Frailty is also common among older adults, particularly among elderly with CVD (Veronese et al., 2017). Despite methodological and conceptual debates regarding the optimal method to assess frailty, there is general agreement in defining frailty as a state of increased vulnerability to stressors, with limited reserves to stabilize declines across multiple physiologic systems (Clegg et al., 2013). Frail adults with CVD typically suffer with worse disease outcomes, as well as increased susceptibility to harmful effects from standard therapies.

Disability refers to a physical or mental condition that limits a person's movements, senses, or activities. Whereas younger adults with CVD are usually able to fully recover after a successful CVD hospitalization or therapy, full recuperation is less certain among older adults with similar disease. Multimorbidity, frailty, polypharmacy, and other geriatric syndromes compound risks of disability in hospitalized elderly, especially in the context of acute illness, deconditioning, cognitive impairment, poor sleep quality, poor nutrition, dehydration, oversedation, and other common geriatrics patterns.

Older patients with CVD have high susceptibility to cognitive impairment and related susceptibility to delirium (Silbert et al., 2007; Dodson et al., 2013). Delirium is a state of an acute disturbance in awareness and attention that commonly arises amidst hospitalizations and postacute care. Delirium predisposes to higher mortality rates, frailty, and disability (McPherson et al., 2013). Efforts should be made to integrate protocols to detect delirium and moderating risks, including efforts to minimize medications (e.g., benzodiazepines) and circumstances (e.g., pain, poor sleep quality) that may precipitate the condition (Falsini et al., 2017; Salluh et al., 2015).

Research Opportunities

While CVD has been extensively studied in terms of disease mechanisms, the impact of nondisease aspects of care becomes increasingly relevant in old age. Geriatric syndromes arise from the same underlying molecular and biological substrate as CVD and inherently confound many precepts of disease-based care. Treating CVD amidst multimorbidity, frailty, polypharmacy, and other geriatric dimensions is now typically left to physician judgment, but research holds the potential to better clarify and respond to these challenges with more information regarding complex interdynamics and implications regarding qualitative (e.g., quality of life, patient reported outcomes) and quantitative (e.g., mortality, function, cognition, lengths of stay, rehospitalization) endpoints.

Ischemic Heart Disease

Atherosclerosis tends to be more severe and diffuse in older adults and is the most common etiology of ischemic heart disease (IHD). Other predisposing factors include microvascular dysfunction, endothelial dysfunction, vascular spasm, or microembolism

Table 2 Overview of geriatric syndromes

Geriatric syndrome	*Definition and prevalence*	*Prognosis and clinical implication*	*Management*
Multiple chronic conditions	• Presence of two or more concomitant chronic disorders • Prevalence: ~2/3 of older adults • Classification: Cardiovascular and non-cardiovascular conditions[a]	• Influence CVD management • ↓↓ QOL • Loss of independence • ↑↑ mortality • ↑↑ disability • ↑ polypharmacy • ↑ falls • ↑ therapeutic burdens	• Geriatric Assessment • ↑ importance of patient-centered (not disease-centered) approach in disease management • ↑ importance of shared decision making between patient and providers • ↑ importance of inter-specialty collaboration and communication • ↑ importance of quality of life and functional outcomes
Polypharmacy	• Use of ≥5 medications • ∝ to number of comorbidities • ~40% of older adults take ≥5 medications	• ↑ Iatrogenesis and medication errors • ↑ Nursing home admissions • Exacerbation of other medical condition (~20%)	• Review drug-drug interaction and indication of therapy • Review of drug-disease interaction • Simplify frequency of medication to maximize adherence. • Incorporate patient goals and preferences in treatment decisions • Gradual deprescribing of non-essential medications to maximize compliance • Adoption of checklist to identify errors and interactions
Frailty	• A state of reduced physiologic reserve in multiorgan system • ↑↑ susceptibility to stressful event • Tends to increase with CVD Prevalence can reach ≥50% of older adults with CVD	• Worsens CVD prognosis and confounds management • ↓↓ QOL • Loss of independence • ↑↑ mortality • ↑↑ disability • ↑ falls • ↑↑ heart failure • ↑↑↑ hospitalization	• Integration of frailty assessment with CVD management in older adults • Treatment of underlying disorders • Physical activity can help to moderate frailty • Nutritional supplementation can help to moderate frailty • Comprehensive geriatric assessment is useful
Cognitive impairment and delirium	• Mild cognitive impairment→↓ cognitive function without loss of function; 10%–15% per year develop dementia • Dementia→Severe memory loss that interferes with daily life and loss of functional independence • Dementia: 8.8%–11.6% in adults ≥ 65 years • Delirium → disturbance in cognition, attention, and consciousness or perception with fluctuating course • Delirium: as high as 14% in older adults living in community; 17%–61% after major surgery; up to 83% at end of life.	• Loss of independence • Difficulty performing complex executive activities • ↓↓ QOL • ↓↓ medication compliance • ↑↑ frailty • ↑↑ hospitalization • ↑↑ mortality	• Weighing risks of invasive procedure in older adults with neurocognitive impairment • Integration of patient and family wishes in CVD care & routine assessment of life expectancy • Routine integration of delirium assessment in cardiovascular care for older adults • Avoidance of precipitating factors (psychoactive medications; benzodiazepines; urinary catheters. . .etc) • ↑ Utility of palliative care service to address goals of care

CVD, cardiovascular disease; *QOL*, quality of life; *no*, number; *CVD*, cardiovascular disease.

[a]Cardiovascular comorbidities include: hypertension, dyslipidemia, ischemic heart disease, heart failure, stroke, valvular heart disease, heart rhythm disorders; Noncardiovascular comorbidities include: diabetes, osteoarthritis, obstructive lung disease, anemia, chronic kidney disease, dementia, depression, and geriatric syndromes.

(Marzilli et al., 2012). Age-related susceptibility to disease relates to increased media and intimal thickness of coronary arteries, endothelial dysfunction, and heightened inflammation and oxidative stress in the arterial wall (**Table 1**). Although IHD can result in classic angina pectoris, in older adults less specific complaints of exercise tolerance and dyspnea are more likely.

Prevalence of IHD among older men and women is rising (Dai et al., 2016a). Age-related pathophysiological susceptibility to IHD pathophysiology is compounded by increased survival from acute ischemic events, as well as improved diagnostic testing (e.g., imaging and biomarker testing) to diagnose IHD. The rising prevalence of IHD in older adults poses significant challenges in clinical decision-making and frequent application of pharmacologic and invasive therapies that have not been well studied in very old adults with multimorbidity, frailty, and other complexities of care.

Given the complexity of care, the 2012 ACCF/AHA/ACC/ACP/AATS/PCNA/SCAI/STS Guidelines for the Diagnosis and Management of Patients with Stable IHD included a section on older adults (Fihn et al., 2012). Although the management of stable IHD is generally similar to that of younger patients, the guideline recommendations acknowledged the complexity of care for older

adults >75 years of age. The presence of concomitant coexisting medical conditions that can result in chest pain including pulmonary, gastrointestinal, and musculoskeletal systems can render the diagnosis of IHD more difficult. Furthermore, older adults are more likely to present with atypical symptoms such as exertional dyspnea, lack of energy, nausea and vomiting, diaphoresis, syncope, and altered mental status rather than typical chest pain (Alexander et al., 2007a). Finally, given the higher prevalence of left-ventricular diastolic dysfunction in older adults, acute HF is a common consequence of acute myocardial ischemia (Lakatta, 2002).

Given the presence of muscle loss, deconditioning, neuropathy, lung disease, and degenerative joint disease, exercise ECG protocols with sufficient intensity to diagnose IHD are often difficult to perform. Moreover, high prevalence of baseline ECG abnormalities, left ventricular hypertrophy, and arrhythmias often limit the value of standard ECG testing (Fihn et al., 2012). For older patients who are unable to exercise, pharmacologic stress imaging is recommended. Older adults referred for coronary angiography often have more extensive atherosclerosis than younger patients, including multivessel disease or left main artery involvement (Alexander et al., 2007a). In general, guideline-directed medical therapy is recommended as an initial approach. Invasive therapies to improve symptoms are considered useful, but only with consideration of each patient's personal preferences, functional capacity, quality of life, and end-of-life preferences (Fihn et al., 2012).

Geriatric Complexities

Challenges in the management of older adults with IHD are numerous. Prior studies revealed that older adults who exhibited frailty were less likely to receive the same extent of therapy as compared to adults without frailty (Lupon et al., 2008). For example, the use of guideline-directed medical therapy with ACE inhibitors and beta-blockers was lower when frailty was encountered, and these patients were less likely to be admitted to coronary care units and to undergo cardiac catheterization or coronary artery bypass surgery (Afilalo et al., 2014; Graham et al., 2013). Furthermore, adults ≥80 years usually have higher prevalence diabetes mellitus, HF, atrial fibrillation, renal failure, anemia, chronic kidney disease, and dementia (Alexander et al., 2007a; Mogensen et al., 2011). As such, treatment with invasive procedures that requires prolonged dual antiplatelet therapy with or without the need for antithrombotic therapy for cerebrovascular vascular accident prevention may not produce the same results in comparison to younger counterparts with a single disease process. The risk of contrast-induced nephropathy after coronary angiography is higher in older adults, which often reinforces rationale for conservative approaches. Generally, pharmacotherapy is challenging in older adults as reduced renal function results in different bioavailability and drug elimination profiles. Drug–drug and drug–disease interactions are common specially in setting of polypharmacy (Fihn et al., 2012). Intolerance to beta-blockers because of underlying fatigue may exert a significant challenge to achieve a reduced work load of the heart. Many older adults are intolerant to statin therapy because of muscle aches (see section on dyslipidemia). Impaired mobility may mask underlying exertional symptoms. Similarly, impaired cognition may diminish adherence to healthful to medications and diet (Arnett et al., 2014).

Research Opportunities

The impact of IHD and management (pharmacological vs invasive revascularization procedures) on symptoms, quality of life, and functional independence must be better elucidated in respect to age-related contextual factors (Rich et al., 2016). Steps to standardize these approaches are needed especially as iatrogenic risks also increase with age. Furthermore, research is needed to clarify therapies that are better tailored to each older patient's functional capacities (physical and cognitive), comorbidities, personal goals, and medication profiles. Studies would also be useful to better clarify the role of noninvasive cardiac imaging to detect IHD associated with atypical symptoms such that under- and overdiagnosis are minimized. Likewise, the optimal duration of antiplatelet therapy or other adjunctive therapies after percutaneous revascularization in older adults merits further analysis to better balance the tradeoffs between therapeutic benefits versus bleeding and other medication-related risks.

Acute Coronary Syndrome

Advanced age is the strongest risk factor for poor outcome following acute coronary syndromes (ACS) (Dai et al., 2016b; Goldberg et al., 1989). The pathophysiology of ACS entails plaque rupture or cap erosion, triggering a thrombotic cascade and supply/demand mismatch (Damluji et al., 2015a). The spectrum of ACS depends on the degree of obstructive disease. Unstable angina and non-ST elevation ACS (NSTE-ACS) result from subtotal occlusion of coronary flow along with associated vasospasm. ST segment elevation myocardial infarction (STEMI) refers to the total occlusion of the coronary artery (Damluji et al., 2015a). While some older adults with ACS present with typical angina symptoms of chest pain, atypical symptoms become more likely with age, including shortness of breath, nausea, vomiting, presyncope or syncope, weakness, or changes in cognitive function. ACS in older adults is also often induced by coexisting conditions (e.g., urinary tract infections, sepsis, chronic lung disease, pneumonia, or anemia) that provoke type II myocardial infarctions.

Although the standards of ACS care do not fundamentally vary between older and younger adults, revascularization complications and medication iatrogenic effects are more likely and often impact care therapeutic choices (Goldberg et al., 1989). Older patients are also more prone to development of mechanical complications, especially after STEMI when immediate revascularization is not available or withheld resulting in higher mortality rates (e.g., free wall rupture, papillary muscle rupture, ventricular septal defects, left ventricular aneurysm, or pseudoaneurysm).

The American Heart Association Council on Clinical Cardiology produced a scientific statement specifically outlining recommendations for older adults with ACS (Alexander et al., 2007a; Alexander et al., 2007b). For patients with STEMI, prompt treatment with reperfusion therapy (e.g., percutaneous coronary intervention or fibrinolysis) is recommended when possible. Delays in reperfusion therapies are common in older patients because of atypical symptoms, abnormal baseline ECG, associated cardiogenic shock, or the presence of multiple chronic conditions that complicate management. Reduced cognition and constricted medical access are also pertinent. Older patients with STEMI who receive percutaneous coronary intervention (PCI) as compared to fibrinolysis have been demonstrated to benefit with reduced rates of reinfarction and target-vessel revascularization (Alexander et al., 2007b). Early invasive strategy (within the first 48 h of presentation) is also recommended for older adults with NSTE-ACS or unstable angina, particularly if high risk features are present (i.e., angina at rest, ischemia at low activity levels despite treatment with two anginal medications, elevated cardiac biomarkers, dynamic ECG changes, congestive HF or depressed ejection fraction (<40%), history of surgical or percutaneous revascularization) (Alexander et al., 2007a). Utilization of techniques to decrease the risk of bleeding in older adults (e.g., transradial catheterization, use of ultrasound/fluoroscopic guided femoral access, bivalirudin infusion) are important considerations when considering invasive percutaneous therapies for older patients. Given their high risk profiles, older adults who are candidates for surgical revascularization particularly benefit from a "Heart Team" approach wherein care is coordinated by experts with synergistic insights and skills (Holmes et al., 2013).

Post ACS medical therapy is inherently complicated by age. Dual antiplatelet therapies are critical post PCI/stenting but with higher risks of bleeding. Beta blockers reduce risks of reinfarction and are especially useful in patients with systolic dysfunction, but with greater risks of chronotropic incompetence, heart block, and fatigue. In patients with systolic dysfunction or diabetes mellitus, the concomitant use of ACE inhibitors and ARB pharmacotherapy improve survival but with increased risks of renal insufficiency (especially in those with renal artery stenosis). Statins for secondary cardiovascular prevention result in improved cardiovascular outcomes even for very older patients >80 years of age (Dai et al., 2016b; Damluji et al., 2015b), but with increased risks of myalgias.

Geriatric Complexities

Multimorbidity and other geriatric syndromes contribute to atypical ACS symptoms that often result in delayed care. Furthermore, management of ACS in the elderly is often impeded by coexisting cardiovascular (e.g., HF, arrhythmia, PAD) and noncardiac (e.g., chronic obstructive pulmonary disease, chronic kidney disease, diabetes, and frailty) factors that increase complexity and instability. Major bleeding, complications of invasive therapies, contrast-induced nephropathy, delirium, and drug–drug interactions are all relatively more common in older versus younger ACS patients. The presence of frailty in very old adults also contributes to longer hospital length of stay, increased rehospitalization, increased bleeding, and greater cardiovascular mortality (Alonso Salinas et al., 2016a; Ekerstad et al., 2011; Alonso Salinas et al., 2016b).

Discrepancies in the management of ACS in older adults have been observed in several clinical studies. In the GRACE registry (Avezum et al., 2005), patients >65 years were less likely to receive standard medical therapy, and in those >74 years, coronary angiogram and PCI were less likely to be performed. Furthermore, major bleeding doubled in patients >85 years. In the CRUSADE study, four different age groups were compared: <65 years, 65–74 years, 75–84 years, and >85 years (Alexander et al., 2005). Approximately 35% of the patients were aged >75 years and 11% were >85 years. The rate of utilization of antiplatelet and antithrombin therapy within the first 24 h of presentation was significantly lower with advancing age.

Because of the higher risk of bleeding, the use of multiple antithrombotic and antiplatelet agents is particularly challenging (Forman et al., 2016). In older adults with ACS and concomitant atrial fibrillation who require oral antithrombotic therapy, prolonged dual antiplatelet therapy after PCI with oral antithrombotic therapy increases the long-term risk of bleeding events. However, recent studies indicate that the use of clopidogrel in combination with oral anticoagulant (i.e., omitting aspirin) was as effective in preventing cardiovascular events, with reduced risks of bleeding (Lamberts et al., 2013). Similarly, in another trial, among patients with atrial fibrillation undergoing stent placement the administration of low-dose rivaroxaban plus $P2Y_{12}$ for 12 months or very low dose rivaroxaban plus dual antiplatelet therapy for 1, 6, or 12 months are associated with lower rate of clinically significant bleeding with efficacy that was similar to traditional standard triple therapy (Gibson et al., 2016).

In older patients with myocardial infarction, early revascularization results in improved clinical outcomes and better symptom control. In TACTICS-TIMI 18, an early invasive strategy was compared to conservative medical therapy, and a subgroup analysis was performed in older patients (Bach et al., 2004; Cannon et al., 2001). This analysis showed a treatment benefit for an early invasive strategy even with advancing age. In patients ≥75 years of age, there was a 56% relative risk reduction with an invasive strategy compared to only 20.4% relative risk reduction in younger patients. However, there was also a 3-fold risk of major bleeding, particularly among older patients. In the After Eight Study, approximately 450 patients 80 years or older with non-ST elevation ACS or unstable angina were randomized to an early invasive strategy with PCI or coronary bypass grafting versus medical therapy alone, and the early invasive strategy was shown to be superior to conservative medical treatment (Tegn et al., 2016). DeBelder et al. examined stent placement in octogenarians for symptomatic angina in 22 centers in the XIMA trial (de Belder et al., 2014). Approximately 800 patients received either drug-eluting stents or bare metal stents, and drug-eluting stents were associated with a lower incidence of myocardial infarction and target vessel revascularization without increased incidence of major hemorrhage. Despite concerns relating to procedural complications, bleeding risks, and worse long-term prognosis, many older adults benefit from invasive therapies.

Data from the GUSTO-I trial showed that 30-day mortality after a STEMI increased 10-fold in patients ≥85 years of age compared to those <65 years of age (White et al., 1996). Older STEMI patients often do not receive revascularization because of late presentation (>6 h after symptoms onset) (Alexander et al., 2007b), cognitive impairment and dementia, nondiagnostic EKG, atypical symptoms, associated geriatric syndromes, poorly controlled hypertension, prior stroke, or chronic anticoagulation (Antman et al., 2004). Nonetheless, older STEMI patients who do not get revascularized then become more susceptible to complications (e.g., HF, ventricular arrhythmias, and cardiogenic shock). Thus, early revascularization in selected older adults with STEMI is typically associated with improved longevity and reduced risks of recurrent events (de Boer et al., 2002; Goldenberg et al., 2003; Grines, 2005).

Research Opportunities

Improved diagnosis of ACS can help overcome notorious delays in initiating care. The utility of revascularization and other ACS therapies in relation to frailty, multimorbidity, and other geriatric syndromes is also a key research consideration (Afilalo et al., 2014). Likewise, the dose, intensity, and duration of pharmacologic therapy after ACS needs greater clarification, with benefits of antiplatelet therapy, statins, beta-blockers, ACE inhibitors/ARB, and other medications all counterbalanced by increased iatrogenic risks (Rich et al., 2016) amidst geriatric vulnerabilities.

Risk stratification tools for better patient selection to undergoing invasive procedures are needed. The influence of nonpharmacologic therapies, including cardiac rehabilitation, may have a role in improving physical function and quality of life parameters in older adults after ACS as well as with stable IHD.

Enrolling older ACS patients into trials to evaluate the effects of interventions on clinical and quality of life outcomes is inherently challenging yet feasible (Sinclair et al., 2016). This will entail creative strategies to enroll and facilitate participation for candidates who may lack sophisticated health literacy or logistical access. Finally, studies to better study advanced care planning and methods for decision-making are needed because it can influence the goals of care and choice of therapy for IHD and ACS (Rich et al., 2016).

Heart Failure

Heart failure is more common in older adults, rising in prevalence from <1.5% of the population in patients <60 years old to approximately 12% (10.6% in men and 13.5% in women) in patients ≥80 years of age (Writing Group Members et al., 2016). Both HF with reduced ejection fraction (HFrEF) and HFpEF increase with age, but incident HFpEF is more prevalent as it is essentially intertwined with the elements of cardiovascular aging (**Table 1**). HFpEF is also exacerbated by the increasing prevalence of CHD, hypertension, diabetes, atrial fibrillation, and other factors which commonly coexist in older patients (Shah et al., 2016; Paulus and Tschope, 2013).

Many pivotal HF trials have systematically excluded older adults given the degree of complexity associated with their management, and caution is warranted when implementing guideline-directed therapies for older patients. Nonetheless, basic precepts of care for older HFrEF and HFpEF patients are similar to younger adults. Routine serum measurements of electrolytes, renal, kidney, and thyroid functions, and surface ECG may provide important clues to the etiology of the disease. Transthoracic echocardiography is a corner stone in the diagnosis given the availability, noninvasive nature, and lower cost. Echocardiograms are useful for the evaluation of structural feature, mechanical function, and/or flow abnormalities. If underlying coronary disease is suspected, coronary angiography can evaluate coronary anatomy and stratify older adults suitable for coronary revascularization. Right heart catheterization may be useful to clarify intracardiac hemodynamics especially for HFpEF.

The goals of management of acute HF in the elderly are similar to younger adults, which are focused on immediate symptomatic improvement and prevention of disease progression. Improvement in shortness of breath with use of diuretic therapy may result in improvement in functional status and maintenance of independence. However, routine screening for electrolytes disturbances, worsening renal function, and evidence of hypoperfusion are important because of coexisting chronic kidney disease, drug–drug interactions, or presence of other medical conditions in older patients (Azad and Lemay, 2014).

In HFrEF, prevention of disease progression is achieved by adherence to pharmacotherapy that have been proven to improve survival (particularly ACE inhibitors, ARB, beta-blockers, and mineralocorticoid receptor antagonists [MRA]) (Yancy et al., 2013). Although beta-blockers are associated with significant mortality reduction in combination with ACE inhibitors or ARB, their use may be confounded by advanced conduction disease, severe obstructive lung disease, or sick sinus syndrome. In general, medication choices must be individualized, with the assumption that guidelines' precepts may not be fully implementable. Moreover, routine assessment of kidney function is prudent with up titration of ACE inhibitors, ARB, or MRA as a significant rise in serum creatinine is expected (Azad and Lemay, 2014).

The recent PARADIGM-HF trial showed that symptomatic HFrEF patients (ejection fraction ≤40%) treated with a combination of the ARB valsartan and the neprilysin inhibitor sacubitril resulted in significantly improved clinical outcomes compared to treatment with enalapril pharmacotherapy. Substantial benefits extended to adults ≥75 years, including reduced cardiovascular death or rehospitalization, all-cause mortality, cardiovascular mortality, heart failure exacerbation, and symptoms related to heart failure (Forman et al., 2016; McMurray, 2014). Thus, it is now felt that many older adults may benefit from combined valsartan–sacubitril instead of ACE inhibitors or ARB, in combination with beta-blockers and possibly MRA. Still, the risks of polypharmacy from this regimen, especially in combination with medications from concurrent diseases, remain an enduring concern.

In contrast to HFrEF, treatment for HFpEF remains relatively more ambiguous. Treatment of hypertension, atrial fibrillation, and other cardiac instability are all recommended, but there is less certainty regarding medications to treat HFpEF on a more fundamental level. Although the TOPCAT trial found that MRA reduced HF hospitalization in the setting of HFpEF, it resulted in higher rates of hyperkalemia and renal impairment (Pitt et al., 2014). Nonetheless, other analyses reinforce the utility of MRA as posthoc analysis of TOPCAT suggest that even greater benefits may result in specific subsets of HFpEF patients (Pfeffer et al., 2015). Ongoing trials continue to explore new pharmacological agents that target other steps in this complex age-related disease (Shah et al., 2016).

The observed benefit of device-based therapy in older HF patients remains controversial (Rich, 2001). Cardiac transplantation and mechanical support devices, such as left-ventricular assist devices (LVAD), improve overall survival for younger adults with advanced HF, but older adults are not routinely considered for these advanced therapies (Richards et al., 2016). In general, selection for implantable cardioverter defibrillator should include overall assessment of quality of life measures, patients' preferences, and life expectancy (North and Sinclair, 2012) Furthermore, end of life care and palliative domains in management are important considerations for older HF patients (Yancy et al., 2013; Yancy et al., 2016). Prognosis is inherently grim for this progressive disease, and discussion regarding quality of life as well as death is an important dimension of care (Forman et al., 2016).

Geriatric Complexities

Exercise intolerance and dyspnea are common symptoms of HF in older adults, but they are nonspecific and thus often attributed to other etiologies. Similarly, HF symptoms may include confusion, weakness, anorexia, cognitive decline, or somnolence which are frequently misinterpreted and/or undertreated (Forman and Rich, 2003). Standard therapy for HF is often complicated by side effects of medications and preexisting chronic conditions (Forman and Rich, 2003). Prior studies have shown that >90% of older adults with HF have at least two comorbidities and 60% have five or more (Chamberlain et al., 2015; Wong et al., 2011), further complicating the presentation, diagnosis, and management of HF.

Objective data may help ascertain the diagnosis of HF in these patients including the use of clinical exam (particularly elevated internal jugular pressure), chest X-ray, and echocardiography. Biomarkers (natriuretic peptide BNP or N-terminal pro-BNP [NT-pro-BNP]) can be informative, but with the caveat that diagnostic cut-points are relatively higher in older versus younger adults. While biomarkers are less specific for diagnosis of HF in old age, they still have valuable prognostic utility (van Veldhuisen et al., 2013).

Given the substantial role of comorbidity in HF pathophysiology and instability, treatment of concomitant cardiac (e.g., CAD, valvulopathy, and atrial fibrillation) and noncardiac (e.g., anemia, diabetes) diseases are critical parts of management, both in respects to symptoms and quality of life. Standardized approaches to comorbid diseases, including choices of medications and procedures, remain an important challenge to care.

Research Opportunities

Studies are needed to evaluate the utility and safety of newer pharmacologic therapies and mechanical support devices in older adults, particularly HFpEF. Furthermore, it is increasingly important to clarify and facilitate more patient-centered approaches for management of HF as it is a disease of complex multimorbidity, frailty, and disability. A broader range of patients (e.g., broader ranges of age, frailty, multimorbidity) and pertinent endpoints (e.g., mortality, hospitalization, quality of life, or functional capacity for older adults) need to be studied. HFpEF remains a particularly dynamic area of research, especially as new mechanisms underlying disease are still being delineated. Based on these expanding insights, many novel medications are being studied (e.g., valsartan/sacubitril in the Paramount trial) (Rich et al., 2016; Solomon et al., 2012).

The impact of frailty and cognitive impairment merits more study in a disease, wherein these risks are endemic in the vulnerable population, and also predictive of iatrogenesis and poor adherence. The impact of nonpharmacologic interventions like supervised exercise programs and diet modification may improve quality of life, symptoms, and function and lead to options for reduced pharmacotherapy. Early introduction of palliative therapy, including consideration for hospice care, minimizes burden associated with advanced heart failure in older adults and may also result in improvement in quality of life.

Valvular Heart Disease

Just as aging physiology affects the coronary vasculature and myocardium, cardiac valves also undergo changes that predispose to disease (**Table 1**). Myxomatous degeneration, collagen infiltration, and calcification are common, especially in the left heart (Cheitlin, 2003a; Cheitlin, 2003b). Fixation of valvular leaflets can also cause substantial valvular regurgitation (Hu et al., 2016; American College of Cardiology et al., 2006). According to the 2014 AHA/ACC Valvular Heart Disease Guidelines, 12%–13% of patients older than 75 years have moderate to severe valvular heart disease. While surgery is often technically indicated, many elderly patients are suboptimal surgical candidates, and thus their treatment options are more limited (Nishimura et al., 2014). In a U.S. population-based study of 11,911 patients, Nkomo et al. showed that 13.3% of patients ≥75 years had valvular disease, with prevalence increasing with age (Nkomo et al., 2006). There were no differences in prevalence between men and women. Approximately 9% of patients had mitral valve disease, and 4.5% had aortic valve disease (Nkomo et al., 2006).

Given the relatively high prevalence of valve disease in older adults and high surgical risks, the option to use innovative transcatheter aortic and mitral valve technologies in lieu of valve surgery have rapidly proliferated. For severe symptomatic aortic stenosis, transcatheter aortic valve replacement (TAVR) is now an alternative treatment in high-risk patients for conventional surgical aortic valve replacement (SAVR). Many of the patients in the initial TAVR implementation efforts have been of advanced age. The PARTNER A & B trials were multicenter, randomized clinical trial that compared standard medical therapy for severe aortic stenosis to TAVR and showed that transfemoral TAVR was superior (30% mortality vs 50% mortality) (Leon et al., 2010). Risks of stroke, heart block, vascular complications, and paravalvular leak are generally higher with TAVR, but these risks have progressively lowered as TAVR technology has advanced. In OBSERVANT, TAVR was compared to SAVR; a substudy of patients aged >80 years showed similar early and midterm mortality (Fraccaro et al., 2016). In the PARTNER 2 trial, TAVR was also demonstrated to be equivalent to SAVR in terms of death or disabling stroke in intermediate risk patients with severe aortic valve disease (Leon et al., 2016).

Over the past several years, transcatheter mitral therapies for repair and replacement of the mitral valve have also advanced. The MitraClip is the device with the widest clinical experience and has been studied on a larger scale in both the TRAMI and ACCESS-EU trials (Baldus et al., 2012; Maisano et al., 2013). In the German trial for percutaneous repair of mitral regurgitation (TRAMI), 486 patients (median age 75 years), most of whom had severe mitral regurgitation and NYHA Class III/IV heart failure, were enrolled, and 94% of these patients successfully underwent MitraClip placement leading to an acute reduction in the severity of mitral regurgitation (Baldus et al., 2012). Functional capacity also improved in approximately 2/3 of patients, which lends support to this therapy as an important nonsurgical option for elderly patients with HF who are high-risk surgical candidates.

The first randomized trial comparing the MitraClip to conventional mitral valve surgery was the EVEREST II study. One-year results showed that the MitraClip was superior in terms of safety, but less effective in reducing mitral regurgitation. However, there were no differences at the end of a 4-year follow-up period in terms of the prevalence of moderate or severe mitral regurgitation or mortality (De Backer et al., 2014; Mauri et al., 2013). There are also multiple transcatheter mitral valve replacement systems that are being tested as an option for severe mitral regurgitation treatment in nonsurgical candidates (De Backer et al., 2014).

Research Opportunities

Although many of the valve studies have included older adult patients, refinement in patient selection and age-tailored care is still critical. The key goal is to pinpoint patients who will most likely recover from valve interventions. Therefore, comorbid disease, frailty, and other dimensions of care often become determinant of outcomes. Management of low-gradient aortic stenosis, multivalve disease, pulmonary hypertension, and amyloid heart disease are other issues which merit additional research and refinement. The long-term durability of the current transcatheter valves and devices in older adults and the utility of anticoagulation are other key issues which warrant further study.

Heart Rhythm Disorders

As the conduction system ages, degenerative changes predispose older patients to sinus node disease, sick sinus and tachycardia–bradycardia syndromes, supraventricular, and ventricular arrhythmias. These include fibrous, fatty, and calcific infiltration of the conduction system, cardiac fibrous skeleton, and reduction in the number of pacemaker cells (**Table 1**) (Dai et al., 2012; Chow et al., 2012). Atrial fibrillation is the most prevalent arrhythmia in older populations, and the incidence only increases with age. Seventy percent of patients with atrial fibrillation are between the ages of 65 and 85 years (Kistler et al., 2004). Atrial ectopy is common in older adults, and ventricular ectopy becomes more prevalence in patients with structural heart disease (Chow et al., 2012). Management of these heart rhythm disorders is complex because many older adults have limited life expectancy, multimorbidity, frailty, and polypharmacy. Benefits of anticoagulation to reduce thromboembolic risks of atrial fibrillation are counterbalanced by burdensome monitoring, dietary restriction, and bleeding risks. Benefits of implantable cardioverter defibrillators (ICD) to reduce sudden death in heart failure patients are often surpassed by the risks created by the multimorbidity and frailty in these patients.

Treatment options for atrial fibrillation range from rate control, systemic anticoagulation, and antiarrhythmic drugs to more invasive therapies such as radiofrequency ablation and left atrial appendage closure devices (Fang et al., 2007; Fuster et al., 2007; Damluji et al., 2015c). Antiarrhythmic medications have disproportionately unfavorable side effect profiles in older adults, (Dayer and Hardman, 2002; Fleg et al., 2011) and rate control with AV nodal blocking agents is a more common strategy of care (Curtis and Rich, 2007). Direct acting oral anticoagulants (DOACs) are generally considered advantageous for prevention of thromboembolic events as they are relatively simpler to administer than warfarin and lack the need for dietary restriction or routine blood monitoring. In a recent metaanalysis, DOACs were superior to warfarin therapy in preventing events in atrial fibrillation patients with reduced adverse events, even in elderly patients (Sharma et al., 2015).

Percutaneous left atrial appendage closure devices such as the Watchman and Amplatzer devices have also emerged as reasonable alternative therapies to chronic anticoagulation for stroke prevention in patients with atrial fibrillation at high risk of bleeding. PROTECT AF showed that left atrial appendage occlusion closure with the Watchman device was noninferior to anticoagulation with warfarin for stroke prevention (Reddy et al., 2013). In the PREVAIL trial, 407 patients (mean age ~75 years old) were randomly assigned to either left atrial appendage occlusion with the Watchman device without warfarin versus chronic warfarin therapy, and again, the Watchman was shown to be noninferior to chronic anticoagulation for ischemic stroke prevention (Holmes et al., 2014).

Implantable cardioverter defibrillators for prevention of sudden cardiac death in older adults are sometimes controversial. A recent metaanalysis of 4,915 patients ≥75 years of age showed that ICDs can reduce all-cause mortality in selected older adults (Fleg and Forman, 2013), but life expectancy of at least one year is necessary for ICDs to achieve such significant clinical benefit. The utility of ICDs becomes less straightforward in the context of mounting comorbidity and complexity. In fact, many now assert the critical importance of deactivating ICDs if comorbidities advance and overwhelm any likelihood of benefit (Kirkpatrick et al., 2012).

Research Opportunities

Research is warranted to better clarify the influence of multimorbidity, inflammation, and other constitutional changes in relation to arrhythmia (Richards et al., 2016) both to better elucidate pathophysiology and optimize therapies. Whereas catheter-based ablation therapy holds much promise in older populations, utility for older adults is still relatively unclear. One study evaluated 587 patients ≥75 years of age with atrial fibrillation; 261 who underwent ablation. Based on this study, ablation therapy for atrial fibrillation was determined to be safe and effective in older populations (Nademanee et al., 2015). However, larger studies with study populations that include more comorbidities are still warranted.

Older adults are at increased risk of bleeding with antithrombin therapies, and thus new percutaneous left atrial appendage closure devices show promise as an effective alternative to chronic anticoagulation, but more research is needed to better guide patient selection and choice of device. New oral anticoagulants also hold much promise to moderate bleeding risks; however more research is needed to ascertain safety amidst frailty and complexity.

Given the many concerns about ICDs for elderly with complex comorbid disease, alternative therapy with chronic resynchonization therapy (CRT) to reduce sudden death in eligible elderly without the risk of shocks is also an important area of investigation (Kron et al., 2009).

Peripheral Arterial Disease

Peripheral arterial disease (PAD) entails noncardiac atherosclerotic disease, and it is common in older adults. The Rotterdam Study showed that the prevalence of PAD, defined as ankle-brachial systolic blood pressure index <0.9 in either leg, was 19.1% overall, and almost 60% in patients ≥85 years (Meijer et al., 1998; Aronow, 2008). The risk factors for PAD are analogous to those of CAD, and thus patients with PAD are at increased risk for cardiovascular events including myocardial infarction and death (**Table 1**) (Ankle Brachial Index Collaboration et al., 2008). Although many older PAD patients are asymptomatic, CVD risks are still significant. Diehm et al. conducted a prospective cohort study to assess the mortality and morbidity risk in patients aged ≥65 years and demonstrated that both symptomatic and asymptomatic patients had similarly high CVD mortality compared to patients without PAD (Diehm et al., 2009).

The management of PAD in older adults is similar to younger patients. A thorough physical examination with attention to pulses, bruits, and ulcerations is fundamental. Assessment of the ankle-brachial index (ABI) is recommended. The toe-brachial index is an alternate consideration for patients with noncompressible ankle arteries. Duplex ultrasound, computed tomography angiography, or magnetic resonance angiogram may be needed to ascertain the diagnosis and extent of PAD. Treatment is mainly focused on symptom relief and risk factor modification, including exercise programs, smoking cessation, and pharmacologic therapy (Armstrong et al., 2014). However, when symptoms persist or critical limb ischemia occur despite optimal medical management, revascularization with surgical bypass, angioplasty, or major amputation may be required (Hirsch et al., 2006).

Stains have been demonstrated to increase walking distance in PAD patients (Aronow et al., 2003). Cilostazol has also been demonstrated to reduced claudication symptoms and increase walking distance (Lee and Nelson, 2014). Exercise is a particularly effective way to improve function and quality of life in older adults with obstructive PAD. The CLEVER study compared medical therapy alone to medical therapy with supervised exercise as well as to medical therapy with stent revascularization. It showed that supervised exercise and stent revascularization each achieved superior outcomes to medical therapy alone. Improvement in claudication onset time was greater for supervised exercise compared with medical therapy, but not for stent revascularization compared with medical therapy (Murphy et al., 2015).

Endovascular intervention including angioplasty, stents, and atherectomy is recommended for those patients with life-limiting claudication with hemodynamically significant aortoiliac occlusive disease or femoropopliteal disease but is recommended only to prevent progression to critical limb ischemia (Gerhard-Herman et al., 2016). Surgical revascularization has also been demonstrated to improve survival and offset the burden of symptoms. In the BASIL trial, 452 patients with severe infra-inguinal limb ischemia were randomized to bypass surgery versus angioplasty, and results showed that either strategy achieved similar mortality benefits and amputation-free survival (Adam et al., 2005).

Research Opportunities

While many PAD trials include patients >65 years of age, those aged >80 years (when PAD is most prevalent) remain noticeably understudied. Therefore, key perspectives regarding quality of life and functional outcomes are not well studied, despite significant implications pertaining to activities of daily living, mobility, frailty, and functional independence (Rich et al., 2016). Similarly, the

effects of pharmacological versus nonpharmacologic interventions in this population warrants much greater understanding. In addition, the interplay between PAD and age-related muscular decline and sarcopenia are important determinants of functional outcomes that have sparked great interest and research opportunity.

Cerebrovascular Disease

Prevalence of cerebrovascular disease increases dramatically with age, rising from 2% in patients 40–59 years of age to almost 15% in patients aged >80 years (Writing Group Members et al., 2016; Fleg and Forman, 2013). Given that the pathophysiology and risk factors for ischemic stroke and CAD overlap, mechanisms of vascular aging are similarly pertinent (**Table 1**), and adequate control of risk factors (e.g., hypertension, hyperlipidemia, and diabetes) are vital as primary prevention, especially as 76% of strokes are first events (Meschia et al., 2014).

In older adults undergoing bypass surgery or with past medical histories of PAD, history of smoking, or stroke or transient ischemic attack (TIA), screening with carotid ultrasound is often useful. The presence of atrial fibrillation increases the risk of thromboembolic disease, and antithrombotic therapy becomes an added consideration. Carotid endarterectomy has shown to be beneficial in reducing stroke risk in patients with 70%–99% stenosis of the internal carotid artery (Adams, 2009). The CREST trial showed carotid endarterectomy was superior to carotid artery stenting for reducing the stroke risk in patients >70 years of age (Brott et al., 2010).

For acutely presenting ischemic stroke, intravenous plasminogen activator inhibitor is recommended for selected patients who can be treated within 3 h of symptoms (door-to-needle time <60 mins from hospital arrival) (Jauch et al., 2013), but many older adults have absolute or relative contraindications for therapy. For patients with noncardioembolic ischemic stroke or TIA, antiplatelet therapy (aspirin monotherapy at a dose of 50–325 mg/day; the combination of aspirin and extended-release dipyridamole at a dose of 25/200 mg twice a day; or clopidogrel monotherapy at 75 mg per day) (Jauch et al., 2013) and high-intensity statin therapy have been demonstrated to reduce the risk of recurrent stroke, nonfatal myocardial infarction, and vascular death; however, even these options tend to be more complicated in the context of geriatric syndromes (Jauch et al., 2013; Chen et al., 2010).

Research Opportunities

Given the common and devastating nature of cerebrovascular disease, research to better ascertain risk and acute management are both essential. Utility of carotid screening, for example, is less certain for adults aged >80 years. Utility of TPA is often surpassed by risks associated with therapy, but alternative mechanical options (arteriography and thrombus extraction) have not been well studied in older populations. While risk factor modification is widely recommended, optimal strategies regarding blood pressure, diabetes, blood pressure targets, and antiplatelet therapy all remain uncertain in advanced age.

Hypertension

Age-associated changes in the arterial wall of the vascular systems, along with endothelial dysfunction, and chronic inflammatory changes result in decreased arterial dispensability and increased in wall stiffness (**Table 1**) and associated predisposition to isolated systolic hypertension. Historically, these elevations were considered "normal" aging and treatment was not advised by cardiovascular experts. However, many recent studies have shown that elevated blood pressure in older adults is associated with increased cardiovascular mortality and morbidity (Damluji et al., 2015b). Isolated systolic hypertension (ISH) is directly associated with development and progression of CAD, cerebrovascular disease, HF, and obstructive PAD. Although treatment of hypertension has been demonstrated to improve outcomes in adults aged into their 80s, it is often complicated by the presence of coexisting conditions, falls, fatigue, renal failure, and other iatrogenic sequelae.

There is heterogeneity in the guideline recommendations regarding the optimal blood pressure targets in older adults. The American College of Cardiology Foundation (ACCF) and American Heart Association (AHA) recommend systolic blood pressure (SBP) goal <140 mmHg in adults ≤79 years of age and SBP 140–145 mmHg in adults >80 years of age (Aronow et al., 2011). Similarly, the American Society of Hypertension and International Society of Hypertension recommend BP <140/90 mmHg in adults <80 years old and BP <150/90 mmHg for adults ≥80 years. The Joint National Commission 8 recommends BP <150/90 for all adults >60 years of age (Weber et al., 2014; James et al., 2014). Although several clinical trials and subgroup analyses examined different antihypertensive drug regimens in older adults, the exact class of medication which is most efficacious and with least adverse events remains ambiguous. Several studies have highlighted benefits of calcium channel blockers and angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blockers (ARB) in older adults. There is no evidence that elderly women respond to antihypertensives differently than elderly men, and thus both genders are usually treated similarly (Oparil, 2006).

The lack of consensus among these societies reflect the underlying special characteristics of older adult populations, including the potential for polypharmacy, and the greater risk of pharmacokinetic and pharmacodynamics complexities (Damluji et al., 2015b). For older adults with underlying CKD, history of falls, or preexisting conditions, Individualized treatment plans tailored to

achieve a more liberal blood pressure control may be acceptable. Notably, aggressive antihypertensive therapy associated with reduced diastolic blood pressure may also reduce coronary blood flow and exacerbate ischemic symptoms. However, for healthier older adults with fewer comorbidities in the SPRINT trial, low blood pressure (<120 mmHg) led to reduced cardiovascular events and all-cause mortality (Group et al., 2015). As such, a thorough evaluation for the patient's medical, cognitive, and functional status is important for a tailored individualized treatment plan to achieve optimal cardiovascular outcomes.

Geriatric Complexities

While the conceptual value of treating hypertension is clear, older adults are especially sensitive to adverse drug reactions given the prevalence of polypharmacy and hemodynamic lability (Butt et al., 2010). These risks range from postural hypotension (with increased propensity to falls) to increased medication toxicity due to reduced renal clearance. One of the mainstays of the treatment of hypertension in the elderly is to start with the lowest dose of a medication and gradually increase as tolerated (Damluji et al., 2015b). White coat syndrome can often result in the inappropriate escalation of therapy in older adults, and thus ambulatory blood pressure monitoring or ambulatory blood pressure logs can be an effective way to help avoid this common source of error.

Although multiple clinical trials evaluated different antihypertensive regimens in older adults (**Table 3**), therapy is frequently guided by the patient's cardiovascular comorbidities or risk factors. For example, ACE inhibitors are important first-line options for diabetes or HF. Beta-blockers may be relatively more useful in patients with CAD, HF, and/or atrial fibrillation (Jamerson et al., 2008). Multiple trials have shown that combination therapy of a variety of antihypertensives with a diuretic is efficacious in the elderly (Beckett et al., 2008; Staessen et al., 1997; Amery et al., 1985; MRC Working Party, 1992; Dahlof et al., 1991). Thiazide diuretics warrant added caution given the possibility of metabolic derangements and orthostatic hypotension (Beckett et al., 2008; Aronow, 2010), as well as risks pertaining to incontinence and dehydration.

Research Opportunities

Major gaps in knowledge remain target blood pressure goals in the setting of geriatric syndromes. Falls, frailty, cognition, and other dimensions of health may all worsen in some older patients who are treated too aggressively with antihypertensive medication. Outcomes for future trials should not only include the traditional cardiovascular outcomes but treatment related adverse event in older adults, including orthostatic hypotension, fall risks, cognition, functional capacity, and patient-based metrics. The recently released SPRINT Trial has sparked much controversy, as purported benefits of lower blood pressure targets implicit call for greater efforts to tailor care relative to each patient's idiosyncratic vulnerabilities (Patel et al., 2017).

Options to control hypertension also highlight the role of lifestyle modification. Aerobic exercise, intentional weight loss, alcohol moderation, and reduced salt have all been associated with improved blood pressure control in younger subgroups of elderly (Aronow et al., 2011). Nonetheless, the data substantiating these benefits in very old adults are relatively sparse. Furthermore, strategies to best achieve healthy lifestyles amidst the vulnerabilities and limitations of aging are often unclear.

Hyperlipidemia

Vascular aging (**Table 1**) results in increased arterial wall thickness and stiffening, reduced vasodilation, and increased oxidative stress and inflammation. These events lead to faster development and progression of atherosclerotic plaques and reduced microvascular function. Sustained exposure to low-density lipoprotein, along with other metabolic risk factors (e.g., hyperglycemia, tobacco), are implicated in the chronic inflammatory state, which initiate and drive vascular wall injury. Prior studies have shown that higher levels of low-density lipoproteins result in significantly increased proportion of CVD events and cardiovascular mortality, even among older adults (Pepe and Lakatta, 2005). Multiple studies have demonstrated that statin therapy reduces CVD mortlity and morbidity in older adults.

The 2013 ACC/AHA guideline on the treatment of blood cholesterol outlined the treatment algorithms for primary and secondary prevention of cardiovascular events (Stone et al., 2014). In that document, recommendations for adults $\geq$75 years of age without clinical evidence of CAD remain largely based on expert opinion. For older adults with low-density lipoprotein $\geq$190 mg/dL without clinical evidence of cardiovascular disease or diabetes, the consensus is to treat hyperlipidemia unless contraindications or intolerance exist (Stone et al., 2014). Patient preference to initiate, continue, or intensify statin therapy is considered a key part of decision-making.

For older adults with preexisting atherosclerotic CVD, secondary cardiovascular prevention with moderate- or high-intensity statin therapy is recommended, but with associated considerations regarding life expectancy, goals of care, and comorbid conditions. In the Heart Protection Study, which included over 20,000 patients aged 40–80 years with CVD, statin therapy decreased all-cause mortality, CHD, nonfatal myocardial infarction, need for revascularization, and stroke, including older patients (Heart Protection Study Collaborative Group, 2002). A posthoc analysis from the Scandinavian Simvastatin Survival Study showed that simvastatin use in patients >65 years of age provided similar benefits in terms of reducing the relative risk of major adverse cardiac events similar to younger patients (Miettinen et al., 1997). In PROSPER, one of the first randomized controlled trials exclusively conducted in 5,804 older adults (age 70–82 years), pravastatin reduced the risk of CAD by showing a significant 22% reduction in the combined endpoint of CHD death + MI + stroke in the 43% of the study population with known CVD (Shepherd et al., 2002).

Table 3 Main trials in hypertension involving older patients

Trial	*Year*	*Design*	*Drug therapy*	*Outcome*	*Recommendations*
EWPHE Substudy (Amery et al., 1985)	1985	Total 840 pts 691 in substudy Mean age = 71.5	Active tx with HCTZ + triamterene vs placebo	Relation between mortality and treated blood pressure	In elderly patients with HTN given active treatment, total mortality had a U-shaped relation with treated systolic pressure and an inverse association with treated diastolic pressure.
Coope and Warrender (Coope and Warrender, 1986)	1986	884 pts Mean age = 69	Active tx with either atenolol ± bendrofluazide vs control	Primary endpoint—Incidence of stroke or coronary disease; effect on overall mortality Secondary Endpoints—adverse side effects, unwanted morbidity	42% reduction in incidence of stroke, 22% reduction in cardiovascular death (NS); no effect on overall mortality or incidence of fatal or nonfatal heart attacks
SHEP (SHEP Cooperative Research Group, 1991)	1991	4736 pts Mean age = 72	Active tx with Chlorthalidone 12.5 followed by atenolol 25 vs placebo	Primary endpoint—nonfatal and fatal stroke Secondary endpoint—cardiovascular and coronary morbidity and mortality, all-cause mortality, QOL	Antihypertensive stepped-care drug treatment with low-dose chlorthalidone as step 1 medication reduced the incidence of total stroke by 36%; major cardiovascular events were also reduced
STOP-hypertension (Dahlof et al., 1991)	1991	1627 pts 70–84yo	Active tx with atenolol, HCTZ + amiloride, metoprolol, or pindolol vs placebo	Primary endpoint—total stroke, total MI, other cardiovascular death	Active treatment resulted in significantly fewer primary endpoints, lower morbidity and mortality from stroke, and lower total mortality compared to placebo
Medical Research Council (MRC Working Party, 1992)	1992	4396 pts Mean age = 70yo	Atenolol 50 vs HCTZ 25 or 50 and amiloride 2.5 or 5 vs Placebo	Actively treated subjects had 17% reduction in all cardiovascular events and the diuretic group showed significant reduction in all cardiovascular events where beta-blockers did not	HCTZ and Amiloride decrease risk of stroke, coronary events, and all cardiovascular events in older pts
Syst-Eur (Staessen et al., 1997)	1997	6403 patients Mean age = 70	Treatment with nitrendipine with ACE inhibitor/diuretic if necessary to reduce SBP <150 vs placebo	Primary endpoint—fatal and nonfatal stroke Secondary Endpoints—myocardial infarction, CHF, dissecting aortic aneurysm, renal insufficiency, retinal hemorrhage	42% reduction in total stroke and 31% reduction in all fatal and non-fatal cardiovascular endpoints; treatment of BP starting with nitrendipine can reduce the rate of cardiovascular complications
Syst-China (Wang et al., 2000)	1998	2394 pts Mean age = 66.5yo	Nitrendipine + captopril/ HCTZ vs placebo	Primary endpoint—fatal and nonfatal stroke Secondary endpoints—myocardial infarction, CHF, dissecting aortic aneurysm, renal insufficiency, retinal hemorrhage	Active treatment reduced total mortality by 39%, cardiovascular mortality by 39%, and stroke mortality by 58%; Treatment of hypertension in older Chinese patients can prevent cardiovascular complications, especially stroke
LIFE (Dahlof et al., 2002; Lindholm et al., 2002; Kjeldsen et al., 2002)	2002	9193 pts Mean age = 70yo	Losartan vs atenolol	Primary endpoint—cardiovascular event such as death, MI, or stroke	Relative risk reduction Losartan prevents more cardiovascular morbidity and death than atenolol for a similar reduction in BP and is better tolerated
SCOPE (Lithell et al., 2003)	2003	4964 patients Mean age = 76.4	Candesartan vs placebo with open-label antihypertensive therapy as needed	Primary endpoint—major cardiovascular events, composite of cardiovascular death, nonfatal stroke, and nonfatal MI Secondary endpoint—cardiovascular death, nonfatal and fatal stroke and MI, cognitive function	Candesartan-based tx assocated with modest, but not statistically significant reduction in MACE with a marked reduction in nonfatal stroke; cognitive function well maintained in both groups
HYVET (Beckett et al., 2008)	2008	3845 patients Mean age = 84yo	Indapamide + perindopril vs placebo	Primary endpoint—fatal or non-fatal stroke Secondary endpoints—death from any cause, death from cardiovascular causes, death from stroke	30% reduction in rate of any stroke but NS; 21% reduction in rate of death from any cause and 64% reduction in rate of heart failure in treatment group SBP 140–145 for pts >80

Table 3 (Continued)

Trial	*Year*	*Design*	*Drug therapy*	*Outcome*	*Recommendations*
JATOS (Group, 2008)	2008	4418 pts Pts 65–85yo	Efonidipine for strict (SBP <140) vs mild (SBP 140–160) control of BP	Primary endpoint—combined incidence of cerebrovascular dz, cardiac and vascular dz, and renal failure Secondary endpoint—death from any cause	No significant difference in outcomes between strict and mild treatment of BP, but complex clinical features associated with aging thought to have obscured tx effect
CARDIO-SIS (Verdecchia et al., 2009)	2009	Total 1111 pts Mean age = 67	Usual (<140) vs tight control (<130) of BP in non-DM pts with HTN	Primary endpoint—rate of electrocardiographic LVH 2 years after randomization Secondary endpoint—composite of all-cause mortality, fatal or non-fatal MI, fatal or non-fatal stroke, TIA, decompensated CHF Stage III/IV, angina with objective ischemia, new onset Afib, coronary revasularization, aortic dissection, occlusive PAD, ESRD on HD	Lower BP goal is recommended in nondiabetic patients with HTN; hazard ratio of 0.5 between usual and tight control; side effects did not significantly differ
VALISH (Ogihara et al., 2010)	2010	3260 pts Mean age = 76 yo	Valsartan for strict vs moderate control of BP	Primary endpoint—composite of cardiovascular events: sudden death, fatal or nonfatal stroke, fatal or nonfatal MI, death because of heart failure, other cardiovascular death, unplanned hospitalization for CV disease, and renal dysfunction Secondary endpoints—components of the primary end point, total mortality, new onset/exacerbation of angina pectoris	SBP <140 safely achievable in patients >70yo; but trial underpowered to determine if strict better than less strict BP control
INVEST (Denardo et al., 2010; Pepine et al., 2003)	2010	22,576 pts with HTN and CAD enrolled in full trial 2180 looked at in substudy Mean age = 84yo	Verapamil SR vs atenolol	Primary endpoint—first occurrence of all-cause death, total MI, total stroke, and revascularization with PCI/CABG	No difference in morbidity and mortality between antihypertensive drug treatment strategies, but possibility of increased risk of adverse events with BP <140/70
SPRINT (Group et al., 2015; Williamson et al., 2016)	2015	Total 9361 pts with HTN, no DM 2636 patients >75yo Mean age = 80yo	Intensive therapy with SBP <120 vs standard therapy with SBP <140 with any number of antihypertensive agents	Primary endpoint—composite outcome of MI, ACS not resulting in MI, stroke, acute decompensated CHF, death from cardiovascular cause Secondary endpoint—individual components of primary outcome, death from any cause	SBP <120 better than SBP <140

Geriatric Complexities

Despite signals of improved outcomes for secondary cardiovascular prevention with statin therapy, important treatment considerations for older adults include limited life expectancy, physiologic age, neurocognitive status, frailty, comorbidities, and polypharmacy (Table 2). The expected time to benefit of statins is 2–5 years, and this may factor decisively in decisions to discontinue the medication. Nonetheless, statins have also been associated with reduced claudication and other benefits which may occur relatively more quickly. These nuanced differences need greater clarification for a population inherently vulnerable to drug interactions, myalgias, and other complexities of management (Navar-Boggan et al., 2015; Grundy, 2014).

The intensity of LDL reduction in older adults also remains unclear. SAGE, TNT, and PROVE-IT TIMI 22 trials all showed benefit of higher-intensity therapy, but also with reversible worsening in liver function tests (Damluji et al., 2015b; Ray et al., 2006). Older

adults with sarcopenia and deconditioning may experience pain with statin therapy that may only exacerbate functional impairments (Jacobson, 2006). As a result, low-intensity statins, such as pravastatin, are sometimes preferable because of improved safety profile and lower to drug interaction (Grundy, 2014; Han et al., 2011).

Research Opportunities

Primary and secondary prevention in older adults with lipid lowering agents remains a highly controversial area. Benefits include stroke, PAD, and CAD event reduction, and even the potential to moderate many insidious changing of aging that contribute to subclinical disease and functional decline. Novel PCSK9 therapies have erupted into the field with great promise to reduce atherosclerotic risks even more effectively (Sabatine et al., 2017), but at the trade-off of high expense and many uncertain medications effects. However, even statins raise conceptual controversies amidst age-related susceptibility to disease, juxtaposed to risks of polypharmacy, and iatrogenic effects, especially at higher doses. Research can help to better delineate thresholds of age physiology, aggregate risk, cumulative medication burdens, and other dimensions of risk and implementation to better optimize care. Until then, secondary prevention is rarely straightforward as it is confounded by multimorbidity, frailty, exercise intolerance, and other complexities of care. Rationale and therapeutic standards for primary prevention are even less clear. Existing guidelines are derived primarily by expert consensus, but the fact remains that many experts in this medical field do not agree.

For now, a patient-centered approach seems indicated that incorporates each patient's preferences. However, this assumes there is an effective decision-making process for a medication and that has diffuse effects and much controversy associated with its effectiveness and value. Ongoing research seems essential.

Conclusions

Cardiovascular disease and atherosclerosis are mainly diseases of older adults, and as this population grows, the prevalence of CVD worldwide continues to increase. However, many of the trials that have been conducted do not include older adults with typical geriatric complexities such as multimorbidity, polypharmacy, frailty, and neurocognitive impairment. Thus, data pertaining to therapies best suited to this age group are lacking. Furthermore, health outcomes in older adults need be tailored to improve symptoms, health-related quality of life, and functional status that incorporate aging complexities, and that move beyond an exclusively disease-centered approach. The rising costs of healthcare and the increasing prevalence of cardiovascular disease drive the need for preventative cardiovascular care for older adults. Basic science and translational research focused on cardiovascular aging in as well as clinical trials that include representative populations of complex elderly will help develop better treatment insights with greater potential to improve quality of life, reduce adverse side effects, and reduce cardiovascular mortality and morbidity among CVD patients.

Introduction

Sarcoidosis is a noninfectious granulomatous disorder of unknown cause that affects many organ systems, most often the lungs but not uncommonly the heart. Cardiac sarcoidosis (CS) is more prevalent than previously thought and is the second leading cause of sarcoidosis-related mortality following pulmonary complications. In older observational studies, sarcoidosis was thought to be relatively uncommon, affecting the heart in approximately 5% of patients; however, in autopsy studies and in studies using more sophisticated imaging techniques, the prevalence of cardiac involvement was closer to 25%–30% (Silverman et al., 1978). This variability suggests that the diagnosis of CS is difficult to establish based upon standard clinical criteria and that the methods for disease detection need to be better standardized.

Epidemiology

The prevalence and actual incidence of sarcoidosis are not known with certainty, and this is partly due to the fact that the incidence varies among geographic regions and different ethnicities. Furthermore, differences in environmental exposures, predisposing genetic factors, and different surveillance methods likely play a large role in the variable worldwide incidence. In northern European countries, the incidence of sarcoidosis is estimated to be 5–40 cases per 100,000 people. In the United States, this number varies between 10 and 40 cases for every 100,000 with African Americans three times more likely to be affected than Caucasians. This number is even higher in smaller studies conducted on a city-by-city basis. Moreover, sarcoidosis is more likely to be chronic and fatal in African Americans. Finally, mortality secondary to sarcoidosis in the United States has increased, and cardiac involvement certainly impacts this increase, especially in African American males (Rybicki et al., 1997; Pietinalho et al., 1995; Baughman et al., 2001; Swigris et al., 2011). Therefore, it is imperative that we understand the true burden of sarcoidosis and specifically the impact of CS.

Furthermore, certain ethnic differences in the epidemiology and presentation of CS have been reported. For example, Japanese pathologists reported cardiac involvement in 50%–78% of patients diagnosed with sarcoidosis; this is in comparison with 13%–50% involvement seen in US patients and <2% involvement in patients in Israel (Yoshida et al., 1997; Kim et al., 2009; Yigla et al., 2002).

Etiology

The precise etiology of CS remains unknown; however, numerous hypotheses including environmental, occupational, and infectious causes have been discussed. It is hypothesized that certain agents, such as infectious exposures, trigger an immunologic response in genetically susceptible individuals (Newman et al., 2004). These agents enter via the respiratory tract and incite an inflammatory response that is then carried over into the circulatory system, eventually reaching the heart.

Pathogenesis and Histopathology

Though the exact etiology of sarcoidosis remains unknown, it is thought that repeated exposures to specific antigens in genetically susceptible individuals lead to granuloma formation. This can either resolve or progress to fibrosis. It is thought that sarcoidosis requires at least three major events, including exposure to an antigen, acquired cellular immunity against the antigen and activation of CD4+ cells, and finally a nonspecific inflammatory response, initially with a Th1 response leading to inflammation and later with a Th2 response leading to tissue scarring (Sekhri et al., 2011). Moreover, a recent study suggests that certain lifestyle factors, namely, occupational exposures, may increase the severity of sarcoidosis (Liu et al., 2016).

CS is associated with noncaseating granulomas, which can be found in any part of the heart; however, sarcoidosis has a predilection for the conduction system. The most common areas of involvement include the basal segment of the inferolateral left ventricular free wall and the basal interventricular septum, followed by the atrium, the papillary muscles, the right ventricle, and finally the pericardium (Roberts et al., 1977).

Typical Presentation

Clinical manifestations of CS depend on the location and extent of granulomatous disease (Fig. 1). Given the predilection for the conduction system (the interventricular basal septum), complete heart block (CHB) is the most common manifestation and has been reported in up to one-third of patients with clinical evidence of sarcoidosis. CHB in patients with sarcoidosis occurs at a younger age than in patients with CHB from other causes (Silverman et al., 1978; Fleming, 1974). Moreover, in young to middle-aged, otherwise healthy individuals, who present with CHB, CS should be considered. Furthermore, patients with sarcoidosis who present with presyncope or syncope should be evaluated for CHB with an electrocardiogram (ECG). Sudden cardiac death may be a direct result of CHB.

Sudden cardiac death accounts for 25%–65% of deaths caused by CS and is often due to ventricular arrhythmias or CHB (Sekiguchi et al., 1980). Ventricular tachycardia is one of the most common arrhythmias noted in patients with CS with an incidence of up to 20% (Furushima et al., 2004). Granulomatous inflammation causes abnormal foci leading to ventricular activation and/or reentrant tachycardias. Patients with CS that have documented ventricular tachycardia, syncope, symptomatic congestive heart failure, or high-grade atrioventricular block are at high risk for sudden cardiac death.

Though less common than ventricular arrhythmias, atrial arrhythmias are also associated with CS. Both atrial fibrillation and atrial tachycardia have been noted and are due to atrial dilatation or pulmonary involvement. Atrial arrhythmias occur in 15%–20% of patients with CS (Roberts et al., 1977).

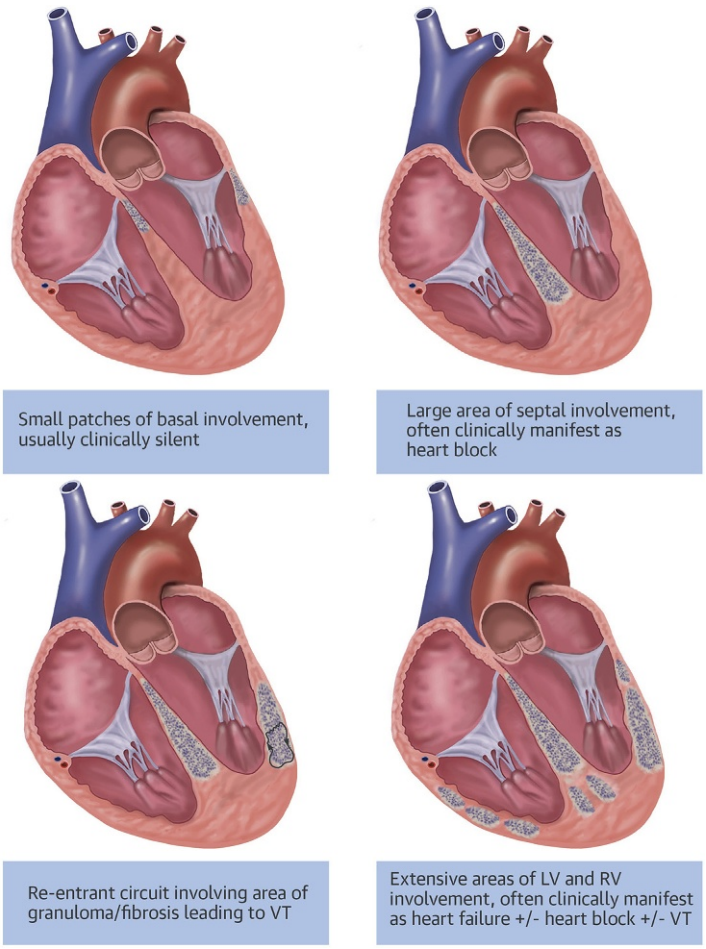

Fig. 1 Clinical manifestations of cardiac sarcoidosis based on myocardial involvement. Reproduced with permission from Birnie, D. H., Nery, P. B., Ha, A. C. and Beanlands, R. S. (2016). Cardiac sarcoidosis. *Journal of the American College of Cardiology* **68**(4), 411–421.

CS can also manifest as congestive heart failure, which accounts for 25%–75% of cardiac deaths (Yazaki et al., 2001). Heart failure can either be diastolic or systolic and is secondary to extensive involvement of the myocardium. During the early inflammatory phase, diastolic dysfunction is more common. In the later fibrotic stages, systolic dysfunction predominates.

Pulmonary hypertension (PH) is another manifestation of CS, and this typically portends a poor clinical outcome. PH may arise as a direct consequence of impaired forward flow and reduced left ventricular function. It may also occur in patients with hypoxic vasoconstriction as alveolar hypoxia can lead to pulmonary vascular remodeling. Finally, PH can be a direct result of infiltration of the vasculature by noncaseating granulomas (Sekhri et al., 2011). The management of PH associated with sarcoidosis is not clear; however, treatment typically involves pulmonary vasodilators, endothelin receptor antagonists, and supplemental oxygen.

Pericardial involvement is relatively uncommon affecting approximately 10% of patients with CS, most of which are asymptomatic (Garrett et al., 1984; Pesola et al., 1987). Though direct valvular involvement is rare, valvular incompetence secondary to papillary muscle dysfunction may occur (Lewin et al., 1985). Ventricular aneurysms, typically resulting from extension of ventricular lesions, can be seen in approximately 10% of patients with sarcoidosis. Furthermore, corticosteroid therapy has been associated with ventricular aneurysms (Lull et al., 1972; Jain et al., 1990). Myocardial aneurysms may lead to complex ventricular arrhythmias; however, these often resolve after resection.

Detection

Sarcoidosis is diagnosed based on clinical symptoms consistent with the disease in addition to noncaseating granulomas seen on biopsy of appropriate tissues. If patients have signs or symptoms suggestive of cardiac involvement, additional testing is required not only to confirm these manifestations are in fact related to sarcoidosis but also to risk stratify patients for specific treatments. However, the diagnosis of CS remains challenging due to nonspecific clinical manifestations and the lack of gold standard diagnostic test secondary to low specificity and/or sensitivity. Furthermore, the current practice of CS diagnosis appears to be insufficient as evidenced by the high prevalence of undetected or undiagnosed CS prior to death.

In keeping with recent recommendations from the Japanese Society of Sarcoidosis and Other Granulomatous Disorders (Table 1), all patients with sarcoidosis should have a detailed history, inquiring about palpitations, presyncope, and syncope, in addition to a thorough physical exam. Moreover, all should be screened with a resting ECG as changes are seen in up to 50% of patients with systemic disease. Any electric abnormality noted on ECG, such as arrhythmia or prolonged QT interval, should be further investigated as it may indicate myocardial involvement. An ECG should be repeated at any time if symptoms develop that suggest cardiac involvement.

Though transthoracic echocardiography lacks the sensitivity for myocardial detection, it helps risk stratify patients with suspected CS based on right and left ventricular function and provides insight into anatomical features (e.g., myocardial thinning) corresponding with CS. Moreover, echocardiography is also helpful in assessing the response of patients with documented ventricular dysfunction to immunosuppressive therapy.

Twenty four hour Holter monitoring should also be considered as it may discover rhythm disturbances not seen on ECG. In patients with sarcoidosis and greater than 100 ectopic ventricular beats per day, Holter monitoring has a reported sensitivity and specificity for detecting CS of 67 and 80%, respectively (Suzuki et al., 1994). Though somewhat controversial, most experts conclude that inducible ventricular arrhythmias should be assessed, and their presence would favor implantation of an implantable

Table 1 Diagnosis of cardiac sarcoidosis

Pathologic diagnosis
Confirmed when noncaseating granuloma seen on endomyocardial biopsy
Clinical diagnosis
If biopsy does not demonstrate noncaseating granulomas, however, the following is true:
1. More than two of four major criteria are satisfied
2. One in four major criteria and more than two in five minor criteria are satisfied
Major criteria
(a) Advanced atrioventricular block
(b) Basal thinning of the interventricular septum
(c) Positive cardiac ^{67}Ga uptake
(d) Depressed ejection fraction of the left ventricle (LVEF $<$ 50%)
Minor criteria
(a) Abnormal ECG findings, including ventricular arrhythmias (ventricular tachycardia, multifocal or frequent premature ventricular contractions), complete right bundle branch block, axis deviation, or abnormal Q-wave
(b) Abnormal echocardiography: regional abnormal wall motion or morphological abnormality (ventricular aneurysm or wall thickening)
(c) Nuclear medicine: perfusion defect detected by ^{201}Tl myocardial scintigraphy or ^{99}Tc myocardial scintigraphy
(d) Gadolinium-enhanced MRI: delayed enhancement of myocardium
(e) Endomyocardial biopsy: interstitial fibrosis or monocyte infiltration over moderate grade

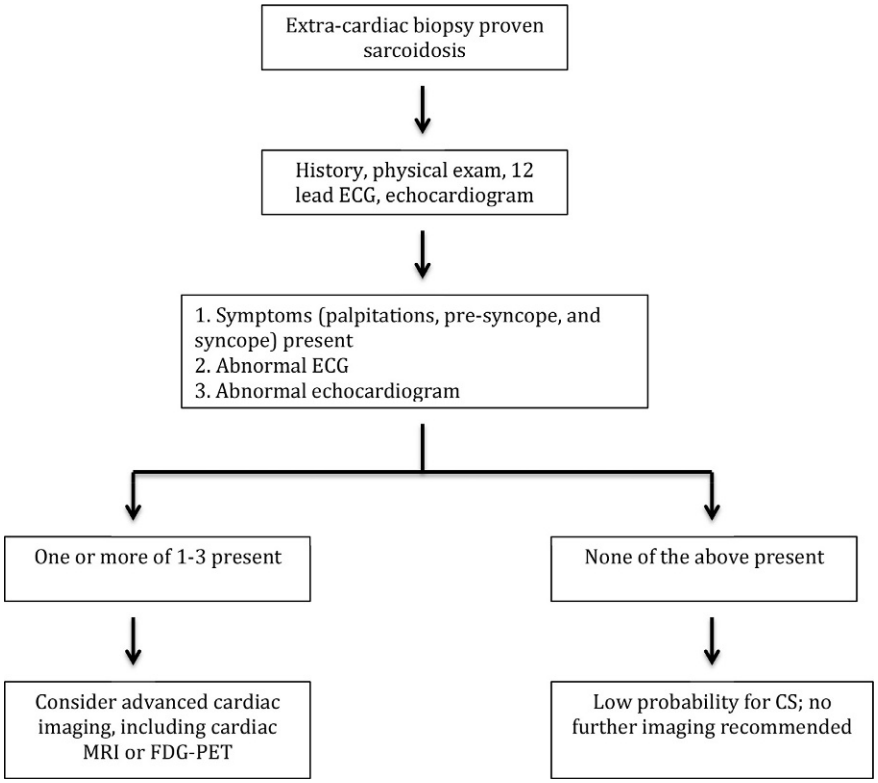

Fig. 2 Algorithm for screening of patients with extracardiac biopsy-proved sarcoidosis. Reproduced with permission from Birnie, D. H., Sauer, W. H., Bogun, F., Cooper, J. M., et al. (2014). HRS expert consensus statement on the diagnosis and management of arrhythmias associated with cardiac sarcoidosis. *Heart Rhythm***11**, 1304–1323.

cardioverter defibrillators (ICD) (Birnie et al., 2014). In combination, ECG, Holter monitoring, and echocardiography are quite sensitive for detecting cardiac involvement; however, they lack specificity for CS.

In summary, per expert consensus on screening for CS with biopsy-proved extracardiac sarcoidosis (Fig. 2), it is a class I recommendation that all sarcoidosis patients be screened for specific symptoms, including presyncope, syncope, and significant palpitations, and should undergo screening with a 12-lead ECG. It is a class IIa recommendation that patients be screened with an echocardiogram and further advanced cardiac imaging, including cardiac MRI (CMR) or FDG-PET (positron emission tomography) scan, if an abnormality is detected on screening ECG, echocardiogram, electrophysiology testing, or based on unexplained cardiac symptoms (Birnie et al., 2014). An abnormal ECG was defined as the presence of at least one of the following: complete left or right bundle branch block, unexplained pathological Q waves in two or more leads, sustained second-degree or third-degree AV block, or sustained or nonsustained ventricular tachycardia. An abnormal echocardiogram was defined as a regional wall motion abnormality, basal septum thinning, left ventricular ejection fraction (LVEF) $<40\%$, or a ventricular wall aneurysm.

Ideally, the diagnosis of CS would rest on confirmatory pathological findings on tissue samples derived from the heart. However, this approach is rarely employed for several reasons. First, due to patchy myocardial involvement, endomyocardial biopsies have low diagnostic sensitivity at $<20\%$ (Uemura et al., 1999). Second, cardiac biopsy is not without risk, and given the low sensitivity of the test and the availability of alternatives serving as surrogates for definitive biopsy, the risk/benefit analysis is not favorable for routine performance of endomyocardial biopsy (EMB) for the diagnosis of CS. However, EMB should still be considered when the diagnosis remains in question to rule out other causes of cardiomyopathy, such as idiopathic dilated cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, giant-cell myocarditis, and viral myocarditis and in situations wherein no other clues to the diagnosis are apparent. In this regard, isolated cases of CS, albeit rare, are well documented (Isobe and Tezuka, 2015). If cardiac biopsy is planned, image guided with CMR or PET scan or using electroanatomical bipolar voltage mapping can improve the diagnostic yield. Though data are limited with regard to yield of EMB using electrogram guidance, it is an approach that allows the physician to differentiate between normal myocardium and areas of active inflammation or chronic fibrosis based on electrogram amplitude (Liang et al., 2014). Further data are needed to determine the role of EMB in the routine diagnosis of CS, particularly isolated CS cases wherein other diagnostic options are limited.

Radionuclide studies can be helpful in patients with clinical or electrocardiographic findings that suggest CS; however, they should not be used to screen patients. Thallium 201 and technetium 99m sestamibi are radionuclides normally absorbed by viable myocardium; however, in areas of inflammation, scarring, or ischemia, they accumulate less. Sestamibi has higher radioactivity than thallium and is therefore more sensitive for CS (Le Guludec et al., 1994; Eguchi et al., 2000). These modalities can be considered as

alternatives to CMR or PET scans in individuals with MRI incompatible implants or with significant renal impairment (those with glomerular filtration rates <30 mL/min are at risk of nephrogenic systemic fibrosis due to gadolinium accumulation) or in whom insurance coverage for a PET scan is not approved.

In CS, granulomatous lesions in the myocardium demonstrate decreased uptake of radionuclide. Improvement or resolution of decreased uptake after dipyridamole or adenosine administration helps differentiate CS from coronary artery disease. Perfusion abnormalities in CS are reversible with pharmacological dilatation due to microvascular vasoconstriction; this phenomenon, though not specific to CS, is called reverse distribution (Fields et al., 1990; Tellier et al., 1988). It is recommended that a baseline resting myocardial scan be performed in addition to scan after exercise or dipyridamole or adenosine administration (Haywood et al., 1982).

With the evolvement of cardiac imaging, CMR has become paramount in establishing the diagnosis of CS. CMR is highly sensitive, low risk, and readily available at most tertiary care centers. Furthermore, CMR is able to differentiate CS from other cardiac processes, and when compared with other imaging modalities, including radionuclide tests, CMR is more than twice as sensitive for detection of CS in patients with biopsy-proved pulmonary sarcoidosis (Smedema et al., 2005). The appearance of CS on CMR depends on the stage of disease. In the early and acute inflammatory stage of CS, myocardial thickening and increased signal intensity on T2-weighted images are often seen, indicating edema (Smedema et al., 2005). In the later chronic stages of CS, characterized by focal areas of scar formation, myocardial thinning and LV dysfunction can be detected with delayed gadolinium enhancement (Smedema et al., 2005). In patients with CS, the presence of delayed gadolinium enhancement was associated with an increased (11-fold) risk of cardiac death (Patel et al., 2009).

PET is another modality used to detect the presence and severity of cardiac involvement. In a meta-analysis, PET-CT was estimated to have a sensitivity of 89% and specificity of 78% for detection of CS (Youssef et al., 2012). PET-CT is a strong alternative to CMR in patients with pacemakers or cardioverter defibrillators that are not MRI compatible. Another advantage of PET-CT is that it is able to detect the active inflammatory stage of the disease and is therefore useful in monitoring and predicting response to immunosuppressive therapy. In contrast, perfusion defects on nuclear imaging and delayed gadolinium enhancement on CMR change minimally with treatment (Treglia et al., 2011). This said, recent data suggest that T2 enhancement on MRI, which presumably represents active inflammation, is reversible to some degree following immune suppression treatment (Crouser et al., 2016).

Finally, cardiac catheterization is indicated to rule out atherosclerotic coronary artery disease in patients with sarcoidosis that present with chest pain, newly diagnosed heart failure, or abnormal imaging. It is important to note that sarcoidosis rarely involves the coronary arteries (Butany et al., 2006).

Treatment

Due to the increased risk of sudden cardiac death, all patients with biopsy-proved or high clinical suspicion of CS should be treated with immunosuppression in order to control inflammation and minimize fibrosis. Glucocorticoids are the initial treatment of choice because the onset of action is rapid and the dose is readily titrated to achieve the desired effect. Studies have shown that long-term glucocorticoid use in patients with normal LVEF may reduce the risk of remodeling. Furthermore, an increase in the LVEF was seen in patients on long-term glucocorticoids and an initial LVEF of <54%; however, in patients with significantly reduced LVEF (<30%), steroid therapy did not improve ventricular function. This suggests that glucocorticoids may have a preventative and therapeutic effect in early and middle stages, at which time active inflammation is present rather, but minimal effect in those with advanced CS, at which point myocardial scarring prevails (Chiu et al., 2005).

The optimal dose of glucocorticoid is not established; however, it is reasonable to start prednisone 60–80 mg daily with a plan to taper to a dose of 10 mg daily over a period of 6 months based upon the clinical response. Given the likelihood that patients will require immunosuppression for months or years, it is reasonable to initiate a steroid-sparing agent during the initial phases of treatment to facilitate the achievement of this goal. If at any time there are signs of recurrence, higher doses of prednisone should be provided; the dose of steroid-sparing agents can be adjusted. Of the steroid-sparing agents, including methotrexate, azathioprine, mycophenolate, and cyclophosphamide (see Table 2), methotrexate is most commonly used. The typical dose of methotrexate is 10–20 mg weekly. Of note, a recent study indicates that the concurrent use of methotrexate with prednisone is superior to prednisone therapy alone and can actually aid in tapering the prednisone dose (Baughman et al., 2000).

Azathioprine is often used if patients fail in methotrexate therapy; the initial dose is 50 mg daily with a target dose of 2 mg/kg daily. Infliximab, a TNF alpha inhibitor, should be considered in patients who have persistent disease despite treatment with glucocorticoids and at least 1 s line immunosuppressive agent. In a randomized, double-blind, placebo-controlled study, infliximab was found to be beneficial in the treatment of extrapulmonary sarcoidosis in patients already receiving corticosteroid therapy (Pacheco et al., 1985; Müller-Quernheim et al., 1999; Baughman and Lower, 2001; Baughman et al., 2006; Rossman et al., 2006; Judson et al., 2008).

Ventricular tachycardia and other arrhythmias are common in patients with CS, and glucocorticoids have not been shown to prevent these. Antiarrhythmic drug therapy for ventricular tachycardia has been associated with a high rate of recurrence or sudden cardiac death. Amiodarone is difficult to use in patients with CS and arrhythmias due to the occurrence of pneumonitis and/or pulmonary fibrosis and the inability to distinguish pulmonary sarcoidosis from medication effect. Beta blockers have been shown to increase the risk of heart block in patients with CS. Given these limitations, ICD and catheter ablation should be considered.

Table 2 Treatment options for cardiac sarcoidosis

All patients with biopsy-proved or high clinical suspicion of cardiac sarcoidosis should be treated
Glucocorticoids: initial treatment of choice
(a) Long-term use may reduce risk of remodeling
(b) Associated with preventative and therapeutic effect in early and middle stages
(c) Typical starting dose of prednisone is 60–80 mg daily with plan to taper to 10 mg daily over a 6-month period
Steroid-sparing agents: used in patients whose disease is refractory to high-dose glucocorticoids, those requiring prolonged glucocorticoid taper, or those unable to tolerate the adverse effects of glucocorticoids
Methotrexate
(a) Most common steroid-sparing agent used
(b) Typical dose starting dose is 10–20 mg weekly
Azathioprine
(a) Often used if methotrexate therapy fails
(b) Initial starting dose is 50 mg daily with target dose of 2 mg/kg daily
Infliximab
(a) TNF alpha inhibitor
(b) Should be considered in patients with persistent disease despite treatment with glucocorticoids and at least 1 s line immunosuppressive agent
Antiarrhythmic drug therapy
(a) Glucocorticoids have not been shown to prevent arrhythmias related to cardiac sarcoidosis
(b) Antiarrhythmic drug therapy is associated with high rate of recurrence or sudden cardiac death
(c) Amiodarone is difficult to use due to medication-related pneumonitis
(d) Beta blockers increase the risk of heart block
ICD implantation
(a) Indicated in patients presenting with sustained ventricular tachycardia or significant LV dysfunction (LVEF $<$ 35%)
(b) Should be strongly considered in patients with mild LV dysfunction (LVEF 35%–50%), RV dysfunction, or high-grade AV block
(c) EP testing may be helpful in patients that are asymptomatic and do not have a high risk of sudden cardiac death
Heart transplantation
(a) Should be considered in patients with refractory heart failure or ventricular tachycardia
(b) Five-year posttransplant survival is $\sim$80%
(c) Sarcoidosis can recur in transplanted patients but is rare

In one study, catheter ablation was successful in terminating clinical or inducible ventricular tachycardia and ventricular storm in the majority of patients. Though VT recurrence after catheter ablation was common, most patients achieved arrhythmia control with repeat ablation and fewer antiarrhythmic medications as compared with patients that did not undergo ablation (Kumar et al., 2015).

ICD implantation is an invasive procedure with potential risks including lead displacement or fracture, inappropriate firing, and infection. In one study, approximately 15% of patients had an adverse event related to ICD implantation for CS (Betensky et al., 2012). Therefore, most experts now agree that not all patients with CS should have an ICD implanted. As per a recent consensus statement (Birnie et al., 2014), an ICD is strongly recommended in patients with spontaneous sustained ventricular arrhythmias and/or reduced LVEF (<35%) despite optimal medical therapy and a period of immunosuppression. An ICD might be helpful in patients with an indication for a permanent pacemaker and/or unexplained syncope or presyncope felt to be arrhythmogenic and/or inducible ventricular arrhythmias. Finally, an ICD should be considered in patients with moderately reduced LVEF (36%–49%) or reduced RVEF (<40%) despite optimal medical therapy and at least 3 months of immunosuppression demonstrating that the arrhythmias are otherwise preventable. A CMR and/or an EP study may be helpful to further risk stratify these patients (Birnie et al., 2016).

Heart transplantation should be considered in patients with refractory heart failure or ventricular tachycardia. One-year survival posttransplant was higher in patients transplanted due to sarcoidosis when compared with all other transplanted patients and 5-year survival is estimated at 80%. Sarcoidosis can recur in transplanted patients; however, the incidence is low, and the recurrence rarely leads to death (Uusimaa et al., 2008; Jefic et al., 2009; Mehta et al., 2011; Zaidi et al., 2007; Valantine et al., 1987; Oni et al., 1992; Diagnostic standard and guidelines for sarcoidosis, 2007).

With the emergence of new imaging modalities, including CMR, CS is being diagnosed more often and earlier than before; however, CS is still often missed or diagnosed in a delayed manner and can present tragically as sudden cardiac death. Furthermore, despite a growing pool of clinical evidence from large retrospective studies, there is a lack of prospective data relating to the course of the disease in response to various treatments, such that the optimal management of CS remains uncertain. Given the intricacies of the disease, a multidisciplinary approach to the patient should be utilized, and standards of care should be established. To this end, it is useful to follow the consensus guidelines provided for the diagnosis (Fig. 2, Table 1) and treatment of CS (Table 2). It is recognized that additional evidence derived from well-designed prospective clinical trials will be required to arrive at more definitive recommendations guiding the diagnosis and optimal management of CS.

Introduction

The role of magnetic resonance imaging (MRI) in patient care has greatly expanded over the past several decades, providing unique value across a wide range of illness. Concurrently, the prevalence of implantable cardiac devices has increased and presents a challenge given that such devices have been conventionally been considered a contra-indication to this technique. However, substantial knowledge has been gained, both contextualizing theoretical concerns and migrating technology toward an era of MRI-compatible devices.

In this article we: (i) highlight the potential challenges of performing MR imaging in patients with implantable cardiac devices, (ii) describe contemporary rates of complications among those same patients undergoing MRI, (iii) summarize protocols to safe performance of MRI in these patients, and (iv) summarize the current status of MRI-compatible devices.

Potential Challenges of MRI Scanning in Patients With Implanted Cardiac Devices

Three broad categories of technical challenges encountered when introducing implantable cardiac devices into an external magnetic field are as follow: mechanical effects, device heating, and other electromagnetic effects. (Ainslie et al., 2014; Miller et al., 2016) Contributing to these adverse effects are magnetic fields and radiofrequency energy emitted by MRI systems.

Mechanical Effects

Mechanical effects on devices arise mainly from the static magnetic field of the MRI system. Static fields, as their name implies, do not vary with time. Importantly, these static magnetic fields are always considered to be "on" for all clinical MRI units as scanners must be maintained in their magnetized state. Current clinical MRI scanners range in strength from 1.5 to 3.0 tesla (T). 1 T corresponds to approximately 10,000 G, a unit of measure that can be compared to the earth's magnetic field which is approximately 0.5 G. Thus, standard contemporary clinical MRI machines have a magnetic field that is approximately 30,000–60,000 times stronger than the Earth's magnetic field (Levine et al., 2007). This static magnetic field can result in ferromagnetic objects (i.e., those with intrinsic magnetic field induced when exposed to an external magnetic field) gaining significant kinetic energy while exposed to the magnet. Ultimately this can lead to objects being pulled into the magnet "bore" leading to potential injury to patients and/or MRI staff, a phenomenon known as the "projectile" or "missile" effect (Levine et al., 2007; Yilmaz and Misirlioglu, 2013; Hartwig et al., 2009; Jerrolds JaK, 2009; Gowland, 2005). Alternatively, for implanted ferromagnetic material, this energy may result in device repositioning or dislodgment or may transfer energy to adjacent tissue resulting in trauma (Shellock et al., 1993). The latter concern is primarily focused upon vascular clips, particularly intracranial, where small displacement movement may lead to intracranial hemorrhage (Kanal and Shellock, 1993).

While theoretical concerns for mechanical effects posing risk for the scanning of implanted cardiac devices, these have not proven to be of major concern in clinical practice. While static magnetic fields can produce linear (translational) or rotational (torque) forces on the ferromagnetic components of implanted cardiac devices, these forces are typically insufficient to result in local trauma or device malposition.

Heating

During MRI scanning, a pulsed radiofrequency energy is transferred to the patient at the resonant frequency of protons (typically), this frequency dependent upon the applied field strength. While the primary aim is to alter the net magnetic vector of precessing protons in order to generate signal (also in the radiofrequency range), some of this energy is converted to heat (Ainslie et al., 2014; Levine et al., 2007; Loewy et al., 2004; Achenbach et al., 1997; Gimbel et al., 2005a; Gimbel, 2009; Fontaine et al., 1998). Quantification of this absorbed radiofrequency energy is described as the specific absorption rate (SAR), a value representing the RF power absorbed per unit mass of tissue and is expressed in watts per kilogram (W/kg) and inherently being greater at higher field strengths (Levine et al., 2007). Both the FDA and International Electrotechnical Commission (IEC) provide SAR limit recommendations that range from 2 W/kg in the brain to 20 kg/W in the extremities. However, most scanners are preset to a maximum of 4 W/kg for routine clinical imaging. For patients with implanted cardiac devices SAR levels should, in general, not exceed 2 W/kg for body imaging and 3.2 W/kg for head imaging. As SAR increases approximately fourfold from 1.5 to 3 T, this poses challenges for maintenance of such levels at higher field strengths and therefore 1.5 T is generally preferred.

The transfer of radiofrequency energy to ferromagnetic devices, particularly device leads and wires, is commonly described as the "antenna effect." This energy can theoretically lead to local tissue heating, injury, and fibrosis, which may alter pacing thresholds (Miller et al., 2016; Sommer et al., 2006). Fortunately, device generators innately act as a "sink" to absorb significant amounts of energy. However, this means that abandoned leads (or fractured leads) are especially susceptible to heating and are considered an absolute contraindication to MRI (Langman et al., 2011).

Other Electromagnetic Effects

Electromagnetic effects also occur from nonstatic, gradient magnetic fields created by rapidly turning on and off (often referred to as "switching") gradient coils (Levine et al., 2007). These changing gradients can induce electrical currents within leads that have the potential to invoke arrhythmias (Levine et al., 2007). This is particularly problematic for old unipolar leads which effectively transmit currents, and may result in life-threatening arrhythmias (Verma et al., 2014). Further, the same mechanism can lead to over- and/or undersensing by pacemakers and ICDs through misinterpretation of induced current as native cardiac rhythm. Oversensing can lead to the erroneous "detection" of ventricular arrhythmias leading to inappropriate ICD therapy, while undersensing may lead to an inability to detect true arrhythmia (Verma et al., 2014). Invoked currents within the pulse generator may also lead to power-on-reset events or trigger activation of the reed-switch, leading to asynchronous pacing for permanent pacemakers and the inability to detect tachycardia for ICDs (Miller et al., 2016; Roguin et al., 2004). Finally, electromagnetic interference during imaging can lead to the production of artifacts and their subsequent inappropriate tracking. Ultimately, this may culminate in inappropriate therapy (Ainslie et al., 2014; Miller et al., 2016; Nazarian et al., 2013; Nazarian et al., 2006).

Defining Risk in the Real World—MRI Scanning With "Noncompatible" Pacemakers or ICDs

While the aforementioned concerns led to initial trepidation regarding the scanning of patients with "noncompatible" implantable cardiac devices, many have accepted such theoretical risks in the face of clinical need, resulting in a significant amount of observational data over the past decade. Importantly, all reported data have been from imaging performed at major centers following strict periprocedural protocols, as are outlined later in this article.

Table 1 provides a summary of these studies, the vast majority being reported at 1.5 T. The first study was performed by Martin et al. (2004). They prospectively studied 63 patients with permanent pacemakers (49 dual chamber and 14 single chamber) undergoing MRI examinations at 1.5 T across a variety of indications, including cardiac, vascular, and general body MRI. Overall, 9.4% of the systems studied demonstrated an alteration in pacing threshold following MRI. However, only 1.9% of such cases required reprogramming of output to maintain capture and no other complications were noted (Martin et al., 2004). Within a year, studies emerged describing similar procedures performed in patients with ICDs, also suggesting no significant alteration in pacing, sensing, impedances, charge times, or battery status. However, one patient experienced a "power-on-reset" of his ICD without permanent device malfunction (Gimbel et al., 2005b). Nazarian et al. subsequently evaluated 55 patients (undergoing 68 MRI studies), 31 having a permanent pacemaker, and 24 an ICD. No episodes of inappropriate inhibition or activation of pacing were observed. There were no significant differences between baseline and immediate or long-term sensing amplitudes, lead impedances, or pacing thresholds (Nazarian et al., 2006). Since these sentinel studies, numerous additional reports have confirmed low rates of complications related to scanning devices at 1.5 T MRI. To date, approximately 1100 patients undergoing 1.5 T scanning have been studied with an overall device complication rate of approximately 3.5% (**Table 1**). The vast majority of these cases did not result in patient-related outcomes and were not related to mechanical forces or device heating. Rather, the majority were alterations in system performance due to "other electromagnetic effects" (see section "other electromagnetic effects") (Miller et al., 2016; Verma et al., 2014).

To elaborate on some of these rarely reported complications, several studies warrant highlighting. Sommer et al. examined 82 pacemaker patients in a prospective study and did identify a statistically significant rise in mean pacing capture thresholds from pre- to post-MRI interrogations. Further, in one case a mild, asymptomatic rise in serum troponin was observed (troponin I pre-MRI 0.02 ng/mL to post-MRI 0.16 ng/mL). Both the rise in mean pacing capture threshold and the troponin elevation were not felt to be

Table 1 Summary of studies examining safety of MRI scanning in nonconditional pacemakers and ICDs at 1.5 T or 3 T field strengths as of January 2017

Study	*Number patients*	*Included devices*	*Field strength (Tesla)*	*Adverse events*
(Boilson et al., 2012)	32	Dual chamber PPM ($N=28$) Single chamber PPM ($N=3$) CRT ($N=1$)	1.5	Power-on-reset ($n=5$)
(Buendia et al., 2010)	33	PPM ($N=28$) ICDs ($N=5$)	1.5	Oversensing due to electromagnetic artifact ($n=2$) Safety signal (VOO pacing at maximal frequency and output during the MRI scan) ($n=1$)
(Burke et al., 2010)	38	PPM ($N=24$) CRT-D ($N=4$) ICD ($N=10$)	1.5	None
(Cohen et al., 2012)	109	Single, dual, and biventricular PPMs and ICDs	1.5	Reduced battery voltage ($n=5$) Lead impedance changes ($n=7$) Increase in pacing threshold ($n=4$)
(Del Ojo et al., 2005)	13	Dual chamber PPM	2.0	None
(Gimbel et al., 2005b)	7	ICDs	1.5	Increase in pacing threshold ($n=7$)
(Halshtok et al., 2010)	18	PPM ($N=11$) ICDs ($N=7$)	1.5	Power-on-reset ($n=2$)
(Martin et al., 2004)	63	Dual chamber PPM ($N=49$) Single chamber PPM ($N=14$)	1.5	Change in lead parameters or thresholds ($n=5$)
(Mollerus et al., 2008)	37	PPM ($N=31$) ICD ($N=5$) CRT ($N=1$)	1.5	None
(Mollerus et al., 2009)	52	PPM ($N=42$) CRT ($N=4$) ICD ($N=6$)	1.5	Asymptomatic ventricular ectopy during scanning ($n=4$) [No significant complications]
(Burke et al., 2010; Mollerus et al., 2010)	103	PPM ($N=81$) ICD ($N=22$)	1.5	None
(Naehle et al., 2009)	47	Single chamber PPM ($N=14$) Dual chamber PPM ($N=33$)	1.5	None
(Naehle et al., 2008)	44	PPM (single and dual chamber)	3.0	None
(Nazarian et al., 2006)	55	PPM ($N=31$) ICD ($N=24$) CRT (N-7)	1.5	None
(Nazarian et al., 2011)	438	PPM ($N=237$) ICD ($N=201$)	1.5	Power-on-reset ($n=2$)
(Pulver et al., 2009)	11	Single chamber PPM ($N=5$) Epicardial leads ($N=6$)	1.5	None
(Sommer et al., 2006)	82	PPM (single and dual chamber devices)	1.5	Increase in pacing threshold ($n=1$)
Total	1182			41 (3.5%)

clinically significant by the attending electrophysiologists (Sommer et al., 2006). Boilson et al. examined 32 patients undergoing spine or head imaging in a prospective cohort study. Of these, 28 had dual chamber pacemakers, 3 single chamber pacemakers, and 1 had a biventricular pacemaker implanted. Five patients had episodes of "power-on reset." However, no significant changes in battery voltage, lead impedance, thresholds, or pacing functions were noted following MRI or at 1-month follow-up (Boilson et al., 2012). Buendia et al. also performed a prospective study of electrical and clinical parameters before and after an MRI in 33 patients, 38 with pacemakers, and 5 with ICDs. There were minor electrical changes reported after the MRI. MRI-induced artifact was interpreted as atrial fibrillation in one case and ventricular fibrillation in the other. In both cases, there was no therapy provided by the device as the antitachycardic pacing and defibrillating functions were turned off prior to the scan. Another device, a DDDR pacemaker, began to pace in VOO mode at maximum frequency and output during the MRI scan. After the MRI scan had been completed, the device was reprogrammed to its prior settings. Of note, none of the observed adverse effects resulted in clinically meaningful irreversible changes in PM or ICD function. Further, there were no clinical adverse events that occurred as the result of the MRI scanning (Buendia et al., 2010).

Cohen et al., utilizing a retrospective chart review study design, examined 109 patients with noncompatible devices undergoing 1.5 T MRI. This group was compared to 50 patients with devices who did not undergo MRI. No differences in device-related events

were seen, although statistically significant changes in battery voltage occurred in 4% of patients, pacing thresholds in 3%, and pacing lead impedance in 6%. While statistically significant differences were observed between the intervention and control groups in the earlier-mentioned parameters, these differences were deemed to not be clinically significant by electrophysiologists (Cohen et al., 2012).

A large study examining the safety of devices in MRI scanning was performed by Nazarian et al. in 2011. In this prospective, multicenter study a total of 438 patients (54% pacemakers, 46% ICDs, and 12% being biventricular systems) were prospectively followed for adverse events after undergoing 1.5 T MRI scanning of various regions including in the brain, heart, spine, abdominal, and pelvic. Importantly, in this study no SAR limits were mandated. All patients underwent device interrogations and clinical visits before and following scans, with a median time to follow-up of 214 days (IQR, 64–478 days). Early outcomes registered three patients having "power-on-reset" events with temporary reversion to back-up asynchronous pacing. One study was terminated due to the patient experiencing mechanical forces from the device. Long-term follow up reported reductions in median battery voltage, RV sensing, and RV lead impedance with an increase in median RV capture thresholds. None of these changes were deemed of clinical importance or even sufficient to require device reprogramming (Nazarian et al., 2011).

The largest examination to date of device safety in MRI environments was provided by the MagnaSafe Registry (www.magnasafe.org), recently publishing its results from 1500 patients (1000 pacemaker, 500 ICD) at 21 US sites undergoing nonthoracic imaging at 1.5 T (Russo et al., 2017). This landmark study confirmed successful imaging in these patients with no adverse events occurring during imaging (inclusive of death, lead failure, capture loss, or ventricular arrhythmia) and only six patients having partial power-on reset of their pacemakers. One patient with an ICD experiencing a device malfunction requiring replacement, however, was related to battery depletion due to incorrect programming prior to scanning.

Overall, based on cumulative published evidence to date in over 1200 patients, the risk of device malfunction or requirement for re-programming following a single MRI scan, performed under controlled conditions at 1.5 T, is very low (approximately 3.5%), and is associated with no significant risk of major clinical adverse events.

The New Era of MRI Conditional Devices

Recognizing a necessity to accommodate for expanding MRI demands in patients with a variety of illness, substantial efforts focused on the development of devices compatible with MRI environments. This goal has been achieved by the majority of device vendors through focused efforts to reduce ferromagnetic material, replace components sensitive to rapidly alternative gradient magnetic fields, and integrating dedicated software to protect patient and device.

With respect to lead design, ferromagnetic steel components have been replaced by nickel and copper alloys with the use of platinum lead tip electrodes. Geometric changes, for example, in lead parameters such as area and length, have also resulted in net reductions in heating risk (Ainslie et al., 2014; Miller et al., 2016; Verma et al., 2014; Kalin and Stanton, 2005; Sutton et al., 2008).

A reduction in pulse generator size has inherently reduced the net mass of ferromagnetic material in devices and reduced the potential of both mechanical forces and heating in applied magnetic fields. These changes reduce the amount of heat generated within the generator and also reduce electromagnetic interference (Verma et al., 2014; Roguin et al., 2004). Incremental benefit is realized through a reduction of field-related image artifacts, improving the capacity to maintain diagnostic image quality in regions close to the generator, such as the great vessels, atria, and right ventricle.

Reed switches have been replaced by Hall effect sensors: transducers that modify their voltage output based upon the ambient magnetic field. This prevents the induction of asynchronous pacing that was described with conventional Reed switch-based devices in MRI environments (Verma et al., 2014; Cronin and Wilkoff, 2012).

Finally, significant advancements in pacing software and circuitry have been implemented to improve filtering of MRI-generated signal, provide circuit protection, and enhance heat dissipation. Pacemaker modes (e.g. "MRI-mode") have been introduced to deactivate advanced pacing and defibrillation features during the scan while allowing easy postimaging reactivation. A recognized consequence of this is that patients are considered "unprotected" when in this mode and require monitoring during scanning with external defibrillators or "crash carts" readily available to a supervising physician. It is also therefore recommended that patients not be pacemaker dependent.

While recommendations for imaging noncompatible implantable cardiac devices using MRI have been previously published, (Miller et al., 2016; Verma et al., 2014) we provide in **Fig. 1** a summary outlining a standardized algorithm for minimizing patient and device complications. Given limited experience of imaging noncompatible devices at higher field strengths, these recommendations are specific to hardware operating at a 1.5 T field strength and SAR levels $\leq$2 W/kg.

Currently Available MRI-Conditional Devices

The American Society for Testing and Material certifies a device as MRI conditional if it does not demonstrate any hazards under prespecified imaging conditions. Of note, there may be jurisdictional differences in terms of this approval. While it is our aim to provide a comprehensive list of MRI compatible devices (see **Table 2**), we cannot guarantee its completeness given rapid evolutions in this field. We therefore suggest contacting the manufacturers in order to determine the most up to date recommendations for specific devices.

Conventional (Lead) Pacemaker Systems

Medtronic delivered the first commercial pacing system with approval in Europe in 2010 and subsequent US Food and Drug Administration (FDA) approval for 1.5 T scanning. This dual-chamber capacity system, called the EnRhythm, MRI™ SureScan™ pacing system was validated in a randomized controlled trial published in 2011 by Wilkoff et al. (2011) Only minor alterations in pacing thresholds were observed with no adverse events following MRI. However, limitations were placed upon this device to prevent imaging within the C1 to T12 vertebral zone (region of pulse generator). Subsequently, Medtronic received FDA approval for the Advisa MRI™ SureScan™ system that lifted such restrictions and was similarly validated in a trial by Gimbel et al. (2013) As with the EnRhythm™ system, no adverse events were identified and only minor alterations in pacing thresholds were observed following MRI imaging.

Table 2 List of MRI conditional devices (pacemakers and ICDs) as of January 2017

Device	*MRI field strength (T)*	*Manufacturer*
Lead pacemakers		
EnRhythm/Advisa MRI Surescan Pacing System	1.5	Medtronic Inc.
Entovis ProMRI Cardiac Pacing System	1.5	Biotronik Inc.
KORA 250 MRI conditional pacemaker	1.5	Sorin Group Inc.
Implantable cardioverter defibrillators leadlesspacemakers		
Evera ICD	1.5	Medtronic Inc.
Iforia 5 & 7 series ICD	1.5	Biotronik Inc.
Lumax 740 Series implantable ICD	1.5	Biotronik Inc.
EMBLEM MRI S-ICD (subcutaneous ICD) system	1.5	Boston Scientific Inc.
Leadless pacemakers		
Micra leadless pacemaker	1.5, 3.0	Medtronic Inc.
Nanostim leadless pacemaker[a]	1.5	St. Jude Medical Inc.

[a]As of October 28, 2016 implants of the Nanostim leadless pacemaker were paused by the manufacturer due to concerns of battery malfunction. No update was available at the time of this review.

A similar pacemaker device, available from Biotronik called the Entovis® ProMRI Cardiac Pacing System, was validated for safety at 1.5 T for imaging of the head and lower lumbar spine. This study reported the freedom from serious device adverse effects to be 99.6% (one adverse event possibly related to MRI; pericardial effusion requiring lead repositioning) with freedom from atrial and ventricular threshold increase being 100% at study completion. Further, freedom from P and R wave amplitude changes were 98.2% and 100%, respectively (Bailey et al., 2016).

Leadless Pacemaker Systems

Rapid growth in leadless pacemaker technology is anticipated over the next decade. All such devices are being developed with MRI compatibility in mind, yet are innately less challenged by external magnetic fields. The latter is owing to their small mass and lack of leads, both of which reduce the potential for heating and current generation.

Two leadless systems, Micra® by Medtronic, and Nanostim® by St Jude Medcial, are currently approved by the FDA, and both are MRI-compatible at 1.5 T. The Micra® system is also approved for imaging at 3 T. Neither device has restrictions placed on the imaging region. Both vendors provide clear recommendations for scanning parameters that should be adhered to comply with FDA labeling.

The safety of MRI imaging in patients with leadless pacemakers was recently reported via modeling data for the Micra leadless pacemaker (Soejima et al., 2016). These models evaluated potential MRI risks including device heating, torque and movement, and device malfunction. In addition, assessments of MRI-induced device heating were conducted using a phantom followed by simulations using various combinations of human body models, device positioning, and coil designs. Overall, this study reported no significant device-related changes or anticipated secondary effects related to device heating or mechanical force. The authors also presented a clinical case study where no adverse effects were identified with MRI scanning of this device (Soejima et al., 2016).

Implantable Cardioverter Defibrillators (ICDs)

Several MRI-compatible ICDs have been approved for clinical use by the FDA. Medtronic's Evera® ICD is compatible at a 1.5 T field strength when combined with MRI compatible leads and was found in a randomized controlled trial to demonstrate noninferior safety and efficacy data (Gold MRS et al., 2015). In this study, 275 patients from 42 centers received either a single- or dual-chamber ICDs and were randomized (2:1) to receive MRI scanning at 1.5 T of chest, cervical, and head regions to a maximal SAR of 2 W/kg. No patients experienced the primary MRI-related adverse outcome (ventricular arrhythmia or device complication within 30 days of scan) and all devices performed appropriately in follow-up for observed tachy-arrhythmias.

Biotronic's ProMRI Iforia® ICD system was tested for safety endpoints in patients undergoing cardiac and thoracic spine imaging at 1.5 T. In this study, 170 patients were enrolled in 39 centers across the United States. 169/170 had freedom from predetermined endpoints (ventricular pacing threshold increases >0.5 V, R wave amplitude decrease $>50\%$ after the MRI scan or significant adverse device effects). One patient had reduced R wave amplitude which was not felt to be of clinical importance (Awad et al., 2015).

Subsequently, another Biotronik ICD system (Lumax) was studied in a single center study consisting of 16 patients. (Kypta et al., 2016) Study endpoints were the absence of (1) serious adverse device events (SADE), or (2) ventricular pacing threshold increase >0.5 V, or of an R-wave amplitude attenuation $<50\%$, or (3) R-wave amplitude <5.0 mV at 1-month follow-up. Freedom from the study endpoints was 100% at 1 and 3 months post MRI scan for all three endpoints.

Finally, Boston Scientific has released the EMBLEM® MRI S-ICD, a subcutaneous ICD system approved for imaging at 1.5 T. This unique design maintains complete independence from leads contacting the cardiovascular system, implanted only within the subcutaneous tissue of the thorax.

Table 3 List of MRI conditional implantable loop recorders (ILRs) as of January 2017

Reveal XT and DX implantable loop recorders	1.5, 3.0	Medtronic Inc.
SJM confirm implantable cardiac monitor (certain models)	1.5	St. Jude Medical Inc.

Safety of MRI Scanning of Implantable Loop Recorders (ILRs)

Similar to leadless pacemaker systems, owing to low mass and lack of lead components, ILRs pose low risk for mechanical and heating related complications. Two commonly used ILRs (Medtronic's Reveal and St. Jude's medical's SJM Confirm) have each been tested and approved for MRI conditional use following clinical testing showing no clinical adverse events (**Table 3**) (Miller et al., 2016). Of note, while scanning is safe, artifact mimicking arrhythmia is common. Therefore, it is important to collect all data prior to imaging and clear device recordings immediately following MRI scanning to avoid misdiagnoses of arrhythmia (Gimbel et al., 2005c).

Conclusions

While migration toward MRI-compatible implantable cardiac devices is underway, a comprehensive knowledge of acceptable versus unacceptable risk surrounding MR imaging, and available approaches to mitigate such risk, is required for both imagers and cardiovascular specialists. With independently expanding clinical indications for MRI and device therapy within our aging population, equally expanded attention to appropriate imaging protocols and device monitoring will inherently be required.

Introduction

This article will review the general principles in the management of pregnancy in women with both congenital heart defect (CHD) and acquired heart disease (AHD). As survival in women with congenital and AHD improves, more women of childbearing years are considering having a family and as a consequence face many issues related to pregnancy. CHD is now the predominant form of heart disease encountered during pregnancy in developed countries (Pitkin et al., 1990) in contrast to rheumatic heart disease in developing countries. While CHD does not preclude pregnancy in most cases, it does increase the risk to both the mother and fetus, requiring specialized knowledge of the burden of pregnancy and appropriate management of such patients.

Epidemiology

Heart disease complicates less than 1% of all pregnancies, but this number is increasing. In a UK study, a quarter of women who died during pregnancy or in the first 6 weeks after delivery died from a cardiovascular cause (the leading cause of death) (Knight et al., 2016). Interestingly, more than half the deaths were deemed to be due to substandard care—highlighting the need for a greater understanding of the burden of pregnancy on the heart. While cardiac death in pregnancy is rare, the main causes have been similar for years: peripartum cardiomyopathy, myocardial infarction, aortic dissection, and pulmonary hypertension. Morbidity is much more common.

 https://doi.org/10.1016/B978-0-12-809657-4.99724-2

In developing countries, rheumatic heart disease is the predominant lesion not congenital anomalies. In developed countries, women present with both congenital and acquired cardiac conditions. Congenital heart disease occurs in 0.8% of live births, and 85% of these patients now reach adulthood. Success of cardiac surgery has led to an increase in the number of women presenting for obstetric care. As surgeries have improved, this has reduced the maternal and fetal risks associated with pregnancy and has increased the underlying fertility rate in such women. That said, CHD remains a significant source of mortality and morbidity risk for women. In a registry from the European Society of Cardiology covering 28 countries and 1321 patients, CHD was the most prevalent form of structural heart disease (66%) affecting pregnancy worldwide (Roos-Hesselink et al., 2013). Furthermore, the precise impact of multiple pregnancies on long-term outcome is as yet unclear but probably varies depending on the underlying lesions. Arrhythmias are the most common acquired problem seen. Coronary disease may be seen in older, obese women who smoke and have increased rates of diabetes. Historically, myocardial infarction in pregnancy has been due to coronary dissection, but the rates of atheromatous disease are increasing.

In a review of maternal morbidity from 1985 to 2006, in 2491 pregnancies, cardiac complications were documented in 11% of completed pregnancies, with heart failure in 5% and arrhythmias in 4.5%. Patients with Eisenmenger syndrome and palliated or unrepaired cyanotic heart disease were at highest risk of myocardial infarction, stroke, and cardiovascular mortality(Drenthen et al., 2007). A more extensive report in the United States from 1995 to 2006 revealed that the prevalence of deliveries complicated by chronic heart disease was stable at 1.5%. However, during the same period, the frequency of specific CHD, arrhythmias, cardiomyopathy, heart failure, and severe complications had increased (Kuklina and Callaghan, 2011), suggesting that the rate of maternal morbidity will continue to increase over the coming years.

Hemodynamic Changes During Pregnancy, Labor, and Delivery

A clear understanding of the hemodynamic changes associated with pregnancy will allow for better management of patients with underlying cardiac abnormalities. In general, systemic vascular resistance falls, and there is an increase in cardiac output (Regitz-Zagrosek et al., 2011). Absorption, excretion, and bioavailability of drugs are also altered (Anderson, 2005). Management of specific lesions is beyond the scope of this article although the issue of anticoagulation is addressed in some detail.

Red blood mass increases 20%–30%, and plasma volume increases 30%–50%. This usually begins at 12–14 weeks' gestation and peaks at 32–34 weeks. As a consequence, there is an increase in total blood volume with the development of relative anemia (Elkayam and Gleicher, 1998). Cardiac output increases by 30%–50% during pregnancy again peaking around 32 weeks. In early pregnancy, the increase in cardiac output is related to a rise in stroke volume; in late pregnancy, heart rate is the primary driver. Heart rate starts to rise at 20 weeks and increases until 32 weeks. It remains higher until 2–5 days after delivery. With increasing metabolic needs of the mother and the fetus, oxygen consumption rises by approximately 30%. During late pregnancy, the physical size of the fetus affects cardiac output due to compromised venous return. Positioning in a left lateral decubitus position will alleviate that to some degree. In those patients with myocardial dysfunction or stenotic valves such adaptations are compromised leading to congestive heart failure signs and symptoms. These patients frequently start to present with complaints from 18 to 22 weeks.

Systemic BP usually falls early in gestation, and diastolic BP is usually 10 mmHg below baseline in the second trimester. This is in part due to local mediators such as prostacyclin and nitric oxide. In the third trimester, diastolic BP returns to prepregnancy levels. The heart size can increase by 30%. Data on myocardial systolic and diastolic function are limited, but changes in both have been reported (Mone et al., 1996; Moran et al., 2002).

Pregnancy is associated with an increased incidence of thrombosis. Factors influencing that include—lower extremity stasis due to inferior vena cava compression and a hypercoagulable state due to increases in vitamin K-dependent clotting factors and a reduction in protein S activity. Patients with congenital heart disease appear to have a 40-fold increase in thrombosis risk compared with normal pregnancies (Drenthen et al., 2013; Toglia and Weg, 1996). This is of particular importance in patients with prosthetic valves, atrial arrhythmias, Fontan surgery, and prior thromboembolic events.

Normal labor and delivery also lead to changes in cardiac output. There is up to a further 50% increase in cardiac output during the first stage of labor into second stage (Robson et al., 1987). The documented increase in blood pressure and heart rate during labor reflects this. Systolic and diastolic BP can increase during uterine contractions by 15%–25% and 10%–15%, respectively, elevating ventricular afterload. An increase in venous return with the release of vena caval obstruction and from uterine contraction (300–500 mL) is also noted. If postpartum hemorrhage occurs, volume shifts can be seen. Administration of epidural anesthesia can reduce cardiac output, with general anesthesia reducing cardiac output even further. Blood loss at delivery will also impact on hemodynamics. It is estimated that 500 mL of blood is lost at the time of vaginal delivery and 1000 mL during a normal cesarean section. After delivery, venous return increases, and spontaneous diuresis occurs during the first 24–48 h. It takes 2–8 weeks for hemodynamics to return to normal.

Risk Stratification

Maternal Risk Stratification

To date, there are three scoring systems available for maternal risk stratification—the modified WHO classification, the CARPREG score, and the ZAHARA scoring system. All three provide insights into at-risk women and what issues should be assessed when such

women present to the cardiologist for preconception counseling or when pregnant. A prospective study of patients with congenital heart disease (203 women) reported maternal events in 10% of pregnancies. The study found that the modified WHO system performed best with an area under the cover (AUC) level of 0.77. The CARPREG system performed no better than chance with an AUC score of 0.57 (Balci et al., 2014). More recently, the use of biomarkers has been studied (N-terminal pro-B-type natriuretic peptide, NT-proBNP) and has been shown to help with maternal risk stratification (Kampman et al., 2014). An NT-proBNP greater than 128 pg/mL at 20 weeks' gestation in patients with congenital heart disease was independently associated with an increased incidence of cardiovascular events (10.3%, odds ratio of 10.6). A level less than 128 pg/mL had a negative predictive value of 96.9%.

Modified WHO classification

The modified WHO classification groups conditions into four classes based on mortality and morbidity risk for the mother. This has been adopted by the European Society of Cardiology and is central to their guidelines on the management of such patients (Regitz-Zagrosek et al., 2011; see **Table 1**).

Class I conditions have no increase in mortality with no or mild increase in morbidity. Class II conditions carry a small increase in mortality or moderate increase in morbidity. Class III conditions carry a significant increase in mortality or severe increase in morbidity. Finally, class IV conditions carry such an extremely high maternal mortality risk or severe morbidity risk that pregnancy is essentially contraindicated. Conditions classed as WHO class IV would include severe mitral stenosis, symptomatic severe aortic stenosis, bicuspid aorta with an aortic diameter >50 mm, Marfan syndrome with an aortic diameter >45 mm, severe LV systolic dysfunction (EF <30%, NYHA III–IV), native severe coarctation, and significant pulmonary hypertension (systolic pulmonary artery pressure >25 mmHg at rest or >30 mmHg with exercise).

ZAHARA score

The ZAHARA score is a risk score derived from weighting of factors that are used to predict adverse maternal cardiac events. It is derived from a retrospective observational study of 1302 completed pregnancies in women with congenital heart disease (Drenthen et al., 2010). Arrhythmias (4.7%) and heart failure (1.6%) were the most prevalent complications. Factors associated with maternal cardiac complications included cyanotic heart disease, cardiac medications used prior to pregnancy, left heart obstruction,

Table 1 Modified WHO classification of maternal cardiovascular risk (Regitz-Zagrosek, 2011; Thorne et al., 2006)

Conditions in which pregnancy risk is WHO I
- Uncomplicated, small, or mild
  - Pulmonary stenosis
  - Patent ductus arteriosus
  - Mitral valve prolapse
- Successful repair of simple lesions (ASD, VSD, PDA, PAPVR)
- Atrial or ventricular ectopic beats, isolated

Conditions in which pregnancy risk is WHO II or III

WHO II
- Unoperated atrial or ventricular septal defect
- Repaired tetralogy of Fallot
- Most arrhythmias

WHO II–III (depending on patient)
- Mild left ventricular impairment
- Hypertrophic cardiomyopathy
- Native or tissue valvular heart disease not considered WHO I or II
- Marfan syndrome without aortic dilation
- Aorta <45 mm in aortic disease associated with bicuspid aortic valve

WHO III
- Mechanical valve
- Systemic right ventricle
- Fontan circulation
- Cyanotic heart disease (unrepaired)
- Other complex heart disease
- Aortic dilation 40–45 mm in Marfan syndrome
- Aortic dilation in 45–50 mm in aortic disease associated with bicuspid aortic valve

Conditions in which pregnancy risk is WHO IV (pregnancy contraindicated)
- Pulmonary arterial hypertension of any cause
- Severe systemic ventricular dysfunction (EF <30%, NYHA III or IV)
- Previous peripartum cardiomyopathy with any residual impairment of left ventricular function
- Severe mitral stenosis, severe symptomatic aortic stenosis
- Marfan syndrome with aorta dilated >45 mm
- Aortic dilation >50 mm in aortic disease with bicuspid aortic valve
- Native severe coarctation

Table 2 ZAHARA score and risk factor weighting

Risk factor weighting included
- Mechanic valve—4.25 points
- Severe LV outflow obstruction (peak gradient >50 mmHg or aortic valve area <1.0 cm^2)—2.50 points
- Cardiac medication use prior to pregnancy—1.50 points
- Cyanotic heart disease (repaired or unrepaired)—1.00 points
- Moderate to severe pulmonary or systemic AV valve regurgitation—0.75 points
- Symptomatic heart failure before pregnancy (NYHA ≥ II)—0.75 points

Five categories of risk were created
- 0–0.5 points: 2.9%
- 0.51–1.50 points: 7.5%
- 1.51–2.50 points: 17.5%
- 2.51–3.50 points: 43.1%
- ≥3.51 points: 70.0%

mechanical valve replacement, and systemic or pulmonary AV valve regurgitation related to moderately complex heart disease. This study also identified adverse fetal outcomes. Others have yet to validate this scoring system in a prospective manner (**Table 2**).

CARPREG scoring system

Siu et al. (1997) created a risk score based on a retrospective study of women with cardiac disease. It was then applied prospectively to 562 women with congenital, AHD or arrhythmias. Seventy-four percent of those pregnancies were in women with congenital heart disease (Siu et al., 2001).

Four predictors were identified:

- Poor functional class (NYHA III or IV) or cyanosis
- Prior CV event including heart failure, TIA, stroke, or arrhythmia
- Left heart obstruction (mitral valve area <2 cm^2, aortic valve area <1.5 cm^2, and peak LV outflow gradient of >30 mmHg)
- LV systolic dysfunction (EF <40%)

One point is assigned to each finding. An overall rate of cardiac event (pulmonary edema, arrhythmia requiring treatment, stroke, cardiac arrest, or death) was 13% with 55% occurring antepartum. The risk of events in the prospective study increased with increasing point score: 0 point, 5%; 1 point, 27%; ≥2 points, 75%.

A subsequent study evaluating this scoring system in patients with CHD showed similar findings with adverse events occurring in 25% of pregnancies. The presence of subpulmonary ventricular dysfunction and/or severe pulmonary regurgitation further increased the risk of adverse events (Khairy et al., 2006).

Pulmonary Hypertension

Given the significant hemodynamic loads of pregnancy and labor, the presence of pulmonary hypertension is a major risk factor for poor outcome. Great care should be placed on avoiding a sudden drop in systemic vascular resistance as this can lead to an increase in right to left shunting and a resultant drop in oxygenation. The poor prognosis is particularly true for patients with Eisenmenger syndrome. Maternal mortality in patients with Eisenmenger syndrome was originally reported to be as high as 50% (Kahn, 1993). More recent studies suggest that the mortality rate while remaining high at 25% has improved with the advent of newer therapies (17% mortality rate in the idiopathic pulmonary hypertension group and 28% mortality rate in the CHD–pulmonary hypertension groups) (Bedard et al., 2009). Preterm labor and fetal growth restriction occur in 50% of such patients with only 15%–20% progressing to term. Maternal mortality appears to be highest during delivery and in the first postpartum week. In general, women with Eisenmenger syndrome should be counseled to avoid pregnancy. If they become pregnant, then termination should be discussed. If termination is declined, then heparin therapy and the use of novel pulmonary vasodilators should be considered. Invasive hemodynamic monitoring would be indicated at the time of delivery at a center with appropriate expertise.

Fetal Risk Stratification

Two elements of risk should be considered for the fetus—(i) the likelihood of successful completion of pregnancy and (ii) the risk of a cardiac fetal anomaly. To date, a fetal risk assessment score has not been established. Adverse outcomes include spontaneous abortions, intrauterine growth retardation, and prematurity (Siu et al., 2001; Khairy et al., 2006; Drenthen et al., 2007). Preterm delivery and growth restriction lead to an increase in perinatal morbidity and mortality. The growth of the fetus is influenced by the functional class of the mother; the degree of maternal cyanosis; the maternal medications; and the presence of congenital heart disease, AHD, and arrhythmias. Siu et al. found that adverse fetal events including premature birth, small-for-gestational age, respiratory distress syndrome, intraventricular hemorrhage, and fetal/neonatal death were associated with poor maternal functional class (class III or IV), cyanosis, maternal left heart obstruction, maternal age <20 or >35 years, obstetric risk factors (history of

premature delivery, premature rupture of membrane, incompetent cervix, cesarean section, intrauterine growth retardation, antepartum bleeding beyond 12 weeks' gestation, febrile illness, and uterine/placental abnormality), multiple gestation, tobacco use during pregnancy, anticoagulant therapy, and known lesion-specific risk (Siu et al., 2001).

Risk of adverse events during pregnancy

The maternal functional class appears to correlate with the risk of fetal mortality. Those with serious symptoms have a 30% fetal mortality risk (Child, 2009). Patients with Eisenmenger syndrome have only a 15%–25% chance of reaching term (Kahn, 1993). Spontaneous abortion risk is increased.

While a woman with cyanosis and no pulmonary hypertension can go through pregnancy with low maternal risk, the effect on the fetus is increased. The level of maternal hypoxia (cyanosis) has a direct effect on fetal growth, risk of spontaneous abortion, and risk of prematurity. Presbitero et al. (1994) studied 44 women (96 pregnancies) with cyanosis and found that only 26 pregnancies reached term while 49 spontaneous abortions and 6 still births were recorded. The best possible outcomes were seen when the hemoglobin was less or equal to 16 g/dL and/or arterial oxygen saturation equal or greater than 90%. In addition, the underlying anatomical lesion influenced the likelihood of a live birth (**Table 3**).

Risk of congenital heart disease in offspring

Offspring of women with congenital heart disease are at increased risk of congenital heart disease. This risk will vary depending upon the mother's own cardiac condition (Drenthen et al., 2007; Burn et al., 1998). The incidence of a cardiac anomaly in offspring is as high as 10.7% (Whittemore et al., 1994). In a study by Burn et al. (1998), cardiac defects were seen in 4.1% of offspring with the risk being higher if the mother has the cardiac defect (5.7% if mother vs. 2.2% if father). Whittemore et al. (1994) however found no difference between offspring of a father or mother with congenital heart disease. The incidence of the same defect occurring is approximately a third (Gill et al., 2003). Parental left heart obstructive lesions are associated with higher rates of transmission (13%–18%). Autosomal dominant conditions such as Noonan syndrome, William syndrome, Holt–Oram syndrome, Marfan syndrome, and 22q11 deletion syndrome confer a 50% risk of recurrence in the offspring. Genetic syndromes can be associated with specific lesions. For example, Holt–Oram is associated with atrial septal defects and DiGeorge syndrome with conotruncal abnormalities. Preconception use of multivitamins containing folic acid has been shown to decrease the incidence of congenital defects and should be encouraged (Czeizel, 1996). A fetal echocardiogram is indicated when a parent has congenital heart disease to assess the fetal cardiac anatomy and is typically completed between 18 and 22 weeks' gestation.

Preconception and Prenatal Management

Preconception/Initial Evaluation

Ideally, a comprehensive preconception evaluation should be performed, but if the patient presents during pregnancy, the initial evaluation should be performed at that time by someone knowledgeable about the implications of pregnancy for both the fetus and the mother. Frequently, the woman is unaware of the risks so that education of the mother and spouse is critical (Kovacs et al., 2008).

The initial evaluation should include a detailed history (including prior interventions/surgeries), symptoms, complete physical examination, 12-lead ECG, and transthoracic echocardiogram. Where appropriate, a more comprehensive assessment of functional status should be considered (exercise testing). The transthoracic echocardiogram will help determine underlying repairs, residual lesions, right-sided pressures, and ventricular function. This evaluation allows for a comprehensive risk assessment of the woman and fetus (see prior sections for details) with appropriate counseling to follow.

If significant lesions are present, then correction or palliation prior to pregnancy is ideal using percutaneous and surgical techniques. Such an approach should improve fertility, improve the woman's ability to tolerate the aforementioned hemodynamic changes, and reduce fetal risks. Such discussions are complex and require thoughtful discussion with the woman. This is particularly true when valve replacement is needed. The risk benefit trade-off with tissue valves versus mechanical valves must be discussed and adequate time provided for the patient to make an informed decision.

Surgery and percutaneous interventions during pregnancy while possible should be avoided. The maternal risks are similar during cardiac surgery to the nonpregnant state, but the risks to the fetus are increased (Weiss et al., 1998; Parry and Westaby, 1996; Strickland et al., 1991; Chambers and Clark, 1994; John et al., 2011). Similarly, catheter interventions including balloon

Table 3 The impact of the underlying anatomy in mothers with cyanosis on pregnancy outcome

Group	*Examples*	*% Live birth*
I	Single ventricle	31
II	Tetralogy of Fallot or pulmonary atresia with aortopulmonary collaterals	33
III	Ebstein anomaly with an ASD	86
IV	Corrected transposition (L-TGA) VSD and pulmonary stenosis	60

valvuloplasty have been reported. Specific consideration should be given to reduce radiation exposure to the fetus with a greater reliance on transesophageal echocardiography for imaging (Bhargava et al., 1998; Esteves et al., 2006; Myerson et al., 2005).

Prenatal Care

Prenatal care is determined by the underlying conditions of the woman and fetus. The frequency of follow-up will depend on the severity of the heart condition(s). Using the WHO classification of maternal risk assessment, the following are general rules: class I, one to two visits; class II, every trimester at a minimum; class III, once or twice a month, with consideration for alternatives to pregnancy; class IV, pregnancy is contraindicated and termination considered, but if pregnancy continues, then once or twice a month evaluations. The management of arrhythmias is beyond the scope of this article. The management of anticoagulation is discussed later.

An understanding of normal pregnancy is important to help detect the presence of abnormal hemodynamic changes. Peripheral edema due to an increase in total exchangeable sodium and water is commonly seen and a decrease in air entry bibasally in the lungs. Early development of pitting edema or the development of fine crackles on auscultation should be thoughtfully evaluated. In addition, anemia occurs, but the routine use of iron during pregnancy should be avoided, in particular in cyanotic patients.

Pregnancy leads to an increase in thromboembolic risk and requires careful follow-up, especially in high-risk patients (prosthetic valves, atrial fibrillation, and prior thromboembolic events). Such patients need appropriate anticoagulation. The therapy chosen will balance the risk for the fetus (teratogen effect in early pregnancy and later bleeding) and the woman (bleeding risk vs. risk of thrombus formation).

Careful and comprehensive evaluation of the fetus at 18–22 weeks' gestation should be offered to all at-risk women, especially those with congenital heart disease.

Labor, Delivery, and Postpartum Care

Endocarditis

Both the European Society of Cardiology and the American Heart Association do not recommend endocarditis prophylaxis during uncomplicated cesarean sections or vaginal delivery (Habib et al., 2015; Wilson et al., 2007). Endocarditis is rare during and after a completed pregnancy (Drenthen et al., 2007) but carries with it both high maternal and fetal mortality (Campuzano et al., 2003). Some centers do however consider endocarditis prophylaxis in higher-risk groups as defined by the American Heart Association and American College of Cardiology in their 2008 adults with congenital heart disease guidelines (prosthetic valve, cyanotic heart disease, residual lesions near prosthetic material, and those with surgical repair within the prior 6 months) (Warnes et al., 2008).

Labor

Typically, repaired cardiac conditions or those with minor residua can tolerate vaginal delivery and are allowed to go into spontaneous labor. If there are concerns about the ability of the heart to tolerate the stresses of labor, then induction should be considered. Timing should be dictated by cardiac status, suitability of the cervix and fetal maturity with every effort made to avoid long durations of induction. Typically, oxytocin and artificial rupture of membranes are well tolerated. Ripening of the cervix is generally done using mechanical methods although many use misoprostol. Avoiding a sudden drop in BP or systemic vascular resistance is important especially in patients with cyanotic heart disease. This concern would support not using dinoprostone.

During labor, the woman should be placed in a left lateral decubitus position to avoid compression of the abdominal aorta and IVC, which would exacerbate the hemodynamic changes seen during uterine contraction. Pushing by the mother should also be avoided as such Valsalva maneuvers will affect blood circulation. Delivery is frequently done using a low forceps or vacuum extraction for similar reasons.

Anesthesia

Effective regional anesthesia that abolishes the pain of labor and the associated cardiovascular changes has allowed for controlled delivery during stage two of labor. This has made vaginal delivery the preferred mode of delivery for the majority of women with heart disease. Low concentrations and gradual introduction of anesthesia agents cause minimal hypotension (Suntharalingam et al., 2001). In general, noninvasive monitoring of blood pressure, heart rate, oxygen saturation, and rhythm is performed in all patients. Invasive blood pressure monitoring can be used in high-risk patients. During the third stage of labor (delivery of the placenta), oxytocic agents are administered at lower doses and with slow infusions to minimize systemic vasodilation (Pinder et al., 2002). Regional anesthesia is contraindicated if the patient is receiving anticoagulation therapy.

During cesarean sections, the majority are now performed under regional anesthesia. The choice of regional versus general anesthesia should be considered well before the day of delivery, necessitating an elective consultation with anesthesia for patients with heart disease. If regional anesthesia is chosen, then deliberation between epidural and spinal anesthesia is made. Typically, catheter techniques allow for the titration of effect (Durbridge and Yentis, 2011) making this approach the preferred one.

Oxygen

Oxygen is often used during labor although maternal benefit has not been demonstrated. Typically, transcutaneous oxygen monitoring is performed.

Preterm labor

The incidence of preterm labor is increased in patients with heart disease (especially women with cyanotic heart disease). Several pharmacological therapies are used to manage premature contractions including the use of magnesium, indomethacin, nifedipine, beta-adrenergic agonists, or an oxytocin receptor antagonist (atosiban). An understanding of their pharmacological effects is important to predict adverse effects on the woman. Beta-agonists will increase heart rate, increase volume, and can trigger heart failure (Armson et al., 1992). Magnesium has a limited role and is generally used for the prolongation of pregnancy for brief time periods (2016). Nifedipine and indomethacin are general preferred although nifedipine due to its reduction in systemic vascular resistance may be harmful in aortic stenosis or cyanotic heart disease.

Cesarean section

In general, vaginal delivery is the mode of choice even in the presence of heart disease. Compared with a cesarean section, vaginal delivery has less blood loss, more rapid recovery, the absence of abdominal surgery, lower infection risk, and reduced thrombogenic risk. Cesarean delivery is reserved for obstetric indications (breech, failure to progress, placenta previa, abnormal fetal heart rates, etc.). The European Society of Cardiology states that cesarean delivery should be considered for patients on oral anticoagulants in preterm labor, women in severe heart failure, Marfan syndrome with an aortic root diameter >45 mm, and patients with acute or chronic aortic dissection (Regitz-Zagrosek et al., 2011). Some consideration for cesarean section is also given to severe aortic stenosis and severe forms of pulmonary hypertension.

Despite the recommendations from professional societies, women with cardiac disease have a higher likelihood of delivering by cesarean section compared with those without heart disease (Josefsson et al., 2011; Karamlou et al., 2011). A recent study of 1262 women showed that in the absence of a firm indication for cesarean section, a vaginal delivery can be safely attempted and if circumstances change, the outcome from an emergency cesarean section is no worse than in patients with a planned cesarean section (Ruys et al., 2015). In a single-center study of 116 patients with CHD, severity of CHD was an independent determinant of risk for primary cesarean section. Functional status was a predictor of the risk of a secondary cesarean section. Higher rates of cesarean section were also found to follow the induction of labor (Hrycyk et al., 2016).

Postpartum care

After the placenta is delivered, bleeding is reduced by uterine massage and slow infusion of oxytocin (to avoid hypotension). Early ambulation and preventative measures to reduce the risk of deep venous thrombosis are also important. In patients who are cyanotic, heparin use should be used judiciously as it can paradoxically worsen the intrinsic hemostatic abnormalities present leading to fatal hemorrhage (Child, 2009). Heparin therapy is mandated in patients with prosthetic valves.

Contraception

The approach and options for contraception are beyond the scope of this article.

Anticoagulation During Pregnancy

The management of patients with prosthetic valves is complex as all the available therapeutic options pose risks and benefits to both the mother and fetus (Salazar et al., 1984). Thoughtful preconception counseling is best done to allow the mother to make a fully informed decision on the best therapeutic approach for their circumstance. In general, heparin does not completely prevent valve thrombosis, and warfarin can cause an embryopathy.

Pregnancy results in a hypercoagulable state in part related to an increase in clotting factors and platelet adhesiveness and a decrease in the degree of fibrinolysis and protein S activity. This leads to an increase in the risk of thrombosis and embolism.

Warfarin

Warfarin does cross the placenta and leads to fetal anticoagulation. The warfarin effect is greater in the fetus due to reduced K-dependant factors. Increases in spontaneous abortion, fetal deformity, stillbirth, retroplacental hemorrhage, and intracranial hemorrhage have all been seen.

The risk of warfarin embryopathy was thought to be as high as 30%, although recent reports suggest that the incidence is lower at 4%–10% (Oakley, 1995; Sbarouni and Oakley, 1994). Characteristic features include bone and cartilaginous abnormalities with chondrodysplasia, nasal hypoplasia, optic atrophy, blindness, intellectual impairment, and seizures. The teratogenic risk is highest during warfarin exposure between 6 and 12 weeks' gestation. The risk is also dose-dependent. The risk is significantly reduced if the dose is less than 5 mg/day (3% vs. 8%) during the first trimester (Vitale et al., 1999). The risk of CNS effects (spasticity and optic atrophy) continues throughout pregnancy.

Heparin

Heparin does not cross the placenta. The use of subcutaneous heparin is associated with a 12%–24% incidence of thromboembolic complications including fatal valve thrombosis and so is not recommended in either American or European guidelines. Intravenous

unfractionated heparin is used especially in the late third trimester. Risks associated with intravenous heparin include valve thrombosis, heparin-induced thrombocytopenia, and osteoporosis. Monitoring is usually with APTT levels, but periodic checks of their antifactor Xa level are important. Typically, unfractionated heparin is given as a continuous infusion. Low-molecular-weight heparin is now being used, with an increasing number of reports supporting its use, although it continues to carry a black box warning from the FDA that was issued in 2004 when valve thrombosis occurred at higher rates than seen with Coumadin use. Benefits of low-molecular-weight heparin include the following: It does not cross the placenta, it has a lower incidence of heparin-induced thrombocytopenia compared with unfractionated heparin, and its half life is more predictable than unfractionated heparin (Melissari et al., 1992). If used, meticulous monitoring of the woman's antifactor Xa level aiming for a level of 0.8–1.2 U/mL is recommended. Even with therapeutic levels of antifactor Xa levels 4–6 h post administration, the predosing levels can be subtherapeutic. The need to maintain predose levels over 0.6 U/mL has not been sufficiently studied (Friedrich and Hameed, 2010) but should be considered.

First-trimester anticoagulation

Numerous guidelines have been published including from the American Heart Association, American College of Cardiology (Nishimura et al., 2014), American College of Chest Physicians (Hirsh et al., 2008), and the European Society of Cardiology (Regitz-Zagrosek et al., 2011). In general, warfarin doses are less than or equal to 5 mg/day that provides the best protection for the mother with the lowest risk to the embryo. If the dose is higher than 5 mg/day, then warfarin is typically discontinued and either intravenous unfractionated heparin (with a target APTT two to three times control) or low-molecular-weight heparin given subcutaneously (with a target antifactor Xa level of 0.8–1.2 U/mL 4 h after drug administration) is used. Aspirin therapy is typically continued throughout pregnancy especially during the second and third trimesters.

Second-trimester anticoagulation

Warfarin is typically used during the second trimester with usual INR targets. If unfractionated heparin or low-molecular-weight heparin is used, then the mother needs to be aware of the higher risk of valve thrombosis.

Third-trimester anticoagulation

Warfarin can be continued until the 36th week of pregnancy. At that time, the patient should be transitioned to unfractionated heparin (with the earlier targets). The early transition is required since it takes 3 weeks for warfarin to be cleared from the fetal liver. If low-molecular-weight heparin is chosen, then hospitalization is not required until 36 h prior to delivery when the patient is transitioned to intravenous unfractionated heparin.

During the peripartum period, delivery needs to be planned, and intravenous heparin is discontinued 6 h prior to delivery. Heparin can be resumed 4–6 h after delivery. A cesarean section would be necessary if labor occurs during the use of warfarin to minimize the risk of fetal intracranial hemorrhage. Heparin can be resumed 4–6 h after delivery in the absence of ongoing bleeding.

Conclusion

Improvements in surgical and medical care of patients with cardiac anomalies have led to an increase in women of childbearing age becoming and successfully navigating pregnancy. A clear understanding of the hemodynamic changes (fall in systemic vascular resistance and increase in cardiac output) associated with pregnancy and labor allows for a more targeted approach to patient care. Pregnancy also increases the hypercoagulable state of the woman necessitating an anticoagulation regimen that protects both the mother and fetus.

Appropriate risk assessment of the mother (using the modified WHO risk classification scheme) allows for better counseling of women and helps determine the frequency of follow-up needed. High-risk maternal conditions include pulmonary artery hypertension, mitral stenosis, aortic stenosis, bicuspid aortic valves with aortic aneurysms >50 mm, Marfan syndrome with aortic aneurysms >45 mm, severe left ventricular dysfunction (EF <30%, NYHA III or IV), and native severe coarctation. Impaired maternal functional class, maternal cyanosis, and maternal medications can put the fetus at risk.

Labor and delivery carry with it certain risks, but vaginal delivery with the appropriate use of epidural and assisted delivery is typically preferred over cesarean section. Cesarean section is generally reserved for obstetric reasons and some unique cardiac issues including active labor while on oral anticoagulants, severe heart failure, aortic diameter >45 mm in patients with Marfan syndrome, and patients with acute or chronic aortic dissection.

Where appropriate, at-risk women should be managed in a multidisciplinary way at a center with high level of comfort and expertise in such conditions.

Introduction

Ventricular arrhythmias, ranging from asymptomatic ventricular premature beats (VPBs) to ventricular fibrillation (VF), are common in patients with ischemic and nonischemic cardiomyopathy(NICM) (Holmes et al., 1985). VPBs, nonsustained ventricular tachycardia, and accelerated idioventricular rhythm were shown to be associated with an increased risk of sudden cardiac death (SCD) in patients with ischemic cardiomyopathy but not in NICM (Packer, 1992). In contrast, sustained monomorphic ventricular tachycardia (SMVT)/VF occur in less than 5% of cardiomyopathy patients (Teerlink et al., 2000; Meinertz et al., 1984) and are associated with high risk of sudden death (Poll et al., 1984; Milner et al., 1988). SMVT in this setting is most commonly a result of reentry through myocardial scar, most commonly following prior infarction. This type of VT typically occurs in the absence of acute ischemia (Wit et al., 1982; El-Sherif et al., 1981). Ventricular scars leading to reentrant VT also occur in nonischemic cardiomyopathies, including idiopathic dilated cardiomyopathy, hypertrophic cardiomyopathy, infiltrative heart diseases (e.g., sarcoidosis), arrhythmogenic right ventricular cardiomyopathy, and repaired congenital heart disease or valvular heart disease.

Prognosis of patients with ventricular tachycardia is generally dependent on the nature of the underlying heart disease. Persons with VT and a structurally normal heart have an excellent prognosis. In contrast, VT in ischemic cardiomyopathy has worse survival (Trappe et al., 1988).

Management of VT in Ischemic and NICM

Therapy for SMVT involves acute termination and long-term treatment to prevent recurrences and SCD. The initial therapy should be directed based on hemodynamic status and the presence or absence of symptoms. Additionally, treatment of any underlying precipitating factors (e.g., myocardial ischemia, heart failure, electrolyte disturbances) is an important part of the therapy.

Acute Management

For patients with SMVT who are hemodynamically *unstable*, severely symptomatic, or pulseless, urgent synchronized electrical cardioversion should be performed (Link et al., 2015). Antiarrhythmic therapy (intravenous amiodarone, procainamide, lidocaine, or oral agents such as sotalol or amiodarone) is generally indicated if SMVT recurs. For repetitive episodes of SMVT, consideration should be given to catheter ablation.

For patients who are hemodynamically *stable* during SMVT, intravenous pharmacologic therapy with procainamide, amiodarone, or lidocaine may be attempted prior to electrical cardioversion (Link et al., 2015; Ortiz et al., 2016). Sometimes, additional antiarrhythmic therapy may be administered (e.g., a second bolus of amiodarone, adding lidocaine to amiodarone, etc.).

Treatment of underlying conditions, which may precipitate VT, such as myocardial ischemia, electrolyte disturbances, and heart failure, as well as decreasing the sympathetic facilitation of SMVT, are important components of the acute management of VT. However, it should be recognized that most episodes of SMVT do not have identifiable precipitating factors, and SMVT is rarely precipitated by acute ischemia, although it most commonly occurs in patients with prior myocardial infarction (MI). Thus,

appropriate treatment of heart failure and ischemia is important for improving the overall prognosis of patients with SMVT after MI, but they may not directly affect the occurrence of VT.

Adjunctive treatment

- Adjunctive use of beta blockers, in combination with antiarrhythmic agents, is effective in reducing sympathetic facilitation of SMVT, especially in patients with frequent recurrences of VT within a short time period (VT storm) (Hirsowitz et al., 1986).
- In the postoperative or intensive care unit setting, eliminating or decreasing the use of inotropic or adrenergic agents may facilitate pharmacological control of SMVT (Jazayeri et al., 1989). Similarly, the judicious use of sedative-hypnotic agents to lower anxiety, as the patient's hemodynamic status allows, may be beneficial.
- Electrolyte disturbances, particularly hypokalemia and hypomagnesemia, are not usually responsible for precipitating SMVT, but when present, they should be treated aggressively.
- In appropriate patients, insertion of an intraaortic balloon pump (IABP) may help stabilize patients with refractory recurrent VT until ablation or surgical treatment is performed. The IABP can reduce ischemia and help in maintaining blood pressure until definitive therapy is implemented.

Prevention of Recurrent Arrhythmias and SCD

Long-term therapy of patients with SMVT usually requires utilization of multiple therapeutic modalities, including the implantable cardioverter defibrillator (ICD), antiarrhythmic drugs, and/or radiofrequency (RF) catheter ablation (Pedersen et al., 2014) (**Fig. 1**).

Revascularization is usually not antiarrhythmic in patients with SMVT, although such patients should be investigated for myocardial ischemia, which, if present, should be treated aggressively. Effective treatment of congestive heart failure does reduce both heart failure mortality and sudden death (Domanski et al., 2003; Deedwania and Carbajal, 2012; Pitt et al., 1999; Das and Zipes, 2010) but has not been effective in reducing recurrences of VT. It had been hoped that cardiac resynchronization therapy would significantly reduce VT; unfortunately, this only appears to be the case in those without a history of VT (submitted) (Sapp et al., 2016), particularly if the EF improves (Ruwald et al., 2014). Once the substrate for VT becomes manifest, reduction of VT requires specific therapy, either antiarrhythmic drug therapy or catheter ablation.

ICD therapy

Three large prospective trials (AVID, CASH, and CIDS) evaluated ICD therapy compared to amiodarone or other antiarrhythmic drugs in survivors of cardiac arrest or life-threatening ventricular tachyarrhythmias, including hemodynamically unstable SMVT. Although the AVID trial was the only one to demonstrate a statistically significant mortality benefit, similar point estimates of benefit were seen in all three, and a meta-analysis of all three trials showed a significant improvement in overall mortality (Connolly et al., 2000a). These trials did not address patients with hemodynamically stable SMVT who may be more challenging to manage because of frequent VT recurrences.

There is evidence and/or general agreement that ICD therapy may be beneficial in patients with structural heart disease and spontaneous sustained VT, whether hemodynamically stable or unstable (Epstein et al., 2008; Priori et al., 2015; Zipes et al., 2006). The principal benefit in patients with hemodynamically stable VT derives from the ability to reduce the need for antiarrhythmic drugs in patients with infrequent tachycardia episodes, as well as the ability to terminate SMVT with antitachycardia pacing rather than shocks. Earlier trials of programming ICDs to treat VT without shocks were successful and form the basis for modern programming (Wilkoff et al., 2006; Wathen et al., 2004). It was hoped that further shock reduction could be achieved with prolongation of detection—this was successful for patients with primary prophylactic ICDs (Moss et al., 2012), but less so for patients who already have VT (Gasparini et al., 2013; Sterns, 2015; Sterns et al., 2016).

There remains some debate regarding the optimal management of sustained, hemodynamically stable VT in persons with a prior MI but normal or near normal left ventricular systolic function, in whom there is increasing consensus that VT ablation should be considered for primary or initial therapy (Aliot et al., 2009).

Long-term antiarrhythmic drug therapy

Both empiric (Waldo et al., 1996) and tailored antiarrhythmic drug therapy based on electrophysiologic studies (Buxton et al., 1999; The Cardiac Arrhythmia Suppression Trial II Investigators, 1992; The Cardiac Arrhythmia Suppression Trial (CAST) Investigators, 1989) have been disappointing. Only four drugs have been studied in randomized trials in the ICD era to reduce recurrent VT:

1. *Amiodarone* is the most effective available antiarrhythmic drug for the reduction of VT (Ferreira-Gonzalez et al., 2007). It substantially reduces 1 year recurrent VT for patients with ICDs who have experienced VT (HR 0.27, $P<0.001$) (Connolly et al., 2006). It is however, plagued by the long-term risk of complications. When used as preventive therapy for patients with heart failure, it has resulted in reductions in sudden arrhythmic death, but no effect on overall mortality (Burkart et al., 1990; Cairns et al., 1997; Doval et al., 1994; Julian et al., 1997). In the SCD-HeFT trial, patients with reduced EF and heart failure were randomly allocated to placebo, amiodarone, or ICD implant, stratified by functional class. In the functional class III stratum, amiodarone resulted in increased risk of mortality (Bardy et al., 2005) suggesting that some of amiodarone's benefits are offset by harm. Potential amiodarone side effects are numerous and often relate to longer tem exposure. Two of the largest amiodarone trials (AVID and CIDS) reported frequent amiodarone-related adverse events: AVID (The Antiarrhythmics versus Implantable Defibrillators (AVID) Investigators, 1997), during 2 years follow-up, reported a 21% adverse event rate, including pulmonary toxicity in 5%, and thyroid toxicity in 16%, while CIDS (Connolly et al., 2000b), over 3 years follow-up, reported 5.7% pulmonary toxicity, 14.5% ocular symptoms, 6% skin toxicity, 10.3% photosensitivity, 17% ataxia, 15% tremor, 19% insomnia, and 0.5% neuropathy. In an 11-year long-term extension of this study, side effects were seen in 82% of patients and drug was discontinued in 50% over a mean follow-up 5.6 years, and within 8 years, 100% of patients assigned to amiodarone had either died, had recurrent VT, or did not tolerate the drug (Bokhari et al., 2004). In a meta-analysis which included studies with follow-up ≥ 1 year, even relatively low-dose amiodarone was significantly associated with frequent side effects (Vorperian et al., 1997).
2. *Sotalol* demonstrated a trend to reduced recurrences of VT at a 1-year follow-up in comparison to beta-blocker in the OPTIC trial (HR 0.61, $P=0.055$) (Connolly et al., 2006) and a significant reduction in recurrent VT in the trial by Pacifico et al. (49% relative risk reduction, $P<0.001$) (Pacifico et al., 1999). Other smaller ($n\leq 100$) single center trials previously estimated the relative reduction in VT with sotalol at 39% in comparison to placebo (Kuhlkamp et al., 1999) or found either a neutral or increased risk in comparison with beta-blockers (Seidl et al., 1998; Kettering et al., 2002). Sotalol has been similar to other antiarrhythmic drugs, conferring a dose-dependent risk of ventricular proarrhythmia (Waldo et al., 1996) necessitating a careful assessment of risk versus benefit before its use. Sotalol thus has moderate effectiveness compared to amiodarone, but in the presence of an ICD, it is considered to have a relatively good safety profile and is thus a frequent choice for first line therapy for patients without high risk of sotalol-induced proarrhythmia (Pedersen et al., 2014). The risk of mortality related to proarrhythmia from sotalol may be reduced in patients with ICDs. Sotalol should be avoided in patients with severe reactive airways, severe heart failure, severe renal insufficiency, or severe QT prolongation (Fuster et al., 2011; Piccini et al., 2014; Wolbrette, 2003).
3. *Dofetilide* (Mounsey and DiMarco, 2000) was studied in a multicenter randomized trial, which failed to demonstrate a reduction in incident VT, and revealed a risk of torsade de pointes in 10% in the Dofetilide arm (O'Toole et al., 1999; Food and Administration, 2015). When tried in heart failure, it did not demonstrate any benefit (Kober et al., 2000; Torp-Pedersen et al., 1999) and has not been approved for this indication.
4. *Azimilide* successfully reduced VT, but is not clinically available (Dorian et al., 2004; Hohnloser et al., 2006).

Catheter ablation for VT in ischemic cardiomyopathy

Ablation is a nonpharmacologic alternative to antiarrhythmic drug therapy for patients with recurrent VT and ischemic cardiomyopathy, and is recommended, like antiarrhythmic drug therapy, as a possible first line therapy (Pedersen et al., 2014). Its use for post-MI VT has tripled in the last decade (Palaniswamy et al., 2014). During an ablation, intracardiac electrode catheters are placed via the central vasculature. Catheter mapping techniques have been developed, which can identify myocardial scar, and the surviving conduction channels within scar, which form the substrate for reentrant VT. RF energy can then be applied to these sites, interrupting VT circuits (**Fig. 2**). Efficacy and adverse effects of this procedure are summarized in **Table 1**.

Three randomized trials of ablation for scar-related VT have been published. The SMASH-VT trial compared ICD implant with prophylactic ablation to ICD implant alone in patients with recent VT (Reddy et al., 2007). In this trial, ablation of VT reduced ICD shocks from 31% to 9% over a mean follow-up of 22.5 ± 5 months ($P = 0.003$), and reduced VT from 33% to 12% ($P = 0.007$), but no antiarrhythmic therapy was used in the control group. The VTACH trial (Kuck et al., 2010) studied the effect of catheter ablation in patients with ischemic cardiomyopathy, again without specific antiarrhythmic drugs in the control arm (although 1/3 of patients in both arms were treated with amiodarone). Over a mean follow-up of 22.5 months, ablation prolonged time to recurrent VT significantly (HR = 0.61), with a relative risk reduction of 25% and an absolute risk reduction of 18% at 2 years. The VANISH trial was the first trial to randomize VT patients to either catheter ablation or escalation of antiarrhythmic medical therapy (Sapp et al., 2016). During 28 months of follow-up, catheter ablation was associated with 28% relative risk reduction in the composite endpoint of death, VT storm, and appropriate ICD shock ($P = 0.04$).

While catheter ablation for VT is "minimally invasive," it does require instrumentation of the left ventricle in patients who have significant ventricular dysfunction and frequent comorbidities. In a contemporary cohort experience (unselected patients undergoing VT ablation), procedural risks included a mortality risk of 0.4%, as well as risks of cardiac perforation (1.4%), systemic embolism including stroke/MI (0.8%), vascular complications (2%), and other complications, with a major complication rate in the 5%–6% range (Bohnen et al., 2011). This is in the same range as the observed complication rate in multicenter experiences: in the Multicenter Thermocool prospective cohort study of 231 patients, 30-day mortality was 3%, mostly due to VT which was not successfully ablated rather than due to complications, while overall there were significant complications in 7.3%. In phase 2 of this study, when investigators had experience with the catheter, the complication rate fell to 5.1%, with the major contributors including

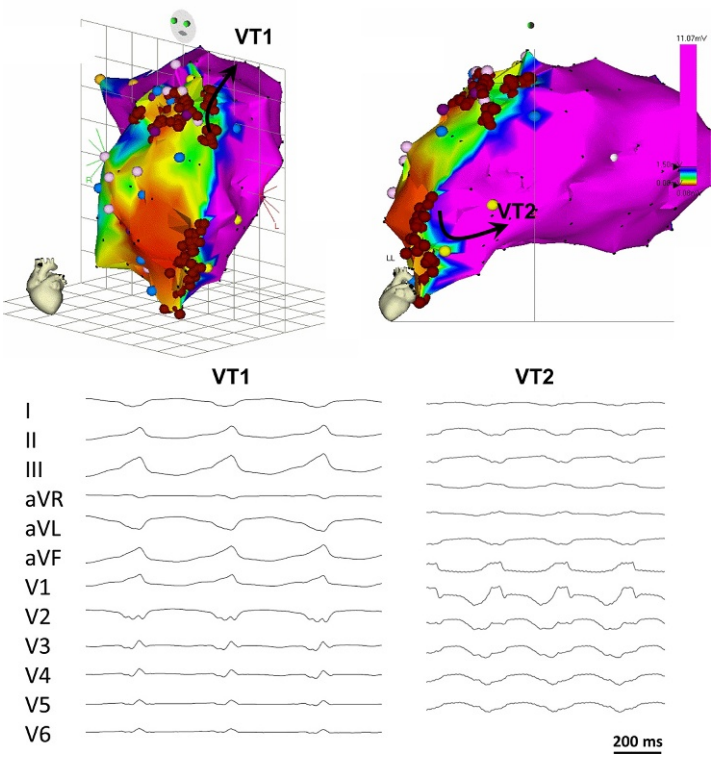

Fig. 2 Bipolar voltage map of the left ventricle during sinus rhythm in left anterior oblique cranial view (Top-left) and left lateral view (Top-right). This patient had a previous anterior STEMI that resulted in a large anteroapical aneurysm and presented with multiple ICD shocks. Reduced sinus rhythm bipolar contact electrogram signal amplitude (<1.5 mV) was recorded throughout the aneurysm. Two poorly tolerated VT morphologies were induced, VT1 (Bottom-left) exiting from the basal margin of the scar and VT2 (Bottom-right) exiting from the lateral margin. VT1 had RBBB morphology with TCL of 380 ms, precordial transition in V2 and QRS axis of 120, while VT2 had RBBB morphology with TCL of 280 ms, precordial transition in V3 and QRS axis of −120. Ablation lesions (*dark red dots*) were delivered along these exits with the endpoint of exit block across the lines. VTs were rendered noninducible at the end of the procedure.

cardiac perforation 0.4%, CHF 1.3%, and respiratory complications 0.8% (Waldo et al., 2012); concordant with other multicenter experiences (Tanner et al., 2010).

Catheter ablation for VT in nonischemic cardiomyopathy

Nonischemic cardiomyopathy represents a heterogeneous group of patients with multiple underlying etiologies. Hence, the resultant scar has a wider distribution in the endocardium, epicardium, and mid-myocardium (**Fig. 3**). The long-term success rate is modest and ranges between 26% and 86% (**Table 2**). Reentry circuits require epicardial ablation in more than a third of patients (Soejima et al., 2004). Advances in electroanatomic mapping, cardiac imaging, and epicardial access have improved ablation strategies. Occasionally, incessant idiopathic VT or PVCs cause a cardiomyopathy that improves after ablation (Yarlagadda et al., 2005).

Bundle branch reentry represents the second most common mechanism of VT in this subset of patients. In the two largest series reported, acute success rates were 100% (Blanck et al., 1993; Lopera et al., 2004). Intraprocedural high grade AV block has been reported to occur in 10%–30% of patients after successful ablation (Lopera et al., 2004). Recurrence of the BBR VT appears to be uncommon but has not been thoroughly documented with follow-up testing. The long-term prognosis is usually more guarded, however, reflecting the underlying heart disease. Of 20 patients treated, Lopera et al. (2004) reported need for pacing or ICD implantation in 19. Of the 14 patients who required an ICD, 7 (50%) had VT recurrence within 16 months. Five of these patients had VTs of myocardial origin which, were different than the original BBR VTs.

Recent retrospective multicenter analyses examining the outcomes of catheter ablation in the setting of structural heart disease are suggesting a possible survival benefit among those with a successful procedure. Tung et al. (2015) analyzed 2061 SRVT ablation

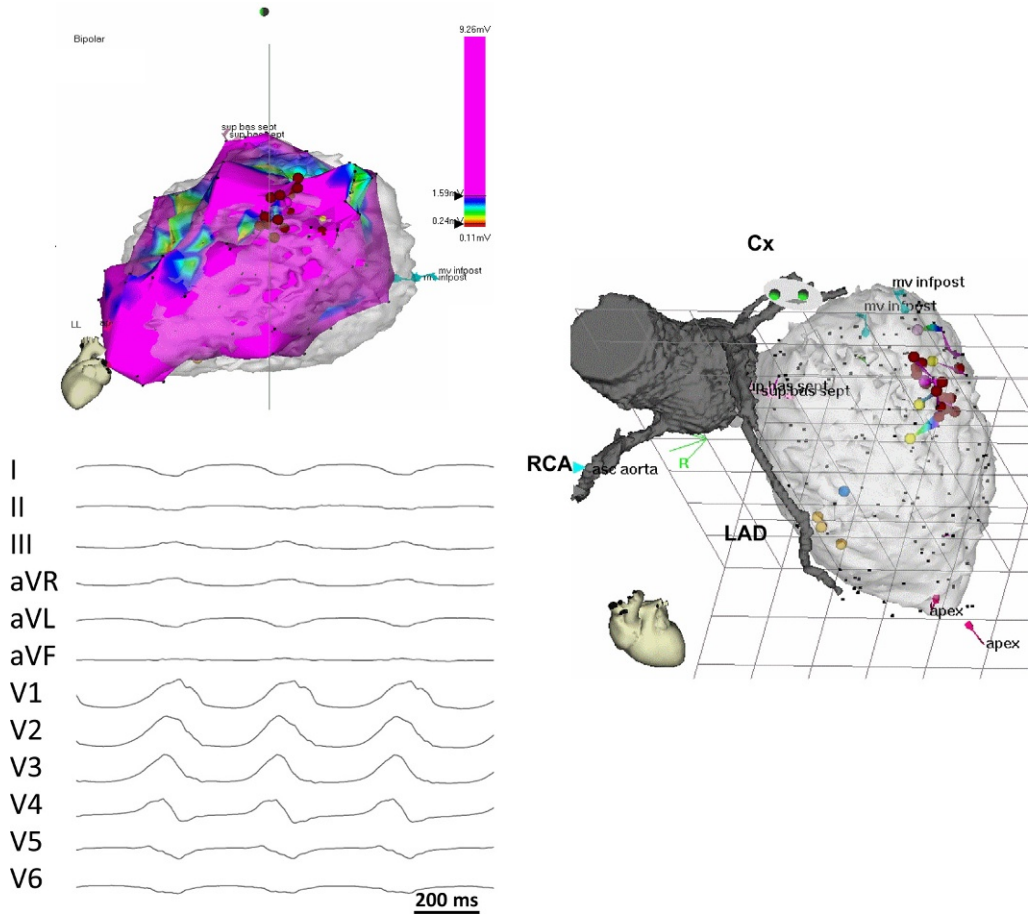

Fig. 3 Bipolar voltage map of the left ventricle during sinus rhythm in left lateral view (Top-left) and the corresponding integrated CT scan reconstruction of the LV and aorta in a left anterior oblique cranial view (Right). This patient had nonischemic dilated cardiomyopathy and presented with multiple ICD shocks. Notice the normal proximal coronary arteries in the reconstructed CT scan image. Small patchy areas of endocardial reduced bipolar voltage (<1.5 mV) were recorded over the anterolateral LV. A single poorly tolerated sustained monomorphic VT (Bottom-left) was inducible with RBBB morphology, TCL of 355 ms, precordial transition in V4 and QRS axis of 170. Successful ablation was performed at the basal lateral LV wall (*dark red dots*) in an area of relatively preserved endocardial bipolar voltage suggesting deeper midmyocardial or epicardial scar with endocardial exit. VT was rendered noninducible at the end of the procedure.

