

The anterolateral abdominal muscles contribute little to the movements of the trunk during normal sitting and standing: these movements are controlled predominantly by the muscles of the back. However, movements of the trunk against resistance or when an individual is supine require the anterolateral abdominal muscles. Rectus abdominis is the most important in these situations, producing flexion of the trunk. If the pelvic girdle is fixed, the trunk is flexed. With a fixed thorax, contraction of rectus abdominis causes the pelvis to tilt and lift. Lateral flexion and rotation of the trunk against resistance is provided by unilateral contraction of external and internal abdominal obliques and transversus abdominis.

Rectus abdominis

Rectus abdominis is a paired, long, strap-like muscle that extends along the entire length of the anterior abdominal wall on either side of the linea alba (**Fig. 60.8**). It varies widely in width and thickness from individual to individual but is generally widest in the proximal abdomen. The muscle fibres of rectus abdominis are usually interrupted by one to four fibrous bands (three being the most common) or tendinous intersections, which pass transversely or obliquely across the muscle. One is usually situated at the level of the umbilicus, another opposite the free end of the xiphoid process and the third about midway between the other two. They are rarely full-thickness and usually extend only half-way through the anterior thickness of the muscle, fusing with the fibres of the anterior layer of the rectus sheath. Occasionally, one or two incomplete intersections are present distal to the umbilicus. The intersections may represent the myosepta delineating the myotomes that form the muscle (Rai et al 2018).

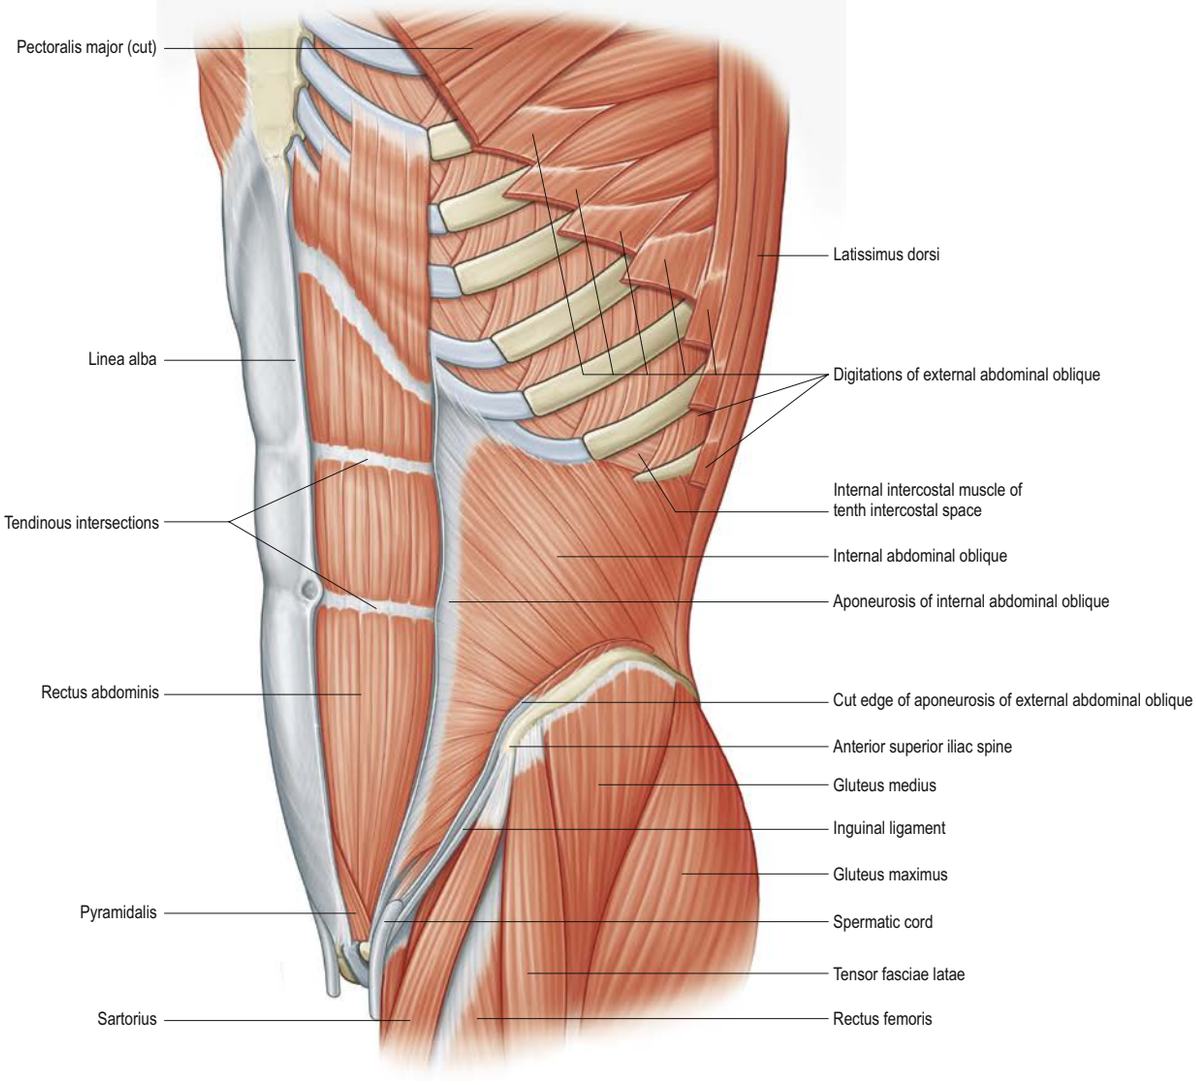

Fig. 60.8 Muscles of the left side of the trunk. External abdominal oblique has been removed to show internal abdominal oblique, but its digitations from the ribs have been preserved. The anterior layer of the rectus sheath has been removed.

The anterolateral abdominal wall muscles are innervated by several segmental nerves and injury to a single nerve rarely causes a clinically detectable loss of muscle tone. The overlap between sequential dermatomes means that significant cutaneous anaesthesia and muscle denervation are appreciated only after at least two sequential nerves have been surgically sectioned (Fig. 60.6).

The transversus abdominis plane (TAP) blockade is a regional anaesthetic technique for abdominal surgery. It involves delivery of analgesic medication between internal abdominal oblique and transversus abdominis, thus providing local anaesthesia to the skin, muscles of the anterior abdominal wall and the parietal peritoneum, while avoiding the epidural-associated risks of central nervous system depression, urinary bladder retention, hypotension, or epidural catheter dislodgement. In abdominal surgeries, TAP blockade has been shown to reduce overall narcotic use (and narcotic-associated side effects), improve overall pain relief and reduce hospital length of stay.

TAP blockade can be performed 'blind'(using anatomical landmarks and feeling a blunt needle 'pop' through myofascial planes) by using real-time sonography to visualize an appropriately positioned needle tip, or by direct visualization of a needle entering the correct plane with subsequent bulging of transversus abdominis as fluid enters this plane (Fig. 60.7).

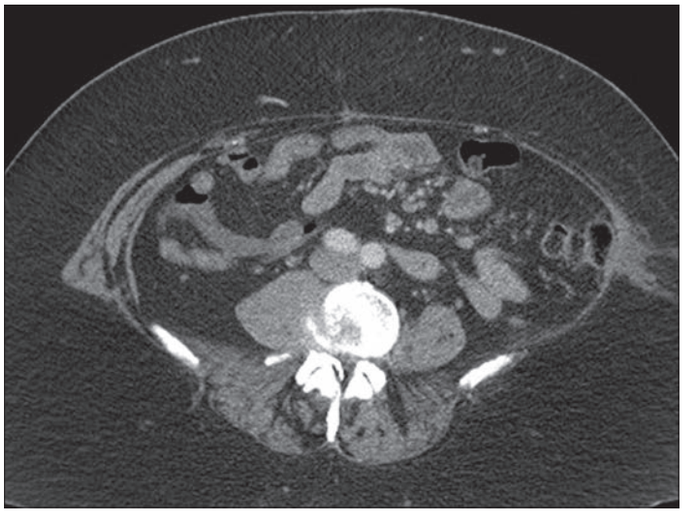

Fig. 60.6 Denervation loss of the entire left abdominal wall (rectus abdominis, external abdominal oblique, internal abdominal oblique and transversus abdominis) as a result of a traumatic flank injury. Note the loss of muscle mass and bulging on the left compared to the normal (contralateral) right side.

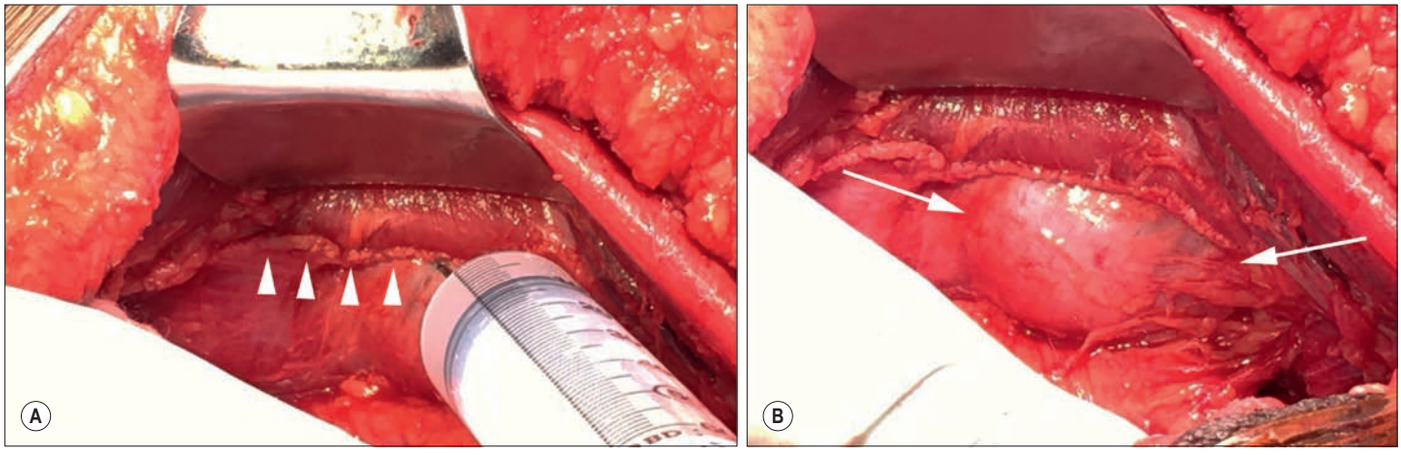

Fig. 60.7 Direct visualization of a transversus abdominis plane block. **A**, An anaesthetic, liposomal bupivacaine, is delivered into the intramuscular plane immediately adjacent to the cut edge of transversus abdominis (arrowheads). **B**, Correct placement is visually confirmed by identifying posterior bulging of the muscle belly as it is displaced by the injected bolus (arrows).

The medial border of each rectus abdominis abuts the linea alba. Its lateral border is sometimes visible on the surface of the anterior abdominal wall as a gently curved groove, the semilunar line, which extends from the tip of the ninth costal cartilage to the pubic tubercle. In a muscular individual it is readily visible, even when the muscle is not actively contracting, but in many obese and non-obese individuals it can be completely obscured.

Attachments Rectus abdominis arises by two tendons. The larger, lateral tendon is attached to the pubic crest and can extend beyond the pubic tubercle to the pecten pubis. The medial tendon interlaces with the contralateral muscle and blends with ligamentous fibres covering the front of the pubic symphysis. Additional fibres may arise from the distal part of the linea alba. The pubic attachment of the tendon of rectus abdominis and the anterior layer of the rectus sheath run over the anterior surface of the pubic symphysis and become continuous with the attachments of gracilis and adductor longus (Norton-Old et al 2013). Superiorly, rectus abdominis is attached by three slips of muscle to the fifth, sixth and seventh costal cartilages. The most lateral fibres are usually attached to the anterior end of the fifth rib; occasionally this slip is absent or it extends to the third and fourth ribs. The most medial fibres are occasionally connected to the adjacent ligaments of the costosternal joint and the side of the xiphoid process.

Vascular supply Rectus abdominis is supplied principally by the superior and inferior epigastric arteries, the latter being the dominant supply. Small terminal branches from the distal three posterior intercostal arteries, the subcostal artery, the lumbar arteries and the deep circumflex iliac artery can contribute, particularly at the lateral edges and the distal parts of the muscle, where they anastomose with small lateral branches of the epigastric arteries. Rectus abdominis provides a reliable and versatile myocutaneous flap, either pedicled or free, because of the excellent vascularity provided by the epigastric vessels and because the muscle belly can be separated from its surrounding sheath.

Innervation Rectus abdominis is innervated segmentally by the terminal branches of the ventral rami of the distal six or seven thoracic spinal nerves (Stecco et al 2017). It can also receive a branch from the ilioinguinal nerve (Rozen et al 2008).

Actions Rectus abdominis contributes to flexion of the trunk and the maintenance of abdominal wall tone required during straining.

Rectus sheath

Rectus abdominis on each side is enclosed by a fibrous sheath (**Figs 60.9–60.12**). The anterior layer of the rectus sheath extends the entire length of the muscle and fuses with periosteum and ligaments at sites of the muscle's attachments. The posterior layer of the rectus sheath is complete behind the proximal two-thirds of the muscle but absent distal to this level, which corresponds to approximately one-third of the distance between the umbilicus and the pubis (Loukas et al 2008). The termination of the posterior layer of the rectus sheath is usually gradual but can be abrupt and marked by a clearly visible curved horizontal line known as the arcuate line.

The rectus sheath is formed from the aponeuroses of external and internal abdominal oblique and transversus abdominis. Each aponeurosis is bilaminar; the fibres from all three anterior leaves run obliquely upwards, whereas the posterior leaves run obliquely downwards at right angles to the anterior leaves. Proximal to the arcuate line, the anterior layer of the rectus sheath is composed of both leaves of the aponeurosis of external abdominal oblique and the anterior leaf of the aponeurosis of internal abdominal oblique fused together. The posterior layer of the rectus sheath is composed of the posterior leaf of the aponeurosis of internal abdominal oblique and both leaves of the aponeurosis of transversus abdominis. Thus, both the anterior and posterior layers of the rectus sheath consist of three layers of fibres, the middle layer running at right-angles to the other two. Distal to the arcuate line, all three aponeuroses from external and internal abdominal oblique and transversus abdominis pass into the anterior layer of the rectus sheath leaving only the transversalis fascia, extraperitoneal tissues (fat and connective tissue) and the parietal peritoneum to cover the posterior aspect of rectus abdominis (see Fig. 60.9).

At the midline, the anterior and posterior layers of the rectus sheath are closely approximated. Fibres from each layer decussate to the opposite side of the sheath, forming a continuous aponeurosis with the contralateral muscles; they also decussate anteroposteriorly, crossing from the anterior layer of the rectus sheath to the posterior layer of the rectus sheath. The dense fibrous line caused by this decussation is called the linea alba. External and internal abdominal oblique and transversus abdominis can therefore be regarded as digastric muscles with a central tendon comprising the linea alba (Rizk 1980). The decussating fibres at the linea alba can be used to identify the midline during surgical incisions.

Linea alba and umbilicus

The linea alba is a tendinous raphe extending from the xiphoid process to the pubic symphysis and pubic crest. It lies between the left and right rectus abdominis and is formed by the interlacing and decussating aponeurotic fibres of external and internal abdominal oblique and transversus abdominis. At its distal end, the linea alba has two attachments to the pubis: superficial fibres are attached to the pubic symphysis, and deeper fibres form a triangular lamella that is attached behind rectus abdominis to the posterior surface of both pubic crests

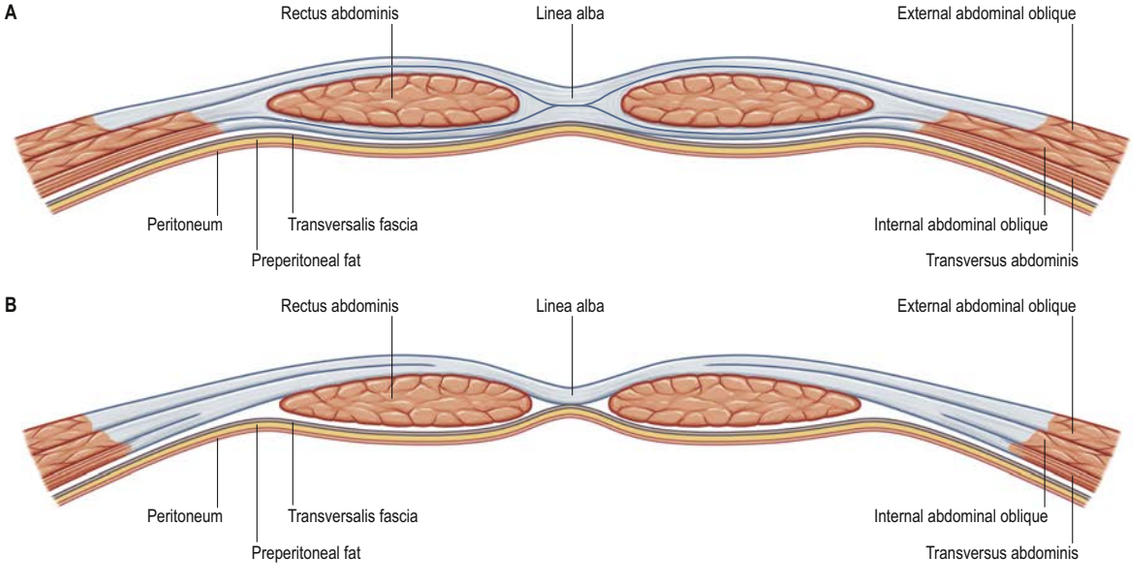

Fig. 60.9 Transverse sections through the anterior abdominal wall. **A**, Immediately proximal to the umbilicus. **B**, Distal to the arcuate line. The bilaminar nature of each muscular aponeurosis is difficult to illustrate in cross-section. The fibres appear to fuse into a single sheet during formation of the rectus sheath. Note that rectus abdominis is supported directly by the transversalis fascia distal to the arcuate line. (C–D, *continued online*)

Without vascular division (a pedicled flap), the proximal half of the muscle can be used for breast reconstruction; the distal half can be transposed to the inguinal region or proximal thigh or rotated on its distal attachments into the perineum for reconstruction after radical pelvic and perineal resections. Because the inferior epigastric vessels are sufficiently large, the distal portion of rectus abdominis can be harvested as a free flap. The vessels are ligated at their junction with the external iliac vessels and are taken together with the distal portion of rectus abdominis. The overlying fascia, adipose tissue and skin can be taken as part of the flap as necessary to manage the soft tissue defect. The free flap is then revascularized by creating anastomoses between the epigastric vessels and the vessels near the defect that is being managed by placement of the flap.

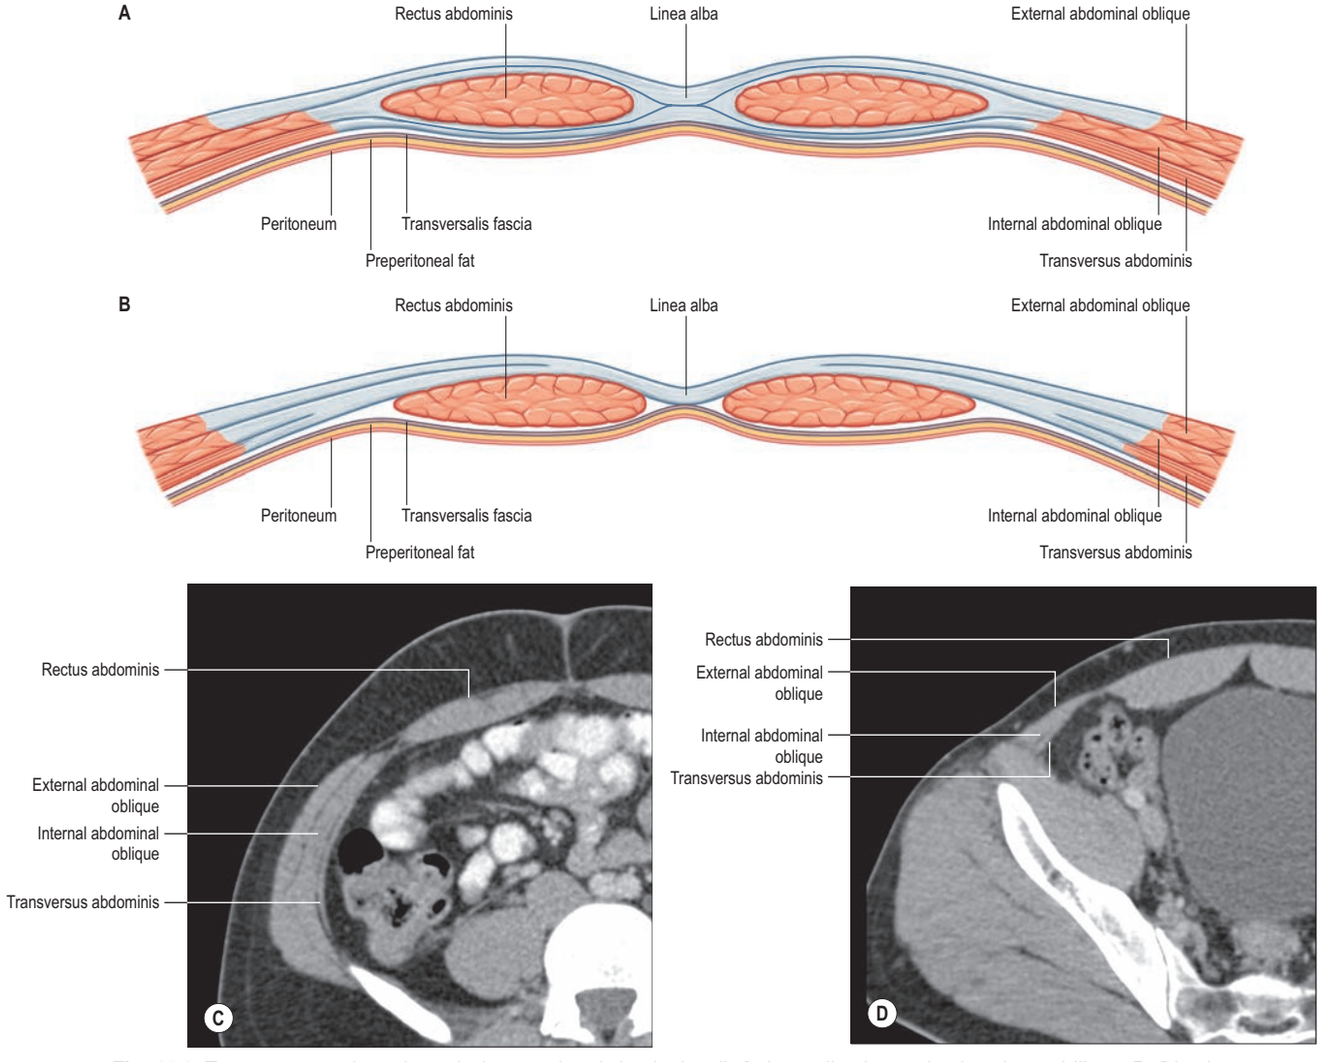

Fig. 60.9 Transverse sections through the anterior abdominal wall. **A**, Immediately proximal to the umbilicus. **B**, Distal to the arcuate line. The bilaminar nature of each muscular aponeurosis is difficult to illustrate in cross-section. The fibres appear to fuse into a single sheet during formation of the rectus sheath. Note that rectus abdominis is supported directly by the transversalis fascia distal to the arcuate line. **C–D**, CT of the abdomen and pelvis with intravenous and oral contrast medium (within small bowel loops) showing the muscle and aponeurotic layers of the anterior abdominal wall above (**C**) and below (**D**) the arcuate line. Note how the aponeurosis of internal oblique splits either side of rectus abdominis in **D**.

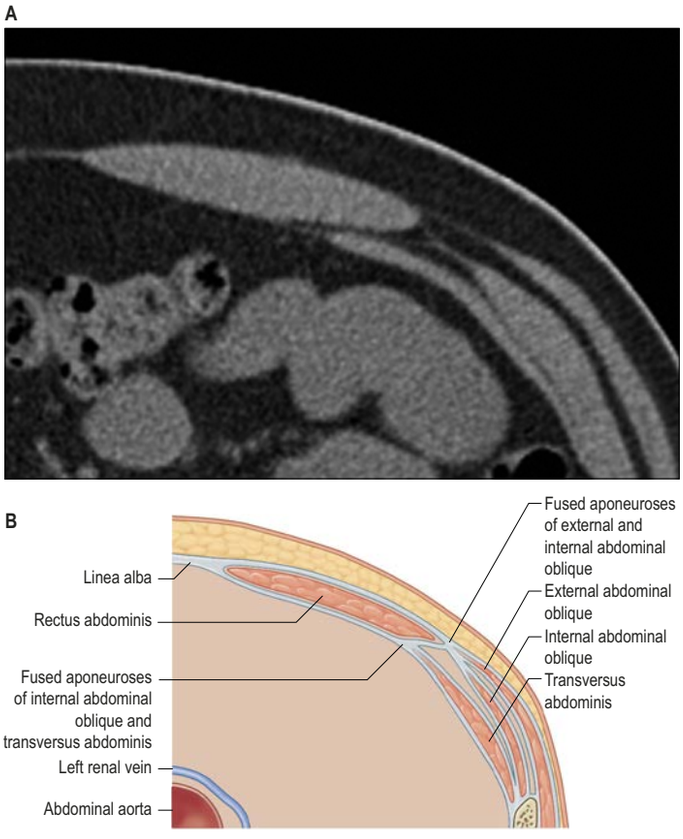

Fig. 60.10 The rectus sheath. CT (**A**) and diagram (**B**) of the anterior abdominal wall, demonstrating the formation of the rectus sheath proximal to the umbilicus. The anterior layer of the rectus sheath is composed of both leaves of the aponeurosis of external abdominal oblique and the anterior leaf of the aponeurosis of internal abdominal oblique, fused together. The posterior layer of the rectus sheath is composed of the posterior leaf of the aponeurosis of internal abdominal oblique and both leaves of the aponeurosis of transversus abdominis.

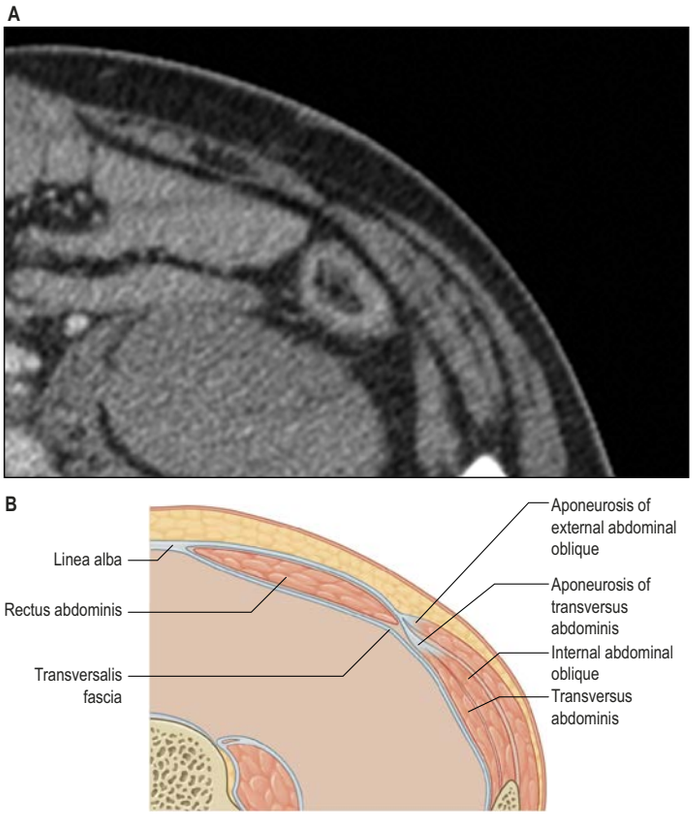

Fig. 60.11 The rectus sheath. CT (**A**) and diagram (**B**) of the anterior abdominal wall, demonstrating the formation of the rectus sheath distal to the umbilicus. The posterior layer of the rectus sheath is replaced by the transversalis fascia and extraperitoneal connective tissue.

(adminiculum lineae albae). The pyramidalis is attached to the suprapubic part of the linea alba. The linea alba is visible externally in those who are lean and muscular as a shallow midline groove in the anterior abdominal wall. Its width varies along its length: it is wider superior to the umbilicus than inferior to it and generally widest at the level of the umbilicus (Rath et al 1996). It is wider and thinner in women, in adults aged over 50 years and in obese individuals and multiparous women (Naraynsingh et al 2012). Its tensile strength is proportional to its thickness and density (Korenkov et al 2001). The linea alba is relatively bloodless but it is crossed superficially from side to side by a few small blood vessels.

The umbilicus is a fibrous cicatrix that lies just distal to the midpoint of the linea alba and is covered by an adherent area of skin. It consists of skin, a fibrous layer (representing the area of fusion between the round ligament of the liver, the median umbilical ligament and two medial umbilical ligaments), the transversalis fascia, the umbilical fascia surrounding the urachal remnant, and peritoneum (Fathi et al 2012). Its appearance and position are variable (Fathi et al 2012). In adults, it tends to lie at a relatively more distal position with advancing age, in men and in individuals with a higher body mass index.

In the fetus the umbilicus transmits the umbilical vessels, urachus and, up to the third month of gestation, the vitelline or yolk stalk. It closes a few days after birth, but the vestiges of the vessels and urachus remain attached to its deep surface. The remnant of the embryonic left umbilical vein forms the round ligament of the liver. The obliterated umbilical arteries form the medial umbilical ligaments on the deep surface of the anterior abdominal wall: when covered with parietal peritoneum they form the medial umbilical folds. The partially obliterated remains of the urachus persist as the median umbilical ligament: when covered with parietal peritoneum, it forms the median umbilical fold. Both congenital and acquired umbilical hernias are common; most childhood umbilical hernias close spontaneously and do not require surgical repair. The umbilicus is the most common site for laparoscopic access to the peritoneal cavity.

Divarication of the left and right rectus abdominis

The linea alba can thin and widen in the upper abdomen, most commonly as a result of pregnancy, obesity or chronic straining (Akram and Matzen 2014). Abdominal viscera protrude beneath the thinned tissue as a broad, lenticular, midline bulge, particularly when intra-abdominal pressure is raised, and the left and right rectus abdominis become widely separated or divaricated. This state is not true herniation because all the layers of the anterior abdominal wall in the region are intact. Divarication (or diastasis of the rectus muscles) is generally considered a cosmetic issue alone, but can be associated with true hernias of the abdominal wall, most commonly at the umbilicus. Surgical correction of this issue requires suture plication (performed either anterior or posteriorly to rectus abdominis) of the thinned linea alba with or without the addition of mesh for support.

Pyramidalis

Pyramidalis is a triangular muscle that lies anterior to the distal part of rectus abdominis within the rectus sheath. It varies considerably in size, and can be larger on one side than on the other. It may be absent on one or both sides (in as many as 20% of individuals) or, rarely, can be duplicated. Pyramidalis is generally rudimentary in humans and is of little clinical or surgical relevance.

Attachments Pyramidalis is attached by tendinous fibres to the anterosuperior margin of the pubis and to ligamentous fibres anterior to the pubic symphysis. The muscle becomes smaller as it runs upwards and ends in a pointed apex that is attached medially to the linea alba: this attachment often lies midway between the umbilicus and pubis, but can lie higher.

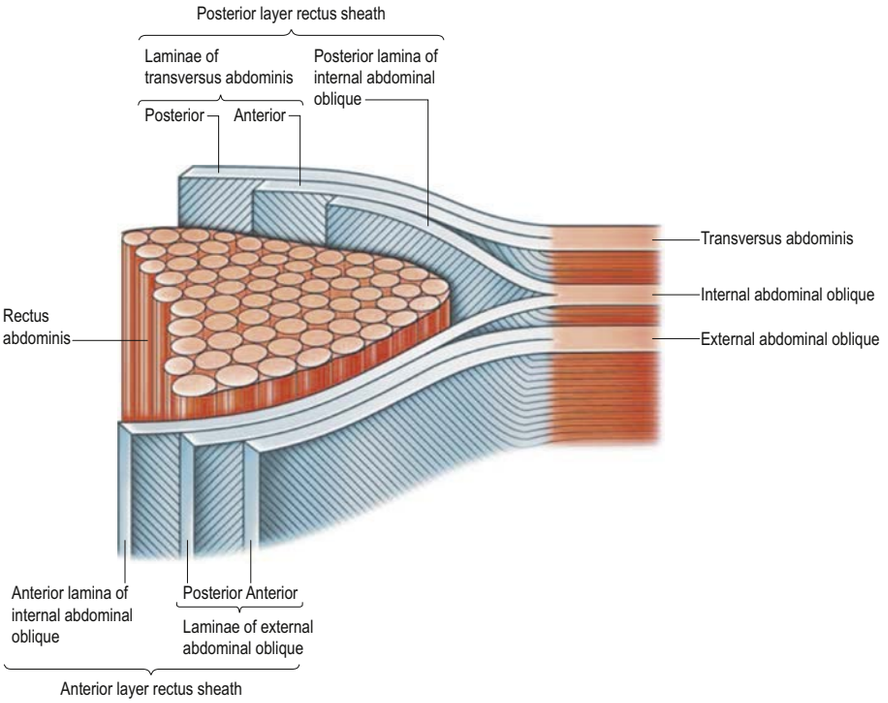

Fig. 60.12 The concept of bilaminar aponeuroses of external and internal abdominal oblique and transversus abdominis. Note that the fibres of the superficial and deep laminae are approximately at right-angles; decussations occur as part of the linea alba.

Vascular supply Pyramidalis is supplied by branches of the inferior epigastric artery. A small artery frequently crosses the midline posterior to the belly of the muscle to anastomose with the contralateral vessel.

Innervation Pyramidalis can be innervated via the ventral rami of the twelfth thoracic, first lumbar or second lumbar spinal nerves: fibres travel in anterior cutaneous branches of the subcostal nerve, the ilio-inguinal nerve or the genital branch of the genitofemoral nerve (Tokita 2006).

Actions Pyramidalis contributes to tensing the distal linea alba but is of doubtful physiological significance.

External abdominal oblique

Attachments External abdominal oblique is the largest and most superficial of the three anterolateral abdominal muscles (**Fig. 60.13**). It curves around the lateral and anterior parts of the abdomen and is attached to the external surfaces and inferior borders of the distal eight ribs. The attachments rapidly become muscular and interdigitate with the distal fibres of serratus anterior and latissimus dorsi along an imaginary oblique line that extends downwards and backwards. The proximal attachments are close to the costal cartilages of the corresponding ribs, the middle ones arise from the ribs at some distance from their cartilages, and the most distal are close to the distal end of the twelfth rib. The fibres of external abdominal oblique diverge as they pass to their distal attachments. Those from the distal two ribs pass nearly vertically downwards and attach to the anterior half or more of the outer lip of the iliac crest. The middle and upper fibres pass downwards and forwards, and end in the anterior aponeurosis, the fibres of which cross the midline. The junction between muscle and aponeurosis extends along an imaginary vertical line from the ninth costal cartilage to just distal to the level of the umbilicus; muscle fibres do not usually descend beyond an imaginary line from the anterior superior iliac spine to the umbilicus.

The inguinal ligament is formed by the inferior margin of the aponeurosis of external abdominal oblique extending between the anterior superior iliac spine and the pubic tubercle. The fibres of the aponeurosis of external abdominal oblique are not parallel to the long axis of the inguinal ligament; they approach the ligament obliquely at an angle of 10–20° and then turn medially to run along the ligament to reach the pubic tubercle (Lytle 1974). The deepest fibres of the aponeurosis spread out posteromedially to insert into the pecten pubis.

The proximal and distal rib attachments of the muscle can be absent. Digitations or even the entire muscle can be duplicated. The proximal attachments of the muscle are sometimes continuous with pectoralis major or serratus anterior.

Vascular supply External abdominal oblique is mainly supplied by branches from the distal posterior intercostal and subcostal arteries proximally and the deep circumflex iliac artery distally. There are additional smaller contributions (Schlenz et al 1999).

Innervation External abdominal oblique is innervated by the ventral rami of the distal six thoracic spinal nerves via the terminal branches of the distal five intercostal nerves and the subcostal nerve.

Actions External abdominal oblique contributes to the maintenance of abdominal tone, increasing intra-abdominal pressure, and lateral flexion of the trunk against resistance.

Inguinal ligament

The inguinal ligament is the thick distal border of the aponeurosis of external abdominal oblique that stretches between the anterior superior iliac spine and the pubic tubercle. Its medial half is curled in on itself, forming the gutter-like 'floor' of the inguinal canal (sometimes referred to surgically as the 'shelving edge'). The ligament is not exactly linear but has an inferior and an anterior convexity. At its distal border it is fused with the fascia lata. Laterally it is fused with the iliopsoas fascia (Lytle 1974). At the medial end of the inguinal ligament, near its site of attachment to the pubic tubercle, some of its fibres extend posteriorly and laterally to attach to the pecten pubis, forming the triangular, shelf-like lacunar ligament. Other fibres pass upwards and medially behind the superficial inguinal ring and external abdominal oblique aponeurosis to join the rectus sheath and linea alba; these constitute the reflected part of the inguinal ligament (Tubbs et al 2009). Fibres from both sides decussate in the linea alba.

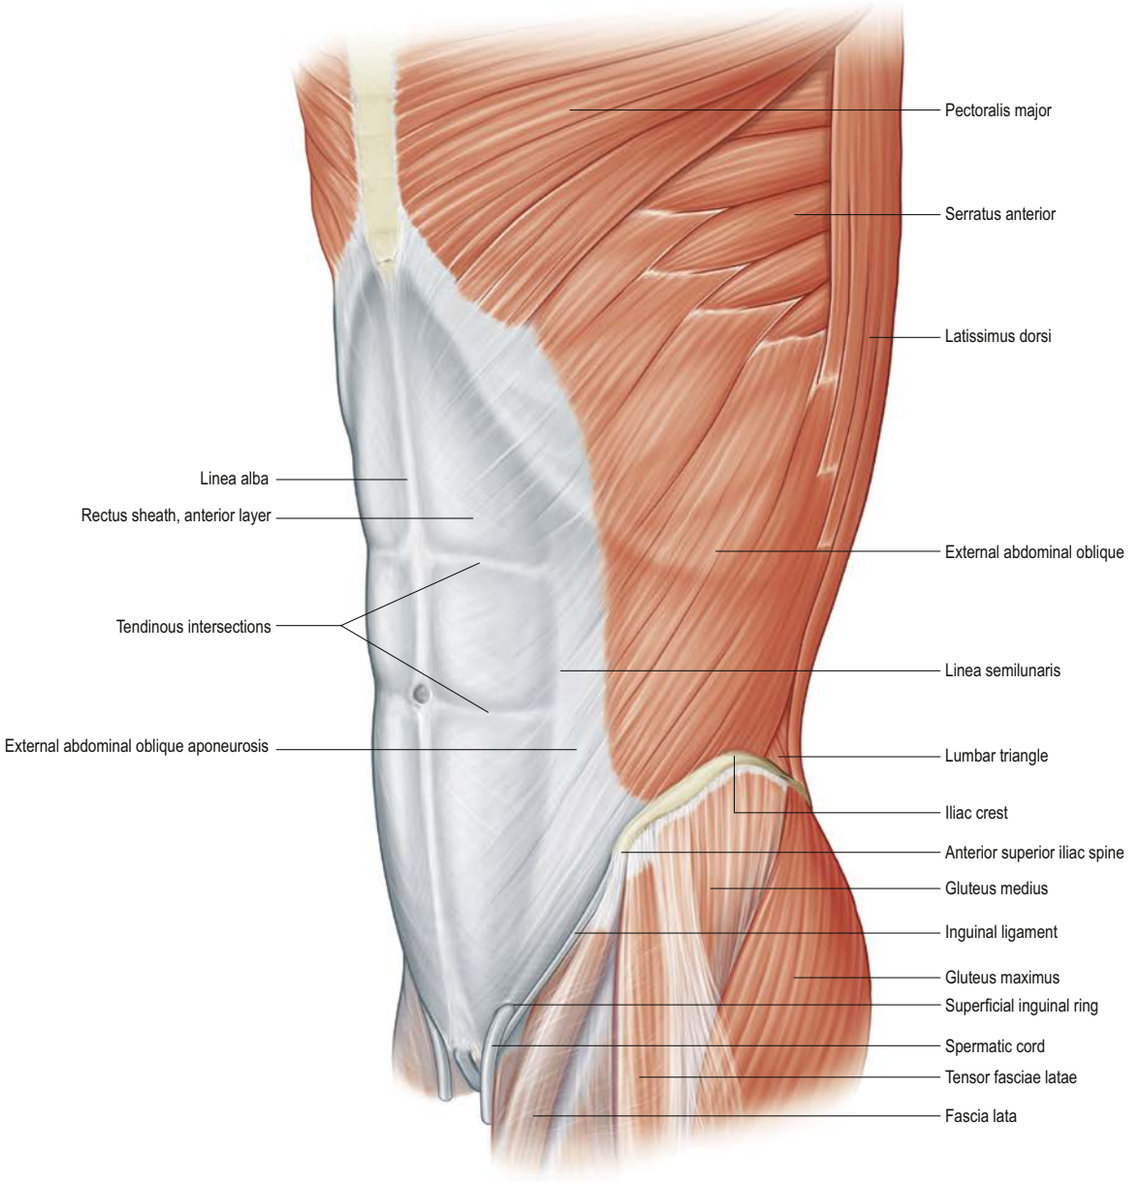

Fig. 60.13 The left anterolateral abdominal wall muscles.

Internal abdominal oblique

Attachments Internal abdominal oblique lies deep to external abdominal oblique for most of its course (see Fig. 60.8). It is thinner and less bulky than external abdominal oblique. Its fibres are traditionally stated to arise from the lateral two-thirds of the inguinal ligament but in fact they arise from the corresponding length of a slightly deeper structure known as the iliopectineal arch (Acland 2008), a thickened band of iliopsoas fascia that passes downwards and medially from the anterior superior iliac spine to the iliopubic eminence of the pubis. Further laterally, internal abdominal oblique is attached to the anterior two-thirds of the iliac crest deep to the attachment of external abdominal oblique. Posteriorly, some fibres are attached to the thoracolumbar fascia. The fibres originating from the posterior end of the iliac attachment pass obliquely upwards and are attached to the inferior borders and tips of the distal three or four ribs and their cartilages. Here, the attachments merge with those of internal intercostal. The fibres from the anterior end of the iliac crest diverge and end in the anterior aponeurosis, which gradually broadens in a distal to proximal direction. The most proximal part of the aponeurosis is attached to the cartilages of the seventh to ninth ribs. The fibres that originate adjacent to the inguinal ligament arch downwards and medially across the spermatic cord in the male and the round ligament of the uterus in the female. They become tendinous, fuse with the corresponding part of the aponeurosis of transversus abdominis, and attach to the pubic crest and medial part of the pecten pubis, forming the conjoint aponeurosis.

Vascular supply Internal abdominal oblique is mainly supplied by branches from the distal posterior intercostal and subcostal arteries, the inferior epigastric artery and the deep circumflex iliac artery. There are several smaller contributions (Yang et al 2003).

Innervation Internal abdominal oblique is innervated by the ventral rami of the distal six thoracic spinal nerves via the terminal branches of the distal five intercostal nerves and the subcostal nerve. In addition, it receives a small contribution derived from the ventral ramus of the first lumbar spinal nerve via the iliohypogastric and ilio-inguinal nerves.

Actions Internal abdominal oblique contributes to the maintenance of abdominal tone, increasing intra-abdominal pressure, and lateral flexion of the trunk against resistance.

Although thinner and less bulky than external abdominal oblique, the muscle undergoes compensatory hypertrophy following surgical release of the external abdominal oblique aponeurosis from its insertion on the anterior layer of the rectus sheath. This operation, a so-called anterior component separation myofascial release, is often performed as part of a complex hernia repair.

Transversus abdominis

Attachments Transversus abdominis is the deepest of the anterolateral abdominal muscles (Fig. 60.14). It is attached to the iliopectineal arch deep to the lateral third of the inguinal ligament, the anterior two-thirds of the inner lip of the anterior part of the iliac crest, the

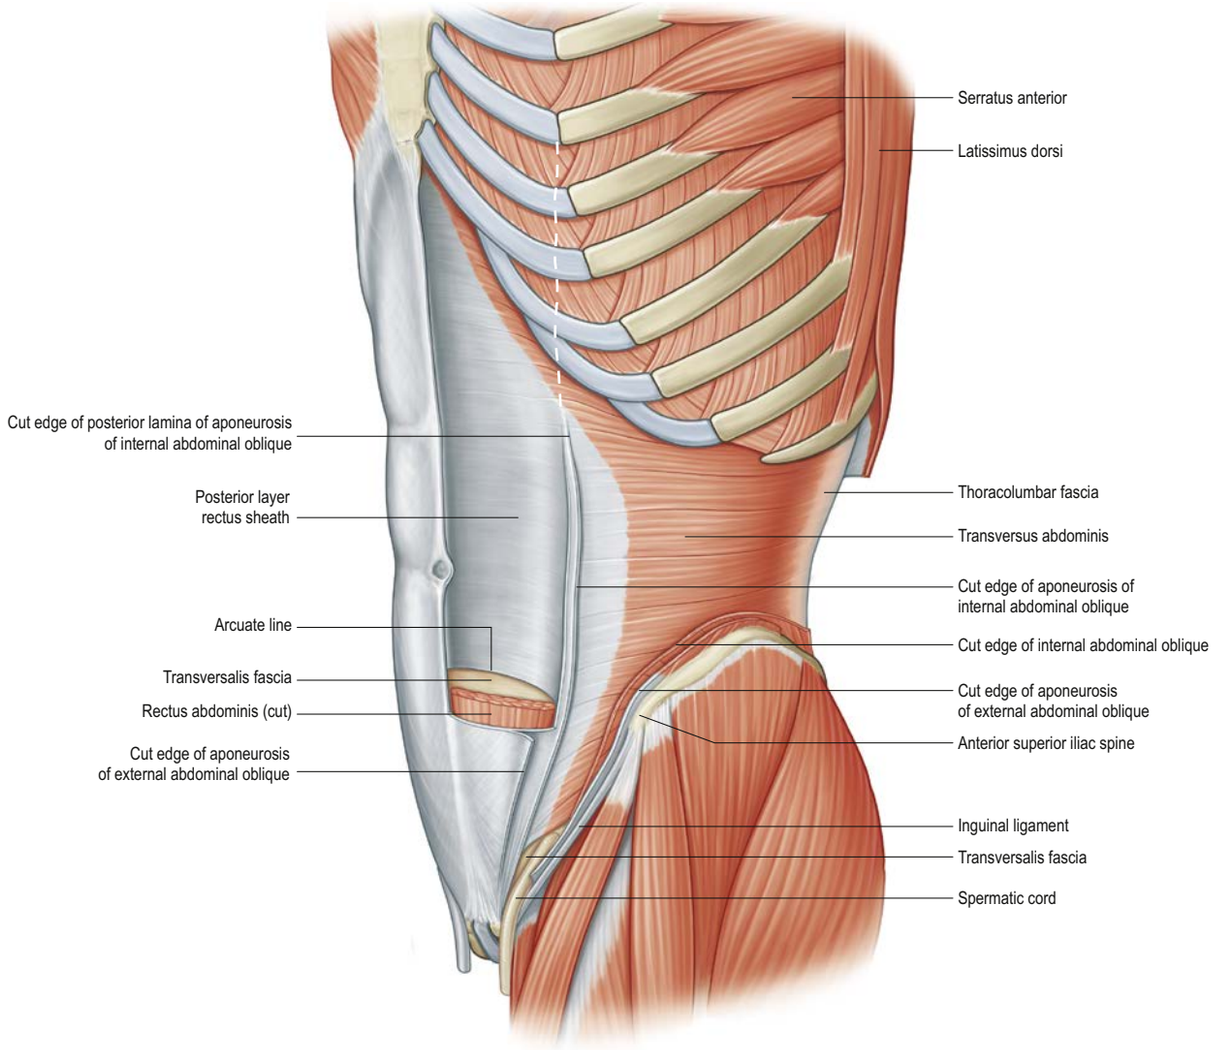

Fig. 60.14 Left transversus abdominis. The aponeurosis of transversus abdominis fuses into the posterior layer of the rectus sheath proximal to the arcuate line. The position of the lateral border of rectus abdominis is shown by the dotted white line.

thoracolumbar fascia between the iliac crest and the twelfth rib, and the internal aspects of the distal six costal cartilages. The costal attachments interdigitate with those of the respiratory diaphragm. The muscle ends anteriorly in an aponeurosis; the distal fibres of the aponeurosis curve downwards and medially, together with those of the aponeurosis of internal abdominal oblique, and insert into the pubic crest and pecten pubis to form the conjoint aponeurosis. A few muscle fibres may run from the distal border of transversus abdominis to the inguinal ligament and reinforce the interfoveolar ligament (see above). The remainder of the aponeurosis passes medially and the fibres decussate at, and blend with, the linea alba. The proximal costal and anterior iliac fibres of transversus abdominis are short and the thoracolumbar fibres are the longest. Near the xiphoid process, the aponeurosis is formed only a few centimetres from the linea alba and so the muscular part of transversus abdominis extends behind rectus abdominis into the posterior layer of the rectus sheath. The medial edge of the muscle, at the origin of the aponeurosis, curves downwards and laterally, and is furthest from the lateral edge of the rectus sheath at the level of the umbilicus. It then curves downwards and medially towards the superficial inguinal ring giving the muscle belly its characteristic half-hourglass shape.

Occasional defects in the distal muscular and aponeurotic parts of both internal abdominal oblique and transversus abdominis result in intermuscular hernia formation (lateral ventral or Spigelian hernia). The two muscles are sometimes fused and, rarely, transversus abdominis is absent (Saga and Takahashi 2016).

Vascular supply Transversus abdominis is supplied by branches from the distal posterior intercostal and subcostal arteries, the superior and inferior epigastric arteries, the superficial and deep circumflex iliac arteries and the lumbar arteries.

Innervation Transversus abdominis is innervated by the ventral rami of the distal six thoracic and first lumbar spinal nerves via the terminal branches of the distal five intercostal nerves, the subcostal nerve and the iliohypogastric and ilio-inguinal nerves.

Actions Transversus abdominis contributes mainly to the maintenance of abdominal tone and increasing intra-abdominal pressure.

Conjoint aponeurosis

The conventional description of a conjoined or conjoint tendon has been challenged since the 1940s, when the alternative term conjoined aponeurosis was proposed on the grounds that it more properly described the distal union of internal abdominal oblique and transversus abdominis (Chandler and Schadewald 1944). A local thickening in the conjoined aponeurosis that might be called a conjoint tendon occurs rarely. (For a review of the literature associated with Henle's ligament, falx inguinalis, conjoined tendon, conjoined area, conjoint tendon and conjoint area, see Gnanadev et al (2018).)

The conjoint aponeurosis is formed from the distal fibres of internal abdominal oblique and the distal part of the aponeurosis of transversus abdominis. It is attached to the pubic crest and extends to a variable extent along the pecten pubis (see Fig. 60.18). It descends behind the superficial inguinal ring and acts to strengthen the medial portion of the posterior wall of the inguinal canal. Medially, the proximal fibres of the aponeurosis fuse with the anterior layer of the rectus sheath, and laterally, some fibres can blend with the interfoveolar ligament.

Cremaster

Attachments Cremaster consists of loosely arranged muscle fasciculi lying along the spermatic cord or round ligament of the uterus. It is

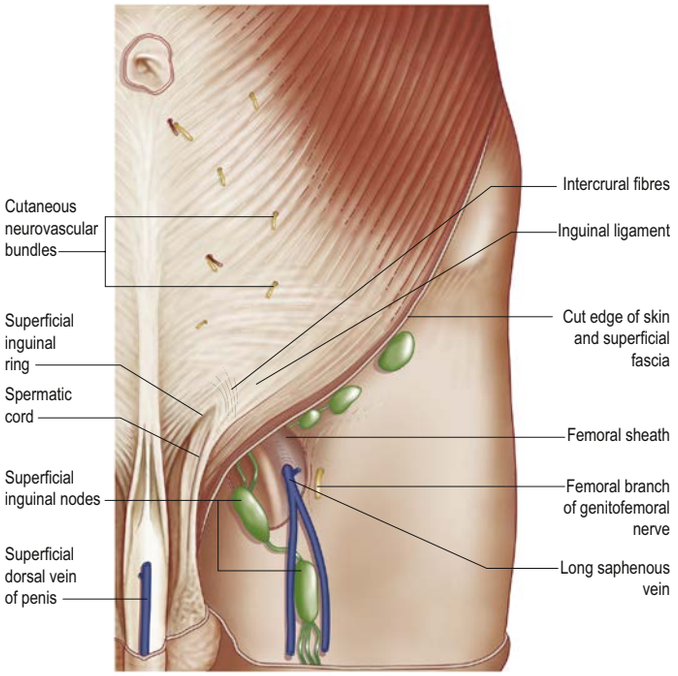

Fig. 60.15 Superficial structures of the inguinal region and distal part of the anterior abdominal wall on the left side.

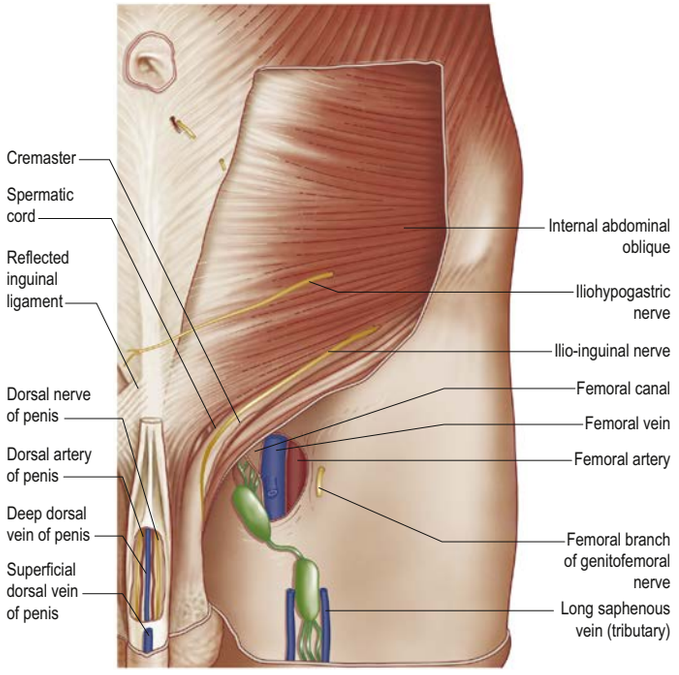

Fig. 60.16 Dissection of the regions shown in Fig. 60.15, with part of external abdominal oblique removed.

variable in thickness but thickest in young males. Together with connective tissue, it forms an incomplete coating around the spermatic cord known as the cremasteric fascia, which extends down around the testis deep to the external spermatic fascia. The muscle consists of a lateral part that arises mainly from the inferomedial border of internal abdominal oblique and transversus abdominis but also has attachments to the middle of the inguinal ligament, and a medial part attached to the pubic tubercle, lateral pubic crest and the distal border of transversus abdominis; this part is variably developed and can be absent (Shafik 1977). The longitudinal muscle fibres spread out over the spermatic cord as it approaches the superficial inguinal ring. Cremaster is composed of both striated and smooth muscle fibre bundles (Schwarz and Hirtler 2017).

Vascular supply Cremaster is supplied by the cremasteric artery, a branch of the inferior epigastric artery.

Innervation Cremaster is innervated by the genital branch of the genitofemoral nerve, derived from the first and second lumbar spinal nerves.

Actions Cremaster pulls the testis up towards the superficial inguinal ring. Although it contains striated muscle fibres, it is not usually under voluntary control. Stroking the skin of the medial side of the thigh evokes a reflex contraction of the muscle, the cremasteric reflex, which is most pronounced in boys and may be a protective reflex. Cremaster could also be involved in testicular thermoregulation since it is activated by the cold.

Inguinal canal

The inguinal canal is a natural passageway between the muscle layers of the anterior abdominal wall in the inguinal region (Lytle 1979) (**Figs 60.15–60.17**; see Figs 74.15–74.16). Its size and form vary with age, and although it is present in both sexes it is best developed in males. The canal is an oblique tunnel with deep and superficial openings or rings. It transmits the spermatic cord in males, the round ligament of the uterus in females, and the ilio-inguinal nerve and genital branch of the genitofemoral nerve in both sexes.

Superficial inguinal ring

The superficial inguinal ring is a hiatus in the aponeurosis of external abdominal oblique, just proximal and lateral to the pubic crest. The ring is actually triangular, its apex pointing laterally towards the anterior superior iliac spine. Although it varies in size it does not usually extend laterally beyond the medial third of the inguinal ligament. It is smaller in females. The base of the triangular opening lies along the pubic crest and its sides are the lateral and medial crura of the opening in the aponeurosis. The lateral crus is stronger and is attached to the pubic tubercle. The medial crus is thinner and its fibres attach to the front of the pubic symphysis and interlace with contralateral fibres. A few

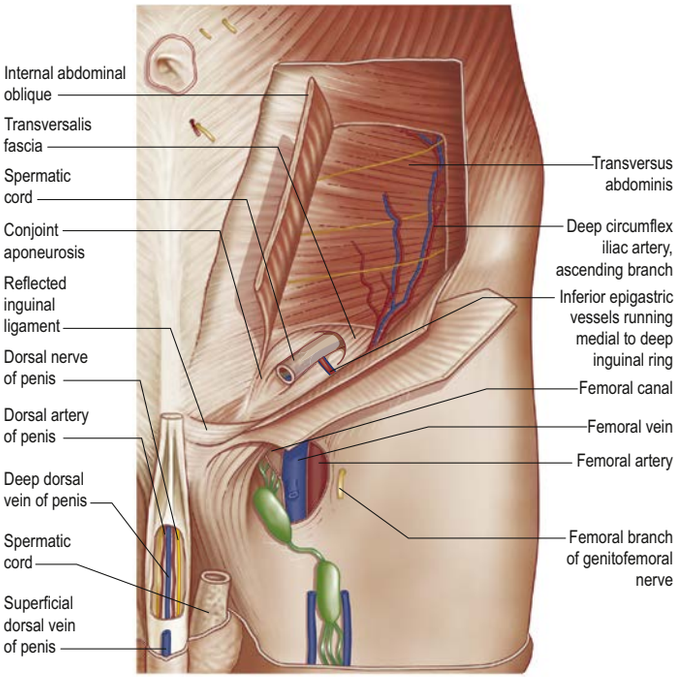

Fig. 60.17 Dissection of the inguinal region and distal part of the anterior abdominal wall on the left side, with parts of external and internal abdominal oblique removed.

intercrural fibres arch proximal to the apex of the superficial inguinal ring (see Fig. 60.15). Some fibres from the aponeurosis of external abdominal oblique and its overlying fascia continue downwards from the medial crus over the spermatic cord, and form the delicate external spermatic fascia; consequently, the superficial 'ring' appears less of a discrete opening.

Deep inguinal ring

The deep inguinal ring is an opening in the transversalis fascia, approximately midway between the anterior superior iliac spine and the pubic symphysis, and about 1 cm proximal to the inguinal ligament (Hale et al 2010). It is oval with a roughly vertical long axis. Its size varies among individuals but it is usually 1–2 cm wide in adults and larger in males. It is related superiorly to the arched distal margin of transversus abdominis and medially to the interfoveolar ligament (see Fig. 60.18). The inferior epigastric vessels run in the medial border of the deep inguinal ring. Traction on the fascial ring exerted by contraction of

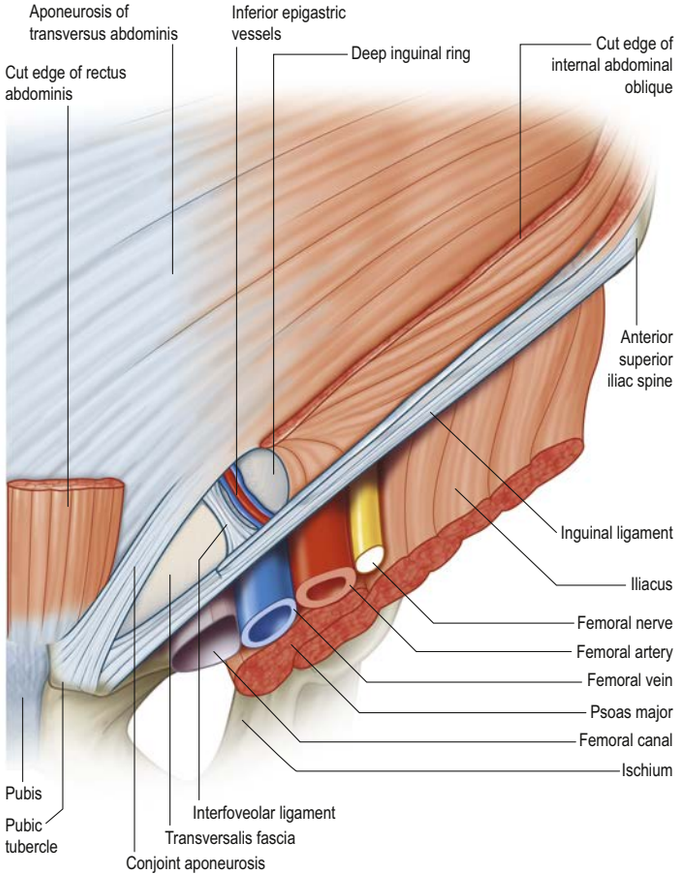

Fig. 60.18 Deep structures of the inguinal canal. The aponeurosis of external abdominal oblique has been removed. For clarity, the fibres of internal abdominal oblique and rectus abdominis have been divided, and the structures passing postero-inferiorly to the inguinal ligament have been excluded.

internal abdominal oblique can narrow the opening when intra-abdominal pressure is increased.

Boundaries

The inguinal canal slants obliquely downwards and medially, parallel to and just proximal to the medial part of the inguinal ligament. It extends from the deep to the superficial inguinal rings; its length depends on the age of the individual, but in adults it is 3–6 cm. The canal is bounded anteriorly by skin, superficial fascia and the aponeurosis of external abdominal oblique. In its lateral third the anterior wall is reinforced by the muscular fibres of internal abdominal oblique. Posteriorly, the reflected inguinal ligament, the conjoint aponeurosis and the transversalis fascia separate it from extraperitoneal connective tissue and peritoneum. Superiorly, the arched fibres of internal abdominal oblique and transversus abdominis form the conjoint aponeurosis medially. Inferiorly, the transversalis fascia unites with the inguinal ligament; the lacunar ligament lies at the medial end.

In the newborn the deep and superficial inguinal rings are nearly superimposed and the inguinal canal is extremely short, only about 1 cm long (Parnis et al 1997). As a child grows, the anterior abdominal wall muscles develop further, causing the rings to separate and the inguinal canal to lengthen. The canal becomes progressively more oblique, so by adulthood it has separate anterior and posterior walls. As the arched fibres of internal abdominal oblique and transversus abdominis contract, they straighten and move closer to the inguinal ligament. This motion serves as a protective mechanism against hernia formation, the so-called 'shutter' effect. At the superficial inguinal ring and the medial end of the anterior wall of the inguinal canal, where the canal is weakest, the posterior wall is strengthened by the conjoint aponeurosis and reflected inguinal ligament. Increases in intra-abdominal pressure transmitted to the posterior wall of the canal are resisted by contraction of the three anterolateral abdominal wall muscles. The fibres of internal abdominal oblique and transversus abdominis, which form the conjoint aponeurosis, are constantly active in standing; this activity increases during episodes of increased intra-abdominal pressure.

Lacunar ligament

The lacunar ligament is a triangular band of fibrous tissue lying mainly posterior to the medial end of the inguinal ligament. It measures approximately 2 cm from base to apex and is a little larger in males. It is formed by fibres of the medial end of the inguinal ligament and fibres from the fascia lata that join the medial end of the inguinal ligament distally (Lytle 1974). The fibres of the inguinal ligament run posteriorly and laterally to the medial end of the pecten pubis and are continuous with the fascia associated with pectineus. They form a near-horizontal, triangular sheet with a curved lateral border that forms the medial border of the femoral canal. The apex of the triangle is attached to the pubic tubercle. A strong fibrous band, the pectineal ligament (Cooper's ligament), extends laterally along the pecten pubis from the attachment of the lacunar ligament (Faure et al 2001).

Relations

The inferior epigastric vessels are important medial relations of the deep inguinal ring (**Fig. 60.18**). They lie on the transversalis fascia as they ascend obliquely behind the conjoint aponeurosis to enter the rectus sheath. The inguinal triangle is an important clinical landmark related to the posterior wall of the inguinal canal and is best appreciated by examining the inguinal canal region from within the abdomen (see Fig. 60.3). The triangle is bounded inferiorly by the medial third of the iliopubic tract, medially by the distal lateral border of rectus abdominis, and laterally by the inferior epigastric vessels.

Myofascial flaps and component separation

Available with the *Gray's Anatomy* e-book

HERNIAS OF THE ANTERIOR ABDOMINAL WALL

A wide range of spontaneously occurring anterior abdominal wall hernias has been described, including inguinal, femoral, umbilical, epigastric and Spigelian (Larson and Farley 2002, Dabbas et al 2011, Novitsky 2016). These hernias occur at areas of intrinsic weakness in the layers of the abdominal wall, whereas incisional hernias are a common postoperative complication of surgery and can occur at any location in the abdominal wall.

Hernias of the myopectineal orifice

The myopectineal orifice (of Fruchaud) (see Fig. 60.3) is the surgical name given to the inferomedial aspect of the anterior abdominal wall. It encompavsses the deep inguinal ring, the inguinal triangle and the portal inferior to the inguinal ligament that transmits femoral neurovascular structures (Wolloscheck and Konerding 2009). The inguinal ligament travels diagonally through the myopectineal orifice dividing it into two parts. Although the myofascial anatomy is arranged to support these areas of weakness (e.g. the deep inguinal ring, the superficial inguinal ring, the femoral canal and the inguinal triangle), the region is a common site of herniation, particularly in males. Such hernias are described by their origin within the pelvic cavity into inguinal hernias (direct and indirect) or femoral hernias (**Fig. 60.19**).

Indirect inguinal hernia

An indirect inguinal hernia arises through the deep inguinal ring lateral to the inferior epigastric vessels (see Fig. 60.19A). Many indirect hernias are related to the abnormal persistence of a patent processus vaginalis, a tube-like extension of peritoneum through the inguinal canal that is present during normal development and normally becomes occluded soon after birth. Others are acquired as a result of progressive weakening of the posterior wall of the inguinal canal in the region of the deep inguinal ring. The hernia can pass through the deep inguinal ring or expand the deep inguinal ring such that it is no longer a clear entity. Small indirect hernias lie distal and lateral to the fibres of the conjoint aponeurosis, but larger hernias often distort and thin the tendon superiorly. Small indirect hernias that do not protrude beyond the inguinal canal are covered by the same inner layers as the spermatic cord: namely, the internal spermatic fascia and cremaster. If the hernia extends through the superficial inguinal ring, it is also covered by the external spermatic fascia. In hernias related to a persistent fully patent processus vaginalis, the hernia contents can descend as far as the tunica vaginalis anterior to the testis. In many individuals with a partial or fully patent processus vaginalis, an indirect hernia manifests during childhood; but an actual hernia into the potential sac may not develop until adult life, often as a consequence of increased intra-abdominal pressure or sudden muscular strain.

The goal of repairing massive midline ventral hernias lies in re-approximation of the linea alba, thereby restoring anatomy and maximizing the physiological potential of the anterior abdominal wall. However, large fascial defects often will not permit primary re-approximation without undue tension. Many techniques have been developed that use the layered nature of the abdominal wall musculature, allowing additional mobiliztion of the fascial edges by 'releasing' incisions in myofascial layers (Rosen 2017). These repairs are often reinforced with synthetic or bioprosthetic mesh applied in various ways: onlay (superficial to the superficial fascia), sublay (within the myofascial layers or placed in an extraperitoneal position) or underlay (deep to the peritoneum and exposed to intra-abdominal contents).

Anterior component separation, originally described by Ramirez in 1990, refers to bilateral release of the external abdominal oblique muscles, which potentially can provide up to 10 cm, 20 cm and 8 cm of medial mobilization at the proximal, mid and distal abdomen, respectively (Ramirez et al 1990). This mobilization permits midline approximation of rectus muscles and creates a large pocket for the onlay placement of mesh. A disadvantage of this technique is that in order to access and isolate external abdominal oblique lateral to the semilunar line from a midline incision, large subcutaneous flaps must be raised. This necessitates ligation of perforating vessels that supply the overlying subcutaneous tissue, rendering the flaps vulnerable to ischaemia, necrosis and infection. In an attempt to overcome this limitation, methods of external abdominal oblique release have been developed to preserve the periumbilical perforating vessels that traverse rectus abdominis and the anterior layer of the rectus sheath. Endoscopic techniques access the same myofascial layer through smaller, lateral incisions, while perforating-sparing open techniques create a subcutaneous tunnel proximal and distal to the umbilicus that is connected laterally (thus preserving all the blood supply that enters the abdominal wall near the umbilicus). While reducing the likelihood of wound necrosis and infection, these methods also reduce the maximum medial advancement by 1–2 cm on each side and do not create the large pocket necessary for onlay placement of mesh. When the release of external abdominal oblique is insufficient, an additional 2–4 cm of fascial advancement can be gained by simultaneous release of the posterior layer of the rectus sheath. A posterior layer of the rectus sheath release can also be added to create a pocket deep to rectus abdominis for the sublay placement of mesh, which for a variety of reasons could be preferable to onlay placement of mesh.

The posterior layer of the rectus sheath can be incised independently of external abdominal oblique release, allowing access to the retromuscular space and providing several other options for medial advancement. The traditional Rives–Stoppa–Wantz technique, developed during the 1970s, involves incising the posterior layer of the rectus sheath just lateral to the linea alba, allowing a retromuscular dissection to the lateral edge of the rectus sheath. If this does not gain sufficient medial advancement, further extension can be obtained by release of transversus abdominis (Novitsky et al 2012). The posterior layer of the rectus sheath can again be incised 1–2 cm medial to the semilunar line, safely preserving the laterally perforating neurovascular bundles. The division of the posterior lamella of internal abdominal oblique exposes the underlying transversus abdominis muscle belly. Delicate transection of this muscle at its most medial insertion allows access to a plane deep to transversus abdominis and superficial to the transversalis fascia, extraperitoneal fat and peritoneum. This plane of dissection can be extended laterally to psoas major, inferiorly to the retropubic space (of Retzius), and superiorly beneath the respiratory diaphragm.

The same extraperitoneal plane can be entered directly at the linea alba. While this allows for lateral dissection, it does not provide the benefit of any fascial advancement/release. Moreover, the peritoneum is exceptionally thin and can be particularly adherent to the transversalis fascia. As a result, holes are created in predictable locations during an extraperitoneal hernia repair (such as at the costal arch and at the semilunar line at the level of the umbilicus).

In addition to the medial mobilization of fascia aided by myofascial flap component separations, these myofascial planes allow for mesh reinforcement with extensive overlap of the hernia defect. They also prevent mesh exposure to intra-abdominal contents (Heller et al 2012). Multiple other component separation operations have been described, several of which necessitate division of the neurovascular bundles that enter rectus abdominis laterally. While affording medial tissue advancement and wide mesh overlap, these operations result in denervation of rectus abdominis and can lead to abdominal wall dysfunction.

Incorrectly performed component separation procedures can result in unintended complete division of the semilunar line. This devastating complication results in iatrogenic hernias lateral to rectus that can extend from the costal arch to the inguinal ligament. Options for repairing these defects are limited, which makes a robust knowledge of abdominal wall anatomy critical for the surgeon performing such operations.

Indirect inguinal hernias are present in as many as 3–5% of full-term infants and upwards of 30% of premature babies. They are more common on the right (60%) than the left (25%) and less commonly bilateral (15%). They can go unnoticed at the time of birth, but become apparent as a bulge in the inguinal region noticed when the baby is crying.

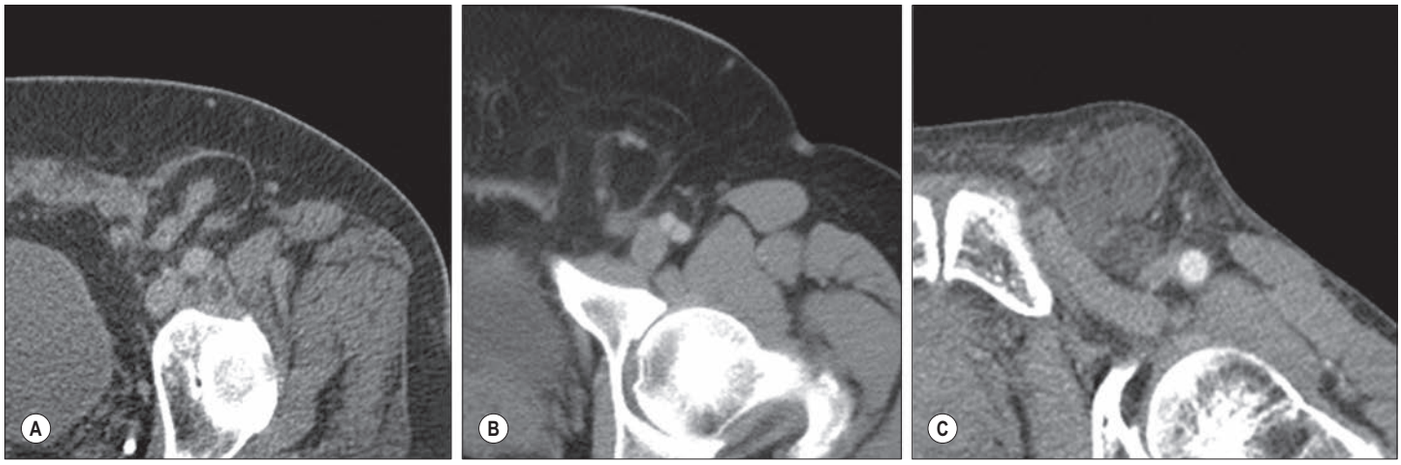

Fig. 60.19 CT of hernias of the myopectineal orifice. **A**, Indirect hernia occurring lateral to the inferior epigastric vessels containing part of the sigmoid colon. **B**, Direct inguinal hernia occurring medial to the inferior epigastric vessels containing extraperitoneal fat. **C**, Incarcerated femoral hernia occurring medial to the femoral vein and containing ischaemic omental fat.

Direct inguinal hernia

A direct inguinal hernia arises medial to the inferior epigastric vessels, within the inguinal triangle (see Fig. 60.19B). Direct hernias are caused by an acquired weakness of the posterior wall of the inguinal canal (see Fig. 60.3B); as they enlarge, they frequently extend through the anterior wall of the inguinal canal or superficial inguinal ring, becoming covered by the external spermatic fascia in the process. A direct inguinal hernia can closely resemble an indirect hernia and can be difficult to distinguish on physical examination.

Clinical features of inguinal hernias

Available with the *Gray's Anatomy* e-book

Femoral hernia

The femoral sheath is continuous with the transversalis fascia anteriorly and the iliopsoas fascia posteriorly. The medial compartment of the sheath is the femoral canal, which typically contains lymphatics embedded in loose adipose connective tissue. The opening of this canal is the femoral ring, bounded anteriorly by the inguinal ligament, posteriorly by the pectineal ligament, medially by the crescentic lateral margin of the lacunar ligament and laterally by the femoral vein. A femoral hernia protrudes through the femoral ring, which is normally closed by a femoral septum of extraperitoneal tissue and is therefore a site of potential weakness: variations in the attachment of the lacunar ligament can also contribute to hernia formation.

Umbilical hernia

Umbilical defects arise from a failure of closure of the umbilical ring after return of the herniated midgut loop into the embryo. The most common variety of umbilical hernia is caused by a weakness of the umbilical scar tissue and is often seen in babies, especially those of African descent. Unlike inguinal hernias in infants, which require surgical repair, the vast majority of umbilical hernias will eventually close spontaneously during early childhood. Most umbilical hernias in adults are acquired as a result of stretching the supporting umbilical fascia (Fig. 60.20), commonly as a result of obesity and chronically increased intra-abdominal pressure (e.g. multiple pregnancies or ascites). The most extreme variety of umbilical hernia is known as an omphalocele or exomphalos, a congenital anomaly in which abdominal viscera, covered by a membrane, protrude through a wide umbilical defect (Fig. 60.21).

Epigastric hernia

Epigastric hernias arise from defects caused by incomplete fusion of the bilateral fibres that decussate to form the linea alba and represent 2–3% of all abdominal wall hernias. They are generally small (often too small to palpate) and asymptomatic, although they can be a source of pain and discomfort if extraperitoneal fat becomes trapped in the defect (Fig. 60.22).

Spigelian hernia

A Spigelian hernia is a protrusion of extraperitoneal fat or a peritoneal sac through a congenital or acquired defect in the abdominal wall in the region of the intersection of the semilunar line with the arcuate line (Larson and Farley 2002, Skandalakis et al 2006). Distal to this level, the aponeuroses of external and internal abdominal oblique and transversus abdominis all pass anterior to rectus abdominis and the posterior layer of the rectus sheath ends. A Spigelian hernia is an interstitial (or intraparietal) hernia in that the hernia passes through a defect in the aponeuroses of transversus abdominis and internal abdominal oblique but remains deep to the overlying aponeurosis of external abdominal oblique (Fig. 60.23). Because external abdominal oblique is intact, the fascial defect cannot be palpated on physical examination, often leading to a delay in diagnosis.

Incisional hernia

Incisional hernias comprise as many as 20% of all anterior abdominal wall hernias. They arise as a postoperative complication of abdominal incisions as a result of technical failures, wound infection and patient-related factors such as obesity, smoking, medical comorbidities and old age (Carlson et al 1995). Incisional hernias range in size from a few millimetres (hernias related to laparoscopic port site incisions) to massive defects that contain most of the abdominal contents and include a large fascial defect (Fig. 60.24).

Overall, transversus abdominis release could be an important addition to the armamentarium of surgeons undertaking major abdominal wall reconstructions.

Indirect inguinal hernias descend from lateral to medial, following the path of the inguinal canal, whereas direct inguinal hernias tend to protrude more directly anteriorly. With the hernia reduced, pressure applied over the region of the deep inguinal ring can prevent the appearance of an indirect hernia on standing or straining, but even so, distinguishing an indirect from a direct inguinal hernia by physical examination alone is not reliable (Ralphs et al 1980, Tromp et al 2014). Direct hernias are more likely to have a wide neck, making strangulation less likely.

In females, the femoral ring is relatively wider and it changes during pregnancy, which helps to explain why femoral hernias account for about 20% of all inguinal hernias in females but less than 1% of inguinal hernias in males (Whalen et al 2011). The ring also widens with advancing age, which is one reason why femoral hernias are more common in older females. Nevertheless, inguinal hernias remain the most common hernias in females and the elderly, despite a higher prevalence of femoral hernias in this patient demographic.

When a tongue of omentum or a loop of intestine bulges through the ring, it pushes out a hernia sac of peritoneum that is covered by extraperitoneal tissue (the femoral septum) and descends within the femoral canal to the saphenous opening (see Fig. 60.19C). It is prevented from descending further by the configuration of the femoral sheath and by the attachment of fascia to the inferior horn of the saphenous opening. The hernia sac can turn anteriorly, stretching the cribriform fascia and curving upwards over the inguinal ligament within the subcutaneous tissues. While in the canal, the hernia is usually small because it is contained by the surrounding tissues, but it enlarges as it expands into the subcutaneous tissues.

The small size and anatomical location of femoral hernias explains why they can easily be missed on physical examination, particularly in obese individuals. They are also much more prone to strangulation than inguinal hernias (Whalen et al 2011). The site of strangulation varies: it can be at the neck of the hernia sac, at the saphenous opening, or at the junction of the falciform margin of the saphenous opening with the free edge of the lacunar ligament. If the lacunar ligament must be divided to widen the neck of the hernia and to permit reduction of the herniated contents, care must be taken to avoid or control an aberrant obturator artery (see above).

The pubic tubercle can be a useful landmark during attempts to distinguish an inguinal from a femoral hernia: a femoral hernia lies distal and lateral to this landmark, whereas an inguinal hernia is proximal to it. However, clinical differentiation of inguinal region hernias can be relatively unreliable (Hair et al 2001), prompting the use of radiological imaging in suspected cases (Whalen et al 2011).

There is currently little consensus among surgeons as to the optimum method of repairing incisional hernias: numerous techniques have been described (Cassar and Munro 2002). Repairs can be conducted open, laparoscopically or robotically. They may or may not involve the use of mesh (of which there are hundreds of varieties), which can be placed in multiple locations among the layers of the abdominal wall. They can involve separating myofascial or lipocutaneous flaps to effect a repair. Needless to say, an understanding of abdominal wall anatomy is paramount in providing a durable repair without compromising physiological function.

Parastomal hernias are a sub-class of incisional hernias. When the gastrointestinal or urinary systems are no longer able to remain in continuity (for any number of reasons), a loop of intestine is delivered through rectus abdominis to serve as a conduit for stool or urine. When this myofascial trephine expands it can permit the omentum, a loop of intestine, or the stoma loop itself to herniate into the subcutaneous tissues (**Fig. 60.25**). Parastomal hernias are exceptionally common, occurring in up to 50% of all patients with an ostomy, and are often found in association with midline incisional hernias. They represent an extraordinarily challenging clinical problem because the ostomy loop of intestine and the myofascial orifice defect must remain at the conclusion of the repair. This has implications for mesh configuration, mesh interaction with the intestine, the risk of mesh infection and the likelihood of hernia recurrence.

CHAPTER 61

Posterior abdominal wall and retroperitoneum

DEFINITIONS, BOUNDARIES AND CONTENTS

The posterior abdominal wall has no agreed uniform definition. It is the posterior boundary of the abdominal cavity, and in common with the anterior and lateral abdominal walls, it is composed of several layers (skin, superficial fascia, muscle, extraperitoneal fat/fascia and parietal peritoneum). The vertebral column and paravertebral muscles are part of the posterior abdominal wall, but are usually discussed as part of the back. The posterior abdominal wall is continuous with the posterior thoracic wall at the posterior attachment of the respiratory diaphragm, with the posterior wall of the pelvis inferiorly, and with the anterolateral abdominal wall laterally.

The retroperitoneum is nestled between the posterior abdominal wall and its lining layer of posterior parietal peritoneum. Inferiorly and laterally, it is continuous with the extraperitoneal connective tissues lining the pelvis and anterolateral abdominal wall, respectively. The posterior border of the retroperitoneum is variably defined, depending on whether psoas major and quadratus lumborum are regarded as its contents or boundaries. Advances in cross-sectional imaging techniques have improved our understanding of the anatomy of the retroperitoneum but terminology is not standardized with regard to its components. Terms such as spaces, compartments, subcompartments, recesses and domains have been used to describe the whole and parts of this region.

The retroperitoneum houses parts of the gut tube in whole or in part, namely the duodenum, and the ascending and descending colons, and their vessels and nerves; and the pancreas, kidneys, ureters and suprarenal glands and their vessels and nerves. The mesentery of the small intestine, transverse and sigmoid colons and the ligaments of the liver and spleen all arise from the posterior parietal peritoneum as it covers the posterior abdominal wall. The retroperitoneum also contains the abdominal aorta and its branches; the inferior vena cava and its tributaries; the origins of the azygos and hemiazygos veins; the pre- and lateral aortic nodes, the cisterna chyli and the origin of the thoracic duct; the diaphragmatic crura; the lumbar plexus and lumbosacral trunk; and the autonomic plexuses of the abdomen.

SKIN AND SOFT TISSUES

The skin of the posterior abdominal wall is supplied by musculocutaneous branches of the lumbar arteries and veins, and is innervated by the dorsal rami of the lower thoracic and lumbar spinal nerves. The cutaneous distribution of the dorsal rami of the fourth and fifth lumbar spinal nerves is variable and controversial (Lee et al 2008).

Various fascial and connective tissues within the retroperitoneum have been defined and used to divide this region into smaller parts: the boundaries of these smaller parts are not universally agreed and clinical observations often do not support the described anatomical margins (Dodds et al 1986).

Thoracolumbar fascia

The thoracolumbar fascia is a complex arrangement of multilayered fascial planes and aponeurotic sheets that separates the paraspinal muscles from the muscles of the posterior abdominal wall (quadratus lumborum and psoas major) (Willard et al 2012) (**Figs 61.1–61.3**; see Fig. 46.6). It is most prominent at the caudal end of the lumbar spine where layers of aponeurotic tissue unite and blend to form a thickened brace between the two posterior superior iliac spines and extend caudally to reach the ischial tuberosities. The thoracolumbar fascia is described in detail in Chapter 46.

Iliopsoas fascia

Psoas fascia

The anterior surface of psoas major is covered by a relatively dense layer of fascia. Medially, this fascia is continuous with the attachments of the muscle to the transverse processes and bodies of the lumbar vertebrae. Laterally, it blends with the fascia over quadratus lumborum superiorly and is continuous with the iliac fascia inferiorly. Superiorly, it merges with the medial arcuate ligament; inferiorly, it extends into the thigh around the tendon of iliopsoas. The psoas fascia separates the anterior surface of the muscle and the lumbar plexus within it from the retroperitoneal structures lying anteriorly. An abscess within psoas major, which can arise by haematogenous seeding or by direct extension of infection from adjacent structures, e.g. the spine, kidneys or colon, often tracks along the muscle within the fascia.

Iliac fascia

The iliac fascia overlies iliacus. Superiorly and laterally it is attached to the inner aspect of the iliac crest, and medially it blends with the anterior layer of the thoracolumbar fascia over quadratus lumborum and with the psoas fascia. Inferiorly and laterally it continues into the thigh to fuse with the femoral sheath, while medially it is attached to the periosteum of the ilium and iliopubic eminence near the linea terminalis. Both the femoral nerve and lateral femoral cutaneous nerve lie under the iliac fascia in the pelvis, where they can be targeted for image-guided anaesthetic nerve blockade (Hebbard et al 2011).

Visceral fasciae

The organization of the retroperitoneum is most easily conceptualized in terms of subsections rather than delineation by fasciae (Dodds et al 1986). The fasciae bounding these parts are variable and difficult to see on cross-sectional imaging. Moreover, clinical observations of the spread of pathological fluids and air often do not match anatomically defined fascial boundaries.

The fascial layers located between the parietal peritoneum lining the posterior abdominal wall and quadratus lumborum have been described in confusing eponymous terms in the literature. Different authors have used the same eponym for different fasciae; different eponyms have been used to refer to the same fascia. For example, 'Gerota's fascia' has been used to denote the entire renal fascia or to its anterior or posterior layers (Chesbrough et al 1989). 'Toldt's fascia' has been used to denote the fusion fascia behind the ascending or descending colon (Culligan et al 2013), or the posterior layer of renal fascia, or the fusion fascia posterior to the tail of the pancreas (Kimura et al 2010). 'Zuckerkandl's fascia' has been used to refer to the posterior or anterior layers of renal fascia (Chesbrough et al 1989). 'Treitz's fascia' has been used to describe the fusion fascia behind the head of the pancreas (Kimura et al 2010). The concept of 'fusion fascia' describes a retroperitoneal fascia formed by the fusion of an embryonic mesentery with the anterior wall of the embryonic retroperitoneum (Hikspoors et al 2019). It is an avascular layer that allows a dissection plane to be developed and also limits the spread of disease. Many of these fasciae and the subsections they create are not recognized in *Terminologia Anatomica* but are well established in the clinical literature and are discussed below.

Traditional teaching of the retroperitoneum divides it into the anterior and posterior pararenal spaces and the perirenal space. The anterior pararenal space lies between the parietal peritoneum lining the posterior abdominal wall and the anterior layer of renal fascia. This oversimplification fails to explain all patterns of disease containment or spread (Dodds et al 1986). The smallest set of divisions within the retroperitoneum sufficient to explain most such phenomena is as follows. Some of the spaces are illustrated in the context of clinical disease in **Figs 61.4-61.6**.

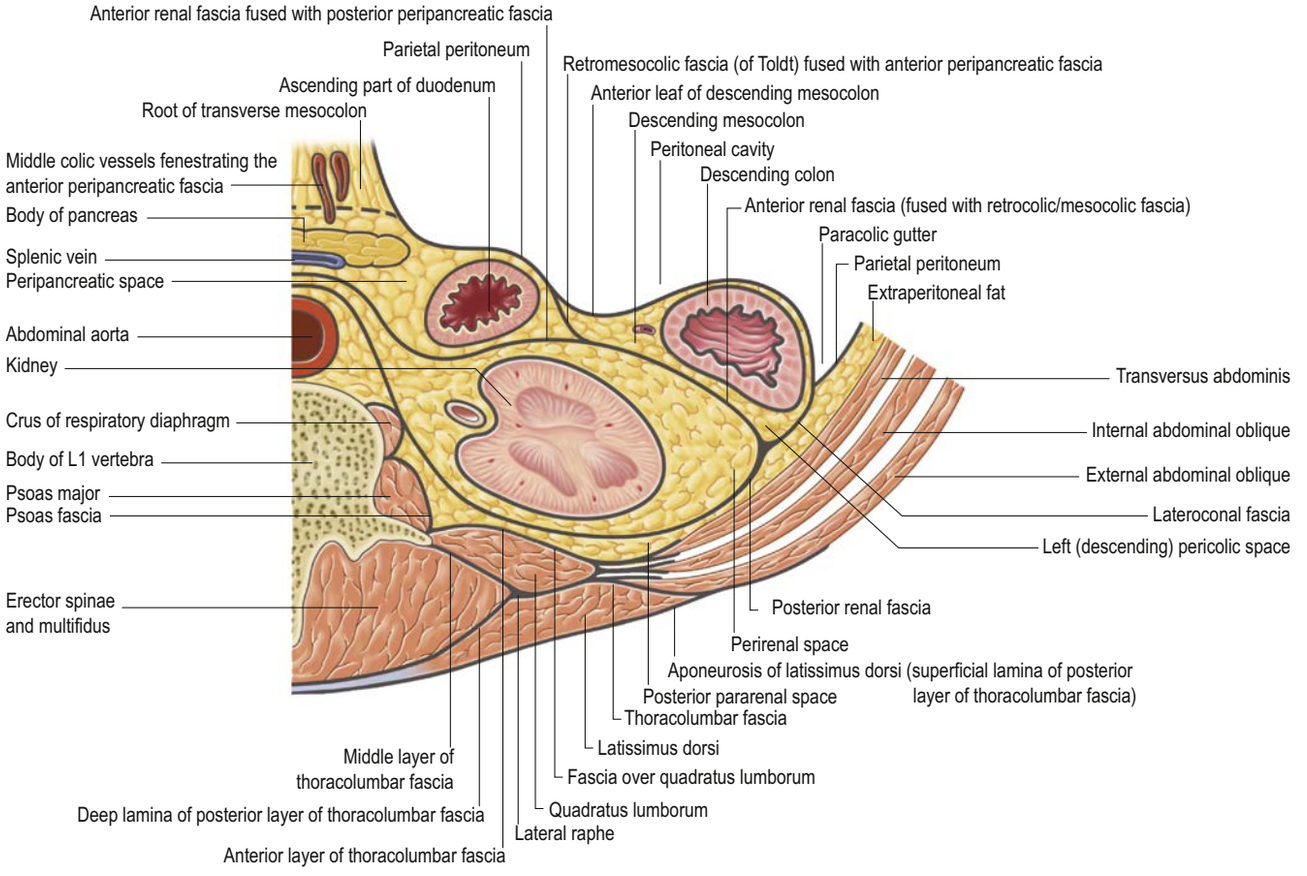

Fig. 61.1 Anatomy of the upper retroperitoneum (left side). A transverse section at approximately the level of the first lumbar vertebra, showing the location and relationships of the peripancreatic space.

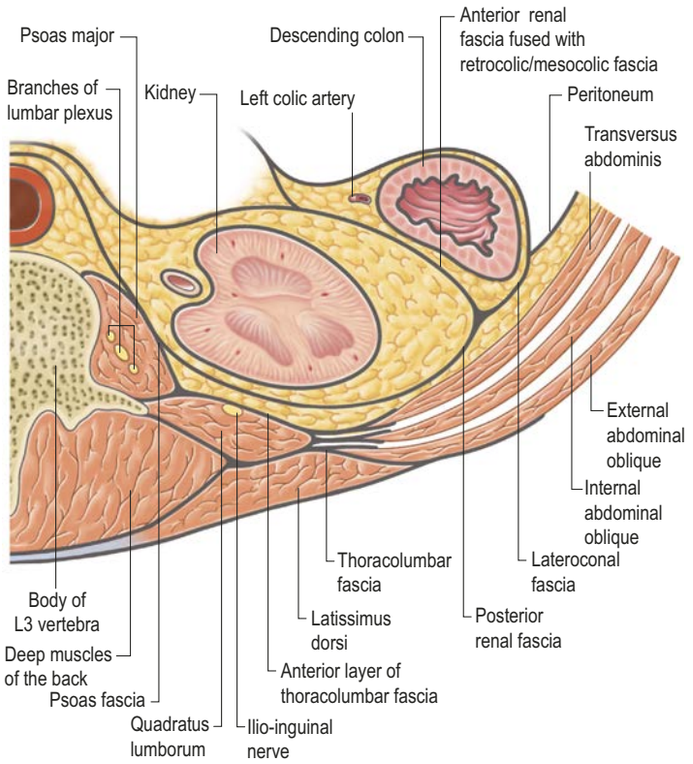

Fig. 61.2 Anatomy of the mid-retroperitoneum (left side). A transverse section at approximately the level of the third lumbar vertebra, showing the location and relationships of the perirenal space.

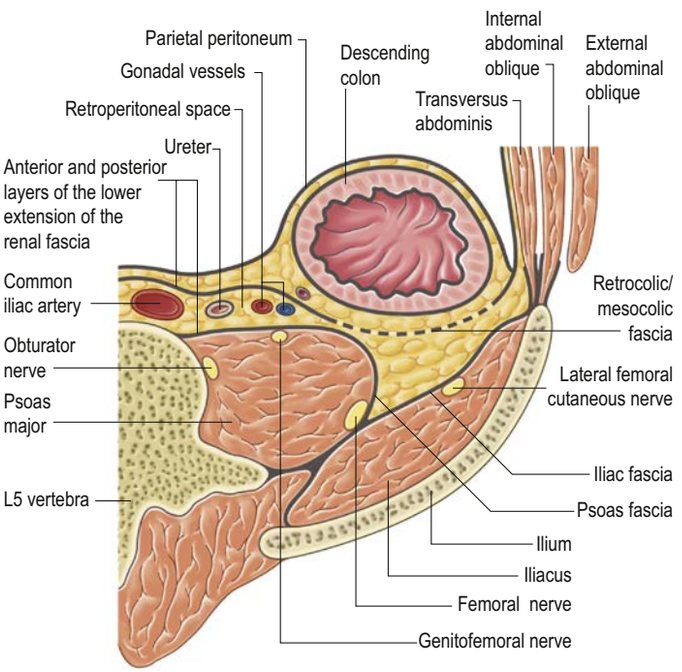

Fig. 61.3 Anatomy of the lower retroperitoneum (left side). A transverse section at approximately the L4 vertebral level, showing the location and relationships of the pericolic space.

Perirenal space

The paired perirenal spaces are bounded by the renal fascia, which envelops the kidney and suprarenal gland on each side. The renal fascia is traditionally described as having anterior and posterior layers which are continuous with each other laterally (see Figs 61.1–61.3 and Chapter 72). It can usually be identified on cross-sectional radiological imaging as a thin layer surrounding the kidney and suprarenal gland, separated from the fibrous capsule of the kidney by a variable amount of perirenal fat. Inferiorly, the perirenal space continues distally around the ureter but becomes progressively narrower and may or may not extend into the pelvis posterior to the posterior parietal peritoneum lining. Medially, the two perirenal spaces may interconnect anterior to the abdominal aorta and inferior vena cava (Kneeland et al 1987). The existence of a fascial partition separating the kidney and ipsilateral suprarenal gland within the envelope of renal fascia is controversial (Amin et al 1976).

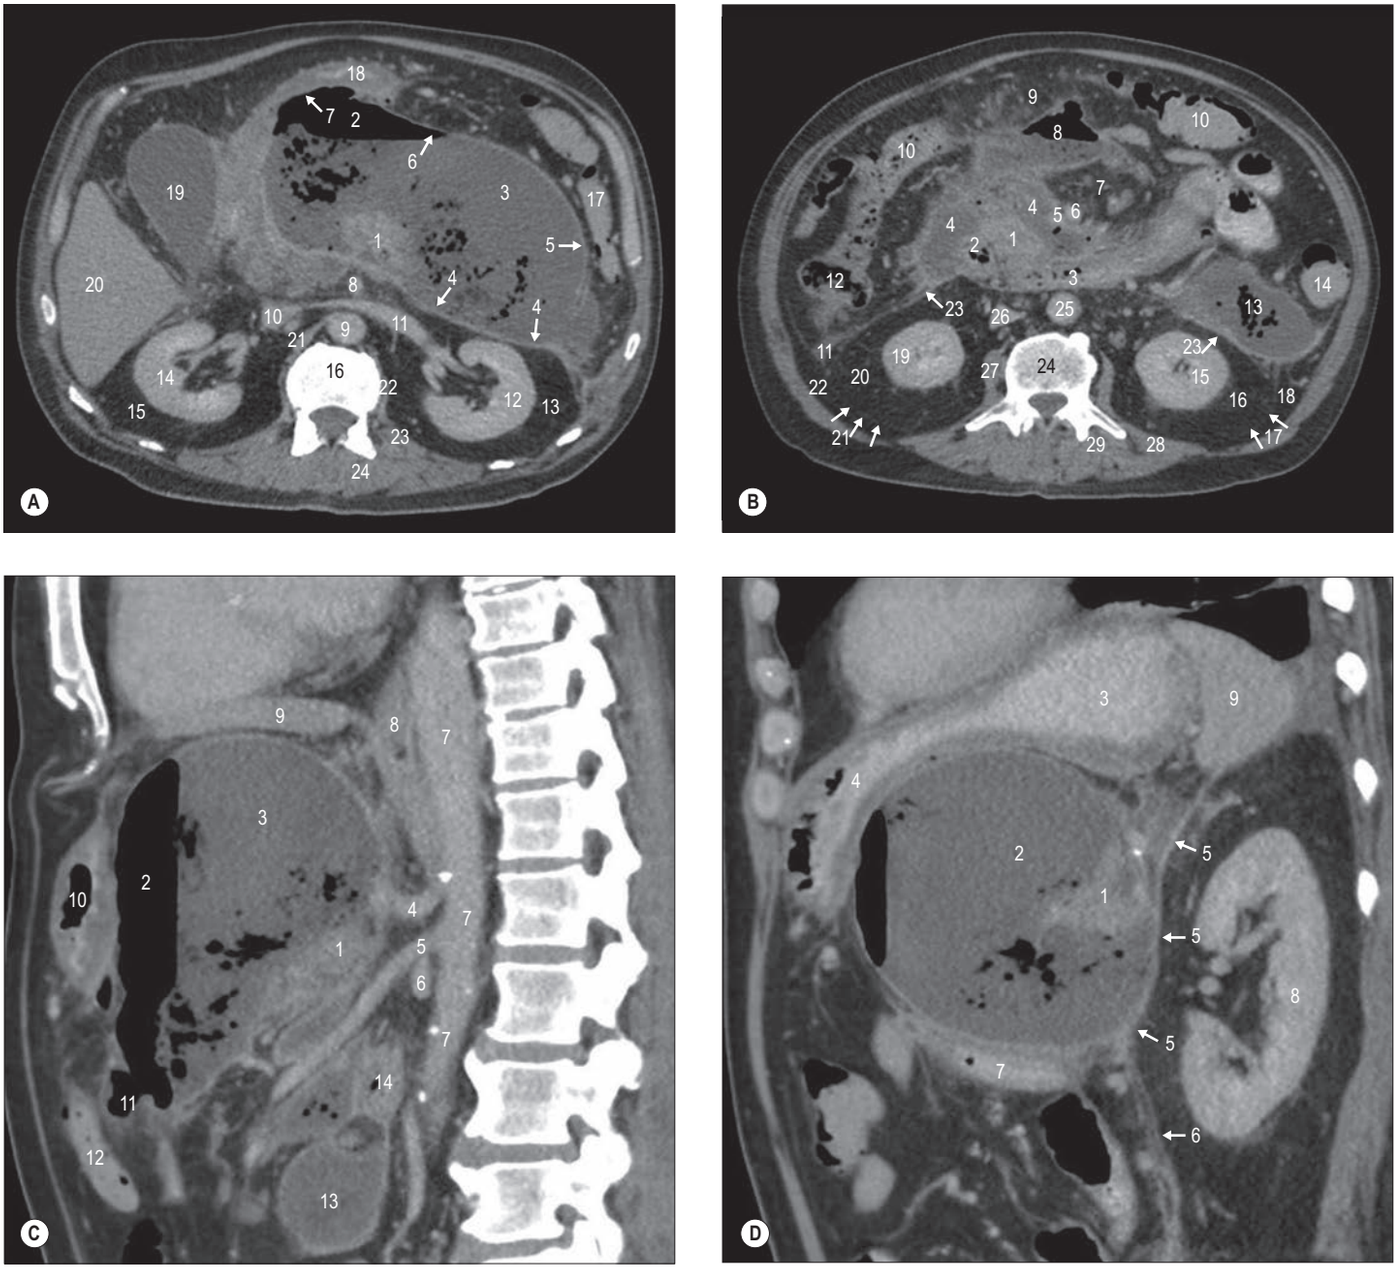

Fig. 61.4 A 58-year-old male with chronic pancreatitis and a peripancreatic pseudocyst. Oral and intravenous contrast-enhanced CT (axial and sagittal planes). The pseudocyst, containing air and fluid, has expanded the peripancreatic space. The fusion fasciae forming the boundaries of the peripancreatic space are thickened through chronic inflammation and are easily visible. **A**, A transverse section at the level of the body of the second lumbar vertebra. Key: 1, neck of pancreas; 2, air in anterior part of collection (outlining peripancreatic space); 3, fluid and debris in posterior (dependent) part of collection (outlining peripancreatic space); 4, retropancreatic fusion fascia; 5, anterior peripancreatic fascia fused to right leaf of left mesocolon; 6, anterior peripancreatic fascia deep to left mesocolon and collapsed omental bursa; 7, anterior peripancreatic fascia fused to peritoneum of omental bursa; 8, superior mesenteric artery; 9, abdominal aorta; 10, inferior vena cava; 11, left renal vein; 12, left kidney; 13, left perirenal space (not distinguishable from left posterior pararenal space); 14, right kidney; 15, right perirenal space (not distinguishable from right posterior pararenal space); 16, upper L2 vertebral body; 17, left colic flexure; 18, stomach (elevated and compressed by collection); 19, gallbladder; 20, right lobe of liver (segments 5 and 6); 21, right crus of respiratory diaphragm; 22, origin of left psoas major; 23, left quadratus lumborum; 24, left erector spinae. **B**, A transverse section at the level of the body of the fourth lumbar vertebra. Key: 1, inferior part of body and uncinate process of pancreas; 2, distal descending part of duodenum; 3, horizontal part of duodenum; 4, peripancreatic space collection (around and anterior to pancreas and duodenum); 5, superior mesenteric vein; 6, superior mesenteric artery; 7, mesentery of small intestine; 8, part of collection dissecting into transverse mesocolon; 9, transverse mesocolon (fused to greater omentum); 10, transverse colon; 11, collection dissecting behind ascending colon; 12, ascending colon; 13, collection (with air) dissecting behind descending colon; 14, descending colon; 15, left kidney; 16, left perirenal space; 17, left posterior layer of renal fascia (normal thickness, therefore faint); 18, left posterior pararenal space; 19, right kidney; 20, right perirenal space; 21, right posterior layer of renal fascia; 22, right posterior pararenal space; 23, anterior pararenal fascia (thickened through chronic inflammation); 24, superior L4 vertebral body; 25, abdominal aorta; 26, inferior vena cava; 27, right psoas major; 28, left quadratus lumborum; 29, left erector spinae. **C**, A mid-sagittal section. Key: 1, neck of pancreas; 2, air in anterior part of collection; 3, fluid in posterior part of collection; 4, coeliac trunk; 5, superior mesenteric artery; 6, left renal vein; 7, abdominal aorta; 8, diaphragmatic crura; 9, left lobe of liver; 10, antrum of stomach (collapsed); 11, part of collection dissecting into transverse mesocolon; 12, transverse colon; 13, part of collection dissecting into mesentery of small intestines; 14, horizontal part of duodenum. **D**, A left sagittal section through left hilum of the kidney. Key: 1, body of pancreas; 2, fluid collection; 3, fundus of stomach (containing oral contrast); 4, body of stomach (containing oral contrast and displaced); 5, left anterior layer of renal fascia fused with retropancreatic fascia; 6, left anterior layer of renal fascia fused with right leaf of left mesocolon (fusion fascia of Toldt); 7, ascending part of duodenum; 8, left kidney; 9, spleen.

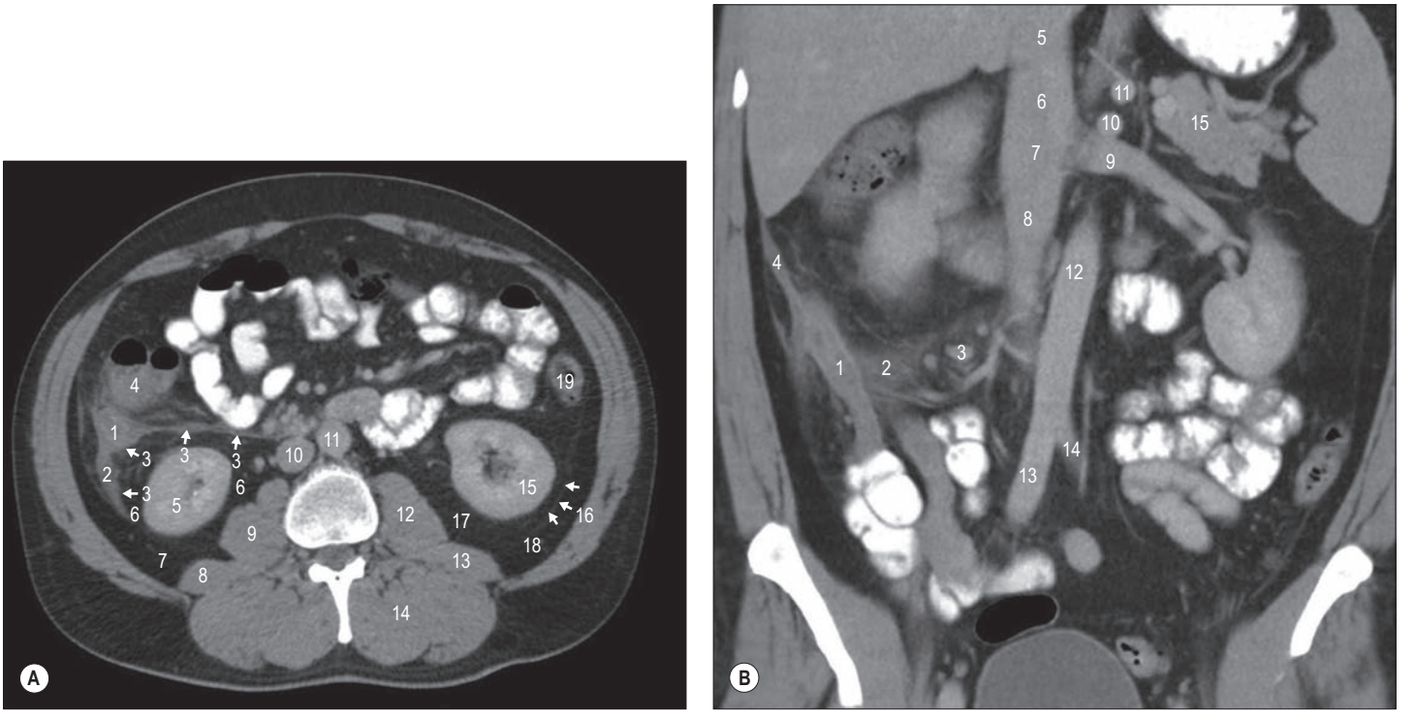

Fig. 61.5 A 43-year-old male with subacute retrocaecal appendicitis. Inflammatory fluid in the right pericolic space. The fused right anterior layer of renal fascia and right mesocolon (the fusion fascia of Toldt) are visible. **A**, A transverse section through the appendix. Key: 1, thickened and inflamed retrocaecal appendix; 2, inflammatory fluid tracking posteriorly in right pericolic space, anterior to right perirenal space; 3, anterior layer of renal fascia (fused with retrocolic/mesocolic) fascia; 4, caecum/ascending colon; 5, right kidney; 6, right perirenal space; 7, right posterior pararenal space (the posterior layer of renal fascia is difficult to identify); 8, right quadratus lumborum; 9, right psoas major; 10, inferior vena cava; 11, abdominal aorta; 12, left psoas major; 13, left quadratus lumborum; 14, left erector spinae; 15, left kidney parenchyma; 16, left posterior layer of renal fascia; 17, left perirenal space; 18, left posterior pararenal space; 19, descending colon. **B**, A coronal section through the appendix. Key: 1, thickened and inflamed retrocaecal appendix; 2, inflammatory fluid and oedema extending along right mesocolon towards root of mesentery; 3, enlarged inflamed right ileocolic node; 4, inflammatory fluid tracking in right mesocolon; 5, inferior vena cava – retrohepatic segment; 6, inferior vena cava – infrahepatic segment; 7, inferior vena cava – renal segment; 8, inferior vena cava – infrarenal segment; 9, left renal vein; 10, superior mesenteric artery; 11, coeliac trunk; 12, abdominal aorta; 13, right common iliac artery; 14, left common iliac artery; 15, tail of pancreas.

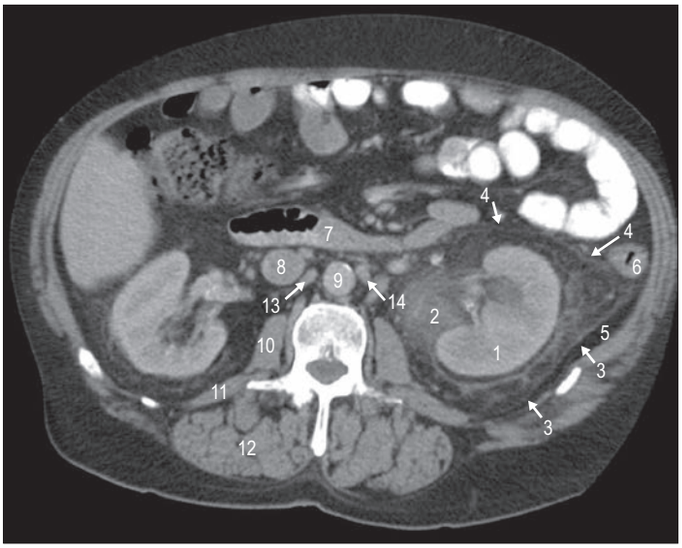

Fig. 61.6 A 61-year-old male with mid-ureteric calculus causing high-grade obstruction of the left ureter and extravasation of urine from the left renal hilum. Oral and intravenous contrast-enhanced CT. A transverse section through the left renal hilum (the calculus is inferior to the plane of this section). Key: 1, left kidney; 2, extravasated urine in left perirenal space; 3, posterior layer of renal fascia; 4, anterior layer of renal fascia; 5, left posterior pararenal space; 6, descending colon; 7, horizontal part of duodenum; 8, inferior vena cava; 9, abdominal aorta; 10, right psoas major; 11, right quadratus lumborum; 12, right erector spinae; 13, lumbar node (borderline enlarged); 14, left lateral aortic nodes (borderline enlarged).

Anterior and posterior pararenal spaces

The anterior pararenal space (an oversimplification) refers to the region between the anterior layer of renal fascia and the parietal peritoneum lining the posterior abdominal wall. On the right, it contains the descending (second) part of the duodenum and the ascending colon, and on the left, the ascending (fourth) part of the duodenum and the descending colon.

The posterior pararenal space lies between the posterior layer of renal fascia anteriorly and the thoracolumbar and psoas fasciae posteriorly. It contains a variable amount of fat. Laterally it is continuous with the extraperitoneal fat of the anterolateral abdominal wall, and inferiorly with the retroperitoneal fat overlying iliacus and the pelvic wall, and the fat around the urinary bladder (Coffin et al 2015).

When the ascending or descending colon is retrorenal (an anatomical variant), these structures and pericolic space lie in a groove between the posterior layer of renal fascia and the posterior pararenal space.

Peripancreatic space

The peripancreatic space contains the duodenum and pancreas, the origins of the superior mesenteric vessels and the retroperitoneal segments of the bile duct, hepatic portal vein and hepatic artery. The posterior boundary is a fusion fascia formed by fusion of the embryonic duodenal mesentery to the anterior wall of the embryonic retroperitoneum (Dodds et al 1986). This fascia is termed the 'retropancreatic' or 'retropancreaticoduodenal' fascia in the imaging literature, and 'fusion fascia of Treitz' in the surgical literature (Kimura et al 2010). It forms a relatively avascular dissection plane that is used to mobilize the duodenum and head of the pancreas.

The lateral extent of the peripancreatic space is variable; it lies posterior to the ascending and descending colons and anterior to the perirenal space (see Fig. 61.1). At the tail of the pancreas, the peripancreatic space lies in continuity with the splenorenal ligament. Anteriorly, it is in continuity with the transverse mesocolon and mesentery of the small intestine. Consequently, peripancreatic fluid collections can extend into both mesenteries and extend posterior to the ascending and descending colons but do not usually cross into the perirenal and pericolic spaces.

Pericolic spaces

The ascending and descending pericolic spaces are the narrow regions surrounding the respective parts of the colon and are continuous medially with the mesocolon (see Figs 61.1–61.3). The pericolic spaces contain a variable amount of fat and are limited anteriorly, superiorly and laterally by the serosa of the colon. Inferiorly, they are continuous with the retroperitoneum of the iliac fossae. Posteriorly, each pericolic space is limited by a fusion fascia formed by the right leaf of the embryonic mesocolon fusing to the left leaf of the embryonic duodenal mesentery and anterior wall of the embryonic retroperitoneum further laterally (Dodds et al 1986). This retrocolic fascia (of Toldt) (Culligan et al 2013, Culligan et al 2014) forms the classic avascular plane of dissection when a hemicolectomy is performed. Its plane is entered by incising the junction of the serosa of the colon with the parietal peritoneum at the white line (of Toldt) in the paracolic gutter. Radiologically, the retrocolic fascia may be indistinguishable from the anterior layer of renal fascia when lateral to the duodenum and pancreas. Variation in colonic retroperitonealization can produce a free mesocolic pedicle (most commonly seen at the caecum).

Lateroconal fascia

The lateroconal fascia was originally defined as the fascial layer extending from the junction of the anterior and posterior layers of renal fascia to the parietal peritoneum in the paracolic gutter (Congdon and Edson 1941). It is better understood as the lateral extension of the retrocolic fusion fascia that blends with the parietal peritoneum (see Figs 61.1–61.3).

BONES

The posterior abdominal wall is supported by the vertebral column and pelvic girdle. The individual bones are the last two ribs, the twelfth thoracic and five lumbar vertebrae, and the sacrum and ilium, together with their interconnecting ligaments.

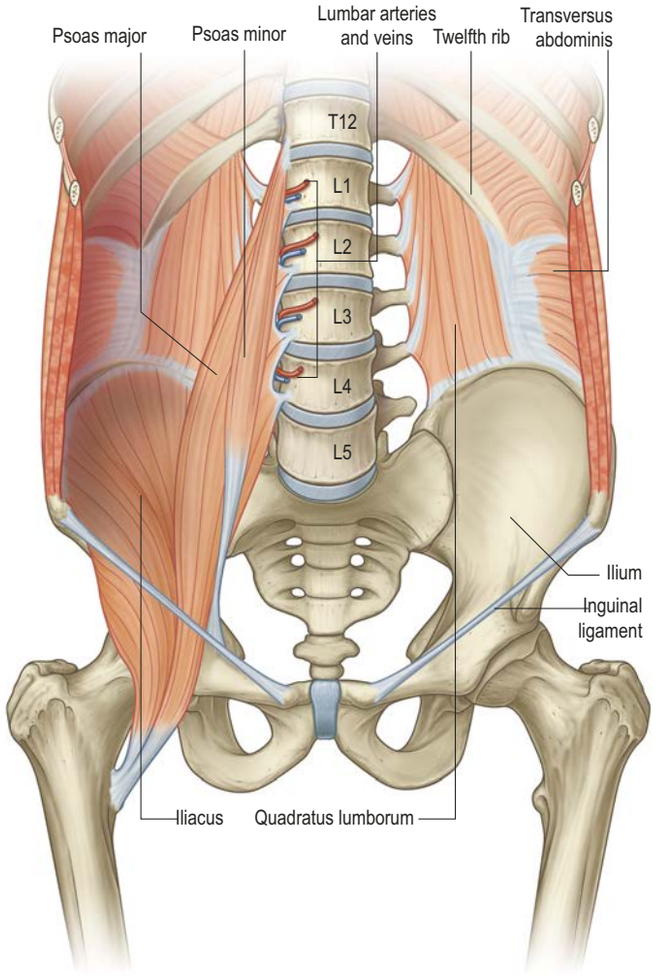

Fig. 61.7 Bones and muscles of the posterior abdominal wall. Left psoas major and the diaphragm have been removed. (Adapted from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

MUSCLES

Most of the muscles of the posterior abdominal wall are functionally part of the pelvic girdle/lower limb or vertebral column. They provide the surface against which the neurovascular and visceral structures of the retroperitoneum lie (**Fig. 61.7**; see Fig. 61.15).

Quadratus lumborum

Quadratus lumborum is an irregularly shaped rectangular muscle, broader at its inferior attachment than superiorly.

Attachments The inferior attachment is by aponeurotic fibres to the iliac crest over an area 5–7 cm lateral to the distal end of the transverse process of the fourth lumbar vertebra and/or the iliolumbar ligament. Fascicles pass from the iliac crest to be attached superiorly to either the anteroinferior surface of the twelfth rib (iliocostal), or the distal ends of the transverse processes of the upper four lumbar vertebrae (iliolumbar), or the lateral surface of the twelfth thoracic vertebra (iliothoracic). Some fascicles may pass from the lumbar transverse processes to the twelfth rib (lumbocostal). Fascicles vary in number and size but typically are arranged in three layers. The anterior layer consists primarily of iliocostal and iliothoracic fascicles, the middle layer consists primarily of lumbocostal fascicles, and the posterior layer consists primarily of iliocostal fascicles laterally and iliolumbar fascicles medially (Phillips et al 2008).

Relations Anteriorly are the colon (ascending on the right, descending on the left), kidney, psoas major and minor (when present), and diaphragm. The subcostal, iliohypogastric and ilio-inguinal nerves lie on the fascia anterior to the muscle, bound down to it by the medial continuation of the transversalis fascia.

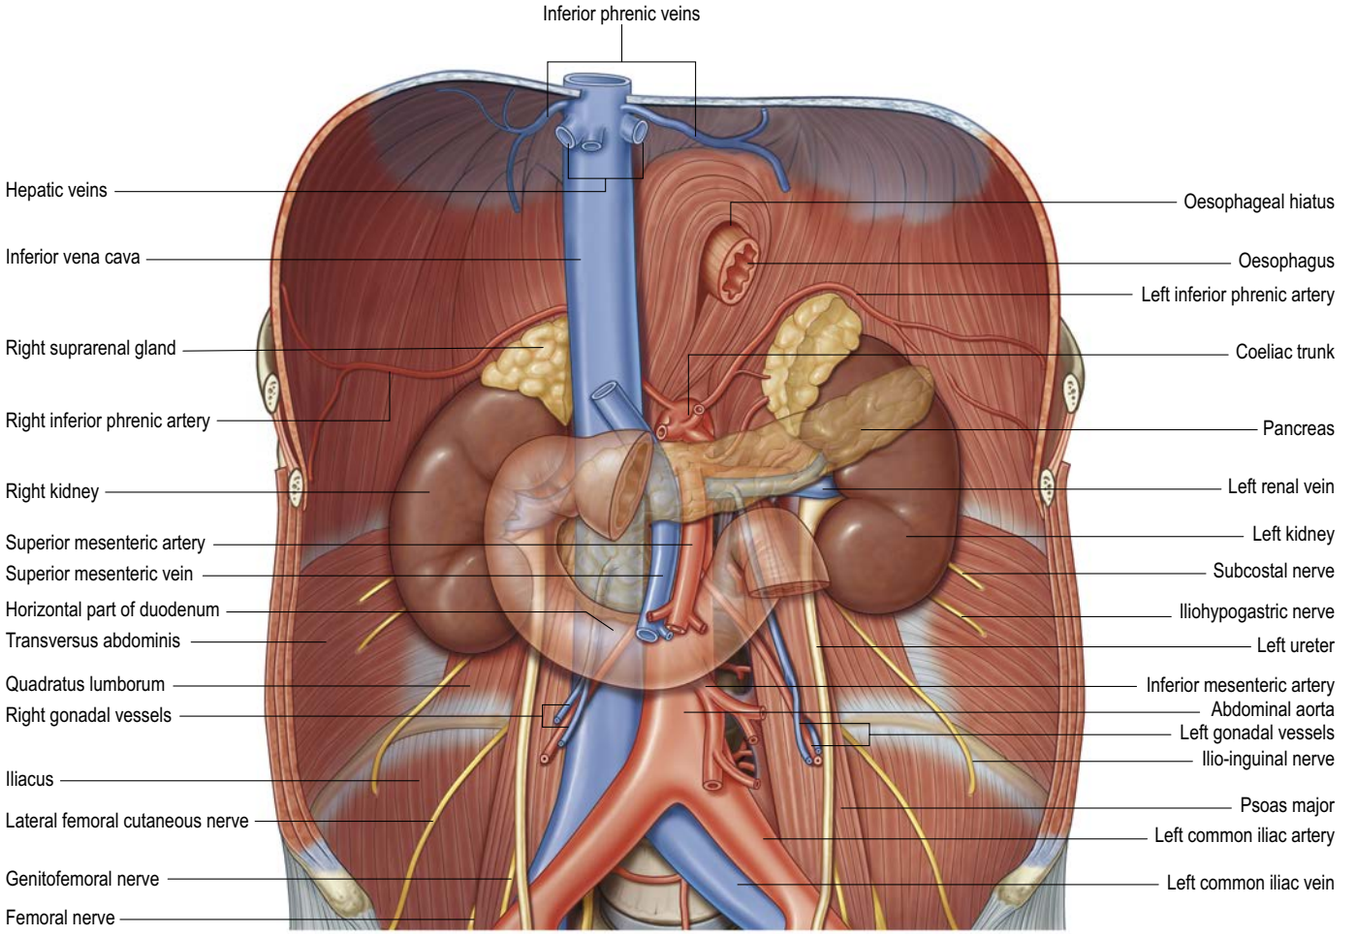

Fig. 61.8 The abdominal aorta and inferior vena cava and their branches. The fasciae, lymphatics and connective tissues have been removed for clarity.

Vascular supply Quadratus lumborum is supplied by branches of the lumbar arteries, the arteriae lumbales imae from the median sacral artery, the lumbar branch of the iliolumbar artery, and branches of the subcostal artery.

Innervation Quadratus lumborum is innervated by the ventral rami of the twelfth thoracic and upper three or four lumbar spinal nerves.

Actions The iliocostal fascicles of quadratus lumborum fix the twelfth rib, helping to stabilize the lower attachments of the respiratory diaphragm during inspiration. The actions of the iliolumbar fascicles are less clear: their contribution to lateral flexion or extension are reported to be weak (Phillips et al 2008, Park et al 2012). Quadratus lumborum is reported to undergo considerable hypertrophy in some sporting activities (Ranson et al 2008).

Psoas major, psoas minor and iliacus

Psoas major and iliacus are functionally important in the lower limb and are described together with psoas minor in Chapter 77.

Posterior abdominal wall hernias

In the absence of a previous surgical incision, visceral herniation through the posterior abdominal wall is rare because the muscular and fascial layers usually protect against protrusion. However, the posterior free border of external abdominal oblique, the inferior free border of latissimus dorsi and the iliac crest delimit the inferior lumbar triangle (of Petit), an area of potential weakness through which a lumbar hernia may develop (see Fig 60.13) (Stamatiou et al 2009).

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Abdominal aorta

The abdominal aorta begins at the aortic hiatus of the respiratory diaphragm anterior to the twelfth thoracic vertebra. It descends anterior to the lumbar vertebrae and bifurcates into two common iliac arteries anterior to the fourth lumbar vertebra or the intervertebral disc between the fourth and fifth lumbar vertebrae, slightly to the left of the midline (Mirjalili et al 2012a, 2012b, Moussallem et al 2012) (**Figs 61.8-61.11**). The angle of bifurcation is very variable (Moussallem et al 2012). The mean adult diameter of the aorta inferior to the origin of the renal arteries measured by computed tomography is 19–21 mm (males) and 16–18 mm (females) (Rogers et al 2013), but there are ethnic variations (Jasper et al 2014). Measured by ultrasound, equivalent values are 20±2.5 mm (males) and 17±1.5 mm (females) (Needleman 2006). The mean calibre of the abdominal aorta decreases slightly from proximal to distal. With advancing age, there is a progressive increase in abdominal aortic diameter in both sexes and the tapering becomes more pronounced (Fleischmann et al 2001). In the elderly, the abdominal aorta frequently becomes ectatic and tortuous, changing the angle and position of the bifurcation and rotating the origins of the major branches.

Relations

The proximal abdominal aorta is directly related anteriorly to the coeliac trunk and its branches, autonomic nerve plexuses and lymphatics. Inferior to the coeliac trunk, the superior mesenteric artery leaves the aorta and descends anterior to the left renal vein. The body of the pancreas is anterior to these vessels; the splenic vein is on its posterior surface and extends obliquely up and to the left. Further anteriorly, the omental bursa separates the proximal abdominal aorta from the lesser omentum, stomach and left lobe of the liver. Inferior to the pancreas, the horizontal part of the duodenum crosses the aorta anteriorly.

The twelfth thoracic vertebra, the upper four lumbar vertebrae, intervening intervertebral discs and the anterior longitudinal ligament lie posterior to the abdominal aorta. Lumbar arteries arise from its posterior aspect, and the third and fourth (and sometimes the second) left lumbar veins cross posterior to it to reach the inferior vena cava. The abdominal aorta can overlap the medial border of psoas major on the left.

On the right, the abdominal aorta is related superiorly to the cisterna chyli and thoracic duct, the azygos vein and the right crus of the respiratory diaphragm, which overlaps and separates it from the inferior vena cava and right coeliac ganglion. Below the second lumbar vertebra it is

Approximately 80% of abdominal aortic aneurysms occur in the aorta inferior to the origin of the renal arteries. Males with atherosclerosis are most at risk of developing the condition, particularly from the sixth decade onwards (Takayama and Yamanouchi 2013). The high mortality risk from spontaneous rupture has prompted the development of ultrasound screening programmes to detect aneurysms and repair them electively. Overall, surgery is performed in patients with an aneurysm greater than 5.0 cm (females) and 5.5 cm (males) in diameter (Groeneveld et al 2018). Repair is most commonly performed by open surgery or endovascular stenting (endovascular aneurysm repair).

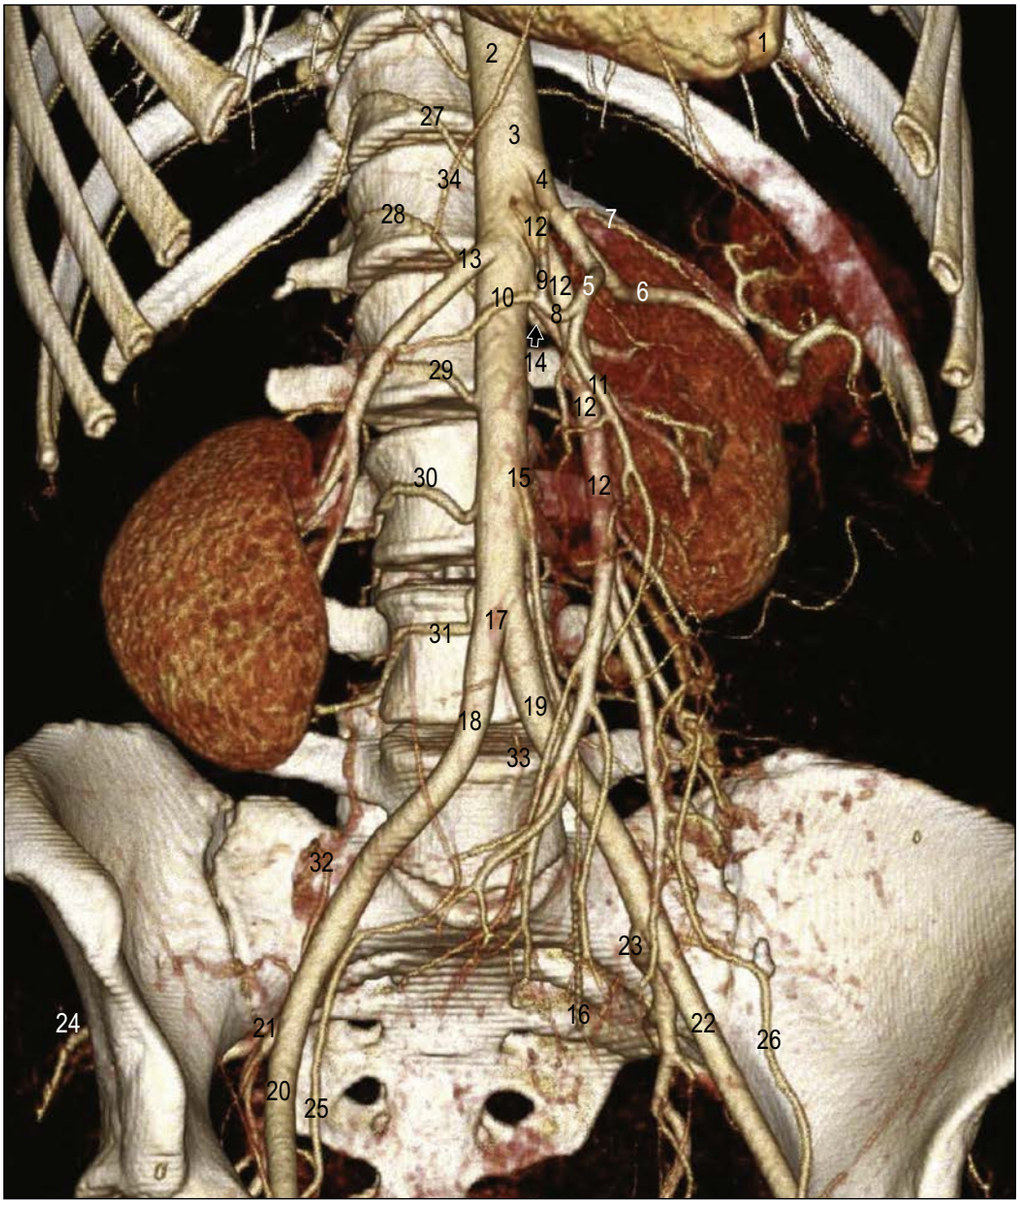

Fig. 61.10 The abdominal aorta and its branches. A 36-year-old female investigated by CT aortogram for possible Marfan's aortic dissection; only the normal abdominal aorta part of the dataset is shown in this three-dimensional reconstruction. Surface shaded display. Key: 1, apex of left ventricle; 2, distal thoracic aorta; 3, approximate position of aortic hiatus; 4, coeliac trunk; 5, common hepatic artery; 6, splenic artery; 7, left gastric artery; 8, proper hepatic artery; 9, left hepatic artery; 10, right hepatic artery; 11, gastroduodenal artery; 12, superior mesenteric artery; 13, right renal artery; 14, left renal artery partly obscured by proper hepatic artery lying more superficial (with arrow); 15, inferior mesenteric artery; 16, superior rectal artery; 17, aortic bifurcation anterior to the fourth lumbar vertebra; 18, right common iliac artery; 19, left common iliac artery; 20, right external iliac artery; 21, right internal iliac artery; 22, left external iliac artery; 23, left internal iliac artery; 24, right superior gluteal artery; 25, right inferior epigastric artery; 26, left inferior epigastric artery; 27, right subcostal artery; 28, right first lumbar artery; 29, right second lumbar artery; 30, right third lumbar artery; 31, right fourth lumbar artery; 32, right iliolumbar artery; 33, median sacral artery; 34, right superior epigastric artery (continuing from right internal thoracic artery). Note the low-lying right kidney.

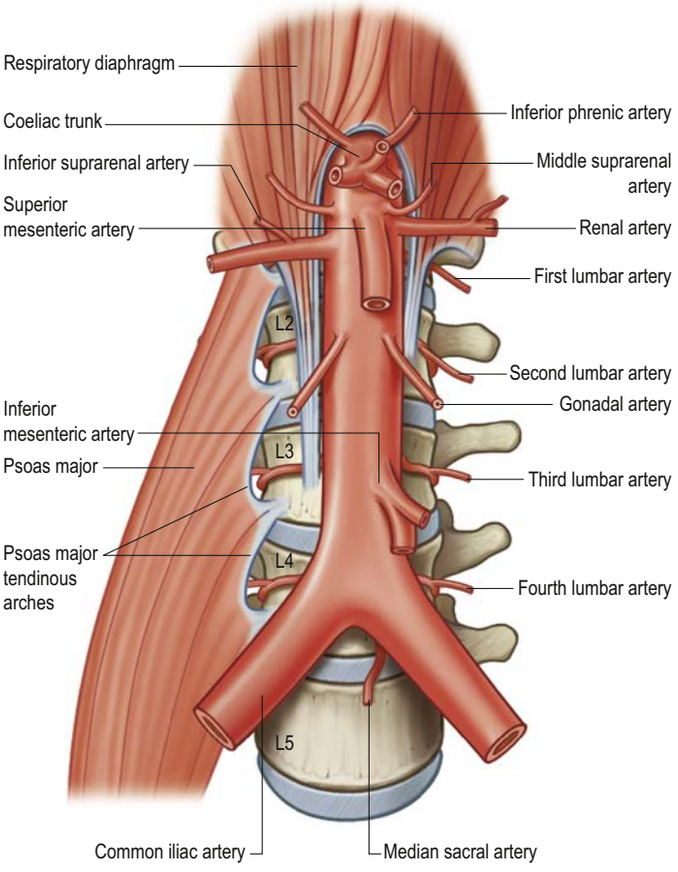

Fig. 61.9 The branches of the abdominal aorta.

closely applied to the left side of the inferior vena cava. This close relationship allows a fistula to develop between the aorta and adjacent inferior vena cava, a rare complication of aneurysmal disease or trauma. On the left, the aorta is related superiorly to the left crus of the respiratory diaphragm and left coeliac ganglion. Level with the second lumbar vertebra, it is related to the ascending part of the duodenum, the left sympathetic trunk and the inferior mesenteric vein.

Branches

The branches of the abdominal aorta are described as anterior, lateral and dorsal (see Fig. 61.9). The anterior (unpaired) and lateral (paired) branches are distributed to the viscera, while the dorsal branches supply the body wall, vertebral column and the vertebral canal and its contents. The aorta terminates by dividing into the right and left common iliac arteries.

Anterior group

Coeliac trunk

The coeliac trunk is the first anterior branch and arises just inferior to the aortic hiatus, usually at the level of the vertebral body of the twelfth thoracic vertebra. It is 1–3 cm long and passes almost horizontally anteriorly and slightly to the right superior to the body of the pancreas and splenic vein. In most individuals it trifurcates into the left gastric, common hepatic and splenic arteries. Variations occur and include a separate origin of the left gastric artery from the abdominal aorta, one or both inferior phrenic arteries arising from the coeliac trunk, and the superior mesenteric artery or one or more of its branches arising in common with the coeliac trunk (Panagouli et al 2013). Anterior to the coeliac trunk lies the omental bursa. The coeliac plexus surrounds the coeliac trunk, sending extensions along its branches. On the right lie the right coeliac ganglion, right crus of the respiratory diaphragm and the caudate lobe of the liver. To the left lie the left coeliac ganglion, left crus of the respiratory diaphragm and the cardia of the stomach. Rarely, the coeliac trunk can be compressed by the median arcuate ligament (Dunbar syndrome), resulting in visceral ischaemia and abdominal pain (Ho et al 2017).

Superior mesenteric artery

The superior mesenteric artery originates from the aorta approximately 1–2 cm below the coeliac trunk, at the level of the body of the first lumbar vertebra (Mirjalili et al 2012b) (Chs 64, 65). It lies posterior to the body of the pancreas and splenic vein and is separated from the aorta by the left renal vein. It passes anteriorly and inferiorly, anterior to the uncinate process of the pancreas and the horizontal (third) part of the duodenum, to enter the root of the mesentery of the small intestines and supply derivatives of the midgut. Numerous anatomical variants have been described (Tubbs et al 2016), the most common being an accessory or replaced right hepatic artery arising near the origin of the superior mesenteric artery. Present in about 15% of individuals, the accessory or replaced right hepatic artery courses posterior to the hepatic portal vein and ascends posterolateral to the bile duct (Winston et al 2007).

Inferior mesenteric artery

The inferior mesenteric artery is smaller than the superior mesenteric artery. It arises from the anterior or left anterolateral aspect of the abdominal aorta at about the level of the body of the third lumbar vertebra, 3-4 cm proximal to the aortic bifurcation and posterior to the inferior border of the horizontal part of the duodenum (Ch. 65).

Lateral group

Suprarenal artery

The right and left middle suprarenal arteries arise from each side of the abdominal aorta, level with the superior mesenteric artery. Each passes laterally over the crus of the respiratory diaphragm to the suprarenal gland, where it anastomoses with the suprarenal branches of the ipsilateral inferior phrenic and renal arteries (Toni et al 1988) (Ch. 70). The right middle suprarenal artery passes posterior to the inferior vena cava near the right coeliac ganglion. The left middle suprarenal artery passes close to the left coeliac ganglion, splenic artery and the superior border of the pancreas.

Renal artery

The renal arteries are two of the largest branches of the abdominal aorta and arise laterally just inferior to the origin of the superior mesenteric artery at about the level of the body of the first lumbar vertebra (Mirjalili et al 2012b) (Ch. 72). When the arteries arise at different cranio-caudal levels, the right ostium is usually superior to the left. The right renal artery is longer and passes posterior to the inferior vena cava, right renal vein, head of the pancreas and descending part of the duodenum. The left renal artery passes behind the left renal vein, the body of the pancreas and the splenic vein. Variations in the number, origin, course and branching patterns of the renal arteries are common.

Gonadal artery

The gonadal arteries (ovarian or testicular) are two long, slender vessels that arise from the aorta a little inferior to the renal arteries. Each passes inferolaterally deep to the posterior parietal peritoneum covering psoas major to supply the ipsilateral gonad (Chs 74, 75). One or both gonadal arteries can arise from a renal artery or be double.

Dorsal group

Inferior phrenic arteries

The inferior phrenic arteries usually arise either from the aorta, just superior to the level of the coeliac trunk, or directly from the coeliac trunk; occasionally, they originate from the renal artery (Loukas et al 2005a, Gwon et al 2007). They contribute to the arterial supply of the respiratory diaphragm. Each artery ascends laterally, anterior to the crus of the respiratory diaphragm, near the medial border of the ipsilateral suprarenal gland and then divides into an ascending and a descending branch. The left ascending branch passes behind the oesophagus and runs anteriorly on the left side of the oesophageal hiatus, where it bifurcates; one branch curves anteriorly to anastomose with its counterpart anterior to the central tendon of the respiratory diaphragm and the other approaches the thoracic wall to anastomose with the musculophrenic and pericardiacophrenic arteries. The right ascending branch passes posterior to the inferior vena cava and then bifurcates; one branch runs anteriorly on the right side of the caval foramen before anastomosing with its counterpart anterior to the central tendon of the respiratory diaphragm, and the other passes laterally on the inferior surface of the respiratory diaphragm. The descending branches on each side supply the respiratory diaphragm and anastomose with the lower posterior intercostal and musculophrenic arteries. Each inferior phrenic artery gives off two or three small superior suprarenal arteries. The abdominal part of the oesophagus, fibrous capsule of the liver and the superior border of the spleen may also receive small arterial twigs from this vessel.

The inferior phrenic artery may be a source of significant collateral blood flow to large hepatocellular cancers and is sometimes specifically

occluded, along with the relevant hepatic artery, when such tumours are treated by arterial embolization.

Lumbar arteries

There are usually four lumbar arteries on each side, in series with the posterior intercostal arteries. They arise from the posterolateral aspect of the abdominal aorta, opposite the lumbar vertebrae. A fifth, smaller, pair occasionally arises from the median sacral artery, but lumbar branches of the iliolumbar arteries often take their place. The lumbar arteries run posterolaterally on the first to the fourth lumbar vertebral bodies, passing behind the sympathetic trunk and tendinous arches formed by the attachments of psoas major to the vertebral bodies. The right lumbar arteries pass posterior to the inferior vena cava. The superior two right lumbar arteries and the first left lumbar artery lie behind the corresponding crus of the respiratory diaphragm. Just beyond the intervertebral foramina, each lumbar artery divides into a medial branch, which gives off spinal and ganglionic branches; a middle branch, from which dorsal and anastomotic branches arise; and a lateral branch, which supplies the abdominal wall (Arslan et al 2011). Of particular importance is the spinal branch known as the great radicular artery (artery of Adamkiewicz), which frequently originates from an upper lumbar artery, particularly on the left side (Biglioli et al 2004) (Ch. 47). Injury to this vessel, e.g. during thoracoabdominal aortic surgery, can cause spinal cord infarction.

The lateral branch of each lumbar artery runs posterior to psoas major and the lumbar plexus, then across the anterior surface of quadratus lumborum, before piercing the posterior aspect of transversus abdominis to run forwards between it and internal abdominal oblique. Perforating branches pass posteriorly to supply the muscles and skin of the posterior abdominal wall (Kiil et al 2009). The lumbar arteries anastomose with one another and the lower posterior intercostal, subcostal, iliolumbar, deep circumflex iliac and inferior epigastric arteries.

The dorsal branch of each lumbar artery passes backwards between the adjacent transverse processes to supply the back muscles, vertebrae and their joints and the skin of the back.

Median sacral artery

The median sacral artery is a small branch that usually arises from the posterior aspect of the aorta a little above its bifurcation. It descends close to the midline, anterior to the fourth and fifth lumbar vertebrae, sacrum and coccyx. At the level of the fifth lumbar vertebra it is crossed by the left common iliac vein and often gives off a small lumbar artery (arteriae lumbales imae), whose small branches reach the anus and rectum via the anococcygeal ligament. Anterior to the fifth lumbar vertebra, the median sacral artery anastomoses with a lumbar branch of the iliolumbar artery. Anterior to the sacrum, it anastomoses with the lateral sacral arteries and sends branches into the anterior sacral foramina.

Inferior vena cava

The inferior vena cava (Figs 61.12–61.13) conveys blood to the right atrium from almost all of the structures inferior to the respiratory diaphragm. Most of its course is within the abdomen, but a small segment lies within the pericardium in the thoracic cavity.

The inferior vena cava is formed by the junction of the left and right common iliac veins anterior to the fifth lumbar vertebral body, about 1 cm to the right of the midline. It ascends anterior to the vertebral column, to the right of the aorta, and lies in a deep groove on the posterior surface of the liver, sometimes completely surrounded by liver tissue. It traverses the central tendon of the respiratory diaphragm and passes through the fibrous pericardium and a posterior inflection of the serous pericardium to open into the posteroinferior part of the right atrium. Its abdominal portion is devoid of valves. The inferior vena cava can be encircled and controlled between the renal veins inferiorly and the hepatic veins superiorly, e.g. during operations on a renal cell carcinoma extending into the inferior vena cava.

Relations of the abdominal part of the inferior vena cava

The inferior vena cava lies behind the parietal peritoneum lining the posterior abdominal wall. At its origin it is related anteriorly to the right common iliac artery. From below upwards, its anterior surface is crossed obliquely by the root of the mesentery of the small intestine and its contained vessels and nerves, the right gonadal artery and the horizontal part of the duodenum. Further cranially, it lies posterior to the head of the pancreas and superior (first) part of the duodenum, separated from those structures by the bile duct and hepatic portal vein. Superior to the duodenum, its anterior surface is covered by the parietal peritoneum lining the posterior abdominal wall, which forms the posterior wall of the omental foramen and separates the inferior vena cava from the right free border of the lesser omentum, i.e. the hepatoduodenal ligament and its contents. Superior to this, it is intimately related to the liver anteriorly.

The posterior relations of the inferior vena cava include the lower three lumbar vertebral bodies and their intervertebral discs, the anterior longitudinal ligament, sympathetic trunk, right third and fourth lumbar arteries, and psoas major on the right. Superior to these structures, it is

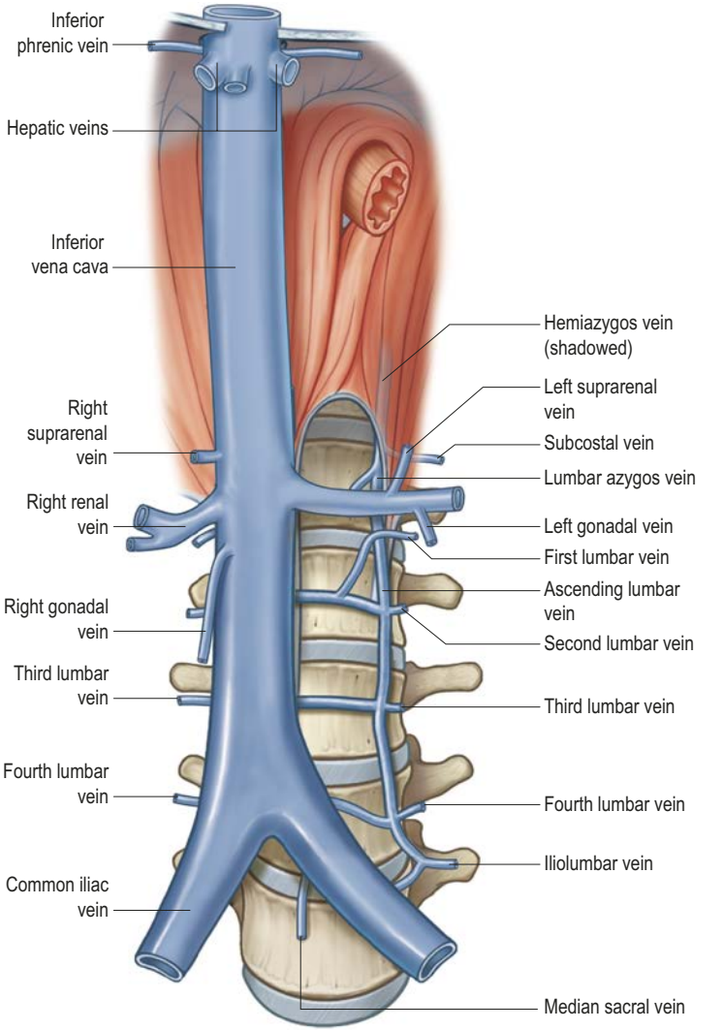

Fig. 61.12 Tributaries of the inferior vena cava emphasizing the left lumbar veins and their interconnections.

related posteriorly to the right renal and middle suprarenal arteries, the medial part of the right suprarenal gland, the right coeliac ganglion and the right inferior phrenic arteries.

The right ureter, medial border of the right kidney, descending part of the duodenum and the right lobe of the liver are all lateral to the right side of the inferior vena cava. The abdominal aorta, right crus of the respiratory diaphragm and the caudate lobe of the liver are on its left side.

The normal diameter of an adult inferior vena cava is up to 30 mm (Moeller and Reif 2000); its cross-sectional shape and calibre reflect the degree of venous filling. Anatomical variants, related to its complex embryogenesis (Ch. 13), are well described. Among these are a double inferior vena cava (the left-sided vessel usually joins the left renal vein); azygos continuation of the inferior vena cava; a left-sided inferior vena cava (which may exist in isolation or as part of situs inversus) (Ang et al 2013, Spentzouris et al 2014).

Tributaries

The inferior vena cava usually receives the common iliac veins at its origin and the lumbar, right gonadal, renal, right suprarenal, hepatic and inferior phrenic veins throughout its course (see Fig. 61.12).

Lumbar veins

Four pairs of lumbar veins collect blood from the territories supplied by the corresponding lumbar arteries, including the posterior, lateral and anterior abdominal walls. These branches anastomose posteriorly with tributaries of the azygos and hemiazygos veins, and anteriorly with branches of the epigastric, circumflex iliac and lateral thoracic veins. These superficial anastomoses provide alternative routes of venous drainage from the pelvis and lower limbs to the heart when the inferior vena cava is obstructed. The lumbar veins communicate with the external and internal vertebral venous plexuses, providing an additional collateral pathway for venous return.

The paired longitudinal ascending lumbar veins connect the individual ipsilateral lumbar veins. The third and fourth lumbar veins usually pass anteriorly on the sides of the corresponding vertebral bodies to enter the posterior aspect of the inferior vena cava; the left lumbar veins pass posterior to the abdominal aorta and are therefore longer. The first and second lumbar veins are much more variable and may drain into the inferior vena cava or the ascending lumbar, lumbar azygos or renal veins (on the left); they are often connected to each other. The first lumbar vein often passes inferiorly to join the second lumbar vein or, less commonly, drains either directly into the ascending lumbar vein or passes anteriorly over the body of the first lumbar vertebra to join the lumbar azygos vein. The second lumbar vein may join the inferior vena cava at or near the level of the renal veins or, less commonly, join the third lumbar or ascending lumbar vein.

