The posterior surface of the prostate is transversely flat and vertically convex. Near its base is a depression where it is penetrated by the two ejaculatory ducts. Below this, a shallow median sulcus is usually considered to mark a partial separation of the prostate into right and left lobes. The prostate is separated from the rectum by fatty areolar tissue and by the prostato-seminal fascia, a condensation of pelvic fascia that develops by obliteration of the rectovesical pouch from below upwards as fetal life progresses. At birth, the prostato-seminal fascia separates the prostate, the seminal glands and the ampullae of the ducti deferentia from the rectum. The superior limit of the prostato-seminal fascia is formed by the peritoneum of the rectovesical pouch; laterally, the fascia fuses with the lateral pelvic fascia. The lateral pelvic fascia is called the lateral fascia of the prostate anterior to the prostato-seminal fascia, and the lateral rectal fascia posterior to the prostato-seminal fascia.

The prostate is traversed by the urethra and ejaculatory ducts and contains the prostatic utricle. The urethra enters the prostate near its

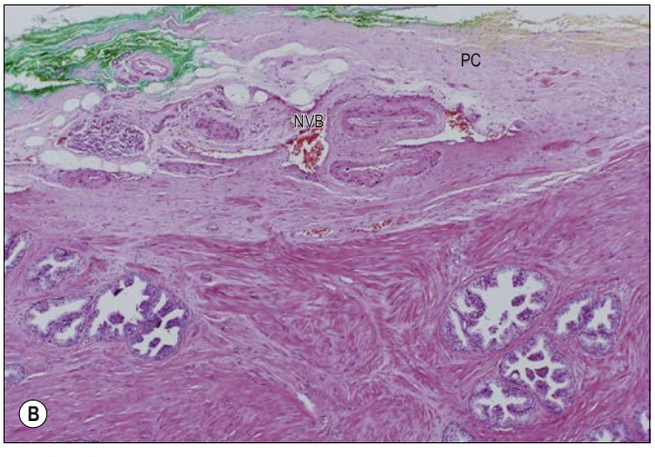

Fig. 73.15 A, The endopelvic fascia. The fascia covers the pelvic viscera and continues posteriorly over the lateral aspect of the prostate as the lateral fascia of the prostate and, on the lateral aspect of the rectum, as the lateral rectal fascia. Its relationship with the prostato-seminal fascia can be visualized as an 'H'. The deep dorsal vein and lateral branches run deep to the endopelvic fascia and the lateral fascia of the prostate, although they communicate with venous perforators to the pelvic side wall. The prostato-seminal fascia adheres to the prostate in the posterior midline but, like the lateral fascia of the prostate, is separated from the prostatic tissue by the neurovascular structures and fatty tissues elsewhere. Between the prostato-seminal fascia and the rectum is a fatty potential plane, clinically referred to as the prerectal space. **B**, The capsule of the prostate (PC) is a condensation of connective tissue (green) on the surface of the gland and encloses the neurovascular bundle (NVB). The prostatic fibromuscular stroma and glands lie beneath the capsule. (C, *continued online*)

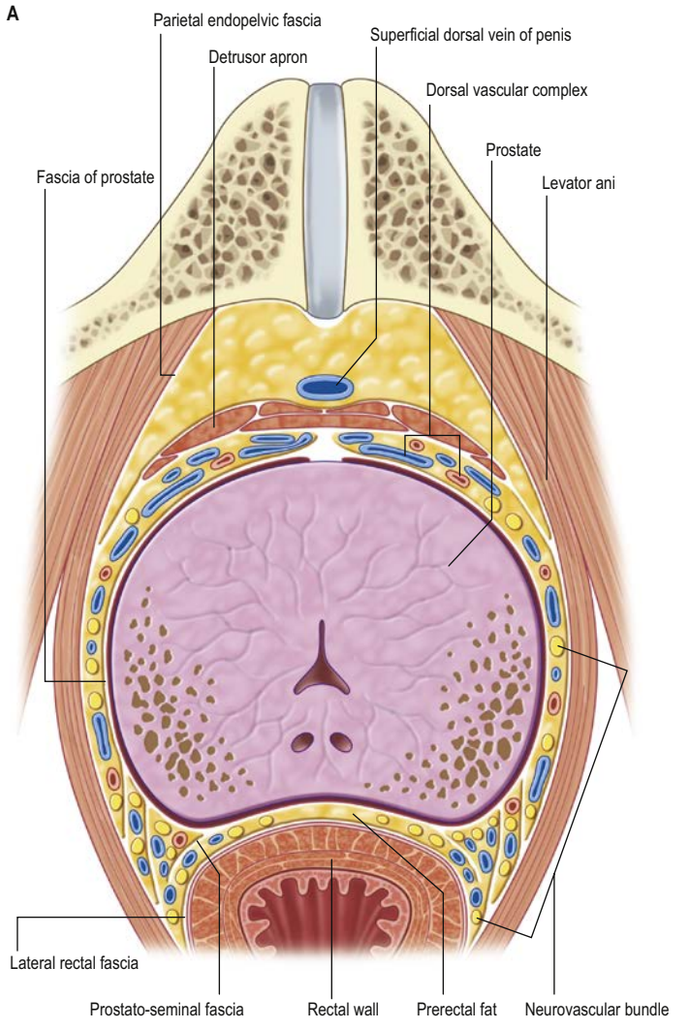

Fig. 73.15 A, The endopelvic fascia. The fascia covers the pelvic viscera and continues posteriorly over the lateral aspect of the prostate as the lateral fascia of the prostate and, on the lateral aspect of the rectum, as the lateral rectal fascia . The prostato-seminal fascia adheres to the prostate in the posterior midline but, like the lateral fascia of the prostate, is separated from the prostatic tissue by the neurovascular structures and fatty tissues elsewhere. Between the prostato-seminal fascia and the rectum is a fatty potential plane, clinically referred to as the prerectal space. **B**, The capsule of the prostate (PC) is a condensation of connective tissue (green) on the surface of the gland and encloses the neurovascular bundle (NVB). The prostatic fibromuscular stroma and glands lie beneath the capsule. (C, continued online)

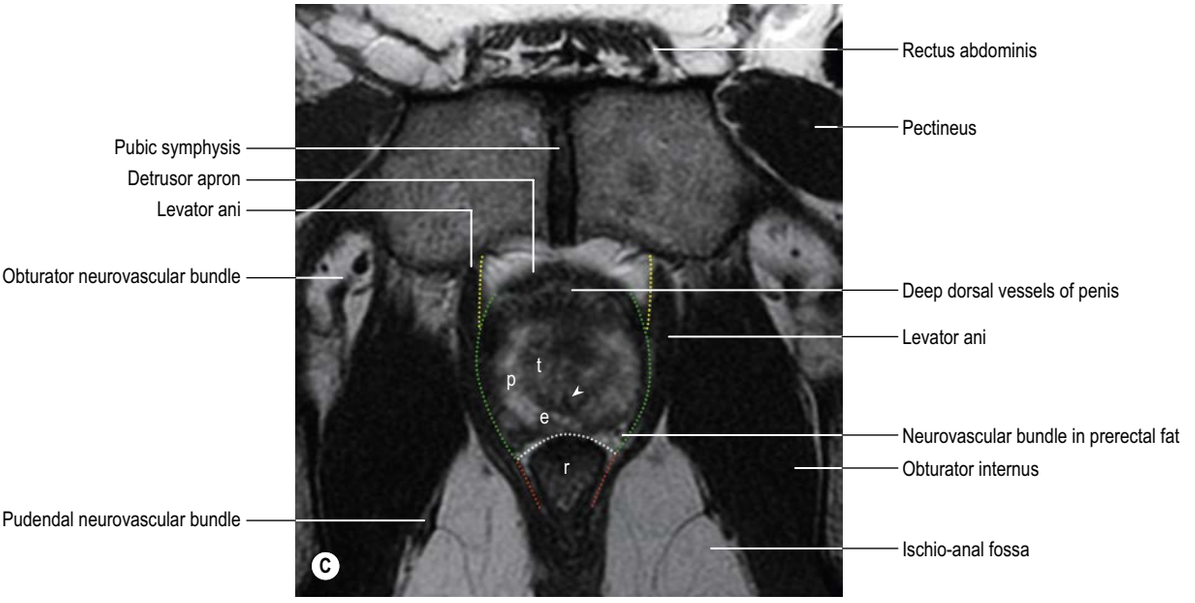

Fig. 73.15, cont'd C, A T2-weighted high resolution axial MRI of the prostate showing the courses of the endopelvic fascia as colour coded dotted lines: parietal endopelvic fascia (yellow); lateral prostatic fascia (green); lateral rectal fascia (red); Denonvilliers' fascia (white). The prostatic urethra is marked with an arrowhead. Abbreviations: e, ejaculatory duct; p, peripheral zone of prostate; r, rectum; t, transitional zone of prostate.

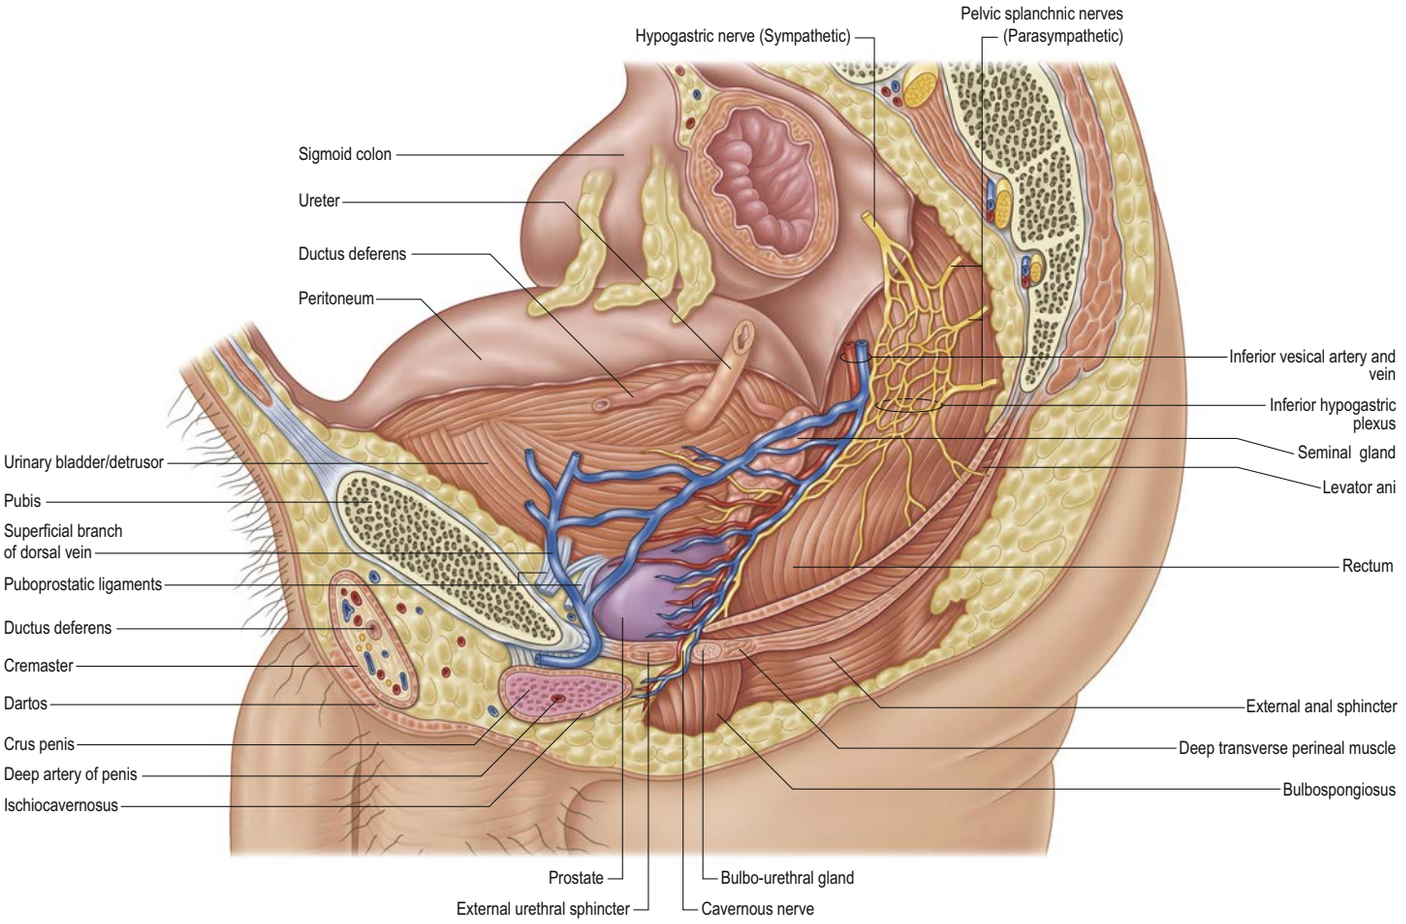

Fig. 73.16 A sagittal section of the male pelvis. The inferior hypogastric plexus lies with its midpoint level with the tip of the seminal glands. It gives branches to the prostate, bladder urethra, seminal glands, rectum and corpora cavernosa via the cavernous nerves. The cavernous nerves are the continuation of the neurovascular bundles, lying posterolateral to the prostate. These bundles can be injured at radical prostatectomy, resulting in impotence.

anterior border and usually passes between its anterior and middle thirds. The ejaculatory ducts pass anteroinferiorly through its posterior region to open into the prostatic urethra.

Zonal anatomy of the prostate

Based largely on histological studies, the prostate was once thought to be divided into five anatomical 'lobes' during early fetal life. Lowsley (1912) described five bilateral groups of prostatic buds that he designated as lobes: it is now recognized that prostatic bud initiation during development is stochastic, and that prostatic buds emerge and recede during the budding process (Cunha et al 2018, Shen et al 2018). In humans, until the onset of BPH, only three lobes are recognizable: left, right and middle lobes. Clinicians refer to left and right 'lobes' when they describe either what can be felt during transrectal palpation, or the endoscopically visible abnormalities in the diseased state when prostatic anatomy is distorted by, for example, BPH.

From an anatomical, and particularly from a morbid anatomical, perspective, the glandular tissue can be subdivided into three distinct zones (**Fig. 73.18**): peripheral (70% by volume), central (25% by volume) and transition (5% by volume) (Mundy et al 1999b). The zonal anatomy of the prostate is clinically important because most carcinomas arise in the peripheral zone, whereas BPH affects the transition zone, which may grow to form the bulk of the prostate (Yacoub and Oto 2018).

Non-glandular tissue (fibromuscular stroma) fills the space between the peripheral zones anterior to the intramural part of the urethra. The central zone surrounds the ejaculatory ducts posterior to the intramural part of the urethra and is more or less conical in shape, with its apex at the seminal colliculus. The fibromuscular stroma includes the smooth muscle detrusor apron superoanteriorly and striated urethral sphincter fibres that extend anteriorly over the anterior prostate on to the neck of the bladder. The transition zone lies around the distal part of the intramural part of the urethra just proximal to the apex of the central zone and the ejaculatory ducts; it includes the smooth muscle of the intramural part of the urethra. Its ducts enter the prostatic urethra just below the internal urethral sphincter and just above the ducts of the peripheral zone. The peripheral zone is cup-shaped and encloses the central transition zone and the intramural part of the urethra, except anteriorly, where the space is filled by the anterior fibromuscular stroma. Simple mucus-secreting glands lie in the tissue around the intramural part of the urethra, above the transition zone and surrounded by the internal urethral sphincter. These simple glands are similar to those in the female urethra and unlike the glands of the prostate.

On magnetic resonance imaging (MRI), the prostate has a zonal anatomy on T2-weighted images (see Fig. 73.17AB). The normal peripheral zone has high-signal intensity, as does fluid within the seminal glands. The central and transition zones have relatively low signal intensity and are often referred to as the 'central gland'. The seminal colliculus can be seen as high-signal within the central gland. The relations of the zones of the gland normally change with age. The central zone atrophies and the transition zone enlarges secondary to BPH. This often produces a low-signal band at the margin of the hypertrophied transition and compressed peripheral zones: the surgical pseudocapsule, which is well seen on T2-weighted MRI (Yacoub and Oto 2018).

As the transition zone grows, it produces the appearance of 'lobes' on either side of the urethra. In due course, these lobes can compress or distort the intramural and prostatic parts of the urethra and produce symptoms. The central zone surrounding the ejaculatory ducts is rarely involved in any disease. It shows certain histochemical characteristics that differentiate it from the rest of the prostate; it is thought to be derived from the mesonephric ducts (much like the epididymi, ducti deferentia and seminal glands), whereas the rest of the prostate is derived from the urogenital sinus (Ch. 22).

Vascular supply and lymphatic drainage

Arteries

The prostate is supplied by branches arising variably from the anterior division of the internal iliac, obturator, inferior vesical, internal pudendal and middle anorectal arteries or from a common trunk between the internal pudendal and inferior gluteal arteries (see Fig. 73.16). Less

Fig. 73.17 Magnetic resonance imaging (MRI) of the prostate. **A**, A T2-weighted MRI showing the normal high signal of the peripheral zone and the intermediate signal of the central and transition zones and the seminal colliculus in the central gland. **B**, A T2-weighted coronal MRI of the prostate showing the zonal anatomy.

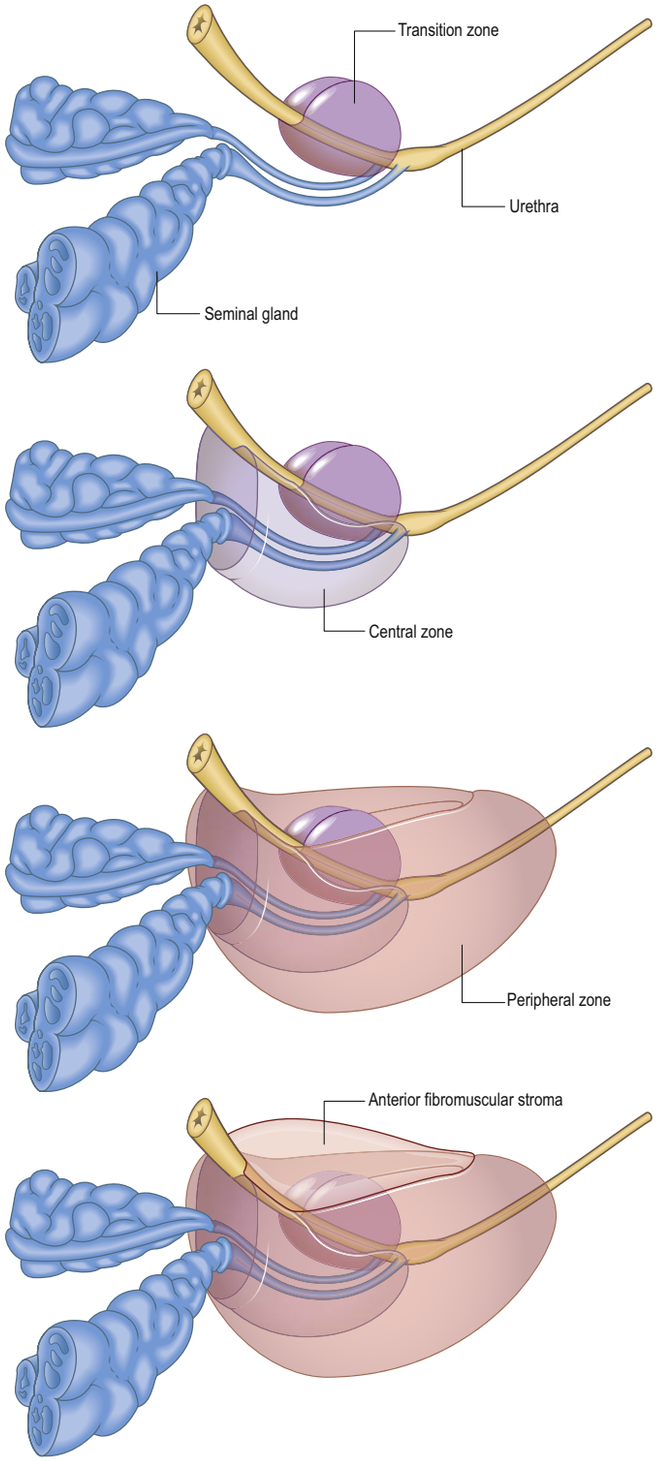

Fig. 73.18 The zonal anatomy of the prostate. (With permission from Walsh PC, Retik AB, Vaughan ED et al (eds) 2002 Campbell's Urology, 8th ed. Philadelphia: Saunders.)

common origins of this vessel include the gluteal arteries, posterior division of the internal iliac artery, and accessory internal pudendal artery (Moya et al 2017). These perforate the gland along a posterolateral line from the junction of the prostate with the bladder down to the apex of the gland.

The inferior vesical artery often arises from the internal iliac artery with the middle anorectal artery. It gives rise to two groups of branches: the urethral and capsular. The urethral vessels enter at the junction between the bladder and prostate, principally posteriorly at the 5 and 7 o'clock positions, but also anteriorly at 1 and 11 o'clock positions. This arterial anatomy around the neck of the bladder is always apparent at transurethral resection of the prostate and open removal of BPH adenomas. The arteries to the capsule of the prostate run posterolaterally and inferiorly in the neurovascular bundles, providing perpendicular perforating vessels to the gland. The most constant in position and prominence is the apical perforator at the prostatourethral junction, an important landmark for this point and for the neurovascular bundle during radical prostatectomy.

Veins

The veins of the prostate run into a venous plexus around its anterolateral aspects, posterior to the inferior pubic ligament and the inferior part of the pubic symphysis. The chief tributary is the deep dorsal vein of the penis. The plexus also receives vesical and prostatic veins (which connect with the vesical venous plexus and internal pudendal vein) and drains into the internal iliac veins.

Lymphatic drainage

Lymphatic vessels from the ductus deferens drain into the external iliac nodes, while those from the seminal glands drain to the internal and external iliac nodes. Lymphatic vessels from the prostate end mainly in the internal iliac, sacral and obturator nodes. A vessel from the posterior surface

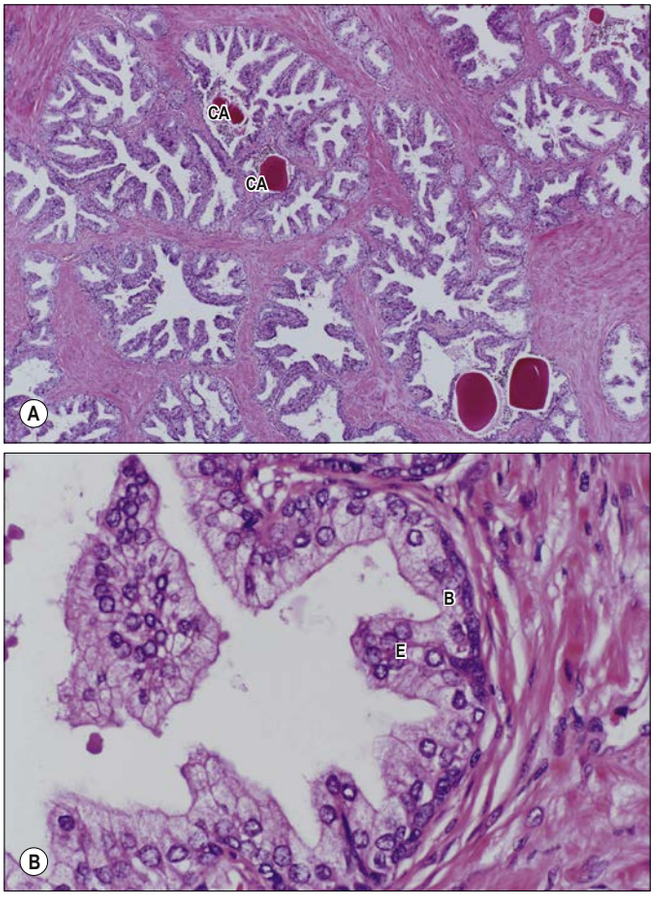

Fig. 73.19 **A**, Prostatic acini show papillary infoldings at the base of the gland (central zone). They are irregularly divided by fibromuscular stroma. Some acini contain eosinophilic (pink) secretions called corpora amylacea (CA) or prostatic concretions (×10, haematoxylin and eosin stain). **B**, Prostatic acini consist of a pseudostratified layer of epithelial cells (E), which line the lumen, including basal cells (B), which give rise to the mature epithelial cells.

of the prostate accompanies the urinary bladder vessels to the external iliac nodes, and another from the anterior surface of the prostate reaches the internal iliac nodes by joining vessels that drain the membranous urethra.

Innervation

The prostate is innervated by the inferior hypogastric plexus (see Figs 59.4, 73.8). The capsule of the prostate is covered by numerous nerve fibres and ganglia posterolaterally, forming the prostatic plexus. The greatest density of nerves is found in the internal urethral sphincter; there are fewer fibres in the anterior fibromuscular stroma, and the peripheral zone is the least densely innervated. Nerves containing neuropeptide Y and vasointestinal polypeptide are located in the subepithelial connective tissue, in the smooth muscle layers of the gland and in the walls of its blood vessels. Neurovascular bundles (Walsh and Donker 1982) containing autonomic nerves that supply the prostate, seminal glands, prostatic urethra, ejaculatory ducts, corpora cavernosa penis, corpus spongiosum penis, membranous and spongy parts of the urethra, and the bulbo-urethral glands are closely applied to, but separable from, the posterolateral surfaces of the prostate. They are intimately related to the fascia of the prostate. These nerves can be injured during radical prostate surgery for organ-confined prostate cancer, causing impotence, or sacrificed as part of wide local excision of the prostate (Tewari et al 2006, Pisipati et al 2014).

The pudendal nerve innervates the external urethral sphincter. The branches enter the muscle at the 5 and 7 o'clock positions. Sensory branches pass to the dorsal penis in association with the dorsal vascular complex and dorsal vein of the penis.

Microstructure

The glandular tissue consists of numerous follicles with frequent internal papillae. Follicles open into elongated canals that join to form 12–20 main ducts. The follicles are separated by loose connective tissue supported by extensions of the fibrous capsule and muscular stroma and enclosed in a delicate capillary plexus. Follicular epithelium is variable but predominantly columnar, and either single-layered or pseudostratified. Small colloid amyloid bodies (corpora amylacea) are frequent in the follicles (Fig. 73.19).

Prostatic ducts open mainly into the prostatic sinuses in the floor of the prostatic urethra. They have a pseudostratified epithelium in which the luminal layer is columnar and the basal layer is populated by small cuboidal cells. Secretions from the prostate and seminal gland form the bulk of seminal fluid: prostatic secretions are slightly acidic and contain acid phosphatase, amylase, prostate-specific antigen, fibrinolysin and zinc. Numerous neuroendocrine cells, containing neurone-specific enolase, chromogranin and serotonin (5-hydroxtryptamine, 5-HT), are present in the glandular epithelium; their numbers decline after middle age and their function is unknown.

Histological sections just above the level of the seminal colliculus reveal two concentric, partially circumurethral, zones of glandular tissue. The larger, outer peripheral zone contains long, branched glands with ducts that open mainly into the prostatic sinuses. The inner transition zone contains glands with ducts that open on the floor of the prostatic sinuses and seminal colliculus, and a group of simple mucosal glands that surround the intramural part of the urethra. Anteriorly, the peripheral zone and submucosal glands are absent in the anterior commissure of the prostate.

Age changes in the prostate

At birth, the prostate has a system of ducts embedded in a stroma that forms a large part of the gland. Follicles are represented by small end-buds on the ducts. Before birth, the epithelium of the ducts, seminal colliculus and prostatic utricle display hyperplasia and squamous metaplasia, possibly due to maternal oestrogens in the fetal blood. This subsides after birth and is followed by a period of quiescence lasting for 12–14 years.

At puberty, between the ages of approximately 14 and 18 years, the prostate enters a maturation phase and more than doubles in size. Growth is almost entirely due to follicular development, partly from end-buds on ducts and partly from modification of the ductal branches. Morphogenesis and differentiation of the epithelial cords starts in an intermediate part of the epithelial anlage and proceeds to the urethral and subcapsular parts of the gland; the latter is reached by the age of 17–18 years. The glandular epithelium is initially multilayered squamous or cuboidal and is transformed into a pseudostratified epithelium consisting of basal, exocrine secretory (including mucous) and neuroendocrine cells. The mucous cells are temporary and are lost as the gland matures. The remaining exocrine secretory cells produce a number of products, including acid phosphatase, prostate-specific antigen and β-microseminoprotein. Growth of the secretory component is associated with condensation of the stroma, which diminishes relative to the glandular tissue. These changes are probably a response to the secretion of testosterone by the testis.

During the third decade, the glandular epithelium grows by irregular multiplication of the epithelial infoldings into the lumen of the follicles. After the third decade, the size of the prostate remains virtually unaltered until 45–50 years, when the epithelial foldings tend to disappear, follicular outlines become more regular and amyloid bodies increase in number: all signs of prostatic involution. After 45–50 years, the prostate tends to develop BPH: an age-related condition (Roehrborn 2008). If a man lives long enough then BPH is inevitable, although not always symptomatic. Common symptoms include urinary frequency, hesitancy, urgency, nocturia, weak urinary stream and straining to urinate.

BPH begins as micronodules in the transition zone, which grow and coalesce to form macronodules around the inferior margin of the intramural part of the urethra just above the seminal colliculus. Macronodules, in turn, compress the surrounding normal tissue of the peripheral zone posteroinferiorly, creating a 'false capsule' around the hyperplastic tissue, which, coincidentally, provides a plane of cleavage for its surgical enucleation.

CHAPTER
74

Male reproductive system

The male reproductive system includes the gonads, spermatic cord, accessory sex glands and external genitalia. The male gonads, the testes, are responsible for spermatogenesis and steroidogenesis, thereby regulating reproductive function as well as normal physical and sexual development and behaviour. The accessory sex glands include the prostate, seminal glands (vesicles) and bulbo-urethral glands. Prostatic and seminal gland secretions constitute most of the seminal fluid volume, containing nutrients, growth factors and enzymes that are essential for normal spermatogenic function. Additionally, the anatomy of the male external genitalia, the scrotum and penis, is uniquely suited both to optimize the testicular environment for spermatogenesis and to facilitate seminal fluid delivery to the female reproductive tract. These functions are dependent on sensory and erectile capabilities.

TESTIS AND EPIDIDYMIS

Testis

In adults, the testes typically measure 4–5 cm in length, 2–3 cm in breadth and 3–4 cm in anteroposterior diameter (Tishler 1971); their weight ranges between 12 and 20 g. Average testicular volume ranges from 15 to 25 ml (Prader 1966, Goede et al 2011).

The testes are suspended in the scrotum by the spermatic cord (**Figs 74.2–74.3**). The left testis usually lies more inferiorly than the right; both are positioned obliquely, such that the superior pole is tilted anterolaterally while the inferior pole is tilted anteromedially. Their location in the scrotum, combined with the characteristics of the scrotal skin and the counter-current heat exchange mechanism of the pampiniform plexus, maintains the testes at a temperature 3–4 °C below body temperature.

The testes are enclosed in a tough capsule made up of three layers: an innermost vascular layer, an intermediate tunica albuginea and an outer tunica vaginalis (**Fig. 74.4**). The posterior aspect of the testis is the site of attachment of the epididymis and is therefore only partly covered by serosa. Here, the tunica albuginea projects inwards to form the mediastinum of the testis, and the tunica vaginalis projects outwards to cover the epididymis. Within the scrotum, the testes are separated by a septum.

Vascular layer The vascular layer (tunica vasculosa) contains a plexus of blood vessels and loose connective tissue. It lines the inner surface of the tunica albuginea and all of the surfaces and septations within the testis.

Tunica albuginea The tunica albuginea is a dense, blue–white layer composed primarily of collagen fibres. It covers the vascular layer and is surrounded by the visceral layer of the tunica vaginalis. At the posterior aspect of the testis it projects inwards as a thick but incomplete fibrous septum, the mediastinum of the testis, which extends from the superior to the inferior pole of the testis. It is here that vessels, nerves and efferent ductules traverse the testicular capsule (**Fig. 74.5**).

Tunica vaginalis The tunica vaginalis is a continuation of the processus vaginalis, the formation of which precedes the descent of the fetal testis from the abdomen to the scrotum. Following testicular migration into the scrotum, the portion of the processus vaginalis between the deep inguinal ring and the testis is obliterated, leaving a distal sac containing the testis. Failure to obliterate the processus vaginalis results in

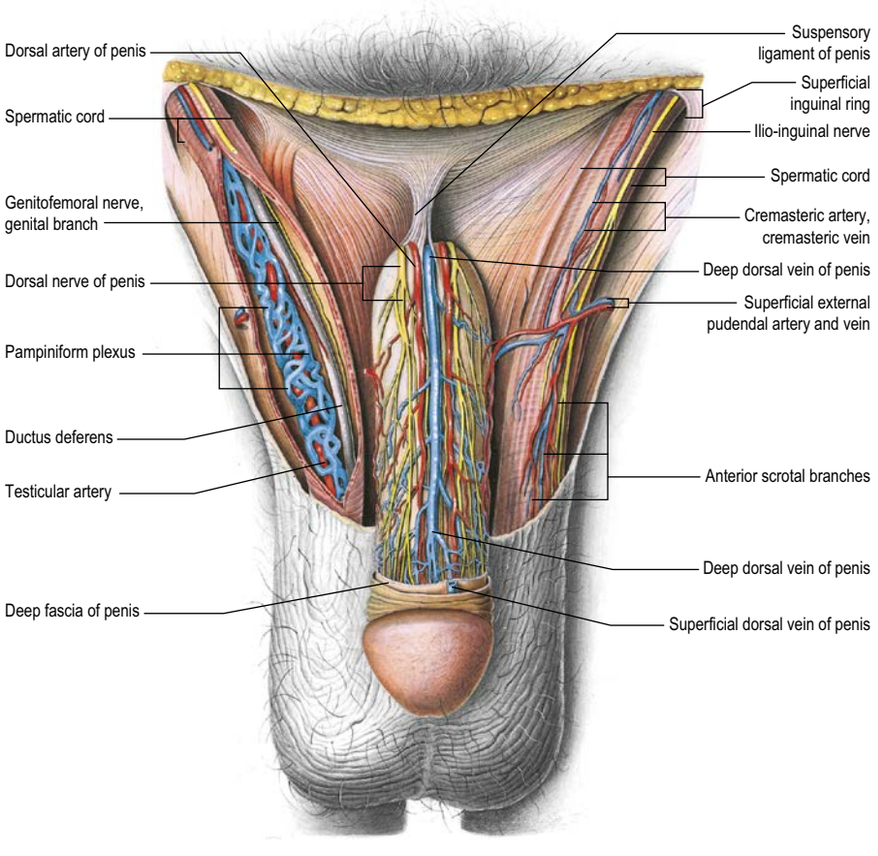

Fig. 74.2 The male external genitalia illustrating the dorsal aspect of the penis. Nerves and vessels exposed by extensive removal of the skin and the superficial fascia of the penis. The layers of the spermatic cord have been incised on the right; note the pampiniform plexus surrounding the testicular artery. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

TABLE 74.1 Volumes of the left and right testis as measured by ultrasonography.

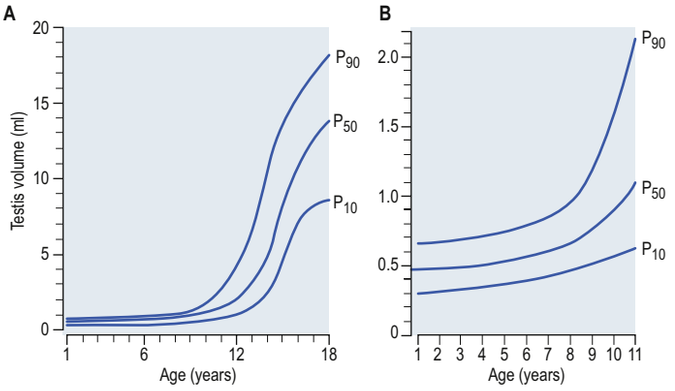

Fig. 74.1 A, Reference curves for mean testicular volume measured by ultrasonography. P_{10}, P_{50} and P_{90} indicate tenth, fiftieth and ninetieth centiles, respectively. **B**, Enlargement of the reference curves for mean testicular volume measured by ultrasonography. (With permission from Goede J, Hack WW, Sijstermans K et al 2011 Normative values for testicular volume measured by ultrasonography in a normal population from infancy to adolescence. Horm Res Paediatr 76:56–64.)

The volume of the left and right testis in males between infancy and adolescence as measured by ultrasonography is shown in Table 74.1; reference curves for mean testicular volume are shown in Fig. 74.1.

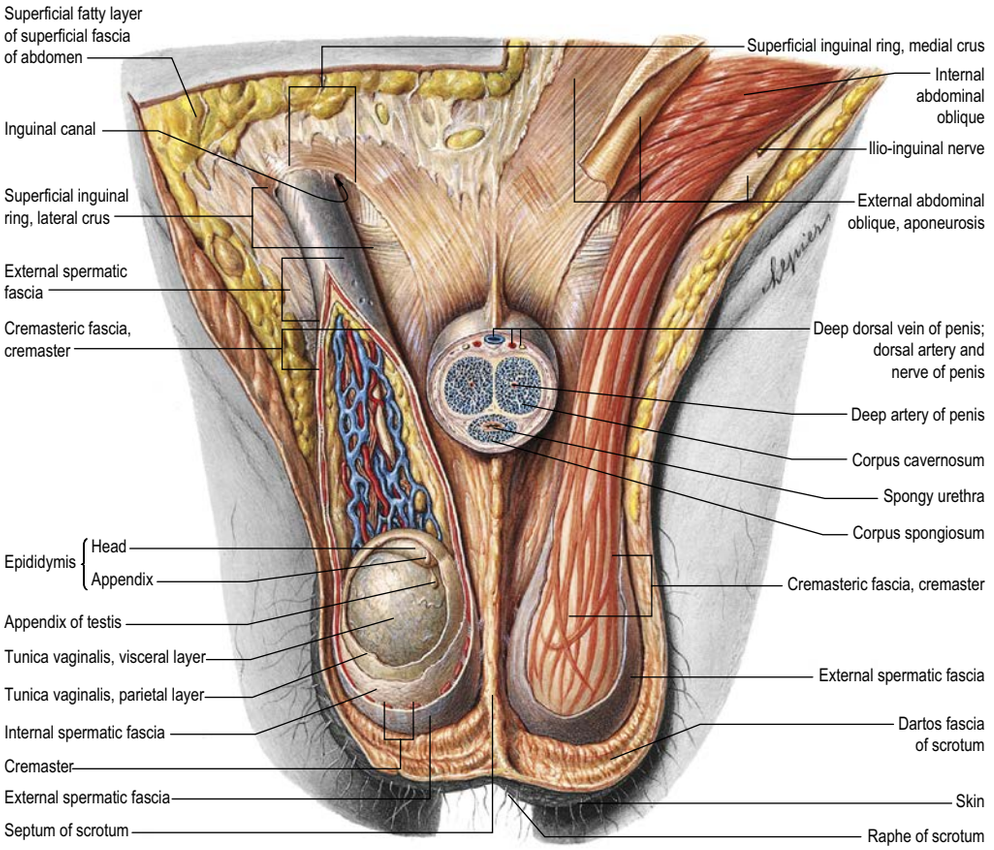

Fig. 74.3 The male external genitalia. The skin of the abdomen and parts of the skin of the scrotum have been removed, and the body of the penis has been transected revealing the internal structure of the penis. The layers of the spermatic cord and the coverings of the testis have been dissected on the right. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

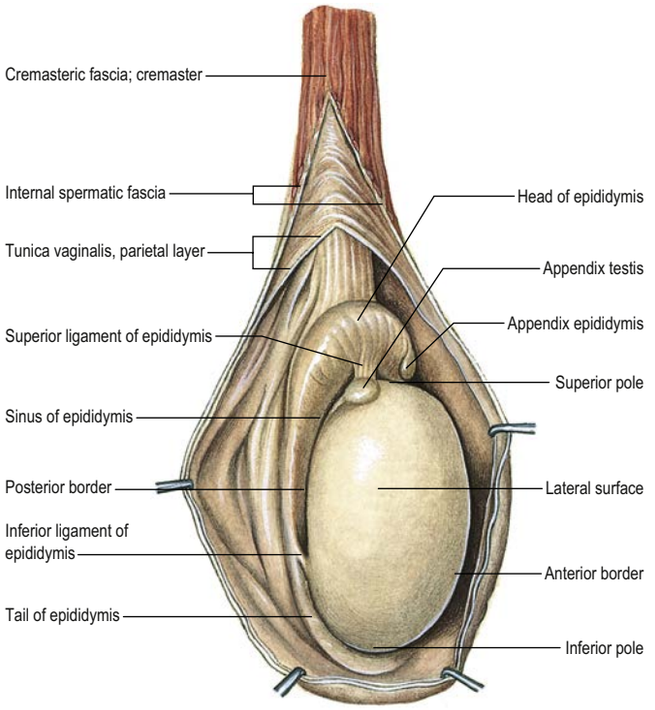

Fig. 74.4 The right testis, exposed by incising and laying open the cremasteric fascia and parietal layer of the tunica vaginalis on the lateral aspect of the testis. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

a persistent communication between the scrotum and peritoneal cavity (Fig. 74.6), which can lead to hydroceles and indirect inguinal hernias.

The tunica vaginalis is reflected from the surface of the testis on to the inner surface of the scrotum, forming visceral and parietal layers that are continuous at both poles of the testis. The visceral layer covers all aspects of the testis except the posterior aspect, where it is reflected towards the epididymis before becoming continuous with the parietal layer. The inner surface of the parietal layer has a smooth, moist mesothelium. The potential space between the visceral and parietal layers, the cavity (cavum) of the tunica vaginalis, is normally occupied by a thin film of clear, straw-coloured fluid. The volume of this fluid can increase with obstruction of lymphatic drainage due to inflammatory, traumatic or neoplastic conditions of the testis, resulting in a hydrocele.

Vascular supply and lymphatic drainage

Arteries

The arterial supply to the testis and epididymis is derived from three sources. In descending order of contribution, these are the testicular artery (supplying approximately two-thirds of the testicular blood supply), the artery to ductus deferens and the cremasteric artery (together contributing approximately one-third of the testicular blood supply) (Fig. 74.7) (Harrison and Barclay 1948, Raman and Goldstein 2004).

Testicular artery

The testicular artery usually arises from the abdominal aorta, inferior to the origin of the renal artery, and courses inferolaterally under the parietal peritoneum, along psoas major towards the pelvis. On the right, it courses anterior to the inferior vena cava and posterior to the middle colic and ileocolic arteries and the terminal ileum. On the left, it courses posterior to the inferior mesenteric vein, left colic artery and the descending colon. As the right and left testicular arteries enter the pelvis they lie anterior to the genitofemoral nerves, ureters and external iliac arteries. Both arteries then enter the deep inguinal ring and travel within the ipsilateral spermatic cord in the inguinal canal to the scrotum (see Figs 74.2, 74.5). The origin, number and course of the testicular arteries can vary (Asala et al 2001, Pai et al 2008, Kotian et al 2016, Kayalvizhi et al 2017).

Proximally, it supplies the upper and middle parts of the ureter (Daniel and Shackman 1952). Distally, in its course to the testis the testicular artery gives off one or more internal testicular arteries (MacLennan 2012) an inferior testicular artery, and branches supplying the head, body and tail of the epididymis (Macmillan 1954). The level at which this branching occurs is variable; in 31–88% of cases it occurs within the inguinal canal (Beck et al 1992, Jarow et al 1992). At the level of the testis, branches of the testicular artery enter the tunica albuginea in the mediastinum of the testis and ramify in the vascular layer before reaching their distribution. The testicular arteries ramify primarily in the anterior, medial and lateral portions of the inferior pole of the testis and in the anterior segment of the superior pole (Jarow 1991,

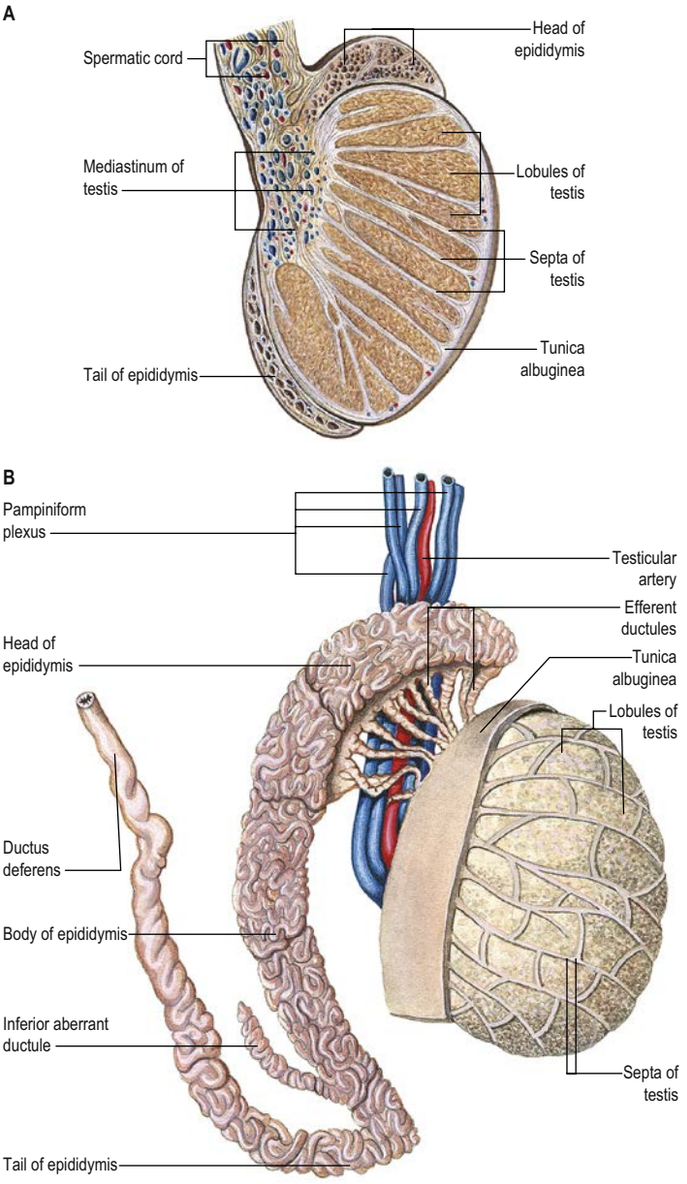

Fig. 74.5 **A**, A sagittal section through the testis and epididymis. **B**, The arrangement of the efferent ductules of the testis and the mode of formation of the epididymis and ductus deferens. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

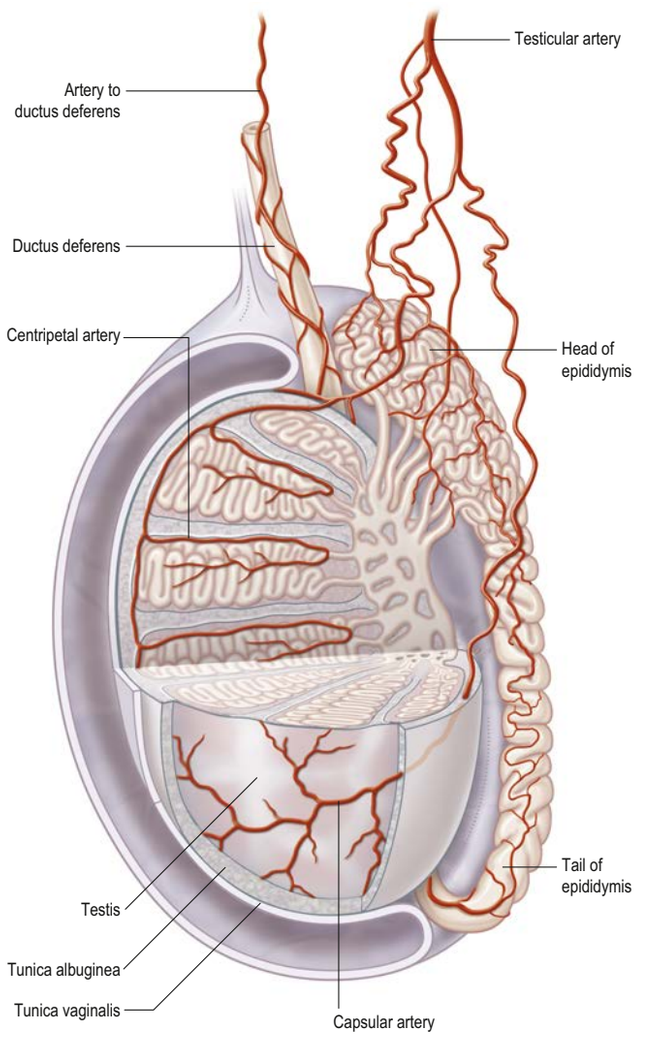

Fig. 74.7 Sagittal and axial sections through the testis, to demonstrate its blood supply. Note the blood supply to the epididymis and ductus deferens.

Mostafa et al 2008), which has important implications for planning testicular biopsies.

Artery to the ductus deferens

The artery to the ductus deferens is a branch of the superior or inferior vesical artery, which arises from the internal iliac artery (Mostafa et al 2008).

Cremasteric artery

The cremasteric artery is a branch of the inferior epigastric artery. It accompanies the spermatic cord and supplies cremaster and other coverings of the cord. Both the artery to the ductus deferens and the cremasteric artery enter the inguinal canal at the deep inguinal ring and travel the length of the spermatic cord alongside the testicular artery. The testicular artery and pampiniform plexus lie within the internal spermatic fascia, whereas the ductus deferens and its vessels, as well as cremaster and its vessels, lie outside the internal spermatic fascia but within the external spermatic fascia. In the scrotum there is a rich vascular anastomosis at the head of the epididymis, between the testicular artery and the epididymal artery, and at the tail of the epididymis between the testicular, epididymal, and cremasteric arteries and the artery to the ductus deferens.

Veins

Pampiniform plexus

Testicular veins emerge posteriorly from the testis, drain the epididymis and unite to form several highly anastomotic channels surrounding the testis known as the pampiniform plexus, a major component of the spermatic cord (see Fig. 74.2). This vascular arrangement means that counterflowing arteries and veins are separated only by the thickness of their vascular walls, permitting the exchange of heat and small molecules (Harrison 1949) and facilitating the maintenance of lower testicular temperatures. The pampiniform plexus ascends anterior to the ductus deferens and is drained by 3–4 veins in the inguinal canal. The veins enter the abdomen through the deep inguinal ring and coalesce into a single testicular vein that drains into the inferior vena cava on the right and the renal vein on the left. The right testicular vein joins the inferior vena cava at an acute angle, just inferior to the level of the renal veins, while the left testicular vein joins the left renal vein at a right angle (**Fig. 74.8**). The testicular veins contain valves.

Lymphatic drainage

Testicular lymphatic flow is abundant and consistent and follows the general retroperitoneal scheme of vertical drainage, with lateral flow from right to left. Lymphatic vessels from the right testis drain primarily into the right lateral aortic and lateral caval nodes, with some drainage into the left lateral aortic nodes. Lymphatic vessels from the left testis drain into the left and right lateral aortic and lateral caval nodes.

Innervation

The testis is innervated either by nerve fibres that arise from the tenth and eleventh thoracic spinal segments via the renal and aortic plexuses and accompany the testicular vessels, or by fibres that arise from the inferior hypogastric plexus and accompany the ductus deferens (Rauchenwald et al 1995). Interestingly, some afferent and efferent nerves have been shown to cross over to the contralateral inferior hypogastric plexus (Taguchi et al 1999), which could be one reason why pathological processes in one testis can affect the other.

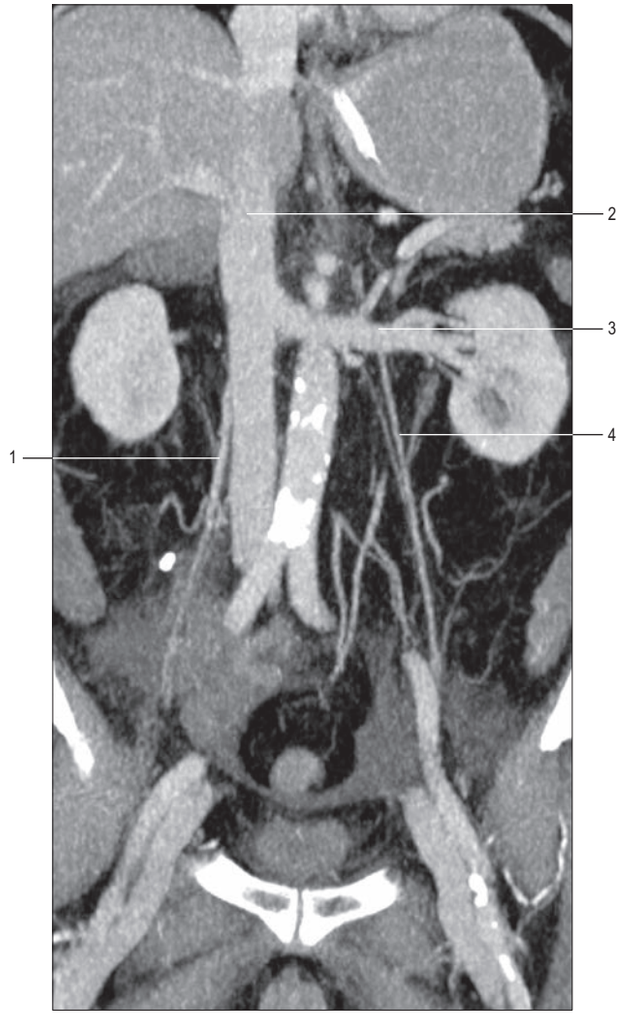

Fig. 74.8 Computed tomography showing the left testicular vein draining to the left renal vein and the right testicular vein draining to the inferior vena cava. Key: 1, right testicular vein; 2, inferior vena cava; 3, left renal vein; 4, left testicular vein.

The greater length of the left testicular vein and its angle of attachment into the left renal vein have been suggested as possible aetiologies for the occurrence of varicoceles. Additionally, the testicular veins can anastomose with the external pudendal and cremasteric veins and veins of the ductus deferens, allowing varicoceles to persist or recur after ablative procedures that do not address these potential collaterals.

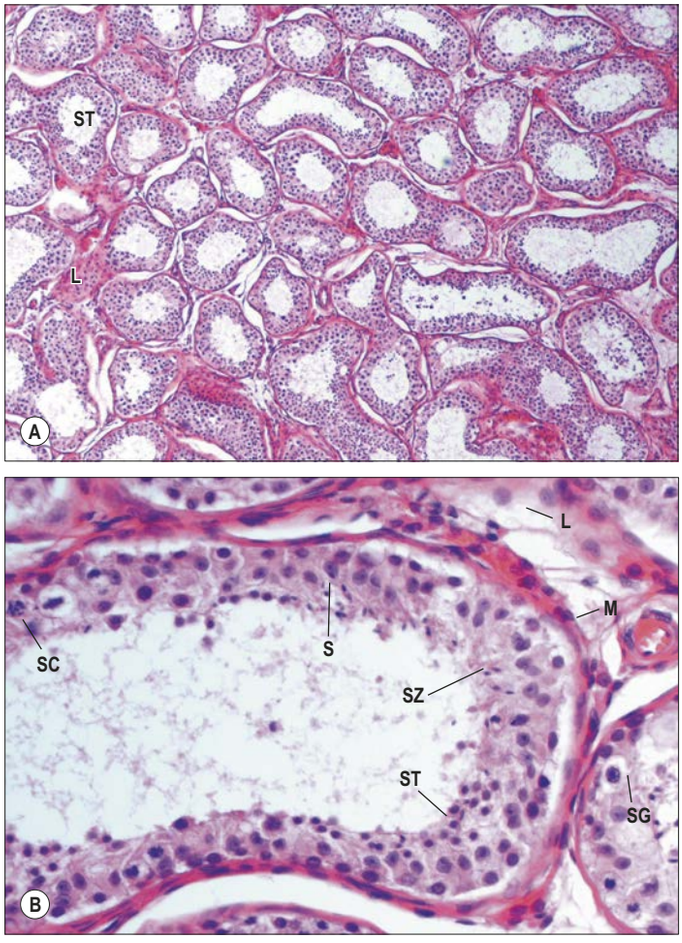

Fig. 74.10 A, Seminiferous tubules (ST; cut in various planes of section) and the interstitial endocrine cells (Leydig cells, L) of the testis. The seminiferous tubules are highly convoluted and lined by a stratified epithelium, which consists of cells in various stages of spermatogenesis and spermiogenesis (collectively referred to as the spermatogenic series). Non-spermatogenic cells are the Sertoli cells. **B**, A human seminiferous tubule showing the differentiation sequence of spermatozoa from basally situated spermatogonia (SG). Large primary spermatocytes (SC) have characteristic thread-like chromatin in various stages of prophase of the first meiotic division. Smaller haploid spermatids (ST) have round nuclei initially but mature to possess the dense, elongated nuclei and flagella of spermatozoa (SZ). Sertoli cells (S) are identified from their oval or pear-shaped nuclei, orientated perpendicular to the basal lamina, and from their prominent nucleoli. The tubule is surrounded by peritubular myoid cells (M). Clusters of interstitial endocrine cells (L) are seen in the interstitial connective tissue.

Microstructure

The testis is enclosed within a tough, collagenous tunica albuginea, which thickens posteriorly as the mediastinum of the testis. Blood and lymphatic vessels, and genital ducts all enter and leave the testis at the mediastinum (Fig. 74.9). Septations originating at the mediastinum of the testis extend internally to partition the testis into approximately 250 lobules that differ in size, the largest and longest lobules being near the centre (see Fig. 74.5). Each lobule contains 1–4 convoluted seminiferous tubules and interstitial tissue composed of interstitial endocrine cells (Leydig cells), mast cells, macrophages, nerves and blood vessels.

Seminiferous tubules are typically long, highly coiled and looped; both ends terminate in the mediastinum of the testis. Spermatogenesis occurs in the highly coiled portions (Fig. 74.10). As the tubules reach the apical portion of the lobule near the mediastinum of the testis they become much less convoluted and form short straight tubules (tubuli recti), which lack spermatogenic cells and are instead lined by cuboidal epithelium. Within the mediastinum of the testis, straight tubules anastomose to form the rete testis, which is lined by a flat epithelium. Here, tubular fluid is reabsorbed and spermatozoa become concentrated. The rete testis coalesces to form 7–15 efferent ductules, which act as conduits to carry spermatozoa into the head of the epididymis. The efferent ductules are lined by a ciliated columnar epithelium that also contains non-ciliated, actively endocytic cells. Outside the epithelial lining, the ductules are surrounded by a thin circular coat of smooth muscle.

The diameters of the seminiferous tubules decrease during the third trimester of pregnancy and immediately before birth, then gradually increase throughout childhood (Mendez and Emery 1979). Seminiferous tubules are responsible for up to 80% of the total testicular volume. It is estimated that the combined length of the 600–1200 tubules in the human testis is approximately 250 metres. Each tubule is surrounded by a basal lamina resting on a complex, stratified epithelium. In cross-section, the lumen of the seminiferous tubule is lined by Sertoli cells (sustentocytes) and contains spermatozoa in various stages of development, from spermatogonial stem cells near the base to progressively maturing forms (spermatogonia, spermatocytes, spermatids and spermatozoa) arranged systematically towards the centre of the tubule. Residual bodies, spherical structures derived from surplus spermatid cytoplasm shed during spermatozoal maturation, can be found among the spermatids.

Specialized tight junctional complexes between adjacent Sertoli cells form a functional 'blood–testis barrier' that subdivides the seminiferous tubule epithelium into basal and adluminal compartments. Spermatogonia and developing spermatocytes lie outside the blood–testis barrier in the basal compartment, whereas mature spermatocytes and spermatids are sequestered above the blood–testis barrier in the adluminal compartment.

Spermatogonia Spermatogonia, the germ cells for all spermatozoa, are descended from primordial germ cells that migrate into the genital cords of the developing testis. In the fully differentiated testis they are located along the basal laminae of the seminiferous tubules (see Fig. 74.10B). On the basis of their cellular and nuclear dimensions, distribution of nuclear chromatin, and histochemical and ultrastructural properties, spermatogonia are characterized as either dark-type A (Ad), pale-type A (Ap) or type B cells. Ad spermatogonia divide mitotically to maintain their own population and can differentiate to give rise to Ap cells, the precursors of type B cells, which are committed to the spermatogenesis cycle. Type B cells give rise to type I spermatocytes; they leave the basal compartment of the seminiferous tubule and cross the blood–testis barrier to enter the adluminal compartment in a step coordinated by Sertoli cells.

The generation of mature spermatozoa from spermatogonia takes approximately 64 days. In cross-section, a seminiferous tubule shows more than one phase of the cycle around its circumference because waves of progression through a spermatogenic cycle occur in spirals along the length of a tubule (see Fig. 74.10B).

Primary and secondary spermatocytes Primary spermatocytes have a diploid chromosome number with duplicated sister chromatids (4N DNA content). They are large cells with round nuclei in which the chromatin is condensed into dark, thread-like, coiled chromatids. They undergo meiosis I to give rise to secondary spermatids (2N), which rapidly undergo meiosis II to form haploid spermatids (N). Theoretically, each primary spermatocyte produces four spermatids; however, a proportion of spermatids degenerate during maturation, reducing the expected yield.

Spermatids Spermatids undergo a series of nuclear and cytoplasmic changes, termed spermiogenesis, in order to develop into mature spermatozoa. These changes take place while the spermatids are closely associated with Sertoli cells and linked to one another by cytoplasmic bridges. Spermiogenesis includes the development of the acrosome from Golgi vesicles, generation of the axoneme from the centrioles and formation of the acrosomal cap at the anterior pole of the spermatozoon. Concurrently, the nuclear chromatin condenses and the nucleus assumes a spearhead shape. The cytoplasmic volume shrinks, bringing the wall of the acrosomal vesicle into contact with the plasma membrane. A perinuclear sheath of microtubules develops from the posterior edge of the acrosome and extends towards the posterior pole of the spermatozoon. Here, the microtubules are arranged in the typical flagellar pattern of nine outer microtubules surrounding two central microtubules, the axonemal complex that extends longitudinally to form the tail of the spermatozoon. Mitochondria migrate along the axonemal complex and concentrate in the mid-piece of the tail. During the final phase of spermiogenesis, excess cytoplasm is detached from the spermatozoon as a residual body that is phagocytosed and degraded by Sertoli cells. During the formation of residual bodies, spermatids lose their cytoplasmic bridges and separate from one another before being released into the lumen of the seminiferous tubule.

Spermatozoa Spermatozoa released into the seminiferous tubule are structurally mature but usually non-motile. In the presence of excurrent ductal obstruction, testicular sperm can acquire motility (Jow et al 1993). The shape of the spermatozoon is ideally suited to rapid progressive motility (Fig. 74.11). Its head has minimal cytoplasm and measures approximately 4 μm × 3 μm. It contains an elongated, flattened nucleus

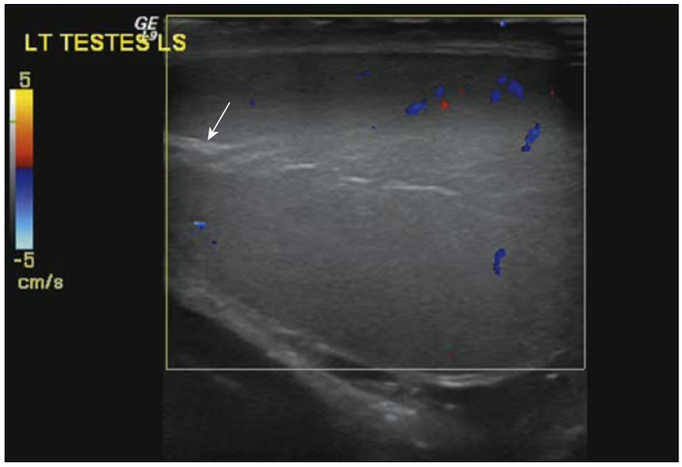

Fig. 74.9 A colour Doppler scan of the scrotal contents showing normal flow. The linear echogenic band (arrow) seen centrally represents the mediastinum of the testis, which is composed of fibroadipose tissues.

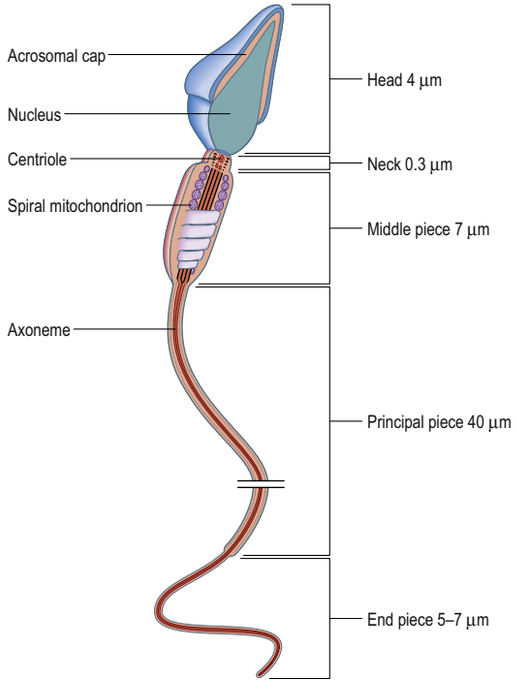

Fig. 74.11 The main ultrastructural features of a mature spermatozoon.

with condensed, dark-staining chromatin, covered anteriorly by an acrosomal cap. The latter contains acid phosphatase, hyaluronidase and proteases necessary for oocyte fertilization. The head is connected by a short neck approximately 0.3 μm in length to a long tail, which is divided into middle, principal and end pieces. The mid-piece of the tail is a cylinder approximately 7 μm long. It consists of an axial bundle of microtubules, the axoneme, surrounded by a cylinder of nine outer dense fibres (ODFs), surrounded in turn by a helical mitochondrial sheath. The mid-piece is the powerhouse of the spermatozoon. The principal piece of the tail is responsible for motility. With a length of 40 μm and a diameter of 0.5 μm, the tail forms most of the volume of a spermatozoon. The axonemal complex is continuous from the neck region to the terminus of the tail, only the axoneme persisting in the final 5–7 μm.

Sertoli cells Sertoli cells (sustentocytes, nurse cells, supporting cells) have euchromatic and irregular nuclei that are aligned perpendicular to the basal lamina and contain one or two prominent nucleoli. They are variable in shape. Their basal end rests on the basal lamina while their apical end extends into the tubule lumen. Consistent with their phagocytic function, their cytoplasm is rich in lysosomes. Sertoli cells provide key support for spermatogenesis within the seminiferous tubules. Complex recesses in their plasma membranes serve to envelop spermatogonia, spermatids and spermatozoa until the latter are mature enough for release. Long cytoplasmic processes extend between spermatogonia in the basal compartment and spermatocytes in the adluminal compartment of the seminiferous tubule. Adjacent Sertoli cells are joined at this level by tight junctions that create a diffusion barrier between the extratubular and intratubular compartments. This so-called blood–testis barrier can be disrupted by trauma or inflammation, allowing self-directed immune responses to develop against sperm antigens, potentially leading to subfertility.

In addition to their role in spermatogenesis, Sertoli cells secrete proteinaceous fluid to facilitate spermatozoal transport through the seminiferous tubules and into the excurrent ducts. They also regulate the intratesticular hormonal milieu by secreting inhibin B and androgen-binding protein in response to stimulation by pituitary gland gonadotropins.

Interstitial endocrine cells and interstitial tissue The interstitial tissue between seminiferous tubules includes peritubular myoid cells, vessels, nerves and clusters of interstitial endocrine cells (Leydig cells). Myoid cells are contractile; their rhythmic activity helps propel non-motile spermatozoa through the seminiferous tubules towards the rete testis and excurrent ductal system. Interstitial endocrine cells are large polyhedral cells with eccentric nuclei containing 1–3 nucleoli, and pale-staining cytoplasm containing smooth endoplasmic reticulum, lipid droplets and characteristic needle-shaped, crystalloid inclusions (crystals of Reinke). In response to stimulation by pituitary gonadotropins they synthesize and secrete testosterone.

Age-related changes

Available with the *Gray's Anatomy* e-book

Puberty is associated with the development of an adult population of androgen-producing interstitial endocrine cells, which persist throughout adult life. The testes grow slowly until the age of 10 or 11 years, at which time there is a marked acceleration of growth. This increase in testicular size is largely due to the onset of spermatogenesis, characterized by proliferation and differentiation of previously dormant spermatogonial stem cells. Testicular size, sperm quality and quantity, and the numbers of Sertoli cells and interstitial endocrine cells have all been reported to decline with age, although no consistent or definitive age for the onset of this decline has been identified. Testicular volume occupied by seminiferous tubules decreases, whereas that occupied by interstitial tissue remains approximately constant.

The most frequently observed histological change in the ageing testis is the apparent variability in spermatogenesis; spermatogenesis is complete in some areas and reduced in others, or absent altogether as a result of tubular sclerosis. In tubules where spermatogenesis is complete, morphological abnormalities such as multinucleation can be observed in the germ cells. Germ cell loss, beginning with spermatids and progressively affecting the earlier stages of spermatogenesis, can also be seen. As a result, both sperm quality and quantity can be affected. In some males, this change is notable as early as the third or fourth decade of life.

Sperm motility and maturation Human spermatozoa acquire an increased capacity for motility as they migrate through the epididymis, which is manifested not only as an increase in the percentage of spermatozoa with motile tails but also as a qualitative change from an immature to a more mature pattern of motility. Spermatozoa in the proximal epididymis demonstrate high-amplitude, low-frequency tail movements, producing little motion. This is in contrast to spermatozoa in the tail of the epididymis, which demonstrate low-amplitude and high-frequency tail movements, resulting in considerably greater forward progression (Bedford et al 1973).

Whether and to what extent sperm motility depends on the interaction of human spermatozoa with a particular section of the epididymis is unknown. In patients with congenital absence or obstruction of the ductus deferens, spermatozoa in the distal epididymis demonstrate less effective motility than those in the proximal epididymis (Silber 1989, Schoysman and Bedford 1986). Therefore, intrinsic sperm processes as well as intrinsic epididymal function appear to be important in sperm maturation.

Following ejaculation, spermatozoa display their full pattern of motility. Although sperm motility is highest in the hours following ejaculation, motile human spermatozoa have been recovered from cervical mucus several days after insemination. However, this survival period may be of little relevance given that human spermatozoa are capable of migrating to their tubal destination within an hour of insemination.

After entering the female reproductive tract, spermatozoa undergo a process known as capacitation to render them capable of fertilizing the oocyte. Capacitation involves a number of structural and biochemical changes, including the development of hyperactivated motility and completion of the acrosome reaction. Independent of other sperm characteristics such as motility and morphology, capacitation is necessary for the development of functional spermatozoa.

Epididymis

The epididymis lies posterior and slightly lateral to the testis. Anatomically, it is divided into three sections: head, body and tail. Between 8 and 12 efferent ductules from the superior pole of the testis drain into and form the head of the epididymis. Distally, the tail of the epididymis becomes continuous with the convoluted portion of the ductus deferens (see Fig. 74.5B). The epididymis is invested by the tunica vaginalis, continuous with that covering the testis. Laterally, a deep groove, the sinus of the epididymis, marks the boundary between the testis and epididymis. Testis–epididymis non-fusion has been described in children with cryptorchidism; non-fusion may involve the epididymal head or tail or the whole epididymis (Kraft et al 2011).

Epididymal cyst and spermatoceles
Available with the *Gray's Anatomy* e-book

Microstructure

The epididymal tubule is 3–4 metres long (Turner et al 1978) and is entirely encapsulated by the tunica vaginalis. Extensions from this connective tissue sheath enter the interductal spaces, forming septa that divide the tubule into histologically similar regions (Kormano and Reijonen 1976).

Functionally, the fetal testis is primarily an endocrine organ that produces testosterone and anti-Müllerian hormone. Seminiferous tubules do not become canalized until approximately the seventh month of gestation. Fetal interstitial endocrine cells responsible for androgen-induced differentiation of the male genitalia, degenerate after birth. A second wave of interstitial endocrine cell differentiation occurs 2–3 months after birth, briefly elevating testosterone levels in male infants. The interstitial endocrine cells of early infancy subsequently regress and the testis remains dormant during childhood. In a study of Japanese boys, gonocytes were reported to appear at about the age of 2 years, spermatocytes by 4 years and spermatids by 11 years (Yuasa et al 2001).

Sertoli cells are also affected by ageing and show a range of morphological changes including loss of differentiated characteristics, mitochondrial metaplasia and multinucleation. In interstitial endocrine cells there is a decline in the number of mitochondria and the quantity of smooth endoplasmic reticulum, paralleled by an increase in lipid droplets, crystalline inclusions and residual bodies. Some cells also become multinucleated. Functionally, these changes are manifested as a gradual age-related decline in circulating testosterone levels.

The descent of the testes from the abdominal cavity to the scrotum can be arrested at any point along the pathway of the testis, e.g. the deep inguinal ring, in the inguinal canal, or between the superficial inguinal ring and the scrotum. Retention in the inguinal canal is associated with a patent processus vaginalis and can be further complicated by a congenital hernia. Occasionally, the testis migrates outside its normal path of descent and lies in an ectopic location.

At birth, 3% of full-term male infants have a unilaterally undescended testis. By six months of age, this number decreases to less than 1%. Undescended testes are associated with a higher risk of infertility and testicular cancer later in life.

Orchidopexy is therefore recommended for patients with persistent cryptorchidism after 6 months of age and within 18 months of age. Available evidence suggests that orchidopexy at any age can improve spermatogenesis (Shin et al 1997) but does not decrease the risk of testicular cancer in a cryptorchid (undescended) testis. An inverse relationship has been reported between age at orchidopexy and total sperm count and sperm motility. The data support orchidopexy in the first year of life (Canavese et al 2009). Nevertheless, surgical correction maximizes the chance of early detection of a testicular mass and is the only means of restoring a normal milieu for spermatogenesis. Interestingly, interstitial endocrine cell function is usually unchanged by maldescent, so serum testosterone levels remain within the normal range in affected patients. In contrast, maldescent in children in the age range of 1–15 years is associated with Sertoli cell degeneration (Rune et al 1992).

Retractile testes are more common than undescended testes in boys. A retractile testis is one that moves to and fro between the inguinal region and the scrotum. Unlike undescended testes, retractile testes can be manipulated to the distal part of the scrotum on clinical examination. They are smaller than normal testes, having a mean volume of approximately 0.50 ml in children.

Testicular torsion refers to rotation of the testis around its blood supply leading to testicular ischaemia. Torsion can be extravaginal or intravaginal depending on whether it involves a rotation of both the testis and the tunica vaginalis, or of the testis alone, within an intact tunica vaginalis. In either case, torsion results in severe testicular pain secondary to tissue ischaemia. Fertility can be affected by a single episode of torsion. If unrelieved within 4–6 hours, permanent tissue loss can occur. Testicular torsion is therefore considered a surgical emergency.

Other structures in the scrotum such as the appendix of the testis (hydatid of Morgagni) (**Fig. 74.12**) and appendix of the epididymis (see Fig. 74.4) can also undergo torsion, resulting in scrotal pain that can be difficult to differentiate from testicular torsion. In some instances a 'blue dot' sign is noted at the superior pole of the testis, which is diagnostic. These structures are developmental remnants of the paramesonephric (Müllerian) and the mesonephric (Wolffian) ducts, respectively. There are no associated long-term sequelae.

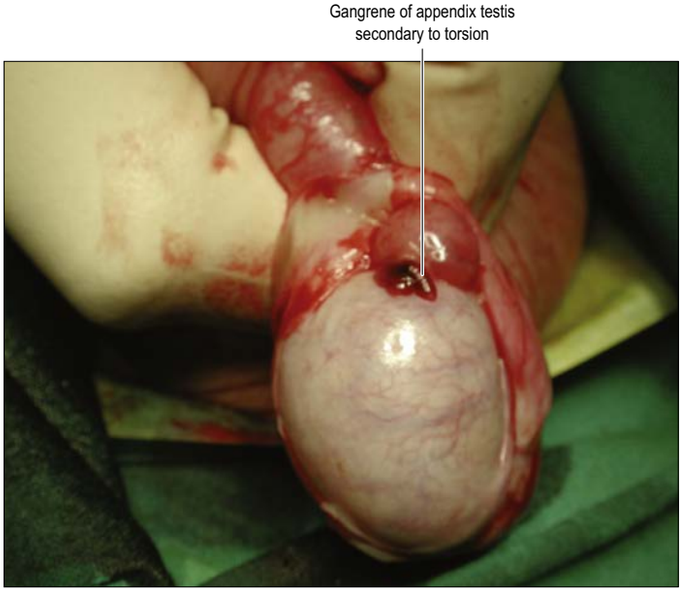

Fig. 74.12 Gangrene of the appendix of the testis secondary to torsion of the testis in an 8-year-old boy.

A patent processus vaginalis allows communication to occur between the peritoneal cavity and the spermatic cord or scrotum. Passage of peritoneal fluid into the scrotum presents as a communicating hydrocele and usually resolves spontaneously once the processus is obliterated by 18–24 months of age. Alternatively, if the processus vaginalis is patent proximally but obliterated distally, there could be a hydrocele or cyst of the spermatic cord. Surgical treatment can be indicated for persistent, non-communicating hydroceles. Hydroceles can also result from lymphatic vessel obstruction from a testicular tumour, epididymitis, orchitis or trauma. A 20% incidence of hydrocele has been reported in children having laparoscopic *en bloc* ligation of the spermatic vessels on the posterior abdominal wall (Palomo procedure). This complication is avoided by lymphatic-sparing surgery (Schwentner et al 2006).

Splenogonadal fusion is a rare congenital anomaly characterized by splenic tissue being connected to the gonad, resulting from an abnormal connection between the spleen and the gonad during gestation. It is more predominant in males and is almost invariably on the left side. It can be of the continuous type, where the testis is connected to the main spleen, or of the discontinuous type, where the testis is connected to ectopic splenic tissue.

Transverse/crossed testicular ectopia is an extremely rare condition in which both testes descend into a single inguinal canal or one side of the scrotum. The origin of the spermatic cord is normally located on each side. It can occur in association with persistent Müllerian duct syndrome (Tiryaki et al 2005).

Polyorchidism is a rare congenital anomaly in which there are more than two testes. The most common type consists of three testes; cases with four testes have also been reported. The supernumerary testes may or may not be connected to a ductus deferens.

Epididymal cysts arise from the epididymal tubules and can occur anywhere in the head, body or tail of the epididymis. Removal is unnecessary if they are asymptomatic, particularly given the risk of iatrogenic epididymal obstruction. Spermatoceles are cysts that are basically aneurysms of the efferent ducts that form the head of the epididymis and contain sperm. Removal is unnecessary unless they grow large and cause pain (Kaufman et al 2011). However, spermatoceles can be aspirated as a source of spermatozoa.

The head of the epididymis consists of 8–12 efferent ducts and the proximal segment of the duct of the epididymis. The efferent ducts become larger and more convoluted than they are in the testis. Each duct is 15–20 cm long and opens into an individual epididymal tubule. These tubules anastomose with one another along the length of the epididymis, eventually becoming a single, coiled tubule in the body of the epididymis. They are surrounded by contractile smooth muscle cells (**Fig. 74.13**), which are larger and more numerous in the distal epididymis. Peristaltic contractions generated by the smooth muscle propel the spermatozoa in an antegrade direction towards the tail of the epididymis.

Epithelium The pseudostratified epithelial lining of the epididymal tubule contains principal, basal, apical and clear cells. Principal cells are tall columnar cells with basally located, oval nuclei. They bear long stereocilia (15 µm) and function to resorb testicular fluid; approximately 90% of the total secretory fluid volume is absorbed in the epididymis. They also endocytose other components of seminal fluid and produce glycoproteins that are essential for sperm maturation. Basal cells lie between the bases of the principal cells and are thought to be precursors of them. Apical and clear cells are far less common than principal and basal cells. Apical cells are rich in mitochondria and are most abundant in the head of the epididymis. In contrast, clear cells are columnar and most abundant in the tail of the epididymis. They have few microvilli but numerous endocytic vesicles and lipid droplets. One of their functions is to acidify luminal fluid.

DUCTUS DEFERENS, SPERMATIC CORD AND EJACULATORY DUCT

Ductus deferens

The ductus deferens (vas deferens) is a tubular structure derived from the mesonephric duct. Its primary function is to transport sperm from the epididymis to the urethra, though absorptive and secretory functions have also been described (Hoffer 1976). As it arises from the tail of the epididymis, the ductus deferens is tortuous for 2–3 cm (see Fig. 74.5B). Beyond this convoluted segment it lies posterior and parallel to the vessels of the spermatic cord, passes through the inguinal canal (see Fig. 74.16), and emerges in the pelvis lateral to the inferior epigastric vessels (see Fig. 60.3). At the deep inguinal ring, the ductus deferens diverges from the testicular vessels, coursing medial to the structures of the pelvic side wall in order to reach the base of the prostate posteriorly. Here, the ductus deferens once again becomes tortuous and dilated (the ampulla of the ductus deferens) before culminating at the ejaculatory duct (see Fig. 72.21).

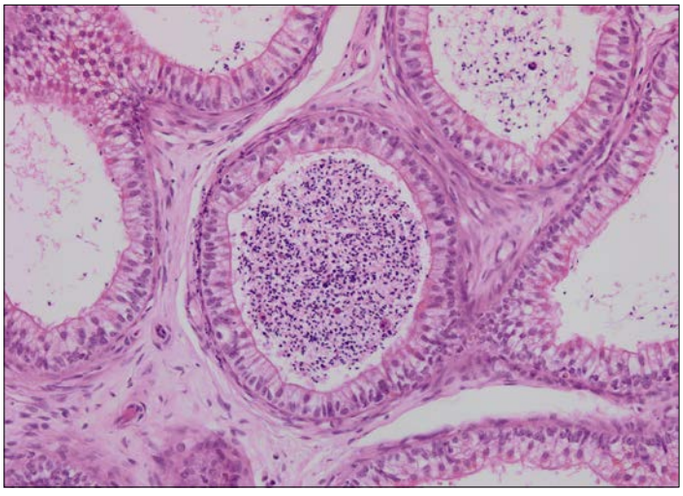

Fig. 74.13 The microstructure of the epididymis. The epididymal duct is lined by tall columnar pseudostratified epithelium bearing apical stereocilia. Accumulations of spermatozoa are seen in the lumen, e.g. centre field. (Courtesy of Mr Peter Helliwell, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Vascular supply and lymphatic drainage

The ductus deferens is supplied by the artery to the ductus deferens, which is derived from the superior or inferior vesical arteries, both of which are branches of the internal iliac artery (Zhang et al 2015). Rarely, it is derived directly from the internal iliac artery. Veins from the ductus deferens and seminal glands drain to the prostatic venous plexus, whereas the associated lymphatic vessels drain into the external and internal iliac nodes (MacLennan 2012, Mirilas and Mentessidou 2012).

Innervation

The ductus deferens is innervated by a rich autonomic plexus of primarily postganglionic sympathetic fibres derived from the inferior hypogastric plexus.

Microstructure

In humans, the ductus deferens is 30–35 cm in length and 2–3 mm in diameter, with a luminal diameter of 300–500 µm. In cross-section it consists of an outer adventitial sheath containing blood vessels and nerves; a thick, three-layered muscular wall of inner and outer longitudinal and middle circular smooth muscle; and an inner mucosal lining of pseudostratified columnar epithelium with non-motile cilia (**Fig. 74.14**). It has the greatest muscle to lumen ratio (approximately 10:1) of any hollow organ in the body. During ejaculation, the smooth muscle layers contract reflexively, propelling the sperm in an antegrade direction (see above).

Developmental anomalies of the ductus deferens

Available with the *Gray's Anatomy* e-book

Spermatic cord

The spermatic cord begins at the deep inguinal ring, extends the length of the inguinal canal, exits the canal at the superficial inguinal ring and suspends the testis in the scrotum (**Fig. 74.15**; see Fig. 74.3). Between the superficial inguinal ring and the testis the spermatic cord lies anterior to the proximal tendon of adductor longus. It is flanked anteriorly by the superficial external pudendal artery and posteriorly by the deep external pudendal artery. The ilio-inguinal nerve most commonly lies anterior to the spermatic cord as it traverses the inguinal canal (Oelrich and Moosman 1977, Ndiaye et al 2007).

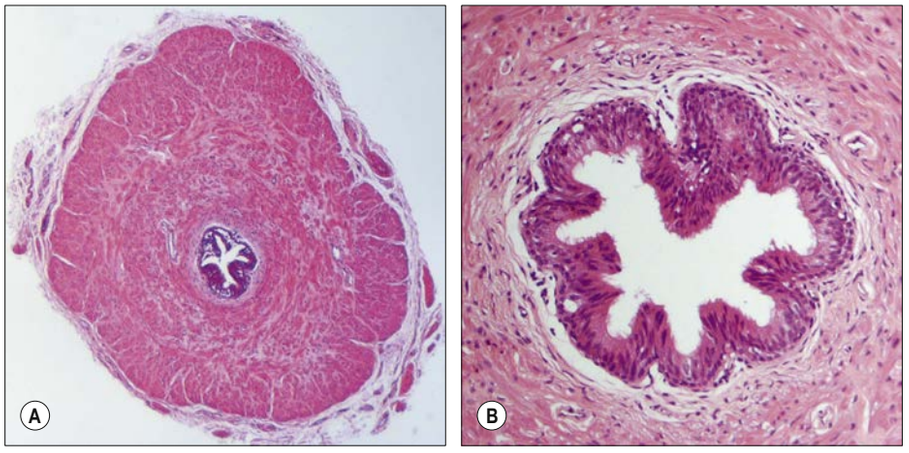

Fig. 74.14 The ductus deferens. **A**, A low-power view, transverse section. **B**, A higher-power view. The convoluted lumen is lined by pseudostratified columnar epithelial cells.