Table 2 Clinical series of catheter ablation for ventricular tachycardia in nonischemic cardiomyopathy

Authors	*Year*	*N*	*EF*	*Epicardial mapping and/or ablation*	*F/U*	*VT free on F/U (%)*
Kumar et al. (2016)	2016	239	40	30% (sarcoid and ARVC included)	72	38

Hsia et al. (2003)	2003	19	34	16%, coronary venous mapping, no ablation	22	26
Marchlinski et al. (2000)	2000	7	44	0	8	57

patients from 12 international centers. At 1 year of follow up, transplant-free survival was significantly higher in patients without VT recurrence than in those with recurrence (90% vs. 71%, $P<0.001$). This observation was independent of ejection fraction or heart failure severity. Similarly, Yokokawa et al. (2015) analyzed data from 1064 patients who underwent VT ablation for postinfarction VT at seven international centers. Noninducibility of VT at the end of the procedure was found to be independently associated with lower mortality (adjusted hazard ratio: 0.65; 95% confidence interval: 0.53–0.79; $P<0.001$) over 2-year follow-up period.

Conclusions

Ventricular arrhythmias are common in patients with ischemic and NICM. Their prognosis is often dependent on the nature of the underlying heart disease. SMVTs are associated with high risk of sudden death. They are usually related to reentry involving an established myocardial scar. While antiarrhythmic drugs can reduce the arrhythmia burden, they are not associated with survival benefit and some of them can be harmful. ICDs are effective in reducing the risk of sudden death but they do not prevent recurrences. Catheter ablation can significantly reduce arrhythmic burden by selectively targeting reentrant circuits within the scar. It has a reasonable long-term efficacy and a possible survival benefit but still has a significant complications rate.

Call for Further Research

Our knowledge of the underlying substrate responsible for VT in patients with ischemic and nonischemic cardiomyopathies has grown remarkably in the past 3 decades. Further research is needed to better understand the underlying pathophysiology that promotes the development of VT many years following myocardial scarring. Noninvasive characterization of the underlying scar as well as localization of potential VT circuits within the scar is another field of research that is showing remarkable progress, particularly with the advances in cardiac scar imaging and ECG imaging. Moreover, treatment options for VT still need further investigation. New antiarrhythmic medications that are both effective and have a favorable safety profile are strongly needed. Catheter ablation for VT is playing an increasing role in treating those patients. Well-designed randomized studies comparing antiarrhythmic drugs and catheter ablation as a first line therapy for VT are ongoing. Further refinement and improvement of ablation tools, procedure technique, and mapping technology will hopefully improve the efficacy of the procedure and lower its risk. Finally the signal toward better survival with catheter ablation needs further investigation in prospective well-designed large studies.

Introduction

Participation in competitive sport and vigorous recreational exercise has grown rapidly worldwide. USA Triathlon membership has increased by over 350,000 members in the last 15 years (2015 Running USA Annual Marathon Report, 2015) and nontraditional running events (themed races and obstacle events) have had over 3 million finishers from 2009 to 2013 (State of the Sport—Part I: Non-Traditional Running Events, 2014). Contemporary athletes are a heterogeneous group ranging from dedicated lifelong athletes to weekend warriors alike that encompass a broad spectrum of age, athletic prowess, performance goals, and underlying cardiovascular risk profiles. Athletes become patients in one of two principal ways, either following "abnormal" findings during preparticipation screening and general medical care or after the development of symptoms suggestive of underlying cardiovascular disease (Baggish and Wood, 2011).

In 2015, updated guidelines on the eligibility and disqualification for competitive athletes were published by the American College of Cardiology and American Heart Association (Maron et al., 2015a). These guidelines serve as an update to the 36th Bethesda Conference published in 2005 (Maron and Zipes, 2005). The purpose of the guidelines is to ensure the health and safety of young competitive athletes with the end goal of preventing sudden cardiac death (SCD). The intent of this chapter is not to review the guidelines, but to provide clinicians valuable insight into the unique approach and management of athletes with cardiovascular disease that may be encountered in everyday practice. We will highlight sport classification, the incidence, causes and prevention of SCD, the impact of exercise on cardiovascular risk factors, and the management of specific cardiovascular diseases that are common among athletes.

Sport Classification

Each athletic endeavor has its own associated hemodynamic conditions with unique changes in cardiac output and peripheral vascular resistance. In general, exercise activities are separated into two forms with characteristic hemodynamic differences. Isotonic

 https://doi.org/10.1016/B978-0-12-809657-4.99713-8

exercise or endurance exercise, involves sustained elevations in cardiac output, with normal or reduced peripheral vascular resistance. The principal effect is a volume challenge that affects all four heart chambers and downstream cardiac remodeling results in eccentric remodeling (Fig. 1). Endurance activities include, but are not limited to, long-distance running, cycling, and swimming. In contrast, isometric exercise is defined by an increase in peripheral vascular resistance without significant change in cardiac output leading to concentric hypertrophy. This can cause transient but marked systolic hypertension with increased left ventricular (LV) afterload. Isometric exercises are synonymous with strength training and are the dominant form of exercise in weightlifting, track and field throwing events, and American-style football. Many sports, including team sports such as soccer, lacrosse, basketball, hockey and field hockey, and specific endurance disciplines including rowing, cycling, and triathlon involve significant elements of both isotonic and isometric physiology. Sport classification may provide a useful clinical framework for the provision of eligibility recommendations following a cardiovascular diagnosis in a competitive athlete (Fig. 2) (Levine et al., 2015).

Shared Decision-Making

It is important to recognize that the updated practice guidelines necessarily provide a conservative management approach to athletes as they are based on limited existing research and expert consensus that are applied by physicians with or without expertise in treating athletes with cardiovascular disease. For clinicians who routinely care for competitive athletes it is clear that these guidelines are not always in line with an athlete's goals, ambitions, and livelihoods. Additionally, many habitual athletes use sport as a means to treat depression and anxiety so limitation to IA sport could expose other pathologic conditions. Lastly, there is clear evidence that living a sedentary lifestyle results in weight gain, hypertension, diabetes, depression, and cardiovascular disease. Thus, sports cardiologists are encouraged to rely on guidelines as a reference while simultaneously recognizing the potential long-term consequences of athletic disqualification during shared decision-making with an athlete and his/her family.

Shared decision-making is the process by which an athlete engages in an open dialogue with his/her physician to make a collaborative decision regarding exercise eligibility and prescription. The clinician's role is to review the underlying cardiovascular condition and management strategies with an emphasis on the risks and benefits of all available strategies. The sports cardiologist's final recommendation should ultimately take into account all factors including the athlete's underlying cardiovascular risk, athletic aspirations, and unquantifiable benefits such as stress relief, personal satisfaction, and avoidance of unhealthy habits. Importantly however, safety must be considered the ultimate priority and is the shared responsibility of the provider, athlete, and his/her family.

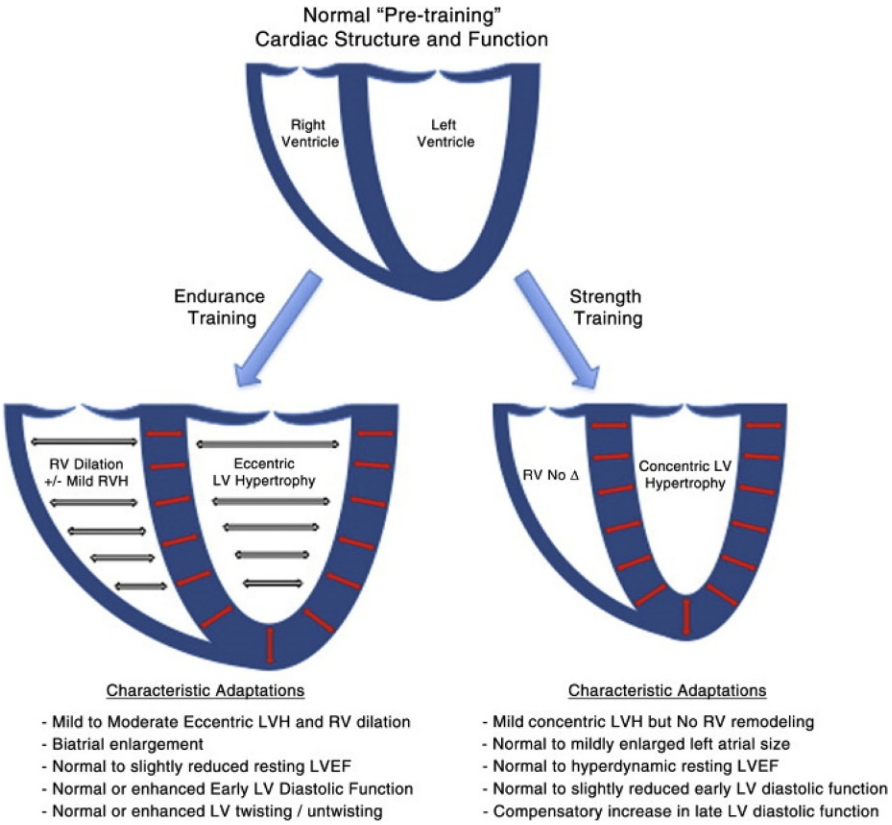

Fig. 1 Summary of ventricular remodeling during sustained exercise training, highlighting the sport-specific nature of exercise-induced cardiac remodeling. Reprinted from Weiner, R. B. and Baggish, A. L. (2012). Exercise-Induced cardiac remodeling. *Progress in Cardiovascular Diseases* **54**, 380–386, 2012 with permission from Elsevier.

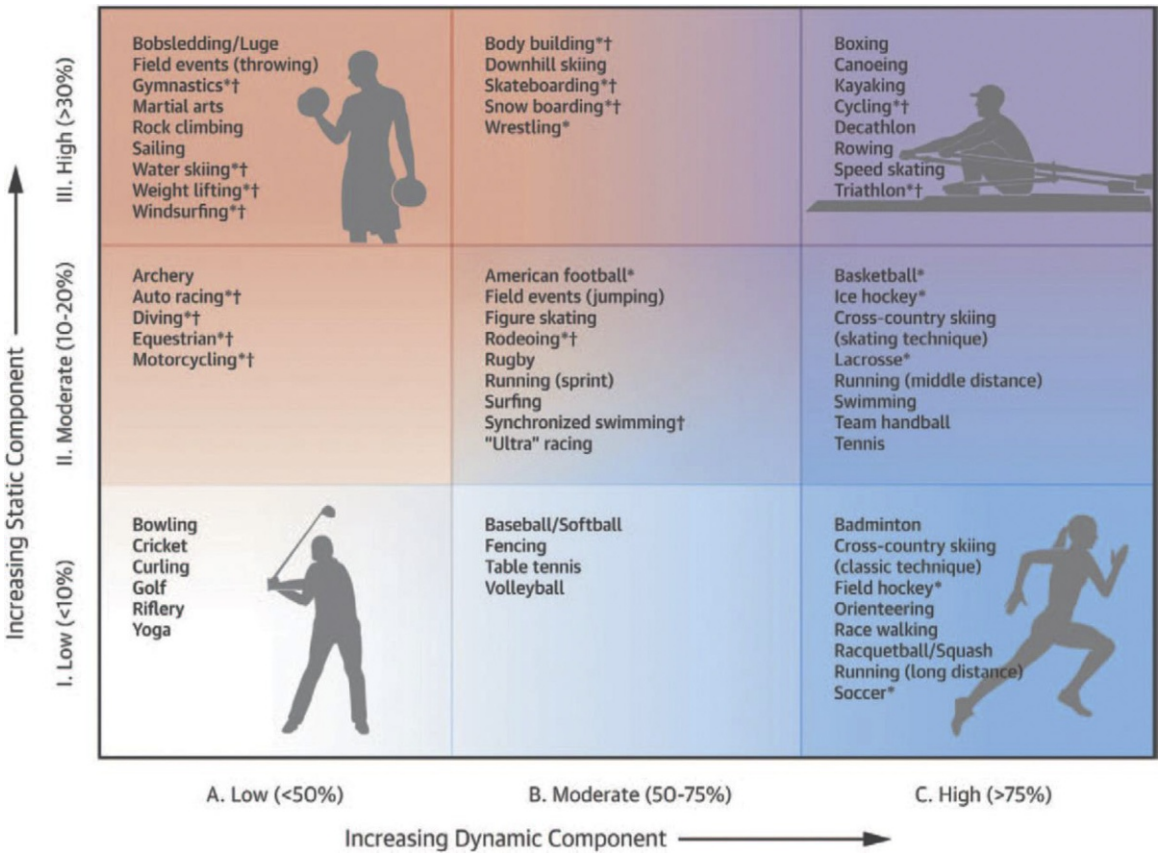

Fig. 2 *Classification of sport.* This classification is based on peak static and dynamic components achieved during competition; however, higher values may be reached during training. The increasing dynamic component is defined in terms of the estimated percentage of maximal oxygen uptake (VO_{2max}) achieved and results in an increasing cardiac output. The increasing static component is related to the estimated percentage of maximal voluntary contraction reached and results in an increasing blood pressure load. The lowest total cardiovascular demands (cardiac output and blood pressure) are shown in the *palest color*, with increasing dynamic load depicted by increasing *blue intensity* and increasing static load by increasing *red intensity*. Note the graded transition between categories, which should be individualized on the basis of player position and style of play. *Danger of bodily collision. †Increased risk if syncope occurs. All athletes should identify care providers that understand the breadth of cardiovascular disease pathogenesis and competitive sport and then partner with this provider to identify and address individual risk.

Sudden Cardiac Death: Incidence and Causes

SCD in the athlete is a rare but tragic event that receives significant attention from the media. Such unexpected deaths are often met with a sense of confusion as being an athlete is thought to be synonymous with health and immunity from cardiovascular disease. In reality, acute bouts of vigorous physical exercise transiently increase the risk of sudden death among people with and without underlying cardiovascular disease (Thompson et al., 1982; Siscovick et al., 1984). However, routine vigorous physical activity lowers overall risk of sudden death in a dose dependent fashion, meaning the fittest people are at the lowest risk. Among athletes, absolute risk of sudden death is highest among those with underlying genetic or acquired cardiovascular disease (Mittleman et al., 1993; Albert et al., 2000; Kim et al., 2012). Incidence data defining the risk of sudden death during running come from the RACER study which cataloged cardiac arrests among US-based runners participating in organized marathon or half marathon races over a decade long period of study. The overall incidence of sudden death in the RACER study was 1 per 259,000 runners (Kim et al., 2012), which has been confirmed in smaller studies (Webner et al., 2012). In addition to defining sudden death risk among competitive runners, the RACER study confirmed higher rates among men, increasing risk with longer race distance, and a strong clustering of events in very close proximity to the finish line. Of note, the incidence of cardiac arrest among male marathon runners increased threefold during the study period which almost certainly reflects changes in the underlying health status of men turning to marathon running. It is important to note that sudden death incidence appears to vary across different athletic populations with statistics including 1 death per 43,770 participants/year among NCAA athletes (Harmon et al., 2011), 1 death per 52,630 among US triathlon participants (Harris et al., 2010), and 1 death per 7620 previously healthy middle aged joggers (Thompson et al., 1982).

Consideration of population specific risk has important implications during implementation of screening strategies and emergency action planning.

Causes of SCD among athletes vary as a function of age. Younger athletes, defined as <35 years of age, most commonly succumb to sudden death attributable to congenital or genetic cardiovascular conditions including hypertrophic cardiomyopathy (HCM), arrhythmogenic right ventricular cardiomyopathy (ARVC), congenital coronary artery anomalies (CCAA), and inherited arrhythmia syndromes. Mild forms of these diseases may not impair cardiac function enough to limit exercise capacity rendering them "silent diseases" but may sufficiently increase the risk of malignant, potentially fatal arrhythmias. Contemporary autopsy series derived from athletic victims of sudden death increasingly include cases without clear anatomic abnormalities. Such cases, often termed sudden unexplained death, are likely attributable to occult cardiac channelopathies or other less well understood arrhythmia syndromes.

In contrast, sudden death among athletes above the age of 35 years is more commonly caused by diseases acquired during an athlete's lifetime. In practice, the vast majority of sudden death among older athletes is caused by atherosclerotic coronary disease. The accumulation of coronary artery plaque may lead to sudden death via one of two distinct mechanisms. Coronary plaques, usually those of only mild to moderate severity, may rupture during exercise causing a thrombotic occlusion, myocardial infarction, and subsequently a malignant arrhythmia. In our experience, this pathophysiologic process typically leads to symptoms characteristic of classic myocardial infarction; chest pain, nausea, increases in perspiration, etc., rather than unheralded sudden death. In contrast, moderate to severe coronary plaques rupture relatively infrequently but promote sudden death from demand or ischemia-mediated arrhythmia. Here, fixed blood supply that is limited by the diseased artery segment may sufficiently supply the heart muscle at low to moderate exertion but become insufficient at higher workloads. When this threshold is exceeded, a common occurrence during the often unavoidable "finish line surge," oxygen starved myocardium may become sufficiently unstable to precipitate ventricular arrhythmias. Thus, timely diagnosis and effective management of atherosclerotic coronary artery disease (CAD) is of paramount importance in aging athletes.

Sudden Cardiac Death: Prevention

Sudden death may be a preventable tragedy. As discussed above, underlying diseases of the cardiovascular system cause most cases of sudden death during exercise. Athletes with these conditions may experience warning symptoms including exertional chest pain, inappropriate exertional breathlessness, or a new inability to keep up with peers. It is thus of vital importance that athletes of all ages are educated to be on vigilant watch for such symptoms and to report their occurrence immediately to medical professionals. Unfortunately however, warning symptoms may be absent and the first manifestation of disease may be catastrophic collapse.

Recognition of this fact has been the driving force behind efforts to design, develop, and disseminate preparticipation cardiovascular screening (PPCS) programs. The rationale for PPCS is predicated on the concept that some, if not most, forms of high-risk heart disease fail to produce warning symptoms but are detectable by some form of screening. The purpose of PPCS is thus to identify cardiovascular disorders or abnormalities that can potentiate sudden cardiac arrest during athletic participation, and to take steps to reduce this risk by sport restriction and/or medical intervention. The American Heart Association and American College of Cardiology recommend a mandatory PPCS protocol for young competitive athletes that is limited to a focused medical history and physical examination (Maron et al., 2014a). The impact of this PPCS approach on sudden death incidence is unknown and its ability to detect culprit diseases may be of limited value (Maron et al., 2013, 2014b; Maron, 2012). This has led to some expert consensus panels recommending the inclusion of a 12-lead electrocardiogram (ECG) as part of a more comprehensive PPCS protocol (Corrado et al., 2005, 2006). Indeed, data comparing PPCS confined to medical history and physical examination to one that includes ECG demonstrate that the ECG significantly increases PPCS's ability to detect high-risk conditions. However, it must be emphasized that the inclusion of ECG comes with increased risk of false positive testing. This is a problem of decreasing magnitude in the era of increasingly accurate athlete ECG interpretation algorithms but one that will remain substantial for the foreseeable future. As such, the addition of the ECG to a medical history and physical examination-based PPCS remains controversial and the interested reader is directed to several excellent discussions on this topic (Maron et al., 2009, 2014a, 2015b; Steinvil et al., 2011). All practitioners and organizations considering implementation of a PPCS program, with or without ECG, are urged to consult recent documents that address the strengths and limitations of this process (Maron et al., 2015b).

Screening of older athletes is less comprehensively dictated and receives comparatively little attention. We encourage runners above the age of 35 to work closely with primary care and sports cardiology experts to identify and treat cardiovascular disease risk factors. For older athletes planning to embark on or to intensify a training program, exercise testing should strongly be considered based on its ability to screen for many high-risk, often occult forms of acquired cardiovascular disease.

No PPCS approach will eliminate the problem of sport-associated SCD. Thus, the ability to resuscitate cardiac arrest victims is a critical component of preparedness for those engaged in or those sponsoring races and events. Survivors of cardiac arrest uniformly receive early bystander-administered cardiopulmonary resuscitation (CPR) and have rapid access to automated external defibrillators (AED) at the scene of cardiac arrest (Kim et al., 2012). An effective resuscitation strategy, one key component of an overall emergency action plan, must include ample team members trained in CPR, the availability of AEDs, and rapid access to Emergency Medical Services with advanced cardiac life support capacities. Development and practice of an emergency action plan that integrates these key elements is mandatory for individuals and organizations that host athletic events.

Benefits of Exercise

Participation in regular- and moderate-intensity exercise attenuates cardiovascular risk factors, reduces incident cardiovascular disease, and reduces cardiovascular morbidity and mortality (Sattelmair et al., 2011; Sofi et al., 2008; Wen et al., 2011; Paffenbarger et al., 1993; Wasfy and Baggish, 2016). However, routine exercise does not confer a free pass for dietary indiscretion and does not undo the risks associated with bad habits such as smoking and excessive alcohol intake. It is also noteworthy that exercise used in isolation as a risk factor reduction technique is often inadequate and many athletes therefore benefit from a comprehensive approach that focuses on exercise dose, dietary modification, stress reduction, and conventional medical therapy. The following sections address the current knowledge base defining the impact of exercise on traditional cardiovascular risk factors.

Lipids

Aerobic exercise training has been demonstrated to have a favorable impact on serum cholesterol. The strongest relationship seems to be with increased levels of high-density lipoprotein (Kodama et al., 2007). While data is less consistent, exercise results in decreased low-density lipoprotein and triglycerides (Zilinski et al., 2015; Kelley et al., 2005). It should be noted that lowering total cholesterol by even 10% through diet or medication has been shown to result in a 27% reduction in the incident of cardiovascular disease (Law et al., 1994). Beneficial effects of this magnitude on cholesterol can be seen with adherence to recommended guidelines of 150 min of moderate-intensity or 75 min of vigorous intensity exercise weekly (Eckel et al., 2014). Additionally, incremental benefit may be achieved with exercise routines that exceed the minimum recommended levels (Wasfy and Baggish, 2016). It must be emphasized that many athletes with a genetic predisposition to high cholesterol will be unable to obtain optimal cholesterol profiles through diet and exercise alone. Thus, many athletes will benefit from the addition of medication, most commonly the use of an HMG-Co-A reductase inhibitor, which is well tolerated by most athletes, particularly when flexible dosing schedules are employed.

Blood Pressure

Hypertension is common among otherwise healthy athletes and is associated with the development of numerous forms of heart disease. While the beneficial impact of exercise training on blood pressure is well established, its impact is typically small with reductions in both systolic and diastolic blood pressure in the 2%–4% range (Fagard, 2001; Cornelissen and Fagard, 2005; Whelton et al., 2002; Halbert et al., 1997; Kelley and Tran, 1995). Reductions in blood pressure are more pronounced in those with preexisting hypertension (Fagard, 2001; Cornelissen and Fagard, 2005; Kelley et al., 2001). Endurance athletes routinely exceed the minimum recommended weekly exercise which should confer this beneficial effect on blood pressure. As such, endurance athletes with documented hypertension rarely reverse this problem with increasing training mileage and therefore should be treated with antihypertensive medications that have minimal effect on exercise physiology such as ACE-inhibitors or calcium channel blockers.

Body Mass

The degree of change in body mass related to exercise is dependent on the net energy balance and thus requires increased energy expenditure while concomitantly relying on reduced caloric intake. Effective weight loss or stability is best achieved through a weekly exercise dose that is at least double the baseline recommended weekly activity (Irwin et al., 2003; Slentz et al., 2005; McTiernan et al., 2007; Donnelly et al., 2003). There is a direct dose–response relationship between exercise and body mass with higher exercise workloads resulting in a greater decrease in body mass. Endurance sporting activities (i.e., jogging, cycling, swimming, etc.) are therefore one very effective component of an overall weight management strategy. It must be emphasized that athletes seeking to reduce body mass must couple with deliberate control of caloric intake and should expect sustainable weight loss to occur slowly over months not weeks.

Metabolic Syndrome and Diabetes Mellitus

Exercise training improves metabolic health, including increased insulin sensitivity and noninsulin-mediated skeletal muscle glucose metabolism (Goodyear and Kahn, 1998; Henriksen, 2002). The dose of exercise is directly associated with improvements in insulin sensitivity in a graded fashion with greatest improvements seen in those with high intensity and high duration of exercise (Johnson et al., 2007; Dube et al., 2012). Studies evaluating the impact of exercise on prevention and treatment of metabolic syndrome and diabetes mellitus have shown that weight loss is the most important determinant to reduce the incidence of diabetes mellitus (Tuomilehto et al., 2001; Knowler et al., 2002). Athletes with the greatest exercise exposure have the lowest risk of developing diabetes mellitus even after controlling for weight loss and diet (Tuomilehto et al., 2001). Taken together, comprehensive lifestyle choices including exercise, diet and, weight loss have been shown to prevent metabolic syndrome and diabetes mellitus.

Physical Fitness

There is an inverse relationship between cardiorespiratory fitness and both all-cause and cardiovascular mortality (Blair et al., 1989, 1996; Kokkinos et al., 2010). Put simply, fitter people tend to live longer than less fit people. Fitness can be improved by increasing exercise frequency, intensity, or duration among people of all ages and both sexes (Spina, 1999; Seals et al., 1984). Physical fitness is determined by many factors in addition to exercise including age, sex, body mass, and genetics (Bouchard and Rankinen, 2001). Physical fitness is far more responsive to exercise training than any of the traditional cardiovascular risk factors mentioned above. Additionally, routine physical activity attenuates the risk of cardiovascular disease and mortality more than that which can be explained by its impact on individual risk factors.

Management of Cardiovascular Disease in the Athlete

Clinicians must be thorough with their history taking, as athletes may be less willing to be forthright with symptoms or exertional limitations. When exercise stress testing is utilized in athletes it is imperative that they are maximal effort tests designed to simulate race type workloads and efforts. Additionally, cardiovascular limitations, ischemia, and arrhythmia may only be seen at peak efforts so tests should not be terminated after achieving a submaximal target heart rate. As endurance athletes can achieve much higher workloads than their sedentary counterparts, achieving a normal workload during an exercise test may represent a significant functional impairment in an athlete. Thus, all data should be interpreted in the context of an athlete and clinicians should have an appreciation for basic exercise physiology.

Coronary Arteries

Coronary Artery Disease

Despite the cardiovascular benefits of routine moderate intensity exercise, vigorous exertion actually transiently increased the risk of acute myocardial infarction and SCD in individuals with underlying CAD (Siscovick et al., 1984; Mittleman et al., 1993; Giri et al., 1999). CAD remains the leading cause of exercise-related cardiac events, defined as those occurring during or within one hour of strenuous exercise, in adults (Rai and Thompson, 2011). Additionally, it has been shown that there are higher event rates among those who are occasionally active (i.e., weekend warriors) as compared with those who are habitually active (Mittleman et al., 1993; Willich et al., 1993). Thus, routine and habitual moderate aerobic activity is not only the best for cardiovascular health and longevity but also the safest from a cardiac event perspective. Furthermore, the relative cardiovascular stress of exercise will vary from individual to individual based on underlying fitness, cardiovascular disease, and age. Athletes with obstructive CAD generally present with chest discomfort that reproducibly develops with exertion, resolves with rest and is located in the substernal and/or left chest area. The constellation of symptoms are typical of stable angina with the discomfort characterized as an ache, pressure, or tightness that can radiate to the jaw or arm and may be accompanied with a sense of air hunger.

In addition to routine questions regarding chest pain, pressure, and dyspnea on exertion, more subtle changes and symptoms should be assessed. Due to their competitive nature, athletes may minimize symptoms so careful assessment can provide subtle clues to changes in exercise habits or symptoms. Unexplained decreases in exercise tolerance or an inability to maintain prior training regimens or race paces may indicate underlying CAD. Many victims of exertion-related SCD reported possible cardiac symptoms within a week of their death (Thompson et al., 1979). Some athletes may experience chest discomfort during the initial few minutes of exercise that abates with continued exertion. This is commonly referred to as "warm up angina," a process that reflects focal early exercise coronary artery blood flow insufficiency that is relieved by the subsequent recruitment of collateral arteries, and should prompt comprehensive assessment for underlying atherosclerotic CAD (Parker and Thompson, 2012). Similarly, gastrointestinal symptoms that occur with exertion should be treated as cardiac in nature until proven otherwise.

We prefer functional assessment with maximal effort cardiopulmonary exercise testing (CPET) to evaluate for ischemia, arrhythmia, and cardiopulmonary capacity. In general, we avoid coronary artery calcium scoring (CACS) as in our experience we have seen a high prevalence of left main and proximal left anterior descending calcification in endurance athletes without risk factors, a clinical scenario that is devoid of outcome data and one that we have not anecdotally seen as a marker for future adverse events. Maximal effort exercise testing in these individuals typically reveals supranormal exercise capacity without symptoms, ischemia or arrhythmia. Thus, it is probable that the mechanism and prognostic significance of coronary artery calcification among aging athletes may be different from those with traditional risk factors. Until further literature defining the clinical significance of coronary artery calcification among aging athletes is available, we recommend against the routine use of CACS in this population. In cases when an athlete's degree of CAD is disproportionate to his/her risk factors, an elevated Lipoprotein (a) (Lp(a)) may be a possible explanation (Danesh et al., 2000). Niacin therapy has been shown to reduce Lp(a) levels but there is no data that decreasing Lp(a) improves outcomes at this time (Parker and Thompson, 2012).

Athletes diagnosed with CAD by noninvasive imaging or after a cardiac event benefit from aggressive medical and in some cases interventional management. Prevention of an incident or subsequent event is the goal of therapy. Standard of care requires treatment with platelet inhibition, optimal blood pressure control, aggressive lipid management, and exercise counseling. Recommendations regarding returning to exercise and competitive sport are based on the presence of residual disease, wall motion

abnormalities, LV systolic function, and adherence/tolerability of comprehensive medical therapy. We recommend that all athletes undergo cardiac rehab after an acute coronary syndrome followed by a maximum effort CPET to evaluate for signs of residual ischemia, arrhythmia, or cardiopulmonary limitations. If testing is unremarkable, we recommend a gradual increase in activity with the goal of returning to competitive sport by 1 year after the initial event.

Coronary Anomalies

While the majority of people with CCAA live a full life without symptoms and die of unrelated causes, CCAA are the second most frequent cause of SCD in young athletes, accounting for about 20% of cases (Cheitlin et al., 1974; Liberthson et al., 1979; Taylor et al., 1992; Basso et al., 2000). Malignant anomalies, with either the left main or right coronary artery arising from an inappropriate coronary sinus, are those that traverse in an anterior course between the aorta and pulmonary trunk leading to transient compression during strenuous exercise (Taylor et al., 1997). The prevalence of wrong sinus coronary anomalies is thought to be less than 0.2% but prevalence data are sparse. Additional risk factors dictating sudden death risk include a stenotic or a slit-like ostium, an intramural arterial course, and the presence of distal arterial atresia (Pelliccia, 2001). The mechanism of SCD is thought to be triggered by myocardial ischemia and is supported by pathologic evidence of myocardial damage in the region supplied by the anomalous coronary artery (Liberthson et al., 1979; Taylor et al., 1997). In those with sudden death, ventricular fibrillation is likely the final event (Liberthson et al., 1979; Cheitlin, 1998).

Many people with CCAA go undiagnosed as symptoms of chest discomfort, atypical chest pain, and/or syncope are reported in less than 30% of patients (Basso et al., 2000; Taylor et al., 1997). Symptoms are most commonly reported in those with left main arising from the right coronary sinus and generally occur with exercise (Taylor et al., 1992). CCAA cannot be identified on screening ECG and the absence of ischemia during an exercise stress test is not sensitive enough to rule out the diagnosis in those with symptoms (Basso et al., 2000). In the case of a young athlete with exertional chest pain or syncope, the coronary origins should be identified as part of the work up. Echocardiography has been shown to visualize the ostium and proximal epicardial course of the left main in 97% and right coronary artery in 80% of subjects (Pelliccia et al., 1993; Davis et al., 2001). When the origin of both coronary arteries cannot be appropriately visualized with echocardiography, magnetic resonance imaging (MRI), cardiac computer tomography, or conventional coronary angiography should be employed based on institutional and provider preferences.

Treatment recommendations should be tailored to individual characteristics of the athlete and the type coronary anomaly. In general, young athletes with CCAA presenting with symptoms or documented ischemia should undergo surgery to repair the anomaly. In young asymptomatic athletes without ischemia, a shared decision-making should be undertaken. Despite being asymptomatic, an accurate risk assessment cannot be made and to avoid the risk of sudden death it is reasonable to undergo repair of the anomaly, particularly in the case of left coronary arteries that arise off the right sinus of Valsalva. Patients >35 years old who are asymptomatic may forego surgery as the greatest risk of SCD seems to be at a younger age but again shared decision-making is imperative (Taylor et al., 1997; Kragel and Roberts, 1988).

Arrhythmias

Conduction Abnormalities

It is well established that incomplete right bundle branch block (RBBB) is common, particularly among endurance athletes (Kim et al., 2011). In addition, complete RBBB are not uncommon among endurance athletes and may be a marker of physiologic adaptations in response to the repetitive volume challenge in isotonic exercise (Kim and Baggish, 2015). In a study of collegiate endurance athletes, athletes with incomplete and complete RBBB demonstrated increased biventricular chamber dimensions and relative reductions in right ventricular (RV) systolic function, with the degree of change in RV size and function correlating with increased QRS duration and exercise exposure (Kim et al., 2011). In the absence of clinical symptoms or associated right precordial repolarization abnormalities suggestive of ARVC, the presence of incomplete RBBB should not be considered to represent cardiac pathology (Bussink et al., 2013). In our experience, asymptomatic endurance athletes with isolated RBBB and QRS duration <140 ms without repolarization abnormalities apart from concordant T wave inversions in V1 and V2 are unlikely to harbor significant cardiovascular disease. In contrast, atypical RBBB that have a QRS duration in excess of 140 ms or those that are associated repolarization abnormalities that extend beyond V2 should be pursued further, as they are likely to represent underlying structural cardiac disease. Similarly, there is a low prevalence of left bundle branch block (LBBB) reported in healthy athletic cohorts and although data is sparse, the presence of LBBB in an athlete does not appear to represent a physiologic response to exercise. LBBB is more likely a result of structural heart disease and data suggests that LBBB is a marker of future cardiovascular morbidity and mortality (Rabkin et al., 1980; Schneider et al., 1979).

Bradycardia

Sinus bradycardia is common and normal among trained endurance athletes. Profound bradycardia (<40 bpm), a result of heightened parasympathetic activity, can be seen during sleep or rest and is not associated with a poor prognosis. Bradycardia is not a concern in the asymptomatic well-trained athlete. Documentation of an appropriate increase in heart rate with exercise is typically sufficient to exclude a pathologic process.

Premature Beats

Premature beats (both atrial and ventricular) may be observed in trained athletes. Palpitations caused by premature beats are a common reason for athletes to seek medical assistance. Endurance athletes may be particularly aware of such alterations in rhythm, as they are typically lean and in sync with their bodies. Symptomatic premature beats are often described as a slight pause followed by a heavy, single, central thump. Evaluation with an echocardiogram is often required to exclude structural and valvular heart disease. Treadmill exercise stress testing can be utilized to assess the frequency of premature beats during exercise. Absence of structural heart disease in conjunction with suppression of premature beats during exercise is reassuring, and in this scenario premature atrial and ventricular beats are considered benign and without long-term consequences (Biffi et al., 2002, 2004).

Atrial Fibrillation

Atrial fibrillation (AF) may be problematic in the trained athlete. Studies suggest that AF is more common in endurance athletes, especially in the older athlete, compared to their sedentary counterparts (Sorokin et al., 2011; Mont et al., 2002; Molina et al., 2008). The mechanisms responsible for development of AF in endurance athletes are speculative. Postulated mechanisms include atrial dilatation seen in dynamic sports with increases in preload (Pelliccia et al., 2005), increased vagal tone, and inflammatory changes related to sports participation (Swanson, 2006). AF in endurance athletes presents in two distinct forms. The first is parasympathetically mediated and is characterized by the onset of AF during times of slow resting heart rate that can potentiate atrial escape (Stein et al., 2002). Athletes with this form of AF generally experience bouts of arrhythmia during sleep, quiet rest, or after meals. This is commonly referred to as "vagally-mediated" AF and accounts for about 70% of AF in athletes (Mont et al., 2008). Vagally induced AF almost never occurs with exercise, is four times more common in men (Coumel, 1994), and can be precipitated by alcohol (Yesil et al., 1999). The second form of AF is sympathetically mediated and is commonly triggered by exercise or significant psychological stress. The importance of differentiating these two forms of AF lies in their diametrically opposed treatment algorithms.

Initial evaluation includes a thorough history and physical followed by blood tests with evaluation of electrolytes and thyroid function. Additional testing to evaluate for cardiac structure and function with an echocardiogram is recommended. It is imperative that questioning include the use of supplements, caffeine, alcohol, and drugs as use of any of these may increase the likelihood of developing AF. Evaluation and treatment of underlying hypertension at rest and/or during exercise is required. Treatment is based on risk factors and symptoms with management options that include detraining, which can decrease the number of AF episodes (Hoogsteen et al., 2004), negative chronotropic or antiarrhythmic medications, and catheter-based ablation. For patients with paroxysmal AF and a structurally normal heart, a pill in the pocket approach with flecainide or propafenone can be effective in converting more than 90% of outpatient episodes (Alboni et al., 2004). Verapamil may be effective in athletes with sympathetically mediated AF. If ineffective, we recommend trial of antiarrhythmic agents. We reserve catheter-based ablation for athletes who have failed to remain in sinus rhythm on medications, those who experience side effects on medications, or those who prefer an ablation.

Ventricular Arrhythmias

Healthy athletes undergoing exercise testing may demonstrate short bursts of asymptomatic nonsustained ventricular tachycardia (VT). This finding should prompt testing to exclude structural heart disease which, if absent, portends a benign prognosis and does not require medical therapy or sport restriction. Sustained VT in a structurally normal heart is likely of RV outflow tract or fascicular origin and is generally amenable to catheter-based ablation. If the arrhythmia is successfully ablated and cannot be induced, we recommend that athletes wait a minimum of four weeks before resuming exercise. This may be longer than other recommendations but in our experience there is increased recurrence of arrhythmia if athletes resume play prematurely. VT in a structurally abnormal heart requires many considerations and should be managed according to guidelines (Pedersen et al., 2014). Symptomatic or sustained ventricular arrhythmias carry a high risk of adverse events and represent a medical emergency or at least a reason to prohibit training and competition until a competent sports cardiologist conducts a comprehensive assessment.

Patients deemed to be high risk for SCD independent of sports participation are recommended to have implantable cardioverter defibrillators (ICD)s. Importantly, guidelines specifically state that ICDs should not be placed for the sole purpose to allow sport participation. In those with preexisting ICDs or ICDs placed for high risk individuals there are concerns of device malfunction or injury. The interested reader is directed to a thorough discussion regarding sport participation with ICDs (Lampert, 2012).

Valvular Heart Disease

The evaluation of cardiac murmurs is a frequent source of consultation for the sports cardiologist. Assessing valvular heart disease in athletes is challenging as exercise-induced cardiac remodeling can create physiologic innocent flow murmurs that are difficult to distinguish from pathologic murmurs during physical examination. In young athletes, innocent flow murmurs reflect increased physiologic flow across the pulmonic valve and through the main pulmonary artery, while in older athletes this may be related to aortic sclerosis (Thompson, 2001). Athletes evaluated for valvular disease generally fall into one of three categories. In the first, examination and work up reveal a physiologic flow murmur. In the second, work up reveals severe valve disease or symptoms that

require valve intervention. In the third, there is clear valvular heart disease but treatment and/or activity recommendations are not clearly defined.

Echocardiography is essential in evaluating those with suspected valvular heart disease. However, in cases with equivocal history and echocardiograms, exercise testing can help with timing of intervention as it provides an objective functional assessment of an athletes' cardiopulmonary capacity and an indication as to whether the athlete is truly asymptomatic. The relevant findings include a drop or inadequate increase in blood pressure, arrhythmias, ischemic ECG changes, or impaired exercise tolerance.

Aortic stenosis (AS) is generally a result of degenerative valve disease, but in a younger athletic population bicuspid aortic valve and congenital AS are also commonly seen. The hemodynamic significance of any specified aortic valve area depends on the cardiac output. Since muscle mass is a determinant of resting cardiac output, larger individuals may have more severe hemodynamic impairment despite a larger absolute aortic valve area (Thompson, 2001). This may be a factor in athletes with increased body size and muscle mass. AS typically has a long asymptomatic period, but when symptoms do occur patients present with syncope, exertional intolerance, angina pectoris, and heart failure. Exercise testing can be invaluable in the assessment of athletes with severe AS who suggest that they are asymptomatic. Our practice is to closely observe asymptomatic athletes with severe AS, normal ejection fractions, and appropriate exercise capacity as the risk of surgery and anticoagulation likely outweigh any benefit of proceeding with surgery. In these cases, serial follow-up is paramount with the goal to intervene immediately at the onset of symptoms as a delay in intervention can lead to worse outcomes once there is a reduction in ejection fraction.

Chronic regurgitant lesions, including mitral and aortic regurgitation, can be well tolerated by endurance athletes for extended periods as the LV has undergone exercise-induced cardiac remodeling and thus is well adapted to accept the volume challenge. However, the bradycardia that is also seen in these athletes can worsen aortic regurgitation at rest. Additionally, static exercise, which is accompanied by increases in afterload, can worsen regurgitant valvular disease and thus athletes are advised to avoid isometric exercises. While generally well tolerated, it is important that athletes are queried for exercise-induced symptoms of heart failure.

Managing athletes with valvular heart disease requires a careful history, examination, and review of echocardiogram and exercise testing. Additionally, a sound understanding of each patient's goals and preferences will play a role in final recommendations. Due to high workloads, athletes may become symptomatic at earlier disease stages when compared to less active patients. Such cases are not part of the recently updated valvular heart disease guidelines (Nishimura et al., 2014) as athletes may become symptomatic at high intensity exercise with moderate levels of valve disease. The clinician must weigh the risk of intervening too soon and its downstream consequences of having a mechanical valve or finite life of bioprosthesis. If available, access to prior echocardiograms allows the clinician to follow changes in valve pathology and chamber dimensions over time and can help in determining timing of intervention.

Sports cardiologists should seek out surgeons that have an understanding of exercise physiology and surgeons should be made aware of the athletic ambitions of these patients. For instance, it would be important to discuss with a surgeon prior to mitral valve repair for severe mitral regurgitation that a slightly larger annuloplasty ring with mild residual mitral regurgitation is an acceptable and preferred outcome over facing the challenges of functional mitral stenosis if a smaller annuloplasty ring is placed.

Aortopathies

The hemodynamic load on the aorta is dependent on the type of sport. Endurance activities result in high volume aortic flow with modest systemic hypertension while isometric activities can cause profound systemic hypertension with normal aortic flow (Baggish and Wood, 2011). The impact of sport specific exercise training on aortic dimensions has not been definitively delineated as prior studies have had contradictory findings. Pelliccia et al. (2010) found that endurance trained athletes, specifically swimmers and cyclists, had the largest aortic root dimensions in a heterogeneous group of 2317 Italian athletes. Meanwhile, D'Andrea et al. (2010) measured aortic dimensions in 615 elite athletes (370 endurance-trained athletes and 245 strength-trained athletes) and found that the aortic root diameter was significantly larger among strength trained athletes. While conclusions regarding sport specific effects on aortic dimensions cannot be made, a finding in common among such studies is that the aortic root rarely exceeds the clinically accepted upper limits of normal (40–42 mm) in trained athletes. Thus, pending further studies, it seems that athletic training alone does not cause marked aortic dilation. Readers are referred to a review of this topic (Pelliccia et al., 2012). In athletes with aortic root >40–42 mm in the absence of diagnostic criteria for Marfan syndrome, bicuspid aortic valve, or any identifiable systemic disease, close evaluation and if athletic participation is allowed, close serial assessment is paramount.

Cardiomyopathies

The clinical task of differentiating marked exercise-induced cardiac remodeling from mild forms of HCM, familial or acquired dilated cardiomyopathy and ARVC should be undertaken by clinicians with sound understanding of each clinical entity. Missing a diagnosis of a cardiomyopathy can inappropriately put an athlete at increased risk for SCD. Alternatively, improperly diagnosing an athlete with a cardiomyopathy can have long term social, economic, and cardiovascular and mental health consequences.

There is no single diagnostic test with adequate accuracy to differentiate adaptive from pathological cardiomyopathy. Thus, we encourage clinicians faced with this diagnostic dilemma to begin the assessment with an integrated assessment of personal and family history, 12-lead ECG, and echocardiography. In many cases, information derived from this initial work up is sufficient for

diagnostic decision-making. If the diagnosis remains unclear, further measures including cardiac MRI, CPET, prescribed detraining and disease specific genetic testing may be considered. Cardiac MRI has become an invaluable tool for evaluation of the athlete with indeterminate cardiac enlargement. Cardiac MRI provides highly accurate assessment of myocardial thickness, chamber volumes, tissue composition, extracardiac anatomy and cardiac magnetic resonance-derived reference values in athletes have been published (Prakken et al., 2010). Additionally, use of gadolinium contrast with delayed imaging provides information about the presence and location of myocardial fibrosis. Specific myocardial fibrosis patterns are seen in distinct cardiomyopathies and can lead to the diagnosis in athletes with indeterminate cardiac enlargement (Maron et al., 2008; Prakken et al., 2009; Rubinshtein et al., 2010).

Hypertrophic Cardiomyopathy

HCM, characterized by ventricular hypertrophy in the absence of another cause and myocardial relaxation abnormalities, is a common condition encountered amongst those who care for athletes. With the prevalence of 1 in 500 people and increasing rates of screening and SCD awareness, more and more athletes are being diagnosed and followed. HCM is inherited in an autosomal dominant fashion and is caused by mutations in cardiac sarcomeric proteins. Phenotypic expression of the disease is highly variable within families. Diagnosis can be especially difficult if an athlete is in the "Maron grey zone" (Maron, 2003) and has properties of both athletic remodeling and HCM. A valuable approach to the origin of LV hypertrophy has been outlined (Maron et al., 1995). Tissue Doppler assessment can be valuable as early diastolic relaxation velocity has been shown to be normal or enhanced in athletes with LV hypertrophy resulting from exercise-induced cardiac remodeling (Pela et al., 2004; Zoncu et al., 2002). In contrast, pathologic forms of LV hypertrophy are typically associated with reduced early diastolic relaxation velocity and peak systolic tissue velocity (Matsumura et al., 2002; McMahon et al., 2004; Nagueh et al., 2001).

Management guidelines of symptomatic and obstructive HCM have been published (Gersh et al., 2011). These guidelines also discuss ICD criteria for primary prevention. Sport participation guidelines recommend IA sports for athletes with HCM. Our approach starts with a maximal effort CPET to evaluate for blood pressure response to exercise as well as for arrhythmias. If exercise testing is unremarkable and the athlete does not have any high-risk features as per the guidelines, we use a less conservative approach for our exercise recommendations. Due to the known long-term risks of a sedentary lifestyle and knowledge that arrhythmias tend to be provoked with sympathetic surges, we recommend that athletes with HCM engage in low to moderate sustained aerobic exercise for cardiovascular health. It is vital to stress the importance of an appropriate warm up and a cool down and avoidance of activities that require sprint physiology such as high intensity interval training or cross fit type training. Additionally, we recommend that athletes stay below their ventilatory threshold (determined by CPET) as prior studies in healthy subjects show an initial linear increase in catecholamines with increasing exercise intensity but a sharp increase in catecholamine levels after crossing the ventilatory threshold (Urhausen et al., 1994; Weltman et al., 1994). We review the guidelines with athletes, discuss our approach and rationale, and engage in shared decision-making.

Arrhythmogenic Right Ventricular Cardiomyopathy

Managing athletes with ARVC is complex. While it is clear that patients with ARVC should not participate in competitive or endurance sports, current guidelines also subject those with borderline or even a possible diagnosis of ARVC to these recommendations (Maron et al., 2015c). This is because patients with ARVC have a predisposition to sudden death and RV dysfunction. Exercise has been shown to both increase the incidence of VT and the progression of RV dilation. In heterozygous plakoglobin-deficient mice, vigorous exercise was associated with greater RV enlargement, RV systolic dysfunction, and ventricular arrhythmias when compared to wild-type control (Kirchhof et al., 2006). These findings were corroborated in a study of gene positive endurance athletes. Gene positive athletes had symptoms at a younger age, lower lifetime survival from VT/ventricular fibrillation and heart failure compared to more sedentary gene positive individuals (James et al., 2013).

A recent consensus statement published on the treatment of ARVC gives a IIa recommendation to using beta blockers in all patients with ARVC irrespective of arrhythmias (Corrado et al., 2015). This recommendation stems from the fact that beta blockers may reduce exercise-induced VT, may decrease progression to heart failure, and have a potential to decrease disease progression by lowering RV wall stress.

Dilated Cardiomyopathy

Dilated cardiomyopathy is characterized by dilation and impaired systolic function of one of both ventricles. Individuals may be asymptomatic or have end-stage heart failure, arrhythmias, and/or thromboembolic complications (Saberi and Day, 2016). About 20%–30% are familial and inherited in an autosomal dominant pattern and if present, children and family members should be screened (Grunig et al., 1998; Goerss et al., 1995). Management guidelines have also been published (Yancy et al., 2013).

Left Ventricular Noncompaction

LV noncompaction is characterized by prominent LV trabeculization and deep intertrabecular recesses resulting in an outer compacted and inner noncompacted myocardial layer. Autosomal dominant inheritance is most common but can be sporadic (Zaragoza et al., 2007; Weiford et al., 2004). Clinical expression is variable, and reduced ejection fraction, ventricular arrhythmias,

thromboembolic disease, and sudden death have all been reported (Greutmann et al., 2012; Oechslin et al., 2000). Diagnosis can be made by echocardiography but cardiac MRI can better define the extent of disease and presence of fibrosis. Few competitive athletes with LV noncompaction have been reported clinically and as a result, the consequences of the disease in this population remain unknown. The risk for adverse outcomes seems to be associated with LV systolic dysfunction or VT (Brescia et al., 2013). Similarly, nonathletes with a normal ejection fraction and chamber size have a good prognosis (Murphy et al., 2005). However, without data on long-term follow up, we cannot adequately risk stratify these athletes.

Conclusions

There has been a steady rise in competitive sport participation worldwide. Regular exercise has many cardioprotective effects including mitigating traditional cardiovascular risk factors and reducing cardiovascular death. However, athletes are not immune to cardiovascular disease and the majority of SCD in athletes is in the presence of underlying and previously undetected cardiovascular disease.

Additionally, participants in competitive sport now range from lifelong habitual athletes to weekend warriors of different ages, social habits, and cardiovascular risk factors. Thus, the benefits of increased exercise doses may be offset by underlying risk factor profiles. Updated guidelines on competitive sport participation should be used as a reference but prove to be too conservative for many athletes and thus a shared decision-making model is essential in the care of athletes with cardiovascular disease. As a result, providers caring for athletes need to be aware of the nuances in history taking, appropriate work up and management of cardiovascular disease in this unique patient subset.

Introduction

Cardiovascular diseases account for about one out of three deaths in the industrial world, and about 45% of the cardiac deaths are sudden cardiac deaths attributed to abnormal cardiac electrical activity (arrhythmic events) such as ventricular fibrillation (VFib) (Mozaffarian et al., 2016; Abdelghani et al., 2016). In this article, we will consider underlying mechanisms of the most prominent cardiac arrhythmias such as ventricular tachyarrhythmias (VT and VFib), long QT syndrome (LQTS), short QT syndrome (SQTS), catecholaminergic polymorphic ventricular tachycardia (CPVT), arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D), and Brugada syndrome (BrS). To aid understanding of this material, we will start from brief overview of pertinent electrophysiological concepts.

Important Electrophysiological Concepts

Understanding of mechanisms of arrhythmias relies on several important electrophysiological concepts that describe membrane currents, changes in membrane potential (action potential, AP), and how these changes in membrane potential produce macroscopic cardiac electrical activity (electrocardiogram, ECG).

Membrane Currents

Membrane currents are movements of ions across cell membrane that are driven by electrochemical gradients. At its simplest, electrochemical gradient can be viewed as a difference in ion concentration between inside and outside of the cell (**Fig. 1A**). Currents are grouped by carrier ions: Na^+ currents (I_{Na}), Ca^{2+} currents (I_{Ca}), and K^+ currents (I_K) are the major currents underlying electrical activity in cardiac cells (Catterall, 2014; Nerbonne, 2014; Oudit et al., 2004; Rose and Backx, 2014). Depending on the direction of the flow, currents can be inward (current flows from outside to inside the cell) or outward (current flows from inside to outside of the cell). Since currents are driven by ionic gradients, which are generally stable under normal physiological conditions, each type of the major current has a typical direction of the flow. I_{Na} and I_{Ca} are inward, and I_K is outward. Directions of the current flow will determine its action on membrane potential. Inwardly flowing currents will bring more positive ions (Na^+ and Ca^{2+}) inside the cell making inside of the cell less negative or polarized; hence, inwardly flowing currents, such as I_{Na} and I_{Ca}, are depolarizing. Conversely, outwardly

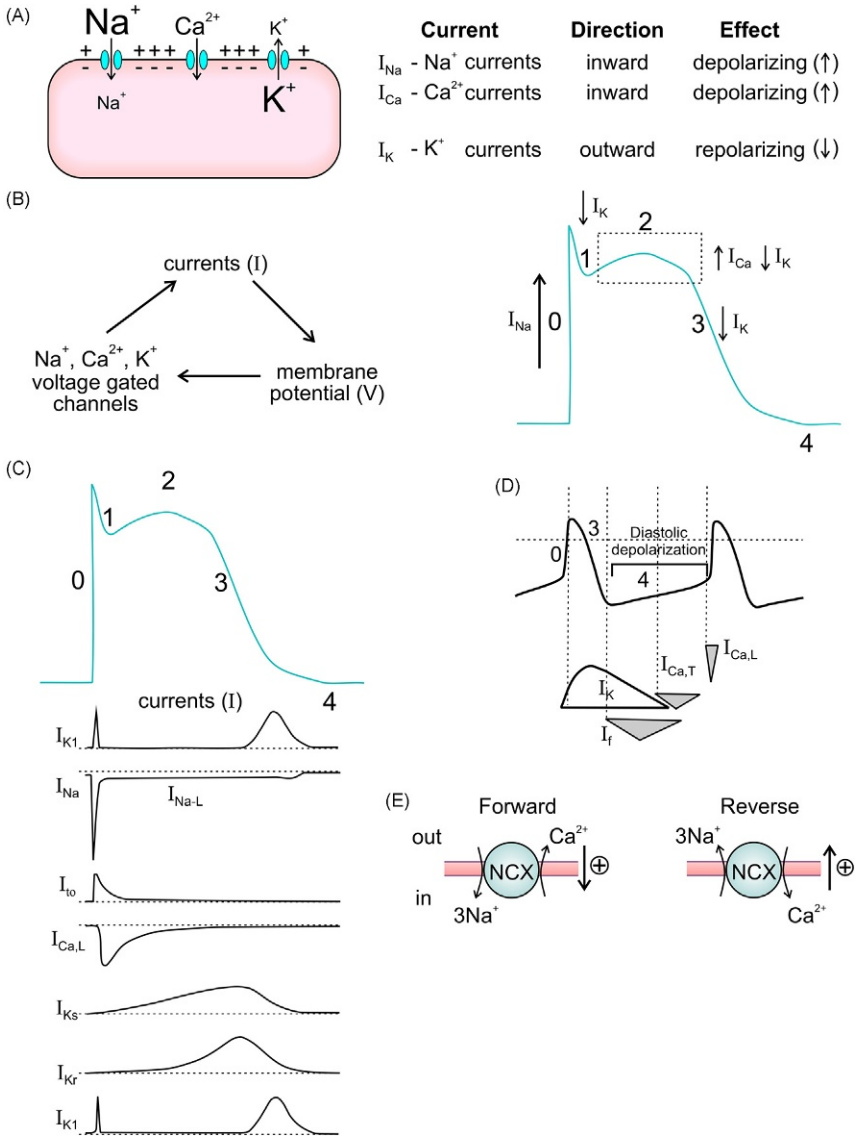

Fig. 1 Electrophysiological concepts of normal electrical activity. (A) Main membrane currents of ventricular myocyte and their effects on the membrane potential. (B) Ventricular action potential and its phases. (C) Currents underlying ventricular action potential. (D) Currents underlying pacemaker action potential. (E) Modes of function of Na^+–Ca^{2+} exchanger NCX and current via NCX.

flowing currents will remove positive ions (K^+) from inside the cell making inside of the cell more negative restoring cell membrane polarization; hence, outwardly flowing currents, such as various I_K, are repolarizing (Fig. 1A).

Membrane Potential: Action Potential

Self-propagating change in membrane potential that goes from depolarization to repolarization is called AP. AP is driven by ionic currents that depolarize and repolarize the membrane and changes in the ionic currents (I) brought by voltage-gated channels reacting to the changes in membrane potential (V) (Fig. 1B). Ventricular AP is divided in phase 0 (fast depolarization), phase 1 (initial repolarization), phase 2 (plateau that is characterized by slow change of membrane potential), phase 3 (repolarization), and phase 4 (resting phase that is characterized by a stable negative potential) (Fig. 1B). During phases 0 through 2 cardiac myocytes are in an absolute refractory period and cannot be re-excited. In phase 3, excitation is possible, but threshold of stimulation is higher. Finally, in phase 4, the myocyte enters a state of normal excitability.

Ionic Currents Underlying Ventricular Action Potential

Normally, ventricular myocytes have stable negative membrane potential due to presence of large number of constituently open K^+ channels (Kir2.1, *KCNJ2*). These channels produce outward repolarizing current (I_{K1}) in response to any depolarization or injection

of inward current counteracting depolarizing influence and stabilizing membrane potential at the resting levels. However, if depolarization is strong enough to produce inward current (I_{Na}) larger, then counteracting outward I_{K1}, AP begins (Fig. 1C). In phase 0, large inward Na^+ current (I_{Na}) via $Na_v1.5$ (*SCN5A*) depolarizes the cell producing upstroke of AP (Fig. 1C). Initial repolarization (phase 1) follows and is driven mainly by repolarizing outward K^+ current I_{to} mainly via $K_v4.1$ (*KCND1*). In the absence of I_{to}, APs do not have "notch" and transition gradually to plateau (phase 2) (Fig. 1C). Plateau phase is characterized by relative balance of inward currents (mainly L-type Ca^{2+} current, $I_{Ca,L}$, via $Ca_v1.2$, *CACNA1C*) and outward K^+ currents I_{Ks} (via $K_v7.1$, *KCNQ1*) and I_{Kr} ($K_v11.1$, *KCNH2*) (Fig. 1C). Once balance is decidedly shifted toward K^+ currents, repolarization (phase 3) begins. This phase is dominated by I_{Ks}, I_{Kr}, and later I_{K1}, which finishes repolarization and stabilizes the cell in the rest phase (phase 4) (Fig. 1C).

Ionic Currents Underlying Pacemaker Action Potential

Pacemaker cells of sinoatrial node (SA) have a distinct AP that is characterized by diastolic depolarization in phase 4 and relatively slow depolarization in phase 0 that is driven by $I_{Ca,L}$ (Fig. 1D) rather than I_{Na} as in ventricular myocytes. Diastolic depolarization is driven by inward "funny" current I_f (via HCN channels, *HCN4*) that unlike many other voltage-gated channels increases with more negative voltages hence "funny." As diastolic depolarization progresses T-type Ca^{2+} current, $I_{Ca,T}$, overtakes as depolarizing current, and once membrane is depolarized enough to activate L-type Ca^{2+} current upstroke or phase 0 of pacemaker AP begins (Fig. 1D). Phase 0 of pacemaker AP transition to repolarization (phase 3) as K^+ currents start to activate. Repolarization phase of pacemaker AP has a large contribution from acetylcholine-activated K^+ current $I_{K,Ach}$ (GIRK4, *KCNJ5*). Pacemaker rate is promoted by β-adrenergic agonists and by reduction of external K^+ (leading to reduction in repolarizing I_{K1} that counteracts the depolarization of membrane potential during diastolic depolarization).

Na^+–Ca^{2+} Exchanger (NCX) as a Modulator of Action Potential

NCX is an exchanger that exchange 3 Na^+ for 1 Ca^{2+}. In forward mode, 3 Na^+ ions move inside the cell extruding 1 Ca^{2+} ion and producing (3+)–(2+)=(1+) net charge transfer that generates inward current (Fig. 1E, left). In reverse mode, 3 Na^+ ions move out of the cell bringing in 1 Ca^{2+} ion resulting in outward current (Fig. 1E, right). Direction of the flow through NCX is determined by gradient of Na^+ and Ca^{2+} across membrane, and normally, during plateau phase, NCX is in reverse mode and in the forward mode during repolarization (Courtemanche et al., 1998). The dependence of NCX on intracellular Ca^{2+} (Ca^{2+} gradient across membrane) creates a feedback link between Ca^{2+} release and AP affecting repolarization of pacemaker and ventricular AP (Antzelevitch and Burashnikov, 2011). Depolarizing current of forward mode of NCX is responsible for the generation of arrhythmogenic responses such as delayed afterdepolarizations (DAD) and late phase 3 early afterdepolarization (EAD).

Variability in Electrophysiological Properties Across Myocardium

Within ventricle, going from outside in, three types of ventricular myocytes can be distinguished functionally and electrophysiologically: epicardial, M-, and endocardial cells (Antzelevitch and Burashnikov, 2011; Antzelevitch et al., 1991). These cells differ in current composition and thus AP shape (Fig. 2A). Epicardial myocytes have very prominent "notch"-shaped early repolarization due to large repolarizing K^+ current (I_{to}) and relatively short duration due to large contribution from repolarizing K^+ current (I_{Ks}) (Fig. 2A, left). M-myocytes have relatively low density of I_{to} and less prominent notch than epicardial myocytes, and their AP is long due to joint effects of lower density of repolarizing K^+ current (I_{Ks}) and higher density of depolarizing Na^+ current I_{Na}-late (I_{Na-L}) (Fig. 2A, middle). Endocardial myocytes have no "notch" phase (the lowest I_{to} density) and AP duration similar to epicardial myocytes (Fig. 2A, right).

From Action Potential to ECG

Spread of excitation through cardiac tissue can be measured at macroscopic level as ECG. ECG reflects important features of underlying AP in different parts of the heart. Spread of excitation through atria produces P-wave of ECG (Fig. 2B). QRS complex of ECG represents spread of excitation through ventricles and followed by normally isoelectric ST segment. At that time, ventricles are fairly uniformly depolarized and membrane potential through ventricular tissue changes little because ventricular myocytes are in plateau phase of AP, and thus heart as a whole becomes isoelectric. Transition of AP from plateau to repolarization produces T-wave of ECG (Fig. 2B). Since Q-wave corresponds to the beginning of ventricular excitation and the T-wave reflects repolarization of ventricles, QT intervals correlate with the duration of ventricular AP.

Mechanisms of Arrhythmias

Arrhythmias can arise from changes in AP, abnormal automaticity, abnormal and triggered electrical activity, and re-entry. In this section, we will consider underlying mechanism of these phenomena and how they manifest themselves at cellular and organ level.

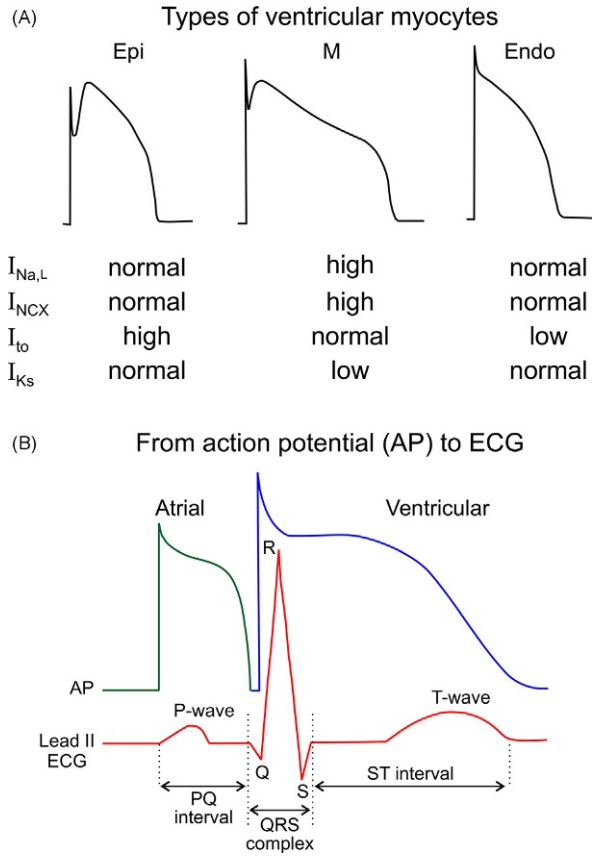

Fig. 2 Action potential in different types of ventricular myocytes (A) and correspondence between cellular excitation of cardiac tissue (action potentials, AP) and electrocardiogram (ECG) (B).

Changes in ECG and Action Potential in QT Syndromes

In long QT (LQT) and short QT (SQT) syndromes, QT interval is prolong or shortened, respectively. These changes arise from changes in AP, which becomes longer (LQT) or shorter (SQT) due to mutations that alter currents underlying AP. In many cases, mutations happen in channel proteins and these mutations are classified as channelopathies. Since AP duration is a delicate balance between opposite influences of depolarizing (I_{Na} and I_{Ca}) and repolarizing (various K^+ currents) currents, the effect of channelopathy depends on the direction of the current and the timing of the current flow within AP. In the case of LQT syndromes, loss-of-function mutation in channels carrying repolarizing K^+ currents will leads to reduction ($-\Delta$) in repolarizing currents, prolongation of AP, and prolongation of QT interval (Fig. 3A). For example, loss-of-function mutations LQT1 and LQT2 affect Ks channels and Kr channels, respectively, producing reductions ($-\Delta$) in corresponding repolarizing K^+ currents I_{Ks} or I_{Kr} and leading to prolongation of AP and in turn QT interval. Conversely, LQT syndrome may arise from the increase ($+\Delta$) in depolarizing currents that will lead to prolongation of AP duration and in turn QT interval (Fig. 3B). For example, gain-of-function LQT3 mutations increase ($+\Delta$) depolarizing Na^+ current (I_{Na}). In the case of SQT syndromes, mutations that cause increases ($+\Delta$) in repolarizing K^+ currents (gain-of-function mutation) will lead to promotion of repolarization, and as a result shortening of AP leading to shorter QT interval (Fig. 3C). Gain-of-function mutations SQTS1, SQTS2, and SQTS3 affect Kr, Ks, and K1 channels, respectively, producing increases in corresponding repolarizing K^+ currents I_{Kr}, I_{Ks}, and I_{K1} shortening AP duration and QT interval as a consequence. Conversely, SQT syndrome can result from decrease ($-\Delta$) in depolarizing currents that will lead to similar effect in shortening of AP duration and in turn QT interval (Fig. 3D). Both SQTS4 and SQTS5 reduce depolarizing $I_{Ca,L}$ by affecting either α (SQTS4) or β (SQTS5) subunit of the L-type Ca^{2+} channel. Abnormal changes in length of AP predispose to arrhythmic events such as EAD in the case of LQT syndromes and re-entrant arrhythmia in the case of SQT syndromes.

Abnormal Automaticity

Abnormal automaticity includes reduced automaticity, enhanced automaticity, and protected pacemaker (parasystole). In the case of *reduced automaticity*, reduction in the rate of primary pacemaker (SA) may lead to shift of the rhythm generation to subsidiary pacemakers (atrioventricular (AV) node or His bundle). The underlying causes might be (i) impaired or blocked impulse

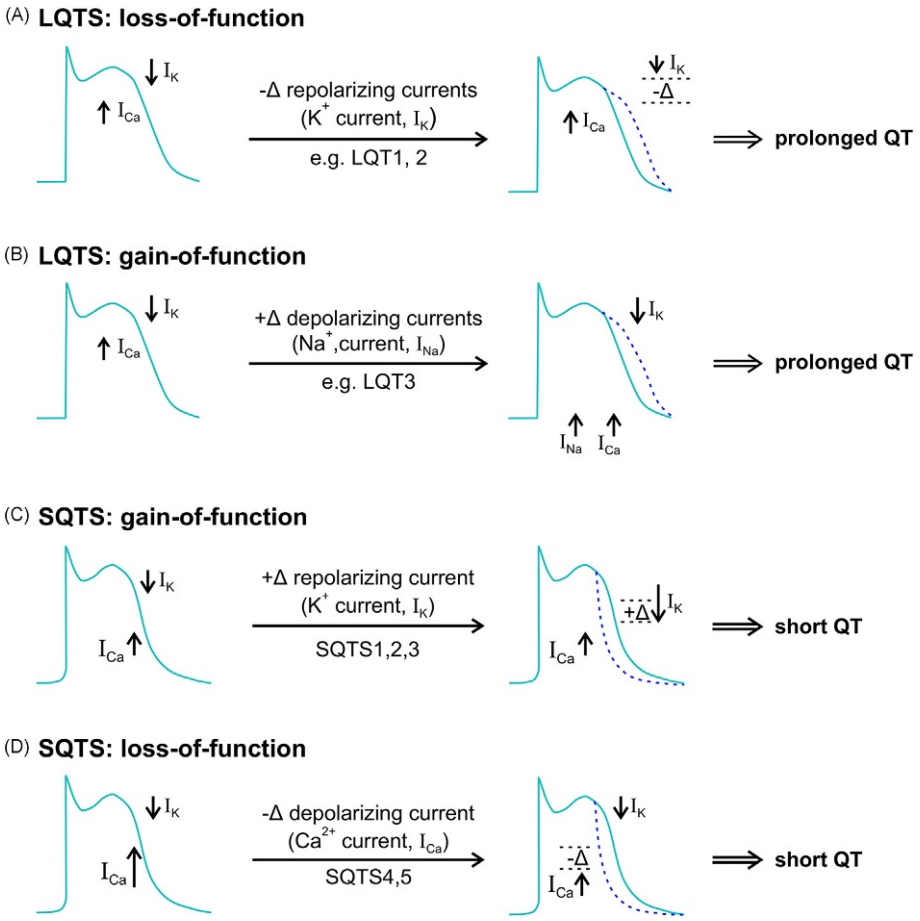

Fig. 3 Changes in action potentials due to long QT syndrome (LQTS) and short QT syndrome (SQT). (A) LQTS: prolongation of action potential due to loss-of-function mutation in repolarizing current. (B) LQTS: prolongation of action potential due to gain-of-function mutation in depolarizing current. (C) SQTS: shortening of action potential due to gain-of-function mutation in repolarizing current. (D) SQTS: shortening of action potential due to loss-of-function mutation in depolarizing current.

conductance out of SA node or (ii) increased vagal activity that suppresses SA node (Antzelevitch and Burashnikov, 2011). In either case, since the intrinsic rate of subsidiary pacemakers is lower, reduced automaticity will manifest itself as bradycardia. Another possible reason for reduced automaticity can be channelopathy of HCN channel responsible for I_f that drives diastolic depolarization. Loss-of-function mutations in *HCN4* gene cause familial bradycardia (Schulze-Bahr et al., 2003; Nof et al., 2007).

Enhanced automaticity arises when atrial and/or ventricular myocytes that normally do not display diastolic depolarization acquire that property. This type of automaticity develops in response to various conditions that lead to more depolarized resting potential (e.g., ischemia, infarction, experimental current injection) and is called depolarization-induced automaticity (Antzelevitch and Burashnikov, 2001). It is characterized by the rates substantially higher than normal automaticity, and similarly to normal automaticity, it arises from time-dependent reduction in repolarizing I_K and time-dependent activation of I_{Ca} that makes it sensitive to external K^+, β-adrenergic agonists, and Ca^{2+} channel blockers (Antzelevitch and Burashnikov, 2001, 2011).

Parasystole is arrhythmia caused by activity of additional secondary pacemaker that is protected (fully or partially conductively isolated) from primary pacemaker (SA node). Normally, secondary pacemakers are reset by excitation front generated by the activity of primary pacemaker. However, damage of the tissue (ischemia, infarction) may leads to creation of parasystolic focus. A region of cardiac tissue that is conductively isolated from entrance of excitation (entrance block) generated by primary pacemaker, but permit excitation generated with isolated tissue to exit. Such parasystolic focus will produce ectopic beats and may mimic re-entry patterns (Antzelevitch and Burashnikov, 2011; Jalife and Moe, 1979; Antzelevitch et al., 1983).

Abnormal and Triggered Electrical Activity at the Cellular Level

Abnormal electrical activity at cellular level can be divided in two major groups by their timing in relation to repolarization phase of AP: EAD and DAD. EAD occurs during phase 2 (late plateau) or phase 3 (repolarization) of AP, whereas DAD happens after repolarization has been completed. In either case, when EAD or DAD reach threshold potential spontaneous AP (triggered activity) is generated that may lead to extrasystole or initiation of re-entrant arrhythmias.

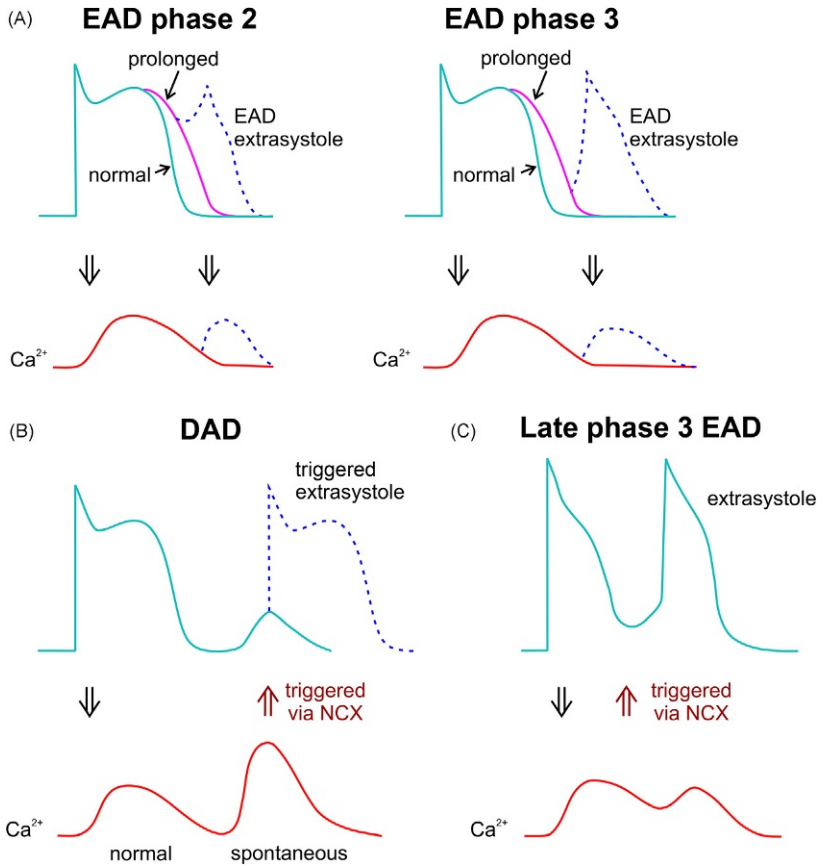

Fig. 4 Abnormal and triggered electrical activity at the cellular level. (A) Depictions of action potential with early afterdepolarization (EAD): phase 2 EAD (left), phase 3 EAD (right) and their corresponding Ca^{2+} releases (bottom). (B) Depiction of action potential followed by delayed afterdepolarization (DAD) and triggered extrasystole (*dashed line*) driven by spontaneous Ca^{2+} release (bottom). (C) Late phase 3 EAD triggered by normal Ca^{2+} release (bottom) from abnormally short action potential.

EAD are mainly arise when AP duration is prolonged due to slowing of the rate of repolarization. Slow repolarization allows inward (depolarizing) currents such as I_{Ca} and/or I_{Na} to recover and re-activate prematurely (**Fig. 4A**). Activation of recovered inward currents create an additional depolarization (abnormal electrical activity). EAD during phase 2 are mainly triggered by recovering of I_{Ca}, whereas EAD during phase 3 are triggered by recovering of I_{Na} (**Fig. 4A**). Pharmacological interventions and pathophysiological conditions promoting EADs act through one or more of four mechanisms: (i) reduction of repolarizing K^+ currents (I_{Kr}, class IA and III antiarrhythmic drugs; I_{Ks}, chromanol 293B; I_{K1}); (ii) increase in the availability of Ca^{2+} current (Bay K 8644, catecholamines); (iii) increase in the Na^+–Ca^{2+} exchanger current (I_{NCX}) caused by increase in intracellular Ca^{2+} or upregulation of the I_{NCX}; and (iv) increase in late Na^+ current (I_{Na-L}) (aconitine, anthopleurin-A, and ATX-II) (Antzelevitch and Burashnikov, 2011). EAD are mainly invoked in M-myocytes due to relatively weak slow delayed rectifier K^+ current (I_{Ks}) and larger contribution of late Na^+ current (I_{Na-L}) and NCX. Block of I_{Ks} (e.g., block with chromanol 293B) allows to generate EAD in other myocardial cells (Aiba and Tomaselli, 2010).

DAD are induced at relatively rapid rates and under conditions that promote increase in intracellular Ca^{2+} (block of Na^+/K^+ pump by digitalis) (Ferrier et al., 1973; Rosen et al., 1973) and build-up of Ca^{2+} in sarcoplasmic reticulum (β-adrenergic stimulation by catecholamines) (Priori and Corr, 1990). DAD is a result of abnormal spontaneous Ca^{2+} release from sarcoplasmic reticulum (**Fig. 4B**), which leads to depolarization of membrane by forward mode of NCX: intracellular Ca^{2+} is exchanged to three extracellular Na^+ producing net positive movement of ions into the cell (depolarizing inward current). This mechanism is responsible for the generation of arrhythmias in CPVT (Priori and Chen, 2011; Kazemian et al., 2011; Zhabyeyev et al., 2013). In CPVT, mutations in cardiac Ca^{2+} release channel (*RYR2*) or cardiac calsequestrin (*CASQ2*) lead to increase in probability of spontaneous Ca^{2+} release (store overload induced Ca^{2+} release, SOICR) that triggers DADs and sometimes EADs via NCX. The hallmark feature of CPVT is that abnormal Ca^{2+} overload happens as a consequence of increased concentration of circulation catecholamines during exercise or stress (Priori and Chen, 2011).

Late phase 3 EAD is abnormal electrical activity that combines properties of classical EAD and DAD (Burashnikov and Antzelevitch, 2003, 2006). Similarly to classical EAD, late phase 3 EAD happens before repolarization is completed. Similarly to DAD, late phase 3 EAD is triggered by Ca^{2+} release from SR, but unlike DAD it triggered by normal and not spontaneous (abnormal) Ca^{2+} release (**Fig. 4C**). The triggering of EAD by normal Ca^{2+} release is possible because AP is shortened considerably

and Ca^{2+} release is enhanced (Burashnikov and Antzelevitch, 2003). Such conditions may arise when both sympathetic and parasympathetic influences are active at the same time. Late phase 3 EADs have been shown to be responsible for atrial and ventricular fibrillations (Patterson et al., 2005; Ogawa et al., 2009).

Re-Entrant Arrhythmias

Besides abnormal electrical activity on cellular level, arrhythmia at tissue/organ level can also be produced through re-entry of excitation. Re-entry can be classified as anatomical or functional. Anatomical re-entry is re-entry around anatomical obstacle like scar or damaged tissue. Functional re-entry requires spatial heterogeneity in repolarization and/or conductivity to arise. Re-entry may or may not require a circular movement of excitation.

Re-entry around anatomical obstacle is conceptually the simplest form of re-entry. In this type of re-entry, excitation travels in a closed circuit within tissue (**Fig. 5A**) generating its own rhythm independent of normal automaticity generated in right atrial node, and this abnormal rhythm can propagate through the heart by conduction system. Re-entry circuit can be very limited and local resulting in local re-entry, or the circuit can encompass the whole heart producing global re-entry. In the simplest instance, ring model (Mayor, 1906), re-entry occurs around an obstacle (e.g., scar) provided criteria of (i) unidirectional block and (ii) size of the circuit are met. In this model, excitation travels by two different pathways: "slow" and "fast" (**Fig. 1F**) (Wit et al., 1972). Difference in conduction may be either geometrical ("slow" pathway is longer than fast) or intrinsic (tissue in "slow" pathway conducts excitation slower). In either instance, initial excitation spreads through both pathways with different durations. In the "fast" pathway excitation spreads and excites tissue in the "slow" pathway from the other end until excitations meet. That creates region of depolarized cells (+), which acts as a barrier for subsequent regular excitations creating a unidirectional block (**Fig. 5B**, initial). When the next regular excitation arrives, it cannot travel through the "slow" pathway because cells in this pathway are still depolarized (+) and cannot be re-excited, so excitation travels via "fast" pathway reaches slow pathway, spreads in the opposite direction, and passes to the "fast" pathway because, by the time the excitation reaches reflection point, the depolarized cells have

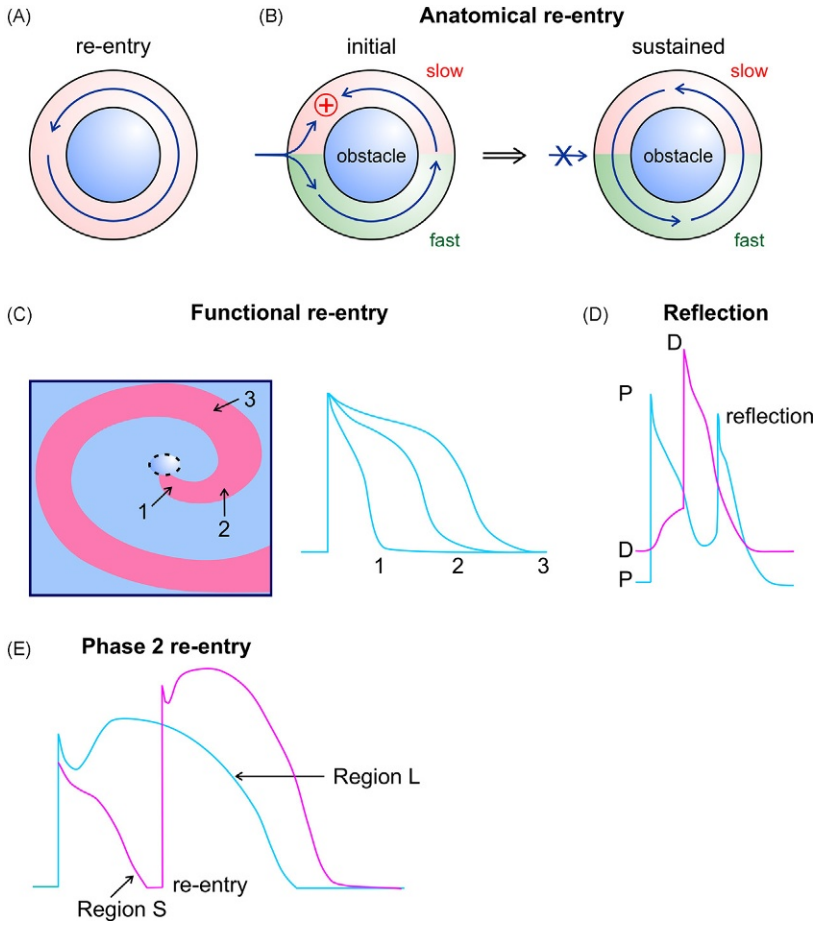

Fig. 5 Mechanisms of re-entry. (A) Re-entry around anatomical obstacle. (B) Formation of re-entry around anatomical obstacle. (C) Functional re-entry: spiral wave of excitation (right: excited regions in *pink* and repolarized regions in *blue*) and corresponding action potentials. (D) Reflection of the excitation across inexcitable segment: electrical activity at the proximal end (P) and electrical activity at distant end (D). (E) Phase 2 re-entry between region with long action potential duration (L) and the region with the short action potential duration (S).

repolarized and became excitable again allowing the excitation to pass to the "fast" pathway producing sustained re-entry (**Fig. 5B**, sustained). Sustained re-entry requires a circuit that is large enough for excitation to travel to allow cells to recover in between excitations. Reduction of conduction velocity (CV) or duration of AP (refractory period) can significantly reduce the required limit of the path length for the development and maintenance of re-entry (Antzelevitch and Burashnikov, 2011).

Re-entry without anatomical obstacle can arise if two conditions are met: (i) considerable heterogeneity in repolarization of AP and (ii) considerable slowing of conduction. This type of re-entry manifest itself as spiral waves (**Fig. 5C**) centered on cores. Slowing of conduction velocity toward the core allows curvature of wave to increase and wave length (WL; spatial extension of the excited state) to decrease toward the core and form a spiral (**Fig. 5C**) (Jalife, 2004). Spiral waves are used to explain the ECG patterns observed during monomorphic and polymorphic ventricular tachycardias (VT) as well as during fibrillation. Monomorphic VT can be explained as the spiral wave with "anchored" core, whereas polymorphic VT produced if the core drift through myocardium. In VFib, there are multiple drifting and breaking up spiral waves (Gray et al., 1995).

Reflection is a re-entry that does not require circular movement of excitation. Reflection arises as a result of back-and-forth impulse transmission across inexcitable segment of the tissue. Inexcitable segment of the tissue (gap) will produce delay in forward (proximal (P) to distal (D)) transmission, and in the distal segment of the tissue AP (D) will arise with considerable delay. That AP in turn will impose back a depolarizing (excitatory) influence across the same gap with a delay, and that delayed depolarization across the gap can produce another AP (reflection) at the proximal end (P) provided that proximal end had repolarized enough to be re-excited again (**Fig. 5D**) (Antzelevitch et al., 1980; Antzelevitch and Moe, 1981).

Phase 2 re-entry is a re-entry of focal origin, and this type of re-entry does not require circular movement of excitation for initiation. Phase 2 re-entry occurs under conditions of severe spatial heterogeneity of repolarization. The re-entry arises when one region with "long" AP (L) that has phase 2 (plateau) is linked and closely located near another region with "short" AP (S) that lack phase 2 (plateau). In this situation, phase 2 of region L will re-excite another AP in region S shortly after termination of normal AP in region S that was initiated in lockstep with original excitation (**Fig. 5E**) (Krishnan and Antzelevitch, 1993; Di Diego and Antzelevitch, 1993; Lukas and Antzelevitch, 1996). Phase 2 re-entry can initiate circular movement re-entry in ischemic conditions due to activation of repolarizing ATP-dependent K^+ current ($I_{K,ATP}$) in ischemic regions of the heart creating necessary steep gradient in repolarization between still perfused (no $I_{K,ATP}$ and long AP with phase 2) and ischemic regions ($I_{K,ATP}$ activated and short AP lacking phase 2) (Lukas and Antzelevitch, 1996). Also, phase 2 re-entry is considered a mechanism responsible for closely coupled extrasystole and initiation of ventricular tachycardia (VT)/ventricular fibrillation (VFib) episodes connected to BrS (Antzelevitch and Burashnikov, 2011; Antzelevitch, 2006; Antzelevitch and Yan, 2010).

Spatial dispersion of repolarization: Ventricular myocardium is electrophysiologically heterogeneous tissue that consists of at least three distinct cell types: epicardial, M, and endocardial myocytes. The cells are differ in phase 1 (I_{to} and I_{Na-L}) and phase 3 (I_{Ks}) repolarization as well as AP duration (Antzelevitch and Burashnikov, 2011; Antzelevitch et al., 1991). Beside different types of myocardial cells, epicardial and M-myocytes differ between left and right ventricle with right ventricle having more prominent I_{to} (Di Diego et al., 1996; Volders et al., 1999). Amplification of normally present transmural differences is responsible for transition of relatively benign changes in APs associated with Brugada, LQT, and sort QT syndromes as well as CPVT to re-entrant arrhythmias such as VT and VFib (Antzelevitch and Burashnikov, 2011; Antzelevitch and Patocskai, 2016). The presence of large dispersion of repolarization within cardiac tissue increase the risk that one still depolarized part of myocardium (long AP duration, EAD, DAD, and/or extrasystole) will re-excite another already repolarized part of myocardium (short AP duration) initiating and sustaining re-entry. In the case of ARVC/D, spatial dispersion of repolarization can arise from mutations of desmosome related genes leading to impaired cell-to-cell coupling, fibrosis, and adiposis (Gerull et al., 2004; Thiene and Basso, 2001). These disruptions give rise to re-entry circuits and local automaticity, which in turn can lead to the development of re-entrant arrhythmias (VT and VFib).

Brugada Syndrome: Action Potential Changes, Dispersion of Repolarization, and Re-Entrant Arrhythmias

BrS is arrhythmia characterized by ST-elevation in the right precordial leads (V1–V3) that produces two distinct ECG patterns "saddle back" and "coved." The syndrome is linked to 4%–12% of sudden cardiac deaths in the general population (Juang and Huang, 2004; Watanabe and Minamino, 2016). Prevalence of the syndrome ranges from 1–5 in 10,000 for western countries (Berne and Brugada, 2012) to 12 in 10,000 for Southeast Asia and Japan with an average age of diagnosis of 41 ± 5 years (Antzelevitch and Patocskai, 2016; Watanabe and Minamino, 2016). Arrhythmic events associated with BrS occur mainly at rest, during sleep, and after meal (Shimizu, 2005). The diagnosis of BrS is based exclusively on the presence of a specific ST segment elevation in one or more right precordial leads spontaneously or due to provocative agents (Richter et al., 2010). BrS is associated with mutation in 19 genes (for review see (Antzelevitch and Patocskai, 2016)).

Mechanism of Brugada syndrome: Electrocardiographic changes associated with BrS has been explained as (i) conduction delay in the epicardium of free wall of right ventricular outflow tract (Tukkie et al., 2004) and/or (ii) premature repolarization in RV epicardium with or without the loss of plateau phase of epicardial action potential (AP) (Antzelevitch, 2001). The cellular mechanisms underlying the latter are summarized in **Fig. 6**. Normally, there is small difference between epicardial (Epi) and endocardial (Endo) APs during plateau (**Fig. 6A**) resulting in little transmural voltage gradient and the isoelectric ST segment (**Fig. 6A**). In addition to that, epicardial repolarization (Epi) precedes endocardial (Endo) producing positive transmural gradient (red arrow) and positive T-wave (**Fig. 6A**). In the case of BrS, two main ECG patterns can appear: "saddle back" or "coved." Saddle back pattern is a result of an increase in early repolarization in epicardium with little or no change in endocardial repolarization (transmural dispersion in early repolarization). That dispersion produces positive transmural voltage gradient during plateau phase

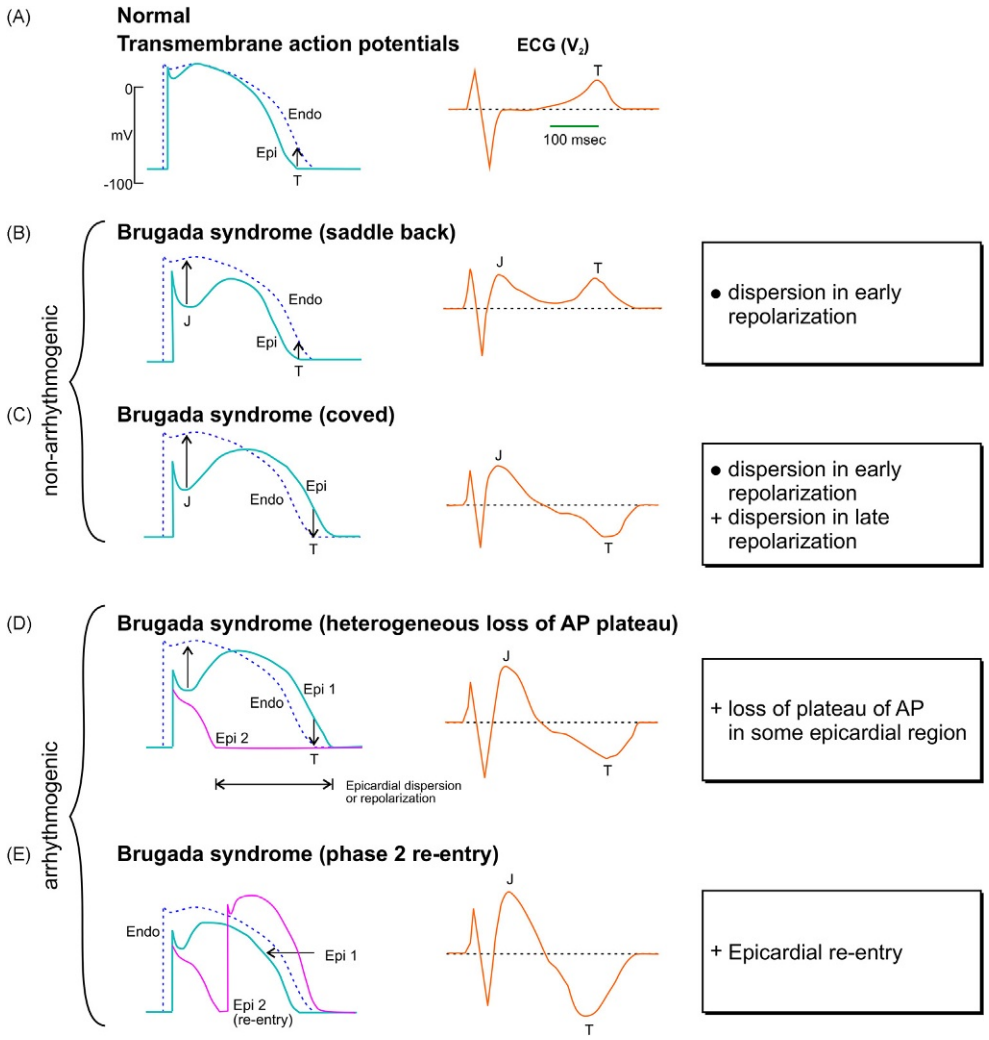

Fig. 6 Brugada syndrome (BrS). (A) Normal transmembrane action potential (Epi, epicardial [*cyan*]; Endo, endocardial [*blue dash*]) and normal ECG. (B) Formation of Brugada syndrome (*saddle back pattern*) ECG due to changes in transmembrane action potentials. (C) Formation of Brugada syndrome (coved pattern) ECG due to changes in transmembrane action potentials. (D) Brugada syndrome with heterogeneous loss of plateau of action potential (AP) in some epicardial regions (epicardial dispersion of repolarization: Epi1 [*cyan*]—epicardial AP with plateau; Epi2 [*magenta*]—epicardial AP without plateau) and corresponding ECG. (E.) Brugada syndrome with epicardial re-entry and corresponding ECG.

of AP resulting in elevated ST-segment (J wave) or "saddle back" pattern of ECG (Fig. 6B). "Coved" patter is generated when, in addition to changes in early repolarization, late repolarization of epicardium is prolonged in comparison to endocardium (transmural dispersion in late repolarization) that leads to inversion of transmural voltage gradient during late repolarization and inversion of T-wave giving a "coved" pattern of ECG (Fig. 6C). However, these changes in itself are not immediately arrhythmogenic. To create arrhythmogenic substrate, further increase in early repolarization is required to achieve a loss of plateau phase of AP in some regions of epicardium (Fig. 6D, Epi2 trace). The regions with abnormally short AP give possibility for re-entry and epicardial extrasystole (Fig. 6E, Epi2 trace with re-entry). The epicardial extrasystole accentuates the inverted T-wave producing an ECG of a more symmetrical appearance. The presence of epicardial regions with abnormally short AP creates a substrate for the development of re-entrant VT and VFib (Lukas and Antzelevitch, 1996; Yan and Antzelevitch, 1999). BrS is mostly right ventricular disorder (Antzelevitch and Burashnikov, 2011; Antzelevitch and Patocskai, 2016) because in this case re-entrant arrhythmia are produced due to transmural dispersion of early repolarization caused by I_{to} syndrome and right ventricle have more prominent I_{to} facilitating early termination of epicardial AP creating possibility for phase 2 re-entry (Di Diego et al., 1996; Volders et al., 1999).

Overview of Ventricular Tachyarrhythmias

Ventricular tachyarrhythmia is one of the most common types of arrhythmia producing cardiac arrest and sudden cardiac death. According to American Heart Association statistics, sudden cardiac arrests happen to over half a million people in North America

(Mozaffarian et al., 2016). Ventricular tachyarrhythmia is an abnormal electrical activity that originates in the ventricular conduction system, ischemic myocardium, or scar tissue and characterized by high rhythm. Spread of electrical impulses through the ventricles can result in either crossing of the atrioventricular (AV) node, capturing the atria retrograde, or bypassing AV node producing ventriculoatrial dissociation. Arrhythmogenic factors responsible for ventricular tachyarrhythmia include alterations in autonomous nervous system activity, myocardial ischemia, and proarrhythmic effects of various drugs; alternatively, ventricular tachyarrhythmia may arise from abnormal electrical automaticity produced by structural heart diseases (Baldzizhar et al., 2016; Parajuli et al., 2015). Ventricular tachyarrhythmias are induced by re-entry mechanism: localized re-entry (local or macroscopic), abnormal automaticity, triggered activity, or combination of the above.

Classification of Ventricular Tachyarrhythmias

Ventricular tachyarrhythmias are subdivided into four types by pattern characteristics (organized vs. disorganized), by pattern duration (non-sustained vs. sustained), and by heart rate. The four types are non-sustained ventricular tachycardia (NSVT), sustained ventricular tachycardia (VT), ventricular fibrillation (VFib), and *torsade de pointes* (TdP) (**Fig. 7**).

- NSVT is characterized by a rapid heart rate ($\geq$120 bpm) with three or more consecutive ventricular beats, but with an overall short duration ($\leq$30 s).
- VT, similarly to NSVT, is characterized by a rapid heart rate ($\geq$120 bpm) with three or more consecutive ventricular beats, but unlike NSVT, sustained VT last more than 30 s.

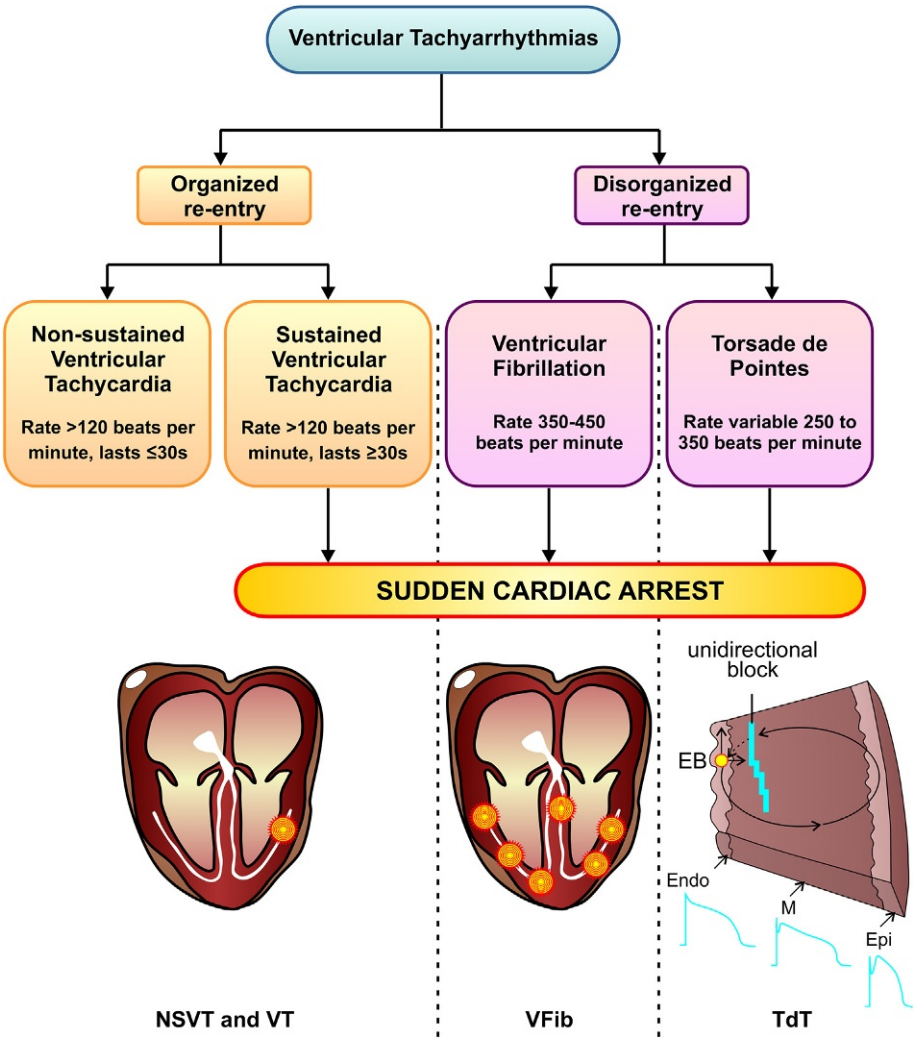

Fig. 7 Classification of ventricular tachyarrhythmias by the type of re-entry with the depictions of their respective mechanisms at the bottom: Left: nonsustained ventricular tachycardia (NSVT) and sustained ventricular tachycardia (VT) are generated by an activity of a single ectopic focus; Center: ventricular fibrillation (VFib) is generated by an activity of a multiple ectopic foci; Right: *torsade de pointes* (TdP) is generated by transmural re-entry with M-myocytes acting as a region of unidirectional block.

- VFib is a chaotic electrical activity with high ventricular heat rate (350–400 bpm) that arises from uncoordinated electrical activity of individual fibers and muscle groups. As a result of such electrical activity, myocyte contractions become disorganized and cardiac output nonexistent leading to hemodynamic collapse followed by cardiac arrest and death.
- Torsade de Pointes (TdP) is an atypical form of ventricular tachyarrhythmia that is closely linked with LQTS and therefore will be considered in the next section.

Mechanisms of Ventricular Tachyarrhythmias

Both NSVT and VT are generated by an activity of a single ectopic focus that sends its impulses through the ventricle(s) bypassing normal conduction pathways (**Fig. 7**). In the case of VFib multiple ectopic foci generate electrical activity that overrides normal rhythm coming from the atria via conductive system (**Fig. 7**).

Torsade de Pointes (TdP)

Initially described by Dessertenne (Dessertenne, 1966), Torsade de Pointes (French "twisting of the spikes") is a distinctive form of polymorphic ventricular tachycardia (VT) that is not related to the spectrum NSVT–VT–VFib and characterized by gradual change in the amplitude or "twisting" of the spikes around isoelectric line (misshaped QRS complexes). TdP is strongly linked with LQTS, medication-induced LQT (e.g., quinidine, procainamide, tricyclic antidepressants) and changes in repolarization due to electrolyte imbalances (hypokalemia, hypomagnesemia, and hypocalcemia) (Baldzizhar et al., 2016; Maisel et al., 1997; Straus et al., 2005). The underlying mechanism of TdP is the increase in transmural dispersion of AP prolongation and EAD associated with excessive prolongation of AP due to slow repolarization rate. At the heart level, transmural differences in repolarization allow M-cells, which have longest AP duration, to act as unidirectional block (**Fig. 7**). Extrasystole (ES) from EAD will propagate in retrograde (toward apex) where cell is already repolarized until it can cross the line of unidirectional block (M-myocytes finished their repolarization) to initiate re-entry by re-exciting M-myocytes and then epicardial myocytes initiating transmural re-entrant arrhythmia *torsade de pointes* (**Fig. 7**) (Antzelevitch and Burashnikov, 2011; Antzelevitch and Shimizu, 2002; Belardinelli et al., 2003).

Conclusions

In general, arrhythmias arise due to involvement of one or more arrhythmogenic mechanisms: (i) abnormal automaticity (decreased or enhanced, as well as isolated pacemaker), (ii) changes in AP duration (LQT and SQTSs, as well as medication-induced LQT), (iii) abnormal and triggered activity (EADs, DADs, late phase 3 EADs that can lead to extrasystole), and (iv) spatial dispersion of repolarization, which allows different parts of the cardiac tissue to re-excite each other and initiate re-entry. In many cases, natural or accentuated heterogeneity in repolarization is required for proarrhythmic changes in AP to become malignant re-entrant arrhythmias.

Background

The use of ventricular assist devices (VADs) to treat end-stage heart failure is now considered standard of care for appropriately selected patients. The use of mechanical circulatory support (MCS) was first shown to improve survival versus medical therapy in advanced heart failure in the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial (Rose et al., 2001). Subsequent trials using newer versions of VADs continued to show benefits as well (Miller et al., 2007; Slaughter et al., 2009; Rogers et al., 2017). In fact, the survival benefit for VADs has continued to improve, even contemporary post-trial use which is different than many other therapies used for heart failure (Jorde et al., 2014). The use of VADs to treat advanced heart failure is recommended as part of both U.S. and European guidelines (McMurray et al., 2012; Yancy et al., 2013).

Current VADs Technologies

Currently, two approved types of MCS are available for clinical use in the United States, with a third option available in certain European regions. The first, the HeartMate II (Abbott/Thoratec, Pleasanton, CA), is a continuous flow device, which currently has approval in the United States for both Bridge to Transplant and Destination Therapy use. The second, the HeartWare HVAD (Medtronic/HeartWare, Framingham, MA), is a centrifugal flow device approved for Bridge to Transplant Use in the United States. The final is the HeartMate 3 (Abbott/Thoratec, Pleasonton, CA) which employs a magnetically levitated rotor to produce flow. The HeartMate 3 is currently an investigational device in the United States but is available in CE mark countries along with the HeartMate II and the HVAD.

Pump Management

Although each of the available pump styles is unique, the basic principles underlying VAD management are generally applicable to all patients with MCS. Each pump operates around a programmed speed; however the operating speed does not singularly define flow through the pump. Rather, flow is determined by several factors, including the afterload on the pump. Pump-operating characteristics, referred to as HQ curves, demonstrate the effect of varying afterload on pump flow (Moazami et al., 2013).

Clinically, pump speeds are selected by balancing the amount of flow desired with secondary effects. Higher pump speeds may decrease pressure and volume within the left ventricle, which can affect the preload to the pump and cause unwanted drops in flow. Likewise, drops in pressure and volume can induce septal shift toward the left ventricular free wall and away from the right ventricle, which may lead to right ventricular failure. Echocardiography and invasive hemodynamics can aid in the selection of the appropriate pump speed for a patient (Slaughter et al., 2010).

Anticoagulation

All current generation VADs require systemic anticoagulation to prevent pump thrombosis. Oral vitamin K antagonists, such as warfarin, are the recommended agent to achieve adequate anticoagulation. The standard target international normalized ratio (INR) for VADs is 2–3 although specific situations may require adjustments to this goal. Examples include the presence of a mechanical heart valve, which may necessitate an INR goal of 2.5–3.5. Likewise, gastrointestinal bleeding, and in particular, recurrent gastrointestinal bleeding, may prompt a reduction in goal INR if not complete cessation of therapeutic anticoagulation (Feldman, 2013, p. 4455). The risks versus benefits of reduced anticoagulation need to be considered on an individual basis prior to changing targets from device-manufacturer recommended ranges. No evidence exists to support the use of other forms of non-vitamin K oral anticoagulants such as direct thrombin inhibitors or factor Xa inhibitors.

Concurrent with the use of oral vitamin K antagonists is the use of antiplatelet therapies, and in particular the use of aspirin. Recommended practices for centrifugal pumps include the use of 325 mg daily of aspirin, while axial flow and magnetically levitated flow devices currently recommend between 81 and 325 mg of aspirin daily. Additional antiplatelet therapies can be used in conjunction with aspirin if clinically indicated but can increase the bleeding risk in the VAD population similar to other populations. Some evidence exists that antiplatelet therapy may not be required at all for the subset of VAD patients without coronary artery disease; however this hypothesis has not been conclusively shown and therefore routinely withholding aspirin is not yet recommended (Netuka, 2017, p. 4474).

Blood Pressure Control

Systemic blood pressure control remains an important component of VAD patient management. As previously noted, afterload plays a role in determining flow through a VAD. Clinically, afterload is represented by systemic blood pressure; therefore inadequate blood pressure control can have negative effects on pump function and subsequent consequences. Indeed, stroke rates are noted to be higher in VAD patients not on antihypertensive medications versus those who were treated (Lampert et al., 2014).

No data exist to suggest superiority of any given class of antihypertensive agents over others. Generally, antihypertensive agents that concurrently treat heart failure, such as those targeting the renin–angiotensin system (ACE inhibitors, ARBs) or neurohormonal pathways (beta-blockers, mineralocorticoid receptor antagonists) are used before other agents are employed. Often, multiple agents are required to control blood pressure (Lampert et al., 2014). As with the general use of these agents, appropriate monitoring and follow-up is recommended for VAD patients.

Treating blood pressure in MCS patients requires a reliable method of measuring. Current generations of VADs create continuous flow in the arterial system, which creates minimal variations in pressures over time. Whereas the traditional cardiac cycle results in systolic and diastolic pressures, continuous flow VADs may not have discernable differences to label as such. Traditional blood pressure measurement methods that rely on Korotkoff sounds to determine systolic and diastolic pressures may not be accurate in VAD patients. Due to this phenomenon, the recommended practice for measuring blood pressure in a VAD patient is to use Doppler devices to determine a return to flow. In the absence of a detectable pulse, the Doppler return to flow blood pressure is considered a mean arterial pressures (MAP). In the setting of a palpable pulse, the Doppler return to flow pressure is considered to be a systolic blood pressure. Although some doubts to these correlations exist, present clinical practice is to assign the Doppler return to flow based on the presence or absence of a palpable pulse (Lanier et al., 2013; Feldman et al., 2013). The guideline recommended practice is to target a systolic blood pressure less than 130 mmHg or a MAP $<$80 mmHg (Feldman et al., 2013). More recent data correlate a MAP maintained $<$90 mmHg with positive outcomes, particularly for axial flow pumps (Maltais et al., 2017).

Heart Failure Therapies

As noted, medical therapies for heart failure are traditionally utilized when medical therapy is required and tolerated. Some data exist demonstrating the potential benefit of these therapies including improvement in underlying cardiac function (Birks et al., 2015; Dandel and Hetzer, 2015). Despite the use of these medications, and the presence of the VAD itself, episodes of worsening heart failure are still common among MCS patients (Lampert and Emani, 2015). Traditional therapies for acute heart failure, including diuretic therapies, are often required to treat these patients.

Summary

Certain specific considerations are required when considering the management of patients with VADs. These considerations should be incorporated into the overall management of the VAD patients and individualized as appropriate, especially when considering comorbidities that should be concurrently managed. The medical management of a VAD patient should be undertaken in conjunction with a certified VAD center to ensure proper care.

Introduction

Metabolomics is the systematic study of small molecules (metabolites) in biological samples. Metabolomics can be targeted, that is, focused on a few specified metabolites only, or untargeted aiming at detecting and quantifying all metabolites, known or unknown, in a sample. The product of the latter is the metabolome, the collection of all metabolites detectable in the sample. Metabolomics can produce a person's metabolic phenotype ("metabotype"), which reflects the person's metabolic health at the time of sampling. The metabotype is partially a functional output of the person's genotype but, in contrast to genotype, it is highly variable over time due to various environmental influences. Like genomics and other "omics" research, metabolomics has progressed rapidly in recent years and advancements in laboratory technology have now enabled the investigation of thousands of metabolites from thousands of individuals.

In cardiovascular research the utilization of metabolomics is becoming common. In fact, the main risk factors for cardiovascular diseases, total cholesterol, smoking, and blood pressure, have remained amazingly similar for the past 30 years. Since metabolomics technologies can now produce hundreds and even thousands of biomarkers from a single sample, they have the potential to bring new precision to cardiovascular research and clinical treatments. There are diverse applications for metabolomics in cardiovascular medicine: (a) to improve our understanding of molecular mechanisms underlying various cardiovascular disorders; (b) to enable subclassification of cardiovascular disorders and help with patient stratification based on the metabolic pathways impacted; (c) to provide new biomarkers or biomarker profiles which improve cardiovascular risk estimation and improve targeting of preventive efforts; (d) to provide biomarkers which help with efficacious selection and monitoring pharmacological treatment.

Technologies for Metabolomics Profiling

Two principal technologies can be used for high-throughput metabolomic profiling, nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS). The NMR technology has been described in detail (Jeyarajah et al., 2006; Mora et al., 2009; Soininen et al., 2015; Larive et al., 2015). It can provide quantitative data on lipoprotein subclasses, their lipid concentrations and composition, apolipoproteins A-I and B, multiple cholesterol and triglyceride measures, albumin, various fatty acids as well as on numerous low-molecular-weight metabolites, including amino acids. NMR is not destructive to the sample and can detect metabolites down to the low-micromolar concentration range. The analysis of a single sample takes only a few minutes and can produce quantitative data on about 200 metabolites. Strengths of the NMR metabolomics are simple sample preparation, low costs, and high throughput, which have made the examination of large cohorts possible. The main limitations are the lesser number of quantifiable metabolites and the clearly lower sensitivity compared to MS metabolomics with the main focus on various lipoprotein particles and their lipid concentrations.

MS is usually coupled with liquid chromatography or gas chromatography for initial separation of different molecules before ultimately identifying them on the basis of their mass-to-charge (m/z) ratio. The samples must first be ionized to measure the m/z ratio. The "shotgun" approach, sometimes used for nontargeted lipidomics, simplifies the process by omitting the chromatography

step but this approach is only able to detect and quantify abundant lipid species. These technologies and their applications in medical research have been recently described (Hinterwirth et al., 2014; Lind et al., 2016; Dona et al., 2016; Lei, 2011). In particular, the chromatography step requires careful sample preparation and control of analysis conditions, which makes MS-based methods more laborious and more expensive than the NMR-based methods. The higher costs are compensated by the much higher sensitivity of MS compared to NMR. Metabolites can be detected and quantified down to low nano- or high picomolar concentrations. At the moment, published studies using MS-based technologies have been smaller than those using NMR, but developments in laboratory technology and automation are rapidly reducing the costs and the time needed for a measurement. Thus, it is likely that the throughput of MS-based metabolomics will increase substantially in the near future.

Several freely available online data repositories are designed to help with metabolite identification and characterization as well as interpretation of their biological roles. The list of relevant websites is presented in more detail at the end of the article.

The metabolites quantified by MS and NMR platforms are largely different but some metabolites, for example, certain amino acids, can be obtained from both. It should be noted, however, that there are no broadly accepted standardizations between the different technologies or even between different platforms using the same technology. Thus, biomarker results obtained with different platforms may not be comparable. Despite this, robust biological findings have been found across platforms, such as the associations of aromatic amino acids with different manifestations of atherosclerosis which are consistent in both MS- and NMR-based studies (Würtz et al., 2015; Magnusson et al., 2013).

Sample Requirements, Quality Control, and Data Preprocessing

A schematic overview of metabolomics workflow and aspects to be considered is given in Fig. 1.

The most appropriate sample type for metabolomics studies depends on the study questions. In practice, biofluids such as serum, plasma, urine, and stool are most often used in large-scale studies because of easy availability. As in all laboratory studies, preanalytical conditions like fasting or nonfasting status, hour of blood drawing, storage time and storage temperature of the samples, and the number of freeze-thaw cycles can have a major impact on the results and must be carefully considered at the planning stage of the study. Common problems at the analysis stage are batch-to-batch variation and analytical drift over time,

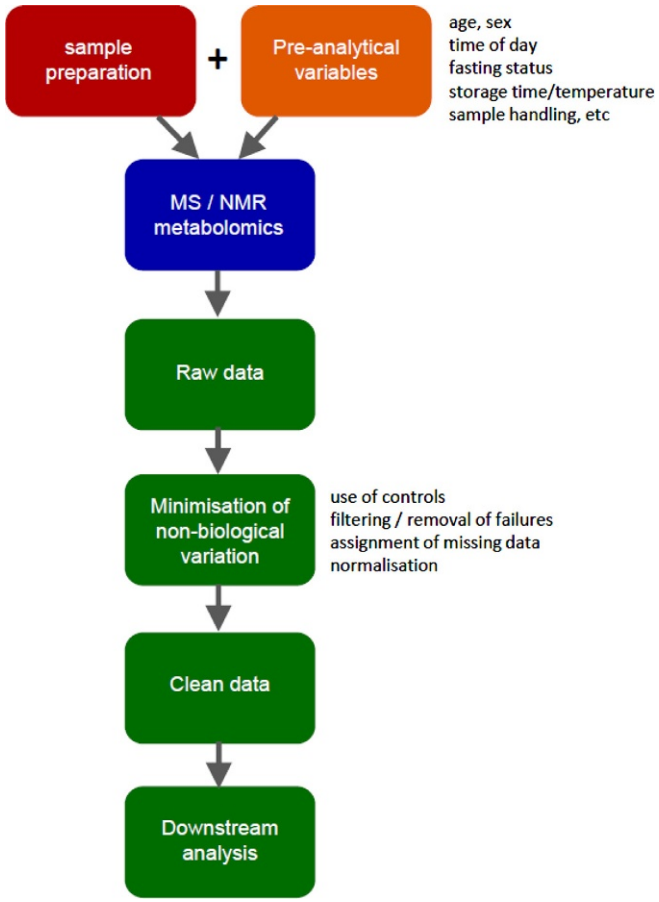

Fig. 1 Schematic overview of metabolomics workflow and aspects to be considered.

which can be controlled using internal standards. After the analysis, data are usually normalized, centered, and scaled to produce a set of metabolites which minimize technical variation and maximize biological variation. Because a large number of metabolites are quantified, some may have unacceptably high coefficients of variation (CV) and may need to be excluded from data analyses. With careful quality control, however, the majority of metabolites will have CVs, which are only slightly larger than those of single biomarker measurements.

Strategies for Analyzing Metabolomics Data

In principle, metabolomics data can be analyzed using linear models similar to other quantitative biomarker data. This can be done on each metabolite separately or multiple metabolites simultaneously using multivariate approaches or metabolic pathway analysis (Xia and Wishart, 2010; Inouye et al., 2012). However, analysis and subsequent interpretation typically must account for complex correlations among metabolites and the large numbers of metabolite variables tested, making statistical control for multiple testing necessary. Several methods can be used to control for multiple testing and to reduce the number of statistical tests needed, including Bonferroni correction, false discovery rate, and principal component analysis. In addition to controlling for multiple testing, the findings should ideally be replicated in an independent cohort, to ascertain their robustness and to avoid false positive results.

A more challenging opportunity is the integration of metabolomics data with genomics and other omics for systems level analyses. These kinds of analyses can be more sensitive in detecting novel biomarkers and give more insights into the underlying biology than association analyses that only consider one type of omic data (Inouye et al., 2010; Kastenmüller et al., 2015; Fearnley and Inouye, 2016). Also, genome-wide association study (GWAS) analyses on metabolomics profiles as interim traits seem to be more powerful than corresponding analyses on traditional cardiovascular risk factors traits (Suhre et al., 2011). Kettunen et al. (2016) reported recently a GWAS on 123 metabolites quantified by NMR and identified 62 associated loci, many of them relevant for cardiovascular traits. The median proportion of variance explained by the genetic variants was 5% with the highest being for glycine (12.5%). An even more extensive exploration of genetic influences on metabolites detected by MS has been published by Shin et al. (2014). In addition to metabolite concentrations, their analysis included relevant metabolite/metabolite ratios, which in principle offered additional reaction rate information within metabolic pathways. Another advantage from combining metabolomics with genomics is the opportunity to assess causality of the metabolite-disease associations using Mendelian randomization techniques as demonstrated in the studies mentioned earlier. Ganna et al. (2014) have applied these techniques for analyzing cardiovascular manifestations in Swedish cohorts and found a weak but probably causal association of monoglyceride 18:2 with incident coronary heart disease.

Associations of Metabolite Profiles With Cardiometabolic Risk Factors

Diabetes, Insulin Resistance, and Obesity

Metabolite profiling may refine traditional cardiovascular risk factors, inform on underlying biology and suggest new targets for therapeutic interventions. Probably the most studied entity is the triad of diabetes, insulin resistance and obesity. Both MS- and NMR-based studies have consistently shown that branched-chain amino acids are associated with increased risk of diabetes (Wang et al., 2011; Stancáková et al., 2012). Similar findings were observed for fasting and 2-h glucose, and for insulin resistance (Würtz et al., 2012) (**Fig. 2**).

In an MS analysis of the Framingham Offspring cohort, body mass index was associated with the same amino acids as diabetes and insulin resistance, as well as with citric acid cycle, the tryptophan pathway and the urea cycle (Ho et al., 2016). In an NMR-based study of Finnish cohorts, body mass index was associated with 66 metabolites in men and 61 in women, and higher body mass index was associated with generally atherogenic metabolite profiles (Würtz et al., 2014). Furthermore, a Mendelian randomization study was performed with a genetic risk score for body mass index as the instrument to assess causality. The results suggested causal adverse effects of adiposity on multiple metabolites, including lipoprotein lipid subclasses and particle size, branched-chain and aromatic amino acids, and inflammation-related glycoprotein acetyls. Consistently, a dramatic weight reduction caused by bariatric surgery was paralleled by declining trends in branched-chain amino acids, phenylalanine, alanine, and choline, and increasing trends in indoxyl-sulfate and trimethylamine-*N*-oxide (TMAO) (Narath et al., 2016).

Lipidomics

Lipid metabolism plays a key role in cardiovascular disease development. For decades, cardiovascular risk estimation has been based on relatively crude measurements of total and HDL cholesterol and triglycerides, complemented with calculated or directly measured LDL cholesterol. Both NMR- and MS-based metabolomics methods can provide much more detailed lipid profiling than the methods currently in clinical use. NMR is mainly focused on measuring lipoprotein particle sizes and their lipid concentrations, while MS measures molecular lipid species with great sensitivity (Soininen et al., 2015; Hinterwirth et al., 2014). Some promising findings have been published (Alshehry et al., 2016; Stegemann et al., 2014) but at the moment the clinical benefit of more precise lipidomics profiling still needs to be demonstrated.

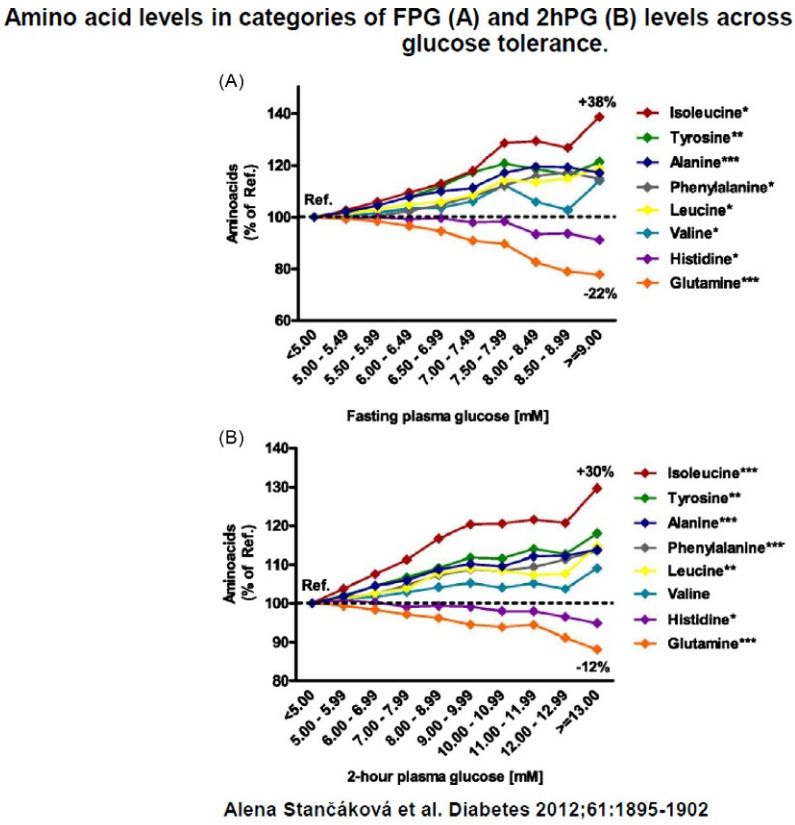

Fig. 2 Amino acid levels in categories of fasting plasma glucose (A) and 2-h plasma glucose (B) levels across the entire range of glucose tolerance. Points represent unadjusted means of amino acid levels in each glucose category. *P* values were calculated using general linear model adjusted for age and BMI. $^{*}P<0.05$, $^{**}P<10^{-10}$, $^{***}P<10^{-30}$. Blood Pressure and Hypertension

Few studies have been published on metabolomics of elevated blood pressure or hypertension. Investigators of the Atherosclerosis Risk in Communities (ARIC) study examined metabolomic predictors of incident hypertension in African Americans with high incidence of hypertension (Zheng et al., 2013). They found that 1 standard deviation difference in 4-hydroxyhippurate, which is a product of gut microbial fermentation, was associated with 17% higher risk of incident hypertension and the association remained significant after adjusting for other risk factors of hypertension, including baseline systolic and diastolic blood pressure. Sex steroid pattern was also associated with incident hypertension and the association was consistent in both sexes.

Menni et al. (2015) analyzed 280 metabolites in 3980 Twins UK females for associations with blood pressure. Only a dicarboxylic acid, hexadecanodioate, showed an independent association with systolic blood pressure which consistently replicated in two other cohorts. In a series of elegant animal experiments the authors showed that hexadecanodioate may have a causal influence on blood pressure. They speculated that hexadecanodioate may be a "low hanging fruit" and that there will be other metabolites associated with blood pressure, which can be detected in larger studies.

Smoking and Physical Activity

Metabolomic studies on smoking have been mainly focused on nicotine metabolism and risk of lung cancer as well as other cancers, but largely have not considered cardiovascular disease outcomes. Gu et al. (2015) carried out an untargeted MS metabolomics study in 892 men and women from four countries. They found 25 metabolites associated with smoking behaviors, 24 with current smoking and 8 with the number of cigarettes per day. Possibly relevant for cardiovascular diseases is that serum bilirubin concentrations were lowered among smokers. Circulating bilirubin is a powerful antioxidant and has been inversely associated with cardiovascular disease. Investigators of the KORA cohort from Germany showed in a longitudinal study with a follow-up of 7 years that metabolite alterations associated with smoking were reversible after smoking cessation (Xu et al., 2013).

Physical activity has consistently been associated with lower levels of branched chain amino acids in multiple metabolomics studies (Fukai et al., 2016; Xiao et al., 2016; Kujala et al., 2013). Glucose and monosaccharides were also lower in persons with high physical activity level (Xiao et al., 2016; Kujala et al., 2013).

Metabolomics and Cardiovascular Outcomes

A few prospective studies have been published on metabolomics and cardiovascular outcomes (**Table 1**). The study of Würtz et al. (2015) is the largest of the listed prospective studies. The investigators first carried out NMR metabolomics profiling in 7256 persons free of cardiovascular disease at baseline. In this discovery cohort, 19 metabolites were associated with cardiovascular disease risk independently of traditional risk factors. In replication cohorts, levels of four metabolites (phenylalanine, monounsaturated fatty acids, omega-6 fatty acids, and docosahexaenoic acid) robustly replicated (**Fig. 3**).

Table 1 Prospective studies on metabolomics and cardiovascular outcomes

Study	N, *design*	*Metabolomics technology*	*Main findings*
Shah et al. (2012)	2023 Patients undergoing cardiac catheterization	Targeted MS	Dicarboxylacylcarnitines, medium-chain acylcarnitines, and fatty acids predictive of future CVD
Magnusson et al. (2013)	506, nested case-control study	Targeted MS	A score consisting of three amino acids is predictive for incident CVD
Stegemann et al. (2014)	685, population-based cohort study	Shotgun lipidomics, MS	Triacylglycerols, cholesterol esters, and phosphatidyletanolamides predictive for incident CVD
Ganna et al. (2014)	3668, population-based cohort study	Untargeted MS	Monoglyceride 18:2 causally associated with incident CHD, three other metabolites also associated
Würtz et al. (2015)	13,441, population-based cohort study	NMR	Phenylalanine and MUFA directly, ω-6 FA and docosahexaenoic acid inversely associated with incident CVD
Laaksonen et al. (2016)	3384, case-control study among patients with CHD	Targeted MS	Ceramides significantly associated with CVD death
Havulinna et al. (2016)	8101, population-based cohort study	Targeted MS	Ceramides significantly associated with incident CVD

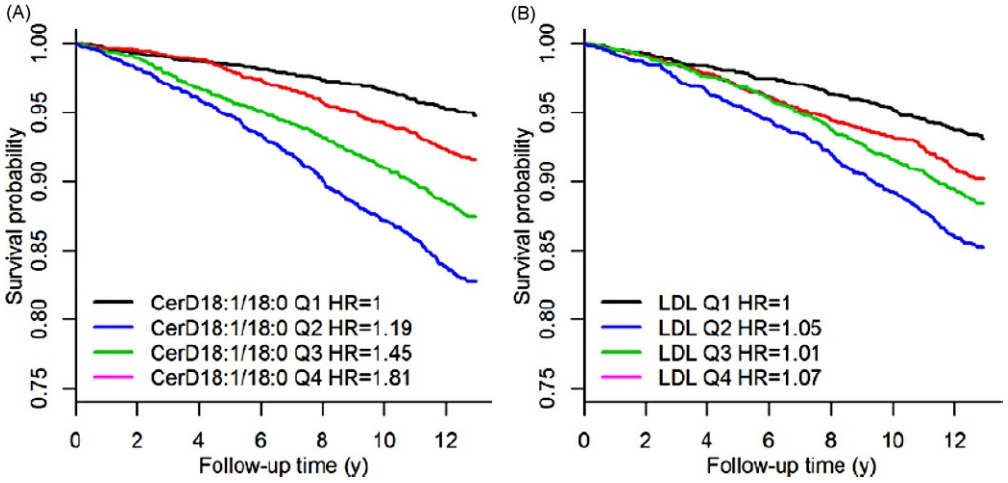

Fig. 4 (A and B) Kaplan–Meier estimates of incident major adverse cardiovascular event (MACE) in Cer(d18:1/18:0) and low-density lipoprotein-cholesterol (LDL-C) quartiles. A hazard ratio in the legend indicates the quartile-specific hazard relative to the first quartile (models stratified for sex). Source: Havulinna et al. *ATVB* 2016. https://doi.org/10.1161/ATVBAHA.116.307497. With permission from Wolters Kluwer.

The metabolite associations were further corroborated with MS in the Framingham Offspring study. A risk score was derived in the discovery cohort using these four metabolites and tested in the replication cohorts. The score improved risk classification, especially in the intermediate risk group ("clinical NRI") but discrimination, assessed using C-statistics, was not improved. Laaksonen et al. (2016) have carried out a targeted MS analysis in three different cohorts of coronary heart disease patients from Finland, Switzerland, and Norway. Ceramides, especially the Cer(d18:1/16:0)/Cer(d18:1/24:0) ratio, were associated with the risk of cardiovascular death in all cohorts. In a follow-up study, Havulinna et al. (2016) investigated the associations of the same ceramides with the risk of incident major cardiovascular events in a general population-based Finnish cohort, FINRISK. In this case cer(d18:1/18:0) showed the strongest association with the outcome. When considered quartile by quartile, the association of cer(d18:1/18:0) with incident major cardiovascular events seemed stronger than that of LDL cholesterol (**Fig. 4**). Reclassification of risk due to ceramides remained, however, modest.

Metabolomic studies on other specific cardiovascular outcomes are so far limited and with small sample sizes, but it has been reported that lysophosphadidylcholine is associated with stroke recurrence in patients with transient ischemic attack (Jové et al., 2015), two conjugated bile acids are associated with incident atrial fibrillation in African Americans (Alonso et al., 2015), and that long-chain acylcarnitine is associated with heart failure with higher levels in patients with reduced ejection fraction compared to those with preserved ejection fraction (Hunter et al., 2016). Cheng et al. (2015) demonstrated recently that metabolomics is a promising tool for the diagnosis and prognosis of heart failure. In their study, a metabolite panel consisting of the asymmetric methytarginine/arginine-ratio, butyrylcarnitine, spermidine, and the total amount of essential amino acids, provided significant prognostic value independent of brain natriuretic peptide and other traditional risk factors.

Pharmacometabolomics

Pharmacometabolomics is the application of metabolomics for the study of drug effects and variation in drug responses, which together with pharmacogenetics has the potential to improve possibilities for selecting each individual patient a more effective drug treatment with fewer side effects. Investigators of the KORA cohort from Germany have reported 41 metabolites, which were significantly associated with various antihypertensive and lipid lowering drugs (Altmaier et al., 2014). In another study, the same group reported that the metabolite differences between users and nonusers of angiotensin convertase inhibitors were dependent on genetic variant at the ACE locus (Altmaier et al., 2016). Two of the observed peptides, aspartylphenylalanine and phenylalanylserine, showed significant association with blood pressure and may thus be functional markers of ACE activity.

Würtz et al. (2016) used NMR profiling to examine the metabolic effects of statin use in four cohorts in the United Kingdom and Finland. Substantial lowering of remnant cholesterol was observed but only modest lowering of triglycerides. Omega-6 fatty acids decreased substantially while the effects on amino acids, glycolysis, and gluconeogenesis-related metabolites were minimal. The metabolic changes closely matched the association pattern of a single nucleotide variant (rs12916) in the HMGCR gene, itself shown to be associated with cholesterol levels (Teslovich et al., 2010).

Gut Microbial Metabolites and Cardiovascular Disease

In the past decade it has become evident that the gut microbiome influences human health, including cardiovascular diseases and their risk factors, through introduction of diverse small molecules into circulation. These molecules can be detected and

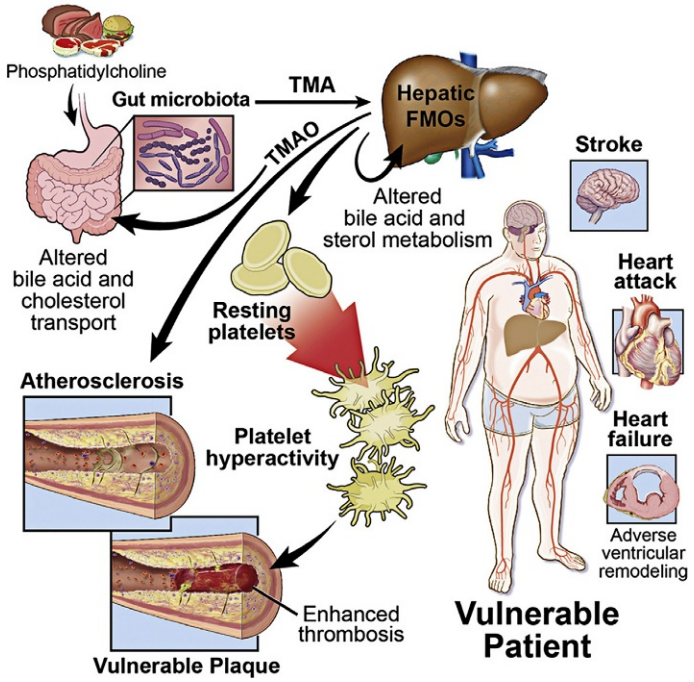

Fig. 5 Pathways linking dietary phosphatidylcholine, intestinal microbiota, and incident adverse cardiovascular events. Source: Zhu et al. *Cell* 2016:165:111–124, with permission from Elsevier.

quantified by plasma and stool metabolomics. At the moment, most evidence exists for choline and carnitine, and for branched-chain amino acids. Tang et al. have shown that intestinal microbiota participates in metabolizing dietary phosphaditylcholine to trimethylamine which is then oxidized to TMAO (Tang et al., 2013; Zhu et al., 2016). They next measured TMAO in 4007 patients undergoing elective diagnostic cardiac catheterization and showed that increased plasma levels of TMAO were associated with increased risk of a major adverse cardiovascular event. Zhu et al. provided more insight into the biological mechanisms by showing that plasma TMAO enhanced platelet hyperreactivity and thrombosis risk (**Fig. 5**) (Zhu et al., 2016; Tilg, 2016).

It should be noted, however, that a smaller European study was unable to corroborate the association of TMAO with angiographically assessed coronary atherosclerosis or with cardiovascular events during 8 years of follow-up (Mueller et al., 2015).

Pedersen et al. (2016) examined untargeted MS metabolomics in serum samples of 277 nondiabetic Danish individuals and in a separate group of 75 patients with type 2 diabetes. Both groups had quantitative gut metagenomics data available. They showed that the serum metabolome of insulin-resistant individuals is characterized by increased levels of branched-chain amino acids, which correlate with a gut microbiome that has an enriched biosynthetic potential for branched-chain amino acids. *Prevotella copri* and *Bacteroides vulgatus* were identified as the main drivers of the association between insulin resistance and the biosynthesis of branched-chain amino acids. The investigators further demonstrated in mice that *Prevotella copri* can induce insulin resistance, aggravate glucose intolerance, and increase circulating levels of branched-chain amino acids.

Short-chain fatty acids produced by gut bacteria have also been implicated in the development of obesity and metabolic syndrome but so far the data have been largely based on animal experiments and the data in humans are limited and findings not entirely consistent (Perry et al., 2016; Trajkovski and Wollheim, 2016).

Summary

Metabolomics is a rapidly developing field and the new technologies have shown great promise in uncovering novel biological pathways leading to cardiovascular disease. The improved understanding of disease pathogenesis suggests new targets for prevention and treatment. However, we are still at an early stage of the development; human data on the emerging novel pathways and biomarkers are still limited and to some extent inconsistent. Sufficiently powered prospective cohort studies and clinical trials are clearly needed for more definitive conclusions. Likewise, standardization of sample processing and laboratory technology would greatly help in comparing and combining results from different studies. Ultimately, metabolomics data must be integrated with genomics, microbiome, and other "omics" data using system level analyses to properly understand the complex functions of human metabolism at the cellular level.

Introduction

The heart is the first functional organ established during embryogenesis. Heart development is characterized by exceptionally rapid transitions in gene activity, with complex integration of molecular information giving way to precise on/off patterns of gene expression. Posttranscriptional repression plays a pivotal role in this process, delineating sharp developmental transitions by suppressing residual transcripts that were specific to the previous stage (Ebert and Sharp, 2012).

One of the landmark discoveries of the 20th century was of small noncoding RNAs, microRNAs (miRNAs). miRNAs repress the expression of genes by accelerating messenger RNA (mRNA) degradation and inhibiting translation, thereby reducing the level of protein (Lim et al., 2005; Guo et al., 2010; Schmiedel et al., 2015). It is now recognized that miRNAs constitute an integral part of the gene regulatory program. They act as rheostats and switches to modulate multiple facets of cardiac development and function by interacting with the network of protein-coding genes, transcription factors, and signaling pathways (Voinnet, 2009; Liu and Olson, 2010). This article presents an overview of the role of miRNAs as key players in cardiac development, and discusses the implications of exploiting miRNAs in regenerative medicine to treat heart diseases.

miRNAs Biogenesis and Function

miRNAs are approximately 22 nucleotides in length and are evolutionarily conserved in metazoans (Bartel, 2004). miRNAs negatively regulate gene expression by accelerating mRNA degradation and inhibiting translation (Lim et al., 2005; Guo et al., 2010). They have emerged as key modulators in many biological processes, including developmental timing, cell proliferation, apoptosis, metabolism, cell differentiation, and morphogenesis (Stark et al., 2005; Ebert and Sharp, 2012). Current insights about miRNA functions in the heart have been influenced by outcomes using animal models with loss- and gain-of-function of miRNAs and their targets and assessing heart development and mature function. These miRNAs have been described as developmental switches to modulate multiple facets of cardiac development and function (Liu and Olson, 2010; Malizia and Wang, 2011; Porrello, 2013; Fuller and Qian, 2014; Piubelli et al., 2014; Hodgkinson et al., 2015; Katz et al., 2016; Yan and Jiao, 2016).

miRNAs can be transcribed either individually or in clusters. Based on their location in the genome, miRNAs are classified as intergenic miRNAs, which are transcribed from their own promoters, or intronic and exonic miRNAs, which are usually cotranscribed and coexpressed with their host genes (Bartel, 2004). The biogenesis of miRNAs starts with initial gene transcription by RNA polymerase II. This results in a primary miRNA transcript (pri-miRNA), which can be several hundreds to several thousands of nucleotides long. Pri-miRNAs are processed by the endonuclease Drosha and its cofactor DiGeorge syndrome critical region 8 (Dgcr8) into 60–100 nucleotide hairpins known as pre-miRNAs. Once exported from the nucleus into the cytoplasm, pre-miRNAs are further processed into the miRNA duplexes by the RNase III endonuclease Dicer. One strand of the duplex becomes a mature miRNA, which is incorporated into the RNA-induced silencing complex (RISC). The mature miRNA directs the RISC to specific mRNA targets usually by binding to the 3′ untranslated region (UTR) of the target mRNA. The miRNA–mRNA interaction causes gene silencing either by promoting mRNA degradation or by inhibiting protein translation (Braun et al., 2011). At the molecular level, each miRNA molecule may target hundreds of mRNAs, and have multiple target sites in the 3′UTRs of a particular mRNA, thereby increasing repression efficiency (John et al., 2004; Krek et al., 2005; Lewis et al., 2005; Stark et al., 2005; Xie et al., 2005; Hornstein and Shomron, 2006). Each mRNA is also predicted to be targets of many distinct miRNAs, suggesting that different miRNAs might work together to regulate mRNA stability and translation. Furthermore, miRNAs are found to act in feedforward and feedback regulations that can reinforce the transcriptional gene expression program (Tsang et al., 2007; Ebert and Sharp, 2012; Rottiers and Näär, 2012).

miRNAs in Cardiac Development

Cardiac development is a well-defined multistep process controlled by an evolutionarily conserved complex of genetic pathways and an extended network of transcriptional and posttranscriptional regulatory programs. The major stages of cardiac development in vertebrates are depicted in **Fig. 1**. The first myocardial cells derive from two major cardiac progenitor cell populations, referred to as heart fields (Buckingham et al., 2005). The first heart field contributes to the left ventricle and parts of the atria. The second heart field contributes to the rest of the heart, including the right ventricle, outflow tract, sinus venosus, and atria (Kelly et al., 2001; Cai et al., 2003; Zaffran et al., 2004; Verzi et al., 2005; Galli et al., 2008; Bruneau, 2013). The development of cardiac progenitors is governed by a core set of transcriptional regulatory networks such as Nkx2.5, Gata, Tbx, Hand, and Mef2 (Olson, 2006). Mouse embryos with mutations in these genes display abnormalities in the heart (Buckingham et al., 2005). In addition to the differentiation of cardiac progenitors into cardiomyocytes, the proliferation of existing cardiomyocytes is responsible for the formation and growth of mature cardiac structures, such as the layered compact muscle comprising the chamber walls and the fingerlike trabeculae that protrude inside the developing chambers. These processes are driven by interactions between the myocardium and adjacent endocardium via molecular signals including neuregulin/ErbB, Notch, Ephrin/Eph, and BMP10 (Gassmann et al., 1995; Meyer and Birchmeier, 1995; Wang et al., 1998; Chen et al., 2004; Grego-Bessa et al., 2007).

miRNAs have a variety of roles in cardiac development and function (**Table 1**). Several studies have provided evidence of differential expression of miRNAs during cardiac development, both during embryogenesis (Chinchilla et al., 2011) and postnatal stages (Porrello et al., 2013). The critical role of miRNAs in cardiac development was identified by deletion of Dicer, the RNase III endonuclease essential for miRNA biogenesis in mammals. Cardiac deletion of Dicer results in embryonic lethality. When Dicer was deleted in cardiac progenitor cells using Cre recombinase under control of Nkx2.5 regulatory elements, embryos exhibit cardiac failure with hypoplastic ventricular myocardium (Zhao et al., 2007; Saxena and Tabin, 2010). The myocardial deletion of Dicer at midgestation stage (E10.5-11.5) using cTnt-Cre leads to embryonic lethality at embryonic day (E) 13.5-E15.5. Mutant hearts display severe myocardial defects including increased cell death and noncompaction of ventricular myocardium (Peng et al., 2014). Deletion of Dicer in cardiomyocytes during early postnatal life using α-myosin heavy chain (MHC)-Cre causes dysregulation of cardiac contractile proteins and sarcomere disarray, resulting in dilated cardiomyopathy, heart failure, and early postnatal lethality (Chen et al., 2008). Similarly, postnatal deletion of Dgcr8, another component of the miRNA biogenesis pathway, in cardiomyocytes using muscle creatine kinase-Cre, leads to dilated cardiomyopathy and premature death within 2 months after birth (Rao et al., 2009). Taken together, these studies demonstrate the importance of miRNA biogenesis in maintaining proper cardiac function and survival during embryonic and postnatal life.

miRNA Regulation of Cardiac Muscle Differentiation

miRNA-1 and miRNA-133 are specifically expressed in cardiac and skeletal muscle cells with expression increasing substantially from E8.5 to adulthood in vertebrates (Lagos-Quintana et al., 2002; Sempere et al., 2004; Chen et al., 2006; Rao et al., 2006). The miRNA-1 family has two members, miRNA-1-1 and miRNA-1-2, each of which is co-transcribed with miRNA-133a-2 and miRNA-133a-1 gene, respectively. The expression of miRNA-1/133a clusters is regulated by upstream and intragenic enhancers controlled by combinations of the basic helix-loop-helix protein MyoD and the MADS-box transcription factors serum response factor (SRF) and myocyte enhancer factor 2 (Zhao et al., 2005; Rao et al., 2006; Liu et al., 2007). In *Drosophila*, deletion of the single miRNA-1 gene (dmiRNA-1) results in a defect in muscle differentiation (Kwon et al., 2005; Sokol and Ambros, 2005). dmiRNA-1 represses the expression of the Notch ligand, Delta, a known regulator of cardiogenesis and myogenesis in fruit flies (Kwon et al., 2005). In *Xenopus* embryos, mi RNA-1 promotes myoblast differentiation as a consequence of its negative regulation of histone deacetylase 4, a transcriptional repressor of muscle gene expression (Chen et al., 2006).

Table 1 Examples of miRNA null mutant mice and cardiac phenotypes during development

miRNA name	*miRNA null mouse phenotype*	*Target genes*	*References*
miRNA-1-2	~50% embryonic lethal, VSD in embryos, increased cardiomyocyte proliferation, cardiac arrhythmias in surviving mutants	Hand2, Irx5	Zhao et al. (2007), Heidersbach et al. (2013)
miRNA-1-2	Viable, no phenotype		Wystub et al. (2013), Wei et al. (2014)
miRNA-1-1	Similar to miRNA-1-2		Heidersbach et al. (2013), Wystub et al. (2013), Wei et al. (2014)
miRNA-1-1/ miRNA-1-2 double null	Lethal within 3 weeks after birth, sarcomere disruption, impaired cardiac function, increased expression of fetal sarcomere-associated genes, increased cardiomyocyte proliferation	Myocardin, Telokin, Errβ	Heidersbach et al. (2013), Wei et al. (2014)
miRNA-133a-1	Viable, no phenotype		Liu et al. (2008), Wystub et al. (2013)
miRNA-133a-2	Viable, no phenotype		Liu et al. (2008), Wystub et al. (2013)
miRNA-133a-1/ miRNA-133a-2 double null	~56% lethal during late embryonic and neonatal stages, VSD and chamber dilation at P1, disrupted sarcomere structure, increased cardiomyocyte proliferation and smooth muscle gene expression at P1	SRF, Myocardin, Cyclin D2	Liu et al. (2008)
miRNA-1-2/133a-1 cluster	Viable, abnormal cardiac conduction triggered by β-adrenergic signaling		Besser et al. (2014)
miRNA-1-1/133a-2 cluster	Similar to miRNA-1-2/133a-1		Besser et al. (2014)
miRNA-1/133a cluster double null	Lethal before E11.5, decreased cardiomyocyte proliferation, hypoplastic ventricular myocardium, increased expression of smooth muscle genes	Myocardin	Wystub et al. (2013)
miRNA-208a	Viable, abnormal sarcomere structure, decreased expression of slow muscle gene β-MHC, abnormal cardiac conduction	Thrap1, Myostatin, Cx40, Hop, Gata4	Van Rooij et al. (2007), Callis et al. (2009)
miRNA-208b	Viable, no phenotype		Van Rooij et al. (2009)
miRNA-499	Viable, no phenotype		Van Rooij et al. (2009)
miRNA-208b/ miRNA-499 double null	Viable, decreased expression of slow muscle gene β-MHC	Thrap1	Van Rooij et al. (2009)
miRNA-17-92 cluster (cardiac specific)	Viable, decreased cardiomyocyte proliferation and hypoplastic ventricular myocardium in embryonic heart	Pten	Chen et al. (2013)
miRNA-302-367 cluster (cardiac specific)	Viable, decreased cardiomyocyte proliferation, and hypoplastic ventricular myocardium in embryonic heart	Mst1, Lats2, Mob1b	Tian et al. (2015)

Studies in embryonic stem (ES) cells reveal the role of miRNA-1 and miRNA-133 in driving cardiac differentiation. The expression of miRNA-1 and miRNA-133 is enriched in ES cell-derived cardiomyocytes but not in undifferentiated ES cells (Ivey et al., 2008). Overexpression of these miRNAs in embryoid body-based culture of ES cells enhances mesodermal lineage commitment and inhibits endoderm or neuroectoderm differentiation. In contrast, miRNA-1 and miRNA-133 seem to exert opposite functions on further differentiation of ES cells toward the cardiac muscle lineage. miRNA-1 promotes differentiation of ES cells toward the cardiac lineage by repressing the Notch ligand Delta-like 1 (Dll-1), whereas miRNA-133 suppresses the cardiac differentiation of ES cells (Ivey et al., 2008). Moreover, in ES cell-derived multipotent cardiovascular progenitors, overexpression of miRNA-1 promotes cardiomyocyte differentiation and inhibits endothelial cell commitment by repressing the Wnt receptor Fzd7 and fibroblast growth factor receptor substrate 2 (Frs2) (Lu et al., 2013). However, the effects of miRNA-1 and miRNA-133 on ES cell cardiac differentiation may be dependent on the model used because behavior of ES cells in 2D is markedly different. In this setting, forced expression of miRNA-1 and miRNA-133 by lentivirus reduces cardiac gene expression (Takaya et al., 2009). miRNA-1 acts by repressing cyclin-dependent kinase 9 (Cdk9), which interacts with p300/Gata4 to active expression of cardiac-specific genes (Takaya et al., 2009). Although there are discrepancies related to miRNA-1 function, these studies have demonstrated the importance of miRNA-1 and miRNA-133 in regulating cardiac muscle differentiation.

miRNA Regulation of Cardiomyocyte Sarcomere Organization

Sarcomeres are the basic contractile units of cardiac muscle. They are composed of thick and thin filaments essential for generation and propagation of mechanical force. Myosin, the major component of the thick filament, is comprised of MHC subunits and

myosin light-chain (MLC) subunits. α-MHC (Myh6) and β-MHC (Myh7) are both expressed in the heart during development and in the adult. In rodents, expression of β-MHC is downregulated after birth so that in the adult, α-MHC is the dominant MHC isoform in the heart (Lyons et al., 1990; England and Loughna, 2013). MHC isoform switches in response to cardiac stress or hypothyroidism. Pathologic hypertrophy is associated with upregulation of β-MHC and downregulation of α-MHC (Krenz and Robbins, 2004; Gupta, 2007).

Expression of α- and β-MHC isoforms is controlled by miRNA-208a, miRNA-208b, and miRNA-499 (van Rooij et al., 2007, 2009; Callis et al., 2009). miRNA-208a and miRNA-208b are encoded in an intron of the α-MHC and β-MHC gene, respectively. Mice null for miRNA-208a are viable but show abnormalities in sarcomere structure and declined cardiac function at 6 months of age (van Rooij et al., 2007). However, miRNA-208a null mice are resistant to cardiac hypertrophy in response to stress induced by transverse aortic banding or calcineurin (van Rooij et al., 2007; Callis et al., 2009). This is concomitant with decreased expression of slow skeletal muscle contractile protein, β-MHC, in the miRNA-208a null heart. The function of miRNA-208a is mediated, in part, by repression of thyroid hormone receptor associated protein 1 (Thrap1), which negatively regulates the expression of β-MHC.

miRNA-208a controls not only the expression of β-MHC in the heart but also that of the closely related slow myosin isoform, Myh7b (van Rooij et al., 2009). Both β-MHC and Myh7b genes encode intronic miRNAs, miRNA-208b, and miRNA-499, respectively (Berezikov et al., 2006; Landgraf et al., 2007). Mice lacking the miRNA-208b or miRNA-499 gene have no obvious developmental defects (van Rooij et al., 2009). However, miRNA-208b/-499 double null mutant mice display reduced expression of slow myofiber β-MHC and increased expression of fast type myosin isoforms. By contrast, overexpression of miRNA-499 leads to increased expression of β-MHC and drives muscle toward a slow myofiber phenotype. Forced cardiac miRNA-499 expression promotes hypertrophy in mice (Shieh et al., 2011; Matkovich et al., 2012). Together, these miRNAs are important in the specification of the identity of muscle fibers by stimulating slow myofiber gene programs at the expense of those that control fast myofiber gene expression (Hodgkinson et al., 2015).

It has been demonstrated that miRNA-1 and miRNA-133 can act as specific activators or suppressors of sarcomere formation and muscle gene expression. Deletion of both miRNA-1-2 and miRNA-1-1 in mice (miRNA-1 null) leads to sarcomere disruption in cardiomyocytes and impaired cardiac function. All the miRNA-1 null mice died before weaning age (Heidersbach et al., 2013; Wei et al., 2014). miRNA-1 functions to negatively regulate myocardin, the major regulator of smooth muscle gene expression, and telokin, the smooth muscle-specific inhibitor of MLC-2 phosphorylation (Heidersbach et al., 2013; Wystub et al., 2013). The upregulation of myocardin and telokin in miRNA-1 null hearts may, in part, contribute to the defect in sarcomere organization. Furthermore, studies from Wei et al. indicated that miRNA-1 directly represses nuclear receptor estrogen-related receptor β (Errβ). The increased level of Errβ in miRNA-1 null heart activates the expression of fetal sarcomere-associated genes (Wei et al., 2014).

miRNA-133a represses smooth muscle gene expression in the heart by directly targeting myocardin and SRF for repression (Liu et al., 2008; Wystub et al., 2013). Deletion of both miRNA-133a-1 and mIRNA-133a-2 (miRNA-133a null) causes late embryonic and neonatal lethality due to ventricular septal defect (VSD) and chamber dilation (Liu et al., 2008). miRNA-133a null mice display sarcomere disorganization and ectopic activation of the smooth muscle gene program (Liu et al., 2008). In addition, mice lacking both miRNA-1 and miRNA-133a displayed severe cardiac dysfunction and died before embryonic day 11.5 (E11.5). Mice with a null mutation in miRNA-1/133a showed increased expression of myocardin and smooth muscle genes in the heart. These studies indicate that miRNA-1 and miRNA-133a clusters are important in cardiomyocyte differentiation and sarcomere formation during embryonic and postnatal life. They act cooperatively to govern the gene transition program from an immature state characterized by expression of smooth muscle genes to a mature phenotype (Wystub et al., 2013).

miRNA Regulation of Cardiomyocyte Proliferation

Mammalian cardiac growth during development is predominantly through cardiomyocyte proliferation (Meilhac et al., 2003). After birth, cardiomyocytes exit the cell cycle, and further increase in myocardial mass is primarily due to hypertrophic increase in cardiomyocyte size (Li et al., 1996; Soonpaa et al., 1996). In mice, cardiomyocyte proliferation peaks between embryonic day 10 (E10) and E12 and again at postnatal day 4 (P4) (Soonpaa et al., 1996). Several studies have highlighted the role of miRNAs in the regulation of cardiomyocyte proliferation during development and early postnatal life (**Fig. 2**).

Mice lacking miRNA-1 exhibit increased cardiomyocyte proliferation and hyperplastic myocardial wall in the developing hearts (Zhao et al., 2007; Wei et al., 2014). miRNA-1 inhibits cardiomyocyte proliferation, in part, by repressing the expression of the heart-and neural crest derivative-expressed (Hand)-2 transcription factor, a positive regulator of cardiac growth (Zhao et al., 2005; Zhao et al., 2007). Similar to miRNA-1, mice lacking miRNA-133a show excessive cardiomyocyte proliferation at postnatal day 1 (Liu et al., 2008). Conversely, overexpression of miRNA-133a in the developing heart reduces cardiomyocyte proliferation. miRNA-133a inhibits cardiomyocyte proliferation by directly repressing cyclin D2 (Liu et al., 2008).

Over the first week of postnatal life in mice, most cardiomyocytes exhibit cell cycle withdrawal (Li et al., 1996; Soonpaa et al., 1996). Cessation of cardiomyocyte proliferation is associated with downregulation of cyclins and cyclin-dependent kinases specific to G1/S and G2/M phases and upregulation of cell cycle inhibitors (Flink et al., 1998; Poolman and Brooks, 1998; Engel et al., 2005). Studies in neonatal hearts have identified the miRNAs that are responsible for the withdrawal of cardiomyocytes from the cell cycle. A microarray analysis for miRNAs differentially regulated during postnatal life identified miRNA-195 as the most highly upregulated miRNA in the mouse heart ventricles at postnatal day 10 (P10), the time point at which mouse cardiomyocytes exit the cell cycle (Porrello et al., 2011). Overexpression of miRNA-195, a member of miRNA-15 family, in the embryonic heart reduces

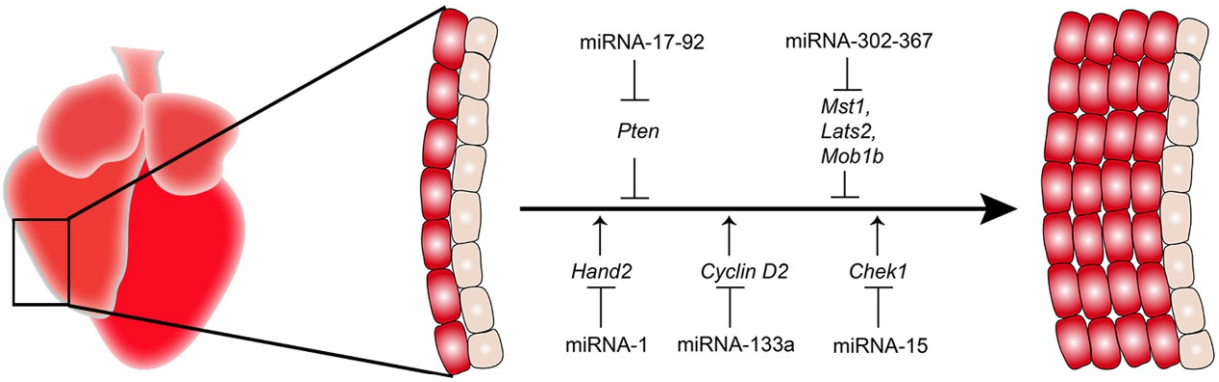

Fig. 2 miRNA regulation of cardiomyocyte proliferation. miRNAs and their target genes in cardiomyocyte proliferation during cardiac development are shown.

cardiomyocyte proliferation and causes ventricular hypoplasia and VSDs (Porrello et al., 2011). Checkpoint kinase 1 (Chek1) was identified as the miRNA-195 target mediating these effects (Porrello et al., 2011, 2013). In contrast, knockdown of the miRNA-15 family in neonatal mice with locked nucleic acid-modified anti-miRNAs leads to increased cardiomyocyte proliferation in both neonates and adult mice (Porrello et al., 2011, 2013).

Other miRNAs of recent interest are the miRNA-17-92 and miRNA-302-367 clusters. Cardiac-specific deletion of either the miRNA-17-92 or miR-302-367 cluster during development leads to reduced cardiomyocyte proliferation and hypoplastic ventricular myocardium (Chen et al., 2013; Tian et al., 2015). Conversely, overexpression of either of these two miRNA clusters causes a profound increase in cardiomyocyte proliferation. The miRNA-17-92 cluster was found to downregulate the tumor suppressor gene, proliferation through repressing phosphatase, and tension homology (Pten) (Chen et al., 2013). The miRNA-302-367 cluster induces cardiomyocyte proliferation by repressing the Hippo signal pathway (Tian et al., 2015). Hippo signaling regulates cell proliferation and organ size in many species (Pan, 2010). Inactivation of this pathway during fetal development in mice leads to marked cardiomegaly (Heallen et al., 2011; Xin et al., 2011; von Gise et al., 2012). miRNA-302-367 represses several Hippo signaling kinases, Mst1, Lats2 and Mob1b, to promote cardiomyocyte proliferation (Tian et al., 2015).

miRNA Function in the Cardiac Conduction System

Cardiomyocytes are excitable cells that can generate and propagate electrical activities. The strict coordination of excitation, impulse propagation, and polarization within cardiomyocytes is important to maintain a normal rhythm in sync with the mechanical actions of the heart. Cardiac excitability is regulated by ion channels, transmembrane proteins that control the movement of ions across the cytoplasmic membrane. Specifically, sodium (Na^+), calcium (Ca^{2+}), and potassium (K^+) channels and gap junction proteins such as connexin43 (Cx43) are critical regulators of cardiomyocyte polarization and depolarization during contraction and relaxation. Several miRNAs, including miRNA-1 and miRNA-133a, target ion channels and gap junction proteins. They might have important pathophysiological functions in the heart, and are potential targets for antiarrhythmic agents.