Ascending lumbar veins

The paired ascending lumbar veins run medial to psoas major and connect the ipsilateral common iliac, iliolumbar and lumbar veins. The ascending lumbar vein is variable in its course and connections; rarely, the whole vein or a segment is absent on one side (Lolis et al 2011). It commonly joins the subcostal vein to form the azygos vein on the right and the hemiazygos on the left. The azygos and hemiazygos veins run anteriorly over the body of the twelfth thoracic vertebra and pass deep to or through the right and left crura of the respiratory diaphragm, respectively, into the thoracic cavity (Ch. 56). The ascending lumbar vein is usually joined by a small vein, the lumbar azygos vein, from the back of the inferior vena cava or left renal vein. Sometimes, the ascending lumbar vein ends in the first lumbar vein, which then joins the lumbar azygos vein at the level of the first lumbar vertebra. Blood can flow in either direction in the ascending lumbar veins (Morita et al 2007).

Gonadal veins

The right gonadal vein enters the inferior vena cava directly on its right anterolateral aspect at an acute angle about 2 cm inferior to the left renal vein in adults; occasionally, it drains into the right renal vein (Tubbs et al 2016). The left gonadal vein terminates in the left renal vein. Both veins may be replaced by multiple vessels in the lower abdomen and sometimes remain double as far as their termination. Of the two gonadal veins, the left is more prone to develop venous incompetence.

Renal veins

The renal veins are large-calibre vessels that lie anterior to the renal arteries and open into the inferior vena cava almost at right angles (Ch. 72). The left is three times longer than the right (approximately 7.5 cm and 2.5 cm, respectively), and lies on the posterior abdominal wall posterior to the splenic vein and body of the pancreas. It passes to the right in the angle between the abdominal aorta posteriorly and the superior mesenteric artery anteriorly and empties into the inferior vena cava. Occasionally, the left renal vein or an accessory left renal vein is retro-aortic. The right renal vein lies posterior to the descending part of the duodenum and sometimes to the lateral part of the head of the pancreas.

Suprarenal vein

Most commonly, a single vein drains each suprarenal gland (Ch. 70). The short right suprarenal vein drains directly into the inferior vena cava at the level of the twelfth thoracic vertebra; the longer left vein usually joins the left renal vein and may receive the left inferior phrenic vein. Numerous anatomical variations of this vein have been described (Cesmebasi et al 2014).

Inferior phrenic veins

The inferior phrenic veins usually originate on the superior surface of the respiratory diaphragm but run mostly on its inferior surface to drain into the posterolateral aspect of the inferior vena cava. Both veins receive several diaphragmatic tributaries. The left vein runs to the left of the oesophageal hiatus, whereas the right courses to the right of the caval foramen; each receives a venous tributary from the oesophagus (Loukas et al 2005b). The left inferior phrenic vein frequently communicates with the left gastric vein and may therefore become prominent in portal hypertension. Both inferior phrenic veins usually drain directly into the inferior vena cava just inferior to the respiratory diaphragm, sometimes joining anteriorly to form a short common trunk. The right occasionally drains into the right hepatic vein or inferior vena cava superior to the respiratory diaphragm, whereas the left frequently drains into the left suprarenal, left renal or left hepatic vein.

Collaterals developing as a result of occlusion of the inferior vena cava

Obstruction of the inferior vena cava from thrombosis, embolism, extrinsic compression (e.g. tumour or pregnancy) or intrinsic disease results in the development of an extensive venous collateral circulation via tributaries that ultimately connect to the superior vena cava. These include the azygos–hemiazygos venous system, the vertebral venous plexuses and the superficial veins of the thoracic and abdominal walls. The lumbar veins contribute significantly to these pathways (Golub et al 1992).

Lymphatic drainage

Lymph from the skin and subcutaneous tissues of the abdominal wall drains via small calibre superficial lymphatics to axillary and inguinal nodes (Tourani et al 2013). The midline and the level of the umbilicus form inconstant and variable watershed boundaries for these drainage territories. Lymphatics from the deeper layers of the body wall and the abdominal and pelvic viscera drain almost exclusively to the cisterna chyli and thoracic duct. The former drains via ipsilateral nodes in the retroperitoneum concentrated around the external iliac and common iliac vessels and along the lateral aspects of the aorta and inferior vena cava. There is considerable overlap between the lymphatic drainage of individual viscera. At certain sites there is a cranio-caudal sequence of lymph nodes, e.g. lateral aortic nodes; and parasternal and inferior epigastric nodes. Some lymphatic drainage from the bare area of the liver occurs directly across the respiratory diaphragm to the thoracic cavity.

The paired viscera of the retroperitoneum drain to lateral aortic nodes around the origin of their arterial supply. Thus, the kidneys and suprarenal glands drain to nodes around the hilum of the kidney and to lateral aortic nodes around the origin of the renal arteries (first and second lumbar vertebral levels). The testes drain to lateral aortic and lateral, precaval and retrocaval nodes (approximately second lumbar vertebral level); the pattern of lymphatic spread from a testicular malignancy suggests that lymph from the left testis drains to left lateral aortic nodes en route to the cisterna chyli, whereas lymph from the right testis drains to right and then left lateral aortic nodes before reaching the cisterna chyli. Lymph from the ovary may drain via lymphatics in the broad ligament of the uterus and round ligament of the uterus to internal iliac and inguinal nodes, respectively. Lymphatic drainage of the ureters is less well defined but follows a regional pattern to nearby nodes.

The lymphatic drainage of the retroperitoneal colon and rectum is described in Chapter 65. The pancreas drains to numerous pancreatic nodes (Ch. 68) and to nodes between the hepatic portal vein and inferior vena cava (clinically referred to as portacaval nodes), splenic, superior mesenteric and coeliac nodes. The lymphatic drainage of the duodenum is not well described but the lymphatics generally drain to nodes related to local arteries (Ch. 64). Whilst the clinical pattern of nodal metastases usually reflects normal lymphatic drainage pathways, lymphatic obstruction may lead to metastases at unusual nodal sites.

Cisterna chyli and abdominal lymph trunks

The abdominal origin of the thoracic duct usually lies to the right of the midline at the level of the body of the twelfth thoracic vertebra or the intervertebral disc between the twelfth thoracic and first lumbar vertebrae. It receives almost all the lymph from below the respiratory diaphragm via the cisterna chyli, a localized saccular or fusiform lymphatic dilation formed most commonly by the union of the intestinal trunk and the left lumbar trunk (Phang et al 2014). The cisterna chyli is approxinately 1 cm wide and 2 cm long in the cadaver (Loukas et al 2007): studies using magnetic resonance imaging (MRI) *in vivo* have shown that it expands considerably during movement from supine to sitting and again from sitting to standing (Niggemann et al 2010).

The formation of the cisterna chyli is variable and it may be absent. When present, it usually lies anterior to the first and second lumbar vertebrae, posterior to the right crus of the respiratory diaphragm and to the right of the abdominal aorta, but it may be located at a more proximal vertebral level (**Fig. 61.14**). The most common configuration, found in approximately two-thirds of individuals, is a single structure formed from the union of the intestinal trunk and the left (or, less commonly, the right) lumbar trunk (Loukas et al 2007). In most other individuals it is formed by the confluence of the intestinal and both lumbar trunks, with additional small branches from intercostal lymphatics (intercostal trunks) and retro-aortic nodes (Skandalakis et al 2004). The proximal two right lumbar arteries and the right lumbar azygos vein lie between the cisterna chyli and the vertebral column.

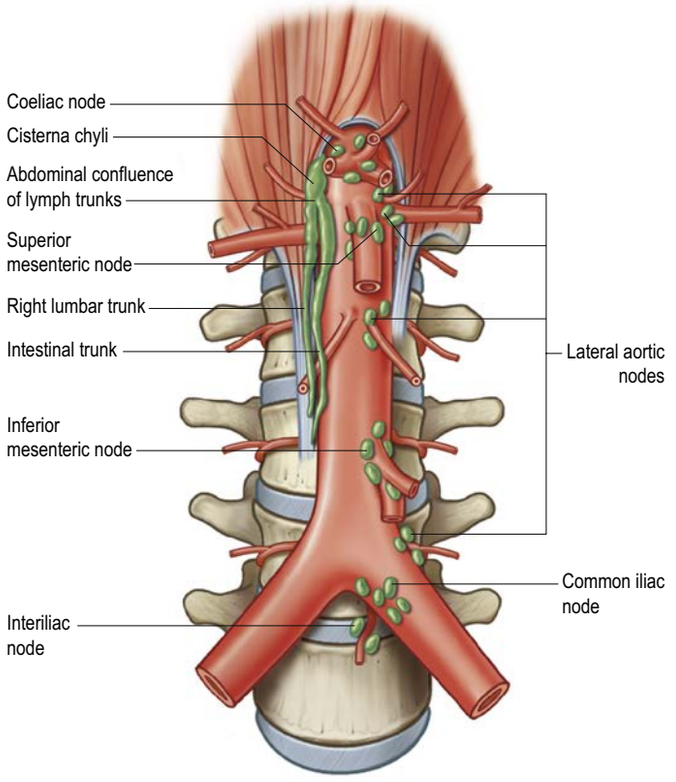

Fig. 61.14 Abdominal nodes emphasizing the main pre-aortic groups. Only the left-sided lateral aortic nodes are shown, for clarity. NB: the cisterna chyli is more commonly formed by the intestinal trunk and the left lumbar trunk (rather than the right lumbar trunk shown in this diagram).

The paired lumbar trunks are formed by lymphatic vessels draining lateral aortic nodes. The intestinal trunk (which may be double) receives vessels draining from coeliac, superior and inferior mesenteric nodes that collectively drain the entire abdominal gastrointestinal tract down to the anal canal. The thoracic duct leaves the superior end of the cisterna chyli and passes through the aortic hiatus of the respiratory diaphragm posterolateral to the right side of the aorta. Its thoracic continuation is described in Chapter 56.

The major lymphatic vessels adjacent to the abdominal aorta are at risk of injury during surgical procedures that involve peri-aortic dissection and/or lymphadenectomy. Injury to these lymphatic vessels or their obstruction by malignant disease can cause leakage of lymph manifesting as chylous ascites or chylothorax.

Retroperitoneal lymph node groups

The lymphatic drainage of the rectum, colon, stomach, pancreas, oesophagus and other organs is often described in terms of lymph node stations and levels of dissection that relate to the management of malignant disease. The terminology and classification of retroperitoneal lymph nodes are based on their location. In classic anatomical descriptions, the lymph nodes of the retroperitoneum around the abdominal aorta are grouped into pre-aortic, lateral and retro-aortic nodes, but adjacent nodal groups merge into one another with no clear demarcating boundaries. Normal lymph node dimensions are very variable. Cross-sectional imaging frequently uses 10 mm as an approximate measurement for the upper limit of normal lymph node dimensions in the adult (Moeller and Reif 2000): some normal retroperitoneal nodes such as the portacaval nodes are typically larger.

Pre-aortic nodes

Pre-aortic nodes drain the gastrointestinal viscera including the pancreas, liver and spleen. They lie anterior to the aorta clustered around its anterior unpaired visceral branches and can be subdivided into coeliac, superior mesenteric and inferior mesenteric nodes. Their efferent lymphatics contribute to the formation of the intestinal lymph trunk.

Coeliac nodes

Coeliac nodes drain lymph from nodes around the stomach, splenic hilum, porta hepatis, cystic duct, lesser omentum, portacaval nodes,

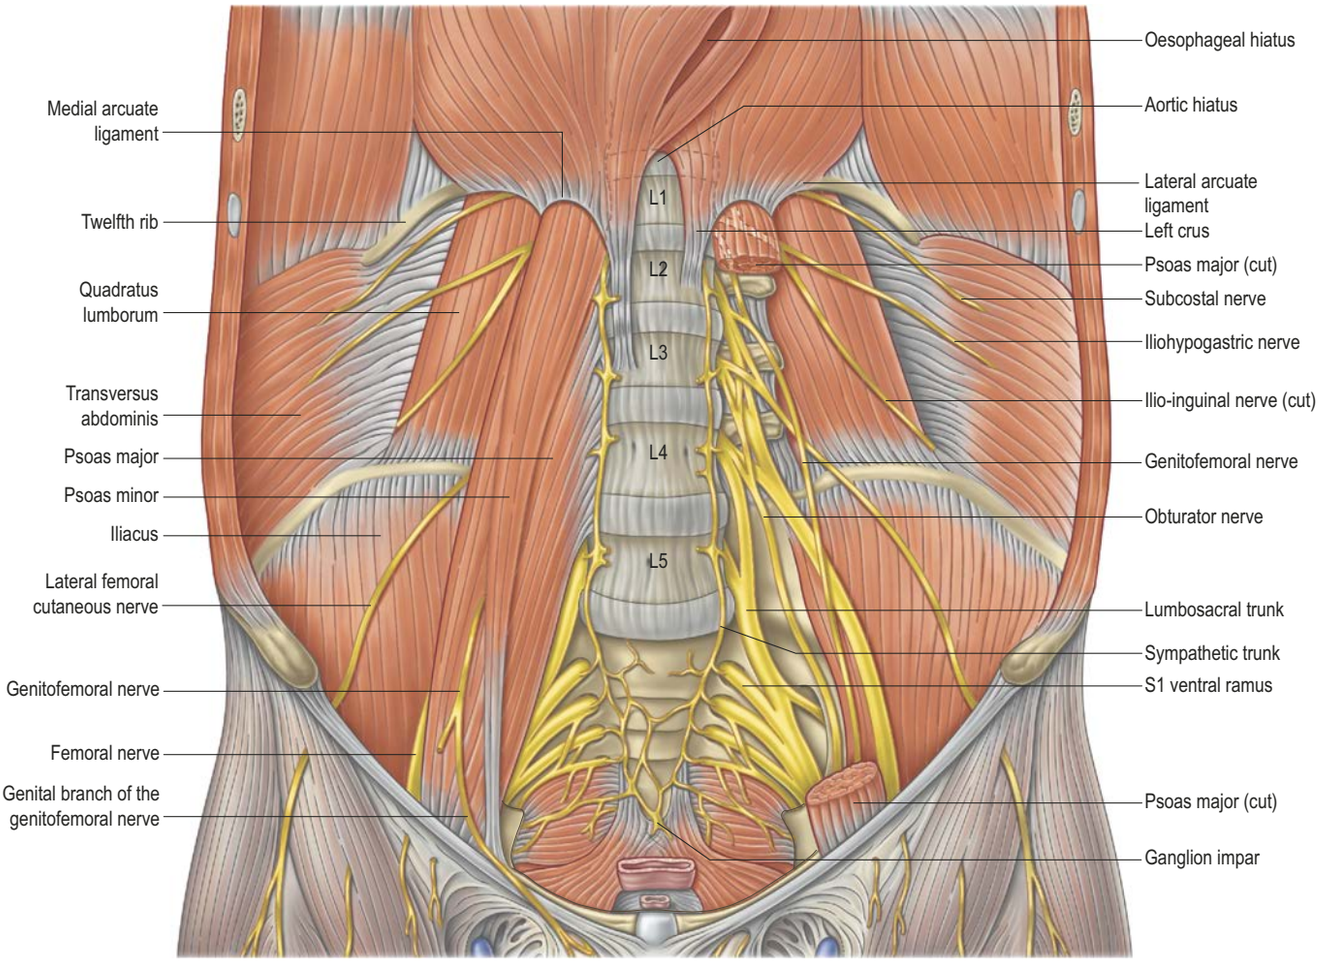

Fig. 61.15 Muscles and nerves of the posterior abdominal wall. Psoas major on the left has been removed to expose the ventral rami contributing to the lumbar plexus and quadratus lumborum.

pancreatic nodes and pancreaticoduodenal nodes. They also receive lymph from superior and inferior mesenteric nodes and their efferent lymphatics drain to the intestinal trunks.

Superior mesenteric nodes

Superior mesenteric nodes share an extensive overlap with the drainage territory of coeliac nodes, with subsidiary nodal groups that include pancreatic, pancreaticoduodenal, portacaval, ileocolic, mesenteric and inferior mesenteric nodes. Efferent lymphatics drain to the intestinal trunks either directly or via coeliac nodes.

Inferior mesenteric nodes

Inferior mesenteric nodes such as the superior rectal nodes drain lymph from derivatives of the hindgut, including the distal transverse, descending and sigmoid colons, and the rectum.

Lateral aortic groups

Lateral aortic (para-aortic) nodes lie on either side of the abdominal aorta and inferior vena cava anterior to the medial margins of psoas major, the crura of the respiratory diaphragm and the sympathetic trunks. Constituent nodal groups that are recognized clinically include the retrocrural (posterior to the diaphragmatic crura at the aortic hiatus); left and right hilar (of the kidney); aortocaval, lateral caval, retrocaval and precaval groups. Retro-aortic nodes are sometimes included within the lateral aortic group. The latter drain into the paired intestinal trunks that terminate directly or indirectly in the cisterna chyli and thoracic duct. There are lymphatic connections between lateral aortic, pre-aortic, retro-aortic and contralateral lateral aortic nodes. The lateral aortic nodes drain the deep layers of the body wall, the retroperitoneal paired viscera (including the gonads) and tributaries from the iliac nodes. Lymph from the right ovary or testis drains via lymphatics travelling with the gonadal vessels to the right lateral aortic and pre-aortic nodes at the level of the second lumbar vertebra, whereas lymph from the left ovary or testis drains to the left lateral aortic nodes just inferior to the left renal vein (Morton and Thomas 2008, Paño et al 2011).

Iliac nodes

Paired iliac nodes are distributed around the common, external and internal iliac arteries and veins. Constituent groups include the common iliac, external iliac, internal iliac and obturator nodes. The latter are located near the obturator foramen and, together with the iliac nodes, are a common site of lymph node metastasis in prostate cancer. 'Pelvic side-wall' nodes, lying adjacent to the ilium but not associated with a large artery or vein, are also described in the clinical literature. The iliac nodes drain the pelvic viscera and walls, except for the ovaries and those parts of the rectum drained by superior anorectal nodes. They also drain lymph from the inguinal nodes and lower limbs.

INNERVATION

The posterior abdominal wall contains the lumbar plexus and numerous autonomic plexuses and ganglia that lie close to the abdominal aorta and its branches (**Figs 61.15–61.16**).

Lumbar plexus

The lumbar ventral rami pass laterally into the posterior part of psoas major, anterior to the transverse processes of the lumbar vertebrae (Moro et al 2003, Benglis et al 2009). The first four lumbar ventral rami, usually together with a contribution from the twelfth thoracic ventral ramus, form the lumbar plexus. Although there are many variations, the most common arrangement of the plexus is described here (Tubbs et al 2018).

The first lumbar ventral ramus is often joined by a branch from the twelfth thoracic ventral ramus, and these contribute to the formation of the iliohypogastric and ilio-inguinal nerves, which run laterally on the posterior abdominal wall. A branch from the first lumbar ventral ramus unites with a branch from the second lumbar ventral ramus to form the genitofemoral nerve. The second, third and most of the fourth lumbar ventral rami divide into ventral and dorsal

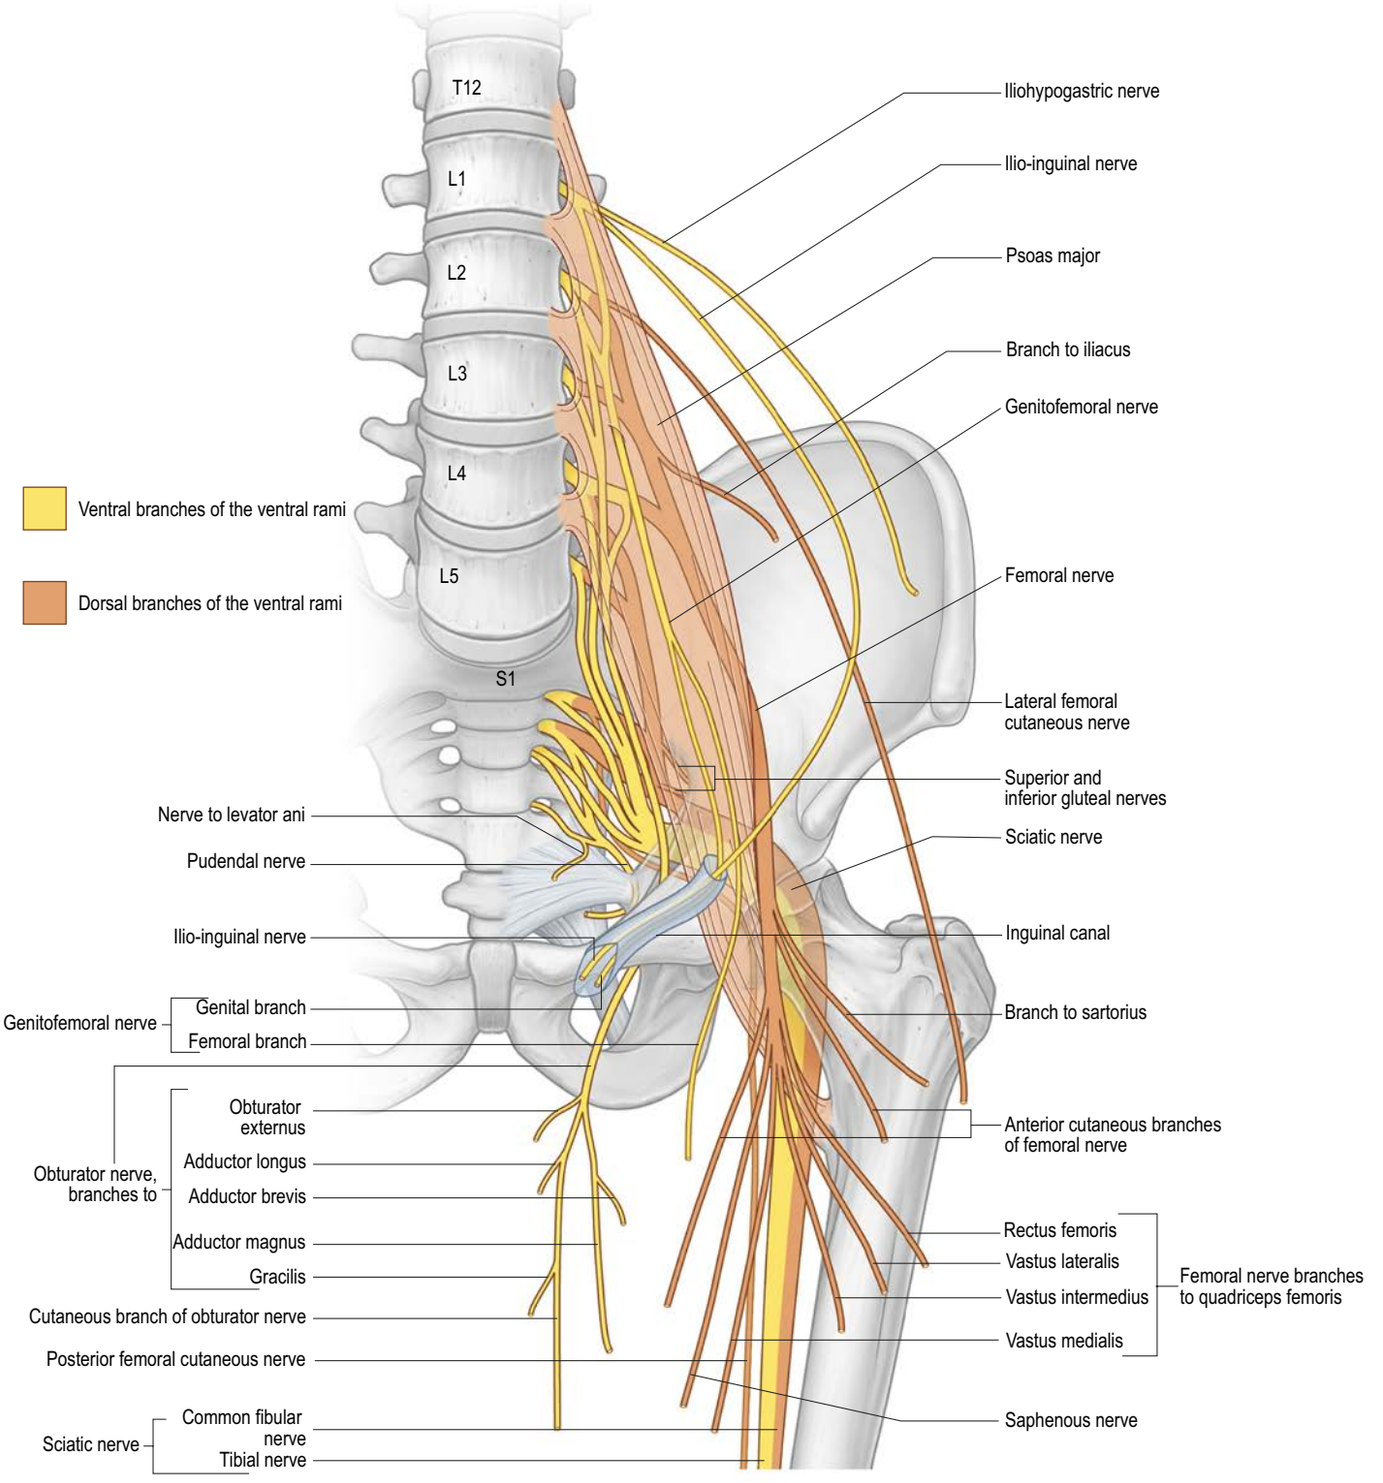

Fig. 61.16 The lumbar plexus and its branches.

divisions; the ventral divisions unite to form the obturator nerve, while most of the nerve fibres in the dorsal divisions form the femoral nerve. The remaining fibres from the fourth lumbar ventral ramus join the fifth lumbar ventral ramus to form the lumbosacral trunk, which descends to join the sacral plexus. Branches from the dorsal divisions of the second and third lumbar ventral rami unite to form the lateral femoral cutaneous nerve. The accessory obturator nerve, when present, usually arises from the third and fourth ventral rami. The lumbar plexus is supplied by branches from the lumbar vessels that supply psoas major.

The division of constituent ventral rami into ventral and dorsal branches is not as clear in the lumbar and sacral plexuses as it is in the brachial plexus. Lateral cutaneous branches of the twelfth thoracic and first lumbar ventral rami are drawn into the gluteal skin, but otherwise these nerves are similar to intercostal nerves. The second lumbar ventral ramus is more complex. It contributes substantially to the femoral and obturator nerves, and also has an anterior terminal branch (the genital branch of the genitofemoral) and a lateral cutaneous branch that contributes to the lateral femoral cutaneous nerve and the femoral branch of the genitofemoral nerve. Anterior terminal branches of the third to fifth lumbar and first sacral ventral rami are suppressed, but the corresponding branches of the second and third sacral ventral rami supply the perineal skin.

The furcal nerve is an independent nerve with its own ventral and dorsal rootlets most commonly arising alongside the fourth lumbar spinal nerve. Its branches contribute to the femoral and obturator nerves arising from the lumbar plexus and to the lumbosacral trunk (Harshavardhana and Dabke 2014). The term 'furcal' refers to its forked nature, since it links the lumbar and sacral plexuses. Occasionally, the furcal nerve arises at the level of either the third or the fifth lumbar spinal nerves, in which case the sacral plexus is considered prefixed or postfixed, respectively.

Inflammatory processes, such as retrocaecal appendicitis on the right and diverticular abscess on the left, can occur in the posterior abdominal wall in the tissues immediately anterior to psoas major. These may irritate one or more branches of the lumbar plexus, causing pain or sensory disturbance in the distribution of the affected nerves, e.g. the skin of the thigh, hip or buttock.

Muscular branches

Small branches from the lumbar ventral rami supply adjacent muscles such as psoas major and quadratus lumborum (Mahan et al 2017).

Iliohypogastric nerve

Distribution

The iliohypogastric nerve usually originates from the first lumbar ventral ramus but may arise wholly or in part from the twelfth thoracic ventral ramus (Klaassen et al 2011). It emerges from the upper lateral border of psoas major and crosses obliquely posterior to the inferior pole of the kidney on the anterior surface of quadratus lumborum. Above the iliac crest, it enters the posterior part of transversus abdominis and then runs anteriorly between transversus abdominis and internal abdominal oblique, which it supplies. It gives off a lateral cutaneous branch that pierces internal and external abdominal oblique above the iliac crest and supplies the posterolateral gluteal skin. It continues forwards, pierces internal abdominal oblique approximately 3 cm medial and 1 cm inferior to the anterior superior iliac spine (in adults), and then penetrates the external abdominal oblique aponeurosis approximately 3 cm above and medial to the superficial inguinal ring to supply the skin of the hypogastric region. The iliohypogastric nerve frequently connects with the ilio-inguinal nerve and less commonly with the subcostal nerve. Motor branches of the iliohypogastric nerve innervate transversus abdominis and internal abdominal oblique. Cutaneous branches innervate the skin of the posterolateral gluteal and hypogastric regions.

Injury

The iliohypogastric nerve is occasionally injured by a surgical incision in the right inguinal region, e.g. during an inguinal hernia repair, open appendicectomy or abdominal wall trocar placement, but there is rarely any noticeable sensory loss because the skin of the hypogastric region is innervated from several sources. Division of the iliohypogastric nerve above the anterior superior iliac spine may weaken the posterior wall of the inguinal canal and predispose to formation of a direct inguinal hernia.

Ilio-inguinal nerve

Distribution

The ilio-inguinal nerve usually originates from the first lumbar ventral ramus but may receive a contribution from the twelfth thoracic or second lumbar ventral rami (Klaassen et al 2011). It emerges from the lateral border of psoas major, with or just inferior to the iliohypogastric nerve, passes obliquely across the anterior aspect of quadratus lumborum and the superior part of iliacus and enters transversus abdominis about 3 cm medial and 4 cm inferior to the anterior superior iliac spine (in the adult); at this site, it is readily blocked by local anaesthetic. In this region, a branch may connect with the iliohypogastric or lateral femoral cutaneous nerve. It pierces internal abdominal oblique more inferiorly, supplies it, and then traverses the remainder of the inguinal canal superficial to the spermatic cord or round ligament of the uterus. It emerges with the spermatic cord from the superficial inguinal ring and divides into terminal cutaneous branches.

Numerous anatomical variations have been described (Al-dabbagh 2002, Ndiaye et al 2007). The ilio-inguinal and genitofemoral nerves may interconnect within the inguinal canal, so that each innervates the skin of the genitalia to a variable extent (Rab et al 2001, Cesmebasi et al 2015). The ilio-inguinal nerve may pierce the aponeurosis of external abdominal oblique proximal to the superficial inguinal ring or divide into terminal branches within the inguinal canal. It may form a common trunk with the iliohypogastric nerve as far as the midpoint of the inguinal canal or may be very small or absent, in which case the iliohypogastric nerve and genital branch of the genitofemoral nerve supply its territory. Rarely it arises as a branch of the genitofemoral nerve. Motor branches of the ilio-inguinal nerve supply transversus abdominis and internal abdominal oblique; the fibres are given off before the nerve enters the lateral aspect of the inguinal canal. Sensory branches innervate the skin of the proximal medial thigh and the skin over the root of the penis and proximal part of the scrotum in males (anterior scrotal nerve), or the skin covering the mons pubis and the adjoining labium majus in females (anterior labial nerve).

Injury

The ilio-inguinal nerve may be injured or entrapped during inguinal surgery, particularly for inguinal hernia repair, leading to sensory disturbances including pain from the external genitalia and proximal medial thigh (Ndiaye et al 2007).

Genitofemoral nerve

Distribution

The genitofemoral nerve originates from the first and second lumbar ventral rami and is formed within the substance of psoas major. It descends obliquely anteriorly through the muscle to emerge on its anterior surface nearer the medial border, opposite the third or fourth lumbar vertebra (Moro et al 2003). It then descends deep to the posterior parietal peritoneum overlying psoas major, crosses obliquely posterior to the ureter, and divides into genital and femoral branches; it may divide close to its origin such that its branches emerge separately from psoas major. The genital branch crosses the distal part of the external iliac artery, enters the inguinal canal through the deep ring and accompanies the spermatic cord or round ligament of the uterus. It exits the superficial inguinal ring, usually posterior to the spermatic cord or round ligament of the uterus, and supplies cremaster and the skin of the external genitalia. The femoral branch descends lateral to the external iliac artery before crossing the deep circumflex iliac artery to pass deep to the inguinal ligament (occasionally, through it) (Rab et al 2001) and enter the femoral sheath lateral to the femoral artery. It pierces the anterior aspect of the femoral sheath and fascia lata and supplies the skin over the proximal part of the femoral triangle. It may connect with the lateral femoral cutaneous nerve and anterior femoral cutaneous branches of the femoral nerve. Motor branches of the genitofemoral nerve innervate cremaster via its genital branch. Sensory fibres travelling in the genital branch innervate the skin of the scrotum in males and of the mons pubis and labium majus in females; there is considerable variability and overlap with the cutaneous distribution of the ilio-inguinal nerve (Cesmebasi et al 2015).

Injury

The genital branch of the genitofemoral nerve may be injured during inguinal hernia repair (open or laparoscopic), leading to neuralgia (Cesmebasi et al 2015).

Femoral nerve

The femoral nerve descends through psoas major and emerges on or deep to its lateral border, about 4 cm above the inguinal ligament (Moore and Stringer 2011). It passes between psoas major and iliacus deep to the iliac fascia and lies lateral to the femoral artery and sheath as it runs posterior to the inguinal ligament into the thigh. It gives off motor branches that supply iliacus, pectineus, sartorius and quadriceps femoris; articular branches to the hip, knee and ankle joints; branches to the femoral artery; cutaneous branches that supply the majority of the skin covering the anterior thigh, medial leg and medial foot (see Fig. 61.16). Injury to the femoral nerve may result in loss of sensation and paraesthesias within its cutaneous distribution, as well as difficulty ambulating, especially descending stairs. The further course and distribution of the femoral nerve are described in Chapter 77.

Lateral femoral cutaneous nerve

The lateral femoral cutaneous nerve (lateral cutaneous nerve of the thigh) is usually derived from the second and third lumbar ventral rami, but variable contributions from the first to the third lumbar ventral rami have been described (de Ridder et al 1999). The nerve emerges from the posterolateral border of psoas major and crosses iliacus obliquely, running towards the anterior superior iliac spine. It supplies sensory fibres to the parietal peritoneum in the iliac fossa. On the right, the nerve passes posterolateral to the caecum, from which it is separated by the iliac fascia and peritoneum; on the left, it passes posterior to the inferior part of the descending colon. Both nerves usually pass posterior to the inguinal ligament about 1–2 cm medial to the anterior superior iliac spine; occasionally they pass through or, rarely, anterior to the ligament (Tubbs et al 2016). A separate fascial canal for this nerve has been described (Hanna 2017). Occasionally, the nerve lies anterior or superior to the anterior superior iliac spine as it enters the thigh. In the thigh,

the lateral femoral cutaneous nerve usually passes anterior or lateral to sartorius but may pierce the muscle. Its further course and distribution are described in (Chapter 77).

Obturator nerve

The obturator nerve is formed within the substance of psoas major to emerge from its posteromedial border near the fifth lumbar vertebra (Kirchmair et al 2008). It passes posterior to the common iliac vessels and lateral to the internal iliac vessels, descends on the lateral wall of the pelvis attached to the obturator fascia, and lies anterosuperior to the obturator vessels before running into the obturator canal to enter the thigh. The obturator nerve is said to have no branches in the abdomen or pelvis, although it has been reported to send articular branches to the anterior aspect of the sacroiliac joint. Its sensory branches innervate the hip and knee joints, and a small, variable patch of skin on the proximal medial thigh, and its motor branches innervate obturator externus, adductor longus, adductor brevis, adductor magnus, gracilis and sometimes pectineus (see Fig. 61.16) (Tubbs et al 2016).

Compression of the obturator nerve, e.g. by an obturator hernia, may result in weakness of the muscles of the adductor compartment of the thigh and pain and paraesthesias along the medial thigh, inferiorly to the knee (Howship-Romberg sign). The further course and distribution are described in Chapter 77.

Accessory obturator nerve

The accessory obturator nerve is sometimes present, more often on the left (Turgut et al 2017), and is usually formed by the third and fourth lumbar ventral rami. It emerges from the medial border of psoas major, lateral to the obturator nerve, and runs over the superior pubic ramus posterior to pectineus, where it gives off branches to the muscle and sometimes to the hip joint; it may join with the anterior branch of the obturator nerve (Ch. 77).

Lumbar sympathetic system

The lumbar part of each sympathetic trunk usually contains four interconnected ganglia lying in extraperitoneal connective tissue on the anterolateral aspects of the lumbar vertebrae along the medial margin of psoas major (see Fig. 61.10). Superiorly, it is continuous with the thoracic part of the sympathetic trunk posterior to the medial arcuate ligament at the level of the first and second lumbar vertebrae (Feigl et al 2011). Inferiorly, it passes posterior to the common iliac vessels and is continuous with the sacral part of the sympathetic trunk. On the right side, it lies posterior to the inferior vena cava; on the left, it is posterior to the lateral aortic nodes. It is anterior to most of the lumbar vessels but may pass behind some lumbar veins.

The first, second, and sometimes the third, lumbar ventral rami are each connected to the lumbar part of the sympathetic trunk by a white ramus communicans. All lumbar ventral rami are joined near their origins by long, slender grey rami communicantes from the four lumbar ganglia. Their arrangement is irregular: one ganglion may give rami to two or three lumbar ventral rami; one lumbar ventral ramus may receive rami from two ganglia; grey rami communicantes may leave the sympathetic trunk between ganglia (Murata et al 2003).

The lumbar sympathetic trunks are vulnerable during retroperitoneal lymph node dissection: their injury can impair emission of seminal fluid and lead to retrograde ejaculation.

Lumbar parasympathetic system

The parasympathetic supply to the abdominal viscera is provided by the vagus nerve to the coeliac and superior mesenteric plexuses, and by pelvic splanchnic nerves that are distributed through the inferior hypogastric and inferior mesenteric plexuses to derivatives of the hindgut (Ch. 59).

Para-aortic bodies

The para-aortic bodies (also known as paraganglia or, collectively, as the organ of Zuckerkandl), are collections of neural crest-derived chromaffin tissue closely related to the aortic autonomic plexuses. They are relatively large in the fetus, where they may have a role in maintaining blood pressure by catecholamine secretion. They reach a maximum size at around 3 years of age and have normally regressed by adulthood. They are usually found as paired structures lying anterolateral to the abdominal aorta in the region of the inferior mesenteric and superior hypogastric plexuses, but multiple smaller collections may be present. Occasionally they are found as far proximally as the coeliac plexus or as far distally as the inferior hypogastric plexus, or they may be closely applied to the ganglia of the lumbar part of the sympathetic trunk. Scattered cells that persist into adulthood may, rarely, be the sites of paraganglioma (Pacak and Tella 2018).

CHAPTER
62

Peritoneum, mesentery and peritoneal cavity

The peritoneum is the largest serous membrane in the body. In males the peritoneum forms a closed sac, but in females it is open at the abdominal ostia of the uterine tubes. Its smooth appearance is unremarkable, but its conformation varies. Directly beneath the single layer of mesothelium is a well-developed basement membrane, outside which is a rich lymphatic plexus. Microscopic mesothelial pores or peritoneal stomata are distributed throughout the peritoneum but particularly on the undersurface of the respiratory diaphragm and anterior abdominal wall (Wassilev et al 1998). At the peritoneal stomata the mesothelium is close to underlying lymphatic endothelial cells and there is no intervening basement membrane. Both peritoneal stomata and sites of macrophage and lymphoid aggregates ('milky spots') in the omenta contribute to peritoneal fluid absorption, and their occlusion by malignant cells can result in ascites (diZerega and Rodgers 1992, Hagiwara et al 1994). Neighbouring mesothelial cells are joined by junctional complexes but permit macrophages to pass. Some regions of the submesothelial connective tissue also contain macrophages, lymphocytes and adipocytes.

The normal pressure within the peritoneal cavity is about 2–10 mmHg (higher in pregnant and obese individuals) (Sanchez et al 2001). It can be measured directly using a catheter inserted into the abdomen, or indirectly by monitoring the pressure in the urinary bladder or stomach. The pressure inside the abdomen can increase after trauma as a result of the accumulation of blood, fluid or oedema, leading to 'abdominal compartment syndrome'. In such patients, monitoring of intra-abdominal pressure can identify major increases (above about 25 mmHg) that could jeopardize blood flow to vital organs and dictate the need for urgent decompression.

PERITONEAL FLUID

The peritoneal cavity lies between the parietal peritoneum, which lines the abdominal walls, the visceral peritoneum (covering abdominal viscera and mesentery) and the peritoneal reflection. It contains a small amount of peritoneal fluid, rarely more than 5 ml in healthy males and postmenopausal females (Yoshikawa et al 2013). Up to 25 ml of fluid can be present in healthy young females, depending on the phase of the menstrual cycle (Koninckx et al 1980). The fluid allows the viscera covered with peritoneum, i.e. intermesenteric, to glide freely within the peritoneal cavity. Normal peritoneal fluid contains water, proteins (less than 30 g per litre), electrolytes and solutes derived from interstitial fluid in the adjacent tissues and from plasma in local capillaries. It also contains a few cells, including desquamated mesothelium, nomadic peritoneal macrophages, mast cells, fibroblasts, lymphocytes and other leukocytes. Macrophages migrate freely between the peritoneal cavity and the surrounding connective tissue. In females, blood or fluid can enter the peritoneal cavity from a ruptured ovarian follicle or from the retrograde flow of menstrual fluid along the uterine tubes (which can cause endometriosis). Under normal circumstances, the peritoneal cavity contains no air.

The peritoneum and its fluid have important defensive properties (Autio 1964). Peritoneal fluid flows in a predominantly clockwise direction around the peritoneal cavity and gravitates to dependent sites within the cavity: diaphragmatic respiratory movements, negative intrathoracic pressure and intestinal peristalsis encourage flow from the pelvis to the subphrenic regions, even when the individual is erect (Meyers et al 1987, Meyers 1994). Fluid preferentially ascends from the inferior abdomen and pelvis to the right subhepatic and subphrenic spaces via the right paracolic gutter (deeper than the left paracolic gutter in the supine position and there is no phrenicocolic ligament or reflection to obstruct flow) (Meyers 1973). Passage across the midline to the left subphrenic space is prevented by the falciform ligament. Malignant cells can become trapped within peritoneal recesses or in the milky spots of the greater omentum, where they proliferate and produce visible and palpable tumour deposits. These sites must be deliberately examined during searches for peritoneal metastases (Zonca et al 2008). Gross infiltration of the omentum by cancer is often referred to as an 'omental cake'. The movement of peritoneal fluid explains the presence of disease at sites such as the undersurface of the right half of the respiratory diaphragm and the pelvic pouches. An example is Fitz–Hugh–Curtis syndrome, in which organisms causing gonorrhoea or chlamydia organisms enter the peritoneal cavity through the uterine tubes and are transported in the peritoneal fluid to the right upper quadrant, where they cause perihepatic inflammation. Disruption of the integrity of the peritoneum by percutaneous puncture, laparoscopy or open surgery profoundly affects its defensive function and can create 'sticky' sites where pathogens or malignant cells can settle and proliferate.

Rarely there are direct communications (pleuroperitoneal fenestrae) between the peritoneal and pleural cavities (Simmons and Mir 1989, Pestieau et al 2000).

PERITONEAL ATTACHMENTS

The parietal peritoneum is attached to the muscular layers of the abdominal wall by extraperitoneal connective tissue. It detaches from the abdominal wall to continue as the visceral peritoneum of nearby viscera (including the mesentery). The region of detachment is referred to as the peritoneal reflection (**Fig. 62.1A**). The parietal peritoneum is only loosely attached around the urinary bladder and rectum so as to accommodate alterations in their size, whereas it adheres firmly to the inferior surface of the respiratory diaphragm and linea alba. The extraperitoneal tissue over the posterior abdominal wall frequently contains large amounts of fat, especially in obese males. Visceral peritoneum adheres firmly to the underlying viscera, often blends with connective tissue in the wall of the organ and rarely contains loose connective or adipose tissue.

GENERAL ARRANGEMENT OF THE PERITONEUM

The gastrointestinal tract develops as a single tube suspended in the abdominal cavity by ventral and dorsal regions of the mesentery (Ch. 21). The mesentery is derived from the dorsal and ventral mesenteries. The rotation and subsequent attachment of parts of the gastrointestinal tract to the posterior abdominal wall create the impression that these structures are retroperitoneal. However, it is now acknowledged that the mesentery is continuous and that all regions of the intestine are centrally connected via the attached mesentery (Byrnes et al 2019a–2019d) (see Fig. 62.1A). The intestines can be divided into attached and non-attached regions. Attached regions include the duodenum, ascending and descending colons and the rectum. Non-attached regions include the stomach, small intestine, and the transverse and sigmoid colon.

The mesentery is continuous from the gastro-oesophageal to the anorectal junctions (Byrnes et al 2019a–2019d). All abdominal digestive organs are continuous with a region of the mesenteric frame. Some regions (the greater and lesser omenta) differ considerably in appearance from others, including the mesocolon and mesosigmoid (sigmoid mesocolon). Where the parietal peritoneum detaches from the abdominal wall as the peritoneal reflection, and extends to adjacent viscera such as the liver, it is often termed a 'ligament'. The mesentery contains neurovascular bundles and lymphatic **vessels** that supply digestive system organs. In individuals with obesity, extensive adipose tissue within the mesentery can obscure neurovascular bundles. In contrast, in the very young, elderly or malnourished, the mesentery lacks adipose tissue and neurovascular bundles are more obvious within 'mesenteric pedicles' that are routinely used as anatomical landmarks to guide abdominal surgeons.

The surfaces of viscera attached to the mesentery contribute to the visceral component of the peritoneal landscape. The latter is often subdivided into potential 'spaces' where fluids such as blood or purulence can accumulate under pathological conditions.

Surgical planes are defined by anatomical structures

Abdominal surgeons rigorously follow an anatomical roadmap when conducting resections, in order to minimize blood loss and trauma to tissues. The map is created by the mesentery and its continuity with abdominal digestive organs, and the surrounding peritoneal reflection. The surgeon incises the peritoneum to access the plane between the mesentery and underlying fascia (**Fig. 62.1B**). When the intact mesentery has been detached from the fascia back to the midline, it can be disconnected by dividing major vascular trunks. These activities are repeated at all levels from the oesophagus to the rectum and are based on the anatomical foundation provided by the mesentery and associated peritoneum (**Figs 62.2-62.4**).

Peritoneum of the upper abdomen

The abdominal part of the oesophagus, stomach, liver and spleen all lie within a region that runs from the posterior to the anterior abdominal walls and is broadly termed the mesogastrium (Coakley and Hricak 1999). Its attachments are divisible into regions such as the falciform ligament, coronary ligament, lesser omentum (hepatogastric and hepatoduodenal ligaments), greater omentum (including the gastrocolic ligament), gastrosplenic ligament, splenorenal ligament and phrenicocolic ligament (see Fig. 62.1A; **Fig. 62.5**).

Falciform ligament

The falciform ligament is a thin anteroposterior double fold of peritoneum that represents an anterior portion of the mesentery connecting the liver to the posterior aspect of the anterior abdominal wall. It extends inferiorly to the level of the umbilicus and superiorly it narrows to a depth of 1–2 cm as the distance between the liver and anterior abdominal wall decreases. Its two peritoneal layers separate to enclose the liver, to which it adheres firmly. Superiorly, the two peritoneal layers are continuous with the parietal peritoneum on the undersurface of the respiratory diaphragm, from which they are reflected laterally to form the superior layer of the coronary ligament of the liver on the right and the left triangular ligament of the liver on the left. The inferior aspect of the falciform ligament forms a free border, where the two peritoneal layers are continuous with each other as they enclose the round ligament of the liver (ligamentum teres hepatis), a remnant of the umbilical vein. Because the peritoneum of the falciform ligament is continuous with that covering the posterior abdominal wall and with the parietal peritoneum of the anterior abdominal wall, blood from a retroperitoneal haemorrhage (commonly, acute haemorrhagic pancreatitis) can track beneath the peritoneum and appear as haemorrhagic discoloration around the umbilicus (Cullen's sign). The blood-tinged fluid reaches the peri-umbilical region via the lesser omentum and the falciform ligament.

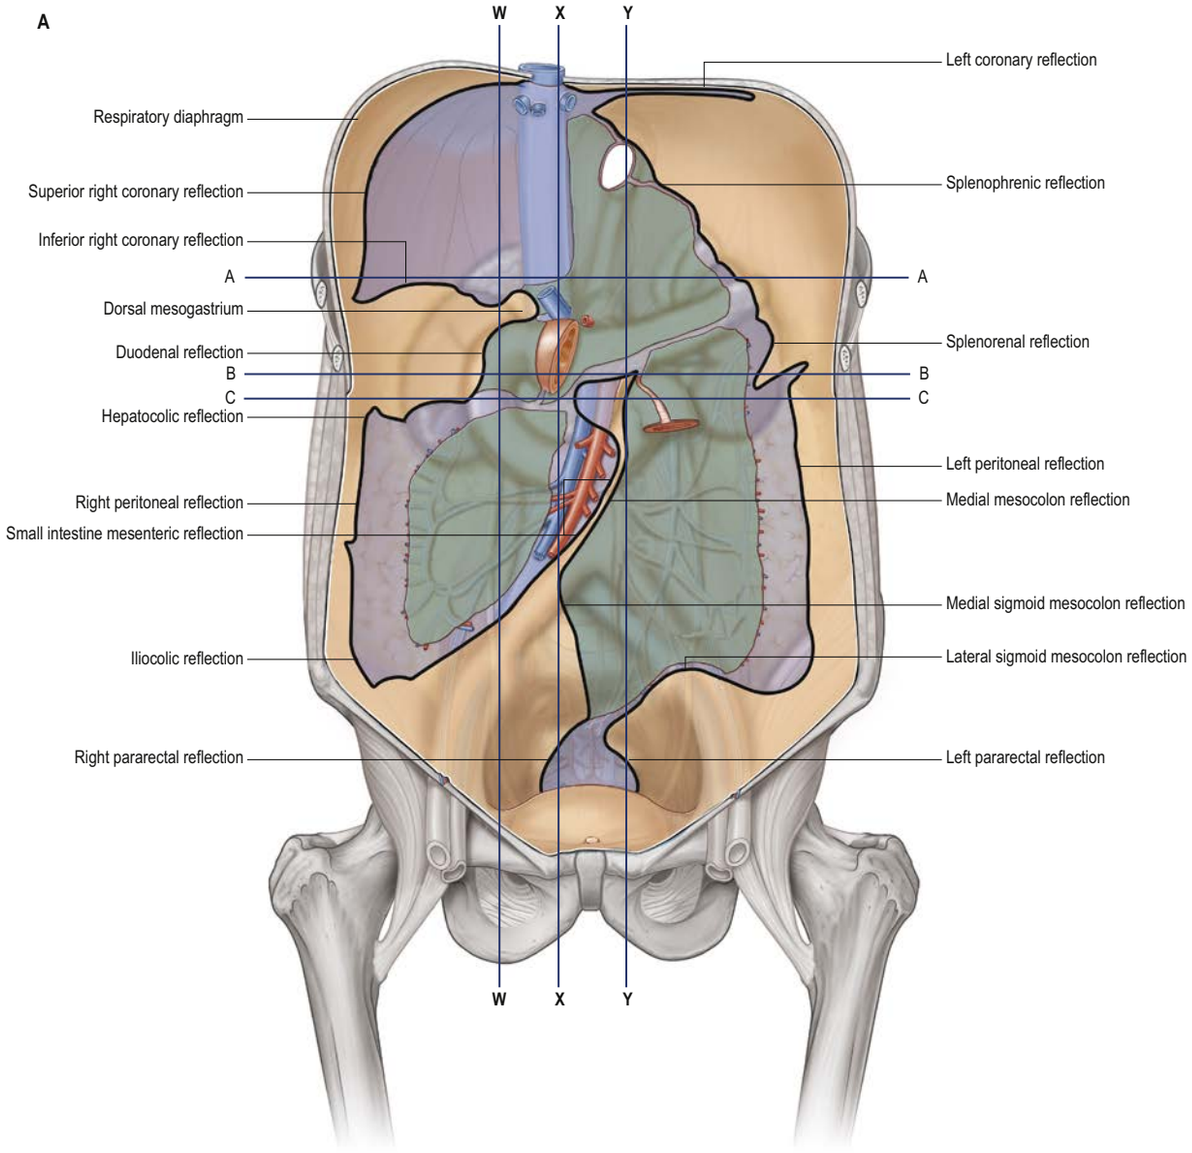

Fig. 62.1 A, The posterior abdominal wall, showing the lines of peritoneal reflection, after removal of the liver, spleen, stomach, jejunum, ileum, caecum, transverse colon and sigmoid colon. The various sessile organs can be seen through the posterior wall of the parietal peritoneum. Note the ascending and descending colons, duodenum, kidneys, suprarenal glands, pancreas and inferior vena cava. Line W–W represents the plane of Fig. 62.2. Line X–X represents the plane of Fig. 62.3. Line Y–Y represents the plane of Fig. 62.4. Line A–A represents the plane of Fig. 62.5A. Line B–B represents the plane of Fig. 62.5B. Line C–C represents the plane of Fig. 62.5C. *Continued*

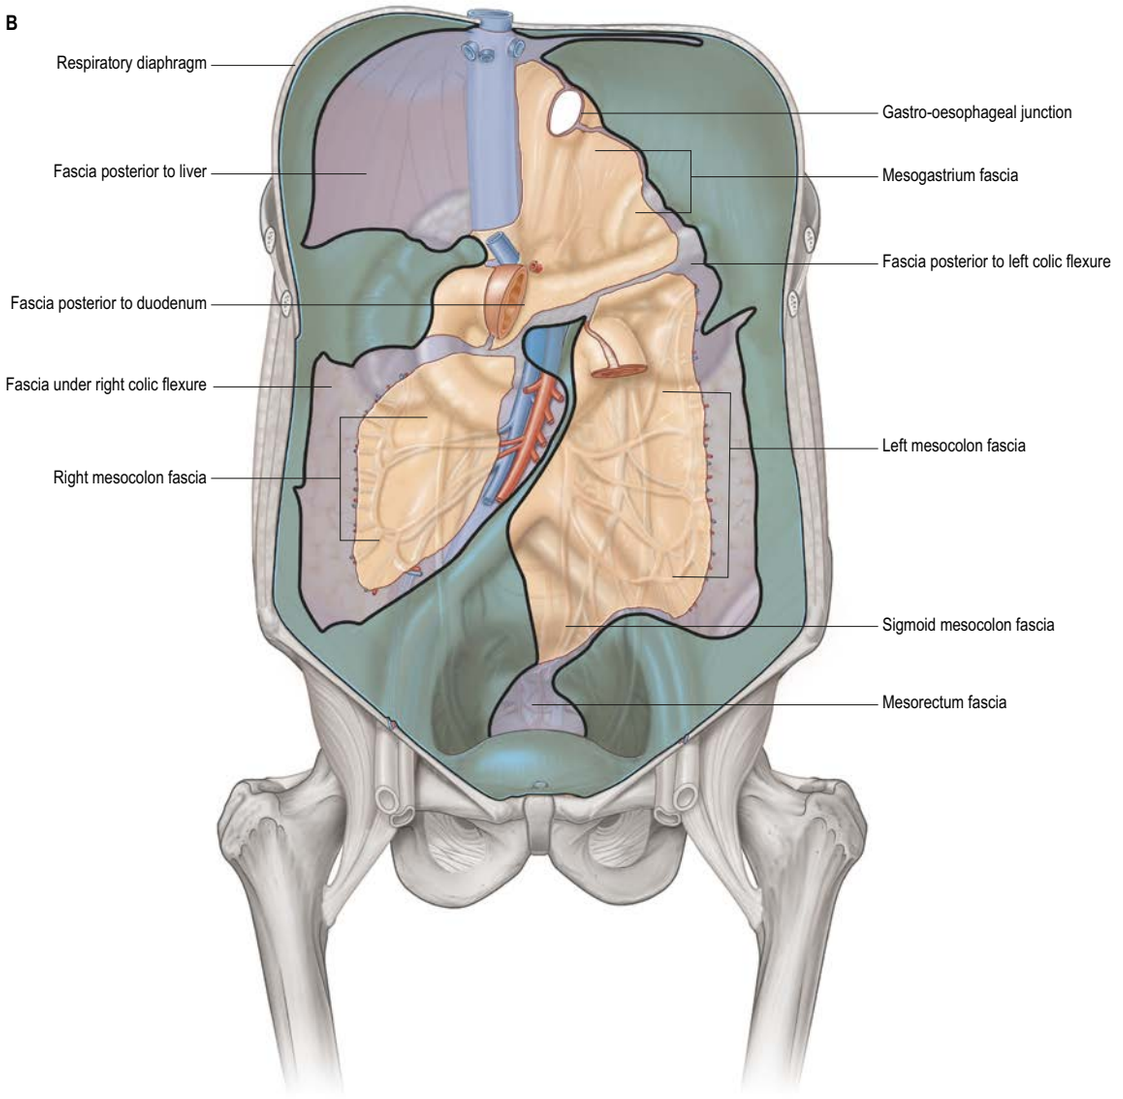

Fig. 62.1 cont'd B, Regions of fascial attachment of various abdominal organs.

Peritoneal and mesenteric connections of the liver

The liver is almost completely covered in visceral peritoneum, and only the 'bare area' posteriorly is directly apposed to the right half of the respiratory diaphragm. Peritoneal ligaments (also referred to as peritoneal reflections) and regions of mesentery run from the liver to the surrounding viscera and to the abdominal wall and respiratory diaphragm (see Figs 62.1A, 62.2); they are described in detail in Chapter 66.

The coronary ligament is formed by the reflection of the peritoneum from the respiratory diaphragm onto the superior and posterior surfaces of the right lobe of the liver. Between the two layers of this ligament, a large triangular area, the bare area of the liver, is devoid of peritoneal covering. Here, the liver is connected to, but separated from, the respiratory diaphragm by a thin layer of areolar tissue. On the right, the two layers of the coronary ligament converge laterally to form the right triangular ligament. On the left, the two layers of peritoneal reflection fuse to form the left triangular ligament. The superior layer of the coronary ligament is reflected superiorly onto the undersurface of the diaphragm and inferiorly onto the right and superior surfaces of the liver. The inferior layer of the coronary ligament is reflected inferiorly from the posterior surface of the liver onto the posterior abdominal wall, where it is continuous with the parietal peritoneum overlying the right kidney, and continues to the superior (first) part of the duodenum and right colic flexure (see Fig. 62.3). Medially, it passes in front of a short segment of the inferior vena cava lying between the superior part of the duodenum inferiorly and the caudate process of the liver superiorly, forming the posterior wall of the omental foramen. It continues to the left as the peritoneum overlying the anterior surface of the dorsal mesogastrium, turns anteriorly and continues as the undersurface of the greater omentum.

The peritoneal recess between the inferior surface of the liver and the colic component of the right colic flexure is known as the hepatorenal recess (pouch of Morison) (Stringer 2009). In the supine position, this is the most dependent part of the peritoneal cavity in the upper abdomen and is a site toward which fluid or peritoneal metastases can gravitate.

The right triangular ligament is a short, V-shaped fold at the right lateral limit of the bare area of the liver where the two layers of the coronary ligament converge. As it is reflected onto the abdominal wall it is continuous with the parietal peritoneum of the right posterolateral abdominal wall. Surgical division of the right triangular and coronary ligaments allows the right lobe of the liver to be retracted anteriorly, exposing the lateral aspect of the inferior vena cava posterior to the liver.

The left triangular ligament is a double layer of peritoneum that extends for a variable distance over the superior border of the left lobe of the liver. Medially, the anterior leaf is continuous with the left layer (or left surface) of the falciform ligament, while the posterior leaf is continuous with the lesser omentum. The left triangular ligament lies anterior to the abdominal part of the oesophagus, the superior limits of the lesser omentum, and part of the fundus of the stomach. It is continuous with the parietal peritoneum lining the undersurface of the left side of the respiratory diaphragm, which is continuous with the parietal peritoneum lining the posterior abdominal wall. Division of the left triangular ligament allows the left lobe of the liver to be mobilized; the ligament is an important stabilizing factor for the left lobe after excision of the right lobe of the liver.

Lesser omentum

The lesser omentum is a region of mesentery derived from the ventral mesogastrium. Formed by two layers of peritoneum separated by a variable amount of connective tissue and fat, it runs between the inferior, visceral surface of the liver and the abdominal part of the oesophagus, stomach, pylorus and superior part of the duodenum. Superiorly, its attachment to the inferior surface of the liver forms an L shape. The

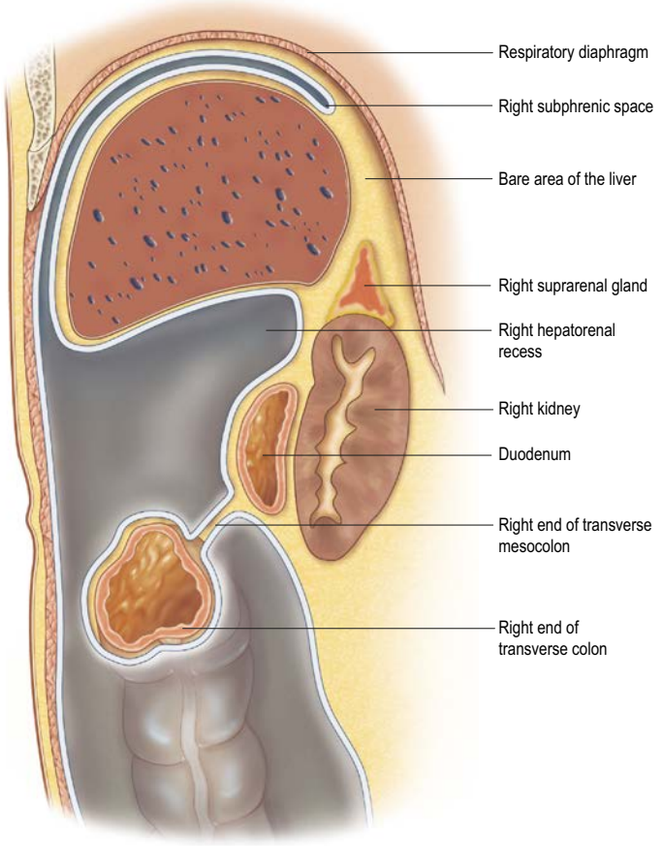

Fig. 62.2 A sagittal section through the abdomen to the right of the omental foramen along the line of W–W in Fig. 62.1.

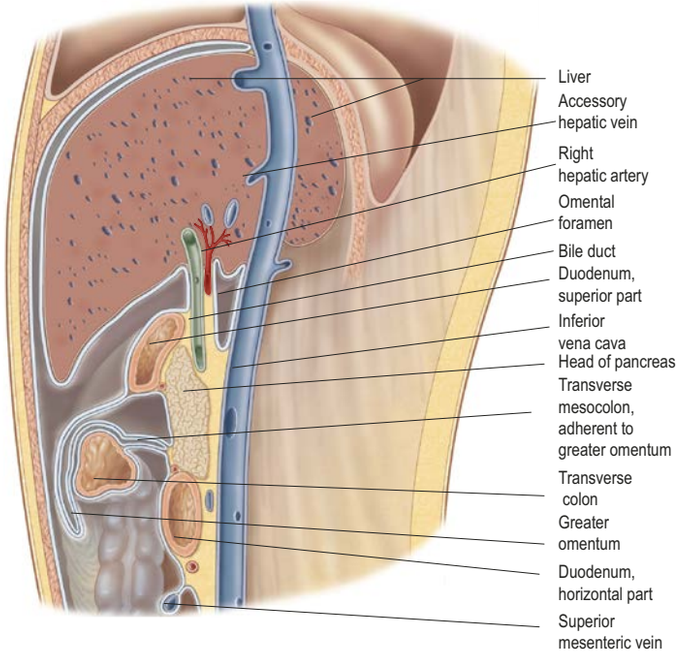

Fig. 62.3 A section through the superior part of the abdominal cavity, along the line X–X in Fig. 62.1. The boundaries of the omental foramen are shown and a small recess of the omental bursa is displayed anterior to the head of the pancreas. Note that the transverse colon and its mesocolon adhere to the posterior two layers of the greater omentum. Four peritoneal layers contribute to the formation of the greater omentum.

vertical component of the L shape is formed by the fissure for the ligamentum venosum, and inferiorly, the attachment turns horizontally to complete the L in the porta hepatis. The part of the lesser omentum running between the liver and the stomach is the hepatogastric ligament and the part between the liver and duodenum is the hepatoduodenal ligament. The right and left gastric vessels, branches of the vagal trunks and lymph nodes are contained within the two layers of the

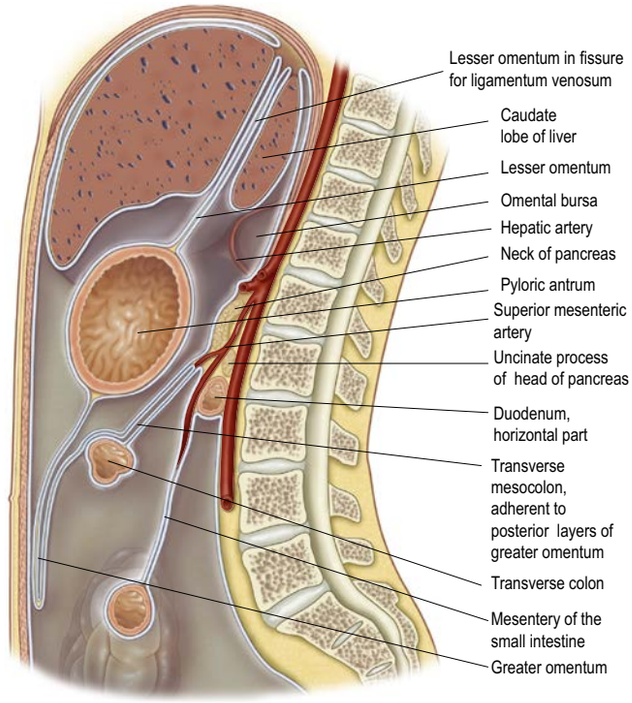

Fig. 62.4 A sagittal section through the abdomen, approximately in the median plane. Compare with Fig. 62.1. The section cuts the posterior abdominal wall along the line Y–Y in Fig. 62.1. The peritoneal cavity is shown by blue shading; the peritoneum and its cut edges are in pale blue.

hepatogastric ligament close to its attachment to the stomach. An accessory or replaced left hepatic artery is sometimes present. The anterior layer of the lesser omentum descends from the fissure for the ligamentum venosum on to the anterior surface of the abdominal part of the oesophagus, stomach and duodenum. The posterior layer descends from the fissure and runs on to the posterior surface and pylorus of the stomach: it forms part of the anterior surface of the omental bursa (see Fig. 62.4). At the lesser curvature of the stomach, the peritoneal layers of the lesser omentum become continuous with the visceral peritoneum covering the anterior and posterior surfaces of the stomach.

The free right lateral border of the lesser omentum (i.e. the hepatoduodenal ligament) is thickened to form a mesenteric pedicle that extends from the porta hepatis to the junction between the superior and descending (second) parts of the duodenum. It forms the anterior boundary of the omental foramen and contains the hepatic portal vein (posteriorly), the bile duct (anteriorly to the right) and proper hepatic artery (anteriorly to the left) (see Figs 62.3, 62.5B), together with lymphatic vessels, lymph nodes and hepatic autonomic nerves. An accessory or replaced right hepatic artery sometimes arises from the superior mesenteric artery in the free edge of the lesser omentum, usually running posterior to the hepatic portal vein. Often the free margin of the lesser omentum extends to the right as the cystoduodenal ligament that contains the gallbladder, cystic artery and duct and lymph nodes (Ashaolu et al 2011). This is of considerable clinical significance: this mesenteric appendage must be visualized in order to remove the gallbladder safely (i.e. cholecystectomy). The hepatoduodenal ligament continues distally posterior to the superior part of the duodenum and merges with the mesentery of the duodenum.

The superior border of the lesser omentum is short and runs over the inferior surface of the respiratory diaphragm between the liver and the medial aspect of the abdominal part of the oesophagus. The lesser omentum is thinner in this region and contains a variable amount of connective tissue, especially fat. It has a translucent appearance where it is thinnest, a feature that guides surgeons in identifying regions that can be divided safely.

Greater omentum

The greater omentum is the largest peritoneal fold and hangs inferiorly from the greater curvature of the stomach. When the undisturbed abdomen is opened, the greater omentum is frequently draped over the superior abdominal organs, but often not in the even distribution shown in many illustrations. It is usually thin but always contains some adipose tissue and is a common site for storage of fat in obese individuals, particularly males (Coulier 2009). The greater omentum

is a double sheet: each sheet consists of two layers of peritoneum separated by a small amount of connective tissue. The two sheets are folded back on themselves and adhere firmly to each other inferior to the transverse colon. Above this level the anterior sheet separates from the posterior sheet and is attached to the greater curvature of the stomach (see Fig. 62.4); this supracolic part of the greater omentum is known as the gastrocolic ligament. The most anterior layer of peritoneum of the greater omentum is continuous with the visceral peritoneum over the anterior surface of the stomach and duodenum. The anterior sheet descends from the greater curvature of the stomach and superior part of the duodenum for a variable distance into the peritoneal cavity and then turns sharply backwards on itself to ascend as the posterior sheet. The posterior sheet is extremely thin where it attaches to the transverse colon and superior surface of the transverse mesocolon. It extends cephalad, attached to (but not fused with) the superior surface of the transverse mesocolon, until it reaches the inferior border of the body and head of the pancreas (see Figs 62.4, 62.5C). At the pancreas the anterior layer envelops the pancreas and continues cephalad as the dorsal mesogastrium (see above). During surgery, the transverse mesocolon and greater omentum are separated by dividing through the posterior layer of the greater omentum, where this first attaches to the transverse colon. Alternatively, surgeons frequently divide directly through the greater omentum at the level where it approaches the greater curvature of the stomach. These activities are essential for gaining entry into the omental bursa.

On the left side of the abdomen, the greater omentum is attached to the gastrosplenic ligament or the peritoneal reflection in this region; on the right side, it extends to the beginning of the duodenum (see Fig. 62.4). A region of peritoneal reflection, the hepatocolic ligament, always extends from the inferior surface of the right lobe of the liver to the right colic flexure. The right border of the greater omentum usually adheres to the anterior surface of this region of reflection and thereafter to the right colic flexure and superior part of the ascending colon. In individuals, with obesity the right border of the greater omentum often extends laterally to adhere to the lateral border of the ascending colon and its associated region of peritoneal reflection (Jackson's membrane). Less commonly, the left border of the greater omentum adheres to the anterior surface of the descending colon.

The greater omentum has a rich blood supply derived from the right and left gastro-omental (gastro-epiploic) vessels that run between the two peritoneal layers of the anterior sheet of greater omentum, close to the greater curvature of the stomach. These vessels give off numerous omental branches that run the length of the omentum. Microscopic capillary convolutions, sometimes termed 'omental glomeruli', lie directly beneath the mesothelium of the greater omentum. They are surrounded by aggregations of macrophages and lymphocytes (milky spots) that drain into lymphatic vessels (Shimotsuma et al 1993); the macrophages form clusters near the mesothelial surface, while B and T lymphocytes are grouped around vessels. The fenestrated endothelium lining the omental glomeruli and the mesothelium overlying the milky spots form sites of leukocyte migration and peritoneal fluid absorption (Platell et al 2000). The number and size of milky spots increase when there is peritoneal inflammation, highlighting their defensive role.

The greater omentum serves several important functions. It is highly mobile and frequently adheres to inflamed viscera or foreign bodies within the abdominal cavity. This can limit the spread of infection, as in the walling-off of acute appendicitis, and promote haemostasis. However, it can also block peritoneal drains and catheters (such that omentectomy is sometimes performed when intraperitoneal catheters are placed). It absorbs peritoneal fluid. It contains macrophages and lymphoid tissue capable of destroying pathogens; for example, macrophages and neutrophils readily migrate from the greater omentum into the peritoneal cavity when there is peritonitis. It promotes neovascularization of the structures to which it adheres and thus promotes healing of ischaemic tissues and supports splenic autotransplantation (Ch. 69).

The remarkable capacity of the greater omentum to participate in reparative processes is highlighted by its use as an omental pedicle flap or free flap in reconstructive surgery: it has been used to support closure of gastrointestinal perforations, fill 'dead space' after surgical excision of pathology, and cover wound defects. A greater omental pedicle or free flap based on the right gastro-omental vessels can be mobilized by dividing the gastric branches of these vessels close to the surface of the stomach and the left gastro-omental vessels near their origin.

Peritoneal connections of the spleen

The peritoneal connections of the spleen anchor it in the left upper quadrant of the abdomen. Although they are called ligaments, they are regions of peritoneal reflection from the parietal peritoneum of the left upper quadrant to the spleen. They include the gastrosplenic, splenorenal and phrenicocolic ligaments. The gastrosplenic ligament runs between the greater curvature of the stomach and the splenic hilum, and is the cephalad continuation of the greater omentum. The peritoneal layers of the gastrosplenic ligament separate to enclose the spleen. The outer layer then detaches from the spleen to form the splenorenal and phrenicocolic ligaments that continue posteriorly as the dorsal mesogastrium, forming the posterior wall of the omental bursa. The splenorenal ligament extends from the spleen to the posterior abdominal wall and the phrenicocolic ligament connects the left colic flexure to the respiratory diaphragm.

The splenorenal ligament (see Figs 62.1, 62.5B) is continuous medially with the peritoneum of the posterior wall of the omental bursa over the left kidney and runs up to the splenic hilum, where it is continuous with the posterior layer of the gastrosplenic ligament. The posterior layer of the splenorenal ligament is continuous laterally with the peritoneum over the inferior surface of the respiratory diaphragm and runs onto the splenic surface over the renal impression. The splenic vessels lie between the layers of the splenorenal ligament; the tail of the pancreas is usually present in its inferior portion.

As the gastrosplenic ligament is a cephalad extension of the greater omentum, it also consists of two layers of peritoneum (see Fig. 62.5B). The posterior layer is continuous with the peritoneum of the splenic hilum and the peritoneum over the posterior surface of the stomach. This layer continues medially as the anterior surface of the dorsal mesogastrium. The anterior layer is continuous with the peritoneum reflected off the gastric impression of the spleen and with the peritoneum over the anterior surface of the stomach. The short gastric and left gastro-omental branches of the splenic artery, with their corresponding veins, pass between the layers of the gastrosplenic ligament.

The phrenicocolic ligament is a region of peritoneal reflection extending from the colic component of the left colic flexure to the adjacent parietal peritoneum. Medially, it is attached to the left border of the greater omentum. Inferiorly, it continues as the left lateral reflection. Superiorly, it continues as the splenorenal ligament or region of reflection.

Undue traction on the peritoneal attachments of the spleen at surgery can cause a capsular tear and serious bleeding. A clear understanding of peritoneal anatomy in this region is therefore essential for the surgeon. Downward traction on the phrenicocolic ligament during mobilization of the left colic flexure is particularly hazardous; medial traction on the greater omentum can also injure the spleen if the omentum adheres to the fibrous capsule of the spleen. Unfortunately, surgical trauma is the main cause for splenectomy.

Peritoneum of the lower abdomen

The posterior surface of the inferior anterior abdominal wall is lined by parietal peritoneum, which extends from the linea alba centrally to the lateral paracolic gutters, where it is reflected over the front and sides of the ascending colon on the right and the descending colons on the left (see Fig. 62.5C). The ascending and descending colons are now regarded as having attached regions of mesentery (i.e. the right and left mesocolon respectively). The surface of the viscus is considered to be lined by visceral peritoneum that is continuous with the parietal peritoneum at regions of peritoneal reflection. In keeping with this, the parietal peritoneum is reflected onto the small intestine mesentery where this approaches the posterior abdominal wall, and continues laterally as the right mesocolon. The anatomical organization of the small and large intestines and associated mesentery explain the organization of their surrounding peritoneal reflection at all levels from the duodenojejunal flexure to the mesorectum.

Transverse mesocolon

The mesentery of the transverse colon is a region of the mesentery associated with the large intestine that suspends the transverse colon in the peritoneal cavity. The transverse mesocolon attaches centrally and obliquely from the anterior aspect of the descending part of the duodenum, over the head and neck of the pancreas superior to the duodenojejunal junction, and over the superior pole of the left kidney to the left colic flexure (see Figs 62.2–62.4). It contains the middle colic vessels and their branches, together with autonomic nerves from the aortic plexus, lymphatic vessels and lymph nodes. Near the left colic flexure, the ascending branch of the left colic artery terminates within the transverse mesocolon. Its two peritoneal layers pass to the posterior surface of the transverse colon, where they separate to invest it. In between the flexures, the superior layer of mesocolic peritoneum is attached to the

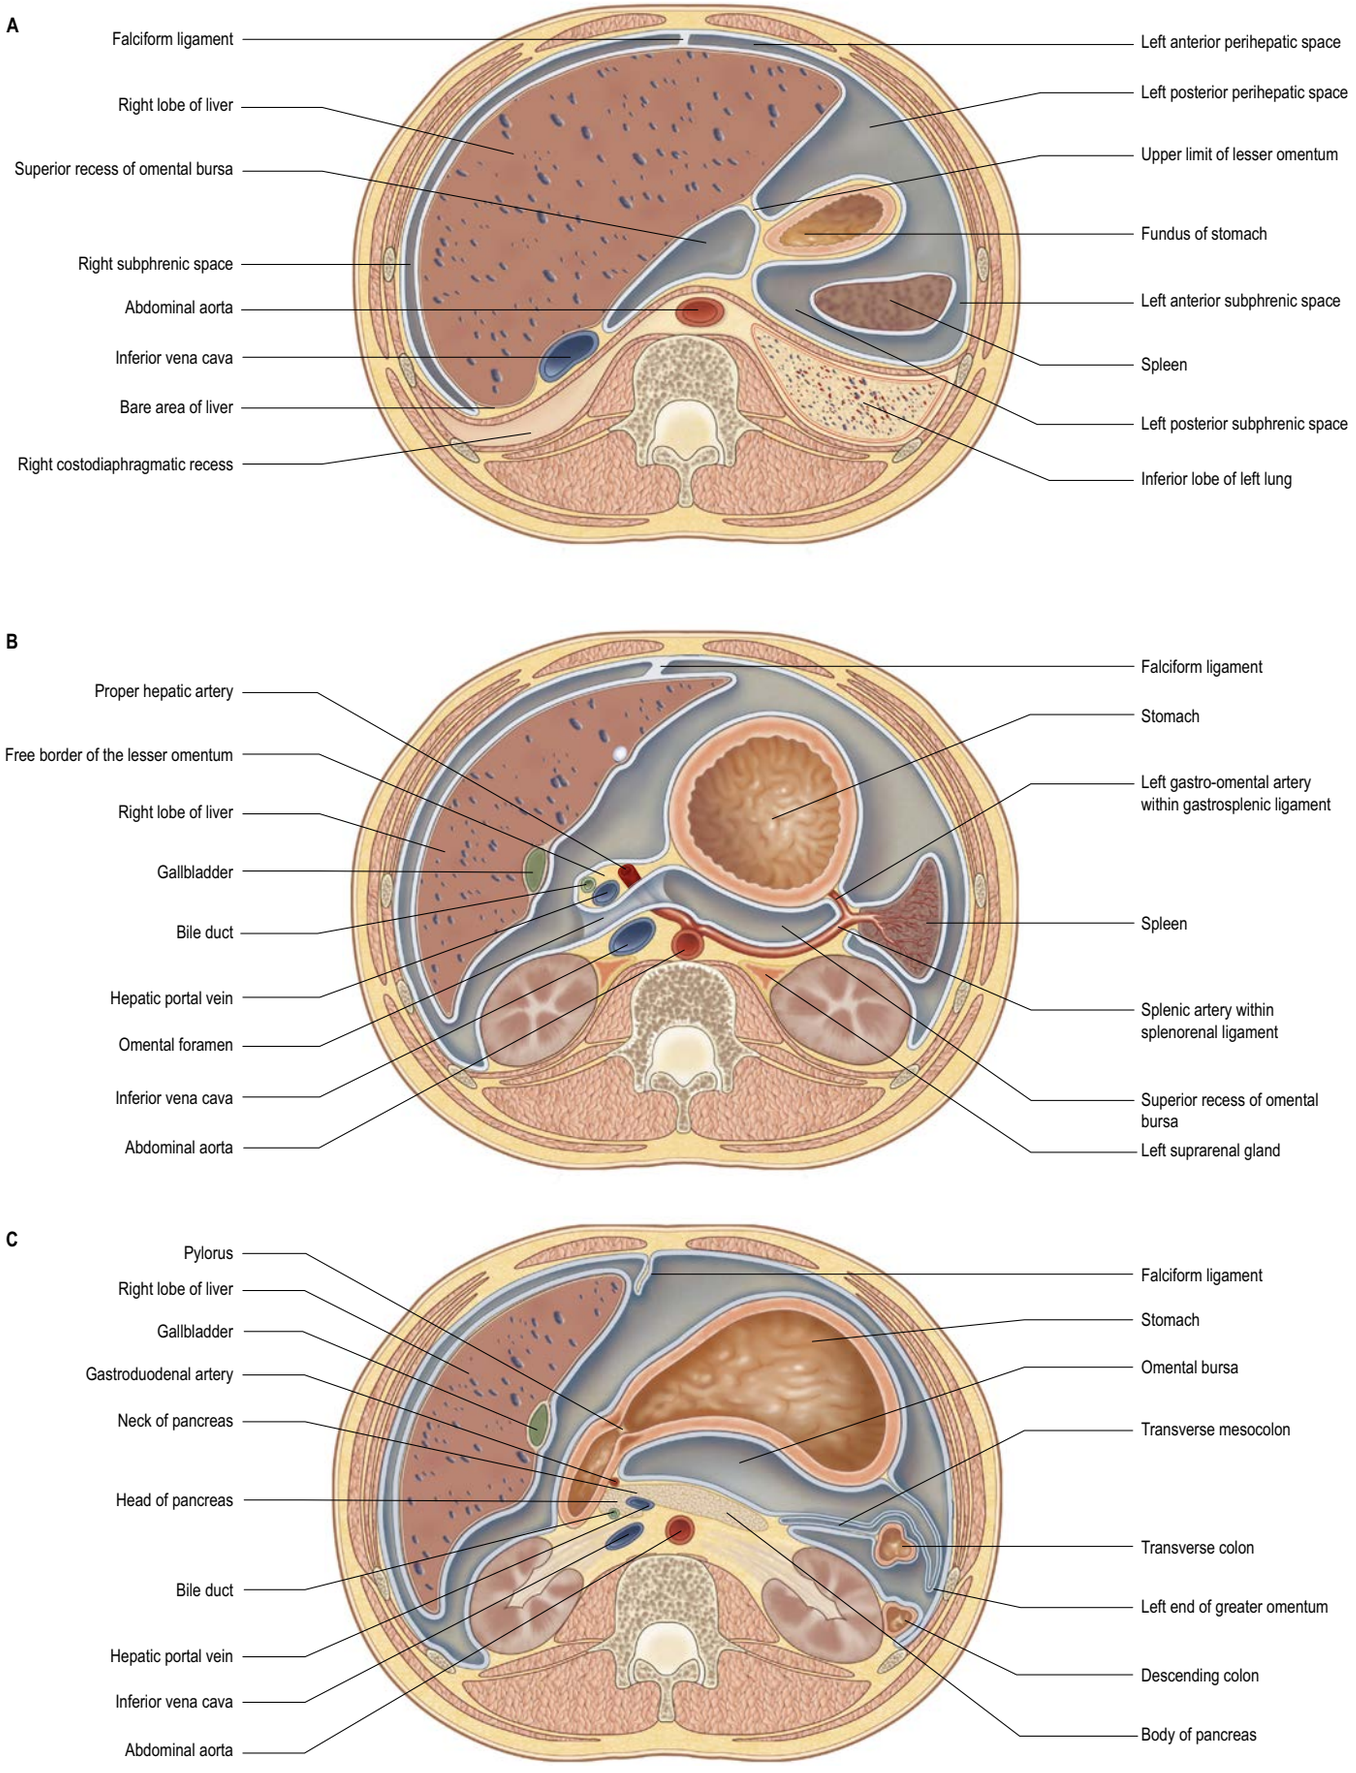

Fig. 62.5 Transverse sections through the abdomen viewed from below. The peritoneal cavity is shown by blue shading; the peritoneum and its cut edges are in pale blue. **A**, At the approximate level of the line A–A in Fig. 62.1. The line passes through the bare area of the liver at the superior end of the lesser omentum. The parts of the left subphrenic space are clearly seen, although they are continuous with each other. **B**, At the approximate level of line B–B in Fig. 62.1. **C**, Approximately at the level of the line C–C in Fig. 62.1.

posterior layer of the greater omentum (see Fig. 62.4). The inferior layer of peritoneum is continuous with the anterior surface of the mesentery of the small intestine and right mesocolon in the midline and to the right, and with the anterior surface of the left mesocolon to the left. The transverse and right mesocolon and the mesentery of the small intestine converge centrally to form a region of considerable technical and pathological importance that contains the superior mesenteric artery and vein.

Mesentery of the small intestine

The mesentery of the small intestine is formed from two layers of peritoneum (anterosuperior and posteroinferior) that fan out towards an intestinal margin from a diagonal origin running across the posterior abdominal wall from the duodenojejunal flexure to the ileocaecal junction (see Fig. 62.1A). It continues as the right mesocolon, and where it does so it is attached to the posterior abdominal wall, although the attachment of mesentery to posterior abdominal wall is obscured by the peritoneal reflection at this level. The mesentery of the small intestine and the right and transverse mesocolon converge on a central region that is more appropriately termed the root of the mesentery. Jejunal and ileal branches of the superior mesenteric vessels, nerves related to the superior mesenteric plexus, lymphatic vessels and regional lymph nodes, all lie in the adipose tissue of the mesentery of the small intestine. The length and mobility of this mesentery can make it difficult to determine the site and orientation of a loop of small intestine through a small surgical incision. Tracing the continuity of a peritoneal layer of mesentery onto the posterior abdominal wall can be useful for orientating an isolated loop if the duodenojejunal flexure or ileocaecal junction is not readily accessible.

Right mesocolon

The right mesocolon is a continuation of the mesentery of the small intestine. It is apposed to the posterior abdominal wall from which it is separated by a fascial layer. Laterally it is directly connected to the caecum and ascending colon. It continues as the hepatic component of the transverse mesocolon. Where the small intestinal region of the mesentery continues as the right mesocolon, a mesothelial bridge (reflection) between the visceral peritoneum of the mesentery and the parietal peritoneum of the posterior abdominal wall is an important anatomical landmark defining the medial boundary of the right mesocolon (Byrnes et al 2019a–2019d).

Meso-appendix

The mesentery of the appendix, the meso-appendix, arises from the posterior surface of the mesentery in the ileocaecal region. It attaches to the appendix along its length, but it can end just short of the distal end of the appendix. It encloses the blood vessels, nerves and lymph vessels of the appendix and usually contains a lymph node. A fold of peritoneum is sometimes observed between the terminal ileum and the anterior layer of the meso-appendix (the 'bloodless fold of Treves'). The position of the meso-appendix is of considerable clinical importance. As it arises from the posterior surface of the main body of the mesentery, the appendix frequently takes up a retrocaecal position. Its positioning in this location means that appendicitis is often a difficult diagnosis, and that the appendix and meso-appendix can be difficult to expose and divide during surgery.

Left mesocolon

The left mesocolon is the region of mesocolon between the transverse mesocolon proximally and the sigmoid mesocolon distally. It is apposed to the posterior abdominal wall from which it is separated by a fascial layer. A mesothelial bridge (reflection) occurs at the medial boundary of the left mesocolon and links the parietal peritoneum of the posterior abdominal wall with the visceral peritoneum of the left mesocolon. The left mesocolon is directly connected to the medial border of the descending colon and is the distal continuation of the splenic component of the transverse mesocolon.

Sigmoid mesocolon

The sigmoid mesocolon (mesosigmoid) is the distal continuation of the left mesocolon (see Fig. 62.1A). At the rectosigmoid junction it continues distally into the pelvis as the mesorectum. Medially, it is attached to the posterior abdominal wall. Laterally, this region separates from the posterior abdominal wall as the mobile region of the sigmoid mesocolon.

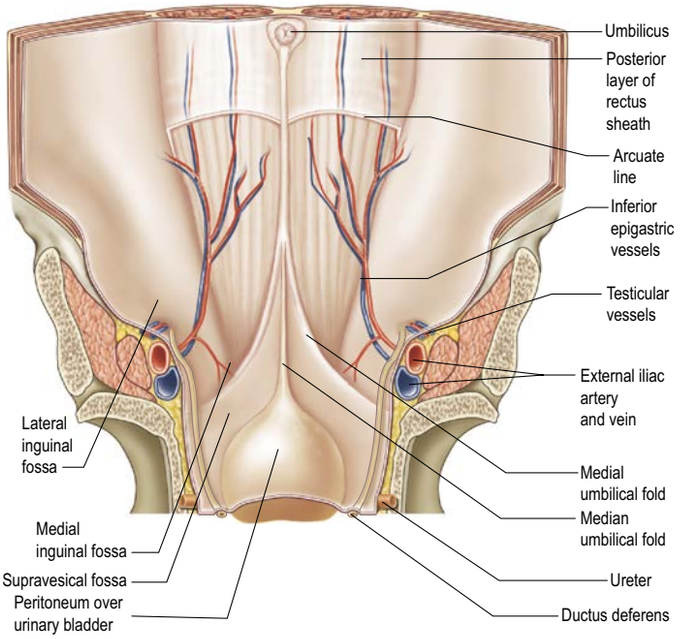

Fig. 62.6 The infra-umbilical part of the male anterior abdominal wall: posterior surface, with the peritoneum *in situ*.

The medial and lateral boundaries of the attached region of sigmoid mesocolon are obscured from direct visualization by the peritoneal reflection at this level. Bands of peritoneum can run from the proximal sigmoid colon to the abdominal wall in the left iliac fossa: they are congenital adhesions that are often mistaken for the peritoneal reflection at this level. The sigmoid mesocolon contains the inferior mesenteric artery and the superior anorectal artery (i.e. the continuation of the inferior mesenteric artery). Sigmoid arteries arise primarily from the inferior mesenteric artery and travel in the sigmoid mesocolon to the sigmoid colon.

Peritoneum of the inferior anterior abdominal wall

The peritoneum of the inferior anterior abdominal wall is raised into five folds (sometimes referred to as 'ligaments') that diverge as they descend from the umbilicus. They are the median, right and left medial, and right and left lateral, umbilical folds (**Fig. 62.6**; see Figs 73.5, 73.6). The median umbilical fold extends from the umbilicus to the apex of the bladder and contains the urachus or its remnant. The medial umbilical fold overlies the obliterated umbilical artery. The lateral umbilical fold covers the inferior epigastric vessels inferior to their entry into the rectus sheath. The supravesical fossa lies between the medial and median umbilical folds on each side of the midline. The medial and lateral inguinal fossae lie on either side of a lateral umbilical fold. The lateral inguinal fossa overlies the deep inguinal ring, and the medial inguinal fossa overlies the femoral ring (Healy and Reznek 1999).

Peritoneum of the pelvis

The parietal peritoneum of the abdominal wall is continuous with the parietal peritoneum that lines the side walls of the pelvis. The arrangement of the pelvic visceral peritoneum differs between the sexes.

Peritoneum of the male pelvis

In males, peritoneum is reflected off the pelvic side walls and on to the rectum and mesorectum. These are the pararectal regions of the reflection and are surgically important because they must be divided to access the plane between the mesorectum and underlying fascia. They coalesce anteriorly in the distal pelvis to form the anterior reflection. A gulley, the rectovesical pouch, is created by the organization of the peritoneum at this level. The urinary bladder, seminal glands and ductus deferens are positioned deep to the anterior region of peritoneum. The peritoneum covering the posterosuperior surface of the urinary bladder forms a paravesical fossa on each side that is limited laterally by a ridge of peritoneum containing the ductus deferens (**Fig. 62.7**); the depths of the paravesical fossae depend on the volume of urine in the bladder. When the urinary bladder is empty, a transverse vesical fold is sometimes visible at laparoscopy; its medial portion overlies the superior

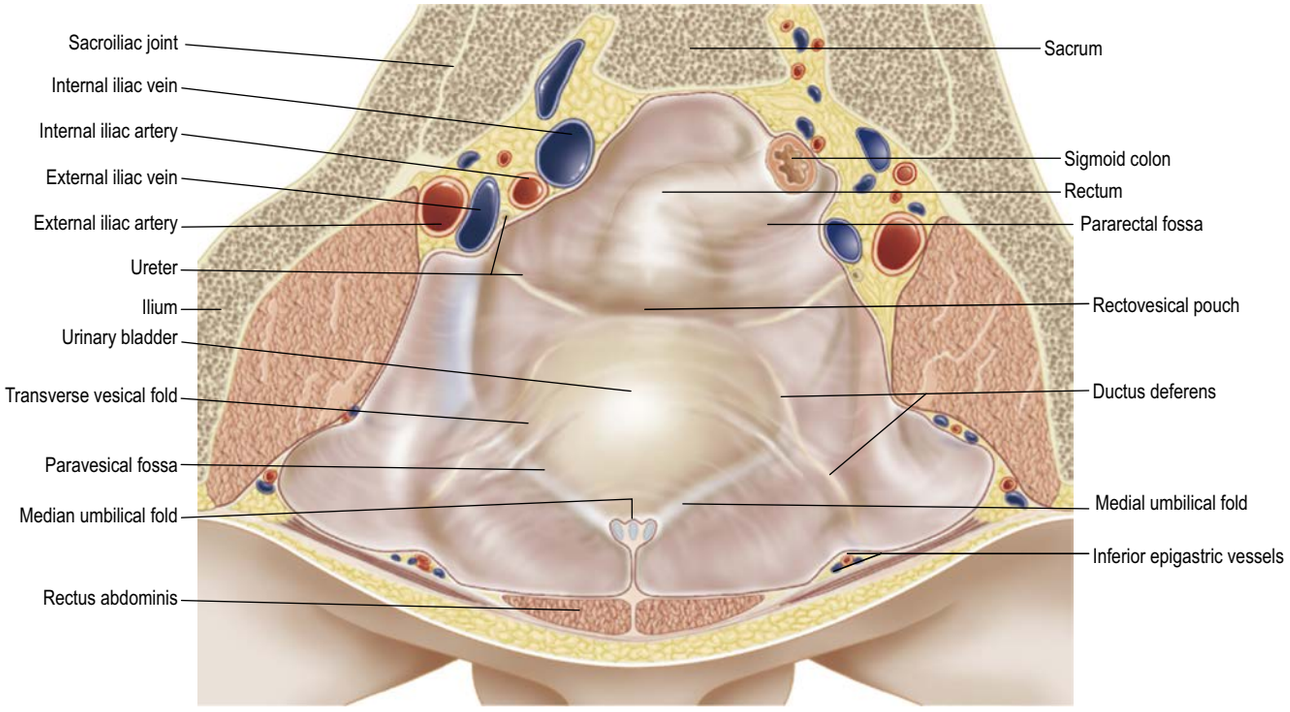

Fig. 62.7 The peritoneum of the male pelvis: anterosuperior view. Note that the ureter, urinary bladder, rectum and ductus deferens are all deep to the peritoneum.

vesical artery or arteries (Boaz et al 2011). The ureters and internal iliac vessels can cause slight elevations in the peritoneum between the paravesical and pararectal fossae. The median umbilical fold extends superiorly from the apex of the bladder on the posterior surface of the inferior anterior abdominal wall to the umbilicus: when the urinary bladder distends, the overlying peritoneum is lifted so that part of the underlying surface of the bladder comes into direct contact with the anterior abdominal wall.

Peritoneum of the female pelvis

In females, peritoneum covers the anterolateral surface of the proximal rectum and mesorectum, as it does in males, but it descends further over the anterior surface of the rectum. The pararectal and paravesical fossae are limited laterally by the peritoneum that covers the uterosacral ligaments and round ligaments of the uterus, respectively (see Figs 75.11B, 75.18). The presence of the uterus and vagina means that there are two pelvic pouches instead of the single rectovesical pouch seen in males. The peritoneum from the rectum is reflected anteriorly on to the posterior surface of the posterior part of the vaginal fornix and the uterus, forming the recto-uterine pouch (of Douglas). The depth of the pouch, i.e. the extent to which it descends on the posterior surface of the vagina, is variable (Baessler and Schuessler 2000). The peritoneum covers the fundus and body of the uterus, descending on its anterior surface as far as the junction of the body and cervix, and from there it is reflected forwards on to the posterosuperior surface of the urinary bladder, forming a shallow vesico-uterine pouch. As in males, the peritoneum over the urinary bladder is reflected on to the posterior surface of the inferior anterior abdominal wall. Recto-uterine folds containing the uterosacral ligaments pass posteriorly from the sides of the cervix of the uterus to the sacrum, running lateral to the rectum.

Peritoneum is also reflected from the anterior and posterior uterine surfaces to the lateral pelvic walls as the broad ligament of the uterus (see Fig. 75.18). This consists of anterior and posterior layers that are continuous at the superior border of the ligament. The broad ligament contains the uterine tubes in its free superior peritoneum and it merges with the pelvic parietal peritoneum at its base. The ovarian fossa is a shallow depression in the peritoneal lining of the lateral pelvic wall between the peritoneal ridges formed by the occluded part of the umbilical arteries anteriorly, the ureter posteriorly, and the external iliac vessels above; it lies posterior to the lateral attachment of the broad ligament of the uterus and usually contains the ovary in nulliparous females.

Vascular and lymphatic drainage

Parietal and visceral peritonea develop from the somatopleural and splanchnopleural layers, respectively, of the lateral plate mesoderm. Parietal peritoneum is supplied by the somatic blood vessels of the abdominal and pelvic walls, and its lymphatics join vessels in the body wall and drain to parietal nodes. Visceral peritoneum is best considered as an integral part of the viscus it covers; its blood supply and lymphatic drainage therefore correspond to those of the associated viscus. The region between, i.e. the peritoneal reflection, represents a transitional zone in terms of the origins of its vascular and lymphatic drainage and innervation.

Innervation

The parietal peritoneum is innervated by somatic efferent and afferent nerves that also supply the muscles and skin of the overlying body wall. The visceral peritoneum is innervated by afferent nerves that travel with the autonomic supply in the mesentery to the underlying viscera. Sensations arising from pathologies that affect the parietal or visceral peritoneum reflect these different patterns of innervation. Well-localized pain is elicited by mechanical, thermal or chemical stimulation of nociceptors in the parietal peritoneum; the pain is usually limited to the affected region. Somatic nerves that innervate the parietal peritoneum also supply the corresponding segmental skin and muscles: when the parietal peritoneum is irritated there is local reflex muscle contraction, resulting in clinical signs of guarding or even rigidity of the anterior abdominal wall. The parietal peritoneum covering the respiratory diaphragm is supplied centrally by afferent fibres from the phrenic nerves and peripherally by the inferior intercostal nerves and subcostal nerves: peripheral irritation of the diaphragm can therefore result in pain localized in the distribution of the inferior thoracic spinal nerves, while central irritation causes referred pain in the cutaneous distribution of the third to fifth cervical spinal nerves (the shoulder region). The innervation of the parietal peritoneum of the lesser pelvis is poorly documented.

Irritation or stretching of the visceral peritoneum causes poorly localized discomfort. The sensation of pain is referred to a diffuse area of the abdominal wall. Discomfort from structures derived from the foregut is felt in the epigastric region; that from structures derived from the midgut in the umbilical region; and that from structures derived from the hindgut in the hypogastric region. None of these sensations is significantly lateralized. Pain from the pancreas, gallbladder and small intestine can radiate to the back. Stretching or irritation of the visceral peritoneum can also elicit profound reflex vasomotor and cardiac changes mediated by autonomic nerves, including a vasovagal response. This is of considerable clinical relevance. Painful responses to manipulation of the parietal peritoneum can be abolished by local or regional anaesthesia. In marked contrast, the direct central connections of visceral afferents, particularly via the vagus nerve, mean that stretching the visceral peritoneum can have profound effects, including acute haemodynamic instability, despite local or regional (including spinal) anaesthesia.

GENERAL ARRANGEMENT OF THE PERITONEAL CAVITY

The peritoneum is organized into parietal and visceral parts and intervening areas of reflection (where the parietal peritoneum is reflected onto adjacent viscera with which it merges). Together, these form the peritoneal cavity. The region of the cavity that is attached to the lateral and anterior abdominal wall is relatively featureless. In contrast, while the contour of the reflection and visceral peritoneum appears more complex, it is explained by the shape of the underlying digestive system organs, including the mesentery. The cavity can be subdivided into the greater sac and the omental bursa. The greater sac is the main peritoneal cavity surrounding most of the abdominal and pelvic viscera. The omental bursa is a substantial diverticulum of the dorsal mesentery at this level and is situated posterior to the stomach and lesser omentum. The greater sac and omental bursa communicate via the omental foramen.

For clinical purposes, the peritoneal cavity can be divided into several 'spaces' (see below); pathological processes are often contained within these spaces and their anatomy can influence diagnosis and treatment. It has also been divided into two regions separated by the transverse mesocolon: the supramesocolic (often simply called supracolic) region superior to the transverse mesocolon and the infracolic region inferior to the transverse mesocolon. It should be noted that this classification is little used in current clinical practice.

Supramesocolic region

Available with the *Gray's Anatomy* e-book

Right subphrenic space

The right subphrenic space lies between the respiratory diaphragm and the anterior, superior and right lateral surfaces of the right lobe of the liver. It is bounded on the left by the falciform ligament and posteriorly by the superior layer of the coronary ligament (see Fig. 62.3).

Hepatorenal recess (right subhepatic space)

The hepatorenal recess (right subhepatic space) lies between the inferior surface of the right lobe of the liver and the superior pole of the right kidney. It is bounded superiorly by the inferior layer of the coronary ligament, laterally by the right lateral abdominal wall, posteriorly by the anterior surface of the superior pole of the right kidney, and inferomedially by the right colic flexure, transverse mesocolon, descending part of the duodenum and part of the head of the pancreas. In the supine position, the hepatorenal recess is more dependent than the right paracolic gutter. Pathological fluid collections can develop at this site.

Omental bursa

The omental bursa is a cavity lined with peritoneum and connected to the main peritoneal cavity (greater sac) by the omental foramen

(of Winslow). It develops under the left half of the respiratory diaphragm, providing a mesenteric platform into which the stomach, spleen and pancreas can emerge. It has posterior and anterior walls and superior, inferior, right and left borders. The bursa varies in size according to the volume of the viscera making up its walls, and it can be partially obliterated by natural adhesions between its anterior and posterior walls.

The anterior wall of the omental bursa consists of the posterior peritoneal layer of the lesser omentum, the peritoneum over the posterior wall of the stomach and superior part of the duodenum, and the posterior superior part of the anterior layer of the greater omentum (see above) (see Fig. 62.4). At its right border, the anterior wall is mostly formed by the lesser omentum, but towards the left, the lesser omentum becomes progressively shorter and more of the anterior wall is formed by the posterior surface of the stomach and greater omentum. The spleen is positioned at the left lateral extent of the bursa.

The greater omentum curves posterolaterally at the lateral border of the bursa and is continuous posteriorly with the posterior wall of the bursa, which is the dorsal mesogastrium, and is attached to the posterior abdominal wall under the left half of the respiratory diaphragm. The body of the pancreas is located in the inferior part of the posterior wall. The posterior wall detaches at the inferior margin of the pancreas to continue distally over the superior surface of the transverse mesocolon. It detaches from the transverse colon to continue as the greater omentum (see Fig. 62.4).

The inferior phrenic, splenic, left gastric and common hepatic arteries are located in the mesentery of the omental bursa: they use the frame of the bursa to travel to their target organs. The superior border of the omental bursa is narrow and lies between the right side of the abdominal part of the oesophagus and the superior end of the fissure for the ligamentum venosum and is sometimes referred to as the superior recess of the omental bursa. Here, the peritoneum of the posterior wall of the omental bursa is reflected anteriorly from the respiratory diaphragm to join the posterior layer of the lesser omentum.

The right border of the omental bursa is where the peritoneum overlying the head and neck of the pancreas is reflected onto the inferior aspect of the superior part of the duodenum. The line of this reflection ascends to the left, along the medial side of the gastroduodenal artery. Near the superior border of the duodenum, the right border of the omental bursa joins the inferior aspect of the omental foramen round the proper hepatic artery. The omental foramen therefore interrupts the right border. Superior to the omental foramen, the right border is formed by the peritoneal reflection from the respiratory diaphragm to the right margin of the caudate lobe of the liver, which then crosses the inferior vena cava. The left border of the omental bursa runs from the left end of the transverse mesocolon and is mostly formed by the inner peritoneal layers of the splenorenal and gastrosplenic ligaments. The region of the omental bursa between the splenorenal and gastrosplenic ligaments is referred to as the splenic recess. Superior to the spleen, the two ligaments merge to form the short gastrophrenic ligament, which passes anteriorly from the respiratory diaphragm to the posterior aspect of the fundus of the stomach and forms part of the superior left border of the omental bursa. The two layers of the gastrophrenic ligament diverge near the abdominal part of the oesophagus, leaving part of the posterior surface of the stomach devoid of peritoneum. The left gastric artery runs forwards here into the lesser omentum.

The omental bursa is indented by a crescentic mesenteric arch that runs from the superior border of the neck of the pancreas to the superior part of the lesser curvature of the stomach: it is variously described but commonly known as the gastropancreatic fold. The superior part of this arch contains the left gastric artery as it runs from the coeliac trunk to the lesser curvature of the stomach. The inferior part contains the common hepatic artery as it runs from the coeliac trunk to the lesser omentum. When the arch is prominent, it divides the omental bursa into a smaller superior and a larger inferior recess. The superior recess lies posterior to the lesser omentum and encloses the caudate lobe of the liver; it extends superiorly into the fissure for the ligamentum venosum and lies adjacent to the right crus of the respiratory diaphragm posteriorly. The inferior recess of the omental bursa lies between the stomach and pancreas, and is contained within the double sheet of greater omentum.

Acute pancreatitis is probably the most common cause of a fluid collection within the omental bursa (or just posterior to its posterior wall). Bleeding from trauma or a ruptured aneurysm of the splenic artery and perforation of a posterior gastric ulcer are other causes of omental bursa fluid collections.

Omental foramen

The omental foramen is a short, vertical slit, about 3 cm in height in adults, posterior to the free right border of the lesser omentum, and is the entrance to the omental bursa from the greater sac. The hepatoduodenal ligament, the thickened free right margin of the lesser omentum that extends between the porta hepatis above and the superior border of the superior part of the duodenum below, forms the anterior boundary of the omental foramen. Within this free border lie the bile duct (anteriorly on the right), the proper hepatic artery (anteriorly on the left) and the hepatic portal vein (posteriorly), together with nerves and lymphatics. Rapid control of the proper hepatic artery and hepatic portal vein can be exerted by compression of the free edge of the lesser omentum (a 'Pringle' manoeuvre), which is a potentially useful technique during surgery. Superiorly, the peritoneum of the posterior layer of the hepatoduodenal ligament runs over the caudate process of the liver, forming the roof of the omental foramen. This layer of peritoneum is then reflected onto the inferior vena cava, forming the posterior border of the foramen. The floor of the foramen is formed by the peritoneal reflection overlying the superior border of the superior part of the duodenum as it runs anteriorly, superior to the head of the pancreas. A narrow passage, the vestibule of the omental bursa, can be formed to the left of the foramen between the caudate process superiorly and the superior part of the duodenum inferiorly. To the right, the rim of the foramen is continuous with the peritoneum of the greater sac. The anterior and posterior walls of the foramen are normally apposed, which partly explains why patients can develop large fluid collections isolated to the greater sac or omental bursa (Shrestha et al 2010).

Left subphrenic space

The left subphrenic space lies between the respiratory diaphragm, the anterior and superior surfaces of the left lobe of the liver, the anterosuperior surface of the stomach and the diaphragmatic surface of the spleen. To the right it is bounded by the falciform ligament. It is expanded in the absence of the spleen and is a common site for fluid collection after splenectomy. The left subphrenic space is substantially larger than the right and can be divided into a left perihepatic space and anterior and posterior subphrenic spaces, all of which are in continuity in the absence of disease. The definitions of the boundaries of these spaces vary.

The left anterior subphrenic space is large and lies between the superior and anterolateral surfaces of the spleen and the respiratory diaphragm. Inferiorly and medially, this space is bounded by the phrenicocolic and splenorenal regions of peritoneal reflection and the gastrosplenic ligament. The left subphrenic space is a relatively common site of fluid collection after upper abdominal surgery, particularly surgery involving the spleen or adjacent pancreas. The left posterior subphrenic space is small and lies between the fundus of the stomach and the diaphragm superior to the origin of the splenorenal region of peritoneal reflection.

The left perihepatic space is sometimes subdivided into anterior and posterior spaces. The left anterior perihepatic space lies between the anterosuperior surface of the left lobe of the liver and the respiratory diaphragm. The left posterior perihepatic space, also known as the gastrohepatic recess, lies inferior to the left lobe of the liver. It extends into the fissure for the ligamentum venosum on the right. Posteriorly, it is separated from the superior recess of the omental bursa by the lesser omentum.

Extraperitoneal subphrenic spaces

There are two potential subphrenic spaces that actually lie outside the peritoneum but are clinically relevant because they can be sites of fluid accumulation. The right extraperitoneal space is bounded by the two layers of the coronary ligament, the bare area of the liver and the inferior surface of the right half of the respiratory diaphragm. The left extraperitoneal space lies anterior to the left suprarenal gland and superior pole of the left kidney.

Inframesocolic region

The inframesocolic region (also called the infracolic region) lies inferior to the transverse mesocolon and transverse colon and is divided into two unequal spaces by the mobile region of the mesentery of the small intestine. It contains the right and left paracolic gutters lateral to the ascending and descending colons, respectively.

The supramesocolic region lies between the respiratory diaphragm and the transverse mesocolon and can be arbitrarily divided into right and left supramesocolic spaces. The right supramesocolic space can be subdivided into the right subphrenic space, the right subhepatic space and the omental bursa. The left supramesocolic space can be divided into the left subphrenic space and the left perihepatic space. These 'spaces' usually communicate but can nevertheless be sites of localized fluid collection.

Right and left infracolic spaces

Available with the *Gray's Anatomy* e-book

Paracolic gutters

The right and left paracolic gutters are peritoneal depressions on the posterior abdominal wall alongside the ascending and descending colons, respectively. The principal paracolic gutter lies lateral to the colon on each side. The right paracolic gutter runs from the superolateral aspect of the right colic flexure down the lateral aspect of the ascending colon and caecum and is continuous with the peritoneum of the pelvic cavity inferiorly. Superiorly, it is continuous with the hepatorenal recess and with the omental bursa through the omental foramen. Bile, purulence, blood or other fluids can run along the gutter and collect in sites distant to the viscus of origin. In supine patients, infected fluid from the right iliac fossa can ascend in the gutter to the right subphrenic space. In erect or semi-recumbent positions, fluid from the stomach, duodenum or gallbladder can run down the gutter to collect in the right iliac fossa (mimicking acute appendicitis) or pelvis to form an abscess. The right paracolic gutter is deeper than the left, which could explain why subphrenic collections are more common on the right.

Recesses of the peritoneal cavity

Peritoneal fossae or recesses are difficult to standardize, so they are less discussed in the literature than they were in the past. However, these recesses are occasionally sites of internal herniation. If a loop of intestine becomes trapped in a fossa or recess, it can become obstructed or strangulated from constriction at the entrance to the recess. The contents of the peritoneal fold forming the fossa/recess must be considered when such a hernia is repaired.

Additional clinical aspects of the peritoneal cavity

Peritoneal fluid collections

Fluid collections frequently develop within the peritoneal cavity in response to a wide range of pathological processes. In the absence of inflammation, peritoneal adhesions or previous surgery, serous fluid tends to be distributed widely between the peritoneal spaces. Simple ascites can therefore be drained freely from any convenient dependent part of the peritoneal cavity; drainage is most commonly performed by blind puncture or ultrasound-guided insertion of a catheter into the inferior left or right paracolic gutters. The mobility of the small intestine makes iatrogenic injury during this procedure very unlikely.

Fluid collections caused by inflammatory processes are often much thicker because they contain purulence, fibrin or blood. Furthermore, they are usually associated with peritoneal adhesions arising from peritoneal inflammation. These factors predispose to the formation of localized fluid collections that can become walled-off as the inflammatory process progresses. Any region of the peritoneum can develop a localized collection, but the subphrenic and subhepatic spaces and pelvic pouches are the most common sites because they are well defined by the peritoneal folds and viscera that form their boundaries and they are the most dependent regions within the peritoneal cavity.

Surgical access to the peritoneum is less often needed today because advances in radiologically guided percutaneous drainage using fluoroscopy, ultrasound, computed tomography (CT) or magnetic resonance imaging (MRI) offer reliable and versatile methods for accessing the peritoneum, including relatively inaccessible subhepatic, perihepatic or intermesenteric collections. Posterolateral approaches or approaches through the greater sciatic foramen can be used to access the retroperitoneum or pelvis, respectively. Occasionally, a surgical approach is required, for example, a subcostal or lateral intercostal incision to drain a subphrenic abscess or an inguinal incision to drain a pelvic abscess.

Peritoneal dialysis

The mean surface area of the peritoneum in the adult female has been estimated to be about 1.4 m^2 (the visceral peritoneum accounting for about 80% of the total) (Albanese et al 2009). Mesothelium resembles vascular endothelium in that it allows the passage of ions and small molecules. Normally, the volume of fluid transmitted by peritoneal surfaces is small, but large volumes can be instilled into the peritoneal cavity and then siphoned out, using the peritoneum as a dialysing membrane, for example to support individuals with acute or chronic renal failure.

Ventriculoperitoneal shunts

The absorptive capabilities of the peritoneum can be exploited to absorb excess transitional fluids from several sites in the body. The most common of these is the absorption of cerebrospinal fluid in patients with hydrocephalus, diverted into the peritoneal cavity using a shunt (a fine catheter) from the cerebral ventricles. The catheter placed within the peritoneal cavity is connected to a one-way valve placed over the skull so that reflux of peritoneal fluid into the cerebral ventricles is prevented. The cerebrospinal fluid is continuously absorbed by the peritoneum, maintaining normal pressure within the ventricles.

Intraperitoneal cancer chemotherapy

In patients with peritoneal metastases, attempts to optimize the benefits of cytoreductive surgery can involve the administration of chemotherapeutic agents (diluted in large volumes of fluid) directly into the peritoneal cavity. The peritoneum can be accessed via an intraperitoneal catheter connected to a subcutaneous port or by repeated paracentesis. The infused chemotherapeutic agents can be retained locally for longer than systemically administered agents. Targeting drugs to the peritoneal space can improve the results of treatment if complete tumour resection is not possible.

The right and left infracolic spaces are conceptual zones without defined anatomical boundaries and are little referenced in current clinical practice. The right space is the region of the peritoneal cavity inferior to the transverse mesocolon and lateral to the right side of the mobile region of the mesentery of the small intestine. The left space is the corresponding space on the opposite side of the mobile region of the mesentery of the small intestine.

There can be several folds of peritoneum around the ascending (fourth) part of the duodenum and the duodenojejunal junction. They form a number of named recesses, which are highly variable in anatomical organization, and that arise after the duodenojejunal junction (and associated mesentery) adopts a final position *in utero*. Although it has been suggested that these recesses are sites of internal herniation, this is extremely rare (Zonca et al 2008).

Superior duodenal recess

The superior duodenal recess is occasionally present, often in association with an inferior duodenal recess. It lies directly to the left of the ascending part of the duodenum, adjacent to the second lumbar vertebra, and posterior to a crescentic superior duodenal fold of peritoneum. This fold has a semilunar free inferior margin that merges laterally with the peritoneum overlying the left kidney. The inferior mesenteric vein lies within the left mesocolon and is positioned close to the recess (when present).

Inferior duodenal recess

The inferior duodenal recess is usually present, often in association with a superior recess, with which it can share an orifice. It lies to the left of the ascending part of the duodenum, adjacent to the third lumbar vertebra, posterior to an avascular, triangular inferior duodenal fold, which has a sharp superior edge. It usually admits one or two fingertips and extends inferiorly, sometimes posterior to the ascending part of the duodenum and to the left, anterior to the ascending branch of the left colic artery and the inferior mesenteric vein.

Paraduodenal recess

The paraduodenal recess can occur in conjunction with superior and inferior duodenal recesses. It lies a little to the left and slightly posterior to the ascending part of the duodenum, posterior to a falciform fold of peritoneum. The free right edge of this fold contains the inferior mesenteric vein and ascending branch of the left colic artery, and is part of the left mesocolon. Herniation here is extremely rare (Khan et al 1998).

Retroduodenal recess

The retroduodenal recess is the largest of the duodenal recesses but is rarely present. It lies posterior to the horizontal and ascending parts of the duodenum and anterior to the abdominal aorta, is up to 10 cm deep, and has a wide orifice flanked by duodeno-parietal peritoneal regions of reflection. The recess arises because the confluence between the mesentery of the small intestine and right mesocolon has failed to attach to the posterior abdominal wall and incomplete attachment creates the impression of a recess.

Duodenojejunal recess

The duodenojejunal or mesocolic recess occurs in a minority of adults; when present, it is almost never associated with other duodenal recesses. It is approximately 3 cm deep and lies to the left of the abdominal aorta, between the duodenojejunal junction and the central region of the mesentery. It is bounded superiorly by the pancreas, on the left by the kidney, and inferiorly by the left renal vein. Its circular opening lies between two peritoneal folds and faces inferiorly and to the right.

Mesentericoparietal recess

The mesentericoparietal recess or fossa is rarely present. It lies just inferior to the horizontal part of the duodenum and invaginates the superior part of the mesentery of the small intestine towards the right. Its orifice is large and faces to the left, posterior to a fold of mesentery raised by the superior mesenteric artery. This recess is the site of the rare 'right paraduodenal hernia'.

Folding of the peritoneal reflection at the ileocaecal level generates a variety of recesses that have the potential to become sites of internal herniation (Rivkind et al 1986). Paracaecal recesses are common sites for abscess formation after acute appendicitis.

Superior ileocaecal recess

The superior ileocaecal recess is usually best developed in children and is often absent in the aged or obese. It is a narrow slit bounded anteriorly by a vascular fold of peritoneum containing the anterior caecal vessels, posteriorly by the ileal mesentery, inferiorly by the terminal ileum and on the right by the ileocaecal junction. Its orifice opens to the left.

Inferior ileocaecal recess

The inferior ileocaecal recess is similarly well developed in the young but frequently obliterated by fat in adults. It is formed by the ileocaecal fold, which extends from the antero-inferior aspect of the terminal ileum to the anterior aspect of the meso-appendix (or to the appendix or caecum). It is also known as the 'bloodless fold of Treves', although it sometimes contains blood vessels that bleed if divided during surgery. If inflamed, especially when the appendix and its mesentery are retrocaecal, it can be mistaken for the meso-appendix. The recess is bounded anteriorly by the ileocaecal fold, superiorly by the terminal ileum and associated mesentery, to the right by the caecum, and posteriorly by the superior part of the meso-appendix. Its orifice opens inferiorly and to the left.

Retrocaecal recess

The retrocaecal recess lies posterior to the caecum. It ascends posterior to the ascending colon to a variable extent, often being large enough to admit an entire finger. It is bounded anteriorly by the caecum (and sometimes the ascending colon), posteriorly by the parietal peritoneum, and on each side by caecal folds (parietocolic folds) passing from the caecum to the posterior abdominal wall. The appendix frequently occupies this retrocaecal recess. There can also be one or more shallow paracaecal or paracolic recesses: they are simply depressions within the right paracolic gutter and are not sites of internal herniation.

The intersigmoid recess is present in fetal life and infancy but often subsequently disappears. It lies lateral to the mobile region of the sigmoid mesocolon, between it and the parietal peritoneum of the left iliac fossa. As these structures are its anatomical determinants, it is highly variable in appearance.

An internal hernia is a protrusion of a viscus through a normal or abnormal aperture (which includes a surgically created opening) within the confines of the abdominal cavity (Martin et al 2006). It is possible for any of the peritoneal recesses, foramina or cul-de-sacs described in this chapter to be associated with the development of an internal hernia; but with a clinically apparent internal hernia, the relevant peritoneal recess is usually enlarged and its aperture narrower than normal. Although they are rare, the most common sites for internal hernia (in the absence of adhesions) are the paraduodenal recess, followed by the recesses around the caecum and omental foramen.

CHAPTER
63

Abdominal oesophagus and stomach

ABDOMINAL PART OF THE OESOPHAGUS

The abdominal part of the oesophagus is 1–2.5 cm long, lies to the left of the midline and is slightly broader at the cardiac orifice than at the oesophageal hiatus, which lies at the level of the eleventh thoracic vertebra (Mirjalili et al 2012). It runs obliquely to the left and slightly posteriorly and ends at the gastro-oesophageal junction, where it is continuous with the cardiac orifice of the stomach. Its anterior wall is effectively longer than its posterior wall because of the obliquity of the diaphragmatic crura. The abdominal part of the oesophagus lies posterior to the left lobe of the liver and anterior to the left crus of the respiratory diaphragm, the left inferior phrenic vessels and the left greater and lesser thoracic splanchnic nerves. Its surface is covered by a thin layer of connective tissue and visceral peritoneum that contains the anterior and posterior vagus nerves and the oesophageal branches of the left gastric vessels. The anterior and posterior vagal trunks can be single or composed of multiple trunks (Jackson 1949); the anterior vagal trunk is closely applied to the anterior outer surface of the longitudinal muscle coat of the oesophagus lying in the 2 o'clock position. It is often a thread-like nerve and difficult to visualize. It is imperative that the surgeon appreciates the position of the anterior vagal trunk to avoid injury leading to gastroparesis during a cardiomyotomy or fundoplication. The posterior vagal trunk is a more substantial structure that usually lies within loose connective tissue immediately posterior and to the right of the oesophagus, making its identification during surgery somewhat easier. However, the position of the trunk can vary; it can lie anywhere on the right side of the oeosphagus. Again it is imperative that the surgeon identify the nerve at fundoplication to avoid injury or incorporation into the wrap. Unlike the more proximal parts of the oesophagus, the muscular wall of the abdominal part of the oesophagus is composed entirely of smooth muscle.

The abdominal part of the oesophagus is effectively tethered to the margins of the oesophageal hiatus by the phrenico-oesophageal ligament and probably acts to limit upward and downward mobility of the oesophagus within the oesophageal hiatus (Kwok et al 1999, Apaydin et al 2008). The importance of this anchor function has been recognized in more recent times by surgeons performing fundoplications, many of whom now reconstruct the ligament with sutures between the left lateral oesophagus and the left crus (**Fig. 63.1**). The ligament is formed by two circumferential layers of elastin- and collagen-rich connective tissue containing smooth muscle fibres. The distal layer is an extension of the transversalis fascia inferior to the respiratory diaphragm; it is thin and only loosely attached to the oesophagus. The proximal layer is continuous with the endothoracic fascia superior to the respiratory diaphragm; it is thicker, contains more elastin than its inferior counterpart, and runs cranially and obliquely to fuse firmly with the wall of the oesophagus. A variable amount of adipose tissue lies in the triangular interval between the two layers of the ligament. In the elderly, the ligament tends to become attenuated: it loses collagen fibres and contains more adipose tissue. The phrenico-oesophageal ligament is denser anteriorly where it bridges between the outer layer of the oesophageal wall and the arching fibres of the crura of the diaphragm. Identification of the phrenico-oesophageal ligament on the thinner portion of the left crus is the gateway to safe mobilization of the oesophagus during surgery: once it is breached, the oesophagus can be easily mobilized and the aorta viewed posteriorly.

The peritoneal reflection posterior to the abdominal part of the oesophagus is short and continues directly on to the posterior surface of the fundus of the stomach; it is sometimes referred to as the gastrophrenic ligament. It encloses the oesophageal branches of the left gastric vessels and the coeliac branches of the posterior vagal trunk and can thus be considered to form an extremely short, wide mesentery to the abdominal part of the oesophagus. In adults, a fat pad is sometimes visible beneath the peritoneum over the anterior surface of the gastro-oesophageal junction and can be a useful surgical marker of the gastro-oesophageal junction.

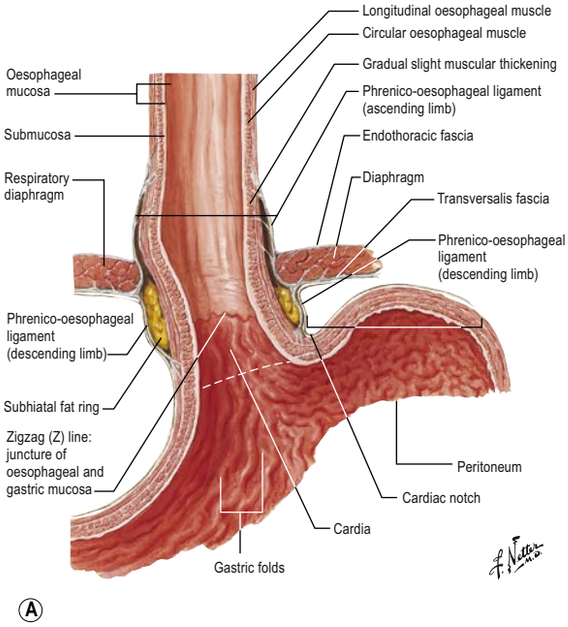
Hiatal hernia

Available with the *Gray's Anatomy* e-book

Vascular supply and lymphatic drainage

Arteries



The abdominal part of the oesophagus is supplied by numerous oesophageal branches of the left gastric artery that ascend beneath the visceral peritoneum to supply perforating branches to the intramural and submucosal plexuses. The posterior surface usually receives an additional blood supply via branches of the upper short gastric arteries, reinforced by terminal arteries from the oesophageal branches of the descending thoracic aorta and occasionally an ascending branch of the posterior gastric artery (Liebermann-Meffert et al 1987).

Veins

Mucosal and submucosal veins drain via plexuses to the left gastric and upper short gastric veins in the abdomen and to the azygos/hemiazygos system of veins in the thorax. The distal oesophagus is an important site of porto-systemic anastomosis where oesophageal varices develop in portal hypertension (see below).

Lymphatic drainage

The lymphatics of the oesophagus are concentrated into submucosal and intermuscular plexuses. Both of these plexuses receive lymph from all layers of the oesophageal wall (Kuge et al 2003, Rice et at 2016). Terminology is not straightforward. In general, lymphatic drainage from the oesophagus communicates with nodes in the adventitia, paraoesophageal nodes or the thoracic duct directly (Wang et al 2018). However, the lymphatics of the distal third of the oesophagus do not

Hiatal hernia is a relatively common condition involving expansion of the oesophageal hiatus and herniation of the stomach through the respiratory diaphragm into the thorax. It is more common in elderly and obese individuals. There are two types of hiatal hernia: the sliding type accounts for at least 90%, and the para-oesophageal or mixed type makes up the remainder (Roman and Kahrilas 2014). In a sliding hiatal hernia the abdominal part of the oesophagus and cardia of the stomach traverse the oesophageal hiatus. In contrast, with a para-oesophageal hiatal hernia the abdominal part of the oesophagus and pylorus lie beneath the diaphragm and a varying portion of the stomach passes through the hiatus. On occasion, the entire stomach can rotate, forming an 'upside-down stomach' with the stomach twisted around its axis. It is important that endoscopists appreciate the anatomical differences between the two herniae in order to distinguish correctly between them. A hiatal hernia can be asymptomatic or associated with symptoms of gastro-oesophageal reflux. Para-oesophageal hiatal hernias can cause obstruction and/or ischaemia of the herniated part of the stomach. Treatment of a symptomatic sliding hiatal hernia is directed at managing associated gastro-oesophageal reflux. If suppression of acid production by medication fails, the patient may require anti-reflux surgery. This has traditionally consisted of a fundoplication, but a small flexible band of interlinked titanium beads with magnetic cores applied around the lower oesophageal sphincter is increasingly becoming the first line in the surgical management of medically recalcitrant gastro-oesophageal reflux.

drain to para-oesophageal nodes of the same level but distally to the left gastric nodes and nodes around the cardia, and then to coeliac nodes (Tachimori 2017). Therefore, cancer of the lower thoracic oesophagus tends to metastasize to nodes of the upper abdominal area (Tamaki et al 2012).

Innervation

The oesophagus has a well-developed intrinsic nervous system consisting of a ganglionated myenteric plexus and a sparsely ganglionated submucosal plexus, modulated by extrinsic autonomic nerves. Parasympathetic innervation of the abdominal part of the oesophagus is derived directly from the oesophageal plexus and, to a lesser extent, from the anterior and posterior vagal trunks. These nerves are motor to the distal oesophagus and both stimulatory and inhibitory to the lower oesophageal sphincter, maintaining basal tone and coordinating distal oesophageal peristalsis with relaxation of the sphincter during swallowing (the latter being mediated by intrinsic nitrergic inhibitory neurones under vagus nerve control). Sympathetic supply to the distal oesophagus originates from the fifth to twelfth thoracic spinal segments mainly via the greater and lesser thoracic splanchnic nerves and the coeliac plexus. Nociceptive signals are conveyed by afferent nerves accompanying sympathetic nerves and by vagus nerve afferents, which are also involved in mechanosensory signalling (Neuhuber et al 2006).

STOMACH

The stomach is the widest part of the alimentary tract and lies between the oesophagus and the duodenum. It performs numerous functions, including the temporary storage of ingested nutrients, mechanical breakdown of solid food, chemical digestion of proteins, regulation of the passage of chyme into the duodenum, secretion of intrinsic factor for vitamin B_{12} absorption, secretion of gut hormones and secretion of acid to aid digestion (including the absorption of iron). It is also important in microbial defence.

The stomach is situated in the upper abdomen, extending from the left upper quadrant downwards, forwards and to the right, lying in the left hypochondriac, epigastric and umbilical regions. It occupies a recess beneath the respiratory diaphragm and anterior abdominal wall bounded by the upper abdominal viscera on either side. Its mean capacity increases from approximately 20–30 ml at birth to approximately 1000–1500 ml in adults. The peritoneal surface of the stomach is interrupted by the attachments of the greater and lesser omenta, which define the greater and lesser curvatures and separate the anterior and posterior surfaces.

Parts of the stomach

For descriptive purposes, the stomach can be divided into fundus, body, pyloric antrum and pylorus by artificial lines drawn on its external surface (Fig. 63.2). The internal appearance and microstructure of these regions vary. The fundus is dome-shaped and projects above and to the left of the oesophageal opening (cardiac orifice) to lie in contact with the left side of the respiratory diaphragm; it lies above a horizontal line drawn from the cardiac notch to the greater curvature. The body extends from the fundus to the angular incisure, a constant external notch at the lower end of the lesser curvature. The cardia is the region of the stomach adjacent to the oesophageal opening. A line drawn from the angular incisure to an inconstant indentation on the greater curvature defines the lower boundary of the body. The pyloric antrum extends from this line to where the stomach narrows to become the pyloric canal (1–2 cm long), which terminates at the pyloric orifice (Didio and Anderson 1968).

Gastric relations

Gastric curvatures

Lesser curvature

The lesser curvature extends between the cardiac and pyloric orifices and forms the medial border of the stomach. It descends from the medial side of the oesophagus in front of the decussating fibres of the right crus of the respiratory diaphragm, curves downwards and to the right, and lies anterior to the superior border of the pancreas (Fig. 63.3). It ends at the pylorus, just to the right of the midline. In the most dependent part there is typically a notch, the angular incisure; the position and appearance of the incisure vary with gastric distension. The lesser omentum is attached to the lesser curvature and contains the right and left gastric vessels.

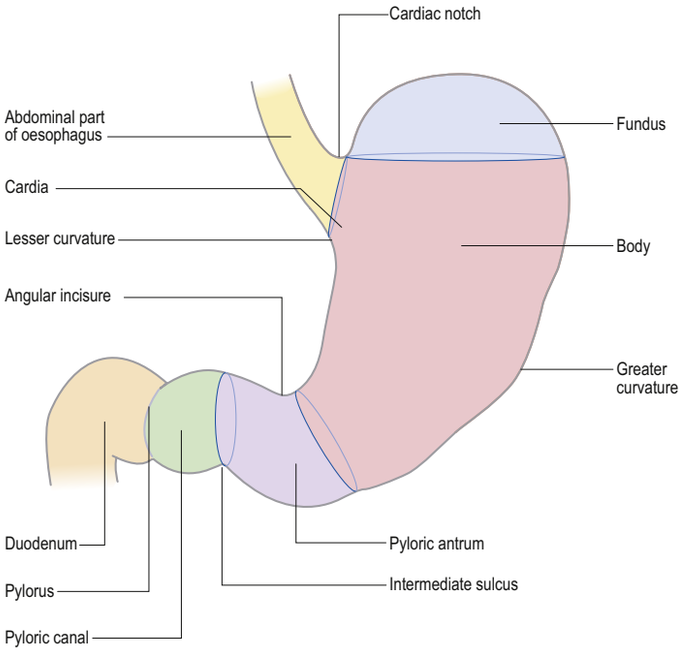

Fig. 63.2 The parts of the stomach.

Greater curvature

The greater curvature is two to three times longer than the lesser curvature (Csendes and Burgos 2005). It starts from the cardiac notch, formed between the lateral border of the abdominal part of the oesophagus and the fundus of the stomach, and arches upwards, posterolaterally and to the left. Its highest convexity, the apex of the fundus, is approximately level with the left sixth rib anteriorly but varies among individuals and during respiration (Mirjalili et al 2012). From this point, it sweeps inferiorly and anteriorly, slightly convex to the left, almost as far as the tenth costal cartilage in the supine position, where it turns medially to end at the pylorus in the transpyloric plane at the lower border of the first lumbar vertebra. There is frequently a groove, the intermediate sulcus, in the curvature close to the pyloric canal. The start of the greater curvature is covered by peritoneum, which continues over the anterior surface of the stomach. Laterally, the greater curvature gives attachment to the gastrosplenic ligament and, below this, to the greater omentum, which contains the gastro-omental (gastro-epiploic) vessels. The gastrosplenic ligament and the greater omentum, together with the gastrophrenic and splenorenal ligaments, are continuous derivatives of the original dorsal mesogastrium; their names merely indicate regions of the same continuous sheet of peritoneum and its associated connective tissue.

Gastric volvulus

Available with the *Gray's Anatomy* e-book

Gastric surfaces

When the stomach is empty and contracted, the anterior and posterior surfaces tend to face superiorly and inferiorly; but as the stomach distends, they face progressively more anteriorly and posteriorly (Fig. 63.4).

Anterior surface

The entire anterior surface of the stomach is covered by peritoneum. The lateral part of the anterior surface lies posterior to the left costal arch in contact with the respiratory diaphragm, which separates it from the left parietal pleura, the base of the left lung, the pericardium and the left seventh to ninth ribs and costal cartilages (Fig. 63.5). It also lies posterior to the costal attachments of the proximal fibres of transversus abdominis. The superior left part of this surface curves posteriorly and lies in contact with the visceral surface of the spleen. The right half of the anterior surface is related superiorly to the left lobe of the liver and inferiorly to the anterior abdominal wall, through which it can be accessed by a needle for placement of a gastrostomy tube (see below). When the stomach is empty, the transverse colon can lie adjacent to the anterior surface.

Gastric volvulus is much less common than volvulus of either the sigmoid colon or the caecum. It occurs when the stomach rotates abnormally and may be organo-axial or mesentero-axial. In organo-axial volvulus, the axis of rotation runs from below the cardiac orifice to the pylorus: the pyloric antrum, body and fundus rotate upwards such that the greater curvature comes to lie above the lesser curvature. In mesentero-axial volvulus, rotation occurs about an axis drawn 'across' the body of the stomach, usually just above the angular incisure. This type of volvulus is perpendicular to the axis of organo-axial volvulus. The distal body and pyloric antrum rotate anteriorly, superiorly and laterally while the upper body and fundus rotate posteriorly, medially and inferiorly. Although it is relatively mobile within the upper abdomen, the stomach is normally tethered at the gastro-oesophageal junction and the pylorus; to the spleen by the gastrosplenic ligament; and to the liver by the hepatogastric ligament. The attachment to the transverse colon via the gastrocolic ligament also restrains the stomach but this is the most mobile attachment. For either type of gastric volvulus to occur, some or all of these points of tethering must be loosened either by previous surgical division or by chronic lengthening and laxity of their connective tissue. Organo-axial volvulus is more common because the lesser omentum, and gastrosplenic and gastrocolic ligaments are more likely to undergo chronic lengthening by traction than the other attachments of the stomach. Mesentero-axial volvulus requires the gastro-oesophageal junction and pylorus to be sufficiently mobile so as to come into close approximation, which is much less common. Despite the rich arterial supply to the stomach, either type of volvulus can cause a strangulating obstruction.

Provided the detorted stomach is viable, gastric volvulus is typically managed by fixation of the anterior surface of the stomach to the anterior abdominal wall ('gastropexy') (García et al 2013): the recurrence rate is very high. An alternative is to insert one or more percutaneous endoscopic gastrostomy (PEG) tubes to fix the stomach to the anterior abdominal wall, a manoeuvre that is particularly useful in the unfit patient when a lengthy surgical procedure is contraindicated. Gastric volvulus of the organo-axial type is frequently associated with a para-oesophageal hiatal hernia that must also be repaired. This surgery can usually be carried out laparoscopically and most surgeons would advocate performing a combination of a hiatal repair, fundoplication with or without a gastropexy.

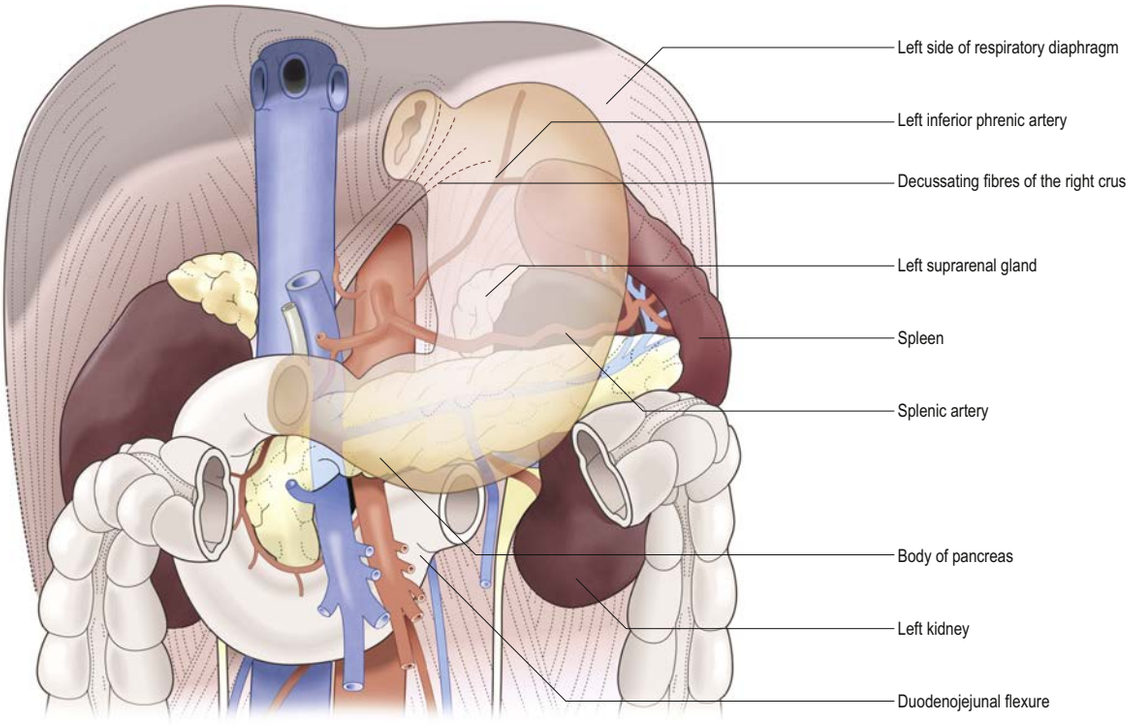

Fig. 63.3 The posterior relations of the stomach.

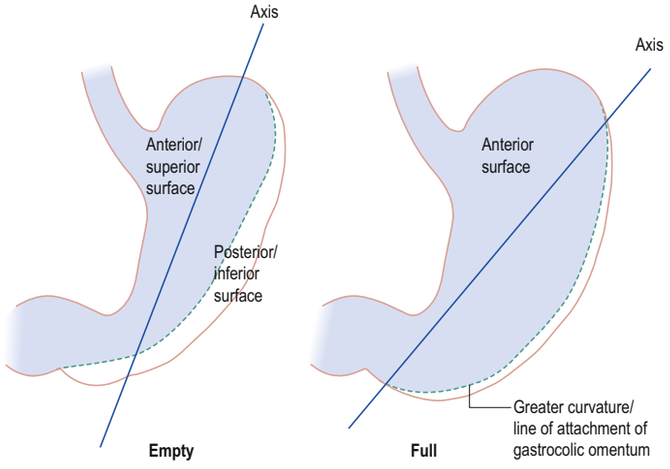

Fig. 63.4 Axes of the empty and full stomach. As the stomach distends, the greater curvature 'rolls' downwards and the anterosuperior surface comes to lie almost completely vertical as the anterior surface.

Posterior surface

The posterior surface is covered by peritoneum except near the cardiac orifice, where a small, triangular area contacts the left crus of the respiratory diaphragm and sometimes the left suprarenal gland. The left gastric vessels reach the lesser curvature at the right extremity of this bare area. The gastrophrenic ligament passes from the lateral aspect of this bare area to the inferior surface of the respiratory diaphragm. The posterior surface of the stomach lies anterior to the left crus and inferior fibres of the diaphragm, the left inferior phrenic vessels, the left suprarenal gland, the superior pole of the left kidney, the splenic artery, the anterior surface of the pancreas and the superior layer of the transverse mesocolon (see Fig. 63.3). Together, these form the shallow stomach bed, which is separated from the stomach by the omental bursa (over which the stomach slides as it distends). The upper left part of the posterior surface curves anterolaterally and lies in contact with the visceral surface of the spleen. The transverse mesocolon separates the stomach from the duodenojejunal flexure and proximal jejunum.

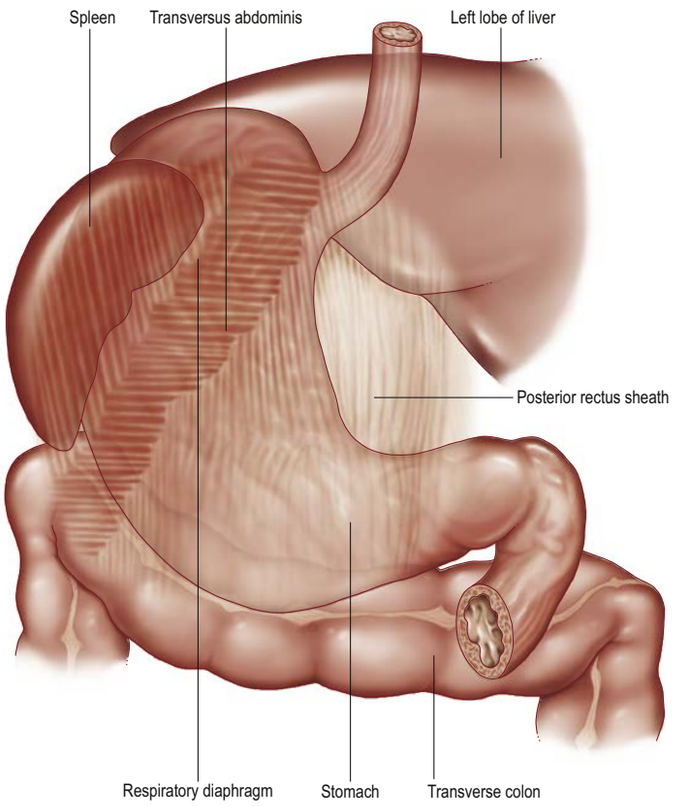

Fig. 63.5 Anterior relations of the stomach, viewed from behind. The fibres of the respiratory diaphragm (oblique), transversus abdominis (transverse) and rectus abdominis (vertical) can be seen through the outlines of the stomach and its visceral relations.

Gastric orifices

Cardiac orifice and gastro-oesophageal junction

The oesophagus opens into the stomach at the cardiac orifice (see Fig. 63.1). This is usually situated to the left of the midline behind the seventh costal cartilage at the level of the eleventh thoracic vertebra (Mirjalili et al 2012). It is, on average, about 40 cm from the incisor teeth in the adult. The right side of the abdominal part of the oesophagus is continuous with the lesser curvature and the left side with the greater curvature.

Internally, the transition between the oesophagus and stomach is difficult to define because gastric fundal mucosal folds extend a variable distance up the abdominal part of the oesophagus. For practical purposes, the gastro-oesophageal junction is usually identified by a circumferential

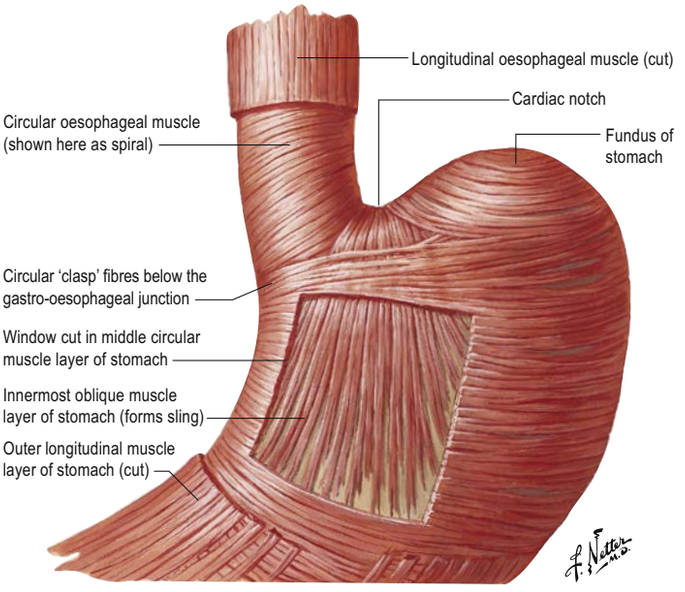

Fig. 63.6 Detail of the arrangements of the muscle layers of the oesophageal and gastric walls. (Reproduced and modified from Netter Anatomy Illustration Collection, © Elsevier Inc. All Rights Reserved.)

'zigzag' line ('Z line') between the pale pink oesophageal squamous epithelium above and the red columnar epithelium below. In the healthy oesophagus, the Z line is located at the proximal extent of the gastric mucosal folds. When metaplastic columnar epithelium extends above the gastric folds into the distal oesophagus, it is regarded as pathological and termed Barrett's oesophagus. A sliding hiatal hernia with or without Barrett's oesophagus can make endoscopic identification of the gastro-oesophageal junction particularly difficult.

Externally, a fat pad is often present in adults beneath the peritoneum over the anterior surface of the gastro-oesophageal junction. The junction is also demarcated by a sling of longitudinal and oblique gastric muscle fibres that forms a loop on the superior, left, side of the gastro-oesophageal junction between the oesophagus and the stomach.

Lower oesophageal sphincter and gastro-oesophageal reflux

At rest, there is a pressure gradient across the gastro-oesophageal junction, reflecting the negative intrathoracic pressure transmitted to the thoracic oesophagus and the positive intra-abdominal pressure transmitted to the stomach (augmented by any contraction of the stomach). Several anatomical and physiological factors normally prevent gastro-oesophageal reflux. The two major antireflux mechanisms are the tonically contracted, specialized, thickened intrinsic circular smooth muscle of the distal oesophagus, which is reinforced by the extrinsic encircling fibres of the right crus of the respiratory diaphragm. Together, these exert a radial pressure on the lower 2–4 cm of oesophagus, creating an effective high-pressure zone (HPZ) that can be measured by electromyography or manometry (Paterson 2001, Mittal and Goyal 2006, Hershcovici et al 2011). The description of the intrinsic muscles of the lower oesophageal sphincter can be refined further to include clasp-like semicircular smooth muscle fibres on the right side of the oesophagus and sling-like oblique gastric muscle fibres on the left side (Stein et al 1995, Preiksaitis and Diamant 1997). The distribution of these muscle fibres corresponds to the anatomical and functional asymmetry of the HPZ.

At and just below the level of entry of the abdominal part of the oesophagus into the stomach, the circular fibres of the intermediate layer of the muscularis externa lying over the upper lesser curvature are particularly pronounced; they are sometimes referred to as 'clasp' fibres and exert fairly constant myogenic tone (**Fig. 63.6**). Since the oesophagus passes obliquely into the stomach, the tone in the clasp fibres rises with increasing gastric distension and these fibres can act to draw the anterior and posterior surfaces together, increasing the tone at the gastro-oesophageal junction and contributing to the HPZ. There are also several minor antireflux factors: the folds of gastric mucosa present at the gastro-oesophageal junction form a mucosal rosette that helps to create a fluid- and gas-tight seal from the basal tonic contraction of the muscular wall of the distal oesophagus; the angle of the cardiac orifice (angle of His), formed in part by the pull of the oblique fibres of the innermost layer of gastric smooth muscle, thereby constituting a type of 'flap valve'; and the length of the abdominal part of the oesophagus, which is buttressed externally by pads of adipose tissue at and distal to the level of the oesophageal hiatus. These anatomical and physiological features are collectively referred to as the lower oesophageal sphincter. The oesophageal part of the lower oesophageal sphincter is controlled by the intramural plexuses of the enteric nervous system; activation of inhibitory neurones releasing nitric oxide leads to relaxation of the sphincter. Muscle tone is reduced in advance of the oesophageal peristaltic wave during swallowing and raised again after the food bolus has passed. During inspiration, the greater negative intrathoracic pressure increases the gastro-oesophageal pressure gradient, but this is offset by increased pressure in the HPZ from contraction of the peri-oesophageal fibres of the right crus of the respiratory diaphragm. Activation of the crura slightly before the rest of the respiratory diaphragm facilitates this antireflux mechanism.