The ductus deferens can be congenitally absent, either unilaterally or bilaterally. When bilateral, the condition is associated with a mutation of the cystic fibrosis transmembrane conductance gene in 80% of affected males. This condition is characterized by low semen volume due to absent or hypoplastic seminal glands and azoospermia, though spermatogenesis is usually normal. An absent ductus deferens is usually the only genital manifestation of cystic fibrosis.

The anatomy of the ductus deferens is worthy of note in children with cryptorchidism (see above). At laparoscopic orchidopexy for intra-abdominal testis, it is important to exclude a 'looping ductus deferens' that enters the inguinal canal and loops back to the abdominal cavity (Shalaby et al 2011); failure to recognize this anatomical anomaly can result in iatrogenic injury to the ductus deferens.

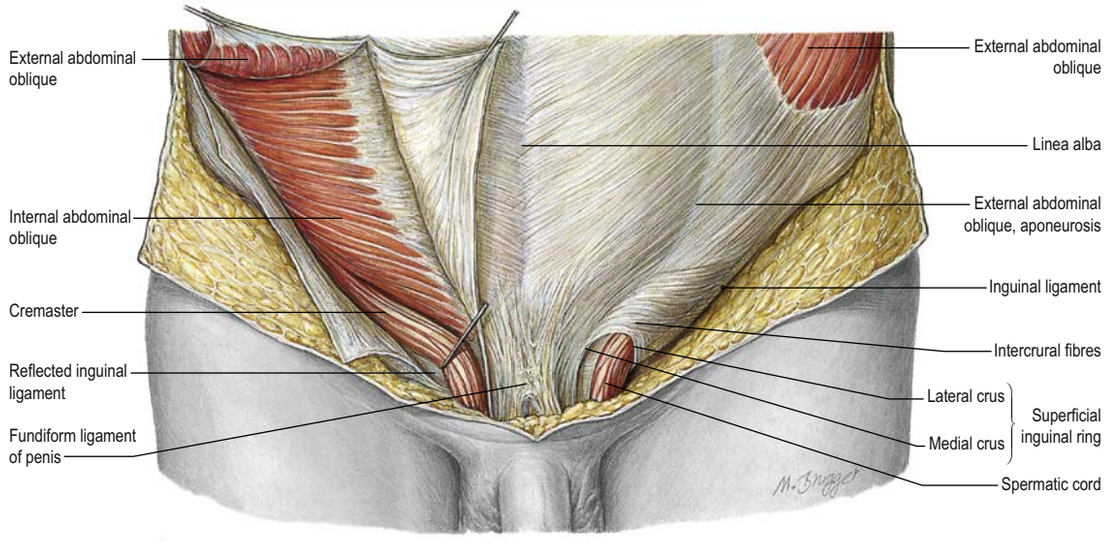

Fig. 74.15 The relation of the spermatic cord to the anterior abdominal wall. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

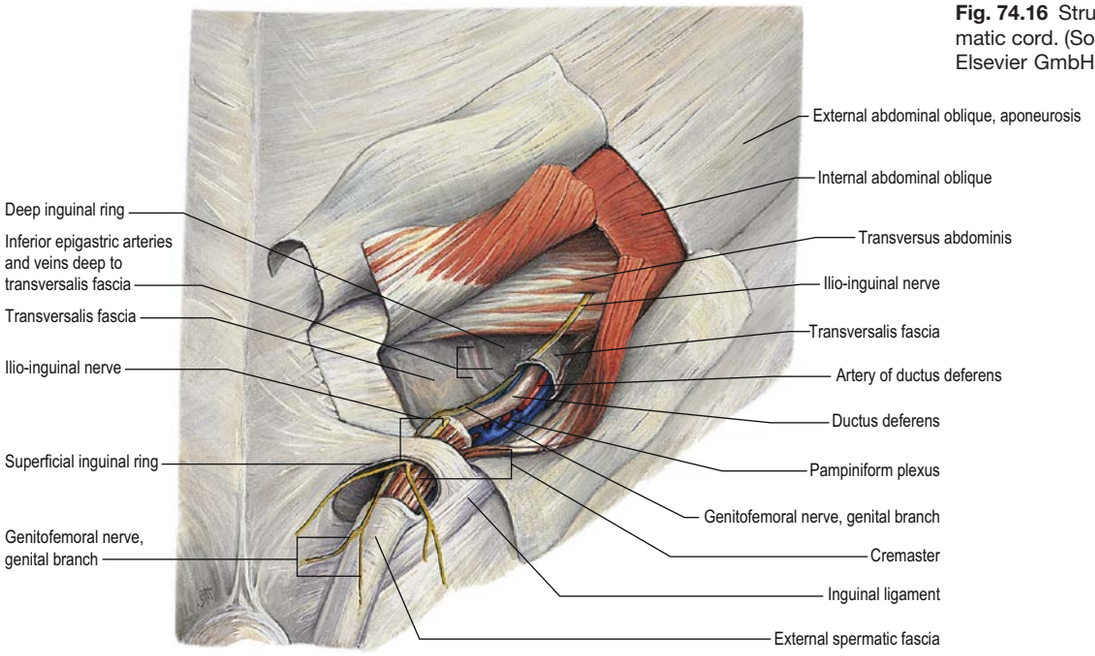

Fig. 74.16 Structures contained within the spermatic cord. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

In addition to the artery, veins, lymphatic vessels and nerves serving the testis, which are contained within the internal spermatic fascia, the spermatic cord also includes the genital branch of the genitofemoral nerve, the cremasteric artery, the pampiniform plexus, and the artery to the ductus deferens all of which are contained within the external spermatic fascia (**Fig. 74.16**; see Fig. 74.2). The ilio-inguinal nerve usually lies on the anterior surface of the spermatic cord. Also, with immunohistochemistry, Oka et al (2016) identified parasympathetic fibres in the spermatic cord. The fascial layers are continuous with the layers of the abdominal wall. The internal spermatic fascia is derived from the transversalis fascia and forms a thin, loose layer around the spermatic cord. The cremasteric fascia contains skeletal muscle fibres derived from internal abdominal oblique and smooth muscle fibres (Schwarz and Hirtler 2017). The external spermatic fascia is continuous with the aponeurosis of external abdominal oblique.

Ejaculatory duct

The paired ejaculatory ducts are formed from the union of the duct of the seminal gland with the ampulla of the ductus deferens. Each is approximately 2 cm long and extends from the base of the prostate, between the median and lateral lobes, towards its opening on the seminal colliculus (see Fig. 73.11). The ducts become smaller and converge towards their ends. Ejaculatory duct obstruction, though rare, can lead to oligospermia or azoospermia. Causes include congenital cysts such as Müllerian duct cysts, or iatrogenic injury arising during urethral manipulation. In contrast to the walls of the ductus deferens, the walls of the ejaculatory ducts are thin. They consist of an outer fibrous layer, which decreases in thickness on their entry into the prostate; a thin layer of smooth muscle fibres; and a mucosa lined by columnar epithelium. The ducts dilate during ejaculation. Normal luminal wall dimensions of the ejaculatory duct are remarkably uniform among males; a luminal diameter greater than 2.3 mm defines a dilated or obstructed efferent duct (Nguyen et al 1996).

ACCESSORY GLANDULAR STRUCTURES

Seminal glands

The seminal glands (vesicles) are paired outpouchings of the terminal ductus deferens, located at the base of the prostate between the urinary bladder and the rectum (**Fig. 74.17**, see Fig. 72.21). In adults, the seminal gland measures 5–10 cm in length and 3–5 cm in diameter, with an average volume of 13 ml (Goldstein 2012). In most males the right seminal gland is slightly larger than the left; both glands become smaller with age.

In essence, each seminal gland is a coiled tube with irregular diverticula, contained within a dense, fibromuscular sheath and partly covered by peritoneum. The superior pole is a cul-de-sac while the

Ectopic suprarenal tissue (adrenal rest) is encountered within the distal end of the spermatic cord in 2% of children undergoing inguinal procedures. These tissues are typically bright yellow to orange in colour, round or oval in shape, and up to 5 mm in diameter; they contain the three layers of the suprarenal cortex but no medulla (Savas et al 2001).

The paradidymis (organ of Giraldes) is a small and variant collection of convoluted tubules arising from the ductus deferens just above the head of the epididymis. The tubules are lined with columnar ciliated epithelium and are likely to represent a vestigial remnant of the mesonephric duct (Sahni et al 1996, Favorito et al 2004).

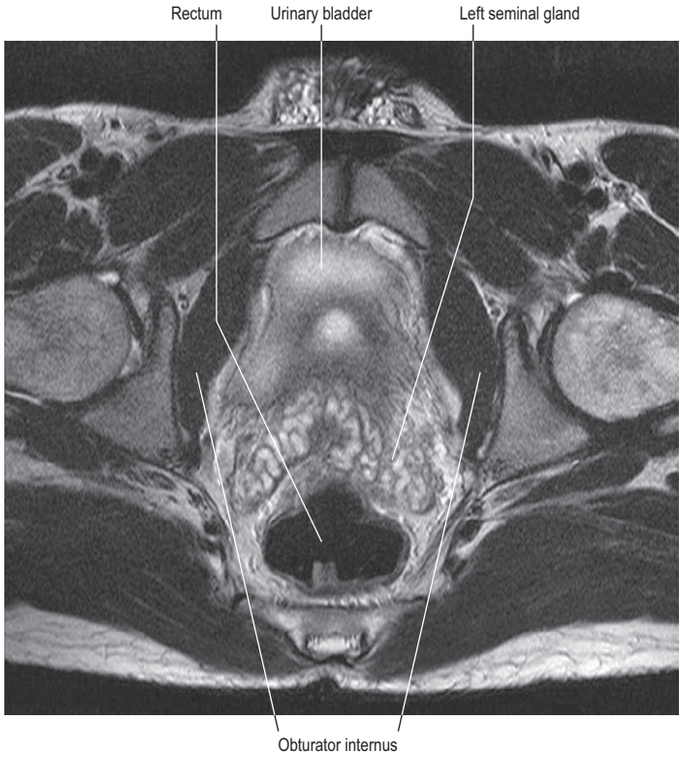

Fig. 74.17 T2-weighted axial magnetic resonance imaging (MRI) demonstrating the normal high signal in the seminal glands.

inferior pole narrows to a straight duct, which, together with the ductus deferens, culminates as the ejaculatory duct. The seminal glands are intimately associated with the prostate and urinary bladder anteriorly, the distal ureter superiorly, and the rectum and prostato-seminal fascia (Denonvilliers' fascia) posteriorly. The ampullae of the ductus deferens lie along the medial margins of the seminal glands, while the prostatic venous plexus lies laterally.

Agenesis of the seminal glands is a congenital anomaly associated with absence of the ductus deferentes (Tubbs et al 2016).

Vascular supply and lymphatic drainage

The primary blood supply to the seminal glands is from the vesiculodeferential artery, a branch of the umbilical artery (Braithwaite 1952). An additional source of blood supply is the inferior vesical artery, which arises from the internal iliac or the inferior gluteal artery. Venous drainage is provided by the vesiculodeferential veins and the vesical venous plexus. Lymphatic drainage, accordingly, occurs via the internal iliac nodes.

Innervation

The seminal glands receive preganglionic parasympathetic input from the pelvic splanchnic nerves and sympathetic (postganglionic) and parasympathetic (preganglionic) input from the inferior hypogastric plexus.

Microstructure

After puberty, the seminal glands mature into elongated, sac-like structures, produce a viscous white–yellow fluid that contributes at least two-thirds of the total ejaculate volume, and play an important role in sperm motility and metabolism. The secreted fluid is rich in fructose, coagulation proteins and prostaglandins and has a pH in the neutral to alkaline range. The wall of the seminal gland is composed of an external connective tissue layer, a middle smooth muscle layer (significantly thinner than the corresponding layer in the ductus deferens) and an internal mucosal layer with a highly folded, labyrinthine structure (**Fig. 74.18**). The mucosal layer is lined by cuboidal to pseudostratified columnar epithelium featuring typical protein-secreting cells. The seminal glands are not reservoirs for spermatozoa, except in cases of ejaculatory duct obstruction; they contract during ejaculation to release secretions into the ejaculatory duct.

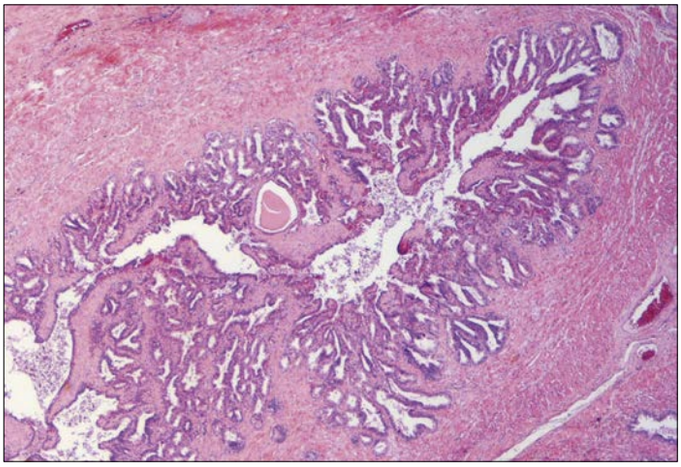

Fig. 74.18 The microstructure of the seminal glands, showing the tubuloacinar structure.

Bulbo-urethral glands

The bulbo-urethral glands (Cowper's glands) are small, round, yellow, lobulated structures measuring approximately 1 cm in diameter and located lateral to the membranous urethra and superior to the perineal membrane. They are drained by long excretory ducts, each duct being almost 3 cm long, which pass obliquely and anteriorly from the region of the membranous urethra to penetrate the perineal membrane and open on the floor of the spongy urethra, approximately 2.5 cm below the perineal membrane. The glands are surrounded by muscle fibres that have long been considered to be part of the urinary sphincter. However, small bundles of muscle lying immediately lateral to the glands have been identified histologically as elements of the deep transverse perineal muscles that are apparently continuous with a 'tail' of the external urethral sphincter (Nakajima et al 2007). During sexual excitement, contraction of the muscle fibres leads to expulsion of clear mucus from the glands into the spongy urethra. Secretions of the bulbo-urethral glands constitute 5–10% of the total ejaculate volume.

Microstructure

Each bulbo-urethral gland consists of several lobules enclosed by a fibrous capsule. The secretory units are tubulo-alveolar in form. The glandular epithelium is columnar and secretes acidic and neutral mucins into the spongy urethra prior to ejaculation; the primary function of the secretions is lubrication. Diffuse mucosa-associated lymphoid tissue (MALT) is associated with the glands.

Peri-urethral glands

The peri-urethral glands (glands of Littré) are most numerous in the spongy urethra. Like the bulbo-urethral glands they secrete mucus into the urethra prior to ejaculation; the secretions also have a lubricating function.

EXTERNAL GENITALIA

Penis

The penis consists of an attached root in the perineum and a free, pendulous body, which is completely enveloped in skin (**Fig. 74.19**). At the junction of its fixed and pendulous parts, the penis is supported by the fundiform and suspensory ligaments, which anchor it to the pubic symphysis; they are composed primarily of elastic fibres continuous with the deep fascia of the penis (**Fig. 74.20B**). The body of the penis contains three erectile columns, the paired corpora cavernosa and the corpus spongiosum; the urethra; and the investing fasciae, blood vessels and nerves associated with these structures (**Fig. 74.20A**).

The corpora cavernosa lie in intimate apposition with one another along the length of the body of the penis (**Fig. 74.21**); the corpus spongiosum lies in the ventral groove between the corpora cavernosa. Proximally, posterior to the suspensory ligament of the penis, the corpora cavernosa diverge to form two tapering processes, the crura of the penis, which are firmly anchored to the ischiopubic rami (see Fig. 74.20B). The

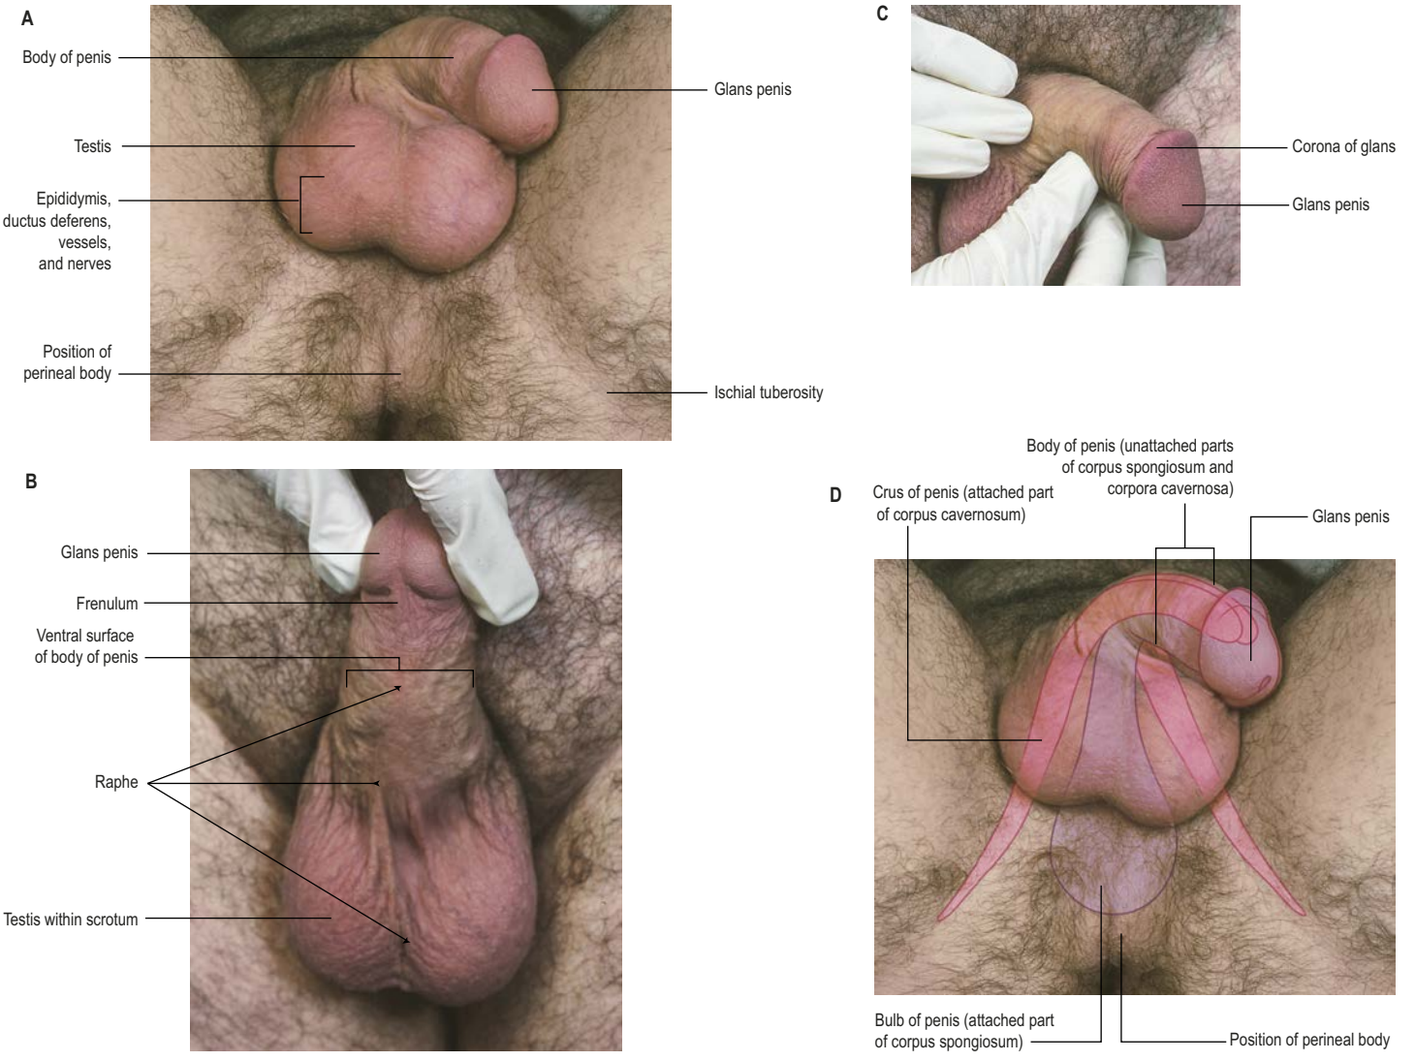

Fig. 74.19 Male external genitalia. **A**, An inferior view. **B**, The ventral surface of the body of the penis. **C**, A lateral view of the body of the penis and glans. **D**, An inferior view of the male perineum; the erectile tissues of the penis are indicated with overlays. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

corpus spongiosum broadens between the two crura to form the bulb of the penis (**Fig. 74.20C**). At the distal end of the penis, the corpus spongiosum again enlarges and assumes a bulbous shape to form the glans penis. The rounded base of the glans, the corona, separates the glans from the body of the penis. The glans is covered by the prepuce, a loose fold of retractable skin attached to the ventral surface of the glans penis, under the corona, at the frenulum. The prepuce is a double membrane that variably encases the glans penis from which it is separated by a potential space (Favorito et al 2012).

Skin The skin of the body of the penis is thin, highly elastic and devoid of appendages (hair or glandular elements), except for preputial glands located at the base of the corona. It is also devoid of fat and quite mobile because of loose attachments between the superficial fascia of the penis and the underlying deep fascia of the penis (Buck's fascia) (Angermeier 2006). In contrast, the skin of the glans penis is immobile because it is directly attached to the underlying tunica albuginea. Blood supply to the penile skin is independent of the erectile bodies and is derived from the external pudendal arteries that enter the root of the penis and run longitudinally within the superficial fascia of the penis, forming a rich anastomotic network distally to the glans penis (Tuffaha et al 2014). Thus, it is possible to mobilize skin of the body of the penis on a vascular pedicle for surgical procedures such as urethral reconstruction.

The superficial penile fascia is devoid of fat and consists of loose connective tissue interspersed by fibres of dartos from the scrotum. In contrast, the deep fascia of the penis is a denser fascial sheath, which envelops both corpora cavernosa and splits to envelop the corpus spongiosum (**Fig. 74.22B**). Distally, it blends with the tunica albuginea covering all three corporal bodies. Proximally, it is continuous with dartos and the deep perineal fascia. Bleeding from a tear in the corporal bodies is usually contained within the deep fascia of the penis, and ecchymosis is limited to the body of the penis.

Root The root of the penis consists of three masses of erectile tissue in the urogenital triangle, namely the two crura and the bulb, firmly attached to the pubic arch and the perineal membrane respectively. The crura are the posterior extensions of the corpora cavernosa while the bulb is the dilated posterior end of the corpus spongiosum. The urethra enters the bulb via its posterior surface and travels the length of the body of the penis within the corpus spongiosum.

Body The major portion of the body of the penis consists of the paired corpora cavernosa. These contain erectile tissue enclosed within a dense fibroelastic sheath of connective tissue, the tunica albuginea (see Fig. 74.21E; **Fig. 74.22**). The outer longitudinal and inner circular fibres of the tunica form an undulating meshwork when the penis is flaccid but become tightly stretched on erection. The circular fibres surround each corpus separately, and the corpora are then surrounded as a unit by the outer longitudinal fibres. Smooth muscle bundles traverse the erectile bodies to form endothelium-lined cavernous sinuses, which give the erectile tissue a spongy appearance on gross examination. Blood flow into the sinuses leads to penile engorgement and compression of venous outflow channels, resulting in penile erection.

The corpora cavernosa are not distinct, separate structures but are divided in the midline by a fibrous septum that is continuous with the deep circular fibres of the tunica albuginea. The septum of the penis is complete and thick proximally but incomplete distally, permitting communication and exchange of blood flow between the corporal bodies. The wide median groove along the ventral aspect of the corpora cavernosa is occupied by the corpus spongiosum, containing the urethra. Dorsally, a similar but narrower groove contains the dorsal

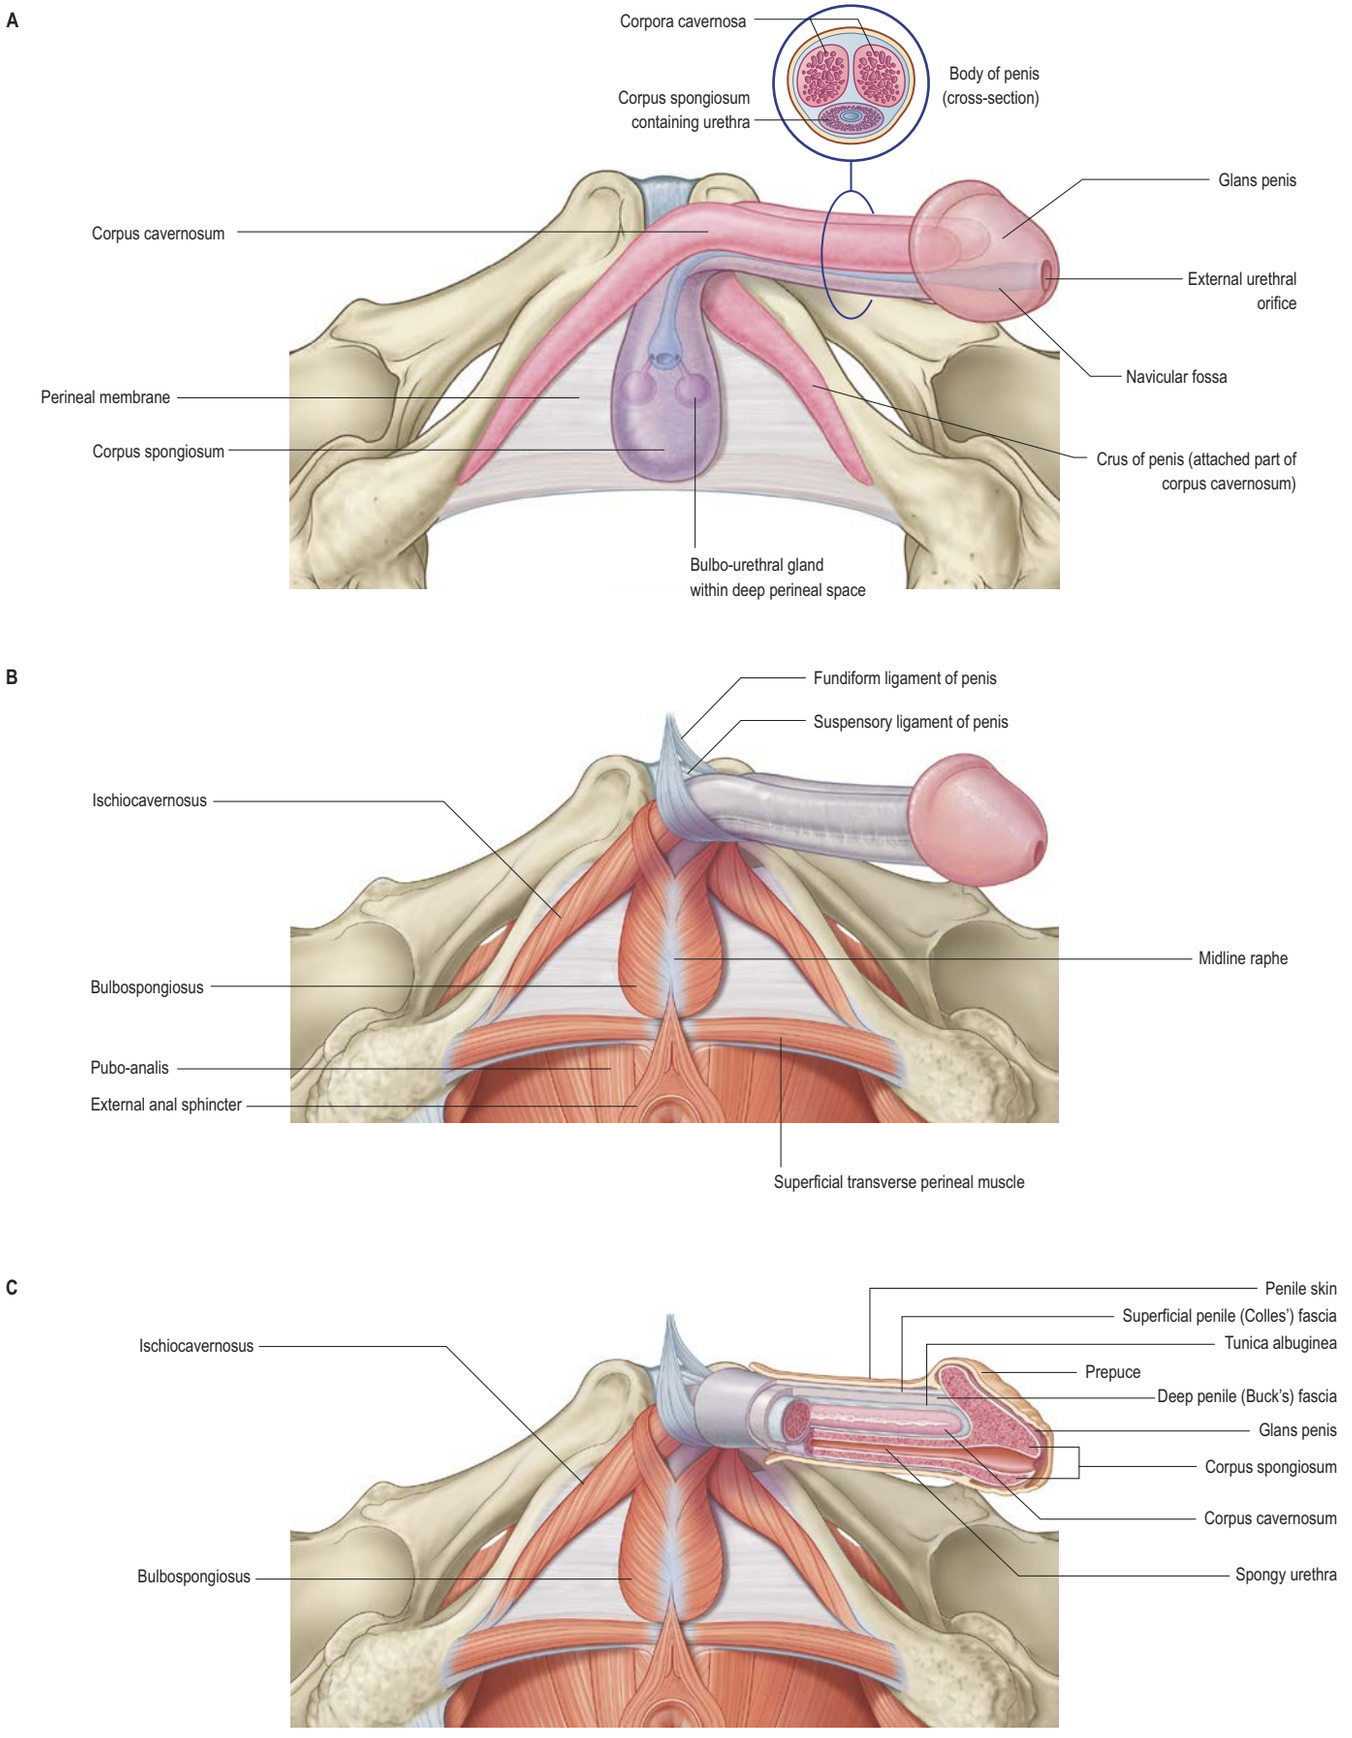

Fig. 74.20 A, The erectile tissues of the penis. **B**, The muscles in the superficial perineal space. **C**, The muscles and erectile tissues of the penis in section. neurovascular bundle. The corpora cavernosa end distally within the glans penis as individual, rounded cones (see Fig. 74.19D). The corpus spongiosum contains less erectile tissue than the corpora cavernosa and is enclosed by a thinner layer of tunica albuginea. The urethra traverses the length of the corpus spongiosum, terminating in a slit-like external urethral orifice at the distal end of the glans penis, which is itself an expansion of the corpus spongiosum. Numerous small sebaceous glands (preputial glands) lie along the proximal glans penis and their secretions combined with desquamated epithelial cells comprise smegma.

Vascular supply and lymphatic drainage

Arteries

Blood supply to the corporal bodies is derived from the internal pudendal artery, a branch of the internal iliac artery, which travels within the pudendal canal (Alcock's canal) before reaching the penis and perineum (Fig. 74.23). As it emerges from the pudendal canal, the internal pudendal artery gives rise to the perineal artery to supply ischiocavernosus and bulbospongiosus and the posterior surface of the scrotum, as well as the deep artery of the penis that supplies the deep structures of the penis (Fig. 74.24).

Arising from the perineal artery, the penile artery has three main branches: the artery to the bulb of the penis, the dorsal artery of the penis and the deep artery of the penis (Fig. 74.25) (Quartey 2006, MacLennan 2012).

Artery to the bulb of the penis The artery to the bulb of the penis penetrates the perineal membrane to enter the corpus spongiosum from above its posterolateral border and supplies the bulb of the penis and the urethra, in addition to the corpus spongiosum and glans penis.

Dorsal artery of the penis The dorsal artery of the penis passes between the crus of the penis and the pubis to reach the dorsal surface of the corpus cavernosum. It runs alongside the deep dorsal vein of the penis and the dorsal nerve of the penis and is attached, together with these structures, to the underside of the deep fascia of the penis. As it courses to the glans penis it gives off circumferential branches to the corpus spongiosum and spongy urethra. The rich blood supply to the corpus spongiosum allows the urethra to be divided safely during stricture repair.

Deep artery of the penis The deep artery of the penis is often a paired vessel that pierces the tunica albuginea of the corpora cavernosa proximally and then travels near the centre of the corporal bodies in the direction of the glans penis. Along its course it gives off several straight and helicine branches at regular intervals; they open directly into the cavernous spaces of the corporal bodies.

Variations in penile vascular anatomy are common and can include a single or absent cavernous artery or the presence of accessory pudendal arteries (Bare et al 1994, Matin 2006). While the penile arterial supply is commonly derived from both accessory and internal pudendal arteries, it can be derived exclusively from either the internal pudendal arteries or the accessory pudendal arteries (Droupy et al 1997). Recognizing such variation is extremely important for any surgeon contemplating penile revascularization surgery.

Veins

Blood leaving the penis is drained by one of three venous systems: superficial, intermediate or deep (see Figs 74.22B, 74.23). The superficial veins are contained within the superficial fascia of the penis and on its dorsolateral surface. They receive blood from the skin of the body of the penis and prepuce and coalesce to form a single superficial dorsal vein that drains into the long saphenous vein via the superficial external pudendal veins.

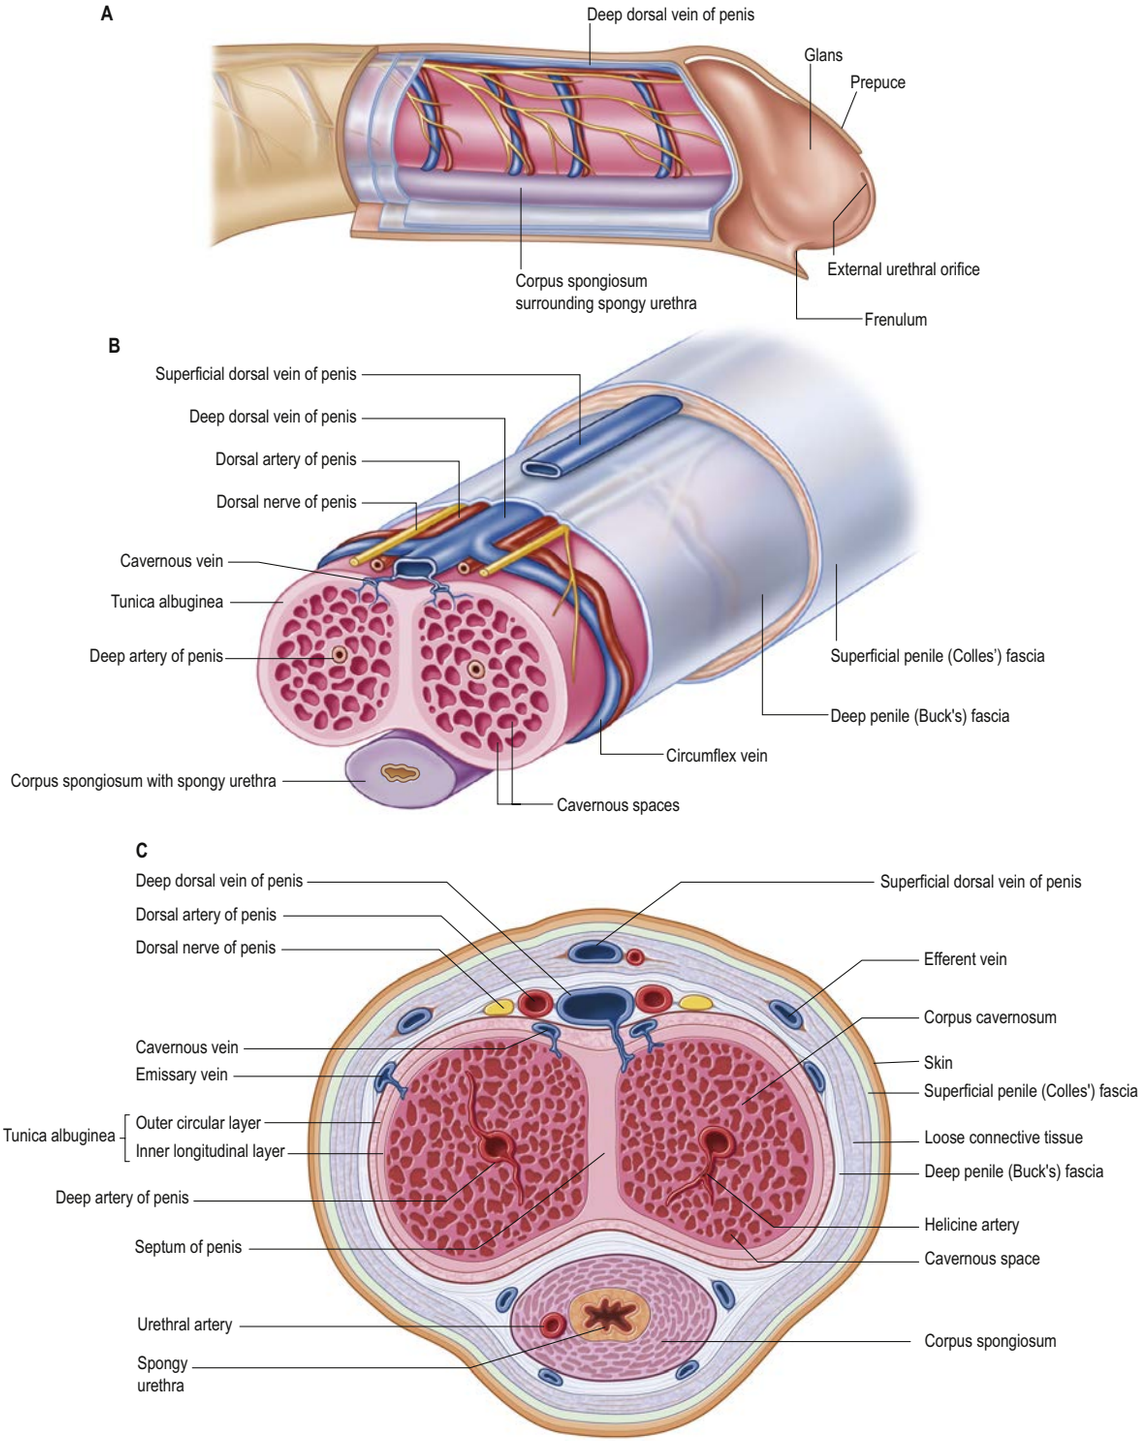

Fig. 74.22 **A**, Layers of the penis and main structures. **B–C**, Cross-sectional anatomy of the body of the penis.

The intermediate drainage system contains the circumflex and deep dorsal veins, which lie within and beneath the deep fascia of the penis. This system receives blood from the glans penis, corpus spongiosum and distal two-thirds of the penis. Circumflex veins originate in the corpus spongiosum and course around the corpora cavernosa to meet the deep dorsal vein of the penis perpendicularly. They are only present in the distal two-thirds of the body of the penis and there are 3–10 of them. Intermediate venules in the erectile tissue of the corpora cavernosa arise from the cavernous spaces and drain into a subtunical capillary plexus. This plexus gives rise to emissary veins that course obliquely through the tunica albuginea and drain either into the circumflex veins or directly into the deep dorsal vein. The deep dorsal vein lies in the midline groove between the two corpora cavernosa. It passes inferior to the pubic symphysis at the level of the suspensory ligament of the penis, leaving the body of the penis at the crus, and drains into the prostatic venous plexus.

Deep venous drainage occurs via the crural and cavernous veins of the penis, the latter which travel almost the entire length of the corpus cavernosum and ultimately drain independent of the deep dorsal vein of the penis into the prostatic venous plexus (Hsu et al 2003). The emissary veins consolidate into 2–5 veins on the dorsomedial surface of the corpora cavernosa.

Lymphatic drainage

The penile and perineal skin is drained by lymphatic vessels that accompany the external pudendal veins to the superficial inguinal nodes. Lymphatic vessels from the glans penis pass to the deep inguinal and external iliac nodes, and those from the erectile tissue and spongy urethra pass to the internal iliac nodes.

Innervation

A rich sensory innervation to the glans penis is provided by the dorsal nerve of the penis, a branch of the pudendal nerve; it follows the course of the dorsal penile arteries (**Fig. 74.26**, see also Fig. 74.2). Small branches from the perineal nerve innervate the skin on the ventral surface of the penis as far distally as the glans (Uchio et al 1999).

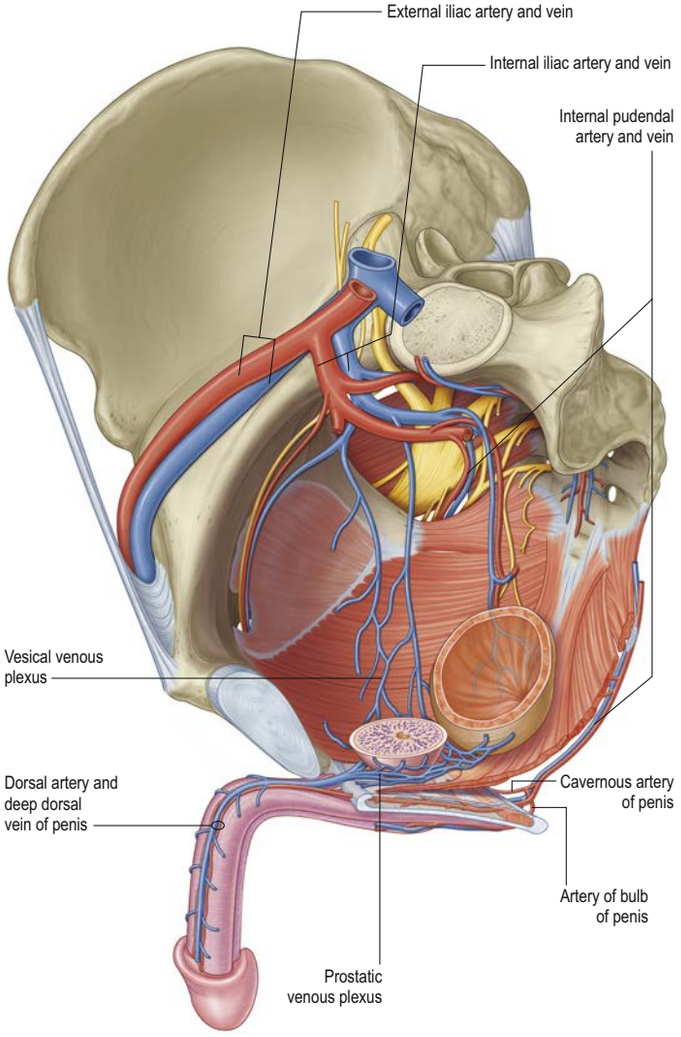

Fig. 74.23 Vessels related to the penis. (Adapted from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Sympathetic and parasympathetic input to the corpora cavernosa is provided by the cavernous nerves of the penis, which originate from the inferior hypogastric plexus. They course along the posterolateral aspect of the prostate before exiting the pelvis, together with the urethra, and entering the corpora cavernosa at the crura of the penis. Before entering the cavernous bodies, the cavernous nerve sends branches to the corpus spongiosum. Parasympathetic input to the penis (excitatory) originates in the neurones of the first four sacral spinal cord segments and travels via the pelvic splanchnic nerves to the inferior hypogastric plexus (see Fig. 74.26), where preganglionic fibres synapse on postganglionic neurones that give rise to the cavernous nerve. Sympathetic input to the penis (inhibitory) originates in the intermediolateral grey matter of the eleventh and twelfth thoracic and first lumbar spinal cord segments and travels through the sympathetic trunk before descending to the inferior hypogastric plexus. Parasympathetic stimulation produces vasodilatation while sympathetic innervation causes vasoconstriction, contraction of the seminal glands and prostate, and seminal fluid emission.

Microstructure

The corpora cavernosa are cylinders of spongy erectile tissue composed of interconnected endothelium-lined cavernous spaces, separated by smooth muscle trabeculae and surrounded by elastic and collagen fibres and loose areolar tissue. The cavernous spaces are larger in the centre. Terminal cavernous nerves and helicine arteries are intimately associated with smooth muscle. The helicine arteries are contracted and tortuous in the flaccid state and straight and dilated in the erect state.

The tunica albuginea surrounding the corpora consists of an inner circular and outer longitudinal layer of elastic fibres arranged in a latticed network. Venous drainage from the corpora cavernosa originates in the trabeculae between the peripheral cavernous spaces and the tunica albuginea (the subtunical capillary plexus) before exiting the corpora via the emissary veins (Banya et al 1989).

Emissary veins travel between the two layers of the tunica albuginea and exit the outer layer obliquely. The outer layer compresses the emissary veins when the penis becomes engorged with blood, preventing venous outflow, and thereby maintains the erection.

The structure of the corpus spongiosum is similar to that of the corpora cavernosa, with the exception of larger cavernous spaces and a thinner tunica albuginea. The glans penis has no tunical covering.

Erection and ejaculation

Penile erection is a neurovascular process, initiated by sexual stimulation and relaxation of the smooth muscle of the corpora cavernosa and mediated by various neurotransmitters produced by the parasympathetic nerves and the endothelium. The most important neurotransmitter is nitric oxide, which acts via the cyclic guanosine monophosphate (cGMP) second messenger system. Following smooth muscle relaxation there is rapid influx of blood from the helicine arteries, filling the cavernous spaces and leading to penile tumescence. The resulting distension compresses the emissary veins, preventing venous outflow. This so-called 'veno-occlusive mechanism' converts tumescence into an erection. Continuing cutaneous stimulation of the glans penis and frenulum contributes significantly towards maintaining an erection and initiating orgasm and ejaculation. Erection, therefore, depends on a variety of factors, including a normal psychogenic response to stimulation, intact parasympathetic nerves, healthy corporal smooth muscle capable of relaxation, patent arteries capable of delivering blood at the required rate, and a normal venous system. Following ejaculation, the sequence just described is reversed; smooth muscle contraction in response to sympathetic stimulation leads to penile detumescence.

Emission and ejaculation are separate but related processes. Emission is the transmission of seminal fluid from the ductus deferens, prostate and seminal glands into the prostatic urethra and is under sympathetic control. Ejaculation is the expulsion of seminal fluid from the prostatic urethra to the exterior and has both autonomic and somatic components. The first discernible event during ejaculation is contraction of bulbospongiosus, which occurs approximately six times and is under somatic control. Antegrade ejaculation also requires concomitant closure of the neck of the urinary bladder (Ch. 73). Relaxation of the external urethral sphincter, under autonomic control, permits seminal fluid to be expelled from the prostatic urethra to the spongy urethra and from there out the external urethral meatus to the exterior. The timing of this process is such that the ejaculate is expelled from the external urethral orifice between the second and final contraction of bulbospongiosus; in some males, ejaculation is pulsatile.

Erectile dysfunction and priapism

Available with the *Gray's Anatomy* e-book

Scrotum

The scrotum is composed of multiple layers of tissues including skin, dartos and external spermatic, cremasteric and internal spermatic fasciae (see Fig. 74.3). The internal spermatic fascia is loosely attached to the parietal layer of the tunica vaginalis.

The scrotal skin is thin, pigmented, devoid of fat, hair-bearing and rich in sebaceous and sweat glands. It is also richly innervated by cutaneous nerves that respond to stimulation of the skin and hairs and to changes in temperature. The appearance of the scrotal skin can vary from smooth to rugated depending on the degree of contraction of the underlying dartos. The midline raphe of the scrotum extends from the external urethral orifice down the ventral body of the penis and to the anus, signifying the line of fusion of the genital tubercles (see Fig. 22.20). It is a relatively avascular plane so it is a common location for single incisions used to access both scrotal compartments. Deep to the raphe of the scrotum, the scrotum is separated into two compartments by the septum of the scrotum composed of all the layers of the scrotal wall except the skin. The testes are suspended by the spermatic cords within these compartments.

Dartos is continuous with the superficial fascia of the penis (Colles' fascia) and the membranous layer of the superficial fascia of the abdomen (Scarpa's fascia). The external spermatic, cremasteric and internal spermatic layers of the scrotum are continuous with the corresponding layers in the spermatic cord and arise from the aponeuroses of external abdominal oblique and internal abdominal oblique and the transversalis fascia of the abdominal wall,

Erectile dysfunction is the inability to achieve tumescence despite adequate sexual stimulation. The pathophysiology of erectile dysfunction is complex and involves vascular, neurogenic and psychogenic components. Common aetiologies underlying a diagnosis of erectile dysfunction include: inability to relax the cavernous smooth muscle; arterial insufficiency due to atheromatous disease; neurogenic dysfunction due to diabetes or surgery; and radiation therapy.

A prolonged erection that fails to subside after ejaculation is called priapism. Priapism can broadly be classified as high-flow (non-ischaemic) or low-flow (ischaemic). Low-flow priapism, which is due to impaired efflux of venous blood from the penis, is characterized by significant pain and is a medical emergency. If untreated, priapism leads to ischaemia of the corporal smooth muscle and irreversible erectile dysfunction. The aetiology of low-flow priapism includes conditions such as sickle-cell disease and leukaemia, and the use of intracavernosal injection therapy with prostaglandins. In contrast, high-flow priapism is the consequence of excessive blood flow into the penis, usually secondary to a fistula between the deep artery of the penis and cavernous spaces.

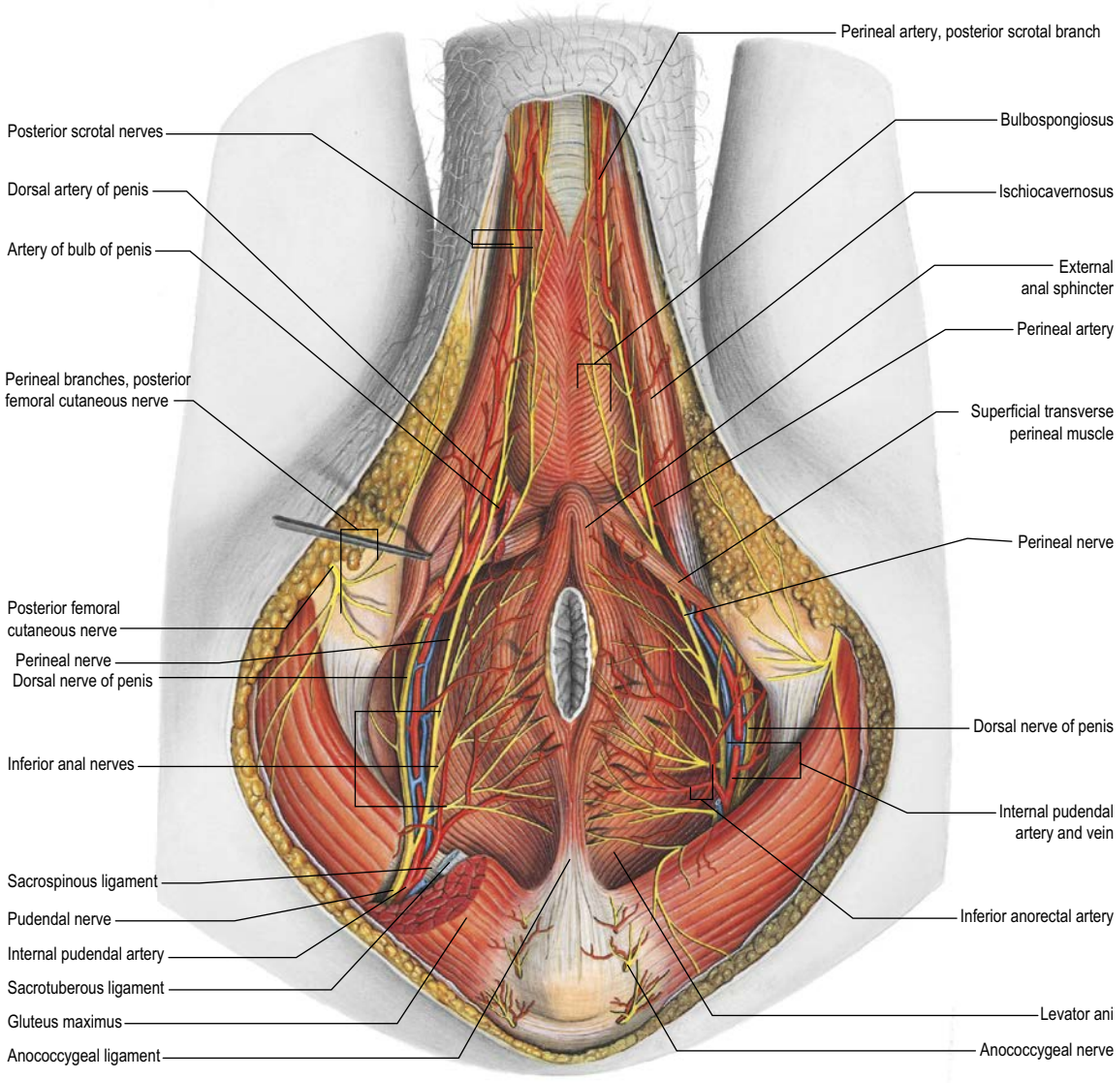

Fig. 74.24 The blood vessels and nerves of the perineal region and external genitalia in the adult male. Fig. 74.25 The arterial blood supply to the body of the penis.

respectively. The testis is also sometimes fixed to the scrotal wall at its inferior pole by a fibrous band known as the scrotal ligament (Cavalie et al 2018).

Developmental anomalies of the scrotum Congenital agenesis of the scrotum is a very rare anomaly characterized by absence of the scrotum; no rugae are noted in the perineum (Yilmaz et al 2013). Penoscrotal transposition, in which the scrotum is located superior and anterior to the penis, is a consequence of abnormal genital tubercle development and is associated with hypospadias, renal agenesis and dysplasia, and imperforate anus.

Vascular supply and lymphatic drainage

The arterial supply to the scrotum includes external pudendal branches of the femoral artery, posterior scrotal branches of the internal pudendal artery and the cremasteric artery, a branch from the inferior epigastric artery. Of note, the anterior scrotal wall is supplied primarily by branches of the external pudendal artery, which run parallel to the rugae and do not cross the raphe of the scrotum; this anatomical detail is important for planning appropriate incisions during scrotal surgery.

The scrotal vessels are arranged in a dense subcutaneous network, which facilitates heat loss and regulation of scrotal temperature. Venous drainage follows the arterial network and simple arteriovenous anastomoses are common.

Scrotal lymphatic vessels do not cross the raphe of the scrotum and therefore lymphatic drainage from the scrotum is always routed to the ipsilateral superficial inguinal nodes.

Innervation

Innervation of the skin of the anterior third of the scrotum is primarily derived from the first lumbar spinal cord segment by way of the ilioinguinal nerve (anterior scrotal nerves) and genital branch of the

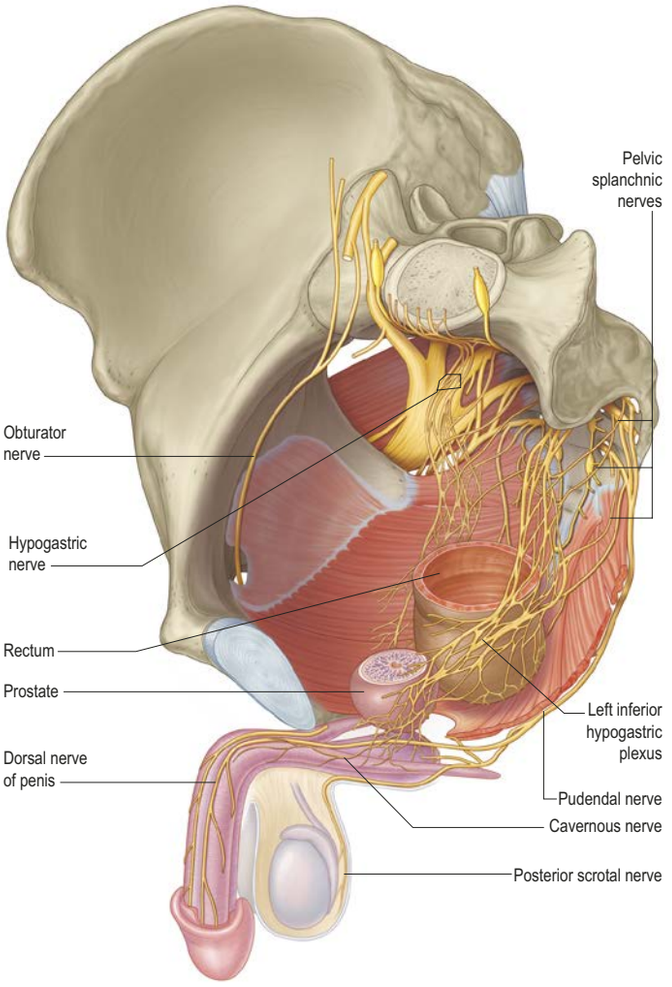

Fig. 74.26 The nerve supply to the penis. The corpus cavernosum of the penis receives both a parasympathetic and a sympathetic innervation from the cavernous nerves. Multiple cavernous nerves emanate from the prostatic plexus and intertwine with both dorsal nerves of the penis. The afferent fibres from the glans travel via the dorsal nerves of the penis and via the pudendal nerve. (Adapted from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

genitofemoral nerve (see Fig. 74.2). Innervation of the skin of the posterior two-thirds of the scrotum is primarily derived from the third sacral spinal cord segment via the perineal nerve and perineal branches of the posterior femoral cutaneous nerve. In order to anaesthetize the scrotum, spinal anaesthesia must therefore be injected proximal to the L1 spinal cord level.

CHAPTER 75

Female reproductive system

The female reproductive system consists of the lower genital tract (vulva and vagina) and the upper tract (uterus and cervix with associated uterine (Fallopian) tubes and ovaries).

LOWER GENITAL TRACT

Vulva

The female external genitalia or vulva (pudendum) include the mons pubis, labia majora, labia minora, clitoris, vestibule of the vagina, vestibular bulbs and the greater vestibular glands (Bartholin's glands) (**Fig. 75.1**).

Mons pubis

The mons pubis is the rounded, hair-bearing area of skin and adipose tissue over the pubic symphysis and adjacent pubic bone. Before puberty, it is relatively flat and hairless, and the labia minora are poorly formed. Through adolescence and into adult life the mons pubis becomes prominent and develops coarse hair. It atrophies slightly after menopause.

Labia majora

The labia majora are two prominent, longitudinal folds of skin that extend back from the mons pubis to the perineum (see Fig. 75.1B). They form the lateral boundaries of the vulva. Each labium has an external pigmented surface covered with hairs and a smooth pink internal surface with large sebaceous follicles. Between these surfaces there is loose connective and adipose tissue intermixed with smooth muscle (resembling the dartos muscle of the scrotum), vessels, nerves and glands. The subcutaneous layer consists of a superficial fatty layer similar to the superficial fatty layer (Camper's fascia) of the anterior abdominal wall, and a deep membranous layer (Colles' fascia) continuous with the deep membranous layer (Scarpa's fascia) of the anterior abdominal wall. The round ligament of the uterus may end in the adipose tissue and skin in the anterior part of the labium majus. A patent processus vaginalis may also reach a labium majus. The labia majora join anteriorly to form the anterior commissure below the mons pubis. Posteriorly they do not join but instead merge into neighbouring skin, ending near and almost parallel to each other. The connecting skin between them posteriorly forms a ridge, the posterior commissure, which overlies the perineal body and is the posterior limit of the vulva.

Labia minora

The labia minora are two small cutaneous folds, devoid of fat and hair, that lie between the labia majora. They extend from the clitoris obliquely down, laterally and back, flanking the vaginal orifice. Anteriorly, each labium minus bifurcates. The upper layer of each side passes above the clitoris to form the prepuce, while the lower layer passes below the clitoris to form the frenulum of the clitoris (Fig. 75.1A–C). There are numerous sebaceous follicles on the medial surfaces. Sometimes, an extra labial fold (labium tertium) is found on one or both sides between the labia minora and majora. Adhesions between the labia minora are common in prepubertal girls; in postmenopausal females with severe atrophy they can predispose to urinary infections (Leung and Robson 1992, Gandhi et al 2016).

Vestibule of the vagina

The vestibule of the vagina is the cavity between the labia minora. It contains the vaginal and external urethral orifices and the openings of the two greater vestibular glands and of numerous mucous secreting, lesser vestibular glands. There is a shallow vestibular fossa between the vaginal orifice and the frenulum of the labia minora (Lee et al 2015). The posterior part of the vestibule of the vagina is a classic site where a fistulous opening of the rectum may be located in girls born with an imperforate anus (Bill et al 1975).

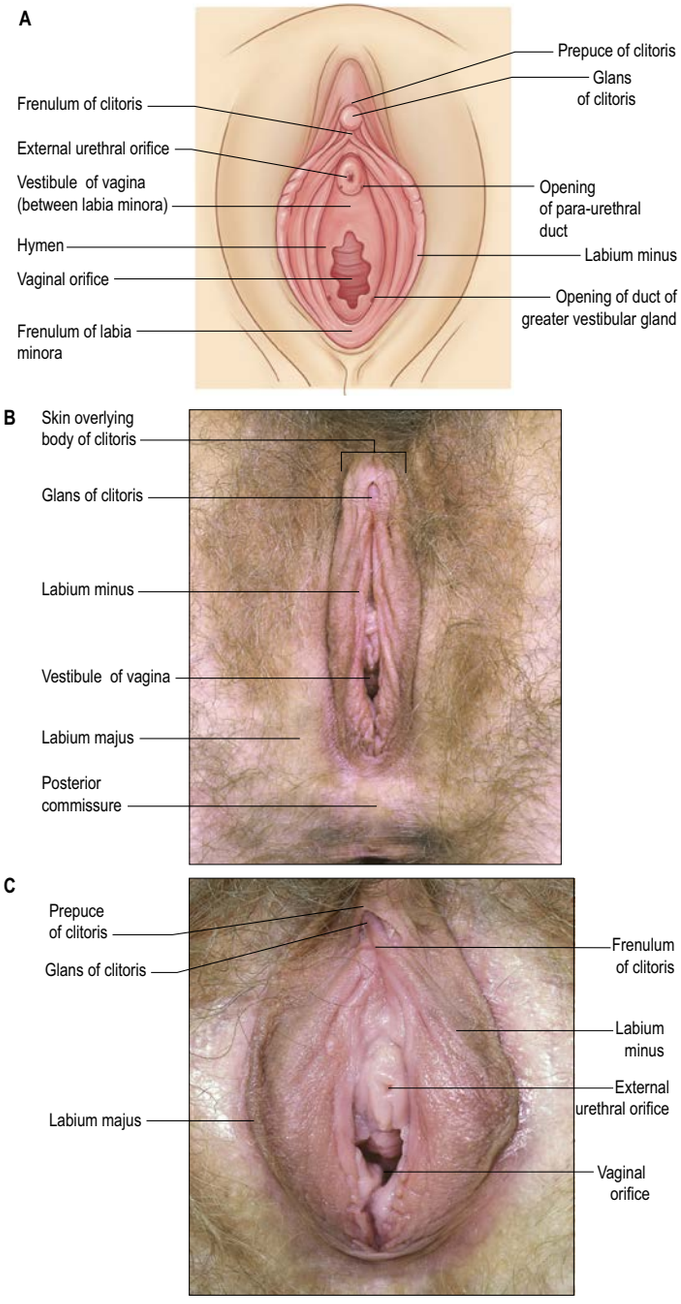

Fig. 75.1 A, The superficial features of the vulva. **B**, The labia majora and other surrounding external genitalia. **C**, The labia minora. (A, With permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008. B–C, With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Urethra

The urethra opens into the vestibule of the vagina about 2.5 cm below the clitoris and above the vaginal orifice via the external urethral orifice, a short, sagittal cleft with slightly raised margins. The external urethral orifice is very distensible and varies in shape: the aperture can be rounded, slit-like, crescentic or stellate. The ducts of the para-urethral glands (Skene's glands) open on each side of the lateral margins of the urethra.

Bulbs of the vestibule

The bulbs of the vestibule lie on each side of the vestibule of the vagina (**Fig. 75.2B**). They are two elongated masses of erectile tissue, 3 cm long, which flank the vaginal orifice and unite anterior to it by a narrow commissure of the bulbs. Their posterior ends are expanded and are in contact with the greater vestibular glands. Their deep surfaces contact the inferior aspect of the perineal membrane; superficially, each is covered by bulbospongiosus (**Fig. 75.2A**) (Delancey 2011).

Greater vestibular glands (Bartholin's glands)

The greater vestibular glands are homologues of the male bulbourethral glands. They consist of two small, round or oval, reddish-yellow bodies that flank the vaginal orifice, in contact with and often overlapped by the posterior end of the vestibular bulb. Each opens into the vestibule of the vagina by a 2 cm long duct, situated in the groove between the hymen and the labium minus at approximately the 5 and 7 o'clock positions (Corton 2012). The glands are composed of tubulo-acinar tissue; the secretory cells are columnar and secrete a clear or whitish mucus for lubrication during sexual arousal.

Clitoris

The clitoris is an erectile structure, partially enclosed by the anterior bifurcated ends of the labia minora. It has a crus, root, body and glans (see Fig. 75.2). The body can be palpated through the skin. It contains two corpora cavernosa, composed of erectile tissue and enclosed in dense fibrous tissue, and separated medially by an incomplete fibrous pectiniform septum (septum of the corpora cavernosa). The fibrous tissue forms a suspensory ligament that is attached superiorly to the pubic symphysis. Each corpus cavernosum is attached to its ischiopubic ramus by a crus that extends from the root of the clitoris. The glans clitoris is a small, round tubercle of spongy erectile tissue at the end of the body, connected to the bulbs of the vestibule by thin bands of erectile tissue (pars intermedia). It is exposed between the anterior ends of the labia minora. Its epithelium has high cutaneous sensitivity, important in sexual responses. Congenital absence of the clitoris is very rare.

Vascular supply and lymphatic drainage of the vulva

Arteries

The arterial blood supply of the female external genitalia is derived from the superficial and deep external pudendal arteries which arise from the femoral artery superiorly and the internal pudendal artery inferiorly (**Figs 75.3A, 75.4**).

The blood supply to the adipose tissue of the labia majora must be carefully preserved during vaginal surgery, e.g. in creating a Martius fat pad flap to repair a vesicovaginal fistula where the blood supply has already been compromised by radiation or fibrosis (Delancey 2011).

Veins

Venous drainage of the skin of the external genitalia is via external pudendal veins to the long saphenous vein. Venous drainage of the clitoris is via deep dorsal veins to the internal pudendal vein, and via superficial dorsal veins to the external pudendal and long saphenous veins.

Lymphatic drainage

A meshwork of connecting vessels from the skin of the labia, clitoris and perineum join to form three or four collecting trunks that drain to superficial inguinal nodes lying on the cribriform fascia covering the femoral artery and vein; these nodes drain through the cribriform fascia to the deep inguinal nodes lying medial to the femoral vein (Corton 2012). The deep inguinal nodes drain via the femoral canal to the pelvic nodes (**Table 75.1**) . The last of the deep inguinal nodes lies under the inguinal ligament within the femoral canal and is often called Cloquet's node. Lymph vessels from the clitoris drain directly to the deep inguinal nodes, and direct clitoral lymphatics may pass to the internal iliac nodes (**Fig. 75.3B**). Lymph vessels in the perineum and lower part of the labia majora drain primarily to inguinal nodes.

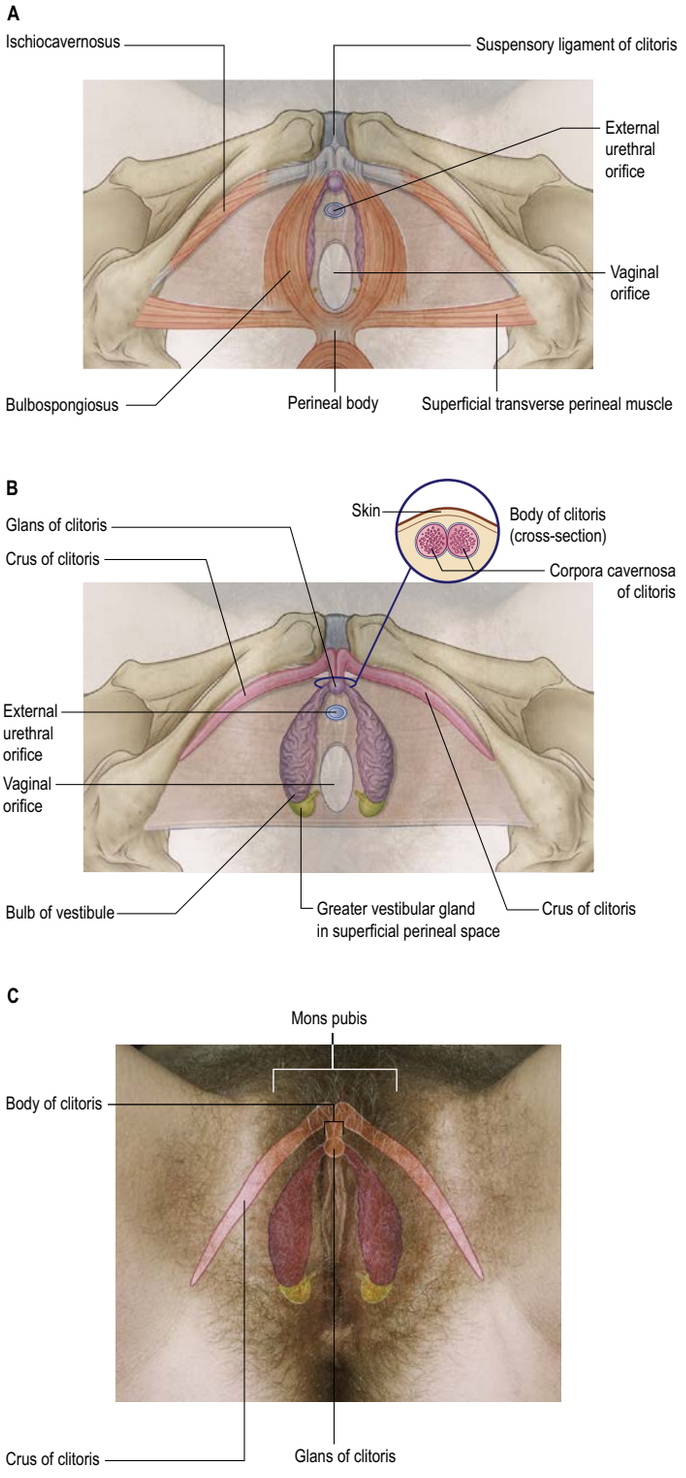

Fig. 75.2 A, The muscles of the vestibule of the vagina and clitoris. **B**, The erectile tissues of the clitoris. **C**, The erectile tissues of the clitoris, vestibule of the vagina and greater vestibular gland with a surface anatomy overlay. (A–B, Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010. C, With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

Innervation

The main nerve supply of the vulva is the pudendal nerve (S2, S3 and S4) and its branches, the inferior anal and perineal nerves and the

dorsal nerve of the clitoris (**Table 75.2**, **Fig. 75.5**; see Fig. 75.4; Shoja et al 2013, Jackson et al 2019). The sensory innervation differs between the anterior and posterior parts of the labium majus. The anterior third of the labium majus is supplied by the ilioinguinal nerve (anterior labial nerve) (L1), the posterior two-thirds are supplied by the pudendal nerve through the posterior labial branches of the perineal nerve (S3), and the lateral aspect is also innervated by the perineal branch of the posterior femoral cutaneous nerve (S2). Nerves of the external genitalia are susceptible to trauma and inflammation, leading to external genitalia pain syndromes or vulvodynia (Shoja et al 2013). The intimate relationship of the vagina to the urinary bladder, rectum and nerves of the external genitalia predispose to pelvic pain and dyspareunia.

Vagina

The vagina is a fibromuscular tube lined by non-keratinized stratified epithelium. It extends from the vestibule of the vagina (the opening between the labia minora) to the uterus. The upper end of the vagina surrounds the vaginal projection of the cervix of the uterus. The recess formed between the vaginal part of the cervix and vagina is the fornix; the different parts of the fornix are given separate names, i.e. anterior, posterior and lateral, but they are continuous (**Fig. 75.6**).

In the standing position, the vagina ascends posteriorly and superiorly, forming an angle of 60–70° with the horizontal plane (Corton 2012). It forms an angle of over 90° to the uterine axis (see Fig. 75.12); this angle varies with the contents of the urinary bladder and rectum. The proximal vagina is directed posteriorly towards the ischial spines. The width of the vagina increases as it ascends. The inner surfaces of the anterior and posterior vaginal walls are in contact with each other, forming a transverse slit. The vaginal mucosa is attached to the cervix of the uterus higher on the posterior cervical wall than on the anterior; the anterior wall is approximately 7.5 cm long and the posterior wall is approximately 9 cm long. The fibromuscular anterior wall of the vagina supports the fundus of the urinary bladder in its middle and upper portions, and the urethra (which is embedded in it) inferiorly. The fibromuscular posterior wall of the vagina supports the rectum. The upper quarter of the posterior vagina is separated from the rectum by the peritoneum of the recto-uterine pouch (pouch of Douglas), and by moderately dense fibromuscular tissue in its middle half (Delancey 2011). In its lower quarter, it is separated from the anal canal by the fibromuscular perineal body. The proximal vagina is supported laterally by levator ani, together with such ligaments as the cardinal and uterosacral. Pubovaginalis provides a U-shaped muscular sling around the mid-vagina. The distal vagina is surrounded by bulbospongiosus (see Fig. 75.4). As the ureters pass anteromedially to reach the fundus of the urinary bladder they pass close to the lateral parts of the fornix, where care must be taken to avoid injury during hysterectomy (**Fig. 75.7**). As they enter the urinary bladder, the ureters are usually anterior to the vagina; at this point, each ureter is crossed transversely by a uterine artery (**Fig. 75.8**).

The vagina opens externally via a sagittal orifice positioned below the external urethral orifice (see Fig. 75.1C). The size of the vaginal orifice varies; it is capable of great distension during childbirth and, to a lesser degree, during sexual intercourse. The hymen is a thin fold of mucous membrane situated just within the vaginal orifice. The internal surfaces of the folds are normally in contact with each other and the vaginal orifice appears as a cleft between them. The hymen varies greatly in shape and dimensions. When stretched, it is anular and widest posteriorly; it can also be semilunar and concave towards the mons pubis, cribriform, fringed, absent or complete and imperforate. The hymenal ring normally ruptures after first sexual intercourse, but can rupture earlier during non-sexual physical activity. Small round carunculae hymenales are its remnants after it has been ruptured. It has no established function.

Remnants of the caudal end of the mesonephric duct (Gartner's duct) (see Figs 22.13, 22.19) are occasionally seen protruding through the lateral parts of the fornix or lateral parts of the vagina and can cause cysts (Gartner's cysts). Prepubertal distal longitudinal folds are common within the vagina and they disappear during puberty (Altchek et al 2008).

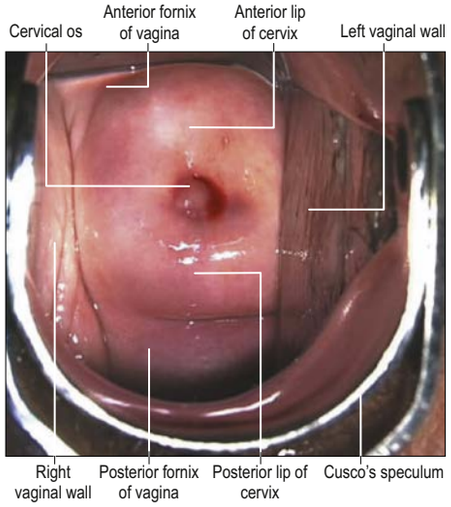

Fig. 75.6 The cervix and vaginal fornix, as seen via a Cusco's bivalve speculum.

Vascular supply and lymphatic drainage

Arteries

The arterial supply of the vagina is derived from branches of the internal iliac arteries. Vaginal arteries anastomose with cervical branches of the uterine artery to form the midline azygos arteries of the vagina, which descend anterior and posterior to the vagina; these vessels also supply the bulb of the vestibule, fundus of the urinary bladder, and adjacent part of the rectum (see Fig. 75.3A). The uterine, internal pudendal and middle anorectal arteries may contribute to the blood supply of the vagina.

Veins

The vaginal veins, one on each side, arise from lateral venous plexuses that communicate with uterine, vesical and anorectal venous plexuses and drain to the internal iliac veins. The uterine and vaginal venous plexuses can provide collateral venous drainage for the lower limb.

Lymphatic drainage

Vaginal lymphatic vessels link with those of the cervix, rectum and vulva. They form three groups but the regions drained are not sharply demarcated. Upper vessels accompany the uterine artery to the internal and external iliac nodes; intermediate vessels accompany the vaginal artery to the internal iliac nodes; and vessels draining the vagina below the hymen, and from the vulva and perineal skin, pass to the superficial inguinal nodes (see Table 75.1).

Innervation

The distal vagina is supplied by the pudendal nerve (S2, S3 and S4). The proximal vagina is supplied by the pelvic splanchnic nerves (S2, S3 and, sometimes, S4) (see Fig. 75.5 and Table 75.2).

Developmental anomalies of the vagina

Available with the *Gray's Anatomy* e-book

Microstructure

The vagina has an external epithelial and an internal muscular layer: the epithelium adheres firmly to the muscular layer. There are two median longitudinal ridges on its epithelial surface, one anterior and the other posterior. Numerous transverse bilateral vaginal rugae extend from these vaginal columns, divided by sulci of variable depth, giving an appearance of conical papillae. These transverse rugosities are most

Developmental anomalies of the vagina include vaginal agenesis, absent hymen, transverse vaginal septum and persistent cloaca. Vaginal and renal agenesis, in the presence of other paramesonephric duct (Müllerian duct) anomalies, is termed Mayer–Rokitansky-Küster Hauser syndrome. An absent hymen in patients with vaginal agenesis is associated with renal agenesis (Kimberley et al 2012). A congenital transverse septum within the vagina manifests clinically during adolescence with primary amenorrhoea and haematocolpos. Children with a persistent cloaca have a congenital defect characterized by fusion of the rectum, vagina and urethra into a single common channel that varies in length from 1 to 7 cm.

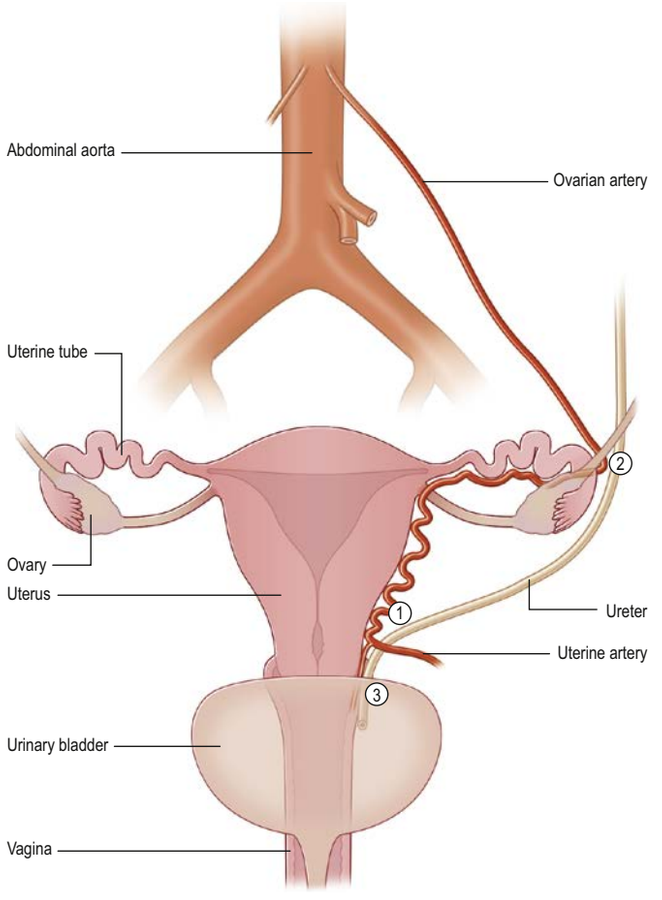

Fig. 75.7 The most common sites of ureteric injury during hysterectomy. Key: 1, distal ureter at the level of the uterine artery; 2, dorsal to the suspensory ligament of the ovary, near the pelvic brim; 3, intramural part of the ureter at the angle of the proximal vagina.

numerous on the posterior wall and near the orifice; they increase under the influence of oestrogen during puberty and pregnancy, are especially well developed before parturition, and decrease after the menopause

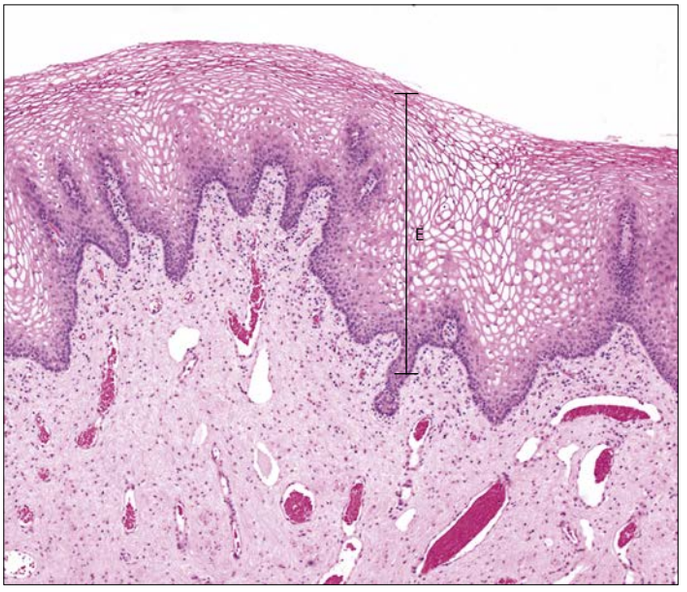

Fig. 75.9 Non-keratinized stratified squamous epithelium (E) covering the exocervical mucosa and vagina. The cells of the middle and upper layers appear clear owing to their glycogen content. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

(Corton 2012). The surface cells are stratified squamous non-keratinized epithelium, similar to and continuous with that of the ectocervical mucosa. After puberty the epithelium thickens and its superficial cells accumulate glycogen, which gives them a clear appearance in histological preparations.

The vaginal epithelium does not change markedly during the menstrual cycle, but its glycogen content increases after ovulation and then diminishes towards the end of the cycle. Natural vaginal bacteria, particularly *Lactobacillus acidophilus*, break down glycogen in the desquamated cellular debris to lactic acid. This produces a highly acidic (pH 3) environment that inhibits the growth of most other micro-organisms. There is less glycogen before puberty and after the menopause, when vaginal infections are more common. There are no mucous glands, but a fluid transudate from the lamina propria, supplemented by mucus production from the cervical glands (Fig. 75.9). The muscular layers are composed of smooth muscle and consist of a thick outer longitudinal and an inner circular layer; the two layers are not distinct but are connected by oblique interlacing fibres. The longitudinal fibres are continuous with the superficial muscle fibres of the uterus. A layer of loose connective tissue containing extensive vascular plexuses surrounds the muscle layers.

UPPER GENITAL TRACT

Uterus

The uterus is a thick-walled, muscular organ situated in the pelvis between the urinary bladder and the rectum (Figs 75.10–75.12). It lies posterior to the urinary bladder and vesico-uterine pouch and anterior to the rectum and recto-uterine pouch; it is mobile, which means that its position varies with distension of the urinary bladder and rectum. The broad ligaments are lateral.

The uterus is divided structurally and functionally into two main regions: the muscular body forms the upper two-thirds, and the fibrous cervix forms the lower third. In the adult nulliparous state, the cervix usually tilts forwards relative to the axis of the vagina (anteversion), and the body of the uterus tilts forwards relative to the cervix (anteflexion) (see Fig. 75.12). In 10–15% of females the whole uterus leans posteriorly at an angle to the vagina and is said to be retroverted. A uterus that angles posteriorly on its cervix is described as retroflexed.

Body

The body of the uterus is pear-shaped and extends from the fundus superiorly to the isthmus inferiorly. The uterine tubes enter the uterus on both sides at the utero-tubal junction: the round ligament of the uterus and proper ovarian ligament are inferoanterior and inferoposterior, respectively, to each junction. The dome-like fundus is superior

to the entry points of the uterine tubes and is covered by peritoneum continuous with that of neighbouring surfaces. The fundus of the uterus is in contact with the small intestine and, occasionally, with a distended sigmoid colon. The lateral margins of the body of the uterus are convex; on each side, their peritoneum is reflected laterally to form the broad ligament, which extends as a flat sheet to the pelvic wall (see Figs 75.11B, 75.16). The anterior surface of the body of the uterus is covered by peritoneum reflected on to the urinary bladder at the vesico-uterine fold (see Fig. 75.14). This normally occurs at the level of the anatomical internal os, the most inferior margin of the body of the uterus. The vesico-uterine pouch, between the urinary bladder and uterus, is obliterated when the bladder is distended, but may be occupied by small intestine when the bladder is empty. The posterior surface of the uterus is convex transversely. Its peritoneal covering continues down to the cervix and proximal vagina and is then reflected back to the rectum along the surface of the recto-uterine pouch, which lies posterior to the uterus (see Fig. 75.15). The sigmoid colon and occasionally the terminal ileum lie posterior to the uterus.