Ablation of the miRNA-1-2 gene in mice results in arrhythmias, cardiac conduction defects, and sudden cardiac death within 2–3 months of age (Zhao et al., 2007). Cardiac arrhythmias in the miRNA-1-2 mutants may be caused by elevated levels of the transcription factor Iroquois homeobox 5 (Irx5), a direct target of repression by miRNA-1. Irx5 regulates the cardiac ventricular repolarization gradient by negatively regulating the expression of potassium channel genes such as Kcnd2. Similar to miRNA-1-2 null mutants, mice lacking miRNA-1-1 exhibit cardiac conduction abnormalities (Heidersbach et al., 2013). Independent mouse strains with null mutations in miRNA-1-1 and miR-1-2 were engineered by two groups (Wystub et al., 2013; Wei et al., 2014). Cardiac conduction defects were not observed in either of the single knockout strains (Wystub et al., 2013; Wei et al., 2014). The differences between these studies could be due to the methods used to generate the null mice, or genetic background. Interestingly, gain-of-function of miRNA-1 also caused cardiac arrhythmia. miRNA-1 expression is elevated in humans with coronary artery disease and in rats subjected to myocardial infarction (Yang et al., 2007). Overexpression of miRNA-1 in normal or infarcted rat hearts increased the occurrence of arrhythmias. Delivery of an antisense oligonucleotide to suppress miR-1 expression in the heart prevented arrhythmias in the rat infarct model. miRNA-1 regulates cardiac electrophysiology most likely via repressing the expression of KCNJ2 (which encodes the K+ channel subunit Kir2.1) and GJA1 (which encodes connexin 43) (Yang et al., 2007). In addition, miRNA-1 regulates calcium signaling through repressing B56α, the protein phosphatase PP2A regulatory subunit (Terentyev et al., 2009). Overexpression of miRNA-1 results in hyperphosphorylation of L-type calcium channels and ryanodine receptor 2, and promotes arrhythmogenic alterations in myocyte calcium cycling (Terentyev et al., 2009).

It has been further demonstrated that the two miRNA-1/133a clusters are involved in regulation of adrenergic signaling in cardiomyocytes and in the modulation of the electrical properties of the postnatal and adult heart (Besser et al., 2014). The tight regulation of QT duration is essential for general heart function to prevent potentially fatal arrhythmias. Deletion of one or the other miRNA-1/133a cluster leads to longer QT intervals as well as altered calcium currents triggered by β-adrenergic signaling

(Besser et al., 2014). Application of propranolol or verapamil, to block either adrenergic signaling or L-type calcium-channels, abrogated the long QT phenotype in miRNA-1/133a single cluster mutant mice (Besser et al., 2014).

Although muscle myosin-related miRNAs generally act by regulating myofiber identify, miRNA-208a has been shown to control cardiac conduction by regulating expression of gap junction protein connexin 40 (Cx40) and the homeodomain-only protein (Hop) and Gata4 transcription factors (Callis et al., 2009). Functional studies in animal models reveal that mice lacking miRNA-208a display electric conduction defects and cardiac arrhythmias. Overexpression of miRNA-208a in mouse heart induces cardiac hypertrophy and arrhythmias (Callis et al., 2009).

miRNA in Cardiac Patterning

Heart development is a highly organized process. A tight gene regulatory network is required to create stable differences or boundaries between the myocardium of different chambers (Harvey, 2002). Recent studies in zebrafish have indicated that miRNAs control cardiac chamber-specific gene expression patterns. The zebrafish heart contains a single atrium and a single ventricle. During heart development, these two chambers are separated by the atrioventricular canal (AVC), which eventually gives rise to the cardiac valves (Stainier, 2001; Yin and Pacifici, 2001). miRNA-138 is specifically expressed in the ventricular chamber of the zebrafish heart (Morton et al., 2008). Knockdown of miRNA-138 by morpholino or anti-miRNA in zebrafish embryos results in the expansion of AVC gene expression into the ventricular chamber. The mutant hearts display impaired cardiomyocyte maturation and pericardial edema, indicative of cardiac dysfunction. miRNA-138 restricts AVC gene expression in the cardiac ventricle by negative regulation of the cell adhesion molecule versican (Cspg2) and the retinoic acid synthesis enzyme aldehyde dehydrogenase-1a2 (Adlh1a2) (Morton et al., 2008).

Slit ligands and roundabout (Robo) receptors function as crucial regulators of heart tube formation. In zebrafish, Slit-Robo signaling provides a short-range directional cue for the migration of cardiac progenitor cells (Fish et al., 2011). miRNA-218a-1 and miRNA-218a-2 genes are within an intron of the Slit2 and Slit3 genes, respectively. miRNA-218 directly targets Robo1 and Robo2 transcripts for repression. Knockdown of miRNA-218 by morpholinos in zebrafish embryos leads to impaired migration of cardiac progenitor cells and incomplete heart field fusion. The miRNA-218 mutant heart shows increased Robo1 expression and knockdown of Robo1 rescues the miRNA-218 mutant phenotype. This study suggests that miRNA-218 modulates the levels of Robo1 to control cardiac progenitor cell migration and heart tube formation (Fish et al., 2011). In addition, other studies identified different roles for miRNA-218 in zebrafish heart development. Overexpression of miRNA-218 in zebrafish embryos causes heart looping defects and cardiac chamber abnormalities. However, miRNA-218 knockdown does not cause any defects in cardiac development (Chiavacci et al., 2012). The differences between these two studies may reflect that miRNA-218 controls heart development through multiple pathways, or the requirement of miRNA-218 during cardiac development is limited only to a distinct temporal window of early cardiac fusion, and is dispensable thereafter. miRNA-138 and miRNA-218 are conserved from zebrafish to humans. Thus it will be interesting to study whether these miRNAs play similar roles in patterning mammalian heart.

Conclusions and Implications for Regenerative Medicine

Heart development is a paradigm of organogenesis. The study of miRNA in developing heart has yielded important insights into the molecular mechanisms that control cardiac formation and function. miRNAs act to confer accuracy and uniformity to developmental transitions. Loss of miRNAs may result in cardiac abnormalities and dysfunction. Understanding how interactions of miRNAs and targets can drive concerted development during cardiac growth is critical for future prospects in regenerative medicine. For example, the identification of miRNAs that are important in cardiomyocyte proliferation during development has allowed for development of miRNA-based therapeutics that can promote myocardial proliferation and regeneration in adulthood (Chen et al., 2013; Porrello et al., 2013; Tian et al., 2015). With delivery of these miRNA mimics or anti-miRNAs into the ischemic heart of adult mouse, this treatment promotes the regeneration of new myocardial tissues and improved cardiac function (Porrello et al., 2013; Tian et al., 2015).

In addition, many pathologies and abnormalities can occur when miRNAs are dysregulated, including cardiac hypertrophy and heart failure. For excellent reviews on pathological conditions resulting from improper miRNAs, see Small et al. (2010).

miRNA-mediated posttranscriptional gene repression has been recognized as fundamentally important to understand cardiac developmental processes. Changes in miRNAs cause changes in spatial and temporal organizations of tissues, which affect biological function. Heart organogenesis thus requires a greater understanding of the relationships between the posttranscriptional regulatory programs and their physiological effects.

Introduction

The microvasculature is an integral component to all tissues, necessary for establishing and maintaining tissue health and function via blood perfusion and a dynamic interplay with tissue cells and environment. A microvasculature capable of supporting effective perfusion consists of a properly arranged hierarchical tree of thousands of heterogeneous vessel types generating effective and regulatable blood flow pathways. Comprised of a variety of cell types, the microvasculature is a sophisticated system intimately associated with the tissue environment. As such, it mediates blood:tissue communication important for tissue homeostasis including gas/nutrient exchange, paracrine and endocrine signaling, immune cell dynamics, reparative processes, and specific tissue functions. Because of this central importance of the microvasculature in tissue health, any treatment strategy for a disease state should consider the impact on the microvasculature, including reversing microvascular dysfunction. With this in mind, new treatment strategies targeting specifically the dysfunctional microvasculature are emerging with great promise in managing health and disease.

Microvasculature: Form and Function

The microvasculature, comprised of the most distal aspects of the vasculature, serves as the blood:tissue interface in any tissue. While often considered separately, the microvasculature is an integrated component to any tissue and is necessary for that tissue's function and health. This is highlighted by the many pathologies that either occur due to or are complicated by microcirculatory dysfunction (MCD) (Olsen et al., 1983; Jeremy et al., 1987; Lamah et al., 1999; Georgi et al., 2011; Duncan and Faris, 1986; Futrakul et al., 1995; Claxton and Fruttiger, 2005; Darland et al., 2003; Benjamin et al., 1998; Hallerstam et al., 2004; Cutolo et al., 2010; Faber et al., 2011; Bauer et al., 2005; Humar et al., 2009; Mourad and Levy, 2011; Ryschich et al., 2002; Weidner and Folkman, 1996; Gutterman et al., 2016). In order for a microvasculature to function as an effective circulatory circuit, each microvessel must be properly organized into a microcirculatory network. Native, functional microcirculations, while topologically unique for different tissue

Table 1 Example diseases and conditions linked to microvascular dysfunction

Aging	No-reflow phenomenon
Cancer	Ischemic disease
Hypertension	Reperfusion injury
Pulmonary hypertension	
Atherosclerosis	Peripheral limb ischemia
Cardiomyopathy	
Coronary microvascular disease	Obesity
Cardiac hypertrophy	Metabolic syndrome
Coronary artery disease	Chronic inflammatory disease
Heart failure	Stroke
Atrial fibrillation	Kawasaki disease
Systemic sclerosis	Autoimmune disease
Peripheral neuropathy	Rheumatoid arthritis
Obstructive sleep apnea	Diabetes (Type I & Type II)
Chronic kidney disease	Vascular dementia
Dementia	Radiation injury
Reynaud's syndrome	Amyotrophic lateral sclerosis

types, consist of hierarchically organized microvessels, heterogeneous in size and phenotype, generating a network with short, homogeneous diffusion distances between individual capillaries, low resistances to flow through the network, and no oxygen gradients across the tissue (Pries and Secomb, 2014; Pries et al., 2010). The absence of one or more of these features results in compromised perfusion and/or exchange despite adequate microvessel densities (**Table 1**) (LeBlanc et al., 2012a).

How microvascular networks form and adapt is less well known than how new microvessels form (i.e., angiogenesis). Yet, these network-related dynamics occurring after new vessel segments have grown are critical to the proper regeneration and/or repair of a microcirculation. Questions related to what are the factors promoting and regulating this "postangiogenesis" progression, how do newly formed, immature neovessels integrate into a network, what level of plasticity is required in network formation, and how is microvascular stability maintained during periods of intense neovessel adaptation and remodeling need to be answered before we can develop an effective regenerative strategy for establishing therapeutically competent microcirculations.

Microvascular Networks

As mentioned, a functional microcirculation consists of an ordered arrangement of microvessels with a heterogeneous distribution of diameters in a diameter- and function-based hierarchical topology. With caveats (e.g., in skeletal muscle arcades or arterio-venous shunts), healthy blood flow is unidirectional through this network from arterioles to capillaries to venules. An often described example of a microvascular network in which this diameter-based hierarchical network architecture is disrupted is the tumor microcirculation in which these three microvascular compartments are compromised (Pries et al., 2009, 2010; Secomb et al., 2012). Thus the perfusion circuit in a tumor is disorganized and unregulated, resulting in zones of flow stasis, regional inhomogeneous blood:tissue exchange, and hypoxia. Importantly, many regions of the tumor microvasculature contain higher than typical microvessel densities, highlighting the additional point that more vessels do not necessarily equal more perfusion; effective perfusion requires proper microvascular network organization.

Topology

Branching is a hallmark of a microvascular network and is the means by which blood is distributed throughout the tissue via low resistance pathways (Koller et al., 1987; Ley et al., 1986; Ellsworth et al., 1987). Often, microvascular networks are schematized as a symmetrical hierarchical distribution of progressively branching vessels with the inflow paths located on one side of the network and the outflow paths located on the opposite side. However, most native vascular networks are asymmetrical in organization; feed arteries are often adjacent to draining veins with the hierarchical network distributed around them in the tissue. This asymmetrical topology eliminates tissue-wide oxygen and exchange gradients, which are present in the contrived symmetrical networks (Pries and Secomb, 2014).

Vessel Density and Perfusion

Intuitively, more vessels should provide more perfusion. However, this is not always the case and, in fact, too many vessels within a network can compromise perfusion. For example, in the aforementioned solid tumors, there are high microvessel densities yet tumor perfusion is chaotic and limited (Pries et al., 2009; Dewhirst et al., 1989). Also, perfusion in granulation tissue—which has high vessel density—is abnormal, highlighted by congested flow (Dewhirst et al., 1989; Dudar and Jain, 1983). In the repairing mouse ischemic hindlimb 1–2 weeks following the ischemic insult, vessel densities are almost twice that of normal, yet resting perfusion is roughly half that of the uninjured contralateral hindlimb (Sullivan et al., 2002; Couffinhal et al., 1998). Similarly,

coronary flow reserve (CFR) is compromised postmyocardial infarction, despite an elevated vessel density (Leblanc et al., 2013). Thus, perfusion and vessel density are not necessarily coupled and while it is necessary to have sufficient numbers of microvessel segments in a network, other components related to network form and function are needed to provide sufficient perfusion.

Indeed, skeletal muscle vascularity following chronic exercise increases leading to proportional increases in muscle bed perfusion (Egginton and Hudlicka, 1999; Egginton et al., 1998). Importantly, this increase in vascularity occurs while preserving normal network topology with concomitant increase in arterioles and capillaries (Hansen-Smith et al., 1998, 2001). In tissues of growing juvenile rats, similar proportional changes occur in the network in the growing heart preserving coronary microvascular architecture (Batra and Rakusan, 1992). Yet, in the growing intestine, arteriole density and branching remain constant but microvessel segment lengths and caliber increase (Unthank et al., 1990; Unthank and Bohlen, 1987). The implications from these and other observations related to repair of microvasculatures are profound. Changes in vascular volume and not microvessel numbers appear to be a more productive objective. Of course one way to increase vascular volume, for example, is by promoting the formation of new microvessels (e.g., via angiogenesis). However, without the coordinated integration of these new microvessels into the network, perfusion will not be increased. In this regard, network architecture (as well as flow control) are, perhaps, more important in expanding a perfusion bed than vessel numbers. This argues for a new approach in vascular regeneration; one that targets the determinants of microvascular network form and function.

Microvascular Dysfunction

In a system as complex as the microvasculature, a number of biological problems may arise and contribute to dysfunction and disease, including alterations in vessel density, faulty flow control, prothrombotic conditions, and oxidative stress (**Fig. 1**). The endothelial cell (EC) lining of the microvasculature comprises the majority of ECs within the circulatory system and, as such, EC dysfunction is a significant contributor to the onset and progression of various forms of microvascular dysfunction. In health, the EC integrally regulates angiogenesis, vasomotor tone, vascular permeability, thrombolysis, immune cell targeting/extravasation, and wound healing. Characteristic changes that occur in the transition from healthy to dysfunctional EC signaling include significant metabolic perturbations with increased reactive oxygen species (ROS) generation (Goveia et al., 2014), decreased nitric oxide (NO) bioavailability (Karbach et al., 2014), proinflammatory signaling (Pober and Sessa, 2007), and blunted flow-mediated dilation (Anderson et al., 1995). While the EC is a focus of many investigations into microvascular health and disease, it is important to note that the microvessel wall consists of a system of cell types including the EC. Thus, dysfunction often reflects deficits in control and regulation between the other vascular cells, in particular the vascular smooth muscle cells (Alexander and Owens, 2012), comprising the microvessel.

Vascular Density

As previously mentioned, diameter mismatch and overall network disorganization between vessels within the microcirculation can lead to blood perfusion discrepancies, such as in tumor biology (Pries et al., 2009, 2010; Secomb et al., 2012). Oftentimes, the

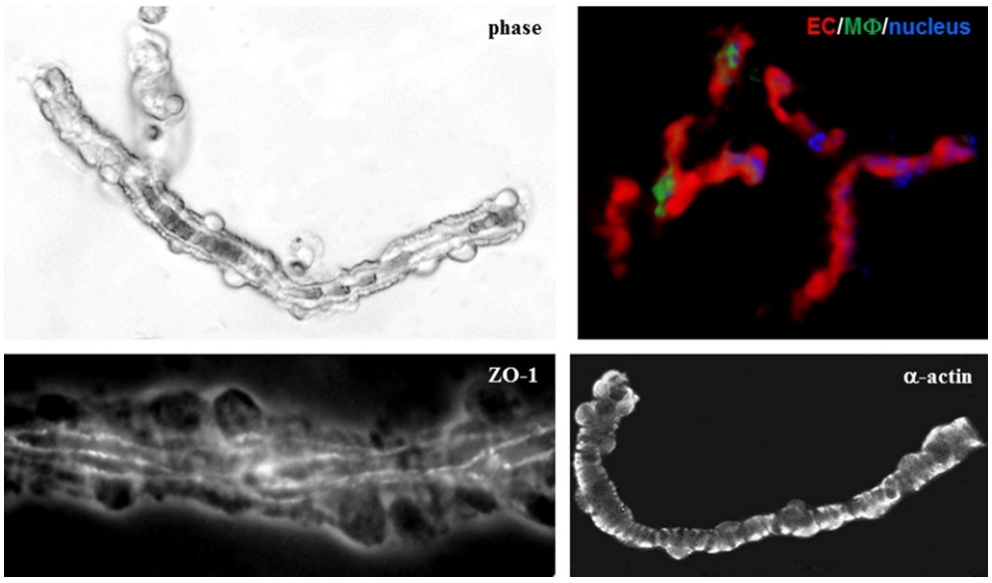

Fig. 1 Example structure of microvessels isolated from adipose tissue (phase panel is a precapillary arteriole) highlighting the complex and multicellular structure of the microvessel wall. Cells within the microvessel are in intimate contact and communication with each and the surrounding tissue environment.

perfusion inefficiency seen in tumors is a result of hypervascularization (Pries et al., 2009), a phenomenon perhaps driven by the overexpression of angiogenic factors within the tumor (Pries et al., 2010). The aberrant vascular conditions within the tumor milieu leads to an environment that is simultaneously hypoxic and flooded with ROS, including hydrogen peroxide (H_2O_2). This environment can lead to gap junction dysfunction and impaired cell-cell communication within the tumor microvasculature (Secomb et al., 2012; Pries et al., 2010).

On the opposite end of the microvascular density spectrum, capillary rarefaction, as seen in hypertension (Humar et al., 2009; Mourad and Levy, 2011; Lubrano and Balzan, 2016) and systemic sclerosis (Cutolo et al., 2010), leads to a reduction in overall capillary number. Indeed, microvascular rarefaction is quite common in hypertensive patients, beginning with loss of endothelium function followed by a narrowing of the vessel lumen. This irregular vasoconstriction of the capillaries ultimately leads to a loss of perfusion; subsequently, the cells within these vessels may undergo apoptosis (Mourad and Levy, 2011). In a deleterious positive feedback loop, this capillary loss causes increased resistance through the remaining peripheral vasculature, resulting in even higher blood pressure (Humar et al., 2009). Interestingly, patients who receive antiangiogenic drugs to treat tumors commonly exhibit increased blood pressure following treatment. VEGF-A is an important target of these drugs; the decrease in VEGF-A following antiangiogenic treatment may decrease the transcription of endothelial nitric oxide synthase (eNOS), thus reducing endogenous levels of the vasodilator NO. Less NO in the system leads to vasoconstriction, thereby inducing hypertension in these patients (Mourad and Levy, 2011).

Flow Control

Compromised tone and flow control is the hallmark of MCD, and may be manifested in several diseases (Gutterman et al., 2016). Indeed, the rarefaction of capillaries previously discussed with regard to hypertension is, at least initially, due to compromised vascular tone in these small vessels (Humar et al., 2009). Additionally, many patients who present with angina but do not exhibit signs of coronary artery disease (CAD) yet are thought to be experiencing ischemic disease likely due to coronary microvascular dysfunction (CMD) brought on by diminished vasodilatation of the coronary arterioles and small arteries. This microvascular tone dysfunction inhibits CFR, leaving the heart with insufficient resources when challenged by stress or exercise (Marinescu et al., 2015). Furthermore, other patients without signs of CAD have presented with angina associated with atrial fibrillation (AF) caused by microvascular flow disturbance. In these patients, oxidized LDL receptor-1 (LOX-1) was upregulated by increased systemic angiotensin II (Ang II) brought on by the AF. This cascade led to an increase in ROS in the blood, resulting in reduced NO levels and therefore decreased vasodilatory ability within the microvessels (Lubrano and Balzan, 2016).

Impaired vascular tone is also seen in both Type I and Type II diabetes. Some diabetic patients exhibit decreased CFR in response to a cardiac challenge, as well as impaired coronary vasodilation (Nahser et al., 1995; Gutterman et al., 2016; Di Carli et al., 2003). In addition, in a rat model of prediabetic metabolic syndrome, microvascular atrophy as well as decreased lumen size and vessel wall thickness were all observed (Stepp et al., 2004). In humans, patients diagnosed with both diabetes and metabolic syndrome exhibited reduced vasoconstriction in resistance arteries following exogenous administration of endothelin (ET-1), likely caused by a downregulation of receptors due to overproduction of endogenous ET-1 (Cardillo et al., 2002). This abundance of endogenous ET-1 in diabetic patients may also be linked to the increased rate of hypertension in this population (Cardillo et al., 2002). Taken together, it is apparent that microvascular tone is an important regulatory component of blood flow, and numerous diseases can have deleterious effects on the system.

Thrombosis

Ischemia arises from perfusion deficits due to failures in the microcirculation often related to EC activation secondary to insult or inflammation. Microvascular ischemia often occurs as clumped leukocytes and/or platelets lodge in the bloodstream (Gutterman et al., 2016); the smaller diameters of the microvessels within the microcirculation make it particularly susceptible to these thrombotic events. Inevitably, the location of the ischemic episode will play a large role in the deficits manifested in the patient. An ischemic microcirculatory event in the heart can lead to angina, cardiovascular disease, and even death, whereas similar incidents in other organs or tissues of the periphery may only lead to localized impairment (Gutterman et al., 2016; Kothawade and Bairey Merz, 2011). Following an ischemic event of the coronary microvasculature, reperfusion injury is a common occurrence. Perivascular edema, cell swelling, increased capillary permeability, and increased levels of ROS within the coronary compartment can lead to further complications including necrotic cell death and destruction of the coronary microcirculation (Heusch and Gersh, 2016). In a prediabetes model of microvascular disease, reduced lumen size and thinner vessel walls in the microcirculation have been observed (Lubrano and Balzan, 2016). These physiological deficits inherently put the system at greater risk for a thrombotic event, especially as the patient progresses into full manifestation of Type II diabetes. Another example is that of capillary leakage. Depending on the location of the compromised vessels within the microcirculation, this can lead to sepsis and/or multiorgan failure (Lubrano and Balzan, 2016).

Shear Stress

EC responses to shear stress are markedly different in health and disease. A notable example is the switch from NO as a primary effector of flow-mediated dilation, to a secondary mediator like H_2O_2 (Gutterman et al., 2016). In the context of vascular disease with an increasingly oxidative milieu, NO is scavenged through reactions with superoxide (O_2^-) radicals and produced at a lower

rate as eNOS is uncoupled through various mechanisms (Chen et al., 2010; Antoniades et al., 2009; Landmesser et al., 2003). Loss of NO availability can result in: vascular smooth muscle cell (VSMC) proliferation (Jeremy et al., 1999), impaired postischemic angiogenesis (Murohara et al., 1998), impaired neovascularization (Aicher et al., 2003) and increased EC expression of leukocyte adhesion molecules (Liao, 2013). For these reasons, restoration of eNOS functionality and NO bioavailability are major focuses in treating EC dysfunction.

Microparticles/Exosomes

Recently, microparticles/exosomes generated by ECs have been investigated for their role in paracrine signaling during the progression of disease, particularly EC-originated microparticles (Zernecke et al., 2009; Wang et al., 2016; Deng et al., 2015; Xue et al., 2015; Diamant et al., 2004). Microparticles and exosomes are vesicular products released from the plasma membranes and endosomal membranes, respectively, of cells in response to a variety of stimuli. They contain a wide spectrum, depending on the originating cell type, of regulatory, signaling, and transcriptional molecules (Mause and Weber, 2010; Raposo and Stoorvogel, 2013). Microparticle-microRNA (miR) delivery has restorative effects in the context of EC inflammation (Ma et al., 2016), though microparticles released from dysfunctional ECs are sufficient to induce pathology in vitro and in vivo when introduced into an otherwise healthy circulatory system (Jansen et al., 2013). Low, disturbed shear stress and other CVD risk factors appear to be physiological regulators of EC microparticle release (Vion et al., 2013). These findings support a hypothesis that localized microvascular EC dysfunction has the capacity to induce dysfunction in otherwise healthy ECs through increased microparticle secretion into the vasculature. For these reasons there is an emerging consensus that early diagnosis of MCD through biomarkers among the lipids, proteins, and microRNAs within EC-released microparticles will improve patient outcomes and lead to identification of unique therapeutic targets in MCD (Gutterman et al., 2016; Gulati et al., 2012). This approach of identifying circulating EC microparticle biomarkers may provide a much needed standard diagnostic criterion for various forms of MCD (Marinescu et al., 2015). Novel therapeutic approaches for EC dysfunction may include specific miR inhibition (Sun et al., 2012; Loyer et al., 2014; Menghini et al., 2014), or pharmacological suppression of microparticle secretion once there is a more complete understanding of their mechanism of release.

Oxidative Stress

The interplay between ROS, reactive nitrogen species (RNS), and the physiological mechanisms of the microvascular network is complicated. Excess levels of ROS and RNS are involved in a number of disease states, including tumor growth (Pries et al., 2010; Secomb et al., 2012), ischemia/reperfusion injury (Lubrano and Balzan, 2014; Montezano and Touyz, 2012), diabetes mellitus (Lubrano and Balzan, 2014, 2016; Montezano and Touyz, 2012; Gutterman et al., 2016), hypertension (Lubrano and Balzan, 2014, 2016; Montezano and Touyz, 2012; Gutterman et al., 2016; Simplicio et al., 2016), atherosclerosis (Beckman and Koppenol, 1996; Lubrano and Balzan, 2014; Montezano and Touyz, 2012), chronic kidney disease, systolic cardiac failure, pulmonary hypertension, dementia, inflammatory disease, and radiation-induced endothelial dysfunction (Montezano and Touyz, 2012). ROS/RNS levels also play an important role in the loss of function due to aging seen in coronary arterioles (Kang et al., 2011; LeBlanc et al., 2008, 2009; Nevitt et al., 2016) and collateral microvessels (Faber et al., 2011). On the other hand, ROS and RNS have also been described as beneficial to the microvasculature in a number of ways. For example, they play a role in inflammation and induction of host defense genes (Montezano and Touyz, 2012; Beckman and Koppenol, 1996), activation of transcription factors, stimulation of ion transport systems, and controlling endothelial function and vascular tone (Montezano and Touyz, 2012). They are also integral to the flow-mediated dilation of the microvasculature (Gutterman et al., 2016; Beyer and Gutterman, 2012; Kang et al., 2011; LeBlanc et al., 2008, 2009). Low levels of ROS are required for the growth of new microvessels (Lubrano and Balzan, 2014), and also help to modulate blood flow, thrombosis, and neural activity in healthy individuals (Beckman and Koppenol, 1996). Thus, it becomes apparent that endogenous levels of ROS and RNS within the microvascular system involves an intricate balance; too much or too little of one or more may lead the system into dysfunction and disease.

Superoxide (O_2^-) and hydrogen peroxide (H_2O_2) are clearly important players and a number of enzymes are involved in the production and elimination of both of these compounds. The primary source of ROS in the vasculature is nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, which reduces O_2 to O_2^- using NADPH as an electron donor (Simplicio et al., 2016). The ROS generated from the activity of NADPH oxidase can induce injury and/or disease via mitogen-activated protein kinase pathways, resulting in inflammation, hypertension, and atherosclerosis (Simplicio et al., 2016). In addition, as previously mentioned, oxidized LDL binding to its receptor LOX-1 has been shown to activate NADPH oxidase to produce high levels of both ROS and RNS, including O_2^-, H_2O_2, hydroxyl radical (OH^-), peroxynitrite ($ONOO^-$), and NO in patients with hypercholesterolemia (Lubrano and Balzan, 2016). This system creates a positive feedback loop in which the elevated levels of ROS and RNS stimulate the upregulation of LOX-1 receptors, leading to further binding of oxidized LDL and production of still higher levels of ROS and RNS, ultimately resulting in decreased vasodilation and EC apoptosis (Lubrano and Balzan, 2014, 2016).

The NADPH oxidase pathway is also involved in hypertension; in these patients, Ang II is upregulated, leading to increased NADPH oxidase levels. This in turn produces higher levels of O_2^-, which binds with NO to produce the toxic oxidant $ONOO^-$, thereby causing endothelial dysfunction. This reaction also depletes the bioavailability of NO in the microvasculature, resulting in further vasoconstriction in hypertensive patients (Lubrano and Balzan, 2016). This role of NADPH oxidase-derived ROS is also critical in the development of alcohol-induced hypertension in adult rats, with the potential for similar ROS-driven symptoms in humans (Simplicio et al., 2016). Similarly, excess ROS—especially O_2^-—can be produced by ECs, macrophages, and other immune

cells following an ischemic event in small vessels such as arterioles and capillaries. As in hypertension, the higher levels of O_2^- in the ischemic system reacts with NO to produce $ONOO^-$ and can lead to reperfusion injury, and ROS scavengers may help prevent this reperfusion insult (Lubrano and Balzan, 2014; Escobales et al., 2014).

Notably, the enzyme superoxide dismutase (SOD) acts to deter $ONOO^-$ formation and the subsequent reduction in NO from the microvascular system by rapidly converting the potentially harmful O_2^- into H_2O_2. The role of H_2O_2 within the cardiovascular system is complex; excess levels have been linked with tumor development (Secomb et al., 2012; Pries et al., 2010), ischemia/reperfusion injury (Escobales et al., 2014), inflammation-induced thrombosis (Gutterman et al., 2016), and alcohol-induced hypertension (Simplicio et al., 2016). Given its involvement in these disease models, it is perhaps surprising that H_2O_2 is also an important regulator of vasodilation when NO bioavailability is reduced, as the endothelium can stimulate smooth muscle cells of the microvasculature to generate compensatory H_2O_2 when NO levels drop due to disease or aging (Gutterman et al., 2016). In a healthy cardiovascular environment, SOD can keep pace with spontaneous generation of O_2^- and convert it to H_2O_2; problems arise when SOD becomes inefficient and/or the levels of O_2^- become so high that it becomes toxic to the system. Increasing the levels of SOD in the diseased system—for example, via the antioxidant Resveratrol—helps to reduce the potentially damaging levels of O_2^- radicals (Spanier et al., 2009). There is also evidence that estrogen plays an important role in regulation of SOD; in aged female rats, there is decreased NO-mediated vasodilation of the coronary arterioles due to inadequate buffering of O_2^- radicals (Kang et al., 2011). Estrogen treatment helps to reverse this symptom via upregulation of SOD expression in the microvasculature (Kang et al., 2011) and an increase in phosphorylation of eNOS (LeBlanc et al., 2009).

The primary enzyme for maintaining adequate NO levels in the blood vessel wall, eNOS catalyzes L-arginine to produce NO. In a healthy vascular system, eNOS monomers spontaneously form dimers, allowing eNOS to bind tetrahydrobiopterin (BH_4) and L-arginine to produce NO. When the monomers become uncoupled, they produce O_2^- rather than NO; thus, eNOS uncoupling is another source of potentially harmful ROS within the microvascular system (Zhao et al., 2015). For example, uncoupled eNOS plays a role in cardiac dysfunction and hypertrophy (Gutterman et al., 2016), hypertension (Zhao et al., 2015; Montezano and Touyz, 2012), diabetes mellitus (Montezano and Touyz, 2012; Zhao et al., 2015), and hypercholesterolemia (Zhao et al., 2015; Lubrano and Balzan, 2016; Montezano and Touyz, 2012). NADPH oxidase is also important in the uncoupling of eNOS; as previously discussed, NADPH oxidase can generate increased levels of O_2^-, which binds with NO to form $ONOO^-$. In addition to the deleterious effects of $ONOO^-$ already discussed, it can also oxidize BH_4 to BH_3 radical, resulting in insufficient levels of BH_4 and thus leading to eNOS uncoupling (Zhao et al., 2015).

Finally, inhibition of eNOS via other chemical-dependent pathways can have similar negative effects on NO levels in the microvasculature. For example, in aged rats, increased levels of thrombospondin-1 (Thbs-1) has been shown to inhibit NO production via eNOS, and also decreases the downstream soluble guanylyl cyclase, all of which leads to an increase in O_2^- levels (Nevitt et al., 2016). Similarly, aged mice exhibit decreased phospho-eNOS in the walls of collateral microvessels, a possible player in the reduced collateral remodeling often seen in old age (Faber et al., 2011). The diminished eNOS activity in these older mice leads to increased EC apoptosis, further adding to the complications associated with aging microvasculature (Faber et al., 2011).

Taken together, the complex interplay between ROS, RNS, and their associated enzymes offer important insight into a number of cardiovascular disease models. Therapeutic strategies that reduce harmful oxidants and/or increase levels of antioxidants have shown promising results for ameliorating the deleterious effects of oxidative stress. Cell therapies offer another potential avenue for treatment of microvascular dysfunction. Adipose-derived stromal vascular fraction (SVF) cells injected into normal mice led to enhanced pressure-dependent relaxation in the saphenous artery (Morris et al., 2015). In these vessels, both H_2O_2 and O_2^- were significantly increased within the vessel walls, indicating enhanced production of both (Morris et al., 2015). Thus, as previously mentioned, it is important to consider that, despite extensive literature on the negative effects of ROS and RNS, their roles within the microvasculature are not fully understood. Effective treatment of microvascular dysfunction in the many disease models in which it is implicated will likely depend on a multifaceted strategy involving ROS/RNS attenuation and/or enhancement.

Microvascular Therapeutics

Given the causative role of the microvasculature in disease, it is worthwhile to develop therapies targeting specifically the microcirculation as a means to treat the disease (Hill et al., 2009; Flammer et al., 2012). Indeed, others have championed establishing clinical programs focused on EC medicine similar to the organ-specific programs traditionally in place (Aird, 2007, 2012). There are a number of vascular-targeting medical, surgical, and interventional therapies available to clinicians. However, most of these are focused on manipulating large vessels such as bypass and stenting. The high level of complexity and heterogeneity, in both the cell biology and physiology, intrinsic to the microvasculature has made current macrovascular therapies difficult to translate to the microvasculature. Microvascular-specific therapies currently being explored relate to regenerating a new microvasculature and/or normalizing microvascular function (e.g., flow control). Both approaches offer significant promise, but have yet to be fully realized clinically (**Table 2**).

Microvascular Regeneration

In microvascular regeneration, the objective is to rebuild or reconstitute a microcirculation. Originally explored in the context of ischemic disease in which the objective was/is to expand the microvasculature to improve compromised blood flow to an effective tissue, this is also known as "therapeutic angiogenesis" (Annex, 2013; Silvestre et al., 2013). Based on successful animal studies trials

Table 2 Therapies for microvascular dysfunction[a]

Vasoactivity/tone: compromised flow/reserve	
Antioxidants	Exercise
ACE inhibitors	Weight loss
Angiotensin blockers	Smoking cessation
β-Blockers	
Calcium-channel blockers	*Cell therapy*
Nitric oxide donors	*Exosome/microparticle therapy*
Phosphodiesterase inhibitors	*MicroRNA inhibition*
Sodium current inhibition (ranolazine)	
Statins	
Vessel stability/density: rarefaction, hypervascularity	
Exercise	*Angiogenic factor therapy*
Smoking cessation	*ACE inhibitors*
Weight loss	*Cell therapy*
	MicroRNA inhibition
	Nitric oxide donors
Hemostasis: thrombosis, inflammation	
Antioxidants	Exercise
Statins	Weight loss
Hormone therapy	Smoking cessation
Cell therapy	
Exosome/microparticle therapy	
MicroRNA inhibition	
Nitric oxide donors	
Remodeling/topology: perfusion deficit	
Exercise	*Cell therapy*
Smoking cessation	*MicroRNA therapy*
Weight loss	*Nitric oxide donors*
	Angiogenic factor therapy

[a]Italics indicates those therapies being developed or may have unproven effects.

(Giordano et al., 1996; Baffour et al., 1992; Takeshita et al., 1994; Tsurumi et al., 1996), a number of clinical trials involving the delivery of angiogenic factors intended to grow new vascular elements were performed with limited overall success (Henry et al., 2003, 2007; Losordo et al., 2002; Fortuin et al., 2003; Hedman et al., 2003; Annex, 2013). The poorer than expected outcomes likely reflected an inability to reestablish competent perfusion to the affected tissues, although technical issues related to angiogenic factor delivery and patient selection were likely also relevant. While it is important to promote the generation of new microvessel segments (i.e., via angiogenesis) in these ischemic tissue beds, it is equally if not more important that the regeneration strategy promote the progression of these newly formed neovessels into a mature, stable microvascular network capable of supporting effective tissue perfusion (LeBlanc et al., 2012a). Because the therapies were designed to promote vascular growth and not necessarily postangiogenesis maturation and stabilization of the neovascular network that formed, perfusion posttreatment likely remained compromised. Due to the difficulties related to measuring deep-tissue perfusion in the microvasculature, measurements necessary to confirm this were not possible in these studies, yet there is experimental evidence that functional compromise occurs in newly formed or remodeled microvasculatures. For example, hyperemic flow-reserve in the profunda femoris artery of the postischemic revascularizing mouse hindlimb is reduced (Cardinal et al., 2011). Similarly, in an animal model of myocardial ischemia, coronary endothelium-dependent vasoactivity was compromised in the remodeled small arteries in the affected myocardium (Sellke et al., 1994; Sellke and Quillen, 1992).

Postangiogenesis

Overall, native formation of a microcirculation involves the generation of numerous immature neovessels which interconnect to form a simple, nonhierarchical, and homogeneous network (all via angiogenesis) which then, upon the introduction of blood flow into the network, revises and remodels (via post-angiogenesis) to derive a new, stable microcirculation that is lower in microvessel density (via pruning) than initially present and comprised of hierarchically arranged, heterogeneous microvessels (both in diameter and phenotype) forming effective perfusion paths (Nunes et al., 2010) (**Fig. 2**). This implies that the considerable plasticity and adaptation (and the requisite instability) that is occurring postangiogenesis are necessary aspects of normal postangiogenesis maturation. Furthermore, conditions that do not permit or promote these dynamic changes will result in poorly formed and ineffective microcirculations. Strategies focused on regenerating the microcirculation must permit this dynamic stability and adaptation to occur in order to form a functional microvasculature.

A number of vascular processes impact the evolution of a functional microvascular network. These include maturation, pruning, arterio-venous specification, phenotypic specification, and structural remodeling. During the generation of a new microvascular network in the adult (i.e., neovascularization), new vessel elements are usually formed via sprouting angiogenesis. These newly

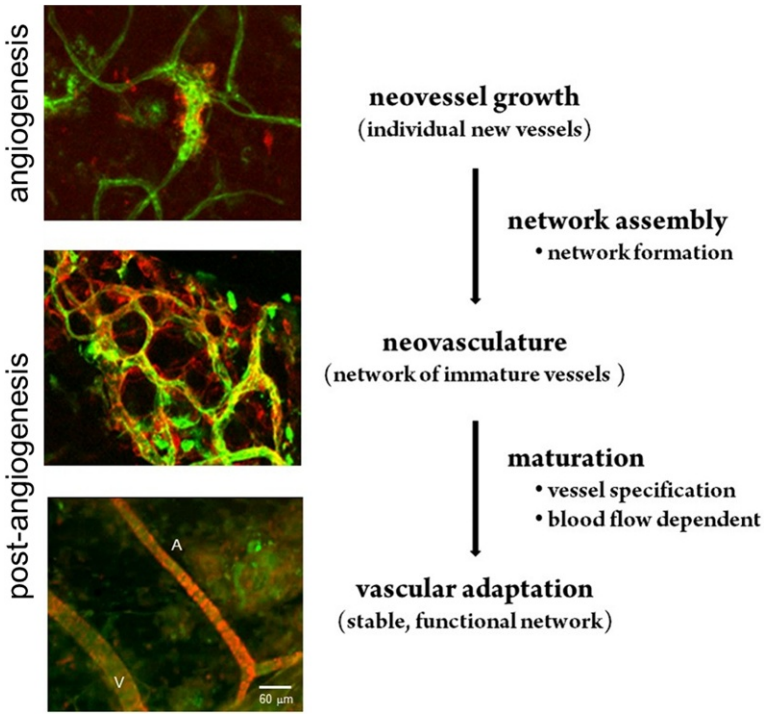

Fig. 2 Progression of a regenerating microvasculature through the different vascular phenotypic phases. Following angiogenesis, the immature and disorganized neovasculature undergoes extensive remodeling and revision in order to eventually form a new, mature microcirculation. Progression through the two postangiogenesis phases are blood flow dependent. *A*, arteriole; *V*, venule.

formed neovessels then integrate into an existing network or assemble into a new network of their own as they simultaneously reacquire an arteriole/capillary/venule identity, revise in caliber, and mature in function, all in the context of an interconnected network. Consequently, we have come to collectively call these processes postangiogenesis activities, because they occur after the initial sprouting angiogenesis event. Thus, while angiogenesis generates new vessel segments, postangiogenesis generates a new, mature microcirculation.

Neovascular plasticity and adaptation

Neovascular adaptation is inherent to the formation of a perfusion-competent microvascular network as the newly formed, immature neovasculature revises and matures into a microcirculation that reflects the specific needs of the tissue (LeBlanc et al., 2012a). Microvascular adaptation reflects considerable plasticity in the individual microvessels but also in the spectrum of topological arrangements of the network. Necessarily, microvessel phenotype and network organization reciprocally interact to determine the final microcirculatory outcome following any regeneration event. Superimposed on this necessarily intrinsic vascular dynamic are external cues such as hemodynamic forces and stromal influences (e.g., tissue biomechanics, stromal cells, etc.). Ultimately, these external cues act to influence the adaptation activities, providing the context for the final microcirculation form and function (Secomb et al., 2012). Important to a successful neovascularization outcome is the generation of microvascular network topologies that (1) have short, homogenous diffusion distances, (2) are comprised of low-resistance perfusion paths, and (3) are free of oxygen gradients across the relevant tissue bed (Pries and Secomb, 2014) (**Fig. 3**). In the absence of satisfying all three criteria, microvascular networks will not fully support a tissue. How these normalized topologies form as an integrated dynamic of multiple vascular activities, such as collateralization, structural adaptation, vasoactive changes, and shear stress and pressure responses, is not fully clear.

Based on work involving an implantation model of neovascularization, progression through the relevant postangiogenesis vascular activities appears to require a necessarily unstable, yet distinct, phenotypic phase (Nunes et al., 2010). Following the generation of neovessel segments and their inosculation with each other to form an immature network during angiogenesis, the neovascular network progresses into a morphologically, transcriptionally, and functionally distinct dynamic phase initiated by intravascular perfusion into the neovessels and characterized by significant cell turnover characteristics of vessel pruning, the reacquisition of perivascular cells to the EC-derived neovessels, and the specification of arterio-venous identity (Nunes et al., 2010, 2011). Importantly, it is during this phase that flow paths, which are initially chaotic and nonproductive, are remodeled and revised into a more effective perfusion circuit (Nunes et al., 2010). As might be expected, proper progression through this phase depends on blood flow; without it, the immature network collapses and regresses, leading to maturation into a more refined, hierarchical, low-resistance network.

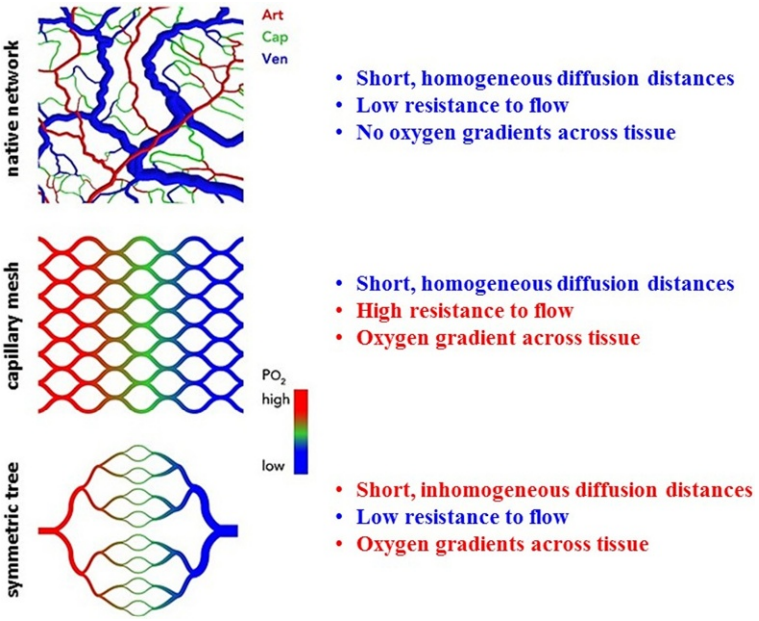

Fig. 3 Comparison of different microvascular network topologies, native and contrived, and the consequences of each to tissue perfusion. In each of the contrived example networks, blood enters the network from the left side. *Art*, arterioles; *Cap*, capillaries; *Ven*, venules. Modified from Pries, A. R. and Secomb, T. W. (2014). Restoring Vasoactivity

Typical approaches to treating perfusion deficits involve restoring vasodilation capabilities of the microvasculature, thus targeting the underlying vascular dysfunction which led to the deficits. Given that NO is pivotal in vasoactivity of healthy vessels, organic nitrates are often used as vasodilators. Originally thought to serve as NO donors, these agents are now thought to produce a spectrum of vascular-acting ROS via intracellular enzymes (Munzel et al., 2014). Other therapeutic agents include calcium-channel blockers or, more recently, ranolazine (a late inward sodium current inhibitor), which disrupt the electrical-contraction coupling of the vascular smooth muscle (Ennis et al., 2014; Lamendola et al., 2013). Additional drug classes used include those affecting the angiotensin system either reducing the production of Ang II or blocking its interactions with cellular receptors (Cameron et al., 2016). Finally, phosphodiesterase inhibitors, which block the degradation of cyclic nucleotides such as cGMP, are becoming more commonly used to treat vascular dysfunction. In vascular smooth muscle, cGMP acts to reduce contractility via cGMP-dependent kinases, reducing intracellular Ca^{2+} levels and promoting K^{+} efflux (Sausbier et al., 2000; Bobin et al., 2016). Phosphodiesterase inhibitors reduce the breakdown of cGMP by these enzymes, thereby prolonging turnover of the cGMP and maintaining vasorelaxation (Bobin et al., 2016). Almost invariably, other agents are included in combination therapies to control comorbid conditions, although many of these agents can also influence vascular cell function. For example, statins are concomitantly prescribed to manage lipid dynamics that lead to EC dysfunction (e.g., dyslipidemia). However, in addition to the effects on lipid metabolism, statins also appear to regulate EC function directly, impact inflammation, and alleviate oxidative stress (Agouridis et al., 2016). Similarly, β-blockers for hypertension, antiplatelet therapy to manage thrombosis, and a spectrum of agents for managing diabetes are often prescribed in conditions involving suspected microvascular dysfunction (Thompson and Davis, 2016; Cameron et al., 2016; Mousa, 2010).

Exercise

It is well known that physical activity improves cardiovascular health and outcomes. For example, daily exercise alleviates the pain associated with limb ischemia and improves limb function in peripheral artery disease (Hiatt et al., 1990). Based on experimental studies in animals, the clinical improvement is thought to be due, in part, to improved vascularity and microvascular flow secondary to muscle activity and the increased metabolic demand (Prior et al., 2004; Yang et al., 2008). Concomitant with the increase in distal vessel density is elevated collateral flow secondary to arteriogenesis (Bondke Persson et al., 2011). Muscle activity, such as that associated with exercise, also promotes adaptive changes in vascular cells leading to improved vasoactivity dynamics (Dora, 2016).

Cell-Based Approaches

An emerging therapy for improving vascular function, particularly in the microvasculature, involves the broadly defined class of mesenchymal cell therapies. Generally explored as potential regenerative therapies for improving overall tissue health and repair,

these cells appear to have indirect and direct provascular therapeutic effects. While bone marrow-derived mesenchymal stem cells (BM-MSCs) were among the first cell types explored, a variety of MSC sources are now actively investigated with adipose-derived stromal cells (ASCs) representing another widely used therapeutic cell population. Bone marrow and circulating derivatives of bone marrow consist of a variety of cell types including mesenchymal stem cells, hematopoietic stem cells, endothelial progenitors and others normally involved in hemostasis, homeostasis, inflammation, and tissue repair (Yan et al., 2013). When collected either as a whole or as discreet subpopulations, and almost always involving cell culturing, the BM-MSCs are thought capable of forming new vascular elements and improving tissue perfusion. Some evidence indicates that these cells can differentiate into vascular cells and/or incorporate into existing microvascular structures, possibly normalizing microvessel function (Jackson et al., 2001; Kamihata et al., 2001; Davani et al., 2003; Gojo et al., 2003; Hatzistergos et al., 2010). However, additional evidence indicates that increased vascularity and perfusion in the absence of vascular incorporation by these cells in ischemic muscle suggests that other provascular mechanisms exist (Kinnaird et al., 2004). These findings, as well as evidence that MSCs actively produce a variety of cytokines and growth factors, suggest that MSCs act primarily via a paracrine mechanism, including the production of angiogenic and vascular factors (Kamihata et al., 2001; Tang et al., 2004; Kinnaird et al., 2004; Gnecchi et al., 2006; Tse et al., 2007). As mentioned, ASCs promote similar therapeutic outcomes as BM-MSCs, also via a putative paracrine mechanism (Rigol et al., 2014; Wang et al., 2009; Cai et al., 2007). In the context of cardiac ischemia, ASCs cultured on a degradable patch and delivered to the epicardial surface of the postinfarcted heart arrested lesion progression which was correlated with improved coronary perfusion (LeBlanc et al., 2012b, 2013). While incorporation of the delivered cells into the coronary vasculature occurred, it was not at a level that would explain the increased vascularity and functional improvements (LeBlanc et al., 2012b; Kim et al., 2013). Alternatively, freshly harvested adipose tissue cells representing the SVF of the adipose tissue can be used as is without the subsequent culturing used to derive ASCs. In this form, the adipose SVF retains many of the vascular cell types comprising the adipose microvasculature (Zimmerlin et al., 2010; James et al., 2012). Consequently, this therapeutic preparation has profound vasculogenic potential and can readily form new microvasculatures *de novo* in an EC-dependent manner (Nunes et al., 2013; Koh et al., 2011). The appeal of using cell therapies to promote vascular health is high given that cells are dynamically involved in tissue form and function, potentially using a variety of mechanisms to promote repair and health. Cell therapies are currently being explored for a spectrum of disease conditions in a large number of clinical trials, testing this promise. Interestingly, MSCs that reside within tissues are thought to be intimately associated with the microvasculature. Called the "perivascular niche," many of the cell types collected from tissues, such as adipose, to derive the therapeutic MSC population appear to originate at sites associated with the microvasculature (Caplan, 2008). Presumably, these cells are playing an essential role in endogenous microvascular health analogous to their therapeutic activities.

Example: Microvascular Angina

While there are many disease conditions in which microvascular dysfunction is a cause or complication, microvascular angina, perhaps, represents an ideal example. Traditionally, ischemic heart disease has been viewed as a coronary macrovascular disease in which the major coronary arteries are compromised, ultimately leading to occlusion and arrest of blood flow to the downstream myocardium. In patients presenting with angina symptoms (e.g., chest pains, abnormal stress test, shortness of breath), examination of the coronary arteries often reveals significant reduction in lumen cross-sectional area such that flow is restricted sufficiently to compromise oxygen supply to the heart. In the past, a "clear" angiogram (usually viewed as less than 50% occlusion in one or more coronary arteries) indicated an absence of CAD and that angina symptoms reflected a nonvascular etiology and/or a nonlife-threatening situation. However, there is a growing appreciation for different manifestations of ischemic heart disease that does not necessarily center on coronary artery involvement and instead focuses on CMD as the primary disease etiology.

Building on insights of others, much of our new understanding of coronary microvascular disease has arisen from the Women's Ischemia Syndrome Evaluation (WISE) study established in 1996 (Bairey Merz et al., 2006), which has been systematically characterizing and evaluating patients with symptoms of angina in the absence of occlusive CAD. Importantly, women are inordinately more affected (5+ times more) by this manifestation of ischemic heart disease than men. Traditionally thought to be benign, WISE investigators have found that the majority of the affected women will continue to have symptoms, a declining quality of life, repeated hospitalizations and tests, and an increased risk for a sudden cardiac event (Gulati et al., 2012).

While there remain potentially many etiologies for angina without coronary artery involvement, a growing consensus is that this type of ischemic heart disease is a manifestation of CMD. As such, it is often termed "microvascular angina." There are a number of recent reviews describing microvascular angina, its manifestation, the challenges of diagnosing and treating microvascular angina, and the underlying disease mechanisms (Dean et al., 2015; Gori and Fineschi, 2012; Kothawade and Bairey Merz, 2011; Lim et al., 2009; Marinescu et al., 2015; Scalone and Niccoli, 2015). Importantly, the prevalence of microvascular angina is inordinately high in women; over half of the women with ischemic heart disease will present with microvascular angina as compared to about 6% in men (Kothawade and Bairey Merz, 2011).

Coronary Microvascular Dysfunction

Typically, the coronary microvasculature is considered to be that portion of the coronary circulation comprised of vessels smaller than 200 μm in diameter with a focus on the resistance vessels regulating downstream blood flow. This includes not only the more distal arterioles, but also the distal, smaller feed arteries to a microvascular bed. In CMD, this compartment of the coronary microcirculation is unable to properly maintain blood flow to meet the needs of the working myocardium. Clinically, this manifests

as an inappropriate coronary blood flow response leading to deficient myocardial perfusion (Beltrame et al., 2009). While this dysfunction is often attributed to extension of atherosclerosis (i.e., plaque accumulation) into these smaller vessels (Panza, 2010), it is likely that the CMD reflects a broader spectrum of compromised function arising from many causes leading to EC dysfunction, ROS imbalances within the vessel wall, smooth muscle dysfunction, and undoubtedly decompensating microvascular remodeling (Ahmed, 2014; Widmer et al., 2014; Kothawade and Bairey Merz, 2011; Durand and Gutterman, 2013; Phillips et al., 2007). Highlighting this, others have described both EC dependent and independent vasoactive dysfunction in women with nonobstructive ischemic heart disease (Pepine et al., 2010; Diver et al., 1994).

Diagnosing Microvascular Angina

Accurately diagnosing microvascular dysfunction can be difficult (Bairey Merz and Pepine, 2011). A definitive test, although invasive, is coronary reactivity testing in which microvascular coronary function is assessed by use of a Doppler guide wire in the cardiac catheterization laboratory and pharmacological agents to determine endothelium-dependent and -independent function (Phan et al., 2009; Mehta et al., 2011). Typically, flow responses to intracoronary delivery of adenosine (EC-independent) and acetylcholine (EC-dependent) are used as measures of CFR, as these agents normally induce a flow hyperemia in the distal coronary circulation. Recently, an NHLBI-funded study demonstrated that cardiac MRI-based measurements of myocardial perfusion reserve index was as effective at assessing microvascular dysfunction as coronary reactivity testing (Thomson et al., 2015). Importantly, these assessments are designed to measure the vascular dynamics of the coronary circulation, the very aspect thought compromised in microvascular angina (Thomson et al., 2015). As with most disease, an accurate and informative diagnosis is critical to the formulation of a treatment strategy.

Treatment of Microvascular Angina

Current treatment guidelines for microvascular angina are not focused on targeting the MCD, perhaps reflecting a paucity of microvascular targeting drugs. Most medical therapies reflect atherosclerosis and coronary artery occlusive disease as the primary etiology (Fraker et al., 2007). An emphasis is on managing the atherosclerosis and relieving angina symptoms. Thus, patients are often prescribed statins and life-style changes to manage plasma lipid/cholesterol levels and a spectrum of agents intended to lessen cardiac work load and thus myocardial oxygen demand (Bairey Merz and Pepine, 2011). Additionally, standard of care for microvascular angina involves one or more of nitrates (to promote vasodilation), β-blockers (to reduce cardiomyocyte work), and calcium channel blockers (also to reduce cardiomyocyte work). Recent clinical trials indicate that typical "1st-line" drugs used for obstructive angina can be effective at relieving angina symptoms only in subsets of microvascular angina patients (Bairey Merz and Pepine, 2011). These include the use of β-blockers, ACE inhibitors, nitrates, and calcium channel antagonists. Sildenafil, a phosphodiesterase inhibitor, appears to improve CFR, a measure of microvascular coronary function, in women with microvascular angina (Marinescu et al., 2015; Denardo et al., 2011). Despite nitrates being effective in CAD, they are less effective in microvascular angina, reflecting the microvascular aspect of microvascular angina in that nitrates selectively target larger caliber coronary vessels (Russo et al., 2013). Interestingly, particularly given the close association of microvascular angina with women, low-dose hormone therapy was not effective (Bairey Merz et al., 2006). This reflects, perhaps, that women of premenopausal age who are still producing estrogen also manifest microvascular angina (Gulati et al., 2012). Recently, new generation antiangina drugs are being used. The best example is ranolazine, which is promising in the treatment of microvascular angina, particularly when the more standard, 1st-line agents are ineffective (Mehta et al., 2011; Codolosa et al., 2014; Tagliamonte et al., 2015). Ranolazine is a relatively new antiangina agent that is thought to reduce calcium loading in cardiomyocytes secondary to the inhibition of the late sodium current (Chaitman, 2006; Undrovinas et al., 2006). However, in animal model studies, ranolazine promoted precapillary vasodilation and increased microvascular perfusion in skeletal muscle in rats when administered acutely (Fu et al., 2013). Similarly, ranolazine promoted endothelium-independent vasodilation in rat and rabbit aorta rings (Paredes-Carbajal et al., 2013; Malavaki et al., 2015). This suggests that perhaps ranolazine influences microvascular function directly in addition to moderately improving cardiomyocyte function. While all of these agents can relieve symptoms of angina, none are disease modifying. Furthermore, patient responsiveness to these agents is variable, with women being less responsive than men, and treatment often involves a progression through the spectrum of medical agents until positive results are obtained (i.e., angina symptoms are lessened).

Comorbidities

As with most cardiovascular disease, microvascular angina is associated with a variety of comorbidities. It is well known that diabetes, metabolic syndrome, hypertension, and smoking have profound negative impacts on the cardiovascular system and the microvasculature in particular (Briones et al., 2014; Legein et al., 2013; Durand and Gutterman, 2013; Schleithoff et al., 2012; Clough and Cracowski, 2012; LeBlanc et al., 2012a; Ruiter et al., 2010). In a recent prospective study of women being evaluated for chest pains in the Southeastern United States, ~97% were determined to have microvascular angina. Of the subjects who consented, all were relatively young (mean age 43.8 ± 12.5) and obese (mean body mass index of 30.8 ± 7). The prevalence of diabetes was 10.3%, hypertension was 37.1%, hyperlipidemia was 17.8%, and current tobacco use was 23.5% (Winchester et al., 2015). Interestingly, obesity and hypertension, both of which lead to systemic microvascular complications, were the most prevalent comorbidities in these women with microvascular angina.

Mechanisms of Disease

These comorbidities complicate an already complex process of disease mechanisms leading to ischemic heart disease and CMD. Beyond a generalized understanding that vascular (both endothelial and smooth muscle cell) dysfunction is at the core of microvascular deficits, very little is known about the CMD specific to microvascular angina. In CAD, the coronary microvasculature is altered such that the balance of vasodilators mediating vasoactivity in the coronary microcirculation is, in part, H_2O_2 mediated rather than NO mediated (Freed et al., 2014; Durand and Gutterman, 2013; Phillips et al., 2007). Similar switching of vasomediators is associated with the diminished vasoactivity of coronary microvessels in aging (Miura et al., n.d.; Durand and Gutterman, 2013). In the no-reflow phenomenon, wherein microvascular dysfunction complicates reperfusion of the myocardium following revascularization of an obstructed coronary artery, problems related to microemboli and EC dysfunction secondary to reperfusion injury drive distal vessel-mediated perfusion deficits (Durante and Camici, 2015; Feher et al., 2014; Ito, 2006). Whether all of these mechanisms are involved in microvascular angina is unknown. Furthermore, the impact of antiangina drugs routinely used to treat microvascular angina is unclear; whether these drugs alter microvascular function directly or simply moderate angina symptoms by reducing cardiac work is also unknown at this time.

Summary

Given the ubiquitous and intimate presence of the microvasculature in tissues, it is intuitive that it plays a central role in tissue health and disease. Not only it is essential in distributing blood to the tissues, but also the microvasculature mediates all forms of blood:tissue interface, contributes directly to tissue and organ function, and critically participates in tissue repair. Consequently, deficits in any one of these microvascular functions can lead to tissue dysfunction. Additionally, a limited functional microvasculature in a tissue will undoubtedly compromise healing and likely exacerbate disease. Despite considerable knowledge of microvascular biology and physiology, the microvasculature itself remains a relatively under-treated target in the clinic. Certainly, therapies that target generalized imbalances such as statins and antioxidants will benefit the microvasculature. However, there remain few options available for clinicians to improve specific deficits in microvascular function. This is, in part, due to the challenges related to assessing the microvasculature in the patients; these deficits in diagnostic methods have hampered our understanding of microvascular dysfunction and its contribution to the disease state. Traditional methods of assessment, such as histological vessel density measurements, tell only part of the story and do not assess the functional status of the microvasculature in question. This is particularly relevant given that vessel density is not directly correlated to perfusion capacity. Experimental means of measuring function, such as vasoactivity, are difficult to translate into clinical practice as they involve invasive approaches (e.g., diagnosis of microvascular angina). All of this is compounded by the likelihood of varied causes of microvascular dysfunction leading to perfusion deficits. Nevertheless, the renewed appreciation of the critical roles the microvasculature plays in tissue health and disease is increasing our understanding of the microvasculature to promote health and reverse disease.

Disclosure of Potential Conflicts of Interest

The authors indicate no potential conflicts of interest.

Introduction

The heart is a critical organ. The circulation of blood delivers absolutely vital O_2. The heart beats 60 bpm, = 3600/h, = 86,400/day = 31.536 million/year = 2.207 billion/life span. The engine for beating is the mitochondria, which provide energy in the form of ATP.

Structure

Contractile Apparatus

Cardiac muscle fibers are syncytia of individual cells (cardiomyocytes) joined end-to-end at intercalated discs, which not only provide the structural stability of the fiber, but their content of gap junctions permits the free flow of the action potential down the length of the fiber (Fig. 1). Like skeletal muscle, cardiomyocytes are striated, consisting of A and I bands; this appearance is based on the distribution of actin and myosin filaments. Contraction is based on the sliding of the actin relative to the myosin filament. It is in this action that mitochondrial ATP comes into play (Hernandez et al., 2001).

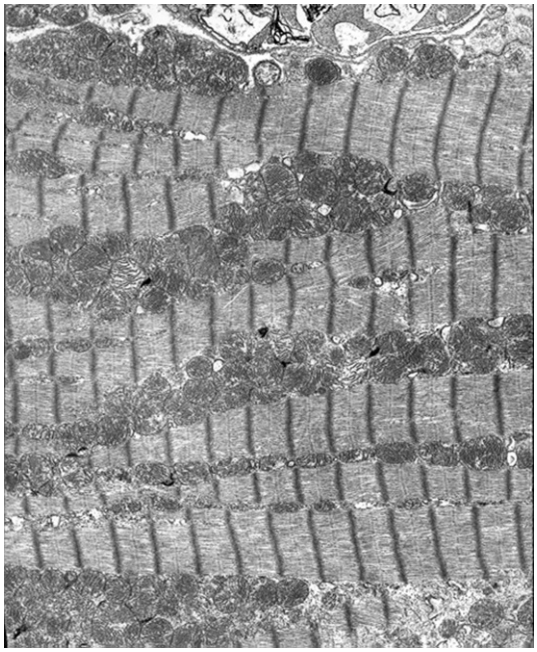

Fig. 1 A survey of a portion of a cardiomyocyte showing a series of apposed sarcomeres that are joined to each other by the densely-stained Z-discs. The parallel myofibrils are separated by rows of interfibrillar mitochondria.

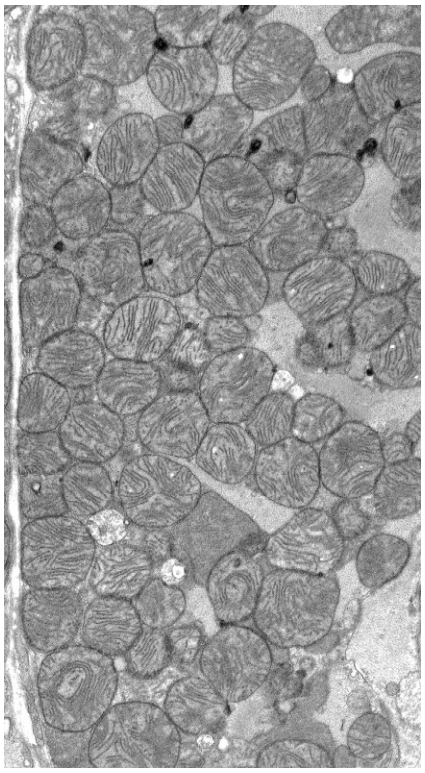

Fig. 2 Electron micrograph of clustered subsarcolemmal mitochondria.

Cardiac Mitochondria

As seen using transmission electron microscopy (TEM), cardiac mitochondria, in general, have a relatively simple silhouette that ranges from ovoid to elliptical, and numerous cristae. The latter structures appear as simple invaginations of the internal mitochondrial membrane and appear to lack any subspecialization (Fig. 2). However, when examined by high-resolution scanning

electron microscopy (HRSEM), differences in the structure of cristae become apparent when the subsarcolemmal mitochondria (SSM) are compared to the interfibrillar mitochondria (IFM) (Riva et al., 2005; Hoppel et al., 2009; **Fig. 3**). Because the SSM are somewhat larger than the IFM, the cristae tend to be longer and are attached to the boundary membrane by means of cristae junctions. Moreover, HRSEM revealed that the overall shape of cristae varies in these two populations of mitochondria in that those in the SSM are largely lamelliform, whereas those in the IFM tend to have a tubular shape (Riva et al., 2005; Hoppel et al., 2009; **Fig. 4**). In the latter, cristae junctions could not be clearly identified. The forgoing description of mitochondrial cristae applies to in situ organelles; interestingly in isolated SSM, the cristae retain their lamelliform structure whereas in IFM the cristae appear to be more plastic and their shape varies. In cardiac mitochondria examined by TEM, the matrix often contains scattered dense granules

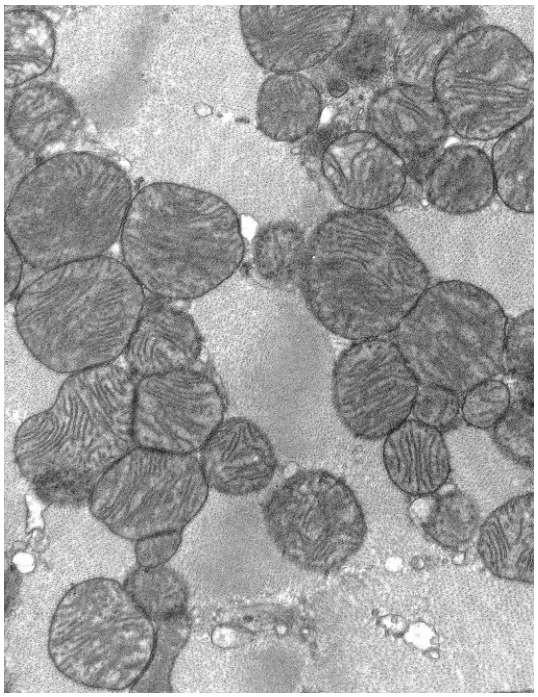

Fig. 3 Electron micrograph of a transversely sectioned cardiomyofiber showing aggregates of interfibrillar mitochondria.

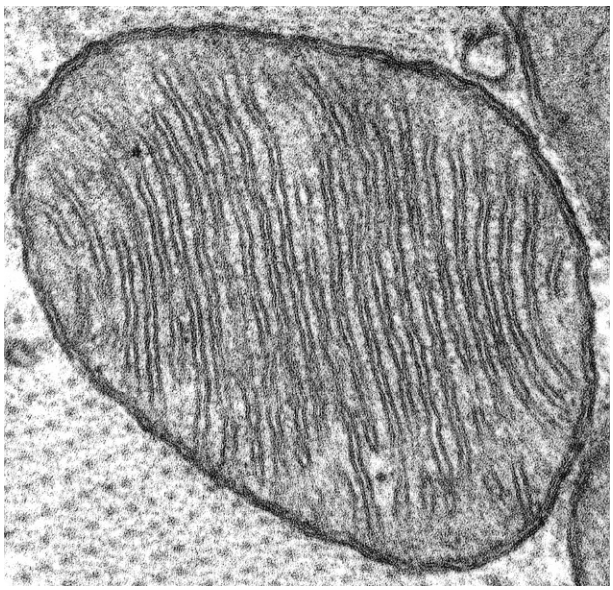

Fig. 4 High-resolution electron micrograph of cardiac mitochondria showing the unit membrane of its component membranes. The same structure prevails in both subsarcolemmal and interfibrillar mitochondria.

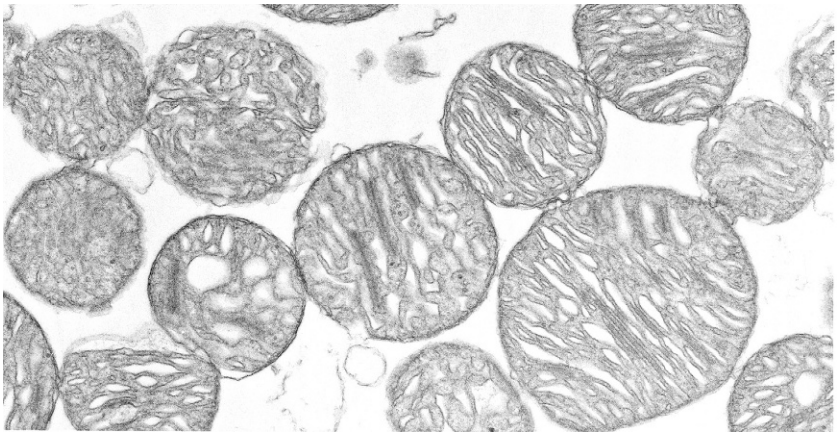

Fig. 5 Electron micrograph of a pellet of isolated cardiac mitochondria. No differences are observable between isolated subsarcolemmal or interfibrillar mitochondria. These organelles retain the same basic structure they exhibit in situ.

that are deposits of divalent cations (Peachey, 1964). The presence of these matrix granules appears to be associated with the modality of specimen preparation for TEM; under some conditions of fixation, the granules are starkly apparent, while with other fixatives the granules are either few in number or lacking altogether.

Earlier studies of cardiac mitochondria function were based on isolation of the total mitochondrial content of cardiomyocytes by exposure to the protease, Nagarse, which solubilized the contractile apparatus and released all mitochondrial irrespective of their intracellular localization (Jacobus et al., 1975). The fortunate circumstance that mitochondria are resistant to the rigors of isolation allows their ready identification (**Fig. 5**). This technique allowed identification of the multifarious metabolic roles played by the mitochondria. These findings became the standard for cardiac mitochondrial metabolic function. With the passage of time, the Polytron, which mechanically disrupts the sarcolemma, became the popular tool for isolation of cardiac mitochondria. An aspect of the use of this methodology that was largely ignored was that the yield of mitochondria was reduced 60%–70%. The reason for this discrepancy was revealed when the mitochondrial fraction and the "debris" fraction were examined ultrastructurally. It turned out that although the Polytron released the SSM, a large portion of the mitochondria remained in their original position between myofibrils, thus unavailable for isolation. We found that after Polytron treatment, exposure of the debris fraction to Nagarse freed the entrapped IFM and made their separate isolation a relatively simple matter (Palmer et al., 1977). The result of this approach was that two distinct populations of mitochondria became available for biochemical investigation (Palmer et al., 1977).

Network

The mitochondria that are abundant in each cardiomyocyte have been established by TEM (Fawcett, 1966). These organelles are situated both beneath the sarcolemma and between the myofibrils. A school of thought holds that all of the mitochondria within a given myocyte are interconnected, in effect forming a continuous network (Skulachev, 2001). If this interpretation is correct, the entire mitochondrion operates as a single organelle and no part of the cell is deficient in ATP. Moreover, this organization would eliminate the necessity for exchange of intramitochondrial components such as substrates and intermediates from one organelle to the other via transfer through the cytosol.

Substrate Selection

In the baseline state, the heart is a metabolic omnivore, utilizing fatty acids, glucose, and lactate (**Fig. 6**). Glucose uptake requires insulin-mediated uptake via the membrane glucose transporter, GLUT4 (Abel, 2004). In the absence of insulin, glucose uptake by the heart is minimal. Fat substrates are provided via long-chain fatty acids with uptake via the CD36 membrane transporter, and by intracellular lipolysis followed by the formation of acyl-CoA esters by long-chain fatty acid CoA synthetase (van der Vusse et al., 2002). The acyl-CoAs are subsequently activated for mitochondrial uptake via the formation of acylcarnitines by carnitine palmitoyltransferase-I (CPT-I) (Lee et al., 2011), as discussed below. The enzymes involved in fatty acid activation and transport are located in the mitochondrial outer membrane and contact sites (Lee et al., 2011).

Glucose

Glucose metabolism via glycolysis generates pyruvate for mitochondrial uptake and subsequent intramitochondrial activation by the pyruvate dehydrogenase complex (**Fig. 7A**). Lactate is taken up by the monocarboxylate transporter and is converted to pyruvate by the enzyme, lactate dehydrogenase, which is located in the cytosol (Lesnefsky et al., 2001c; Dym et al., 2000). Mitochondrial

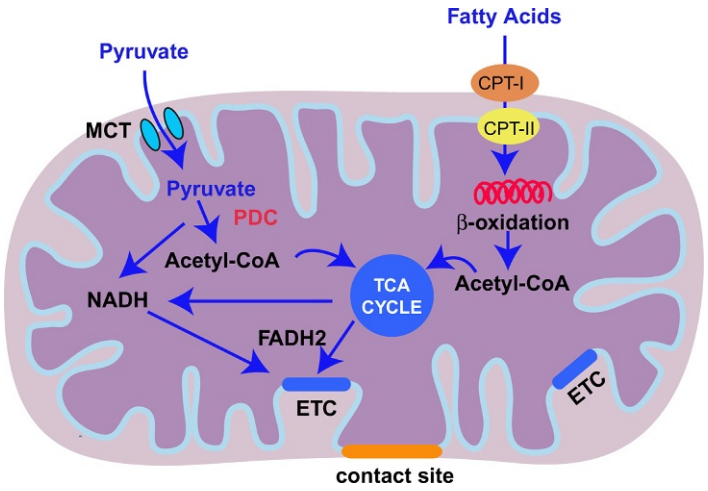

Fig. 6 A diagram showing in a superficial manner the elementary pathways of fatty acid and pyruvate oxidation leading to the intermediate metabolite, acetyl-CoA on its way to the tricarboxylic acid cycle (TCA).

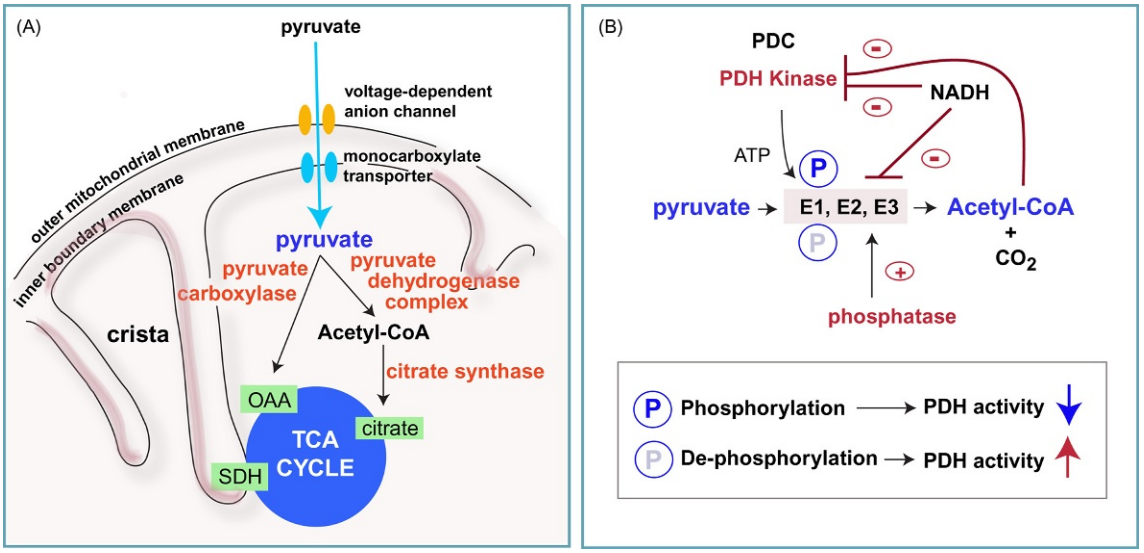

Fig. 7 (A) A diagram showing in detailed fashion the pathways of pyruvate through the outer membrane via the voltage-dependent anion channel and subsequent transport through the inner boundary membrane by the monocarboxylate transporter. In the matrix, pyruvate can be metabolized by pyruvate dehydrogenase complex to produce acetyl-CoA, which enters the TCA after conversion to citrate. Alternatively, pyruvate is carboxylated by pyruvate carboxylase to form oxaloacetate (OAA), which enters the TCA as the other substrate for citrate synthase. The TCA itself is anchored to the crista membrane by means of succinate dehydrogenase (SDH) of complex II. (B) A schematic of the pyruvate dehydrogenase complex by phosphorylation/dephosphorylation and inhibition by the products acetyl-CoA and NADH.

substrate selection is tightly controlled and is affected not only by exogenous substrate availability but also by metabolic regulation in response to differing physiologic conditions (Lesnefsky et al., 2001c). Pyruvate dehydrogenase complex and CPT-I coregulate carbohydrate and fatty acid oxidation in a reciprocal manner via crosstalk mediated by metabolic intermediates and via regulation by intracellular signaling systems (Lesnefsky et al., 2001c, 2016).

Pyruvate Dehydrogenase Complex

The pyruvate dehydrogenase complex catalyzes oxidative decarboxylation of pyruvate to acetyl-CoA, which enters the tricarboxylic acid (TCA) cycle (Folmes et al., 2010; Sugden and Holness, 2006; Arjunan et al., 2002). The pyruvate dehydrogenase complex is composed of three enzymes: pyruvate dehydrogenase (PDH, E1), dihydrolipoamide acetyltransferase (E2), and dihydrolipoamide dehydrogenase (E3) (Folmes et al., 2010; Sugden and Holness, 2006; **Fig. 7B**). In mammalian cells, PDH is found in the mitochondrial matrix and includes four subunits: α_1, α_2, β_1, and β_2. PDH activity is decreased by a reversible phosphorylation of the α (Sugden and Holness, 2006) or β (Folmes et al., 2010) subunits through pyruvate dehydrogenase kinase (PDK). In the heart,

PDH kinase isoform 4 predominates and is rapidly induced by starvation and diabetes, leading to decreased PDH activity (Sin et al., 2015). Overexpression of PDK4 in mice inhibits PDH activity and subsequent glucose oxidation (Chambers et al., 2011). Activation of PDH is achieved by dephosphorylation of the subunits by pyruvate dehydrogenase phosphate phosphatase (PDP) (Sugden and Holness, 2006). Fatty acids directly decrease PDH activity via activation of peroxisome proliferator-activated receptor-α, leading to increased PDH kinase expression (Gao et al., 2014). PDH kinase activity is directly inhibited by pyruvate, leading to increased PDH activity. High rates of fatty acid oxidation inhibit PDH via elevated mitochondrial content of acetyl-CoA and NADH, which directly inhibits PDH as well as activate PDH kinase (Latipaa et al., 1985). The activity of PDH phosphatase is increased by Ca^{2+} and Mg^{2+}, leading to increased PDH activity (Rutter et al., 1989). The Ca^{2+}-mediated activation is in line with activation of electron transport by calcium, the net calcium activation of PDH complex providing increased substrates for the downstream electron transport chain (ETC).

Fatty Acid Oxidation

Increased oxidation of pyruvate from carbohydrates inhibits fatty acid oxidation by increasing the content of malonyl-CoA, leading to inhibition of CPT-I (**Fig. 8A** and **B**). The molecular basis of this inhibition is the extreme sensitivity of the muscle isoform of CPT-I (the predominant isoform in the heart) to malonyl-CoA (Fillmore et al., 2014; Stanley et al., 2005). Although acetyl-CoA produced from the oxidation of pyruvate and that produced from fatty acids are biochemically identical, these molecules are utilized in different ways by the heart, possibly due to compartmentalization. One pool of acetyl-CoA derived from pyruvate oxidation would be amenable to export to the cytosol for malonyl-CoA synthesis and subsequent inhibition of CPT-1, which is located on the outer mitochondrial membrane. In contrast, acetyl-CoA derived from β-oxidation of fatty acids remains contained within mitochondria and likely does not have access to CPT-1 (Lesnefsky et al., 2001c). Consistent with the importance of malonyl-CoA as a regulator of fatty acid oxidation, enzymes for synthesis (acetyl-CoA carboxylase) and degradation (malonyl-CoA decarboxylase) exist (Fillmore et al., 2014; Ussher and Lopaschuk, 2009). These synthetic and degradation enzymes are under control of signaling cascades, providing key regulation of fatty acid oxidation in response to the physiologic state of the myocyte. In addition to malonyl-CoA content, other mechanisms can regulate fatty acid oxidation. These factors include cytoskeletal proteins, as well as palmitoyl-CoA, the latter a major substrate of fatty acid oxidation. Thus, increasing concentrations of palmitoyl-CoA attenuate CPT-I inhibition and increase the flux through fatty acid oxidation (Fillmore et al., 2014). An increased palmitoyl-CoA to malonyl-CoA ratio due to increased uptake and activation of fatty acids and decreased malonyl-CoA content also explains the high rates of fatty acid oxidation observed during cardiac reperfusion following ischemia (Stanley et al., 2005).

Mitochondria

Compartmentalization

The matrix contains the enzymes of the TCA cycle, antioxidant defense enzymes, and biosynthetic enzymes. TCA cycle oxidation of acetyl-CoA generates NADH and $FADH_2$ for oxidation by the ETC. The ETC consists of four multisubunit enzyme complexes, with

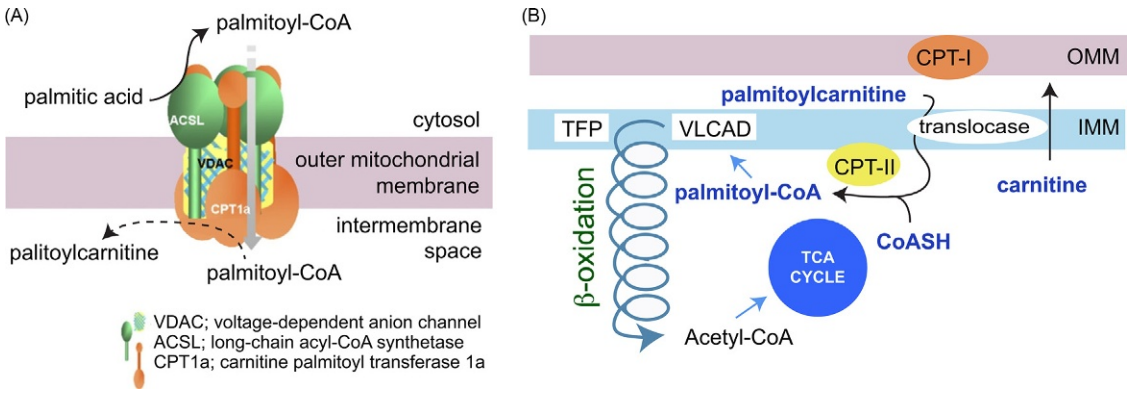

Fig. 8 (A) A model of the mitochondrial outer membrane complex for entry of fatty acyl groups into the intermembrane space. Long-chain fatty acid (using palmitate as an example) is first activated to palmitoyl-CoA by the long-chain acyl-CoA synthetase (ACSL), on the outer membrane. Palmitoyl-CoA passes through the outer membrane through the VDAC and is converted to palmitoylcarnitine by carnitine palmitoyltransferase 1 (CPT-I) on the inner surface of the outer membrane. (B) A diagram tracking the fate of the palmitoylcarnitine formed by CPT-I. Palmitoylcarnitine is transported via the carnitine–acylcarnitine translocase (translocase) into the matrix in exchange for carnitine and the palmitoylcarnitine is converted to palmitoyl-CoA by carnitine palmitoyltransferase 2 (CPT-II) using matrix Coenzyme A (CoASH). Palmitoyl-CoA enters fatty acid oxidation as a substrate for the very-long-chain acyl-CoA dehydrogenase (VLCAD) followed by β-oxidation using the trifunctional protein (TFP), both of which are inner membrane proteins. The subsequent cycles of β-oxidation all form acetyl-CoA, which enters the TCA cycle whose fate is illustrated in **Fig. 6**. From Lee, K., Kerner, J. and Hoppel, C. L. (2011). Mitochondrial carnitine palmitoyltransferase 1a is part of an outer membrane fatty acid transfer complex. *Journal of Biological Chemistry* **286**, 25655–25662. The American Society for Biochemistry and Molecular Biology.

the mobile electron carriers, coenzyme Q (complexes I and III as well as II and III), and cytochrome *c* (III and IV), interspersed between specific complexes (Lesnefsky et al., 2001c). Electron transfer down the redox potential gradient from NADH or $FADH_2$ to oxygen is coupled to the active transport of hydrogen ions from the matrix to the cytosolic side of the inner membrane, as described by the chemiosmotic theory of Mitchell (Mitchell, 1976). Complexes I, III, and IV translocate protons from matrix to cytosolic aspect of the inner membrane, coupled to electron flux through the complex. The multisubunit complexes of the ETC are organized into higher levels organization of supercomplexes that maximize electron transfer via substrate channeling (Rosca et al., 2008; Nubel et al., 2009; Schagger et al., 2004; Schagger and Pfeiffer, 2000).

Inner Membrane

The inner membrane is impermeable to ions and small molecules. The chemiosmotic theory of Mitchell (Mitchell, 1976) features the active transport of hydrogen ions from the matrix side to the cytosolic side of the inner membrane (vectorial proton transfer) during the flow of electrons down their free energy gradient through the redox centers of complexes I, III, and IV. The inner membrane consists in part of specific transporters that regulate the uptake of small molecules and ions, such as inorganic phosphate and ADP into the matrix.

Coupling

These forgoing components work in concert to harness the stored energy of the inner membrane electrochemical gradient to phosphorylate ADP as protons flow down the electrochemical gradient from cytosol to the matrix, providing energy that drives complex V to phosphorylate ADP (Mitchell, 1976). This ATP synthesis couples mitochondrial oxidation to energy demand. In energy-replete states, a decrease in the availability of ADP leads to a slower rate of phosphorylation that in turn results in a greater electrochemical gradient across the inner membrane and a lessened rate of electron transport to oxygen, leading to decreased oxygen consumption. An increase in ADP content secondary to increased energy demand and consumption will increase phosphorylation and utilization of the proton gradient that consequently stimulates the rate of electron transport and oxygen consumption (Lesnefsky et al., 2001c; Lesnefsky and Hoppel, 2006). The coupling of respiration to phosphorylation is the key concept in integrated mitochondrial respiration of oxidative phosphorylation.

Uncoupling

The uncoupling of respiration from phosphorylation can occur via multiple mechanisms. First, the presence of naturally occurring uncoupling proteins that allow proton movement down the electrochemical gradient without ATP synthesis can dissipate membrane potential (Fink et al., 2005). Second, there is regulated or pathologic lack of vectorial proton movement within an ETC complex [as seen for complex IV (Papa et al., 1997) or complex V (Yagi and Hatefi, 1987)] despite electron flux through the complex, so-called proton slip. Last, inner membrane damage will decrease the integrity of the inner membrane, allowing unregulated back-diffusion of protons and dissipating electrochemical gradient.

The Electron Transport Chain

The ETC is composed of four multisubunit enzyme complexes. NADH is oxidized by complex I, reducing the lipid soluble mobile electron carrier, coenzyme Q. Complex III oxidizes reduced coenzyme Q and in turn reduces the mobile carrier protein, cytochrome *c*, that donates its electron to cytochrome oxidase (complex IV) for the reduction of oxygen to water. Complexes of the ETC have two degrees of translational freedom within the inner membrane (Chazotte and Hackenbrock, 1988; Gupte and Hackenbrock, 1988), leading to complexes that are organized into larger supercomplexes to form a respirasome (Schagger and Pfeiffer, 2000; Schagger et al., 2004) in order to optimize channeling of reducing equivalents.

Complex I

Complex I (NADH:quinone oxidoreductase) is the largest respiratory complex of the ETC (Fiedorczuk et al., 2016). Complex I is an L-shaped molecular cluster that crosses the mitochondrial inner membrane and consists of 45 protein subunits. A portion of complex I is situated within the matrix and includes the NADH dehydrogenase, flavin mononucleotide (FMN), and eight iron–sulfur clusters that are responsible for electron transfer, whereas the membrane portion of the complex is involved in proton translocation across the inner membrane. Complex I activity is decreased when its protein subunits are degraded. Alteration of phospholipids, especially cardiolipin, also decreases complex I activity (Fiedorczuk et al., 2016; Paradies et al., 2004). Complex I activity also is affected by its conformational change—a switch from the normal "active" A-form to the "deactive" dormant D-form leads to decreased complex I activity (Galkin et al., 2009).

Complex II

Complex II (succinate:quinone oxidoreductase) oxidizes succinate to fumarate with coupled reduction of ubiquinone to ubiquinol (Kim et al., 2012). Unlike complex I, there is no net proton translocation across the inner membrane during succinate oxidation.

Complex III

Complex III (ubiquinol:cytochrome *c* oxidoreductase, *bc*1 complex) is a dimer embedded in the inner membrane (Kim et al., 2012; Lesnefsky et al., 2016). Electron transfer through complex III leads to the translocation of protons across the inner membrane to the intermembrane space. There are 11 protein subunits in complex III. Cytochrome *b*, c_1, and iron–sulfur protein (ISP) are the three catalytic subunits. Complex III is a key site of reactive oxygen species (ROS) generation within mitochondria. Blockade of electron transport at cytochrome *b* using antimycin A dramatically increases ROS generation from complex III (Turrens, 2003; Chen et al., 2003; Moghaddas et al., 2003). A dysfunction of its catalytic domain in ISP blocks electron transport to cytochrome c_1 and subsequently decreases complex III activity in ischemia-damaged mitochondria (Lesnefsky et al., 2001a).

Complex IV

Complex IV (cytochrome oxidase) is the terminal enzyme of the ETC. Cytochrome oxidase reduces molecular oxygen to water, coupled with the oxidation of cytochrome *c*. Like complex I and complex III, proton translocation across the inner mitochondrial membrane occurs during the redox reactions within complex IV. There are 13 subunits in complex IV. Three subunits (Cox1, Cox2, and Cox3) are encoded by mitochondrial DNA, and other structural subunits are encoded by the nuclear DNA (Kim et al., 2012). Complex I, III, and IV form supercomplexes to optimize electron transportation within respiratory substrates (Schagger et al., 2004; Schagger and Pfeiffer, 2000).

Mitochondrial Dynamics

Mitochondrial Remodeling

Metabolic homeostasis requires that damaged mitochondria must eventually undergo repair or removal (Gustafsson and Gottlieb, 2008). Genetic mouse models have been generated to study proteins involved in the process of mitochondrial remodeling. These studies have shown that remodeling plays a key role in preserving cellular homeostasis by the timely and appropriate clearance of damaged mitochondria. Important contributors to the mechanics of mitochondrial remodeling are fusion proteins (mitofusin-1, 2, and Opa1) and fission proteins (Fis1, Drp1) (Gottlieb and Gustafsson, 2011; Gottlieb et al., 2011; Youle and van der Bliek, 2012; Papanicolaou et al., 2012). Fission leads to increased number of mitochondria, whereas fusion produces larger and sometimes interconnected organelles (Youle and van der Bliek, 2012). There is a dynamic homeostasis between fission and fusion (Chen et al., 2011). Fission can eliminate damaged portions of mitochondria—the latter are removed by mitophagy (Gottlieb and Gustafsson, 2011; Gottlieb et al., 2011). Thus, mitochondrial integrity is maintained at a high level. Genetic deletion of mitofusin-1 and mitofusion-2 in adult mouse hearts results in mitochondrial individualization and cardiomyocyte respiratory dysfunction accompanied by the early onset of dilated cardiomyopathy (Chen et al., 2011; Papanicolaou et al., 2012). Thus, lack of mitochondrial fusion during normal metabolic states is detrimental to the heart. Following coronary ligation, fusion is attenuated with a decreased content of Opa-1 and mitochondrial fragmentation (Chen et al., 2009).

Mitophagy has an important role in the removal of damaged mitochondria, leading to the basal turnover of organelles (Gottlieb and Gustafsson, 2011). However, excessive mitophagy in response to stress may result in increased cardiomyocyte death (Lee et al., 2012). Damaged mitochondria generated during either the ischemic insult or the stress of reperfusion can eventually be cleared by mitophagy (Narendra and Youle, 2011; Youle and van der Bliek, 2012). The collapse of the inner membrane electrochemical gradient is a critical physiologic step that points mitochondria toward the pathway to destruction. The loss of $\Delta\Psi$ triggers a kinase PINK1-dependent translocation of the E3 ubiquitin ligase Parkin from cytosol to the surface of mitochondria (Narendra et al., 2009; Narendra and Youle, 2011; Youle and van der Bliek, 2012). Thus, the PINK1–Parkin system is continuously monitoring mitochondria for quality control, with preservation of inner membrane electrochemical gradient, a key readout of mitochondrial health. The PINK1 content of mitochondria with intact $\Delta\Psi$ is low, owing to its rapid import and cleavage by mitochondrial proteases (Ziviani et al., 2010). Upon $\Delta\Psi$ depolarization, the import and degradation of PINK1 are inhibited, leading to PINK1 accumulation on the outer membrane, initiating a mitochondrial signal for its removal. The localization of PINK1 on the mitochondrial outer membrane is necessary for Parkin recruitment to the depolarized mitochondria. The precise mechanism of interaction between PINK1 and Parkin remains unclear. In addition to the recruitment of Parkin with potential phosphorylation of Parkin, PINK1 probably phosphorylates other targets, including mitofusin-2, converting mitofusin-2 to participation in Parkin recruitment to depolarized mitochondria. Parkin subsequently ubiquitinates proteins on the outer mitochondrial membrane (Gegg et al., 2010; Geisler et al., 2010), favoring removal of the damaged mitochondrion (Narendra and Youle, 2011). Ubiquitinated mitochondrial proteins are recognized by the autophagy adaptor protein, p62/SQSTM1 (Seibenhener et al., 2004), which favors interaction with the LC3 protein on the mitophagosome (Pankiv et al., 2007), with subsequent engulfment of the damaged mitochondria by an LC3-positive mitophagosome.

Transgenic mouse models of overexpression or knockout of PINK1 and Parkin clearly support the notion that these key proteins mediate mitophagy in response to cardiac stress (Siddall et al., 2013; Kubli et al., 2013a,b). However, the in situ regulation of these key mediators in the cardiac myocyte remains less clear. Of interest, and perhaps leading to an integrated cell biology response, one response of cardiac mitochondria to severe metabolic stress—including oxidative damage and calcium overload—is to undergo abrupt permeation of the inner mitochondrial membrane with catastrophic loss of the electrochemical gradient across the inner

membrane, so-called mitochondrial permeability transition (Weiss et al., 2003). Such a loss of inner membrane potential as a marker of substantial mitochondrial damage recruits PINK1 and Parkin, activating mitophagy and favoring removal of severely damaged mitochondria that pose a threat to cardiomyocyte survival. Intervention to protect cardiac mitochondria during cell stress, including the early reperfusion period of the treatment of myocardial infarction, leads to preservation of membrane potential, attenuating loss of the cardiac mitochondrial pool (Chen et al., 2012; Xu et al., 2013).

Caveolae and Subsarcolemmal Mitochondria

Caveolae are small inpouchings of the plasma membrane that are involved in the uptake of molecules that are too large to pass through the sarcolemma. This uptake may be of the bulk variety or receptor-mediated. A second important function of these structures involves cell signaling, particularly cardiomyocyte stress responses (Head et al., 2014; Fridolfsson et al., 2014). Caveolae are closely apposed to SSM (Fridolfsson et al., 2012). Ischemic stress increases this association that is accompanied by the increased mitochondrial localization of the caveolae protein, caveolin-3 (Fridolfsson et al., 2012). Transgenic mice that overexpress caveolin-3 exhibit increased mitochondrial content of caveolin-3 concomitant with an increase in respiration rate, decreased production of ROS, and enhanced resistance to calcium-overload damage. Increased localization of the protein caveolin-3 to SSM favors enhanced stress tolerance of the cardiac myocyte, including a relative resistance to cell death induced by cardiac ischemia–reperfusion injury (Fridolfsson et al., 2012). Crosstalk between plasma membrane microdomains and mitochondria is a novel adaptation of the jeopardized cardiomyocyte to dynamically alter mitochondrial metabolism and enhance cardiac stress response.

Mitochondria-Associated Membranes and Mitochondria

There are particular sites in cardiac muscle cells where endoplasmic reticulum (ER) membranes are linked to mitochondria; these associations, which persist during isolation of the mitochondria, are known as mitochondria-associated membranes (MAM) (Wieckowski et al., 2009). MAMs are involved in directing calcium to mitochondria to regulate metabolism. They also act in concert with the mitochondrial outer membrane proteins to regulate mitochondrial fission and fusion (Bravo-Sagua et al., 2013). It is by interaction with MAM that lipid is transferred from ER to mitochondria (Bravo-Sagua et al., 2013). MAM consist, in part, of the outer membrane including VDAC (Paillard et al., 2013; Wieckowski et al., 2009). Contact sites facilitate the flow of metabolites from the cytosol and perhaps ER into the mitochondrial matrix, a key aspect of ER-MITO crosstalk via MAM. Interaction of VDAC with ER proteins IP3R1 and Grp75 occurs (Paillard et al., 2013) and is involved in regulation of calcium flux from ER to mitochondria (Gomez et al., 2016). An area of emerging study is the role of dysfunction of the MAM in cardiac injury including myocardial stress due to ischemia–reperfusion (Gomez et al., 2016) or congestive heart failure.

Cardiolipin: Role in Mitochondrial Structure and Physiology

Cardiolipin is a phospholipid unique to mitochondria that is critical for the optimal activity of the ETC. Cardiolipin contains two phosphatidic acid groups linked by a glycerol with the majority of cardiolipin species containing four linoleic acid groups (C18:2). The four C18:2 acyls are essential for normal cardiolipin function in the inner mitochondrial membrane (Sparagna and Lesnefsky, 2009). Cardiolipin interacts with cytochrome *c* to retain this mobile electron carrier on the outer surface of the inner membrane. The delocalization and release of cytochrome *c* from mitochondria, a key signal of the irreversible loss of mitochondrial integrity, activates cell death programs. Cardiolipin is required for the optimal activity of complex I, complex III, and complex IV of the ETC (Lesnefsky and Hoppel, 2006; Lesnefsky et al., 2001d; Paradies et al., 2004).

Oxidatively-sensitive cardiolipin is a major target of ETC-mediated damage in pathologic cardiac stress settings, including ischemia–reperfusion, heart failure, and the comorbid condition of aging (Sparagna and Lesnefsky, 2009). During ischemia–reperfusion, cardiolipin is oxidatively damaged (Lesnefsky and Hoppel, 2008; Paradies et al., 1999) and depleted (Lesnefsky et al., 2001d). Cardiolipin is oxidatively sensitive due to the presence of the C18:2 residues that contain conjugated double bonds. Oxidative damage to cardiolipin occurs via both random chemical oxidation and a specific cardiolipin peroxidase (Kagan et al., 2005). Oxidation of a sensitive methionine of cytochrome *c* creates a pathologic function for cytochrome *c* to oxidize and deplete cardiolipin, activating programmed cell death (Kagan et al., 2005); this occurs during ischemia–reperfusion (Aluri et al., 2014).

Oxidized cardiolipin is remodeled with the net replacement of the oxidized residue. In contrast to its canonical role in the remodeling of newly synthesized cardiolipin, it appears that the enzyme, tafazzin, does not substantially contribute to the remodeling of cardiolipin in response to ischemia–reperfusion stress (Schlame, 2013; Szczepanek et al., 2016). In contrast, it appears that ALCAT-1, located in the ER (Baile et al., 2013), is a major enzyme in cardiolipin remodeling in response to disease. ALCAT-1 is a nonselective acyltransferase (Zhao et al., 2009; Cao et al., 2009) and replaces the lost C18:2 group with a different acyl group, unsaturated and often of longer chain length (Sparagna et al., 2007; Sparagna and Lesnefsky, 2009). The change in the composition of cardiolipin observed following acute ischemia–reperfusion and subsequently in models of congestive heart failure is consistent with this mechanism.

Conditions Associated With Mitochondrial Dysfunction

Diabetes

Mitochondrial dysfunction is manifested in the diabetic db/db mouse heart by decreased rates of oxidative phosphorylation, greater ROS generation, and increased fatty acid-driven uncoupling of mitochondrial respiration (Boudina et al., 2007; Boudina and Abel, 2006). The mitochondrial defect in the db/db mouse is localized to SSM (Dabkowski et al., 2010). In contrast, the mitochondrial defect in type I diabetic mouse is limited to IFM (Dabkowski et al., 2009; Hollander et al., 2014). The previously observed defects in oxidative phosphorylation in respiration with complex I substrates in the db/db heart was attenuated by activation of protein kinase G, achieved by long-term treatment with the phosphodiesterase inhibitor, tadalafil (Koka et al., 2014).

Aging

Aging leads to a decrease in the number of cardiomyocytes, increases the size of individual myocytes due to myocyte hypertrophy, and increases the number of small focal areas of myocardial fibrosis, probably through myocyte dropout due to inappropriate activation of programmed cell death (Wei, 1992). Mitochondrial dysfunction is a key contributor to the aging cardiac phenotype with enhanced ROS production due to the presence of age-related ETC defects (Suh et al., 2003), enhanced susceptibility to mitochondrial permeability transition (Hafner et al., 2010), and a greater predisposition to release cytochrome *c* (Phaneuf and Leeuwenburgh, 2002). The age-related mitochondrial phenotype predisposes to increased cardiomyocyte injury in the aged heart during the tissue stress of ischemia–reperfusion (Lesnefsky et al., 1994), where ischemic damage to mitochondria is superimposed upon the age-related changes in mitochondrial metabolism (Lesnefsky et al., 2016).

The initial studies of age-related changes in mitochondrial function yielded conflicting results, latter rescinded (Lesnefsky et al., 2001c; Lesnefsky and Hoppel, 2003; Fannin et al., 1999). The rate of oxidative phosphorylation in mitochondria (SSM) obtained by the use of the Polytron was similar in mitochondria isolated from adult and aged hearts (Takasawa et al., 1993). When a combined mitochondrial population of SSM and IFM was obtained by the use of protease digestion, some studies reported a decrease in the rate of oxidative phosphorylation (Chen et al., 1972; Hansford, 1978), whereas a single one did not (Manzelmann and Harmon, 1987), due to differences in isolation technique that resulted in variable admixtures of SSM and IFM. These divergent findings were reconciled by the subsequent study of the two individual subpopulations of cardiac mitochondria (Fannin et al., 1999).

The protein content of IFM is decreased in the aged heart (Fannin et al., 1999). The enzyme cytology approach of DeDuve (1967) conclusively showed that the recovery of mitochondria did not differ in adult and aged hearts (Fannin et al., 1999). Thus, supported by marker enzyme studies, the decreased protein yield of IFM from aged hearts reflects a true decreased content of mitochondria in the myocardium (Fannin et al., 1999).

Oxidative phosphorylation was studied in SSM and IFM isolated from 6-month adult and from 24 and 28 months aged Fischer 344 rat hearts (Fannin et al., 1999). Respiration was tightly coupled in both adult and aged heart mitochondria (Fannin et al., 1999). The maximal rate of oxidative phosphorylation was decreased only in IFM in aged hearts compared to adult controls, whereas rates in SSM were unaltered by age (Fannin et al., 1999).

The decrease in uncoupled respiration in IFM localized the age-related defect to the ETC rather than to the phosphorylation apparatus (Fannin et al., 1999). Substrates that donate reducing equivalents to specific electron transport complexes were employed to localize the aging defect in IFM to specific sites in the ETC. The decrease in the oxidation rate of TMPD-ascorbate, an electron donor to cytochrome oxidase via the reduction of cytochrome *c*, localized a defect to cytochrome oxidase (Fannin et al., 1999). Measurement of the enzyme activities of the individual ETC complexes also disclosed an aging defect in complex III due to alteration of the quinol binding site, with potential involvement of a regulatory subunit of complex III (subunit VII, "hinge protein") as well (Moghaddas et al., 2003; Lesnefsky et al., 2001b).

Age-induced reductions in mitochondrial content and respiration occur in IFM, whereas SSM are unaffected. In addition to respiration, further studies of SSM found that ROS production (Muscari et al., 1990) and protein import (Craig and Hood, 1997) were unaltered by age. The ability to separate and study SSM and IFM separately permits the uncovering of key pathogenic mitochondrial defects (Lesnefsky and Hoppel, 2003; Hoppel et al., 2002; Lesnefsky et al., 2016; Judge et al., 2005).

Ischemia

Following coronary occlusion with the cessation of myocardial perfusion, the oxygen content of myocardium declines precipitously, leading to a marked slowing in the rate of respiration. As a consequence, ischemia does not immediately lead to anoxia and during the evolution of ischemic injury, some oxygen remains available in the tissue (Ilangovan et al., 2004). The slowed respiration favors the leak of electrons from complexes I and III directly to the remaining oxygen to form ROS, as shown by experimental studies in cardiomyocytes (Becker et al., 1999; Vanden Hoek et al., 1997). Consistent with the presence of some remaining oxygen in this pathologic milieu, ROS production increases during stop-flow ischemia in the intact heart (Kevin et al., 2003; Lee et al., 2000; Riess et al., 2004) until all the oxygen is consumed (Levraut et al., 2003).

Ischemia progressively damages the ETC (Lesnefsky et al., 2001c), in part due to this ROS production. The first target of the electron transport driven damage is the mitochondria themselves (Chen et al., 2006a, 2007; Lesnefsky et al., 2004a). The catalytic centers of complexes I and III sustain damage (Chen et al., 2007; Lesnefsky et al., 2001c). Ischemia damages complex I at sensitive iron–sulfur centers and the flavin-containing center (Chen et al., 2008; Ohnishi et al., 2005). Complex III suffers deactivation of the

Rieske iron–sulfur protein (Lesnefsky et al., 2001a). The ischemic damage decreases electron transfer capacity and favors electron leak to generate ROS. Thus, complex I and complex III become key sites that generate ROS during reperfusion (Ambrosio et al., 1993; Chen et al., 2003; Han et al., 2003; St-Pierre et al., 2002). The initial damage from ischemia predisposes to increased oxidant production during reperfusion.

Complex IV requires the inner membrane phospholipid, cardiolipin, for optimal activity (Vik and Capaldi, 1977). Ischemia decreases enzyme activity via a decrease in cardiolipin content (Lesnefsky et al., 2001d). The proximity to the ETC makes cardiolipin, containing oxidatively sensitive linoleic acid (C18:2) groups, a prime target for oxidative damage. Rather than random oxidative damage, the decrease in cardiolipin during ischemia probably occurs via targeted oxidative damage from the cytochrome *c* cardiolipin peroxidase discussed above (Kagan et al., 2005). The neopathologic function of cytochrome *c* as a cardiolipin peroxidase directs ROS-mediated oxidation of cardiolipin to lipid peroxide formation (Kagan et al., 2005). Furthermore, the methionine-oxidized cytochrome *c* is no longer effective in normal electron transport (Kagan et al., 2005). An increase in oxidized cardiolipin delocalizes cytochrome *c* from the inner membrane into the intermembrane space (Kagan et al., 2005), in turn activating cell death programs (Kagan et al., 2005; Ott et al., 2002).

Reperfusion

Mitochondria are a major source of oxidative damage during reperfusion (Chen et al., 2006b, 2007). The decrease in complex IV activity and the oxidation and loss of cytochrome *c* (Borutaite et al., 2001; Lesnefsky et al., 1997; Kagan et al., 2005) results in impaired electron flow through the distal ETC. The blockade of electron flux downstream of the sites of electron leak at complexes I and III enhances ROS production from these proximal sites by favoring greater reduction of their catalytic centers and enhanced electron leak to oxygen (Chen et al., 2007). The block in the distal ETC at complex III and cytochrome c also may favor reverse electron transport with succinate as a complex II substrate from complex II through complex I to NAD+ as a source of ROS production (Chouchani et al., 2013; Pell et al., 2016). The extent of reformation of the inner membrane electrochemical potential during early reperfusion dictates the relative contribution of forward and reverse electron transport to oxidative injury (Ross et al., 2013). In the presence of only moderate ischemic damage to mitochondria that allows the ETC to generate an electrochemical potential, reverse electron transport is favored. In contrast, in the absence of a significant inner membrane potential, electrons will flow down their free energy gradient from complex I or complex II into complex III, with ROS generation (Chen et al., 2003).

Blockade of electron transport at or proximal to the sites of electron leak attenuates ROS production (Chen et al., 2003, 2007). The blockade of electron transport at the quinone-binding site of complex I will block ROS from forward electron transport (complex I forward into complex III with III as the ROS source) and reverse electron transport (complex II retrograde into complex I with I as the ROS source). Not surprisingly, this intervention is highly protective of mitochondria (Chen et al., 2006b, 2007; Chouchani et al., 2013; Lesnefsky et al., 2004a), whereas chemical blockade of the distal ETC at complex IV during ischemia is not protective (Chen et al., 2010). Thus, strategic blockade of the ETC at specific sites is critical to prevent flow into more distal sites of the chain that generates the damage (Chen et al., 2007). As a result of these studies, complex III and the modified cytochrome *c* peroxidase are the likely mediators of damage to the ETC during ischemia and probably early reperfusion as well (Chen et al., 2006a, 2010; Lesnefsky et al., 2004a).

Damage to the ETC clearly begins during ischemia (Borutaite et al., 2001; Lesnefsky et al., 1997, 2004b). Although the bulk of the damage to electron transport occurs during ischemia (Lesnefsky et al., 2004b), reperfusion results in additional damage at complexes I and III (Flameng et al., 1991). The critical structural damage to mitochondrial membranes that jeopardizes cell survival occurs mainly during reperfusion (Halestrap et al., 2004; McCully et al., 2004; Murphy and Steenbergen, 2008; Weiss et al., 2003). Although other sites of ROS generation during early reperfusion include monoamine oxidase (Di Lisa et al., 2009), NADPH oxidase (Sciarretta et al., 2013), and possibly xanthine oxidase (Cantu-Medellin and Kelley, 2013), and lipoxgenases (Li et al., 2009), impaired electron transport remains the predominant source of intramitochondrial and extramitochondrial oxidative damage to the cardiomyocyte.

Cytosolic calcium content increases during ischemia, especially during reperfusion. Calcium accumulation by mitochondria occurs via the inner membrane calcium uniporter (Murphy and Steenbergen, 2008). ER-driven calcium overload of mitochondria during reperfusion exacerbates injury (Paillard et al., 2013). Increased matrix calcium content leads to cycles of mitochondrial calcium release and reuptake, generating futile energy-consuming cycles. Elevated matrix calcium activates proteases and phospholipases, degrading inner membrane phospholipids and matrix proteins (De Windt et al., 1998; Chen and Lesnefsky, 2015). Calcium overload is a key stimulant for opening of the mitochondrial permeability transition pore (MPTP), leading to permeation of the inner mitochondrial membrane with collapse of the inner membrane electrochemical gradient with subsequent mitochondrial swelling and outer membrane rupture that favors release of cytochrome *c*, apoptosis-inducing factor, and other intermembrane space proteins that activate programmed cell death (Halestrap et al., 2004; Weiss et al., 2003; Rasola and Bernardi, 2014).

Congestive Heart Failure

Reduction of bio-energy generation due to impaired mitochondrial function is a major factor in the development of heart failure. Impaired ETC leads to decreased generation of ATP that is a general feature of heart failure (Dolinsky et al., 2016; Parihar and Parihar, 2017; Rosca and Hoppel, 2010, 2013; Rosca et al., 2013). Cardiac energy levels are decreased in patients with cardiomyopathies and in animal models of heart failure (Fosslien, 2003). In addition to ischemia-induced mitochondrial dysfunction,

defective mitochondrial metabolism occurs in nonischemic models of cardiomyopathy (Griffiths, 2012). Complex IV activity is decreased in the failing heart due to dysregulation of respirasome formation (Quigley et al., 2000; Rosca and Hoppel, 2013; Rosca et al., 2013). Mitochondrial dysfunction not only decreases energy production, but also activates signaling pathways to trigger myocyte death. Loss of cardiomyocytes is an important step in the development of heart failure. Cardiomyocyte loss can be due to apoptosis, necrosis, and autophagy. Therapeutic approaches to improve metabolic energy generation would be beneficial for the treatment of heart failure.

Mitochondria are the major source of ROS in cardiomyocytes (Chen et al., 2003). An impaired ETC markedly augments the production of ROS, contributing to the development of heart failure. Increased ROS generation leads to oxidation of cardiolipin, which decreases cytochrome oxidase activity and favors release of cytochrome *c* from mitochondria into the cytosol. Cardiolipin oxidation results in a reduction of energy generation and an increase in apoptosis (Dolinsky et al., 2016).

The opening of the MPTP is a final step in triggering necrotic cell death (Weiss et al., 2003). MPTP is activated by mitochondrial calcium overload or by enhanced oxidative stress, leading to a depolarized inner mitochondrial membrane potential that contributes to decreased ATP synthesis. MPTP opening is involved in the progression of heart failure through decreased energy production and enhanced cell death.

In addition to apoptotic and necrotic cells, autophagic cells also are found in failing human hearts with dilated cardiomyopathy (Tong and Sadoshima, 2016). Autophagy, an adaptive response designed to preserve cardiomyocytes during stress, removes damaged macromolecules as well as damaged mitochondria. However, extensive autophagy can lead to cell injury (Shires and Gustafsson, 2015). It is still unclear whether autophagy, including mitophagy, is an adaptive response to keep cardiomyocytes healthy or is a means to eliminate injured cardiomyocytes during the development of heart failure.

Conclusion

Cardiac performance is critically dependent on mitochondrial function in health and disease. The heart is able to use a variety of fuel sources to support metabolism and can change fuel preference in response to changing conditions at the organismic and cardiac levels. Damage to mitochondria is a critical mechanism underpinning many cardiac diseases, with resultant deficits in energy production and enhanced generation of ROS contributing to cardiac injury. Defective mitochondria need to be repaired or eliminated and replaced. Mitochondria are critical checkpoints for cardiac myocyte survival versus death, with indicators of severe, unrepairable mitochondrial injury including oxidation of cardiolipin and the loss of select mitochondrial proteins activating pathways of cardiomyocyte suicide. Comorbid conditions such as aging and diabetes independently cause mitochondrial dysfunction, which exacerbates disease-mediated mitochondrial-driven injury. Cardiac dysfunction and cell death lead ultimately to cardiomyopathy and heart failure. Mitochondria present intriguing targets for new therapies to reduce cardiac cell injury in acute and chronic disease settings. When all is said and done, it is the mitochondria, minuscule inhabitants of the cardiomyocyte, that by their incessant bioenergetic activity enable the heart to beat without surcease, a sine qua non of life itself.

Introduction

The first implantable cardioverter defibrillators (ICD) were implanted by cardiac surgeons through lateral thoracotomy, with a large 250–300 cc abdominal generator with battery life lasting 1.5 years, no programmable features, and no pacing capability. Modern ICDs have a 30 cc generator, are often implanted in less than an hour, can include single- or dual-coil ICD leads, VVI, DDD, or CRT pacing including use of quadripolar and multisite pacing capability. ICDs commonly can deliver in excess of 35 J shocks following several attempts at ATP (antitachycardia pacing), which is often effective at painless termination of ventricular arrhythmias (VA). "Leadless" defibrillation is also available with an entirely subcutaneous ICD system. ICD implantation has grown exponentially after a series of randomized trials demonstrating the lifesaving benefits of ICDs in well-selected patients with cardiomyopathy, prior MI, or prior cardiac arrest (Moss et al., 1996, 2002; Bardy et al., 2005). CRT (cardiac resynchronization) pacing benefits in patients with LBBB and QRS duration >130 ms have demonstrated improved morbidity and reduced mortality independent of the lifesaving effect of ICD on VAs. Along with a massive growth in implantation has come a greater number of complications, lead fractures, lead recalls, ICD generator recalls, battery failures, and device-related infections, all of which demand more careful attention to strategies to reduce these risks.

In the modern era, the choice of whether or not to implant an ICD is the first of many for the electrophysiologist. There are now a variety of device types and programming schema available to individualize device therapy for a particular patient, and considerations to reduce the risk of complications for our ICD recipients.

Choice of Device

Single- Versus Dual-Chamber ICDs

There is no expert consensus recommendation regarding the choice of a single- or a dual-chamber ICD as the data available to guide the electrophysiologist in making this decision is quite inconclusive.

First, patients with an indication for atrial pacing such as a history of symptomatic sinus node dysfunction (sick sinus syndrome), high degree A–V block, sinus arrest with syncope, or a history of Torsades de Pointes should likely receive dual-chamber devices based on the indication for atrial pacing or the benefit of maintaining AV synchrony alone. Additionally, if atrial fibrillation diagnostics are needed to guide decisions on anticoagulation, a dual-chamber device may be considered. The high rate of inappropriate ICD shocks for patients with rapidly conducted AF gives another rationale for dual-chamber systems; however, formal studies have been disappointing on its ability to actually reduce ICD shocks.

What is less clear is whether the addition of atrial sensing can decrease the rate of inappropriate therapies due to supraventricular tachycardias. A recent randomized controlled trial (the RAPTURE Trial) found no reduction in inappropriate shocks with a dual-chamber ICD as compared to a single-chamber device when used for primary prevention and modern shock reduction programming with SVT discrimination was utilized (Friedman et al., 2014). Another recent randomized trial (the OPTION study) did find a

7% absolute risk reduction of inappropriate shocks when dual-chamber programming was utilized in a population of both primary and secondary prevention ICD patients (Kolb et al., 2014). Several prospective and retrospective cohort studies as well as one meta-analysis have failed to show any reduction in inappropriate shocks in patients with dual-chamber devices compared to those with single-chamber devices (Theuns et al., 2008; Ruwald et al., 2013; Deisenhofer et al., 2001; Van Rees et al., 2011). Finally, the randomized detect supraventricular tachycardia study found a small 8% absolute risk reduction for inappropriate detection of SVT when a dual-chamber system was used (Friedman et al., 2006).

The disadvantages of a dual versus single-chamber ICD include the potential for atrial lead complications, increased cost, and decreased device longevity. Upgrade or revision of a single-chamber system to add an atrial pacing lead has been associated with at least a 7% complication rate related to hematoma, pneumothorax, and lead dislodgement (Dewland et al., 2011; Poole et al., 2010). One appealing ICD lead choice for atrial diagnostics in a single-chamber MRI conditional device is using a DX lead (Biotronik, Germany) which provides a large bipolar sensing ring in place of an SVC coil, however this does not provide atrial or AV synchronous pacing.

Cardiac Resynchronization

The addition of left ventricular pacing, or cardiac resynchronization therapy, is another consideration when implanting an ICD. CRT is most commonly accomplished by placement of a pacing lead into a posterolateral branch of the coronary sinus, thus reaching the epicardial surface of the left ventricle. Unlike ICDs, CRT devices are not only beneficial in the case of malignant arrhythmias but have the potential to improve both symptoms and prognosis in patients with heart failure and left ventricular dyssynchrony. The premise of CRT is to improve the efficiency of cardiac function by allowing for simultaneous contraction of the septal and free walls of the left ventricle and avoiding wasted energy moving the blood-pool back and forth laterally. Invasive and echocardiographic studies have shown that CRT can dramatically improve myocardial performance within a single heart beat when active. The randomized controlled CARE-HF trial demonstrated that patients with class III or IV heart failure, LVEF less than 35%, and a QRS duration greater than 120 ms had a 10% reduction in the absolute risk of death at 2 years follow-up when treated with CRT compared to standard pharmacologic therapy alone (Cleland et al., 2005). Similarly, the randomized COMPANION trial demonstrated a reduction in mortality in patients with class III or IV CHF, QRS duration >120 ms, and LVEF <35% when treated with either a CRT pacemaker or defibrillator compared to pharmacologic therapy alone (Bristow et al., 2004). Finally, the randomized controlled MADIT–CRT trial enrolled patients with class I or II CHF, LVEF <30%, and QRS duration greater than 130 ms and compared outcomes after randomization to either CRT and ICD or ICD alone. This trial demonstrated a significant 41% reduction in the risk of heart failure events (Moss et al., 2009). Subsequent subgroup analyses of the MADIT–CRT trial as well as a long-term follow-up examination of randomized patients have demonstrated that this benefit appears to be restricted to patients with a true LBBB morphology with the optimal response in those with QRS duration >150 ms (Zareba et al., 2011). Ideally, for optimal resynchronization, CRT lead position should be targeted to the latest site of left ventricular activation. As such, patients with LBBB are expected to benefit more from CRT compared to those with RBBB as activation of their posterolateral left ventricle, the most common site of LV lead implantation, should be delayed by their conduction system disease. The advent of quadripolar LV leads has helped to facilitate higher rates of success delivering CRT. These leads have resulted in a lower incidence of phrenic capture or lead dislodgment, and provide an option for multipoint LV pacing which may further augment CRT response by targeting sites of late activation for pacing.

Single Versus Dual-Coil Defibrillation Leads

When implanting a transvenous ICD system, one of the intraoperative decisions an implanting physician must make is whether or not to utilize a single- or dual-coil defibrillation lead. The vast majority of implanted systems today utilize a dual-coil system (Neuzner and Carlsson, 2012). This preference is attributed to studies demonstrating that the use of a dual-coil system reduces the defibrillation threshold (DFT) by 2–3 J at the time of system implantation (Bardy et al., 1994; Gold et al., 1998); however in several retrospective analyses of large cohorts of patients with ICDs, the use of a dual-coil system has not been associated with improved clinical outcomes nor with higher first shock efficacy (Aoukar et al., 2013; Kutyifa et al., 2013; Mokabberi et al., 2011; Ellis and Hurt, 2012). Specifically, patients who have a right-sided ICD system implantation derive no benefit on DFT from an SVC coil. Since the shock vector an ICD delivers includes the pulse generator as part of the circuit ("hot-can"), a right-sided implant necessarily directs energy toward the right hemithorax making the position of the SVC coil within the dominant path of the defibrillation vector, lowering shock impedance. Right-sided systems tend to have higher DFTs; however, conversion efficacy for both spontaneous VA (VAs; i.e., VT/VF) and induced ventricular fibrillation has been found to be no different between right- and left-sided systems (Gold et al., 2007). In prospective randomized trials of ICD implantation and lead surveillance registries, the dominant clinically treated VA is sustained ventricular tachycardia not ventricular fibrillation (~90% of ICD shocks delivered for VT, not VF) (Ellis and Hurt, 2012). Antitachycardia pacing therapy is at least 75% effective to terminate sustained VT and ATP is independent of the presence of an SVC coil (Wathen et al., 2004; Wilkoff et al., 2008a).

While there are few apparent clinical benefits of a dual-coil system, the risk of extraction of these leads, should it become necessary, is significantly higher. The major risk of lead extraction is vascular injury including SVC tears. The most common site of major vascular injury during transvenous extraction is in the SVC or SVC right atrial junction. It is felt that the presence of a defibrillation coil in the SVC increases the fibrotic response of the vasculature at this site, increasing the likelihood of injury during

extraction (Epstein et al., 2013). This is particularly problematic for nonsilicone back-filled ICD coils (i.e., St. Jude Medical, Riata), and may be somewhat mitigated with the use of Gore-ePTFE coated coils (Boston Scientific, Reliance) (Kohut et al., 2013). Given the availability of modern ICD generators capable of delivering 40 J maximum output shocks, the added 2–3 J DFT reduction from an SVC coil is unlikely to be clinically relevant. An exception are patients with a significantly elevated DFT where consideration of dual-coil leads should be made, HOCM, LV EDD dilation >6 cm, male gender, African-American race, and use of chronic Amiodarone (Shih et al., 2016).

In summary, in current transvenous ICD systems, despite a 2–3 J improvement in DFT there appears to be no demonstrable clinical benefit to an SVC coil on the efficacy of termination VT or VF. The default choice of dual-coil ICD leads appears unwarranted apart from unique circumstances, and may pose future harm long term, conferred through the risk of lead extraction and SVC tear.

The Subcutaneous ICD

While ICDs are widely accepted as an established therapy for the prevention of sudden cardiac death, these devices have traditionally required the implantation of either epicardial patches or transvenous leads for cardiac sensing and defibrillation. Unfortunately, despite decades of engineering innovations in lead design, defibrillator leads truly remain the "weakest link" in the ICD system. Lead failure can lead to inappropriate shocks, or worse, ICD generator short circuit or failure to deliver appropriate therapy. Furthermore, the presence of an intravascular lead can allow a portal of entry to the circulation if local infection occurs around an ICD generator, allowing a soft tissue infection to become a potentially life-threatening intravascular or endocardial infection. With this in mind the subcutaneous ICD system was created.

Hardware

The subcutaneous ICD consists of a generator and single electrode. The generator is implanted in the left mid-axillary line, typically tucked under the anterior edge of the latissimus dorsi muscle and overlying the cardiac apex and the single electrode is tunneled subcutaneously from the generator to the lower sternum near the xiphoid process and then extending to the superior sternum near the manubriosternal junction (**Fig. 1**).

Patient selection

The obvious advantage of a subcutaneous system is the lack of any intravascular component, obviating the need for vascular access and significantly decreasing the chances of device-related endovascular infection. As such, this device is considered preferable in patients with poor vascular access and those at high risk for infectious complications (prior history of endocarditis, hemodialysis, mechanical valves, etc.; see **Table 1** and **2**). This type of device is also potentially advantageous in younger patients with an indication for ICD protection as it avoids the long-term risk of lead-related complications. The greatest disadvantage of a subcutaneous ICD system is its lack of ability to pace. As such, patients who require pacing have an absolute contraindication to a subcutaneous system and those who would benefit from antitachycardia pacing have a relative contraindication. The advent of transcatheter pacemakers may allow a "leadless" communication with an S-ICD, and potentially provide pacing therapy in the future for those patients who would benefit from ATP.

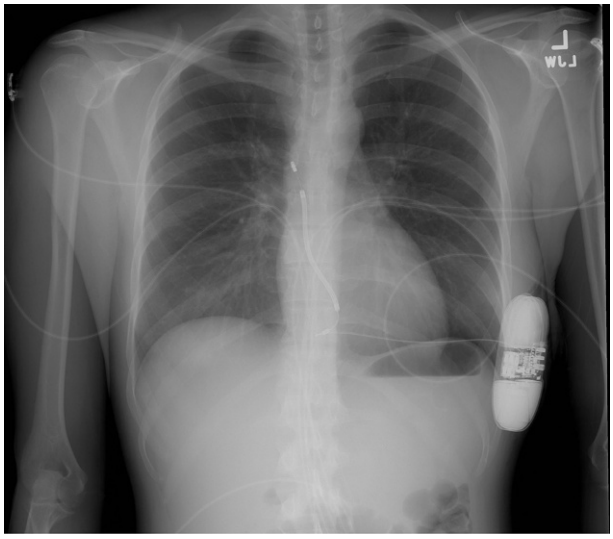

Fig. 1 Typical position of a subcutaneous ICD with generator in the mid-axillary line and electrode tunneled to the sternum.

Table 1 Patient selection for S-ICD

Patient selection for S-ICD		
Preferred	*Strongly considered*	*Avoid*
• Lack of venous access (occluded veins or congenital anomalies) • High risk of TV-complications (dialysis, pediatric, and immunocompromised) • Channelopathies (LQT, Brugada, and HCM) • Previous device infections/lead failures • History of endocarditis	• Young patients • Life expectancy >10 years • Primary prevention indicated patients with ischemic/nonischemic heart failure • Prosthetic valves • Cosmetic consideration (preferred generator placement lateral wall) • Secondary prevention with no evidence of monomorphic VT	• CRT indicated • Symptomatic bradycardia • Recurrent sustained MVT

Table 2 Comparison of outcomes and complications between a transvenous ICD and subcutaneous ICDs

Study	*Mortality (at 2 years)*	*Average age*	*1^0 prevention*	*Ischemic*	*NYHA*	*LVEF*
S-ICD pooled (Burke et al., 2015)	3.2%	50	70%	38%	37.5% classes II–IV	39%
MADIT-RIT (Moss et al., 2012)	5%–7% High rate and delayed therapy arms	63	100%	53%	98% class II or III	26%

Acute major complications (% of patients)	S-ICD (Burke et al., 2015)	TV-ICD
	Pooled data	NCDR analysis (Peterson et al., 2013) Meta-analysis (Van Rees et al., 2011)
	2%	3%–5%
	(Hematoma, lead or device malposition or displacement, pneumothorax)	

Sensing and defibrillation

Sensing is performed in one of three configurations, either from the electrode tip (at the upper sternum) to the generator, the mid electrode (which is located at the lower sternum) to the generator, or from the tip to mid electrode. In order for this device to properly discriminate tachyarrhythmias from sinus rhythm, a patient must be "screened" with electrocardiographic measurements in these three sensing vectors to ensure that their QRS complex fits into the devices template (Groh et al., 2014). Thus, patients with unusual QRS morphologies, hypertrophic cardiomyopathy, or symptomatic bradycardia may not be appropriate for this device. Indeed, inappropriate shocks have proven to be the biggest potential pitfall of the S-ICD system with rates on inappropriate shocks as high as 13%–15% in initial clinical experience with up to 80% of these shocks being attributed to T-wave oversensing (Olde Nordkamp et al., 2012, 2015; Jarman and Todd, 2013). The addition of dual-zone programming and discrimination algorithms has reduced this rate significantly, in the most recent data available the rate of inappropriate shocks has been reported as low as 4.5%–6.9% (Burke et al., 2015).

Programming Considerations

Shock Reduction

While ICDs can provide lifesaving antitachycardia therapies, the counterpoint to this benefit is the possibility of delivering unneeded, painful shocks. These inappropriate therapies have not only been found to be quite common (15% of patients in MADIT II and 17% of SCD-HeFT patients received at least one inappropriate shock) but are also frequently associated with depression and anxiety resulting in both immediate and long-term morbidity for patients affected. Multiple studies have demonstrated that careful device programming can significantly reduce the burden of inappropriate therapies.

PREPARE

The PREPARE study was a prospective cohort study comparing patients with a primary prevention biventricular ICD programmed with high rate detection limits, prolonged detection intervals, initial ATP therapy, and initial high energy shocks to (see **Table 3** for particular of programming) control patients from two other trials, the MIRACLE-ICD and EMPIRIC studies. This trial demonstrated a statistically significant reduction in overall shocks as well as inappropriate shocks (3.6% versus 7.5%) after controlling for baseline differences in the cohort (Wilkoff et al., 2008b).

Table 3 PREPARE tachycardia programming parameters

Detection		*Threshold*	*Time to detection*	*Therapies*
VF	On	250 BPM	30 of 40	30–35 J (max output) × 6
FVT	Via VF	182 BPM	30 of 40	Burst × 1, 30–35 J (max output) × 5
VT	Monitor only	167 BPM	32	Off

Table 4 RELEVANT tachycardia programming parameters

Detection		*Threshold*	*Time to detection*	*Therapies*
VF	On	250 BPM	30 of 40	30 J (max output) × 6
FVT	Via VF	181 BPM	30 of 40	Burst × 1, 30–35 J (max output) × 5
VT	Monitor only	167 BPM	32	Off

Table 5 MADIT-RIT tachycardia programming parameters

Detection		*Threshold*	*Time to detection*	*Therapies*
Standard programming				
VF	On	200 BPM	1 s delay	Quick convert ATP + shock
VT	On	170 BPM	2.5 s delay	ATP + shock
High rate cutoff programming				
VF	On	200 BPM	2.5 s delay	Quick convert ATP + shock
VT	Monitor only	170 BPM	Off	Off
Long delay programming				
VF	On	250 BPM	2.5 s delay	Quick convert ATP + shock
VT	On	200 BPM	12 s delay	ATP + shock
VT-1	On	170 BPM	60 s delay	ATP + shock

RELEVANT

The RELEVANT trial was a prospective, nonrandomized trial enrolling patients with a primary prevention indication for a biventricular ICD. Patients received either a simplified BiV ICD with a monitor only VT zone and a fixed long detection interval in the FVT/VF zones with a single round of ATP prior to shocks in the VF zone, or a standard programmable BiV ICD (see **Table 4**). The main difference in the trial was that patients in the control arm had a much shorter time to detection requiring only 12 of 16 intervals rather than 30 of 40 in the intervention arm. This trial demonstrated a significant reduction in overall as well as inappropriate device therapies. Patients in the control arm experienced 289 treated episodes versus only 36 in the intervention. There were 48 inappropriate treatments in the control arm versus 10 in the intervention arm (Gasparini et al., 2009).

MADIT-RIT

The MADIT-RIT study was a multicenter randomized controlled trial enrolling patients with a primary prevention indication for an ICD. Patients were randomized to one of three programming schema as outlined in **Table 5**. Both a high rate cutoff and long delay strategy led to a significant reduction in both total shocks and inappropriate shocks at an average of 1.4 years follow up. In the control group, 5% of patients received appropriate and 6% of patients inappropriate shocks compared with 5% and 3% in the high rate group and 4% and 3% in the long delay group. Interestingly, a statistically significant reduction in mortality was also observed in both the long delay and high rate groups (0.12% vs. 0.09% vs. 0.05%) (Moss et al., 2012).

While the details of these studies differ slightly they at least establish that in a primary prevention cohort the use of more conservative programming measures such as long detection delays and high rate cutoffs can significantly reduce the morbidity of ICD therapy without any change, and possibly improvement in mortality. The generalizability of these results to a secondary prevention population is not known and an individual patient's risk profile should be carefully considered when making programming decisions in this group. Other groups of patients such as those with catecholaminergic polymorphic ventricular tachycardia (CPVT) or an implanted left ventricular assist device may also benefit from a conservative programming strategy.

CPVT

The available data regarding defibrillator therapy in patients with CPVT is somewhat conflicting. While these patients are at high risk for life-threatening tachyarrhythmias, ICD therapy can be ineffective in a significant portion of these patients and potentially even

harmful. Retrospective cohort studies have demonstrated that arrhythmia mechanism appears to be a major determinant of the likelihood of success of defibrillation. In one cohort no episodes of observed polymorphic or bidirectional ventricular tachycardia (PMVT, BDVT) successfully terminated with ICD therapy, while 100% of episodes of sustained VF terminated with shock (Miyake et al., 2013). With these results in mind the authors recommended device programming with a single VF zone with rates as high as 250–300 BPM. A second retrospective cohort found similar results with only 3% of shocks delivered for PMVT or BDVT being successful and 83% of shocks for VF being successful (Roses-Noguer et al., 2014).

LVAD

While patients with implanted left ventricular devices obviously have severe cardiomyopathy and high risk of ventricular tachyarrhythmias, the clinical implications of these arrhythmias and the benefits of ICD therapy remain unknown. Additionally, the effects of CRT in this population have also not been defined. It has been well described that patients with LVAD in place may hemodynamically tolerate what are typically malignant VAs but potentially experience a reduction in right ventricular function leading to eventual decompensation. Retrospective studies have demonstrated that increased rates of VAs are associated with poor outcomes and that the presence of an ICD may be associated with improved outcomes. However, these studies are subject to potential confounding as all retrospective analyses are. Prospective, randomized controlled trials of ICD programming and therapies are needed in this population.

Battery Life

Device longevity is a vital component of ICD performance. Current drain in a pacemaker generator is fairly low output, and typically can be accomplished with a traditional lithium-Iodide battery. ICD shocks require up to 830 V of stored charge per full output ICD shock and require large capacitors. Shorter pulse generator battery life leads to more frequent replacement of ICD generators particularly with a CRT system, exposing patients to increased risk for lead damage, hematoma formation, infection, and even death. Many factors play a role in ICD longevity, including both device factors and patient factors. For example, patients who require pacing support from their ICD, or those who receive defibrillation will predictably experience a lower expected device longevity. A typical single full capacitor charge from an ICD battery will reduce the usable device capacity by roughly 1 month. In contrast, capture thresholds will have a variable effect on longevity depending on the frequency of pacing support required, that is, if pacing never occurs stimulation threshold has little to no effect on longevity.

Recent analyses of patients with CRT devices, which ideally pace both ventricles 100% to provide heart failure therapy through CRT, have additionally demonstrated that not only did a lower pacing threshold on left ventricular leads improve longevity but so did high LV impedance values (Ellis et al., 2016; Zanon et al., 2016). A rudimentary understanding of the principles of electric circuits clarifies this finding as circuits with higher impedance will conduct less total current at a given voltage. As such, higher impedance circuits will require less power (current multiplied by voltage) leading to longer battery life. Additionally, the particulars of device circuitry including AF diagnostics and wireless monitoring vary greatly between manufacturers, and can play a significant role in determining ICD longevity. Features such as automatic remote transmissions and automated capture threshold management will lead to variable rates of energy consumption depending on the manufacturer's design. These studies imply that physicians should carefully consider manufacturer's battery technology, whether certain device features are truly necessary, choice of lead type and programmed vector to optimize lead impedance and threshold, and ICD and LV lead position at the time of implantation to ensure maximal device longevity for their patients. Avoidance of an additional ICD generator change may reduce morbidity, mortality, and overall health care cost utilization.

Introduction

MRI Physics

Magnetic resonance imaging (MRI) generates images by harnessing the properties of hydrogen atoms, which are ubiquitously concentrated throughout the human body, particularly in water and fat. The main principle of MRI relies on using perturbations of the hydrogen atoms to create differential signals between unique tissue types, with generation of images. Initially, the stable magnetic field (B_0) of the MRI aligns hydrogen nuclei with its magnetic axis, a process called precession. Small additional magnetic fields are then applied in a controlled fashion (pulse sequence) to disturb this baseline precession. The shift in precession of the hydrogen atoms and relaxation properties of the atoms within each tissue are detected and processed to create visual images of tissue characteristics. The pulse sequences can be varied to investigate different aspects of the cardiovascular system and the large number of clinical relevant pulse sequences leads to the immense versatility of MRI.

The strength of a scanner's magnetic field is measured in tesla (T). Field strengths of 1.0, 1.5, and 3.0 T are commercially available for clinical application, and greater strengths are advantageous for animal studies. An increase in field strength offers improvement in spatial resolution leading to a better delineation of the heart and great vessels, but also to more artifacts.

Advantages of CMR as a Noninvasive Imaging Modality

Cardiac magnetic resonance (CMR) imaging has several advantages over other noninvasive cardiovascular imaging modalities. First, it achieves high spatial and temporal resolution. At field strength of 1.5 T, a spatial resolution of $1 \times 1 \times 3$ mm can be obtained with most pulse sequence strategies. Routinely, frame rates of 20–40 ms are acquired with cine sequences. CMR permits the comprehensive assessment of multiple different parameters of cardiovascular anatomy and function, integrating parameters that cannot be assessed by other techniques. In a single study, CMR can characterize anatomy and structure of the cardiac chambers, myocardium,

 https://doi.org/10.1016/B978-0-12-809657-4.64201-1

and coronary arteries, visualize and quantify myocardial perfusion, assess myocardial viability and scarring, characterize myocardial tissue composition, and evaluate metabolism with spectroscopic techniques. CMR is able to acquire images in any tomographic plane, allowing manipulation of three-dimensional images. Though CMR may be susceptible to artifacts with greater body habitus, image quality remains significantly improved and may overcome suboptimal acoustic windows with transthoracic echocardiography or attenuation artifacts with radionuclide scintigraphy. Additionally, CMR is well suited for serial examinations in the clinical and research setting. It is able to differentiate tissue characteristics without need for ionizing radiation or administration of iodinated contrast or radioactive isotopes. Given that patients frequently require serial monitoring for cardiovascular disease, CMR eliminates the cumulative radiation exposure of other techniques such as myocardial perfusion imaging and computed tomography. The high reproducibility and low measurement variance in repeated samples underscores the high accuracy of CMR (Gandy et al., 2008) and is ideal for comparison of change in measured parameters over time.

MRI Safety

Though CMR has several outlined advantages, MRI safety is paramount. Two major considerations include implanted metallic cardiovascular devices and intravenous contrast administration. Regarding the former, the magnetic field of the CMR may theoretically cause shift in the position of ferromagnetic objects in the body. Additionally, the magnetic resonance pulse sequences can produce electric currents in leads, with associated arrhythmias shown in a small number of patients (Russo et al., 2017). The MRI radiofrequency pulses have been shown to generate a small amount of heat ($<1°C$) in implanted devices, resulting in possible interference with electronic components and wires (Russo et al., 2017).

Understanding of the risks and benefits of Gadolinium contrast agents in CMR is important. Intravenous gadolinium chelates are routinely used in contrast-enhanced MR angiography, myocardial perfusion, late gadolinium enhancement to identify scarring and viability, and the evaluation of cardiac masses. Adverse effects associated with gadolinium contrast agents range from mild allergic reactions (most commonly nausea, vomiting, cough, rash, or hives), moderate allergic reactions (e.g., tachycardia, hypertension, generalized erythema, or dyspnea), severe anaphylactic reactions (e.g., convulsion, unresponsiveness, cardiopulmonary arrest, or profound hypotension), and nephrogenic systemic fibrosis. In an international multicenter registry with 37,788 patients, the occurrence rate for mild, moderate, and severe allergic reactions was 0.11%, 0%, and 0.005%, respectively (Bruder et al., 2015). Nephrogenic systemic fibrosis is very rare but an important complication of gadolinium administration in patients with severe chronic or acute renal failure. As a result, screening for a reduction in renal function prior to a CMR study is recommended and gadolinium is contraindicated in patients with an estimated glomerular filtration rate <30 mL/min per 1.73 m^2. The doses of contrast agent given should be adjusted in patients with mild to moderate renal dysfunction.

Assessment of Vascular Anatomy

A variety of CMR methods exist to visualize vascular anatomy. T1- and T2-weighted dark blood techniques allow proper delineation of vessel walls (Krinsky et al., 1997) and bright blood imaging techniques make the assessment of blood flow possible.

Imaging the Coronary Arteries

Coronary magnetic resonance angiography (MRA) can detect the extent and severity of obstructive native coronary artery disease with high accuracy. Due to tortuosity, motion, and the small caliber of the coronary arteries (3–6 mm in diameter), as well as signals from adjacent epicardial fat and myocardium (Bunce et al., 2003), it is more technically challenging to image the coronary arteries than the great vessels and systemic vasculature. The diagnostic accuracy of coronary MRA depends on the scan technology used as well (Di Leo et al., 2016). For instance, scanning at 1.5 compared with 3 T yields lower sensitivity (1.5 vs. 3 T, 78%–88% vs. 82%–94%) and specificity (1.5 T vs. 3 T, 68%–91%; vs. 77%–89%) (Schuijf et al., 2006; Yang et al., 2009; Kato et al., 2010; Hamdan et al., 2011; Nagata et al., 2011; Di Leo et al., 2016). Also, 1.5 T CMR has been reported to have lower accuracy than cardiac computed tomography angiography when compared with quantitative invasive angiography as the reference standard (Schuijf et al., 2006), upon which 3 T CMR may improve (Hamdan et al., 2011). In an international multicenter study, coronary MRA had an accuracy of 87% and a negative predictive value of 100% for the diagnosis of left main or three-vessel disease, whereas the accuracy for the diagnosis of CAD in general, including single vessel disease, was only 72% (Kim et al., 2001). Accordingly, the negative predictive value of coronary CMR is valuable in patients with low to intermediate pretest probability to exclude significant CAD. Coronary MRA is also able to assess the anatomy and patency of coronary artery bypass grafts (Engelmann et al., 2000), though the advantage of CMR is evaluation of the proximal, rather than distal, vessels.

Other applications of coronary MRA are the identification of coronary anomalies, for example, suspected anomalous origins (**Fig. 1**) (McConnell et al., 1995) or coronary aneurysms (Mavrogeni et al., 2004).

CMR of the Thoracic Aorta

CMR is a versatile tool to image the aorta and aorta-related pathologies. It is used to assess anatomic abnormalities or to identify the location and extent of aortic disease as well as predisposing or resulting changes (Russo et al., 2006). This includes the identification

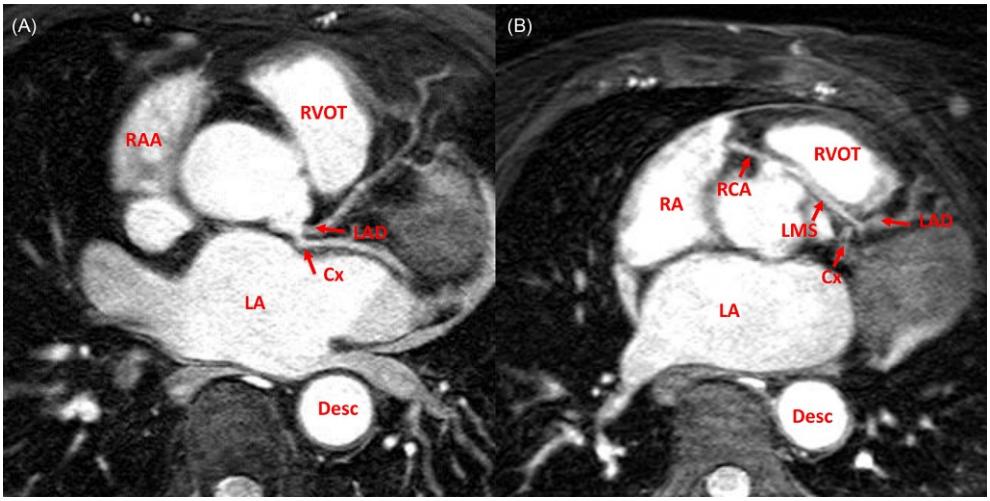

Fig. 1 Coronary MRA of a patient with anomalous origin of the coronary arteries. Submillimeter resolution free-breathing navigator gated/corrected T2 prep 3D turbo field echo coronary MR angiography of the aortic root and proximal coronary arteries were obtained in the transverse imaging planes. Shown are separate ostia of the left anterior and left circumflex coronary artery (A) and an anomalous origin of the left main stem arising anteriorly from the right coronary cusp with continuation between aorta and pulmonary artery in an interarterial course (B). In both the cases, the arteries have normal signal characteristics and caliber. *LMS*, left main stem; *LAD*, left anterior descending coronary artery; *RCA*, right coronary artery; *Cx*, circumflex coronary artery; *Desc*, descending aorta; *LA*, left atrium; *RA*, right atrium; *RAA*, right atrial appendage; *RVOT*, right ventricular outflow tract.

of aortic pathology such as aortic atherosclerotic plaque, aneurysm, ulcer, intramural hematoma, aortitis, or dissection (**Movie 1**) (Gebker et al., 2007). Due to three-dimensional imaging and the ability to reconstruct images in any plane, CMR can also be used to accurately measure the caliber of the aortic root, aortic arch, and supra-aortic branches. Similarly, CMR is able to delineate the location and degree of stenosis secondary to coarctation with accuracy similar to conventional angiography (**Fig. 2**). In a large cohort of children undergoing evaluation for congenital obstructive aortic abnormalities, such as coarctation or interruption, the diagnostic sensitivity and specificity of MR angiography in comparison with conventional angiography and/or surgery were 98% and 99%, respectively (Ming et al., 2006). However, CMR is superior to other imaging modalities with integration of anatomical and physiological assessment (e.g., trans-coarctation pressure gradient determination, collateral flow measurements) (Oshinski et al., 1996). Accordingly, CMR is able to distinguish pseudocoarctation (lack of hemodynamically significant narrowing, or collateral vessels) from true coarctation of the aorta.

CMR is a versatile tool to image the aorta and aorta-related pathologies. It is used to assess anatomic abnormalities or to identify the location and extent of aortic disease as well as predisposing or resulting changes (Russo et al., 2006). This includes the identification of aortic pathology such as aortic atherosclerotic plaque, aneurysm, ulcer, intramural hematoma, aortitis, or dissection (**Movie 1**) (Gebker et al., 2007). Due to three-dimensional imaging and the ability to reconstruct images in any plane, CMR can also be used to accurately measure the caliber of the aortic root, aortic arch, and supra-aortic branches. Similarly, CMR is able to delineate the location and degree of stenosis secondary to coarctation with accuracy similar to conventional angiography (**Fig. 2**). In a large cohort of children undergoing evaluation for congenital obstructive aortic abnormalities, such as coarctation or interruption, the diagnostic sensitivity and specificity of MR angiography in comparison with conventional angiography and/or surgery were 98% and 99%, respectively (Ming et al., 2006). However, CMR is superior to other imaging modalities with integration of anatomical and physiological assessment (e.g., trans-coarctation pressure gradient determination, collateral flow measurements) (Oshinski et al., 1996). Accordingly, CMR is able to distinguish pseudocoarctation (lack of hemodynamically significant narrowing, or collateral vessels) from true coarctation of the aorta.

The accuracy of CMR in the diagnosis of thoracic aortic dissection is at least equal to computed tomography and transesophageal echocardiography (Sommer et al., 1996). However, the greater scan time for CMR as compared with computed tomography and limited acute clinical care available in the scanner area limit the use of CMR in emergent or clinically unstable situations.

CMR is able to detect and evaluate aortic atherosclerosis including information about plaque characteristics such as regions with lipid components, calcification, or plaque thrombosis (Fayad et al., 2000). An example of a patient with significant complex aortic atheroma is shown in **Fig. 3**. However, CMR has other limitations in comparison with alternate imaging modalities: limited temporal resolution to detect small mobile aspects of atherosclerotic plaque, for example, plaque itself or associated thrombi; lower spatial resolution in comparison with computed tomography; and greater estimation of plaque thickness in comparison with transesophageal echocardiography (Saam et al., 2007) leading to possible overestimation of cardiovascular risk.

CMR imaging of the aorta is useful for serial evaluation of pathology and to assess progression or regression of the underlying disease process. It is particularly favorable in younger individuals and women, in whom avoidance of exposure to ionizing radiation

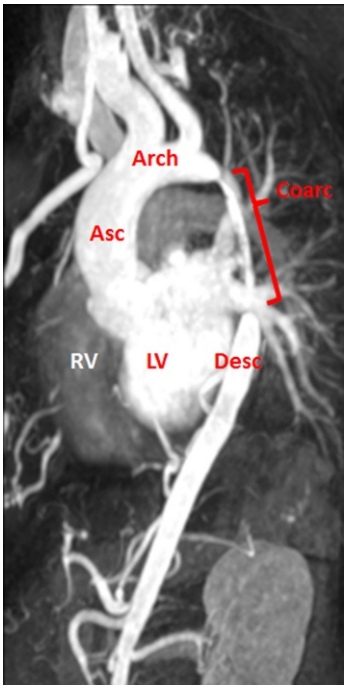

Fig. 2 MR angiography of a coarctation of the descending aorta after take-off of the left subclavian artery. First pass angiography of the aorta was obtained after administration of a bolus of gadopentetate dimeglumine 0.2 mmol/kg (40 mL Magnevist® solution). Shown is a three-dimensional reconstruction of the thoracic and abdominal vasculature. The diameter of the ascending aorta and arch was normal. The origin of the coarctation is very narrow and the coarctation extends for a total of 64 mm. *Asc*, ascending aorta; *arch*, aortic arch; *Desc*, descending aorta; *Coarc*, coarctation; *RV*, right ventricle; *LV*, left ventricle.

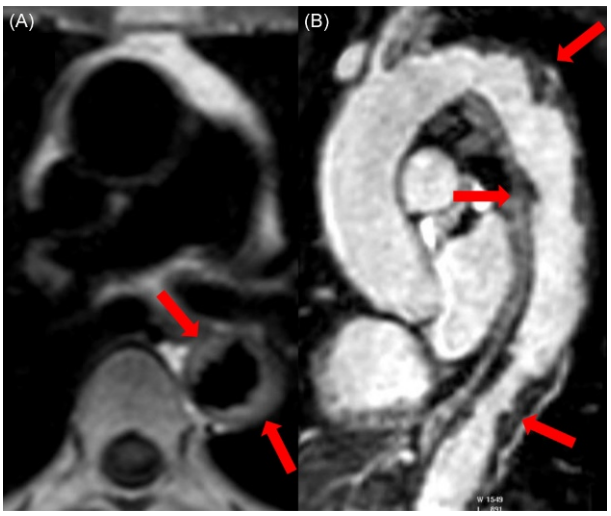

Fig. 3 Diffuse extensive atherosclerotic plaque within the thoracic aorta (*arrows*). Shown are a T1-weighted (*black blood*) dual-inversion T1-weighted fast spin echo images in axial orientation (A) and a 3D SSFP thoracic MRA reconstructed in a candy-cane orientation (B).

is preferred. CMR evaluation may also assist in pre- and postoperative assessment, for example, the identification of complications of surgery such as graft infections (Gaubert et al., 1995; Kawamoto et al., 1997). Additionally, CMR can provide functional data, including assessment of aortic wall stiffness and compliance, and quantification of forward and reverse aortic flow (Whitlock and Hundley, 2015). This information can be clinically relevant. For instance, in 2122 participants of the Dallas Heart Study, ascending aortic distensibility and aortic arch pulse wave velocity predicted nonfatal cardiac events and nonfatal extracardiac events, respectively (Maroules et al., 2014).

CMR Evaluation of the Pulmonary Vasculature

CMR angiography can be used to assess the pulmonary arteries and veins.

CMR is an effective method to image the anatomy of pulmonary veins. It is an accurate method to delineate congenital pulmonary venous abnormalities including an abnormal course (Fig. 4), to quantify pulmonary vein anatomy and size prior to electrophysiological studies and pulmonary vein isolation, and to visualize scar formation or pulmonary vein narrowing after ablation procedures (Fig. 5). A role for CMR in assessment of the pulmonary arteries and their pathologies is less established.

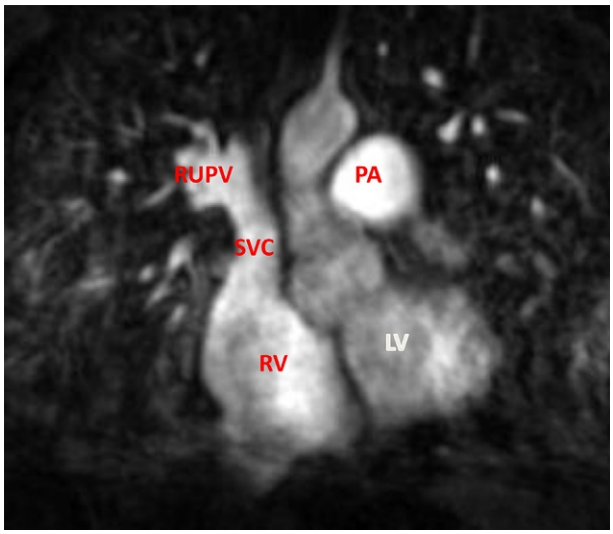

Fig. 4 MR angiography showing the right upper pulmonary vein draining into the superior vena cava. This image is acquired by first pass angiography of the pulmonary veins after administration of a bolus of gadopentetate dimeglumine 0.2 mmol/kg (33 mL Magnevist® solution). *RUPV*, right upper pulmonary vein; *SVC*, superior vena cava; *RV*, right ventricle; *LV*, left ventricle.

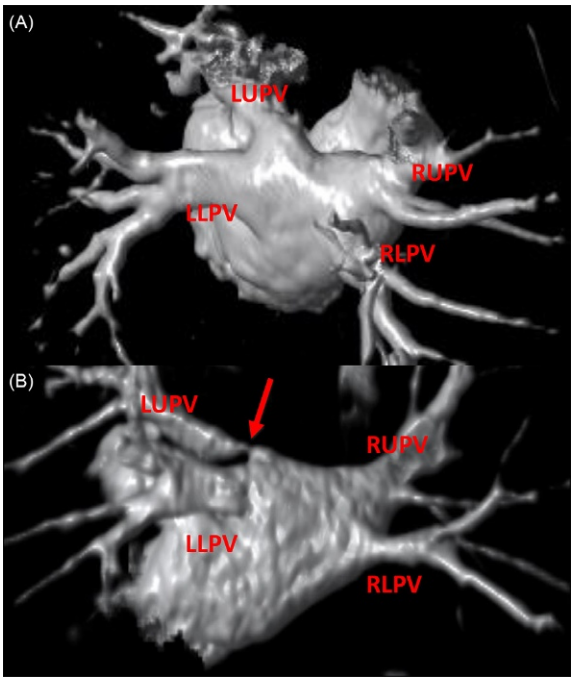

Fig. 5 Three-dimensional reconstruction of the pulmonary veins pre- (A) and post- (B) pulmonary vein ablation. The reconstruction is based on a first pass pulmonary vein angiography obtained after administration of a bolus of gadopentetate dimeglumine 0.2 mmol/kg (34 mL Magnevist® solution). Shown are a normal pulmonary vein anatomy with two left and two right pulmonary veins (A) and a focal stenosis (arrow) at the ostium of the left upper pulmonary vein after pulmonary vein ablation (B). *RUPV*, right upper pulmonary vein; *RLPV*, right lower pulmonary vein; *LUPV*, left upper pulmonary vein; *LLPV*, left lower pulmonary vein.

Imaging of Cardiac Anatomy

Congenital Heart Disease

Several features of CMR provide significant advantages in the evaluation of congenital heart disease in both the pediatric and adult populations: high spatial and temporal resolution, three-dimensional image acquisition, tissue characterization, blood flow quantification, and the lack of ionizing radiation. The latter in combination with the high reproducibility of CMR is very useful in a pediatric or a relative young population where repetition of scans pre- or postsurgical and/or during follow-up is crucial for clinical management. Supported by the listed features, CMR is used to accurately describe the anatomy of lesions (including the atria, ventricles, and great vessels) (**Movie 2**), their physiology (including conduit and great vessel blood flow) (**Movie 3**), and their effect on ventricular function. When validated against other gold standard techniques, anatomical assessment of congenital heart disease by CMR is more accurate than echocardiography (Fogel et al., 1994; Geva et al., 1994). Functionally, CMR can be used to quantify biventricular function (Markiewicz et al., 1987), to assess intracardiac shunts with pulmonary to systemic flow ratios (Beerbaum et al., 2001), and to measure regurgitation fractions after tetralogy of Fallot repair (van den Berg et al., 2007). Also, the identification of fibrosis and scar tissue by late gadolinium enhancement can guide electrophysiological procedures, pacemaker lead positioning, or risk stratification (Kilner et al., 2010; Fratz et al., 2013).

Pericardial Disease

CMR provides excellent visualization of the entire pericardium, allowing assessment of pericardial thickness, effusion, and abnormal structures, such as cysts (Sechtem et al., 1986). Also, CMR can detect abnormal cardiovascular pathophysiology to identify pericardial disease. Hepatic vein distension as well as flattening and paradoxical motion of the interventricular septum are signs of increased right heart pressures and seen in constrictive physiology. Real-time CMR of respirophasic changes in ventricular septal motion (Francone et al., 2005) and ventricular inflow (Thavendiranathan et al., 2012) can be used to assess ventricular coupling. These findings and pericardial contrast enhancement (Zurick et al., 2011) contribute to the differentiation of constrictive pericarditis from restrictive cardiomyopathy. CMR contrast enhancement of the pericardium (**Fig. 6**) by itself is, however, a relative nonspecific finding which may represent inflammation, infection, or tumor infiltration (Wang et al., 2003). Myocardial tagging, a technique applying a grid pattern to moving structures and allowing assessment of deformation, can be used to visualize the lack of systolic myocardial distortion adjacent to the pericardial cavity, a finding representing pericardial adhesion (Kojima et al., 1999). When present, the lack of myocardial movement adjacent to the pericardium, known as tethering, can be observed.