Barrett's oesophagus

Available with the *Gray's Anatomy* e-book

Pyloric orifice

The pyloric orifice is the opening from the stomach into the duodenum. When the body is supine and the stomach empty, it typically lies 1–2 cm to the right of the midline in the transpyloric plane, which passes through the lower border of the body of the first lumbar vertebra. The pyloric sphincter is formed by a circumferential thickening of circular muscle interlaced with connective tissue septa and some longitudinal muscle fibres, and is palpably thicker than the adjacent stomach and duodenum. The circular pyloric constriction on the surface of the stomach usually indicates the location of the pyloric sphincter, and may be marked by a prepyloric vein (of Mayo) that crosses the anterior surface in a caudal direction.

Gastric form and internal appearances

Numerous factors influence both the form and the position of the stomach, including the posture and build of the individual, the extent to which the stomach is filled, the position of the surrounding viscera, and the tone of the abdominal wall and gastric musculature. The empty stomach is most commonly J-shaped; the fundus usually contains air; and in the erect posture, the pylorus descends to the level of the second or third lumbar vertebra. The lowest part of the pyloric antrum can lie distal to the level of the umbilicus, and the overall axis of the organ is slightly inclined from the vertical (**Fig. 63.7**). In short, obese individuals the axis of the stomach lies more towards the horizontal with a 'steerhorn' shape.

The extent of filling mainly affects the shape and position of the body of the stomach. As the stomach fills it expands forwards and downwards, but when the colon or small intestine are distended the fundus enlarges towards the liver and the respiratory diaphragm. As stomach capacity increases, the pylorus is displaced to the right and the axis of the whole organ lies in a more oblique direction (see Fig. 63.4).

Internal appearances

During endoscopic examination (**Fig. 63.8**) the stomach is typically at least partially distended by air. The cardiac orifice and the lowest portion of the abdominal part of the oesophagus viewed from above are typically closed at rest by tonic contraction of the lower oesophageal sphincter. The transition between the pale pink squamous epithelium of the oesophagus and the red columnar epithelium of the stomach, the 'Z line', is usually clearly visible at the proximal extent of the gastric mucosal folds (Silverstein and Tytgat 1991). Viewed retrogradely from within the distended stomach, the cardiac orifice lies medial to the fundus, with a mucosal fold between the two corresponding to the acute angle at this orifice. The mucosa also appears slightly thickened, forming part of the 'mucosal rosette' that lines the orifice and contributes to its closure (see above).

In the partially distended stomach, the mucosa of the body and to a lesser extent the fundus is thrown into longitudinal folds (gastric folds or rugae) (see Fig. 63.7). These are most obvious on the anterolateral, lateral and posterolateral parts of the stomach towards the greater curvature. The smoother mucosa along the lesser curvature forms a 'gastric canal' or '*magenstrasse*' that enables liquids entering the stomach to be fast-tracked to the pylorus (see Fig. 63.8).

The gastric areas within the pyloric antrum are small undulations of the mucosal surface that give a subtle cobblestone-type appearance on double contrast barium meal examination (see Fig. 63.7) (Mackintosh and Kreel 1977). The few folds present in the pyloric antrum when the stomach is relaxed disappear with distension. The pyloric antrum adjacent to the pyloric canal, the prepyloric antrum,

Reflux of gastric contents into the distal oesophagus as a result of transient relaxation of the lower oesophageal sphincter occurs as a normal daily event in most individuals. Prolonged episodes of acid reflux as a result of a weak lower oesophageal sphincter or sliding hiatal hernia can cause oesophagitis and its associated complications. Surgical procedures to prevent abnormal reflux are aimed at restoring a normal length of intra-abdominal oesophagus, repairing any hiatal hernia and increasing the pressure surrounding the intra-abdominal part of the oesophagus. This last is usually achieved by wrapping the fundus of the stomach around the intra-abdominal part of the oesophagus (fundoplication).

The converse type of lower oesophageal sphincter dysfunction occurs in achalasia, which is characterized by reduced or absent ganglion cells in the myenteric plexus of the distal oesophagus and gastro-oesophageal junction. The loss of inhibitory neurones at this site leads to impaired relaxation of the lower oesophageal sphincter on swallowing, causing dysphagia: oesophageal contraction becomes disorganized, resulting in proximal oesophageal dilatation. Classically, achalasia is characterized by a 'bird's beak' appearance on a barium swallow examination. The dilated oesophagus tapers sharply distally, there is poor oesophageal emptying and a non-relaxing lower oesophageal sphincter. Oesophageal manometry reveals aperistalsis of the oesophagus and a high pressure non-relaxing lower oesophageal sphincter. The main treatment options include surgical myotomy (Heller's cardiomyotomy), balloon dilatation or botulinum toxin injection, all of which address the hypertonic muscle fibres at the distal end of the oesophagus. Per-oral endoscopic myotomy (POEM) has been described as an alternative intervention (Schlottmann and Patti 2018).

Barrett's oesophagus can be defined as a change in the epithelium of the oesophagus in which any portion of the normal squamous epithelium lining has been pathologically replaced by a metaplastic 'intestinalized' columnar epithelium (see Commentary 1.3). There is a strong association between gastro-oesophageal reflux and the development of Barrett's oesophagus, which is also seen more commonly in Caucasian males and obese patients. The abnormal intestinal metaplasia can extend for a variable length proximally from the gastro-oesophageal junction, and associated macroscopic mucosal changes can be seen on endoscopy. The Prague classification is used to document the nature of the Barrett's oesophagus accurately in terms of its circumferential and maximal extents above the gastro-oesophageal junction. Barrett's oesophagus is recognized as the most important precursor lesion for oesophageal adenocarcinoma (Naini et al 2016)

Infantile hypertrophic pyloric stenosis is due to idiopathic hypertrophy of the circular muscle of the pylorus and causes gastric outlet obstruction in early infancy. It is readily treated by dividing the thickened pyloric muscle (pyloromyotomy) without dividing the pyloric gastric mucosa. Division of the vagal innervation to the pylorus can result in a functional gastric outlet obstruction or delayed gastric emptying; both common sequelae of gastric mobilization and oesophagectomy. To counter this possibility, a pyloroplasty can be fashioned involving full division of the anterior pyloric wall and reconstruction in the counter direction to promote drainage. Historically, pyloroplasty was performed to promote gastric drainage when vagotomy was used to treat peptic ulceration.

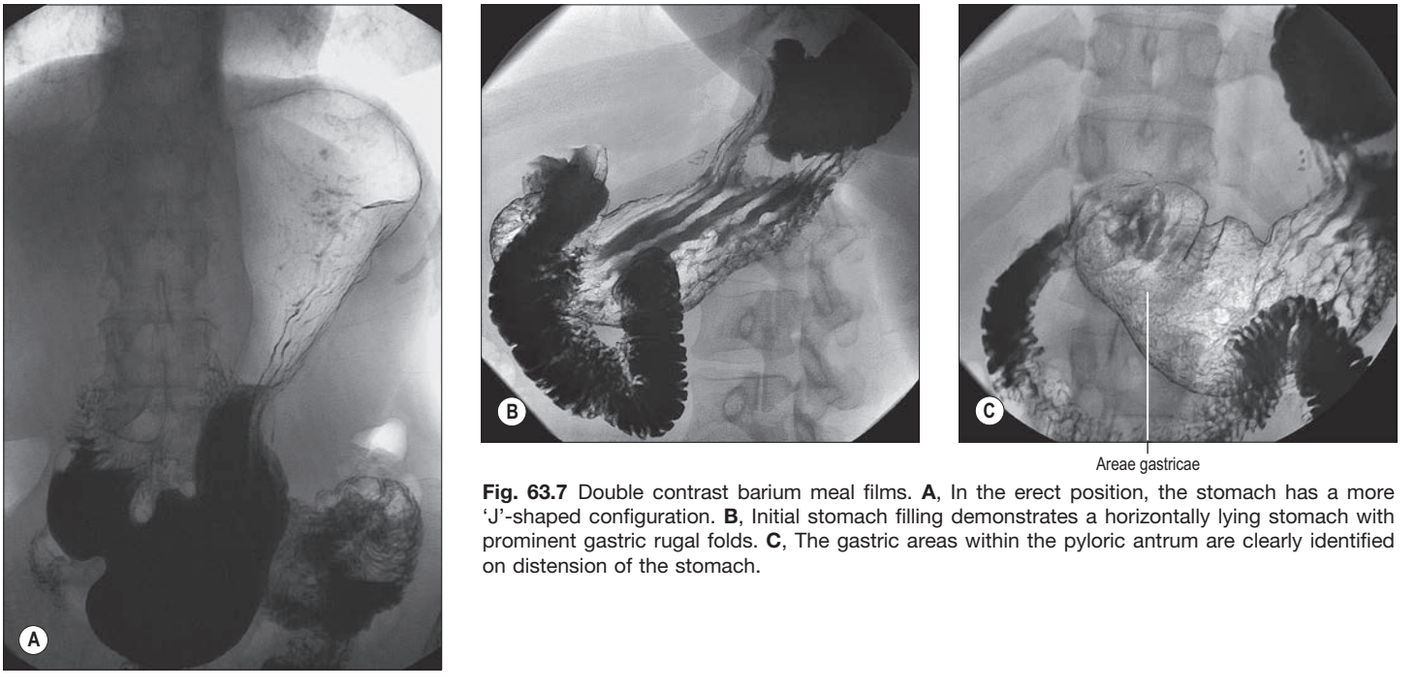

Fig. 63.7 Double contrast barium meal films. **A**, In the erect position, the stomach has a more 'J'-shaped configuration. **B**, Initial stomach filling demonstrates a horizontally lying stomach with prominent gastric rugal folds. **C**, The gastric areas within the pyloric antrum are clearly identified on distension of the stomach.

has a smooth mucosal surface that culminates in a slight puckering of the mucosa at the pyloric orifice caused by contraction of the pyloric sphincter.

Gastrostomy

Available with the *Gray's Anatomy* e-book

Vascular supply and lymphatic drainage

Arteries

The arterial supply to the stomach comes predominantly from the coeliac trunk, although there are intramural anastomoses with arteries of other origins at the two ends of the stomach (Figs 63.9–63.11).The left gastric artery usually arises directly from the coeliac trunk. The short gastric arteries, left gastro-omental artery and, when present, the posterior gastric artery are branches of the splenic artery. The right gastric artery and right gastro-omental artery usually arise from the proper hepatic artery and the gastroduodenal artery, respectively.

Left gastric artery

The left gastric artery is the smallest branch of the coeliac trunk. It ascends to the left of the midline and crosses over the distal end of the left crus of the respiratory diaphragm beneath a fold of peritoneum in the upper posterior wall of the omental bursa (the gastropancreatic fold). Here, it lies adjacent to the left inferior phrenic artery and medial or anterior to the left suprarenal gland. It runs forwards into the superior portion of the lesser omentum adjacent to the proximal end of the lesser curvature, and then it turns anteroinferiorly to run along the lesser curvature between the two peritoneal leaves of the lesser omentum. At the highest point of its course it gives off one or more oesophageal branches. In its course along the lesser curvature it gives off multiple branches that run on to the anterior and posterior surfaces of the

Since the inferior half of the anterior surface of the stomach lies adjacent to the anterior abdominal wall in the left upper quadrant, it can be readily accessed to form a gastrostomy. The mobility of the stomach means that it can be approximated to the parietal peritoneum on the proximal anterior abdominal wall and a communication can then be established between the lumen of the stomach and the skin surface. This is commonly undertaken by percutaneous puncture of the stomach guided by an endoscope within the gastric lumen, and is termed a percutaneous endoscopic gastrostomy (PEG). Other versions include a radiologically inserted gastrostomy (RIG) and either open or laparoscopic insertion of a gastrostomy tube that can then be used for feeding or drug administration. Caution is needed to avoid inadvertent transfixion of the transverse colon, which may be interposed between the stomach and anterior abdominal wall.

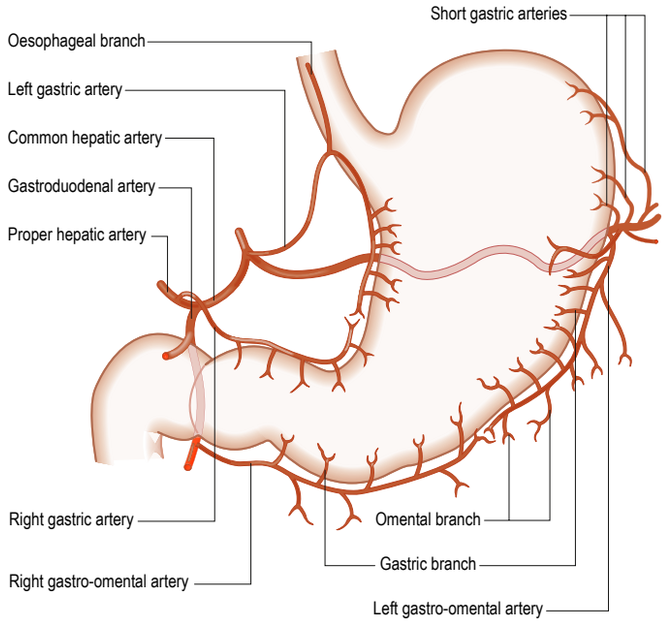

Fig. 63.9 The arterial supply of the stomach. A posterior gastric artery is not shown in this illustration.

stomach, after which it anastomoses with the right gastric artery in the region of the angular incisure.

Rarely, the left gastric artery (replaced or accessory) arises from the common hepatic or left hepatic arteries, or directly from the abdominal aorta (Panagouli et al 2013). The most common of these variations is an origin from the left hepatic artery, when the left gastric artery passes between the peritoneal layers of the proximal lesser omentum to reach the lesser curvature of the stomach. However, a replaced/accessory left hepatic artery arising from the left gastric artery is more common than a replaced/accessory left gastric artery origin.

Short gastric arteries

For practical purposes, the short gastric arteries can be defined as those arteries arising above the level of the splenic artery and supplying the fundus of the stomach on its greater curvature. The short gastric arteries vary in number, commonly between five and seven. They arise from the splenic artery or its terminal divisions, or from the proximal left gastro-omental artery, and pass between the layers of the gastrosplenic ligament to supply the fundus of the stomach and cardiac orifice. They anastomose with branches of the left gastric and left gastro-omental arteries. Rarely, an accessory left gastric artery arises with these vessels from the distal splenic artery.

Left gastro-omental artery

The left gastro-omental artery is the largest branch of the splenic artery. It arises near the splenic hilum and runs anteroinferiorly between the layers of the gastrosplenic ligament into the proximal gastrocolic part (gastrocolic ligament) of the greater omentum. Here, it descends between the layers of peritoneum close to the greater curvature and often anastomoses with the right gastro-omental artery. It gives off gastric branches to the fundus of the stomach through the gastrosplenic ligament, and to the body of the stomach through the gastrocolic ligament. These are necessarily longer than the gastric branches of the right gastro-omental artery and can be up to 8 cm long. Omental branches arise along the course of the vessel and descend between the layers of the greater omentum. A particularly large omental branch commonly originates close to the origin of the left gastro-omental artery, descends in the lateral portion of the greater omentum and provides a large arterial supply to this part.

Posterior gastric artery

A posterior gastric artery supplying the posterior wall of the upper part of the body of the stomach is commonly present but there has been a lack of consensus regarding its origin, course and distribution. When present, it usually arises from the splenic artery (typically from its midsection) posterior to the body of the stomach (see Fig. 63.11) and ascends behind the peritoneum of the omental bursa towards the fundus to reach the posterior surface of the stomach. It can also arise from the left gastric artery or coeliac trunk (Loukas et al 2007).

Right gastric artery

The right gastric artery is a relatively small artery that usually arises from the proper hepatic artery and runs forwards into the lesser omentum just above the superior part of the duodenum. It then travels within the lesser omentum along the lesser curvature of the stomach, giving off multiple branches to the anterior and posterior surfaces of the stomach, before anastomosing with the left gastric artery. Less commonly, the right gastric artery arises from the common hepatic, left hepatic or gastroduodenal arteries (Tubbs et al 2016).

Right gastro-omental artery

The right gastro-omental artery usually originates from the gastroduodenal artery behind the superior part of the duodenum, anterior to the head of the pancreas. It passes inferiorly towards the midline just below the pylorus and then runs laterally along the greater curvature between the layers of the greater omentum about 1–2 cm from the greater curvature of the stomach. It ends by anastomosing with the left gastro-omental artery (although this anastomosis is variably developed (Ndoye et al 2006) and can be absent). The right gastro-omental artery gives off gastric branches that ascend onto the anterior and posterior surfaces of the pyloric antrum and distal body of the stomach, omental branches that descend into the greater omentum, and duodenal branches that contribute to the supply of the inferior aspect of the superior part of the duodenum (Settembre et al 2018). The course of the right gastro-omental artery can vary: it can pass down into the greater omentum before arching back towards the greater curvature; it is important that the surgeon appreciates this anatomical variation if relying on the right gastro-omental artery to supply a surgically fashioned gastric conduit during reconstruction following oesophagectomy.

Arterial anastomoses of the stomach

The major named vessels supplying the stomach form extensive arterial anastomoses throughout the wall of the stomach but particularly in the submucosa. The rich arterial supply to the stomach ensures that the high mucosal blood flow required for physiological functioning is maintained even if one or more vessels become occluded: the stomach shows considerable resistance to ischaemia, even when multiple arterial supplies are lost.

Oesophageal arteries originating from the descending thoracic aorta anastomose with vessels supplying the fundus of the stomach in the region of the cardiac orifice. At the pyloric orifice, the extensive network of vessels supplying the duodenum allows for some anastomosis between branches of the superior mesenteric artery and pyloric vessels derived from arteries arising from the coeliac trunk. The right and left gastro-omental arteries and left and right gastric arteries anastomose along the greater and lesser curvatures, respectively. The short gastric and left gastric arteries anastomose in the fundus. The pyloric arteries are branches of the right gastric and right gastro-omental arteries. They pierce the duodenal wall around its entire circumference just distal to the pyloric sphincter and reach the submucosa. Here, they divide into two or three rami that run towards the stomach in the submucosa of the pyloric canal and terminate in the mucosa of the pyloric antrum (**Fig. 63.12**) (Piasecki 1974). The pyloric arteries anastomose with submucosal arteries in the duodenum and pyloric antrum close to their origin and termination, respectively. The pyloric sphincter is supplied by gastric and pyloric arteries via branches that leave their parent vessels in the subserosal and submucosal levels to penetrate the pyloric sphincter.

The extensive arterial anastomoses in the stomach wall allow the surgeon to run a gastric conduit off just the right gastro-omental and right gastric arteries, thereby providing reconstructive options following oesophagectomy: the blood supply can be sufficient to anastomose the gastric conduit as far proximally as the cervical part of the oesophagus.

Dieulafoy lesions

Abnormalities of the intramural vascularity of the stomach are a rare cause of acute upper gastrointestinal haemorrhage. The so-called 'Dieulafoy' lesion consists of an abnormally large artery that penetrates the muscular coat of the stomach, runs a tortuous course in the submucosa, and protrudes through a small mucosal defect where it is vulnerable to rupture: it occurs most often near the lesser curvature within a few centimetres of the gastro-oesophageal junction (Baxter and Aly 2010). The vessel can usually be clipped endoscopically, but if this fails, under-running of the vessel at open surgery may be required.

Veins

The veins draining the stomach ultimately empty into the hepatic portal vein. A rich submucosal and intramural venous network gives rise to veins

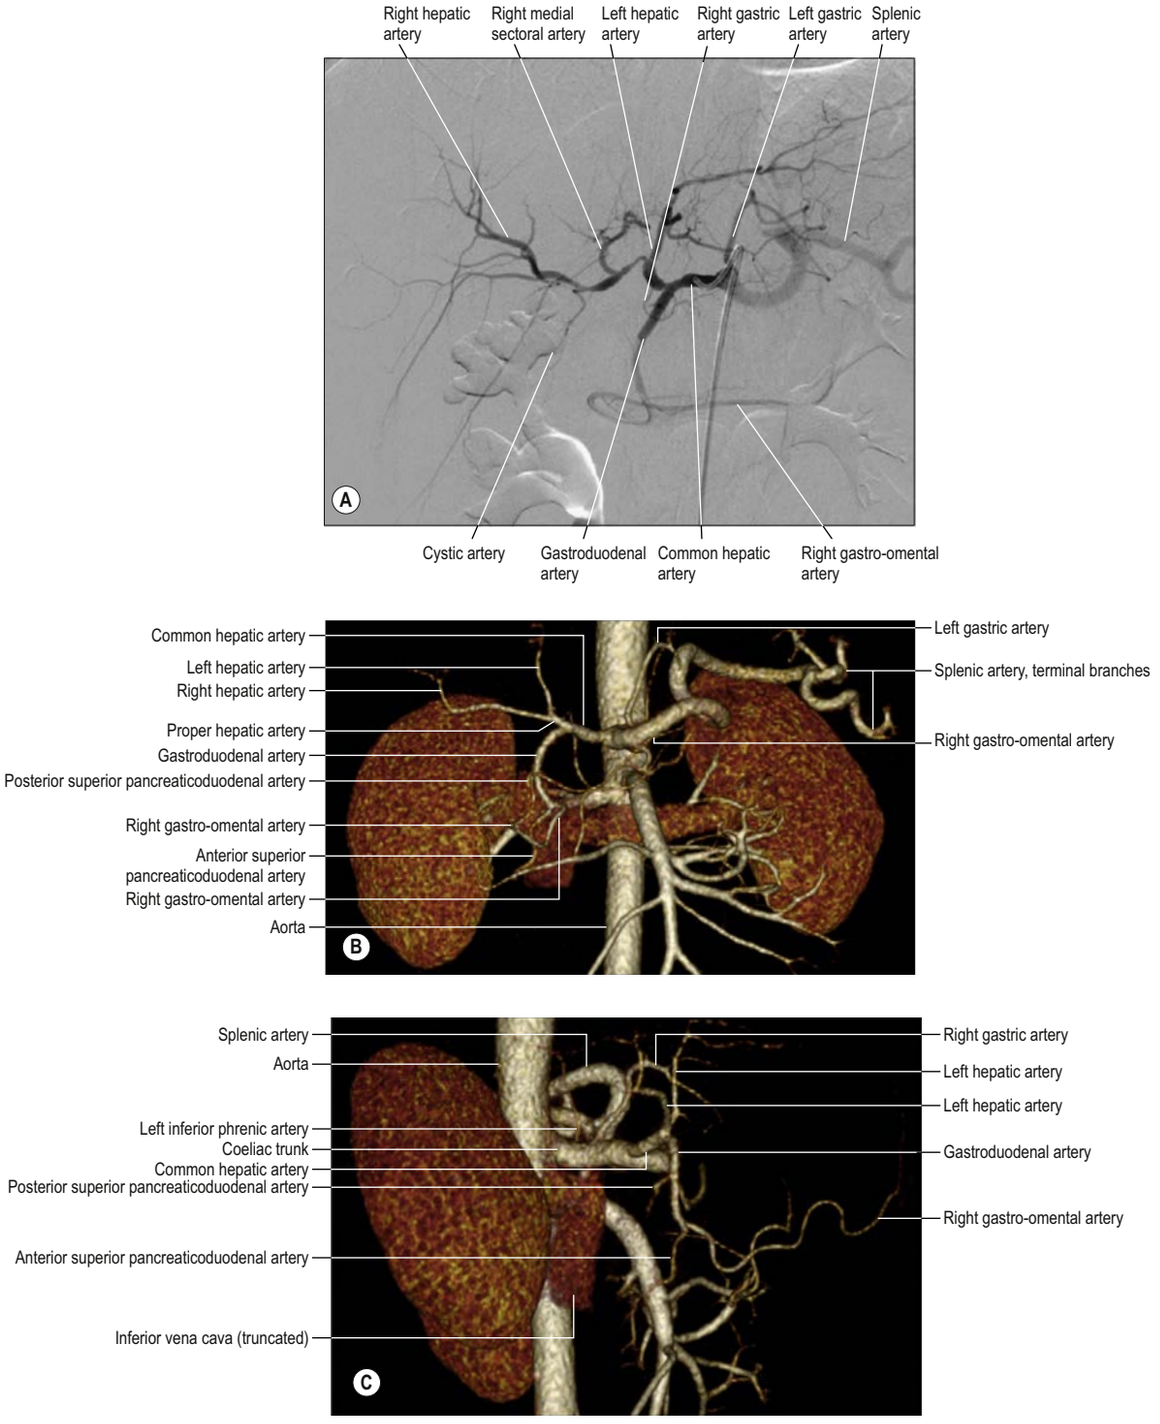

Fig. 63.10 The coeliac trunk and its branches. **A**, Digital subtraction angiogram. **B–C**, Volume-rendered CT angiograms of the abdominal aorta: frontal view (**B**) and right lateral view (**C**). (A, Courtesy of Dr James McCall, Chelsea & Westminster Hospital, London.) (D–F, *continued online*)

that usually accompany the corresponding named arteries and drain into either the splenic or superior mesenteric veins, although some pass directly into the hepatic portal vein. The course and distribution of the veins is highly variable even up to the level of the major named vessels.

Short gastric veins

Three to five short gastric veins drain the fundus and the upper part of the greater curvature of the stomach into the splenic vein or one of its large tributaries: they travel within the gastrosplenic ligament (Power et al 2001).

Left gastro-omental vein

The left gastro-omental (gastro-epiploic) vein drains both the anterior and posterior surfaces of the body of the stomach and the adjacent greater omentum via multiple tributaries. It runs superolaterally along the greater curvature, between the layers of the gastrocolic ligament, and drains into the splenic vein within the gastrosplenic ligament.

Right gastro-omental vein

The right gastro-omental (gastro-epiploic) vein drains the greater omentum, distal body and pyloric antrum. It runs medially along the greater curvature in the upper part of the gastrocolic omentum. Just proximal to the pylorus, it passes posteriorly to drain into the superior mesenteric vein posterior to the neck of the pancreas. The right gastro-omental vein can receive the right colic vein (forming a 'gastrocolic trunk') and/or the superior pancreaticoduodenal vein close to its entry into the superior mesenteric vein (Yamaguchi et al 2002, Stefura et al 2018).

Left gastric vein

The left gastric vein drains the proximal body and fundus of the stomach. It ascends along the lesser curvature to the gastro-oesophageal junction, where it receives several distal oesophageal veins. It then curves posteriorly and medially behind the posterior wall of the omental bursa. It usually passes anterior or posterior to the common hepatic artery and drains into the hepatic portal vein at the level of the proximal border of the superior part of the duodenum (which corresponds to 1–2 cm from

the origin of the portal vein) (Rebibo et al 2012). In up to one-third of individuals, it passes anterior or posterior to the common hepatic artery but terminates in the splenic vein. On rare occasions, it drains into the left branch of the hepatic portal vein within the liver (Ohkubo 2000), a variant that may be clinically important in portal hypertension. Knowledge of these venous variations is important during lymphadenectomy for gastric cancer to avoid unexpected venous bleeding.

Right gastric vein

The right gastric vein is typically small and runs along the medial end of the lesser curvature, passing under the peritoneum as it is reflected from the posterior aspect of the pylorus and superior part of the duodenum on to the posterior wall of the omental bursa. It drains directly into the hepatic portal vein at the level of the superior part of the duodenum. It receives the prepyloric vein as it ascends anterior to the pylorus at the level of the pyloric orifice. Rarely, the right gastric vein drains directly into a branch of the hepatic portal vein within the liver.

Posterior gastric veins

One or more distinct posterior gastric veins can be present, draining the middle of the posterior surface of the stomach into the splenic vein: they can become particularly prominent in portal hypertension (Kimura et al 1990).

Oesophageal and gastric varices

Blood from the oesophageal mucosa normally drains into a submucosal venous plexus, then into a deeper intrinsic venous plexus and finally into oesophageal veins via perforating veins. In the abdominal part of the oesophagus, the perforating veins drain into tributaries of the left gastric vein, whereas in the distal thoracic part of the oesophagus, they drain into tributaries of the azygos and hemiazygos venous systems. Bidirectional flow is possible in this region and accommodates pressure changes during breathing and Valsalva manoeuvres.

Oesophageal and gastric varices are abnormally dilated veins that occur in the submucosal plexus of the distal oesophagus and fundus of the stomach when portal venous pressure is chronically elevated (typically greater than 15 mmHg). This can arise as a consequence of liver fibrosis or cirrhosis, or hepatic portal vein thrombosis, or from a variety of other causes. Portal hypertension leads to the recanalization of occluded embryonic venous channels connecting tributaries of the portal system and the systemic venous circulation (e.g. the round ligament of the liver), and progressive dilation of small, naturally occurring venous anastomoses between portal and systemic venous tributaries (Paquet 2000). The raised pressure causes the valves within these veins to become incompetent, permitting retrograde flow and the development of varices. Varices in the distal oesophagus are readily visible at endoscopy because they are situated superficially and protrude into the lumen of the oesophagus (Fig. 63.13); they are vulnerable to rupture and are a source of major gastro-intestinal bleeding. Gastric varices can also be present on the inferior aspect of the cardiac orifice. Isolated gastric varices can also develop as a result of splenic vein thrombosis. The close anatomical relationship between the splenic vein and the pancreas means that inflammation or cancers of the pancreas can result in the formation of a thrombus in the splenic vein. Because the short gastric veins drain into the splenic vein, thrombosis of that vein will result in increased pressure and engorgement, leading to varices in the fundus of the stomach.

Lymphatic drainage

The stomach has a rich network of lymphatics that connect with lymphatics draining other viscera within the proximal abdomen. At the gastro-oesophageal junction the lymphatics are continuous with those draining the distal oesophagus; in the region of the pylorus they are continuous with those draining the duodenum and pancreas. In general, lymphatics follow the course of the arteries supplying the stomach. However, many separate groups of nodes are now recognized (Fig. 63.14) and their relationship to the specific regions and vascular territories of the stomach is of great importance during resection of the stomach, particularly for malignancy. Pancreatic and hepatic lymphatics are significant in draining the stomach during disease.

Gastrectomy and gastric lymphadenectomy

Surgery for gastro-oesophageal malignancy involves various degrees of radical resection of lymph nodes that drain the tumour. Locoregional lymphatic spread can occur in the absence of haematogenous spread and gastric cancer can therefore remain a localized disease, even when lymph nodes are involved (Brierley et al 2017). Hence, gastrectomy with meticulous lymphadenectomy can be curative in a proportion of patients with gastric cancer and lymph node involvement.

The extent of potential/actual lymph node involvement by the tumour is classified as N1 (locoregional nodes specific to the tumour site); N2 (regional and major named vessel nodes draining the tumour); and N3 (wider-draining nodes, including lateral aortic nodes). Gastrectomies can be classified according to the node groups excised with the tumour: D1 (removal of the affected portion of the stomach and *en bloc* resection of N1 nodes); D2 (total gastrectomy, including all N1 and N2 nodes); and D3 (total gastrectomy plus extensive lymphadenectomy that includes the associated proximal abdominal lymph nodes: namely, pancreatic, superior mesenteric, coeliac, hepatic and middle colic) (Japanese Gastric Cancer Association 2011).

Innervation

The stomach is innervated by sympathetic and parasympathetic nerves. A variety of neurotransmitters have been identified within the pyloric sphincter, including acetylcholine, nitric oxide, enkephalins and vasoactive intestinal polypeptide. Inhibition of the pyloric sphincter is mediated by nitrergic fibres whilst basal tone is mostly cholinergic (although it should be noted that many other factors, including acid and luminal

nutrients, influence pyloric sphincter contraction; Ramkumar and Schulze (2005)).

Sympathetic innervation

The sympathetic supply to the stomach originates from the fifth to twelfth thoracic spinal cord segments and is mainly distributed via the greater and lesser thoracic splanchnic nerves and the coeliac plexus. Peri-arterial plexuses form along the arteries arising from the coeliac trunk. Additional innervation comes from fibres of the hepatic plexus, which pass to the proximal body and fundus via the lesser omentum and by direct branches from the greater thoracic splanchnic nerves.

Sympathetic activity causes vasoconstriction, inhibits gastric motility and constricts the pylorus.

Parasympathetic innervation

The parasympathetic supply to the stomach is from the vagus nerves (**Fig. 63.15**). The anterior vagal trunk (formed mainly from fibres from the left vagus nerve within the oesophageal plexus) is often double or even triple and supplies filaments to the cardiac orifice. The nerve is closely applied to the anterior surface of the outer muscle of the abdominal part of the oesophagus and usually divides near the gastro-oesophageal junction into gastric, pyloric and hepatic branches (Jackson 1949). The proximal gastric branches radiate on the anterior surface of the proximal body and fundus of the stomach but the main gastric branch (also known as the anterior nerve of the lesser curvature or greater anterior gastric nerve) lies in the lesser omentum near the lesser curvature. It supplies branches to the body and pyloric antrum and usually terminates near the angular incisure in a crow's foot type of pattern (Shanthi and Sudhayesshayyan 2011). The hepatic branch runs almost transversely between the peritoneal layers of the lesser omentum towards its free edge to reach the porta hepatis, where hepatic branches ramify. From here, some fibres descend adjacent to the common hepatic artery and its branches to supply the pylorus, duodenum and pancreas. An additional pyloric branch often arises from the main gastric branch during its course; this runs inferomedially to the pyloric antrum, where it gives off branches to the pylorus before running superiorly to contribute to the hepatic plexus. Variations in the main gastric branch include accessory pyloric branches and high and low courses of the hepatic and pyloric branches in the lesser omentum.

The posterior vagal trunk usually lies within loose connective tissue immediately posterior and to the right of the oesophagus. It divides into gastric branches and one or more coeliac branches. Gastric branches run posterior to the cardiac orifice and body of the stomach and extend to the proximal pyloric antrum, but do not normally reach the pyloric sphincter. The largest gastric branch (also known as the posterior nerve of the lesser curvature or the greater posterior gastric nerve) descends posteriorly near the lesser curvature. The coeliac branch arises from the posterior vagal trunk and carries most of the fibres contributing to the coeliac plexus. One or two small hepatic branches can also originate from the coeliac branch of the nerve.

The parasympathetic nerve supply is secretomotor to the gastric mucosa and motor to the gastric musculature. It is responsible for coordinated relaxation of the pyloric sphincter during gastric emptying. However, most fibres within the vagus nerves are afferent and convey gut sensation, including fullness, nausea and probably pain.

Referred pain

Pain sensation from the stomach is poorly localized and, in common with other structures of foregut derivation, is referred to the epigastric region. Pain arising from the gastro-oesophageal junction is commonly referred to the distal retrosternal and subxiphoid areas.

Microstructure

The gastric wall consists of the major layers found elsewhere in the gut, i.e. mucosa, submucosa, muscularis externa and serosa, together with gastric vessels and nerves (**Figs 63.16–63.17**). The microstructure reflects the functions of the stomach as an expandable muscular sac lined by secretory epithelium, although there are local structural and functional variations in this pattern.

Mucosa

The mucosa is a thick layer with a soft, smooth surface that is mostly reddish brown in life but pink in the region of the pylorus. In the contracted stomach, the mucosa is folded into numerous folds (gastric folds) most of which are longitudinal. They are most marked towards the pylorus and along the greater curvature. The gastric folds represent large furrows in the submucosal connective tissue (see below) rather than variations in the thickness of the mucosa covering them, and they are obliterated when the stomach is distended. As elsewhere in the gut, the mucosa is composed of a surface epithelium, lamina propria and muscularis mucosae.

Epithelium

When viewed microscopically at low magnification, the internal surface of the stomach wall appears honeycombed by small, irregular gastric pits: there are approximately 60–100 gastric pits per square millimetre of mucosa, each pit having a diameter of approximately 70 µm and a depth of about 0.2 mm (Lillibridge 1964) (see Figs 63.16–63.17). The base of each gastric pit receives several long, tubular gastric glands that extend deep into the lamina propria as far as the muscularis mucosae. Simple columnar mucus-secreting epithelium covers the entire luminal surface, including the gastric pits, and comprises a continuous layer of surface mucous cells that release gastric mucus from their apical surfaces to form a thick, protective, lubricant layer over the gastric lining. This epithelium commences abruptly at the Z line at the cardiac orifice, where there is a sudden transition from oesophageal stratified squamous epithelium.

Gastric glands

Although all gastric glands are tubular, they vary in form and cellular composition in different parts of the stomach (**Fig. 63.18**). They can be divided into three groups: cardiac, principal and pyloric. The most highly specialized are the principal glands.

Principal gastric glands

The principal glands are found in the body and fundus of the stomach, three to seven opening into each gastric pit. Their junction with the base of the pit is the isthmus; immediately basal to this is the neck; and the remainder is the base. The walls of the gland contain at least five distinct cell types: chief, parietal, mucous neck, stem and neuroendocrine.

Chief (peptic) cells (see Fig. 63.16) are the source of the digestive enzymes pepsin and lipase. They are usually basal in position and cuboidal in shape, and their nuclei are rounded and euchromatic. They contain secretory zymogen granules and their abundant cytoplasmic RNA renders them strongly basophilic. Parietal (oxyntic) cells are the source of gastric acid and of intrinsic factor, a glycoprotein necessary for the absorption of vitamin B_{12}. They are large, oval and strongly eosinophilic and have centrally placed nuclei.

Parietal cells occur intermittently along the walls of the more apical half of the gland but can reach as far as the isthmus; they bulge laterally into the surrounding connective tissue. They have a unique ultrastructure related to their ability to secrete hydrochloric acid. The luminal side of the cell is deeply invaginated to form a series of blind-ended channels (canaliculi) that bear numerous irregular microvilli covered by a plasma membrane rich in H^+/K^+ ATPase antiporter channels. The latter actively secrete hydrogen ions into the lumen; chloride ions

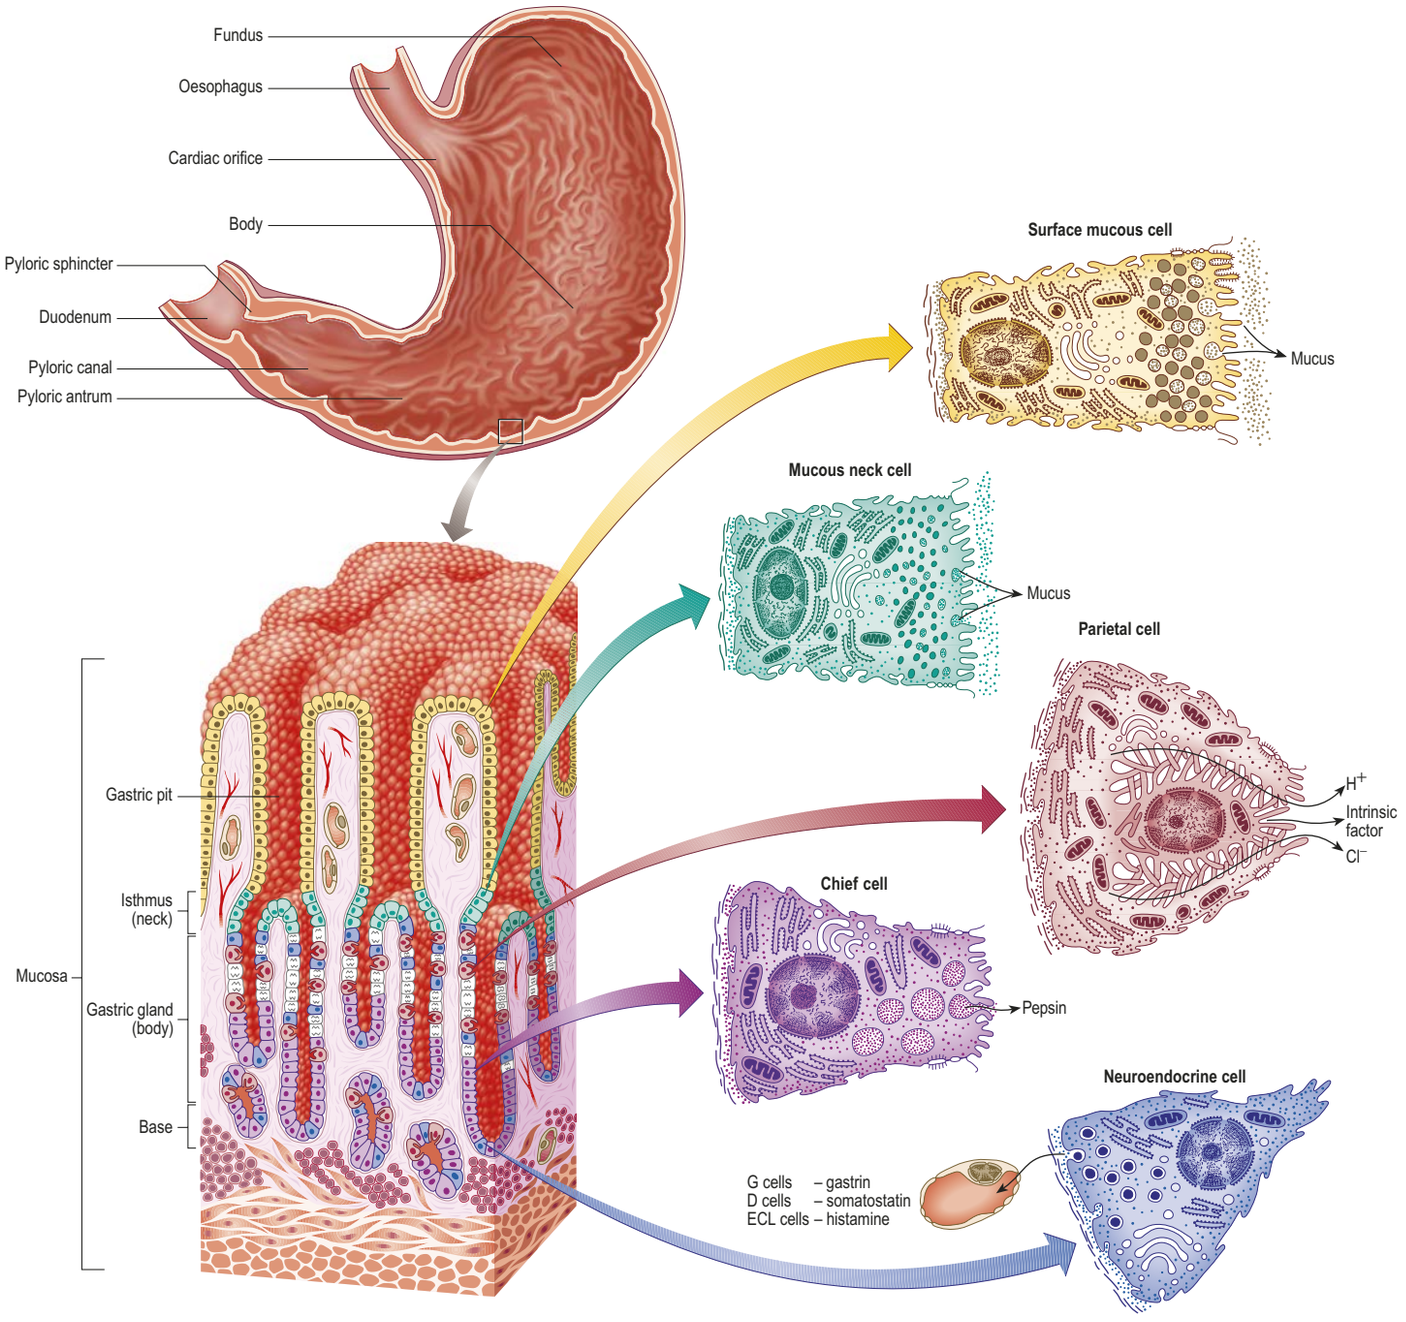

Fig. 63.16 Principal regions of the interior of the stomach and the microstructure of tissues and cells within its wall. Undifferentiated, dividing cells are shown in white. Abbreviations: ECL, enterochromaffin-like.

follow along the electrochemical gradient. The mitochondria-rich cytoplasm facing these channels contains a tubulo-vesicular system of abundant fine membranous tubules directed towards the canalicular surface. The precise structure of the cell varies with its secretory phase: when stimulated, the number and surface area of microvilli increases up to five-fold, probably as a result of the rapid fusion of the tubulo-vesicular system with the plasma membrane. This process is reversed at the end of stimulated secretion, when the excess membrane retreats back into the tubulo-alveolar system and microvilli are lost.

Mucous neck cells are numerous at the necks of the glands and are scattered along the walls of the more basal regions. They are typical mucus-secreting cells, displaying apical secretory vesicles containing mucins and basally displaced nuclei; their products are distinct histochemically from those of the superficial mucous cells.

Stem cells are relatively undifferentiated mitotic cells from which the other types of gland cell are derived. They are relatively few in number and are situated in the isthmus of the gland and the bases of the gastric pits. Stem cells are columnar and possess a few short apical microvilli. They periodically undergo mitosis; their progeny migrate either apically, to differentiate into new surface mucous cells, or basally, to form mucous neck, parietal, chief or neuroendocrine cells. All of these cells have a limited lifespan, especially the mucus-secreting types, so they are continually replaced. The typical replacement period for surface mucous cells is three days, and that for mucous neck cells is one week. Other cell types appear to live much longer.

Neuroendocrine (enteroendocrine) cells occur in all types of gastric gland but more frequently in the body and fundus of the stomach. They are situated mainly in the deeper parts of the glands, among the chief cells. They are basally situated, pleomorphic cells and display irregular nuclei surrounded by granular cytoplasm that contains clusters of large (0.3 μm) secretory granules. Neuroendocrine cells synthesize a number of biogenic amines and polypeptides that are important in the control of gut motility and glandular secretion. They are part of the system of dispersed neuroendocrine cells (Ch. 3). In the stomach they include gastrin-producing G cells; somatostatin-producing D cells; histamine-producing ECL (enterochromaffin-like) cells; serotonin-producing enterochromaffin cells; and ghrelin-producing P/D(1)-type endocrine cells (Sakata and Sakai 2010).

Cardiac glands

Cardiac glands are confined to a small area near the cardiac orifice; some are simple tubular glands, others are compound branched tubular glands. Mucus-secreting cells predominate; parietal and chief cells are present but sparse.

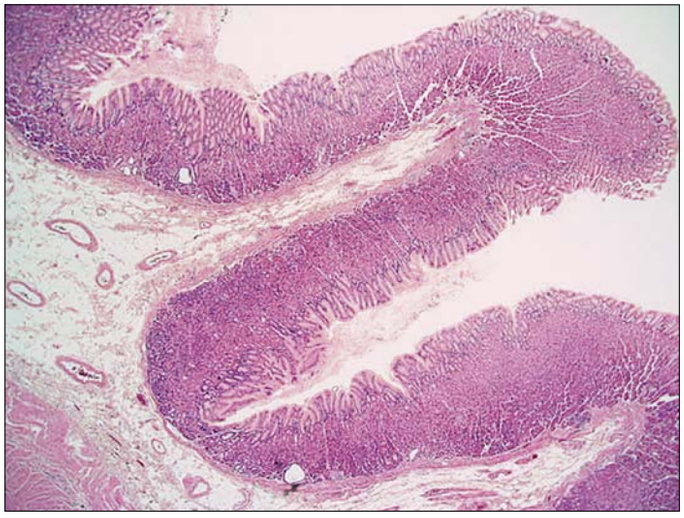

Fig. 63.17 A low-power micrograph showing the stomach wall, thrown into gastric folds that are visible macroscopically. The surface epithelium is infolded microscopically to form gastric pits. Gastric glands extend through the thickness of the mucosal lamina propria and open into the bases of the gastric pits. A muscularis mucosae layer and submucosa follow the contours of the gastric folds. Part of the external muscularis layers is seen below left. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fig. 63.18 A micrograph showing gastric glands in the mucosa of the wall of the stomach. Pale-staining surface mucous cells and mucous cells lining the gastric pits (arrow) are shown in the upper field. Tubular glands open into gastric pits and are lined by mucous neck cells, with parietal cells, chief cells, stem cells and neuroendocrine cells at deeper levels (not readily distinguishable at this magnification). Note the muscularis mucosae (MM), with the submucosa below. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Pyloric glands

Pyloric glands empty via groups of two or three short, convoluted tubes into the bases of the deep gastric pits of the pyloric antrum; the pits occupy about two-thirds of the mucosal depth. The glands are populated mainly by mucus-secreting cells but they also contain neuroendocrine cells, especially G cells, which secrete gastrin when activated by appropriate mechanical stimulation (causing increased gastric motility and secretion of gastric juices). Although parietal and chief cells are scarce, parietal cells are always present in both fetal and postnatal pyloric glands. They can also appear in the duodenal mucosa, proximally near the pylorus, in adult tissue.

Lamina propria

The lamina propria forms a connective tissue framework between the glands. It contains small masses of lymphoid tissue, gastric lymphatic follicles, which resemble solitary intestinal follicles (especially in early life). It also contains a complex periglandular vascular plexus involved in maintaining the mucosal environment, e.g. the removal of bicarbonate produced in the tissues as a counterpart to acid secretion, and neural plexuses rich in both sensory and motor terminals.

Muscularis mucosae

The muscularis mucosae is a thin layer of smooth muscle fibres lying external to the layer of glands, arranged as continuous inner circular and outer longitudinal layers and a discontinuous external circular layer. The inner layer sends strands of smooth muscle cells between the glands; their contraction probably assists in emptying into the gastric pits.

Submucosa

The submucosa is a variable layer of loose connective tissue. It contains thick bundles of collagen, numerous elastin fibres, blood vessels and nervous plexuses, including the ganglionated submucosal (Meissner's) plexus.

Muscularis externa

The muscularis externa is a thick muscle coat immediately under the serosa, with which it is closely connected by subserous loose connective tissue. From innermost outwards it contains oblique, circular and longitudinal layers of smooth muscle fibres (see Fig. 63.6). The layers are variably developed in different regions of the stomach and not easily separated. Clasp-like semicircular smooth muscle fibres are present on the right side of the oesophagus and sling-like oblique gastric muscle fibres on the left side; the latter radiate horizontally towards the greater curvature and maintain the angle between the oesophagus and stomach. The circular muscle layer is thicker in the distal pyloric antrum, where it forms the pyloric sphincter. The outer longitudinal layer is most pronounced in the proximal two-thirds of the stomach.

The muscularis externa enables the stomach to produce churning movements that mix food with the gastric secretions. When the muscles contract they reduce the volume of the stomach and throw the mucosa into longitudinal folds, i.e. gastric folds (see above). Muscle activity is controlled by a network of unmyelinated autonomic nerve fibres and their ganglia, which lie between the muscle layers in the myenteric (Auerbach's) plexus.

Interstitial cells of Cajal

As in smooth muscle elsewhere in the gut, interstitial cells of Cajal are present within the submucosa and muscular layers of the stomach. These spindle-shaped cells contact nerve fibres and form gap junctions with smooth muscle cells, consistent with their role in modulating motor neurotransmission. Interstitial cells of Cajal are involved in generating rhythmic gastric slow-wave contractions and are important in gastric motility. They have been implicated in the pathogenesis of gastric motility disorders such as diabetic gastric paresis (Negreanu et al 2008) and in the development of gastrointestinal stromal tumours (GISTs) (Roggin and Posner 2012). These are uncommon mesenchymal tumours that usually develop in a submucosal location and exhibit a spectrum of clinical behaviour from benign to malignant based upon size and mitotic rate. Surgical resection is usually indicated for localized tumours greater than 2 cm in diameter.

Serosa or visceral peritoneum

The serosa is an extension of the visceral peritoneum. It covers the entire surface of the stomach other than along the attachments of the greater and lesser omenta to the greater and lesser curvatures, respectively, where the peritoneal layers are separated by vessels and nerves, and over a small posterosuperior area near the cardiac orifice, where the stomach contacts the respiratory diaphragm at the reflections of the gastrophrenic and left gastropancreatic folds.

Endoscopic mucosal resection and submucosal dissection

Endoscopic mucosal resection (EMR) is a technique that can be applied in the oesophagus and stomach in order to excise dysplastic lesions or early cancers that remain confined to the mucosa (Pech et al 2008). EMR is a misnomer since the technique involves resection of both the mucosa

and submucosa. This is a safe and effective technique for removing superficial lesions within the upper gastrointestinal tract. The resected specimen can then be assessed histologically. This is important for early oesophageal adenocarcinoma since EMR can be curative for a T1a cancer (which is confined to the mucosa) as the risk of lymph node metastasis is very low, in contrast to a T1b cancer invading the submucosa, when the risk of lymph node metastasis is much greater (various studies show 10–40%) so alternative treatment is required, such as formal surgical resection (oesophagectomy or gastrectomy) and lymphadenectomy (Ancona 2008, Dubecz et al 2015). EMR is limited to small superficial lesions up to about 20 mm. Endomucosal-submucosal dissection (ESD) has recently become available through the development of small knives that can be used down the endoscope allowing en bloc resection of larger lesions.

GASTRIC MOTILITY

In simple terms, the proximal region of the stomach (fundus and proximal body) functions mostly as a temporary storage compartment, regulating intragastric pressure and the onward passage of chyme into the distal stomach. Proximal gastric tone decreases with swallowing (receptive relaxation) and in response to gastric distension (gastric accommodation). Its activity is modulated by enterogastric reflexes (e.g. acid, protein or fat in the duodenum inhibits proximal gastric muscle contraction) and gut hormones (e.g. cholecystokinin, gastrin, glucagon and vasoactive intestinal polypeptide). The vagus nerve plays a key role in these reflexes. In contrast to this activity, the muscle of the distal region of the stomach exhibits strong phasic contractions that increase in amplitude towards the pylorus; these occur about three times per minute and act to grind the food mechanically and propel it towards the pylorus. Solid material lags behind liquids, and when the contents of the pyloric antrum reach the contracted pylorus, only the liquid and small particulate solids can be expelled into the duodenum; larger solid matter is retropulsed back into the stomach for further breakdown (Patrick and Epstein 2008).

Small intestine

CHAPTER 64

OVERVIEW

The small intestine consists of the duodenum, jejunum and ileum. It extends from the pylorus to the ileocaecal junction and has a mean length of 5 metres (3–8.5 metres) when measured intraoperatively in adults (Teitelbaum et al 2013). The duodenum extends from the stomach to the duodenojejunal junction, marked by the suspensory ligament of the duodenum (ligament of Treitz). There is no clear boundary between the jejunum and ileum, but there is a gradual transition in morphology from the proximal to distal ends of the small intestine. The distal 30 cm or so of the ileum is often referred to as the terminal ileum: it has some specialized physiological functions.

The duodenum is in the proximal abdomen and is mostly retroperitoneal. The jejunum and ileum occupy the central and distal parts of the abdominal cavity and usually lie within the boundary formed by the colon. The small intestine is attached to the anterior wall of the retroperitoneum by a mesentery that allows the intestinal loops to be relatively mobile. In the supine position, loops of jejunum can be found anterior to the transverse colon, stomach and lesser omentum, whereas in the erect position, loops of ileum can descend into the pelvis anterior to the rectum. The greater omentum covers the proximal jejunum and ileum to a variable extent. The jejunum and ileum are covered by visceral peritoneum on all but their mesenteric borders, where the peritoneum is reflected to enclose the adipose tissue of the mesentery. The small intestine mesentery abuts about 20% of the circumference of the muscular wall of the ileum and somewhat less of the jejunum.

DUODENUM

The adult duodenum is approximately 25 cm long and is the shortest, widest and most predictably located part of the small intestine. The proximal 2.5 cm is intraperitoneal and the remainder is retroperitoneal. The duodenum forms an elongated 'C' shape that lies between the level of the first and third lumbar vertebrae in the supine position (Kellogg 1933). The inferior 'limb' of the C extends further to the left of the midline than the superior limb. The head of the pancreas lies within the concavity of the duodenum, which is 'draped' over the prominence formed by the lumbar spine; the duodenum therefore curves in an anteroposterior direction as well as forming a 'C' shape. The duodenum lies entirely proximal to the level of the umbilicus. It is described as having four parts (**Fig. 64.1**).

Superior part

The superior (first) part is the most mobile part of the duodenum and is about 5 cm long. It starts at the termination of the pylorus of the stomach and ends at the superior duodenal flexure. The proximal 2.5 cm is intraperitoneal. The distal 2.5 cm is covered by peritoneum on its anterior and superior surfaces and forms the inferior boundary of the omental foramen (of Winslow). The lesser omentum is attached to its superior border and the greater omentum to its inferior border. The first 2–3 cm of the duodenum is lined by relatively smooth mucosa and readily distends on insufflation during endoscopy. This part is frequently referred to as the duodenal bulb (duodenal cap). Beyond the duodenal bulb, the internal appearance is characterized by circular folds of mucosa that remain pronounced, even during endoscopic insufflation (**Fig. 64.2**). During contrast radiology, the duodenal bulb shows a few longitudinal folds continuous with the pylorus (Mather Cordiner and Calthrop 1936) and appears triangular; it is often visible on plain radiographs of the abdomen as an isolated air shadow to the right of the first or second lumbar vertebra. The superior part of the duodenum passes superiorly, posteriorly and laterally before curving sharply inferiorly at the superior duodenal flexure. This portion transitions to a retroperitoneal position where peritoneum only covers its anterior aspect. The section from the duodenal bulb to the superior duodenal flexure lies posterior and inferior to the quadrate lobe of the liver.

The superior part of the duodenum lies anterior to the gastroduodenal artery, bile duct and hepatic portal vein and anterosuperior to the head and neck of the pancreas. The gastroduodenal artery lies immediately posterior to the posterior wall of the duodenum; a penetrating peptic ulcer on the posterior wall can erode into the gastroduodenal artery or one of its branches and cause dramatic haemorrhage. A penetrating peptic ulcer on the anterior wall can perforate into the peritoneal cavity, causing peritonitis because the anterior surface of the superior part of the duodenum is covered only by peritoneum.

Lymph nodes near the common hepatic and hepatoduodenal arteries lie close to the superior part of the duodenum (see Fig. 63.14B). They can be visualized using endoscopic ultrasound and sampled using a fine needle under endoscopic ultrasound guidance. The nodes are important in the staging of gastric, pancreatic or bile duct tumours, or identifying metastases from other solid tumours of the abdominal cavity. The proximity of the bile duct to the superior part of the duodenum enables endoscopic ultrasound examination of the distal bile duct and surgical anastomosis between bile duct and duodenum (choledochoduodenostomy) when required.

Descending part

The descending (second) part of the duodenum is approximately 8 cm long. It starts at the superior duodenal flexure and runs inferiorly in a gentle curve, convex to the right side of the vertebral column and extending to the inferior border of the third lumbar vertebral body. It then turns sharply medially at the inferior duodenal flexure, which marks its junction with the horizontal (third) part of the duodenum. The descending part of the duodenum is covered by peritoneum only on its proximal anterior surface. It lies posterior to the gallbladder and the right lobe of the liver at its start and is crossed anteriorly by the transverse colon. The right end of the gastrocolic ligament and the origin of the transverse mesocolon are attached to the anterior surface of the duodenum by loose connective tissue. The connective tissue and vessels forming the mesentery of the superior aspect of the ascending colon and right colic flexure are loosely attached to its anterior surface, inferior to the attachment of the transverse mesocolon. This part of the duodenum is at risk of iatrogenic injury during surgical mobilization of the ascending colon and right colic flexure.

The descending part of the duodenum lies anterior to the hilum of the right kidney, the right renal vessels, the lateral edge of the inferior vena cava and right psoas major (see Fig. 64.1C). The head of the pancreas and the bile duct are medial and the right colic flexure is cephalad and lateral. Part of the head of the pancreas is sometimes embedded in the medial duodenal wall, and pancreatic 'rests' in the duodenal wall can produce small filling defects on contrast radiology. The internal appearance is similar to that of the distal portion of the superior part of the duodenum, with pronounced mucosal folds (**Fig. 64.3**). The bile duct and pancreatic duct (of Wirsung) enter the medial wall, where they usually unite to form a common channel, which frequently contains a dilated segment known as the hepatopancreatic ampulla (of Vater) (Ch. 68). The narrow distal end of this channel opens on the summit of the major duodenal papilla, a mucosal elevation situated on the posteromedial wall of the descending part of the duodenum, 8–10 cm distal to the pylorus. A duodenal mucosal fold often partially encircles the major papilla, forming a hood (Horiguchi and Kamisawa 2010) (see Fig. 64.3). A second, accessory pancreatic duct (of Santorini) is sometimes present and usually opens about 2 cm proximal to the major duodenal papilla on the minor duodenal papilla (Kamisawa et al 2010, Suda 2010).

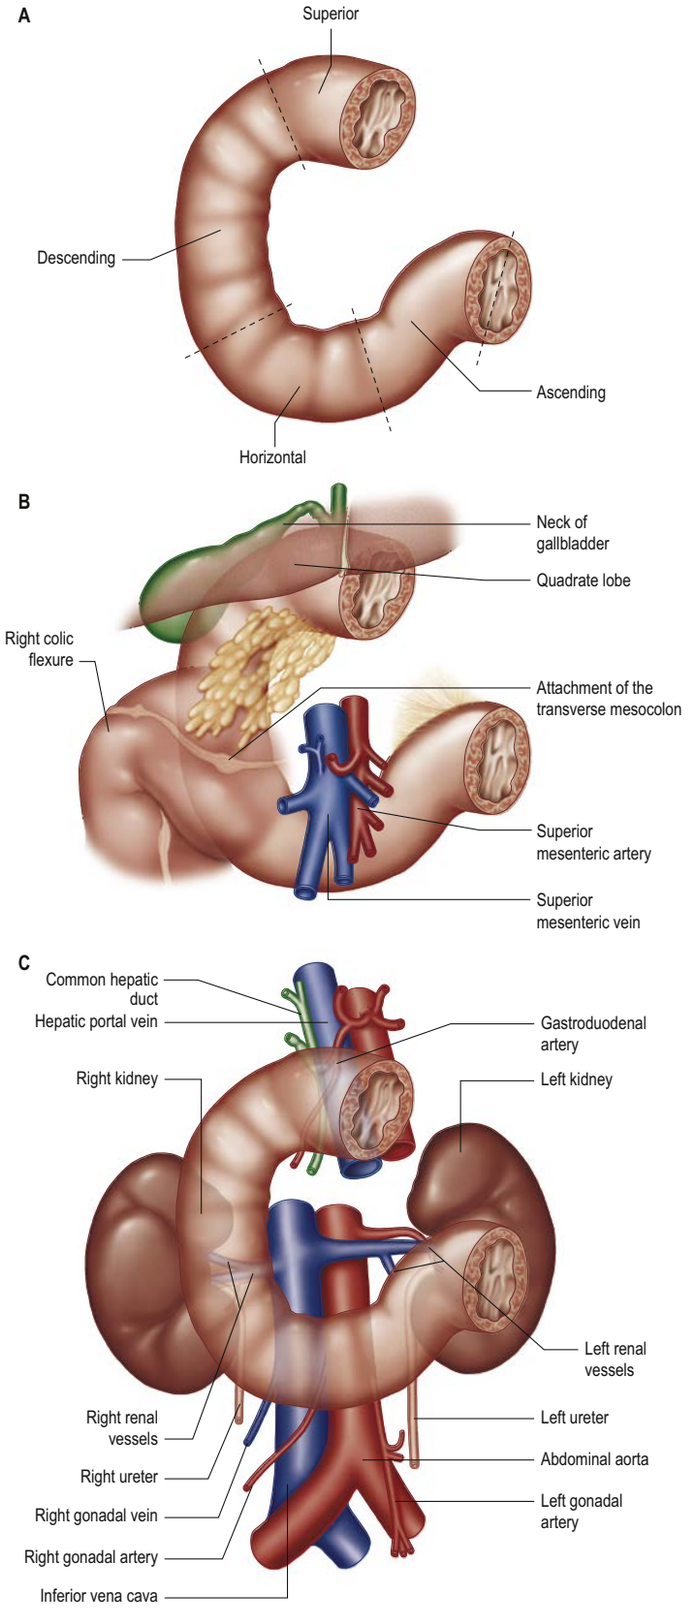

Fig. 64.1 **A**, The four parts of the duodenum. **B**, Anterior relations of the duodenum. **C**, Posterior relations of the duodenum.

Duodenal diverticula

Available with the *Gray's Anatomy* e-book

Horizontal part

The horizontal (third) part of the duodenum starts at the inferior duodenal flexure and is approximately 10 cm long. It runs from the right side of the inferior border of the third lumbar vertebra and passes to the left and slightly superiorly, anterior to the inferior vena cava and abdominal aorta, becoming continuous with the ascending part of the duodenum (see Fig. 64.1C). It lies posterior to the transverse mesocolon and is crossed anteriorly by the origin of the mesentery of the small intestine and the superior mesenteric vessels. The inferior portion of its anterior aspect is covered by peritoneum, reflected anteriorly to form the posterior layer of the root of the mesentery of the small intestine. The anterior surface of its left end, close to the junction with the ascending (fourth) part, is also covered by peritoneum.

The horizontal part of the duodenum lies anterior to the right ureter, right psoas major, right gonadal vessels, inferior vena cava and abdominal aorta (at the origin of the inferior mesenteric artery), and inferior to the head of the pancreas. Anteroinferiorly, loops of jejunum lie in the right and left infracolic compartments. The middle of the horizontal part lies in the angle between the superior mesenteric artery anteriorly and the abdominal aorta posteriorly. Loss of perivascular adipose tissue can cause narrowing of this angle and is a rare cause of duodenal obstruction, known as superior mesenteric artery syndrome (Merrett et al 2009).

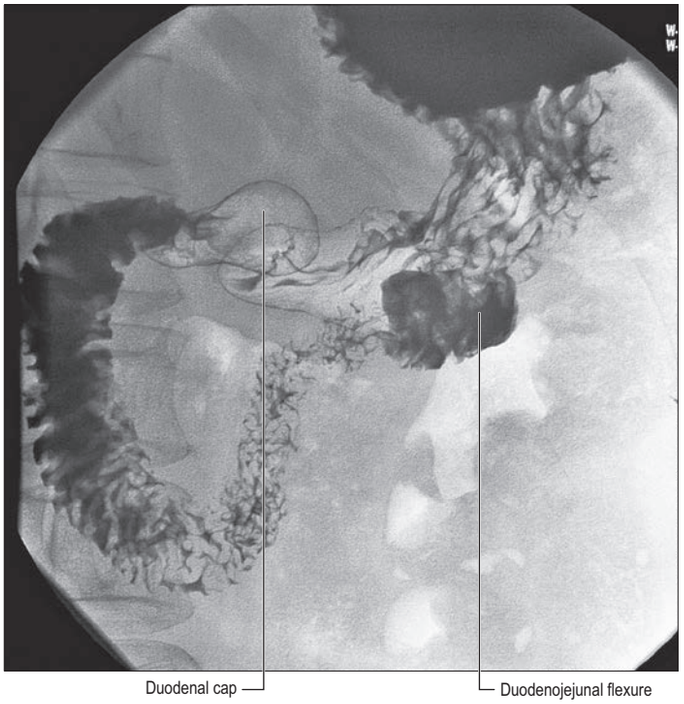

Fig. 64.2 The contrast radiographic appearance of the duodenum showing a distended duodenal bulb (duodenal cap) and the remainder of the duodenum up to the duodenojejunal flexure.

Ascending part

The ascending (fourth) part of the duodenum is 2.5 cm long. It starts just to the left of the abdominal aorta, runs superiorly and laterally to the level of the superior border of the second lumbar vertebra, then turns sharply anteroinferiorly at the duodenojejunal flexure to become continuous with the jejunum. The inferior mesenteric vein lies either posterior to the duodenojejunal flexure or at its lateral margin, deep to a peritoneal fold: the duodenojejunal flexure is a useful landmark for locating the inferior mesenteric vein radiologically or surgically. The abdominal aorta, left sympathetic trunk, left psoas major, left renal and left gonadal vessels all lie posterior, the left kidney and left ureter lie posterolateral, and the transverse colon and mesocolon are anterior, separating it from the stomach (see Fig. 61.8). The inferior border of the body of the pancreas is superior. The peritoneum of the root of the mesentery of the small intestine descends over its anterior surface.

At its left lateral limit, the ascending part of the duodenum becomes progressively invested in peritoneum such that the duodenojejunal flexure is suspended from the anterior wall of the retroperitoneum by a double fold of peritoneum, the suspensory ligament of the duodenum. This has two parts: the first part may contain skeletal muscle fibres and runs from the right crus of the diaphragm to connective tissue around the coeliac trunk, and the second part contains smooth muscle and descends from connective tissue around the coeliac trunk to the

The duodenum is the most common site for a diverticulum in the small intestine. Diverticula are usually solitary and can be congenital (containing all layers of the duodenal wall) or acquired (protrusion of the mucosa and submucosa through a defect in the muscular coat of the intestinal wall). They are typically located on the medial wall of the descending part of the duodenum, intimately related to the head of the pancreas: the major duodenal papilla is frequently found either on the mucosal fold at the mouth of a diverticulum or arising from the mucosa within it. Diverticula can complicate the interpretation of contrast radiographs of the duodenum or biliary system, and can cause difficulties during attempted endoscopic cannulation of the major duodenal papilla. Most are asymptomatic but they can be complicated by bleeding, inflammation, perforation and, occasionally, pancreatitis or biliary complications (Fotiades et al 2005).

The Kocher manoeuvre is used to expose retroperitoneal structures, such as an injury to the inferior vena cava, or the hilum of the kidney or the head of the pancreas, especially as an early step in a pancreaticoduodenectomy operation. The manoeuvre describes the division of the posterior and lateral attachments of the descending portion of the duodenum to allow medial rotation and reflection of the duodenum and head of the pancreas. The inferior vena cava is identified posterior to the horizontal portion of the duodenum and the attachments posterior to the duodenum, medial to the right ureter and anterior to the inferior vena cava, are divided. This is carried cephalad along the lateral aspect of the descending part of the duodenum. The right renal vein and right gonadal vein are often visualized during this manoeuvre. A complete Kocher manoeuvre is carried to the lateral edge of the abdominal aorta, allowing full inspection of the inferior vena cava and the superior mesenteric artery.

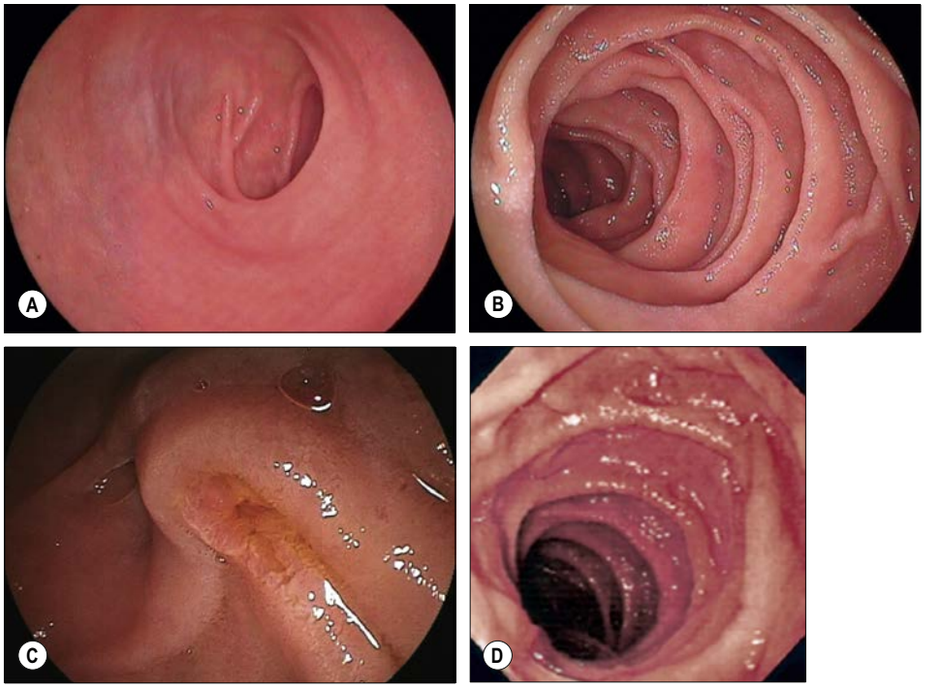

Fig. 64.3 The endoscopic appearance of the duodenum. **A**, Duodenal bulb. **B**, Descending part, showing the pronounced, 'branched' mucosal folds. **C**, Major duodenal papilla. **D**, Horizontal part.

duodenum, passing posterior to the pancreas anterior to the left renal vein. The ligament is often absent or rudimentary in adults and its function is unknown (Kim et al 2008). Its length determines the location of the duodenojejunal junction. A short, narrow suspensory ligament causes the ascending part of the duodenum to take a commonly depicted course cephalad prior to the sharp inferior turn to the jejunum, whereas a broad, flat ligament makes this angle less acute. The suspensory ligament of the duodenum is avascular. The vascular supply to the ascending part of the duodenum enters its wall from the posteromedial aspect.

The duodenojejunal flexure and the suspensory ligament of the duodenum are important landmarks in the radiological and surgical diagnosis of incomplete rotation and malrotation of the small intestine (Ch. 21). For many small intestine resection operations, distance is measured from the suspensory ligament of the duodenum.

Vascular supply and lymphatic drainage

Arteries

The main vessels supplying the duodenum are the superior and inferior pancreaticoduodenal arteries. The superior and descending parts of the duodenum also receive contributions from other sources including the right gastric, supraduodenal, right gastro-omental, common hepatic and gastroduodenal arteries (Fig. 64.4). Branches of the superior pancreaticoduodenal artery may contribute to the supply of the pyloric canal, anastomosing to a minor extent with the gastric arteries within the muscular layer of the junction between the pylorus and duodenum. Because of this robust vascular supply, ischaemia of the duodenum is a rare clinical finding and is often a bellwether of severe and generalized circulatory compromise.

Gastroduodenal artery

The gastroduodenal artery usually arises from the common hepatic artery posterior or superior to the superior part of the duodenum. It descends posterior to the retroperitoneal portion of the superior part of the duodenum to the left of the bile duct. At the inferior border of the superior part of the duodenum it is commonly described as dividing into the right gastro-omental and superior pancreaticoduodenal arteries, but this anatomical arrangement is rare (Bradley 1973, Bertelli et al 1995, Bertelli et al 1996) and its usual branching pattern is as follows. As it descends posterior to the superior part of the duodenum it usually gives off the posterior superior pancreaticoduodenal artery, several retroduodenal branches that supply the superior part and the proximal portion of the descending part of the duodenum, and a supraduodenal artery that supplies the anterosuperior part of the proximal duodenum (Bianchi and Albanèse 1989). As the gastroduodenal artery emerges

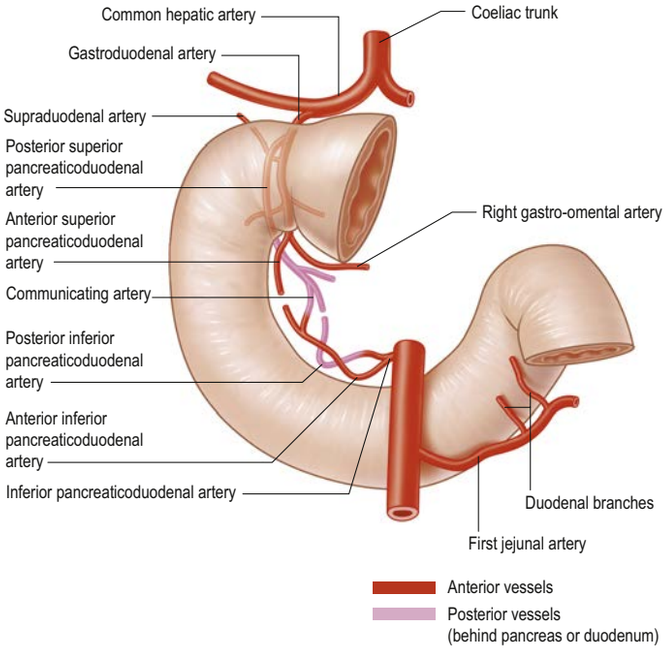

Fig. 64.4 The arterial supply of the duodenum. Only representative branches of the small vessels, which can be multiple, are shown.

inferior to the superior part of the duodenum it usually gives off the right gastro-omental artery and several pyloric branches. It then descends on the anterior surface of the pancreas, where it divides into the anterior superior pancreaticoduodenal artery and pancreatic branches. Although the gastroduodenal artery usually branches from the common hepatic artery, it occasionally originates from other sources including the coeliac trunk, the superior mesenteric artery, as a trifurcation with the right and left hepatic arteries, or from the right or left hepatic artery. The gastroduodenal artery or one of its branches can be a source of haemorrhage from a penetrating posterior duodenal ulcer (see above) or a site of aneurysm or pseudoaneurysm formation, and for these reasons, it is an important vessel for interventional radiologists.

Superior pancreaticoduodenal arteries

There are usually two superior pancreaticoduodenal arteries: posterior and anterior. The posterior superior pancreaticoduodenal artery is usually a separate branch of the gastroduodenal artery and is given off posterior to the superior border of the superior part of the duodenum. It descends to the right, anterior to the hepatic portal vein and bile duct,

where the latter lies posterior to the superior part of the duodenum. It then spirals around the right side of the bile duct to run posterior to the head of the pancreas, crosses posterior to the pancreatic segment of the bile duct (which is embedded, to a variable degree, in the head of the pancreas), and anastomoses with the posterior inferior pancreaticoduodenal artery (Bertelli et al 1996). The posterior superior pancreaticoduodenal artery supplies branches to the head of the pancreas, the superior and descending parts of the duodenum, and several branches to the distal part of the bile duct.

The anterior superior pancreaticoduodenal artery is usually a terminal branch of the gastroduodenal artery and descends in the anterior groove between the descending part of the duodenum and the head of the pancreas or on the anterior surface of the pancreas parallel to the groove (Bertelli et al 1995). It supplies branches to the superior and descending parts of the duodenum and to the head of the pancreas, and then passes posteriorly to anastomose with the anterior inferior pancreaticoduodenal artery.

Inferior pancreaticoduodenal artery

The inferior pancreaticoduodenal artery usually arises from the superior mesenteric artery or its first jejunal branch near the superior border of the horizontal part of the duodenum (Bertelli et al 1996). It crosses posterior to the superior mesenteric vein and passes posterior to the uncinate process of the pancreas, where it divides into the anterior and posterior pancreaticoduodenal arteries. The anterior pancreaticoduodenal artery passes to the right, immediately inferior and then anterior to the inferior border of the head of the pancreas, and runs superiorly to anastomose with the anterior superior pancreaticoduodenal artery. The posterior branch runs posteriorly to the right posterior to the head of the pancreas and anastomoses with the posterior superior pancreaticoduodenal artery (Bertelli et al 1997). Both branches supply the head of the pancreas, its uncinate process, and the superior and descending parts of the duodenum. Occasionally, the anterior and posterior pancreaticoduodenal arteries arise separately from the superior mesenteric or first jejunal artery.

Jejunal artery branches

Branches from the first jejunal branch of the superior mesenteric artery supply the ascending part of the duodenum and frequently anastomose with a terminal branch of the anterior superior pancreaticoduodenal artery. The ascending part of the duodenum therefore receives a potential collateral supply from the coeliac trunk and superior mesenteric artery, which means that it is not commonly affected by ischaemia.

Veins

Submucosal and intramural veins give rise to small veins that accompany the corresponding named arteries. The venous anatomy of this region is variable and not well characterized. The superior pancreaticoduodenal vein runs superiorly on the posterior surface of the head of the pancreas, posterior to the distal bile duct, and usually drains into the hepatic portal vein. The inferior pancreaticoduodenal vein runs inferiorly and usually drains into the superior mesenteric vein or its first jejunal tributary. Small veins from the superior part and the superior aspect of the descending part of the duodenum drain directly into the hepatic portal vein, and veins from the horizontal and ascending parts can drain directly into the superior mesenteric vein. Numerous small anastomoses are present between veins of the descending and horizontal parts of the duodenum and retroperitoneal veins (Murakami et al 1999).

Lymphatic drainage

Duodenal lymphatics run to nodes associated with the superior and inferior pancreaticoduodenal arteries, and from there to nodes related to the common hepatic and superior mesenteric arteries and coeliac trunk and to nodes in supra- and infra-pyloric positions and within the hepatoduodenal ligament. Lymphatic drainage to lateral aortic nodes has also been described (Hirai et al 2001).

Duodenal feeding

Available with the *Gray's Anatomy* e-book

Innervation

The duodenum is innervated by both parasympathetic and sympathetic neurones.

Preganglionic sympathetic neurones have their cell bodies in the intermediolateral grey matter in the fifth to the twelfth thoracic spinal cord segments. Their fibres travel via the greater and lesser thoracic splanchnic nerves to the coeliac plexus and synapse in the coeliac and superior mesenteric ganglia; postganglionic axons are distributed to the duodenal wall via peri-arterial plexuses on the branches of the coeliac trunk and superior mesenteric artery. The sympathetic nerves are vasoconstrictor to the duodenal vasculature and inhibitory to duodenal musculature.

The preganglionic parasympathetic supply is carried by vagal fibres that travel from the coeliac plexus and synapse on neurones in the duodenal wall. The parasympathetic supply is secretomotor to the duodenal mucosa and motor to the duodenal musculature.

Referred pain

In common with other structures derived from the foregut, pain arising from the proximal duodenum is poorly localized and referred to the epigastric region. It is mediated by afferent fibres that accompany the sympathetic neurones.

JEJUNUM

The jejunum has an external diameter of about 4 cm and an internal diameter of about 3 cm. It has a thicker wall than the ileum and a rich arterial blood supply. The circular folds (plicae circulares) (see below) are most pronounced in the proximal jejunum, where they are more numerous and deeper than elsewhere in the small intestine (**Figs 64.5–64.6**). They frequently 'branch' around the lumen and can appear to be stacked on top of each other, giving the jejunum a characteristic appearance during single contrast radiography (see Fig. 64.6), computed tomography enterography (**Fig. 64.7A**) or magnetic resonance (MR) enterography (**Fig. 64.7B**). The circular folds are also clearly visible by capsule endoscopy, in which images of the small intestine are transmitted wirelessly from a small swallowed camera the size of a pill (**Fig. 64.8**).

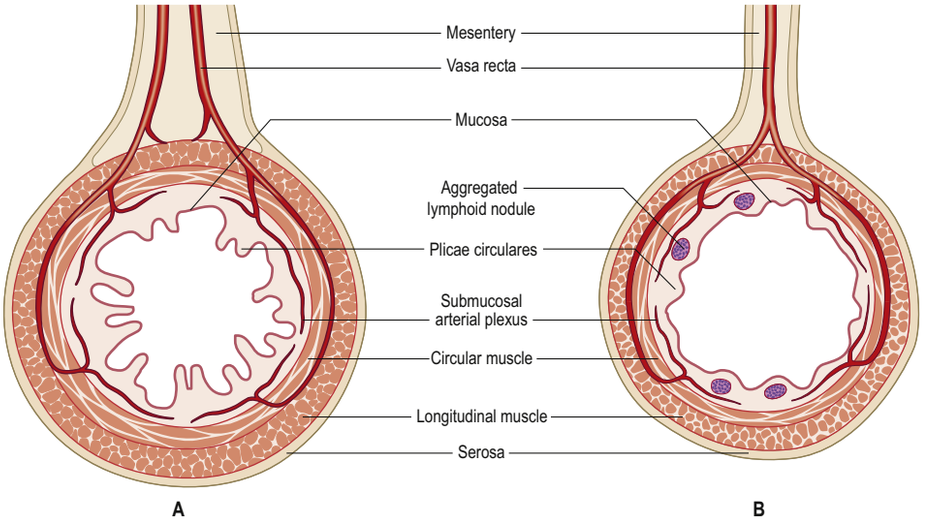

Fig. 64.5 Typical cross-sections through the proximal jejunum (**A**) and terminal ileum (**B**). The mesenteric attachment is wider in the jejunum and two leaves of vessels enter the intestinal wall. The latter is also thicker in the jejunum.

When gastric emptying is functionally impaired – as, for example, in gastroparesis – nutrition can be delivered directly into the duodenum or jejunum via a nasal transpyloric feeding tube.

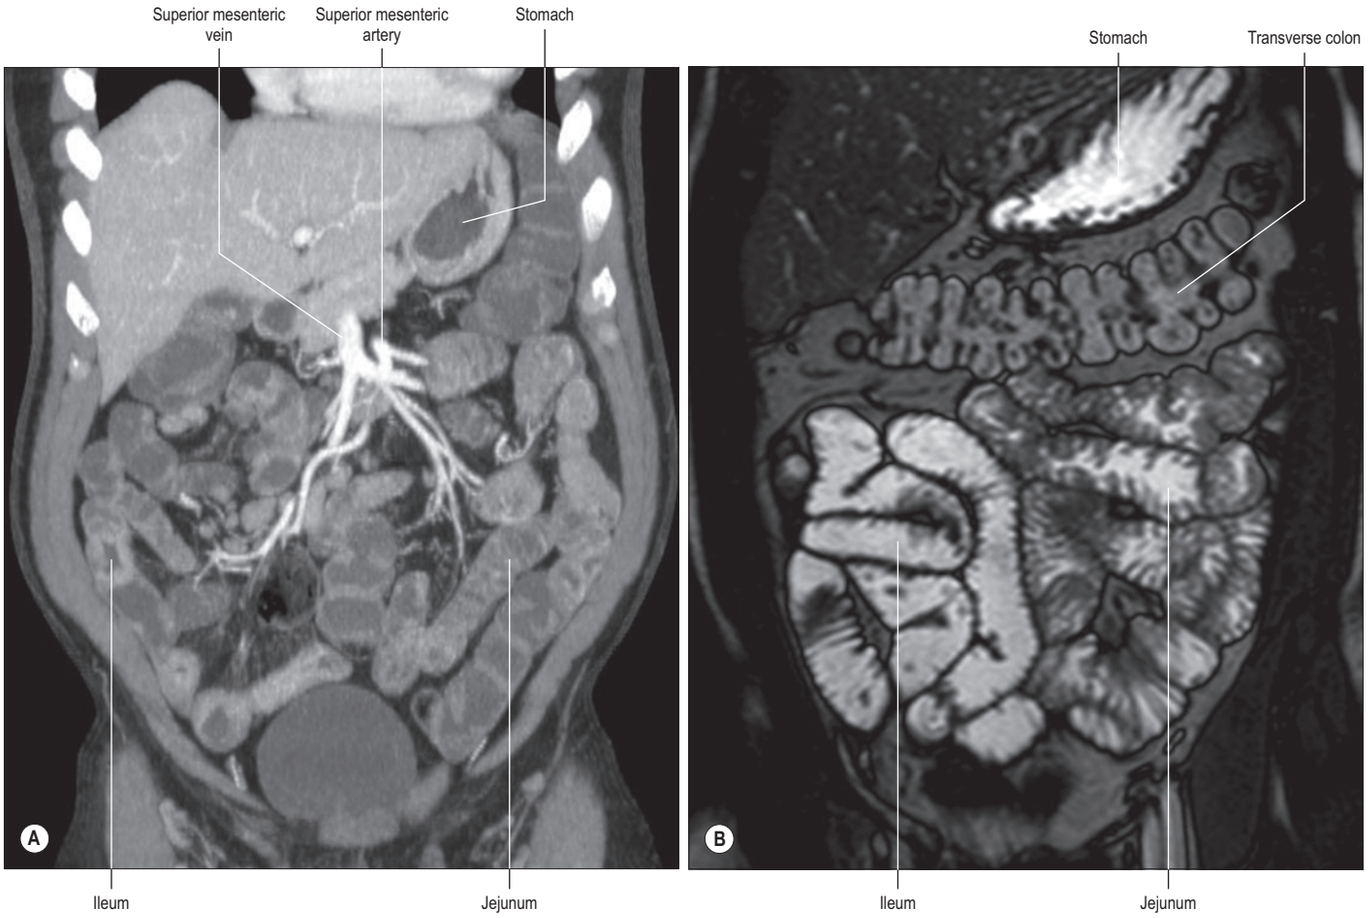

Fig. 64.7 **A**, Computed tomography enterography. Coronal image showing small intestinal loops and superior mesenteric vessels. **B**, Magnetic resonance (MR) enterography. Coronal image showing the small intestine and transverse colon.

In the supine position, the jejunum usually occupies the proximal left infracolic compartment, extending distally to the umbilical region. The first one or two loops often occupy a recess between the left part of the transverse mesocolon and the left kidney. On supine radiological examination, the jejunal loops are characteristically situated in the proximal abdomen, to the left of the midline, whereas the ileal loops tend to lie in the inferior right part of the abdomen and pelvis. This distribution can be reversed in small intestine obstruction owing to rotation of the dilated intestine around its mesenteric attachment.

Jejunal feeding

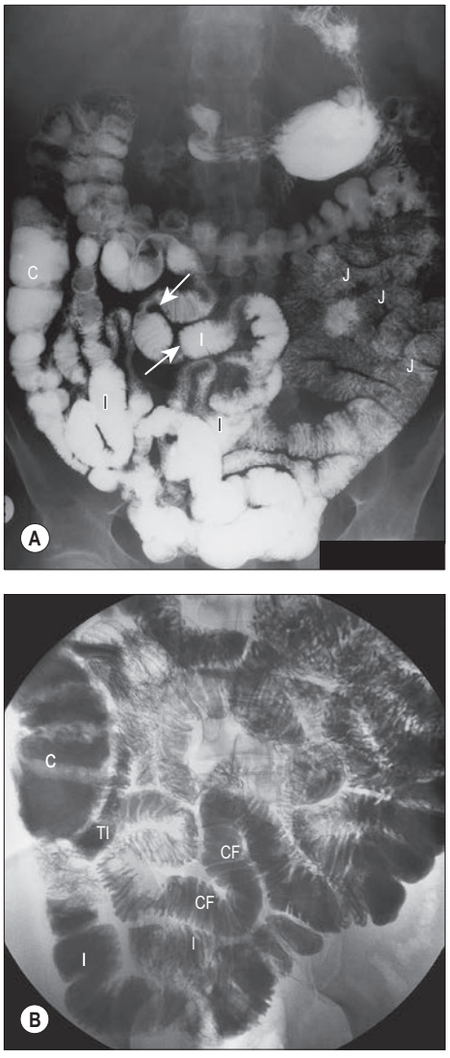

Fig. 64.6 Barium studies of the jejunum and ileum. **A**, Barium follow-through. The feathery appearance of the small intestine is due to the circular folds and is most prominent in the jejunum. The constrictions (arrows) are the result of peristalsis. **B**, Small intestine enteroclysis. The circular folds are clearly demonstrated by this technique. Abbreviations: C, caecum; I, ileum; J, jejunum; CF, circular folds; TI, terminal part of ileum.

ILEUM

The ileum has an external diameter of about 3 cm, an internal diameter of about 2.5 cm and tends to have a thinner wall than the jejunum (see Fig. 64.5B). The circular folds become progressively less obvious in the distal ileum; they tend to be single and flatter (see Figs 64.6–64.7; **Fig. 64.9**). The mucosa of the terminal ileum immediately proximal to the ileocaecal junction can appear almost flat at endoscopy, although the villi can be seen when viewed at near focus (see Fig. 64.9) and at capsule endoscopy (see Fig. 64.8).

In the supine position, the ileum lies mainly in the hypogastric region and right inguinal region. The terminal ileum frequently lies in the pelvis, from where it ascends over the right psoas major and right iliac vessels and ends by opening at the ileocaecal junction in the right inguinal region.

Anatomical differences between the jejunum and ileum

While there is no clear boundary between the jejunum (the proximal two-fifths of the small intestine beyond the duodenum) and the ileum (the distal three-fifths), there are general anatomical differences between those regions. The wall of the jejunum is thicker and more vascular, has a greater number of more prominent circular folds, and contains less lymphoid tissue than the ileum. There are also differences between the mesenteric vessels in the jejunum and ileum (Conley et al 2010). The jejunal mesentery, measured from the superior mesenteric artery to the mesenteric border of the intestine, is shorter than the ileal mesentery, and the jejunal arteries are slightly larger than their ileal counterparts. The jejunum typically contains 1–3 tiers of vascular arcades, whereas there are often 2–6 tiers in the ileum (**Fig. 64.10**). The straight arteries (vasa recta) in the ileum are more numerous, shorter and narrower than in the jejunum. The jejunal and ileal arteries, arcades and straight arteries are muscular arteries capable of influencing blood flow, which can range between 10% and 35% of cardiac output (Rosenblum et al 1997).

Solitary lymphoid nodules are scattered throughout the small intestinal mucosa but are most numerous in the distal ileum. Aggregated lymphoid nodules, Peyer's patches, are circular or oval masses containing 5–260 follicles. They vary in size, shape and distribution, most measuring 2–8 cm and visible macroscopically as dome-like elevations, usually along the antimesenteric border of the intestine. They are rarely present in the duodenum; small, circular, few in number and impalpable in the distal jejunum; and larger, more numerous and often palpable in the ileum (particularly in the terminal 25 cm; Van Kruiningen et al 2002). Intestinal villi are small or absent over the larger lymphoid nodules. Aggregated lymphoid nodules are most prominent in early childhood and, when enlarged in viral infections, may form the apex of an intussusception. They become less prominent around puberty and become fewer during adult life (Cornes 1965a, 1965b).

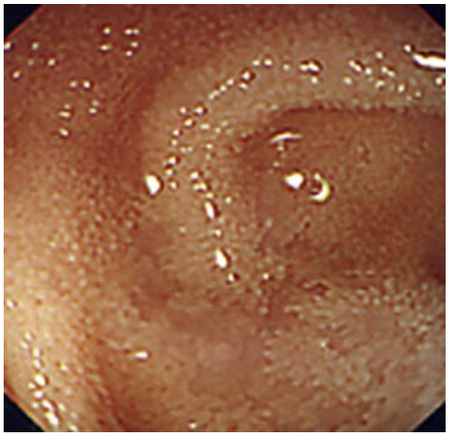

Fig. 64.9 The endoscopic appearance of the terminal ileum.

In patients with a functioning intestine who cannot tolerate adequate oral or intragastric feeding, jejunal feeding is often the preferred option. Enteral feeding is associated with fewer complications than parenteral (intravenous) nutrition: it maintains the integrity of the gut mucosa (thereby reducing bacterial translocation from the gut lumen), decreases the likelihood of aspiration from gastro-oesophageal reflux, is less of a stimulus for pancreaticobiliary secretion, and mitigates the need for central venous access and its accompanying risks. Jejunal feeds can be delivered via a nasojejunal or gastrojejunal tube or directly into the jejunum; gastrojejunal and jejunal tubes can be inserted endoscopically, radiologically or surgically. The distal end of the feeding tube must lie beyond the duodenojejunal flexure to prevent reflux of feeding into the duodenum and stomach.

A rare congenital ileal diverticulum (Meckel's diverticulum) represents the remnant of the proximal part of the omphalo-enteric duct (vitello-intestinal duct, yolk stalk). It projects from the antimesenteric border of the terminal ileum and is commonly located between 50–100 cm from the ileocaecal junction. It is variable in length (usually 2–5 cm in adults) and often possesses a short 'mesentery' of adipose tissue containing an omphalomesenteric artery (vitelline artery), from the termination of the superior mesenteric artery, that extends from the ileal mesentery to its base (**Fig. 64.11**). The lumen of the diverticulum usually has a calibre similar to that of the ileum. The tip is normally free but occasionally it is connected to the anterior abdominal wall near the umbilicus by a fibrous band. The mucosa is typically ileal, but small heterotopic areas of gastric body type epithelium, pancreatic, colonic or other tissues can also occur in the wall of a diverticulum. Unopposed acid secretion by heterotopic gastric body type epithelium can cause ulceration and bleeding in the adjacent normal ileal mucosa. Diverticular inflammation can mimic acute appendicitis: because the congenital ileal diverticulum and the appendix are both derived from the midgut, pain from either structure is referred to the periumbilical region. Rarer complications of a congenital ileal diverticulum include intestinal obstruction, intussusception, perforation, calculi and tumours (Sagar et al 2006, Uppal et al 2011).

In clinical practice, a stoma is a surgically created opening from a hollow viscus to the skin, classified according to its location. An intestinal stoma can be either an end stoma, in which only the proximal end of the divided intestine is anastomosed to the skin, or a loop stoma, in which both the proximal and distal ends of the intestines are exteriorized on the surface (**Fig. 64.12**). The volume output of a jejunostomy is greater than that of an ileostomy, less solid in character, and more likely to result in excessive fluid, electrolyte and nutrient losses.

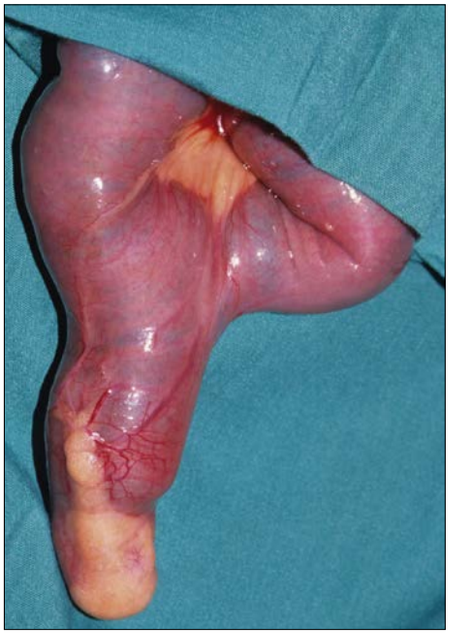

Fig. 64.11 A congenital ileal diverticulum (Meckel's diverticulum) containing ectopic mucosa at its tip. (Courtesy of Professor Mark Stringer, Christchurch Hospital, New Zealand.)

The mean length of the small intestine, measured from the duodenojejunal flexure to the ileocaecal junction *in vivo*, is about 5 m but can range from 3 to 8.5 m (Teitelbaum et al 2013). Males have a longer small intestine than females, and height is positively associated with the length of the small intestine (Teitelbaum et al 2013). Short bowel syndrome results from surgical resection, congenital deficiency or disease-associated loss of absorption, and is characterized by the inability to maintain protein-energy, fluid, electrolyte or micronutrient balances on a conventionally accepted normal diet (O'Keefe et al 2006). If untreated, short bowel syndrome leads to dehydration, malnutrition and weight loss. Adults with the greatest risk of developing intestinal failure fall into three groups: those with an end-jejunostomy and <100 cm of residual small intestine; those with a jejunocolic anastomosis and <50 cm residual small intestine; and those with a jejunoileal anastomosis and <35 cm of residual small intestine (despite the presence of an ileocaecal junction and colon) (Nightingale and Woodward 2006, Jeppesen 2013).

After surgical resection the remaining small intestine undergoes an adaptive process that involves morphological and functional changes: it dilates and intestinal villus height and intestinal gland depth increase, thereby expanding the absorptive surface area. Adaptation begins soon after intestinal resection and can continue for up to two years (Jeppesen and Mortensen 2002). The ability of the proximal and distal small intestine to adapt differ. The likelihood of regaining intestinal autonomy is greatest in patients with a retained segment of ileum and colon in continuity, in contrast to patients with a residual duodenojejunal segment and an end-jejunostomy (Jeppesen 2013). Many patients with short bowel syndrome are maintained on parenteral nutrition for lengthy periods.

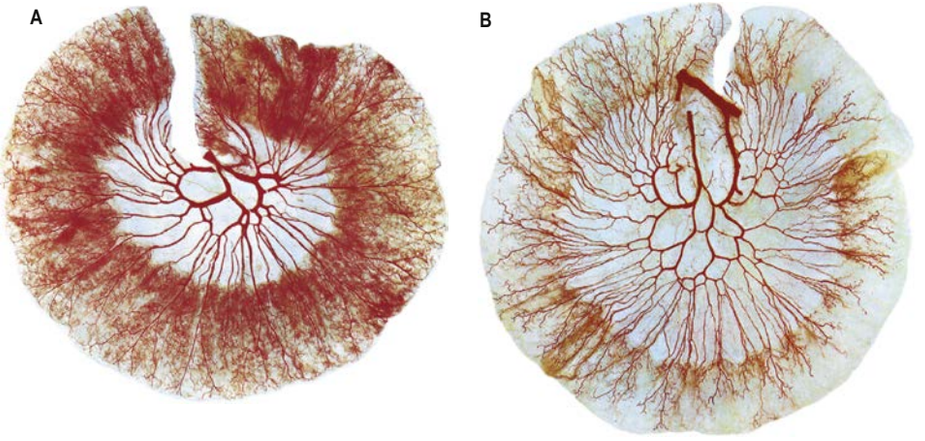

Fig. 64.10 Specimens of the jejunum (**A**) and ileum (**B**) from a cadaver where the superior mesenteric artery was injected with red-coloured gelatin before fixation. Subsequently, the specimens were dehydrated and then cleared in benzene, followed by methyl salicylate. The largest vessels present are the jejunal and ileal branches of the superior mesenteric artery and these are succeeded by anastomotic arterial arcades, which are relatively few in number (1–3) in the jejunum, becoming more numerous (2–6) in the ileum. From the arcades, straight arteries pass towards the gut wall; frequently, successive straight arteries are distributed to opposite sides of the gut. Note the denser vascularity of the jejunal wall. (Specimens prepared by MCE Hutchinson; photographs by Kevin Fitzpatrick on behalf of GKT School of Medicine, London.)

Vascular supply and lymphatic drainage

Arteries

Branches from the superior mesenteric artery supply the jejunum and ileum. The arteries divide as they approach the mesenteric border of the intestine (see Fig. 64.5), giving off numerous branches that extend between the muscular layers before forming a submucosal arterial plexus that supplies the mucosa. Although there is a rich anastomotic network of arteries within the intestinal mesentery, there are few anastomoses between the terminal branches close to the intestinal wall. The intramural and submucosal arterial networks consist of small-calibre vessels only. Consequently, division or occlusion of several consecutive straight arteries can produce segmental ischaemia of the intestine, while division of more proximal arterial branches in the small intestine mesentery might not cause ischaemia because of collateral flow through vascular arcades.

Superior mesenteric artery

The superior mesenteric artery originates from the abdominal aorta 1 cm inferior to the coeliac trunk, at the level of the inferior border of the first lumbar vertebra in the transpyloric plane (**Figs 64.13–64.15**). The angle of its origin from the aorta is acute (mean value 45°, range 38–60° and greater in individuals with a greater body mass index; Ozkurt et al 2007). Among the major branches of the descending aorta, the superior mesenteric artery typically has the most acute take-off angle. The result is less turbulent flow, which makes embolic events more likely than in the other visceral arterial branches of the abdominal aorta. The acuteness of the angle between the aorta and superior mesenteric artery can make intravascular cannulation via the transfemoral route somewhat difficult. The artery is usually surrounded by fat, lymphatics and neural tissue at its origin, which helps to increase the angle and the distance between it and the aorta, thereby preventing compression of the duodenum where it is crossed by the artery. The artery descends anterior to the uncinate process of the pancreas and the horizontal part of the duodenum and posterior to the splenic vein and the body of the pancreas. The left renal vein lies posterior to it and separates it from the aorta (see Fig. 64.15B). Within the small intestine mesentery, the superior mesenteric artery crosses anterior to the inferior vena cava, right ureter and right psoas major. Its calibre progressively decreases as successive branches are given off to the jejunum and ileum, and its terminal branch anastomoses with the termination of the ileocolic artery.

The superior mesenteric artery usually gives off the inferior pancreaticoduodenal, middle colic, right colic and ileocolic arteries from its right side, and jejunal and ileal arteries from its left side. Its jejunal and ileal arteries form vascular arcades within the small intestine mesentery. The last of these arcades forms an irregular and incomplete marginal artery (of Drummond) of the small intestine. Straight arteries are given off from the most distal arcades and pass directly to the small intestine.

Anatomical variations in the origin and branching pattern of the superior mesenteric artery are well described (Winston et al 2007, Horton and Fishman 2010) (see also Ch. 65). It can be the source of

Small intestine transplantation has become a standard clinical procedure for selected patients with intestinal failure (Abu-Elmagd et al 2009). Intestinal failure can result from an inadequate surface area for nutrient absorption, as in short bowel syndrome, or dysmotility of the stomach or small intestine. The small intestine can be transplanted in isolation or along with the liver and/or other abdominal organs such as the pancreas (multivisceral transplant). Postoperatively, patients are recommenced on parenteral nutrition, and enteral feeding is started via a feeding jejunostomy once intestinal motility has returned. Protein is delivered as peptides and fats as medium-chain triglycerides, which are absorbed directly into the mesenteric veins and not via the lymphatics (divided when the graft is taken from the donor and not anastomosed to recipient lymphatics). Parenteral nutrition can usually be discontinued 3–6 weeks after small intestine transplantation but may continue to be used to supplement enteral feeding when stoma losses are large.

Intestinal dysmotility is common after intestinal transplantation. There is no extrinsic nerve supply to the graft but intrinsic small intestine motility usually recovers within 48–72 hours after transplantation (Gunning and Friend 1998). Adequate gastric emptying is often delayed for several weeks, despite pyloroplasty and the administration of drugs to enhance gastric motility. Reinnervation of the allograft via its vascular pedicle is slow (Walther et al 2013). Intestinal motility is also affected by any inflammatory response caused by rejection. Denervation and division of the lymphatic drainage of the intestinal allograft do not appear to impair long-term function seriously. In animal models, lymphatic drainage is re-established within 21–28 days, which is consistent with observations in patients (Kocandrle et al 1966).

the common hepatic, gastroduodenal, accessory or replaced right hepatic, accessory pancreatic, splenic or rarely the inferior mesenteric artery. Also rare is a superior mesenteric artery arising from a common coeliacomesenteric trunk (Rountas et al 2013).

The remnant of the omphalomesenteric artery (vitelline artery) (the embryonic artery that originally connected the intestinal circulation to the yolk sac) is usually obliterated; when present, it forms the artery supplying a congenital ileal diverticulum. It is occasionally represented in the mesentery by a fibrous strand from the termination of the superior mesenteric artery to the ileum.

Surgical exposure of the superior mesenteric artery

Available with the *Gray's Anatomy* e-book

Jejunal branches Usually, 4–6 jejunal branches arise from the left side of the proximal portion of the superior mesenteric artery (see Figs 64.13–64.14). They are distributed to the jejunum via 1–3 tiers of arterial arcades, the most distal of which gives rise to straight arteries. The latter run almost parallel in the mesentery before being distributed alternately to either side of the small intestine, forming two distinct 'leaves' of vessels within the mesentery separated by a relatively avascular plane (see Fig. 64.5A).This vascular arrangement allows a dilated segment of small intestine to be bisected longitudinally and tubularized to double its length, a potentially useful technique for achieving small intestine lengthening in short bowel syndrome (Bianchi 1984). Small twigs from the jejunal arteries supply regional mesenteric nodes.

Ileal branches Ileal branches are more numerous (around 8–12) and slightly smaller in calibre than jejunal branches. They arise from the left and anterior aspects of the superior mesenteric artery. The length of the mesentery from the superior mesenteric artery to the mesenteric border of the intestine is greater in the ileum, and so the branches form between two and six arcades before giving rise to multiple straight arteries that run directly towards the ileal wall (see Fig. 64.10B). These branches run parallel in the mesentery and are distributed to both aspects of the ileum. They are shorter and thinner than their jejunal counterparts, particularly in the distal ileum, and do not form such distinct parallel 'leaves' of vessels. The terminal ileal arcades are supplied by the ileal branch of the ileocolic artery and the last ileal branch of the superior mesenteric artery (see Fig. 64.13). Few other vessels connect the ileocolic and superior mesenteric artery territories, and this makes surgical dissection of the ileocolic artery up to its origin relatively simple.

Veins

Superior mesenteric vein

The superior mesenteric vein drains the small intestine, caecum, ascending and transverse colons, and parts of the stomach and greater omentum (**Fig. 64.16**; see Fig. 59.7). It is formed in the mesentery of the small intestine by the union of tributaries from the terminal ileum, caecum and appendix. It ascends in the mesentery to the right of the superior mesenteric artery, passing anterior to the right ureter, inferior vena cava, horizontal part of the duodenum and uncinate process of the pancreas. It joins the splenic vein posterior to the neck of the pancreas in the transpyloric plane (inferior border of L1 vertebra) to form the hepatic portal vein.

The superior mesenteric vein receives jejunal, ileal, ileocolic, right colic, middle colic, right gastro-omental and inferior pancreaticoduodenal veins. A major proximal jejunal branch usually runs transversely posterior to the superior mesenteric artery to enter the right posterolateral aspect of the superior mesenteric vein (Kim et al 2007). The right colic vein is highly variable. When present, it can drain directly into the superior mesenteric vein or join the right gastro-omental or inferior pancreaticoduodenal vein to form a 'gastrocolic trunk', which then drains into the superior mesenteric vein (Yamaguchi et al 2002). Although the inferior mesenteric vein usually drains into the splenic vein, it can join the superior mesenteric vein directly or its confluence with the splenic vein (Graf et al 1997).

Lymphatic drainage

The lymphatic system of the small intestine regulates tissue fluid homeostasis, participates in immune surveillance, and transports dietary fat and fat-soluble vitamins from the gut lumen. It is organized into two networks. First, lacteals from the villi drain into a plexus of lymphatics in the submucosa and are joined by vessels from lymph spaces at the bases of solitary lymphoid follicles; these lymphatic vessels have few if any valves. Second, a coarse plexus of lymphatics also runs in the muscularis externa between the two muscle layers. The submucosal and muscular networks share few connections but both communicate freely with larger valved collecting lymphatics at the mesenteric border of the small intestine (Miller et al 2010). Mesenteric lymphatics pass between the layers of the mesentery and drain via a series of mesenteric nodes concentrated around the regional mesenteric vessels. Individual segments of small intestine have a relatively wide field of lymphatic drainage, which makes radical surgical resection of draining lymph nodes difficult if the blood supply to the remaining unaffected small intestine is to be preserved. Mesenteric nodes drain into superior mesenteric nodes around the proximal part of the superior mesenteric artery.

Innervation

The jejunum and ileum are innervated by parasympathetic and sympathetic fibres via the superior mesenteric plexus (see Figs 59.2–59.4). Preganglionic sympathetic axons originate from neurones in the intermediolateral grey matter of the mid-thoracic spinal cord segments and travel in the greater and lesser thoracic splanchnic nerves to the coeliac and superior mesenteric ganglia, where they synapse. Postganglionic axons accompany the superior mesenteric artery into the mesentery and are distributed along branches of the artery. The sympathetic nerves are vasoconstrictor to the vasculature and inhibitory to the musculature of the jejunum and ileum. Sympathetic neurotransmitters also have an

The superior mesenteric artery can be exposed through transperitoneal or retroperitoneal approaches. For a retroperitoneal approach, a left flank incision is used and the superior mesenteric artery is exposed at the base from the left lateral aspect. From the transperitoneal approach the superior mesenteric artery can be accessed through the omental bursa with medial visceral rotation. These exposures are important for either gaining control of a bleeding distal vessel, or more often to expose the superior mesenteric artery for bypass or embolectomy in the setting of intestinal ischaemia.

Retroperitoneal flank approach to expose the superior mesenteric artery

The patient is typically positioned in a modified right lateral decubitus position for this approach. In this position, the shoulders lie at an angle to the operating table with the left upper limb supported on an arm board, but the pelvis is maintained in a position with as much posterior rotation as possible. An incision can be made in the ninth, tenth or eleventh intercostal space extending posteriorly to the mid-axillary line and anteriorly to the lateral edge of rectus abdominis. The incision can be extended in either direction to provide additional exposure. External and internal intercostal are divided, as well as transversus abdominis. Intercostal muscles are divided over the top of the corresponding rib and the thorax can then be entered. Often the respiratory diaphragm must be divided as well. Anteriorly, blunt dissection is typically used to elevate the peritoneum off posterior muscles and the thoracolumbar fascia. The colon, spleen and tail of the pancreas are reflected anteriorly. The plane can be developed posterior to the kidney. The left lateral edge of the abdominal aorta is identified and the superior mesenteric artery can be visualized from the left lateral aspect as well.

Transperitoneal approaches to expose the superior mesenteric artery

A number of different incisions can be used to gain access to the peritoneal cavity, though a vertical midline incision is probably the most common. There are three approaches, with specific exposure determined by which aspect of the superior mesenteric artery needs to be exposed.

Transperitoneal omental bursa approach

The left lobe of the liver is reflected anteriorly. With leftward retraction on the stomach, the hepatogastric ligament can be divided either superior or inferior to the left gastric artery. Dissection of the muscular fibres of the left crus of the respiratory diaphragm will expose the anterior surface of the abdominal aorta. Typically, the coeliac artery is encountered first, overlaid with decussating muscle fibres and the nerves of the coeliac plexus. Large lymphatic channels can also be encountered. Inferior retraction of the body of the pancreas will expose the first few centimetres of the superior mesenteric artery.

Transperitoneal approach with medial visceral rotation

A full left medial visceral rotation (Mattox manoeuvre) provides exposure to the entire abdominal aorta and proximal visceral vessels. The lateral peritoneal reflection of the descending colon is divided and extended superiorly, curving towards the aortic hiatus. A retroperitoneal plane is developed as the colon, spleen and the tail of the pancreas are rotated to the right. The left crus of the respiratory diaphragm may need to be divided to expose the anterior aspect of the abdominal aorta, depending on its inferior extent. The kidney is generally left in position, which provides broad exposure to the origin of the proximal superior mesenteric artery.

Inframesocolic approach

The transverse colon is reflected superiorly to expose the root of the mesentery, while the jejunum and ileum are reflected inferiorly and to the right. The superior mesenteric artery can typically be palpated. A transverse incision made to the right of the suspensory ligament of the duodenum, and inferior to the pancreas, will typically expose both the superior mesenteric artery and vein. Typically, the middle colic artery and the first jejunal branch of the superior mesenteric artery are also visualized, but access to the origin of the superior mesenteric artery might be limited.

immunomodulatory role by influencing mucosa-associated lymphoid tissue (Straub et al 2006). Preganglionic parasympathetic axons travel in the vagus nerves and are secretomotor to the mucosa and motor to the smooth muscle of the jejunum and ileum. Visceral afferents from the small intestine, conveying pain and other gut sensations, travel with the splanchnic and vagus nerves.

Referred pain

In common with other structures derived from the midgut, the visceral sensation of pain arising from the jejunum or ileum is poorly localized and is usually referred to the periumbilical region.

MICROSTRUCTURE

The small intestinal wall is composed of mucosa, submucosa, muscularis externa and serosa or adventitia (see Fig. 59.8). The mucosa is thick and very vascular in the proximal small intestine but thinner and less vascular distally. In places, it is ridged by the underlying submucosa to form circular folds, which protrude into the lumen; mucosal finger- or leaf-like intestinal villi cover the whole surface (Fig. 64.17). There are numerous simple, tubular intestinal glands between the bases of the villi, and additional duodenal submucosal glands (see Fig. 59.8). The submucosa contains aggregated lymphoid nodules, most numerous in the ileum.

Circular folds

Except in the superior (first) part of the duodenum, large circular folds of mucosa (plicae circulares, valvulae conniventes, valves of Kerckring) project into the lumen of the small intestine, orientated either transversely or slightly obliquely to its long axis (see Figs 64.8, 64.17; **Fig. 64.18**). Unlike gastric folds, they do not disappear during distension of the intestine. Most extend round half or two-thirds of the luminal circumference, some are complete circles, some bifurcate and join adjacent circular folds, while others are spiral and extend one or more times round the lumen. Larger circular folds are up to 8 mm deep but most are smaller than this, and larger folds often alternate with smaller ones. Circular folds begin to appear 2.5–5 cm beyond the pylorus and are

The principal functions of the small intestine are fluid and electrolyte haemostasis, digestion and absorption of nutrients, immunoregulation and secretion of hormones. The absorptive capacity of the small intestine is greatly enhanced by the circular folds, intestinal villi and microvilli, which increase its surface area by factors of approximately 2, 7 and 13, respectively (Helander and Fändriks 2014), yielding a total estimated surface area of almost 30 m^2.

The secretion and absorption of electrolytes and fluid are two essential functions of the small intestinal epithelium. In healthy adults, the gastrointestinal tract is capable of secreting 8–10 litres of fluid per day in addition to the 1.5–2 litres ingested each day. To reduce this volume to the typical ileocaecal daily flow of approximately 2 litres per day, the small intestinal epithelium has a large number of transport molecules and regulatory proteins. Net fluid movement across the gastrointestinal epithelium is primarily the result of the active transport of sodium, chloride and bicarbonate ions. The jejunum can only absorb sodium across a small sodium gradient and therefore does not normally absorb salt and water, but secretes it into the lumen. Most fluid and electrolyte absorption occurs in the ileum, which is able to absorb across a larger sodium gradient (Nightingale and Spiller 2001): proximal small intestine fistulae or surgical jejunostomies therefore have a higher volume output with greater electrolyte losses than more distal stomata.

The mucosal brush border has an abundance of enzymes and pumps on its surface. Examples include the sodium-dependent glucose transporter protein (SGLT1) and the fructose transporter protein (GLUT5). Oligosaccharides are broken down to monosaccharides by enzymes at the brush border of the small intestine before being transported across the mucosa. A deficiency of lactase on the mucosal brush border is relatively common and results in lactose intolerance. Proteins are broken down into single amino acids and small peptides. The peptidase gradient across the microvillus brush border increases along the length of the small intestine, suggesting that amino acids are absorbed more distally than carbohydrates. Dietary fats are emulsified by biliary secretions and then broken down by pancreatic lipase into free fatty acids and phospholipids, which form micelles. The lipid components are then absorbed within the distal small intestine and converted into chylomicrons in the enterocytes before being secreted into the lymphatic system. Minerals such as calcium, magnesium, phosphorus and iron, and the water- and fat-soluble vitamins, are predominantly absorbed in the duodenum and proximal jejunum (Farrell 2002, Malik and Westergaard 2002). Vitamin B_{12} is absorbed in the terminal ileum after binding to intrinsic factor released by gastric parietal cells. Bile is largely composed of bile acid salts conjugated to taurine or glycine. These salts are deconjugated by bacteria in the ileum to either a free acid or a secondary bile acid. The free acids are reabsorbed by passive transport in the jejunum and ileum. The terminal ileum has an active sodium cotransporter that scavenges conjugated bile acids. Reabsorbed bile acids enter the portal circulation and are returned to the liver for re-secretion.

The motility of the small intestine differs depending on whether the individual is fasting or postprandial. In the fasting state, the smooth muscle of the small intestine exhibits cyclical myoelectrical activity, the so-called migrating motor complex (MMC). The frequency of these slow waves is regulated by interstitial cells of Cajal and is about 11/minute in the jejunum, decreasing along the length of the small intestine to 7–8/minute in the ileum (Husebye 1999). When slow waves are amplified beyond a threshold by neural, endocrine or paracrine stimulation, action potentials are generated, resulting in smooth muscle contraction. This spreads circumferentially at first and then propagates along the entire circumference of the intestine in an aboral direction, causing a ring-like contraction of the circular smooth muscle that progresses distally along the small intestine (about 10% of contractions reaching the ileum).

The MMC consists of three phases: phase I is a period of quiescence, phase II is composed of irregular contractions and phase III is a short burst of phasic contractions at the maximum frequency of the slow waves for that part of the intestine. The velocity of migration is 5–10 cm/minute in the jejunum, decreasing gradually along the small intestine to about 1 cm/minute in the ileum. The MMC requires an intact enteric nervous system and does not depend on extrinsic innervation. Consequently, MMCs are present in transplanted (denervated) small intestine. However, there is evidence that extrinsic innervation modulates the MMC. For example, sleep causes the almost complete disappearance of phase II. Phase III activity normally recovers in the proximal small intestine within a few hours of major abdominal surgery, although the pressure wave amplitude is temporarily reduced. Somatostatin and opioids decrease phase II activity. After a meal, the cyclical fasting activity is abolished for several hours and replaced by irregular contractions that consist of both segmental 'stationary' contractions and propulsive contractions (Barnert 2007).

Assessment of small intestine motility can complement detailed microscopic examination of full-thickness biopsy specimens of the intestine when conditions associated with intestinal dysmotility are characterized, helping to distinguish intestinal neuropathy from visceral myopathy. Wireless motility capsules are also finding increasing use. These devices are pill-shaped and can be either swallowed or placed into the stomach with an endoscope. Sensors for pH, pressure and temperature record measurements and send these wirelessly to an external recording device. Based on the patterns of these pH, temperature and pressure curves, gastric emptying, small intestine transit and colonic transit times are easily decipherable.

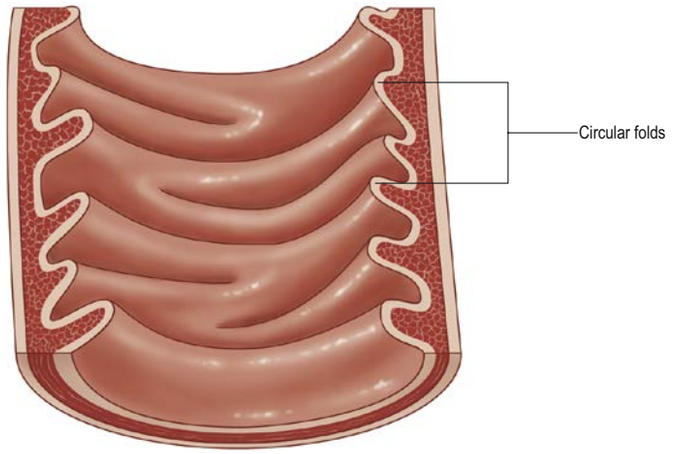

Fig. 64.17 The internal aspect of a representative sample of the proximal jejunum, showing circular folds.

Fig. 64.18 A low-power micrograph showing several circular folds (arrows) in the wall of the ileum. The folds are covered with villi (V) projecting into the lumen, and the submucosa (SM) extends into the core of each fold. Circular (innermost) and longitudinal smooth muscle layers form the underlying muscularis externa. Large masses of aggregated lymphoid nodules (Peyer's patches, P) lie in the mucosa. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

relatively large and close together in the distal duodenum and proximal jejunum. Beyond this point, they diminish in size and disappear almost completely in the terminal ileum, which therefore has a relatively thin wall. The circular folds increase the absorptive surface area and enhance mechanical segmentation in the small intestine. They are visible at endoscopy (see Fig. 64.3), during small intestine contrast studies (see Fig. 64.6), and sometimes on plain radiographs.

Intestinal villi

Intestinal villi are highly vascular projections of the mucosal surface, just visible to the naked eye (see Fig. 64.18; **Figs 64.19–64.21**). They cover the entire small intestinal mucosa, increase the surface area of the lumen about seven-fold (Helander and Fändriks 2014), and give it a velvety texture. Villi are large and numerous in the duodenum and jejunum but smaller and fewer in the ileum. In the superior part of the duodenum they appear as broad ridges, become tall and foliate in the distal duodenum and proximal jejunum, and then gradually shorten to a finger-like form in the distal jejunum and ileum. Villi range from 10 to 40 per mm^2 in density and from 0.5 to 1.0 mm in height (see Fig. 64.19). Infoldings of the mucosa dip down from the bases of the villi for a short distance into the lamina propria: these intestinal glands (crypts of Lieberkühn) are most prominent in the proximal small intestine (see Fig. 64.20).

Mucosa

The mucosa consists of epithelium, lamina propria and muscularis mucosae.

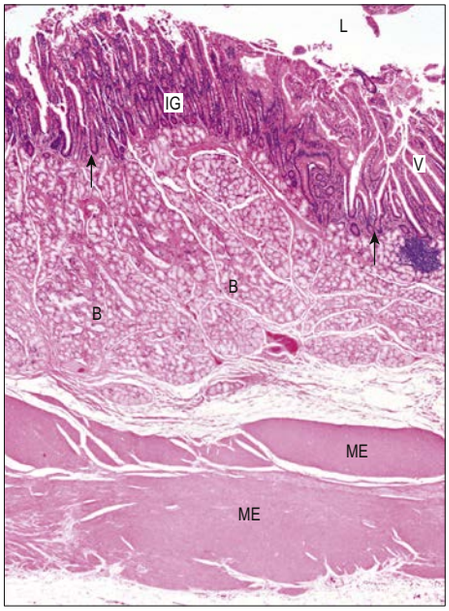

Fig. 64.19 A low-power micrograph showing the wall of the duodenum, with villi (V) projecting into the lumen (L); intestinal glands (IG) in the mucosa, seen mainly in transverse section; muscularis mucosae (arrows); submucosal seromucous glands (B); and muscularis externa (ME). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Epithelium

A single-layered epithelium covers the intestinal villi (see Figs 64.20, 2.2C) and also lines the intestinal glands that open between the bases of villi. Two types of cell, enterocytes and goblet cells, cover the surfaces of the villi. Microfold cells (M cells) are restricted to the dome epithelium that covers localized accumulations of lymphoid tissue. All three cell types contact and adhere basally to a basal lamina, and all are derived from a common stem cell in the intestinal glands.

Enterocytes Enterocytes are columnar absorptive cells, approximately 20 μm tall, and are the most numerous cell type in the small intestinal lining. They are responsible for nutrient absorption: their surfaces bear up to 3000 microvilli, greatly increasing the surface area for absorption (Marsh and Swift 1969). Collectively, microvilli are visible by light microscopy as a 1 μm thick brush border (microvillous border or striated border): individual microvilli can be resolved only by electron microscopy. Enterocyte nuclei are elongated vertically, mainly euchromatic and located just below the centre of the cell.

The apical cell surface is resistant to protease attack because microvilli possess a specialized glycoprotein-rich surface coat (glycocalyx; see Fig. 1.26). Together with an overlying layer of mucus (Johansson et al 2011), this glycocalyx protects the epithelium against pancreatic enzymes in the intestinal lumen. The cell coat also contains a number of digestive enzymes as integral membrane proteins, including enzymes that degrade disaccharides and oligopeptides prior to absorption.

The luminal surface is an important barrier to diffusion. Nutrients generally have to pass through enterocytes (transcellular absorption) before they reach the underlying lamina propria and its blood vessels and lymphatics (central lymphatic vessels or lacteals). Classical epithelial junctional complexes encircle the apical plasma membranes of adjacent enterocytes, their tight junctions forming an effective barrier to non-selective diffusion between the gut lumen and the body as a whole. The lateral plasma membranes of enterocytes are highly folded and interdigitate to form complex intercellular boundaries that are anchored periodically by desmosomes and that make contact at gap junctions. The lateral intercellular space expands during active absorption; by supplementing transport across the basal cell surface it is an additional conduit for the passage of fluids with nutrients and other solutes to the vessels of the lamina propria.

After differentiation, enterocytes have a lifespan of about five days. Their position on the intestinal villus wall reflects their stage in the life cycle. They undergo programmed, apoptotic cell death and are shed from the tips of the villi. They are replaced at the bases of the villi by stem cell mitosis. Enterocytes located in the bases of the intestinal villi have a mainly secretory role, contributing more to absorption as they migrate towards the lumen.

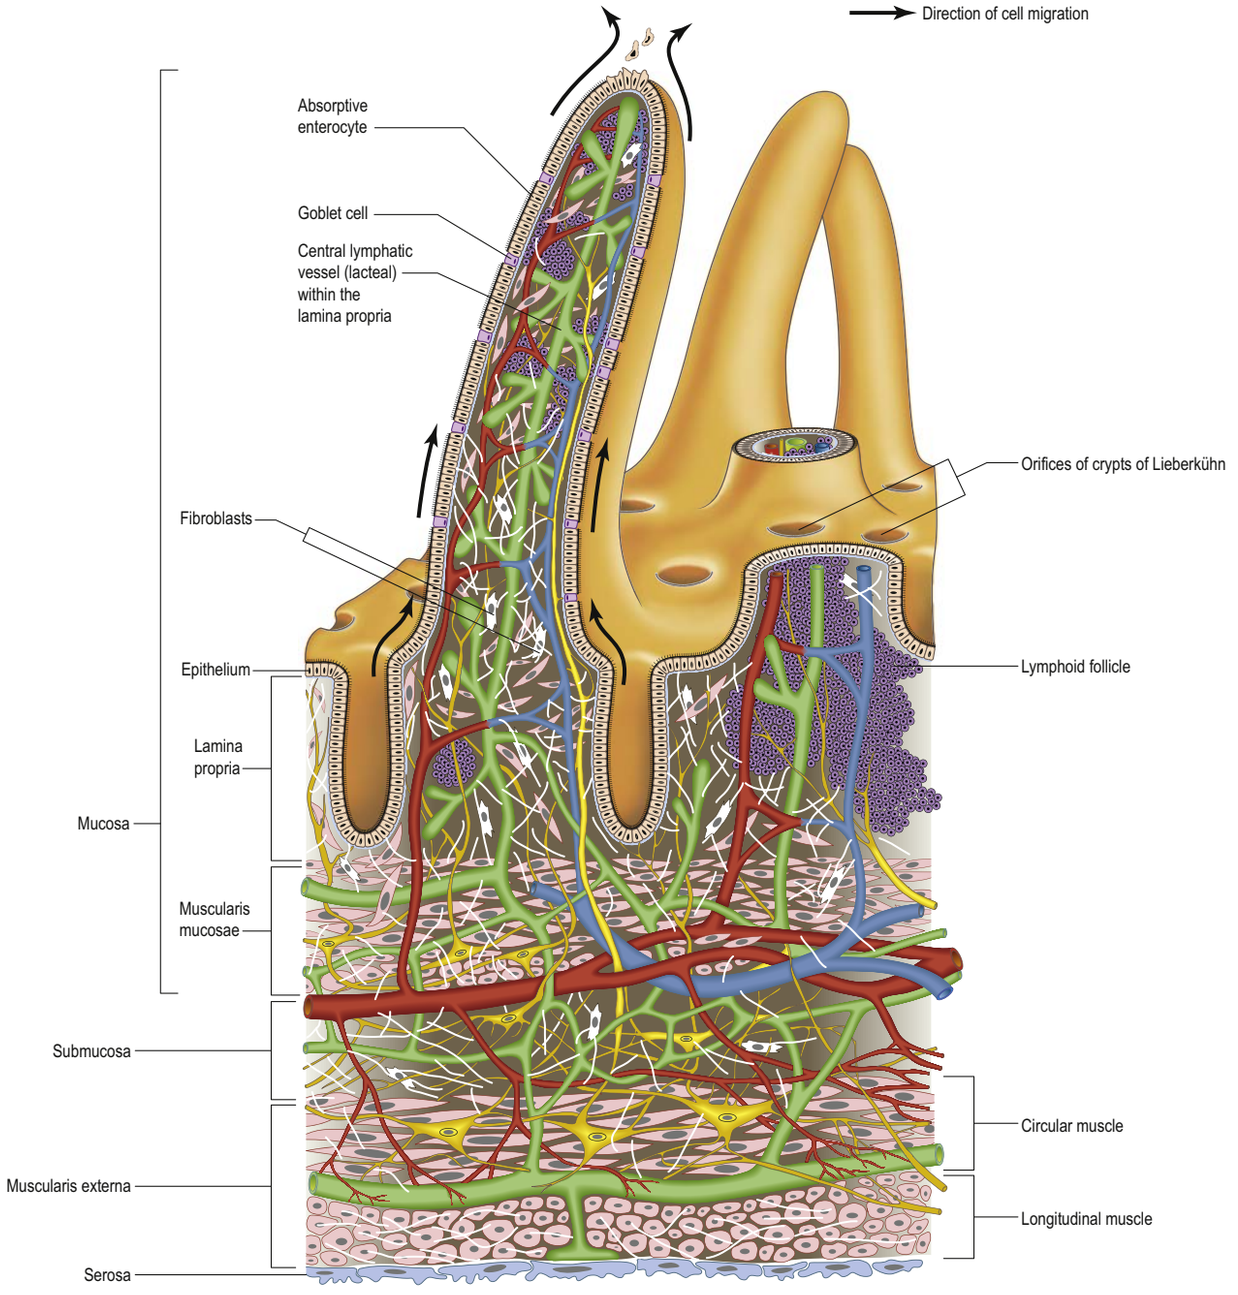

Fig. 64.20 The architecture of an intestinal villus. The various layers and cells are not drawn to scale.

Fig. 64.21 The endoscopic appearance of the terminal villi (magnified).

Goblet cells Goblet cells increase in number from the duodenum to their highest density in the terminal ileum. They have elongated basal nuclei, an apical region containing many membrane-bound mucinogen granules, and apical surfaces that bear a few short microvilli. Goblet cell mucins contribute to protection against microorganisms and toxins in the gut lumen, and also provide lubrication and mechanical protection from the intestinal contents.

Microfold (M) cells Microfold cells are present where the epithelium covers lymphoid aggregates in the intestinal wall. They are cuboidal or flattened and have long, widely spaced microfolds rather than microvilli on their apical surfaces. They sample luminal antigens by endocytosis and transport antigens to lymphocytes lying within intercellular pockets formed by deep invaginations of the M-cell basolateral plasma membranes. (See Chapter 4 for details of antigen processing and presentation.)

Lymphocytes Intraepithelial lymphocytes are found in close association with M cells and also between the basolateral regions of enterocytes and goblet cells. They are migratory cells derived from the underlying lymphoid tissue and constitute an important means of immune defence.

Intestinal glands

Intestinal glands (intestinal crypts, crypts of Lieberkühn) are tubular pits that open into the lumen throughout the intestinal mucosa via

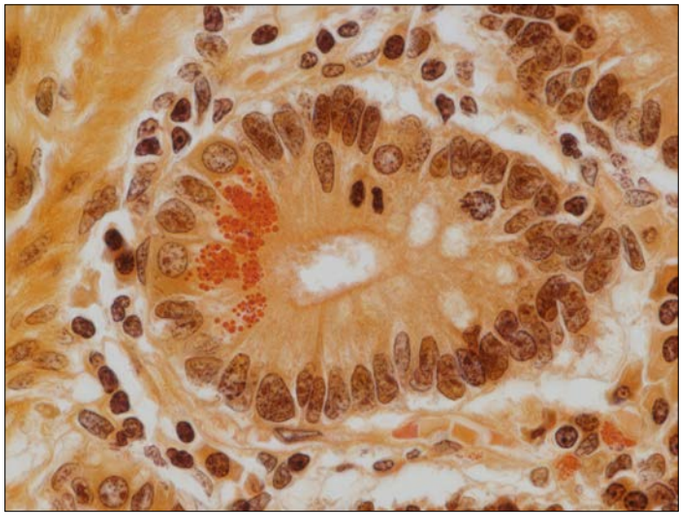

Fig. 64.22 Transverse section through a crypt in the ileum, lined by columnar epithelial cells with vertically elongated nuclei (a mitotic figure is seen in the upper field). Paneth cells with round nuclei and orange-stained secretory granules in their apical cytoplasm are seen on the left. Lendrum's phloxine–tartrazine stain. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

small circular apertures between the bases of the villi (see Fig. 64.20). Their thin walls are composed of columnar enterocytes supplemented by mucous cells of the duodenal submucosa, Paneth cells, stem cells and neuroendocrine cells. They are separated by a basal lamina from a rich capillary plexus within the lamina propria.

Enterocytes Enterocytes in the intestinal glands secrete ions and alkaline fluid to dilute chyme and aid absorption by structurally similar cells that cover the villi.

Mucous cells The mucous cells of the duodenal submucosa in the intestinal glands are similar to the goblet cells of the villi.

Paneth cells Paneth cells are highly specialized epithelial cells of the small intestine, involved in the coordination of many physiological functions. They were first identified more than a century ago on the basis of their readily discernible secretory acidophilic granules that stain strongly with eosin or phosphotungstic acid-haematoxylin (**Fig. 64.22**). Paneth cells are numerous in the deeper parts of the intestinal glands. They synthesize and secrete lysozyme, a highly specific antibacterial enzyme, other defensive proteins (alpha-defensins), tumour necrosis factor alpha (TNF-α), and phospholipase A that help to protect the luminal surface. These antimicrobial molecules are key mediators of host–microbe interactions, including maintaining the homeostatic balance with colonizing microbiota and providing innate immune protection from enteric pathogens (Clevers and Bevins 2013). Paneth cells secrete factors that help sustain and modulate epithelial stem and progenitor cells in the intestinal glands.

Stem cells Stem cells occur in a zone just above the basal region of the intestinal glands. Lineage tracing has demonstrated that $Lgr5^{hi}$ crypt base columnar stem cells generate all cell types of the small intestinal epithelium (Barker et al 2007, Clevers 2013). These cells divide rapidly in the intestinal gland compartment directly above the Paneth cells. Their progeny (transit-amplifying cells) move upwards from this compartment onto the surfaces of the intestinal villi while differentiating into goblet cells, tuft cells, neuroendocrine cells and enterocytes. An individual cell takes only 4–5 days to reach the tip of an intestinal villus and undergo apoptosis. Paneth cells escape this upward flow and migrate downwards to settle at the bases of the intestinal glands, where they can remain for one month or more (Clevers and Bevins 2013). Stem cell daughter cells and young transit-amplifying cells retain their plasticity and can revert back to stem cells if an intestinal gland is injured and existing stem cells are lost.

Neuroendocrine cells Several types of neuroendocrine cell are scattered among the walls of the intestinal glands and less commonly over the intestinal villi. They can all be identified by their clear cytoplasm and round nucleus. They secrete bioactive peptides such as gastrin, cholecystokinin and secretin basally into the surrounding lamina propria. Eleven distinct subpopulations of neuroendocrine cells have been described, distributed throughout the gastrointestinal tract, each producing unique signalling molecules. Intestinal gland neuroendocrine cells are derived from stem cells, that also give rise to enterocytes and other epithelial elements (Posovszky 2017).

Lamina propria

The lamina propria is composed of connective tissue and provides mechanical support for the epithelium. It has a rich vascular plexus, receives nutrients absorbed by the enterocytes, and forms the cores of the intestinal villi. It contains lymphoid tissue, fibroblasts and connective tissue extracellular matrix fibres, smooth muscle cells, eosinophils, macrophages, mast cells, capillaries, lymphatic vessels and unmyelinated nerves. Plasma cells are numerous. Lymphocytes may be clustered in solitary or aggregated follicles, some of which extend through the muscularis mucosae into the submucosa.

Villus core

Each intestinal villus has a core of delicate connective tissue that contains a large, blind-ending lymphatic vessel or lacteal (so called because of its milky content of suspended chylomicrons, the droplets of apoprotein–lipid complex elaborated by enterocytes from absorbed dietary fats). The core also contains blood vessels, nerves and smooth muscle cells derived from fine extensions of the muscularis mucosae. Each lacteal, usually single but occasionally double, starts in a closed dilated extremity near the tip of an intestinal villus and extends through the core to the base of the villus, where it joins a narrower lymphatic plexus in the deeper lamina propria. Its wall is a single layer of endothelial cells. Smooth muscle cells surround the lacteal throughout each villus, and their contraction propels its contents into the underlying lymphatic plexus. Capillaries within the core are lined by fenestrated endothelium to facilitate the rapid intake of nutrients that diffuse from the covering absorptive epithelium.

Mucosa-associated lymphoid tissue

Mucosa-associated lymphoid tissue (MALT; Ch. 4) consists of lymphoid follicles covered by follicle-associated intestinal epithelium that includes scattered M cells. MALT is found mainly in the lamina propria but sometimes expands into the submucosa; it is the source of B and T lymphocytes and other related cells involved in the immune defence of the gut wall. MALT produces immunoglobulin A (IgA), the most abundant immunoglobulin in the body and the major class of antibody secreted by the gut mucosa. IgA regulates the composition, geographical distribution and function of bacterial communities along the gastrointestinal tract via T cell dependent and independent pathways and has also been implicated in autoimmune and inflammatory conditions of the gut.

Like other masses of MALT (except lymph nodes), solitary and aggregated lymphoid follicles are most prominent around the age of puberty, after which they decrease in number and size, although many persist into old age. For further details of intestinal MALT and its function, including aggregated lymphoid nodules, see Didierlaurent et al (2005).

Muscularis mucosae

The muscularis mucosae forms the base of the mucosa and has external longitudinal and internal circular layers of smooth muscle cells. It follows the surface profiles of the circular folds and sends fine fascicles of smooth muscle cells into the cores of the villi.

Submucosa

The submucosa is composed of loose connective tissue and contains blood vessels, lymphatics and nerves. Its ridged elevations form the cores of the circular folds. The geometry of its collagen and elastin fibres permits the considerable changes in transverse and longitudinal dimensions that accompany peristalsis whilst still providing adequate support, elasticity and strength. The submucosa is an important histological landmark in the pathological staging for some gastrointestinal malignancies.

Submucosal glands

Submucosal glands (Brunner's glands) are limited to the submucosa of the duodenum (see Fig. 64.19). Their ducts traverse the muscularis mucosae to enter the bases of the intestinal glands. They are largest and most numerous near the pylorus and form an almost complete layer in the proximal half of the descending part of the duodenum; thereafter, they gradually diminish in number and disappear at the duodenojejunal junction. They are small, branched tubuloacinar glands; each has several secretory acini lined by low columnar epithelial cells, which produce an alkaline (pH 9) mucoid secretion that effectively neutralizes acidic chyme from the stomach. Many neuroendocrine cells are present among the acinar cells.

Muscularis externa

The muscularis externa, sometimes known as muscularis propria, consists of a thin external longitudinal layer and a thick internal circular layer of smooth muscle cells. It is thicker in the proximal small intestine and is mainly responsible for the differential appearance of the proximal jejunum and distal ileum on computed tomography.

Interstitial cells of Cajal

Interstitial cells of Cajal (ICC) are found throughout the gastrointestinal tract, lying in close contact with nerve terminals (Farrugia 2008). They originate from mesenchymal cells and can be considered as specialized smooth muscle cells. However, whereas smooth muscle cells develop an extensive array of contractile elements, ICC are fusiform cells with a large oval nucleus, sparse cytoplasm, dendritic-like processes, few contractile elements, an abundance of endoplasmic reticula and mitochondria, and characteristic sets of channels in their membranes, including CD117, a tyrosine kinase receptor (Mostafa et al 2010). ICC contact each other and neighbouring smooth muscle cells via gap junctions. They form distinct networks in the myenteric plexus between the circular and longitudinal muscle layers: looser arrangements occur within the individual muscle layers and the submucosa of the gut. Isolated or small groups of ICC are also found in connective tissue septa and the subserosal layer. ICC are involved in generating pacemaker signals, propagating electrical slow wave activity, neuromuscular transmission, and mechanosensation (Sanders et al 2014): defective ICC function has been implicated in a wide range of intestinal motility disorders (Al-Shboul 2013).

Serosa

The serosa is visceral peritoneum. It consists of a subserosal layer of loose connective tissue covered by mesothelium. Serosa covers most of the muscularis externa, with the exception of the parts adjacent to mesenteric adipose tissue and the retroperitoneal portions of the duodenum, both of which are covered mainly by connective tissue.

CHAPTER 65

Large intestine

The large intestine extends from the ileocaecal junction to the anus (**Fig. 65.1**). It begins as the caecum and vermiform appendix, which are usually located in the right iliac fossa. The ascending colon passes superiorly in the right lateral region to the right hypochondriac region, where it bends to the left to form the right colic flexure and become the transverse colon. This loops across the abdomen with an anteroinferior convexity until it reaches the left hypochondriac region, where it curves inferiorly to form the left colic flexure (**Fig. 65.2**). From there, it descends in the left lateral region as the descending colon before continuing as the sigmoid colon in the left iliac region. The sigmoid colon descends into the lesser pelvis and becomes the rectum anterior to the third sacral vertebra. The rectum transitions to the anal canal at the level of the pelvic diaphragm. Embryologically, the large intestine is formed from the distal midgut, all of the hindgut and the anal pit (proctodeum) (Ch. 22 and Figs 22.4, 22.7E). Knowledge of the development of the large intestine not only helps to explain its anatomy, relations (including peritoneal attachments) and neurovascular supply, but is also fundamental to understanding congenital large intestine disorders such as anorectal malformations and malrotation of the gut.

In the adult, the large intestine is approximately 1–1.5 m long *in vivo*, although there is considerable individual variation. It differs from the small intestine in several ways: it has a greater calibre; for much of its course it is more fixed in position; the outer longitudinal muscle layer of the colon is concentrated into three longitudinal bands, taeniae coli; small fatty projections, omental appendices, are scattered over its free surface (although these tend to be absent from the caecum, appendix and rectum); and the colonic wall is puckered into haustra, visible on plain radiographs as incomplete septations arising from the wall of the intestine (**Fig. 65.3**; see Fig. 65.2). Its calibre is greatest near the caecum, gradually diminishes towards the sigmoid colon, and then increases again in the rectum, where the distal third is dilated to form the rectal ampulla. The mean internal diameter of the large intestine is 4.8 cm (Helander and Fändriks 2014).

During development, the large intestine is temporarily suspended by a midline dorsal mesentery. However, after rotation of the gut *in utero*, large portions of it come to lie adherent to the retroperitoneum, while other segments remain suspended by a mesentery within the abdominal cavity, i.e. an intermesenteric position. The mesenteries of the colon consist of two layers of visceral peritoneum enclosing adipose and connective tissues and surrounding vessels, nerves and lymphatics that run forward from retroperitoneal structures. The caecum may be firmly adherent to the retroperitoneum but is frequently suspended by a short mesentery, especially in infants. The ascending colon is usually adherent to the retroperitoneum, while the transverse colon is suspended by a mesocolon and is freely mobile within the upper abdomen. The left and right colic flexures may have a short mesentery. The descending colon is adherent to the retroperitoneum, usually down to the level of the iliac crest, and the sigmoid colon has a mesentery of variable length. The sigmoid mesentery shortens as it approaches the pelvis and practically disappears at the level of the rectosigmoid junction. The proximal third of the rectum is covered by peritoneum on its anterior and lateral aspects, and the middle third by peritoneum on its anterior aspect only; the distal third is below the peritoneum.

The microstructure of the large intestine corresponds to the general pattern of the gut wall, comprising a mucous membrane consisting of epithelium, lamina propria and muscularis mucosae, surrounded by inner circular and outer longitudinal layers of smooth muscle and a serosa (see Figs 65.3, 65.50, 65.51). The mucosa also contains scattered neuroendocrine cells derived from the amine precursor uptake and decarboxylation (APUD) cell lineage; these cells produce amines and/or peptides, which act as hormones or neurotransmitters. Unlike the small intestine, the mucosa of the large intestine lacks villi, and the intestinal glands contain a high proportion of goblet (mucin-secreting) cells. In the appendix, the intestinal glands are sparse and numerous lymphoid follicles are found in the mucosa and submucosa. Although it is not a vital organ, the primary function of the colon is transmission and elimination of intestinal contents, but it also has important absorptive and secretory roles. The large intestine has its own intrinsic (enteric) nerve supply, the activity of which is modulated by extrinsic innervation.

External appearance

The haustra of the colon are frequently absent in the caecum and often relatively sparse in the ascending and proximal transverse colon. They become more pronounced beyond the middle of the transverse colon. The sigmoid colon often has marked haustra. Omental appendices are small, fat-filled pouches of peritoneum that project from the external surface of the colon and are supplied by blood vessels that perforate its wall. There are few, if any, omental appendices on the serosal surface of the caecum, and only a limited number scattered along the ascending colon. They are more common over the distal colon and particularly numerous on the surface of the sigmoid colon, where they can be large in the obese individual. The rectum has no omental appendices.

The three taeniae coli are located in fairly constant positions beneath the serosa of the colon, except in the transverse colon. They are found on the antimesenteric aspect of the colon directly opposite the mesentery (free taenia), posterolaterally (omental taenia) and posteromedially (mesocolic taenia) midway between the free taenia and the mesentery (see Fig. 65.3). In the ascending and descending colon, the omental taeniae are often hidden by the peritoneal reflection on to the colonic wall. In the transverse colon, the taeniae are rotated as a consequence of the dependent position of this segment of colon, so anterior becomes inferior, posteromedial becomes posterior, and posterolateral becomes superior. The width of the taeniae coli remains fairly constant throughout the colon but they broaden out in the distal part of the sigmoid colon and gradually merge to form a complete longitudinal muscle layer around the rectum, which therefore has no external haustra.

Internal appearance

The haustra of the colon represent sites where the mucosa and submucosa of the colonic wall are infolded; these folds partially span the lumen of the colon but never form a complete circumferential ring. The pattern of haustra and appearance of the colonic mucosa help the clinician appreciate the level reached during flexible endoscopic examinations of the colon (Silverstein and Tytgat 1991). In the caecum, the three taeniae coli converge to form a characteristic 'trefoil' pattern on the caecal wall (**Fig. 65.4**). The distal caecum is usually devoid of haustra, although a spiral mucosal pattern is often seen in the region of the orifice of the appendix (**Fig. 65.5**). The ileal orifice can be identified as a thickened fold (**Fig. 65.6**) and can be cannulated endoscopically to examine the terminal ileum. In the distal caecum and ascending colon, the haustra can extend across one-third of the lumen. In the transverse colon, the haustra often confer a triangular appearance to the cross-section of the lumen when it is viewed along its axis at colonoscopy (**Fig. 65.7**). The haustra of the descending and sigmoid colon tend to be thicker and shorter, producing a more circular lumen cross-section (**Figs 65.8–65.9**). The wall of the colon is thinnest in the region of the caecum and ascending colon, where it is at risk of perforation during therapeutic endoscopic procedures. The overall luminal diameter is often smallest in the descending colon. The tortuosity of the sigmoid colon means that shorter lengths of it are visible during endoscopy than elsewhere in the colon. The haustra of the rectum usually form consistent and recognizable transverse rectal folds (spiral valves of Houston) and the submucosal vessels tend to be more pronounced than in the colon (**Fig. 65.10**). Most patients are found to have two or three folds and these are useful landmarks for planning rectal surgery (Abramson 1978). Distinct veins are usually visible during endoscopy, and are most marked above the anorectal junction.