The uterine cavity usually measures 6 cm from the external os of the uterus to the wall of the fundus and is flat in its anteroposterior plane (Salardi et al 1985). In coronal section, it is triangular, broad above where the two uterine tubes join the uterus, and narrow below at the anatomical internal os of the uterus. There is no change in the size of the uterus until approximately 7 years of age, when the body of the uterus enlarges more than the cervix.

Developmental anomalies of the uterus

Available with the *Gray's Anatomy* e-book

Cervix of the uterus

The adult, non-pregnant cervix is narrower and more cylindrical than the body of the uterus and is typically 2.5 cm long. The proximal end communicates with the isthmus of the uterus, and the distal end opens into the vagina at the external os (see Fig. 75.6). In

The paramesonephric (Müllerian) ducts can fail to fuse, resulting in a uterus that is not pear-shaped. There may only be a septum (septate uterus) or partial clefting of the uterus (bicornuate uterus); the most extreme example is a septate vagina, two cervices and two discrete uteri, each with one uterine tube (uterus didelphys) (Minto et al 2001) (see Fig. 22.15).

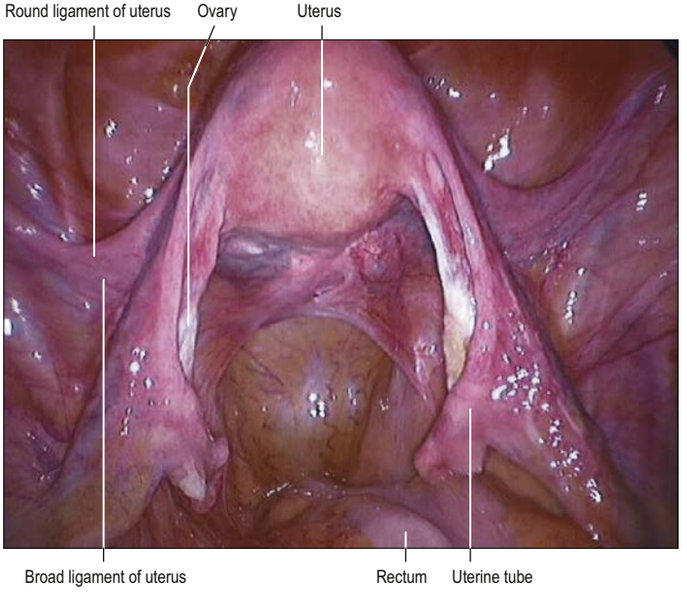

Fig. 75.13 A laparoscopic view of the uterus. The patient is tilted head down so that the small intestine is moved away from the uterus to give this view.

nulliparous females the external os is usually a circular aperture, whereas it is a transverse slit after childbirth. Two longitudinal ridges, one each on its anterior and posterior walls, give off small, oblique, palmate folds that ascend laterally like the branches of a tree (arbor vitae uteri); the folds on opposing walls interdigitate to close the cervical canal. Once considered part of the cervix, the isthmus of the uterus (approximately 1 cm long) demarcates the body of the uterus from the cervix. Although unaffected in the first month of pregnancy, it is gradually taken up into the body of the uterus during the second month to form the 'lower uterine segment' (see below). In non-pregnant females the isthmus undergoes menstrual changes, although these are less pronounced than those occurring in the body of the uterus. The distal end of the cervix enters the proximal end of the vagina, thereby dividing the cervix into supravaginal and vaginal parts. The supravaginal part is separated anteriorly from the urinary bladder by connective tissue, the parametrium, which also passes to the sides of the cervix and laterally between the two layers of the broad ligaments.

Peritoneal folds and ligaments of the pelvis

The uterus is connected to a number of 'ligaments'. Some are true ligaments, in that they have a fibrous composition and provide support to the uterus; some provide no support to the uterus; and others are simply folds of peritoneum.

Peritoneal folds

The parietal peritoneum is reflected over the upper genital tract to produce anterior (vesico-uterine), posterior (recto-uterine) and lateral peritoneal folds. The lateral folds are commonly called the broad ligaments (Fig. 75.13).

Vesico-uterine and rectovaginal folds

The anterior or vesico-uterine fold consists of peritoneum reflected onto the urinary bladder from the uterus at the junction of its cervix and body (Fig. 75.14). The recto-uterine fold extends lower than the anterior fold and consists of peritoneum reflected from the posterior part

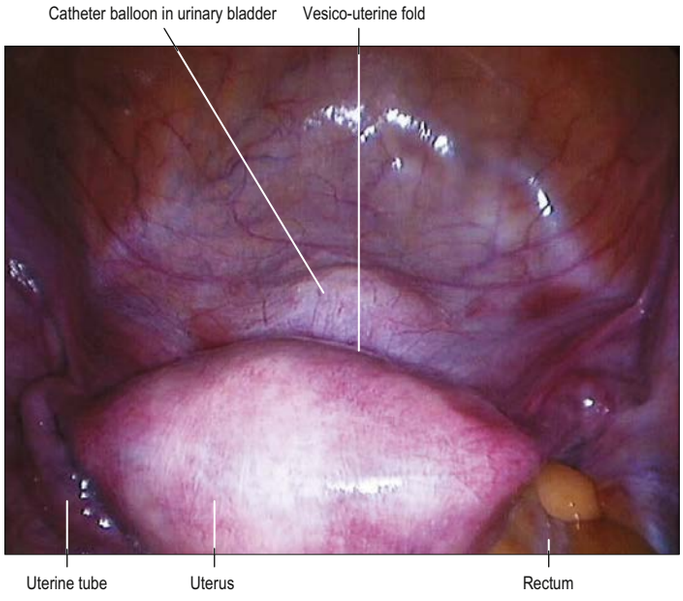

Fig. 75.14 A laparoscopic view of the anterior part of the pelvis, showing the vesico-uterine pouch anterior to the uterus.

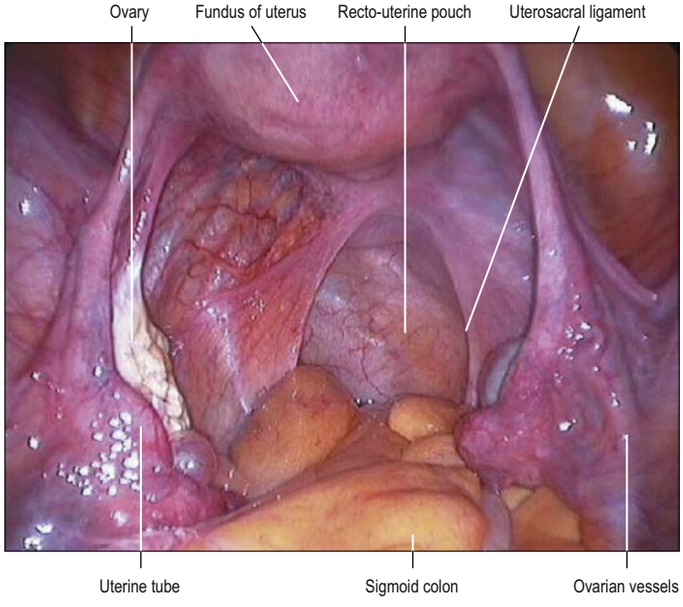

Fig. 75.15 A laparoscopic view of the posterior pelvis, showing the recto-uterine pouch (pouch of Douglas) with the sigmoid colon descending towards the rectum.

of the vaginal fornix on to the anterior surface of the rectum, thereby creating the recto-uterine pouch. The recto-uterine pouch is bounded anteriorly by the uterus, supravaginal part of the cervix and posterior part of the vaginal fornix; posteriorly by the rectum; and laterally by the uterosacral ligaments (**Fig. 75.15**).

Broad ligament

The lateral folds, or broad ligaments, extend on each side from the uterus to the lateral pelvic walls, where they become continuous with the peritoneum covering those walls (**Figs 75.16–75.18**). The upper border is free and the lower border is continuous with the peritoneum over the urinary bladder, rectum and side wall of the pelvis. The borders are continuous with each other at the free edge via the fundus of the uterus and diverge below near the superior surface of levator ani. A uterine tube lies in the upper free border on either side. The broad ligament is divided into an upper mesosalpinx, a posterior mesovarium and an inferior mesometrium.

Mesosalpinx and mesovarium

The mesosalpinx is attached above to the uterine tube and posteroinferiorly to the mesovarium (see Fig. 75.17). Superior and laterally it is attached to the suspensory ligament of the ovary; medially it is attached

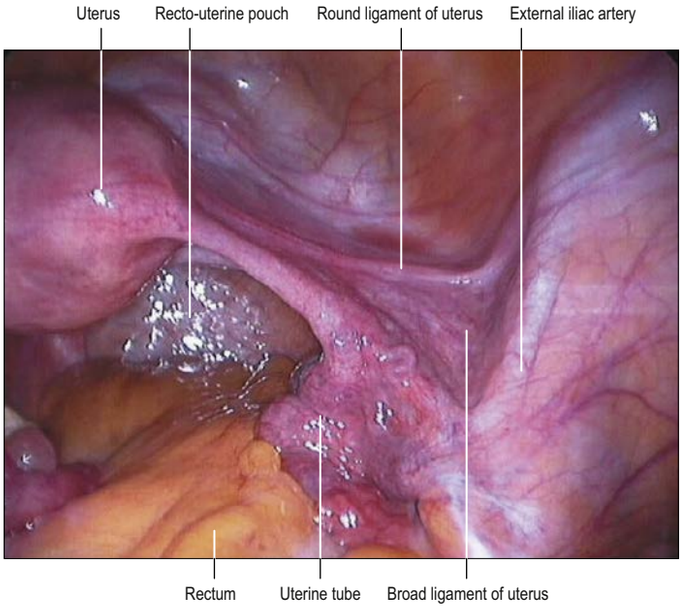

Fig. 75.16 A laparoscopic view of the broad ligament.

to the proper ovarian ligament. The fimbria of the uterine tube projects from its free lateral end. Between the ovary and uterine tube, the mesosalpinx contains vascular anastomoses between the uterine and ovarian vessels, the epoophoron and the paroophoron. The mesovarium projects from the posterior aspect of the broad ligament, of which it is the smaller part. It is attached to the hilum of the ovary and carries vessels and nerves to the ovary (see Fig. 75.17 and page 1321).

Mesometrium

The mesometrium is the largest part of the broad ligament and extends from the pelvic floor to the proper ovarian ligament and body of the uterus. The uterine artery passes between its two peritoneal layers typically 1.5 cm lateral to the cervix; it crosses the ureter shortly after its origin from the internal iliac artery and gives off a branch that passes superiorly to the uterine tube, where it anastomoses with the ovarian artery (**Fig. 75.19**). Between the pyramid formed by the infundibulum of the uterine tube, the upper pole of the ovary and the lateral pelvic wall, the mesometrium contains the ovarian vessels and nerves lying within the suspensory ligament of the ovary. This ligament continues laterally over the external iliac vessels as a distinct fold. The mesometrium also encloses the proximal part of the round ligament of the uterus, as well as smooth muscle and loose connective tissue.

Visceral ligaments of the pelvis

The visceral ligaments of the female pelvis include the round ligament of the uterus and the uterosacral, cardinal and pubocervical ligaments.

Round ligament of the uterus

Each round ligament of the uterus is a narrow band of smooth muscle 10–12 cm long, that extends from the utero-tubal junction through the broad ligament to enter the deep inguinal ring lateral to the inferior epigastric artery (see Figs 75.13, 75.16, 75.18). Although conventionally described as ending in the labium majus, a cadaveric dissection study showed that the round ligament of the uterus ended just outside the superficial inguinal ring in approximately 50% of specimens, with neither attachment nor extension to the caudal labium in any specimen (Bellier et al 2018). Near the uterus, the round ligament contains a considerable amount of smooth muscle, but this gradually diminishes and the terminal portion is purely fibrous. It also contains skeletal muscle, blood vessels, nerves and lymphatics that drain the uterine region around the utero-tubal junction to the superficial inguinal lymph nodes.

In the fetus, a projection of peritoneum (processus vaginalis) is carried with the round ligament of the uterus for a short distance into the inguinal canal. Although generally obliterated in adults, it is sometimes patent even in old age. A patent processus vaginalis in the inguinal canal is often referred to as the canal of Nuck; it can be asymptomatic or give rise to an indirect inguinal hernia or hydrocele of the canal of Nuck. In the canal, the ligament receives the same coverings as the spermatic cord, although they are thinner and blend with the ligament itself, which might not reach the mons pubis.

Uterosacral, cardinal and pubocervical ligaments

The uterosacral, cardinal and pubocervical ligaments are condensations of the visceral or endopelvic connective tissue that connect the pelvic viscera to the side wall of the pelvis; they radiate like the spokes of a wheel around the hub of the cervix of the uterus, providing it with considerable support (**Fig. 75.20**) (Delancey 2011). The connective tissue lateral to the uterus and the cervix, the parametrium, continues alongside the vagina as the paracolpium: it contains the vascular and connective tissues associated with the vagina. The uterosacral ligaments contain fibrous tissue and smooth muscle. They pass back from the cervix and body of the uterus on both sides of the rectum and are attached to the anterior aspect of the sacrum. They can be palpated laterally on rectal examination and can be felt as thick bands of tissue passing downwards on both sides of the posterior part of the vaginal fornix on vaginal examination. The cardinal ligaments (ligaments of Mackenrodt) extend from the sides of the cervix and lateral parts of the vaginal fornix, and are attached extensively on the pelvic wall (Eid et al 2018). The lower parts of the ureters and pelvic blood vessels traverse the cardinal ligaments. Fibres of the pubocervical ligament pass forwards from the anterior aspect of the cervix and upper vagina to diverge around the urethra, and are attached to the posterior aspect of the pubic bones.

The cardinal and uterosacral ligaments are almost vertically orientated in the standing position and maintain the near-horizontal axis of the upper vagina. The uterus and vagina are supported by the close interaction of the uterosacral and cardinal ligaments with the muscles of the pelvic floor, including the pelvic diaphragm, the perineal membrane and the perineal body. The support of the pelvic floor has been reviewed in detail by Delancey (2011) (see also Ch. 71).

Vascular supply and lymphatic drainage

Arteries

The arterial supply to the uterus comes primarily from the uterine artery (see Fig. 75.19; **Fig. 75.21**), which arises as a branch of the anterior division of the internal iliac artery. From its origin, the uterine artery crosses the ureter anteriorly in the broad ligament before branching as

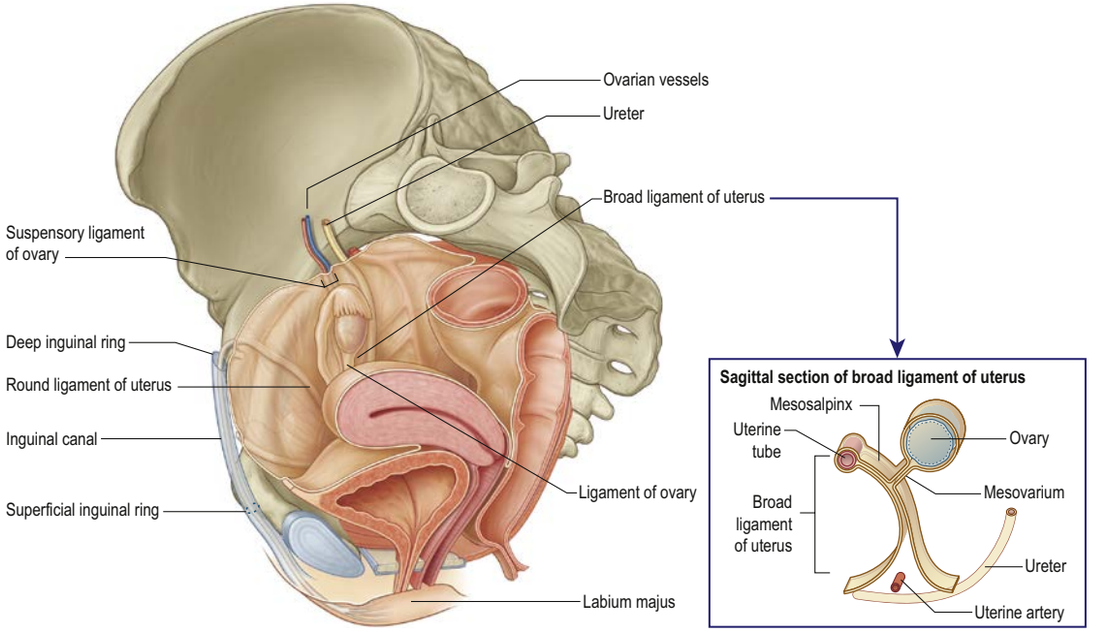

Fig. 75.17 Pelvic peritoneal reflections, demonstrating the broad ligament and its contents. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

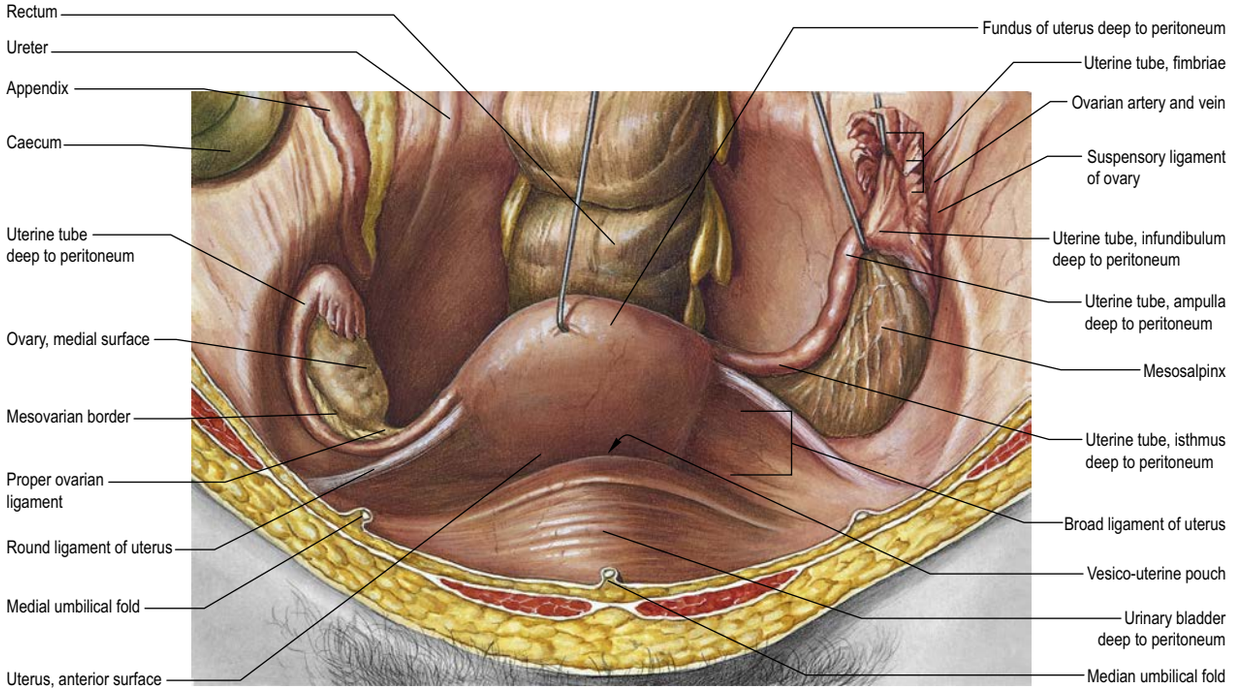

Fig. 75.18 The ovaries and broad ligament of the uterus: superior view with the uterus lifted away from the urinary bladder. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

it reaches the uterus at the level of the cervico-isthmic junction (see Fig. 72.20B). One major branch ascends the uterus tortuously within the broad ligament until it reaches the region of the hilum of the ovary, where it anastomoses with branches of the ovarian artery. Another branch descends to supply the cervix and anastomoses with branches of the vaginal artery to form two median longitudinal vessels, the azygos arteries of the vagina, which descend anterior and posterior to the vagina. Although there are anastomoses with the ovarian and vaginal arteries, the dominance of the uterine artery is indicated by its marked hypertrophy during pregnancy.

The tortuosity of the vessels as they ascend in the broad ligaments is repeated in their branches within the uterine wall. Each uterine artery gives off numerous branches. These enter the uterine wall, divide and run circumferentially as groups of anterior and posterior arcuate arteries. They ramify and narrow as they approach the anterior and posterior midline so that no large vessels are present in these regions. However, the left and right arterial trees anastomose across the midline and unilateral ligation can be performed without serious effects. Terminal branches in the uterine muscle are tortuous and are called helicine arterioles. They provide a series of dense capillary plexuses in the myometrium and endometrium. From the arcuate arteries, many helical arteriolar rami pass into the endometrium. Their detailed appearance changes during the menstrual cycle. Helical arterioles are less prominent during the proliferative phase, whereas they grow in length and calibre, becoming even more tortuous, during the secretory phase.

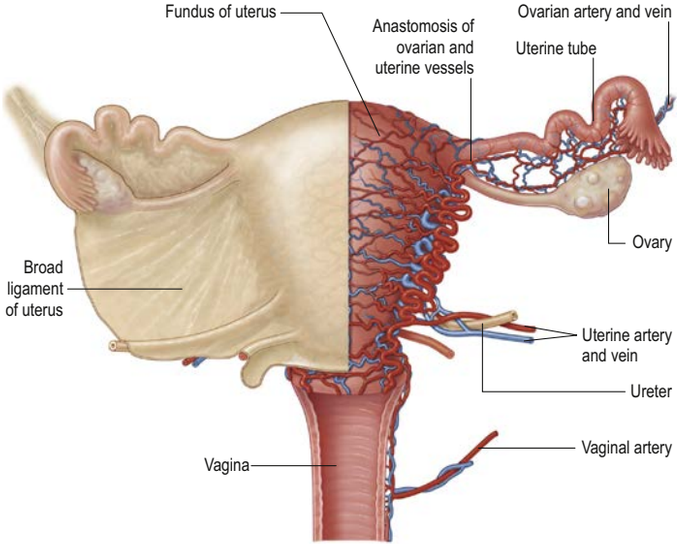

Fig. 75.19 The broad ligament (left) and blood supply to the uterus and ovaries (right). (With permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008.)

Veins

The uterine veins extend laterally within the broad ligaments, running adjacent to the arteries and passing over the ureters. They drain into the internal iliac veins (see Fig. 75.3). The uterine venous plexus anastomoses with the vaginal and ovarian venous plexuses.

Lymphatic drainage

There are uterine lymphatics in the superficial (subperitoneal) and deep parts of the uterine wall. Collecting vessels from the body of the uterus and cervix pass laterally in the parametrium to three main groups of lymph nodes: the external and internal iliac and the obturator nodes (see Table 75.1). The external and internal iliac nodes surround their corresponding arteries. The obturator nodes lie in the so-called obturator fossa between the external and internal iliac vessels; the obturator nerve passes through the lower part of this group of lymph nodes.

Lymph vessels from the fundus of the uterus and the uterine tubes can accompany the lymph drainage of the ovaries to lateral aortic nodes (see Fig. 75.3B). The region surrounding the isthmus of the uterine tube can drain along the round ligament of the uterus to the superficial inguinal nodes.

Innervation

The nerve supply to the uterus is predominantly from the inferior hypogastric plexus (see Fig. 75.5) (Shoja et al 2013). Some branches ascend with, or near, the uterine arteries in the broad ligament. They supply the body of the uterus and uterine tubes and connect with tubal branches from the inferior hypogastric plexus and with the ovarian plexus. The branches to the uterus terminate in the myometrium and endometrium and usually accompany the vessels (see Table 75.2). Nerves to the cervix form a plexus that contains small paracervical ganglia. Branches can pass directly to the cervix of the uterus or be distributed along the vaginal arteries.

Efferent preganglionic sympathetic fibres are derived from neurones in the last thoracic and first lumbar spinal cord segments; the sites where they synapse on their postganglionic neurones are unknown but are presumably in the superior and/or inferior hypogastric plexus (Lee et al 1973). Preganglionic parasympathetic fibres arise from neurones in the second to fourth sacral spinal cord segments and relay in the paracervical ganglia. Sympathetic activity can produce uterine contraction and vasoconstriction, and parasympathetic activity can produce uterine inhibition and vasodilation, but these activities are complicated by hormonal control of uterine functions.

Microstructure

Body of the uterus

The uterus is composed of three main layers. From its lumen outwards, these are the endometrium (mucosa), myometrium (smooth muscle layer) and serosa (or adventitia) (Fig. 75.22).

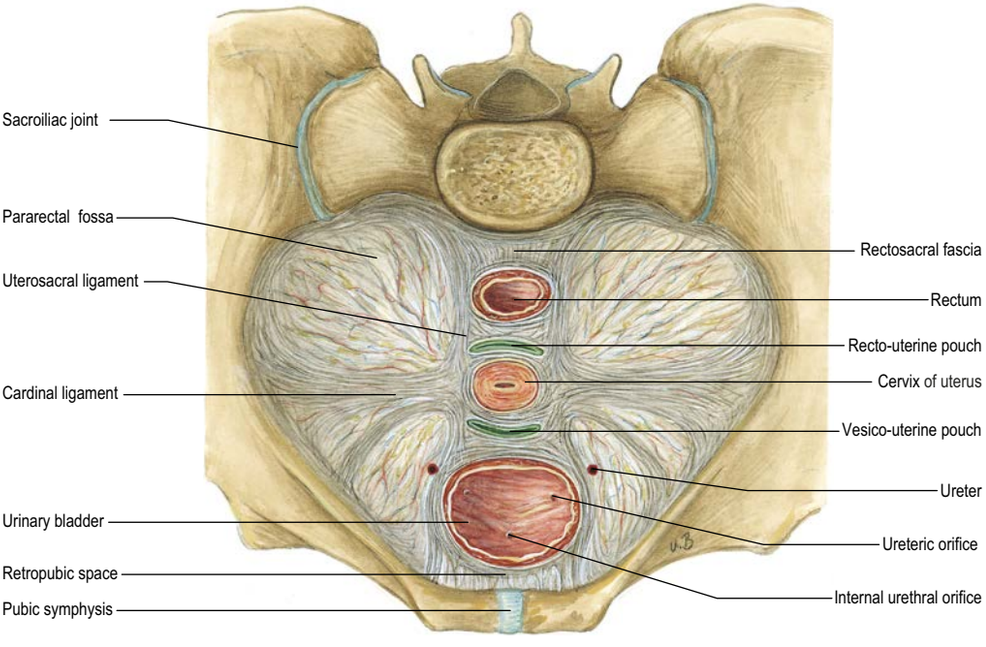

Fig. 75.20 The supporting ligaments of the pelvis, showing the cardinal ligaments. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

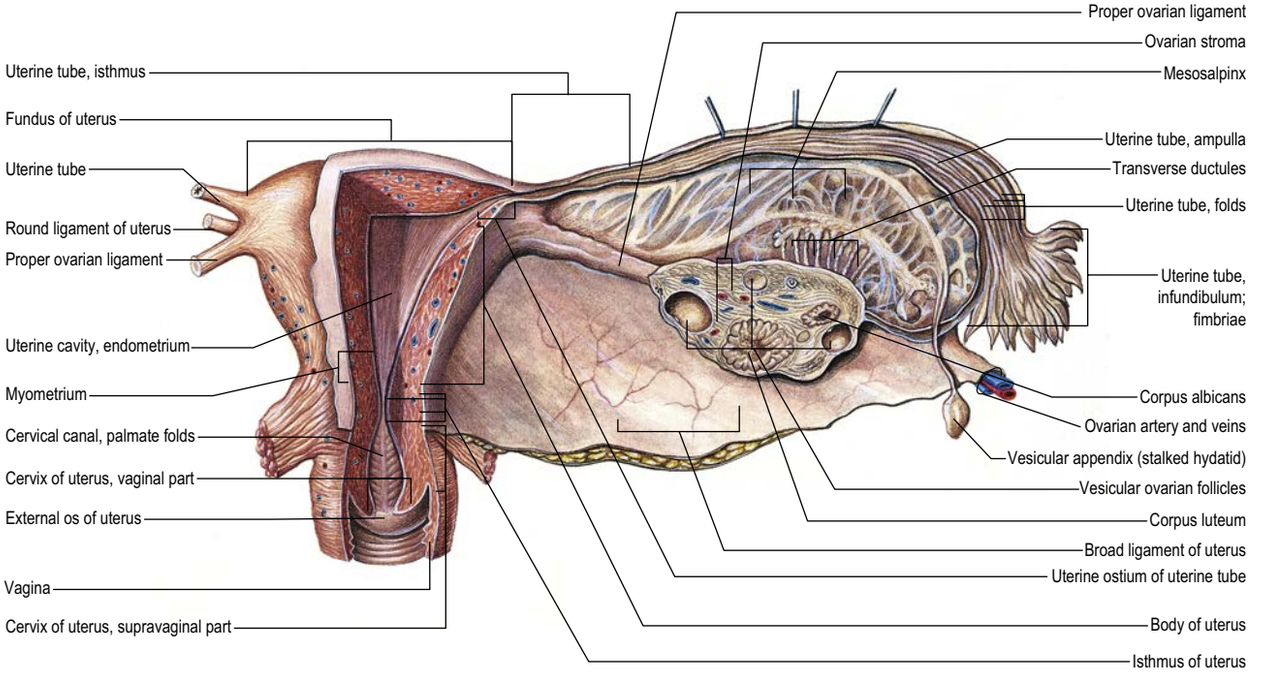

Fig. 75.22 The uterus, uterine tubes and ovaries. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Endometrium

The endometrium is formed by a layer of connective tissue, the endometrial stroma, which supports a single-layered columnar epithelium. Before puberty, the epithelium is ciliated and cuboidal. It contains glands that are composed largely of columnar cells secreting glycoproteins and glycogen. After puberty, the structure of the endometrium varies with the stage of the menstrual cycle (see below). The glands are tubular, run perpendicular to the luminal surface and penetrate up to the myometrial layer. The stroma consists of a highly cellular connective tissue between the endometrial glands and contains blood and lymphatic vessels.

Myometrium

The myometrium is composed of smooth muscle and loose connective tissue and contains blood vessels, lymphatic vessels and nerves. It is dense and thick at the uterine midlevel and fundus but thin at the uterine ostium of the uterine tube. The body of the uterus has four muscular layers, submucosal, vascular, supravascular and subserosal. The submucosal (innermost) layer is composed of longitudinal and some oblique smooth muscle fibres. The vascular layer is external to the submucosal layer and is rich in blood vessels and longitudinal muscle. It is succeeded by the supravascular muscle layer where the muscle fibres are predominantly circular. The outer,

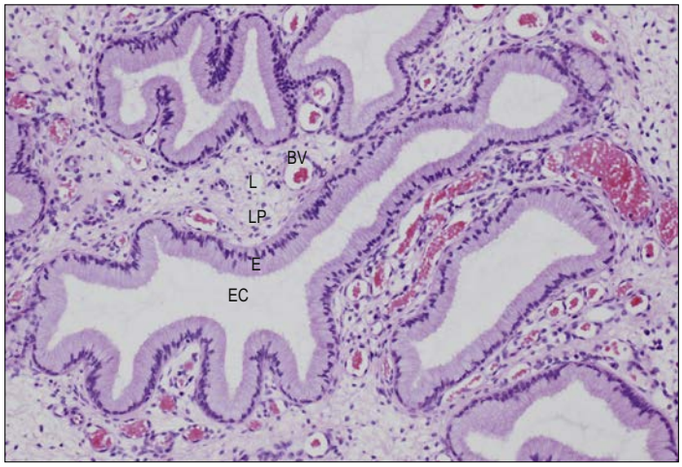

Fig. 75.23 The cervical glands. These are deep infoldings of the lining of the cervical canal (EC). The epithelium (E) is simple columnar and mucus-secreting. The underlying lamina propria (LP) is richly supplied with blood vessels (BV) and lymphatics (L). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

thin longitudinal muscle layer, the subserosal muscle layer, lies adjacent to the serosa.

The muscular fibres of the supravascular and subserosal layers converge at the lateral angles of the uterus and continue into the uterine tubes. Some fibres enter the broad ligaments as the round ligament of the uterus and the proper ovarian ligament, while others turn back into the uterosacral ligament. At the junction between the body and the cervix, the smooth muscle merges with dense, irregular connective tissue containing both collagen and elastin and forms most of the wall of the cervix. Bilateral longitudinal fibres extend in the lateral submucosal layer to the cervix. Their muscle fibres differ structurally from those of typical myometrium, and they may provide fast conducting pathways that coordinate the contractile activities of the uterine wall.

Serosa

The body of the uterus is covered by serosa, which continues downwards posteriorly to cover the supravaginal part of the cervix. The anterior cervix and the lateral surfaces of the body and cervix are not covered by peritoneum.

Cervix of the uterus

The cervix consists of fibroelastic connective tissue and contains relatively little (10%) smooth muscle. The elastin component of the cervical stroma is essential for the stretching capacity of the cervix during childbirth. The cervical canal is lined by a deeply folded mucosa with a surface epithelium of columnar mucous cells (Fig. 75.23). Branched tubular glands present within the mucosa are lined by a similar secretory epithelium. These glands extend obliquely upwards and outwards from the canal. They secrete clear, alkaline mucus, which is relatively viscous except at the midpoint of the menstrual cycle, when it becomes more copious and less viscous to encourage the passage of sperm. At the vaginal end of the cervix, the aperture of a gland may be blocked and it then fills with mucus to form a Nabothian follicle (or cyst). None of the mucosa is shed during menstruation, so unlike the body of the uterus it is not divided into functional and basal layers and lacks spiral arteries. The surface of the vaginal part of the cervix (ectocervical mucosa) is covered by stratified squamous non-keratinized epithelium, which contains glycogen.

The squamocolumnar junction, where the columnar secretory epithelium of the endocervical canal meets the stratified squamous covering of the ectocervical mucosa, is located at the external os of the uterus before puberty. As oestrogen levels rise during puberty the cervical os opens, exposing the endocervical columnar epithelium on to the ectocervical mucosa. This area of columnar cells on the ectocervical mucosa forms an area that is red and raw in appearance, called an ectropion (cervical erosion). It is then exposed to the acidic environment of the vagina and, through a process of squamous metaplasia (Ch. 2), transforms into stratified squamous epithelium. This area is thus known as the 'transformation zone' (Fig. 75.24). Other hyperoestrogenic states, such as pregnancy and the use of oral contraceptive pills, can also result in an ectropion. This area is the most usual site of cervical intraepithelial neoplasia (CIN), which can progress to malignancy. In postmenopausal females, the squamocolumnar junction recedes into the cervical canal.

Fig. 75.24 The transformation zone of the cervix of the uterus. The single-layered columnar epithelium lining the cervical canal (EC) and its cervical glands (EG) changes abruptly (arrow) to the non-keratinized stratified squamous epithelium of the external os and exocervical mucosa (below arrow).

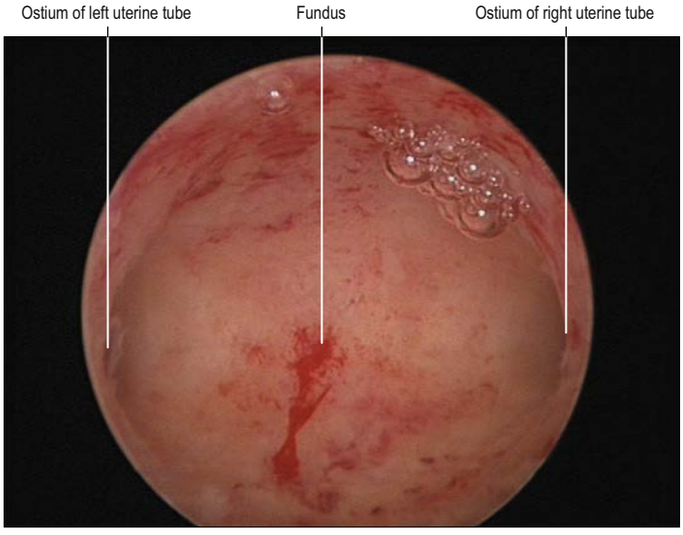

Fig. 75.26 A hysteroscopic view of the uterine cavity.

Magnetic resonance imaging of the uterus and vagina

Available with the *Gray's Anatomy* e-book

Uterine (Fallopian) tubes

The uterine tubes are attached to the upper part of the body of the uterus and their ostia open into the uterine cavity (Figs 75.26–75.28). The medial opening of the tube (uterine ostium of the uterine tube) is located at the superior angle of the uterine cavity. The tube passes laterally and superiorly and consists of four parts: uterine part, isthmus, ampulla and fimbria (see Fig. 75.22). The uterine part is 0.7 mm wide and 1 cm long and lies within the myometrium. It is continuous laterally with the isthmus, which is 1–5 mm wide and 3 cm long; it is rounded, muscular and firm. The isthmus is continuous laterally with the ampulla, the widest portion of the uterine tube with a maximum luminal diameter of 1 cm. The ampulla is 5 cm long and has a thin wall and a tortuously folded luminal surface. Typically, fertilization takes place in its lumen. The ampulla opens into the trumpet-shaped infundibulum at the abdominal ostium of the uterine tube. Fimbriae, numerous mucosal finger-like folds 1 mm wide, are

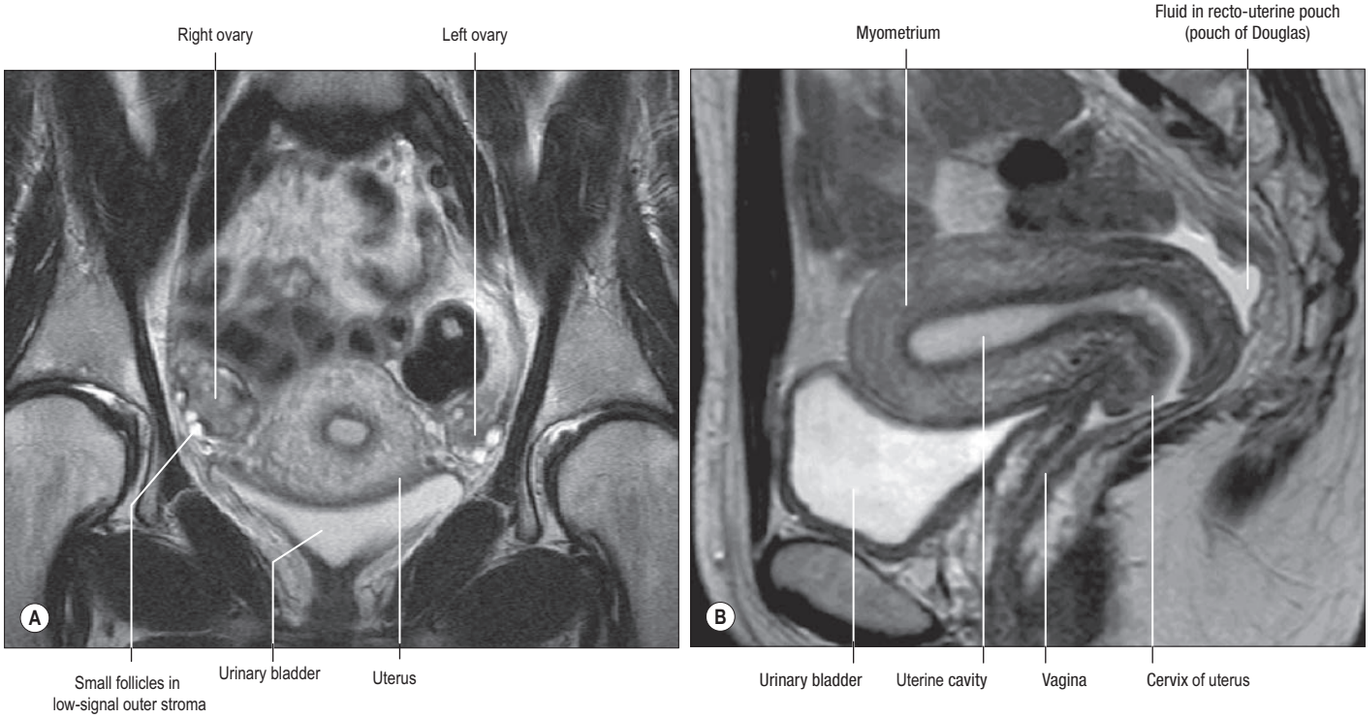

Fig. 75.25 T2-weighted MRI of the uterus and ovaries. **A**, A coronal T2-weighted MRI showing the uterus and both ovaries with the high-signal central stroma and lower-signal outer stroma. **B**, A sagittal T2-weighted MRI showing the zonal anatomy of the uterus.

Although MRI has limited clinical value for viewing the uterus and vagina, on T2-weighted magnetic resonance imaging (MRI) the uterus displays a zonal anatomy with three distinct zones: the endometrium, junctional zone and myometrium (**Fig. 75.25**) (Minto et al 2001). The endometrium and uterine cavity appear as a high-signal stripe; its thickness varies with the stage of the menstrual cycle. In the early proliferative phase it measures up to 5 mm, and widens to up to 1 cm in the mid-secretory phase. A low signal band, the junctional zone, borders the endometrium and represents the inner myometrium. It is of constant thickness and signal throughout the menstrual cycle and usually measures 5 mm. The outer myometrium is of medium-signal intensity during the proliferative phase and of high-signal intensity during the mid-secretory phase because of the increased vascularity and prominence of the arcuate vessels.

The uterus is smaller (only 4 cm in length) in prepubertal females, and on T2-weighted MRI the endometrium is minimal or absent and the junctional zone indistinct. In postmenopausal females the body of the uterus shrinks and the zonal anatomy is indistinct.

On T2-weighted MRI, the cervix has an inner, low-signal stroma continuous with the junctional zone of the uterus. This is often surrounded by an outer zone of intermediate signal intensity continuous with the outer myometrium. The appearances do not change with the menstrual cycle or oral contraceptive pill use. The central stripe is very high-signal and is a consequence of the secretions produced by the cervical glands.

The vagina is best seen on T2-weighted MRI as a thin layer of high-signal intensity of the mucosa and an outer low-signal layer of the submucosa and muscular layer (see Fig. 75.25). MRI accurately demonstrates congenital and acquired Müllerian duct anomalies including uterine and vaginal aplasia, duplication and septa (Grant et al 2010). Vaginal and perivaginal cysts are also well visualized with T2-weighted MRI.

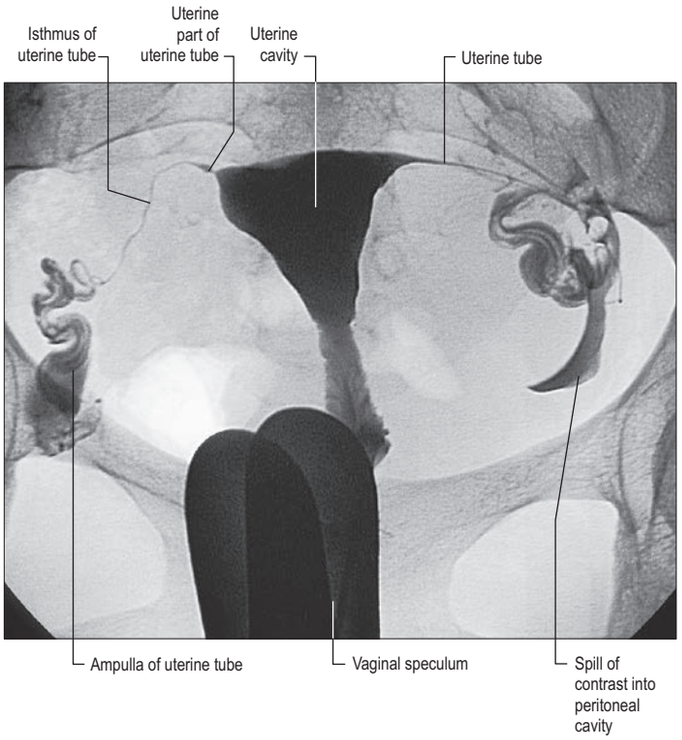

Fig. 75.27 A digitally subtracted hysterosalpingogram. Radiopaque contrast is introduced via a catheter inserted through the cervical os; the catheter is introduced using a vaginal speculum. The contrast fills the triangular-shaped uterine cavity. The lumina of the narrow uterine and isthmic parts of the uterine tubes may be traced inferolaterally from the superior angles as they expand into the wider ampullae. Some contrast media has escaped into the pelvic cavity from the abdominal ostia of the uterine tubes. (Courtesy of Dr Julia Hillier, Chelsea and Westminster Hospital, London.)

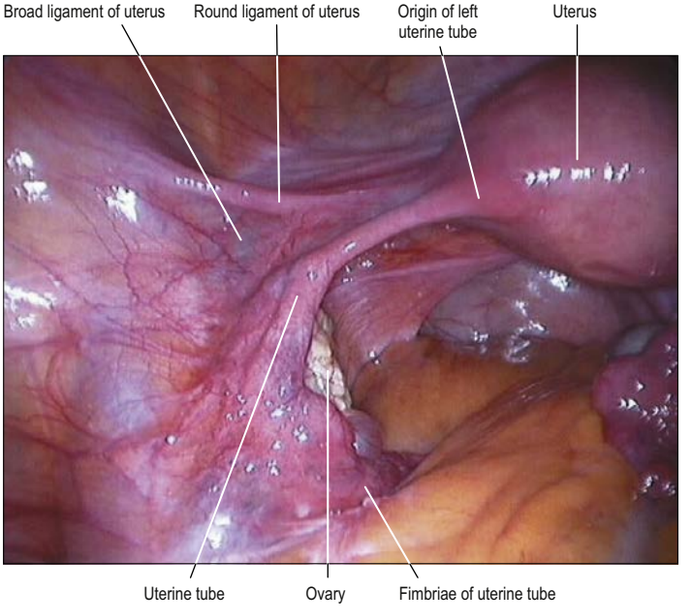

Fig. 75.28 A laparoscopic view of the origin of the uterine tube from the uterus.

attached to the ends of the infundibulum and extend from its inner circumference beyond the muscular wall of the uterine tube. One of these, the ovarian fimbria, is longer and more deeply grooved than the others and is typically applied to the tubal extremity of the ovary. At the time of ovulation, the fimbriae swell and extend as a result of engorgement of the vessels in the lamina propria, which aids capture of the released oocyte. All fimbriae are covered, like the mucosal lining throughout the tube, by a ciliated epithelium whose cilia beat towards the ampulla of the uterine tube.

Fig. 75.29 The uterine tube (ampulla) with the mucosal lining thrown into extensive folds that fill the lumen. The superficial epithelium includes both secretory and ciliated cells, covering a lamina propria (LP). Smooth muscle (SM) occupies the wall of the tube. (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Vascular supply and lymphatic drainage

Arteries

The blood supply to the uterine tubes is derived from ovarian and uterine arteries (see Fig. 75.21A). The lateral third of the tube is supplied by the ovarian artery, which continues in the mesosalpinx to anastomose with branches from the uterine artery. The medial two-thirds of the uterine tube are supplied by the uterine artery.

Veins

Venous drainage is similar to the arterial supply. The venous drainage of the lateral two-thirds of the uterine tube is via the pampiniform plexus to the ovarian veins, which open into the inferior vena cava on the right side and the renal vein on the left. The medial two-thirds of the uterine tube drain via the uterine plexus to the internal iliac vein.

Lymphatic drainage

Lymph drainage is via ovarian vessels to the lateral aortic nodes and uterine vessels to the internal iliac nodes. It is possible for lymph to reach the inguinal nodes via the round ligament of the uterus (see Table 75.1).

Innervation

The uterine tubes are innervated by autonomic fibres that are distributed mainly with the ovarian and uterine arteries. Most of the tube has a dual sympathetic and parasympathetic supply (see Table 75.2). Preganglionic parasympathetic fibres are derived from the pelvic splanchnic nerves. The preganglionic sympathetic supply is derived from neurones in the intermediolateral nuclei of the tenth thoracic to the second lumbar spinal cord segments; postganglionic sympathetic fibres are most likely derived from the superior hypogastric plexus via the hypogastric nerves (see Fig. 75.5) (Chen et al 2014). Visceral afferent fibres travel with the sympathetic nerves and enter the spinal cord through corresponding dorsal roots; they can also travel with parasympathetic fibres. The ampullary submucosa contains modified Pacinian corpuscles.

Microstructure

The walls of the uterine tubes show typical visceral mucosal, muscular and serosal layers (Fig. 75.29). The mucosa is thrown into longitudinal folds, which are most pronounced distally at the infundibulum and decrease to shallow bulges in the uterine part. The mucosa is lined by a single-layered, tall, columnar epithelium, which contains mainly ciliated cells and secretory (peg) cells (so called because they project into the lumen further than their ciliated neighbours), and occasional intraepithelial lymphocytes. In the uterine tube, ciliated cells predominate distally and secretory cells proximally. Their activities vary with the

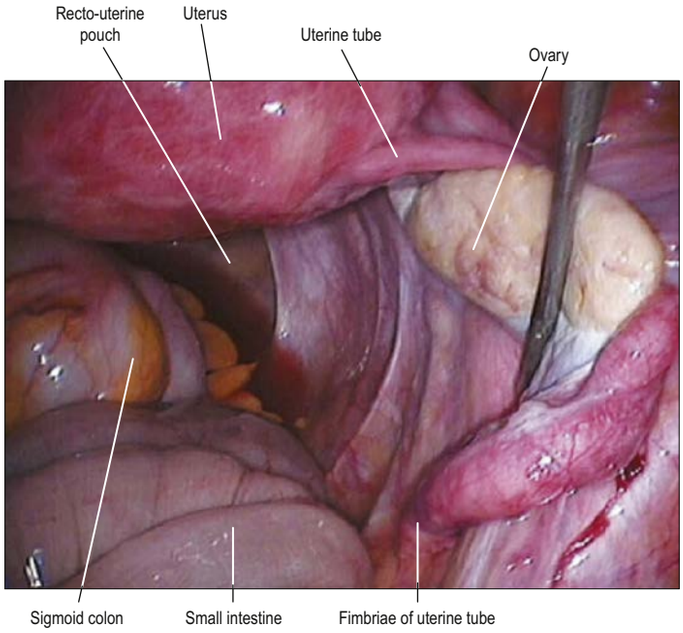

Fig. 75.30 A laparoscopic view of the right ovary, showing its distorted surface.

stage in the menstrual cycle and with age. Secretory cells are most active around the time of ovulation. Their secretions include nutrients for the gametes and aid capacitation of the spermatozoa. Ciliated cells increase in height and develop more cilia during the oestrogenic first half of the menstrual cycle. Their cilia waft the oocyte from the open-ended infundibulum towards the uterus in fluids secreted by the peg cells. The epithelium regresses in height towards the end of the cycle and postmenopausally, when ciliated cells are reduced in number.

The lamina propria provides vascular connective tissue support and abundant lymphatic drainage vessels. The smooth muscle of the muscular layer is arranged as an inner circular or spiral layer and an outer, thinner longitudinal layer. Together, their contractile activity produces peristaltic movements of the uterine tube, which assist propulsion of the gametes and the fertilised ovum. The uterine tubes are covered externally by a highly vascular serosa.

Ovaries

In the non-pregnant adult, the ovaries lie on each side of the uterus close to the lateral pelvic wall. They are suspended in the pelvic cavity by a double fold of peritoneum, the mesovarium, which is attached to the upper limit of the posterior aspect of the broad ligament. They are dull white in colour and consist of dense fibrous tissue, in which ova are embedded. Before regular ovulation begins they have a smooth surface, but their surfaces are distorted by scarring that follows the degeneration of successive corpora lutea, thereafter (Fritz and Speroff 2011) (**Fig. 75.30**). In the neonate, their dimensions are 1.3 × 0.6 × 0.4 cm. Before the first menstrual period (menarche) the ovaries are about one-third of the normal reproductive adult size. They gradually increase in size with body growth (Sforza et al 1993, Badouraki et al 2008): their average dimensions are 4 × 2 × 3 cm in reproductively mature females. The ovaries more than double in size during pregnancy and shrink significantly after menopause.

The lateral surface of the ovary contacts parietal peritoneum in the ovarian fossa. Behind the ovarian fossa are retroperitoneal structures including the ureter, internal iliac vessels, obturator vessels and nerve, and the origin of the uterine artery. The medial surface faces the uterus and uterine vessels in the broad ligament. Above the superior extremity are the fimbria and distal section of the uterine tube. The inferior extremity points downwards towards the pelvic floor. The mesovarian border faces the posterior leaf of the broad ligament. The free border faces the peritoneum, which overlies the upper part of the internal iliac artery and vein, and the ureter. On the right side, superior and lateral to the ovary, are the ileocaecal junction, caecum and appendix. On the left side, the sigmoid colon passes over the superior aspect of the ovary and joins the rectum, which lies between the medial surfaces of the two ovaries. The mesosalpinx lies below the uterine tube. The proper ovarian ligament is inferior and medial. The mesovarium and ovary lie inferiorly at its fimbrial end. The round ligament of the uterus is anterior to the uterine tube. The superior and posterior surfaces of the uterine tube lie free in the peritoneal cavity.

During embryonic and early fetal life the ovaries are situated in the lumbar region near the kidneys. They gradually descend along the gubernaculum, stopping at the lesser pelvis. The relationship between the location of the ovaries and surface landmarks is important for enabling the ovaries to be shielded from exposure to radiation during radiological procedures. In girls the ovaries lie at or below the iliac crest, just medial to the anterior superior iliac spine, and they lie above the pubic symphysis at all ages (Bardo et al 2009). There may be accessory ovarian tissue in the mesovarium or along the course of the gubernacula; rarely, the ovaries descend along the whole course of the gubernacula and are found in the labia majora. During pregnancy the ovaries are lifted high in the pelvis; by 14 weeks of gestation they become partly abdominal structures, and by the third trimester they are totally abdominal structures and lie vertically behind and lateral to the parous uterus.

Peritoneal and ligamentous supports of the ovary

The peritoneal and ligamentous supports of the ovary consist of the suspensory ligament of the ovary, proper ovarian ligament and the mesovarium.

Suspensory ligament of the ovary

The suspensory ligament of the ovary is a peritoneal fold attached to the upper part of the lateral surface of the ovary, which contains the ovarian vessels and nerves (see Fig. 75.18). On the right side, the suspensory ligament of the ovary is attached to a fold of peritoneum that is posterior and inferior to the caecum and appendix. The peritoneal attachment is higher on the left side than the right and is lateral to the junction of the descending and sigmoid colons. As it joins the peritoneum covering psoas major, the suspensory ligament of the ovary passes superiorly over the external iliac vessels, genitofemoral nerve and ureter.

Proper ovarian ligament

The proper ovarian ligament attaches the uterine (inferomedial) extremity of the ovary to the lateral angle of the uterus, posteroinferior to the uterine tube (see Fig. 75.22). It lies in the posterior leaf of the broad ligament and contains some smooth muscle cells. It is continuous with the medial border of the round ligament.

Mesovarium

The mesovarium is a short peritoneal fold that attaches the ovary to the back of the broad ligament. It carries blood vessels and nerves to the hilum of the ovary. The uterine tube arches over the ovary and ascends in relation to its mesovarian border, then curves over its tubal end and passes down on its posterior, free, border and medial surface.

Vascular supply and lymphatic drainage

Arteries

The ovarian arteries are branches of the abdominal aorta and originate below the renal arteries. Each descends behind the peritoneum and, at the linea terminalis, crosses the external iliac artery and vein to enter the lesser pelvis. Here, the artery turns medially in the suspensory ligament of the ovary and splits into a branch to the mesovarium that supplies the ovary and a branch that continues into the broad ligament, below the uterine tube, and supplies the tube. There are variations in the site of the division to the ovary and tube (see Fig. 75.21). On each side a branch passes lateral to the uterus to unite with the uterine artery. Other branches accompany the round ligaments through the inguinal canal to the skin of the labium majus and the inguinal region. Early in intrauterine life, the ovaries flank the vertebral column inferior to the kidneys, so the ovarian arteries are relatively short; they gradually lengthen as the ovaries descend into the pelvis.

Veins

The ovarian veins emerge from the ovary as a plexus (pampiniform plexus) in the mesovarium and suspensory ligament of the ovary (see Fig. 75.3A). Two veins emerge from the plexus and ascend with the ovarian artery; they usually merge into a single vessel before entering either the inferior vena cava on the right side or the renal vein on the left.

Lymphatic drainage

The main lymphatic drainage of the ovaries is along vessels that follow the ovarian veins to lateral aortic nodes situated near the origin of the renal arteries (see Table 75.1). There can also be drainage via pelvic nodes into lower lateral aortic nodes and, less commonly, via the round ligament of the uterus to the inguinal nodes (Kleppe et al 2015).

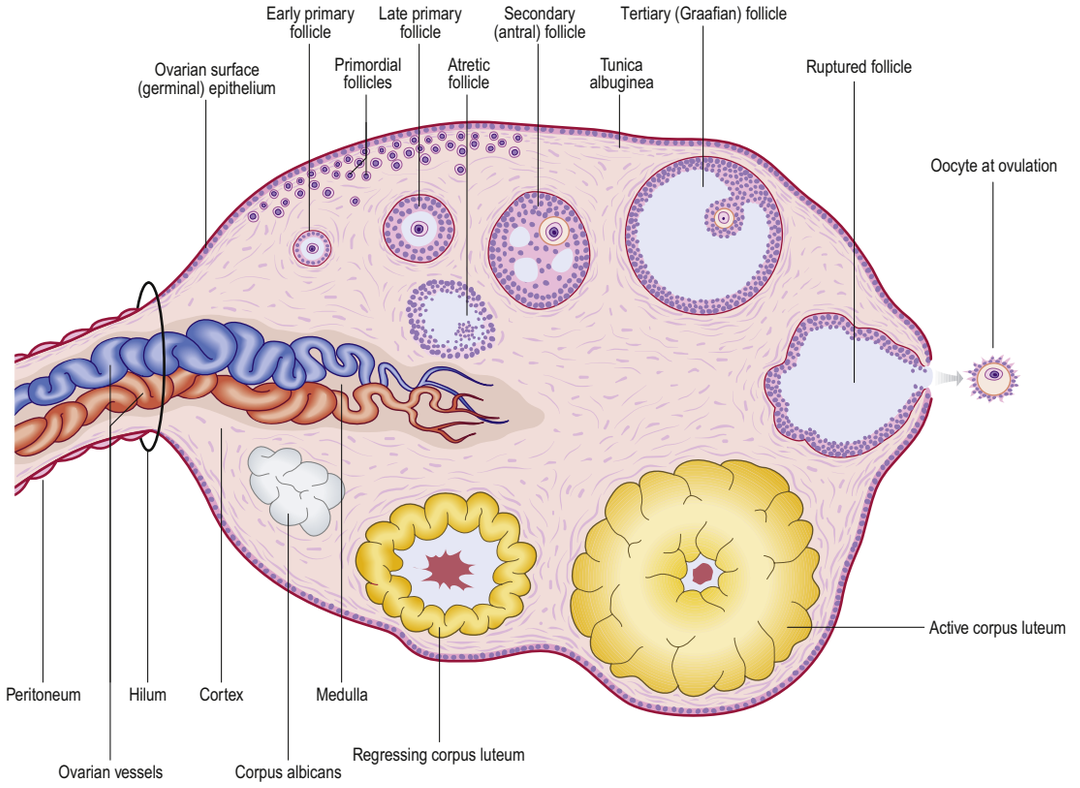

Fig. 75.31 The microstructure of the ovary and follicles at various stages in their cyclical development and the formation of corpora lutea and albicantia. Note that developing follicles are rarely seen in the human ovary.

Innervation

The ovarian innervation is derived from autonomic plexuses (see Table 75.2). The upper part of the ovarian plexus is formed from branches of the renal and aortic plexuses and the lower part is reinforced from the superior and inferior hypogastric plexuses. These plexuses consist of postganglionic sympathetic fibres, preganglionic parasympathetic fibres from the pelvic splanchnic nerves, and visceral afferent fibres (Lee et al 1973). The efferent preganglionic sympathetic fibres are derived from the tenth and eleventh thoracic spinal segments.

Microstructure

In young females the surface of the ovary is covered by a single layer of cuboidal epithelium, which contains some flatter cells. It appears dull white, in contrast to the shiny, smooth peritoneal mesothelial covering of the mesovarium, with which it is continuous. A white line around the anterior mesovarian border usually marks the transition between peritoneum and ovarian epithelium. The surface epithelium is also termed the germinal epithelium, but this is a misnomer because it is not the source of germ cells. Immediately beneath the epithelium there is a tough collagenous coat, the tunica albuginea. The ovarian tissue it surrounds is divisible into a cortex, containing the ovarian follicles, and a medulla, which receives the ovarian vessels and nerves at the hilum.

Ovarian cortex

Before puberty the cortex forms 35%, the medulla 20% and interstitial cells up to 45% of the volume of the ovary. After puberty, the cortex forms the major part of the ovary, enclosing the medulla except at the hilum. The cortex contains the ovarian follicles at various stages of development, and corpora lutea and their degenerative remnants, depending on age or stage of the menstrual cycle. The follicles and the structures derived from them are embedded in a dense stroma comprising a meshwork of thin collagen fibres and fusiform fibroblast-like cells, arranged in characteristic whorls. Stromal cells differ from fibroblasts in general connective tissue in that they contain lipid droplets, which accumulate during pregnancy. Stromal cells give rise to the thecal layers of maturing ovarian follicles.

Ovarian follicles

Primordial follicles

The development of ovarian follicles can be divided into different stages (Fig. 75.31). At birth, the ovarian cortex contains a superficial zone of primordial follicles. These consist of primary oocytes 25 μm in diameter,

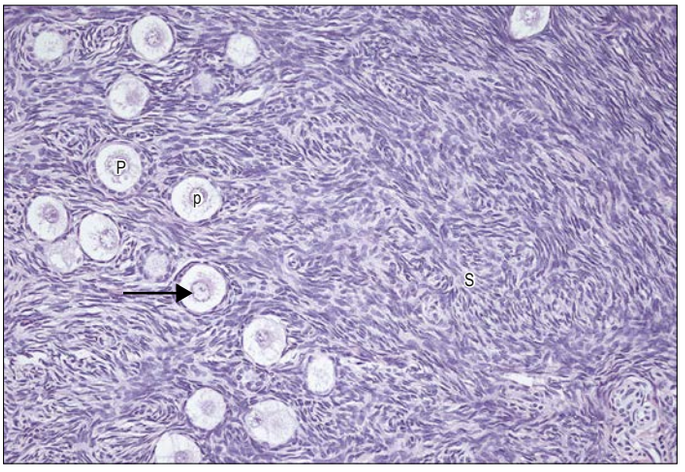

Fig. 75.32 Ovarian cortex with primordial (p) and early primary (P) follicles within the stroma (S); stimulated primary follicles have cuboidal cells forming their wall. A large oocyte nucleus is visible in the plane of section of most of the follicles (arrow). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

each surrounded by a single layer of flat follicular cells. The oocyte nuclei are slightly eccentric and have a characteristically prominent nucleolus. They contain the diploid number of chromosomes (duplicated as sister chromatids), arrested at the diplotene stage of meiotic prophase after 16–20 weeks of fetal life (Fritz and Speroff 2011) (Fig. 75.32). Many follicles degenerate either during prepubertal (including prenatal) life, or through atresia at some stage after beginning the process of cyclical maturation during the child-bearing period. Their remnants are visible as atretic follicles, the remains of which accumulate throughout the period of reproductive life. After puberty, cohorts of up to 20 primordial follicles become activated in each menstrual cycle (fewer are activated with advancing age). Their development takes a number of cycles. Among the follicles activated in each cohort, usually only one from one or the other ovary becomes dominant, reaches maturity and releases its oocyte at ovulation.

Abnormal, non-growing follicles with indistinct germinal vesicle membranes and absent nucleoli are sometimes found in prepubertal

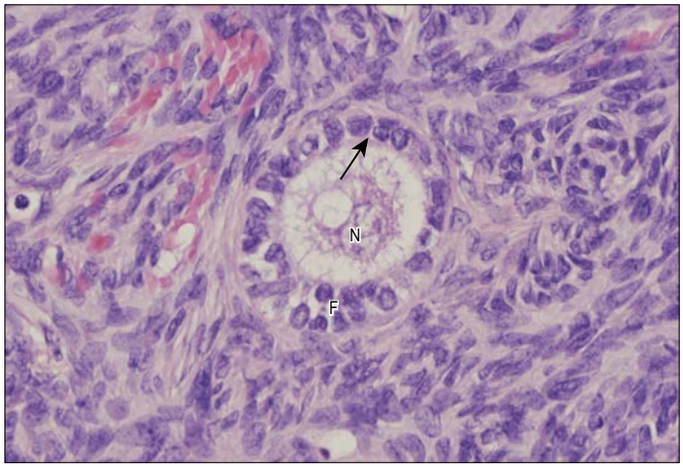

Fig. 75.33 A high-magnification micrograph of a primary follicle in a human ovarian cortex. The pale oocyte, with its eccentric nucleus (N), is separated from the follicle (F) by the zona pellucida (arrow). Cells of the follicle wall are in the early stages of proliferation to form a multilayered, late primary follicle. Fig. 75.34 An antral follicle, showing the layers of the developing follicle wall. Granulosa cells (GC) enclose the antrum (A), filled with follicular fluid, and surround the oocyte (not seen in the plane of section) within an eccentric cellular mass (right). The outer theca interna (TI) is a highly vascular layer that develops steroid secretory activity and is enclosed by the outermost theca externa (TE). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

ovaries and occasionally in pubertal ovaries, but not in adult ovaries (Anderson et al 2014).

Primary follicles

Primary follicles develop from primordial follicles. The first sign is a change in the follicle cells from flattened to cuboidal, followed by their proliferation to give rise to a follicle consisting of a wall of granulosa cells surrounded by a thick basal lamina (Fig. 75.33).

Secondary follicles

Granulosa cell proliferation continues to form a multilayered follicular wall. Stromal cells immediately surrounding the follicle begin to differentiate into spindle-shaped cells that constitute the theca folliculi and which will become the theca interna. They are later surrounded by a more fibrous layer, the theca externa. At the same time, the oocyte increases in size and secretes a thick layer of extracellular proteoglycan-rich material – the zona pellucida – between its plasma membrane and the surrounding granulosa cells of the early follicle; this is important for the process of fertilization. The granulosa cells in contact with the zona pellucida send cytoplasmic processes radially inwards; these contact and communicate with oocyte microvilli at gap junctions (Motta et al 2003).

Antral follicles

Antral follicles develop from secondary follicles; the transition is not well defined and is a continuous process. The number of granulosa cells continues to increase. Cavities begin to form between them during a pre-antral phase and are filled with a clear fluid (follicular fluid), derived largely as an exudate from the thecal vasculature, containing hyaluronate, growth factors and steroid hormones secreted by the granulosa cells. The follicle is now about 200 µm in diameter and usually lies deep in the cortex. The cavities coalesce to form one large fluid-filled space, the antrum, which is surrounded by a thin uniform layer of granulosa cells, except at one pole of the follicle where a thickened granulosa layer envelops the eccentrically placed oocyte to form the cumulus oophorus. The oocyte has now reached its maximum size of about 160 µm (including the zona pellucida) and the inner and outer thecae are clearly differentiated (Fig. 75.34). As follicles mature, the theca interna becomes more prominent and its cells more rounded and typical of steroid-secreting endocrine cells. They produce androstenedione, from which the granulosa cells synthesize oestrogens (primarily oestradiol). Follicular development is stimulated by follicle-stimulating hormone (FSH).

Preovulatory (tertiary, Graafian) follicle

Although a number of follicles can progress to the secondary stage by about the first week of a menstrual cycle, usually only one follicle develops to maturity; the remainder become atretic. The surviving follicle increases considerably in size as the antrum takes up fluid from the surrounding tissues and expands to a diameter of 2 cm. The term 'Graafian follicle' is often used to describe this mature follicular stage (vesicular ovarian follicle). The oocyte with a surrounding ring of tightly adherent cells, the corona radiata, breaks away from the follicle wall and floats freely in the follicular fluid. The primary oocyte, which has remained in the first meiotic prophase since fetal life (see Fig. 1.24), completes its first meiotic division to produce the almost equally large secondary oocyte and a small first polar body with very little cytoplasm. The secondary haploid oocyte immediately begins its second meiotic division, but when it reaches metaphase the process is arrested until fertilization has occurred. The follicle moves to the superficial cortex, causing the surface of the ovary to bulge. The tissues at the point of contact (the stigma) with the tough tunica albuginea and ovarian surface epithelium are eroded until the follicle ruptures and its contents are released into the peritoneal cavity for capture by the fimbriae of the uterine tube. The oocyte at ovulation is still surrounded by its zona pellucida and corona radiata of granulosa cells. If fertilization does not occur, it begins to degenerate after 24–48 hours.

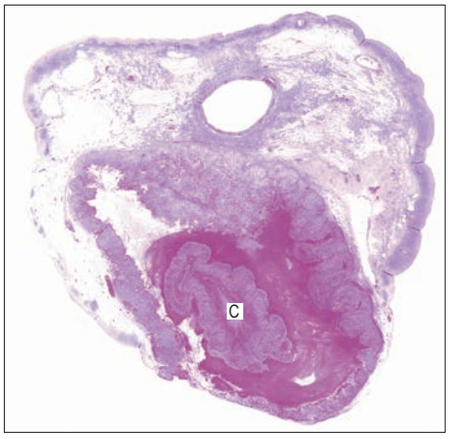

Fig. 75.35 A low-power view of a section of a human ovary, containing a corpus luteum (C). (Courtesy of Mr Peter Helliwell and the late Dr Joseph Mathew, Department of Histopathology, Royal Cornwall Hospitals Trust, UK.)

Corpus luteum

After ovulation, the remainder of the follicle becomes the corpus luteum (Fig. 75.35). The walls of the empty follicle collapse and fold. The granulosa cells increase in size and synthesize a cytoplasmic carotenoid pigment (lutein), giving them a yellowish colour (hence, corpus luteum). These large (30–50 µm) granulosa lutein cells form most of the corpus luteum. The basal lamina surrounding the follicle breaks down and numerous smaller theca lutein cells infiltrate the folds of the cellular mass, accompanied by capillaries and connective tissue. Extravasated blood from thecal capillaries accumulates in the centre as a small clot, but this rapidly resolves and is replaced by connective tissue. All lutein cells have a cytoplasm filled with abundant smooth endoplasmic reticulum, characteristic of steroid-synthesizing endocrine cells. Granulosa lutein cells secrete

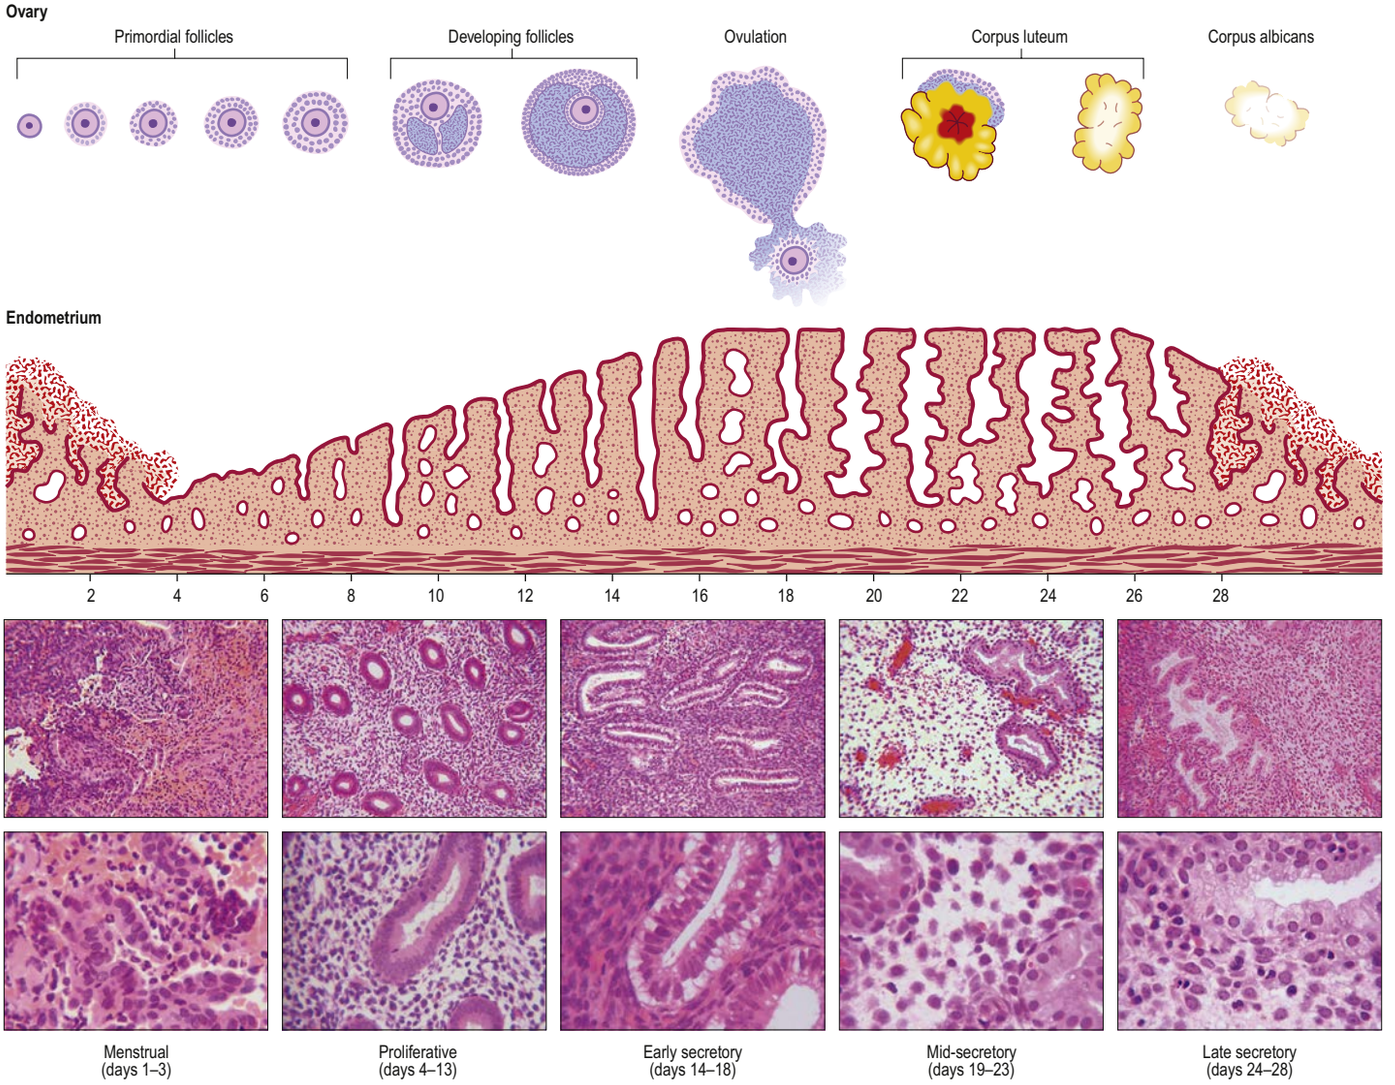

Fig. 75.36 Stages in the menstrual cycle with concomitant changes in the endometrium. Note that developing antral follicles are selected from cohorts of follicles recruited in earlier cycles. The ten lower panels are histological sections of endometrium at the cycle times indicated (low magnification on top and high magnification below in each case).

progesterone and oestradiol (from aromatization of the androstenedione synthesized by theca lutein cells). The two cell types also respond differently to circulating gonadotropins: theca lutein cells respond to luteinizing hormone (LH) and granulose lutein cells to FSH. Theca lutein cells express receptors for human chorionic gonadotrophin (hCG). If the oocyte is not fertilized, the corpus luteum (of menstruation) functions for 12–14 days after ovulation, then atrophies. The lutein cells undergo fatty degeneration, autolysis, removal by macrophages and gradual replacement with fibrous tissue. Eventually, after 2 months, a small, whitish, scar-like corpus albicans is all that remains.

If fertilization does occur, implantation of the blastocyst into the uterine endometrium usually begins 7 days later and the embryonic trophoblast then starts to produce hCG. The chorionic gonadotrophin stimulates the corpus luteum of menstruation to grow and it becomes a corpus luteum of pregnancy. It normally increases in diameter from 10 mm to 25 mm at 8 weeks of gestation and can be seen clearly on ultrasound. It secretes progesterone, oestrogen and relaxin and functions throughout pregnancy, although it gradually regresses as its endocrine functions are largely replaced by the placenta after 8 weeks' gestation. Its diameter is reduced by the end of pregnancy to 1 cm. Over the next few months it degenerates, like the corpus luteum of menstruation, to form a corpus albicans.

Ovarian medulla

The ovarian medulla is highly vascular. It contains numerous veins and spiral arteries that enter the hilum from the mesovarium and lie within a loose connective tissue stroma (Delson et al 1948). Small numbers of cells (hilus cells) with characteristics similar to interstitial (Leydig) cells in the testis are found in the medulla at the hilum; they may be a source of androgens.

Menopause

At the menopause, ovulation ceases and various microscopic changes ensue within the ovarian tissues. The stroma becomes denser, the tunica albuginea thickens and the ovarian surface epithelium thins. However, many follicles persist within the cortex.

MENSTRUAL CYCLE

The onset of menstruation (menarche) occurs between the tenth and seventeenth years of life, with a peak between 12 and 14 years. The uterus, ovaries and vagina undergo changes during the menstrual cycle, which normally lasts approximately 28 days. Usually, a single mature follicle ruptures mid-cycle (approximately day 14 of a 28-day cycle) to release a secondary oocyte. The wall of the follicle is then transformed into the corpus luteum, which secretes progesterone (luteal phase). About 10 days after ovulation the corpus luteum begins to regress, then it ceases to function and is replaced by fibrous tissue. The breakdown of the endometrium that follows this cessation of function is due to the falling levels of progesterone and oestrogen as the corpus luteum degenerates.

The changes that occur in the endometrium during the menstrual cycle can be divided into three phases: proliferative, secretory and menstrual (Fig. 75.36).

Proliferative phase

During the early proliferative phase, even before the menstrual flow ceases, the epithelium from the persisting basal parts of the uterine glands grows over the surface of the endometrium, which has been denuded by menstruation. Re-epithelialization is complete 5–6 days

after the start of menstruation. Initially, the tissue is only 1–2 mm thick and is lined by low cuboidal epithelium. The glands are straight and narrow and their lining cells are low columnar. The apical cell surface contains microvilli; some cells are ciliated. The stroma is dense and contains small numbers of lymphocytes. During days 10–12 of the proliferative phase, the endometrium thickens. Cells divide in response to rising levels of oestrogen, which is produced by the ovary and acts through receptors present on both the stromal and the epithelial cells. The glands become tortuous and their lining epithelial cells become tall columnar in nature (Fritz and Speroff 2011).

Secretory phase

The secretory phase coincides with the luteal phase of the ovarian cycle. The endometrial changes are driven by progesterone and oestrogen, secreted by the corpus luteum. Steroid receptors in the endometrium activate a programme of new gene expression that over the following 7 days produces a highly regulated sequence of differentiative events, presumably required to prepare the tissue for blastocyst implantation. Part of the response is direct, but there is evidence that some of the effects are mediated through growth factors (Fritz and Speroff 2011). The first morphological effects of progesterone are evident 24–36 hours after ovulation (which occurs approximately 14 days before the next menstrual flow). During the early secretory phase, glycogen masses accumulate in the basal cytoplasm of the epithelial cells lining the glands, where they are often associated with lipids; giant mitochondria appear. There is an obviously increased polarization of the gland cells: nuclei are displaced towards the centre of the cells, and Golgi apparatus and secretory vesicles accumulate in the supranuclear cytoplasm. The nuclear channel system is prominent and the nuclei enlarge. Nascent secretory products can be detected immunohistochemically within the cells. Progestational effects on the stroma (known as the decidual reaction) are also evident in the early secretory phase. The nuclei are enlarged and the packing density of the resident stromal cells increases, due in part to the increase in volume of gland lumina and the onset of secretory activity in the epithelial compartment.

By the mid-secretory phase, the endometrium can be up to 6 mm deep. The basal epithelial glycogen mass is progressively transferred to the apical cytoplasm and nuclei return to the cell bases. The Golgi apparatus dilates and produces glycogen, mucin and other glycoproteins, secreted from the glandular epithelium into the lumen by a combination of apocrine and merocrine mechanisms; this activity reaches a maximum 6 days after ovulation. These secretory changes are considerably less pronounced in the basal gland cells and the luminal epithelium than in the glandular cell population of the functional layer. There is a notable stromal oedema and a corresponding decrease in the density of collagen fibrils. At the same time, the endoplasmic reticulum and Golgi apparatus become more prominent, and collagen is synthesized and degraded, presumably reflecting ongoing matrix remodelling.

During the late secretory phase, glandular secretory activity declines. Decidual differentiation occurs in the superficial stromal cells that surround blood vessels; this transformation includes nuclear rounding and an increased cytoplasmic volume, reflecting an increase in and dilation of the rough endoplasmic reticulum and Golgi systems, and cytoplasmic accumulation of lipid droplets and glycogen. The cells begin to produce basal lamina components including laminin and type IV collagen.

Ultrasound imaging of the uterus and its contents

Ultrasound is frequently used in the clinical evaluation of the endometrium. During the early secretory phase the endometrium is identified as a thin echogenic line, a consequence of specular reflection from the interface between its opposing surfaces. During the late proliferative phase the endometrium appears as a triple layer: a central echogenic line (produced by the apposed endometrial surfaces), surrounded by a thicker hypoechoic functional layer and bounded by an outer echogenic basal layer. During the secretory phase, the functional layer surrounding the echogenic line becomes more hyperechoic because of the increased mucus and glycogen within the glands and the increased number of interfaces caused by the development of tortuous spiral arteries (**Fig. 75.37**).

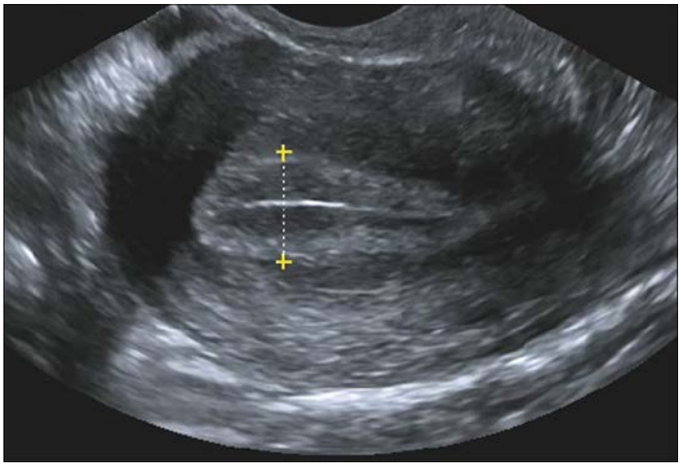

Fig. 75.37 Transvaginal ultrasound of the uterus, showing the triple-layered endometrium. The central echogenic line is produced by the interface of the opposing surfaces of the endometrium. The functional layer of the endometrium surrounding the echogenic line is hypoechoic on the left, in keeping with late proliferative phase, but is becoming more hyperechoic on the right, indicating the early secretory phase.

Menstrual phase

The premenstrual endometrium consists of two layers, an upper two-thirds, the functional layer (which will be shed), overlying the basal layer (which is retained). In the upper part of the functional layer (the compact layer), the necks of the glands are only slightly expanded and the stromal cells show a distinct decidual reaction. In the deeper part of the functional layer (the spongy layer) the uterine glands are tortuous, dilated and, ultimately, separated from one another by a small amount of connective tissue. The basal layer, next to the myometrium, is thin and contains the tips of the uterine glands embedded in an unaltered stroma.

As the corpus luteum regresses, those parts of the stroma showing a decidual reaction, together with the glandular epithelium, undergo degenerative changes and the endometrium often thins. Blood escapes from the superficial vessels of the endometrium, forming small haematomata beneath the surface epithelium (see below). The functional layer, next to the free surface, is shed piecemeal, leaving mainly the basal layer adjacent to the myometrium; 65–75% of the thickness of the endometrium can be shed. Blood and necrotic endometrium then begin to appear in the uterine lumen, to be discharged from the uterus through the vagina as the menstrual flow, which usually lasts 3–6 days.

Vascular changes within the uterus during the menstrual cycle

The vascular bed of the endometrium undergoes significant changes during the menstrual cycle. The arteries to the endometrium arise from a myometrial plexus and consist of short, straight vessels to the basal portion of the endometrium and more muscular spiral arteries to its superficial two-thirds. The venous drainage, consisting of narrow perpendicular vessels that anastomose by cross-branches, is common to both the superficial and the basal layers of the endometrium. The capillary bed consists of an endothelium with a basal lamina that is discontinuous during the proliferative phase but becomes more distinct by the mid-secretory phase. Pericytes make contact with the endothelial cells via cytoplasmic extensions that project through the basal lamina. Enlargement of the pericytes starts early in the secretory phase and leads to a conspicuous cuff of cells in the mid- and late secretory phases. The arterial supply to the basal part of the endometrium remains unchanged throughout the menstrual cycle. However, the spiral arteries supplying the compact (superficial) layer lengthen disproportionately, becoming increasingly coiled as their tips approach the uterine epithelium. This leads to a slowing of the circulation in the compact layer with some vasodilation. Immediately before the menstrual flow, these vessels begin to constrict intermittently, causing stasis of the blood and anaemia of the compact layer. During the periods of relaxation of the vessels, blood escapes from the devitalized capillaries and veins, causing the menstrual blood loss. The breakdown of the endometrium is a consequence of the falling levels of progesterone and oestrogen as the corpus luteum degenerates.