Valvular Function

CMR can be used to evaluate stenotic or regurgitant valve lesions. CMR sequences with high temporal resolution (20–40 ms) provide accurate visualization of the aortic cusp anatomy and measures of systolic valve opening area in aortic stenosis (**Movie 4**) (Kupfahl et al., 2004). However, as a consequence of longitudinal cardiac movement CMR likely overestimates the diastolic valve opening area of mitral stenosis (Djavidani et al., 2005). CMR provides the gold standard assessment of right and left ventricular volumes and systolic function, measured traditionally by ejection fraction (Bellenger et al., 2000). This allows accurate assessment of single-valve regurgitation by comparison of right and left ventricular stroke volumes (Didier et al., 2000). Quantitative calculation of degree of valve insufficiency, regurgitant volume and fraction, is facilitated by direct measurements of blood flow

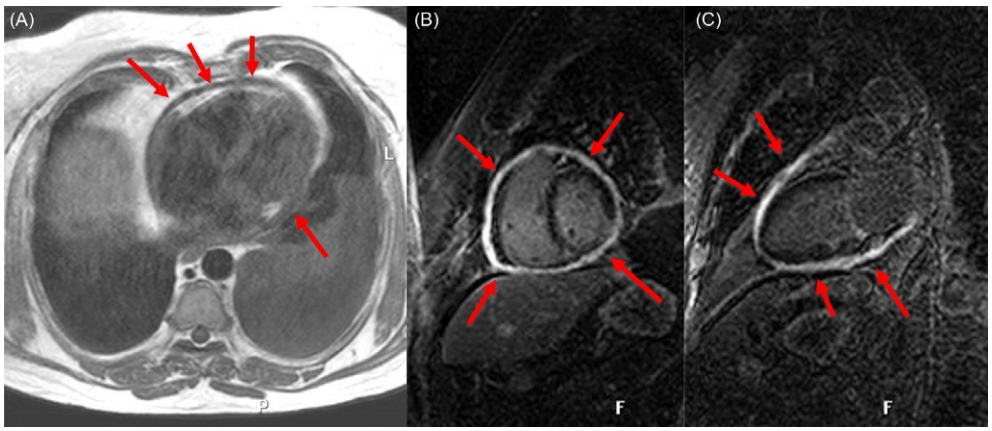

Fig. 6 CMR of pericardial thickening (*arrows*) without (A) and with late gadolinium enhancement (B and C). Shown are T1 weighted images of the pericardium (*black*) in a four-chamber orientation and late gadolinium enhancement images obtained with a segmented inversion-recovery TFE acquisition with a spectral fat saturation prepulse. The short-axis (B) and two-chamber long-axis (C) images were obtained 15 min after injection of a total of 0.1 mmol/kg gadopentate dimeglumine (10 mL Magnevist® solution).

(Didier et al., 2000; Dall'Armellina et al., 2007) or the combination of flow and stroke volumes (Hundley et al., 1995). CMR can also be used to quantify the regurgitant orifice area directly (Buchner et al., 2011). Compared with transthoracic echocardiography for evaluation of mitral regurgitation, CMR offers improved reproducibility (Cawley et al., 2013), improved prediction of left ventricular remodeling after surgery (Uretsky et al., 2015), and identification of myocardial fibrosis and scarring (Fernandez-Golfin et al., 2011). Due to accurate assessment of the proximal thoracic aorta, CMR has also advantages in assessment of aortic regurgitation if aortic root enlargement is suspected or established (e.g., Marfan syndrome, bicuspid aortic valve). In patients with severe aortic stenosis, mid-wall fibrosis also predicts worse improvement in left ventricular function after aortic valve replacement and is an independent predictor of long-term survival (Azevedo et al., 2010).

Cardiac Masses

CMR is an excellent method to characterize masses. Features such as size, location, mobility, impact on surrounding structures (e.g., infiltration or compression), and hemodynamic effects of cardiac and extracardiac adjacent masses are readily imaged. In addition to its superior accuracy when compared with echocardiography (Gulati et al., 2004), CMR has the advantage of tissue characterization. Quantification of water content allows the differentiation of edematous tissue or cystic structures from others (Dawson and Mohiaddin, 2011). The vascularity of a mass can be evaluated with first pass perfusion CMR (Fussen et al., 2011). Late gadolinium enhancement establishes the presence of extracellular matrix, its absence can be used to diagnose thrombus (Srichai et al., 2006; Pazos-Lopez et al., 2014), and in a small cohort study it had the accuracy of 79% for the differentiation between 17 benign and 25 malignant tumors (Pazos-Lopez et al., 2014). Also, the ability of specific CMR sequences to suppress the signal of fatty tissue enables the differentiation of lipomatous septal hypertrophy, lipomas, and liposarcomas from other cystic or solid cardiac tumors (Fussen et al., 2011). This technique was applied in **Fig. 7**, where the lack of suppression with a fat saturation prepulse excluded a lipoma/liposarcoma. Shown is a myxoma with low signal intensity with T1-weighted imaging and minimal enhancement after contrast administration suggesting low extracellular matrix content and low vascularity, respectively.

Evaluation of the Ventricular Myocardium

Heart Failure

Being the gold standard for volume assessment (Bellenger et al., 2000), CMR provides an accurate assessment of cardiac function (**Movie 5**) and morphology, such as left and right ventricular ejection fraction, left ventricular mass or wall thickness, in almost all patients. Regional wall motion abnormalities are well demarcated with cine SSFP sequences or with myocardial tagging (Castillo et al., 2006). For visualization of the advantages of CMR in anatomical and functional assessment of heart failure, **Movie 5** depicts the heart of a patient with dilated cardiomyopathy including severe left ventricular systolic impairment. Additionally, CMR can be used to identify tissue abnormalities indicative for specific pathologies (see "Ischemic Heart Disease" to "Nonischemic Cardiomyopathy" sections). For example, information about myocardial perfusion, viability, and fibrosis helps to identify an ischemic etiology in patients with new-onset heart failure (Valle-Munoz et al., 2009). Patterns of subendocardial or transmural in comparison with mid-wall fibrosis can also be used to differentiate between ischemic and nonischemic cardiomyopathies, respectively (McCrohon et al., 2003). The etiology of nonischemic cardiomyopathies can also be investigated with CMR: inflammation in acute myocarditis can be detected with T2-weighted pulse sequences (Skouri et al., 2006a), iron overload cardiomyopathy can be established with T2* relaxation times (Meloni et al., 2014), or late gadolinium enhancement following a noncoronary distribution is frequently seen in cardiac sarcoidosis (Greulich et al., 2016). Also, the quantity of late gadolinium-enhanced myocardium has a prognostic value in different nonischemic cardiomyopathies (Adabag et al., 2008; Green et al., 2012).

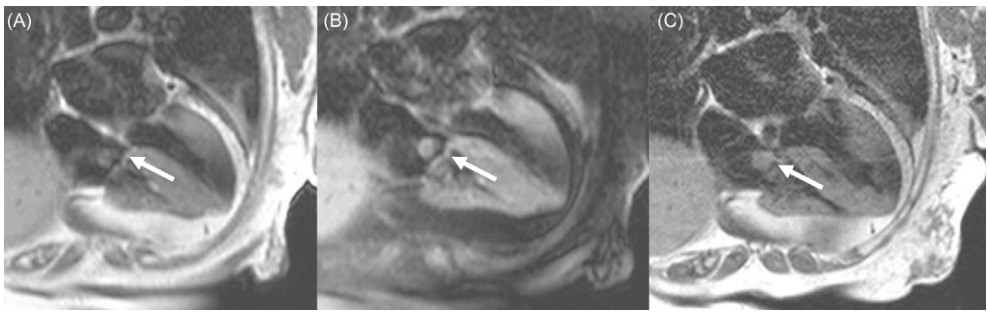

Fig. 7 CMR of a right atrial myxoma (*arrow*). Axial dual-inversion T1-weighted images of the myocardium were obtained in the four-chamber orientations with (A) and without (B) spectral fat saturation prepulses. C represents an image after the administration of gadopentate demeglumine 0.1 mmol/kg (8 mL Magnevist® solution). Shown is an 8 mm by 11 mm mass in the right atrium with low signal intensity with T1-weighted imaging (A), lack of suppress with fat saturation prepulse imaging (B), and minimal enhancement after the administration of contrast (C).

Ischemic Heart Disease

In addition to anatomic assessment of the coronary arteries (see "Imaging of Coronary Arteries" section), CMR is useful to detect the physiologic consequences of ischemia such as wall motion, perfusion, and metabolic abnormalities. Myocardial perfusion imaging and functional assessment with pharmacological stress are well-established for clinical practice, while CMR spectroscopy is a developing technique mostly limited to research. These will be explained in more detail in the following sections.

Myocardial perfusion imaging

CMR perfusion imaging visualizes the first passage of a gadolinium-based contrast agent through the myocardium. After contrast injection in the peripheral circulation, the appearance of contrast in the heart can be noticed as a rapid brightening of dark (nulled) myocardium during vasodilation stress. The signal intensity correlates with contrast concentration and the intensity mismatch between hypoperfused and normally perfused, brighter myocardium allows next to CMR reader dependent, qualitative also quantitative assessment. In a meta-analysis of 24 independent studies, the sensitivity and specificity of stress perfusion CMR for the detection of coronary artery disease were 0.91 and 0.81, respectively (Nandalur et al., 2007). When used to triage patients with suspected coronary artery disease in comparison with guideline-directed standard care, stress perfusion CMR significantly reduced the number of unnecessary invasive coronary angiographies (Greenwood et al., 2016). A negative perfusion CMR result in patients with established or suspected coronary artery disease has also a very good prognostic value (Jahnke et al., 2007).

Stress CMR: Evaluation of ischemia and viability

Stress imaging of ventricular function may be performed with CMR, similar to other stress imaging methods. As with pharmacologic stress echocardiography, dobutamine, in gradually increasing doses, may be administered to evaluate wall motion. Dobutamine infusion for CMR has a small risk (1:1000) of complications such as onset of sustained ventricular tachycardia (Wahl et al., 2004). In a meta-analysis of 14 independent studies, stress-functional CMR detected coronary artery disease with a sensitivity of 83% and a specificity of 86% (Nandalur et al., 2007). Another clinical question that can be answered with stress CMR is myocardial viability. In patients having LV wall motion abnormalities at rest, stress-functional CMR with low dosages of dobutamine allows to identify the contractile reserve, an improvement of wall motion under pharmacological influence. The presence of a contractile reserve indicates a recovery of systolic thickening after coronary arterial revascularization (Sayad et al., 1998; Trent et al., 2000). Stress-functional CMR, similar to perfusion imaging, has also prognostic value with a very low risk of cardiovascular death and myocardial infarction in patients with normal studies (Jahnke et al., 2007; Lipinski et al., 2013).

Magnetic resonance spectroscopy

A CMR technique with future promise in the diagnostic process of ischemic heart disease is magnetic resonance spectroscopy. Its strength is the assessment of myocardial metabolism without the application of contrast agents or radionuclides. For instance, phosphorus-31 nuclear magnetic resonance spectroscopy is able to measure directly high-energy phosphates in the myocardium and to identify metabolic evidence of ischemia (Bottomley et al., 1987; Weiss et al., 1990; Neubauer et al., 1992; Buchthal et al., 2000; Johnson et al., 2004). The technique measures the phosphocreatine to ATP ratio which is for instance reduced in myocardial infarction (Bottomley et al., 1987) or in the myocardium supplied by coronary arteries with flow limiting stenosis after isometric exercise (Weiss et al., 1990). Also, patients with dilated cardiomyopathy, where the ratio correlates with myocardial dysfunction (Neubauer et al., 1992), and women after isometric exercise with normal coronary arteries and chest pain syndrome (Buchthal et al., 2000) were shown to have abnormal values. In the latter, a decreased ratio predicted recurrent symptoms and hospitalizations (Johnson et al., 2004).

Myocardial Infarction

CMR in combination with gadolinium-based contrast agents can be used to image the extent and location of infarcted myocardium in patients with chronic or acute ischemic heart disease. The visualization of late gadolinium enhancement is based on the agent's ability to alter myocardial T1 values and to enter healthy myocardium from the blood pool within 1–3 min, the wash-in phase. Due to renal excretion, the myocardial concentrations decline 10–30 min after contrast administration, the washout phase. The large molecular size of gadolinium prevents the contrast agent from crossing cell membranes. Therefore, gadolinium effectively labels the extracellular space and, secondary to a delayed washout, accumulates for instance in regions of replacement fibrosis (Weber et al., 1995). These areas can be detected using T1-weighted sequences 15–20 min after contrast injection.

In myocardial infarction, late gadolinium enhancement is the gold standard technique to quantify infarct size. During different postinfarction stages, the area of delayed hyperenhancement mirrors closely the region of reduced perfusion, and overlaps with areas of necrotic or fibrotic histological changes (Fieno et al., 2000). The distribution of enhancement follows a subendocardial to transmural pattern and covers the effected vessel territory (**Fig. 8**). The presence of hypo-enhanced regions at the core of delayed hyperenhancement reflects on postinfarct microvascular obstruction (Judd et al., 1995) and predicts poor functional recovery of the infarcted territory (Rogers et al., 1999) as well as an increased risk of future cardiovascular events (Homback et al., 2005). Also, the transmural extent of late gadolinium enhancement relates to functional recovery of contractile function. In a study examining patients shortly after reperfusion, late gadolinium enhancement in no or less than 25% left ventricular wall thickness was a good predictor of global improvement (Choi et al., 2001). In patients without history of myocardial infarction but clinical suspicion for

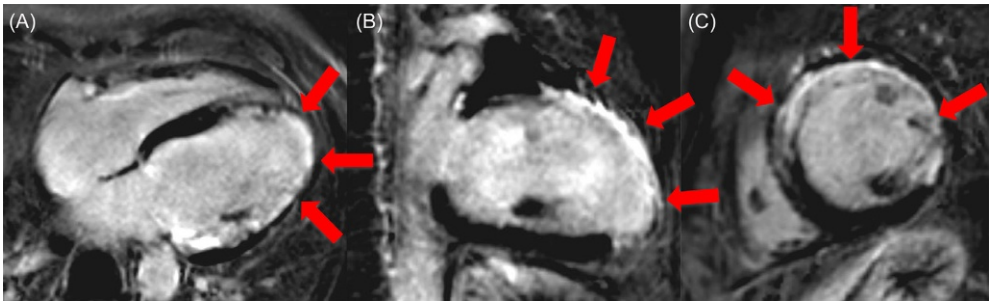

Fig. 8 Subendocardial to transmural late gadolinium enhancement (*arrows*) after a myocardial infarct in the mid segment of the left anterior descending artery. Late gadolinium images were acquired using a navigator-gated 3D phase sensitive inversion-recovery (PSIR) sequence with spectral fat saturation prepulse 15 min after injection of a total of 0.1 mmol/kg (18 mL) Gd-BOPTA (Multihance). Shown are transmural late gadolinium enhancement of the basal anterior and basal anterolateral wall segments in long-axis four-chamber (A), two-chamber (B), and short-axis orientation (C).

ischemic heart disease, the detection of a small area of late gadolinium enhancement carries a high risk for future cardiovascular events (Kwong et al., 2006). The prevalence of delayed enhancement with subendocardial distribution in a US-community based multiethnic cohort was 3.8% (Turkbey et al., 2015). If other distribution patterns were included, the number increased to 7.9% of which 78% were undetected by electrocardiography or clinical evaluation. In a small cohort of 70-year olds, undetected myocardial infarctions, defined as the presence of delayed hyperenhancement with subendocardial distribution and lack of prior diagnosis, doubled the risk of major adverse cardiac events (Barbier et al., 2016).

Nonischemic Cardiomyopathies

The term nonischemic cardiomyopathy covers a large variety of diseases which include genetic forms (arrhythmogenic right ventricular cardiomyopathy, hypertrophic cardiomyopathy, left ventricular noncompaction, and others), mixed forms (restricted, and dilated cardiomyopathy), and acquired forms (stress-induced cardiomyopathy, peripartum cardiomyopathy, myocarditis, and others). Diagnostic, therapeutic, and prognostic implications make the identification of a particular etiology important. CMR provides a noninvasive technique to distinct mentioned etiologies from each other through a combination of the following features: chamber size and structure assessment, left and right ventricular regional and global function quantification, perfusion imaging, and tissue characterization.

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy is characterized by inappropriate myocardial hypertrophy ($\geq$15 mm), possible dynamic systolic obstruction of the left ventricular outflow tract, loss of diastolic function, and development of intramyocardial fibrosis. Of these, CMR is able to accurately quantify myocardial mass and regional wall thickness, to visualize increased flow velocities in the left ventricular outflow tract as well as the related systolic anterior motion of the mitral valve, and to examine for fibrosis.

Late gadolinium enhancement, as illustrated in Fig. 9, is present in 65% of patients with hypertrophic cardiomyopathy (range 33%–84%). It is typically distributed in a patchy mid-wall pattern in areas of hypertrophy and at the anterior and posterior right ventricular insertion points (Rudolph et al., 2009). Delayed enhancement is unusual in areas without hypertrophy with the exception of advanced stages in which transmural late gadolinium enhancement in regions of wall thinning is common (Rudolph et al., 2009).

The prognostic value of late gadolinium enhancement in patients with hypertrophic cardiomyopathy has been investigated in several studies, which were limited by incomplete risk assessment, selection, and referral bias. In a meta-analysis of four studies covering 1063 patients, a relationship between late gadolinium enhancement and all-cause death, cardiovascular mortality, and heart failure death was seen, while only a trend toward an increased risk of sudden cardiac death was noted (Green et al., 2012). In a more recent study of 1293 patients, the presence of late gadolinium enhancement in $\geq$15% the left ventricular mass was however associated with a twofold increase in sudden cardiac death event risk (Sado et al., 2013).

CMR rarely differentiates the causes of cardiac hypertrophy by their magnetic properties alone. The pattern and quantity of interstitial expansion can however indicate a specific diagnosis. For instance, Anderson-Fabry disease frequently features a reduced noncontrast T1 signal (Chan et al., 2014) and late gadolinium enhancement in inferolateral wall segments (Deva et al., 2016). Cardiac amyloidosis, on the other hand, often presents with similar myocardial and blood T1 signals (Vogelsberg et al., 2008) and with circumferential, subendocardial to transmural late gadolinium enhancement (Fontana et al., 2015a).

Nonischemic dilated cardiomyopathy

The majority of patients with heart failure and cavity enlargement in the absence of coronary artery disease have no late gadolinium enhancement (McCrohon et al., 2003). In a small cohort study, 28% of patients with dilated cardiomyopathy had late gadolinium enhancement in the mid-wall (McCrohon et al., 2003), which corresponds to fibrotic tissue on histology of explanted

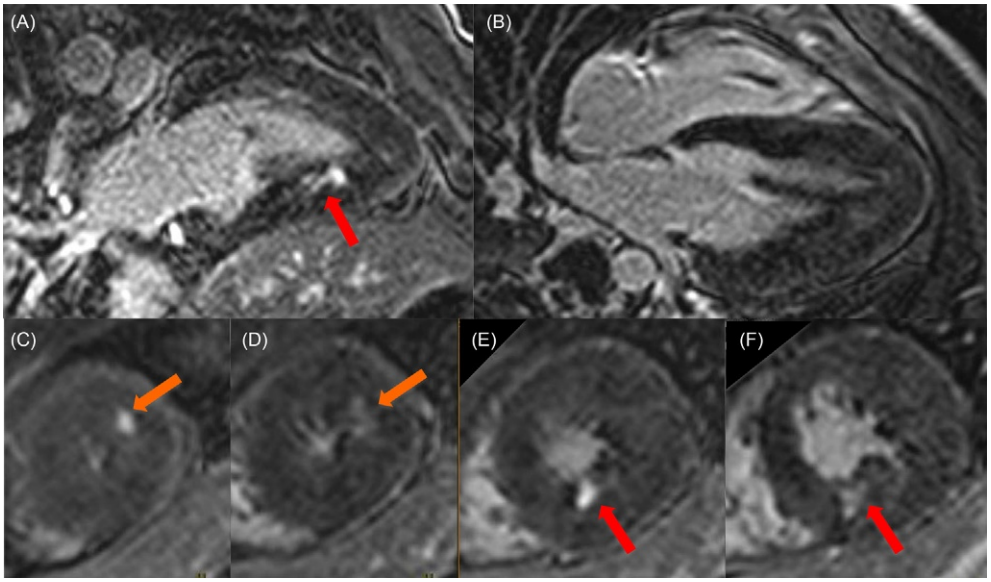

Fig. 9 Late gadolinium enhancement of the myocardium in a patient with hypertrophic cardiomyopathy. Using a segmented inversion-recovery TFE acquisition, images in long-axis two-chamber (A), four-chamber (B), and short-axis (apical C and E, mid E and F) orientation were obtained 15 min after injection of the total of 0.2 mmol/kg gadopentetate dimeglumin (24 mL Magnevist solution) with spectral fat prepulses. *Arrows* point toward areas of mid-wall late gadolinium enhancement in the inferior (*red*) and anterolateral wall (*orange*).

hearts (Gulati et al., 2013) and potentially represents the chronic healing phase of myocarditis. In a single-center observation study of 472 patients with dilated cardiomyopathy, detection of mid-wall fibrosis by CMR was associated with higher all-cause mortality and an increase risk for sudden cardiac death (Gulati et al., 2013). In patients undergoing cardiac resynchronization, the presence of fibrosis in dilated cardiomyopathy had a similar predictive value as its presence in ischemic cardiomyopathy patients (Leyva et al., 2012).

Myocarditis

CMR plays an important role in the diagnosis of myocarditis (Skouri et al., 2006b). Late gadolinium enhancement in the mid-wall and subepicardium, predominantly in the lateral wall of the left ventricle, is a typical finding in viral myocarditis (Mahrholdt et al., 2004). Also, early postcontrast T1-weighted enhancement of the myocardium (Friedrich et al., 1998) and T2-weighted imaging demonstrating myocardial edema are potential marker of inflammation in myocarditis (**Fig. 10**). In this context, the Lake Louise Consortium suggested in 2009 to base the diagnosis of myocarditis on the presence of at least two positive results from these three techniques (Friedrich et al., 2009). Nowadays other approaches might be more feasible, as the early enhancement ratio is difficult to reproduce and the more recently developing quantitative T2 mapping has several advantages over T2-weighted imaging alone. Also, quantitative T1 mapping has been shown to correlate with histologic inflammation in a rat model (Jeuthe and Wassilew, 2016) and, using the cut-off of 990 msec at 1.5 T, was able to distinguish patients with suspected myocarditis from controls with a sensitivity, specificity, and accuracy of 90%, 91%, and 91%, respectively (Ferreira et al., 2013). In another study, T1 and T2 mapping were also able to differentiate between patients with clinically suspected myocarditis and control subjects (Luetkens et al., 2016). The combination of these newer techniques with late gadolinium enhancement may be the best approach to a CMR diagnosis of myocarditis. For example, the diagnostic yield of the combination of native T1 and delayed enhancement was much better than the individual techniques in a small study comparing chronic myocarditis patients with control subjects (Hinojar et al., 2015).

Sarcoidosis

A large proportion (~50%) of patients with pulmonary have coexisting cardiac sarcoidosis, despite the lack of cardiac symptoms in the majority of cases. As myocardial involvement contributes largely to mortality, a proper diagnosis is clinically warranted. CMR's capacity for tissue characterization in addition to the accurate identification of typical features such as biventricular dilation and dysfunction is hereby helpful. The pattern of late gadolinium enhancement with cardiac sarcoid is variable. Classically, mid-wall or epicardial late gadolinium enhancement can be observed. Other distributions such as subendocardial or transmural enhancement in any location are however also possible (**Fig. 11**). In a study investigating 58 patients with biopsy-proven pulmonary sarcoid, one-third had evidence of late gadolinium enhancement, which occurred predominantly in the lateral and basal myocardium (Smedema et al., 2005). In another small cohort study of 81 patients with proven extracardiac sarcoidosis, patients with late gadolinium enhancement had a ninefold higher incidence of adverse events than those without (Patel et al., 2009). In both studies, CMR was able to identify more patients with cardiac sarcoidosis than standard assessment including a 12-lead ECG and at least one non-CMR cardiac imaging study (Standard Japanese Ministry of Health guidelines, Smedema et al., 2005).

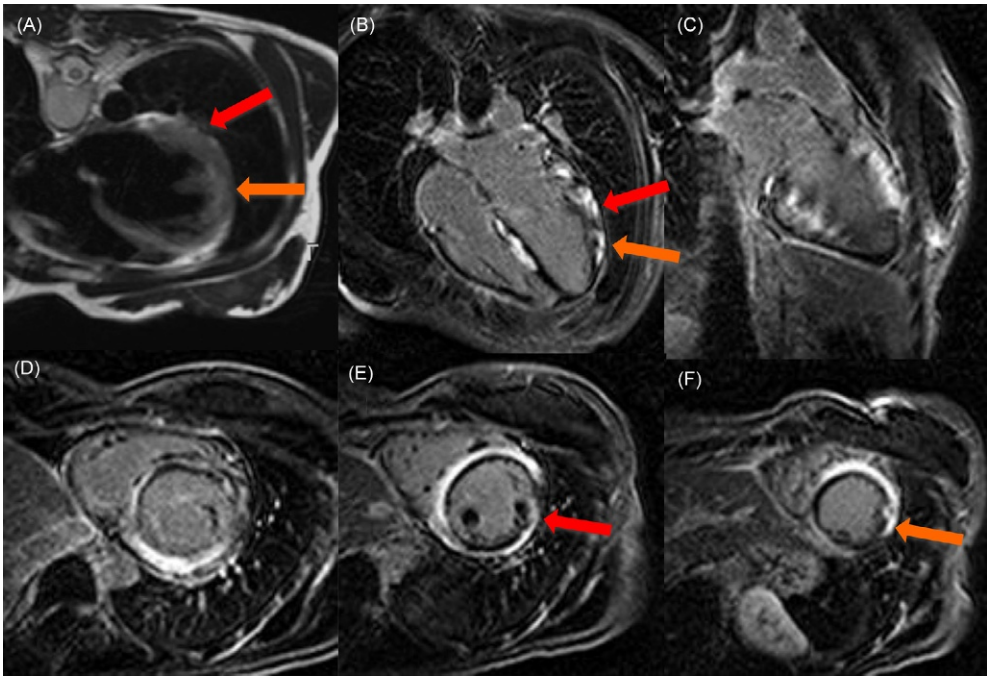

Fig. 10 CMR in a patient with acute myocarditis. Shown are a T2-weighted four-chamber long-axis image (A) and late gadolinium enhancement images obtained using a segmented inversion-recovery TFE acquisition (B–F). Short-axis (basal D, mid E, apical F), four-chamber (B), and two-chamber (C) long-axis images were obtained 15 min after injection of the total of 0.2 mmol/kg gadopentetate dimeglumin (24 mL Magnevist solution) with spectral fat prepulses. There is increased signal intensity of the left ventricular myocardium in comparison with the skeletal musculature on the T2-weighted image (A). There is late gadolinium enhancement with epicardial distribution of the basal and mid left ventricle and relative sparing of the apex (B–F). Color-coded arrows correspond to the basal lateral wall segment (*red*) and the mid lateral wall segment (*orange*). The overlap between increased intensity on T2 images (A) with late gadolinium enhancement images (B) suggests oedema/inflammation instead of fibrosis.

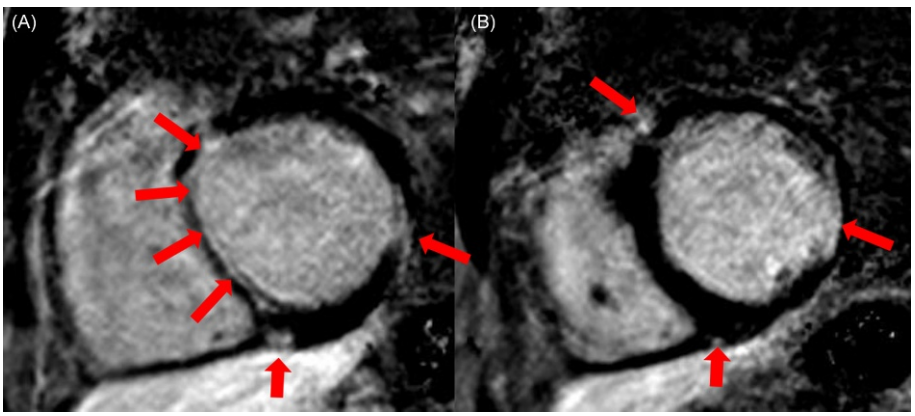

Fig. 11 Short-axis CMR at the basal-(A) and mid-(B) left ventricle in a patient with cardiac sarcoidosis. There is a moderate enlargement of the left ventricular cavity size and late gadolinium enhancement of the basal septum (endocardial), the basal to mid lateral wall (transmural), and the anterior and inferior right ventricular insertion points (*arrows*).

Arrthythmogenic right ventricular cardiomyopathy

CMR is the gold standard imaging technique for the diagnosis of arrthythmogenic right ventricular cardiomyopathy. The technique allows assessment of focal or global dilatation or dysfunction of the right ventricle (e.g., right ventricular bulging or aneurysms) and identification of fatty and/or fibrous replacement of the myocardium (**Fig. 12**). In up to 61% of cases these changes also involve the left ventricle (Santangeli et al., 2010; Marra et al., 2012). It is important to note that tissue characterization is not incorporated in current diagnostic criteria and that the diagnosis of arrthythmogenic right ventricular cardiomyopathy is based on a multimodality approach and not CMR alone (Marcus et al., 2010). Several reports showed that the detection of intramyocardial fat with CMR suffers from a high interobserver variability (Tandri et al., 2006; Macedo et al., 2007). Also, the detection of late gadolinium enhancement can be difficult due to disease-related right ventricular thinning and potential confusion with fat (Tandri et al., 2005).

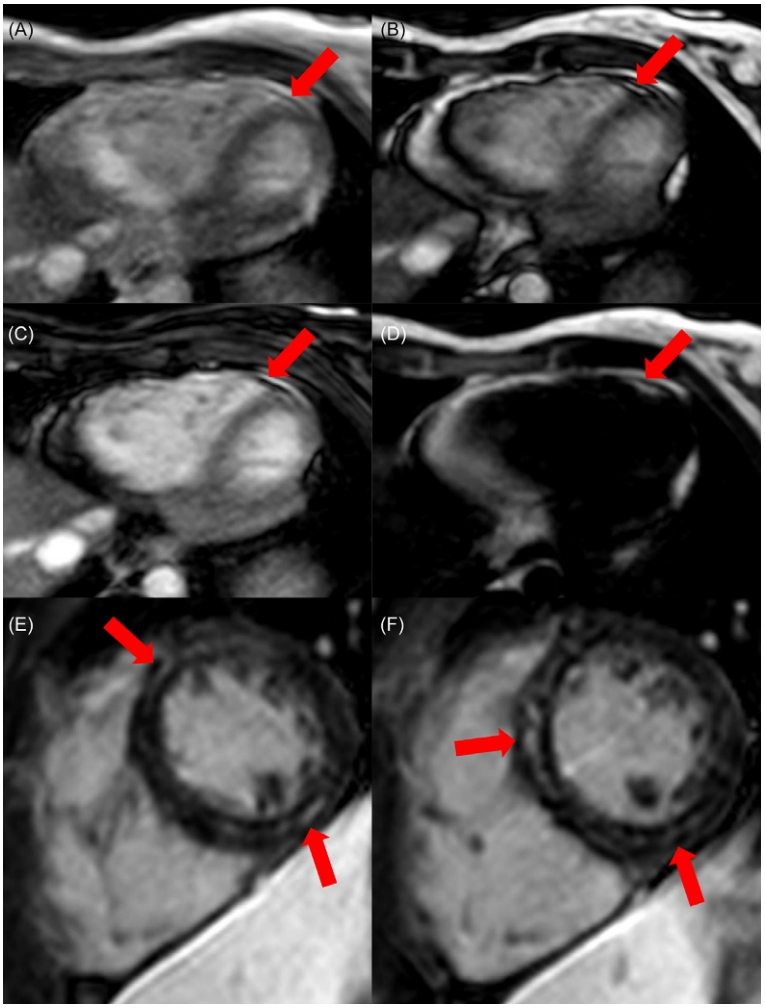

Fig. 12 CMR images of a patient with arrhythmogenic right ventricular cardiomyopathy. Shown are a Dixon-type pulse sequences (A, in-phase; B, out-of-phase; C, water only; D, fat only) in axial orientation and late gadolinium enhancement images acquired using a 3D phase sensitive inversion-recovery sequence with spectral fat saturation prepulses 15 min after contrast injection in short-axis orientation. There is fatty replacement of the distal right ventricular free wall (A–D, *arrows*) and late gadolinium enhancement in the septum, anterior, and inferior wall of the mid left ventricle (E–F, *arrows*).

Left ventricular noncompaction

Left ventricular noncompaction is a relative rare congenital abnormality that results from the failure of the myocardial development during embryogenesis. The diagnosis of noncompaction cardiomyopathy (**Movie 6**) with CMR is based on the end-diastolic ratio of noncompacted to compacted myocardium $\geq$2.3 on long-axis views (Peterson et al., 2005). Additional criteria, such as a ratio $\geq$3.0 on short-axis views (Stacey et al., 2013) or a noncompacted mass >20% of the global left ventricular mass (Jacquier et al., 2010), both at the end of diastole, have been suggested. In a study with 1480 asymptomatic participants free of cardiovascular disease, approximately 15% were positive for at least one of the mentioned CMR markers (Weir-McCall et al., 2016). These findings suggest that the established criteria are either quite unspecific for noncompaction cardiomyopathy or that a positive result might represent an anatomical phenotype instead of a distinct cardiomyopathy (Weir-McCall et al., 2016).

Amyloidosis

Amyloid deposition in the myocardium occurs frequently in patients with systemic amyloidosis. This leads to hypertrophy with reduced ventricular function. As mentioned (see 4.4.1), amyloid leads to abnormally T1 relaxations times (Vogelsberg et al., 2008), to an accelerate gadolinium clearance from the blood pool, and to a significant accumulation of gadolinium within the affected tissue (Am, 2005). CMR, with the characteristic pattern of global subendocardial late enhancement coupled with abnormal myocardial and blood-pool gadolinium kinetics, is therefore highly accurate to make the diagnosis (**Fig. 13**). The presence of subendocardial circumferential late gadolinium enhancement, for instance, provided a sensitivity of 80% and a specificity of 94% in 33 patients with cardiac amyloid on endomyocardial biopsy (Vogelsberg et al., 2008). In progressive disease stages, transmural late gadolinium enhancement can also occur and was shown to have a poor prognostic value in a study including 250 amyloidosis patients (Fontana et al., 2015b).

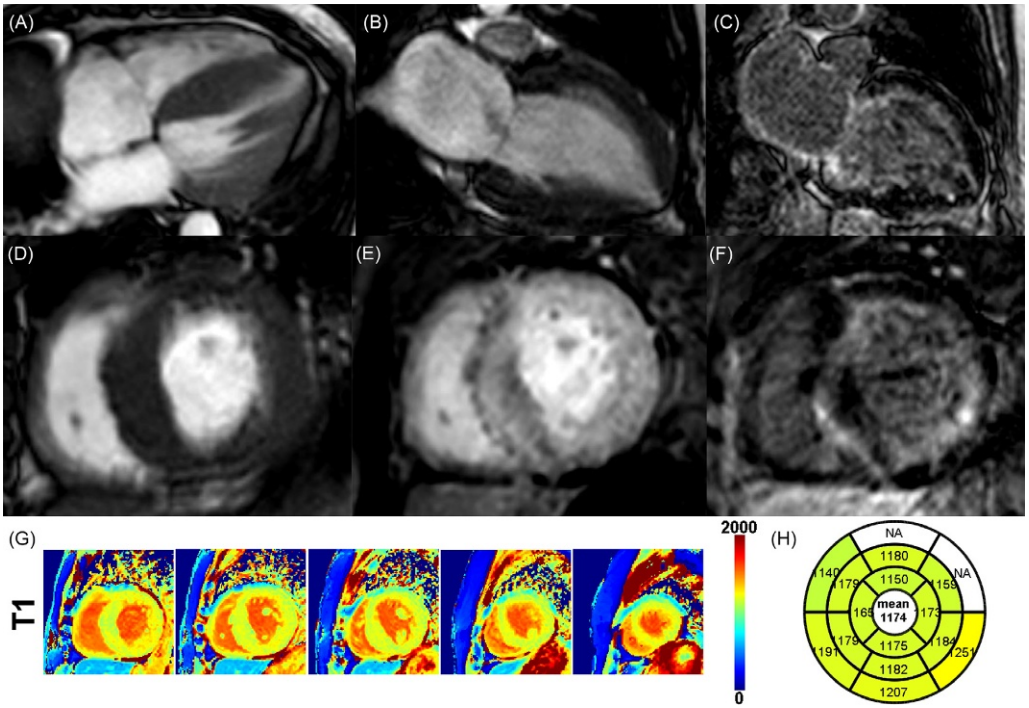

Fig. 13 CMR findings in a patient with cardiac amyloid. Depicted are the following pulse sequences: breath-hold bSSFP cine (A, B, D), early gadolinium enhancement with ultrafast 3D GRE inversion-recovery (E), late gadolinium enhancement with 2D/3D phase sensitivity inversion-recovery sequence (C, F), and free-breathing slice-interleaved T1 (STONE). The latter was used to generate T1 maps (G). Relevant findings were: asymmetric severe septal hypertrophy, atrial enlargement, diffuse circumferential early (E) and late gadolinium enhancement (C, F) with predominant subendocardial distribution, hypointense blood signal on late gadolinium enhancement images suggestive of abnormal blood-pool gadolinium (C, F), and an elevated mean T1 signal of $\geq$1157 ms as listed in the center of 16-segment model (H). *NA*, not applicable.

Conclusions

CMR is an advancing, noninvasive technique for comprehensive evaluation of the heart and great vessels. With sequences that can evaluate anatomy, function, and tissue characteristics at high spatial resolution and reproducibility, CMR has wide applications in the diagnosis and prognosis of patients with diverse cardiovascular pathologies and in research. With ongoing research designed to improve image quality, reduce acquisition time, develop noncontrast sequences to minimize risk, create novel methods for analyzing tissue characteristics and function, CMR will continue to remain a powerful modality for the clinician and medical researcher.

Introduction

Myocardial perfusion imaging (MPI) is an important clinical tool that allows the noninvasive assessment of myocardial blood supply. It is a useful tool for patient diagnosis and prognostication. Frequently ordered for perioperative cardiovascular evaluation and chest pain, it allows the detection of flow-limiting coronary artery disease (CAD) without the risks of diagnostic coronary angiography.

There are various methods of performing MPI. The most widely used is single-photon emission computed tomography (SPECT) MPI, described in detail later. Other methods, depending on institution preference and technology availability, include positron emission tomography (PET) MPI, cardiac MRI perfusion, myocardial contrast echo, and cardiac computed tomography (CT). Each of these methods will be discussed in detail in this article, outlining the sensitivity and specificity of each, the technology involved, and the radiation risk, all important considerations for the clinician when deciding which modality to choose.

SPECT MPI

The history of nuclear cardiology dates back to 1973 when the exercise stress-test myocardial scan was introduced (Zaret et al., 1973). Since that time, it has been increasingly used in clinical cardiology, to the current day where it is a widely available imaging modality used in the assessment of patients with suspected or known myocardial ischemia. Technical developments that have fueled this increase are single-photon emission computed tomographic (SPECT) imaging, pharmacological stress, and electrocardiogram (ECG)-gated imaging.

SPECT MPI is a nuclear medicine topographic imaging technique that uses gamma rays and involves flow-dependent and/or metabolism-dependent selective myocardial uptake of a radioactive tracer. Under conditions of stress, diseased myocardium receives less blood flow than normal myocardium. Poststress SPECT imaging reveals the distribution of the radiopharmaceutical and therefore the relative blood flow to the different myocardial regions. Comparing stress images with a set of images obtained at rest aids in diagnosis of reversible myocardial ischemia. A small amount of radioactive tracer (gamma-emitting radioisotope) injected intravenously is avidly taken up by normally functioning cardiomyocytes. Images acquired during dynamic exercise or pharmacologically induced stress and rest injections enable independent assessment of myocardial perfusion and viability.

To acquire SPECT images, the gamma camera rotates around the patient. Projections are acquired at defined points during the rotation, typically every 3–6 degrees. Typically, a full 360-degree rotation is used to obtain an optimal reconstruction. The time taken to obtain each projection is also variable, but 15–20 s is typical, giving a total scan time of 15–20 min. Multiheaded gamma cameras can provide accelerated acquisition. Conventional Anger cameras (Anger, 1953) typically have two large thallium-doped sodium iodide (NaI(Tl)) crystal detectors coupled to arrays of photomultiplier vacuum tubes, allowing two projections to be acquired simultaneously, with each head requiring 180 degrees of rotation.

Cardiac electrocardiogram (EKG)-gated acquisitions are possible with SPECT. Triggered by EKG to obtain differential information about the heart in various parts of the cardiac cycle, gated myocardial SPECT can obtain quantitative information about myocardial perfusion, thickness, and contractility and also allows the calculation of left ventricular ejection fraction (LVEF), stroke volume, and cardiac output. The D-SPECT camera was designed to increase sensitivity and spatial and energy resolution compared with A-SPECT.

Radiopharmaceuticals Commonly Used in Clinical Practice

Many choices exist for a myocardial perfusion agent. The ideal properties of a nuclear perfusion agent include the following:

1. A linear relationship between myocardial perfusion agent uptake and blood flow
2. High first-pass extraction over a wide range of blood flow rates
3. Low extracardiac radiotracer uptake
4. Minimal myocardial redistribution
5. Intrinsic chemical stability
6. Relatively straightforward radiochemical synthesis and purification

For SPECT, a family of technetium-99m-based radiotracers was developed in the 1990s including sestamibi, tetrofosmin, and teboroxime. Of these tracers, sestamibi and tetrofosmin are used widely in clinical practice and meet the majority of the earlier criteria (**Table 1**). 99mTc-teboroxime, despite its initial FDA approval, is not in widespread clinical use. Due to the high initial uptake and rapid washout, image acquisition must occur within 2 min of injection, which is technically challenging.

Thallium-201, first introduced in the early 1970s and having many favorable characteristics, has been extensively used as a perfusion radiotracer for this reason. It has a high first-pass extraction rate of 85%, and a better relationship is observed between blood flow and myocardial uptake at higher flow rates during stress testing (Krahwinkel et al., 1988). Often used as an agent to establish underlying myocardial viability in addition to ischemia, it has excellent myocardial first-pass extraction. However, its relatively low photon energy means that myocardial perfusion images with 201Tl are more prone to attenuation artifacts, especially seen affecting the inferior wall, as compared with 99mTc-labeled tracers, which have a higher-energy (140 keV) photopeak.

Table 1 Radiopharmaceuticals used in routine clinical practice

Radioisotope	*Chemical symbol*	*Chemical form*	*Emission energy (keV)*	*Half-life*	*Trade name*	*Diagnostic use*
Technetium-99M	99m Tc	Technetium 99m-pyrophosphate	140	6 h	Technescan PYP	SPECT
Technetium-99M	99m Tc	Technetium 99m-sestamibi	140	6 h	Cardiolite	SPECT
Technetium-99M	99m Tc	Technetium 99m-tetrofosmin	140	6 h	Myoview	SPECT
Thallium-201	201 Tl	Thallium-201 chloride	60–80	72.9 h	Amersham	SPECT
Rubidium-82	223 Ra	Rubidium-82 chloride		1.27 min	Cardiogen-82	PET
N13 ammonia	13 N	Nitrogen-13 ammonia		9.97 min		PET

Protocols for MPI

Imaging protocols are set out for each individual patient depending on certain factors such as the clinical question being asked, patient age and gender, ability to exercise, and body mass index. Small doses of radiotracer are injected at rest and peak stress, and subsequent images are acquired after the adequate circulation of radiotracer. As most Tc-based radiotracers are predominantly excreted through the gut, offering the patient food and plenty of liquids to assist with the passage of radiotracer through the gut is an important step prior to image acquisition. Failure to do so leads to attenuation artifact that can affect the perceived radiotracer uptake in the inferior wall and thus lead to erroneous results. Because the radiotracer is trapped at the time of injection, the images provide a view of myocardial perfusion at that precise moment, even in the case of delayed acquisition. If the patient is having ongoing chest pain at rest, a rest-only scan can provide important information, without stress, as to the underlying myocardial blood flow (MBF) at that precise moment.

Contemporary SPECT scanners are often combined with a CT scanner. The CT portion of the exam is used to guide patient positioning in the field of view and to correct inhomogeneities in radiotracer distribution from attenuation by soft tissue (known as attenuation correction (AC)). It can also be used for obtaining information regarding coronary calcium score +/− CT coronary angiography.

Detection of Ischemia and Viability

SPECT imaging performed post stress reveals the distribution of the radiopharmaceutical used and therefore the relative blood flow to different regions of the myocardium. Comparing stress images with a set of images obtained at rest aids in the diagnosis of myocardial ischemia by detecting reversibility (consider inserting example).

The presence of LV cavity dilation at rest or during exercise is noted upon the review of the rest and stress images. Dilation on both the stress and resting studies suggests LV dysfunction but may occur in volume overload states with normal ventricular function. Transient ischemic dilation (TID) is a marker for multivessel CAD. It is typically described qualitatively but may be quantified (Weiss et al., 1987).

The detection and localization of perfusion defects is typically performed by the use of visual analysis of the unprocessed images. Perfusion defects are assigned to a particular myocardial segment or segments according to the 17-segment model. Standardized nomenclature is used. Perfusion defect severity is typically expressed qualitatively with terms such as mild, moderate, or severe. Defect extent may be characterized qualitatively as small, medium, or large. A semiquantitative scoring approach standardizes the visual interpretation of scans, reduces the likelihood of overlooking significant defects, and provides an important semiquantitative index that is applicable to diagnostic and prognostic assessments. Furthermore, semiquantitative scoring can be used to reproducibly and objectively designate segments as normal or abnormal, as outlined later.

Category Score

- Normal perfusion 0
- Mild reduction in counts – not definitely abnormal 1
- Moderate reduction in counts – definitely abnormal 2
- Severe reduction in counts 3
- Absent uptake 4

Summed scores are calculated by adding all segment scores together to provide an integrated index of severity and extent of myocardial ischemia and infarction. This is done on the initial and resting or delayed images, and a summed difference score is then used to represent the amount of defect reversibility (Porenta et al., 1994), that is, the calculated difference between the score at stress and rest. Reversibility of perfusion defects is categorized qualitatively as minimal, partial, or complete. Reversibility can be defined quantitatively as defects in which pixels improve to fewer than 2.5 SDs from the normal reference distribution at that location. Through the use of SPECT imaging, it is now possible to view ventricular perfusion in any plane, to map the systolic function of the LV myocardium into single images, and to estimate chamber volumes (Garcia et al., 1981; Loong and Anagnostopoulos, 2004).

The use of polar maps allows a standardized 2-D representation of the 3-D myocardium for reproducible pixel-by-pixel comparisons of rest and stress studies. In addition, they allow follow-up of a patient over time or comparison between patients. Several different polar map generation algorithms are in widespread use. All have been clinically validated for regional perfusion, wall motion, and wall thickening (Kaul et al., 1987; Lin et al., 2006) (**Figs. 1** and **2**).

ECG Gating

ECG gating requires a stable and consistent heart rhythm in addition to sufficient temporal resolution to correctly characterize the cardiac cycle. A stable heart rate and rhythm are achieved by rejecting heartbeats that fall out of range at the expense of a longer

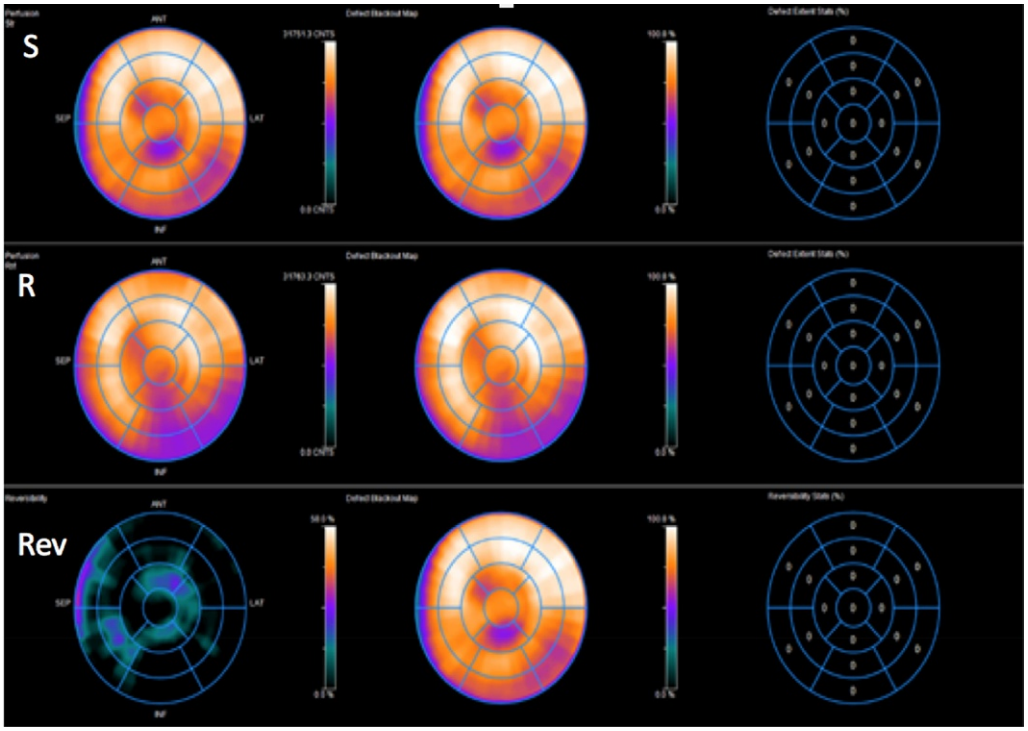

Fig. 1 Normal polar map showing normal perfusion with no defect identified. S, stress; R, rest; Rev, reversibility. The *left panel* represents perfusion, the *middle panel* represents a blackout map that would reveal the areas of perfusion defect present, and the *right panel* reveals a scoring chart laid out in a fashion similar to the 17-segment model, indicative of defect extent. The presence of zeros here indicated normal perfusion, that is, 0% abnormality.

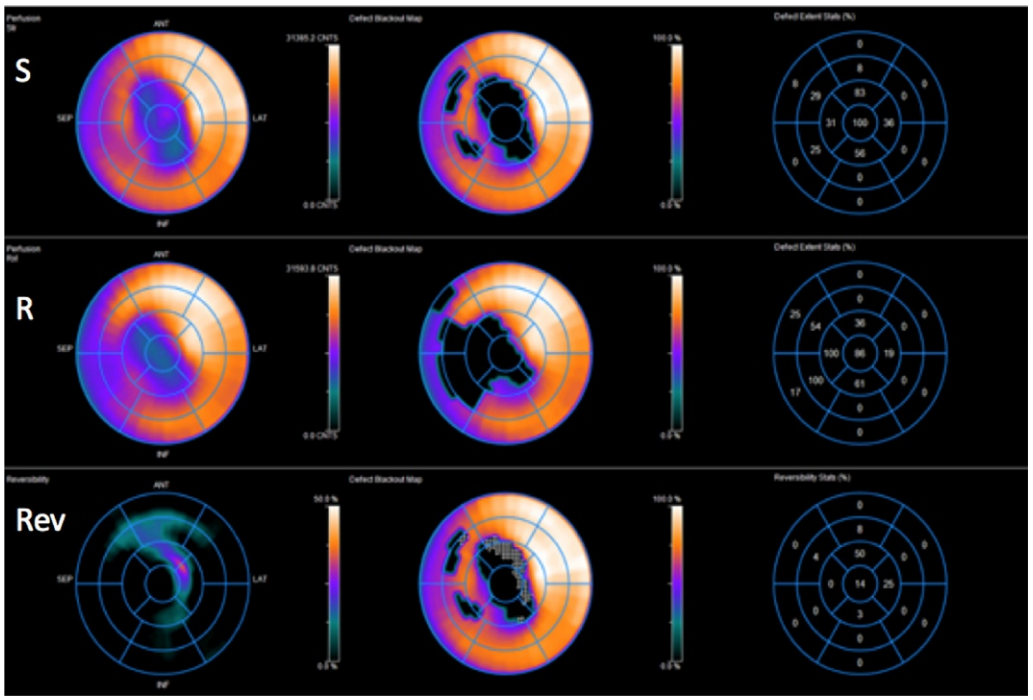

Fig. 2 Abnormal polar map with a medium to large area of scar in the region of the mid LAD, with partial reversibility: S, stress; R, rest; Rev, reversibility. In a similar fashion to the polar map earlier, the *left panel* represents perfusion, the *middle panel* represents a blackout map indicating the distribution of the perfusion defect, and the *right hand panel* indicates the defect extent (0%–100%) as set out by the 17-segment model.

image acquisition time. This "beat length acceptance window" can vary from 20% to 100% of the expected R-to-R duration. The recommended value is 20% if an "extra frame" is provided that allows the accumulation of rejected counts. Most stress laboratories gate the heart for eight frames per cycle. An increasing number of laboratories have reported good results with 16 frames per cycle and have used the increased temporal sampling to derive more accurate estimates of LVEF and parameters of diastolic function.

Sensitivity and Specificity of SPECT MPI

The value of SPECT in the diagnosis of CAD was highlighted in a meta-analysis (Loong and Anagnostopoulos, 2004), which demonstrated it to be a highly effective method of assessing myocardial perfusion with a sensitivity of 86%, a specificity of 74%, and a normalcy rate of 89%. The negative predictive value of the test is up to 98%, thus offering excellent prognostic value. A normal technetium-201 or technetium-99m scan is typically associated with a low risk of future cardiac events (less than 1% per year) (Hachamovitch et al., 1998). High-risk features on SPECT that have been shown to predict an increased risk of cardiac events include the following:

1. Extensive ischemia involving more than 20% of the left ventricle
2. Defects in more than one coronary vascular supply region
3. Reverse ischemia in multiple segments
4. Transient or persistent left ventricular cavity dilatation
5. Left ventricular ejection fraction <45% (Hachamovitch et al., 1998)
6. Increased lung uptake of thallium or sestamibi (Gill et al., 1987)

These factors predict an annual mortality rate of >3%. Normal, mildly abnormal, moderately abnormal, or severely abnormal perfusion defects have been reported to carry an annual rate of cardiac death of 0.5%, 2.7%, 2.9%, and 4.2%, respectively (Hachamovitch et al., 1998).

Case Examples

Case 1: Use of MPI to guide management in patient presenting with resting abnormal EKG. A 60-year-old female with hypertension, family history of CAD, and atypical chest pain presented with nonspecific T-wave changes on her EKG. Exercise SPECT was carried out. She achieved a moderately high workload on a Bruce treadmill protocol, and the following images were obtained (**Fig. 3**).

Case 2: Preoperative risk stratification in a patient with cardiac risk factors (high CHD risk) undergoing surgery. A 68-year-old male with a past history of coronary artery bypass graft surgery and severe peripheral vascular disease presented with an acutely ischemic limb. A preoperative risk stratification evaluation was sought. Given some recent symptoms of dyspnea on exertion and the inability to exercise, a pharmacological SPECT MPI was performed (**Fig. 4**).

The gated images revealed akinesis of the basal and mid inferolateral segment and hypokinesis of the basal anteroseptum. These findings were overall consistent with a prior transmural infarction in the distribution of the left circumflex coronary artery and a small area of ischemia in the distribution of the LAD/LIMA graft.

The patient was managed medically and proceeded with vascular surgery without cardiac adverse effects.

Case 3: SPECT MPI and cardiac catheterization correlation. A 69-year-old patient with a history of paroxysmal atrial fibrillation, hypertension, type 2 diabetes, and obesity presented to the office complaining of worsening dyspnea. A SPECT MPI was scheduled for further evaluation (**Figs. 5** and **6**).

Overall, the consensus from these images was that the inferior/inferolateral reversible perfusion defect seen on the SPECT was a result of the most severe coronary lesion in the setting of three-vessel disease in a diabetic with diffuse coronary disease. The high-risk findings from the SPECT included increased RV tracer uptake and TID. The patient underwent coronary artery bypass grafting (CABG) and did well post-op.

Myocardial Perfusion PET Imaging

Fundamentals

PET is a nuclear medicine technique that utilizes positron-emitting radionuclides to generate images of myocardial perfusion and metabolism. Through the use of positron-emitting radionuclides, unique quantitative information of important biological processes, such as myocardial perfusion, glucose metabolism, and fatty acid metabolism, can be obtained in vivo (Le Meunier et al., 2006). The fundamental principle is that positron-emitting radionuclides (e.g., carbon-11, nitrogen-13, oxygen-15, and fluorine-18) decay by emitting "positively" charged electrons called positrons. Once released from the nucleus, positrons travel short distances in tissue and annihilate when they encounter nearby electrons. Annihilation releases energy in the form of two gamma rays or photons that are emitted in opposite directions, typically 180 degree from each other. The opposite high-energy photons (511 keV) are captured externally by an array of detector elements (scintillators) located in the PET gantry. The PET system is designed to facilitate the detection of 511 keV photons arriving at opposite detectors within a specific narrow temporal window and

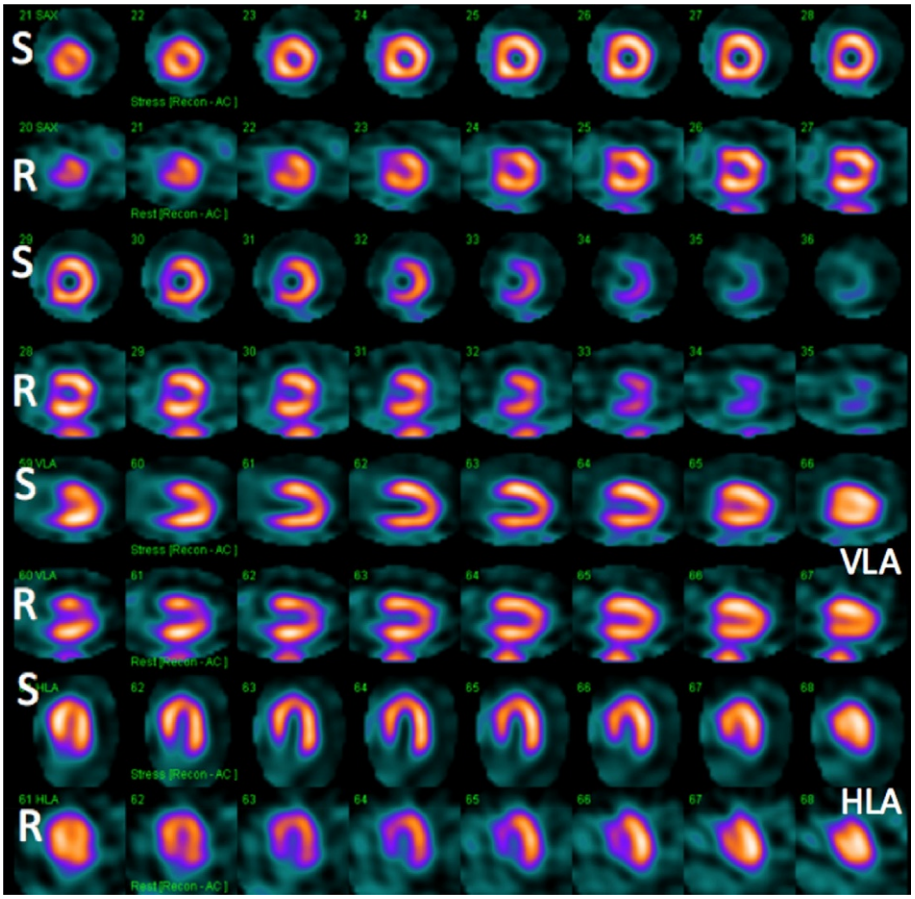

Fig. 3 Short-axis (top four rows, apex to base from left), vertical long-axis (VLA), and horizontal long-axis (HLA) images depict homogeneous radiotracer uptake at stress (S) and rest (R) with no significant perfusion defect identified. Gated images revealed normal LV volumes and ejection fraction (EF).

reject scattered photons arriving outside the preset temporal window, thus enhancing the spatial and contrast resolution of the images obtained.

The technical advantages that account for the improved image quality and diagnostic ability of PET compared with SPECT include the following:

(a) Routine measured AC, which decreases the number of false positives and thus increases specificity.
(b) High spatial and contrast resolution allowing for improved detection of small perfusion defects.
(c) High temporal resolution allowing fast dynamic imaging of tracer kinetics. This makes the absolute quantification of myocardial perfusion (in milliliters per minute per gram of tissue) possible.
(d) The use of short-lived radiopharmaceuticals allowing fast, sequential assessment of regional myocardial perfusion (e.g., rest mand stress), thus improving laboratory efficiency and patient throughput.

Despite the earlier factors, SPECT scanners and imaging radiotracers (e.g., 99mTc agents and 201Tl) remain more widely available and less expensive than PET scanners and positron-emitting radiotracers (e.g., 82Rb and 13N-ammonia).

Patient Preparation

Similar to that for stress and rest myocardial SPECT imaging, it includes an overnight fast of 6 h or more. Patients should avoid caffeinated beverages for at least 12 h, and avoid theophylline-containing medications for at least 48 h.

Radiation Dose

Because of the use of short-lived radiopharmaceuticals, radiation doses to patients are lower with PET than SPECT (Knuuti, 2009). Also, PET imaging offers true-stress (rather than poststress) functional measurements and allows time-efficient (<30 min) stress–rest protocols (Di Carli et al., 2007) (**Table 2**).

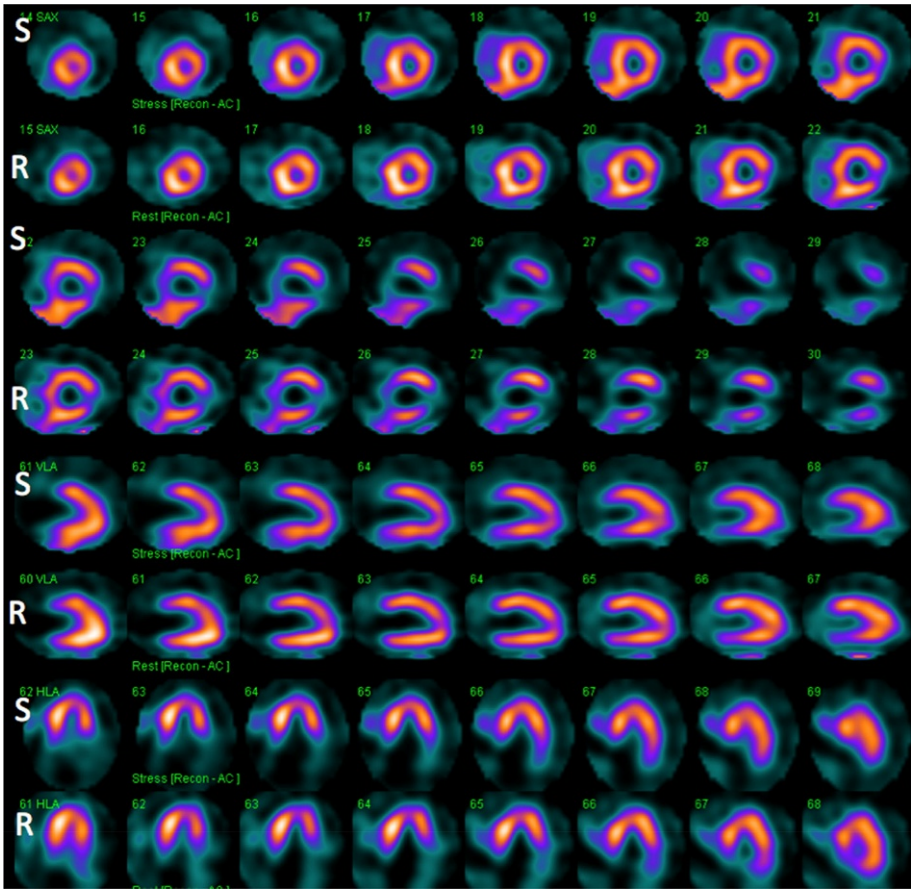

Fig. 4 This reveals the stress (S) and rest (R) perfusion images in short-axis (top four rows), VLA, and HLA projections. These reveal a large perfusion defect of severe intensity that is predominantly fixed affecting the basal and mid inferolateral segment. In addition, there is a small defect of moderately severe intensity with reversibility affecting the basal anteroseptum. The gated images revealed akinesis of the basal and mid inferolateral segment and hypokinesis of the basal anteroseptum. These findings were overall consistent with a prior transmural infarction in the distribution of the left circumflex coronary artery and a small area of ischemia in the distribution of the LAD/LIMA graft.

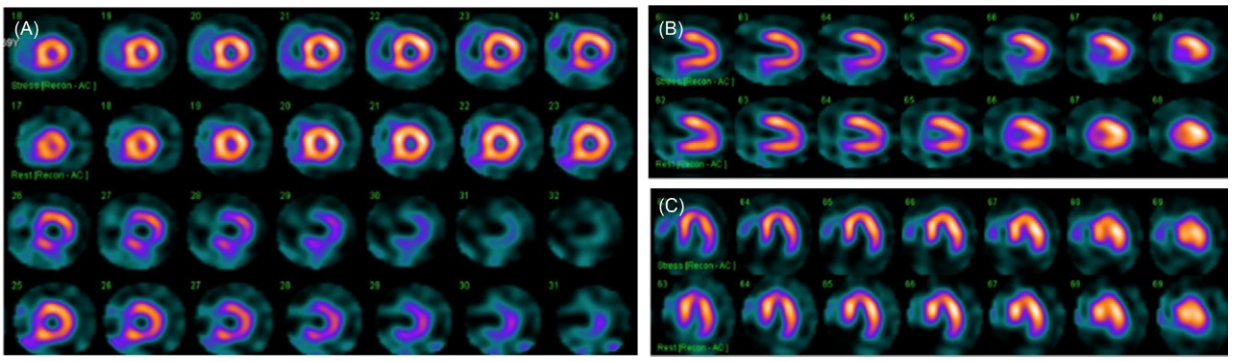

Fig. 5 (A) Short-axis slices, stress on top row, apex (*left*) through base (lower rows). (B) Vertical long-axis, anterior and inferior walls, stress on top row. (C) Horizontal long-axis, stress on top row, septal and lateral walls. These images demonstrate prominent RV radiotracer uptake at stress in addition to a medium in size, mild–moderate in intensity reversible perfusion defect involving the entire inferior and inferolateral walls, consistent with ischemia in the circumflex/PDA territory. The percentage of abnormal myocardium was 10%.

Comparative Studies of PET MPI Versus SPECT

The superior diagnostic accuracy and risk stratification of obstructive coronary disease of PET when compared with SPECT perfusion imaging has been demonstrated in several publications including a systematic review by Mc Ardle et al. (2012), which demonstrated that the sensitivity and specificity utilizing Rb-82 was 90% and 88%, respectively, higher than for comparable SPECT

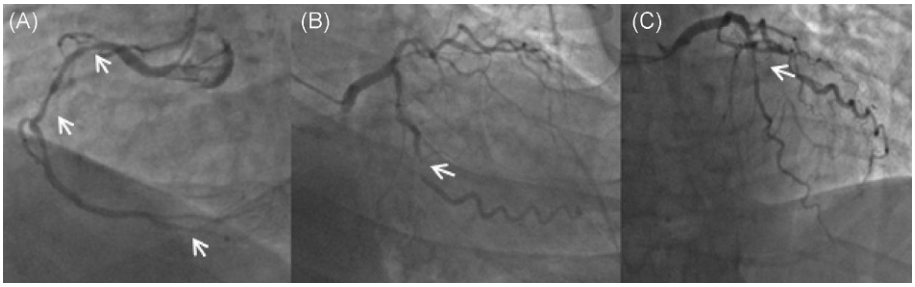

Fig. 6 (A–C) Still images of cardiac catheterization reveal significant disease involving the RCA (A), left circumflex (B), and LAD (C), *arrows*. Moderate-to-severe diffuse disease is seen in the RCA with a proximal 70%–80% stenosis. In the circumflex (panel B), the *arrow* indicated a severe stenosis in the midcircumflex. In the LAD (panel C), there is a proximal 80% stenosis (*arrow*).

Table 2 Common PET radiotracers in clinical use

Radiotracer	*Physical half-life (min)*	*Availability*	*Application*	*Advantages*	*Disadvantages*
Rubidium-82 (82Rb)	1.27	Strontium 82 generator	MPI	Simplicity of use	Relatively poor resolution
Nitrogen13 ammonia	9.97	Cyclotron	MPI	High extraction simplifies quantitation	Requires cyclotron Heterogeneous uptake
18F-FDG	110	Cyclotron	Myocardial viability imaging	Simplicity of radiotracer use	Oral glucose load can pose a problem for diabetic patients, requiring insulin use

data. Similarly, Parker et al. reported how PET MPI demonstrated a higher sensitivity for CAD than SPECT MPI (Parker et al., 2012). Myocardial PET also plays an important role in risk stratification. Dorbala et al. recently described how the extent and severity of ischemia and scar on PET MPI can provide powerful and incremental risk estimates of cardiac death and all-cause death compared with traditional coronary risk factors (Dorbala et al., 2013).

PET also has the capability to accurately evaluate regional and global MBF in addition to blood flow reserve. MBF (in milliliters per minute per gram of myocardium) is quantified during both rest and stress perfusion, and the ratio between peak stress and rest blood myocardial flow, the so-called coronary flow reserve (CFR), offers an enhanced ability to delineate the extent and severity of CAD to the level of coronary circulation (Schelbert, 2012). The ability to quantify MBF has been shown to have an incremental prognostic value for predicting adverse cardiac events (Ziadi et al., 2011; Taqueti et al., 2015).

Attenuation Correction

Positron-emitting tracers are more sensitive to attenuation artifacts than single photons. Coincidence detection systems must detect both simultaneously emitted photons. As each of the two photons is susceptible to tissue attenuation, attenuation artifacts are generally greater. Therefore, only attenuation-corrected images should be used for clinical interpretation (Dilsizian et al., 2016). Potential sources of errors include misalignment between emission and transmission data resulting from patient motion. Misalignments of 1.5–2 cm, for example, can lead to as much as a 30% change in the observed regional myocardial radioactivity (Le Meunier et al., 2006; Gould et al., 2007; Loghin et al., 2004).

Myocardial Viability Assessment Using PET

Stunned myocardium is viable myocardium that has been reperfused but exhibits prolonged postischemic dysfunction following reperfusion. On the other hand, hibernating myocardium is ischemic myocardium supplied by a narrowed coronary artery in which ischemic cells remain viable but contraction is chronically depressed. Stunned myocardium usually returns to normal after a prolonged period of time (hours to weeks). Hibernating myocardium returns to normal function quickly if the cause is removed. Cardiac PET is useful for the evaluation of patients with known CAD, in whom the amount of viable myocardium is unclear. In clinical practice, 18F-FDG is the radiotracer used to assess myocardial viability. Accompanying rest perfusion images may be obtained using either ammonia or Rb PET.

Myocardial viability assessment using PET consists of injecting radiotracer in order to acquire resting images and comparing these with a set of stress images as well as often using FDG in order to assess myocardial cell viability.

FDG imaging is performed following a 6–12 h fast followed by a glucose load. Under glucose-loaded conditions, FDG uptake by normal myocardium is maximized. A common approach includes using 25–100 g of oral glucose followed by supplemental IV

insulin as needed. Use of IV insulin promotes maximum uptake of FDG by the normal myocardium and optimal image quality. Once the patient has been injected with FDG, monitoring of the patient's glucose levels is continued until a stable glucose level is reached and the patient is asymptomatic.

Procedure

Rest images are acquired first (SPECT or PET) so that the areas of hypoperfusion are identified. LV volume assessment can be carried out by assessing LV size and function. A severely dilated left ventricle is unlikely to recover global function even if FDG uptake is present in segments with contractile dysfunction. Unless contraindications for stress testing exist, stress MPI is then performed to identify the presence and amount of reversible perfusion defects. This is because patients with moderate-to-severe (>10%) reversible perfusion defects will likely benefit from revascularization. Where possible, the rest/stress perfusion images should be interpreted prior to the commencement of the FDG study because if there is a moderate-to-large reversible perfusion defect or normal rest perfusion, then there may be no need to proceed with FDG PET imaging.

Four distinct resting perfusion–metabolism patterns may be observed in dysfunctional myocardium (Dilsizian et al., 2016; Marshall et al., 1983; Tillisch et al., 1986; vom Dahl et al., 1996; Beanlands et al., 1998; Gerber et al., 2001):

1. Normal blood flow associated with normal FDG uptake
2. Reduced blood flow associated with preserved or enhanced FDG uptake (perfusion–metabolism mismatch)
3. Normal or near-normal blood flow with reduced FDG uptake (reversed perfusion–metabolism mismatch)
4. Proportionally reduced blood flow and FDG uptake (perfusion–metabolism match)

The patterns 1–3 are all indicative of viable myocardium, whereas pattern 4 represents nonviable tissue.

PET MPI Protocols

Typically, clinical imaging protocols are sequential with stress following rest MPI, with time in between the tests for myocardial radiotracer activity to be decayed or diminish by biological pathways. Unlike SPECT, PET images are always corrected for attenuation. Conventional dedicated PET scanners typically use radionuclide transmission imaging in contrast to hybrid scanners that use CT transmission imaging for the measurement and correction of soft-tissue attenuation (Al-Mallah et al., 2010). The most commonly used CT protocol is a nongated low-dose CT in shallow tidal breathing. AC is important because inaccurate registration of transmission and emission images from respiratory or patient motion can lead to artifactual defects in up to 40% of cases (Kennedy et al., 2009; Lang et al., 2006; Lautamaki et al., 2008). Most commercial PET/CT systems now include software tools that correct for transmission–emission misalignments from respiratory motion or patient movement between the transmission and emission images (Al-Mallah et al., 2010). However, patient motion during either the transmission or the emission imaging will limit image quality and cannot be easily corrected using software (Naum et al., 2005).

Stress Protocols

Exercise stress with treadmill or bicycle and pharmacological stress with adenosine, dipyridamole, or dobutamine have all been used since the 1970s. In practice, due to the short half-life of most of the PET radiotracers, pharmacological stress is preferred. Adenosine produces maximal hyperemia and is short-lived, but it necessitates two intravenous lines for use with 82Rb and is hence somewhat cumbersome to use. More recently, regadenoson, an adenosine A2A receptor agonist, has been approved for SPECT MPI (Al Jaroudi and Iskandrian, 2009). Advantages of use include bolus administration with standardized dosing regardless of body weight and better tolerability. Regadenoson as the pharmacological stress agent, when used in conjunction with 82Rb PET, allows ultrashort imaging protocols with complete stress and rest MPI completed in approximately 17 min. It is also possible to use dobutamine as a stress agent, in patients with contraindications to the earlier agents. This agent requires more than one IV access site, careful timing is necessary especially when used in conjunction with ammonia as timing of dose arrival from the cyclotron, and peak stress needs to be coordinated carefully.

Quantification of Left Ventricular Function

ECG-gated PET imaging has the capability to assess LV function, both at rest and during stress. The addition of stress LVEF measurement to clinical and perfusion information has significantly enhanced the value of the 82Rb MPI to predict all-cause mortality (Lertsburapa et al., 2008). A large body of evidence supports the prognostic value of PET MPI-derived EF in intermediate- to high-risk subjects, in female patients, in obese individuals, and in post CABG individuals (Dorbala et al., 2007). A normal perfusion study indicates low risk (<1% annualized rate of cardiac events), while an abnormal study indicates high risk (Dorbala et al., 2007). Dorbala et al. (2007) demonstrated that LVEF at rest increases during peak vasodilator stress in patients with normal MPI. Patients with severe ischemia however and those with three-vessel/left main disease demonstrate a significantly lower LVEF during peak vasodilator stress and a lower LVEF reserve. They found that an LVEF reserve <+5% is a highly sensitive marker of left main/three-vessel CAD (sensitivity of 94% and a negative predictive value (NPV) of 97%) (Dorbala et al., 2007). Rest and peak stress LVEF is therefore routinely incorporated into the clinical practice of PET MPI.

MBF and CFR Assessment

Measurement of MBF (in milliliters per minute per gram of myocardium) is validated for most PET perfusion tracers (Camici and Rimoldi, 2009). In recent years, accurate AC and simultaneous tomographic acquisition of counts in list mode (with newer PET scanners) in addition to quick quantitation using commercial software have made MBF and CFR assessment the mainstream clinical practice rather than a predominantly research tool. These absolute measurements of tissue perfusion are accurate and reproducible (Dorbala et al., 2013). A relatively normal CFR (>1.9) essentially excludes the possibility of significant coronary stenosis (Naya et al., 2014). CFR is also a useful tool in the prognostication of patients with suspected CAD (Dorbala et al., 2013).

Coronary Artery Calcification

Myocardial PET/CT imaging also has the capability to screen for and measure coronary artery calcification. A high calcium score is associated with a greater burden of coronary atherosclerosis (Leber et al., 2001) and ischemia (Berman et al., 2004). This additional information is helpful in cases of small mild perfusion defects or where artifacts are suspected, causing falsely abnormal perfusion. In such cases, the absence of coronary artery calcification makes significant CAD (Bellasi et al., 2007) highly unlikely.

TID of the Left Ventricle

TID of the left ventricle with exercise and vasodilator SPECT MPI is a risk marker for multivessel severe obstructive CAD (Mazzanti et al., 1996; Chouraqui et al., 1990). It suggests underlying true ischemic cavity dilation or global subendocardial ischemia resulting in apparent cavity dilation (Dorbala et al., 2013).

Recent study data indicate that abnormal TID in 82Rb PET is associated with more extensive left ventricular dysfunction, ischemic compromise, and reduced global flow reserve. Preliminary outcome analysis suggests that TID-positive subjects have a lower overall survival probability and a lower likelihood of recovery of overall myocardial function post successful revascularization (Rischpler et al., 2012).

RV Tracer Uptake

Increased RV tracer uptake may be seen on both perfusion and metabolism images in the presence of pulmonary hypertension with or without significant RV hypertrophy (Schulman et al., 1993). Assessment of increased RV uptake is usually assessed in relation to the radiotracer uptake in the LV myocardium. Since the septum is shared by both ventricles, assessment of increased RV uptake should be made in relation to nonseptal regions of the LV myocardium. Abnormally increased RV tracer uptake is a qualitative assessment.

Lung Uptake

Increased lung uptake on the perfusion images especially when severe may reflect severe LV dysfunction and is a marker of increased LV end-diastolic and capillary wedge pressures. It can also reflect infiltrative diseases of the lungs and can be seen in smokers (Harper et al., 1973).

Clinical Case Examples

Case 4: A 71-year-old female with a femoral neck fracture who developed chest pain and a mild troponin rise postoperatively. Peak troponin was 0.05 ng/mL. She underwent myocardial PET perfusion with the measurement of CFR to assess for demand ischemia postoperatively (**Fig. 7** and **Table 3**).

Given the patient's comorbidities, her flat troponin trend, and how well her symptoms responded to medical therapy, the decision was made to manage her acute cardiac event medically. She thus avoided an invasive coronary catheterization, the rationale being that despite the reduced CFR, the normal perfusion images were reassuring. She was however treated with dual antiplatelet therapy, statin, and beta-blockade as a result of the PET findings. In addition, the CT for AC revealed moderate three-vessel coronary calcification that supported the decision for medical therapy.

Case 5: A 61-year-old female developed chest discomfort and ECG changes post mastectomy. She had a background history of CABG 10 years prior. Cardiac risk factors include hypertension, dyslipidemia, diabetes, and obesity. Coronary angiography revealed multivessel disease, and it was not clear which vessel was the culprit lesion for the NSTEMI. She underwent myocardial perfusion PET imaging to determine regional ischemia and flow and to further guide revascularization (**Figs. 8** and **9**).

Following these results, the patient underwent revascularization of the left main stem, first diagonal branch, and left circumflex arteries (**Table 4**).

Case 6: A 58-year-old man with a background of type 2 diabetes mellitus and hypertension presented with clinical evidence of a stroke and was found to have ECG changes consistent with a late presentation STEMI. Given his acute CVA with hemorrhagic transformation on initial brain imaging, emergent coronary angiography and PCI were deferred. Subsequent coronary angiography

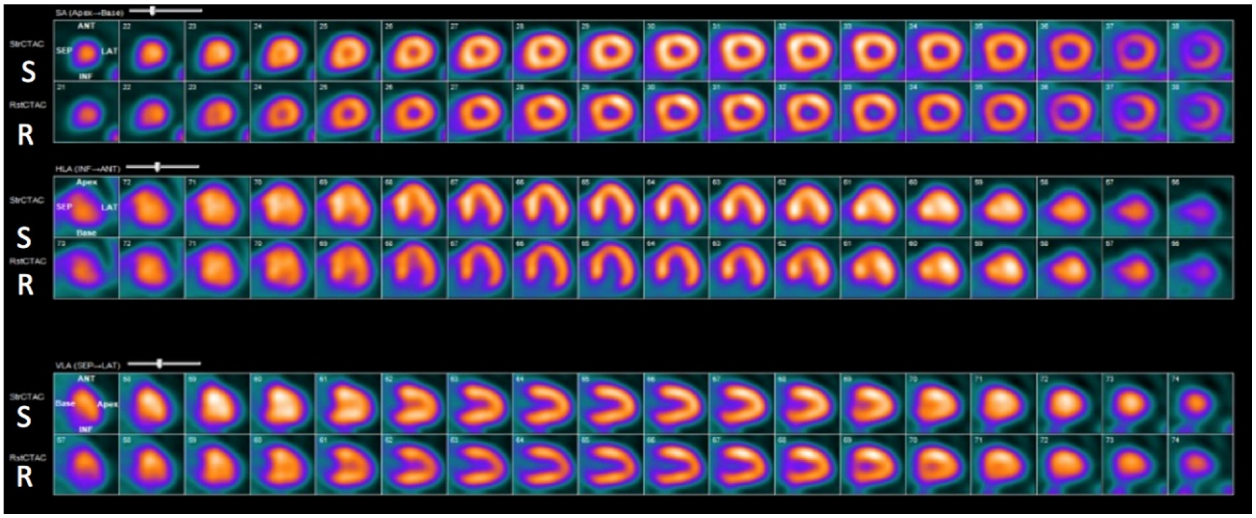

Fig. 7 PET perfusion images reveal stress (S) and rest (R) perfusion with short-axis slices represented in the *top row*, horizontal long-axis (HLA) view in the *middle row* and vertical long-axis (VLA) view in the *bottom row*. Images reveal normal myocardial perfusion. Gated images in this case revealed normal LV systolic function (LVEF 72% at rest and 82% with stress). Coronary flow reserve was also measured and was particularly useful in this case given the normal perfusion and function in the setting of an elevated troponin (see later). Images courtesy of Marcelo Di Carli MD, Brigham and Women's Hospital.

Table 3 Coronary flow reserve indicates globally reduced flow in all three coronary artery territories

Region	*Stress (mL/min/kg)*	*Rest (mL/min/kg)*	*Reserve (mL/min/kg)*
LAD	2.22	2.02	1.1
LCX	1.79	1.35	1.33
RCA	2.43	1.5	1.62
Total	2.13	1.67	1.27

Normal flow reserve is usually indicated by a value >2 mL/min/kg. Flow in this case was reduced to an overall value of 1.27 mL/min/kg

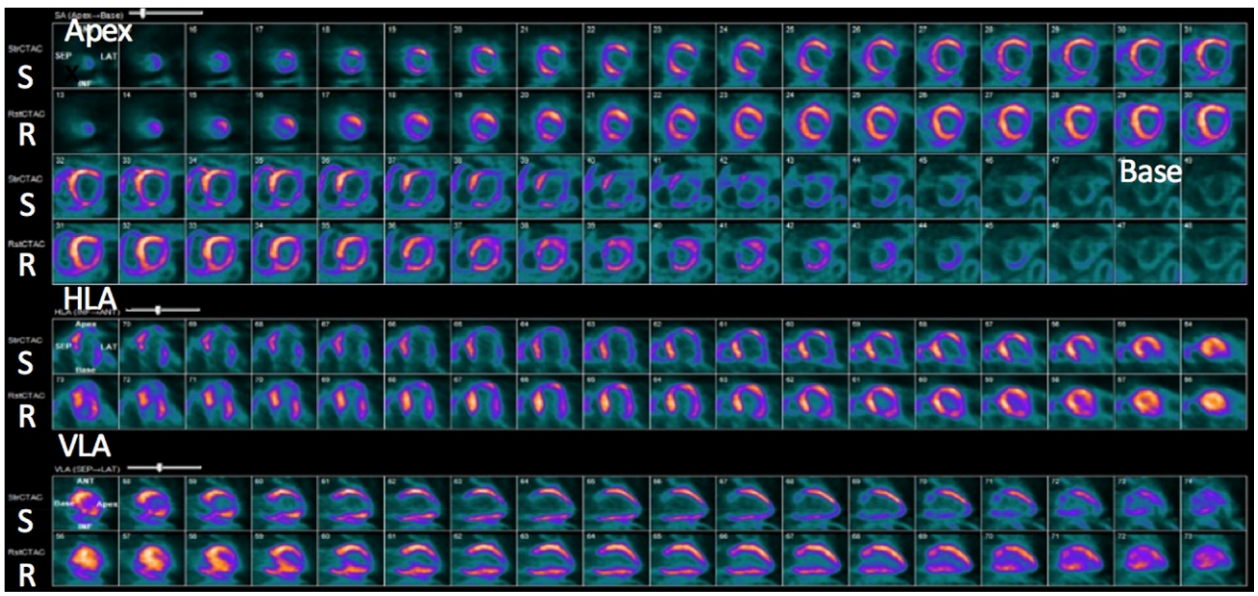

Fig. 8 Myocardial perfusion PET images reveal a large area of ischemia involving the apical, mid, and basal inferolateral segments (LCx territory); a medium sized area of ischemia in the apical, mid, and basal inferior and inferolateral segments (PDA territory); and a small amount of ischemia affecting the true apex on the HLA and VLA images (LAD territory). ECG-gated functional imaging reveals abnormal global LV systolic function. Images courtesy of Marcelo Di Carli MD, Brigham and Women's Hospital.

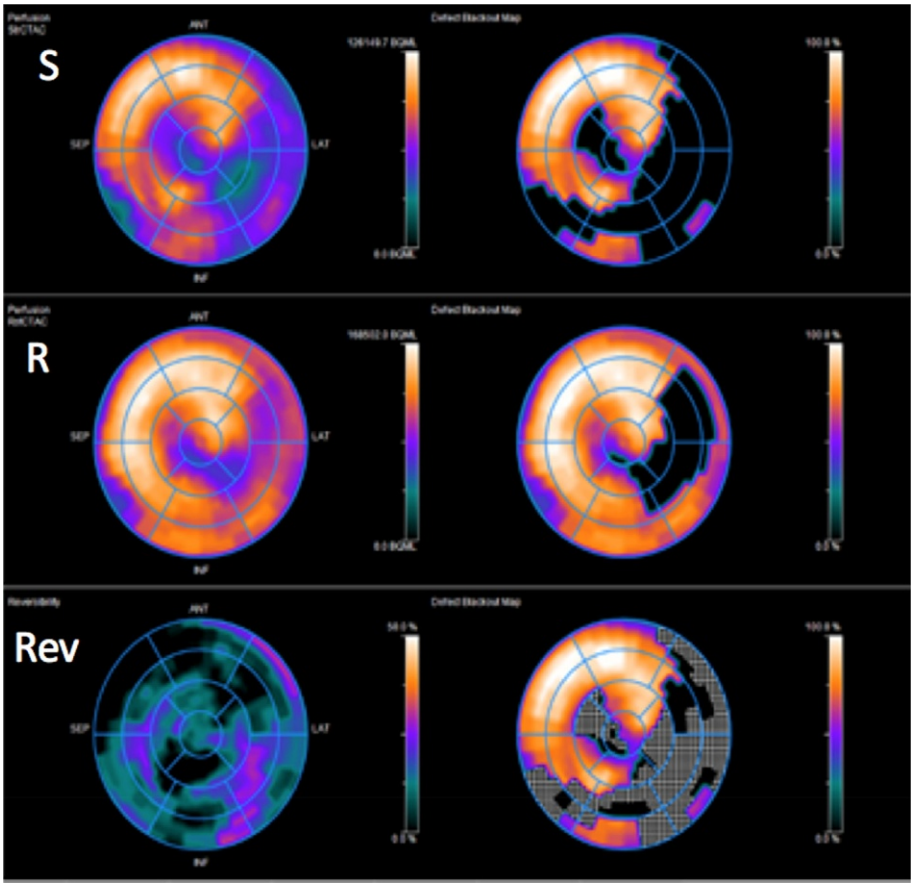

Fig. 9 Polar maps reveal the distribution of the perfusion defect (*left panel*), worse at stress (S, *top*) than rest (R, *middle*), and the blackout map on the right panel confirms the presence of reversible perfusion abnormalities in the distribution of LCX, PDA, and LAD, as described earlier. The reversibility is seen in the lower row. Images courtesy of Marcelo Di Carli MD, Brigham and Women's Hospital.

Table 4 Coronary flow reserve revealed severely reduced flow in all three coronary territories and overall severely reduced coronary flow

Region	*Stress (mL/min/g)*	*Rest(mL/min/g)*	*Reserve (mL/min/g)*
LAD	1.28	1.07	1.19
LCX	0.87	0.87	0.94
RCA	0.97	0.97	1.05
Total	0.99	0.99	1.09

revealed significant three-vessel disease. He underwent rest-only PET MPI to assess for ischemia/infarct burden and FDG imaging for viability assessment and to risk stratify prior to revascularization. Bedside echo revealed LVEF 30%–35% with anterior, anteroseptal, and apical hypokinesis to akinesis (Figs. 10–12).

The gated images revealed the presence of a dilated LV with severely reduced LV systolic function and an EF of 32%. The patient had an LV thrombus detected during contrast echocardiography, and therefore, intervention was deferred at that time. He was commenced on single-antiplatelet therapy and a novel oral anticoagulant in view of the LV thrombus. Four months later, he returned for repeat PET MPI, which is displayed in comparison with the initial rest imaging later (Figs. 13 and 14).

These findings support the hypothesis that in this particular case, the initial abnormal myocardium was likely stunned rather than hibernating, and with medical therapy, there was interval improvement in perfusion. Also, the LV remodeled with smaller LV volumes and an improvement in LVEF from 32% to 44%. The patient opted to continue with medical therapy rather than undergo high-risk PCI/CABG, given his recent stroke and multiple comorbidities.

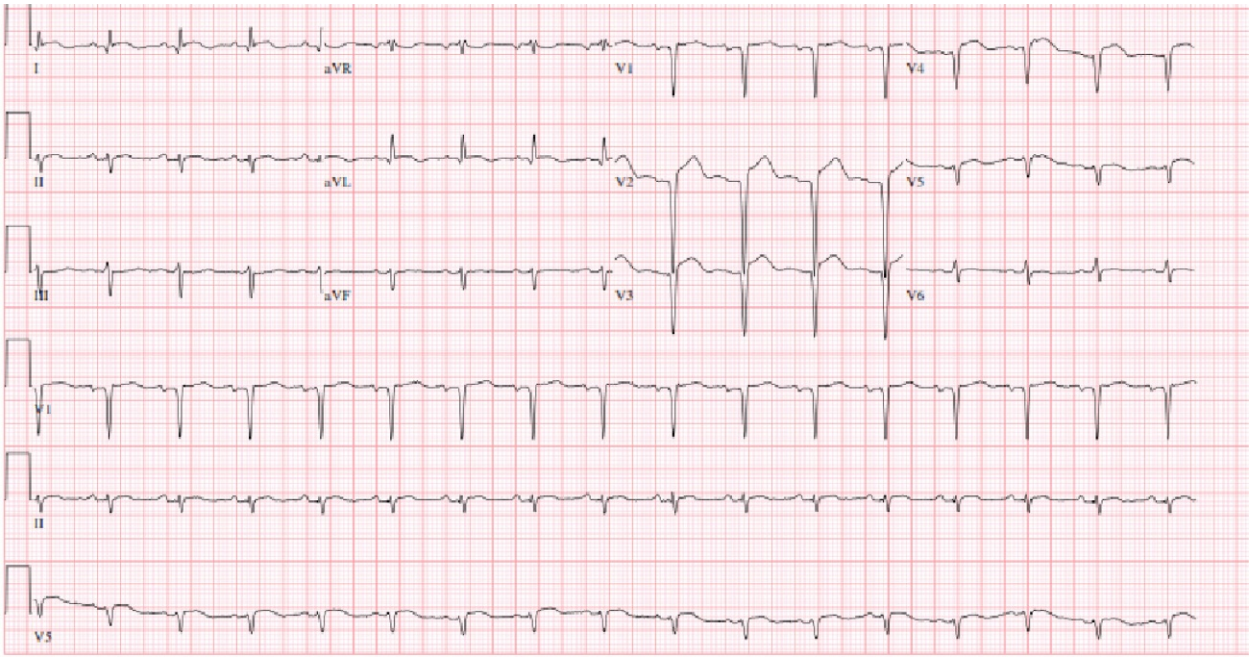

Fig. 10 EKG reveals anterior ST elevation and q waves. The patient denied chest pain.

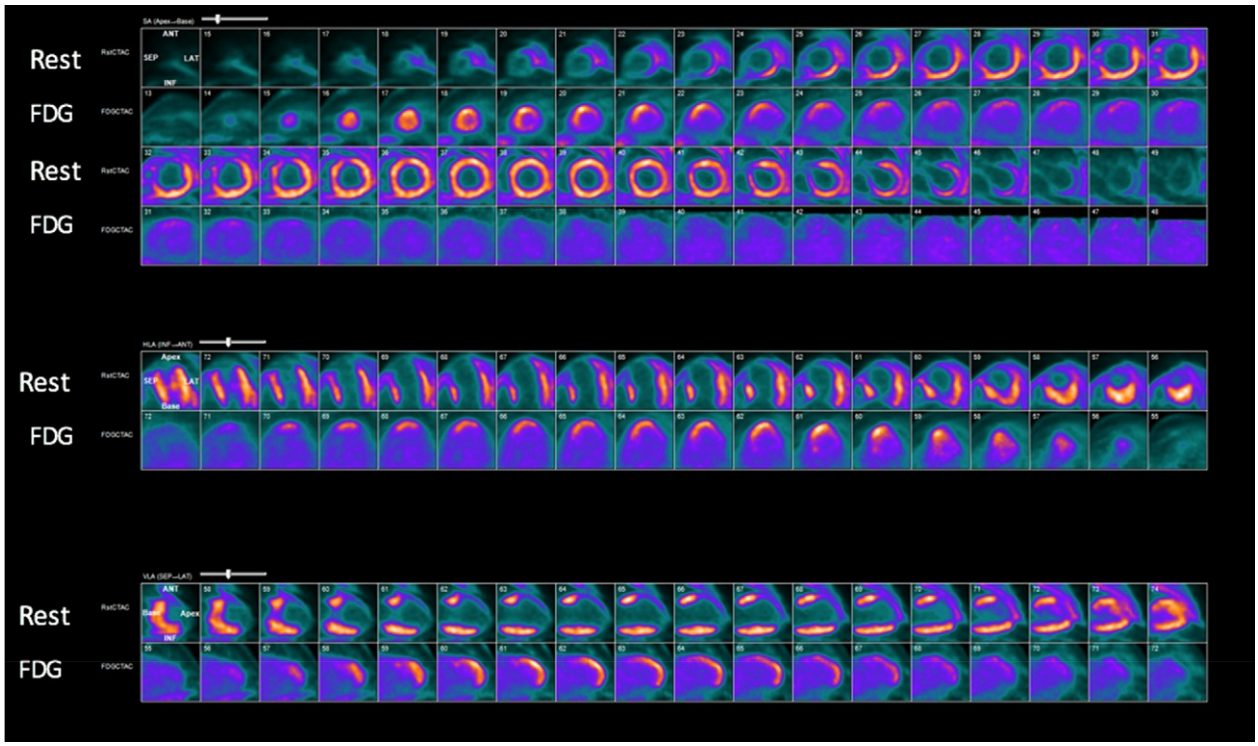

Fig. 11 Rest ammonia PET (*top row*) and FDG PET in short-axis (*top*), HLA (*middle*), and VLA (*bottom*) views reveal a matching perfusion defect and corresponding FDG avidity in the distribution of the LAD indicating a large area of hibernating myocardium in the LAD territory. This finding was confirmed by the polar maps later. Images courtesy of Marcelo Di Carli MD, Brigham and Women's Hospital.

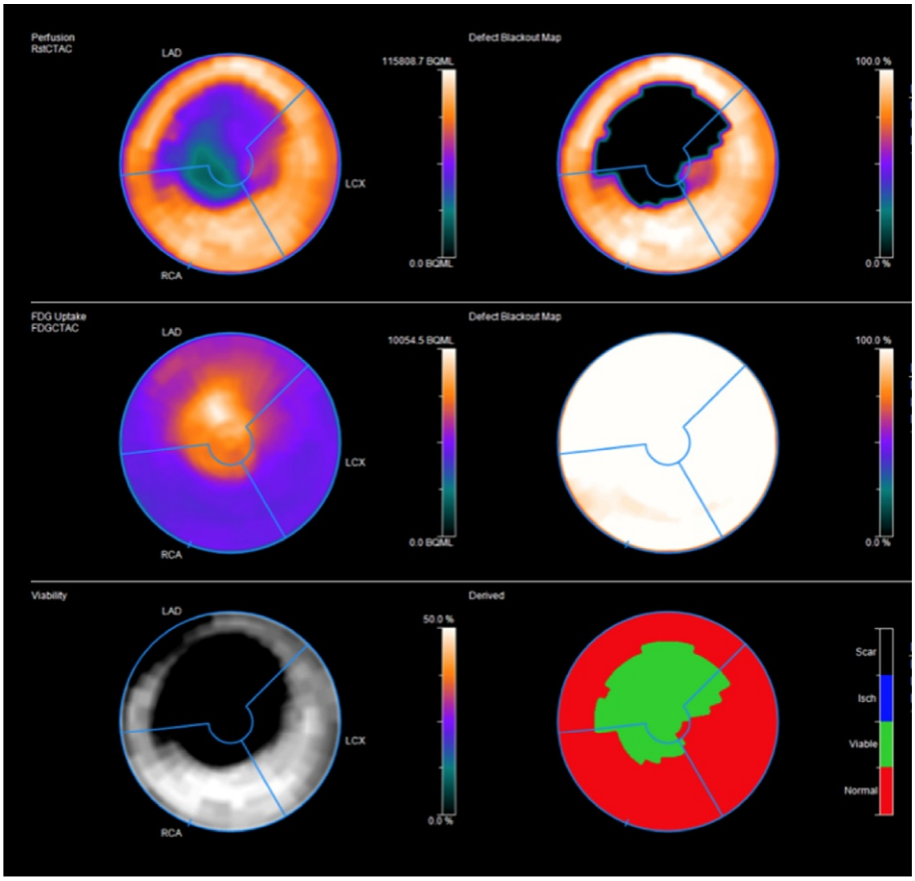

Fig. 12 This reveals the perfusion defect (*top*), FDG uptake (*middle*), and viability as indicated by the *green region* (*bottom*). In total, 42% of the myocardium was abnormal and viable. Images courtesy of Marcelo Di Carli MD, Brigham and Women's Hospital.

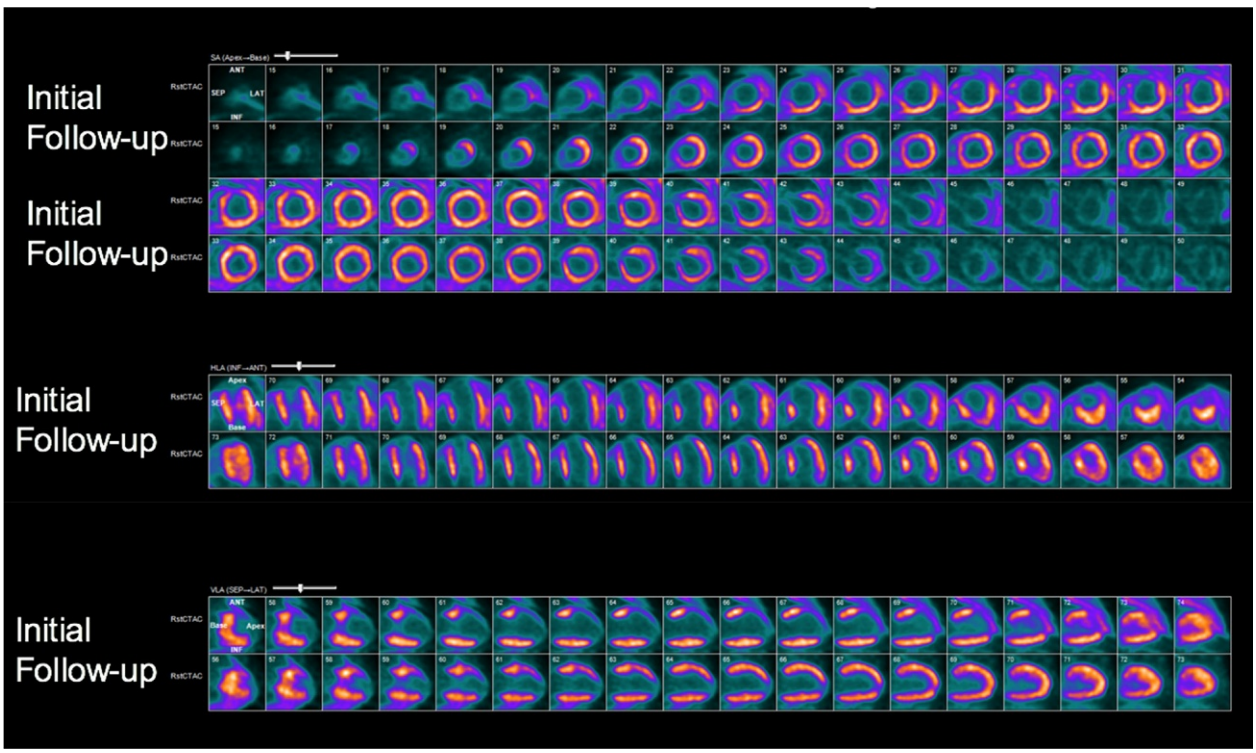

Fig. 13 The initial NH4 rest perfusion (*top row*) and follow-up NH4 rest perfusion (*bottom row*) images reveal an interval improvement in rest perfusion in all coronary artery territories, with a reduction in total abnormal myocardium from 42% to 9% (see polar maps later). Images courtesy of Marcelo Di Carli MD, Brigham and Women's Hospital.

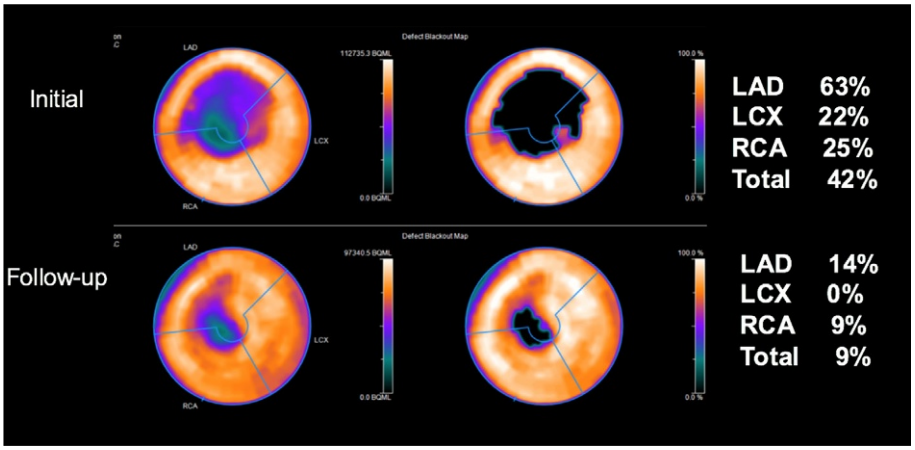

Fig. 14 Polar maps of initial rest perfusion (*top*) and follow-up rest perfusion (*bottom*) and corresponding blackout map with coronary artery distribution abnormality as a percentage of myocardium on the right. Images courtesy of Marcelo Di Carli MD, Brigham and Women's Hospital.

Cardiac Magnetic Resonance Imaging (MRI) Perfusion

With significant improvements in cardiac MRI scanning protocols and reduced scanning duration, the availability and feasibility of CMR perfusion has improved in recent years. The physiological basis for stress perfusion imaging rests in the concept of CFR (Klocke, 1987). CFR measures the capacity of the coronary circulation to increase blood flow through the coronary tree, under conditions of maximal vasodilation. This is typically achieved using pharmacological vasodilators such as adenosine or regadenoson. In healthy adult subjects, these agents cause an up to fourfold increase in coronary flow, and they are particularly effective in minimizing the resistance of the distal coronary perfusion bed. This process can reveal the presence of flow-limiting lesions in the epicardial coronary arteries. When the patient is at rest, an epicardial lesion will become flow limiting only then the luminal narrowing becomes approximately 85% or higher. In contrast, with maximal vasodilation, this threshold is lowered to approximately 50% or higher (Coelho-Filho et al., 2013). Vigorous exercise used as a stressor will produce the same CFR response as maximal vasodilation achieved with adenosine (Duncker and Bache, 2008).

CFR is typically measured during PET MPI and is described in earlier. It can also be measured by CMR but is more cumbersome. It is measured using direct visualization of the lumen of the proximal coronary artery and with the quantification of blood flow velocity in the vessel lumen by using the phase-contrast technique (Nagel et al., 2003). This technique can prove challenging due to cardiac and respiratory motion and the relatively small coronary lumen dimensions (approximately 1.5–3 mm).

In contrast, myocardial perfusion reserve (MPR) is typically measured by CMR. In this case, myocardial perfusion refers to the blood flow through the coronary microcirculation, that is, the volume of blood flowing through a volume, or mass unit of the myocardium, per unit of time (Coelho-Filho et al., 2013). Perfusion is quantified independently at rest and during maximal vasodilation, and thus, one can calculate the MPR, analogous to the CFR, as the ratio of hyperemic flow divided by the resting flow. In the normal coronary circulation, the CFR and the MPR agree in magnitude; however, in the case of epicardial disease, the presence of coronary collaterals can result in an epicardial flow reserve, which is lower than the MPR measured downstream from the lesion (Geldof et al., 1995). Thus, one can argue that the MPR, rather than CFR, is, perhaps, a closer and potentially more accurate measurement of the capacity of the coronary circulation to deliver sufficient oxygen to the myocardium. An abnormal MPR is thus considered a useful surrogate marker for ischemia, although the threshold below which it needs to decrease to cause clinically significant ischemia is not well-defined (Coelho-Filho et al., 2013).

Myocardial First-Pass Perfusion

It is only possible to measure flow through the coronary microcirculation indirectly. This is done either by labeling the blood and observing signal intensity changes resulting from the transit of the labeled blood or alternatively by introducing a blood-borne MR-detectable tracer and observing the injected tracer through the myocardium (Coelho-Filho et al., 2013). The so-called myocardial first-pass perfusion or first-pass imaging is currently the most widely used and reliable technique to assess myocardial perfusion by CMR. It is performed by measuring contrast enhancement during the first pass of a contrast agent bolus through the cardiac chambers and the myocardium. Cardiac MR perfusion studies rely primarily on the use of T1-weighted techniques, and during frozen cardiac motion, one applies dynamic imaging techniques that allow the acquisition of an image during a fraction of a heartbeat, which is repeated every heartbeat during the first pass and ideally covers a stack of sections through the heart (Coelho-Filho et al., 2013). Typically, a 0.05 mmol/kg bolus of gadolinium-based contrast agent is injected during three heartbeats after the start of image acquisition by using a power injector at a rate of 4 mL/s. Three short-axis LV slices at base, mid, and apical LV

level are selected, along with a four-chamber view prior to scanning. These are the views thus obtained for the evaluation of first-pass perfusion. Analysis of post perfusion images can be performed using either qualitative or quantitative techniques. In research CMR labs, quantitative measures are used. For clinical purposes, qualitative assessment is typically performed.

Stress Perfusion Imaging

Typically, stress perfusion images are obtained before rest, following localizing images and using a standard dose of intravenous regadenoson (0.4 mg). The images are acquired during approximately 60 heartbeats to cover a precontrast phase, the first pass of the contrast agent after its injection, and the recirculation of contrast agent (Coelho-Filho et al., 2013). Breath holding is typically performed for the initial phase of the study, and the patient resumes breathing when necessary. Breathing motion is sufficiently slow that it typically does not cause motion artifacts, but it is possible using post processing techniques to correct for breathing motion if required. Heart rate and blood pressure are monitored throughout and recorded. Adverse effects of regadenoson are infrequent but can include severe dyspnea, chest discomfort, headache, and GI upset due to the vasodilation of the vessels in the gut; thus, IV aminophylline is typically held in close proximity for reversal where required.

Rest Perfusion Imaging

Usually acquired at the end of the study, allowing sufficient time for the effect of the stress agent to have dissipated. A further contrast bolus is given, and similar slices are obtained in the manner described earlier. Rest and stress perfusion images can thus be compared side by side to assess for reversible or fixed perfusion defects using the standard 17-segment model.

Image Interpretation

Visual interpretation of myocardial contrast enhancement displaying the perfusion images in cine mode is the standard used in routine clinical practice. Myocardial regions with perfusion defects are identified by a reduced rate of contrast enhancement. Such regions appear hypointense during early myocardial contrast enhancement. Playing the images in cine mode is essential for differentiating between image artifacts (in particular, so-called dark-rim artifacts at the endocardial border) and true perfusion defects (Di Bella et al., 2005). The key to distinguish between dark-rim artifacts and true perfusion defects is the number of frames during which the signal hypointensity can be observed. Artifacts typically only appear in a couple of frames during peak contrast enhancement in the blood pool and before peak contrast enhancement in the myocardial tissue (Coelho-Filho et al., 2013).

Sensitivity and Specificity of CMR Perfusion Imaging for the Detection of Underlying CAD

Multiple single- and multicenter trials have shown that CMR perfusion has excellent sensitivity and specificity in the detection of underlying CAD (Panting et al., 2001; Klem et al., 2006; Schwitter et al., 2001; Al-Saadi et al., 2000; Wolff et al., 2004; Giang et al., 2004), including comparison with alternative methods of MPI such as SPECT and PET. In 2001, Schwitter et al. described a sensitivity and specificity for the detection of underlying coronary stenosis of >50% of 0.86 and 0.8, respectively, using dipyridamole as a stress agent. More recently, Manka et al. described a sensitivity and specificity of 0.92 and 0.75, respectively, for lesions >50% (Manka et al., 2011) using adenosine compared with dobutamine as the stress agent. Such data have led to the increasing utilization of stress cardiac MRI in recent years for the detection of underlying CAD, particularly in young patients where radiation dose is a concern and a noninvasive means of assessment is desirable. Compared with well-established nuclear techniques and the more recently developed stress multidetector CT, stress perfusion CMR studies can also provide additional information about LV and RV size and systolic function, regional function (wall thickening or strain imaging), and edema (T2 SPAIR) and infarction imaging, all at high spatial resolution and tissue contrast.

Limitations of Stress CMR

At present, the commonly used gadolinium-based cardiac MR contrast agents such as Dotarem or Gadavist do not have regulatory approval for any cardiac indication in the United States, and their use is therefore off-label. From a practical standpoint, the administration of vasodilator stress agents (e.g., adenosine) in the MR imaging environment can be more challenging than when other imaging modalities (e.g., PET or SPECT) are used. Adenosine and dobutamine require the use of MRI compatible infusion pumps and tubing; however, a new FDA-approved vasodilator stress agent, regadenoson (Al Jaroudi and Iskandrian, 2009), has reduced symptom intensity and is associated with better patient tolerance. It is delivered as a single bolus, which allows easier administration without the use of a pump.

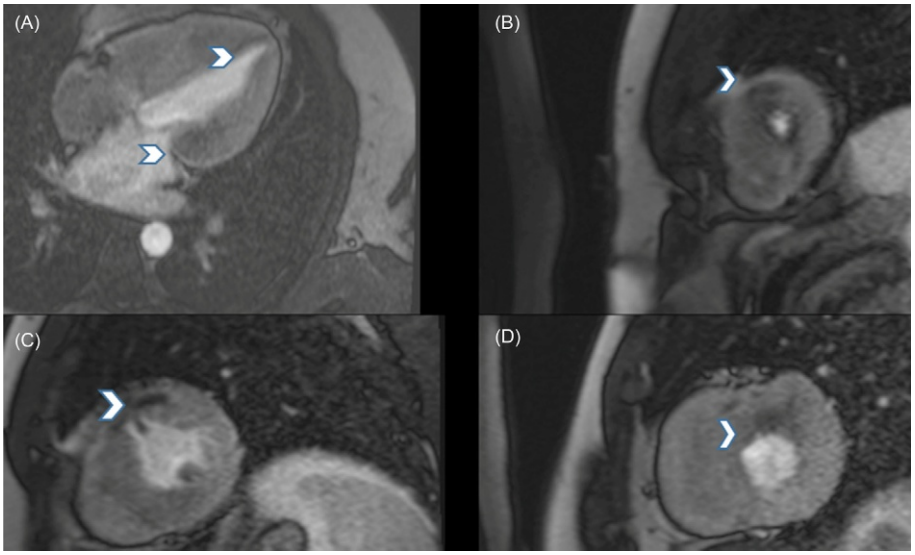

Fig. 15 Panels A–D: four-chamber view (A), short-axis apical (B), mid (C), and basal (D) LV slice in still frame indicate the presence of subendocardial perfusion defects (*black area* marked by *arrows*) affecting the apical anterior, mid anteroseptum, and basal anterior segments. Subsequent coronary angiography revealed significant LAD stenosis that was amenable to percutaneous coronary intervention (PCI). Rest perfusion in this case was normal. Images courtesy of Raymond Kwong MD, Brigham and Women's hospital.

Gadolinium use is typically avoided in patients with EGFR <30 mL/min/m^2. The incidence of the described gadolinium-associated risk of nephrogenic systemic fibrosis (NSF) (Marckmann et al., 2006) is extremely rare but given its severity care is taken in this subgroup of patients. Newer gadolinium-based agents have lower reported rates of NSF than older ones (Bruce et al., 2016).

Clinical Example

A 47-year-old patient with recently diagnosed hypertrophic cardiomyopathy complained of chest pain. He underwent a cardiac MRI to evaluate the degree of LV hypertrophy in addition to the assessment of late gadolinium enhancement as a marker of underlying myocardial fibrosis. A stress perfusion sequence was carried out to evaluate for potential underlying CAD (**Fig. 15**).

MPI Utilizing Echocardiography (Myocardial Contrast Echocardiography (MCE))

Myocardial perfusion can be readily assessed at the bedside using contrast echocardiography. Echo-contrast agents consist of tiny microbubbles (approximately 1–8 μm in diameter), which persist in the systemic circulation for ~3–5 min after intravenous injection. Low-intensity ultrasound imaging is required to prevent the destruction of the microbubbles. Myocardial perfusion is assessed by a process of the destruction of the microbubbles with a "flash" of higher-intensity ultrasound and then analyzing their replenishment rate as the microbubbles seep back into the myocardial circulation.

Echo-contrast agents consist of microbubbles that contain a hemodynamically inert gaseous core (e.g., octafluoropropane and sulfur hexafluoride) and a stabilizing outer shell (e.g., lipid, albumin, or biopolymer), which oscillate when under the influence of ultrasound waves (Postema et al., 2005). These contrast echo microbubbles form multiple small liquid–air interfaces whose boundaries have a high acoustic impedance mismatch resulting in enhanced ultrasound reflection (Orde and McLean, 2016). Contrast microbubbles are small enough to traverse the pulmonary capillaries to enter the systemic circulation. When ultrasound interacts with the microbubbles, they oscillate, and this effect is dependent on the ultrasound acoustic pressure in addition to the shell and core gas properties of the contrast agent. Ultrasound acoustic pressure is described as the "mechanical index" and corresponds to the power output of the scanner (Pathan and Marwick, 2015). With standard 2-D echo, the mechanical index is typically ~1.4. At this level, the microspheres would oscillate to burst and be destroyed. Thus, when performing contrast echo imaging, the mechanical index is set much lower (<0.2) to avoid this phenomenon. Microbubbles reflect ultrasound in a nonlinear format compared to body tissues, which reflect ultrasound in a linear manner. Thus, microbubble reflection can also be detected using higher harmonic frequencies, producing a contrast between highly vascular and less vascular tissues.

Initial animal studies, subsequently validated in humans, investigated the hypothesis that MBF could be assessed using contrast echocardiography by destroying the contrast microbubbles with a "flash" of high-diagnostic-intensity ultrasound and subsequently assessing the rate of replenishment of the microbubbles into the myocardium (Jayaweera et al., 1994; Wei et al., 1998; Vogel et al., 2005). This is assessed by the change in intensity or brightness in a "region of interest" (ROI). Microbubbles behave like RBCs. Therefore, any change in signal intensity indicates a change in MBF.

Under normal conditions, that is, normal MBF, 90% of the coronary circulation resides within myocardial capillaries, and red blood cells travel at approximately 1 mm/s at rest (Orde and McLean, 2016). After the destruction of the echo contrast, signal intensity usually returns to normal after approximately five to seven cardiac cycles (Wei et al., 1998). Under stress, where vasodilation and increased capillary blood flow are present, the rate of return of signal intensity is approximately two to three cardiac cycles. Qualitative assessment of the rate of microbubble replenishment is possible, but it is also possible to assess it quantitatively by reviewing the change in signal intensity over time in a specific ROI. MBF is considered the product of plateau signal intensity and rate of replenishment. The slower the rate of replenishment and the lower the plateau signal intensity, the poorer the MBF.

Side effects of intravenous echo-contrast administration are rare and include a headache, flushing, or back pain. Symptoms are usually relieved on the cessation of contrast agent administration. There is a reported 1:10,000 chance of an anaphylaxis-type reaction (Orde and McLean, 2016).

Quantification during MCE has not become widespread due to a number of factors including (a) attenuation, (b) underlying tissue signals, (c) incomplete microbubble destruction with high MI impulses, and (d) difficulties with software quantification techniques (Porter and Xie, 2010). MCE compares well with other myocardial perfusion techniques. Kaul et al. (1997) described a 92% concordance between segmental perfusion scores by MCE and 99mTc-sestamibi SPECT at rest and during dipyridamole stress. In another study, Heinle et al. (2000) compared MCE perfusion with 99mTc-sestamibi SPECT in 123 patients with suspected CAD and found an overall concordance between both techniques of 83%; concordance was higher in patients with no or multivessel CAD. Despite these data, the use of MCE in routine clinical practice is low, and most centers prefer the use of nuclear MPI.

Myocardial CT Perfusion

In a similar fashion to CMR perfusion, CT assessment of myocardial perfusion is based on the distribution of contrast (iodinated in the case of CT) material during its first pass through the myocardium. The contrast material's distribution is affected by the underlying arterial blood supply. Myocardial perfusion defects can be identified as hypoattenuating areas containing reduced amounts of contrast material. Static CT perfusion imaging allows the visual qualitative assessment of a single snapshot of myocardial iodine contrast attenuation. This snapshot is acquired during the early arterial phase of first-pass contrast enhancement. The optimal time frame for stress perfusion acquisition is 8–16 s after contrast enhancement in the aorta reaches 100 HU (Bischoff et al., 2013). Static single-shot myocardial CT perfusion can be performed using any CT scanner capable of acquiring diagnostic-quality coronary CTA (Vliegenthart et al., 2012).

Static rest myocardial perfusion evaluation is generally performed using coronary CTA image sets already obtained for the morphological assessment of the coronary arteries. If the assessment of myocardial perfusion at stress is desired, an additional acquisition during pharmacological stress should be obtained (Varga-Szemes et al., 2015).

Assessment of static myocardial CT perfusion is performed qualitatively by the visual evaluation of LV myocardial contrast enhancement. To improve discrimination between artifacts and true perfusion defects, the recommendation is that the evaluation of myocardial perfusion takes place in multiphase reconstructions (Varga-Szemes et al., 2015). Artifacts typically affect only a single cardiac phase, whereas true defects will typically persist throughout the entire cardiac cycle (Vliegenthart et al., 2012). It is also possible to carry out a semiquantitative assessment of myocardial perfusion using the transmural perfusion ratio, that is, the ratio between subendocardial and subepicardial attenuations (Cury et al., 2011). Further, advanced image processing methods, including color-coding myocardial attenuation and indexing signal density, are also available and may enhance diagnostic accuracy (George et al., 2006; Mahnken et al., 2008; Kachenoura et al., 2009).

When compared with SPECT or SPECT plus invasive coronary angiography, most of the static single-energy studies showed high specificity and sensitivity for the detection of hemodynamically significant CAD (Cury et al., 2011; George et al., 2006; Kachenoura et al., 2009; Blankstein et al., 2009; Ko et al., 2012). Sensitivity for the detection of reversible perfusion defects significantly improves under pharmacological stress (Gould and Lipscomb, 1974). As with other methods of MPI, various agents are available to induce pharmacological stress with the vasodilator adenosine most commonly used. Adenosine is administered in a continuous IV infusion at a dose of 140 μg/kg/min for at least 120 s to induce an increase in the heart rate of 10–20 beats above the resting heart rate. Regadenoson is advantageous because it can be administered in a single dose, making stress CT studies using regadenoson more time-efficient (Kurata et al., 2005).

Conclusion

MPI is an important tool that adds much information in the assessment of cardiac patients, and it can take many forms, most commonly involving nuclear imaging. However, depending on the institutional availability of cardiac MRI, contrast echo, and perfusion CT, the preferred technique may vary. Patient characteristics can also affect this decision such as the age and presenting characteristics of the patient, whether radiation should be avoided at all costs and whether iodinated contrast can be used depending on renal function. This article explores the use of each modality and highlights the pros and cons of each method. In addition, clinical case examples in the case of nuclear cardiology and cardiac MRI highlight the clinical use of such techniques in everyday clinical practice.

Approaches to Myocardial Repair

The human heart has very limited regenerative capacity. The estimated rate of cardiomyogenesis of 0.5%–1% per year (Bergmann et al., 2009, 2015) is not sufficient to compensate for the loss of cells after injury such as myocardial infarction. Therefore, regenerating an injured heart requires stimulation of the low endogenous cardiomyocyte proliferation, addition of new cardiomyocytes, or reprogramming fibroblasts (in the scar) to cardiomyocytes (**Fig. 1**).

Stimulation of Endogenous Cardiomyocyte Proliferation

During murine development cardiomyocyte DNA synthesis occurs in two temporally distinct phases. The first phase occurs during fetal development and is associated solely with cardiomyocyte proliferation. The second phase takes place during early neonatal life and is associated with binucleation (Soonpaa et al., 1996). A recent study in mice reported a second proliferative burst during preadolescence, leading to an increase in cardiomyocyte number by ~40% (Naqvi et al., 2014). However, another group analyzing cardiomyocyte DNA synthesis and cell-cycle activity could not confirm this finding (Soonpaa et al., 2015), leaving this an open question. In the adult zebrafish heart cardiomyocyte proliferation occurs at a low rate but is increased after cardiac injury (Poss et al., 2002; Gemberling et al., 2013; Arnaout et al., 2014). Regeneration was also observed in newborn rat (Robledo, 1956) and mice (Porrello et al., 2011). The mechanisms are not entirely clear. Genetic fate mapping experiments in adult mice concluded that myocardial infarction led to the formation of new cardiomyocytes from a noncardiac (=non-α-myosin heavy chain-positive) population of progenitor cells (Ellison et al., 2013; Loffredo et al., 2011; Hsieh et al., 2007). In contrast, other studies showed that progenitor cells do not contribute to the low renewal rate of cardiomyocytes in adult mammals but that cardiomyocytes can reenter the cell cycle at a low rate (Malliaras et al., 2013; Senyo et al., 2013; Porrello et al., 2013).

Despite these partially opposing results, stimulation of cardiomyocyte proliferation in vivo is a possible therapeutic avenue for cardiac regeneration without the in vitro culture, invasive intervention, and immunosuppression likely needed for cell-based therapies. But unrestricted proliferation might promote tumor formation and cause arrhythmias. Different strategies have been developed, whose efficiency, safety, and feasibility regarding a clinical application remain to be investigated, especially because most studies have used transgenic approaches to stimulate cardiomyocyte proliferation.

One possibility to increase the proliferative activity is to overexpress proteins that naturally promote the progression of the cell cycle, or knockdown their respective regulatory factors. Overexpression of cyclin B1-CDC2 (Bicknell et al., 2004) or knockdown of p21/p27 (Di Stefano et al., 2011) was shown to increase cell-cycle activity of cardiomyocytes in vitro. After myocardial infarction in mice, overexpression of cyclin D2 (Pasumarthi et al., 2005) or A2 (Chaudhry et al., 2004; Woo et al., 2006) led to an increased proliferation of cardiomyocytes, regeneration of the scar, and improved cardiac function. Similarly, the overexpression of the transcription factor E2F2 (Ebelt et al., 2008) or knock-out of its regulators Rb and p107 led to elevated proliferation of cardiomyocytes (Sdek et al., 2011; MacLellan et al., 2005).

Another approach is the administration of growth factors or activation of their receptors. Periostin (Kuhn et al., 2007) and fibroblast growth factor (Engel et al., 2005) were described to promote cardiomyocyte proliferation, but both were also shown to cause hypertrophy (Baliga et al., 1999; House et al., 2010; Oka et al., 2007). Others showed that periostin is not expressed in cardiomyocytes, but within noncardiomyocytes throughout the rest of the heart, where it enables normal valvular remodeling and

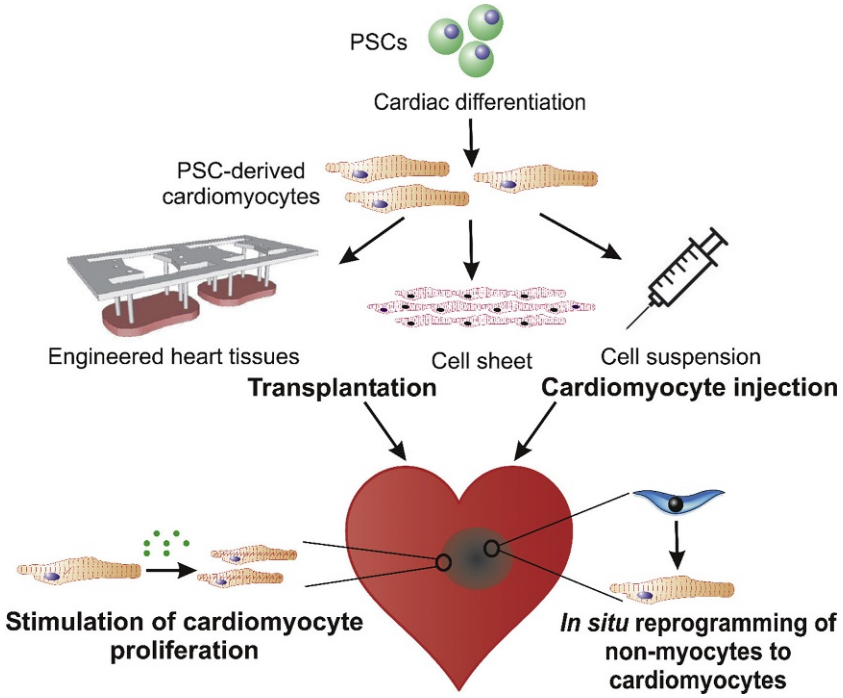

Fig. 1 Approaches to cardiac regeneration.

establishment of a mature cardiac skeleton (Snider et al., 2008). Neuregulin stimulated cardiomyocyte proliferation in some (Bersell et al., 2009; Polizzotti et al., 2015), but not in other studies (Reuter et al., 2014). Overexpression of the receptors for neuregulin, ErbB2 (D'Uva et al., 2015) and ErbB4 (Bersell et al., 2009) induced cardiomyocyte proliferation. While the induction of a constitutively active ErbB2 in neonatal, juvenile, or adult cardiomyocytes resulted in cardiomegaly, transient induction of ErbB2 following myocardial infarction triggered cardiomyocyte dedifferentiation and proliferation followed by redifferentiation and regeneration (D'Uva et al., 2015).

A third possibility to stimulate proliferation is to recapitulate developmental pathways such as the Wnt-signaling pathway. Knock-out of GSK3β was associated with increased cardiomyocyte cycling (Tseng et al., 2006; Kerkela et al., 2008). Several cross-regulations occur between the Wnt/β-catenin and Hippo signaling pathways (**Fig. 2**). Inhibition of Wnt signaling by the Hippo pathway limits cardiomyocyte proliferation and fetal heart growth (von Gise et al., 2012; Xin et al., 2013; Heallen et al., 2011; Heallen et al., 2013) (reviewed in Zhou et al., 2015; Zhou et al., 2015). Mst1/2 (homologues of hippo), Lats1/2 (homologues of Wts), Sav1, and YAP/TAZ (Yki homologues) are the core proteins of the Hippo/Yap pathway in mammals. Activation of Mst1/2 leads to the phosphorylation of Sav1, which in turn activates Lats1/2, which phosphorylates and thereby inhibits the transcriptional coactivators YAP/TAZ. Cardiomyocyte-specific deletion of YAP led to decreased cardiomyocyte cell-cycle activity during embryonic development (von Gise et al., 2012). Conversely, Yap gain of function increased proliferation of neonatal cardiomyocytes in vivo (von Gise et al., 2012; Xin et al., 2013; Xin et al., 2011). Furthermore, inactivation of Lats1/2 led to a moderate stimulation of adult cardiomyocyte proliferation (Xin et al., 2013; Heallen et al., 2013).

miRNAs are another promising tool to increase proliferation of cardiomyocytes, both in in vitro culture and in vivo. After myocardial infarction in mice, administration of miR-590 or miR-199a stimulated cardiac regeneration and improved cardiac function (Eulalio et al., 2012). There is evidence that the mechanism of miRNA-induced proliferation is associated with a suppression of the expression of sarcomeric genes, disassembly of the strict sarcomeric organization of myocytes, and inhibition of the Hippo pathway (Tian et al., 2015). Long noncoding RNAs contribute to cell-cycle regulation and cardiac development (Klattenhoff et al., 2013; Werber et al., 2014; Ounzain et al., 2015), but their possible role in cardiac regeneration has to be further investigated.

Taken together, multifold experimental evidence suggests that cardiomyocyte quiescence in the adult mammalian heart can be therapeutically addressed. Future studies need to address the following issues. (i) To which extent do findings in (cultured) neonatal cardiomyocytes translate to the adult heart? (ii) Do the reported rates of cardiomyocyte proliferation match the functional recovery of injured hearts? In other words, are improvements of contractile function fully explained by new myocardium? Answering this question requires thorough absolute quantification of new myocardium. (iii) How can a potentially tumorigenic concept of cell-cycle activation be translated in a therapeutic concept without causing harm? This will likely require the design of short-term, pulsed interventions early after myocardial infarction as shown, for example, in studies overexpressing ErbB2 receptors (D'Uva et al., 2015).

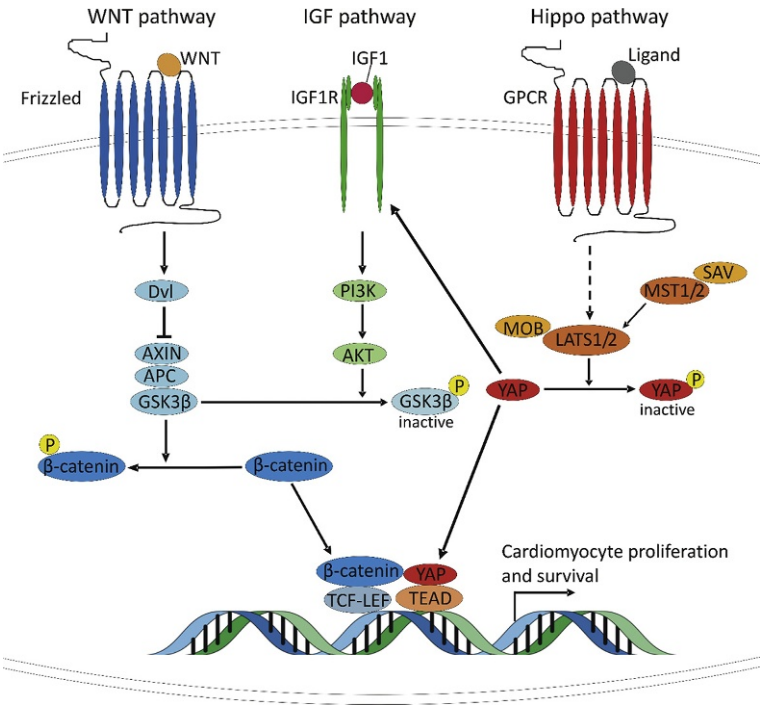

Fig. 2 Cross-regulation between the Wnt/β-catenin, IGF, and Hippo signaling pathways. Activation of the Hippo pathway results in the phosphorylation and nuclear exclusion of the transcriptional coactivator Yes-associated protein (YAP) and thereby impedes cardiomyocyte proliferation. Deletion of the upstream scaffold protein Salvador (SAV) or the inhibitory Hippo kinases large tumor suppressor 2 (LATS2), the kinases mammalian STE20-like protein kinase 1 (MST1) or MST2 promotes cardiomyocyte proliferation, as unphosphorylated YAP can activate the expression of genes in the WNT-signaling pathway by interacting with β-catenin. YAP also promotes cardiomyocyte proliferation through the activation of the insulin-like growth factor 1 (IGF1) pathway. *APC*, adenomatosis polyposis coli; *AXIN*, axis inhibition protein; *GPCR*, G protein-coupled receptor; *DVL*, Dishevelled; *GSK3β*, glycogen synthase kinase 3 β; *IGF1R*, IGF1 receptor; *LEF*, lymphoid enhancer-binding factor; *MOB*, Mps one binder; *TCF*, T cell factor.

Cellular Therapies

In this article we focus on cellular therapies aiming to replace damaged or necrotic heart muscle cells by new cardiomyocytes or to add new myocytes/muscle tissue to the injured heart. Therapies using other cell types addressing paracrine factors are described in reviews with a wider scope (Garbern and Lee, 2013; Eschenhagen et al., 2012). The prerequisite for cellular therapies aiming at the addition of new heart muscle is the generation of human cardiomyocytes in vitro at a high scale. The concept is principally straightforward, namely to transplant preformed cardiomyocytes into or onto the injured heart, expecting them to integrate and couple to the remaining host myocardium, and overtake the contractile function of the lost tissue.

Cell type

Human pluripotent stem cells (hPSC), that is, human embryonic stem cells (hESC), human-induced pluripotent stem cells (hiPSC), human parthenogenetic stem cells (hPGSC), and human nuclear transfer-mediated ESC (hNT-ESC), can differentiate into all cell types of the three germ layers ectoderm, endoderm, and mesoderm. They are the only cell source that can be differentiated to *bona fide* cardiomyocytes at high efficiency.

Human embryonic stem cells

hESCs were for the first time derived from the inner cell mass of a blastocyst in 1998 (Thomson et al., 1998). They show high levels of telomerase activity (Thomson et al., 1998), which prolongs the replicative life-span (Harley, 1991; Harley et al., 1992) and allows the completion of embryonic development. Differentiation protocols have been established that mimick embryonic development (Yang et al., 2008) and yield principally unlimited numbers of cardiomyocytes with a purity of up to >90% (Lian et al., 2013; Zhang et al., 2015; Kempf et al., 2015; Palpant et al., 2017; Lin et al., 2016; Burridge et al., 2011). The transplantation of hESC-derived cardiomyocytes into injured myocardium showed positive effects after infarction in different species (Klug et al., 1996; Behfar et al., 2007; Laflamme et al., 2007; van Laake et al., 2007; Shiba et al., 2012; Chong et al., 2014). Human grafts showed cell–cell contacts and electrical coupling and were associated with improved left-ventricular function in the damaged tissue (Behfar et al., 2007). Early studies injected hESC-derived cardiomyocytes in mouse and rat and observed reduced infarct area, increased vascularization, and at least transiently improved heart function (Laflamme et al., 2007; van Laake et al., 2007). Injection of large amounts of hESC-derived cardiomyocytes into cryo-injured guinea-pig hearts generated relatively large human grafts, improved heart function, and reduced arrhythmia susceptibility (Shiba et al., 2012). In a follow-up study in nonhuman primates significant graft formation was observed

that were proven to electrically couple to the host myocardium when applied shortly after injury (Chong et al., 2014). Given that infarct size in the monkeys was small and contractile function was not compromised by the infarct, grafting had no beneficial effect on heart function, but was associated with the transient induction of ventricular arrhythmias in all of the five experimental animals. In chronic injury models, hESC-derived cardiomyocytes failed to electrically integrate into the host myocardium after injection in suspension (Shiba et al., 2014) or to improve heart function after transplantation of engineered heart muscle (Riegler et al., 2015).

Human-induced pluripotent stem cells

The first iPSCs were reprogrammed from mouse fibroblasts by retroviral transduction with the four transcription factors c-MYC, OCT3/4, SOX2, and KLF4 in 2006 (Takahashi and Yamanaka, 2006). One year later, human iPSCs were generated by two similar approaches in parallel (Takahashi et al., 2007; Yu et al., 2007). Like hESCs, iPSCs can differentiate into cells of all three germ layers in vitro and in vivo (Takahashi et al., 2007). As the random genetic integration of retro- or lentivirus into the genome could have unpredictable effects, nonintegrating virus-based protocols (e.g., Sendai virus, Fusaki et al., 2009) are now widely used as a better alternative. The permanent presence of the oncogene c-*MYC* in the genome bears tumorigenic risks, which can nowadays be circumvented by plasmid-, RNA-, or protein-based reprogramming methods (Fusaki et al., 2009; Okita et al., 2008; Stadtfeld et al., 2008; Kaji et al., 2009; Woltjen et al., 2009; Kim et al., 2009; Warren et al., 2010). Interestingly, the reprogramming factors are only transiently induced and not measurable after 10-15 passages, but the endogenous pluripotency factors OCT4 and NANOG are permanently increased, indicating that the process of reprogramming stably induces the endogenous pluripotency program. Depending on the method used, reprogramming efficiencies are between 0.001% and 4.4% (Robinton and Daley, 2012).

By recapitulating the most important stages of embryonic cardiac development, hiPSCs can reproducibly and efficiently be differentiated to >90% pure cardiomyocytes (Lian et al., 2013; Kempf et al., 2015; Palpant et al., 2017; Lin et al., 2016; Burridge et al., 2011, 2014; Breckwoldt et al., 2017). Different transplantation studies showed positive effects of hiPSC-derived cardiomyocytes on heart function after myocardial infarction. In a guinea-pig model of myocardial infarction human engineered heart tissue (hEHT) strips from hiPSC-derived cardiomyocytes and hiPSC-derived endothelial cells formed large, vascularized grafts in the scar, improved left-ventricular function and were, at least in a subset of experiments, able to electrically couple to the host myocardium (Weinberger et al., 2016) (**Fig. 3**). Allogeneic, cynomolgus monkey iPSC-derived cardiomyocytes injected into infarcted primate hearts survived, showed electrical coupling with host cardiomyocytes and improved cardiac contractile function (Shiba et al., 2016). In a study with human hiPSC-derived cardiomyocyte cell sheets transplanted into infarcted minipig hearts, only few cells survived but cardiac function was improved (Kawamura et al., 2012), suggesting that paracrine mechanisms contributed to the beneficial effect.

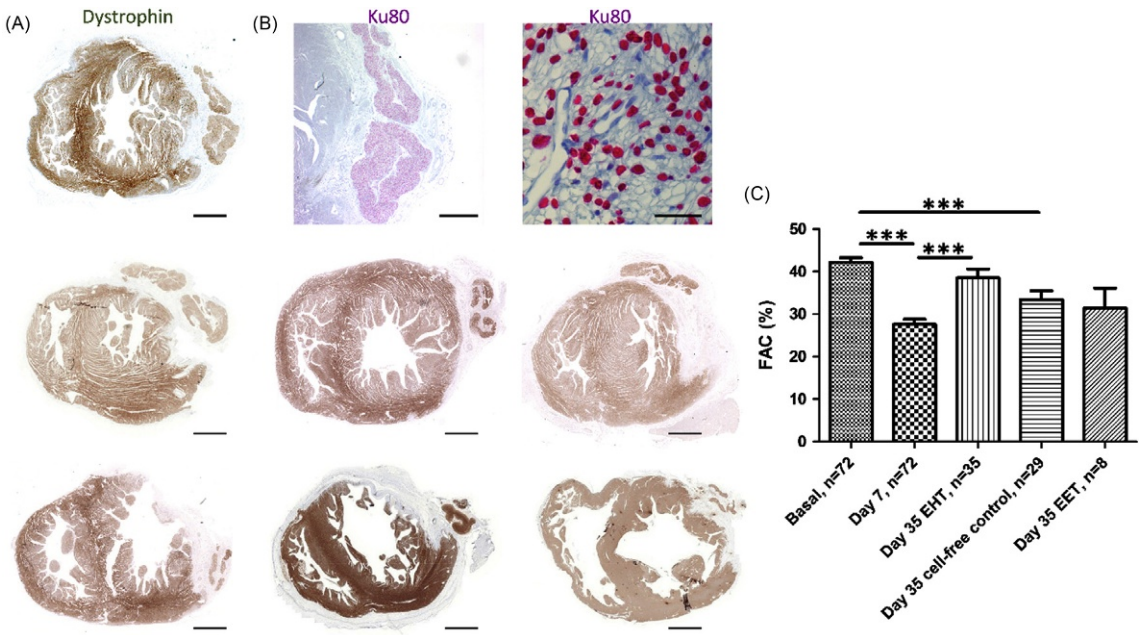

Fig. 3 EHTs partially remuscularize the scar after injury and improve left-ventricular function. (A) Short axis sections of seven different guinea-pig hearts 28 days after hEHT transplantation. (A) Staining for dystrophin. Scale, 2 mm. (B) Staining for human Ku80 in low (scale, 1 mm) and high magnification (scale, 40 μm) of the graft in the corresponding section in (A). (C) Fractional area change (FAC) before cryoinjury (basal, $n=72$), 7 days after cryoinjury prior to transplantation ($n=72$), and 35 days after cryoinjury (hEHT $n=35$, cell-free control $n=29$, hEET $n=8$). Data are individual animals with means ± SEM (A). $^{***}P<0.001$ determined by one-way ANOVA analysis, followed by Bonferroni test. Figures are taken from Weinberger, F., et al. (2016). Cardiac repair in guinea pigs with human engineered heart tissue from induced pluripotent stem cells. *Science Translational Medicine* 8, 363ra148, doi:10.1126/scitranslmed.aaf8781 with permission.

Human parthenogenetic stem cells

Parthenogenesis is a naturally occurring form of uniparental, asexual reproduction, leading to different meiosis and zygosity outcomes (Chapman et al., 2007). Although the mechanism underlying this phenomenon is still not fully understood, different protocols aiming to imitate parthenogenesis have been described (reviewed by Daughtry and Mitalipov, 2014). Parthenogenesis does not normally occur in mammals, but still PGSC-derived embryos of most mammalian species are developing to blastocysts. After transfer into recipients, mouse parthenotes can implant and reach day E9.5 of development (Kaufman et al., 1977). Further development failed. This may be partially due to impaired placental formation (Tarkowski et al., 1970) but also to defective genomic imprinting, because many imprinted genes are directly involved in fetal growth pathways (Kono, 2006). PGSC derivation efficiencies (Paull et al., 2013; Mai et al., 2007), morphological, growth and culture characteristics, transcriptional profile (Sritanaudomchai et al., 2010) and in vitro and in vivo differentiation potential (Paull et al., 2013; Mai et al., 2007; Sritanaudomchai et al., 2010) are similar to ESCs. hPGSCs were differentiated to fibroblasts, cardiomyocytes, neurons, and β cells (Paull et al., 2013; Gonzalez et al., 2013). After transplantation of mouse PGSC-derived cardiomyocytes in MHC-matched allogeneic or syngeneic mice, the engraftment was as efficient as that of ESC-derived cells (Kim et al., 2007; Didie et al., 2013; Liu et al., 2013). PGSC-derived cardiomyocytes promoted regeneration after cardiac infarction (Didie et al., 2013; Liu et al., 2013) and formed a functional syncytium with the healthy host myocardium when transplanted as PGSC-derived engineered heart tissues (EHTs) (Didie et al., 2013) or injected as suspended cells (Yang et al., 2015).

Human nuclear transfer-mediated ESC

Somatic cells can be reprogrammed to pluripotent ESCs by somatic cell nuclear transfer (SCNT) into a previously enucleated human oocyte. Since sheep Dolly in 1997 (Wilmut et al., 1997), cells from different mammalian species have been generated by SCNT. The technology is now routinely used to generate transgenic pigs or other farm animals (Fischer et al., 2016). A recent advancement was the derivation of hNT-ESC lines (Tachibana et al., 2013), whose nuclear genome resulted exclusively from parental somatic cells. These hNT-ESCs had normal diploid karyotypes and gene expression profiles comparable to ESCs derived from blastocysts. Further progress was the generation of hNT-ESCs using nuclei from adult cells (Chung et al., 2014) and not from fetal and infant somatic cells, as aging-related diseases are the main application of regenerative approaches.

Application procedure

Cell injection

The most straightforward way to deliver PSC-derived cardiomyocytes into an injured heart is to inject them directly into the infarcted area and its border zone (Gerbin and Murry, 2015a), where successful integration into healthy tissue and electrical coupling to the host myocardium has been demonstrated (Shiba et al., 2012; Chong et al., 2014). On the other hand, low cell retention and high cell death rates (partly pressure-induced) lead to less than 10% of cells remaining a few days after injection into animal hearts (Dow et al., 2005; Qiao et al., 2009; Zhang et al., 2001; Hofmann et al., 2005). Therefore, high cell numbers are needed and at least some cells will be distributed into other organs, thereby increasing the risk of tumor formation due to remaining pluripotent cells in a differentiated cell population (Cao et al., 2007). Studies that achieved relevant remuscularization, that is, a graft size of 1%–8% of scar size, injected 100 Mio hESC-derived cardiomyocytes in a 2.5 g guinea-pig heart (Shiba et al., 2012) or 1000 Mio in a 40 g nonhuman primate heart (Chong et al., 2014). This number has to be compared with the normal 10–15 Mio cardiomyocytes/g native heart tissue (Bergmann et al., 2015; Adler and Friedburg, 1986). To enhance engraftment the cells were delivered in a prosurvival cocktail (Laflamme et al., 2007; Shiba et al., 2012; Chong et al., 2014) and surgical techniques were used to reduce washout (Chong et al., 2014).

Cell sheets

An elegant approach is the application of cell sheets, which are based on the propensity of cardiomyocytes to detach from their growth surface as a cell monolayer in long-term culture. Temperature-sensitive culture dish surfaces facilitate the detachment of cell monolayers from the culture dish at room temperature (Okano et al., 1995; Shimizu et al., 2002). These scaffold-free thin sheets can be transplanted to the heart without sutures or glue, which has been shown with different cell types in rat (Masumoto et al., 2014), minipig (Kawamura et al., 2012), and even humans (skeletal myoblasts, Sawa et al., 2012). Compared to single cell injections the cell retention rate is higher due to cell–cell contacts within the sheet at the time of transplantation.

Cell sheets containing hiPSC-derived cardiomyocytes engrafted, were vascularized, and significantly improved cardiac function of infarcted rat hearts (Masumoto et al., 2014). The limitation in tissue thickness, which is due to the natural diffusion limits, has been dealt with by repeated surgeries to allow progressive vascularization (Shimizu et al., 2006). In a porcine model of ischemic cardiomyopathy the transplantation of cell sheets led to a significantly improved cardiac function although only few cells survived a period of 8 weeks after transplantation (Kawamura et al., 2012). The discrepancy between few surviving cells and improved heart function was observed in several studies (Kawamura et al., 2012; Ye et al., 2014) and is usually explained by paracrine effects and mechanical stabilization of the injured myocardium.

Cell–matrix injection

Cell retention can also be increased by injecting cells suspended in extracellular matrices that form hydrogels and immobilize the cells at the injection site, while preventing direct contact to the infarcted muscle (Anderl et al., 2009; Danoviz et al., 2010;

Kofidis et al., 2005). Hydrogels provide a microenvironment, which could facilitate cell survival and engraftment. On the other hand, pressure-induced cell death and the number/volume of maximally applicable cells remain a current limitation. Despite initial positive results (Kofidis et al., 2005), it was shown later that significant fractions of injected microspheres were lost from the injection site and that the long-term retention rate was low (Anderl et al., 2009).

Heart muscle patches

Another approach is to generate 3-D artificial heart muscle tissues in vitro and transplant them onto injured hearts. Several techniques for generating such tissues have been developed (Schaaf et al., 2011; Tulloch et al., 2011; Kensah et al., 2013; Nunes et al., 2013; Thavandiran et al., 2013; Turnbull et al., 2014; Radisic et al., 2008; Radisic et al., 2006; 2007; Zhang et al., 2013) and differ in construct size, extracellular matrix, and the mode of tissue anchoring. One possibility is to generate EHTs from liquid hydrogels such as collagen I (Bian et al., 2009; Eschenhagen et al., 1997; Zimmermann et al., 2002a), matrigel (Morritt et al., 2007), or fibrin (Hansen et al., 2010) to immobilize cells in a 3-D form. In this tissue format the cells align, form intercellular connections, produce their own extracellular matrix, and show improved sarcomeric organization compared to single cell cultures. Exposure to auxotonic stretching (the physiological mode of stretching within the heart) by attaching the ends of the tissue to flexible PDMS posts is essential for the formation of force generating tissue with parallel orientation of the cardiomyocytes (Bian et al., 2009; Eschenhagen et al., 1997; Zimmermann et al., 2002a; Fink et al., 2000). EHTs from hPSC-derived cardiomyocytes beat spontaneously and exhibit canonical reactions to changes in extracellular calcium-concentrations, sympathetic (isoprenaline) and parasympathetic (carbachol) stimulation, and changes in preload/length (Schaaf et al., 2011; Eschenhagen et al., 1997; Zimmermann et al., 2002a; Mannhardt et al., 2016).

Allogeneic transplantation of EHTs with neonatal rat (Zimmermann et al., 2006) or PGSC-derived mouse cardiomyocytes (Didie et al., 2013) onto infarcted hearts led to the formation of new myocardium on the scar, which electrically coupled to the recipient hearts, increased the conduction velocity in the scar and were associated with improved left-ventricular function. The transplantation of EHTs generated from hiPSC-derived cardiomyocytes and hiPSC-derived endothelial cells onto injured guinea-pig hearts led to a profound remuscularization of the scar (mean 12% of infarct scar size), accompanied by improved left-ventricular function. The grafts showed cardiomyocyte proliferation, vascularization, and evidence for electrical coupling to the intact heart tissue in a subset of tissues (Weinberger et al., 2016). While these positive results were observed in a subacute injury setting (transplantation 7 days after infarction), transplantation of EHTs from hESC-derived cardiomyocytes did not improve heart function in a chronic injury rat model (Riegler et al., 2015). It is not clear whether the lack of functional impact in the latter study was due to the chronic model and/or the choice of the rat as recipient which may impede coupling of the human cardiomyocytes. Data with hESC-cardiomyocytes in a chronic guinea-pig infarct model indicate that coupling may be less efficient than in a more acute model (Shiba et al., 2014).

Direct Cardiac Reprogramming

Instead of reprogramming somatic cells to iPSCs and subsequently differentiating them to different cell types, somatic cells can be directly transdifferentiated into another cell type. In 2010 Ieda et al. showed that fibroblasts can be transdifferentiated to cardiomyocyte-like cells with the three transcription factors GATA4, MEF2C, and TBX5 in vitro (Ieda et al., 2010). Intramyocardial retroviral delivery of the same factors led to the formation of cardiomyocyte-like cells from resident fibroblasts and improved myocardial function after infarction in young mice (Qian et al., 2012). Similar results were obtained with the transcription factors GATA4, HAND2, MEF2C, and TBX5 (Song et al., 2012); the transcription factors ETS2 and MESP1 (Islas et al., 2012); and with micro RNAs (Jayawardena et al., 2012). Despite these encouraging results, the reprogramming efficiency is currently still low, the phenotype of the generated cardiomyocytes appears incomplete (Chen et al., 2012), and the mechanisms of transdifferentiation are poorly understood. Furthermore, the in vivo delivery of reprogramming factors could have an influence on adjacent noncardiac tissue and uncontrolled reprogramming could lead to cardiomegalies and cause arrhythmias. Delivery of reprogramming factors could be realized by intramyocardial injections of lentiviruses, but their random integration in the genome constitute a significant safety concern. Nonintegrating vectors like adeno-associated virus (AAV) could circumvent this problem. AAVs (esp. AAV serotypes 1, 6, 8, and 9) efficiently transduce nondividing cells including cardiomyocytes (Bish et al., 2008; Wang et al., 2008; Palomeque et al., 2007). Cardiomyocyte-specific promoters further enhance organ specificity (Muller et al., 2006). So far AAVs have only been applied in preclinical models to stimulate cardiomyocyte proliferation by intramyocardial (Eulalio et al., 2012) or intravenous injections. A clinical application likely requires intracoronary application (reviewed in Katz et al., 2010 and Ishikawa et al., 2011). Clinical trials with AAVs have been conducted for several diseases. Alipogene tiparvovec (Glybera), an AAV 1 vector, was approved in 2012 by the European Medicines Agency to treat patients with familial LPL deficiency, and an AAV 1 coding for the sarcoplasmatic reticulum ATPase has been used in clinical trials for patients with heart failure (Greenberg et al., 2014). Although clinically relevant immune reactions and preexisting neutralizing antibodies have been described, translation toward the clinic seems feasible. Advantages of direct cardiac reprogramming are that it would circumvent time-consuming in vitro culture to generate a sufficient number of cardiomyocytes and avoid the need for immunosuppression. It would also be a simpler product in term of regulatory requirements and would be easier to administer.

Clinical Perspectives of Cellular Therapies

The Right Approach

As described earlier, each cell application technique has advantages and disadvantages regarding simplicity, required cell number, cell survival, biodistribution, accuracy of application, and efficiency of electrical integration. A direct comparison of the efficacy of cell injections, matrix-assisted cell injection, cell sheets, and muscle patches would be desirable but requires large group numbers in a relevant animal model to statistically demonstrate superiority or noninferiority of one over the other technique. An important additional limitation is that such a direct head-to-head comparison required high expertise in all application techniques while currently most laboratories specialize in one or the other technique.

Theoretically, endocardial or intramural injection of cells might provide better electromechanical coupling and effects on contractile function than the epicardial application of cell sheets or muscle patches (Gerbin et al., 2015). Especially because epicardially grafted tissue is often separated from the remaining subendocardial muscle layers of the host heart by a fibrous layer. However, endocardial application of cell sheets or muscle patches would require a larger surgical intervention with extracorporal circulation and would expose the transplanted tissue to the high intraventricular pressure. Thus, the vast majority of studies used the epicardial approach (Weinberger et al., 2016; Kawamura et al., 2012; Masumoto et al., 2014; Sawa et al., 2012; Zimmermann et al., 2006).

Independent of the application method and electromechanical coupling, the transplanted tissue has to be large enough to cover the scar and support contractile function. But the size of a nonperfused transplant is limited to a thickness of 100–200 μm in vitro (Shimizu et al., 2006; Hansen et al., 2010; Radisic et al., 2004,2005; Zimmermann et al., 2002b) by the diffusion limits of oxygen and nutrients. One possibility to minimize hypoxia-induced cell death is to implant thin tissue constructs composed of a loose network of immature and thereby hypoxia-resistant and proliferating cardiomyocytes. After host-derived vascularization of the transplant, cardiomyocytes in the graft can proliferate, likely explaining why some studies have observed compact muscle layers of 0.5–5.5 mm thickness (Weinberger et al., 2016; Zimmermann et al., 2006; Thompson et al., 1988; Wake et al., 1994; Mikos et al., 1993; Peters et al., 2002). An alternative strategy is to engineer prevascularized thicker tissues with a dense network of cardiomyocytes. Cocultures of cardiomyocytes, endothelial cells, and smooth muscle were shown to improve the formation of myocardial tissue in vitro and in vivo (Sekine et al., 2008; Stevens et al., 2009; Narmoneva et al., 2004; Levenberg et al., 2005). Artificial or biological vessels have been integrated into growing tissues (Masumoto et al., 2014; Tulloch et al., 2011; Chiu et al., 2012; Vollert et al., 2014), and heart constructs were grown on arterial-venous loops (Morritt et al., 2007; Tee et al., 1992–1999). While most studies showed improvement of cardiac tissue structure and function, the connection of the preformed vasculature to host vessels directly after transplantation remains a conceptional problem (for detailed review, see Coulombe et al., 2014). Furthermore, prevascularization increases the complexity of the tissue-engineered product in regulatory terms.

The next difficulty is the correct integration of the graft into the complex tissue structure of the heart, in which muscle strands wind around the heart lumen and align in several layers perpendicular to each other. Immature cardiomyocytes orient to the direction of mechanical load in a hydrogel (Zimmermann et al., 2002a; Hansen et al., 2010). Whether this holds true for injected cell suspensions or tissue-engineered muscle patches remains to be elucidated. A radically different approach is to use entire decellularized hearts (Ott et al., 2008) as a scaffold that comes with the full complexity of normal myocardial tissue and the entire organ. However, reintroducing cells into these matrices at sufficient cell density remains challenging (Guyette et al., 2016).

The Right Cell Type

The different types of PSCs have advantages and disadvantages (**Table 1**), which have to be considered for a therapeutic approach. The therapeutic application of PSCs could be realized by using cells from stem cells banks. Disadvantages of all PSC types are the risk of teratoma formation (Ohnishi et al., 2014; Blin et al., 2010; Riegler et al., 2016), immaturity of PSC-derived cardiomyocytes (reviewed in Yang et al., 2014), and the risk of increased arrhythmia susceptibility (Chong et al., 2014) (see also "Risks" section).

hESC are considered to be the most native hPSC cell source, as their genetic material has not been manipulated during isolation. But most hESC lines are being used for more than a decade and it is known that long-term cell culture itself may lead to genetic and epigenetic changes (Silva et al., 2008; Mitalipov et al., 2007). Therapy with hESC-derived cardiomyocytes could be realized by allogeneic transplantation of optimally MHC-matched cells from stem cells banks. Nevertheless, life-long immunosuppression with its severe adverse effects is inevitable. Up to date, ESC therapies are restricted to organs like the eye and the central nervous system (Drukker and Benvenisty, 2004), which are protected from immune response, to minimize rejection of transplanted cells. But due to their isolation from blastocysts, ESCs are ethical controversial and their use is restricted in many countries.

Advantages of human iPSCs are the lack of ethical concerns and their potential for autologous transplantation. But generating a stable patient-specific hiPSC line and differentiating sufficient numbers of high-purity cardiomyocytes (100–1000 Mio) is very time-consuming. Additionally, each single cell line would constitute an own "therapeutic product," requiring sufficient safety testing before a therapeutic application gets approved. This includes screening for genetic variations due to reprogramming, age-acquired mutations in coding regions (Young et al., 2012; Abyzov et al., 2012), and copy number variations (Hussein et al., 2011; Martins-Taylor et al., 2011). It is questionable if such time-consuming and expensive procedures can be carried out for each individual patient. Furthermore, even autologous iPSCs provoked low-level immune responses in mice (Zhao et al., 2011).

Table 1 Advantages and disadvantages of pluripotent stem cells for cardiac regeneration

Cell type	*Advantages*	*Disadvantages*
hESC	● High levels of telomerase activity (Thomson et al., 1998) ● No genetic modification ● High differentiation efficiency (Lian et al., 2013; Zhang et al., 2015; Kempf et al., 2015; Palpant et al., 2017; Lin et al., 2016; Burridge et al., 2011)	● Genetic and epigenetic consequences due to long-term culture (Silva et al., 2008; Mitalipov et al., 2007) ● Ethically controversial and currently restricted/not allowed in many countries ● Allogenic approach, life-long immunosuppression
hiPSC	● No ethical concerns ● High differentiation efficiency (Lian et al., 2013; Kempf et al., 2015; Palpant et al., 2017; Lin et al., 2016; Burridge et al., 2011, 2014; Breckwoldt et al., 2017)	● Inefficient reprogramming (0.001%–4.4%, Robinton and Daley, 2012) ● Heterogeneity in the levels of telomerase and telomere length (Wang et al., 2012) ● Tumorigenic risks of the permanent presence of the oncogene c-*MYC* in the genome ● Relatively high risk of chromosomal aberrations, mutations, and gene duplications (Gore et al., 2011; Hussein et al., 2011; Young et al., 2012; Abyzov et al., 2012; Martins-Taylor et al., 2011)
hPGSC	● No ethical concerns (some countries) ● Efficient parthenogenetic activation protocols (16.6%–28.6%) (Rogers et al., 2004; Lin et al., 2003) ● Less immunogenic than hESCs ● Higher heterozygosity compared to their oocyte donor (Dighe et al., 2008), which prevents the activation of cytotoxic natural killer cells (Kim et al., 2007) ● Homozygous HLA-loci allow for a coverage of the majority of a population with a limited amount of cell lines	● Ethical concerns (other countries including Germany) ● Loss of heterozygosity might cause immune rejection by cytotoxic killer cells (Kim et al., 2007) ● Loss of heterozygosity might be associated with cancer (Cavenee, 1989)
hNT-ESC	● No ethical concerns (some countries)	● Ethical concerns (other countries incl. Germany) ● Age-acquired mutations (Young et al., 2012; Abyzov et al., 2012) ● Less efficient generation than hPGSC (2.3%–20%, Paull et al., 2013; Tachibana et al., 2013) ● Mismatched mitochondria in NT-ESCs induce adaptive immune rejection (Deuse et al., 2015)

Although potentially occurring immune reactions will likely be lower than with HLA-matched allogeneic cells, thereby lowering the need for immunosuppression, the use of cells from stem cells banks seems more realistic.