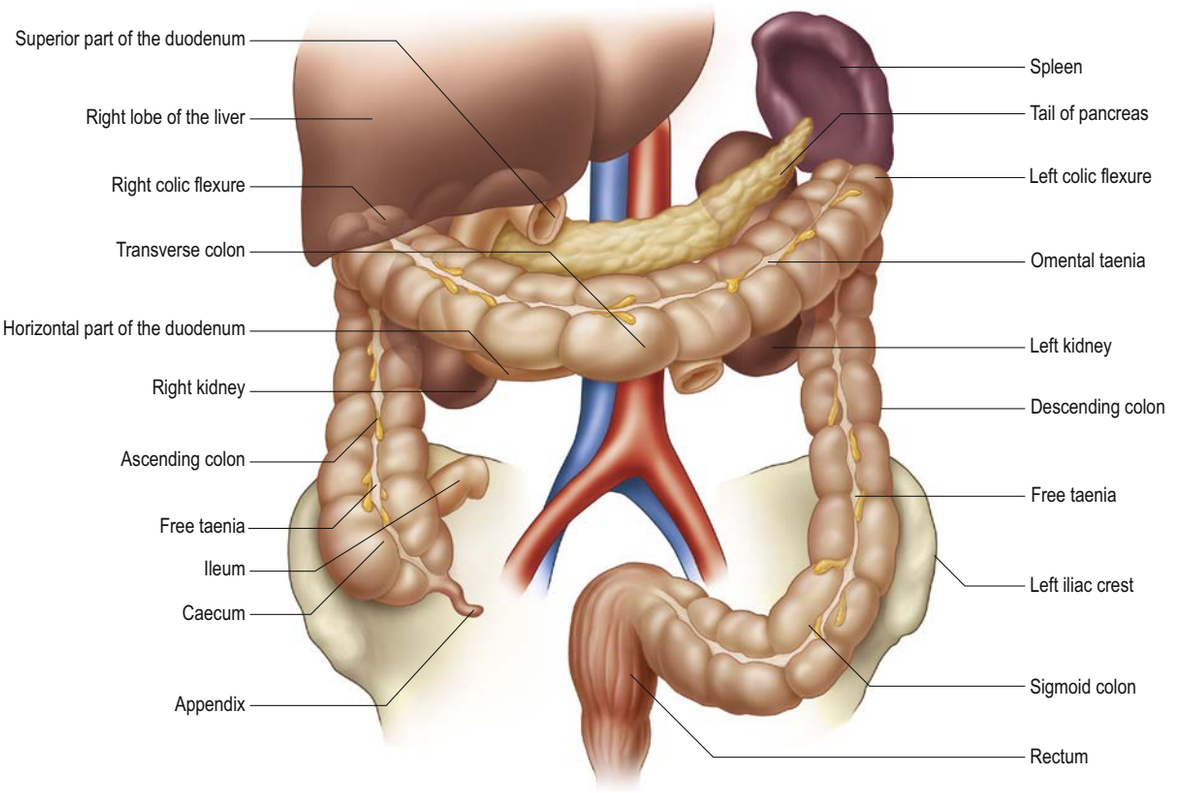

Fig. 65.1 An overview of the colon and its relations.

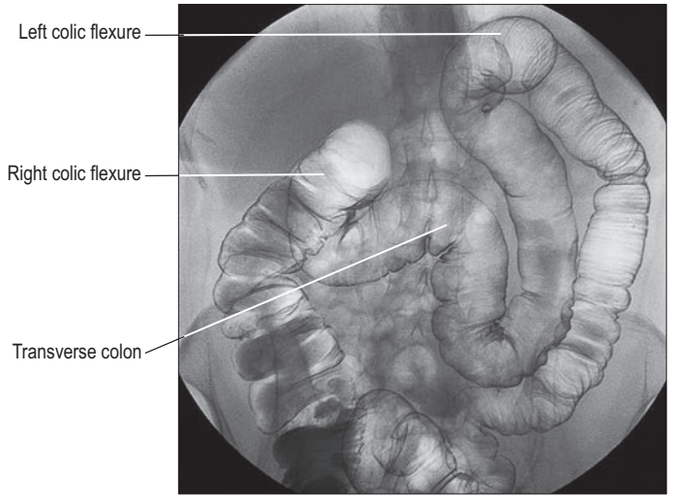

Fig. 65.2 The appearance of the colon on double contrast barium enema examination, demonstrating the transverse colon and left and right colic flexures.

Radiological appearances

Cross-sectional imaging of the colon can be performed with computed tomography (CT) and magnetic resonance imaging (MRI). On axial images, the colon may be filled with particulate faeces and flatus (Fig. 65.11). The wall in normal individuals is thin. The caecum and ascending colon often contain faecal residue. The transverse colon may contain faeces or flatus and lies in a variable position, suspended by its mesentery. The descending colon lies in the retroperitoneum on the left and seldom contains much faecal residue. The volume data sets produced by multislice CT can generate virtual colonoscopic mucosal images of the distended and cleaned colon, and surface-rendered images of the internal surface of the colon (Fenlon 2002).

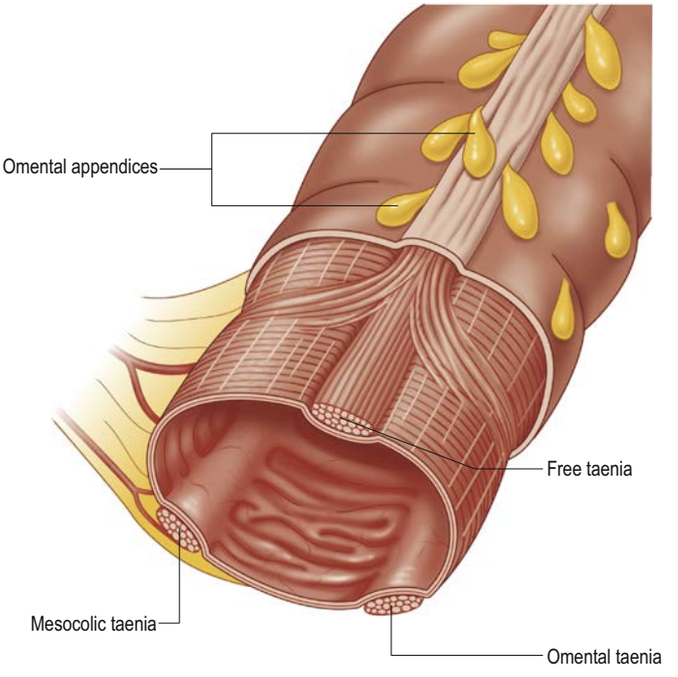

Fig. 65.3 Layers of the colonic wall.

Vascular supply and lymphatic drainage

Arteries

The arterial supply of the large intestine is derived from both the superior and the inferior mesenteric arteries (Fig. 65.12) (Jackson 1999). The caecum, appendix, ascending colon and proximal two-thirds of the transverse colon (derived from the midgut) are supplied from ileocolic, right colic and middle colic arteries, branches of the superior mesenteric

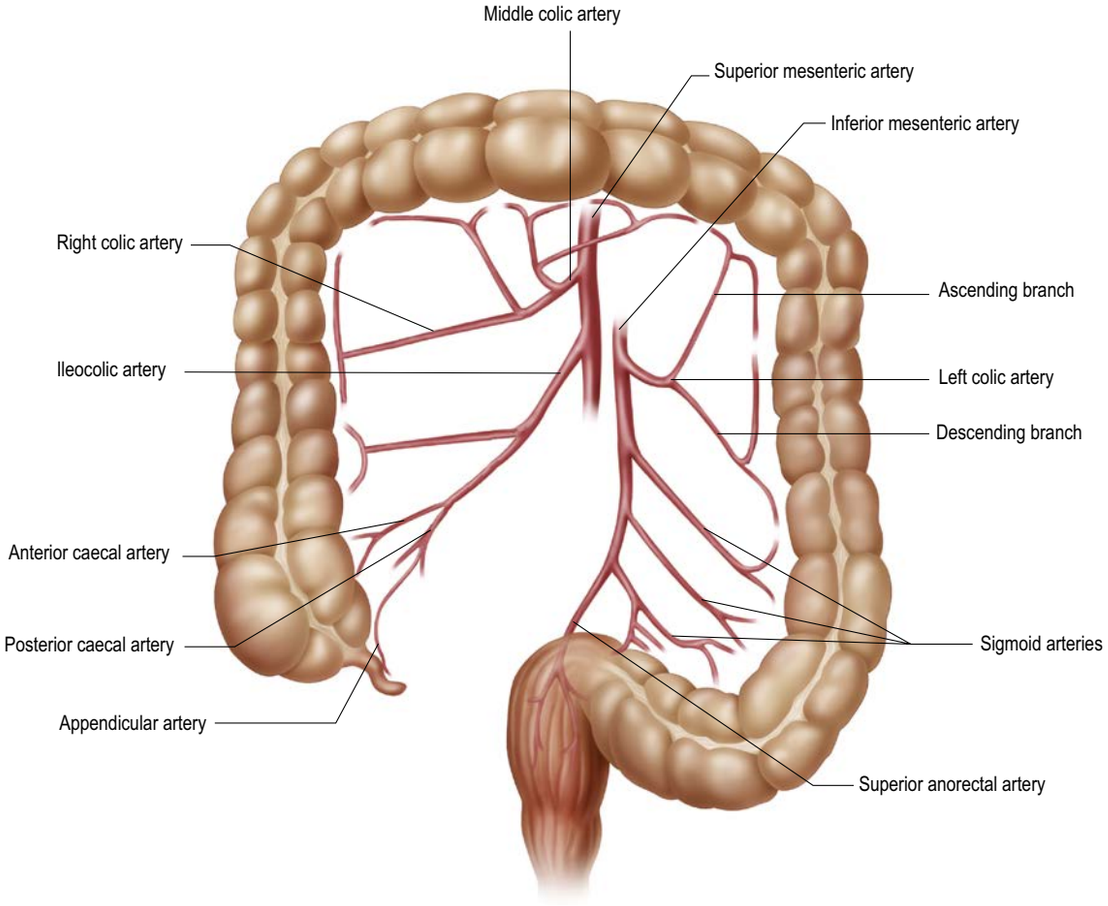

Fig. 65.12 The main branches of the superior and inferior mesenteric arteries.

artery. The distal third of the transverse colon, descending and sigmoid colon, rectum and proximal anal canal (hindgut derivatives) are supplied predominantly from the inferior mesenteric artery via the left colic, sigmoid and superior rectal arteries, with a small contribution from branches of the internal iliac artery (the middle and inferior anorectal arteries).

The arteries of the midgut- and hindgut-derived intestine contribute to an anastomotic vessel, the marginal artery (of Drummond), which runs in the mesentery along the inner margin of the colon and gives off short terminal branches to the wall of the intestine. These divide into vasa brevia, which pass directly through the muscular layer of the colonic wall, and vasa longa, which travel through the subserosa for a short distance before running through the circular muscle, giving off branches to the omental appendices (Fig. 65.13). The marginal artery is formed by the main branches and arcades arising from the ileocolic, right colic, middle colic and left colic arteries. It is most apparent in the ascending, transverse and descending colons (Fig. 65.14) but poorly developed in the sigmoid

colon. The marginal artery in the region of the left colic flexure can be absent or too narrow to be of functional significance. Nevertheless, it can dilate considerably when one of the main visceral arteries is compromised since it then provides a collateral arterial supply to the colon. The most susceptible part of the chain of anastomosing vessels is at the junction of midgut- and hindgut-derived intestine in the distal transverse colon near the left colic flexure. However, the arterial supply to this region may be augmented by an inner arterial arc (of Riolan), which runs a meandering course in the colonic mesentery between the main trunk of the middle colic artery and the ascending branch of the left colic artery (Fisher and Fry 1987, Gourley and Gering 2005). When present, this vessel is usually only prominent when there is occlusion of the superior or inferior mesenteric artery.

Colonic vascular occlusion

The marginal artery of the colon can become massively dilated when there is chronic stenosis or occlusion of the superior or inferior mesenteric artery. The latter may occur, for example, in association with an abdominal aortic aneurysm, when the descending colon remains viable because the marginal artery continues to receive an adequate blood supply from left branches of the middle colic artery and the sigmoid colon gains its blood supply from the middle anorectal and inferior anorectal arteries. When colonic ischaemia does occur, it is usually maximal in the region of the left colic flexure and proximal descending colon because this segment is farthest from the collateral arterial supplies. Occlusion of the common iliac arteries can also result in dilation of the marginal and inferior mesenteric arteries, which become an important collateral supply to the lower limbs via dilated middle anorectal arteries commonly arising from either the internal pudendal or inferior gluteal artery (Bilhim et al 2013).

Veins

The venous drainage of the large intestine is primarily into the hepatic portal vein via the superior mesenteric and inferior mesenteric veins, although some drainage from the rectum occurs via middle anorectal veins into the internal iliac veins, and inferior anorectal veins into the internal pudendal veins. Those parts of the colon derived from the midgut (caecum, appendix, ascending colon and proximal two-thirds of the transverse colon) drain into colic branches of the superior mesenteric vein, while hindgut derivatives (distal third of the transverse colon, descending and sigmoid colon, rectum and proximal anal canal) drain into the inferior mesenteric vein (Fig. 65.15).

Lymphatic drainage

Lymph drainage from the large intestine follows the course of the arteries. Thus, lymphatic vessels of the caecum and the ascending and proximal transverse colon drain ultimately into lymph nodes related to the superior mesenteric artery, while those of the distal transverse colon, descending colon, sigmoid colon and rectum drain into nodes following the course of the inferior mesenteric artery (Fig. 65.16). In cases where the distal transverse colon or left colic flexure is predominantly supplied by vessels from the middle colic artery, most of the lymphatic drainage of this area may be to superior mesenteric nodes.

Colic nodes

Lymph nodes related to the colon form four groups: epicolic, paracolic, intermediate colic and preterminal colic. Epicolic nodes are minute whitish nodules on the serosal surface of the colon, sometimes within the omental appendices. Paracolic nodes lie along the medial borders of the ascending and descending colon and along the mesenteric borders of the transverse and sigmoid colon. Intermediate colic nodes lie along the named colic vessels (the ileocolic, right colic, middle colic, left colic, sigmoid and superior rectal arteries). Preterminal colic nodes lie along the main trunks of the superior and inferior mesenteric arteries and drain into pre-aortic nodes at the origin of these vessels.

Ascending mesocolic nodes are significantly larger than sigmoid mesocolic ones; this is relevant to lymph node retrieval and examination after resection for colonic cancer (Ahmadi et al 2015).

Radical lymphadenectomy during resection of colorectal cancer requires removal of the highest possible lymph nodes draining the region of colon in which the tumour is located. In cases of cancer of the rectum or sigmoid colon, this usually involves excision of the preterminal colic nodes along the inferior mesenteric artery with ligation of the artery at its root or just below the origin of the left colic artery. At least 12 lymph nodes must be excised in an oncologically resected partial colectomy for cancer.

MIDGUT-DERIVED PART OF THE LARGE INTESTINE

Caecum

This blind pouch, approximately 6 cm long, lies below the level of the ileocaecal junction (Fig. 65.17), anterior to the right iliac and psoas fasciae, with the lateral femoral cutaneous nerve interposed. The caecum

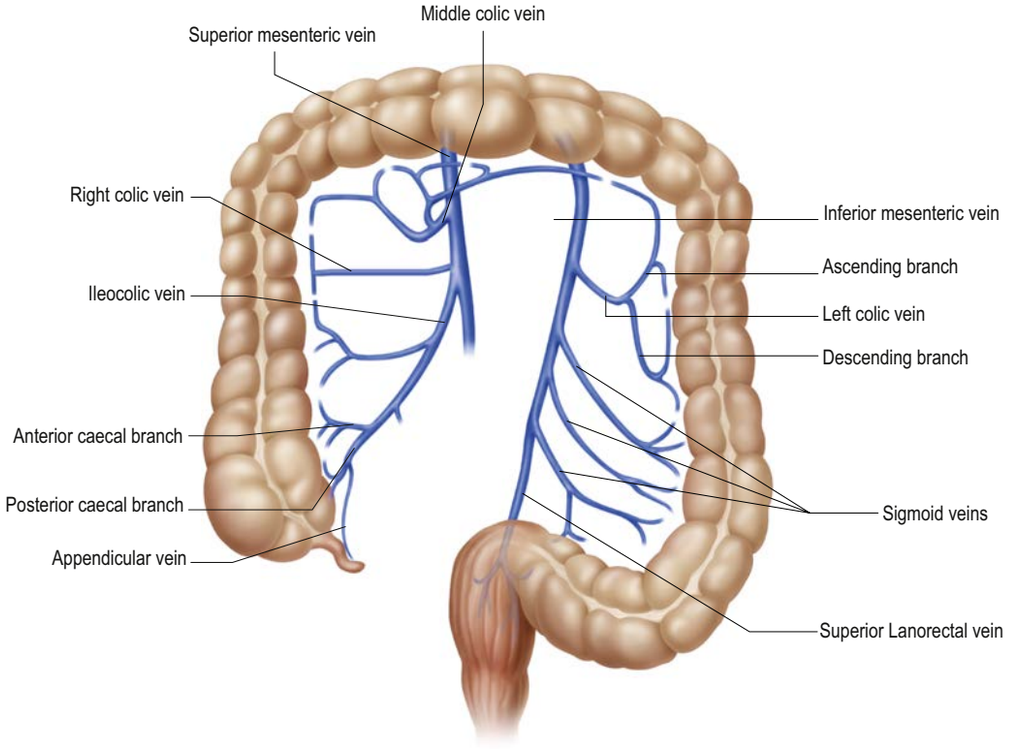

Fig. 65.15 The main branches of the superior and inferior mesenteric veins.

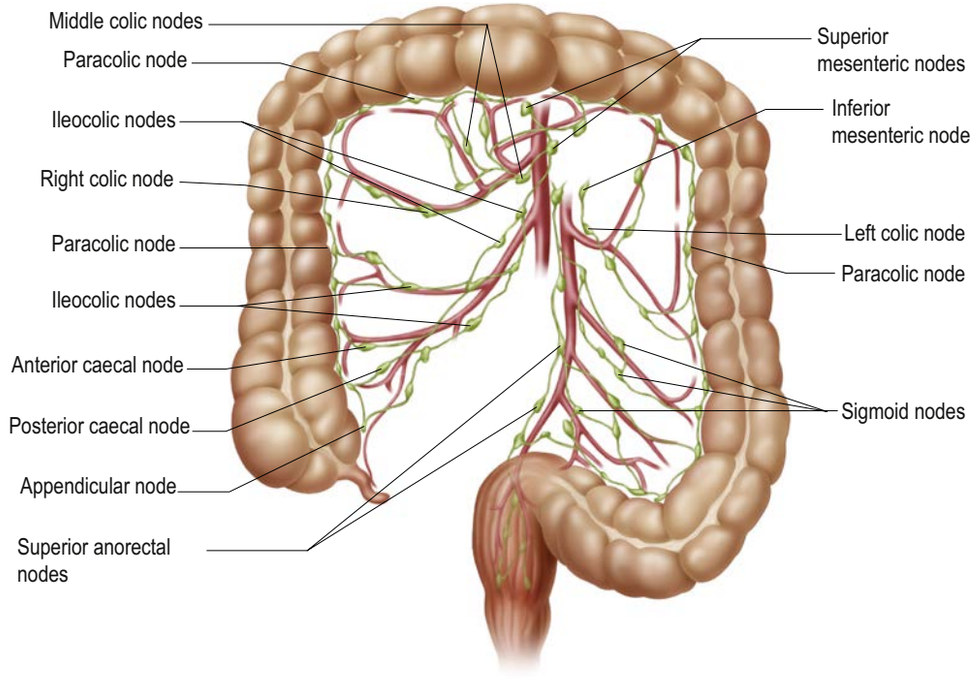

Fig. 65.16 The lymph vessels and nodes draining the large intestine.

usually lies adjacent to the anterior abdominal wall unless the greater omentum or loops of small intestine are interposed. It is often completely covered by peritoneum, which is reflected posteriorly and inferiorly to the floor of the right iliac fossa. The three taeniae coli lie anteriorly, posteromedially and posterolaterally and converge on the base of the appendix. During childhood, the lateral wall of the caecum outgrows the medial wall such that the orifice of the appendix, which is originally at the distal caecum, usually comes to lie slightly posteromedially.

Fluid and electrolyte reabsorption by the large intestine begins in the caecum but occurs mostly in the ascending and transverse colon. The distensible 'sac-like' morphology of the caecum allows large volumes of semi-liquid chyme from the small intestine to be stored. Its relatively large diameter makes it liable to distension with increased intracolonic pressure and it is the region of the large intestine at greatest risk of perforation secondary to colonic distension (from obstruction or other pathology).

Ileocaecal junction

The terminal ileum joins the posteromedial aspect of the large intestine at the junction of the caecum and colon, where it projects into the lumen of the large intestine as the ileal papilla (Fig. 65.18A). This projection consists of two lips and its precise shape and form varies from slit-like to an oval mucosal rosette, depending, in part, on the state of contraction or distension of the caecum. The ileocolic lip is approximately horizontal and is at the junction between the ileum and colon; the ileocaecal lip is longer and more concave, and is at the junction between the ileum and caecum. At their bases, the lips fuse and continue as the frenulum of the ileal orifice.

The ileal papilla is formed by the mucosa, submucosa and external muscle layers of the ileum, continuing through the wall of the large intestine and combining with corresponding layers from the

caecum inferiorly and the colon superiorly (Fig. 65.18B). Its internal surface is lined by small intestinal mucosa and its large intestine surface is covered by large intestine mucosa; these epithelial surfaces meet near the tip of the ileal papilla. A localized thickening of the muscle at the base of the ileal papilla is consistent with physiological data that suggest the presence of an intrinsic anatomical sphincter (Pollard et al 2012). In addition, the bilabial configuration of the ileal papilla could confer a valvular function. The ileocaecal junction performs several roles: it provides partial mechanical and functional separation of the luminal environments of the small and large intestine, which differ in composition, pH and bacterial content; it impedes reflux from the colon; and it helps to regulate antegrade small intestine transit.

Caecal volvulus

If the caecum and ascending colon are attached to the posterior abdominal wall by a narrow mesentery, the ileocaecal region is at risk of twisting about its mesenteric pedicle, creating a caecal volvulus. In such cases, the caecum becomes markedly distended because of the strangulating closed loop intestinal obstruction that develops. Non-anatomical factors such as caecal distension can also contribute to the pathogenesis of caecal volvulus (Madiba and Thomson 2002, Tannouri et al 2017).

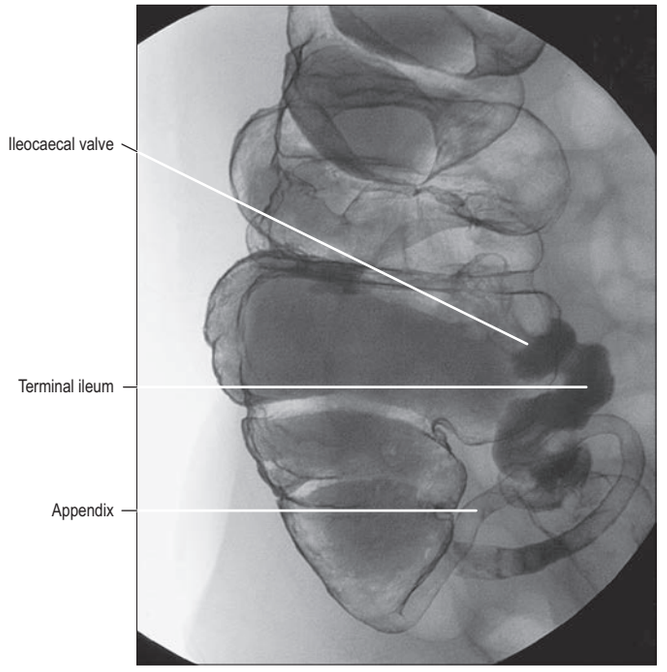

Fig. 65.17 The caecum and ileocaecal junction, double contrast barium enema appearance.

Appendix

The appendix is a narrow, blind-ending tube, usually 6–10 cm long in the adult. It joins the posteromedial wall of the caecum below the ileocaecal junction. The appendix grows in length and diameter during early childhood, reaching almost mature dimensions by about three years of age (Searle et al 2013). It usually lies in the right iliac fossa but its distal end may occupy one of several positions (Fig. 65.19) (Buschard and Kjaeldgaard 1973). In clinical practice, the tip is most commonly retrocaecal or retrocolic (behind the caecum or proximal ascending colon, respectively, anterior to iliacus and psoas major), or pelvic (when the appendix descends over the linea terminalis, close to the right uterine tube and ovary in females). Other positions include subcaecal, and pre- or post-ileal (anterior or posterior to the terminal ileum, respectively), especially when a long meso-appendix allows greater mobility. The surface marking for the base of the appendix has traditionally been described by McBurney's point (two-thirds of the way along a line between the umbilicus and right anterior superior iliac spine) but its position is variable and is affected by posture, caecal distension and other factors (Hale et al 2010).

The appendix has a continuous outer layer of longitudinal muscle formed by the coalescence of the three taeniae coli. Its lumen is irregularly narrowed by submucosal lymphoid tissue. The meso-appendix is a triangular mesentery running between the terminal ileum and appendix; it contains a variable amount of fat and frequently ends short of the distal end of the appendix. A fold of peritoneum runs between the terminal ileum and the anterior layer of the meso-appendix (the 'bloodless fold of Treves'), and another fold of peritoneum containing the anterior caecal vessels extends from the terminal ileal mesentery to the anterior wall of the caecum (and contains the anterior caecal artery). The luminal orifice is sometimes partially covered by a mucosal fold forming an asymmetric 'valve' (see Fig. 65.5). The lumen can be widely patent in early childhood but is often partially or wholly obliterated in the elderly. Agenesis and duplication of the appendix are exceptionally rare (Barlow et al 2013, Tubbs et al 2016).

Microstructure

The layers of the wall of the appendix are similar to those of the large intestine in general but with some notable differences. The serosa forms a complete covering, except along the mesenteric attachment. The outer longitudinal muscle is a complete layer of uniform thickness, except in a few small areas where the muscularis externa is deficient, allowing the serosa to come into contact with the submucosa.

Microscopic examination of the appendix reveals the epithelial layer, prominent lymphoid tissue of the mucosa, and the underlying submucosa, muscularis propria, serosa and subserosal connective tissue. The conspicuous (and often confluent) lymphoid aggregates are a characteristic feature of the appendix that can involve both the mucosa and the submucosa (Fig. 65.20). The mucosa is covered by columnar epithelium, which contains M cells where it overlies the mucosal lymphoid tissue. Intestinal glands are similar to those of the colon but are fewer and less densely packed. They penetrate deep into the lamina propria. The submucosal lymphoid tissue frequently exhibits germinal centres within its follicles, indicative of B cell activation. Lymphoid follicles are absent at birth but accumulate during the first 10 years of life to become

prominent. In adults, the lymphoid follicles gradually atrophy; in the elderly, the lumen of the appendix can be partially obliterated by fibrous tissue (Barlow et al 2013).

Acute appendicitis

Acute appendicitis can develop if the lumen is obstructed by inspissated material, a faecolith (appendicolith) or lymphoid swelling. This can lead to suppuration, infarction and necrosis. Appendicoliths are more common in children than adults but their prevalence is variable, reflecting differences among populations, definitions and methods of detection. In one radiographic study of normal appendices removed incidentally at surgery or at autopsy, calcified faecoliths were identified in 2.7% (Felson 1949). The increased size of the appendicular orifice in early childhood and the decreased size of the lumen in the elderly could explain why acute appendicitis is less common in these age groups. Low suspicion can lead to delayed diagnosis in the elderly resulting in higher morbidity and mortality (Bhullar et al 2014). Although the appendix is well supplied by arterial anastomoses at its base, the appendicular artery is an end artery; its close proximity to the wall of the appendix makes it

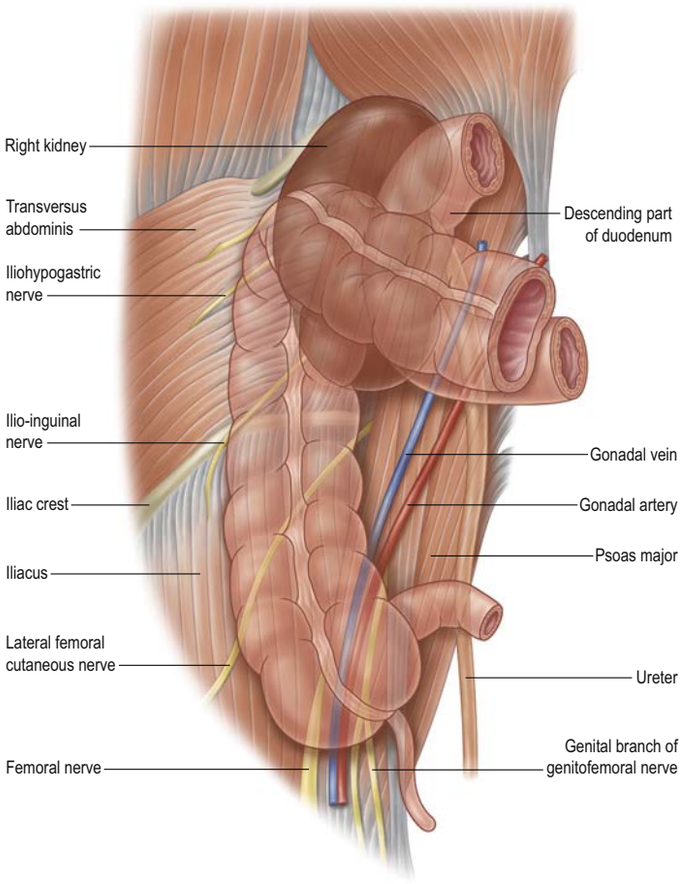

Fig. 65.21 Posterior relations of the ascending colon.

susceptible to thrombosis during acute appendicitis, which explains the high frequency of gangrenous perforation seen in the disease.

Visceral afferent fibres within adjacent nerves are responsible for the initial symptoms of acute appendicitis (colicky pain with or without emesis) that are caused by distension and inflammation of the appendix. Abdominal pain from appendicitis is poorly localized initially and referred to the umbilical region of the abdomen, consistent with the midgut derivation of the appendix. It is not until parietal peritoneum adjacent to the appendix becomes involved in the inflammatory process that somatic nociceptors are stimulated, resulting in localization of pain to the right iliac fossa. Removal of the appendix is not in itself associated with any discernible long-term sequelae but this does not mean it is an entirely vestigial organ. There is some evidence that it acts as a reservoir for normal gut flora, enabling the large intestine flora to recover more rapidly after severe gastroenteritis (Randal Bollinger et al 2007).

Ascending colon

The ascending colon is 15–20 cm long and passes upwards from the ileocaecal junction to the right colic flexure, separated posteriorly by loose connective tissue from the iliac fascia, iliolumbar ligament, quadratus lumborum, transversus abdominis and the renal fascia anterior and inferolateral to the right kidney. The lateral femoral cutaneous nerve, usually the fourth lumbar artery, and sometimes the ilio-inguinal and iliohypogastric nerves lie posteriorly as they cross quadratus lumborum (Fig. 65.21). Both the lateral and anterior surfaces of the ascending colon are covered by peritoneum which is composed of two layers of mesothelium containing fat embedded within a connective tissue lattice, vessels and nerves; it is attached to the retroperitoneum via a layer of connective tissue (Coffey 2013, Culligan et al 2014) known as Toldt's fascia, which forms the plane of dissection when a right hemicolectomy is performed.

Right colic flexure

The right colic flexure, forming the junction between the ascending and transverse colon, is variable in position and has a less acute angle than the left colic flexure. It overlies the anterior surface of the inferior pole

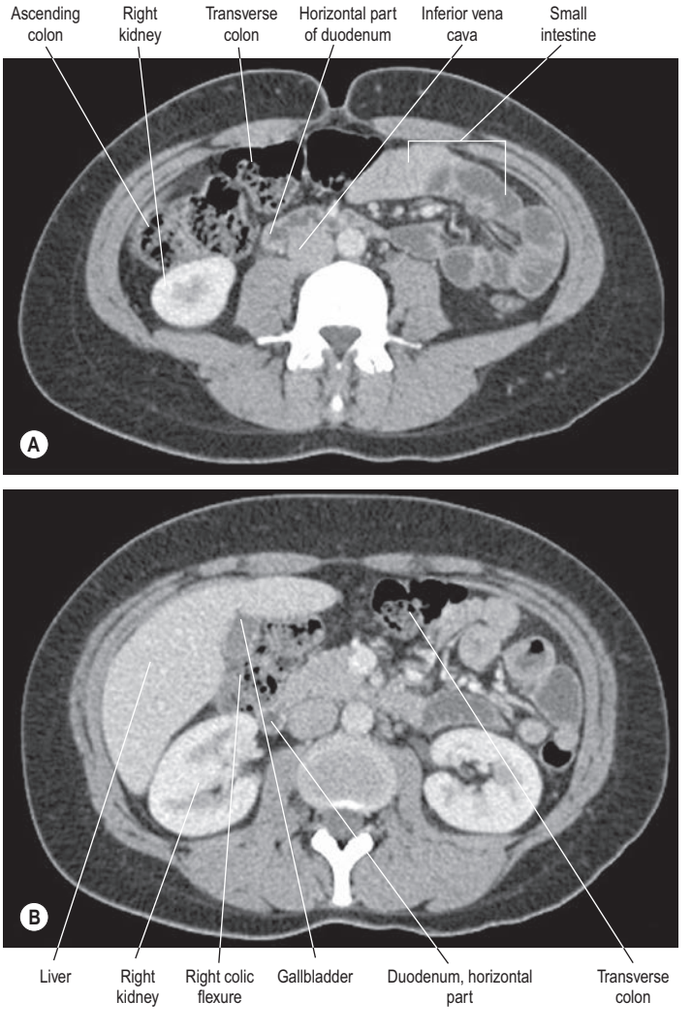

Fig. 65.22 Axial CT of the ascending colon obtained (**A**) at the level of the mid ascending colon and (**B**) at the level of the right colic flexure, showing the relationship of the ascending colon and right colic flexure to the right lobe of the liver, the right kidney, the descending part of the duodenum and the gallbladder. (Courtesy of Dr Louise Moore, Chelsea and Westminster Hospital, London.)

of the right kidney, abutting the inferior surface of the right lobe of the liver above (see Fig. 65.21; **Fig. 65.22B**), the descending part of the duodenum medially, and the fundus of the gallbladder anteromedially. The posterior aspect of the right colic flexure is not covered by peritoneum and is in direct contact with renal fascia. The greater omentum often extends from its attachment to the transverse colon on to the right colic flexure.

Transverse colon

The transverse colon is highly variable in both length (approximately 50 cm on average) and the extent to which it hangs down anterior to the small intestine between sites of attachment at the right and left colic flexures. The greater curvature of the stomach and the gastrocolic ligament, which fuses with the transverse colon anteriorly and continues inferiorly as the greater omentum, are superior. The transverse colon is suspended by the transverse mesocolon, which is attached from the inferior pole of the right kidney, across the descending part of the duodenum and pancreas, to the superior pole of the left kidney. The left colic flexure lies at a more superior level than the right colic flexure, often abutting the spleen under the lower ribs. Because of the disposition of the transverse colon and the more posteriorly sited flexures, the free taenia of the ascending and descending colon is positioned inferiorly. The transverse mesocolon affords considerable mobility to the transverse colon. Occasionally, the colon is interposed between the liver and the diaphragm, when it can be mistaken for free intraperitoneal flatus on imaging; when this is associated with gastrointestinal symptoms it is referred to as Chilaiditi's syndrome (Murphy et al 2000).

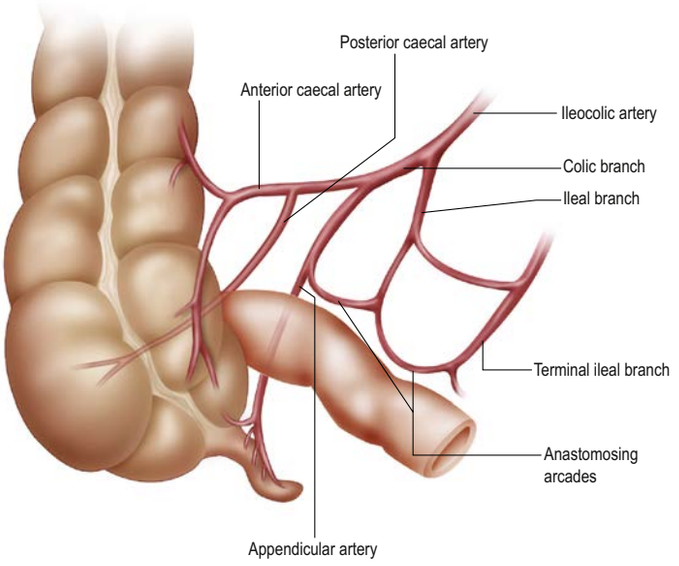

Fig. 65.23 The arteries of the caecum, appendix and ascending colon.

Vascular supply and lymphatic drainage of the midgut-derived large intestine

Arteries

Superior mesenteric artery

The artery of the midgut is the superior mesenteric artery, which arises from the anterior surface of the aorta at the level of the lower border of the body of the first lumbar vertebra. It runs steeply downwards, posterior to the splenic vein and body of the pancreas, with the superior mesenteric vein on its right, and directly anterior to the left renal vein, the uncinate process of the pancreas and the horizontal part of the duodenum. It then enters the root of the mesentery of the small intestine and passes obliquely downwards and to the right, giving off several branches to the large intestine.

Ileocolic artery

The ileocolic artery arises from the superior mesenteric artery near the root of the mesentery of the small intestine, descending within that mesentery to the right towards the caecum, and crossing anterior to the right ureter, gonadal vessels and psoas major. It usually divides into superior and inferior branches, the superior branch running up along the left side of the ascending colon to anastomose with the right colic artery (or right branch of the middle colic artery) (Veeresh et al 2012). The inferior branch runs to the ileocaecal junction and divides into anterior and posterior caecal arteries, the appendicular artery and an ileal branch that passes to the left in the ileal mesentery to anastomose with a terminal ileal branch of the superior mesenteric artery (**Fig. 65.23**). The latter therefore provides a collateral arterial supply to the caecum. The ileocolic artery provides the major arterial supply to the caecum; traction on the caecum in the direction of the anterior superior iliac spine will cause the artery to tent up the mesentery, allowing the vessel to be easily identified.

The appendicular artery usually arises directly from the ileocolic artery and descends posterior to the terminal ileum to enter the mesoappendix a short distance from the base of the appendix (see Fig. 65.23). Here, it gives off a recurrent branch that anastomoses at the proximal appendix with a branch of the posterior caecal artery. The appendicular artery approaches the distal end of the organ, at first near to and then in the edge of the meso-appendix. Its terminal part lies on the wall of the appendix and can become thrombosed in appendicitis, resulting in distal gangrene or necrosis. Less commonly, the appendicular artery arises from the posterior caecal artery or an ileal artery (Ouattara et al 2007) (see Fig. 65.12). Accessory appendicular arteries are common; two or more arteries may supply the appendix.

Right colic artery

The right colic artery is relatively small and variable in its anatomy (Batra et al 2013, Haywood et al 2017). It usually arises as a common trunk with the middle colic artery, but can originate directly from the superior mesenteric artery or from the ileocolic artery (when it is referred to as an accessory right colic artery) (**Fig. 65.24**). It passes to the right, across the right psoas major and quadratus lumborum,

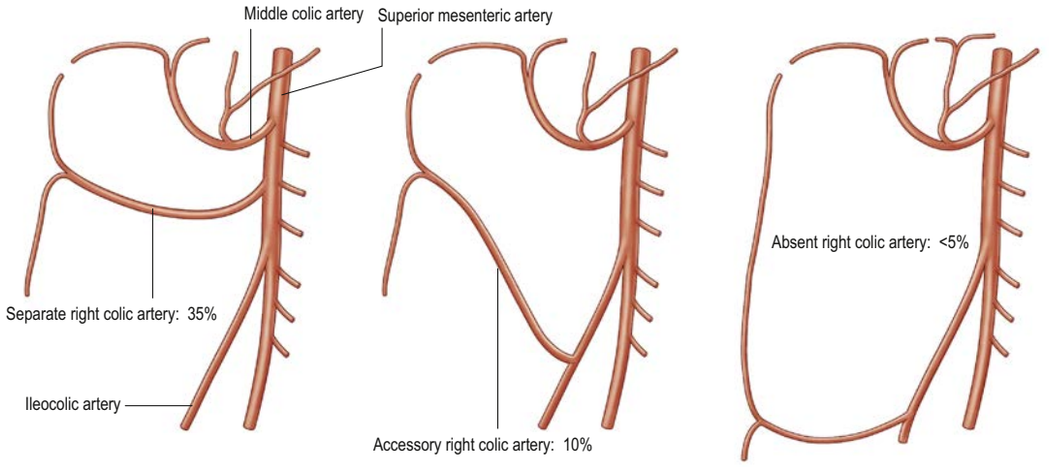

Fig. 65.24 Anatomical variants of the right colic artery.

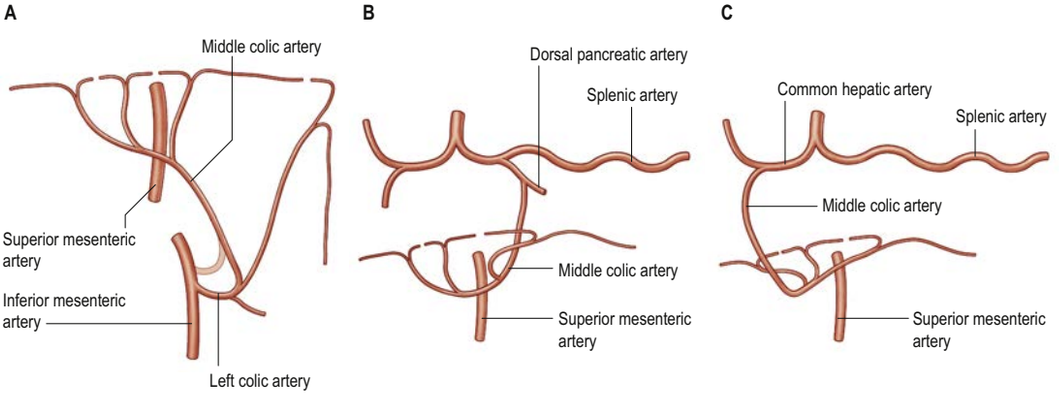

Fig. 65.25 Variants in the origin of the middle colic artery; only replaced arteries have been illustrated for simplicity. Accessory arteries are more common than completely replaced arteries. **A**, The left colic artery or inferior mesenteric artery. **B**, The dorsal pancreatic artery. **C**, The common hepatic artery. Each variant accounts for fewer than 5% of cases.

crossing the right gonadal vessels and ureter. Near the left side of the ascending colon it divides into a descending branch, which runs down to anastomose with the superior branch of the ileocolic artery, and an ascending branch, which passes up across the inferior pole of the right kidney to the right colic flexure, where it anastomoses with a branch of the middle colic artery. Together, these anastomoses form the marginal artery at the right colic flexure.

Middle colic artery

The middle colic artery arises from the right side of the superior mesenteric artery, either separately or in common with the right colic artery, just inferior to the neck of the pancreas, and passes anteriorly and superiorly within the transverse mesocolon, just to the right of the midline. As it approaches the colon, it usually divides into right and left branches. The right branch anastomoses with the ascending branch of the right colic artery. The left branch supplies the terminal part of midgut derivatives and anastomoses with a branch of the left colic artery near the left colic flexure. The marginal artery thus formed lies a few centimetres from the mesenteric edge of the transverse colon. Sometimes, the middle colic artery divides into three or more branches within the transverse mesocolon, in which case the most lateral branches form the arterial anastomoses. An accessory, or rarely a replaced, middle colic artery can arise directly from the abdominal aorta (Yoshida et al 1993), dorsal pancreatic, hepatic, inferior mesenteric or left colic arteries (Fig. 65.25). In addition, an accessory middle colic artery is occasionally found arising from the superior mesenteric artery proximal to the origin of the actual middle colic artery (Turmezei and Cockburn 2009).

Veins

All the branches of the superior mesenteric artery are accompanied by correspondingly named veins. These tributaries drain into the superior mesenteric vein, which ascends to the right of the artery, crossing the horizontal part of the duodenum and uncinate process of the pancreas. Behind the neck of the pancreas, at the level of the transpyloric plane (the inferior border of the body of the first lumbar vertebra), it joins the splenic vein to form the hepatic portal vein, which ascends behind the superior part of the duodenum to reach the liver. The right colic vein is highly variable: it can drain either directly into the superior mesenteric vein, or into the right gastro-omental or inferior pancreaticoduodenal veins to form a 'gastrocolic trunk' that drains into the superior mesenteric vein, or it can be entirely absent (Yamaguchi et al 2002, Stefura et al 2018). Several tributaries draining into one or more middle colic veins are highly variable in extent and position. The middle colic veins drain either into the superior mesenteric vein, just before its junction with the splenic vein, or directly into the hepatic portal vein. The appendicular vein usually joins the caecal vein to become the ileocolic vein; infection from the appendix can therefore be carried directly to the liver via the hepatic portal vein.

Lymphatic drainage

Lymphatic vessels originate from both anterior and posterior aspects of the colon. Lymph drainage from midgut derivatives follows the course of the superior mesenteric artery. Thus, lymph from the caecum and appendix drains to nodes associated with the ileocolic artery, and lymph from the distal ascending colon and right colic flexure drains to nodes along the right colic artery (see Fig. 65.16). When the distal transverse colon and left colic flexure are predominantly supplied by the middle colic artery, lymph drainage of this segment is also largely to superior mesenteric nodes. Lymphatic vessels in the appendix are numerous and combine to form vessels that ascend in the meso-appendix, occasionally interrupted by one or more nodes. They unite to form three or four larger vessels that anastomose with lymphatic vessels draining the ascending colon into ileocolic nodes.

HINDGUT-DERIVED REGION OF LARGE INTESTINE

Left colic flexure

The left colic flexure marks the junction between the transverse and descending colons and lies in the left hypochondriac region, anterior to the tail of the pancreas and the left kidney (Fig. 65.26). Its position

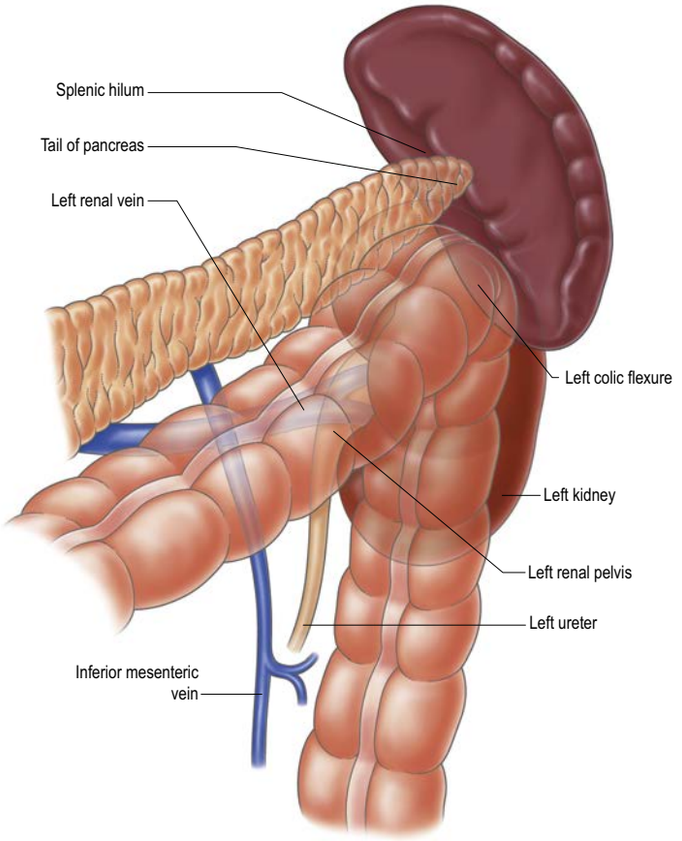

Fig. 65.26 Relations of the left colic flexure.

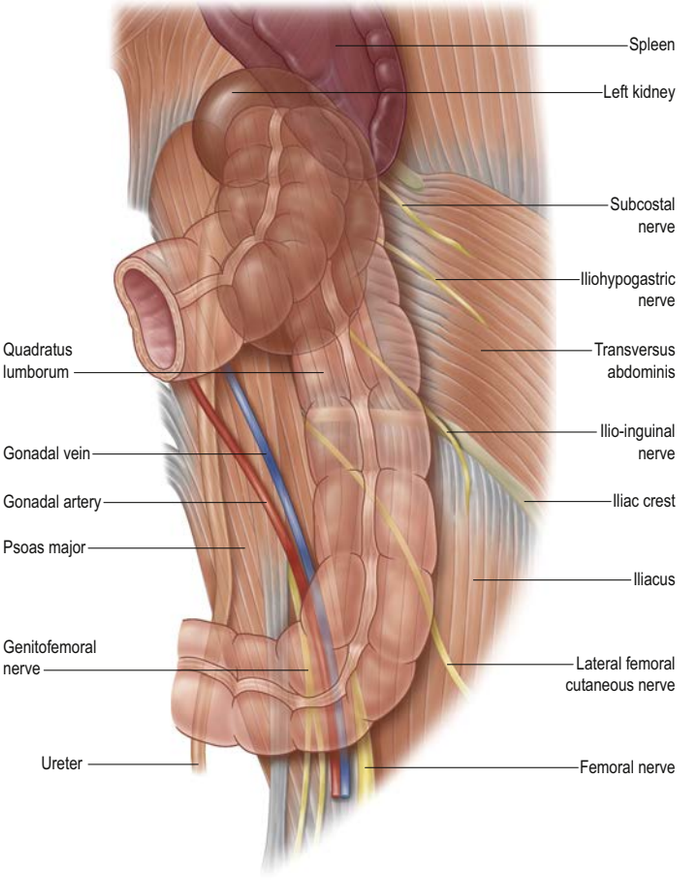

Fig. 65.27 Posterior relations of the descending colon.

with respect to the spleen is variable: it usually lies inferomedial to the anterior extremity, forming the colic impression, but it can lie anterior to the splenic hilum or even a little above. The left colic flexure is often attached to the splenic capsule by a peritoneal ligament and inadvertent downward traction on the flexure during surgery can tear the capsule. The phrenicocolic ligament attaches the left colic flexure to the respiratory diaphragm below the anterior extremity of the spleen at about the level of the tenth rib. The left colic flexure lies more superiorly and posteriorly than the right colic flexure and often adopts a very acute angle such that the distal transverse colon overlaps the proximal descending colon; there may be peritoneal and omental adhesions between the two structures.

Descending colon

The descending colon is 25–30 cm long and descends from the left colic flexure in the left hypochondriac region to the level of the iliac crest, where it curves medially anterior to iliacus to transition to the sigmoid colon. In most individuals it is retroperitoneal, covered anteriorly and on both sides by peritoneum, but it is occasionally more mobile, being suspended from the posterior abdominal wall by a short mesocolon (Saunders et al 1995). Its lateral peritoneal reflection in the left paracolic gutter is marked by a white line (of Toldt). The posterior surface of the descending colon is separated by a layer of loose connective tissue from the anterior layer of renal fascia inferolateral to the left kidney, transversus abdominis, quadratus lumborum, iliacus and the lateral margin of psoas major (Fig. 65.27). The subcostal vessels and nerve, iliohypogastric, ilio-inguinal, lateral femoral cutaneous, femoral and genitofemoral nerves, and, usually, the fourth lumbar artery also lie posteriorly, and loops of jejunum are anterior. The descending colon is narrower and more deeply placed than the ascending colon. Omental appendices are more common in this part of the colon.

Sigmoid colon

The sigmoid colon runs from the greater pelvis to the beginning of the rectum at the level of the third sacral vertebra. It is usually suspended from the posterior abdominal and pelvic walls by a fan-shaped sigmoid mesocolon, but may be tethered by congenital adhesions to the parietal peritoneum over iliacus. Consequently,

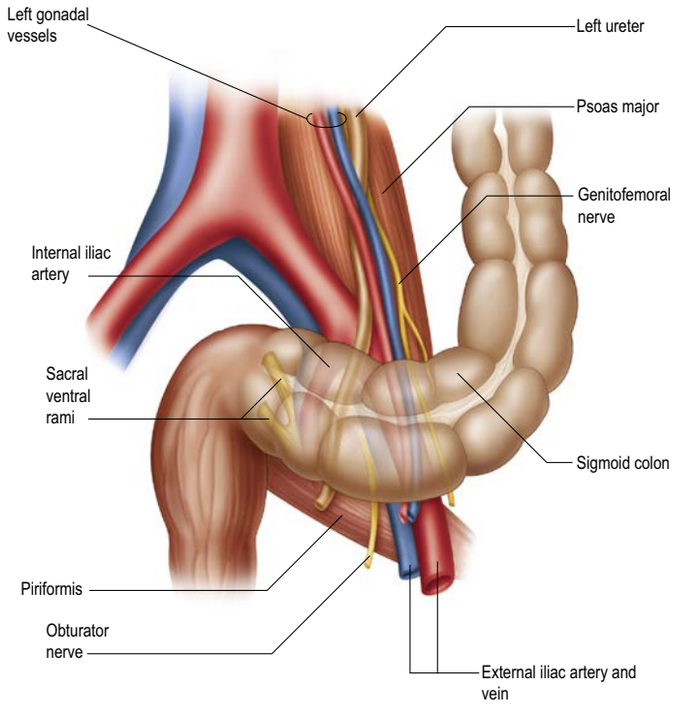

Fig. 65.28 Posterior relations of the sigmoid colon.

its length and position are highly variable. It usually lies within the pelvic cavity anterior to the rectum on the peritoneum covering the urinary bladder (and uterus in the female). It is usually completely invested in peritoneum. The root of the sigmoid mesocolon has an inverted V-shaped attachment; the right limb of this inverted 'V' ascends from a point anterior to the third sacral vertebra to the bifurcation of the left common iliac vessels (crossed by the left ureter) and descends from this point along the external iliac vessels.

Between the fixed junctions with the descending colon and rectum, the relations of the sigmoid colon are quite variable (Fig. 65.28). Laterally lie the left external iliac vessels, the obturator nerve, ovary or ductus deferens, and the lateral pelvic wall; posteriorly lie the left external and internal iliac and gonadal vessels, ureter, piriformis and the sacral plexus; anteroinferiorly lie the urinary bladder in males, or the uterus and urinary bladder in females; superiorly and to the right, the sigmoid colon is in contact with loops of the ileum. The gonadal vessels and ureter lie in a distinct fascial plane, which is the inferior extension of the renal fascia and is separate from the sigmoid mesocolon. This plane can be recognized and separated during surgical resection of the sigmoid mesocolon. The taeniae coli of the sigmoid colon are wider than elsewhere in the colon, and coalesce at its distal end to form a complete circumferential longitudinal muscle layer. Omental appendices are particularly prominent in the sigmoid colon.

The position and shape of the sigmoid colon depend on its length (which increases with age) and mobility; the length of the sigmoid mesocolon (usually longer in males); and the degree of distension of the colon, rectum, urinary bladder and uterus. The length of the sigmoid colon and its mesosigmoid differ among ethnic groups (Alatise et al 2013).

Sigmoid volvulus Rotation or volvulus of the sigmoid colon can occur around its mesenteric attachment. Volvulus is more likely when the sigmoid colon is longer and its mesosgimoid is longer and wider (Akinkuotu et al 2011). It does not occur when the sigmoid colon and its mesocolon are short. The anatomical features predisposing to sigmoid volvulus are most commonly found in sub-Saharan Africans and chronically institutionalized patients.

Diverticular disease Acquired diverticula commonly occur in the sigmoid colon, particularly in Western populations. Most patients with diverticular disease are asymptomatic, 10–25% progress to diverticulitis, and 10–15% of those develop complications (Kaushik et al 2016). These diverticula frequently develop in parallel rows between the mesenteric taenia coli and the two antimesenteric taeniae where the colonic wall is weaker; at this site the outer longitudinal muscle is deficient and the circular muscle is traversed by arteries supplying the submucosal vascular plexus (Slack 1962). However, the predilection to diverticula in the sigmoid colon probably relates to causative factors rather than intrinsic differences in the structure of this segment of the colon. In contrast, congenital diverticula can occur at any site in the colon (Fig. 65.29) and are often found along the mesenteric border.

Mesocolon

The mesocolon extends along the entire length of the colon and is continuous with the small intestine mesentery proximally and the mesorectum distally. The mesocolon consists of fat embedded within a connective tissue lattice and sandwiched between two layers of mesothelium; it also contains nerves, blood and lymphatic vessels, and lymph nodes. A layer of loose connective tissue, known as Toldt's fascia, lies immediately posterior to the mesocolon (Culligan et al 2014). Complete excision of the relevant segment of mesocolon by dissecting within or posterior to the plane of Toldt's fascia has been shown to improve survival in colon cancer (Søndenaa et al 2014).

Rectum

The rectum is continuous with the sigmoid colon at the level of the third sacral vertebra and ends as it passes through the pelvic diaphragm (the pubo-analis (puborectalis) part of levator ani) (Fig. 65.30), where it is continuous with the anal canal. It descends within the concavity of the sacrum and coccyx, at first running posteriorly and then curving anteriorly. The junction between the anteriorly directed distal rectum and the posteriorly directed anal canal is the anorectal flexure, which is maintained by pubo-analis. This is 2–3 cm anterior to and slightly below the tip of the coccyx, level with the apex of the prostate in males. The rectum also deviates in three lateral curves: upper, convex to the right; middle (the most prominent), convex to the left; and lower, convex to the right. Both ends of the rectum are in the median plane.

Although variable in absolute length, the rectum is often defined in clinical practice as extending approximately 15 cm above the anal orifice. Its proximal diameter is similar to that of the sigmoid colon, but more distally it becomes dilated as the rectal ampulla. Unlike the sigmoid colon, the rectum has no haustra, omental appendices or taeniae coli. The taeniae merge a few centimetres above the rectosigmoid junction, initially forming wide anterior and posterior muscular bands; these then fuse to form a continuous outer layer of longitudinal muscle investing the entire length of the rectum. At the rectal ampulla, a few longitudinal muscle fibres pass forwards from the anterior rectal wall to the perineal body and urethra (recto-urethralis).

The proximal third of the rectum is covered by peritoneum on its anterior and lateral aspects, and the middle third by peritoneum on its anterior aspect only; the distal third is below the peritoneum. The peritoneum is reflected anteriorly on to the urinary bladder in males to form the rectovesical pouch, or on to the posterior part of the vaginal fornix in females to form the recto-uterine pouch (of Douglas). The level of this reflection is more superior in males. In male neonates, the peritoneum extends on the anterior rectal wall as far as the inferior limit of the prostate. Superiorly, it is firmly attached to the muscle layer of the sigmoid colon by fibrous connective tissue, but as it descends on to the rectum it is more loosely attached by fatty connective tissue, which allows considerable expansion of the proximal half of the rectum.

When the rectum is empty, the mucosa has several longitudinal folds in its inferior part, which become effaced during distension. The rectum commonly has two to three permanent semilunar transverse rectal folds (although the number can vary), which are most marked in rectal distension (see Fig. 65.10) (Abramson 1978). Two types of transverse rectal folds have been recognized. One consists of the mucosa, the circular muscle layer and part of the longitudinal muscle, and is marked externally by an indentation. The other is devoid of longitudinal muscle and has no external marking. When three transverse rectal folds are found, the most superior fold at the beginning of the rectum can be on either the left or the right and it occasionally encircles the rectal lumen. The middle fold is largest and most constant and lies immediately superior to the rectal ampulla, projecting from the anterior and right wall just below the level of the anterior peritoneal reflection; the circular muscle is particularly prominent in this fold. The inferior fold is on the left and is the most variable. Although the function of these structures is unknown, some have opined that they might retard faecal passage allowing for distinction between faeces and flatus (Shafik et al 2001).

Relations Posterior to the rectum and mesorectum, separated by the presacral fascia, are the lower three sacral vertebrae, coccyx, median and lateral sacral vessels, and the most distal portion of the sacral part of the sympathetic trunk. Laterally, the proximal rectum is related to the sigmoid colon and/or small intestine, while below the peritoneal reflection lie levator ani, obturator internus, the obturator nerve and vessels, ureters, the inferior hypogastric plexus, internal iliac vessels, piriformis and the sacral plexus. Anteriorly, the rectum is related to the sigmoid colon and/or small intestine in both sexes, and the fundus of the urinary bladder, seminal glands, ductus deferens, terminal parts of the ureters, and the prostate in males (see Figs 65.34, 74.17). In females, the cervix/body of the uterus and vagina are anterior, the latter separated from the rectum by a rectovaginal septum. In postmenopausal females, and after childbirth, the connective tissue of the rectovaginal septum can atrophy or become thinned, reducing the support of the anterior rectal and posterior vaginal walls.

Mesorectum and rectal fasciae

The mesorectum is the distal continuation of the mesosigmoid. It encases the proximal rectum posterolaterally and the distal rectum circumferentially and tapers towards the anorectal junction (Figs 65.31–65.36). It contains adipose connective tissue, the superior anorectal artery and its branches, the superior anorectal vein and its tributaries and lymphatic vessels and nodes. It is much bulkier posteriorly and is enclosed by mesorectal fascia, a distinct layer of connective tissue that is also called the fascia propria of the rectum and that separates the mesorectum from the bony pelvis (see Figs 65.31, 65.32). This fascia limits the mesorectum posteriorly and lies anterior to the presacral fascia (of Waldeyer), separated by a so-called retrorectal 'space'. The rectum and mesorectal fascia are connected to the parietal fascia of the pelvis by two 'lateral ligaments' and one posterior ligament, the rectosacral fascia (Gaudio et al 2010). The latter is a thin layer of connective tissue that passes obliquely downwards from the presacral fascia to fuse with the mesorectal fascia posterior to the rectum 3–5 cm above the anorectal junction (García-Armengol et al 2008). The mesorectal fascia is surrounded by a thin and relatively avascular layer of loose areolar tissue, which separates

In prolapse of the rectum involving all layers of the rectal wall, the mid and proximal rectum descend towards the pelvic diaphragm on straining. Descent occurs within the lumen of the rectum as a form of intussusception, and could be a consequence of the large diameter of the rectal ampulla and relative fixation of the anal canal. The loose adipose tissue of the upper mesorectum and the 'lateral ligaments' offer only limited resistance against rectal descent. It is common for the region around the anus and rectum bound by levator ani to be chronically enlarged in patients suffering from recurrent rectal prolapse, but this is probably a consequence rather than a cause of the prolapse. In females, the recto-uterine pouch also descends with the anterior rectal wall.

When the rectovaginal septum is grossly effaced, especially in postmenopausal females, the pressure of defecation can cause bulging of the rectal wall into the posterior vagina and, in extreme cases, through the vaginal orifice. Weakness of the pelvic diaphragm contributes to the prolapse by allowing the perineum to descend during straining.

An important concept in the surgical treatment of adenocarcinoma of the rectum is the need to excise the rectum in continuity with the mesorectum and its contained lymph nodes in order to avoid local tumour recurrence (Heald et al 1982). In total mesorectal excision, the posterolateral plane of dissection is outside the mesorectal fascia but anterior to the presacral fascia and its underlying venous plexus. Laterally, the plane is interrupted only by small branches of the middle anorectal vessels; anteriorly, it merges with the rectovesical or rectovaginal septum. The inferior hypogastric plexus is closely related to the plane of dissection laterally; these nerves must be preserved to retain urinary bladder and sexual function. Total mesorectal excision involves complete excision of the rectum down to the level of the pelvic diaphragm, where the pubo-analis component of levator ani merges with the deep component of the external anal sphincter. Superiorly, the inferior mesenteric artery is ligated near its origin.

In abdominoperineal excision of the rectum, it should be noted that the mesorectum becomes extremely thin at the point where the rectum passes through levator ani. To achieve adequate surgical margins, the plane of dissection is through the ischio-anal fossa and levator ani outside pubo-analis and into the mesorectal plane well above the pelvic diaphragm.

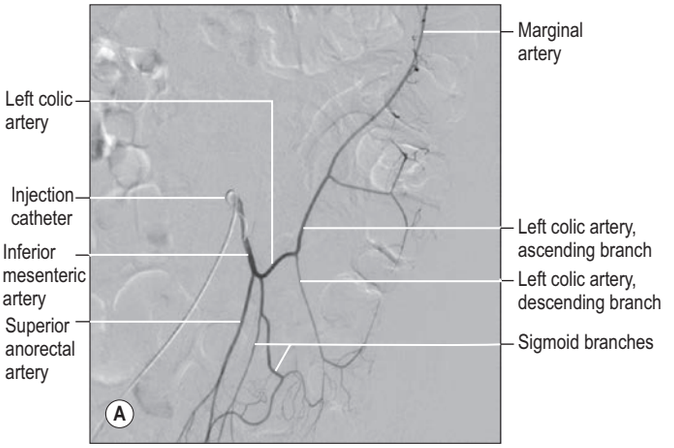

Fig. 65.37 A, Digital subtraction angiogram of the inferior mesenteric artery. (B, *continued online*)

it from the posterior and lateral walls of the true pelvis. Superiorly, the mesorectal fascia blends with the connective tissue bounding the mesosigmoid. Laterally, it extends around the rectum and mesorectum, and becomes contiguous anteriorly with a denser condensation of fascia, Denonvilliers' fascia. A number of terms are used interchangeably for the fascia in this region, thus, for example, this fascia is also known as the rectovesical septum in males although it extends caudal to the urinary bladder and is particularly dense posterior to the prostate and seminal glands (prostato-seminal fascia); it lies immediately anterior to the mesorectal fascia, to which it may be fused (Lindsey et al 2000). It appears that there is no clearly identified membranous layer consistent with Denonvilliers' fascia between the posterior vaginal and the anterior rectal walls (Zhang et al 2016).

The mesorectal fascia is visible by CT, MRI and dissection (Bissett et al 2001). On MRI, the mesorectum appears as a fat-filled envelope containing blood vessels and lymph nodes; small nerves are not visible but interlacing connective tissue strands can be seen. The mesorectal fascia is recognizable on axial MRI as a low-signal layer surrounding the mesorectum, corresponding to a distinct condensation of fascia seen on histological sections (Brown et al 1999). Identification of this layer in patients with a malignant rectal tumour can help predict the success of surgical resection. Branches of the inferior hypogastric plexus and middle anorectal vessels enter the mesorectum anterolaterally: they are ensheathed by fascia and are sometimes referred to collectively as the 'lateral rectal ligaments'. The number and calibre of the middle anorectal vessels are highly variable; they can be very small or even absent (Sato and Sato 1991). The 'lateral ligaments' are not clearly seen on MRI or CT, and only appear as an identifiable structure with surgical traction on the rectum. The fascia of the 'ligaments' is flimsy and probably contributes little to support of the rectum. Parietal fascia covers levator ani and the muscles of the side wall of the pelvis, and is continuous posteriorly with the presacral fascia.

Vascular supply and lymphatic drainage of the hindgut-derived intestine

Arteries

Inferior mesenteric artery

The artery of the hindgut-derived gut is the inferior mesenteric artery (Figs 65.37–65.39), which arises from the anterior or left anterolateral aspect of the aorta behind the inferior border of the horizontal (third) part of the duodenum 3–4 cm above the aortic bifurcation, at the level of the third lumbar vertebra. It runs obliquely down to the linea terminalis (pelvic brim) initially anterior to and then to the left of the abdominal aorta. It gives off the left colic and sigmoid arteries and crosses the origin of the left common iliac artery medial to the ureter, with the inferior mesenteric vein lying between. Beyond the linea terminalis it continues in the root of the sigmoid mesocolon as the superior anorectal artery.

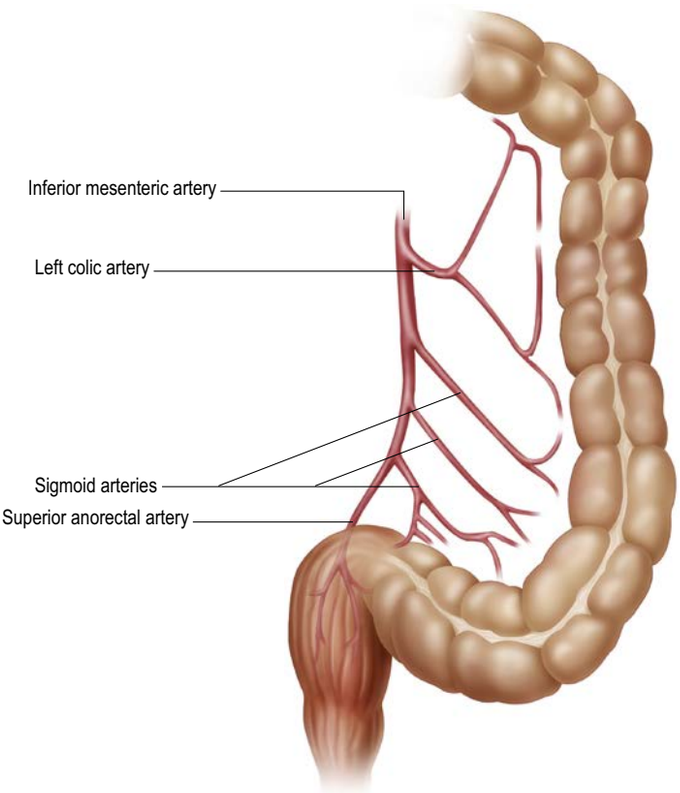

Fig. 65.38 The inferior mesenteric artery.

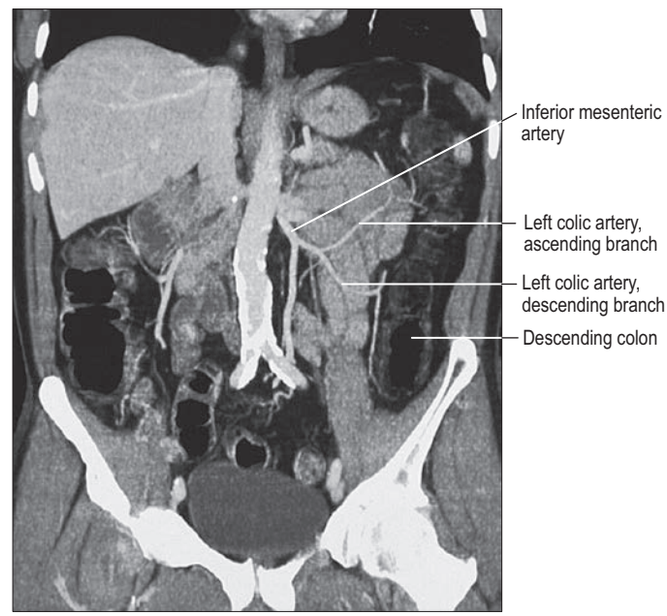

Fig. 65.39 Coronal reformat CT of the vascular supply of the descending colon from the inferior mesenteric artery via the ascending and descending branches of the left colic artery. (Courtesy of Dr Louise Moore, Chelsea and Westminster Hospital, London.)

Left colic artery

The left colic artery usually arises from the inferior mesenteric artery shortly after its origin, ascends within the left colic mesentery and divides into an ascending and a descending branch (see Figs 65.38–65.39). The ascending branch passes upwards across the left psoas major, gonadal vessels, ureter and left kidney, and is crossed by the inferior mesenteric vein; its terminal branches anastomose with those of the left branch of the middle colic artery within the

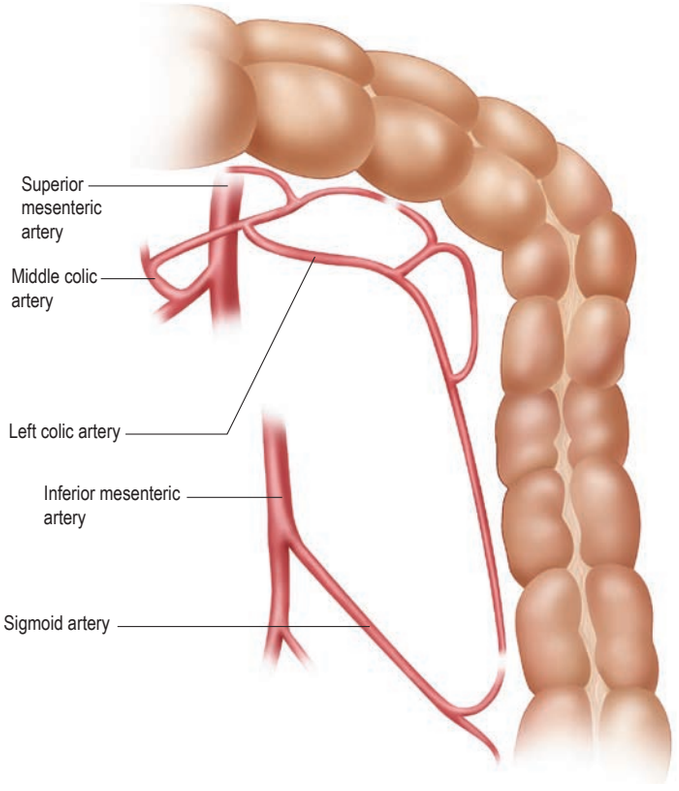

Fig. 65.40 A replaced left colic artery arising from the middle colic artery.

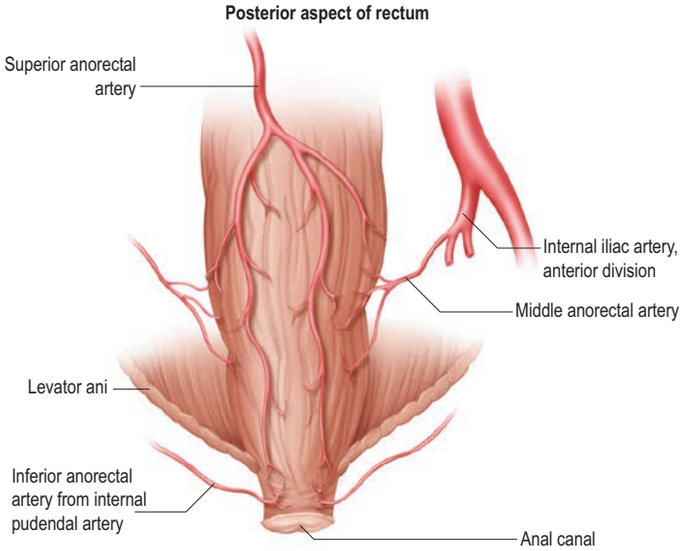

Fig. 65.41 The arterial supply of the rectum.

transverse mesocolon. The descending branch passes laterally and inferiorly and anastomoses with branches from the ascending branch and the most proximal sigmoid artery to form part of the marginal artery. The arterial arcades thus formed supply the distal third of the transverse and the descending colons. The left colic artery can originate from or in common with a sigmoid artery (Murono et al 2015). Occasionally, an accessory, or rarely, a replaced, left colic artery originates from the trunk of the superior mesenteric artery or its middle colic or first jejunal artery (**Fig. 65.40**). When present, it runs laterally in the upper left colic mesentery just inferior to the duodenojejunal flexure to supply the proximal descending colon, and forms all or part of the marginal artery in the region of the distal transverse colon. The left colic artery can itself give rise to an accessory left middle colic artery. Occasionally it gives rise to a branch shortly after its origin, which ascends in the mesentery and anastomoses directly with a similar descending branch of the left branch of the middle colic artery (the so-called arc of Riolan; van Gulik and Schoots 2005).

The dominant arterial supply of the left colic flexure is usually from the left colic artery but can be from the left branch of the middle colic artery. The marginal artery in this region may be absent or small, but it can enlarge considerably if the inferior mesenteric artery is stenosed or occluded.

Sigmoid arteries

The inferior mesenteric artery gives rise to between two and five sigmoid arteries, which descend obliquely in the sigmoid mesocolon anterior to the left psoas major, ureter and gonadal vessels. They supply the distal descending colon and sigmoid colon and anastomose superiorly with the left colic artery and inferiorly with the superior anorectal artery. Unlike the arrangement in the small intestine, arterial arcades do not form until the arteries are close to the wall of the colon, when small branches arise to supply the sigmoid colon directly. A true marginal artery is less obvious in the sigmoid colon. There is often a significant interval in the mesentery between the highest sigmoid artery and the descending branch of the left colic artery; this forms a useful guide to the arterial territories during surgical dissection.

Vascular ligation in left colonic resections

During resection of the distal descending and sigmoid colon, ligation of the inferior mesenteric artery close to its origin preserves the bifurcation of the left colic artery and helps to maintain the arterial supply to the proximal descending colon via the anastomosis between the left branch of the middle colic artery and the ascending branch of the left colic artery. Ligation of the left colic artery close to its bifurcation can interfere with this supply and render the proximal descending colon ischaemic. Similarly, if the inferior mesenteric vein is ligated, then the bifurcation of the left colic vein forms the route of venous drainage from the proximal descending colon to the middle colic vein.

Superior anorectal artery

The principal arterial supply to the upper two-thirds of the rectum is via the superior anorectal artery (**Fig. 65.41**). The inferior mesenteric artery crosses the left common iliac vessels medial to the ureter and descends in the medial limb of the sigmoid mesocolon, straddled by the hypogastric nerves on either side. As it crosses the linea terminalis it becomes the superior anorectal artery. At the level of the third sacral vertebra, where the rectum begins, the artery enters the proximal mesorectum in the midline and divides into two branches that descend, initially posterolaterally and then on each side of the rectum. Terminal branches pierce the rectal wall and anastomose with branches of the middle anorectal and inferior anorectal arteries within the rectal submucosa.

Middle and inferior anorectal arteries

The middle anorectal arteries, when present, arise from the internal pudendal, inferior gluteal, internal iliac arteries and less frequently from other internal iliac artery branches (DiDio et al 1986, Bilhim et al 2013). When present, they enter the mesorectum anterolaterally in the 'lateral ligaments' and provide some additional supply to the middle third of the rectum. The inferior anorectal arteries are terminal branches of the internal pudendal arteries. They cross the ischio-anal fossa to enter the proximal anal canal laterally and supply the internal and external anal sphincters, the anal canal and peri-anal skin. Ascending branches supply the distal third of the rectum, anastomosing with terminal branches of the superior anorectal artery in the rectal submucosa. The rectum also rarely receives a small arterial supply from the median sacral artery via a branch that enters posteriorly at the level of the anorectal junction (Young 1897).

Veins

Inferior mesenteric vein

The inferior mesenteric vein drains the rectum and the sigmoid, descending and distal transverse colon (see Fig. 65.15; **Fig. 65.42**). It begins as the continuation of the superior anorectal vein from the rectal plexus, through which it connects with the middle anorectal and inferior anorectal veins. The inferior mesenteric vein lies to the left of the inferior mesenteric artery in the retroperitoneum and ascends anterior to the left psoas major and left ureter; it may cross the gonadal vessels or ascend medial to them. It lies just lateral or occasionally posterior to the duodenojejunal flexure, where it can be located intraoperatively. The inferior mesenteric vein receives the superior anorectal vein, several sigmoid veins and the left colic vein. It usually passes posterior to the inferior border of the body of the pancreas and anterior to the left renal

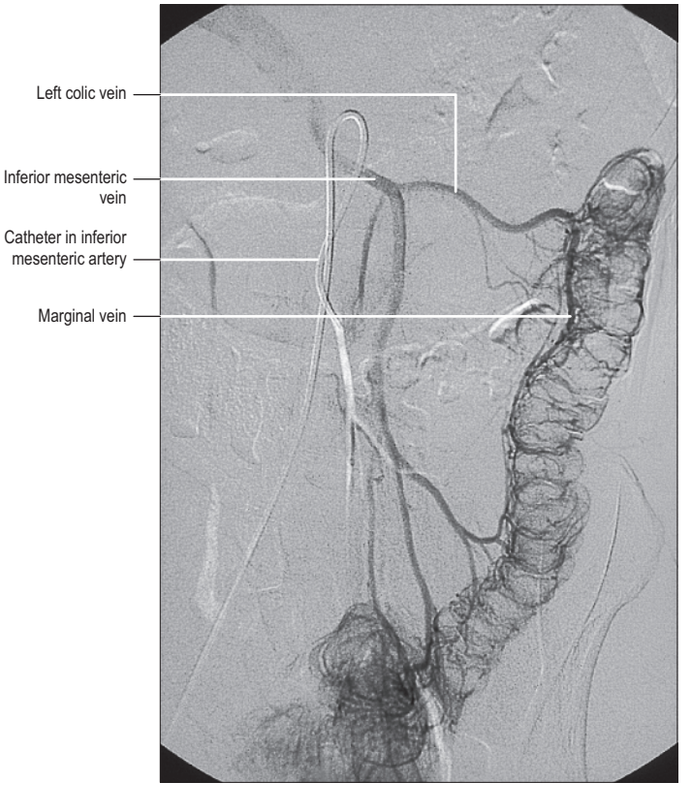

Fig. 65.42 The inferior mesenteric vein and its tributaries, digital subtraction arteriogram. (Courtesy of Dr Adam Mitchell, Charing Cross Hospital, London.)

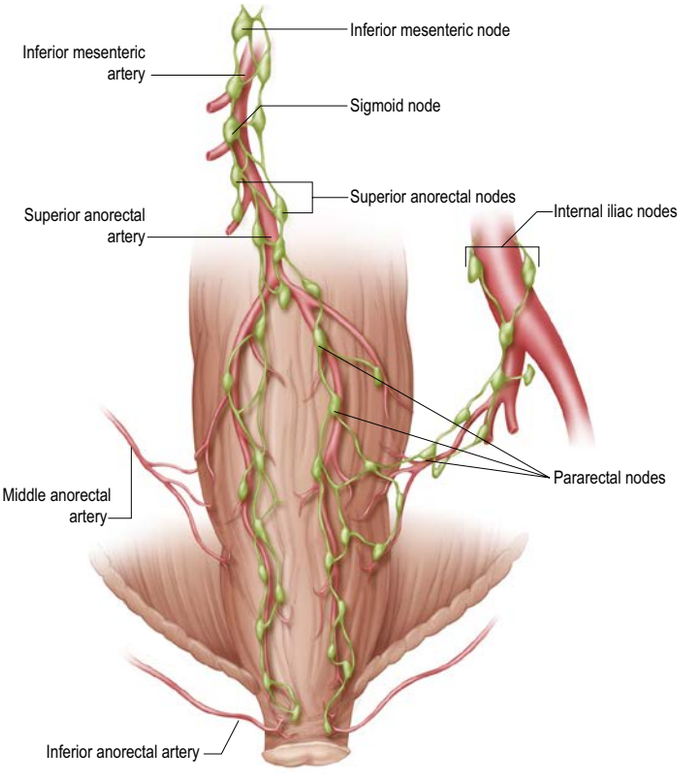

Fig. 65.43 Lymph nodes of the rectum and proximal anal canal (posterior view).

vein to drain into the splenic vein, but it can also drain into the confluence of the splenic and superior mesenteric veins or directly into the superior mesenteric vein (Graf et al 1997).

Rectal venous plexus

The rectal venous plexus surrounds the rectum and connects anteriorly with the vesical plexus in males or the uterine and vaginal venous plexuses in females. It consists of internal veins beneath the mucosa of the rectum and proximal anal canal, and external veins lying outside the muscular wall. The proximal two-thirds of the rectum and the internal part of the rectal venous plexus drain mainly to the superior anorectal vein and, from there, to the inferior mesenteric vein; the middle third of the rectum drains via one or more middle anorectal veins into the internal iliac vein; and the distal third of the rectum and anal canal drains via inferior anorectal veins into the internal pudendal veins. The rectal venous plexus is therefore a site of communication between the hepatic portal and systemic venous systems.

Superior anorectal vein

Venous tributaries from the rectal venous plexus ascend in the rectal submucosa and pierce the rectal wall to form the superior anorectal vein. This runs in the proximal mesorectum and root of the sigmoid mesocolon to the left of the superior anorectal artery, crossing the linea terminalis and left common iliac vessels to form the inferior mesenteric vein (see Fig. 65.44).

Left colic vein

The left colic vein is formed from several tributaries, including ascending and descending branches that correspond to the similarly named arteries. The left colic vein usually lies superior to its corresponding artery, and has a shorter course because the inferior mesenteric vein lies lateral to the inferior mesenteric artery (see Fig. 65.42). Occasionally there are two left colic veins that both drain into the inferior mesenteric vein (Tubbs et al 2016).

Lymphatic drainage

Small lymphoid aggregates measuring no more than a few millimetres are occasionally visible on the surface of the large intestine (epicolic and epirectal nodes). Lymph from the descending colon drains to paracolic nodes in the mesentery adjacent to the colon and from there to intermediate nodes along the left colic artery (Jamieson and Dobson 1909). Lymphatics from the sigmoid colon follow a similar pathway from paracolic to intermediate nodes in the sigmoid mesocolon. Intramural lymph from the rectum and anal canal above the pectinate line drains predominantly to pararectal nodes in the adipose tissue of the mesorectum and then along lymphatics accompanying the superior anorectal artery (**Fig. 65.43**). These intermediate nodes then drain to lymph nodes along the inferior mesenteric artery and from there to pre-aortic nodes. Some lymphatics from the distal rectum travel with the middle and inferior anorectal arteries to internal iliac nodes and along the median sacral artery to sacral nodes. The clinical significance of such drainage for the spread of malignancy from the distal rectum is debated (Bell et al 2009).

Innervation of the large intestine

The innervation of the large intestine is complex and includes the enteric nervous system (made up of motor neurones, intrinsic sensory neurones and interneurones lying within the wall of the gut); the autonomic nervous system (sympathetic and parasympathetic innervation); and extrinsic sensory innervation (visceral afferents) (Brookes et al 2009).

The enteric nervous system consists of ganglionated nerve plexuses lying in the submucosa (Meissner's plexus) and between the longitudinal and circular smooth muscle layers (Auerbach's myenteric plexus). Collectively, these nerves are concerned with control of mucosal functions (secretion, blood flow) and the propulsion of luminal contents by rhythmic and synchronized contractions. Motor neurones can be inhibitory or excitatory. Intrinsic sensory neurones are activated by mechanical stimuli such as stretch and muscle tension, and by chemical stimuli released by neuroendocrine cells in the wall of the gut (see Fig. 3.28). Sensory neurones project locally on to myenteric interneurones and motor neurones, allowing reflex activity to spread along the gut. Interstitial cells of Cajal are present within the submucous and myenteric neural plexuses. In summary, they act as a link between smooth muscle cells and extrinsic neurones, and are responsible for the intrinsic pacemaker activity of the gut; their activity is modulated by external autonomic nerves.

The large intestine is richly innervated by sympathetic neurones that originate either directly from the sympathetic trunk or indirectly via the aortic plexus; the former are mostly involved in the control of blood flow (vasoconstriction), while the latter also influence the secretory activity and motility of the gut. The cell bodies of preganglionic sympathetic fibres supplying the midgut-derived intestine are found in the intermediolateral nuclei of the fifth to the twelfth thoracic spinal segments and those of the hindgut-derived intestine in the intermediolateral nuclei of the first and second lumbar spinal segments. Postganglionic sympathetic neurones from both sources release noradrenaline (norepinephrine), causing presynaptic inhibition within enteric circuits, slowing gut motility and driving

contraction of sphincters, e.g. internal anal sphincter. Sympathetic supply to the midgut-derived intestine is conveyed to the coeliac and superior mesenteric plexuses via the greater and lesser thoracic splanchnic nerves; postganglionic axons are distributed with branches of the superior mesenteric artery. Sympathetic supply to the hindgut-derived intestine is conveyed via the lumbar splanchnic nerves that synapse in the abdominal aortic and inferior mesenteric plexuses, and via sacral splanchnic nerves that synapse in the superior and inferior hypogastric plexuses; postganglionic fibres are distributed with branches of the inferior mesenteric artery and are inhibitory to smooth muscle of the hindgut-derived colon.

The midgut-derived intestine receives its parasympathetic innervation from the vagus nerve, via the coeliac and superior mesenteric plexuses, whereas the hindgut-derived intestine receives its parasympathetic innervation from the pelvic splanchnic nerves. The cell bodies of the pelvic splanchnic nerves are located in the second to fourth sacral spinal cord segments, the sacral parasympathetic nucleus. These parasympathetic fibres enter the inferior hypogastric plexus, where some synapse. From here, some pass directly to the rectum and other pelvic viscera while others ascend by one of two routes: either within the hypogastric nerves to the superior hypogastric plexus to be distributed along branches of the inferior mesenteric artery, or by passing directly through the retroperitoneal tissues to reach the left colic flexure and the descending and sigmoid colon. Most preganglionic parasympathetic neurones synapse in intramural plexuses in the gut wall; from there, postganglionic neurones innervate the glands (secretomotor) and muscle (motor) of the large intestine. Parasympathetic stimulation is integral to colonic propulsion and defecation and to relaxation of the internal anal sphincter.

Visceral afferent impulses mediating sensations of distension and spasm from the midgut-derived intestine travel with the vagus nerve while the hindgut-derived intestine is innervated by afferent neurones with cell bodies in the lumbar (mostly L2 and L3) and sacral (mostly S1 and S2) dorsal root ganglia and these travel alongside autonomic nerves (Brookes et al 2009). Visceral afferent innervation of intramural colonic blood vessels probably conveys the sensation of colonic distension (Song et al 2009), while visceral afferents in the rectum convey the sensation of rectal filling and are involved in reflex propulsive activity.

Motor function of the large intestine

Healthy colorectal function includes absorption of water and sodium from the intestinal lumen, net antegrade propulsion of intestinal contents at an adequate rate, and temporary faecal storage. Colonic motor activity is greatest during the day and increases on waking and after meals. It is characterized by sustained tonic contractions and brief phasic contractions. Phasic contractions are subdivided according to whether or not they propagate along the colon. Non-propagating contractions are associated with segmental mixing of luminal contents, whereas propagated sequences can be retrograde or antegrade. In the normal colon, antegrade activity is more frequent than retrograde sequences, which are seen more in the proximal colon. High-amplitude propagated contractions occur in adults 4–6 times per day, originate anywhere in the colon (but mostly proximally), and migrate for a variable distance distally (Narducci et al 1987, Bharucha 2012). They are often associated with defecation or passing flatus. The sigmoid colon exhibits cyclical bursts of motor activity, which may be important in modulating the delivery of faeces to the rectum. A high-pressure zone with unique contractile properties in response to sigmoid colon and rectal distension or contraction has been demonstrated in the distal sigmoid colon (the so-called rectosigmoid sphincter; Shafik et al 2003). Rectal motor activity is characterized by motor complexes that can be triggered by propagating contractions from the proximal colon and by the delivery of faeces or flatus from the sigmoid colon. However, since their propagation is frequently retrograde, it has been suggested that they help to keep the rectum empty, thereby preventing the untimely delivery of colonic contents.

ANAL CANAL

Although often defined differently between anatomists and clinicians, the anal canal begins at the pelvic diaphragm and ends at the anal orifice (**Figs 65.44–65.46**) (Lee and Kim 2018). It is directed posteriorly because the sling-like pubo-analis pulls the rectum anteriorly to create the anorectal flexure. The anal canal lies 2–3 cm anterior and slightly inferior to the tip of the coccyx, opposite the apex of the prostate in males. At the anal orifice, the squamous epithelium lining the distal anal canal becomes continuous with the skin of the perineum. The area of pigmentation of skin around the anal orifice corresponds approximately to the extent of the external anal sphincter. The anal orifice can

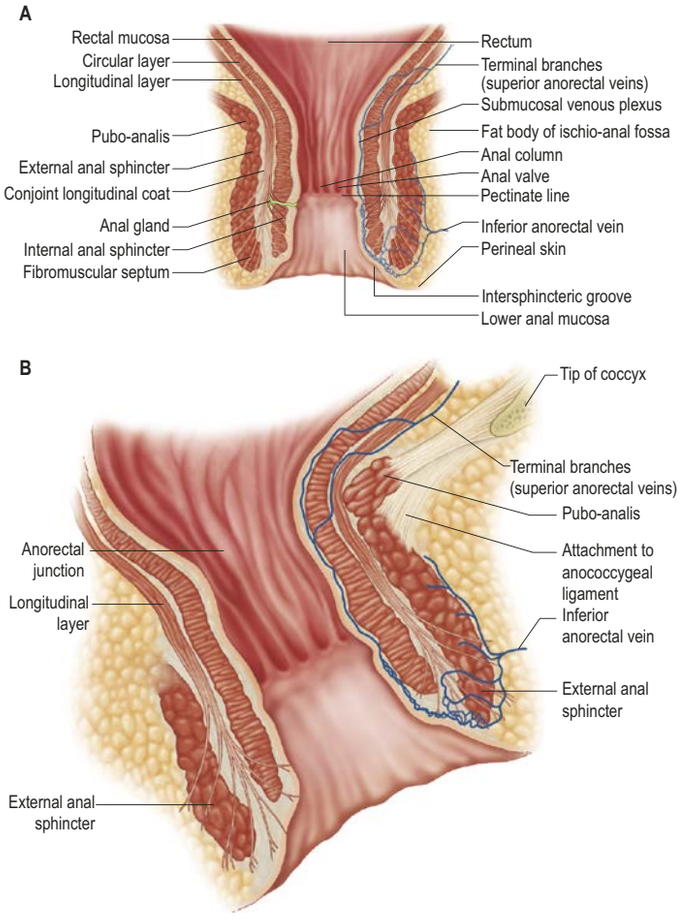

Fig. 65.44 A, A coronal section through the anal canal; glandular and vascular structures are shown unilaterally for clarity. **B**, A sagittal section through the anal canal; the anal canal is angled posteriorly and so anterior sphincteric structures appear to be lower than posterior structures. The glandular, vascular and fibromuscular structures have been omitted for clarity. (C, *continued online*)

be difficult to identify, particularly in males in whom the perineum can 'funnel' upwards into the distal anal canal, but the characteristic puckering of the skin formed by the penetrating fibres of the conjoint longitudinal muscle of the anal canal provides a useful landmark. Such penetrating fibres have been termed corrugator cutis ani.

The anal canal consists of an inner epithelial lining, a vascular subepithelium, the internal and external anal sphincters, fibromuscular supporting tissue, and dense neuronal networks of autonomic and somatic origin. Functionally, it represents a zone of high pressure. It is 2–5 cm long in adults; the anterior wall is slightly shorter than the posterior. It is usually shorter in females. At rest, it forms an oval or triradiate slit in the anteroposterior plane rather than a truly circular canal. The arrangement of the external anal sphincter and its attachments to the perineal body and coccyx create sites of maximum pressure in the anterior and posterior midline of the canal.

Anteriorly, the middle third of the anal canal is attached by dense connective tissue to the perineal body, which separates it from the membranous urethra in males and from the distal vagina in females. Laterally and posteriorly, the anal canal is surrounded by the loose adipose tissue of the ischio-anal fossae; this arrangement allows the canal to expand but offers a potential pathway for the spread of perianal sepsis. Posteriorly, it is attached to the coccyx via the anococcygeal ligament, a midline connective tissue band containing smooth and skeletal muscle fibres that runs between the posterior aspect of the middle region of the external anal sphincter and the coccyx. The anococcygeal ligament is traditionally regarded as lying just inferior to the midline raphe of levator ani but its relationship to the raphe is more complex (Kinugasa et al 2011). Kinugasa et al (2012) hypothesized that the classically described anococcygeal raphe is in fact, simply a superficial part of the anococcygeal ligament.

The ischial spines can be palpated laterally by an examining finger in the proximal anal canal. The pudendal nerves pass over the attachment of the sacrospinous ligament onto the ischial spine and pudendal nerve motor terminal latency can be measured digitally using a modified electrode worn on the examining glove.

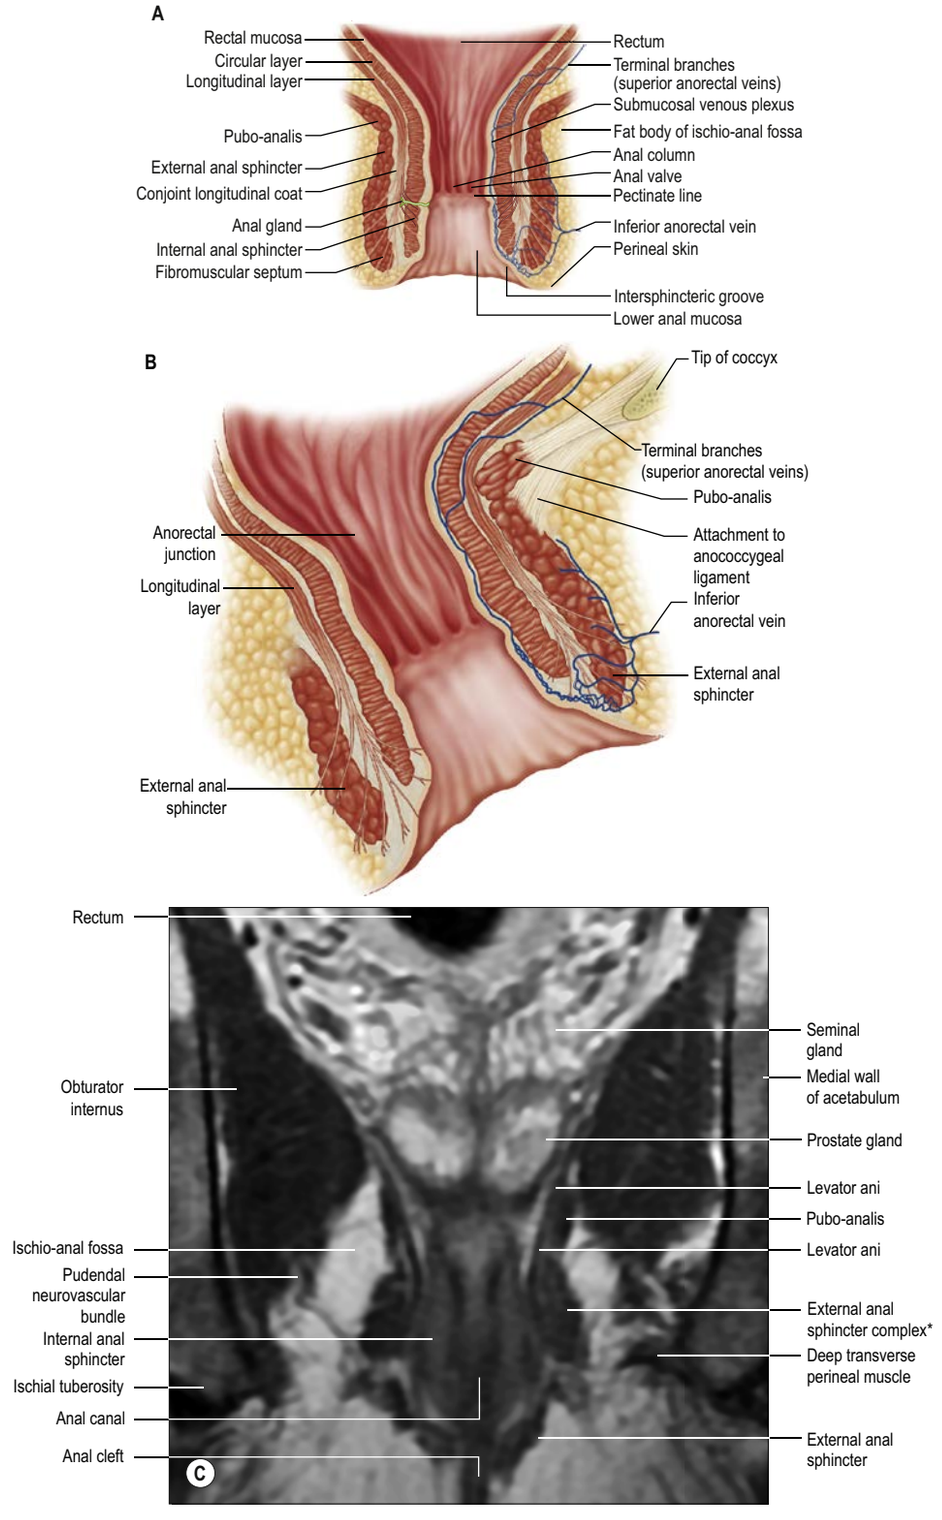

Fig. 65.44 A, A coronal section through the anal canal; glandular and vascular structures are shown unilaterally for clarity. **B**, A sagittal section through the anal canal; the anal canal is angled posteriorly and so anterior sphincteric structures appear to be lower than posterior structures. Lining of the anal canal

The proximal part of the anal canal is lined by reddish columnar epithelium similar to that of the rectum; it contains secretory and absorptive cells with numerous tubular intestinal glands. Distally, the epithelium becomes cuboidal and darker just above the level of the anal valves (Fig. 65.47). The subepithelial tissues are mobile and relatively distensible and contain submucosal arterial and venous plexuses.

In the mid anal canal there are 6–10 vertical mucosal folds, the anal columns (of Morgagni). These are better defined in children than in adults. They frequently contain a terminal branch of the superior anorectal artery and vein, supplemented to a variable degree by middle and inferior anorectal vessels (Thomson 1975). Dilated submucosal veins in the proximal anal canal form an internal rectal plexus. Tiny arteriovenous connections to these dilated submucosal veins give the blood within them a higher oxygen tension and therefore a redder colour than normal venous blood. The submucosal vessels are most prominent in the left-lateral, right-posterior and right-anterior quadrants of the wall of the canal (approximately 3, 7 and 9 o'clock when viewed in the lithotomy position); here, the subepithelial tissues are expanded into three 'anal cushions'. Although variable in number and position, these help to seal the anal canal and contribute to the maintenance of continence to flatus and fluid. The anal cushions are important in the pathogenesis of haemorrhoids. The distal ends of the columns form small crescentic folds, called anal valves, between which lie small recesses known as anal sinuses. The anal valves and sinuses together form the scalloped pectinate line, which is firmly anchored to submucosal connective tissue. Anal glands open into small depressions, anal crypts (sinuses), in the anal valves. The glands are branched and lined by stratified columnar epithelium. Cystic dilations in the intestinal glands can extend through the internal anal sphincter and even into the external anal sphincter (Seow-Choen and Ho 1994).

The epithelium below the pectinate line is smooth and typically shows an abrupt transition to parchment-coloured, non-keratinized, stratified squamous epithelium, which lacks sweat and sebaceous glands and hair follicles but contains numerous somatic sensory nerve endings conveying sensations of touch, pain and temperature (Duthie and Gairns 1960). It extends down to the intersphincteric groove, a palpable depression at the distal border of the internal anal sphincter. Distal to the intersphincteric groove, the anal canal is lined by hair-bearing, keratinizing, stratified squamous epithelium, which is continuous with the perianal skin. Dilated veins in the subepithelial tissue below the pectinate line contribute to an external rectal plexus (see Fig. 65.44); this can be seen on clinical examination as a circumferential ring at the anal orifice if the subject is asked to bear down.

The junction between the columnar epithelium above and the squamous epithelium below is referred to as the anal pecten. It is variable in length and position but often extends about 1 cm proximal to the pectinate line (Fenger 1987). There are nerve endings including thermoreceptors in the submucosa around the proximal anal transition zone; they probably play a role in continence by providing a highly specialized 'sampling' mechanism to identify the contents of the distal rectum when the proximal anal canal relaxes (Kadam-Halani et al 2018).

The well-defined muscularis mucosae of the rectum continues into the proximal anal canal. Some fibres from the conjoint longitudinal muscle of the anal canal traverse the internal anal sphincter and turn cranially to merge with the muscularis mucosae, forming the submucosal muscle of the anal canal (also called the musculus submucosae ani, or musculus canalis ani, or Treitz's muscle). Attachments of the longitudinal fibres to the submucosal muscle of the anal canal are particularly dense at the pectinate line (the mucosal suspensory ligament (of Parks)), causing the mucosa to be tethered more firmly at this level and approximately marking the watershed between the hepatic portal and systemic venous drainage of the rectal plexuses. The

attachments of fibres from the longitudinal muscle layer, the muscularis mucosae of the anal canal, also create 'spaces' within the submucosa: a proximal submucous space, a marginal space extending from the pectinate line to the intersphincteric groove, and a perianal space distally.

Muscles of the anal canal

The anal canal is surrounded by internal and external anal sphincters, separated by the conjoint longitudinal muscle layer, the whole arrangement being named the anal sphincter complex (**Figs 65.48–65.49**) (Al-Ali et al 2009). The anatomy of this region has been clarified in recent years using endoanal sonography and MRI.

Internal anal sphincter

The internal anal sphincter is the specialized, thickened terminal part of the inner circular muscle of the large intestine. It is thicker in males and in patients with chronic constipation. The muscle fibre arrangement is not truly circular, but rather a tight spiral that shortens and widens with relaxation. It commences at the anorectal junction and ends proximal to the anal orifice; its distal border is palpable at the intersphincteric groove. It is traversed by fibres passing medially from the conjoint longitudinal muscle into the submucosa.

The internal anal sphincter is tonically contracted at rest but it relaxes as a consequence of reflex activity, predominantly during defecation. Transient relaxation of the upper internal anal sphincter occurs in response to rectal distension (the recto-anal inhibitory reflex) and postprandial rectal contractions (the sampling reflex). Relaxation allows the distal rectal contents to pass into the proximal anal canal, enabling their physical nature to be consciously or subconsciously perceived; this is accompanied by sustained contraction of the distal internal anal sphincter and contraction of the external anal sphincter to maintain continence. The recto-anal inhibitory reflex is primarily mediated by the enteric nervous system, although spinal pathways could modulate it. It is absent in patients with Hirschsprung's disease.

Vascular supply and innervation

The internal anal sphincter is supplied by terminal branches of the superior rectal and inferior anorectal vessels and innervated extrinsically by autonomic nerves. Sympathetic fibres originate in the L1 and L2 parts of the spinal cord and parasympathetic fibres in the S2 to S4 parts of the spinal cord, both being distributed via the inferior hypogastric plexus. Stimulation of cholinergic muscarinic receptors (parasympathetic) causes internal anal sphincter relaxation and longitudinal anal muscle contraction, while α-adrenergic receptor stimulation (sympathetic) causes both the internal anal sphincter and longitudinal muscle to contract. Activation of nitrergic nerves also mediates internal anal sphincter relaxation and is the rationale for using topical nitroglycerine and other drugs that promote nitric oxide for treating pathological conditions associated with increased resting anal tone.

Conjoint longitudinal muscle

The conjoint longitudinal muscle of the anal canal is a direct continuation of the outer longitudinal smooth muscle of the rectum, descending between the internal and external anal sphincters, and augmented in its proximal part by striated muscle fibres from the medial aspect of levator ani (Lunniss and Phillips 1992). It is particularly prominent in the fetus, where it is actually thicker than the internal anal sphincter. With advancing age, there is gradual replacement of muscle by connective tissue, so the layer becomes thin in the elderly and few muscle fibres are seen in its distal part. As it passes down the anal canal, muscle fibres peel off in three directions: internally, through the internal anal sphincter to reach the anal submucosa; inferiorly, through the striated muscle of the distal and subcutaneous part of the external anal sphincter to insert into the perianal skin (some of these fibres, e.g. corrugator cutis ani encircling the anal orifice); and outwards, through the upper part of the external anal sphincter (see Fig. 65.44). The most inferior fibres create a honeycomb arrangement in the subcutaneous fat and separate a superficial perianal space from the deeper ischio-anal fossa. Additional ramifications of this muscle beyond the external anal sphincter have been described, emphasizing its central role in anorectal stability (Courtney 1950).

The conjoint longitudinal muscle is innervated by autonomic nerves that share their origin with those supplying the internal anal sphincter. Its contraction during defecation shortens and widens the anal canal and everts the anal orifice. The muscle degenerates and is gradually replaced by connective tissue with age (Haas et al 1984). Its extensions provide pathways for the spread and containment of infection.

External anal sphincter

The external anal sphincter forms the bulk of the anal sphincter complex. It is an oval tube of striated muscle composed mostly of type I slow twitch muscle fibres adapted for prolonged contraction. It is shorter and thinner in females (Rociu et al 2000). The historical concept of the muscle having three parts (deep, superficial and subcutaneous) is no longer valid, but proximal (deep) and distal (superficial or subcutaneous) parts are still described by some authors. The superior part surrounds the internal anal sphincter while the inferior part encircles the anal canal inferior to the internal anal sphincter (Fritsch et al 2002, Al-Ali et al 2009).

The external anal sphincter is attached to the anococcygeal ligament posteriorly and to the perineal body anteriorly; some muscle fibres on each side of the sphincter decussate to form a commissure in the anterior and posterior midline. The most proximal fibres blend with the inferior medial fibres of pubo-analis and attach to the anococcygeal raphe posteriorly and superficial transverse perineal muscle anteriorly. The distal part of the external anal sphincter extends below the internal anal sphincter and is traversed by the terminal fibres of the conjoint longitudinal muscle (see above). Anteriorly, it is attached to bulbospongiosus and bulbocavernosus (Shafik et al 2007). Like levator ani and the internal anal sphincter, the external anal sphincter is tonically contracted at rest (the postural reflex).

Vascular supply and innervation

The external anal sphincter is supplied by the inferior anorectal vessels with a small contribution from the median sacral artery. It is innervated bilaterally by the inferior anal nerve from the pudendal nerve (containing contributions from the second, third and fourth sacral ventral rami). The pudendal nerve also carries afferent fibres from the lining of the anal canal and perianal skin. The proximal external anal sphincter may also receive motor fibres from the nerve to levator ani, which is derived from the ventral rami of predominantly the third through fifth sacral spinal nerves (Loukas et al 2016).

Intersphincteric space and anal glands

The intersphincteric 'space' is a potential space between the conjoint longitudinal muscle layer and the external anal sphincter. It can be entered surgically to provide access in a variety of operations (e.g. intersphincteric excision of the rectum and intersphincteric approaches to fistulae). Within the space lie the anal glands, the source of most anal fistulae (Parks 1961). There is an average of 12 anal glands within the adult anal canal, evenly distributed around the circumference. Their function is unknown, but they secrete mucin (different in composition from that secreted by rectal mucosa) and they communicate with the anal lumen via ducts (lined by epithelium similar to that of the anal pecten), which cross the internal anal sphincter to open at the level of the anal valves immediately above the pectinate line (Seow-Choen and Ho 1994). Retrograde passage of bacteria from the anal canal to the gland is understood to cause infection; inflammatory occlusion of the duct prevents spontaneous drainage back into the anal canal. Sepsis can then spread along different routes to cause abscesses and fistulae within various spaces (Parks et al 1976). High trans-sphincteric fistulae involving the proximal two-thirds of the external anal sphincter remain a surgical challenge because division of muscle involving more than one-third of the sphincter can result in incontinence (Subhas et al 2012).

Vascular supply and lymphatic drainage of the anus

Arteries

The anal canal is supplied by terminal branches of the superior anorectal artery and the inferior anorectal artery from the internal pudendal artery, together with a small contribution from the median sacral artery. The arterial supply to the epithelium of the distal anal canal in the midline, particularly posteriorly, is relatively deficient (Klosterhalfen et al 1989); it is further diminished if the internal anal sphincter is hypertonic (Schouten et al 1996). The epithelium is more firmly tethered to underlying structures in the midline, which may also be a focal point of pressure in the anal canal. Collectively, these factors are thought to predispose to the occurrence of acute and chronic anal fissures, which are most commonly found in the midline, especially posteriorly.

Veins

The venous drainage of the anal canal parallels the arterial supply. The proximal canal is drained predominantly by the superior anorectal veins, tributaries of the inferior mesenteric vein; some blood returns to the internal iliac veins via the middle anorectal veins. The distal part of

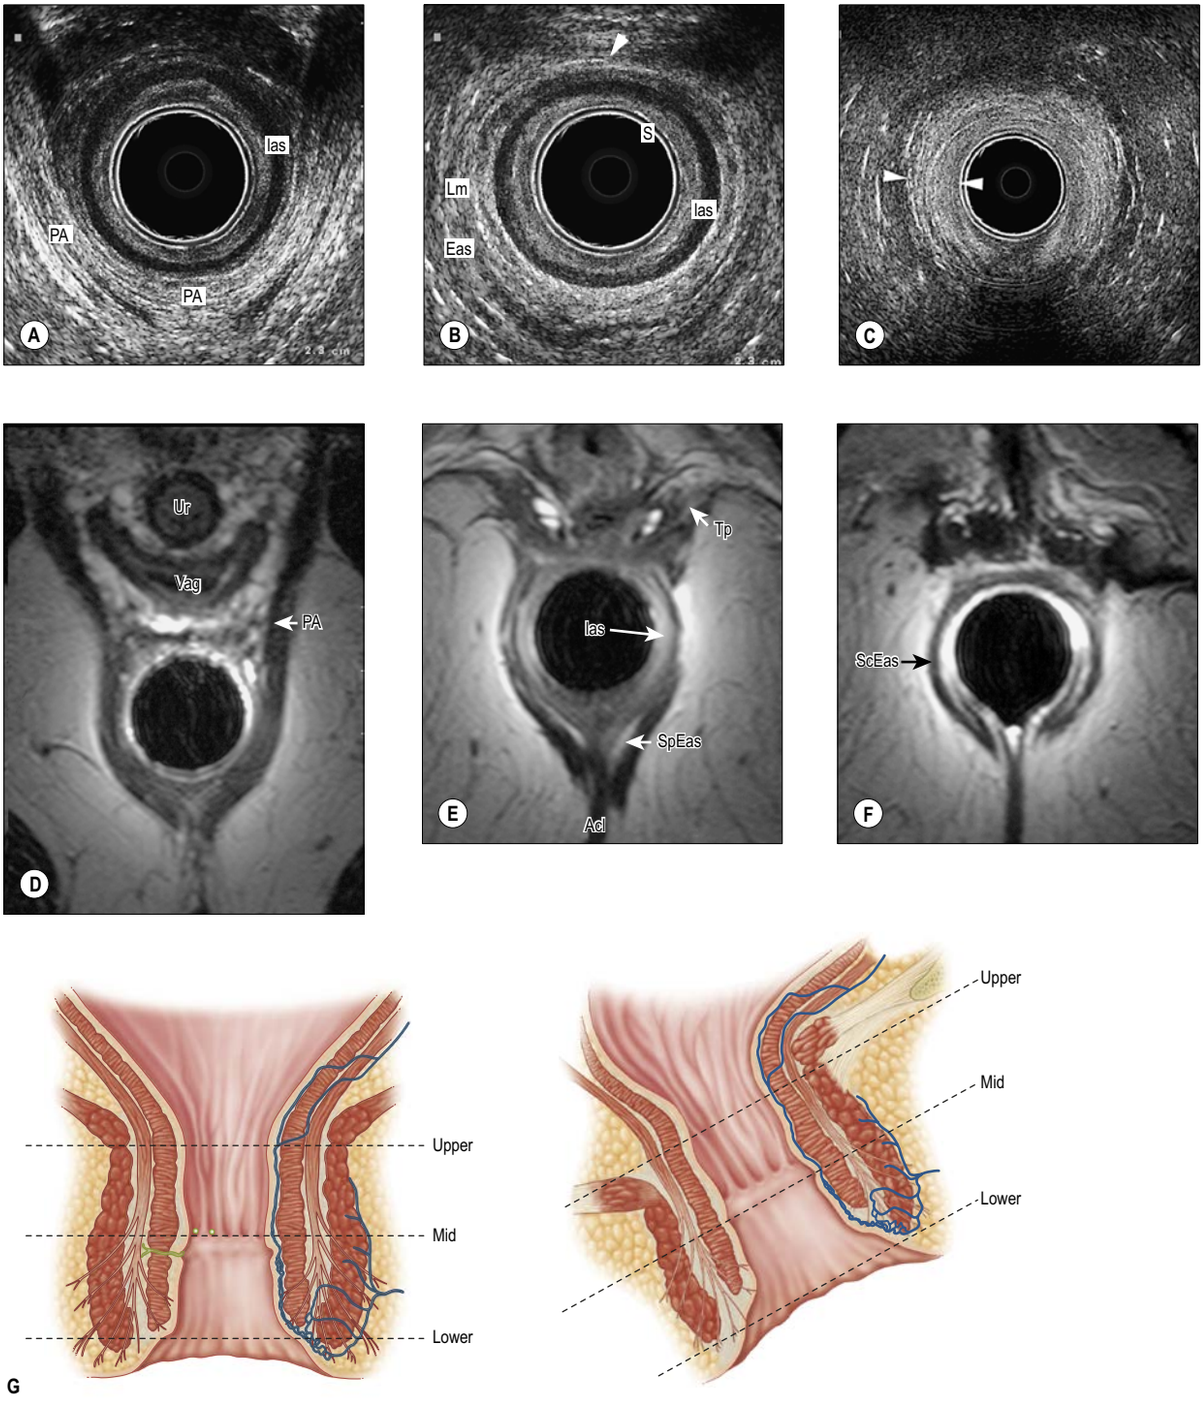

Fig. 65.48 A–C, Axial views of the anal canal at three levels on endoanal ultrasound in a female. The endoanal ultrasound probe is the central black structure. **A**, The proximal part of the anal canal. The 'U' shape of pubo-analis is visible. **B**, The middle part of the anal canal. The external anal sphincter is now a complete ring anteriorly (arrowhead). **C**, The distal part of the anal canal. Below the termination of the internal anal sphincter, the longitudinal layer extends through the subcutaneous external anal sphincter (between arrowheads). **D–F**, MRI of the anal canal. **D**, At proximal anal canal level, the sling of pubo-analis extends anteriorly to the pubic bones. **E**, At mid anal canal level, the superficial transverse perineii fuse into the external anal sphincter anteriorly. The distal part of the external anal sphincter is attached either side of the anococcygeal ligament. **F**, The distal anal canal level, below the internal anal sphincter. **G**, A key for levels of the anal canal. Abbreviations: Acl, anococcygeal ligament; Eas, external anal sphincter; las, internal anal sphincter; Lm, longitudinal muscle; PA, pubo-analis; S, subepithelial tissues; ScEas, subcutaneous (lower) part of the external anal sphincter; SpEas, superficial (middle) external anal sphincter; Tp, transverse perineii; Ur, urethra; Vag, vagina.

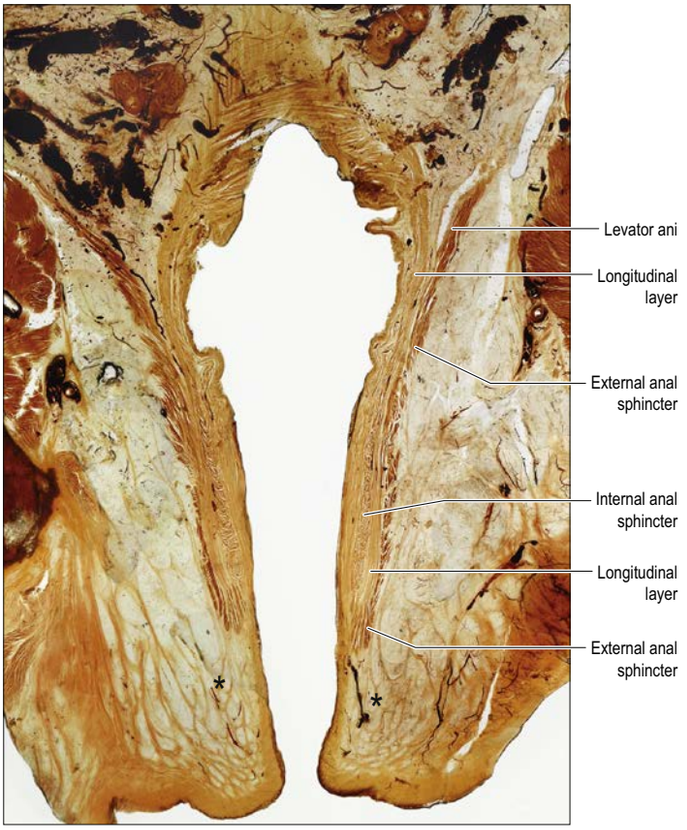

Fig. 65.49 A transilluminated 2.5 mm thick coronal section of a male pelvis processed for epoxy resin E12 sheet plastination, showing the entire length of the anal canal and its muscular layers: namely, the external anal sphincter, conjoint longitudinal muscle and internal anal sphincter. Note the continuity of the external anal sphincter with levator ani superiorly, consisting of two parts, upper and lower. The proximal part of the conjoint longitudinal muscle is continuous with the longitudinal muscular layer of the rectum and, inferiorly, its fibres traverse the lower part of the external anal sphincter to blend with or form fibro-fatty, honeycomb-like compartments around the peri-anal region (asterisks). The internal anal sphincter ends above the lower part of the external anal sphincter. (Courtesy of Dr Saad Al-Ali, with permission from Al-Ali S, Blyth P, Beatty S et al (2009) Correlation between gross anatomical topography, sectional sheet plastination, microscopic anatomy and endoanal sonography of the anal sphincter complex in human males. J Anat 215:212–20.)

the anal canal, including the external rectal plexus, drains via the inferior anorectal veins of the internal pudendal vein into the internal iliac vein.

Haemorrhoids

Available with the *Gray's Anatomy* e-book

Lymphatic drainage

Lymph from the proximal anal canal drains cranially into the submucosal and intramural lymphatics of the rectum. Lymphatics around pubo-analis drain to internal iliac nodes. Lymph from the distal anal canal and external anal sphincter drains to inguinal nodes. This pattern of drainage is particularly relevant to the lymphatic spread of malignant tumours from the distal rectum and anal canal. Blockage of lymph drainage along normal routes can lead to unusual patterns of dissemination.

Defecation

Defecation is the act of voiding stool from the anus and involves the coordinated function of the colon and rectum, pelvic diaphragm and anal sphincters. It is influenced by multiple factors including colonic transit, stool volume and consistency, posture, age, sex, psychology and behaviour, culture and lifestyle (Palit et al 2012). Social behaviour entrains defecation to occur at a time of convenience rather than simply in response to a defecatory urge. The urge to defecate is preceded by high-amplitude propagated contractions in the colon, which result in the antegrade propulsion of intraluminal contents to the rectum; these contractions increase in frequency and intensity just before expulsion. The response to rectal filling involves intact afferent fibres travelling from the rectum, reflex rectal contractions and normal rectal wall biomechanics. The rectum acts as a reservoir and is able to relax to accommodate faecal material and flatus (adaptive relaxation). Periodic sampling within the proximal anal canal helps to determine the nature of the rectal content. If the defecatory urge is inconvenient, pubo-analis and the external anal sphincter, which are tonically contracted at rest, can be further contracted voluntarily to move stool back up from the distal rectum. If the defecatory urge is associated with a conscious decision to evacuate, distal progression of colonic high-amplitude propagating complexes, rectal contractions, raised intra-abdominal pressure from voluntary straining (the efficiency of which is influenced by posture) and relaxation of pubo-analis (which straightens the anorectal flexure) and the anal sphincters all combine to enable defecation. Relaxation of the internal anal sphincter is a reflex response to rectal distension, whereas relaxation of the external anal sphincter is voluntary. During defecation, contraction of the conjoint longitudinal muscle shortens and opens the anal canal and flattens the anal cushions. Rectal contents and a variable quantity of colonic contents are evacuated. After defecation, the external anal sphincter contracts (the closing reflex), the internal anal sphincter gradually recovers its resting tone and the postural reflex is reactivated. The conjoint longitudinal muscle relaxes, permitting the anal canal to elongate and the anal cushions to re-expand.

Problems with defecation can result from impaired colonic transit or from various functional or mechanical rectal disorders (Lunniss et al 2009). Functional causes include inadequate or ineffective expulsive effort, paradoxical contraction of the pelvic diaphragm and external anal sphincter (dyssynergia) and lack of normal sensation (rectal hyposensitivity). Mechanical causes include impedance to evacuation when straining (rectal intussusception, obstructing masses or anal stenosis), misdirection of force vectors during straining (rectocele), or dissipation of evacuatory forces (ballooning perineum).

Anal continence and incontinence

As long as anal pressure exceeds rectal pressure, faecal continence will be maintained. Anal resting tone is derived mainly from sympathetically mediated tonic contraction of the internal anal sphincter, augmented by contraction of the external anal sphincter. Anal continence involves central, spinal and peripheral pathways, somatic, autonomic and enteric nerves, intact sacral sensorimotor reflexes, and structurally and functionally intact smooth and striated musculature.

Sphincteric causes of faecal incontinence can be structural (disruption or atrophy of part of the sphincter musculature) or neuropathic (injury to the nerve supply to the sphincters), or a combination of both. The most common causes of sphincter disruption are obstetric injury,

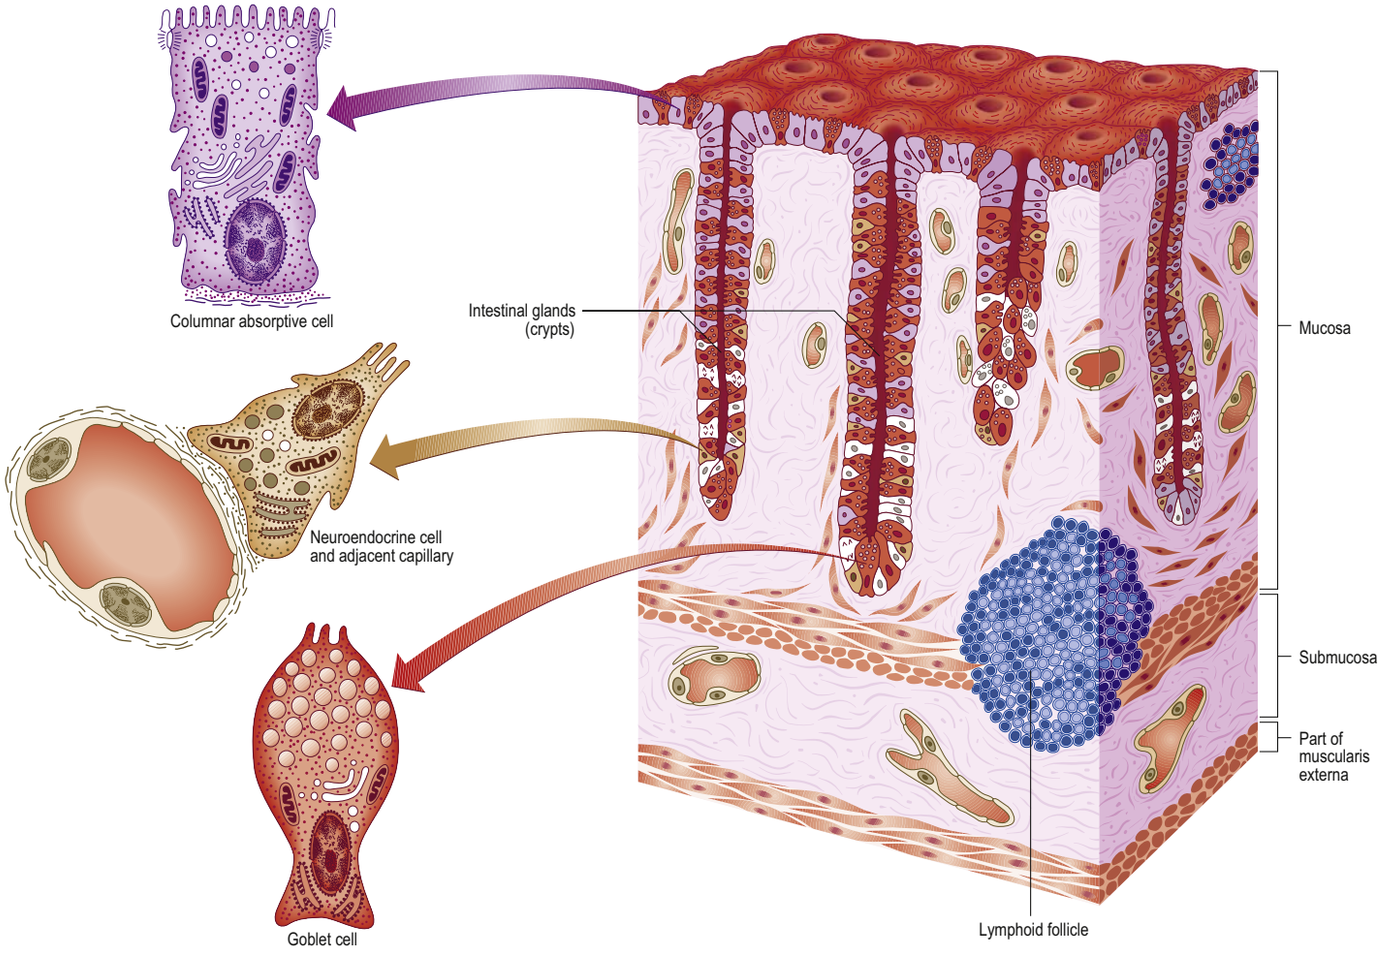

Fig. 65.50 The microstructure of the colonic wall and its epithelial cells. Note the aggregations of lymphocytes (blue) and undifferentiated epithelial cells (white).

'Haemorrhoids' refer to the abnormal downward displacement of anal cushions, which are prominences of anal mucosa formed by loose connective tissue, smooth muscle, and arteries and veins. Around 5% of the general population has haemorrhoidal disease to some extent (Randhawa et al 2015). Haemorrhoids are associated with laxity of the anal canal submucosa and enlargement of the terminal branches of the superior anorectal artery supplying the anal cushions.

Fig. 65.51 A low-power view of the large intestine showing macroscopic folds of the mucosa and submucosa due to contraction of the external musculature. The surface epithelium receives the secretions of tubular glands in the lamina propria. They are supported by a well-defined muscularis mucosae, seen as a thin pink layer of smooth muscle separating the mucosa from the submucosa; the latter extends into the macroscopic folds. The muscularis externa lies beneath (not shown). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

anal surgery (for haemorrhoids, fistulae or fissures) and trauma. Pudendal neuropathy is most commonly associated with childbirth (prolonged second stage of labour) and chronic straining.

Although the anus constitutes the final barrier to faecal incontinence, factors operating proximal to the anal sphincters, such as the rate at which the stool is delivered to the rectum, rectal sensation and compliance, and adaptive relaxation, are also essential for maintaining faecal continence. Even if the sphincter mechanisms are structurally and functionally intact, faecal incontinence can occur, e.g. in diarrhoeal states or conditions where there is loss of rectal reservoir function (Scott and Lunniss 2007). Conversely, chronic rectal distension with retained faeces can result in passive (overflow) leakage, e.g. because the recto-anal inhibitory reflex is persistently activated, producing a chronically relaxed internal anal sphincter, and/or rectal sensation is blunted, causing diminished conscious contraction of the external anal sphincter.

MICROSTRUCTURE OF THE LARGE INTESTINE

The submucosal and muscularis layers of tissue in the large intestinal wall (**Fig. 65.50**) resemble those in the small intestine, whereas the mucosal layer differs in that that villi and circular folds are absent and the intestinal glands are longer and predominantly mucus-secreting. The microscopic structure of the colonic wall (**Fig. 65.51**) shows the characteristic four layers, mucosa, submucosa, muscular layer and serosa.

Mucosa

The mucosa is pale, smooth and, in the colon, raised into numerous crescent-shaped folds between the sacculi. It is thicker, darker, more vascular and more loosely attached to the submucosa in the rectum.

Epithelium

The luminal surface of all but the anorectal junction is lined by columnar cells, mucous (goblet) cells and occasional microfold (M) cells that are restricted to the epithelium overlying lymphoid follicles.

Columnar (absorptive) cells Columnar (absorptive) cells are the most numerous of the epithelial cell types. Although there is some variation in their structure, they all bear apical microvilli that are shorter and less regular than those on enterocytes in the small intestine. Typical junctional complexes around their apices limit extracellular diffusion from the lumen across the intestine wall.

Mucous (goblet) cells Mucous cells have a structure similar to those of the small intestine but are more numerous. They are outnumbered by absorptive cells for most of the length of the colon but they are equally frequent towards the rectum, where their numbers increase.

Microfold (M) cells Microfold cells overlie mucosal lymphoid tissue and are similar to those of the small intestine.

Intestinal glands

Intestinal glands are narrow, perpendicular tubular glands; they are longer, more numerous and more closely spaced than those of the small intestine. Their orifices lend a cribriform appearance to the mucosa in surface view. The glands are lined by low columnar epithelial cells, mainly goblet cells, augmented by columnar absorptive cells and neuroendocrine cells. The latter are situated mainly at the bases of the glands and secrete basally into the lamina propria. In general, the glands lack Paneth cells, although some may be present in the caecum. Stem cells located at or near the bases of the intestinal glands are the source of the other epithelial cell types in the large intestine. They provide cells that migrate towards the luminal surface of the intestine; their progeny differentiate, undergo apoptosis and are shed after approximately five days.

Lamina propria

The lamina propria is composed of connective tissue that supports the epithelium, forming a specialized periglandular myofibroblast sheath around each intestinal gland. Solitary lymphoid follicles within the lamina propria, similar to those of the small intestine, are most abundant in the caecum, appendix and rectum, but are also found scattered along the rest of the large intestine; efferent lymphatic vessels originate within them. Lymphatic vessels are absent from the intercryptal lamina propria.

Muscularis mucosae

The muscularis mucosae of the large intestine is essentially similar to that of the small intestine.

Submucosa

The submucosa of the large intestine is similar to that of the small intestine.

Muscularis externa

The muscularis externa has outer longitudinal and inner circular layers of smooth muscle, as elsewhere in the intestinal tract. The longitudinal muscle fibres form a continuous layer aggregated into macroscopically visible longitudinal bands or taeniae coli (see Figs 65.3 and 65.13). Between the taeniae coli the longitudinal muscle layer is much thinner, less than half the thickness of the circular muscle layer. The circular muscle fibres form a thin layer over the caecum and colon, a thicker layer in the walls of the rectum and the internal anal sphincter in the anal canal. Fascicles are exchanged between circular and longitudinal muscle layers, especially near the taeniae coli: deviation of longitudinal muscle fibres from the taeniae coli to the circular muscle layer could in some instances explain the haustra of the colon.

Serosa

The serosa or visceral peritoneum is variable in extent. Small, fat-filled omental appendices are most numerous on the sigmoid and transverse colons but generally absent from the rectum.

CHAPTER 66

Liver

The liver is the largest of the abdominal viscera, occupying a substantial portion of the upper abdominal cavity. It occupies most of the right hypochondriac and epigastric regions and frequently extends into the left hypochondriac region as far as the left anterior axillary line (**Fig. 66.1**). As the body grows from infancy to adulthood, the liver rapidly increases in size. This period of growth reaches a plateau around 18 years and is followed by a gradual decrease in liver weight from middle age. The ratio of liver to body weight decreases with growth from infancy to adulthood. The liver weight is 4–5% of body weight in infancy and decreases to approximately 2% in adulthood. The size of the liver also differs between the sexes (being smaller in females) and body size (enlarging with fat deposition in obese individuals). It has an overall wedge shape, in part determined by the form of the upper abdominal cavity into which it grows. The narrow end of the wedge lies towards the left hypochondriac region and the anterior edge points anteriorly and inferiorly. The superior and right lateral aspects are shaped by the anterolateral abdominal and thoracic walls, and by the respiratory diaphragm. The inferior aspect is shaped by the adjacent viscera. The fibrous capsule of the capsule is no longer considered important in maintaining the shape of the liver; it allows expansion when the liver hypertrophies in response to disease, surgical resection or contralateral embolization of the hepatic portal vein or hepatic artery.

The liver is reddish-brown in colour. It assumes a more yellowish tinge with increasing fat (steatosis) and the edges become more rounded. These changes occur commonly in individuals who are obese and/or drink an excessive amount of alcohol. The liver gains a bluish tinge with venous outflow obstruction (Budd–Chiari syndrome) or congestive heart failure. The texture of the organ is usually soft to firm, though this depends partly on the volume of blood it contains and on its content of adipose and fibrous connective tissues.

The liver performs a wide range of metabolic activities required for homeostasis, nutrition and immune defence. For example, it is important for the removal and breakdown of toxic or potentially toxic materials from the blood; the regulation of blood glucose and lipids; the storage of certain vitamins, iron and other micronutrients; the synthesis of proteins and clotting factors; the metabolism of amino acids; and bile production. It is involved in a plethora of other biochemical reactions. Since most of these processes are exothermic, a substantial part of the thermal energy production of the body, especially at rest, is provided by the liver. The liver is populated by phagocytic macrophages, components of the mononuclear phagocyte system capable of removing particulates from the blood stream. It is an important site of haemopoiesis in the fetus; extramedullary haemopoiesis in the setting of haematological disease.

An account of the more common eponyms relating to the anatomy and surgery of the liver is provided in Stringer (2009).

Surfaces of the liver

The liver is usually described as having superior, anterior, right, posterior and inferior surfaces with a distinct inferior border (**Figs 66.2–66.3**). However, the superior, anterior and right surfaces are continuous and no definable borders separate them. It is more appropriate to group them as the diaphragmatic surface, which is mostly separated from the inferior, or visceral, surface by a narrow inferior border. At the infrasternal angle, the inferior border is adjacent to the anterior abdominal wall and accessible to physical examination by percussion, but not usually palpable except on deep inspiration. In the midline, the inferior border of the liver is near the transpyloric plane. In women and children the border often projects a little inferior to the right costal arch (margin).

Superior surface The superior surface is the largest and lies immediately below the respiratory diaphragm, separated from it by peritoneum, except for a small triangular area where the two layers of the falciform ligament diverge. Most of the superior surface lies beneath the right superior aspect of the respiratory diaphragm, but there is a shallow cardiac impression centrally that corresponds to the position of the heart above the central tendon of the diaphragm. The left side of the superior surface lies beneath part of the left side of the diaphragm.

Anterior surface The anterior surface is approximately triangular and convex and is covered by peritoneum, except at the attachment of the

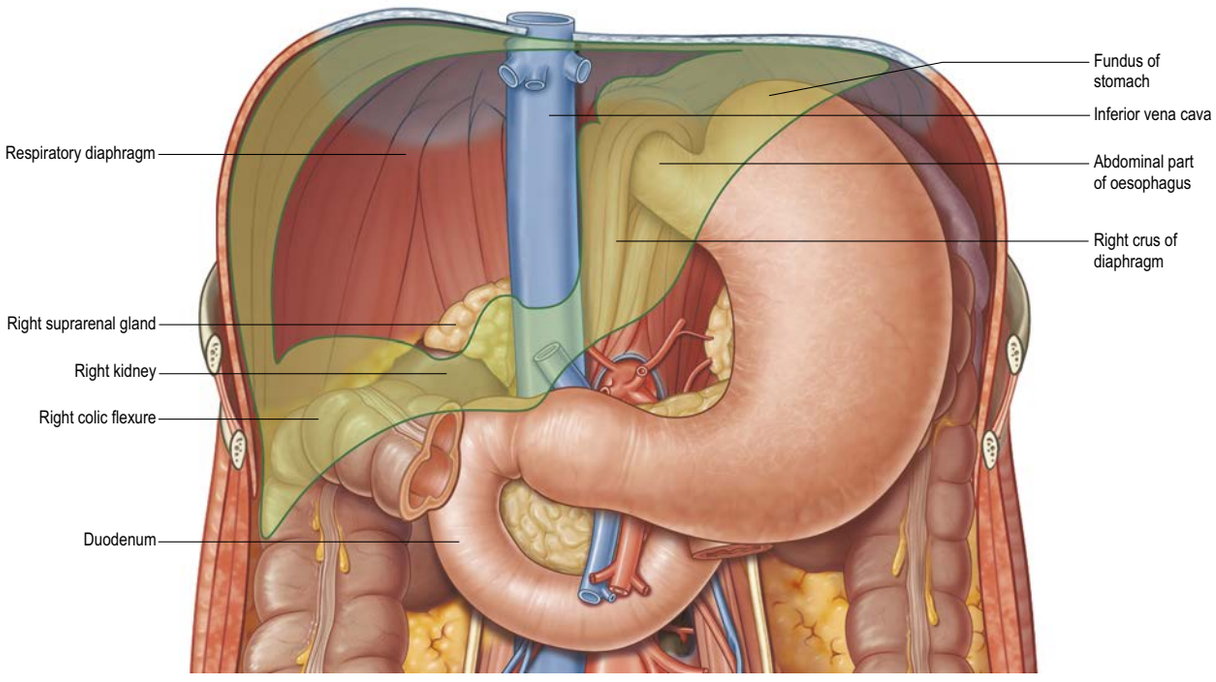

Fig. 66.1 The 'bed' of the liver. The outline of the liver is shaded green. The bare area of the liver is unshaded.

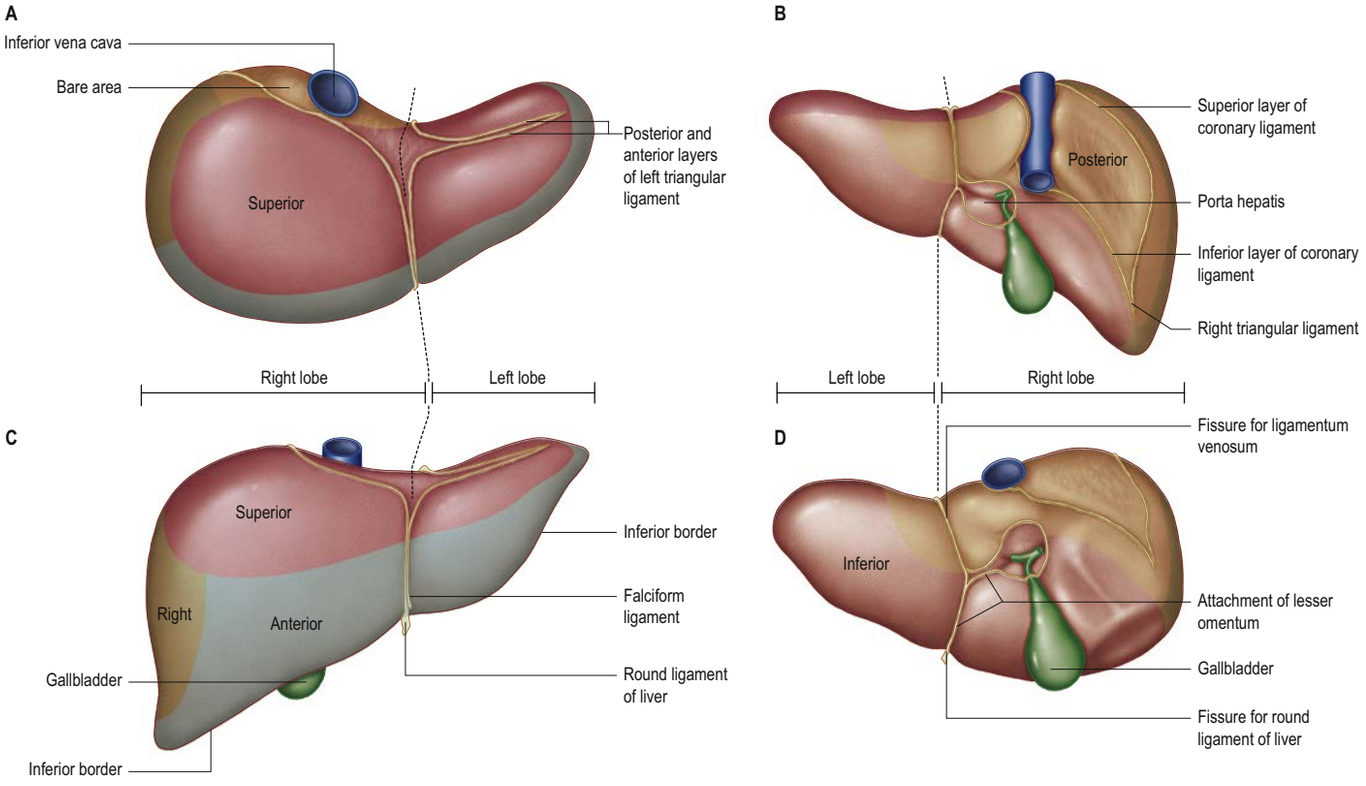

Fig. 66.2 The surfaces and external features of the liver. **A**, Superior view. **B**, Posterior view. **C**, Anterior view. **D**, Inferior view.

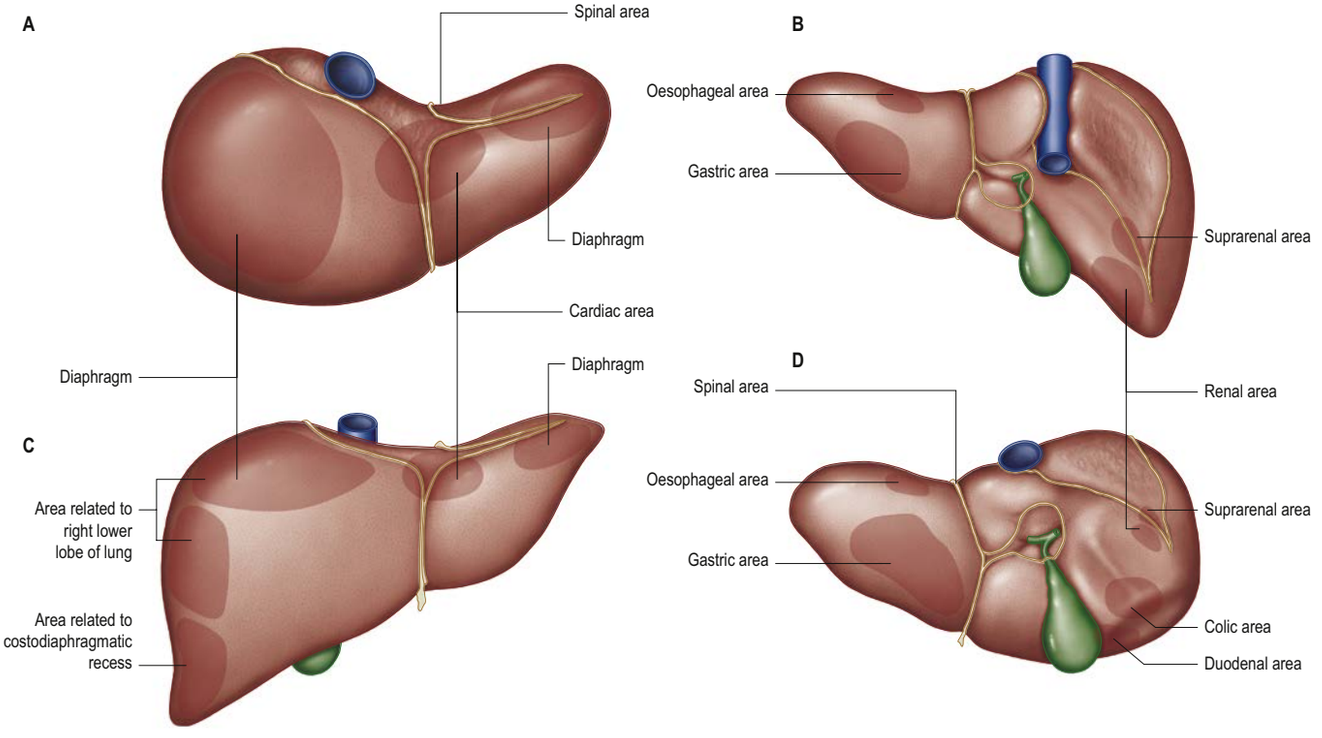

Fig. 66.3 Relations of the liver. **A**, Superior view. **B**, Posterior view. **C**, Anterior view. **D**, Inferior view.

falciform ligament. Much of it is in contact with the anterior attachment of the respiratory diaphragm. On the right, the diaphragm separates it from the pleura and the sixth to the tenth ribs and costal cartilages, and on the left, from the seventh and eighth costal cartilages.

Right surface The right surface is covered by peritoneum and lies adjacent to the right superior aspect of the respiratory diaphragm, which separates it from the right lung and pleura and the seventh to the eleventh ribs. The right lung and basal pleura lie superior and lateral to its proximal third, between the diaphragm and the seventh and eighth ribs. The diaphragm, the costodiaphragmatic recess lined by pleura, and the ninth and tenth ribs lie lateral to the middle and lower thirds of the right surface. Lateral to the lower third, the diaphragm and thoracic wall are in direct contact. Rarely, the right colic flexure and proximal transverse colon lie on a long mesentery over the right, anterior and superior surfaces of the liver; this can lead to misdiagnosis of pneumoperitoneum on a radiograph or very rarely cause symptoms (Chilaiditi's syndrome) (Ch. 65).

Posterior surface The posterior surface is convex, wide on the right but narrow on the left. A median concavity corresponds to the forward convexity of the vertebral column close to the attachment

of the ligamentum venosum. Much of the posterior surface is attached to the respiratory diaphragm by loose connective tissue, forming the triangular 'bare area'. The inferior vena cava lies in a groove or tunnel in the medial end of the bare area. To the left of the groove for the inferior vena cava, the posterior surface of the liver is formed by the caudate lobe and is covered by a layer of peritoneum continuous with that of the inferior layer of the coronary ligament and the layers of the lesser omentum. The caudate lobe is related to the diaphragmatic crura and the right inferior phrenic artery superior to the aortic hiatus, and is separated by these structures from the descending thoracic aorta.

The fissure for the ligamentum venosum separates the caudate lobe from the left lobe. It cuts deeply in front of the caudate lobe and contains the two layers of the lesser omentum. The posterior surface of the left lobe bears a shallow impression near the superior end of the fissure for the ligamentum venosum that is caused by the abdominal part of the oesophagus. The posterior surface of the left lobe to the left of this oesophageal impression is related to the fundus of the stomach. Together, these posterior relations make up what is sometimes referred to as the 'bed' of the liver (see Fig. 66.1).

Inferior surface The inferior surface is bounded by the inferior edge of the liver. It blends with the posterior surface in the region of the origin of the lesser omentum, the porta hepatis and the inferior layer of the coronary ligament, and is marked near the midline by a sharp fissure that contains the round ligament of the liver (ligamentum teres hepatis; the obliterated fetal left umbilical vein). The gallbladder usually lies in a shallow fossa of variable depth: it can have a short mesentery or be completely intrahepatic. The quadrate lobe lies between the fissure for the round ligament of the liver and the gallbladder.

The inferior surface of the left lobe is related inferiorly to the fundus of the stomach and the superior aspect of the lesser omentum. The quadrate lobe lies adjacent to the pylorus, the superior part of the duodenum and the inferior part of the lesser omentum. Occasionally, the transverse colon lies between the duodenum and the quadrate lobe. To the right of the gallbladder, the inferior surface is related to the right flexure of the colon, the right suprarenal gland and right kidney, and the superior part of the duodenum (see Fig. 66.1).

Supports of the liver

Available with the *Gray's Anatomy* e-book

Gross anatomical lobes

Historically, the liver has been divided on the basis of its external appearance into right, left, caudate and quadrate lobes, defined in part by peritoneal ligamentous attachments. Additional liver lobes have been reported but are rare.