PREGNANCY AND PARTURITION

During pregnancy many morphological changes occur in the female reproductive system and associated abdominal structures. The uterus enlarges to accommodate the developing fetus and placenta, and

Fig. 75.38 Transabdominal ultrasound at 12 weeks, showing measurement of the crown–rump length to calculate the gestational age.

various alterations take place in the pelvic walls, floor and contents that allow for this expansion, and which anticipate parturition. At the end of gestation dramatic changes occur that facilitate the passage of the baby through the birth canal and, subsequently, allow the pelvic organs to return to the non-pregnant state (involution).

On average, human gestation is approximately 280 days (or 40 weeks) from the date of the last menstrual period (LMP): the duration of pregnancy can be expressed in postmenstrual weeks (Ch. 23). However, cycle irregularity or inaccurate recollection can lead to an inaccurate menstrual history: an accurate gestational age can be calculated by ultrasound measurement of the fetal crown–rump length during the first trimester (Fig. 75.38). A discrepancy of more than 5–7 days from the LMP-estimated age is usually reason to revise the estimated date of confinement. For females presenting after the first trimester, gestational dating can be based on other sonographically obtained fetal biometric measurements, such as the fetal biparietal diameter, head circumference and femur length, although precision gradually decreases in later pregnancy (see Fig. 23.5). The increased accuracy of gestational dating using sonographic fetal biometry rather than menstrual history alone has significantly reduced the number of pregnancies requiring induction of labour for post-term females.

Uterus in pregnancy

The function of the uterus in pregnancy is to retain the developing fetus and to provide a protected environment until a stage at which the fetus is capable of surviving *ex utero*. The uterus must grow, facilitate delivery of the fetus and then involute.

The uterus grows dramatically during pregnancy, increasing in weight from about 50 g at the beginning of pregnancy to up to 1 kg at term. Most of the weight gain is the result of increased vascularity and fluid retention by the myometrium. The increased growth of the uterine wall is driven by a combination of mechanical stretching and endocrine input. The mechanical load imposed on the uterine wall as gestation advances induces hypertrophy of uterine smooth muscle cells and is the major stimulus for increasing smooth muscle mass. There is some hyperplasia early in pregnancy, mainly from the growth of the media of the myometrial arteries and veins. The myometrium is relatively unresponsive to additional endocrine stimulation during most of pregnancy, a relative quiescence that is in part attributed to progesterone. However, a number of growth factors, e.g. insulin-like growth factor-1 (IGF-1), have been identified, which interact with oestrogen in promoting uterine growth. The myometrium thins with advancing gestation from 2–3 cm thick in early pregnancy to 1–2 cm at term.

The upper third of the cervix is gradually taken up into the body of the uterus during the second month to form the 'lower segment' (Fig. 75.39). The isthmus of the uterus hypertrophies like the body of the uterus during the first trimester and triples in length to about 3 cm. From the second trimester, the wall of the isthmus and that of the body are the same thickness and their junction is no longer visible externally. This condition persists until the middle of the third trimester, when the lower uterine segment thins to less than 1 cm in thickness. The thicker myometrium above this transition is the main contractile portion of the uterus that will generate the expulsive forces during labour. The thin lower uterine segment, which is thought to correspond to the level of the anatomical internal os, is just superior to the bladder and the reflections of the vesico-uterine pouch. It is more compliant and allows for the descent of the fetus in late pregnancy and during labour: it is the preferred site of incision during a caesarean section because it is thinner and less vascular than the upper uterus. In addition, because it is less contractile, there is a lower risk of uterine rupture in subsequent pregnancies than with an incision made in the body of the uterus during a 'classic' caesarean section.

The growing uterus generally emerges from the pelvis by postmenstrual week 12 and can be palpated on the maternal abdomen just above the pubic symphysis. By the 20th week of pregnancy the uterine fundus is at the level of the umbilicus and it reaches the xiphoid process of the sternum by 36 weeks. After 24 weeks, the distance between the pubic symphysis and the fundus of the uterus generally corresponds to the number of postmenstrual weeks and is often used in clinical care as a screening method to detect a pregnancy that is measuring suspiciously larger or smaller than expected. If there is more than a 2 cm discrepancy between uterine size and gestational week, a more accurate, sonographic assessment of fetal size and amniotic fluid volume is indicated.

Cervix of the uterus during pregnancy

During pregnancy the cervix of the uterus is a relatively rigid, fibromuscular structure that retains the developing fetus within the uterus. The rigidity of the cervix appears to be related to the orientation of its collagen fibres within a regular connective tissue matrix. The cervix gradually softens and shortens in the weeks preceding labour. During active labour, the cervix dilates to allow the fetus to descend through the birth canal. The exact processes that allow softening, effacement and dilation of the cervix are unclear, but are believed to include remodelling of the connective tissue matrix, probably mediated by increased activities of enzymes such as matrix metalloproteinase-1, reduced collagen concentration, a significant increase in the water content in the cervix, macrophage and neutrophil infiltration, and an increased level of apoptosis.

Transvaginal ultrasound examination allows for a robust evaluation of the cervix during pregnancy. Cervical length, dilation of the anatomical internal os and bulging of the membranes into the cervical canal can all be assessed. A shortened cervical length in mid-gestation detected by transvaginal ultrasound is a strong risk factor for premature delivery and has been used clinically to identify females at high risk of preterm delivery in order to plan appropriate management (Fonseca et al 2007, Owen et al 2009, Hassan et al 2011). Emerging sonographic and MRI technologies are being used to investigate both the biomechanical properties and the microstructure of the cervix in pregnancy and are beginning to shed light on the poorly understood mechanisms involved in both normal and pathological cervical shortening in human pregnancy (Feltovich et al 2012, House et al 2013). The advent of commercially available histochemical studies such as those testing for fetal fibronectin also look for substances known to increase with dilation of the cervix (Daskalakis et al 2000).

Relations of the uterus in pregnancy

With uterine expansion, the ovaries and uterine tubes are displaced upwards and laterally. The round ligaments of the uterus become hypertrophied and their course from the uterus down to the deep inguinal ring becomes more vertical. The broad ligaments tend to open out to accommodate the massive increase in sizes of the uterine and ovarian vessels. The uterine veins in particular can reach about 1 cm in diameter and appear to act as a significant reservoir for blood during uterine contractions. Lymphatics and nerves expand their territories (the significance of this increased innervation is not clear because paraplegic females are able to labour normally, albeit painlessly). Later in pregnancy, the increase in intra-abdominal pressure produced by the gravid uterus can cause eversion of the umbilicus. On the skin over the abdomen, a combination of stretching and hormonal changes can produce stretch marks (striae gravidarum). In multiparous patients, diastasis (divarification) of right and left rectus abdominis can occur to accommodate the enlarging fundus of the uterus further. In the supine position, the gravid uterus can cause aortocaval compression, leading to reduced venous return to the heart and decreased cardiac output. In some females this can result in symptomatic hypotension and symptoms of nausea and syncope. These symptoms are minimized if the patient lies on her left side, thereby deviating the gravid uterus and reducing compression of the inferior vena cava.

The jejunum, ileum and transverse colon tend to be displaced upwards by the enlarging uterus, whereas the caecum and appendix are displaced to the right and the sigmoid colon posteriorly and to the left. Upward and lateral displacement of the appendix in later pregnancy can cause difficulties in the diagnosis of appendicitis. The ureters are pushed laterally by the enlarging uterus and, in late pregnancy, can be

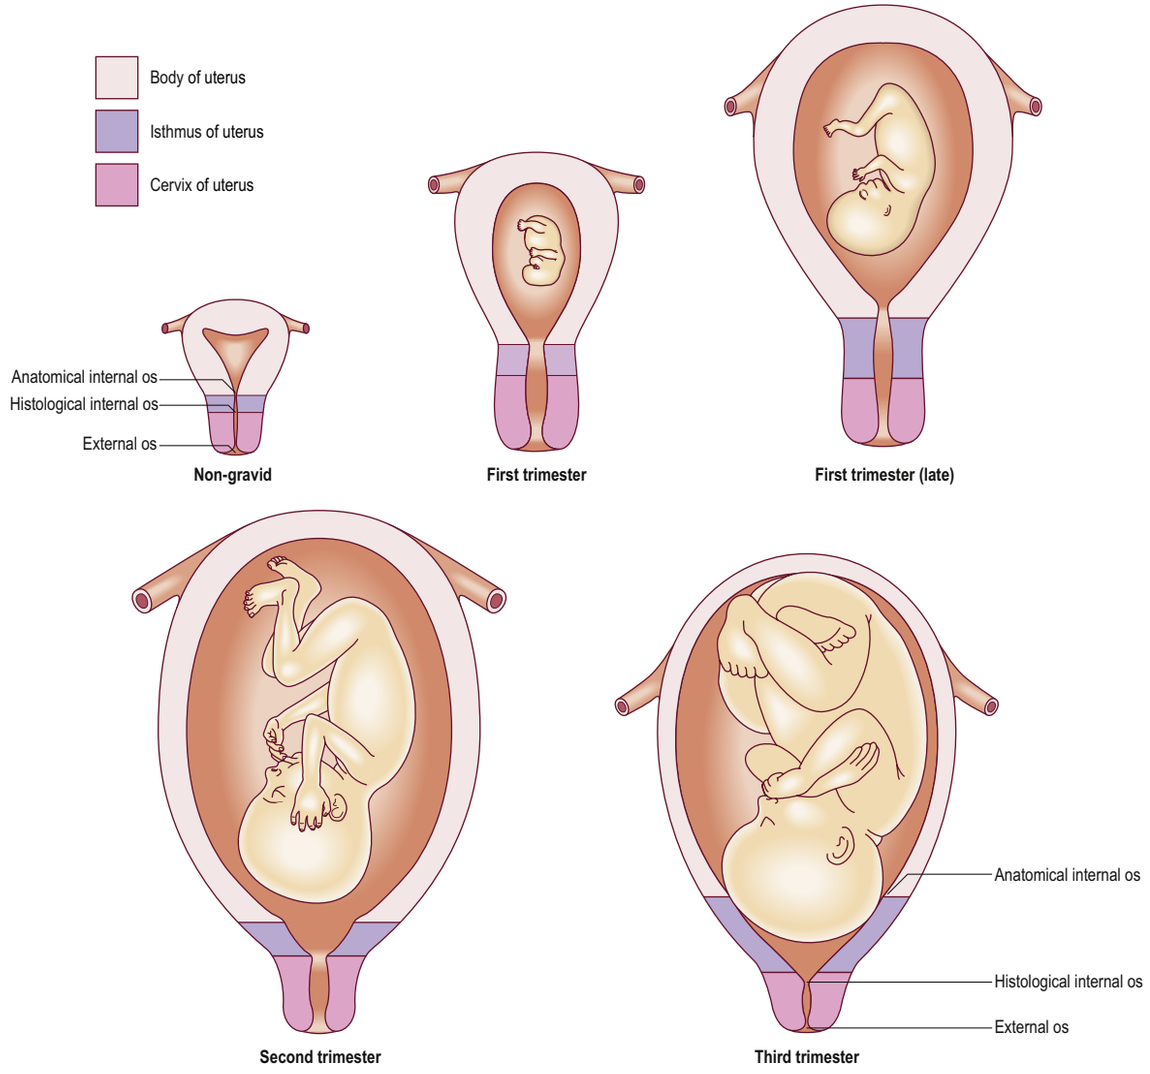

Fig. 75.39 A frontal view of the uterus, showing the location and extent of the body, isthmus and cervix in the non-gravid and gravid uterus at different stages in gestation. The isthmus forms the lower uterine segment with advancing gestation.

compressed at the level of the linea terminalis, resulting in hydronephrosis and pain in the lower back. However, mild ureteric dilation is normal in pregnancy and is caused by progesterone-induced relaxation of smooth muscle in the ureteric walls. The axis of the uterus is often dextrorotated by the presence of the sigmoid colon; this rotation must be considered when a hysterotomy is performed at the time of caesarean section to avoid injuring the large uterine vessels located bilaterally.

Pelvic changes in pregnancy

A pregnant uterus changes the centre of gravity of the body, especially in late pregnancy. In order to compensate for this, the mother tends to straighten her cervical and thoracic spine and throw her shoulders back, resulting in a compensatory increase in lumbar lordosis. There is also a softening of the pubic symphysis and sacroiliac joints, caused by production of relaxin and other pregnancy hormones, leading to mild pelvic instability that can result in a waddling gait. Softening also produces an increase in pelvic diameter, which is beneficial during labour. Significant joint relaxation can lead to pubic symphysis diastasis, which in severe cases can produce debilitating pain during walking.

Advances in three-dimensional ultrasound imaging permit real-time visualization of the anatomical relations and adaptations of the pelvic floor during pregnancy. They also make it possible to identify a pelvic diaphragm injury that can lead to symptomatic postpartum pelvic organ prolapse (Dietz and Lanzarone 2005, Shek et al 2012).

Placental development

The placenta is attached to the uterus at the point where the blastocyst becomes embedded, which is determined by a multitude of molecular signalling pathways (Ch. 9). In early pregnancy, the placental disc occupies a large proportion of the uterine cavity and will often appear to be situated near the anatomical internal os of the uterus. In most cases, growth and stretching of the uterus will usually draw the placenta upwards, away from the cervix of the uterus, by the end of pregnancy.

In about 1% of pregnancies, the position of the placenta will remain over or in close proximity to the anatomical internal os of the uterus at the end of pregnancy (**Fig. 75.40A–B**). This condition is called placenta praevia and can be associated with vaginal bleeding during pregnancy and labour. If the placenta covers the anatomical internal os of the uterus, or the lower edge is less than 1–2 cm from the anatomical internal os (marginal placental praevia), delivery by caesarean section is generally indicated.

Normal trophoblastic development includes the remodelling of maternal spiral arterioles to allow for low-resistance flow into the intervillous space. The uteroplacental vasculature is thus a low-resistance, high-capacitance system. Antenatal ultrasound Doppler velocimetry can be used during pregnancy to assess the resistance to flow in both the uterine and the umbilical arteries and can help in the management of high-risk pregnancies (**Fig. 75.41**).

Abnormally invasive placentation can occur when trophoblastic tissue invades through the decidua basalis and reaches the myometrium; this can lead to a morbidly adherent placenta and significant maternal morbidity. This condition, placenta accreta, occurs in approximately 3 per 1000 births. When the trophoblastic tissue invades the myometrium it is referred to as placenta increta; if the placental tissue reaches the uterine serosa it is called a placenta percreta. In extreme cases, a placenta percreta can also invade as far as the maternal bladder mucosa. These conditions often require a hysterectomy. Although several characteristics are known to increase the risk for placental invasion (such as placenta praevia, smoking, and multiple gestation), prior

uterine surgery, especially multiple prior caesarean sections, is the most significant risk factor (Fig. 75.42).

Labour

The onset of labour is defined as the combination of regular uterine contractions that are of sufficient intensity to produce progressive effacement and dilation of the cervix of the uterus. The process of labour is described in three main stages.

First stage

The first stage of labour is the period during which the cervix progressively dilates until the fetus is able to descend into the birth canal and the cervix of the uterus is no longer palpable on vaginal examination. There is little change in the uterine volume because myometrial contractions are isometric, so there is minimal shortening of the muscle fibres. Progress is determined by the equilibrium between forces generated by myometrial contractions, especially from the fundus, and the resistance of the cervix.

Second stage

The second stage of labour begins once the cervix is fully dilated, and ends with the delivery of the fetus. Cervical resistance is lost and myometrial activity results in isometric contractions that aid descent of the fetus through the birth canal. The head of the fetus usually enters the pelvis with the occiput facing laterally. As the head descends further, the occiput contacts the gutter-shaped levator ani and this promotes flexion and rotation of the occiput to the anterior position. With further descent, the occiput escapes under the pubic symphysis and the head is born by extension. At this point, the head of the fetus regains its normal relationship with its shoulders, and there is slight rotation (or restitution) of the head. Further external rotation occurs as the leading shoulder is directed medially by the maternal pelvic diaphragm. The body of the fetus is now born by lateral flexion as one shoulder slips underneath the pubic symphysis and the posterior shoulder is drawn over the frenulum of the labia minora.

Third stage

The third stage of labour is the time from delivery of the fetus until delivery of the placenta. Prior to separation of the placenta, a large proportion of the mother's cardiac output passes through the uterine circulation. After separation in the third stage of labour, maternal exsanguination is only prevented by marked uterine contraction; the criss-crossing myometrial fibres act as a tourniquet, restricting blood flow to the area that was the placental site. This process is usually expedited clinically by the administration of oxytocic drugs in an attempt to limit maternal blood loss. Any condition that predisposes to poor uterine contraction, such as retained placental tissue, polyhydramnios or multiple gestations, will increase the likelihood of postpartum haemorrhage (Salafia et al 2005).

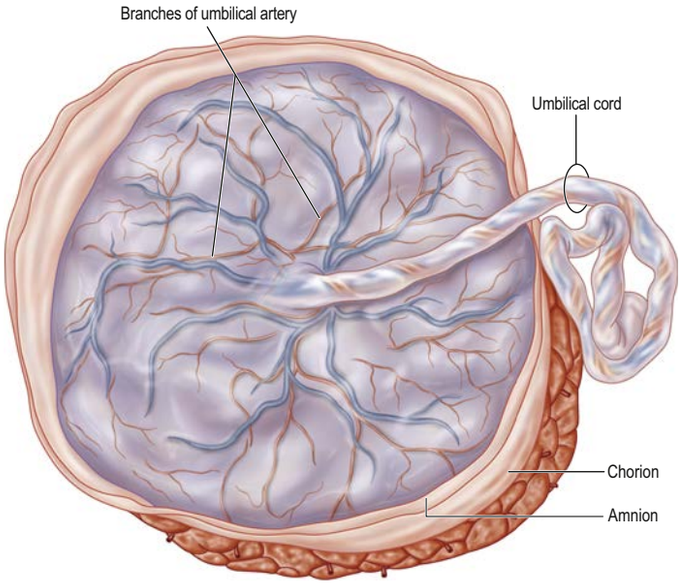

Fig. 75.43 Drawing of the fetal surface of a recently delivered placenta. The spiral umbilical vessels in the umbilical cord and their radiating branches are seen through the transparent amnion. The maternal surface is exposed in the lower and right corner of the figure. Note the fringes of amnion and chorion, the majority of which have been cut away near the placental margin.

Placenta after delivery

The placenta separates from the uterine wall along the plane of the functional layer and extends beyond the placental area, detaching the villous placenta with associated fibrinoid matrix and small amounts of basal decidua, the chorioamnion, together with a superficial layer of the fused capsular decidua, and the parietal decidua. When the placenta and membranes have been expelled, a thin functional layer remains above the uterine basal layer; it soon degenerates and is cast off in the early part of the puerperium. A new epithelial lining is regenerated from the remaining basal layer.

The expelled placenta is a flattened discoid mass with an approximately circular or oval outline (Fig. 75.43). It has an average volume of 500 ml (range 200–950 ml), a mean weight of 470 g (range 200–800 g), a diameter of 185 mm (range 150–200 mm), a thickness of 23 mm (range 10–40 mm), and a total villous surface area of 12–14 m^2. It is thickest at its centre (the original embryonic pole), and rapidly thins towards its periphery, where it continues as the chorion laeve (smooth chorion). The size of the placenta correlates well with the birth weight of the neonate.

Macroscopically, the fetal or inner surface, covered by amnion, is smooth, shiny and transparent, so that the mottled appearance of the subjacent chorion, to which it is closely applied, can be seen. The umbilical cord is usually attached near the centre of the fetal surface, and branches of the umbilical vessels radiate out under the amnion from this point; the veins are deeper and larger than the arteries. The maternal surface of the placenta is finely granular and mapped into some 15–30 lobes by a series of fissures or grooves. The placental lobes, which are often somewhat loosely termed cotyledons, correspond in large measure to the major branches of the umbilical vessels. The grooves correspond to the bases of incomplete placental septa, which become increasingly prominent from the end of the first trimester. They extend from the maternal aspect of the intervillous space towards the chorionic plate (see Fig. 9.5) but do not quite reach it. The septa are complex structures composed of components of the cytotrophoblastic shell and residual syncytium, together with maternally-derived material including decidual cells, occasional blood vessels and gland remnants, collagenous and fibrinoid extracellular matrix, and, in the later months of pregnancy, foci of degeneration.

In multiple pregnancies, the number of placentas is determined by the zygosity; for example, in twin gestations, dizygotic pregnancies will always have two placentas (dichorionic). Monozygotic pregnancies usually have a single placenta (monochorionic), but about one-third will have two; the number is determined by the timing of splitting of the embryonic mass (see Ch. 8 and Fig. 8.9). If the split occurs within 3 days of fertilization, each fetus will have its own placenta and amniotic sac (dichorionic diamniotic); splitting after the third day following fertilization results in a monochorionic diamniotic pregnancy (two amniotic sacs) and vascular communication within the two placental

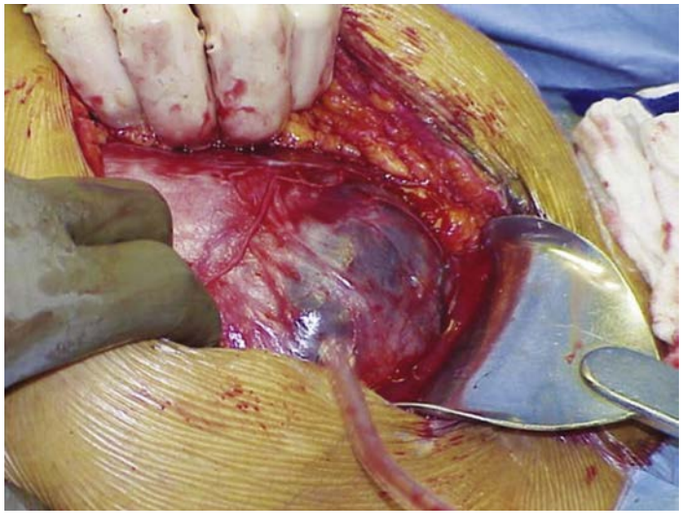

Fig. 75.42 Intraoperative photograph taken during a caesarean section in a patient with a placenta accreta. Note the hypervascularity caused by the placental tissue invading into, and almost through, the myometrial layer of the lower uterine segment, which is still covered with its serosal layer.

circulations (Fig. 75.44); splitting after the ninth day results in a single placenta and single amniotic sac (monochorionic monoamniotic); and splitting after the twelfth day results in conjoined twins.

Placental variations

The umbilical cord is usually attached near the centre of the placenta, although it can occasionally insert more laterally and closer to the placental margin; this condition is known as a battledore placenta (Fig. 75.45). Occasionally, the cord fails to reach the placenta itself and ends in the membranes as a velamentous insertion. When insertion of the cord is velamentous, the larger branches of the umbilical vessels traverse the membranes before they reach and ramify on the placenta (Fig. 75.46). They travel unprotected through the membranes to the placenta, and this puts the fetus at risk because compression or tearing of the vessels can disrupt blood flow to and from it. This can be particularly problematic when the vessels present themselves across the external os of the uterus, a condition called vasa praevia. An accessory (succenturiate) placental lobe is occasionally present, connected to the main organ by membranes and blood vessels. If it is inadvertently retained *in utero* after delivery of the main placental mass it can cause postpartum haemorrhage or infection. Other variations include membranous placenta, in which villous stems and their branches persist over the whole chorion; and vallate (circumvallate) placenta, where the placental margin is undercut by a deep groove caused by an abnormally central insertion of the membranes (Fig. 75.47).

COMMENTARY

8.1

The mesentery and the mesenteric model of abdominal compartmentalization

John Calvin Coffey, Kevin Gerard Byrnes, Peter Dockery, Dara Walsh

Abdominal compartmentalization

The peritoneal model of abdominal compartmentalization has long been the starting point for descriptions of abdominal anatomy. According to this model, abdominal digestive organs are organized along peritoneal lines and the position of each is described using the terms 'intra'-, 'extra'-, or 'retro'-peritoneal (Snell 1992). However, some organs have both intra- and retro-peritoneal regions, a feature that is not explained by conventional embryological models of abdominal development. For example, the duodenum in the adult is 'retro'-peritoneal in position while the rest of the small intestine is 'intra'-peritoneal. The peritoneal landscape appears complex and regionalized into sacs, fossae and pouches that are described using an array of terms including fold, ligament, membrane and reflection. This heterogeneous terminology makes understanding abdominal anatomy challenging.

Abdominal organs are usually described as being individually connected to the rest of the body, typically mediated by a network of vascular and peritoneal links. The small intestine and the transverse and sigmoid colons are exceptions to this pattern and are conventionally described as linked to the rest of the body via their respective 'mesenteries' (Snell 1992). The peritoneal and fascial models that have been generated by the concept of multiple mesenteries are dauntingly complex. Fasciae within the abdomen are described as individual entities, a practice that arose in part because they were described separately, e.g. Toldt's, Denonvilliers' and Waldeyer's fasciae (Congdon et al 1942, Coffey and Kiran 2017).

Mesenteric anatomy distal to the duodenojejunal flexure was clarified by the demonstration that the mesentery is continuous and connects the small and large intestines to the rest of the body (Coffey et al 2017). This perspective also explains peritoneal and fascial anatomy distal to the duodenojejunal flexure (Coffey et al 2017). Further research has now clarified the organization of the entire abdominal mesentery and all abdominal digestive organs, peritoneum and fasciae, on the basis of a mesenteric- rather than a peritoneal-based model of abdominal anatomy and compartmentalization.

Mesenteric model of abdominal compartmentalization

The abdominal mesentery is a collection of tissues that supports the growth of all abdominal digestive organs during embryological development and connects those organs to systems of the body throughout life. It is a continuous organ, beginning and ending at the oesophagogastric and anorectal junctions, respectively; all abdominal digestive organs are connected to it (Coffey and O'Leary 2016). The mesentery can be subdivided into three regions (upper, mid and lower) using two axes: the coeliac trunk represents the inferior boundary of the upper region and the upper limit of the mid-region (**Fig. 8.1.1**), and the superior mesenteric axis is the distal limit of the mid-region and the proximal limit of the lower region (see Fig. 8.1.1).

Emerging data indicate that the abdomen and its contents are compartmentalized along mesenteric lines. According to the mesenteric-based model of abdominal anatomy and compartmentalization, the abdomen is divided into two principal domains, mesenteric and non-mesenteric. The mesenteric domain contains all abdominal digestive organs positioned on the mesentery. The non-mesenteric domain comprises all non-digestive organs (i.e. the genitourinary organs) positioned on the musculoskeletal mainframe of the abdomen. The domains are connected, attached and linked anatomically. They are *connected* at the arterial inflow and venous drainage of the mesentery. The arterial inflow occurs at the coeliac trunk, and superior and inferior mesenteric arteries. Venous drainage occurs at the junction between the hepatic veins and the inferior vena cava. Both domains are *attached*, which means the posterior surface of the mesenteric domain is apposed to the anterior surface of the non-mesenteric domain: there is a fascia between apposed surfaces (Coffey et al 2017). The junction between fascia and the overlying mesentery is a conceptual zone that surgeons access when they detach the mesentery from its attachment to the posterior abdominal wall. At the periphery of the mesenteric domain, the two domains are *linked* by the peritoneal reflection, a serous mesothelial membrane that bridges the parietal peritoneum lining the non-mesenteric domain and the visceral peritoneum of the mesenteric domain.

The mesenteric-based model of abdominal compartmentalization explains several aspects of abdominal anatomy. Whilst the peritoneal landscape is generally regarded as extremely complex, it can be understood readily if approached with reference to the mesentery. From this perspective, the lining of organs of the mesenteric domain corresponds to 'visceral' peritoneum. The lining of the non-mesenteric domain corresponds to 'parietal' peritoneum. At the periphery of the mesenteric domain, parietal peritoneum detaches from the non-mesenteric domain and is reflected onto the mesenteric domain, where it continues as the lining of the latter (**Fig. 8.1.2**). The regions, sacs, pouches and cavities of the peritoneal landscape are regions of this model. Folds, ligaments and membranes are terms applied to different regions of peritoneal reflection.

Since all abdominal digestive organs are directly connected to the mesentery, it provides a reference frame for describing the positional anatomy of each. For example, the head of the pancreas is located in the mid-region of the mesentery whilst its neck and body are located in the upper region (**Fig. 8.1.3**). The location of each of the arteries supplying individual organs can also be explained in mesenteric terms. The same principle applies to the extrahepatic portal venous system. For example, the inferior mesenteric vein travels in the left mesocolon to reach the central zone of the mesentery, where it merges with the splenic and/or superior mesenteric vein to generate the hepatic portal vein (**Fig. 8.1.4**). The latter utilizes the mesoduodenum posterior to the pancreas to reach the liver. The shape of the periphery of the mesentery also explains the double spiral trajectory of the abdominal digestive tract (**Fig. 8.1.5**).

Mesenteric-based compartmentalization helps to clarify the organization of the fasciae of the abdomen. Where surfaces of the mesenteric and non-mesenteric domains are apposed, there is a fascia between them: the fasciae originally described by separate investigators are now perceived as different regions of the same tissue layer.

Mesenteric-based compartmentalization explains how abdominal digestive organs are linked to systems of the body. They are directly connected to the mesentery and, in turn, the mesentery collectively connects all of them to each system (and hence to the body). This perspective represents a radical departure from conventional descriptions, which hold that all abdominal digestive organs are centrally connected via a network of peritoneal derivatives.

Embryological development of mesenteric and non-mesenteric compartments

The earliest mesenteric correlate is a double fold of mesothelium directly connected to the developing abdominal wall along the posterior midline. Its shape changes rapidly as it stretches in different directions to generate an upper diverticulum, mid-region fold and lower region (de Bakker et al 2016). Early in development the posterior connection regresses until it is reduced to vascular and surface mesothelial (i.e. peritoneal) continuity. All abdominal digestive organs develop within, and remain connected to, the mesentery. Later in development, regions of the mesentery flatten back against the posterior abdominal wall (i.e. they become attached) as they are packaged into a final

conformation. The mesenteric primordium is disconnected well in advance of differentiation of the abdominal digestive organs (i.e. the mesentery emerges first) (Byrnes et al 2019b). In the adult setting, all abdominal digestive organs remain connected to it, and it collectively connects them all to the posterior abdominal wall. This means the mesenteric organ occupies a structural and developmental primacy in the human digestive system.

History

Interestingly, the mesenteric model of abdominal anatomy and compartmentalization is not new. There are suggestions in classical texts that it was apparent to some Italian anatomists during the Renaissance. Several drawings from this era depict a complex of structures that includes all abdominal digestive organs centred on the mesentery (Byrnes et al 2019a). A vogue developed in the 19th century for describing multiple separate mesenteries (e.g. Gray 1858), and this approach was subsequently reflected in all mainstream reference texts. The concept of multiple separate mesenteries generated a complex peritoneal and fascial landscape that hampered investigation of the mesentery, which was largely ignored until recently. Interest in the mesentery was rekindled when surgeons recognized that its resection was required for good outcomes in patients undergoing surgery for cancer of abdominal digestive organs. Re-appraisal of mesenteric anatomy and embryological development led to the recognition of mesenteric continuity and connection with all abdominal digestive organs. These anatomical properties, which were recognized after adaptation of surgical techniques to dissection of the cadaveric human abdomen, could then be combined to generate the mesenteric model of abdominal compartmentalization. They were corroborated by observations related to embryological development of the mesentery. Given this, the mesenteric model is the first to comprehensively reconcile embryological, anatomical and surgical approaches to the abdomen, fields that had diverged considerably during the past century.

Implications

The model has wide scientific and clinical implications. Because it clarifies the organization of the abdomen and its contents, it enables the abdomen to be characterized systematically (i.e. scientifically). The characterization of mesenteric organ pharmacokinetics, lymphatic angiology, radiology and immunology has recently gained considerable momentum (Dalla Pria et al 2019). The model also enables the radiologist to build a composite picture of abdominal anatomy in paediatric and adult populations, which will facilitate a non-invasive interpretation of the nature and stage of abdominal diseases (Dalla Pria et al 2019). It will guide the surgeon in applying

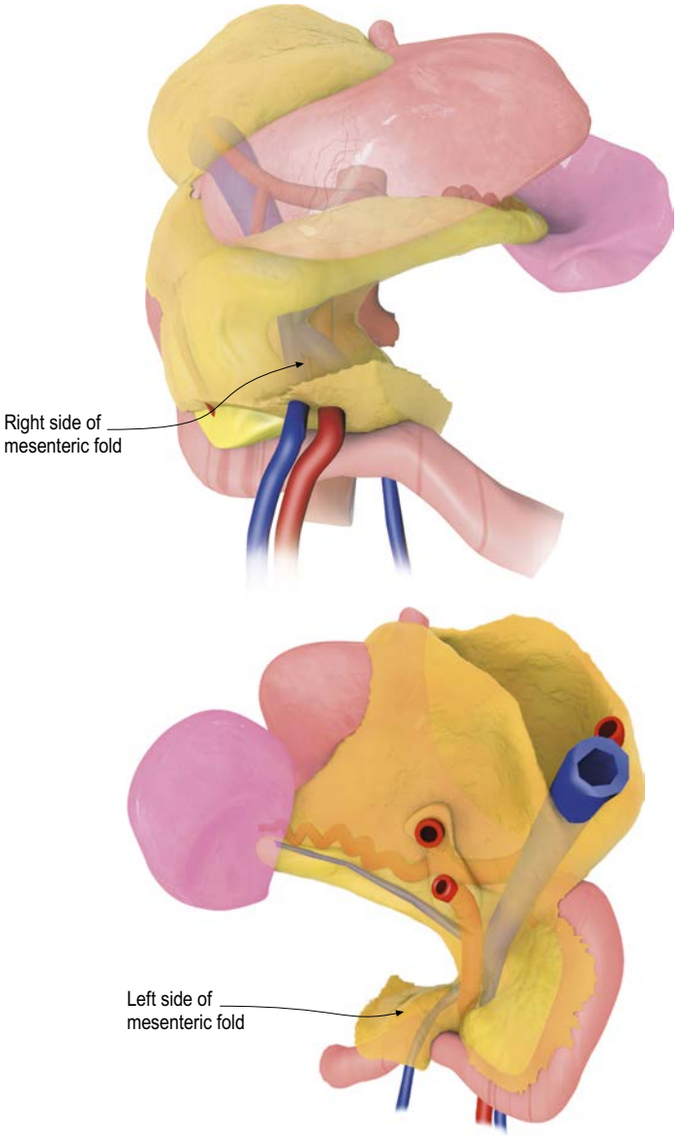

Fig. 8.1.3 The relationship of the pancreas to the mesentery. (**A**) A right lateral view of the central zone of the mesentery. The head of the pancreas is in the mesoduodenum forming the right side of the mesenteric fold at the central zone. The neck and body of the pancreas are in the mesentery of the upper region arching over the superior mesenteric artery and hepatic portal vein. (**B**) A left lateral view of the central zone of the mesentery. The position of the neck and body of the pancreas (within upper region mesentery) is apparent. The superior mesenteric artery and vein are in the apex of the central zone, where right and left sides converge, and are located posterior to the neck of the pancreas.

mesenteric-based strategies for managing intestinal cancer and inflammatory bowel disease (Heald et al 1982, Hohenberger et al 2009). For example, emerging data demonstrate that surgical techniques that reduce mesenteric inputs lead to improved outcomes in patients undergoing surgery for Crohn's disease (Coffey et al 2018, Fichera et al 2012). Mesenteric-based strategies are also showing promise in the surgical management of congenital abnormalities such as malrotation.

Future directions

It is important to determine the histological nature of the junction between each abdominal digestive organ and the mesentery. All signals that pass between the gastrointestinal tract and nervous system must traverse the mesentery. Accordingly, the gut–brain axis becomes the gut–mesentery–brain axis (Coffey and O'Leary 2016). The junction between the mesentery and abdominal digestive organ is highly relevant to the normal functioning of the body. It is noteworthy that despite the anatomical magnitude of this zone, it remains largely unstudied.

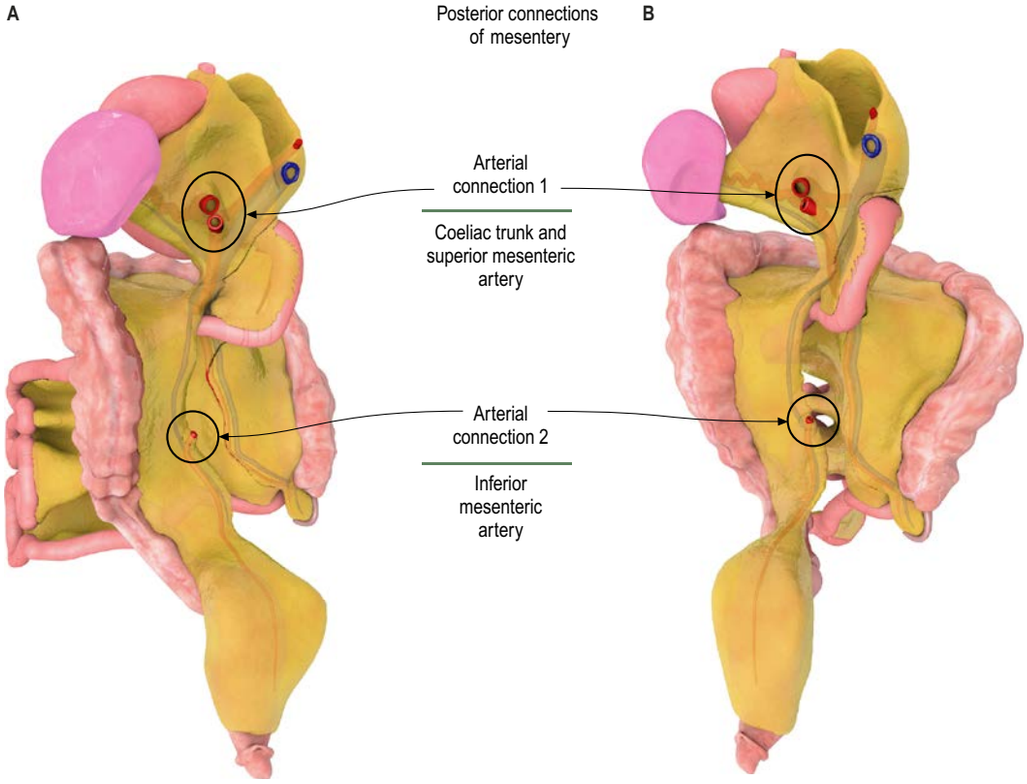

Fig. 8.1.4 Left and right (**A** and **B**, respectively) posterolateral views of the mesenteric domain demonstrating the arterial connections and the course of the inferior mesenteric vein. The latter is located in the left mesocolon and travels from here to the splenic region of the transverse mesocolon. From there it accesses the left side of the central zone of the mesenteric fold where it joins either the splenic or superior mesenteric vein to form the hepatic portal vein.

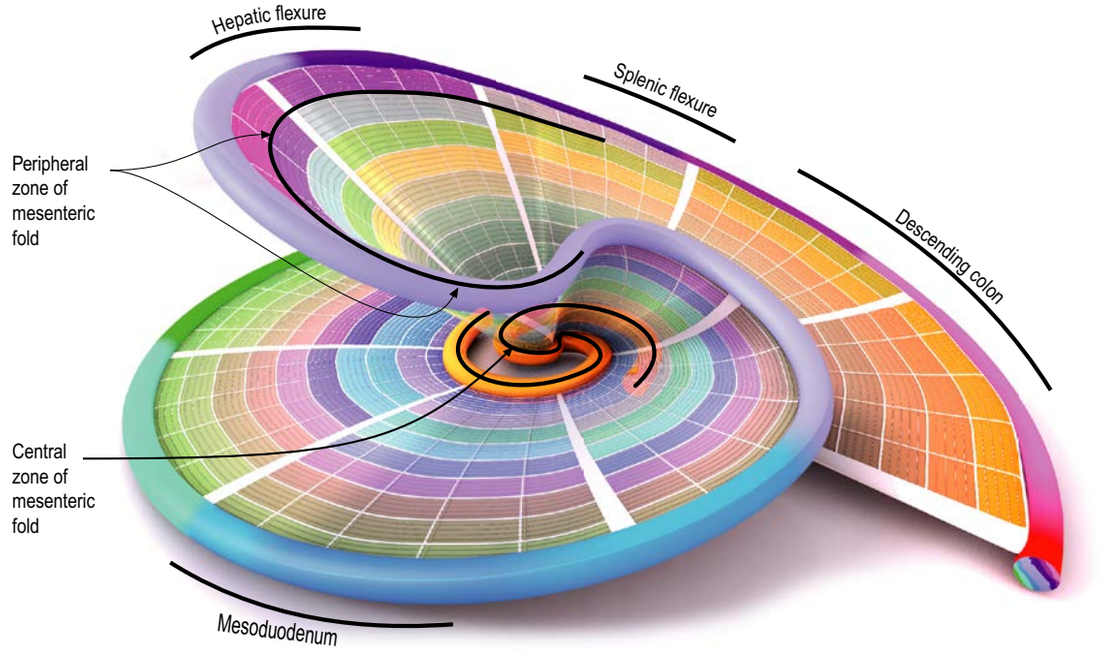

Fig. 8.1.5 Double spiral. The central zone corresponds to the central zone of the mesenteric fold and the peripheral zone corresponds to the peripheral zone of the mesenteric fold. The edge of the shape broadly corresponds to the trajectory from the duodenum to the anorectal junction. The shape explains how an object (i.e. the mesentery) can have a folded shape centrally and a double spiral shape peripherally.

The contributions of the mesentery to visceral adiposity require investigation: the scale of the mesentery means it is the single largest contributor to visceral adiposity. Given the links between visceral adiposity and atherosclerosis, diabetes and hypertension, it is feasible that mesenteric inputs are major influences on the development of these conditions (Coffey and O'Leary 2016).

The mesenteric-based model of abdominal anatomy and compartmentalization is likely to provide surgeons with an anatomical roadmap that they can follow during multivisceral transplantation and is also likely to facilitate *ex vivo* surgical approaches in which a complex of organs is removed, surgically altered and then replaced *in situ*. This approach is adopted in the surgical management of tumours that are extensively invasive. Attempts to harness or re-activate the embryological potential of the mesentery are increasing in number and it is hoped such a mesentery-based approach could address the deficit in knowledge of the digestive organs available for transplantation (García-Arrarás et al 2019).

Conclusion

The mesenteric model of abdominal anatomy and compartmentalization provides an overarching model of abdominal anatomy. This is likely to help students better understand abdominal anatomy, assist the scientific investigation of human biology and the diagnosis and treatment of abdominal and systemic diseases.

CHAPTER 76

Pelvic girdle and lower limb: overview and surface anatomy

The structure of the lower limb is specialized for support of the body's weight, locomotion and maintenance of body stability (balance). Indeed, adaptations for weight-bearing and stability account for the major structural and functional differences between the upper and lower limbs. The inguinal (pelvicrural) and gluteal (buttock) regions are important anatomical junctional zones between the trunk and the lower limb through which longitudinally running nerves and vessels travel (Fig. 76.1). The inguinal region includes the transitional zones between the lower limb and abdominal cavity via the myopectineal orifice (the gap between the inguinal ligament and hip joint) and inguinal canal, and provides a gateway for the passage of various structures. Similarly, the obturator canal allows for the obturator nerve and vessels to traverse between the pelvis and thigh. The gluteal region communicates with the lower limb and the abdominopelvic cavity via the greater sciatic foramen, and with the lower limb and pelvic cavity and perineum via the lesser sciatic foramen.

BONES AND JOINTS

The bones of the lower limb are the three fused components of the pelvic girdle; the femur and patella (thigh); the tibia and fibula (leg; in anatomical nomenclature, leg refers to the part of the lower limb between the knee and ankle); and the tarsus, metatarsus, phalanges and sesamoid bones (foot) (Fig. 76.2). The pelvic bones (especially the ilium and ischium), femur, tibia and bones of the hindfoot are strong and their external (cortical) and internal (trabecular) structure is adapted for weight-bearing.

The joints of the pelvic girdle are the sacroiliac joints and the pubic symphysis. The lower limb is connected to the axial skeleton via the sacroiliac joint, a joint that consists of syndesmotic and synovial parts, and in which mobility has been sacrificed for stability and strength to allow for effective weight transmission from the trunk to the lower limb. Anteriorly, the two pubic bones are united at the pubic symphysis, a secondary cartilaginous joint that may display a slight degree of mobility during hip and sacroiliac movement, and during late pregnancy and childbirth. The hip joint is a synovial ball-and-socket articulation, and exhibits an effective compromise between mobility and stability that allows movement in all three orthogonal planes. The more distal joints have gained mobility at the expense of stability. The knee joint includes a complex synovial joint between the femur and the tibia, and a plane joint between the femur and the patella. This permits a range of up to about 140° of active flexion, extension to neutral or beyond, and voluntary medial and lateral rotation (approximately 60–70°) of the leg. The tibia and fibula articulate with each other at the superior and inferior tibiofibular joints. The superior joint, a plane synovial joint, allows slight gliding movement only. The inferior fibrous joint lies just above the ankle and allows a degree of fibular rotation linked to ankle motion. The ankle (talocrural) joint is formed by the distal ends of the tibia and fibula 'gripping' the talus, and enables about 70° of dorsiflexion and plantar flexion. There are multiple joints in the foot that may be classified topographically on the basis of whether they are in the hindfoot, midfoot or forefoot. Collectively, these joints allow the complex movements required as the foot fulfils its functional roles as a platform for standing and for shock absorption and propulsion in gait. The terminology used to describe motion of the ankle and foot, especially with respect to defining supination/pronation and inversion/eversion, is inconsistent (Greiner 2007, Doya et al 2010).

Both the knee and ankle are commonly subject to closed injuries, and the relatively superficial location of the knee renders it susceptible to open injury and infection. Although the ankle is frequently injured and is a major load-bearing joint, the incidence of clinically significant degenerative arthritis is surprisingly low when compared with that found in the hip and knee joints.

SKIN AND FASCIA

In the young adult and as an adaptation to weight-bearing, the skin of the lower limb is generally thicker than that of the upper limb. The soft tissues of the sole of the foot are particularly thickened in order to support weight during standing. The skin of the buttocks and posterior

According to Cruveilhier (1841), all aponeurotic fasciae, including the deep fascia of the lower limb, are put under tension by specific myofascial expansions (more evident around joints) or dedicated muscles (e.g. tensor fasciae latae). These thickenings may act functionally as additional tendons. The pattern of soft tissue organization has a bearing on the physiological effects of the muscles and is crucial for efficient venous return from the limb. The fascial planes also control and direct the spread of pathological fluids (blood, pus) within the limb and play an important part in determining the degree and direction of displacement seen in long bone fractures.

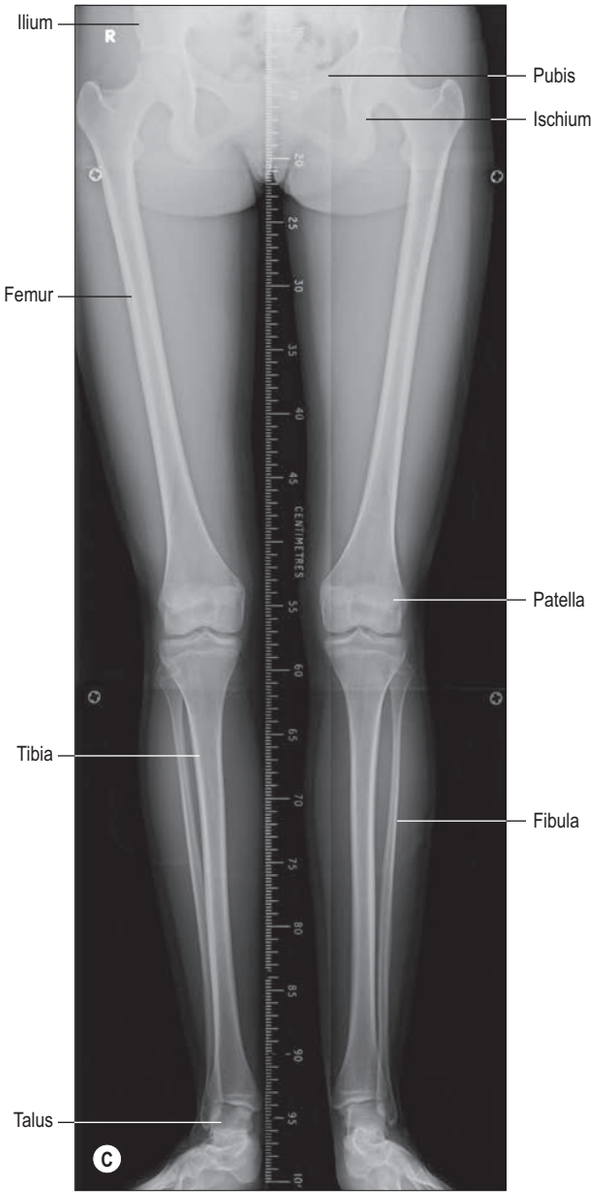

Fig. 76.2 C, Standing anteroposterior radiographs of the lower limbs of a 16-year-old female; two separate acquisitions stitched together. Note that the more distal long bone growth plates are still visible.

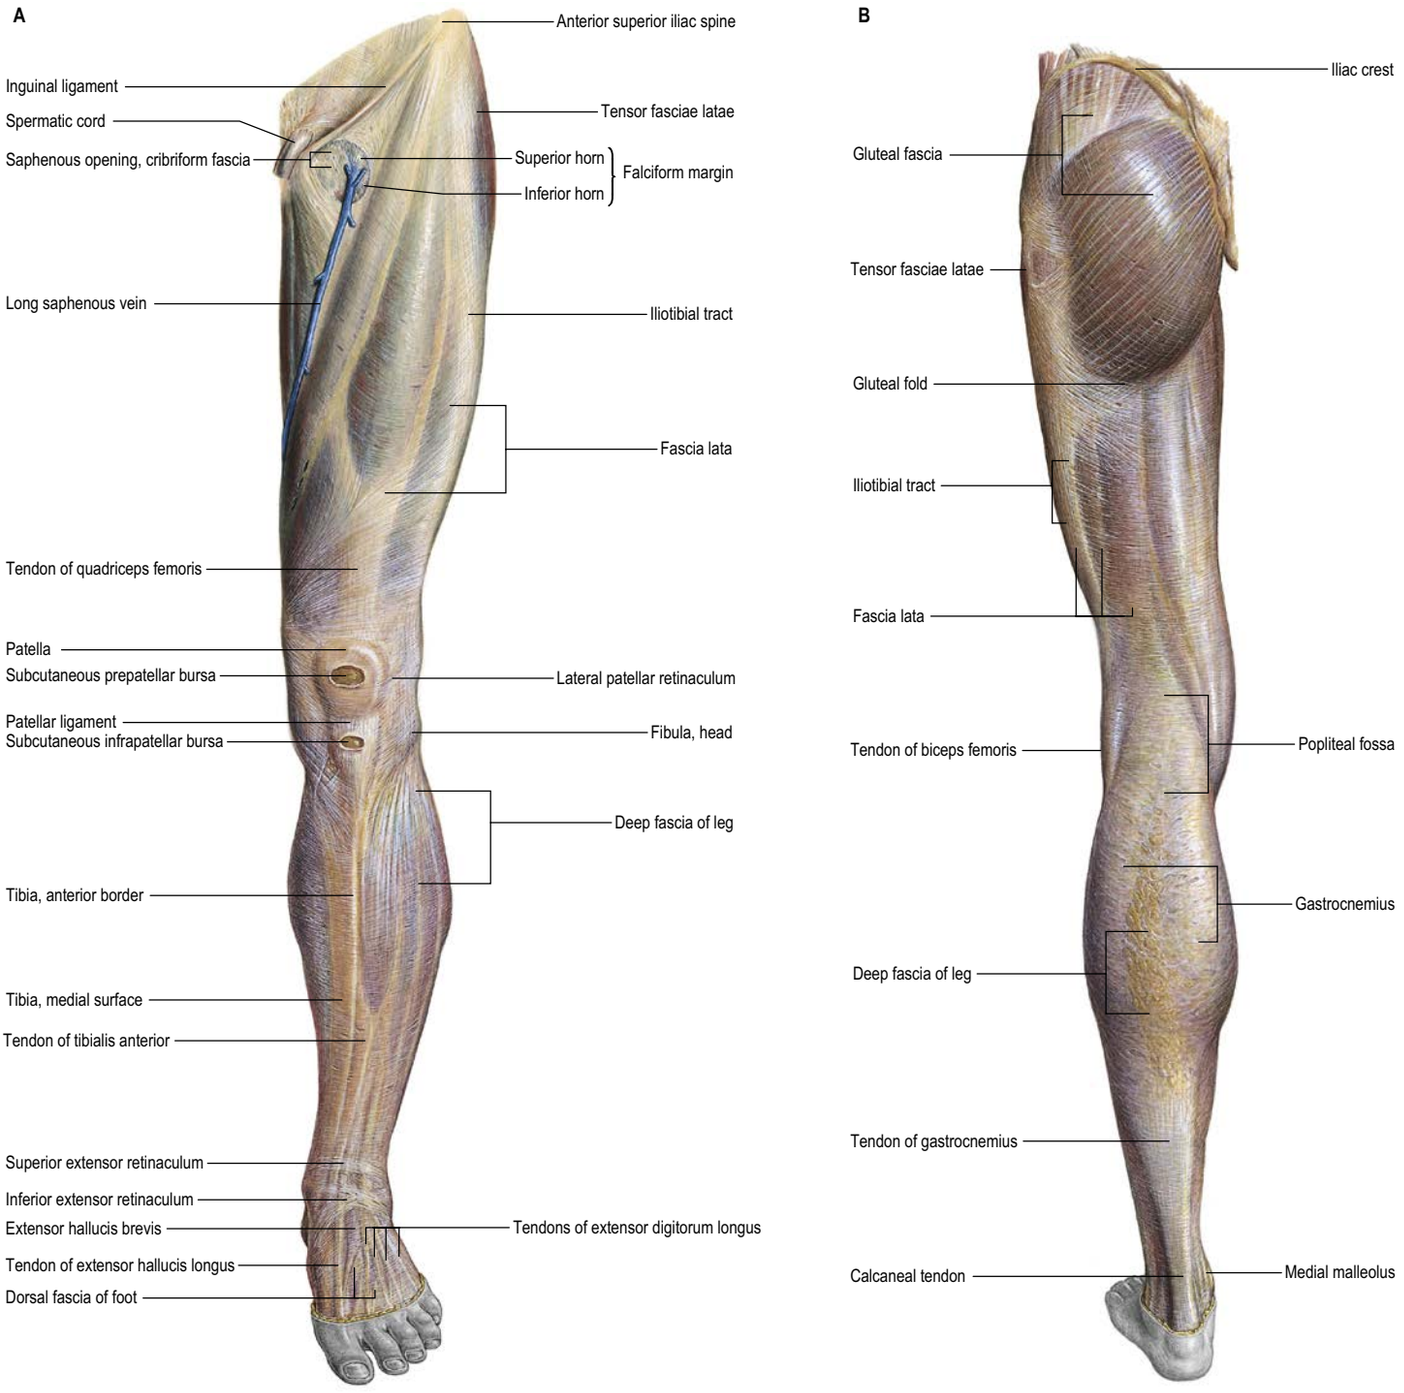

Fig. 76.3 The deep fascia of the lower limb. **A**, Anterior view. **B**, Posterior view. (A, B, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

thigh bears weight in the sitting position and is relatively thick. The skin over the anteromedial aspect of the leg is particularly fragile and vulnerable in the elderly.

The superficial fascia (subcutaneous tissue; tela subcutanea; hypodermis) of the lower limb becomes thinner distally. It provides support for subcutaneous structures such as superficial veins and cutaneous nerves, and is connected to the adventitia of the superficial veins by thin bands that prevent the displacement of the veins during movement. The hypodermal plexus of arteries and veins controls blood flow through the skin, helping to regulate body temperature (Sterzi 1910).

The deep fascia of the gluteal region varies in thickness. The deep fascia of the thigh and leg is a well-defined layer that forms a tough circumferential 'stocking-like' structure that constrains the musculature (Fig. 76.3). It is attached to the medial and lateral intermuscular septa in the thigh, the patellar ligament, patella, tibial tuberosity and condyles, the head of the fibula at the knee, and the periosteum of the tibia, fibular head and lateral malleolus. The iliotibial tract, medial and lateral patellar retinacula, and the extensor, flexor and fibular retinacula at the ankle are important condensations. Septa pass from the deep surface of this fascial sheath to the bones within, defining discrete (osteofascial) compartments that contain functional muscle groups. The intermuscular septa and the interosseous membrane between the tibia and fibula also provide additional areas for the attachment of muscles.

The muscles of the thigh may be grouped into three compartments according to their function: anterior (extensor), medial (adductor) and posterior (flexor). Only the anterior and posterior compartments possess distinct fascial boundaries. A definite fascial separation into anterior (extensor), posterior (flexor) and lateral (evertor) compartments exists in the leg, and compartment syndrome is most common in this region (see below). The deep and superficial muscles in the flexor compartment of the leg are separated by the transverse intermuscular septum. The compartments of the foot, one on the dorsal aspect and four on the plantar surface, are described in Chapter 79.

Vessels and nerves run through all of the compartments and supply the muscles contained within them. The muscles acting within these closed compartments assist in maintaining the anti-gravity flow of venous blood.

The fascial boundaries that limit the compartments are largely inelastic, which means that any acute condition that leads to an increase in the volume of the compartmental contents, e.g. muscle swelling caused by trauma, haemorrhage or local infection, is likely to cause an increase in intracompartmental pressure. If unrelieved, this increased pressure will lead to compressive occlusion of the vessels in the compartment and consequent ischaemic damage to the nerves and muscles of the compartment, a phenomenon known as acute compartment syndrome. Chronic exertional compartment syndrome is characterized by exercise-induced leg pain that usually subsides with rest, thought to be caused by elevated intramuscular pressure that may result in decreased tissue perfusion, ischaemia and transient neurological impairments (Burrus et al 2015). The normal compartmental pressure of the leg is significantly higher in children than in adults: the average pressure in the compartments, measured when supine, varies between 13.3 and 16.6 mmHg in children, compared with 5.2 and 9.7 mmHg in adults (Staudt et al 2008). Pressures are higher when standing (Antle et al 2018).

The treatment of compartment syndrome relies on reducing abnormally elevated tissue pressure. Surgical decompression of the fasciae of the restricting compartment may be necessary; in order to prevent neurovascular injury during a fasciotomy, the exact course of the nerves and vessels within the affected compartment must be known (Apaydin et al 2008).

MUSCLES

The effects of extension and medial rotation of the limb that occur during fetal development are manifest in the relative positions of the muscle groups in the thigh and the leg, and in the adult pattern of segmental cutaneous innervation (dermatomes). The role of the muscles of the lower limb in the maintenance of equilibrium during gait and in stance is rarely emphasized sufficiently. Many of the muscles act frequently or predominantly from their distal attachments. During both stance and gait, the distal attachment is often fixed and the proximal attachment is mobile, e.g. the predominant action of gluteus medius is as a pelvic stabilizer rather than as a hip abductor. In contrast, in the upper limb, the proximal muscle attachments are usually fixed and the distal attachments are mobile, an arrangement that is consistent with the prehensile function of the hand. The lower limb contains many muscles that act on more than one joint, and it is unusual for any joint of the lower limb to move in isolation. Certain muscles are morphologically and functionally segregated, e.g. the anterior part of gluteus medius is active with medial (internal) rotation of the hip, while the posterior part contributes to lateral (external) rotation of the hip.

Muscles of the lower limb may be subdivided according to their location. (1) Muscles of the iliac region, psoas major and iliacus (together called iliopsoas) are the main flexors of the hip. They arise from the lumbar spine and inner surface of the ilium and are attached distally on the lesser trochanter of the femur. When present, psoas minor runs from the lumbar spine to the pubis. (2) The gluteal region includes the three named gluteal muscles and the deeper, short lateral rotators of the hip joint. Gluteus maximus lies most superficially and is a powerful extensor of the hip joint. Gluteus medius and minimus, passing between the ilium and the greater trochanter of the femur, are abductors of the hip. Their most important action is to stabilize the pelvis on the femur during gait, helped by tensor fasciae latae. Two of the short lateral rotators of the hip, piriformis and obturator internus, arise from within the pelvis, while the others, obturator externus, the gemelli and quadratus femoris, originate externally; all of these muscles are attached distally to the proximal femur. (3) The muscles of the thigh lie in three functional compartments. The anterior (extensor) compartment includes sartorius and quadriceps femoris (rectus femoris and vasti medialis, lateralis and intermedius). Sartorius and rectus femoris are attached proximally to the pelvis and can thus act on the hip joint as well as on the knee, whereas the vasti arise from the femoral shaft and are powerful knee extensors. The medial (adductor) compartment contains adductors brevis, longus and magnus and gracilis; pectineus may also be included. All five muscles cross the hip joint but only gracilis reaches beyond the knee. The muscles of the posterior (flexor) compartment, semitendinosus, semimembranosus and biceps femoris, are attached proximally to the ischial tuberosity and act to extend the hip and to flex and rotate the knee. Part of adductor magnus, as may be inferred from the extent of its proximal attachment and its dual innervation, shares the first of these functions with the hamstrings. Biceps femoris is the only muscle of the thigh that is attached distally to the fibula. (4) In the leg, the anterior (extensor) compartment includes the extensors (dorsiflexors) of the foot and the extrinsic toe extensors. Tibialis anterior, the main foot dorsiflexor, also inverts the foot at the subtalar joint, while the smallest muscle of the compartment, fibularis (peroneus) tertius, is a dorsiflexor that everts the foot. The lateral compartment contains the main evertors of the foot, fibularis (peroneus) longus and brevis; both muscles are also plantar flexors. The posterior (flexor/plantar flexor) compartment has superficial and deep components. The superficial component contains gastrocnemius, soleus and plantaris. Gastrocnemius and soleus are powerful plantar flexors of the foot: gastrocnemius and plantaris are attached proximally to the femur and distally to the calcaneus and can therefore act on the knee as well as at the ankle. The deep component of the flexor compartment contains popliteus, a rotator of the knee, tibialis posterior, the main invertor of the foot, and the extrinsic flexors of the toes. (5) The intrinsic muscles of the foot include one muscle on the dorsal surface (extensor digitorum brevis), and the muscles of the sole, arranged in four layers. The intrinsic muscles facilitate the actions of the extrinsic flexors of the toes, and provide subtle changes in the shape of the foot, thereby contributing to the control of foot posture during stance and gait.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

The detailed regional descriptions of these systems are found in Chapters 77, 78 and 79.

Arteries

The femoral artery (the continuation of the external iliac artery) provides the principal arterial supply to the lower limb distal to the inguinal ligament and the gluteal fold (**Figs 76.4–76.5**). The femoral artery courses within the subsartorial (adductor) canal, which is located on the anteromedial aspect of the thigh. It passes through the adductor hiatus to become the popliteal artery on entering the posterior compartment of the thigh and soon thereafter divides into the anterior and posterior tibial arteries. The obturator and inferior gluteal vessels also contribute to the supply of the proximal part of the limb. In the embryo, the inferior gluteal artery supplies the main axial artery of the limb, which is represented in the adult by the artery to the sciatic nerve.

The bones of the lower limb receive their arterial supply from nutrient vessels, metaphysial arterial branches of the peri-articular anastomoses, and the arteries supplying the muscles that attach to their periosteum. The pattern of arterial supply is particularly relevant to fracture healing, the spread of infection and malignancy, and the planning of reconstructive surgical procedures. For further details, consult Cormack and Lamberty (1984), Taylor and Razaboni (1994) and Crock (1996).

Ischaemia of the lower limb due to peripheral arterial disease is a tremendous burden on healthcare resources. Obesity and smoking and diseases including diabetes, hypertension and atherosclerosis contribute to this pathology. Symptoms include intermittent claudication and wounds that do not heal well (see Sampson et al 2017). Physical examination of such patients may reveal decreased distal pulses (e.g. of the posterior tibial artery), pallor or a cool extremity.

Arterial perforators of the lower limb and surgical flaps

Achieving adequate and aesthetically satisfactory skin and soft tissue cover for large, superficial tissue defects is a perennial challenge in the field of plastic and reconstructive surgery, and accounts for a substantial part of a plastic surgeon's workload. Generally, split-thickness and full-thickness skin grafts are suitable only for very superficial defects. To achieve tissue coverage for deeper and larger tissue defects, one of a variety of autologous tissue flaps may be used. A fasciocutaneous flap is composed of skin, fat and deep fascia (fascia musculorum); a lower-extremity fasciocutaneous flap (Pontén 1981) is very useful in the repair of soft tissue defects of the leg.

The viability of a flap transplanted from one part of the body to another is crucially dependent on the blood supply of the flap. An appreciation of the angiosome concept (Chs 6, 7), coupled with technological advances in reconstructive microsurgery, has stimulated the development and use of perforator (or perforator-based) flaps. These

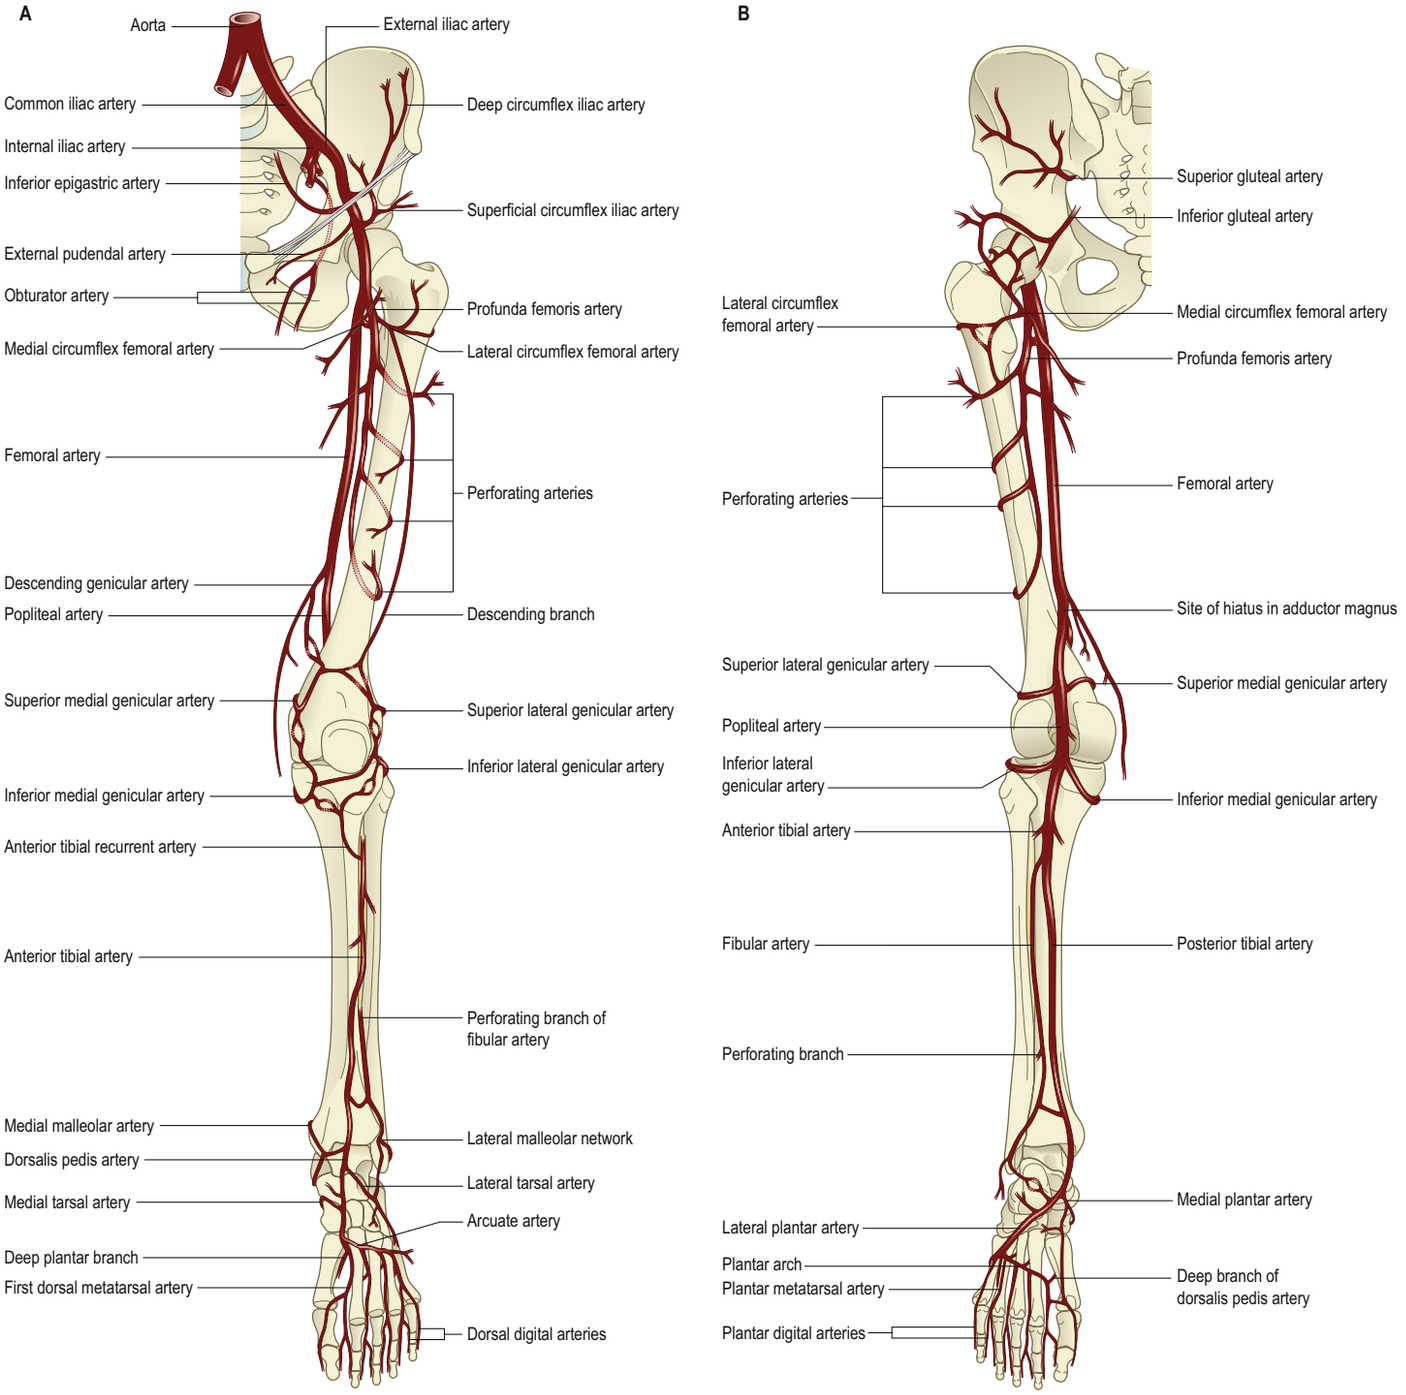

Fig. 76.4 An overview of the arteries of the lower limb. **A**, Anterior aspect. **B**, Posterior aspect.

are flaps of skin or subcutaneous tissue supplied by one or more fascial 'perforators', i.e. arteries that reach the suprafascial plexus either directly from a source vessel, or indirectly from some other neighbouring tissue (Harry et al 2009) (Fig. 76.6). Perforator-based flaps are typically harvested with sparing of underlying muscle tissue and minimal trauma; their use is said to reduce postoperative pain, donor site morbidity and functional loss.

The lower limb is the largest donor site in the body for perforator-based flaps. Commonly used flaps include anterolateral thigh flaps, which provide a large amount of skin; superior and inferior gluteal artery perforator flaps used in breast reconstruction; vascularized fibular flaps for reconstruction of deficient bone; vascularized tensor fasciae latae flaps for tendon reconstruction; vascularized sural nerve flaps for nerve reconstruction; and the gracilis muscle flap, used in, for example, reanimation of paralysed muscle.

In the context of perforator flap surgery, the lower limb may be considered in terms of four anatomic regions: gluteal; anterior hip and thigh; knee and leg; ankle and foot. Each lower limb accounts for approximately 23% of the total body surface area (thigh 10.5%, leg 6.5%, buttock 2.5% and foot 3.5%) and contains an average of 90 arterial perforators (Fig. 76.7).

Pulses

The pulsation of the femoral artery is palpable as it enters the femoral triangle. Posterior to the knee joint, the popliteal pulse is difficult to identify due to the depth of the popliteal artery, and is best assessed with the knee in slight flexion. Distally, the posterior tibial artery is palpable just posterior to the medial malleolus and the dorsalis pedis pulse is located over the tarsal bones, immediately lateral to the tendon of extensor hallucis longus. Clinical signs of decreased or absent peripheral pulses, particularly the pedal pulses (posterior tibial artery and dorsalis pedis) bilaterally may be indicative of peripheral artery disease (Londero et al 2016).

Veins

The veins of the lower limb can be subdivided into a superficial group lying in the subcutaneous tissue and vessels that lie deep to the deep fascia and accompany the major arteries and their branches (Figs 76.8–76.9). Valves are present in both groups, but are more numerous in the deep veins. (They are also more numerous than in the veins of the upper limb.) Venous plexuses occur within and between some of the lower limb

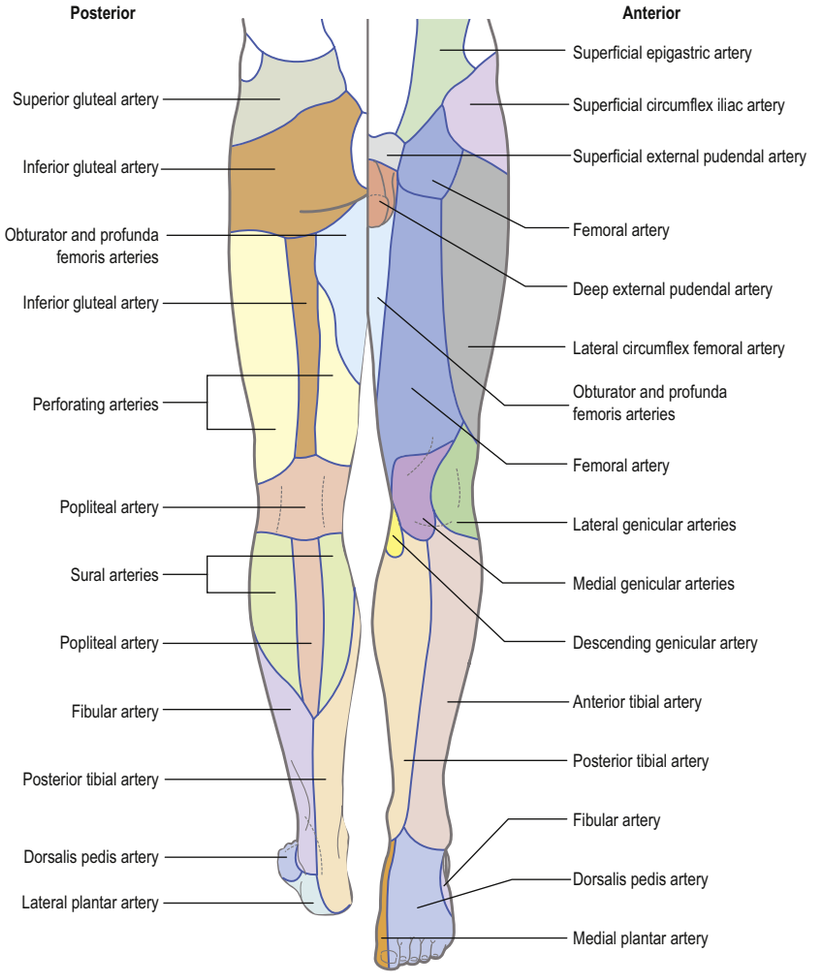

Fig. 76.5 The anatomical territories served by the cutaneous blood supply to the lower limb.

muscles. The two principal superficial veins are the long (great) and short (small) saphenous veins; their numerous tributaries are mostly unnamed, however, changes in clinical practice are driving a revision of the terminology (Caggiati et al 2002, 2005). The long saphenous vein can be harvested and used as a graft for peripheral vascular surgery, including coronary artery bypass (Kosinski 1926).

Plantar digital veins arise from plexuses in the plantar regions of the toes, connect with dorsal digital veins and unite to form four plantar metatarsal veins. These run in the intermetatarsal spaces and connect first with dorsal veins by means of perforating veins and then connect with each other to constitute a deep plantar venous arch adjacent to the deep plantar arterial arch. Medial and lateral plantar veins from the venous arch run near the corresponding arteries and communicate with the long and short saphenous veins before forming the posterior tibial veins posterior to the medial malleolus.

The posterior tibial veins accompany the posterior tibial artery. They receive veins from the calf muscles, especially the venous plexus in soleus, and connect with superficial veins and with the fibular veins. The latter accompany the fibular artery and receive tributaries from both soleus and superficial veins. The anterior tibial veins are continuations of the venae comitantes of the dorsalis pedis artery. They leave the extensor region between the tibia and fibula, pass through the proximal end of the interosseous membrane and unite with the posterior tibial veins at the distal border of popliteus to form the popliteal vein.

Venous (muscle) pumps

While standing, venous return from the lower limb depends largely on muscular activity, especially contraction of the calf and foot muscles, known as the 'muscle pump', aided by the tight sleeve of deep fascia (Ricci 2017). 'Perforating' veins connect the long saphenous vein with the deep veins, particularly near the ankle, distal calf and knee. Their valves are arranged so as to prevent flow of blood from the deep to the superficial veins. At rest, pressure in a superficial vein is equal to the height of the column of blood extending from that vein to the heart. When the posterior leg muscles contract, blood is pumped proximally into the deep veins and is normally prevented from flowing into the superficial veins by the valves in the perforating veins. During muscular relaxation, blood is drawn into the deep veins from the superficial veins. If the valves in the perforating veins become incompetent, these veins become sites of 'high-pressure leaks' during muscular contraction, and the superficial veins become dilated and varicose. There are similar perforating connections in the anterolateral region, where varicosities may also occur. Incompetence of the valves in the connecting veins between the long saphenous vein and femoral vein in the adductor canal may predispose to superficial varicosities along the medial aspect of the thigh (Dodd and Cockett 1976). Venous plexuses, which may be intramuscular (soleus) or intermuscular (in the foot and gluteal region), communicate with the axially running deep veins and are components of the 'muscle pump' mechanism.

Lymphatic drainage

Most lymph from the lower limb traverses a large intermediary inguinal group of nodes (Fig. 76.10). Peripheral nodes are few and are all deeply sited in the popliteal fossa except for an inconsistent node lying proximally on the interosseous membrane near the anterior tibial vessels. Enlarged popliteal nodes, often as a result of inflammation, malignancy or injury to the lateral side of the foot, may be palpated along the line of the popliteal vessels while the passively supported knee is gradually moved from extension to semi-flexion. Inguinal lymph nodes are found superficial and deep to the deep fascia. The superficial nodes may be divided into a lower vertical group that clothe the proximal part of the long saphenous vein, and an upper group that lie parallel to, but below, the inguinal ligament and which are related laterally to the superficial circumflex iliac and medially to the superficial external pudendal vessels. The deep nodes are few and lie alongside the medial aspect of

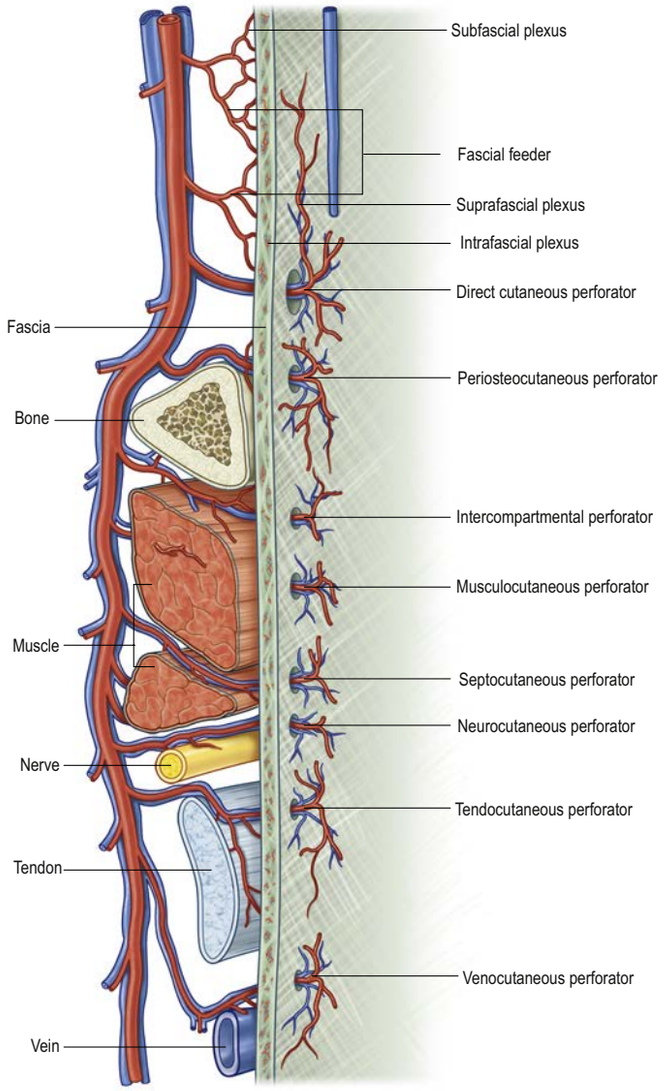

Fig. 76.6 Types of arterial perforators.

the femoral vein. Lymph from the lower limb passes from the inguinal lymph nodes to the external and common iliac nodes, and ultimately drains to the lateral aortic nodes. Deep gluteal lymph reaches the same group through the internal and common iliac lymphatic vessels.

Superficial tissues

The superficial lymph vessels begin in subcutaneous plexuses. Collecting vessels leave the foot either medially with the long saphenous vein, or laterally with the short saphenous vein. Medial vessels are larger and more numerous. They start on the medial side of the dorsum of the foot, ascend anterior or posterior to the medial malleolus, accompany the long saphenous vein and drain to the distal superficial inguinal nodes. Lateral vessels begin on the fibular side of the dorsum of the foot. Some cross anteromedially in the leg to join the medial vessels and so pass to the distal superficial inguinal lymph nodes, while others accompany the short saphenous vein and drain to the popliteal nodes. Superficial lymph vessels from the gluteal region run anteriorly to the proximal superficial inguinal nodes.

Deeper tissues

The deep lymph vessels accompany the anterior and posterior tibial, fibular, popliteal and femoral vessels. Popliteal nodes interrupt the deep vessels from the foot and leg; deep vessels from the thigh pass to the deep inguinal nodes. The deep lymphatic vessels of the gluteal region follow their corresponding blood vessels. Those accompanying the superior gluteal vessels end in a node near the intrapelvic part of the superior gluteal artery, adjacent to the superior border of the greater sciatic foramen, while those that follow the inferior gluteal vessels traverse one or two of the small nodes inferior to piriformis and then pass to the internal iliac nodes.

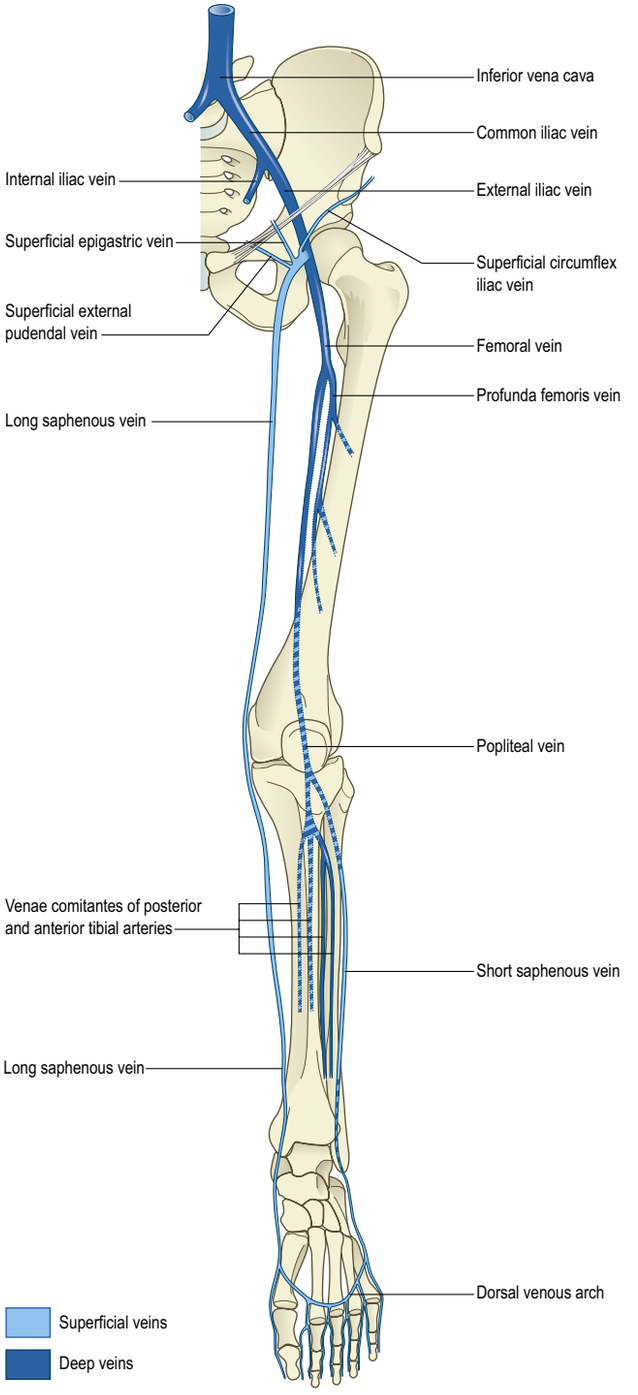

Fig. 76.8 An overview of the veins of the lower limb.