The use of hPGSCs has advantages. Parthenogenetic activation protocols are rather simple and at the same time more efficient (16.6%–28.6%) (Rogers et al., 2004; Lin et al., 2003) than those resulting in NT-ESCs (2.3%–20%, Paull et al., 2013; Tachibana et al., 2013) or hiPSCs (0.001%%–4.4%, Robinton and Daley, 2012). On the other hand, PGSCs show aberrant genomic imprinting. Disruption or inappropriate expression of imprinted genes is associated with severe clinical syndromes and carcinogenesis in humans (Nakagawa et al., 2001). Another safety issue is genomic homozygosity anticipated in diploid, monoparental PGSCs, since extensive loss of heterozygosity is the most common genetic alteration in human cancers (Cavenee, 1989). However, PGSCs showed high heterozygosity compared to their oocyte donor (Dighe et al., 2008), which is due to the shuffling of alleles between parental chromosomes in prophase I. This is also an immunological advantage. Next to non-self-alleles, the immune system recognizes missing alleles within the major histocompatibility complex (or human leucocyte antigen, HLA). Thereby, heterozygosity is pivotal to prevent the activation of cytotoxic natural killer cells (Kim et al., 2007). To implement histocompatible transplantations, banked PGSC lines should be analyzed for heterozygosity in HLA loci to avoid transplant rejections and to reduce the need for immunosuppressive therapy (Bray et al., 2008).

NT-ESCs share some advantages and disadvantages with iPSCs. NT-ESCs theoretically allow an autologous therapeutic approach. Indeed, SCNT was thought to allow for the production of patient-matched stem cells, even in patients with hereditary mitochondrial diseases. But mismatched mitochondria in NT-ESCs were observed to induce adaptive immune rejection (Deuse et al., 2015), thereby necessitating the development of strategies to produce mitochondrial-matched NT-ESCs. Possible disadvantages are age-acquired mutations (Young et al., 2012; Abyzov et al., 2012) and the associated screening for coding region mutations before clinical use.

Cell Number

The minimum effective cell number for functional improvement is an important parameter in terms of feasibility, safety, and therapy costs. Studies utilized 0.03 (Ye et al., 2014) to 25 (Chong et al., 2014) Mio PSC-derived cardiomyocytes/g heart tissue and observed similar, albeit not identical improvements of cardiac function, sometimes even in the absence of substantial formation of new myocardium. This discrepancy is usually explained by poorly defined paracrine effects (Loffredo et al., 2011; Kawamura et al., 2012; Ye et al., 2014; Gnecchi et al., 2005; Iso et al., 2007; Williams and Hare, 2011; Li et al., 2012). Dose–response studies are

difficult due to multifold reasons like varying infarct size, variability of echocardiography or magnetic resonance imaging to measure cardiac function, and considerable graft size differences even with a constant dose of cells (Weinberger et al., 2016; Laflamme et al., 2005). In some studies the induced injury was not sufficient to significantly decrease heart function, partly due to high mortality rates associated with large injuries (Chong et al., 2014; Blin et al., 2010). Systematic trials with large study cohorts have to further investigate the effect of different cell numbers on therapeutic outcome.

Risks

Risks have to be carefully considered before clinical application of PSC-derived cardiomyocytes becomes a real therapeutic option. As differentiation protocols do not completely eliminate pluripotent stem cells, PSC-based cell therapies inevitably bear the risk of teratoma formation. The problem is further aggravated by biodistribution of cells after transplantation (Laflamme et al., 2007; Weinberger et al., 2016; Dow et al., 2005). Teratoma formation has been observed after application of ESC-derived cardiac progenitor cells into immunosuppressed Rhesus monkeys or of hiPSC-derived cardiomyocytes into immunocompromised rat hearts (Blin et al., 2010; Riegler et al., 2016). The problem may be circumvented by further improvement of purification protocols for differentiated cardiomyocytes (Laflamme et al., 2007; Dubois et al., 2011; Kim et al., 2010; Hattori et al., 2010; Uosaki et al., 2011; Tohyama et al., 2013) or elimination of remaining pluripotent cells with selection media (Matsuura et al., 2015). Nevertheless, long-term experiments in sufficient numbers of immunodeficient animals are needed to quantify the risk. For such experiments, a combination of serum biomarkers with MRI screening could be useful (Riegler et al., 2016).

Another problem of hiPSCs is their relatively high risk of chromosomal aberrations, mutations, and gene duplications (Gore et al., 2011; Hussein et al., 2011; Young et al., 2012; Abyzov et al., 2012; Martins-Taylor et al., 2011). All of these could affect not only the function of iPSC-derived cardiomyocytes and the functional outcome of transplantation studies but also safety. Whole-genome sequencing of a therapeutic cell line is probably required before clinical application. The same holds true for PGSCs, which show expression of mutated genes associated with cancer (Knudson, 1971), thereby bearing the risk of tumor formation.

It is well known that PSC-derived cardiomyocytes are rather immature. hiPSC-CMs, for example, beat spontaneously; show proliferation (Weinberger et al., 2016); and exhibit fetal-like ion channel patterns (Beqqali et al., 1956–1967), electrophysiological signals (Davis et al., 2011), and gene expression profiles (Cao et al., 2008). Long-term cultivation, mechanical loading, pattern of extracellular matrix, and electrical stimulation can improve maturation (Tulloch et al., 2011; Hirt et al., 2014; Domian et al., 2009; Piccini et al., 2015; Ruan et al., 2016; Weber et al., 2016; Dai et al., 2017). While immaturity is a disadvantage for in vitro testing, transplanting immature cardiomyocytes could also have advantages. Due to their ability of anaerobic metabolism, they are hypoxia-resistant and thereby able to survive without sufficient oxygen and nutrient support before vascularization occurs. Their proliferative activity could compensate cell loss after transplantation and increase graft size. On the other hand, unrestricted proliferation might promote tumor formation and cause arrhythmias.

The latter complication could also occur if transplanted cardiomyocytes continued to beat spontaneously and autonomically. Next to the functional contribution of transplanted cells to contraction force of the recipient's heart, this is why electrical coupling of transplanted to host cardiomyocytes is crucial for a successful and safe therapy. The hitherto published studies give opposing results. While an antiarrhythmic effect of ESC-derived cardiomyocytes was described after injection into injured guinea-pig hearts (Shiba et al., 2012), the follow-up study in nonhuman primates showed the opposite (Chong et al., 2014).

Important Questions to be Answered on the Way to Cardiac Regeneration in Patients

Recent progress in regenerative therapies is exciting and the first hPSC-derived product has already been applied in a patient (Menasche et al., 2015). Yet, important questions remain to be answered before these therapies can be translated to patients at a larger scale.

1. Can the promising results of proproliferative intervention (e.g., with miRNAs or overexpression of growth factor receptors) in mice be transferred to large animal models?
2. To which extent can the functional recovery observed after such therapies be explained by new heart muscle formation?
3. How can the low efficiency of direct reprogramming of (scar) fibroblasts into cardiomyocytes be improved without causing unwanted effects?
4. How can such therapy be restricted in terms of time and space to prevent unwanted effects?
5. Can the promising results of PSC-cardiomyocyte transplantation (as cell suspension or tissue) in small animal models be transferred to large animal models?
6. To which extent can the functional recovery after PSC-cardiomyocyte transplantation (as cell suspension or tissue) be explained by remuscularization and new contractile mass participating in overall heart function?
7. How can cell retention after injection be improved?
8. How many cells (in suspension or as tissue) are needed to repair an injured (human) heart?
9. How can electrical coupling be improved to allow robust functional integration of hPSC-cardiomyocytes and prevent arrhythmias?
10. Is coupling truly a more relevant issue in chronic injury models that better mimic the situation in patients than acute injury models?

11. How to overcome hPSC-associated immunological issues and the need for immunosuppression?
12. What is the ideal patient population for the first clinical studies of the different approaches?

Answering these questions will need time, but the ground is laid to make these approaches a realistic scenario in the foreseeable future.

Further Reading

As described earlier, encouraging progress was achieved in cell transplantation approaches, but there is still no consensus on the best cell type to use. Clinical trials aiming to regenerate the heart used bone-marrow-derived cells (Assmus et al., 2010; Marban and Malliaras, 2012; Traverse et al., 2012), mesenchymal stromal cells (Hare et al., 2012; Guijarro et al., 2016; Lee et al., 2014; Trachtenberg et al., 2011; Gao et al., 2015; Can et al., 2015; Mathiasen et al., 2015), or cardiac progenitor cells (Bolli et al., 2011; Makkar et al., 2012). Although signals of improved cardiac function were observed, the effect on morbidity and mortality remains unclear (Clifford et al., 2012), and regeneration of the injured myocardium was not observed. Detailed information on this topic can be found in reviews with a wider scope (Singh and Sen, 2016; Madonna et al., 2016; Gouadon et al., 2016; Gerbin and Murry, 2015b; Lin and Pu, 2014; Behfar et al., 2014).

Introduction

Myocarditis does not have a typical clinical presentation and may mimic other noninflammatory diseases. Thus, in current classifications from the World Health Organisation/International Society and Federation of Cardiology (WHO/ISFC) (Richardson et al., 1996), the European Society of Cardiology (ESC) (Elliott et al., 2007), the American Heart Association (AHA) (Maron et al., 2006) as well as in ESC expert consensus statements (Caforio et al., 2013a), myocarditis is defined as an inflammatory myocardial disease, diagnosed on endomyocardial biopsy (EMB) using established histological, immunological, immunohistochemical, and molecular criteria (to identify possible infectious agents, mainly cardiotropic viruses by gene amplification techniques). The definition of "inflammatory cardiomyopathy" is applied to biopsy-proven myocarditis in patients with associated ventricular dysfunction. The current nomenclature is summarized in **Table 1**. Although EMB is the gold standard for myocarditis and is the only tool which allows distinction of its different etiologies, it is mainly used in tertiary expert referral centers (Cooper et al., 2007; Leone et al., 2012). Thus, there is a relative paucity of unbiased epidemiology data. Biopsy-proven myocarditis may heal spontaneously, relapse, or become chronic leading in about one third of cases to dilated cardiomyopathy (DCM), death, or heart transplantation (Caforio et al., 2007; Schultheiss et al., 2011). Historically, when the diagnosis was based upon the Dallas criteria, myocarditis was considered a relatively rare cause of heart failure or sudden cardiac death (Aretz et al., 1987). Nowadays, the application of immunohistochemistry and highly sensitive molecular tools to EMB (Leone et al., 2012; Schultheiss et al., 2011) as well as new noninvasive tissue imaging techniques, in particular cardiovascular magnetic resonance (CMR) (Friedrich et al., 2009; Francone et al., 2014) suggest that myocarditis prevalence in the population may be substantially underestimated.

Pathology

The pathological picture is described by the Dallas definition of inflammatory cell infiltrate with associated cardiomyocyte necrosis, not typical of ischemic necrosis, observed on EMB or at autopsy (**Table 1**) (Aretz et al., 1987). Myocarditis is histologically classified

 https://doi.org/10.1016/B978-0-12-809657-4.99718-7

Table 1 Definitions

Myocarditis
According to WHO /ISFC (Richardson et al., 1996), myocarditis is defined as:
Inflammatory disease of the myocardium diagnosed by established histological*, immunohistochemical** and immunological criteria***
*Established histological Dallas criteria defined as follows (Aretz et al., 1987):
"histological evidence of inflammatory infiltrates within the myocardium associated with myocyte degeneration and necrosis of non-ischemic origin"
**Immunohistochemical criteria, abnormal inflammatory infiltrate defined as follows (Leone et al., 2012; Caforio et al., 2013a):
"$\geq$14 leucocytes/mm^2 including up to 4 monocytes/mm^2 with the presence of CD 3 positive T-lymphocytes $\geq$7 cells/mm^2"
***Immunological criteria and myocarditis etiology defined as follows (Caforio et al., 2013a):
–Viral: histology (Hx) and immunoHx positive (pos), polymerase chain reaction (PCR) pos for $\geq$virus
–Autoimmune: Hx and immunoHx pos; viral PCR negative (neg); with or without pos cardiac autoantibodies (aabs); exclusion of other known inflammatory causes
–Viral and immune ^: Hx and immunoHx pos; viral PCR pos; cardiac aabs pos
^N.B. a follow-up EMB may identify persistent viral myocarditis, resolved myocarditis (Hx and virological), or persistent virus-negative myocarditis, e.g. post-infectious autoimmune
Inflammatory Cardiomyopathy and Dilated Cardiomyopathy (DCM)
According to WHO /ISFC (Richardson et al., 1996), inflammatory cardiomyopathy is defined as: Myocarditis in association with cardiac dysfunction
Inflammatory cardiomyopathy is involved in the pathogenesis of DCM and includes idiopathic, autoimmune and infectious subtypes
According to WHO /ISFC (Richardson et al., 1996) and ESC (Elliott et al., 2007) DCM is defined as:
DCM is a clinical diagnosis characterized by dilation and impaired contraction of the left or both ventricles that is not explained by abnormal loading conditions or coronary artery disease
DCM includes idiopathic, familial/genetic, viral and/or immune, alcoholic/toxic subtypes

according to the predominant cellular infiltrate as lymphocytic, eosinophilic, polymorphic, giant cell myocarditis, or cardiac sarcoidosis. Although the Dallas criteria represent an important first attempt to standardize histological diagnosis, in the subsequent decades several limitations have been pinpointed: (a) inflammatory cell characterization by immunohistochemistry and fibrosis amount are not considered; (b) the type and extent of myocyte damage are not specified; (c) the term borderline myocarditis, including also chronic forms, remains equivocal and does not help in the clinical setting; (d) any reference to etiological agents is lacking (Leone et al., 2012). Thus, more recently the Dallas criteria have been implemented by adding immunohistochemical and molecular criteria (Leone et al., 2012; Caforio et al., 2013a) (**Table 1**). In particular, an international Task Force of the Association for European CardioVascular Pathology (AECVP) and the Society for CardioVascular Pathology (SCVP) (Leone et al., 2012) and the European Society of Cardiology (ESC) Working Group on Myocardial and Pericardial Disease Myocarditis Task Force (Caforio et al., 2013a) published consensus papers concerning the current role of EMB in myocarditis. In these documents, it has been emphasized that pathological analysis of EMB is complex and requires standard protocols. Optimal specimen procurement and triage indicates at least three, preferably four, EMB fragments, each 1–2 mm in size, that should immediately be fixed in 10% buffered formalin at room temperature for light microscopic examination. In expected focal myocarditis additional sampling is recommended. Moreover, in this clinical setting, one or two specimens should be snap-frozen in liquid nitrogen and stored at −80°C for possible molecular tests or specific stains. Otherwise, fragments may be stored in RNAlater (a solution preventing RNA degradation). Infectious myocarditis is diagnosed by a positive result for one or more infectious agents, mainly viruses, using molecular techniques, mainly reverse transcriptase polymerase chain reaction (R-T PCR) on EMB (**Table 2**) (Leone et al., 2012; Pankuweit and Klingel, 2012; Caforio et al., 2007; Schultheiss et al., 2011).

Etiology and Pathogenesis

Etiopathogenetic agents in myocarditis are listed in **Table 2**.

Viral Myocarditis

Viral agents are presumed to be the most frequent causes of myocarditis in North America and in Europe. Viral genomes are detected to a variable extent on EMB by molecular techniques, mainly R-T PCR (Pankuweit and Klingel, 2012; Caforio et al., 2007; Schultheiss et al., 2011; Bock et al., 2010; Martin et al., 1994; Bowles et al., 2003; Kühl et al., 2005; Kindermann et al., 2008). In recent studies the most commonly detected viruses, particularly in Germany, are Parvovirus B-19 (PVB-19) and Human Herpes virus 6 (HHV6) and these two agents are both present in a sizable proportion of patients (Pankuweit and Klingel, 2012; Schultheiss et al., 2011; Bock et al., 2010; Kühl et al., 2005; Kindermann et al., 2008). The mechanism of cardiomyocyte damage in myocarditis associated with PVB-19 and/or HHV6 is still poorly understood. Some, but not all studies suggest that PVB-19 infection may be pathogenic only in a selected patient group (Pankuweit and Klingel, 2012; Bock et al., 2010, 2014). The frequency of biopsy-proven viral myocarditis may vary as a function of the disease stage, as well as the diverse epidemiology of viral infection in distinct populations and ethnic groups (Pankuweit and Klingel, 2012; Caforio et al., 2007; Schultheiss et al., 2011; Bock et al., 2010, 2014; Martin et al., 1994; Bowles et al., 2003; Kühl et al., 2005; Kindermann et al., 2008).

Table 2 Etiopathogenesis of myocarditis

1. *Infectious agents*	
Bacterial	Haemophilus influenzae, Mycobacterium (tuberculosis), Mycoplasma pneumoniae, others (rare)
Spirochetal	Borrelia (Lyme disease), Leptospira (Weil disease)
Fungal	Uncommon, mainly immunocompromised patients
Protozoal	Trypanosoma cruzi (common in South America), others (rare)
Parasitic	Rare
Rickettsial	Rare
Viral (common)	*RNA viruses*: coxsackievirus A and B, echovirus, influenza A and B virus, respiratory syncytial virus, human immunodeficiency virus-1, others (rare)
	DNA viruses: parvovirus B19 (most common in recent German series), adenovirus (mainly pediatric cases) cytomegalovirus (immunocompromised patients), herpes simplex virus, human herpes virus-6, common in recent German series, often in association with parvovirus B19), Epstein-Barr virus, others (rare)
2. *Immune-mediated (infection-negative)*	
Allergic	Tetanus toxoid, vaccines, serum sickness
	Drugs: penicillin, cefaclor, colchicine, furosemide, isoniazid, lidocaine, tetracycline, sulfonamides, phenytoin, phenylbutazone, methyldopa, thiazide diuretics, amitriptyline
Alloantigenic	Heart transplant rejection
Autoimmune	Organ-specific: lymphocytic (common), giant cell (rare)
	Associated with autoimmune or immune-oriented disorders: systemic lupus erythematosus, rheumatoid arthritis, Churg-Strauss syndrome, Kawasaki's disease, inflammatory bowel disease, scleroderma, polymyositis, myasthenia gravis, insulin-dependent diabetes mellitus, thyrotoxicosis, sarcoidosis, Wegener's granulomatosis
3. *Toxic*	
Drugs	Amphetamines, anthracyclines, cocaine, cyclophosphamide, ethanol, fluorouracil, lithium, catecholamines, hemetine, interleukin-2, trastuzumab, clozapine
Heavy metals	Copper, iron, lead
Miscellaneous	Scorpion sting, snake, and spider bites, bee and wasp stings, carbon monoxide, inhalants, phosphorus, arsenic, sodium azide
Hormones	Pheochromocytoma, vitamins: beri-beri
Physical agents	Radiation, electric shock

Adapted from Caforio, A., Pankuweit, S., Arbustini, E., et al. (2013) Current state of knowledge on aetiology, diagnosis, management, and therapy of myocarditis: a position statement of the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases. *European Heart Journal* **34**(33), 2636–2648.

Postinfectious autoimmune myocarditis

Postinfectious myocarditis has been best studied in experimentally enterovirus-induced murine models (Pankuweit and Klingel, 2012). Several strains show persistence of enteroviral RNA and myocardial inflammation for several weeks, with subsequent autoimmune reaction. In addition, it is clinically observed that patients with previous biopsy-proven viral myocarditis develop persistent virus-negative disease with production of serum anti-heart autoantibodies (AHAs), for example, postinfectious autoimmune myocarditis (Caforio et al., 2007). Thus, the clinical diagnosis of postinfectious autoimmune myocarditis requires a follow-up EMB (**Table 1**). The same murine strains susceptible to postinfectious myocarditis develop autoimmune myocarditis following immunization with cardiac myosin, or spontaneously (Pankuweit and Klingel, 2012; Caforio et al., 2013b), under control of major histocompatibility complex (MHC) and non MHC genes, similar to other autoimmune conditions (Caforio et al., 2013b). The human equivalent of the murine MHC is the human histocompatibility complex (HLA) and it has been shown that HLA is involved in genetic predisposition to inflammatory DCM (Meder et al., 2014).

Primarily autoimmune myocarditis

The diagnosis of primarily autoimmune myocarditis requires exclusion of cardiotropic virus genome on EMB and of other causes, for example, toxic (**Table 1**). The detection of serum organ-specific AHAs is additional evidence in support of autoimmunity, although, as for other autoimmune conditions, the absence of these markers does not rule out an autoimmune process, since there may be predominant cell-mediated forms (Caforio et al., 2013a,b). In addition, AHAs titers may be reduced in advanced stages of the disease (Caforio et al., 2013b). Autoimmune myocarditis is most commonly an organ-specific disease, e.g. confined to the heart, or takes place in the context of systemic immune-mediated diseases (SIDs) (**Table 2**). In these cases, the heart may host self-antigens or neoantigens against which specific autoreactive clones are expanded and directed (autoimmune organ-specific myocarditis and autoimmune myocarditis in the context of multisystem autoimmune diseases). Alternatively, the myocardium may be passively infiltrated and damaged in the course of localized or generalized proliferation of immunocompetent cells or during systemic hyper-inflammatory reactions. This mechanism may be involved in eosinophilic myocarditis in the setting of drug-induced reaction with eosinophilia and systemic symptoms syndrome (DRESS syndrome) (Caforio et al., 2013b).

Table 3 Fulfilled Rose-Witebsky autoimmune features in myocarditis and inflammatory cardiomyopathy

Major
- Mononuclear cell infiltrates and abnormal HLA expression on EMB in the absence of infectious agents (by PCR) or known inflammatory causes
- Serum autoantibodies in patients and in unaffected family members
- Autoantibody and/or autoreactive lymphocytes in situ within the affected tissue
- Identification and isolation of autoantigen (s) involved
- Disease induced in animals by immunization with relevant autoantigen, and/or passive transfer of serum, purified autoantibody and/or lymphocytes
- Efficacy of immunosuppressive therapy and of immunoadsorption in patients

Minor

(a) Common to all autoimmune disorders
  - Familial aggregation
  - HLA association
  - Clinical course characterized by exacerbations and remissions
  - Autoimmune diseases associated in the same patient or in family members

(b) Typical of organ-specific autoimmune disorders
  - Autoantibodies directly against organ-specific autoantigens
  - Induction of antibodies induces an organ-specific disease/phenotype
  - Transfer of autoantibodies also transfers the disease/phenotype

Adapted from Caforio, A., Marcolongo, R., Jahns, R., et al. (2013). Immune-mediated and autoimmune myocarditis: clinical presentation, diagnosis and management. *Heart Failure Reviews* **18**(6), 715–732.

In human autoimmune diseases the diagnosis requires fulfillment of at least two major Rose-Witebsky criteria (Table 3). Autoimmune features in myocarditis or cardiomyopathy include: familial aggregations and HLA associations; detection of lymphomonocytic cellular infiltrates in the myocardium on EMB tissue, in conjunction with enhanced HLA and adhesion molecule expression of cardiac endothelial cells, in the absence of infectious agents in patients and affected family members; abnormal serum cytokine and cardiac autoantibodies (aabs) in patients and affected family members (Fig. 1) and efficacy of immunosuppression/immunomodulation. Using different immunological techniques and antigenic substrates, many cardiac aabs have been detected and for some aabs a direct pathogenic role has been demonstrated. Proofs of their role include: (1) functional effects of aabs in vitro; (2) demonstration of myocarditis, or cardiomyopathy features in genetically predisposed experimental animals following immunization with specific autoantigens, for example, myosin or troponin; (3) transfer of myocarditis, or cardiomyopathy features from immunized to healthy animals following injection of aabs or immune cells, for example, passive transfer experiments; (4) improvement of cardiac chamber dimension and pump function following removal of aabs by immunoadsorption (IA) both in animals and in patients (Table 3).

Pathophysiology

The myocarditis process can result in: (1) cardiomyocyte necrosis, with an increase in troponin levels; (2) systolic and diastolic dysfunction, which can be transient, as a result of spontaneous or drug-induced healing, or persistent with reactivations or a more chronic subacute downhill course leading, if untreated, to interstitial fibrosis and end-stage burned-out DCM; (3) arrhythmias, which may be associated with the acute inflammatory and/or the irreversible post-myocarditic phases. These three features may be variably intermingled in single patients.

Clinical Presentation

In myocarditis cardiac signs and symptoms are heterogeneous and unspecific, depending upon the extent of inflammation and of cardiac dysfunction; they may be subtle and the disease may be unrecognized for months or years. The disease should be suspected especially in young patients with unexplained heart failure signs and/or symptoms, unexplained arrhythmias, and/or chest pain with unobstructed coronary arteries with or without troponin release, fever, and associated respiratory or gastrointestinal viral syndromes. However, although less frequently, myocarditis may occur at any age. The spectrum of arrhythmia in myocarditis is wide, including syncope and sudden cardiac death. Similarly, the heart failure spectrum includes acute, subacute, chronic presentations, also in the peri-partum period, mimicking a peri-partum cardiomyopathy as well as unexplained cardiogenic shock. The so-called "fulminant" myocarditis is defined by the following features: a viral prodrome within 4 weeks from symptom onset, new-onset heart failure, hemodynamic instability, and a favorable outcome, provided that giant cell or eosinophilic forms are excluded as well as myocarditis associated with SIDs. Since myocarditis may mimic other noninflammatory disease (valvulopathy, coronary artery disease, Takotsubo, peri-partum, or arrhythmogenic cardiomyopathy) it is a diagnosis of exclusion.

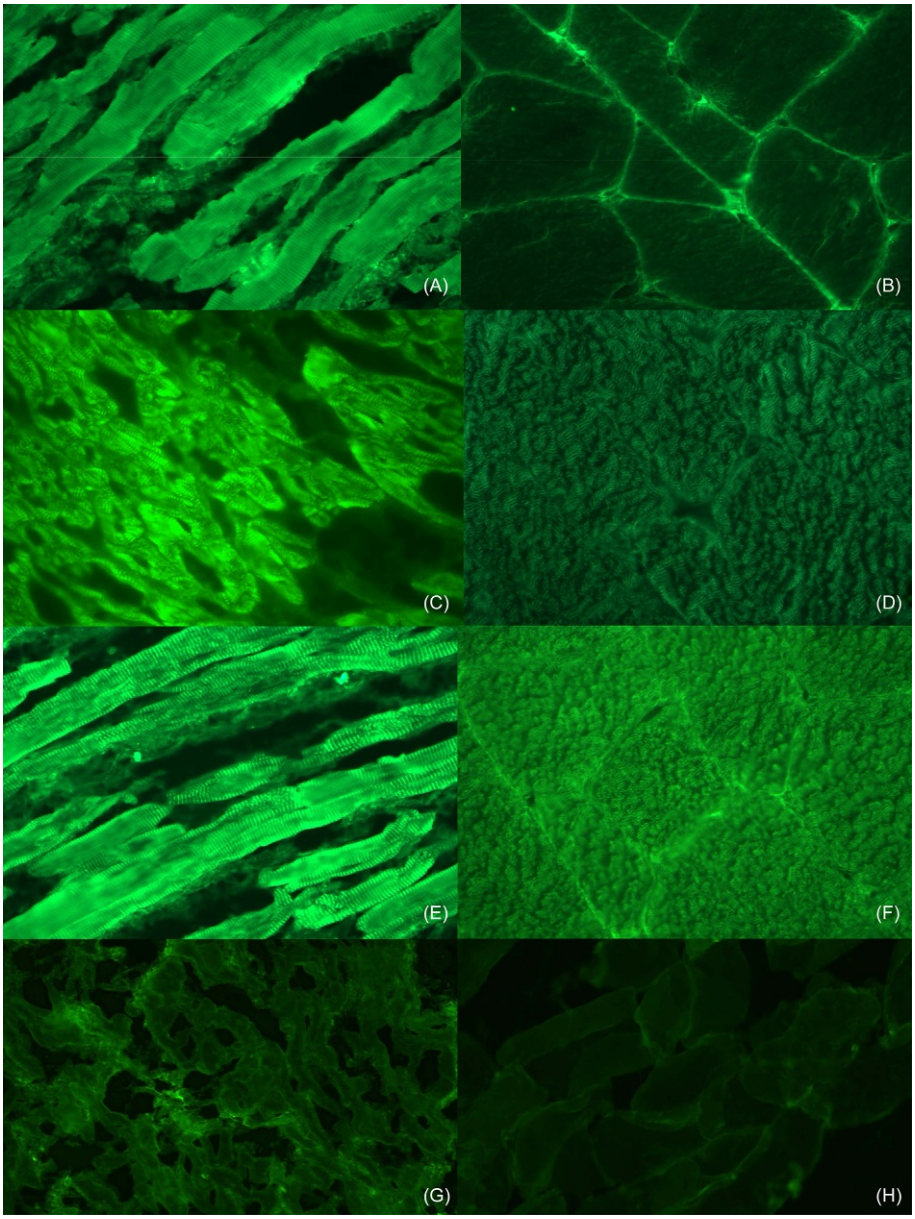

Fig. 1 Anti-heart aabs (AHA) patterns by indirect immunofluorescence test. *Organ-specific AHA pattern: panel A* on human heart tissue: cytoplasmic diffuse staining of cardiac myocytes (organ-specific AHA pattern) (×400); *panel B* (×400) on human skeletal muscle tissue: negative. *Partially organ-specific (or cross-reactive 1) AHA pattern: panel C* on human heart tissue: positive fine striational pattern (×400), and *panel D* on human skeletal muscle: weak positive fine striational pattern (×400). *Other example of cross-reactive 1 AHA pattern: panel E* on human heart tissue: strong positive fine striational pattern (×400), and *panel F* on human skeletal muscle: positive pattern (×400). *Negative AHA control serum pattern: panel G* on human heart tissue: negative (×400), and *panel H* on human skeletal muscle: negative (×400).

Diagnostic Work-Up

Electrocardiography and Echocardiography

Electrocardiography (ECG) features in myocarditis are unspecific and may include any kind of idiopathic supraventricular or ventricular brady or tachyarrhythmias, as well as ST-T segment abnormalities. Some suggestive ECG findings include: diffuse ST segment elevation without reciprocal changes, PR depression in myocarditis associated with pericarditis. Pathological Q waves are uncommon in myocarditis. T wave inversion generally takes place after ST-T segment normalization.

Echocardiography is useful to study morphology and function of the cardiac chambers and valves, but it is unspecific, may be normal, with segmental wall motion abnormalities or diffuse hypokinesis similar to DCM. Pericardial effusion is not common, although may be present and suggest associated pericarditis.

Left ventricular aneurisms may be present in Chagas disease or in cardiac sarcoidosis. In fulminant myocarditis ventricular walls may be thickened and ventricular chambers are most often mildly dilated and severely hypokinetic. Echocardiography helps in excluding associated causes of heart dysfunction, such as valve disease. In addition, it is key in monitoring cardiac function noninvasively at follow-up, since biventricular function may change as a result of resolution or reactivation of the inflammatory process.

Nuclear Imaging and Cardiovascular Nuclear Magnetic Resonance

Nuclear imaging is currently rarely used, except for Gallium-67 scintigraphy and positron emission tomography using 18 fluorodeoxyglucose in clinically suspected cardiac sarcoidosis. CMR gives morpho-functional information similar to echocardiography, but provides tissue characterization data using contrast sequences (gadolinium).

An International CMR consensus report (Friedrich et al., 2009) in clinically suspected myocarditis recommends the combined use of three techniques (the so-called Lake-Louise criteria), which include: regional or global myocardial signal intensity increase in T2-weighted edema images (myocardial edema); increased global myocardial early gadolinium enhancement ratio between myocardium and skeletal muscle in gadolinium-enhanced T1-weighted image (early myocardial hyperemia); at least one focal lesion with nonischemic regional distribution in inversion recovery-prepared gadolinium-enhanced T1-weighted images, for example, late gadolinium enhancement (LGE) (myocardial necrosis/fibrosis). In myocarditis LGE location is typically subepicardial, often located at the infero-lateral or septal left ventricular wall segments. The combination of these three parameters carries the highest diagnostic accuracy (78%), although correlative data with EMB are still scarce. CMR is not specific for a particular type of myocardial infiltrate (e.g., eosinophilic, lymphocytic) or for a specific etiology (viral vs. autoimmune). In hemodynamically stable patients, CMR may strengthen the diagnostic suspicion of myocarditis before EMB is performed, but, in life-threatening conditions, EMB should be performed as soon as possible. During follow-up CMR can be a valid tool to monitor evolution of myocardial inflammation, especially in virus-negative forms. Conversely a follow-up EMB can proof viral clearance in previously diagnosed viral myocarditis.

Biomarkers

Erythrocyte sedimentation rate (ESR) and C reactive protein (CRP) serum levels are not increased in the majority of myocarditis patients, unless associated pericarditis is present. Cardiac troponins are unspecific markers of cardiomyocyte necrosis and, if normal, do not exclude myocarditis. The same applies to cardiac hormones, for example, natriuretic peptides, and circulating cytokines.

Viral Serology

Serological positivity does not imply an active myocardial infection. In the general population IgG seroprevalence against common cardiotropic viruses is high in the absence of myocardial infection and inflammation. Moreover, noncardiotropic enteroviral infection can induce reactive antibodies indistinguishable from those induced by cardiotropic strains and major studies demonstrated no correlation between viral serology and EMB viral genome positivity. Therefore, the ESC 2013 Task Force did not recommend viral serology in myocarditis patients, except when hepatitis C virus, Rickettsia, Borrelia Burgdorferi, or HIV infections are suspected, especially in high risk groups (Caforio et al., 2013a).

Serum AHAs

In myocarditis/idiopathic DCM patients and relatives, AHAs are directed against various antigens, some of which are cardiac-specific (e.g., organ-specific), others expressed both in myocardium and skeletal muscle (e.g., muscle-specific), as shown in **Fig. 1**. Different aabs have different prevalence between patients and healthy controls (e.g., organ-specific and type 1 cross-reactive AHAs are specific for myocarditis/DCM, whereas some other muscle aabs are not) (Caforio et al., 2013a,b). IgG class aabs, which are specific for heart tissues and myocarditis/DCM, can be used as autoimmunity markers to identify patients candidate to immunosuppressive therapy and their at risk relatives. Some aabs have a demonstrated functional pathogenic role and may have a therapeutic and prognostic potential. The 2013 ESC Task Force recommends AHA testing in patients with clinically suspected or biopsy-proven myocarditis, using one or more of the validated tests, and preferably testing for those AHAs that have a demonstrated good diagnostic accuracy for myocardial inflammatory disease (Caforio et al., 2013a).

Clinically Suspected Myocarditis: 2013 ESC Task Force Criteria

The 2013 ESC Task Force on myocarditis introduced new criteria for clinically suspected myocarditis, to help clinicians in identifying myocarditis, even at centers in which EMB is not routinely performed. In the setting of a compatible clinical presentation, additional criteria from other categories are required to establish a strong clinical suspicion, provided noninflammatory causes of cardiac disease have been excluded.

Clinically suspected myocarditis is defined in the presence of at least one of the compatible clinical presentations (with or without ancillary features) and at least one diagnostic criteria from the four diagnostic categories summarized in Fig. 2, in the absence of:

- Coronary artery disease (stenosis $\geq$50%);
- Previously diagnosed cardiovascular disease or extra-cardiac causes explaining the clinical syndrome (e.g., valvulopathy, congenital diseases, etc.)

The suspicion is higher when an elevated number of criteria is fulfilled; in asymptomatic patients the diagnosis can be established if at least two criteria from the four diagnostic categories have been satisfied, for example ECG abnormalities and increased myocytolysis makers.

In clinically suspected myocarditis, the following anamnestic clues should be carefully reviewed:

- Family history of: DCM, other cardiomyopathies, sudden cardiac death, autoimmune disease;
- Personal history of: a recent (within 2 weeks) viral syndrome of the upper respiratory airways or of the gastrointestinal tract, allergies, extra-cardiac autoimmune diseases, previous clinically suspected or biopsy-proven myocarditis, alcoholism, exposure to toxics or recreational drugs (e.g., cocaine), vaccination, travels to countries at high risk for cardiotropic microbiological agents (e.g., Brazil, Argentina for Chagas cardiomyopathy), domestic animals, classical risk factors for coronary disease, etc. The aim is to identify potentially curable causes of cardiac disease.

Regarding the clinical presentations shown in Fig. 2:

- Infarct-like disease can present with or without global or regional right and/or left ventricular dysfunction, and troponin release pattern can simulate ischemic necrosis or follow a more prolonged course with possible increases in the case of myocarditis reactivation.
- Life-threatening presentations include malignant arrhythmia and aborted sudden cardiac death, cardiogenic shock, and severely depressed left ventricular systolic function.

Biopsy-Proven Myocarditis: Task Force Criteria 2013

In patients with clinically suspected myocarditis, the 2013 ESC Task Force recommends to perform coronary angiography and EMB with histological and immunohistochemical analysis as well as the search of viral genome by polymerase chain reaction (PCR) (Fig. 2). To increase the diagnostic sensitivity of histological analysis and to characterize the inflammatory infiltrate, immunohistochemical analysis uses a panel of monoclonal and polyclonal antibodies, which include antibodies against CD3, a pan-T lymphocyte marker, CD68, a macrophage marker. Anti-HLA-DR staining may identify its increased expression on myocardial tissue, which, in the absence of infection, may identify reversible immune-mediated myocarditis. These recommendations also apply to patients with infarct-like presentation although this specific scenario has not been included in the list of EMB indications listed by the American Heart Association/American College of Cardiology/European Heart Society consensus statement (Cooper et al., 2007). The 2013 ESC Task Force has developed these recommendations based upon the following considerations: (a) EMB complication rate is very low and comparable to that of standard coronary angiography (0%–0.8%); (b) EMB confirms the diagnosis and actually is the only tool that allows etiological diagnosis and etiology-driven therapy; (c) EMB is key for safe and efficacious immunosuppressive therapy in EMB-proven absence of viral genome. Thus, main contributions of EMB are summarized in Table 4.

Clinical Features of Specific Forms of Myocarditis

Infectious, Nonviral, Myocarditis

Lyme disease, caused by Borrelia Burgdorferi, has a wide spectrum of organ involvement and clinical presentations, ranging from asymptomatic cardiac disease to grade I to III atrioventricular block and/or transient or permanent severe heart failure. Advanced atrio-ventricular block may require a temporary pacemaker implantation since, in the majority of cases, it resolves within 1 week from onset.

Trypanosoma Cruzi is a common cause of myocarditis/DCM in central and south America (Chagas cardiomyopathy), characterized by an acute infectious febrile phase followed by a chronic asymptomatic autoimmune phase, lasting till 30 years. This agent is transmitted to humans through a tick's bite. Clinically, the acute phase manifests with heart failure and arrhythmia and usually lasts some months. In about 20% of patients who survive the acute phase, a more chronic disease ensues, leading to DCM, usually after a symptom-free interval of 20 years. The main clinical features are biventricular dilatation with systo-diastolic dysfunction, apical aneurysms of the left ventricle, severe hypo- or hyper-kinetic arrhythmia, partially due to abnormal autonomic nervous system heart firing, intracavitary thrombus formation with cardio-embolization and finally cardiac death.

Toxoplasma gondii myocarditis, often in the setting of fungal coinfection, is typical of seronegative transplanted recipients of seropositive donors, and of immunosuppressed patients, particularly HIV-infected patients, who are at risk of serious life-threatening opportunistic infections.

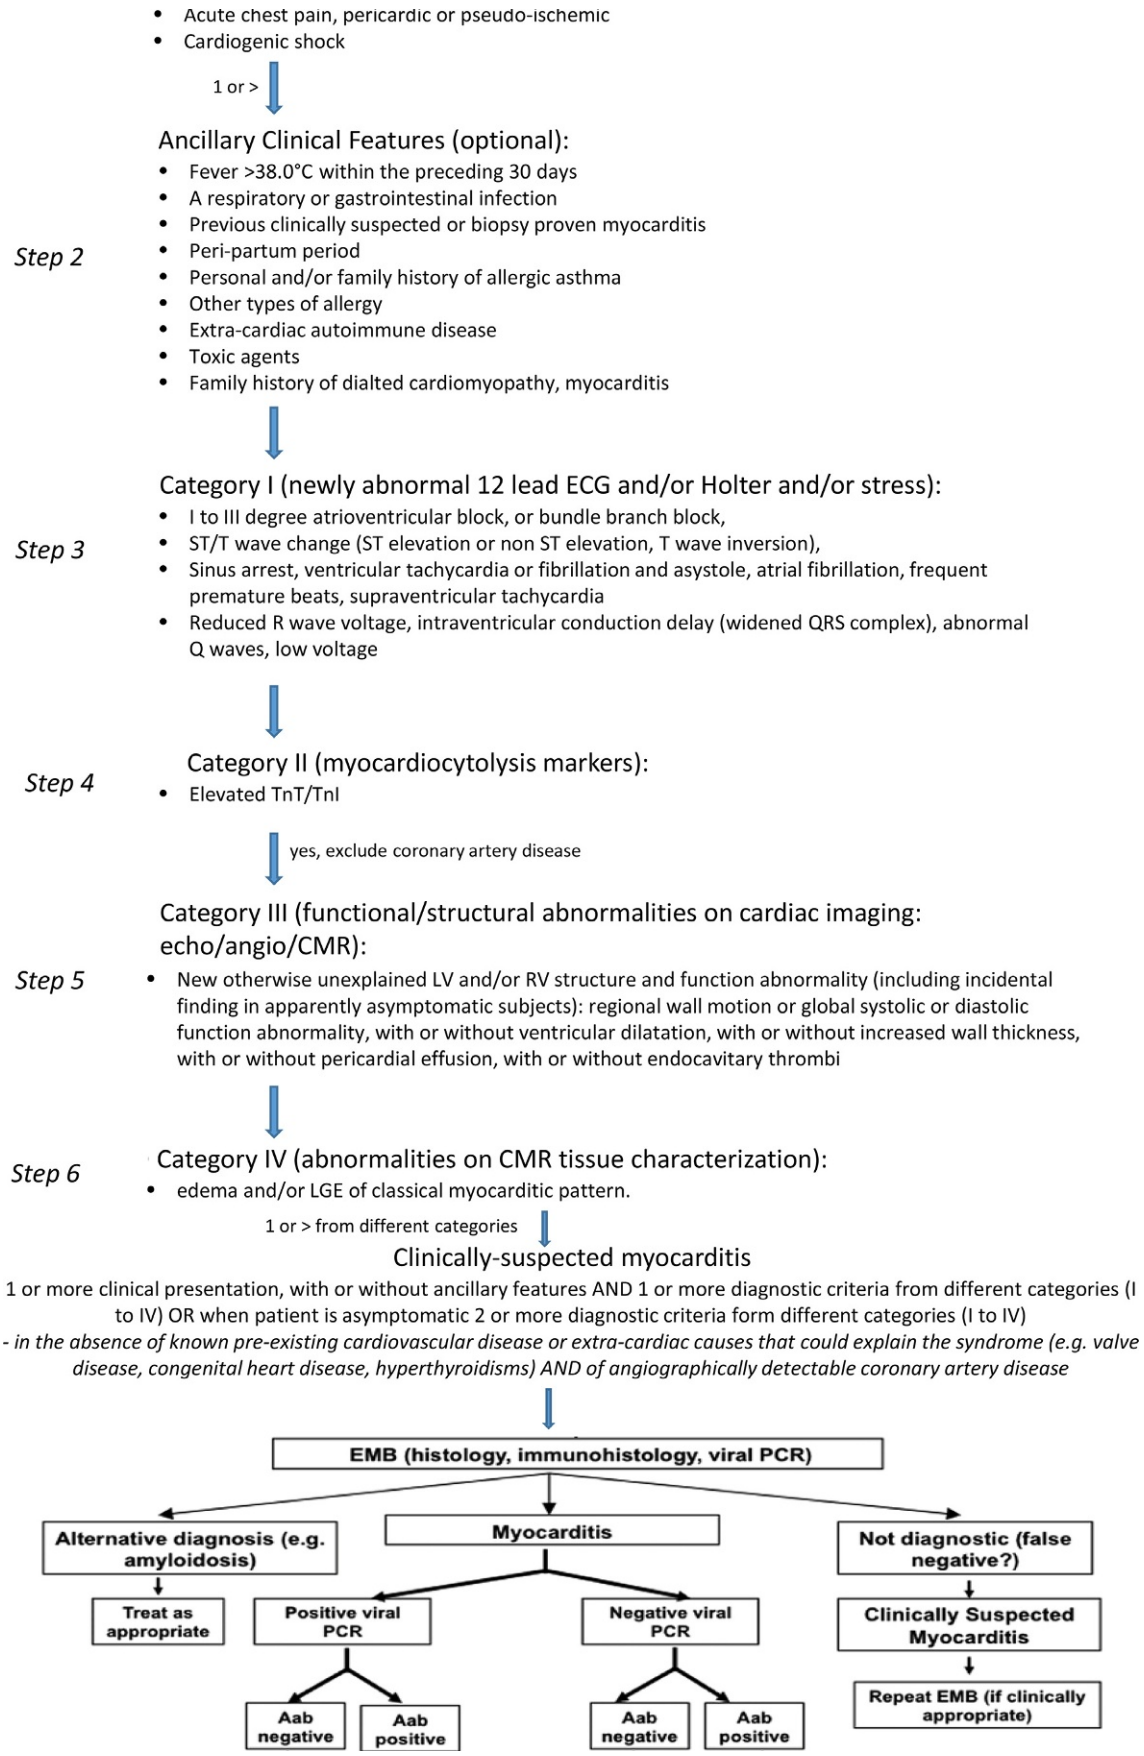

Fig. 2 Diagnostic work-up and etiology-based management in myocarditis according to ESC 2013 Task Force criteria (adapted from Caforio, A., Pankuweit, S., Arbustini, E., et al. (2013) Current state of knowledge on aetiology, diagnosis, management, and therapy of myocarditis: a position statement of the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases. *European Heart Journal* **34**(33), 2636–2648). Myocarditis (acute or chronic, lymphocytic or other inflammatory infiltrate). Dallas criteria positive (active or borderline myocarditis) and/or immunohistology positive (see text), with positive or negative viral polymerase chain reaction (PCR) on endomyocardial biopsy (EMB), with or without a DCM clinical phenotype, with normal or depressed biventricular function. Specific myocarditis types would also be included in this definition according to standard histopathological diagnosis (e.g., giant cell, eosinophilic, polymorphic, granulomatous myocarditis).

Table 4 Contributions of EMB to the diagnosis of myocarditis

- EMB is the gold standard for the diagnosis of myocarditis, provided that traditional Dallas histologic criteria (table) immunological and immunohistochemical criteria are fulfilled
- Absence of infectious agents on EMB, including viral genome detection by PCR, identifies immune-mediated myocarditis, whether primary or post-infectious variant, and supports the use of immunosuppressive agents
- EMB allows definition and identification of specific histopathological patterns of myocarditis (e.g., giant cells, eosinophils, etc.) which may require disease-specific therapeutic approaches and follow-up
- EMB helps ruling out cardiac diseases that can simulate myocarditis (Takotsubo cardiomyopathy, peri-partum cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy (ARVC), infiltrative/storage diseases, cardiac neoplasms)
- EMB complication rate is comparable to that of coronary angiography, if performed by expert operators
- EMB samples can be obtained from left and/or right ventricles according to operator's expertise and preferences
- Immunosuppressive treatment is recommended, in the absence of contraindications, in biopsy-proven infection-negative autoimmune myocarditis (giant-cell, lymphocytic and eosinophilic forms, cardiac sarcoidosis, myocarditis in the context of systemic autoimmune diseases)
- EMB may be repeated during the follow-up to guide posology adjustments and immunosuppression withdrawal

Giant Cell Myocarditis, Sarcoidosis, and SID Associated Myocarditis

Giant cell myocarditis, considered the prototype of autoimmune myocarditis, is a very rare but devastating disease, presenting similarly to other forms of myocarditis, but characterized by an aggressive rapidly progressing course and refractoriness to standard medical therapy. It can be associated with extra cardiac or systemic autoimmune diseases and can relapse in a considerable proportion of transplanted recipients (25%).

Sarcoid cardiac involvement, whether isolated or in the setting of multisystem sarcoidosis, may mimic ARVC. The interventricular septum is preferentially affected resulting in atrio-ventricular conduction abnormalities and/or hypo- or hyper-kinetic arrhythmias. The clinical suspicion of myocarditis in the setting of connective tissue disease or other immune-mediated diseases is based on the same criteria proposed for isolated forms.

Myocarditis and Rheumatic Fever

Myocardial involvement in the setting of acute rheumatic fever (RF) is usually associated with valvular and/or pericardial disease. RF is an inflammatory multisystem disease, occurring few weeks to 6 months following group A streptococcal (GAS) infection of the tonsillopharynx. Its diagnosis is still based upon the 2015 revised Jones' criteria (Dajani et al., 1992; Gewitz et al., 2015) (**Table 5**). Major criteria include: (1) carditis; (2) polyarthritis; (3) chorea; (4) erythema marginatum; (5) subcutaneous nodules. Minor criteria are represented by: (1) fever; (2) arthralgia; (3) elevated ESR or CRP; (4) prolonged P-R interval on standard 12-lead ECG. If supported by evidence of GAS, for example, positive throat culture or rapid streptococcal antigen test, high or rising antistreptococcal antibody titer, the presence of two major criteria (or one major and two minor) indicates a high probability of acute RF. The diagnosis of clinical carditis during acute RF is based upon unequivocal fulfillment of any of the following findings: (1) new onset of nonfunctional cardiac murmurs, (2) cardiac enlargement, (3) sign and symptoms of heart failure, (4) pericardial friction rubs or accumulation of pericardial fluid. Importantly, in the 2015 revised criteria a greater use of echocardiography with Doppler analysis is recommended to confirm clinically suspected carditis, in particular mitral and aortic valvular regurgitation, typical of acute rheumatic carditis (Gewitz et al., 2015). Although RF remains a leading world cause of acquired cardiac disease, EMB-based studies are lacking since RF is rare in Europe and the North America, most of the literature dating back to the 1950s. The histological finding of Aschoff bodies is the hallmark of rheumatic inflammation in the heart (Leone et al., 2012). Rheumatic myocarditis is thought to be a component of acute rheumatic carditis, which also includes pericarditis and valvulitis. However, in acute rheumatic myocarditis, histopathology reveals no necrosis and for this feature there are authors who have questioned that isolated rheumatic myocarditis exists (Leone et al., 2012). When myocarditis is present, high dose steroid therapy should be considered.

Toxic and Hypersensitivity Myocarditis

Hypersensitivity myocarditis, the most prevalent form of drug-induced myocardial toxicity, is unpredictable and dose independent. It can be accompanied by unspecific cutaneous rash, fever, peripheral blood eosinophilia, and general malaise. On the other hand, direct cardiac toxicity is dose dependent, totally or partially reversible and favored by concomitant oncological treatment, for example radiotherapy.

Pediatric Myocarditis

Myocarditis is considered a frequent cause of new-onset DCM in the pediatric age range; some small observational cohort studies have documented a high rate of myocardial recovery in this setting. Most epidemiological data are retrospective, observational, and often based on administrative records. Moreover, the diagnosis of myocarditis is biopsy-proven in a minority of patients. The most

Table 5 Revised 2015 Jones criteria for acute rheumatic fever (ARF)

Criteria	*Low risk populations*[a]	*Moderate-high risk populations*
Major	Clinical or subclinical[b] carditis Arthritis ● Polyarthritis Chorea Erythema marginatum Subcutaneous nodules	Clinical or subclinical[b] carditis Arthritis ● Mono or polyarthritis ● Polyarthralgia Chorea Erythema marginatum Subcutaneous nodules
Minor	Polyarthralgia Fever >38.5°C *ESR* >60 mm in the first hour and/or *CRP* >6 mg/L[c] *Prolonged P-R interval*, age-corrected (unless carditis is a major criterion)	Monoarthralgia Fever >38°C *ESR* >30 mm in the first hour and/or *CRP* >6 mg/L[c] *Prolonged P-R interval*, age-corrected (unless carditis is a major criterion)

Initial ARF diagnosis = evidence of preceding GAS infection and 2 major criteria or 1 major plus 2 minor.

Recurrent ARF diagnosis = evidence of preceding GAS infection and 2 major criteria or 1 major plus 2 minor or 3 minor.

[a]Low risk populations = ARF incidence ≤2 per 100,000 school-aged children or all-age rheumatic heart disease prevalence of ≤1 per 1000 population per year.

[b]Subclinical carditis is defined as presence of valvulitis on echocardiographic and doppler analysis (detailed by Gewitz et al., 2015).

[c]CRP should be higher than the upper limit of normal for laboratory.

Adapted from Gewitz, M., Baltimore, R., Tani, L., et al. (2015). Revision of the Jones criteria for the diagnosis of acute rheumatic fever in the era of Doppler echocardiography: a scientific statement from the American Heart Association. *Circulation* **131**(20), 1806–1818.

prevalent clinical presentations include heart failure, refractory arrhythmia, and syncope. Some high-risk patients may benefit from mechanical ventricular assist protocols, as a bridge to cardiac transplantation or to ventricular recovery, with a survival rate of 73% and complete remission without sequelae in 2/3 of patients. In pediatric myocarditis new longitudinal studies are needed to clarify the prognostic impact of etiological factors and disease severity.

Prognosis

Myocarditis clinical outcome depends on its cause, clinical presentation, and clinical severity at the time of diagnosis. Acute myocarditis spontaneously resolves in about 50% of patients without sequelae in the first 2–4 weeks, in about 25% of patients a persistent ventricular dysfunction ensues, and in 12%–25% of cases worsening cardiac function leads to end-stage DCM with heart failure and need for heart transplant listing. Biventricular dysfunction at presentation represents the main predictor of adverse prognosis. The prognostic value of viral genome detection on EMB has provided controversial results in different studies, with mainly enterovirus persistence being associated with progressive deterioration, viral clearance (spontaneous or drug-induced) with improvement in pump function and 10 years' prognosis (Schultheiss et al., 2011). Conversely, other studies describe a negative prognostic value for chronic immunohistochemical inflammatory findings, not for a positive viral PCR (Kindermann et al., 2008). These discrepancies may relate to different frequency of viral agents in different populations.

Therapy

Standard Cardiological Management

Standard myocarditis treatment includes symptomatic management of arrhythmias and heart failure. Hemodynamically unstable patients are treated in keeping with international heart failure guidelines, and, if necessary, providing advanced respiratory and cardiac support in Intensive Care Units. In refractory cardiogenic shock, with severely depressed ventricular pump function, implantation of an extracorporeal membrane oxygenation system (ECMO) or other mechanical assist devices may be required as a bridge to transplant or to recovery. In hemodynamically stable asymptomatic or mildly symptomatic patients, meeting criteria for clinically suspected myocarditis, admission to the cardiological ward is recommended until a final diagnosis is reached. During the acute phase ergometric testing for inducible ischemia is contraindicated due to the high arrhythmic risk. When heart failure is present, diuretics, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, and then beta-blockers are used until symptoms are well controlled; if symptoms persist, mineralocorticoid receptor antagonists are indicated. Nonsteroidal antiinflammatory drugs are not strictly indicated in myocarditis, since experimental animal studies have demonstrated an increased mortality rate in treated animals. In advanced atrio-ventricular block a temporary pacing may be necessary. Implantable cardioverter defibrillator (ICD) implantation is debatable since myocarditis-induced ventricular pump dysfunction may undergo spontaneous, though unpredictable, recovery. A wearable defibrillator may be considered in young patients with perceived high arrhythmic risk as

a bridge to recovery or definitive ICD implantation. Physical activity, a potential arrhythmia trigger, is contraindicated during the acute phase and until complete resolution of the inflammatory substrate. Athletes and nonathletes should be temporarily excluded from any kind of amatorial or competitive sport activity for at least 6 months. After 6 months, physical activity may be gradually resumed, provided an exercise test is negative for inducible arrhythmia. Athletes should be monitored every 6 months.

Immunomodulating Therapy

Antiviral therapy with acyclovir, ganciclovir, or valaciclovir may be considered in patients with biopsy-proven active herpesvirus myocardial infection, although its efficacy is unproven in myocarditis (Caforio et al., 2013a,b). Preliminary data are available for interferon beta treatment of enteroviral or adenoviral myocarditis, showing improved NYHA class and prognosis (Kühl et al., 2012). In general terms, an interdisciplinary approach including infectious disease specialists and clinical immunologists is advisable. High dose intravenous immunoglobulin (IVIG) treatment is a standard therapeutic approach in some systemic autoimmune diseases and has shown some therapeutic advantage in terms of improving ventricular function and prognosis in chronic symptomatic heart failure of various causes (Gullestad et al., 2001). Conversely, IVIG had a neutral effect in the IMAC trial of recent-onset DCM where only 15% of patients had biopsy-proven myocarditis of unspecified etiology (McNamara et al., 2001), but therapy was well tolerated. IVIG may be used in biopsy-proven infectious or autoimmune, particularly autoantibody-mediated, myocarditis, refractory to standard management (Caforio et al., 2013a). IA, by removing pathogenic serum aabs, might represent a promising therapeutic option in autoimmune myocarditis/DCM. Small randomized trials in selected DCM patients have demonstrated improvement of pump function and reduced inflammatory myocardial infiltration in treated patients (Felix et al., 2000). A larger multicentric trial is ongoing to confirm these preliminary results and justify the routinary use of such a highly expansive technique.

Immunosuppressive Treatment

The results of immunosuppressive treatment in biopsy-proven virus-negative myocarditis and inflammatory cardiomyopathy are extremely promising, both in terms of efficacy and safety. Immunosuppression efficacy has been proven in virus-negative, giant-cell and lymphocytic autoimmune myocarditis. The most frequently adopted regimen in clinical trials includes the use of prednisone 1 mg kg^{-1} day^{-1} for 4 weeks, then tapered to 0.33 mg kg^{-1} day^{-1} for 5 months, and azathioprine 2 mg kg^{-1} day^{-1} for 6 months (Frustaci et al., 2009). In giant-cell myocarditis, in light of its particularly aggressive course, intensified immunosuppressive regimens are usually adopted, including, beside prednisone and azathioprine, cyclosporine, anti-thymocyte globulins, and biologics (alemtuzimab, rituximab) (Cooper et al., 2008). Both careful selection of patients and exclusion of potential contraindications and comorbidities are key points in the therapeutic strategy. A constant dialog between cardiologists and clinical immunologist is essential for this purpose. In this emerging field of cardiology, EMB reveals its important diagnostic and therapeutical role (**Table 4**).

For specific myocarditis forms, immunosuppression is actually an established therapy, but further data from multicentric randomized trials are needed to optimize therapeutic regimens and duration. Moreover, the same approach will pave the way to test new antiviral and immunomodulatory drugs in virus-positive patients that, at present, are not candidates to immunosuppression.

Myocarditis is a specific phenotype of cardiac disease, characterized by inflammatory involvement of the myocardium and, sometimes, pericardium. Though the diagnosis is strictly defined by established histological (Aretz et al., 1987), immunological, and immunohistochemical criteria (Caforio et al., 2013; Leone et al., 2012), clinical presentation is highly variable, ranging from asymptomatic myocarditis to over heart failure or even sudden death (Sinagra et al., 2016; Anzini et al., 2013, 2016). Modern techniques of cardiovascular imaging and the exhaustive molecular evaluation of the myocardium with endomyocardial biopsy have provided valuable insight into the pathophysiology of this disease. Moreover patient-tailored diagnostic and therapeutic management appear pivotal to improve outcomes of these patients. Nevertheless, many gaps of knowledge persist in crucial issues of the practical management of patients with suspected myocarditis. In particular the prompt management, the early accurate prognostic stratification of patients with myocarditis, the indications, and the role of endomyocardial biopsy and cardiac magnetic resonance are currently challenging tasks for clinical cardiologists.

Epidemiology and Etiology

The incidence of myocarditis in the real world is very difficult to establish because of the large heterogeneity of clinical presentation of the disease and challenging diagnosis. Its prevalence changes considerably in relationship to the population under study and to the adopted diagnostic criteria. A recent epidemiological study identified myocarditis as the final diagnosis for 0.5% of all hospital admissions for cardiovascular reasons, frequently affecting a young population of mainly male patients (Kyto et al., 2013). Previous studies detected myocarditis on endomyocardial biopsy (EMB) in 10%–17% of patients with otherwise unexplained cardiomyopathy (Hufnagel et al., 2000; Felker et al., 2000). Similarly, myocarditis was found in 5% of individuals in a series of unselected and consecutive autopsies, but the disease was considered the main cause of death in only a minority (Carniel et al., 2004). In this sense, it appears that myocarditis is underdiagnosed.

Myocarditis can be triggered by different causes: infections (i.e., viruses, bacteria, parasites), autoimmune diseases, hypersensitivity, high catecholamine states, drugs, toxic substances, or physical agents (Dennert et al., 2008). Autoimmune myocarditis may occur with exclusive cardiac involvement or in the context of autoimmune disorders with extracardiac manifestations, most frequently in sarcoidosis, hypereosinophilic syndrome, scleroderma, and systemic lupus erythematosus. Hypersensitivity myocarditis may result from drug- or vaccine-related heart-specific autoimmunity. Methyldopa, hydrochlorothiazide, furosemide, ampicillin, tetracycline, azithromycin, aminophylline, phenytoin, benzodiazepines, tricyclic antidepressants, and tumor necrosis factor antagonists all have a low rate of myocarditis (Burke et al., 1991). Although most cases of hypersensitivity myocarditis develop early in the course of drug use, up to 15% of clozapine-induced myocarditis develops later, up to 2 years after initiation of drug therapy (Cook et al., 2015; Youssef et al., 2016; Haas et al., 2007). Bacteria, such as diphtheria and Borrelia burgdorferi (Lyme disease), or parasites, such as Trypanosoma cruzi (Chagas disease), are very important in specific regions (Marin-Neto et al., 2007; Karatolios et al., 2015).

Although the several causes listed above most of cases of myocarditis observed in clinical practice are attributable to viral infections. In particular, even when no viruses are detected by serologic and polymerase chain reaction (PCR) analyses, an unrecognized viral infection remains the most probable cause of the so-called idiopathic myocarditis. These cases are presumably observed in an advanced phase (usually 3 or 4 weeks after the infection) when the immune system has already achieved a complete clearance of the virus (Anzini et al., 2013). In the past 2 decades, polymerase chain reaction and in situ hybridization have identified a range of cardiotropic viruses, including enterovis, adenovirus, influenza viruses, human herpes virus-6 (HHV-6), Epstein–Barr virus, cytomegalovirus, Hepatitis C virus, and parvovirus B19 in heart biopsy samples. Even if the etiologic role of the viruses is undoubtable, their role in maintaining the chronic inflammatory process is controversial.

Pathophysiology

Several above-mentioned noxae may damage the myocardium, directly and indirectly. Although the viruses are the most frequent (i.e., about 90%) cause of myocarditis encountered in clinical practice, the pathophysiology of viral myocarditis remains widely

unknown. This is the main reason of the lack of specific and reliable therapies for this polymorphic disease. The time course of the myocarditic process consequent to viral infection may be resembled in three distinct phases (Pollack et al., 2015; Dennert et al., 2008; Sinagra et al., 2016):

1. *The acute phase*. In predisposed subjects, acute viral infection may harm the myocardium. Viruses are internalized leading to activation of innate immune response, viral myocytolysis, virus-mediated apoptosis/necrosis, or production of autoantibodies against the infected myocyte. In this phase the viral titer is generally high. Usually this phase takes up to 7 days and the diagnosis is done often later to this phase.
2. *The intermediate phase*. Innate immunity stoops to acquired immune response, thus infiltration of T-cells and macrophage may be found in the injured myocardium. Also in this phase elevated viral titers may be found. This phase typically lasts from 7 days to 1 month, depending on the clinical presentation. This phase, indeed, is generally characterized by severe symptoms/arrhythmias.
3. *The chronic phase*. This phase is characterized by either complete resolution or evolution to end-stage postinflammatory cardiomyopathy (Anzini et al., 2013). Indeed, as viral titers decrease, inflammation usually subsides leading to complete resolution of myocardial injury and normalization of cardiac function. However, chronic inflammatory and host innate immunity activation may lead to the development of dilated cardiomyopathy and end-stage heart failure with possible need for heart transplantation (Pollack et al., 2015). The role of viral genome persistence within the myocytes in the chronic inflammatory myocardial process remains extremely controversial (Kuhl et al., 2005). Indeed some of those viruses (i.e., Parvovirus B19) has been found also in nonmyocarditic patients (Moimas et al., 2012); similarly the prognostic role of persistent viral genome in cardiomyocytes is still debated (Kindermann et al., 2008).

Although pathophysiology appears to be straightforward, clinical presentation and natural history of myocarditis is extremely polymorphic and unpredictable. Both the nature of the infectious agent (i.e., virus or bacteria) and individual predisposition may contribute to the wide range of clinical presentations and several human–host factor interactions, such as the formation of the inflammasome (Toldo et al., 2014), might favor myocarditis, influence the severity of process, or protect from myocardial inflammatory injury. However, the gap of knowledge linking pathophysiology to the different clinical presentations remains still unfilled.

Clinical Features and Diagnosis

As stated earlier, the clinical presentation of myocarditis is extremely variable. Indeed it ranges from subclinical and asymptomatic forms to severe heart failure, life-threatening ventricular arrhythmias, and ultimately to sudden death (Anzini et al., 2013).

According to the most important studies and recent statement (Caforio et al., 2007, 2013; Anzini et al., 2013), clinical presentation of myocarditis is grouped into three main categories:

- recent-onset heart failure (usually within 6 months)
- arrhythmic events
- infarct-like syndrome (the so-called myopericarditis or perimyocarditis).

Clinical suspicion of inflammatory heart disease is crucial in the evaluation of patients admitted with one of the above-mentioned scenarios. Indeed, exclusion of other etiologies, such as ischemic heart diseases, valvular heart diseases, congenital heart diseases, and hypertensive cardiomyopathy, should be made rapidly and possibly precede the diagnosis of myocarditis (Caforio et al., 2013).

Recently, practical and clinically oriented classification of myocarditis has been proposed based on event-risk derived by clinical and laboratory presentation and short-term evolution (Sinagra et al., 2016). This classification has important implications in management and prognostic stratification of those patients. Indeed, patients with myocarditis can be divided into three different subcategories (**Fig. 1**):

1. *Low risk myocarditis*: usually presenting with chest pain and/or supraventricular arrhythmias with preserved left ventricular function. This clinical scenario often has a rapid (1–4 weeks) and complete resolution of the electrocardiographic and echocardiographic abnormalities with good long-term prognosis.
2. *Intermediate risk myocarditis*: characterized by mild-to-moderate ventricular dysfunction with persistent wall motion abnormalities, presence of LGE, electrocardiographic changes, and nonsustained ventricular arrhythmias.
3. *High risk myocarditis*: usually presenting with recent-onset severe left ventricular dysfunction and heart failure and/or life-threatening arrhythmias. Typically prognosis is highly dependent on the short-term response to therapy.

Common diagnostic tools, such as personal history, biochemical, ECG, and Echocardiographic features, are the cornerstones for the clinical suspicion of myocarditis. Each test has specific indications and some hurdles, and their potential applications in this clinical setting are summarized in **Table 1**. Those tests should drive clinicians to further assessment with cardiac magnetic resonance and/or endomyocardial biopsy.

Cardiac magnetic resonance imaging (MRI) represents the gold standard for morphofunctional evaluation of cardiac structures and characterization of the myocardium, providing useful diagnostic and prognostic information in various clinical settings (Francone et al., 2014; Caforio et al., 2007). In patients with low risk myocarditis, particularly in patients with infarct-like onset, cardiac MRI has a good accuracy and allows a distinction between myocarditis and acute coronary syndromes (subepicardial vs

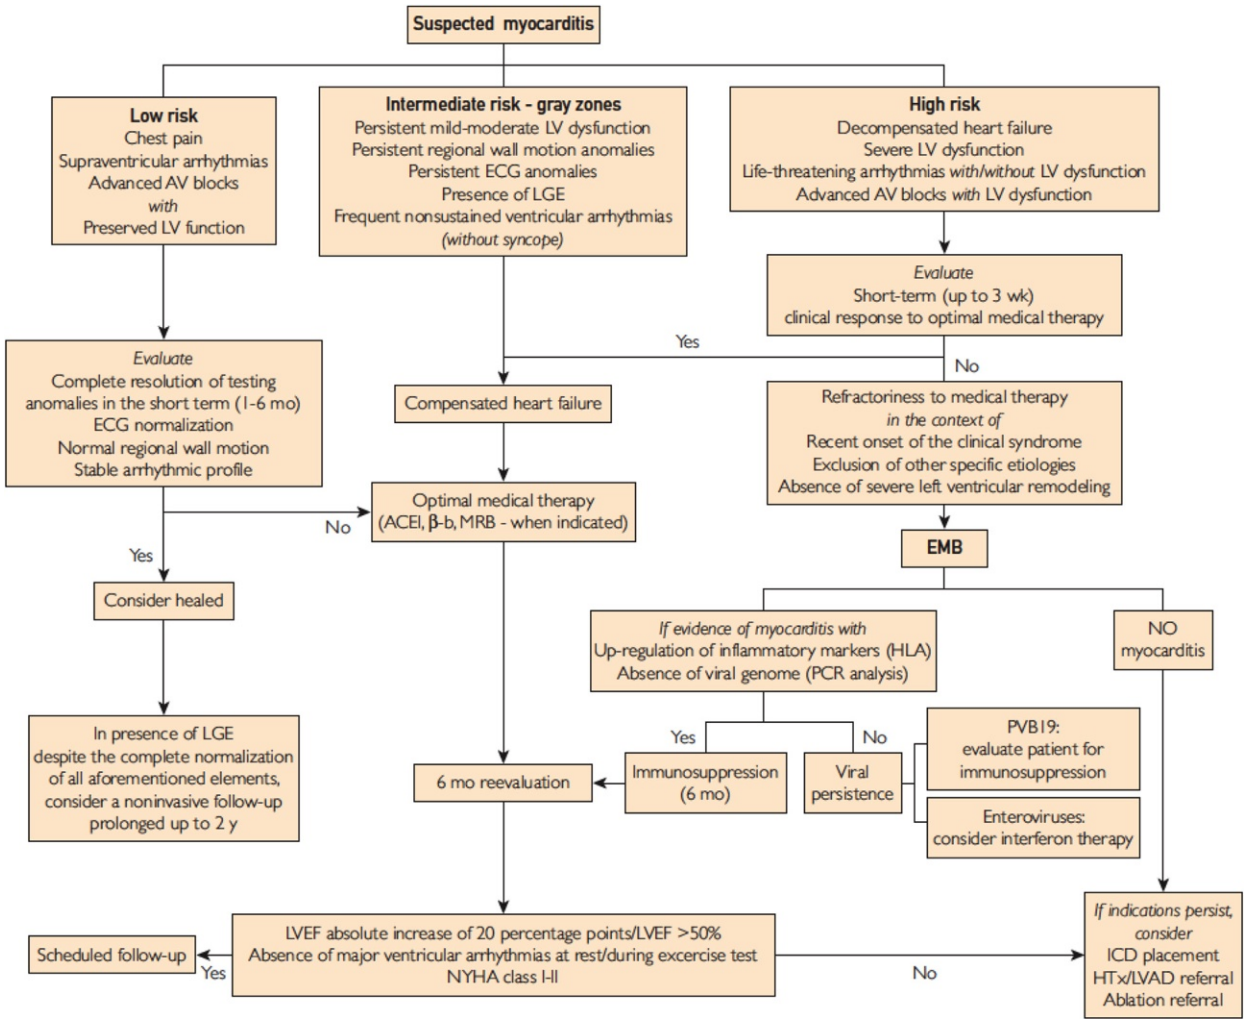

Fig. 1 Clinical work-up for suspected myocarditis. *ACE-i*, angiotensin-converting enzyme inhibitors; *AV*, atrio-ventricular; *β-b*, beta-blockers; *EMB*, endomyocardial biopsy; *HTx*, heart transplantation; *ICD*, implantable cardioverter-defibrillator; *LGE*, late gadolinium enhancement; *LV*, left ventricular; *LVAD*, left ventricular assit device; *LVEF*, left ventricular ejection fraction; *MRB*, mineralcorticoid receptor blockers; *PVB19*, Parvovirus B19. Adapted from Sinagra, G., Anzini, M., Pereira, N. L., et al. (2016). Myocarditis in clinical practice. *Mayo Clinic Proceedings* **91** (9), 1256–1266.

subendocardial/transmural LGE distribution) (Lurz et al., 2012). MRI should be performed on the right time in order to be accurate, and the low accessibility of this technique currently still represents a concern. In high- and intermediate-risk forms cardiac MRI has modest diagnostic accuracy, in fact the edema in T2-weighted images may be absent, its presence highly depends on the time of MRI performance. In patients with biopsy-proven viral myocarditis the presence of myocardial scar, indicated by LGE, is the best independent predictor of all-cause mortality and cardiac mortality; no data are available about the prognostic value of additional cardiac MRI-related parameters, such as the pattern of distribution and the extension of LGE (Grun et al., 2012). These data support the need for future prospective studies to establish the prognostic role of LGE in viral myocarditis, as well as to evaluate the incremental value of additional MRI parameters.

Noteworthy, the role of endomyocardial biopsy (EMB) is still controversial (**Fig. 1**). Though this test is the gold standard for the diagnosis of myocarditis, it remains associated with a nonnegligible rate of major complications, even in specialized Centers (around 1% of the cases) (Chimenti and Frustaci, 2013; Yilmaz et al., 2010). Furthermore, diagnostic accuracy and yield of EMB is still debated, highly depending on the operator experience who performs the EMB and who analyze the samples obtained, on the number and the location of tissue samples and, finally, on the timing of the EMB. Although no clear recommendations are available, biventricular approach is preferred (Yilmaz et al., 2010; Sinagra et al., 2016). Besides, the possible usefulness of cardiac magnetic resonance imaging in selecting the site of biopsy is still not demonstrated (Yilmaz et al., 2010). Therefore, EMB should be performed only in selected life-threatening scenarios, such as heart failure with severe ventricular dysfunction and/or life-threatening arrhythmias refractory to optimized medical therapy in the short term (usually 3 weeks) (Heymans et al., 2016; Sinagra et al., 2016). In low-risk myocarditis, typically characterized by a good long-term prognosis, EMB could not provide useful information and be potentially harmful for the patients (Imazio et al., 2013; Buiatti et al., 2013; Pollack et al., 2015; Sinagra

Table 1 Role and typical findings of noninvasive testing and endomyocardial biopsy in the diagnostic work-up of myocarditis

	Low risk	*Intermediate Risk*	*High risk*
Personal history	Flu-like symptoms: 35%–65% of cases; insect bite (for borrelia or ricketsiae suspicion). Not to be considered in the diagnostic work-up.		
Biomarkers	Troponin tipically elevated (without prognostic value). *Antimicrobial serology*: low accuracy for detection of myocardial infection. Not to be routinely considered in the diagnostic work-up. It may be useful to detect infections by Borrelia or Rickettsia in the presence of bradyarrhythmias, advanced AV blocks, and clinical suspicion. *Serologic analyses for autoimmune diseases*: should be considered only in presence of clinical suspicion.	Troponin and acute phase reactants: low accuracy for detection of myocardial inflammation.	
Electrocardiography	Diffuse and saddle-shapes ST segment elevation. Bradyarrhythmias or advanced AV conduction defects in the absence of LV dysfunction may be suggestive for infections by borrelia or rickettsia.	Low voltages. Discordance between the severity of the clinical scenario and the "scarcity" of electrocardiographic alterations (absence of left atrial dilation and left intraventricular conduction delay). Bradyarrhythmias or advanced AV conduction defects in the presence of LV dysfunction may be suggestive for sarcoidosis or giant cell myocarditis.	
Echocardiography	Normal ventricular dimensions, morphology,wall motion and global function. Transient wall motion anomalies. Transient mild ventricular dysfunction. Pericardial effusion.	Global impairment of left or biventricular function without significant remodeling. Diastolic dysfunction. Patchy alterations of the wall motion not respondent to coronary distribution or electrocardiographic alterations. Pericardial effusion. Transient pseudohypertrophy of the ventricular wall. Alteration of the echocardiographic myocardial texture.	
Cardiac magnetic resonance	Good accuracy. Distinction between myocarditis and acute coronary syndromes (subepicardial vs subendocardial/ transmural LGE distribution).	Modest accuracy. May be considered a conclusive diagnostic test.	Modest accuracy. Cannot be considered a conclusive diagnostic test in the context of a major clinical syndrome.
Coronary angiography	Evaluate risk factors for coronary artery disease.	Evaluate risk factors for coronary artery disease.	Indicated.
Endomyocardial byopsy	Not indicated.	Controversial.	Indicated in presence of refractoriness to medical therapy*in order to*evaluate potential reversibilityand plan eventual specific therapy.

Adapted from: Sinagra, G., Anzini, M., Pereira, N. L. et al. (2016). Myocarditis in clinical practice. *Mayo Clinic Proceedings* **91** (9), 1256–1266.

et al., 2016). In intermediate-risk syndromes, EMB may be considered and a case-by-case decision is mandatory in these patients (Sinagra et al., 2016).

Natural History and Prognostic Stratification

According to their initial presentation, patients with myocarditis appear to have different prognosis (Pollack et al., 2015; Anzini et al., 2013). For a long time, clinical presentation was considered a major predictor of worse outcomes (Caforio et al., 2007). Indeed, prognosis of patients presenting with overt heart failure is significantly worse than those presenting with chest pain and patients presenting with life-threatening arrhythmias show an intermediate outcome (Mason et al., 1995; Magnani and Dec, 2006; Anzini et al., 2013; Caforio et al., 2007). Actually, recently it is emerged the independent role of LV dysfunction and derangement. Patients with preserved LV function at diagnosis have better prognosis compared to patients with severe LV and biventricular dysfunction. Similarly the presence of late gadolinium enhancement at cardiac magnetic resonance, expression of myocardial fibrosis, is associated with worse outcome. Other important markers, such as syncopes, prolonged QRS duration, left bundle branch block, pulmonary hypertension, have to be taken into account and are expression of myocardial involvement (Kindermann et al., 2012). Finally even in the prognostication of the most challenging myocarditis patients (i.e., those presenting with life-threatening arrhythmias) left ventricular ejection fraction (LVEF) <35%, the presence of 2 or more contiguous akinetic segments or aneurysmatic deformation at the baseline echocardiography, the presence of Late Gadolinium Enhancement (LGE) at the baseline CMR, may predict worse outcomes (Anzini et al., 2013, 2016). Extensive ventricular remodeling at the time of admission may be the expression of a severe and irreversible structural derangement predicting worse prognosis during the follow-up. An exception is represented by patients with aggressive clinical presentation, such as cardiogenic shock and fulminant myocarditis, that appear to

have better outcomes than acute nonfulminant myocarditis once the acute phase of the disease has been resolved (McCarthy et al., 2000). Specific subtypes, such as giant cell myocarditis, necrotizing eosinophilic myocarditis, or cardiac sarcoidosis, have worse 5-year prognosis without immunosuppressive treatment or advanced mechanical support (Baughman, 2006; Vaideeswar and Cooper, 2013; Chaudhry et al., 2015).

Management and Treatment

Therapeutic regimens and intensity of treatment change according to initial presentation, severity of symptoms, and LV involvement. Currently, therapy for myocarditis is focused on supportive care and on heart failure/arrhythmias management (Caforio et al., 2013).

In the setting of myopericarditis (i.e., concomitant myocardial involvement in pericarditis), management is similar to that recommended for pericarditis (Adler et al., 2015). Prognosis of myopericarditis, with absent or mild left ventricular dysfunction, and without symptoms of heart failure, is benign. Therefore endomyocardial biopsy is not indicated for definite diagnosis (Adler et al., 2015).

Long-term arrhythmic risk of patients with myocarditis presenting with sustained ventricular tachyarrhythmias without LV dysfunction is still unclear, and current guidelines do not provide clear indications for Implantable Cardioverter Defibrillator (ICD) for these patients (Priori et al., 2015). However, clinical and instrumental characteristics at baseline may be helpful to predict the risk of arrhythmic events in this setting of patients (Anzini et al., 2016). Therefore indications for ICD implantation should be individually evaluated according to clinical presentation (i.e., aborted sudden cardiac death or syncope), the magnitude of structural–functional ventricular derangement (i.e., ventricular remodeling, presence of akinetic segments or aneurysmal deformation, extent of LGE), histopathological substrate (i.e., cardiac sarcoidosis or giant cell myocarditis), and therapeutic response to standard care (Anzini et al., 2013, 2016). In patients with active myocarditis and severe left ventricular dysfunction, major clinical decisions like the indication for a prophylactic ICD should be deferred for at least 3–6 months, and in this intermediate phase a LifeVest wearable defibrillator could be considered for sudden cardiac death prevention.

Hemodynamically unstable patients presenting with fulminant or severe myocarditis and cardiogenic shock should be immediately referred to intensive care units possibly with availability of invasive hemodynamic support, such as left ventricular assist device (LVAD) or extracorporeal membrane oxygenator (ECMO) (Ponikowski et al., 2016; Hsu et al., 2011).

Patients presenting with acute myocarditis and severe left ventricular dysfunction without cardiogenic shock should be avoided in the short term (3–6 months) from aggressive invasive managements, such as heart transplantation, left ventricular assist device, or prophylactic implantable cardioverter defibrillator, unless refractoriness to standard therapy in the short term (Anzini et al., 2013). Likewise, inotropic support should be considered in cardiogenic shock. Treatment with angiotensin-converting enzyme inhibitors (ACE-I) or angiotensin receptor blockers (ARBs), beta-blockers, and additional treatment with mineralocorticoid receptor antagonists (MRAs) and diuretics should be promptly initiated and uptitrated to the maximum tolerated dosage (Ponikowski et al., 2016; Pollack et al., 2015; Sinagra et al., 2016; Anzini et al., 2013).

As stated earlier, baseline left ventricular function is an important prognostic marker regardless of clinical presentation, the reassessment of the ejection fraction after 6 months appears to be also more useful for predicting long-term outcomes. Patients who experience an increase of LVEF $>20\%$ or have LVEF $\geq 50\%$ and a low NYHA functional class at 6 months demonstrated an excellent long-term prognosis (Anzini et al., 2013). Also in this setting, LifeVest wearable defibrillator can be considered during the reassessment time period of 3–6 months.

Treatment with nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided in this setting because they have been associated with higher mortality rate in animal models of acute viral myocarditis (Costanzo-Nordin et al., 1985; Feldman and McNamara, 2000).

Treatment with immunomodulating agents, such as steroids, immunosuppression, antiviral drugs, and intravenous immunoglobulin, is still controversial. Though some trials showed improvement of left ventricular function (Frustaci et al., 2009; Wojnicz et al., 2001), large randomized studies on the use of immunosuppression are not available and recent meta-analysis showed that immunomodulation did not have positive impact on outcomes of patients with myocarditis (Caldeira et al., 2015). Immunosuppressive therapy with prednisone and azathioprine appears to be suitable for patients with EMB-proven active myocarditis with major clinical symptoms such as HF with severe ventricular dysfunction and/or life-threatening ventricular arrhythmias in whom conventional treatments have failed in the short term of 7–10 days. In lymphocytic myocarditis, immunosuppressive treatment should be considered only in the absence of the viral genome on EMB, whereas giant cell myocarditis, necrotizing eosinophilic myocarditis, and cardiac sarcoidosis represent clear indications for immunosuppressive therapy (Frustaci et al., 2009; Pollack et al., 2015; Sinagra et al., 2016). However the role of persistent viral genome in cardiomyocytes is still unclear. In particular the role of parvovirus B19, recently emerged as an endemic virus encountered with similar frequency in almost half of patients with dilated cardiomyopathy (Moimas et al., 2012) or other noninflammatory heart diseases (Kubanek et al., 2012), is still controversial. Therefore, careful and comprehensive evaluation is a priority to guide the selection of patients at higher risk who could benefit from a comprehensive molecular evaluation of the myocardial substrate with EMB (Pollack et al., 2015; Sinagra et al., 2016).

IFN-beta-1b treatment given over 24 weeks to patients with chronic viral cardiomyopathy and moderate heart failure is safe, can eliminate or reduce the virus burden, ameliorates symptoms, and diminishes physical disability; however the role of interferon

treatment in acute myocarditis is still debated. Currently it seems to be limited to the presence of entero-virus and its efficacy on hard end-point is not yet demonstrated (Schultheiss et al., 2016; Sinagra et al., 2016).

Conclusions

Myocarditis remains a challenging clinical scenario. Often under-diagnosed, essentially due to variable clinical presentation, prompt diagnosis and tailored therapy often lead to favorable outcomes and to almost complete *restitutio ad integrum*. However still much has to be done to deeply investigate pathophysiology and to improve treatment of this condition.

Risk stratification is, at the moment, the most important tool for the management of this disease. Conservative managements should be reserved to low-risk patients while progressively more intensive treatments should be pursued for life-threatening situations.

Neurohormonal Blockade

Overview

Chronic activation of neurohormonal pathways has deleterious effects on the cardiovascular system and has been the focus of considerable study in heart failure (HF). Following a cardiac insult such as a myocardial infarction (MI) or exposure to a myocardial toxin or stress there is activation of neurohormonal compensatory mechanisms. The goal of these compensatory mechanisms is to maintain cardiac output and end-organ perfusion in the setting of myocardial function compromise. In acute and subacute states, following an initial drop in cardiac function, these mechanisms are of benefit to the host; however, chronically they play a role in the progressive decline of myocardial function and ventricular remodeling (Jessup and Brozena, 2003).

Immediately following a myocardial insult, baroreceptors within the aorta and the myocardium recruit the sympathetic nervous system (SNS) to maintain homeostasis. The SNS primarily mediates its effects via catecholamines and provides signaling within the heart, kidneys, brain, and musculature. Subsequently, stimulation from the SNS as well as intrinsic renal mechanisms activates the renin-angiotensin and aldosterone system collectively referred to as the RAAS. The combined effect of the two systems leads to increased myocardial inotropy, chronotropy, sodium and water retention (leading to an increase in pre-load), and vasoconstriction (causing an increase in afterload). These effects over the short term help maintain cardiac output (CO) and blood pressure (BP) (**Fig. 1**). However, chronic activation of these neurohormonal systems results in increased hemodynamic stress and deleterious effects on the heart and vasculature which cause disease progression in HF. This is referred to as the *neurohormonal hypothesis* (Packer, 1992).

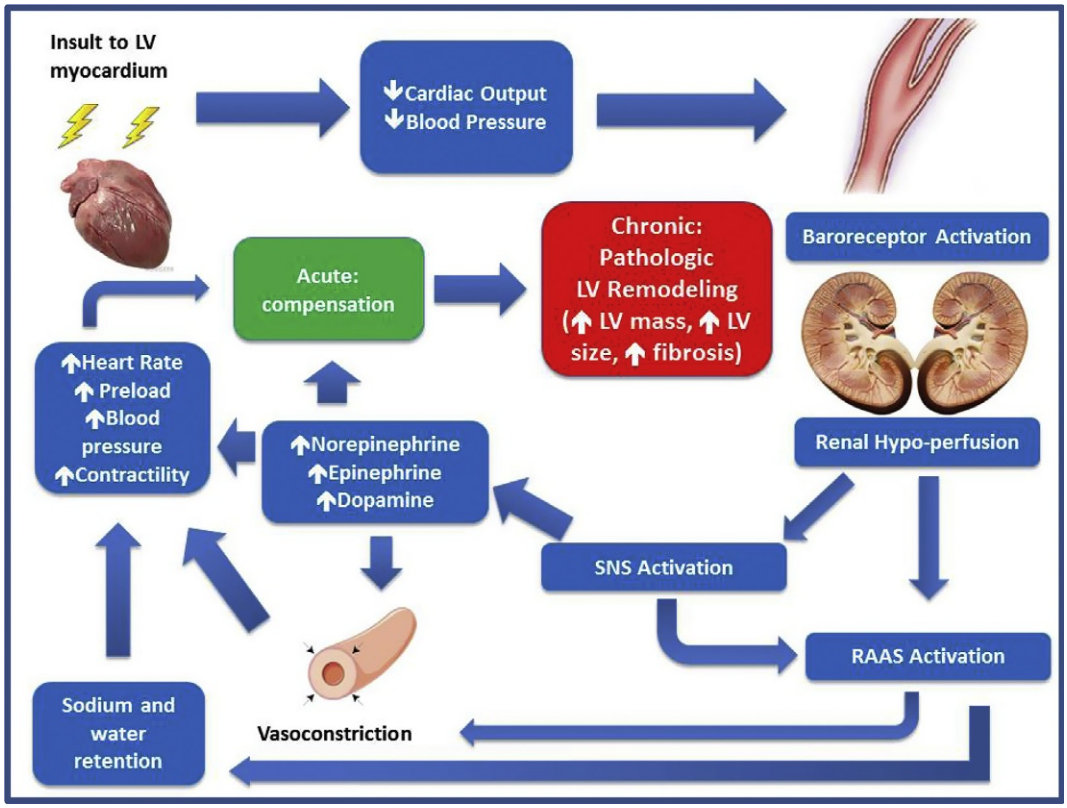

Fig. 1 The pathophysiology of HF with activation of the renin-angiotensin-aldosterone system and sympathetic nervous system. *LV*, left ventricle; *RAAS*, renin-angiotensin-aldosterone system; *SNS*, sympathetic nervous system.

Normally, several feedback pathways are activated to offset the actions of RAAS. For example, the natriuretic peptides cause vasodilation and natriuresis, and have antifibrotic effects that can counterbalance the effects of the RAAS. However, in HF there is increased peripheral resistance to natriuretic peptides thus potentiating the effects of the RAAS (Volpe et al., 2016).

Currently, medical therapies that have demonstrated benefit in the treatment of HF with reduced ejection fraction (HFrEF) block the RAAS and the SNS, and augment the beneficial effects of the natriuretic system. These agents have incremental benefit through reduction of clinical symptoms, morbidity, and mortality. While these therapies do have hemodynamic effects, their alteration of neurohormonal signaling appears to dictate their beneficial effects on long-term clinical improvements and outcomes (Packer, 1992). Although much better studied in HFrEF, regardless of the etiology, some of these mechanisms may play a role in HF with preserved ejection fraction (HFpEF).

Renin-Angiotensin-Aldosterone Receptor Blockade

The RAAS has been characterized in detail through investigation of HF treatment. The cascade begins with renin causing cleavage of angiotensinogen, produced by the liver, to form the peptide angiotensin I. Renin is produced in the kidneys as a result of increased sympathetic tone, decreased systolic BP perceived at the juxtaglomerular cells, or decreased sodium or chloride ion delivery to the macula densa. Angiotensin I is an inactive peptide which is cleaved by angiotensin converting enzyme (ACE) to angiotensin II, which is the end product of the cascade. Angiotensin II produces its long-term deleterious effects predominantly through the angiotensin II receptor-type 1 (AT1) receptors which have been described in the heart, brain, kidneys, adrenal tissue, adipocytes, and vascular smooth muscle.

The RAAS causes vasoconstriction, and sodium and water retention (Packer, 1992; Burnier and Brunner, 2000; Hartupee and Mann, 2016). The AT_1 receptor stimulation causes cellular migration, proliferation, hypertrophy, and hyperplasia of fibroblasts with increased extracellular matrix deposition in the myocardium and vasculature. Finally, these systems lead to myocardial fibrosis, remodeling of the left ventricle (LV), and alterations in the vasculature resulting in endothelial dysfunction. LV remodeling describes the changes in LV mass, volume, and shape and in the composition of the heart after injury or abnormal hemodynamic loading (Mann and Bristow, 2005; Shah and Mann, 2011; van Berlo et al., 2013) (**Figs. 1** and **2**). Direct myocyte stimulation leads to cellular hypertrophy and an increase in cellular volume. Grossly the LV increases in volume (dilates), develops thinned walls, and becomes more spherical in shape due to the increased volume.

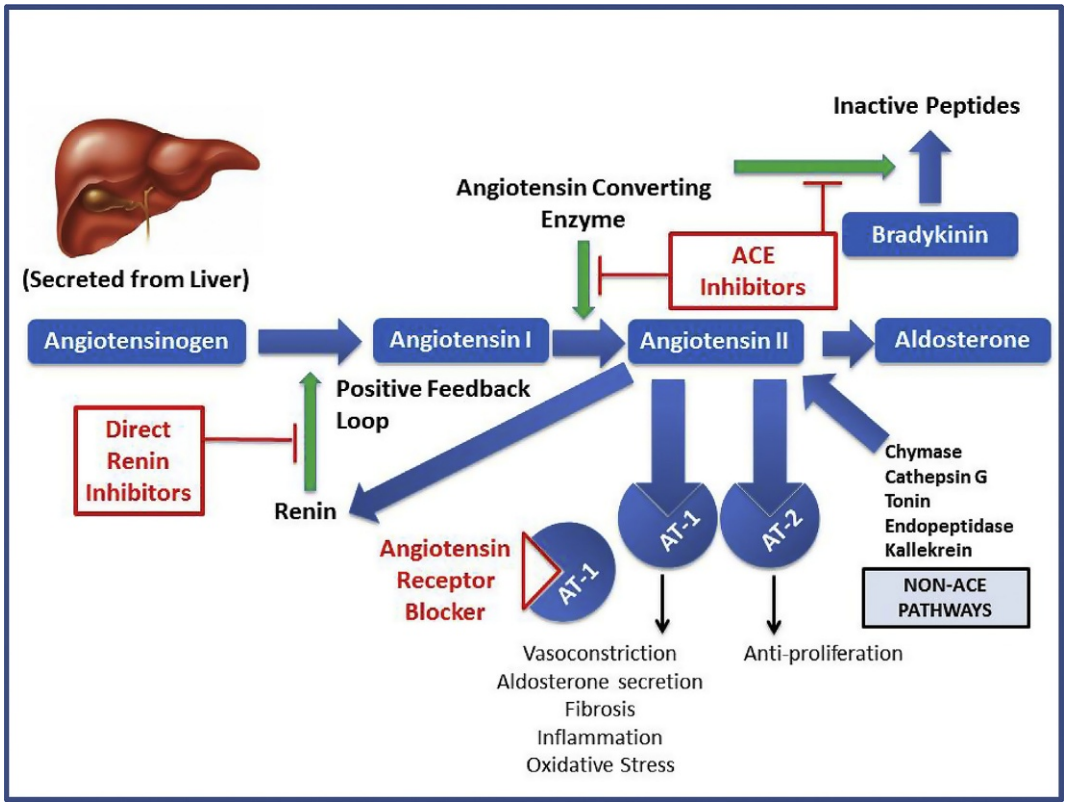

Fig. 2 The renin angiotensin aldosterone system and sites of action of ACE inhibitors and angiotensin receptor blockers (ARBs). Angiotensinogen is secreted from the liver and cleaved by renin (produced in the kidneys) to produce Angiotensin I. Angiotensin I is then cleaved by Angiotensin Converting Enzyme (ACE) to produce Angiotensin II. Angiotensin II can also be produced via non-ACE pathways. Angiotensin II acts on Angiotensin II Type 1 (AT1) and Type 2 (AT2) receptors. When activated the AT1 receptor produces vasoconstriction and augments aldosterone secretion. Angiotensin II produces a positive feedback loop to increase renin production.

The beneficial effects of vasodilation have been documented in the early years of HF research and were found to provide improvement in HF symptoms and mortality. Interest in ACE inhibitors in HF therapy initially stemmed from their vasodilator properties and renal effect of improved natriuresis. The ACE enzyme, in addition to its role in converting angiotensin I to angiotensin II, also facilitates the degradation of bradykinin and substance P, both of which are potent vasodilators (Fig. 2). All of these effects of ACE inhibitors lead to increased vasodilation and facilitate natriuresis and diuresis.

ACE inhibitors have side effects which manifest due to the effects on the RAAS pathway. One common side effect of ACE inhibitors is a medication-induced cough which is due to accumulation of upstream byproducts like bradykinin. The resultant dry cough can be responsible for discontinuation of up to 19% of ACE inhibitors. Accumulation of these byproducts can also lead to more serious complications such as angioedema which has been reported to occur in up to 0.1%–1% of those on ACE inhibitors. Importantly, angioedema can occur at any time point while a patient is on therapy and should prompt expeditious evaluation if any patient on therapy develops lip, tongue, or throat swelling (Mahmoudpour et al., 2013).

In addition, clinicians must also use caution with initiation of these agents in HF patients with low blood pressure or renal failure as their vasodilatory effects may lead to hypotension and exacerbation of symptoms. ACE inhibitors are avoided or used very carefully in patients with severe renal dysfunction and a creatinine of over 3 mg per deciliter. ACE inhibitors have the specific mechanism to vasodilate the efferent arteriole of the kidney which mildly decreases glomerular filtration rate (Denton et al., 1992). In patients with severe HF and renal dysfunction, this can lead to worsening of renal function and further fluid retention.

ACE Inhibitors in Heart Failure with Reduced Ejection Fraction (HFrEF)

Chronologically, investigation of ACE inhibitors in HF was completed prior to evaluation of beta-blockers and other neurohormonal blocking agents. There has also been a great diversity of HF patients in which ACE inhibitors have been evaluated including those with mild to severe symptomatic HF, in patients with asymptomatic left ventricular systolic dysfunction and in post-MI HF, with improvement in symptoms and outcomes. The predominant proportions of these patients were in the category of those with heart failure with reduced ejection fraction (HFrEF). Enalapril and captopril are the best studied ACE inhibitors; however, their effects are thought to be class effects and there are several more guideline-recommended ACE inhibitors available.

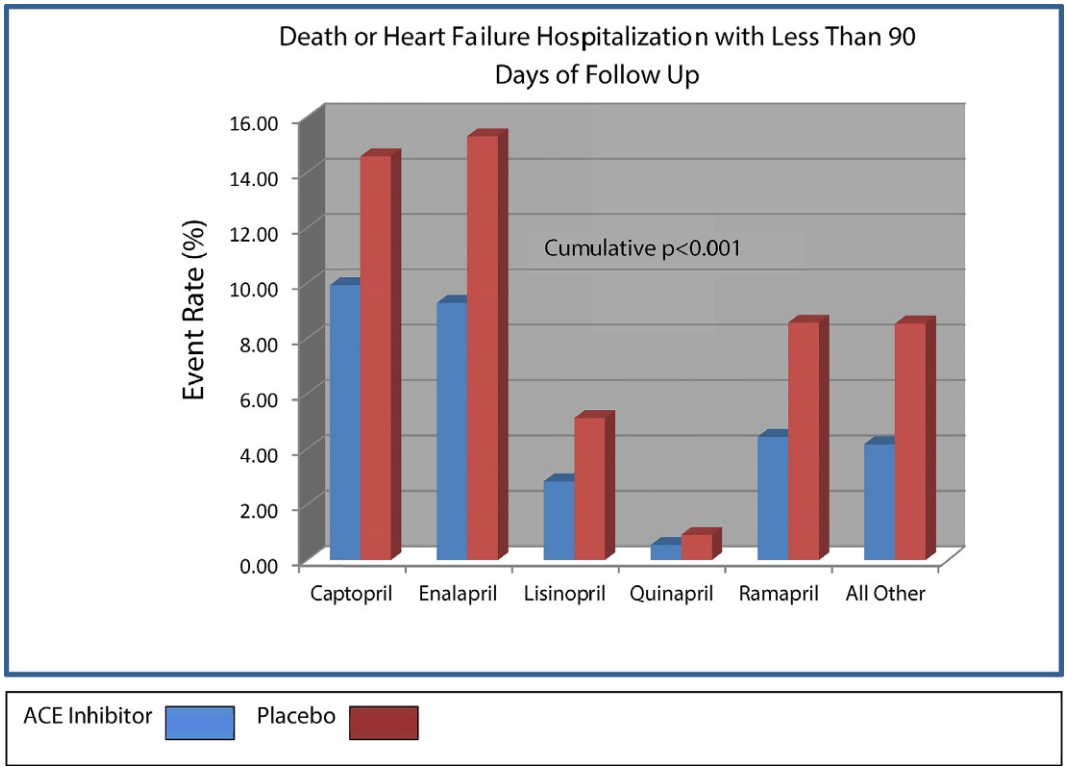

Fig. 3 Summary of ACE inhibitor therapy compared to placebo in patients with HFrEF with the combined end point of death or heart failure hospitalization with less than 90 days of follow-up. Data from Garg, R., Yusuf, S. (1995). Overview of randomized trials of angiotensin-converting enzyme inhibitors on mortality and morbidity in patients with heart failure. *Journal of American Medical Association* 273, 1450–1456.

Enalapril was initially studied in 253 patients with NYHA Class IV HF who were randomly assigned to maximally tolerated enalapril versus placebo in the Effects on Enalapril in Severe Congestive Heart Failure: Results of the Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS) (Swedberg and Kjekshus, 1988). Concomitant use of diuretic and/or digitalis was allowed among enrolled patients and diagnosis of HF was made based on clinical evaluation and radiologic evaluation of heart size (>600 mL/m^2 for men, >550 mL/m^2 for women). Among the patients who received enalapril there was an improvement in clinical symptoms and a reduction in mortality of 31% at 1 year compared to placebo (HR 1.44; $P=0.001$).

Further studies found symptomatic and clinical outcome benefit translated to patients with mild or moderate congestive HF symptoms (Magnani and Magelli, 1986; Lewis, 1989; Lechat et al., 1993) and included the landmark Studies of Left Ventricular Dysfunction (SOLVD) Prevention Trial and the SOLVD Treatment Trial, which evaluated the effect of enalapril on mortality and HF progression in patients with asymptomatic and symptomatic HFrEF, respectively. The SOLVD prevention trial enrolled 4228 predominantly NYHA Class I patients randomly assigned to either enalapril 2.5–20 mg daily (mean daily dose 12.7 mg) or placebo. While the risk of death was not significantly reduced, there was a 20% risk reduction in heart failure hospitalization (HR 0.8; 95% CI 0.9–0.7, $P<0.001$) and a 29% reduction in the development of HF symptoms (HR 0.71; 95% CI 0.64–0.79, $P<0.001$) in those receiving enalapril (The SOLVD Investigators, 1992). The SOLVD Treatment Trial randomized 2569 symptomatic patients with HFrEF to enalapril or placebo. The use of enalapril was associated with a significant risk reduction of 16% in mortality and 26% in mortality or HF hospitalization over an average follow-up of 41 months (The SOLVD Investigators, 1991).

A meta-analysis reviewing 32 trials comparing various ACE inhibitors versus placebo in 7105 symptomatic HFrEF patients of ischemic and non-ischemic etiology showed an overall 23% reduction in time to death among the pooled cohort (OR 0.77, 95% CI 0.67–0.88). The effect was demonstrated among 8 ACE inhibitors; however, the majority of the effect was noted from early trials using enalapril. Importantly, reduction in mortality predominantly came from a decrease in death due to worsening HF (**Figs. 3** and 4) (Garg and Yusuf, 1995).

ACE Inhibitors in Heart Failure with Preserved Ejection Fraction

To date no single trial has provided definitive evidence that ACE inhibitors offer similar benefits to patients with HFpEF as have been demonstrated in those with HFrEF. The largest trial in those with HFpEF was the Perindopril in Elderly People with Chronic Heart Failure (PEP-CHF) trial which randomized 850 patients with HFpEF to the ACE inhibitor perindopril versus placebo. This study failed to show a significant improvement in the primary outcome (composite of all-cause mortality and unplanned HF-related hospitalization) with the ACE inhibitor. However, significant improvements were observed favoring ACE inhibitor

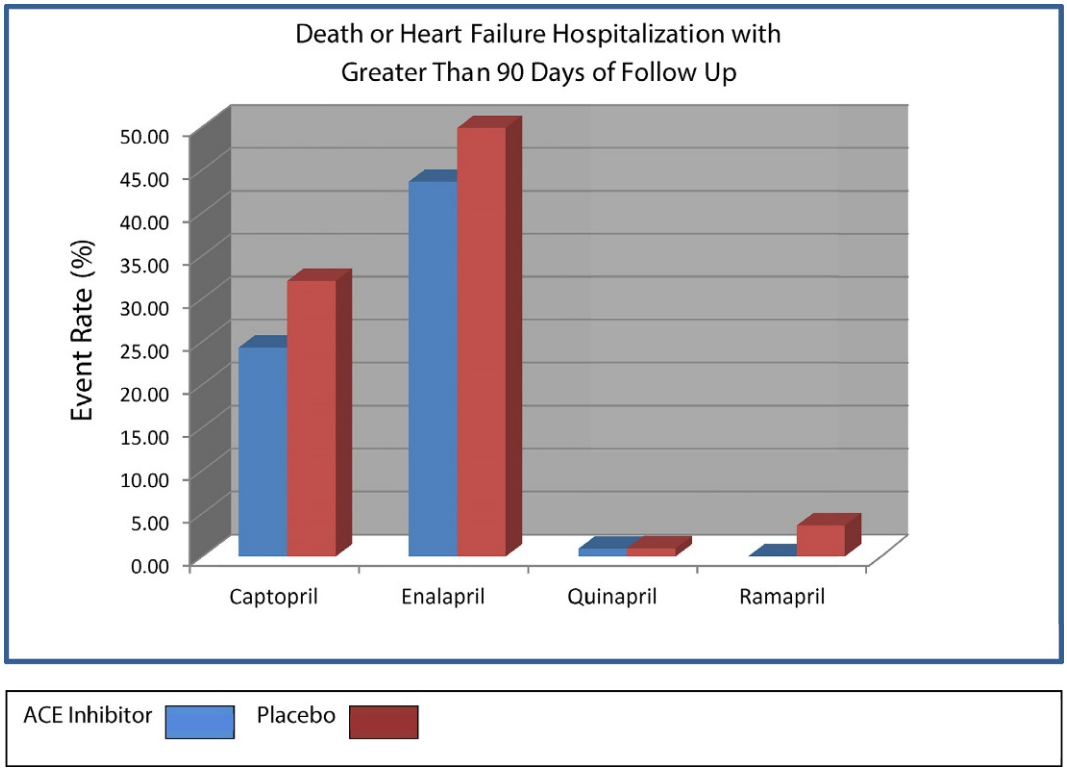

Fig. 4 Summary of ACE inhibitor therapy compared to placebo in patients with HFrEF with the combined end point of death or heart failure hospitalization greater than 90 days of follow-up. Data from Garg, R., Yusuf, S. (1995). Overview of randomized trials of angiotensin-converting enzyme inhibitors on mortality and morbidity in patients with heart failure. *Journal of American Medical Association* 273, 1450–1456.

therapy in some secondary end points, including improving the NYHA functional class and improvement in the six-minute-walk distance at one year of follow-up in the trial (Cleland et al., 2006).

A meta-analysis of 7 trials reviewing the outcomes of 1309 patients with HFpEF receiving ACE inhibitors also failed to show improvement in mortality due to worsening HF, rehospitalization due to HF, or all-cause rehospitalization. This study included the outcomes of the PEP-CHF trial and in subgroup analysis demonstrated a reduction in rehospitalization for HF in a subgroup of patients over the age of 75 years (Fu et al., 2012).

Angiotensin Receptor Blockers

As previously described angiotensin II is an end product of the RAAS pathway and has important effects including sodium and water retention, vasoconstriction, cardiomyocyte hypertrophy, cardiomyocyte inotropy, and vascular/myocardial fibrosis. While ACE inhibitors have upstream effects on the RAAS pathway it has been shown that they do not fully suppress conversion of angiotensin I to angiotensin II. Other enzymatic substances are also capable of producing angiotensin II, including, trypsin, cathepsin, and the heart chymase; however, it is unclear how much an effect these enzymes have on production (**Fig. 2**) (Burnier and Brunner, 2000). This provided the rationale for the development of angiotensin receptor blockers (ARBs) that could theoretically offer more complete protection against angiotensin II by directly blocking the AT1 receptor. In addition, during chronic AT1 receptor blockade, the increased levels of angiotensin II that occur as a result of interruption of the normal negative feedback mechanism, can stimulate the AT2 receptors, and therefore could theoretically be a beneficial target in patients with HF; however, this remains controversial (Burnier and Brunner, 2000). On the other hand, the beneficial effects of ACE inhibitors are also thought in part to be due to their augmentation of the effects of bradykinin, which would not be affected by ARBs. Therefore, several trials evaluated the effects of ARBs compared with ACE inhibitors in HFrEF, as well as the effects of both ACE inhibitors and ARBs used in combination.

Angiotensin Receptor Blockers in HFrEF

A direct comparison of ARBs and ACE inhibitors was completed in the Evaluation of Losartan In The Elderly I and II trials (Pitt et al., 1997, 2000) and in high risk patients after acute myocardial infarction with HF and/or LV dysfunction in the Optimal Trial In Myocardial Infarction with the Angiotensin II Antagonist Losartan (OPTIMAAL) (Dickstein et al., 2002) trials. These trials compared losartan 50 mg daily with captopril 50 mg three times daily in patients with NYHA Class II-IV HF and those patients post MI,

respectively. There was no evidence of superiority of the ARB over the ACE inhibitor as mortality was similar in the ELITE II trial (11.7% vs. 10.4%), but there was greater improvement in LV systolic function and remodeling in patients receiving captopril in the OPTIMAAL trial. However, there were fewer patients who discontinued the study medication in the losartan group (9.7% vs. 14.7%, $P<0.001$) suggesting better tolerability. It has been argued that the dose of losartan (50 mg daily) may have been inadequate in these trials (Gring and Francis, 2004).

Going one step further, the Valsartan in Acute Myocardial Infarction (VALIANT) trial compared valsartan 160 mg daily, captopril 50 mg three times a day, and valsartan 160 mg daily plus captopril 50 mg thrice daily in a 1:1:1 fashion in patients within 10 days post MI with LV systolic dysfunction and HF. Outcomes in the ACE inhibitor and ARB study groups were similar in terms of overall mortality as well as fatal and nonfatal cardiovascular outcomes. The VALIANT trial showed that combined therapy of ACE inhibitor and ARB after myocardial infarction resulted in increased incidence of adverse events without improving overall survival. Adverse events were less common for monotherapy, with hypotension and renal dysfunction being more common in the ARB group and cough, skin rash, and taste disturbance more common in the ACE inhibitor group (Pfeffer et al., 2003).

To determine if ARBs had a benefit in addition to ACE inhibitors in chronic HF patients, the Valsartan in Chronic Heart Failure Trial (Val-HeFT) randomized 5010 patients with stable NYHA class II-IV HF and a left ventricular ejection fraction of $\leq$40% to either maximally tolerated valsartan or placebo in addition to currently prescribed therapies. Of note, in this study 93% of patients were already receiving ACE inhibitors prior to the addition of valsartan. Compared to placebo there was a 13.2% reduction in the primary end point of combined mortality, cardiac arrest with resuscitation, hospitalization for worsening HF, or new requirement of inotropic medications. However, mortality was similar in the two groups, and the benefit was primarily because of a 24% reduction in the rate of HF hospitalizations in patients in the valsartan arm. Also, subgroup analysis demonstrated that the small subgroup of 366 patients (7%) who were not receiving ACE inhibitors received maximal benefit with a 33% reduction in mortality and a 49% decrease in mortality and morbidity with valsartan compared to placebo, whereas the morbidity and mortality benefit of valsartan observed in the overall trial was no longer significant in patients already receiving background ACE inhibitor therapy (HR 0.92; $P=0.0965$); this modest favorable trend in the group receiving an ACE inhibitor was largely driven by the patients receiving less than the recommended dose of an ACE inhibitor (Konstam, 2002).

Similarly, the Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM-Alternative) trial provided the definitive answer to whether ARBs are an effective alternative to ACE inhibitors in patients with HFrEF. In this trial, patients with symptomatic HFrEF and history of intolerance to ACE inhibitors were randomized to either the ARB, candesartan, or to placebo (history of ACE intolerance included cough in 72%, symptomatic hypotension in 13%, and renal dysfunction in 12% of patients). The use of candesartan was associated with a significant 23% reduction in the primary composite outcome of cardiovascular mortality or HF hospitalization with benefits on both cardiovascular death and HF hospitalization (Granger et al., 2003).

A second large study that evaluated the combined effects of ACE inhibitors and ARBs in patients with chronic HFrEF was the Effect of Candesartan in Patients with Chronic Heart Failure and Reduced Left-Ventricular Systolic Function Taking Angiotensin Converting Enzyme Inhibitors (CHARM-Added Trial). This study evaluated 2548 patients with NYHA Class II-IV HF, LV ejection fraction $\leq$40%, and receiving an ACE inhibitor, who were randomized to either candesartan once daily or placebo and monitored for a combined clinical end point of death and/or hospitalization for HF. There were a higher proportion of patients also prescribed additional medical therapy including 55% on beta-blockers and 17% on aldosterone receptor blockers (McMurray et al., 2003). In this trial a modest benefit was seen with the use of combination therapy with ACE inhibitor and ARB versus ACE inhibitors alone for both outcomes that were included in the primary outcome of cardiovascular death or HF hospitalization (overall HR 0.85; 95% CI 0.75–0.96: $P=0.01$).

One important end point seen in Val-HeFT and the CHARM-Added trials, as well as other studies reviewing concomitant use of ACE inhibitors and ARBs, is the higher incidence of hypotension, hyperkalemia, and renal dysfunction. Using the trial data, the recommendations for the use of ACE inhibitors and ARBs in HFrEF in the AHA/ACC HF guidelines are detailed in **Table 1**.

Table 1 Summary of ACE inhibitor and ARB treatment guidelines

Therapy	*Recommendation*	*Treatment effect*[a]
ACE inhibitors		
	(1) ACE inhibitors are recommended for all patients with HFrEF	Class I
ARBs		
	(1) ARBs are recommended in patients with HFrEF who are ACE inhibitor intolerant	Class I
	(2) ARBs are reasonable as alternative to ACE inhibitors as first-line therapy in HFrEF	Class IIa
	(3) Addition of an ARB may be considered in persistently symptomatic patients with HFrEF on guideline directed therapy	Class IIb
	(4) Routine combined use of an ACE inhibitor, ARB, and aldosterone antagonist is potentially harmful	Class III: Harm

[a]Class I: indicates treatment SHOULD be performed, Class IIa: indicates therapy is REASONABLE, Class IIb: indicates therapy MAY BE CONSIDERED, Class III: indicates therapy is HARMFUL.

Angiotensin Receptor Blockers in HFpEF

There is no compelling evidence for the use of ARBs specifically for patients with HFpEF. In the Effects of Candesartan in Patients with Chronic Heart Failure and Preserved Left Ventricular Ejection Fraction (CHARM-Preserved) study, 3023 patients with NYHA Class II-IV HF with a left ventricular ejection fraction $\geq$40% were randomized to either candesartan or matched placebo. While there was no significant difference in cardiovascular death between the Candesartan and placebo groups, there was a modest reduction in patients with HF hospitalization (15.1% vs. 18.5%, $P=0.017$) and a marginal reduction in risk for HF hospitalization (HR 0.85, 95% CI 0.72–1.01, $P=0.072$) (Yusuf et al., 2003). However, the subsequent and larger Irbesartan in Heart Failure with Preserved Ejection Fraction (I-PRESERVE) study randomized a larger number and better ascertained patients with HFpEF and left ventricular ejection fraction of $\geq$45% to either irbesartan or placebo. In total 4128 patients were randomized and followed for a duration of 49.5 months. At the end of the trial there were no significant differences in mortality or the rate of cardiovascular hospitalization between the two groups (Massie et al., 2008).

Due to lack of sufficient evidence for benefit of both ACE inhibitors and ARBs in patients with HFpEF the ACC/AHA guidelines on heart failure recommend these agents as a Class IIb therapy for reduction of hospitalization. In addition, both can be used in patients with HFpEF if a non-HF indication is present such as in patients with hypertension or diabetes (Yancy et al., 2013).

Aldosterone Receptor Antagonists

Further evaluation of the influence of the neurohormonal axis revealed that plasma volume regulation also is influenced by the adrenal hormone, aldosterone. Aldosterone is a short-lived plasma hormone which is synthesized in the zona glomerulosa of the adrenal cortex. It exerts its effects predominantly on the distal collecting tubule of the renal nephron through the mineralocorticoid receptors which upregulate and promote expression of the $3Na^+/2K^+$ pump. Secretion of aldosterone is promoted by elevated levels of potassium, angiotensin II, angiotensin III and through stretch receptors of the SNS within the myocardium (Dzau et al., 1981; Weber and Villarreal, 1993).

Stimulation of the mineralocorticoid receptor promotes water retention as activation of the Na/K pump drives sodium into the interstitium and potassium is secreted into the collecting duct. The resultant osmotic gradient promotes volume retention in HF patients and leads to the clinical syndrome of volume overload. Aldosterone also leads to loss of magnesium through secretion in the nephron and has been associated with a greater incidence of arrhythmias. Moreover, chronically elevated aldosterone levels increase myocardial and vascular fibrosis as well as left ventricular hypertrophy (Dzau et al., 1981; Swedberg et al., 1990).

As the use of ACE inhibitors and ARBs has increased in HF, "aldosterone escape" or "aldosterone breakthrough," a phenomenon resulting from only partial inhibition of aldosterone by inhibitors of the renin–angiotensin system (RAS) due to non-RAS activation of aldosterone has been described (Schrier, 2010). Following these observations, the safety and efficacy of add-on therapy with aldosterone receptor antagonists including spironolactone and eplerenone has been evaluated in HF patients.

Aldosterone Receptor Antagonists in Heart Failure with Reduced Ejection Fraction

The aldosterone receptor antagonist, spironolactone, was initially evaluated in patients with severe HFrEF already receiving an ACE inhibitor in the Randomized Aldactone Evaluation Study (RALES). In this study 1663 patients with left ventricular ejection fraction of $\leq$35% and NYHA Class III or IV HF symptoms were randomly assigned to either 25 mg of spironolactone daily or placebo. At least 94% of enrolled patients were receiving ACE inhibitors but only ~10% were receiving beta-blockers at the time of enrollment. Among those receiving spironolactone there was a 30% reduction in mortality (RR = 0.70, 95% CI 0.60–0.82; $P<0.001$) compared to those receiving placebo, after a mean follow-up of 24 months. Additionally, there was a 35% decrease in the frequency of hospitalization for worsening HF and a significant improvement in symptoms of HF based on NYHA classification (Pitt et al., 1999).

In the RALES trial there were approximately 50% of patients designated with HF due to ischemic causes; however, animal models had also demonstrated efficacy among those with HFrEF and coronary artery disease. Therefore, the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) was conducted to evaluate treatment in humans, specifically post-MI with a reduction in left ventricular ejection fraction and HF symptoms. The study randomized 6642 patients to either eplerenone 25 mg daily or placebo at least 3–14 days following an MI and documented left ventricular ejection fraction of $\leq$40%. Among those treated, at least 86% were already receiving ACE inhibitors and 75% were receiving beta-blockers. After a mean follow-up of 16 months, compared to placebo, there was a modest 13% reduction in the primary end point of combined death or hospitalization for HF among those assigned to eplerenone (RR 0.87, 95% CI 0.79–0.95; $P=0.002$) (Pitt et al., 2003).

Most recently, the Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (EMPHASIS-HF) further evaluated the effect of aldosterone antagonism in those patients with HF and milder symptoms. Patients enrolled had a documented left ventricular ejection fraction of no more than 30% and NYHA class II HF symptoms. Ultimately, 2737 patients were enrolled to either 25 mg eplerenone (with titration to 50 mg at 4 weeks if tolerated) or placebo with an evaluated primary end point of death or HF hospitalization. At a median follow-up of 21 months there was a 37% reduction in the primary end point (HR 0.63, 95% CI 0.54–0.74; $P<0.001$) as well as a 24% reduction in cardiovascular death (HR 0.76, 95% CI 0.61–0.94; $P=0.01$) (Zannad et al., 2011). In contrast to the RALES trial where only ~10% of patients were on beta-blockers at baseline, most patients in the EMPHASIS-HF trial (87%) were on baseline beta-blocker therapy. This trial solidified the significant incremental benefit of aldosterone antagonists on outcomes in HFrEF patients already on guideline-directed therapy of ACE inhibitors and beta-blockers.

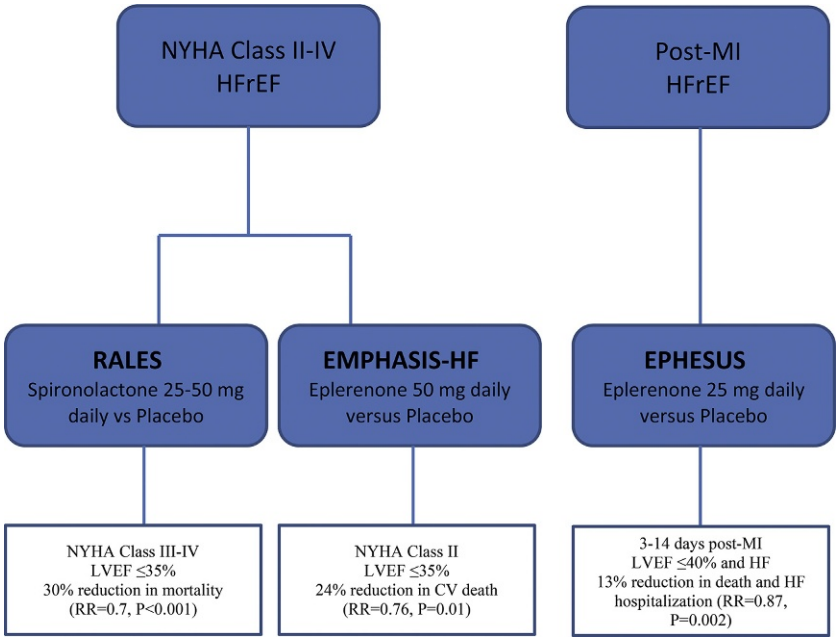

Fig. 5 Trials of aldosterone receptor blockers (eplerenone and spironolactone) in HFrEF with differing severity of HF. *RALES*, Randomized Aldactone Evaluation Study (Pitt et al., 1999); *EPHESUS*, Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (Pitt et al., 2003); *EMPHASIS*, Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (Zannad et al., 2011).

Based on the above evidence, the 2013 ACC/AHA guidelines for the management of HF provide a class I recommendation for the use of aldosterone receptor antagonists in patients with NYHA Class II-IV HF symptoms and a left ventricular ejection fraction ≤35% or ≤40% in those with recent MI (**Fig. 5**). Caution is advised in the initiation of these agents in patients with renal insufficiency or a history of hyperkalemia (Yancy et al., 2013). In the trials patients were excluded from analysis that had a creatinine level greater than 2.5 mg per deciliter, an estimated glomerular filtration rate <30 mL/min/1.73 m^2 of body-surface area, or a serum potassium level of greater than 5.0 mmol per liter prior to randomization. Rates of hyperkalemia ranged from 2% to 8% among those receiving aldosterone receptor antagonists; however, definitions varied between studies.

Aldosterone Receptor Antagonist in Heart Failure with Preserved Ejection Fraction

Use of aldosterone receptor antagonists has also been evaluated in HFpEF without definitive evidence of improvement of outcomes. The Spironolactone for Heart Failure with Preserved Ejection Fraction (TOPCAT) study randomized 3445 patients with symptomatic HF and a left ventricular ejection fraction of 45% or higher to receive either spironolactone (15–45 mg daily) or placebo. After a mean follow-up of 3.3 years there was no difference in the primary end point of death from cardiovascular causes, aborted cardiac arrest, or hospitalization for HF among those receiving spironolactone versus placebo group (hazard ratio, 0.89; 95% confidence interval, 0.77–1.04; $P=0.14$). Notably in the spironolactone group a small reduction in hospitalizations for HF was observed (hazard ratio, 0.83; 95% CI, 0.69–0.99, $P=0.04$); however, total hospitalizations were not different between the two arms (Pitt et al., 2014).

To further evaluate this effect a post hoc analysis of TOPCAT patients enrolled in the Americas versus Russia/Georgia (from where almost 50% of patients were enrolled) was completed and demonstrated significant heterogeneity in underlying patient risk and clinical response to spironolactone. In the subgroup enrolled in the Americas, the primary composite end point in the placebo arms occurred at ~4 times higher rate in the placebo arm compared with the subgroup enrolled from Russia/Georgia. In the higher risk subgroup in the Americas, the primary end point was reduced by spironolactone compared to placebo (HR 0.82, 95% CI 0.69–0.98), but there was no effect in the subgroup enrolled in Russia/Georgia (HR 1.10, 95% CI 0.79–1.51) (**Fig. 6**) (Pfeffer et al., 2015).

Similar investigations have also been completed evaluating the effect of aldosterone antagonists on exercise capacity in patients with HFpEF including the Effect of Spironolactone on Diastolic Function and Exercise Capacity in Patients with Heart Failure with Preserved Ejection Fraction (ALDO-HF) (Edelmann et al., 2013) and Randomized Aldosterone Antagonism in Heart Failure with Preserved Ejection Fraction (RAAM-PEF) (Deswal et al., 2011) trials. In both there was no significant change in maximal oxygen consumption and six minute walk test after treatment with spironolactone 25 mg daily (with an increase to 50 mg daily if tolerated in the RAAM-PEF study) for 12 and 6 months, respectively. Given the lack of clear benefit of aldosterone antagonism in HFpEF on mortality, hospitalization, or symptoms, the use across all patients with HFpEF cannot be advocated. However, given the paucity of

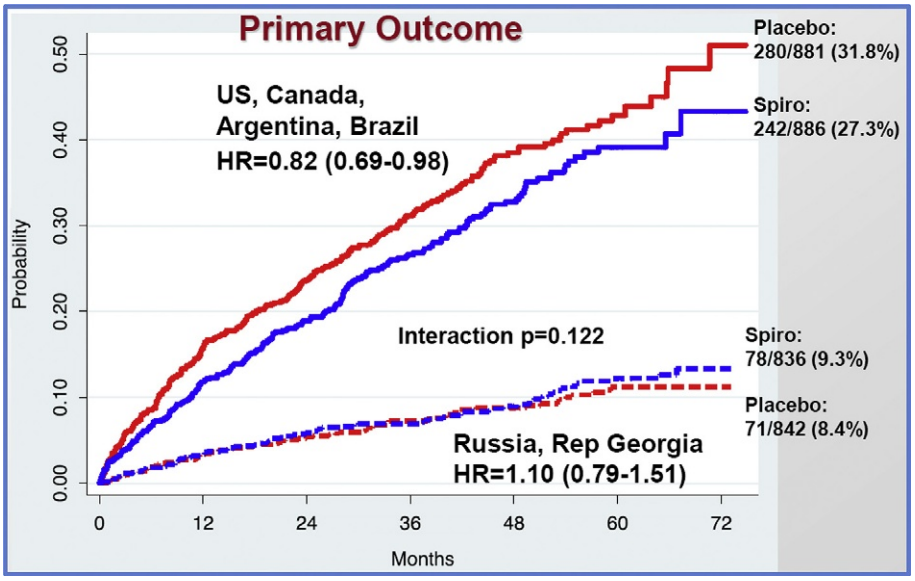

Fig. 6 Kaplan-Meier curves for the post hoc analysis in Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist (TOPCAT) trial of spironolactone in HFpEF delineating significant differences in those patients treated in the Americas versus those in Russia/Georgia (Adapted from Pfeffer et al., 2015). The primary outcome was time to cardiovascular death, heart failure hospitalization, or resuscitated cardiac arrest.

clearly beneficial treatment in this group of patients and the heterogeneity of data across regions, the 2017 ACC/AHA/HFSA Focused Update of the 2013 ACCF/AHA Guideline for the Management of Heart Failure has provided a weak Class IIb recommendation for its use in HFpEF as follows:

> In appropriately selected patients with HF*p*EF (with EF ≥45%, elevated BNP levels or HF admission within 1 year, estimated glomerular filtration rate >30 mL/min, creatinine <2.5 mg/dL, potassium <5.0 mEq/L), aldosterone receptor antagonists might be considered to decrease hospitalizations (Yancy et al., 2017).

Direct Renin Inhibitors

Feedback loops within the RAAS cascade provide regulation of the signaling peptides and therapies such as ACE inhibitors and ARBs disrupt these signals. It has been demonstrated in early trials that elevated levels of plasma renin confer a higher risk of mortality. The use of ACE inhibitors or ARBs leads to an increase in renin despite their benefits of decreased symptoms and improved mortality as they target downstream substrates (Fig. 2). This is thought to occur by competitive saturation of ACE due to high levels of ACE inhibition. Additionally, high levels of renin directly act at the renin receptor of the myocardium causing hypertrophic, apoptotic activity, and extracellular matrix remodeling. Therefore use of direct renin inhibitors (DRI) was evaluated as a treatment in HF as it may produce similar effects as an ACE inhibitor and may overcome the effects of renin in conjunction with ACE inhibitor use (Nguyen, 2011; Schroten et al., 2012).

Aliskiren was the most evaluated DRI in HFrEF. However, studies have not demonstrated any incremental benefit of DRI in addition to an ACE inhibitor or with DRI in comparison with an ACE inhibitor in HFrEF (McMurray et al., 2008, 2016; Solomon et al., 2011). No studies have been published to date to evaluate DRIs in patients with HFpEF.

Sympathetic Nervous System (SNS) Blockade

Cardiac insults such as myocardial infarction or necrosis impair cardiac output or contractility leading to activation of the sympathetic nervous system (SNS). There are multiple complex interactions that play a role in increased sympathetic output including input from arterial baroreceptors, cardiopulmonary baroreceptors, muscle metaboreceptors, and renal nerves (Fig. 7). As left ventricular function decreases in patients with HF, a proportionate dysfunction between sympathetic and parasympathetic regulation occurs (Floras and Ponikowski, 2015).

Baroreceptors within the carotid sinus and aortic arch as well as mechanoreceptors within the myocardium provide an inhibitory signal for sympathetic output from the central nervous system in healthy individuals. A decrease in cardiac output or effective arterial volume will result in decreased output from these baroreceptors and increase signaling with sympathetic hormones, including norepinephrine and epinephrine (Hartupee and Mann, 2016; Floras and Ponikowski, 2015). Early in the development of HF, these neurohormonal changes are seen due to decreased effective cardiac output. The sympathetic signaling increases as a compensatory mechanism to improve end-organ perfusion through inotropic and chronotropic effects.

Specifically, increased sympathetic output will lead to increased heart rate through stimulation of beta-1-adrenergic receptors and increased peripheral vasoconstriction through alpha-1-adrenergic receptors. In addition, there is crossover in the RAAS pathway

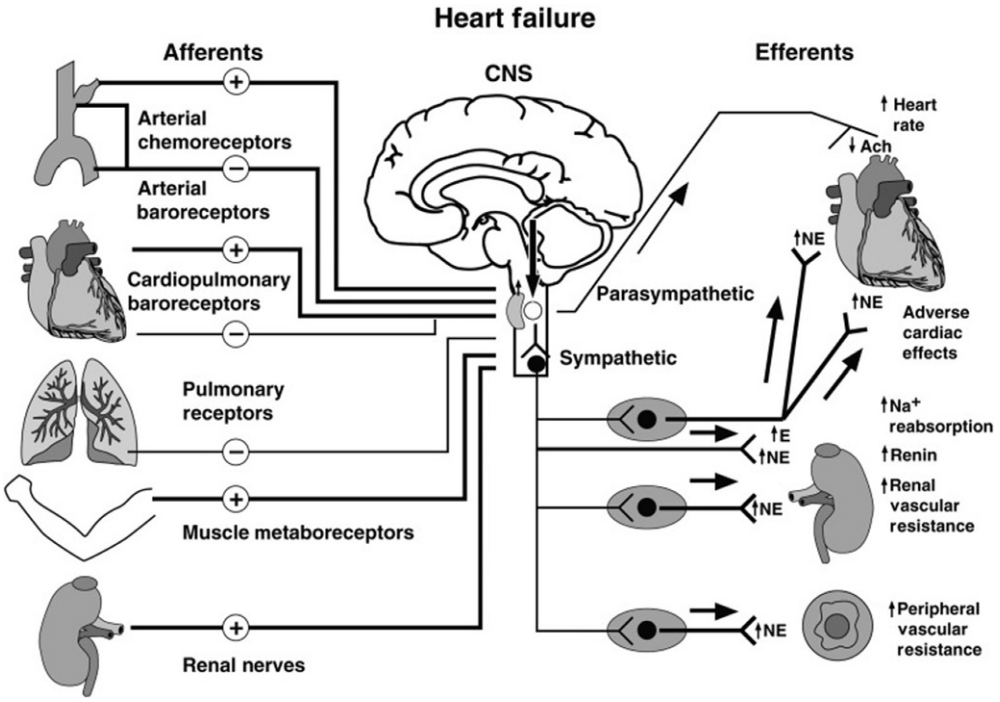

Fig. 7 Autonomic mechanisms of HFrEF. Outflow from cardiac and vascular mechanoreceptors, pulmonary stretch receptors, muscle metaboreceptors, and the renal afferent arterioles activate central sympathetic signaling through norepinephrine (NE) and epinephrine (E). NE and E have end organ effects of vasoconstriction, fibrosis, increased renin secretion, increased sodium reabsorption, and increased peripheral vascular resistance. There is also parasympathetic inhibition leading to decreased acetylcholine (Ach) secretion and thus increased heart rate (Floras and Ponikowski, 2015).

as sympathetic output stimulates the juxtaglomerular apparatus in the kidney (Floras and Ponikowski, 2015). Increased sympathetic tone, therefore, will also lead to increased fluid and sodium retention through increased levels of renin and thus angiotensin II.

Levels of norepinephrine are not routinely checked in patients with HF; however, elevated levels have been directly correlated with mortality in patients with HFrEF (Anand et al., 2003; Cohn et al., 1984). Despite this correlation hormonal measurement does not seem to correlate with left ventricular function or quality of life measurements. During evaluation of patients in the Vasodilator-Heart Failure II Trial (V-HeFT II) it was found that those with higher levels of neuroendocrine activation had a greater benefit from the vasodilator and RAS blocker, enalapril (Francis et al., 1993).

In addition to the direct physical changes seen due to SNS activation, chronically heightened sympathetic tone has intracellular effects. As described previously sympathetic neuroendocrine hormones, norepinephrine and epinephrine, act through the G-protein-coupled beta-adrenergic receptors which increase inotropy, heart rate, and peripheral vascular resistance. This compensatory mechanism leads to increased myocardial stress through upregulation of cyclic adenosine monophosphate which produces elevated levels of intracellular calcium. Ultimately, the rise in cellular calcium and oxidative stress leads to cellular death. In addition, the cellular shifts in calcium appear to promote after depolarizations and ventricular arrhythmias (Floras and Ponikowski, 2015; Sackner-Bernstein JaM, 1995; Ponikowski et al., 2001; Lown and Verrier, 1976).

Chronic activation of the SNS leads to deleterious effects in the heart including desensitization of beta adrenergic receptors, myocyte hypertrophy, necrosis, apoptosis, and fibrosis; in the kidney including activation of the RAAS, increase in salt and water retention, and an attenuated response to natriuretic peptides; and in the peripheral vessels including neurogenic vasoconstriction and vascular hypertrophy (Hartupee and Mann, 2016).

Beta-blockers in Heart Failure with Reduced Ejection Fraction

Beta-blockers have become a Class I guideline-recommended medical therapy in addition to ACE inhibitor or ARB therapy in patients with HFrEF. Unlike ACE inhibitors, which demonstrate a class effect in HF therapy, mortality benefit has only been seen with three specific beta-blocking agents, including metoprolol succinate (MERIT-HF-Investigators, 1999), carvedilol (Packer et al., 2001), and bisoprolol (CIBIS II-Authors, 1999). Bisoprolol and sustained-release metoprolol (succinate) selectively block beta-1–receptors and carvedilol blocks alpha-1-, beta-1-, and beta-2-receptors. Beta-blockers have been demonstrated to ameliorate the effects of chronic catecholamine activation and lead to improvement in symptoms and clinical outcomes of chronic HF. Several trials have shown that beta-blocker use can lead to improvement in survival, left ventricular function (Groenning et al., 2000;

Bristow, 2000), reduction in left ventricular size (reverse remodeling) (Colucci et al., 2007; Lowes et al., 1999), and reduced HF hospitalization (CIBIS II-Authors, 1999) among those with HFrEF, across all NYHA classes.

Despite initial reports demonstrating improvement in symptoms in patients with HF (Bristow et al., 1994; Eichborn et al., 1994; Fisher et al., 1994; Woodley et al., 1991), enthusiasm initially remained limited over initiation of these medications due to the potential early risk of adverse effects after initiation of this class of negative inotropic medications, especially in patients with decompensated HF (Epstein and Braunwald, 1966). One early trial aimed at detecting improvement in mortality was the Cardiac Insufficiency Bisoprolol Study (CIBIS) in which 641 patients with predominantly NYHA Class III CHF (95% of enrollees) and a left ventricular ejection fraction of ≤40% were randomized to either the beta-blocker bisoprolol or matched placebo. Many of the patients were already receiving vasodilators, digitalis, and ACE inhibitors with 90% receiving the latter therapy. After a mean follow-up of 1.9 years despite significant improvements seen in functional class, the 20% mortality reduction that was seen among those receiving bisoprolol was not statistically significant (RR 0.8, 95% CI 0.56–1.15; $P=0.22$). Of note, there were no forced titration protocols for bisoprolol dosing among participating clinicians with only 50% of the enrolled patients reaching the target dose of 5 mg daily (The CIBIS Investigators, 1994).

However, the U.S. Carvedilol Heart Failure trial helped beta-blocker therapy gain traction. In this study patients with NYHA Class II-IV symptoms for at least 3 months were randomized to maximally tolerated doses of carvedilol (starting with 6.25 mg twice daily) or placebo. Therapy with vasodilators, digitalis, and ACE inhibitors was allowed with 95% of patients already receiving the latter. Among the 1094 patients enrolled in the trial, a 65% relative reduction in mortality was seen after a median follow-up time of 6.5 months (95% CI 39%–80%; $P<0.001$), leading to early termination of the study (Packer et al., 1996).

Based on results of the studies it was suggested that the beneficial effect of carvedilol was seen due to its nonselective blockade of beta-1 and beta-2 receptors. However, a follow-up study to CIBIS was completed in the Cardiac Insufficiency Bisoprolol Study II (CIBIS-II) which demonstrated beneficial effects of bisoprolol in 2647 NYHA Class III and IV patients on a background of diuretic and ACE inhibitor therapy with a 34% reduction in all-cause mortality in the bisoprolol group compared to placebo (OR 0.66, 95% CI 0.54–0.81; $P<0.0001$). Notably, follow-up analysis showed a significant reduction in hospitalization for ventricular fibrillation and ventricular tachycardia ($P=0.006$), along with a 44% reduction in sudden cardiac death (CIBIS II-Authors, 1999). Subsequent improvement in mortality was also demonstrated with another selective beta-1 adrenergic antagonists metoprolol succinate in the MERIT-HF trial (MERIT-HF-Investigators, 1999) (**Table 2**). Analysis of benefits in mode of death in the MERIT-HF trial, which enrolled patients in NYHA class II-IV functional class, showed similar results, with a 41% reduction in sudden cardiac death as well as 49% reduction in the HF death. Taking results of both trials together, it suggests that beta-blockers demonstrate benefit in both sudden cardiac death as well as HF death. When mode of death was evaluated overall in the MERIT-HF trial, consistent with prior literature, sudden death was more common in patients with less severe HF (NYHA class II) and death from worsening HF was more common in patients with increased severity of HF (NYHA class III and IV) (**Fig. 8**).

Initiation of beta-blocker therapy should be considered in patients who clinically are not currently exhibiting signs of volume overload, cardiogenic shock, symptomatic bradycardia, or with reactive airway disease exacerbation. In patients with an ongoing signs of severe acute HF, initiation of beta-blockers may blunt the compensatory response of increased heart rate and vascular tone which could lead to precipitation of cardiogenic shock. However, it has been demonstrated that introduction of beta-blocker therapy is safe in patients with stable advanced heart failure symptoms. In a study evaluating patients with an estimated left ventricular ejection fraction of less than 25% and with relatively stable, euvolemic NYHA Class IV HF symptoms, a reduction in mortality of 35% was seen in patients receiving maximally tolerated carvedilol versus placebo (Packer et al., 2001). While there were higher incidences of hypotension, edema, and bradycardia among the carvedilol group than placebo, the most common severe

Table 2 Summary of beta-blocker therapy in HFrEF

Study	*CIBIS (The CIBIS Investigators, 1994)*	*Carvedilol Heart Failure Study Group (Packer et al., 1996)*	*CIBIS II (CIBIS II-Authors, 1999)*	*MERIT-HF (MERIT-HF-Investigators, 1999)*
Medication	Bisoprolol 5 mg daily versus Placebo (51% reached max dose)	Carvedilol 25–50 mg twice daily[a] versus Placebo (MDD = 45 mg)	Bisoprolol 10 mg daily versus Placebo (43% reached max dose)	Metoprolol CR/XL (Succinate) 200 mg daily versus Placebo (MDD = 159 mg daily)
Study subjects	641 Patients with LVEF ≤40% and NYHA Class III or IV heart failure	1094 Patients with LVEF ≤35% and 3 months of heart failure symptoms	2647 Patients with LVEF ≤35% and NYHA Class III or IV heart failure	3991 Patients with LVEF ≤40% and NYHA Class III-IV heart failure
Key points	• Reduced CHF Hospitalization ($P<0.01$) • Nonsignificant reduction in mortality (RRR = 20%, $P=0.22$) • Improvement in NYHA Class ($P=0.03$)	• 65% RRR in death (95% CI 0.2–0.61, $P<0.001$) • Reduced CHF hospitalization (RRR = 27%, $P=0.036$)	• 44% RRR in death (95% CI 0.54–0.81, $P<0.001$) • Reduced all cause and CHF hospitalization ($P=0.0049$ and $P=0.001$, respectively) • Reduced hospitalization for VT and VF	• 44% RRR in death (95% CI 0.53–0.81, $P<0.001$) • Reduction in progression of heart failure at 18 months ($P=0.0023$)

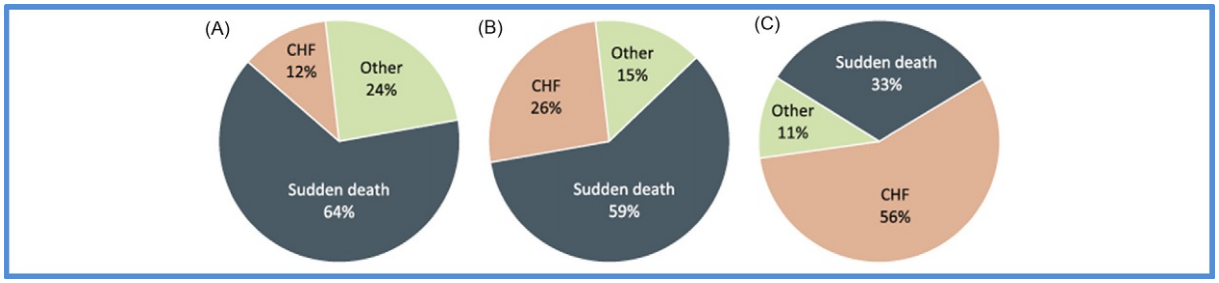

Fig. 8 Mode of cardiovascular death based on severity of HF at baseline in the MERIT-HF trial. Panels A, B, and C demonstrate NYHA Class II, Class III, and Class IV patients, respectively (MERIT-HF-Investigators, 1999). *CHF*, chronic heart failure.

adverse events were worsening HF which occurred at similar rates among both randomized groups. All major trials of beta-blockers in HFrEF have been carried out on a background of ACE inhibitors which had previously been proven of benefit in these patients. It has been suggested that initiation of beta-blockers prior to achieving higher doses of ACE inhibitors or ARB may lead to a greater improvement in symptoms and mortality in patients with HFrEF (Packer et al., 1999).

Based on the strong evidence, the AHA/ACC HF guidelines recommend use of one of the three beta-blockers proven to reduce mortality (e.g., bisoprolol, carvedilol, and sustained-release metoprolol succinate) for all patients (hemodynamically stable) with current or prior symptoms of HFrEF, unless contraindicated, to reduce morbidity and mortality (Yancy et al., 2013).

Beta-blockers in HFpEF

The same clinical benefits of beta-blockers in HFrEF have not been proven in patients with HFpEF. In HFpEF the underlying pathology seen is increased filling pressures of the left ventricle which leads to increased pulmonary arterial pressures which clinically presents as pulmonary edema and decreased exercise tolerance. Elevated filling pressures are measured on echocardiography during diastole and occur typically due to increased viscoelastic properties, increased wall thickness, or changes in left ventricular size and shape leading to a compromised contribution of pre-load to cardiac output (Bhuyian and Mauer, 2011; Bourlaug and Paulus, 2010). These physiologic derangements lead intuitively to thinking that beta-blockers would be of benefit by decreasing beta-adrenergic drive, lowering heart rate, and prolonging the diastolic filling phase allowing improved filling of the left ventricle (Bourlaug and Paulus, 2010). However, current data does not support the routine use of beta-blocker therapy in patients with HFpEF to primarily improve clinical outcomes (Aronow et al., 1997; Farasat et al., 2010; Flather et al., 2005). Therefore, beta-blockers are indicated only for use in the treatment of comorbidities in HFpEF, such as atrial fibrillation, angina, postmyocardial infarction, and hypertension.

Natriuretic Peptide System Potentiation

Natriuretic peptides have ameliorating effects on manifestations of HF including increased natriuresis, diuresis, and vasodilation. Atrial natriuretic peptide and B-type natriuretic peptide are released from the atrial and ventricular myocardium, respectively, in response to chamber distention, wall stress, or increased activation of the SNS or RAAS. They exert their effects by counter-regulation including decreasing renin production and increasing cyclic GMP production (Levin et al., 1998). However, in HF there is increased peripheral resistance to natriuretic peptides, thus potentiating the effects of the RAAS (Volpe et al., 2016). In addition, the half-life of natriuretic peptides is short as they are degraded by neutral endopeptidases, including neprilysin. Neprilysin is involved in breakdown of vasoactive peptides like angiotensin I, angiotensin II, endothelin-1, kinins, adrenomedullin, and atrial and B- type natriuretic peptides. Studies have demonstrated that through augmentation of active natriuretic peptides through neprilysin inhibition, an increase in myocardial cyclic guanosine 3′5 mono phosphate can be achieved, which improves myocardial relaxation, reduces hypertrophy, and stimulates diuresis, natriuresis, and vasodilation (Mangiafico et al., 2013). Neprilysin inhibition may be a useful target in patients with HF. However, neprilysin is a nonspecific enzyme which has a variety of nonvasoactive peptide targets such as opioid peptides, encephalin, gastrin, and amyloid beta (Aβ). Importantly, angiotensin II breakdown is also decreased which may potentiate RAAS effects; therefore, in HF, neprilysin inhibitors need to be combined with inhibitors of RAS (**Fig. 9**).

Angiotensin Receptor Blocker-Neprilysin Inhibitors (ARNI) in HFrEF

Combined angiotensin receptor blocker–neprilysin inhibitors (ARNI) have recently been validated as a mortality-reducing therapy in patients with HFrEF. LCZ696 or Valsartan/Sacubitril is the first angiotensin receptor-neprilysin inhibitor (ARNI) that combines the molecular moieties of the neprilysin inhibitor prodrug AHU377 and the ARB, valsartan in one compound. The Prospective comparison of ARNI with ACE inhibitor to Determine Impact on Global Mortality and Morbidity in Heart Failure (PARADIGM-HF) trial studied the efficacy and safety of LCZ696 200 mg twice daily compared to enalapril 10 mg twice daily in 8458 patients with chronic HF (NYHA Class II–IV and EF <35%). The drug was evaluated for the primary end point of combined cardiovascular

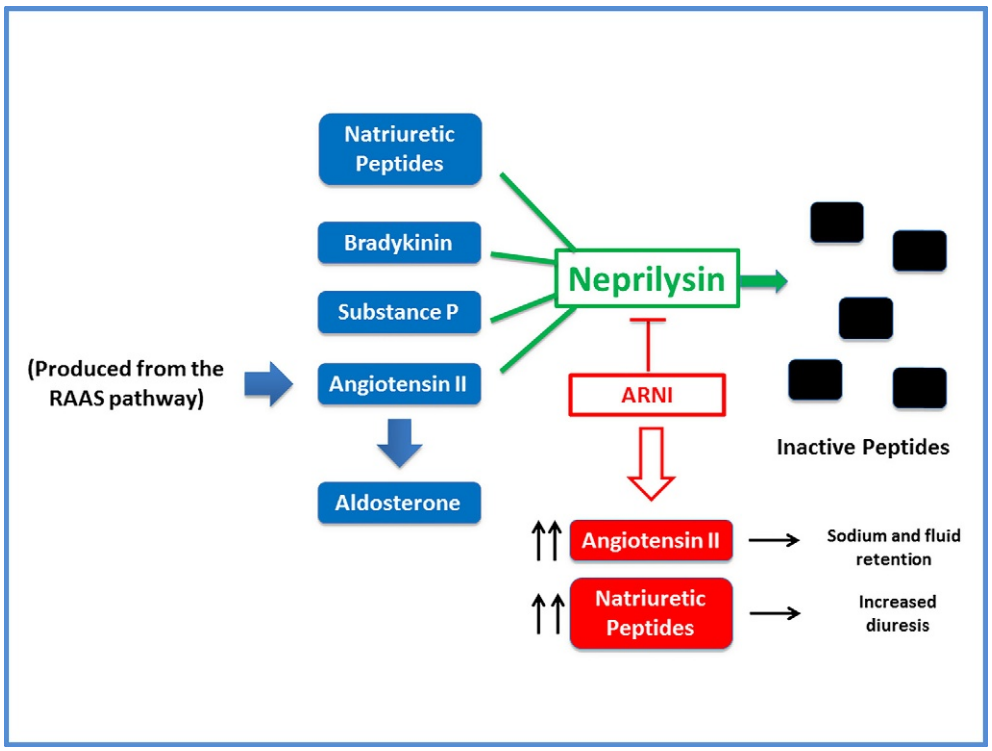

Fig. 9 Mechanism of ARNI in HF. Under normal conditions neprilysin is responsible for enzymatically degrading natriuretic peptides, bradykinin, substance P, and angiotensin II. When ARNI is used there is a downstream increase in angiotensin II and natriuretic peptides which have competing actions.

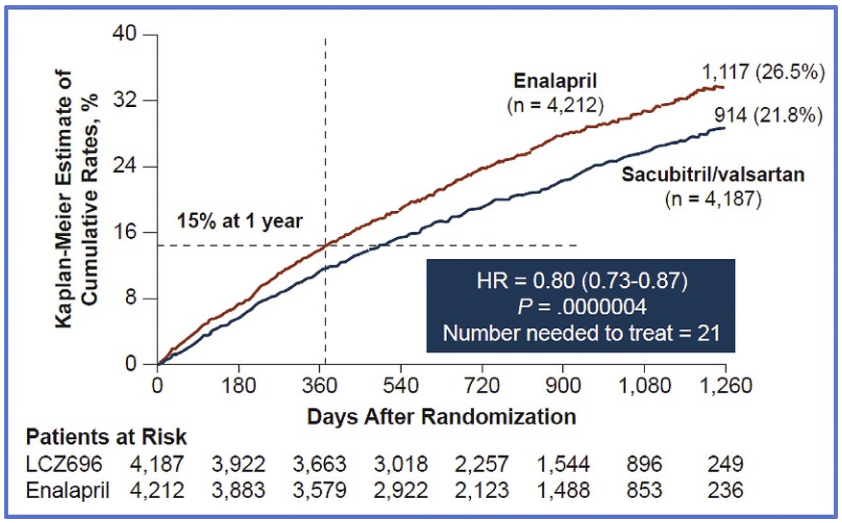

Fig. 10 Kaplan-Meier curves detailing the outcomes in the PARADIGM trial. After a median follow-up of 27 months, an absolute reduction of 4.8% was seen in the primary end point of cardiovascular death and HF hospitalization (Adapted from McMurray et al., 2014).

death and HF hospitalization. After a median follow-up of 27 months, an absolute reduction of 4.8% was seen in the primary end point (HR 0.80, 95% CI 0.73–0.87; $P < 0.001$) (Fig. 10). A similar beneficial effect was seen for cardiovascular death (HR 0.8, 95% CI 0.71–0.89), hospitalization for HF (HR 0.79, 95% CI 0.71–0.89), as well as death from any cause (HR 0.84, 95% CI 0.76–0.93) (McMurray et al., 2014). Subgroup analysis revealed that the significant reduction in cardiovascular death was driven primarily due to the reduction in NYHA Class II patients rather than Class III and IV.

The LCZ696 group had a higher incidence of hypotension and nonserious angioedema but lower incidence of renal impairment, hyperkalemia, and cough than the enalapril group. In a more recent report, the PARADIGM investigators indicated that, in comparison with enalapril, LCZ696 exhibited additional evidence of clinical benefit, including a reduced need for intensification

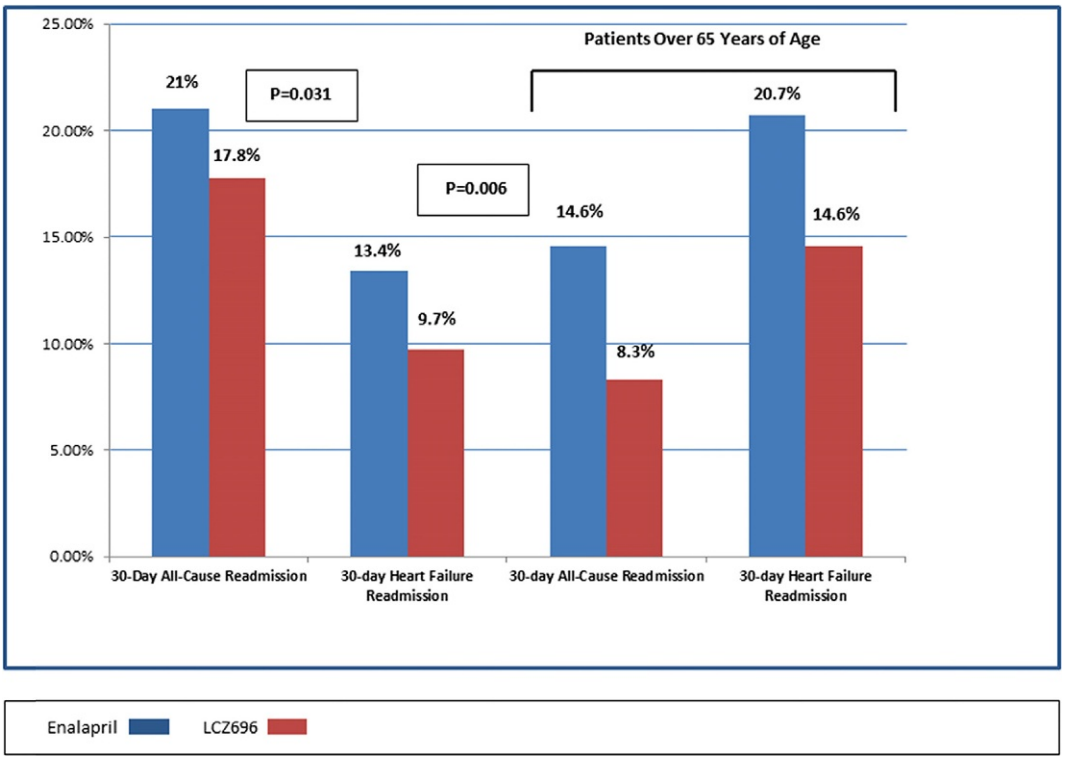

Fig. 11 Post hoc analysis of the PARADIGM-HF Trial is reviewed showing 30-day all-cause readmission and heart failure readmission is shown with applicable p-values. Subgroup analysis of patients over 65 years of age is also shown (Adapted from Desai et al., 2016).

of the treatment for HF, fewer visits to an emergency department for HF, and a lower requirement for intensive care or need for inotropic agents, an HF device, or cardiac transplantation (Packer et al., 2015).

Following completion of the PARADIGM-HF trial further review was completed to assess the effect of LCZ696 on 30 day rehospitalization rates. Given the increase in mortality of HF patients after readmission (Bello et al., 2014; Setoguchi et al., 2007) and reimbursement driven incentives, interest has grown in agents that can decrease rehospitalization in this group of patients. In their analysis it was found that at 30 days after initiation of LCZ696 there was a 38% reduction in HF hospitalization (OR 0.62, 95% CI 0.45–0.87; $P=0.006$) as well as a 26% decrease in hospitalization for any cause (OR 0.74, 95% CI 0.56–0.97; $P=0.031$) (Fig. 11).

It should be noted that in the PARADIGM trial there was a 2-week run-in phase where patients had an open label period in which they demonstrated tolerability to enalapril and then to LCZ696 before they were randomized. Therefore, only patients who tolerated both drugs were randomized in the trial and in practice clinicians will need to get experience with the tolerability and titration of this medication. Nevertheless, the benefits seen with this medication prompted an update of the ACC/AHA HF guidelines in 2016 with the following class I indications (Yancy et al., 2016):

> The clinical strategy of inhibition of the renin-angiotensin system with ACE inhibitors OR ARBs, OR ARNI in conjunction with evidence-based beta blockers, and aldosterone antagonists in selected patients is recommended for patients with chronic HFrEF to reduce morbidity and mortality.
>
> In patients with chronic symptomatic HFrEF NYHA class II or III who tolerate an ACE inhibitor or ARB, replacement by an ARNI is recommended to further reduce morbidity and mortality.

Due to the higher risk of angioedema, ARNI should not be administered concomitantly with ACE inhibitors or within 36 h of the last dose of an ACE inhibitor. Furthermore, in the PARADIGM trial, patients with stable HF were started on this medication. The safety and tolerability of ARNI, when initiated at the time of HF hospitalization, is being examined in the PIONEER trial (ClinicalTrials, 2015).

Of note, with the use of ARNI serum BNP levels will be elevated due to their inhibitory elevated effect on neprilysin (Fig. 9). This was seen among enrollees in the PARADIGM trial where serum levels of BNP were significantly reduced among those receiving LCZ696 versus those receiving enalapril. This reduces the usefulness of serum BNP for monitoring of volume status and prognosis. Additionally, enhanced diuresis is noted as a side effect and may lead to orthostatic hypotension. This should prompt clinicians to adjust diuretics as indicated.

Some concern remains about the safety of ARNI due to the nonselective nature of blockade, specifically the inhibition of amyloid β degradation. Amyloid β (Aβ) accumulation has been demonstrated to play a primary role in the etiology of Alzheimer's

disease (AD). Similar mechanisms also appear to play a role in age-related macular degeneration (AMD) (Ohno-Matsui, 2011). In AD the accumulation of Aβ leads to synaptic loss and clinically neurologic decline. Neprilysin has been identified as one of the predominant amyloid-degrading enzymes of Aβ (Leissring et al., 2003; Marr et al., 2003; Spencer et al., 2014) and levels of neprilysin have been shown to decrease with age as well as following a hypoxic event or ischemic stroke all which are precursors of AD. Additionally, mice studies have shown that with neprilysin inhibition and neprilysin-deficient mice there is a rise of specific peptide targets, Aβ1-40 and Aβ1-42 (Iwata et al., 2001; Shirotani et al., 2001).

The PARADIGM-HF trial investigators attempted to allay fears about Aβ deposition by citing a 2-week study in which healthy volunteers received sacubitril/valsartan and there was no significant increase in cerebrospinal fluid (CSF) concentration of Aβ1-40 and Aβ1-42, but an increase in Aβ1-38 (Langenickel et al., 2016). It was also noted that other enzymes have been shown to contribute to the degradation of Aβ, including insulin-degrading enzyme, endothelin-converting enzyme, angiotensin-converting enzyme, thimet oligopeptidase, and plasmin (Carson and Turner, 2002; Wang et al., 2006; Baranello et al., 2015). However, despite this evidence questions still remain about the influence of sacubitril/valsartan on the possible development of Aβ deposition and neurocognitive deficits. Given subjects used in the CSF study were healthy volunteers critics suggest this model does not represent the more permeable blood-brain barrier that is present in more elderly and ill HF patients. Therefore, the Food and Drug Administration is requiring the sponsor of the PARADIGM-HF study to complete a follow-up study entitled "multicenter, randomized, double-blind, active-controlled trial to evaluate the effects of Entresto compared to valsartan on cognitive function as assessed by comprehensive neurocognitive battery and [positron emission tomography] imaging in patients with chronic heart failure with preserved ejection fraction" (US Food and Drug Administration, 2015). Until results are available, clinicians should remain aware of the theoretical neurodegenerative and visual deficits that could occur with neprilysin inhibition.

Combined Angiotensin Blocker-Neprilysin Inhibitor (ARNI) in HFpEF

LCZ696 was tested in HFpEF patients in the Prospective comparison of ARNI with ARB on Management Of heart failUre with preserved ejectioN fracTion (PARAMOUNT) trial, a phase II clinical trial. Three hundred and one patients with LVEF $\geq$45%, NYHA II-III, and NT-pro BNP >400 ng/mL were randomized to LCZ696 or valsartan. The primary outcome, NT-proBNP, was significantly reduced at 12 weeks in the LCZ696 group compared with the valsartan group. Moreover, a significant improvement was seen in NYHA class and an improvement in echocardiographic parameters like left atrial size with LCZ696 at 36 weeks compared with valsartan. However, left ventricular ejection fraction, volume, and Doppler parameters of diastolic function did not improve with LCZ696 (Solomon et al., 2012). Given the overall encouraging results, the PARAGON (Prospective Comparison of LCZ696 with ARB Global Outcome in HF with Preserved Ejection Fraction), phase III trial has begun. It is intended to enroll 4300 patients with LVEF >45% and will evaluate the effects of LCZ696 on morbidity and mortality end points in HFpEF (ClinicalTrials, 2016).

Incremental Therapies in Heart Failure with Reduced Ejection Fraction (HFrEF)

Each of the neurohormonal blockade therapies discussed have individually been shown to be of benefit in patients with HFrEF. However, current guidelines recommend addition of therapies in a stepwise fashion in appropriately selected patients. Additionally, many of the trials completed selected patients already on treatment for HF as therapies were gaining evidence for benefit. Based on the clinical trials completed thus far, there is evidence that each drug class has an incremental benefit with its addition including ACE inhibitor/ARB, β-blockers, and aldosterone antagonists. In a review of each added therapy based on prior randomized controlled trials a calculated relative reduction in mortality of 17% for ACE inhibitor/ARB therapy, 34% for β-blocker therapy, and 30% for aldosterone antagonists (**Table 3**) was estimated (Fonarow et al., 2011). Use of the ARNI provided an incremental reduction of 16% in mortality relative to ACE inhibitors, in patients already on β-blockers +/- aldosterone antagonists.