Right lobe The right lobe is the largest in volume and contributes to all surfaces of the liver. It is divided from the left lobe by the falciform ligament anteriorly and superiorly and by the ligamentum venosum and fissure for the round ligament of the liver inferiorly. On the inferior surface, to the right of the grooves formed by the round ligament of the liver and ligamentum venosum, the porta hepatis separates two prominences: the caudate lobe lies posterior and the quadrate lobe lies anterior. The gallbladder lies in a shallow fossa on the inferior surface of the liver between the quadrate lobe on the left and the right lobe on the right.

Left lobe The left lobe is the smaller of the two main lobes, though it is nearly as large as the right lobe in young children. It lies to the left of the falciform ligament with no subdivisions. It is substantially thinner than the right lobe, having a thin apex that points into the left upper quadrant.

Quadrate lobe The quadrate lobe is visible as a prominence on the inferior surface of the liver to the right of the groove formed by the round ligament of the liver. Although it is anatomically part of the right lobe, its vascular inflow is from the left branch of the hepatic portal vein and left hepatic artery and its biliary outflow is to the left hepatic duct. It lies anterior to the porta hepatis and is bounded by the fossa of the gallbladder to the right, a short portion of the inferior border anteriorly, the fissure for the round ligament of the liver to the left, and the porta hepatis posteriorly. Like the caudate lobe, its morphology varies among individuals (Joshi et al 2009).

Caudate lobe The caudate lobe is visible as a prominence on the inferior and posterior surfaces to the right of the groove formed by the ligamentum venosum: it lies posterior to the porta hepatis and the hepatogastric ligament. To its right is the groove for the inferior vena cava. Above, it continues into the superior surface on the right of the superior end of the fissure for the ligamentum venosum. In gross anatomical descriptions, this lobe is said to arise from the right lobe but it is functionally separate.

Functional anatomical divisions

Current understanding of the functional anatomy of the liver is based on Couinaud's division of the liver into eight functional segments (subsequently nine, then later revised back to eight), based on the distribution of portal venous branches in the parenchyma (Couinaud 1957). Understanding the intrahepatic biliary anatomy, especially of the right ductal system, was enhanced by contributions from Hjortsjö (1951) and Healey and Schroy (1953), who used the biliary system as the main guide for division of the liver (**Fig. 66.4**). All models use the branching pattern of either the portal and hepatic veins (the 'French' model) or the bile ducts (the 'American' model) as segmentation criteria, but differ in their nomenclature (Terminology Committee of the International Hepato-Pancreato-Biliary Association 2000, Strasberg 2005, Bismuth 2013, Strasberg and Phillips 2013, Makuuchi 2013, Majno et al 2014, Hikspoors et al 2017).

The liver is divided into four portal sectors (right anterior, right posterior, left medial and left lateral) by the four main branches of the hepatic portal vein. The three main hepatic veins lie between these sectors as intersectoral veins. The intersectoral planes are also called portal fissures (or scissures). Each sector is subdivided into segments (usually two) on the basis of their supply by tertiary divisions of the perivascular fibrous capsules (Glissonian sheaths) (see below).

Fissures and sulci of the liver

Knowledge of the fissures of the liver is essential for understanding liver surgery. Three major portal fissures, main, left and right portal fissures, not visible on the surface, run through the liver parenchyma and contain the three main hepatic veins. Three minor fissures, umbilical, venous and fissure of Gans (Rouvière's sulcus, incisura hepatis dextra) are visible as physical clefts in the liver surface. Accessory fissures are rare. However, diaphragmatic sulci are seen in approximately 40% of livers and usually on the superior surface of the right lobe (Macchi et al 2003).

Main portal fissure The main portal fissure (Cantlie's line) extends from the midpoint of the fossa of the gallbladder at the inferior margin of the liver back to the midpoint of the inferior vena cava. It contains the middle hepatic vein and separates the liver into right and left hemilivers. Segments V and VIII lie immediately to the right, and segment IV immediately to the left, of the main portal fissure.

Left portal fissure The left portal fissure divides the left hemiliver into left medial and left lateral sectors. It extends from the midpoint of the inferior edge of the liver between the falciform ligament and the left triangular ligament to the point that marks the confluence of the left and middle hepatic veins. It contains the left hepatic vein and separates the left medial (anterior) and left lateral (posterior) sectors; segment III lies immediately anteriorly and segment II posteriorly.

Right portal fissure The right portal fissure divides the right hemiliver into right posterior and right anterior sectors. The plane of the right portal fissure is the most variable of the portal fissures: it runs approximately diagonally through the anatomical right lobe from the lateral end of the inferior border to the termination of the right hepatic vein. The portal fissure divides the right anterior sector (segments V and VIII) from the right posterior sector (segments VI and VII) and contains the right hepatic vein. It traverses the thickest portion of liver parenchyma that is commonly transected during liver resection.

Umbilical fissure The umbilical fissure (fissure for the round ligament of the liver) separates segments II and III from segment IV and contains a major branch of the left hepatic vein (the umbilical fissure vein). It is marked anteriorly by the attachment of the falciform ligament and inferiorly by the round ligament of the liver, where it may be

The liver is stabilized and maintained in its position in the right upper quadrant of the abdomen by both static and dynamic factors. A three-tier classification of supporting structures has been proposed: the suspensory attachments of the inferior vena cava, hepatic veins, and coronary and triangular ligaments to the posterior abdominal wall (primary factors); the support provided by the right kidney, right colic flexure and duodenopancreatic complex (secondary factors); and the attachment of the falciform ligament to the anterior abdominal wall and respiratory diaphragm (tertiary factors) (Flament et al 1982). The surgical implications of these different factors are important for understanding the pathophysiology of blunt liver trauma and the stability of transplanted liver grafts. The inferior vena cava and the hepatic veins, especially the right hepatic vein, appear to be the most important anatomical structures supporting the bulk of the liver. Other factors that influence the position of the liver within the abdominal cavity include positive intra-abdominal pressure and the movement of the diaphragm during respiration.

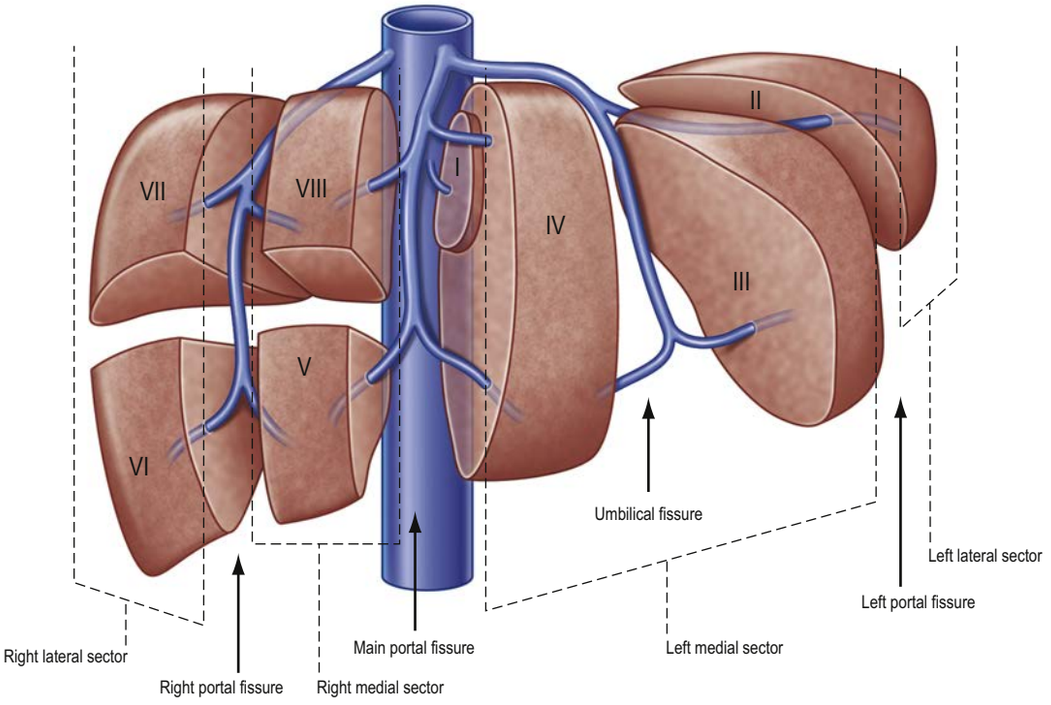

Fig. 66.4 The fissures and sectors of the liver. (Right lateral = right posterior; right medial = right anterior.)

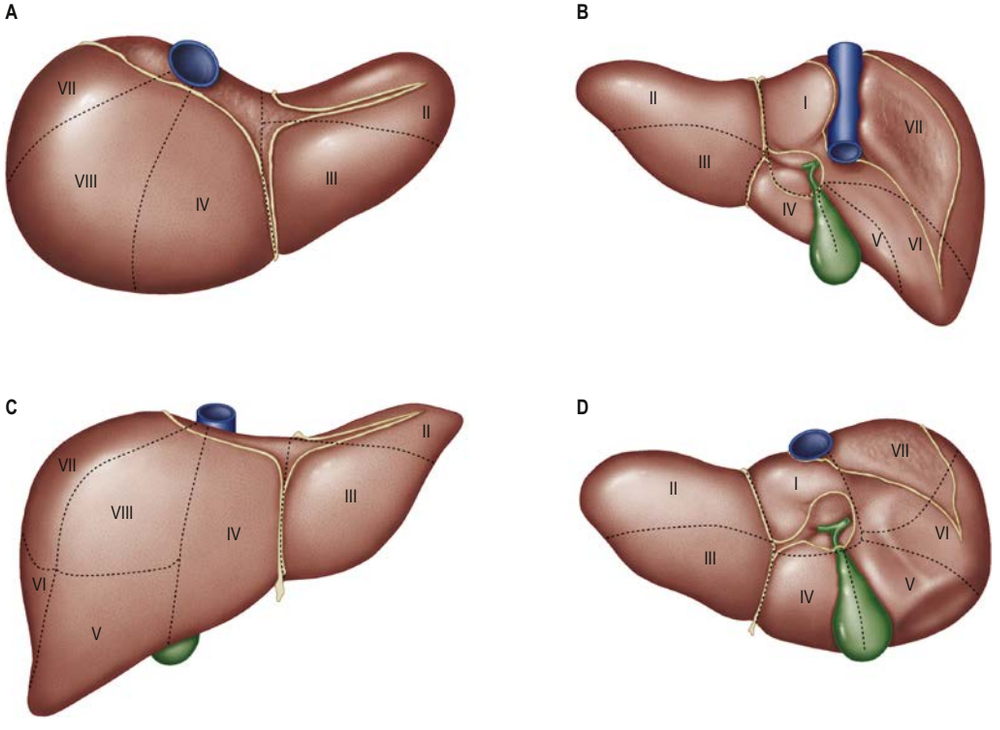

Fig. 66.5 Segments of the liver (after Couinaud). **A**, Superior view. **B**, Posterior view. **C**, Anterior view. **D**, Inferior view. The segments are usually referred to by number (name): I (caudate); II (left lateral superior); III (left medial inferior); IV (left medial superior) (sometimes subdivided into superior and inferior parts); V (right medial inferior); VI (right lateral inferior); VII (right lateral superior); VIII (right medial superior).

covered by a bridge of liver tissue extending between segments III and IV. When present, this bridge is usually avascular and can be divided safely with diathermy during surgery. The umbilical fissure also contains the umbilical portion of the left branch of the hepatic portal vein, segmental bile ducts converging to form the left hepatic duct, and the terminal branches of the left hepatic artery. The umbilical portion of the left branch of the hepatic portal vein offers direct surgical access to the left branch of the hepatic portal vein during surgery for cholangiocarcinoma of the porta hepatis and in operations to restore intrahepatic portal blood flow after hepatic portal vein occlusion. Knowledge of the arrangement of the vascular and biliary structures within the umbilical fissure is also essential when the liver is split for an adult and paediatric recipient and for live donor liver transplantation for a child recipient.

Venous fissure The fissure for the ligamentum venosum (venous fissure) is directly continuous with the umbilical fissure on the undersurface of the liver. It contains the ligamentum venosum (the obliterated ductus venosus) and lies between the caudate lobe and segment II.

Fissure of Gans The fissure of Gans (Rouvière's sulcus) lies on the undersurface of the right lobe of the liver posterior to the fossa of the gallbladder and anterior to segment I. It occurs in over 80% of normal livers, often marks the variable site of division of the portal pedicle to the right posterior sector and is a useful landmark during laparoscopic cholecystectomy (Singh and Prasad 2017, Lockhart and Singh-Ranger 2018).

Sectors and segments of the liver

Sectors

Each sector of the liver contains between one and three segments: the right posterior sector contains segments VI and VII; the right anterior sector contains segments V and VIII; the left medial sector contains segment IV (and part of I); the left lateral sector contains segments II and III (**Fig. 66.5**). The segments are numbered clockwise from below, starting with segment I and ending with segment VIII (see Figs 66.4–66.5; **Fig. 66.6**).

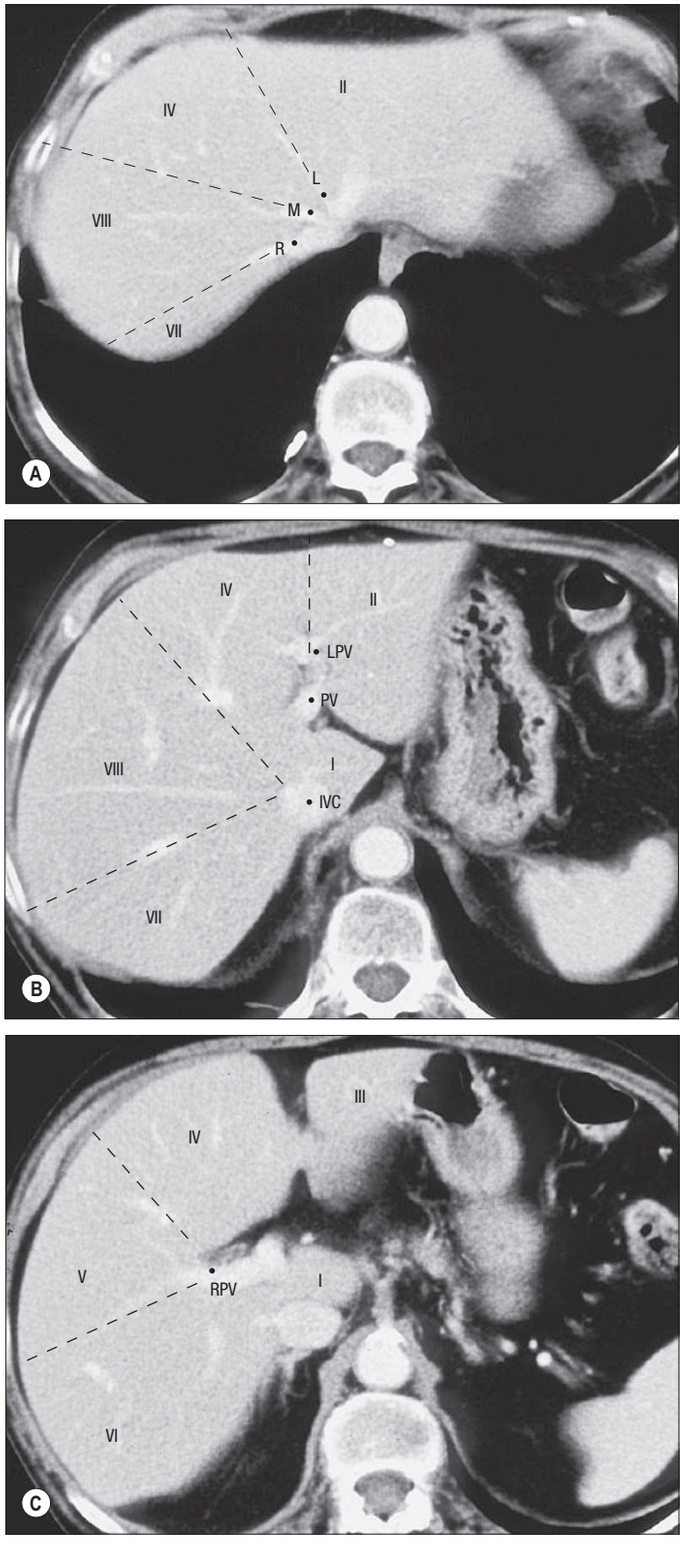

Fig. 66.6 Segments of the liver seen on axial computed tomography (CT). **A**, A contrast enhanced CT shows the left (L), middle (M) and right (R) hepatic veins at the superior aspect of the liver, marking the left, main and right portal fissures. **B**, Inferior to this, the caudate lobe (segment I) lies between the inferior vena cava (IVC) and the portal vein (PV). The left branch of the hepatic portal vein (LPV) separates segment II superiorly from segment III inferiorly. **C**, The right branch of the hepatic portal vein (RPV) divides segments V and VI inferiorly from segments VII and VIII superiorly (**B**).

Segment I Segment I corresponds to the anatomical caudate lobe and additional adjacent parenchyma supplied by branches of the hepatic portal vein at the porta hepatis and arterial branches that arise from the left and/or the right hepatic arteries. Segment I lies posterior to segment IV; the caudate process extends to the left, posterior to the hepatogastric ligament. The segment straddles the inferior vena cava, with its left half directly adjacent to segment II and its right half wrapped to a variable extent around the retrohepatic portion of the inferior vena cava. The segment that wraps around the inferior vena cava most often includes a larger vein that drains directly into the inferior vena cava. In the European literature, segment I is subdivided into three parts, the caudate process, caudate lobe (Spiegel's lobe) and paracaval portion; right and left subdivisions are recognized in Asia. The perivascular fibrous capsules to segment I arise from both right and left main capsules, which means that the segment receives vessels from both the left and right branches of the hepatic portal vein and hepatic arteries. The venous drainage of the caudate lobe is directly into the inferior vena cava by multiple small tributaries that usually arise from the lower third of the segment, occasionally from the middle third, but rarely from the upper third. The bile ducts draining the segment are closely related to the confluence of the right and left hepatic ducts (Ch. 67), such that excision of bile duct tumours affecting the porta hepatis of the liver usually requires removal of segment I.

Segment II Segment II lies posterolateral to the left portal fissure, often has only one perivascular fibrous capsule, and drains into the left hepatic vein. Rarely, a separate vein drains directly into the inferior vena cava.

Segment III Segment III lies between the umbilical fissure and the left portal fissure. It is supplied by one to three perivascular fibrous capsules and drains into the left hepatic vein: the veins of the falciform ligament can provide an alternative drainage route. Very rarely, the segment drains to the middle hepatic vein; when this occurs, reconstruction is required following a right hepatectomy involving resection of the middle hepatic vein and in split liver transplantation (Dar et al 2008).

Segment IV Segment IV lies between the umbilical fissure and the main portal fissure, immediately anterior to segment I. It is supplied by three to five perivascular fibrous capsules, most of which arise in the umbilical fissure; their origins are often close to the fibrous capsules that supply segments II and III. Occasionally, segment IV is supplied by branches from the main left pedicle. Segment IV is typically divided into IVa superiorly and IVb inferiorly by two separate perivascular fibrous capsules. This subdivision is relevant to transverse hepatectomy, in which segments IVb, V and VI are removed along a transverse portal plane (Sugarbaker 1990). Segment IV usually drains into the middle hepatic vein, but it can also drain into the left hepatic vein through veins of the falciform ligament.

Segment V Segment V is the inferior segment of the right anterior sector and lies between the middle and the right hepatic veins. Its size is variable, as are the number of perivascular fibrous capsules that supply it from the right anterior capsule. Venous drainage is usually into the right and middle hepatic veins but can be directly into the inferior vena cava via an inferior right hepatic vein.

Segment VI Segment VI forms the inferior part of the right posterior sector, which is posterior to the right portal fissure. It is often supplied by two to three branches from the right posterior perivascular fibrous capsule. Occasionally, the perivascular fibrous capsule to segment VI arises directly from the right pedicle. Venous drainage is normally into the right hepatic vein but, as in segment V, can be directly into the inferior vena cava via an inferior right hepatic vein.

Segment VII Segment VII forms the superior part of the right posterior sector and lies posterior to the right hepatic vein. The sheath to segment VII is often single. The venous drainage is into the right hepatic vein; occasionally, the segment drains directly into the inferior vena cava.

Segment VIII Segment VIII is the superior part of the right anterior sector. The right anterior sectoral sheath ends in segment VIII and supplies it, after giving off branches to segment V. Venous drainage is to the right and middle hepatic veins.

Peritoneal attachments and ligaments of the liver

The liver is attached to the anterior abdominal wall, diaphragm and other viscera by several peritoneal ligaments.

Falciform ligament and round ligament of the liver

The liver is attached to the anterior abdominal wall by the falciform ligament, derived from the ventral mesogastrium in the embryo. The two layers of this ligament pass posteriorly and slightly to the right from

the posterior surface of the anterior abdominal wall and the undersurface of the diaphragm in the midline, and are attached to the anterior and superior surfaces of the liver. On the most superior surface, the right leaf runs laterally and is continuous with the superior layer of the coronary ligament. The left layer of the falciform ligament turns medially and is continuous with the anterior layer of the left triangular ligament. The round ligament of the liver is the obliterated remnant of the left umbilical vein of the fetus; it runs in the inferior free border of the falciform ligament and continues into a fissure on the inferior surface of the liver. In fetal life, the left umbilical vein opens into the left branch of the hepatic portal vein and usually becomes obliterated soon after birth. However, it sometimes remains partially patent such that it can be dissected at the umbilicus, dilated and used to access the left branch of the hepatic portal vein in some individuals. Typically, the round ligament of the liver reopens in the setting of portal hypertension caused by cirrhosis of the liver, and it can become a sizeable collateral channel to the anterior abdominal wall.

The round ligament of the liver is important in abdominal surgery for several reasons. It is often divided in upper abdominal surgery to optimize access to the upper abdominal viscera or as the first step in mobilizing the liver. It is vascularized by numerous small arterial branches (mainly from the artery to segment IV) that anastomose with branches of the superior epigastric artery; it is therefore important to ligate or coagulate the ligament during its division. The round ligament of the liver is a guide to the segment III hepatic duct in hepaticojejunostomy formation, and to the left branch of the hepatic portal vein lying in the umbilical fissure during mesenterico-portal vein bypass (Vellar et al 1998, di Francesco et al 2014).

Coronary ligament

The coronary ligament is formed by the reflection of the peritoneum from the respiratory diaphragm onto the superior and posterior surfaces of the right lobe of the liver. A large triangular area of liver devoid of peritoneal covering, the so-called 'bare area', lies between the two layers of the coronary ligament. Here, the liver is attached to the diaphragm by loose connective tissue that is continuous inferiorly with the 'anterior pararenal space'. On the right, the two layers of the coronary ligament converge laterally to form the right triangular ligament. On the left, the two layers become closely applied and form the left triangular ligament. The superior layer of the coronary ligament is reflected superiorly onto the inferior surface of the respiratory diaphragm and inferiorly onto the right and superior surfaces of the liver. The inferior layer of the coronary ligament is reflected inferiorly over the right suprarenal gland and right kidney and superiorly onto the inferior surface of the liver. Surgical division of the right triangular and coronary ligaments allows the right lobe of the liver to be rotated anteriorly and to the left to expose the lateral aspect of the inferior vena cava posterior to the liver.

Triangular ligaments

The left triangular ligament is a double layer of peritoneum that extends for a variable length over the superior border of the left lobe of the liver. Medially, the anterior leaf is continuous with the left layer of the falciform ligament, and the posterior layer is continuous with the left layer of the lesser omentum. The left triangular ligament lies in front of the abdominal part of the oesophagus and part of the fundus of the stomach: its division allows the left lobe of the liver to be mobilized for exposure of the abdominal part of the oesophagus and crura of the respiratory diaphragm. However, the left triangular ligament is also an important stabilizing factor for the left lobe after excision of the right lobe of the liver: its division destabilizes the left lobe so that it can rotate and displace into the space created under the right half of the diaphragm, compromising the venous outflow of the left lobe and/or portal venous inflow to the left lobe, with consequent liver dysfunction. If the left triangular ligament is divided, the left lobe should be stabilized by reattaching the falciform ligament to the anterior abdominal wall.

The right triangular ligament is a short structure that lies at the right lateral limit of the 'bare area' of the liver and represents the convergence laterally of the two layers of the coronary ligament.

Lesser omentum

The lesser omentum is a double layer of peritoneum that extends from the lesser curvature of the stomach and proximal duodenum to the inferior surface of the liver. Its free margin contains the portal triad (Ch. 62). Its attachment to the inferior surface of the liver is L-shaped. The vertical component follows the line of the fissure for the ligamentum venosum, the fibrous remnant of the ductus venosus. More inferiorly, the attachment runs horizontally to complete the L-shape in the porta hepatis. At its superior end, the left layer of the lesser omentum is continuous with the posterior layer of the left triangular ligament, and the right layer is continuous with the coronary ligament as it encloses the inferior vena cava. At its inferior end, the two layers of the lesser omentum diverge to surround the structures of the porta hepatis. A thin, fibrous condensation of fascia usually runs from the medial end of the porta hepatis into the fissure for the round ligament of the liver. This fascial condensation is continuous with the lower border of the falciform ligament where the round ligament of the liver re-emerges at the inferior border of the liver. Care should be taken when dividing the lesser omentum because it may contain a replaced or accessory left hepatic artery; when present, this invariably extends to the liver at the base of the umbilical fissure and can be identified by a pulsation in the lesser omentum close to that fissure.

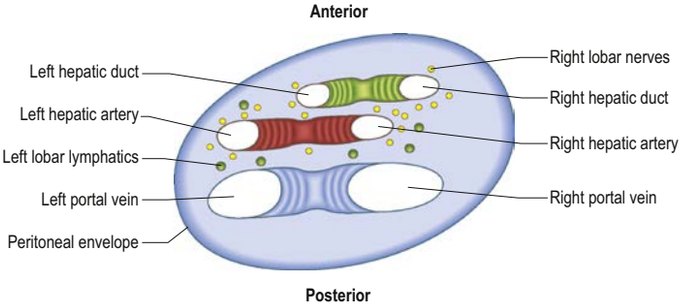

Fig. 66.7 A cross-section of the structures at the porta hepatis viewed from above.

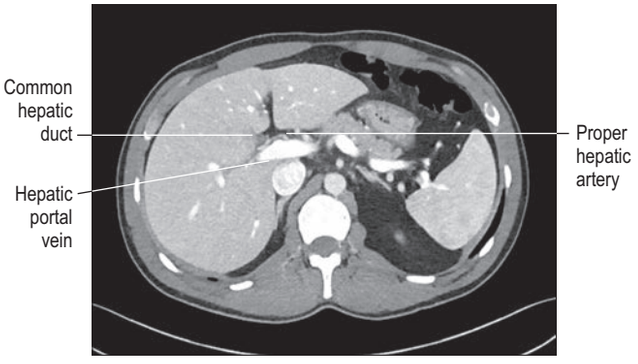

Fig. 66.8 An axial CT of the porta hepatis. The hepatic ducts lie anteriorly, the hepatic portal vein posteriorly and the hepatic artery between the two.

Ligamentum venosum

The ligamentum venosum represents the obliterated venous connection that existed in the fetus between the left branch of the hepatic portal vein and the termination of the left hepatic vein (the ductus venosus). It is used as a guide to gain control of the left hepatic vein outside the liver during surgery. By dividing the ligament close to its insertion into the left hepatic vein and retracting it laterally, the angle between the left and the middle hepatic veins can be accessed.

This manoeuvre can be helpful in left liver resection with preservation of the caudate lobe, but if the caudate lobe is to be removed, the left hepatic vein (or more usually the confluence of the left and middle hepatic veins with the inferior vena cava) can be approached more posteriorly without division of the ligamentum venosum.

Porta hepatis, hepatoduodenal ligament and hilar plate

The porta hepatis is a deep transverse fissure on the inferior surface of the liver, between the quadrate lobe anteriorly and the caudate process posteriorly. It contains the hepatic portal vein, hepatic artery and hepatic nervous plexuses as they ascend into the parenchyma of the liver, and the right and left hepatic ducts and some lymph vessels that emerge from the liver. The hepatic ducts usually lie anterior to the hepatic portal vein and its branches, and the hepatic artery with its branches lies between the two (**Figs 66.7–66.8**). However, the right hepatic artery sometimes lies anterior to the common hepatic duct, a variation that is important during bile duct reconstruction by hepaticojejunostomy (Michels 1966). All these structures are enveloped within a sheath of loose connective tissue (perivascular fibrous capsule) that

surrounds the vessels and bile ducts as they course through the liver parenchyma and is continuous with the fibrous capsule. The dense aggregation of vessels, supporting connective tissue and liver parenchyma just superior to the porta hepatis is often referred to as the 'hilar plate' of the liver (Kawarada et al 2000). Understanding the concept of the hilar plate is important in surgical approaches to the hilar structures, and division or lowering of the hilar plate is essential for optimum surgical access to the left hepatic duct.

The hepatic artery, bile duct and hepatic portal vein extend between the porta hepatis and the superior border of the duodenum in the free edge of the hepatoduodenal ligament, which forms the anterior boundary of the omental foramen (of Winslow). Rapid control of the vessels entering the porta hepatis (the hepatic pedicle) can be obtained by compressing them in the free edge of the lesser omentum (a 'Pringle' manoeuvre); this is conveniently done by dividing the lesser omentum immediately to the left of these structures and passing a tape around them through the omental foramen.

The left hepatic duct is extrahepatic as it descends obliquely along the undersurface of segment IV (the quadrate lobe) to the confluence of the hepatic ducts. Access to this extrahepatic segment of the left hepatic duct is particularly useful during a biliary-enteric bypass procedure to treat a stricture of the hepatic duct confluence. The right hepatic duct is more intrahepatic and extension of a hepaticojejunal anastomosis on to the right hepatic duct necessitates incision of the liver in the fossa for the gallbladder.

Perivascular fibrous capsules

The fibrous capsule of the liver (Glisson's capsule) becomes condensed as the perivascular fibrous capsules (Glissonian sheaths) around the branches of the portal triad structures as they enter the liver and subdivide into segmental branches (Kuntz and Kuntz 2008). Thus, each bile duct, hepatic artery and hepatic portal vein is surrounded by a single fibrous capsule. Within each capsule, the hepatic portal vein is surrounded by loose areolar connective tissue, making dissection of the hepatic portal vein relatively easy. The fibrous tissue around the bile ducts and hepatic artery is tougher so dissection of these structures is more difficult. This capsular arrangement facilitates surgical control of the right and left vasculobiliary pedicles of the liver, as well as sectoral and segmental divisions in complex liver resections (Yamamoto et al 2012).

Vascular supply and lymphatic drainage

The hepatic artery, hepatic portal vein and hepatic veins supply or drain the liver. The portal vein and hepatic artery ascend in the lesser omentum to the porta hepatis, where each usually bifurcates. The common hepatic duct and lymphatic vessels descend from the porta hepatis alongside the hepatic portal vein and hepatic artery (see Fig. 66.8). The hepatic veins leave the liver via its posterior surface and run directly into the inferior vena cava.

Hepatic artery

During fetal and early postnatal life the common hepatic artery is the largest branch of the coeliac trunk, whereas in adults it is intermediate in size between the left gastric and splenic arteries. The common hepatic artery (Fig. 66.9) gives off the right gastric and gastroduodenal arteries (Fig. 66.9A). After originating from the coeliac trunk, it passes anteriorly and laterally, above the superior border of the pancreas, to the superior aspect of the first part of the duodenum. It is subdivided into the common hepatic artery, from the coeliac trunk to the origin of the gastroduodenal artery, and the proper hepatic artery, from that point to its bifurcation. Both parts ascend anterior to the hepatic portal vein and medial to the bile duct within the free margin of the hepatoduodenal ligament in the anterior wall of the omental foramen. The left and right hepatic arteries arise at a variable level

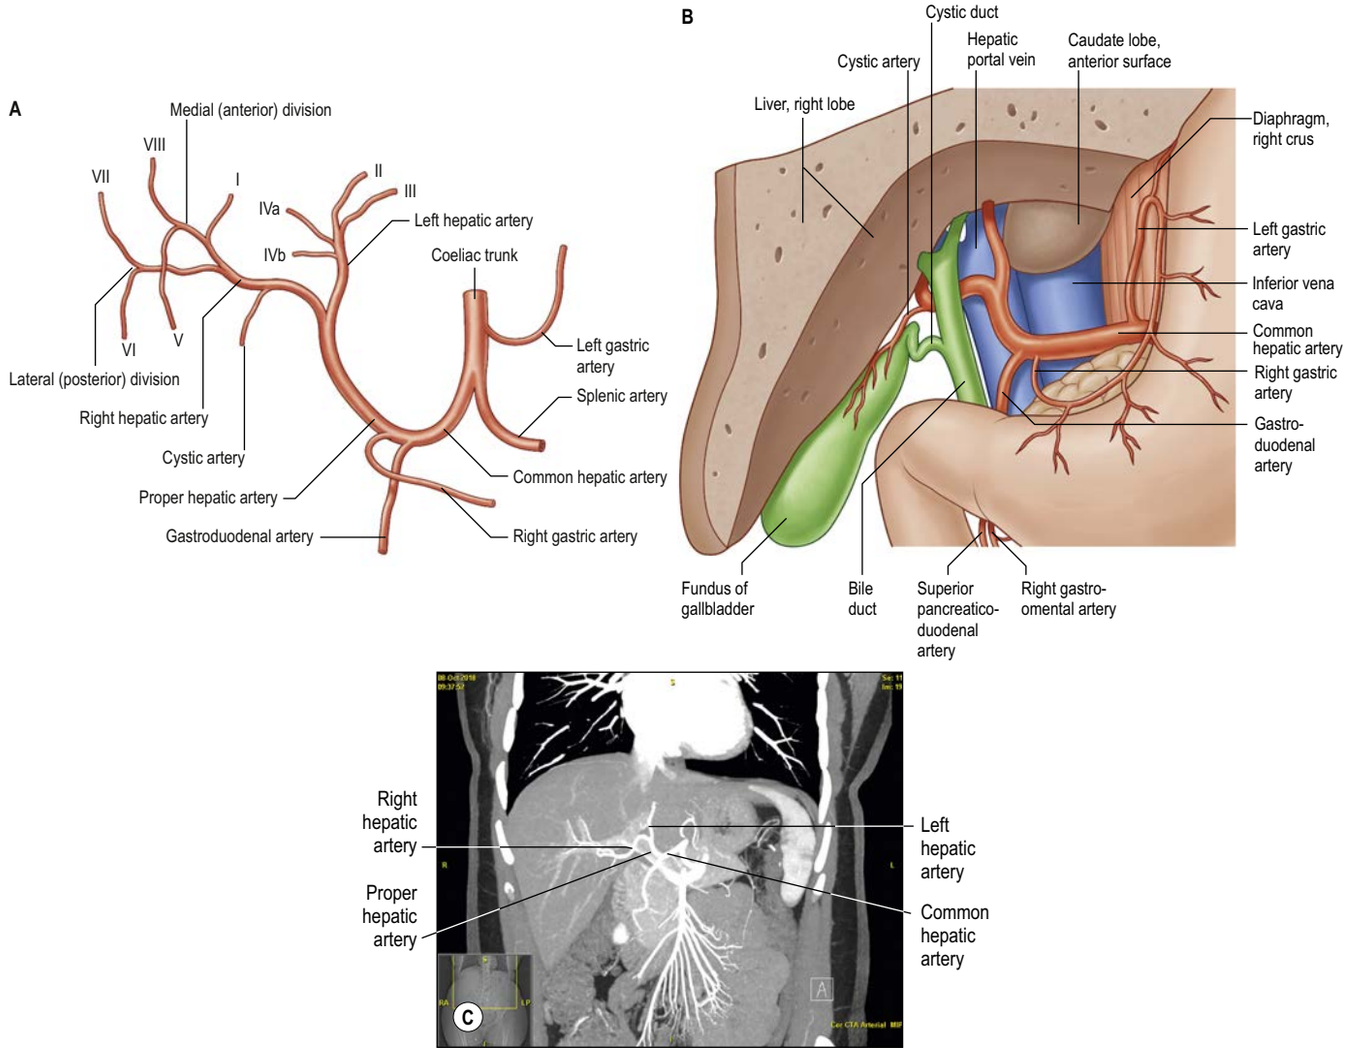

Fig. 66.9 The hepatic artery. **A**, Branches. **B**, Usual relations of the hepatic artery, bile duct and hepatic portal vein to each other in the lesser omentum: anterior aspect, portion of the liver removed. Note that the left gastric artery more commonly arises from the coeliac trunk. **C**, CT showing hepatic artery anatomy. (D, *continued online*)

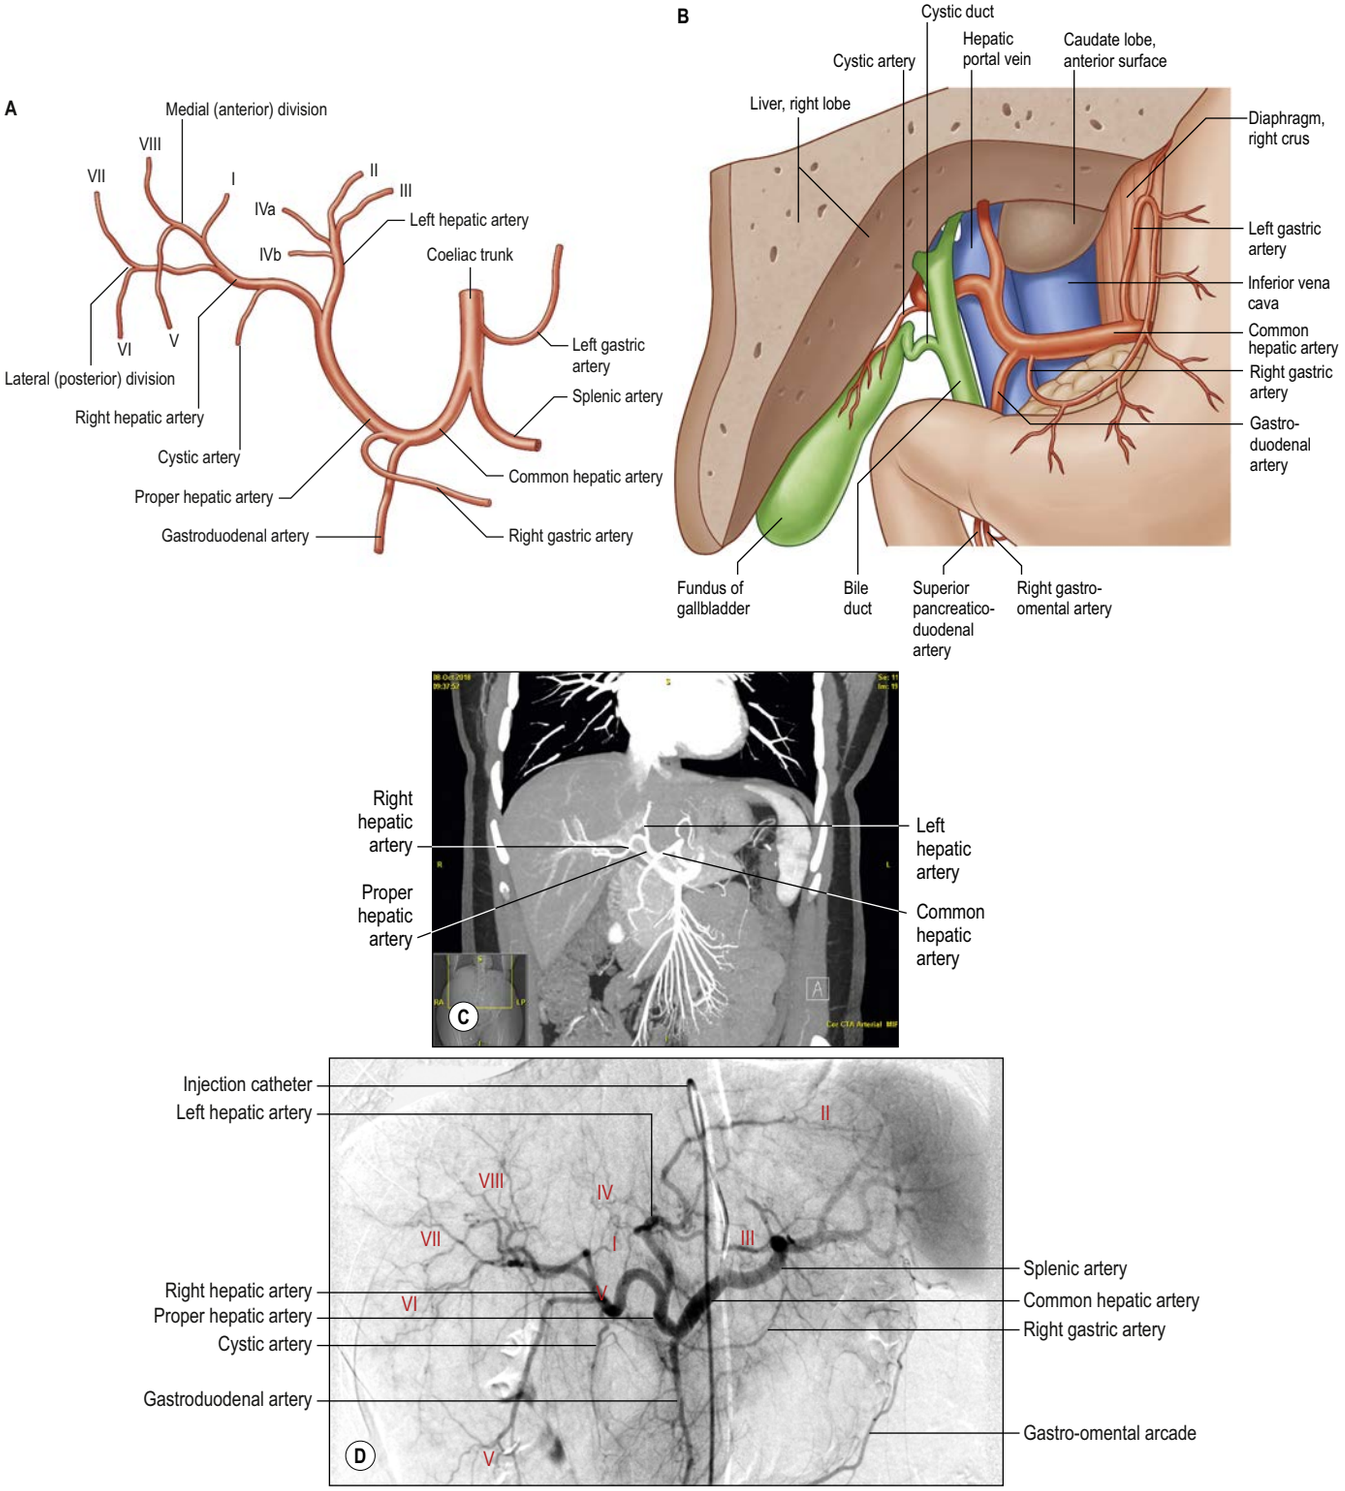

Fig. 66.9 The hepatic artery. **A**, Branches. **B**, Usual relations of the hepatic artery, bile duct and hepatic portal vein to each other in the lesser omentum: anterior aspect, portion of the liver removed. Note that the left gastric artery more commonly arises from the coeliac trunk. **C**, CT showing hepatic artery anatomy. **D**, Digital subtraction angiogram of the coeliac trunk showing the hepatic arterial tree; note that the left gastric artery has not filled.

below the porta hepatis. The right hepatic artery typically crosses posterior (occasionally anterior) to the common hepatic duct (**Fig. 66.9B**). Its usual course is toward the common hepatic duct: it bends inferiorly before crossing posterior to the duct and then bends back up toward the right hepatic duct lateral to the common hepatic duct and hepatic portal vein. Its close proximity to the bifurcation of the bile duct means that it is often involved or encased by bile duct cancers that arise at the bifurcation (hilar cholangiocarcinoma). The right hepatic artery is more frequently involved than the left hepatic artery in bile duct cancers of the porta hepatis. Occasionally, the right hepatic artery crosses anterior to the common hepatic duct and is more vulnerable to injury during biliary surgery. It almost always divides into an anterior branch supplying segments V and VIII and a posterior branch supplying segments VI and VII. The anterior division also often supplies a branch to segment I and the gallbladder. The proper hepatic artery sometimes divides at a more proximal level close to its origin; occasionally it divides distally, well to the left of the porta hepatis. The main significance of a proximal division is that the right hepatic artery can pass posterior to the hepatic portal vein (Launois and Jamieson 1993). The segmental arteries of the liver are macroscopically end arteries, although some collateral circulation occurs between segments via fine terminal branches.

Anatomical variants of the normal arrangement of the hepatic arteries are found in about one-third of individuals and are important to recognize because they are relevant to surgical and interventional radiological procedures (Michels 1966, Covey et al 2002, López-Andújar et al 2007, Saba and Mallarini 2011). An artery that supplies a part of the liver in addition to the normal artery supplying that part is defined as an accessory artery. A replaced hepatic artery is an artery that does not originate from an orthodox position and provides the sole supply to that part of the liver.

The most common anatomical variants are a replaced or accessory left hepatic artery that arises from the left gastric artery, or a replaced or accessory right hepatic artery that arises from the superior mesenteric artery, both occurring in 10–20% of individuals.

Variations in the intrahepatic arteries are common and can be important surgically. For example, the segment IV artery most commonly arises from the left hepatic artery, but in up to 30% of cases it arises from the right hepatic artery or the proper hepatic artery (Onishi et al 2000). The segment IV artery never arises to the right of the common hepatic duct, which means that if the right hepatic artery is divided to the right of the common hepatic duct, the arterial supply to segment IV is not endangered. Failure to recognize this variation can compromise the blood supply to segment IV following right hepatectomy, and it is especially important during right liver donation for live donor liver transplantation.

Veins

The liver has two venous systems. The portal venous system conveys blood from the majority of the gastrointestinal tract and its associated organs to the liver. The hepatic venous system drains blood from the liver parenchyma into the inferior vena cava.

Hepatic portal vein

The hepatic portal vein is formed posterior to the neck of the pancreas, usually from the convergence of the superior mesenteric and splenic veins (**Fig. 66.12**; see also Fig. 59.7). Its origin lies in the transpyloric plane between the inferior border of the body of the first lumbar vertebra and the superior border of the body of the second lumbar vertebra (Mirjalili et al 2012). The hepatic portal vein is approximately 8 cm long and ascends obliquely to the right, posterior to the superior (first) part of the duodenum, bile duct and gastroduodenal artery, and anterior to the inferior vena cava. It enters the hepatoduodenal ligament and ascends anterior to the omental foramen to reach the right end of the porta hepatis, where it divides into right and left main branches that enter the liver. In the lesser omentum, the hepatic portal vein lies posterior to both the bile duct and the hepatic artery. It is surrounded by the hepatic nervous plexus and accompanied by numerous lymphatics and some lymph nodes. The hepatic portal vein contains smooth muscle in its wall and, in experimental animals at least, has well-developed spontaneous contractions with frequencies between 0.01 and 1 Hz (Burt 2003). It is typically valveless.

The main extrahepatic tributaries of the hepatic portal vein are the left gastric vein, which ends in the left margin of the hepatic portal vein, and the posterior superior pancreaticoduodenal vein near the head of the pancreas. The hepatic portal vein divides into right and left branches at the porta hepatis of the liver (**Fig. 66.13**). The left branch of the hepatic portal vein has a longer extrahepatic course (4–5 cm) than the right branch of the hepatic portal vein, tends to lie more horizontally, and is often smaller in calibre. The horizontal portion runs along the inferior surface of segment IV and invariably gives branches to segment I and sometimes to segment IV. The left branch of the hepatic portal vein continues within the liver, giving off a segment II branch laterally before taking a more anterior and vertical course in the umbilical fissure, where it gives off branches to segments III and IV and receives the obliterated left umbilical vein (round ligament of the liver). Most of the portal venous supply to segment IV comes from the left branch of the hepatic portal vein and only occasionally from either the right branch of the hepatic portal vein or its branches to segments V or VIII. The right branch of the hepatic portal vein is only 2–3 cm in length and usually divides into a right medial (anterior) sectoral division supplying segments V and VIII, and a right lateral (posterior) sectoral division supplying segments VI and VII. The medial division can give a branch to segment I.

Hepatic portal vein variations usually involve the right branch (Covey et al 2004). When this branch is absent (10–15% of livers), the hepatic portal vein usually trifurcates into left portal, right anterior and right posterior sectoral veins. Absence of the right branch of the hepatic portal vein might be considered as a relative contraindication for split liver and live donor liver transplantations because this variation is often associated with a similar variation in biliary anatomy. The right anterior sectoral portal vein can arise from the hepatic portal vein, or the right posterior sectoral portal vein can originate from the left branch of the hepatic portal vein, variations that are important to remember during left-sided liver resection. When the bifurcation of the hepatic portal vein is absent, the hepatic portal vein enters the liver, giving off the right sectoral branches, and then turns left to supply the left lobe, a variation that presents an added complexity in major liver surgery (Chaib 2009).

Porto-systemic shunts

Increased pressure within the portal venous system can result in dilation of portal venous tributaries and reversed flow at sites of porto-systemic anastomoses. Common sites of porto-systemic shunts are listed in **Table 66.1**, and see also Sharma and Rameshbabu (2012).

Hepatic veins

The liver drains by three major hepatic veins into the suprahepatic part of the inferior vena cava and via numerous minor hepatic veins that drain into the retrohepatic inferior vena cava. The adult retrohepatic inferior vena cava is 6–7 cm long and is surrounded to a variable extent by segment I (Camargo et al 1996). The three major veins are located between the four sectors of the liver (see Fig. 66.6A; **Figs 66.14–66.15**). Thus, the right hepatic vein lies between the right anterior and posterior sectors, the middle hepatic vein lies between the right and left hemilivers, and the left hepatic vein lies between the left medial and lateral sectors. During hepatic resection, the surgeon should transect the liver parenchyma slightly to the left or right of the particular fissure that is being opened to avoid the main trunk of a hepatic vein.

Right hepatic vein

The right hepatic vein is the longest and largest hepatic vein. It is usually single, but occasionally remains as two trunks until it terminates by draining into the inferior vena cava. It runs in the right portal fissure between the right medial and lateral sectors. It drains the whole of segments VI and VII and variable proportions of segments V and VIII, depending on the extent to which these segments drain into the middle hepatic vein. The right hepatic vein is formed anteriorly near the inferior border of the liver and lies in a coronal plane through most of its course. It drains into the inferior vena cava near the superior border of the caudate lobe. Of the three major hepatic veins, the right hepatic vein is most variable in calibre, reflecting the variable contribution of the middle hepatic vein to the drainage of segments V and VIII and the existence of an accessory right inferior (30%) and/or middle hepatic vein (10%) (Fang et al 2012). The hepatic venous anatomy is particularly important in right lobe living donation and can be assessed preoperatively by computed tomography (CT) or magnetic resonance imaging (MRI), and/or by intraoperative ultrasound.

Middle hepatic vein

The middle hepatic vein lies in the main portal fissure between the right and left hemilivers. It usually joins the left hepatic vein and terminates in the inferior vena cava as a short common trunk; it ends as a single trunk in the inferior vena cava in fewer than 10% of individuals. The middle hepatic vein drains the central part of the liver and receives constant tributaries from segments IV, V and VIII. The vein from segment IV lies in a sagittal plane and enters the middle hepatic vein on its left side. The vein from segment VIII runs transversely into the right side of the middle hepatic vein and is sometimes large enough to be mistaken for the middle hepatic vein. Anteriorly, the middle hepatic vein drains some of segment V; the calibres of the tributaries draining segments V and VIII are variable. Intrahepatic venous anastomoses between the middle and right hepatic veins, particularly in segment VIII, have been reported in up to one-third of adult livers (Hribernik and Trotovšek 2014).

A replaced proper hepatic artery can arise from the superior mesenteric artery (**Fig. 66.10**) and can be suspected at surgery by a relatively superficial hepatic portal vein (reflecting the absence of a hepatic artery that would normally ascend in front of the vein). More commonly, a replaced or accessory right hepatic artery arises from the superior mesenteric artery (see Fig. 66.10; **Fig. 66.11**). In such cases, the variant artery runs in the lesser omentum posterior to the hepatic portal vein and bile duct and can usually be identified at surgery by palpable pulsation posterior to the hepatic portal vein. An accessory right hepatic artery can be injured during resection of the pancreatic head because it lies close to the hepatic portal vein. Occasionally, a replaced or accessory left hepatic artery arises from the left gastric artery, entering the liver through the umbilical fissure; this artery provides a source of collateral supply in cases where the arteries at the porta hepatis are occluded, but it can also be injured during mobilization of the stomach as it lies in the superior portion of the lesser omentum. Rarely, an accessory left or right hepatic artery arises from the gastroduodenal artery or directly from the aorta. The presence of replaced arteries can be life-saving in patients with bile duct cancer; because they are further away from the bile duct they tend to be spared from infiltration by the cancer, making excision of the tumour feasible. Knowledge of these variations is also essential when whole and split liver transplantation is performed, and their presence often requires reconstruction.

TABLE 66.1 Common sites of porto-systemic anastomoses in portal hypertension and associated clinical implications

Hepatic portal vein tributaries	Systemic veins	Clinical presentations
Left gastric vein	Distal oesophageal veins draining into azygos and hemiazygos veins	Oesophageal and gastric varices
Superior anorectal veins	Middle and inferior anorectal veins draining into internal iliac and internal pudendal veins	Rectal varices
Persistent tributaries of left branch of hepatic portal vein in round ligament of the liver	Periumbilical branches of epigastric and intercostal veins	'Caput medusae'
Tributaries of right branch of hepatic portal vein overlying 'bare area' of liver	Retroperitoneal veins draining into azygos, hemiazygos, lumbar, intercostal and inferior phrenic veins	Dilated retroperitoneal veins at risk during surgery or interventional procedures
Omental and colonic veins near right and left colic flexures	Retroperitoneal veins near right and left colic flexures	Can be problematic during surgery

Left hepatic vein

The left hepatic vein lies between the left medial and left lateral sectors of the liver and drains segments II, III and occasionally IV. Small veins draining segment II and occasionally the superior part of segment IV, can drain directly into the inferior vena cava. The umbilical fissure vein, a major tributary of the left hepatic vein, usually runs between segments III and IV and contributes to their drainage. Occasionally, the vein draining segment III ends separately in the confluence of the left and middle hepatic veins. These variations in venous drainage are significant in split liver transplantation and live donor liver transplantation.

Minor hepatic veins

Segment I veins, ranging in number from one to five, drain directly into the inferior vena cava. Since this segment has a venous drainage independent of the rest of the liver, segment I often continues to drain effectively and undergoes compensatory hypertrophy in patients with Budd–Chiari syndrome, where the major hepatic veins are obstructed. There can be an accessory inferior or middle right hepatic vein, and several smaller 'retrohepatic' veins that drain the right lobe directly into the inferior vena cava. When present, these veins are surgically important, especially if they exceed 5 mm in diameter. They drain segments V and VI independently of the three major hepatic veins, which means that a tumour involving the latter can be resected safely as long as venous drainage from the accessory veins is preserved. In live donor and split liver transplantations, larger accessory veins must be individually anastomosed to the recipient inferior vena cava to ensure adequate venous drainage.

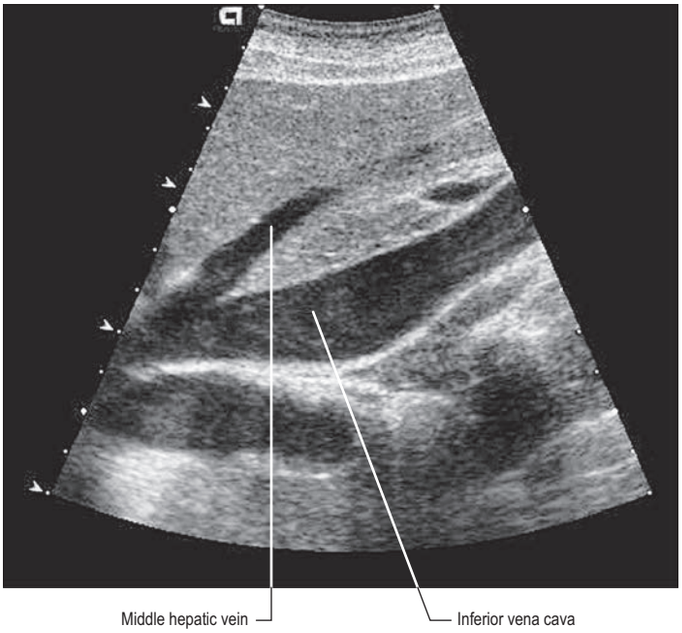

Fig. 66.14 Ultrasound of the liver in the sagittal plane. The middle hepatic vein is seen draining into the inferior vena cava.

Transjugular intrahepatic porto-systemic shunt (TIPS) procedure for portal hypertension

Available with the *Gray's Anatomy* e-book

Lymphatic drainage

Lymph from the liver is rich in protein and is mostly a product of the hepatic sinusoids (Ohtani and Ohtani 2008). It passes via deep and superficial pathways to nodes superior and inferior to the respiratory diaphragm (Trutmann and Sasse 1994). Obstruction of hepatic venous drainage increases the flow of lymph in the thoracic duct.

Superficial hepatic lymphatics

Superficial lymphatics run in subserosal areolar tissue over the surface of the liver and drain in four directions. Lymphatics from most of the posterior surface, including the caudate lobe, drain into nodes alongside the inferior vena cava; a few lymphatics from the posterior surface of the left lobe pass towards the oesophageal hiatus and nodes around the cardia of the stomach. Lymphatics in the coronary and right triangular ligaments can pass directly to the thoracic duct. Lymphatics from most of the inferior, anterior and superior surfaces drain into hepatic nodes at the porta hepatis. A few lymphatics from the right superior surface accompany the inferior phrenic artery across the right crus of the respiratory diaphragm to drain into coeliac nodes.

Deep hepatic lymphatics

Fine lymphatics within the portal triads and around interlobular veins merge to form larger vessels. Some ascend through the parenchyma to pass through the caval foramen of the respiratory diaphragm and drain into nodes located in the inferior mediastinum, but most drain to lymph nodes at the porta hepatis.

Innervation

The parenchyma of the liver is supplied by nerves arising from the hepatic plexus that all enter the liver at the porta hepatis. Some nerve fibres also appear to arise from the right phrenic nerve and this might be the basis of referred shoulder pain in patients with biliary colic (Skandalakis et al 2004). The fibrous capsule of the liver is supplied by fine branches of the inferior intercostal nerves that also supply the parietal peritoneum, particularly around the 'bare area' and superior surface of the liver: distension or disruption of the fibrous capsule causes well-localized sharp pain.

Hepatic plexus

The hepatic plexus receives preganglionic parasympathetic fibres from the anterior and, to a lesser extent, the posterior vagal trunk, and postganglionic sympathetic fibres via the coeliac and superior mesenteric plexuses. Nerve fibres accompany the branches of the portal triad into the liver, penetrating as far as the hepatocytes. Aminergic, cholinergic, peptidergic and nitrergic nerve fibres have been identified and appear to be involved in hepatic metabolism and the control of sinusoidal blood flow (McCuskey 2004): the transplanted, denervated liver indicates that this role is not essential. Multiple fine branches from the plexus supply the extrahepatic bile ducts and gallbladder; parasympathetic fibres are motor to the smooth muscle of the bile ducts and gallbladder and inhibitory to the sphincter of the bile duct. Branches from the plexus also run inferiorly with the right gastric artery to contribute to the supply of the pylorus; with the gastroduodenal artery and its branches to reach the pylorus, proximal duodenum and pancreas; and with the right gastro-omental (gastro-epiploic) artery to provide a small contribution to the nerve supply of the stomach.

Referred pain

Pain arising from the parenchyma of the liver is poorly localized. In common with other structures of foregut origin, pain is referred to the epigastric region. Stretch or irritation of the fibrous capsule of the liver by inflammation or neoplasia produces well-localized 'somatic' pain. Pathology involving the diaphragmatic surface of the liver can be referred via the phrenic nerve to the right shoulder region (C3, C4, C5 dermatomes).

Microstructure

The liver is essentially an epithelial-mesenchymal outgrowth of the caudal part of the foregut, with which it remains connected via the biliary tree (Ch. 59). Most of the surface of the liver is covered by a typical serosa, the visceral peritoneum. Beneath this, and enclosing the whole organ, is a thin (50–100 μm) capsule of connective tissue, from which extensions pass into the liver as septa and trabeculae. Branches of the hepatic artery and hepatic portal vein, together with bile ductules and ducts, run within these connective tissue trabeculae (portal tracts). The combination of two types of blood vessel and a bile duct is termed a portal triad, and is usually accompanied by one or more lymphatic vessels and nerves (Fig. 66.16).

The liver parenchyma consists of a complex network of epithelial cells, supported by connective tissue and perfused by a rich blood supply from the portal vein and hepatic artery. The epithelial cells, hepatocytes, carry out the major metabolic activities, but additional cell types have storage, phagocytic and mechanically supportive functions. In the mature liver, hepatocytes are arranged mainly in plates (or cords when seen in two-dimensional sections) that are usually only one cell thick, separated by venous sinusoids that anastomose with each other via gaps in the plates (Fig. 66.17).

Bile is secreted by hepatocytes and is collected in a network of minute channels (canaliculi) between adjacent hepatocyte plasma membranes. Hepatocytes can therefore be regarded as exocrine cells, secreting bile into the gastrointestinal tract via the extrahepatic bile ducts. Their other metabolic functions involve complex biochemical exchanges with the blood.

The fetal liver is a major haemopoietic organ; erythrocytes, leukocytes and platelets develop from mesenchyme covering the sinusoidal endothelium.

In cases of extreme chronic portal hypertension a large calibre anastomosis between the portal and systemic circulations can be created within the liver parenchyma by inserting a stent between a large hepatic portal vein and a hepatic vein within the liver. The stent is introduced through a catheter inserted into the internal jugular vein and guided into the liver under radiological control (Siramolpiwat 2014). This large shunt relieves the severe portal hypertension but tends to worsen hepatic encephalopathy.

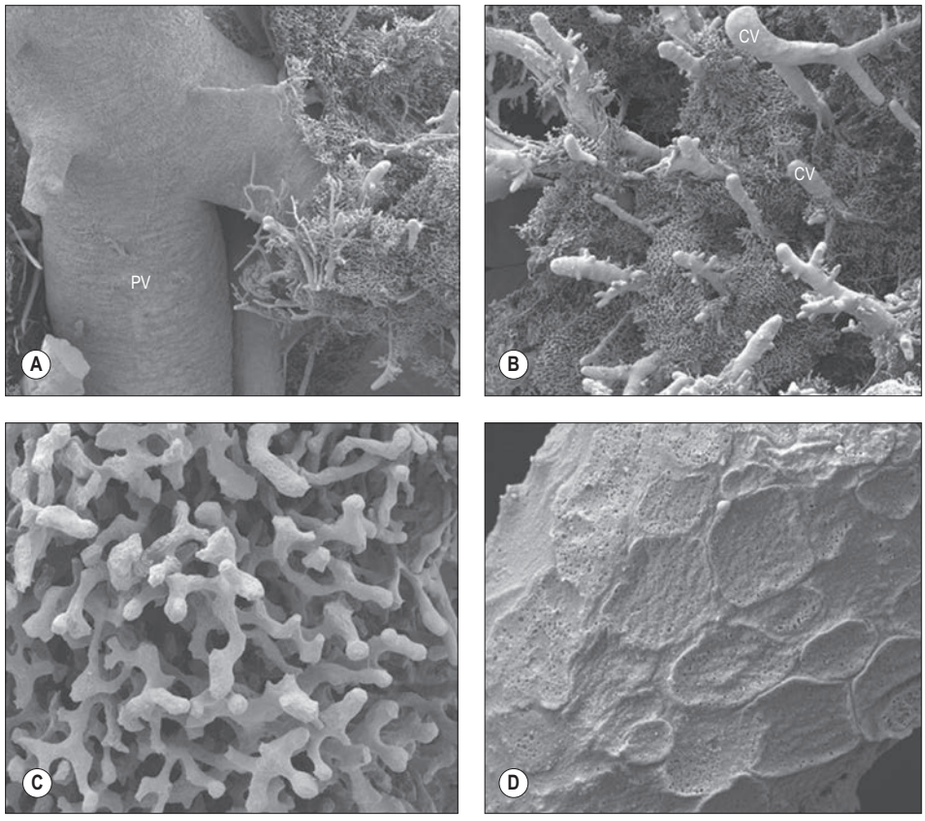

Fig. 66.17 Scanning electron micrographs of a resin corrosion cast of the liver demonstrating the three-dimensional arrangement of the hepatic sinusoids. **A**, A hepatic portal vein (PV) branch within a portal triad ×33 100 μm. **B**, Sinusoids and central veins (CV) ×37 100 μm. **C**, A sinusoidal network ×330 10 μm. **D**, Sinusoidal endothelial cells ×7000 1 μm. Fig. 66.16 The structural organization of the liver. **A**, Lobules bordered by delicate connective tissue septa (arrows) in which run branches of the hepatic portal vein, hepatic artery and bile duct, grouped as portal triads. A central vein drains each lobule. **B**, A portal triad containing branches of the hepatic portal vein (PV; generally the largest profile), the hepatic artery (A) and a bile duct (B), with typical round epithelial nuclei. Other small bile ductule and arteriolar branches are also visible. **C**, A functional view, in which the territories of the hepatic lobules are shown as regular hexagons (unlike their real appearance, which is highly variable). Functionally, the liver microarchitecture is better considered in terms of acini extending between adjacent central venules and divided into three zones as shown. (A, With permission from Dr JB Kerr, Monash University, from Kerr JB 1999 Atlas of Functional Histology. London: Mosby. B, Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Lobulation of the liver

The structural unit of the liver is the lobule: a roughly hexagonal arrangement of plates of hepatocytes, separated by intervening sinusoids that radiate outwards from a central vein, with portal triads at the vertices of each hexagon (**Fig. 66.18**; see Fig. 66.16). The central veins drain into the hepatic veins. In some species the classic lobular units are delimited microscopically by distinct connective tissue septa. However, the lobular organization of the human liver is not immediately evident in histological sections; the lobules do not have distinct boundaries, and connective tissue is sparse. The plates do not pass straight to the periphery of a lobule like the spokes of a wheel but run irregularly as they anastomose and branch.

Detailed studies of human liver, using three dimensional reconstruction and morphometric analyses combined with histopathological observations, have revealed a highly ordered arrangement of functional units, the liver acini. Each acinus is an approximately ovoid mass of tissue, orientated around the terminal branches of a hepatic arteriole and portal venule, with its long axis defined by two adjacent central veins. It includes the hepatic tissue served by these afferent vessels and is bounded by adjacent acini. Acinar functional heterogeneity is related to blood supply, thus the functional capacities of hepatocytes in a periportal zone (zone 1) differ from those in an intermediate zone (zone 2) or in a perivenous (pericentral or centrilobular) zone (zone 3) (Kietzmann 2017) (see Fig. 66.16C).

The acinar definition of hepatic microarchitecture has clarified the interpretation of liver histopathology, particularly in relation to zones of hypoxic damage, glycogen deposition and removal, and toxic injury, all of which are related to the direction of blood flow.

Blood supply

Preterminal hepatic arterioles within the acini convey arterial blood to the sinusoids, mostly via a fine capillary plexus that drains to branches of the hepatic portal vein. A small proportion of arterial blood passes directly to the hepatic sinusoids, bypassing these capillary plexuses. Sinusoids thus contain mixed venous and arterial blood. Central veins from adjacent lobules form interlobular veins that unite as hepatic veins and drain to the inferior vena cava.

Hepatic plates (cords)

The endothelium of the sinusoids is fenestrated and lacks a continuous basal lamina, enabling the endothelial cells to act as a dynamic blood filter (Fraser et al 1995). The sinusoids are separated from the plates of hepatocytes by a narrow gap, the perisinusoidal space (of Disse), that is normally 0.2–0.5 μm wide but which distends in hypoxic states. The space contains interstitial fluid, the microvilli of adjacent hepatocytes, hepatic stellate cells, fine collagen fibres (mostly type III with some types I and IV), and occasional non-myelinated nerve terminals.

A network of minute, interconnecting biliary canaliculi (approximately 1 μm in diameter) runs between the hepatic plates. The canaliculi are formed by the apposed plasma membranes of adjacent hepatocytes, sealed by tight junctions that isolate the canalicular lumen (and bile) from adjacent intercellular space. Canaliculi conduct bile to the bile canals (of Hering), trough-like structures lined by cholangiocytes and hepatocytes within the liver lobules. Each canal collects bile from multiple canaliculi and empties into a bile ductule (lined by cholangiocytes) that drains into an interlobular bile duct within the portal tracts (Roskams et al 2004, Saxena and Theise 2004). The flow of bile is thus towards the periphery of the lobule, in the opposite direction to the centripetal blood flow.

Cells of the liver

Resident cells of the liver include hepatocytes, hepatic stellate cells (perisinusoidal cells; fat-storing cells; cells of Ito), sinusoidal endothelial cells, stellate macrophages (Kupffer cells), the epithelial cells of the biliary tree (cholangiocytes), hepatic stem cells, hepatic natural killer lymphocytes (pit cells) and connective tissue cells of the capsule and portal tracts (see Fig. 66.16B).

Hepatocytes About 80% of the volume of the liver and 60% of its cellular population is made up of hepatocytes (parenchymal cells) (see Fig. 66.18). They are polyhedral, with 5–12 sides, and measure 20–30 μm across. The nuclei are round, euchromatic and often tetraploid, polyploid or multiple, with two or more in each cell. The cytoplasm typically contains a considerable amount of rough and smooth endoplasmic reticulum, many mitochondria, lysosomes and well-developed Golgi apparatus, all features indicating high metabolic activity. Glycogen granules and lipid vacuoles are usually prominent. Numerous large peroxisomes and vacuoles containing enzymes, e.g. urease in distinctive crystalline forms, indicate the complex metabolism of these cells. Their role in iron metabolism is reflected by the presence of storage vacuoles containing crystals of ferritin and haemosiderin.

The cell surface facing the sinusoids exhibits numerous microvilli, approximately 0.5 μm long, creating a large surface area (approximately

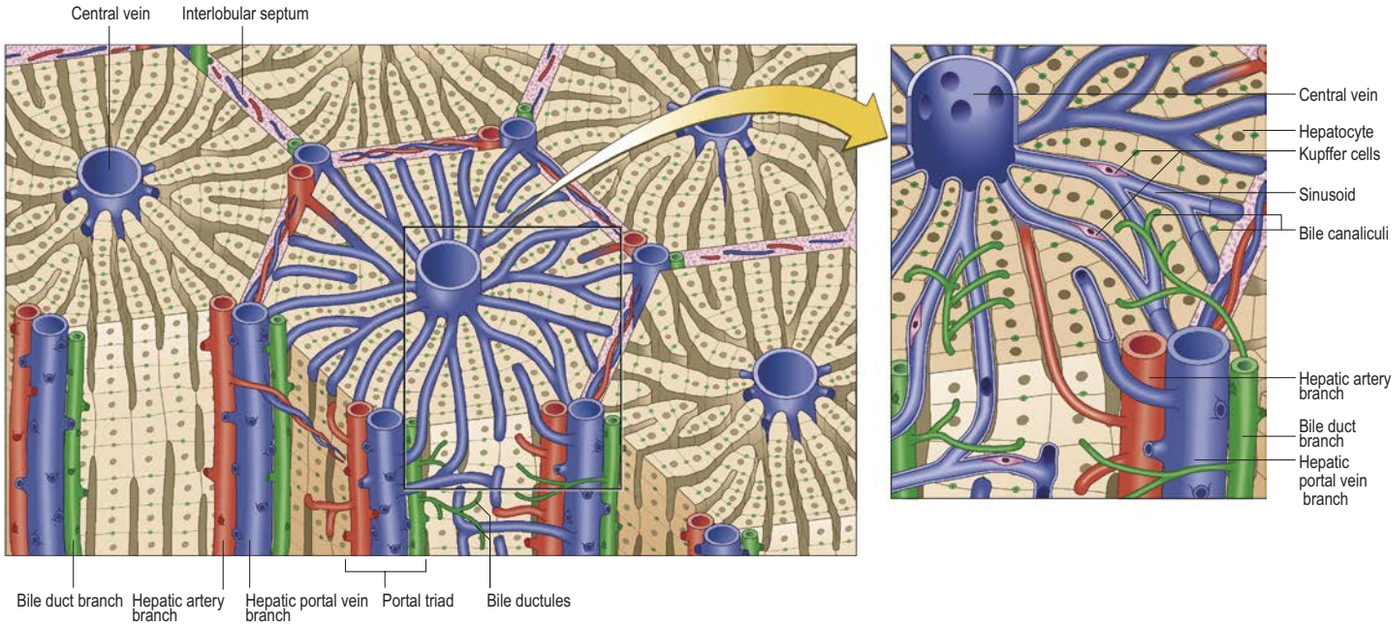

Fig. 66.18 Hepatic microstructure: sinusoidal endothelial cells are not shown.

70% of the hepatocyte surface) exposed to blood plasma. Elsewhere, hepatocytes are linked by numerous gap junctions and desmosomes. The lateral plasma membranes of adjacent hepatocytes form microscopic channels, bile canaliculi, which are specialized regions of intercellular space formed by apposing grooves in the membranes and sealed from extraneous interstitial space by tight junctions. Four types of transmembrane molecules (occludins, claudins, junctional adhesion molecules and Coxsackie virus and adenovirus receptors) constitute the core units of the functional protein complexes of the tight junctions (Lee 2012) (see Fig. 1.27). Individual tight junction complexes, either alone or in combination, are involved in signalling pathways in health and disease. Numerous membrane-bound exocytotic vesicles cluster near the lumina of the canaliculi because the secretion of bile is targeted at the canalicular plasma membrane. The tight junctions surrounding the biliary canaliculi prevent bile from entering the interstitial fluid or blood plasma, thereby creating a blood–bile barrier.

Hepatic stellate cells Hepatic stellate cells are much less numerous than hepatocytes. They lie within the perisinusoidal space between the sinusoids and the hepatocyte plates. Irregular in outline, they are characterized by numerous cytoplasmic lipid droplets in which the fat-soluble vitamin A is stored. They secrete most of the intralobular matrix components, including collagen type III (reticular) fibres and are a significant source of growth factors involved in liver homeostasis and regeneration. They play a major role in pathological processes (Yin et al 2013). In response to liver injury hepatic stellate cells become activated and predominantly myofibroblast-like. They are responsible for the replacement of damaged hepatocytes with collagenous scar tissue, hepatic fibrosis, seen initially in zone 3 around central veins. Fibrosis can progress to cirrhosis, where the parenchymal architecture and pattern of blood flow within the liver are both destroyed, with major systemic consequences.

Sinusoidal endothelial cells Hepatic venous sinusoids are generally wider than blood capillaries and are lined by a thin but highly fenestrated endothelium that lacks a complete basal lamina. The endothelial cells are typically flattened, each with a central nucleus, and are joined to each other by junctional complexes. The fenestrae are grouped in clusters with a mean diameter of 100 nm, allowing plasma direct access to the basal plasma membranes of hepatocytes. Their cytoplasm contains numerous transcytotic vesicles.

Stellate macrophages Stellate macrophages (Kupffer cells) of the liver are derived from circulating blood monocytes and originate in the bone marrow. They are long-term hepatic residents and lie within the sinusoidal lumina attached to the endothelial surface. They can be found in both the centrilobular and periportal zones but are typically more concentrated in the periportal zones: their function and structures differ depending on their location. They form the largest population of the mononuclear phagocyte system responsible for removing cellular and microbial debris from the circulation and for secreting cytokines involved in defence: they have been implicated in the pathogenesis of various hepatic diseases, including endotoxin tolerance, liver transplantation, nonalcoholic fatty liver disease, and alcoholic liver disease (Li et al 2017). They remove aged and damaged red blood cells from the hepatic circulation, a function normally shared with the spleen but fulfilled entirely by the liver after splenectomy.

Hepatic stem cells Hepatic stem cells are undifferentiated, pluripotent cells and are understood to reside around the bile canals; they are derived from the ductal plate in fetal livers. Their progeny are small epithelial cells (8–18 μm) with large oval nuclei and scanty cytoplasm, expressing both biliary epithelial and hepatocyte markers (Roskams et al 2010).

Gallbladder and biliary tree

CHAPTER 67

The biliary tree comprises the system of ducts that collect and deliver bile from the liver to the descending (second) part of the duodenum. It is conventionally divided into intrahepatic and extrahepatic biliary trees. The intrahepatic ducts are formed from bile ductules that join to form segmental ducts. These merge to form right and left hepatic ducts close to the porta hepatis. The extrahepatic biliary tree comprises the extrahepatic segments of the right and left hepatic ducts, the common hepatic duct, the cystic duct and gallbladder, and the bile duct (**Fig. 67.1**).

GALLBLADDER

The gallbladder is a pear-shaped, blind-ending diverticulum attached to the bile duct by the cystic duct (**Fig. 67.2**). It stores and concentrates bile. In life it is grey–blue in colour and is usually firmly attached by connective tissue to the inferior surface of the right lobe of the liver, between segments IV and V at the lower limit of the principal plane. In the adult the gallbladder is between 7 and 10 cm long, with a resting volume of about 25 ml and a capacity of up to 50 ml (Di Ciaula et al 2012). It usually lies in a shallow fossa (fossa for the gallbladder) on the visceral surface of the right lobe of the liver, covered by peritoneum continued from the surface of the liver. This attachment can vary widely. Rarely, the gallbladder is almost completely buried within the liver (intrahepatic gallbladder; Guiteau et al 2009), or suspended from the liver by a mesentery (when it is at risk of torsion; Gupta et al 2009), or connected to the duodenum by a variant component of the lesser omentum, the cystoduodenal ligament (which has been found in up to 35% of dissections; Ashaolu et al 2015).

The gallbladder is described as having a fundus, body, infundibulum and neck. The neck lies at the medial end, close to the porta hepatis, and almost always has a short peritoneal attachment (see above) (mesentery) to the liver, which usually contains the cystic artery. The mucosa at the medial end of the neck is obliquely ridged, forming a crescentic fold that is continuous with the spirally arranged mucosal folds in the cystic duct (Dasgupta and Stringer 2005). The neck usually lies anterior to the descending part of the duodenum. The body of the gallbladder normally lies in contact with the visceral surface of the liver. The body lies anterior to the descending part of the duodenum and the proximal end of the transverse colon. The bulbous fundus lies at the lateral end of the body and usually projects past the inferior border of the liver to a variable extent. Here it frequently lies in contact with the anterior abdominal wall deep to the ninth costal cartilage, where the lateral edge of the right rectus abdominis crosses the costal arch. This is where enlargement of the gallbladder is best sought on clinical examination. The fundus commonly lies adjacent to the transverse colon. The infundibulum is a tapered and sometimes angulated part of the gallbladder between the body and neck of the gallbladder.

The gallbladder varies in size and shape. The fundus can be elongated and highly mobile. Rarely it is folded back on the body of the gallbladder, the so-called Phrygian cap; on ultrasound, this can be wrongly interpreted as an apparent septum within an otherwise normal gallbladder. Other anatomical variants of the gallbladder include duplication, with or without a double cystic duct; agenesis; internal septation; and an ectopic location (most commonly left-sided) (Gross 1936, Faure et al 2008, Tubbs et al 2016). Although rare, these congenital anatomical variations are particularly important if the patient requires surgery for gallbladder or gallstone disease (Lamah et al 2001, Chowbey et al 2004, Singh et al 2006, Castorina et al 2014).

INTRAHEPATIC BILIARY TREE

Segmental and sectoral ducts

The segmental ducts of the left part of the liver have a relatively constant pattern, although more than one segmental duct can drain each particular segment. The left hepatic duct is formed by the union of segments II and III ducts, most often deep to or to the left of the umbilical part of the left branch of the hepatic portal vein (see Fig. 67.1). The biliary drainage of segment IV is more variable but is usually by a single duct into the left hepatic duct. The right hepatic duct is formed by the union of the right anterior (medial) and posterior (lateral) sectoral ducts. The right anterior (medial) sectoral bile duct drains segments V and VIII, and the right posterior (lateral) sectoral duct drains segments VI and VII. The right posterior sectoral duct usually curves around the posterior aspect of the right anterior duct before fusing with its medial aspect; this is known as Hjortsjö's crook and is an important technical consideration when the liver is resected (**Fig. 67.3**). The right posterior sectoral duct (and associated blood vessels) is frequently located in Rouvière's sulcus (see below), which is a reasonably constant cleft 2–3 cm in length on the liver surface to the right of the porta hepatis anterior to the caudate lobe. An average of three small ducts drain the caudate lobe (segment I) at the hilar plate; the right-sided duct usually drains to the right hepatic duct or the posterior sectoral branch whereas the left-sided duct frequently crosses over to drain into the right posterior sectoral duct (Makki et al 2018).

The right hepatic duct and its branches are more often subject to variation than the left ductal system (Cucchetti et al 2011, Chaib et al 2014). These variations have been classified into seven main types (**Table 67.1**, **Fig. 67.4**) (Yoshida et al 1996), although additional very rare variants have also been described (Nayman et al 2016, Stringer 2016). Left intrahepatic ductal variations mostly relate to the drainage pattern of segment IV; this segmental bile duct usually drains into the left hepatic duct but in some cases it opens into a segment II or III bile duct, the right anterior sectoral duct, or even the common hepatic duct (Chaib et al 2014).

EXTRAHEPATIC BILIARY TREE

Cystic duct

The cystic duct drains the gallbladder into the bile duct. In adults it is usually 2–4 cm long and has a luminal diameter of 2–3 mm (Dasgupta and Stringer 2005). Occasionally it is very short, which makes its division during cholecystectomy potentially hazardous. It passes posteriorly and medially from the neck of the gallbladder, often in a tortuous fashion, to unite with the common hepatic duct and form the bile duct. The anatomy of the junction between the cystic duct and common hepatic duct is variable (see Fig. 67.4). In most individuals the cystic duct joins the middle third of the combined lengths of the common hepatic and bile ducts (Shaw et al 1993), but it can also drain into the distal bile duct ('low insertion') or into a more proximal duct such as the proximal common hepatic duct or right hepatic duct. It usually joins the right lateral aspect of the common hepatic duct but can merge medially, anteriorly or posteriorly; and it usually forms an oblique angle with the common hepatic duct but can spiral around it or run parallel to it in the hepatoduodenal ligament for a variable distance before merging (Lamah et al 2001, Onder et al 2013, Stringer 2016) (**Fig. 67.8**). Irrespective of the site or type of union, the terminal part of the cystic duct is frequently fused to the common hepatic duct for a variable distance.

An oblique groove on the inferior surface of the liver posterior to the fossa for the gallbladder is present in 70–80% of livers. It is variously known as the fissure of Gans, Rouvière's sulcus or the incisura hepatis dextra (Ch. 66). It overlies the division of the right posterior (lateral) portal pedicle, where it gives off the inferior segment VI branch. It has been increasingly recognized as a useful anatomical landmark during hepatic resection and in laparoscopic cholecystectomy (since the cystic duct and artery lie anterosuperior to the sulcus while the bile duct lies posteroinferior) (Dahmane et al 2013).

A pouch-like structure (Hartmann's pouch) may occasionally project from the neck of the gallbladder at its junction with the body of the gallbladder (Davies and Harding 1942, Anandhi and Alagavenkatesan 2018). It is thought to be produced by adhesions between the neck of the gallbladder and the cystic duct: once these adhesions are separated and the cystic duct is mobilized, Hartmann's pouch disappears. A significant association between the presence of a Hartmann's pouch and gallstones has been reported, but the aetiology is unclear (Skandalakis et al 2004, van Eijck et al 2007).

A small, rare bile duct known as a subvesical duct from segment V of the liver can traverse the fossa for the gallbladder and join the right hepatic duct or its anterior sectoral branch or the common hepatic duct (Schnelldorfer and Sarr 2012). This duct is important because it can be injured during cholecystectomy, causing a postoperative bile leak (Spanos and Syrakos 2006). These ducts are more likely to be injured if the gallbladder is not dissected close to its wall. A subvesical duct may also drain directly into the gallbladder (cholecystohepatic duct) or cystic duct (cystohepatic duct) and should not be confused with a hepatocystic duct (which is present when the bile duct is absent and both hepatic ducts drain directly into the gallbladder, which in turn drains via the cystic duct into the duodenum) (Losanoff et al 2002) (**Figs 67.5-67.7**).

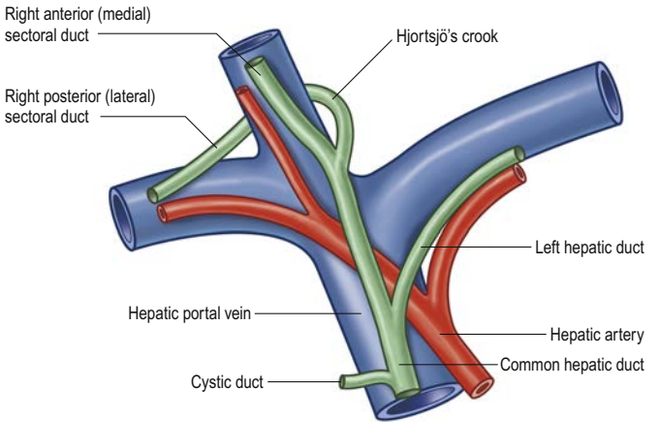

Fig. 67.3 Hjortsö's crook. The right posterior (lateral) sectoral bile duct usually hooks around the right anterior (medial) sectoral pedicle, rendering it vulnerable to injury when an extended left hepatectomy is performed that includes segments V and VIII of the liver (left trisectionectomy).

Fig. 67.7 Cystohepatic duct. Operative cholangiogram showing a posterior sectoral duct draining into the cystic duct. Also known as a 'cystohepatic duct' this is one of the rare variants referred to in Table 67.1. (With permission from Brown AW, Wilson RB 2018 Legacy of Le Quesne: operative cholangiography in the modern era. Aust NZ J Surg 88(9):819–20.)

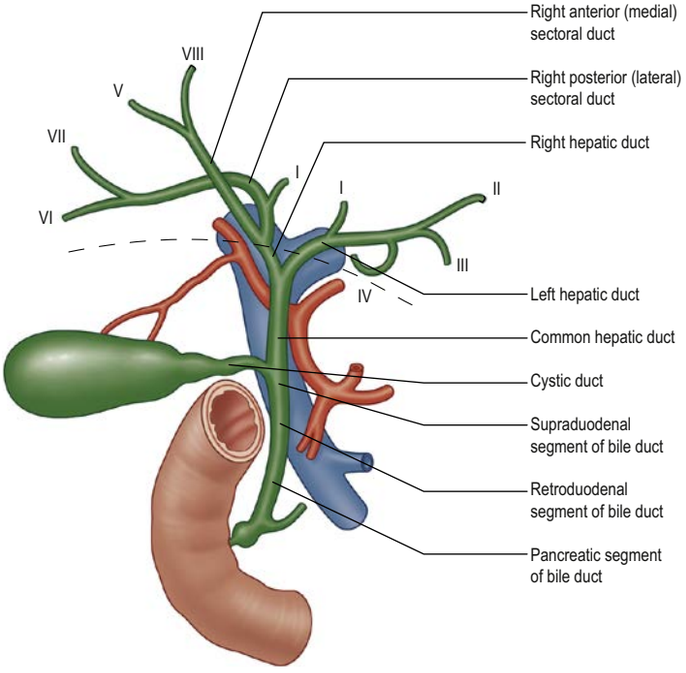

Fig. 67.1 The overall arrangement of the intrahepatic and extrahepatic biliary tree. The segmental ducts often branch just before they enter the main ducts, or are multiple as they enter the main ducts, but for clarity are shown here as single ducts. Note that segment I often drains via both right and left hepatic ducts. The level of the liver at the porta hepatis is shown by the dashed line.

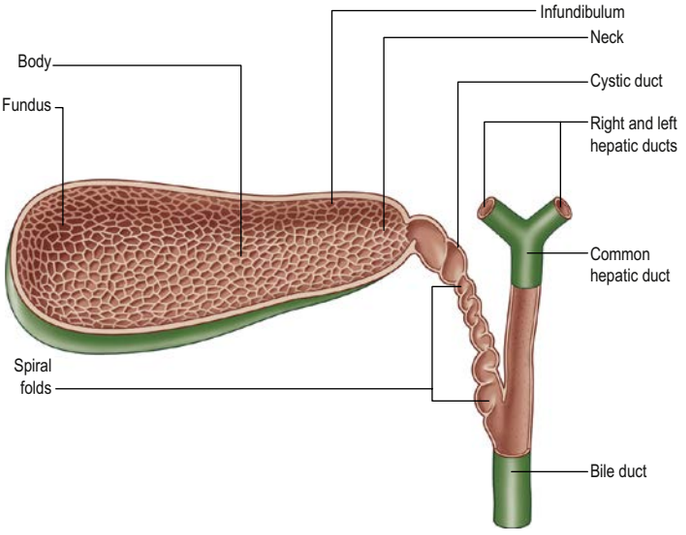

Fig. 67.2 The interior of the gallbladder and bile ducts.

TABLE 67.1 Major variations of the intrahepatic duct drainage patterns

Type	Approximate % of population	Description
1	60*	'Normal' anatomy
2	10–15	No right hepatic duct. The common hepatic duct is formed by the union of right anterior sectoral, right posterior sectoral and left hepatic ducts (trifurcation pattern)
3	10–15	One of the right sectoral ducts (more often the posterior) joins the left hepatic duct
4	5–10	Low drainage of one of the right sectoral ducts (more often the posterior) into the common hepatic duct
Rare	<10	The segment V duct or the right posterior sectoral duct drains into the cystic duct or gallbladder

Data from Cucchetti et al 2011, Chaib et al 2014, Gupta et al 2016, Nayman et al 2016.

*This figure is higher in males and lower in females, who are more likely to have variant intrahepatic bile duct anatomy. NB The percentages of different types vary among populations.

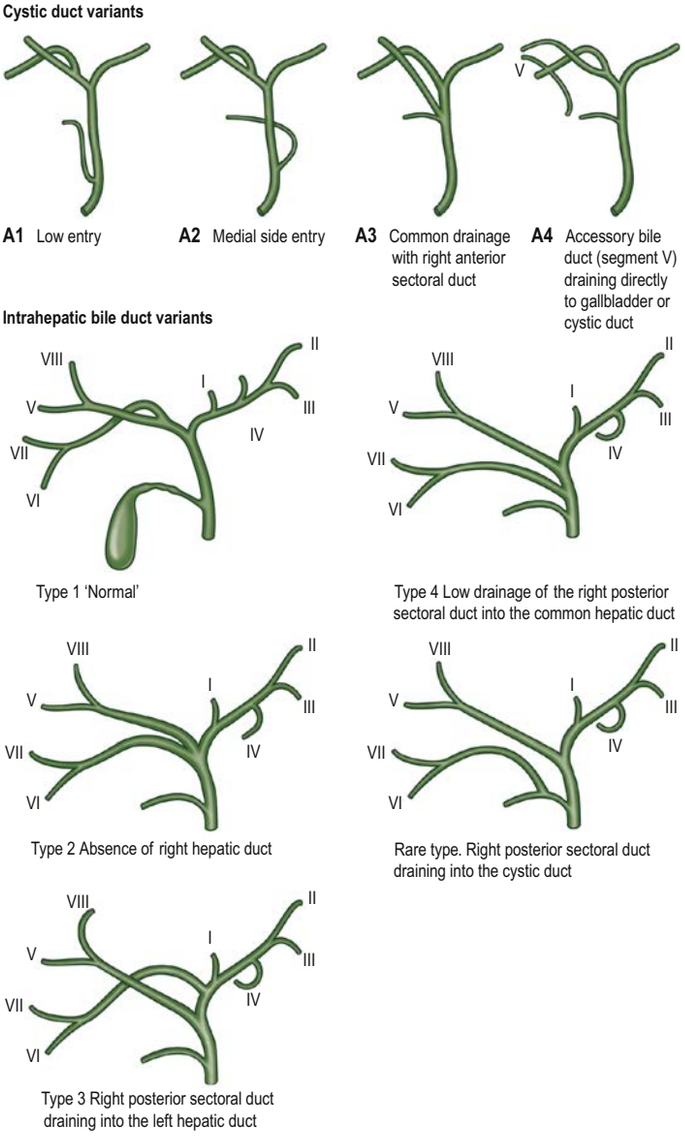

Fig. 67.4 Variations in the anatomy of the cystic and intrahepatic bile ducts. The cystic duct variations are labelled A1–A4 and the intrahepatic bile duct variations as types 1–4 (see Table 67.1). In the type 2 pattern, the right sectoral ducts may have a short extrahepatic segment.

Rarely, the cystic duct is double or absent (when the gallbladder drains directly into the bile duct), or receives an anomalous hepatic duct from segment V of the liver. These variations in cystic duct anatomy are of considerable importance during surgical excision of the gallbladder (cholecystectomy). The cystic duct must be identified passing to the neck of the gallbladder and must be occluded some distance away from the bile duct to prevent injury to the latter (Fig. 67.8). A preliminary operative cholangiogram is essential if the anatomy is unclear or anomalous.

The mucosa of the cystic duct has 2–10 crescentic folds that project into the lumen and form a spiral; these are continuous with those in the neck of the gallbladder. The function of these spiral folds (of Heister) is unknown but they could help to preserve the patency of this narrow, tortuous duct rather than regulate the flow of bile, as is commonly stated (Dasgupta and Stringer 2005).

Hepatic ducts

The right and left hepatic ducts emerge from the liver and unite near the right end of the porta hepatis to form the common hepatic duct. The extrahepatic segment of the right hepatic duct is short (0.5–2.0 cm in adults) and nearly vertical, while the left hepatic duct is longer (1.5–3.5 cm) and more horizontal, and lies along the inferior border of segment IV of the liver. The accessibility of the extrahepatic segment of the left hepatic duct is exploited when performing a surgical biliary bypass in patients with benign extrahepatic biliary duct strictures (Myburgh 1993).

In adults, the common hepatic duct descends approximately 3 cm before being joined obliquely on its right by the cystic duct to form the

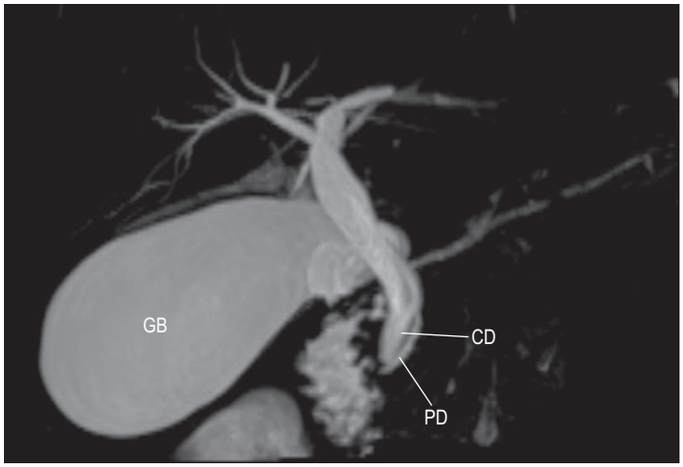

Fig. 67.8 Magnetic resonance cholangiopancreatogram showing a low medial union between the cystic duct (CD) and the distal bile duct. Other abbreviations: PD, pancreatic duct; GB, gallbladder. (Courtesy of Dr Matthew MacKay, Radiologist, Wellington, New Zealand.)

bile duct. The common hepatic duct lies to the right of the hepatic artery and anterior to the hepatic portal vein in the hepatoduodenal ligament. In healthy adults the luminal diameter of the common hepatic duct, as measured by ultrasound, is less than 5 mm.

Bile duct

The bile duct is formed near the porta hepatis by the junction of the cystic and common hepatic ducts (**Figs 67.9–67.10**). In adults, it is usually between 6 and 8 cm long and its luminal diameter, as measured by ultrasound, is no more than 7 mm (Perret et al 2000); the diameter increases slightly with advancing age from a mean of 3.6 mm below 60 years to a mean of 4 mm after 80 years. The bile duct can be divided into supraduodenal, retroduodenal and pancreatic segments. The supraduodenal segment descends posteriorly and slightly to the left, anterior to the omental foramen and inferior vena cava, in the hepatoduodenal ligament, where it lies anterior and to the right of the hepatic portal vein and to the right of the hepatic artery. This part of the bile duct is the most accessible at surgery. The retroduodenal segment lies behind the superior part of the duodenum with the gastroduodenal artery on its left. The pancreatic segment runs in a groove on the posterior surface of the head of the pancreas, embedded in the gland to a variable degree; it lies up to 2 cm away from the medial wall of the descending part of the duodenum and anterior to the right renal vein. The pancreatic segment of the bile duct typically has a tapered appearance (see Fig. 67.9; **Fig. 67.11**). The posterior superior pancreaticoduodenal artery, a branch of the gastroduodenal artery, descends anterior to the retroduodenal segment of the bile duct (at the superior border of the pancreas) before spiralling around the right side of the bile duct to reach the posterior surface of the head of the pancreas (Bertelli et al 1996).

Hepatopancreatic ampulla

As it descends behind the head of the pancreas medial to the descending part of the duodenum, the bile duct approaches the right end of the pancreatic duct. The two ducts usually enter the duodenal wall together in a Y configuration to form a 2–10 mm long common channel (Flati et al 1994). This common channel often contains a dilation known as the hepatopancreatic ampulla (of Vater) and it opens via a single orifice on to the medial wall of the descending part of the duodenum at the major duodenal papilla (see Fig. 67.9B). In clinical practice, the whole region is often termed the pancreaticobiliary junction. Occasionally, the bile duct and pancreatic duct unite outside the duodenal wall to form an abnormally long common channel or the two ducts are separated by a septum or drain into the duodenum separately (Kamisawa and Okamoto 2008).

The mucosa of the terminal 5–10 mm of the bile and pancreatic ducts has a complex arrangement of circumferentially arranged folds (Purvis et al 2013) (**Fig. 67.12**). Their distribution and orientation impede reflux of duodenal contents into the bile and pancreatic ducts, and they sometimes cause difficulty cannulating the major duodenal papilla during endoscopic retrograde cholangiopancreatography (ERCP).

A complex arrangement of smooth muscle with prominent circular fibres surrounds the distal bile duct as the sphincter of the bile duct and the sphincter of the ampulla (sphincter of Oddi); to a lesser extent, it also surrounds the terminal part of the pancreatic duct as the sphincter of the pancreatic duct (Boyden 1957, Didio and Anderson 1968, Ironside et al 2019). The whole sphincter muscle complex lies mostly within the wall of the duodenum and, in adults, is approximately 15–20 mm long; it contains a high pressure zone that can be detected by manometry (Habib et al 1988, Teilum 1991). The smooth muscle of the sphincter of the ampulla is developmentally and anatomically distinct from the adjacent duodenal muscle. The sphincter regulates the flow of bile and pancreatic secretions into the duodenum and impedes reflux of duodenal contents into the ductal system (Guelrud et al 1990); it is inhibited by cholecystokinin (CCK), which not only relaxes the sphincter but also causes gallbladder contraction (Woods et al 2005). Division of the upper part of the sphincter of the ampulla (sphincterotomy) can be required to allow access to the bile duct during ERCP.

The pancreaticobiliary junction is clinically important because it can be affected by various congenital and acquired disorders. An anomalous union between the bile and pancreatic ducts, particularly one resulting in an abnormally long common channel, can be associated with congenital bile duct dilation, recurrent pancreatitis and/or gallbladder cancer (Kimura et al 1985, Misra and Dwivedi 1990, Stringer 2018). Acquired pathology in this region also includes gallstone obstruction and periampullary tumours.

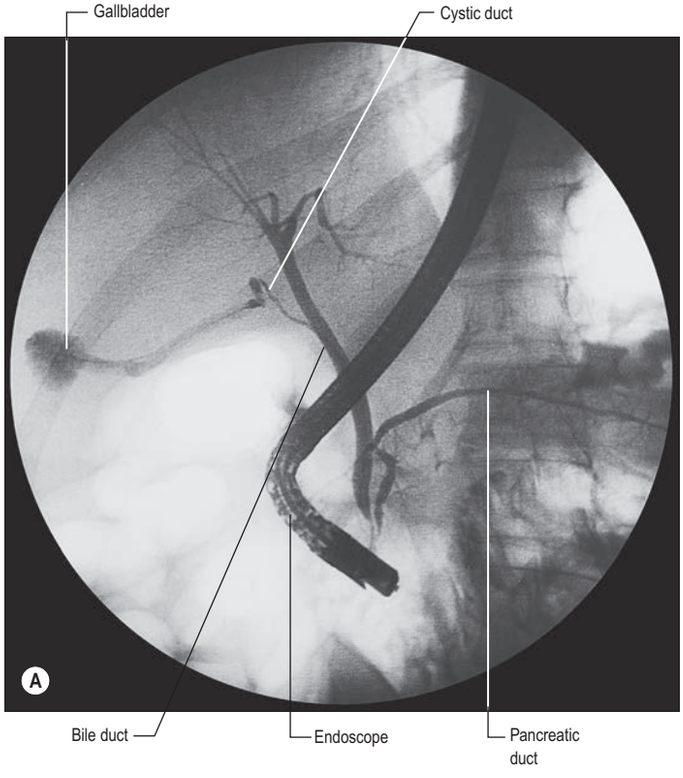

Fig. 67.9 A, An endoscopic retrograde cholangiopancreatogram. (B, *continued online*)

Cystohepatic triangle

The triangular region formed between the cystic duct, the common hepatic duct and the inferior surface of the liver is the cystohepatic (hepatobiliary) triangle (**Fig. 67.13**). It is often mistakenly referred to as Calot's triangle, which is an isosceles triangle based on the common hepatic duct, with the cystic artery and cystic duct forming its sides (Stringer 2009). The cystohepatic triangle is bridged by the double layer of peritoneum that forms the short and variable mesentery of the cystic duct. Between these two layers there is a variable amount of adipose and connective tissues, lymphatics, the cystic node, autonomic nerves and usually the cystic artery as it travels from the right hepatic artery to the gallbladder. Occasionally there is also an accessory cystic duct located in the triangle (see above). Understanding the variations in biliary and arterial anatomy as they relate to the triangle is of considerable importance during excision of the gallbladder in order to avoid injury to the common hepatic or bile duct or right hepatic artery (Suzuki et al 2000, Talpur et al 2010).

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Cystic artery

The cystic artery usually (approximately 80%) arises from the right hepatic artery (**Fig. 67.14**, but see Fig. 67.15) and most often passes posterior to the common hepatic duct within the cystohepatic triangle,

Gallstones are relatively common and usually form in the gallbladder. Gallbladder contraction can move a gallstone towards the narrow cystic duct, where it can cause obstruction and pain (biliary colic). If the stone continues to occlude the cystic duct, it will lead to inflammation of the gallbladder (acute cholecystitis) or a sterile distension of the gallbladder (mucocele); providing the gallbladder has not been inflamed previously, it will be non-fibrotic and distensible, and the fundus often becomes palpable below the costal arch. A gallstone lodged in the cystic duct or neck of the gallbladder can also produce an inflammatory swelling that compresses the common hepatic duct, resulting in partial obstruction to the flow of bile and the development of jaundice (the so-called 'Mirizzi syndrome'; Stringer 2009). If the gallstone passes through the cystic duct, it can become impacted in the distal bile duct or at the pancreaticobiliary junction, causing obstructive jaundice, cholangitis and/or acute pancreatitis.

The bile duct and/or pancreatic duct can be accessed endoscopically from the duodenum for diagnostic cholangiography and/or pancreatography, and for therapeutic interventions such as the relief of biliary obstruction by insertion of an internal stent. The acute angle between the distal bile duct and pancreatic duct can make direct cannulation of the bile duct difficult. In such cases, the superior part of the major duodenal papilla can be incised (pre-cut sphincterotomy) to facilitate cannulation of the bile duct. This incision, and the more extensive sphincterotomy that is sometimes needed to release an impacted gallstone (Sakai et al 2012), is occasionally complicated by arterial bleeding. The risk can be reduced by making the incision in the 10–11 o'clock region of the sphincter (Mirjalili and Stringer 2011). Endoscopic sphincterotomy can result in uncontrolled reflux of duodenal contents into the distal bile duct and ascending biliary infection.

The proximity of the fundus of the gallbladder to the anterior abdominal wall facilitates ultrasound-guided percutaneous drainage of a distended, obstructed gallbladder. Because the cystic duct has a small calibre and spiral folds, drainage of the gallbladder is rarely sufficient to decompress the biliary tree when the bile duct is obstructed. In such cases, temporary or permanent biliary drainage can be achieved by the endoscopic insertion of a biliary stent through the obstruction via the major duodenal papilla, surgical bile diversion, or percutaneous transhepatic drainage. The last-named involves image-guided puncture of a dilated intrahepatic bile duct and the insertion of an external drain or an internal stent through the biliary obstruction.

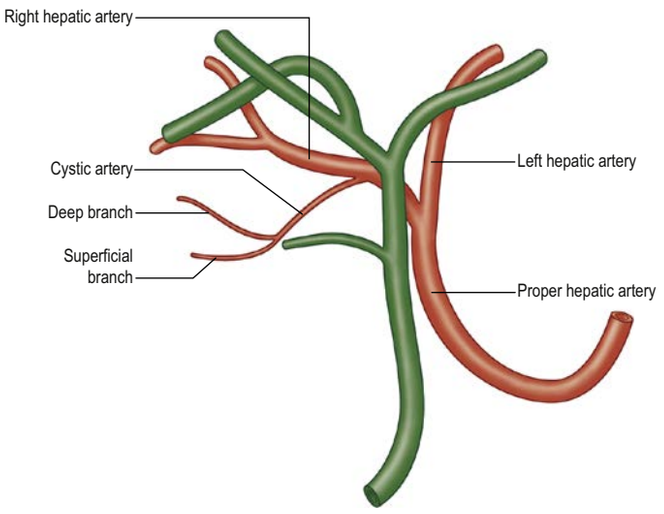

Fig. 67.14 Normal anatomy of the cystic artery.

where it lies superior to the cystic duct (Andall et al 2016). On reaching the superior aspect of the neck of the gallbladder it divides into superficial and deep branches that anastomose over the surface of the body and fundus. The cystic artery is usually less than 3 mm in diameter; a larger artery in the cystohepatic triangle is more likely to be the right hepatic artery. While the cystic artery usually traverses the cystohepatic triangle it may lie outside when it passes anterior, posterior or inferior to the cystic duct (Xia et al 2015).

The origin of the cystic artery is variable (**Fig. 67.15**). The most common variant is an origin from the proper hepatic artery, when it often crosses anterior to the bile or common hepatic ducts to reach the gallbladder. Rarely it arises from the coeliac trunk or left hepatic, gastroduodenal, superior pancreaticoduodenal, right gastric, or superior mesenteric arteries; in these cases, the cystic artery might not traverse the cystohepatic triangle. The cystic artery frequently bifurcates close to its origin, giving rise to two vessels. Alternatively, an accessory cystic artery can arise from the proper hepatic artery or one of its branches. If the right hepatic artery passes anterior to the bile or hepatic duct the cystic artery is short. Small arterial branches from segment IV or V of the liver can contribute to the supply of the body of the gallbladder, particularly when it is substantially intrahepatic; these help to protect the gallbladder from ischaemic necrosis if inflammation results in thrombosis of the cystic artery.

The cystic artery also gives rise to multiple fine branches that contribute to the blood supply of the extrahepatic bile ducts.

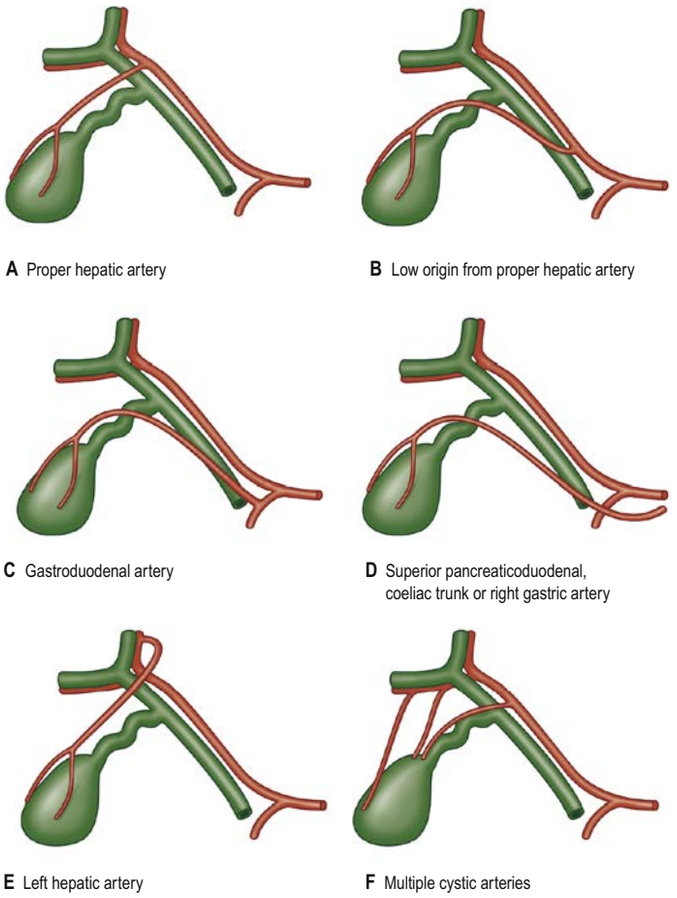

Fig. 67.15 Variant anatomy of the cystic artery.

Ductal arteries

The bile and hepatic ducts are supplied by a fine network of arteries arising from several sources. The bile duct is frequently supplied by 2–4 small-calibre arteries that form a long, tortuous, anastomotic network along its length; these narrow vessels tend to be concentrated at the 3 and 9 o'clock positions around the circumference of the duct (Northover and Terblanche 1979). The network is fed by arteries from the right hepatic artery above, reinforced by fine branches from the cystic artery. Branches from three main arterial sources often supply the bile duct from below: the posterior superior pancreaticoduodenal artery, the retroduodenal artery (both of which originate from the gastroduodenal artery and cross anterior to the retroduodenal segment of the bile duct), and a retroportal artery arising from the superior mesenteric artery or coeliac trunk and passing to the right on the posterior surface of the hepatic portal vein and anastomosing with the right hepatic or retroduodenal arteries (Northover and Terblanche 1979, Chen et al 1999). The supraduodenal segment of the bile duct is less well vascularized than the retroduodenal and pancreatic segments, and excessive dissection of this segment can result in an ischaemic bile duct stricture.

The extrahepatic right and left hepatic ducts are supplied by a fine network of arteries that arise from the right and left hepatic arteries and form an anastomotic plexus within the connective tissue of the hilar plate (Kawarada et al 2000, Castaing 2008). The intrahepatic ducts are supplied by segmental branches of the hepatic artery arising within the Glissonian sheaths (Stapleton et al 1998, Vellar 1999). These form a microvascular network around the ducts that drains into intrahepatic portal venules. The dependence of the intrahepatic bile ducts on their hepatic arterial blood supply is well recognized in liver transplantation since hepatic artery thrombosis can lead to diffuse intrahepatic biliary strictures despite preservation of portal venous blood flow.

Cystic veins

The venous drainage of the gallbladder is rarely by a single cystic vein and there are usually multiple small veins. Those arising from the superior surface of the body and neck lie in loose connective tissue between the gallbladder and liver and drain into the branches of the hepatic portal vein within the liver. The remainder of the organ drains by one or two

small cystic veins into either branches of the hepatic portal vein within the liver or portal venous tributaries draining the hepatic ducts and proximal bile duct (Sugita et al 2000). Only rarely does a single or double cystic vein drain directly into the right branch of the hepatic portal vein. A fine venous plexus on the surface of the common hepatic and bile ducts communicates laterally with so-called marginal veins that drain inferiorly to the posterior superior pancreaticoduodenal vein and superiorly primarily into the hepatic portal vein (Vellar 2001).

Lymphatic drainage

Lymph from the gallbladder and cystic duct drains via several pathways: to the cystic node, which usually lies above the cystic duct in the cystohepatic triangle, and from there via nodes in the hepatoduodenal ligament and along the common hepatic artery to coeliac nodes; via lymphatics that descend along the bile duct to the superior retropancreaticoduodenal nodes (which communicate with lateral aortic nodes); and directly to superior mesenteric nodes (Sato et al 2013). Lymphatics on the deep aspect of the gallbladder connect directly with intrahepatic lymph vessels.

Lymphatic vessels accompanying the hepatic ducts and proximal bile duct drain to hepatic nodes at the porta hepatis and then via lymph nodes in the hepatoduodenal ligament to coeliac nodes. Lymphatics from the distal bile duct also drain to the latter but some pass directly to pancreatic and superior mesenteric nodes.

INNERVATION

The gallbladder and the extrahepatic biliary tree are innervated by branches from the hepatic plexus. The gallbladder contracts in response to cholecystokinin (CCK) and parasympathetic (vagus nerve) stimulation. Postganglionic sympathetic nerve fibres from the coeliac and superior mesenteric ganglia are inhibitory to gallbladder smooth muscle. Sympathetic afferents from the gallbladder convey pain sensation; they travel with the greater and lesser thoracic splanchnic nerves and have their cell bodies in the T7–T9 spinal cord segments. Pain from the gallbladder is referred to the right hypochondriac and epigastric regions and can radiate around the back inferior to the right scapula. As the phrenic nerves and especially the right phrenic nerve extend onto the gallbladder, these might be involved in such pain (Yi et al 2007). Inflammation of the parietal peritoneum overlying the gallbladder produces localized right upper quadrant pain. Diverse neurotransmitters have been identified within intrinsic neurones of the gallbladder (Balemba et al 2004).

The bile duct and smooth muscle of the hepatopancreatic ampulla are also innervated by the vagus nerves, either directly or via the hepatic plexus, and by sympathetic nerves.

MICROSTRUCTURE

Gallbladder

The fundus of the gallbladder is completely covered by a serosa, and the inferior surfaces and sides of the body and neck of the gallbladder are usually covered by a serosa. If the gallbladder has a mesentery, the serosa extends around the sides of the body and neck onto the superior surface and continues into the serosa of the mesentery, whereas the serosa is limited to the inferior surfaces only if the gallbladder is intrahepatic. Beneath the serosa is subserous loose connective and adipose tissue. The microstructure of the wall of the gallbladder generally resembles that of the small intestine. The mucosa is yellowish-brown and elevated into minute folds (rugae) with a honeycomb appearance (see Fig. 67.2). In section, projections of the mucosa into the gallbladder lumen resemble intestinal villi, but they are not fixed structures and the surface flattens as the gallbladder fills with bile. The epithelium is a single layer of columnar absorptive cells with apical microvilli; basally, the spaces between epithelial cells are dilated by resorbed fluid, as bile is concentrated (Fig. 67.16). There are no goblet cells in the epithelium. The epithelial cells actively absorb water and solutes from the bile and concentrate it up to ten-fold. Many capillaries and lymphatic vessels lie beneath the basal lamina. The thin fibromuscular layer is composed of collagenous tissue and smooth muscle cells arranged loosely in longitudinal, circular and oblique bundles.

Mesentery of the gallbladder

Available with the *Gray's Anatomy* e-book

(Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Bile ducts

The walls of the large biliary ducts consist of external fibrous and internal mucosal layers (Fig. 67.17). The outer layer is fibrous connective tissue containing a variable number of longitudinal, oblique and circular smooth muscle cells. The mucosa is continuous with that in the hepatic ducts, gallbladder and duodenum. The epithelium is columnar and there are numerous tubulo-alveolar (or tubulo-acinar) mucosal glands in the duct walls.

Expulsion of gallbladder contents is under neuroendocrine control. Fat in the duodenum causes the release of CCK by intestinal neuroendocrine cells, which stimulates the gallbladder to contract because muscle cells in its walls bear surface CCK receptors. When the pressure exceeds 100 mm H_2O of bile, the sphincter of the ampulla relaxes and bile enters the descending part of the duodenum. The termination of the united bile and pancreatic ducts is packed with villous, valvular folds of mucosa that contain muscle cells in their connective tissue cores. Contraction is thought to result in retraction and clumping of these folds, thus preventing reflux of duodenal contents and controlling the exit of bile.

A mesentery of the gallbladder is an anatomical variant where either the gallbladder or the cystic duct and artery have a mesentery that allows the gallbladder to hang freely from the undersurface of the liver (the so-called mobile or floating gallbladder). The presence of a mesentery may predispose to torsion (volvulus) of the gallbladder with resultant vascular compromise (Gross 1936, Stieber and Bauer 1983, Shaikh et al 2005).

CHAPTER 68

Pancreas

The pancreas is one of the largest digestive glands. Its primary function is exocrine, secreting enzymes involved in the digestion of lipids, carbohydrates and proteins. It has an additional endocrine function derived from clusters of cells scattered throughout the gland, which take part in glucose homeostasis and the control of upper gastrointestinal tract motility and function.

The healthy pancreas is yellow, with a soft to firm consistency and a lobulated surface. Its texture (hard or soft) has important implications for pancreatic surgery: the harder the gland, the lower the rate of leakage of pancreatic fluid after a pancreatic reconstruction procedure.

The pancreas is divided into a head, neck, body and tail (**Figs 68.1–68.3A**). The head of the pancreas usually has a distinct uncinate process. In adults, the pancreas is between 12 and 15 cm long and is shaped like a flattened 'tongue' of tissue lying in the retroperitoneum, thicker at its medial end (head) and thinner towards the lateral end (tail). The head lies within the curve of the duodenum and the remainder of the gland extends transversely and slightly cranially across the retroperitoneum and posterior to the stomach to the splenic hilum. It is 'draped' over the inferior vena cava, the hepatic portal vein/superior mesenteric vein and splenic vessels. In adults it has an average volume of 70–80 cm^3, although this varies considerably among individuals (with a range of 40–170 cm^3) and tends to be greater in males (Djuric-Stefanovic et al 2012). Pancreatic volume increases with age, reaching a peak during the fourth decade. From about 60 years of age the gland atrophies and adipose connective tissue replaces exocrine tissue (Saisho et al 2007, Caglar et al 2012). Pancreatic diameters tend to be smaller in patients with diabetes mellitus (DeSouza et al 2018).

The anterior (ventral) surface of the pancreas is covered by parietal peritoneum and its inferior border abuts the root of the transverse mesocolon. A loose connective tissue layer immediately posterior to the pancreas (sometimes known as the fusion fascia of Treitz in the region of the head of the pancreas and as the fusion fascia of Toldt in the region of the body and tail) contains vessels that supply the gland (Kimura 2000).

Head

The head of the pancreas lies to the right of the midline, anterior and to the right of the vertebral column, within the curve of the duodenum. This is the thickest and broadest part of the pancreas but it is still flattened in the anteroposterior plane. Superiorly, it lies adjacent to the superior part of the duodenum; however, close to the pylorus, where the duodenum is on a short mesentery, the superior part of the head is overlapped anteriorly by the duodenum. The duodenal border of the head is flattened, slightly concave and adherent to the descending part of the duodenum, particularly around the hepatopancreatic ampulla. The superior and inferior pancreaticoduodenal arcades supply the head of the pancreas. The inferior border of the head of the pancreas lies superior to the horizontal part of the duodenum and is continuous with the uncinate process. The anterior surface of the head is covered by peritoneum and abuts the transverse mesocolon (**Fig. 68.3B**). Posteriorly, the bile duct is partially embedded within the head of the gland just proximal to its junction with the pancreatic duct near the major duodenal papilla (Burgard et al 1991, Nagai 2003). The posterior surface of the head of the pancreas lies anterior to the inferior vena cava at the level of the termination of the right gonadal vein. Near the midline, the head continues as the neck.

Uncinate process

The uncinate process is a hook-shaped continuation of the inferomedial part of the head of the pancreas. Embryologically, it is separate from the rest of the gland. It extends medially anterior to the abdominal aorta and superior to the horizontal part of the duodenum, which can be obstructed by a pancreatic tumour at this site. On sagittal cross-sectional imaging, the left renal vein, the uncinate process and the horizontal part of duodenum can be seen lying between the superior mesenteric artery anteriorly and the abdominal aorta posteriorly.

Neck

The neck of the pancreas is approximately 2 cm wide and connects the head to the body. It is often the most anterior part of the gland and can be defined as that part of the pancreas lying anterior to the formation of the hepatic portal vein (usually the union of the superior mesenteric and splenic veins) (**Fig. 68.4D–E**). This relationship is crucial for the evaluation of pancreatic cancer because malignant involvement of the hepatic portal vein may have to be considered when the cancer is resected. Encasement of the superior mesenteric artery running posterior to the head of the pancreas is usually considered a contraindication to resection. The superior mesenteric and hepatic portal veins groove the posterior aspect of the neck. The inferior mesenteric vein joins the confluence of the superior mesenteric and splenic veins in one-third of individuals (Kimura 2000; see Fig. 68.7). The anterior surface of the neck of the pancreas is covered by peritoneum and lies inferior to the pylorus. The anterior superior pancreaticoduodenal branch of the gastroduodenal artery runs through the pancreas at the junction of the head and neck.

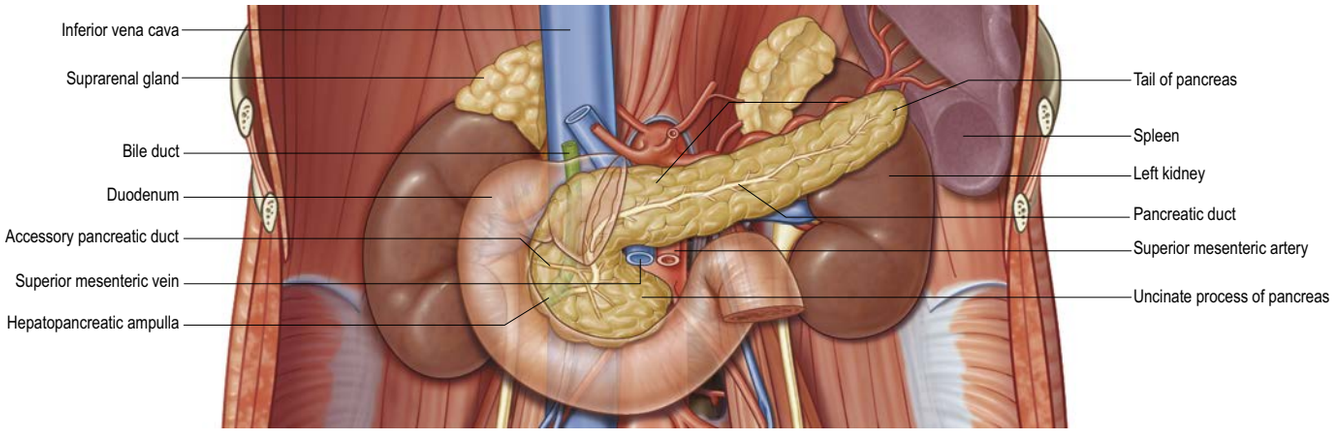

Fig. 68.1 The relations of the pancreas.

Body

The body of the pancreas is the longest part of the gland and runs from the neck to the tail, becoming progressively thinner. It is slightly triangular in cross-section and has anterior and posterior surfaces and superior and inferior borders. It lies to the left of the superior mesenteric vessels.

Anterior surface The anterior surface is covered by peritoneum, which is reflected anteroinferiorly from the surface of the pancreas to be continuous with the posterior layer of the greater omentum and the transverse mesocolon (see Fig. 62.3). The two layers of the transverse mesocolon diverge along this surface (see Fig. 68.3B). Above the attachment of the transverse mesocolon, the anterior surface of the pancreas is separated from the stomach by the omental bursa.

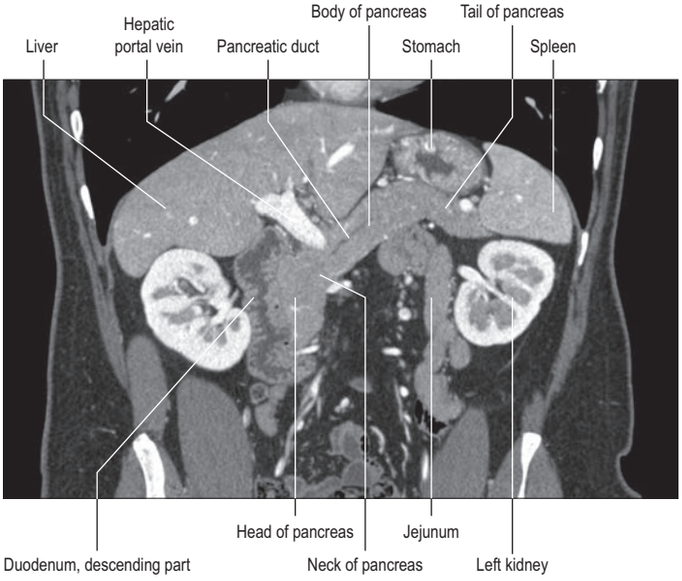

Fig. 68.2 A coronal reformat CT of the pancreas showing its relations in the upper abdomen. (Courtesy of the Department of Radiology, Global Hospital, Chennai, India.)

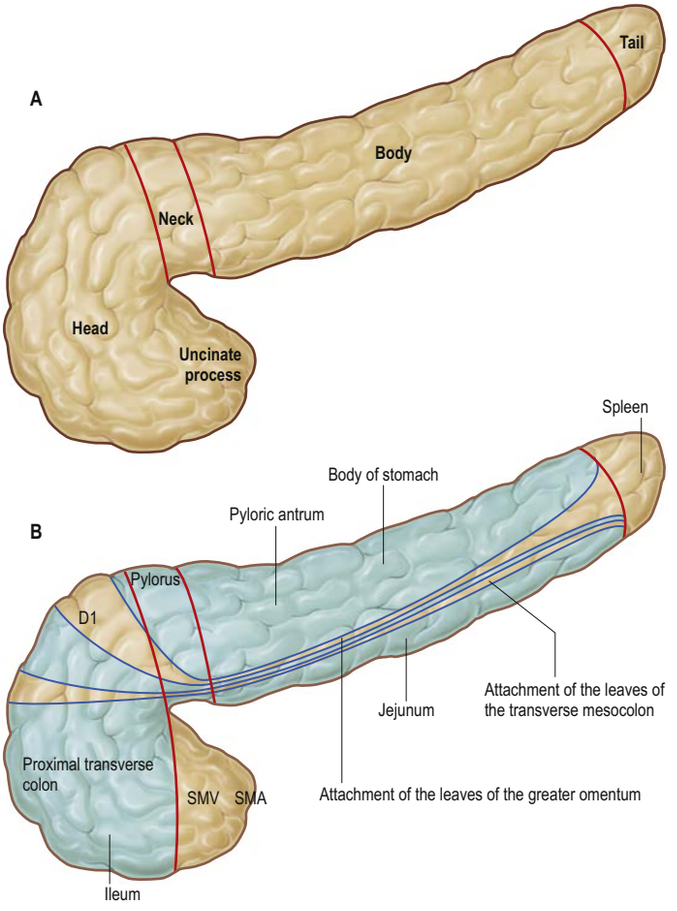

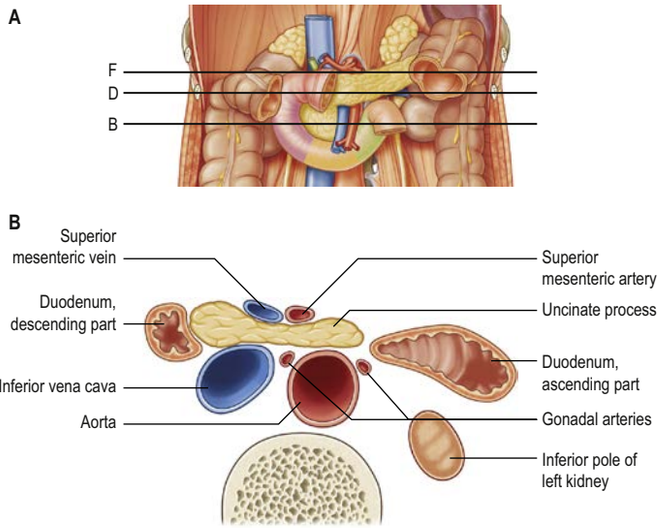

Fig. 68.3 **A**, The regions and anterior surfaces and borders of the pancreas. **B**, The anterior relations of the pancreas. Areas covered in peritoneum are shown in blue. The spleen lies anterior to the anterior leaf of the splenorenal ligament and not in direct contact with the pancreas. Abbreviations: D1, superior (first) part of the duodenum; SMA, superior mesenteric artery; SMV, superior mesenteric vein.

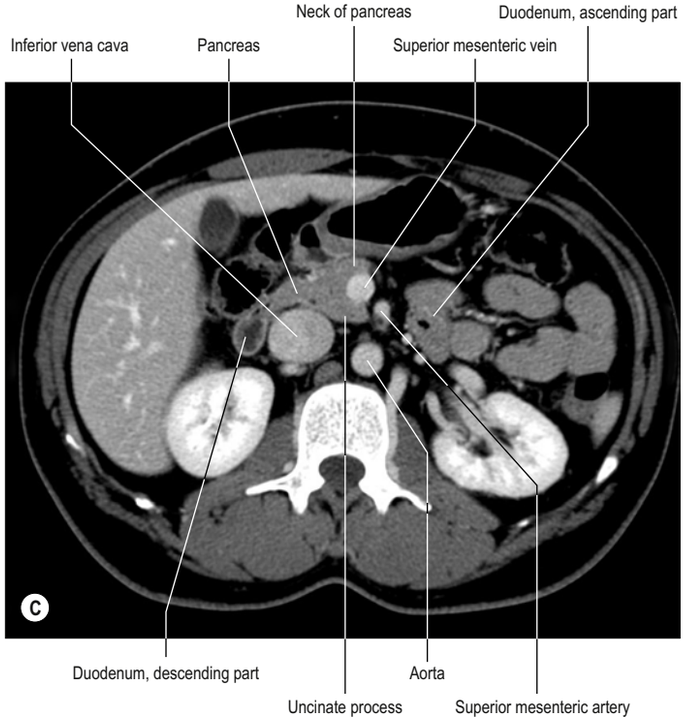

Fig. 68.4 **A**, The posterior relations of the pancreas, with planes of section labelled as shown in **B**, **D** and **F**. **B**, Diagrammatic cross-section taken at the mid level of the uncinate process, and equivalent CT axial image (**C**).

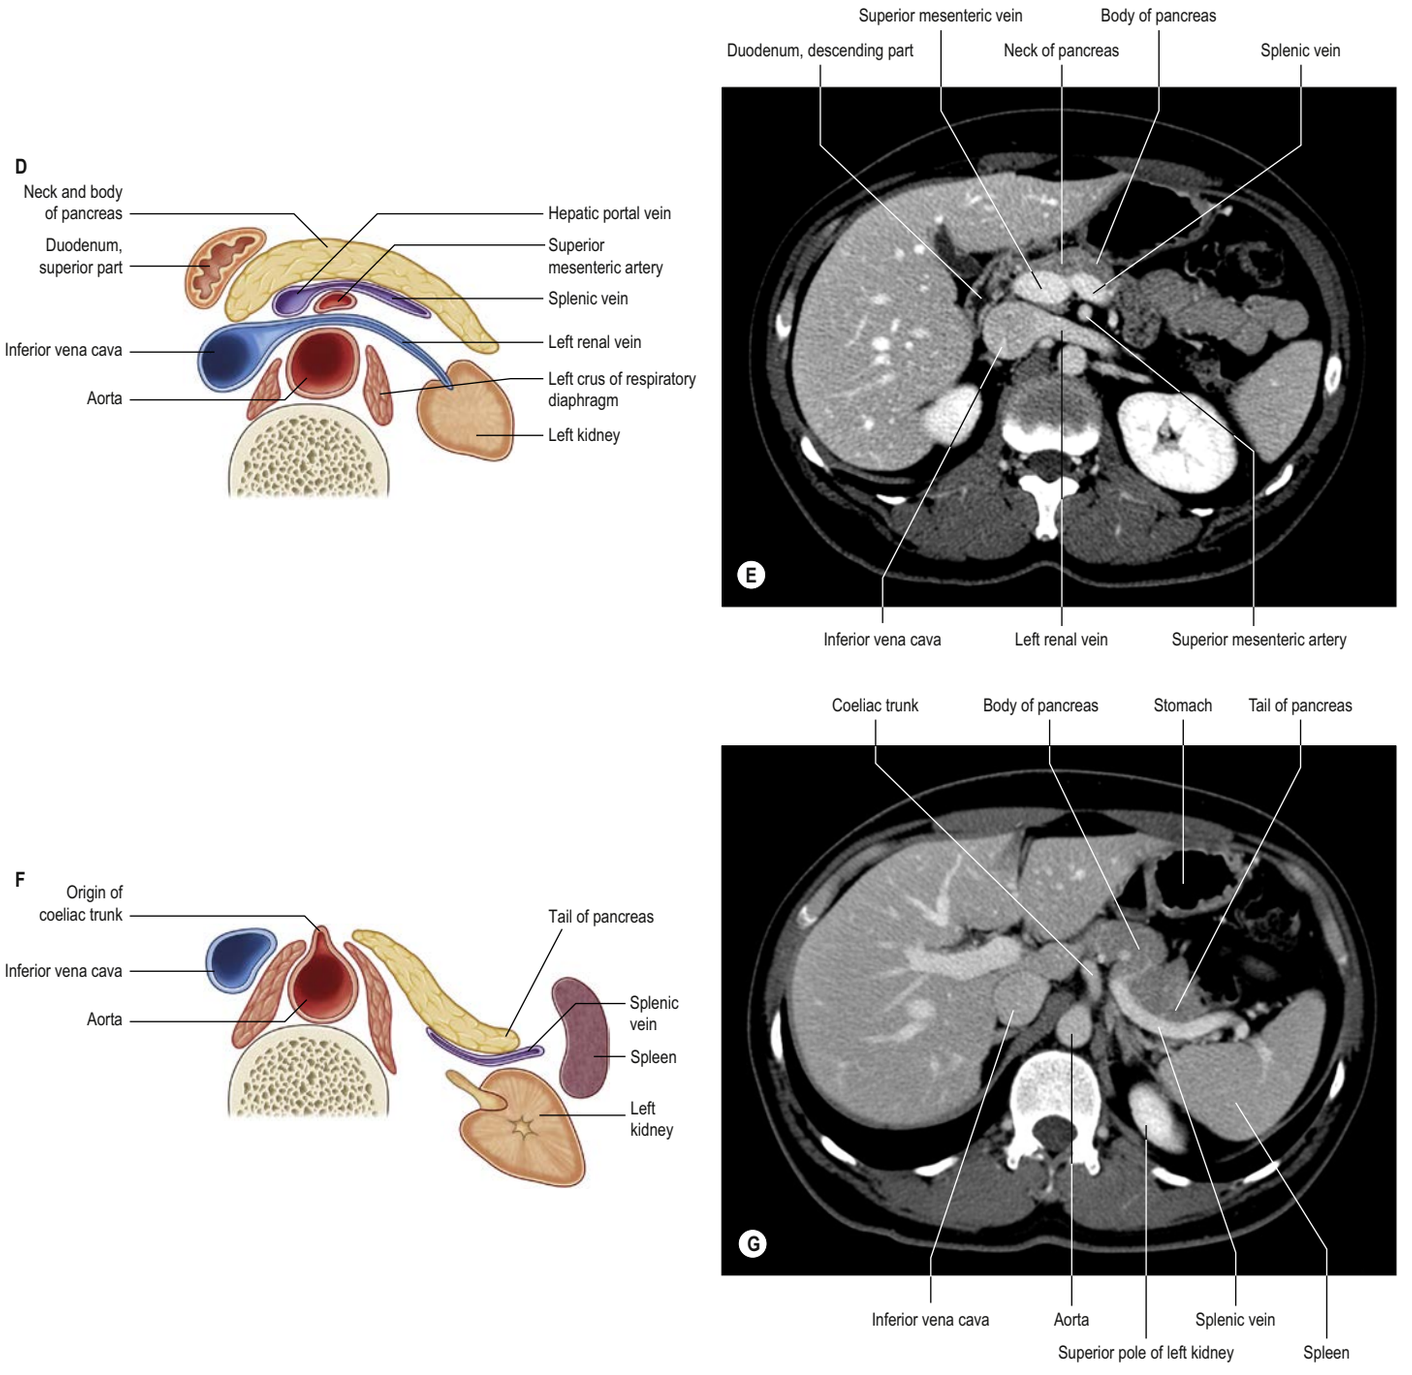

Fig. 68.4, cont'd Diagrammatic cross-sections and equivalent CT axial image taken at the head and neck **(D–E)**, and tail **(F–G)** of the pancreas.

Posterior surface The posterior surface of the pancreas is devoid of peritoneum. It lies on the fusion fascia of Toldt anterior to the abdominal aorta and the origin of the superior mesenteric artery, the left crus of the diaphragm, the left suprarenal gland, the superior pole of the left kidney surrounded by renal fascia, and the left renal vein (Kimura 2000; see Figs 68.1, 68.4A–G). The splenic vein runs from left to right directly on this surface of the gland and indents it to a variable extent, ranging from a shallow groove to nearly a tunnel.

Superior border To the right, the superior border of the body of the pancreas is rounded, but it becomes narrower and sharper to the left. An omental eminence usually projects from the right end of the superior border above the level of the lesser curvature of the stomach. The superior border lies anterior to the coeliac trunk and its branches, the common hepatic and splenic arteries: the common hepatic artery runs to the right just superior to the gland, and the splenic artery passes tortuously to the left, projecting above the superior border at several points.

Inferior border At the medial end of the inferior border of the neck of the pancreas, the superior mesenteric vessels travel posterior to the gland. Laterally, the inferior mesenteric vein runs posterior to the inferior border to join the splenic vein or the confluence of the splenic and superior mesenteric veins. This is a useful site for identification of the inferior mesenteric vein on computed tomography (CT) and during resection of the descending colon. The superior mesenteric artery lies medial to the superior mesenteric vein and is a critical structure that must be identified when the pancreas is divided between its head and neck during a pancreaticoduodenectomy (Whipple procedure).

Tail

The tail of the pancreas is the narrowest, most left-lateral portion of the gland and is continuous with the body. It is between 1.5 and 3.5 cm long in adults and lies between the splenorenal ligament and the splenic hilum. It either terminates at the base of the splenorenal ligament or extends into the splenic hilum, where it is at risk of injury during a splenectomy when the splenic vessels are divided. The splenic artery and its branches, and the splenic vein and its tributaries, lie posterior to the tail (see Fig. 68.4F–G).

Pancreatic ducts

The exocrine pancreatic tissue drains into multiple small lobular ducts. There are several anatomical variations of the ducts draining the pancreas. The most common variation is a single pancreatic duct and a single accessory duct (**Fig. 68.5**) that reflects the embryological development of the dorsal and ventral pancreatic ducts (see Figs 21.3–21.4). The pancreatic duct (of Wirsung) usually runs through the gland slightly diagonally from left to right, from a more inferior location in the head to a more superior location. Its size varies, which has significant implications for pancreatic surgery when a reconstruction is planned. The duct is formed by the junction of several lobular (secondary) ducts in the tail. It increases in calibre within the body of the pancreas as it receives further lobular ducts that join almost at right-angles to its long axis, forming a herringbone pattern. It can often be visualized on ultrasonography, measuring approximately 3 mm in diameter in the head, 2 mm in the body and 1 mm in the tail; the calibre of the duct increases from about the fifth decade onwards (Glaser et al 1987). As it reaches the neck of the gland, the pancreatic duct runs inferiorly and posteriorly towards the bile duct, which descends through the head of the pancreas. The two ducts unite and enter the wall of the descending part of the duodenum obliquely; a dilation, the hepatopancreatic ampulla (of Vater) is sometimes found at this union. The terminal part of the pancreatic duct contains a few mucosal folds that impede reflux of pancreatic juice (Purvis et al 2013). The length of the common pancreaticobiliary channel is variable and measures up to 5–7 mm in most individuals (Horaguchi et al 2014). An abnormally long common channel can occur in isolation or with congenital choledochal dilation and is associated with pancreaticobiliary reflux and an increased risk of biliary tract cancer (Kamisawa et al 2010a).

The accessory pancreatic duct (of Santorini) drains the superior part of the anterior portion of the head of the pancreas. Much smaller in calibre than the pancreatic duct, it is formed within the head of the pancreas from several lobular ducts and usually communicates with the pancreatic duct near the neck of the gland or near its first inferior branch (Kamisawa 2004, Kamisawa and Okamoto 2008). The accessory duct usually opens onto a small, rounded minor duodenal papilla that lies about 2 cm proximal to the major duodenal papilla (see Fig. 68.5A). If the duodenal end of the accessory duct fails to develop, the lobular ducts drain via small channel(s) into the pancreatic duct (Hernandez-Jover et al 2011). The anatomy of the pancreatic duct and accessory pancreatic duct can vary, reflecting variations in the development and fusion of the dorsal and ventral pancreatic ducts.

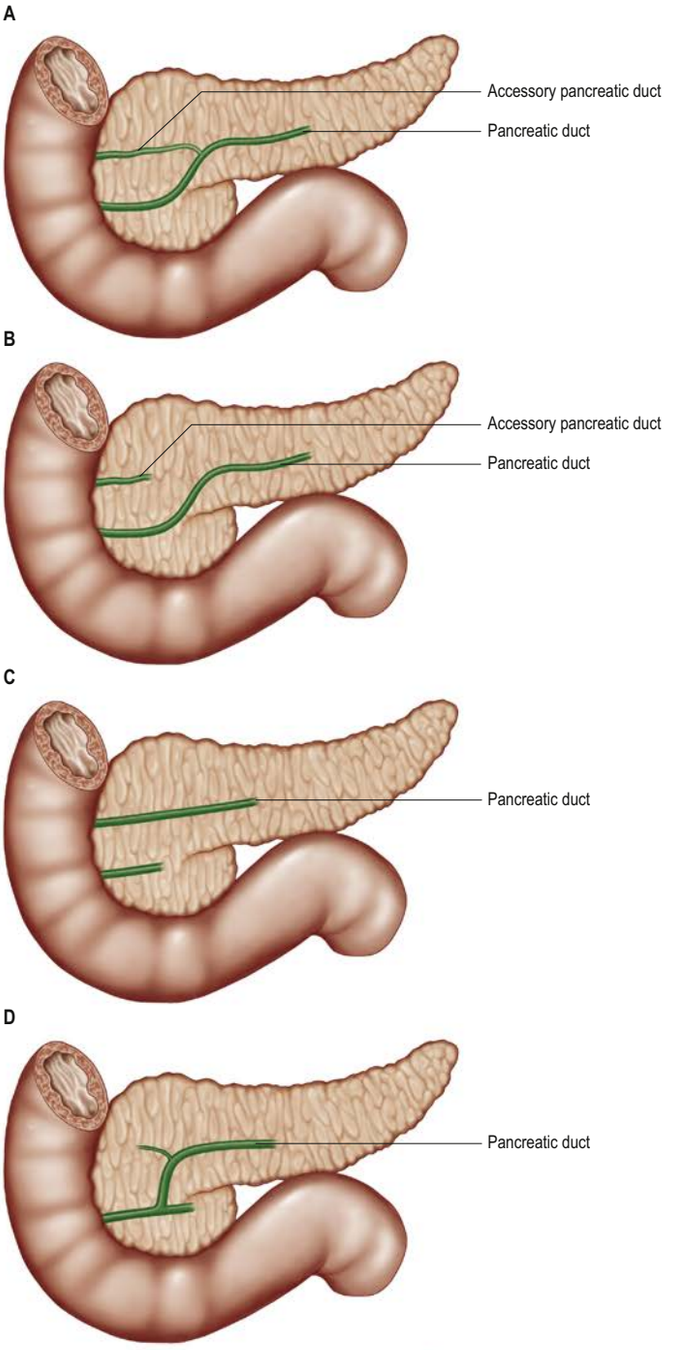

Fig. 68.5 The normal and variant ductal anatomy of the pancreas. **A**, Normal. The pancreatic duct is formed by fusion of the dorsal and ventral bud ducts, and communicates with the accessory pancreatic duct. **B**, Normal. There is no communication between the pancreatic duct and a normally positioned accessory duct. **C**, Pancreas divisum. Most of the pancreas drains via a dominant dorsal duct that enters the duodenum at the minor duodenal papilla. A short ventral duct is seen draining, along with the bile duct, into the major duodenal papilla. **D**, Absence of accessory duct. (E–G, *continued online*)

Vascular supply and lymphatic drainage

Arteries

The pancreas has a rich arterial supply from branches of the coeliac trunk and superior mesenteric artery (**Figs 68.6A–C**; see also Fig. 64.4). The head of the pancreas and adjoining duodenum are supplied mainly by four arteries: anterior and posterior superior pancreaticoduodenal arteries via the gastroduodenal artery from the coeliac trunk, and anterior and posterior inferior pancreaticoduodenal arteries via the inferior pancreaticoduodenal artery from the superior mesenteric artery. The two anterior arteries supply the anterior aspects of the duodenum, head of the pancreas, and uncinate process, and join to form the anterior pancreaticoduodenal arcade. The two posterior arteries supply the posterior (dorsal) aspect of the head of the pancreas, adjacent duodenum and distal bile duct, and can join to form a posterior pancreaticoduodenal arcade.

The body and tail of the pancreas are supplied by multiple small direct branches from the splenic artery, including the dorsal pancreatic artery. Small arteries characteristically run along the superior and inferior borders of the gland, lying either in a deep groove or within the gland. They are fed along their length by the pancreaticoduodenal and splenic arteries. When the pancreas is transected during pancreatic surgery, bleeding from these vessels is avoided by ligating the superior and inferior borders of the pancreas using transfixion sutures prior to transection.

Posterior superior pancreaticoduodenal artery

The posterior superior pancreaticoduodenal artery usually arises as the first branch of the gastroduodenal artery at the superior edge of the superior (first) part of the duodenum. It runs to the right, anterior to the supraduodenal segment of the bile duct, before spiralling posteriorly around the pancreatic segment of the bile duct and descending on the posterior surface of the head of the pancreas. It gives branches to the duodenum, head of the pancreas, and bile duct before anastomosing with the posterior inferior pancreaticoduodenal artery to form the posterior pancreaticoduodenal arcade. The posterior superior pancreaticoduodenal artery can also give origin to the retroduodenal and supraduodenal arteries that supply the duodenum (Bertelli et al 1996a). The spiral course of the posterior superior pancreaticoduodenal artery reflects its embryonic development: it is the artery to the anterior aspect of the ventral pancreatic bud and the bile duct that subsequently rotate clockwise posterior to the duodenum and dorsal pancreatic bud (Bertelli et al 1997).

Anterior superior pancreaticoduodenal artery

The anterior superior pancreaticoduodenal artery usually arises as the smaller terminal branch of the gastroduodenal artery, together with the right gastro-omental artery. It originates posterior to the superior portion

Patients who develop acute pancreatitis are more likely to have a poorly developed minor duodenal papilla: if this were not so, the patent accessory duct system could act as a secondary drainage mechanism for the main ductal system and thus prevent the elevation of intraductal pressure likely to cause acute pancreatitis (Kamisawa et al 2010b). One clinically important variation is pancreas divisum, which is seen in 5–10% of individuals (Rana et al 2012; see Fig. 68.5C,G). In this condition, normal duct fusion fails and the accessory pancreatic duct drains the entire pancreas, except that part of the head that develops from the ventral bud, via the minor duodenal papilla. The relatively small size of the minor duodenal papilla could impair pancreatic drainage, leading to recurrent pancreatitis.