INNERVATION

Overview of the lumbar and sacral plexuses

Nerves derived from the lumbar and sacral plexuses innervate the lower limb (Fig. 76.11). The lumbar plexus lies deep within psoas major, anterior to the transverse processes of the first three lumbar vertebrae. The sacral plexus lies in the pelvis on the anterior surface of piriformis, external to the pelvic fascia, which separates it from the inferior gluteal and internal pudendal vessels. The lumbosacral trunk (fourth and fifth lumbar ventral rami) emerges medial to psoas major on the posterior abdominal wall and lies on the ala of the sacrum before crossing the pelvic brim to join the first sacral ventral ramus. Contributions to the lumbosacral trunk may also be derived from the third lumbar nerve (Apaydin 2016).

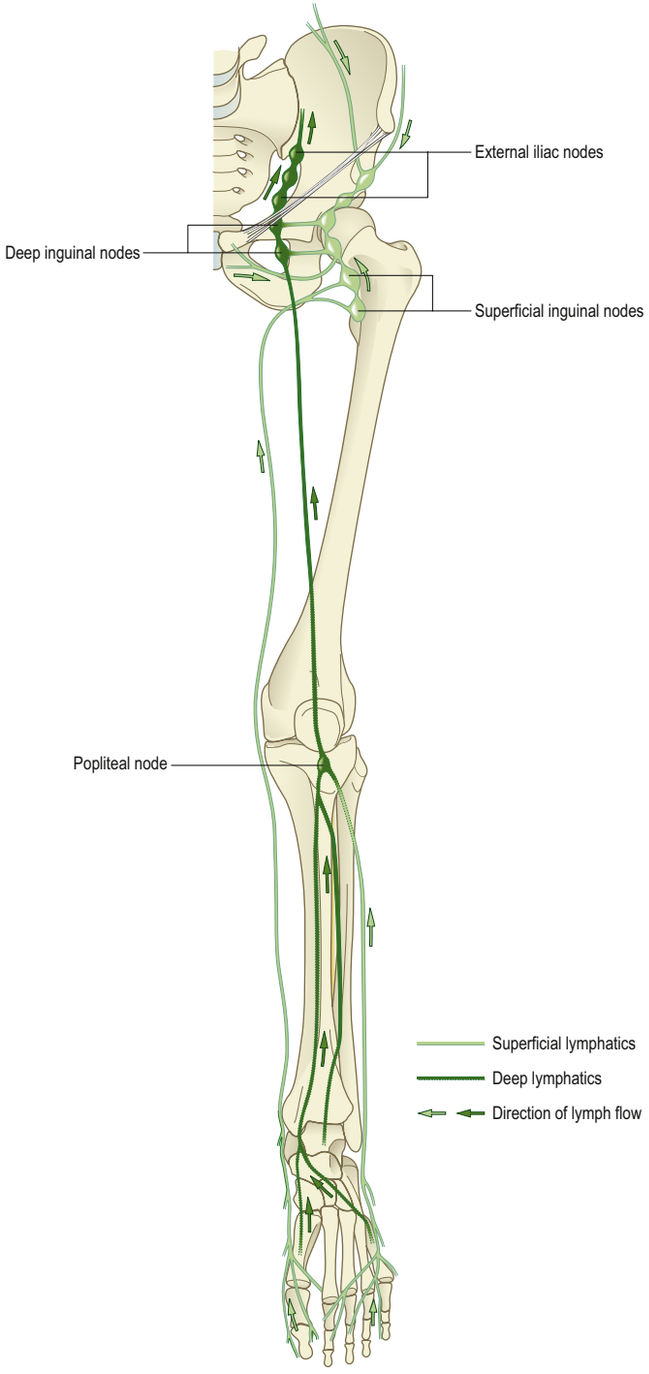

Fig. 76.10 An overview of the lymphatics of the lower limb.

Lesions of the lumbar and sacral plexuses

The deep and protected situation of the plexuses means that lesions are not common. The lumbar plexus may be involved in retroperitoneal pathology and the sacral plexus may be invaded by pelvic malignancies and both may be involved in the reticuloses, affected by plexiformneuromas, or damaged in fractures of the lumbar spine and pelvis or in other conditions that cause severe retroperitoneal and pelvic haemorrhage. Temporary lesions may occur after pregnancy and childbirth, e.g. after difficult forceps delivery of a large baby. Pain, which may be diffuse, is the most common feature. Iatrogenic injury can occur during surgical approaches to the abdomen and pelvis, particularly when operating within the retroperitoneal space and also during the lateral approach to spine.

Sciatica is pain in the lower back and hip region, radiating inferiorly along the posterior thigh to the leg. It is often caused by a herniated intervertebral disc, compressing the L5 or S1 ventral rami. The so-called piriformis syndrome, which may result from a variant or anomalous relationship between piriformis and the sciatic nerve, may also produce hip pain that radiates inferiorly along the course of the sciatic nerve. Diagnosis of specific nerve injuries relies on the distribution and characteristics of clinical findings in combination with supportive electrophysiological studies and/or MRI and CT scans. The clinical presentation of lesions can vary as a result of anatomical variation and overlapping innervation patterns. Generally, loss of hip flexion and knee extension indicates a lumbar lesion; loss of hip abduction, knee flexion, and plantarflexion and dorsiflexion are symptoms of sacral lesions (Ahmadian et al 2015).

Overview of the principal nerves of the lower limb

Femoral nerve (L2–L4)

The femoral nerve is the nerve of the anterior compartment of the thigh. It arises from the posterior divisions of the second to fourth lumbar ventral rami, descends through psoas major and emerges on its lateral border to pass between it and iliacus. It enters the thigh behind the inguinal ligament and lateral to the femoral sheath. Its terminal branches form in the femoral triangle about 2 cm distal to the inguinal ligament. In the abdomen, the nerve supplies small branches to iliacus and a branch to the proximal part of the femoral artery. It subsequently supplies a large cutaneous area on the anterior and medial thigh, medial leg and foot, and gives articular branches to the hip, knee and ankle. The femoral nerve is described in detail on pages 1391–1392.

The femoral nerve is susceptible to compression, resulting in isolated motor or sensory deficits, either within psoas major or as it passes under the inguinal ligament. Partial or complete nerve injury can occur during surgery directed to the hip, pelvis or spine; with femoral artery catheterization; from trauma; or as a result of a retroperitoneal haematoma or mass. Consequences include paralysis of the hip flexors and quadriceps (with loss of the patellar reflex) and sensory deficits in the medial and anterior thigh and medial side of the leg (saphenous branch).

Obturator nerve (L2–L4)

The obturator nerve is the nerve of the medial compartment of the thigh. It arises from the anterior divisions of the second to fourth lumbar ventral rami, descends through psoas major and emerges from its medial border at the pelvic brim. It crosses the sacroiliac joint behind the common iliac artery and lateral to the internal iliac vessels, runs along the lateral pelvic wall medial to obturator internus, and enters the thigh through the upper part of the obturator foramen. Near the foramen, it divides into anterior and posterior branches that are initially separated by part of obturator externus and more distally by adductor brevis. It provides articular branches to the hip and knee, and can supply the skin of the medial thigh and leg. An accessory obturator nerve may also be present and leaves the pelvis anterior to the pubis. The obturator nerve is described in detail on page 1392.

Isolated lesions of the obturator nerve are rare, and usually occur in combination with injury to other nerves of the lumbosacral plexus. They can result from an acetabular fracture, pelvic tumour, obturator hernia, prolonged labour or direct trauma, and can be produced iatrogenically following manipulation, transection or retraction during pelvic surgery. The obturator nerve can become entrapped within the fascia overlying adductor brevis. Resulting symptoms include radiating pain and numbness on the medial side of the thigh and adductor muscle paralysis. Pain or loss of sensation in the groin with weakness of adduction and medial rotation of the thigh may be noted.

Sciatic nerve (L4, L5, S1–S3)

The sciatic nerve is typically 2 cm wide at its origin and is the thickest nerve in the body. It travels in the posterior compartment of the thigh and supplies the leg and foot. It is formed in the pelvis from the ventral rami of the fourth lumbar to third sacral spinal nerves, enters the lower limb via the greater sciatic foramen inferior to piriformis and descends between the greater trochanter and ischial tuberosity. In its descent along the posterior thigh it is crossed by the long head of biceps femoris. The sciatic nerve 'divides' into the tibial and common fibular (peroneal) nerves proximal to the knee. The tibial nerve is derived from the anterior divisions of the sacral plexus and the common fibular nerve is derived from the posterior divisions of the plexus: the two large nerves are only loosely held together as the sciatic nerve and the level of their separation in the thigh is variable.

The sciatic nerve sends articular branches to the hip joint through its posterior capsule (these can be derived directly from the sacral plexus) and to the knee joint. The medial (tibial) component innervates the posterior thigh muscles, including the ischial part of adductor

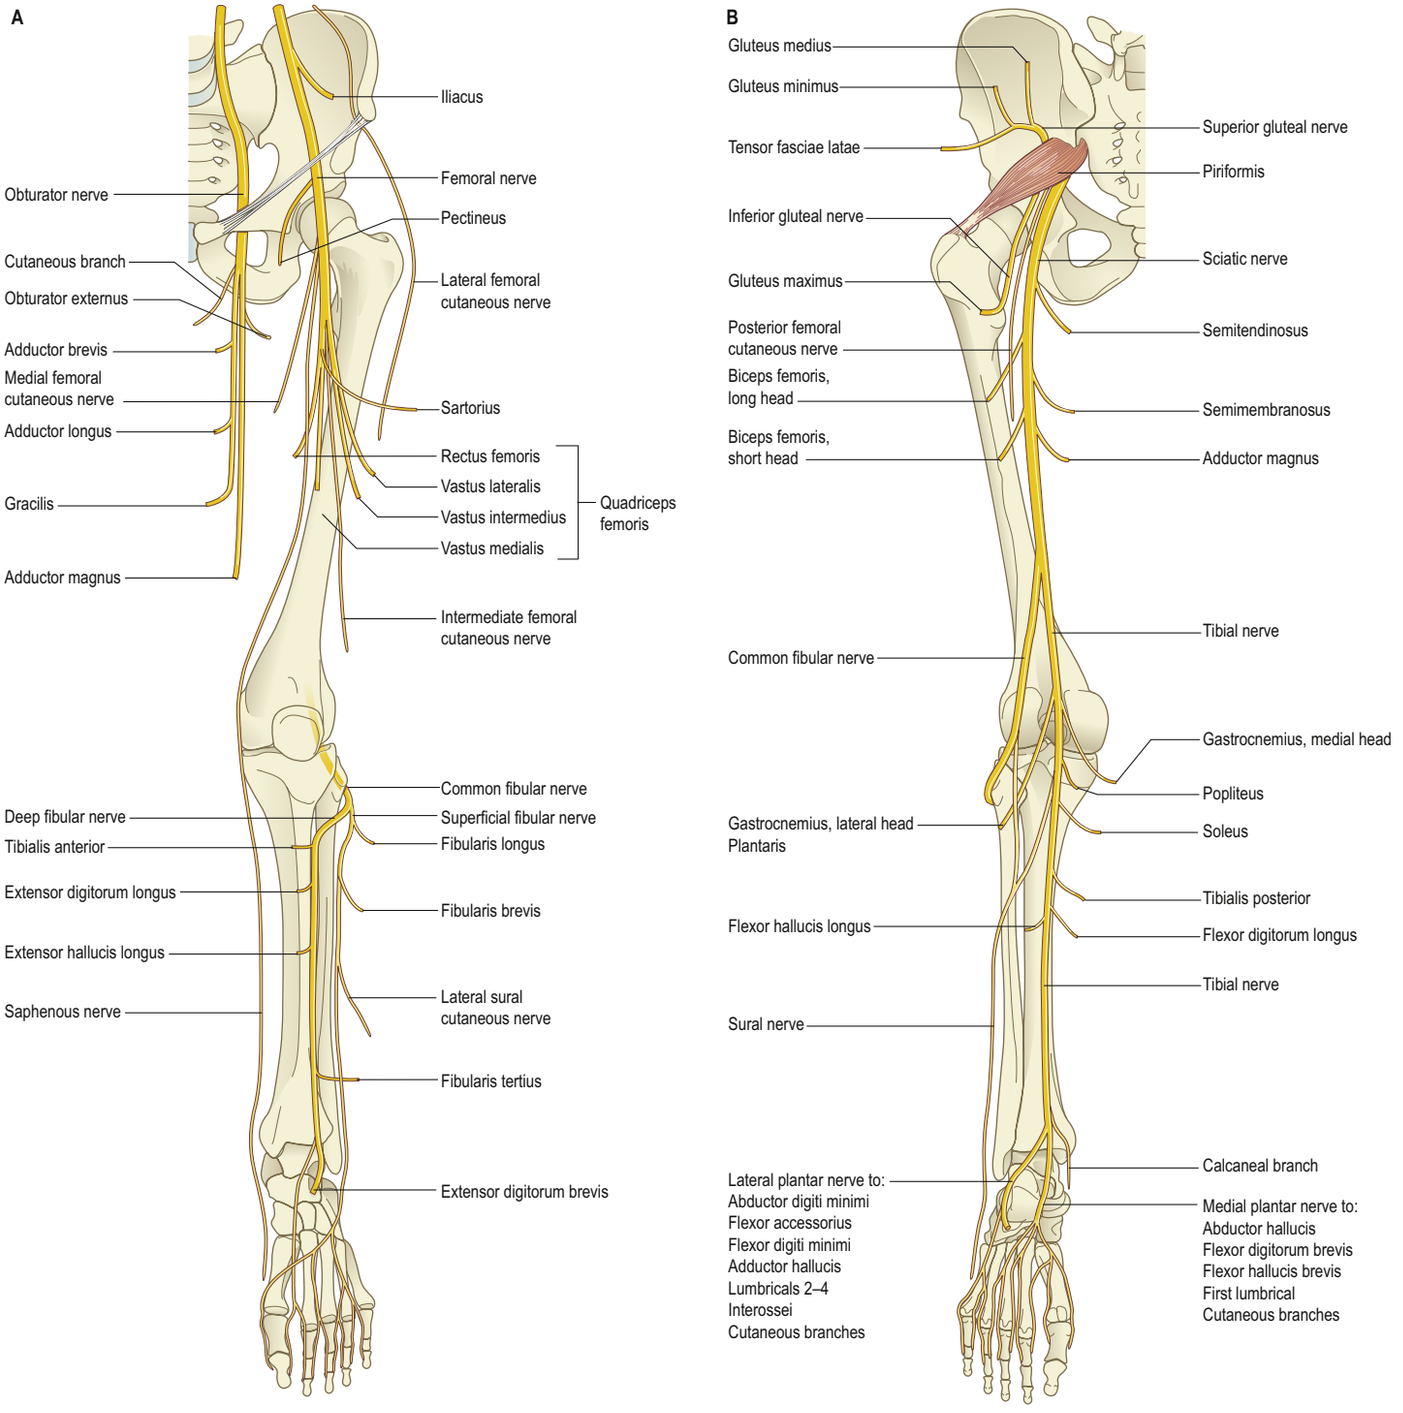

Fig. 76.11 The nerves of the lower limb, with their cutaneous and muscular branches. **A**, Anterior aspect. **B**, Posterior aspect. Adductor magnus has dual innervation.

magnus, but not the short head of biceps femoris, which is supplied by the lateral (common fibular) component. The common variations of the sciatic nerve have been classified into six types (Beason and Anson 1937). The sciatic nerve is described in detail on pages 1392–1393.

Sciatic nerve injury may result from gluteal trauma, hip fracture, vasculitis, myositis piriformis syndrome or iatrogenically damaged by misplaced gluteal injections or during total hip replacement surgery. Complete sciatic nerve palsy is rare, with injury to its common fibular component more frequent, possibly because it lies posterior, lateral and superficial to the tibial nerve.

Tibial nerve (L4, L5, S1–S3)

The tibial nerve is derived from the anterior divisions of the sacral plexus. It descends through the posterior thigh and popliteal fossa to the distal border of popliteus, passes anterior to soleus with the popliteal artery and continues into the leg. In the popliteal fossa, it initially lies lateral to the popliteal vessels, then becomes superficial to them and crosses to the medial side of the artery. In the leg, it is the nerve of the posterior compartment, descending with the posterior tibial vessels to lie between the heel and the medial malleolus and ending deep to the flexor retinaculum by dividing into the medial and lateral plantar nerves. The tibial nerve supplies articular branches to the knee and ankle joints, cutaneous branches to the back of the calf, the sole, the lateral border of the foot and the medial and lateral sides of the heel, and motor branches to gastrocnemius, plantaris, soleus, popliteus, tibialis posterior, flexor digitorum longus and flexor hallucis longus. The tibial nerve is described in detail on pages 1427–1428.

The tibial nerve is at risk of direct injury in the popliteal fossa, and can be compressed at the level of the tarsal tunnel as the nerve passes under the flexor retinaculum (tarsal tunnel syndrome). The medial plantar nerve may be compressed between abductor hallucis and the navicular bone ('jogger's foot'). Depending on the level of the injury, weakness of knee flexion, plantarflexion, inversion and toe flexion may result, accompanied by sensory loss in the lower lateral leg, heel and sole of the foot.

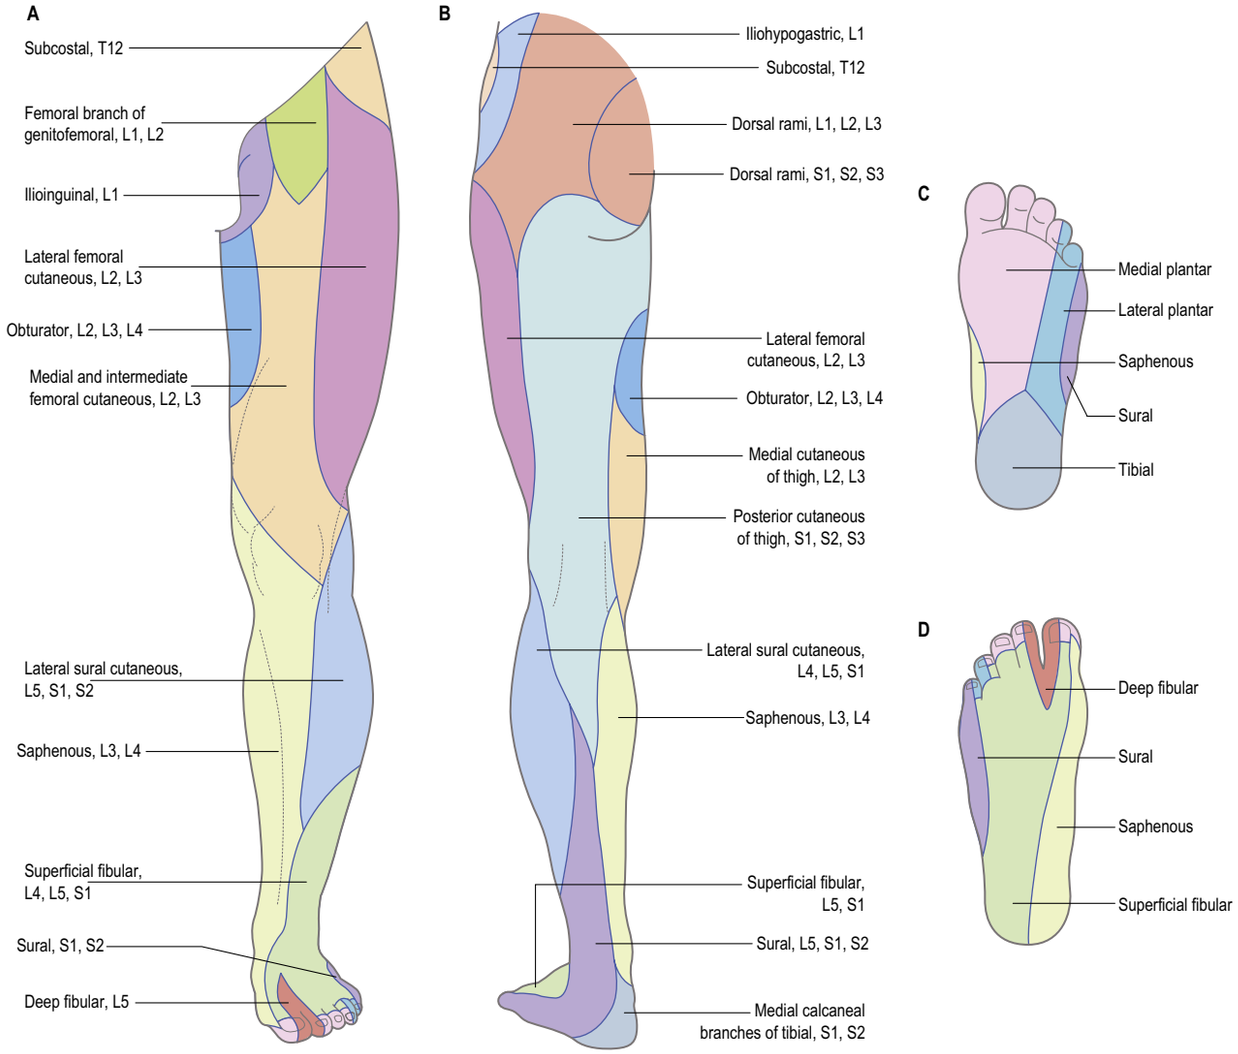

Fig. 76.12 The cutaneous nerves of the lower limb: areas of distribution and spinal segments of origin. **A**, Anterior aspect. **B**, Posterior aspect. **C**, The sole of the foot. **D**, The dorsum of the foot.

Common fibular nerve (L4, L5, S1, S2)

The common fibular nerve (common peroneal nerve) is derived from the posterior divisions of the sacral plexus and is the nerve of the anterior and lateral compartments in the leg. It descends obliquely along the lateral side of the popliteal fossa to the fibular head, lying between the tendon of biceps femoris and the lateral head of gastrocnemius, then curves lateral to the neck of the fibula, lying on the bone deep to fibularis longus, and divides into superficial and deep fibular (peroneal) nerves. The common fibular nerve supplies the anterolateral part of the knee joint capsule and the proximal tibiofibular joint and the skin on the anterior, posterior and lateral surfaces of the proximal leg. The superficial fibular (peroneal) nerve supplies fibulares longus and brevis and the skin of the lower leg before dividing into medial and intermediate dorsal cutaneous nerves. The deep fibular (peroneal) nerve supplies muscular branches to tibialis anterior, extensors hallucis longus and digitorum longus and fibularis tertius, and an articular branch to the ankle joint, before dividing into lateral and medial terminal branches. The common fibular nerve is described in detail on page 1428.

The common fibular nerve is prone to iatrogenic or traumatic injury: patients with common fibular neuropathy present with foot drop. Injury specifically to the superficial fibular nerve will result in paralysis of eversion and sensory loss in the lower lateral aspect of the leg extending onto the dorsum of the foot. Damage to the deep fibular nerve results in paralysis of dorsiflexion and toe extension with sensory loss in the first interdigital web space.

Gluteal nerves (L4, L5, S1, S2)

The gluteal nerves arise from the posterior divisions of the sacral plexus. The superior gluteal nerve (L4, L5, S1) leaves the pelvis through the greater sciatic foramen superior to piriformis and supplies gluteus medius, gluteus minimus, tensor fasciae latae and the hip joint. The inferior gluteal nerve (L5, S1, S2) passes through the greater sciatic foramen inferior to piriformis and supplies gluteus maximus. The gluteal nerves are described in detail on page 1393.

Focal lesions of the superior and inferior gluteal nerves usually occur concurrently with those of the sciatic nerve, posterior femoral cutaneous nerve and/or pudendal nerve. However, both gluteal nerves are vulnerable to injury during total hip replacement, and less commonly due to blunt trauma or misplaced gluteal injections. Injury to the superior gluteal nerve causing paralysis of gluteus medius and minimus can result in Trendelenburg's sign, where the pelvis drops on the unsupported side (in the coronal plane) when standing on the affected limb. Injury to the inferior gluteal nerve results in weakness of gluteus maximus causing impaired hip extension (Kretschmer and Heinen 2015).

Cutaneous innervation

The cutaneous nerves supplying the skin of the lower limb are all branches of the lumbar and sacral plexuses, with the exception of some proximal nerves. The areas of distribution and spinal segments of origin of the cutaneous nerves of the lower limb are illustrated in Fig. 76.12. Variations in the composition and course of the cutaneous nerves of the lower limb are common.

For example, the ilioinguinal and iliohypogastric nerves may arise from a common trunk or the ilioinguinal nerve may be absent. The ilioinguinal nerve may also join the iliohypogastric nerve at the iliac crest. When the obturator nerve makes a more significant contribution to the cutaneous innervation, the medial cutaneous branch of the femoral nerve is relatively small. The cutaneous branch of the obturator nerve may be absent. The lateral femoral cutaneous nerve normally arises from L2 and L3, but L1 may also contribute. Although this nerve usually bifurcates after it exits the pelvis, it may bifurcate within the

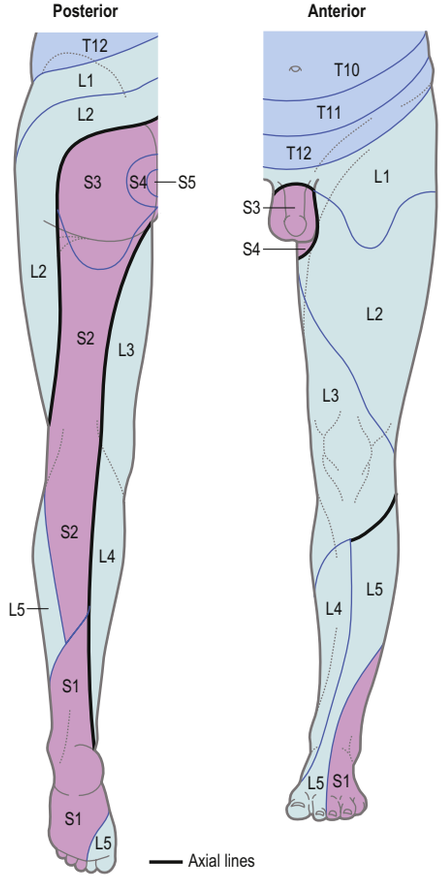

Fig. 76.14 Dermatomes of the lower limb. There is considerable variation and overlap between dermatomes, but the overlap across axial lines (heavy black) is minimal. (With permission from O'Brien M Aids to the Examination of the Peripheral Nervous System, 5th ed. Elsevier, Saunders. Copyright 2010.)

pelvic cavity: it may be absent on one side and/or may be replaced by the ilioinguinal nerve or a branch of the anterior femoral cutaneous nerve. The genital and femoral branches of the genitofemoral nerve may arise as separate offshoots of the lumbar plexus. The genital branch may receive fibres from the twelfth thoracic nerve or may be completely absent, and the femoral branch may have an extensive distribution to the skin of the upper two-thirds of the thigh. The sural nerve is subject to wide variation and may supply the dorsal cutaneous aspect of the lateral two-and-a-half toes, or may terminate in the foot without any digital branches.

Injury to the iliohypogastric, ilioinguinal and genitofemoral nerves most commonly occurs during surgical procedures involving the lower abdomen or spine, particularly inguinal surgery. Injury can result in anaesthesia, hyperaesthesia, neuralgia, or causalgia in the associated sensory distributions. The lateral femoral cutaneous nerve is most vulnerable to entrapment as it passes beneath the inguinal ligament just medial to the anterior superior iliac spine: injury results in paraesthesia or dysaesthesia on the anterolateral aspect of the thigh (meralgia paraesthetica) (Grossman et al 2001), which is usually intensified by walking or hip extension. Symptoms may be exacerbated when wearing tight belts or waist bands or as a result of pregnancy, obesity, rapid weight gain, diabetes or during hip surgery, hernia repair or iliac bone harvesting. The sural nerve may be injured at the level of the ankle joint following a fracture or sprain, compressed by wearing tight-fitting shoes or damaged during surgical procedures such as ankle arthroscopy or repair of the Achilles tendon: symptoms include pain or diminished sensation along the posterolateral aspect of the lower leg extending onto the lateral surface of the ankle and foot (Craig 2015).

Dermatomes

Our knowledge of the extent of individual dermatomes, especially in the limbs, is largely based on clinical evidence (Ladak et al 2014). While dermatomes have an orderly sequence and areas of consistency, they also demonstrate overlap and variability (Lee et al 2008). The dermatomes of the lower limb are innervated by spinal nerves T12 to S3 (see Fig. 76.12; **Figs 76.13–76.14**).

The preaxial border starts near the midpoint of the thigh and descends to the knee, then curves medially, descending to the medial malleolus and the medial side of the foot and hallux. The postaxial border starts in the gluteal region and descends to the centre of the popliteal fossa, then deviates laterally to the lateral malleolus and the lateral side of the foot. The ventral and dorsal axial lines exhibit corresponding obliquity. The ventral axial line starts proximally at the medial end of the inguinal ligament and descends along the posteromedial aspect of the thigh and leg to end proximal to the heel. The dorsal axial line begins in the lateral gluteal region and descends posterolaterally in the thigh to the knee; it inclines medially and ends proximal to the ankle. Considerable overlap exists between adjacent dermatomes innervated by nerves derived from consecutive spinal cord segments.

Autonomic innervation

The autonomic nerve supply to the limbs is exclusively sympathetic. Preganglionic sympathetic fibres to the lower limb are derived from neurones in the lateral horn of the lower thoracic (T10–T12) and upper lumbar (L1, L2) spinal cord segments. Fibres pass in white rami communicantes to the sympathetic trunk and synapse in the lumbar and sacral ganglia. Postganglionic fibres pass in grey rami communicantes to enter the lumbar and sacral plexuses; many are distributed to the skin via the cutaneous branches of the nerves derived from these plexuses. The blood vessels to the lower limb receive their sympathetic nerve supply via adjacent peripheral nerves. Postganglionic fibres accompanying the iliac arteries are destined mainly for the pelvis but may supply vessels in the proximal thigh.

Surgical or chemical lumbar sympathectomy may be indicated in arterial disease and in the management of plantar hyperhidrosis, and may be used to treat rest pain or other troublesome sensory symptoms of arterial disease, or in causalgia. A segment of the sympathetic trunk including the second and third lumbar ganglia is removed; preservation of the first lumbar ganglion is said to lessen the risk of ejaculatory problems.

Movements, muscles and segmental innervation

Most limb muscles are innervated by neurones derived from more than one segment of the spinal cord. The predominant segmental origin of the nerve supply for each of the muscles of the lower limb and for the movements that take place at the joints of the lower limb is summarized in **Tables 76.1–76.4** (Sharrard 1955). There is no consensus about the contribution that individual spinal nerves make to the innervation of individual muscles, and these listings are not exhaustive. The most positive identifications, which are limited, have been obtained by electrically stimulating spinal nerves and recording the evoked electromyographic activity in the muscles. Much of the information in Tables 76.1–76.4 is based on the clinical appreciation of deficits following lesions to various nerves. At the central nervous level of control, muscles

*The muscles listed in the 'Upper motor neurone' column are those that are preferentially affected in upper motor neurone lesions. The root level is the principal supply to a muscle.

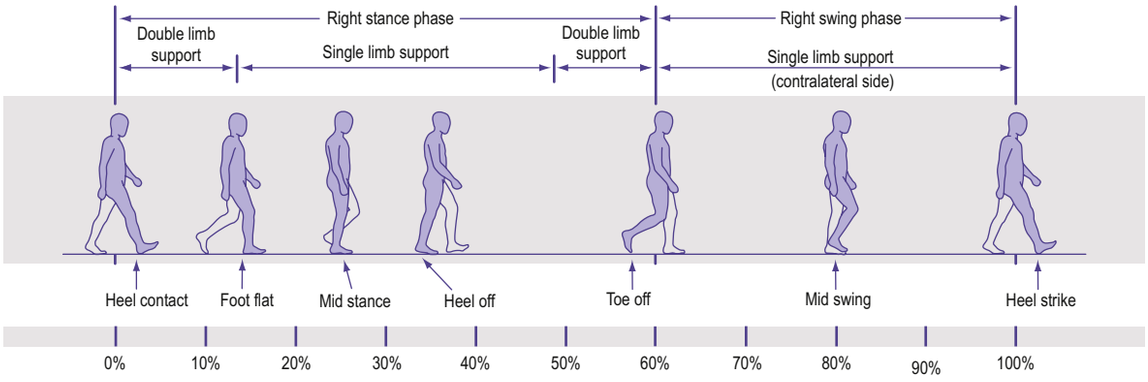

Fig. 76.15 An overview of the different phases of a normal gait cycle.

are not recognized as individual actuators but as components of movement, which means that they can contribute to several types of motion, acting variously as prime movers, antagonists, fixators or synergists. Some muscles have been included in more than one place in Table 76.3 on the basis that a muscle that acts across one joint can produce a combination of movements (e.g. flexion with medial rotation, or extension with adduction) and a muscle that crosses two joints can produce more than one movement.

Reflexes

Knee reflex (L2–L4). With the patient sitting and the knee supported and partially flexed, the patellar ligament is struck with a finger or percussion hammer. This results in extension of the knee joint.

Ankle reflex (S1, S2). With the patient sitting and the lower limb laterally rotated and partially flexed at the hip and knee, the foot is dorsiflexed by the examiner and the calcaneal tendon struck with a percussion hammer. This results in plantar flexion of the foot.

Plantar reflex. The plantar reflex is an important part of the clinical examination of the central nervous system. With the foot relaxed, the outer edge of the sole is stroked longitudinally with a blunt object such as the tip of the handle of a percussion hammer. Normally, this action elicits flexion of the toes. However, in patients with upper motor neurone lesions, the response includes extension of the great toe (Babinski's sign).

Neurological localization of a lesion

GAIT

Overview of the gait cycle

Walking involves a cyclic repetition of movements that propel the body forwards (see Video 76.1). The gait cycle is usually defined as the interval between initial heel contact of one foot to the successive heel contact of the same foot. The terms used to describe the point at which the foot makes first contact with the ground varies. Heel contact or heel strike are used in some instances, but individuals with altered or pathological gait patterns may not be able to initiate contact with their heel (Wall et al 1987) and therefore the terms initial contact or foot strike are also common. Each gait cycle consists of two steps which together constitute a stride, and can be divided into two main phases: stance phase (when the foot is in contact with the ground) and swing phase (when the foot is off the ground).

At normal walking speed, the stance phase accounts for approximately 60% of the gait cycle, and swing phase occupies 40%. There are two single-limb support phases (where one foot is on the ground) which alternate with two periods of double-limb support (where both feet are on the ground simultaneously; at 0–10% and 50–60% of the gait cycle) (**Fig. 76.15**). Both stance and swing can be further divided into a number of different events or phases, although the terms ascribed to these vary.

The stance phase is usually described to consist of five events: heel contact, foot flat, mid stance, heel off and toe off. The gait cycle starts with heel contact, the point at which the heel meets the ground. With the foot still positioned in front of the body, foot flat (where the entire plantar surface of the foot is in contact with the ground) is reached, at approximately 10% of the gait cycle. This is sometimes also referred to as the 'loading response'. Transition is made to mid stance, the point at which the body's weight is aligned directly above the planted foot (at approximately 30% of the gait cycle). The point at which the heel rises off the ground is termed heel off (between approximately 30% and 40% of the gait cycle), and this occurs just before the contralateral foot makes contact with the ground (the double stance phase). The last event of stance is toe off defined as the instant the toes come off the ground (60% of the gait cycle). Push off is a term used to describe the period of ankle plantar flexion (approximately 40–60% of the gait cycle), but there is a lack of consensus on the primary functional role of this phase of gait (Zelik and Adamczyk 2016). The swing phase typically comprises three events: early (or initial), mid and late (or terminal) swing. Early swing encompasses the period between toe off to mid swing (60–75% of the gait cycle). Mid swing occurs slightly before to just after the mid stance phase of the opposite limb (approximately 75–85% of the gait cycle) and late swing encompasses the period from the end of mid swing through to heel contact (85–100% of the gait cycle) (Simoneau and Heiderscheit 2017) (see Fig. 76.15).

Joint kinematics and muscle activity

SURFACE ANATOMY

Skeletal landmarks

Pelvis

The anterior superior iliac spine lies superior to the lateral end of the inguinal skin crease: the iliac crest is palpable from this point along its entire length (**Fig. 76.18**). A line (Tuffier's) or plane (supracristal) joining the most superior aspects, or highest points, of the iliac crests commonly crosses the vertebral body of L4 or L4–L5 intervertebral disc, corresponding to the region from the L3–L4 to the L4–L5 interspinous space (Render 1996, Walsh et al 2006) (**Fig. 76.19**). The supracristal plane is used as a landmark when performing a lumbar puncture. Its localization via palpation, especially in females and patients with a high body mass index (BMI), often places it at a more superior vertebral level, up to the L2–L3 interspinous space (Chakraverty et al 2007, Kim et al 2003). Inferiorly, the line may intersect the vertebral column at the spinous process of L5. Vertebral column flexion in the adult has little effect on the level of the supracristal plane (Kim et al 2003). In neonates, the plane sits at the L4–L5 interlaminar space level whilst prone, moving to the superior one third of the vertebral body of L5 during vertebral column flexion (van Schoor et al 2014): palpation commonly locates the plane at the L4–L5 or L5–S1 interspinous space (Baxter et al 2016).

The iliac crest terminates posteriorly as the posterior superior iliac spine, which is marked by an indentation in the overlying skin. Palpation places the posterior superior iliac spines most commonly at the level of the spinous process of S1 or S2 (range spinous process of S1 or S2). Radiographic assessment shows that the inferior margin of the posterior superior iliac spine consistently marks the S2 spinous process in most individuals (McGaugh et al 2007). The inferior limit

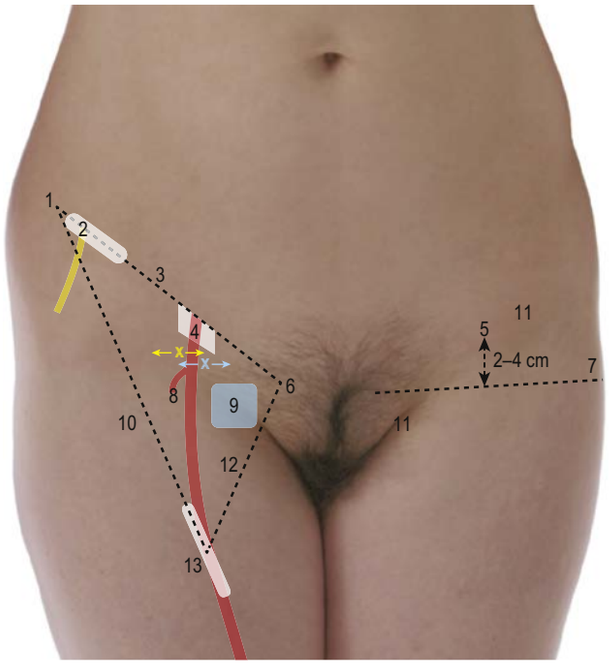

Fig. 76.18 The inguinal region and femoral triangle. Key: 1, anterior superior iliac spine; 2, lateral femoral cutaneous nerve and its zone of emergence into femoral triangle (white): range 0.3–7.3 cm (mean 2.1–3.5 cm) from the anterior superior iliac spine; 3, inguinal ligament; 4, femoral artery and zone of emergence (mid-inguinal point ±1.5 cm either side) into femoral triangle (white): the femoral nerve (yellow cross) and vein (blue cross) sit adjacent to the artery, and follow any variation in its position (arrows); 5, femoral head: located 2–4 cm above the midpoint of a line joining the greater trochanter to pubic tubercle; 6, pubic tubercle; 7, line joining the greater trochanter to the pubic tubercle; 8, profunda femoris artery: commonly arises 6.5±1.5 cm distal to the mid-inguinal point, on or just superior to the inguinal/groin crease; 9, zone of saphenofemoral junction location: almost always sits within a 3 cm × 3 cm zone situated 1–4 cm lateral and 0–3 cm inferior to the pubic tubercle; 10, sartorius; 11, inguinal/groin crease; 12, adductor longus; 13, zone of femoral artery entry into the adductor canal (white), approximately 28 cm (range 24–31 cm) from the anterior superior iliac spine. Fig. 76.19 The gluteal region and sciatic nerve. Key: 1, zone of supracristal plane intersection with vertebrae (white): ranges from the L2–L3 interspinous space to the spinous process of L5; 2, highest point of iliac crests (supracristal plane or Tuffier's line): most commonly intersects the vertebrae from the spinous process of L4 to the L4–L5 interspinous space; 3, zone of intersection between the vertebrae and a horizontal plane between the posterior superior iliac spines (white): ranges from the spinous process of L5 to S3 when determined via palpation (note the overlap with 5); 4, posterior superior iliac spine and interspinous plane: marked by a skin indentation, and commonly intersects the vertebral body or spinous process of S1 or S2; 5, zone of termination of dural sac (blue): ranges from L5–S1 intervertebral disc to vertebral body of S4, most commonly sits level with the inferior part of S1 to the inferior part of S2 vertebral body (note the overlap with 3); 6, gluteus maximus; 7, sacral hiatus bordered by sacral cornua, located at the apex of an approximately equilateral triangle with baseline measurement taken between the posterior superior iliac spines; 8, course of sciatic nerve: from a point 30 ± 5% of the distance down a line joining the posterior superior iliac spine to the ischial tuberosity (black X and white zone) to a point 50 ± 5% of the way along a line joining the ischial tuberosity to the upper greater trochanter (red X and white zone); 9, tip of coccyx within intergluteal cleft; 10, greater trochanter; 11, ischial tuberosity; 12, gluteal fold. (Adapted from Drake R, Vogl AW, Mitchell AW et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008.)

of the dura mater, and therefore of the subarachnoid space, typically ranges from the inferior part of the vertebral body of S1 to the inferior part of the vertebral body of S2 (equating to the spinous processes of S1and S2, respectively) (Hansasuta et al 1999, Binokay et al 2006, Senoglu et al 2013): the inferior limit of the dura mater may vary from the L5–S1 intervertebral disc to the vertebral body of S4. The ischial tuberosity is covered by gluteus maximus and is palpable during hip flexion. The coccyx is palpable in the superior part of the intergluteal (natal, anal) cleft, which is the deep vertical midline groove between the left and right gluteal muscle masses. The sacral hiatus sits superior to the tip of the coccyx at a mean of 5.8 ± 0.9 cm and is flanked by the raised and palpable sacral cornua, which serve as reliable landmarks (Aggarwal et al 2009). In adults, the hiatus can be located at the inferior apex of an inverted equilateral triangle with its base measured between the posterior superior iliac spines; this arrangement may not always be observed (Senoglu et al 2005). The triangle is an unreliable marker of the sacral hiatus in neonates and young infants, since surface identification of the sacral hiatus by palpation is only possible when the sacral cornua are developed (Mirjalili et al 2015). The linear distance from the apex of the sacral hiatus to the termination of the dural sac is variable, from a mean of 3.2 ± 1.2 cm to 4.5 ± 1.2 cm, which is of relevance to caudal anaesthetic administration.

Femur

The greater trochanter of the femur is palpable on the superior part of the lateral thigh, inferior to the midpoint of the iliac crest and approximately level with a horizontal plane passing through the pubic tubercle (see Fig. 76.18). It can be used to guide surgeons during anterolateral approaches to the hip joint. A line (Nelaton's/Roser–Nelaton's) drawn from the anterior superior iliac spine to the ischial tuberosity passes superior to or over the greater trochanter. In a patient with hip dislocation or femoral neck fracture, the greater trochanter can be palpated superior to this line. The femoral shaft is not directly palpable but runs inferomedially from a point 2–3 cm medial to the lateral aspect of the greater trochanter to the midpoint of the patella. The femoral head sits 2–4 cm superior to the midpoint of a line joining the superior margin of the greater trochanter and the pubic tubercle.

When the knee is flexed, the medial surface of the medial condyle and the lateral surface of the lateral condyle of the femur may both be palpated, and portions of the articular surfaces of the femoral condyles can be examined on each side of the patellar ligament. The adductor tubercle is palpable superior to the medial femoral condyle, and is found by tracing the vertical tendon of adductor magnus inferiorly to its insertion.

Patella

The entire patella is palpable except for its articular surface. When the quadriceps femoris is relaxed in the fully extended knee, the patella can

In clinical practice, it is only necessary to test a relatively small number of muscles in order to determine the location of a lesion. Any muscle to be tested must satisfy a number of criteria. It should be visible, so that wasting or fasciculation can be observed, and the muscle consistency with contraction can be felt. It should have an isolated action, so that its function can be tested separately. It should help to differentiate between lesions at different levels in the neural axis and in the peripheral nerve, or between peripheral nerves. It should be tested in such a way that normal can be differentiated from abnormal, so that slight weakness can be detected early with reliability. Some preference should be given to muscles with an easily elicited reflex. Table 76.4 gives a list of movements and muscles chosen according to these criteria; in practice, these tests would be combined with tests of sensory function. Knowledge of the sequence in which motor branches leave a peripheral nerve to innervate specific muscles is helpful in localizing the level of a lesion.

The following provides an overview of lower limb joint kinematics of the pelvis, hip, knee, and ankle and foot during gait, along with associated muscle activity in each of the three planes. While most of the joint motion during gait takes place in the sagittal plane, important but smaller movements are also observed in the coronal (frontal) and horizontal (transverse) planes. Most of the data relating to muscle activity are derived from electromyographic studies, and relate to walking at a normal speed of about 1.3–1.4 m/sec (Murray et al 1964, Bohannon 1997). While general patterns of muscle activity are outlined (**Fig. 76.16**), it is important to note that significant variation may occur between individuals. In addition, other factors such as age, sex and gait speed can influence some aspects of joint kinematics and muscle activity. The trunk and upper limbs assist in maintaining balance and minimizing energy expenditure during gait, but their contributions are not considered in this section. For further details on gait, including kinetics (study of forces), please refer to Simoneau and Heiderscheit (2017).

Pelvis

In the sagittal plane, pelvic movement occurs through small arcs of anterior and posterior pelvic tilt (approximately 2–4° in total) and results from the forces produced by the hip joint capsule and the hip flexor and extensor muscles. At heel contact the pelvis is neutral, moving into a small amount of posterior pelvic tilt during the first period of double limb support. The pelvis then tilts anteriorly, reaching a position of anterior pelvic tilt just after mid stance. During the second half of the stance phase, the pelvis tilts posteriorly until around toe off. This changes to anterior pelvic tilt during early to mid swing, and then to posterior pelvic tilt in late swing (Thurston and Harris 1983).

A total excursion of about 10–15° of pelvic movement occurs in the coronal plane, termed 'pelvic-on-femoral (hip) abduction and adduction', in relation to the stance limb (Ch. 77, 'Movements'). During weight acceptance the contralateral side of the pelvis drops (pelvic on femoral adduction), due to the effect of body weight, controlled by eccentric activity of the hip abductors on the stance limb. During the remainder of the stance phase (20–60% of the gait cycle), the contralateral side of the pelvis (swing limb) is elevated (pelvic on femoral abduction) by concentric contraction of the hip abductors.

In the horizontal plane, pelvic rotation occurs around a vertical axis of rotation (Baker 2001). The total amount of pelvic rotation varies (range approximately 4–14°), and it is uncertain if differences exist between sexes. At heel contact of the right foot, the ipsilateral anterior superior iliac spine is further forward compared with its contralateral counterpart. Pelvic rotation occurs in a medial (internal, counterclockwise) direction for the first 15–20% of the gait cycle, and then changes to lateral (external, clockwise) rotation, whereby the contralateral anterior superior iliac spine moves forward along with the swing limb (Simoneau and Heiderscheit 2017). The anterior portions of gluteus medius and gluteus minimus contribute to the forward contralateral rotation of the pelvis (Semciw et al 2013, 2014).

Hip

In the sagittal plane, the hip moves through two arcs of motion during a normal stride, being extended during stance and flexed through the swing phase. The total range of motion is approximately 40–50°, with an average of 30–40° flexion and 5–10° extension. Maximum hip flexion is reached just before heel contact, at which stage the hip starts to extend in preparation for weight acceptance. Hip extension is produced by gluteus maximus (active in the first 30% of the gait cycle, from heel contact through to mid stance), and the hamstring muscles (active during the first 10% of gait cycle), with some assistance from adductor magnus during weight acceptance (Lyons et al 1983) (see Fig. 76.16). At heel contact, gluteus maximus also acts to control trunk flexion. The hip progressively extends as the body moves forward over the fixed foot, with maximum hip extension occurring just before toe off. Hip flexion is initiated at push off, and during the swing phase the hip flexors (including iliopsoas, rectus femoris and sartorius), assisted initially by the hip adductors, function to move the lower limb forwards and to elevate it to enable toe clearance. Iliopsoas activates before toe off, and together with the other hip flexors is active throughout approximately the first 50% of the swing phase (Keagy et al 1966, Andersson et al 1997); hip flexion during the second half of the swing phase occurs as a result of forward momentum obtained in early swing. The hip extensors contract eccentrically late in swing to decelerate the flexing hip.

As described in relation to pelvic kinematics, hip motion in the coronal plane during stance primarily occurs through 'pelvic-on-femoral' abduction and adduction. Gluteus medius and gluteus minimus, the two primary hip abductor muscles, demonstrate two bursts of activity during stance, and are most active during the first 40% of the gait cycle (see Fig. 76.16). These muscles initially function eccentrically to control the lowering of the contralateral pelvis on the side of the swing limb. They then contract concentrically, and are critical to ensuring frontal pelvic stability across the stance phase, particularly during single limb support (Ch. 77). During the swing phase the hip returns to its neutral frontal plane position, achieved through a combination of the motion of the pelvis (about the stance limb) and that of the advancing femur.

Hip medial and lateral rotation in the horizontal plane equates to approximately 6–7° in each direction. At heel contact, the femur is slightly laterally rotated. For most of the stance phase (the first 50% of the gait cycle) a net medial rotation movement occurs at the hip, as the contralateral pelvis is moved forward in the horizontal plane by the medial rotator muscles (tensor fasciae latae, anterior gluteus medius and gluteus minimus). This muscle group, together with the lateral rotators (six short lateral rotators, posterior gluteus medius, gluteus maximus), control the alignment of the hip in the horizontal plane. In particular, eccentric contraction of the lateral rotators may be important in controlling medial rotation of the lower limb during early stance. From early to mid-swing, the hip rotates laterally as the lower limb advances forward, and from mid swing to heel contact slight medial rotation is apparent.

Knee

The knee moves through a total sagittal range of motion from nearly full extension to approximately 65° flexion during the gait cycle (Bruening et al 2015). At heel contact, the knee is flexed slightly (approximately 5°), and continues to flex during the initial 15% of the gait cycle, to reach about 15–20°. This slight knee flexion contributes to shock absorption during weight acceptance onto the stance limb, and is controlled by eccentric activity of the quadriceps muscles (see Fig. 76.16). As body weight is transferred onto the stance limb, the knee gradually extends via contraction of the quadriceps muscles, attaining near full extension at the end of stance. The knee then begins to flex, serving to shorten the lower limb so to facilitate toe clearance, reaching 35° flexion at toe off and maximum flexion of approximately 60° at mid swing. Most of the knee flexion during swing occurs passively as a result of the hip flexing, with a potential small contribution from the plantar flexor muscles (Winter 1983, Sutherland 2001). Between mid to late swing the knee extends, nearly reaching full extension, and then begins to flex slightly just before heel contact. In the period just before to just after heel contact, the hamstrings contract eccentrically to decelerate knee extension. Co-contraction of the quadriceps and hamstring muscles in early stance, push off and late swing (highest levels of muscle excitation) (see Fig. 76.16) preserve knee joint stability during normal gait (Strazza et al 2017).

The knee is relatively stable in the coronal plane, but variation is evident in the direction of the reported motions. The knee is abducted slightly at heel contact (Lafortune et al 1992) and moves through a small range (approximately 3°) of inconsistent abduction–adduction during the first 80% of stance, with up to 5° of adduction apparent throughout the final 20% of stance (Ishii et al 1997, Benoit et al 2007). Throughout swing, the knee is abducted, with maximum abduction occurring near the point of maximum knee flexion.

Similar to coronal plane motion, knee movements in the horizontal plane are small (approximately 5–10° in total) and highly variable between individuals. The tibia is rotated laterally just before heel contact, with medial rotation initiated at heel contact and sustained during the first 25% of stance. At mid stance the tibiofemoral joint is

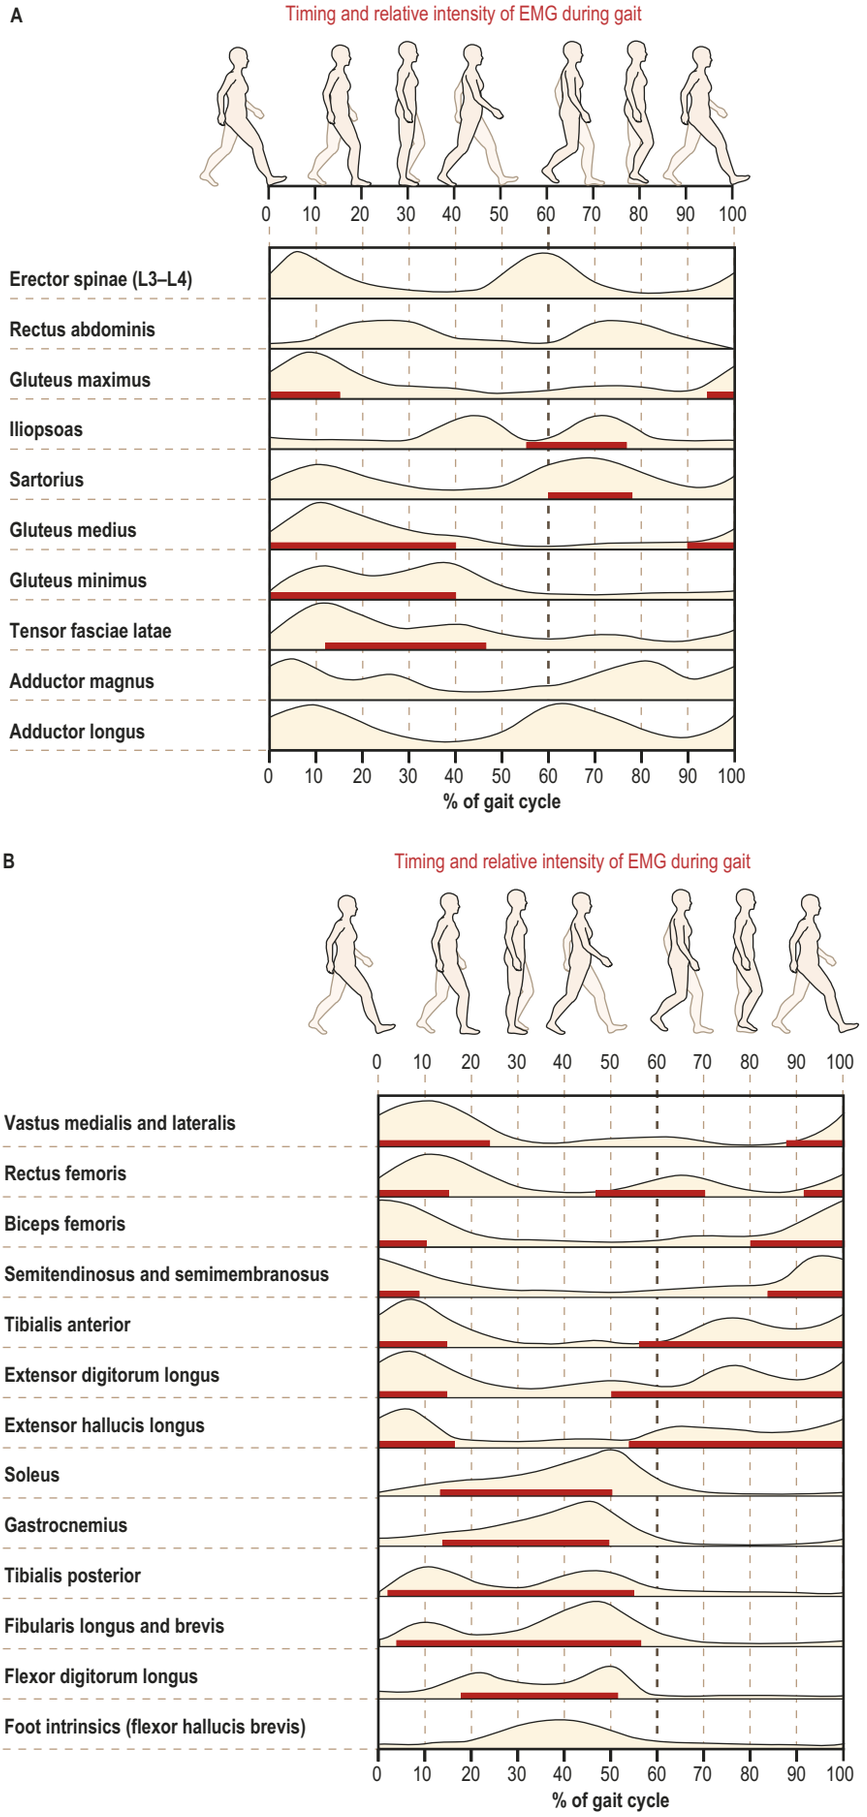

Fig. 76.16 A–B, An electromyographic (EMG) illustration showing the timing (red bars) and relative intensity (light brown shading) of muscle activation during walking. The Y axes depict the relative intensity of muscle activation for each muscle as a proportion of their maximum value obtained during the gait cycle. Based on this scaling, all muscles nearly fill the full vertical dimension of their respective graph, therefore precluding direct comparison of magnitude of muscle activation across muscles. (Adapted with permission from Simoneau GG, Heiderscheit BC Kinesiology of walking. In: Neumann DA (ed) Kinesiology of the Musculoskeletal System: Foundations for Rehabilitation, 3rd ed. Elsevier, Mosby. Copyright 2017.)

close to neutral, with lateral tibial rotation occurring in conjunction with the final 30° of extension, an event referred to as the 'screw home' movement or rotation (Levens et al 1948). Initiation of knee flexion, through to mid swing, is accompanied by medial rotation of the tibia (Perry and Burnfield 2010).

Ankle and foot

The total excursion of ankle (talocrural) joint plantar flexion and dorsiflexion in the sagittal plane is approximately 33°. At heel contact the foot is positioned in neutral or slight plantar flexion (0–5°). A short phase of rapid plantar flexion follows during the first 8% of the gait cycle, controlled by the eccentric activity of the ankle dorsiflexors (tibialis anterior, extensors digitorum longus and hallucis longus), enabling the foot to be positioned flat on the ground (Gray and Basmajian 1968, Hunt et al 2001). During stance (8–45% of the gait cycle), dorsiflexion occurs as the tibia moves forward over the foot. Dorsiflexion in this phase of gait reaches a maximum of approximately 10°, and is controlled by the plantar flexor muscles (gastrocnemius and soleus) which work eccentrically from just after foot flat to heel off to control the forward progression of the leg (see Fig. 76.16).

Just after heel off, the ankle begins to plantar flex due to concentric plantar flexion muscle contraction (including fibularis longus), with a major burst of activity occurring around push off (see Fig. 76.16): there are contrasting opinions as to whether push off contributes to the production of forward motion of the body during normal gait (centre of mass acceleration) and/or acceleration of leg swing (Hof et al 1992, Zelik and Adamczyk 2016). As the heel leaves the ground, gradual extension (up to 45°) occurs at the metatarsophalangeal joints. Due to the indirect connections between the deep plantar fascia and the toes, extension, of the great toe particularly, increases tension throughout the medial longitudinal arch (referred to as the 'windlass effect'). Maximum plantar flexion (approximately 15–20°) occurs just after toe off. During swing phase the ankle dorsiflexors (particularly tibialis anterior) contract concentrically to return the ankle to a neutral position, allowing the toes to clear the ground (Winter and Yack 1987). The intrinsic muscles of the foot are active from mid stance to toe off, stabilizing the forefoot and raising the medial longitudinal arch (see Fig. 76.16).

In the coronal plane interaction between the subtalar and transverse tarsal joints results in the tri-planar movements of supination and pronation. At heel contact, the subtalar joint is inverted (approximately 2–3°), and then rapidly everts until mid stance (Hunt et al 2001). Tibialis posterior is active throughout most of the stance phase, with muscle activity peaking from just after heel contact and then again at about 35% of the gait cycle (see Fig. 76.16). This muscle acts to resist pronation of the hindfoot (calcaneus and talus), and works synergistically with fibularis longus, to assist with mediolateral foot stability (Murley et al 2009, 2014). Following mid stance, the subtalar joint reverses its direction of movement, inverting (through concentric invertor muscle activity) to reach a neutral position about the time of heel off (Arndt et al 2004). Calcaneal inversion continues between heel off and toe off to reach approximately 6° of inversion, and during swing the hind foot returns to a slightly inverted position prior to heel contact.

Little ankle and foot movement occurs in the horizontal plane, and so this is not considered in this section.

Development of walking

The average child sits at 6 months, crawls at 9 months, walks with support at 10 months and walks without support around 12–14 months. The characteristic early gait matures rapidly and is similar to that of the adult by about 4–5 years (Sutherland et al 1980, Chester et al 2006). Some minor changes occur up to 7 years, which are largely a reflection of neurological development but are also related to stature (Volpe 2001). Early gait is jerky, unsteady and wide-based. Initial ground contact varies, and heel–toe, whole foot and toe–heel are all possible. Generally, a plantar flexed posture is adopted, which contrasts with the adult pattern. In adults, heel contact is accompanied by a straight knee which then flexes. A child strikes the ground with a flexed knee which is then extended in response to weight-bearing, and a short time is spent in single-leg stance (**Fig. 76.17**). The earliest changes are development of heel contact, knee flexion during stance, adult pattern of joint angles and reciprocal upper limb swing. Maturation is associated with diminution of base width and an increase in step length and velocity (Sutherland et al 1980).

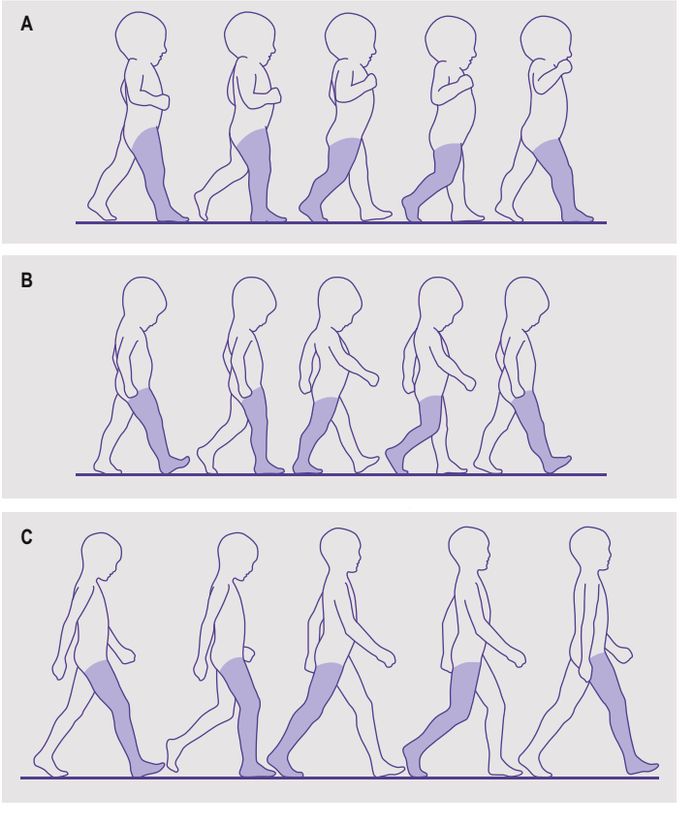

Fig. 76.17 Development of a mature gait. **A**, A 1-year-old infant. Note the flexed elbows and lack of arm swing. The foot is plantar flexed at contact. **B**, A 3-year-old child. Arm swing is now present, as is heel strike. **C**, A 6-year-old child. There is now an adult-type gait. (With permission from Benson MKD, Fixsen JA, MacNicol MF (eds) 2001 Development of mature gait. In: Children's Orthopaedics and Fractures, 2nd ed. Edinburgh: Churchill Livingstone.)

Ageing

With ageing, walking becomes more challenging as a consequence of reduced lower limb muscle strength and range of motion and impaired balance (Pirker and Katzenschlager 2016). Mean gait speed is relatively consistent up to about 70 years of age, and then declines by up to 1.2% per year (Alcock et al 2013), reaching less than 1.0 m/sec in those aged 80 years and over (Bohannon and Williams Andrews 2011). This decrease in speed is a function of both a shorter step length and an increase in time spent in the double-limb support phase; step width also increases thereby increasing the base of support, and gait becomes more variable and asymmetrical due to stride-to-stride fluctuations (Lord et al 2013). Alterations in kinematic attributes, that are independent of a reduced gait speed, include reduced hip extension with an associated increase in anterior pelvic tilt (Kerrigan et al 1998). Reductions in plantar flexion range with decreased ankle plantar flexion power during push off are also evident. Some of these age-related changes may indicate the adoption of a more stable walking pattern, to compensate for reduced physical ability (Menz et al 2003), or represent adaptations to alterations in sensory or motor systems (Aboutorabi et al 2016). Altered gait performance influences falls risk, and progressive deterioration in gait parameters occurs with cognitive impairment, with greater declines evident in the advanced stages of dementia (Allali et al 2016).

Running

The spatiotemporal descriptors of running are defined in a similar way to those of walking (see Video 76.2). However, while walking involves two periods of double-limb support phases (where both feet are on the ground simultaneously), in running each foot is on the ground (stance phase) for 40% (jogging, approximately 2.0–3.5 m/sec) to approximately 25% (sprinting, greater than 8.0 m/sec) of the stride (Högberg 1952, Mann and Hagy 1980). This results in an aerial phase – the 'double-float' phase – when neither foot is on the ground, a feature that demarcates running from walking. An increase in running speed is generally the result of taking longer strides and increasing stride frequency (Dorn et al 2012). The faster an individual runs, the shorter the stance phase, with the main difference between running and sprinting being the acceleration at the start of a sprint (Haugen et al 2019).

The stance and swing phases of the running gait cycle can be divided into a number of key events that include heel contact, mid stance, heel off, toe off and mid swing (Heiderscheit and Simoneau 2017). The start of the running cycle is defined as the instant the foot comes into contact with the ground, often referred to as foot strike. This can occur in three ways, with either the rearfoot (hindfoot or heel), midfoot or forefoot contacting the ground first; the rearfoot strike pattern is most common, accounting for up to approximately 85% of all runners (Lieberman et al 2010, Almeida et al 2015). Mid stance occurs when the body's weight is aligned directly above the planted foot or when the knees are side by side (at approximately 20% of the gait cycle), with the 'loading response' occupying the first 15% of the cycle. The timing of heel off (approximately 25% of the cycle) and toe off (30–40% of the cycle) varies with running speed. Like walking, mid swing occurs around the middle of the swing phase (approximately 70% of the running gait cycle).

The other periods of the running gait cycle include pre swing, early swing and late swing. During pre swing, which occurs between heel off and toe off, the lower limb muscles generate mechanical energy for propulsion. Early swing encompasses the period between toe off to mid swing, while late swing occurs from the end of mid swing through to foot strike (Heiderscheit and Simoneau 2017).

There are many factors that influence running mechanics including age, sex, speed and type of surface, and injuries are common. While the overall kinematics of running are similar to those of walking, the magnitude and timing of joint motion is different. For further details on the biomechanics of running, refer to Novacheck (1998) and Heiderscheit and Simoneau (2017).

TABLE 76.5 Common sites for iatrogenic upper limb nerve injury in primary care (adapted from Wallis et al 2018)

Nerve	Site	Procedure
Sciatic nerve	Gluteal region	Intramuscular injection
Lateral cutaneous of thigh	Anterior thigh	
Common fibular nerve	At the level of the fibular neck	Minor surgical procedure (skin lesion removal)
Sural nerve	Posterior leg	

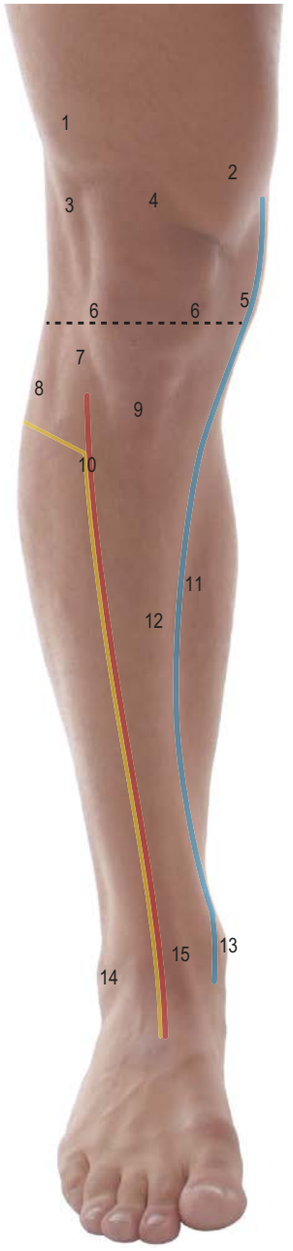

Fig. 76.20 The anterior aspect of the knee and leg. Key: 1, vastus lateralis; 2, vastus medialis; 3, iliotibial tract; 4, quadriceps tendon overlying suprapatellar bursa; 5, sartorius; 6, anterior horns of menisci: located above knee joint line (dotted line) and either side of patellar ligament; 7, tubercle of the iliotibial tract (Gerdy's); 8, fibular head; 9, patellar ligament insertion into tibial tuberosity; 10, anterior tibial artery and deep fibular nerve: the artery passes from halfway between fibular head and tibial tuberosity to a point halfway between the medial and lateral malleoli; 11, soleus and long saphenous vein (blue); 12, medial tibial border (subcutaneous); 13, medial malleolus: long saphenous vein and saphenous nerve pass anterior; 14, lateral malleolus; 15, tendon of tibialis anterior. Fig. 76.21 The posterior aspect of the knee and leg. Key: 1, popliteal artery: passing from a point (black X) 2.5 cm medial to the posterior midline of the thigh at the junction of its middle and inferior one thirds to a point halfway between the femoral condyles/the midaxial line of the calf (blue X); 2, iliotibial tract; 3, tendon of biceps femoris and common fibular nerve (yellow) located medially; 4, semimembranosus and semitendinosus; 5, gracilis; 6, popliteal fossa; 7, head of fibula; 8, lateral head of gastrocnemius; 9, medial head of gastrocnemius; 10, soleus; 11, posterior tibial artery and tibial nerve: pass along a line from the midaxial line of the posterior leg, at the level of the fibular neck, to a point one-third of the way from the posterior border of the medial malleolus to the distal insertion of the calcaneal tendon; 12, medial malleolus; 13, lateral malleolus and short saphenous vein passing posteriorly; 14, calcaneal tendon insertion into calcaneus. (Adapted from Drake R, Vogl AW, Mitchell AW et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008.)

be tilted and moved on the distal aspect of the femur. The inferior limit of the apex of the patella is located superior to the knee joint line by 1–2 cm (Fig. 76.20).

Knee

The patella and the femoral condyles have been described above. The tibial condyles form visible and palpable landmarks on the medial and lateral sides of the patellar ligament (see Fig. 76.20). The latter may be traced inferiorly from the apex of the patella to the tibial tuberosity, which is both visible and palpable. When the knee is flexed, the anterior margins of the tibial condyles can be felt: each forms the lower boundary of a depression at the side of the patellar ligament. The lateral condyle is the more prominent of the two. The joint line of the knee (tibiofemoral joint) corresponds to the upper margins of the tibial condyles and can be approximated by a line drawn around the limb at this level. The anterior horns of the menisci lie in the angles between this line and the edges of the patellar ligament. The iliotibial tract is attached to a bony prominence, the tubercle of the iliotibial tract (Gerdy's tubercle), on the anterior surface of the lateral tibial condyle which is normally approximately 1 cm inferior to the joint line and about 2 cm superolateral to the tibial tuberosity.

The head of the fibula forms a slight surface elevation on the posterior part of the proximal lateral leg. It lies vertically below the posterior part of the lateral condyle of the femur, 1–2 cm inferior to the knee joint line.

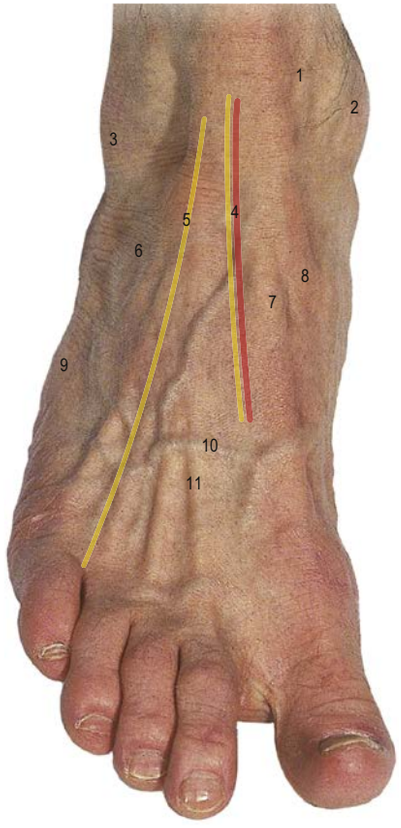

Fig. 76.22 The dorsal aspect of the foot and ankle. Key: 1, long saphenous vein and saphenous nerve; 2, medial malleolus; 3, lateral malleolus; 4, dorsalis pedis artery and deep fibular nerve: located immediately lateral to the tendon of extensor hallucis longus; 5, intermediate dorsal cutaneous nerve: visible passing towards the fourth toe during toe and ankle plantarflexion; 6, extensor digitorum brevis; 7, tendon of extensor hallucis longus; 8, tendon of tibialis anterior: insertion into medial cuneiform; 9, tuberosity of fifth metatarsal; 10, dorsal venous arch of foot; 11, tendon of extensor digitorum longus (to the second toe). Leg and ankle

The subcutaneous medial surface of the tibia corresponds to the flat anteromedial aspect of the leg. Superiorly, this surface merges with the medial condyle of the tibia, and inferiorly, it is continuous with the visible prominence of the medial malleolus of the tibia (see Fig. 76.20; Figs 76.21–76.22). The anterior border of the tibia can be palpated distinctly throughout most of its extent, but inferiorly, it is partially covered by the tendon of tibialis anterior, which lies to its lateral side. The lateral malleolus of the fibula forms a large prominence on the lateral side of the ankle; it descends to a more inferior level than the medial malleolus and is located on a more posterior plane. The lateral aspect of the lateral malleolus is continuous superiorly with an elongated, subcutaneous, triangular area of the inferior shaft of the fibula. The lateral part of the anterior margin of the inferior end of the tibia can be palpated immediately anterior to the base of the lateral malleolus; the line of the ankle joint can be determined from it.

Foot

The anterior part of the upper surface of the calcaneus can be identified on the dorsum of the foot slightly anterior to the lateral malleolus. When the foot is passively inverted, the upper and lateral parts of the head of the talus can be both seen and palpated on the dorsal surface approximately 3 cm anterior to the distal end of the tibia; the extensor tendons cover the talus when the toes are extended. Regional tenderness can indicate a talar neck fracture.

The dorsal aspects of the bodies of the metatarsals can be palpated but they are partly covered by the extensor tendons of the toes. The tuberosity on the base of the fifth metatarsal forms a distinct palpable and visible projection on the lateral border of the foot.

The flat lateral surface of the calcaneus can be palpated on the lateral aspect of the heel and can be traced anteriorly, inferior to the lateral malleolus, where the tendons of fibularis longus and brevis cover it. The fibular (peroneal) trochlea, when sufficiently large, can be palpated as a raised tubercle of bone approximately 2 cm inferior to the tip of the lateral malleolus. A palpable depression just anterior to the lateral malleolus leads to the lateral end of the tarsal sinus.

On the medial side of the foot, the sustentaculum tali can be felt approximately 2 cm inferior to the medial malleolus; the tendon of flexor hallucis longus can be located inferiorly (Fig. 76.23). The tuberosity of the navicular is palpable and usually visible approximately 2.5 cm anterior to the sustentaculum tali. Anterior to this, the medial cuneiform can be identified, with the tendon of tibialis anterior

inserting onto it. The superior and medial parts of the joint line between the medial cuneiform and the first metatarsal can be felt as a narrow groove.

When the foot is placed on the ground, it rests on the posterior part of the inferior surface of the calcaneus, the heads of the metatarsals and, to a lesser extent, on its lateral border, and the medial longitudinal arch of the foot is elevated from the ground. The medial and lateral tubercles of the calcaneus can be palpated on its inferior surface through the anterior part of the fibro-fatty heel pad, which covers them and may make their palpation difficult. The heads of the metatarsals are similarly covered by a fibro-fatty pad on the plantar surface of the foot, they are most easily palpated on the dorsum of the foot, with the digits in flexion.

The calcaneocuboid joint is about 2 cm posterior to the tuberosity on the base of the fifth metatarsal and is almost in line with the talonavicular joint: the position of the latter may be gauged from the talar head (**Fig. 76.24**). The calcaneocuboid and talonavicular joints collectively form the transverse tarsal (Chopart) joint. The tarsometatarsal (Lisfranc) joints approximate to a line joining the tip of the tuberosity of the fifth metatarsal to the tarsometatarsal joint of the great toe; the latter is located 2–3 cm anterior/distal to the tuberosity of the navicular and is palpable. The joint between the second metatarsal and the intermediate cuneiform is located 2–3 mm posterior to the line of the other tarsometatarsal joints. The metatarsophalangeal joints are located about 2.5 cm posterior to the web spaces of the toes and are palpable on the dorsal foot, from where they are accessible via a needle.

Musculotendinous and ligamentous landmarks

See **Video 76.3**.

Gluteal region and hip

The bulky prominence of the gluteal region is formed by gluteus maximus, a variable amount of subcutaneous fat and the normal alignment of the pelvis, which angles the ischial tuberosities posteriorly (see Fig. 76.19).

The gluteal fold, an almost horizontal fold of skin located inferior to the main bulk of the gluteal muscles, marks the upper limit of the posterior aspect of the thigh. It does not correspond to the inferior border of gluteus maximus but is formed by fibrous connections between the skin and the deep fascia. The vertical intergluteal (natal, anal) cleft, which separates the left and right gluteal regions inferiorly, begins superiorly level with the vertebral body of S3 or S4. The superior border of gluteus maximus begins on the iliac crest approximately 5–7 cm superolateral to the posterior superior iliac spine and runs inferiorly and laterally towards the apex of the greater trochanter. Its inferior border corresponds to a line drawn from the ischial tuberosity, through the midpoint of the gluteal fold, to a point approximately 9 cm below the greater trochanter. Although gluteus maximus overlaps the ischial tuberosity in the standing position, on sitting, it slides superior to the tuberosity, leaving it free to bear weight. Gluteus maximus can be felt to contract when the hip is extended against resistance. In neonates, gluteus maximus is relatively small and poorly developed.

Gluteus medius completely covers the underlying gluteus minimus. Both muscles lie in a slight depression superolateral to gluteus maximus and inferior to the anterior part of the iliac crest and both pass inferiorly to insert into the greater trochanter. They constitute the major abductors of the hip and can be felt to contract by asking the subject to stand on one limb. The ipsilateral muscles contract to stabilize the centre of gravity and maintain a relatively horizontal pelvic position. Paresis or paralysis causes the pelvis to drop towards the unsupported, contralateral side (Trendelenburg's sign).

Thigh

The inguinal ligament can be felt running between the anterior superior iliac spine and the pubic tubercle, especially when the thigh is abducted and laterally rotated (see Fig. 76.18). The inguinal/groin crease (line of Holden), where the membranous layer of the superficial fascia of the abdomen (Scarpa's fascia) joins the fascia lata of the thigh, lies inferior to the inguinal ligament by a mean of 6.7 ± 1.9 cm and is more inferior to the inguinal ligament in females than in males (7.5 ± 1.9 cm versus 6.3 ± 1.9 cm) (see Fig. 76.18) (Lechner et al 1988).

The femoral triangle is located on the proximal anterior thigh. It is bounded superiorly by the inguinal ligament and laterally by the medial border of the strap-like sartorius, which can be both seen and felt in a reasonably thin and muscular subject when the hip is flexed in the sitting position, while the knee is kept extended and the thigh is slightly abducted and rotated laterally. Sartorius can be traced inferomedially from the anterior superior iliac spine to approximately halfway down the medial side of the thigh; distally, it may be identified as a soft longitudinal ridge passing towards the posterior part (region) of the medial surface of the medial femoral condyle. The adductor group of muscles forms the bulky mass at the upper part of the medial thigh. The medial border of adductor longus forms the medial boundary of the femoral triangle and can be felt as a distinct ridge when the thigh is adducted against resistance. At its superior end, its prominent tendon of origin can be seen and palpated immediately inferior to the pubic tubercle, which is a useful guide to this bony landmark.

The anterior convexity of the anterior thigh is caused by the curvature of the femur covered by the muscle mass of quadriceps femoris. Rectus femoris appears as a raised ridge passing down the anterior aspect of the thigh to the base of the patella, when the sitting subject flexes the hip with the knee extended. Vastus medialis forms a rounded elevation both medial and superior to the patella, and vastus lateralis forms an elevation superolateral to the patella that is more proximal and less pronounced than that of vastus medialis (see Fig. 76.20). Vastus intermedius follows the course of the femoral shaft, and is covered by the three other muscles in the quadriceps group. The thick tendon of adductor magnus can be palpated on the distal medial thigh, deep within the indentation located between vastus medialis anteriorly and gracilis and sartorius posteriorly.

The iliotibial tract, a thickened portion of the deep fascia of the thigh (fascia lata), runs from the lateral aspect of the iliac crest to the tubercle of the iliotibial tract and produces the flattened appearance of the lateral thigh. It forms a defined ridge that is visible on the lateral aspect of the knee either when the knee is extended against gravity or when the contralateral limb is lifted from the floor while standing.

The muscles of the posterior thigh may be palpated from the ischial tuberosity inferiorly along the lateral (biceps femoris) and medial (semitendinosus and semimembranosus) aspects of the posterior thigh.

Knee

The large depression posterior to the knee that is visible when the joint is actively flexed against resistance corresponds to the popliteal fossa. The transverse skin crease of the popliteal fossa lies about 2–3 cm superior to the knee joint line. The fossa is bounded on its superolateral side by the prominent tendon of biceps femoris, which can be palpated between the finger and thumb and traced inferolaterally to the head of the fibula. Three tendons (of semitendinosus, gracilis and semimembranosus) can be felt on the superomedial side of the fossa. Semitendinosus is the most lateral and posterior, while gracilis is the most medial and anterior; both tendons stand out sharply and can be seen when the knee is flexed against resistance and the hip adducted against resistance. The tendon of semimembranosus may be palpated deeply in the interval between the tendons of semitendinosus and gracilis: it is much thicker than the other two tendons and broadens rapidly as it is traced proximally. The superior borders of the medial and lateral heads of gastrocnemius form the inferomedial and inferolateral boundaries, respectively, of the popliteal fossa.

The cord-like fibular collateral ligament may be felt passing from the apex of the fibular head to the lateral epicondyle of the femur when the knee is flexed and laterally directed pressure (varus force) is applied to the medial side of the knee. The medial and lateral patellar retinacula pass from the patella to the medial and lateral femoral condyles, respectively. They are best observed and palpated on either side of the patella when pushing the patella laterally or medially, whilst the knee is fully extended and quadriceps femoris is relaxed.

Leg

The muscles in the anterior osteofascial compartment of the leg form a raised prominence over the superior two-thirds of its anterolateral aspect; this prominence is accentuated when the foot is actively dorsiflexed against resistance. The muscles continue as tendons in the inferior one third of the leg. The tendon of tibialis anterior can be seen just lateral to the anterior border of the distal tibia and traced inferiorly and medially across the anterior aspect of the ankle to the medial cuneiform (see Figs 76.20, 76.22). The other tendons cannot be examined satisfactorily superior to the ankle. The tendons of tibialis posterior and flexor digitorum longus can be felt (rather indistinctly) immediately superior to the posterior border of the medial malleolus and close to the medial border of the tibia, when the foot is actively inverted and plantar flexed.

On the lateral aspect of the leg, fibularis longus can be seen as a narrow almost vertical ridge following the line of the fibula during

active eversion and plantar flexion of the foot. It covers and hides fibularis brevis. The shaft of the fibula can only be palpated indistinctly between its neck and the area above the lateral malleolus.

The bulky muscular prominence of the posterior leg is formed by gastrocnemius and soleus, both of which can be identified either when the foot is plantar flexed against resistance, or when the heel is raised from the ground by standing on tiptoes (see Fig. 76.21). The two heads of gastrocnemius unite to form the inferior borders of the popliteal fossa. The medial head of gastrocnemius descends to a more inferior level than the lateral head. Soleus lies deep to gastrocnemius; when tensed, it bulges from under the medial and lateral margins of gastrocnemius, particularly on the lateral side, and its fleshy belly extends to a more distal level. Both muscles end inferiorly in the prominent calcaneal tendon, which can be palpated between the finger and thumb and followed inferiorly to its insertion into the posterior aspect of the calcaneus.

Foot

When the toes are actively extended, the bellies of extensor digitorum brevis and extensor hallucis brevis form a small elevation on the dorsal foot, just anterior to the lateral malleolus (see Fig. 76.22). During inversion of the ankle and extension of the toes, the prominent tendon of tibialis anterior is visible on the medial side of the dorsal foot, passing inferiorly and medially to the medial cuneiform. The tendon of extensor hallucis longus can be identified laterally as it passes toward the great toe; the tendons of extensor digitorum longus and fibularis tertius are further lateral as they pass deep to the inferior extensor retinaculum and immediately anterior to the lateral part of the distal tibia. More distally, the tendons of extensor digitorum longus and fibularis tertius diverge and can be traced to their insertions.