Table 3 Incremental benefit of neurohormonal blockade in HFrEF (Yancy et al., 2013; Desai et al., 2016)

Therapy	*RR in mortality (%)*	*RR in HF hospitalization (%)*
ACE Inhibitor or ARB	17	31
Beta-Blocker	34	41
Aldosterone Antagonist	30	35
ARNI	26	28

RR, relative reduction; *ACE*, angiotensin converting enzyme; *ARB*, angiotensin receptor blocker; *ARNI*, angiotensin receptor neprilysin-inhibitor.

The estimated benefit of ARNI is based on its use instead of ACE inhibitors or ARBs.

Adapted from Yancy et al. (2013). ACCF/AHA guideline for the management of heart failure—A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation 138*, e270.

Conclusions

HF is a chronic, progressive disease which leads to reduced quality of life due to volume overload, dyspnea, and recurrent hospitalization as well as reduction in longevity when compared to healthy patients. These pathologic changes have been linked to volume and sodium retention, myocardial remodeling, and increased vasoconstriction through neurohormonal mechanisms in patients with HFrEF and HFpEF. Evidence has shown reduction in mortality, hospitalization for HF, and improvement in myocardial function with blockade of the neurohormonal systems using ACE inhibitors, ARBs, beta-blockers, aldosterone antagonists, and ARNI, specifically among those HFrEF. Clinicians should strive to initiate these agents and gradually increase the doses toward target doses, as tolerated, and based on the published AHA/ACC HF guidelines to modify clinical outcomes in patients with HF.

Introduction

The autonomic nervous system (ANS) is an organized compendium of afferent and efferent neurons that enable the central nervous system to communicate with organs and tissues throughout the body. The ANS functions constantly and involuntarily and is regulated by centers located in the spinal cord, brain stem, and hypothalamus. It is comprised of two differentially regulated cholinergic preganglionic pathways, named the sympathetic nervous system (SNS) and parasympathetic nervous system (PNS), which innervate ganglia (e.g., paravertebral or prevertebral sympathetic ganglia), glands (e.g., adrenal and mammary glands), and neural networks servicing the cardiovascular system. As such, the ANS serves as a key player in blood pressure (BP) regulation and blood flow/hematocrit redistribution.

The SNS and PNS exert antagonistic effects on the heart (see section "**Neurological Regulation of the Heart**"), which regulate BP via alterations in cardiac output (CO). In contrast, in a majority of tissues, the SNS provides the primary efferent input regulating vascular resistance (in arteries and arterioles) and blood volume (in veins and venules) through alterations in vascular tone.

This article aims to give an overview of major neurological inputs and receptor ligand interactions that contribute to cardiovascular homeostasis. The discussion begins with neurological regulation of the heart, moves chronologically through the vascular system, and ends with a discussion of modifiers of neurological regulation of the circulation (see **Fig. 1** for overview).

Neurological Regulation of the Heart

The heart serves as the main energy source of the circulation and is responsible for the movement of blood throughout the periphery with every beat, where the ANS serves to modify function and energy output of the heart. In light of discussing neural control of the circulation, it is important to address the effects of the ANS on heart function, as its efferent control is integrated into the afferent circulatory reflex regulated at the level of the brainstem. The heart is innervated by both parasympathetic and sympathetic postganglionic fibers arising from the vagus, stellate, and middle cervical ganglion, respectively (Gourine et al., 2016; Coote, 2013; Coote and Chauhan, 2016). Together, parasympathetic and sympathetic neurons modulate chronotropy (heart rate, HR), dromotropy, (conduction of cardiac impulse), lusitropy (myocyte relaxation), and inotropy (contraction force) of the heart.

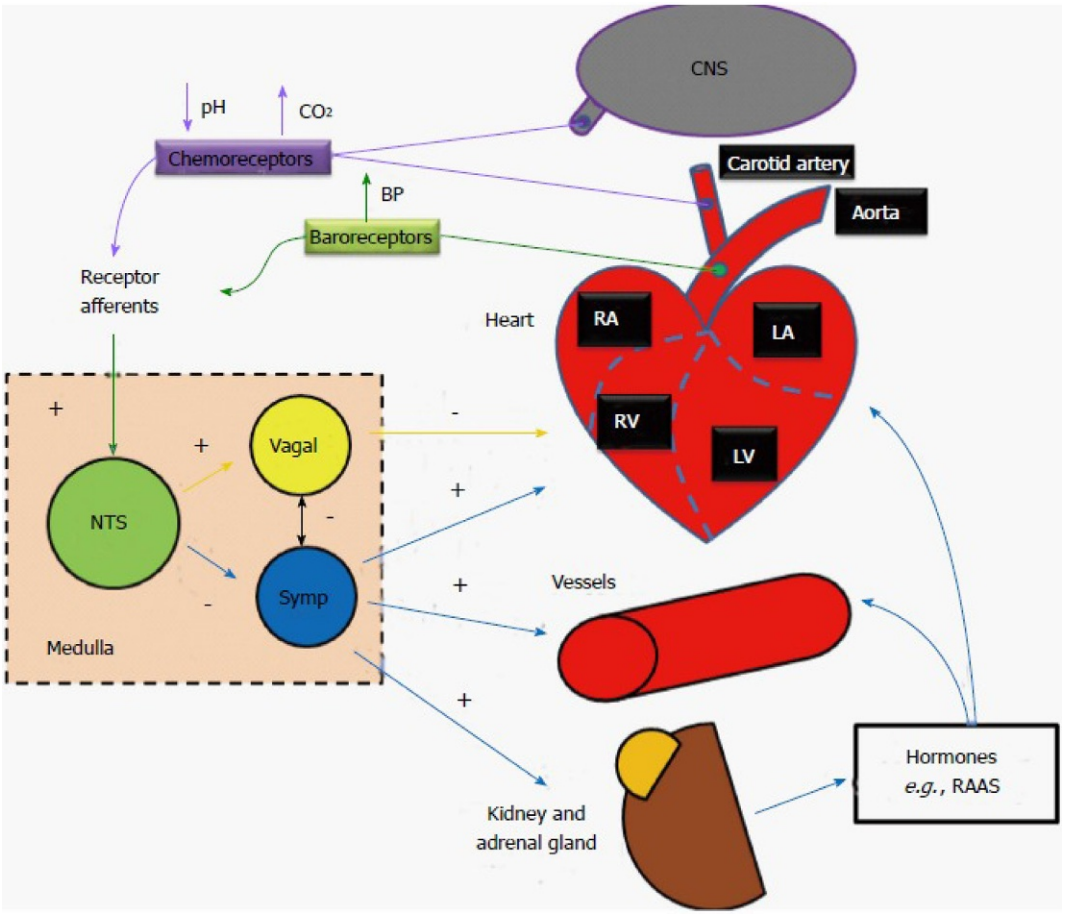

Fig. 1 Schematic of cardiovascular reflexes and their influences on heart and vessel functions. *NTS*, nucleus tractus solitarii; *Symp*, sympathetic; *CNS*, central nervous system; *RAAS*, renin-angiotensin-aldosterone system. From *World Journal of Cardiology* 2015, **7**(4), 204–214. https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4404375/figure/F3.

The sinoatrial (SA) and atrioventricular (AV) nodes, and the atria receive dense neural innervation from the PNS and SNS. In contrast, the ventricular myocardium receives dense neural innervation from mostly sympathetic fibers and less from parasympathetic nerve fibers (Levy et al., 1981). It was not until recently that anatomical and functional evidence have highlighted a putative role of parasympathetic neural control on ventricular contractility (Coote, 2013).

Parasympathetic postganglionic nerve fibers release acetylcholine upon activation. Acetylcholine binds to cholinergic M_2 muscarinic receptors expressed on nodal cells (G_i-protein-coupled receptors) which activate the opening of G-protein-coupled inward rectifying potassium channels, causing hyperpolarization (Harvey and Belevych, 2003). This leads to a decrease of the intrinsic firing rate of the SA node, as well as the slowing of impulse conduction through the AV node, thus slowing HR. In addition, activation of the cholinergic M_2 receptor also leads to the inhibition of adenylyl cyclase (AC). This inhibits the formation of cyclic adenosine monophosphate (cAMP), and depending on the effector cardiac tissue, can inhibit the pacemaker channel (funny current) of the SA and AV nodes and decrease calcium channel activity (membrane-bound L-type- and ryanodine receptor-mediated changes in cellular calcium) necessary for cardiac muscle contraction (Harvey and Belevych, 2003; Gordan et al., 2015).

Sympathetic postganglionic nerve fibers are adrenergic and release norepinephrine (NE) to activate β_1- and α_2-, and β_1-, β_2, and β_3 adrenergic receptors expressed in nodal cells and cardiomyocytes, respectively (Harvey and Belevych, 2003; Gordan et al., 2015). However, the effects of NE on cardiac function are mediated primarily by β_1-adrenergic receptor (β_1R) activation and are the predominant receptor subtypes found in healthy mammalian hearts (Kaumann, 1997; Brodde and Michel, 1999). The β_1R is a G_s-protein-coupled receptor and elicits downstream responses via activation of AC, generation of cAMP, and activation of protein kinase A (PKA). Within the cells of the SA node, β_1R-mediated elevation of cAMP activates the pacemaker current (funny current), increasing the steepness of diastolic depolarization, and increasing HR (Difrancesco, 2010). β_1R activation also increases the lusitropic and inotropic effects of cardiomyocytes via heightened activation of PKA and downstream phosphorylation of cardiac cell regulatory proteins. PKA decreases myofilament calcium sensitivity and accelerates cross bridge cycling, leading to enhanced relaxation of cardiomyocytes (positive lusitropic effect). In addition, PKA can interact with sarcoplasmic reticulum (SR) proteins, accelerating the uptake of calcium into the SR to enhance relaxation. This also sequesters greater amounts of calcium within the SR that becomes available for release upon the next contraction (positive inotropic effect). Further contributing to the inotropic effects

of β-adrenergic receptor activation, PKA activates cardiac cell L-type calcium channels, increasing calcium influx during the action potential and activating calcium-mediated calcium release via SR ryanodine receptors, ultimately increasing contraction force of the cardiomyocytes (Najafi et al., 2016). Both the positive lusitropic and inotropic effects of sympathetic stimulation of the heart therefore increase stoke volume.

Recently, the β_3R's role in the heart has been described as "brakes" for the SNS, as they are activated at high catecholamine concentrations, which elicits a negative inotropic effect. It is postulated that this system antagonizes the actions of β_1R and β_2R to buffer sympathetic overstimulation of the heart. β_3R stimulation has been shown to produce nitric oxide (NO), which essentially prevents pressure overload-induced myocardial nitric oxide synthase (NOS) uncoupling (Moens et al., 2010).

In addition to NE, the sympathetic cotransmitter neuropeptide Y (NPY) plays a role in mediating cardiac function; however, its actions are complex and must often be assayed in the presence of β-blockers. NPY is found in the peripheral nerves of the heart, the intracardiac ganglia, endocardium, and myocardium. It is costored with NE and on its own within large dense-cored secretory vesicles of postganglionic neurons, and its release is often associated with elevated levels of sympathetic drive to the heart (Horackova et al., 1999; Dalsgaard et al., 1986; Kennedy et al., 1998; Malmstrom, 2002). NPY interacts with its respective Y1 (Y1R) and Y2 (Y2R) receptors to elicit its effects on heart function, and recently the Y3 receptor (Y3R) has also been suggested to contribute to NPY's actions on the heart (Balasubramaniam, 1997; Smith-White et al., 2002; Protas and Robinson, 1999). Interestingly, NPY can modify prejunctional sympathetic and vagal neurotransmitter release, contractility of the ventricles, and vascular resistance of coronary blood vessels (Herring et al., 2008). NPY can act on presynaptic Y2Rs to inhibit its own release, as well as on Y2Rs of prejunctional vagal cholinergic neurons to modify acetylcholine release and reduce the magnitude of vagal bradycardia (Malmstrom, 2002; Herring, 2015; Awad et al., 1991; Potter et al., 1989). In addition to its cross-talk with vagal afferents, NPY can also act on Y1Rs and Y2Rs of the ventricular myocytes to modify myocardial contractility and has recently been implicated in contributing to arrhythmias occurring with heart disease (Herring, 2015; Awad et al., 1991). NPY has been shown to modify transient outward potassium currents (Heredia et al., 2002), L-type calcium currents (Bryant and Hart, 1996; Millar et al., 1991), and pacemaker currents within the right ventricles (Qu et al., 2000), as well as increase cell shortening and calcium transients of venticular myocytes (Heredia Mdel et al., 2005).

Based on the dynamic blood flow requirements of the body, the ANS modifies HR and stroke volume to increase or decrease CO accordingly. Under basal conditions, there is still a need for active autonomic drive to the heart and a balance between parasympathetic and sympathetic discharge to maintain resting HR and CO. Due to the intrinsic spontaneity of the SA node, HR would be 90–100 beats/min in the absence of extrinsic neural influences. Thus, elevated vagal activation maintains resting HR 30% lower than the intrinsic rate of the heart and moderate tonic sympathetic activation maintains CO 30% higher than in the absence of sympathetic discharge (Thomas, 2011). The required changes in CO can therefore be governed by the amount of vagal and sympathetic withdrawal and/or activation.

Neurological Regulation of Arteries and Arterioles

Due to the high resistance offered by the arteriolar microcirculation, blood moves through the arterial system under relatively high pressure and velocity. As such, the arterial side of the cardiovascular system is considered a pressure reservoir. Sympathetic nerves servicing arteriolar beds provide the chief extrinsic input regulating resistance (and blood flow) to organs. Postganglionic sympathetic nerves are localized to the adventitial-medial border of most arteries, arterioles, and veins throughout the body (Thomas, 2011). Postganglionic sympathetic neurotransmitters are released based on neuronal firing frequency and amplitude (i.e., sympathetic nerve activity, SNA), with increases in SNA associated with potent and prolonged vasoconstriction. Like the autonomic nerves that innervate the heart, the sympathetic nerves innervating the vasculature also display ongoing tonic activity. This background of SNA sets baseline tone (i.e., level of vasoconstriction) in resistance vessels. As such, modulating sympathetic outflow via increased SNA or sympathetic withdrawal promotes rapid changes in contractile state thereby increasing or decreasing resistance as needed. In the majority of peripheral vascular beds (particularly skeletal muscle), sympathetic neurotransmission is adrenergic (via the catecholamine NE), purinergic (via adenosine triphosphate, ATP), and peptidergic (via NPY).

Isolated in situ and in vivo stimulation of sympathetic nerves has demonstrated the corelease of NE, ATP, and NPY from axon terminals (Morris, 1999; Lundberg et al., 1990). However, NE, ATP, and NPY have different potencies for vasoconstriction and are not released in the same relative concentrations. For example NPY's potent vasoconstrictor effects are realized at concentrations $\sim$1000 $\times$ lower than similar responses elicited by NE and ATP. The release of each transmitter is dependent on the intensity and the pattern of SNA, where ATP and NE concentrations peak under relatively low SNA and NPY concentration peaks at much higher SNA intensities (Hirsch and Zukowska, 2012). Although our knowledge of SNS-mediated vasoconstriction has expanded in the past decades, the roles of NPY and ATP in skeletal muscle blood flow regulation remain to be characterized to the level of NE.

Adrenergic Control

SNS-mediated adrenergic regulation of small arteries and arterioles occurs when NE is released from sympathetic neurons to interact with adrenergic receptors located on the abluminal surface of vascular smooth muscle. Currently, at least nine adrenergic receptor subtypes have been cloned (α_{1A}, α_{1B}, α_{1D}, $\alpha_{2A/D}$, α_{2B}, α_{2C}, β_1, β_2, and β_3); however, their functional roles are yet to be fully described (Guimaraes and Moura, 2001). In terms of SNS-mediated adrenergic vasoconstriction, postjunctional α_1R and α_2-adrenergic

receptors (α_2R) predominate, albeit, the specific receptor subtypes that are involved vary among different vascular beds (Thomas, 2011). Currently, α_{1A}-, α_{1D}-, $\alpha_{2A/D}$-, and α_{2B}-receptor subtypes are most commonly associated with vascular regulation. The α_1R belongs to the $G_{q/11}$ family of heterotrimeric G proteins. Upon activation, β-isoforms of phospholipase C are stimulated, which leads to an IP3-induced release of intracellular calcium (Ca^{2+}) and activation of protein kinase C (PKC; to phosphorylate and activate a downstream cascade of protein signaling). This release of Ca^{2+} binds onto calmodulin, which activates myosin light chain kinase to phosphorylate myosin heads, increasing myosin ATPase activity and promoting contraction of vascular smooth muscle. In contrast, postjunctional α_2Rs belong to the G_i family of the heterotrimeric G proteins. Activation of this receptor promotes AC inhibition, ultimately attenuating cAMP production from ATP. The drop in cAMP increases the activity of myosin light chain kinase, thereby phosphorylating myosin light chain and resulting in overall vasoconstriction. In skeletal muscle arterioles, α_1R- and α_2R-mediated constriction occurs with greatest potency in lager diameter proximal arterioles, suggesting that they are primarily involved in redistributing bulk blood flow to tissues (Al-Khazraji et al., 2015; Jackson et al., 2004, 2010).

Most small arteries and arterioles also express β-adrenergic receptor subtypes (β_1, β_2, and β_3), with the β_2-receptor (β_2R) subtype being the best described. Specific activation of vascular β-adrenergic receptors promotes vasodilation; however, since β-adrenergic receptors are most commonly exposed to the lumen of vessels, they are activated by interactions with circulating catecholamines (see section "Neurohumoral Regulation of the Circulation" below) as opposed to direct activation by the SNS. Of note, although β_3-adrenergic receptors (β_3R) belong to the superfamily of G-protein-coupled receptors (like the β_1R and β_2R), β_3R can interchangeably couple to both Gs and Gi without the requisite for receptor phosphorylation. β_3R activation promotes vasodilation via the production of NO and occurs at catecholamine concentrations that are higher than those required for β_1R and β_2R activation (Conti et al., 2013). Taken together, the β_3R likely provides protective "dilatory escape" under hyper-adrenergic conditions.

Purinergic Control

Sympathetic neurons release ATP to act on purinergic P2X1 receptors (P2X1R) located on the abluminal surface of arteries and arterioles. The P2X1R is an inotropic receptor and a member of the ligand-gated ion channel P2X receptor family (Valera et al., 1994). Upon binding of ATP, the P2X1R changes conformation and allows for Ca^{2+} to enter the cell, depolarizing smooth muscle cells and resulting in overall vasoconstriction of the arteriole. The role of ATP-mediated arteriolar constriction in microvascular networks was recently evaluated and, in contrast to adrenergic control, ATP elicits its greatest constrictor effects in small diameter, distal arterioles, suggesting a role for the P2X1R in red blood cell/hematocrit distribution to capillary beds (Al-Khazraji et al., 2015).

Peptidergic Control

NPY is a vasoconstrictive neuropeptide released from neuronal varicosities that act on NPY receptors located abluminally on vascular smooth muscle and prejuctionally on axon terminals. NPY Y1Rs are abundant throughout mammalian systems and peripherally located Y1Rs are expressed mainly in arteries, arterioles, and veins, where they are associated with vasoconstriction and potentiation of other vasoconstrictors of neurogenic origin. The NPY Y1R is a G-protein-coupled receptor located mainly postjunctionally on vascular smooth muscle cells. When activated, there is inhibition of AC and via cAMP/Phospholipase C coupling, which elicits increases in intracellular Ca^{2+} leading to potent and long-lasting vasoconstriction.

Neuronally released NPY can be modified by proteolytic processing via enzymes that reside throughout mammalian systems. The exopeptidase dipeptidyl peptidase IV (DPPIV) is a membrane-bound metalloprotease, which cleaves the Tyr-Pro dipeptide (in the penultimate position) from the N-terminus of the complete 36 amino acid NPY_{1-36}. The resulting fragment, NPY_{3-36}, has a low affinity for the Y1R, but favorably binds to the Y2R (Mentlein and Roos, 1996). In blood vessels, DPPIV is abundant on endothelial cells and a soluble form of DPPIV is found in plasma. Another proteolytic enzyme that targets NPY is Aminopeptidase P (APP). APP cleaves the N-terminal Tyr residue from NPY_{1-36} resulting in the NPY_{2-36} fragment that has low affinity for Y1R, but high affinity for Y2R. APP is present on neurons, smooth muscle, and endothelial cells; furthermore, a soluble form is present in the circulation.

The NPY Y2R was first cloned in 1995 (Gerald et al., 1995). Current data indicates that Y2Rs are located mostly presynaptically; however, past research has shown that postjunctional Y2Rs can exist at low levels in pig spleen, causing vasoconstriction (Modin et al., 1991). Such postjunctional effects have not yet been observed in other tissues; as such, Y2R activation is generally associated with inhibition of neurotransmitter release. This effect is manifested though inhibition of AC and voltage-dependent Ca^{2+} channels via Y2R linked G proteins. Research has shown that endogenous, neuronally released NPY activates prejunctional Y2R to exert autoinhibition of its own release (Malmstrom et al., 2002a,b). This effect has also been exhibited using exogenous NPY or its truncated analogs (Malmstrom et al., 2002b). Cleavage of NPY at the ultimate N-terminus residue Tyr_1 or penultimate Tyr_1-Pro_2 residues results in NPY analogs (NPY_{2-36} and NPY_{3-36}, respectively), these analogs are equipotent to NPY with respect to Y2R binding affinity (Beck-Sickinger and Jung, 1995).

Ligand Potentiation

As stated above, sympathetic postganglionic neurons release NE, ATP, and NPY, with release of these contents being more prevalent at high nerve stimulation frequencies (Lundberg et al., 1994). This cocktail of neurochemical messengers enables a number of

biological effects and interactions (i.e., slow, intermediary, and quick sympathetic signaling) (Lundberg, 1996). For example, NPY produces a slow acting, potent, and persistent increase in vascular tone. In contrast, NE-induced vasoconstriction occurs more quickly and disappears at a similar rate. Moreover, ATP-induced vasoconstriction has been shown to be immediate and very short acting. It has been postulated that the duration of each transmitter's effects relies on each one's unique mode of deactivation/removal. For example, NE's vascular effects are removed quickly (via NE reuptake) compared to the prolonged duration of NPY-induced vasoconstriction that is eliminated by enzymatic degradation of "free" NPY (Lundberg, 1996).

In several early investigations, NPY was shown to potentiate α-adrenergic vasoconstriction in vivo (Dahlof et al., 1985; Revington and McCloskey, 1988; Linder et al., 1996; Jackson et al., 2005) and in vitro (Edvinsson et al., 1984; Ekblad et al., 1984; Glover, 1985). The synergistic interaction between NPY and NE is receptor-mediated, as NPY also enhanced the vasoconstrictive response to sympathetic nerve stimulation and phenylephrine (specific α1R agonist)-induced vasoconstriction (Dahlof et al., 1985). The interactive effects are not a result of general changes in the reactivity of smooth muscle cell to increased Ca^{2+} concentration, because in some tissues/preparations NPY does not modify the effects of other neurotransmitters (Edvinsson et al., 1984). Thus, the interactive effects should not only be tissue specific, but these effects must also be due to consequent modification of specific receptor properties and/or second messengers.

Neurological Regulation of the Venous System

Once blood has made its way out of the heart, through the arteries, and into the microcirculation it is collected by the venous system, where it has lost most of the energy (i.e., pressure) originally imparted on it by the heart. As such, venous pressure represents the lowest pressure in the circulation, and since approximately 70% of the total blood volume is stored by the venous system (Rothe, 1983), it is regarded as a capacitor or volume reservoir. Based on this ideology, any alteration in venous capacity has profound effects on venous return and CO.

Similar to arteries and arterioles, the SNS is the primary regulator of venomotor tone (Mellander and Lewis, 1963; Tabrizchi and Pang, 1992), with sympathetic nerve fibers directly innervating vascular smooth muscle cells of the venous system. However, in contrast to arterioles, increased SNA to small veins and venules results in alterations in venous compliance, thus altering venous volume (capacitance) with little impact on systemic resistance. Notably, compared to arteries and arterioles, there is a relative dearth of literature describing neurogenic regulation of the venous system.

Adrenergic Control

SNS influence on the venous circulation occurs primarily through the α-adrenoceptors that are found on vascular smooth muscle cells (De Mey and Vanhoutte, 1981). Like arterioles, α_1 and α_2 adrenoceptors expressed on the smooth muscle of the vasculature induce venoconstriction upon activation (van Brummelen et al., 1986), which increases central venous pressure and venous return to the heart (de Souza Rossignoli et al., 2015). Overall, both α_1R and α_2R are involved in regulation of venous resistance, but magnitude of responses varies among vascular beds and between species.

Evidence of β_2R involvement in venous circulation is relatively scant; however, stimulation of β_2Rs results in venodilation (Schindler et al., 2004). For example, studies using isoproterenol (β_2R agonist) observed a venodilation in the veins of the hand (Schindler et al., 2004; Harada et al., 1996), but only in conditions of elevated venous tone induced by vasoactive drugs. Furthermore, a study which blocked β_2Rs with propranolol in the splanchnic vasculature showed evidence of β-adrenergic involvement in venous circulation (Mastai et al., 1987). Overall, there is evidence that β-adrenoceptors are involved in regulation of the venous circulation, but only under experimental conditions where venoconstriction is induced or sympathetic tone is impaired. It has been postulated that stimulation of venous β_2Rs is most likely due to interactions with circulating catecholamines (described below: section "Neurohumoral Control"), instead of direct SNS stimulation (Thomas, 2011).

Peptidergic Control

Like arterioles, the SNS also exhibits peptidergic control in the venous system, as NPY is colocalized with NE in sympathetic neurons servicing most venous and venular networks (Ekblad et al., 1984). As well, NPY containing nerve fibers have been shown to innervate hepatic veins in several species (Pongor et al., 2010). In support, a study by Luu et al. reported NPY-induced constriction in the saphenous vein of humans (Luu et al., 1992) illustrating that, in addition to α_1- and α_2R control, sympathetic activity can modify venous tone through NPY Y1R activation.

Modifiers of Cardiovascular Neurological Regulation

Neurogenic regulation of the circulation is modulated by reflex alterations in autonomic activity on a moment-to-moment basis responsible for maintaining CO, mean arterial BP, and adequate tissue perfusion. Importantly, the greatest contributor to the central neurological regulation of the circulation is the modulation of SNA due to its potent effects on peripheral vascular

resistance, that is vasoconstrictive, and thus the ability to impact changes in BP. The most fascinating phenomenon highlighting the activity of reflex neurogenic control of the circulation is the profound cardiovascular and hemodynamic modifications encountered from rest to dynamic exercise. Such reflexes exist to meet the increased metabolic demand of active skeletal muscle. In addition to exercise, postural changes, temperature, altitude, and microgravity have also been associated with cardiovascular reflex activation (Mitchell and Victor, 1996). In light of exercise, precise cardiovascular and hemodynamic tuning occurs in an intensity-dependent manner via the integrated nature of several neural mechanisms in place to support skeletal muscle perfusion, sufficient oxygen (O_2) delivery, and waste removal over time. From as early as the late 1800's, the notion of descending signals from higher brain centers and the presence of neural afferent feedback from skeletal muscle, the carotid artery, and aortic arch, and pulmonary circulation have been studied in depth and demonstrate their involvement in effecting cardiovascular and hemodynamic responses to exercise (Zuntz and Geppert, 1886; Fadel, 2015; Krogh and Lindhard, 1913; Johansson, 1895). Such important neural mechanisms have been primarily identified as: (1) central command (feedforward mechanism associated with perception of exercise), (2) the exercise pressor reflex (encompasses feedback mechano- and chemoreflexes), (3) arterial baroreflex (negative feedback from carotid sinus and aortic arch), and (4) cardiopulmonary baroreflex (negative feedback from the chambers of the heart and pulmonary circulation).

Together, the integrated compliment of these cardiovascular control mechanisms has been best described by Mitchell in 1990, where responses to exercise are dependent upon the "type of exercise (static or dynamic), the intensity of exercise, the time after onset of exercise (immediate, steady state, exhaustion, etc.), and the effectiveness of blood flow in meeting the metabolic needs of the contracting muscles (Mitchell, 1990)." However, present-day knowledge lends itself to the numerous human and animal studies allowing for the discrete identification of each mechanism in modulating cardiovascular and hemodynamic parameters. The neural modulation reflexes are discussed in further detail below.

Central Command

It is often stated that central command encompasses the descending neural signals from higher brain centers that can influence sympathetic- and parasympathetic-mediated cardiovascular responses to exercise even before the onset of activity, that is vagal withdrawal and elevated BP (Williamson et al., 1995; Nobrega and Araujo, 1993). The original concept of higher brain centers was introduced when Zuntz and Zeppert suggested a feed-forward "central control mechanism" responsible for simultaneous activation of respiratory centers and locomotor pathways that caused the increased breath rate at the onset of exercise in conjunction with voluntary activity (Zuntz and Geppert, 1886; Fadel, 2015). Building on this hypothesis, Nobel Prize Winners Krogh and Lindhard coined "cortical irradiation" to describe the signals responsible for activation of not only respiratory neural circuits but also neural reflex control of the circulation during the initial stages of exercise (Fadel, 2015; Krogh and Lindhard, 1913; Paterson, 2014). Now known as "central command," this concept is commonly defined as a "feedforward mechanism" involving parallel descending neural signals from motor centers in the brain that activate somatomotor, respiratory, and cardiovascular centers (Goodwin et al., 1972).

In effort to identify these "higher brain centers" associated with cardiovascular control, animal and human studies have attempted to isolate the specific role of "central command" amidst various intricate and often redundant central and peripheral neural contributions. Both animal and human studies have demonstrated the role for the subthalamic locomotor region of the posterior hypothalamus and mesencephalic locomotor region as key structures in cardiorespiratory neurocircuits (Paterson, 2014; Pitts et al., 1941; Smith et al., 1960; Eldridge et al., 1981). In addition, accumulating evidence has demonstrated the periaqueductal gray as an important structure associated with the neural circuitry involved in "central command" as it is activated with exercise and is an area associated with cardiorespiratory control during stress and emotional states (Paterson, 2014; Bandler and Shipley, 1994; Basnayake et al., 2011, 2012; Dampney et al., 2013; Green et al., 2007; Green and Paterson, 2008). Albeit a lack of direct neural measurements from these brain regions in humans, muscle SNA, HR, and arterial BP changes associated with "central command" input have been identified in studies using neuromuscular blockade, tendon stimulation, and electrically stimulated muscle contraction (Goodwin et al., 1972; Victor et al., 1995; Secher et al., 1988; Leonard et al., 1985; Boulton et al., 2016). The magnitude of the "central command" on cardiovascular and hemodynamic variables have also been demonstrated by altering one's perception of effort or exertion, thus removing the direct effect of workload on cardiovascular responses to exercise (Mitchell, 1990; Borg, 1973; Williamson et al., 2001; Thornton et al., 2001). It must be noted that other factors may also modify cardiovascular responses to perception of effort, such as somatosensory signals from muscle and cardiorespiratory changes (Amann et al., 2008), neurocognitive factors (environment, trained or experienced cues, anticipation of work end point) (Faulkner and Easton, 2008), general discomfort (pain, heat exhaustion) (Cabanac, 2006), and attitude/emotion toward activity performance (Morgan, 1994). To further complicate identification of the cardiovascular and hemodynamic changes elicited by "central command," the traditional feed-forward component of the response may also be accompanied by a feedback component (Fadel, 2015; Amann et al., 2008; Williamson et al., 2006; Williamson, 2010). Indeed, cardiovascular and hemodynamic changes during exercise may be a result of input signals modifying the effects of "central command." In theory, this would correct any "error" in output activity from "central command" between perceived and actual level of effort necessary to meet and maintain cardiovascular and hemodynamic parameters sufficient to the level of activity (Williamson, 2010). Further studies are needed to ascertain the integration of feed-forward and feedback function of "central command," as well as identify the involvement of sensory signals modifying the neural control of cardiovascular and hemodynamic responses to exercise.

Exercise Pressor Reflex

Pioneering work by Alam and Smirk established the involvement of neural afferent feedback from skeletal muscle that evoked adjustments of cardiovascular and hemodynamic variables in response to exercise (Alam and Smirk, 1937, 1938). Two main feedback reflexes originating within skeletal muscle have been identified and are known as the mechanoreflex and metaboreflex (i.e., chemoreflex), which together compose the exercise pressor reflex. These afferent components relay both mechanical and chemical sensory information to the cardiovascular centers within the medulla of the brainstem, which becomes integrated within corresponding efferent signals of central command to modify BP, HR, and muscle SNA in response to exercise (Fadel, 2015; Mitchell, 1990; Rowell and O'Leary, 1990; Smith et al., 2006; Crisafulli et al., 2015; Kaufman et al., 1984; McCloskey and Mitchell, 1972; Potts, 2001).

The afferent fibers of the muscle mechanoreflex and metaboreflex are primarily comprised of thin slow-conducting unmyelinated type III and IV neurons, respectively. Their receptors are activated by intramuscular mechanical deformation via changes in pressure or stretch, and by skeletal muscle metabolites produced during muscle contraction. The rapid onset and recovery of group III afferent activity corresponds with mechanoreflex function and the initial event of muscle contraction at exercise onset. In contrast, group IV afferent activity increases gradually after exercise onset, characterizing the function of the metaboreflex with the production and accumulation of metabolites by contracting skeletal muscle. Of note, the functional classification of group III and IV afferents is indefinite as both fiber types can act dually as mechano- and metaboreceptors. In addition, the responsiveness of both fiber types can be sensitized by changes in local metabolites (Fadel, 2015; Rowell and O'Leary, 1990; Crisafulli et al., 2015; Kaufman et al., 1983, 1988; Cui et al., 2008). Regardless of fiber type activation, afferent feedback from skeletal muscle is essential for the increase in BP associated with the exercise pressor reflex and for modulation of efferent sympathetic and parasympathetic activity mediated by central command at the onset of exercise (Rowell and O'Leary, 1990; McCloskey and Mitchell, 1972; Strange et al., 1990; Nobrega et al., 2014).

The array of evidence defining the muscle mechanoreflex and its role in cardiovascular modification with exercise is rather limited, and often can only be characterized at the onset of exercise with initial skeletal muscle contraction (Kaufman et al., 1983; Cui et al., 2006; Gladwell and Coote, 2002; Gladwell et al., 2005). This is simply due to the difficulties encountered upon isolating mechanoreceptor activity in the midst of central command and metaboreflex activation accompanying skeletal muscle contraction. In addition, skeletal muscle metabolites can sensitize mechanoreceptor afferents, further complicating the identification of discrete effects of the mechanoreflex compared to the metaboreflex during muscle contraction. The metaboreflex, however, has been identified to evoke significant neural effects on cardiovascular and hemodynamic variables in response to exercise, specifically by postcontraction occlusion in effort to maintain interstitial levels of metabolites after skeletal muscle contraction has ceased. This isolates the metaboreflex from both the neural effects of central command and the mechanoreflex once physical activity has ceased. Using this technique, the metaboreflex has been identified through its ability to increase BP and muscle SNA (i.e., increased systemic vascular resistance) during moderate and intense exercise (Rowell and O'Leary, 1990; Crisafulli et al., 2015; Strange et al., 1993; Piepoli et al., 1995; Mark et al., 1985; Amann et al., 2010, 2011). Although initially observed as insignificant, the effects of the metaboreflex on HR and CO are also apparent. Using postexercise ischemia does not implicate the metaboreflex in HR changes; however, initiating muscle ischemia during exercise can indeed elicit a HR response (Crisafulli et al., 2011; O'Leary, 1993, 1996). In addition to HR, there is evidence supporting the metaboreflex as a mediator of cardiac contractility, preload, and stroke volume during exercise (Crisafulli et al., 2003, 2011, 2015; Nobrega et al., 2014; Bastos et al., 2000). Reports have also identified a role of the metaboreflex in modulating venoconstriction and splanchnic vasoconstriction to increase venous return and right ventricular filling pressure. This is imperative during exercise as adequate diastolic function is important for the metaboreflex modifications of stroke volume (Crisafulli et al., 2009, 2015; Piepoli et al., 2008).

Multiple metabolic/chemical substances have been associated with activation of the metaboreceptors and the reciprocal changes in cardiovascular, hemodynamic, and cardiac function have been associated with exercise. There is no consensus on a particular substance per se, but rather an accumulation of evidence for multiple contributors to this response. Several metabolites produced by muscle contraction have been identified in contributing to the metaboreflex, such as lactic acid, potassium, bradykinin, arachidonic acid, deprotonated phosphate, ATP, adenosine, and hydrogen ion (Mitchell, 1990; Smith et al., 2006; Murphy et al., 2011; Mortensen et al., 2013; Kaufman, 2012). Among such studies there are conclusions that both oppose and support the involvement of certain metabolites involved, and thus it is likely that the metaboreflex can be activated by a number of interstitial substances.

Arterial Baroreceptors

The arterial baroreflex is a crucial negative feedback mechanism that serves to rapidly adjust autonomic activity in effort to maintain arterial BP on a moment-to-moment basis. The arterial baroreceptors are sensitive to stretch and are located in the carotid sinus and the aortic arch (Sheehan et al., 1941; Sagawa, 1983). A branch of the glossopharyngeal nerve and small vagal branches carry baroreflex afferents from the carotid and aortic baroreceptors, respectively, to the nucleus tract solitarus in the medulla oblongata of the brain stem (Aicher and Randich, 1990). When changes in pressure are sensed via baroreceptor stretch or compression, activated afferents reflexively elicit alterations in sympathetic and parasympathetic nerve activity to the heart and blood vessels, modifying CO and peripheral vascular resistance to maintain arterial BP at its operating pressure point (Melcher and Donald, 1981; Potts et al., 1993; Raven et al., 1997, 2006; Fadel et al., 2003). Under basal conditions, a rise in BP increases baroreceptor activity leading to

decreased SNA, activation of parasympathetic nerve activity, and corresponding decreases in vascular resistance and HR. Conversely, a fall in BP decreases baroreceptor activity, leading to increased SNA, inhibition of parasympathetic nerve activity, and increased vascular resistance and HR. Under conditions of exercise however, a shift in the operating pressure point of the baroreflex occurs as BP is regulated within a higher range and with the same level of reflex sensitivity, continuing to rise with increasing exercise intensity (Potts et al., 1993; Raven et al., 2006; Fadel et al., 2003; Papelier et al., 1994; Norton, 1985; Ogoh et al., 2003). Studies have also demonstrated that such "resetting" of the arterial baroreflex during exercise can be influenced by central command, the exercise pressor reflex, and cardiopulmonary baroreflex (Ogoh et al., 2002, 2006, 2007; Smith et al., 2003; Fisher et al., 2008; Drew et al., 2008a,b; Potts and Mitchell, 1998). With exercise, blood flow is directed to active skeletal muscle by means of metabolic vasodilation/active hyperaemia, which in theory would promote a drop in BP. Thus the baroreflex functions to buffer these drops in pressure via increased SNA to generate greater vascular resistance. Of importance, changes in CO and vascular conductance that are mediated by baroreflex modulation of BP are primarily a consequence of its ability to alter total vascular resistance at rest and during exercise. Therefore, the ability of the baroreflex to regulate SNA during exercise provides a means of tuning skeletal muscle perfusion while maintaining BP, and it also buffers the BP effects of central command and exercise pressor reflex (Crisafulli et al., 2015).

Cardiopulmonary Baroreflex

The cardiopulmonary baroreceptors are low-pressure sensory receptors sensitive to mechanical stretch that respond to changes in central venous volume and pressure, and left atrial pressure. They reside in the cardiac chambers of the heart, the great veins, and within the pulmonary circulation. Despite the limited availability of literature, the cardiopulmonary baroreflex can modulate BP, vagal afferent nerve firing, muscle SNA, and is involved in the resetting of the arterial baroreflex operating point during exercise (Fadel, 2015; Fadel and Raven, 2010; Oren et al., 1993; Desai et al., 1997; Karim et al., 1972; Hainsworth, 1991). The most seminal findings identifying a role for the cardiopulmonary baroreflex in modulating muscle SNA during exercise come from the studies of Ray et al. (1993) and Saito et al. (1985), where humans performed one-legged kicking exercise in different postures in effort to modify cardiopulmonary load. Muscle SNA decreased significantly when one-legged kicking was performed in the upright posture and central venous pressure was increased due to greater venous return. In contrast, no change in muscle SNA was observed from baseline when exercise was performed in the supine position, as no change in central venous pressure was induced. In a separate study, light-intensity cycling in the upright position also caused a decrease in muscle SNA. Together, these studies concluded that increasing central blood volume via the muscle pump activates cardiorespiratory baroreflexes and decreases muscle SNA (Fadel, 2015; Fadel and Raven, 2010). With increasing intensity of exercise however, a rise in muscle SNA would correspond with the activated skeletal muscle afferents associated with the exercise pressor reflex and the change in baroreflex operating point of modulating BP.

In addition to increasing vagal drive and decreasing SNA with increased venous pressure and volume, the cardiopulmonary baroreceptors can decrease SNA to the kidneys and vasopressin release from the pituitary. This causes a decrease in renal sodium and water reabsorption, increasing urine production and decreasing blood volume. Modification of blood volume provides another mechanism by which the cardiopulmonary baroreflex can affect BP and CO (Thomas, 2011).

Sympatholysis

Sympatholysis describes the intrinsic ability of the vasculature to overcome the vasoconstrictive effects of elevated SNA accompanying muscle contraction (i.e., exercise), whereby the vasculature maintains the ability to increase blood flow via vasodilation despite the presence of heightened sympathetic drive for vasoconstriction (Buckwalter and Clifford, 2001; Remensnyder et al., 1962). In contracting muscle, some level of sympathetic vascular tone must be conserved since the maintenance of BP is a key component of baroreflex regulation (Joyner and Casey, 2015). Thus, sympatholysis is an optimal mechanism for maintaining blood flow to active skeletal muscle, demonstrating increased effectiveness at higher intensities of exercise (Buckwalter et al., 2001; Ruble et al., 2002; Tschakovsky et al., 2002). The production of vasoactive metabolites has been suggested as a potential mechanism for functional sympatholysis during muscle contraction. Substances such as NO (Thomas and Victor, 1998; Sander et al., 2000; Chavoshan et al., 2002), adenosine, prostacyclin (Quayle and Standen, 1994; Nelson and Quayle, 1995; Keller et al., 2004), and interstitial hydrogen (Mcgillivray-Anderson and Faber, 1990) have been identified as potential sympatholytics as they have been shown to reduce NE release from sympathetic nerves, or inhibit vasoconstriction caused by sympathetic nerve stimulation or αR agonists. Most recently, ATP has received much attention for its ability to alter sympathetically mediated increases in vascular resistance, and is also favored as a key player in exercise hyperaemia. It has also been shown to alter αR sensitivity, thus decreasing the vasoconstrictor effectiveness of sympathetic activation (Mortensen et al., 2009) (**Fig. 2**).

Neurohumoral Regulation of the Circulation

Direct SNS innervation of the vasculature will induce a rapid response at the vascular level, but the SNS can also upregulate humoral responses which have a more prolonged effect on the vasculature. The two main neurohumoral systems are (1) the sympathoadrenal system and (2) the renin-angiotensin-aldosterone system (RAAS).

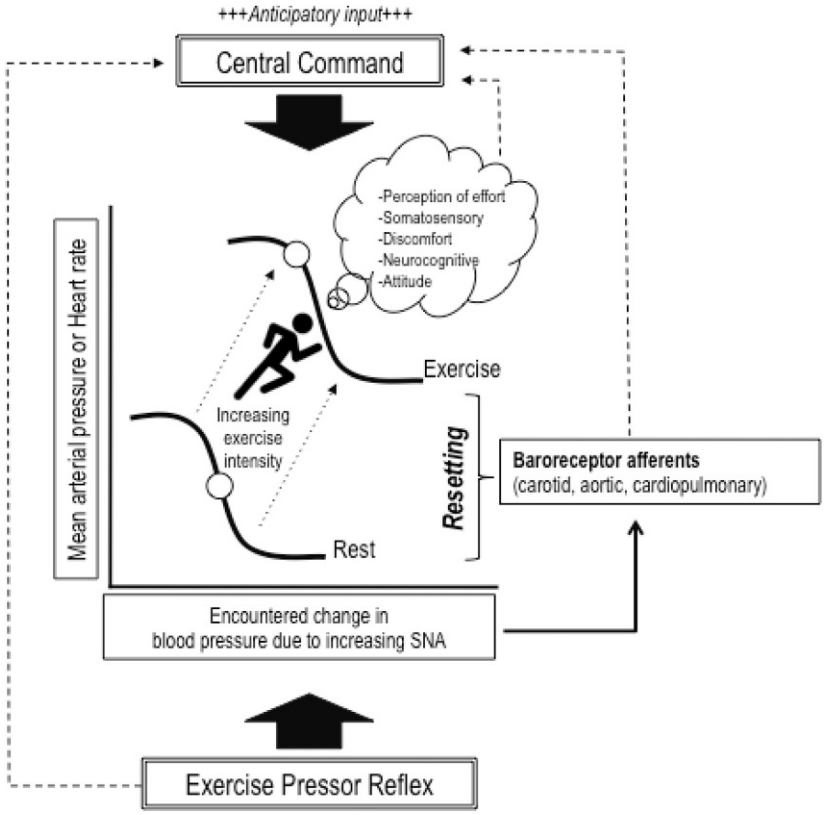

Fig. 2 The integration of multiple cardiovascular reflex components modifies baroreceptor resetting of operating blood pressure from rest to exercising conditions. Under resting conditions, the baroreflex negative feedback loop functions within an operating blood pressure range (curved tracing). Any encountered changes in blood pressure sensed by the baroreceptors reflexively modify sympathetic and parasympathetic outflow to the heart and blood vessels in an effort to maintain blood pressure (and heart rate) at a basal operating point *(white circle)*. Under exercising conditions, a shift in the operating pressure point of the baroreflex occurs as BP (and heart rate) is regulated within a higher range, continuing to rise with increasing exercise intensity. The "resetting" phenomenon of the arterial baroreflex is mediated by central command (higher cardiovascular brain centers), which continues to receive afferent information from the exercise pressor reflex, the cardiopulmonary baroreflex, and determinants of psychological perception, thus continuously modifying the "resetting" of the operating pressure point and range of baroreceptor activity. As the need for skeletal muscle perfusion increases, and arterial vasodilation and hyperemia increases, the baroreflex buffers the potential drop in blood pressure by increasing sympathetic nerve activity and promoting greater vascular resistance. Adapted from Raven, P. B., Fadel, P. J. and Ogoh, S. (2006). Arterial baroreflex resetting during exercise: a current perspective. *Experimental Physiology* **91**, 37–49.

Sympathoadrenal System

Preganglionic cholinergic sympathetic nerve fibers release acetylcholine to activate chromaffin cells of the adrenal medulla of the kidney. Chromaffin cell activation promotes the release of catecholamines, epinephrine (E) and NE, into the blood stream where they circulate as hormones. Typically, more E (80%) than NE (20%) is released and consequently the effects of circulating E have been a primary area of study (Thomas, 2011). The original studies in 1960, which have since been validated, demonstrate vasodilation in conditions of elevated circulating E (Richardson et al., 1967; Weisbrod et al., 2001).

Epinephrine preferentially binds to β_2R, a G_S-protein-coupled adrenoceptor predominately found on vascular smooth muscle cells, upregulating AC leading to the formation of cAMP which activates PKA. PKA phosphorylates, and inactivates, myosin light chain kinase leading to vascular smooth muscle relaxation. There is also evidence of β_2R on endothelial cells which play a role in NO-mediated vasodilation (Guimaraes and Moura, 2001). However, the involvement of NO in β_2R-mediated dilation is debated as most studies used in vitro preconstricted models for evidence. Epinephrine also has affinity for αRs and can induce vasoconstriction, but this is only observed at supraphysiological levels of E (Thomas, 2011). In contrast, NE targets αRs to induce vasoconstriction, but the effects are more potent with NE as a neurotransmitter versus hormone. However, the combined release of E and NE suggests that E vasodilation offsets NE vasoconstriction to prevent BP overshoot during elevated SNA (Ziegler et al., 2012).

Renin-Angiotensin-Aldosterone System

Sympathetic fibers innervate the juxtaglomerular cells, specialized smooth muscle cells of the afferent arterioles of the kidney, and activate β_1Rs resulting in renin release into the circulation (Thomas, 2011). Renin converts circulating plasma angiotensinogen, produced by the liver, to angiotensin I, then angiotensin converting enzyme, located on endothelial cells of the pulmonary

capillaries and renal arterioles, converts angiotensin I to angiotensin II (AII). AII binds to a heterogeneous population of AII receptors, identified as AT1 and AT2. AT1 receptors are well understood and play a role in vasoconstriction, aldosterone (ALDO) release, increase in SNS transmission, and cellular growth (Dinh et al., 2001). AT1 is a G-protein-coupled receptor and upregulates five different transduction mechanisms, involving activation of phospholipase A_2, phospholipase C, phospholipase D, L-type calcium channels, and inhibition of adenylate cyclase. Activated phospholipase C, D, and L-type calcium channels lead to vasoconstriction, while activated phospholipase A_2 is associated with production of arachidonic acid and induces a vasodilation which is generally overpowered by the vasoconstriction and unnoticed overall (Dinh et al., 2001). In contrast, the AT2 receptor has recently been identified to oppose functions of the AT1 receptor through antiproliferation functions, apoptosis, and vasodilation (Carey et al., 2000). Signal transduction of AT2 receptors is still not well defined but NO, bradykinin, and cyclic GMP are thought to play a role in its vasodilatory function (Carey et al., 2000). Overall, AT2 receptors are less expressed than AT1 receptors, with the expression being greatest during fetal development and then rapidly decreases at birth to undetectable levels in most adult tissues (Carey et al., 2000). However, expression of both AT1 and AT2 is not static and can be enhanced or suppressed in response to certain stimuli (Chopra et al., 2011; Carey and Siragy, 2003; Kaschina and Unger, 2003). AII has several cardiovascular functions, each of which will be discussed below.

Enhancement of Sympathetic Neurotransmission

SNS stimulated production of AII is supported via a positive feedback loop. Circulating AII further enhances sympathetic neurotransmission by directly augmenting sympathetic outflow and increasing neurotransmission at the nerve endings by increasing NE release into the synaptic cleft (Ebert and Stowe, 1996; Peach, 1977). The primary sites of AII action are CNS, adrenal medulla, adrenergic nerve terminals, and postsynaptic effector cells (Saxena, 1992). At the CNS level, AII attenuates the baroreceptor reflex-mediated decrease in SNA. At the adrenal medulla, AII liberates adrenomedullary catecholamines by directly depolarizing chromaffin cells. AII may also inhibit the reuptake of NE by the nerve terminal and augment biosynthesis of NE at the adrenergic nerve terminals (Peach, 1977; Khairallah, 1972; Zimmerman et al., 1984; Roth, 1972; Boadle et al., 1969; Davila and Khairallah, 1971; Khairallah et al., 1971; Panisset and Bourdois, 1968). Finally, at high concentrations, AII enhances the vasoconstrictor effects of NE on the effector cells by facilitating the vasoconstrictory effects of α1R and α2R (Van Zwieten and De Jonge, 1986).

Vasoconstriction

AII binds to AT1 receptors on the vascular smooth muscle to induce a powerful vasoconstriction. Stimulated AT1 receptor works via similar mechanisms as α2R by coupling to $G_{q/11}$ protein, stimulating phospholipase C, leading to increased cytosolic calcium concentration via opening of L-type calcium channels or release of calcium from intracellular stores leading to contraction of arteriolar smooth muscle. Systemically produced AII at the lung results in an overall increase in TPR and BP. The increase in systemic resistance would have a decreasing effect on glomerular filtration rate (GFR) at the kidney; however, the endogenous production of AII at the kidney counteracts this decrease in GFR by constricting efferent arterioles more than the afferent arterioles. This difference in level of constriction at the efferent and afferent renal arterioles is likely due to the AT1 receptor population being higher in efferent compared to afferent arterioles (Razga and Nyengaard, 2008). Overall, the greater constriction of the efferent versus afferent arterioles maintains pressure through the glomerulus during decreased TPR and thus maintains GFR during elevated AII levels.

In contrast, at supraphysiological concentrations, endogenous AII has an opposing effect on renal medullary circulation by acting on AT1 receptors on the smooth muscle to induce a vasodilation of kidney medullary arterioles. This dilation works primarily by stimulating NOS to increase NO and cyclooxygenase activity to increase prostaglandin production (Evans et al., 2010). The cellular sources of NO and prostaglandin must be from the endothelial cells; however, the mechanisms of how AII leads to increases of NO and prostaglandins remain to be elucidated.

Aldosterone

Circulating AII stimulates the AT1 receptor in the adrenal zona glomerulosa cells of the adrenal cortex resulting in ALDO secretion into the blood stream (Wang et al., 1998). The primary role of ALDO is to maintain body sodium homeostasis. It acts at the kidney to increase renal sodium and water reabsorption. However, ALDO's actions go beyond its role as a renal regulator of sodium reabsorption and has been identified to play a role on vascular reactivity, vascular growth, and development. At the vascular level, ALDO binds to the mineralocorticoid receptor (MR) located on endothelial cells and induces a vasodilation regulated via NO, prostacyclin, and endothelium-derived hyperpolarizing factor (Feldman and Gros, 2013; Heylen et al., 2009; Palmer et al., 1987). Conversely, ALDO induces constrictor responses if it binds to MR on the smooth muscle cell (Liu et al., 2003). The constrictor response works by increasing endothelin-1 (ET-1) and vasoconstrictor prostanoids (Yanagisawa et al., 1988).

Endothelin-1

ET-1 is the most potent, long-lasting vasoconstrictor ever discovered and serves to increase peripheral resistance. ET-1 binds to class A G-protein-coupled receptors, ET_A or ET_B located on vascular smooth muscle, in quasi-irreversible manner (Shihoya et al., 2016). ET_A and ET_B exert opposing actions on several physiological processes. For example, activation of ET_A activates phospholipase

C leading to increases in inositol triphosphate (IP_3) and diacylglycerol (DAG). These increases in IP_3 and DAG levels result in the release of calcium from intracellular stores, specifically the SR, and activation of PKC, respectively, leading to vasoconstriction (Kedzierski and Yanagisawa, 2001; La and Reid, 1995; Resink et al., 1988; Van Renterghem et al., 1988; Griendling et al., 1989; Marsden et al., 1989). Calcium is released in a biphasic fashion, with the initial increase related to calcium released from intracellular stores, and the second and sustained increased related to calcium from extracellular stores likely through the opening of L-type Ca^{2+} channels (Yanagisawa et al., 1988). In contrast, activation of ET_B leads to an NO-mediated vasodilation but can further act as a "clearance receptor" by scavenging the circulating ET-1 (Shihoya et al., 2016). The pathway by which ET_B functions is largely unknown, but it is thought that intracellular degradation of ET-1 is the primary means of removing ET-1 from the circulation via ET_B (Bremnes et al., 2000).

Vasopressin

AII stimulates the release of antidiuretic hormone (ADH), also known as vasopressin, from the posterior pituitary gland. The primary role of ADH is to stimulate reabsorption of water by the kidneys by acting on their vasopressin V_2 receptors. However, ADH can bind to vasopressin V_{1a} G-protein-coupled receptors on the vascular smooth muscle to induce vasoconstriction (Henderson and Byron, 2007). Activation of V_{1a} leads to increases in IP_3 and consequently increases in Ca^{2+} release from intracellular stores as well as extracellular stores through L-type Ca^{2+} channels (Henderson and Byron, 2007). The vasoconstrictor response to ADH is tissue dependent, where the highest sensitivity is observed in skin, muscle, and splanchnic arteriolar beds, possibly to shunt blood to more vital organs during elevated levels which occur in response to decreased blood volume or increased plasma osmolality.

Atrial Natriuretic Peptide

Lastly, atrial natriuretic peptide (ANP) acts in a neurohumoral fashion as it is released into the circulation in response to stretch at the atria (e.g., under conditions of increased blood volume). Its primary role is to regulate normostatic BP (Potter et al., 2009). In the vasculature, ANP acts as a vasodilator by binding to natriuretic peptide receptor-A on vascular smooth muscle and upregulates a NO pathway (Potter et al., 2009; Edvinsson et al., 2016). Finally, ANP also antagonizes the RAAS, consequently affecting BP and circulation (Brandt et al., 1993).

Introduction

The pericardium is a fibroserous sac composed of a serous visceral layer and a fibrous parietal layer with a small amount of pericardial fluid between the two layers. The fibrous parietal layer helps anchor the heart in place, and the pericardial fluid helps provide lubrication and reduce friction during cardiac activity. The pericardium is also an important barrier to infection. Perhaps most importantly, however, the pericardium has a restraining effect on cardiac volume. Although the pericardium can adapt to accommodate chronic increases in cardiac volume, more rapid dilatation of the cardiac chambers is often not well tolerated due to this effect.

Diseases of the pericardium can occur in isolation or in conjunction with more systemic disease processes. The leading manifestations of pericardial disease include pericarditis, which can present acutely, subacutely, or as a chronic fibrinous process, and pericardial effusion. Although pericarditis is the most common pericardial disease encountered in clinical practice, epidemiologic data on it is lacking. It has been estimated that acute pericarditis is diagnosed in 1 of every 1000 hospital admissions and comprises 1% of emergency room visits in patients with ST-segment elevation (Spangler, 2014). The etiology of pericardial diseases can be divided into infectious and noninfectious causes. Noninfectious causes can be further classified into idiopathic, inflammatory, neoplastic, metabolic, and traumatic causes, among others. This article will focus on the noninfective, inflammatory disorders of the pericardium, which are shown in **Table 1**.

Acute pericarditis, the most common of the pericardial diseases, typically presents with pleuritic chest pain. A pericardial friction rub may be present, and diffuse ST-segment elevation with PR depression is classically seen on an electrocardiogram. A new or worsening pericardial effusion may be seen on echocardiography. Diagnosis of pericarditis requires that at least two of the aforementioned features are present (Adler et al., 2015). Elevation of inflammatory markers or evidence of pericardial inflammation on other imaging modalities can help support the diagnosis in atypical cases but are not part of the diagnostic criteria. An electrocardiogram, transthoracic echocardiography, chest X-ray, and assessment of inflammatory markers (e.g., C-reactive protein) and myocardial injury (e.g., creatinine kinase and troponin) are recommended in patients with suspected acute pericarditis (Adler et al., 2015).

Table 1 Etiology of noninfective, inflammatory pericardial diseases

Idiopathic pericarditis
Pericarditis associated with inflammatory diseases
• Connective tissue diseases
• Systemic vasculitidies
• Granulomatous diseases
• Autoinflammatory disesases
• Miscellaneous diseases
Post-MI and post-cardiac injury pericarditis
• Early post-MI pericarditis
• Late post-MI pericarditis (Dressler syndrome)
• Postpericardiotomy syndrome
Drugs and toxins

An extensive evaluation to elucidate the etiology of pericarditis is not always necessary, especially given the low yield of a diagnostic work up. Patients who have manifestations of an underlying systemic process, such as an inflammatory disease, or those with high-risk features (i.e., fever >38°C, subacute course, treatment failure, suspected myopericarditis, large pericardial effusion, or cardiac tamponade) typically warrant hospitalization and further work up. Patients who present with a pericardial effusion have a higher likelihood of having an etiology discovered, especially when pericardial fluid is examined and bacterial or neoplastic pericarditis is suspected (Zayas et al., 1995).

Treatment of most cases of acute pericarditis consists of nonsteroidal antiinflammatory drugs (NSAIDs) or aspirin (ASA). Colchicine is often added for its efficacy in symptom reduction, improving remission rates, and reducing the incidence of recurrent pericarditis. Corticosteroids should generally be avoided as a first line treatment agent due to an increase in recurrent pericarditis with its use. Patients presenting with pericardial effusions and echocardiographic evidence of cardiac tamponade may require pericardiocentesis. Treatment options related to specific etiologies will be further discussed in the appropriate sections to follow.

Idiopathic Pericarditis

In the vast majority of cases, the etiology of pericardial disease cannot be determined. Traditionally, 85%–90% of the cases of acute pericarditis have been deemed idiopathic. Attempting to reach a diagnosis is frequently limited by the lack of or inaccessibility to pericardial fluid. While these cases are sometimes presumed to be of infectious etiology, the lack of cost effective, accurate, and timely diagnostic viral testing frequently prohibits further attempts at a diagnosis. However, a recent large prospective cohort demonstrated that using a systematic prescription of tests for the different etiological causes of pericarditis can increase diagnostic yield and reduce the number of idiopathic cases (Gouriet et al., 2015). In this study, the authors used a number of noninvasive tests, such as blood cultures, viral serologies, antinuclear antibodies, and thyroid stimulating hormone, as well as invasive studies to test pericardial fluid, if available. If an etiology was not reached from these studies, but the patient had a history of an underlying disease process associated with pericardial disease, the etiology was presumed to be secondary to that disease process. If the patient's history was unremarkable, the etiology was classified as idiopathic. Using this method, an etiology was established in 45% of patients, which is significantly higher than that previously reported. Similarly, other studies have shown that a specific etiology can often be determined in those patients with pericardial effusions when clinical history and inflammatory signs are considered (Sagrista-Sauleda et al., 2000).

First line treatment for most patients with idiopathic pericarditis consists of combination therapy with colchicine plus NSAIDs/ASA, with ibuprofen or indomethacin being the most common NSAIDs used. While most patients have resolution of symptoms with the use of NSAIDs alone, colchicine has been shown to decrease the rate of recurrent pericarditis. The COPE (COlchicine for acute PEricarditis) trial was a randomized, prospective trial that sought to evaluate the safety and efficacy of colchicine as adjunctive therapy for patients with a first episode of pericarditis. The addition of colchicine to ASA led to a statistically significant reduction in symptom persistence at 72 h (11.7% vs. 36.7%) as well as a significant reduction in recurrence rate at 18 months (10.7% vs. 32.3%) (Imazio et al., 2005b). In the ICAP (Investigation on Colchicine for Acute Pericarditis) trial, the use of colchicine versus placebo, in addition to antiinflammatory therapy alone, significantly reduced the risk of recurrence (17% with colchicine vs. 38% with placebo). This trial also showed significantly better remission rates and fewer hospitalizations with the addition of colchicine (Imazio et al., 2013). Colchicine is generally administered for 3 months, while duration of therapy with NSAIDs is based upon duration of symptoms. Patients with contraindications to NSAID/ASA therapy or those with symptoms refractory to colchicine and NSAIDs may be treated with systemic glucocorticoids, although this practice is associated with an increase in recurrent pericarditis (Lilly, 2013). Prophylaxis against gastrointestinal bleeding with histamine-2 antagonists or proton pump inhibitors is warranted, particularly in those at high risk or who require longer durations of treatment.

Recurrent Pericarditis

Approximately one-third of patients with idiopathic pericarditis develop recurrent disease, sometimes with a pericardial effusion. Cases with persistent symptoms within 6 weeks of the acute attack are considered "incessant." In most cases, recurrent pericarditis is thought to be autoimmune mediated, but some cases may represent reactivation of viral pericarditis or a new infection. Recurrence can occur any time after the index event but usually occurs weeks to months later. Presenting symptoms are similar to symptoms of the initial presentation, with pleuritic chest pain being the most prominent manifestation; however, symptoms usually are not as severe and are rarely life threatening. Nonetheless, these recurrent symptoms can affect one's quality of life. Importantly, symptom severity does not predict the risk of recurrence. Patients treated with glucocorticoids during the index event have a higher rate of recurrence, while patients who respond well to NSAIDs/ASA and colchicine during the index event tend to have a lower risk of recurrence.

Colchicine can also help in reducing the risk of further recurrent episodes in patients who have experienced a recurrent episode of pericarditis. The CORE (COlchicine for REcurrent pericarditis) trial compared use of colchicine plus ASA to ASA alone for treatment of first recurrence of pericarditis. Use of colchicine significantly decreased the recurrence rate at 18 months (24.0% vs. 50.6%) as well as persistence of symptoms at 72 h (10% vs. 31%) (Imazio et al., 2005a). Therefore, treatment for recurrent pericarditis should consist of combination therapy with colchicine plus NSAIDs or ASA. For patients with contraindications to NSAIDs/ASA therapy or those who fail to respond to colchicine and NSAIDs/ASA, a slow taper of systemic glucocorticoids is an option. Intrapericardial steroid therapy and immunosuppression agents such as azathioprine (Vianello et al., 2011), human intravenous immune globulin (Imazio et al., 2016), and anakinra (Jain et al., 2015) have also been shown to help prevent recurrent episodes. Although the disease can be prolonged and frustrating, the overall prognosis for patients with recurrent pericarditis is good. Effective communication with patients is critical. Restriction of activity until there is resolution of symptoms, and in some instances (e.g., athletes) inflammatory markers, is warranted. Patients who have failed repeated attempts at medical therapy may be considered for pericardiectomy.

Pericarditis Associated With Inflammatory Diseases

Pericardial disease can be associated with numerous systemic inflammatory diseases, such as connective tissue diseases, systemic vasculitides, inflammatory bowel diseases (IBD), and a variety of other systemic processes. The degree of pericardial involvement usually correlates with the severity of the underlying disease and can range from small, asymptomatic pericardial effusions that are found incidentally to severely symptomatic pericarditis with more significant effusions. Likewise, progression of the pericardial involvement can range from subtle to rapid. Pericardial effusions are more prevalent and tend to be larger in these patients compared to patients with idiopathic pericarditis. While pericardial involvement is most often seen later in the disease course, it can also be a presenting symptom of the disease. A definitive diagnosis of pericardial disease related to inflammatory diseases requires specific findings in the pericardium or pericardial fluid, but a clinical diagnosis is often made presumptively in patients with systemic inflammatory diseases.

Treatment of pericardial involvement in inflammatory diseases typically depends on the level of symptoms, and collaboration with a rheumatologist is often needed. Treatment of the underlying systemic disease should be the focus for asymptomatic patients. On the other hand, patients with a pericardial effusion and cardiac tamponade require pericardiocentesis. Most patients with symptoms of acute pericarditis should be treated with a combination of NSAIDs and colchicine. The overall prognosis for patients with pericardial involvement from inflammatory diseases is good. While some patients may have recurrent episodes of pericarditis that can affect their quality of life, serious long-term complications are rare (Imazio, 2011).

Connective Tissue Diseases

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is one of the most common autoimmune diseases to involve the pericardium. Patients with SLE can have a number of cardiac abnormalities, but presence of a pericardial effusion and pericarditis are the most common (Doria et al., 2005). In fact, over half of all patients with SLE reportedly have a pericardial effusion, although the vast majority are asymptomatic and detected incidentally by echocardiography (Roman and Salmon, 2007). Pericardial and myocardial involvement is seen frequently at autopsy (Doherty et al., 1988). Large pericardial effusions or effusions that cause tamponade physiology are rare, but tamponade may be the first manifestation of SLE. An example of a pericardial effusion in a patient with newly diagnosed SLE is shown in **Fig. 1**. **Figs. 2–4** demonstrate indicators of cardiac tamponade, including right ventricle diastolic collapse, respiratory variation of mitral valve inflow velocities, and inferior vena cava plethora, respectively. An example of a pericardial effusion on CT scan is demonstrated in **Fig. 5**. Pericardial fluid analysis in these patients, although rarely of clinical value, typically shows high protein content, normal or slightly low glucose content, low complement levels, and may contain antinuclear antibodies and phagocytic cells with nuclei. Pericarditis in patients with SLE is less common than pericardial effusions, but can be seen, especially in those patients with other types of serositis, such as ascites or pleural effusions, and often accompanies flare-ups. On rare occasions, patients with SLE develop long-term complications such as recurrent pericarditis or constrictive pericarditis.

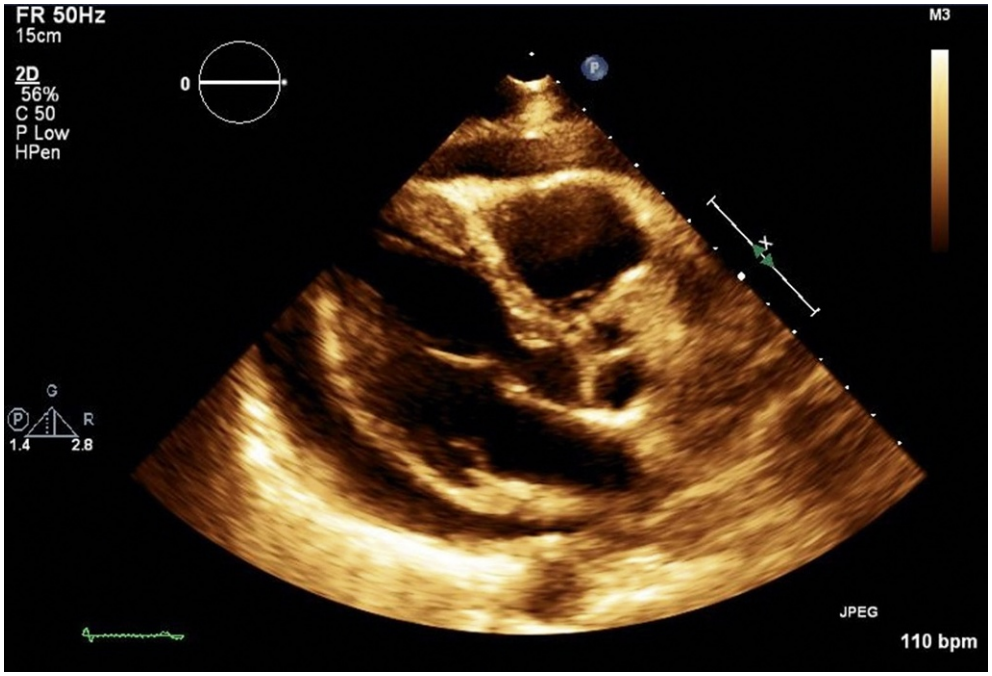

Fig. 1 Parasternal long axis view of a 26-year-old female with a circumferential pericardial effusion due to newly diagnosed systemic lupus erythematosus seen on a transthoracic echocardiogram.

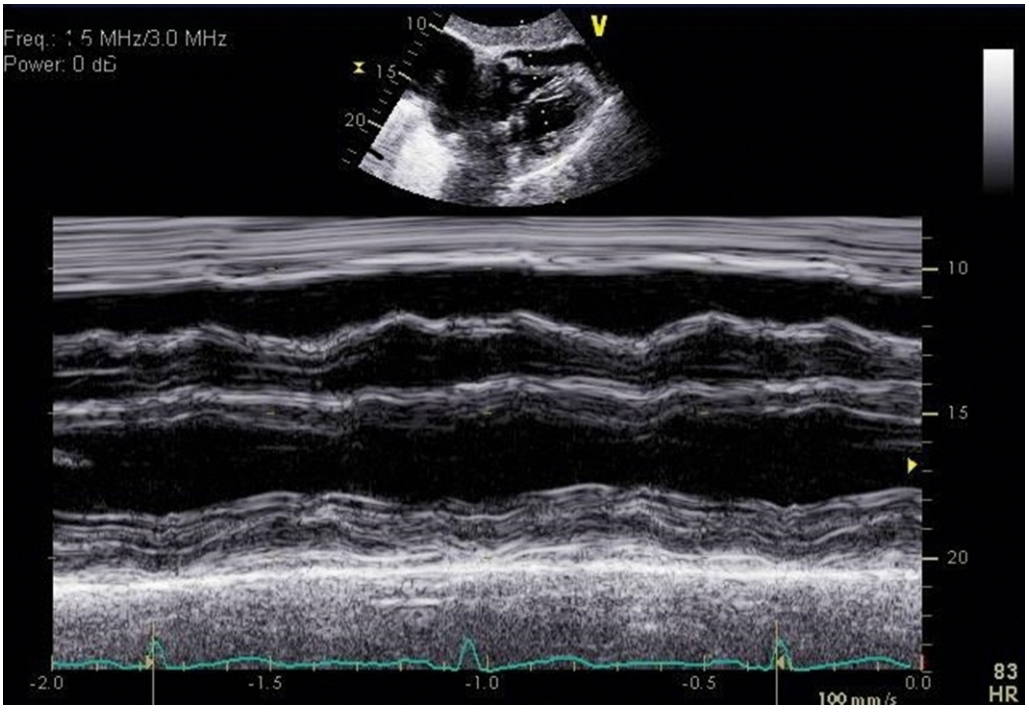

Fig. 2 M-mode echocardiography showing evidence of right ventricle diastolic collapse, suggestive of cardiac tamponade.

Treatment for symptomatic pericarditis, in addition to treatment of the underlying SLE, consists of NSAIDs in combination with colchicine to reduce the risk of recurrence. Glucocorticoids are an option for patients with contraindications to NSAID therapy or those who fail to respond to colchicine and NSAIDs. Very rarely, patients may require drainage for hemodynamically significant pericardial effusions, but case reports suggest that even these patients do well over time with medical therapy (Castier et al., 2000).

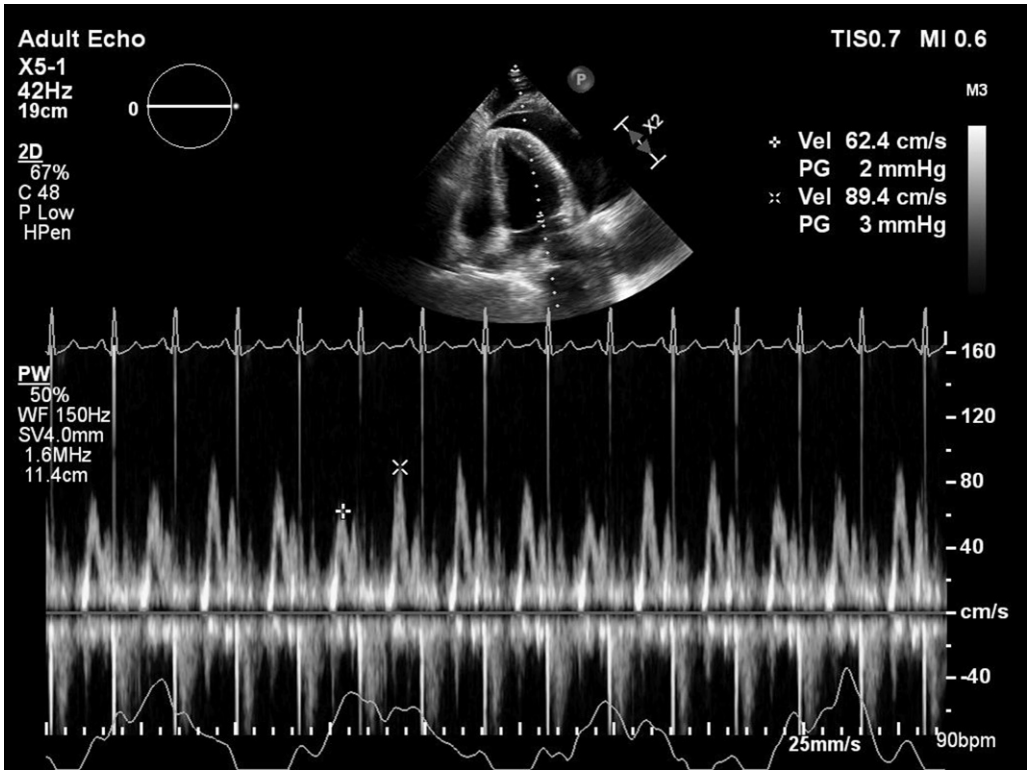

Fig. 3 Significant respiratory variation during mitral valve inflow suggestive of cardiac tamponade.

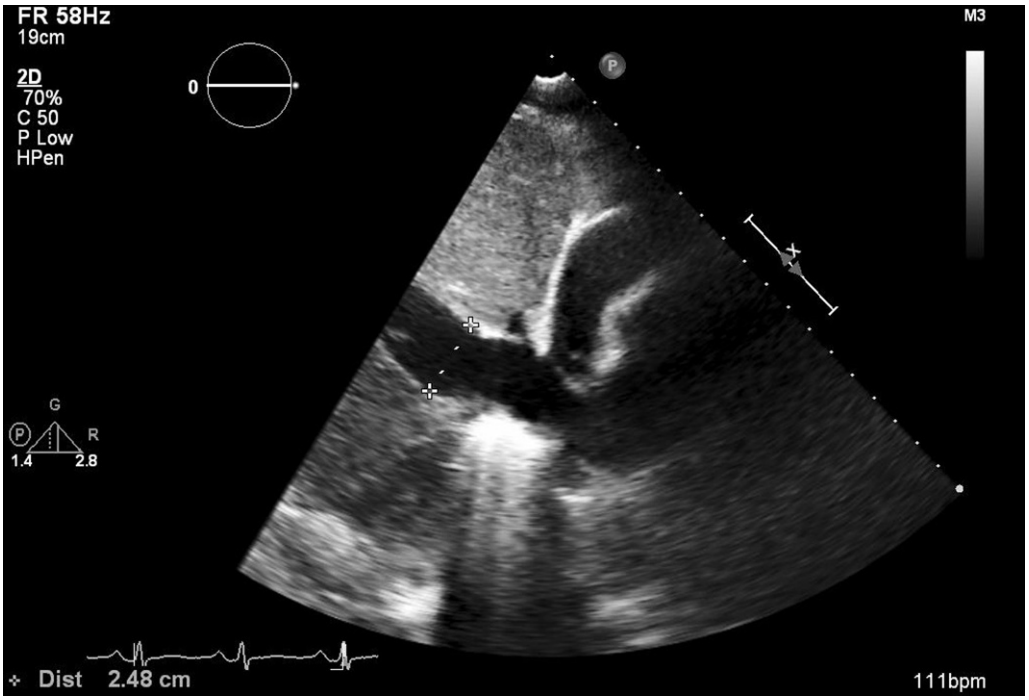

Fig. 4 Plethoirc inferior vena cava seen on a subcostal view of a transthoracic echocardiogram, which can be seen in cardiac tamponade.

Rheumatoid arthritis

Rheumatoid arthritis (RA) is a chronic, inflammatory disease that primarily involves the joints, although a number of other organ systems can be involved. The pathology is usually a fibrous obliterative pericarditis with pericardial deposits of calcium, fibrin, and

Fig. 5 Pericardial effusion on CT scan for the same patient shown in **Fig. 1**.

cholesterol (Ferrans and Rodriguez, 1985); acute fibrinous pericarditis is seen in the remainder. RA has a slightly lower incidence of pericardial disease than does SLE; nearly one-third of patients have a pericardial effusion, which is usually asymptomatic (Imazio, 2011). Pericardial fluid tends to contain low glucose, neutrophilic leukocytosis, high titers of rheumatoid factor, and low complement levels. Rarely, fluid with high cholesterol concentration can be found. As is the case with SLE, pericarditis is less common in patients with RA than are pericardial effusions. When pericarditis does occur, it most commonly affects patients with active rheumatoid disease and positive serum testing for rheumatoid factor, especially middle-age men with acute onset of arthritis (Hoit, 2011). Some studies have also suggested a correlation between pericardial involvement, especially the development of cardiac tamponade, and duration of disease with RA (Escalante et al., 1990). Notably, patients with RA can occasionally develop constrictive pericarditis, which may develop with surprising rapidity, as a result of long-standing inflammation. Treatment for rheumatoid pericarditis is the same as that for pericarditis in SLE, with treatment of the underlying disease process being essential. Pericardial disease also complicates systemic juvenile RA (Still's disease) (Jamieson, 1983).

Systemic sclerosis

Systemic sclerosis, also known as scleroderma, is a disease most notably known to cause hardening of the skin and can cause fibrosis of other organs as well. Over half of patients with systemic sclerosis show evidence of pericardial involvement at the time of autopsy, but symptomatic pericarditis occurs only in approximately 10% of patients (Imazio, 2011). Pericardial involvement in patients with scleroderma is often associated with a cardiomyopathy (Hoit, 2011). Pericardial effusions, if present, are usually small and asymptomatic, but large or rapidly occurring effusions leading to tamponade can occur. Cardiac complications in patients with systemic sclerosis are most commonly due to pulmonary vascular disease. This can make the diagnosis of symptomatic pericardial disease more problematic, as it can be difficult to distinguish the etiology of symptoms such as dyspnea. Response to treatment for pericarditis with NSAIDs or ASA in patients with systemic sclerosis is often suboptimal. Furthermore, patients with symptomatic cardiac involvement tend to have a poor prognosis, with 2-year mortality estimated at 60% (Imazio, 2011).

Miscellaneous connective tissue diseases

A number of other connective tissue diseases may have pericardial involvement at a lower incidence rate. Dermatomyositis and polymyositis are inflammatory myopathies known for causing muscle weakness. Pericarditis or pericardial effusion is less common but can be associated with cardiac tamponade. Mixed connective tissue disease (MCTD) is a generalized connective tissue disorder that often presents with nonspecific symptoms. Pericarditis is the most common cardiac abnormality in MCTD, affecting up to 30% of patients, but significant pericardial effusions causing tamponade are exceedingly rare (Lundberg, 2005). Sjogren's syndrome is an autoimmune disease that results in dry mouth and dry eyes. Pericarditis is the most common form of cardiac involvement in patients with Sjogren's syndrome but is still rare nonetheless.

Systemic Vasculitides

The vasculitides are defined by the presence of inflammatory leukocytes in vessel walls with reactive damage to mural structures. Classification has traditionally been based on the size of the vessels involved. Pericardial involvement in the vasculitides is less common than in the connective tissue diseases, and pericardial involvement in large vessel vasculitis, such as Takayasu arteritis and giant cell arteritis, is especially rare. Among the medium vessel vasculitides, Kawasaki disease more commonly has pericardial involvement than does polyarteritis nodosa. Estimates suggest that up to 30% of patients with Kawasaki disease have pericardial involvement (Knockaert, 2007). However, a study of 198 patients with Kawasaki disease documented that less than 5% had a pericardial effusion >1 mm (Printz et al., 2011). Of the small vessel vasculitides, granulomatosis with polyangiitis (Wegener's) and eosinophilic granulomatosis with polyangiitis (Churg–Strauss) have been most frequently implicated.

Behcet's disease is a rare inflammatory disease that is unique in that it can affect arterial and venous vessels of all sizes. The most typical manifestations include recurrent aphthous stomatitis, genital ulcerations, and uveitis, but a number of cardiac manifestations can occur as well. Acute or recurrent pericarditis, although rare, has been reported (Geri et al., 2012).

Granulomatous Diseases

Sarcoidosis, likely the most recognized granulomatous disease, is characterized by noncaseating granulomas in multiple organ systems, with the lungs being most commonly involved. The etiology of this disorder remains unclear. Clinically, cardiac involvement in sarcoidosis is seen rarely, but subclinical cardiac sarcoidosis seen on autopsy is not uncommon. Signs and symptoms of cardiac sarcoidosis are broad and depend upon the location and extent of granulomatous inflammation. Pericarditis due to sarcoidosis is rare but has been reported (Wyplosz et al., 2010). Small pericardial effusions are much more commonly seen.

Autoinflammatory Diseases

Autoinflammatory diseases are a group of clinical conditions caused by dysregulation of innate immunity without any apparent involvement of antigen-specific T cells or significant production of autoantibodies. They result in intense episodes of inflammation that result in fever and other intermittent symptoms such as rash or joint swelling. These disorders usually present in the pediatric population, although some patients do not present until adulthood. While there has been an increase in prevalence of these diseases recently, they remain rare. The two most prevalent diseases in this group include familial Mediterranean fever (FMF) and tumor necrosis factor receptor-1 associated periodic syndrome (TRAPS).

Familial Mediterranean fever

FMF, as the name suggests, occurs more commonly in ethnic groups of the Mediterranean region. It is an autosomal recessive disease characterized by paroxysmal attacks of fever and serosal inflammation. Pericarditis is not uncommon in patients with FMF but is usually self-limiting when it occurs. Colchicine should be given as prophylactic therapy in order to prevent recurrent attacks and the development of secondary (AA) amyloidosis, a major complication of FMF (Zemer et al., 1986). Patients resistant or intolerant to colchicine should receive therapy with an antiinterleukin (IL-1) agent, such as anakinra, cankinumab, or rilonacept.

Tumor necrosis factor receptor-1 associated periodic syndrome

TRAPS, an autosomal dominant disorder caused by mutations in the TNFRSF1A gene encoding the 55-kD receptor for TNF-alpha, is characterized by recurrent febrile attacks with serosal inflammation that lasts at least 5 days to weeks. Recurrent pericarditis is seen commonly in patients with TRAPS, and family history is often positive, suggesting the possibility of a genetic predisposition to pericardial involvement. Unlike FMF, TRAPS does not respond well to colchicine (Cantarini et al., 2009), and researchers are still investigating treatment options.

Miscellaneous

Acute rheumatic fever

Acute rheumatic fever can occur 2–4 weeks after group A streptococcus pharyngitis. The incidence of rheumatic fever has significantly decreased in developed countries due to treatment of group A streptococcus pharyngitis with antibiotics. Classic symptoms include fever, arthritis, chorea, erythema marginatum, subcutaneous nodules, and sometimes carditis, including acute pericarditis. NSAIDs and colchicine are typically first line treatment options for pericarditis associated with rheumatic fever.

Immunoglobulin G4-related systemic disease

Immunoglobulin G4-related systemic disease (IgG4-RD) is an increasingly reported syndrome of unknown etiology. It most commonly occurs in middle-aged and older men and can involve one organ or multiple organs, with autoimmune pancreatitis being one of the most frequent manifestations in early observations of the disease. Constrictive pericarditis has been associated with IgG4-RD, and case reports have demonstrated that glucocorticoids, which are typically a first-line therapy for active IgG4-RD, can be effective in treatment of constrictive pericarditis in these patients (Sekiguchi et al., 2012).

Erdheim–Chester disease

Erdheim–Chester disease (ECD) is a rare disorder most commonly affecting middle-aged adults that is classified as a form of non-Langerhans cell histiocytosis. Histiocytosis in these patients leads to inflammation and scarring that typically involves long bones as well as at least one nonosseous site. Cardiovascular manifestations of the disease are underdiagnosed. An analysis of 178 cases of ECD from 2004 showed that 54 patients had heart involvement, and 32 of these patients had pericardial infiltration (Haroche et al., 2004). Five of those patients developed cardiac tamponade. There is no cure or standard treatment regimen for ECD, and the prognosis tends to be poor.

Inflammatory bowel diseases

Cardiac involvement in IBD is uncommon, but pericardial involvement seems to be the most frequent complication when heart involvement does occur (Katsanos and Tsianos, 2012). Cases of Crohn's disease with an initial presentation of pericarditis have been reported, with these patients presumably having had longstanding, virtually asymptomatic intestinal disease prior to presentation. Pericardial involvement may be associated with the degree of bowel activity, but this is not always the case. Additionally, it may be difficult to ascertain whether pericarditis in these patients is due to IBD itself or a side effect of IBD therapy, such as with sulfasalazine or 5-aminosalicylic acid. Patients with severe cases of IBD may have pericardial involvement due to a pericardio-colonic fistula. Cases of pericarditis in patients with IBD tend to respond well to therapy with corticosteroids.

Post-MI and Post-Cardiac Injury Pericarditis

Early Post-MI Pericarditis

Early post-MI pericarditis, or peri-infarct pericarditis (PIP), occurs during the first few days after myocardial infarction. It is caused by transmural myocardial necrosis with inflammation affecting the adjacent pericardium. Pericardial involvement is related to infarct size and is associated with a poor prognosis. The incidence of PIP has decreased dramatically in the era of improved early revascularization. When it occurs, early PIP is often asymptomatic and is identified only by the presence of a friction rub on physical examination. When patients are symptomatic, it is essential to distinguish between recurrent ischemic pain and pericardial pain. This can be done clinically and with ECG guidance. However, patients with PIP often do not have the classic ECG changes associated with pericarditis. Instead, the presence of atypical T wave evolution consisting of persistent upright T waves or early normalization of inverted T waves can be very useful in diagnosing pericarditis in these patients (Adler et al., 2015).

Treatment for PIP is generally supportive, as most cases are self-limiting. Symptomatic patients may be treated with high dose ASA for 1–2 weeks. Addition of colchicine may be helpful in reducing inflammation and reducing the risk for recurrent pericarditis. NSAIDs and glucocorticoids should be avoided due to the possibility of harmful effects in the early post-MI setting. Patients with an associated pericardial effusion generally do not need to have antiplatelet therapy or anticoagulation held. However, those with large or enlarging pericardial effusions, or signs of tamponade, may need cessation of anticoagulation to avoid hemorrhagic conversion of the pericardial effusion.

Late Post-MI Pericarditis (Dressler's Syndrome)

Late post-MI pericarditis, or Dressler's syndrome, one of the postcardiac injury syndromes, occurs from 10 days to a few months after myocardial infarction. Improved early revascularization has also led to a significant decrease in Dressler's syndrome. Dressler's syndrome is believed to be autoimmune in etiology with myocardial antibodies causing an inflammatory reaction that tends to be diffuse (Imazio and Hoit, 2013). Patients may present with pleuritic chest pain, friction rub, fever, leukocytosis, and sometimes pleural effusion or pulmonary infiltrates. The diagnosis is clinical, although objective findings, such as elevated inflammatory markers, electrocardiographic changes, and pericardial effusion on echocardiogram, can be helpful.

Like PIP, late post-MI pericarditis may also be treated with high dose ASA. NSAIDs may be considered, but the risk of NSAID use in patients with ischemic heart disease should be considered. Colchicine may be helpful in this population, although data are lacking. Glucocorticoids can be considered if necessary, but the benefit must be weighed against the risk of delayed myocardial healing. Pericardial effusions in late post-MI pericarditis have a higher tendency for hemorrhagic conversion than in early post-MI pericarditis, and anticoagulation, if absolutely necessary, should therefore be used with caution in this population.

Postpericardiotomy Syndrome

Postpericardiotomy syndrome (PPS), like all of the postcardiac injury syndromes, is initiated by the combination of damage to mesothelial pericardial cells and blood in the pericardial space, which releases cardiac antigens and stimulates an immune response. An inflammatory response is later generated by immune complexes that deposit in the pericardium, pleura, and lungs. PPS occurs several days to weeks after cardiothoracic surgery. It most commonly occurs after surgery involving the pericardium, but it can also occur after pacemaker lead implantation, coronary stenting, and other therapeutic misadventures. Like late post-MI pericarditis, symptoms may include chest pain and fever. Physical examination may disclose a pericardial friction rub. Leukocytosis and elevated

inflammatory markers are common laboratory findings. Pericardial effusions are commonly seen, but tamponade physiology is rare. Pleural effusions or pulmonary infiltrates may also be seen.

Two large randomized, placebo-controlled control trials, COlchicine for the Prevention of Post-pericardiotomy Syndrome (COPPS) and COPPS-2, have suggested a benefit to prophylactic use of colchicine after cardiac surgery in preventing PPS. In the COPPS trial, postoperative cardiac surgery patients were randomly assigned to receive colchicine or placebo. Colchicine significantly reduced the occurrence of PPS at 12 months (8.9% vs. 21.1%) and postoperative atrial fibrillation (0.6% vs. 5.0%) without a significant increase in side effects (Imazio et al., 2010). The COPPS-2 trial again showed a reduction in PPS in postoperative cardiac surgery patients treated with colchicine (19.4% vs. 29.4%). However, colchicine did not reduce the incidence of postoperative pleural/pericardial effusions or the incidence of postoperative atrial fibrillation. Furthermore, there was an increase in adverse effects, primarily gastrointestinal, in patients on colchicine (Imazio et al., 2014). Nonetheless, colchicine may be recommended after cardiac surgery, especially in those patients deemed at high risk for the development of PPS. ASA or NSAIDs are again the treatment of choice. Combination therapy with colchicine may be helpful, but data in this population is limited. Glucocorticoids are an alternative treatment, and intrapericardial triamcinolone has also been proposed as a possible treatment option, although further research is needed regarding its efficacy.

Drugs and Toxins

Drugs and toxins can cause pericardial disease by a variety of mechanisms, including through inflammatory pathways. A number of drugs can induce a lupus-like syndrome; procainamide, tocainide, hydralazine, isoniazid, methyldopa, and phenytoin are most commonly responsible, but over forty drugs have been implicated. Clinical and laboratory features are similar to SLE, but patients generally make a full recovery after the offending agent is discontinued.

Drug-induced lupus differs from typical drug hypersensitivity reactions in a few ways. Drug-induced lupus usually takes months to years of drug exposure and is dose dependent. It generally does not result in immune sensitization to the drug. Drug hypersensitivity has a number of possible adverse reactions, including pericarditis, particularly with penicillins. Mesalamine and sulfasalazine have also been associated with hypersensitivity reactions causing pericarditis. As these drugs are often used in the treatment of IBD, it can be challenging to determine if the development of pericarditis in this population should prompt discontinuation of the drug or rather be attributed to the underlying disease process (Kupferschmidt et al., 1996).

Conclusion

Pericardial diseases can occur in isolation or in the setting of systemic disease processes. Although diseases of the pericardium tend to manifest in only a limited number of ways, the causes of pericardial disease are vast. This chapter focused on the noninfective, inflammatory causes of pericardial disease, including idiopathic pericarditis, which are frequently seen in clinical practice. While the diagnosis and treatment of pericarditis is often straightforward, it can be frustrating and challenging to diagnose and manage, and long-term sequelae may occur. Fortunately, good medical therapy exists, and advances in diagnostic tools and treatment options have helped maintain a generally benign prognosis for patients with noninfective, inflammatory pericardial diseases.

Introduction

Ischemic heart disease remains the primary cause of mortality worldwide and represents the leading cause of years of life lost in developed nations (Lozano et al., 2012). Patients presenting with acute coronary syndrome (ACS), the acute manifestation of atherosclerotic heart disease, have a continuum of disease severity shown to benefit from prognosis-guided treatment strategies. Within ACS, contemporary management algorithms for patients with ST-segment elevation myocardial infarction (STEMI) have become highly standardized and protocol-driven to favor primary percutaneous coronary intervention (PCI) or fibrinolysis given the established benefit of immediate reperfusion therapy in these patients (O'Gara et al., 2013). In contrast, non-ST-segment elevation ACS (NSTE-ACS), a term encompassing unstable angina (UA) and non-ST-segment elevation myocardial infarction (NSTEMI), represents a significantly more heterogeneous disease with a wider variability in prognosis. As the absolute benefit of aggressive management and early invasive strategies is greater in patients with high-risk NSTE-ACS (Fanning et al., 2016), accurate assessment of the prognosis and risk of complications in NSTE-ACS is vital to reliably identify such patients and direct them toward appropriate streams of care.

In the emergency department setting, this risk stratification should be performed immediately for suspected NSTE-ACS (Amsterdam et al., 2014; Roffi et al., 2016). This may be challenging to accomplish accurately in practice as current literature suggests that NSTE-ACS patients are presenting with increasingly complex risk profiles. As discussed in greater detail later, the patient demographics and associated risk profiles constituting NSTE-ACS have shifted considerably over the last three decades (Yeh et al., 2010; Rogers et al., 2008). Notably, the widespread use of high-sensitivity troponin assays has led to an increasing re-classification of UA to NSTEMI (Costa et al., 2012), coupled to epidemiological trends producing reductions in the incidence of STEMI and, consequently, NSTEMI emerging as the predominant presentation of ACS (Rogers et al., 2008). These trends have had the net effect of considerably widening of the risk profiles of patients diagnosed as NSTEMI, resulting in greater heterogeneity of their potential prognoses. Subjective risk assessment by physicians in the context of these ongoing shifts in patient characteristics is

 https://doi.org/10.1016/B978-0-12-809657-4.99748-5

challenging and may be subject to cognitive bias (Yan et al., 2009). Several studies have demonstrated that physicians systematically underestimate risk in patients with high-risk NSTE-ACS (Lee et al., 2008), and that their assessments only weakly correlate with formally validated risk scores (Yan et al., 2009). This may be in part responsible for an observed treatment-risk paradox, with associated worse outcome (Yan et al., 2007a; Fox et al., 2007a).

Early, individualized risk-stratification of patients with NSTE-ACS at their time of presentation serves to empirically guide physicians in their choice of therapy, optimize resource allocation, and inform patients of their anticipated likelihood of recovery or complication. In the acute phase of care, a major consideration is determining which patients will benefit from an early invasive strategy during their index hospitalization. Closer to the time of discharge, subsequent risk assessment should be aimed at determining which patients are at high long-term risk of recurrent adverse cardiovascular events. Following a brief survey of the evolution of prognosis in NSTE-ACS over the past three decades, this article will review the individual prognostic factors generally available to physicians upon patient presentation, compare validated bedside clinical prognostic models, and consider the role of additional testing during hospitalization. We will conclude with a discussion of the application of these prognosticators and risk models in NSTE-ACS, as well as emerging future avenues of individualized risk determination.

Temporal Trends in Prognosis

Several notable trends have changed the frequency distribution and underlying characteristics of NSTE-ACS in developed countries which merit consideration when evaluating the prognosis of contemporary patients diagnosed with NSTEMI or UA. Broad implementation of primary preventative strategies may have resulted in fewer cases of STEMI (Go et al., 2006; Mukamal et al., 1999) while the concurrent aging of the population over time, increasing rates of comorbid diabetes, hypertension, and dyslipidemia, and recent trends in smokers presenting with NSTE-ACS have contributed to an increase in the proportion of NSTEMI among patients hospitalized with MI (Yeh et al., 2010; Fox et al., 2007b; Hall et al., 2016; Arbel et al., 2016). From a diagnostic standpoint, considering that acute MI is now defined by positivity in biomarkers of myocardial necrosis (Thygesen et al., 2012), ongoing improvements in the test characteristics of these diagnostic tools have also led to a shift in the classification of patients presenting with ACS (Costa et al., 2012). The wide adoption of high-sensitivity troponin in particular has moved the diagnosis of NSTE-ACS away from UA to NSTEMI (Rogers et al., 2008), likely due to increased detection of small infarcts. The net consequence of these trends has resulted in NSTEMI becoming the predominant presentation of MI, representing nearly 60% of all cases in 2006, compared to just 14% in 1990 (Rogers et al., 2008). Concomitantly, there has been a gradual increase in the incidence rates of NSTE-ACS since 1999 despite falling rates of STEMI and MI overall (Yeh et al., 2010; Rogers et al., 2008).

Large population studies in NSTE-ACS during this time period have found an 18%–23% relative decrease in risk-adjusted odds of short-term mortality (Yeh et al., 2010; Rogers et al., 2008; Fox et al., 2007b; Hall et al., 2016; Krumholz et al., 2009) (Figure). Data from the National Registry of Myocardial Infarction in the United States demonstrated an in-hospital mortality of 5.2% in 2006 for NSTEMI, down from 7.1% in 1994 (Rogers et al., 2008), while 30-day mortality similarly decreased from 10.0% in 1999 to 7.6% in 2008 (Yeh et al., 2010). In the Global Registry of Acute Coronary Events (GRACE) which grouped NSTE-ACS data from 14 developed countries, risk-adjusted in-hospital mortality in 2005 was 2.2%, down from 2.9% in 1999 (Fox et al., 2007b) and 6-month mortality was similarly decreased to 3.3% from 4.9% during the same time period. Further data from the Myocardial Ischemia National Audit Project (MINAP) in England and Wales demonstrated the continuation of this trend between 2003 and 2013, with 30-day mortality decreasing from 2.6% to 2.0% and 6-month mortality from 10.8% to 7.6% over the 10-year period (Hall et al., 2016). Previous studies comparing long-term outcome between STEMI and NSTEMI have established that, while short-term mortality in STEMI is higher, rates of death in NSTEMI beyond 6-month follow-up approach or exceed that of STEMI (Armstrong et al., 1998; McManus et al., 2011; Yan et al., 2004). This phenomenon still persists in contemporary cohorts of ACS despite advances in pharmacotherapy and high rates of revascularization (Alnasser et al., 2015). Beyond the 6-month mark, case fatality among patients with NSTEMI in GRACE exceeded that of STEMI, with a significantly higher age- and sex-adjusted odds of mortality for the former at 2 years following MI and the absolute mortality reaching 9.5% among NSTEMI patients and 4.9% in UA patients (Alnasser et al., 2015). In addition to reductions in case fatality rates, hospital-level analyses in the United States have also observed decreasing variability in mortality among institutions (Krumholz et al., 2009), suggesting improved standardization of care. Rates of complications have similarly decreased, with patients less likely to develop heart failure, cardiogenic shock or reinfarction during their initial hospitalization (Fox et al., 2007b).

These ameliorations in patient outcome result from the substantial advancements in prevention, diagnosis, and management of ACS that have been accomplished over the past three decades as a product of intense clinical research efforts. The increasingly robust body of evidence for the implementation of pharmacotherapeutic and interventional treatments has led to modifications in the clinical guidelines on NSTE-ACS management (Amsterdam et al., 2014; Roffi et al., 2016). Increases in the adoption of these recommendations over the course of a 5- to 10-year period following their publication have been demonstrated in large, representative, observational studies (Yeh et al., 2010; Fox et al., 2007b; Hall et al., 2016; Yan et al., 2007b; Rao et al., 2009). Notably, evidence-based pharmacological therapies (aspirin, adenosine diphosphate receptor inhibitors, β-blockers, statins, angiotensin receptor inhibitors/angiotensin II-receptor blockers, low-molecular weight heparins) are now routinely employed in the majority of patients with NSTE-ACS, while the frequency of angiography and PCI in NSTE-ACS have risen considerably (Fox et al., 2007b; Hall et al., 2016; Yan et al., 2007b). Improvements in clinical outcome thus likely reflect a combination of improved adherence to evidence-based

management strategies (Fox et al., 2007b; Yan et al., 2007b), increased use of in-hospital revascularization (Hall et al., 2016; Gale et al., 2014), and, in part, the success of quality improvement initiatives (Jha et al., 2005; Jencks & Wilensky, 1992) addressing early concerns of disparities in the uptake of guideline recommendations (Fox et al., 2003; Rogers et al., 1994).

Consequent to these trends, the underlying risk profiles of contemporary patients classified as NSTEMI have also likely changed, although the net effect of these changes is not readily apparent in the context of multiple tendencies, some with opposing effects on risk. Data from GRACE have demonstrated a significant increase in the GRACE risk scores of NSTE-ACS patients enrolled over an 8-year period; all other factors kept constant, this represents an expected in-hospital mortality rise from 2.5% to 3.2% between 1999 and 2006 (Fox et al., 2007b). This contrasts with later data from MINAP demonstrating a significant decrease from 2003 to 2013 in the proportion of cases with intermediate to high GRACE risk scores (Hall et al., 2016). However, these net changes in baseline risk likely do not fully reflect the underlying distribution of risk scores, considering that the advances in NSTE-ACS diagnosis and management have allowed both detection of small infarcts earlier in their course of presentation, in addition to tendencies toward higher-risk, more comorbid, presentations of NSTEMI (Hall et al., 2016). This ongoing dual trend is likely responsible for increases in the heterogeneity of risk profiles underlying NSTEMI, and heightens the difficulty in clinically assessing prognosis or risk of complications in contemporary patient populations.

Clinical History and Exam

The initial clinical assessment of patients presenting with NSTE-ACS offers an opportunity to rapidly identify factors predictive of subsequent complicated clinical course or unfavorable outcome. Both baseline patient characteristics and mode of presentation are highly prognostic and contribute information to this assessment. Age is by far one of the most important prognostic factors in NSTE-ACS; patients over the age of 75 presenting with NSTE-ACS have more diffuse coronary atherosclerosis and more severe angiographic disease compared with those below 75 (Stone et al., 1996). In multivariable models such as GRACE and PURSUIT, age carries the strongest independent predictive value for mortality (Granger et al., 2003; Fox et al., 2014; Boersma et al., 2000). Despite this, underappreciation of the impact of age has been identified as one of the main reasons physicians misclassify patients with NSTE-ACS during risk assessment (Yan et al., 2009) and may explain why older patients are less likely to receive aggressive therapy despite high risk (Stone et al., 1996; Yan et al., 2006a). Current guidelines do not recommend the decision to pursue conservative management be solely based on age (Alexander et al., 2007), as age-stratified subgroup analyses from trials such as TACTICS-TIMI 18 suggest elderly patients ($\geq$75 years) may still benefit significantly from an early invasive strategy (Bach et al., 2004).

History of prior atherosclerotic disease predicts worse outcome in NSTE-ACS and has been established in the case of past history of MI, stroke, transient ischemic attack, and symptomatic peripheral artery disease (Cotter et al., 2003; Januzzi et al., 2005; Lee et al., 2010; Mohareb et al., 2013). Studies based on observational registries have demonstrated that these patients paradoxically tend to receive less intensive treatments and less frequently undergo in-hospital angiography due to an underappreciation of risk by physicians (Lee et al., 2010; Mohareb et al., 2013). Similarly, NSTE-ACS patients with a history of chronic heart failure have more high-risk presentations and greater rates of acute decompensated heart failure, cardiogenic shock, renal failure, and reinfarction complicating their hospital course (Zhang et al., 2016; Ranasinghe et al., 2012). Prior heart failure is an independent predictor of both in-hospital and long-term mortality and readmission following discharge (Zhang et al., 2016; Ranasinghe et al., 2012). Large trials (Anavekar et al., 2004; Al Suwaidi et al., 2002) and observational studies (Fox et al., 2014; Yan et al., 2006b; Wong et al., 2009) have recognized renal dysfunction as an independent predictor of adverse prognosis in NSTE-ACS (Fox et al., 2014). Despite being underrepresented in randomized controlled trials (Coca et al., 2006), subgroup analyses in FRISC and TACTICS-TIMI 18 have suggested a potential role for early invasive therapy in selected NSTE-ACS patients with renal dysfunction (Johnston et al., 2006; Januzzi et al., 2002). Among patients presenting with UA, the character and time course of anginal pain have prognostic value. Braunwald's classification of UA is based on the presenting angina provoking factor and relationship with exertion (Braunwald, 1989; Hamm & Braunwald, 2000); this categorization correlates with angiographic disease and independently discriminates mortality at 6 months, with the greatest risk in patients with recent rest pain (class III) and postinfarction angina (class C) (van Miltenburg-van Zijl et al., 1995).

On physical examination, initial hemodynamic parameters are highly predictive of mortality and early clinical course. Tachycardia and hypotension are powerful independent predictors of short- and long-term mortality in NSTE-ACS, and both heart rate and systolic blood pressure are central components of several risk models (Granger et al., 2003; Fox et al., 2014; Boersma et al., 2000). This association remains valid in patients with preexisting hypertension and is independent of prior antihypertensive medication use (Lee et al., 2013). A simple risk index calculated from heart rate, systolic pressure, and age alone is a strong predictor of 30-day mortality and allows rapid bedside risk assessment (Morrow et al., 2001a). These continuous variables have nonlinear relationships with outcome, and the GRACE 2.0 model demonstrated improved discrimination by employing nonlinear models for these indicators (Fox et al., 2014). New mitral regurgitation may complicate the presentation of NSTE-ACS as a result of ischemic damage to papillary muscles or left ventricle dilatation. Besides causing left ventricular dysfunction, the presence of mitral regurgitation itself is an independent prognostic factor for mortality and heart failure at 10-year follow-up even in patients with preserved left ventricular ejection fraction (LVEF) at presentation (Persson et al., 2010).

Overt heart failure is a feature associated with very high short-term risk and complicates the presentation of approximately one-tenth of contemporary NSTE-ACS admissions (Bahit et al., 2013). Its presence on admission is associated with older age, diabetes, prior MI (Khot et al., 2003), and a markedly higher 30-day mortality (Bahit et al., 2013; Steg et al., 2004; van Diepen et al., 2014). The Killip classification is a convenient clinical score for categorizing the severity of heart failure in acute MI based on clinical

exam (Killip & Kimball, 1967). Higher Killip classes on presentation predict greater short- and long-term mortality in contemporary international cohorts (Bahit et al., 2013; Khot et al., 2003; Steg et al., 2004). Paradoxically, despite this substantially higher risk of poor outcome, NSTE-ACS patients with heart failure on admission have lower rates of invasive management with coronary catheterization and PCI than those without heart failure, and are less likely to receive evidence-based pharmacotherapy such as β-blockers or statins upon discharge (Steg et al., 2004, 2008; Spencer et al., 2002; Shah et al., 2012). In NSTE-ACS patients presenting with heart failure, revascularization during index-hospitalization is associated with substantially decreased mortality at 6 months and is likely underutilized compared to patients without heart failure (Steg et al., 2008).

Electrocardiogram

The resting 12-lead electrocardiogram (ECG) remains essential in the immediate evaluation of NSTE-ACS and is one of the core components of clinical risk models. The first ECG should be acquired and screened for ischemic changes within 10 minutes of patient presentation, considered in parallel to initial clinical assessment, and repeated at any instance of change in symptomatology or clinical status (Amsterdam et al., 2014; Roffi et al., 2016). If initial ECG is nondiagnostic despite ongoing symptoms, current guidelines suggest serial ECGs be acquired in 15- to 30-minute intervals to screen for dynamic changes suggestive of evolving ischemia; continuous 12-lead ECG monitoring may also be considered in such patients (Amsterdam et al., 2014; Roffi et al., 2016). Continuous cardiac monitoring following admission to hospital permits further screening for occurrence of reinfarction or arrhythmia.

Beyond the evaluation of ST-segment deviation, assessing abnormalities on the initial ECG or evolving changes on subsequent repeat ECGs in the acute setting is important for dynamic risk assessment which may guide management. Several findings on ECG are recognized to be predictive of unfavorable outcome at short and long term, and novel analyses using repeat or continuous ECG data have emerged which may enhance precision in risk assessment.

ST-Segment Depression

ST-segment depression on initial ECG is strongly associated with unfavorable outcomes in NSTE-ACS and is a major independent prognostic factor in most risk prediction models. Its presence at admission has been shown to significantly correlate with short-term (Savonitto et al., 1999) and long-term ($\geq$1 year) (Kaul et al., 2001; Cannon et al., 1997) mortality. While ST depression as minimal as 0.5 mV has been demonstrated to reflect myocardial ischemia and unfavorable prognosis (Cannon et al., 1997), greater magnitudes of depression predict higher short-term mortality. Both the depth of the ST depression within a single lead (Kaul et al., 2001) and the cumulative sum of the depressions in all leads (Savonitto et al., 2005) carry independent prognostic weight. In an analysis from GUSTO-IIb, the latter was demonstrated to have a graded association with 30-day mortality and to predict the presence of three-vessel or left main coronary disease on angiography (Savonitto et al., 2005).

As patients may present at variable time points during the course of NSTE-ACS evolution, repeat ECGs are valuable for tracking dynamic ST-segment changes reflecting the progression or development of myocardial ischemia. The persistence of ST depression from initial to early repeat ECG performed at 12–24 or 24–36 h after presentation is strongly predictive of increased mortality at 30 days and 6 months, whereas the development of new ST depression on follow-up ECG also identifies patients at higher risk than on the basis of their admission ECG alone (Yan et al., 2010; Alkaabi et al., 2008). Similar associations with outcome were found when repeat ECG was undertaken at the time of discharge; persistent or new ST depression on late repeat ECG despite in-hospital therapies conveys significantly increased long-term risk of death and reinfarction (Hersi et al., 2003).

In the acute management of NSTE-ACS, the presence of ST-segment depression identifies patients most likely to benefit from an early invasive strategy. As opposed to patients with no acute ECG findings or T-wave inversion (TWI) only, those with ST-segment depression have significantly lower mortality if they undergo early invasive management (Cannon et al., 2001; Diderholm et al., 2002a). Furthermore, the extent of this survival benefit increases as the number of affected leads or the cumulative sum of ST depression increases (Holmvang et al., 2003). Assessing ST depression on initial and repeat ECG as a dynamic marker of ischemic burden is thus valuable for guiding the decision to pursue early invasive management.

T-Wave Inversion

Compared with ST depression, the presence of isolated TWI on admission ECG in NSTE-ACS is associated with lower prevalence of atherosclerotic disease on coronary angiography and lower rates of short- or long-term mortality or reinfarction (Savonitto et al., 1999; Collinson et al., 2006; Mueller et al., 2004). Neither TWI on the admission (Tan et al., 2013) nor early repeat (Sarak et al., 2016) ECG was a significant predictor of poor outcome beyond known prognostic factors.

Conduction Abnormalities

In patients with NSTE-ACS, the presence of left bundle branch block (LBBB) at presentation is independently associated with increased severity of angiographic disease, especially in the right coronary artery distribution, and nearly twofold higher cumulative mortality at 1-year follow-up (Rose et al., 2013; Damman et al., 2012). Similarly, new right bundle branch block (RBBB) is associated with higher-risk presentations, more extensive comorbidities, and multivessel disease (Chan et al., 2016). Following adjustment for these variables, RBBB also retains a strong association with early mortality (Chan et al., 2016), comparable in

magnitude to LBBB and twice that of STEMI (Widimsky et al., 2012). Paradoxically, observational studies of unselected patient populations have demonstrated patients with left or right bundle branch block to be less likely to receive evidence-based pharmacotherapy (Go et al., 1998) or to undergo coronary angiography or PCI than those with normal conduction, despite a much higher likelihood of significant stenosis of major epicardial arteries (Chan et al., 2016; Widimsky et al., 2012).

High-grade atrioventricular block (HAVB), comprising either type II Mobitz second-degree or third-degree atrioventricular block, occurs in less than 2% of contemporary cases of NSTE-ACS (Singh et al., 2015). Its presence is associated with higher GRACE risk scores and predicts a complicated hospital course, with significantly higher rates of reinfarction, heart failure, cardiogenic shock, and ventricular arrhythmias (Singh et al., 2015; Haim et al., 1997). Odds of in-hospital death are consequently over sixfold higher in patients with HAVB; however, among those surviving discharge, subsequent long-term mortality is comparable to patients without HAVB (Singh et al., 2015; Haim et al., 1997).

While left anterior hemi-block on admission ECG is associated with greater frequency of comorbidity and high-risk presentations among patients with ACS, this finding is not an independent predictor of mortality in contemporary cohorts (Zhang et al., 2014).

Left Ventricular Hypertrophy

Presence of electrocardiographic criteria for left ventricular hypertrophy (LVH) on initial ECG is associated with higher-risk clinical presentations (Ali et al., 2011; Westerhout et al., 2007). While a substudy of NSTE-ACS patients in the GUSTO IV ACS trial found that women with LVH had increased long-term mortality independent of NT-pro-BNP levels (Westerhout et al., 2007), a significant relationship with adverse outcome was not found in less selected patients from GRACE following multivariable adjustment with the GRACE risk score (Ali et al., 2011). The latter study demonstrated that ST depression, however, remains a strong prognostic indicator of mortality, regardless of the presence of LVH.

Continuous ECG Monitoring

Recurrent ischemia is common in NSTE-ACS patients following their initial event and frequently occurs without any accompanying symptoms (Cohn et al., 2003). Beyond the admission 12-lead ECG, continuous ECG ST-segment monitoring (CSTM) during index hospitalization provides further risk stratification (Scirica et al., 2009; Akkerhuis et al., 2001; Goodman et al., 2000). In the MERLIN-TIMI 36 trial, a single episode of recurrent ST depression lasting at least 1 minute in the week following admission for NSTE-ACS was independently associated with heightened short- and long-term risk of reinfarction and cardiovascular death, improving risk assessment beyond clinical and biomarker data alone (Scirica et al., 2009). Furthermore, ischemic events on CSTM during just the first 24 h of presentation can predict the occurrence of death or MI at as early as 5 days following admission (Akkerhuis et al., 2001). When considered in addition to risk models used for risk stratification at presentation, CSTM adds significant incremental prognostic information beyond that provided by the TIMI, PURSUIT, and GRACE risk scores (Carmo et al., 2011; Yan et al., 2007c). Use of CSTM may guide invasive management decisions as the presence of ST shifts on continuous ECG identifies high-risk patients who would benefit from in-hospital revascularization (Yan et al., 2007c).

Other ECG Findings

While lead aVR is generally viewed as providing reciprocal information to the left lateral distribution of leads (aVL, II, V_5, and V_6) (Gorgels et al., 2001), angiographic studies have demonstrated ST-segment elevations in aVR to also be a marker of left main coronary artery disease (CAD), possibly mediated via ischemia of the basal interventricular septum (Gorgels et al., 2001; Yamaji et al., 2001). In NSTE-ACS, the presence of ST-segment elevation in aVR has been strongly associated with high-risk angiographic disease, with increasing magnitudes of ST elevation independently predicting progressively higher prevalence of significant left main or three-vessel disease (Barrabes et al., 2003; Kosuge et al., 2006, 2008; Yan et al., 2007d; Taglieri et al., 2011). While small studies have associated this ECG finding to in-hospital (Barrabes et al., 2003; Taglieri et al., 2011) and long-term mortality (Kosuge et al., 2006; Taglieri et al., 2011), the incremental prognostic value of ST elevation in aVR beyond known prognosticators was not confirmed following comprehensive multivariable adjustment in a large 5064-patient cohort from GRACE (Yan et al., 2007d).

Low QRS voltage is an infrequent finding on admission ECG in patients presenting with NSTE-ACS. It is defined by a peak-to-peak QRS amplitude of <0.5 mV in all limb leads and <1.0 mV in all precordial leads. In addition to obesity or pericardial effusion, this abnormality may be a result of globally reduced action potentials due to diffuse myocardial injury (Isobe et al., 2002, 2006). In a large observational cohort from GRACE, the presence of low QRS voltage on admission ECG in NSTE-ACS independently predicted increased in-hospital mortality, but this association did not persist at 6 months (Tan et al., 2015). Further studies in contemporary populations are required to confirm the role of low QRS voltage as a routine prognostic indicator.

Heart rate turbulence (HRT) is a novel Holter monitor-based electrocardiographic marker of baroreflex (Bauer et al., 2008). The measurement is made by assessing heart rate patterns following isolated premature ventricular contractions (PVC). In healthy patients, the occurrence of a hemodynamically inefficient PVC results in low cardiac output causing vagal inhibition and a period of brief sinus rate acceleration. This is followed by baroreceptor trigger and a subsequent overcorrection via vagal stimulus, causing gradual heart rate deceleration prior to a return to the normal pre-PVC rate (Bauer et al., 2008). This normal pattern of HRT reflects integrity of the autonomic arc and its blunting in post-MI has been strongly associated with long-term unfavorable outcomes (Exner et al., 2007; Barthel et al., 2003). The detection of early HRT blunting during index hospitalization following acute MI has been validated as a powerful independent predictor of all-cause mortality (Sade et al., 2003) and a complement to LVEF for predicting risk of cardiac arrest or sudden cardiac death (Exner et al., 2007).

Biomarkers

Troponin

Acute MI is defined by the presence of an elevated concentration of serum cardiac troponin in the context of clinical history compatible with myocardial ischemia (Thygesen et al., 2012). Both cardiac troponin I (*c*TnI) (Adams et al., 1993; Cummins & Perry, 1978) and T (*c*TnT) (Perry, 1998; Katus et al., 1991) are highly specific to the myocardium and their presence in the peripheral circulation in elevated quantities is a very sensitive marker of myocardial injury (Saenger & Jaffe, 2008). Its superiority in diagnostic accuracy compared to creatine kinase MB isoenzyme (CK-MB) has led to troponin supplanting CK-MB as the preferred biomarker of myocardial necrosis (Morrow et al., 2007). The Third Universal Definition of Myocardial Infarction recommends a troponin value above the 99th percentile of the upper reference level as a cutoff for diagnostic positivity (Amsterdam et al., 2014; Roffi et al., 2016; Thygesen et al., 2012); studies of prognosis in troponin have also shown this to be the useful cutoff for risk prediction (James et al., 2003a).

The prognostic value of elevated troponin has been clearly demonstrated in NSTEMI, with both *c*TnI and *c*TnT carrying similar predictive value (Olatidoye et al., 1998). A metaanalysis of 21 studies of patients with NSTEMI found that patients with elevated troponin had increased mortality at 30 days and long-term follow-up (5 months to 3 years) (Ottani et al., 2000). In large head-to-head comparisons with CK-MB, analyses from CRUSADE (Newby et al., 2006) and GRACE (Goodman et al., 2006) found troponin superior to CK-MB in predicting mortality and enhancing overall prognostication. Major trials such as GUSTO IV ACS (James et al., 2003b), GUSTO IIa (Ohman et al., 1996), TIMI IIIB (Antman et al., 1996), and FRISC (Lindahl et al., 2000) have demonstrated a graded relationship between the degree of troponin elevation and short-term mortality; furthermore, any detectable elevation in presenting troponin level negatively impacts short-term outcome. Similarly, this mortality gradient was also observed when troponin was analyzed in an unselected, real-world series of 16,318 NSTE-ACS patients from GRACE (Jolly et al., 2011). The magnitude of peak troponin in the first 24 h following presentation had a powerful independent relationship with the incidence of life-threatening arrhythmia, cardiogenic shock, and new heart failure; the degree of troponin elevation modeled as a continuous variable independently predicted both short- and longer-term mortality (Jolly et al., 2011) and is a component of several validated risk scores (Granger et al., 2003; Fox et al., 2014; Antman et al., 2000).

The increased mortality associated with troponin elevation is likely mediated by greater severity or extent of underlying CAD impairment of coronary flow and complex lesion characteristics such as thrombus formation or downstream microembolization (Lindahl et al., 2001; Heeschen et al., 1999a). Peak *c*TnT and *c*TnI levels have also been correlated with infarct size determined by both magnetic resonance imaging (Vasile et al., 2008; Steen et al., 2006) and scintigraphy (Licka et al., 2002; Panteghini et al., 2002).

NSTE-ACS patients with troponin elevation should be managed more aggressively in the acute phase owing to their higher risk of complications and short-term mortality (Amsterdam et al., 2014; Roffi et al., 2016). These patients derive greater benefit from pharmacotherapy with antithrombotic agents such as low-molecular weight heparin (Morrow et al., 2000) and glycoprotein IIb/IIIa inhibitor (Heeschen et al., 1999b). Furthermore, patients with elevated troponins at presentation are more likely to benefit from an early invasive strategy (Diderholm et al., 2002b; Kleiman et al., 2002); this benefit can be substantial even if the magnitude of the troponin elevation is relatively minor (Morrow et al., 2001b). In a metaanalysis of seven randomized trials, patients with elevated troponin had lower short- and long-term adverse outcomes when managed with an early invasive strategy compared to a conservative strategy during index hospitalization (Bavry et al., 2006).

C-Reactive Protein

C-reactive protein (CRP) is an acute-phase reactant and marker of inflammation (Armstrong et al., 2006). Increased levels of CRP are detectable acutely following ACS and have been hypothesized to represent focal and systemic inflammatory processes underlying the destabilization and eventual rupture of vulnerable coronary plaques (Morrow et al., 2007). Several studies in patients presenting with NSTE-ACS have shown early high-sensitivity (hs)-CRP to predict short- and long-mortality in multivariable analyses (He et al., 2010). Importantly, studies have found that hs-CRP yields prognostic information complementary to cardiac troponin results (James et al., 2003b), and may supply supplemental prognostic value in patients without rise in their troponin levels (Lindahl et al., 2000; Morrow et al., 1998). Following ACS, monitoring CRP levels in patients on statin therapy allows improved prognostication of cardiac events beyond low density lipoprotein monitoring alone. The role of a combined biomarker approach to prognostication of NSTE-ACS is a subject of active investigation but not yet validated for routine clinical use (Tello-Montoliu et al., 2007).

BNP and NT-pro-BNP

Brain natriuretic peptide (BNP) is a hormone synthesized predominantly in the myocardium of the left ventricle and secreted secondary to myocyte stretch from pressure overload or ventricular dilatation. Rapid assays have been developed to detect BNP or the N-terminal fragment of its prohormone precursor (NT-pro-BNP) and are now widely available. Elevated levels of both BNP and NT-pro-BNP measured in NSTE-ACS early following symptom onset are independent predictors of mortality (Jernberg et al., 2003; Bazzino et al., 2004; Heeschen et al., 2004; Eggers et al., 2009). Furthermore, an analysis of 6809 patients from the GUSTO IV ACS trial found that increasing N-pro-BNP levels had a gradient relationship with 1-year mortality independent of troponin or CRP

(James et al., 2003c). Serial measurements of BNP following discharge after index hospitalization for NSTE-ACS may further evaluate risk during follow-up (Morrow et al., 2005). Additional research is required to conclusively determine if the addition of BNP or NT-pro-BNP to existing risk stratification methods offers incremental predictive information beyond known prognosticators and results in improved patient management.

Other Emerging Biomarkers

Heart-type fatty acid binding protein (H-FABP) is a cytosolic protein found in, and relatively specific to, cardiomyocytes (Van Nieuwenhoven et al., 1995); it is detected peripherally following myocardial insult and is currently under investigation as a potential biomarker in ACS (Glatz et al., 1994). Small preliminary studies suggest that early measurement of H-FABP may carry prognostic ability to predict long-term mortality independent of troponin, or in troponin-negative NSTE-ACS (Viswanathan et al., 2010; Kilcullen et al., 2007; O'Donoghue et al., 2006). However, larger and more rigorous studies with contemporary troponin assays are required to adequately assess the incremental predictive value of this biomarker prior to clinical use.

Copeptin is the C-terminal segment of the precursor peptide to arginine vasopressin; this molecule is secreted from the pituitary gland early during acute MI (Khan et al., 2007). As a potential emerging biomarker of MI, copeptin's role in diagnosis and prognostication is currently under investigation (Nickel et al., 2012). Initial studies in NSTE-ACS, however, have failed to demonstrate an independent relationship with outcome following adjustment with patient characteristics and troponin (Sanchez et al., 2014).

Additional emerging biomarkers are under investigation in NSTE-ACS. Growth differentiation factor (GDF) 15 (Widera et al., 2012), ST2 (Eggers et al., 2010), corin (Zhou et al., 2016), midregional proadrenomedullin (MR-proADM) and pro-atrial natriuretic peptide (MR-proANP) (O'Malley et al., 2014), and circulating microRNAs (miRNAs) (Navickas et al., 2016), among others, have been associated with clinical outcome in NSTE-ACS and may allow novel avenues of prognostication in the future.

Clinical Prognostic Models

Comprehensive risk assessment in NSTE-ACS should take a wide number of prognostic factors into account to allow an overall assessment of the probability of unfavorable outcome (Steg et al., 2009). While a rare number of clinical predictors are so strong that they may be used individually to guide management decisions, adequate prognostication in most cases of NSTE-ACS at their presentation requires evaluation of multiple clinical parameters simultaneously. For clinicians to effectively perform these assessments at the time of initial patient encounter, current clinical practice guidelines strongly recommend the use of well-validated clinical risk scores to determine prognosis (class I recommendation) and guide management decisions (class IIa recommendation) (Amsterdam et al., 2014; Roffi et al., 2016). While most of these tools share similar core elements, they differ in their structure, setting, and predicted outcomes (Table).

GRACE

The Global Registry of Acute Coronary Events (GRACE) risk model is a tool derived from a multinational registry of less selected ACS patients (Granger et al., 2003). Spanning 30 countries, the registry enrolled patients diagnosed with ACS from nearly 250 hospitals; recruitment was aimed at minimizing selection bias and ensuring representation of the entire spectrum of patients with ACS. While the majority of other risk models are based on data originating from trial databases, GRACE had minimal exclusion criteria and encouraged consecutive enrollment of cases in its participating hospitals.

The original GRACE risk score is an eight-item multivariable model estimating the risk of in-hospital mortality in ACS based on data from 11,389 patients (Granger et al., 2003) and 6-month mortality derived from 21,688 patients (Fox et al., 2006). This risk model was updated in 2014 (Fox et al., 2014) as GRACE 2.0, derived from 32,037 patients, and further extended to also predict mortality at 1 and 3 years, with simplification of some variables and improvement in discrimination. While the underlying regression models differed, the same eight clinical variables were independently responsible for nearly 90% of the predictive accuracy of the model: age, systolic blood pressure, heart rate, creatinine, Killip class, cardiac arrest on presentation, positive biomarkers of myocardial necrosis, and ST deviation on ECG.

The GRACE risk score may be employed early as it is based on information generally available at initial assessment in the emergency department. In the original GRACE risk score, points are assigned via a nomogram for each of the model predictors and totaled to provide an estimate of the absolute risk of in-hospital mortality. In this model, a score of $\leq$108 represents a $<$1% probability of in-hospital death and may be considered low risk, whereas a score of $\geq$141 is indicative of high ($>$3%) mortality risk (Hamm et al., 2011). GRACE 2.0 simplifies assessment of the Killip and creatinine variables as these may be interchanged with the presence of diuretic use and renal dysfunction, respectively (Fox et al., 2014; Simms et al., 2013). Rather than a points-based system, absolute risk in V2.0 is calculated directly by an electronic application to benefit from nonlinear modeling of some of the continuous variables (Fox et al., 2014).

For patients surviving hospitalization, a separate GRACE risk score was developed to determine late prognosis in ACS. This score was derived in a cohort of 15,007 GRACE patients who survived index hospitalization; nine variables independently predicted all-cause mortality at 6 months postdischarge: age, history of MI, history of heart failure, tachycardia at presentation, hypotension at presentation, elevated creatinine at presentation, positive biomarkers of myocardial necrosis, ST depression on initial ECG, and not undergoing in-hospital PCI (Eagle et al., 2004).

The GRACE risk score has been demonstrated to have excellent discrimination in its validation studies, with a c-statistic of 0.83 for in-hospital mortality in the original GRACE study (Granger et al., 2003) and 0.81, 0.83, and 0.82 for 6-month, 1-year, and 3-year morality, respectively, in the subsequent follow-up studies (Fox et al., 2006, 2014). It has since also been extensively validated in independent datasets, including cohorts from multiple continents (Bradshaw et al., 2006, 2015; Elbarouni et al., 2009; Kelly et al., 2012; Yusufali et al., 2011; Thalib et al., 2016; Prabhudesai et al., 2012; Shaikh et al., 2014). When compared to alternative NSTE-ACS prediction models, a metaanalysis pooling validation studies found the GRACE risk score to have significantly higher discrimination compared to the TIMI risk score (D'Ascenzo et al., 2012). Furthermore, a National Institute for Health and Care Excellence (NICE) analysis testing eight ACS risk prediction scores head-to-head in a 64,312 patient database from the MINAP registry found the GRACE risk score to outperform all other models with a c-statistic of 0.825. Similar results were found in the

Canadian ACS II registry and other patient populations (Yan et al., 2007e; Aragam et al., 2009). Given this overall robustness, it is one of the preferred risk stratification tools recommended in contemporary guidelines (Amsterdam et al., 2014; Roffi et al., 2016). In addition to prognostication, the GRACE risk score may also aid management decisions (Amsterdam et al., 2014; Roffi et al., 2016; de Araujo et al., 2005; Mehta et al., 2009; Yan et al., 2005). A prespecified subgroup analysis of the TIMACS trial showed that an early invasive strategy in NSTE-ACS within 24 h of presentation improves outcomes in high-risk patients (GRACE risk score >140), but not those at low or intermediate risk (Mehta et al., 2009); similar discriminatory value was demonstrated in a less-selected ACS cohort (Yan et al., 2005).

TIMI

The Thrombolysis in Myocardial Ischemia (TIMI) risk score is a simple seven-variable prediction model derived from two large trials of NSTE-ACS patients (TIMI 11B and ESSENCE) (Antman et al., 2000). Multivariable analyses from these datasets demonstrated seven dichotomous variables which independently predicted major adverse events at 14 days (mortality, new or recurrent MI, or severe ischemia requiring revascularization). The number of variables present (age $\geq$65 years, presence of three or more risk factors for CAD, prior evidence of coronary stenosis, ST deviation at presentation, positive cardiac biomarkers, two or more angina episodes in the 24 h before presentation, and aspirin use in the 7 days prior to presentation) is summated to determine the total score and the corresponding absolute risk of major adverse outcome.

The TIMI risk score is simple to calculate at bedside and has been validated in unselected cases of NSTE-ACS (Scirica et al., 2002; Soiza et al., 2006). Increasing TIMI scores have been well correlated with severity of angiographic disease, predicting both overall burden of atherosclerotic CAD (Garcia et al., 2004) and presence of high-risk features, such as impaired flow or coronary thrombus (Mega et al., 2005). Stratification by TIMI risk categories may help predict which NSTE-ACS patients are most likely to benefit from an early invasive management approach; subgroup analyses in the TACTICS-TIMI 18 trial, for example, found that only intermediate and high-risk patients (TIMI score $\geq$ 3) derived clinical benefit from this strategy (Cannon et al., 2001).

PURSUIT

The PURSUIT risk score was created from a trial cohort of 9461 NSTE-ACS patients recruited from 28 hospitals across North and South America and Europe to predict 30-day mortality or reinfarction (Boersma et al., 2000). Multivariable regression analysis established seven variables as predictive of unfavorable outcome: age, male sex, heart rate, systolic blood pressure, ST-segment depression, signs of heart failure, and worse Canadian Cardiovascular Society Angina class in the 6 weeks prior to presentation. By assigning points for each variable, risk of death at 30 days may be calculated from a nomogram; this risk score predicted mortality with good discrimination in the original validation study (c-statistic = 0.81) and when applied in an independent dataset (Gale et al., 2009). Patients deemed high-risk by a PURSUIT score of >14 have been demonstrated to benefit from early myocardial revascularization during index hospitalization, although its accuracy for predicting this benefit was inferior to that of the GRACE risk score (de Araujo et al., 2005).

Other Risk Scores

In contrast to the more exhaustive prediction models described previously, several simple risk scores designed to incorporate only age and hemodynamic parameters have been demonstrated to maintain strong predictive value (Morrow et al., 2001a; Dorsch et al., 2001; Huynh et al., 2013). The TIMI risk index (TRI) (Morrow et al., 2001a) is a simple calculation relating together the absolute values of the patient's age, systolic blood pressure, and heart rate. In NSTEMI patients, the resulting score has a graded association with 30-day mortality, spanning a 30-fold difference between the highest and the lowest deciles (Wiviott et al., 2006). Similar to the TRI, The Evaluation of the Methods and Management of Acute Coronary Events (EMMACE) risk score (Dorsch et al., 2001) is based on age, systolic blood pressure, and heart rate modeled via logistic regression to predict 30-day mortality. This score was demonstrated to have high discrimination in validation cohorts across the ACS spectrum (Gale et al., 2009). The Canadian Acute Coronary Syndrome risk score (C-ACS) (Huynh et al., 2013) dichotomizes four variables, with one point assigned for the presence of each: age $\geq$75, Killip class >1, systolic blood pressure <100 mmHg, and heart rate >100 beats/min. This score is a highly sensitive prognosticator for both short- and long-term mortality, with negative predictive values of a C-ACS score of $\geq$1 at 98% for 30-day mortality and 93% for 1- or 5-year mortality.

In patients with acute chest pain but absence of troponin elevation or ST-segment deviation, a simple risk score taking into account age, chest pain severity score, chest pain frequency, history of insulin-dependent diabetes, and prior PCI predicts 1-year mortality with better discrimination than the TIMI risk score (Sanchis et al., 2005). The OASIS risk score (Mehta et al., 2016) incorporates two novel biomarkers, NT-proBNP and hemoglobin A1c, to five traditional variables (age, sex, prior history of MI or stroke, ST-segment deviation, and cTnT) to create a 20-point risk stratification tool strongly predicting 1-year mortality. The FRISC score (Lagerqvist et al., 2005) is determined by the number of factors present among: age >70 years, male sex, diabetes, previous MI, ST depression, troponin elevation, and increase in markers of inflammation; a score of $\geq$3 predicts significant reductions in death and MI at 1-year for patients who undergo an early invasive management strategy. The Clinical SYNTAX Score (CSS) (Farooq et al., 2013) incorporates angiographic lesion information with baseline clinical variables to predict 1-year mortality, with validation studies in NSTE-ACS patients demonstrating good discrimination.

Noninvasive Cardiac Imaging

Echocardiography

Point-of-care ultrasound is increasingly available in most emergency rooms and use of early resting two-dimensional transthoracic echocardiography (TTE) is feasible at initial assessment of patients with NSTE-ACS. In this context, rapid, targeted bedside TTE may be performed as an extension of the physical examination in the prognostic evaluation of such patients. The presence of wall motion abnormalities on early TTE in patients with NSTE-ACS is associated with severity of angiographic disease (Di Pasquale et al., 2004). A more detailed assessment of regional systolic function with the wall motion score index (WMSI) (Nishimura et al., 1984) early after admission strongly predicts long-term mortality and future admission for heart failure, offering incremental value over LVEF alone (Moller et al., 2006). Novel predictors assessed with speckle-tracking echocardiography may further enhance early risk stratification, as both the evaluation of myocardial strain (Dahlslett et al., 2014) and the duration of systolic lengthening of ischemic myocardial segments during isovolemic contraction (Zahid et al., 2014) in patients with NSTE-ACS have been found to be predictive of coronary stenosis or occlusion on angiography.

Evaluation of resting LVEF following NSTE-ACS offers critical prognostic information and should be undertaken routinely in all patients prior to discharge (Amsterdam et al., 2014; Roffi et al., 2016). Left ventricular systolic dysfunction is a powerful predictor of long-term mortality, arrhythmia, and heart failure (Mukherjee et al., 2016; Bauer et al., 2009; Solomon et al., 2005; Nicolosi et al., 1996; St John Sutton et al., 1994; Van Reet et al., 1984; The Multicenter Postinfarction Research Group, 1983). While several modalities may accurately assess LVEF, TTE is often the most routinely accessible imaging tool and simultaneously permits the detection of other indicators of poor outcome; echocardiographic evidence of restrictive left ventricular filling (Moller et al., 2008), myocardial strain (Milewska et al., 2016), right ventricular dysfunction (Zornoff et al., 2002), left atrial enlargement (Moller et al., 2003), and ischemic MR (Persson et al., 2010; Grigioni et al., 2001) are all associated with unfavorable long-term prognosis independent of left ventricular dysfunction.

In low- to intermediate-risk NSTE-ACS patients treated with an ischemia-guided strategy, noninvasive stress testing is recommended prior to discharge following absence of ischemia for 12–24 h (Amsterdam et al., 2014; Roffi et al., 2016). This may be accomplished via an ECG exercise tolerance test in patients with resting ECGs allowing ST-segment interpretation (Nyman et al., 1992). In patients with baseline ECG abnormalities precluding dynamic interpretation during ECG stress testing, use of an imaging modality such as stress echocardiography is an accurate alternative for identifying patients at higher risk of having angiographically significant disease who may benefit from revascularization (Marwick et al., 1995).

Nuclear Myocardial Perfusion Scintigraphy

Although NSTE-ACS patients with high-risk presenting characteristics have been shown to benefit from an early invasive strategy (Fanning et al., 2016), their low- or intermediate-risk counterparts may be adequately managed with an ischemia-guided approach (Amsterdam et al., 2014; Roffi et al., 2016). Following initial medical stabilization, early stress myocardial perfusion scintigraphy (MPS) has been shown to have significant prognostic value in further risk-stratifying such patients (Brown, 1997). The presence and extent of inducible perfusion defect on MPS is highly predicative of short- and long-term mortality and adverse cardiac events (Mahmarian et al., 1995, 2006; Stratmann et al., 1995a,b; Zhu et al., 1991; Younis et al., 1989) and can guide the decision to pursue in-hospital cardiac catheterization. Conversely, the absence of significant reversible defects may reliably identify patients at low risk who can be considered for conservative management and rapid discharge (Mahmarian et al., 2006).

Hybrid imaging combines a functional myocardial perfusion test (such as single photon emission computed tomography (SPECT) or positron emission tomography (PET)) with anatomical imaging (such as computed tomography coronary angiography (CTCA)). Early hybrid imaging identifies the presence of angiographically significant CAD (Gaemperli et al., 2011) and thus could be employed as a potential noninvasive prognosticator in NSTE-ACS for identifying low- or intermediate-risk patients who may benefit from coronary angiography during initial hospitalization (Rispler et al., 2011). However, hybrid imaging currently has limited availability and further studies should be awaited to establish its incremental prognostic value over clinical risk-stratification prior to routine clinical application (Gaemperli et al., 2011).

Computed Tomography Coronary Angiography

The use of computed tomography coronary angiography (CTCA) in the acute setting of suspected ACS is rapidly expanding as multidetector scanners capable of acquiring ≥ 64 slice images are becoming widely available (Hoffmann & Bamberg, 2009). However, the utility of CTCA in the risk stratification of NSTE-ACS has not yet been clearly demonstrated and is currently of limited clinical application. Preliminary studies have found characterization of culprit (Thomsen & Abdulla, 2016) and nonculprit plaques (Dedic et al., 2014) on CTCA performed during index hospitalization for ACS to predict long-term major adverse cardiovascular events; however, further studies are required to determine the incremental prognostic value of these findings and their role in guiding the acute management of NSTE-ACS.

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance (CMR) is an emerging imaging modality in NSTE-ACS capable of undertaking detailed assessment of myocardial structure, function, viability and ischemia. Evaluation of myocardial edema, microvascular obstruction, and

intramyocardial hemorrhage are further capabilities unique to this technique (Lockie et al., 2009). Minimal data are available on the role of early CMR in ACS; however, in a study of 68 patients diagnosed with NSTE-ACS who underwent CMR within 72 h of presentation, CMR was found to be highly accurate in predicting flow-limiting coronary stenosis on invasive coronary angiography (Plein et al., 2004). With a sensitivity of 96% and specificity of 83%, acute phase CMR outperformed the TIMI risk score for predicting angiographically significant CAD (Plein et al., 2004). Similarly, the presence of myocardial edema on CMR performed early following NSTE-ACS was found to predict need for in-hospital revascularization and prognosticate risk of long-term cardiac events (Raman et al., 2010). Infarct size is most accurately assessed by CMR, and its measurement early after acute MI has been found to be both a predictor of left ventricular remodeling and a strong independent prognosticator of long-term adverse cardiac events independent of LVEF (Wu et al., 2008). Other specific CMR findings following ACS or primary PCI have been shown to be predictive of clinical outcome (Lockie et al., 2009); however, their prognostic value in early risk stratification soon after NSTE-ACS and role in management has not yet been established.

Coronary Angiography

Coronary angiography is the gold standard for assessing acute manifestations of CAD and provides incremental prognostic information in patients with NSTE-ACS. In ACS patients treated with an early invasive strategy, the presence on angiography of high disease burden, plaque calcification, lesion eccentricity, postprocedural TIMI flow grade, and left ventricular dysfunction measured by left ventriculogram are all independently predictive of unfavorable short- and long-term prognosis (Lansky et al., 2010; Song et al., 2010); however, culprit vessel (Halim et al., 2016) and myocardial blush grade (Ng et al., 2016) have limited predictive value.

The Synergy Between PCI with Taxus and Cardiac Surgery (SYNTAX) score is a system for grading the complexity of coronary anatomy via angiography (Sianos et al., 2005) and has been validated in patients with NSTE-ACS for discriminating risk of death and MI at 30 days, 1 year, and 3 years follow-up when used in concert with clinical variables (Farooq et al., 2013; Palmerini et al., 2011; Iqbal et al., 2014). In a head-to-head comparison with other angiographic risk scores, the SYNTAX score maintained superior model characteristics (Palmerini et al., 2012).

The absence of culprit lesion on coronary angiography is seen in 9%–14% of patients with NSTE-ACS undergoing an invasive management strategy (Agewall et al., 2016; Bugiardini et al., 2006; Patel et al., 2006; Roe et al., 2000; Diver et al., 1994). The finding of absent or mild coronary disease (<50% stenosis of a major epicardial artery) predicts more favorable clinical course; in both the PURUSIT trial (Roe et al., 2000) and the CRUSADE registry (Patel et al., 2006), patients with such insignificant coronary disease had significantly lower short-term mortality. This favorable prognosis was also seen at 1-year follow-up in a study pooling 7656 patients from three TIMI trials where the outcome of death or MI occurred in only 2.1% of such patients, compared to 11.2% in those with obstructive disease (Bugiardini et al., 2006).

Summary

The last four decades have witnessed significant advances in the treatment of NSTE-ACS with the emergence of evidence-based pharmacological agents and the increased availability of cardiac catheterization and early revascularization. While rapid improvements have been achieved in both short- and long-term outcomes, including reductions in death, heart failure, and life-threatening arrhythmias, gaps persist in the use of evidence-based therapies and NSTE-ACS continues to be a major global cause of morbidity and mortality. Ongoing epidemiological trends have resulted in a significantly higher proportion of patients presenting with NSTE-ACS as opposed to STEMI among contemporary cohorts of ACS, with increasingly heterogeneous risk profiles. Systematic underappreciation of patient risk likely in part accounts for gaps in the application of guideline-recommended management, and may perpetuate the ongoing treatment-risk paradox.

Comprehensive early risk assessment entails systematically integrating information from the initial clinical history, hemodynamic profile, physical exam, ECG, and biomarkers of cardiac injury to estimate prognosis. While risk assessment should always be tailored and interpreted in the context of each unique clinical scenario, an unstructured approach to risk stratification may lead to overemphasis of certain individual indicators and the neglect of others. Indeed, studies investigating the treatment-risk paradox have found that certain well-established and common prognosticators such as age, renal dysfunction, heart failure, and hemodynamic variables are systematically underrecognized. An integrated approach using validated risk scores can significantly improve risk stratification of NSTE-ACS and identify high-risk patients most likely to benefit from intensive therapies.

Moving forward, additional investigation is required to further elucidate physicians' attitudes toward risk assessment and their real-world application of standardized prognostic models. Current gaps in matching patient risk to appropriate intensity of treatment may be at least partly responsible for poor outcomes in NSTE-ACS. Quality improvement programs aimed at standardizing risk assessment at patient presentation may consequently improve decision-making and long-term outcome.

Low	2	2	5	4	169	242	270	317	347	350	324
Intermediate to high	18	15	34	48	1362	1709	1940	2292	2203	2175	1967

Legend: NSTE-ACS, non-ST elevation acute coronary syndrome; GRACE, Global Registry of Acute Coronary Events.

Curves were fitted using local polynomial smoothing. Median and range of patients per month for each year are based on complete case data for GRACE risk score only. Numbers of patients per month with lowest, low, and intermediate to high GRACE risk scores ranged from 0 to 301, 0 to 395, and 1 to 2406, respectively, across all time periods.

Patient Evaluation and Risk Assessment

The evaluation of patients with suspected acute coronary syndromes (ACS) is based on medical history—including chest pain characteristic evaluation and cardiovascular risk factor assessment—clinical presentation, electrocardiogram (ECG), and biomarkers (preferably high-sensitivity cardiac troponin) (Roffi et al., 2016). While an assessment of left ventricular (LV) function is indicated in all patients with ACS during hospitalization to guide management and assess prognosis, urgent echocardiography is indicated in case of hemodynamic instability or if life-threatening alternative pathologies are suspected, such as pulmonary embolism, aortic dissection, or cardiac tamponade (Roffi et al., 2016).

Based on this first assessment of noncardiac chest pain, unstable angina, non-ST-elevation myocardial infarction (NSTEMI) and ST-elevation myocardial infarction (STEMI) can be differentiated. After the diagnosis of NSTEMI is established, management includes medical therapy (as acute treatment and as secondary prevention) and invasive strategy with coronary angiography and, if appropriate, revascularization. The mainstays of medical therapy are antithrombotic treatment and control of cardiovascular risk factors. Guidelines recommend performing coronary angiography within 24 h of admission in patients with NSTEMI (Roffi et al., 2016). A subset of NSTEMI patients at very high risk, such as individuals with ongoing ischemic chest pain refractory to medical therapy, heart failure secondary to ACS, life-threatening arrhythmias, or cardiogenic shock, require immediate (i.e., within 2 h) coronary angiography (Roffi et al., 2016). The acronyms of the trials mentioned in the manuscript are spelled in **Table 1**.

Medical Therapy

General Measures

The main goal of initial medical therapy is the containment of the coronary thrombotic process and of myocardial ischemia, with subsequent relief of chest pain. In addition to the antithrombotic treatment, pharmacological management of NSTEMI aims to increase myocardial oxygen supply and to decrease myocardial oxygen demand. Oxygen supplement should be limited to patients whose hemoglobin saturation in arterial blood is $<90\%$ or in patients with respiratory distress or failure (Roffi et al., 2016). While no dedicated oxygen-supplementation trial has been performed in the NSTEMI setting, the AVOID trial randomized 441 STEMI patients with arterial blood oxygen saturation $\geq 94\%$ to routine oxygen supply and no oxygen. The study showed an increase in the rate of recurrent myocardial infarction (MI) in the oxygen group compared with the no oxygen group (5.5% vs. 0.9%, $p=0.006$) and increase in the incidence of cardiac arrhythmias, defined as sustained and nonsustained ventricular and atrial tachyarrhythmia requiring medical intervention in the oxygen group (40.4% vs. 31.4%, $p=0.05$). Finally, in a subgroup of 139 AVOID patients investigated with cardiac magnetic resonance at 6 months, an increase in myocardial infarct size (20.3 g vs. 13.1 g, $p=0.04$) was detected in patients receiving oxygen treatment (Stub et al., 2015).

Nitrates are coronary vasodilators that can be used to control the pain/ischemia in the absence of contraindications such as hypotension or recent intake of phosphodiesterase type 5 inhibitors (Schwartz and Kloner, 2010). While opiates may mask ongoing ischemia, their administration is appropriate to relieve chest pain in patients awaiting coronary angiography (Roffi et al., 2016),

Table 1 Acronyms of clinical trials

ACCOAST	Comparison of prasugrel at the time of percutaneous coronary intervention or as pretreatment at the time of diagnosis in patients with non-ST-elevation myocardial infarction
AFTER EIGHTY	Invasive versus conservative strategy in patients aged 80 years or older with non-ST-elevation myocardial infarction or unstable angina pectoris
AVOID	Air versus oxygen in ST-segment-elevation myocardial infarction
COMFORTABLE AMI	Comparison of biolimus eluted from an erodible stent coating with bare metal stents in acute ST-elevation myocardial infarction
CURE	Clopidogrel in unstable angina to prevent recurrent events
FRISC-II	Fragmin and fast revascularization during instability in coronary artery disease—II
LEADERS FREE	Prospective randomized comparison of the BioFreedom biolimus A9 drug-coated stent versus the Gazelle bare-metal stent in patients at high bleeding risk
MATRIX	Minimizing adverse hemorrhagic events by transradial access site and systemic implementation of angiox
PEGASUS-TIMI 54	Prevention of cardiovascular events in patients with prior heart attack using ticagrelor compared with placebo on a background of aspirin-thrombolysis in myocardial infarction 54
PIONEER AF-PCI	Open-label, randomized, controlled, multicenter study exploring two treatment strategies of rivaroxaban and a dose-adjusted oral vitamin K antagonist treatment strategy in subjects with atrial fibrillation who undergo percutaneous coronary intervention
PLATO	Platelet inhibition and patient outcomes
PRODIGY	Prolonging dual-antiplatelet treatment after grading stent-induced intimal hyperplasia
TIMACS	Timing of intervention in patients with acute coronary syndromes
TRILOGY ACS	Targeted platelet inhibition to clarify the optimal strategy to medically manage acute coronary syndromes
TRITON-TIMI 38	Trial to assess improvement in therapeutic outcomes by optimizing platelet inhibition with prasugrel–thrombolysis in myocardial infarction 38

though morphine can delay the onset of action of $P2Y_{12}$ inhibitors (Kubica et al., 2016; Parodi et al., 2015). Early beta-blocker therapy is recommended in NSTEMI patients who do not have contraindications (Chatterjee et al., 2013). A registry study including 34 661 patients with STEMI or NSTEMI identified patient characteristics associated with at higher risk of developing cardiogenic shock or death within 24 h of hospital admission if treated with beta-blockers: age >70 years, systolic blood pressure <120 mmHg, and heart rate >110 bpm (Kontos et al., 2011). Thus, early administration of beta-blockers should be avoided in these subgroups of patients prior to an assessment of LV function (Roffi et al., 2016). In patients with suspected vasospastic angina or chest pain/ischemia related to cocaine use, calcium channel blockers and nitrates should be used instead of beta-blockers (Roffi et al., 2016; Yasue et al., 1988).

Antiplatelet Therapy

Aspirin

Acetylsalicylic acid (aspirin) is an irreversible inhibitor of cyclooxygenase-1 activity. A meta-analysis of trials comparing aspirin with no aspirin in unstable angina patients showed that aspirin administration up to 2 years was associated with a significant 46% odds reduction in major vascular events (Antithrombotic Trialists' Collaboration, 2002). A nonenteric-coated formulation of aspirin as loading dose of 150–300 mg as soon as the diagnosis is made and a maintenance dose of 75–100 mg/day is recommended in all non-ST-elevation (NSTE)-ACS patients without contraindications such as documented severe allergy or ongoing bleeding (Antithrombotic Trialists' Collaboration, 2002; Lewis et al., 1983; Theroux et al., 1988).

Oral $P2Y_{12}$ inhibitors

Clopidogrel is an oral prodrug, a thienopyridine derivative and an irreversible inhibitor of the platelet $P2Y_{12}$ receptor (**Table 2**). In the CURE trial with 12 562 NSTE-ACS patients treated mainly conservatively—and in the subgroup of patients undergoing PCI (PCI-CURE, $N = 2658$),—the combination of clopidogrel and aspirin significantly reduced cardiovascular events compared with aspirin alone in patients with NSTE-ACS, independently of revascularization strategy, at a follow-up of 3–12 months (mean duration, 9 months) (Mehta et al., 2001; Yusuf et al., 2001). Ticagrelor (administered as 180 mg loading dose followed by 90 mg twice daily as maintenance) is an oral, reversible, inhibitor of the $P2Y_{12}$ receptor. The PLATO trial, including 18 624 patients with NSTE-ACS or STEMI, demonstrated the superiority of ticagrelor over clopidogrel in the overall study population and in the 11 080

Table 2 Pharmacological properties of $P2Y_{12}$ inhibitors

	Clopidogrel	*Prasugrel*	*Ticagrelor*	*Cangrelor*
Chemical class	Thienopyridine	Thienopyridine	Cyclopentyl-triazolopyrimidine	Stabilized ATP analogue
Administration	Oral	Oral	Oral	Intravenous
Dose	300–600 mg orally then 75 mg a day	60 mg orally then 10 mg a day	180 mg orally then 90 mg twice a day	30 μg/kg bolus and 4 μg/kg/min infusion
Dosing in CKD				
Stage 3 (eGFR 30–59 mL/min/1.73 m^2)	No dose adjustment	No dose adjustment	No dose adjustment	No dose adjustment
Stage 4 (eGFR 15–29 mL/min/1.73 m^2)	No dose adjustment	No dose adjustment	No dose adjustment	No dose adjustment
Stage 5 (eGFR <15 mL/min/1.73 m^2)	Use only for selected indications (e.g., stent thrombosis prevention)	Not recommended	Not recommended	No dose adjustment
Binding reversibility	Irreversible	Irreversible	Reversible	Reversible
Activation	Prodrug, with variable liver metabolism	Prodrug, with predictable liver metabolism	Active drug, with additional active metabolite	Active drug
Onset of loading dose effect[a]	2–6 hours[b]	30 min[b]	30 min[b]	2 min
Duration of effect	3–10 days	7–10 days	3–5 days	1–2 h
Withdrawal before surgery	5 days[c]	7 days[c]	5 days[c]	1 h
Plasma half-life of active $P2Y_{12}$ inhibitor[d]	30–60 min	30–60 min[e]	6–12 h	5–10 min
Inhibition of adenosine reuptake	No	No	Yes	Yes ("inactive" metabolite only)

ADP, adenosine diphosphate; *ATP*, adenosine triphosphate; *CKD*, chronic kidney disease; *eGFR*, estimated glomerular filtration rate.

[a]50% inhibition of ADP-induced platelet aggregation.

[b]Onset of effect may be delayed if intestinal absorption is delayed (e.g.,\ by opiate).

[c]Shortening may be considered if indicated by platelet function tests and low bleeding risk.

[d]Affecting the response to platelet transfusion.

[e]The distribution phase half-life is reported since it most likely reflects duration of clinically relevant plasma levels, while the corresponding elimination phase half-life is approximately 7 h.

Reproduced with permission from Roffi et al. (2016).

NSTE-ACS patients, enrolled regardless of the revascularization strategy, with a significant reduction of the primary endpoint of death from cardiovascular reasons, MI or stroke at 1 year. In the NSTE-ACS group, the hazard ratio [HR] for the primary endpoint was 0.83 (95% confidence interval [CI] 0.74, 0.93), $p=0.0013$ (Wallentin et al., 2009; Lindholm et al., 2014). Paralleling the overall study results, in the NSTE-ACS subgroup there was an increased risk of noncoronary artery bypass grafting (CABG)-related thrombolysis in myocardial infarction (TIMI) major bleeds in the ticagrelor group compared with the clopidogrel group (2.9% vs. 2.2%; HR 1.39 [95% CI 1.07, 1.80], $p=0.0131$), while no difference in life-threatening or fatal bleeds was observed (Lindholm et al., 2014). Prasugrel is a prodrug inhibiting the $P2Y_{12}$ receptor irreversibly. The TRITON-TIMI 38 trial, including 13 608 patients with NSTE-ACS or STEMI scheduled for PCI, demonstrated the superiority of prasugrel (60 mg loading dose followed by 10 mg once a day) over clopidogrel with respect to the composite endpoint of death from cardiovascular reasons, MI and stroke in the overall study populations and in the 10 074 NSTE-ACS patients at 15-month follow-up (relative risk [RR]:0.82 [95% CI 0.73, 0.93], $p=0.002$) (Wiviott et al., 2007; De Servi et al., 2014). Severe bleeding complications were significantly higher in the prasugrel NSTE-ACS subgroup both in terms of TIMI non-CABG major bleeds (2.4% vs. 1.8%; HR 1.40 [95% CI 1.05, 1.88], $p=0.02$) and fatal bleeds (0.4% vs. 0.1%; HR 4.19 [95% CI 1.58, 11.11], $p=0.002$) (De Servi et al., 2014). Prasugrel should not be used in patients with ongoing bleeding or with previous cerebrovascular event due to more frequent bleeding rates in this group of patients. Furthermore, no benefit was observed in patients >75 years of age or with low bodyweight: <60 kg (Wiviott et al., 2007). Finally, prasugrel was not superior to clopidogrel in NSTE-ACS patients treated conservatively in the TRILOGY ACS trial (Roe et al., 2012).

In all NSTEMI patients without increased risk of bleeding, ticagrelor and prasugrel are recommended in addition to aspirin for 12 months. While prasugrel administration is limited to patients undergoing PCI, ticagrelor can be administered independently of revascularization strategy (Wallentin et al., 2009; Wiviott et al., 2007). While the superiority of ticagrelor over clopidogrel is established, the timing of ticagrelor administration [i.e., prior to coronary angiography (pretreatment) or at the time of PCI] in patients undergoing coronary angiography still remains to be determined. Pretreatment with prasugrel is not recommended because the ACCOAST study—the only trial one testing $P2Y_{12}$ pretreatment versus no pretreatment in NSTE-ACS—showed no reduction in

ischemic events but an increase in major bleeding associated with prasugrel pretreatment compared with prasugrel administered at the time of PCI (Montalescot et al., 2013).

While standard duration of dual-antiplatelet therapy (DAPT), consisting of aspirin and a $P2Y_{12}$ inhibitor, is 12 months in NSTE-ACS, a shorter (i.e., 3–6 months) DAPT period may be applied in patients at high bleeding risk, while prolonged DAPT beyond 12 months may be considered in patients who did not have bleeding complications in the first year and who remain at high ischemic risk (e.g., patients with multiple stents, multivessel diffuse disease, or advanced diabetes-related coronary artery disease) (see section "Long Term Prevention" after NSTEMI).

Intravenous platelet inhibitors

Glycoprotein IIb/IIIa inhibitors (GPIIb/IIIa) (e.g., tirofiban, eptifibatide and abciximab) block the contact between fibrinogen and the glycoprotein IIb/IIIa receptor on the surface of platelets (Patrono et al., 2011). In a meta-analysis of randomized controlled trial (RCT) allocating 29 570 patients with NSTE-ACS to GPIIb/IIIa inhibitors or placebo, the overall benefit of this agents over placebo was modest and confined to patients undergoing PCI (Roffi et al., 2002). As the benefit of these agents in the era of potent $P2Y_{12}$ inhibitors (ticagrelor or prasugrel) has not been tested and the association is associated with an increased bleeding risk, recommended usage of GPIIb/IIIa inhibitors is currently limited to bailout of thrombotic complications during PCI (Roffi et al., 2016).

Cangrelor is an intravenous (i.v.) adenosine triphosphate (ATP) reversible analogue that binds with high affinity to the platelet $P2Y_{12}$ receptor and has a short plasma half-life (<10 min) (**Table 2**). It produces a highly effective inhibition of platelet aggregation immediately after i.v. bolus administration and allows for restoration of platelet function within 1–2 h of infusion discontinuation (Roffi et al., 2016). Although the benefit of cangrelor over placebo has been demonstrated in NSTE-ACS patients treated with aspirin and clopidogrel, its benefit in addition to a ticagrelor or prasugrel-based regimen remains to be demonstrated (Steg et al., 2013).

Anticoagulation

Several studies demonstrated the benefit of the anticoagulant therapy in patients with NSTEMI (Eikelboom et al., 2000). The major therapeutic targets in this setting are thrombin, factor Va and factor Xa. Parenteral anticoagulation is recommended in the initial management of patients with NSTEMI, in addition to antiplatelet therapy, irrespective of management strategy (Roffi et al., 2016). Recommended drugs include unfractionated heparin, enoxaparin, fondaparinux, and bivalirudin. Dosages according to renal function are detailed in **Table 3**.