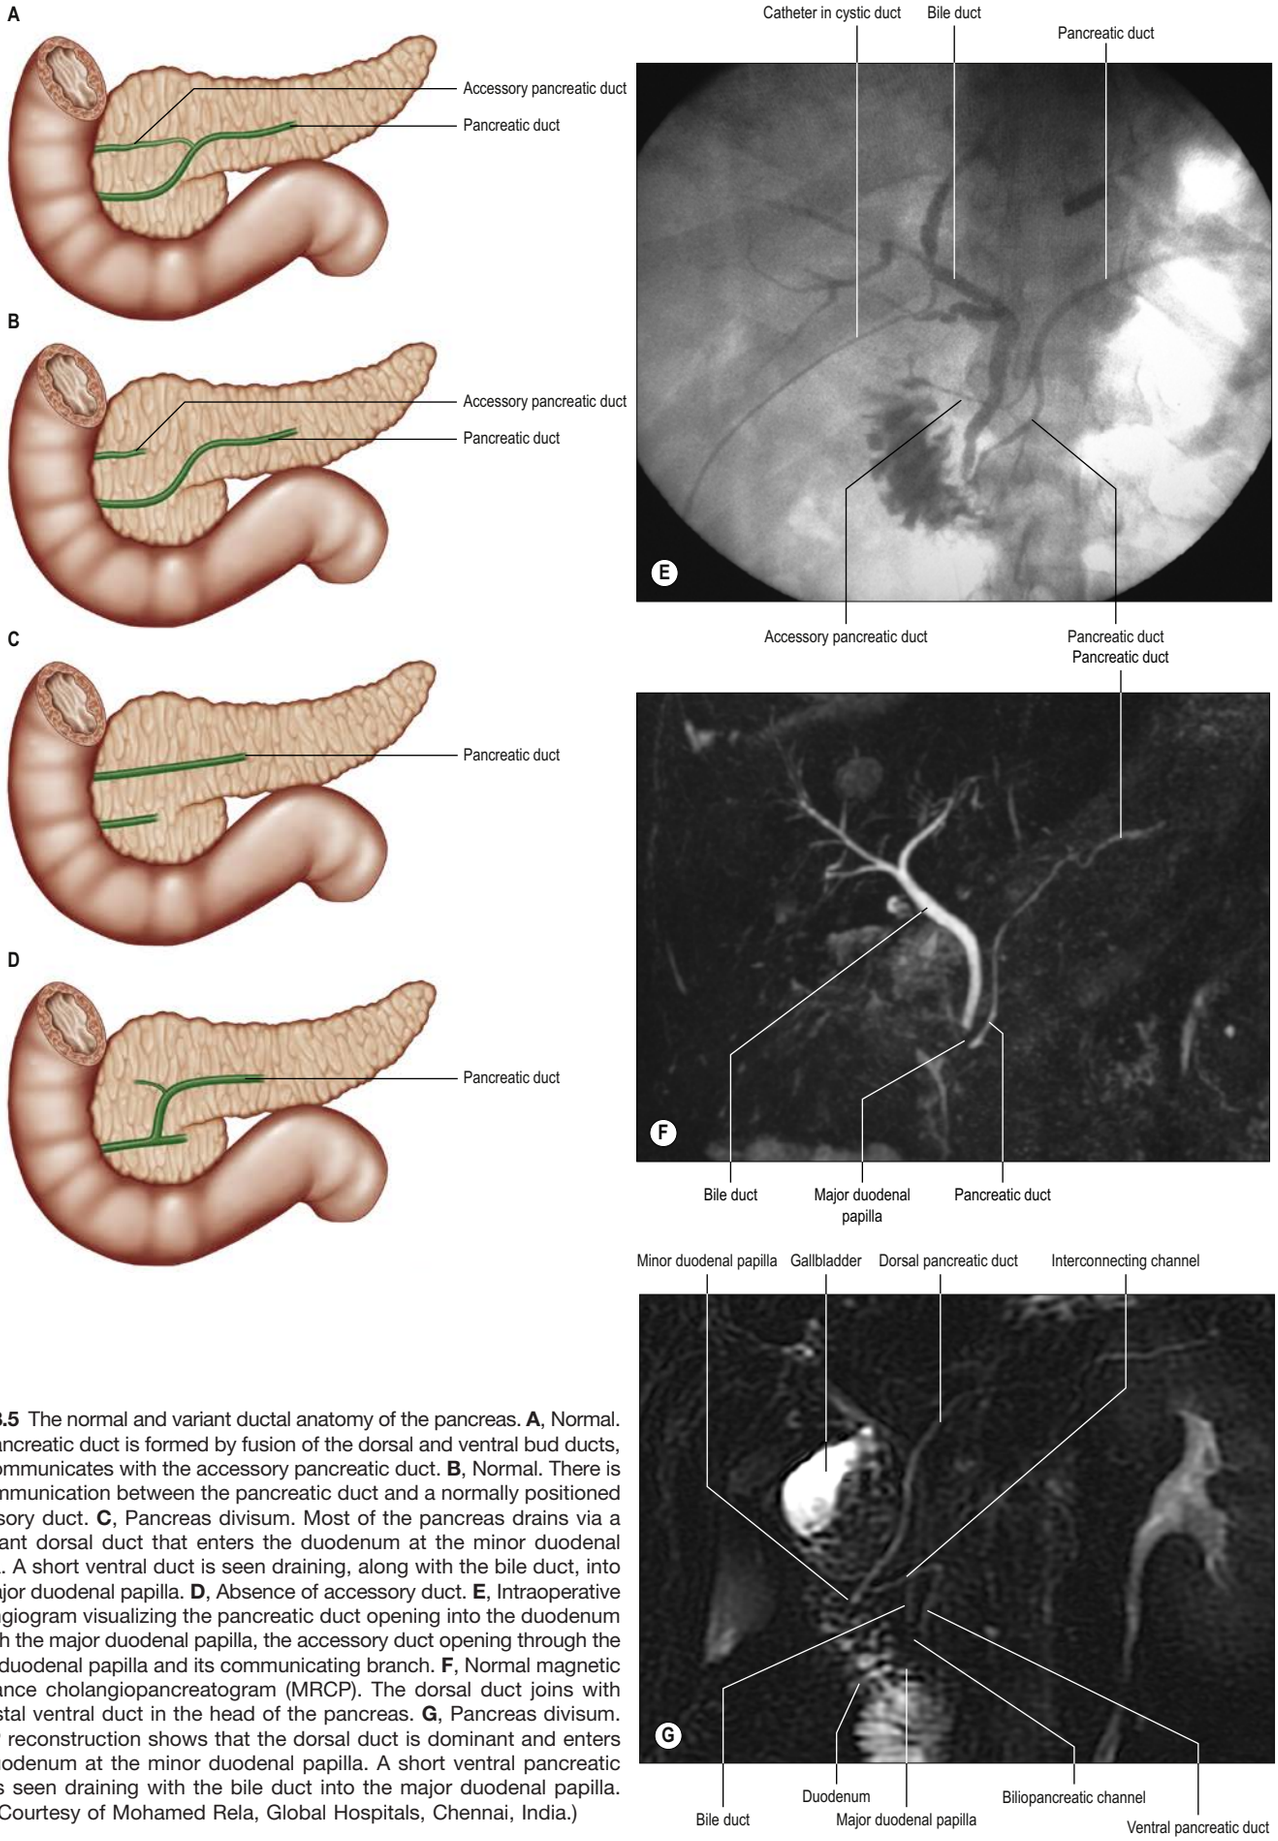

Fig. 68.5 The normal and variant ductal anatomy of the pancreas. **A**, Normal. The pancreatic duct is formed by fusion of the dorsal and ventral bud ducts, and communicates with the accessory pancreatic duct. **B**, Normal. There is no communication between the pancreatic duct and a normally positioned accessory duct. **C**, Pancreas divisum. Most of the pancreas drains via a dominant dorsal duct that enters the duodenum at the minor duodenal papilla. A short ventral duct is seen draining, along with the bile duct, into the major duodenal papilla. **D**, Absence of accessory duct. **E**, Intraoperative cholangiogram visualizing the pancreatic duct opening into the duodenum through the major duodenal papilla, the accessory duct opening through the minor duodenal papilla and its communicating branch. **F**, Normal magnetic resonance cholangiopancreatogram (MRCP). The dorsal duct joins with the distal ventral duct in the head of the pancreas. **G**, Pancreas divisum. MRCP reconstruction shows that the dorsal duct is dominant and enters the duodenum at the minor duodenal papilla. A short ventral pancreatic duct is seen draining with the bile duct into the major duodenal papilla. (E–G, Courtesy of Mohamed Rela, Global Hospitals, Chennai, India.)

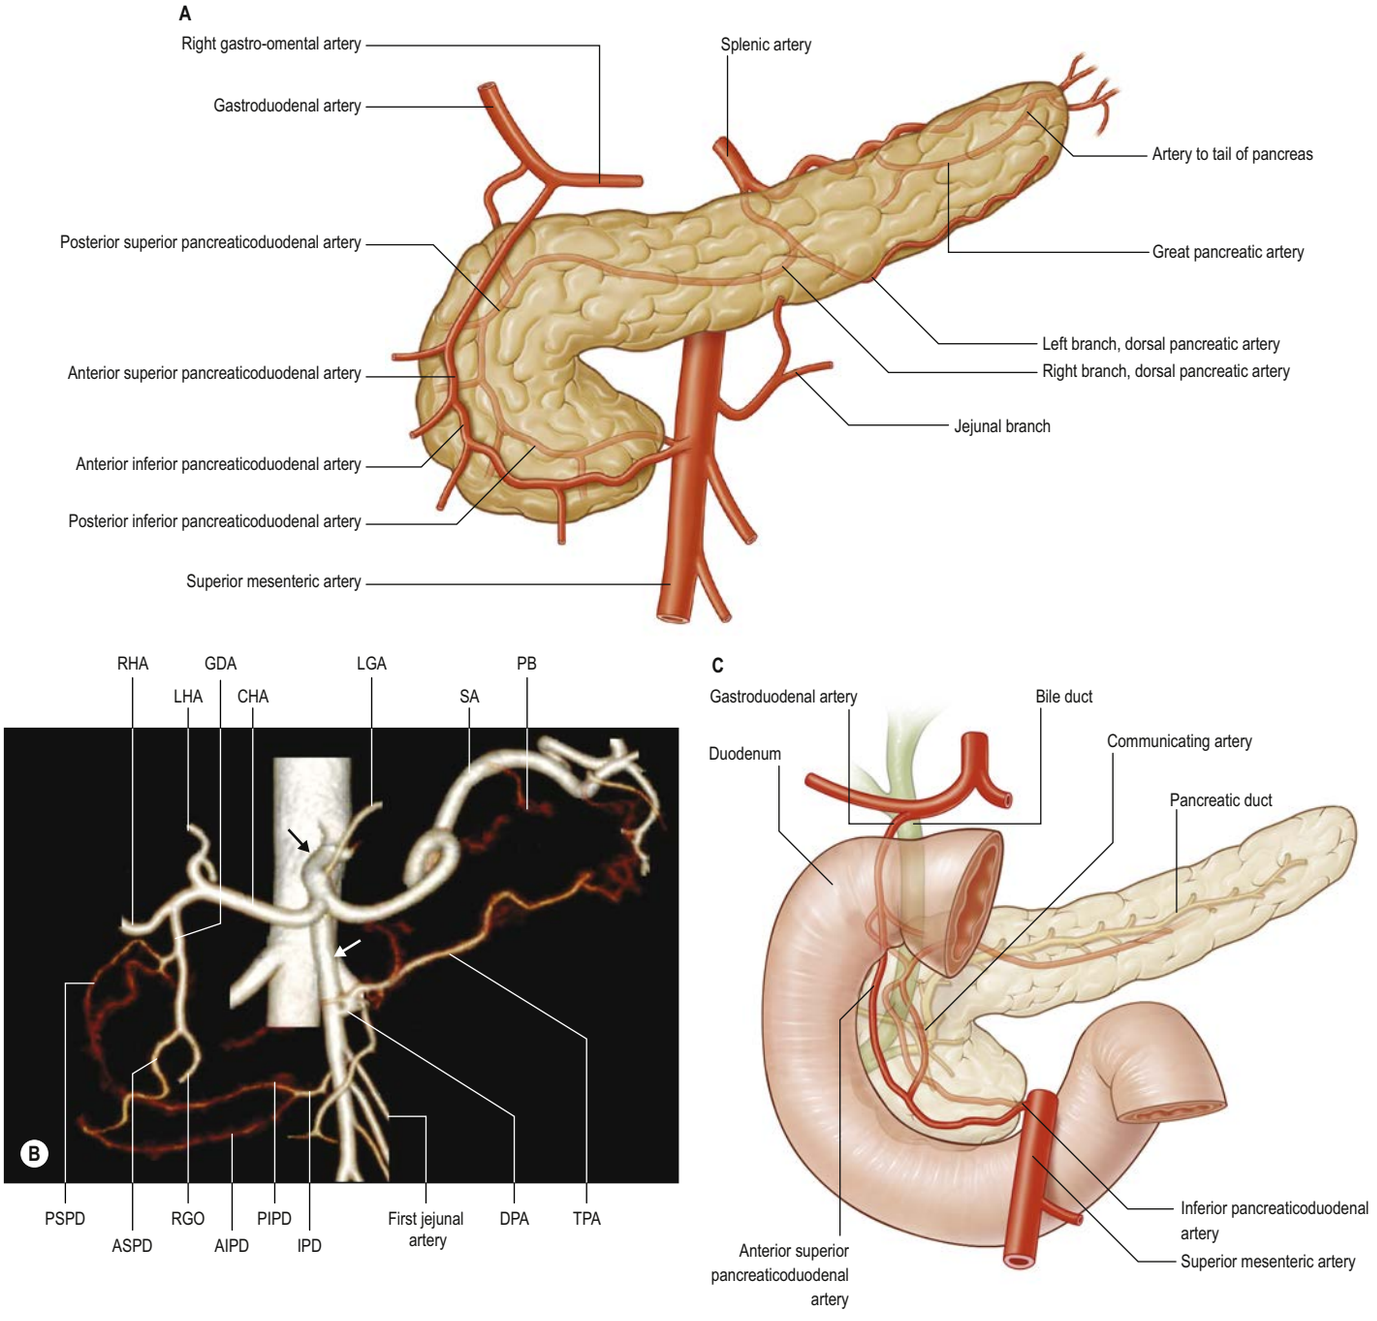

Fig. 68.6 A, The arterial supply of the pancreas. **B**, A CT angiographic reconstruction. The black arrow points to the coeliac trunk, and the white arrow points to the superior mesenteric artery. Anastomotic arcades, both anterior and posterior, can be seen coursing around the head of the pancreas. The body and tail of the pancreas are supplied by multiple pancreatic branches (PB) from the splenic artery and the dorsal pancreatic artery (DPA), which, in this example, arises from the superior mesenteric artery, and gives origin to the inferior (transverse) pancreatic artery (TPA). Other abbreviations: AIPD, anterior inferior pancreaticoduodenal artery; ASPD, anterior superior pancreaticoduodenal artery; CHA, common hepatic artery; GDA, gastroduodenal artery; IPD, inferior pancreaticoduodenal artery; LGA, left gastric artery; LHA, left hepatic artery; PIPD, posterior inferior pancreaticoduodenal artery; PSPD, posterior superior pancreaticoduodenal artery; RGO, right gastro-omental artery; RHA, right hepatic artery; SA, splenic artery. **C**, The anterior and posterior pancreaticoduodenal arterial arcades and a typical communicating artery. (Adapted with permission from Mirjalili SA, Stringer MD 2011 The arterial supply of the major duodenal papilla and its relevance to endoscopic sphincterotomy. Endoscopy 43(4):307–11.)

of the duodenum and runs inferiorly on the anterior aspect of the head of the pancreas at a variable distance medial to the groove between the descending duodenum and head of the pancreas. It passes inferiorly around the right or inferior border of the head of the pancreas, often piercing the gland to reach the posterior surface of the uncinate process, where it joins the anterior inferior pancreaticoduodenal artery to form the anterior pancreaticoduodenal arcade (Bertelli et al 1995).

Inferior pancreaticoduodenal artery

An inferior pancreaticoduodenal artery is present in most individuals. It usually arises either directly from the superior mesenteric artery at the inferior border of the pancreas or as a common vessel with the first jejunal artery (a pancreaticoduodenojejunal trunk) from the posterior or left aspect of the superior mesenteric artery (Bertelli et al 1996b, Horiguchi et al 2008). It runs to the right, posterior to the superior mesenteric vein, to reach the posterior surface of the uncinate process, where it divides into anterior and posterior inferior pancreaticoduodenal arteries. When it arises as a pancreaticoduodenojejunal trunk, the artery gives off a jejunal branch and then runs posterior to both the superior mesenteric artery and vein before dividing into its terminal branches. The inferior pancreaticoduodenal artery is at risk of bleeding during the retroperitoneal dissection of a Whipple procedure. Occasionally, it is absent and the anterior and posterior inferior pancreaticoduodenal arteries arise separately from the superior mesenteric artery.

The smaller anterior inferior pancreaticoduodenal artery runs to the right on the posterior surface of the uncinate process to join the anterior

superior pancreaticoduodenal artery and form the anterior pancreaticoduodenal arcade. The larger posterior inferior pancreaticoduodenal artery runs on the posterior surface of the head of the pancreas, parallel and superior to the anterior inferior pancreaticoduodenal artery and joins the posterior superior pancreaticoduodenal artery to form the posterior pancreaticoduodenal arcade (Bertelli et al 1997).

Communicating arteries

Multiple small arteries run between the anterior and posterior pancreaticoduodenal arcades, either via the pancreaticoduodenal groove or through the substance of the gland. The largest and most consistent of these is the communicating artery (sometimes known as the middle pancreaticoduodenal arcade) that passes between the pancreatic duct and accessory pancreatic duct and connects the anterior pancreaticoduodenal arterial arcade and the posterior superior pancreaticoduodenal artery (Yamaguchi et al 2001; see Fig. 68.6C). This artery gives rise to most of the small arteries that supply the major duodenal papilla (Mirjalili and Stringer 2011).

Other arterial arcades in the head of the pancreas

Kirk's arcade is formed by a right branch of the dorsal pancreatic artery that emerges on to the anterior surface of the head of the gland and anastomoses with a branch of either the gastroduodenal artery or the anterior pancreaticoduodenal arcade (Woodburne and Olsen 1951). It supplies the anterior surface of the head and neck of the gland.

Splenic artery

The splenic artery arises from the coeliac trunk and runs posterior to the superior border of the pancreas to the splenic hilum (see Fig. 68.6A). It gives off multiple small branches along its course that penetrate and supply the pancreas, including the dorsal pancreatic artery; the great pancreatic artery, arising approximately two-thirds of the way along the gland; and the artery to the tail of the pancreas, arising near the tail. These branches lie on or within the posterior aspect of the gland and often anastomose with the inferior pancreatic artery. Anatomical variations are not unusual, and the dorsal, great or inferior pancreatic arteries can be dominant in any one individual (Wu et al 2011).

Dorsal pancreatic artery

The dorsal pancreatic artery commonly arises from the initial 2 cm of the splenic artery, although it can also take origin from the common hepatic or superior mesenteric arteries or the coeliac trunk (Horiguchi et al 2008). It is short and gives off numerous branches, including a terminal left branch near the inferior border of the gland. Several right-sided branches run to the head of the pancreas, passing either posterior or anterior to the superior mesenteric vein to supply the posterior or anterior surface of the head of the pancreas, respectively; they anastomose with arteries of the pancreaticoduodenal arcade (Tsutsumi et al 2014). The terminal left branch anastomoses with the inferior pancreatic artery.

The length and course of the dorsal pancreatic artery depend primarily on its site of origin. When it arises from the splenic artery, common hepatic artery or coeliac trunk, it runs inferiorly on the posterior surface of the pancreas, whereas if it arises from the superior mesenteric artery, it runs superiorly. These variations should be taken into account during organ procurement because injury to the dorsal pancreatic artery, including at its origin, can jeopardize the pancreatic graft as a result of inadequate perfusion of the tail of the pancreas (Baranski et al 2016). The artery uniformly terminates near the inferior border of the pancreas close to the confluence of the splenic and superior mesenteric veins (Bertelli et al 1998).

Inferior pancreatic artery

The inferior (transverse) pancreatic artery commonly originates from the left terminal branch of the dorsal pancreatic artery. It runs to the left on the posterior surface of the gland close to its inferior border, gives multiple branches to the body and tail, and anastomoses with other pancreatic branches of the splenic artery. Occasionally, the inferior pancreatic artery originates from the gastroduodenal artery or the anterior superior pancreaticoduodenal artery, crossing the anterior surface of the head of the pancreas to reach the inferior border of the neck of the gland and then the tail. In such cases it may be the dominant artery to the body of the pancreas, and its injury or deliberate ligation during pancreaticoduodenectomy can cause ischaemia of the pancreas.

Arterial segmentation of the pancreas

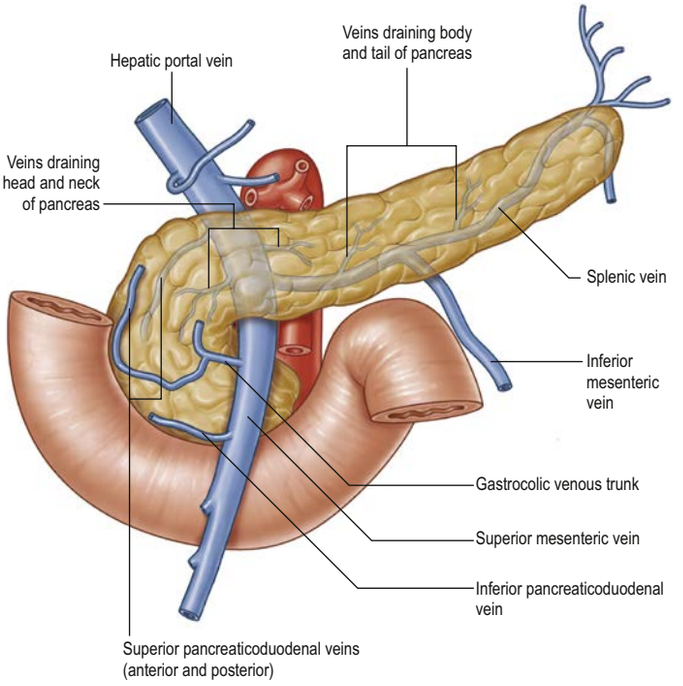

Fig. 68.7 Venous drainage of the pancreas. (Adapted from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Veins

Multiple veins drain the pancreas into the hepatic portal, superior mesenteric and splenic veins (Mourad et al 1994; **Fig. 68.7**). Although variations are common, the anterior superior pancreaticoduodenal vein typically joins either the confluence of the right gastro-omental and right colic veins (the gastrocolic trunk of Henle) or the right gastro-omental vein alone, to drain into the superior mesenteric vein at the inferior border of the neck of the pancreas (Mourad et al 1994, Lange et al 2000). The posterior superior pancreaticoduodenal vein drains cranially into the hepatic portal vein. Both anterior and posterior inferior pancreaticoduodenal veins usually drain directly into the posterior aspect of the superior mesenteric vein inferior to the uncinate process. These veins can be a major source of blood loss when the uncinate process is dissected off the superior mesenteric vein during a pancreaticoduodenectomy procedure. In most individuals the first and second jejunal veins form a single vein known as the first jejunal trunk that drains into the superior mesenteric vein (Ishikawa et al 2017). Veins from the body and tail of the gland drain directly into the splenic vein. An inferior (transverse) pancreatic vein sometimes runs along the inferior border of the pancreas to join the inferior mesenteric vein. A few pancreatic veins communicate with systemic veins in the retroperitoneum (veins of Retzius) and can form retroperitoneal varices in patients with portal hypertension.

Lymphatic drainage

The lymphatic drainage of the pancreas is extensive (see Fig. 63.14B), which partly explains the poor prognosis of individuals with pancreatic cancer. Lymphatic vessels start within the interlobular septa within the gland and join to form larger lymphatic vessels that follow the paths of local arteries (Deki and Sato 1988, O'Morchoe 1997). Lymphatics from the tail and body of the pancreas drain mostly into nodes along the splenic artery and inferior border of the gland, and from there to pre-aortic nodes between the coeliac trunk and superior mesenteric artery. Lymphatics from the neck and head drain more widely into nodes along the pancreaticoduodenal, superior mesenteric and hepatic arteries, and ultimately into pre-aortic nodes (Donatini and Hidden 1992, Cesmebasi et al 2015). There is no evidence of lymphatic channels within the pancreatic islets.

Innervation

The pancreas is innervated by extra- and intra-pancreatic plexuses of autonomic nerves (Love et al 2007, Zuo et al 2012). Preganglionic vagal efferents with cell bodies in the posterior nucleus of the vagus nerve reach the pancreas via hepatic, gastric and coeliac branches of the vagus nerve.

The pancreas can be divided into two arterial 'segments' separated by a relatively avascular plane. There is disagreement about the definition of these segments. One view is that they are separated by a plane passing to the left of the superior mesenteric artery, such that the head and neck are supplied by branches of the gastroduodenal and superior mesenteric arteries and the body and tail are supplied by branches of the splenic artery (Busnardo et al 1988). An alternative view holds that the anterior segment consists of the superior part of the pancreatic head, neck, body and tail (derived from the dorsal pancreatic bud), and the posterior segment consists of the inferior part of the head and the uncinate process (derived from the ventral pancreatic bud) (Sakamoto et al 2000). In both schemes, the pancreatic duct crosses between the segments. Currently, segmental anatomy is of limited practical surgical significance.

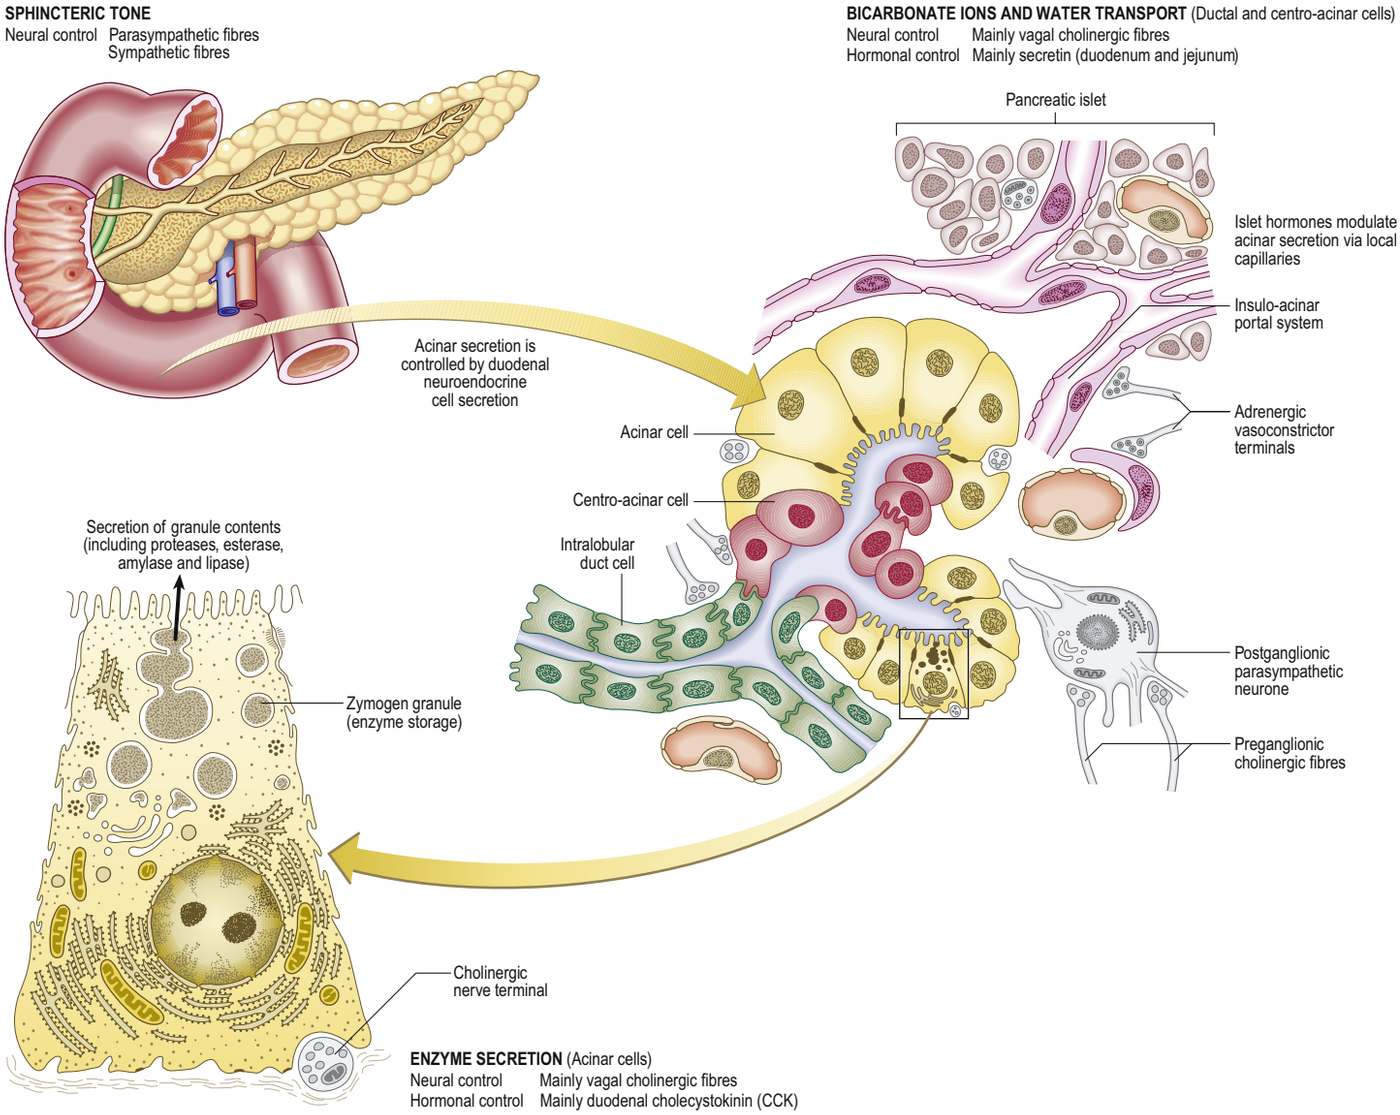

Fig. 68.8 The microstructure of the exocrine pancreas and the mechanisms by which its secretion is controlled. Pancreatic stellate cells (see text) are not shown.

They synapse with postganglionic parasympathetic pancreatic neurones that are distributed singly or clustered in ganglia in the interlobular connective tissue, lobules and islets. Postganglionic fibres ramify in the interacinar spaces and supply acinar cells and islets, modulating both exocrine and endocrine secretion (see Fig. 68.10). They reach the islets via the blood vessels: in marked contrast to mouse pancreas (widely used in experimental models analysing pancreatic function), relatively few parasympathetic axons terminate in the human endocrine pancreas (Pénicaud 2017) and endocrine cells of the human islet do not appear to be directly innervated (Rodriguez-Diaz et al 2012). Postganglionic parasympathetic neurones are also contacted by enteric neurones from the stomach and duodenum, sympathetic efferents and other pancreatic neurones and a network of interstitial cells (of Cajal) provides an additional link between autonomic nerves and pancreatic acini.

The cell bodies of preganglionic sympathetic nerves are located in the intermediolateral nuclei of the spinal cord (T6–T12); their axons travel in the thoracic splanchnic nerves and synapse in the coeliac and superior mesenteric ganglia. Postganglionic sympathetic nerves innervate the smooth muscle cells of vessels and ducts within the pancreas, causing vasoconstriction and inhibiting exocrine secretion.

Visceral afferents, travelling via parasympathetic and sympathetic routes, convey sensory information from the pancreas via the inferior (nodose) ganglion of the vagus nerve (terminating in the solitary tract), and via the coeliac plexus and greater thoracic splanchnic nerves (terminating in the dorsal horn of the spinal cord, T5–T9).

Extrapancreatic nerve plexuses are particularly abundant in the head and neck of the pancreas, where two plexuses have been identified (Yoshioka and Wakabayashi 1958). Pancreatic head plexus I originates from the coeliac ganglia and plexus and travels on the posterior surface of the head of the pancreas and along the medial margin of the uncinate process. Pancreatic head plexus II originates from the superior mesenteric ganglion and plexus and travels along the inferior pancreaticoduodenal artery on the uncinate process (Mochizuki et al 2010, Zuo et al 2012, Isaji et al 2018).

Perineural invasion is relatively common in pancreatic cancer and not only adversely affects prognosis, but may also be a factor in the pain associated with this disease (Bapat et al 2011).

Referred pain

Pain arising in the pancreas is poorly localized. Inflammatory or cancerous processes arising from the gland rapidly involve the tissues of the retroperitoneum that are innervated by somatic nerves and pain is localized to the lower thoracic spine, consequently patients complain of low back pain. Intractable pain from chronic pancreatitis or inoperable pancreatic tumours can be controlled by thermal or chemical ablation of the coeliac plexus.

Microstructure

The pancreas is composed of exocrine and endocrine tissues. The main tissue mass, forming 98% of the pancreas, is exocrine; the pancreatic islets that form the endocrine component are embedded in it (**Figs 68.8–68.10**).

Exocrine pancreas

The exocrine pancreas is a branched acinar gland (see Fig. 2.6) surrounded and incompletely lobulated by delicate loose connective tissue. Individual acini are composed of roughly spherical clusters of pyramidal cells that secrete digestive enzymes. A narrow intralobular duct lined by flattened or cuboidal centro-acinar cells originates from

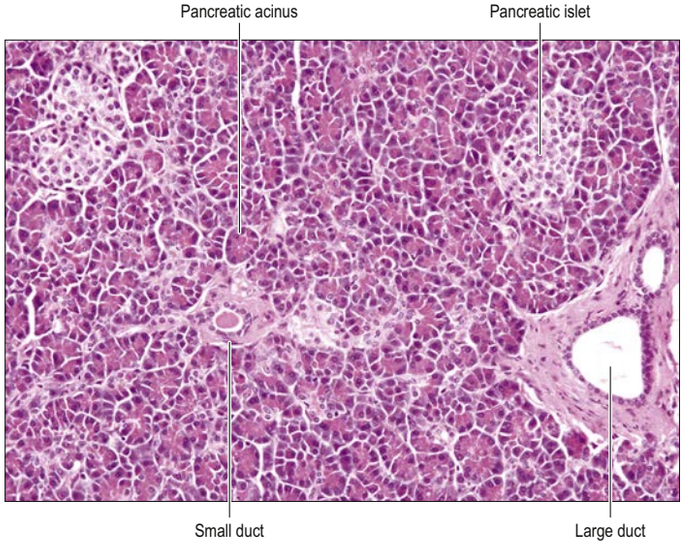

Fig. 68.9 Microstructure of the pancreas. The exocrine tissue consists of acini with pyramid-shaped columnar cells arranged in spherical clusters. Acinar secretions drain into intralobular ducts, which, in turn, join larger interlobular ducts, present in interlobular septa containing blood vessels. Interspersed between the acini are islets of Langerhans, which appear as clusters of pale-staining cells surrounded by a network of capillaries, seen as narrow clear spaces. Adipocytes are also sometimes present. Haematoxylin and eosin. (Courtesy of Dr Mukul Vij, Global Hospital, Chennai, India.)

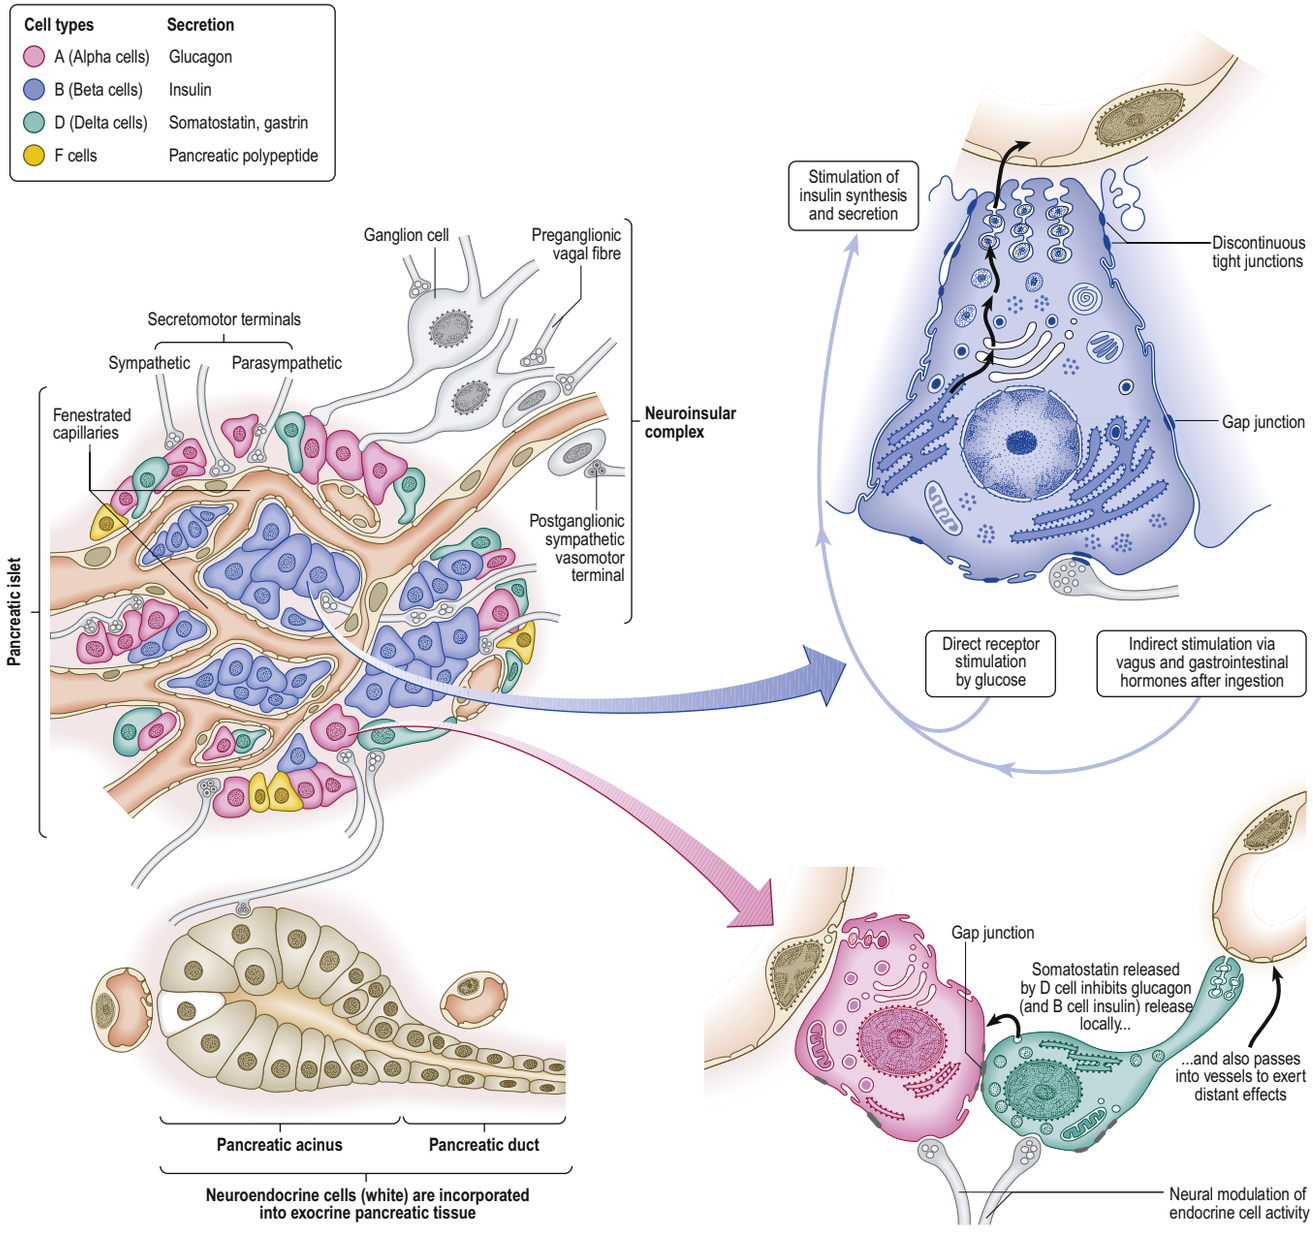

Fig. 68.10 The microstructure and control of function of the endocrine pancreas.

within each secretory acinus. Intralobular ducts, which release bicarbonate ions and water into their lumina, unite to form larger interlobular ducts lined by taller cuboidal and eventually columnar epithelium. The latter are surrounded by connective tissue septa containing smooth muscle, autonomic nerves and adipose tissue. Neuroendocrine cells are present among the columnar ductal cells, and mast cells are numerous in the surrounding connective tissue. A network of intralobular arteries, arterioles and capillaries forms around the terminal ducts, acini and the richly vascularized endocrine islets (Love et al 2007).

Acinar cells Acinar cells have a basal nucleus surrounded by abundant basophilic rough endoplasmic reticulum and an apical region containing dense eosinophilic secretory zymogen granules. A prominent supranuclear Golgi complex is associated with large, membrane-bound granules containing the protein constituents of pancreatic secretion, including enzymes that are only active after release. Ganglionic neurones and cords of undifferentiated epithelial cells are also found within the acini. The structure of the exocrine pancreas and its functional regulation are summarized in Fig. 68.8.

Stellate cells Pancreatic stellate cells are myofibroblast-like cells distributed in the exocrine part of the pancreas, mainly in the peri-acinar space, where their long cytoplasmic processes encircle the base of the acinus, and in perivascular and periductal regions of the pancreas. They are usually in a quiescent state but have been implicated in the pathogenesis of chronic pancreatitis and pancreatic cancer when activated (Omary et al 2007, Masamune and Shimosegawa 2013).

Endocrine pancreas

Pancreatic islets (of Langerhans) constitute the endocrine component of the pancreas. The human pancreas can contain more than a million islets distributed throughout the gland but most numerous in the tail. Each islet consists of a highly vascularized cluster of polyhedral cells arranged in a trabecular pattern, closely approximated to a dense network of fenestrated capillaries that enables substrates to be transported bidirectionally between the islet cells and the circulation (In't Veld and Marichal 2010). Islets are innervated by autonomic nerve fibres that travel with the blood vessels and end blindly in the pericapillary spaces. True synaptic contact between these nerve fibres and islet cells has not been demonstrated, although it has been suggested that they have a role in islet function (Rodriguez-Diaz et al 2012). Specialized staining techniques are necessary to distinguish various islet cells, designated alpha, beta, delta, epsilon and pancreatic polypeptide (PP) or F cells. Beta cells secrete insulin and are the most abundant cell type (nearly 50% in human islets); alpha cells secrete glucagon (30–40%). Delta cells and PP cells are less common and secrete somatostatin and pancreatic polypeptide, respectively. Epsilon cells secrete ghrelin. Unlike murine islets, where beta cells form the core and are surrounded by alpha cells, human islets show no cell-type-specific localization. The various cell types are uniformly distributed along the microvasculature and have extensive interlinkages with other islet cells. Their general organization is shown in Fig. 68.10.

Acute inflammation of the pancreas can result from a variety of pancreatic insults, including gallstone obstruction of the hepatopancreatic ampulla, causing reflux of bile and pancreatic fluid into the pancreatic duct. This precipitates intraparenchymal activation of inactive digestive enzymes, leading to cell injury, an inflammatory cascade and destruction of pancreatic tissue.

The regional anatomy of the pancreas explains most of the clinical complications of acute pancreatitis. Irritation of the stomach contributes to gastric stasis and emesis inflammation of the superior mesenteric plexus can contribute to paralytic ileus; vascular inflammation can cause superior mesenteric or hepatic portal vein thrombosis, arterial bleeding or pseudoaneurysms and ischaemia of the transverse colon. Haemorrhaged blood can accumulate in the retroperitoneal tissues around the pancreas and track laterally to the flanks (Grey Turner's sign), inferiorly to the inguinal ligaments (Fox's sign), or via the lesser omentum and bare area of the liver to the falciform ligament and the skin around the umbilicus (Cullen's sign), manifesting as diffuse bruising.

Acute peripancreatic fluid collections frequently resolve spontaneously as the inflammation in the pancreas subsides. Accumulation of fluid anterior to the pancreas, just deep to the posterior wall of the omental bursa, can result in a 'pseudocyst' containing amylase-rich fluid and debris but lacking a true epithelial lining (Banks et al 2013). A large pseudocyst bulges anteriorly into the omental bursa in contact with the posterior wall of the stomach, lesser omentum and gastrosplenic ligament. If it does not resolve spontaneously, the pseudocyst can be drained internally through the posterior wall of the stomach by endoscopic or open surgery, or externally by means of a percutaneous drain inserted under radiological guidance.

Sustained injury to the pancreas can result in permanent damage, leading to parenchymal fibrosis and calcification within the parenchyma and the pancreatic ducts. This often causes chronic pain, diabetes mellitus and pancreatic exocrine insufficiency with steatorrhoea and malnutrition. Fibrosis can involve the bile duct in the head of the pancreas, leading to obstructive jaundice, and/or the splenic vein, causing splenic vein thrombosis and 'left-sided' portal hypertension.

Most pancreatic tumours are ductal adenocarcinomas derived from exocrine ductal epithelium. Up to two-thirds of such tumours are located in the head of the pancreas and often obstruct the pancreatic segment of the bile duct early in the course of disease, leading to obstructive jaundice. The appearance of a dilated bile duct and pancreatic duct on cross-sectional imaging (the 'double duct' sign) is characteristic of tumours of the head of the pancreas. Advanced tumours can invade the adjacent duodenum, causing obstruction of the gastric outlet and/or the hepatic portal or superior mesenteric veins posterior to the neck of the pancreas. A tumour in the body or tail of the gland often grows to a large size before presenting as an abdominal mass or with back pain and weight loss (Yeo et al 2002). Tumours of the uncinate process can cause early involvement of the superior mesenteric vessels and duodenum (O'Sullivan et al 2009). Peripancreatic and pre-aortic nodes can be involved, together with hepatic nodes, in tumours of the head of the pancreas, and nodes of the splenic hilum can be involved in tumours of the tail of the pancreas.

Surgery for tumours of the head of the pancreas usually involves combined resection of the head and duodenum (pancreaticoduodenectomy) as a consequence of their shared blood supply. The resectability of the tumour depends on the presence and extent of major vascular involvement, particularly the hepatic portal vein and superior mesenteric vessels. An accessory or replaced right hepatic artery running cranially on the posterior surface of the head of the pancreas and posterior to the supraduodenal segment of the bile duct is at risk of injury during such procedures (Turrini et al 2010). Recognition of this variation and preservation of the artery are essential to maintain the arterial supply to the right lobe of the liver. In distal or total pancreatectomy, spleen-preserving resections are generally undertaken if the underlying pathology does not involve the splenic vein lying in the groove on the posterior surface of the gland, taking care to control the multiple small pancreatic venous tributaries. In duodenum-preserving resection of the head of the pancreas, which is sometimes undertaken for chronic pancreatitis and benign pancreatic tumours, preservation of an adequate duodenal blood supply from the pancreaticoduodenal arterial arcades is important (Kimura and Nagai 1995). Stenosis of the coeliac trunk is common in elderly individuals with atherosclerosis. Here, the arterial blood supply to the liver is provided by the superior mesenteric artery through hypertrophied arteries of the anterior and posterior pancreaticoduodenal arcades. Care should be taken to avoid ligation of these branches during pancreatic surgery because this could cause hepatic ischaemia.

The pancreas is usually transplanted together with the kidney (a simultaneous pancreas–kidney transplant) in patients with end-stage renal disease caused by diabetes mellitus. In selected patients, the pancreas alone can be transplanted to treat poor glycaemic control and hypoglycaemia unawareness (White et al 2009).

The donor pancreas is recovered from a deceased donor, usually as part of a multi-organ recovery procedure. The entire pancreas and the duodenal C loop (attached to the head of the pancreas) and spleen (closely related to the tail of the pancreas) are recovered to prevent injury to the vascular arcades in the pancreaticoduodenal groove and minimize handling of the pancreas during organ recovery (Abu-Elmagd et al 2000). The arterial supply for the donor pancreas is based on the splenic artery and the superior mesenteric artery, both of which are carefully preserved during the donor operation and reconstructed to a Y-shaped deceased donor iliac artery graft to enable a single arterial anastomosis to be performed in the recipient. The venous drainage is through the hepatic portal vein. The donor pancreas is implanted in the pelvis and the reconstructed artery is anastomosed to the external iliac artery. The hepatic portal vein of the graft can be anastomosed to either an iliac vein or the superior mesenteric vein of the recipient: there is no evidence to support the superiority of one technique over the other (Bazerbachi et al 2012). Drainage of the exocrine pancreatic secretions is into the ileum through a duodeno-ileal anastomosis or into the recipient urinary bladder through a duodeno-cystic anastomosis. Complications of the procedure result mainly from injury sustained by the donor pancreas during the organ recovery, storage and transplantation process, and include graft pancreatitis and graft necrosis leading to bleeding, thrombosis of vascular anastomoses and sepsis (Delis et al 2004, Troppmann 2010). In most patients, pancreas transplantation provides the potential for an insulin-free life and retards the development of diabetes-related complications (Gruessner et al 2012).

CHAPTER
69

Spleen

The spleen is a large, encapsulated, complex mass of vascular and lymphoid tissues situated in the upper left quadrant of the abdominal cavity between the fundus of the stomach and the respiratory diaphragm. It is mainly concerned with phagocytosis and immune responses but is also important in immunological defence, metabolism and maintenance of circulating blood elements (Steiniger 2015, Tarantino et al 2013; **Table 69.1**). In the fetus, the spleen is a major site of haemopoiesis and can resume this role postnatally in certain pathological conditions (Üngör et al 2007). However, it is not essential for life; if the spleen is removed, many of its functions can be assumed by the liver and other tissues of the mononuclear phagocytic system.

Gross anatomy

The size and weight of the spleen vary with age and sex, and can also vary slightly in the same individual under different conditions. The adult spleen is usually 9–14 cm long, 6–8 cm wide and 3–5 cm thick. It reaches its largest dimension in puberty and diminishes in size thereafter (DeLand 1970, Sprogøe-Jakobsen and Sprogøe-Jakobsen 1997). Although its weight increases during puberty, it is comparatively largest in the young child and tends to diminish in size and weight in old age (Skandalakis et al 1993, Üngör et al 2007, Coquet et al 2010). The average weight of an adult spleen depends on the volume of blood it contains; emptied of blood it weighs between 70 and 120 g, whereas *in vivo* its weight ranges from 150 to 350 g (Nakamura et al 1989, Skandalakis et al 1993, Petroianu 2011).

TABLE 69.1 Summary of splenic functions

General functions	Specific functions
Haematological and immunological	Haemopoiesis
	Maturation of blood elements
	Immunoglobulin activation
	Recirculation of T and B lymphocytes
Production	Leukocytes
	Peptides
	Immunoglobulins (mainly IgM)
	Opsonins
	Tuftsin
	Properdin
	Complement factors
	Stem cells
Storage	Leukocytes, e.g. monocytes, B and T lymphocytes
	Platelets
	All metals
Clearance	Microorganisms
	Parasites
	Circulating antigens
	Altered circulating cells
	Circulating foreign bodies
Synthesis	Precursor of hepatic functions
Metabolism	Lipids
	Cholesterol
	Bilirubin
	Amino acids
Control	Bone marrow
	Mononuclear phagocytic function
	Somatic growth

The shape of the spleen is also variable: it is mostly determined by its relations to neighbouring structures during development and often appears as a slightly curved wedge. The superolateral aspect is covered by the respiratory diaphragm and the inferomedial aspect mostly by the neighbouring stomach, left kidney and left colic flexure. In the fetus, the spleen is lobulated (Ch. 21); the adult spleen usually retains a notch(es) on its superior border, although additional surface notches can persist (Mikhail et al 1979). In a study of 113 post mortem, i.e. unfixed, specimens, Parsons (1901) observed 1–7 splenic notches in over 90% of specimens; two notches were the most common finding and the majority were located on the superior border of the spleen.

A splenic lobule that fails to coalesce with the developing spleen can persist as an accessory (supernumerary) spleen. This fully functional island of splenic tissue is found in approximately 14% of individuals and may be located in any part of the abdomen, or even outside it, but is most commonly present near the splenic hilum within the gastrosplenic ligament or greater omentum (Faller 1985, Vikse et al 2017; **Fig. 69.1**). Other anatomical variations of the spleen include asplenia, hyposplenia, and splenogonadal and splenopancreatic fusions.

A normal adult spleen is not palpable on abdominal examination and has to triple in size before it becomes palpable below the left costal arch (Mikhail et al 1979). In supine healthy adults it is most frequently located between the tenth and twelfth ribs, with its long axis along the eleventh rib (Gupta et al 1976, Mirjalili et al 2012).

Relations

The spleen has superolateral diaphragmatic and inferomedial visceral surfaces (**Fig. 69.2**), superior and inferior borders, and anterior and posterior extremities. The convex, smooth diaphragmatic surface faces mostly superiorly and laterally. The diaphragmatic surface is separated from the left costodiaphragmatic recess, lower lobe of the left lung and the left tenth to twelfth ribs by the underside of the respiratory diaphragm (**Figs 69.3–69.4**).

The visceral surface is irregular, faces inferomedially towards the abdominal cavity and is marked by gastric, renal and colic impressions. A pancreatic impression is sometimes present. Michels (1942) found that the tail of the pancreas contacts the spleen in approximately one-third of individuals. The gastric impression faces anteromedially and is broad and concave where the spleen lies adjacent to the posterior aspect of the fundus, upper body and upper greater curvature of the stomach. It is separated from the stomach by a peritoneal recess, limited by the gastrosplenic ligament. The renal impression is slightly concave and lies on the posteroinferior part of the visceral surface, separated from the gastric impression above by a ridge of splenic tissue and the splenic hilum. It faces inferomedially and slightly backwards and is related to the upper lateral area of the anterior surface of the left kidney and sometimes to the superior border of the left suprarenal gland. The colic impression is usually flat; it lies at the anterior extremity of the spleen and is related to the left colic flexure and the phrenicocolic ligament. The splenic hilum is a long fissure pierced by the splenic vessels, nerves and lymphatics, and lies on the visceral surface closer to the inferior border.

The superior border separates the diaphragmatic surface from the gastric impression and is usually convex. The inferior border separates the renal impression from the diaphragmatic surface and is more rounded and blunt than the superior border. The posterior extremity usually faces the vertebral column. The anterior extremity is longer and less angulated than the posterior extremity and connects the superior and inferior borders anteriorly; it is related to the colic impression and often lies adjacent to the left colic flexure and phrenicocolic ligament.

The anterior extremity of the spleen is particularly at risk of injury from blunt abdominal trauma or during surgical procedures on the stomach, tail of the pancreas, left kidney, left suprarenal gland and

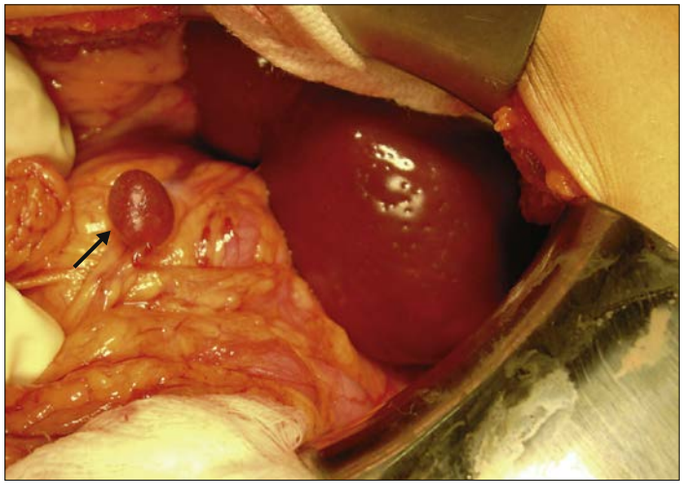

Fig. 69.1 A supernumerary spleen located in the greater omentum (arrow). Supernumerary spleens are usually isolated and may be connected to the spleen or splenic pedicle by thin vessels.

The most common clinical manifestations of splenic disorders are splenomegaly and a decrease in the number of cellular elements in the blood (cytopenias). The most serious long-term consequence of removal of the spleen is severe sepsis. One study of children who underwent splenectomy found that 7% were hospitalized for sepsis and 38% of these occurred within the first year following the procedure (Madenci et al 2018).

Spleens in men are proportionally heavier than those in women. In pathological conditions, the spleen may expand and retain blood; weights rarely exceed 700 g, but gigantic spleens exceeding 10 kg have been reported (DeLand 1970, Skandalakis et al 1993, Sprogøe-Jakobsen and Sprogøe-Jakobsen 1997). Splenomegaly compresses and displaces adjacent organs, causing abdominal discomfort, dyspepsia, respiratory restriction and difficulty walking (Coetzee 1982, Petroianu 2011).

colon. Excessive traction of the stomach, transverse colon or greater omentum can tear the splenic fibrous capsule and superficial parenchyma by way of their peritoneal attachments, causing bleeding that can be difficult to control (Merchea et al 2012).

Splenic ligaments

The spleen develops between the two leaves of the dorsal mesogastrium (see Figs 21.6–21.7) and so it is almost entirely invested in visceral peritoneum that is firmly adherent to its fibrous capsule (Üngör et al 2007). The dorsal mesogastric attachments persist as peritoneal ligaments. The superior part of the splenic hilum is connected to the stomach via the gastrosplenic ligament, and to the posterior abdominal wall by a variably developed phrenicosplenic ligament. A presplenic fold connecting the spleen to the stomach is sometimes seen anterior to the gastrosplenic ligament and may contain the left gastro-omental (gastro-epiploic) vessels (Skandalakis et al 2004). The inferior part of the splenic hilum is further connected to the posterior abdominal wall by the splenorenal ligament and to the left colic flexure by the splenocolic ligament. A spleno-omental fold may connect the spleen to the greater omentum: this is known as the 'criminal' fold of Morgenstern because careless surgical traction on it can traumatize the spleen (Skandalakis et al 2004). Each of these ligaments is made up of two layers of peritoneum containing fat, blood and lymphatic vessels and nerves. The phrenicosplenic ligament runs between the spleen and the peritoneum covering the undersurface of the respiratory diaphragm. The anterior layer of the splenorenal ligament is continuous with the

peritoneum of the posterior wall of the omental bursa over the left kidney, and with the posterior layer of the gastrosplenic ligament at the splenic hilum. The posterior layer of the splenorenal ligament is continuous with the peritoneum over the inferior surface of the respiratory diaphragm and anterior surface of the left kidney. The terminal portions of the splenic artery and vein, and, more inferiorly, the tail of the pancreas, lie between the two peritoneal layers of the splenorenal ligament. The tail of the pancreas can be injured during dissection when ligating and dividing the splenic vessels, resulting in bleeding, local pancreatitis and pancreatic fistula formation (Skandalakis et al 1993).

The gastrosplenic ligament is continuous with the fibrous capsule of the spleen, the serosa of the stomach and the greater omentum. It contains the short gastric artery and its branches and the left gastroomental artery, all of which arise from the splenic artery, together with their corresponding veins. During splenectomy or mobilization of the fundus of the stomach, the short gastric vessels must not be ligated too close to the stomach because there is a risk of local gastric necrosis, perforation and their consequences.

The phrenicocolic ligament connects the left colic flexure to the respiratory diaphragm and runs inferior and lateral to the anterior extremity of the spleen (see Fig. 69.4). It is continuous with the peritoneum of the left lateral end of the transverse mesocolon at the end of the tail of pancreas, and the splenorenal ligament at the splenic hilum (Merchea et al 2012, Skandalakis et al 1993). When the phrenicocolic ligament is being divided, particularly when electrocautery is used, the colon is at risk of injury.

Mobile spleen

Vascular supply and lymphatic drainage

Arteries

The spleen is supplied by the splenic artery, one of the most tortuous arteries in the body (**Fig. 69.5**, see Figs 63.10, 63.14B, 69.6). The reason for the tortuosity, which can become more pronounced with advancing age, is not understood, although there have been several proposals (Cortés and Pellico 1988, García-Porrero and Lemes 1988, Borley et al 1995, Sylvester et al 1995, Liu et al 1996, Pandey et al 2004). The splenic artery almost always arises from the coeliac trunk, in common with the left gastric and common hepatic arteries. However, it can originate from the common hepatic artery or the left gastric artery, or, rarely, directly from the abdominal aorta either in isolation or as a splenomesenteric trunk (Tubbs et al 2016).

From its origin, the artery runs a little way inferiorly before turning to the left behind the stomach to run horizontally posterior to the superior border of the body and tail of the pancreas. Multiple loops or even coils of the artery appear above the superior border of the pancreas (McFee et al 1995, Pandey et al 2004). The splenic artery courses anterior to the left kidney and left suprarenal gland and runs in the splenorenal ligament behind or above the tail of the pancreas. In its course it gives off numerous branches to the pancreas (dorsal pancreatic, great pancreatic artery, and artery to the tail of the pancreas) and, near its termination, it gives off the short gastric arteries and the left gastroomental artery (Skandalakis et al 1993). Additional variant branches include a posterior gastric artery and small retroperitoneal branches.

The splenic artery is 8–32 cm long and its calibre usually exceeds that of the common hepatic and left gastric arteries, ranging from 3 to 12 mm. Splenic arterial blood flow is approximately 3 ml/sec/100 g, corresponding to approximately 7% of cardiac output (Trubel et al 1985, Cortés and Pellico 1988, García-Porrero and Lemes 1988, Nakamura et al 1989, Skandalakis et al 1993, Pandey et al 2004).

The splenic artery usually divides into two, or occasionally three, branches before entering the splenic hilum. The superior and inferior branches are sometimes known as superior and inferior polar arteries; as they enter the hilum they divide into four or five segmental arteries, each of which supplies a segment of splenic tissue. There is relatively little arterial collateral circulation between segments, which means that occlusion of a segmental vessel often leads to infarction of part of the spleen. Segmental arteries divide within the splenic trabeculae, becoming trabecular arteries. These leave the trabeculae and give rise to central arterioles that are surrounded by thick lymphoid sheaths of white pulp. Central arterioles ramify into several penicillar arterioles that feed the sinusoids of the red pulp. There is considerable communication among arterioles (Mikhail et al 1979, García-Porrero and Lemes 1988, Trubel et al 1988, Sow et al 1991, Liu et al 1996).

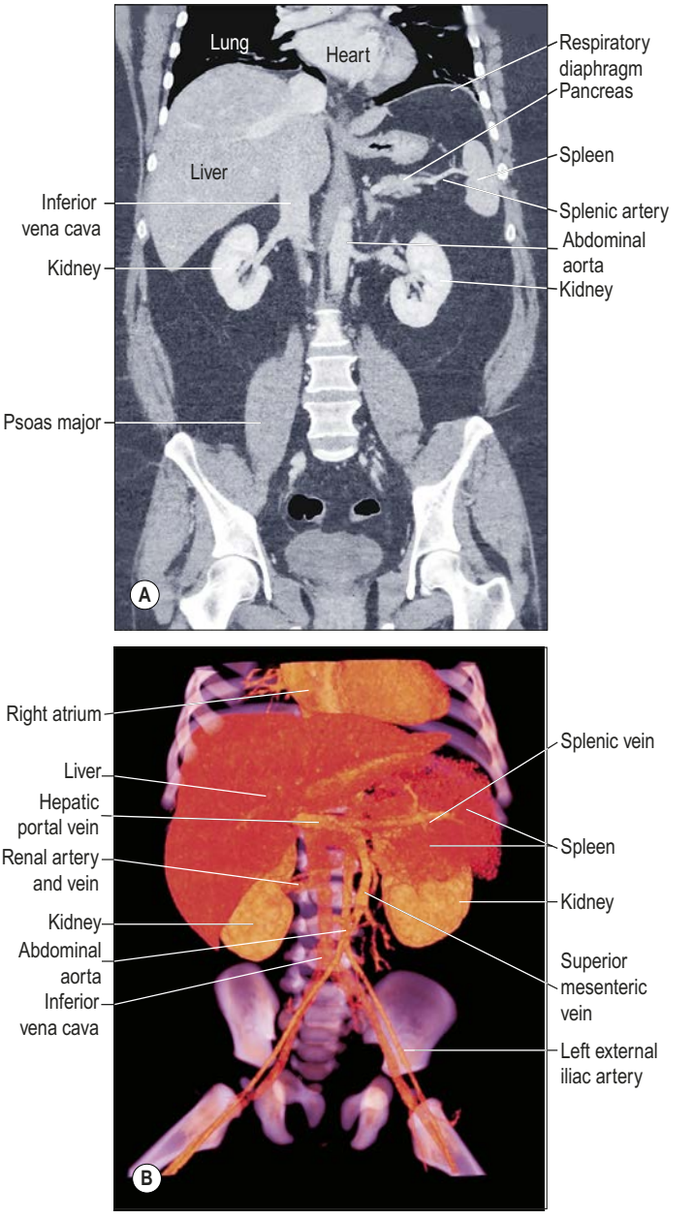

Fig. 69.5 **A**, Coronal MRI of an adult female: note the spleen and splenic artery. **B**, Volume-rendered abdominal angiogram from a paediatric patient showing the spleen and splenic vein. Note the unfused segments of the sacrum and juvenile forms of the hip and parts of the pelvic girdle. (Courtesy of Jon C Betts Jr, Children's of Alabama, Birmingham, AL, USA.)

The short gastric arteries in the gastrosplenic ligament provide an additional arterial supply to the posterior extremity of the spleen that is distinct from the splenic hilar vessels. These short gastric vessels connect the posterior extremity of the spleen to the fundus of the stomach and preserve the viability of this region of the spleen after surgical ligation of the splenic pedicle (Skandalakis et al 1993).

Veins

Blood from the spleen is collected by trabecular veins that join to form the segmental veins draining individual splenic segments. In general, there are no anastomoses between intrasegmental venous tributaries. The segmental veins join to form two (superior and inferior) or three (superior, middle and inferior) 'lobar' veins that emerge from the length of the splenic hilum and unite to form the splenic vein within the splenorenal ligament (see Fig. 69.2). Communicating veins may interconnect lobar veins (Par et al 1965, DeLand 1970, Gupta et al 1980, Sow et al 1991, Liu et al 1996).

The splenic vein most commonly runs posterior to the splenic artery and tail and body of the pancreas (Skandalakis et al 2004) (see Figs 68.4D–G, 69.5, 69.6) (Par et al 1965, Gürleyik et al 2000). It crosses the posterior abdominal wall anterior to the left kidney and abdominal aorta, separated from the left sympathetic trunk and left crus of the respiratory diaphragm by the left renal vessels, and from the abdominal aorta by the

Operating on a normal-sized spleen is a relatively straightforward procedure for most surgeons. Mobilization of the spleen requires division of the phrenicocolic, gastrosplenic and phrenicosplenic ligaments. Undue traction on the phrenicocolic ligament during mobilization of the left colic flexure can tear the splenic fibrous capsule, causing bleeding: this is less likely if the phrenicocolic ligament is retracted laterally rather than inferiorly and medially (Merchea et al 2012). The diaphragmatic surface of the spleen is occasionally adherent to the peritoneum on the undersurface of the respiratory diaphragm: adhesions can be a consequence of inflammation of the spleen or may be congenital (Skandalakis et al 1993, Petroianu 2011).

The peritoneal ligaments associated with the spleen vary in length; longer ligaments, especially the splenorenal ligament, afford the spleen greater mobility, and can stretch its vascular pedicle. While this facilitates surgical mobilization, it can render the spleen more susceptible to injury from shear forces during trauma.

A floating or wandering spleen is characterized by excessive mobility and migration of the spleen outside the left hypochondriac region. In such cases, the spleen can undergo torsion or cause urinary bladder or rectal symptoms from local pressure; imaging usually confirms the diagnosis. If surgical treatment is necessary, the spleen is freed from local adhesions and returned to the left hypochondriac region, the surgeon shortening and suturing its ligaments to the respiratory diaphragm (McFee et al 1995, Petroianu 2011).

superior mesenteric artery and left renal vein (Par et al 1965, Gupta et al 1976, Gupta et al 1980, Liu et al 1996). It ends posterior to the neck of the pancreas, where it joins the superior mesenteric vein to form the hepatic portal vein. Along its course it receives the short gastric veins, left gastro-omental veins, pancreatic veins, posterior gastric vein, left gastric vein and inferior mesenteric veins (the latter two do so in approximately 30% of individuals (Gerber et al 1951)). Anastomoses between the splenic vein and left renal vein have been reported, particularly in cases of portal hypertension (Bowdler 2002). Approximately 60% of hepatic portal vein blood flow is derived from the gut and the remainder from the spleen and pancreas (Par et al 1965, Gupta et al 1980, Dawson et al 1986, Oguro et al 1993, Liu et al 1996, Gürleyik et al 2000). Obstruction of the hepatic portal or splenic veins can lead to reversed venous flow through the splenic vein and its tributaries, resulting in splenomegaly and widespread varices (Re et al 1985, Skandalakis et al 1993, Petroianu 2011).

Lymphatic drainage

The lymphatic drainage of the spleen begins with the peri-arteriolar lymphoid sheaths (PALS) in the white pulp. The lymphatic vessels run toward the splenic hilum along trabecular arteries in the trabeculae, and then flow into the lymph nodes at the hilum. The lymphatic vessels from the subcapsular plexus also flow to the lymph nodes at the splenic hilum (**Fig. 69.6**). From there lymph drains to superior pancreatic, inferior pancreatic and pancreaticoduodenal nodes, and from there to coeliac nodes and the cisterna chyli (Bowdler 2002). There are no lymphatic vessels in the red pulp.

In malignant neoplasms of the greater curvature of the stomach, pancreas or distal transverse colon, it may be necessary to remove the spleen and tail of the pancreas to achieve a radical resection. In leukaemias and lymphomas, lymphadenopathy of splenic nodes and splenomegaly may be found during staging investigations (Petroianu 2011).

Innervation

The spleen is innervated by both components of the autonomic nervous system; the sympathetic supply is dominant. Postganglionic sympathetic nerves from the coeliac plexus travel with the splenic vessels. They innervate arteries at least to the trabecular level and have the potential to influence blood flow within the human spleen (Kudoh et al 1979). Parasympathetic nerves from the posterior vagal trunk may travel with the splenic vessels to the spleen, but this innervation has been questioned (Skandalakis et al 2004, Martelli et al 2014, Jung et al 2017). In contrast to some animals, the motor innervation of the human splenic fibrous capsule is largely vestigial: the fibrous capsule contains minimal quantities of smooth muscle and therefore does not contract. However, the fibrous capsule and parenchyma are innervated by sensory fibres that convey pain. Mild to moderate splenomegaly is often painless but splenic inflammation from infection, infarction,

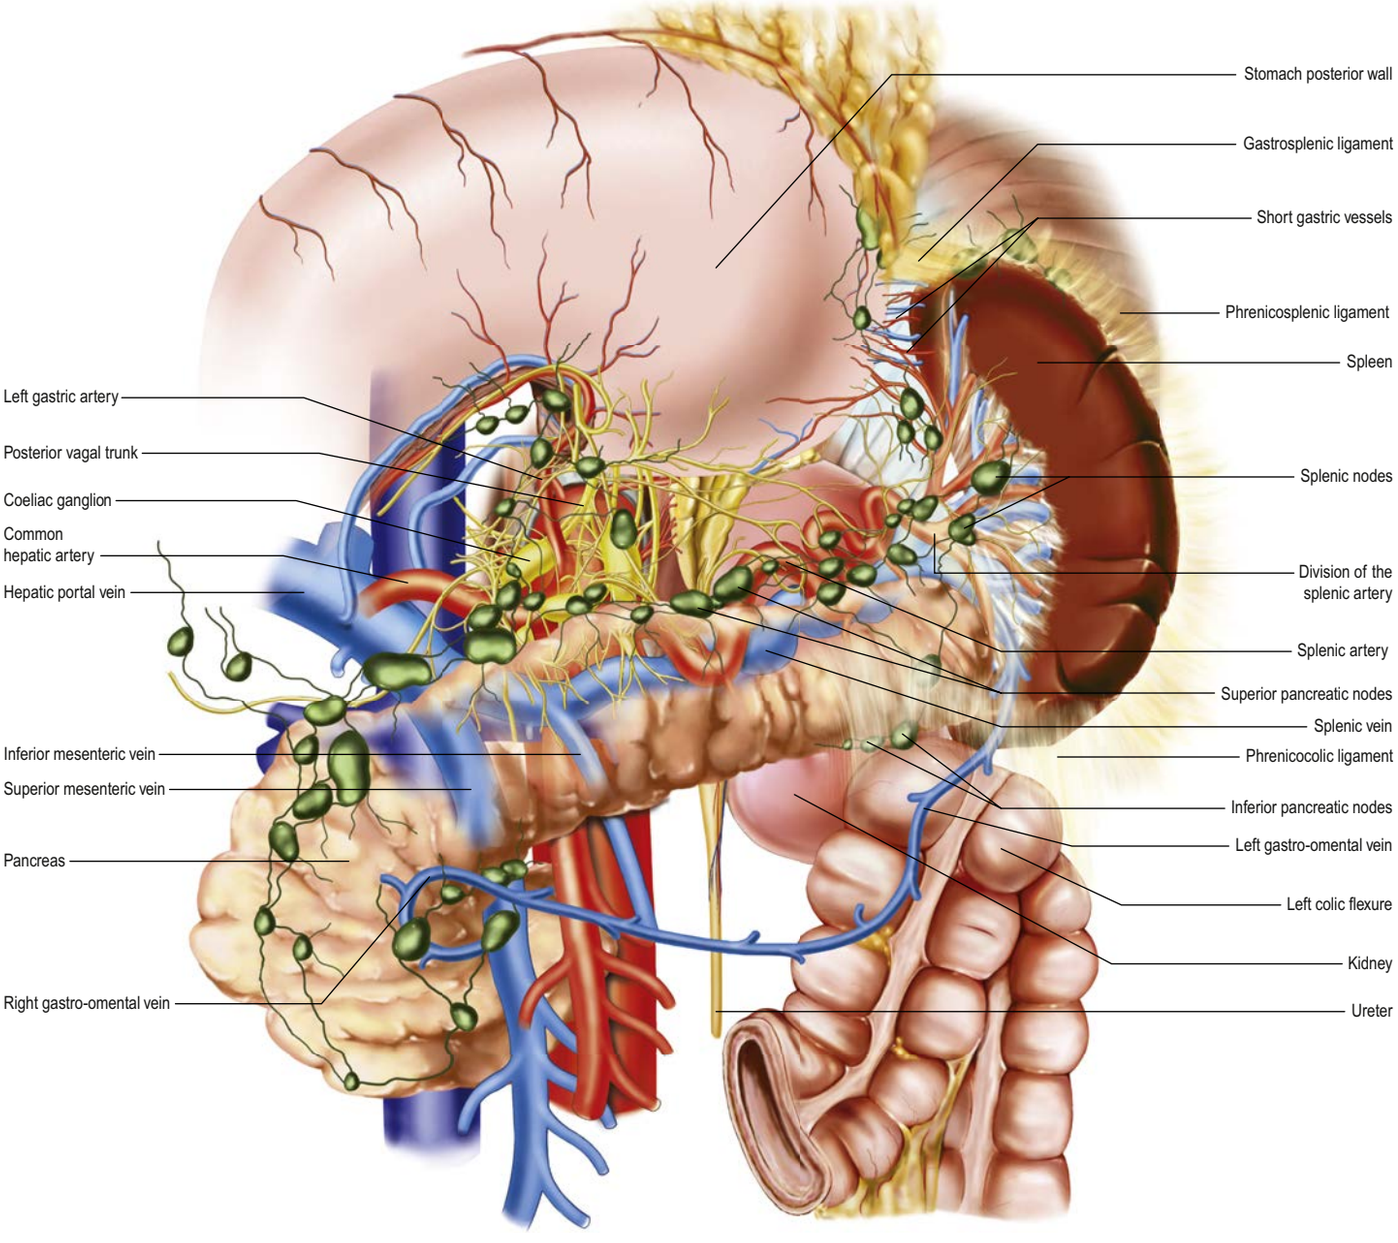

Fig. 69.6 The lymph nodes related to the spleen. The pancreas has been rendered partially transparent to visualise the major blood vessels lying posteriorly. The greater curvature of the stomach has been reflected superiorly to expose its posterior surface and the posterior wall of the omental bursa has been removed. (Courtesy of Dr Andy Petroianu and Dr Iriam Starling.)

sickle cell disease, splenic artery embolization or abrupt distension of the fibrous capsule (e.g. haematoma) can cause severe pain, intensified by inflammation of the overlying parietal peritoneum. Referred pain from the splenic parenchyma is poorly localized to the epigastric region.

Microstructure

The spleen contains the largest single mass of lymphoid tissue in the body in direct continuity with the circulation. Splenic parenchyma is divided into two principal regions, white pulp and red pulp, named according to the appearance of the cut surface of a fresh spleen (**Fig. 69.7**). The microstructure of the spleen has been studied in many animals, most extensively in rats, mice and humans. However, species-specific differences have caused some terminological confusion when describing what are probably functionally equivalent zones: for example, the human spleen does not appear to contain large marginal or perimarginal sinuses or ellipsoids (although macrophage-sheathed capillaries may be equivalent to ellipsoids), and the so-called marginal zones (a B-cell compartment between red and white pulps) are arranged differently in rodent and human spleens. In humans, white pulp contains accumulations of T and B lymphocytes in periarteriolar lymphatic sheaths (PALS) and lymphatic follicles. Red pulp is a loose connective tissue containing many different types of blood cell, arterioles and macrophage sheathed capillaries, the latter consisting mainly of endothelial cells, pericytes, $CD271^+$ stromal capillary sheath cells of varying phenotype (CD271 is the low affinity nerve growth factor receptor p75), $CD68^+CD163^-$ macrophages and recirculating B lymphocytes (Steiniger 2015).

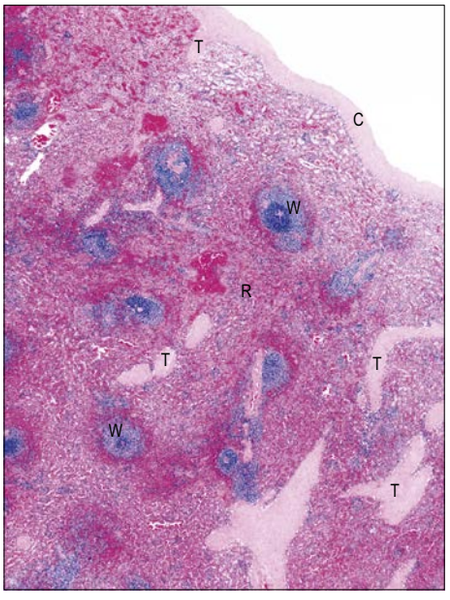

Fig. 69.7 A section through the spleen. White pulp (W) is present as ovoid areas of basophilic tissue. Red pulp (R) lies between white pulp tissue and consists of splenic sinusoids and intervening cellular cords. Part of the fibrous capsule (C) is seen top right, from which trabeculae (T) extend into the splenic tissue. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Fibrous framework

The serosa of the peritoneum covers the entire spleen, except at its hilum and where the peritoneal ligaments are attached. The connective tissue fibrous capsule, deep to the serosa, is approximately 1.5 mm thick and contains abundant type I collagen fibres and some elastin fibres. It consists of an outer and inner lamina in which the directions of the collagen fibres differ, so increasing its strength. Numerous trabeculae extend from the fibrous capsule into the substance of the spleen, where they branch to form a connective tissue scaffold (Faller 1985, Scothorne 1985). The largest trabeculae enter at the splenic hilum and divide into branches in the splenic pulp, providing conduits for the splenic vessels and nerves (see Fig. 69.9). Within the spleen, these branches become continuous with a delicate network of type III (reticular) collagen fibres that pervades both the red and white pulps and is maintained by fibroblasts within its interstices (Gupta et al 1976, Scothorne 1985, Krieken and Velde 1988).

White pulp

The white pulp in an adult human spleen accounts for up to 20% of the total splenic volume. Spherical lymphoid follicles form the major compartment. Branches of the splenic artery radiate out into the parenchyma from the splenic hilum, ramifying within the trabeculae. In their terminal few millimetres, their connective tissue adventitia is replaced by a sheath of T lymphocytes, the peri-arteriolar lymphoid sheath (PALS) (**Figs 69.8–69.9**). This is expanded in places by aggregations of B lymphocytes, lymphoid follicles measuring 0.25–1 mm in diameter and visible to the naked eye on the freshly cut surface of the spleen as white semi-opaque dots, in contrast to the surrounding deep reddish purple of the red pulp. Follicles are usually situated near the terminal branches of arterioles and typically protrude to one side of a vessel, which consequently appears to be eccentrically placed within the follicle. Arterioles branch laterally within follicles to form a series of parallel terminal arterioles, the penicillar (follicular) arterioles (Scothorne 1985, Krieken and Velde 1988; see Fig. 69.9).

Follicles are centres of lymphocyte aggregation and proliferation. After antigenic stimulation they become sites of intensive B cell proliferation, developing germinal centres similar to those found in lymph nodes; antigen presentation by follicular dendritic cells is involved in this process. Germinal centres regress when the stimulus abates. Follicles tend to atrophy with advancing age and may be absent in the very elderly (Scothorne 1985, Krieken and Velde 1988).

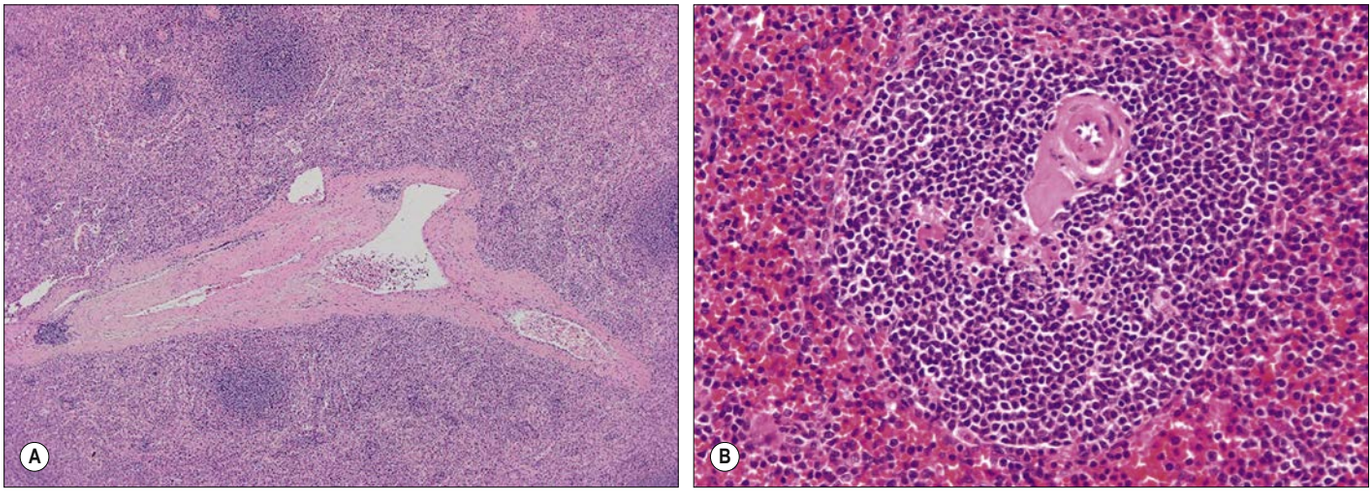

Fig. 69.8 A, Human spleen, showing a connective tissue trabeculum (centre field) enclosing several profiles of splenic arterioles and venules, surrounded by red pulp. Embedded in the red pulp are several white pulp follicles, seen as islands of basophilic tissue. **B**, High-power view of spleen, showing a white pulp follicle (centre) with an eccentrically placed follicular arteriole surrounded by a peri-arteriolar lymphoid sheath. Red pulp lies around the follicle. (Courtesy of Mr Peter Helliwell, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

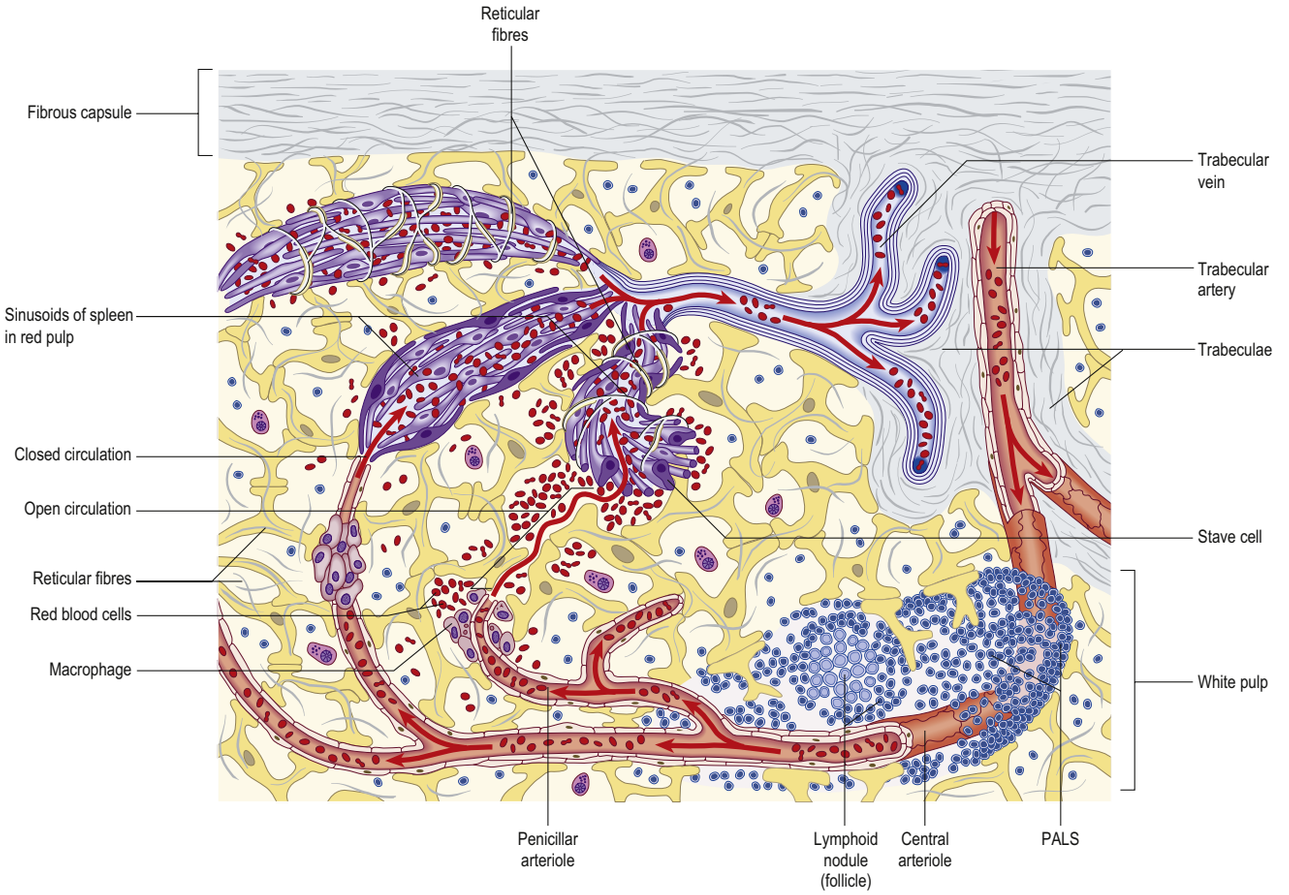

Fig. 69.9 The main features of splenic structure, not to scale. The fibrous capsule, trabeculae, reticular fibres and cells, the peri-arteriolar lymphoid sheaths and follicles (white pulp), and the cellular cords and venous sinusoids of the red pulp are shown. The 'open' and 'closed' theories of splenic circulation are illustrated: it is likely that most of the circulation is of the open form. The venous sinusoids are lined by specialized endothelial 'stave' cells; the intercellular gaps of these have been over-emphasized for clarity.

Red pulp

The red pulp constitutes approximately 75% of the total splenic volume and is a unique filtration device that enables the spleen to clear particulate material from the blood as it perfuses the organ (Scothorne 1985, Krieken and Velde 1988, Mishra 2016; see Fig. 69.7). It contains large numbers of venous sinusoids that ultimately drain into tributaries of the splenic vein. The sinusoids are separated from each other by a fibrocellular network of small bundles of collagen fibres, the reticulum, numerous reticular fibroblasts and splenic macrophages. Seen in two dimensions, these intersinusoidal regions appear as strips of tissue, the splenic cords (cords of Billroth; pulpar strands) (see Fig. 69.9), whereas in reality they form a three-dimensional continuum around the venous spaces (Chen 1978, Weiss 1983, Scothorne 1985, Krieken and Velde 1988).

Venous sinusoids are elongated ovoid vessels, approximately 50 µm in diameter, supported externally by circumferential and longitudinal reticular fibres and lined by a characteristic, discontinuous endothelium that is unique to the spleen. The long, narrow endothelial cells are aligned with the long axes of the sinusoids; previously called stave cells because of their resemblance to the planks in a barrel, they are now often called rod- or rib-shaped cells (see Fig. 69.9). These cells are attached to their neighbours at intervals along their length by short stretches of intercellular junctions that alternate with intercellular slits that allow blood cells to squeeze into the lumen of the sinusoid from the surrounding splenic cords (Pivkin et al 2016). A discontinuous basal lamina is present on the abluminal aspect of the sinus.

Large, stellate fibroblasts, reticular cells, lie around the sinusoids. They synthesize the matrix components of the reticulum, including collagen and proteoglycans, and their cytoplasmic processes help to compartmentalize the reticular space. Blood from the open ends of the capillaries that originate from penicillar arterioles percolates through the reticular spaces within the splenic cords. Macrophages in the reticular spaces remove blood-borne particulate material, including ageing and damaged erythrocytes. If the number of damaged erythrocytes increases, the reticular cells proliferate and the red pulp expands, causing the spleen to enlarge (Kudoh et al 1979, Scothorne 1985).

Perifollicular zone

The perifollicular zone lies between the follicular marginal zone and the red pulp: it is the site where blood is delivered into the red pulp and where many lymphocytes leave the circulation to migrate to their respective T and B lymphocyte aggregations in the white pulp (Steiniger et al 2001). These lymphocytes are more loosely arranged than they are in the white pulp, and are held in a dense network of reticular fibres and cells.

Splenic microcirculation

Segmental splenic arteries ramify in the trabeculae as trabecular arteries which taper to become central arterioles that pass through the white pulp and give off penicillar arterioles. These leave the white pulp and traverse the perifollicular zone to enter the red pulp, where the capillaries and sinuses at the end of the arterial tree and the beginning of the venous part of the circulation, respectively, are not connected so that blood flows in spaces delimited by fibroblasts rather than endothelial cells (Gupta et al 1976, Scothorne 1985, García-Porrero and Lemes 1988, Steiniger 2015, Steiniger et al 2018). Evidence supports a predominantly 'open' splenic circulation in humans, in which blood empties into and percolates slowly through the reticular tissue of the splenic cords before re-entering the vascular lumen through slits in the walls of the venous sinusoids (Chen 1978, Cavalli et al 1982, Pivkin et al 2016). From the venous sinusoids, blood collects in venules that unite to form small veins that run within the trabeculae and drain into segmental splenic veins (Chen 1978, Cavalli et al 1982, Scothorne 1985, Petroianu 2011).

Whether there is an alternative, 'closed' route in which blood enters the venous sinusoids directly from arterioles and capillaries in the perifollicular zone is unclear: it has been suggested that there is a totally open circulation system in the human spleen (Steiniger et al 2015). Either way, the blood is exposed to macrophages and the filtering mechanism of the spleen responsible for removing abnormal and effete cells, blood cell particles, bacteria, parasites and foreign antigens.

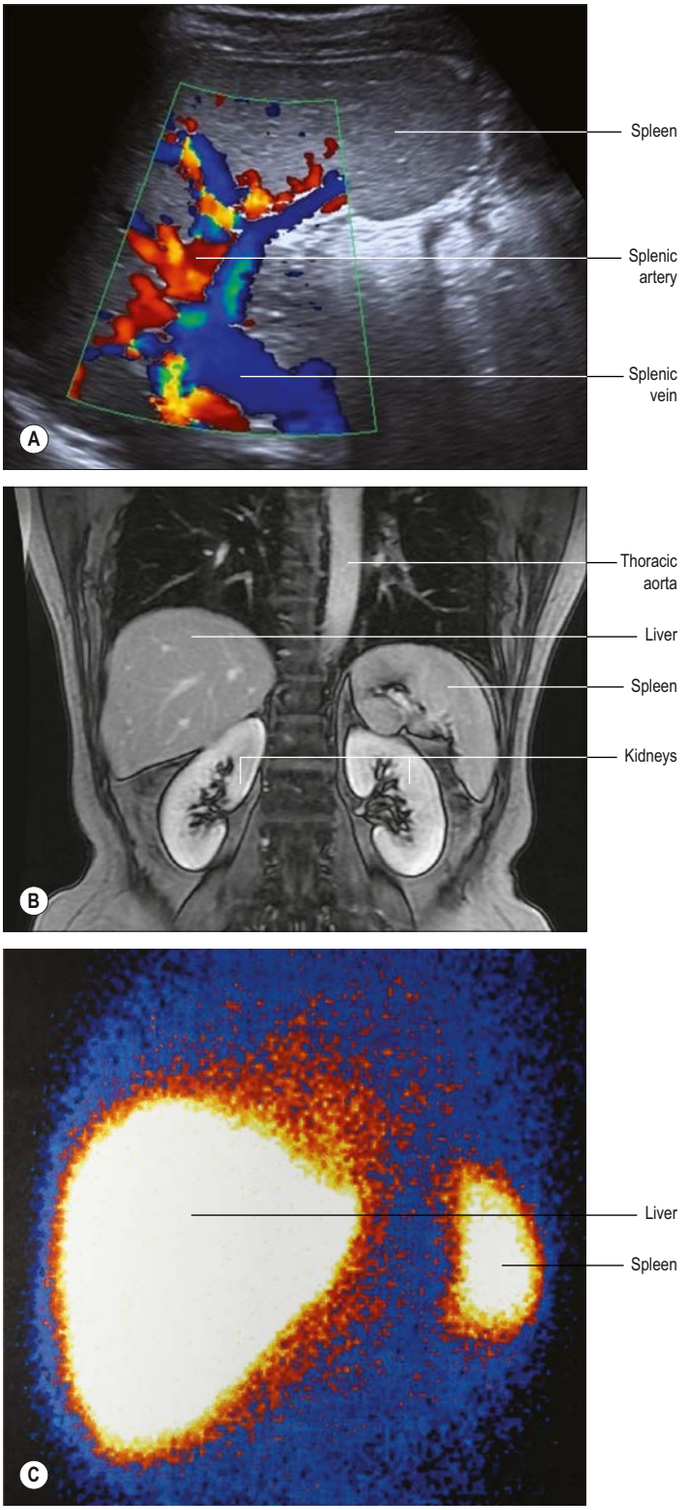

Fig. 69.10 Splenic imaging. **A**, Ultrasound with colour Doppler. **B**, Magnetic resonance image. **C**, A radioisotope scan (^{99m}Tc sulphur colloid).

Imaging

Imaging modalities used to observe the spleen include ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), arteriography, splenoportography and scintigraphy (Buntain et al 1988, Nakamura et al 1989, Merran et al 2007, Xu et al 2009, Omar and Freeman 2016) (**Fig. 69.10**, see Fig. 69.5). Cross-sectional imaging is particularly useful for assessing tumours and infiltrations of the spleen. Percutaneous drainage of splenic and perisplenic fluid collections is routinely performed under image guidance, and percutaneous splenic biopsy is being increasingly used in diagnosis. Arteriography is essential for selective embolization and the insertion of an arterial stent to treat splenic artery aneurysms. Scintigraphy can be used to investigate splenic phagocytic function by quantifying the uptake of radioactive labelled agents (e.g. ^{99m}Technetium sulphur colloid or heat-damaged erythrocytes) (Hermann and Winkel 1977, Merran et al 2007, Xu et al 2009, Petroianu 2011).

The numerous causes of splenomegaly can be classified broadly into haematological (e.g. lymphoproliferative, myeloproliferative, erythrocyte disorders); vascular (e.g. portal hypertension); infectious (e.g. viral, bacterial, other); autoimmune; and infiltrative (e.g. storage disorders and tumours) (Cavalli et al 1982, Re et al 1985, Petroianu 1988, 2011; **Fig. 69.11**).

The spleen is one of the most frequently injured organs during blunt abdominal trauma (**Fig. 69.12**). It is particularly prone to injury during rapid deceleration or compression, and its peritoneal ligaments render it vulnerable to shearing injuries of the parenchyma and splenic vessels. Irritation of the respiratory diaphragm from splenic haemorrhage with resultant referred left shoulder pain is known as Kehr's sign. Fractures of the lower left ribs can be associated with blunt injuries and can lacerate the spleen (Buntain et al 1988). Traction on peritoneal ligaments or adhesions can lead to inadvertent tears of the splenic capsule during surgical procedures such as mobilization of the left colic flexure.

Contrast-enhanced CT imaging is particularly useful for assessing splenic trauma. Most splenic injuries from blunt abdominal trauma are successfully treated by conservative management. Extensive burst injuries with persistent bleeding or major injuries to the hilar vessels may require splenectomy but various repair techniques are available. With hilar injuries, a subtotal splenectomy, preserving the short gastric vessels and posterior extremity only, is one option. Minor intraoperative capsular tears can be controlled by the application of topical haemostatic agents and sutures, although direct suture repair is challenging because the splenic pulp is fragile. Arteriography and embolization are additional techniques that can be used to control bleeding or treat vascular lesions (Petroianu 2011).

Most surgical procedures performed on the spleen should start with ligation of the splenic artery at the superior border of the tail of the pancreas. This can be difficult in patients with portal hypertension, splenic artery aneurysm, retroperitoneal fibrosis, regional lymphadenopathy or inflammatory conditions. After splenic artery ligation, the spleen becomes softer because most of its contained blood returns to the circulation. Despite the interruption of splenic artery inflow, the posterior extremity of the spleen continues to be perfused by the short gastric arteries, and the anterior extremity may be supplied retrogradely via the left gastro-omental artery. Ligation and division of the splenic vein should be the last step before removal of the spleen to maximize autotransfusion of blood from the spleen (Petroianu et al 1989, Sow et al 1991, Skandalakis et al 1993, Petroianu and Petroianu 1994, Liu et al 1996, Petroianu 2011).

In partial or subtotal splenectomy, the vessels that supply the part of the spleen to be removed are ligated and divided close to the organ. The devascularized region turns dark blue, demarcating it from the residual viable splenic tissue; the organ is then divided in this plane (Sow et al 1991, Petroianu and Petroianu 1994, Liu et al 1996, Christo and DiDio 1997, Gürleyik et al 2000). Wedge excision leaves two flaps of splenic fibrous capsule that can be sutured or stapled to cover the remaining raw parenchyma, after suture of any visible bleeding vessels (Petroianu 1988, 1993, 2011; **Fig. 69.12B**).

If total splenectomy is required to treat splenic trauma, autotransplantation of splenic tissue into the greater omentum or mesentery of the intestines can preserve useful splenic function. Approximately 20% of the original splenic mass needs to be transplanted and venous drainage of this tissue must be to the hepatic portal venous system to maintain the metabolic and immunological functions of the splenic tissue (Oguro et al 1993, Petroianu 2011).

Total splenectomy has numerous potential consequences. Intraoperatively, bleeding or injury to the pancreas, stomach or colon can occur, while early postoperative complications include left-sided basal pulmonary atelectasis and pleural effusion; abscess in the subphrenic space; transient leukocytosis and thrombocytosis with the risk of thrombotic complications. As mentioned earlier, there is an increased risk of infection (especially from encapsulated bacteria), which can be fatal (Petroianu 2011).

Conservative management of splenic trauma and partial splenectomy now enables splenic function to be preserved in situations where splenectomy would once have been routinely performed. Furthermore, most surgical procedures on the spleen can now be performed laparoscopically, which readily affords inspection of the spleen from multiple perspectives (Sow et al 1991, Poulin and Thibaut 1993).

CHAPTER 70

Suprarenal gland

The suprarenal (adrenal) glands lie immediately superior and slightly anterior to the superior pole of each kidney (see Figs 72.5, 61.8). The glands are golden yellow in colour and are enclosed within the renal fascia, where they are separated from the kidneys by a small amount of loose connective tissue. Each gland possesses two functionally and structurally distinct areas: an outer cortex and an inner medulla derived from mesoderm and neural crest cells, respectively.

Macroscopically, the glands are slightly different in external appearance (**Fig. 70.1**). The right suprarenal gland is pyramidal in shape and has two well-developed lower projections (limbs), giving a cross-sectional appearance similar to a three-pointed star. The left is more semilunar in shape, flattened in the anteroposterior plane, and marginally larger than the right. The bulk of the right suprarenal gland sits on the superior pole of the right kidney and the bulk of the left suprarenal gland lies on the anteromedial aspect of the superior pole of the left kidney.

The dimensions of the suprarenal glands in adults have been measured *in vivo* from axial computed tomography (CT) (Vincent et al 1994). The mean maximum width of the suprarenal gland is approximately 50 mm, and the mean width of each limb of the gland (medial and lateral) is approximately 30-40 mm (Carsin-Vu et al 2016). No individual limb should measure more than 5 mm in transverse section. In adults, each suprarenal gland weighs approximately 5 g (the medulla contributes about one-tenth of the total weight) and has a volume of approximately 3–6 cm^3 (Wang et al 2013).

At birth, the suprarenal glands are proportionately larger and are approximately one-third the size of the ipsilateral kidney. The cortex of each gland is expanded by a well-developed inner 'fetal zone', responsible for producing dehydroepiandrosterone (DHEA), the substrate for placental oestrogen in the fetus. The suprarenal cortex, specifically the fetal zone, shrinks immediately after birth and the medulla grows comparatively little. By the end of the second postnatal month, the weight of the suprarenal gland has decreased by more than 50%. The glands begin to grow again by the end of the second year of life and regain their weight at birth by puberty. There is little further weight increase in adult life.

Small accessory nodules composed mainly of cortical tissue, also known as 'adrenal rests', can occur in the areolar tissue near the suprarenal glands. They are also occasionally found in the spermatic cord, epididymis or testis (Altin et al 1992) and the ovary or broad ligament of the uterus. Ectopic suprarenal gland tissue can cause diagnostic confusion and is rarely the site of neoplastic change.

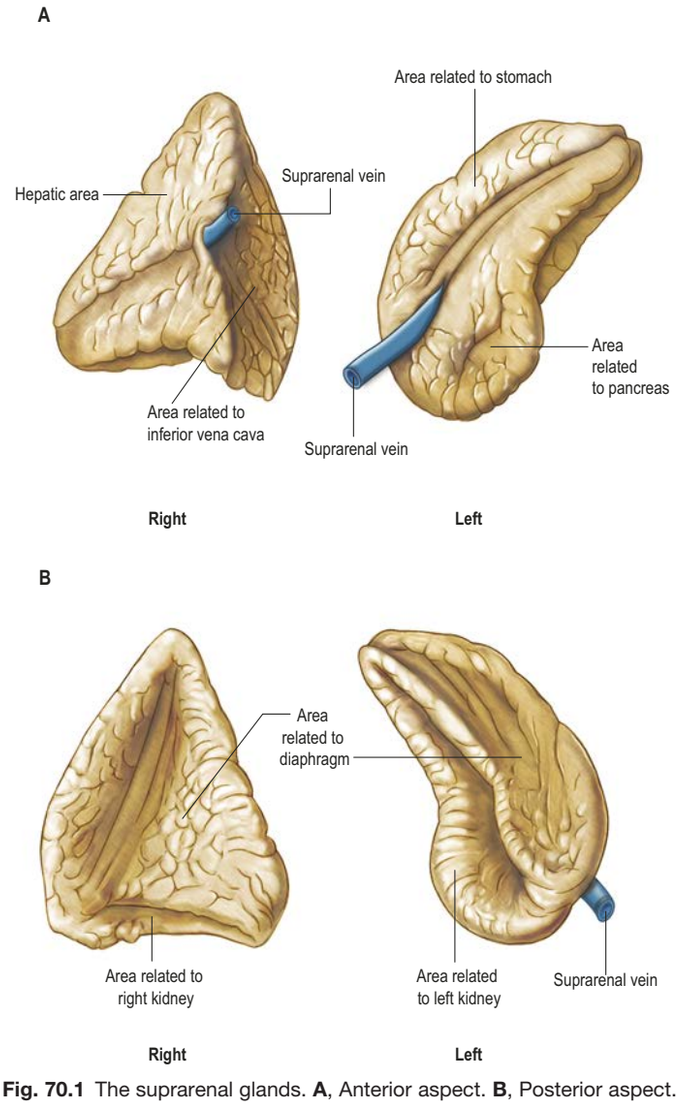

Fig. 70.1 The suprarenal glands. **A**, Anterior aspect. **B**, Posterior aspect.

Right suprarenal gland

The right suprarenal gland lies posterior to the inferior vena cava, separated from it by only a thin layer of renal fascia and connective tissue. It also lies posterior to the right lobe of the liver and anterior to the right crus of the respiratory diaphragm and superior pole of the right kidney (**Fig. 70.2**). The renal surface of the right suprarenal gland overlaps the anterosuperior aspect of the superior pole of the right kidney, the two lower projections (limbs) of the gland straddling the kidney. The anterior surface has two distinct facets: a narrow medial facet that lies posterior to the inferior vena cava and a triangular lateral facet that lies in contact with the bare area of the liver. The most inferior part of the anterior surface may be covered by the peritoneal reflection of the coronary ligament, which also represents the upper aspect of the hepatorenal recess. Here, the gland lies posterior to the lateral border of the descending part of the duodenum. Below the superior border, near the anterior surface of the gland, the right suprarenal vein emerges from the hilum to join the inferior vena cava. This vein is short, which makes surgical resection of the gland or mobilization of the inferior vena cava potentially hazardous. It can be inadvertently avulsed from the inferior vena cava during surgery or, occasionally, by high-energy deceleration injuries. The posterior surface of the gland is divided into upper and lower areas by a curved transverse ridge. The larger upper area is slightly convex and abuts the respiratory diaphragm, whereas the smaller lower area is concave and lies in contact with the superior aspect of the superior pole of the right kidney. The medial border of the gland is thin and lies lateral to the right coeliac ganglion and the right inferior phrenic artery where the artery runs over the right crus of the respiratory diaphragm.

Left suprarenal gland

The left suprarenal gland lies close to the left crus of the respiratory diaphragm (Fig. 70.2). Its medial aspect is convex longitudinally, whereas the lateral aspect is concave because it is moulded by the medial surface of the superior pole of the left kidney. The superior border is sharply defined while the renal surface is more rounded. The upper part of the anterior surface is covered by the peritoneum of the posterior wall of the omental bursa, which separates it from the stomach and sometimes from the inferior border of the spleen. A small lower part of the anterior surface is not covered by peritoneum and lies adjacent to the pancreas and splenic artery. The hilum faces inferiorly from the lower part of the medial aspect. The left suprarenal vein emerges from the hilum and runs inferomedially to join the left renal vein. The posterior surface of the gland is divided by a ridge into a lateral area adjoining the kidney and a smaller medial area that lies in contact with the left crus of the respiratory diaphragm. The medial border lies lateral

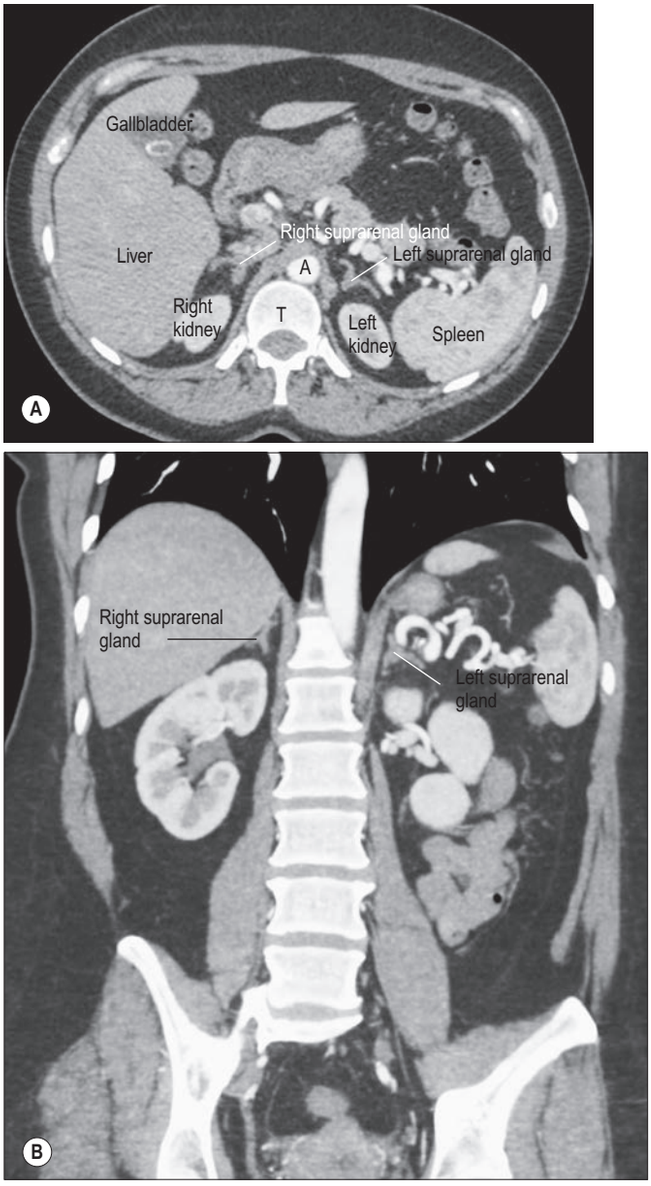

Fig. 70.2 Computed tomography (CT) of the suprarenal glands. **A**, Axial contrasted abdominal CT. **B**, Coronal contrasted abdominal CT. Abbreviations. A, aorta. T, thoracic vertebral body. (Courtesy of Dr R Shane Tubbs, Tulane University School of Medicine, New Orleans, LA, USA.)

to the left coeliac ganglion and the left inferior phrenic and left gastric arteries, which ascend on the left crus of the diaphragm.

Vascular supply and lymphatic drainage

Arteries

The suprarenal glands have one of the highest arterial flow rates per gram of tissue (up to 5 ml/g/min) (Williams and Leggett 1989). Each gland is supplied by superior, middle and inferior suprarenal arteries, the main branches of which can be multiple (**Fig. 70.3**). These vessels ramify over the capsule before penetrating the gland to form a subcapsular arterial plexus, from which fenestrated sinusoids pass around clustered glomerulosa cells and between the columns of the zona fasciculata to a deep plexus in the zona reticularis. Venules from this plexus pass between medullary chromaffin cells to the central vein, which they enter between prominent bundles of smooth muscle fibres. Some relatively large arteries bypass this indirect route and pass directly to the medulla (**Fig. 70.4**). The arterial supply of the suprarenal gland is prone to considerable variation (Manso and DiDio 2000, Dutta 2010) and only the more common variants will be described here.

Superior suprarenal arteries

The superior suprarenal artery usually arises from the ipsilateral inferior phrenic artery and passes to the gland as four or five small branches. It occasionally arises from the abdominal aorta.

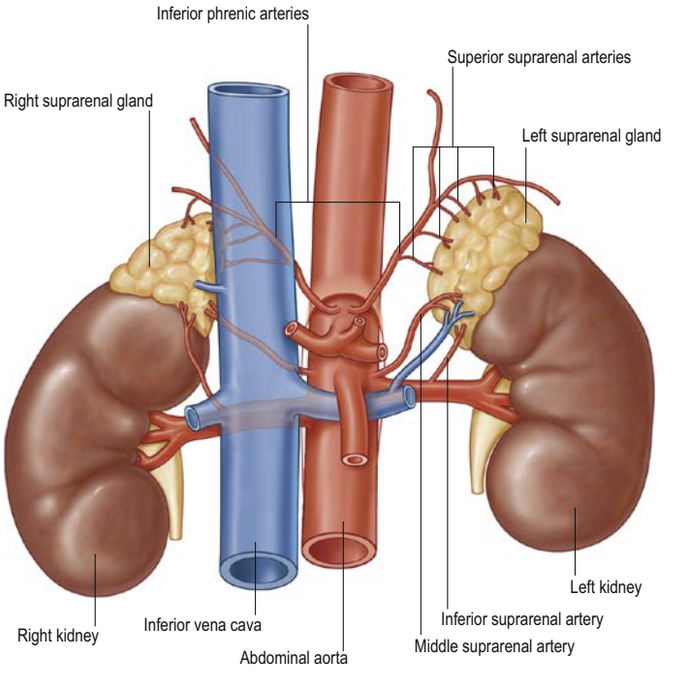

Fig. 70.3 The arterial supply and venous drainage of the suprarenal glands. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Middle suprarenal arteries

The middle suprarenal artery is usually single, but can be multiple or absent. It often arises from the lateral aspect of the abdominal aorta at around the level of the superior mesenteric artery and ascends slightly over the crura of the respiratory diaphragm to anastomose with the other suprarenal arteries on the surface of the suprarenal gland. The right middle suprarenal artery passes behind the inferior vena cava close to the right coeliac ganglion, whereas the left middle suprarenal artery passes close to the left coeliac ganglion, splenic artery and the superior border of the pancreas. The middle suprarenal artery can originate from either the ipsilateral inferior phrenic or renal artery.

Inferior suprarenal arteries

The inferior suprarenal arteries often contribute most of the arterial supply to the suprarenal gland. One or two arteries usually arise from the ipsilateral renal artery, but the inferior suprarenal arteries can originate from either the abdominal aorta or the ipsilateral gonadal artery.

Veins

The central vein emerges from the hilum of the suprarenal gland to form the suprarenal vein, which is usually single (Dobbie and Symington 1966). The right vein is very short and passes directly and horizontally into the posterior aspect of the inferior vena cava. An accessory right suprarenal vein is occasionally present and runs from the hilum superomedially to join the inferior vena cava above the right suprarenal vein. The short course renders the right suprarenal vein(s) vulnerable to injury or even avulsion from the inferior vena cava during surgery if undue traction is applied. The left suprarenal vein is longer and descends medially, anterolateral to the left coeliac ganglion, then passes posterior to the body of the pancreas. This vessel usually drains into the left renal vein and may receive the left inferior phrenic vein (Loukas et al 2005). Since the venous drainage from each suprarenal gland is usually via a single vein, infarction of the gland is more likely to be caused by injury to a suprarenal vein than to one of the suprarenal arteries.

Understanding the variant venous anatomy of the suprarenal gland is important to preclude haemorrhage during adrenalectomy. Cadaveric studies have shown little variation in suprarenal venous anatomy but suggest that variants are more common on the right (Cesmebasi et al 2014). However, a large surgical series of patients undergoing laparoscopic removal of the suprarenal gland found that 13% had variant venous anatomy for this structure (Scholten et al 2013). Common variants included an absent main suprarenal vein, accessory suprarenal veins, a branch to the inferior phrenic vein, and draining to the right hepatic vein on the right or, on the left, to the inferior vena cava.

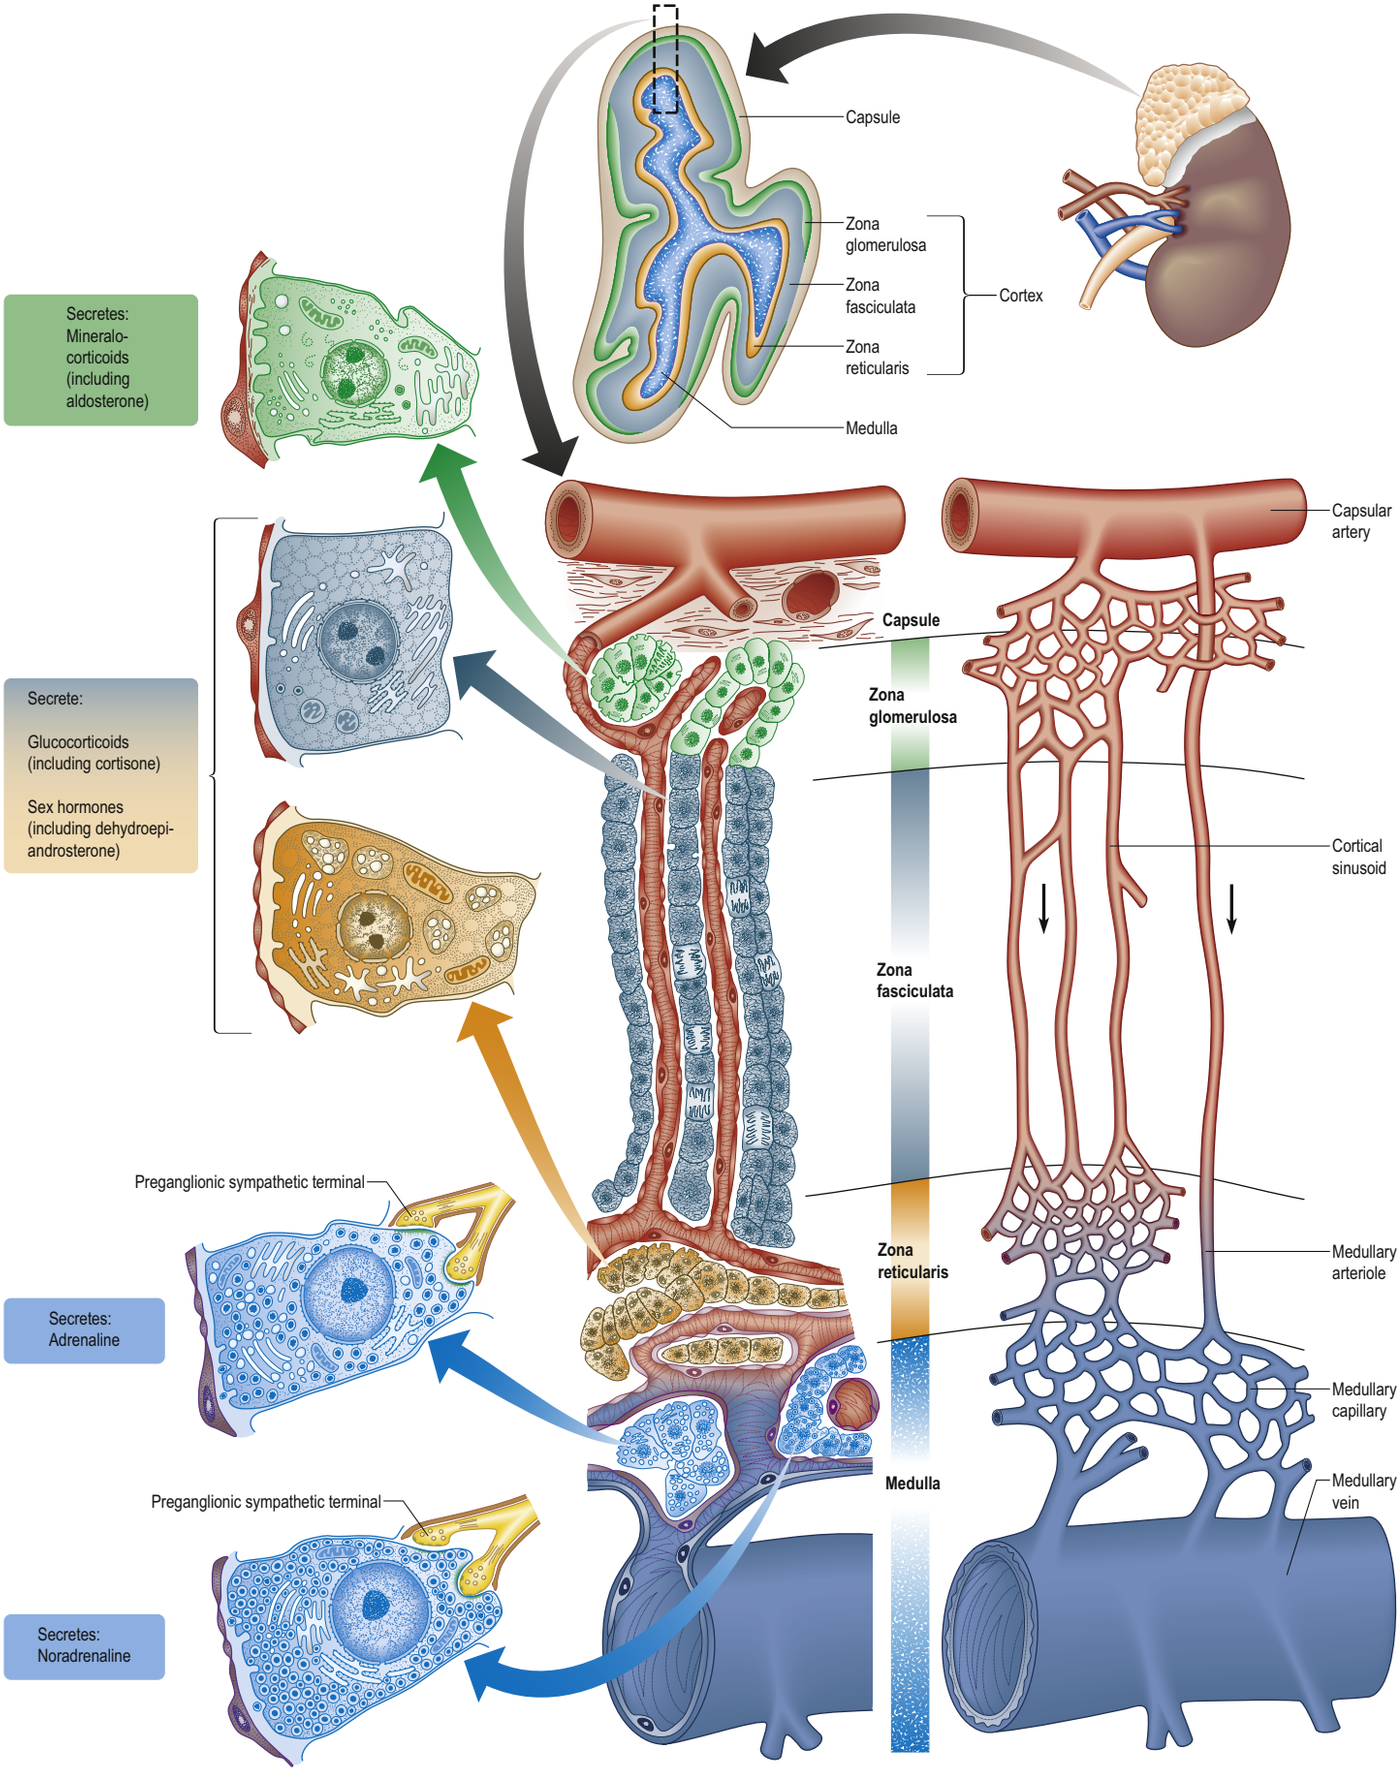

Fig. 70.4 The gross sectional appearance, microstructure, vasculature and ultrastructure of the suprarenal gland. Brief functional summaries are included.

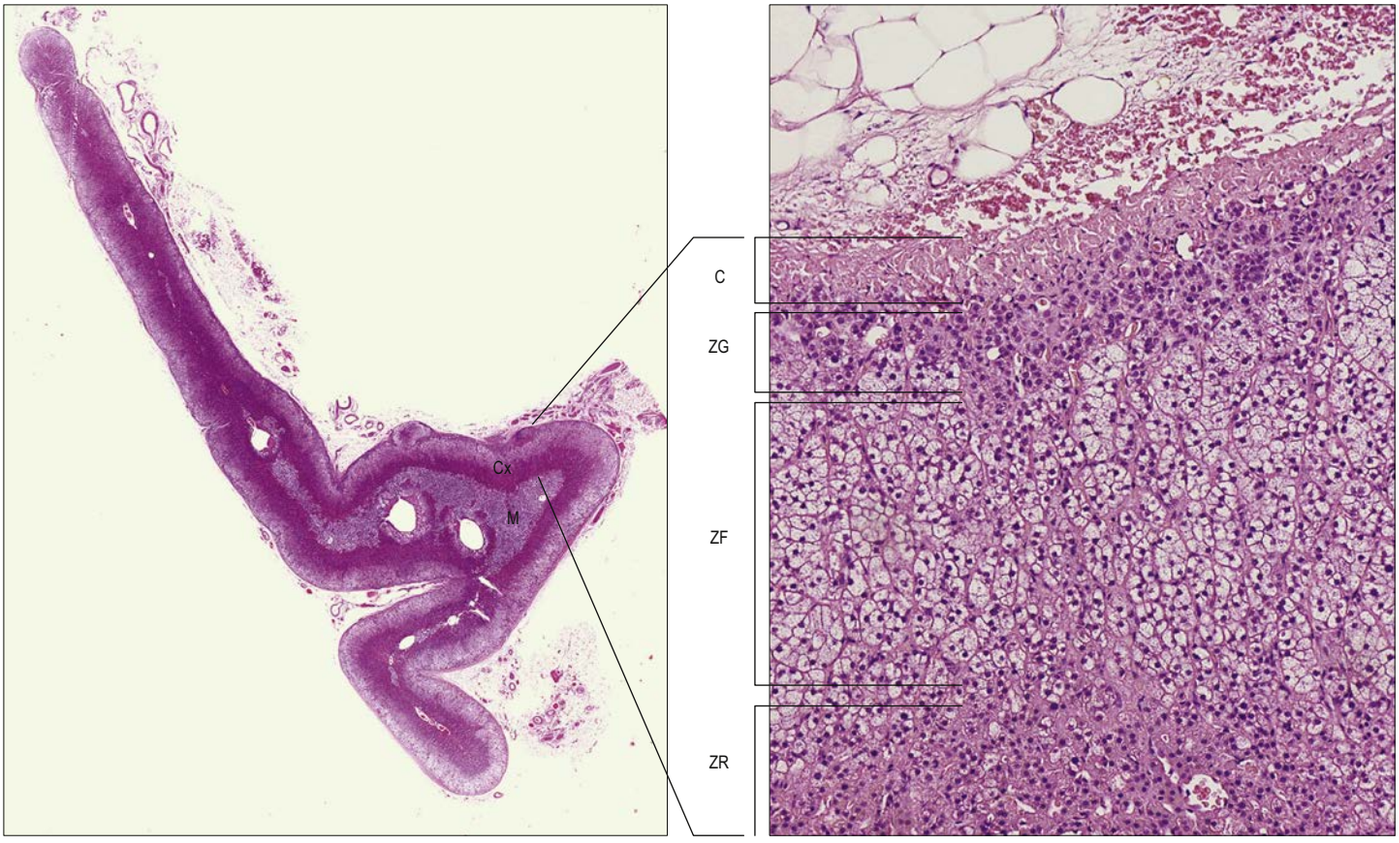

Fig. 70.5 A cross-section through an adult suprarenal gland showing the cortex (Cx) and highly vascular medulla (M). The cortex is shown at higher magnification to demonstrate the capsule (C), the zona glomerulosa (ZG), zona fasciculata (ZF) and zona reticularis (ZR). The boundaries between zones are indistinct and variable. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Lymphatic drainage

Lymphatic vessels within the capsule of the suprarenal gland communicate with subcapsular lymphatics that drain medially to lumbar nodes (Merklin 1966, Skandalakis et al 2004). A few capsular lymphatics communicate with lymph vessels that pass through the respiratory diaphragm (Tokiwa et al 1993).

Innervation

Relative to its size, the suprarenal gland has a greater autonomic nerve supply than any other organ. The nerves are distributed throughout the gland, including around blood vessels, where they act to regulate blood flow; in the medulla, where they stimulate the release of catecholamines from chromaffin cells; in the cortex, where they can influence steroid hormone production (Tóth et al 1997). A suprarenal plexus lies between the medial aspect of each gland and the coeliac and aorticorenal ganglia. Cholinergic preganglionic sympathetic fibres travelling mainly in the greater thoracic splanchnic nerves reach the plexus and synapse on clusters of large medullary chromaffin cells. The precise spinal level of origin of these preganglionic fibres is uncertain and some may also travel in the lesser and least thoracic splanchnic nerves: cadaveric dissection studies in humans, both adult and fetal, have revealed significant differences not only in the origin and number of the splanchnic nerve rami but also in the communications between them (Naidoo et al 2001, Yang et al 2008, Loukas et al 2010). A smaller proportion of postganglionic sympathetic nerve fibres innervate cortical blood vessels. Other nerve fibres containing a variety of neurotransmitters have been identified within the suprarenal cortex and could be involved in modulating steroid hormone secretion (Li et al 1999). Experimental tracing studies in rats, guinea-pigs and marmosets found that the cell bodies of afferent nerve fibres arising in the suprarenal medulla were almost all located in dorsal root ganglia, and, less often, in the nodose ganglia of the vagus nerves (Coupland 1989, Parker et al 1993).

Microstructure and function

In section, the suprarenal glands have an outer cortex, which is yellowish in colour and forms the main mass. The suprarenal glands also have a thin medulla, forming about one-tenth of the gland, which is dark red or greyish depending on its content of blood (see Fig. 70.4; **Fig. 70.5**). The medulla is completely enclosed by cortex except at the hilum. The gland has a thick collagenous capsule from which trabeculae extend deep into the cortex. The capsule contains a rich arterial plexus that supplies branches to the suprarenal gland.

Suprarenal cortex

The suprarenal cortex is composed of a zona glomerulosa, zona fasciculata and zona reticularis (see Fig. 70.5). The outer, subcapsular, zona glomerulosa consists of a narrow region of small polyhedral cells arranged in rounded clusters. These cells have deeply staining nuclei and a basophilic cytoplasm containing a few lipid droplets. Ultrastructurally, they each have an abundant smooth endoplasmic reticulum that is typical of steroid-synthesizing cells. The broader, intermediate, zona fasciculata consists of large polyhedral basophilic cells arranged in straight columns, two cells wide, separated by parallel fenestrated venous sinusoids. These cells each contain many lipid droplets and large amounts of smooth endoplasmic reticulum. The innermost part of the cortex, the zona reticularis, consists of branching interconnected columns of rounded cells, each with a cytoplasm containing smooth endoplasmic reticulum, numerous lysosomes, and aggregates of brown lipofuscin pigment that accumulate with age.

Cortical cells produce several hormones: cells in the zona glomerulosa produce mineralocorticoids, e.g. aldosterone, which regulates electrolyte and water balance; cells in the zona fasciculata produce hormones maintaining carbohydrate balance, e.g. the glucocorticoid cortisol (hydrocortisone); and cells in the zona reticularis produce sex hormones, e.g. progesterone, oestrogens and androgens. The suprarenal cortex is essential for life and complete bilateral removal is lethal without replacement therapy.

Suprarenal medulla

The suprarenal medulla is composed of groups and columns of chromaffin cells (phaeochromocytes), separated by wide venous sinusoids and supported by a network of reticular fibres. Medullary chromaffin cells, so called from their colour reaction to dichromate fixatives, form

part of the neuroendocrine system and are functionally equivalent to postganglionic sympathetic neurones. These cells store the catecholamines noradrenaline (norepinephrine) and adrenaline (epinephrine) and release them into the medullary venous plexus. Release is under preganglionic sympathetic control and is mediated by the sympathetic neurones that occur either singly or in small groups in the medulla.

Most medullary chromaffin cells synthesize adrenaline and store it in small granules with a dense core. The less numerous noradrenaline-secreting cells have larger granules with a dense eccentric core. Some cells synthesize both hormones. Chromogranin proteins package catecholamines within the granules, which also contain encephalins, opiate-like proteins that have endogenous analgesic effects under some circumstances. All of the cells are large, with large nuclei and basophilic, faintly granular cytoplasm. They form single rows along the venous sinusoids. Sympathetic axon terminals synapse with the medullary chromaffin cells on the surfaces that face away from the sinusoids.

The sinusoids are lined by a fenestrated endothelium and drain to the central vein and suprarenal vein. Under normal circumstances, little adrenaline or noradrenaline is released. Secretion of these substances increases in response to fear, anger or stress. Unlike the cortex, the suprarenal medulla is not essential for life.

A comprehensive chapter on the surgical anatomy of the suprarenal (adrenal) glands.

Several neoplastic lesions can be encountered arising from the suprarenal glands, including adenomas, phaeochromocytomas, myelolipomas, oncocytomas, cysts, adrenocortical carcinomas (ACC), and metastases from other malignancies. Many of these lesions require surgical resection, and therefore a firm understanding of suprarenal gland anatomy is critical for their successful treatment. In this section the most common and clinically relevant lesions of the suprarenal gland are reviewed.

Adenomas

Adenomas most commonly arise from the zona glomerulosa or the zona fasciculata of the suprarenal cortex. Up to 10% of incidentally detected suprarenal gland adenomas are functional and autonomously produce hormones (Mantero et al 1997). These lesions, which are composed of lipid-rich cells, commonly show low attenuation (less than 10 Hounsfield units) on unenhanced computed tomography (CT) (Young 2007, Johnson et al 2009). Alternatively, suprarenal adenomas can be detected on CT by their characteristic high degree of washout (greater than 60%) on delayed phase imaging performed 10–15 minutes after contrast administration. Suprarenal adenomas can also be reliably detected on chemical shift magnetic resonance imaging (MRI).

Functional adenomas arising from the zona glomerulosa cause a symptom complex known as Conn's syndrome. This syndrome is characterized by hypertension, hypokalaemia and metabolic alkalosis. Bilateral adrenal hyperplasia can cause identical symptoms and must be distinguished from an aldosterone-producing adenoma, as the treatment of hyperplasia is medical with aldosterone-blocking medications, such as spironolactone, whereas aldosterone-producing adenomas require surgical excision. The two conditions can typically be differentiated on the basis of imaging findings or with selective suprarenal vein sampling, which is indicated in elderly patients who are prone to equivocal imaging findings that can lead to incorrect lateralization of the source of mineralocorticoid excess. Primary hyperaldosteronism is diagnosed by measuring morning plasma aldosterone and renin levels (Fassnacht et al 2016). A high ratio between the two hormones (typically defined as an aldosterone:renin ratio greater than 20) is indicative of disorders of aldosterone excess. Some recommend a salt loading test as further confirmation of the diagnosis.

Adenomas arising from the zona fasciculata can result in cortisol excess or what is known as Cushing's syndrome. This syndrome is clinically characterized by central obesity, increased adiposity/rounding of the face (moon face), fat deposition between the shoulders (buffalo hump), hypertension, glucose intolerance, fatigue, abdominal striae and easy bruising. Functional adenomas causing cortisol excess also require surgical excision.

An autonomous cortisol-producing adenoma is diagnosed after observing an elevated cortisol level on an overnight 1 mg dexamethasone suppression test (Fassnacht et al 2016). This finding can be confirmed with the late-night salivary cortisol test or with a 24-hour urinary cortisol level. Other conditions that cause cortisol excess include exogenous steroid use, pituitary gland adenomas (also known as Cushing's disease), adrenocortical carcinoma (ACC) and paraneoplastic syndromes. None of these alternative causes of cortisol excess will show suppression on the overnight 1 mg dexamethasone suppression test. However, Cushing's disease will show suppression with a higher 2 mg dose of dexamethasone. Through a combination of imaging findings and metabolic testing, the precise cause of cortisol excess can typically be identified and addressed.

While rare, adenomas can also arise from the zona reticularis. These tumours can lead to excess production of sex hormones leading to virilization in women and feminization in men. Because of the rarity of these lesions, metabolic testing for sex hormones is not indicated in asymptomatic patients who present with an incidentally detected suprarenal gland tumour. However, it is worth noting that ACCs commonly present with symptoms of excess sex steroid production and patients presenting with related symptoms should be evaluated with an eye for this potentially aggressive malignancy.

Phaeochromocytomas

Phaeochromocytomas are catecholamine-producing tumours that arise from the medulla of the suprarenal glands. They are most commonly sporadic and unilateral; however, several hereditary syndromes can give rise to multifocal lesions. Syndromes associated with the development of phaeochromocytomas include von Hippel–Lindau disease, neuro fibromatosis type 1, succinate dehydrogenase deficiency, and multiple endocrine neoplasia 2A and 2B.

Phaeochromocytomas commonly result in symptoms of catecholamine excess, including hypertension, tachycardia, headache and hyperhidrosis. On CT, phaeochromocytomas are highly vascular and typically display delayed contrast washout (Young 2007). On T2-weighted MRI, these lesions are markedly hyperintense and display the characteristic 'light bulb sign'. Phaeochromocytomas have the potential for metastatic spread, which can be assessed with contrast-enhanced cross-sectional imaging (CT or MRI), or functional imaging with either ^{131}I-metaiodobenzylguanidine single-photon imaging or 2-deoxy-2-[^{18}F]fluoro-D-glucose positron emission tomography.

The presence of a phaeochromocytoma is confirmed with metabolic testing for plasma-free metanephrines or urinary fractionated metanephrines (Fassnacht et al 2016). Phaeochromocytomas require surgical resection with adrenalectomy. Prior to surgery, alpha-adrenergic blockade, most commonly with phenoxybenzamine, is needed to prevent an intraoperative hypertensive crisis.

Myelolipomas

Myelolipomas are benign non-metabolically active tumours of the suprarenal gland that are composed of trilineage haemopoietic precursor cells and mature fat. These lesions can be distinguished on CT from other suprarenal masses by the finding of large areas of macroscopic fat with negative Hounsfield units. Myelolipomas are most commonly asymptomatic and do not require treatment or follow-up imaging. Treatment in the form of surgical resection is only indicated for symptom management.

Adrenocortical carcinoma (ACC)

ACC is a rare primary malignancy of the suprarenal gland. Most cases of ACC are sporadic, unilateral and present at an advanced stage. Upwards of 50% of ACCs have hypersecretion of one or more of the cortical suprarenal gland hormones (Terzolo et al 2007). ACCs tend to be larger than other suprarenal gland tumours, with an average size of approximately 10 cm at presentation (Gröndal et al 1990). It is estimated that 10–20% of all suprarenal gland tumours greater than 4 cm are ACCs, so surgical resection should be considered for tumours meeting this size cut-off that are otherwise without the imaging hallmarks of a benign tumour (Young 2007, Azoury et al 2017). On CT imaging, ACCs tend to have irregular borders, calcifications and areas of necrosis. Additionally, extension into adjacent organs or the inferior vena cava is common.

Surgical excision is the mainstay of treatment for ACC. *En bloc* resection of the tumour and any involved organs should performed. A regional lymphadenectomy is also commonly performed for the purposes of disease control and tumour staging. Surgical resection is indicated for patients with localized and locally advanced disease. For patients with metastatic disease, primary tumour resection is indicated to alleviate symptoms. This is typically performed in combination with metastasectomy. Following surgical resection, consideration should be given to administration of adjuvant mitotane, a derivative of the insecticide dichlorodiphenyltrichloroethane (DDT), which inhibits steroidogenesis and remains the first line agent for metastatic ACC (Fassnacht et al 2018). The prognosis of ACC is quite poor, with 5-year survival rates often reported as less than 50% (Kim et al 2016).

Other metastases

The suprarenal glands are a common site for metastases from other malignancies. One study found that in patients with a history of a previous malignancy, approximately 50% of newly discovered suprarenal gland lesions were metastatic (Lenert et al 2001). Tumours that commonly metastasize to the suprarenal glands include melanoma, renal cell carcinoma, lung cancers and breast cancer. Metastatic lesions can be distinguished from primary lesions of the suprarenal gland through a combination of clinical history, imaging findings (lesions will be greater than 10 Hounsfield units on non-contrasted CT and will enhance) and percutaneous biopsy. Depending on the underlying malignancy and extent of metastatic spread, some metastases can be treated with surgical resection while others require systemic therapy.

One or both of the suprarenal glands may be removed using 'open surgery', which remains the standard of care for patients with ACC who require *en bloc* resection of their tumour. For other lesions of the suprarenal gland requiring surgery, minimally invasive techniques are now generally preferred. The original laparoscopic approaches for removal of the suprarenal gland were described during the 1990s and have since been adopted throughout most of the world (Gagner et al 1992, Mercan et al 1995). Both the open and minimally invasive techniques for removal of the suprarenal gland can be performed via a transabdominal or retroperitoneal approach. The retroperitoneal approach offers the advantage of remaining outside the abdominal cavity and so avoids encountering adhesions and potentially causing iatrogenic injury to other organs. Advantages of the transabdominal approach include a larger working space and more familiar anatomical relations. Ultimately, the choice of surgical technique is dictated by a combination of surgeon experience and patient-specific factors.

CHAPTER
71

Lesser pelvis and perineum

LESSER PELVIS

The lesser pelvis is a bowl-shaped structure formed from the sacrum, pubis, ilium, ischium, the ligaments that interconnect these bones, and the muscles that line their inner surfaces. It begins at the level of the plane passing through the promontory of the sacrum, the arcuate line of the ilium, the pecten pubis and the posterior surface of the pubic crest. This plane, or 'inlet', lies at an angle of between 35° and 50° up from the horizontal; the bony structures above it are sometimes referred to as the greater pelvis. They form part of the walls of the lower abdomen. In children, the width of the pelvic inlet is an age-independent predictor of chest width and thoracic dimensions (Emans et al 2005). The ischiopubic synchondrosis is the temporary cartilage formed between the pubis and ischium prior to the completion of ossification around 12 years of age (Herneth et al 2000). The 'outlet' of the lesser pelvis is formed by the ischiopubic rami, ischial tuberosities, sacrotuberous ligaments and distal sacrum. The bones surround a central pelvic canal that forms an anteriorly concave curve (the curve of Carus); in the female, it constitutes the birth canal. The topography of the bony and ligamentous pelvis is considered in full detail in Chapter 77.

Muscles and fasciae

Pelvic muscles

The muscles arising within the pelvis form two groups. Piriformis and obturator internus form part of the walls of the pelvis and are considered primarily as muscles of the lower limb (Fig. 71.1). Levator ani and ischiococcygeus form the pelvic diaphragm and delineate the inferior limit of the lesser pelvis (Fig. 71.2). The fasciae investing the muscles are continuous with visceral pelvic fascia superiorly, perineal fascia inferiorly and obturator fascia laterally.

Piriformis

Piriformis forms part of the posterolateral wall of the lesser pelvis and is attached to the anterior surface of the sacrum, the gluteal surface of the ilium near the posterior inferior iliac spine, the capsule of the adjacent sacroiliac joint and, sometimes, to the superior part of the pelvic surface of the sacrotuberous ligament. It passes out of the pelvis through the greater sciatic foramen superior to the sacrospinous ligament. Within the pelvis, the posterior surface of this muscle lies against the sacrum, and its anterior surface is related to the rectum (especially on the left), the sacral plexus and branches of the internal iliac vessels. Piriformis is described in more detail in Chapter 77.

Obturator internus

Obturator internus and its fascia form part of the anterolateral wall of the lesser pelvis. These attach to the structures surrounding the obturator foramen, ischiopubic ramus, the pelvic surface of the hip bone inferior and posterior to the linea terminalis, and the superior part of the greater sciatic foramen. These structures are also attached to the medial part of the pelvic surface of the obturator membrane. Specialized portions of the obturator fascia give attachment to some of the fibres of levator ani (tendinous arch of levator ani), so that only the superior portion of obturator internus can be seen from above. The inferior portion forms part of the boundaries of the ischio-anal fossa. In the male, the superior portion lies lateral to the urinary bladder, the obturator and vesical vessels, and the obturator nerve. In the female, the attachments of the broad ligament of the uterus, the distal end of the uterine tubes and the uterine vessels also lie medial to obturator internus and its fascia.

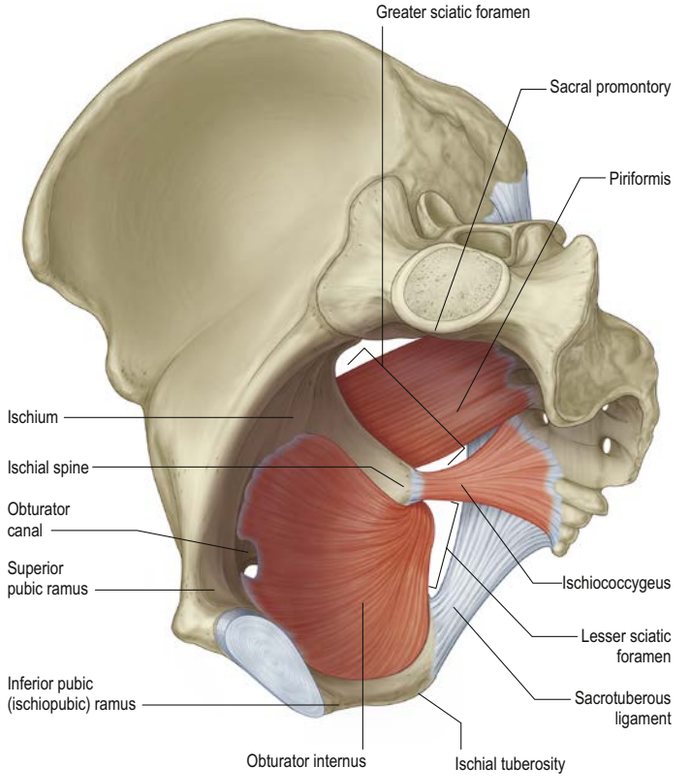

Fig. 71.1 Piriformis, obturator internus and the ligaments of the pelvis. Those muscles relating only to the pelvis or perineum have been omitted for clarity. (Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds), Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

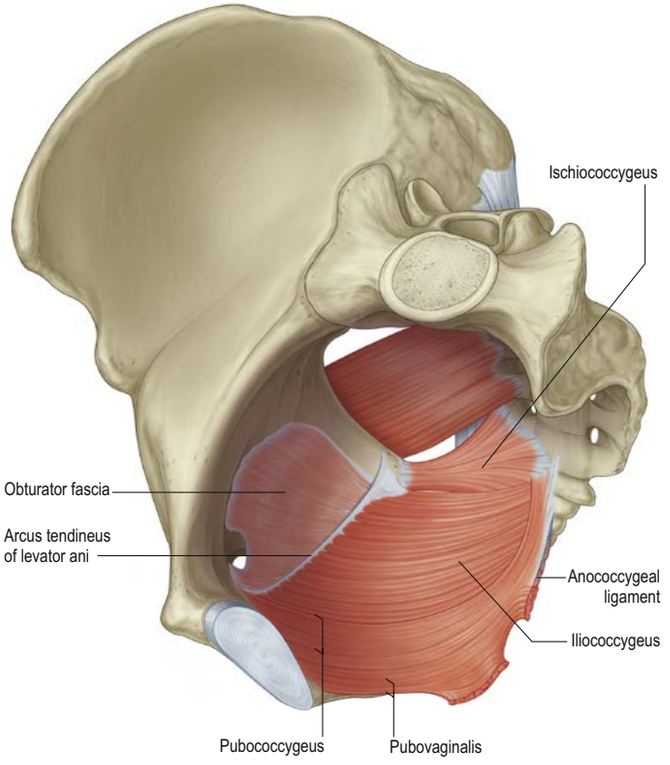

Fig. 71.2 Muscles of the female pelvis. The superior gluteal and obturator vessels and nerves, and the pelvic viscera, have been omitted for clarity. (Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

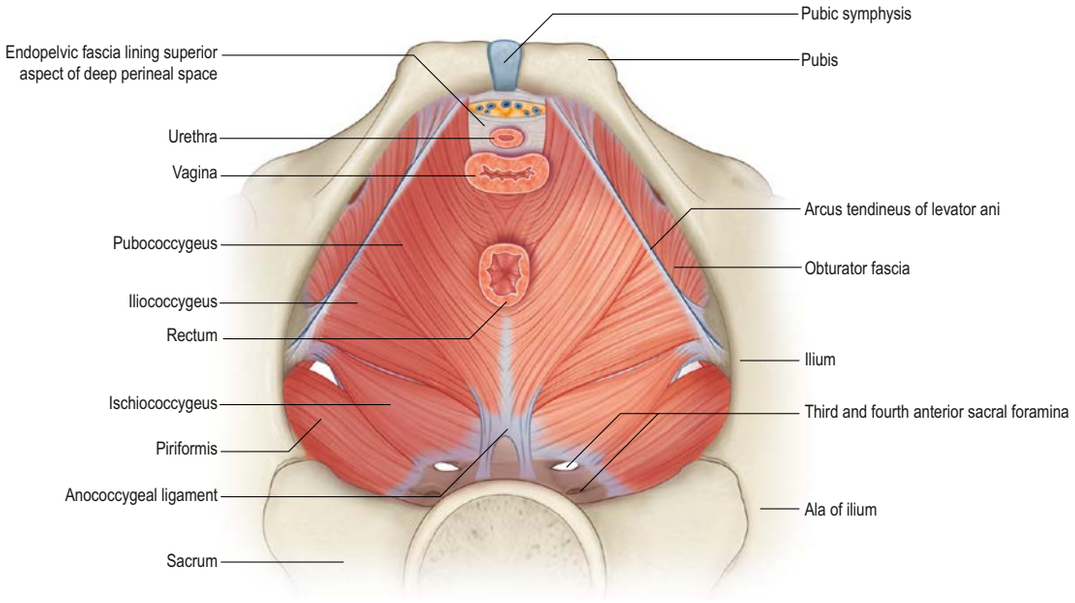

Fig. 71.3 Muscles of the female pelvis viewed from above. The anorectal junction, vagina and urethra have been divided at the level of the pelvic diaphragm.

Levator ani (pubococcygeus, iliococcygeus and pubo-analis)

Levator ani is a broad muscular sheet of variable thickness attached to the internal surface of the pelvis. It forms a large portion of the pelvic diaphragm (**Fig. 71.3**) (Lawson 1974a, Roberts et al 1988, Wendell-Smith and Wilson 1991). The muscle is subdivided into named portions according to their attachments and the pelvic viscera to which they are related (pubococcygeus, iliococcygeus and pubo-analis). These parts are often referred to as separate muscles but the boundaries between them cannot easily be distinguished; moreover, they perform many similar physiological functions. Pubococcygeus is often subdivided into separate parts according to the pelvic viscera to which each part relates (e.g. puboprostaticus, pubovaginalis). Levator ani arises from each side of the walls of the pelvis along the condensation of the obturator fascia (the tendinous arch of levator ani). Fibres from ischiococcygeus attach to the sacrum and coccyx but the remaining parts of the muscle converge in the midline. Fibres from iliococcygeus join via a partly fibrous intersection and form the iliococcygeal raphe posterior to the anorectal junction. Closer to the anorectal junction, and elsewhere in the pelvic diaphragm, the fibres are nearly continuous with those of the opposite side, such that the muscle forms a sling (iliococcygeus and pubo-analis).

Attachments The attachments for pubococcygeus, iliococcygeus and pubo-analis are as follows.

Pubococcygeus Pubococcygeus originates from the posterior aspect of the body of the pubis and passes posteriorly almost horizontally. Its most medial fibres run directly lateral to the urethra and its sphincter as it passes through the pelvic diaphragm; here, the muscle is correctly called puboperinealis, although it is often referred to as pubo-urethralis because of its juxtaposition to the proximal half of the urethra in both sexes, however, no direct connection with the urethra is present. In males, some of these fibres lie lateral and inferior to the prostate and are referred to as puboprostaticus. In females, fibres run further back and attach to the lateral walls of the vagina, where they are referred to as pubovaginalis. In both sexes, fibres from this part of pubococcygeus attach to the perineal body; a few elements also attach to the anorectal junction. Some fibres decussate and blend with the longitudinal rectal muscle and fascial elements to contribute to the conjoint longitudinal coat of the anal canal. Behind the rectum, other fibres of pubococcygeus form a tendinous intersection as part of the anococcygeal raphe.

Iliococcygeus Iliococcygeus is attached to the inner surface of the ischial spine inferior and anterior to the attachment of ischiococcygeus, and also to the tendinous arch of levator ani as far anteriorly as the obturator canal (see Fig. 71.2). The most posterior fibres are attached to the apex of the sacrum and coccyx, but the majority join fibres from the contralateral side to form a raphe that is effectively continuous with the fibroelastic anococcygeal ligament, which is closely applied to its inferior surface; some muscle fibres may attach into the ligament. The raphe provides a strong attachment for the pelvic diaphragm posteriorly and must be divided to allow wide excisions of the anorectal canal to be performed during abdominoperineal excisions for malignancy. An accessory slip sometimes arises from the most posterior part and is referred to as iliosacralis.

Pubo-analis Pubo-analis lies lateral to pubococcygeus and cannot be seen from inside the pelvis. It originates from the inner surface of the ischiopubic rami immediately adjacent to, and sometimes partly arising from, the perineal membrane. Its fibres pass lateral to those of iliococcygeus and pubococcygeus to decussate posterior to the rectum at the anorectal junction. The border between pubo-analis and some fibres of the external anal sphincter is indistinct.