The tendon of tibialis posterior winds posterior to the medial malleolus and then curves anteriorly in the interval between the medial malleolus and the sustentaculum tali to reach the tuberosity of the navicular (see Fig. 76.23). The tendon is visible and palpable posterior to the malleolus when the foot is forcibly plantar flexed and inverted. The tendon of flexor digitorum longus lies immediately posterolateral to that of tibialis posterior. It curves forwards inferior to tibialis posterior and lies on the medial aspect of the sustentaculum tali. From there, it passes anteriorly and laterally to the centre of the plantar foot, where it divides into four tendons that pass to the base of the distal phalanx of each of the lateral four toes. The tendon of flexor hallucis longus lies inferior to, and grooves, the sustentaculum tali. As it passes towards the base of the distal phalanx of the great toe, it crosses the line of the flexor digitorum longus opposite the interval between the sustentaculum tali and the tuberosity of the navicular. Abductor hallucis may be seen or palpated in some subjects as a bulky mass along the medial border of the foot, passing from the medial calcaneal tubercle to the medial side of the base of the proximal phalanx of the great toe, just distal to the first metatarsophalangeal joint.

When the toes are maximally dorsiflexed, the plantar aponeurosis is easily palpated along the medial border of the foot, from just distal to the heel pad to the first metatarsophalangeal joint. It originates from the calcaneal tubercles, which may be palpable through the anterior part of the heel pad. Pain in the region of the medial calcaneal tubercle is commonly associated with plantar fasciitis.

Vessels, pulses and nerves

Arteries

The femoral artery enters the anterior thigh either halfway between the anterior superior iliac spine and the pubic symphysis (mid-inguinal point), or up to 1.5 cm on either side (medial to lateral) of this point (Hale et al 2010) (see Fig. 76.18). The artery normally passes directly anterior to the hip joint; its course may be represented by the upper two-thirds of a line joining its entry point into the thigh with the adductor tubercle, when the thigh is flexed, slightly abducted and rotated laterally. The profunda femoris artery (deep artery of the thigh) normally arises from the lateral side of the femoral artery, 6.5 ± 1.5 cm distal to the mid-inguinal point (Choy et al 2013), which is most commonly at or just superior to the level of the inguinal/groin crease (Lechner et al 1988). The femoral artery enters the adductor canal at the apex of the femoral triangle, about 27 cm (range 24–31 cm) from the anterior superior iliac spine along the line of sartorius, a point that is almost always distal to the midpoint of the thigh. It then travels deep to sartorius and the vastoadductor membrane towards the adductor hiatus. The length of the adductor canal is variable: 11.5 cm (range 8.9–14.5 cm) measured with ultrasound imaging (Wong et al 2017) and 7.6 cm (range 5.5–15 cm) in cadaveric dissections (Tubbs et al 2007). The adductor hiatus is commonly located approximately one third of the way up a line joining the midpoint of the femoral interepicondylar line to the superior part of the greater trochanter (Kale et al 2012).

Alternatively the adductor hiatus is located 65–75% of the way down a line drawn to join the midinguinal point (the midpoint of a line drawn between the anterior superior iliac spine and the pubic symphysis) to the adductor tubercle.

The course of the popliteal artery can be represented by a line extending from the junction of the middle and inferior one-third of the thigh, 2.5 cm medial to its posterior midline, to a point halfway between the femoral condyles, and continuing inferolaterally to the level of the tibial tuberosity, medial to the fibular neck, where it bifurcates into the anterior and posterior tibial arteries (see Fig. 76.21).

The anterior tibial artery may be represented by a line extending from a point halfway between the tibial tuberosity and the fibular head to a point midway between the anterior borders of the two malleoli (see Fig. 76.20). It passes onto the dorsal foot and becomes the dorsalis pedis artery, lateral to the tendon of extensor hallucis longus. The dorsalis pedis artery travels to the space between the bases of the first and second metatarsal bones. Near the second tarsometatarsal joint it gives off the arcuate artery which curves laterally over the bases of the second to fifth metatarsals.

The posterior tibial artery may be represented by a line drawn from a midaxial point on the posterior leg (approximately midway between the tibial condyles) at the level of the neck of the fibula, to a point one-third of the way between the posterior border of the medial malleolus and the distal part (insertion) of the calcaneal tendon (see Figs 76.21, 76.23). The same line represents the course of the tibial nerve. The nerve initially lies lateral to the popliteal artery, but then crosses the vessel to sit on its medial side. The posterior tibial artery bifurcates into the plantar arteries halfway between the medial malleolus and the medial calcaneal tubercle, approximately 1–2cm inferior to the inferior border of the medial malleolus.

The medial plantar artery passes anteriorly towards the base of the first metatarsal, where it branches. The lateral plantar artery passes obliquely laterally, towards the midpoint of the fifth metatarsal, reaching a point approximately 2–3 cm medial to the tuberosity of the fifth metatarsal. The deep plantar arch passes medially from the proximal end of the fourth to the proximal end of the first intermetatarsal space. Plantar and dorsal metatarsal arteries branch from the plantar arch and arcuate arteries, respectively, and pass along the intermetatarsal spaces toward the web spaces where they divide into plantar or dorsal digital arteries. These, together with the respective digital nerves, pass along the medial and lateral sides of the toes.

Pulses

Femoral artery. The pulsations of the femoral artery can be felt at its entry point into the proximal femoral triangle, where it can be compressed against either the superior pubic ramus or the hip joint. The pulse of the femoral artery is of value in assessing whether there is any significant cardiac output in cases of circulatory collapse. It is a common site for catheter insertion for radiological examinations such as cardiac angiography and for arterial puncture for blood gas analysis.

Popliteal artery. The pulse of the popliteal artery is the most difficult of the peripheral pulses to feel because the artery lies deep in the popliteal fossa. It is best examined with the subject lying supine or prone, with the knee flexed in order to relax the otherwise tense popliteal fascia that roofs the popliteal fossa. The popliteal pulse is then felt over the midline of the fossa by deep pressure against the popliteal surface of the femur.

Posterior tibial artery. The pulse of the posterior tibial artery can be felt by gentle palpation posterolateral to the medial malleolus as the artery lies between the tendons of flexor hallucis longus and flexor digitorum longus, approximately one-third of the way along a line connecting the posterior border of the medial malleolus to the distal part (insertion) of the calcaneal tendon.

Dorsalis pedis artery. The dorsalis pedis arterial pulse is found by palpation against the underlying tarsal bones, immediately lateral to the tendon of extensor hallucis longus, in the region extending from the midpoint between the malleoli to the proximal end of the first intermetatarsal space.

Veins

The femoral vein is located immediately medial to the femoral artery pulse, where it can be accessed (see Fig. 76.18). While femoral vein

puncture is relatively easy and enables access to the right atrium, the use of this approach is relatively unpopular for long-term cannulation because of a greater incidence of thrombosis and sepsis. However, it is a useful site for venous sampling in a patient with collapsed veins. For femoral vein cannulation, the skin puncture site is approximately 1 cm medial to the femoral artery and just inferior to the inguinal ligament.

The dorsal venous arch of the foot is visible and curves across the metatarsals (see Fig. 76.22). The long saphenous vein arises from the medial end of the arch, and the short saphenous vein arises from the lateral end. The long saphenous vein can be seen and palpated anterior to the medial malleolus, after which it runs superiorly and posteriorly across the distal medial surface of the tibia: this is a useful site for surgical venous access (cut-down) or venous harvesting for cardiac bypass surgery (see Figs 76.20, 76.23). The vein then runs proximally along the posterior part of the medial border of the tibia, where it is accompanied by the saphenous nerve, to reach a point about 7–10 cm posterior to the medial patellar border. From here, the vein ascends the thigh to the saphenous opening, where it passes deep to enter the femoral vein. The saphenofemoral junction is almost always located in a 3 cm×3 cm zone located 1–4 cm lateral and 0–3 cm inferior to the pubic tubercle (Mirjalili et al 2014) (see Fig. 76.18). The junction may be nearer to the pubic tubercle in younger and thinner subjects. A saphena varix may form at the junction, producing a swelling.

The course of the short saphenous vein may be represented by a line passing superiorly along the midline of the posterior leg, from the posterior surface of the lateral malleolus to the popliteal fossa; together with the sural nerve, this vein is the key anatomical guide to surgical dissection of the popliteal fossa (see Fig. 76.21).

Nerves

The femoral nerve, or its terminal branches, is located immediately lateral to the femoral artery pulse in the proximal femoral triangle.

The surface marking for the course of the saphenous nerve in the leg matches that of the long saphenous vein (see above). The lateral femoral cutaneous nerve enters the femoral triangle 2.1–3.5 cm (range 0.3–7.3 cm) inferomedial to the anterior superior iliac spine, deep to the inguinal ligament (see Fig. 76.18) (Grothaus et al 2005, Bjurlin et al 2007, Ropars et al 2009). It then passes over the lateral border of sartorius up to 11.3 cm distal to the anterior superior iliac spine and over the anterior border of tensor fasciae latae 2.4–9.2 cm distal to the anterior superior iliac spine. The nerve is at risk of damage during anterolateral surgical approaches to the hip.

The course of the sciatic nerve can be represented by a curved line that starts at a point 30 ± 5% of the distance down a line joining the posterior superior iliac spine to the ischial tuberosity, and passes to a point 50 ± 5% along a line joining the ischial tuberosity to the greater trochanter (see Fig. 76.19) (Currin et al 2015). It then continues vertically and inferiorly in the midline of the posterior aspect of the thigh, deep to biceps femoris, to the superior apex of the popliteal fossa, where it divides into the tibial and common fibular nerves (if it has not already done so at a more superior level). In children up to 10 years of age, the sciatic nerve in the gluteal region is most commonly located within the middle one third of two reference lines: a line joining the posterior superior iliac spine to the ischial tuberosity and a line joining the greater trochanter to the ischial tuberosity (Selkirk et al 2016).

The surface marking for the course of the tibial nerve in the leg matches that of the posterior tibial artery (see above). The course of the sural nerve at the ankle can be approximated by a line running parallel to the calcaneal tendon that is situated halfway between the tendon and the lateral malleolus: this position is variable and the sural nerve is at risk from surgery in this region.

The course of the common fibular nerve can be indicated by a line that passes from the superior apex of the popliteal fossa, along the inferomedial side of the tendon of biceps femoris towards the neck of the fibula (see Fig. 76.21). The nerve then curves inferiorly and anteriorly around the neck of the fibula approximately 3 cm distal to the apex of the fibular head. The common fibular nerve is palpable medial and distal to the tendon of biceps femoris and over the neck of the fibula, although here it becomes less distinct as it passes deep to the origin of fibularis longus. The nerve is at particular risk of damage at the neck of the fibula, from either a tightly applied plaster cast or a fracture.

The deep fibular nerve starts on the lateral aspect of the neck of the fibula, passes downwards and medially, and becomes associated with the anterior tibial artery, with which it is landmarked (see Fig. 76.21). The superficial fibular nerve also begins on the lateral aspect of the neck of the fibula. It passes inferiorly along the line of the fibula to a point on the anterior border of fibularis longus, at the junction of the middle and inferior one-thirds of the leg, where it pierces the deep fascia to become subcutaneous and divides into intermediate and medial dorsal cutaneous branches. The intermediate dorsal cutaneous branch is normally both visible and palpable as a fine ridge passing over the dorsolateral aspect of the ankle and foot toward the fourth toe, especially with the ankle and toes in plantarflexion (see Fig. 76.22). The medial dorsal cutaneous branch is rarely visible and passes towards the second toe. These superficial nerves are at risk from surgery in the anterior ankle region (especially during arthroscopy).

Several of the nerves within the lower limb can be iatrogenically damaged along their course by relatively minor procedures (**Table 76.5**).

Clinical procedures

Regional nerve blocks

Nerves can be effectively anaesthetized with local anaesthetic injection for surgical or post-injury pain relief. Common injection sites for the lower limb are around the hip for thigh and knee pain, and around the ankle for foot surgery. For the deeper nerves around the hip, ultrasound guidance enables the anaesthetist to secure an accurate needle position and to monitor the distribution of the local anaesthetic in real time (Munirama and McLeod 2013). For example, blockade of the sciatic nerve in the gluteal region, femoral nerve in the anterior thigh and obturator nerve in the medial thigh may be undertaken to provide pain relief following total knee replacement; the tibial nerve at the posteromedial ankle, the sural nerve at the posterolateral ankle and the superficial fibular nerves at the anterior ankle may all be anaesthetized at the ankle to allow 'awake foot surgery'.

Intramuscular injection

Intramuscular injections into the gluteal region using the classic dorsogluteal approach, with injections sited in the superior lateral quadrant, should be avoided to prevent iatrogenic damage to the sciatic nerve. Ventrogluteal approaches reduce the risk of iatrogenic neurovascular injury and are now recommended (Wallis et al 2018). For this approach, the palm of the examiner's hand, contralateral to the side being injected, is placed over the greater trochanter with the index finger pointing toward the anterior superior iliac spine and the remaining fingers abducted. The injection is made at the centre of the region bordered by the index finger, the iliac crest and the middle finger. Many so-called 'intramuscular' injections given into the gluteal region are actually given into the fat due to an insufficient needle length. Another safe alternative is to inject into the lateral aspect of the thigh (vastus lateralis).

Joint injection and aspiration

Careful aseptic technique is essential for all joint aspirations and injections.

Hip. Intra-articular hip injections are typically performed under fluoroscopic or ultrasonographic guidance. With the patient lying supine, and after the positions of the femoral artery and the anterior superior iliac spine have been marked out, the needle is introduced anteriorly, approximately 5 cm distal to the anterior superior iliac spine and 4 cm lateral to the femoral arterial pulse, and passed posteriorly, a little proximally and medially. An alternative technique that is dependent on relative distances from surface landmarks, rather than imaging guidance, utilizes the site of the proximal anterolateral portal for hip arthroscopy as the point of needle insertion (Masoud and Said 2013).

Knee. The lateral retropatellar approach is used. With the patient supine and the knee extended, the needle is introduced at the level of the superior border of the patella and guided towards the suprapatellar bursa.

Popliteal fossa. Sciatic nerve blocks at the popliteal fossa in infants and children can be effectively performed above the popliteal skin crease by correcting the adult landmark of 10 cm by the calculated ratio of the femoral shaft length of a child to the femoral shaft length of an adult (Bernière et al 2008).

Ankle. The anterior approach entails introducing the needle between the tendons of tibialis anterior and extensor hallucis longus with the foot partially plantar flexed.

Arthroscopy portals

The placement of portals for arthroscopy is important for maximizing surgical access for visualization and for surgical instruments, and also for avoiding damage to structures such as nerves and blood vessels.

Hip. Arthroscopy of the hip is used for conditions such as femoro-acetabular impingement, acetabular labral tears, chondral defects and extra-articular causes of hip pain. A variety of entry portals have been described. The anterolateral portal is sited on the skin approximately 4 cm lateral to the femoral artery pulse and 4 cm inferior to the inguinal ligament. Under fluoroscopy, a needle traversing the skin 30–45° proximally is advanced into the joint. Other more lateral portals can be used; the lateral femoral cutaneous nerve and the sciatic nerve are potentially at risk.

Knee. The knee is the joint most frequently examined arthroscopically. The standard portals are placed anteriorly. When the knee is flexed at a right-angle, 'soft triangles' bordered by the patellar ligament, the femoral condyles and the tibia and anterior horns of the menisci are palpable on either side of the superior third of the patellar ligament. Small incisions can be made in the apices of these triangular areas at about the level of the inferior pole of the patella for the anterolateral portal, and slightly lower for the anteromedial portal. These portals will allow passage of an arthroscope and instruments, with good access to most of the joint. The patellar ligament and the infrapatellar branch of the saphenous nerve are at risk from the skin incisions. The nerve is less vulnerable than the ligament; its position is variable but it usually lies below the appropriate portal sites. In the days of open meniscal surgery, the nerve was usually divided and painful neuroma formation was not uncommon.

Posteromedial and posterolateral portals are useful when better access to the posterior knee is required. The saphenous and common fibular nerves, respectively, are at risk with these approaches, and anatomical knowledge is vital to ensure safe portal placement. Laterally, the incision should be anterior to the tendon of biceps femoris, which can easily be palpated. Medially, the situation is more difficult because the saphenous nerve and long saphenous vein travel superficial to the medial epicondylar region of the knee, approximately a hand's breadth posterior to the medial border of the patella. It is essential that sharp incision includes the skin only, and that dissection down to the joint capsule is undertaken bluntly. If the medial meniscus is sutured, the capsule must be exposed before tying off sutures to avoid ensnaring the nerve.

Ankle. The use of ankle arthroscopy is well established, especially in treating sports-related injuries. Anterior portals are standard. The anteromedial portal can be placed just medial to the tendon of tibialis anterior, in the palpable soft spot. However, this comes close to the long saphenous vein and saphenous nerve; limiting the sharp incision to the skin, followed by blunt deeper dissection, reduces the risk. Alternatively, the anteromedial portal can be chosen to pass between the lateral edge of tibialis anterior and extensor hallucis longus. The anterolateral portal is placed with the help of the arthroscope in the joint to check the position of a preliminary needle passed into it. The portal should pass lateral to fibularis tertius and extensor digitorum longus. The intermediate dorsal cutaneous branch of the superficial fibular nerve is at risk as it crosses the ankle anterior to the lateral malleolus, and therefore it is wise to mark the positions of the nerves and blood vessels with a pen before making any incision. The nerves can usually be felt at the front of the ankle, even in obese patients, and they are often seen if the ankle is pulled into maximal plantar flexion. Posterior ankle arthroscopy is controversial: there is a view that the proximity of the neurovascular bundle (medially) and the sural nerve (laterally) renders the procedure too hazardous. Keeping lateral to the tendon of flexor hallucis longus will safeguard the medial neurovascular bundle.

Placement of surgical incisions

Hip. Surgery of the hip joint is usually undertaken for congenital issues, slipped capital femoral epiphysis in children, trauma or arthroplasty. Anterior and anterolateral approaches, often used in children, put the lateral femoral cutaneous nerve at considerable risk. Even in more lateral approaches, the lateral femoral cutaneous nerve and the femoral and sciatic nerves are all at risk through traction. A popular anterolateral approach to the hip joint involves splitting and separating forwards the anterior part of gluteus medius and vastus lateralis as a single sheet of tissue for subsequent reattachment to the greater trochanter. This technique relies on the anatomical continuity of the tissue. If the splitting of gluteus medius is more than a few centimetres superior to the tip of the greater trochanter, then the superior gluteal nerve and vessels are at risk, and weakness of hip abduction and a limp may result. In the posterior approach to the hip joint, gluteus maximus is incised in the line of its fibres. This is followed by division of the tendons of the short lateral rotators (piriformis, obturator internus and externus and the gemelli) near their trochanteric attachments to reveal the joint capsule. Reflecting these cut tendons medially protects the sciatic nerve. The inferior and superior gluteal nerves are at risk during posterior approaches to the hip.

Knee. Most open knee surgery can be undertaken through an anterior midline longitudinal incision, which gives good access and means that any future surgery can usually be undertaken via the same wound. New incisions run the risk of skin necrosis and poor wound healing as a consequence of interfering with the cutaneous blood supply. Inevitable interruption of cutaneous nerves, including the infrapatellar branch of the saphenous nerve, means that there is always numbness lateral to a longitudinal incision.

The extensile approach to the posterior knee is extensive. The key is to expose the sural nerve and short saphenous vein and to trace them proximally. This will lead the surgeon into the popliteal fossa and, after opening the deep fascia, safely to the neurovascular bundle. The wound crosses a flexure crease. A scar perpendicular to the crease might induce a fixed flexion contracture of the joint and therefore an S-shaped incision is employed where the transverse segment runs in the line of the flexure crease.

Ankle and foot. Incisions around the foot and ankle frequently put cutaneous nerves at risk and such an injury can result in a neuroma. The sural nerve at the ankle has a notorious tendency to form neuromas if transected, often after repair of a ruptured calcaneal tendon.

CHAPTER
77

Pelvic girdle, hip, gluteal region and thigh

The pelvic girdle consists of the paired hip bones (each composed of the ilium, ischium and pubis) and the sacrum. The two pubic bones articulate anteriorly at the pubic symphysis and the sacrum articulates posteriorly with the two iliac bones at the sacroiliac joint; the bones are virtually incapable of independent movement, except in the female during parturition or because of pathological change. The pelvic girdle serves as a weight-bearing and protective structure, as an attachment for trunk and lower limb muscles, and as the skeletal framework of a birth canal capable of accommodating the passage of a fetus.

The hip joint is a large synovial ball-and-socket type articulation between the head of the femur and the cup-shaped acetabulum. It permits extensive movements between the thigh and the pelvis, and between the trunk-and-pelvis (as a functional unit) and the thigh. The pivotal location of the hips serves as an essential mechanical link for many movements and postures of the body, including upright standing, locomotion, and bending toward and away from the ground.

The gluteal region or buttock is an area demarcated by the gluteal fold inferiorly, a line joining the greater trochanter and the anterior superior iliac spine laterally, the iliac crest superiorly and the midline medially. It contains a large bulk of skeletal muscle that covers several vulnerable neurovascular structures, and incorporates junctional zones between the lower limb, pelvis and perineum at the sciatic foramina. Direct and indirect musculoskeletal injuries in this region may damage the sciatic nerve and gluteal vessels.

The thigh consists of a cylinder of compact bone, the femoral shaft, surrounded by muscle groups traversed by important neurovascular structures. The muscles are grouped according to function and lie within three osteofascial compartments (anterior, posterior and medial) that are defined by fascial septa running between the femur and an enveloping tube of thick fascia, the fascia lata. The femoral artery gives off its major branch, the profunda femoris artery (deep artery of the thigh), in the anterior compartment. The sciatic nerve usually divides into its main branches, the tibial and common fibular nerves, as it passes through the posterior compartment of the thigh. The femoral nerve divides soon after entering the anterior compartment of the thigh beneath the inguinal ligament; the obturator nerve enters the medial thigh proximally and medially from the pelvis and divides into its main branches, which run anterior and posterior to adductor brevis.

SKIN AND SOFT TISSUES

Skin

See also Chapter 78.

Cutaneous vascular supply and lymphatic drainage

Buttock

Most of the skin of the buttock is supplied by musculocutaneous perforating vessels from the superior and inferior gluteal arteries. There are also small peripheral contributions from similar branches of the internal pudendal, iliolumbar and lateral sacral arteries.

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic drainage is to the superficial inguinal nodes.

Thigh

The skin of the thigh distal to the inguinal ligament and gluteal fold is supplied mainly by branches of the femoral and profunda femoris arteries. There is some contribution from the obturator, inferior gluteal and popliteal arteries, and from direct cutaneous, musculocutaneous and fasciocutaneous vessels. For further details, consult Cormack and Lamberty (1994).

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic drainage is to the superficial inguinal nodes, mainly via collecting trunks accompanying the long saphenous vein.

Innervation

For the dermatomes and cutaneous nerves, see Figs 76.12B, 76.13–76.14.

Soft tissues

Superficial fascia

The superficial fascia (subcutaneous tissue; tela subcutanea) of the thigh and buttock consists, as elsewhere in the limbs, of loose areolar tissue containing a variable quantity of fat. In some regions, particularly near the inguinal ligament, it splits into recognizable layers, between which may be found the branches of superficial vessels and nerves. It is thick in the inguinal region, where its two layers enclose the superficial inguinal lymph nodes, long saphenous vein and other smaller vessels. Here, the superficial layer is continuous with that of the abdominal fascia. The deep layer, a thin fibroelastic stratum, is most marked medial to the long saphenous vein and inferior to the inguinal ligament, and is interposed between the subcutaneous vessels and nerves and the deep fascia, fusing with the latter a little below the ligament. This membranous layer of subcutaneous tissue overlies the saphenous opening, blending with its circumference and with the femoral sheath. Over the opening, it is perforated by the long saphenous vein, by the superficial branches of the femoral artery other than the superficial circumflex iliac branch (which perforates the fascia lata separately), and lymphatic vessels; hence the term cribriform fascia. The subcutaneous tissue of the buttock is continuous superiorly with that over the low back and contains a variable quantity of fat.

Deep fascia

The deep fascia (fascia musculorum) covering the gluteal muscles varies in thickness. Over gluteus maximus it is thin, but over the anterior two-thirds of gluteus medius it forms the thick, strong gluteal aponeurosis. This is attached to the lateral border of the iliac crest superiorly, and splits anteriorly to enclose tensor fasciae latae and posteriorly to enclose gluteus maximus.

Fascia lata

The fascia lata, the expansive deep fascia that surrounds the thigh, is thicker in the proximal and lateral parts of the thigh where tensor fasciae latae and an expansion from gluteus maximus are attached to it. It is thin posteriorly and over the adductor muscles, but thicker around the knee, where it is strengthened by expansions from the tendon of biceps femoris laterally, sartorius medially and quadriceps femoris anteriorly. The fascia lata is attached superiorly and posteriorly to the back of the sacrum and coccyx, laterally to the outer margin of the iliac crest, anteriorly to the inguinal ligament, the iliac fascia and superior ramus of the pubis, and medially to the inferior ramus of the pubis, the ramus and tuberosity of the ischium, and the lower border of the sacrotuberous ligament. From the iliac crest, it descends as a dense layer over gluteus medius to the upper border of gluteus maximus, where it splits into two layers, one passing superficial and the other deep to the muscle, the layers reuniting at the lower border of the muscle.

Iliotibial tract

Over the flattened lateral surface of the thigh the fascia lata thickens to form a strong band, the iliotibial tract. The upper end of the tract splits into two layers, where it encloses and anchors tensor fasciae latae and receives, posteriorly, most of the tendon of gluteus maximus. The superficial layer ascends lateral to tensor fasciae latae to the iliac crest; the deeper layer passes up and medially, deep to the muscle, and blends

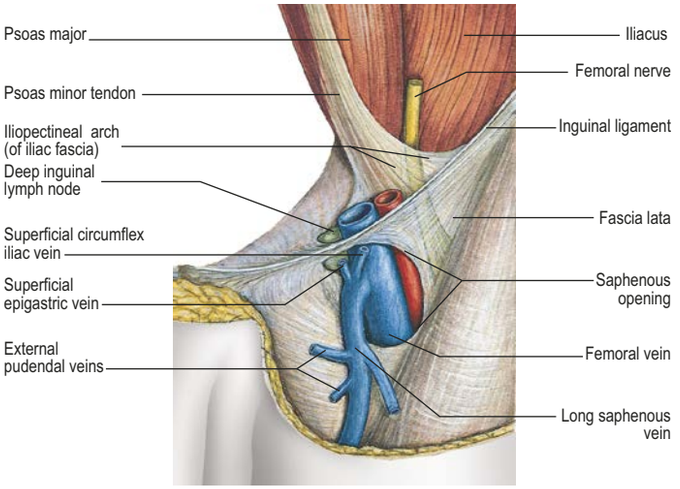

Fig. 77.1 The saphenous opening following removal of the cribriform fascia. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

with the lateral part of the capsule of the hip joint. Distally the iliotibial tract is attached to a smooth, triangular facet (Gerdy's tubercle) on the anterolateral aspect of the lateral condyle of the tibia, where it is superficial to, and blends with, an aponeurotic expansion from vastus lateralis. When the knee is extended against resistance, it stands out as a strong, visible ridge on the anterolateral aspect of the thigh and knee.

Distally the fascia lata is attached to all exposed bony points around the knee joint, such as the condyles of the femur and tibia, and the head of the fibula. On each side of the patella the deep fascia is reinforced by transverse fibres, which receive contributions from the lateral and medial vasti. The stronger lateral fibres are continuous with the iliotibial tract.

Intermuscular septa

The deep surface of the fascia lata yields two intermuscular septa, which are attached to the whole of the linea aspera of the posterior femur and to its proximal and distal prolongations. The lateral septum, thicker and stronger than the medial one, extends from the attachment of gluteus maximus to the lateral femoral condyle; it lies between vastus lateralis in front and the short head of biceps femoris behind, and provides partial attachment for them. The medial, thinner and weaker septum lies between vastus medialis and the adductors and pectineus. Numerous smaller septa, such as that separating the thigh adductors and flexors, pass between the individual muscles, ensheathing them and sometimes providing partial attachment for their fibres.

Saphenous opening

The saphenous opening is an aperture in the deep fascia, inferolateral to the medial end of the inguinal ligament, which allows passage for the long saphenous vein and other smaller vessels (**Fig. 77.1**). The cribriform fascia, which is pierced by these structures, fills in the aperture and must be removed to reveal it. Adjacent subsidiary openings may exist to transmit venous tributaries. In the adult, the approximate centre of the saphenous opening is 3 cm lateral to a point just distal to the pubic tubercle. The length and width of the opening vary considerably. The fascia lata in this part of the thigh displays superficial and deep strata (not to be confused with the superficial and deep layers of the subcutaneous tissue described above). They lie, respectively, anterior and posterior to the femoral sheath, with the saphenous opening situated where the two layers are in continuity. This serves to explain the somewhat oblique and spiral configuration of the saphenous opening.

The superficial layer, lateral and superior to the saphenous opening, is attached, in continuity, to the crest and anterior superior spine of the ilium, to the whole length of the inguinal ligament, and to the pecten pubis and lacunar ligament. It is reflected inferolaterally from the pubic tubercle as the arched falciform margin, which forms the superior, lateral and inferior boundaries of the saphenous opening; this margin adheres to the anterior layer of the femoral sheath, and the cribriform fascia is attached to it. The falciform margin is considered to have superior and inferior horns. The inferior horn is well defined, and is continuous behind the long saphenous vein with the deep stratum of the fascia lata.

The deep layer is medial to the saphenous opening and is continuous with the superficial stratum at its lower margin. Traced upwards, it covers pectineus, adductor longus and gracilis, passes behind the femoral sheath, with which it blends, and continues to the pecten pubis.

Femoral sheath

The femoral sheath is a funnel-shaped distal prolongation of extraperitoneal fascia, formed of transversalis fascia anterior to the femoral vessels, and of the iliac fascia posteriorly. It is wider proximally and its tapered distal end fuses with the vascular adventitia 3 or 4 cm distal to the inguinal ligament. At birth the sheath is shorter; it elongates when extension at the hips becomes habitual. The femoral branch of the genitofemoral nerve perforates its lateral wall. The medial wall slopes laterally and is pierced by the long saphenous vein and lymphatic vessels. Like the carotid sheath, the femoral sheath encloses a mass of connective tissue in which the vessels are embedded. Three compartments are described: a lateral compartment containing the femoral artery; an intermediate one for the femoral vein; and a medial compartment, the femoral canal, which contains lymph vessels and an occasional lymph node embedded in areolar tissue. The presence of this canal allows the femoral vein to distend. The canal is conical and approximately 1.25 cm in length. Its proximal (wider) end, termed the femoral ring, is bounded in front by the inguinal ligament, behind by pectineus and its fascia and the pectineal ligament, medially by the crescentic, lateral edge of the lacunar ligament and laterally by the femoral vein. The spermatic cord, or the round ligament of the uterus, is just above its anterior margin, while the inferior epigastric vessels are near its anterolateral rim. It is larger in women than in men: this is due partly to the relatively greater width of the female pelvis and partly to the smaller size of the femoral vessels in women. The ring is filled by condensed extraperitoneal tissue, the femoral septum, which is covered on its proximal aspect by the parietal peritoneum. Numerous lymph vessels that connect the deep inguinal to the external iliac lymph nodes traverse the femoral septum (**Fig. 77.2**).

Femoral hernia

Femoral hernia is described with other groin hernias in Chapter 60.

Iliac fascia

The iliac fascia covers psoas and iliacus. It is thin above but thickens progressively towards the inguinal ligament. The part covering psoas is thickened above as the medial arcuate ligament. Medially the fascia over psoas is attached by a series of fibrous arches to the intervertebral discs, the margins of vertebral bodies and the upper part of the sacrum. Laterally, it blends with the fascia anterior to quadratus lumborum above the iliac crest, and with the fascia covering iliacus below the crest. The iliac part is connected laterally to the whole of the inner lip of the iliac crest and medially to the pelvic brim, where it blends with the periosteum. At approximately the height of the anterior superior iliac spine, the iliac fascia forms an open, curved superior edge, known as the iliopectineal arch (see Fig. 77.1). This arch passes directly over the femoral nerve, and iliacus and psoas major. The medial extent of the arch is attached to the iliopubic ramus, where it receives a slip from the tendon of psoas minor, when this muscle is present (Neumann and Garceau 2015). The external iliac vessels are anterior to the fascia but the branches of the lumbar plexus are posterior to it. The fascia is separated from the peritoneum by loose extraperitoneal tissue. Lateral to the femoral vessels the iliac fascia is continuous with the posterior margin of the inguinal ligament and the transversalis fascia. Medially, it passes behind the femoral vessels to become the pectineal ligament, attached to the pecten pubis. At the junction of its lateral and medial parts, it is attached to the iliopubic ramus and the capsule of the hip joint. It thus forms a septum between the inguinal ligament and the hip bone, dividing the space here into a lateral part, the muscular space, containing psoas major, iliacus and the femoral nerve, and a medial part, the vascular space, transmitting the femoral vessels (see Fig. 77.2). The iliac fascia continues downwards to form the posterior wall of the femoral sheath.

Obturator membrane

The obturator membrane (**Fig. 77.3**; see Fig. 77.2A) is a thin aponeurosis that closes (obturates) most of the obturator foramen, leaving a superolateral aperture, the obturator canal, through which the obturator vessels and nerve leave the pelvis and enter the thigh. The membrane is attached to the sharp margin of the obturator foramen except at its inferolateral angle, where it is fixed to the pelvic surface of the ischial ramus, i.e. internal to the foramen. Its fibres are arranged mainly transversely in interlacing bundles; the uppermost bundle, which is attached to the obturator tubercles, completes the obturator canal. The outer and inner surfaces of the obturator membrane provide attachment for the obturator externus and internus, respectively. Some fibres of the pubofemoral ligament of the hip joint are attached to the outer surface.

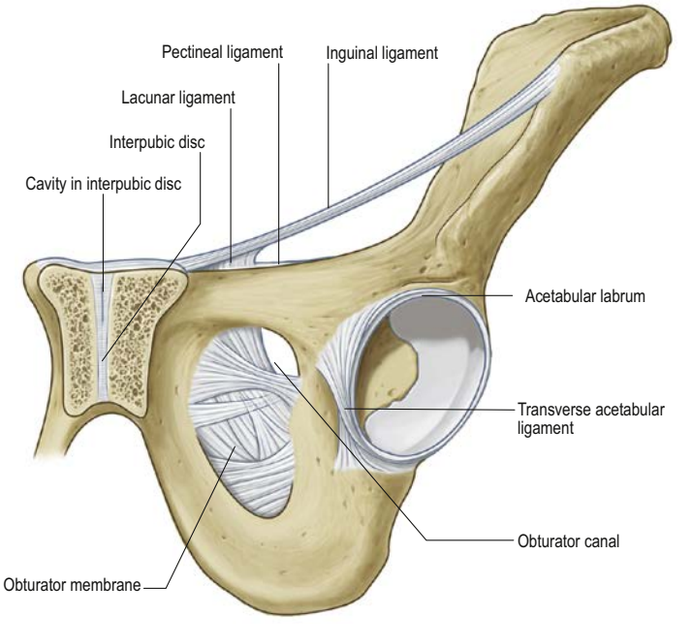

Fig. 77.3 An anterolateral view of left bony pelvis, showing associated ligaments and the obturator membrane.

BONES

The relevant bones in this region include the pelvic girdle (which consists of two hip bones, sacrum and coccyx) and the two femurs.

Hip bone

The hip bone is large, irregular, constricted centrally and expanded above and below (Figs 77.4–77.5). Its lateral surface has a deep, cup-shaped acetabulum, articulating with the femoral head, anteroinferior to which is the large, oval or triangular obturator foramen. Above the acetabulum, the bone widens into an undulant plate surmounted by a sinuously curved iliac crest. The bone articulates in front with its fellow and posteriorly with the sacrum to form the pelvic girdle. Each hip bone has three parts, ilium, ischium and pubis, connected to each other by cartilage in youth but united as one bone in adults. The principal union is in the acetabulum. The ilium includes the upper acetabulum and expanded area above it; the ischium includes the posteroinferior acetabulum and bone posteroinferior to it; the pubis forms the anteroinferior acetabulum.

Acetabulum

The acetabulum (see Fig. 77.4A) is an approximately hemispherical cavity situated about the centre of the lateral aspect of the hip bone. It faces anteroinferiorly and is circumscribed by an irregular margin deficient inferiorly at the acetabular notch. The acetabular fossa forms the central floor and is rough and non-articular. The articular lunate surface is widest above (the 'dome'), where weight is transmitted to the femur. Consequently, fractures through this region tend to be associated with unsatisfactory outcomes. All three components of the hip bone contribute to the acetabulum, although unequally. The pubis forms the anterosuperior fifth of the articular surface, the ischium forms the floor of the fossa and rather more than the posteroinferior two-fifths of the articular surface, and the ilium forms the remainder.

Obturator foramen

The obturator foramen lies below and slightly anterior to the acetabulum, between the pubis and ischium. It is bordered above by the grooved obturator surface of the superior pubic ramus, medially by the pubic body and its inferior ramus, below by the ischial ramus, and laterally by the anterior border of the ischial body, including the margin of the acetabulum. It is almost closed by the obturator membrane, which is attached to its margins, except superolaterally, where a communication remains between the pelvis and thigh. This free edge of the membrane is attached to an anterior obturator tubercle at the anterior end of the inferior border of the superior pubic ramus, and a posterior obturator tubercle on the anterior border of the acetabular notch; these tubercles are sometimes indistinct. The foramen is large and oval in males, but smaller and nearly triangular in females.

Structure

The thicker parts of the hip bone are trabecular, encased by two layers of compact bone, while the thinner parts, as in the acetabulum and central iliac fossa, are often translucent and consist of a single lamina of compact bone. In the upper acetabulum and along the arcuate line, i.e. the route of weight transmission from the sacrum to the femur, the amount of compact bone is increased and the subjacent trabecular bone displays two sets of pressure lamellae. These start together near the upper auricular surface and diverge to meet two strong buttresses of compact bone, from which two similar sets of lamellar arches start and converge on the acetabulum. The anterior part of the iliac crest has been much studied with regard to distribution of cortical and trabecular bone. Whitehouse (1977) described the cortical bone as very porous, being only 75% bone, decreasing to 35% near the anterior superior iliac spine.

Studies of the internal stresses within the hip bone have revealed a pattern of trabeculae that corresponds well with the theoretically expected patterns of stress trajectories (Holm 1980). These patterns are considerably more complex than in any other major bone. Stresses are higher in the acetabular than in the iliac region. In the ilium, the pelvic surface is subjected to considerably less stress than is the gluteal surface.

Muscle attachments

See individual bones.

Fig. 77.4 Left hip bone. **A**, External aspect. **B**, Muscle attachments. **A**, Key: 1, iliac crest; 2, anterior superior iliac spine; 3, anterior inferior iliac spine; 4, iliopubic (iliopectineal) eminence; 5, acetabulum; 6, pubic tubercle; 7, acetabular notch; 8, pubis; 9, tubercle of iliac crest; 10, ilium; 11, posterior superior iliac spine; 12, greater sciatic notch; 13, posterior inferior iliac spine; 14, ischial spine; 15, lesser sciatic notch; 16, obturator foramen; 17, ischial tuberosity; 18, ischium. **B**, Key: 1, internal abdominal oblique; 2, external abdominal oblique; 3, tensor fasciae latae; 4, gluteus minimus; 5, sartorius; 6, rectus femoris, straight head; 7, rectus femoris, reflected head; 8, junction between ilium, ischium and pubis; 9, pectineus; 10, rectus abdominis, lateral head; 11, pyramidalis; 12, adductor longus; 13, obturator externus; 14, adductor brevis; 15, gracilis; 16, junction between ischium and pubis; 17, latissimus dorsi; 18, gluteus medius; 19, gluteus maximus; 20, piriformis; 21, gemellus superior; 22, semimembranosus; 23, quadratus femoris; 24, biceps femoris and semitendinosus; 25, adductor magnus.

Vascular supply

In the infant, nutrient arteries are clearly demonstrable for each component of the hip bone. Each nutrient artery branches in a fan-like fashion within its bone of supply (Crock 1996). Later, a periosteal arterial network develops, with contributions from numerous local arteries (see under individual bones).

Innervation

Periosteal innervation is by a network of nerves derived from branches of local nerves. These nerves also supply muscles attaching to the periosteum and the joints involving the hip bone. Autonomic nerves accompany nutrient arteries and branch within the bone.

Ossification

Ossification (Figs 77.6–77.7) is by three primary centres: one each for the ilium, ischium and pubis. The iliac centre appears above the greater sciatic notch prenatally at about postmenstrual weeks 9–10; the ischial centre in its body during postmenstrual weeks 13–16; and the pubic centre in its superior ramus during postmenstrual weeks 13–20. The pubis is often not recovered from prenatal remains due to its size and fragility and because it is the last of the hip bones to begin ossification (Scheuer and Black 2004). At birth the whole iliac crest, the acetabular floor and the inferior margin are cartilaginous. Gradual ossification of the three components of the acetabulum results in a triradiate cartilaginous stem extending medially to the pelvic surface as a Y-shaped epiphysial plate between the ilium, ischium and pubis, and including the anterior inferior iliac spine. Cartilage along the inferior margin also covers the ischial tuberosity, forms conjoined ischial and pubic rami, and continues to the pubic symphysial surface and along the pubic crest to the pubic tubercle.

The ossifying ischium and pubis fuse to form a continuous ischiopubic ramus at the seventh or eighth year. Secondary centres, other than for the acetabulum, appear at about puberty and fuse between the fifteenth and twenty-fifth years. There are usually two for the iliac crest (which fuse early), and single centres for the ischial tuberosity (in cartilage close to the inferior acetabular margin and spreading forwards), anterior inferior iliac spine (although it may ossify from the triradiate cartilage) and symphysial surface of the pubis (the pubic tubercle and crest may have separate centres). Progression of ossification of the iliac crest in girls is an index of skeletal maturity and is useful in determining the optimal timing of surgery for spinal deformity.

Between the ages of 8 and 9 years, three major centres of secondary ossification appear in the acetabular cartilage. The largest appears in the anterior wall of the acetabulum and fuses with the pubis, the second in the iliac acetabular cartilage superiorly, fusing with the ilium, and the third in the ischial acetabular cartilage posteriorly, fusing with the ischium. At puberty, these epiphyses expand towards the periphery of the acetabulum and contribute to its depth (Ponseti 1978). Fusion between the three bones within the acetabulum occurs between the sixteenth and eighteenth years. Delaere et al (1992) have suggested that ossification of the ilium is similar to that of a long bone, possessing three cartilaginous epiphyses and one cartilaginous process, although it tends to undergo osteoclastic resorption comparable with that of cranial bones. During development the acetabulum increases in breadth at a faster rate than it does in depth.

Avulsion fractures of pelvic apophyses may occur from excessive pull on tendons, usually in athletic adolescents. The most frequent examples of such injuries are those to the ischial tuberosity (hamstrings) and anterior inferior iliac spine (rectus femoris).

Pubis

The pubis (see Figs 77.4–77.5) is the ventral part of the hip bone and forms a median cartilaginous pubic symphysis with its fellow. The body of the pubis occupies the anteromedial part of the bone, and from the body a superior ramus passes up and back to the acetabulum and an inferior ramus passes back, down and laterally to join the ischial ramus inferomedial to the obturator foramen.

Body

The body, anteroposteriorly compressed, has anterior, posterior and symphysial (medial) surfaces and an upper border, the pubic crest. The

anterior surface also faces inferolaterally; it is rough superomedially and smooth elsewhere, giving attachment to medial thigh muscles. The smooth posterior surface faces upwards and backwards as the oblique anterior wall of the lesser pelvis and is related to the urinary bladder. The symphysial surface is elongated and oval, united by cartilage to its fellow at the pubic symphysis. Denuded of cartilage, it has an irregular surface of small ridges and furrows or nodular elevations, varying considerably with age, features that are of forensic interest. The pubic crest is the rounded upper border of the body and overhangs the anterior surface; the pubic tubercle is a small rounded eminence on its lateral end. Both crest and tubercle are palpable; the latter partly is obscured in males by the spermatic cord that crosses above it from the scrotum to the anterior abdominal wall. The pubic rami diverge posterolaterally from the superolateral corners of the body.

The anterior surface of the pubic body faces the adductor region. The anterior pubic ligament attaches to its medial part along a rough strip, which is wider in females. The posterior surface is separated from the urinary bladder by retropubic fat. The puboprostatic ligaments are attached to this surface medial to levator ani.

Superior pubic ramus

The superior pubic ramus passes upwards, backwards and laterally from the body, superolateral to the obturator foramen, to reach the acetabulum. It is triangular in section and has three surfaces and borders. Its anterior, pectineal surface, tilted slightly up, is triangular in outline and extends from the pubic tubercle to the iliopubic ramus. It is bounded in front by the rounded obturator crest and behind by the sharp pecten pubis (pectineal line), which, with the crest, is the pubic part of the linea terminalis (i.e. anterior part of the pelvic brim). The posterosuperior, pelvic surface, medially inclined, is smooth and narrows into the posterior surface of the body, which is bounded above by the pecten pubis and below by a

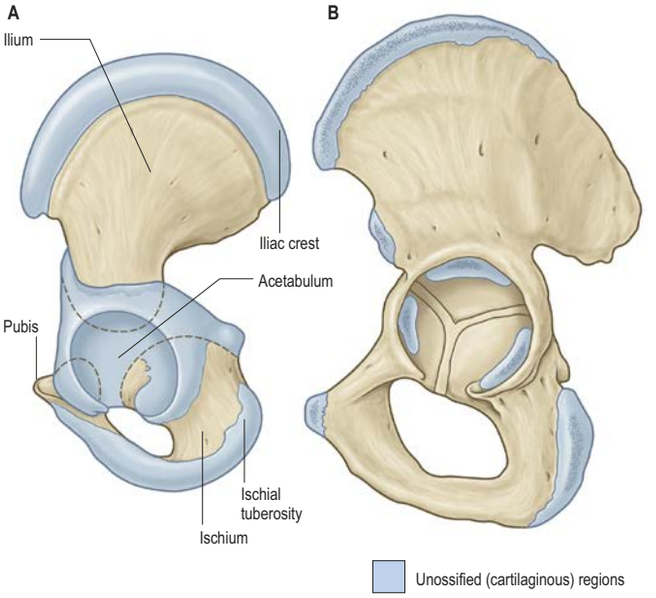

Fig. 77.6 The hip bone. **A**, At birth. **B,** In adolescence; more heavily stippled areas indicate the secondary centres of ossification.

sharp inferior border. The obturator surface, directed down and back, is crossed by the obturator groove sloping down and forwards. Its anterior limit is the obturator crest and its posterior limit is the inferior border.

Inferior pubic ramus

The inferior pubic ramus, an inferolateral process of the body, descends inferolaterally to join the ischial ramus medial to, and below, the obturator foramen. The union may be locally thickened, but not obviously so in adults. The ramus has two surfaces and borders. The anterolateral surface, continuous above with that of the pubic body, faces the thigh and is marked by muscles. It is limited laterally by the margin of the obturator foramen, and medially by the rough anterior border. The posteromedial surface is continuous above with that of the body and is transversely convex; its medial part is often everted in males and gives attachment to the crus of the penis. This surface faces the perineum medially, its smooth lateral part tilted up towards the pelvic cavity.

The internal surface is indistinctly divided into medial, intermediate and lateral areas. The medial area faces inferomedially in direct contact with the crus of the penis or clitoris and is limited above and behind by an indistinct ridge for attachment of the fascia overlying the superficial perineal muscles. The medial margin of the ramus, strongly everted in males, provides attachment for the fascia lata and the stratum membranosum perinei.

Pubic tubercle

The pubic tubercle provides attachment to the medial end of the inguinal ligament. It forms part of the floor of the superficial inguinal ring and is crossed by the spermatic cord.

Pecten pubis

The pecten pubis is the sharp, superior edge of the pectineal surface. The conjoint tendon (inguinal falx) and lacunar ligament are attached at its medial end and a strong, fibrous pectineal ligament is attached along the rest of its surface. The smooth pelvic surface is separated from parietal peritoneum only by areolar tissue, in which the lateral umbilical ligament descends forwards across the ramus and, laterally, the vas ductus deferens (vas deferens) passes backwards. The obturator groove, which is converted to a canal by the upper borders of the obturator membrane and obturator muscles, transmits the obturator vessels and nerve from the pelvis to the thigh. Some fibres of the pubofemoral ligament are attached to the lateral end of the obturator crest.

Muscle attachments

The tendon of adductor longus is attached on the anterior (external) surface of the body, below the pubic crest. Below adductor longus, gracilis is attached to a line near the lower margin extending down on to the inferior ramus. Above gracilis, adductor brevis is attached to the body and inferior ramus. Above again, obturator externus is attached to the anterior surface, spreading on to the inferior pubic and ischial rami. Adductor magnus usually extends from the ischial ramus on to the lower part of the inferior pubic ramus between adductor brevis and obturator externus. Pectineus is attached to the pectineal surface of the superior ramus along its upper part. Ascending loops of cremaster are attached to the pubic tubercle. The lateral part of rectus abdominis and, inferiorly, pyramidalis, are attached lateral to the tubercle, on the pubic crest. Medially, the crest is crossed by the medial part of rectus abdominis, ascending from ligamentous fibres that interlace in front of the pubic symphysis. Anterior fibres of levator ani are attached on the posterior (internal) surface of the body near its centre. More laterally, obturator internus is attached on this surface, extending on to both rami. Psoas minor, when present, is attached near the centre of the pecten pubis (Neumann and Garceau 2015).

Vascular supply

The pubis is supplied by a periosteal anastomosis of branches from the obturator, inferior epigastric and medial circumflex femoral arteries. The superficial and deep external pudendal arteries may also contribute. Multiple vascular foramina are present, mainly at the lateral (acetabular) end of the bone, but there is no consistently placed nutrient foramen.

Innervation

The pubic periosteum is innervated by branches of the nerves that supply muscles attached to the bone, the hip joint and the symphysis pubis.

Ossification

Ossification of the pubis is described on page 1355.

Ilium

The ilium has upper and lower parts and three surfaces (see Figs 77.4–77.5). The smaller, lower part forms a little less than the upper two-fifths of the acetabulum. The upper part is much expanded, and has gluteal, sacropelvic and iliac (internal) surfaces. The posterolateral gluteal surface is an extensive rough area; the anteromedial iliac fossa is smooth and concave; and the sacropelvic surface is medial and posteroinferior to the fossa, from which it is separated by the medial border.

Iliac crest

The iliac crest is the superior border of the ilium. It is convex upwards but sinuous from side to side, being internally concave in front and convex behind. Its ends project as anterior and posterior superior iliac spines. The anterior superior iliac spine is palpable at the lateral end of the inguinal fold; the lateral end of the inguinal ligament is attached to the anterior superior iliac spine. The posterior superior iliac spine is not easily palpable but is often indicated by a dimple, approximately 4 cm lateral to the second sacral spinous process, above the medial gluteal region.

The iliac crest has ventral and dorsal segments. The ventral segment occupies slightly more than the anterior two-thirds of the iliac crest and its prominence is associated with changes in iliac form as a result of the emergence of the upright posture. It has internal and external lips and a rough intermediate zone that is narrowest centrally. The dorsal segment, which occupies approximately the posterior one-third in humans, is a feature of all land vertebrates. It has two sloping surfaces separated by a longitudinal ridge ending at the posterior superior spine. The interosseous and posterior sacroiliac ligaments arise from the medial margin of the dorsal segment. The tubercle of the iliac crest projects outwards from the outer lip approximately 5 cm posterosuperior to the anterior superior spine. The summit of the iliac crest, a little behind its midpoint, is level with the fourth lumbar vertebral body in adults and with the fifth lumbar vertebral body in children aged 10 years or less (Tame and Burstal 2003).

Anterior border

The anterior border descends to the acetabulum from the anterior superior spine. Superiorly, it is concave forwards. Inferiorly, immediately above the acetabulum, is a rough anterior inferior iliac spine, which is divided indistinctly into an upper area for the straight head of rectus femoris and a lower area extending laterally along the upper acetabular margin to form a triangular impression for the proximal end of the iliofemoral ligament.

Posterior border

The posterior border is irregularly curved and descends from the posterior superior spine, at first forwards, with a posterior concavity forming a small notch. At the lower end of the notch is a wide, low projection: the posterior inferior iliac spine. Here the border turns almost horizontally forwards for approximately 3 cm, then down and back to join the posterior ischial border. Together these borders form a deep notch, the greater sciatic notch, which is bounded above by the ilium and below by the ilium and ischium. The upper fibres of the sacrotuberous ligament are attached to the upper part of the posterior border. The superior rim of the notch is related to the superior gluteal vessels and nerve. The lower margin of the greater sciatic notch is covered by piriformis and is related to the exiting sciatic nerve.

Medial border

The medial border separates the iliac fossa and the sacropelvic surface. It is indistinct near the crest, rough in its upper part, then sharp where it bounds an articular surface for the sacrum, and finally rounded. The latter part is the arcuate line, which inferiorly reaches the posterior part of the iliopubic ramus, marking the union of the ilium and pubis.

Gluteal surface

The gluteal surface, facing inferiorly in its posterior part and laterally and slightly downwards in front, is bounded above by the iliac crest, and below by the upper acetabular border and by the anterior and posterior borders. It is rough and curved, convex in front, concave behind and marked by three gluteal lines. The posterior gluteal line is shortest, descending from the external lip of the crest approximately 5 cm in front of its posterior limit and ending in front of the posterior inferior iliac spine. Above, it is usually distinct, but inferiorly it is poorly defined and frequently absent. The anterior gluteal line, the longest, begins near the midpoint of the superior margin of the greater sciatic notch and ascends forwards into the outer lip of the crest, a little

anterior to its tubercle. The inferior gluteal line, seldom well marked, begins posterosuperior to the anterior inferior iliac spine, curving posteroinferiorly to end near the apex of the greater sciatic notch. Between the inferior gluteal line and the acetabular margin is a rough, shallow groove. Behind the acetabulum, the lower gluteal surface is continuous with the posterior ischial surface, the conjunction marked by a low elevation.

The articular capsule is attached to an area adjoining the acetabular margin, most of which is covered by gluteus minimus. Posteroinferiorly, near the union of the ilium and ischium, the bone is related to piriformis.

Iliac fossa

The iliac fossa, the internal concavity of the ilium, faces anterosuperiorly. It is limited above by the iliac crest, in front by the anterior border and behind by the medial border, separating it from the sacropelvic surface. It forms the smooth and gently concave posterolateral wall of the greater pelvis. Below it is continuous with a wide shallow groove, bounded laterally by the anterior inferior iliac spine and medially by the iliopubic ramus.

The converging fibres of iliacus occupy the wide groove between the anterior inferior iliac spine and the iliopubic ramus laterally and the tendon of psoas major medially; the tendon is separated from the underlying bone by a bursa. The right iliac fossa contains the caecum, and often the vermiform appendix and terminal ileum. The left iliac fossa houses the terminal part of the descending colon and the proximal sigmoid colon.

Sacropelvic surface

The sacropelvic surface, the posteroinferior part of the medial iliac surface, is bounded posteroinferiorly by the posterior border, anterosuperiorly by the medial border, posterosuperiorly by the iliac crest and anteroinferiorly by the line of fusion of the ilium and ischium. It is divided into iliac tuberosity and auricular and pelvic surfaces. The iliac tuberosity, a large, rough area below the dorsal segment of the iliac crest, shows cranial and caudal areas separated by an oblique ridge and connected to the sacrum by the interosseous sacroiliac ligament. The sacropelvic surface gives attachment to the posterior sacroiliac ligaments and, behind the auricular surface, to the interosseous sacroiliac ligament. The iliolumbar ligament is attached to its anterior part. The auricular surface, immediately anteroinferior to the tuberosity, articulates with the lateral sacral mass. Shaped like an ear, its widest part is anterosuperior, and its 'lobule' posteroinferior and on the medial aspect of the posterior inferior spine. Its edges are well defined but the surface, though articular, is rough and irregular. It articulates with the sacrum and is reciprocally shaped. The anterior sacroiliac ligament is attached to its sharp anterior and inferior borders. The narrow part of the pelvic surface, between the auricular surface and the upper rim of the greater sciatic notch, often shows a rough pre-auricular sulcus (that is usually better defined in females) for the lower fibres of the anterior sacroiliac ligament. For the reliability of this feature as a sex discriminant, refer to Finnegan (1978) and Brothwell and Pollard (2001). The pelvic surface is anteroinferior to the acutely curved part of the auricular surface, and contributes to the lateral wall of the lesser pelvis. Its upper part, facing down, is between the auricular surface and the upper limb of the greater sciatic notch; the lower part faces medially and is separated from the iliac fossa by the arcuate line. Anteroinferiorly, the pelvic surface extends to the line of union between the ilium and ischium.

Muscle attachments

The attachment of sartorius extends down the anterior border below the anterior superior iliac spine. The iliac crest gives attachment to the anterolateral and dorsal abdominal muscles, and to the fasciae and muscles of the lower limb. The fascia lata and iliotibial tract are attached to the outer lip and tubercle of its ventral segment. Tensor fasciae latae is attached anterior to the tubercle. The lower fibres of external oblique and, just behind the summit of the crest, the lowest fibres of latissimus dorsi are attached to its anterior two-thirds. A variable interval exists between the most posterior attachment of external oblique and the most anterior attachment of latissimus dorsi, and here the crest forms the base of the lumbar triangle through which herniation of abdominal contents may rarely occur. Internal oblique is attached to the intermediate area of the crest. Transversus abdominis is attached to the anterior two-thirds of the inner lip of the crest, and behind this to the thoracolumbar fascia and quadratus lumborum. The most superior fibres of gluteus maximus are attached to the dorsal segment of the crest on its lateral slope. Erector spinae arises from the medial slope of the dorsal segment. The straight head of rectus femoris is attached to the upper area of the anterior inferior spine. Some fibres of piriformis are attached in front of the posterior inferior spine on the upper border of the greater sciatic foramen.

The gluteal surface is divided by three gluteal lines into four areas. Behind the posterior line, the upper rough part gives attachment to the upper fibres of gluteus maximus and the lower, smooth region to part of the sacrotuberous ligament and iliac head of piriformis. Gluteus medius is attached between the posterior and anterior lines, below the iliac crest, and gluteus minimus is attached between the anterior and inferior lines. The fourth area, below the inferior line, contains vascular foramina.

The reflected head of rectus femoris attaches to a curved groove above the acetabulum. Iliacus is attached to the upper two-thirds of the iliac fossa and is related to its lower one-third. The medial part of quadratus lumborum is attached to the anterior part of the sacropelvic surface, above the iliolumbar ligament. Piriformis is sometimes partly attached lateral to the pre-auricular sulcus, and part of obturator internus is attached to the more extensive remainder of the pelvic surface.

Vascular supply

Branches of the iliolumbar artery run between iliacus and the ilium; one or more enter large nutrient foramina lying posteroinferiorly in the iliac fossa. The superior gluteal, obturator and superficial circumflex iliac arteries contribute to the periosteal supply. The obturator artery may supply a nutrient branch. Vascular foramina on the ilium underlying the gluteal muscles may lead into large vascular canals in the bone.

Innervation

The periosteum is innervated by branches of nerves that supply muscles attached to the bone, the hip joint and the sacroiliac joint.

Ossification

Ossification of the ilium is described on page 1355.

Ischium

The ischium, the inferoposterior part of the hip bone, has a body and ramus. The body has upper and lower ends and femoral, posterior and pelvic surfaces (see Figs 77.4–77.5). Above, it forms the posteroinferior part of the acetabulum; below, its ramus ascends anteromedially at an acute angle to meet the inferior pubic ramus, thereby completing the boundary of the obturator foramen. The ischiofemoral ligament is attached to the lateral border below the acetabulum (Fuss and Bacher 1991).

The femoral surface faces downwards, forwards and laterally towards the thigh. It is bounded in front by the margin of the obturator foramen. The lateral border, indistinct above but well defined below, forms the lateral limit of the ischial tuberosity. At a higher level the femoral surface is covered by piriformis, from which it is partially separated by the sciatic nerve and the nerve to quadratus femoris. The posterior surface, facing superolaterally, is continuous above with the iliac gluteal surface, and here a low convexity follows the acetabular curvature. Inferiorly, this surface forms the upper part of the ischial tuberosity, above which is a wide, shallow groove on its lateral and medial aspects. Above the ischial tuberosity the posterior surface is crossed by the tendon of obturator internus and the gemelli. The nerve to quadratus femoris lies between these structures and the ischium. The ischial tuberosity is a large, rough area on the lower posterior surface and inferior extremity of the ischium. Though obscured by gluteus maximus in hip extension, it is more readily palpable in hip flexion. It is 5 cm from the midline and about the same distance above the gluteal fold. It is elongated and widest above, and tapers inferiorly. The posterior aspect of the ischium lies between its lateral and posterior borders. The posterior border blends above with that of the ilium, helping to complete the inferior rim of the greater sciatic foramen, the posterior end of which has a conspicuous ischial spine. Below this the rounded border forms the floor of the lesser sciatic foramen, between the ischial spine and tuberosity. The pelvic surface is smooth and faces the pelvic cavity; inferiorly, it forms part of the lateral wall of the ischio-anal fossa.

Ischial ramus

The ischial ramus has anteroinferior and posterior surfaces continuous with the corresponding surfaces of the inferior pubic ramus. The

anteroinferior surface is roughened by the attachment of the medial thigh muscles. The smooth posterior surface is partly divided into perineal and pelvic areas, like the inferior pubic ramus. The upper border completes the obturator foramen; the rough lower border, together with the medial border of the inferior pubic ramus, contributes to the pubic arch. The fascia overlying the superficial muscles of the perineum is attached below the ridge between the perineal and pelvic areas of the posterior surface of the ischial ramus. Above the ridge, areas give attachment to the crus of the penis or clitoris and the external urethral sphincter. The lower border of the ramus provides an attachment for the fascia lata and the stratum membranosum perinei.

Ischial tuberosity

The ischial tuberosity is divided nearly transversely into upper and lower areas. The upper area is subdivided by an oblique line into superolateral and inferomedial parts. The lower area, narrowing as it curves on to the inferior ischial aspect, is subdivided by an irregular vertical ridge into lateral and medial areas. The medial area is covered by fibroadipose tissue that usually contains the sciatic bursa of gluteus maximus, which supports the body in sitting. Medially the tuberosity is limited by a curved ridge that passes on to the ramus and which gives attachment to the sacrotuberous ligament and its falciform process.

Ischial spine

The ischial spine projects downwards and a little medially (see Fig. 77.4B). The sacrospinous ligament is attached to its margins, separating the greater from the lesser sciatic foramen. The ligament is crossed posteriorly by the internal pudendal vessels, pudendal nerve and the nerve to obturator internus.

Muscle attachments

Part of obturator externus is attached to the lower femoral surface of the ischial body. Part of obturator externus, the anterior fibres of adductor magnus and, near the lower border, gracilis are all attached to the anterior surface of the ischial ramus. Between adductor magnus and gracilis, the attachment of adductor brevis may descend from the inferior pubic ramus. The posterior surface is divided into pelvic and perineal areas. The pelvic area, facing back, has part of obturator internus attached to it. The perineal area faces medially; its upper part is related to the crus of the penis or clitoris, and its lower part gives attachment to sphincter urethrae, ischiocavernosus and the superficial transverse perineal muscle.

The ischial tuberosity gives attachment to the posterior thigh muscles. Quadratus femoris is attached along the upper part of its lateral border. The upper area of the tuberosity is subdivided by an oblique line into a superolateral part for semimembranosus and an inferomedial part for the long head of biceps femoris and semitendinosus. The lower area is subdivided by an irregular vertical ridge into lateral and medial areas. The larger lateral area is for part of adductor magnus. Superomedial to the tuberosity, the posterior surface has a wide, shallow groove, usually covered by hyaline cartilage, with a bursa between it and the tendon of obturator internus. Gemellus inferior is attached to the lower margin of the groove, near the tuberosity. Gemellus superior is attached to the upper margin, near the ischial spine. Forceful activation and/or severe stretch of the hamstrings can result in an avulsion fracture of the ischial tuberosity.

The pelvic surface of the ischial spine gives attachment to coccygeus and to the most posterior fibres of levator ani. Obturator internus is attached to the upper part of the smooth pelvic ischial surface and converges on the bony part of the lesser sciatic foramen, covering the rest of this surface other than the pelvic aspect of the ischial spine; the muscle and its fascia separate the bone from the ischio-anal fossa.

Vascular supply

There are multiple vascular foramina at the acetabular margins and a few are usually present on the pelvic surface. Branches of the obturator, medial circumflex femoral and inferior gluteal arteries supply the ischium.

Innervation

The periosteum is innervated by branches of nerves that supply the hip joint and muscles attached to the bone.

Ossification

Ossification of the ischium is described on page 1355.

Sacrum

See Chapter 46.

Coccyx

See Chapter 46.

Bony pelvis as a whole

The term pelvis ('basin') is applied variously to the skeletal ring formed by the hip bones and the sacrum, the cavity therein and even the entire region where the trunk and lower limbs meet (Fig. 77.8). It is used here in the skeletal sense, to describe the irregular osseous girdle between the femoral heads and fifth lumbar vertebra. It is large because its primary function is to withstand the forces of body weight and musculature. In this section, its obstetric, forensic and anthropological significance will be considered.

The pelvis can be regarded as having greater and lesser segments, the false and true pelves, respectively. The segments are arbitrarily

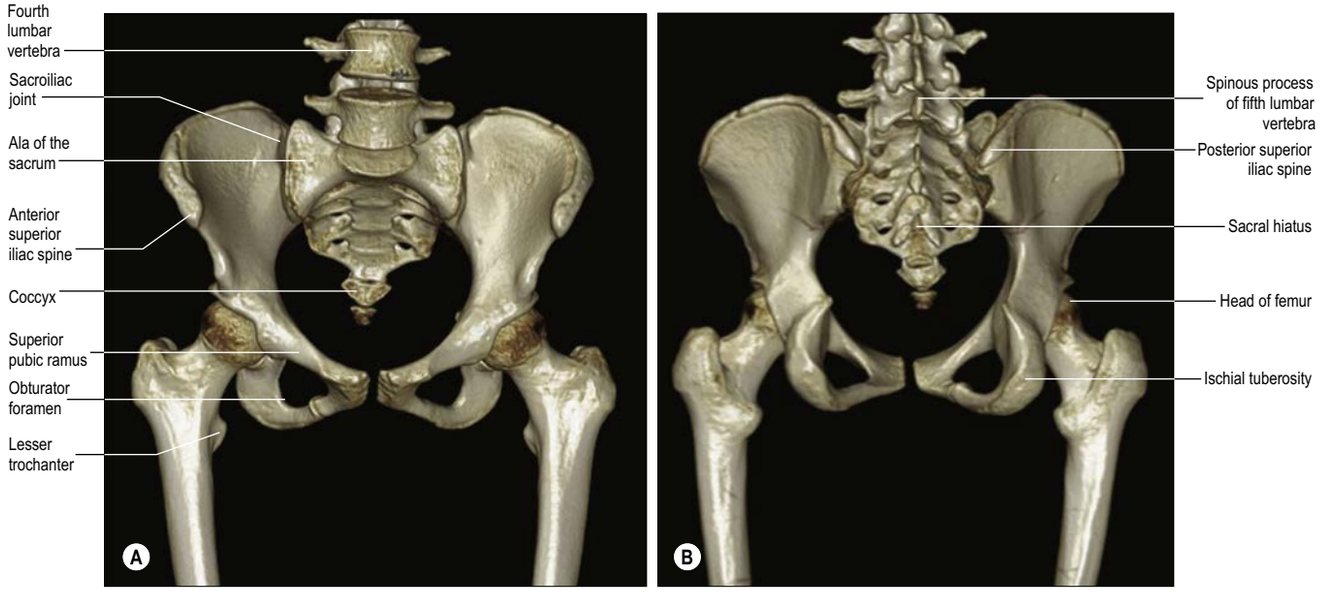

Fig. 77.8 Anterior (**A**) and posterior (**B**) views of the female pelvis, upper femur and lower lumbar spine, using three-dimensional computed tomography. (Courtesy of Dr Yoginder Vaid and Mr Jon C Betts, Jr.)

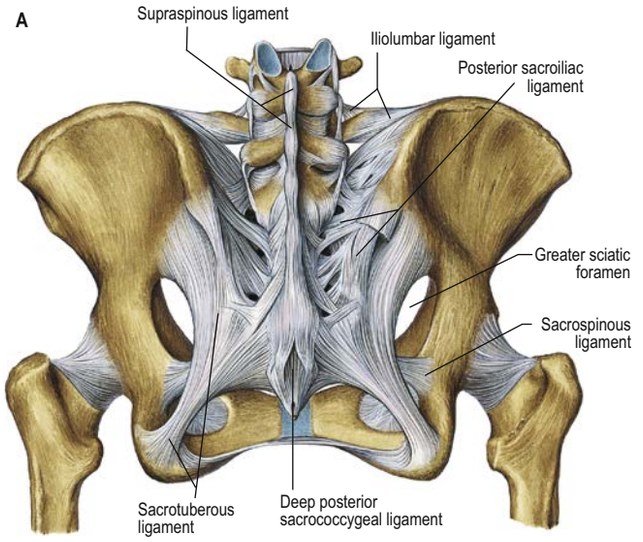

Fig. 77.9 The greater and lesser sciatic foramina, **A**, Posterior aspect of the pelvis. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.) (B, *continued online*.)

divided by an oblique plane passing through the sacral promontory posteriorly and the lineae terminales elsewhere. Each linea terminalis includes the iliac arcuate line, pectineal line (pecten pubis) and pubic crest.

Greater pelvis

The greater pelvis consists of the ilium and pubis above the lineae terminales and the base of the sacrum. This junctional zone is structurally massive and forms powerful arches from the acetabular fossae to the vertebral column around the visceral cavity, which is part of the abdomen. It has little anterior wall because of the pelvic inclination.

Pelvic inlet (superior pelvic aperture)

The pelvic inlet or brim may be round or oval in shape, and is indented posteriorly by the sacral promontory. The pelvic brim is obstetrically important and has also long been measured for anthropological reasons, as has the pelvic cavity.

By convention, the pelvic inlet is described in three dimensions. The anteroposterior diameter (true conjugate) is measured between the midpoints of the sacral promontory and upper border of the pubic symphysis, and on average is 10 cm in the adult male and 11.2 cm in the adult female. The transverse diameter is the maximum distance between similar points (assessed by eye) on opposite sides of the pelvic brim, and is on average 12.5 cm in the adult male and 13.1 cm in the adult female. The oblique diameter is measured from the iliopubic ramus to the opposite sacroiliac joint, and is on average 12 cm in the adult male and 12.5 cm in the adult female. These measurements vary with the individual and with racial group. In children, dimensions of the thorax and spine are significantly correlated with the width of the pelvic inlet, which are age-independent predictors of paediatric chest width and may be useful in assessing growth of the thorax and spine in children with early-onset spinal deformity (Emans et al 2005).

Articulated bony pelvis

The lesser pelvis encloses a true basin when soft tissues of the pelvic floor are in place. Skeletally, it is a narrower continuation of the greater pelvis, with irregular but more complete walls around its cavity. Of obstetric importance, it has a curved median axis, and superior and inferior openings. The superior opening is occupied by viscera. The pelvic floor, viscera and subjacent perineal sphincters close the inferior opening.

Cavity of the lesser pelvis

The cavity of the lesser pelvis is short, curved and markedly longer in its posterior wall. Anteroinferiorly, it is bounded by pubic bones, their rami and symphysis. Posteriorly, it is bounded by the concave anterior sacral surface and coccyx. Laterally, on each side its margins are the smooth quadrangular pelvic aspect of the fused ilium and ischium. The region so enclosed is the pelvic cavity proper, through which pass the rectum, urinary bladder and parts of the reproductive organs. The cavity in females must also permit passage of the fetus.

The pelvic cavity diameters are measured at approximately the mid-level. The anteroposterior diameter is measured between the midpoints of the third sacral segment and posterior surface of the pubic symphysis, and is about 10.5 cm in the adult male and 13 cm in the adult female. The transverse diameter is the widest transverse distance between the side walls of the cavity, and often the greatest transverse dimension in the whole cavity. It measures about 12 cm in the adult male and 12.5 cm in the adult female. The oblique diameter is the distance from the lowest point of one sacroiliac joint to the midpoint of the contralateral obturator membrane, and measures about 11 cm in the adult male and 13.1 cm in the adult female. All measurements vary with the individual and with racial group.

Pelvic outlet (inferior pelvic aperture)

Less regular in outline than the pelvic inlet, the pelvic outlet is indented behind by the coccyx and sacrum, and bilaterally by the ischial tuberosities. Its perimeter thus consists of three wide arcs. Anteriorly is the pubic arch, between the converging ischiopubic rami. Posteriorly and laterally on both sides are the sciatic notches between the sacrum and ischial tuberosities. The sciatic notches are divided by the sacrotuberous and sacrospinous ligaments into greater and lesser sciatic foramina (Fig. 77.9).

With ligaments included, the pelvic outlet is rhomboidal. Its anterior limbs are the ischiopubic rami (joined by the inferior pubic (arcuate) ligament) and its posterior margins are the sacrotuberous ligaments, with the coccyx in the midline. The outlet is thus not rigid in its posterior half, being limited by ligaments and the coccyx, all slightly yielding. Even with the sacrum taken as the posterior midline limit (more reliable for measurement), there is typically slight mobility at the sacroiliac joints. Note also that a plane of the pelvic outlet is merely conceptual. The anterior, ischiopubic part has a plane that is inclined down and back to a transverse line between the lower limits of the ischial tuberosities, and the posterior half has a plane approximating to the sacrotuberous ligaments, sloping down and forwards to the same line.

Three measurements are made for the pelvic outlet. The anteroposterior diameter is usually measured from the apex of the coccyx to the midpoint of the lower rim of the pubic symphysis. The lowest sacral point may also be used (on average: male 8 cm, female 12.5 cm). The transverse (bituberous) diameter is measured between the ischial tuberosities at the lower borders of their medial surfaces (on average: male 8.5 cm, female 11.8 cm). The oblique diameter extends from the midpoint of the sacrotuberous ligament on one side to the contralateral ischiopubic junction (on average: male 10 cm, female 11.8 cm). All measurements vary among individuals and racial groups.

Other measurements

Apart from these main measurements, by consensus the basis of pelvic osteometry, other planes and measurements are used in obstetric practice. The plane of greatest pelvic dimensions is an obstetric concept. It represents the most capacious pelvic level, between the pelvic brim and midlevel plane, and corresponds with the latter anteriorly at the middle part of the pubic symphysis and posteriorly at the level of the second and third sacral segments.

The plane of least dimensions is said to be at about mid-pelvic level. Its transverse diameter is between the apices of the ischial spines. This measurement is about 9.5 cm in an adult female and is just wide enough to allow passage of the biparietal diameter of a fetal head (about 9 cm). Not surprisingly, most difficult parturition occurs here.

The above measurements are sometimes made in clinical practice using radiographs or magnetic resonance imaging (MRI) pelvimetry. Precise measurement is not possible without radiological techniques, and even these do not consider the adjacent soft tissues.

Pelvic axes and inclination

The axis of the superior pelvic aperture traverses its centre at right-angles to its plane, directed down and backwards (Fig. 77.10). When prolonged (projected), it passes through the umbilicus and mid-coccyx. An axis is similarly established for the inferior aperture: projected upwards, it impinges on the sacral promontory. Axes can likewise be constructed for any plane, and one for the whole cavity is a concatenation of an infinite series of such lines (see Fig. 77.10).

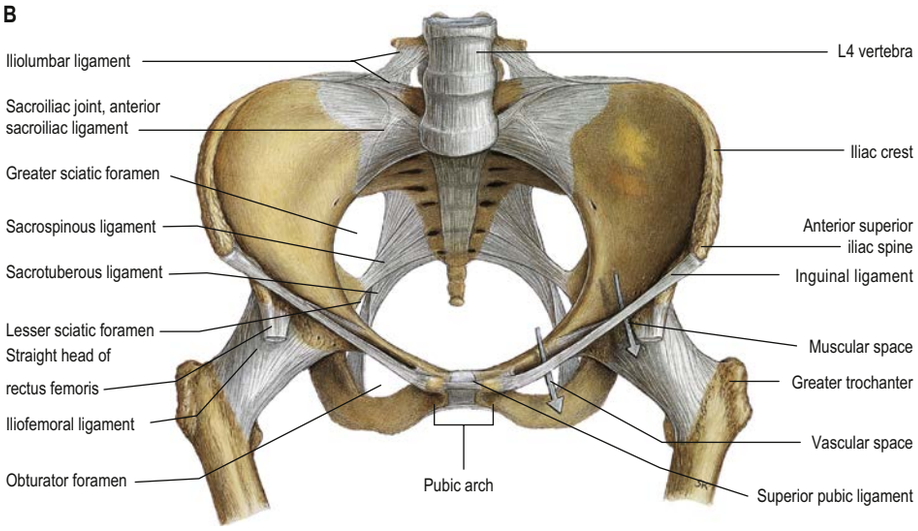

Fig. 77.9 B, Anterior aspect of the pelvis. Note the arrows indicating vascular and muscular spaces. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

The skeletal pelvis supports and protects the contained viscera but is primarily part of the lower limbs, affording wide attachment for muscles of the thigh, leg and trunk. It constitutes the major mechanism for transmitting the weight of the head, trunk and upper limbs to the lower limbs. It may be considered as two arches divided by a coronal transacetabular plane. The posterior arch, chiefly concerned in transmitting weight, consists of the upper three sacral vertebrae and strong pillars of bone from the sacroiliac joints to the acetabular fossae. The anterior arch, formed by the pubic bones and their superior rami, connects these lateral pillars as a tie beam to prevent separation; it also acts as a compression strut against medial femoral thrust. The sacrum, as the summit of the posterior arch, is loaded at the lumbosacral joint. Theoretically, this force has two components: one thrusting the sacrum downwards and backwards between the iliac bones, the other thrusting its upper end downwards and forwards. Sacroiliac joint movements are regulated by osseous shape and massive ligaments. The first component therefore acts against the wedge, its tendency to separate iliac bones resisted by the sacroiliac and iliolumbar ligaments and pubic symphysis.

Vertical coronal sections through the sacroiliac joints suggest division of the (synovial) articular region of the sacrum into three segments. In the anterosuperior segment, involving the first sacral vertebra, the articular surfaces are slightly sinuous and almost parallel. In the middle segment, the posterior width between the articular markings is greater than the anterior, and centrally a sacral concavity fits a corresponding iliac convexity, an interlocking mechanism relieving the strain on the ligaments produced by body weight. In the posteroinferior segment, the anterior sacral width is greater than the posterior and here its sacral surfaces are slightly concave. Anteroinferior sacral dislocation by the second component (of force) is prevented, therefore, mainly by the middle segment, owing to its cuneiform shape and interlocking mechanism. However, some rotation occurs, in which the anterosuperior segment tilts down and the posteroinferior segment up. 'Superior' segmental movement is limited to a small degree by wedging but primarily by tension in the sacrotuberous and sacrospinous ligaments. In all movements, the sacroiliac and iliolumbar ligaments and pubic symphysis resist separation of the iliac bones.

The pelvis provides the most marked skeletal differences between male and female. Although there is some skeletal sexual dimorphism in infancy and childhood, most researchers agree that this is minimal. There are methods that focus on the shape of the greater sciatic notch, but they are quite unreliable. Sexual differences in adults are divisible into metrical and non-metrical features; the range of most features overlaps between the sexes.

Differences are inevitably linked to function. Although the primary pelvic function in both sexes is locomotor, the pelvis, particularly the lesser pelvis, is adapted to parturition in females, and these changes variably affect the proportions and dimensions of the greater pelvis (Betti and Manica 2018). Since males are stereotypically more muscular and therefore more heavily built, overall pelvic dimensions, such as the intercristal distance (distance between the iliac crests), are greater, markings for muscles and ligaments more pronounced, and general architecture more robust. The male iliac crest is more rugged and more medially inclined at its anterior end; in females the iliac crests are less curved in all parts. The iliac alae are more vertical in females but do not ascend so far; the iliac fossae are therefore shallower. These iliac peculiarities probably account for the greater prominence of female hips.

The male is more robust above the pelvis, with consequent differences at the lumbosacral and hip joints. The sacral basal articular facet for the fifth lumbar vertebra and intervening intervertebral disc is more than one-third of the total sacral basal width in males but less than one-third in females, in whom the sacrum is also relatively broader, accentuating this difference. The female has relatively broader sacral alae. The male acetabulum is larger, and its diameter is approximately equal to the distance between its anterior rim and pubic symphysis. In females, acetabular diameter is usually less than this distance, not only because it is smaller but also because the anterolateral wall of the cavity is comparatively and often absolutely wider. The height of the female pubic symphysis and adjoining parts of the pubis and ischium, which form the anterior pelvic wall, are also less, producing a somewhat triangular obturator foramen, which is more ovoid in males. Differing pubic growth is also expressed in the pubic arch below the pubic symphysis and between the inferior pubic rami. It is more angular in males, being 50–60°; in females it is rounded, less easy to measure and usually 80–85°. A greater separation of the pubic tubercles in females contributes to the pubic width. The ischiopubic rami are also much more lightly built and narrowed near the symphysis; in males they bear a distinctly rough, everted area for attachment of the penile crura and in females the corresponding attachment for the clitoris is the ventral arc. The ischial spines are closer in males and are more inturned. The greater sciatic notch is usually wider in females: mean values for males and females are 50.4° and 74.4°, respectively. The greater female values for angle and width are associated with increased backward sacral tilt and greater anteroposterior pelvic diameter, especially at lower levels.

The sacrum also displays metrical sexual differences. Female sacra are less curved, the curvature being most marked between the first and second segments and the third and fifth, with an intervening flatter region. Male sacra are more evenly curved, and relatively long and narrow, and more often exceed five segments (by addition of a lumbar or coccygeal vertebra). The sacral index compares sacral breadth (between the most anterior points on the auricular surfaces) with length (between midpoints on the anterior margins of the promontory and apex): average values for males and females are 105% and 115%, respectively. Auricular surfaces are relatively smaller and more oblique in females, but extend on to the upper three sacral vertebrae in both sexes. The dorsal auricular border is more concave in females. Many differences may be summarized in the generalization that the pelvic cavity is longer and more conical in males, and shorter and more cylindrical in females; the axis is curved in both. Differences are greater at the inferior aperture than at the brim, where in absolute measurements males are not as different from females as sometimes stated.

In forensic practice, identification of human skeletal remains (which are sometimes fragmentary) usually involves estimation of sex, and this is most reliably established from an examination of the pelvis. Even fragments of the pelvis can be useful in this respect, and may be considered alongside skull robusticity or gracility and long bone metrics. Pelvic features taken into account include the subpubic angle, pubic width, sacral curvature, width of the greater sciatic notch, and the proportion of the body of the first sacral vertebra compared to the alae. It is important to consider all data available for measuring skeletal sexual dimorphism of the pelvis and skull, as assessment of sex from isolated and often incomplete human remains is less reliable. For further details, consult White and Folkens (2005).

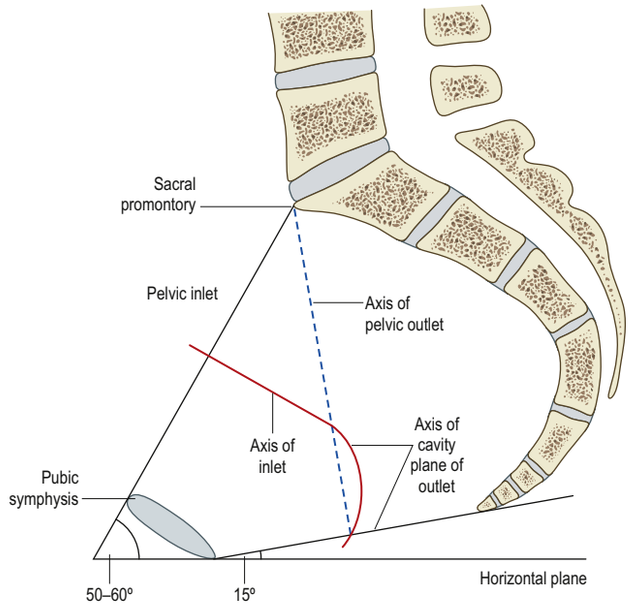

Fig. 77.10 A median sagittal section through the female pelvis, showing the planes of the inlet and outlet and the axis of the pelvic cavity.

The fetal head, however, descends in the axis of the inlet as far as the level of the ischial spines; it is then directed forwards into the axis of the vagina at right-angles to that axis. The form of this pelvic axis and the disparity in depth between the anterior and posterior contours of the cavity are prime factors in the mechanism of fetal transit in the pelvic canal.

In the standing position, the pelvic canal curves obliquely backwards relative to the trunk and abdominal cavity. The whole pelvis is tilted forwards, the plane of the pelvic brim making an angle of 50–60° with the horizontal. The plane of the pelvic outlet is tilted to about 15°. Strictly, the pelvic outlet has two planes: an anterior passing backwards from the pubic symphysis and a posterior passing forwards from the coccyx, both descending to meet at the intertuberous line. In standing, the pelvic aspect of the pubic symphysis faces nearly as much upwards as backwards and the sacral concavity is directed anteroinferiorly. The front of the pubic symphysis and anterior superior iliac spines are in the same vertical plane. While sitting, body weight is transmitted through the inferomedial parts of the ischial tuberosities, with variable soft tissues intervening. The anterior superior iliac spines are in a vertical plane through the acetabular centres, and the whole pelvis is tilted back with the lumbosacral angle somewhat diminished at the sacral promontory.

Femur

The femur is the longest and strongest bone in the human body (**Figs 77.11–77.12**). Its length is associated with a striding gait, and its strength with the weight and muscular forces it is required to withstand. Its shaft, almost cylindrical along most of its length, is bowed forwards. It has a proximal rounded, articular head projecting medially from its short neck, which, in turn, is a medial extension of the proximal shaft. The distal extremity is wider and more substantial, and presents two condyles that articulate with the tibia. In standing, the femoral shafts show an inclination upwards and outwards from their tibial articulations, with the femoral heads being separated by the pelvic width. Since the tibia and fibula descend vertically from the knees, the ankles are also in the line of body weight in standing or walking. The degree of femoral obliquity varies between individuals but is generally greater in women, reflecting the relatively greater pelvic breadth and shorter

femora. Proximally, the femur consists of a head, neck and greater and lesser trochanters.