Antithrombotic treatment in patients requiring oral anticoagulation

Management of patients requiring oral anticoagulation presenting with NSTEMI is a challenging condition due to the increased bleeding risk and the limited data from the RCT. Triple therapy is defined oral anticoagulant (OAC)—either a vitamin K antagonist (VKA) or a nonvitamin K antagonist oral anticoagulant (NOAC)—plus aspirin and a $P2Y_{12}$ inhibitor. Due to the prohibitive risk of bleeding if prasugrel and ticagrelor are used as part of the triple therapy, clopidogrel should be the only $P2Y_{12}$ inhibitor used in this setting (Roffi et al., 2016). For patients with NSTEMI at a low bleeding risk (e.g., HAS-BLED score ≤2), the 2015 ESC NSTE-ACS guidelines recommend triple therapy for 6 months, followed by dual therapy including OAC (VKA or NOAC) and aspirin (75–100 mg/day) or clopidogrel (75 mg/day) up to 12 months (Roffi et al., 2016). For patients with NSTEMI and high bleeding risk (e.g., HAS-BLED score ≥3), the same guidelines recommend triple therapy for 1 month and dual therapy up to 12 months or dual therapy from the very beginning and continued for 12 months, regardless of the stent type. Beyond 12 months, monotherapy with OAC is recommended for the majority of patients, while in individuals deemed at high risk of coronary events, dual therapy including OAC and clopidogrel or aspirin may be continued beyond 12 months. In association with antiplatelet agents, NOAC should be administered at the minimum approved dose for stroke prevention (Roffi et al., 2016).

Table 3 Dosing of anticoagulants in patients with normal and impaired renal function Reproduced with permission from Roffi et al. (2016)

	Recommendations		
Drug	*Normal renal function or stage 1–3 CKD (eGFR ≥ 30 mL/min/1.73 m²)*	*Stage 4 CKD (eGFR 15–29 mL/min/1.73²)*	*Stage 5 CKD (eGFR <15 mL/min/1.73 m²)*
Unfractionated heparin	• Prior to coronary angiography: 60–70 IU/kg i.v. (max 5000 IU) and infusion (12–15 IU/kg/h) (max 1000 IU/h), target aPTT 1.5–2.5 × control • During PCI according to ACT or 70–100 IU/kg i.v. in patients not anticoagulated (50–70 IU/kg if concomitant with GP IIb/IIIa inhibitors)	No dose adjustment	No dose adjustment
Enoxaparin	1 mg/kg s.c. twice a day	1 mg/kg s.c. once a day	Not recommended
Fondaparinux	2.5 mg s.c. once a day	Not recommended if eGFR <20 mL/min/1.73 m²	Not recommended
Bivalirudin	Bolus 0.75 mg/kg i.v., infusion 1.75 mg/kg/h[a]	Not recommended	Not recommended

ACT, activated clotting time; *aPTT*, activation partial thromboplastin time; *CKD*, chronic kidney disease; *eGFR*, estimated glomerular filtration rate; *IU*, international units; *i.v.*, intravenous; *kg*, kilograms bodyweight; *s.c.*, subcutaneous.

Recommendations for the use of drugs listed in this table may vary depending on the exact labeling of each drug in the country where it is used.

[a]Infusion dose 1.4 mg/kg/h if eGFR ≥30 and ≤60 mL/min/1.73 m².

Following publication of the 2015 ESC NSTE-ACS guidelines, two trials have been published that are of relevance for the management of patients requiring oral anticoagulation. First, the LEADERS FREE trial showed that among 2466 patients at high bleeding risk (879 requiring OAC) and receiving only 4 weeks of DAPT, those allocated to the drug-coated stent BioFreedom had better outcomes in terms of both efficacy and safety at 1 year compared with those receiving the bare-metal stent version of the stent (Urban et al., 2015). Of note, patients with ACS derived an even greater benefit from the drug-coated stents, as demonstrated by a statistical significant interaction between ACS status and benefit from device. These results may open the way for shorter triple therapy (e.g., 1 month) for all NSTEMI patients requiring oral anticoagulation. The PIONEER AF-PCI trial randomized 2124 patients with nonvalvular atrial fibrillation following successful PCI in a 1:1:1 ratio to rivaroxaban 15 mg once a day plus a $P2Y_{12}$ inhibitor for 12 months (group 1), rivaroxaban 2.5 mg twice a daily plus DAPT with aspirin and clopidogrel for 1, 6, or 12 months followed by rivaroxaban 15 mg and aspirin (group 2) or dose-adjusted VKA plus DAPT for 1, 6, or 12 months (group 3) followed by VKA and aspirin (Gibson et al., 2016). Clopidogrel was chosen for the majority of patients in all groups. The investigators had to state upfront (prior to randomization) the duration of triple therapy they recommended for each individual patient. The rates of clinically significant bleeding were lower in the two groups receiving rivaroxaban than in the group receiving VKA (16.8% in group 1, 18.0% in group 2 and 26.7% in group 3; HR for group 1 vs. group 3, 0.59; [95% CI 0.47–0.76], $p < 0.001$; HR for group 2 vs. group 3, 0.63; [95% CI 0.50–0.80], $p < 0.001$). The rates of death from cardiovascular causes, MI or stroke were not significantly different, but the trial was not appropriately powered to address ischemic events (Gibson et al., 2016). In particular, the trial was not powered to prove that patients in the rivaroxaban arms were adequately protected from stroke. Additional trials combining non-VKA or NOACS and antiplatelet agents are ongoing and may shed light on the best management of patients requiring both antiplatelet agents and oral anticoagulation.

In NSTEMI patients treated conservatively or undergoing CABG, the guidelines recommend dual therapy (i.e., OAC plus aspirin or clopidogrel) up to 1 year. Lastly, evidence based therapy should be administered also to elderly patients with NSTEMI but taking into account comorbidities, frailty and quality of life and by adapting of the dosage of antithrombotic agents according to patient's renal function and weight, when appropriate (Roffi et al., 2016; Andreotti et al., 2015).

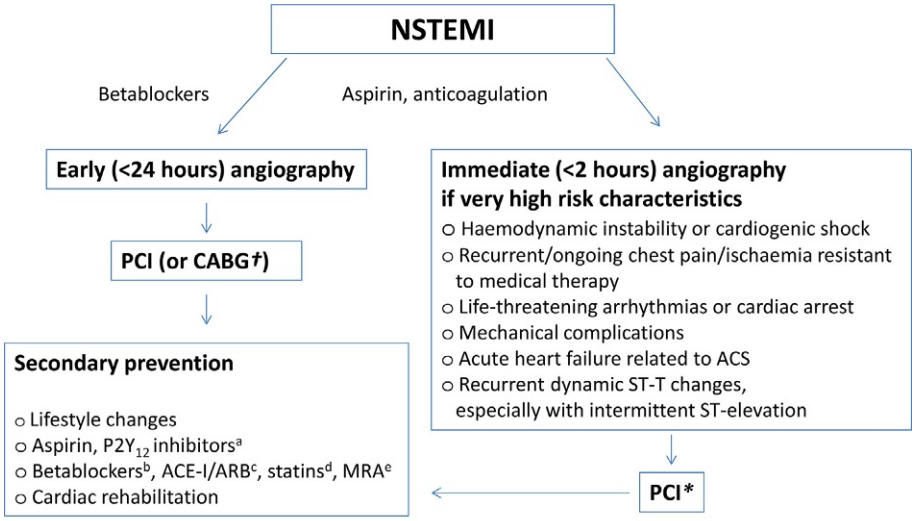
Invasive strategy

Benefit and Timing

Invasive strategy is defined by coronary angiography and, if appropriate, coronary revascularization by either PCI or CABG. Compared with a conservative approach, an invasive strategy was associated with a benefit in terms of ischemic event reduction in NSTEMI patients (Fox et al., 2010). The long-term follow-up of the FRISC-II study, including 2457 patients with NSTE-ACS allocated to either a conservative or an invasive strategy, showed the benefit of invasive management in terms of a difference in time to death or next nonfatal event at 15 years follow-up (Wallentin et al., 2016). Accordingly, the invasive strategy was associated with the postponement of death or recurrence of MI by a mean of 18 months (95% CI 6.8–29.6, $p = 0.002$) compared with the noninvasive treatment strategy. The benefit was mainly driven by postponement of new MI (Wallentin et al., 2016).

According to the 2015 ESC NST-ACS guidelines, NSTEMI patients are considered to be either at high risk or at very high risk. An immediate coronary angiography (<2 h) is recommended for very-high-risk patients, i.e., for individuals with either hemodynamic instability, cardiogenic shock, recurrent or continuous chest pain resistant to medical therapy, life-threatening arrhythmias or cardiac arrest, mechanical complications, acute heart failure related to ongoing ischemia or recurrent dynamic ST-T changes, especially with intermittent ST-elevation (**Fig. 1**). Due to poor prognosis in the absence of prompt revascularization, management of those patients should parallel to one of the STEMI patients (Roffi et al., 2016). Patients with out-of-hospital cardiac arrest and no ST elevation on ECG should be evaluated by a multidisciplinary team in the emergency room or intensive care unit. Conscious survivors with suspected NSTE-ACS should undergo immediate coronary angiography; comatose survivors without any definite noncoronary etiology for the cardiac arrest should also benefit from coronary angiography in the absence of contraindications and if the resuscitation conditions were favorable (Noc et al., 2014).

Early invasive strategy (<24 h) is recommended for all NSTEMI patients (Navarese et al., 2013; Mehta et al., 2009; Katritsis et al., 2011) (**Fig. 1**). This recommendation is based on several studies that compared early and delayed invasive strategy in patients with NSTE-ACS. A meta-analysis including 4013 patients with NSTE-ACS demonstrated that there was a reduction of recurrent ischemia (RR 0.59 [95% CI 0.38, 0.92], $p = 0.02$) and reduction of hospital stay (by 28% [95% CI 22, 35], $p < 0.001$) in favor of early invasive strategy (admission to angiography: 1.16–14 h) versus delayed invasive strategy (admission to angiography: 20.8–86 h) (Katritsis et al., 2011). However, there was no benefit with respect to death or MI (Katritsis et al., 2011). A more recent meta-analysis of 5370 patients with NSTE-ACS enrolled in seven RCTs and 77 499 patients followed in four observational studies compared early invasive strategy (<24 h) and delayed invasive strategy, data from RCTs showed a reduction of refractory ischemia (odds ratio [OR] 0.55 [95% CI 0.35–0.86]; $p = 0.008$) in favor of early invasive strategy (Navarese et al., 2013). Again, there was no significant difference in terms of MI and death (Navarese et al., 2013). The TIMACS study enrolling 3031 NSTE-ACS patients demonstrated the benefit of early invasive management (<24 h) versus delayed invasive strategy (median time 50 h) in prespecified analysis of high-risk patients with the GRACE score >140 at 6 months; early invasive strategy reduced the risk of death, MI, and stroke (HR 0.65 [95% CI 0.48–0.89], $p = 0.006$) in this group while there was no benefit in patients with the GRACE score ≤140 (HR 1.12 [95% CI, 0.81–1.56], $p = 0.48$; $p = 0.01$ for interaction) (Mehta et al., 2009). Real-life data suggests that the elderly population, defined as age



†In patients with advanced multivessel disease PCI vs. CABG discussed within the Heart Team based on: MI extension, LV function, lesions complexity (SYNTAX score), comorbidities, life expectancy.
**Indication for CABG in this setting limited to PCI failures or lesions non amenables to PCI.*

Fig. 1 Management of patients with non-ST-elevation myocardial infarction (NSTEMI). *ACE-I*, angiotensin-converting enzyme inhibitors; *ACS*, acute coronary syndromes; *ARB*, angiotensin receptor blockers; *CABG*, coronary artery bypass grafting; *LV*, left ventricular; *MI*, myocardial infarction; *MRA*, mineralocorticoid receptor antagonist; *NSTEMI*, non-ST-elevation myocardial infarction; *PCI*, percutaneous coronary intervention; *SYNTAX score*, synergy between percutaneous coronary intervention with Taxus and cardiac surgery score.[a]Dual antiplatelet therapy beyond 1 year is discussed in the text. [b]In the long term management, beta-blocker therapy is recommended in patiens with ejection fraction $\leq$40% in the absence of contraindications. [c]ACE inhibitors should be initiated to the patients with ejection fraction $\leq$40% or heart failure, hypertension or diabetes in the absence of contraindication. ARBs can be administered to patients who cannot tolerate ACE inhibitors. [d]In patients with NSTEMI should be administered a high-intensive statin therapy as early as possible unless contraindicated. Ezetimibe can be initiated to patients whose LDL level is $\geq$70 mg/dL ($\geq$1.8 mmol/L) despite the highest tolerated statin therapy. [e]MRAs (especially eplerenone) are recommended in NSTEMI patients with ejection fraction $\leq$35% and either heart failure or diabetes, unless contraindicated.

$\geq$75 years old, have less coronary angiography and revascularization compared with a younger population (Devlin et al., 2008). The AFTER EIGHTY study tested the invasive strategy (mean time 3 days) against the medical treatment alone in 457 patients aged 80 years or older with NSTEMI or unstable angina (Tegn et al., 2016). The primary outcome was a composite of MI, need for urgent revascularization, stroke and death. During a median follow-up of 1.5 years, the primary outcome occurred 40.6% in the invasive strategy group versus 61.4% in the conservative group (HR 0.53 [95% CI, 0.41, 0.69], $p=0.0001$). The difference in MI was also significant (HR 0.52 [95% CI, 0.35, 0.76], $p=0.001$). There was no difference of bleeding complications (Tegn et al., 2016). An early invasive strategy is recommended also in elderly patients, obviously taking into account comorbidities, frailty, mental status, estimated life expectancy and patient wishes (Roffi et al., 2016).

Percutaneous Coronary Intervention

PCI is the preferred strategy of revascularization for the majority of NSTEMI patients, particularly in the setting of ongoing ischemia (Windecker et al., 2014). In patients with advanced multivessel disease and no ongoing ischemia, the revascularization strategy (PCI vs. CABG) should be discussed within the heart team taking into account MI size, LV function, comorbidities, life expectancy and patient's preference (Roffi et al., 2016). New generation drug-eluting stents should be preferred in patients planned for PCI (Roffi et al., 2016). A prespecified analysis from the PRODIGY study compared everolimus-eluting stents (EES), zotarolimus-eluting endeavor sprint stents (ZES-S), paclitaxel-eluting stents (PES), and bare-metal stents (BMS) in 2 013 patients undergoing elective, urgent, and emergent coronary angioplasty (Valgimigli et al., 2014). At 30 days, each stent group received up to 6 or 24 months of clopidogrel therapy. The key efficacy endpoint was the 2-year major adverse cardiovascular events (MACE) (death, MI, or target-vessel revascularization), and the cumulative rate of definite or probable stent thrombosis was the key safety endpoint (Valgimigli et al., 2014). After 2 years of follow-up, the MACE was lowest in EES (19.2%; 95% CI 16.0–22.8), highest in BMS (32.1%; 95% CI 28.1–36.3) and intermediate in PES (26.2%; 95% CI 22.5–30.2) and ZES-S (27.8%; 95% CI 24.1–31.9) groups ($p=0.00029$) (Valgimigli et al., 2014). The 2 year incidence of stent thrombosis in the EES group (1%; 95% CI 0.4–2.2) was similar to that in the ZES-S group (1.4%; 95% CI 0.7–2.8), and it was low compared with the PES (4.6%, 95% CI 3.1–6.8) and BMS (3.6%; 95% CI 2.4–5.6) groups ($p=0.0001$) (Valgimigli et al., 2014).

The COMFORTABLE-AMI trial randomized 1161 patients with STEMI to biolimus-eluting stent (BES) versus BMS, and at 2 years, primary end point (cardiac death, target vessel, and target lesion revascularization) was in favor of BES-treated patients compared

with BMS-treated patients (HR: 0.48 [95% CI 0.31–0.72], $p<0.001$) (Raber et al., 2014). Differences in the primary end point were driven by a decline in target lesion revascularization (3.1% vs. 8.2%; $p<0.001$) and target-vessel reinfarction (1.3% vs. 3.4%; $p=0.023$) (Raber et al., 2014).

Radial access should be preferred instead of femoral approach in ACS (Roffi et al., 2016). In the MATRIX trial, 8404 ACS patients were randomized to radial or femoral access (Valgimigli et al., 2015). Two coprimary outcomes were defined: 30-day MACE (including death, MI, or stroke) and 30-day net adverse clinical events [including MACE or non-CABG Bleeding Academic Research Consortium (BARC) major bleeding]. The first coprimary outcome was (RR 0.85 [95% CI 0.74–0.99] and a two-sided $p=0.0307$) formally nonsignificant at the prespecified α of 0.025 (Valgimigli et al., 2015). The second coprimary endpoint was in favor of radial access (RR 0.83 [95% CI 0.73–0.96], $p=0.0092$) (Valgimigli et al., 2015). Also, radial access was associated with a lower all-cause mortality (RR 0.72 [95% CI 0.53–0.99], $p=0.045$). Rates of cardiac mortality, stroke and MI were not significantly different. Major BARC 3 or 5 bleeding was significantly reduced in the radial group (RR 0.67 [95% CI 0.49–0.92], $p=0.013$) (Valgimigli et al., 2015).

Lastly, for patients on OAC, PCI should be performed without cessation of VKA or NOAC. In patients on VKA, if the international normalized ratio (INR) is more than 2.5, no parenteral anticoagulant is needed at the time of PCI (Roffi et al., 2016). In patients on NOAC, during PCI a low-dose parenteral anticoagulant should be added regardless of timing of last dose (e.g., UFH 60 IU/kg i.v. or enoxaparin 0.5 mg/kg i.v.) (Roffi et al., 2016). Aspirin is recommended in patients under OAC with NSTEMI in the acute settings but a $P2Y_{12}$ inhibitor should not be used as a pretreatment therapy (i.e., prior to coronary angiography) in this group of patients (Roffi et al., 2016).

Coronary Artery Bypass Grafting

Except emergent cases, the management of NSTEMI patients with advanced multivessel disease should be discussed in a heart team (Roffi et al., 2016). Once heart team decision has proposed CABG, timing of surgery should be individualized according to patient's clinical condition. When there is an emergent situation (e.g., hemodynamic instability, ongoing ischemia or major arrhythmias) and PCI is not appropriate, CABG should be performed urgently (Roffi et al., 2016; Windecker et al., 2014; Parikh et al., 2010). Perioperative bleeding is an additional dilemma. Except urgent conditions, CABG should be performed after cessation of ticagrelor and clopidogrel for 5 days and cessation of prasugrel for 7 days, respectively (Held et al., 2011; Nijjer et al., 2011). Due to patient's bleeding risk, aspirin should be continued until CABG and, in the absence of contraindications from a surgical perspective, resumed within 6 h after the surgery (Roffi et al., 2016). RCTs are needed to compare PCI and CABG in patients with NSTEMI. While the SYNTAX score may be beneficial to assess the degree of complexity of coronary lesions, it is important to remember that the SYNTAX trial enrolled mainly patients with stable coronary artery disease (Palmerini et al., 2011).

Long-Term Prevention after NSTEMI

Intensive risk factor adjustment to improve the prognosis is the main goal of secondary prevention of patients with NSTEMI. Secondary prevention comprises medical therapy, lifestyle changes, and cardiac rehabilitation. As mentioned previously, guidelines recommended up to 1-year duration of DAPT in the majority of patients with NSTEMI. DAPT beyond 1 year was also investigated in multiple trials. PEGASUS-TIMI 54 trial including 21 162 patients with the history of MI 1–3 years earlier, compared ticagrelor at a dose of 90 mg twice daily, ticagrelor at a dose of 60 mg twice daily, or placebo at a median follow-up of 33 months. Nearly all the patients (99.9%) received aspirin (Bonaca et al., 2015). The study showed a reduced rate of cardiovascular death, MI or stroke with ticagrelor; 90 mg of ticagrelor group versus placebo group (HR 0.85 [95% CI 0.75, 0.96], $p=0.008$) and 60 mg of ticagrelor group versus placebo group (HR 0.84 [95% CI 0.74, 0.95], $p=0.004$). There were increased rates of major bleeding events with ticagrelor (2.60% with 90 mg, 2.30% with 60 mg, and 1.06% with placebo, $p<0.001$). All-cause mortality was not different significantly between the groups (Bonaca et al., 2015). A recent meta-analysis of 33 435 high-risk patients with prior MI compared more than a year of DAPT and aspirin alone, over a mean of 31 months of follow-up (Udell et al., 2016). DAPT beyond a year decreased the risk of MACE defined as a composite of cardiovascular death, nonfatal MI and nonfatal stroke (6.4 vs. 7.5%; RR 0.78 [95% CI 0.67, 0.90], $p=0.001$) and reduced cardiovascular death (2.3 vs. 2.6%; RR 0.85 [95% CI 0.74, 0.98], $p=0.03$) compared with aspirin alone. All-cause mortality did not differ significantly between the groups. In extended DAPT group, there was an increase risk of major bleeding (1.85 vs. 1.09%; RR 1.73 [95% CI 1.19, 2.50]; $p=0.004$) but not of fatal bleeding (0.14 vs. 0.17%; RR 0.91 [95% CI 0.53, 1.58]; $p=0.75$) (Udell et al., 2016). Due to contemporary evidences, $P2Y_{12}$ inhibitor administration in addition to aspirin beyond 1 year may be considered after careful assessment of the ischemic and bleeding risks of the patients (Roffi et al., 2016).

In patients with NSTEMI should be administered a high-intensive statin therapy as early as possible unless contraindicated (Roffi et al., 2016). Ezetimibe can be initiated to patients whose LDL level is $\geq$70 mg/dL ($\geq$1.8 mmol/L) despite highest tolerated statin therapy (Roffi et al., 2016; Cannon et al., 2015). An angiotensin-converting enzyme inhibitor should be initiated to the patients with ejection fraction (EF) $\leq$40% or heart failure, hypertension, or diabetes if there is no contraindication. Angiotensin receptor inhibitors can be administered to patients who cannot tolerate ACE inhibitors. Beta-blocker therapy should be administered to patients with EF $\leq$40% in the absence of contraindications in the long-term management. Smoking cessation, physical activity, and appropriate diet should be recommended to all patients with NSTEMI (Roffi et al., 2016). Cardiac rehabilitation should be advised to patients after discharge in order to regulate the lifestyle and promote the exercise capacity (Heran et al., 2011).

Key Messages

- Aspirin is indicated in all NSTEMI patients as soon as the diagnosis is made and continued indefinitely.
- The $P2Y_{12}$ inhibitors ticagrelor and prasugrel are preferred over clopidogrel and should be continued for 12 months in absence of contraindications. While ticagrelor can be administered independently of the revascularization strategy, prasugrel should be administered only at the time of PCI.
- Parenteral anticoagulation should be administered in the acute phase of NSTEMI in all patients in addition to antiplatelet therapy, irrespective of management strategy.
- Early (i.e., within 24 h) coronary angiography and, if appropriate, revascularization are indicated in NSTEMI patients, while in the presence of ongoing/refractory ischemia, hemodynamic instability, or life-threatening arrhythmias immediate invasive strategy (i.e., within 2 h) is indicated.
- Radial access is recommended over of the femoral one for coronary angiography and PCI.
- NSTEMI patients with advanced multivessel disease and no ongoing ischemia should be discussed within the heart team to propose the most appropriate revascularization strategy (PCI or CABG).
- Elderly patients should be offered early invasive strategy. However, comorbidities, frailty, mental status, estimated life expectancy and patient wishes should be taken into account.
- Secondary prevention, including drug therapy (and notably statins), life style changes, and cardiac rehabilitation, is critical in long-term prognosis of NSTEMI patients.

Introduction

Cardiovascular disease (CVD) is a chronic inflammatory disease mediated by endothelial damage and circulating blood lipids. Atherosclerosis is affected by abnormal blood lipid and lipoprotein levels, elevated blood pressure, and smoking as well as other risk factors (Glass and Witztum, 2001). Recommended nutritional interventions influence modifiable risk factors and can significantly reduce the progression of atherosclerosis and CVD. These modifiable and nonmodifiable risk factors are shown in **Table 1** (Glass and Witztum, 2001; Sacco, 2011).

High levels of low-density lipoprotein-cholesterol(LDL-C), as well as high levels total cholesterol concentrations, are strong contributors to atherogenesis (Glass and Witztum, 2001). The risk of atherosclerosis is inversely related to high-density lipoprotein-cholesterol (HDL-C) levels that are due to the mediation of reverse cholesterol transport (Gordon et al., 2016). Smoking is a major risk factor for the development of atherosclerosis and is associated with increased triglyceride and decreased HDL-C concentrations (Campbell e,t al., 2008). Another major risk factor for atherosclerosis is high blood pressure, which causes endothelial injury in the artery wall (Campbell e,t al., 2008). Other risk factors, such as overweight, high blood glucose levels, low physical activity, and not healthy diet, play a major role in the progression of atherosclerosis (Falk, 2006). A chronic state of inflammation presented as elevated levels of C-reactive protein (CRP), and other proinflammatory cytokines also has been found to promote atherosclerotic plaque development. It is important that targeting these risk factors is to reduce coronary artery disease. Beneficial effects on reducing mortality risk are also achievable within the general population via combined dietary change (−45%), incorporation of moderate-intensity physical activity at 40%–60% VO_2 max for at least 30 min per day on at least 5 days per week (−25%), moderation of alcohol intake to two drinks per day of women and three drinks per day or men (−20%), and cessation of smoking (−45%) (Iestra et al., 2005).

Role of the Macronutrients

The macronutrient composition of dietary patterns affects lipids and lipoproteins and, consequently, CVD risk. A key question that has been addressed by many researchers concerns which macronutrient should replace calories provided by saturated fat. A metaanalysis of 60 controlled trials by Mensink (Mensink et al., 2003) shown that lipid profile were affected when carbohydrates constituting 1% of energy are replaced isoenergetically with saturated, *cis* monounsaturated, polyunsaturated, or trans monounsatureded fatty acids. Saturated fatty acids (SFAs) increased LDL-C relative to carbohydrates. *cis* monounsaturated fatty acids (MUFAs) were decreasing but trans MUFAs were increasing LDL-C relative to carbohydrate. Polyunsaturated fatty acids (PUFAs) resulted in the greatest LDL-C reduction with slight but significant increase in HDL-C. The total cholesterol: HDL-C ratio did not change when SFA was replaced with carbohydrate; however, the ratio decreased when carbohydrate was replaced with *cis* MUFA or PUFA. In addition, replacing carbohydrates with any type of fatty acid resulted in a lower triglyceride levels. Additional each macronutrients affect CVD risk through a variety of mechanisms that will be discussed in the following section.

CVD and Carbohydrate

In clinical studies, an increase in dietary energy from carbohydrates usually is associated with a moderate increase in fasting plasma triglycerides (TG) levels, a reduction in HDL-C levels, and increased LDL-C levels, which impact adversely on CVD risk. However, no clear evidence has shown that the quantity of dietary carbohydrates alters the risk of CVD independently. According to a

Table 1 Modifiable and nonmodifiable risk factors for atherosclerosis

Nonmodifiable	*Modifiable*	*Goals for modifiable risk factors*
• Age	• Weight	BMI: 18.5–24.9 kg/m^2
• Sex	• Lipid profile	Total cholesterol: <200 mg/dL (5.2 mmol/L)
• Family history/genetics		*LDL-C*:
• Race/ethnicity		Very high risk individuals, <70 mg/dL (1.8 mmol/L)
		High-risk individuals, <100 mg/dL (2.6 mmol/L)
		With optional goal of <70 mg/dL (1.8 mmol/L)
		Moderate-risk individuals, <130 mg/dL (3.4 mmol/L)
		HDL-C:
		Men: ≥40 mg/dL (1.0 mmol/L)
		Women: ≥50 mg/dL (1.3 mmol/L)
		Triglycerides: <150 mg/dL (1.7 mmol/L)
	• Blood pressure	Systolic: <120 mmHg
		Diastolic: <80 mmHg
	• Glycemic control	Fasting blood glucose: <100 mg/dL (5.6 mmol/L)
	• Physical activity	150 min of moderate activity or 75 min of vigorous activity per week
	• Smoking	Stop smoking
	• Diet	Follow a healthy diet
	• Stress	Keep stress as low as possible

Fig. 1 Weighted mean differences in high-density lipoprotein level after 6 (A) and 12 (B) months of follow-up. *Carb*, carbohydrates; *CI*, confidence interval; *UI*, uncertainty interval. To convert cholesterol levels to millimoles per liter, multiply by 0.0259 (Nordmann et al., 2006).

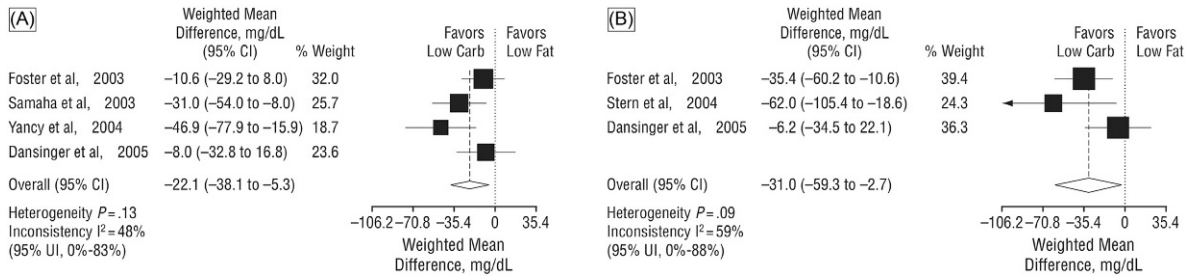

Fig. 2 Weighted mean differences in triglyceride level after 6 (A) and 12 (B) months of follow-up. *Carb*, carbohydrates; *CI*, confidence interval; *UI*, uncertainty interval. To convert triglyceride levels to millimoles per liter, multiply by 0.0113 (Nordmann et al., 2006).

metaanalysis of five randomized controlled trials, it is found that TG and HDL-C values changed more favorably in individuals assigned to low-carbohydrate diets (after 6 months, for triglycerides, weighted mean difference, −22.1 mg/dL (−0.25 mmol/L); and for HDL-C, weighted mean difference, 4.6 mg/dL (0.12 mmol/L) (**Figs. 1** and **2**), but total cholesterol and LDL-C values changed more favorably in individuals assigned to low-fat (LF) diets (Nordmann et al., 2006). Generally, very low-carbohydrate diets restrict energy from carbohydrate to <20–30 g/day, while very LF diets restrict total fat intake to <10%–20% of energy.

Although low-carbohydrate diets have risen in popularity, evidence from intervention trials on the benefit and risks of low-carbohydrate diet to achieve weight loss and modify CVD factors is limited. Furthermore, little is known about the long-term health effects on these diets; micronutrient inadequacy may occur when carbohydrate intake is very low (Bolton-Smith and Woodward, 1995). In conclusion, consuming a diet too high or too low in either fat or carbohydrate may result in adverse health effect, and the relative proportions of the two within the diet should target specific CVD risk factors and personal preferences within current dietary

recommendations. According to 2015–20 Dietary Guidelines for Americans, the acceptable macronutrient distribution range for carbohydrate is 45%–65% of energy.

Glycemic index (GI) and glycemic load (GL) quantify the postprandial blood glucose response to food containing carbohydrate (Jenkins et al., 1981). Specifically, GI is used to compare to increase blood glucose levels (Ludwig, 2002). A high-GI diet may lead to postprandial hyperglycemia and hyperinsulinemia, which are found to increase CVD risk by producing oxidative stress (Lefebvre and Scheen, 1998). However, the evidence for an association between high GI or GL and CVD risk remains limited and inconclusive (Kurotani et al., 2013).

CVD and Fat

Saturated Fatty Acid

Strong evidence indicates a positive association between dietary SFA intake and increased total cholesterol and LDL-C, as well as increased CVD risk (Sanders, 2013). Therefore, reducing SFA intake is a primary focus of dietary interventions to lower LDL-C. Several study indicated that for every 1% increase in energy from SFAs, LDL-C increases by 0.033–0.045 mmol/L and HDL-C by 0.011–0.013 mmol/L. Reducing dietary SFAs typically is associated with an increase in some other macronutrient. The nutrient(s) replacing SFA(s) will differentially affect blood lipid levels (Clarke, et al., 1997; Hegsted et al., 1993; Mensink and Katan, 1992).

Monounsaturated Fatty Acid

MUFAs replacement of SFA for an improvement in blood lipids is reported (Miller et al., 2016). Clinical evidence has shown that MUFA substitution for SFA decreases LDL-C (Berglund et al., 2007). Both MUFA and carbohydrate lower LDL-C levels when replacing SFA, but MUFA can increase HDL-C levels versus carbohydrate, lower the TC:HDL-C ratio, and potentially decrease apolipoprotein B, the main apolipoprotein in LDL-C (Garg, 1998; Mensink et al., 2003).

Primate studies have shown that MUFAs are more thermogenic than PUFAs, eliciting effects similar to SFAs (Rudel et al., 1998, 1995). According a metaanalysis by Cao et al. (2009), it is reported that moderate-fat (MF; average 23.6% of total kcal as MUFA) and LF (average containing 11.4% of total kcal as MUFA) diets both lowered TC and LDL similarly. However, MF diets increased HDL-C and decreased TG compared with LF diets. Thus, the TC: HDL-C ratio was significantly reduced after MF diets. Predicted change in CVD risk estimated that MF diets led to greater reduction in CVD risk compared with LF diets for both men and women. Additional research is needed to explain why animal studies and human studies differ in how MUFAs affect CVD risk.

Polyunsaturated Fatty Acids

It is shown that PUFAs improve in blood lipids, particularly when PUFAs replace SFAs in the diet (Bjermo et al., 2012). PUFAs have multiple double bonds and consequently are more fluid than SFA (Akinshina et al., 2016). Omega-3 (*n*-3) and omega-6 (*n*-6) RUFAs have their first double bond at three and six carbons from the omega end of the fatty acid, respectively. These are essential nutrients that cannot be synthesized by human due to the lack of an enzyme required to insert a *cis* double bond into a carbon backbone. Human can synthesize long-chain (LC) *n*-3 or *n*-6 fatty acids from the essential, parent fatty acids obtained from the diet, albeit at a low rate. The parent fatty acid for the *n*-3 series is α-linolenic acid (ALA), and the parent fatty acid for the *n*-6 series is linoleic acid (LA). **Fig. 3** displays the metabolism of both *n*-3 and *n*-6 FAs (Holligan et al., 2012).

The cardioprotective benefits of marine *n*-3 fatty acids were discovered in the 1970s by Danish researchers assessing the fish-rich diet and CVD occurrence of Greenland Inuits. Since this ecological observation, population, clinical, and basic investigations have confirmed the prospective effect of both marine- and plant-derived *n*-3 FAs against CVD. Flaxseed, walnuts, flaxseed oil, walnut oil, and canola oil are sources of ALA, and cold water fish such as salmon, mackerel, herring, and sardines are the species of seafood that are the richest sources of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (Harris et al., 2008). The evidence for plant-based *n*-3 FAs (rich in ALA) is less conclusive than that for marine-based *n*-3 FAs, EPA, and DHA (Wang et al., 2006).

The association between coronary heart disease (CHD) mortality and fish intake was assessed in a metaanalysis of over 220,000 persons who were followed for an average of 11.8 years (He et al., 2004b). In contrast to non-fish-eating individuals, persons who consumed fish $\geq$5 times per week had a 38 decrease in CHD mortality risk. In addition, for every 20 g/day increase in fish intake there was a 7% decrease in risk of mortality due to coronary events. Also, a moderate intake of one to three servings of fish each month significantly reduced the risk of stroke (9%) and CHD mortality (11%) (He et al., 2004a,b).

LA is primary *n*-6 FA in the diet, accounting for 85%–90% of *n*-6 PUFA intake (Harris et al., 2009). It is metabolically converted to arachidonic acid (AA); however, the amount of AA in cell membranes is tightly regulated so that only about 0.2% of LA is converted (Hussein et al., 2005). AA is provided by meat, poultry, eggs, and some species of fish, while LA is found in vegetable oils such as corn, soybean, and safflower oil, as well as many seeds and nuts. Results from metaanalysis of 60 feeding studies indicated that substituting PUFAs (between 0.6% and 28.8% energy from *n*-6 FAs) for carbohydrate produced favorable effects on the ratio of total to HDL cholesterol in comparison with other fatty acids (Mensink et al., 2003). However, there are suggestions for decreasing LA intake which have been based on the inflammatory nature of CHD and the fact that AA is a major substrate for the production of several proinflammatory molecules (Libby, 2006). In summary, the evidence for the benefits of *n*-6 FA intake and CHD risk is

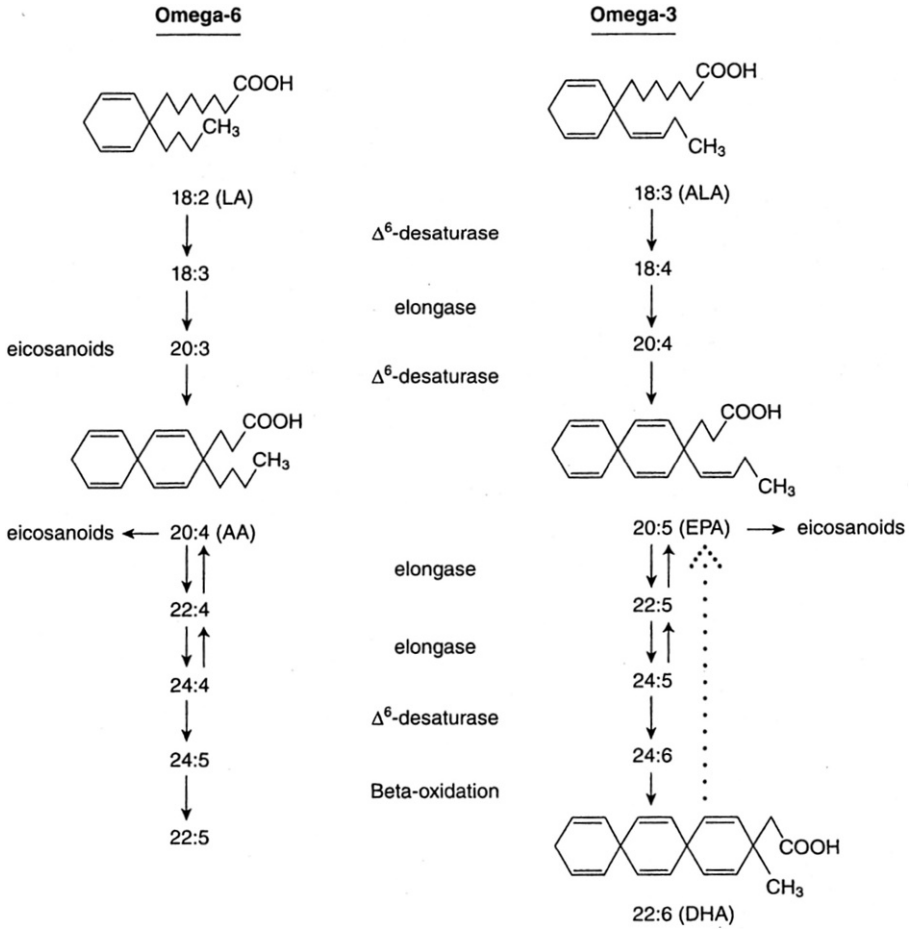

Fig. 3 The metabolism of omega-3 and omega-6 PUFAs. Questions remain about whether DHA is retroconverted to EPA, as shown by the *dotted arrow*.

greater than the evidence to prove otherwise. Estimates show that the ratio of *n*-6 to *n*-3 FAs in the human diet has changed overtime form a ratio of 1:1 to 10:1 or greater, the latter of which is representative of that found in a typical Western diet (Simopoulos et al., 2000).

Intake of long chain *n*-3 FAs is still the most efficient way to increase blood levels of EPA + DHA and thereby decrease risk for CHD, regardless of LA intake. Thus, increasing LC *n*-3 FAs rather than reducing *n*-6 FAs is recommended (Harris, 2006).

Trans Fatty Acid

Trans fatty acids (TFAs) are classified as unsaturated fatty acids containing at least on unsaturated, nonconjugated, double bond in the trans configuration. Industrial TFAs are produced during partial hydrogenation of vegetable oils TFA consumption is of particular concern given the range of its effects on CVD risk. Observational studies and randomised controlled trial (RCTs) have shown adverse effects on lipids such as increased LDL-C levels, reduced HDL-C levels, and increased TC:HDL-C ratio, a proinflammatory response with elevated IL-6 and CRP levels, and TNF-α activity, as well as endothelial dysfunction (Mozaffarian et al., 2009). Epidemiological and clinical studies have shown consistently that TFAs increase cardiovascular risk and adversely affect blood lipids (Ascherio et al., 1999). Studies also have shown that high TFA intakes are associated with increased CHD incidence (Oh et al., 2005), increased levels of inflammatory markers, and impaired endothelial function (Mozaffarian et al., 2004).

CVD and Protein

Protein is a compound in which 20 kinds of amino acids are peptide bonded, nine kinds are essential amino acids. Protein is decomposed and absorbed into amino acids, dipeptides, and tripeptides; reaches the liver via the portal vein; merges with amino acids from body proteins; and is recombined into necessary proteins for the human body. The recommended amount of protein is determined by considering the individual differences in the estimated average requirement calculated by the nitrogen dosing experiment, and it is about 1 g/kg of body weight in adults.

In a cohort study targeting Swedish women, the incidence of CVD was higher as high protein low-carbohydrate diet (Lagiou et al., 2012). It was reported to increase the incidence of CVD in high-protein dietary groups above the recommended amount (Pan et al., 2011), and excessive intake of protein increased the risk of developing diabetes and CVD (Wang et al., 2010).

For obese people, high-protein diet (energy ratio 34%) due to intake energy restrictions improved blood lipids, glucose, insulin and had a positive effect on risk factors for CVD (Clifton et al., 2008). When the effect of high protein (energy ratio 30%) was compared with ordinary protein (15%) under the restriction of energy intake and observation for 4 months, body fat decreased by −22% significantly in high protein diet. Observation without energy limitation for 8 months showed a significant improvement in body composition, TG and HDL-C in high-protein diet (Layman et al., 2009). On the other hand, there was the report that no significant difference was observed in changes in body weight, abdominal circumference, serum LDL cholesterol, triglyceride, systolic blood pressure, diastolic blood pressure, fasting blood glucose, HbA1c, by metaanalyzing the results of intervention studies over 12 months by comparing high-protein food with an energy ratio of 30% or more and normal protein food for CVD and metabolic syndrome (Schwingshackl and Hoffmann, 2013).

However, in studies of Americans, it was reported that the high-protein food group with vegetable protein had significantly lower total mortality and cardiovascular mortality than the animal high-protein food group (de Koning et al., 2011; Fung et al., 2010).These studies suggest that the food source affects the onset of CVD along with protein intake. Vegetarians that are dependent on vegetable proteins tend to have lower CHD mortality than nonvegetarians (Fraser, 2009). Arginine is contained in vegetable protein, and lysine is contained in a large amount in animal protein. The 35-day randomized controlled crossover study was conducted using a high-ratio (lysine/arginine) diet and a low-ratio diet; there was no decrease in serum cholesterol and LDL-C in the low ratio diet (Vega-Lopez et al., 2010). Regarding the relationship between protein and hypertension, it has been reported that the protein has a mild antihypertensive effect in patients who have not yet been treated and whose blood pressure is high (Appel et al., 2005). Soybean protein (Dong et al., 2011), dairy products, and low-fat dairy products (Hodgson et al., 2012; Ralston et al., 2012) also have a hypotensive effect, but its action is minor and should be taken in a balanced manner considering combination with other dietary factors.

CVD and the Macronutrients Balance

Macronutrients, also called energy providing nutrients, produce 4 kcal of protein, 9 kcal of lipid, and 4 kcal of carbohydrate per gram.

As for proper intake of macronutrients, it is necessary to consider the proportion (% energy) of total nutrient intake together with respective quantity and quality from both aspects of avoiding excess and deficiency of each nutrient and prevention of CVD. The intake of macronutrients, for the same ingested energy, if increasing certain nutrients results in a decrease in other nutrients, it is necessary to intake three appropriate proportions of macronutrients.

Among the total energy intake, it is important to secure the recommended amount of protein in the first place. It is effective for improving blood lipids by enabling early weight loss by high-protein diet. But the American Heart Disease Association AHA recommends 15%–20% in terms of energy ratio, to avoid high-protein diet that extremely limits carbohydrates and specific foods (St Jeor et al., 2001).

An extremely low-carbohydrate diet is an excessive intake of protein and lipids, which increases the risk of developing diabetes and CVD (Kurotani et al., 2013; Sluijs et al., 2010).

For example, if the protein energy ratio exceeds 20%, the risk of developing diabetes increases and the CVD increases (Wang et al., 2010). According to a metaanalysis using the interventional study of a high-protein diet with an energy ratio of 30% or more and a normal protein diet, a significant improvement was observed in body weight, body fat, and triglyceride in a short period of 12 weeks on average (Wycherley et al., 2012). In the long term of 12 months or longer, there was not significant difference in changes in body weight, abdominal circumference, serum LDL cholesterol, triglyceride, systolic blood pressure, diastolic blood pressure, fasting blood glucose, HbA1c (Schwingshackl and Hoffmann, 2013). Although high-protein diet has good results in a short period of time, many studies have shown that long-term intervention tests are preferable for prevention of CVD. From the recent systematic review (Pedersen et al., 2013), from the viewpoint of ensuring safety, it is advisable to keep the recommended amount of protein to keep the energy ratio not to exceed 20%.

Introduction: Longevity-Related Diets

Longevity is the wish of mankind. As was said by William Osler, a man is as old as his arteries, two major cardiovascular diseases (CVD) stroke and coronary heart diseases (CHD) are related to vascular aging, and greatly influence life expectancy and longevity (World Health Organization, 2016). Among them CHD is more closely related to average life expectancy because CHD is more prevalent in younger age compared with stroke (Yamori, 2008).

World Health Statistics indicates Japanese have been maintaining the world longest life expectancy. In particular females have kept the number one position since 1985 (UNDP, 2015) and their CHD mortality is maintained at the lowest in the developed countries in the world. Therefore, the diets good for lowering the prevalence of CHD are related to longevity, and Japanese as well as Mediterranean diets, both regarded as good for CHD reduction and longevity (Willett et al., 1995), are similar in the custom of eating much seafood, vegetables, fruits and nuts, or beans (Pallauf et al., 2013; Aiello et al., 2016).

Nutritional merits of these foods, particularly of fish and soy beans, were first experimentally demonstrated in rat models developing stroke genetically (stroke-prone spontaneously hypertensive rats, SHRSP) (Yamori, 1994), and the benefits of fish and soy intakes were further investigated epidemiologically by estimating the biomarkers of fish and soy in 24-hour urine (24U) in WHO-coordinated Cardiovascular Diseases and Alimentary Comparison (CARDIAC) Study covering over 60 populations in the world (Yamori, 2006a,b, 2008; Yamori et al., 2006, 2010, 2015, 2017).

Therefore, in this article, the nutritional impact of fish and soy on CVD is described from experimental and epidemiological findings and accumulating supportive evidence for beneficial effect of fish and soy from various intervention studies and the mechanisms involved in the effects are briefly reviewed.

Experimental Evidence for CVD Prevention by Soy and Fish Intakes

Genetic stroke models in rats were established by the successive breeding of the offspring of spontaneously hypertension rats (SHRs) which were confirmed by autopsy to have died with cerebrovascular hemorrhage and/or infarction (SHRSP) (Okamoto et al., 1974). Since they developed stroke genetically without exception, they were the appropriate model for experimental prevention of stroke (Yamori, 1989, 1994).

The SHRSP, which were fed on high salt diets, 1% salt in drinking water, quickly developed severe hypertension and died of stroke within 3 months, but when they were fed on high soy or fish protein diets, they could survive longer despite high salt diets (Yamori, 1994; **Fig. 1**). The survival rates of SHRSP fed on soy protein alone or soy protein plus magnesium and/or calcium were shown to be so prolonged that the possible nutritional prevention of stroke were experimentally proven in this genetic model (Yamori, 1989, 1994).

These antihypertensive and antistroke effects of dietary protein intakes first noted in experimental study were later confirmed also in humans (Yamori, 1994; Vasdev and Stuckless, 2010; Zhang et al., 2014).

Epidemiological Studies on the Association of the Biomarkers of Soy and Fish Intakes with CVD in the World

The preventive effects of soy, fish, and other nutrients on stroke experimentally proven in SHRSP led Yamori to propose to WHO the CARDIAC Study for investigating the association of the biomarkers of food intake such as soy, fish, salt, and others with CVD

Fig. 2 Geographical distribution of population samples of the CARDIAC Study.

(Yamori, 2006a,b; Yamori et al., 2006, 2010,2015, 2017). About 100 males and 100 females aged 46–58 were randomly selected from each population in over 60 study sites in the world (**Fig. 2**). They were invited for health examination to measure height and weight and blood pressure (BP) estimated by automated BP measurement system and to collect fasting blood samples and 24U by using aliquot cups (Yamori et al., 1984; **Fig. 3**), and the age-adjusted standardized mortality rates for CHD and stroke were obtained for the regions encompassing each study sites.

The CHD mortality rates were significantly inversely related with 24U isoflavone excretion, the biomarkers of soy intake (Yamori, 2006a; **Fig. 4**). CHD mortality rates were low in Japan and China where soy bean products were commonly eaten and 24U isoflavone excretion was over 10 μmol/day.

Fig. 4 Association of 24U isoflavone excretion with age-adjusted CHD morality. *Line* indicates statistically calculated association between CHD mortality and 24-h urinary isoflavone excretion. Graph courtesy Dr. Yamori (2001). Source: WHO ARDIAC Study, 1985–2001.

The amount of daily isoflavone intake of 50 mg is expected to be effective for preventing CHD as well as breast and prostate cancers (Yamori, 2006a,b, 2008).

This amount corresponds to 150 g of tofu, 60 g of fermented soy beans, or 30 g of soy powder commonly eaten in Japan.

WHO CARDIAC Study also revealed significant inverse association between CHD mortality and 24U taurine, the biomarker of fish intake (Yamori, 2006a, Yamori et al., 2010) (**Fig. 5**).

CHD mortality rates were low in Japan and Mediterranean countries where 24U taurine excretion exceeded 1000 μmol/day. *N*-3 fatty acids in the blood phospholipids are also the biomarker of fish intake, and their similar significant inverse relationship with

Fig. 5 Association of 24U taurine excretion with age adjusted CHD mortality. *Line* indicates statistically calculated association between CHD mortality and 24-h urinary taurine excretion. Graph courtesy Dr. Yamori (2006). Source: WHO ARDIAC Study, 1985–2001.

CHD mortality was confirmed by CARDIAC Study (Yamori, 2006a, 2008; Yamori et al., 2006). The inverse associations of stroke mortality with 24U isoflavones or taurine were not significant. It was because CARDIAC Study proved a significant positive association of stroke mortality with 24U salt (Yamori et al., 2006) and these participants who excreted significantly higher isoflavones and taurine in 24U were also proven to excrete significantly higher 24U salt (Fig. 6).

The Association of Biomarkers of Soy and Fish Intakes with CHD Risks in the World

Since the biomarkers of soy and fish intakes were inversely associated with CHD mortality, CHD risks such as obesity, hypertension, and hypercholesterolemia were examined in those who were eating soy regularly (soy consumers), excreting 24U isoflavones over 10 μmol/day (Yamori, 2006b), and in those who were eating fish regularly (fish consumers) and excreting 24U taurine over 1000 and 800 μmol/day in males and females, respectively. They were compared with those who were eating soy and fish less frequently (less soy consumers, less fish consumers), excreting 24U isoflavones and taurine less than the abovementioned levels (Fig. 6).

Soy and fish consumers, both in males and females, had significantly lower body mass index and total cholesterol than less soy and fish consumers and significantly lower BP in females. Since soy and fish consumers had lesser risks of obesity and hypercholesterolemia, the major risks of CHD than less soy and fish consumers, these consumers had significantly lower CHD mortality (Fig. 6) As for salt intakes, soy and fish consumers showed significantly higher 24U salt excretion than less consumers, there were no significant difference in BP between the consumers and less consumers in males who were more salt-sensitive than females (Yamori et al., 2001a).

The Association of Soy and Fish Intakes with CHD in Japanese Regularly Taking Soy and Fish

WHO CARDIAC Study compared Japanese 24U excretions of isoflavone and taurine with the 24U excretions of both biomarkers among worldwide populations and demonstrated the ratio of Japanese in the highest quintiles of both biomarkers was nearly 90%, indicating soy and fish eating customs were common in Japanese (Yamori et al., 2017). Further, the Japanese were divided into the tertiles of 24U excretions of isoflavones and taurine and those who were both in the highest tertile were proven to have significantly higher HDL cholesterol and folate levels in the blood than the lowest tertile of both (Yamori et al., 2017). Since HDL cholesterol and folate were related with lower risks of CHD (Abbott et al., 1988), the common intakes of soy and fish could be related with the lowest CHD mortality of the Japanese in developed countries (Yamori, 2008).

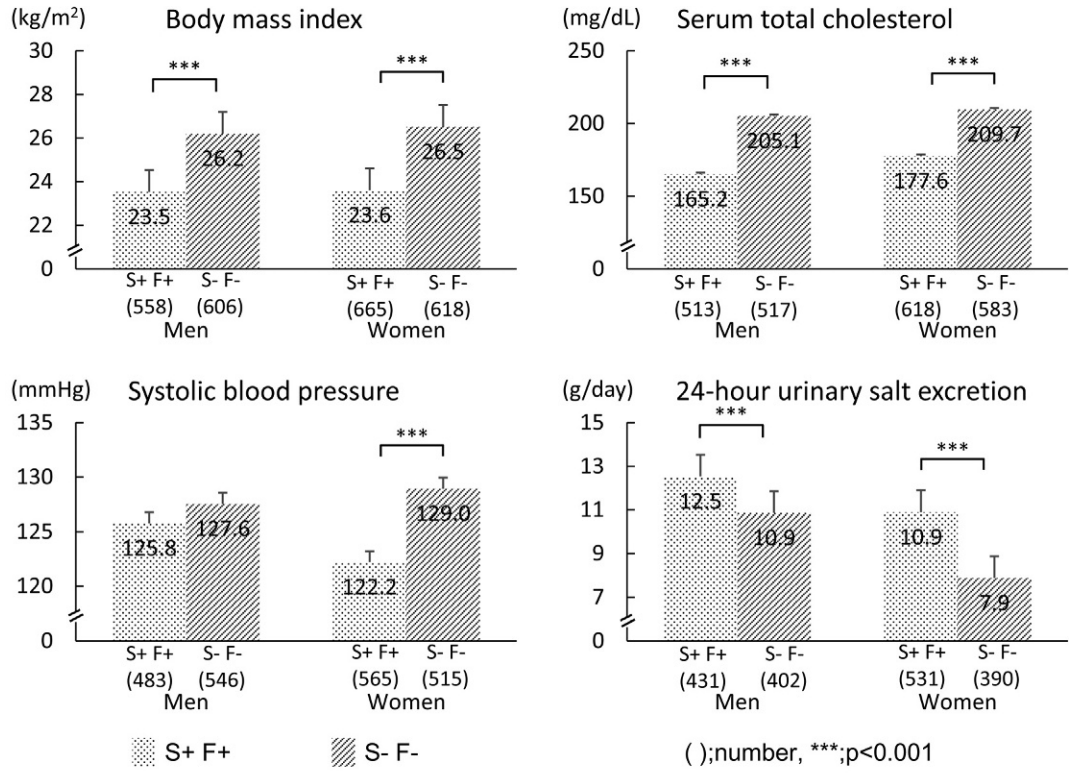

Fig. 6 Cardiovascular risks, body mass index, systolic blood pressure, total cholesterol in soy consumers (S+) and fish consumers (F+) compared with less soy and less fish consumers (S−, F−).

The Japan Public Health Center based (JPHC) study was the most extensive cohort study in Japan, conducted for 40,462 man and women aged 40–59 without CVD or cancer at baseline (1990–1992) and follows up to 2002 (Kokubo et al., 2007). Soy intake was estimated from food frequency questionnaires and was analyzed by the quintiles for the risk of cerebral and myocardial infarction (CI and MI). The multivariable hazard ratios and 95% confidence limits for highest versus the lowest isoflavone quintile were 0.35 (0.21–0.59) for CI, 0.37 (0.14–0.98) for MI, and 0.87 (0.29–2.52) for cardiovascular mortality in women, but no significant association of dietary intake of soy and isoflavones with CI or MI was present in men.

This study indicated the less beneficial effect of soy intakes in man. As Japanese dietary tradition of soy intake was related with high salt intake (Yamori et al., 2017), the adverse effort of high salt intake might reduce the merit of soy intake in men whose BP was significantly associated with salt intake (Yamori et al., 2006). Since salt-associated BP rise was not significant in premenopausal women (Yamori et al., 2001a), the estrogen-agonist effect of isoflavones might reduce the adverse effect of high salt intake accompanied with soy intake in women.

JPHC study also revealed that the higher consumption of fish (eight times per week or 180 g/day) was associated with reduced risk of CHD, more significantly, MI and nonfatal CHD, compared with a modest fish consumption (once a week or 23 g/day) in Japan (Iso et al., 2006). In this study, the *n*-3 fatty acid intakes estimated from questionnaires were also inversely associated with CHD.

The Potential Benefits of Soy Intakes and the Mechanisms

Soy intakes are proven to be beneficial in Japanese taking soy foods regularly, and the intakes have gained attention for the potential role in improving CVD risk factors also in the United States and other Western countries where soy consumption is lower than Asian countries. U.S. Food and Drug Administration (FDA) approved labeling for foods containing soy protein as protective against CHD in 1999 (Erdman, 2000), the effects of soy protein and isoflavones were reviewed from further available articles to report small but significant reduction of total cholesterol or LDL in about half of the literatures (Sacks et al., 2006). Seven human studies on soy protein or isoflavones showed beneficial effects on lipid profiles such as reduced LDL, and ascribed the potential mechanisms to the

reduced intestinal cholesterol absorption by increased fecal bile acid excretion due to soy protein ingestion and/or to the reduction of LDL oxidation by isoflavones (Omoni and Aluko, 2005).

The antihypertensive efforts of soy protein and isoflavones in humane studies were reported (Yang et al., 2005; He et al., 2005) and the BP reduction was ascribed to the higher arginine content of soy protein (Obarzanek et al., 1996) and to enhanced NO production by isoflavones (Si and Liu, 2008; Räthel et al., 2005). Several articles reported no BP effects of soy intervention studies. However, when the compliance of the soy intervention study was confirmed by 24U isoflavone excretion, soy effects on BP and lipid profile were evident (Sagara et al., 2004; Yamori, 2006a,b; Mori and Thorpe, 2005).

The beneficial soy effects may be attributable to other soy nutrients, such as *n*-3 polyunsaturated fatty acids, fibers, vitamins, minerals, saponins, and phytosterols (Omoni and Aluko, 2005).

The other potential benefits of soy on CVD should be the antiinflammatory effect proven by the reduction of C-reactive protein (CRP) (Filiberto et al., 2013) and the antidiabetic effect (Azadbakht et al., 2007) partly through CRP reduction (Xu et al., 2007)and AMP-activated protein kinase activation (Cederroth et al., 2008). The activation of adiponectin (Kim et al., 2014) and the reduction of E-selectin (Rebholz et al., 2013) may also be the benefit of soy and soy products. These pleiotropic effects of soy nutrients may improve arterial compliance (Nestel et al., 1997) and arterial stiffness (Reverri et al., 2015).

The Potential Benefit of Fish Intake and the Mechanisms

Since the pioneering studies on the benefits of fish intakes in 1970 (Bang et al., 1976), fish consumption was proven to be associated with CVD risk reductions by many epidemiological studies (Zhang et al., 1999), including WHO CARDIAC Study in the world as well as in the Chinese (Yuan et al., 2001) and the Japanese consuming the high amount of fish (Iso et al., 2006) as cited in this review.

The merits of fish intakes are mainly considered to be due to *n*-3 fatty acids, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) (Hu et al., 2003). These fatty acids have important biological functions such as prevention of arrhythmia, lowering heart rate and BP, decreasing platelet aggregation, and plasma triglycerides (Harris et al., 2008).

Since inflammation has been identified to be involved in the pathogens of atherosclerosis (Libby, 2002) and of CHD, stroke, and diabetes (Libby, 2006; Ridker, 2007), *n*-3 fatty acids reduce CVD risks by the anti inflammatory effects through their stimulation of G protein-coupled receptor 120 in macrophages (Oh et al., 2010).

Flock et al. (2013) reviewed eight meta-analyses of randomized controlled trials evaluating the effects of EPA and DHA on cardiac and/or all cause mortalities and found six out of eight articles reported significant relative risk reduction of cardiac death. The inverse association of blood levels of *n*-3 fatty acids with telomere shortening in leukocytes was observed by over 5-year prospective study on the cohort of 608 ambulatory outpatients with CHD (Erkkilä et al., 2003). Since leukocyte telomere shortening was noted in the patients with premature MI (Brouilette et al., 2003), *n*-3 fatty acid intake may prolong the survival of CHD patients (Farzaneh-Far et al., 2010).

Taurine was used as the biomarker of fish intake by WHO-CARDIAC Study, and its intake was experimentally and epidemiologically proven to lower BP and serum cholesterol (Yamori et al., 2004; Yamori et al., 2010; Murakami et al., 1996). The inverse association of the population means of 24U taurine excretion with the mortality rates of CHD in WHO-CARDIAC Study populations (Yamori et al., 2001b) was further supported by the quintile analysis of 24U taurine/creatinine in all CARDIAC Study participants (Sagara et al., 2015). This study indicated the significant inverse association of 24U taurine with the major CHD risks, such as BMI, BP, and serum cholesterol.

Since 24U taurine excretion in Tibetans with no custom to eat fish was lowest in the world, 1 g of taurine solved in tea, given three times a day for 2 months significantly reduced BP (Yamori et al., 1996).

Taurine is known to work as antioxidant through the formation of taurine chloramine for trapping hypochlorous acid produced by myeloperoxidase in macrophages and neutrophils (Murakami, 2012). Therefore, taurine's effects on endothelial progenitor cells (EPC) were observed in healthy male volunteers and SHR given 1% salt in drinking water which were previously shown to have impaired endothelial function. In humans 3 g taurine administration per day increased EPC colony numbers, and in SHR 3% taurine in drinking water improved the EPC function and significantly decreased free radicals measured as thiobarbituric acid reactive subtract, indicating dietary taurine intake may prevent CVD by improving EPC function (Katakawa et al., 2016).

Combined Intakes of Soy and Fish Nutrients for CVD Prevention

Since CHD morality in the developed countries of the world is lowest in the Japanese consuming soy and fish regularly and HDL cholesterol and folic acids are high in the Japanese taking both foods enough (Yamori et al., 2017), soy and fish intakes are recommended for CHD prevention.

Soy beans are regarded as an eco-friendly source of protein sustainably available widely in the world and able to support 10 times the number of people consuming beef and pork customarily.

Fish consumption, if recommended throughout the world as being eaten in Japan, may lead to an exhaustion of fish from our planet. This environmental concern may be possibly solved in two ways.

One newly developing solution is stearidonic acid, *n*-3 polyunsaturated fatty acid produced by genetically modified soy, (Surette ME, 2013) the safety of which should be still confirmed.

The other practical recommendation in place of fish should be seaweeds. Seaweeds are traditionally eaten in Japan, and contain taurine and *n*-3 fatty acids (MacArtain et al., 2007). Therefore, soy, fish and seaweeds are recommended for the dietary prevention of CVD to achieve eco-friendly global health.

% BF	Percent body fat

Overview and Background

Overweight and obesity have become a global epidemic and public health problem (Mozaffarian et al., 2016). Since 1980, the worldwide prevalence of individuals who are either overweight or obese has increased by ~28% among adults and ~58% among children and adolescents (Ng et al., 2014). Recent reports indicated that more than two-thirds of adults in the United States (US) are either overweight or obese and 38% are obese. More concerning is the fact that the prevalence of severe obesity (body mass index [BMI] $\geq$ 40 kg/m^2) has been rising and now totals almost 8% of the US population, with certain demographic groups more commonly affected such as women, non-Hispanic blacks, and middle-aged adults (Ogden et al., 2014; Flegal et al., 2016).

Heart failure (HF) is a heterogenous syndrome with multiple underlying etiologies and pathophysiologies. The lifetime risk of HF for US adults $\geq$40 years of age was reported as 13.8% (Djoussé et al., 2009). HF predominantly affects the elderly population, and it is one of the most common causes of hospitalization in adults $\geq$65 years of age (Yancy et al., 2013). Despite the improvements in the management, HF remains an important cause of death with mortality rates of 20% at 1 year and 53% at 5 years following the diagnosis of HF (Gerber et al., 2015). Patients with HF are commonly classified into two distinct groups based on left ventricular (LV) function: HF with preserved ejection fraction (HFpEF, LV ejection fraction [LVEF] $\geq$50%) and HF with reduced EF (HFrEF, LVEF $\leq$40%). Patients with an LVEF of 41%–49% are referred as borderline or intermediate HFpEF (Yancy et al., 2013). HFpEF is characterized by diastolic dysfunction, and it represents 50% of cases with HF. HFpEF is expected to become the predominant form of HF (Owan et al., 2006; Oktay et al., 2013).

Obesity is a well-established modifiable risk factor for HF and other cardiovascular (CV) diseases (CVD), such as coronary heart disease (CHD), stroke, and atrial fibrillation (Mozaffarian et al., 2016). The strong relationship between obesity and HF is underlain by two main factors. (1) Obesity is strongly associated with other major CVD risk factors such as atherosclerosis, hypertension (HTN), diabetes mellitus (DM), dyslipidemia, and obstructive sleep apnea (OSA). (2) Obesity, independent of the effect of other obesity-associated CVD risk factors, can induce alterations in cardiac structure and function (Lavie et al., 2016a). These alterations are primarily triggered by excessive adipose tissue accumulation and subsequent hemodynamic changes and adverse cardiac remodeling (**Table 1**) (Joyce et al., 2016; Lavie et al., 2016b).

Despite the strong relationship between obesity and development of HF, multiple epidemiological studies have demonstrated an "obesity paradox" which is characterized by a better short- and intermediate-term prognosis in overweight or obese HF patients compared to their leaner or normal-weight counterparts (Lavie et al., 2013a, 2016a).

In this chapter, we discuss the current concepts of the relationship between adiposity, cardiac remodeling, and development of HF. We also review the prognostic implications of the obesity paradox in patients with established HF. Finally, we discuss data on the benefits and risks of weight loss and the prognostic impact of cardiorespiratory fitness (CRF) in patients with HF.

Defining Obesity

In simple terms, obesity is defined as an excess of body adiposity due to increased number and/or size of adipocytes (Caballero, 2007). The increase in body weight and overall adiposity derives from a chronic positive energy balance, meaning energy intake

Table 1 Effects of obesity on the cardiovascular system

Effects of obesity on cardiovascular system	
Hemodynamics	• Increased total and central blood volume • Increased stroke volume/cardiac output • Decreased systemic vascular resistance • Increased arterial pressure • Increased LV wall stress • Pulmonary artery hypertension
Cardiac structure	• LV concentric remodeling • LV hypertrophy (eccentric and concentric) • Left atrial enlargement • RV hypertrophy
Cardiac function	• LV diastolic dysfunction • LV systolic dysfunction • LV myocardial dyssynchrony • RV failure
Inflammation	• Increased C-reactive protein • Overexpression of tumor necrosis factor
Neurohumoral	• Insulin resistance and hyperinsulinemia • Leptin insensitivity and hyperleptinemia • Reduced adiponectin • Sympathetic nervous system activation • Over-activation of renin-angiotensin-aldosterone system • Overexpression of peroxisome proliferator-activator receptor
Cellular	• Hypertrophy • Apoptosis • Fibrosis

LV, left ventricular; *RV*, right ventricular.

Table 2 Body weight categories

Body weight categories	
Underweight	BMI <18.5 kg/m^2
Normal/acceptable weight	BMI 18.5–24.9 kg/m^2
Overweight	BMI 25.0–29.9 kg/m^2
Obese	BMI ≥ 30 kg/m^2
Grade 1—obese	BMI 30.0–34.9 kg/m^2
Grade 2—obese	BMI 35.0–39.9 kg/m^2
Grade 3 (severe)—obese	BMI ≥ 40 kg/m^2

BMI, body mass index.

more than energy expenditure (or calories consumed >calories burned) (Lavie et al., 2016a). Multiple studies have repeatedly demonstrated that poor dietary choices characterized by excessive calorie intake (particularly with carbohydrates) are largely, if not completely, responsible for the obesity epidemic (DiNicolantonio et al., 2016; Swinburn et al., 2009). Moreover, our recent studies have demonstrated that the obesity epidemic has been contributed by massive declines in occupational physical activity (PA) in both men and women and household management in women during the past 5 decades (Church et al., 2011; Archer et al., 2013).

BMI (the ratio of total weight to height squared [kg/m^2]) is the most commonly used anthropometric measure to assess relative weight and classify obesity (Bastien et al., 2014). Individuals with a BMI between 18.5 and 24.9 kg/m^2 are considered to have normal or acceptable weight, while those with a BMI ≥ 30 kg/m^2 are classified as obese. The classification of body weight based on BMI is given in **table 2** (WHO, 2016). Overall, obesity is associated with increased all-cause mortality in the general population (Engeland et al., 2003). However, recent epidemiologic studies have demonstrated that grading of obesity helps with better prediction of all-cause mortality (Bastien et al., 2014). A systematic review of 97 studies with a combined sample size of 2.88 million individuals revealed that compared to normal weight, grade 2 and grade 3 (but not grade 1) were associated with increased all-cause mortality. Overweight was associated with significantly lower all-cause mortality in relation to normal-weight (Flegal et al., 2013).

Its simplicity and validation in multiple epidemiological studies have made BMI a popular and widely used parameter (Oliveros et al., 2014). We recently demonstrated, in a cohort of more than 60,000 individuals, that very high BMI can accurately predict the risk of CVD mortality in the general population (Ortega et al., 2016). Despite being a very useful measure in population studies,

BMI is flawed in individual-person level. Because it reflects both fat and nonfat mass which mostly consist of muscle and skeletal mass (Lavie et al., 2016b). Generally, metabolic abnormalities occur as a result of excess body fat (BF) rather than a high level of lean body mass (LBM) (Collaboration et al., 2011). A metaanalysis of 25 studies with a combined sample size of approximately 32,000 individuals demonstrated that BMI has high overall specificity (90%) but poor sensitivity (50%) in regard to identifying excess BF (Okorodudu et al., 2010). These results suggested that many individuals who are not obese according to BMI might indeed have excess BF. On the contrary, athletes with a high muscle mass may be misclassified as overweight or obese (even in the absence of excess adiposity) if only BMI is used for assessment (Oliveros et al., 2014).

Several other anthropometric parameters (i.e., waist circumference [WC] and waist-to-hip, waist-to-height, and waist-to-thigh ratios) can be used for assessment of central (or visceral) adiposity and further risk stratification (Oliveros et al., 2014; Lavie et al., 2016b). Increase in WC or related ratios (as above), referred as abdominal obesity, indicates higher risk of CV and metabolic abnormalities independent of BMI (Després, 2012). In a metaanalysis of 15 prospective studies that included >258,000 individuals, every 1 cm increment in WC was associated with a 2% increase in future risk of CVD (de Koning et al., 2007). The World Health Organization expert consensus has proposed the following WC cutoff values based on CVD risk: 94 cm (men) and 80 cm (women) for increased risk, and 102 cm (men) and 88 cm (women) for substantially increased risk (World Health Organization, 2008).

Several other techniques have been developed for BF assessment such as near-infrared interactance, hydrostatic weighing, air displacement plethysmography, dual-energy X-ray absorptiometry, and bioelectric impedance. We are still away from the routine use of these techniques in general clinical practice. In addition, there exist no standardized cutoff values for defining obesity based on percent BF (% BF). The clinical utility and limitations of these techniques were discussed extensively in a scientific statement by the American Heart Association (Cornier et al., 2011).

Computed tomography (CT) and magnetic resonance imaging (MRI) are considered to be the "gold standard" for measurement of adipose tissue and LBM and evaluation of BF distribution (Cornier et al., 2011). CT and MRI are particularly helpful with quantification of visceral adipose tissue. Growing evidence now suggests that visceral adiposity is much more important for CVD risk stratification than subcutaneous adiposity (Neeland et al., 2015; Abraham et al., 2015). Furthermore, visceral adiposity surrounding the heart (referred as pericardial adipose tissue) is now recognized as an independent risk factor for several CVD. Multiple epidemiological studies have revealed that increased pericardial adipose tissue (detected by CT or MRI) is associated with a significantly increased risk of CV morbidity and mortality even after adjustment for other CVD risk factors and obesity parameters (Mahabadi et al., 2013; Thanassoulis et al., 2010; Fox et al., 2009).

Hemodynamic Changes in Obesity

Weight gain and obesity lead to a variety of alterations in central and peripheral hemodynamics. These hemodynamic changes are characterized by increased total and central blood volume, LV stroke volume, and cardiac output (CO) (Lavie et al., 2016b; Alpert et al., 2014, 2016; Alexander et al., 1962). The rise in CO in individuals with grade I and II obesity is mainly driven by lean body mass since skeletal muscle requires a higher amount of blood flow compared to adipose tissue (Alpert et al., 2014; Collis et al., 2001; Carbone et al., 2017). Moreover, obesity is associated with decreased systemic vascular resistance (in normotensive individuals) which facilitates increased CO despite no significant change in heart rate (Lavie et al., 2015a). It is not uncommon to observe CO values as high as 10 L/min in severe obesity (Alpert et al., 2014). Despite the increase in CO, obese individuals usually have reduced blood flow per unit of weight, particularly in severe degrees of obesity. Coexistent HTN in obesity can cause a relatively lower CO due to the impact of increased systemic vascular resistance.

Increased venous return in individuals with grade II and III obesity leads to a rise in preload and LV filling pressure. This results in elevation of the pulmonary artery and right heart pressures (Lavie et al., 2016b; Alpert et al., 2014, 2016). Moreover, chronic hypoxia due to hypoventilation and/or OSA induces vasoconstriction and remodeling of small pulmonary arteries in severely obese individuals. These changes further contribute to the increase in pulmonary vascular resistance and pulmonary artery pressure (Alpert et al., 2014; Alpert, 2016). In individuals with grade III obesity, exercise induces a 20% rise in central blood volume and a 50% rise in LV end-diastolic pressure (Lavie et al., 2016b).

Cardiac Remodeling in Obesity

Obese individuals are more likely to have abnormal LV geometry compared to leaner counterparts (Lavie et al., 2007). Likewise, studies have shown a strong independent correlation between BMI and LV mass, LV wall thickness, and LV internal dimension (Korre et al., 2016; Lauer et al., 1991; Peterson et al., 2004). There exists a significant variation among studies in regard to the reported frequency of LV structural abnormalities in obese individuals. This variation has mainly been attributed to the duration and severity of obesity and presence or absence of comorbidities (Alpert et al., 1995, 2014).

A complex interaction of several mechanisms such as HTN, neurohumoral and metabolic abnormalities, and hemodynamic alterations plays role in obesity-induced LV remodeling (**Fig. 1**) (Lavie et al., 2015a). According to the conventional concept, increased CO and central blood volume in uncomplicated obesity may predispose to LV dilatation and eccentric LV hypertrophy (LVH) (Alpert, 2016). However, we and others have demonstrated that concentric LV geometry is observed as commonly or more

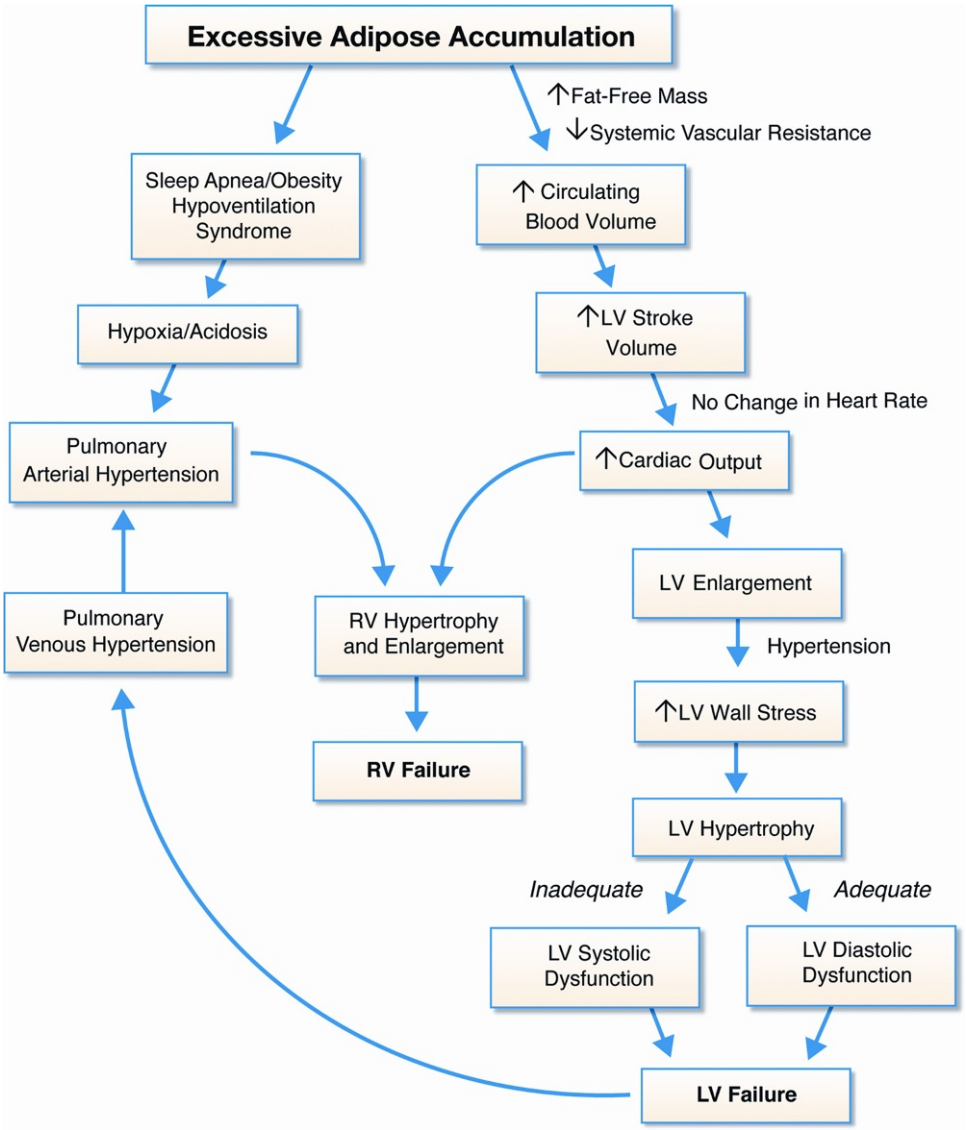

Fig. 1 Pathophysiology of obesity-induced alterations in cardiovascular system. This is a simplified model of mechanisms involved in the development of heart failure due to obesity. *LV*, left ventricular; *RV*, right ventricular. Reproduced with permission from Lavie, C. Impact of obesity and the obesity paradox on prevalence and prognosis in heart failure. *JACC: Heart Failure* **1** (2), 93–102.

commonly than eccentric LVH in obese individuals (Lavie et al., 2007; Woodiwiss et al., 2008). And a report from the Multiethnic Study of Atherosclerosis (MESA) ($n = 5098$), which utilized cardiac MRI to assess LV geometry, demonstrated that obesity is more commonly associated with concentric remodeling which is characterized by a greater increase in LV mass relative to that in LV end-diastolic volume (Turkbey et al., 2010). Moreover, distribution of adipose tissue shows a complex relationship with hemodynamics and alterations in cardiac morphology. Neeland et al., in the Dallas Heart Study cohort, found that visceral obesity was independently associated with concentric LV remodeling and a higher systemic vascular resistance and lower CO (Neeland et al., 2013). In contrast, lower body subcutaneous adiposity was associated with an eccentric LV remodeling pattern, and lower systemic vascular resistance and CO.

Left atrial (LA) enlargement is common in obese individuals with obesity even in the absence of other risk factors (Sasson et al., 1996). Multiple epidemiological studies have confirmed that obesity and BMI are among the strongest predictors of LA enlargement (Gottdiener et al., 1997; Stritzke et al., 2009; Shigematsu et al., 2009). In a prospective study from Europe, obesity was found to have almost twice the effect of HTN on LA size (Stritzke et al., 2009).

Right ventricular (RV) structure and function remain understudied in overweight and obese individuals mainly because of the limitations of echocardiography in assessment of the RV (Alpert et al., 2014). Evidence from studies using cardiac MRI showed that compared to leaner counterparts, overweight and obese individuals have greater RV mass, end-diastolic volume, and stroke volume even after adjustment for respective LV parameters (Chahal et al., 2012).

Cardiac Dysfunction in Obesity

LV diastolic dysfunction is common in obese individuals, and its frequency increases in correlation with the severity of obesity (Lavie et al., 2015a). Peterson et al. demonstrated a strong correlation between BMI and diastolic dysfunction in otherwise healthy women (Peterson et al., 2004). A small study from Europe reported the frequency of LV diastolic dysfunction as 12% in individuals with grade I, 35% with grade II, and 45% with grade III obesity (Pascual et al., 2003). Obesity-associated diastolic dysfunction usually occurs in the setting of increased LV mass or LVH. However, LV diastolic dysfunction can be seen in obese individuals even in the absence of LVH (Lavie et al., 2016b; Alpert et al., 2014).

The frequency of LV systolic dysfunction in obese individuals highly varies depending on the definition of systolic dysfunction and the imaging modality utilized (Gupta et al., 2015). Studies using LVEF to evaluate systolic function have reported preserved systolic function in the majority of asymptomatic obese individuals (Turkbey et al., 2010; Kishi et al., 2014; Barbosa et al., 2013). However, studies using more sensitive echocardiographic modalities have revealed a high frequency of subclinical LV systolic dysfunction in obese individuals even with preserved LVEF (Lavie et al., 2016b; Kishi et al., 2014). Wang et al. investigated the relationship of obesity with global longitudinal strain and myocardial dyssynchrony (both were assessed by speckle tracking echocardiography) in a cohort of adults with no known CVD (Wang et al., 2015). The investigators found that compared to nonobese controls, obese individuals had a higher likelihood of impaired systolic mechanics (reflected by lower longitudinal strain) and dyssynchrony, regardless of the presence or the absence of concomitant metabolic syndrome (**Fig. 2**). Barbosa et al. demonstrated that subclinical systolic dysfunction commonly occurs in obese children and adolescents, as well (Barbosa et al., 2013).

Obesity has been associated with RV systolic dysfunction. Chahal et al., in a cohort of 4127 adults from the MESA, demonstrated an association between obesity and a slight decrease in RV ejection fraction determined by cardiac MRI (Chahal et al., 2012). In fact, their study demonstrated 0.5% decrease in RV ejection fraction for every 5 kg/m^2 increase in BMI. A recent report in a large ($n=4343$) biracial cohort of elderly individuals with no cardiac disease showed an inverse correlation between BMI and RV fractional area change on echocardiography (Bello et al., 2016). Tadic et al., in a cohort of adults ($n=127$) with untreated HTN, found a significant correlation between obesity and depressed RV ejection fraction (by three-dimensional echocardiography) and low RV myocardial strain and strain rate (by speckle-tracking echocardiography) (Tadic et al., 2016).

Obesity and Other HF Risk Factors

In addition to its direct effect on cardiac structure and function, obesity contributes to the development of HF through other intermediate risk factors such as HTN, CHD, and type-2 DM.

HTN leads to LV remodeling and LVH due to chronic pressure overload and the related increase in LV filling pressures and wall stress (Oktay et al., 2016). Hypertensives, compared to normotensives, carry 2-fold higher risk in men and 3-fold higher risk in women for development of HF. And at the population level, 39% of HF cases in men and 59% of HF cases in women are attributed to HTN (Levy et al., 1996). The strong relationship between obesity and HTN was demonstrated in the Framingham Heart Study (FHS) 5 decades ago (Kannel et al., 1967). BMI shows a strong correlation with systolic and diastolic blood pressure (BP) and frequency of HTN even after adjusting for other variables (Shihab et al., 2012; Drøyvold et al., 2005). Obese individuals are also at risk for having resistant HTN despite the use of multiple anti-HTN agents (Jordan et al., 2012; Demarco et al., 2014). Intentional weight reduction in overweight or obese individuals can improve BP profiles (Neter et al., 2003).

Hypertension, obesity, diabetes, and heart failure-free survival: The cardiovascular disease lifetime risk pooling project. *JACC: Heart Failure* **4** (12), 911–919.

Obesity and related comorbidities play significant role in development of atherosclerosis, the hallmark finding of CHD (Bastien et al., 2014). Consistently, CHD occurs more commonly in overweight or obese individuals compared to their leaner counterparts (Rabkin et al., 1977; Hubert et al., 1983; Wilson et al., 2002). Overweight and obese individuals develop acute coronary syndromes at younger ages than those with a normal BMI. Madala et al. retrospectively examined the relationship between adiposity categories and non-ST-elevation myocardial infarction (NSTEMI) in a large cohort ($n=111,847$) of patients with NSTEMI (Madala et al., 2008). The investigators found that obesity was the strongest predictor of NSTEMI at younger ages followed by tobacco use. In fact, the age at the first NSTEMI was 6.8, 9.4, or 12.0 years earlier in individuals with grade 1, grade 2, or grade 3 obesity, respectively.

Type-2 DM is characterized by insulin resistance which predominantly occurs secondary to increased adiposity. Insulin resistance and DM can independently promote the development of a special form of cardiomyopathy which is also referred as diabetic cardiomyopathy (Jia et al., 2016). Moreover, DM markedly increases HF risk especially in the presence of other HF risk factors such HTN and CHD. A metaanalysis with a combined sample size of 193,424 revealed ~4-fold increased risk of HF in individuals with coexistent DM and HTN compared to those with HTN only (Tocci et al., 2008). A recent study by Ahmad et al., in subjects from 4 different epidemiological cohorts in the United States, investigated the lifetime HF risk associated with concomitant HTN, obesity, and DM in mid-life (Ahmad et al., 2016). The study found that absence of HTN, DM, and obesity at age 45 years was associated with 73% (for men) and 85% (for women) lower lifetime HF risk when compared to the presence of all three risk factors. Moreover, individuals with no HTN, DM, and obesity at age 45 years had 10.6 years (for men) and 14.9 years (for women) longer HF-free survival compared those with all three risk factors (**Fig. 3**).

Obesity and HF

Multiple epidemiological studies have established overweight and obesity as risk factors for the development of HF (Ahmad et al., 2016; Kenchaiah et al., 2002; Huffman et al., 2013; Lee et al., 2007; Ndumele et al., 2014, 2016a). The relationship between obesity and HF appears to be stronger compared to the link of obesity with CAD or stroke (Ndumele et al., 2016b). A seminal report from Kenchaiah et al. examined the association between obesity and HF in the FHS participants ($n=5881$) during a mean follow-up of ~14 years (Kenchaiah et al., 2002). The investigators found that BMI correlates with HF risk in a dose-dependent fashion. For instance, the risk of HF was found to increase by 5% in men and 7% in women for every 1 kg/m^2 (Ng et al., 2014) increment in BMI, even after adjustment for other risk factors. Compared to normal-weight women, overweight and obese women were found to have 50% and 100% higher risk of future HF, respectively. In men, obesity was associated with 90% increase in the risk of HF. However, there was no statistically significant difference between normal weight and overweight men in regard to HF risk. In another prospective cohort with a larger sample size ($n=21,094$ men, mean follow-up 20.5 years), Kenchaiah et al. demonstrated 49% and 180% increased risk of HF in overweight and obese individuals, respectively (compared to leaner counterparts) (Kenchaiah et al., 2009). Moreover, the investigators demonstrated that the HF risk associated with overweightedness and obesity is markedly augmented with the presence of physical inactivity. A large prospective cohort study from Norway ($n=61,299$) demonstrated that obesity is associated with markedly elevated HF risk even in metabolically healthy individuals defined by those without HTN, DM, and dyslipidemia (Mørkedal et al., 2014).

Abdominal obesity assessed by WC or waist-to-hip ratio contributes to the risk of future HF (Mørkedal et al., 2014; Loehr et al., 2009; Hu et al., 2004). A recent metaanalysis of 28 prospective studies with a combined sample size of >600,000 participants found

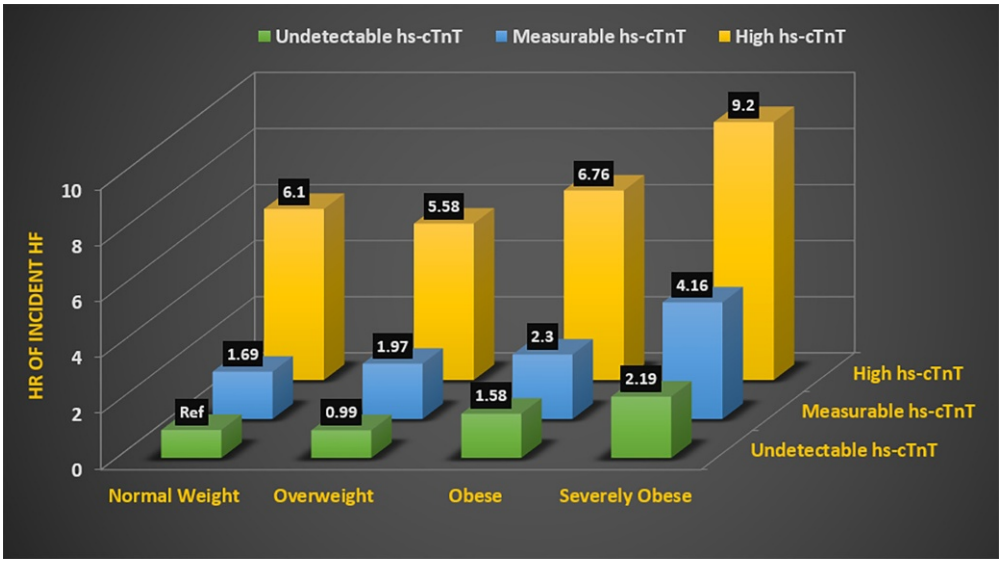

Fig. 4 Combined association of BMI categories and hs-cTnT levels with risk of incident HF. The predicted hazard ratios of incident HF are displayed for both hs-cTnT levels (undetectable [<3 ng/L], measurable [3–13 ng/L], and high [≥14 ng/L]) and BMI categories (normal weight [BMI 18.5 to <25 kg/m^2], overweight [BMI 25 to <30 kg/m^2], obese [BMI 30 to <35 kg/m^2], severely obese [≥35 kg/m^2]) in the Atherosclerosis in The Communities (ARIC) study. The hazard ratio of incident HF was estimated using Cox regression analysis and after adjustment for age, sex, race, smoking status, diabetes mellitus, hypertension, lipid panel, natriuretic peptide level, and estimated glomerular filtration rate. *BMI*, body mass index; *HF*, heart failure; *HR*, hazard ratio; *hs-cTnT*, high sensitivity cardiac troponin T. Reproduced with permission from Ndumele, C. E., Coresh, J., Lazo, M. et al. (2014). Obesity, subclinical myocardial injury and incident heart failure. *JACC: Heart Failure* **2** (6), 600–607.

that every 10 cm increase in WC and 0.1 unit in the waist-to-hip ratio is associated with 29% and 28% higher risk of HF, respectively (Aune et al., 2016). The relationship between BMI and HF risk was found to be nonlinear with a BMI cutoff of 23–24 kg/m^2 for increased HF risk.

Subclinical myocardial injury plays a significant role in the onset of obesity-associated HF. Ndumele et al. evaluated the relationship between adiposity, subclinical myocardial injury, and incident HF in the Atherosclerosis Risk in Communities (ARIC) study participants ($n=9507$) who had no known CVD at baseline (**Fig. 4**) (Ndumele et al., 2014). In the study, the subclinical myocardial injury was assessed by a high-sensitivity cardiac troponin T (hs-cTnT) assay. The study revealed a 2.2 higher rate of subclinical myocardial injury in severely obese. When compared to the reference group (normal weight individuals with undetectable hs-cTnT), individuals with a BMI ≥35 kg/m^2 and undetectable hs-cTnT had 2.2-fold increased risk of incident HF. However, those with a BMI ≥35 kg/m^2 and elevated hs-cTnT had >9-fold higher risk of incident HF than the reference group.

Obesity and Natriuretic Peptides

B-type natriuretic peptide (BNP) and its inactive fragment, N-terminal pro-B-type natriuretic peptide (NT-proBNP), are the biomarkers commonly used in the evaluation and management of patients with HF. In general, natriuretic peptides are secreted from the atria and the ventricles in response to a significant elevation in cardiac filling pressures and related mechanical stretch of the myocardium, with or without the syndrome of HF (Francis et al., 2016). Natriuretic peptides are involved in CV hemostasis and they stimulate natriuresis and diuresis, decrease cardiac preload, and suppress RAAS and sympathetic nervous system (Madamanchi et al., 2014). Data from FHS identified elevated BNP as an independent predictor of future risk of HF, CV events, and death in the general population (without HF at baseline) (Wang et al., 2004a). And BNP-guided prevention strategies were shown to significantly reduce the risk of incident HF in individuals with HF risk factors (Ledwidge et al., 2013; Huelsmann et al., 2013). Moreover, natriuretic peptides are important predictors of adverse outcomes in patients with HFrEF, HFpEF, or acute HF (Anand et al., 2003, 2011; Fonarow et al., 2007a).

BNP and NT-proBNP levels show inverse correlation with BMI in individuals with or without HF (Ndumele et al., 2016a; Wang et al., 2004b; Das et al., 2005; Mehra et al., 2004; Frankenstein et al., 2008). Taylor et al. demonstrated that obese individuals have lower BNP and NT-proBNP despite having higher LV end-diastolic pressure (invasively measured) compared to normal-weight individuals (Taylor et al., 2006). Therefore, a normal BNP does not exclude the diagnosis of HF and volume overload, especially in obese individuals. The cause(s) of lower BNP and NT-proBNP in the setting of obesity and whether this has any role in the increased risk of incident HF in obesity are not well known. The inverse correlation between BMI and natriuretic peptides was initially attributed to the clearance of BNP by adipose tissue (Wang et al., 2004b; Sarzani et al., 1996). However, this assumption was challenged by Das et al. who examined the relationship of BNP and NT-proBNP with body composition (determined by

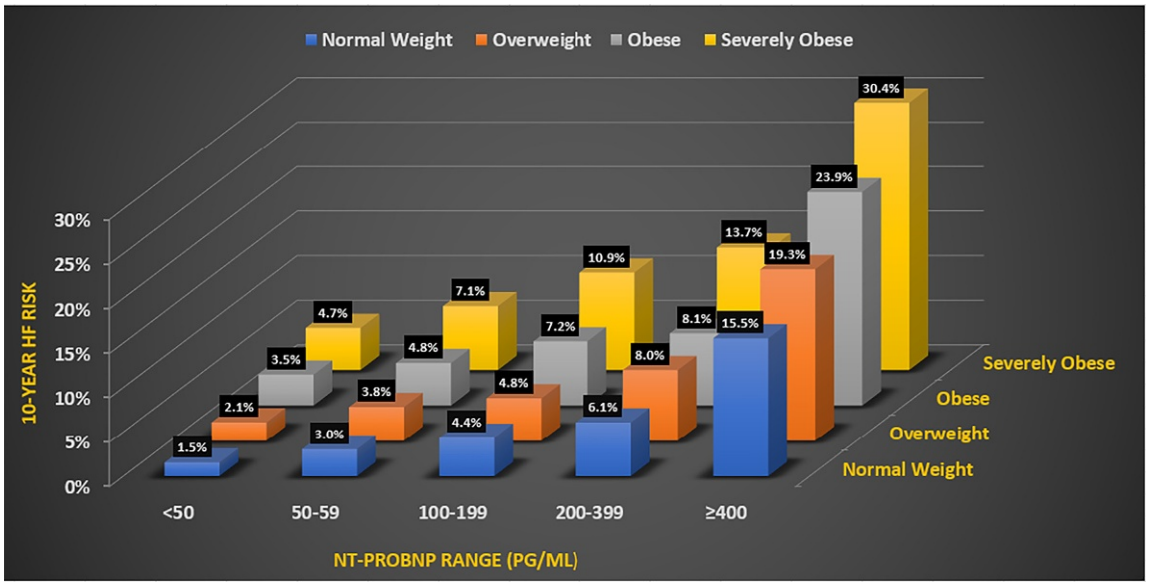

Fig. 5 Combined association of BMI categories and NT-proBNP levels with 10-year Risk of HF. The average predicted 10-year HF risk for the NT-proBNP ranges (<50, 50–99, 100–199, 200–399, ≥400 pg/mL) are displayed for each BMI category (normal weight [BMI 18.5 to <25 kg/m^2], overweight [BMI 25 to <30 kg/m^2], obese [BMI 30 to <35 kg/m^2], severely obese [≥35 kg/m^2]) in the Atherosclerosis in The Communities (ARIC) study. The 10-year HF risk was estimated using Cox regression analysis and after adjustment for age, sex, race, prior coronary artery disease, smoking status, diabetes mellitus, mean systolic blood pressure, use of antihypertensive medications, and heart rate. BMI, body mass index; HF, heart failure; NT-proBNP, N-terminal pro-B-type natriuretic peptide. The figure was drawn based on the data from Ndumele, C. E., Matsushita, K., Sang, Y et al. (2016). N-terminal pro-brain natriuretic peptide and heart failure risk among individuals with and without obesity: The Atherosclerosis Risk in Communities (ARIC) study. *Circulation* **133** (7), 631–638.

dual-energy X-ray absorptiometry) in 2707 subjects from the Dallas Heart Study (Das et al., 2005). The authors found that the association between obesity and BNP/NT-proBNP was mediated by LBM rather than fat mass.

Despite their inverse relationship with BMI, natriuretic peptides still contribute to HF risk prediction in individuals with obesity. The interaction between obesity and NT-proBNP-related HF risk prediction was examined by Ndumele et al. in the ARIC study participants ($n=12230$) who had no HF at baseline (Ndumele et al., 2016a). The investigators found that, even after adjustment for other HF risk factors, elevated NT-proBNP levels were associated with increased relative risk of development of HF within each BMI group and across different demographic subgroups by age, sex, and race. However, relative HF risk attributed to NT-proBNP was blunted among those in the highest BMI groups (Fig. 5). Nadruz et al. examined the interaction between BMI and prognostic impact of natriuretic peptides in patients with HFrEF (Nadruz et al., 2016). The study was conducted in 8217 subjects from the PARADIGM-HF (Prospective Comparison of ARNI with ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure) trial with a median follow-up of 27 months. The investigators found that elevated BNP and NT-proBNP is a predictor of CVD mortality or HF hospitalization across different BMI groups. However, the interaction was weaker in patients with a BMI ≥ 35 kg/m^2 when compared to other BMI groups.

The Obesity Paradox in HF

Despite the significant association between obesity and development of HF, numerous studies have reported an obesity paradox in patients with HF. This phenomenon is usually characterized by a better prognosis in overweight or mildly obese HF patients compared to their leaner counterparts (Lavie et al., 2016b). Moreover, the worst outcomes are usually incurred by underweight HF patients, followed by normal-weight ones (Alpert, 2016). The obesity paradox was first described in 2001 by Horwich et al. who identified higher BMI as an independent predictor of improved survival in patients with advanced HFrEF (Fig. 6) (Horwich et al., 2001). Sharma et al. examined the impact of BMI on HF outcomes in a metaanalysis of six studies with a combined sample size of 22,807 and a mean follow-up duration of 2.9 years (Sharma et al., 2015). The analysis found the highest risk of HF hospitalization and total and CVD mortality in HF patients with the lowest BMI (BMI < 20 kg/m^2). In regard to the same end-points, overweight or obese HF patients had a better prognosis than their counterparts with normal weight (Fig. 7).

Evidence suggests that obesity paradox can be seen with HFrEF, HFpEF and acute decompensated HF (ADHF) (Kenchaiah et al., 2007; Padwal et al., 2014). Fonarow et al., using the ADHF National Registry Data from the United States ($n=108,927$ hospitalizations), demonstrated that a lower in-hospital mortality rate in ADHF patients with a higher BMI (Fonarow et al., 2007b). In fact, every 5-unit increment in BMI resulted in 10% reduction of mortality. A report by Shah et al. in patients with ADHF ($N=6142$) from 12 prospective cohorts followed-up across 4 continents found an association between higher BMI and lower 30-day and 1-year

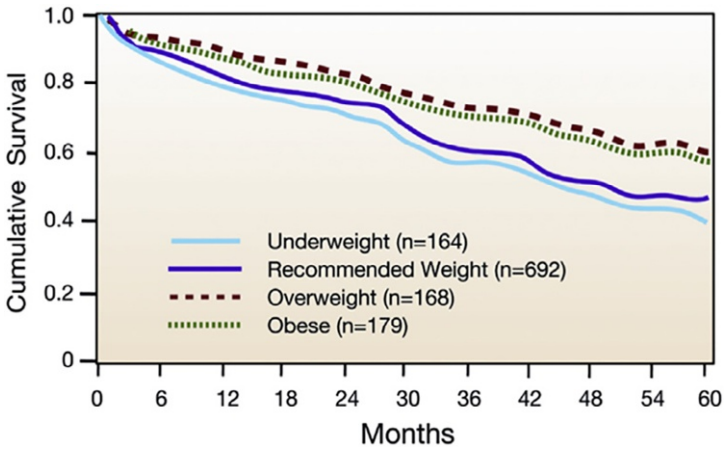

Fig. 6 Risk-adjusted survival curves for four body mass index categories after an average of 5 years of follow-up in a cohort of 1205 patients with advanced heart failure. Survival was significantly better in overweight and obese categories. Reproduced with permission from Horwich, T. B., Fonarow, G. C., Hamilton, M. A., MacLellan, W. R., Woo, M. A., Tillisch, J. H. mortality following ADHF hospitalizations (Shah et al., 2014). The obesity paradox was marked in older persons (>70 years of age), non-DM, and those with HFrEF and de novo HF diagnosis. Similarly, a study from Europe in chronic HF patients ($n = 2527$, mean follow-up = 4.3 years) showed an obesity paradox for only those without type-2 DM. And the obesity survival benefit was lost in the presence of type-2 DM (Zamora et al., 2016).

Most of the previous studies have reported obesity paradox in both sexes (Lavie and Ventura, 2015). However, a recent study by Vest et al. in patients with HFrEF (mostly advanced HF) suggested a sex-specific obesity paradox in their study population (Vest et al., 2015). The unadjusted data from the study revealed an obesity paradox in both sexes in regard to all-cause mortality. However, BMI-related survival benefit disappeared in males after adjustment for potential confounders. And overweight and obese males had a worse prognosis than normal weight males in the multivariable model. Contrarily, females in the overweight range had the lowest risk of mortality among all females after adjustment for confounders (Fig. 8). The cause of the interaction between sex and the obesity paradox remain poorly understood.

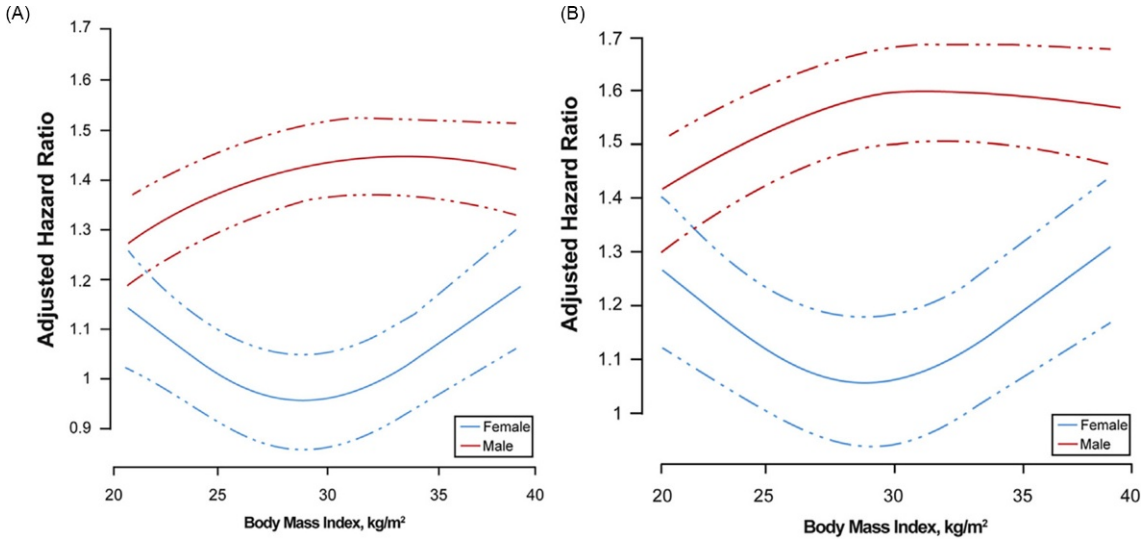

Fig. 8 Interaction plot between BMI and sex for nonischemic (A) and ischemic etiology (B). This retrospective study included 3,811 HFrEF patients who were referred for cardiopulmonary exercise testing. The hazard ratio was adjusted for other variables. The heart failure overweight/obesity survival paradox: The missing sex link. *JACC: Heart Failure* **3** (11), 917–926.

The interaction between BMI and HF prognosis is mostly nonlinear. For instance, in the metaanalysis by Sharma et al., increasing severity of obesity was not associated with further improvement of the outcomes in patients with chronic HF (**Fig. 7**) (Sharma et al., 2015). The obesity paradox observed in the female subjects of the study by Vest et al. had a U-curve-shaped pattern as well (**Fig. 8**) (Vest et al., 2015). In fact, female patients with chronic HF had a nadir in mortality just below 30 kg/m^2 and the mortality risk gradually increased toward the either end of the BMI spectrum. A metaanalysis of 14 HF studies with a total sample size of approximately 24,000 patients found a U-shaped curve for BMI–mortality relationship in both chronic HFrEF and HFpEF (Padwal et al., 2014). Joyce et al. demonstrated a U-shaped curve interaction between BMI and short-term outcomes in patients with ADHF ($n=795$) (Joyce et al., 2016). Different from chronic HF studies, adverse outcomes risk reached a nadir at a higher BMI range (40 kg/m^2).

BMI has been the most commonly tested variable in studies reporting the obesity paradox in HF. Few studies have examined the prognostic role of body composition and other obesity parameters in HF. We previously reported the obesity paradox with both BMI and % BF (estimated with skinfold technique) in 209 patients with chronic HFrEF (Lavie et al., 2003). In fact, every 1% increment in % BF was associated with a 13% reduction in major CVD events. Clark et al. reported improved outcomes with both higher BMI and higher WC in patients with advanced HFrEF (Clark et al., 2011, 2012). The investigators observed the best survival in those with both high BMI and high WC (Clark et al., 2011). A retrospective study by Kamiya et al. examined the prognostic impact of BMI, WC, mid-upper arm circumference (MUAC), a surrogate of muscle mass, in 570 consecutive Japanese patients with ADHF (Kamiya et al., 2016). The study found improvement in the prediction of mortality when BMI was combined with MUAC. Whereas, adding WC to BMI did not change the risk prediction. HF patients with high BMI and high MUAC had the lowest risk, while those with low BMI and low MUAC had the highest risk of mortality. These results suggested that the relationship between adiposity and HF prognosis is altered by muscle mass (**Fig. 9**) (Lavie et al., 2016c). A retrospective study by our group which assessed the effect of body composition on mortality in a large cohort of patients with HFpEF (N=47866) suggested that the protective component of obesity derives from lean body mass rather than fat mass (De Schutter et al., 2014).

Severe Obesity in HF

The prevalence of grade III or severe obesity has been rising dramatically in the general population, and it commonly affects patients with HF (Flegal et al., 2016). Severe obesity is overrepresented in patients with HF partially due to the dose-dependent relationship with BMI and risk of incident HF. Approximately 20% of HF subjects who were enrolled in contemporary ADHF trials were found to have severe obesity (Joyce et al., 2016). Severely obese HF patients tend to have distinctive clinical and biochemical profiles. For example, they are more likely female, younger, hypertensive, and diabetic and have more edema and lower natriuretic peptide levels on presentation (Joyce et al., 2016). HFpEF is more predominantly represented in the severely obese HF population than those in the other BMI groups (Joyce et al., 2016; Fonarow et al., 2007b).

The prognostic impact of severe obesity in patients with HF has not been studied as extensively as that of other weight groups (Alpert, 2016). However, abundant evidence has indicated ominous prognosis associated with severe obesity in HF patients, especially during long-term follow-up (Lavie et al., 2016a; Joyce et al., 2016; Vest et al., 2015; Nagarajan et al., 2013; Nochioka et al., 2010). Joyce et al. demonstrated that the risk of 60-day composite outcome (death, rehospitalization, or unscheduled provider visit)

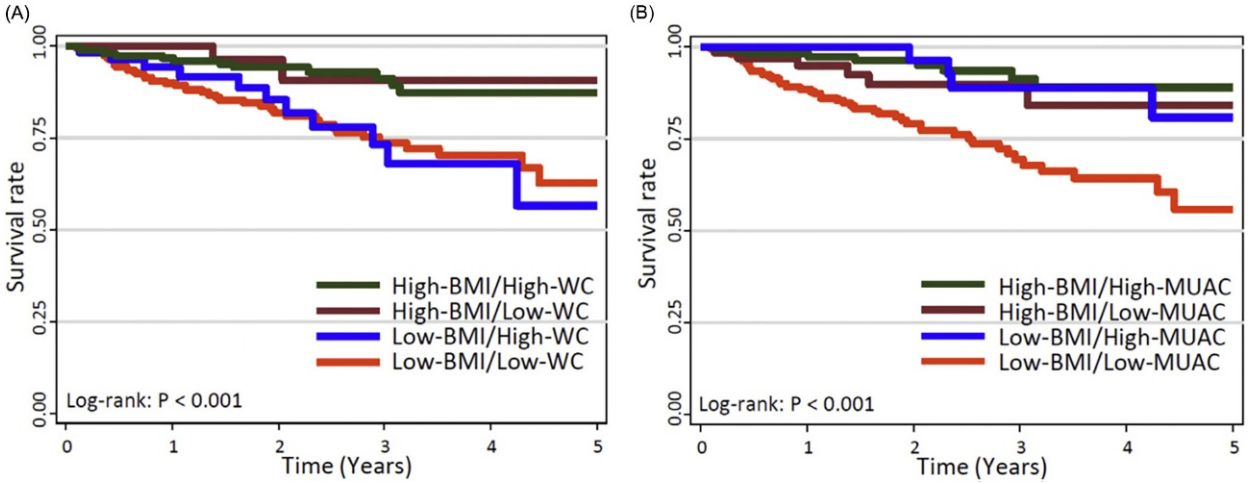

Fig. 9 Kaplan–Meier curves according to combined BMI and WC categories and combined BMI (A) and MUAC categories (B). *BMI*, body mass index; *MUAC*, mid-upper arm circumference; *WC*, waist circumference. Reproduced with permission from Kamiya, K., Masuda, T., Matsue, Y. et al. (2016). sharply rises in ADHF patients with BMI >40 kg/m.^{2} (Joyce et al., 2016) Nagarajan et al. reported that after adjustment for other variables, advanced chronic HF patients with severe obesity (BMI $\geq$40 kg/m^2) had ~2.5-fold higher risk of all-cause mortality/transplantation compared to their counterparts with grade I or II obesity (BMI 30.1–40 kg/m^2) (Nagarajan et al., 2013).

Frailty and Cachexia in HF

Frailty is defined as a state of declining overall and physiologic function that is associated with increased susceptibility to disability (Lavie et al., 2015a; Gustafsson et al., 2009). Frailty is very common in elderly patients with HF, and it is independently associated with risk of readmission, early disability, and long-term mortality (Vidán et al., 2016).

Cardiac cachexia is a serious and poorly understood syndrome which can affect patients with advanced HF. Unintentional weight loss is the seminal feature of cardiac cachexia. Cachexia was identified as a strong independent predictor of mortality in patients with HF even before the obesity paradox in HF was first described (Anker et al., 1997). Moreover, studies describing the obesity paradox usually demonstrated the greatest risk of adverse outcomes in the underweight or lowest-BMI groups (Sharma et al., 2015; Kenchaiah et al., 2007; Nochioka et al., 2010; Curtis et al., 2005). To some extent, better prognosis with higher BMI in HF may represent the reverse of cachexia or in other terms "reverse epidemiology." (Lavie et al., 2014) Melenovsky et al. examined the relative impact of wasting of fat mass and lean mass on adverse outcomes in advanced HF patients with cachexia (Melenovsky et al., 2013). The study found that loss of fat mass rather than LBM was associated with poor outcomes.

Mechanisms of the Obesity Paradox

The mechanisms of the obesity paradox remain poorly understood. **Table 3** lists the potential mechanisms of the obesity paradox. It has been argued that the obesity paradox may partially be explained by the limitations of BMI in reflecting the true level of adiposity (Lavie et al., 2016a). However, we and others have demonstrated that obesity paradox is not specific to BMI and can be seen with other obesity parameters (Lavie et al., 2003; Clark et al., 2011, 2012).

Higher Energy Reserves

HF is a catabolic state and cachexia may be a marker of disease severity in patients with advanced HF. In addition, overweight and obesity indicate higher energy reserves which may help the HF patients effectively deal with the high-energy requirements of the disease (Sharma et al., 2015; Shah et al., 2014). Inability to control for unintentional weight loss is a limitation for many studies examining the relationship between obesity and prognosis in patients with HF. It has been suggested that the worse prognosis observed in leaner HF patients may be due to unintentional weight loss prior to or during the study (Lavie et al., 2016a; Vest et al., 2015). However, a study by Khalid et al. in ARIC study participants (n = 1487 HF patients) showed an obesity paradox even with the BMI values measured 4.3 ± 3.1 years prior to the first diagnosis of HF (Khalid et al., 2014). In fact, premorbid overweight and obesity were associated with increased risk of incident HF. But still, individuals with premorbid overweight and obesity had better survival after the HF diagnosis than their counterparts with premorbid normal weight. This is against the assumption that cardiac cachexia is the main cause of poor prognosis in leaner HF patients.

Table 3 Mechanisms of the obesity paradox

Mechanisms of the obesity paradox
Higher energy reserves
Better nutritional status
Increased muscle mass and strength
Earlier presentation of heart failure
Compression of morbidity in lean individuals
Reverse epidemiology of detrimental effects of cachexia and frailty
Implications related to cardiorespiratory fitness
Better tolerability of heart failure medications
Attenuated response to blockage of the renin-angiotensin-aldosterone system
Genetic factors
Changes in cytokines and neuroendocrine profiles
Immune modulation
Mitochondrial function augmentation

Nutritional Status

The recent line of evidence suggests that nutritional status is an essential prognostic indicator in HF patients, and it plays a role in the obesity paradox. Gastelurrutia et al. examined the prognostic implications of nutritional status in 214 ambulatory HF patients from a single academic center in Spain (Gastelurrutia et al., 2015). The study defined undernourishment based on several variables such as serum albumin, total lymphocyte count, and anthropometric measures such as skinfold thickness and arm muscle circumference. The study found that the frequency of undernourishment was 60%–100% among underweight, 31%–44% among normal-weight, 4%–11% among overweight, and 0%–3% among obese HF patients. Moreover, malnutrition was a more significant predictor of poor survival compared to BMI. A similar interaction between malnutrition and prognosis has been demonstrated in ADHF patients as well (Casas-Vara et al., 2012).

Muscle Mass

Several studies have confirmed the protective effect of muscle mass and strength in patients with CVD, including HF (Kamiya et al., 2016; Casas-Vara et al., 2012; Fülster et al., 2013). The significant association between muscle mass and BMI appears to contribute to the improved outcomes in overweight or obese HF patients. In the study by Kamiya et al. which included 570 consecutive HF patients, 70% of individuals with high BMI (>23.2. kg/m^2) also had high muscle mass (determined by high MUAC) while only 19% of those with low BMI had high muscle mass (Kamiya et al., 2016). And as stated earlier, the study demonstrated the significant contribution of muscle mass in the prediction of improved survival in patients with HF.

It should be noted that not all obese individuals have increased muscle mass and strength. Low muscle mass in the presence of high BMI has been described as sarcopenic obesity (Carbone et al., 2017). This phenotype, in the general population, has been associated with 24% increased risk of all-cause mortality when compared to obese individuals without sarcopenia (Tian and Xu, 2016). Further research is needed to determine the prognostic impact of sarcopenic obesity phenotype in patients with HF.

Tolerability of HF Medications

Obese and overweight patients with HF are more likely to have higher systemic BP than their leaner counterparts because of the strong correlation between BMI and BP levels. This allows overweight and obese HF patients to tolerate more and higher doses of cardioprotective medications, such as beta-blockers and RAAS blockers (Lavie et al., 2013a; Sharma et al., 2015). Also there exists some evidence that individuals with higher BMI, compared to those with normal weight, experience more pronounced regression of LV remodeling in response to blood pressure lowering. A metaanalysis by Zang et al. found that overweight and obesity are independent predictors of marked LV regression in response to anti-HTN treatment (Zhang et al., 2014). In their analysis, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers were found to be the most potent agents for LVH regression in patients with overweight and obesity.

Compression of Morbidity

Obese individuals usually develop HF at an earlier age compared to their leaner counterparts (Ahmad et al., 2016). Some authors have raised the possibility that the BMI-dependent variation in the age of onset of the disease may contribute to the shorter life expectancy in leaner HF patients (Wang, 2016). This is also referred as "compression of morbidity" phenomenon which was first proposed by James Fries in 1980 (Fries, 1980). This phenomenon occurs if the onset of a chronic disease is postponed more rapidly than the improvement in life-expectancy (Fries, 2005).

Genetic Factors and Others

There exist no studies evaluating the genetic background of the obesity paradox. It can be hypothesized that leaner individuals who develop HF may have a more significant genetic predisposition for HF since they develop HF despite not having other HF risk factors, such as HTN, DM, and systemic inflammation. And this genetic predisposition for the onset of the disease may be associated with a poor clinical prognosis as well (Lavie et al., 2016a).

Several other potential mechanisms have been proposed for the obesity paradox. These include but not limited to adiposity-related changes in cytokines and neuroendocrine profiles (i.e., soluble tumor necrosis factor receptors, leptin, adipokines, etc.), immune modulation, and mitochondrial function augmentation (Shah et al., 2014; Lavie et al., 2014; Chess et al., 2009). We still need further research to test the possible interaction of these mechanisms with the obesity paradox in humans.

CRF, the Obesity Paradox, and HF

CRF is a strong predictor of prognosis in healthy individuals and cohorts with CVD (Lee et al., 2012; Kodama et al., 2009; Lavie et al., 2013b). Many studies have established the prognostic significance of CRF and other variables of cardiopulmonary exercise testing in HF (Lavie et al., 2013b; Guazzi et al., 2016; Osman et al., 2000). The classic cut-off point for classifying HF patients into low- and high-risk groups have been the peak oxygen consumption (VO_2) of 14 mL O_2/kg min (Mancini et al., 1991).

Several studies have indicated a strong interaction between CRF and the obesity paradox in patients with CAD and HF (Lavie et al., 2013b; McAuley et al., 2012). We previously demonstrated in a cohort of 2066 patients with chronic HFrEF that patients with a high CRF (peak $VO_2 \geq 14$ mL/kg min) have a better prognosis and an obesity paradox does not affect this patient population (Lavie et al., 2013b). Contrarily, a strong obesity paradox was present in those with a poor CRF. The worse outcomes were observed in leaner individuals with a poor CRF (**Fig. 10**). Similar results were reported in other cohorts of HFrEF from the United States and Europe (Piepoli et al., 2016; Clark et al., 2015).

Purposeful Weight Reduction in HF

Weight loss, achieved via diet, exercise, and/or bariatric surgery, can result in significant improvements of obesity-associated alterations in hemodynamics and cardiac structure and function (Lavie et al., 2015a). Hemodynamic changes associated with weight loss include a reduction in total and central blood volume, stroke volume, and CO. LV end-diastolic pressure and pulmonary capillary pressure usually, but not always, decrease following weight loss (Alpert et al., 2014).

A large body of evidence have demonstrated that weight reduction in overweight and obese individuals is associated with a decrease in LV mass and wall thickness and regression of LVH (Alpert et al., 2014; Ikonomidis et al., 2007; Jhaveri et al., 2009; Haufe et al., 2012). The improvement of LV geometry in response to weight loss is attributed to several mechanisms, such as reduction in cardiac loading and improvement in neurohormonal and metabolic abnormalities such as RAAS activation, sympathetic nervous system, and insulin resistance (Alpert et al., 2014; Ikonomidis et al., 2007).

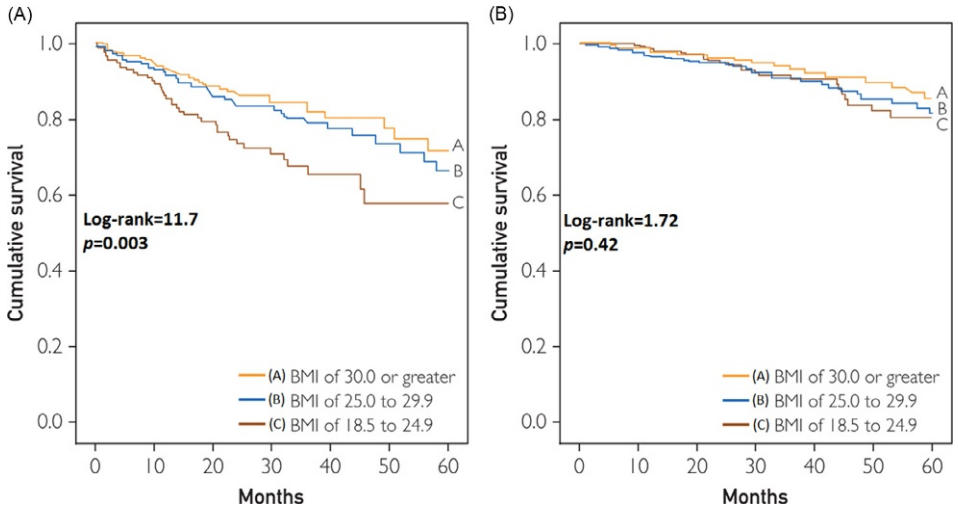

Fig. 10 Kaplan–Meier analysis according to BMI categories in the low cardiorespiratory fitness group (oxygen consumption <14 mL O_2/kg min) (A) and the high cardiorespiratory fitness group (oxygen consumption ≥14 mL O_2/kg min) (B). *BMI*, body mass index. Reproduced with permission from Lavie, C. J., Cahalin, L. P., Chase, P. et al. (2013). Impact of cardiorespiratory fitness on the obesity paradox in patients with heart failure. *Mayo Clinic Proceedings* **88** (3), 251–258.

Weight loss can lead to improvements in diastolic dysfunction (Ikonomidis et al., 2007; Alpert et al., 1997; Ashrafian et al., 2008). Because LVEF is usually within the normal range in obese individuals, most studies have not found any changes in LVEF in response to intentional weight loss (Alpert et al., 2014). A study by Vest et al. demonstrated that weight loss (by bariatric surgery) in severely obese patients with depressed LVEF led to a minimal but statistically significant increase in LVEF (Vest et al., 2016). Recent studies using speckle-tracking echocardiography reported significant improvement in LV and RV strain following bariatric surgeries (Kaier et al., 2014; Koshino et al., 2013; Shin et al., 2016).

Scientific evidence on the safety and efficacy of weight loss with diet, exercise training (ET), or bariatric surgery in obese HF patients remains limited. We still do not know if purposeful weight loss has any impact on mortality in patients with HF. Shimada et al. recently examined HF hospitalization rates in a population-based cohort ($n = 524$) of patients with HF who underwent bariatric surgery (Shimada et al., 2016). The study demonstrated 43% decrease in the rate of ED visits and hospitalizations for ADHF following 2 years after the surgery. Kitzman et al. recently compared the impact of aerobic ET and caloric restriction (via diet) on exercise capacity (measured by peak VO_2 consumption) in obese patients with chronic HFpEF ($n = 100$) (Kitzman et al., 2016). The investigators found that weight loss with diet was associated with significant increase in exercise tolerance. In addition, a combination of diet and exercise training led to a more robust improvement.

The most recent guidelines on the management of patients with HF do not provide firm recommendations regarding purposeful weight loss in obese HF patients (Yancy et al., 2013). Nevertheless, these guidelines recognize the detrimental effect of severe obesity in patients with HF. Based on available data, purposeful weight loss may be reasonable in HF patients with severe obesity. More importantly, interventions in HF patients with obesity should focus on physical activity (PA), ET, and improving CRF, regardless of the effect on BMI (Carbone et al., 2017). Clearly, ET, increased PA, and improved CRF have been demonstrated to reduce the risk of adverse outcomes in patients with HF, regardless of BMI (Lavie et al., 2015b). The ideal type of ET (aerobic-type vs. resistance ET) for HF patients is not well established. Based on the data supporting the protective role of LBM, particularly appendicular muscle mass, resistance ET can be considered to increase muscle mass and strength (Carbone et al., 2017; Lavie et al., 2016c).

Conclusions

Obesity adversely impacts CV structure and function and is associated with increased risk of HF. Not surprisingly, obesity is commonly seen in patients with HF. Despite being a risk factor for the development of HF, overweight and obesity exert protective effects once HF is manifest. The obesity paradox is now a well-established phenomenon which is observed across different ethnicities and regardless of the type (HFpEF vs. HFrEF), acuity (acute vs. chronic) and etiology (ischemic vs. nonischemic) of HF. The relationship between BMI and adverse outcomes in HF usually demonstrates a U-shaped curve pattern with the poorest prognosis in underweight and to a lesser extent in severely obese patients and a nadir of risk with overweight and mild obesity. CRF is the strongest mediator of the interaction between BMI and prognosis in HF. Growing evidence suggests that LBM, compared to fat mass, has more significant prognostic implications in patients with HF. Therefore, instead of just relying on BMI, body composition-based risk stratification in HF may help with identifying patients at higher risk of adverse outcomes. There still exists a knowledge gap in regard to safety, efficacy, and optimal strategy for intentional weight loss in HF patients with obesity. Nevertheless, increased PA/ET with the goal of improved CRF should be considered in all patients with HF to decrease adverse outcomes.

Introduction: The Essential Points of Oral Health

The oral cavity is the entrance to the digestive tract, and as such is not only responsible for ingesting the nutrients and fluids essential to life by means of mastication and swallowing, but it is also an important organ for establishing humans as social beings by way of oral communication. The oral cavity is a luminal structure stretching from the lips to the fauces, which form the border with the oropharynx, which is bordered by the surrounding maxillae (palate), mandible, lips, and cheeks and contains the teeth and tongue. The mobile tissues, including the lips, cheeks, mandible, and tongue, are skillfully controlled by the muscles to enable eating and speech to proceed smoothly, and the coordination of their movements with the shape of the teeth, gingiva, palate, and other immobile tissues is critical for this process. The moist environment of the oral cavity is constantly maintained by saliva distributed from the salivary glands to ensure that the mouth remains mobile.

As the entrance to the digestive tract, the oral cavity is responsible for acting to process food into an easily digestible state (by chewing). The mouth is an extremely delicate sensory organ equipped to tactile sense, pressure, temperature, and taste, instantly discriminating between foods to reject dangerous substances and controlling the muscle activity and mandible movement required for mastication in accordance with their physical properties. These oral sensations create the taste of food and are the source of the psychological action of taking pleasure in eating. Saliva is secreted in large quantities during eating to process food into a bolus that is easily swallowed and digest carbohydrates. The antimicrobial and immune substances in saliva fulfill the role of biochemical defense mechanisms in the oral cavity.

The main goals of dental treatment are to develop, maintain, and restore the functions exerted by the normal morphology of the mouth described previously. Caries and periodontal disease (PD), the two major diseases of the oral cavity, are both caused by bacterial infection, but despite the great efforts expended on their suppression and treatment since the establishment of modern dental science, they have yet to be defeated. The association between chronic inflammation of the periodontal tissue due to periodontal pathogen has become a focus of attention in recent years, and since the turn of the century, research on this subject been particularly active. Diseases and abnormalities already found to be associated with PD include arteriosclerosis (Lockhart et al., 2012), cardiovascular disease (Khader et al., 2004), diabetes mellitus (Saito et al., 2004), obesity (Saito et al., 2001), rheumatism (Hashimoto et al., 2015), aspiration pneumonia (Abe et al., 2006), and premature birth (Offeenbacher et al., 1996).

In its initial stage, PD comprises subgingival inflammation of the gingiva due to periodontal bacteria in plaque that has built up in the gingival sulcus. As it progresses, gingival pockets develop, and the bacteria penetrate more deeply, the alveolar bone breaks down, and symptoms such as ulceration, teeth mobility, and occlusal pain appear, ultimately leading to tooth loss. Among individuals aged 35–44 years, the prevalence of periodontal disease is approximately 50% in Europe and North America (Peterson et al., 2005) and approximately 25% in Japan (Ministry of Health, Labour and Welfare, 2011), making it the most important cause of tooth loss in middle age and later, even in developed countries with widely available dental care. Suffering from PD thus not only diminishes oral health in two senses, both through long-term exposure to inflammation and through loss of masticatory function as a result of tooth loss, but it has also been implicated in the development and aggravation of a range of

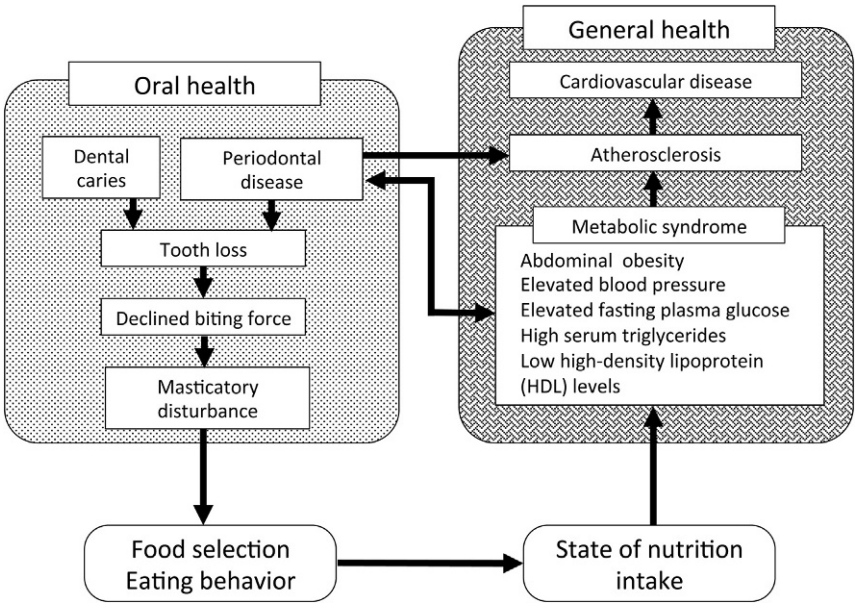

Fig. 1 A simplified image of the impact of oral health on cardiovascular disease with the novel aspect.

systemic conditions. The objective of this review is to outline recent findings on PD as a risk factor for cardiovascular disease and future prospects for its prevention based on the novel aspect of comprehensive oral health (Fig. 1).

Metabolic Syndrome and Oral Health

The association between metabolic syndrome (MetS) and PD has been well studied in the epidemiological way. In this section, we describe findings on the association between MetS and its various risk factors and oral health, particularly PD. Most of studies about the association between MetS and oral health treated PD as a marker of oral health, and few studies treated tooth loss as a surrogate maker of current and past PD. As for the diagnostic criteria for MetS, Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol in Adults (NCEP-ATP III) criteria was most popularly used in those studies, and the Japanese diagnostic criteria, the American Heart Association and the National Heart, Lung and Blood Institute (AHA/NHLBI) criteria, the International Diabetes Federation (IDF) criteria, the European Group for the Study of Insulin Resistance criteria and integrated versions of these diagnostic criteria were also used.

Individuals with MetS have also been found to be at higher risk of PD than those without (Morita et al., 2009; Timonen et al., 2010; Sora et al., 2013; Minagawa et al., 2015). It was found that patients who are positive for a high number of components of MetS have a higher prevalence of PD (Khader et al., 2008; Kushiyama et al., 2009; Han et al., 2010; Andriankaja et al., 2010; Furuta et al., 2013; Lee et al., 2014). Shimazaki et al. (2007) reported that women who were positive for a higher number of components of MetS were at higher risk of PD, and those who were positive for four or more components were 6.6 times more likely to suffer from PD than were individuals with none. Self-reported number of teeth in Swedish of 70 years old was fewer in those with MetS than those without, and inversely related with inflammatory makers such as leukocyte and C-reactive protein (Holmlund et al., 2007).

Conversely, individuals in a poor periodontal state have been found to be at high risk of MetS (D'Aiuto et al., 2008; Li et al., 2009; Han et al., 2010; Nesbitt et al., 2010; Bensley et al., 2011; Chen et al., 2011; Kwon et al., 2011; Fukui et al., 2012; Tu et al., 2013). In Finish people of 45–74 years old, more than four missing teeth and complete edentulousness were associated with MetS with odds ratio at 1.69 and 1.93 respectively (Hyvärinen et al., 2015). Analysis by the data of The National Health and Nutrition Examination Survey also found the increase of odds ratio for MetS depending on the increasing of missing teeth (Zhu and Hollis, 2015). These conclusions have all been derived from cross-sectional epidemiological studies, and mention of possible causality has been regarded as problematic.

In 2010, however, a cohort study was published that suggested that PD may aggravate MetS (Morita et al., 2010). Moreover, Kaye et al. (2016) found that the risk of tooth loss was 1.39 times greater for individuals who suffered from MetS at baseline compared with those who did not, suggesting that MetS may worsen the condition of the gingiva. At present, few cohort studies of MetS and oral health have been performed, and further evidence is required to elucidate the causal relationship between them.

Studies have addressed not only the relationship between PD and MetS, but also its component factors of obesity (Saito et al., 1998; Chafee and Weston, 2010; Morita et al., 2011), impaired glycometabolism (Taylor, 2001; Mealey, 2006; Demmer et al., 2010; Sora et al., 2013), dyslipidemia (Nibali et al., 2007; Lee et al., 2013), and hypertension (Vidal et al., 2011). With respect to hypertension and oral health, the risk of hypertension increases if tooth loss and other aggravated oral conditions are also present in

addition to PD (Iwashima et al., 2014). Although each causal relationship is still controversial, recent longitudinal and intervention studies suggested pathological pathway between PD and obesity (Gorman et al., 2012), impaired glycometabolism (Sgolastra et al., 2013) and dyslipidemia (Acharya et al., 2010), which could be expected to lead new strategies for preventing MetS.

Ischemic Heart Disease and Oral Health

Since Mattila et al. showed in 1989 that oral health is associated with the occurrence of myocardial infarction, attention has focused on the association between PD and ischemic heart disease, and this has now been well studied. According to a 2004 metaanalysis (Khader et al., 2004) that drew on seven cohort studies and four cross-sectional studies, individuals with PD have a relative risk of coronary artery disease of 1.15, but no association was observed between the number of teeth and coronary artery disease. A later metaanalysis (Bahekar et al., 2007) that drew on five cohort studies, five case-control studies, and five cross-sectional studies found that individuals with PD have a relative risk of ischemic heart disease of 1.14 in cohort studies, with the odds ratio of 2.22 in the case-control studies and 1.59 in the cross-sectional studies. An analysis of the association between the number of teeth and ischemic heart disease also found that, for patients with $\leq$10 teeth, the relative risk of coronary artery disease was 1.24. In 2012, however, the American Heart Association (AHA) published a systematic review in which they compared 500 studies that had reported an association between these conditions, and they found that there was insufficient evidence that PD has any effect on the development or progression of ischemic heart disease (Lockhart et al., 2012). After this statement, it was found by 13 years follow-up survey in 8446 Finish people that having more than five missing teeth was associated with coronary heart disease events and acute myocardial infarction with the relative risk of 1.62–1.99 and 2.10–2.39 respectively (Liljestrand et al., 2015).

The Mechanism of Atherosclerosis due to Periodontal Bacteria

A range of factors related to chronic inflammation has been implicated in the progression of arteriosclerosis, including hyperlipidemia, obesity, smoking, and genetic factors (Okuda et al., 2004). Relationship between periodontal pathogens forming a biofilm and arteriosclerosis was researched since the 1980s. It was suggested that infections due to organisms, bacterium and viruses might contribute to arteriosclerosis by causing inflammation within vascular tissue. Based on a series of studies, the theory that cell damage due to vascular inflammation is implicated in the formation of atheromata was published (Ross, 1999). Studies of the mechanism whereby periodontal bacteria contribute to arteriosclerosis have been carried out on the basis of this theory.

Invasion of the Bloodstream by Periodontal Bacteria

Periodontal pathogens in dental plaque frequently enter the bloodstream. This invasion is particularly common when PD is advanced, with the formation of deep pockets. Various studies have showed that pathogenic periodontal bacteria and their toxic products have been implicated in a range of circulatory problems. Firstly, it was found that the aggregation of human red blood cells is caused by lipopolysaccharides (LPS), an endotoxin of periodontal pathogens (Okuda and Kato, 1986). Later studies have shown that the platelet aggregation is also caused by bacteria in dental plaque (Herzberg and Weyer, 1998; Imamura et al., 2003). Moreover it was showed that the aggregation of human blood cells is caused by the platelet-aggregating action of *Porphyromonas gingivalis* (*P. gingivalis*, Naito et al., 2006). These findings showed that pathogenic periodontal biofilm-forming bacteria such as *P. gingivalis* enter the bloodstream of individuals with PD and cause the blood to coagulate, contributing to the impairment of blood flow.

Detection of Periodontal Bacteria at Sites of Arteriosclerosis

Numerous studies have detected periodontal pathogenic bacteria from atherosclerotic foci. It was firstly reported that *P. gingivalis* was detected in carotid artery samples collected during carotid endarterectomy by carrying out immunostaining with specific antibodies (Chiu, 1999). Later, another study group detected periodontal pathogens in extracted DNA from samples collected during carotid endarterectomy (Haraszthy et al., 2000). Furthermore, the detection rates of periodontal pathogens in the mouths of patients who underwent coronary artery bypass surgery and in samples of the arterial wall obtained during surgery was investigated, it was found that periodontal pathogens were detected in coronary artery wall samples, and that the detection rate was higher in patients with severe PD (Ishihara et al., 2004). These results suggest that periodontal pathogens that have transiently entered the bloodstream reach the vascular wall of the coronary artery, and that the frequency with which this occurs is associated with the severity of PD.

Analysis of the Mechanism from Animal Experiments

As stated previously, there has been a huge clinical data accumulation suggesting the relationship between PD and atherosclerosis. However analysis of etiology by using clinical samples has limitations, so various animal experiments have been conducted in order to detect the mechanism by which periodontal pathogens affect on the formation of atherosclerosis.

The apoE-knockout mice that had been fed by a high-fat diet and infected *P. gingivalis* intravenously had more promotion of arteriosclerosis in the proximal aorta than in uninfected mice (Li et al., 2002). In another study, it was found that there were more sites of aortic atherosclerosis in apoE-knockout mice that had been inoculated with *P. gingivalis* intraorally in the mouth than in uninfected apoE-knockout mice (Lalla et al., 2003). These findings showed that *P. gingivalis* promote progression of arteriosclerosis in apoE-knockout mice. Furthermore, it was found that greater fat deposited in the aortas of rabbits received *P. gingivalis* after ligatures around teeth than in those of unaffected rabbits, suggesting that *P. gingivalis* also acts to promote atherosclerosis formation in normal animals that have not undergone any particular gene knockout (Jain et al., 2003). Later, it was found that *P. gingivalis* developed coronary atherosclerosis by an experiment on pigs after having been inoculated intravenously with *P. gingivalis* (Brodala et al., 2005). Taken together, these early findings from animal experiments suggest that the infiltration of the vascular wall by *P. gingivalis*, or the action on vascular endothelial cells or immunocompetent cells of components of bacterial bodies that have infiltrated the bloodstream, may be implicated in promoting the formation of atherosclerosis. Furthermore it was understood by numerous researches that cytokines produced in the inflated periodontal tissue also entered the circulation and might induce general inflammation (Preshaw and Taylor, 2011).

However, a new pathogenic pathway from PD to general inflammation has been provided in recent years. Firstly, it was found that an elevation of serum inflammatory biomarkers in mice with repeated oral inoculation of *P. gingivalis* was not accompanied with detection of bacteria in the blood and remarkable inflammatory cell infiltrate in the gingival tissue (Maekawa et al., 2011). Based on those results, the same research group tested the hypothesis in mice that disturbances of gut microbiota by swallowed *P. gingivalis* induced a metabolic endotoxemia leading metabolic disorders and demonstrated the alteration of gut microbiota and inflammatory changes in various tissue and organs (Arimatsu et al., 2014). Furthermore, it was found that oral administration of *P. gingivalis* caused the dissemination of enterobacteria to liver by increasing intestinal permeability associating the changes in gut microbiota (Nakajima et al., 2015). These findings suggested that disturbance of the gut microbiota composition by swallowed periodontal pathogen might be causal mechanism between PD and systemic disease.

On the other hand, it was reported that *P. gingivalis* infection from the pulp chamber in obese mice accelerated free fatty acid induced endothelial injury with the in vitro finding that *P. gingivalis* and its LPS both attenuated cytokine production in human umbilical vein endothelial cells, suggesting the pathway by which dental infection of *P. gingivalis* might contribute to pathogenesis of atherosclerosis (Ao et al., 2014). Thus it is expected that further researches using animal model provide novel and comprehensive knowledge about the interrelationship between PD and atherosclerosis as well as relating general diseases.

Periodontal Treatment and Improvements in Risk Markers for Arteriosclerotic Disease

Risk markers for arteriosclerotic disease include serum lipids and serum inflammatory markers. In the Japanese Hisayama Study, HDL cholesterol levels were found to be significantly lower in the population with PD than in those in the population without (Shimazaki et al., 2007). Individuals with PD with a high serum antibody titer for periodontal pathogens have also been found to have significantly higher LDL cholesterol levels (Kudo et al., 2015).

CRP is not only a marker of systemic inflammation, but it has also been found to be a useful risk marker for coronary artery disease (Bisoendial et al., 2005), and serum CRP concentration has been shown to be significantly elevated in individuals with PD compared with healthy individuals (Loos et al., 2000). It has been suggested that the inflammatory cytokines TNF and interleukin (IL-1, IL-6, and IL-8) are also elevated as a result of PD (Loos, 2005), but consensus has yet to be achieved on this point. Further studies are required to ascertain whether the elevation of inflammatory markers as a result of PD is sufficient to cause the development or progression of arteriosclerotic disease. Individuals with PD often also develop obesity, diabetes, hypertension, and other lifestyle-related diseases as a result of their own particular lifestyles, and epidemiological studies must also take this fact into account.

The implementation of treatment for PD has been shown to reduce the levels of factors such as IL-6 and CRP (Nakajima et al., 2010). In terms of serum lipid levels, periodontal treatment has been shown to improve the level of HDL (Pussinen et al., 2004). Some studies have also shown that serum inflammatory markers and lipids were more improved when intensive periodontal treatment was performed (D'Aiuto et al., 2006). Lee et al. compared individuals with PD who underwent treatment with untreated individuals, and they found that the incidence of ischemic heart disease was higher in the untreated group (Lee et al., 2013).

Future Prospects for Research

Gender Difference

Although several studies have shown that the association between MetS and oral health is stronger in women (Shimazaki et al., 2007; Andriankaja et al., 2010; Lee et al., 2014), some studies have found a stronger association in men (Morita et al., 2009). A study of postmenopausal women did not find a significant correlation between MetS and oral health (LaMonte et al., 2014). With respect to the association between obesity and oral health, some studies have found a strong correlation in women (Morita et al., 2011), while others have shown that male obesity increases the risk of progression of PD (Saito et al., 1998). These discrepancies may be due to differences in the diagnostic criteria for MetS used and the assessment of indicators of oral health, as well as the age and race

of subjects. More studies are therefore required to identify the reasons underlying sex differences in the association between oral health and MetS, and which should be considered in the future health promotion.

Diagnostic Criteria for Periodontal Disease

As described in Introduction, PD comprises subgingival inflammation of the gingiva due to periodontal bacteria in its initial stage. As it progresses, periodontal tissue is destroyed, gingival pockets develop and the alveolar bone breaks down. Parameters for diagnosing PD and evaluating its severity are quite various such that bleeding from gingival sulcus, pocket depth, tooth mobility, absorption of alveolar bone measured on the X-ray photo, and so on. Inconsistencies between the results of studies of PD and arteriosclerosis may be due to differences in the indices used to measure PD and the diversity of definitions used, as well as to difficulties in comparing data between studies and from different regions. Larger-scale, long-term epidemiological studies are required that utilize a consistent study design, including disease definitions, and that are based on objective, unified assessment indices. Since studies have also found that many risk factors are common to both PD and ischemic heart disease and, therefore, constitute confounding factors (Peacock and Carson, 1995; Hujoel et al., 2000), these confounding factors must also be taken into consideration.

Masticatory Ability

It was pointed out that tooth loss as a result of PD or dental caries reduced masticatory ability and might change in dietary intake having an adverse effect on nutritional intake (Appollonio et al., 1997; Krall et al., 1998; Sheiham et al., 2001; Kanmori et al., 2003). Recent epidemiological surveys with a large number of participants have provided detailed knowledge how the tooth loss influences on the state of food and nutrition intakes. As for the impact of complete tooth loss (edentulism), questionnaire survey in US women revealed that edentulous US women have higher intakes of saturated fat, trans fat, cholesterol, and vitamin B12, and lower intakes of polyunsaturated fat, fiber, carotene, vitamins C, E and B6, folate, and potassium compared with women with 25–32 teeth (Hung et al., 2005). In Sweden, odds ratio for obesity in edentulous women aged 55–74 years increased from 1.64 in 1980 to 3.17 in 2002 (Österberg et al., 2010). Additionally in Pomerania, Germany, edentulism was associated with the increased odds of high inflammatory makers such as C-reactive protein and fibrinogen comparing with dentate subjects (Meisel et al., 2012). These reports suggested that edentulism might have negative impact on the intake of cardiovascular disease related nutrients and could be the risk for obesity.

As for the impact of number of remaining teeth on food and nutrient intakes, it was found in US adult civilians without prosthesis that people with fewer than 28 teeth had lower intakes of carrots, tossed salads, and dietary fiber than did fully dentate people, and lower serum levels for carotene, folate, and vitamin C (Nowjack-Raymer and Sheiham, 2007), and in Japanese dentists that carotene, vitamins A and C, milk, and vegetables decreased with the decreasing number of remaining teeth and carbohydrate, rice and confectionaries increased among people with fewer teeth (Wakai et al., 2010). These findings suggest that the decline in masticatory function caused by the progression of PD or dental caries and the resulting tooth loss may contribute to MetS by way of eating behavior and nutritional intake.

Against this backdrop, novel objective assessments of masticatory function have been introduced in some cohort studies in Japan. In SONIC Study which investigated the health and longevity of septuagenarians, octogenarians, nonagenarians, and centenarians, the maximal biting force measured by pressure-sensitive sheets was associated with intakes of vitamins and dietary fiber rather than number of remaining teeth (Inomata et al., 2014). In the Suita Study (Kokubo et al., 2008), a cohort study on the risk of cardio- and cerebrovascular diseases in Japanese urban general population including dental examinations with objective masticatory performance assessments using gummy jellies (Kosaka et al., 2014; Kikui et al., 2015; Kosaka et al., 2016), it was found that lower masticatory performance and poorer periodontal state associated with the prevalence of MetS in both cross-sectional (Kikui et al., 2017a,b). It is expected that longitudinal analysis on the association among objectively assessed oral health, food and nutrition intakes, prevalence of MetS components, and incidence cardiovascular disease will provide a lot of knowledge.

Consequences

As shown by the results of the numerous studies described in this article, there appears to be some sort of association between cardiovascular disease, MetS, and oral health, mainly PD. However, at this point, the evidence is insufficient to establish the direction of this association and its causality. More studies are therefore required in the future, and basic research and clinical interventional studies, in addition to longitudinal epidemiological studies, may help to clarify the association among them. It is also expected to establish the objective clear-cut methods for evaluating oral health makers such as the state of periodontal disease, masticatory performance, and so on, which enable more concrete collaboration between physicians and dentists, based on the novel aspect of the prevention of cardiovascular disease.

Introduction

Syncope is defined as a sudden transient loss of consciousness secondary to cerebral hypoperfusion with a loss of postural tone followed by a rapid and spontaneous recovery (Moya et al., 2009). It is a very common presenting complaint to many health care providers including physicians working in the emergency department, primary care office, and cardiology or neurology clinics.

There are many underlying etiologies for syncope, however, several broad classifications exist. These include cardiac syncope, neurally mediated (or reflex) syncope, and orthostatic hypotension (OH) (Wieling et al., 2009; Moya et al., 2009). Cardiac syncope refers to syncope occurring secondary to underlying heart disease, most commonly a structural, obstructive, or arrhythmia-based pathology. Vasovagal syncope (VVS), the most common form of neurally mediated syncope, refers to an abrupt change in autonomic control resulting in vasodilation, bradycardia, and subsequent cerebral hypoperfusion (Sheldon et al., 2015). In contrast, OH is most commonly defined as a sustained decline in blood pressure (BP) $\geq$20 mmHg systolic BP or $\geq$10 mmHg diastolic BP within 3 min of assuming an upright position (Freeman et al., 2011).

VVS and OH are two of the most common presentations for syncope. Here, we will review the normal physiology of standing and definitions, etiology, approach to diagnosis, and management strategies for both conditions.

The Physiology of Standing

In a normal individual, approximately 25%–30% of their blood volume is located in the thorax while they are supine (Grubb, 2005). Assuming an upright posture, from either a supine or seated position, triggers the cardiovascular system to react to the increased effects of gravity (**Fig. 1A**). It does so by initiating a downward shift of 500–1000 mL of blood to the capacitance vessels of the lower extremities and splanchnic circulation (Nwazue and Raj, 2013; Chisholm and Anpalahan, 2016). Secondarily, increased hydrostatic pressure in these tissues leads to a substantial loss of plasma volume from the vasculature into the interstitial tissue (Robertson, 2008). These physiological changes result in decreased venous return, decreased cardiac output, and eventually in decreased BP.

The mechanisms involved with the compensatory effects against orthostatic stresses are mainly controlled by the autonomic nervous system, and include both arterial and cardiopulmonary baroreceptors (Tanaka et al., 1996). The high-pressure baroreceptors in the carotid sinus and aortic arch and low-pressure receptors in the heart and lungs are "unloaded," which triggers a reflex sympathetic activation and inhibition of parasympathetic activity (Nwazue and Raj, 2013; Feldstein and Weder, 2012). This causes an increase in heart rate (HR) and systemic vasoconstriction, thereby countering the initial decline in BP (**Fig. 1B**). As a result, in a healthy individual, assumption of an upright posture does not result in major changes in BP. The net effects typically include a transient drop in systolic BP of 10–15 mmHg, a slight increase in diastolic BP of approximately 5–10 mmHg, and a rise in HR of 10–25 bpm (Chisholm and Anpalahan, 2016).

In the instance of a prolonged orthostatic challenge, neurohumoral responses may occur, including the activation of the renin-angiotensin-aldosterone system (Medow et al., 2008). This further contributes to vasoconstriction.

The autonomic nervous system plays a substantial homeostatic role in response to changes in posture. Autonomic dysfunction can result in a lack of counter-regulation and may lead to OH, resulting in falls, presyncope, and syncope (**Fig. 1C**). Alternatively, normal compensatory responses to standing can abruptly turn off leading to a fainting spell, as is the case in VVS (**Fig. 1D**).

Vasovagal Syncope

VVS is defined as a form of syncope that is typically associated with hypotension and relative bradycardia, followed by fatigue (Sheldon et al., 2015). It usually occurs with the assumption of an upright posture for greater than 30 s, or with exposure to emotional stress, pain, or medical settings. There are several common symptoms of the disorder, including diaphoresis, warmth, nausea, and pallor. The 30-s time requirement is used to exclude patients presenting with initial OH (Raj and Sheldon, 2016).

Epidemiology

The incidence of syncope follows a bimodal distribution with an initial peak around 15 years of age with a second rise beginning after 70 years of age (Serletis et al., 2006; Ganzeboom et al., 2006; Colman et al., 2004). The cumulative incidence of an episode of syncope is estimated to be approximately 35% by age 60 (Ganzeboom et al., 2006; Serletis et al., 2006). It is suggested that 30%–50% of patients presenting with syncope have an autonomically mediated form, of which VVS is the most common (Sheldon et al., 2015). VVS is also more common in females (65%F:35%M) (Serletis et al., 2006; Ganzeboom et al., 2006; Sheldon et al., 2006, 2016). VVS is not associated with an increased risk of mortality (Sheldon et al., 2015).

Etiology

The pathophysiological basis for VVS leading to a syncopal episode is secondary to volume depletion leading to decreased venous return and preload; this leads to a baroreceptor response to increase HR, contractility, and increased vascular tone aimed at maintaining BP (Coffin and Raj, 2014a). Such a state can occur following triggers for VVS. The low venous return combined with increased cardiac contractility is thought to lead to an underfilled ventricle, which activates cardiac mechanoreceptors (Coffin and Raj, 2014a). This leads to a sudden reversal of autonomic responses resulting in vasodilation and bradycardia (a form of the Bezold-Jarisch reflex) (Folino, 2007).

The most common precipitants for VVS include pain, fear, orthostatic stress, and emotional distress (Thijs et al., 2009). This form is commonly accompanied by typical prodromal symptoms and is most frequently seen in younger individuals (Freeman et al., 2011).

There are also patients with VVS who present with an atypical presentation, where the precipitating event or trigger is unknown, but patients have a positive response during formal orthostatic stress testing (Alboni, 2015). Older adults are more likely to present clinically in this fashion and will less frequently feature classic prodromal symptoms (Freeman et al., 2011).

Clinical Evaluation

It can be challenging to determine the underlying etiology for a syncopal episode upon initial presentation. An initial assessment of a patient presenting with syncope is estimated to identify the cause of syncope anywhere from 23% to 60% of the time (Crane,

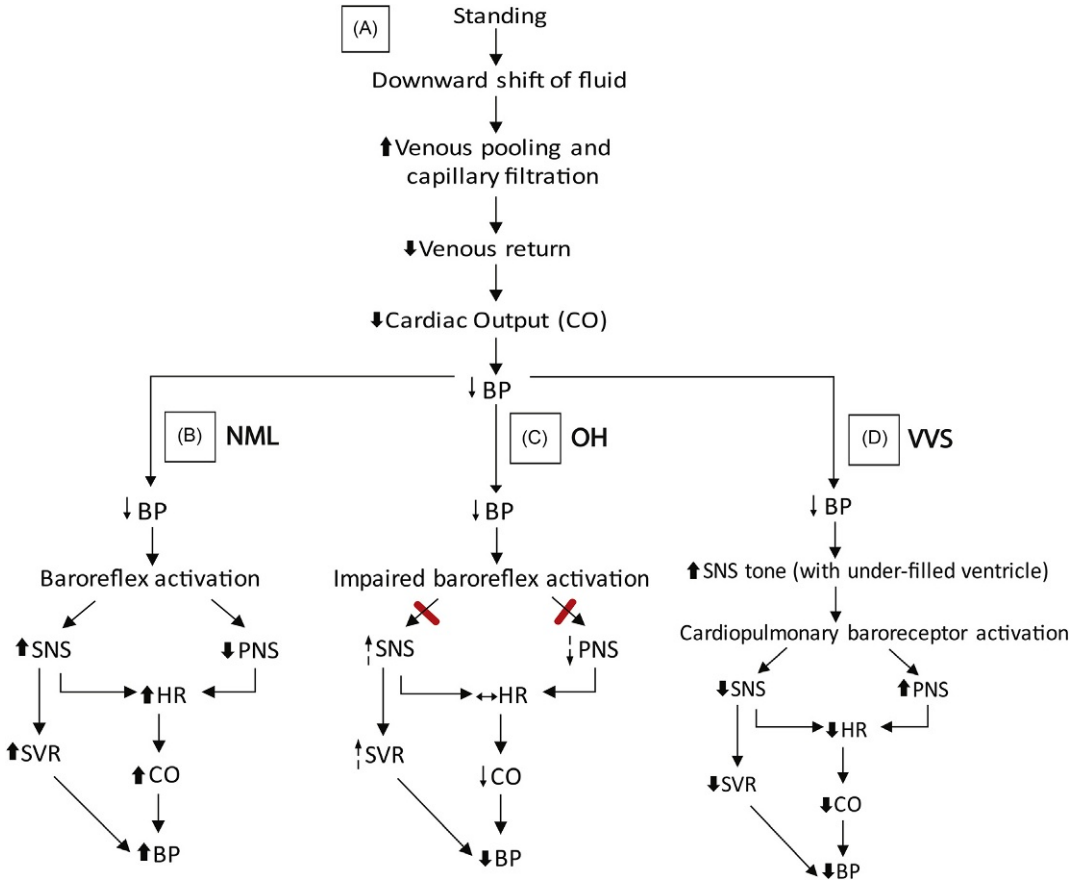

Fig. 1 The physiology of standing (A) with normal compensatory responses (B), as well as the pathophysiology of orthostatic hypotension (C) and vasovagal syncope (D). Normally, the blood pressure decline observed after standing is acutely compensated through a baroreceptor-mediated increase in sympathetic activity and decrease in parasympathetic activity. For patients with orthostatic hypotension, baroreflex responses are impaired resulting in a blunted response that cannot adequately compensate to maintain blood pressure. For patients with vasovagal syncope, standing leads to an underfilled ventricle causing cardiopulmonary baroreceptor activation. This results in a sudden reflex-triggered reversal of normal compensatory responses maintaining blood pressure. *CO*, cardiac output; *BP*, blood pressure; *NML*, normal; *OH*, orthostatic hypotension; *VVS*, vasovagal syncope; *SNS*, sympathetic nervous system; *PNS*, parasympathetic nervous system; *SVR*, systemic vascular resistance.

2002; Croci et al., 2002). This typically will include a careful history, physical examination including orthostatic vital signs, and a resting 12-lead electrocardiogram (ECG) (Moya et al., 2009). Despite the challenges in making the diagnosis on initial evaluation, understanding the key questions to ask on history and signs to look for on examination can be very helpful toward making the correct diagnosis and dictating the need for further investigation.

History and physical exam

The evaluation of a patient presenting with any form of syncope begins with a detailed history. It is important to categorize the nature of the event, including any symptoms or mechanisms leading up to it. Common confounders of a syncopal spell include falls or seizures. It is important to determine if the event was isolated or a recurrent phenomenon and if there were any obvious triggers. A key part of the history is to try and distinguish between an episode of VVS and cardiac syncope; these include inquiring about red flags for an arrhythmia-based precipitant. Concern for an arrhythmia would be heightened if the event happened during (not after) exertion, if palpitations were felt prior to or during the event, if the episode occurred entirely while supine, and if there is any history of sudden cardiac death in the family (Moya et al., 2009). For identifying patients with VVS, there are several diagnostic features to note including prodromal symptoms, physical findings during the event, and during recovery post event (Sheldon et al., 2015).

Distinctive symptoms can occur at different stages of a fainting spell (Wieling et al., 2009). A history of prodromal symptoms can be of value to help discern between different underlying causes. Prodromal symptoms common to VVS include: diaphoresis, abdominal pain, pallor, pupillary dilation, hyperventilation, and nausea (Newman and Graves, 2001; Wieling et al., 2009; Graham and Kenny, 2001). Prodromal symptoms may be noticeably absent in older adults (Wieling et al., 2009). Associated symptoms of cerebral hypoperfusion can also be described including lightheadedness and blurred vision (Alboni, 2015; Graham and Kenny, 2001). Syncope is defined by a transient loss of consciousness that occurs secondary to cerebral hypoperfusion and results in the

patient coming to rest on the ground. "Transient" is a key part of the definition of syncope that is important for distinguishing it from other causes of loss of consciousness including narcolepsy, cataplexy, pseudoseizures, and pseudosyncope (Sheldon, 2015). During a syncopal episode, the patient usually remains unconscious and motionless for only a short period of time (usually less than 1 min) (Sheldon et al., 2015). Syncope patients can have myoclonic shaking with their spell, which can confuse bystanders into thinking that the event is a seizure (Sheldon, 2015; Newman and Graves, 2001). A full recovery will ensue, although patients typically experience profound fatigue for several hours postevent (Graham and Kenny, 2001).

It is important to obtain a detailed past medical history. It is important to note any history of structural heart disease, coronary artery disease, cardiac arrhythmias, or familial sudden cardiac death. A medication history, including any recent medication changes is also valuable, as there are multiple common medications that may predispose an individual to VVS (Hainsworth and Claydon, 2013). Agents that commonly worsen symptoms include diuretics, venodilators, and vasodilators (Coffin and Raj, 2014a).

All patients presenting with a suspected episode of VVS should undergo a physical exam, including a set of orthostatic vitals. These can be helpful in delineating OH from VVS and will be discussed in further detail in the section detailing the clinical evaluation of OH. Patients with VVS should have no significant change in orthostatic HR or BP.

A number of risk stratification tools exist for attempting to identify patients at high risk of adverse events following a syncopal spell (Thiruganasambandamoorthy et al., 2016; Sheldon, 2013; Costantino and Furlan, 2013). These tools are aimed toward emergency department patients presenting with a syncopal episode and can be useful to help identify high-risk features that may necessitate further workup or hospitalization for a patient presenting with a syncopal episode. As of now, there is no gold-standard risk stratification score recommended in current guidelines (Sheldon et al., 2015; Moya et al., 2009).

Overall, a clear history of features consistent with VVS with an absence of any red flags can be sufficient to make the diagnosis (Van Dijk et al., 2008).