Ischiococcygeus Ischiococcygeus lies posterosuperior to and is contiguous with levator ani. It arises as a triangular musculotendinous sheet with its apex attached to the pelvic surface and tip of the ischial spine, and its base attached to the lateral margins of the coccyx and the fifth sacral vertebral segment. Ischiococcygeus is rarely absent, but can be almost completely tendinous rather than muscular. It lies on the pelvic aspect of the sacrospinous ligament and can be fused with it, particularly if it is mostly tendinous. The sacrospinous ligament may represent either a degenerate part or an aponeurosis of the muscle, since muscle and ligament are coextensive.

Relations The superior, pelvic surface of levator ani is separated only by fascia (superior pelvic diaphragmatic, visceral and extraperitoneal) from the urinary bladder, prostate or uterus and vagina, rectum and peritoneum. Its inferior, perineal surface forms the medial wall of the ischio-anal fossa and the superior wall of the anterior recess of the fossa, both being covered by the inferior fascia of the pelvic diaphragm. The posterior border is separated from the coccyx by areolar tissue. The medial borders of the two levator muscles and the inferior ischiopubic rami border the levator hiatus, through which pass the urethra, vagina (in the female) and anus. In the female, that portion of the hiatus that lies anterior to the perineal body is referred to as the urogenital hiatus.

Vascular supply Levator ani is supplied by branches of the inferior gluteal, inferior vesical and internal pudendal arteries.

Innervation The nerves to levator ani originate mainly from the third and fourth sacral ventral (anterior) rami, with lesser contributions from the second sacral ventral ramus. These nerves enter the pelvis just above ischiococcygeus, sometimes piercing it, to pass along the anterior surface of ischiococcygeus and pubococcygeus, supplying these muscles and sending fibres to pubo-analis (Roberts and Krishingner 1967, Sato 1980). The pudendal nerve can also supply pubococcygeus from its lateral surface through its inferior anal and perineal branches.

Actions Pubococcygeus and pubo-analis pull the pelvic and perineal structures anteriorly and superiorly, occluding the levator hiatus. In the female, this action occludes the vagina and prevents prolapse of the pelvic organs through the urogenital hiatus. The constant baseline activity of levator ani is similar to that of the external anal sphincter, modulated to adjust to the loads placed on them. The action of pubo-analis and pubococcygeus also reinforces the external anal sphincter and helps to create the anorectal angle. Iliococcygeus and to a lesser extent the less muscular ischiococcygeus form a relatively horizontal diaphragm, especially in the posterior half of the pelvis, that assists pubo-analis in achieving bowel and bladder continence.

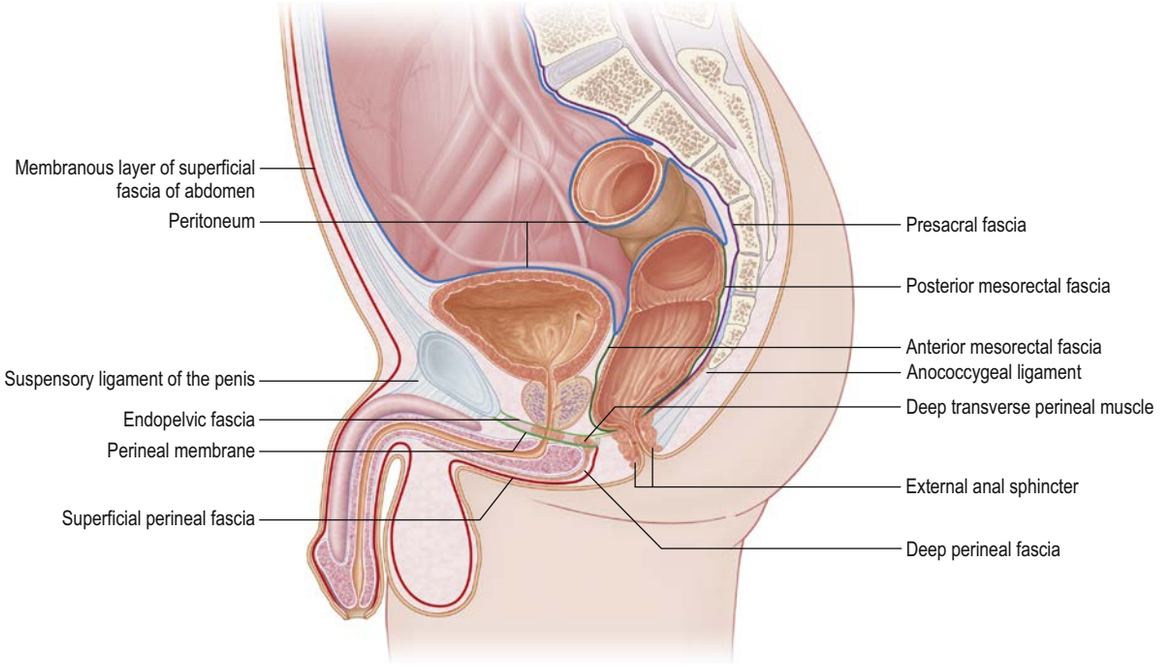

Fig. 71.4 Fasciae of the male pelvis and perineum: median sagittal section. The visceral parietal fasciae have been omitted for clarity.

Levator ani must relax appropriately to permit expulsion of urine and, particularly, faeces; it contracts with the abdominal muscles and the respiratory diaphragm to raise intra-abdominal pressure. It forms much of the muscular pelvic diaphragm, which supports the pelvic viscera. Like the respiratory diaphragm, but unlike the abdominal muscles, levator ani is also active in the inspiratory phase of quiet respiration. In pregnancy, the shape of the pelvic diaphragm can help to direct the fetal head into the anteroposterior diameter of the pelvic outlet.

Pelvic fasciae

It is convenient to divide the pelvic fasciae into the parietal pelvic fascia, which forms the coverings of the pelvic muscles, and the visceral pelvic fascia, which forms the coverings of the pelvic organs and their neurovascular supply (Fig. 71.4).

Parietal pelvic fascia

The parietal pelvic fascia consists of the obturator fascia, piriformis fascia, superior fascia over the pelvic diaphragm and the presacral fascia.

Obturator fascia

The parietal pelvic fascia on the pelvic (medial) surface of obturator internus is well differentiated. In humans, anterior to the lateral attachment of the pelvic organs, a portion of it is derived from the degenerated superior portion of the attachment of levator ani. It is connected to the posterior part of the arcuate line of the ilium and is continuous with iliac fascia. Anterior to this, as it follows the line of origin of obturator internus, it is gradually separated from the attachment of the iliac fascia and a portion of the periosteum of the ilium and pubis spans between them. It arches below the obturator vessels and nerve, investing the obturator canal, and is attached anteriorly to the posterior aspect of the pubis. Behind the obturator canal, the fascia is markedly aponeurotic and gives a firm attachment to the iliococcygeus, usually called the tendinous arch of levator ani (see Figs 71.3, 71.14–71.15). Superior to the attachment of levator ani, the fascia is thin and effectively comprises only the epimysium of the muscle and overlying connective tissue; posteriorly, it forms part of the lateral wall of the ischio-anal fossa in the perineum; anteriorly, it merges with the fasciae of the muscles of the deep perineal space, which is continuous with the ischio-anal fossa. The obturator fascia is continuous with the periosteum of the hip bone and piriformis fascia.

Fascia over piriformis

The fascia over the internal surface of piriformis is very thin and fuses with the periosteum on the anterior sacrum at the margins of the anterior sacral foramina. It ensheathes the ventral rami that emerge from these foramina so that the nerves are often described as lying behind the fascia. The internal iliac vessels lie in front of the piriformis fascia and their branches draw out sheaths of the fascia and extraperitoneal tissue into the gluteal region, superior and inferior to piriformis.

Fascia over levator ani

Both surfaces of levator ani have a fascial covering: the combination of the two fascial layers and the intervening muscle is called the pelvic diaphragm. On the inferior surface, the fascia is continuous with the obturator fascia below the tendinous arch of levator ani laterally. It covers the medial wall of the ischio-anal fossa and blends below with fasciae on the external urethral sphincter and the external anal sphincter. The superior fascia of the pelvic diaphragm is markedly thicker than the inferior fascia and is attached anteriorly to the posterior aspect of the body of the pubis, approximately 2 cm superior to its inferior border. It extends laterally across the superior pubic ramus, blending with the obturator fascia and continuing along an irregular line to the ischial spine. It is continuous posteriorly with the piriformis fascia and the anterior sacrococcygeal ligament. Medially, the superior fascia of the pelvic diaphragm blends with the visceral pelvic fascia to contribute to the endopelvic fascia.

Tendinous arch of the pelvic fascia

Low on the superomedial aspect of the superior fascia of the pelvic diaphragm, a thick white band of condensed connective tissue extends from the inferior part of the pubic symphysis to the superior margin of the ischial spine. It provides attachment for the condensations of visceral pelvic fasciae that provide support to the urethra and urinary bladder, and to the vagina in females (see below).

Presacral fascia

The presacral fascia forms a hammock-like structure behind the posterior portion of the mesorectal fascia. Laterally, it extends to the origin of the piriformis fascia and the superior fascia of the pelvic diaphragm, with which it blends; more inferiorly, it extends between the white line of the parietal pelvic fascia on either side. Inferiorly, it extends to the anorectal junction, where it fuses with the posterior aspect of the mesorectal fascia and the iliococcygeal raphe at the level of the anorectal junction. Superiorly, it can be traced to the origin of the superior hypogastric plexus, where it thins progressively over the sacral promontory and becomes continuous with the retroperitoneal tissues. The right and left hypogastric nerves and inferior hypogastric plexuses lie on its surface. It forms a distinct layer that can be seen both on magnetic resonance imaging (MRI) of the pelvis and during surgery. The presacral fascia provides an important landmark because extension of rectal tumours through it significantly reduces the possibility of curative resectional surgery. Dissection in the plane posterior to the fascia can result in bleeding from the presacral veins. The adventitia of the veins is partly attached to the posterior surface of the fascia, which means that the haemorrhage can be severe (because the veins are unable to contract properly). The presacral fascia is a useful structure to which the rectum can be sutured during rectopexy for rectal prolapse.

Visceral pelvic fascia

The urogenital organs in both sexes are connected bilaterally to the pelvic walls by neurovascular mesenteric condensations ensheathed by a

meshwork of loose connective and adipose tissues and lying above the perineal membrane (Ricci et al 1947, Campbell 1950, Range and Woodburne 1964, Roberts et al 1964, Reiffstuhl 1982). The lateral attachments of the pelvic organs to the pelvic side walls are referred to as the endopelvic fascia. Considered as a unit, the connections provide a conduit for neurovascular elements passing from the pelvic side wall to the organs and serve as attachments that help to retain the pelvic organs in place, playing an important role in preventing pelvic organ prolapse in females (DeLancey 1992). They are associated with loose connective tissue that extends to the midline, separating the bladder from the vagina and the vagina from the rectum in the female, and separating the bladder, prostate and seminal glands from the rectum in the male. The fasciae contain different amounts of connective tissue and smooth muscle: where they are either unusually dense or form visible ridges, they are called 'ligaments' (e.g. cardinal ligament, uterosacral ligament). Clinically, these lateral attachments are often referred to as visceral 'ligaments', but they are quite unlike the bands of dense, regular connective tissue that typify skeletal ligaments. Their lateral attachments sweep off the pelvic walls, arising from the superior fascia over levator ani and from part of the piriformis fascia more superiorly and posteriorly. The ligaments passing to the urinary bladder in the male, or the bladder and proximal vagina and uterus in the female, are relatively long, but these lateral connections become shorter towards the pelvic outlet, until at the level of the perineal membrane there is a direct connection between the organs and the pelvic walls.

In the female, the cardinal ligament surrounds the uterovaginal junction and extends distally to mid-vagina, where the vagina has a more direct lateral attachment at the tendinous arch of the pelvic fascia. The portions that attach to the uterus and vagina are sometimes called the parametrium and paracolpium, respectively. Further accounts of the paravisceral portions of the visceral pelvic fascia are given in the chapters describing the organs to which the fascia relates. The uterosacral ligament is a visible fold of tissue flanking the rectum as it descends posterior to the cervix in the female. It contains a considerable amount of smooth muscle near its attachment to the cervix and some of the pelvic autonomic nerves. A similar vesicosacral fold is present in the male.

Approximately 1 cm above the inferior border of the pubis and 1 cm lateral to the midline, a band of dense pelvic connective tissue, the anterior end of the tendinous arch of the pelvic fascia, is attached to either the paravaginal (female) or the prostatic (male) tissues. This band extends on the inner surface of levator ani and joins the tendinous arch of levator ani to the ischium, just above the ischial spine. The attachment of the paravaginal tissue to the pubis is sometimes called the pubo-urethral ligament, a misnomer because it is not attached to the urethra. The attachment of the anterior vaginal wall to the tendinous arch of the pelvic fascia, the paravaginal attachment, helps to provide support to the vagina, urethra and urinary bladder.

There is much less condensation of connective tissue around the rectum. A layer presumed to be a peritoneal fusion fascia is described between the rectum and either the seminal glands in the male or the vagina in the female (the rectovesical septum or rectovaginal septum, respectively): it is not connected to the rectum. The connective tissue over the longitudinal muscles of the rectum is thickened just superior to the point where it traverses levator ani and fuses with the endopelvic fascia and the anococcygeal ligament, forming a structure that is sometimes referred to as a rectosacral ligament.

Vascular supply and lymphatic drainage

The lesser pelvis contains the internal iliac arteries and veins, and the lymphatics that drain most of the pelvic viscera. The common and external iliac vessels and the lymphatics that drain the lower limb lie along the linea terminalis and in the lower retroperitoneum, but are conveniently discussed together with the vessels of the lesser pelvis. There is remarkable variation in the terminal branching pattern for the iliac vessels and no two individuals have quite the same anatomy. However, there are general patterns, and the following description will consider the common pattern.

Arteries

Common iliac artery

The abdominal aorta bifurcates into the right and left common iliac arteries anterolateral to the left side of the body of the fourth lumbar vertebra (Roberts and Krishingner 1967). These arteries diverge as they descend and they divide at the level of the sacroliac joint into external and internal iliac arteries. The external iliac artery is the principal artery of the lower limb. The internal iliac artery provides the principal supply to the walls and viscera of the pelvis, the perineum and the gluteal region.

Right common iliac artery The right common iliac artery is approximately 5 cm long. It passes obliquely across part of the bodies of the fourth and the fifth lumbar vertebrae, and is crossed anteriorly by the sympathetic rami to the pelvic plexus and, at its division into internal and external iliac arteries, by the ureter. It is covered by the parietal peritoneum, which separates it from the small intestine. Posteriorly, it is separated from the bodies of the fourth and fifth lumbar vertebrae and the intervening intervertebral disc by the right sympathetic trunk, the terminal parts of the common iliac veins and the start of the inferior vena cava, the obturator nerve, lumbosacral trunk and iliolumbar artery. Laterally, the inferior vena cava and the right common iliac vein lie superiorly and the right psoas major lies inferiorly. The left common iliac vein is medial to the proximal part of the right common iliac artery.

Left common iliac artery The left common iliac artery is shorter than the right and is approximately 4 cm long. Lying anteriorly are branches of the sympathetic trunk that contribute to the superior hypogastric plexus, the superior anorectal artery and, at its terminal bifurcation, the ureter. The sympathetic trunk, the bodies of the fourth and fifth lumbar vertebrae and the intervening intervertebral disc, the obturator nerve, lumbosacral trunk and iliolumbar artery are all posterior. The left common iliac vein is posteromedial and the left psoas major is lateral.

Branches In addition to the external iliac and internal iliac branches, each common iliac artery also gives small branches to the peritoneum, psoas major, ureter, adjacent nerves and surrounding areolar tissue. The common iliac artery occasionally gives rise to the iliolumbar artery and accessory or replaced renal arteries if the kidney is low-lying.

Internal iliac artery

Each internal iliac artery is approximately 4 cm long and begins at the common iliac bifurcation, level with the lumbosacral intervertebral disc and anterior to the sacroiliac joint (**Figs 71.5–71.6**). It descends posteriorly to the superior margin of the greater sciatic foramen, where it divides into an anterior division, which continues in the same line towards the ischial spine, and a posterior division, which passes back to the greater sciatic foramen. The anterior division primarily supplies the pelvic organs, while the posterior division primarily supplies muscles in the hip and back. The ureter and, in females, the ovary and distal end of the uterine tube, are anterior to the artery. The internal iliac vein, lumbosacral trunk and sacroiliac joint are posterior. Laterally are the external iliac vein, between the artery and psoas major, and the obturator nerve lying inferior to the vein. Medially, the parietal peritoneum and tributaries of the internal iliac vein separate the artery from the terminal ileum on the right and the sigmoid colon on the left. For details of the considerable variation in the anatomy of the internal iliac artery see Tubbs et al (2016).

In the fetus, the internal iliac artery is twice the size of the external iliac artery and is the direct continuation of the common iliac artery. The main trunk ascends on the anterior abdominal wall to the umbilicus, converging on the contralateral artery, and the two arteries run through the umbilicus to enter the umbilical cord as the umbilical arteries. At birth, when placental circulation ceases, only the pelvic segment remains patent as the internal iliac artery and part of the superior vesical artery and the remainder becomes a fibrous medial umbilical ligament. Persistence of the umbilical artery has been described and can cause extrinsic obstruction of the distal ureter (Gupta et al 1999). In males, the patent part (commonly, the superior vesical artery) usually gives off the artery to the ductus deferens.

Posterior division branches

The branches of the posterior division of the internal iliac artery are the iliolumbar, lateral sacral and superior gluteal arteries.

Iliolumbar artery The iliolumbar artery is the first branch of the posterior division of the internal iliac artery and ascends laterally anterior to the sacroiliac joint and lumbosacral trunk. It lies posterior to the obturator nerve and external iliac vessels, and reaches the medial border of psoas major, dividing behind it into the lumbar and iliac branches. The lumbar branch supplies psoas major and quadratus lumborum, and anastomoses with the fourth lumbar artery. It sends a small spinal branch through the intervertebral foramen between the fifth lumbar and first sacral vertebrae to supply radicular branches to the cauda equina. The iliac branch supplies iliacus; between the muscle and bone it anastomoses with the iliac branches of the obturator artery. A large nutrient branch enters an oblique canal in the ilium. Other branches run around the iliac crest, contribute to the supply of gluteal and abdominal muscles, and anastomose with the superior gluteal, circumflex iliac and lateral circumflex femoral arteries (see Fig. 76.4).

Lateral sacral arteries The lateral sacral arteries are usually double. If they are single, they soon divide into superior and inferior branches.

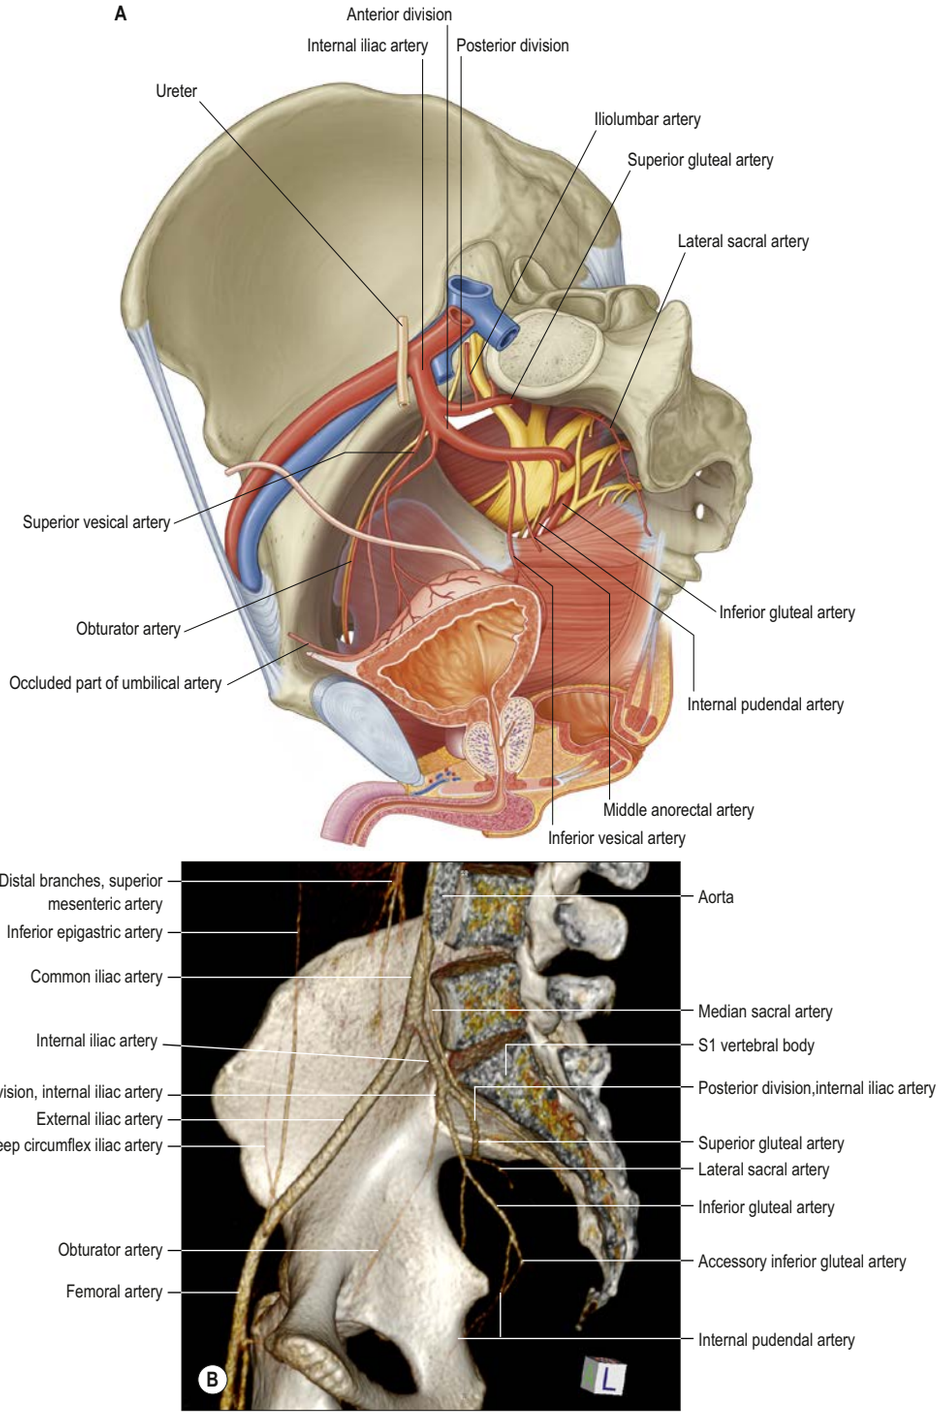

Fig. 71.5 A, Arteries of the male pelvis. **B**, Volume-rendered CT angiogram of a male pelvis. Left anterior oblique view of the right hemipelvis showing branches of the internal iliac artery. The vesical and middle anorectal branches of the anterior division are too small to be visualized.

The superior and larger branch passes medially into the first or second anterior sacral foramen, supplies the sacrum and contents of the sacral canal, and then leaves the sacrum via the corresponding posterior foramen to supply the skin and muscles posterior to the sacrum. The inferior branch crosses obliquely anterior to piriformis and the sacral anterior rami, and then descends lateral to the sympathetic trunk to anastomose with its fellow and the median sacral artery anterior to the coccyx. Its branches enter the anterior sacral foramina and are distributed in the same way as the branches of the superior artery.

Superior gluteal artery The superior gluteal artery is the largest branch of the internal iliac artery and effectively forms the main continuation of its posterior division. It runs posteriorly between the lumbosacral trunk and the first sacral ventral ramus, or between the first and second sacral ventral rami, and then turns slightly inferiorly, leaving the pelvis via the greater sciatic foramen above piriformis and dividing into superficial and deep branches. In the pelvis, it supplies piriformis, obturator internus and a nutrient artery to the ilium. The superficial branch enters the deep surface of gluteus maximus. Its numerous branches supply the muscle and anastomose with the inferior gluteal branches (see Fig. 77.47), while others perforate the tendinous medial attachment of the muscle to supply the skin over the sacrum, where they anastomose with the posterior branches of the lateral sacral arteries. The deep branch of the superior gluteal artery passes between gluteus medius and the ilium, soon dividing into superior and inferior branches. The superior branch skirts the superior border of gluteus minimus to the anterior superior iliac spine and anastomoses with the deep circumflex iliac artery and the ascending branch of the lateral circumflex femoral artery. The inferior branch runs through gluteus minimus obliquely, supplies it and gluteus medius, and anastomoses with the lateral circumflex femoral artery. A branch enters the trochanteric fossa to join the inferior gluteal artery and ascending branch of the medial circumflex femoral artery; other branches run through gluteus minimus to supply the hip joint.

The superior gluteal artery occasionally arises directly from the internal iliac artery with the inferior gluteal artery and sometimes from the internal pudendal artery.

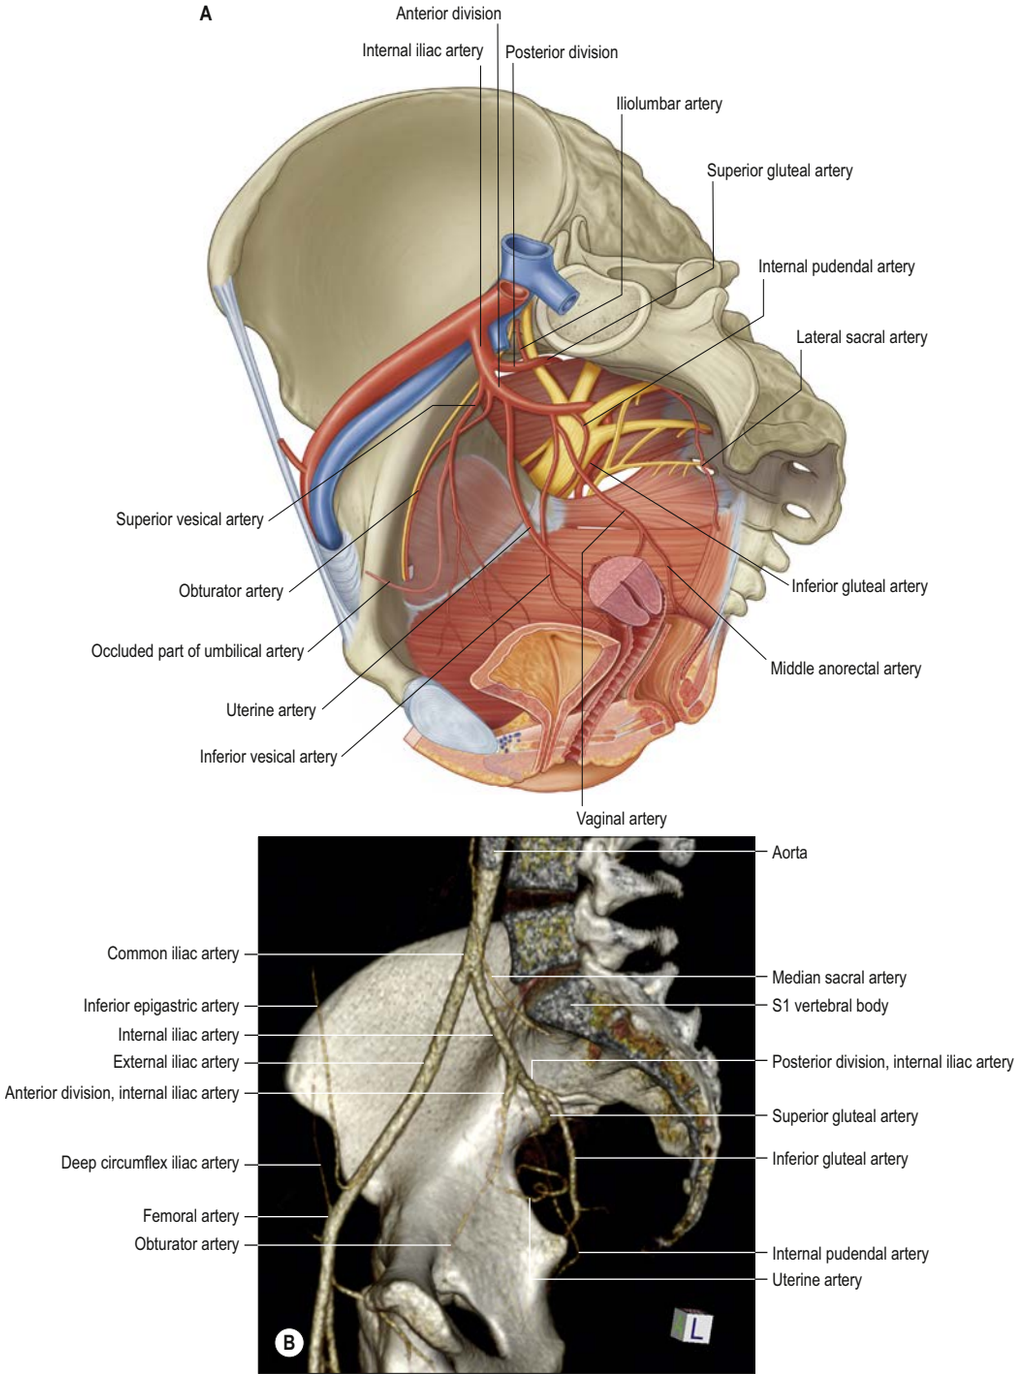

Fig. 71.6 **A**, Arteries of the female pelvis. **B**, Volume-rendered CT angiogram of a female pelvis. Left anterior oblique view of the right hemipelvis showing branches of the internal iliac artery. The vesical and inferior anorectal branches of the anterior division are too small to be visualized. Note that the middle gluteal artery arises from the posterior division as a variant.

Anterior division branches

The branches of the anterior division of the internal iliac artery are the superior and inferior vesical, middle anorectal, vaginal, obturator, uterine, internal pudendal and inferior gluteal arteries (see Fig. 71.6). There is significant variation in the branching patterns of the anterior division and therefore only the general principles will be considered here.

Superior vesical artery The superior vesical artery is the first large branch of the anterior division. It lies on the lateral wall of the pelvis, just inferior to the linea terminalis, and runs anteroinferiorly, medial to the periosteum of the posterior surface of the pubis. It supplies the distal end of the ureter, the urinary bladder, the proximal end of the ductus deferens and the seminal glands. It also gives origin to the umbilical artery in the fetus, which remains as a fibrous cord – the medial umbilical ligament – in the adult. This vessel occasionally remains patent as a small artery supplying the umbilicus.

Inferior vesical artery The inferior vesical artery sometimes arises as a common branch with the middle anorectal artery. It supplies the urinary bladder, prostate, seminal glands and ductus deferens in the male, and the urinary bladder in the female, where it is often replaced by the vaginal artery. De Treigny et al (2017) identified this vessel in roughly one half of females.

Middle anorectal artery The middle anorectal artery runs into the lateral fascial coverings of the mesorectum. It often consists of multiple branches, can be small, and occasionally arises either close to or in common with the origin of the inferior vesical artery in males.

Vaginal artery In females, the vaginal artery sometimes replaces the inferior vesical artery. It can arise from the uterine artery close to its origin as either a single vessel or multiple branches.

Obturator artery The obturator artery usually arises from the anterior division of the internal iliac artery, but it may also arise as a common branch with the iliolumbar or superior gluteal arteries, or from the external iliac artery as a separate branch or with the inferior epigastric artery (Pai et al 2009). It runs anteroinferiorly on the lateral pelvic wall to the

upper part of the obturator foramen. In the pelvis, it is related laterally to the obturator fascia and is crossed on its medial aspect by the ureter and, in the male, by the ductus deferens. The obturator nerve is superior to the artery, the obturator vein inferior to it. The obturator artery provides iliac branches to the iliac fossa that supply the underlying bone and iliacus and anastomose with the iliolumbar artery. It gives off a branch that runs medially to the urinary bladder and sometimes replaces the inferior vesical artery. In the female, the ovary lies medial to the obturator artery. A pubic branch usually arises just before the obturator artery leaves the pelvis and ascends over the pubis to anastomose with the contralateral artery and the pubic branch of the inferior epigastric artery.

The obturator artery leaves the pelvis via the obturator canal. It divides into anterior and posterior branches that encircle the obturator foramen between obturator externus and the obturator membrane. The anterior branch curves anteriorly on the membrane and then inferiorly along its anterior margin to supply branches to obturator externus, pectineus, adductors longus, brevis and magnus and gracilis. It anastomoses with the posterior branch and the medial circumflex femoral artery. The posterior branch follows the posterior margin of the obturator foramen, turning anteriorly on the ischial part to anastomose with the anterior branch. It supplies the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal artery. An acetabular branch enters the hip joint at the acetabular notch, ramifies in the fat of the acetabular fossa and sends a branch along the ligament of the head of the femur.

The obturator artery is occasionally replaced by an enlarged pubic branch of the inferior epigastric artery that descends almost vertically to the obturator foramen. It usually lies near the external iliac vein, lateral to the femoral ring, and is rarely injured during inguinal or femoral hernia surgery. It may curve along the edge of the lacunar ligament, partly encircling the neck of a hernia sac, and can be cut inadvertently during enlargement of the femoral ring in reducing a femoral hernia.

Uterine artery The uterine artery is large. It usually arises inferior to the obturator artery on the lateral wall of the pelvis, running inferomedially within the cardinal ligament. It may arise directly from the internal iliac artery, the superior gluteal artery, obturator artery or from a common trunk with the internal pudendal artery (Chantalat et al 2014).

Internal pudendal artery (pelvic portion) The internal pudendal artery is the smaller terminal branch of the anterior division of the internal iliac artery. Close to its origin it crosses anterior to piriformis, the sacral plexus and the inferior gluteal artery. It descends laterally to the inferior aspect of the greater sciatic foramen, where it leaves the pelvis between piriformis and ischiococcygeus and enters the gluteal region (see Fig. 75.3B). It next curves around the posterior aspect of the ischial spine and enters the ischio-anal fossa via the lesser sciatic foramen. This course effectively allows the nerve to wrap around the posterior limit of levator ani at its attachment to the ischial spine. Posterior to the ischial spine the artery is covered by gluteus maximus, the pudendal nerve is medial and the nerve to obturator internus is lateral. The artery passes through the ischio-anal fossa in the pudendal canal (Alcock's canal) in the fascia covering obturator internus, giving off the inferior anorectal artery early in its course through the fossa (see Fig. 71.12). It gives off several muscular branches in the pelvis and the gluteal region to supply adjacent muscles and nerves.

Inferior gluteal artery The inferior gluteal artery is the larger terminal branch of the anterior division of the internal iliac artery. It descends posteriorly, anterior to the sacral plexus and piriformis but posterior to the internal pudendal artery. It passes between either the first and second, or the second and third, sacral ventral rami, then between piriformis and ischiococcygeus, before running through the inferior aspect of the greater sciatic foramen to reach the gluteal region. It next runs inferiorly with the sciatic and posterior femoral cutaneous nerves, deep to gluteus maximus and between the greater trochanter and ischial tuberosity, and continues down the thigh, supplying the skin and anastomosing with branches of the perforating arteries. The inferior gluteal and internal pudendal arteries often arise as a common stem from the internal iliac artery, sometimes with the superior gluteal artery. In the pelvis, the inferior gluteal artery gives branches to piriformis, ischiococcygeus and iliococcygeus, and occasionally gives rise to the middle anorectal artery. It can supply vessels to the seminal glands and prostate.

External iliac artery

The external iliac arteries are larger than the internal iliac arteries (see Figs 71.5–71.6). Each artery descends laterally along the medial border of psoas major, from the common iliac bifurcation to a point midway between the anterior superior iliac spine and the pubic symphysis, and enters the thigh posterior to the inguinal ligament to become the femoral artery.

The parietal peritoneum and extraperitoneal tissues separate the right external iliac artery from the terminal ileum and, usually, the appendix, and the left external iliac artery from the sigmoid colon and coils of small intestine anteromedially. The external iliac artery can be crossed at its origin by the ureter and it is subsequently crossed by the gonadal vessels, the genital branch of the genitofemoral nerve, the deep circumflex iliac vein, and the ductus deferens or round ligament of the uterus. Posteriorly, the artery is separated from the medial border of psoas major by the iliac fascia. The external iliac vein lies partly posterior to its upper part but is more medial below. Laterally, it is related to psoas major, which is covered by the iliac and psoas fasciae. Numerous lymph vessels and nodes lie on its anterior and lateral aspects. The external iliac artery primarily supplies the lower limb and as such has few branches in the pelvis. It gives off very small vessels to psoas major and neighbouring lymph nodes, but has no other branches until it gives off the deep circumflex iliac and inferior epigastric arteries, near to where it passes deep to the inguinal ligament.

Deep circumflex iliac artery The deep circumflex iliac artery branches laterally from the external iliac artery almost opposite the origin of the inferior epigastric artery (see Fig. 76.4). It ascends and runs laterally to the anterior superior iliac spine deep to the inguinal ligament in a sheath formed by the union of the transversalis and iliac fasciae. There, it anastomoses with the ascending branch of the lateral circumflex femoral artery, pierces the transversalis fascia and skirts the inner lip of the iliac crest. About halfway along the iliac crest, it runs through transversus abdominis, and then between transversus abdominis and internal abdominal oblique, to anastomose with the iliolumbar and superior gluteal arteries. It gives off a large ascending branch at the anterior superior iliac spine that runs between internal abdominal oblique and transversus abdominis, supplies both muscles, and anastomoses with the lumbar and inferior epigastric arteries.

Inferior epigastric artery The inferior epigastric artery originates from the external iliac artery posterior to the inguinal ligament. It curves forwards in the anterior extraperitoneal tissue, ascends obliquely along the medial margin of the deep inguinal ring and continues as an artery of the anterior abdominal wall.

Veins

The lesser pelvis contains a large number of veins that drain the pelvic walls and most of the viscera contained within the lesser pelvis, and also carry venous blood from the gluteal region, hip and thigh. The external iliac veins, which lie close to the linea terminalis, carry the venous drainage from most of the lower limb. The major veins draining the pelvis frequently follow their named arterial counterparts, while the small tributaries exhibit considerable inter-individual variation.

Common iliac vein

The common iliac vein is formed by the union of the external and internal iliac veins, anterior to the sacroiliac joints (see Fig. 76.8). It ascends obliquely to end at the right side of the fifth lumbar vertebra, uniting at an acute angle with the contralateral vessel to form the inferior vena cava. The right common iliac vein is shorter and more nearly vertical, lying posterior and then lateral to its artery; the right obturator nerve passes posteriorly. The left common iliac vein is longer and more oblique and lies first medial, then posterior, to its artery. It is crossed anteriorly by the attachment of the sigmoid mesocolon and superior anorectal vessels. Each vein receives iliolumbar and, sometimes, lateral sacral veins. The left common iliac vein usually drains the median sacral vein. There are no valves in these veins.

The left common iliac vein occasionally ascends to the left of the aorta to the level of the kidney, where it receives the left renal vein and then crosses anterior to the aorta to join the inferior vena cava; this vessel represents the persistent caudal half of the left postcardinal or supracardinal vein.

Median sacral veins The right and left median sacral veins accompany the corresponding arteries anterior to the sacrum, where they unite to form a single vein that usually ends in the left common iliac vein, but sometimes ends at the common iliac junction.

Internal pudendal veins The internal pudendal veins are venae comitantes of the internal pudendal artery and unite as a single vessel that drains into the internal iliac vein. They receive veins from the inferior anorectal veins and either the bulb of the penis and scrotum, or the clitoris and labia.

Internal iliac vein

The internal iliac vein is formed by the convergence of several veins above the greater sciatic foramen. It does not have the predictable trunks and branches of the internal iliac artery but its tributaries drain the same territories. It ascends posteromedial to the internal iliac artery to join

The anteroposterior diameters of the common, external and internal iliac arteries are strongly correlated to body surface area (BSA) in children, in contrast to adults, where the relation is inconsistent. Vessel diameters measured by ultrasonography are significantly larger in boys than in girls. The relationship between vessel diameters and BSA is shown in Fig. 71.7 (Munk et al 2002).

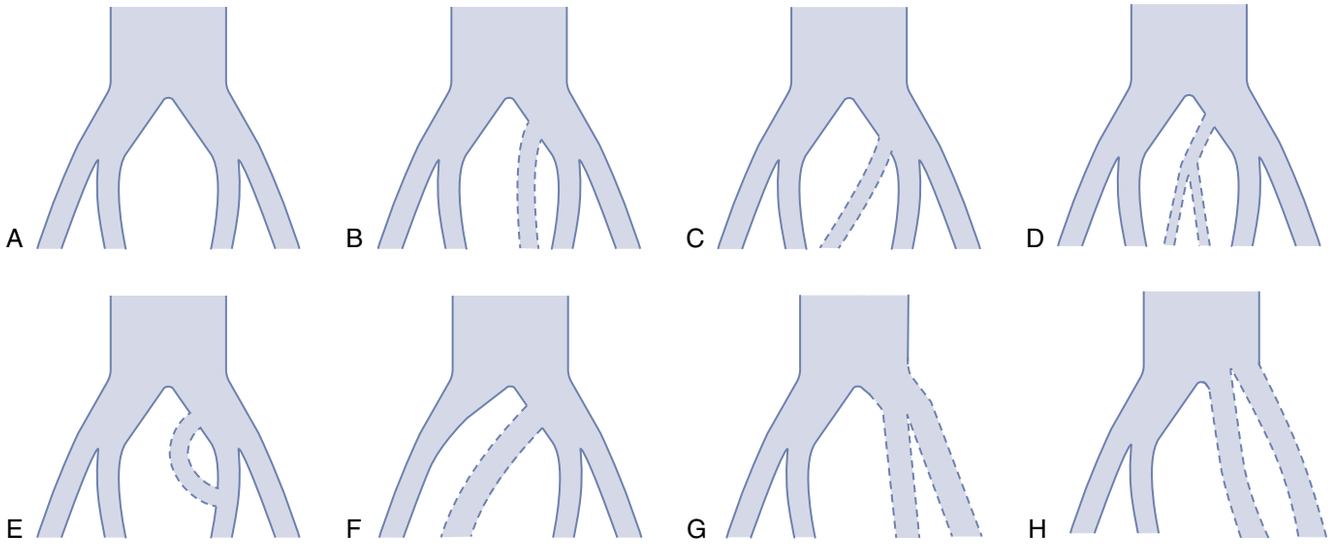

Fig. 71.7 The relations between anteroposterior diameters of the right common, internal and external iliac arteries and body surface area (BSA) in boys and girls between the ages of 1 and 16 years. (Redrawn from DePietro DM, Carlon T, Trerotola SO, Sudheendra D. Endovascular Treatment of an Anatomically Complex Iliac Lesion and a Review of Variant Iliac Venous Anatomy. J Vasc Interv Radiol. 2020;31(2):260–264.)

the external iliac vein, forming the common iliac vein at the linea terminalis, anterior to the lower part of the sacroiliac joint. It is covered anteromedially by parietal peritoneum. Its tributaries are the gluteal, internal pudendal and obturator veins, which originate outside the pelvis; the lateral sacral veins, which run from the anterior surface of the sacrum; and the middle anorectal, vesical, uterine and vaginal veins, which originate in the venous plexuses of the pelvic viscera (Fig. 71.8).

The venous drainage of the leg can be blocked by thrombosis involving the external iliac systems and the inferior vena cava. Under these circumstances, the pelvic veins, particularly the internal iliac tributaries, enlarge and provide a major avenue of venous return from the femoral system. Surgical interference with these veins can seriously compromise venous drainage and precipitate oedema of one or both lower limbs.

Superior gluteal veins The superior gluteal veins are the venae comitantes of the superior gluteal artery. They receive tributaries that correspond to the branches of the superior gluteal artery and enter the pelvis via the greater sciatic foramen, superior to piriformis. They join the internal iliac vein, frequently as a single trunk.

Inferior gluteal veins The inferior gluteal veins are venae comitantes of the inferior gluteal artery. They begin proximally and posteriorly in the thigh, where they anastomose with the medial circumflex femoral and first perforating veins, and they enter the pelvis low in the greater sciatic foramen, joining to form a vessel that opens into the distal part of the internal iliac vein. The inferior gluteal and superficial gluteal veins connect by perforating veins (Doyle 1970). The gluteal veins probably have a venous 'pumping' role, and provide collaterals between the femoral and internal iliac veins.

Obturator vein The obturator vein begins in the proximal adductor region and enters the pelvis via the obturator foramen. It runs posteriorly and superiorly on the lateral pelvic wall below the obturator artery and between the ureter and internal iliac artery, and ends in the internal iliac vein. It is sometimes replaced by an enlarged pubic vein that joins the external iliac or the inferior epigastric veins (Sanna et al 2018).

Lateral sacral veins The lateral sacral veins accompany the lateral sacral arteries and are interconnected by a sacral venous plexus.

Middle anorectal vein The middle anorectal vein begins in the anorectal venous plexus and drains the rectum and mesorectum. Variable in size, it runs laterally on the pelvic surface of levator ani to end in the internal iliac vein. The middle anorectal vein often receives tributaries from the urinary bladder and either the prostate and seminal gland or the posterior aspect of the vagina.

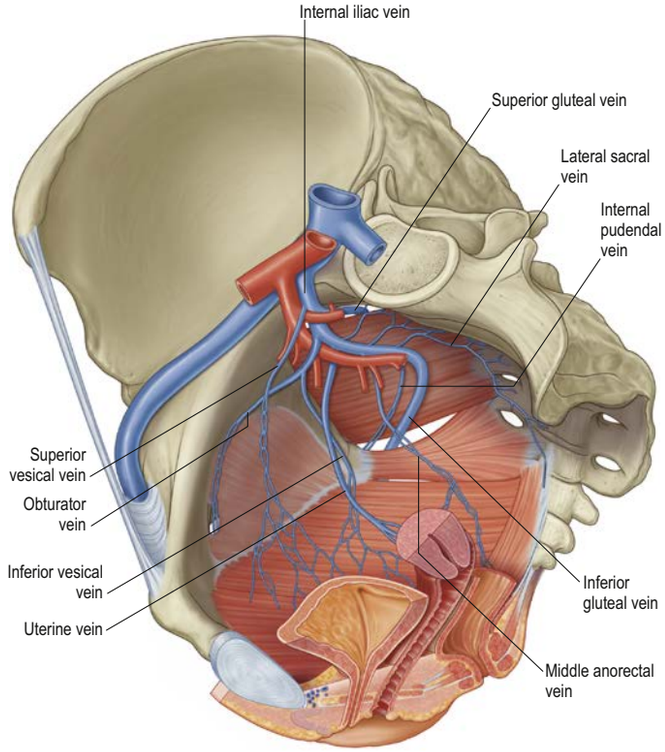

Fig. 71.8 Veins of the female pelvis.

External iliac vein

The external iliac vein is the proximal continuation of the femoral vein (see Figs 76.8, 77.49). It begins posterior to the inguinal ligament, ascends along the linea terminalis and ends anterior to the sacroiliac joint by joining the internal iliac vein to form the common iliac vein. On the right it lies medial to the external iliac artery, gradually inclining behind it as it ascends. On the left it is wholly medial. Disease of the external iliac artery can cause it to adhere closely to the vein at the point where it is in contact, and, particularly on the right side, the walls of the vessels can become fused, making dissection hazardous. The external iliac vein is crossed medially by the ureter and internal iliac artery and by the ductus deferens (males) or the round ligament of the uterus and ovarian vessels (females). Psoas major lies laterally, except where the artery intervenes. The vein is usually valveless but sometimes contains a single valve. Its tributaries are the inferior epigastric, deep circumflex iliac and pubic veins. Agenesis of the external iliac vein has been reported in association with Klippel–Trenaunay syndrome (Doğan et al 2003).

Inferior epigastric vein One or two inferior epigastric veins accompany the inferior epigastric artery and drain into the external iliac vein just proximal to the inguinal ligament.

Deep circumflex iliac vein The deep circumflex iliac vein is formed from venae comitantes of the corresponding artery. It joins the external iliac vein a little above the inferior epigastric vein after crossing anterior to the external iliac artery.

Pubic vein The pubic vein connects the external iliac and obturator veins. It ascends on the pelvic surface of the pubis with the pubic branch of the inferior epigastric artery and occasionally replaces the normal obturator vein.

Lymphatic drainage

The lymph nodes in the pelvis are grouped around the common, external iliac and internal iliac vessels and are named accordingly (Nesselrod 1936).

Common iliac nodes

The common iliac nodes drain both internal and external iliac nodes and therefore receive the entire lymphatic drainage of the lower limb. They usually lie in medial, lateral and anterior chains around the common iliac artery, the lateral chain constituting the main route. One or two nodes lie inferior to the aortic bifurcation and anterior to the fifth lumbar vertebra or sacral promontory. The common iliac nodes drain to the lateral aortic nodes.

External iliac nodes

The external iliac nodes usually form three subgroups, lateral, medial and anterior to the external iliac vessels (see Fig. 75.3B). The medial nodes are considered the main channel of drainage, collecting lymph from the lower limb via the inguinal nodes, the deeper layers of the infra-umbilical abdominal wall, the medial compartment of the thigh, the glans penis or clitoris, the membranous urethra, prostate, fundus of the bladder, cervix of the uterus and proximal vagina. Their efferents pass to the common iliac nodes.

Inferior epigastric and circumflex iliac nodes The inferior epigastric and circumflex iliac nodes are associated with their similarly named vessels and drain the corresponding areas to the external iliac nodes.

Internal iliac nodes

The internal iliac nodes surround the branches of the internal iliac vessels. They receive afferents from most of the pelvic viscera (with the exception of the gonads and most of the rectum), the deeper parts of the perineum and the gluteal and posterior thigh muscles, and drain to the common iliac nodes. The individual groups are considered in the description of the viscera. There are frequent connections between the right and left groups, particularly when they lie close to the anterior and posterior midlines (Fig. 71.9).

Innervation

The pelvis contains the lumbosacral trunk, the sacral and coccygeal plexuses and the pelvic parts of the sympathetic and parasympathetic systems. Collectively, these nerves carry the somatic and autonomic innervation to most of the pelvic organs, and to the muscles of the pelvic diaphragm and perineum, the gluteal region and the lower limb.

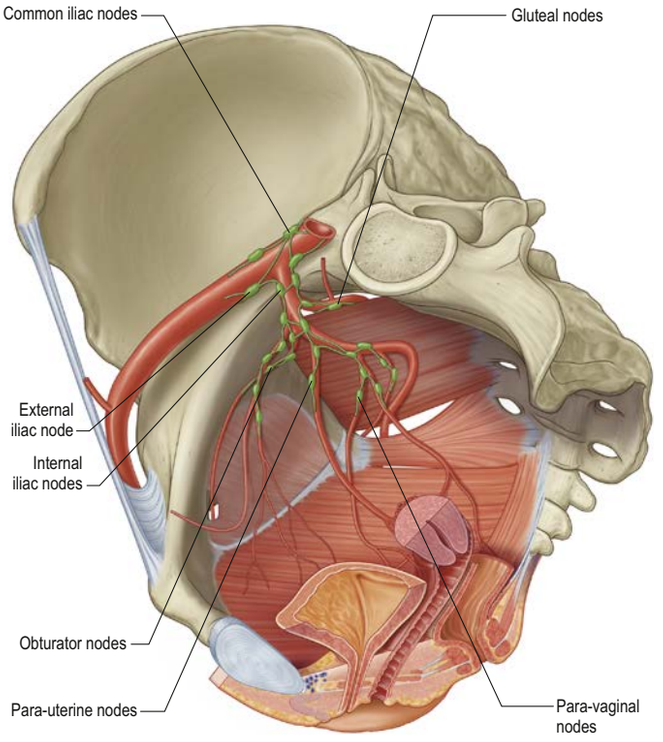

Fig. 71.9 Lymphatic drainage of the female pelvis and urinary bladder.

The ventral rami of the sacral and coccygeal spinal nerves form the sacral and coccygeal plexuses (Fig. 71.10). The upper four sacral ventral rami enter the pelvis via the anterior sacral foramina, the fifth enters between the sacrum and coccyx, and the ventral ramus of the coccygeal nerve curves anteriorly and inferior to the rudimentary transverse process of the first coccygeal segment. The first and second sacral ventral rami are large, the third to fifth diminish progressively in size, and the coccygeal ventral ramus is the smallest. Each receives a grey ramus communicans from a corresponding sympathetic ganglion. Preganglionic parasympathetic fibres leave the second to fourth sacral ventral rami as the pelvic splanchnic nerves and continue to minute ganglia in the walls of the pelvic viscera.

Lumbosacral trunk and sacral plexus

The sacral plexus is formed by the lumbosacral trunk, the first to third sacral ventral rami, and part of the fourth sacral ventral ramus (the remainder of the fourth sacral ventral ramus joins the coccygeal plexus).

The lumbar part of the lumbosacral trunk contains part of the fourth and all of the fifth lumbar ventral rami; it appears at the medial margin of psoas major and descends over the linea terminalis, at first medial to and then distally crossing anterior to the sacroiliac joint, to join the first sacral ventral ramus. The greater parts of the second and third sacral rami converge on the inferomedial aspect of the lumbosacral trunk in the greater sciatic foramen to form the sciatic nerve. The ventral and dorsal divisions of the nerves do not separate physically from each other but their fibres remain separate within the rami; the ventral and dorsal divisions of each contributing root join within the sciatic nerve. The fibres of the dorsal divisions will go on to form the common fibular nerve, and the fibres of the ventral division form the tibial nerve. Occasionally, the sciatic nerve divides into common fibular and tibial nerves inside the pelvis; when this occurs, the common fibular nerve usually runs through piriformis.

The sacral plexus lies against the posterior pelvic wall anterior to piriformis, posterior to the internal iliac vessels and ureter, and posterior to the sigmoid colon on the left. The superior gluteal vessels run either between the lumbosacral trunk and first sacral ventral ramus, or between the first and second sacral anterior rami, while the inferior gluteal vessels lie between either the first and second, or the second and third, sacral ventral rami.

The sacral plexus is not commonly involved in malignant tumours of the pelvis because it lies behind the relatively dense presacral fascia, which resists all but locally very advanced malignant infiltration. When it occurs, there is intractable pain in the distribution of the branches of the plexus, which can be very difficult to treat. The plexus can also be involved in reticuloses or be affected by plexiform neuromas.

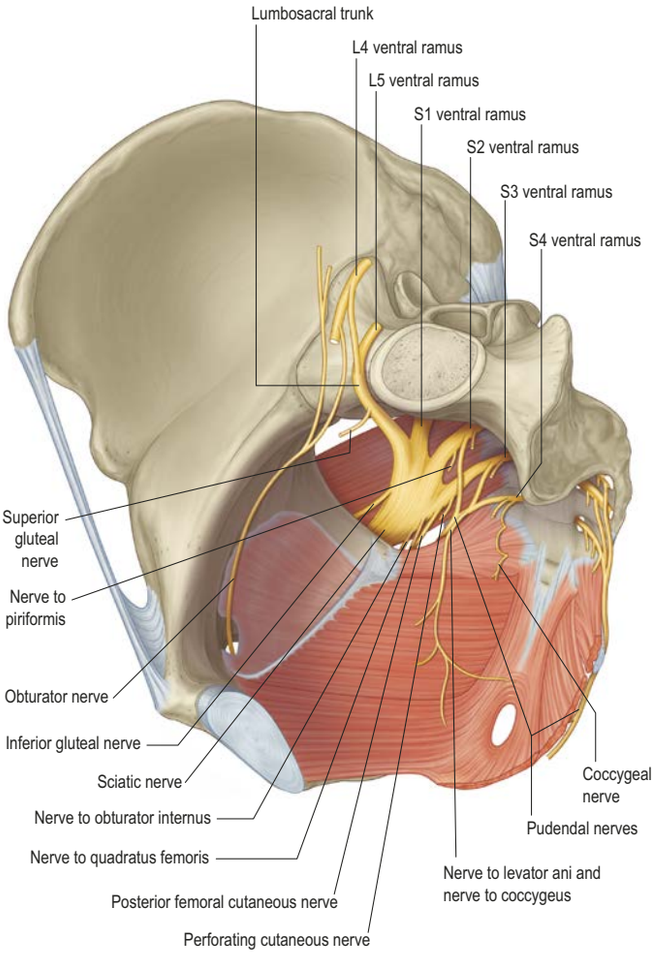

Fig. 71.10 The lumbosacral plexus in the pelvis.

TABLE 71.1 Branches of the sacral plexus

Nerve	Ventral divisions	Dorsal divisions
Nerve to quadratus femoris	L4, L5, S1	
Nerve to obturator internus	L5, S1, S2	
Nerve to piriformis		S1, S2 and direct branches from superior gluteal nerve
Superior gluteal nerve		L4, L5, S1
Inferior gluteal nerve		L5, S1, S2
Posterior femoral cutaneous nerve	S2, S3	S1, S2
Tibial nerve (sciatic nerve)	L4, L5, S1, S2, S3	
Common fibular nerve (sciatic nerve)		L4, L5, S1, S2
Perforating cutaneous nerve		S2, S3
Pudendal nerve	S2, S3, S4	
Nerves to levator ani	S4	

Branches of the sacral plexus

The branches of the sacral plexus are shown in Table 71.1.

The course and distribution of most of these branches are covered fully in Section 9 and in Chapter 80.

Pudendal nerve (in the pelvis)

The pudendal nerve arises from the ventral divisions of the second, third and fourth sacral ventral rami and is formed just above the superior border of the sacrotuberous ligament and the upper fibres of ischiococcygeus (Klink 1953, Sato 1980). It leaves the pelvis via the greater sciatic foramen between piriformis and ischiococcygeus (see Fig. 71.10), enters the gluteal region and passes dorsal to the sacrospinous ligament, close to its attachment to the ischial spine, where it lies medial to the internal pudendal vessels. It accompanies the internal pudendal artery through the lesser sciatic foramen into the pudendal canal on the lateral wall of the ischio-anal fossa. In the posterior part of the canal, it gives rise to the inferior anal and perineal nerves; the dorsal nerve of the penis or clitoris continues anteriorly from this origin.

Sacral visceral branches

Visceral branches, the pelvic splanchnic nerves, arise from the second to fourth sacral ventral rami and innervate the pelvic viscera.

Sacral muscular branches

Several muscular branches arise from the fourth sacral ventral ramus to supply the superior surface of levator ani and the upper part of the external anal sphincter. The branches to levator ani enter the superior surface of the muscle. The branch to the external anal sphincter (also referred to as the perineal branch of the fourth sacral nerve) reaches the ischio-anal fossa by running either through ischiococcygeus or between ischiococcygeus and iliococcygeus: it also supplies the skin between the anus and coccyx.

Coccygeal plexus

The coccygeal plexus is formed by a small descending branch from the fourth sacral ventral ramus and by the fifth sacral and coccygeal ventral rami. The fifth sacral ventral ramus emerges from the sacral hiatus, curves round the lateral margin of the sacrum inferior to its cornu, and pierces ischiococcygeus inferiorly to reach its pelvic surface. Here it is joined by a descending branch of the fourth sacral ventral ramus; the small trunk so formed descends on the pelvic surface of ischiococcygeus, joins the minute coccygeal ventral ramus that emerges from the sacral hiatus, and curves round the lateral coccygeal margin, piercing ischiococcygeus to reach the pelvis. The small trunk that is formed in this way is the coccygeal plexus. Anococcygeal nerves arise from it and form a few fine filaments that pierce the sacrotuberous ligament to supply the adjacent skin.

Pelvic part of the sympathetic system

The pelvic sympathetic trunk lies in the extraperitoneal tissue, anterior to the sacrum beneath the presacral fascia (Fig. 71.11), and supplies the pelvic organs and vascular system. It lies medial or anterior to the anterior sacral foramina and has four or five interconnected ganglia. Superiorly, it is continuous with the lumbar sympathetic trunk. The right and left trunks converge distal to the most inferior ganglia and unite in the small ganglion impar anterior to the coccyx. Grey rami communicantes pass from the ganglia to sacral and coccygeal spinal nerves; there are no white rami communicantes. Medial branches connect across the midline, and twigs from the first two ganglia join the inferior hypogastric plexus or the hypogastric nerve. Other branches form a plexus on the median sacral artery.

Vascular branches

Preganglionic fibres for the vessels supplying the pelvis and lower limb are derived from the lower three thoracic and upper two or three lumbar spinal cord segments. They reach the lower thoracic and upper lumbar ganglia through white rami communicantes and descend through the sympathetic trunk to synapse in the lumbar ganglia. Postganglionic fibres pass from these ganglia via grey rami communicantes to the second, third and fourth lumbar ventral rami and then to the femoral nerve, which carries them to the femoral artery and its branches. Some fibres descend through the lumbar ganglia to synapse in the upper two or three sacral ganglia, from which postganglionic axons pass through grey rami communicantes to the roots of the sacral plexus. Those in the pudendal and superior and inferior gluteal nerves accompany the arteries of the same name to the gluteal and perineal tissues; branches can also supply the pelvic nodes. Those joining the tibial nerve are carried to the popliteal artery and are distributed via its branches to the leg and foot.

Sympathetic denervation of vessels in the lower limb is used, rarely, for treating vascular insufficiency of the lower limb; it can be effected by removing or ablating the upper three lumbar sympathetic ganglia and the intervening parts of the sympathetic trunk.

PERINEUM

Anal and urogenital triangles

The perineum is an approximately diamond-shaped region that lies inferior to levator ani, between the medial aspects of the thighs and anterior to the sacrum and coccyx. It is usually described as if from the position of an individual lying supine with the hips abducted and partially flexed. The surface projection of the perineum and the form of the skin covering it vary considerably, depending on the position of the thighs, whereas the deep tissues themselves occupy relatively fixed positions. The perineum is bounded anteriorly by the pubic symphysis and its inferior pubic ligament, posteriorly by the coccyx, anterolaterally by the ischiopubic rami and the ischial tuberosities, and posterolaterally by the sacrotuberous

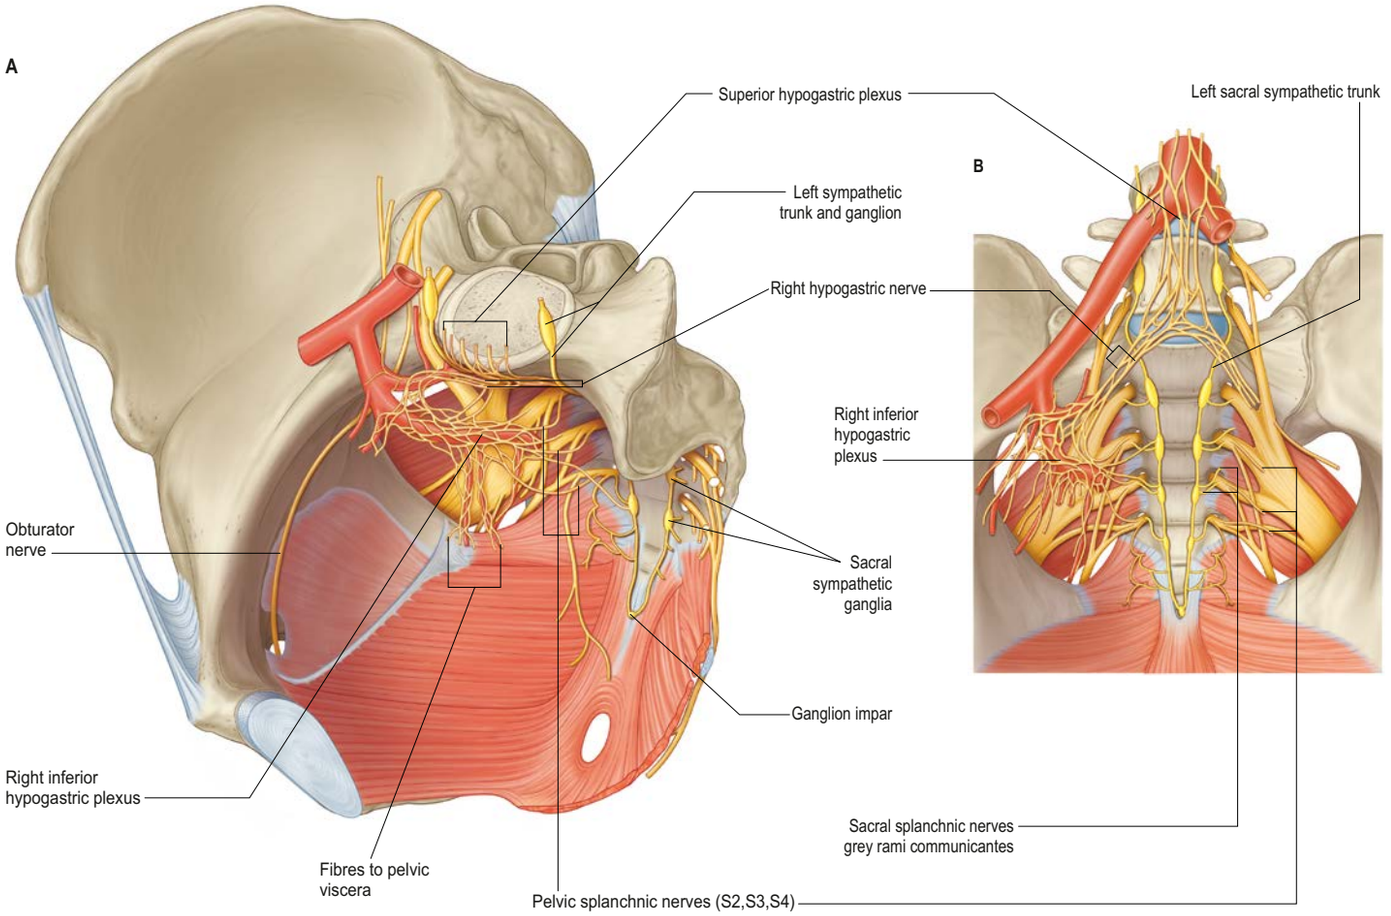

Fig. 71.11 Autonomic nerves of the pelvis.

ligaments. The deep limit of the perineum is the inferior surface of the pelvic diaphragm. The superficial limit is the skin that is continuous with the skin over the medial aspect of the thighs and the lower abdominal wall. An arbitrary line joining the ischial tuberosities (the inter-ischial line) divides the perineum into an anterior urogenital triangle and a posterior anal triangle. The urogenital triangle faces inferiorly and anteriorly, whereas the anal triangle faces inferiorly and posteriorly at an approximate angle of 120° from the plane of the urogenital triangle.

The male urogenital triangle contains the root of the penis (**Fig. 71.12**) (Ch. 74), and the female urogenital triangle contains the mons pubis, the labia majora and minora, the clitoris, the vaginal orifice and the external urethral orifice (Ch. 75).

Anal triangle

The structure of the anal triangle is similar in males and females, the main difference being that in females the wider transverse dimension of the triangle is associated with giving birth. The anal triangle is lined by superficial and deep fasciae and contains the anal canal and its sphincters, and the ischio-anal fossa and its contained nerves and vessels.

Superficial fascia of the anal triangle

The superficial fascia (subcutaneous tissue) of the region is thin and is continuous with the superficial/subcutaneous fascia of the skin of the perineum, thighs and buttocks.

Deep fascia of the anal triangle

The deep fascia lines the inferior surface of levator ani and is continuous at its lateral origin with the fascia over obturator internus below the attachment of levator ani. It lines the proximal portion of the ischio-anal fossa and its lateral walls.

Ischio-anal fossa

The ischio-anal fossa is an approximately horseshoe-shaped region filling most of the anal triangle. It is filled with loose adipose tissue and blood vessels and nerves (see Fig. 71.12). The 'arms' of the horseshoe are triangular in cross-section because levator ani slopes medially from its lateral pelvic origin towards the anorectal junction (see Fig. 65.44). The anal canal and its sphincters lie in the centre of the horseshoe. Above them, the medial limit of the fossa is formed by the deep fascia over levator ani. The outer boundary of the fossa is formed anterolaterally by the fascia over obturator internus and the periosteum of the ischial tuberosities. Posterolaterally, the outer boundary is formed by the inferior border of gluteus maximus and the sacrotuberous ligament.

An anterior recess of the ischio-anal fossa lies cranial to the perineal membrane and transverse perineal muscles and extends anteriorly as far as the posterior surface of the pubis, below the attachment of levator ani. Posteriorly, the fossa contains the attachment of the external anal sphincter to the distal end of the coccyx; above and below this, the adipose tissue of the fossa is uninterrupted across the midline. These continuations of the ischio-anal fossa allow infections, tumours and fluid collections within them to enlarge relatively freely to the side of the anal canal, and also to spread with little resistance to the contralateral side and deep to the perineal membrane. The internal pudendal vessels and accompanying nerves lie in the lateral wall of the ischio-anal fossa, enclosed in fascia forming the pudendal canal. The inferior anorectal vessels and nerves cross the fossa from the pudendal canal and often branch within it.

The ischio-anal fossa is an important surgical plane during resections of the anal canal and anorectal junction for malignancy. It provides an easy, relatively bloodless, plane of dissection that encompasses all of the muscular structures of the anal canal and leads to the inferior surface of levator ani.

External anal sphincter

The external anal sphincter is a band of striated muscle that surrounds the most inferior part of the anal canal (Oh and Kark 1972, Lawson 1974b, Dalley 1987). The most superior fibres blend with the most inferior fibres of pubo-analis; the two are seen to be contiguous on endoanal ultrasound and MRI. Anteriorly, some of these upper fibres decussate into the superficial transverse perineal muscles. Posteriorly, fibres are attached to the anococcygeal raphe. Most of the middle fibres of the external anal sphincter surround the distal part of the internal sphincter, and are attached anteriorly in the perineal body and posteriorly to the coccyx via the anococcygeal ligament. Some fibres from each side of the sphincter decussate in these areas to form a sort of commissure in the anterior and posterior midline. The anterior and posterior attachments of the external anal sphincter give the muscular tube an oval profile lying anteroposteriorly. A subcutaneous portion encircles the anal verge and creates the radial skin creases surrounding the anus. The lower fibres lie below the level of the internal anal sphincter and are separated from the lowest anal epithelium by submucosa. The thickness of the external anal sphincter is positively correlated with age in children (de la Portilla and López-Alonso 2009, Rehman et al 2011) and negatively correlated with age in males (Rociu et al 2000).

Anococcygeal ligament and iliococcygeal raphe

The anococcygeal ligament is a musculotendinous structure running between the external anal sphincter and the coccyx. The iliococcygeal raphe (the decussation of the posterior fibres of iliococcygeus) lies just superior

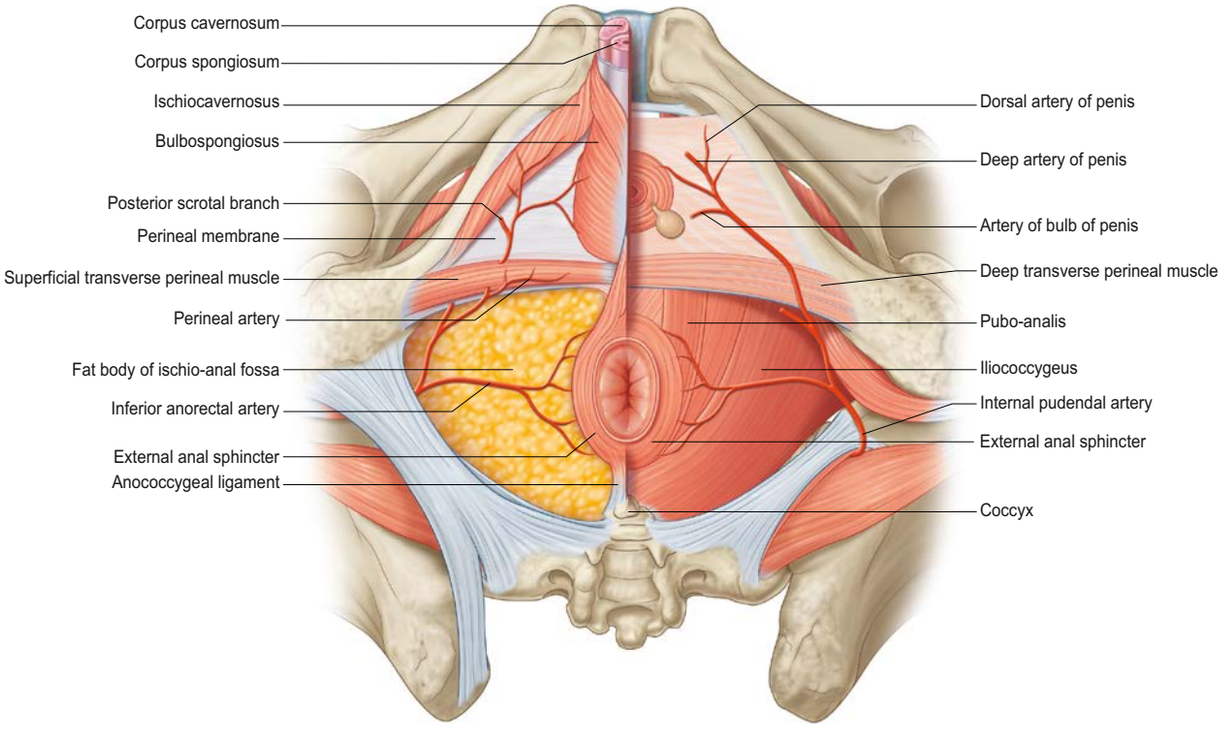

Fig. 71.12 Muscles and fasciae of the male perineum. On the left side of the figure, only the skin and superficial fascia of the perineum have been removed. The posterior scrotal branch of the perineal artery has been shown as it runs anteriorly into the scrotal tissues. On the right side, the corpora cavernosa and corpus spongiosum and their associated muscles, the superficial perineal muscles and perineal membrane have been removed to reveal the underlying deep muscles and arteries of the perineum. All veins and nerves have been omitted for clarity.

to the anococcygeal ligament and is separated from the rectum by presacral fascia: these structures are often referred to as the postanal plate. Division of the anococcygeal raphe can cause descent of the anal canal and a lowering of the posterior part of the anal triangle, but does not demonstrably interfere with the process of defecation (Kinugasa et al 2012).

Urogenital triangle

The urogenital triangle is bounded posteriorly by the inter-ischial line, which usually overlies the posterior border of the transverse perineal muscles. Anteriorly and laterally, it is bounded deeply by the pubic symphysis and ischiopubic rami. In males, the urogenital triangle extends superficially to encompass the scrotum and the root of the penis. In females, it extends to the lower limit of the labia and mons pubis. The urogenital triangle is divided into two parts by a strong perineal membrane: the deep perineal space lies superior to the membrane and the superficial perineal space lies inferior to it.

The female urogenital triangle includes muscles, fasciae, erectile structures and spaces similar to those in the male. There are some differences in size and disposition reflecting the presence of the vagina and female external genitalia.

Deep perineal space

Perineal membrane

It was once thought that the anterior pelvic outlet was spanned by a triangular, trilaminar, musculofascial structure, the urogenital diaphragm, that consisted of urogenital sphincter muscles sandwiched between two layers of fascia and connected to the perineal body, the periosteum of the ischiopubic rami and the inferior pubic ligament of the pubis, and perforated by the urethra and vagina. Oelrich introduced the alternative term 'perineal membrane' (Oelrich 1983). Detailed histological examination of serial cross-sections now supports the concept of the perineal membrane as part of a larger interconnected support apparatus with distinct posterior and anterior portions that are intimately connected with levator ani. The posterior portion is related to the support of the perineal body and lateral vaginal wall by its attachment to the ischiopubic ramus, and the anterior portion is contiguous with the urethral supportive apparatus (Stein and DeLancey 2008). The perineal membrane is particularly thick where it is attached to the inferior pubic ligament, and is here referred to as the transverse perineal ligament. The posterior border of the perineal membrane is continuous with the deep part of the perineal body at its posterior margin and is continuous with the fascia over the superficial transverse perineal muscles.

In the male, the perineal membrane is crossed by the urethra, which traverses it 2–3 cm behind the inferior border of the pubic symphysis; the vessels and nerves to the root of the penis; the ducts of the bulbourethral glands; the deep dorsal vessels and dorsal nerves of the penis, behind the pubic arch in the midline; and the posterior scrotal vessels and nerves, anterior to the transverse perinei.

In the female, the perineal membrane is divided almost into two halves by the vagina and urethra, such that it forms a triangle on each side of these structures. The lateral margins of the vagina are attached to the perineal membrane at the level of the hymenal ring, and levator ani lies on its cranial surface. The ducts of the greater vestibular glands (Bartholin's glands) are at this level in the posterior lateral vaginal orifice. The deep dorsal vessels and dorsal nerves of the clitoris lie within its fibres.

Urethral sphincter mechanism

The urethral sphincter mechanism consists of both striated and smooth muscle sphincters (Oelrich 1980, 1983, Huisman 1983). The striated urogenital sphincter has an upper circular element that surrounds the urethra in the female and the apex of the prostate in the male, between the neck of the bladder and perineal membrane. In the female, at the level of the perineal membrane, it extends laterally outside the urethra in two arch-shaped bands, compressor urethrae and sphincter urethrovaginalis, which lie on the cranial surface of the perineal membrane (**Fig. 71.13**). Compressor urethrae follows the pubic arch and is attached to connective tissue in this area near the inner surface of the ischiopubic ramus. Sphincter urethrovaginalis extends caudally to surround the lateral margin of the vaginal wall. In the male, these lateral extensions are not well developed and the sphincter in this area primarily encircles the membranous urethra, forming a robust constrictor at this level. The smooth muscle sphincter consists of circularly orientated smooth muscle cells that lie between the striated sphincter and the longitudinal smooth muscle and urethral lumen and is not well developed. In children, the inner diameter of the urethral sphincter increases with age: a cutoff value of 3 mm has been reported to predict detrusor–sphincter incoordination (Kakizaki et al 2003).

Innervation The urethral sphincter mechanism extends from the perineum through the urogenital hiatus into the pelvic cavity. It is probably innervated via the perineal branch of the pudendal nerve from below, and direct branches from the sacral plexus and the pelvic splanchnic nerves from above: all of these nerves originate in the second, third and fourth sacral spinal segments.

Actions Urinary incontinence mainly affects females and is more common after vaginal deliveries. Continence is maintained by an elegantly orchestrated system of muscles and connective tissues that involves the urethral sphincters and the tissues that support them. The urethral sphincter mechanism compresses the mid-urethra in females and the membranous urethra in males, particularly when the bladder contains urine. Its location around the region of highest urethral closing pressure suggests it is important in urinary continence. At rest, activity

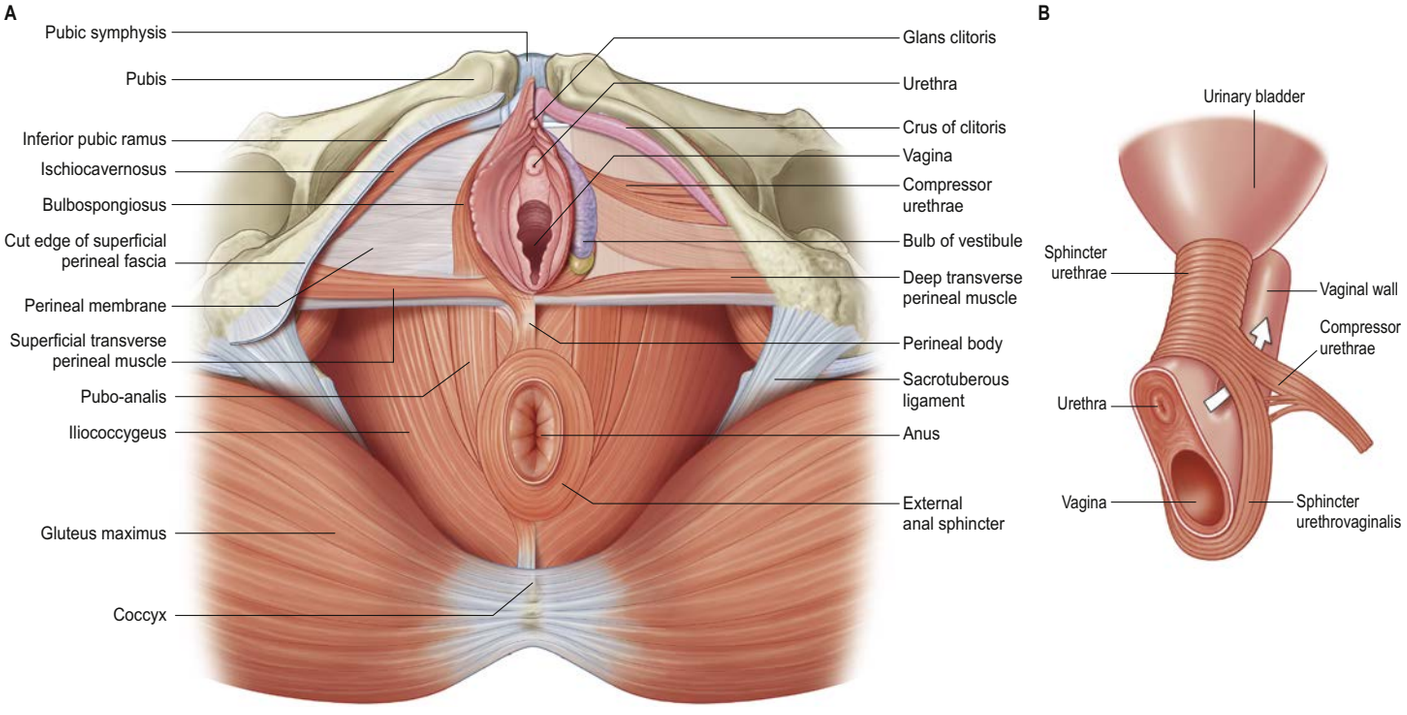

Fig. 71.13 Muscles of the female perineum. **A**, On the right side, the membranous layer of superficial fascia has been removed (note the cut edge). On the left side, superficial perineal muscles and overlying fascia have been removed to show the deep perineal muscles. **B**, The continuity of the deep perineal muscles with sphincter urethrae.

of both the smooth and striated sphincters contributes to this closure and, during times of increased need, voluntary contraction of the striated sphincter augments this closure. In the distal portion of the urethra, where it is adjacent to the perineal membrane, arch-shaped components of the striated sphincter (compressor urethrae and sphincter urethrovaginalis) pass between the urethra and pubis, and contraction compresses the lumen until it is closed. All muscles are relaxed during micturition to aid voiding: striated muscle contraction can help to expel the final drops of urine or semen from the proximal spongy urethra in the male.

During increases in abdominal pressure that occur, for example, during a cough, urinary bladder pressure rises above the urethral closure pressure that normally keeps the lumen of the urethra closed. In this situation, the urethral closure pressures that prevent urine leakage rise because the urethra is compressed against the fascial tissues that lie between it and the vaginal wall. If this layer is stable and unyielding, the urethra can be compressed closed against it, but if it is not well supported, this mechanism is less effective and leakage can occur (DeLancey 1994). Overall urinary continence during such events is a combination of sphincter contraction and pressure transmission with the former being the predominant factor (DeLancey et al 2008).

Superficial and deep perineal fasciae

Superficial perineal fascia

The superficial perineal fascia (Colles' fascia) forms a clear, surgically recognizable, subcutaneous plane of the anterior perineum (Tobin and Benjamin 1949). It is firmly attached posteriorly to the fascia over the superficial transverse perineal muscles and the posterior limit of the perineal membrane. Laterally, it is attached to the margins of the ischiopubic rami as far posteriorly as the ischial tuberosities. From here, it runs more superficially to the skin of the urogenital triangle, lining the skin of the external genitalia; in the male, it is also continuous with the fascial layer in the skin of the scrotum that contains the dartos muscle. In females, the fascia follows the same limits but is much less extensive in the labia majora. This layer runs anteriorly and superiorly into the skin of the lower abdominal wall where it is continuous with the membranous fascia (Scarpa's fascia). English-speaking anatomists refer to these tissue layers as a 'superficial fascia' but this is a misnomer; more accurately, they constitute the membranous layer of subcutaneous tissue.

Deep perineal fascia

The deep perineal fascia is a layer of fascia that overlies the superficial muscles of the perineum (bulbospongiosus, ischiocavernosus, superficial transverse perineal muscle). It is, in effect, the investing fascia of these muscles and, as such, is firmly attached to the borders of the muscles at their attachments to the ischiopubic rami, posterior margin of the perineal membrane and perineal body. Anteriorly, it fuses with the suspensory ligament of the penis or clitoris, and the fasciae of external abdominal oblique and the rectus sheath.

Subcutaneous and superficial perineal spaces

Subcutaneous perineal space

The subcutaneous perineal space lies between the deep and the superficial perineal fasciae. Under normal circumstances, these two layers are only separated by relatively thin subcutaneous connective tissue; the skin of the anterior perineum and external genitalia is relatively mobile over the deeper structures. However, this space is capable of expanding considerably in the presence of fluid accumulation; blood, urine or fluid collecting in the superficial perineal space following trauma or surgery on the urogenital triangle will spread throughout the tissues of the triangle, including the scrotum or labia majora, but cannot pass posteriorly into the anal triangle or laterally into the medial thigh because of the firm tethering of the posterior attachments of the subcutaneous fascia. Since the superficial perineal fascia is continuous with the fascia of the anterior abdominal wall, fluid, blood or purulence can also track freely between the subcutaneous tissues of the anterior abdominal wall and the subcutaneous perineal space (e.g. postsurgical haematomas of the abdominal wall readily cause discoloration of the perineal and genital skin).

Superficial perineal space

The superficial perineal space lies below the perineal membrane and is limited superficially by the deep perineal fascia (**Fig. 71.14**). It contains the corpora cavernosa and corpus spongiosum, ischiocavernosus, bulbospongiosus and the superficial transverse perineal muscles, and branches of the internal pudendal vessels and pudendal nerves. In the female, it is crossed by the urethra and vagina and contains the clitoris. In the male, it contains the spongy urethra as it runs in the root of the penis. It is a fully confined space: injuries to the contents of the space (such as bleeding into the urethra in the root of the penis) do not communicate with the subcutaneous or deep spaces unless the fascial coverings are also lacerated or breached.

Perineal body

The perineal body is an aggregation of fibromuscular tissue located in the midline at the junction between the anal and urogenital triangles, just anterior to the external anal sphincter (Oh and Kark 1973). It is attached to many structures in both the deep and superficial perineal spaces. Posteriorly, it merges with fibres from the external anal sphincter and the conjoint longitudinal coat. Superiorly, it is continuous with the rectovesical or rectovaginal septum, including fibres from levator ani (pubo-analis or pubovaginalis). Anteriorly, it receives a contribution from the deep and superficial transverse perineal muscles and bulbospongiosus (see Figs 71.4, 71.13). The perineal body is continuous with the perineal membrane and the superficial perineal fascia. Since the latter runs forwards into the skin of the perineum, the perineal body is tethered to the skin of the central perineum, which is often puckered

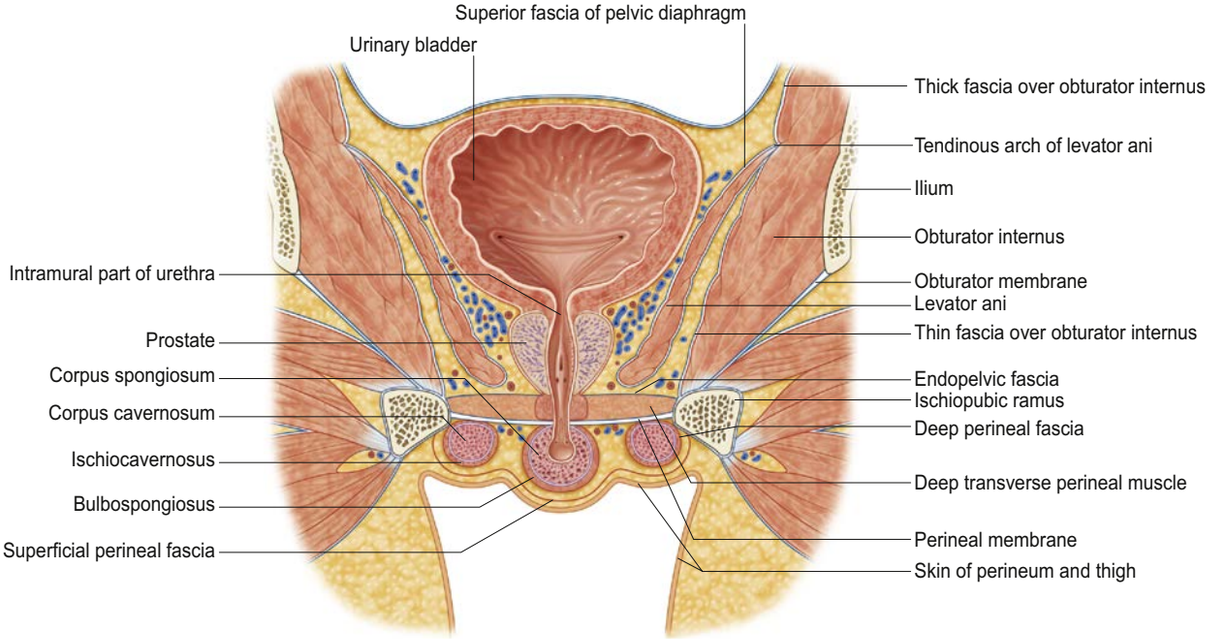

Fig. 71.14 Muscles and fasciae of the male perineum: coronal view. The section passes through the bulb of the penis at the level of the urethra. The deep perineal space is continuous with the ischio-anal fossa posteriorly. The visceral and parietal fasciae have been omitted for clarity. The pelvic fascia over the 'pelvic' aspect of the deep transverse perineal muscle is very thin and does not form a distinct layer: in places it blends with the parietal pelvic fascia over the inferior aspect of levator ani.

over it. In males, this is continuous with the raphe of the scrotum. In females, the perineal body lies directly posterior to, and is attached to, the posterior commissure of the labia majora and the vaginal orifice.

Spontaneous lacerations of the perineal body sustained during vaginal childbirth are often associated with injury to the anterior fibres of the external anal sphincter. The deliberate division of the perineal body to facilitate delivery (episiotomy) is sometimes angled laterally to avoid such sphincteric injuries. The perineal body is often used to position radiological markers in the assessment of pelvic diaphragm dysfunction.

Perineal muscles

Superficial transverse perineal muscles

The superficial transverse perineal muscles are narrow strips of muscle that run more or less transversely across the superficial perineal space anterior to the anus, from the medial and anterior aspects of the ischial tuberosities to the perineal body (see Fig. 71.13). A few fibres can also pass into the ipsilateral bulbospongiosus or external anal sphincter. They are occasionally small or even absent.

Bulbospongiosus

Bulbospongiosus differs between the sexes. In the male, it lies in the midline, anterior to the perineal body (see Fig. 71.12). It consists of two symmetric parts united by a median fibrous raphe. The fibres attach to the perineal body, in which they decussate, and to the superficial transverse perinei and the external anal sphincter; they diverge like the sides of a feather from the median raphe. A thin layer of posterior fibres joins the posterior portion of the perineal membrane. Most of the middle fibres encircle the bulb of the penis and adjacent corpus spongiosum, and attach to an aponeurosis on the dorsal surfaces. The anterior fibres spread out over the sides of the corpora cavernosa, ending partly in them, anterior to ischiocavernosus, and partly in a tendinous expansion that covers the dorsal vessels of the penis. In the female, bulbospongiosus also attaches to the perineal body, but the muscle on each side is separate and covers the superficial parts of the bulbs of the vestibule and greater vestibular glands (see Fig. 71.13). Fibres run anteriorly on either side of the vagina to attach to the corpora cavernosa of the clitoris, and a few fibres cross over the dorsum of the body of the clitoris.

Actions In the male, bulbospongiosus helps to empty the urethra of urine after the urinary bladder has emptied. It can assist in the final stage of erection as the middle fibres compress the erectile tissue of the bulb of the penis and the anterior fibres contribute by compressing the deep dorsal vein of the penis. It contracts six or seven times during ejaculation, assisting in the expulsion of semen. In the female, bulbospongiosus acts to constrict the vaginal orifice and express the secretions of the greater vestibular glands. Anterior fibres contribute to tumescence of the clitoris by compressing its deep dorsal vein.

Ischiocavernosus

In the male, ischiocavernosus covers the crus of the penis. It is attached by tendinous and muscular slips to the medial aspect of the ischial tuberosity posteriorly, and to the ischial ramus on both sides of the crus (see Fig. 71.12). These fibres end in an aponeurosis that is attached to the sides and undersurface of the crus of the penis. In the female, ischiocavernosus is related to the crus of the clitoris but is otherwise similar to the corresponding muscle in the male (**Figs 71.15–71.16**).

Actions Ischiocavernosus compresses the crus of the penis and can help to maintain penile erection. The two muscles form the urogenital triangle with the superficial transverse perineal muscles posteriorly. When contracted, the two ischiocavernosi act together to stabilize the erect penis. In the female, ischiocavernosus can help to promote tumescence of the clitoris.

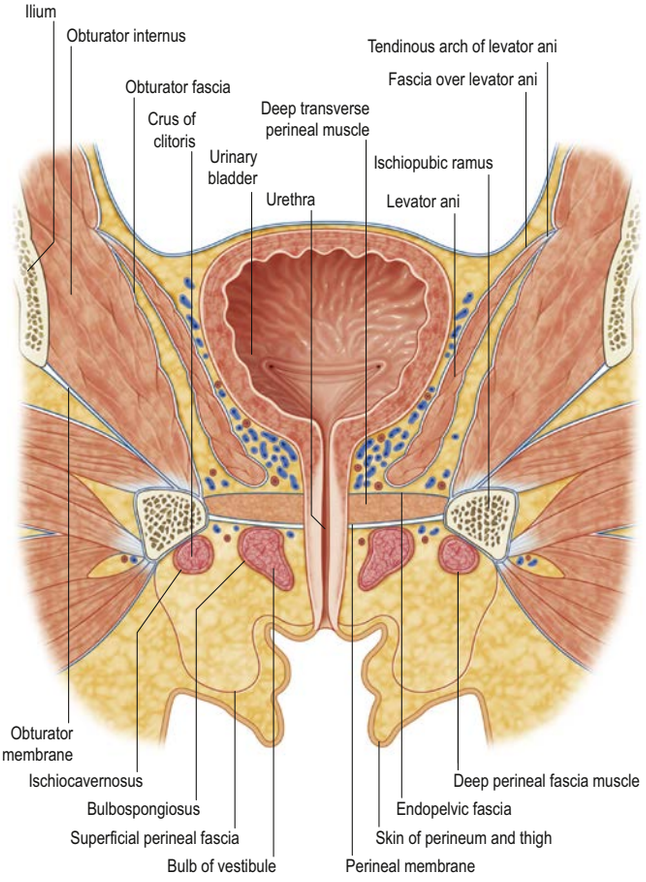

Fig. 71.15 Muscles and fasciae of the female perineum – coronal view. The section passes through the bulb of the vestibule at the level of the urethra. The deep perineal space is continuous with the ischio-anal fossa posteriorly. The visceral and parietal fasciae have been omitted for clarity. The pelvic fascia over the 'pelvic' aspect of the deep transverse perineal muscles is very thin and does not form a distinct layer: in places it blends with the parietal pelvic fascia over the inferior aspect of levator ani.

Vascular supply and lymphatic drainage

Arteries

Internal pudendal artery (in the perineum)

The internal pudendal artery enters the perineum around the posterior aspect of the ischial spine and runs on the lateral wall of the ischio-anal fossa in the pudendal canal with the internal pudendal veins and the pudendal nerve. The canal lies about 4 cm superior to the inferior limit of the ischial tuberosity and is formed by connective tissue binding the internal pudendal vessels and pudendal nerve to the medial surface of the fascia covering obturator internus. As the artery approaches the margin of the ischial ramus, it proceeds superficial or deep to the perineal membrane, along the medial margin of the inferior pubic ramus, en route to its target structures.

In the male, the internal pudendal artery distal to the perineal artery gives a branch to the bulb of the penis before it divides into the deep

and dorsal arteries of the penis (see Fig. 71.12). The artery to the bulb of the penis supplies the corpus spongiosum, and the deep artery of the penis supplies the corpus cavernosum on each side. The dorsal artery runs on the dorsal aspect of the penis and supplies circumflex branches to the corpora cavernosa and corpus spongiosum that end by anastomosing near the corona of the glans and supplying the glans and prepuce of the penis.

In the female, a similar branch of the internal pudendal artery is distributed to the corpus spongiosum and vagina. The deep arteries supply the corpora cavernosa of the clitoris; the dorsal arteries supply the glans and prepuce of the clitoris.

Branches of the internal pudendal artery are sometimes derived from an accessory pudendal artery, which is usually a branch of the internal pudendal artery before its exit from the pelvis.

Inferior anorectal artery

The inferior anorectal artery arises just after the internal pudendal artery enters the pudendal canal on the lateral wall of the ischio-anal fossa. It runs anteromedially through the adipose tissue of the ischio-anal fossa to reach the external anal sphincter and it often branches before reaching the sphincter. During dissections of the anal canal, particularly during perineal excisions of the anus or rectum, the inferior anorectal vessels are encountered in the ischio-anal fossa and must be ligated before division; otherwise they tend to retract laterally, where they can cause troublesome bleeding.

Perineal artery

The perineal artery is a branch of the internal pudendal artery that arises near the anterior end of the pudendal canal and runs through the perineal membrane. In the male, it approaches the scrotum in the superficial perineal space, between bulbospongiosus and ischiocavernosus (see Fig. 74.24). A small transverse branch passes medially, inferior to the superficial transverse perineal muscle, to anastomose with the contralateral artery and with the posterior scrotal and inferior anorectal arteries. It supplies the transverse perinei, the perineal body and the posterior attachment of the bulb of the penis. The posterior scrotal arteries are usually terminal branches of the perineal artery but can also arise from its transverse branch. They are distributed to the scrotal skin and dartos in the male and supply the perineal muscles. In the female, the perineal artery runs an almost identical course to that in the male and gives off posterior labial branches (see Fig. 75.4).

Veins

Internal pudendal veins

The internal pudendal veins are venae comitantes of the internal pudendal artery and unite as a single vessel ending in the internal iliac vein. The perineal tributaries receive veins from the bulb of the penis and the scrotum, or the clitoris and labia, and the inferior anorectal veins join towards the posterior end of the pudendal canal.

Lymphatic drainage

The lymphatics from the skin of the penis and scrotum, or skin of the clitoris and labia, drain together with lymphatics from the perineal skin to the superficial inguinal nodes, and from there to the deep inguinal nodes. The corpora cavernosa and corpus spongiosum of the penis or clitoris drain directly to the deep inguinal nodes (see Fig. 76.10).

Innervation

Pudendal nerve (in the perineum)

The pudendal nerve gives rise to the inferior anal and perineal nerves and to the dorsal nerves of the penis or clitoris. The course of its branches parallels the pudendal vessels (see Figs 74.24, 75.4). The pudendal nerve occupies a constant position over the ischial spine. It can be 'blocked' by infiltration with a local anaesthetic applied via a needle passed through the lateral wall of the vagina to anaesthetize the perineal and anal skin. It can also be palpated over the ischial spine through the lateral wall of the rectum.

Inferior anal nerve

The inferior anal (rectal) nerve runs either through the medial wall of the pudendal canal with the inferior anorectal vessels, or behind the sacrospinous ligament directly from the fourth sacral ventral ramus without passing through the pudendal canal (Maldonado et al 2015), or occasionally it arises directly from the sacral plexus and crosses the sacrospinous ligament or rejoins the pudendal nerve. The nerve crosses the ischio-anal fossa to supply the external anal sphincter, the lining of the distal part of the anal canal and the skin around the anus. It frequently breaks into terminal branches before reaching the lateral border of the external anal sphincter. Its cutaneous branches distributed around the anus overlap the branches of the perineal branch of the posterior femoral cutaneous nerve and of the posterior scrotal or labial nerves. In females, the inferior anal nerve can supply sensory branches to the distal part of the vagina.

Perineal nerve

The perineal nerve is the inferior and larger terminal branch of the pudendal nerve in the pudendal canal. It runs anteriorly, inferior to the internal pudendal artery and accompanies the perineal artery, dividing into posterior scrotal or posterior labial and muscular branches. The posterior scrotal or labial nerves are usually double; they have medial and lateral branches that run over the perineal membrane and pass anteriorly in the lateral part of the urogenital triangle with the posterior scrotal or posterior labial branches of the perineal artery. They supply the skin of the scrotum or labia majora, respectively, overlapping the distribution of the perineal branch of the posterior femoral cutaneous nerve and inferior anal nerve. In females, the posterior labial branches also supply sensory fibres to the skin of the distal vagina.

Muscular branches arise directly from the pudendal nerve to supply the superficial transverse perineal muscles, bulbospongiosus, ischiocavernosus, external urethral sphincter and the anterior parts of the external anal sphincter and levator ani. In males, the branch to bulbospongiosus pierces this muscle to supply the corpus spongiosum penis, and ends in the urethral mucosa.

Dorsal nerve of the penis or clitoris

The dorsal nerve of the penis or clitoris runs anteriorly above the internal pudendal artery along the ischiopubic ramus, deep to the perineal membrane. It supplies the corpus cavernosum and accompanies the dorsal artery of the penis or clitoris between the layers of the suspensory ligament of the penis or clitoris. The dorsal nerve of the penis runs on the dorsum of the penis to end in the glans penis.

CHAPTER 72

Kidney and ureter

KIDNEY

The kidneys excrete end products of metabolism and excess water. These actions are essential for the control of concentrations of various substances in the body, maintaining electrolyte and water balance approximately constant in the tissue fluids. The kidneys also have endocrine functions, producing and releasing erythropoietin, which affects red blood cell formation; renin, which influences blood pressure; 1,25-dihydroxycholecalciferol (the metabolically active form of vitamin D), which is involved in the control of calcium absorption and mineral metabolism; and other soluble factors with metabolic actions.

In the fresh state the kidneys are reddish-brown. They are retroperitoneal, located on either side of the vertebral column, and are surrounded by adipose tissue. Superiorly the kidneys are level with the upper border of the twelfth thoracic vertebra on the left and the first lumbar vertebra on the right, and inferiorly, with the third or fourth lumbar vertebra on the left and the fourth lumbar vertebra on the right (Mirjalili et al 2012). The right is usually slightly inferior to the left, reflecting its relationship to the liver. The left is a little longer and narrower than the right and lies nearer the median plane (Fig. 72.1). The long axis of each kidney is directed inferolaterally and the transverse axis posteromedially, which means that the anterior and posterior aspects usually described are, in fact, anterolateral and posteromedial. An appreciation of this orientation is important in percutaneous and endo-urological renal surgery.

In adults, each kidney is typically 11 cm in length, 6 cm in width and 3 cm in anteroposterior dimension. The left kidney may be 1.5 cm longer than the right; it is rare for the right kidney to be more than 1 cm longer than the left. The average weight is 150 g in men and 135 g in women. In thin individuals with a lax abdominal wall, the lower pole of the right kidney can just be felt in full inspiration by bimanual physical examination of the abdomen, but this is unusual. In the fetus and the newborn, the kidney normally has 12 lobules; in the adult, these lobules are fused to present a smooth surface, although any remaining traces of lobulation can mimic a renal mass on radiological imaging.

Absent and ectopic kidneys A single absent kidney, resulting from the failure of the metanephrogenic blastema to join a ureteric bud (metanephric diverticulum) on the affected side, is seen in one in 1200 individuals. There are no clinical sequelae, but the ipsilateral ductus deferens and/or epididymis can also be absent and there may be other congenital anomalies, including imperforate anus, cardiac valvular anomalies and oesophageal atresia. A single kidney often shows

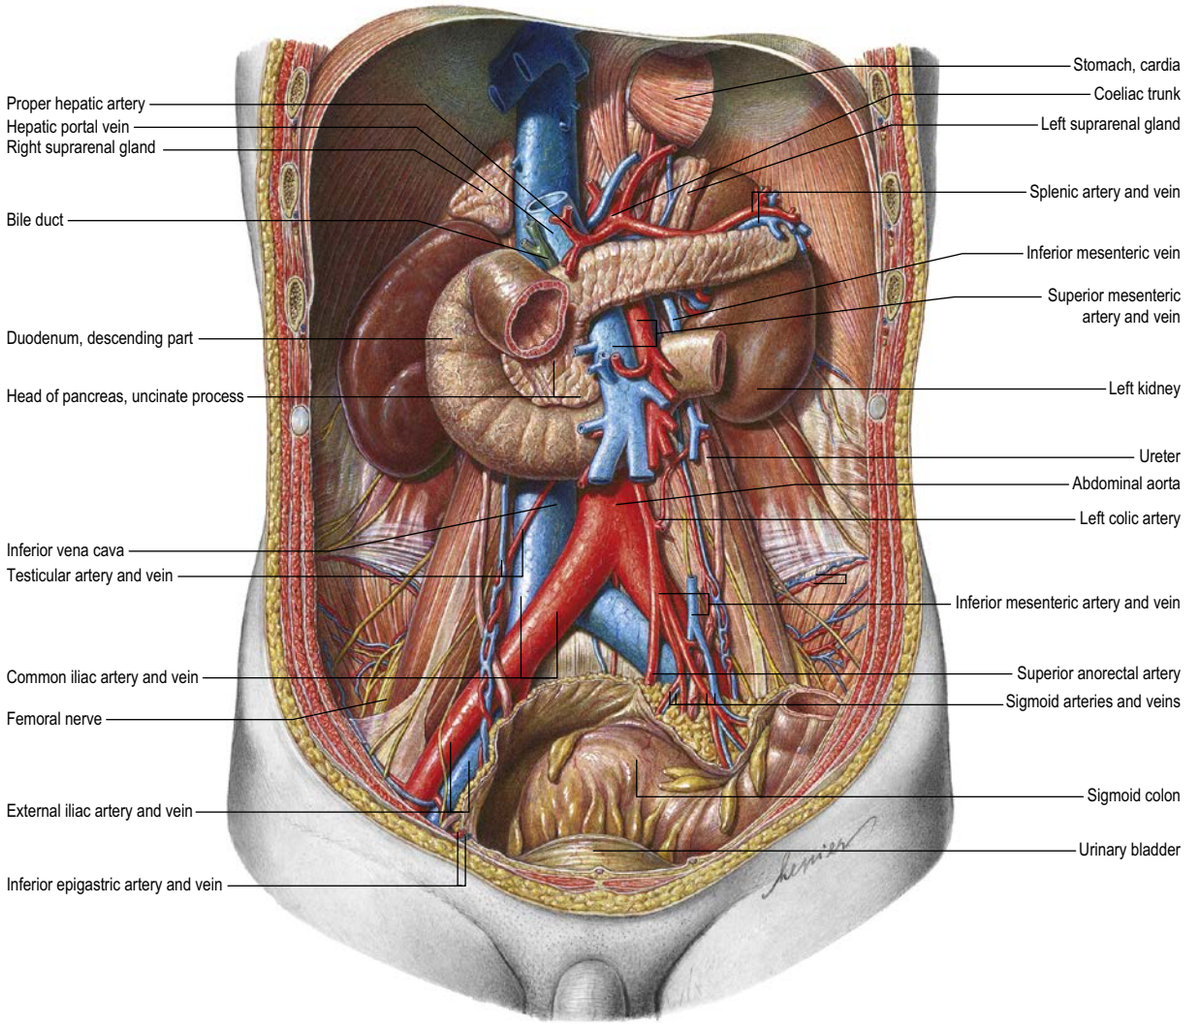

Fig. 72.1 Relations of the kidneys and ureters in the male retroperitoneum. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

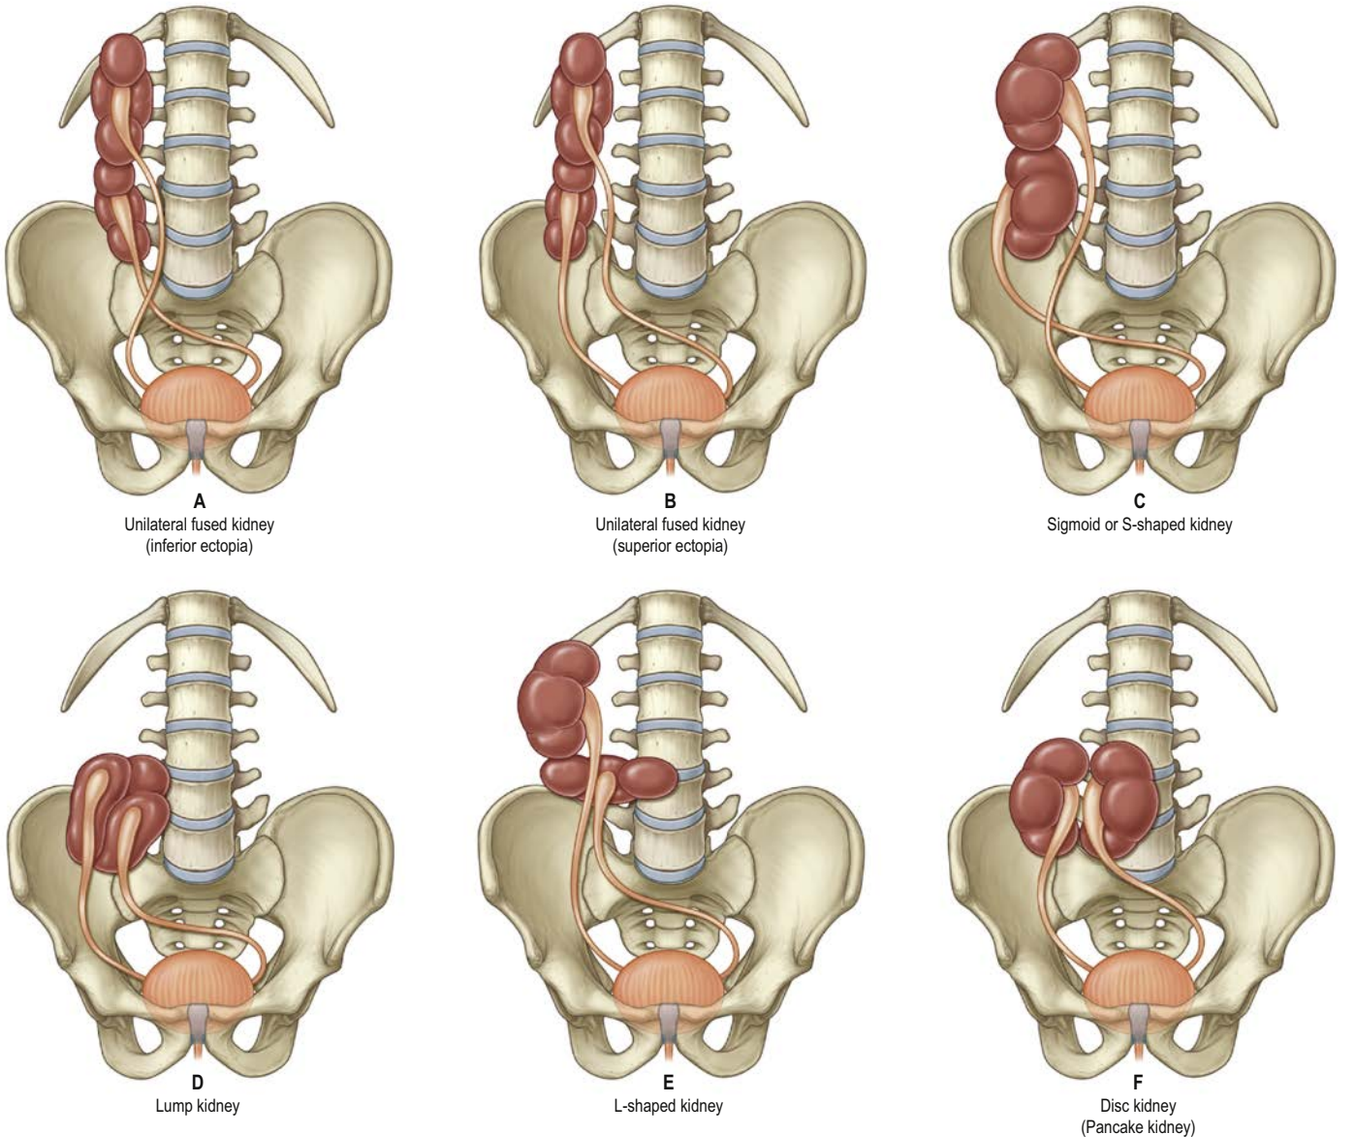

Fig. 72.2 The possible arrangements of crossed fused ectopic kidneys.

compensatory hypertrophy but, provided the single kidney is anatomically and functionally normal, the life expectancy of individuals with a single kidney is no different from that of those with two kidneys.

An ectopic kidney is found in the pelvis in 1 in 2500 live births. Kidneys so placed often have associated malrotation anomalies and can have marked fetal lobulation. Pelvic kidneys frequently become hydronephrotic as a result of an anteriorly placed ureter and an anomalous arterial supply; there is often an associated ureteropelvic (pelviureteric) junction obstruction.

Very rarely, and despite the normal location of the ureteric orifices within the urinary bladder, the two kidneys are on the same side and are usually fused (crossed fused renal ectopia). A solitary crossed fused renal ectopia may be associated with skeletal and other genitourinary anomalies. A number of different anatomical patterns can result, all of which are extremely rare (Fig. 72.2).

Horseshoe kidney Horseshoe kidneys are found in 1 in 400 individuals. A transverse bridge of renal tissue, the isthmus, often containing functioning renal substance, connects the two renal masses. The isthmus lies between the inferior poles, most commonly anterior to the great vessels; it is often inferior to the inferior mesenteric artery because this vessel can obstruct the normal ascent of the kidney during embryological development. The ureters curve anterior to the isthmus and often have a high origin from the renal pelvis (Fig. 72.3).

Renal fascia

The renal fascia (Gerota's fascia), is a dense, elastic connective tissue sheath that envelops each kidney and suprarenal gland, together with a layer of surrounding perirenal fat that is thickest at the renal borders and extends into the renal sinus at the hilum of the kidney (Fig. 72.4; see Fig. 61.2).

The renal fascia was originally described as two separate entities, the posterior fascia of Zuckerkandl and the anterior fascia of Gerota, which fused laterally to form the lateroconal fascia (Chesbrough et al 1989, Burkhill and Healy 2000). According to this view, the lateroconal fascia continued anterolaterally behind the colon to blend with the parietal peritoneum. However, Mitchell (1950) showed that the renal fascia is a single multi-laminated structure that is fused posteromedially with the muscular fasciae of psoas major and quadratus lumborum. It then extends anterolaterally behind the kidney as a bilaminated sheet, which, at a variable point, divides into a thin anterior layer, passing anterior to the kidney, and a thicker posterior layer that continues anterolaterally as the lateroconal fascia and fuses with the parietal peritoneum.

Classically, the anterior layer of renal fascia was thought to blend into the dense mass of connective tissue surrounding the great vessels in the root of the mesentery behind the duodenum and pancreas, thereby preventing communication between perirenal spaces across the midline. However, inspection of computed tomography (CT) images or of anatomical sections of cadavers, following injection of contrast or coloured latex, respectively, into the perirenal space, revealed that fluid could extend across the midline at the third to fifth lumbar levels through a narrow channel measuring 2–10 mm in the anteroposterior dimension. In the midline superiorly, the anterior and posterior layers of renal fascia fuse and are attached to the crura of the respiratory diaphragm. Inferiorly, the fasciae are separate for a variable craniocaudal distance. The posterior layer of renal fascia fuses with the psoas fascia, while the anterior layer of renal fascia extends across the midline anterior to the aorta and inferior vena cava; communication between the

The blood supply to horseshoe kidneys is variable. One vessel to each moiety is seen in 30% of horseshoe kidneys but multiple vessels are common; the isthmus can be supplied by a vessel directly from the aorta or from branches of the inferior mesenteric, common iliac or external iliac arteries. In many cases, aberrant vessels arising below the inferior border of the isthmus supply the isthmus. In view of this variable arterial anatomy, angiography or computed tomography (CT) scanning with vascular reconstruction is very helpful when planning surgery on horseshoe kidneys.

Horseshoe kidneys exhibit an associated congenital ureteropelvic junction obstruction in up to 30% of cases and have a chromosomal anomaly in 56% of cases (Scott 2002). Anomalous vessels crossing the ureter, and the abnormal course of the ureter as it passes over the kidney, can also cause obstruction and result in hydronephrosis or haematuria. The right and left major calyces can exist independently and not cross the midline (Iwanaga et al 2015).

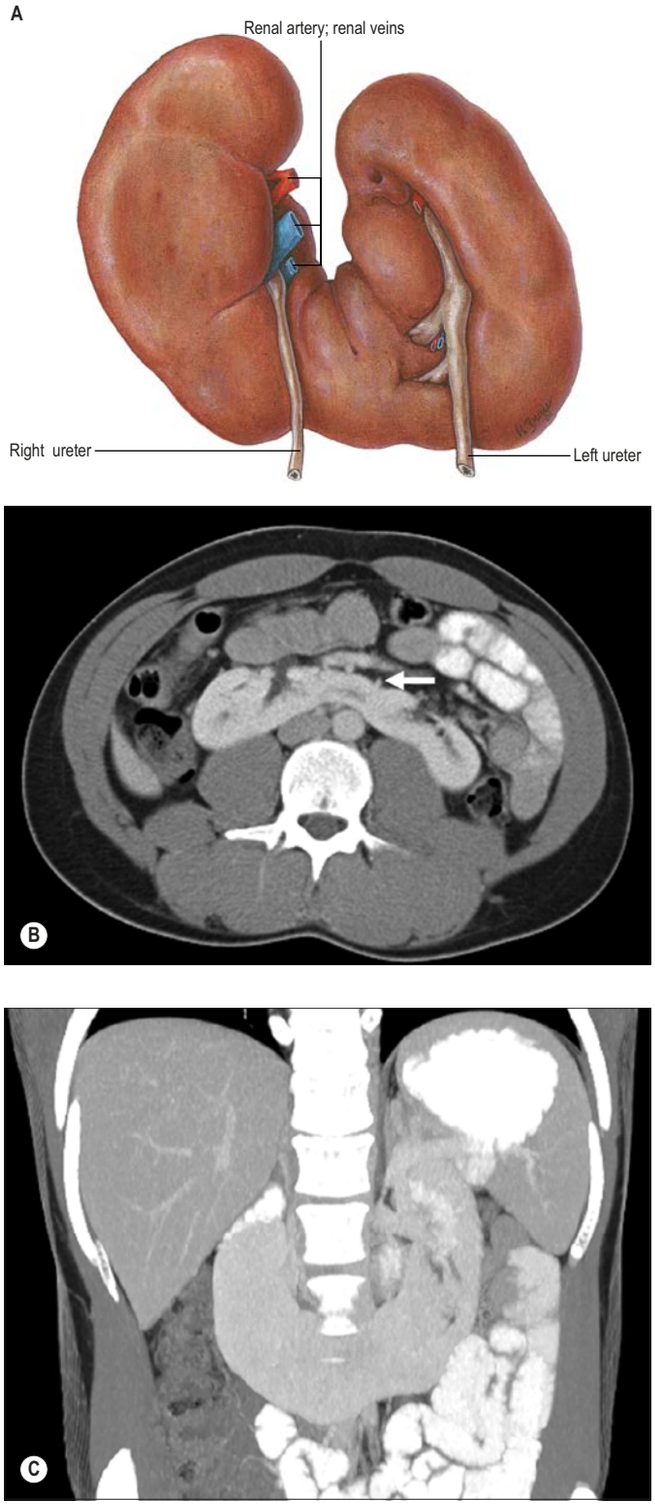

Fig. 72.3 A, A horseshoe kidney. Note the ureters pass anterior to the isthmus, and the relatively high insertion of the ureters into the renal pelvis on the left side. **B**, Axial contrast-enhanced computed tomography (CT) image. **C**, Coronal maximal intensity projection (MIP) image of the abdomen. **B** and **C** demonstrate midline connection of the two kidneys below the inferior mesenteric artery (**B**, arrow), in a horseshoe configuration. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

two sides is permitted, although it is very rarely of clinical significance. Below this level, the two fasciae once again merge and are attached to the aorta and inferior vena cava or iliac vessels. The containment of fluid to one side of the perirenal space that is observed in over two-thirds of clinical cases is attributed to the presence of fibrous septa.

Above the suprarenal glands, the anterior and posterior layers of renal fascia were previously said to fuse with each other and to the diaphragmatic fascia. This description of a closed superior cone is not universally accepted. Cadaveric dissections have shown that the superior aspect of the perirenal space is open and in continuity with the bare area of the liver on the right and the subphrenic space on the left. The posterior fascial layer blends bilaterally with the psoas fascia and fascia over quadratus lumborum, and with the diaphragmatic fascia. The anterior fascial layer on the right blends with the inferior aspect of the right coronary ligament at the level of the upper pole of the kidney and the bare area of the liver. On the left, the anterior layer fuses with the gastrosplenic ligament at the level of the suprarenal gland.

There is some debate concerning the inferior fusion of the renal fascia. Many investigators believe that, inferiorly, the anterior and posterior layers of the renal fascia fuse to produce an inverted cone that is open to the pelvis at its apex. Laterally, the anterior and posterior layers fuse with the iliac fascia; medially, they fuse with the periureteric connective tissue. The apex of the cone is open anatomically towards the iliac fossa but rapidly becomes sealed in inflammatory disease. An alternative view based on dissections of recently deceased cadavers after injections of coloured latex into the perirenal space, has shown that the anterior and posterior layers of renal fascia merge to form a single multilaminar fascia that contains the ureter in the iliac fossa. Anteriorly, this common fascia is loosely connected to the parietal peritoneum, and so denies free communication between the perirenal space and the pelvis, and between the perirenal and pararenal spaces.

Relations

The superior poles of both kidneys are thick and round and related to their respective suprarenal glands. The inferior poles are thinner and extend to within 2.5 cm of the iliac crests. The lateral borders are convex. The medial borders are convex adjacent to the poles and concave between them, and slope inferolaterally. In each, a deep vertical fissure opens anteromedially as the hilum of the kidney, which is bounded by anterior and posterior lips and contains the renal vessels and nerves, and the renal pelvis. The relative positions of the main hilar structures are the renal vein (anterior), the renal artery (intermediate) and the renal pelvis (posterior) (**Fig. 72.5**). Usually, an anterior branch from the renal artery runs over the superior margin of the renal pelvis to enter the hilum on the posterior aspect of the renal pelvis, and often leaves the hilum in the same plane. Above the hilum the medial border is related to the suprarenal gland and below to the origin of the ureter.

The convex anterior surface of the kidney faces anterolaterally and its posterior surface faces posteromedially. The relations of the left and right kidneys are shown in **Fig. 72.6**.

A small area of the superior pole of the right kidney is in contact with the right suprarenal gland, which can overlap the upper part of the medial border of the right kidney (**Fig. 72.7**). A large area below this is immediately related to the right lobe of the liver, separated by a layer of parietal peritoneum. A narrow medial area is directly related to the descending part of the duodenum. Inferiorly, the anterior surface is directly in contact laterally with the right colic flexure and medially with part of the small intestine.

A small medial area of the superior pole of the left kidney is related to the left suprarenal gland (see Fig. 72.7). The lateral half of the superior pole of the anterior surface is related to the spleen, from which it is separated by a layer of peritoneum. A central quadrilateral area lies in direct contact with the pancreas and the splenic vessels. Above this, a small, variable, triangular region, between the suprarenal and splenic areas, is in contact with the stomach, separated by a layer of peritoneum. Below the pancreatic and splenic areas a narrow lateral strip that extends to the lateral border of the kidney is directly related to the left colic flexure and the beginning of the descending colon. An extensive medial area is related to the jejunum. The gastric area is covered with the peritoneum of the omental bursa, and the splenic and jejunal areas are covered by the peritoneum of the greater sac. Behind the peritoneum covering the jejunal area, branches of the left colic vessels are related to the kidney.

The posteromedial surface of the kidneys is embedded in fat and devoid of peritoneum. The right and left kidneys are related to similar structures. Superiorly are the respiratory diaphragm and the medial and lateral arcuate ligaments. More inferiorly, moving in a medial to lateral direction, are psoas major, quadratus lumborum and the aponeurotic tendon of transversus abdominis, the subcostal vessels and the subcostal, iliohypogastric and ilioinguinal nerves. The upper pole of the right kidney is level with the twelfth rib, and that of the left with the eleventh and twelfth ribs. The respiratory diaphragm covered with parietal peritoneum separates the kidney from the parietal pleura, which descends to form the costodiaphragmatic recess; the diaphragm is sometimes defective or absent in the lumbocostal triangle immediately above the lateral arcuate ligament, and this allows perirenal adipose tissue to contact the diaphragmatic pleura.

A simple nephrectomy for benign disease removes the kidney from within the renal fascia; a radical nephrectomy (for cancer) classically removes the entire contents of the perirenal space, including the renal fascia and suprarenal gland, in order to give adequate clearance around the tumour.

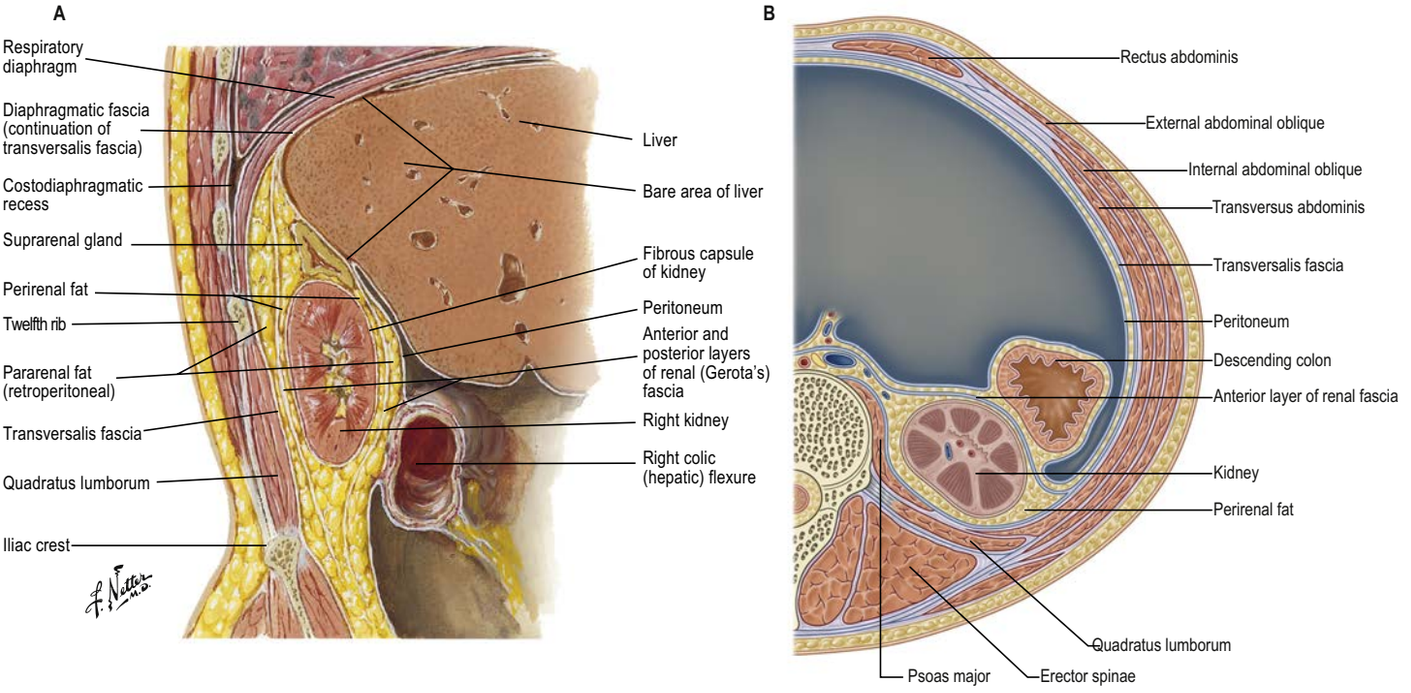

Fig. 72.4 **A**, A sagittal section through the posterior abdominal wall, showing the relations of the renal fascia of the right kidney. **B**, A transverse section, showing the relations of the renal fascia. (A, Reprinted from Netter Anatomy Illustration Collection, © Elsevier Inc. All Rights Reserved.)

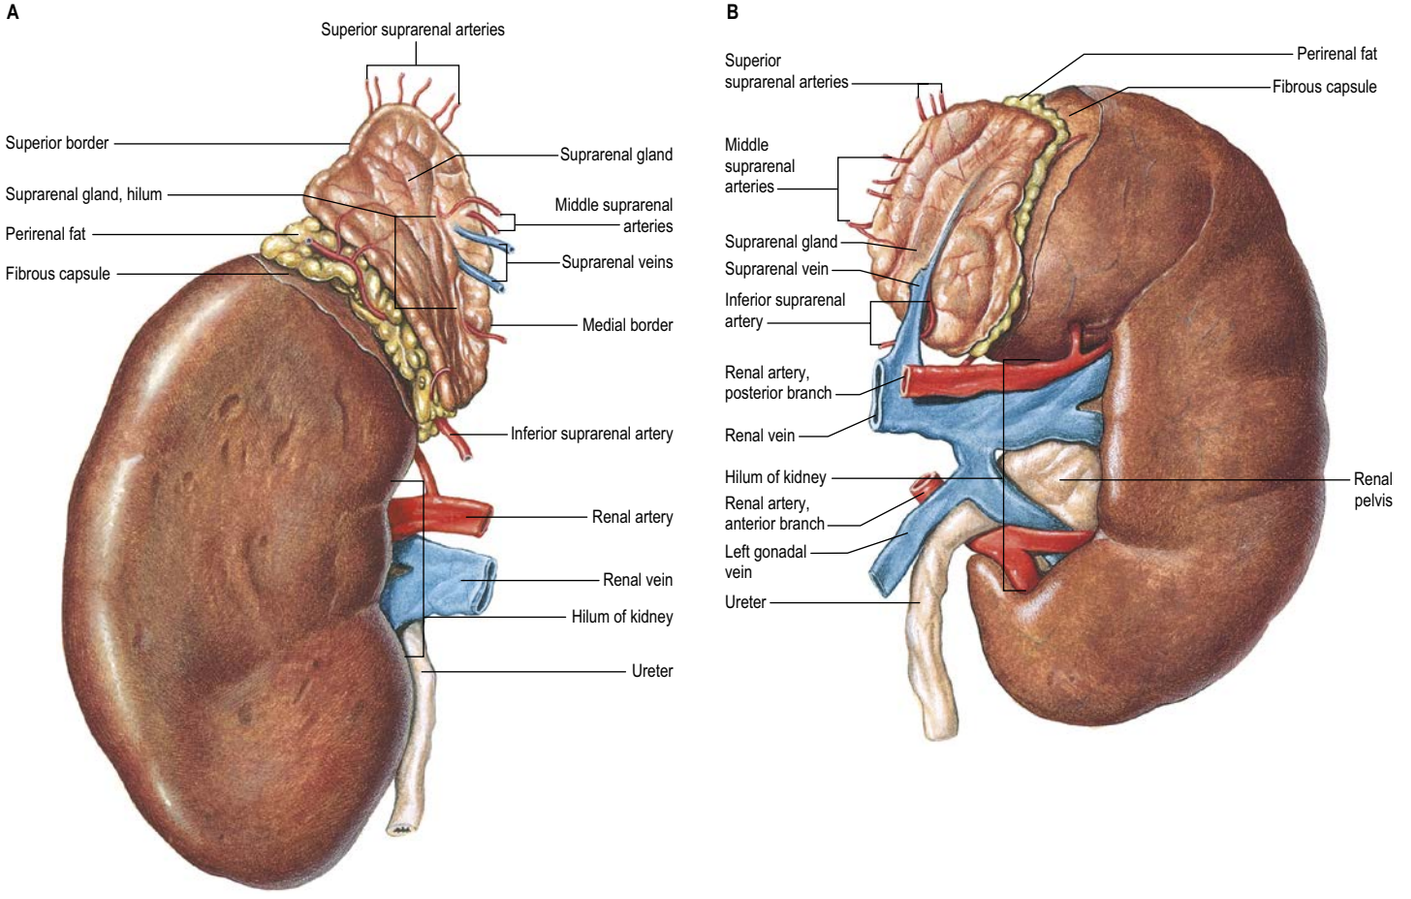

Fig. 72.5 **A**, The anterior aspect of the right kidney and suprarenal gland. **B**, The anterior aspect of the left kidney and suprarenal gland. Note that the left suprarenal vein enters the left renal vein. This is an important relationship to identify when performing a left nephrectomy. (A and B, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Internal macrostructure

The postnatal kidney has a thin fibrous capsule composed of collagen-rich connective tissue with some elastic and smooth muscle fibres. In renal disease, the capsule can become adherent.

The kidney itself can be divided into an internal renal medulla and external renal cortex (Fig. 72.8). The renal medulla consists of pale, striated, conical renal pyramids; their bases are peripheral, and their apices converge to the renal sinus. At the renal sinus, they project into calyces as papillae.

The renal cortex (see Fig. 72.13) is subcapsular, arching over the bases of the renal pyramids and extending between them towards the renal sinus as renal columns. Its peripheral regions are termed cortical arches and are traversed by radial, lighter-coloured

(C–D, *continued online*)

medullary rays, separated by darker tissue, the convoluted part. The rays taper towards the renal capsule and are peripheral prolongations from the bases of renal pyramids. The cortex is histologically divisible into outer and inner zones. The inner zone is demarcated from the renal medulla by tangential blood vessels (arcuate arteries and veins), which lie at the junction of the two; however, a thin layer of cortical tissue (subcortex) appears on the medullary side of this zone. The cortex close to the renal medulla is sometimes termed the juxtamedullary cortex.

Renal pelvis and calyces

The hilum of the kidney leads into a centrally located renal sinus, lined by the renal capsule and almost filled by the renal pelvis and renal vessels; the remaining space is filled by fat. Dissection into this plane can be challenging but is important in surgery on the renal pelvis, particularly open stone surgery. Within the renal sinus the collecting tubules of the nephrons of the kidney open on to the summits of the renal papillae to drain into minor calyces, which are funnel-shaped expansions of the upper urinary tract. The renal capsule covers the external surface of the kidney and continues through the hilum to line the renal sinus and fuse with the adventitial coverings of the minor calyces. Each minor calyx surrounds either a single renal papilla or, more rarely, groups of two or three renal papillae. The minor calyces unite with their neighbours to form two, or possibly three, larger chambers: the major calyces. There is wide variation in the arrangement of the calyces. As the posterior aspect of the kidney rotates laterally during its ascent *in utero*, the calyces that were lateral *in utero* become positioned anteriorly and the medial calyces move more posteriorly. The major calyces drain into the infundibula (MacLennan 2012). The renal pelvis is normally formed from the junction of two infundibula – one from the upper and one from the lower pole greater calyces – but there may be a third, which drains the calyces in the mid portion of the kidney. The major calyces are usually grouped so that three pairs drain into the upper pole infundibulum and four pairs into the lower one. If there is a middle infundibulum, the distribution is normally three pairs at the upper pole, two in the middle, and two at the lower pole. There is considerable variation in the arrangement of the infundibula and in the extent to which the renal pelvis is intrarenal or extrarenal. The funnel-shaped renal pelvis tapers as it passes inferomedially, traversing the hilum to become continuous with the ureter (see Figs 72.8–72.9). It is rarely possible to determine precisely where the renal pelvis ceases and the ureter begins; the region is usually extrahilar and normally lies adjacent to the lower part of the medial border of the kidney. Rarely, the entire renal pelvis has been found to lie inside the renal sinus so that the junction between it and the ureter occurs either in the vicinity of the hilum or completely within the renal sinus.

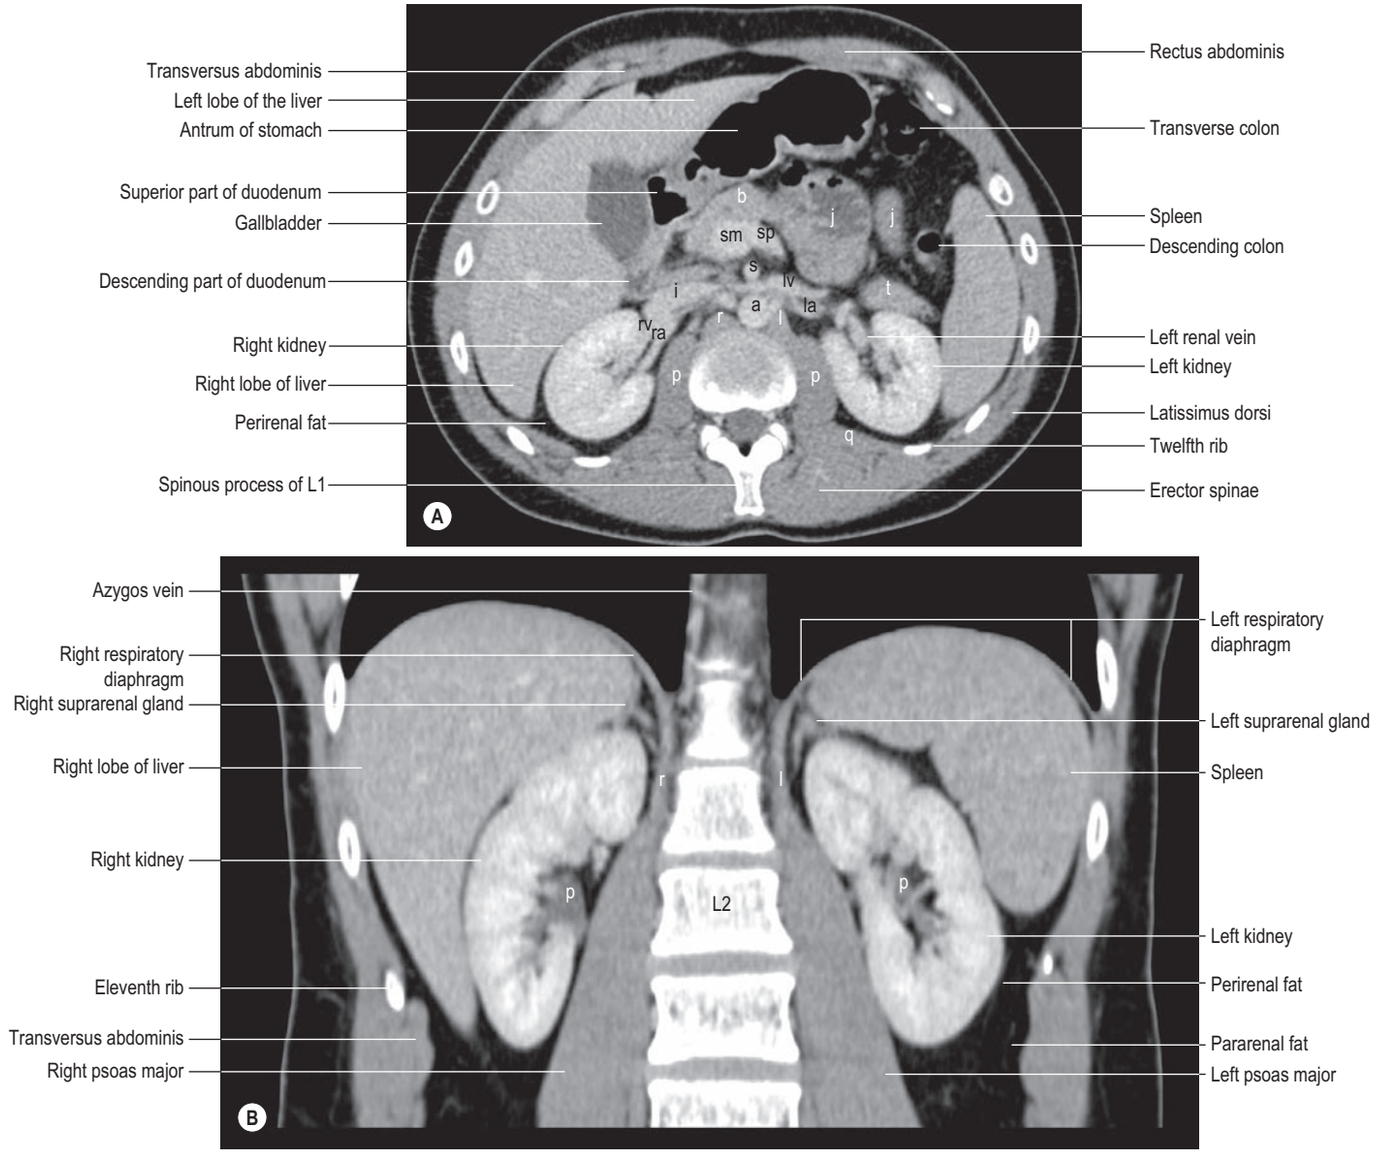

Fig. 72.6 Multislice CT scans of the kidneys. **A**, An axial plane CT with intravenous contrast medium at the level of the renal hila (L1-L2). Abbreviations: a, aorta; b, body of pancreas; i, inferior vena cava; j, jejunal loops; l, left crus of respiratory diaphragm; la, left renal artery; lv, left renal vein; p, psoas major; q, quadratus lumborum; r, right crus of respiratory diaphragm; ra, right renal artery; rv, right renal vein; s, superior mesenteric artery; sm, superior mesenteric vein; sp, splenic vein; t, tail of pancreas. **B**, A coronal multiplanar reformat from a CT with intravenous contrast medium through both kidneys and suprarenal glands. Abbreviations: l, left crus of respiratory diaphragm; r, right crus of respiratory diaphragm; p, renal pelvis.

The calyces, renal pelvis and ureter are well demonstrated radiologically following an intravenous injection of radio-opaque contrast that is excreted in the urine (computed tomographic urography, CTU) (Fig. 72.9), or after the introduction of radio-opaque contrast into the ureter by catheterization through a cystoscope (ascending or retrograde pyelography). Normal cupping of the minor calyces by projecting renal papillae can be obliterated by conditions that cause hydronephrosis, e.g. chronic distension of the ureter and renal pelvis due to upper or lower urinary tract obstruction, resulting in elevated pressure of the renal pelvis. An appreciation of the rotation of the kidneys, which results when the posterior calyces lie relatively medially and the anterior calyces lie laterally, is essential for interpreting contrast imaging of the collecting system of the kidneys.

Vascular supply and lymphatic drainage

Renal arteries

The paired renal arteries take about 20% of the cardiac output to supply organs that represent less than 1% of total body weight. They branch laterally from the aorta at the right-angles just below the origin of the superior mesenteric artery (see Fig. 59.5A; **Fig. 72.10A, C**)). Both cross the corresponding crus of the respiratory diaphragm. The right renal artery is longer and often slightly higher, passing posterior to the inferior vena cava, right renal vein, head of the pancreas, and descending part of the duodenum. The left renal artery is often a little lower and passes behind the left renal vein, the body of the pancreas and the splenic vein. It may be crossed anteriorly by the inferior mesenteric vein.

A single renal artery to each kidney is present in approximately 70% of individuals (**Fig. 72.11**). The arteries vary in their level of origin and in their calibre, obliquity and precise relations (Merklin and Michels 1958). In its extrarenal course, each renal artery gives off one or more inferior suprarenal arteries, ureteric and capsular branches, and branches that supply perirenal tissue and the renal pelvis. Near the hilum of the kidney, each artery divides into an anterior and a posterior branch, and these divide into segmental arteries supplying the renal vascular segments. Accessory renal arteries are common (in approximately 30% of individuals) and usually arise from the abdominal aorta above or below (most commonly below) the renal artery and follow it to the hilum (**Figs 72.10B, D**). Accessory vessels to the inferior pole cross anterior to the ureter and can, by obstructing the ureter, cause hydronephrosis (**Fig. 72.12**). In children with ureteropelvic junction obstruction, a crossing vessel is found in 28% of cases (Veyrac et al 2003). Three anatomical variants of aberrant lower pole crossing vessels have been described: either anterior to the dilated renal pelvis or ureteropelvic junction, or inferior to the ureteropelvic junction, causing kinking of the ureter (Schneider et al 2013). Rarely, accessory renal arteries arise from the coeliac or superior mesenteric arteries near the aortic bifurcation, or from the common iliac arteries.

The subdivisions of the renal arteries are described sequentially as segmental, lobar, interlobar, arcuate and interlobular (cortical radiate) arteries, and afferent and efferent glomerular arterioles (**Fig. 72.13**).

Segmental arteries

Renal vascular segmentation was originally recognized by John Hunter in 1794, but the first detailed account of the primary pattern was produced in the 1950s from casts and radiographs of injected kidneys. Five arterial segments of the kidney have been identified (**Fig. 72.14A**). The superior segment occupies the anteromedial region of the superior pole. The anterior superior segment includes the rest of the superior pole and the central anterosuperior region. The inferior segment encompasses the whole inferior pole. The anterior inferior segment lies between the anterior and inferior segments. The posterior segment includes the whole posterior region between the superior and inferior segments. This is the pattern most commonly seen, and although there can be considerable variation, it is the pattern that clinicians most frequently encounter when performing partial nephrectomy. Anatomical and radiological analyses have suggested that there could be up to nine arterial segments for each kidney (Macchi et al 2019) (**Fig. 72.14B**). Whatever pattern is present, it is important to emphasize that vascular segments are supplied by virtual end arteries. In contrast, the larger intrarenal veins have no segmental organization and anastomose freely.

Brödel described a relatively avascular longitudinal zone (the 'bloodless' line of Brödel) along the convex renal border, which was proposed as the most suitable site for surgical incision (Brödel 1911). However, many vessels cross this zone and it is far from 'bloodless'; planned radial or intersegmental incisions are therefore preferable (Macchi et al 2018). Knowledge of the vascular anatomy of the kidney is important when partial nephrectomy is undertaken for renal cell carcinoma. In this surgery, the branches of the renal artery are defined so that the surgeon can safely excise the tumour while not compromising the vascular supply to the remaining renal tissue (Novick 1998).

Lobar, interlobar, arcuate and interlobular arteries

The initial branches of segmental arteries are lobar, usually one to each renal pyramid. Before reaching the renal pyramid they subdivide into two or three interlobar arteries, extending towards the cortex around each pyramid. At the junction of the renal cortex and medulla, interlobar arteries dichotomize into arcuate arteries, which diverge at right angles. As they arch between the renal cortex and medulla, each divides further, ultimately supplying interlobular arteries that diverge radially into the cortex. The terminations of adjacent arcuate arteries do not anastomose but end in the renal cortex as additional interlobular arteries. Though most interlobular arteries come from arcuate branches, some arise directly from arcuate, or even terminal, interlobar arteries (see Fig. 72.13). Interlobular arteries ascend towards the superficial cortex or can branch occasionally en route. Some are more tortuous and recurve towards the renal medulla at least once before proceeding towards the renal surface. Others traverse the surface as perforating arteries to anastomose with the capsular plexus (which is also supplied from the inferior suprarenal, renal and gonadal arteries).