Femoral head

The femoral head faces anterosuperomedially to articulate with the acetabulum (**Fig. 77.13**). The head, often described as rather more than half a 'sphere', is not part of a true sphere but is spheroidal. Its smoothness is interrupted posteroinferior to its centre by a small, rough fovea, to which the ligament of the head of the femur (ligamentum teres) is attached. The head is intracapsular and is encircled, distal to its equator, by the acetabular labrum. Its articular margin is distinct, except anteriorly, where the articular surface extends on to the neck. The anterior surface of the head is separated inferomedially from the femoral artery by the tendon of psoas major, the iliopectineal bursa and the articular capsule.

Femoral neck

The femoral neck (see Fig. 77.13) is approximately 5 cm long, narrowest in its mid part and widest laterally, and connects the head to the shaft at an average angle of approximately 127° (Gilligan et al 2013) (angle of inclination; neck–shaft angle). The neck is also anteriorly rotated with respect to the shaft (angle of anteversion) some 10–15°, although values of this angle vary between individuals and between populations (Eckhoff et al 1994). The contours of the neck are rounded; the upper surface is almost horizontal and slightly concave, while the lower is straighter but oblique, directed inferolaterally and backwards to the shaft near the lesser trochanter. On all aspects the neck expands as it approaches the articular surface of the head. Morphological variation of this bony expansion may cause painful impingement between the femoral neck and acetabular labrum at the

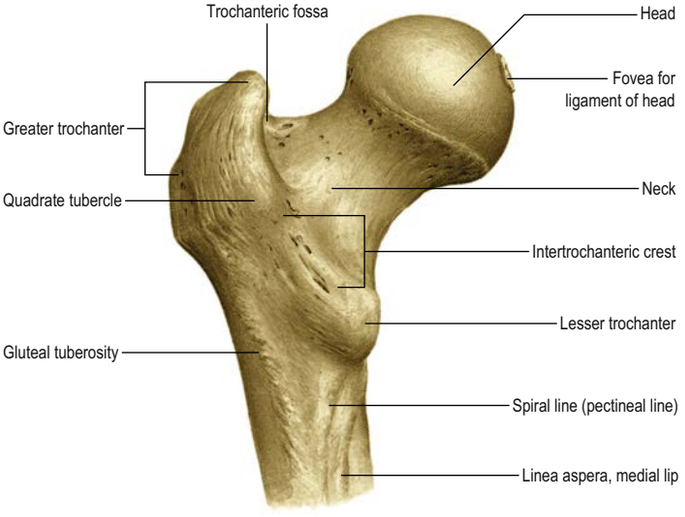

Fig. 77.13 The proximal end of the femur, posterior aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

extremes of flexion and medial (internal) rotation positions. The anterior surface of the neck is flat and marked at the junction with the shaft by a rough intertrochanteric line. The posterior surface, facing posteriorly and superiorly, is transversely convex, and concave in its long axis; its junction with the shaft is marked by a rounded intertrochanteric crest. There are numerous vascular foramina, especially anteriorly and posterosuperiorly.

The anterior surface is intracapsular, the capsule attaching laterally to the intertrochanteric line. Facets, often covered by extensions of articular cartilage, and various imprints frequently occur here. On the posterior surface the capsule does not reach the intertrochanteric crest; little more than the medial half of the neck is intracapsular. The anterior surface adjoining the head and covered by cartilage is related to the iliofemoral ligament. A groove, produced by the tendon of obturator externus as it approaches the trochanteric fossa, spirals across the posterior surface of the neck of the femur in a proximolateral direction.

Greater trochanter

The greater trochanter is large and quadrangular, projecting up from the junction of the neck and shaft (see Fig. 77.13). The leverage of many hip muscles is enhanced by their attachment to this prominent bony feature. Its posterosuperior region projects superomedially to overhang the adjacent posterior surface of the neck and here its medial surface presents the rough trochanteric fossa. The proximal border of the trochanter lies approximately a hand's breadth below the iliac tuberculum, level with the centre of the femoral head. It has an anterior rough impression. Its lateral surface, continuous distally with the lateral surface of the femoral shaft, is crossed anteroinferiorly by an oblique, flat strip, which is wider above. This surface is readily palpable, especially when the muscles are relaxed.

Lesser trochanter

The lesser trochanter is a conical posteromedial projection of the shaft at the posteroinferior aspect of its junction with the neck. Its summit and anterior surface are rough, but its posterior surface, at the distal end of the intertrochanteric crest, is smooth. It is not palpable. The lesser trochanter serves as the primary attachment for the large iliopsoas muscle.

Intertrochanteric line

The intertrochanteric line, a prominent ridge at the junction of the anterior surfaces of the neck and shaft, descends medially from a tubercle on the upper part of the anterior aspect of the greater trochanter to a point on the lower border of the neck, anterior to the lesser trochanter, where there may also be a tubercle. This line is the lateral limit of the hip joint capsule anteriorly. The upper and lower bands of the iliofemoral ligament are attached to its proximal and distal ends and the associated tubercles. Distally, it is continuous with the spiral (pectineal) line.

Intertrochanteric crest

The intertrochanteric crest, a smooth and prominent ridge at the junction of the posterior surface of the neck with the shaft, descends medially from the posterosuperior angle of the greater trochanter to the lesser trochanter. A little above its centre is the low, rounded quadrate tubercle. It is covered by gluteus maximus, from which it is separated, medial to the tubercle, by quadratus femoris and the upper border of adductor magnus.

Gluteal tuberosity

The gluteal tuberosity, accepting the tendon of the gluteus maximus, may be an elongated depression or a ridge. It may at times be prominent enough to merit the title of a third trochanter.

Shaft

The shaft is surrounded by muscles and is impalpable (see Figs 77.11B, 77.12B). The distal anterior surface, for 5–6 cm above the patellar articular surface, is covered by a suprapatellar bursa, between bone and muscle. The proximal two-thirds of the anterior and lateral surfaces are covered by vastus intermedius. The medial surface, devoid of attachments, is covered by vastus medialis.

The shaft is narrowest centrally, expanding a little at its proximal end, and substantially more at its distal end. Its long axis makes an angle of approximately 10° with the vertical, and diverges 5–7° from the long axis of the tibia. Its middle one-third has three surfaces and borders. The extensive anterior surface, smooth and gently convex, is between the lateral and medial borders, which are both round and indistinct. The posterolateral surface is bounded posteriorly by the broad, rough and often raised, linea aspera, usually a crest with lateral

and medial edges. Its subjacent compact bone is augmented to withstand compressive forces, which are concentrated here by the anterior curvature of the shaft. The linea aspera gives at least partial attachment to adductors longus and brevis, adductor magnus, vastus medialis and lateralis, intermuscular septa (partially continuous with the fascia lata of the thigh), and the short head of biceps femoris, all inseparably blended at their attachments. Perforating arteries cross the linea aspera laterally under tendinous arches in adductor magnus and biceps femoris. Nutrient foramina, directed proximally, appear in the linea aspera, varying in number and site, one usually near its proximal end, a second usually near its distal end. The posteromedial surface, smooth like the others, is bounded in front by the indistinct medial border and behind by the linea aspera. In its proximal third the shaft has a fourth, posterior surface, bounded medially by the narrow, rough spiral line. Laterally, this surface is limited by the broad, rough gluteal tuberosity, ascending a little laterally to the greater trochanter and descending to the lateral edge of the linea aspera. In its distal one-third, the posterior surface of the shaft presents a further surface, the popliteal surface (see below) between the medial and lateral supracondylar lines. These lines are continuous above with the corresponding edges of the linea aspera. The lateral line is most distinct in its proximal two-thirds, where the short head of biceps femoris and lateral intermuscular septum are attached. Its distal third has a small, rough area for the attachment of plantaris, often encroaching on the popliteal surface. The medial line is indistinct in its proximal two-thirds, where vastus medialis is attached. Distally, the femoral vessels entering the popliteal fossa from the adductor canal cross the medial line obliquely. Further distally, the line is often sharp for 3 or 4 cm proximal to the adductor tubercle.

The popliteal surface, triangular in outline, lies between the medial and lateral supracondylar lines. In its distal medial part, it is rough and slightly elevated. Forming the proximal part of the floor of the popliteal fossa, the popliteal surface is covered by a variable amount of fat that separates the popliteal artery from bone. The superior medial genicular artery, a branch of the popliteal artery, arches medially above the medial condyle. It is separated from bone by the medial head of gastrocnemius. The latter is attached a little above the condyle; further distally, there may be a smooth facet underlying a bursa for the medial head of gastrocnemius. More medially, there is often an imprint proximal to the articular surface; in deep flexion, this is close to a rough tubercle on the medial tibial condyle for the attachment of semimembranosus. The superior lateral genicular artery arches up laterally proximal to the lateral condyle but is separated from bone by the attachment of plantaris to the distal part of the lateral supracondylar line.

Distal end

The distal end of the femur is widely expanded as a bearing surface for transmission of weight to the tibia (**Fig. 77.14**). It bears two massive condyles, which are partly articular. Anteriorly, the condyles are confluent and continue into the shaft; posteriorly, they are separated by a deep intercondylar fossa and project beyond the plane of the popliteal surface. The articular surface is a broad area, like an inverted U, for the patella and the tibia. The patellar surface extends anteriorly on both condyles, especially the lateral. It is transversely concave, vertically convex and grooved for the posterior patellar surface. The tibial surface is divided by the intercondylar fossa but is anteriorly continuous with the patellar surface. Its medial part is a broad strip on the convex inferoposterior surface of the medial condyle, and is gently curved with a medial convexity. Its lateral part covers similar aspects of the lateral condyle but is broader and passes straight back. The tibial surfaces are convex in all directions. The medial and lateral tibial surfaces have dissimilar anteroposterior curvatures; as evident in Fig. 77.14, the medial condyle curves more obliquely than the lateral. As described in Chapter 78 on the knee, these differences are believed to be important determinants in the mechanics of locking the knee in full extension.

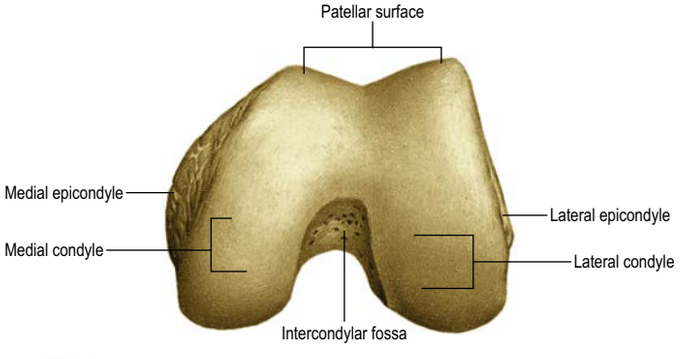

Fig. 77.14 The distal end of the femur, articular surface. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Patellar surface

The patellar surface extends more proximally on the lateral side. Its proximal border is therefore oblique and runs distally and medially, separated from the tibial surfaces by two faint grooves that cross the condyles obliquely. The lateral groove is the more distinct. It runs laterally and slightly forwards from the front of the intercondylar fossa and expands to form a faint triangular depression, resting on the anterior edge of the lateral meniscus when the knee is fully extended. The medial groove is restricted to the medial part of the medial condyle and rests on the anterior edge of the medial meniscus in full extension. Where it ceases, the patellar surface continues back to the lateral part of the medial condyle as a semilunar area adjoining the anterior region of the intercondylar fossa. This area articulates with the medial vertical facet of the patella in full flexion; its outline is indistinct in most femora.

Intercondylar fossa

The intercondylar fossa separates the two condyles distally and behind. In front, the distal border of the patellar surface limits it, and behind an intercondylar line limits it, separating it from the popliteal surface. It is intracapsular but largely extrasynovial. Its lateral wall, the medial surface of the lateral condyle, bears a flat posterosuperior impression that spreads to the floor of the fossa near the intercondylar line for the proximal attachment of the anterior cruciate ligament. The medial wall of the fossa, i.e. the lateral surface of the medial condyle, bears a similar larger area, but far more anteriorly, for the proximal attachment of the posterior cruciate ligament. Both impressions are smooth and largely devoid of vascular foramina, whereas the rest of the fossa is rough and pitted by vascular foramina. A bursal recess between the ligaments may ascend to the fossa. The capsular ligament and, laterally, the oblique popliteal ligament are attached to the intercondylar line. The infrapatellar synovial fold is attached to the anterior border of the fossa.

Lateral condyle

The lateral condyle (see Fig. 77.14) is larger anteroposteriorly than the medial condyle. Its most prominent point is the lateral epicondyle to which the fibular collateral ligament is attached (**Fig. 77.15**). A short groove, deeper in front, separates the lateral epicondyle inferiorly from the articular margin. This groove allows the tendon of popliteus to run deep to the fibular collateral ligament and insert

Fig. 77.15 The distal end of the femur, lateral aspect. Key: 1, attachment of plantaris; 2, attachment of lateral head of gastrocnemius; 3, lateral epicondyle; 4, attachment of fibular collateral ligament; 5, groove for popliteus in full flexion; 6, attachment of popliteus. Note multiple nutrient foramina.

inferior and anterior to the ligament insertion. Adjoining the joint margin is a strip of condyle, 1 cm broad. It is intracapsular and covered by synovial membrane except for the attachment of popliteus.

The medial surface is the lateral wall of the intercondylar fossa. Its lateral surface projects beyond the shaft. Part of the lateral head of gastrocnemius is attached to an impression posterosuperior to the lateral epicondyle.

Medial condyle

The medial condyle has a bulging, convex medial aspect, which is easily palpable. Proximally, its adductor tubercle, which may only be a facet rather than a projection, receives the tendon of adductor magnus. The medial prominence of the condyle, the medial epicondyle, is anteroinferior to the tubercle. The lateral surface of the condyle is the medial wall of the intercondylar fossa. The condyle projects distally so that, despite the obliquity of the shaft, the profile of the distal end is almost horizontal. A curved strip, 1 cm wide and adjoining the medial articular margin, is covered by synovial membrane and is inside the joint capsule. Proximal to this, the medial epicondyle receives the tibial collateral ligament.

Structure

The femoral shaft is a cylinder of compact bone with a large medullary cavity. The wall is thick in its middle third, where the femur is narrowest and the medullary cavity most capacious. Proximally and distally the compact wall becomes progressively thinner, and the cavity gradually fills with trabecular bone. The extremities, especially the articular areas, consist of trabecular bone within a thin shell of compact bone, their trabeculae being disposed along lines of greatest stress. At the proximal end the main trabeculae form a series of plates orthogonal to the articular surface, converging to a central dense wedge, which is supported by strong trabeculae passing to the sides of the neck, especially along its upper and lower profiles (**Fig. 77.16**). Force applied to the femoral head is therefore transmitted to the wedge and from there to the junction of the neck and shaft. This junction is strengthened by dense trabeculae extending laterally from the lesser trochanter to the end of the superior aspect of the neck, thus resisting tensile or shearing forces applied to the neck through the head (**Fig. 77.17**). Tensile and compressive tests indicate that axial trabeculae of the femoral head withstand much greater stresses than peripheral trabeculae. A smaller bar across the junction of the greater trochanter with the neck and shaft resists shearing caused by forces produced by local muscles such as the gluteus medius. A thin vertical plate, the so-called calcar femorale, ascends from the compact wall near the linea aspera into the trabeculae of the neck (see Fig. 77.17). Medially, it joins the posterior wall of the neck; laterally, it continues into the greater trochanter, where it disperses into general trabecular bone. It is thus in a plane anterior to the trochanteric crest and base of the lesser trochanter. Dixon (1910) demonstrated that the trabecular framework of the proximal femur was spiral, and that the 'arches' were simplified sectional profiles of this spiral. At the distal end of the femur, trabeculae spring from the entire internal surface of compact bone, descending perpendicular to the articular surface. Proximal to the condyles these are strongest and most accurately perpendicular. Horizontal planes of trabecular bone, arranged like crossed girders, form a series of cubical compartments.

Muscle attachments

The greater trochanter provides attachment for glutei medius and minimus. Gluteus minimus is attached to its rough anterior impression and gluteus medius to its posterosuperior aspect and an oblique line on its lateral surface. The bone is separated from the tendons of gluteus minimus and medius by several bursae (Woodley et al 2008). The area behind it is covered by deep fibres of gluteus maximus, with part of its trochanteric bursa interposed. The tendon of piriformis is attached to the upper border of the trochanter and the common (tricipital) tendon of obturator internus and the gemelli is attached to its medial surface. The trochanteric fossa receives the tendon of obturator externus. Psoas major is attached to the summit and anteromedial surface of the lesser trochanter, and iliacus to the medial or anterior surface of its base, descending a little behind the spiral line as its tendon fuses with that

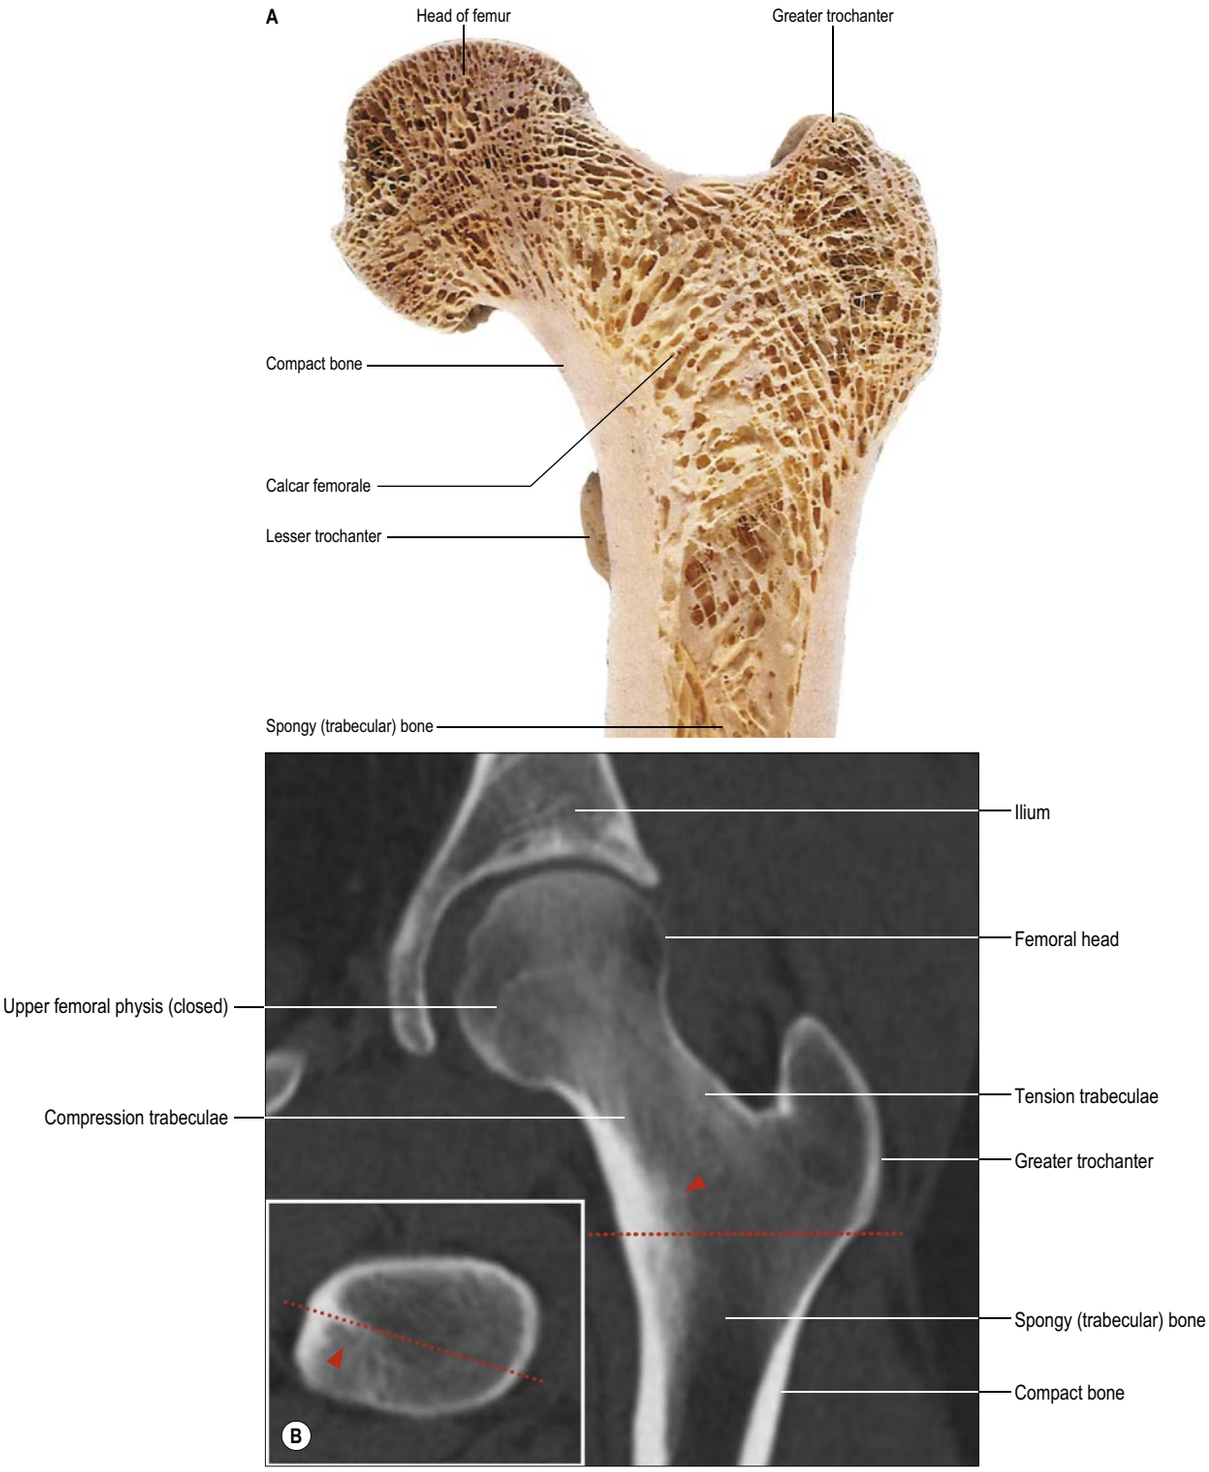

Fig. 77.17 A, A coronal section through the proximal end of the femur showing the trabecular architecture, calcar femorale and variations in cortical thickness. **B**, A coronal oblique CT of the proximal femur showing the calcar femorale (arrowheads) with the axial plane inset; the dotted red lines show the respective cross-sections. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

of psoas major. Adductor magnus (upper part) passes over the posterior surface of the lesser trochanter, sometimes separated by an interposed bursa.

The most proximal fibres of vastus lateralis are attached to the proximal end of the intertrochanteric line, and those of vastus medialis to the distal end. Quadratus femoris is attached to the quadrate tubercle and the immediately distal bone. Vastus intermedius is attached to the anterior and lateral surfaces of the proximal three-quarters of the femoral shaft. Slips of articularis genus are attached distal to this.

The gluteal tuberosity receives the deeper fibres of the distal half of gluteus maximus and, at its medial edge, the uppermost fibres of adductor magnus. Distal to this, adductor magnus is attached to the linea aspera and, by an aponeurosis, to the proximal part of the medial supracondylar ridge. Its remaining fibres form a large tendon attached to the adductor tubercle, with an aponeurotic expansion to the distal part of the medial supracondylar ridge.

Pectineus and adductor brevis are attached to the posterior femoral surface between the gluteal tuberosity and spiral line. The pectineal attachment is a line, sometimes slightly rough, from the base of the lesser trochanter to the linea aspera. Adductor brevis is attached lateral to pectineus and beyond this to the proximal part of the linea aspera, medial to adductor magnus. Adductor longus, intermuscular septa and the short head of biceps femoris are also attached to the linea aspera. Vastus lateralis has a linear attachment from the anterior surface of the base of the greater trochanter to the proximal end of the gluteal tuberosity, and along the lateral margin of the latter to the proximal half of the lateral edge of the linea aspera. Vastus medialis is attached from the distal end of the intertrochanteric line along the spiral line to the medial edge of the linea aspera and thence to the medial supracondylar line, which also receives many fibres from the aponeurotic attachments of adductor magnus.

The medial head of gastrocnemius is attached to the posterior surface a little above the medial condyle. The short head of biceps femoris is attached to the proximal two-thirds of the lateral supracondylar line. Plantaris attaches to the line distally. Vastus medialis is attached to the proximal two-thirds of the medial supracondylar line.

Part of the lateral head of gastrocnemius is attached posterosuperiorly to the lateral epicondyle. Popliteus is attached anteriorly in the groove on the outer aspect of the lateral epicondyle. Its tendon passes deep to the fibular collateral ligament (see Fig. 77.15). The tendon lies in the groove in full knee flexion; in extension it crosses the articular margin and may form an impression on it.

Vascular supply

The blood supply of the femoral head is derived from an arterial ring around the neck, just outside the attachment of the fibrous capsule, constituted by the medial and lateral circumflex femoral arteries with minor contributions from the superior and inferior gluteal vessels. Branches from the arterial ring pierce the capsule (under its zona orbicularis) to ascend the neck beneath the reflected synovial membrane. These vessels become the retinacular arteries and form a subsynovial intracapsular anastomosis. Here the vessels are at risk with a displaced fracture of the femoral neck. Interruption of blood supply in this way can lead to avascular necrosis of the femoral head. If the fracture is intracapsular, not only is the intraosseous blood supply damaged but the retinacular vessels are also vulnerable. If the fracture is extracapsular, the retinacular vessels will remain intact and avascular necrosis of the femoral head is much less likely. The ascending cervical vessels give off metaphysial branches that enter the neck, while the intracapsular ring gives off lateral and inferior epiphysial branches. A small medial epiphysial supply reaches the head along the ligament of the head of femur by the acetabular branches of the obturator and medial circumflex femoral arteries, which anastomose with the other epiphysial vessels (Seeley et al 2016). During growth, the epiphysial plate separates the territories of the metaphysial and epiphysial vessels; these vessels anastomose freely after osseous union of the head and neck. Observations of developmental patterns of this supply in late fetal and early postnatal periods have revealed that although the medial and lateral circumflex femoral arteries at first contribute equally, two major branches of the medial provide the final supply, both posterior to the neck. The supply from the lateral circumflex femoral artery diminishes and the arterial ring is interrupted. As the femoral neck elongates, the extracapsular circle becomes more distant from the epiphysial part of the head.

The trochanteric regions and subtrochanteric shaft are supplied by the trochanteric and cruciate arterial anastomoses. More distally in the shaft, nutrient foramina, directed proximally, are found in the linea aspera, varying in number and site: one is usually near its proximal end and a second usually near its distal end. The main nutrient artery is usually derived from the second perforating artery (see p. 1389). If two nutrient arteries occur, they may branch from the first and third perforators. Periosteal vessels arise from the perforators and from the profunda femoris artery, and run circumferentially rather than longitudinally. The distal metaphysis has many vascular foramina. Arterial supply here is from the genicular anastomosis. For further details, consult Crock (1980, 1996).

In general, the pattern of venous drainage of the head and neck corresponds to that of the arteries, though there may be a single large cervical vein posteroinferiorly.

Innervation

The periosteal innervation is derived proximally from nerves that supply the hip joint, distally from those supplying the knee, and in all areas from nerves that innervate muscles attached to the bone.

Ossification

The femur ossifies from five centres: in the shaft, head, greater and lesser trochanters and the distal end (**Figs 77.18–77.19**). Other than the clavicle, it is the first long bone to ossify.The process starts in the mid-shaft during embryonic stages 22 and 23 (postfertilization days 52–58) and extends to produce a miniature shaft that is largely ossified at birth. Secondary centres appear in the distal end (from which the condyles and epicondyles are formed) during postmenstrual weeks 33–36; in the greater trochanter during the fourth year; and in the lesser trochanter between the twelfth and fourteenth years. In the infant, the femoral head is entirely cartilaginous: it cannot be seen on plain radiographs and is best visualized using ultrasound (**Fig. 77.20**). The centre in the cartilaginous head is restricted to it until the tenth year, so that the epiphysial line (see Fig. 77.7) is horizontal and the inferomedial part of the articular surface is on the neck. The medial epiphysial margin later grows over this part of the articular surface. Thus, the mature epiphysis is a hollow cup on the summit of the neck. The epiphysial line follows the articular margin except where it is separated superiorly from the articular surface by a non-articular area where blood vessels enter the head (Trueta 1957). The epiphyses fuse independently: the lesser trochanter soon after puberty, followed by the greater trochanter. The capital epiphysis fuses in the fourteenth year in females and seventeenth year in males. The epiphysis at the distal end fuses in the sixteenth year in females, and eighteenth year in males. The distal epiphysial plate traverses the adductor tubercle.

Growth plate considerations

Trauma to any epiphysial plate can lead to bony union between epiphysis and metaphysis, and so cause premature cessation of growth. Any surgery in the hip region in children can injure the growth plate, resulting in abnormal proximal femoral development. In the case of fractures involving the epiphysis, expeditious restoration of normal bony alignment is essential in order to minimize the risk of subsequent abnormal growth.

The growth plate represents a line of weakness and predisposes to fracture from injury. Such acute injuries affecting the capital epiphysis are uncommon. However, a more chronic fracture through the capital epiphysis occurs in slipped capital femoral epiphysis (see Fig. 77.29). The condition affects pubescent adolescents, especially males. The femoral head epiphysis displaces posteriorly off the femoral neck. If it heals in this position, lower limb deformity and restricted hip

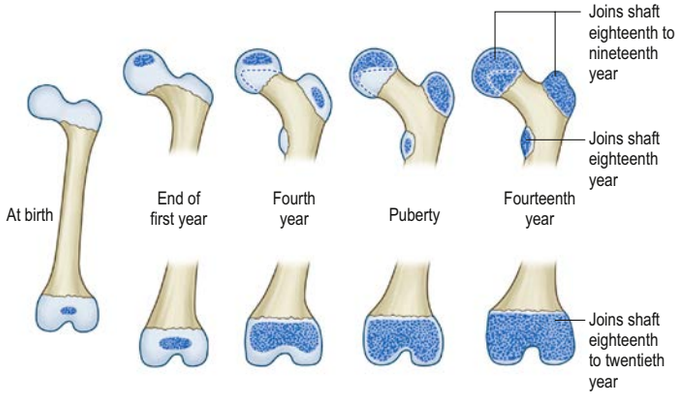

Fig. 77.18 Stages in ossification of the femur (not to scale).

movement occur. A classic hallmark is obligatory lateral (external) rotation of the femur as the hip is flexed. Treatment varies according to the time taken for the 'slip' to occur. Normal anatomical restoration is not attempted because of an increased incidence of avascular necrosis. The position of the femoral head may be accepted as it is and fixed with screws in this position to stop further displacement. This treatment will deliberately cause premature growth plate fusion and so prevent future 'slippage'. Since the distal femoral growth plate accounts for most of the normal increase in longitudinal growth of the femoral shaft, an acceptable limb length difference usually results.

Infection of bone in neonates and young children tends to arise via bacteria in the blood stream that usually 'seed' in the metaphysial region, probably as a consequence of the vascular 'arcade' arrangement of arteries in this part of the bone. The proximal femoral growth plate is intra-articular. As a result, infection in the proximal femoral metaphysis can spread into the joint and result in a septic arthritis that can destroy the hip joint permanently.

The distal end of the femur is the only epiphysis in which ossification consistently starts just before birth; the phenomenon therefore serves as a reliable indicator of the gestational maturity of a stillborn baby. Since the epiphysial plate is level with the adductor tubercle, the epiphysis is partly extra-articular. Operations here may damage the distal epiphysial cartilage in children and result in subsequent shortening of the leg.

JOINTS

Pubic symphysis

The pubic bones meet in the midline at the pubic symphysis, a secondary cartilaginous joint (see Figs 77.2–77.3).

Articulating surfaces The articulating surfaces are the medial (symphysial) surfaces of the pubic bones, each covered by a thin layer of tightly adherent hyaline cartilage (surface growth cartilage in the young). The junction is not flat but is marked by reciprocal crests and papillae. Theoretically, this would resist shearing. The surfaces of hyaline cartilage are connected by fibrocartilage, varying in thickness and constituting the interpubic disc. The interpubic disc often contains a cleft, which rarely appears before the tenth year and may have a synovial lining (Becker et al 2010). The cleft, which is larger and more prevalent in females, is usually posterosuperior but may extend the length and/or depth of the disc.

Ligaments The interpubic disc is strengthened anteriorly by several interlacing collagenous fibrous layers, passing obliquely from bone to bone, decussating with fibres of the external oblique aponeuroses and the medial tendons of the recti abdominis. These layers constitute the anterior pubic ligament. There are less well developed posterior fibres, sometimes named the posterior pubic ligament. The main ligaments of the joint are the superior and inferior pubic ligaments. The superior pubic ligament connects the bones above, extending to the pubic tubercles. The inferior pubic ligament, a thick arch of fibres, connects the lower borders of the symphysial pubic surfaces bounding the pubic arch. It blends superiorly with the interpubic disc and extends laterally to the inferior pubic rami. Its inferior edge is separated from the anterior border of the perineal membrane by an opening, which is traversed by the deep dorsal vein of the penis or clitoris.

Vascular supply The pubic symphysis is supplied by pubic branches of the obturator, superficial external pudendal and inferior epigastric arteries.

Innervation The pubic symphysis is innervated by branches from the iliohypogastric, ilioinguinal and pudendal nerves.

Factors maintaining stability The interpubic disc and the superior and inferior ligaments are the main stabilizing factors of the pubic symphysis.

Movements Angulation, rotation and displacement are possible but slight, and are likely during movement at the sacroiliac and hip joints. The movements at the pubic symphysis range between 0.1 and 2 mm and are greater in the vertical axis than along the sagittal and transverse axes (Walheim et al 1984). Excessive movement may occur following an injury. Some separation occurs late in gestation and during childbirth; on occasion, this is considerable.

Relations Anteriorly the pubic symphysis is related to subcutaneous tissue and skin. Because of the obliquity of the joint, the proximal ends of the penile or clitoral shafts lie anterior to the lower half of the joint. Inferiorly the urethra lies about 2.5 cm away in the male, and somewhat closer in the female, as it passes through the perineal membrane. Closer to the joint, the deep dorsal vein of the penis or clitoris passes between the inferior pubic ligament and the anterior border of the perineal membrane. Posteriorly the upper part of the joint is separated from the inferolateral surfaces of the urinary bladder by the retropubic fat pad. Inferiorly in the male the prostatic venous plexus separates the prostate from the lower part of the joint. The region is sometimes termed the retropubic space (of Retzius). These relationships explain why traumatic disruption of the anterior bony pelvis may be associated with serious urogenital injury.

Sacroiliac joint

The sacroiliac joint occurs between the sacral and iliac auricular surfaces and, in essence, is a stress-relieving joint (Bogduk 2012, Vleeming et al 2012) (see Fig. 77.8A). The joint consists of syndesmotic and synovial parts. Fibrous adhesions and gradual obliteration occur in both sexes, earlier in males and after menopause in females. Radiological evidence of obliteration in normal subjects is occasionally seen before 50 years but is not uncommon thereafter; in old age, the joint may be completely fibrosed and occasionally even ossified.

Articulating surfaces The surfaces are nearly flat in infants, whereas in adults they are irregular, often markedly so, and sometimes undulant. The curvatures and irregularities, greater in males, are reciprocal; they restrict movements and contribute to the considerable strength of the joint in transmitting weight from the vertebral column to the lower limbs. The sacral surface is covered by hyaline cartilage, which is thicker anteriorly than posteriorly in adults. The thinner cartilage on the iliac surface is also hyaline in type, as confirmed by the presence of type II collagen.

Fibrous capsule The capsule is attached close to both articular margins.

Ligaments The ligaments of the sacroiliac joint are the anterior, interosseous and posterior sacroiliac, iliolumbar, sacrotuberous and sacrospinous ligaments.

Anterior sacroiliac ligament The anterior sacroiliac ligament (see Fig. 77.9A), an anteroinferior capsular thickening, is particularly well developed near the arcuate line and the posterior inferior iliac spine, where it connects the third sacral segment to the lateral side of the pre-auricular sulcus. It is thin elsewhere.

Interosseous sacroiliac ligament The interosseous sacroiliac ligament is the major bond between the bones, filling the irregular space posterosuperior to the joint. The posterior sacroiliac ligament covers it superficially. Its deeper part has superior and inferior bands passing from depressions posterior to the sacral auricular surface to those on the iliac tuberosity. These bands are covered by, and blend with, a more superficial fibrous sheet connecting the posterosuperior margin of a rough area posterior to the sacral auricular surface to the corresponding margins of the iliac tuberosity. This sheet is often partially divided into superior and inferior parts, the former uniting the superior articular process and lateral crest on the first two sacral segments to the neighbouring ilium as a short posterior iliac ligament (see Fig. 46.70).

Posterior sacroiliac ligament The posterior sacroiliac ligament (see Fig. 77.9B) overlies the interosseous ligament: the dorsal rami of the sacral spinal nerves and vessels intervene. It consists of several weak fasciculi connecting the intermediate and lateral sacral crests to the posterior superior iliac spine and posterior end of the internal lip of the iliac crest. Inferior fibres, from the third and fourth sacral segments, ascend to the posterior superior iliac spine and posterior end of the internal lip of the iliac crest; they may form a separate long posterior sacroiliac ligament. This ligament is continuous laterally with part of the sacrotuberous ligament and medially with the posterior lamina of the thoracolumbar fascia.

Iliolumbar ligament See Chapter 46.

Sacrotuberous ligament The sacrotuberous ligament (see Figs 77.9, 46.70) is attached by its broad base to the posterior superior iliac spine, the posterior sacroiliac ligaments (with which it is partly blended), lateral sacral crest and the lateral margins of the lower sacrum and upper coccyx. Its oblique fibres descend laterally, converging to form a thick, narrow band that widens again below and is attached to the medial margin of the ischial tuberosity. It then spreads along the ischial ramus as the

falciform process, whose concave edge blends with the fascial sheath of the internal pudendal vessels and pudendal nerve. The lowest fibres of gluteus maximus are attached to the posterior surface of the ligament; superficial fibres of the lower part of the ligament continue into the superficial fibres of the tendon of the long head of biceps femoris. The coccygeal branches of the inferior gluteal artery, the perforating cutaneous nerve and filaments of the coccygeal plexus pierce the ligament.

Sacrospinous ligament The thin, triangular sacrospinous ligament (see Fig. 77.9) extends from the ischial spine to the lateral margins of the sacrum and coccyx anterior to the sacrotuberous ligament, with which it blends in part. Its anterior surface is the coccygeus muscle, i.e. muscle and ligament are coextensive. The sacrospinous ligament is often regarded as a degenerate part of coccygeus.

Sciatic foramina The sacrotuberous and sacrospinous ligaments convert the sciatic notches into foramina (see Fig. 77.9).

Greater sciatic foramen The greater sciatic foramen is bounded anterosuperiorly by the greater sciatic notch, posteriorly by the sacrotuberous ligament and inferiorly by the sacrospinous ligament and ischial spine (see Fig. 77.9). It is partly filled by the emerging piriformis, above which the superior gluteal vessels and nerve leave the pelvis. Below it, the inferior gluteal vessels and nerve, internal pudendal vessels and pudendal nerve, sciatic and posterior femoral cutaneous nerves and the nerves to obturator internus and quadratus femoris all leave the pelvis.

Lesser sciatic foramen The lesser sciatic foramen is bounded anteriorly by the ischial body, superiorly by its spine and sacrospinous ligament, and posteriorly by the sacrotuberous ligament (see Fig. 77.9A). It transmits the tendon of obturator internus, the nerve to obturator internus, and the internal pudendal vessels and pudendal nerve.

Vascular supply and lymphatic drainage The arterial supply of the sacroiliac joint is derived from the iliolumbar, superior gluteal and superior lateral sacral arteries, with corresponding venous drainage. Lymphatic drainage follows the arteries, reaching the iliac and lumbar nodes.

Innervation Nerve fibres ramify within the joint capsule and adjoining ligaments, but their source is uncertain. It is thought that the joint probably receives branches from the anterior and posterior rami of the first two sacral spinal nerves, and from the superior gluteal nerve, and that there may also be contributions from the obturator nerve and the lumbosacral trunk.

The sacroiliac joint has sometimes been implicated as the source of pain in the lower back and buttocks. Diagnosing sacroiliac joint-mediated pain is difficult because the presenting complaints are similar to those seen with other causes of back pain. Patients with sacroiliac joint-mediated pain rarely report pain above the level of L5; most localize their pain to the area around the posterior superior iliac spine.

Factors maintaining stability The sacroiliac joint is one of the most stable joints in the body and supports the weight of the trunk. The reciprocal irregularity of the joint surfaces allows very little movement. The tendency of the sacrum to be forced downwards by the trunk is resisted by the extremely strong posterior ligaments, while the iliolumbar ligaments help to resist displacement of the fifth lumbar vertebra over the sacrum. The sacrotuberous and sacrospinous ligaments oppose upward tilting of the lower part of the sacrum when downward thrust is applied at its upper end.

Movements Primary movement of the sacroiliac joint is minimal (Vleeming et al 2012). All muscles that cross the joint act on the lumbar spine or on the hip. Such movements as do occur are secondarily imposed on the joint as the pelvis moves. Data from living subjects are technically difficult to obtain, and those based on plain radiographs are unreliable. Studies using implanted tantalum spheres and biplanar radiography have shown mean rotational ranges of less than 2°. Even when there is recordable movement, the direction of movement is irregular. Biplanar radiography has also shown that the axes of movement of the sacroiliac joint during hip movement are oblique, and that the axes differ in flexion and extension.

During pregnancy, the pelvic joints and ligaments loosen under the influence of the hormone relaxin. Movements in the joints increase. Relaxation renders the sacroiliac locking mechanism less effective, permitting greater rotation and perhaps allowing alterations in pelvic diameters at childbirth, although the effect is probably small. The impaired locking mechanism diverts the strain of weight-bearing to the ligaments, with frequent sacroiliac strain after pregnancy.

Relations The sacroiliac joints have many important anterior relations. The internal and external iliac veins join to form the common iliac veins immediately anteriorly, separating the joints from the bifurcations of the common iliac arteries and, more anteriorly, the ureters. The lumbosacral trunk and the obturator nerve cross the anterior aspect of the joint behind the vessels. Piriformis partly attaches to the anterior capsule, separating the joint from the upper part of the sacral plexus.

Variants Accessory sacroiliac articulations are not uncommon. They develop behind the articular surface between the lateral sacral crest and posterior superior iliac spine and iliac tuberosity, and are acquired fibrocartilaginous joints resulting from the stresses of weight-bearing. They have a joint capsule, are saddle-shaped, and may be single, double, unilateral or bilateral (Weisl 1954).

Hip

The hip joint is a synovial joint of ball-and-socket (multiaxial spheroidal) type between the head of the femur and the cup-shaped (cotyloid) acetabulum; its centre lies a little inferior to the middle one-third of the inguinal ligament (**Fig. 77.21**).

Key: 1, ossification in right iliolumbar ligament; 2, pubic symphysis; 3, inferior margin of left sacroiliac joint; 4, left anterior superior iliac spine.

Articulating surfaces The femoral head can be landmarked from the surface roughly 2–4 cm superior to an approximate midpoint of a line joining the superior margin of the greater trochanter to the pubic tubercle. The articular surfaces of the femoral head and the acetabulum are reciprocally curved but neither coextensive nor completely congruent (see Fig. 77.21; see Fig. 77.16). The close-packed position of the hip joint is one of full extension, with slight abduction and medial rotation (see also Table 5.4). This position winds up most of the joint's capsular ligaments, which can provide an important element of articular stability. The femoral head is covered by articular cartilage, except over the fovea where the ligament of the head of the femur (ligamentum teres) is attached. Anteriorly, the cartilage extends laterally over a small area on the adjoining neck. Articular cartilage is, generally, thicker centrally than peripherally. Cartilage thickness is maximal anterosuperiorly in the acetabulum and anterolaterally on the femoral head, the two areas that correspond to the principal load-bearing areas within the joint. The acetabular articular surface, the lunate surface, is an incomplete ring, broadest anterosuperiorly where the pressure of body weight falls in the erect posture, and narrowest in its pubic region. It is deficient inferiorly opposite the acetabular notch. The lunate surface is covered by articular cartilage, which is thickest where the surface is broadest. The acetabular fossa, the central non-articular area in the floor of the acetabulum, is devoid of cartilage but contains fibroelastic fat largely covered by synovial membrane. The acetabular labrum, a fibrocartilaginous rim attached to the acetabular margin, serves to deepen the acetabulum and bridges the acetabular notch by attaching to the peripheral edge of the transverse acetabular ligament. The acetabular labrum is triangular in section, attached by its base to the acetabular margin and blending with adjacent articular cartilage; its acute free edge projects beyond the acetabular margin. The diameter of the acetabular cavity is constricted by the labral rim, which embraces the femoral head, thereby contributing to the stability of the articulation. The acetabular labrum increases the surface area for joint contact as well as sealing the joint, allowing optimal intra-articular distribution of synovial fluid (Ferguson et al 2003, Cadet et al 2012). It thus facilitates nutrition of the articular cartilage and helps to reduce intra-articular friction (Safran et al 2011, Song et al 2012). Nerve endings found within the labrum suggest this structure may be a source of proprioception or, when injured, of pain (Kim and Azuma 1995, Alzaharani et al 2014). A torn acetabular labrum can be detected using MRI, to identify the site and severity of the lesion (**Fig. 77.22**).

Acetabular labrum and impingement injury

Available with the *Gray's Anatomy* e-book

Fibrous capsule The fibrous capsule of the hip joint is strong and dense. It is attached superiorly to the acetabular margin 5–6 mm medial to the labral attachment, anteriorly to the outer labral aspect and, near the acetabular notch, to the transverse acetabular ligament and the adjacent rim of the obturator foramen. From its acetabular attachment, it extends laterally to surround the femoral head and neck, and is attached anteriorly to the intertrochanteric line, superiorly to the base of the femoral neck, posteriorly 1 cm superomedial to the intertrochanteric crest, and inferiorly to the femoral neck near the lesser trochanter (see Fig. 77.12B). Anteriorly, many fibres ascend along the neck as longitudinal retinacula, containing blood vessels for both the femoral head and the neck. The capsule is thicker anterosuperiorly, where maximal stress occurs, particularly while standing with the hip extended. Posteroinferiorly, it is relatively thin and loosely attached. The capsule as a whole has two sets of fibres, circular and longitudinal. The circular fibres (zona orbicularis) are internal and form a collar round the femoral neck; although partly blended with the pubofemoral and ischiofemoral ligaments, these fibres are not directly attached to bone. Externally, longitudinal fibres are most numerous in the anterosuperior region, where they are reinforced by the iliofemoral ligament. The capsule is also strengthened inferiorly by the pubofemoral ligament, and posteriorly by the ischiofemoral ligament. Externally the capsule is rough, covered by muscles and tendons, and separated anteriorly from psoas major and iliacus by a bursa. The capsular attachment to the femur lies well distal to the growth plate of the femoral head both anteriorly and posteriorly, and so the upper femoral epiphysis is entirely intracapsular. The capsular attachment intersects the growth plate of the greater trochanter on the superior surface of the base of the neck.

Iliocapsularis

Available with the *Gray's Anatomy* e-book

Relations The joint capsule is surrounded by muscles (**Fig. 77.24**). Anteriorly, lateral fibres of pectineus separate the capsule from the femoral vein. Lateral to this, the tendon of psoas major, with iliacus lateral to it, descends en route to the lesser trochanter, partly separated from the capsule by a bursa. The femoral artery is anterior to the tendon of psoas major, and the femoral nerve lies deep in a groove between the tendon and iliacus. More laterally the straight head of rectus femoris crosses the joint with a deep layer of the iliotibial tract, which blends with the capsule under the lateral border of the muscle. Superiorly the reflected head of rectus femoris contacts the capsule medially, while gluteus minimus covers it laterally, being either closely adherent or comingled (Walters et al 2014). Inferiorly, medial fibres of pectineus adjoin the capsule and, more posteriorly, obturator externus spirals obliquely to its posterior aspect. Posteroinferiorly the capsule is covered by the tendon of obturator externus, separating it from quadratus femoris and accompanied by an ascending branch of the medial circumflex femoral artery. Superior to this the tendon of obturator internus and the gemelli contact the joint capsule, separating it from the sciatic nerve. The nerve to quadratus femoris is deep to the obturator internus tendon and descends medially on the capsule. Superior to this the posterior surface of the joint is crossed by piriformis.

Ligaments The ligaments of the hip joint are the iliofemoral, pubofemoral, ischiofemoral and transverse acetabular ligaments, and the ligament of the head of the femur (**Fig. 77.25**). As the hip moves, the capsular ligaments wind and unwind, tightening around the hip, and affecting stability, excursion and joint capacity (Fuss and Bacher 1991). Joint capacity is maximal when the hip joint is held in a partially flexed and abducted position; a patient with an effusion in the hip joint is therefore most comfortable when the joint is held in this position.

Iliofemoral ligament The iliofemoral ligament is very strong and is shaped like an inverted Y, lying anteriorly and intimately blended with the capsule. Its apex is attached between the anterior inferior iliac spine and acetabular margin, its base to the intertrochanteric line. It is composed of a medially placed, thicker descending part and a laterally placed, transverse part, which is typically distinguishable anteriorly. The obliquely disposed transverse part is attached to a tubercle at the superolateral end of the intertrochanteric line, while the vertically oriented descending part reaches the inferomedial end of the line.

Pubofemoral ligament The pubofemoral ligament is triangular, with a base that is attached to the iliopubic ramus, superior pubic ramus, obturator crest and membrane. It blends distally with the capsule and deep surface of the descending part of the iliofemoral ligament and has been described as consisting of multiple crura (Fuss and Bacher 1991).

Ischiofemoral ligament The ischiofemoral ligament thickens the posterior aspect of the capsule. The central part spirals superolaterally from the ischium, where it is attached posteroinferior to the acetabulum, then courses posterior to the femoral neck to attach distally to the greater trochanter deep to the iliofemoral ligament. Some fibres blend with the zona orbicularis. Some of the more inferior fibres of the ischiofemoral ligament embrace the posterior circumference of the femoral neck.

Transverse acetabular ligament The transverse acetabular ligament (see Fig. 77.3) is continuous peripherally with the labrum but does not possess any cartilage cells. Its strong, flat fibres cross the acetabular notch, forming a foramen through which vessels and nerves pass to enter the joint.

Ligament of the head of the femur The ligament of the head of the femur (ligamentum teres) is a triangular and somewhat flattened band of connective tissue (see Fig. 77.24; **Fig. 77.26**). Its apex is attached anterosuperiorly in the fovea for the ligament of the head of the femur while its base is attached principally to both edges of the acetabular notch, between which it blends with the transverse acetabular ligament. It also receives variable contributions from the margins of the acetabular fossa and hip

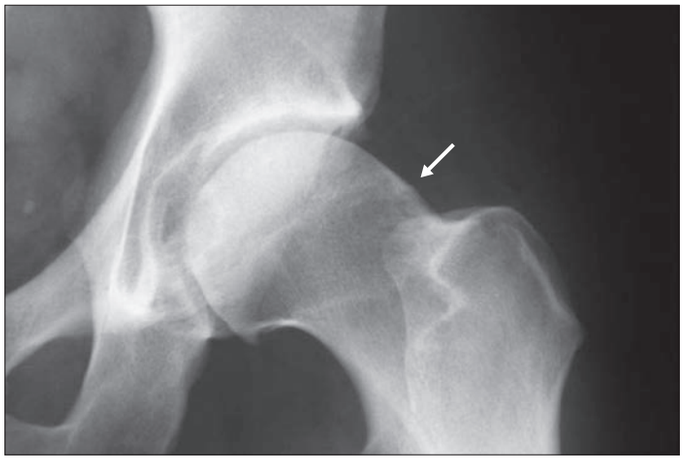

Fig. 77.23 Pre-surgical radiograph of a hip with a cam deformity of the femoral head–neck junction (arrow). Note the loss of sphericity in the femoral head and the loss of the tapering of the neck. (Image courtesy of John T Heinrich, MD, Milwaukee Orthopaedic Group Limited, Milwaukee, WI, USA.)

The shape of the bones of the hip normally limits large and potentially damaging contact stress on adjacent connective tissues, especially during the extremes of movement. Consider, for example, the normal shape of the femoral head and neck region. Similar to the shape of a light bulb, the spherical femoral head narrows gradually at its junction with the neck of the femur. This tapering limits large contact stress between the femoral neck and the margin of the acetabulum. However, tapering may be lost because of natural variation or underlying pathology, resulting in a specific deformity that has been referred to as a cam deformity because the head and neck of the femur, together, resemble a camshaft. Although often subtle, this deformity may be detected radiographically (see arrow in **Fig. 77.23**). In some patients with a cam deformity, extreme and repeated motions of the hip, typically involving combinations of flexion, medial rotation and adduction, can create damaging impingement between the hard and bulbous femoral neck and the softer acetabular labrum. The anterosuperior section of the labrum is particularly vulnerable to this type of injury, which is a painful and often motion-limiting condition referred to as femoroacetabular impingement syndrome. The repeatedly traumatized section of the labrum can become enlarged, fragmented or torn. When the acetabular labrum is torn, a hip joint may become unstable as a consequence of the loss of the natural suction seal around the joint. In some advanced cases, the impingement trauma may create lesions at the chondrolabral junction, resulting in damage to the adjacent articular cartilage, potentially predisposing the hip joint to degenerative arthritis (osteoarthrosis) (Beck et al 2005). Treatment may involve arthroscopic repair of the acetabular labrum and cartilage, as well as reshaping the area of the femoral head and neck responsible for the impingement.

Iliocapsularis (also called iliacus minor or iliotrochantericus) is a little-known but constant muscle that lies immediately deep to the tendon of iliopsoas and overlies the anterior hip capsule (Babst et al 2011, Ward et al 2000). Typically present as just a few strands of fibres, it originates from the anteromedial hip capsule and anteroinferior iliac spine, and is attached just distal to the lesser trochanter. Although the function of the muscle is uncertain, it may draw the capsule taut as a way of reducing its impingement during hip flexion. For reasons not understood, the size of the iliocapsularis has been shown to be larger in hips with radiological evidence of developmental hip dysplasia (Haefeli et al 2015)

joint capsule (Perumal et al 2019), is ensheathed by synovial membrane and varies in strength. The ligamentum teres is typically not physically compressed between the socket and the femoral head because of the depth and shape of the acetabular fossa. Occasionally the synovial sheath exists by itself in the absence of the ligament; rarely, both the ligament and sheath are absent.

Although the ligament of the head of the femur is known primarily for lending structural support to the blood vessels that travel to and from the femoral head, speculation exists that it may also have a role in stabilizing the hip joint *in utero*. In the adult, it is mostly elongated and assumed to be taut when the hip joint is semi-flexed, laterally rotated and adducted, the position where the capsular ligaments, as a whole, offer least stability to the joint (Martin et al 2012). The degree to which the ligament of the head of the femur offers functional stability to the adult hip is uncertain, although it is likely to be secondary to that provided by the capsular ligaments and muscle activation.

Medical interest in the ligament of the head of the femur has increased with the advancing technology associated with medical imaging and arthroscopic hip surgery (Gray and Villar 1997, Botser et al 2011; **Fig. 77.27**).Free nerve endings have been identified within this ligament, suggesting that this structure may be a source of pain when it is injured or degenerating (Leunig et al 2000). The afferent innervation in the healthy state may serve as a source of proprioception or protection of the joint (Bardakos and Villar 2009).

Synovial membrane Starting from the femoral articular margin, the synovial membrane covers the intracapsular part of the femoral neck, and then passes to the internal surface of the capsule to cover the acetabular labrum, the ligament of the head of the femur and fat in the acetabular fossa (**Fig. 77.28**). It is thin on the deep surface of the iliofemoral ligament where it is compressed against the femoral head, and sometimes is even absent here.

Bursae The hip joint may communicate with the subtendinous iliopectineal bursa through a circular aperture between the pubofemoral ligament and the descending part of the iliofemoral ligament. More distant bursae are associated with the tendons of the distal attachments of the gluteus medius (subgluteus maximus or 'trochanteric' bursa) and minimus at the greater trochanter, and between gluteus maximus and the proximal tendon of vastus lateralis (Woodley et al 2008).

Vascular supply and lymphatic drainage Articular arteries are branches from the obturator, medial circumflex femoral, and superior and inferior gluteal arteries; they form the cruciate and trochanteric anastomoses. There is a corresponding venous drainage.

The blood supply to the hip in the child is different from that in the adult and this has very important implications clinically. Since the growth plate is avascular, the only blood supply to the femoral head is conveyed through the retinacular vessels, which are mainly tributaries of the medial circumflex femoral artery. These retinacular arteries enter the joint capsule in the trochanteric fossa and ascend the femoral neck on its outer aspect superiorly and posteriorly. They pass around the edge of the growth plate (physis) and enter the femoral head. A minor contribution to the vascular supply comes from the ligament of the head of the femur. Any damage to these vessels (e.g. trauma, infection) can result in the devastating complication of avascular necrosis of the femoral head. The growth plate represents a line of weakness and predisposes to fracture from injury. Acute injuries affecting the capital epiphysis are uncommon. A more chronic fracture through the capital epiphysis resulting in slipped capital femoral epiphysis, where the femoral head epiphysis displaces posteriorly off the femoral neck, occurs in pubescent adolescents, especially males (**Fig. 77.29**).

Lymphatics from the anterior aspect of the hip joint drain to the deep inguinal nodes, while those from the medial and posterior aspects of the joint travel with the obturator and gluteal arteries, respectively, to reach the internal iliac nodes.

Innervation The anterior capsule of the hip joint is innervated by the femoral, obturator and accessory obturator (when present) nerves. The posterior capsule is innervated by the sciatic and superior gluteal nerves, and by the nerve to quadratus femoris (Gardner 1948, Birnbaum et al 1997).

Hip and groin pain

Pain emanating from the hip and groin has many possible causes. True pain from the hip joint is typically felt deep in the crease of the groin, secondary to intra-articular pathology such as osteoarthritis, a torn acetabular labrum, or femoro-acetabular impingement. Pain over the lateral aspect of the hip usually suggests a local problem such as gluteus medius or minimus tendinopathy and associated trochanteric bursitis (Bird et al 2001, Grimaldi and Fearon 2015). Pain in the buttock is only occasionally derived from the hip joint; most frequently, it is referred from the lumbosacral spine or may be caused by vascular claudication. Pain in the groin may be associated with inguinal or femoral hernias. In the younger age group, it afflicts those engaged in sports, especially running ball sports; the pain is sometimes due to hernia but most often is related to adductor longus tendinosis ('groin strain'). Attritional chronic overload of the anterior abdominal wall at its attachments to the pubis and inguinal ligament, or of external abdominal oblique at

the superficial inguinal ring, is a common occurrence. Rarely, problems may occur at the pubic symphysis.

Biomechanics of the hip joint

The transition from quadrupedal to bipedal gait was a considerable biomechanical milestone in the evolution of *Homo sapiens*. The biomechanical features of the human lower limb, which functions primarily to allow stance and bipedal propulsion, are very different from those of the quadruped lower limb, and these differences are reflected in the anatomy and biomechanics of the human hip, knee, ankle and foot joints.

Stability and movement

The hip joint is normally very stable. The femoral head is closely fitted to the acetabulum in an area exceeding half a sphere, forming a multiaxial spheroidal ('ball and socket') joint that allows relatively unhindered motion in three degrees of freedom, i.e. flexion/extension, abduction/adduction and medial/lateral rotation. However, the femoral head is also embraced closely by the acetabular labrum, which restrains it in the socket and innately limits its capacity for translational motion in anteroposterior, transverse and vertical directions. The thick capsule is reinforced by the three major ligaments: iliofemoral, pubofemoral and ischiofemoral. The iliofemoral ligament is the strongest, and is progressively tightened when the femur extends to and beyond the line of the trunk. The pubofemoral and ischiofemoral ligaments also tighten when this happens and, as the joint approaches the close-packed position, resistance to an extending torque increases rapidly. The transverse acetabular ligament and ligament of the head of the femur may also contribute to stability.

A 'vacuum effect' within the hip joint is present, which means that only slight separation of the articular surfaces can be achieved by strong traction on the joint. To aid insertion of an arthroscope, a needle is first inserted into the joint to eliminate the suction effect; the joint will subsequently open sufficiently with traction. Traumatic dislocation usually occurs only when the joint is subjected to extreme force.

Femur

The femur is essentially a tubular structure with distortions that consist of bows and twists. The most notable is the anterior bow in its mid portion, where the radius of curvature is relatively constant along the length of the femoral shaft. In the coronal plane, the femoral neck is inclined obliquely to the shaft at an angle of about 125°, although this angle can vary considerably (Fig. 77.30). Although both the neck–shaft angle (collodiaphysial angle; Mikulicz angle) and neck length are variable, the centre of the neck in the coronal plane is at the level of the apex of the greater trochanter. The neck–shaft angle facilitates freedom of movement of the femur, enabling it to swing clear of the pelvis. The neck also provides an adequate lever for the action of the muscles acting about the hip joint, most notably the hip abductors, which are attached to the proximal femur. The neck–shaft angle is widest at birth and diminishes gradually until the age of 10 years (Birkenmaier et al 2010); it is smaller in females. In the axial plane, the femoral neck is anteverted, i.e. rotated anteriorly relative to the posterior surfaces of the femoral condyles; in the adult, this angle is typically about 10–15° (Fig. 77.31A). Excessive anteversion may exist when this angle is significantly greater than 10–15° (Fig. 77.31B). At birth, the angle of anteversion is typically about 35–40°. As the child develops, forces from muscles and gravity cause the angle of anteversion to decrease gradually, approaching 15° by young adulthood. Excessive anteversion usually persists beyond childhood in cases of abnormal motor development, such as can be seen with cerebral palsy.

The degree of anteversion affects many aspects of lower limb biomechanics, including the moment (lever) arms of the hip abductor and medial rotator muscles (the perpendicular distance from the centre of rotation of the femur to the line of action of the resultant muscle force); patellar tracking (the motion of the patella relative to the femur); and foot orientation.

Acetabulum

The acetabulum consists of the confluence of the ilium, ischium and pubis at the triradiate cartilage. By itself, the acetabulum covers an area slightly less than a hemisphere; it is deepened by the acetabular labrum. The degree of acetabular anteversion is about 17° (16° males and 18° females) (Reikeras et al 1983). In the coronal plane, the acetabular axis is inclined inferiorly approximately 45° from the horizontal.

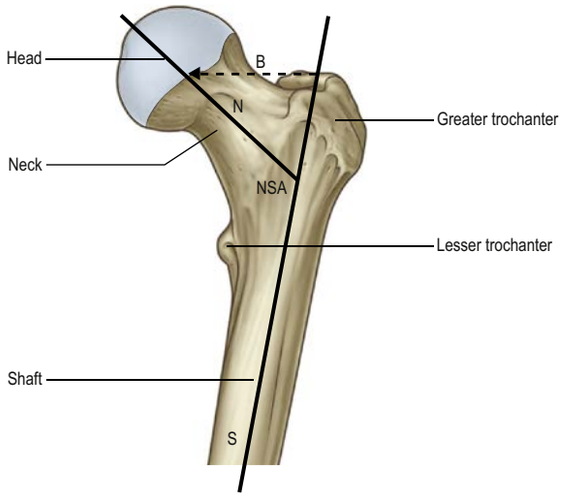

Fig. 77.30 The neck–shaft angle (NSA) is shown between the long axis of the femoral shaft (S) and the axis of the femoral neck (N). In addition, in most hips, a line nearly perpendicular to S from the tip of the greater trochanter (B) passes through the centre of the femoral head. This approximation can be utilized in judging the position of the femoral osteotomy in hip arthroplasty.

Movements

Two terms can conveniently describe the kinematics (movements) at the hip. Femoral-on-pelvic hip kinematics describes the rotation of the femur about a relatively fixed pelvis. Conversely, pelvic-on-femoral (hip) kinematics describes the rotation of the pelvis, and often the superimposed trunk, over a relatively fixed femur or set of femurs. Regardless of whether the femur or the pelvis is the moving segment, kinematics are described for all three cardinal planes on the assumption that movements are initiated from the anatomical position.

Flexion and extension are motions that occur in the sagittal plane. To appreciate the hip joint arthrokinematics that accompany the associated femoral-on-pelvic motions, the length and angulation of the femoral neck in relation to the shaft must be considered. As the hip (femur) is flexed about 120° towards the anterior thoracic wall, or extended 10–20° beyond the plane of the trunk, the femoral head 'spins' in the acetabulum about a side-to-side (medial–lateral) axis of rotation. Conversely, from a pelvic-on-femoral perspective, the acetabula rotate around a similar axis in flexion and extension relative to stationary femoral heads (compare Figs 77.32A and B). Depending on the accompanying trunk movement, the lumbar vertebrae will either flex or extend in rhythm with the rotating pelvis. Consider, for example, a short-arc anterior rotation (or tilt) of the pelvis over both femurs while the upper trunk remains stationary. During this motion, the lumbar vertebrae extend slightly towards greater lordosis. By comparison, rotating both the pelvis and the trunk over both femurs (as in reaching towards the ground with knees held extended), the pelvis and the thoracolumbar vertebrae both flex, thereby augmenting the overall forward motion of the body as a whole.

Abduction and adduction of the hip joint occur in the coronal plane about an anterior-to-posterior axis of rotation through the femoral head. With the pelvis fixed, the femur abducts about 40° (Fig. 77.33A). Conversely, pelvic-on-femoral (hip) motions that occur in the coronal

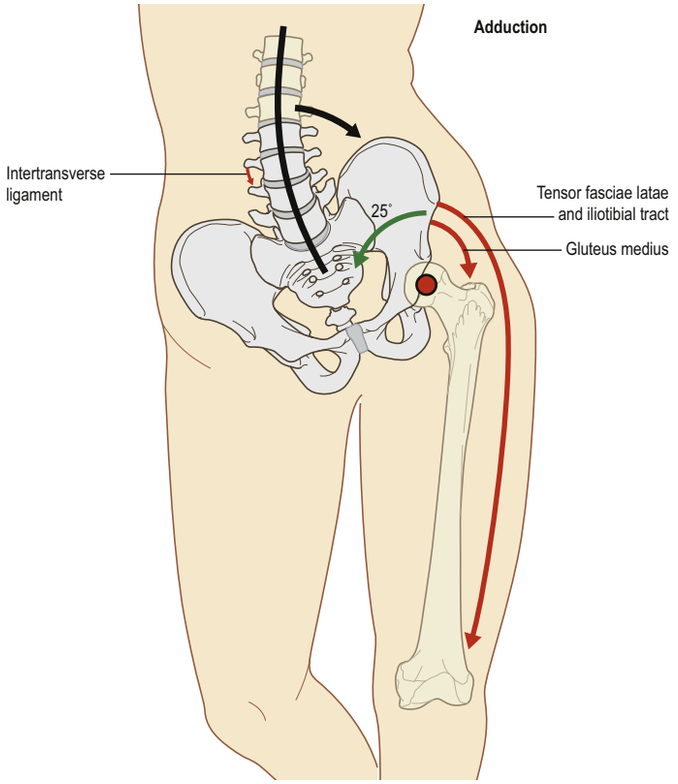

Fig. 77.34 Hip adduction shown from a pelvic-on-femoral perspective, as indicated by the green curved arrow. Note the directional-specific motion of the lumbar spine; this is a necessity, assuming the trunk remains upright. Tissues that are elongated or pulled taut are indicated by orange arrows. In all cases, muscles are assumed to be inactive but stretched. The red circle indicates the axis of rotation at the hip. Copyright 2017.)

plane are best described assuming a person is bearing weight firmly on one lower limb, referred to hereafter as the 'support' hip. Abduction at the support hip occurs by raising the contralateral side of the pelvis a few degrees (Fig. 77.33B). Marked tightness in the hip adductor muscles or medial capsule of the hip on the support hip can limit this pelvic motion. Adduction at the support hip occurs by lowering the contralateral side of the pelvis (Fig. 77.34). Assuming that the trunk remains nearly stationary during these short-arc pelvic-on-femoral motions, the lumbar spine laterally bends slightly as a way to offset undesired thoracic motion. The lumbar vertebrae, therefore, act to decouple motion of the pelvis (moving on the femur) from undesired motions between the thorax and pelvis (Neumann 2017). This decoupling function of the lumbar vertebrae is especially useful during walking as a way of partially fixing the spatial orientation of the upper thorax, as well as the associated craniocervical region and the embedded senses of vision and equilibrium. This kinematic linkage between the spine, pelvis and femur exists in essentially all hip motions to varying degrees, and is an important characteristic of normal walking.

Medial and lateral rotation of the hip joint occurs in the horizontal (transverse) plane about a vertical axis of rotation. With the pelvis fixed, the femur rotates medially about 35°. The extended hip rotates laterally about 45°. Horizontal plane movements of the hip joint from a pelvic-on-femoral perspective, as explained above, are best described assuming a person is bearing weight over a given 'support' hip. Consider, for example, running and rapidly changing directions while one lower limb is securely planted on the ground. During lateral rotation of the support hip, the iliac crest located contralateral to the support limb rotates posteriorly in the transverse plane, an action driven strongly by gluteus maximus (Fig. 77.35). Conversely, pelvic-on-femoral (hip) medial rotation occurs as the contralateral iliac crest region rotates anteriorly.

As stated above, the axis of rotation for horizontal plane motions at the hip joint occurs about a vertical axis of rotation. The slight anterior bowing for the femoral shaft, coupled with the natural angle between the femoral shaft and neck, means that this axis is not intramedullary; rather it passes just posterior and slightly medial to the shaft. The position of this 'mechanical' (versus medullary) axis becomes biomechanically relevant when considering the actions and moment arms of certain hip muscles, most notably for adductor muscles that also function as medial rotators (Neumann 2010).

Forces acting on the hip

In quiet upright standing, the femoral heads support the weight of the trunk, upper limbs and head. About two-thirds of body weight is located above the hips, and so each femoral head normally accepts about one-third of body weight. This force is compressive in nature, as gravity pulls the acetabula against the femoral heads. When viewed in the sagittal plane, minimal muscle forces suffice to maintain equilibrium as long as the weight of the upper body is directed over or behind the femoral heads. If the upper body leans anteriorly, shifting the upper body weight vector anteriorly beyond the femoral heads and thereby producing a hip flexion moment, posterior thigh muscles can counter such rotation. As the capsular ligaments of the hip slacken in flexion, none of them is able to resist the forward lean.

Hip joint compression forces vary from one-third of body weight, when both feet are on the ground during standing at ease, to some four times body weight when the other foot is lifted, as during walking. This represents at least a ten-fold increase in compression forces, explaining, in part, why persons with a painful hip often limit the time spent in single-limb stance. The large compression forces generated while walking originate primarily from two sources: gravity and muscle activation. During the stance phase, gravity pulls the upper body and acetabulum inferiorly on the femoral heads (as described above for quiet standing). More significantly, each femoral head is pushed superiorly against its socket as the foot strikes and then pushes against the ground. Although activation of muscles is responsible for a greater portion of joint compression at the hip, the influences of gravity and of capsular tension (when the hip joint is extended) should not be ignored.

As the lower limb is swinging anteriorly and free of contact with the ground, hip joint compression force is estimated to be at about 50%

of body weight (Correa et al 2010). Such joint force is essentially myogenic. Consider, for example, a contracting iliopsoas pulling the femoral head against the acetabulum as it simultaneously advances the lower limb in walking.

In contrast, during the stance phase of walking, hip joint forces may reach four times body weight. These forces are mainly caused by the pull of the hip abductor muscles (primarily gluteus medius, gluteus minimus and tensor fasciae latae). This muscular action, essential to normal bipedal gait, provides the necessary coronal plane stabilization of the pelvis relative to the femoral head of the stance limb.

The importance of hip abductor muscle activation during the stance phase of walking can be well appreciated by understanding the simple mechanics of standing on one limb (**Fig. 77.36**). The lever arm (a) of left hip abductor force (Ab) is about half the length of the lever arm (b) associated with body weight (BW). To balance the competing (coronal plane) gravitational moments about the stance hip, the hip abductors must produce a force about twice superincumbent body weight. Thus, the acetabulum is pulled inferiorly against the femoral head not only by the body weight but also by the force created by the activated hip abductor muscles. The sum of the muscular and gravitational forces therefore approaches 2.5 times the total weight of the person. These downward forces on the head of the femur are counteracted by an upward joint reaction force of equal magnitude (JRF in Fig. 77.36). Both magnitude and direction of the joint reaction force are strongly influenced by the pull of the hip abductor muscles.

The above analysis is for standing quietly on one limb. During walking, however, the joint reaction force routinely reaches at least four times body weight, reflecting both the high ground reaction forces and the need for the hip abductor muscles to decelerate rotations of the pelvis (Bergmann et al 1993). Hip joint forces reach still greater values during running or stair-climbing (see review in Stansfield and Nicol 2002).

Compression forces produced by the gluteus medius during stance phase are directed superiorly and slightly anteromedially within the acetabulum (Correa et al 2010), a region naturally protected by thick articular cartilage. In the healthy hip joint, the muscular-based compressive forces serve important functions, such as helping to stabilize the articulation and stimulate the morphological development of the growing hip. Forces that cross the hip typically do not harm the joint because they are absorbed by healthy articular cartilage and congruent joint surfaces. Failure of these conditions to absorb forces in the joint may predispose to osteoarthritis of the hip.

The three factors that influence both the magnitude and the direction of compressive forces acting on the hip are the position of the centre of gravity; the abductor moment arm, which is a function of neck length (offset) and neck–shaft angle; and the amount of body weight. Shortening of the lever arm of the abductors, such as occurs in coxa valga or excessive femoral anteversion, or in a remodelled proximal femur in advanced hip osteoarthritis, would increase abductor muscle demand and thus increase joint reaction force as well. If the muscles cannot meet this demand, the pelvis cannot be held level in standing on one limb, a problem known as either a compensated or an uncompensated Trendelenburg sign. The Trendelenburg sign is said to be compensated if the pelvis is brought towards the affected stance limb as a way of shortening the body weight's lever arm. Conversely, the Trendelenburg sign is said to be uncompensated if the pelvis drops away from the affected stance limb uncontrollably.

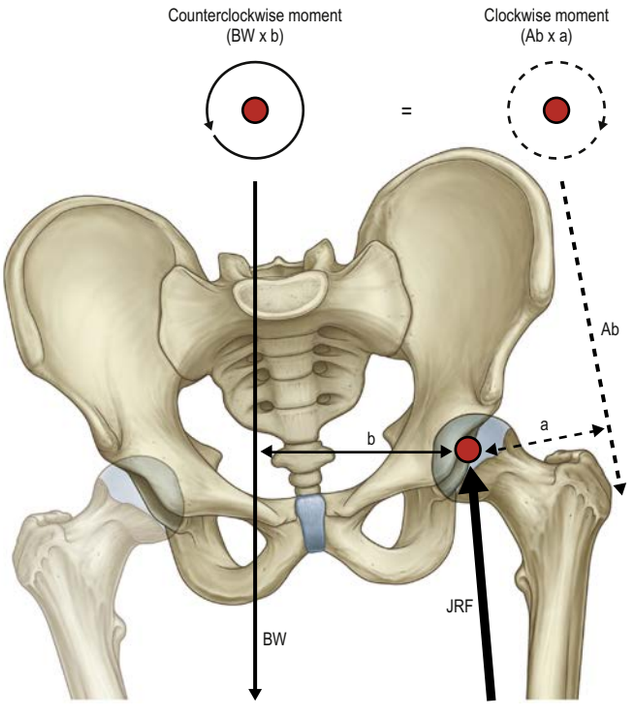

Fig. 77.36 While standing on one (left) lower limb, body weight (BW) line of force, i.e. total body weight minus the weight of the left lower limb, passes just lateral to the midline, exerting a counterclockwise moment about the stance hip (BW × b). An equal but clockwise moment is required about the stance hip for mechanical equilibrium: a moment produced by the force of the abductors (Ab), whose lever arm (a) is approximately half that of the lever arm (b). The two moments are in balance when (Ab × a = BW × b). The abductor force required to maintain equilibrium is approximately twice that of BW, resulting in a joint reaction force (JRF) nearly 2.5 times that of total weight of the subject's body.

Muscles producing hip joint movements

Flexion is primarily produced by psoas major, iliacus and rectus femoris, assisted by pectineus, tensor fasciae latae and sartorius. The adductors, particularly adductor longus and brevis, also assist, especially when the hip is near full extension. Effective action of the hip flexor muscles requires strong synergistic activation of the abdominal muscles to stabilize the pelvis.

Extension is produced by gluteus maximus, the long head of biceps femoris, semitendinosus, semimembranosus and adductor magnus. The posterior fibres of gluteus medius assist with this action (Neumann 2010). In the fully erect posture, a vertical line through the centre of gravity of the body normally passes just posterior to a line joining the centres of the femoral heads. The body therefore tends to incline posteriorly but this is counterbalanced by ligamentous tension and congruence and compression of the articular surfaces within the hip joints in the close-packed position. Under increased loading of the trunk or leaning posteriorly, these resistive but passive factors are assisted by active force produced by the hip joint flexors. In swaying anteriorly at the ankles, or when the arms are stretched forwards, and also in forward-bending at the hip, the line of body weight moves anterior to the medial–lateral axis of rotation through the hip joints. The posture adopted, or the rate of change of posture, is largely controlled by the hamstrings, which, besides being powerful flexors of the knee, are strong extensors of the hip. Gluteus maximus becomes particularly active when the thigh is extended against resistance, as in rising from a bending position or during climbing.

Abduction is produced by gluteus medius, gluteus minimus and tensor fasciae latae, assisted by the piriformis and sartorius. The motion is limited by adductor muscle tension, the pubofemoral ligament and the extreme medial bands of the descending part of the iliofemoral ligament. The abductor muscles, most notably glutei medius and minimus, are active periodically at precise phases of the walking or running cycle to ensure coronal plane stability of the pelvis.

Adduction is produced by adductor longus, brevis and magnus, and gracilis, assisted by pectineus, quadratus femoris and the inferior fibres of gluteus maximus. The range of adduction is limited by the increasing tension in the abductor muscles, the transverse part of the iliofemoral ligament and the fascia lata of the thigh.

Medial rotation is produced by the anterior fibres of glutei minimus and medius, and assisted by most adductor muscles and, to a lesser extent, the tensor fasciae latae. The strength of medial rotation naturally increases as the hip is flexed because this position increases the moment arm of most medial rotator muscles (Delp et al 1999). Medial rotation is limited by tension in lateral rotator muscles such as piriformis, the ischiofemoral ligament and the adjacent posterior joint capsule (Wagner et al 2012).

Lateral rotation is produced by gluteus maximus, obturator internus, superior and inferior gemelli, quadratus femoris and piriformis, assisted by obturator externus and sartorius. Lateral rotation, a stronger motion than medial rotation, is limited by tension in the medial rotator muscles and the transverse part of the iliofemoral ligament (Myers et al 2011).

MUSCLES

Muscles of the iliac region

Although there is no 'iliac region' as such, this heading conveniently describes a group of three muscles that originate from the lumbar

vertebral column (psoas major and minor) and the ilium (iliacus). Psoas major and iliacus are attached together on the femur as flexors of the hip joint and are often considered as a functional unit, iliopsoas. Psoas minor, when present, only reaches the anterior pelvis, near the iliopubic junction, and therefore does not act directly on the femur.

Psoas major

Attachments Psoas major is a long muscle that lies on either side of the lumbar vertebral column and the pelvic brim (Fig. 77.37; see Fig. 61.7). Its proximal attachments are complex. They include the anterior surfaces and lower borders of the transverse processes of all the lumbar vertebrae. There are five digitations, each from the bodies of two adjoining vertebrae and their intervertebral disc. The highest of these arises from the lower margin of the body of the twelfth thoracic vertebra, the upper margin of the body of the first lumbar vertebra and the interposed intervertebral disc. The lowest arises from the adjacent margins of the bodies of the fourth and fifth lumbar vertebrae and the interposed disc. A series of tendinous arches extend across the narrow parts of the bodies of the lumbar vertebrae between the digitations already described. The lumbar arteries and veins, and filaments from the sympathetic trunk, pass medial to these arches. The upper four lumbar intervertebral foramina bear important relations to these attachments of the muscle. The foramina lie anterior to the transverse processes and posterior to the attachments to vertebral bodies, intervertebral discs and tendinous arches. Thus, the roots of the lumbar plexus enter the muscle directly, the plexus is lodged within it, and its branches emerge from its borders and surfaces.

The muscle descends along the pelvic brim, continues posterior to the inguinal ligament and anterior to the capsule of the hip joint, and converges to a tendon that, having received on its lateral side nearly all the fibres of iliacus, becomes attached to the lesser trochanter of the femur. The large subtendinous iliac bursa, which occasionally communicates with the cavity of the hip joint, separates the tendon from the pubis and the capsule of the joint.

The complex vertebral attachments of psoas major sometimes display minor numerical variations.

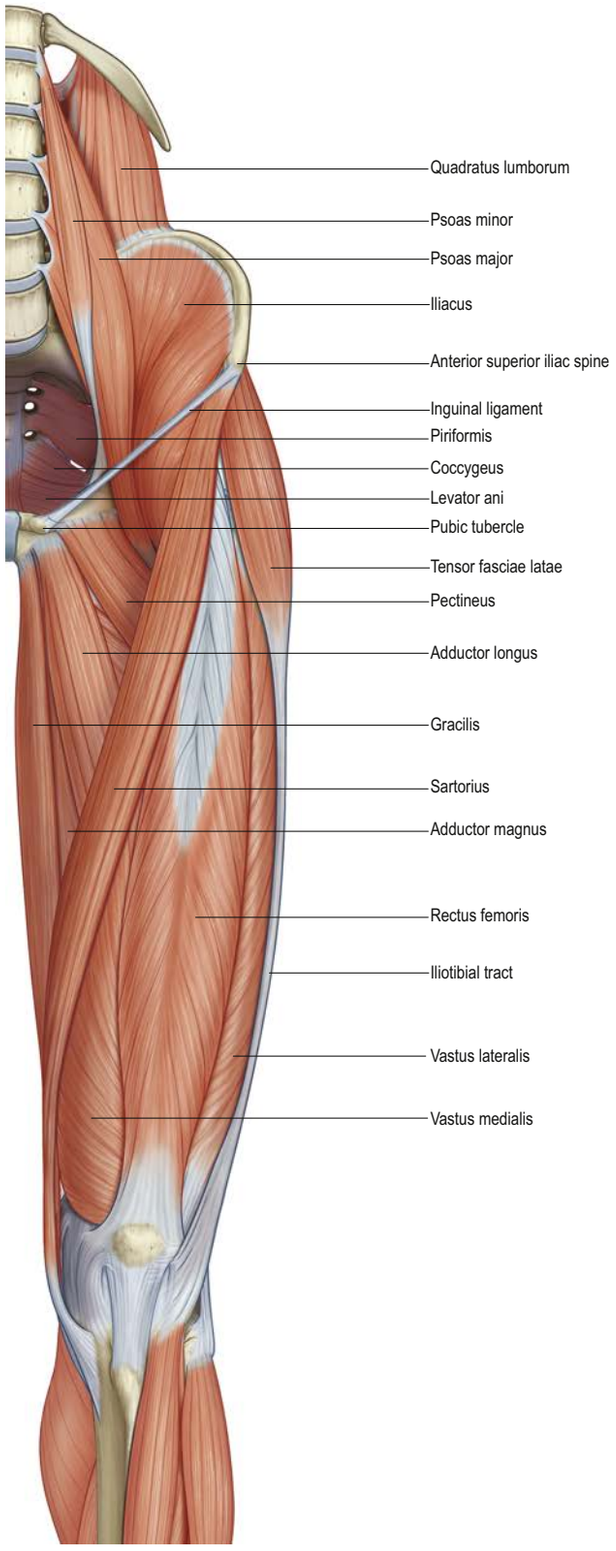

Fig. 77.37 The hip flexors and superficial muscles of the thigh, anterior view.

Relations The upper limit of psoas major is posterior to the diaphragm in the lowest part of the posterior mediastinum. It may be in contact with the posterior extremity of the pleural sac. In the abdomen its anterolateral surface is related to the medial arcuate ligament (a linear, arched thickening in the psoas fascia), extraperitoneal tissue and peritoneum, the kidney, psoas minor, renal vessels, ureter, testicular or ovarian vessels and the genitofemoral nerve. Anteriorly the right psoas is overlapped by the inferior vena cava and crossed by the terminal part of the ileum; the colon crosses the left psoas. Its posterior surface is related to the transverse processes of the lumbar vertebrae and the medial edge of quadratus lumborum. The lumbar plexus is embedded posteriorly in the substance of psoas major. Medially the muscle is related to the bodies of the lumbar vertebrae and lumbar vessels. Along its anteromedial margin it is in contact with the sympathetic trunk, aortic lymph nodes and, along the pelvic brim, with the external iliac artery. This margin is covered by the inferior vena cava on the right side, and lies posterior and lateral to the abdominal aorta on the left side. In the thigh, iliopsoas is related anteriorly to the fascia lata and the femoral artery, and posteriorly to the capsule of the hip joint, from which it is separated by a bursa. At its medial border it is related to pectineus and the medial circumflex femoral artery, and to the femoral vein, which may overlap it slightly. At its lateral border it is related to the femoral nerve and iliacus. The femoral nerve descends at first through the fibres of psoas major, and then in the furrow between it and iliacus.

Branches of the lumbar plexus diverge from the abdominal part of psoas major. Emerging from the lateral border, from above downwards, are the iliohypogastric, ilioinguinal and lateral femoral cutaneous and femoral nerves. Emerging from the anterolateral surface is the genitofemoral nerve. The obturator and accessory obturator nerves (when present) and the upper root of the lumbosacral trunk all emerge from the medial border.