Investigations

Overall, the diagnosis of VVS is a clinical diagnosis. Basic laboratory investigations are of limited value in the initial workup of a suspected episode of VVS. Patients with VVS usually have a normal ECG. An abnormal ECG may increase the likelihood of "cardiac syncope." There are no key blood tests that will be of assistance in the diagnosis of VVS, although the presence of laboratory abnormalities such as severe anemia or electrolyte disturbances may increase the likelihood of an alternative diagnosis (Moya et al., 2009). There are a number of tests that should not be performed in a patient presenting with an initial evaluation that is supportive of an episode of VVS. These include computed tomography or magnetic resonance imaging, cardiac perfusion studies, carotid Doppler ultrasound, Holter monitoring, and an electroencephalogram (Moya et al., 2009; Hatoum and Sheldon, 2014).

Autonomic function testing

Patients with a clear history or with a single episode without any red flag features do not need further testing unless special circumstances warrant it (Moya et al., 2009). In selected cases, formal autonomic testing might be helpful. The overall goal of autonomic function testing in the patient presenting with syncope is to assess for the presence and character of autonomic dysfunction in response to different stimuli. Testing will involve assessment of both the sympathetic and the parasympathetic nervous system. Autonomic function testing is not always necessary. This is important given that access to formal autonomic labs is limited given the specialized equipment and trained personal that are required to administer testing. These services are often only available at tertiary care centers.

Head-up tilt table test

A head-up tilt table test involves the patient lying supine for a period of time while having BP and HR assessed optimally by beat-to-beat BP monitoring. After a period of time (anywhere from 5 to 20 min depending on the protocol), the table is tilted upright to an angle usually between 60 and 80 degrees head up, where the patient is maintained in a "standing" position until a presyncopal or syncopal episode is elicited. There are many different protocols for administering a tilt table test. The most basic method is a passive test where the patient is maintained upright for up to 45 min in duration with no added stimulus (Kapoor et al., 1994). Pharmacological provocation in the form of nitroglycerin, isoproterenol, or clomipramine administration can help provoke a patient to faint if an initial period of passive standing (usually 30 min) is not sufficient (Raj and Sheldon, 2011). An argument against this method is the use of medication serves as a nonphysiological stimulus during testing. A final alternative method is through the use of a lower-body negative pressure suction device that can apply graded negative pressure to the lower extremities to promote increased venous pooling and decrease upright tilt duration prior to syncope (El-Bedawi and Hainsworth, 1994; Protheroe et al., 2013).

A positive response to tilt table testing in a patient with VVS results in a characteristic BP and HR response in the moments preceding test termination (**Fig. 2**). In patients with strong pretest probability for VVS, the sensitivity of a head-up tilt is between 78% and 90%, with a specificity of approximately 90% (Sheldon et al., 2015). A tilt table test is not required to make a diagnosis of VVS. The Heart Rhythm Society (HRS) consensus guidelines suggest that head-up tilt table testing can be useful for patients who lack a confident diagnosis of VVS after initial assessment and for differentiating between syncope with convulsions and seizures (Sheldon et al., 2015). A head-up tilt table test may also be of use if it can replicate the symptoms experienced during an event in the community.

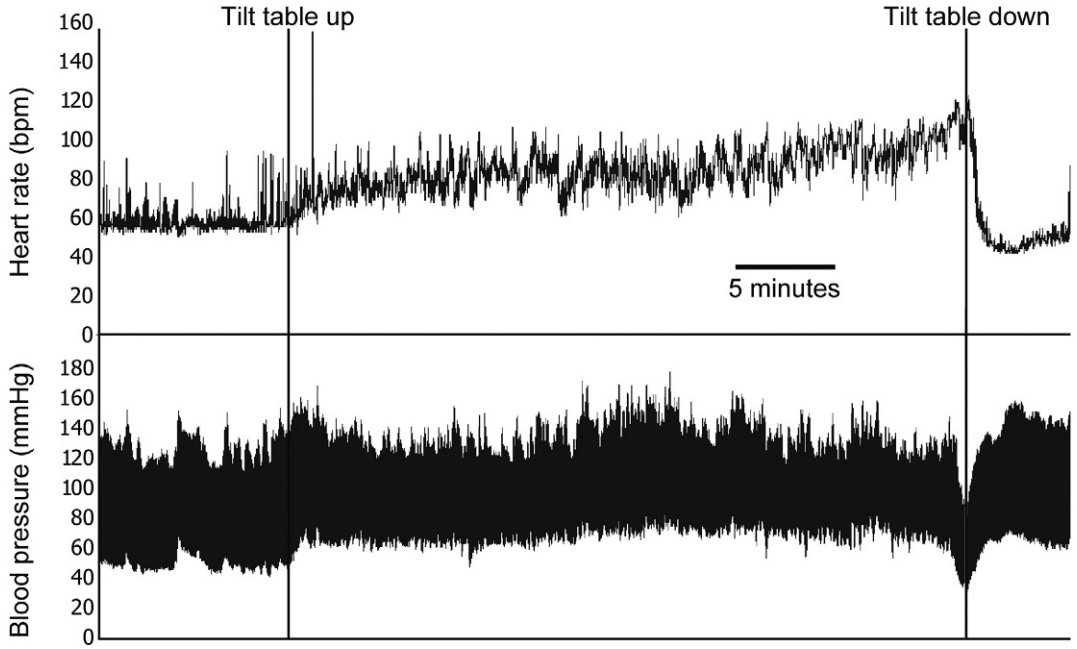

Fig. 2 Sample tracing of vasovagal syncope during head-up tilt testing. Beat-to-beat blood pressure and heart rate responses are shown through the duration of testing. After the patient was tilted upright, blood pressure was maintained for the first 30 min of testing. Heart rate increased during this time. After 35 min of standing, an event consistent with vasovagal syncope occurred, where there was an abrupt decline in blood pressure and heart rate. The test was terminated and the tilt table was brought back to the supine position. *HR*, heart rate; *BP*, blood pressure. From HUTT test chapter 73; Raj and Sheldon.

Management

The management of VVS follows a tiered approach. Most patients respond very well to nonpharmacological management; therefore, these should always be explored and tested prior to pharmacological therapy, as medications will most often not be needed (Raj and Coffin, 2013).

Nonpharmacological approaches

The first step in the management of VVS is to educate the patient on the prognosis and risks associated with this condition. VVS is a common and relatively benign condition (Sheldon et al., 2015). It is important for patients to watch for signs of prodromal symptoms and to avoid precipitating stimuli, such as inadequate hydration and hot environments, or any specific triggers for the individual patient (such as hot showers or needles) (Raj and Coffin, 2013). It is also important to assess for any potential medications that may be contributing to symptoms, such as diuretics, venodilators, and vasodilators and if possible, stopping them (Raj and Coffin, 2013; Coffin and Raj, 2014a).

Increased dietary salt and water intake

The next step in management is to encourage increased intake of dietary salt and water. These recommendations follow a small study that showed that salt supplementation (12 g per day) improved orthostatic tolerance in patients with unexplained syncope (El-Sayed and Hainsworth, 1996). Additionally, acute water ingestion (500 ml) has been shown to improve initial hemodynamics upon standing and overall orthostatic tolerance in healthy controls (Schroeder et al., 2002). In contrast, another study found that increased hydration alone did not improve orthostatic tolerance in patients with neurocardiogenic syncope (Bellard et al., 2007). Overall, there is lack of conclusive evidence for the long-term efficacy of these therapies. In the absence of contraindication against their use (such as preexisting hypertension, heart failure, or chronic kidney disease), salt and/or water supplementation are included with a class I recommendation in the 2015 HRS consensus statement for the management of reflex syncope (Sheldon et al., 2015; Coffin and Raj, 2014a).

Physical counter-measure maneuvers

Physical counter-measure maneuvers are another nonpharmacological therapy that are thought to be beneficial in treating VVS. These maneuvers are performed through isometric contraction of large muscle groups (upper or lower extremities) causing a rise in BP (Raj and Sheldon, 2016; Brignole et al., 2002; Krediet et al., 2002). The thought is to employ these maneuvers when patients experience prodromal symptoms of a syncopal episode. Leg crossing along with clenching of the buttocks is thought to be most effective (Raj and Coffin, 2013). One randomized control trial has shown a 39% risk reduction in patients with syncope employing

physical counter-measure maneuvers (upper and lower extremities) (van Dijk et al., 2006). Overall, the most important maneuver is to lie down flat at the onset of presyncope. If this is not possible, advocate sitting on the ground in a squatting position with knees up against the chest. It is not recommended to sit on a chair as people can faint in this body position. These maneuvers are not felt to be effective in patients who do not experience prodromal symptoms given that patients require time to perform the maneuver to have a beneficial effect (Raj and Coffin, 2013). Given the lack of risk associated with these maneuvers, there is little reason for them to not be employed in the management of VVS.

Compression garments

Compression stockings are often recommended as a potential therapeutic treatment for improving orthostatic intolerance in those with a fainting predisposition based on the physiological rationale that counter-pressure applied to the lower extremities and/or abdomen may reduce venous pooling (Downie et al., 2008; Brown and Hainsworth, 1999) and help improve orthostatic tolerance in patients predisposed to VVS (Privett et al., 2010; Protheroe et al., 2011). The evidence to date is limited primarily to healthy control subjects and astronauts returning from space and does not provide unanimously positive results (Protheroe et al., 2011; Privett et al., 2010; Stenger et al., 2010; Platts et al., 2009). There is also a lack of data in a patient population with VVS. Overall, given that there are very few contraindications or potential harms from their use, compression stockings can be used if a patient does find some symptomatic benefit from using them. The 2015 HRS Expert Statement does not make any recommendations for, or against, their use (Sheldon et al., 2015).

Tilt training

Tilt training is another measure that has been tried in an attempt to do "orthostatic training" as a means to improve orthostatic tolerance through either repeated tilt-tests in the autonomic lab or by standing next to a wall while at home several times a day (Raj and Coffin, 2013). Prolonged inpatient tilt training is impractical and the efficacy and compliance to therapy for outpatient training has been questioned (Coffin and Raj, 2014a). To date, multiple trials have examined outpatient tilt training and have found mixed results, with most studies finding no significant benefit (Foglia-Manzillo et al., 2004; Jang et al., 2013; On et al., 2007; Tan et al., 2010; Zeng et al., 2008). In fact, the 2015 HRS consensus statement does not make any recommendation for its use (Sheldon et al., 2015).

Pharmacological

The majority of patients with VVS do very well with conservative nonpharmacological treatments (estimated at approximately 90%). For the minority of patients that have significant ongoing symptoms despite nonpharmacological management, there are several pharmacological options; these are shown in **Table 1**.

Fludrocortisone

Fludrocortisone is a corticosteroid with primarily mineralocorticoid activity at low doses, resulting in both sodium and water retention. It should be considered as a secondary adjunctive therapy to increased dietary salt and water intake at a dose of 0.2 mg by month (PO) once daily. The Prevention of Syncope Trial (POST)-2 trial examined the effects of fludrocortisone versus placebo in 210 patients with VVS (Sheldon et al., 2016). The study found a nonsignificant trend ($P=0.07$) for a reduction in syncope in the fludrocortisone group by intention to treat analysis. A subanalysis revealed that when dose stabilization was reached (after 2 weeks of treatment), there was a significant reduction in syncope in the group taking fludrocortisone ($P=0.02$). This suggests that there may be benefit for this medication if patients meet the target dose of 0.2 mg once daily. The 2015 HRS consensus statement supports the use of fludrocortisone in appropriate patients given the absence of evidence against its use (Sheldon et al., 2015). Side effects that should be watched for include supine hypertension, fatigue, nausea, and hypokalemia (Lee and Krahn, 2016). The incidence of hypokalemia was very low in the POST2 study (Sheldon et al., 2016).

Table 1 Options for the pharmacological management of vasovagal syncope

Medication	*Dose*	*Comments*	*References*
Fludrocortisone	0.1–0.2 mg PO q daily	The POST2 study suggests that there is a decrease in recurrent syncope if the target dose of 0.2 is reached. Check K^+ for hypokalemia	Sheldon et al. (2016)
Midodrine	2.5–10 mg PO q4h three times daily	Avoid 4 h before bedtime to mitigate risk of supine hypertension. This is being studied in the POST-IV study	Izcovich et al. (2014), Romme et al. (2011), Qingyou et al. (2006), Kaufmann et al. (2002), Ward et al. (1998), Raj et al. (2012)
Metoprolol	25 mg PO BID	Not indicated in younger patients. Maybe helpful in older patients (>40 years) or hypertensive patients. This is being assessed in the POST-V study	Sheldon et al. (2006), Raj et al. (2016)

PO, Per os; *q*, each; *TID*, three times daily.

Midodrine

Midodrine is a prodrug which, when converted to its active form, is an alpha-1 adrenergic receptor agonist. It causes arterial and venous constriction, thereby helping to increase BP and likely venous return by decreasing venous compliance. It has a short-term effect, lasting for about 4 h with a relatively quick onset (20–30 min) (Raj and Coffin, 2013). Typical dosing for the management of VVS is 2.5–10 mg PO every 4 hours three times daily. It is a US Food and Drug administration (FDA) approved medication for the treatment of OH, but is used off-label in the treatment of VVS. Five clinical trials have assessed the efficacy of midodrine, showing an approximate 70% reduction in risk, however none of these trials provide high-level evidence for the drug's use (Izcovich et al., 2014; Sheldon et al., 2015; Raj and Sheldon, 2016). The ongoing POST-IV trial (http://clinicaltrials.gov/show/NCT01456481) is currently comparing the use of midodrine 10 mg three times daily in comparison to placebo (Coffin and Raj, 2014b). There are barriers to the use of midodrine, most notably frequent dosing, supine hypertension, urinary retention in older males, as well as unknown teratogenic effects of the drug (Raj and Sheldon, 2016). The 2015 HRS consensus statement suggests that midodrine is a reasonable option for patient without any contraindications (Sheldon et al., 2015).

Beta-blockers

Beta-blockers have been shown in randomized controlled trials to not be effective for the treatment of VVS (Sheldon et al., 2015). The largest of these trials was the Prevention of Syncope Trial (POST), which tested the effects of metoprolol versus placebo in 208 patients with VVS (Sheldon et al., 2006). There was no benefit for younger patients (<42 years of age). There was, however, a trend suggesting that older patients may benefit. The 2015 HRS consensus statement echoes these findings by suggesting that beta-blockers can be considered in patients older than 40 years of age with recurrent VVS (Sheldon et al., 2015). In the future, the POST-V trial (http://clinicaltrials.gov/show/NCT02123056) may help better clarify the role of beta-blockers in VVS patients >40 years of age. This ongoing study is comparing the use of metoprolol 50 mg twice daily in comparison to placebo (Coffin and Raj, 2014b).

Selective serotonin reuptake inhibitors

Serotonin has an effect that acts to regulate BP and HR. Several studies have examined the use of selective serotonin reuptake inhibitors as a means of increasing serotonin levels to help reduce fainting risk. There have been mixed results in a number of observational studies and small, randomized clinical trials (Takata et al., 2002; Theodorakis et al., 2006; Di Girolamo et al., 1999). To date, the 2015 HRS consensus statement does not provide a recommendation on their use (Sheldon et al., 2015).

Prognosis

The prognosis of VVS is generally quite positive. It is considered a relatively benign condition that is associated with no increased mortality (Colman et al., 2004). Many patients will cease to have episodes of VVS without any medical management needed (Sheldon et al., 2015). For those patients with recurrent VVS requiring management, approximately 90% will do very well on nonpharmacological therapy. Unfortunately, for those individuals with frequent VVS resistant to treatment, quality of life can be greatly impacted (Moya et al., 2009). There are however many ongoing clinical trials to identify better therapies that can help these individuals manage their debilitating symptoms (Coffin and Raj, 2014b).

Orthostatic Hypotension

OH is classically defined as a persistent drop in systolic BP of $\geq$20 mmHg or diastolic BP of $\geq$10 mmHg within 3 min of standing or head-up tilt table testing (Freeman et al., 2011). In patients with baseline hypertension, it may be more appropriate to identify OH as a decline in systolic BP of $\geq$30 mmHg (for hypertension) or in diastolic BP $\geq$15 mmHg (Wieling and Schatz, 2009; Fedorowski et al., 2009) since the magnitude of the BP fall is dependent on the patient's baseline BP (Freeman et al., 2011).

OH is defined by hemodynamic criteria alone. OH can present with symptoms, but also without symptoms. Classic symptoms include lightheadedness, presyncope, and syncope. Others may also report more nonspecific complaints, including weakness, fatigue, classically occipital headaches, "coat-hanger" back and neck pain, orthostatic dyspnea, confusion, and visual blurring.

Epidemiology

The prevalence of OH increases with age (Shibao et al., 2007). OH is associated with overall illness, being much more prevalent in older adults living in long-term care in comparison to an age-matched community cohort (Freeman et al., 2011). OH is independently associated with increased risk of mortality (Masaki et al., 1998; Verwoert et al., 2008) and cardiovascular disease (Luukinen et al., 2004; Rose et al., 2000). A recent meta-analysis suggests that OH is associated with a 36% increased probability of mortality (Angelousi et al., 2014). It is also associated with falling and frailty in older adults (Shaw and Claydon, 2014; Romero-Ortuno et al., 2011). In the United States, OH related hospitalizations occur at a rate of 36 per 100,000 (Shibao et al., 2007). OH is more common in those patients with underlying hypertension and in patients with autonomic dysfunction (Benvenuto and Krakoff, 2011; Fedorowski et al., 2009). It is particularly common in patients with Parkinson's disease and diabetes mellitus (Velseboer et al., 2011; Spallone et al., 2011; Mussi et al., 2009).

Distinguishing VVS From Orthostatic Hypotension

VVS and OH are distinct clinical disorders that can both cause drops in BP and potentially result in syncope; however, they produce distinct hemodynamic patterns during tilt table testing (Nwazue and Raj, 2013). More specifically, the BP falls are experienced at differential rates. VVS involves an intermittent, oversensitive reflex. Patients with VVS usually hold a steady BP for several minutes in an upright posture before developing symptoms and experiencing a rapid drop in their BP and HR. In contrast, patients with classic OH (Fig. 3) undergo immediate and progressive declines in their BPs with upright posture.

Variants of Orthostatic Hypotension

Initial orthostatic hypotension

There are several variants of classic OH. Initial OH is defined as a transient fall in BP (>40 mmHg systolic BP and/or >20 mmHg diastolic BP) within 15 s of standing, with symptoms of cerebral hypoperfusion (Freeman et al., 2011). Patients typically report complaints of lightheadedness immediately on standing, which can occasionally result in syncope.

Initial OH is primarily seen during active standing, and to a significantly lesser extent with passive tilt table testing. It is thought that the initial leg muscle contraction with active standing is a prerequisite for the observed hypotension (Wieling et al., 2007). The fall in BP is proposed to result from a mismatch between cardiac output and vascular resistance as the rapid postural change is experienced. This is a consequence of the normal delay in arterial baroreflex detection and consequent vasoconstriction, as well as the response to gravitational blood volume redistribution (Stewart, 2013). Documentation of Initial OH is very difficult with brachial BP cuffs; it usually requires continuous BP monitoring, as the manual BP equipment (i.e., brachial cuff) is unable to assess the rapid and transient changes in arterial BP (Wieling et al., 2007).

Delayed orthostatic hypotension

Delayed OH is a decrease in BP similar to Classic OH (>20 mmHg systolic BP or >10 mmHg diastolic BP), where this is not observed until after the first 3 min of standing or head-up tilt (Freeman et al., 2011). While the BP drops usually meet the threshold within 10 min, one study also found that 39% of patients experienced BP falls after 10 min of head-up tilt (Gibbons and Freeman, 2006).

Delayed OH may be a consequence of several pathophysiological insults, including increased peripheral venous pooling, increased fluid transudation, and/or gradual impairment of the adaptive neural and humoral mechanisms that counter blood volume redistribution (Ricci et al., 2015; Gibbons and Freeman, 2006). Therefore, it is suspected that these delayed falls in BP may be an early or mild form of sympathetic adrenergic failure.

Confounders for orthostatic hypotension

There are several confounders that may influence the magnitude of the orthostatic BP fall. These include supine hypertension, postprandial hypotension, and diurnal variation in BP.

Orthostatic hypotension with supine hypertension

Supine hypertension can occur in patients with both peripheral and central autonomic failure (Jones et al., 2015). Moreover, supine hypertension can often coexist with neurogenic OH; approximately half of the patients with severe OH also have hypertension when supine (Coffin and Raj, 2014a; Nwazue and Raj, 2013). Upon standing, some of these patients have observed BP drops that fulfill the definition for OH, despite the BP remaining at or above a normal range (Freeman et al., 2011).

Medications used to treat OH may worsen supine hypertension as a side effect; however, a substantial subsection of patients have supine hypertension even prior to pharmacological treatment of OH (Freeman et al., 2011; Goldstein et al., 2003).

Postprandial hypotension

Postprandial hypotension is defined as a decrease in systolic BP of $\geq$20 mmHg, or a decrease in absolute SBP <90 mmHg (from a baseline Systolic BP of $\geq$100 mmHg) within 2 h of meal consumption (Luciano et al., 2010). A significant postprandial BP fall is suggestive of inadequate cardiovascular compensation for meal-induced (or possibly insulin release-induced) splanchnic blood pooling (Trahair et al., 2014; Mathias, 1991). Patients with autonomic failure and the elderly are particularly vulnerable to such meal-associated declines in BP (Freeman et al., 2011; Mathias, 1991). Meal content can also contribute to the degree in which BPs fall; alcohol intake, large meals, and meals high in carbohydrates tend to exacerbate hypotension (Mathias, 1991; Freeman et al., 2011). Specifically, low carbohydrate meals induce significantly smaller BP declines, as well as less frequent and less severe symptoms compared to high carbohydrate meals (Vloet et al., 2001).

Diurnal variation

OH is more common and severe in the mornings compared to other times during the day (Freeman et al., 2011; Ooi et al., 1997). It is suggested that this occurrence is possibly due to higher supine nocturnal BP, which induces an overnight pressure diuresis. This is compounded by a lack of fluid intake overnight. Combined, these cause intravascular volume depletion that is particularly acute in the morning.

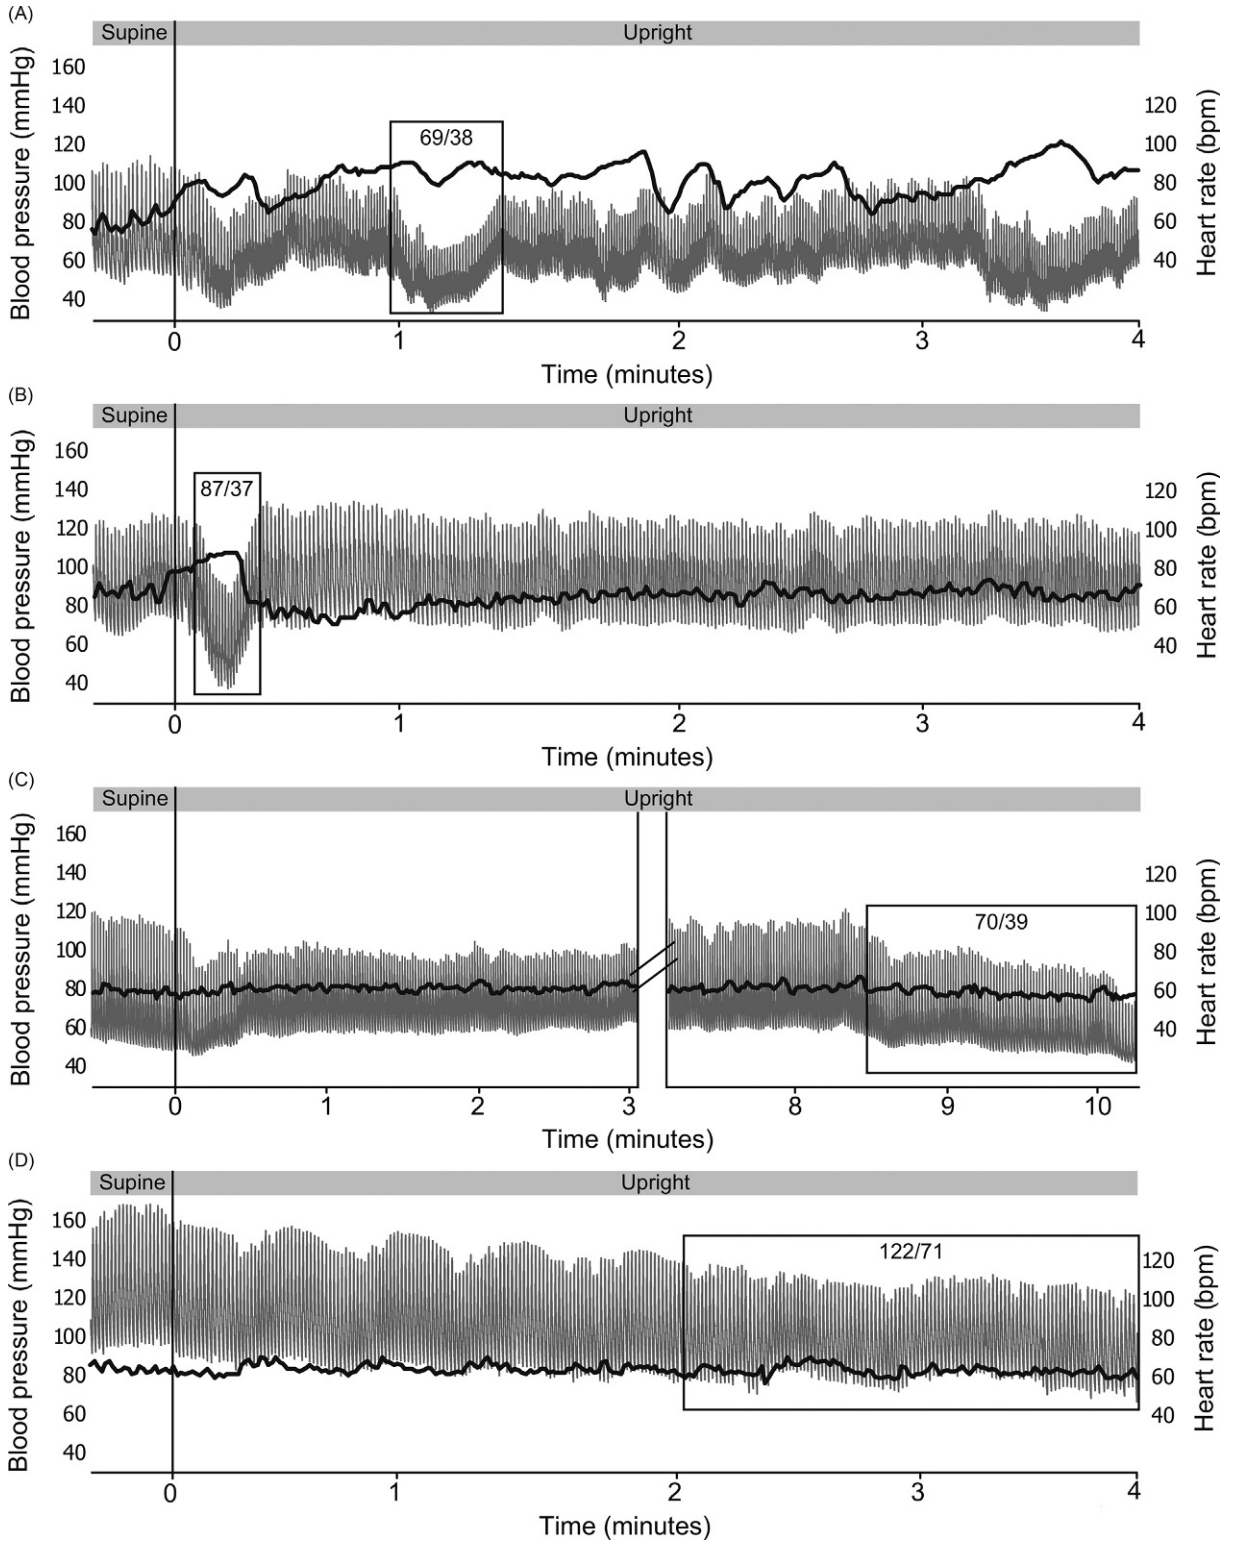

Fig. 3 Examples of orthostatic hypotension variants during head-up tilt testing. Blood pressure and heart rate responses are shown during orthostatic stress testing for patients with (A) classic orthostatic hypotension, in which blood pressure falls during the first 3 min of standing; (B) initial orthostatic hypotension, where blood pressure abruptly falls within the first 30 s of standing; (C) delayed orthostatic hypotension, where blood pressure is maintained during the first 3 min and declines later on during testing; and (D) a patient with classic OH with supine hypertension, who demonstrates a progressive decline in blood pressure with a lack of heart rate response suggestive of a neurogenic cause. From Shaw, B.H.; Claydon, V.E. (2014). The relationship between orthostatic hypotension and falling in older adults. Clinical Autonomic Research 24, 3–13.

Etiology

OH results from inadequate compensatory autonomic nervous system responses to volume redistribution that occurs during standing or position change. The underlying cause for the inadequate compensatory responses during standing can be broken down into nonneurogenic and neurogenic causes of OH.

Nonneurogenic orthostatic hypotension

Causes of nonneurogenic OH are displayed in **Table 2**. There are number of key reversible causes for OH that should be immediately identified including hypovolemia and medications (Gupta and Lipsitz, 2007; Jones et al., 2015). These disturbances lead to diminished cardiac output or decreased effective arterial blood volume resulting in decreased venous return with an appropriate, but inadequate, baroreceptor reflex response leading to a drop in BP. This is frequently accompanied by a compensatory increase in HR.

Neurogenic orthostatic hypotension

Neurogenic OH results from disorders that cause damage to the autonomic nervous system. In contrast to nonneurogenic OH, decreased venous return associated with standing results in an inadequate and impaired baroreceptor reflex response, evidenced by a diminished reflex vasoconstrictive response, resulting in a sustained decrease in BP. Typically, there is also a limited compensatory HR response to orthostatic stress, but the presence of a reflex tachycardia does not rule out neurogenic OH. Other associated manifestations of autonomic failure can include anhidrosis, neurogenic bladder with urinary retention, sexual dysfunction, and gastrointestinal dysmotility (Benarroch, 2014). The etiologies that lead to neurogenic OH can be divided into neurodegenerative, autoimmune, spinal cord injury, and peripheral autonomic causes (**Table 2**).

Neurodegenerative causes

Neurodegenerative disorders that result in the accumulation of alpha-synuclein lead to primary autonomic failure (Low, 2015). Classic causes include Lewy body disorders and multiple system atrophy.

Lewy body disorders Lewy bodies are neurons, which accumulate alpha-synuclein. Lewy body disorders include Parkinson's disease, Lewy body dementia, and pure autonomic failure. Patients with Parkinson's disease typically present with a resting tremor, rigidity, bradykinesia, and postural instability. Constipation is a particularly prominent feature of autonomic dysfunction in Parkinson's disease that becomes more prominent with disease duration (Knudsen et al., 2017). Other autonomic symptoms include bladder dysfunction, erectile dysfunction, and hyperhidrosis (Magerkurth et al., 2005). The prevalence of OH in Parkinson's disease is estimated to be approximately 30% (Velseboer et al., 2011).

Lewy body dementia presents with symptoms of rapidly progressive dementia, autonomic dysfunction, parkinsonian features, and visual hallucinations (Jones et al., 2015). Patients with Lewy body dementia have been found to have lower standing systolic BP in comparison to patients with Alzheimer's disease (Sonnesyn et al., 2009). Among patients with Parkinson's disease, multiple

Table 2 Causes of orthostatic hypotension

Nonneurogenic causes	*Neurogenic causes*
Drugs	Neurodegenerative
Diuretics	Lewy body disorders
Vasodilators	Parkinson's disease
Venodilators	Lewy body dementia
Antidepressants	Pure autonomic failure
Hypovolemia	Multiple system atrophy
Cardiac pump failure	Autoimmune
Cardiac arrhythmias	Autoimmune autonomic ganglionopathy
Valvular heart disease	Paraneoplastic autoimmune neuropathy
Myocardial infarction	Acute autonomic neuropathy
	Sjögren's syndrome
	Spinal cord pathology
	Tumors
	Transverse myelitis
	Tabes dorsalis
	Peripheral Neuropathy
	Diabetes
	Amyloidosis
	Guillain-Barré syndrome

system atrophy and Lewy body dementia, those with Lewy body dementia have been found to be the most affected by autonomic dysfunction (Thaisetthawatkul et al., 2004).

Pure autonomic failure is progressive autonomic failure in the absence of any other neurological deficits (Benarroch, 2014; Thaisetthawatkul, 2016). In contrast to the other Lewy body diseases, pure autonomic failure is an alpha-synucleinopathy isolated to the autonomic nervous system (Thaisetthawatkul, 2016). Patients typically present with typical symptoms of orthostatic hypotension. Other symptoms include urinary symptoms, erectile dysfunction, and chronic constipation (Thaisetthawatkul, 2016).

Multiple system atrophy Multiple system atrophy is a progressive, sporadic, neurodegenerative disorder characterized by combined features of autonomic dysfunction, parkinsonism, cerebellar ataxia, pyramidal symptoms, and urogenital dysfunction (Gilman et al., 2008; Benarroch, 2014). The primary pathological features of multiple system atrophy are glial cytoplasmic alpha-synuclein inclusions, as opposed to neuronal alpha-synuclein in Lewy Bodies (Asi et al., 2014; Papp et al., 1989). The prevalence of multiple system atrophy is estimated to be 4.4 cases per 100,000 (Schrag et al., 1999). Multiple system atrophy can be further delineated by the predominance of parkinsonian features or predominate cerebellar ataxia at initial presentation (Gilman et al., 2008).

Autoimmune causes

Autoimmune causes of autonomic failure include autoimmune autonomic ganglionopathy, paraneoplastic autonomic neuropathy, acute autonomic and sensory neuropathy, and Sjögren's syndrome (Benarroch, 2014). Autoimmune autonomic ganglionopathy is associated with an acetylcholine receptor ganglionic antibody in approximately 50% of cases (Vernino et al., 2009; Sandroni and Low, 2009; Muppidi and Vernino, 2013). These antibodies decrease the synaptic transmission at autonomic ganglia, leading to autonomic failure (Muppidi and Vernino, 2013). Patients often report a subacute onset, often with a preceding event, such as viral illness, recent immunization or surgery (Sandroni and Low, 2009; Muppidi and Vernino, 2013). The majority (70%) of cases will have enteric nervous system involvement, typically in the form of gastroparesis and severe constipation; this can be an important feature to help distinguish this from other autonomic nervous system disorders that may be on the differential (Muppidi and Vernino, 2013).

A paraneoplastic autonomic neuropathy presents in a similar manner to autoimmune autonomic ganglionopathy, but is secondary to a neoplasm, most commonly small-cell lung cancer, adenocarcinoma, or thymoma (Muppidi and Vernino, 2014). Antibodies that may be involved include anti-Hu, voltage-gated potassium channel antibodies or acetylcholine receptor ganglionic antibody (Muppidi and Vernino, 2014).

Acute autonomic and sensory neuropathy is a rare condition that differs from autoimmune autonomic ganglionopathy in that the sensory nervous system is also involved (McKeon and Benarroch, 2016). The most common presenting autonomic symptom is gastrointestinal dysmotility; the sensory deficits tend to be asymmetric, segmental, and affect more proximal areas of the body (McKeon and Benarroch, 2016). To date, no antibody has been identified for this condition (McKeon and Benarroch, 2016).

Sjögren's syndrome classically presents with dry eyes, dry mouth, and a sensory neuropathy, but it can also have autonomic nervous system involvement (Muppidi and Vernino, 2013).

Peripheral causes

Peripheral neuropathies including diabetes, amyloidosis, and Guillain-Barré syndrome can cause autonomic impairment leading to OH. Diabetes is by far the most common cause; the incidence of OH is estimated to be approximately 8%–9% in patients with type 1 diabetes mellitus and slightly lower (7%–8%) in patients with type 2 diabetes mellitus (Low et al., 2004). It is unusual for a patient to develop autonomic failure as a complication of diabetes mellitus in the absence of sensory neuropathy.

Clinical Evaluation

The clinical evaluation of OH is also built on the foundation of a detailed history and physical exam. In contrast to patients with VVS, OH can present with symptoms ranging from being asymptomatic to a complete loss of consciousness (Goldstein and Sharabi, 2009). Common prodromal symptoms include general weakness, lightheadedness, and narrowed vision (Goldstein and Sharabi, 2009).

It is important to ask questions about any precipitating events or recent medication changes. This includes ruling out causes of nonneurogenic cause of OH including dehydration, infection, blood loss, or new onset cardiovascular disease. Common medications that can precipitate OH include diuretics, venodilators, direct vasodilators, and antidepressants (Jones et al., 2015). A detailed past medical history is vital in order to note any medical conditions that may precipitate autonomic dysfunction such as diabetes mellitus or Parkinson's disease.

Similar to the workup of VVS, patients presenting with OH should undergo a physical exam, including a set of orthostatic vital signs. Orthostatic vital signs can be obtained through a variety of testing methods. The most simple, commonly accepted orthostatic stress test is a supine to standing maneuver. A patient is instructed to lie on an examining table for a few minutes. Supine recordings of BP and HR should be recorded with the use of a manual BP cuff. The patient is then instructed to move into a fully upright position. BP and HR measurements are then made at the 1-, 3-, and 5-min intervals while upright. Changes in HR and BP can be used to assess for the presence of orthostatic hypotension at 3-min. The 5-min recording is useful to better define the pattern of the

BP response once OH is detected (Gehrking et al., 2005). In the presence of BP changes suggestive of OH, the severity of OH can be quantified based on duration of standing tolerated, frequency and severity of symptoms, and impact on daily activities (Low, 2015). Changes in HR can be useful to help differentiate between nonneurogenic and neurogenic OH. A lack of HR increase upon standing is consistent with the diagnosis of neurogenic OH; if HR increases, the underlying etiology could still be neurogenic or nonneurogenic in origin.

Investigations

As with the workup of the patient presenting after a syncopal episode, an ECG is a simple, inexpensive test that can help diagnose conduction disease or other abnormalities that could predispose an individual to syncope. Laboratory investigations will generally be guided based on the results of history and physical exam. Common blood work may include a complete blood count and electrolytes to look for severe anemia or electrolyte disturbances. In patients without a clear cause for suspected neurogenic OH further investigations may include a screening test for diabetes mellitus, vitamin B12 levels, and a paraneoplastic or autoimmune workup.

Plasma norepinephrine levels taken while supine and again while standing (after at least the first 5–10 min) can help examine the functioning of adrenergic terminals and the baroreflex (Low et al., 2013; Low, 2015; Goldstein et al., 1989). The supine value provides a baseline measure of postganglionic adrenergic fiber activity; the change between supine and upright can be helpful in describing the degree of baroreflex unloading. A normal change is considered a doubling of norepinephrine levels with standing (Low et al., 2013). Patients with pure autonomic failure will typically have low levels of supine norepinephrine (Low et al., 2013). Patients with OH who have Parkinson's disease, multiple system atrophy, or pure autonomic failure will typically have a blunted increase in plasma norepinephrine levels upon standing (Goldstein, 2014).

Autonomic function testing

Autonomic function testing can be useful in understanding the pattern and degree of autonomic impairment in patients with neurogenic OH. It is of much less utility in patients who have a clear nonneurogenic cause. Similar to the workup for VVS, testing may include head-up tilt testing and Valsalva maneuver. Additional testing for patients with neurogenic OH may include BP changes during hyperventilation or in response to cold pressor, assessment of HR variability, quantitative sudomotor axon reflex testing, thermoregulatory sweat testing, and cardiac iodine-123 metaiodobenzylguanidine (MIBG) uptake (Low, 2015; Nwazue and Raj, 2013; Jones et al., 2015).

Head-up tilt testing

The pattern of BP and HR responses observed during head-up tilt testing can be useful in identifying the type and severity of OH (**Fig. 3**) (Kim et al., 2016; Shaw and Claydon, 2014). It is used primarily as a metric of sympathetic adrenergic function. Patients with neurogenic OH will display a decline in BP that meets criteria for OH as well as a blunted HR increase in response to tilt, in a manner similar to that seen with the supine to stand test.

Valsalva maneuver

The Valsalva maneuver can provide a useful assessment of autonomic function. The test is performed by having the patient perform forced expiration against a closed glottis at a pressure of 40 mmHg for 15 s (Jones and Gibbons, 2014). Continuous recording of BP and HR is vital to interpret the results. The resulting BP and HR waveform can be broken down into four phases (**Fig. 4**). Patients with neurogenic OH can show varying degrees of autonomic impairment during a Valsalva maneuver (Kim et al., 2016). Typically, patients with OH have a poor HR response to the decline in BP experienced during early phase II suggestive of cardiovagal impairment (Low et al., 2013). Patients also display signs of adrenergic dysfunction by the absence of a late phase II systolic BP recovery, absence of phase IV systolic BP overshoot, and a prolonged BP recovery time (Low et al., 2013). These changes become more pronounced with worsening autonomic impairment (Kim et al., 2016).

Other autonomic tests

There are other autonomic function tests that can be used to further delineate changes in cardiovagal and adrenergic function. Cardiovagal function can be assessed by observing variation in HR in response to deep breathing (respiratory sinus arrhythmia) (Bennett et al., 1977); this is performed by inspiring for 5 s (6 breaths per minute), then exhaling for 5 s, and repeating this for 6–8 breathing cycles (Jones et al., 2015). The ratio of HR during expiration divided by the HR during inspiration is the sinus arrhythmia ratio; higher values represent intact cardiovagal function (Low et al., 2013). Patients with impaired cardiovagal function will have ratios closer to 1 (showing a lack of variability).

Cold-pressor testing is a maneuver that uses a cold stimulus to elicit increases in adrenergic activity causing reflex vasoconstriction raising BP as well as increasing HR (Feliciani et al., 2016). The test involves immersing the patient's hand in ice water for 1 min, while recording BP and HR, ideally with beat-to-beat BP technology. A minimal or absent response to cold water immersion can be helpful for indicating adrenergic dysfunction (Feliciani et al., 2016).

Sweat testing is used to test sympathetic sudomotor axon function (Low et al., 2013). Quantitative sudomotor reflex testing (QSART) can test the ability to sweat. It is performed by acetylcholine iontophoresis into the skin, which elicits an axon reflex activating muscarinic receptors at sweat glands (Low, 1993). Sweat responses are typically recorded from four standard sites and compared to a normative data from healthy subjects (Illigens and Gibbons, 2009; Low et al., 1997a). Thermoregulatory sweat

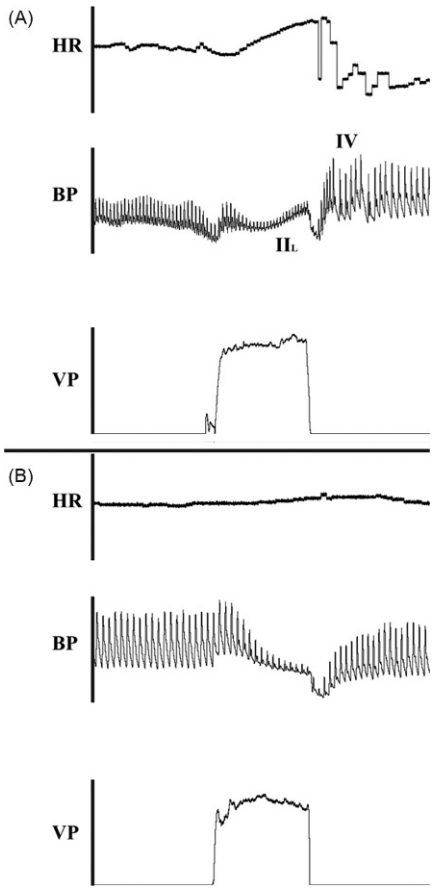

Fig. 4 Valsalva maneuver in a healthy subject (A) and a patient with neurogenic orthostatic hypotension (B). The test is performed by generating approximately 40 mmHg of Valsalva pressure by having the subject expire against a closed glottis. The increased intrathoracic pressure that occurs during Valsalva strain causes decreased venous return resulting in decreased stroke volume and a subsequent baroreflex mediated compensatory increase in heart rate and systemic vascular resistance. In the healthy subject, these compensatory responses create a late phase II (II_L) increase in blood pressure. Upon termination of Valsalva, intrathoracic pressure is suddenly reduced resulting in an increase in venous return and stroke volume. Blood pressure now increases as part of a phase IV (IV) overshoot in systolic blood pressure until the baroreceptor-mediated changes in vascular resistance reverses. In the patient with neurogenic orthostatic hypotension, the compensatory responses to blood pressure change are blunted. This results in a Valsalva pattern with reduced late phase II or phase IV overshoot blood pressure responses. *HR*, heart rate; *BP*, blood pressure; *VP*, Valsalva pressure.

testing can test for an intact sweating response. It elicits a sweating response by increasing body temperature beyond the thermoregulatory set point of the hypothalamus; the test provides an assessment of sympathetic sudomotor pathways traveling from the hypothalamus to the sweat glands (Low et al., 2013). This testing is performed by having the patient lie supine and undressed, so the exposed body can be covered with an indicator powder. The body temperature is warmed to 38°C by increasing ambient room temperature, eliciting a sweating response (Illigens and Gibbons, 2009). As the body sweats, the indicator powder changes color from brown to purple. A photograph can be taken to identify the distribution of sweating to and indicate areas of anhidrosis. The pattern of sweating can be helpful in identifying different types of autonomic disorders, as well as track disease progression over time, and evaluate the effect of treatment (Illigens and Gibbons, 2009; Low et al., 2013).

Planar nuclear imaging can be used to assess the quantitative uptake of iodine-123 metaiodobenzylguanidine (MIBG) (Low et al., 2013). MIBG is a norepinephrine analog that is taken up by presynaptic norepinephrine transporters on postganglionic adrenergic sympathetic terminals in the heart (Nwazue and Raj, 2013). The pattern of uptake can be helpful for differentiating between several autonomic conditions including MSA, pure autonomic failure, and Parkinson's disease (**Fig. 5**) (Nwazue and Raj, 2013).

Management

The initial management of OH is very similar to that of VVS. A detailed review of current medications including recent medication changes is valuable to identify any pharmacological causes for the patient's OH. Overall, the evidence for the treatment of OH (both nonpharmacological and pharmacological) is of poor quality (Logan and Witham, 2012). However, there do exist a number of important recommendations for managing these patients.

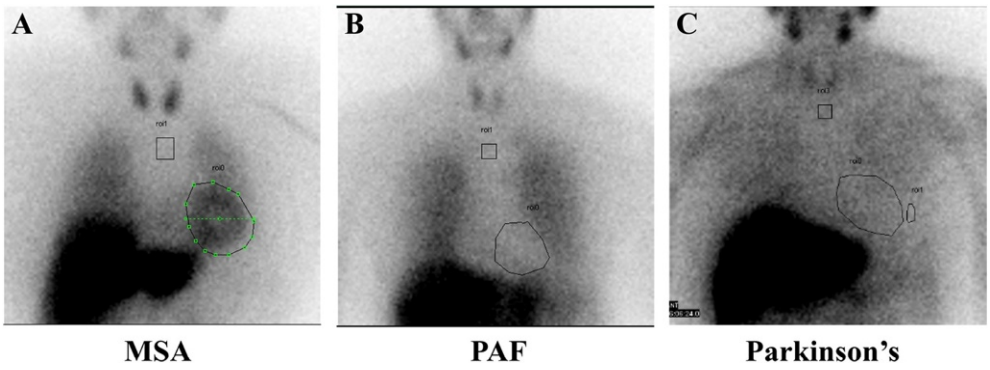

Fig. 5 Planar nuclear imaging assessing uptake of iodine-123 metaiodobenzylguanidine (MIBG) in patients with multiple system atrophy (A), pure autonomic failure (B), and Parkinson's disease (C). MIGB is taken up by postganglionic sympathetic neurons. In a patient with a preganglionic (central) autonomic disorder, such as MSA (A), the uptake of MIGB is normal. In patients with postganglionic disorders, such as primary autonomic failure (B) or Parkinson's disease (C), MIGB uptake is decreased.

Nonpharmacological

It is important to educate the patient of the risks and likely cause of OH in that individual patient. Low and Tomalia (2015) suggest four key educational themes for patients dealing with neurogenic OH: (i) The patient must understand the complications of impaired baroreflex control including OH, supine hypertension, and loss of diurnal BP variation; (ii) the goal of managing their OH will be to alleviate symptoms without causing supine hypertension; (iii) OH severity will vary with different physiological variables including the patient's volume status, meal ingestion, time of day, ambient temperature, and exercise; and (iv) patients have the ability to control plasma volume, degree of venous pooling, and vasomotor tone, which can help improve symptoms (Low and Tomalia, 2015).

Increased dietary salt and water intake

Hydration plays an important role for the patient to help maintain effective plasma volume for managing their symptoms of OH. Patients can be very preload dependent and do not tolerate even mild volume depletion very well. Patients can be advised to consume 2–3 L of water per day. Additionally, dietary salt intake can be increased up to 6–9 g per day.

Rapid ingestion of water can also be beneficial in the management of OH through the osmopressor response. This response can be elicited by rapidly drinking 500 mL of water over 2–3 min. This has been shown to cause an average rise in systolic BP of over 30 mmHg in patients with neurogenic OH (Jordan et al., 1999, 2000). The process begins within about 5 min, peaks between 20 and 40 min postingestion and lasts over 60 min in duration (Jordan et al., 2000). Water has been shown to be most effective in comparison to other solutions, such as salt water, which has been shown to in fact attenuate the response (Raj et al., 2006). This, taken along with work performed in murine models, is suggestive that the osmolality (or hypo-osmolality) of the solution is important (McHugh et al., 2010).

Compression garments

Another nonpharmacological target for patients is to reduce the effects of venous pooling while standing. Both compression stockings and abdominal binders have been shown to reduce the effects of venous pooling in the legs and splanchnic vasculature respectively. The greatest proportion of pooling occurs in the lower abdomen, which suggests that abdominal binding would provide the most effective therapeutic target (Diedrich and Biaggioni, 2004). Several studies have found efficacy with the use of either (or both) of an abdominal binder or waist high compression garments (Smit et al., 2004; Denq et al., 1997; Podoleanu et al., 2006). There are challenges with these treatments. The abdominal binder needs to be tight fitting (applying 20–30 mmHg of pressure) to have much benefit, which can be practically challenging to achieve (Ricci et al., 2015). A recent study used a servo-controlled device that inflated on standing and found it be as effective as midodrine for acutely increasing orthostatic tolerance and decreasing symptom burden (Okamoto et al., 2016). Compression stockings need to be custom fitted and to start, should exert a pressure of 30–40 mmHg (Raj and Coffin, 2013). Proper adherence can be difficult, especially in older adults, given the tightness of the stockings can make them difficult to put on.

Pharmacological

A number of pharmacological therapies exist for the treatment of OH (**Table 3**). There are two key mechanisms to counteract the physiological deficits leading to OH that medication can assist with: volume expansion and/or by increasing the pressor response during standing.

Table 3 Options for the pharmacological management of orthostatic hypotension

Medication	*Dose*	*Comments*	*References*
Volume expansion			
Fludrocortisone	0.1–0.2 mg PO q daily	Significant risk of supine hypertension	Chobanian et al. (1979)
EPO	25–50 units/kg SC	Dosing for Hgb $<$ 120; high risk of supine hypertension; expensive; injections required	Biaggioni et al. (1994), Hoeldtke et al. (1995)
Pressor agents			
Midodrine	2.5–10 mg PO q4 h $\times$3	Should not be taken within 4 h of bedtime to mitigate supine hypertension; agent of choice in the setting of supine hypertension	Wright et al. (1998), Low et al. (1997b), Kaufmann et al. (1988), Dhruva and Redberg (2010), Ramirez et al. (2014), Smith et al. (2016)
Droxidopa	100 mg PO TID up to 600 mg TID	FDA black box warning for supine hypertension	Kaufmann et al. (2014)
Yohimbine	5.4–10.8 mg PO TID	No longer commercially produced; may need to use a compounding pharmacy	Jordan et al. (1998)
Pyridostigmine	60 mg PO TID	A "smarter" drug that works more when patient upright than while supine, but not very potent; increases intestinal motility	Singer et al. (2003), Shibao et al. (2010)
Atomoxetine	18–40 mg PO BID	Low doses only are needed; more potent in patients with MSA than peripheral autonomic failure	Jordan et al. (2015), Ramirez et al. (2014)
Refractory OH			
Pseudoephedrine	40 mg PO TID	Indirect sympathomimetic	Fouad-Tarazi et al. (1995)
Octreotide	12.5–50 μg SC BID	Injectable peptide; often can be effective when other drugs fail	Hoeldtke et al. (1995)
Cafergot	100 mg/1 mg tab PO BID	No longer commercially produced; may need to use a compounding pharmacy	Dewey et al. (1998), Arnold et al. (2014)

PO, Per os; *q*, each; *TID*, three times daily; *BID*, twice daily; *SC*, subcutaneous injection; *Hgb*, hemoglobin; *OH*, orthostatic hypotension.

Volume expansion

Similar to the treatment of VVS, fludrocortisone can be considered as a secondary adjunctive therapy to increased dietary salt and water intake that can help with volume expansion. These expansion effects may provide a short-lived increase in BP. It is believed that long-term exposure to fludrocortisone enhances sensitivity to norepinephrine, thus providing a pressor response in addition to volume expansion (Chobanian et al., 1979). In patients with OH who also have supine hypertension, fludrocortisone could exacerbate the supine hypertension at night. Other side effects include leg swelling, hypokalemia, hypomagnesaemia, and heart failure (Sinn and Gibbons, 2016).

Recombinant erythropoietin (EPO) can be considered in patients with concomitant anemia and OH, which can be a common finding in patients with neurogenic OH (Biaggioni et al., 1994). EPO can be helpful as a volume expander through increased number of red blood cells. The red blood cells and hemoglobin may also cause increased peripheral vasoconstriction by acting as nitric oxide scavengers, providing a second mechanism to boost BP (Rao and Stamler, 2002). The major downsides to EPO administration are the need for injections, high cost, and high incidence of severe supine hypertension (Biaggioni et al., 1994; Hoeldtke et al., 1995).

Pressor agents

Midodrine is an US FDA approved medication for the treatment of OH. Midodrine is useful in that it provides an alpha agonistic effect to raise BP in any position. Midodrine does not however have any impact on the change in BP between positions (Singer et al., 2014). A number of studies have shown that midodrine increases BP and orthostatic tolerance in patients with OH, but the evidence that it provides a major symptomatic improvement has not been clearly demonstrated (Wright et al., 1998; Low et al., 1997b; Kaufmann et al., 1988; Dhruva and Redberg, 2010; Ramirez et al., 2014; Smith et al., 2016).

Droxidopa is a synthetic amino acid precursor to norepinephrine that has been approved by the FDA in 2014 for the treatment of neurogenic OH. Droxidopa is converted to norepinephrine by the enzyme L-amino acid decarboxylase within sympathetic neurons, and it subsequently increases circulating levels of norepinephrine. A recent randomized control trial in 162 patients with symptomatic neurogenic OH found that droxidopa increased standing BP, improved symptoms, decreased symptom impact on daily activities, and was fairly well tolerated (Kaufmann et al., 2014).

Yohimbine is an alpha-2 antagonist. Alpha-2 receptors act both centrally and peripherally in the autonomic nervous system to reduce sympathetic nervous system outflow. Yohimbine is the pharmacological opposite of clonidine. As an alpha-2 antagonist, yohimbine acts to increase sympathetic flow resulting in increased peripheral vasoconstriction and higher BP. The effects of yohimbine on BP have been shown to be similar to that of midodrine (Jordan et al., 1998).

Pyridostigmine is a reversible, peripherally acting acetylcholinesterase inhibitor. It acts by increasing acetylcholine transmission at the level of synaptic junctions that are equipped with nicotinic or muscarinic acetylcholine receptors. Since pyridostigmine amplifies acetylcholine action, but does not directly activate receptors, the effect of pyridostigmine is dependent on synaptic transmission levels. There is less physiological synaptic transmission when supine compared to when upright (Singer et al., 2003). Thus, pyridostigmine works to reduce the decline in BP with standing and does not tend to cause as much supine hypertension (Sinn and Gibbons, 2016). The pressor effects of pyridostigmine on BP are modest compared with agents like midodrine and droxidopa, and may not provide major symptomatic benefit in patients with severe OH (Shibao et al., 2010).

Atomoxetine is a norepinephrine reuptake transporter inhibitor that can help increase BP by raising synaptic norepinephrine levels since it blocks a "clearance transporter" in sympathetic neurons. This medication has been shown to significantly increase BP in patients with OH secondary to MSA (Jordan et al., 2015). One recent study in patients with pure autonomic failure found that atomoxetine induced a greater upright BP and a greater improvement in OH symptoms compared to midodrine (Ramirez et al., 2014). Further studies comparing the effects of atomoxetine in OH to placebo are currently under way (http://clinicaltrials.gov/show/NCT02784535).

There are several other options that can be used in cases of refractory orthostatic hypotension. Octreotide is a peptide that is thought to cause splanchnic vasoconstriction, which helps shunt blood into the peripheral circulation. Octreotide is a peptide that requires refrigeration and parenteral administration. Cafergot is a combination tablet consisting of caffeine and ergotamine that causes vasoconstriction through nonsympathomimetic mechanisms (Dewey et al., 1998). One small study in patients with autonomic failure found that cafergot improved seated BP to a similar degree as midodrine and improved presyncopal symptoms (Arnold et al., 2014). Pseudoephedrine is a mixed alpha-agonist, stimulating alpha-1, beta-1, and beta-2 receptors. This agent has not been found to be superior to midodrine for increasing BP or decreasing symptoms (Fouad-Tarazi et al., 1995).

Conclusions

VVS and OH are two common presentations of syncope. The diagnosis of these conditions begins with a detailed history and physical exam and may require formal autonomic function testing if the diagnosis is in doubt. Management of both conditions starts with a strong foundation of nonpharmacological management with a focus on patient education to understand the risks of both conditions, as well as day-to-day activities and precipitants that can make the conditions worse. To date, the pharmacological options for both conditions are far from perfect and should only be considered in cases that fail conservative management. Overall, VVS and OH represent two relatively common conditions that are far from being completely understood, defined, and effectively treated. There remains a great need for future research and collaboration to help the large number of patients that are affected by these conditions.

Rose KM, Tyroler HA, Nardo CJ, Arnett DK, Light KC, Rosamond W, Sharrett AR, and Szklo M (2000) Orthostatic hypotension and the incidence of coronary heart disease: The Atherosclerosis Risk in Communities study. *American Journal of Hypertension* 13: 571–578.
Sandroni P and Low PA (2009) Other autonomic neuropathies associated with ganglionic antibody. *Autonomic Neuroscience* 146: 13–17.
Schrag A, Ben-Shlomo Y, and Quinn NP (1999) Prevalence of progressive supranuclear palsy and multiple system atrophy: A cross-sectional study. *Lancet* 354: 1771–1775.

Schroeder C, Bush VE, Norcliffe LJ, Luft FC, Tank J, Jordan J, and Hainsworth R (2002) Water drinking acutely improves orthostatic tolerance in healthy subjects. *Circulation* 106: 2806–2811.
Serletis A, Rose S, Sheldon AG, and Sheldon RS (2006) Vasovagal syncope in medical students and their first-degree relatives. *European Heart Journal* 27: 1965–1970.
Shaw BH and Claydon VE (2014) The relationship between orthostatic hypotension and falling in older adults. *Clinical Autonomic Research* 24: 3–13.
Sheldon R (2013) Syncope diagnostic scores. *Progress in Cardiovascular Diseases* 55: 390–395.
Sheldon R (2015) How to differentiate syncope from seizure. *Cardiology Clinics* 33: 377–385.
Sheldon R, Connolly S, Rose S, Klingenheben T, Krahn A, Morillo C, Talajic M, Ku T, Fouad-Tarazi F, Ritchie D, Koshman ML, and Post Investigators (2006) Prevention of Syncope Trial (POST): A randomized, placebo-controlled study of metoprolol in the prevention of vasovagal syncope. *Circulation* 113: 1164–1170.
Sheldon R, Raj SR, Rose MS, Morillo CA, Krahn AD, Medina E, Talajic M, Kus T, Seifer CM, Lelonek M, Klingenheben T, Parkash R, Ritchie D, Mcrae M, and Investigators P (2016) Fludrocortisone for the prevention of vasovagal syncope: A randomized, placebo-controlled trial. *Journal of the American College of Cardiology* 68: 1–9.
Sheldon RS, Grubb BP 2nd, Olshansky B, Shen WK, Calkins H, Brignole M, Raj SR, Krahn AD, Morillo CA, Stewart JM, Sutton R, Sandroni P, Friday KJ, Hachul DT, Cohen MI, Lau DH, Mayuga KA, Moak JP, Sandhu RK, and Kanjwal K (2015) 2015 heart rhythm society expert consensus statement on the diagnosis and treatment of postural tachycardia syndrome, inappropriate sinus tachycardia, and vasovagal syncope. *Heart Rhythm* 12: e41–e63.
Shibao C, Grijalva CG, Raj SR, Biaggioni I, and Griffin MR (2007) Orthostatic hypotension-related hospitalizations in the United States. *The American Journal of Medicine* 120: 975–980.
Shibao C, Okamoto LE, Gamboa A, Yu C, Diedrich A, Raj SR, Robertson D, and Biaggioni I (2010) Comparative efficacy of yohimbine against pyridostigmine for the treatment of orthostatic hypotension in autonomic failure. *Hypertension* 56: 847–851.
Singer W, Joyner MJ, Sandroni P, Benarroch EE, Fealey RD, Mandrekar J, and Low PA (2014) Midodrine efficacy in orthostatic hypotension. *Journal of General Internal Medicine* 29: 1440–1441.
Singer W, Opfer-Gehrking TL, Mcphee BR, Hilz MJ, Bharucha AE, and Low PA (2003) Acetylcholinesterase inhibition: A novel approach in the treatment of neurogenic orthostatic hypotension. *Journal of Neurology, Neurosurgery, and Psychiatry* 74: 1294–1298.
Sinn DI and Gibbons CH (2016) Pathophysiology and treatment of orthostatic hypotension in parkinsonian disorders. *Current Treatment Options in Neurology* 18: 28.
Smit AA, Wieling W, Fujimura J, Denq JC, Opfer-Gehrking TL, Akarriou M, Karemaker JM, and Low PA (2004) Use of lower abdominal compression to combat orthostatic hypotension in patients with autonomic dysfunction. *Clinical Autonomic Research* 14: 167–175.
Smith W, Wan H, Much D, Robinson AG, and Martin P (2016) Clinical benefit of midodrine hydrochloride in symptomatic orthostatic hypotension: A phase 4, double-blind, placebo-controlled, randomized, tilt-table study. *Clinical Autonomic Research* 26: 269–277.
Sonnesyn H, Nilsen DW, Rongve A, Nore S, Ballard C, Tysnes OB, and Aarsland D (2009) High prevalence of orthostatic hypotension in mild dementia. *Dementia and Geriatric Cognitive Disorders* 28: 307–313.
Spallone V, Ziegler D, Freeman R, Bernardi L, Frontoni S, Pop-Busui R, Stevens M, Kempler P, Hilsted J, Tesfaye S, Low P, Valensi P and Toronto Consensus Panel on Diabetic Neuropathy. (2011) Cardiovascular autonomic neuropathy in diabetes: Clinical impact, assessment, diagnosis, and management. *Diabetes/Metabolism Research and Reviews* 27: 639–653.
Stenger MB, Brown AK, Lee SMC, Locke JP, and Platts SH (2010) Gradient compression garments as a countermeasure to post-spaceflight orthostatic intolerance. *Aviation, Space, and Environmental Medicine* 81: 883–887.
Stewart JM (2013) Common syndromes of orthostatic intolerance. *Pediatrics* 131: 968–980.
Takata TS, Wasmund SL, Smith ML, Li JM, Joglar JA, Banks K, Kowal RC, Page RL, and Hamdan MH (2002) Serotonin reuptake inhibitor (Paxil) does not prevent the vasovagal reaction associated with carotid sinus massage and/or lower body negative pressure in healthy volunteers. *Circulation* 106: 1500–1504.
Tan MP, Newton JL, Chadwick TJ, Gray JC, Nath S, and Parry SW (2010) Home orthostatic training in vasovagal syncope modifies autonomic tone: Results of a randomized, placebo-controlled pilot study. *Europace* 12: 240–246.
Tanaka H, Sjoberg BJ, and Thulesius O (1996) Cardiac output and blood pressure during active and passive standing. *Clinical Physiology* 16: 157–170.
Thaisetthawatkul P (2016) Pure Autonomic Failure. *Current Neurology and Neuroscience Reports* 16: 74.
Thaisetthawatkul P, Boeve BF, Benarroch EE, Sandroni P, Ferman TJ, Petersen R, and Low PA (2004) Autonomic dysfunction in dementia with Lewy bodies. *Neurology* 62: 1804–1809.
Theodorakis GN, Leftheriotis D, Livanis EG, Flevari P, Karabela G, Aggelopoulou N, and Kremastinos DT (2006) Fluoxetine vs. propranolol in the treatment of vasovagal syncope: A prospective, randomized, placebo-controlled study. *Europace* 8: 193–198.
Thijs RD, Bloem BR, and Van Dijk JG (2009) Falls, faints, fits and funny turns. *Journal of Neurology* 256: 155–167.
Thiruganasambandamoorthy V, Kwong K, Wells GA, Sivilotti ML, Mukarram M, Rowe BH, Lang E, Perry JJ, Sheldon R, Stiell IG, and Taljaard M (2016) Development of the Canadian Syncope Risk Score to predict serious adverse events after emergency department assessment of syncope. *CMAJ* 188: E289–E298.
Trahair LG, Horowitz M, and Jones KL (2014) Postprandial hypotension: A systematic review. *Journal of the American Medical Directors Association* 15: 394–409.
Van Dijk N, Boer KR, Colman N, Bakker A, Stam JAN, Van Grieken JJM, Wilde AAM, Linzer M, Reitsma JB, and Wieling W (2008) High diagnostic yield and accuracy of history, physical examination, and ECG in patients with transient loss of consciousness in FAST: The fainting assessment study. *Journal of Cardiovascular Electrophysiology* 19: 48–55.
Van Dijk N, Quartieri F, Blanc JJ, Garcia-Civera R, Brignole M, Moya A, Wieling W, and Investigators PC-T (2006) Effectiveness of physical counterpressure maneuvers in preventing vasovagal syncope: The Physical Counterpressure Manoeuvres Trial (PC-Trial). *Journal of the American College of Cardiology* 48: 1652–1657.
Velseboer DC, De Haan RJ, Wieling W, Goldstein DS, and De Bie RM (2011) Prevalence of orthostatic hypotension in Parkinson's disease: A systematic review and meta-analysis. *Parkinsonism & Related Disorders* 17: 724–729.
Vernino S, Hopkins S, and Wang Z (2009) Autonomic ganglia, acetylcholine receptor antibodies, and autoimmune ganglionopathy. *Autonomic Neuroscience* 146: 3–7.
Verwoert GC, Mattace-Raso FU, Hofman A, Heeringa J, Stricker BH, Breteler MM, and Witteman JC (2008) Orthostatic hypotension and risk of cardiovascular disease in elderly people: The Rotterdam study. *Journal of the American Geriatrics Society* 56: 1816–1820.
Vloet LC, Mehagnoul-Schipper DJ, Hoefnagels WH, and Jansen RW (2001) The influence of low-, normal-, and high-carbohydrate meals on blood pressure in elderly patients with postprandial hypotension. *The Journals of Gerontology. Series A, Biological Sciences and Medical Sciences* 56: M744–M748.
Ward CR, Gray JC, Gilroy JJ, and Kenny RA (1998) Midodrine: A role in the management of neurocardiogenic syncope. *Heart* 79: 45–49.
Wieling W, Krediet CT, Van Dijk N, Linzer M, and Tschakovsky ME (2007) Initial orthostatic hypotension: Review of a forgotten condition. *Clinical Science (London)* 112: 157–165.
Wieling W and Schatz IJ (2009) The consensus statement on the definition of orthostatic hypotension: A revisit after 13 years. *Journal of Hypertension* 27: 935–938.
Wieling W, Thijs RD, Van Dijk N, Wilde AA, Benditt DG, and Van Dijk JG (2009) Symptoms and signs of syncope: A review of the link between physiology and clinical clues. *Brain* 132: 2630–2642.
Wright RA, Kaufmann HC, Perera R, Opfer-Gehrking TL, Mcelligott MA, Sheng KN, and Low PA (1998) A double-blind, dose-response study of midodrine in neurogenic orthostatic hypotension. *Neurology* 51: 120–124.
Zeng H, Ge K, Zhang W, Wang G, and Guo L (2008) The effect of orthostatic training in the prevention of vasovagal syncope and its influencing factors. *International Heart Journal* 49: 707–712.

CONTENTS OF ALL VOLUMES

List of Contributors *xvii*

Preface *xxxv*

VOLUME 1

Adult Congenital Heart Disease 1
D Briston and E Bradley

Adverse Impact of Delayed Electrical Activation of the Heart and Benefits of Cardiac Resynchronization 10
A Guha and EG Daoud

AL Cardiac Amyloidosis: Classification, Diagnosis, and Treatment 34
OK Siddiqi and FL Ruberg

Alcohol 49
C Matsumoto

Alcoholic Cardiomyopathy 58
A Voiosu, S Wiese, JD Hove, T Voiosu, F Bendtsen, and S Møller

Amyloid Cardiomyopathy 66
T Sher and MA Gertz

Anemia in Heart Failure 80
A Patel and NL Altman

Angiogenesis 85
N Warmke, AMN Walker, and RM Cubbon

Animal Models of Ischemic Heart Disease: From Atherosclerosis and Thrombosis to Myocardial Infarction 97
R Covarrubias, AS Major, and RJ Gumina

Ankle-Brachial Pressure Index and Pulse Wave Velocity in Cardiovascular Risk Assessment 111
H Tomiyama and A Yamashina

Aortic Aneurysm 123
M Singh, BA Ziganshin, and JA Elefteriades

Aortic Valve Replacement in Patients With Congestive Heart Failure 143
VJ Nardy, JA Crestanello, and NP Jaik

Arrhythmias in Cancer and Cancer Treatment: A Review 162
D Haddad, A Guha, F Awan, EG Daoud, and R Baliga

Arrhythmogenic Right Ventricular Cardiomyopathy 182
MR Afzal, C Evanson, A Cardona, K Rusk, and R Weiss

Arrhythmogenic Right Ventricular Dysplasia/Cardiomyopathy 192
GM Orgeron and H Calkins

Athlete's Heart 205
LM Safi and MJ Wood

Atrial Tachycardia—Mechanisms and Management 212
J Ahmed and P LeLorier

Atrioventricular Node Reentrant Tachycardia 224
AG Carrizo, B Ballantyne, and A Baranchuk

ATTR Cardiac Amyloidosis: Classification, Diagnosis, and Management 242
JA Cowgill and JN Wight Jr.

Behavior Modification and Cardiovascular Disease 257
V Ramirez, B Starobin, and J Monti

Bicuspid Aortic Valve and Sports Activity 263
L Stefani, G Galanti, and N Maffulli

Bioinformatics Principles for Deciphering Cardiovascular Diseases 273
L Shu, D Arneson, and X Yang

Biomarkers in Heart Failure, Use of 293
PU Gandhi

Biomarkers in Ischemic Heart Disease 303
JT Neumann and RB Schnabel

Biomarkers: Heart Failure 315
SS Gogia and JE Ho

Biomarkers: Population Screening and Risk-Stratification 323
I Ratjen, RS Vasan, and W Lieb

Biophysics of Ablation—Radiofrequency and Cryoablation 334
JG Andrade, MW Deyell, and L Macle

Blood Pressure Variability Versus Blood Pressure Level in Risk Stratification 350
F-F Wei, K Asayama, A Hara, TW Hansen, Y Li, and JA Staessen

Brugada Syndrome 356
C Antzelevitch

Cardiac Anatomy, Physiology, and Pathophysiology 373
KN Hor and AJ Trask

Cardiac and Induced Pluripotent Stem Cells 384
A Salerno, W Balkan, K Hatzistergos, and JM Hare

Cardiac Arrhythmia in Heart Failure 394
T Okabe and SJ Kalbfleisch

Cardiac Biomechanics in Normal Physiology and Disease 411
KM Broughton

Cardiac Fibroblast 420
J Park and MD Tallquist

Cardiac Hypertrophy: Signaling and Cellular Crosstalk 434
D Tirziu

Cardiac Magnetic Resonance Imaging in Heart Failure 451
A Reynolds and KM Zareba

Cardiac Pacing and Monitoring: Past, Present, and Future 463
F Chalhoub and T Mela

Cardiac Regeneration and Stem Cells as Therapy for Heart Disease 468
AJ Favreau-Lessard and DB Sawyer

Cardiac Resynchronization Therapy 475
G Voros

Cardiac Transplantation 489
A Hasan

Cardiohepatic Interactions 514
J Shah and E Shao

Cardiopulmonary Exercise Testing 523
V Franco

Cardiovascular Complications and Management in Sarcoidosis: A Review 527
DJ Roberts, S Francis, JA Rosenblatt, and ST Coffin

Cardiovascular Disease and Obesity 535
Y Matsushita

Catecholaminergic Polymorphic Ventricular Tachycardia 542
PJ Kannankeril

Catheter Ablation for Atrial Fibrillation (Methods) 553
JG Andrade, MW Deyell, and L Macle

Catheter Ablation for Ventricular Tachycardia 566
RM John and WG Stevenson

Cellular Sinoatrial Node and Atrioventricular Node Activity in the Heart 576
HJ Jansen, TA Quinn, and RA Rose

Chronic Infections of the Heart 593
M Edwards, C Withers, and K Thakarar

Chronic Kidney Disease as a Risk Factor for Cardiovascular Disease 600
T Ninomiya

Clinical Assessment of the Cardiac Arrhythmia Patient 609
B Olshansky

Clinical Management of Inherited Arrhythmias 620
RL Jones and MV Perez

Clinical Trials for Atrial Fibrillation—What Do We Know? 630
DS Chew and SB Wilton

Complications of Pregnancy and Future Cardiovascular Risk 643
PH Andraweera, GA Dekker, M Arstall, T Bianco-Miotto, and CT Roberts

Comprehensive Lifestyle Modification for Hypertension and Lifestyle-Related Disease Under the New Guidelines 651
Y Kokubo and C Matsumoto

Computational Systems Biology for the VEGF Family in Angiogenesis 659
JC Weddell and PI Imoukhuede

Congenital Heart Valve Disease in the Adult 677
A Luk, J Alvarez, and J Butany

Coronary Anatomy 691
M Sivananthan

Coronary Artery Bypass Grafting 700
RS Kramer, JR Morton, RC Groom, and DL Robaczewski

Cyanotic Congenital Heart Disease 730
MS Renno and JA Johns

VOLUME 2

Dairy Products and Cardiovascular Diseases 1
M Yanagi, N Amano, and T Nakamura

Diabetes Mellitus 9
H Sone

Diagnosis and Imaging of Congenital Heart Disease 17
SR Fuchs and JH Soslow

Diagnosis of Non-ST-Elevation Myocardial Infarction (NSTEMI) 47
M Vafaie and E Giannitsis

Diet in Heart Failure 54
M Rozmahel, E Colin-Ramirez, and JA Ezekowitz

Dietary Fat and Risk of Cardiovascular Disease 60
ES Eshak, K Yamagishi, and H Iso

Digital Data (mHealth and Social Media) 90
R Bhattacharjee and T Hussein

Diseases of the Mitral Valve 98
L Mc Carthy and P Collier

Diuretic Therapy 107
A Vazir, V Sundaram, and AR Harper

Driving and Syncope 117
D Sorajja and W-K Shen

Echocardiography in Heart Failure 126
T Chen and JN Kirkpatrick

Echocardiography: Assessment of Valve Structure and Function 142
S Vallurupalli, A Siraj, and S Kenchaiah

Economics of Heart Failure 187
S Stewart, C Mainland, and A David

Electrocardiographic Monitoring Strategies (Holter, Implantable Loop Recorder, in Between) 197
H Nazzari, L Halperin, and AD Krahn

Electrophysiology Approaches for Ventricular Tachycardia 211
RM John and W Stevenson

Emergency Medicine Approach and Management of Traumatic Injuries: An Overview 221
E Lavine and E Legome

Environmental Air Pollution: An Emerging Risk Factor for Stroke 231
B Delpont, AS Mariet, C Blanc, Y Bejot, M Giroud, and J Reis

Environmental Risk Factors for Stroke and Cardiovascular Disease 238
J Reis, M Giroud, and Y Kokubo

Epidemiology of Atherosclerotic Cardiovascular Disease 248
N Townsend

Epigenomics 258
TA Turunen, M-A Väänänen, and S Ylä-Herttuala

Exercise and Cardiac Rehabilitation in Heart Failure 266
SR Schubert

Exercise, Physical Activity, and Cardiovascular Disease 274
A Bauman, M Alharbi, N Lowres, R Gallagher, and E Stamatakis

Extracorporeal Membrane Oxygenation 281
A Kilic

Familial Hypercholesterolemia 285
A Pirillo and AL Catapano

Frailty in Heart Failure Patients 298
S Pedraza, TA Barrett, and CM Hritz

Genetic Atrial Fibrillation 303
R Chia, A Mehta, H Huang, and D Darbar

Genetic Disorders Involving Valve Function 313
M Afshar and G Thanassoulis

Genetic Disorders of the Vasculature 327
AJ Brownstein, BA Ziganshin, and JA Elefteriades

Genetics of Heart Failure 368
A Briasoulis, R Asleh, and N Pereira

Heart Development 380
E Dees and S Baldwin

Heart Failure in African Americans 399
M Jame, S Jame, and M Colvin

Heart Failure in Cancer Patients 406
A Vallakati, B Konda, and R Baliga

Heart Failure in Low- to Middle-Income Countries 417
S Stewart, F Taylor, and AK Keates

Heart Failure in Minorities 429
ER Fox, ME Hall, JD Pollard, SK Musani, CJ Rodriguez, and RS Vasan

Heart Failure in the Elderly 437
S Katsanos and J Parissis

Heart Failure Monitoring 453
ES Shao

Heart Failure With Preserved Ejection Fraction 464
S Day

Heart Regeneration with Stem Cell Therapies 469
M Natsumeda, BA Tompkins, V Florea, AC Rieger, M Banerjee, W Balkan, and JM Hare

Heart–Lung Transplantation 484
B LeNoir, M Malik, and BA Whitson

Hemodynamic Changes of Pregnancy 489
P Divanji and NI Parikh

Hemodynamics of the Right Heart in Health and Disease 497
DM Gopal and A Alsamarah

Hormonal Therapy in the Treatment of Chronic Heart Failure 508
R Napoli, A Salzano, E Bossone, and A Cittadini

Hypertensive Heart Disease 517
MU Moreno, A González, B López, S Ravassa, J Beaumont, G San José, R Querejeta, and J Díez

Hypertrophic Cardiomyopathy 527
LK Williams

VOLUME 3

Imaging of Mitral Regurgitation 1
JB Strom, KF Faridi, and CW Tsao

Imaging: CT Scanning of the Heart and Great Vessels 12
M Eid, MH Albrecht, CN De Cecco, D De Santis, A Varga-Szemes, D Caruso, VW Lesslie, and UJ Schoepf

Imaging: Echocardiology—Assessment of Cardiac Structure and Function 35
D Bamira and MH Picard

Immune Mechanisms in Cardiac Physiology 55
SM Peterson, DJ Roberts, and S Ryzhov

Immune-Mediated Mechanisms of Atherosclerosis 68
M Bäck, DFJ Ketelhuth, S Malin, PS Olofsson, G Paulsson-Berne, Z-Q Yan, and GK Hansson

Implanted Pacemakers—Indications and Novel Programming 77
R Willems

Induced Pluripotent Stem Cell–Derived Cardiomyocytes in Advancing Cardiovascular Medicine 87
C Zhang, AG Cadar, and CC Hong

Infective Endocarditis in 21st Century 94
VV Kandasamy, S Pant, and JL Mehta

Inflammatory and Infectious Disorders of the Aorta 102
V Noori, B Nolan, and C Healey

Inotropes in Heart Failure 108
M Ginwalla and C Bianco

Interventions: Endomyocardial Biopsy 119
B Kherad, U Kühl, and C Tschöpe

Intra-aortic Balloon Pumps (IABP) and Percutaneous Ventricular Assist Devices (VADs) 126
NK Kapur and ML Esposito

Ion Channelopathy Genetics 132
A Adler and MH Gollob

Ischemic Cardiomyopathy 145
S Airhart and S Murali

Kidney in Heart Failure 155
DN Pratt and A Diez

Lead-Related Complications 166
B Mondesert and R Parkash

Left and Right Ventricular Remodeling 171
D Pinkhas and X Gao

Left Ventricular Assist Device (LVAD) and Circulatory Devices in Heart Failure 186
P Lee

Left-Sided Obstructive Congenital Heart Lesions: Including Hypoplastic Left Heart 200
CJ Prendergast and GT Nicholson

Lipid-Mediated Mechanisms in Atherosclerosis 214
Q Liu, J Martinez, J Hodge, and D Fan

Lipids and Cardiovascular Diseases: Epidemiologic Perspectives 221
T Okamura, D Sugiyama, T Hirata, K Kuwabara, and A Hirata

Long QT Syndrome and Torsade de Pointes 230
N El-Sherif, G Turitto, and M Boutjdir

Management and Care of Older Cardiac Patients 245
AA Damluji, A Ramireddy, and DE Forman

Management of Cardiac Sarcoidosis 266
L Alghothani and ED Crouser

Management of Patients With Implantable Cardiac Devices Referred for Magnetic Resonance Imaging: A Rapidly Changing Landscape 274
I Roifman and JA White

Management of Pregnancy With Underlying Congenital and Acquired Cardiac Disease 282
AM Moran

Management of Ventricular Tachycardia in Ischemic and Nonischemic Cardiomyopathy 292
A AbdelWahab, VP Kuriachan, GL Sumner, LB Mitchell, and J Sapp

Managing Cardiovascular Disease in Sport and Athletes 302
AB Shah and AL Baggish

Mechanisms of Cardiac Arrhythmias: Molecular and Cellular Perspective 316
P Zhabyeyev and GY Oudit

Medical Management of Left Ventricular Assist Devices 328
S Emani

Metabolomics in Cardiovascular Research 331
V Salomaa and M Inouye

MicroRNAs in Cardiac Development and Function 340
Y Tian

Microvasculature in Health and Disease 349
JE Beare, L Curtis-Whitchurch, AJ LeBlanc, and JB Hoying

Mitochondrial Bioenergetics in the Heart 365
EJ Lesnefsky, Q Chen, B Tandler, and CL Hoppel

Modern Considerations in ICD Therapy 381
TD Richardson and CR Ellis

MR Imaging of the Heart and the Great Vessels 388
U Neisius and C Tsao

Myocardial Perfusion Imaging 404
RB Morgan

Myocardial Repair 425
K Breckwoldt and T Eschenhagen

Myocarditis 440
ALP Caforio, G Malipiero, R Marcolongo, and S Iliceto

Myocarditis in Heart Failure 452
G Sinagra, J Artico, P Gentile, E Fabris, R Bussani, A Cannatà, and M Merlo

Neurohormonal Blockade 459
L Cunningham, W Kayani, and A Deswal

Neurological Regulation of the Circulation 477
DN Jackson, NM Novielli, and J Twynstra

Noninfective Inflammatory Disorders of the Pericardium 492
B Ravaee and BD Hoit

Non-ST-Elevation Acute Coronary Syndrome Prognosis 502
H Haghbayan, CP Gale, and AT Yan

Non-ST-Elevation Myocardial Infarction: Management 522
M Cimci, B Gencer, and M Roffi

Nutrition—Macronutrients 531
T Nakamura and S Kuranuki

Nutrition: Soy and Fish 538
Y Yamori, M Sagara, H Mori, and M Mori

Obesity and the Obesity Paradox in Heart Failure 546
AA Oktay, CJ Lavie, and HO Ventura

Oral Health and Cardiovascular Disease: Recent Findings and Future View With a Novel Aspect 565
T Ono, M Kida, T Kosaka, and M Kikui

Orthostatic Hypotension and Vasovagal Syncope 573
BH Shaw, Jessica Ng, and SR Raj

VOLUME 4

Palliative Care in Advanced Heart Failure 1
M Ginwalla and BP Dhakal

Pediatric Catheter Ablation 8
AE Radbill, FA Fish, and TP Graham Jr.

Perioperative Management in Heart Failure 37

PREFACE

The burden of cardiovascular disease is growing across the globe as the leading noncommunicable cause of morbidity and mortality. This is despite outstanding research that has improved our understanding of cardiovascular biology, the determinants of disease, and development of new therapies. We are optimistic that the next generation of scientists and clinicians will further these efforts and ultimately bring about changes that will reduce risk and improve outcomes for patients worldwide. We have assembled this encyclopedia with the explicit intent to provide this generation with easy access to past and current wisdom, with the hope that this helps to accelerate innovation in cardiovascular medicine.

This encyclopedia represents both a dream and a labor of love. The dream is to create a scientific compendium that recognizes that the methods and tools used to access and study the scientific literature have changed, with a burgeoning impact of digital technology—the so-called pocket book encyclopedia that is accessible on a smart phone fitting into medical overalls, and that can also be read as a textbook at a desk! These changes in the access of publications have been accompanied by the evolving need for studying different aspects of biology and disease as stand-alone chapters not necessarily read sequentially. Furthermore, as editors we recognize the fundamental importance of conveying knowledge through brilliantly illustrated texts that are profusely embedded with links to key references. The critical importance to use multimedia tools and to provide downloadable slides for educational purposes is reflected in this encyclopedia. Additionally, we want to ensure the feasibility of updating text, figures, and other reading material iteratively even after a publication date, recognizing the rapid advent of information and huge strides made in cardiovascular medicine every day. Thus, this work represents the end of the beginning of a live text that will metamorphose over time, being guided by the rapid strides and advances in both cardiovascular medicine and publication science.

Overall, we conceptualized this work as providing broad coverage of science and also serving the expansive needs of a readership that is quite diverse, that is, encompassing medical students, residents, fellows, and postdoctoral scientists interested in cardiovascular medicine. We hope the labor of love of an outstanding team of editors and a stellar group of authors is readily evident to the broad readership we have targeted.

Assembling this compendium had many challenges. Early on we made the choice to cover the broad range of cardiovascular biology, pathophysiology, epidemiology, and treatment of disease. We sought to assure equal coverage to foundational cardiovascular cellular and molecular biology as well as state-of-the-art treatments. Covering the breadth inevitably led to some overlap between some chapters, and yet we certainly have some residual gaps. We hope to have the opportunity to fill these gaps in future editions. There is also inevitable variation in the style and scope of articles in this multiauthor publication. We and the section editors felt it was more important to allow our expert authors freedom in how they chose to present their topic.

We invite feedback on how this encyclopedia can be improved as a resource for trainees worldwide. Undoubtedly, as noted above, there are gaps in content areas that need to be bridged in future iterations of this encyclopedia. We look forward to hearing from and listening to our readership about how the text can be better organized or better compiled to serve their scholarship better in future years.

This project was made possible through the hard work of many people from across the globe. We were pleased to have section editors and authors from around the world. Drs. Kessler and Schunkert, renowned cardiologists with an outstanding record of accomplishment in genetic research, have compiled a series of chapters on genetics and genomics. Dr. Baliga, a distinguished cardiologist and educator, has conceptualized a tour de force of chapters that capture all aspects of the heart failure syndrome, whereas Dr. DiSalvo, a master clinician and educator, has synthesized a fine tapestry of chapters focusing on diagnostic testing with key sections on cardiac imaging, interventions, and device therapy. Dr. Raj, an outstanding clinical investigator and

electrophysiologist, brought together an exemplary collection of chapters that offer coverage of a broad spectrum of topics in cardiac electrophysiology. Drs. Major and Liaw, both highly accomplished basic scientists and educators, were instrumental in identifying topics of fundamental importance to the field of cardiovascular biology and medicine. Dr. Lenihan, a pioneering clinical scientist and outstanding cardiologist, brought together a special set of articles that represent interactions between cardiovascular and other fields of medicine. Dr. Gale, a celebrated cardiologist with expertise in comparative effectiveness research and clinical cardiology, offers a series of stellar chapters underscoring various aspects of the pathogenesis and management of atherosclerotic cardiovascular disease. Dr. Kokubo, a leading preventive cardiologist with specialization in cardiovascular epidemiology, has orchestrated state-of-the-art chapters on cardiovascular epidemiology.

We would like to thank our colleagues at Elsevier who provided steadfast support of an exemplary nature throughout this long journey. Last but not the least, the editors would like to thank their families, their mentors, and their respective institutions for the constant encouragement, advice, and support over the years.

Introduction

The incidence of heart failure (HF) is on the rise due to multiple cardiovascular risk factors, including coronary artery disease, diabetes mellitus, obesity, and hypertension. Its prevalence is projected to increase by 46% from 2012 to 2030 to 8 million people in the United States (Writing Group Members et al., 2016). HF patients who are refractory to conventional medical and device therapies are classified under the American College of Cardiology Foundation/American Heart Association (ACCF/AHA) Guideline for the Management of HF as Stage D HF (Yancy et al., 2013). The proportion of advanced or stage D HF patients is uncertain, although it has been estimated to be 5%–10%, which suggests that there are 300,000–600,000 patients in the United States with stage D HF (Mancini and Lietz, 2010). The mortality rate of stage D HF patients remains high with an estimated 1-year mortality rate of 29.6% and 5-year mortality of 50% (Mancini and Lietz, 2010). These patients have limited options, which include cardiac transplantation, mechanical circulatory support, home inotropes, and hospice care (Hunt et al., 2001).

Advanced HF patients have progressive or persistent severe symptoms of HF such as dyspnea, fatigue, and fluid retention which lead to a poor quality of life (Mancini and Lietz, 2010; Metra et al., 2007). Chronic ill-health due to HF can also lead to psychiatric disorders such as depression and anxiety (Mancini and Lietz, 2010). Many patients with advanced HF may not be candidates for advanced therapies or may choose not to avail of these advanced therapies. Palliative care is an important modality in the management of these patients and helps to alleviate their symptoms and improve their quality of life. Palliative care does not exclude conventional life-prolonging treatment, which can be integrated into the overall care of the advanced HF patient (**Fig. 1**) (Ginwalla, 2016a).

Definition of Palliative Care

Various healthcare agencies have defined palliative care in different ways:

- World Health Organization (WHO): An approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual (World Health Organization, 2016).
- Institute of Medicine (IOM): The care that provides relief from pain and other symptoms supports quality of life, and is focused on patients with serious advanced illness and their families (IOM (Institute of Medicine), 2015).
- National Hospice and Palliative care organization: A patient and family-centered care that optimizes quality of life by anticipating, preventing, and treating suffering and it addresses physical, intellectual, emotional, social, and spiritual needs of patient and families and facilitate patient autonomy, access to information, and choice (Organization NHaPC, 2016).

The Conundrum of Timing of Referral to Palliative Care

One dilemma that healthcare providers face is the timing of referral to palliative care. Advanced HF patients go through the waxing and waning phases of their disease and it may be challenging to decide when to offer palliative care to these patients (Allen et al., 2012). The common misconception in the general medical community is equating palliative care to end of life and hospice care (Ziehm et al., 2016). In addition to advanced HF, palliative care can also help in the management of patients with chronic symptomatic HF, and consideration for referral should be made during the entire treatment course by their providers (Goodlin, 2009).

Clinical markers and predictive tools may help in identifying patients with advanced HF (**Table 1**). According to the 2013 ACCF/AHA Guideline for the management of HF, "palliative and supportive care is effective for patients with symptomatic advanced HF to improve quality of life" (Class I, Level of Evidence B). "Before hospital discharge, at the first postdischarge visit, and in subsequent follow-up visits, the need for palliative care and hospice should be addressed in all HF patients" (Class I, Level of Evidence B) (Yancy et al., 2013).

Additionally, all patients undergoing advanced therapy options including cardiac transplantation, LVAD implantation, and home inotrope therapy should be evaluated by the palliative care team for advance care planning. This is the process of defining the types of medical and nonmedical care that a patient would and would not like to receive compatible with individual goals and values. It is helpful to involve the patient's family in the advance care planning process to ensure their awareness of the patient's decisions.

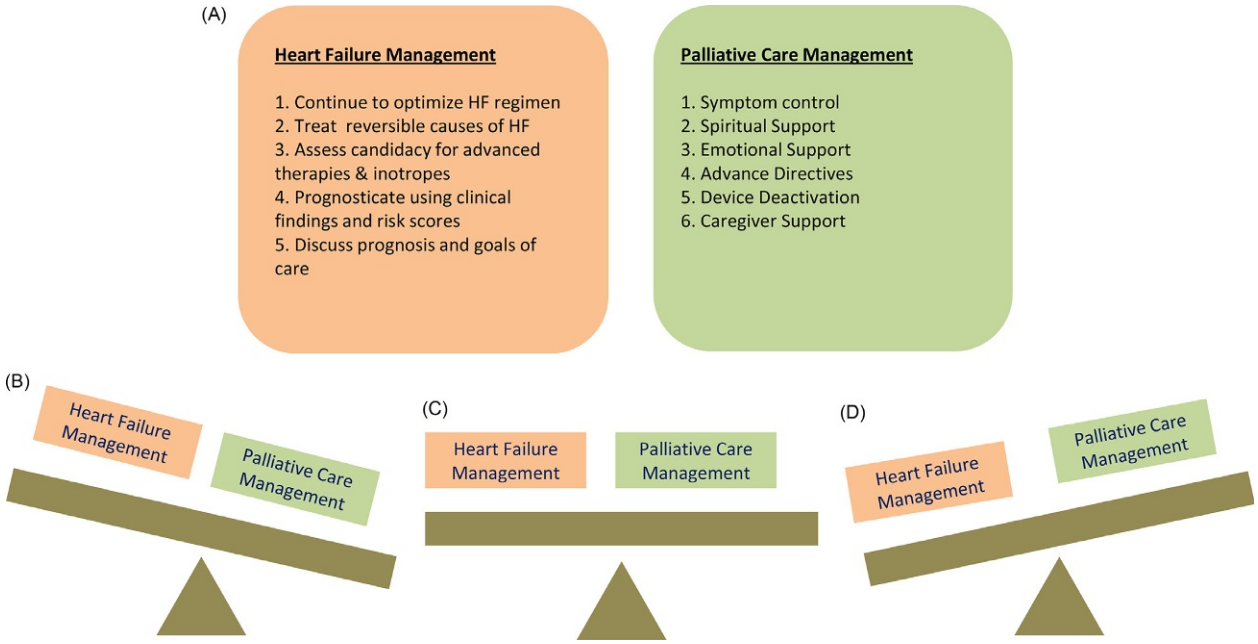

Fig. 1 Balance between the Components of Heart Failure and Palliative Care Management. (A) Shows the components of Heart Failure and Palliative Care Management in patients with heart failure. As the disease progresses, the balance changes at different stages during the course of the patient's illness—during the active medical care (B), advanced stage (C), and end-stage when patients have no other therapeutic options (D).

Table 1 Triggers for referral of heart failure patients to palliative care

1.	Severe heart failure symptoms at rest or with minimal exertion (NYHA class IIIb/IV)
2.	$\geq$1 episode of decompensation leading to hospitalization in the past 6 months despite maximal guideline-directed medical therapy
3.	Need for escalating doses of diuretics or unable to tolerate diuretics due to renal dysfunction or hypotension
4.	Patient intolerant to previously well-tolerated HF medications (renin angiotensin aldosterone blockade or mineralocorticoid receptor antagonist)
5.	Evidence of end-organ failure including renal and hepatic dysfunction
6.	Need for short-term or continuous inotropic support
7.	Reduced functional capacity as evidenced by inability to exercise, 6MWT $<$300 m, peak VO_2 $<$12–14 mL/kg/min
8.	Increased mortality risk ($>$50% within a year) as predicted by various risk scoring models (Seattle Heart Failure Model, Heart Failure Survival Score)
9.	Consideration for Advanced HF therapies such as LVAD or transplant
10.	Signs of cardiac cachexia
11.	Malignant arrhythmias

Modified from Ginwalla (2016a).

Economic Benefits of Palliative Care in Advanced HF

The cost of HF care was nearly $30.7 billion in 2012, 68% of which was attributable to direct medical costs. This cost will increase almost 127% to $69.7 billion in 2030 (Mozaffarian et al., 2015). A major contribution to the cost of HF care is likely related to recurrent hospitalizations, complications, and advanced therapy options for patients with advanced HF.

Palliative care and hospice are documented to be underutilized in advanced HF patients, with some studies reporting less than 10% referral of advanced HF patients (Greener et al., 2014; Bakitas et al., 2013). The goal of palliative care is to alleviate symptoms and improve the quality of life of HF patients and can be integrated into the treatment plan at any stage of HF (Whellan et al., 2014).

In a retrospective analysis of hospital costs of patients with advanced diseases including congestive HF enrolled in Medicaid between 2004 and 2007 at four New York State hospitals, Morrison et al. (Morrison et al., 2011) found that palliative care team consultations reduced the in-hospital costs by $6,900 ($4,098 for patients discharged alive, and $7,563 for patients who died in the hospital) during a given admission for patients who received palliative care than a matched group of patients who received usual care. Patients who received palliative care spent less time in intensive care units and were less likely to die in those units (Morrison et al., 2011). They estimated a potential savings benefit of $84–252 million reduction in annual Medicaid hospital spending in New York State (assuming that 2% and 6% of Medicaid patients discharged from the hospital received palliative care, respectively), if every hospital with $\geq$150 beds had a fully operational palliative care consult team (Morrison et al., 2011). Similarly, post-discharge palliative care program has been found to reduce readmissions and improving symptom control among patients with end-stage HF (Wong et al., 2016). Enrollment of advanced HF patients into a hospice program has been shown to reduce the mean Medicare cost per patient from $53 528 to $46 792 (Pyenson et al., 2004). With increasing healthcare costs, the integration of palliative care in the management of advanced HF patients may reduce costs associated with HF and help patients and their families with overall improved care.

Pharmacologic Therapies in Palliative Care

Patients with advanced HF have multiple symptoms which may be treated by optimizing their HF medications and symptom-directed therapy by the palliative care specialist.

A. *Dyspnea and edema:* Shortness of breath is the cardinal symptom of HF and is usually alleviated with oral diuretics. Torsemide and bumetanide have better bioavailability compared to furosemide and are preferred in advanced HF patients. In patients unable to take oral diuretics and those resistant to orals, intravenous or rarely even subcutaneous (Farless et al., 2013) route can be used for symptom relief. Guideline-directed medical therapy including angiotensin converting enzyme (ACE) inhibitors, angiotensin receptor blocker (ARB), digoxin, mineralocorticoid antagonists, and beta-blockers should be continued unless intolerant. There is significant variability among different hospice services about that (Lum et al., 2016). Dietary salt and fluid restriction are appropriate to reduce the progression of volume overload and need for diuretics (Whellan et al., 2014). Palliative intravenous inotropic support with milrinone or dobutamine may be considered for symptom control in patients with stage D HF who are not eligible for either MCS or cardiac transplantation (Class IIb, Level of Evidence B) (Yancy et al., 2013; Gorodeski et al., 2009). However, long-term use of these therapies may increase the overall mortality due to malignant arrhythmias (Stevenson, 2003; Hauptman et al., 2006).

   Opioid analgesics are helpful in relieving air hunger and dyspnea in patients with advanced HF (Whellan et al., 2014). Hydromorphone and oxycodone can be used orally in the short term but in those patients with worsening renal function, methadone or fentanyl are better options due to less accumulation of toxic metabolites. Oxygen supplementation is beneficial in hypoxic patients and anxiolytics such as benzodiazepines can relieve dyspnea caused by concomitant anxiety (Goodlin, 2009).

B. *Pain:* Pain in advanced HF patients may be due to cardiac ischemia and swelling of the extremities. Effective control of pain can help alleviate secondary disease manifestations such as depression and dyspnea. Opioids may be used to help control pain. Nonsteroidal antiinflammatory agents are generally avoided due to increased risk of gastrointestinal bleed and worsening of renal function.

C. *Depression:* Depression is widely prevalent in HF patients with NYHA functional class IV (Rutledge et al., 2006). Selective serotonin reuptake inhibitors (SSRIs) at low doses are generally considered to be first-line agents for the treatment of depression in HF (Goodlin, 2009; Whellan et al., 2014; Adler et al., 2009). Fluid retention and hyponatremia may occur in patients with renal insufficiency and some antidepressants prolong the QTc interval.

D. *Fatigue:* Low cardiac output, loss of muscle mass, deconditioning due to immobility, and comorbid conditions such as anemia, thyroid dysfunction, sleep disorders, and depression may lead to fatigue and weakness in patients with advanced HF. Regular exercise, including aerobic exercise and resistance training with light weights, should be encouraged in patients who are able to exercise (Goodlin, 2009; Whellan et al., 2014; Adler et al., 2009).

E. *Anxiety:* Anxiety can be a prominent symptom as the disease progresses both due to advanced HF symptoms and fear of dying. Norpharmacologic therapy such as involvement of family members, support group, and HF education about controlling their symptoms may decrease the emotional stress (Sullivan et al., 2009). Short acting benzodiazepines such as lorazepam and sometimes even morphine may alleviate the anxiety in these patients (Goodlin, 2009).

Home Inotrope Therapy

Continuous home inotropic infusion with dobutamine, dopamine, and milrinone can be used as a palliative measure to help improve symptoms in patients with advanced HF (Stevenson, 2003; Hauptman et al., 2006; Sindone et al., 1997). Newer inotropic agents including Levosimendan are currently under investigation in the United States (Fruhwald et al., 2016). Inotrope use in the current era has been shown to have a median survival of 9–18 months, compared with 3–6 months in the previous era, which may be due to the increased use of beta-blockers and defibrillators in this population (Ginwalla, 2016b).

The ACC/AHA guidelines support the use of palliative home inotropes in patients with stage D HF as a IIb (Level of evidence B) recommendation (Yancy et al., 2013). Home inotrope therapy is recommended only if there is clear demonstration of both symptomatic and hemodynamic benefit from the inotrope infusion (20% improvement in cardiac index or reduction in pulmonary capillary wedge pressure) (Fang et al., 2015). Due to the cost associated with home inotropes, very few hospice agencies cover its use in hospice patients.

Pleural and Peritoneal Catheters and Dialysis for Symptom Relief in Palliative Care

Patients who are symptomatic due to pleural effusions or ascites can benefit from thoracentesis or paracentesis. Sometimes permanent indwelling catheter placement may be required if the fluid collection is persistent and is not relieved with intermittent drainage (Harris and Chalhoub, 2012; Herlihy et al., 2009). Those patients who have progressive disease with worsening renal function or who are resistant to diuresis can benefit from hemodialysis (HD). However HD is not recommended as the primary treatment method for end-stage HF patients with worsening renal function. Peritoneal dialysis (Lu et al., 2015; Francois et al., 2015) or ultrafiltration (Frohlich et al., 2015) may be a better option for advanced HF patients who do not tolerate HD due to hypotension.

Palliative Medicine in Patients With Left Ventricular Assist Devices as Destination Therapy

Patients with advanced HF may be candidates for a left ventricular assist device (LVAD) implantation. These can be used as a bridge to transplant (BTT) or as destination therapy (DT) (Feldman et al., 2013). These terms are interchangeable as patients who receive a BTT LVAD may develop contraindications to transplant and continue as DT, and conversely DT patients may become eligible for an LVAD.

Palliative care consultation is recommended in all patients with advanced HF undergoing consideration for mechanical support implantation (Feldman et al., 2013). Although patients often experience significant improvement in their symptoms and functional capacity, other symptoms including pain, depression, and adjustment disorders may remain or occur de novo after device implantation. These patients may develop complications including acute stroke, LVAD-related infections, and gastrointestinal bleeding. Early consultation of palliative care provides patient and caregiver support and help with symptom management longitudinally during the continuum of their illness (Brush et al., 2010).

In addition to symptom management, goals and preferences for end of life including establishing advance directives and a living will should be discussed with patients receiving MCS (Feldman et al., 2013). Advance care planning in these patients, also called preparedness planning, is important to document decisions regarding appointment of a patient surrogate decision maker and patient care preferences in the event of device complications including strokes and acute device failure (Swetz et al., 2011). The 2013 ACCF/AHA HF guideline recommends that clinicians should address symptom control, psychological distress, health-related quality of life, patient preferences, and caregiver support, while providing ongoing access to evidence-based optimal medical therapy (Yancy et al., 2013). Addition of a palliative care member to the core interdisciplinary LVAD team is now included as a requirement for Joint Commission MCS certification (The_Joint_Commission, 2014).

The management of LVAD patients near the end of life poses unique challenges to the patient, family, and care providers. Patients may have acute complications or a progressive decline, and early involvement of the palliative care team can help guide the process and ensure the patient's symptoms are controlled when the LVAD is discontinued. They can also help provide adequate caregiver support and ease the decision-making process at the time of withdrawal of LVAD support.

Device Therapy and Deactivation in Advanced HF

Implantable cardioverter defibrillators reduce mortality from sudden cardiac death in HF patients, however they are not beneficial in the advanced HF with less than 1 year survival (Yancy et al., 2013; Tracy et al., 2012). Cardiac resynchronization therapy (CRT) can improve the functional capacity in advanced HF patients and improve survival, however it is not indicated for patients whose comorbidities limit survival to less than 1 year (Yancy et al., 2013). Sometimes, faster pacing in advanced HF patients may generate higher cardiac output and may improve symptoms. Despite these perceived benefits of ICD and CRT, patients with advanced HF are more likely to receive frequent shocks from ICD, which cause significant pain and anxiety (Sears and Conti, 2002). Device deactivation should be considered to alleviate the discomfort from frequent ICD shocks in the terminal stages of HF.

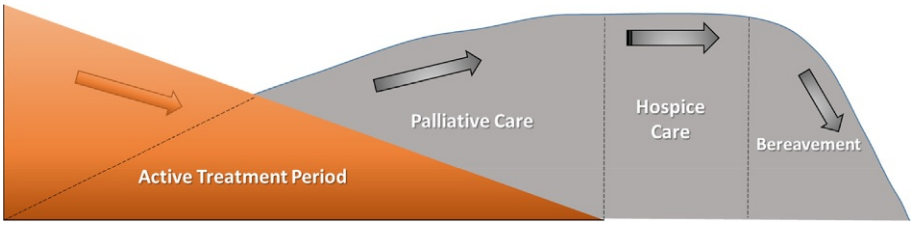

Fig. 2 The integrative model for palliative care with heart failure. Palliative care may be initiated at any point during the care of a heart failure patient. Hospice care ensues when the patient has an expected life expectancy of less than 6 months. Bereavement services help support the patient's family after the patient's demise.

Healthcare providers are recommended to initiate the conversation regarding device deactivation during early stages of the disease, while the patient is still capable of participating in the discussion and able to make decisions (Nohria et al., 2002). Physicians need to help patients determine how the benefits and burdens of device therapy align with their desired outcomes for their health care (Lampert et al., 2010). Multiple options are available with regard to the extent of device deactivation modalities ranging from programming off only certain features such as shock therapy, to discontinuation of all therapy to not replacing a depleting device (Lampert et al., 2010).

Unlike defibrillators, CRT has been shown to improve quality of life. Therefore, it may be appropriate to continue biventricular pacing with CRT for patients even when the decision has been made to turn off the ICDs (Lampert et al., 2010; Cleland et al., 2005). In situations when there is no consensus about discontinuing device support, consideration may be given to consulting with the hospital ethicist or ethics board (Feldman et al., 2013).

Hospice Care

Patients with advanced HF may decide to forego all life-prolonging medications and transition to hospice as the disease progresses (Fig. 2). Hospice provides palliative care for the dying patient who has a prognosis of less than 6 months, and does not want any life-prolonging treatments aimed at curing his or her primary illness. (Adler et al., 2009)

Despite the benefits of hospice care in alleviating discomfort for the patient in the terminal stage and their families, this service is underutilized. Nearly 37% of the patients enrolled in hospice have cancer as a primary diagnosis, and only 14.7% have a primary diagnosis of heart disease (Organization NHaPC, 2015). Reasons for underutilization are proposed to be uncertain prognosis, patient preferences, spiritual beliefs, increasing number of available therapies, lack of awareness of palliative care and hospice services, and inadequate training (Unroe et al., 2012). However, there has been a trend in increased use of hospice service in the past decade.

When a patient is referred to hospice, grieving families can access bereavement counseling and support for up to 1 year following the patient's death (Organization NHaPC, 2015; Goldstein et al., 2011). In 2014, an average of two family members of every deceased patient enrolled in hospice received bereavement support from their hospice which included follow-up phone calls, visits, and mailing (Organization NHaPC, 2015).

Advance directives specifying limitations in end-of-life care have been associated with significantly lower levels of Medicare spending, lower likelihood of in-hospital death, and higher use of hospice care in regions characterized by higher levels of end-of-life spending (Nicholas et al., 2011). Although the primary goal of hospice is symptom alleviation at the time of death, there is data to suggest that HF patients who received hospice had a higher mean survival by 81 days as compared with advanced HF patients who did not receive hospice (Connor et al., 2007).

Future Directions

It is increasingly recognized that in addition to cancer, high-quality end-of-life care should be an integral part of care that is provided for those with other advancing chronic life-limiting conditions such as advanced HF. Despite the recent advances in HF management with newer neurohormonal agents, device therapies, and mechanical circulatory support, there is significant morbidity and mortality associated with advanced HF. Palliative care is an integral part of the advanced HF team to help manage symptoms, complications, and end-of-life issues in these patients.

Introduction

The past two decades have witnessed astounding advances in the efficacy and safety of catheter ablation techniques as definitive therapy of supraventricular and ventricular arrhythmias, allowing curative therapy for many of the arrhythmias affecting young patients. In many regards, catheter ablation in young patients is similar to ablation in adults; the same tools and techniques are utilized. However, the indications and approaches to ablation among the young often require variances in approach and considerations with respect to size, natural history, and mechanisms. This review will cover both general considerations in pediatric ablation and more specific technical issues as they apply to various arrhythmia scenarios. Additionally, recommendations for appropriate use of ablation will be cited throughout the discussion.

Background

The stage for catheter ablation was first predicated on the recognition of accessory pathways as the mechanism underlying the Wolff-Parkinson-White EKG pattern, subsequently followed by the first described surgical interruption of such pathways (Wolferth and Wood, 1933; Sealy et al., 1976). Since the description by Morady and coworkers of nonsurgical endocardial ablation using DC energy, catheter ablation has emerged as the definitive and often preferred treatment for many forms of SVT and Ventricular tachycardia (Morady and Scheinman, 1984; Scheinman, 1995; Calkins et al., 1999; Scheinman and Huang, 2000; Morady, 2004). No less remarkable has been the application of ablation therapy not only to pediatric patients with structurally normal hearts but

 https://doi.org/10.1016/B978-0-12-809657-4.99802-8

also to those with a wide spectrum of congenital structural heart disease (Morady, 2004; Van Hare et al., 1991, 2004a; Dick et al., 1991; Kugler et al., 1997; Chetaille et al., 2004; Triedman et al., 2002). In the three decades since, success rates and the ability to approach increasingly complex mechanisms have been enhanced by technical advances in the tools available to the interventional electrophysiologist. Likewise, through large multicenter collaborative efforts, an improved understanding of special considerations in children has allowed improved safety of this technique, as well as an appreciation for situations for which ablation carries an increased risk. This has led to formal guidelines for appropriate use of catheter ablation in this population (Saul et al., 2016). As technical advances continue to emerge, the ability to provide safe and effective cure of the majority of pediatric arrhythmias continues to improve.

General Considerations

Electrogram Recordings

High-fidelity recording and accurate interpretation of intracardiac electrograms remain the keystone of successful mapping and ablation. Recording of biopotentials ranging from 25 μV to 5 mV with optimized signal-to-noise ratio requires rigorous attention to every detail from physical and electrical organization of the electrophysiology laboratory through signal display on the monitor (Venkatachalam et al., 2011a). Amplification and filtering of the recorded signals must be chosen appropriate to the intracardiac recording site, and interference from nearby electrical equipment must be addressed with careful shielding, grounding, and isolation (Venkatachalam et al., 2011a). The influence of electrode size and spacing on bipolar recordings requires thoughtful catheter selection, and the nuances of "unipolar" recordings utilizing a remote indifferent electrode should be understood. Artifact can arise from amplifier saturation, inappropriate clipping, pacing output, radiofrequency energy, or physical electrode contact (Venkatachalam et al., 2011b). Even when "perfect" electrograms are recorded, accurate interpretation remains in part a subjective art. For example, early in the accessory pathway ablation experience a number of electrogram features such as signal stability, timing of local ventricular signal relative to local atrial signal or the surface ECG, and the presence of an accessory pathway potential or continuous electrical activity were recognized as independent predictors of successful ablation, but the prognostic value of any single feature varied substantially between studies (Calkins et al., 1992; Grimm et al., 1994; Bashir et al., 1993; Silka et al., 1992; Ceresnak et al., 2012; Scheinman et al., 1982). More recently, systems have emerged to provide rapid, high-density maps using automatic acquisition and measurement of electrograms from multipolar catheters as they are moved within the cardiac chambers (Bollmann et al., 2016). It remains to be seen how these systems can be best utilized alongside classic diagnostic techniques such as pacing maneuvers and EGM interpretation which are often nuanced and even subjective, but serve as the cornerstone of interventional electrophysiology.

Energy Sources for Ablation

Direct current ablation utilized nondeflectable catheters which were guided under fluoroscopic imaging to target sites based upon the timing and morphology of bipolar local signal recordings (Scheinman et al., 1982; Gallagher et al., 1982). Similarly, RF ablation initially utilized RF generators developed for neurosurgical techniques as the ablation energy source. Since then, an entire industry has emerged, and ablation catheters today allow deflection and torque with multiple degrees of freedom and bidirectional and even omnidirectional bends when used alone or in conjunction with long, shaped or deflectable sheaths. (Peichl et al., 2009; Schwagten et al., 2010). Catheter placement can be further guided by direct visualization by electroanatomic mapping systems, intracardiac echocardiography (Peichl et al., 2009), or magnetic navigation systems (Schwagten et al., 2010; Wu et al., 2010; Van Hare et al., 2002).

The actual process of mapping most frequently consists of point-by-point acquisition of signals recorded from the distal electrode pair of a mapping catheter placed serially in direct contact with multiple sites along the endocardial surface. Alternative techniques can be utilized in certain scenarios. For targets that do not display sustained electrical stability, noncontact mapping systems utilize a multielectrode array placed within the chamber of interest to derive "virtual" local potentials at remote sites by use of a mathematical inverse solution (Kadish et al., 1999). As mentioned above, automated high-density EGM acquisition is now available for increasingly complex tachycardia mechanisms such as scar-related tachycardias (Bollmann et al., 2016). Recently, there has been a resurgence of interest in body surface mapping; when combined with 3D CT or MRI cardiac imaging, it may be increasingly possible to identify target sites before catheters are even placed within the heart.

Mapping

Regardless of the mapping methodology, the fundamental goal is to determine the activation timing of multiple recorded (or derived) electrograms relative to a stable fiducial reference and apply these to their anatomic location. Initially, this required fluoroscopic imaging and a "mentally visualized" impression of the cardiac anatomy, sometimes augmented by cineangiography or echocardiography (transesophageal, intracardiac).

Increasingly, electroanatomic mapping systems (originally developed for complex anatomic and mechanistic situations) are being utilized with regularity in the majority of ablations in young patients. These systems overlay recorded or derived electrical activation on a 3D anatomic virtual shell portraying the cardiac chamber(s) of interest. Such anatomic shells are constructed in real-time during electrogram acquisition as the catheter moves throughout an externally applied magnetic or electrical current field (Gepstein and Evans, 1998; Wittkampf et al., 1999). Anatomic details can be further resolved by fusing such electroanatomic maps

with anatomy derived by other techniques such as CT, MRI, Intracardiac echo, or rotational angiograph (Knackstedt et al., 2008). Although advanced mapping systems may not be essential for effective routine ablation of supraventricular tachycardia, their use has been associated with improved outcomes during ablation of intra-atrial reentrant tachycardia in patients with congenital heart disease as well as decreased fluoroscopy times in routine pediatric ablation cases (Triedman et al., 2002; Kwong et al., 2012; Miyake et al., 2011).

Energy Application and Lesion Formation

Once the arrhythmogenic target has been precisely localized, delivery of ablative energy to that site allows definitive cure. Radiofrequency energy remains the primary means of destroying tissue containing the arrhythmia target. This involves delivery of an unmodulated sine wave of alternating current in unipolar fashion between the tip of the catheter and a ground electrode located on the patient's skin, with resistive heating of the tissue directly adjacent to the tip electrode and conductive heating of a wider rim of tissue (Nath et al., 1994). Many factors influence the extent of thermal injury achieved in the myocardium, including the maximum temperature achieved, steady-state power amplitude, and stability of tip contact. Given that a common reason of ablation failure in patients with congenital heart disease is inadequate lesion formation, it is important to recognize how these variables may be manipulated to increase depth of thermal injury. Because the radius of the lesion size is directly proportional to the radius of the heat source, catheters with 8 mm or even 10 mm tip electrodes may be used in place of the standard 4 mm tip ablation catheter (Haines et al., 1990; Tsai et al., 1999). Active convective cooling of the catheter tip with open irrigated catheter systems can allow for delivery of higher power, with deeper lesion formation (Jaïs et al., 1998; Triedman et al., 2005). Lastly, there is recent report of real-time measurement of tip electrode contact force (Kuck et al., 2012); however, the translation of this data to improved safety and efficacy remains clinically unproven at this time.

The alternative frequently utilized energy source for ablation is cryoablation therapy. Liquid refrigerant is delivered under pressure to the distal catheter tip, where an accelerated liquid-to-gas phase change produces rapid cooling (Khairy and Dubuc, 2008). Heat extraction from the adjacent tissue produces initial cellular changes that are reversible, allowing assessment of sites without permanent tissue destruction. Further cooling produces direct cell injury with first extracellular and subsequently intracellular ice crystal formation at temperatures colder than −40°C (Gage and Baust, 1998). When repeat lesions are delivered in a "freeze-thaw" pattern, there is additional tissue destruction mediated by vascular changes, with initial vasoconstriction and ischemic necrosis followed by hyperemia and edema (Cesario et al., 2009). Post-ablation, within the myocardium there is further expansion of tissue destruction over time to an extent similar to that seen with radiofrequency ablation lesions (Khairy et al., 2011; Saul et al., 1994). The initial clinical experience with cryoablation in the pediatric population was characterized by an excellent safety profile but acute efficacy and recurrence outcomes that trended inferior to that observed with radiofrequency ablation (Kirsh et al., 2005; Collins et al., 2006). The use of larger catheter tip size and variations on lesion delivery have produced acute success and recurrence rates for slow pathway modification and septal accessory pathway ablation in children similar to that reported with radiofrequency ablation (Silver et al., 2010; Czosek et al., 2010). However, to date there has not yet been a randomized comparison of the two energy sources in pediatrics such as has been performed in adults (Deisenhofer et al., 2010).

Special Considerations in Children

Although there are many common ablation tools shared across pediatric and adult populations, the manner in which they are applied at times diverges widely. Natural history, patient size, procedural sedation, radiation effects, and the potentially broad anatomical spectrum of congenital heart disease each influence the clinical decision-making surrounding ablation in children. For instance, patient age during episodes of orthodromic reciprocating tachycardia mediated by an accessory pathway has a well-described bimodal distribution with a "honeymoon" period free of symptoms through much of early childhood (Perry and Garson, 1990). This pattern, combined with the knowledge that 30%–40% of pathways presenting in infancy will spontaneously regress (Benson et al., 1987), makes the need for ablation in infancy and very young children a generally rare event. An initially conservative approach in these very young children has been further supported by the observation of a higher rate of complications when radiofrequency ablation is undertaken (Kugler et al., 1994; Kantoch et al., 2011). Children of all ages are less tolerant of a procedural sedation strategy relying on conscious sedation, but different general anesthetic agents differentially influence cardiac conduction (Niksch et al., 2010; Lavoie et al., 1995). Ionizing radiation has been the traditional imaging modality allowing visualization of intracardiac catheter position; exposure during childhood carries a different risk-benefit balance than in adults (Mah and Triedman, 2011), and there has been rapidly growing interest in primary use of alternative, nonfluoroscopy systems (Miyake et al., 2011; Smith and Clark, 2007).

The location of both the arrhythmogenic substrate and the normal conduction system can vary widely in children. Children with Ebstein's malformation of the tricuspid valve not infrequently have multiple accessory pathways positioned along the atrialized right ventricle; the fractionated signals that arise diffusely from the abnormal endocardium can confound precise localization of the pathway(s) (Cappato et al., 1996; Roten et al., 2011). Anatomic complexities may be more subtle at initial presentation: physical adherence of either atrial appendage to the adjacent ventricular epicardial surface may harbor accessory atrioventricular (AV) connections that can be challenging to effectively access via a transcatheter approach (Mah et al., 2010; Shah et al., 2001). Conversely, the anatomy of the normal conduction system is strikingly unusual in some forms of congenital heart disease: the compact AV node is positioned anteriorly in children with congenitally corrected transposition of the great arteries (Anderson et al., 1974), and posteriorly in patients with primum atrial septal defect/complete atrioventricular septal defect (Feldt et al., 1970). A less common but fascinating congenital variation is the so-called twin atrioventricular nodes in some patients with atrioventricular discordance, with the first pathologic description by Mönckeberg in 1913 followed almost 90 years later by description of such

substrate supporting clinical AV reciprocating tachycardia (Mönckeberg, 1913; Epstein et al., 2001). Surgical interventions performed to repair or palliate congenital defects introduce an additional layer of complexity, with atriotomy scars and baffle suture lines serving as iatrogenic "central obstacles" creating a myriad of unique macro-reentrant circuits (Love et al., 2001; Zrenner et al., 2003). Independent of the arrhythmia circuit, direct catheter access to the target endocardial surface may be obstructed by congenital anomalies such as interrupted inferior vena cava or surgical intra-atrial baffles placed in the process of Fontan palliation or atrial switch procedures, and trans-hepatic, retrograde, or trans-baffle approach may be necessary (Singh et al., 2011; El Yaman et al., 2009; Perry et al., 2003).

Ablation of Supraventricular Tachycardia in Children: Indications and Outcomes

Given these special considerations in children, it comes as no surprise that pediatric-specific guidelines for ablation have been formulated. In 2002 the North American Society for Pacing and Electrophysiology released consensus indications for ablation (Friedman et al., 2002), and revised in 2016. Details are summarized in **Table 1** (Saul et al., 2016).

There are a variety of ways that ablation outcomes may be measured. Pooled efficacy and complication data from the two largest prospective multicenter studies/registries is presented in **Table 2** (Kugler et al., 1997; Van Hare et al., 2004a,b). The differences between the two studies—performed in different era—are illustrative of the well-documented learning curve, with a strong exponential correlation between prior experience and success and complication rates (Danford and Kugler, 1995). Although there has been recent growing interest in the development of quality of life measures specific for the general congenital heart disease population (Marino et al., 2010), to date there is only pilot data reporting positive patient-oriented outcomes following ablation in children (Strieper et al., 2010). Likewise, cost-effectiveness analysis has been limited, with current pediatric-specific analysis limited to a single study performed in the context of a developing country (Vida et al., 2006).

Target-Specific Considerations

Accessory Pathway

Both surgical and transvenous catheter ablations were initially applied to accessory pathways, as they represent a discrete structural target which can be directly mapped (Wallace et al., 1974; Jackman et al., 1991). Strategies for accessory pathway ablation depend upon several factors, including whether there is manifest preexcitation; location of the pathway, particularly proximity to the AV node; and whether the target represents a typical accessory pathway with rapid, nondecremental conduction or an atypical accessory pathway with slow, decremental conduction, as with a Mahaim fiber or with permanent junctional reciprocating tachycardia. In addition to mapping the sites of earliest activation of the proximal or distal insertion, direct recording of an accessory pathway potential may often prove useful (Otomo et al., 2001; McClelland et al., 1994).

In pediatric patients, there are specific considerations related to pathway location. In many pediatric centers, left-sided pathways are approached exclusively via transseptal puncture. The rationale for this approach includes ease of catheter manipulation once the left atrium is entered, and concerns of potential injury to the aortic and mitral valves (Minich et al., 1992; Lau et al., 1994). Other centers prefer a retrograde transaortic approach as the primary mapping strategy; while somewhat more difficult to master, this approach offers the theoretical advantages of catheter stability when the ablation tip is placed beneath the mitral valve leaflet, as well as assuring more secure contact and heat delivery directly to the mitral valve annulus and thus the pathway. However, familiarity with the transseptal approach remains essential, since a retrograde approach may be inadvisable in very small patients, and some sites (e.g., certain locations near the edge between the anterior and posterior mitral leaflets) may prove difficult from a transaortic approach. Neither approach has been demonstrated to be consistently superior across several published single-center studies in children and adults (Law et al., 2001; Vora et al., 1997; Lesh et al., 1993).

For right-sided pathways inserting on the free-wall of the tricuspid valve annulus, catheter stability is an issue. Often, long sheaths can offer additional stability, and these are manufactured in a variety of shapes. Localization of the accessory pathway can sometimes prove difficult, as multiple sites along the annulus appear to show fusion of the atrial and ventricular components of the local electrogram. Some have utilized a small, multi-electrode catheter placed into the right coronary artery to obtain simultaneous activation times along multiple points of the lateral tricuspid valve annulus (Van Hare et al., 2002). An additional strategy which can be utilized is to perform mapping during right atrial pacing rather than during sinus rhythm. The time from the stimulus artifact to earliest ventricular activation may better discriminate between multiple sites displaying "favorable" local electrogram characteristics.

Several concerns may arise during mapping and ablation of septal accessory pathways. Proximity to the AV and His bundle is especially a concern for parahissian/anteroseptal and midseptal pathways. A variety of strategies may be employed to minimize risk of inadvertent injury to the AV node, including use of cryoablation; performing pacing maneuvers to search for a His potential in the pacing catheter when the accessory pathway blocks; and utilizing general anesthesia so that respiration can be held to optimize catheter stability during the lesion (or until adherence as achieved during cryolesions). If cryoablation is performed, pacing maneuvers should be performed during the lesion to ensure intact AV node conduction until preexcitation is eliminated, followed by careful monitoring of the AH interval while the lesion is carried to full duration. If radiofrequency ablation is employed, great care should be taken, and the lesion should be aborted at the first appearance of accelerated junctional rhythm.

Perhaps one of the most challenging situations is the approach to a parahissian accessory pathway with unidirectional retrograde conduction. Since atrial activation over the accessory pathway during ventricular pacing cannot be reliably distinguished from retrograde conduction over the AV node, both mapping and ablation during tachycardia are necessary. In this situation cryoablation is highly advisable, both to avoid injury to the AV node and to avoid dislodgment of the pacing catheter with tachycardia termination.

Table 1 Indications for SVT ablation (>15 kg), indications for ablation of WPW, indications for ablation of inappropriate sinus tachycardia, indications for ablation of atrial fibrillation, indications for ablation of junctional ectopic tachycardia, indications for ablation in patients with congenital heart disease, indications for ablation in infants and small children (<15 kg), indications for ablation of ventricular arrhythmias

Indications for SVT ablation (>15 kg)

- Class I
  - Documented recurrent/persistent SVT and:
    - Assoc w ventricular dysfunction
    - Medical therapy ineffective or not tolerated
    - Family wishes to avoid chronic meds
    - Assoc with hemodynamic compromise/syncope
    - Required emergency medical care or DCCV (>15 kg)
- Class II
  - Clinical symptoms c/w SVT and evidence of AV accessory pathway or inducible SVT
  - Documented SVT and dual AV node physiology but SVT noninducible
    - "cryotherapy should be considered"

Indications for ablation of WPW

- Class I:
  - Following resuscitated cardiac arrest
  - WPW with syncope when there are predictors of high risk for cardiac arrest
  - SPERRI or 1:1 AP ≤250 ms
  - Multiple accessory pathways
- Class IIA
  - Associated ventricular dysfunction
    - Presumed due to dyssynchrony (>15 kg)
    - Medical therapy ineffective/intolerant <15 kg
  - No sxs with high risk for cardiac events > 15 kg
  - With syncope but no predictors for high risk events in larger pts
  - Without symptoms but absence of PE is prerequisite for personal or professional activities
- Class IIB
  - No sxs, no high risk predictors, but pt/family choice to ablate (>15 kg)
- Class III (not indicated)
  - WPW pattern caused by fasciculoventricular pathway
  - WPW without symptoms and <15 kg

Indications for ablation of inappropriate sinus tachycardia

- Class IIb:
  - Autonomic causes (POTS/OI) have been excluded AND medical Rx ineffective or not tolerated
- Class III:
  - Due to POTS or as part of routine care for IST

Indications for ablation of atrial fibrillation

- Class I—none
- Class IIa
  - Any SVT serving as initiating event including single ectopic atrial focus or foci from a single PV
- Class IIb-Wide-area Circumferential PVI
  - Recurrent AF, and
  - Requires repeated DCCV, and
  - Medical Rx ineffective or adverse events
- Class III
  - Rare, not requiring DCCV or well controlled medically
  - Afib incidentally induced at EPS

Indications for ablation of junctional ectopic tachycardia

- Class I: Idiopathic JET with Ventricular dysfxn and
  - ineffective medical Rx
  - Cryoablation 1st choice modality
- Class IIa: Idiopathic JET with No Dysfxn and
  - Med Rx ineffective or poorly tolerated and >15 kg
- Class IIb: Alternative to effective Med Rx and >15 kg
- Class III:
  - Post op
  - Medically controlled and <15 kg

Indications for ablation in patients with congenital heart disease

- Class IIA
  - SVT due to APs or twin AV nodes (heterotaxy)
    - Ineffective medical Rx <15 kg
    - Alternative to medical Rx >15 kg
  - WPW in Ebstein's anomaly (>15 kg)
  - Asymptomatic AT/Flutter >3–6 months post-op at risk for thromboembolic or CHF complications

Table 1 (Continued)

- Adjunct Tx to ICD to reduce shocks
- Frequent VE contributing to ventricular dysfxn >15 kg or meds ineffective and <15 kg
- Sustained monomorphic VT ± ICD
- AVNRT with ineffective or not tolerated meds, >15 kg
- Pre-emptive ablation to prevent post-op arrhythmias
- Prior to Fontan, Ebstein's anomaly (>15 kg)
- Recurrent AT/AF >3–6 months post-op

- Class IIB
  - SVT w/acute hemodynamic compromise, 15 kg
  - AV node ablation/pacing for atrial tachyarrhythmias
    - refractory to all medications
    - Failed substrate-targeted ablation
    - Not candidate for surgical Rx
  - Early post-op arrhythmias that can be managed medically
  - Asymptomatic ectopy with stable ventricular fxn
  - Prophylactic Rx of ventricular arrhythmias deemed to be at risk for SCD in whom ICD is otherwise indicated

Indications for ablation in infants and small children (*<15 kg*)

- Class I
  - WPW and resuscitated cardiac arrest
  - WPW, syncope with predictors of high-risk
  - SVT, JET, VE, or VT w/Ventricular dysfxn and ineffective/intolerable medical Rx
  - CHD with SVT due to AP, Twin AV nodes or post-op AT (>3–6 months) and ineffective/intolerable medical Rx
- Class IIA
  - WPW, dyssynchrony and reduced LVEF with intolerant/ineffective Rx
  - Monomorphic VT causing sxs despite medical Rx
  - Asymptomatic AT >3–6 months and risk of TE Events/CHF and ineffective Med Rx
  - Preemptive pre-op prior to Fontan
  - Frequent ectopy causing dysfunction in CHD, ineffective meds
- Class IIB
  - Sxs of SVT and AP or inducible SVT at EPS
  - Medical Rx should be considered first
  - Cryotherapy should be considered for slow pathway mod and consider for other substrates
  - SVT with acute compromise
  - Idiopathic JET, ineffective/intolerable med Rx
  - PMVT with triggering focus
  - AVN ablation/PM for otherwise refractory atrial tach and not candidate for surgical therapy
- Class III
  - SVT, controlled on medical Rx
  - Asymptomatic WPW
  - Post-op JET
  - Idiopathic JET controlled with meds
  - VT/VE, effectively treated and no vent dysfxn
  - AVR
  - Early post-op AT

Indications for ablation of ventricular arrhythmias

- Class I
  - Frequent ventricular ectopy or VT
    - single focus thought to be causing ventricular dysfxn and >15 kg
    - <15 kg and meds ineffective or not tolerated
  - Idiopathic RVOT/LVOT or fasciular VT
    - Ineffective meds <15 kg
    - Alternative to meds >15 kg
- Class IIA
  - Frequent ectopy correlated with Sx and >15 kg
- Class IIB
  - AVR correlated with Sx and >15 kg
  - Recurrent PMVT with identifiable triggering focus
- Class III
  - VT controlled medically/well-tolerated <15 kg
  - AVR <15 kg
  - Asymptomatic ectopy, VT or AVR not causing or leading to ventricular dysfxn
  - VT due to transient reversible causes (eg, electrolytes, myocarditis, drug toxicity)

Table 2 Pooled efficacy and complication summary data for ablation of SVT in pediatric patients

	Pediatric radiofrequency ablation registry (PRAR) (Dick et al., 1991)	*Prospective assessment after pediatric cardiac ablation (PAPCA) (Kugler et al., 1997; El Yaman et al., 2009)*
Time period (years)	1991–1996	1999–2003
Patients (*n*)	4135	2761
Contributing centers	46	41
Acute success		
● AP—left lateral	95%	98%
● AP—septal	87%	89%
● AP—right free wall	86%	90%
● AVNRT	96%	97%
Freedom from recurrence[a]		
● AP—cumulative	77%	
● AP—left lateral		91%
● AP—right septal		75%
● AP—right free wall		84%
● AVNRT	71%	95%
Procedural complications	3.2%	3.2%
● AV block	0.7%	1.2%
● Emboli	0.2%	<0.1%
● Death	0.1%	0

[a]Denominator in PAPCA study is limited to the 481 patients in prospective (nonregistry) cohort.

Special approaches to septal pathways are sometimes required, including delivery of lesions within the coronary sinus, for which cryoablation probably offers less risk of thrombosis or coronary artery spasm or injury (Collins et al., 2007). Sometimes septal pathways may have insertions to both the rightward and leftward aspects of the septum, necessitating approach from the septal aspect of the mitral valve annulus, the mid-septal left ventricular outflow, or even the noncoronary cusp of the aortic valve. Finally, right anteroseptal or right anterior pathways may be targeted from a superior approach, with similar advantages in stability and contact with the annulus as the retrograde approach offers on the left side.

Wolff-Parkinson-White syndrome

In many regards, catheter ablation of Wolff-Parkinson-White syndrome is the most conceptually straightforward ablation scenario, and when successful provides one of the more dramatic and definitive endpoints. Abrupt loss of preexcitation on the surface ECG during radiofrequency energy application is the hallmark of a successful lesion (**Fig. 1**). Often this can be observed during sinus rhythm, but if preexcitation is subtle on the surface ECG, atrial pacing from the right atrium or coronary sinus to exaggerate the degree of preexcitation may be useful. It is often useful to map both the antegrade and retrograde insertions during right ventricular pacing or tachycardia, since some accessory pathways display a diagonal orientation with respect to the mitral or tricuspid annuli (Otomo et al., 2001).

An important consideration in the evaluation of Wolff-Parkinson-White is whether ablation is warranted. This is increasingly an issue with the widening use of ECG screening for sports clearance or prior to administering medications for attention-deficit/hyperactivity disorder, resulting in inadvertent discovery of Wolff-Parkinson-White in a patient without prior symptoms. The issues and approaches to risk stratification are complex and remain somewhat controversial, thus beyond the scope of this discussion. Certainly the potential risk of sudden cardiac death in previously asymptomatic children is a chief consideration driving the increasingly common recommendation to perform invasive electrophysiology testing for Wolff-Parkinson-White in the absence of symptoms (Santinelli et al., 2009; Campbell et al., 2003). Furthermore, what criteria are used to determine that risk remain a matter of discussion, as is the decision whether to utilize pathway conduction characteristics in the baseline (usually anesthetized state) or whether to assess the degree that accessory pathway conduction is enhanced with adrenergic stimulation, which can sometimes be quite pronounced (German et al., 1983; Moore et al., 2011). Certainly, other considerations enter into the decision as to whether to proceed with catheter ablation in a given patient, including inducibility of AV reciprocating tachycardia (antidromic reciprocating tachycardia likely representing a more ominous risk than orthodromic reciprocating tachycardia). Not every patient with Wolff-Parkinson-White likely warrants ablation—for instance, if rapid antegrade conduction is not demonstrated and tachycardia is not inducible. Conversely, ablation may still be appropriate in certain cases, and the issues should be individualized on a case-to-case basis and discussed carefully with the family.

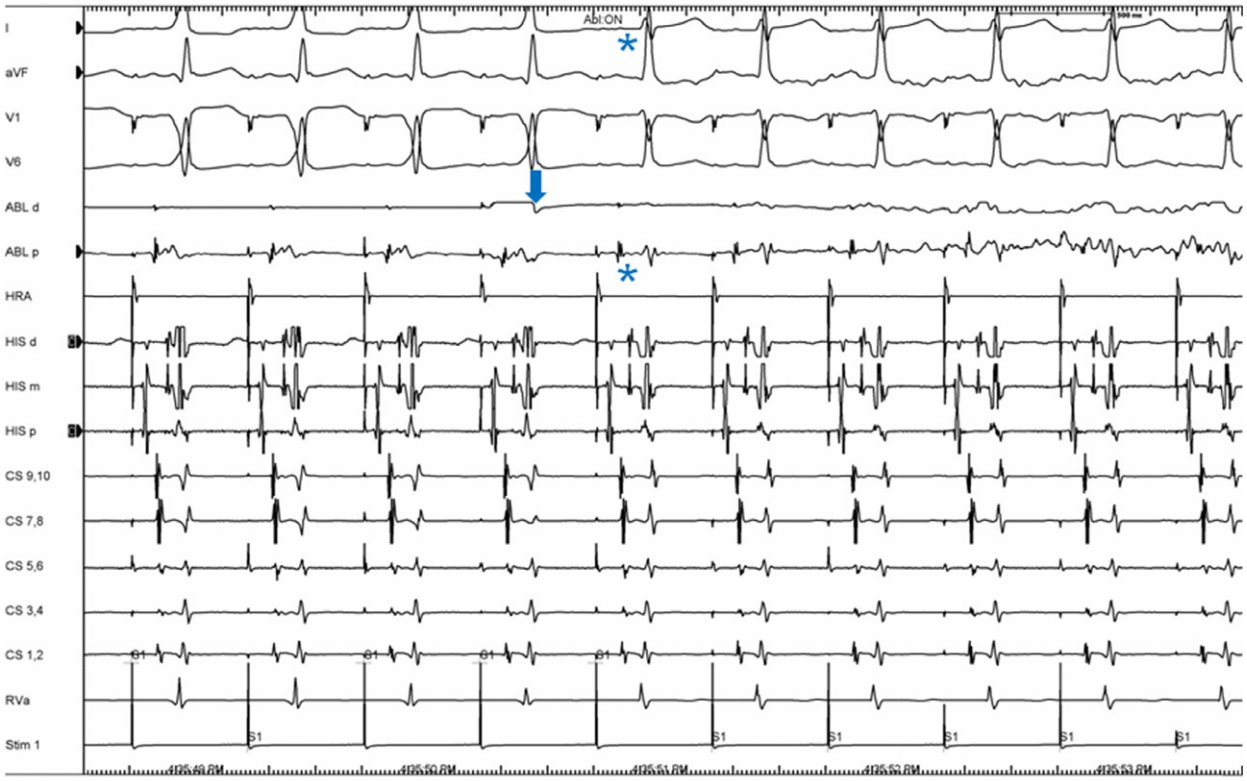

Fig. 1 Acute loss of antegrade accessory pathway conduction with radiofrequency ablation. The solid arrow represents start of lesion; the asterisk marks acute effect as seen on surface ECG and proximal electrode pair on ablation catheter.

Unidirectional retrograde

The approach to a unidirectional retrograde accessory pathway may be rather straightforward for a left-sided accessory pathway. If eccentric VA conduction (early atrial activation in the coronary sinus) is readily displayed during ventricular pacing, this approach can be utilized for both mapping and ablation. The situation becomes somewhat more complex when robust retrograde conduction over the AV node obscures conduction over the accessory pathway during ventricular pacing. These cases require mapping during tachycardia (or at least with orthodromic echo beats), and it may be necessary to ablate during sustained tachycardia. If so, two strategies can minimize the risk of catheter dislodgement with the abrupt rate change accompanying tachycardia termination. Cryoablation offers the clear advantage of adherence, virtually eliminating this risk. Alternatively, ventricular pacing may be performed at a rate slower than the tachycardia rate such that the rate change with tachycardia termination is minimized (**Fig. 2**) (Li et al., 1994). However, it is important to distinguish tachycardia termination due to retrograde block in the accessory pathway due to the lesion itself from VA block due to premature ventricular activation as the result of the asynchronous pacing which results.

For septal pathways with unidirectional retrograde conduction only, the first consideration is verifying the diagnosis, and excluding the alternative possibility of a variant of AV node reentry with VA activation times intermediate between the typical "slow-fast" form of AV node reentry and the atypical "fast-slow" form. A host of pacing maneuvers during tachycardia and sinus rhythm have been described that in sum assist with this distinction (Michaud et al., 2001; Dandamudi et al., 2010; Nakagawa and Jackman, 2005). Since loss of eccentric activation and elimination of inducible tachycardia are the chief markers for successful ablation, careful characterization of any residual VA conduction post-ablation is necessary to identify residual accessory pathway conduction. While adenosine administration during right ventricular pacing is commonly employed in the post-ablation assessment, it should be recognized that transient block with adenosine was demonstrated prior to ablation in up to 20% of accessory pathways in one pediatric study (Fishberger et al., 1995).

Mahaim pathway

The classic description of Mahaim fibers supporting antidromic tachycardia with a left bundle branch block pattern was originally postulated to be nodoventricular or nodofascicular connections. Catheter ablation was instrumental in establishing the current understanding that nearly all accessory pathways displaying decremental antegrade conduction represent atriofascicular connections. The developmental and histologic basis of these structures is uncertain, but they display several characteristics suggesting an accessory AV node-like structure on the right free wall. As such, a His-like potential can usually be recorded over the course of these fibers on the ventricular side of the annulus and extending apically (McClelland et al., 1994). Because the insertion is typically into a fascicle of the right ventricular specialized conduction system, systematic mapping of earliest ventricular activation may not discriminate among widely dispersed recording sites. Therefore, searching for the discrete potential from the atriofascicular fiber

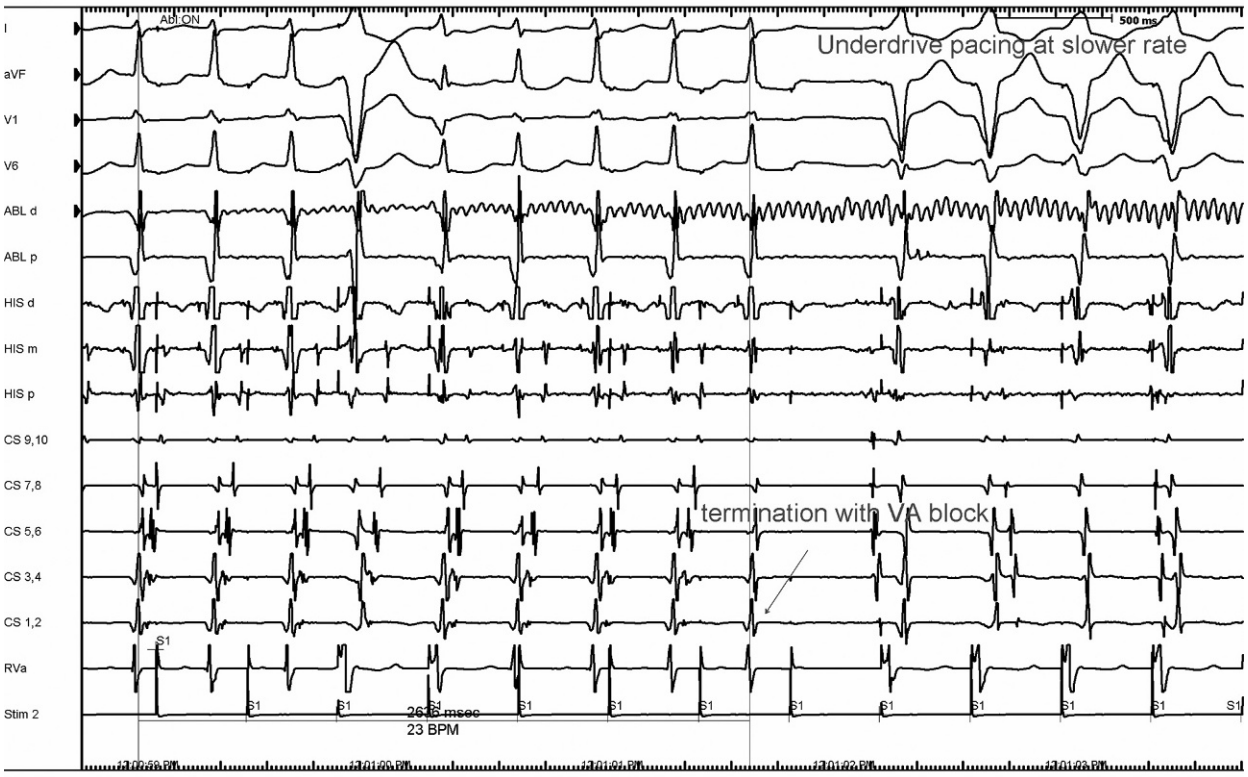

Fig. 2 Ablation of a unidirectional retrograde accessory pathway during orthodromic reciprocating tachycardia. Note that the right ventricular apex is being placed at a cycle length slightly slower than the tachycardia cycle length; when tachycardia terminates during the ablation lesion with acute retrograde block in the pathway, catheter stability is facilitated by the consistent ventricular rate.

is preferable. Ideally, this should be done during ongoing right atrial pacing in order to ensure ongoing conduction through the pathway, since atriofascicular potentials may lie quite superficially and be subject to block with catheter pressure. 3D mapping is helpful in this regard, since the site where such conduction block is encountered can be marked, and if necessary serve as the guide to appropriate ablation sites. Differential pacing from multiple sites along the atrial aspect of the tricuspid valve annulus may also help localize the atrial insertion of the atriofascicular fiber, which should be near the site resulting in the shortest preexcited stimulus to right ventricular interval. However, the pathway's decremental properties may render this a somewhat unreliable maneuver.

Permanent junctional reciprocating tachycardia

Despite the name, the arrhythmia commonly referred to as permanent junctional reciprocating tachycardia is a variant of orthodromic reciprocating tachycardia utilizing a decremental, slowly conducting unidirectional retrograde accessory pathway. In its classic form, the arrhythmia displays several features, including incessant behavior with repeated, self-limited runs of tachycardia with long RP interval which terminate due to VA block; after one or more sinus beats, the arrhythmia spontaneously reinitiates. However, the term permanent junctional reciprocating tachycardia is sometimes used in a broader sense to describe any variant of orthodromic reciprocating tachycardia characterized by a longer than usual VA time such that no sites with VA fusion will be identifiable. While the diagnostic maneuvers to distinguish permanent junctional reciprocating tachycardia from variants of AV node reentry (as well as from atrial tachycardia) are similar to that for characterizing orthodromic reciprocating tachycardia utilizing a septal accessory pathway, the response to ventricular pacing maneuvers may be unique due to the pathway's decremental properties (**Fig. 3**) (Bardy et al., 1985).

Once the diagnosis of permanent junctional reciprocating tachycardia is established, mapping is directed toward the site of earliest atrial activation. Although most commonly the insertion will be septal in location, left-sided and even occasionally right-sided pathways fitting within the spectrum of permanent junctional reciprocating tachycardia will be encountered. Mapping should be performed only during tachycardia to distinguish pathway conduction from retrograde conduction over the AV node. Since the VA time may vary considerably during tachycardia, the site of earliest activation should be measured against a fixed atrial reference site. In some cases, a small electrogram from the pathway itself may be recorded between the ventricular component and the atrial component of the signal at the site of successful ablation. As described above, termination of tachycardia could result in catheter dislodgement, but due to the typically slower rates of this tachycardia, this may be less of a problem than with typical orthodromic reciprocating tachycardia. As discussed above, the factors weighing into the choice of cryoablation versus radiofrequency energy should be considered for each case.

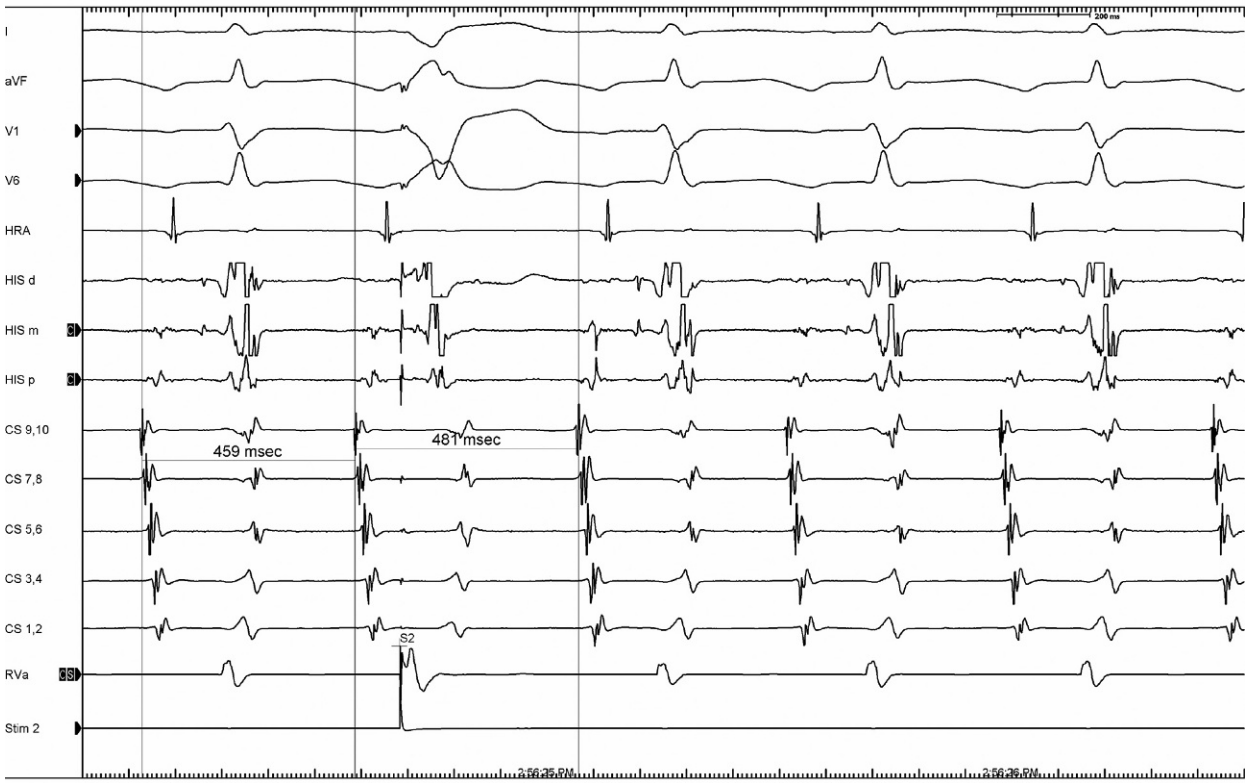

Fig. 3 Delivery of a his-refractory single ventricular premature beat during permanent junctional reciprocating tachycardia produces a paradoxical prolongation of the subsequent retrograde atrial timing, consistent with decremental conduction in the accessory pathway.

AV Nodal Reentrant Tachycardia

In older children and teenagers, AV nodal reentrant tachycardia is encountered with similar frequency as orthodromic reciprocating tachycardia. Thus, the approach to any supraventricular tachycardia in a patient not manifesting preexcitation on the surface ECG should begin with identifying features supportive of either of these two diagnoses. The substrate is usually considered to be two or more regions of inputs to the AV node with differential conduction properties, allowing for reentry into and out of the compact AV node. This concept requires that a portion of atrial tissue in the region of the AV node completes the reentrant circuit. An argument for reentry completely confined to the AV node is still sometimes made, though the distinctions are generally more theoretical than practical in nature. Importantly, a number of variable patterns of AV nodal reentrant tachycardia may be observed, including the potential for antegrade 2:1 conduction due to block above or below the His bundle and atypical locations of the slow pathway inputs.

In general, there is a "fast pathway" and a "slow pathway," which are respectively situated more anteriorly and posteriorly. Usually the slow pathway is in close proximity to the coronary sinus os, and the fast inputs are near the atrial aspect of the apex of Koch's triangle. While interruption of either input should eliminate tachycardia, fast pathway ablation has been all but abandoned as it leaves the patient with first degree AV block and appears to carry a higher risk of inadvertent complete AV block (Jazayeri et al., 1992).

The typical "slow-fast" form of AV nodal reentrant tachycardia is characterized by antegrade conduction over the slow pathway and a very short VA interval. As such, mapping atrial or ventricular activation during this rhythm is of no benefit for determining the site of ablation. In the early experience with this procedure, some investigators stressed the utility of identifying a "slow pathway potential," referring to a low amplitude signal recorded between the local atrial and ventricular components during sinus rhythm (Jackman et al., 1992). However, the identification and interpretation of such signals is at best subjective. It is clear that successful ablation can be achieved at sites not displaying such signals, and conversely, signals which could be construed to be slow pathway potentials may be recorded at sites where effective ablation is not achieved.

For the reasons above, the approach to catheter ablation of the typical form of AV nodal reentrant tachycardia is usually anatomic (Wathen et al., 1992). There can be considerable variation in the site where successful elimination of slow pathway conduction can be achieved. Identification of the AV muscular septum using intracardiac ultrasound has been cited as consistent anatomic marker in adults, but this has not been validated in children (Fisher et al., 1997). It is known that the relative dimensions of this region are decreased in smaller patients, and it has been demonstrated that late fibrosis may emanate from the central scar following radiofrequency ablation with encroachment upon the AV node (Saul et al., 1994; Goldberg et al., 1999). These factors combine to leave younger patients at potentially increased risk for inadvertent AV block (Schaffer et al., 1996). The relative merits of

radiofrequency versus cryoablation are an area of ongoing investigation, as discussed earlier. Because cryotherapy lesions do not elicit junctional acceleration, delivery of cryotherapy during sustained tachycardia may therefore be advisable, with termination of tachycardia due antegrade block serving as the indicator of an effective lesion. If radiofrequency ablation is utilized, careful scrutiny to watch for loss of VA conduction (i.e., loss of conduction over the fast pathway retrograde) during ongoing accelerated junctional rhythm is essential to ensure integrity of the fast pathway.

The most important endpoint of effective ablation is elimination of inducible tachycardia. However, since AV nodal reentrant tachycardia can sometimes be quite difficult to initiate (especially in the sedated or anesthetized patient), surrogate markers of success are useful. Complete elimination of all single AV node echos may be excessively aggressive. Elimination of sustained antegrade slow conduction (manifest as sustained PR > RR interval during atrial pacing) has been proposed as a reasonable proxy endpoint (Kannankeril and Fish, 2006).

In the atypical "fast-slow" form of AV node reentry, retrograde conduction is over the slow pathway. Therefore, direct mapping of the site of earliest atrial activation is a reasonable strategy. Furthermore, this should allow identification of variations in the site of the slow pathway insertions, such as the coronary sinus os, proximal coronary sinus, and less commonly the leftward aspect of the atrial septum. If targeting the slow pathway in this fashion, ablation would ideally be performed during ongoing tachycardia, observing for termination due to retrograde block.

Focal Atrial Tachycardia

Focal atrial tachycardias can vary considerably with respect to clinical behavior and location. Automatic foci represent the most common incessant subtype, but triggered foci may display incessant burst behavior, while other likely reentrant foci have paroxysmal behavior and can be initiated and terminated with pacing. In all cases, the key is to map the site of earliest activation. Electroanatomic mapping is highly useful in this setting since these sites may be recorded in virtually any region of the right or left atrium as well as the pulmonary veins or occasionally the superior vena cava. It is important to ensure that electrograms are recorded during spontaneous tachycardia and not during catheter-induced ectopy. To this end it is often useful to have a multi-electrode reference catheter with 5–10 bipolar signals displayed throughout mapping. In cases where ectopy is unusually quiescent, single-beat mapping with noncontact mapping systems may facilitate mapping in the right atrium.

Ectopic atrial tachycardia

Usually automatic in nature, and thus incessant, ectopic atrial tachycardia commonly originates in the region of the right or left atrial appendages, near the pulmonary vein ostia, or near the coronary sinus os. Mapping sites most likely to produce acute success have local electrical activity 20–60 ms prior to the onset of the surface P wave, and ablation at these sites produces a rapid acute effect on the tachycardia (median 2 s) (Walsh et al., 1992). Several recent series have demonstrated specific benefit from use of 3D electro-anatomic mapping, with acute success rates >90% and recurrence rates of 10%–20% (Cummings et al., 2008; Kang et al., 2011).

Pulmonary vein tachycardia

Occasionally, very rapid, repetitive bursts may emanate from a pulmonary vein. These can sometimes be mistaken for atrial flutter or atrial fibrillation, depending on whether the activation in the right atrium is organized or disorganized. This pattern is similar to focal atrial fibrillation as described by Haissaguerre which served as the springboard for contemporary ablation efforts for atrial fibrillation (Haïssaguerre et al., 1998). In young patients, these sites tend to be isolated and discrete and may be amenable to focal ablation at the venous ostium. However, if not readily extinguished by the first few ablation lesions, pulmonary vein isolation with lesions placed outside the venous ostium should be considered to avoid the creation of pulmonary vein stenosis.

Atrial septal tachycardia

Atrial septal tachycardia, sometimes referred to as "tachycardia from the apex of Koch's triangle," is an unusual tachycardia usually observed in adults which can be mistaken for AV node reentrant tachycardia, and may well be an atypical variant thereof. This arrhythmia may display paroxysmal or incessant behavior, but can be induced and terminated with programmed stimulation. However, no clear link between atrial tachycardia and ventricular activation is evident, and Wenckebach AV conduction during tachycardia is common. Typically, a site of very early, discrete activation is recorded along the mid-superior aspect of the tendon of Todaro (which can often be palpable during catheter manipulation). Care must be undertaken to ensure catheter stability during lesions which must be delivered during tachycardia.

Inappropriate sinus tachycardia

Inappropriate sinus tachycardia (IST) is an ill-defined entity describing unexplained tachycardia during risk or light exertion (Olshansky and Sullivan, 2013). Often the cause is autonomic in nature, overlapping with descriptive characterizations as POTS and Orthostatic Intolerance; in this context ablation is generally inadvisable (Sheldon et al., 2015). Occasionally, what appears to be an ectopic focus with subtle but discernible changes in rate and P wave morphology is mapped to the superior aspect of the crista terminalis. Often the site of activation can be observed near the base of the right atrial appendage with "split" electrograms suggesting this represent the extension of the crista onto the *arcuate ridge*, and may be situated on the septal aspect of the appendage (Killu et al., 2009). Accordingly, ablation of this rhythm may not be readily feasible with a single lesion. Slowing of the rate and a progressively more lateral and inferior origin of the underlying sinus rhythm is observed during effective ablation.

Whether these represent truly ectopic foci or an area of the sinus node which is devoid of normal vagal inputs is a matter of conjecture. Regardless, care must be taken to avoid inadvertent injury to the sinoatrial node; if sinus beats are observed efforts

should be made to map their origin as well as the ectopic focus. Likewise, the right phrenic nerve typically lies nearby and measures to identify the course and ongoing integrity of the phrenic are essential with ablation in this area.

Intra-Atrial Reentry Tachycardia in Congenital Heart Disease

Atrial tachycardias represent one of the most common morbidities late after repair of congenital heart disease. Due to the highly variable and potentially complex interplay between anatomic structures, surgical scars, and subsequent scar and fibrosis within the atrial tissue itself, these macro-reentrant or focal tachycardias can be among the most challenging to address with catheter ablation. Both congenital and acquired vascular anomalies often complicate access to the heart, as described earlier. It is not uncommon for multiple atrial tachycardias to be induced in a single congenital heart disease patient, each of which require individual mapping, often in both the right and left atrial chambers. Accordingly, these cases can be quite lengthy in duration. While acute success rates >70%–90% can be achieved in these cases, recurrences are considerably more frequent than for most other forms of supraventricular tachycardia, likely due to the complex anatomy and the difficulty identifying optimally narrow corridors of conduction to allow block of the reentry circuit (Saul et al., 2016; Kannankeril et al., 2003). Furthermore, the factors leading to the genesis of these arrhythmias are ongoing such that new arrhythmias with different patterns of activation are usually encountered when one returns for repeat ablation following recurrence.

The limitations to intra-atrial reentrant tachycardia ablation must be carefully considered and expectations should be realistic when embarking on this therapy. However, given the limited efficacy of antiarrhythmic therapy in this scenario, ablation is reasonable in a center experienced in this technique and familiar with the complexities and variations in congenital cardiac anatomy which include difficulties in catheter access and challenging catheter manipulation (**Fig. 6A** and **B**).

Isthmus-dependent

In most published series, tachycardias dependent on the cavotricuspid valve isthmus have represented more than 50% of cases (Kannankeril et al., 2003; Lukac et al., 2005; Mah et al., 2011). While conceptually this is the most straightforward situation to address diagnostically and therapeutically, ablation may be complicated by an unusually broad isthmus of atrial tissue (the authors have measured up to 6 cm in a patient with tetralogy of Fallot), hypertrophy of the Eustachian ridge which may be relatively resistant to radiofrequency lesions, and anatomic boundaries found after atrial repair for complete transposition of the great arteries or following Fontan palliation for single ventricle disease.