Afferent and efferent glomerular arterioles

Afferent glomerular arterioles are mainly the lateral rami of interlobular arteries. A few arise from arcuate and interlobar arteries when they vary their direction and angle of origin: deeper ones incline obliquely back towards the renal medulla, the intermediate pass horizontally and the more superficial approach the surface of the kidney obliquely before ending in a glomerulus (see Fig. 72.13). Efferent glomerular arterioles from most glomeruli (except at juxtamedullary and, sometimes, intermediate cortical levels) soon divide to form a dense peritubular capillary plexus around the proximal and distal convoluted tubules; there are therefore two sets of capillaries – glomerular and peritubular – in series in the main renal cortical circulation, linked by efferent glomerular arterioles. The vascular supply of the renal medulla is largely from efferent arterioles of juxtamedullary glomeruli, supplemented by some from more superficial glomeruli, and 'aglomerular' arterioles (probably from degenerated glomeruli). Efferent glomerular arterioles passing into the renal medulla are relatively long, wide vessels, and contribute side branches to neighbouring capillary plexuses before entering the renal medulla, where each divides into 12–25 descending vasa recta. As their name suggests, these run straight to various depths in the renal medulla, contributing side branches to a radially elongated capillary plexus applied to the descending and ascending limbs of renal loops and to collecting ducts. The venous ends of capillaries converge to the ascending vasa recta, which drain into arcuate or interlobular veins. An essential feature of the vasa recta (particularly in the outer medulla) is

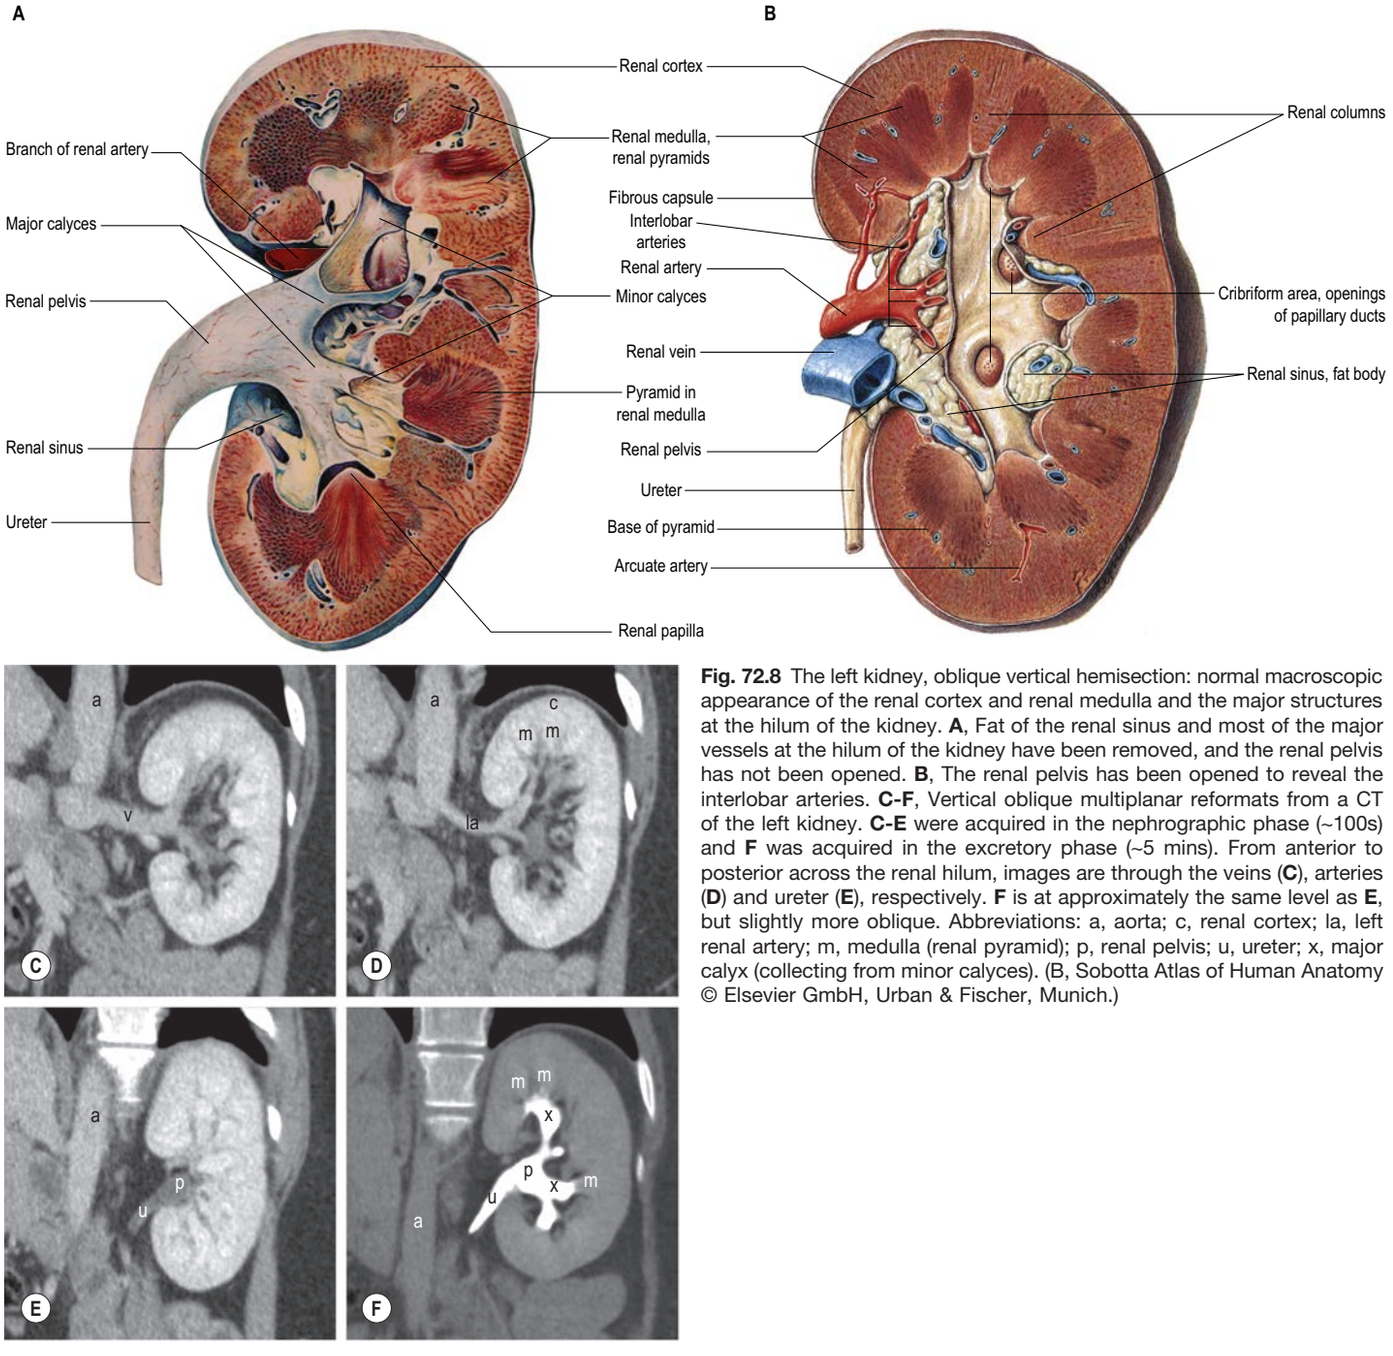

Fig. 72.8 The left kidney, oblique vertical hemisection: normal macroscopic appearance of the renal cortex and renal medulla and the major structures at the hilum of the kidney. **A**, Fat of the renal sinus and most of the major vessels at the hilum of the kidney have been removed, and the renal pelvis has not been opened. **B**, The renal pelvis has been opened to reveal the interlobar arteries. **C-F**, Vertical oblique multiplanar reformats from a CT of the left kidney. **C-E** were acquired in the nephrographic phase (~100s) and **F** was acquired in the excretory phase (~5 mins). From anterior to posterior across the renal hilum, images are through the veins (**C**), arteries (**D**) and ureter (**E**), respectively. **F** is at approximately the same level as **E**, but slightly more oblique. Abbreviations: a, aorta; c, renal cortex; la, left renal artery; m, medulla (renal pyramid); p, renal pelvis; u, ureter; x, major calyx (collecting from minor calyces). (B, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

that both descending and ascending vessels are grouped into vascular bundles, within which the external aspects of both types are closely apposed, bringing them close to the limbs of the nephron loops (of Henle) and collecting ducts. As these bundles converge centrally into the renal medulla, they contain fewer vessels; some terminate at successive levels in neighbouring capillary plexuses. This proximity of descending and ascending vessels to each other and to adjacent collecting ducts provides the structural basis for the countercurrent exchange and multiplier phenomena (Fig. 72.15). These complex renal vascular patterns show regional specializations that are closely adapted to the spatial organization and functions of renal corpuscles, tubules and ducts (see below).

Renal veins

Fine radicles from the venous ends of the peritubular plexuses converge to join interlobular veins, one with each interlobular artery. Many interlobular veins begin beneath the fibrous capsule of the kidney by the convergence of several stellate veins, which drain the most superficial zone of the renal cortex and so are named from their surface appearance. Interlobular veins pass to the corticomedullary junction and also receive some ascending vasa recta before ending in arcuate veins (which accompany arcuate arteries), and anastomose with neighbouring veins. Arcuate veins drain into interlobar veins, which anastomose and form the renal vein.

The large renal veins lie anterior to the renal arteries and open into the inferior vena cava almost at right-angles (see Fig. 59.6; Fig. 72.16). The left renal vein is three times longer than the right (7.5 cm and 2.5 cm, respectively): the left kidney is the preferred side for live donor nephrectomy for this reason. However, the left renal vein can also be double, one vein passing posterior and the other anterior to the aorta before draining into the inferior vena cava, an arrangement that is sometimes referred to as persistence of the 'renal collar'. The anterior vein can be absent, in which case

there is a single retro-aortic left renal vein. These variations could negate any advantage of using the left kidney as a donor (Phelan et al 2009). The left renal vein runs from its origin in the hilum of the kidney, posterior to the splenic vein and the body of the pancreas, and then across the anterior aspect of the abdominal aorta, just below the origin of the superior mesenteric artery. Anterior nutcracker syndrome, characterized by left renal vein hypertension secondary to compression of the vein between the ventral surface of the abdominal aorta and the dorsal surface of the superior mesenteric artery, has been associated with haematuria and varicocele in children (Kurklinsky and Rooke 2010). The left gonadal vein enters the left renal vein from below, and the left suprarenal vein, usually receiving one of the left inferior phrenic veins, enters it above but nearer the midline (see Fig. 61.12). The left renal vein enters the inferior vena cava slightly superior to the right renal vein. The right renal vein lies posterior to the descending part of the duodenum and, sometimes, the head of the pancreas. It can be extremely short (less than 1 cm), such that safe nephrectomy can require excision of a cuff of the inferior vena cava.

Lymphatic drainage

Renal lymphatic vessels begin in three plexuses: around the renal tubules, under the renal capsule and in the perirenal fat (the latter two connect freely). Collecting vessels from the intrarenal plexus form four or five trunks that follow the renal vein to end in the lateral aortic nodes; the subcapsular collecting vessels join them as they leave the hilum of the kidney. The perirenal plexus drains directly into the same nodes.

Innervation

Rami from the coeliac ganglion and plexus, aorticorenal ganglion, least thoracic splanchnic nerve, first lumbar splanchnic nerve and aortic plexus form a dense plexus of autonomic nerves around the renal artery (see Fig. 59.4).

Small ganglia occur in the renal plexus, the largest usually behind the origin of the renal artery. The plexus continues into the kidney around the arterial branches and supplies the vessels, renal glomeruli and, especially, the cortical renal tubules. Axons from plexuses around the arcuate arteries innervate juxtamedullary efferent arterioles and vasa recta, which control the blood flow between the renal cortex and medulla without affecting the glomerular circulation. Axons from the renal plexus contribute to the ureteric and gonadal plexuses.

Microstructure

The kidney is composed of many tortuous, closely packed renal tubules, bounded by a delicate connective tissue in which run blood vessels, lymphatics and nerves. Each tubule consists of two embryologically distinct parts: the nephron, which produces urine, and the collecting duct, which completes the concentration of urine and through which urine passes out into the calyces of the kidney, the renal pelvis, the ureter and urinary bladder.

Nephron

The nephron consists of a renal corpuscle, concerned with filtration from the plasma, and a renal tubule, concerned with selective resorption from the filtrate to form the urine (see Fig. 72.13). Collecting ducts carry fluid from several renal tubules to a terminal papillary duct, opening into a minor calyx at the apex of a renal papilla. Papillary surfaces show numerous minute orifices of these ducts and pressure on a fresh kidney expresses urine from them.

Renal corpuscle

Renal corpuscles are small, rounded structures averaging 0.2 mm in diameter, visible in the renal cortex deep to a narrow peripheral cortical zone (**Fig. 72.17**; see Fig. 72.15). Each has a central glomerulus of vessels and a glomerular (Bowman's) capsule, from which the renal tubule originates.

There are about one million renal corpuscles in each kidney, their number (which can be determined, in part, by intrauterine factors) decreasing with age; this process is accelerated by raised blood pressure. After birth, new nephrons cannot be developed which means that a lost nephron can never be replaced. The decrease in corpuscular numbers with age is reflected in a corresponding reduction in the rate of glomerular filtration from the fourth decade onwards.

Glomerulus

A glomerulus is a collection of convoluted capillary blood vessels, united by a delicate mesangial matrix and supplied by an afferent arteriole that enters the capsule opposite the urinary pole, where the filtrate enters the tubule (the term glomerulus is often used to describe the entire renal corpuscle) (Davies et al 2001). An efferent arteriole emerges from the same point, the vascular pole of the corpuscle. Glomeruli are simple in form until late prenatal life; some remain so for about 6 months after birth, the majority maturing by 6 years and all by 12 years. Low birth weight, defined as a weight less than 2500 g, is associated with a reduction in the number and volume of glomeruli (Manalich et al 2000).

B

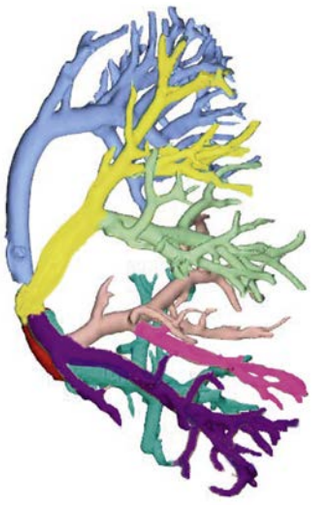

Fig. 72.14, cont'd B, A 3D elaboration of CT imaging of a vascular cast illustrating the segmental arterial anatomy of the right kidney. This specimen illustrates seven arterial segments each indicated with a separate colour. (Courtesy Dr Veronica Macchi, University of Padova, Padova, Italy.)

The left renal vein may have to be ligated during surgery for aortic aneurysm because it has such a close relationship with the aorta; this seldom results in any harm to the kidney, provided that the ligature is placed medial to the draining gonadal and suprarenal veins, since these usually provide adequate collateral venous drainage. The right renal vein has no significant collateral drainage and cannot be ligated with impunity.

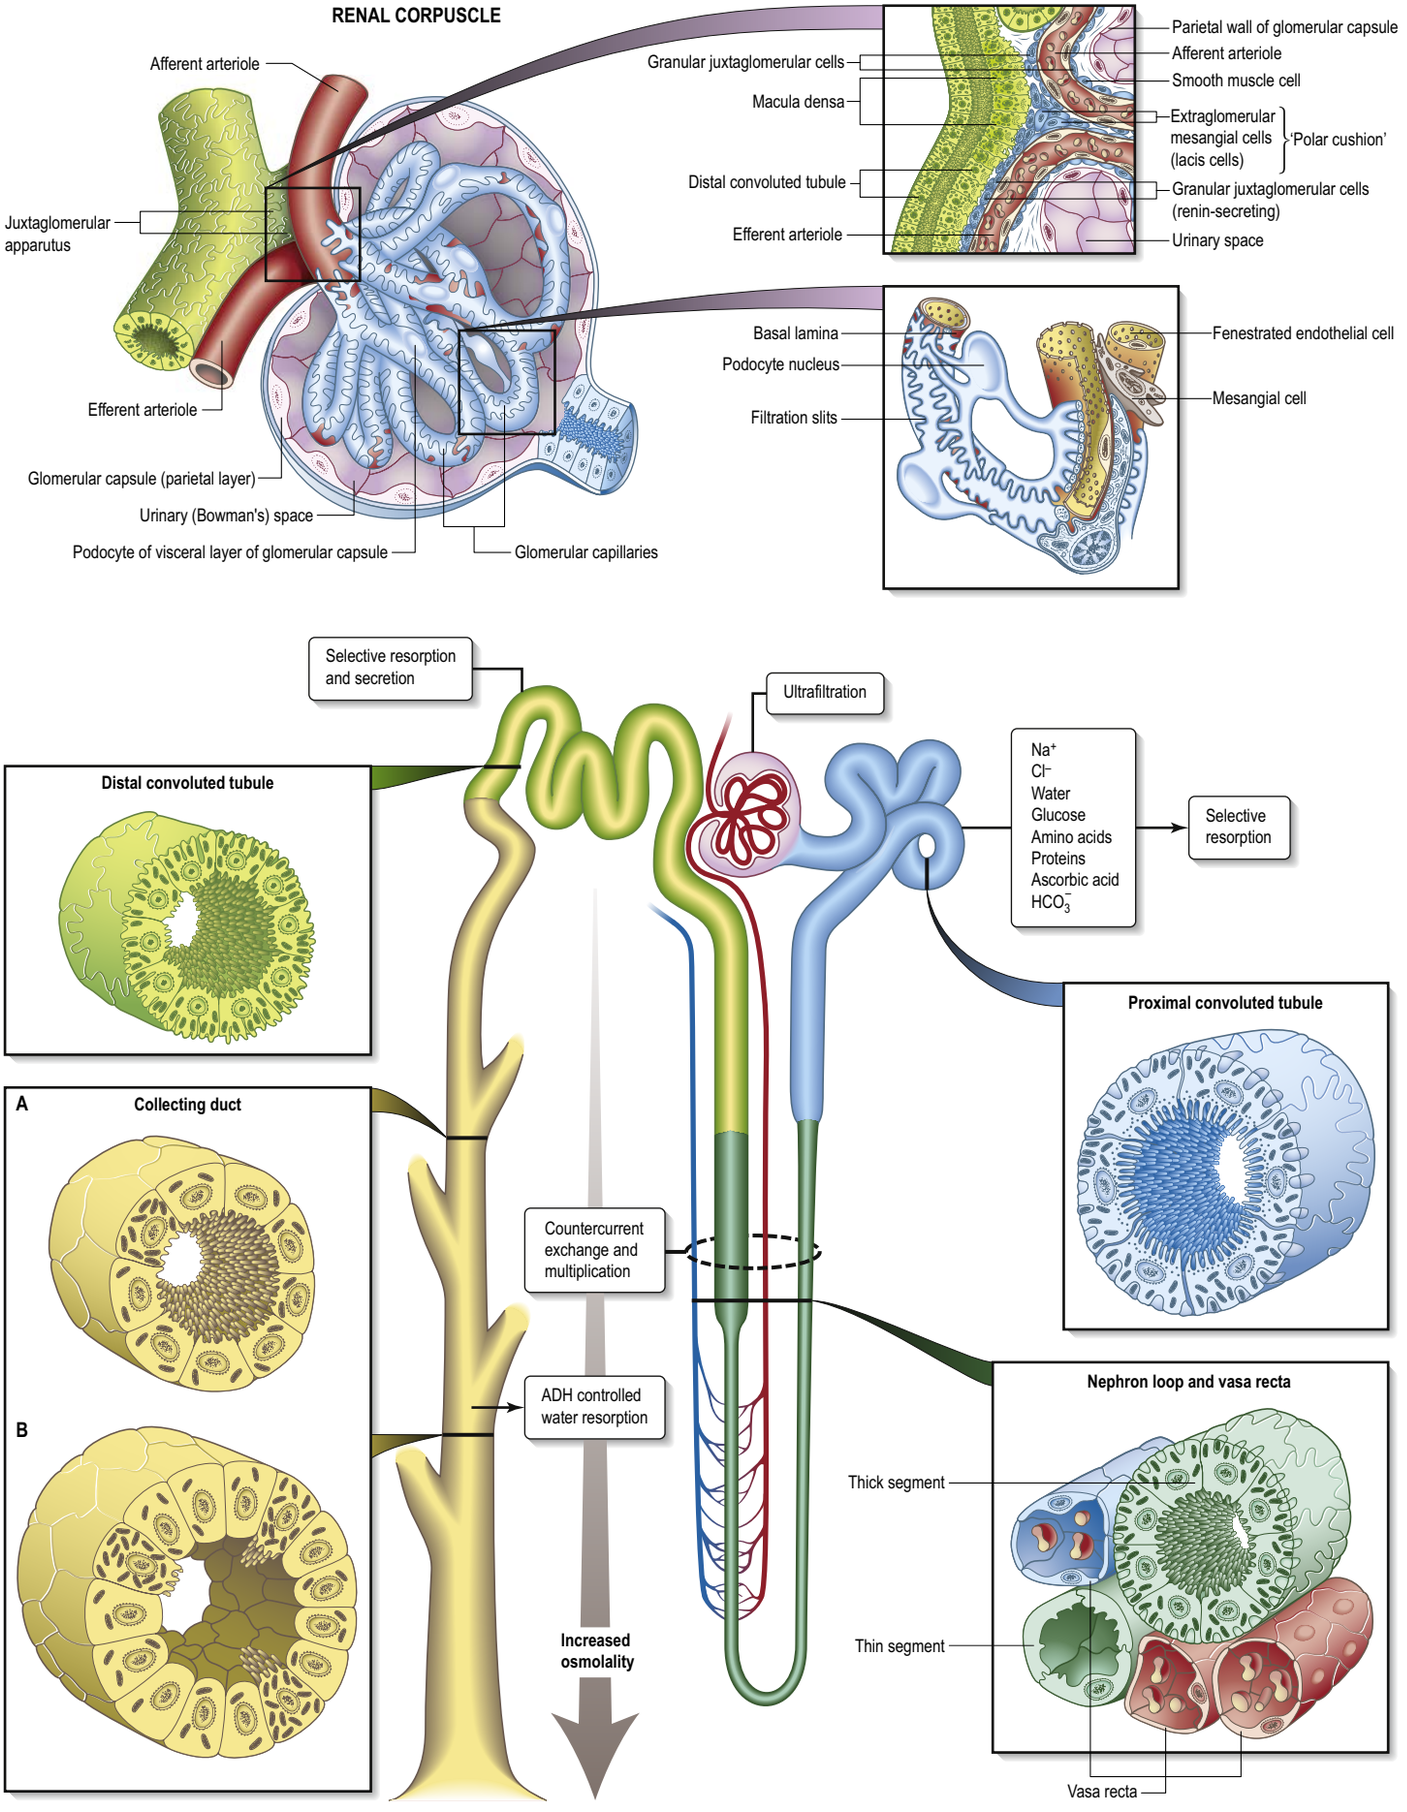

Fig. 72.15 The regional microstructure and principal activities of a nephron and collecting duct. For clarity, a nephron of the long loop (juxtamedullary) type is shown. Abbreviations: ADH, antidiuretic hormone.

Glomerular capsule

The glomerular capsule is the blind expanded end of a renal tubule and is deeply invaginated by the glomerulus. It is lined by a simple squamous epithelium on its outer (parietal) wall; its glomerular, juxtacapillary (visceral) wall is composed of specialized epithelial podocytes. Between the two walls of the capsule is a flattened urinary (Bowman's) space continuous with the proximal convoluted tubule (**Fig. 72.17B**; see Figs 2.2A, 72.15).

Podocytes are stellate cells (Zhao and Burt 2007). Their major (primary) foot processes curve around the capillary loops and branch to form secondary processes that are applied closely to the basal lamina; secondary or tertiary processes give rise to terminal pedicels (**Fig. 72.18A**). Pedicels of one cell alternate with those of an adjacent cell and interdigitate tightly with each other, separated by narrow (25 nm) gaps: the filtration slits (**Fig. 72.18B**). The latter are covered by a dense, membranous, slit diaphragm, through which filtrate must pass to enter the urinary space. The differentiation of the adult podocyte phenotype is associated with the presence of several specific proteins, including nephrin, podocin, synaptopodin and GLEPP-1. Mutations in these proteins can cause important functional problems, e.g. the classic Finnish form of congenital nephritic syndrome is caused by a mutation of *NHPS1*, which codes for nephrin. The luminal membrane and the slit diaphragm are covered by a dense surface coat rich in sialoglycoprotein, which gives this surface a very high negative charge and is one of the key characteristics of the permselectivity barrier. Differentiated podocytes cannot replicate.

The glomerular endothelium is finely fenestrated. The principal barrier to the passage of fluid from capillary lumen to urinary space is the glomerular basal lamina, the fused endothelial and podocyte basal laminae (see Fig. 72.18B). This is usually 0.33 µm thick in humans and acts as a selective filter, allowing the passage from blood, under pressure, of water and various small molecules and ions in the circulation. Haemoglobin can cross the filter, but larger molecules and those of similar size with a negative charge are largely retained. Most protein that does enter the filtrate is selectively resorbed and degraded by cells of the proximal convoluted tubule.

The glomerular basal lamina serves as the skeleton of the glomerular tuft. Its outer aspect is completely covered by podocytes, and the interior is filled by capillaries and a delicate mesangial matrix (mesangium). The major components of the glomerular basal lamina are laminin and type IV collagen (both of which are expressed as unique isoforms), and heparan sulphate proteoglycans. The thickness of the glomerular basal lamina increases throughout childhood; the rate of increase slows after the age of 11 years (Ramage et al 2002).

Irregular mesangial cells, with phagocytic and contractile properties, lie within and secrete the glomerular mesangium, a specialized connective tissue that binds the loop of glomerular capillaries and fills the spaces between endothelial surfaces that are not invested by podocytes (see Figs 72.15, 72.17B). Mesangial cells are related to vascular pericytes and are concerned with the turnover of glomerular basal lamina. They clear the glomerular filter of immune complexes and cellular debris, and their contractile properties help to regulate blood flow. Similar cells, the extraglomerular mesangial (lacis) cells, lie outside the glomerulus at the vascular pole and form part of the juxtaglomerular apparatus.

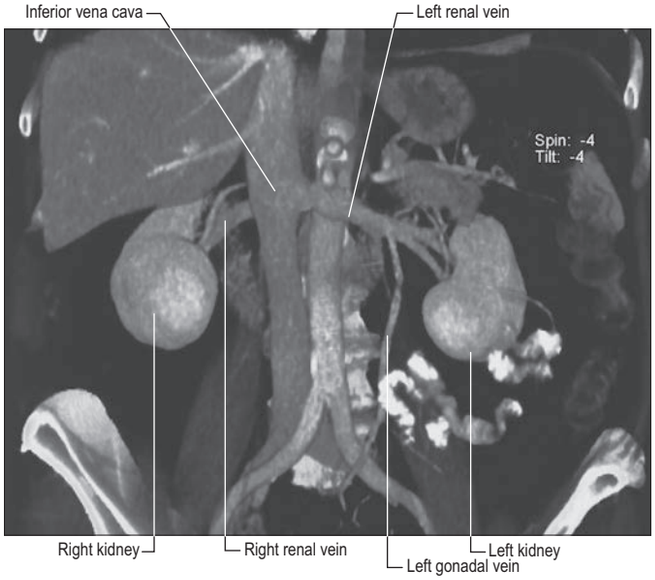

Fig. 72.16 A CT renal venogram, acquired from a multislice CT examination and reconstructed as a three-dimensional, surface-shaded reformat.

Renal tubule

A renal tubule consists of a glomerular capsule that leads into a proximal convoluted tubule, connected to the capsule by a short neck and continuing into a sinuous or coiled convoluted part (see Fig. 72.15). This straightens as it approaches the medulla to become the descending limb of the nephron loop (loop of Henle), and then the ascending limb after an abrupt U-turn. The limbs of the nephron loop are narrower and thinner-walled within the deeper medullary tissue, where they become the descending and ascending thin segments. The thick ascending limb continues into the distal convoluted tubule. The nephron finally straightens once more as the connecting tubule, which ends by joining a collecting duct.

Collecting ducts originate in the cortical medullary rays and join others at intervals. They finally open into wider papillary ducts, which open on to a papilla, their numerous orifices forming a perforated cribriform area on the surface at its tip (see Fig. 72.13).

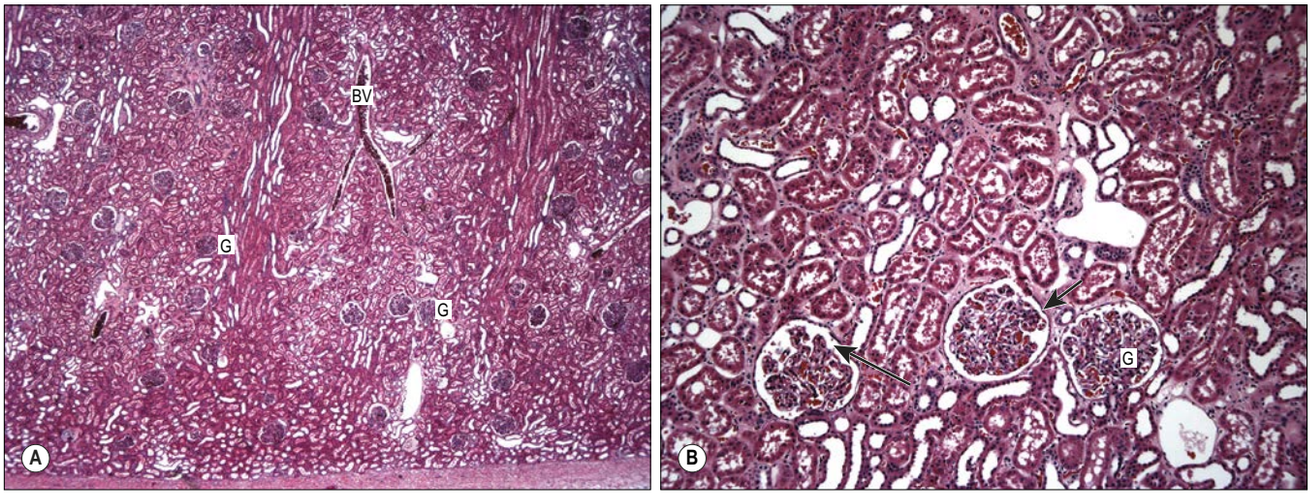

Fig. 72.17 **A**, A low-power histological section of the renal cortex, containing glomeruli (G), proximal and distal convoluted tubules and blood vessels (BV). **B**, A higher-power view of the section demonstrating several glomeruli (G) within a network of mesangium. The glomerular basement membrane of the capillaries is continuous with the glomerular capsule (short arrow) of the glomerulus, and is separated from it by Bowman's space (long arrow).

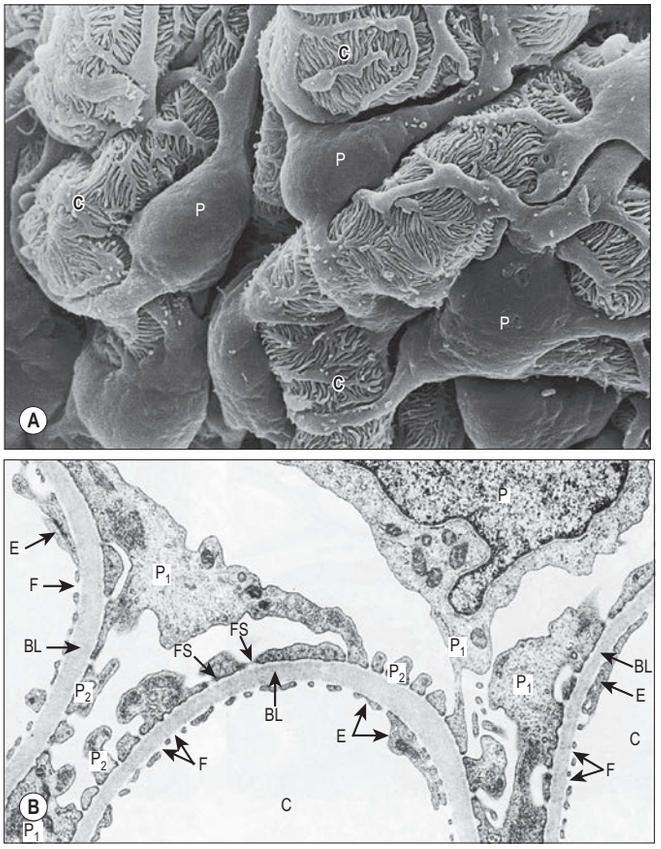

Fig. 72.18 **A**, A scanning electron micrograph showing podocytes forming the visceral layer of the glomerular capsule in the renal corpuscle. Their cell bodies (P) send out primary processes that branch several times and end in fine pedicels, which wrap tightly around the glomerular capillaries (C) and interdigitate with similar pedicels from a neighbouring podocyte. **B**, A transmission electron micrograph demonstrating the glomerular filtration apparatus. Note the endothelial cells of fenestrated capillaries, the filtration slits between podocyte pedicels and their thick shared basal lamina. Abbreviations: BL, basal lamina; C, lumina of capillary loops; E, endothelial cell cytoplasm; F, fenestrations; FS, filtration slits; P, podocyte; P_1 and P_2, primary and secondary foot processes that rest on the glomerular basal laminae. (A, With permission from Igaku-Shoin, Tokyo, from Fujita T, Tanaka K, Tokunaga J 1981 SEM Atlas of Cells and Tissues. B, With permission from Young B, Heath JW 2000 Wheater's Functional Histology. Edinburgh: Churchill Livingstone.)

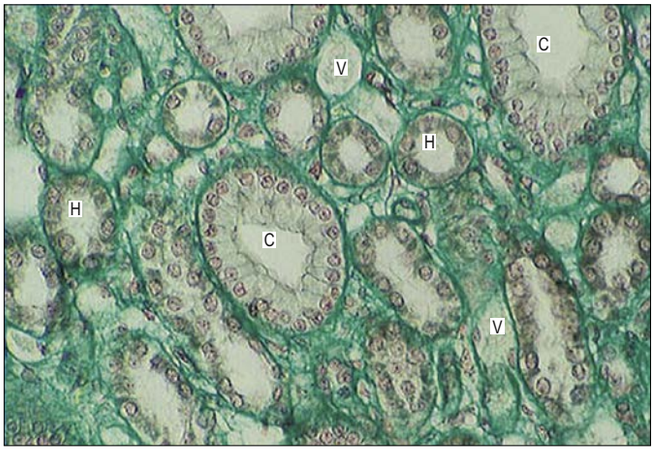

Fig. 72.19 A histological cross-section of a part of the renal medulla. Note the large collecting ducts (C) and smaller segments of the nephron loop (loop of Henle (H)), interspersed with vasa recta (V) (trichrome-stained).

Renal tubules are lined throughout by a single-layered epithelium (see Fig. 72.15; **Fig. 72.19**). The type of epithelial cell varies according to the functional roles of the different regions, e.g. active transport and passive diffusion of various ions and water into and out of the tubules; reabsorption of organic components such as glucose and amino acids; uptake of any proteins that leak through the glomerular filter.

The proximal convoluted tubule is lined by cuboidal or low columnar epithelium and has a brush border of tall microvilli on its luminal surface. The shape of the cells depends on tubular fluid pressure, which, in life, distends the lumen and flattens the cells (they become taller when glomerular blood pressure ceases post mortem or at biopsy). The cytoplasm of proximal tubular cells is strongly eosinophilic and the nuclei are euchromatic and central. The basal cytoplasm is rich in mitochondria, orientated perpendicularly and the basal plasma membrane is highly infolded. The lateral surfaces of adjacent epithelial cells interdigitate, increasing the complexity of the basolateral plasma membrane. The microvilli on the luminal surfaces significantly increase the area of plasma membrane in contact with tubular fluid, facilitating the transport of ions and small molecules against steep concentration gradients. The abundant mitochondria supply the energy, as adenosine triphosphate (ATP), needed for this process. Sodium/potassium adenosine triphosphatase (Na^+/K^+ ATPase) is located in apical and basal membranes, and the cytoplasm contains numerous other enzymes concerned with ion transport. Water and other solutes pass between cells (paracellular transport) passively, along osmotic and electrochemical gradients, probably through leaky apical tight junctions. Pinocytotic vesicles are found near the apical surface and represent the means by which small proteins and peptides from the filtrate are internalized and degraded by associated lysosomes. Peroxisomes and lipid droplets abound in the cytoplasm.

The nephron loop consists of a thin segment (30 μm in diameter), lined by low cuboidal to squamous cells, and a thick segment (60 μm in diameter) composed of cuboidal cells like those in the distal convoluted tubule. The thin segment forms most of the nephron loop in juxtamedullary nephrons, which reach deep into the medulla. Few organelles appear in cells lining the thin segment, indicating that these cells play a passive rather than an active role in ion transport. The thick segment is composed of cuboidal epithelium with many mitochondria, deep basolateral folds and short apical microvilli, indicating a more active metabolic role. The thick ascending limb of the nephron loop is the source of Tamm–Horsfall glycoprotein, which is a crucial defence molecule (Wu et al 2018).

Cells of the distal tubule are cuboidal and resemble those in the proximal tubule. They have few microvilli, so the tubular lumen has a more distinct outline. The basolateral folds containing mitochondria are deep, almost reaching the luminal aspect. Enzymes concerned with active transport of sodium, potassium and other ions are abundant. At the junction of the straight and convoluted regions, the distal tubule comes close to the vascular pole of its parent renal corpuscle. Here, tubular cells form the macula densa, a sensory structure that is concerned with the regulation of blood flow and therefore the filtration rate. Cells in the terminal part of the distal tubule have fewer basal folds and mitochondria and constitute a connecting duct formed from metanephric mesenchyme during embryogenesis. Collecting ducts are lined by simple cuboidal or columnar epithelium. This increases in height from the renal cortex, where the ducts receive the contents of distal tubules, to the wide papillary ducts that discharge at the cribriform area (area cribrosa). The pale-staining principal cells have relatively few organelles or lateral interdigitations, and only occasional microvilli. A second cell type, intercalated or dark cells (also present in smaller numbers in the distal convoluted tubule), has longer microvilli and more mitochondria and secretes H^+ into the filtrate; these cells function in the maintenance of acid–base homeostasis.

Renal vessels

The renal, interlobar and arcuate arteries are typical large muscular arteries and the interlobular vessels resemble small muscular arteries. Afferent glomerular vessels have a typical arteriolar structure with a muscular coat 2–3 cells thick; this coat and the connective tissue components of the wall diminish near a glomerulus until a point 30–50 μm proximal to it, where arteriolar cells begin to show modifications typical of the juxtaglomerular apparatus. The efferent arterioles from most cortical glomeruli have thicker walls and a narrower calibre than corresponding afferents. Although the afferent arteriole is generally considered to be solely responsible for tubuloglomerular feedback, the peritubular and medullary capillaries possess a well-defined basal lamina. Additionally, their endothelial cells have typically fenestrated cytoplasm, as do the ascending vasa recta, whereas the descending vasa recta have a thicker, continuous endothelium (Davies 1991).

Other renal cells

Other cells essential for renal structure and function lie between the renal tubules and blood vessels. Connective tissue is inconspicuous in the cortex but prominent in the medulla, particularly in the papillae. Medullary interstitial cells, which may be modified fibroblasts, form vertical stacks of tangentially orientated cells between the more distal collecting ducts, like the rungs of a ladder. These cells secrete prostaglandins and may contribute, with cortical tubular cells, to the renal source of erythropoietin.

Calyces and renal pelvis

The wall of the proximal part of the urinary tract is composed of three layers: an outer connective tissue adventitia, an intermediate layer of smooth muscle and an inner mucosa. The mucosal lining of the renal calyces and pelvis is identical in structure to that of the ureter (see below). The adventitia consists of loose fibroelastic connective tissue that merges with retroperitoneal areolar tissue. Proximally, the coat fuses with the fibrous capsule of the kidney lining the renal sinus.

The smooth muscle of the renal calyces and pelvis is composed of two distinct types of smooth muscle cell. One type of muscle cell is identical to that described for the ureter and can be traced proximally through the ureteropelvic (pelviureteric) region and renal pelvis, as far as the minor calyces. The other type of cell forms the muscle coat of each minor calyx and continues into the major calyces and renal pelvis, where it forms a distinct inner layer. The cells also form a thin sheet of muscle that covers each minor calyx and extends across the renal parenchyma between the attachments of neighbouring minor calyces, thereby linking each minor calyx to its neighbours. This discrete inner layer of atypical smooth muscle ceases in the ureteropelvic region, so that the proximal ureter lacks such an inner layer. Pacemaker cells that initiate renal pelvic and ureteric peristalsis are sited within the calyces (Gosling and Dixon 1974, Lang et al 2006) and allow coordinated peristalsis of the ureter to take place six times a minute.

Production of urine

Glomerular filtration

Glomerular filtration (see Figs 72.13, 72.15) is the passage of water containing dissolved small molecules from the blood plasma to the urinary space in the glomerular capsule. Larger molecules, e.g. plasma proteins above 70 kDa and those with a net negative charge, polysaccharides, lipids and cells, are largely retained in the blood by the selective permeability of the glomerular basal lamina.

Filtration occurs along a steep pressure gradient between the large glomerular capillaries and the urinary space. Three structures separate the two: the capillary endothelium, the glomerular basal lamina and the foot process of the podocyte. Of these, the principal structure is the glomerular basal lamina (Fig. 72.18B). This gradient far exceeds the colloid osmotic pressure of blood, which opposes the outward flow of filtrate. In the peripheral renal cortex, the arteriolar pressure gradient is enhanced because afferent glomerular arterioles are wider than efferent ones. In all glomeruli, the rate of filtration can be altered by changes in the tone of the glomerular arterioles. When first formed, the glomerular filtrate is isotonic with glomerular blood and has an identical concentration of ions and small molecules.

The assessment of glomerular filtration is fundamental to the diagnosis of renal glomerular pathology and the management of drug therapy, where clearance depends on the glomerular filtration, and in chronic kidney disease to facilitate timely management decisions. Measurements of glomerular filtration rate (GFR) are based on the renal clearance of a marker in plasma, expressed as the volume of plasma completely cleared of the marker per unit time. Markers used to measure GFR can be endogenous (creatinine, urea) or exogenous (inulin, iothalamate). The ideal marker is endogenous, freely filtered by the glomerulus, neither reabsorbed nor secreted by the renal tubule, and eliminated only by the kidney.

Selective resorption

Selective resorption from the filtrate is an active process and occurs mainly in the proximal convoluted tubules, which resorb glucose, amino acids, phosphate, chloride, sodium, calcium and bicarbonate, and take up small proteins (e.g. albumin) by endocytosis. Cells of the proximal tubules are permeable to water, which passes out of the tubules passively, so that the filtrate remains locally isotonic with blood. The rest of the tubule reabsorbs most of the water (to a variable extent up to 95%), so that urine is generally much reduced in volume and hypertonic to blood when it reaches the calyces. The process depends on establishing high osmolality in the medullary interstitium in order to exert sufficient osmotic pressure on water-permeable regions of the tubule, and is achieved by a countercurrent multiplier mechanism.

Countercurrent multiplier mechanism

The countercurrent multiplier mechanism is responsible for producing a high osmolality in the extratubular interstitial tissue of the renal medulla. Water passes freely from the tubular lumen into the adjacent medullary interstitium along the descending limb of the nephron loop. This part of the tubule is less permeable to solutes. In the thick ascending limb, sodium and chloride ions are actively transported from the tubule lumen into interstitial spaces, while the tubular epithelium remains impermeable to water. The increased interstitial osmolality causes water to be withdrawn from the descending part of the nephron loop, thus concentrating the filtrate. Tubular fluid flows in a countercurrent on its descent into and ascent out of the renal medulla; it is augmented by new isotonic fluid entering the nephron loop, and depleted by hypotonic fluid leaving the loop as solutes are actively resorbed. The osmotic gradient within the interstitium is therefore multiplied from the corticomedullary boundary to the renal pyramids, where it reaches equilibrium at four to five times the osmolality of plasma. Although the tonicity of the tubular fluid changes during its passage through the steep osmotic gradient within the renal medulla, the osmotic gradient between ascending and descending limbs at each level never exceeds 200 mOsm/kg, a force that can be sustained by the cells of the tubular wall.

Countercurrent exchange mechanism

Rapid removal of ions from the renal medulla by the circulation of blood is minimized by another looped countercurrent system. This is the countercurrent exchange mechanism, in which arterioles entering the renal medulla pass for long distances parallel to the venules leaving it, before ending in capillary beds around tubules. This close apposition of oppositely flowing blood allows ions to diffuse directly from outflowing to inflowing blood, so that the vasa recta (see Fig. 72.13) conserve the high osmotic pressure in the renal medulla.

Concentration of urine

Because sodium and chloride ions are selectively resorbed by the cells of the ascending limbs and distal tubules under aldosterone control, the filtrate at the distal end of the convoluted tubules is hypotonic. As it reaches the collecting ducts, fluid descends again through the renal medulla and thus re-enters a region of high osmotic pressure. The cells lining the collecting ducts are variably permeable to water, under the influence of antidiuretic hormone (ADH). Water follows an osmotic gradient into the adjacent extratubular spaces, so that the tonicity of the filtrate gradually rises along collecting ducts, until, at the tip of the renal pyramids, it is above that of blood. This complex system is highly flexible and the balance between the rates of filtration and absorption can be varied to meet current physiological demands.

Control of hydrogen and ammonium ion concentrations is essential for the regulation of acids and bases in the blood. Secretion of various ions occurs at several sites. Over 91% of ingested potassium is excreted in urine, largely through secretion by cells of the distal tubule and collecting duct. (For further details of renal physiology, see Madias and Adrogué (2005), Tannen and Hallows (2005), Singh and Thomson (2011).)

Juxtaglomerular apparatus

The juxtaglomerular apparatus provides a tubuloglomerular feedback system that maintains systemic arterial blood pressure during a reduction in vascular volume and decrease in filtration rate. The elements of a juxtaglomerular apparatus are juxtaglomerular and extraglomerular mesangial cells, and the macula densa. The afferent and efferent arterioles at the vascular pole of a glomerulus and the macula densa of the distal tubule of the same nephron lie in close proximity, enclosing a small cone of tissue populated by extraglomerular mesangial cells (see Fig. 72.15). The cells of the tunica media of afferent, and to a lesser extent efferent, arterioles differ from typical smooth muscle cells. These juxtaglomerular cells are large, rounded, myoepithelioid cells and their cytoplasm contains many mitochondria and dense renin-containing vesicles, 10–40 nm in diameter. Each macula densa of the distal tubule is a cluster of up to 40 tightly packed cells in the tubule wall; the cells have large, oval nuclei and apically concentrated mitochondria. They

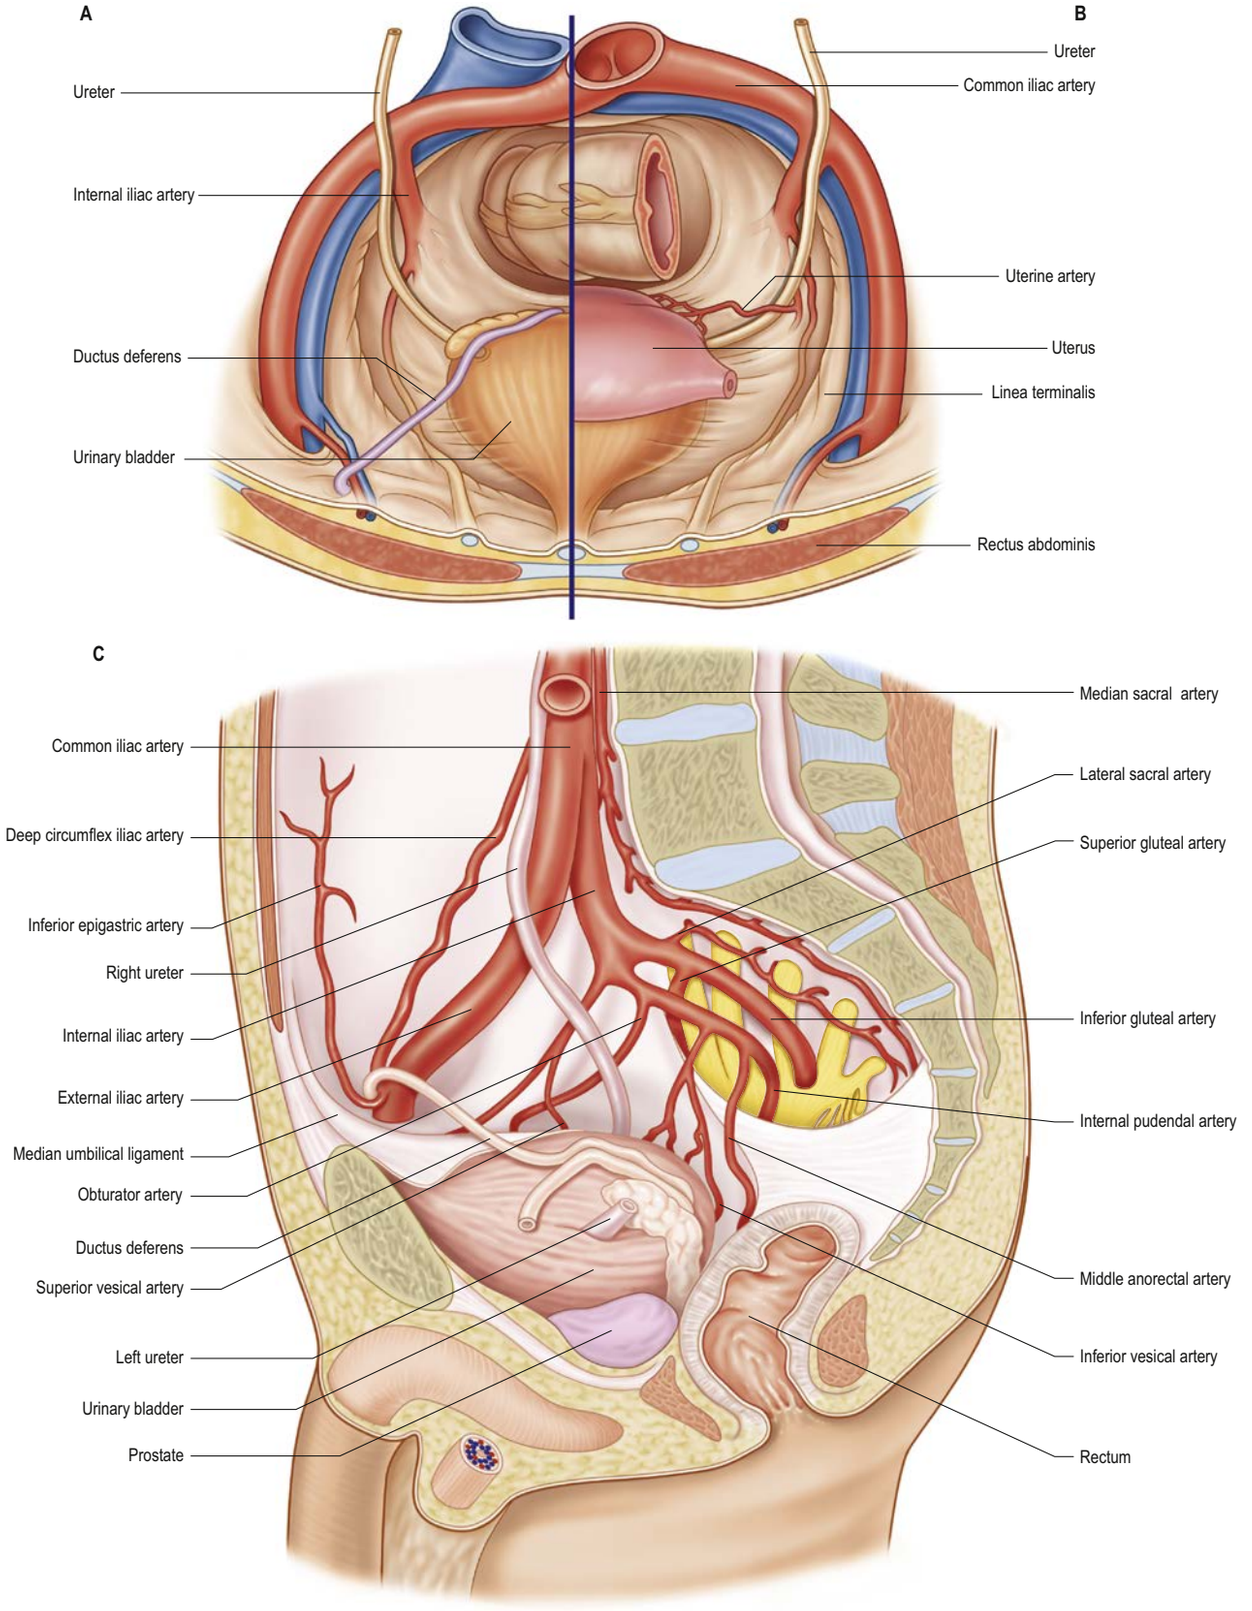

Fig. 72.20 Relations of the abdominal and pelvic parts of the ureter. **A**, **B**, Relations of the distal part of the ureter, superior view. **A**, The male pelvis. **B**, The female pelvis. C, The male pelvis, sagittal section. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich. B–C, With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

are osmoreceptors, sensing the sodium chloride content of the filtrate after its passage through the nephron loop.

When sodium chloride concentrations in the filtrate change, tubuloglomerular feedback mechanisms operate to maintain the inverse relationship between salt concentration and glomerular filtration rate. Juxtaglomerular cells release renin, an enzyme that acts on circulating angiotensinogen to activate the cascade whereby angiotensin II increases blood pressure (and therefore filtration rate), stimulates aldosterone and antidiuretic hormone release and increases sodium ion and water resorption, primarily from the distal tubule, to increase plasma volume. Macula densa cells are thought to respond to high salt concentration in the distal tubule by releasing nitric oxide, which inhibits the tubuloglomerular feedback response and reduces filtration rate. The role of macula densa cells in the stimulation of renin release to increase the filtration rate is less well understood.

The third element of the juxtaglomerular apparatus is a population of extraglomerular mesangial cells that form a network of stellate cells connecting the macula densa sensory cells with the juxtaglomerular

effector cells. It is likely that extraglomerular mesangial cells transmit the sensory signal, possibly through gap junctions. They may also signal to contractile glomerular mesangial cells and effect vasoconstriction directly within the glomerulus. Adrenergic nerve fibres occur in small numbers among these cells.

URETER

The ureters are two muscular tubes that convey urine from the kidneys to the urinary bladder by peristaltic contractions (see Figs 72.1, 72.9, Fig. 72.20). Each measures 25–30 cm in length (in neonates 6–7 cm), is thick-walled and narrow, and is continuous superiorly with the funnel-shaped renal pelvis. Each descends slightly medially, anterior to psoas major and enters the pelvic cavity where it curves initially laterally, then medially, to open into the fundus of the urinary bladder. The diameter of the ureter is normally 3 mm, but is slightly less at its junction with the renal pelvis, at the linea terminalis near the medial border of psoas major, and where it runs within the wall of the urinary bladder, which is its narrowest part. These are the most common sites for renal stone impaction.

Relations

The ureter has abdominal, pelvic and intramural parts. The abdominal part travels from the renal pelvis to the linea terminalis and descends posterior to the peritoneum on the medial part of psoas major, which separates it from the tips of the transverse processes of the lumbar vertebrae. During surgery on intraperitoneal structures, the ureter can be tented up as the peritoneum is drawn anteriorly, resulting in iatrogenic injury. Anterior to psoas major, it crosses anterior to the genitofemoral nerve and is obliquely crossed by the gonadal vessels. It enters the lesser pelvis either anterior to the end of the common iliac vessels or at the origin of the external iliac vessels.

The right ureter is usually overlapped by the descending part of the duodenum at its origin. It descends lateral to the inferior vena cava and is crossed anteriorly by the right colic and ileocolic vessels. Near the superior aperture of the lesser pelvis it passes behind the lower part of the mesentery and the terminal ileum. The left ureter is lateral to the abdominal aorta and is crossed by the gonadal and left colic vessels. It passes posterior to the jejunum and sigmoid colon and its mesentery in the posterior wall of the intersigmoid recess. The inferior mesenteric vein has a long retroperitoneal course lying close to the medial aspect of the left ureter.

The pelvic part of the ureter extends from the linea terminalis to the point where it pierces the wall of the urinary bladder. At first, the ureter descends posterolaterally on the lateral wall of the lesser pelvis along the anterior border of the greater sciatic foramen, lying in extraperitoneal areolar tissue. Opposite the ischial spine, it turns anteromedially into fibrous adipose tissue above levator ani to reach the fundus of the bladder. On the pelvic side wall the ureter is anterior to the internal iliac artery and the origin of its anterior division; the internal iliac vein, lumbosacral trunk and sacroiliac joint are posterior relations. Laterally, it lies on the obturator fascia and progressively crosses to become medial to the umbilical, inferior vesical and middle anorectal arteries.

In males, the pelvic part of the ureter hooks under the ductus deferens (Fig. 72.21); it then passes anterior and slightly superior to the upper pole of the seminal gland to the wall of the urinary bladder. In females, the pelvic part of the ureter initially has the same relations as in males, but anterior to the internal iliac artery it is immediately behind the ovary, forming the posterior boundary of the ovarian fossa (see Fig. 75.8). In the anteromedial part of its course to the urinary bladder it is related to the uterine artery, uterine cervix and vaginal fornix. It lies in extraperitoneal connective tissue in the inferomedial part of the broad ligament of the uterus and can be injured during hysterectomy (see Fig. 75.7). In the broad ligament of the uterus, the uterine artery is anterosuperior to the ureter for approximately 2.5 cm and then crosses to its medial side to ascend alongside the uterus. The ureter turns forwards slightly above the lateral part of the vaginal fornix and is generally 2 cm lateral to the supravaginal part of the uterine cervix in this location. It then inclines medially to reach the urinary bladder, with a variable relation to the anterior aspect of the vagina. As the uterus is commonly deviated to one side, one ureter, usually the left, can be more extensively apposed to the vagina, and may cross the midline.

The distal 1–2 cm of the ureter, the intramural part, is surrounded by an incomplete collar of non-striated muscle (sheath of Waldeyer).

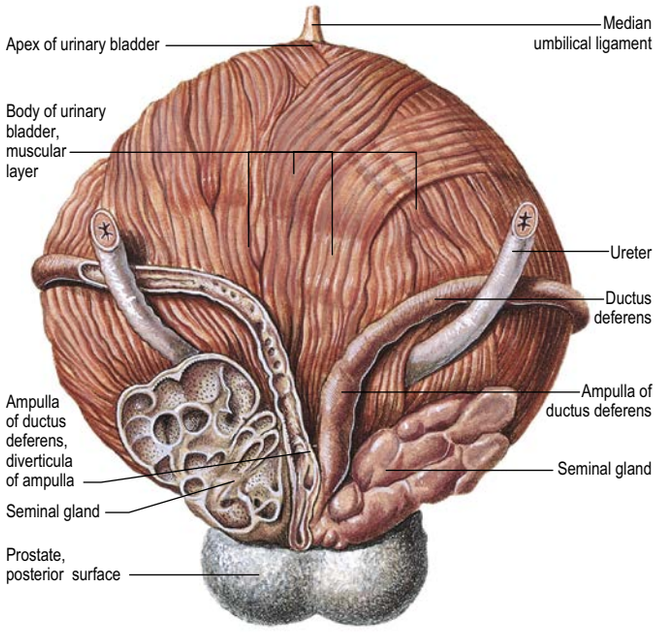

Fig. 72.21 The posterior aspect of the male urogenital organs, showing the relationship of the distal ureter to the ductus deferens and seminal glands. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

The two ureters pierce the posterior aspect of the urinary bladder and run obliquely through its wall for a distance of 1.5–2.0 cm before terminating at the ureteric orifices (see Fig. 73.7B). This arrangement is believed to assist in preventing reflux of urine into the ureter, since the intramural parts of the ureters are thought to be occluded during increases in urinary bladder pressure at the time of micturition. There is no evidence of a classic ureteral sphincter mechanism in humans. The longitudinally orientated muscle bundles of the terminal ureters continue into the urinary bladder wall and become continuous with the superficial trigone muscle at the ureteric orifices. In both sexes, the ureteric orifices are usually 5 cm apart in the distended urinary bladder and 2.5 cm apart when the bladder is empty.

Vascular supply and lymphatic drainage

Arteries

The ureter is supplied by branches from the renal, gonadal and common iliac arteries, the internal iliac artery and its branches, and the abdominal aorta. The pattern of distribution is subject to much variation. The abdominal part of the ureter is supplied from vessels originating medial to the ureter; the pelvic part of the ureter is supplied by vessels lateral to the ureter (Fig. 72.22). There is a good longitudinal anastomosis between these branches on the wall of the ureter, which means that the ureter can be safely transected at any level intraoperatively, and a uretero-ureterostomy performed, without compromising its viability. The branches from the inferior vesical artery are constant in their occurrence and supply the distal part of the ureter, as well as a large part of the trigone of the bladder. The branch from the renal artery is also constant and is preserved whenever possible in renal transplantation to ensure good vascularity of the ureter.

Veins

The venous drainage of the ureters generally follows the arterial supply.

Lymphatic drainage

Lymph vessels draining the ureter begin in the submucosal, intramuscular and adventitial plexuses, which all communicate. Collecting vessels from the upper abdominal part of the ureter can join the renal collecting vessels or pass directly to the lateral aortic nodes near the origin of the gonadal artery; those from the lower abdominal part of the ureter drain to the common iliac nodes; and those from the pelvic part of the ureter drain to common, external or internal iliac nodes.

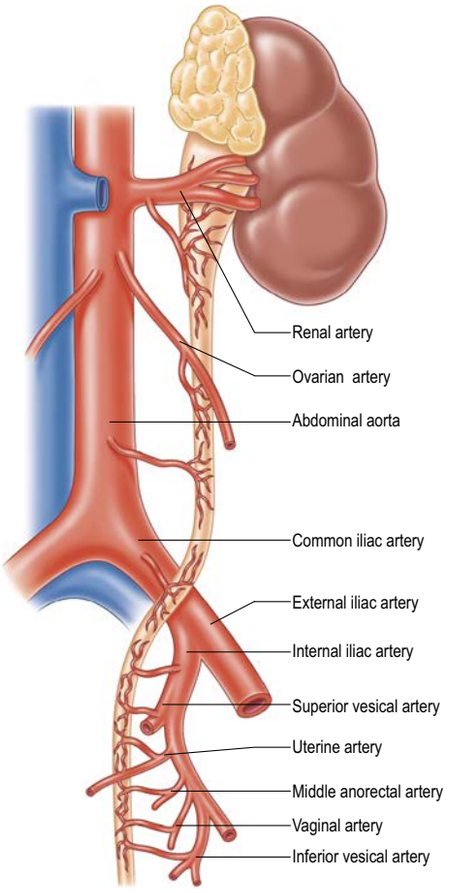

Fig. 72.22 The arterial supply of the female left ureter. The proximal part takes its blood supply medially and the distal part is supplied laterally. (With permission from Walsh PC, Retik AB, Vaughan ED et al (eds) 2002 Campbell's Urology, 8th ed. Philadelphia: Saunders.)

Fig. 72.23 A coronal CT urogram volume-rendered image demonstrates a duplicated right collecting system and ureter, along with dilation of the collecting system of the lower pole moiety. No urothelial lesion is seen.

Innervation

The ureter is supplied from the lower three thoracic, first lumbar and the second to fourth sacral segments of the spinal cord by branches from the renal and abdominal aortic plexuses, and the superior and inferior hypogastric plexuses (see Figs 59.3, 73.8). The ureteric nerves consist of relatively large bundles of axons that form an irregular plexus in the adventitia of the ureter. The ureteric plexus receives branches from the renal and aortic plexuses (in its upper part); from the superior hypogastric plexus and hypogastric nerve (in its intermediate part); and from the hypogastric nerve and inferior hypogastric plexus (in its lower part). Numerous small branches penetrate the ureteric muscle coat; some of the adventitial nerves accompany the blood vessels and branch with them as they extend into the muscle layer; others are unrelated to the vascular supply and lie free in the adventitial connective tissue around the circumference of the ureter.

The density of innervation increases gradually from the renal pelvis and proximal (upper) ureter (where autonomic nerves are sparse) to a maximum density in the juxtavesical segment. At least three different neurotransmitter phenotypes – cholinergic, noradrenergic and peptidergic (substance P) – are well known and others have been reported. The functional significance of these different types of autonomic nerve fibres in relation to ureteric smooth muscle activity is not fully understood; although they are thought to influence the inherent motility of the ureter, they are not essential for the initiation and propagation of ureteric contraction waves. A branching plexus of fine cholinergic, noradrenergic and peptidergic axons occurs throughout the lamina propria and extends from the inner aspect of the muscle coat towards the base of the urothelium. Some of these axons form perivascular plexuses, while others lie in isolation from the vascular supply and could be sensory in function.

Ureteric peristalsis

Under normal conditions, contraction waves originate in the proximal part of the upper urinary tract and are propagated anterogradely towards the urinary bladder. Atypical smooth muscle cells in the wall of the minor calyces act individually or collectively as pacemaker sites. A peristaltic wave begins at one (or possibly more) of these sites. Once initiated, the contraction is propagated through the wall of the adjacent major calyx and activates the smooth muscle of the renal pelvis. Contraction waves are propagated away from the kidney, and so undesirable pressure rises are not directed against the renal parenchyma. Since there are several potential pacemaker sites, the initiation of contraction waves is unimpaired by partial nephrectomy; the minor calyces spared by the resection remain *in situ* to continue their pacemaking function. Pressures within the ureter at the time of peristalsis reach 20–80 cm H_2O.

Referred pain Excessive distension of the ureter or spasm of its muscle can be caused by a stone (calculus) and provokes severe pain (ureteric colic, which is commonly, but mistakenly, called renal colic). The pain is spasmodic and agonizing, particularly if the obstruction is gradually forced down the ureter by the muscle spasm. It is referred to cutaneous areas innervated from spinal segments that supply the ureter, mainly T11–L2, and shoots superomedially down to the scrotum or labium majus; it can extend into the proximal anterior aspect of the thigh by projection to the genitofemoral nerve (L1, L2). The cremaster, which has the same innervation, may retract the testis reflexly.

Renal and ureteric calculi An understanding of intrarenal and ureteric anatomy is essential for managing patients with calculi, particularly now that minimally invasive techniques are widely used to treat this common pathology.

Microstructure

Like the calyces and the renal pelvis, the wall of the ureter is composed of an external adventitia, a smooth muscle layer and an inner mucosal layer. The mucosal layer consists of a urothelium (transitional epithelium) (see Fig. 2.5D) and an underlying connective tissue lamina propria.

The ureteric adventitial blood vessels and connective tissue fibres are orientated parallel to the long axis of the ureter. Throughout its length, the muscle coat of the ureter is fairly uniform in thickness and, in cross-section, measures 750–800 μm in width. The muscle bundles that constitute this coat are frequently separated from one another by relatively large amounts of connective tissue. However, branches that interconnect muscle bundles are common and there is frequent interchange of muscle fibres between adjacent bundles. As a consequence of this extensive branching, individual muscle bundles do not spiral around the ureter, but form a complex meshwork of interweaving bundles. Moreover, unlike the gut, the muscle bundles

Experimental evidence indicates that autonomic nerves do not play a major part in the propagation of peristalsis. It seems more likely that they modulate the contractile events occurring in the musculature of the upper urinary tract. The most likely mechanism to account for impulse propagation is myogenic conduction mediated by the electrotonic coupling of one muscle cell to its immediate neighbours via intercellular gap junctions; there are numerous regions of close approach between ureteric smooth muscle cells and also between both types of muscle cell in the renal pelvis and calyces.

Smaller renal calculi are treated with extracorporeal shock wave lithotripsy. Stones in the lower pole of the kidney clear less well if the angle between the infundibulum of the major calyx containing the stone and the ureter is acute, or if there is a particularly long and narrow infundibulum. Percutaneous stone extraction is most frequently achieved by puncturing a posterior calyx with a needle. Ureteric calculi tend to be arrested in their descent in either the ureteropelvic region, or at the point where the ureter passes over the linea terminalis as it crosses the common iliac artery, or at the ureterovesical junction, because these are the three areas where the ureter is narrowest. The ureterovesical junction is the narrowest of these areas and can be responsible for arresting the passage of stones of as little as 2–3 mm. The kidney and proximal ureter move with respiration within the renal fascia, and this can affect the visualization and tracking of a stone, both at the time of extracorporeal shock wave lithotripsy and at retrograde endoscopy.

are so arranged that morphologically distinct longitudinal and circular layers cannot be clearly distinguished. In the upper part of the ureter, the inner muscle bundles tend to lie longitudinally while those on the outer aspect have a circular or oblique orientation. In the middle and lower parts, there are additional outer longitudinally orientated fibres, and as the ureterovesical junction is approached, the muscle coat consists predominantly of longitudinally orientated muscle bundles.

The mucosa of the ureter consists of an epithelium, the urothelium, lying on a layer of subepithelial fibroelastic connective tissue lamina propria. The latter varies in thickness from 350 to 700 µm and is a conduit for small blood vessels and bundles of unmyelinated nerve fibres. Occasional lymphocytes can be present in the lamina propria but their aggregation into definitive lymph nodules is rare. The urothelium is usually extensively folded, giving the ureteric lumen a stellate outline.

Developmental anomalies of the ureter

Double (duplex) ureters In 1 in 125 individuals, two ureters drain the renal pelvis on one side; this is termed a double (duplex) ureter (Fig. 72.23). Bilateral double ureters occur in approximately 1 in 800 cases. Double ureters are the product of two ureteric buds arising from the mesonephric duct; they share a single fascial sheath and can either fuse at any point along their course or remain separate until they insert through separate ureteric orifices into the urinary bladder.

Care must be taken not to compromise the blood supply of the second ureter when a single ureter of a double ureter system is excised or reimplanted. The ureter from the upper pole of the kidney (the longer ureter) inserts more medially and caudally in the urinary bladder than the ureter from the lower pole (Weigert–Meyer rule). This reflects the embryological development of the ureter: the ureteric bud that is initially more proximal on the mesonephric duct has a shorter time to be pulled cranially in the urinary bladder and so it inserts more distally in the mature bladder. The ureter from the lower pole has a shorter intramural course than the longer ureter and is prone to reflux.

Ectopic ureters An ectopic ureter is a ureter that has an abnormal anatomical location, e.g. not opening into the trigone of the urinary bladder. In the male, the ureter can insert at the neck of the bladder or posterior urethra, or, rarely, into the seminal gland, but it always inserts cranial to the external urethral sphincter. In the female, ectopic insertion can be distal to the external urethral sphincter in the urethra, or into the vagina, resulting in persistent childhood incontinence. Single ureters, and more commonly the longer ureter of a double ureter system, can insert more caudally and medially than is normal in some individuals.

Ureteroceles Ureteroceles are cystic dilations of the lower end of the ureter; the ureteric orifice is covered by a membrane that expands as it is filled with urine and then deflates as it empties. Ureteroceles can vary in size and usually have no influence on ureteric drainage; however, they can be a cause of obstruction in the ureter and pelvicalyceal system more proximally. Prolapsing ureteroceles, though small, prolapse from their position around the ureterovesical junction region into the urethra, causing intermittent urinary bladder outflow obstruction.

They are identified antenatally with ultrasound (Fig. 72.24). In adults, ureteroceles tend to be bilateral and small and are often found incidentally when the urinary tract is being imaged in the investigation of a coincidental pathology. Radiologically, they classically result in a 'cobra-head' halo around the ureteric orifice following administration of contrast on intravenous urography.

Retrocaval ureter Persistence of the posterior cardinal vein, associated with high confluence of the right and left common iliac veins or a double inferior vena cava, can result in a retrocaval (or circumcaval) ureter that passes behind the inferior vena cava, usually at the level of the inferior edge of the third (horizontal) part of the duodenum, before it emerges anterior to it to pass from medial to lateral. A retrocaval ureter occurs in one in 1500 individuals. Most commonly it has no clinical sequelae, although it can result in upper ureteric obstruction (Fig. 72.25).

CHAPTER
73

Bladder, prostate and urethra

URINARY BLADDER

The urinary bladder is a reservoir. Its size, shape, position and relations all vary according to its content and the state of the neighbouring viscera. When the bladder is empty, it lies entirely in the lesser pelvis, but as it distends it expands superiorly into the abdominal cavity (**Video 73.1**). An empty bladder is somewhat tetrahedral and has a fundus, body, neck, apex and superior and inferolateral surfaces.

Relations

The fundus of the bladder is triangular and located posteroinferiorly. In females it is closely related to the anterior vaginal wall (Fig. 73.1); in males it is related to the rectum, although it is separated from it superiorly by the rectovesical pouch and inferiorly by the seminal gland (vesicle) and ductus (vas) deferens on each side, and by the prostatoseminal fascia (Denonvilliers' fascia) (Fig. 73.2). The neck of the bladder, which is most fixed, lies most inferiorly, 3–4 cm behind the lower part of the pubic symphysis and just above the plane of the inferior aperture of the lesser pelvis. Essentially, the neck of the bladder is the internal urethral orifice, which lies in a constant position irrespective of the varying positions of the bladder and rectum. In males the neck rests on and is directly continuous with the base of the prostate; in females it is related to the pelvic fascia that surrounds the upper urethra. In both sexes the apex of the bladder, when not full, faces towards the upper part of the pubic symphysis. The median umbilical ligament (urachus) ascends behind the anterior abdominal wall from the apex of the bladder to the umbilicus, covered by peritoneum to form the median umbilical fold (see below).

The anterior aspect of the urinary bladder is separated from the transversalis fascia by adipose tissue in the potential retropubic space (of Retzius) (see Fig. 73.2D). This adheres more to the bladder than to the anterior surface of the prostate, which aids reliable identification of the region of the neck of the bladder surgically. In males each inferolateral surface is related anteriorly to the pubis and puboprostatic ligaments. In females the relations are similar, except that the pubovesical ligaments replace the puboprostatic ligaments (see later for a fuller description). The inferolateral surfaces are not covered by peritoneum. The triangular superior surface is bounded by lateral borders from the apex to the ureteric entrances, and by a posterior border that joins them. In males the superior surface is completely covered by peritoneum, which extends slightly on to the fundus and continues posteriorly into the rectovesical pouch and anteriorly into the median umbilical fold; it is in contact with the sigmoid colon and the terminal part of the ileum. In females the superior surface is largely covered by peritoneum, which is reflected posteriorly on to the uterus at the level of the anatomical internal os of the uterus (the junction of the body and isthmus of the uterus) to form the vesico-uterine pouch. The posterior part of the superior surface, devoid of peritoneum, is separated from the supravaginal part of the cervix by fibroareolar tissue.

These relations are important in managing bladder trauma. Extraperitoneal injuries can often be managed conservatively because urine is contained, whereas intraperitoneal injuries usually require surgical repair since urine within the abdominal cavity can cause peritonitis, ileus and infection.

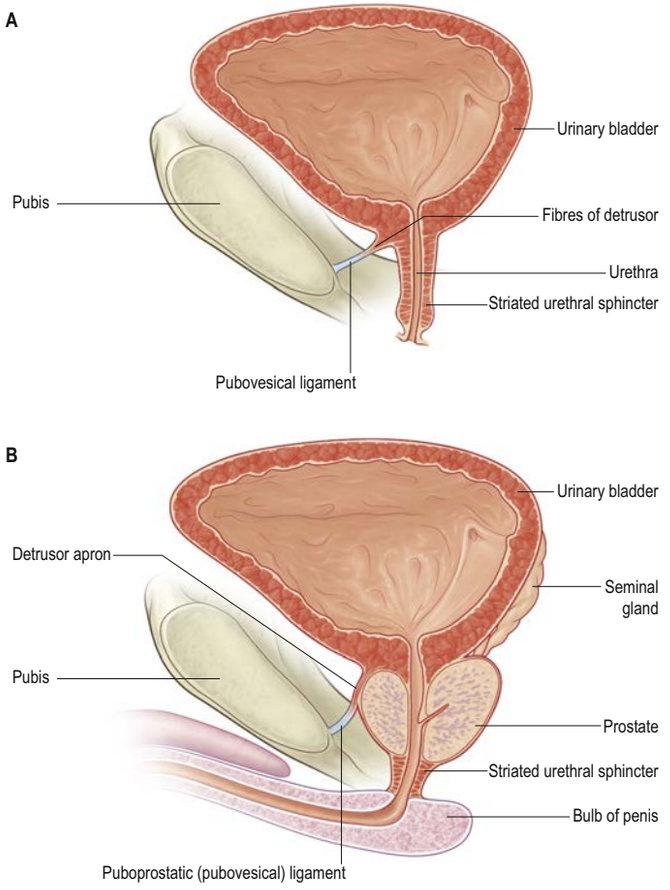

Fig. 73.4 Ligaments that anchor the neck of the bladder and pelvic part of the urethra to the pubis. **A**, In the female. **B**, In the male. In males, detrusor extends over the anterosuperior aspect of the prostate and inserts into the pubis. It condenses to form pubovesical/puboprostatic ligaments. (A, B, With permission from Drake RL, Vogl AW, Mitchell A et al Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008.)

As the bladder fills it becomes ovoid (see Video 73.1). Anteriorly, it displaces the parietal peritoneum from the suprapubic region of the anterior abdominal wall. Its inferolateral surfaces become anterior and rest against the abdominal wall without intervening peritoneum for a distance above the pubic symphysis that varies with the degree of distension, but is commonly 5–7 cm. If normal catheterization of the urinary bladder via the urethra is unsuccessful, the distended bladder can be punctured just above the pubic symphysis without traversing the peritoneum (suprapubic cystostomy) (see Fig. 73.2A); surgical access to the bladder through the anterior abdominal wall is usually by this route. The summit of the full bladder points superiorly and anteriorly above the attachment of the median umbilical ligament, so that the peritoneum forms a supravesical fossa of varying depth between the summit and the anterior abdominal wall; this recess often contains coils of small intestine. The bladder is more cranially located at birth than in the adult because the lesser pelvis is shallow, and the internal urethral orifice is level with the upper border of the pubic symphysis. The bladder is then abdominal rather than pelvic and extends about two-thirds of the distance towards the umbilicus.

Ligaments of the urinary bladder

The urinary bladder is anchored anteroinferiorly to the pubis, lateral pelvic side walls and rectum by condensations of pelvic fascia (Fig. 73.4); although these condensations are not true anatomical ligaments, the term is applied in routine clinical use (see Ch. 71 for a further description of the visceral pelvic fascia).

In both sexes, stout bands of multilayered fibromuscular tissue, the puboprostatic (males only) and pubovesical ligaments, extend from the neck of the bladder to the inferior aspect of the pubis; they lie on each side of the median plane, leaving a midline urogenital hiatus through which numerous small veins pass. The puboprostatic and pubovesical ligaments have been variously and somewhat confusingly described in the literature. In the *Terminologia Anatomica*, both ligaments are listed as having medial and lateral components; the pubovesical ligament (presumably both medial and lateral parts) is also listed as synonymous with the medial puboprostatic ligament. Cadaveric dissection, histological and plastinated section studies (e.g. DeLancey 1989, Xu et al 2017) have identified the puboprostatic ligament as the anterior layer of the detrusor apron joined by decussated and un-decussated fibres of pubococcygeus; or part of the detrusor apron connecting the bladder to the pubic bone; or the merged fibres of the visceral endopelvic fascia. The pubovesical ligaments have been described as either an extension of the detrusor and its adventitia that is attached to the pubic bone and arcus tendineus fasciae pelvis, or the female equivalent of the medial puboprostatic ligaments, and either separate from the pubo-urethral ligaments or the superior extensions of the pubo-urethral ligaments.

The apex of the bladder is connected to the umbilicus by the remains of the urachus, which forms the median umbilical ligament (**Video 73.2**). The urachus is composed of longitudinal muscle fibres derived from detrusor and becomes more fibrous towards the umbilicus. It usually maintains a lumen lined with epithelium that persists into adult life but is only rarely complicated by a urachal cyst, sinus, fistula or adenocarcinoma.

Other ligaments that have been described in relation to the fundus of the urinary bladder are the lateral, uterosacral and cardinal ligaments. The lateral ligament was described by Miles in 1908: although never described in anatomical cadaveric dissection studies, it is recognized clinically as an important structure in the pararectal fossa at operation. It is a broad band of dense connective tissue, ranging in depth from 5 to 7 cm, and passing between the lateral wall of the pelvis and the fundus of the bladder at the point where the ureter terminates. It contains the middle anorectal artery and lymphatic vessels that pass from the distal rectum to the iliac nodes (Takahashi et al 2000). From the superior surface of the bladder, the peritoneum is carried off in a series of folds: the 'false' ligaments of the bladder. Anteriorly, there are three folds (**Fig. 73.5**): the median umbilical fold over the median umbilical ligament (urachus), and two medial umbilical folds over the occluded parts of the umbilical arteries. The inferior epigastric vessels (**Fig. 73.6**) are lateral to these folds on the anterior abdominal wall and when covered with peritoneum are termed lateral umbilical ligaments.

Urinary bladder interior

Mucosa of the bladder

Almost all of the bladder mucosa is attached only loosely to subjacent muscle (**Fig. 73.7**); it folds when the bladder empties, and the folds are stretched flat as it fills. Over the trigone of the bladder, immediately above and behind the internal urethral orifice, it is adherent to the subjacent muscle layer and is always smooth. The anteroinferior angle of the trigone is formed by the internal urethral orifice, its posterolateral angles by the ureteric orifices. The superior boundary of the trigone is a slightly curved interureteric crest, which connects the two ureteric orifices and is produced by the continuation into the bladder wall of the ureteric internal longitudinal muscle. During cystoscopy, the interureteric crest appears as a pale band and is a guide to the ureteric orifices (see Fig. 73.7A, B).

Trigone of the bladder

The smooth muscle of the trigone consists of two distinct layers, sometimes termed superficial trigone and deep trigone muscles. The latter is composed of muscle cells indistinguishable from those of detrusor, and is simply the posteroinferior portion of detrusor proper. The superficial trigone muscle represents a morphologically distinct component of the trigone, which, unlike detrusor, is composed of relatively small-diameter muscle bundles that are continuous proximally with those of the intramural ureters. It is relatively thin but is generally described as becoming thickened along its superior border to form the interureteric crest. Similar thickenings occur along the lateral edges of the superficial trigone. In both sexes, the superficial trigone muscle becomes continuous with the smooth muscle of the proximal urethra, and extends in the male along the urethral crest as far as the openings of the ejaculatory ducts.

Ureteric orifices and distal ureter

The slit-like ureteric orifices are placed at the posterolateral corners of the trigone of the bladder (see Figs 73.2B, 73.7A). In empty bladders they are approximately 2.5 cm apart and 2.5 cm from the internal urethral orifice; these measurements can be doubled when the bladder is distended. The distal 1.5–2.0 cm of the ureter (intramural part) passes obliquely through the bladder wall before ending as the ureteric orifices. As the bladder fills and intravesical hydrostatic pressure increases, the distal ureter is compressed and acts like a flap valve preventing reflux of urine toward the kidney.

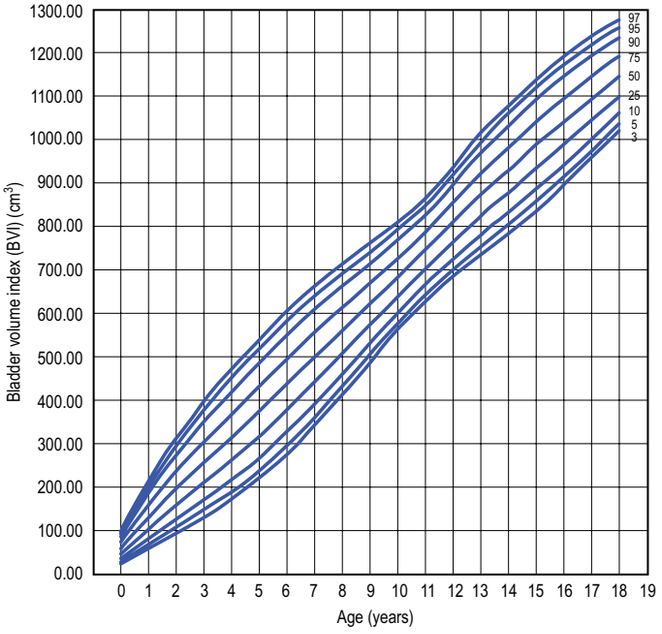

Fig. 73.3 Centiles of bladder volume index in children. (Redrawn with permission from Leung VY, Chu WC, Yeung CK et al 2007 Nomograms of total renal volume, urinary bladder volume and bladder wall thickness index in 3,376 children with a normal urinary tract. Pediatr Radiol 37:181–8.)

Urine samples can, therefore, be obtained in children by performing suprapubic needle puncture. A normogram of bladder volume index (BVI = length × width × depth of bladder), based on sonographic measurements in children, is shown in Fig. 73.3. The bladder progressively descends with growth and reaches the adult position shortly after puberty.

The urachus could be critical for maintaining fetal life when atresia of the urethra results in complete obstruction to the flow of amniotic fluid. Anhydramnios noted at 17 weeks' gestation has been reported to resolve by 21 weeks when the patent urachus acts as a fistula between the bladder and the amniotic cavity, preserving pulmonary and renal function (Stalberg and Gonzalez 2012).

(A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Internal urethral orifice

The internal urethral orifice is sited at the apex of the trigone of the bladder, the lowest part of this organ, and is usually somewhat crescentic in section. There is often an elevation immediately behind it in adult males (particularly past middle age), which is caused by the prostate.

Neck of the bladder

The smooth muscle of the neck of the bladder is histologically, histochemically and pharmacologically distinct from detrusor proper, so the neck of the bladder should be considered as a separate functional unit. Males and females have quite different arrangements of smooth muscle in this region, and will be described separately.

Females

In females the neck of the bladder consists of morphologically distinct smooth muscle (see Fig. 73.7C). The large-diameter fasciculi characteristic of detrusor are replaced by small-diameter fasciculi that extend obliquely or longitudinally into the urethral wall. In the normal female the neck of the bladder sits above the pelvic diaphragm, supported predominantly by the pubovesical ligaments (see Fig. 73.4A), the endopelvic fascia of the pelvic diaphragm and levator ani. These structures support the urethra at rest; with elevated intra-abdominal pressure, the pelvic diaphragm contracts, increasing urethral closure pressure to maintain continence. This anatomical arrangement commonly alters after parturition and with increasing age, such that the neck of the bladder lies beneath the pelvic diaphragm, particularly when intra-abdominal pressure rises. This means that the mechanism described above fails to maintain continence and females can experience stress incontinence (Klutke and Siegel 1995).

Males

In males the neck of the bladder is completely surrounded by a circular collar of smooth muscle with its own distinct adrenergic innervation, which extends distally to surround the intramural part of the urethra. These smooth muscle bundles are distinct from those that run in continuity from the neck of the bladder down to the prostatic urethra, and from the smooth muscle within the prostate. The bundles that form the internal urethral (preprostatic) sphincter are small compared with the muscle bundles of detrusor, and are separated by a relatively large connective tissue component rich in elastic fibres.

The neck of the bladder is sometimes called the proximal or internal urethral sphincter mechanism, to distinguish it from the distal or external urethral sphincter. The internal urethral sphincter contributes to urinary continence and, in the face of distal sphincteric incompetence, can at times maintain continence independently. Unlike detrusor and the rest of the urethral smooth muscle (in males and females), the internal urethral sphincter is richly supplied with sympathetic noradrenergic nerves and is almost totally devoid of parasympathetic cholinergic nerves (see below).

Urinary bladder outflow obstruction

The muscle of the bladder hypertrophies in progressive chronic obstruction to micturition, e.g. as a result of prostatic enlargement or urethral stricture, or in children with congenital bladder outflow obstruction, e.g. posterior urethral valves. The muscle fasciculi increase in size and, because they interlace in all directions, a thick-walled 'trabeculated bladder' is produced (see Fig. 73.7D). Mucosa between the fascicles forms 'diverticula' owing to the increased intravesical pressure required to pass urine through the obstruction. When outflow is obstructed, emptying may not be complete; some urine can remain and lead to infection and stone formation within the bladder. Back-pressure from a chronically distended bladder can gradually dilate the ureters, renal pelves and even the renal collecting ducts bilaterally and can result in progressive renal impairment.

Vascular supply and lymphatic drainage

Arteries

The bladder is supplied principally by the superior and inferior vesical arteries (see Figs 75.3, 72.20C), derived from the anterior division of the internal iliac artery and supplemented by the obturator and inferior gluteal arteries. In females, additional branches are derived from the uterine and vaginal arteries.

Superior vesical artery

The superior vesical artery arises from the patent part of the umbilical artery. It supplies many branches to the fundus of the bladder. The artery to the ductus deferens often originates from one of these branches and accompanies the ductus deferens to the testis, where it anastomoses with the testicular artery. Other branches of the superior vesical artery supply the ureter.

Inferior vesical artery

The inferior vesical artery often arises with the middle anorectal artery from the internal iliac artery. It supplies the fundus of the bladder, prostate, seminal glands and distal ureter, and sometimes provides the artery to the ductus deferens. Branches to the prostate communicate across the midline.

Veins

The veins that drain the bladder form a complicated plexus on its inferolateral surfaces and pass backwards in the lateral ligaments of the bladder to end in the internal iliac veins (see Fig. 75.3).

Lymphatic drainage

Lymphatics that drain the bladder begin in mucosal, intermuscular and adventitial plexuses (see Fig. 75.3). There are three sets of collecting vessels; most end in the external iliac nodes. Vessels from the trigone emerge on the exterior of the bladder to run superolaterally. Vessels from the superior surface of the bladder converge to the posterolateral angle and pass superolaterally to the external iliac nodes (some might drain to the internal or common iliac nodes). Vessels from the inferolateral surface of the bladder ascend to join those from the superior surface or run to the lymph nodes in the obturator fossa. Minute nodules of lymphoid tissue can occur along the lymph vessels of the bladder.

Innervation

The nerves supplying the bladder arise from the inferior hypogastric plexus, a mesh of autonomic nerves and ganglia lying on the lateral aspects of the rectum, internal genitalia and fundus of the bladder (Fig. 73.8). They consist of both sympathetic and parasympathetic components. For further reading, see Mundy et al (1999a).

Efferent fibres

Parasympathetic fibres arise from the second to the fourth sacral segments of the spinal cord and enter the inferior hypogastric plexus on the posterolateral aspects of the rectum as the pelvic splanchnic nerves. The sympathetic fibres are derived from neuronal cell bodies in the lower three thoracic and upper two lumbar segments of the spinal cord and form the coeliac and mesenteric plexuses in the abdomen; from here, the superior hypogastric plexus descends into the pelvis as fairly discrete nerve bundles within the extraperitoneal connective tissue posterior to the ureter on each side. The anterior part of the inferior hypogastric plexus is known as the vesical plexus. Small groups of autonomic neurones occur within the plexus and throughout all regions of the bladder wall. These multipolar intramural neurones are rich in acetylcholinesterase (AChE) and occur in ganglia containing up to 20 neuronal cell bodies. Most of the preganglionic nerve terminals correspond morphologically to presumptive cholinergic fibres. Noradrenergic terminals also relay on cell bodies in the inferior hypogastric plexus; it is not known whether similar nerves synapse on intramural bladder ganglia.

The urinary bladder is profusely supplied with nerves, which form a dense plexus among detrusor muscle cells. Most of these nerves contain AChE and are abundant throughout the muscle layer of the bladder. Axonal varicosities adjacent to detrusor muscle cells possess features that are considered to typify cholinergic nerve terminals, and contain clusters of small (50 nm diameter) agranular vesicles, occasional large (80–160 nm diameter) granulated vesicles and small mitochondria. Terminal regions approach to within 20 nm of the surface of the muscle cells and can be partially surrounded by Schwann cell cytoplasm; more often they are naked nerve endings.

Detrusor possesses a sparse but definite supply of sympathetic noradrenergic nerves that generally accompany the vascular supply and only rarely extend among the myocytes. Non-adrenergic, non-cholinergic nerves have been identified, and a number of other neurotransmitters or neuromodulators have been detected in intramural ganglia, including the peptide somatostatin. The superficial trigone muscle is associated with more noradrenergic (sympathetic) fibres than cholinergic (parasympathetic) nerves, a difference that supports the view that the superficial trigone muscle should be regarded as 'ureteric' rather than 'vesical' in origin. However, it should be emphasized that this muscle forms a very minor part of the total muscle mass of the neck of the bladder and proximal urethra in either sex and is probably of little significance in the physiological mechanisms that control these regions.

The smooth muscle of the neck of the bladder in males is predominantly orientated obliquely or circularly. It is sparsely supplied with cholinergic (parasympathetic) nerves but possesses a rich noradrenergic (sympathetic) innervation. There is a similar distribution of autonomic nerves in the smooth muscle of the prostate, seminal glands and ducti deferentia. Stimulation of sympathetic nerves causes contraction of smooth muscle in the wall of the genital tract, resulting in seminal emission. Concomitant sympathetic stimulation of the proximal urethral smooth muscle causes sphincteric closure of the internal urethral sphincter, preventing reflux of ejaculate into the bladder.

The lamina propria of the fundus and inferolateral walls of the bladder is virtually devoid of autonomic nerve fibres, apart from some noradrenergic and occasional cholinergic perivascular nerves. However, the density of nerves unrelated to blood vessels increases closer to the internal urethral orifice. At the neck of the bladder and trigone a nerve plexus of cholinesterase-positive axons extends throughout the lamina propria, independent of blood vessels. Some of the larger diameter axons are myelinated and others lie adjacent to the basal urothelial cells. In the absence of any obvious effector target sites, the subepithelial nerve plexuses of the bladder and the ureter are assumed to subserve a sensory function.

Afferent fibres

Visceral afferent nerves supplying the bladder are concerned with awareness of distension and pain and are stimulated by distension or spasm due to a stone, inflammation or malignant disease; they travel in sympathetic and parasympathetic nerves, predominantly the latter (Shoja et al 2013). Therefore, division of the sympathetic paths or of the

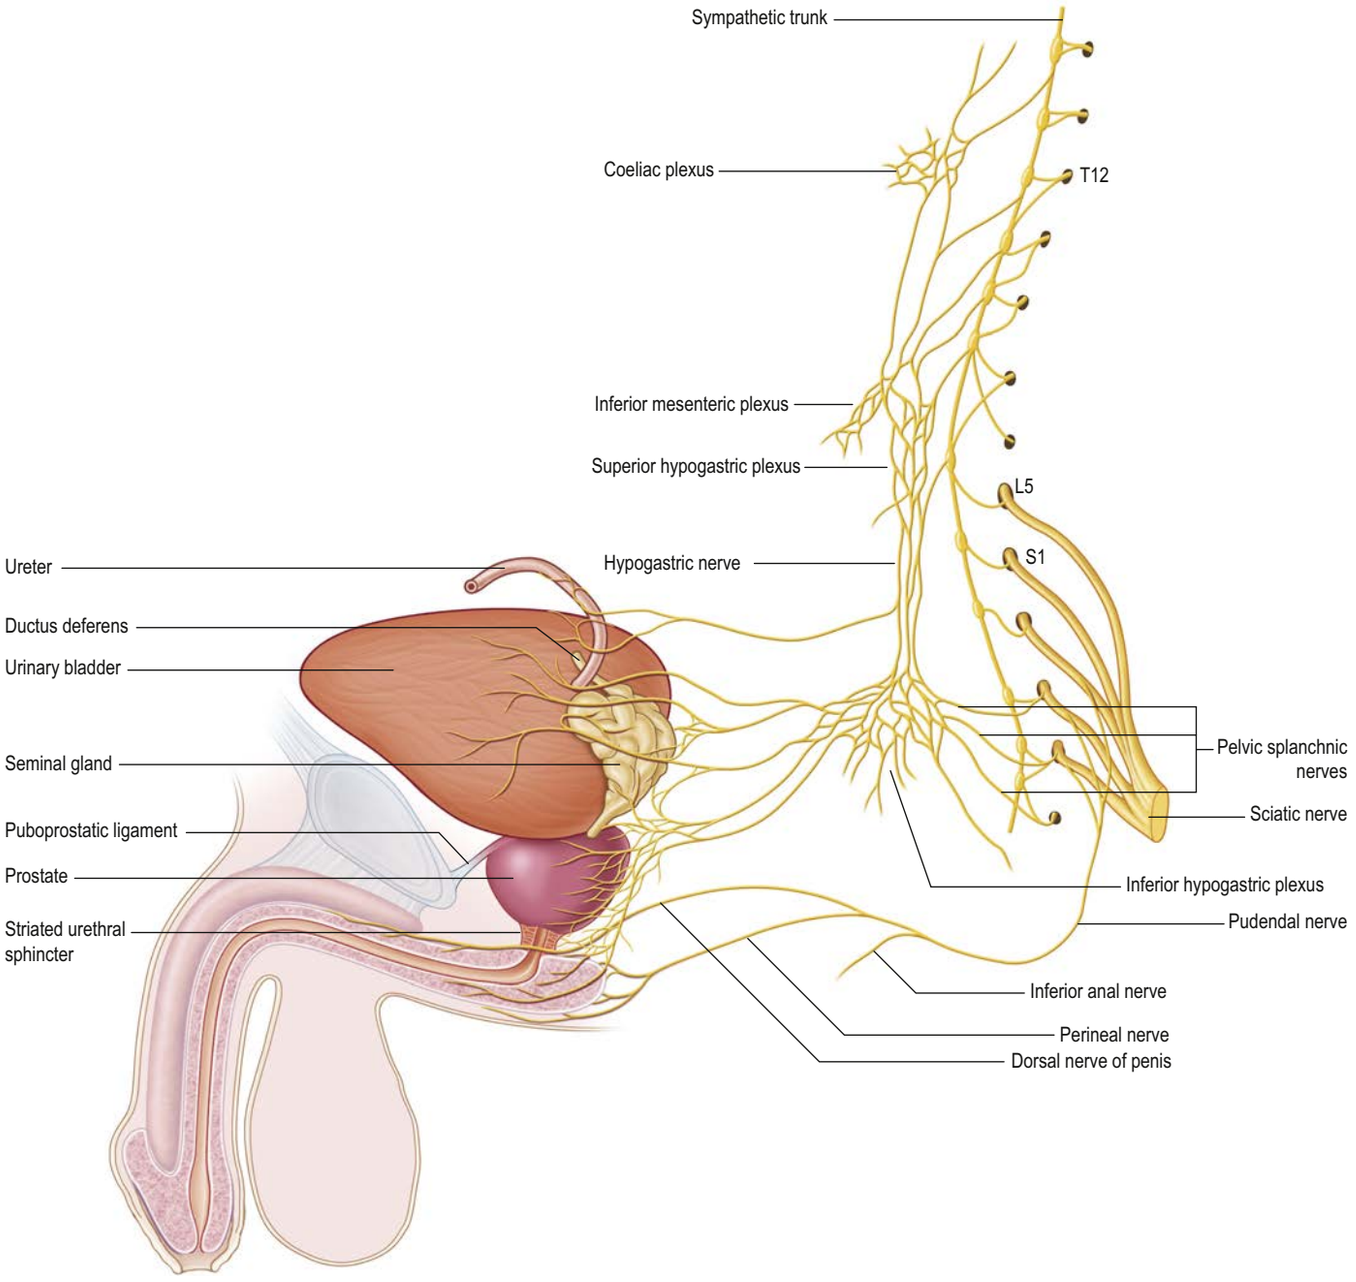

Fig. 73.8 Innervation of the lower urinary tract and male genitalia. (Redrawn with permission from Dyck P, Thomas PK 2005 Peripheral Neuropathy. Saunders, Elsevier.)

superior hypogastric plexus does not materially relieve bladder pain, whereas considerable relief follows bilateral anterolateral cordotomy. Since nerve fibres mediating awareness of distension of the urinary bladder travel in the dorsal (posterior) columns, patients retain awareness of the need to micturate after anterolateral cordotomy. The nerve endings detecting noxious stimuli are probably of more than one type; a subepithelial plexus of fibres containing dense vesicles, which are probably afferent endings, has been described.

MICROSTRUCTURE

The bladder consists of four layers: urothelium (transitional epithelium), lamina propria, muscularis and adventitia (Fig. 73.9).

Urothelium

The urothelium is 4–7 cells thick; it can appear to be attenuated to 2–3 cells thick when the bladder is fully distended. It contains three distinctive cell layers: a basal layer, an intermediate layer and a superficial ('umbrella' cell) layer (see Fig. 73.9). The basal layer consists of small cuboidal cells from which the upper layers arise. The intermediate layers are polygonal and possess the capacity to stretch and flatten. The superficial layer forms a protective, almost impermeable, surface for the

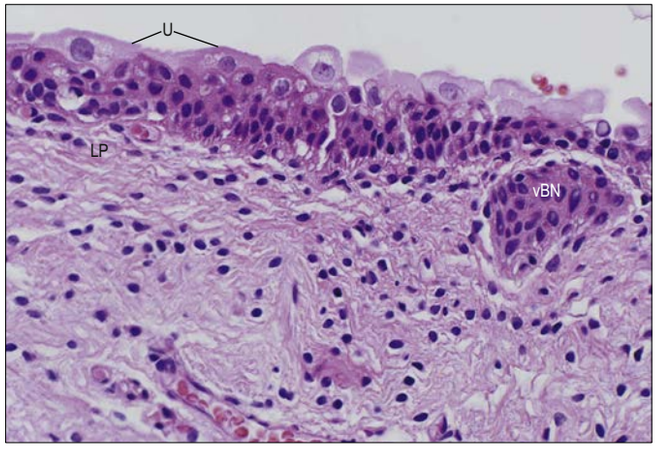

Fig. 73.9 The bladder is lined by urothelium with a surface 'umbrella cell' layer (U) and an intermediate region (3–5 cells thick). The lamina propria (LP) consists of stroma with blood vessels and von Brunn's nests (vBN).

The neck of the bladder is disrupted in the vast majority of men undergoing transurethral resection of the prostate and this can result in retrograde ejaculation. Similarly, an ejaculation can result when the sympathetic fibres are disrupted during retroperitoneal lymph node dissection surgery. Although this genital function of the neck of the bladder of the male is well established, it is not known whether the smooth muscle of this region contributes actively to the maintenance of urinary continence. In contrast, in females the smooth muscle of the neck of the bladder contains relatively few noradrenergic nerves but is richly supplied with cholinergic fibres. The sparse supply of sympathetic nerves presumably relates to the absence of a functioning 'genital' portion of the wall of the female urethra.

bladder mucosa and consists of large, sometimes multinucleated, cells displaying degenerative changes in their cytoplasm; these cells are ultimately exfoliated into the urine. The apical surface of the umbrella cell layer is covered by 16 nm protein particles packed hexagonally to form two-dimensional crystals of asymmetric unit membranes (AUMs), which contribute to the permeability barrier function of the urinary bladder, preventing reabsorption of urine across the urothelium into the blood stream. Islands or nests of urothelium (von Brunn's nests; see Fig. 73.9) can become separated from the surface during development and embedded in the underlying lamina propria; they can undergo central degeneration to form cysts (cystitis cystica).

Lamina propria

The lamina propria forms a connective tissue bed supporting the overlying urothelium, from which it is separated by a basal lamina. It is rich in capillaries, lymphatics and nerve endings, and contains elastic fibres and a thin, poorly defined, layer of smooth muscle fibres, muscularis mucosae, which is variably distributed within the bladder. This layer is often very superficial, lying close beneath the urothelium, but is sometimes deeper in the lamina propria, where it can be well developed; it must be distinguished from muscularis propria. Several functions have been proposed for the lamina propria, including acting as the capacitance layer of the bladder (determining bladder compliance and enabling adaptive changes to increasing volumes); providing factors that influence the growth of the urothelium and/or detrusor; and playing a role in signal transduction (Andersson and McCloskey 2014).

Interstitial cells of Cajal-like cells

Interstitial cells of Cajal (ICC) are a specialized population of cells involved in smooth muscle excitability that were initially described in the gastrointestinal tract (Chs 59, 64). Cells with a similar morphology but expressing platelet-derived growth receptor alpha (PDGFRα) rather than the tyrosine kinase receptor Kit that typifies ICC, and therefore designated interstitial cells of Cajal-like cells (ICC-LC), have been reported in the urethra, ductus deferens, prostate, bladder, corpus cavernosum penis, ureter, uterine tube and uterus, where they form a functional syncytium with nerves and smooth muscle cells. They may function as electrical pacemakers in the urethra and prostate. In the bladder they are closely apposed to detrusor smooth muscle cells, in the lamina propria and within the subepithelium; it has been tentatively suggested that one of their functions in the bladder is to act as intermediary cells transducing nerve signals to detrusor (Drumm et al 2014).

Muscularis propria

Detrusor is the muscularis propria of the bladder wall. It consists of three indistinct layers: an inner and outer longitudinal, and an intermediate circular layer. In contrast to muscularis mucosae, which consists of small wispy fibres, muscularis propria is made up of larger, poorly defined, bundles of smooth muscle cells that form well-defined inner circular and outer longitudinal layers at the neck of the bladder.

Adventitia

The adventitia partially covers the bladder. It is covered externally by mesothelium, beneath which there is a variable amount of vascularized adipose tissue that frequently extends into muscularis propria and, occasionally, into the lamina propria.

MALE URETHRA

The male urethra is 18–20 cm long and extends from the internal urethral orifice in the urinary bladder (**Fig. 73.10**) to the external urethral orifice at the end of the penis. It can be considered in two parts. The anterior urethra is subdivided into a proximal component, the bulbar part of the spongy urethra, which is surrounded by bulbospongiosus and entirely within the perineum, and a pendulous or penile component, which continues to the distal end of the penis. The posterior urethra is divided into intramural (preprostatic), prostatic and membranous parts. The urethra is a mere slit, except during the passage of fluid; in transverse section, it is transversely arched in the prostatic part, stellate in the intramural and membranous parts, transverse in the spongy parts, and sagittal at the external urethral orifice. The anterior urethra is approximately 16 cm long and lies within the perineum (proximally) and the penis (distally), surrounded by the corpus spongiosum penis. The posterior urethra is 4 cm long and lies in the pelvis proximal to the corpus spongiosum penis, where it is acted on by the urogenital sphincter mechanisms. Functionally, both parts act as a conduit.

Posterior part

Intramural part of the urethra

The intramural part of the urethra is approximately 1 cm long and extends from the fundus of the bladder to the prostate (see Fig. 73.7A). Small urethral glands (of Littré) at this site can contribute to benign prostatic hyperplasia (BPH) and symptoms of outflow obstruction in older men.

Prostatic urethra

The prostatic urethra is 3–4 cm long and tunnels through the substance of the prostate, closer to the anterior than the posterior surface of the gland (**Fig. 73.11**; see Fig. 73.7A). It is continuous above with the intramural part and emerges from the prostate slightly anterior to its apex (the most inferior point of the prostate). Throughout most of its length, the posterior wall has a midline ridge, the urethral crest, which projects into the lumen, causing it to appear crescentic in transverse section. On each side of the crest, the floor of a shallow depression, the prostatic sinus, is perforated by the orifices of 15–20 prostatic ducts. An elevation, the seminal colliculus (verumontanum) occurs at about the middle of the length of the urethral crest; at this point, the urethra turns anteriorly and contains the slit-like orifice of the prostatic utricle, a cul-de-sac approximately 6 mm long that runs upwards and backwards in the substance of the prostate behind its middle lobe, when present. The extent of angulation most often approximates 30–35° but can change with age and differs among individuals. The seminal colliculus is used as a surgical landmark for the external urethral sphincter or the membranous urethra during transurethral resection of the prostate (TURP) for benign enlargement of the gland. The two small openings of the ejaculatory ducts open on both sides of the seminal colliculus at 7 o'clock and 5 o'clock positions and are covered with a one-way valve (Li et al 2019).

The prostatic utricle is a cul-de-sac approximately 6 mm long, that runs upwards and backwards in the substance of the prostate behind its middle lobe. Its walls are composed of fibrous tissue, muscular fibres and mucous membrane, the latter pitted by the openings of numerous small glands. It develops from the paramesonephric ducts or urogenital sinus and has been considered homologous with the vagina of the female: it is sometimes called the 'vagina masculina', although the more usual view is that it is a uterine homologue, hence the name 'utricle'. Cystic dilation of the prostatic utricle (**Fig. 73.12**) can present in childhood with urinary tract infections, recurrent epididymitis or haematuria.

The lowest part of the prostatic urethra is fixed by the puboprostatic ligaments and is therefore immobile.

Membranous urethra

The membranous urethra is the shortest (2–2.5 cm), least dilatable and (except for the external urethral orifice), the narrowest section of the urethra. It descends with a slight ventral concavity from the prostate to the bulb of the penis, passing through the perineal membrane 2.5 cm posteroinferior to the pubic symphysis. The wall of the membranous urethra consists of a muscle coat that is separated from the epithelial lining by a narrow layer of fibroelastic connective tissue. The muscle coat contains a relatively thin layer of bundles of smooth muscle, which are continuous proximally with those of the prostatic urethra, and a prominent outer layer of circularly orientated striated muscle fibres, which together form the external urethral sphincter.

Urinary continence at the level of the membranous urethra is mediated by the radial folds of urethral mucosa, the submucosal connective tissue, the intrinsic urethral smooth muscle, the striated muscle fibres and puboperinealis. The muscle coat of the urethra and puboanalis (puborectalis) surround the membranous urethra and are attached to the inner surface of the ischiopubic ramus; fibres also reach up to the lowest part of the neck of the bladder and lie on the surface of the prostate. The striated external urethral sphincter has a posterior fibrous defect and is inserted throughout its length into the perineal body. It is related to the dorsal vascular complex anteriorly, levator ani laterally and the perineal body and rectourethralis posteriorly; it is suspended from the pubis by fibrous tissue that extends from its anterior and lateral parts to the puboprostatic ligaments posteriorly and to the suspensory ligament of the penis anteriorly. The bulbo-urethral glands (Cowper's glands) are embedded in the deep transverse perineal muscle and drain into the spongy urethra during sexual excitement.

Anterior part

The anterior, or spongy urethra lies within the corpus spongiosum penis (see Fig. 74.3). In the flaccid penis it is about 15 cm long and extends from the end of the membranous urethra to the external urethral orifice on the glans penis. It starts below the perineal membrane at a point anterior to the lowest level of the pubic symphysis as the bulbar part of the spongy urethra, the widest part of the urethra, surrounded by bulbospongiosus.

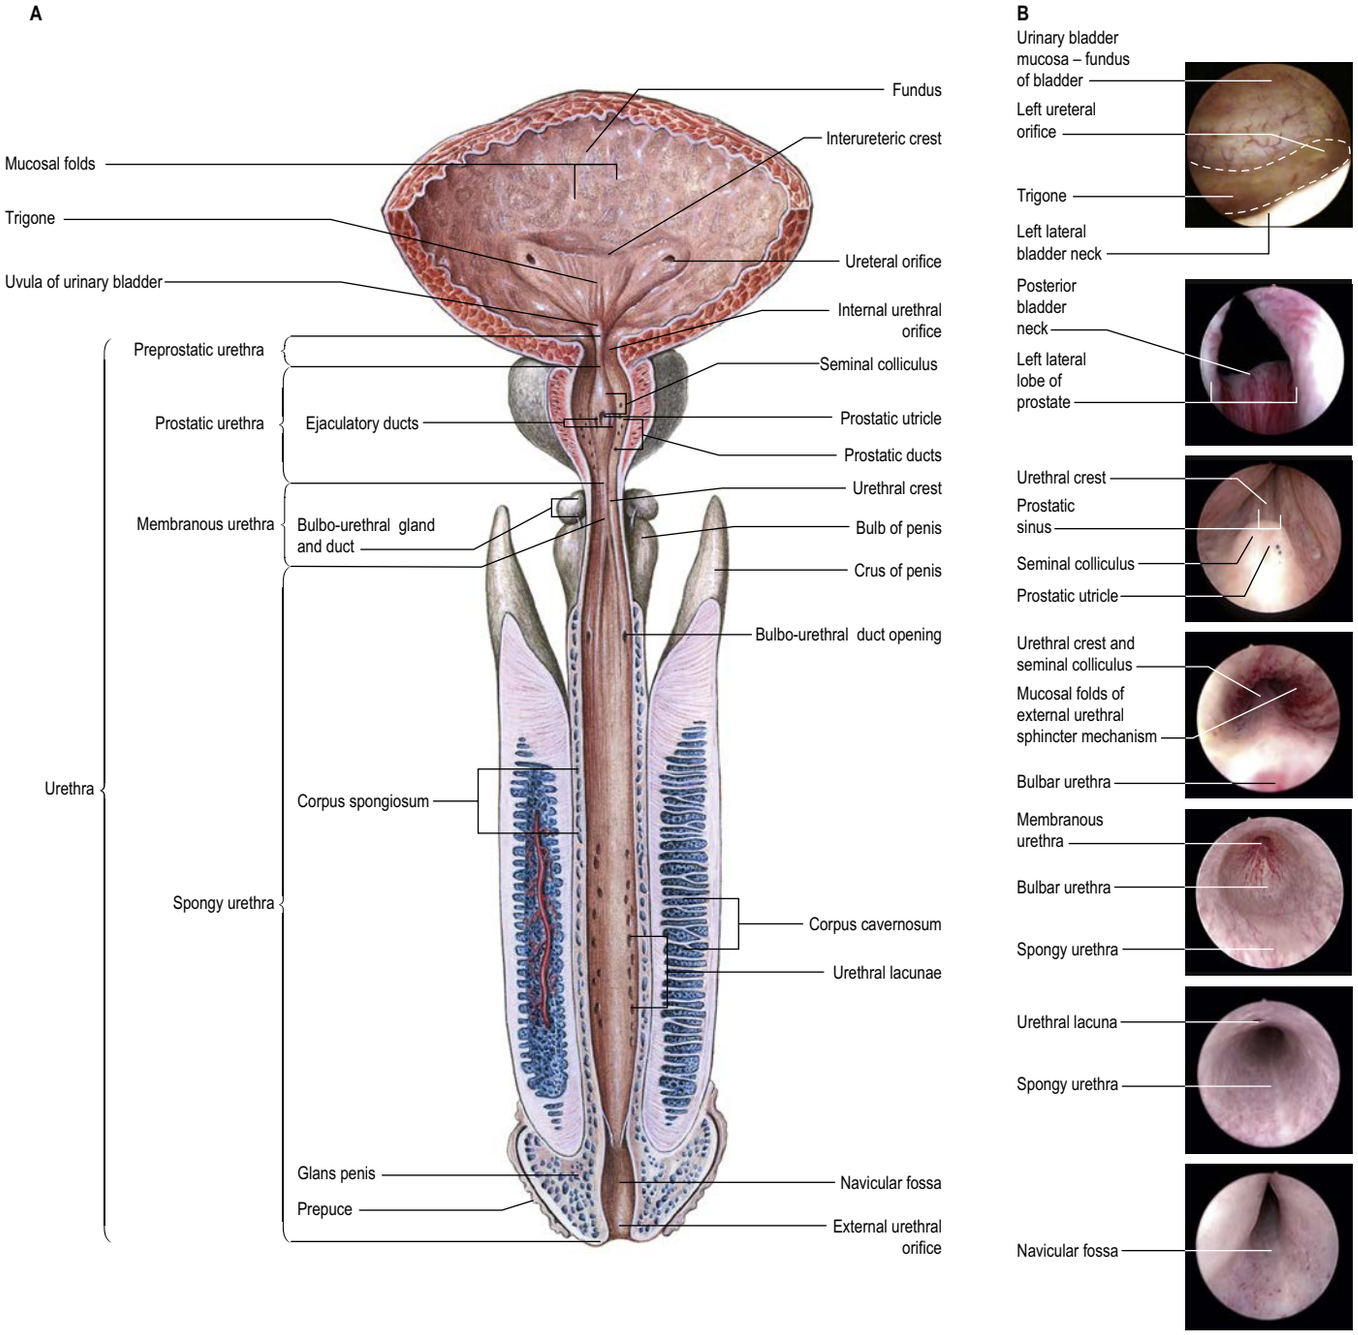

Fig. 73.10 A, The male urethra. **B**, Endoscopic views (top to bottom): posterior bladder wall and trigone, neck of the bladder, urethral crest, membranous urethra, bulbar part of spongy urethra, spongy urethra, navicular fossa. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

The bulbo-urethral glands open into the bulbar part of the spongy urethra approximately 2.5 cm below the perineal membrane. The spongy urethra is a narrow, transverse slit when empty and has a diameter of approximately 6 mm when passing urine. It is dilated at its termination within the glans penis, where it is known as the navicular fossa. The external urethral orifice is the narrowest part of the urethra and is a sagittal slit about 6 mm long in the adult, bounded on each side by a small labium.

Vascular supply and lymphatic drainage

Urethral artery

The urethral artery usually arises from the internal pudendal artery just below the perineal membrane, and travels through the corpus spongiosum penis to reach the glans penis. It supplies the urethra and the erectile tissue around it. The urethra is also supplied by the dorsal artery of the penis via its circumflex branches on each side, and in a retrograde fashion from the glans penis by its terminal branches. The blood supply through the corpus spongiosum penis is so plentiful that the urethra can be divided without compromising its vascular supply.

Veins

The venous drainage of the anterior urethra is to the dorsal veins of the penis and internal pudendal veins, which drain to the prostatic venous plexus. The posterior urethra drains into the prostatic and vesical venous plexuses, which drain into the internal iliac veins.

Lymphatic drainage

Vessels from the posterior urethra pass mainly to the internal iliac nodes; a few end in the external iliac nodes. Vessels from the membranous urethra accompany the internal pudendal artery. Vessels from the anterior urethra accompany those of the glans penis, most ending in the deep inguinal nodes; some can end in superficial inguinal nodes, while others traverse the inguinal canal to end in the external iliac nodes.

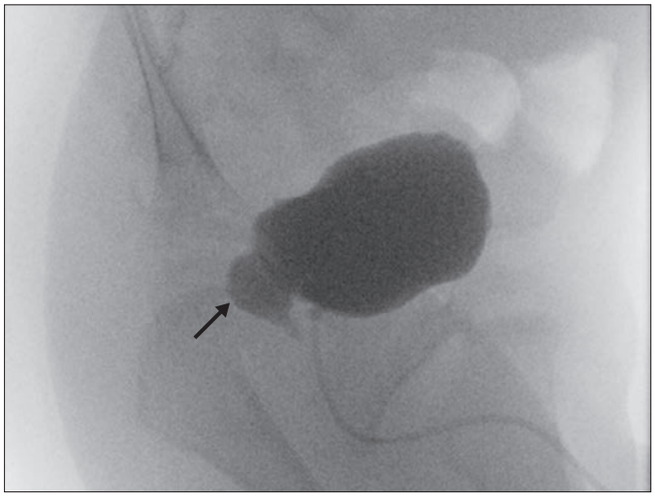

Fig. 73.12 Cystic dilation of the prostatic utricle (arrow) demonstrated in an 8-month-old child during a micturating cystourethrogram. (Courtesy of Mr Alok Godse.)

The mean length of the slit was found to be 5.4 mm in boys with a mean age of approximately seven years (Hutton and Babu 2007). The width of the external urethral orifice in uncircumcised boys between the ages of 5 months and 16 years varied from 3.5 to 7.5 mm (Orkiszewski and Madej 2010).

The urethral epithelium (e.g. distal spongy parts), presents the orifices of numerous small urethral glands that lie in the submucosa. It also contains a number of small pit-like recesses, or lacunae, of various sizes with orifices directed forwards. One, the lacuna magna, is larger than the rest and is situated in the roof of the navicular fossa.

The urethra can be ruptured by a fall-astride (straddle) injury to the bulbar part of the spongy urethra in the perineum, or by an injury related to a pelvic fracture. These injuries usually affect the junction of the membranous with the bulbar part of the spongy urethra across the perineal membrane. One complication associated with such injuries is extravasation of urine. After an injury to the bulbar part of the spongy urethra, urine usually extravasates between the perineal membrane and the membranous layer of the superficial fascia (Colles' fascia). As both of these are attached firmly to the ischiopubic rami, extravasated fluid cannot pass posteriorly because the two layers are continuous around superficial transverse perineal muscles. Laterally, the spread of urine is blocked by the pubic and ischial rami. Urine cannot enter the lesser pelvis through the perineal membrane if this remains intact, and so it tracks anteriorly into the loose connective tissue of the scrotum and penis, and, from there, to the anterior abdominal wall. If the posterior urethra is injured, urine is extravasated into the pelvic extraperitoneal tissue; if the perineal membrane is also torn, then urine may be extravasated into the perineum.

Hypospadias, found in 1 in 300 boys, most often results in the urethra opening on the distal, urethral surface of the penis. There is also an associated abnormality of the prepuce, which is longer dorsally and lacking ventrally, and often an associated chordee, which causes a ventral curvature of the penis. The microvessel density of the prepuce is reduced in children with hypospadias and this has surgical implications when preputial flaps are used for the repair of hypospadias (Yucel et al 2004, Cağrı Savaş et al 2011). Anomalies of arterial vascular anatomy of the prepuce have been described in boys with hypospadias, so it is important for hypospadias to be identified prior to circumcision because the abnormal prepuce is sometimes used for surgical correction of the deformity.

Epispadias occurs in approximately 1 in 100,000 boys; it is typically part of the exstrophy–epispadias complex but can occur in isolation. The urethra is either completely open dorsally or uncovered to the level of the pubic symphysis. Other features of epispadias include a shortened penis and dorsal chordee; the incidence of cryptorchidism is increased ten-fold.

Epispadias is a rare congenital anomaly that can affect the female urethra, either in isolation or as part of the exstrophy–epispadias complex. Isolated epispadias in girls is characterized by the urethra opening at the clitoris, which is typically bifid.

Posterior urethral valves occur in 1 in 5000–8000 males and are the most common cause of urinary outflow obstruction in infants. The most common type (type I) is believed to occur if the mesonephric (Wolffian) ducts open too anteriorly on to the primitive prostatic urethra; this abnormal migration of the ducts leaves behind thick vestigial tissue that forms rigid valve cusps extending caudally from the seminal colliculus. Megalourethra can be associated with posterior urethral valves. Congenital anterior urethral valves are a rare cause of urethral obstruction in boys and may be associated with posterior urethral valves and hypospadias.

Very rarely, urethral duplication occurs; the two urethrae almost invariably lie on top of each other rather than side by side. One of the urethrae, usually the more dorsal, may be blind-ending. A congenital prepubic sinus consists of a midline tract in the skin passing from the suprapubic region towards the anterior aspect of the urinary bladder without communication and is believed to be a variant of dorsal urethral duplication. Congenital urethrocutaneous fistulae are very rare anomalies in which the urethra opens on the ventral surface of the penis in the absence of chordee or hypospadias.

Congenital rectourethral fistulae can be present in children born with anorectal malformation. The prostatic or bulbar part of the spongy urethra is usually affected, and the rectum and urethra share a common wall immediately above the fistula site.

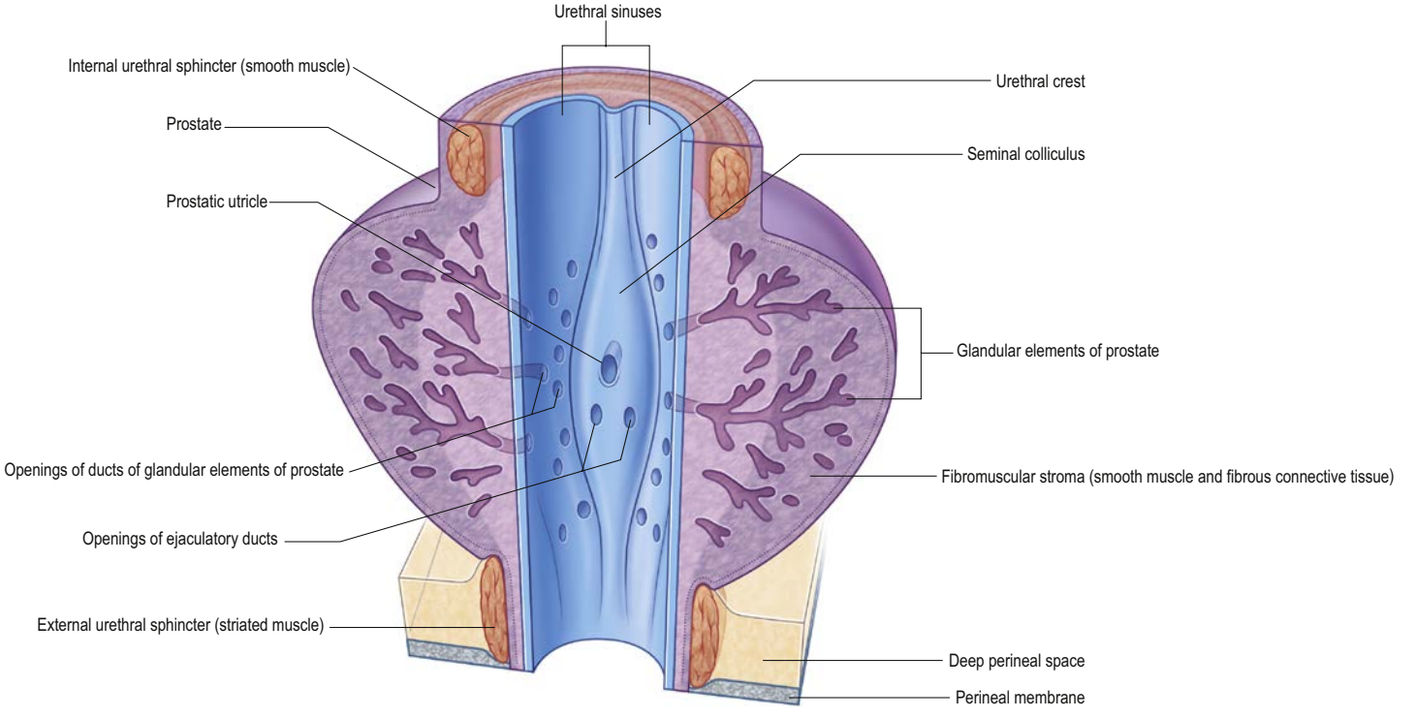

Fig. 73.11 The prostatic urethra. The raised part of the urethral crest is the seminal colliculus. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Philadelphia: Elsevier, Churchill Livingstone. Copyright 2010.)

Innervation

The prostatic plexus supplies the smooth muscle of the prostate and prostatic urethra (see Fig. 73.8). On each side, it is derived from the inferior hypogastric plexus and lies on the posterolateral aspect of the seminal gland and prostate. The cavernous nerves of the penis pierce the bulb of the penis to innervate the corpora cavernosa. Sympathetic nerves that supply the internal urethral sphincter are derived from the inferior hypogastric plexus as it descends in the pelvis adjacent to the prostate; they function to prevent retrograde ejaculation. Parasympathetic preganglionic axons arise from neuronal cell bodies in the second to fourth sacral spinal cord segments. The nerve supply of the external urethral sphincter is controversial. It is generally believed to be supplied by neurones in the nucleus of the pudendal nerve (Onuf's nucleus) travelling in branches of the inferior hypogastric plexus and by perineal branches of the pudendal nerve lying on the perineal aspect of the pelvic diaphragm; in both instances, the axons arise from neurones in the second to fourth sacral spinal segments. In addition to somatic nerve fibres, immunohistochemical labelling has characterized sympathetic and parasympathetic fibres to the external urethral sphincter (Bessede et al 2016). Fibres from the nucleus of the pudendal nerve (somatic) travel with the inferior hypogastric plexus on each side; they subsequently branch off to run on the pelvic aspect of the pelvic diaphragm to enter the membranous urethra.

Microstructure

The epithelium lining the intramural part of the urethra and the proximal prostatic urethra is a typical urothelium (see Fig. 73.9). It is continuous with the urothelium lining the bladder and with the epithelium lining the prostatic ducts and ducts of the bulbo-urethral glands, the seminal glands and the ducti deferentia and ejaculatory ducts. These relations are important in the spread of urinary tract infections.

The epithelium below the openings of the ejaculatory ducts changes to a pseudostratified or stratified columnar type that also lines the membranous urethra and most of the spongy urethra. Mucus-secreting cells are common throughout this epithelium and frequently occur in small clusters in the spongy urethra. Branching tubular urethral glands secrete protective mucus on to the urethral epithelial lining and are especially numerous on its dorsal aspect. In the older male, many of the deep recesses of the urethral mucosa contain concretions similar to those found within prostatic glands (see Fig. 73.19A). Towards the distal end of the spongy urethra the epithelium changes once again, and becomes stratified squamous with well-defined connective tissue papillae. This type of epithelium also lines the navicular fossa and becomes keratinized at the external urethral orifice. The epithelial cells lining the navicular fossa are glycogen-rich, potentially providing a substrate for commensal lactobacilli that provide a defence against pathogenic organisms.

FEMALE URETHRA

The length of the female urethra increases from 23 mm at birth to 32 mm at 15 years (Hirdes et al 2010): it is approximately 4 cm long and 6 mm in diameter in the adult female. It begins at the internal urethral orifice of the bladder, approximately opposite the middle of the pubic symphysis, and runs anteroinferiorly behind the pubic symphysis, embedded in the anterior wall of the vagina (see Fig. 73.1). It crosses the perineal membrane and normally ends at the external urethral orifice in the vestibule of the vagina as an anteroposterior slit with rather prominent margins, directly anterior to the opening of the vagina and 2.5 cm behind the glans clitoris. It sometimes opens into the anterior vaginal wall. Except during the passage of urine, the anterior and posterior walls of the urethra are in apposition and the epithelium is thrown into longitudinal folds, one of which, on the posterior wall of the canal, is termed the urethral crest. Many small mucous periurethral glands and minute pit-like recesses or lacunae open along the urethra and can give rise to urethral diverticula. On each side, near the distal end of the urethra, the para-urethral glands (Skene's glands) are grouped together and open into the para-urethral ducts; each duct runs down in the submucous tissue and ends in a small aperture on the lateral margin of the external urethral orifice.

Vascular supply and lymphatic drainage

Urethral artery

The urethra is supplied principally by the vaginal artery, but also receives a supply from the inferior vesical artery.

Veins

The venous plexus around the urethra drains into the vesical venous plexus around the neck of the bladder and into the internal pudendal veins (see Fig. 75.3). An erectile plexus of veins along the length of the urethra is continuous with the erectile tissue of the vestibular bulb.

Lymphatic drainage

The lymphatics of the distal urethra drain into the internal and external iliac nodes, while those of the proximal urethra drain into the iliac, obturator and sacral nodes.

Innervation

Parasympathetic preganglionic axons arise from neuronal cell bodies in the intermediolateral nuclei of the intermediate column of grey matter of the second to fourth segments of the sacral part of the spinal cord, run in the pelvic splanchnic nerves, and synapse in the vesical plexus in or near the bladder wall (see Fig. 75.5B). Postganglionic fibres are distributed to the smooth muscle of the urethral wall. Somatic fibres to the skeletal muscle are also derived from the second to fourth segments of the sacral part of the spinal cord, and run in the pelvic splanchnic nerves but do not synapse in the vesical plexus. Sensory (visceral afferent) fibres run in the pelvic splanchnic nerves to the second to fourth segments of the sacral part of the spinal cord. Postganglionic sympathetic fibres arise from the plexus around the vaginal arteries.

Microstructure

The mucosa lining the female urethra consists of a stratified epithelium and a supporting lamina propria of loose fibroelastic connective tissue. The latter is bulky and well vascularized, and contains numerous thin-walled veins. Its abundant elastic fibres are orientated both longitudinally and circularly around the urethra. The lamina propria contains a fine nerve plexus, believed to be derived from sensory branches of the pudendal nerves. The proximal part of the urethra is lined by urothelium, identical in appearance to that of the neck of the bladder. Distally, the epithelium changes into a non-keratinized stratified squamous type that lines the major portion of the female urethra. This epithelium is keratinized at the external urethral orifice, where it becomes continuous with the skin of the vestibule of the vagina.

The wall of the female urethra consists of an outer muscular layer and an inner mucosa, which lines the lumen and is continuous with that of the bladder. The muscular layer consists of an outer sheath of skeletal muscle together with an inner coat of smooth muscle fibres. The female external urethral sphincter is anatomically separate from the adjacent periurethral skeletal muscle of the anterior part of the pelvic diaphragm. The muscle cells forming the external urethral sphincter are all small diameter, slow-twitch fibres.

The smooth muscle coat extends throughout the length of the urethra and consists of slender muscle bundles, most of which are orientated obliquely or longitudinally. A few circularly arranged muscle fibres occur in the outer aspect of the non-striated muscle layer and intermingle with the skeletal muscle fibres forming the inner part of the external urethral sphincter. Proximally, the smooth muscle of the urethra extends as far as the neck of the bladder, where it is replaced by fascicles of detrusor. This region of the female urethra lacks a well-defined circular smooth muscle component comparable with that of the male internal urethral sphincter. Distally, urethral smooth muscle bundles terminate in the subcutaneous adipose tissue surrounding the external urethral orifice.

The smooth muscle of the female urethra receives an extensive, presumptively cholinergic parasympathetic nerve supply but contains relatively few noradrenergic nerves. In the absence of an anatomical neck of the bladder sphincter, competence of the female neck of the bladder and proximal urethra is unlikely to depend totally on smooth muscle activity and is more probably related to the support provided by the ligamentous structures that surround them. The innervation and longitudinal orientation of most of the muscle fibres suggest that urethral smooth muscle in the female is active during micturition, serving to shorten and widen the lumen of the urethra.

MICTURITION AND URINARY CONTINENCE

The central integration of nervous control of the bladder and urethra is essential for normal micturition (**Fig. 73.13**). (For further reading see de Groat et al (2015), Bertrand et al (2016).)

Micturition consists of storage and voiding phases and is controlled primarily at cortical, pontine and spinal centres (Weledji et al 2019). Recent imaging studies have also shown that the cerebellum and thalamus are involved (Harvie et al 2019). During the storage phase the bladder accommodates an increasing volume of urine with no change in intravesical pressure, partly because of the viscoelastic properties of its walls and partly because a gating mechanism operates in the spinal cord that reflexively inhibits preganglionic parasympathetic activity. A gating mechanism in the pelvic ganglia prevents the activation of postganglionic parasympathetic neurones until preganglionic activity has reached a threshold level (Chancellor and Yoshimura 2002).

Normal functional bladder capacity in adults ranges from approximately 300 to 400 ml, but micturition commonly occurs at smaller volumes. Voluntary control is imposed from the inferior frontal and anterior cingulate gyri of the cerebral cortex. Filling to 500 ml may be tolerated; beyond this level, pain caused by tension in the bladder wall leads to the urgent desire to micturate. The pain is referred to the cutaneous areas supplied by the tenth thoracic to the second lumbar and the second to the fourth sacral spinal nerves, including the lower anterior abdominal wall, perineum and penis or clitoris. Threshold afferent stimulation activates the micturition centre in the rostral pons (the 'M' centre) (see Fig. 73.13), which drives preganglionic parasympathetic neurones in the intermediolateral nuclei of the intermediate column of grey matter of the second, third and fourth sacral spinal cord segments via descending spinal pathways. The axons of these neurones run to the inferior hypogastric plexus in the pelvic splanchnic nerves; they synapse on postganglionic neurones in ganglia lying within the plexus and in the wall of the bladder. Postganglionic axons ramify throughout the thickness of the detrusor muscle: when stimulated these axons release acetylcholine, which activates muscarinic receptors in detrusor and produces the sustained bladder contraction required for micturition. The external urethral sphincter maintains urethral closure.

Clinical urodynamic studies have demonstrated a number of age-related changes in the lower urinary tract, including reduced bladder capacity; increased uninhibited detrusor contractions; decreased urinary flow rate; and diminished urethral pressure profile (particularly in females) (Siroky 2004).

Urinary continence in the male

Urinary continence at the level of the membranous urethra is mediated by the radial folds of urethral mucosa, the submucosal connective tissue, the urethral smooth muscle, the striated external urethral sphincter and puboperinealis (**Fig. 73.14**). The external urethral sphincter represents the point of highest intraurethral pressure in the normal, contracted, state. The striated muscle component of the external urethral sphincter is devoid of muscle spindles. The skeletal muscle fibres themselves are unusually small in cross-section (15–20 μm in diameter) and are physiologically of the slow twitch type, unlike the pelvic diaphragm, which is a heterogeneous mixture of slow and fast twitch fibres of larger diameter. The slow twitch fibres of the external urethral sphincter are capable of sustained contraction over relatively long periods of time and actively contribute to the tone that closes the urethra and maintains urinary continence. They are innervated by neurones that lie in the nucleus of the pudendal nerve in the anterolateral nuclei of the anterior column of grey matter of the second to fourth sacral spinal cord segments. Their firing is controlled centrally by a storage centre within the rostral pons (the 'L' centre) (see Fig. 73.13). Just before the onset of voiding, the external urethral sphincter is relaxed by central inhibition of the nucleus of the pudendal nerve.

Urinary continence in the female

The urethral sphincter mechanism consists of the intrinsic striated and smooth muscle of the urethra, the mucosa and submucosal connective tissue, and puboanalis (which surrounds the urethra at the point of maximum concentration of those muscles). The striated muscle component of the urethral sphincter mechanism surrounds the middle and lower thirds of the urethra in the female. Proximally, it forms a complete ring around the urethra; more distally, it covers the anterior and lateral aspects of the urethra. It blends above with the smooth muscle of the neck of the bladder and below with the smooth muscle of the distal urethra and vagina. Contraction of this part of the sphincter compresses the urethra against the relatively fixed anterior vaginal wall. The external urethral sphincter has two subdivisions; inferolateral extensions to the ischial rami (compressor urethrae) and a circumferential band encompassing the urethra and vagina (urethrovaginal sphincter). The mucosa and submucosa of the urethra are oestrogen-dependent and atrophy postmenopausally, possibly resulting in stress incontinence.

PROSTATE

The prostate is a globular fibromuscular gland that surrounds the prostatic urethra from the fundus of the bladder to the membranous urethra (Myers 2001). It is enclosed by firmly adherent tissue (endopelvic fascia covering the adjacent part of levator ani) that has been variously termed the capsule of the prostate or the fascia of the prostate (Myers et al 2010) (**Fig. 73.15**). Histologically, it is a multilayered connective tissue (Hinata et al 2013). There is no true fibrous capsule at the base or apex of the prostate.

The muscular tissue within the prostate is mainly smooth muscle. Anterior to the urethra, a layer of smooth muscle merges with the main mass of muscle in the fibromuscular septa; it blends superiorly with vesical smooth muscle. Anterior to this layer, a transversely crescent-shaped mass of skeletal muscle is continuous inferiorly with the external urethral sphincter in the deep perineal space. Its fibres pass

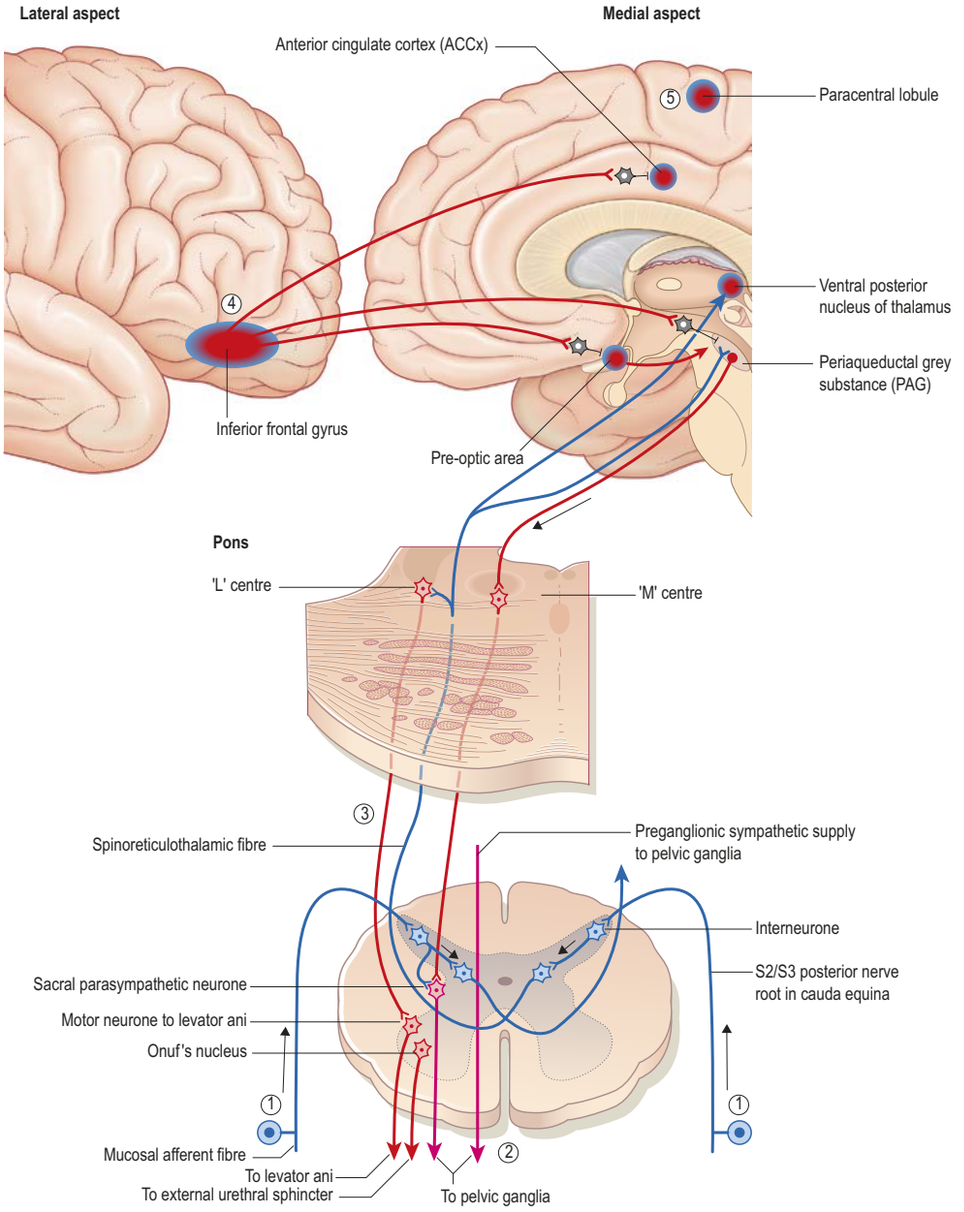

Fig. 73.13 The micturition control centre in the paramedian pontine reticular formation on each side consists of a medially placed micturition centre, 'M', and a laterally placed storage centre, 'L'. Neurones project from the 'M' centre and the storage centre 'L' to parasympathetic neurones in segments 2–4 of the sacral spinal cord, and to the motor neurone pool of the pudendal nerve, which is in the same segments and contains neurones that innervate the external urethral sphincter. At higher levels, neurones in the right prefrontal and anterior cingulate cortex, right preoptic nucleus and periaqueductal grey substance are involved in the control of micturition. Vesical afferents from stretch receptors in detrusor and trigonal mucosa relay the extent of bladder filling to the brain stem and thalamus via spinoreticulothalamic fibres (1). Parasympathetic activity and activity in the sympathetic system that maintains increases in bladder compliance (via β_2 receptors on detrusor fibres) is inhibited (2). Spinoreticular tract fibres synapsing in the 'L' nucleus in the pons activate the nucleus of the pudendal nerve to increase the tone of external urethral sphincter (3). If micturition is deferred, fibres projecting from the inferior frontal gyrus inhibit the right anterior cingulate gyrus, preoptic area and periaqueductal grey substance (4). Voluntary contraction of the pelvic diaphragm, controlled by the prefrontal cortex driving the perineal 'area' of the motor cortex (5), cannot be long sustained once filling is complete. (With permission from FitzGerald MJT, Folan-Curren J 2001 Clinical Neuroanatomy, 4th ed. London: Saunders.)

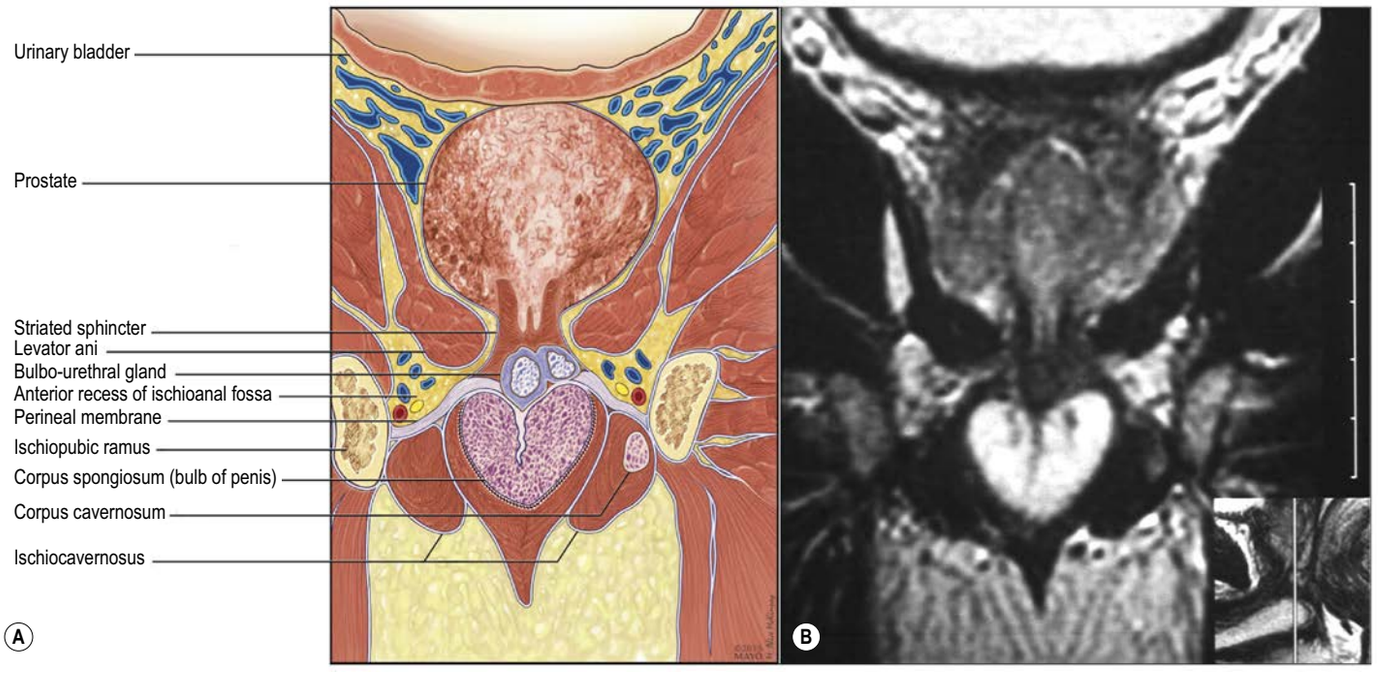

Fig. 73.14 A, Illustration of a coronal section through the male pelvis: prostate above, intervening striated urethral sphincter and perineal membrane with corporal bodies below. **B**, This coronal T2-weighted MRI includes the cephalad extension of the smooth muscle internal urethral sphincter, which cannot be discriminated from striated external urethral sphincter; bulbo-urethral glands are offset from expected symmetry. (A, B Courtesy of Robert P Myers MD, Akira Kawashima MD and Bernard F King MD, used with permission of Mayo Foundation for Medical Education and Research.)

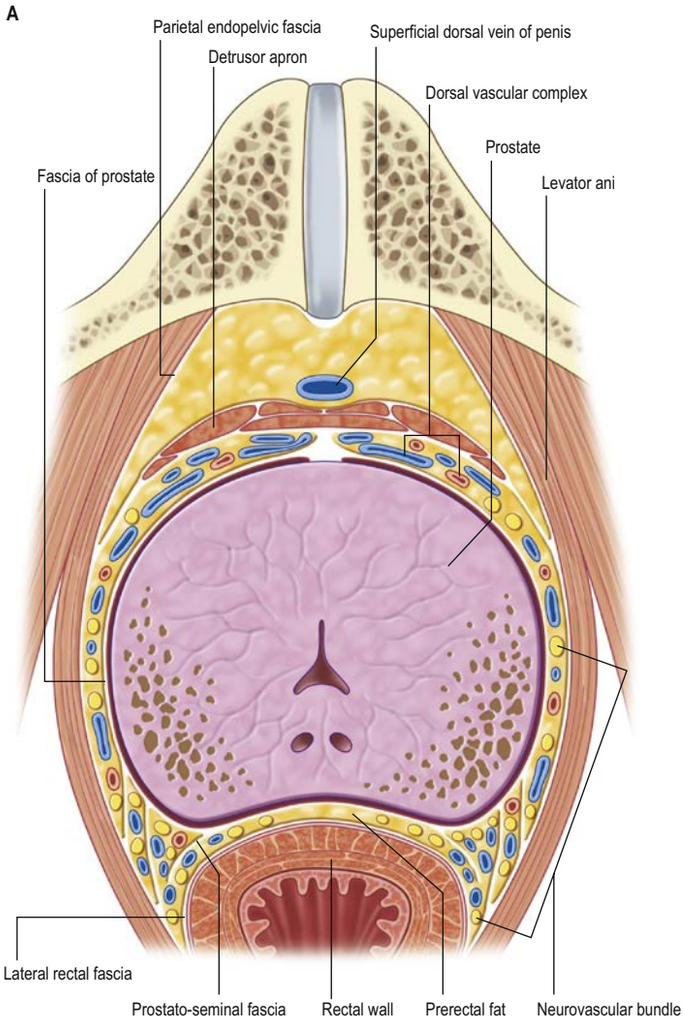
transversely internal to the capsule and are attached to it laterally by diffuse collagen bundles; other collagen bundles pass posteromedially, merging with the prostatic fibromuscular septa and the urethral crest. This muscle, supplied by the pudendal nerve, probably compresses the urethra but it can also pull the urethral crest back and the prostatic sinuses forwards, dilating the urethra. Glandular contents may be expelled simultaneously into the urethra when it has expanded in this way, so that it contains 3–5 ml of seminal fluid prior to ejaculation.

The prostate lies at a low level in the lesser pelvis, behind the inferior border of the pubic symphysis and pubic arch (see Fig. 73.2A; **Figs 73.16–73.17**) and anterior to rectourethralis and the rectal ampulla, through which it can be palpated. It presents a base superiorly, an apex inferiorly, and posterior, anterior, lateral and posterolateral surfaces. The base of the prostate measures about 4 cm transversely. The gland is approximately 2 cm in its anteroposterior diameter and 3 cm in its vertical diameter. It weighs about 8 g in youth but almost invariably enlarges with the development of BPH; it usually weighs 40 g, but sometimes as much as 150 g or even more after the first five decades of life. The small prostate without BPH is described as a croissant shape and the enlarged gland is more doughnut-shaped. The shape of the prostate affects the relation of its apex to external urethral sphincter. This relationship is important when the prostate is removed at radical prostatectomy for cancer, and anastomosing the bladder to the urethra to maintain sphincter integrity. External urethral sphincter is flush to a large doughnut-type gland, so a perpendicular incision will separate the prostate and external urethral sphincter accurately. With a small prostate, external urethral sphincter fills the defect in the anterior aspect of the gland, so a perpendicular incision at the level of the posterior lip of the croissant-shaped gland will excise much of external urethral sphincter and leave the patient incontinent.



Superiorly, the base of the prostate is largely contiguous with the neck of the bladder. The apex is inferior, surrounding the junction of the prostatic and membranous parts of the urethra. The posterior relation of the apex of the prostate and external urethral sphincter is rectourethralis, a Y-shaped smooth muscle that originates from the outer longitudinal layer of the rectum posteriorly and travels to the membranous urethra anteriorly. Some fibres of this muscle insert laterally into levator ani (Muro et al 2018).

The anterior surface lies in the pubic arch, separated from it by the dorsal vascular complex (Santorini's plexus) and loosely attached adipose tissue. It is transversely narrow and convex, extending from the apex to the base of the gland. Near its superior limit it is connected to the pubis by the puboprostatic ligaments. The urethra emerges from this surface anterosuperior to the apex of the gland. The anterior part of the prostate is relatively deficient in glandular tissue and is largely composed of fibromuscular tissue. The anterior and lateral aspects of the prostate are covered by a layer of fascia derived from the endopelvic fascia on each side, called the fascia of the prostate. This adheres medially to the prostate, continues posteriorly over the lateral aspect of the prostate, neurovascular bundles and rectum (lateral rectal fascia), and passes distally over the urethra (see Fig. 73.15A). The prostatic venous plexus (see Fig. 73.16) lies between this extension of the endopelvic fascia and the prostate. Anteroinferiorly, the endopelvic and visceral fasciae of the prostate merge and blend with the puboprostatic ligaments. The anterior surface of the prostate and associated vascular plexus is covered by the detrusor apron (Myers 2002).

The inferolateral surfaces are related to the muscles of the pelvic side wall; the anterior fibres of levator ani embrace the prostate as the puboperinealis (Myers et al 2000). This muscle is separated from the prostate by a thin layer of connective tissue.