Vascular supply Psoas major is supplied by a rich network of arteries derived from the lumbar, iliolumbar, obturator, external iliac and femoral arteries. In general terms, the upper part of the muscle is supplied by the lumbar arteries, the mid part by the anterior branch of the iliolumbar artery (the main artery to the muscle) with contributions from the deep circumflex and external iliac arteries, and the distal part by the femoral artery and its branches. The psoas sheath has an arterial supply independent from that of the muscle, though the same vessels contribute.

Innervation Psoas major is innervated by the ventral rami of the lumbar spinal nerves, mainly L2, L3 and L4 (Mahan et al 2017).

Actions Psoas major acts together with iliacus; the combination is referred to as iliopsoas. See below.

Testing This is considered below with iliacus.

Psoas minor

Attachments The presence of a psoas minor (see Fig. 77.37) has been reported in about 40–60% of individuals (Neumann and Garceau 2015). When present, it lies anterior to psoas major, entirely within the abdomen. It arises from the sides of the bodies of the twelfth thoracic

and first lumbar vertebrae, and from the intervertebral disc between them. It ends in a long, flat tendon that is attached to the pecten pubis, iliopubic ramus and, laterally, to the iliac fascia.

Relations Psoas minor lies on psoas major, and its proximal anterior relations are those of the anterior or anteromedial surface of that muscle.

Vascular supply The main arterial supply to psoas minor is from the lumbar arteries, though there may be minor contributions from other vessels of the network that supplies psoas major.

Innervation Psoas minor is innervated by a branch from L1.

Actions Psoas minor may flex the trunk; although due to the muscle's small size, its relative contribution to this action would be slight. Although speculation, the muscle's firm attachment into the iliac fascia may help stabilize the position of the underlying psoas major (see Commentary 9.2) (Neumann and Garceau 2015).

Testing Psoas minor cannot be tested clinically.

Iliacus

Attachments Iliacus (see Figs 77.37, 61.13) is a triangular sheet of muscle that arises from the superior two-thirds of the concavity of the iliac fossa, the inner lip of the iliac crest, the ventral sacroiliac and iliolumbar ligaments, and the upper surface of the lateral part of the sacrum (see Fig. 46.49). In front, it reaches as far as the anterior superior and anterior inferior iliac spines, and receives a few fibres from the upper part of the capsule of the hip joint (iliocapsularis, p. 1369.e1). Most of its fibres converge into the lateral side of the strong tendon of psoas major, and the muscles then insert together into the lesser trochanter, but some fibres attach directly to the femur 2.5 cm below and in front of the lesser trochanter.

Relations In the abdomen the anterior surface of iliacus is related to its fascia (which separates the muscle from extraperitoneal tissue and peritoneum), the lateral femoral cutaneous nerve, the caecum (on the right) and the iliac part of the descending colon (on the left). On its posterior surface is the iliac fossa, and at its medial border, psoas major and the femoral nerve. In the thigh its anterior surface is in contact with the fascia lata, rectus femoris, sartorius and the profunda femoris artery, and its posterior surface is in contact with the capsule of the hip joint, from which it is partially separated by a bursa it shares with psoas major.

Vascular supply Iliacus is supplied by the same arterial network as psoas major, and there is mutual overlap of the arterial territories of each muscle. The main supply is from the iliac branches of the iliolumbar artery, with contributions from the deep circumflex iliac and obturator arteries, and branches of the femoral artery.

Innervation Iliacus is innervated by branches of the femoral nerve, L2 and L3.

Actions The combined actions of the psoas major and iliacus (iliopsoas) have a large kinetic influence across the midsection of the body, extending between the thoracolumbar junction to the hip joints. The iliopsoas flexes the thigh on the pelvis. When the iliopsoas of both sides acts from fixed femurs, they contract to effectively bend the trunk and pelvis forwards against resistance, as in raising the trunk to sit upright from a recumbent, supine position. In symmetrical upright stance, iliopsoas has some action from below to maintain the vertebral column upright. Psoas major is active in balancing the trunk while sitting. When active bilaterally, the psoas major likely contributes frontal plane stability to the lumbar spine (Hu et al 2011).

Testing Iliopsoas may be tested clinically by actively flexing the hip against resistance, in the supine position with the hip and knee flexed.

Muscles of the gluteal region

Tensor fasciae latae

Attachments Tensor fasciae latae (see Fig. 77.37) arises from the anterior 5 cm of the outer lip of the iliac crest, from the lateral surface of the anterior superior iliac spine and part of the border of the notch below it, between gluteus medius and sartorius, and from the deep surface of the fascia lata. Proximal attachments may extend to the aponeurotic fascia superficial to gluteus medius. The short muscle belly descends between, and is attached to, the two layers of the iliotibial tract of the fascia lata, ultimately attaching to the lateral condyle region of the tibia.

Vascular supply The muscle itself is supplied mainly by a large ascending branch of the lateral circumflex femoral artery. The tensor fasciae latae musculocutaneous flap is raised on this pedicle. The superior part of the muscle receives branches from the superior gluteal artery. The fascia surrounding the muscle is supplied on its superficial aspect by the superficial circumflex iliac artery and on its deep surface by the lateral circumflex femoral artery.

Innervation Tensor fasciae latae is innervated by the superior gluteal nerve, L4, L5 and S1.

Actions Tensor fasciae latae is a hip flexor and abductor; its role in medial rotation (from the anatomical position) is minimal (Neumann 2010). The muscle helps to maintain upright posture while minimizing energy expenditure on muscle activity. When the subject is standing it acts from below to steady the pelvis on the head of the femur and, through the iliotibial tract, helps maintain the extended knee in a locked position. The muscle aids gluteus medius in stabilizing the pelvis over the femur in the frontal plane, when standing on one limb (see Fig. 77.36).

Testing When the thigh is flexed against gravity and the knee is extended, an angular depression appears immediately below the anterior superior iliac spine; its lateral boundary is tensor fasciae latae. If the thigh is then abducted against resistance, the muscle can be felt and sometimes seen.

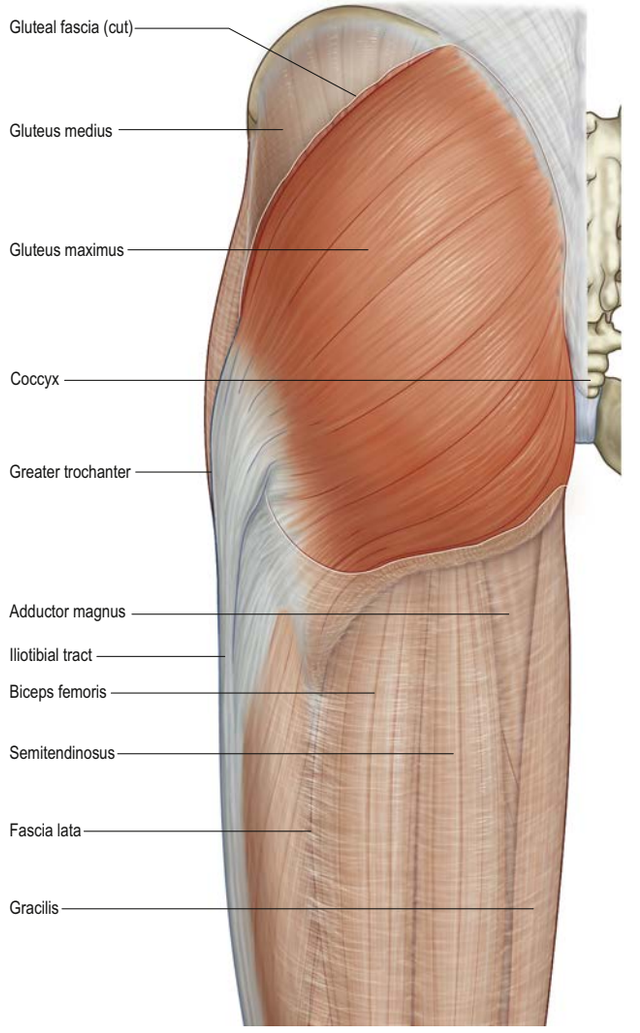

Fig. 77.38 Gluteus maximus, posterior view with the posterior thigh muscles seen through the overlying fascia lata.

Gluteus maximus

Attachments Gluteus maximus (Fig. 77.38) is the largest and most superficial muscle in the gluteal region. It is a broad, thick, quadrilateral mass, which, with its overlying adipose fascia, forms the familiar prominence of the buttock. Gluteus maximus is thicker and more extensive in humans than in any non-human primate, features that presumably correlate with the evolutionary transition to bipedality and a permanently upright posture. The muscle has a coarse fascicular architecture, with large bundles of fibres separated by fibrous septa. It arises from the posterior gluteal line of the ilium and the rough area of bone, including the crest, immediately above and behind it; from the aponeurosis of erector spinae; the dorsal surface of the lower part of the sacrum and the side of the coccyx; the sacrotuberous ligament; and the fascia (gluteal aponeurosis) that covers gluteus medius. There may be additional slips from the lumbar aponeurosis or ischial tuberosity. The muscle may also be bilaminar. The fibres descend laterally; the upper part of the muscle, together with the superficial fibres of the lower part, ends in a thick tendinous lamina that passes lateral to the greater trochanter and is attached to the iliotibial tract of the fascia lata. The deeper fibres of the lower part of the muscle attach to the gluteal tuberosity between vastus lateralis and adductor magnus.

Relations A thin fascia separates the superficial surface of gluteus maximus from the overlying thick, adipose subcutaneous tissue. The deep surface of the muscle is related to the ilium, sacrum, coccyx, sacrotuberous ligament, part of gluteus medius, piriformis, the gemelli, obturator internus, quadratus femoris, the ischial tuberosity, greater trochanter, and the attachments of biceps femoris, semitendinosus, semimembranosus and adductor magnus to the ischial tuberosity. Three main bursae lie deep to gluteus maximus, the: trochanteric, over the greater trochanter; gluteofemoral, between the tendon of gluteus maximus and the proximal tendon of vastus lateralis; and ischiofemoral, over the gluteal tuberosity, which is less commonly present.

The superficial division of the superior gluteal artery reaches the deep surface of the muscle between piriformis and gluteus medius. The inferior gluteal and internal pudendal vessels, the sciatic, pudendal and posterior femoral cutaneous nerves, muscular branches from the sacral femoral cutaneous nerves, and muscular branches from the sacral plexus all typically leave the pelvis below piriformis. The first perforating artery and the terminal branches of the medial circumflex femoral artery are also deep to the lower part of gluteus maximus. The upper border of gluteus maximus is thin and overlies gluteus medius. Its prominent lower border is free and slopes downwards and laterally. The muscle is crossed by the horizontal gluteal fold (the posterior flexure line of the hip joint), which marks the upper limit of the back of the thigh on the surface.

Vascular supply The dominant vascular pedicle is usually that of the inferior gluteal artery, which supplies approximately two-thirds of the muscle. The remainder is supplied mainly by the superior gluteal artery, though this may sometimes be the dominant vessel. The lateral and distal borders of the muscle receive a supply from the first perforator given off from the profunda femoris artery and from the medial circumflex femoral artery. Minor branches may be derived from the lateral circumflex femoral, lateral sacral and internal pudendal arteries.

Gluteus maximus musculocutaneous flaps may be based on either of the gluteal vessels or on the first perforator given off from the profunda femoris artery, depending on the site and size of the defect requiring coverage.

Innervation Gluteus maximus is innervated by the inferior gluteal nerve, L5, S1 and S2.

Actions Acting from the pelvis, gluteus maximus can extend the flexed thigh and bring it to and beyond a line extending from the trunk. Acting from its distal attachment, it may prevent the forward momentum of the trunk from producing flexion at the supporting hip during bipedal gait. The muscle is generally inactive during quiet standing, when swaying forwards at the ankle joints, or when bending forwards at the hip joints to touch the toes. However, it acts with the hamstrings in raising the trunk after stooping, by rotating the pelvis backwards on the head of the femur. It is intermittently active in the walking cycle and in climbing stairs, and continuously active in strong lateral rotation of the thigh. Its upper fibres are active in powerful abduction of the thigh. It is a tensor of the fascia lata, and through the iliotibial tract it stabilizes the femur on the tibia when the extensor muscles of the knee are relaxed.

Testing Gluteus maximus may be tested by extension of the hip against resistance, in the prone position with the knees held flexed.

Gluteus medius

Attachments Gluteus medius is a broad, thick muscle (see Fig. 77.38; Fig. 77.39A). It arises from the outer surface of the ilium between the iliac crest and posterior gluteal line above, and the anterior gluteal line below, and also from the gluteal aponeurosis superficial to its upper part. The fibres converge to a flat tendon that has two attachments: a cord-like tendon that attaches to the posterosuperior aspect of the trochanter, and a ridge that slants downwards and forwards on the lateral surface of the greater trochanter. The distal tendon of gluteus medius commonly fuses with the distal tendon of gluteus minimus as it approaches the greater trochanter, and its posterior edge sometimes blends with piriformis. The muscle may be composed of three parts (anterior, middle and posterior).

Relations The posterior third of gluteus medius is covered by gluteus maximus but it is superficial in its anterior two-thirds, where a strong layer of deep fascia (gluteal aponeurosis) covers it. Its deep surface is related to gluteus minimus. Branches of the deep divisions of the superior gluteal nerve and artery run between the gluteus medius and minimus muscles, and are vulnerable during anterolateral and lateral approaches to the hip that involve splitting gluteus medius. The tendon

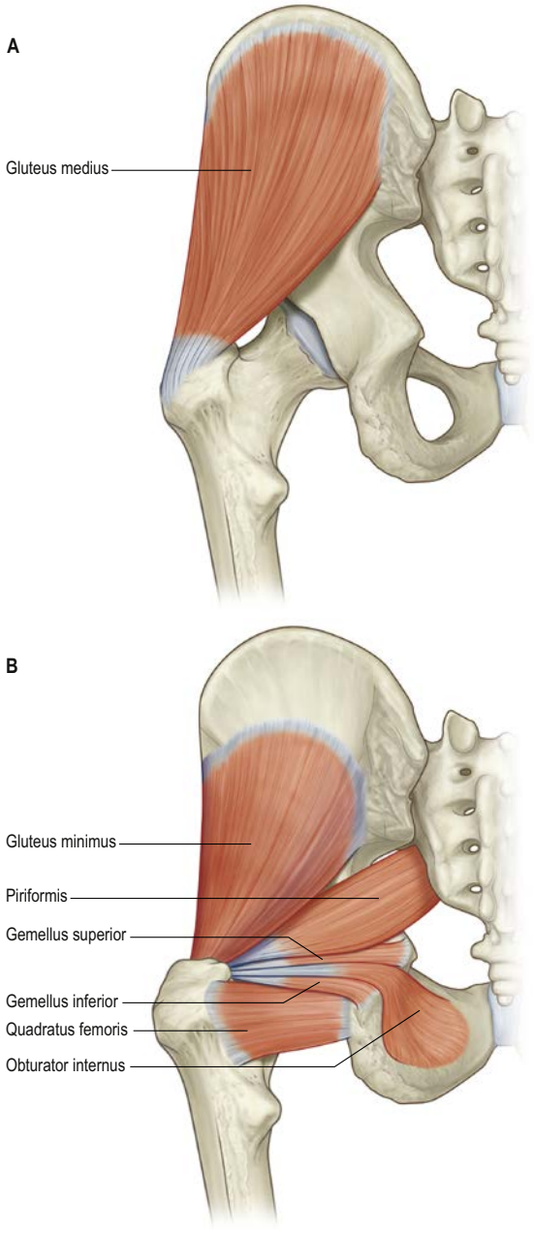

Fig. 77.39 A, Gluteus medius, posterior view. **B**, Gluteus minimus and short lateral rotators of the hip, posterior view.

glides on the anterosuperior part of the lateral surface of the trochanter, where at least one bursa separates it from the bone.

Vascular supply The main supply to gluteus medius is from the deep branch of the superior gluteal artery (**Fig. 77.40A**). The distal part of the muscle is supplied by the trochanteric anastomosis.

Innervation Gluteus medius is innervated by the superior gluteal nerve, L4, L5 and S1.

Actions These are considered below with gluteus minimus.

Testing This is considered below with gluteus minimus.

Gluteus minimus

Attachments Gluteus minimus lies deep to gluteus medius (**Fig. 77.39B**). The fan-shaped muscle arises from the outer surface of the ilium between the anterior and inferior gluteal lines and, behind, from the margin of the greater sciatic notch. The fibres converge below to the deep surface of an aponeurosis that ends in a tendon attached to an anterolateral ridge on the greater trochanter and contributes an expansion to the capsule of the hip joint.

The muscle may be comprised of anterior and posterior parts. Separate slips may pass to piriformis, gemellus superior or vastus lateralis, and its distal tendon often blends with that of gluteus medius.

Relations Branches of the deep division of the superior gluteal artery and nerve run on the superficial surface of the muscle. The reflected tendon of rectus femoris and the capsule of the hip joint are deep to gluteus minimus. At least one bursa separates the tendon from the medial part of the anterior surface of the greater trochanter.

Vascular supply Gluteus minimus is supplied from both its surfaces, from the main trunk and the deep branch of the superior gluteal artery, with a contribution at its femoral attachment from the trochanteric anastomosis (see Fig. 77.40).

Innervation Gluteus minimus is innervated by the superior gluteal nerve, L4, L5 and S1.

Actions of gluteus medius and gluteus minimus Both gluteus medius and minimus, acting from the pelvis, abduct the thigh, and their anterior and posterior fibres rotate it medially and laterally, respectively. Acting from the femur, they play an essential part in maintaining the trunk upright when the foot of the opposite side is raised from the ground in walking and running (see Fig. 77.36). In this phase, the body weight tends to make the pelvis sag downwards on the unsupported side. This is counteracted by the gluteus medius and minimus of the supporting side, which, acting from below, exert such powerful traction on the hip bone that the pelvis is actually raised a little on the unsupported side. In symmetrical standing with the feet somewhat separated, the abductor muscles are usually 'silent' on electromyography.

Testing The supportive effect of the gluteus medius and minimus on the pelvis when the contralateral foot is raised depends on the following conditions. The two muscles, and their innervation, must be functioning normally. The components of the hip joint, which forms the fulcrum, must be in their usual relation. The neck of the femur must be intact, with its normal angulation to the shaft.

When any one of these conditions is not fulfilled, e.g. in paralysis of the glutei, developmental dysplasia of the hip or coxa vara, the supporting mechanism is upset and the pelvis drops on the unsupported side when the patient tries to stand on the affected limb. This is known clinically as an uncompensated Trendelenburg's sign. Individuals with paralysis of gluteus medius and minimus have a characteristic lurching gait:

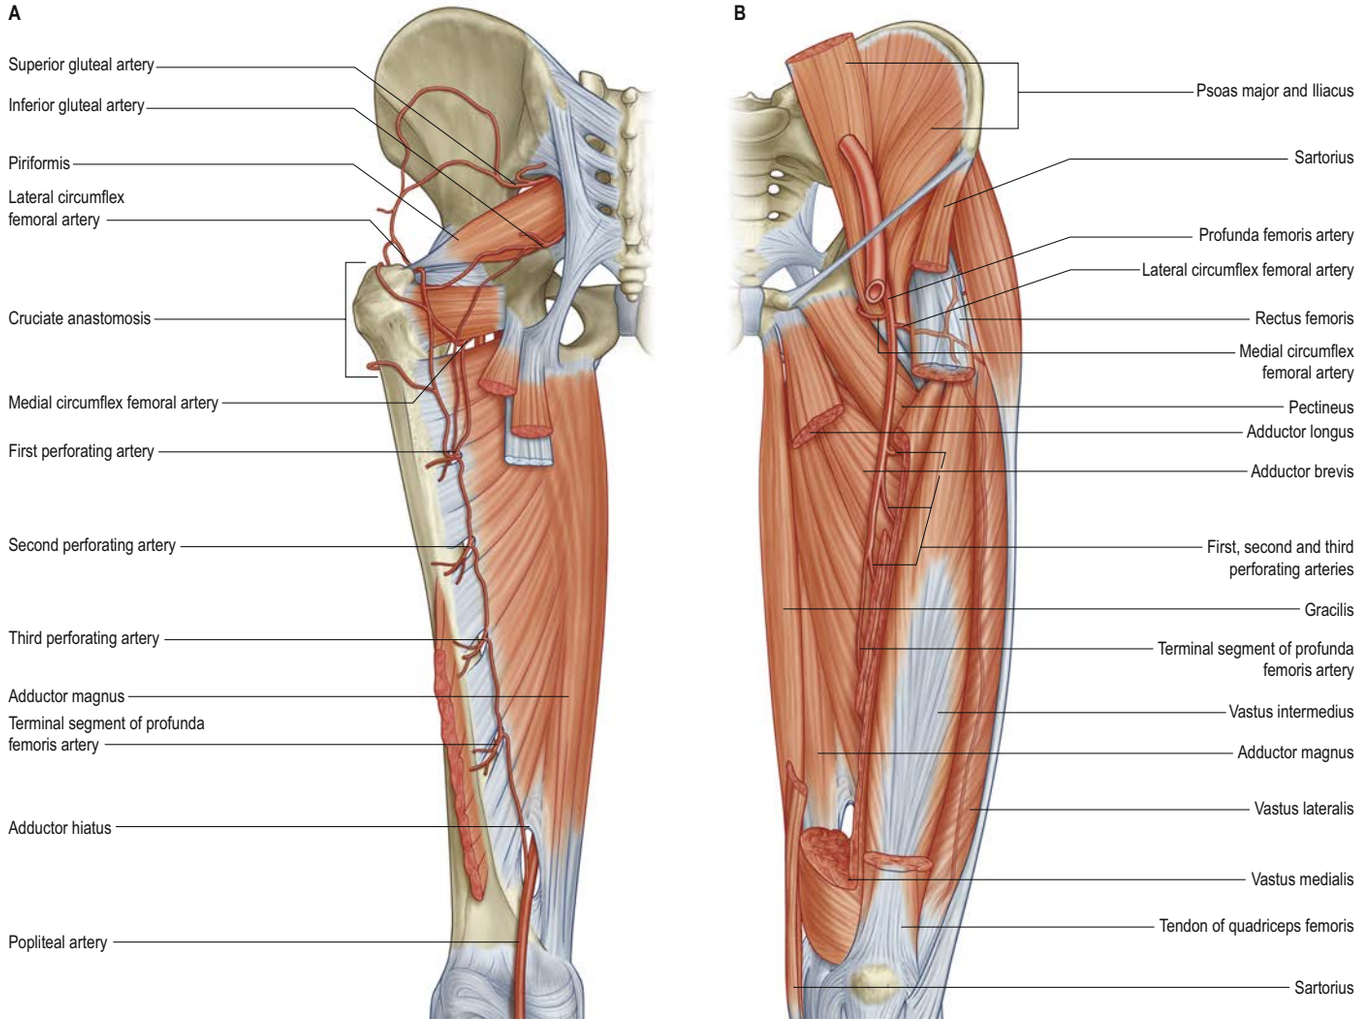

Fig. 77.40 The arteries and muscles of the left gluteal and femoral regions. **A**, Posterior aspect. **B**, Anterior aspect. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

during the single-limb support phase of walking, the trunk leans to the side of the weakened muscles (compensated Trendelenburg sign) (Neumann 2017). Provided that these two muscles are intact, paralysis of other muscles acting on the hip joint produces remarkably little deficit in gait, at least when walking on level surfaces at a relatively slow speed.

Gluteus medius and minimus may be tested together by medial rotation of the thigh against resistance, in the supine position with hip and knee flexed. Both muscles may be tested together with tensor fasciae latae by abduction of the lower limb against resistance, in the supine position with the knee extended.

Piriformis

Attachments Piriformis (see Figs 77.39B, 77.40A) occupies a central position in the buttock, where it lies in the same plane as gluteus medius. It arises from the anterior surface of the sacrum by three digitations, which are attached to the portions of bone between the pelvic sacral foramina, and to the grooves leading from the foramina (see Fig. 46.49). It also arises from the gluteal surface of the ilium near the posterior inferior iliac spine, from the capsule of the adjacent sacroiliac joint, and sometimes from the upper part of the pelvic surface of the sacrotuberous ligament. The muscle passes out of the pelvis through the greater sciatic foramen, which it substantially fills. Here it constitutes an important surgical landmark in the identification of structures that emerge above and below it. It inserts into the medial side of the upper border of the greater trochanter of the femur via a rounded tendon that lies behind and above, but is often partially blended with, the common tendon of obturator internus and the gemelli. The muscle itself may be fused with gluteus medius.

Relations Within the pelvis, the anterior surface of piriformis is related to the rectum (especially on the left), the sacral plexus of nerves and branches of the internal iliac vessels. The posterior surface lies against the sacrum. Outside the pelvis, its anterior surface is in contact with the posterior surface of the ischium and capsule of the hip joint, and its posterior surface with gluteus maximus. Its upper border is in contact with gluteus medius and the superior gluteal vessels and nerve, its lower border with coccygeus and gemellus superior. The inferior gluteal and internal pudendal vessels, the sciatic, posterior femoral cutaneous and pudendal nerves, and muscular branches from the sacral plexus appear in the buttock in the interval between piriformis and gemellus superior. The relationship between piriformis and the sciatic nerve, however, is variable. The undivided nerve may emerge above the muscle or through the muscle. The major divisions of the nerve may lie either side of the muscle, or (the most common variant) one division passes between the heads of a divided muscle and one division either above or below (Beaton and Anson 1937).

Vascular supply In the buttock, piriformis is supplied mainly from the superior gluteal artery, with contributions from the gemellar branches of the internal pudendal. There may be a separate branch from the inferior gluteal artery (see Fig. 77.40A). In the pelvis, the main supply is from the lateral sacral artery, with contributions from both gluteal vessels.

Innervation Piriformis is innervated by the superior gluteal nerve and branches from ventral rami of S1 and S2 (Iwanaga et al 2018).

Actions Piriformis rotates the extended thigh laterally, but abducts the flexed thigh.

Testing Clinically, it is not possible to test piriformis alone; however, for suspected dysfunction of piriformis the best provocative test is to ask the seated subject to abduct the thighs. Buttock pain suggests piriformis involvement.

Obturator internus

Attachments Obturator internus (see Figs 77.39B, 77.42) is situated partly within the true pelvis and partly posterior to the hip joint. It arises from the internal surface of the anterolateral wall of the lesser pelvic cavity. Its attachments, which almost surround the obturator foramen, are to the inferior ramus of the pubis, the ischial ramus and the pelvic surface of the hip bone below and behind the pelvic brim, to the upper part of the greater sciatic foramen above and behind, to the obturator foramen below and in front. It also arises from the medial part of the pelvic surface of the obturator membrane, from the tendinous arch that completes the obturator canal, and, to a small extent, from the obturator fascia that covers the muscle. The fibres converge towards the lesser sciatic foramen and end in four or five tendinous bands on the deep surface of the muscle. These bands make a lateral right-angled turn around the grooved surface of the ischium between its spine and tuberosity. The grooved surface is covered with a smooth layer of hyaline cartilage and is separated from the tendon by a bursa; ridges on the surface correspond to furrows between the tendinous bands. These bands leave the pelvis through the lesser sciatic foramen and unite to form a single flattened tendon that passes horizontally across the capsule of the hip joint. The gemelli fuse with this tendon before it inserts on to an anterior impression on the medial surface of the greater trochanter anterosuperior to the trochanteric fossa. A long, narrow bursa is usually interposed between the tendon and the capsule of the hip joint, and occasionally communicates with the bursa between the tendon and the ischium.

Relations Within the pelvis, the anterolateral surface of the muscle is in contact with the obturator membrane and inner surface of the lateral wall of the pelvis. Its posteromedial surface is related to the obturator fascia, the origin of levator ani and the sheath that surrounds the internal pudendal vessels and pudendal nerve, and forms the lateral wall of the ischio-anal fossa. Outside the pelvis, the muscle is covered by gluteus maximus, is crossed posteriorly by the sciatic nerve and passes behind the hip joint. As the tendon of obturator internus emerges from the lesser sciatic foramen, it may be covered above and below by the two gemelli, which form a muscular canal for it. Near its termination, the gemelli may pass anterior to the tendon and form a groove in which it lies.

Vascular supply The main arterial supply of the extrapelvic part of obturator internus is from the gemellar branches of the internal pudendal artery. Intrapelvic and extrapelvic parts are supplied by the branches of the obturator artery.

Innervation Obturator internus is innervated by the nerve to obturator internus, L5 and S1.

Actions These are considered below with the actions of obturator externus.

Testing This is considered below with the testing of obturator externus.

Obturator externus

Attachments Obturator externus (**Fig. 77.41**) is a flat, triangular muscle covering the external surface of the anterior pelvic wall. It arises from the anteromedial two-thirds of the external surface of the obturator membrane, and from the adjacent bone of the pubic and ischial rami, extending for a short distance on to their pelvic surfaces between the margin of the obturator foramen and the obturator membrane. The whole muscle, and the tendon into which its fibres converge, spiral backwards, laterally and upwards, and thus cross the inferior aspect and

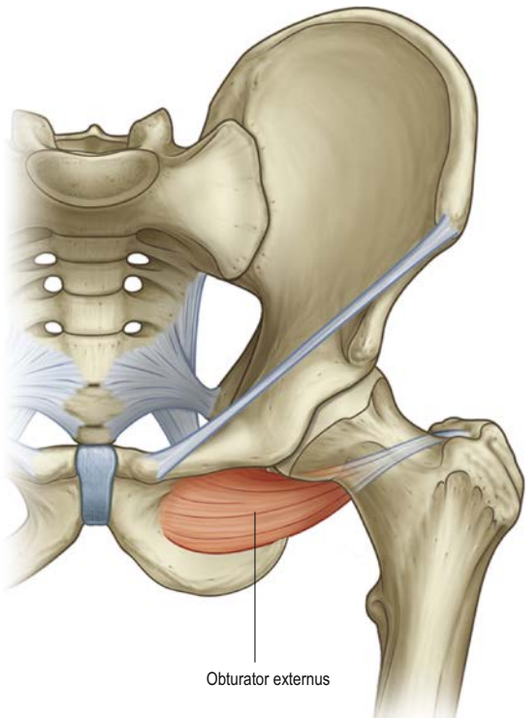

Fig. 77.41 Obturator externus, anterior aspect. (Adapted from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

then the back of the neck of the femur and lower part of the capsule of the hip joint to end in the trochanteric fossa of the femur.

Relations A bursa, which communicates with the hip joint, may be interposed between the tendon and the hip joint capsule and femoral neck. The obturator vessels lie between the muscle and the obturator membrane. The anterior branch of the obturator nerve reaches the thigh by passing in front of the muscle, and the posterior branch by piercing it.

Vascular supply Obturator externus receives a variable pattern of supply from the obturator and medial circumflex femoral arteries.

Innervation Obturator externus is innervated by the posterior branch of the obturator nerve, L3 and L4.

Actions It has been suggested that the short rotator muscles around the hip joint (piriformis, obturator externus and internus, the gemelli and quadratus femoris) are more important as postural muscles than as prime movers, acting as adjustable ligaments to maintain the stability and integrity of the hip. However, these muscles are largely inaccessible to direct observation, and, because of the hazards presented by their close relationship to important neurovascular structures, little electromyographic data are available in humans (Hodges et al 2014). In both bipedal walking and vertical climbing, obturator externus is recruited during the early part of the swing phase; in climbing it effects lateral rotation of the thigh, and in walking it probably counteracts the tendency to medial rotation produced by the anterior adductor muscles at this stage of the cycle. Obturator internus differs from obturator externus in its pattern of use but its role in bipedal walking remains unclear. Its attachments suggest that it, like the gemelli, is a lateral rotator of the extended thigh and perhaps an abductor of the flexed thigh. These actions may be used to antagonize unwanted components of movement produced by the primary locomotor muscles.

Testing The short rotators cannot be tested individually, but lateral rotation of the extended hip and abduction of the flexed hip against resistance tests them as a group.

Gemellus inferior and gemellus superior

Attachments Gemellus inferior arises from the upper part of the lateral surface of the ischial tuberosity, immediately below the groove for the tendon of obturator internus (Fig. 77.42). It blends with the lower border of this tendon, and inserts with it into the medial surface of the greater trochanter.

Gemellus superior, the smaller of the two gemelli, arises from the dorsal surface of the ischial spine, blends with the upper border of the tendon of obturator internus, and inserts with it into the medial surface of the greater trochanter. It is sometimes absent.

The two gemelli can be regarded as accessory to obturator internus (see Fig. 77.39B).

Relations The relations of the gemelli are as described for the extrapelvic part of obturator internus.

Vascular supply Gemellus superior is supplied by the internal pudendal artery and its gemellar branches; by the inferior gluteal artery; and sometimes also by the superior gluteal artery. Gemellus inferior is supplied mainly by the medial circumflex femoral artery.

Innervation Gemellus superior is innervated by the nerve to obturator internus, L5, S1 and S2. Gemellus inferior is innervated by the nerve to quadratus femoris, L4, L5 and S1.

Actions The gemelli rotate the extended thigh laterally and may contribute to abduction of the flexed thigh.

Testing This is considered above with the testing of obturator externus.

Quadratus femoris

Attachments Quadratus femoris (see Fig. 77.39B) is a flat, quadrilateral muscle lying between gemellus inferior and the upper margin of adductor magnus, from which it is separated by the transverse branch of the medial circumflex femoral artery. It arises from the upper part of the external aspect of the ischial tuberosity and inserts on to a small tubercle a little above the middle of the trochanteric crest of the femur and into the bone for a short distance below. It may be absent.

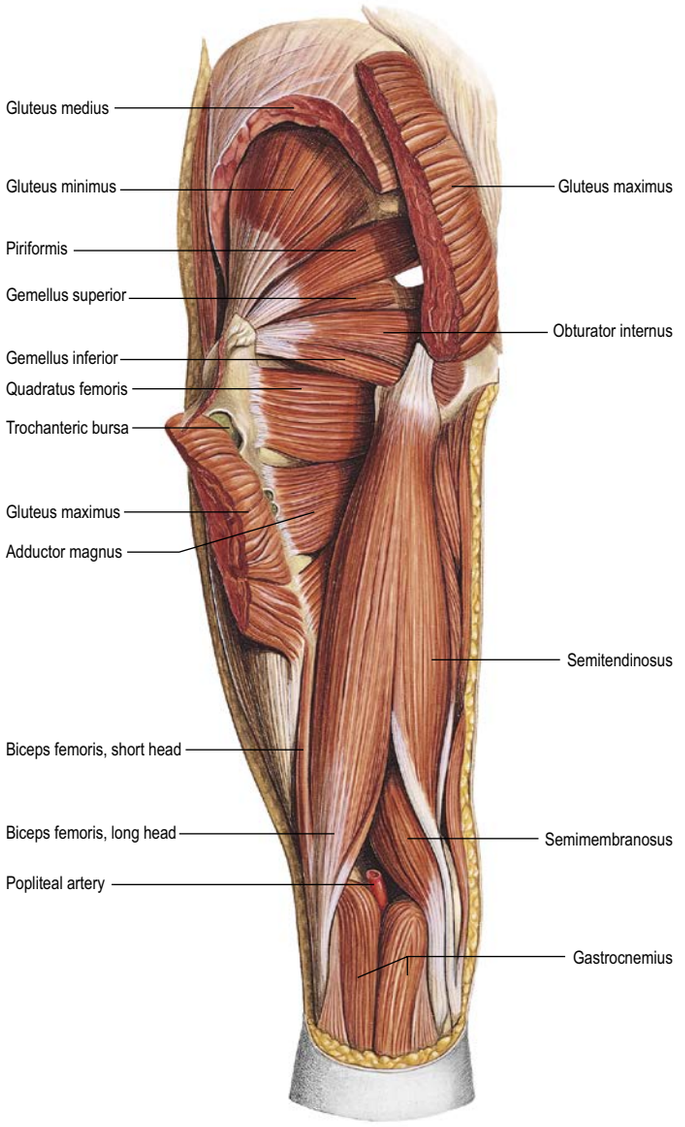

Fig. 77.42 The posterior thigh and gluteal muscles with gluteus maximus and medius partially removed. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Relations The muscle passes behind the hip joint and the neck of the femur, separated from them by the tendon of obturator externus and the ascending branch of the medial circumflex femoral artery (which may cause troublesome bleeding if injured during the posterior surgical approach to the hip). The sciatic nerve crosses the muscle posteriorly. A bursa is often present between the muscle and the lesser trochanter.

Vascular supply Branches pass to the superficial surface of the muscle from the inferior gluteal artery and from the medial circumflex femoral artery, which also supplies the deep surface.

Innervation Quadratus femoris is innervated by the nerve to quadratus femoris, L5 and S1.

Actions Quadratus femoris produces lateral rotation of the thigh.

Testing This is considered above with the testing of obturator externus..

Muscles of the thigh

There are three functional groups of muscle in the thigh, namely: anterior (extensor), posterior (flexor) and medial (adductor). The anterior and posterior groups occupy separate osteofascial compartments that are limited peripherally by the fascia lata and separated from each other by the femur and the medial and lateral intermuscular

septa (see Fig. 77.43). The presence and position of the femoral neck cause the femoral shaft to lie obliquely; consequently, the anterior muscle group, quadriceps femoris, runs obliquely distally and medially and so applies a pull to the patella that is both laterally and proximally directed. The adductor muscles do not possess a separate compartment limited by fascial planes, but occupy the region between quadriceps femoris and the medial margin of the thigh. They are attached distally to the posterior surface of the femur and lie more posteriorly than quadriceps femoris. The posterior muscle group, the hamstrings, lie behind the adductors. The attachments of these muscles often determine the nature and direction of displacement of femoral shaft fractures.

The muscles of the three compartments of the thigh are described below. Of note, adductor magnus, adductor longus and pectineus could each be considered to be constituents of two compartments, i.e. adductor magnus in the posterior and the medial compartments, and adductor longus and pectineus in the anterior and the medial compartments.

The nerve supply to the compartments of the thigh mainly follows the 'one compartment – one nerve' principle. Thus, the femoral nerve supplies the muscles of the anterior compartment, the obturator nerve supplies the medial compartment muscles and the sciatic nerve supplies those in the posterior compartment. The dual functional and compartmental attribution of adductor magnus and pectineus are reflected in their dual nerve supplies.

In contrast to the motor innervation, the arterial supply to the compartmental muscle groups does not exhibit such a direct relationship. All groups receive a supply from the femoral system, particularly from the profunda femoris artery and its branches. The adductors receive a contribution from the obturator artery, and the hamstrings receive a proximal supply from the inferior gluteal artery. Further details are given in the descriptions of the individual muscles.

Anterior compartment

The muscles of the anterior compartment (**Figs 77.43–77.45**; see Fig. 77.37) include sartorius and rectus femoris, which can act at both the hip and knee joints, and vasti medialis, lateralis and intermedius, which act only at the knee. Articularis genus completes the group: it is thought to retract the synovial capsule of the knee joint. Rectus femoris and the vasti extend the knee joint through a common tendon and hence are collectively termed quadriceps femoris. Adductor longus and pectineus are sometimes considered to be part of both the anterior and the adductor compartments.

Sartorius

Attachments Sartorius is a narrow strap muscle and is the longest muscle in the body (Figs 77.44; see Fig. 77.37). It arises by tendinous fibres from the anterior superior iliac spine and the upper half of the notch below it. It crosses the thigh obliquely over to the medial side and then descends more vertically to the medial side of the knee. The muscle fibres terminate at this point and a thin, flattened tendon curves obliquely forwards and expands into a broad aponeurosis. The aponeurosis is attached to the proximal part of the medial surface of the tibia in front of gracilis and semitendinosus, together forming the so-called pes anserinus (**Fig. 77.46**). A slip from its upper margin blends with the capsule of the knee joint, and another from its lower margin merges with the superficial layer of the deep fascia on the medial side of the leg. This sheet of tissue passes inferiorly to lie superficial to and over the distal insertions of gracilis and semitendinosus. It must be split by sharp dissection to reveal these two tendons if they need to be harvested, e.g. in cruciate ligament surgery.

In some cases, sartorius is absent, while in others, the muscle may possess an extra head; when the latter occurs, the extra head is attached to the pectineal line or to the femoral sheath. Variations in the distal attachment of sartorius, in the vicinity of the knee, have been described.

Relations The relations of sartorius are described in the femoral triangle (see below).

Vascular supply The main arterial supply to sartorius is derived from multiple branches of the femoral system and enters the medial half of the muscle from its deep surface. Vessels supplying the proximal third of sartorius may arise from the femoral artery, the profunda femoris artery, the 'artery of the quadriceps' or the lateral circumflex femoral artery. There may be an additional proximal supply from the superficial circumflex iliac artery. Those vessels supplying the middle third of the muscle arise from the femoral artery. The distal vessels arise from the femoral artery within the adductor canal and from the descending genicular artery.

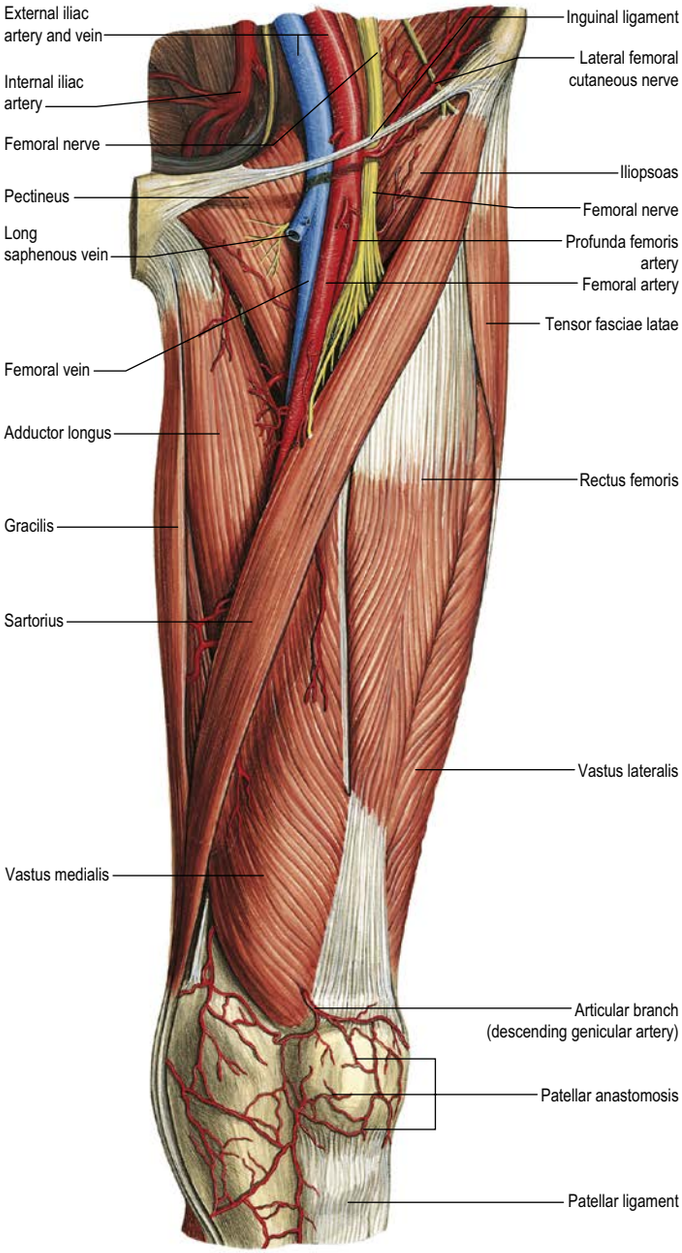

Fig. 77.44 The left femoral triangle; anterior aspect of the thigh. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Innervation Sartorius is innervated by the femoral nerve, L2 and L3.

Actions Sartorius assists in flexing and medially rotating the leg (at the knee). The muscle also flexes the thigh on the pelvis, particularly when combined with knee flexion and helps to abduct the thigh and to rotate it laterally.

Testing When combining flexion and lateral rotation of the hip against gravity, sartorius can typically be seen and felt in the living, lean subject.

Femoral triangle

The femoral triangle is a depressed, intermuscular space in the anteromedial aspect of the proximal thigh, lying immediately distal to the inguinal ligament. The latter constitutes the base of the femoral triangle's inverted triangular outline. Its lateral boundary is the medial margin of sartorius. Its medial boundary is the medial margin of adductor longus. Its distal extremity, the apex, is where sartorius overlaps adductor longus (see Fig. 77.44). Its floor is provided laterally by iliacus and psoas major, and medially by pectineus and adductor longus, and the overlying fascia lata forms the roof. The femoral vessels, passing from mid-base to apex, are in the deepest part of the triangle. Lying

continued

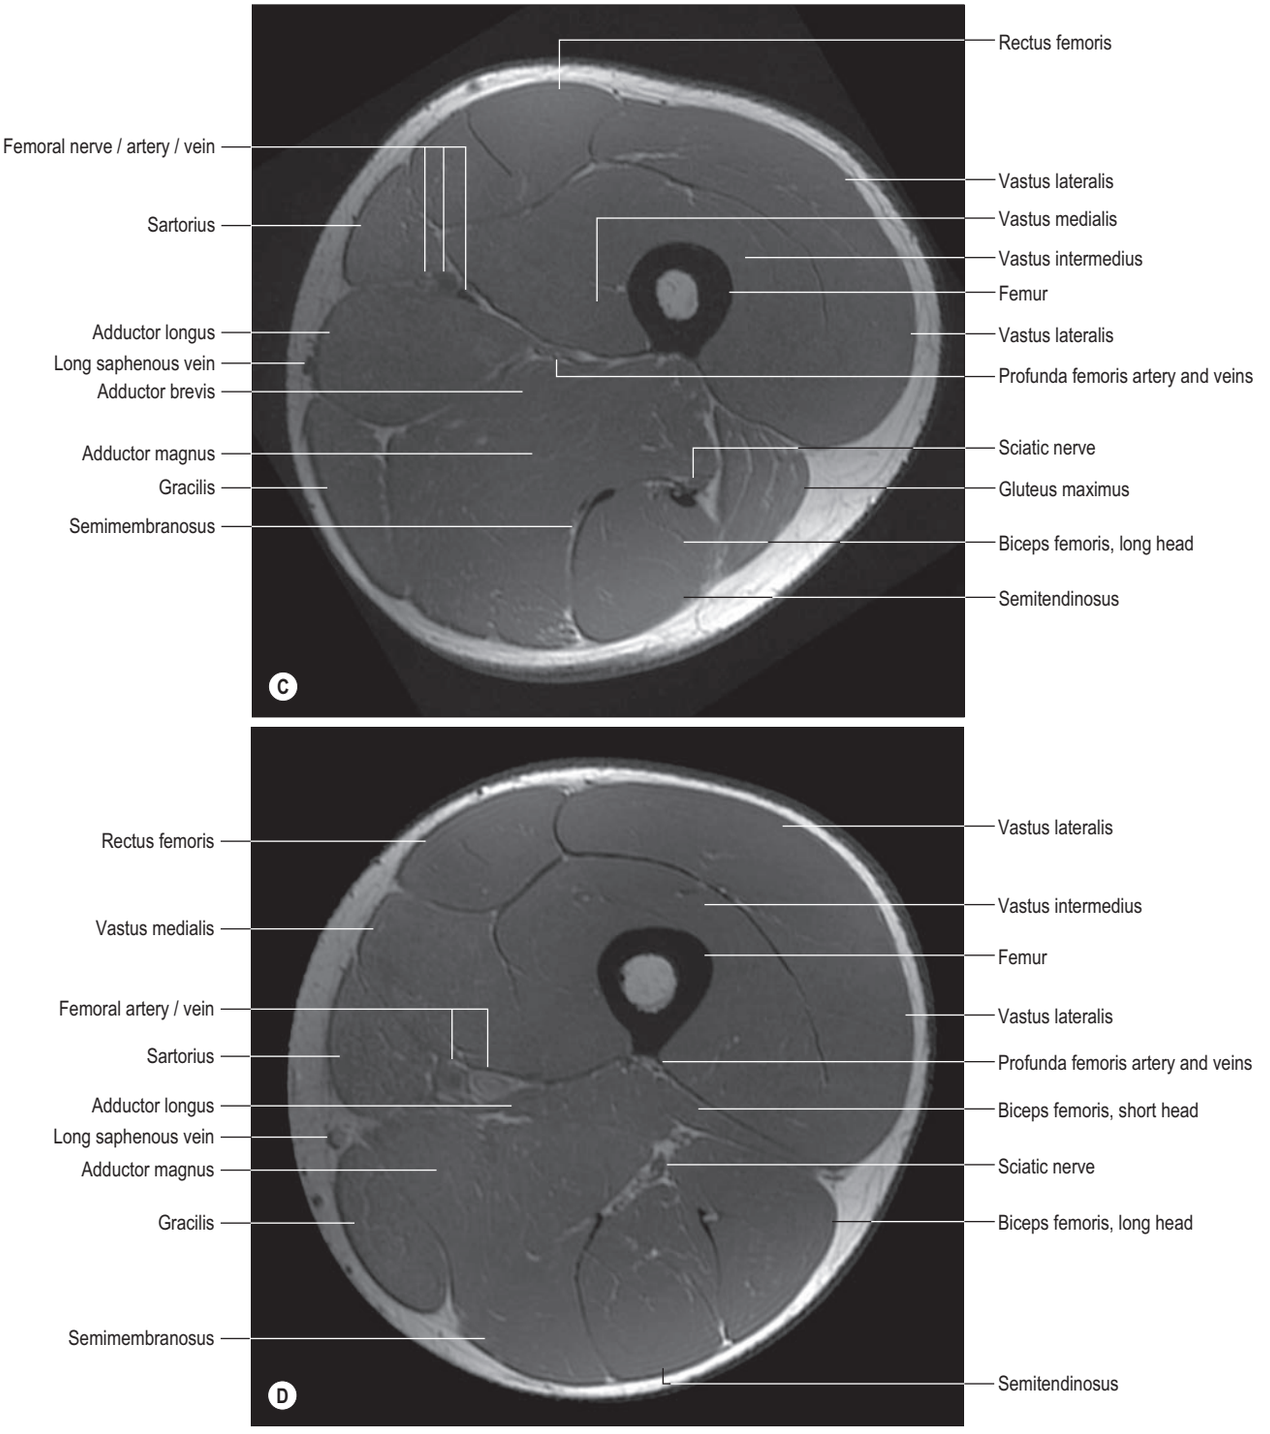

Fig. 77.43, cont'd **C** and **D** are axial T1-weighted images of the thigh, **C** at the level of the apex of the femoral triangle and **D** at the level of the mid-thigh.

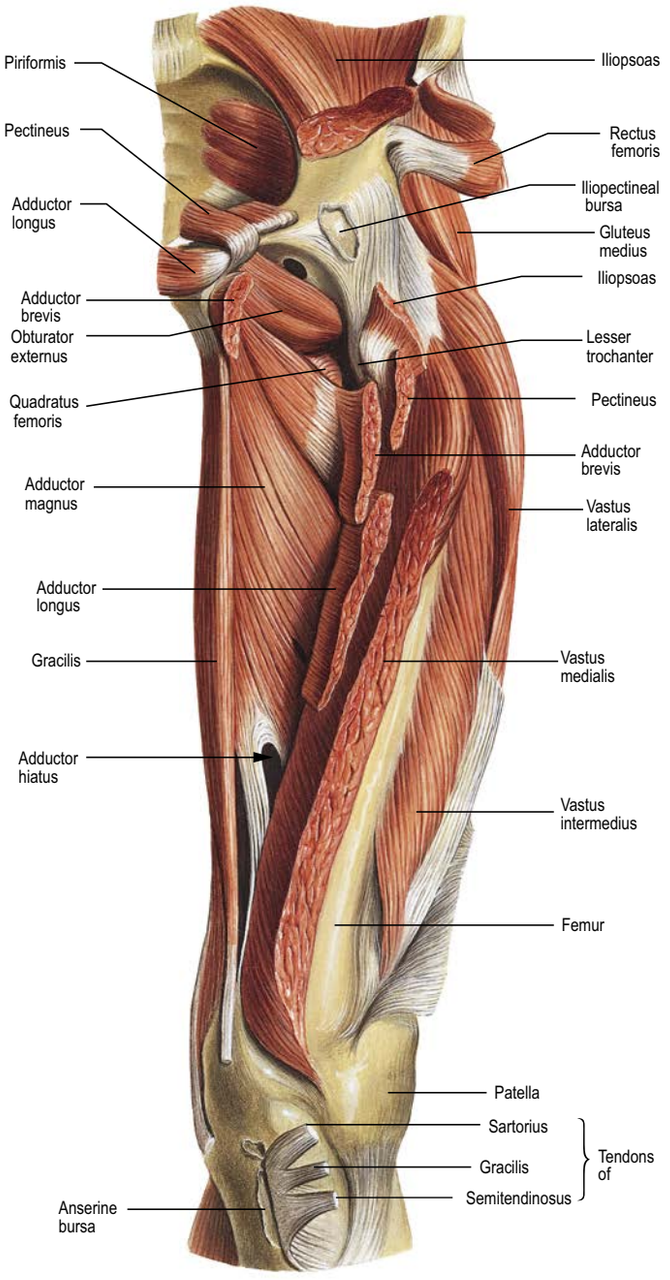

Fig. 77.45 The adductor muscles of the thigh, anterior aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

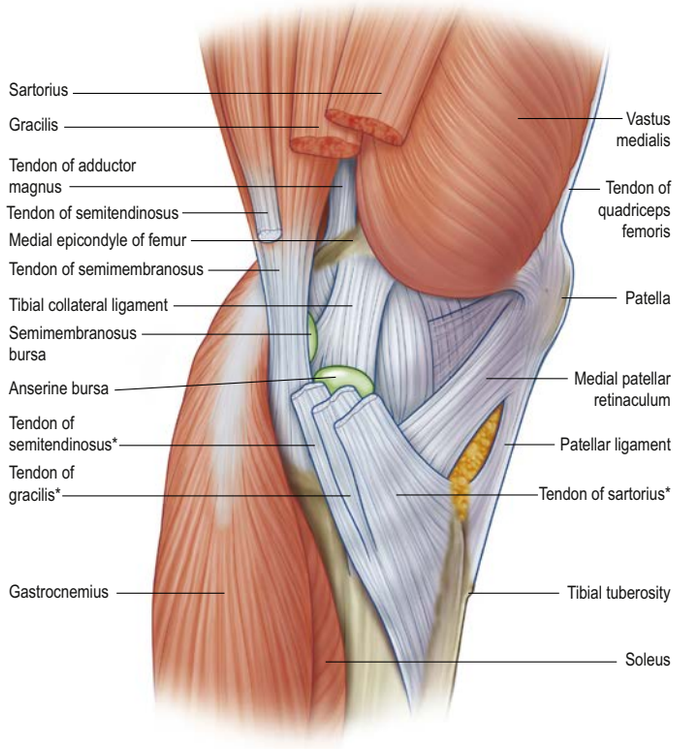

Fig. 77.46 The distal attachment of muscles of the thigh, medial aspect. Note the three tendons of the pes anserinus attaching to the medial, proximal tibia (asterisks).

lateral to the artery and outside the femoral sheath is the femoral nerve, which, on entering the femoral triangle, divides into multiple branches. The triangle also contains fat and lymph nodes.

Quadriceps femoris

Quadriceps femoris (see Figs 77.37, 77.43, 77.44), the great extensor muscle of the leg, covers almost all of the front and sides of the femur. It can be divided into four parts, each named individually. One, rectus femoris, arises from the ilium and travels straight down the middle of the thigh, its shape and path determining its name. The other three arise from the shaft of the femur and surround it (apart from the linea aspera) from the trochanters to the condyles: vastus lateralis is lateral to the femur, vastus medialis is medial to it, and vastus intermedius lies immediately anterior to the femur. Rectus femoris crosses both hip and knee joints, while the three vasti only cross the knee joint.

The tendons of the four components of quadriceps femoris unite in the lower part of the thigh to form a single strong tendon attached to the base of the patella, and some fibres continue over it to blend with the patellar ligament. The patella is a sesamoid bone in the quadriceps femoris tendon, and the patellar ligament, which extends from the patellar apex to the tibial tuberosity, is the continuation of the main tendon. The medial and lateral patellar retinacula are expansions from its borders. The suprapatellar bursa (a synovial extension of the knee joint) lies between the femur and the suprapatellar part of the quadriceps femoris tendon. The deep infrapatellar bursa lies between the patellar ligament and the proximal end of the tibia.

The arterial supply to the quadriceps femoris has been traditionally ascribed to a single branch of either the profunda femoris artery or the lateral circumflex femoral artery, the 'artery of the quadriceps'. This vessel, which may be large, occasionally arises directly from the femoral artery. However, according to Taylor and Razaboni (1994), this artery does not supply all four components of quadriceps femoris; vastus medialis is supplied directly from the femoral artery. The supply of the individual muscle components is described below; their sheaths may have an additional and variable supply.

Quadriceps femoris as a group shows little anatomical variation.

Rectus femoris

Attachments Rectus femoris is fusiform. Its superficial fibres are bipennate, the deep fibres parallel. It has a double origin on the ilium: a straight tendon arises from the anterior inferior iliac spine, and a thinner, flatter reflected tendon from a groove above the acetabulum and from the fibrous capsule of the hip joint. The two unite at an acute angle and spread into an aponeurosis that is prolonged downwards on the anterior surface of the muscle; the muscular fibres arise from this aponeurosis. The fibres end in a broad, thick aponeurosis that forms over the lower two-thirds of its posterior surface and gradually narrows into the thick, flat tendon by which it is attached to the base of the patella. This constitutes the superficial central part of the quadriceps femoris tendon. A third head of rectus femoris may exist; it attaches deeply to the iliofemoral ligament and superficially to the tendon of gluteus minimus as it attaches on to the femur (Tubbs et al 2006). Rectus femoris may also arise from the anterior superior iliac spine, and its reflected head may be absent.

Relations Proximally, the muscle is covered by tensor fasciae latae, iliacus and sartorius. The reflected head lies beneath gluteus minimus. The capsule of the hip joint, vastus intermedius, the anterior borders of vasti lateralis and medius, the lateral circumflex femoral artery and some branches of the femoral nerve all lie deep to rectus femoris.

Vascular supply There are two main vascular pedicles: a superior and an inferior. The superior enters rectus femoris at the junction of its

upper and middle thirds, and arises from the 'artery of the quadriceps'. The inferior and larger branch arises from the 'artery of the quadriceps' at about mid-thigh level and enters the muscle a few centimetres more distally. There are additional contributions from the lateral circumflex femoral artery and, less often, from the superficial circumflex iliac artery.

Vastus medialis

Attachments Vastus medialis arises from the lower part of the intertrochanteric line, spiral line, medial lip of the linea aspera, proximal part of the medial supracondylar line, the tendons of adductor longus and magnus, and the medial intermuscular septum. Its fibres pass downwards and forwards at an average angle of 15° to the long axis of the femur, most of them into an aponeurosis on the deep surface of the muscle that is attached to the medial border of the patella and to the quadriceps femoris tendon. An expansion from this aponeurosis reinforces the capsule of the knee joint and is attached below to the medial condyle of the tibia.

The lowest fibres are nearly horizontal and form a bulge in the living subject, medial to the upper half of the patella. Some authors distinguish this part of the muscle as the vastus medialis obliquus, with fibres that originate largely from the tendon of adductor magnus and insert into the medial border of the patella. This muscle likely has a unique role in dynamically aligning the patellofemoral joint.

Relations Vastus medialis is partly covered by rectus femoris and sartorius. In the central part of the thigh it forms the lateral wall of the adductor canal (Hunter's canal; subsartorial canal).

Vascular supply Vastus medialis is supplied by three branches of the femoral artery. The superior and middle branches arise, sometimes from a common trunk, proximal to the adductor canal, while the inferior arises within the canal. There may also be minor branches from the profunda femoris artery and descending genicular arteries.

Vastus lateralis

Attachments Vastus lateralis is the largest component of quadriceps femoris. It arises by a broad aponeurosis from the upper part of the intertrochanteric line, the anterior and inferior borders of the greater trochanter, the lateral lip of the gluteal tuberosity and the proximal half of the lateral lip of the linea aspera. This aponeurosis covers the proximal three-quarters of the muscle; many additional fibres arise from its deep surface. A few fibres also arise from the tendon of gluteus maximus and the lateral intermuscular septum between vastus lateralis and the short head of biceps femoris. The muscular mass thus formed is attached to a strong aponeurosis on the deep surface of the lower part of the muscle. This narrows to a flat tendon, which attaches to the base and lateral border of the patella and blends into the compound quadriceps femoris tendon. It contributes an expansion to the capsule of the knee joint that descends to the lateral condyle of the tibia and blends with the iliotibial tract.

Relations Vastus lateralis is covered laterally by the fascia lata and the aponeurotic insertions of tensor fasciae latae and gluteus maximus. It is separated from vastus intermedius by branches of the femoral nerve and the lateral circumflex femoral artery. Posteriorly, it is separated from biceps femoris by the lateral intermuscular septum.

Vascular supply There are three main arteries of supply: the superior medial artery arises directly from the lateral circumflex femoral artery; the inferior medial (the largest of the three) from the 'artery of the quadriceps'; and the lateral from the first perforating branch given off from the profunda femoris artery.

Vastus intermedius

Attachments Vastus intermedius arises from the anterior and lateral surfaces of the upper two-thirds of the femoral shaft, and from the lower part of the lateral intermuscular septum. Its fibres end on the anterior surface of the muscle in an aponeurosis that forms the deep part of the quadriceps femoris tendon and is attached to the lateral border of the patella and the lateral condyle of the tibia.

Vastus intermedius appears to be inseparable from vastus medialis. However, when rectus femoris is reflected, a narrow cleft can be seen extending upwards from the medial border of the patella between the two muscles, sometimes as far as the lower part of the intertrochanteric line; proximal to this, the two muscles are frequently fused.

Relations Vastus intermedius is almost completely covered by the other components of quadriceps femoris, except laterally, where a small part becomes superficial behind vastus lateralis.

Vascular supply Vastus intermedius receives a lateral artery of supply, which arises from the 'artery of the quadriceps', and a medial artery that arises directly from the profunda femoris artery. Arteries to the other components of quadriceps femoris may also contribute. There is an anastomotic network deep to the muscle that supplies the suprapatellar bursa and articularis genus, and may form a collateral pathway when the femoral artery is blocked.

Articularis genus

Articularis genus is a small muscle, usually distinct from vastus intermedius but occasionally blending with it. It consists of several relatively thin muscular bundles that arise from the anterior surface of the lower part of the femoral shaft and are attached to a proximal reflection of the synovial membrane of the knee joint (Woodley et al 2012). It is visible during knee arthroscopy when viewed looking superiorly from within the suprapatellar bursa (Ch. 78).

Innervation of quadriceps femoris

Quadriceps femoris and articularis genus are supplied by the femoral nerve, L2, L3 and L4.

Actions of quadriceps femoris

Quadriceps femoris extends the knee. Rectus femoris helps to flex the thigh on the pelvis; if the thigh is fixed, it helps to flex the pelvis on the thigh. Rectus femoris can flex the hip and extend the knee simultaneously. There is little or no activity in quadriceps femoris during quiet standing, as long as the knee is mechanically locked by action of gravity falling through or in front of the centre of rotation at the knee. Rectus femoris pulls the patella along the line of the mechanical axis of the lower limb (i.e. the line connecting the centres of the hip, knee and ankle). The remaining muscles in the group are attached to the shaft of the femur and their pull (notably the vastus lateralis) is lateral as well as proximal. An important dynamic function of vastus medialis obliquus is to counter this lateral vector on the patella during knee extension. Other static factors that help are the depth of the femoral patellar surface, the buttressing effect of the lateral femoral condyle in the groove and the restraining action of the medial patellofemoral ligament. Although difficult to establish a direct cause-and-effect relationship, in theory, inadequacy of vastus medialis obliquus may have a mechanical role in abnormal patellar 'tracking' and associated pain (Sheehan et al 2012). Improving patellar 'tracking' on the femur is an important part of surgical and physiotherapy regimens for patellofemoral problems.

Articularis genus retracts the synovial suprapatellar bursa proximally during extension of the leg, presumably to prevent interposition of redundant synovial folds between patella and femur (Grob et al 2017).

Testing The quadriceps femoris is tested by extending the knee against resistance, in the supine position with the hip flexed.

Adductor compartment

The muscles of the adductor compartment, namely gracilis, pectineus, adductor longus, adductor brevis and adductor magnus (see Figs 77.37, 77.40, 77.43–77.44), have evolved, as their nerve supply suggests, from both flexor and extensor columns. All five muscles cross the hip joint but only gracilis reaches beyond the knee. They are known collectively as the adductors of the thigh, although their actions are more complex than this, e.g. acting from below they have important roles in balancing the trunk on the lower limb during walking.

Their blood supply is derived from the profunda femoris artery, medial circumflex femoral, femoral and obturator arteries. The profunda femoris artery (or sometimes the first perforator) supplies a large branch, the 'artery of the adductor muscles'.

Gracilis

Attachments Gracilis (see Figs 77.43–77.46) is the most superficial of the adductor group. It is thin and flat, broad above, and narrow and tapering below. It arises by a thin aponeurosis from the medial margins of the lower half of the body of the pubis, the whole of the inferior pubic ramus, and the adjoining part of the ischial ramus. The fibres descend vertically into a rounded tendon, often harvested as a knee ligament graft, which passes across the medial condyle of the femur posterior to the tendon of sartorius. It then curves around the medial

condyle of the tibia, where it fans out and is attached to the upper part of the medial surface of the tibia, just below the condyle, forming part of the pes anserinus (see Fig. 77.46). A few fibres from the lower part of the tendon continue into the deep fascia of the lower leg. Often there is a slip that blends with the tendon of the medial head of gastrocnemius. Unless divided, this can lead to problems during surgical harvesting of the gracilis tendon.

Relations The muscle is covered medially by the fascia lata throughout most of its length. Deep to gracilis lie adductor brevis and adductor magnus. The tibial attachment is immediately proximal to that of semitendinosus, and is just behind and blended with the upper edge of the elongated tendon of sartorius. It is separated from the tibial collateral ligament of the knee joint by the anserine bursa.

Vascular supply The arterial supply to gracilis enters via its lateral surface. The main pedicle arises from the 'artery to the adductors', a branch of the profunda femoris artery, and enters at the junction of the upper and middle thirds of the muscle. The gracilis musculocutaneous flap is based on this pedicle. A less important artery enters the distal third of the muscle from the femoral artery. There is a minor proximal supply from the medial circumflex femoral artery.

Innervation Gracilis is innervated by the obturator nerve, L2 and L3.

Actions Gracilis flexes the leg and rotates it medially. It also adducts and assists with flexion of the thigh. When the foot is fixed, gracilis (along with sartorius and semitendinosus) can stabilize the medial side of the knee, and thus may be considered a 'dynamic tibial collateral ligament'.

Testing The tendon can be palpated posteromedially at the knee, as the knee is actively flexed and rotated medially. Gracilis can also be tested with the other adductors of the hip.

Adductor longus

Attachments Adductor longus (see Figs 77.37, 77.43–77.44), the most anterior of the three adductors, is a large, fan-shaped muscle that lies in the same plane as pectineus. It arises by a narrow tendon with a flattened (sometimes C-shaped) cross-section, which is attached to the front of the pubis in the angle between the crest and the symphysis. It expands into a broad fleshy belly that descends posterolaterally and inserts by an aponeurosis into the linea aspera in the middle third of the femur, between vastus medialis and adductors magnus and brevis, usually blending with all of these muscles. Its proximal attachment is vulnerable to overload from sporting activity: this is one cause of sports-related groin pain.

Adductor longus is occasionally double.

Relations Anterior to adductor longus are the spermatic cord, fascia lata (which separates it from the long saphenous vein) and, near its attachment, the femoral artery and vein and sartorius. Posteriorly are adductor brevis and adductor magnus, the anterior branch of the obturator nerve and, near its attachment, the deep artery and vein of the thigh. Lateral and medial to adductor longus are, respectively, pectineus and gracilis.

Vascular supply The main supply to adductor longus is to the central part of the muscle from the 'artery to the adductors', a branch of the profunda femoris artery. There is an additional proximal supply from the medial circumflex femoral artery, and a more distal supply from the femoral artery and sometimes the descending genicular artery.

Innervation Adductor longus is innervated by the anterior division of the obturator nerve, L2, L3 and L4.

Adductor brevis

Attachments Adductor brevis (see Figs 77.40B, 77.43) lies posterior to pectineus and adductor longus. It arises by a narrow attachment from the external aspect of the body and inferior ramus of the pubis, between gracilis and obturator externus. Like adductor longus, it is somewhat triangular, and expands as it descends posterolaterally to insert via an aponeurosis into the femur, along a line from the lesser trochanter to the linea aspera, and on the upper part of the linea immediately behind pectineus and the upper part of adductor longus.

Adductor brevis often has two or three separate parts, or may be integrated into adductor magnus.

Relations Anteriorly lie pectineus, adductor longus, the profunda femoris artery and the anterior branch of the obturator nerve; posteriorly are adductor magnus and the posterior branch of the obturator nerve. The upper border of adductor brevis is related to the medial circumflex femoral artery, obturator externus, and the conjoined tendon of psoas major and iliacus. Its lower border is related to gracilis and adductor magnus. The second perforating artery, or first and second perforating arteries, pierces it near its femoral attachment.

Vascular supply The vascular supply to adductor brevis is variable. Usually the main arterial supply is directly from the profunda femoris artery distally and from the 'artery to the adductors' more proximally. There is an additional proximal supply from the medial circumflex femoral artery. The deep surface receives branches from the obturator artery.

Innervation Adductor brevis is innervated by the obturator nerve, L2 and L3.

Adductor magnus

Attachments Adductor magnus (**Fig. 77.47**; see Figs 77.40, 77.43, 77.45), a massive triangular muscle, arises from a small part of the inferior ramus of the pubis, from the conjoined ischial ramus, and from the inferolateral aspect of the ischial tuberosity. The short, horizontal fibres from the pubic ramus are inserted into the medial margin of the gluteal tuberosity of the femur, medial to gluteus maximus; this part of the muscle, in a plane anterior to the rest, is sometimes called adductor minimus. The fibres from the ischial ramus fan out downwards and laterally, to insert via a broad aponeurosis into the linea aspera and the proximal part of the medial supracondylar line. The medial (ischiocondylar) part of the muscle, composed mainly of fibres from the ischial tuberosity, is a thick mass that descends almost vertically, and ends in the lower third of the thigh in a rounded tendon as it approaches its distal attachment to the adductor tubercle on the medial condyle of the femur. The tendon is connected by a fibrous expansion to the medial supracondylar line.

The long, linear attachment of the muscle is interrupted by a series of osseo-aponeurotic openings, bridged by tendinous arches attached to the bone. The upper four are small and transmit the perforating branches and the termination of the profunda femoris artery. The lowest is large and allows the femoral vessels to cross to the popliteal fossa.

The vertical, ischiocondylar part of the muscle varies in its degree of separation from the rest. The upper border of adductor magnus may fuse with quadratus femoris.

Relations Anteriorly lie pectineus, adductor brevis and adductor longus, the femoral and deep femoral vessels, and the posterior branch of the obturator nerve. A bursa separates the proximal part of the muscle from the lesser trochanter of the femur. Posteriorly are the sciatic nerve, gluteus maximus, biceps femoris, semitendinosus and semimembranosus. The superior border of adductor magnus is parallel with quadratus femoris, and the transverse branch of the medial circumflex femoral artery passes between these two muscles. Its medial border is related to gracilis, sartorius and the fascia lata.

Vascular supply As expected from its position, adductor magnus is supplied from both its anterior and its posterior aspects. The contribution from the anterior compartment is the more important. The profunda femoris artery, obturator artery and femoral artery all contribute; the main supply comes directly from the distal part of the profunda femoris artery. Distally, there may be contributions from the femoral and descending genicular arteries. Posteriorly, there are branches from the medial circumflex femoral, the first and second perforating and the popliteal vessels.

Innervation Adductor magnus is composite and is doubly innervated by the obturator nerve and by the tibial division of the sciatic nerve (L2, L3 and L4), which supplies the ischiocondylar part. Both nerves are derived from anterior divisions in the lumbosacral plexus, indicating a primitive flexor origin for both parts of the muscle.

Actions the adductors

Although the adductors all adduct the femur, they commonly act as synergists in the complex patterns such as that used in walking, running and climbing, and to some degree as controllers of posture. Adductors magnus and longus are probably medial rotators of the thigh. The adductors are relatively inactive during adduction of the abducted thigh in the erect posture (when gravity assists), but active in other postures,

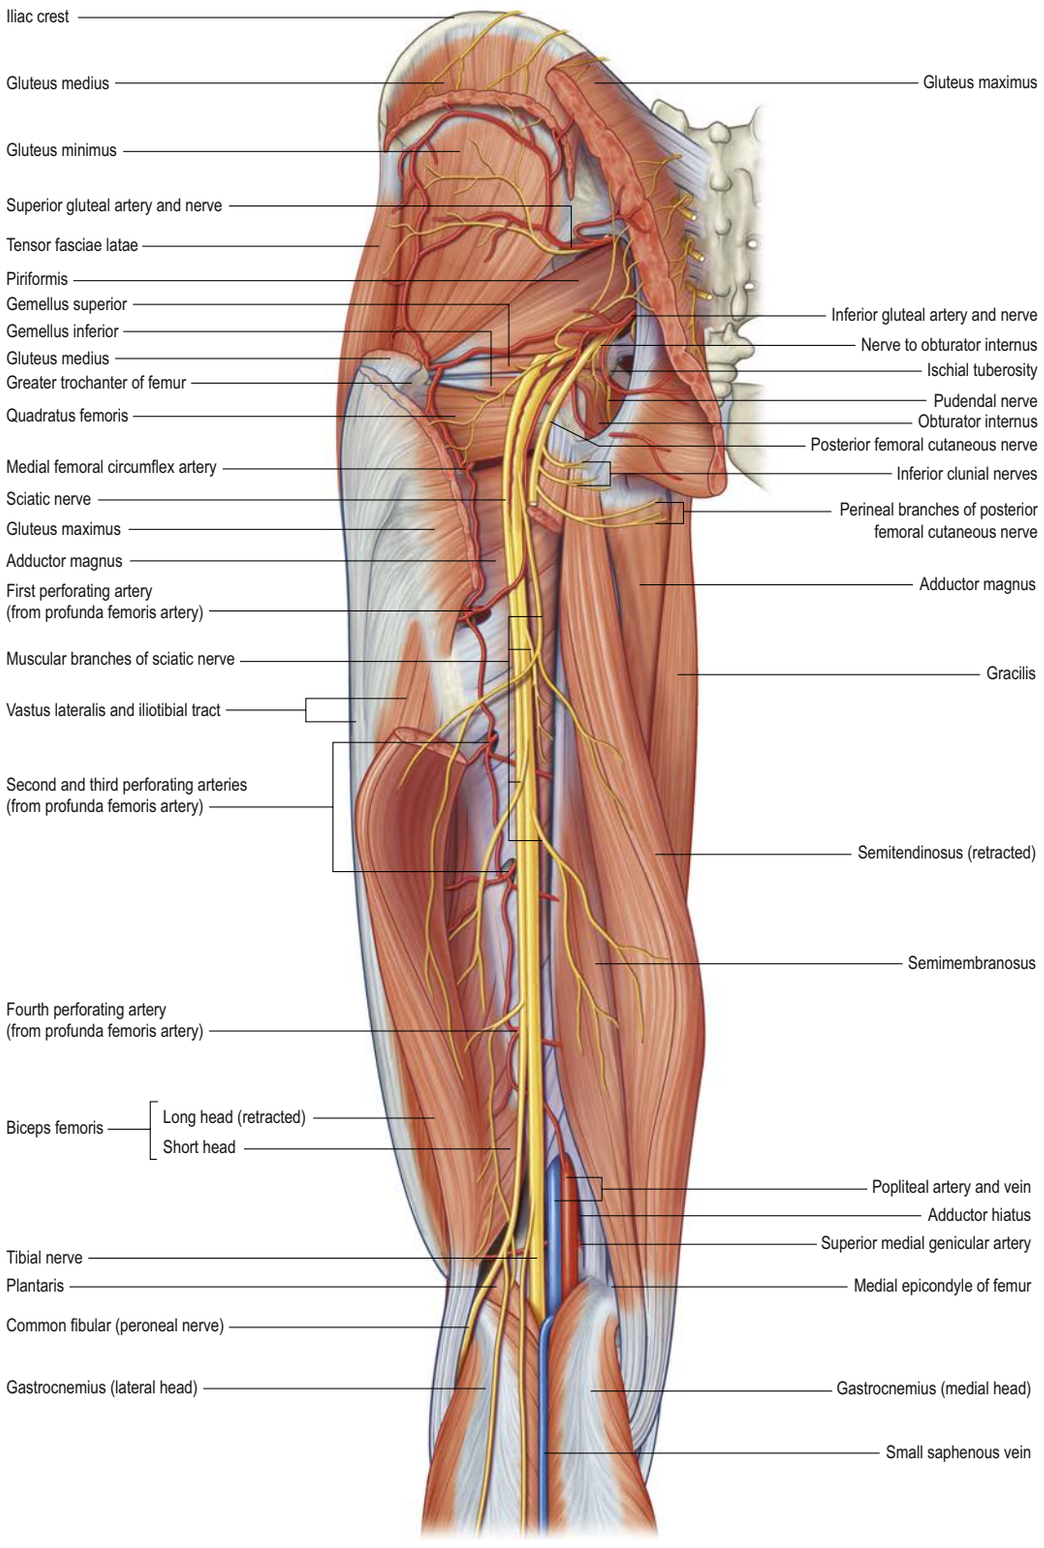

Fig. 77.47 The neurovascular structures of the gluteal region and posterior thigh. (With permission from Netter FH Atlas of Human Anatomy, 5th ed. Elsevier, Saunders. Copyright 2011.)

such as the supine position, or during adduction of the flexed thigh when standing. They are also active during flexion (adductor longus and brevis) and extension (adductor magnus) of the thigh at the hip joint. In symmetrical easy standing their activity is minimal.

Testing the adductors The adductors are usually tested as a group by adduction of the thigh against resistance, in the supine position with the knee extended. The tendon of adductor magnus can be felt just proximal to the adductor tubercle on the medial condyle of the femur. Clinical testing of the other actions mentioned above is not feasible for each of the individual muscles.

Pectineus

Attachments Pectineus (see Figs 77.37, 77.40) is a flat, quadrangular muscle that contributes to the medial aspect of the floor in the femoral triangle. The muscle may also be considered as part of the anterior compartment of the thigh, which is consistent with the muscle's partial femoral nerve innervation. It arises from the pecten pubis, from the bone anterior to it between the iliopubic ramus and the pubic tubercle, and from the fascia on its own anterior surface. The fibres descend posterolaterally to be attached along a line from the lesser trochanter to the linea aspera. Proximally, it may be partially or wholly attached to the capsule of the hip joint.

Relations Pectineus is related anteriorly to the deep lamina of the fascia lata, which separates it from the femoral vessels and long saphenous vein; posteriorly, to the capsule of the hip joint, adductor brevis, obturator externus and the anterior branch of the obturator nerve; laterally, to psoas major and the medial circumflex femoral vessels; and medially, to the lateral margin of adductor longus.

Vascular supply The main arterial supply to pectineus is derived from the medial circumflex femoral artery, which enters the superficial surface of the muscle. There may be a branch from the femoral artery more proximally, and a deep supply from the obturator artery.

Innervation Pectineus is innervated by the femoral nerve, L2 and L3, and the accessory obturator nerve, L3 (when present). Occasionally, it receives a branch from the obturator nerve. The muscle may be incompletely divided into dorsal and ventral layers, which are supplied by the obturator and femoral (or rarely, accessory obturator) nerves, respectively.

Actions Pectineus adducts the thigh and flexes it on the pelvis.

Testing The action of pectineus cannot be tested clinically in isolation.

Adductor canal

The adductor canal is a trough-shaped intermuscular tunnel occupying the distal two-thirds of the medial aspect of the thigh (see Fig. 77.43B). It starts at the apex of the femoral triangle and extends distally as far as the distal attachment of the tendon of adductor magnus. It is triangular in section and is bounded anterolaterally by vastus medialis; posteromedially by adductor longus; and distal to adductor longus, by adductor magnus. Its anteromedial boundary (often referred to as the roof) is a strong and dense fascia that extends from the medial surface of vastus medialis to the medial edge of the adductors longus and magnus, overlapping in its stride the femoral vessels in the adductor canal. This fascia, on account of being overlain by sartorius, is termed the subsartorial fascia.

The adductor canal contains the femoral artery and vein, the descending genicular and muscular branches of the femoral artery and their corresponding venous tributaries, the saphenous nerve, and the nerve to vastus medialis (until it enters its muscle). The femoral vessels pass from the adductor canal into the popliteal fossa via the adductor hiatus, an opening in the tendon of adductor magnus adjacent to the femoral shaft, two-thirds of the way down the adductor canal.

Posterior compartment

The posterior thigh muscles, biceps femoris, semitendinosus and semimembranosus, are colloquially termed the 'hamstrings'. They cross both hip and knee joints, and integrate extension at the hip with flexion at the knee. As the muscles span the back of the knee, they form the proximal lateral and medial margins of the popliteal fossa.

The muscles of the posterior compartment (see Figs 77.38, 77.42–77.43) receive their blood supply from the perforating branches of the profunda femoris artery, most importantly through the first perforator given off from this artery. This vessel has important anastomoses with the inferior gluteal artery (on or within semitendinosus) and with the medial circumflex femoral artery, while the third perforator anastomoses with the superior medial genicular artery within the short head of biceps femoris. This anastomotic chain forms an important collateral arterial pathway when the femoral artery is blocked.

Semitendinosus

Attachments Semitendinosus (see Figs 77.42, 77.43B, 77.47), notable for the length of its distal tendon, lies posteromedially in the thigh. It arises from an inferomedial impression on the upper area of the ischial tuberosity (see Fig. 77.4B), by a tendon it shares with the long head of biceps femoris, and from an aponeurosis connecting the adjacent anterior surfaces of the two muscles for 7.5 cm from their common origin. The belly is fusiform and ends a little below mid-thigh in a long, rounded tendon that runs on the posterior surface of semimembranosus. The tendon curves around the medial condyle of the tibia, passes over the tibial collateral ligament (from which it is separated by the anserine bursa), and inserts into the upper part of the medial surface of the tibia behind the attachment of sartorius and distal to that of gracilis (see Fig. 77.46). At its termination, it is united with the tendon of gracilis and gives off a prolongation to the deep fascia of the leg and to the medial head of gastrocnemius. A tendinous intersection is usually present near the midpoint of the muscle, which may also receive a muscular slip from the long head of biceps femoris. These connections with the medial head of gastrocnemius and biceps femoris can cause difficulty when harvesting the tendon surgically for a graft.

Relations Semitendinosus lies on the posterior surface of semimembranosus throughout its length. The relations of the distal part of the muscle are described above and with the pes anserinus.

Vascular supply The two main arteries of supply to semitendinosus are superior and inferior. The superior is derived from either the medial circumflex femoral artery or the first perforating artery. The inferior and larger branch arises from the first perforator distal to the origin of the superior branch. An accessory supply at the ischial attachment is derived from the inferior gluteal artery, and at the tibial attachment from the inferior medial genicular artery.

Innervation Semitendinosus is innervated by the sciatic nerve, L5, S1 and S2, through its tibial division (see Fig. 77.47).

Semimembranosus

Attachments Semimembranosus (see Figs 77.43, 77.47), so named because of the flattened form of its upper attachment, is posteromedial in the thigh. It arises by a long, flat tendon from a superolateral impression on the ischial tuberosity (see Fig. 77.4B). Inferomedially, the tendinous fibres intermingle to some extent with those of biceps femoris and semitendinosus. The tendon receives, from the ischial tuberosity and ramus, two fibrous expansions that flank adductor magnus. It then broadens and descends deep to semitendinosus and the long head of biceps femoris. Muscle fibres arise from the tendon at about mid-thigh and converge to a second aponeurosis on the posterior aspect of the lower part of the muscle, which tapers to the heavy, rounded tendon of the distal attachment. The tendon divides at the level of the knee into five components. The main one is attached to a tubercle (sometimes called the tuberculum tendinis) on the posterior aspect of the medial tibial condyle. The others are: a series of slips to the medial margin of the tibia, immediately behind the tibial collateral ligament; a thin fibrous expansion to the fascia over popliteus; a cord-like tendon to the inferior lip and adjacent part of the groove on the back of the medial tibial condyle, deep to the tibial collateral ligament; and a strong expansion that passes obliquely upwards to the femoral intercondylar line and lateral femoral condyle, and forms much of the oblique popliteal ligament of the knee joint.

Semimembranosus varies considerably in size and may be absent. It may be double, and arise mainly from the sacrotuberous ligament. Slips to the femur or to adductor magnus may occur.

Relations Semimembranosus overlaps the popliteal vessels and is itself partly overlapped by semitendinosus throughout its extent (see Fig. 77.42). Its deep surface lies on adductor magnus. The sciatic nerve lies laterally and surprisingly close to the surface. The distal end of the muscle partially overlies the medial head of gastrocnemius before passing anteromedially to it. An important bursa lies between the semimembranosus tendon and gastrocnemius, and often communicates with the knee joint and with a smaller bursa between the tendon and the posterior tibial margin.

Vascular supply Semimembranosus is supplied from the perforating arteries, usually from all, though predominantly from the first. Sometimes the predominant artery arises from the fourth perforator. A branch of the femoral or popliteal artery supplies the distal part of the muscle, and there may be a contribution from the inferior gluteal artery at the proximal attachment.

Innervation Semimembranosus is innervated by the sciatic nerve, L5, S1 and S2, through its tibial division.

Biceps femoris

Attachments Biceps femoris (see Figs 77.43, 77.47) occupies a posterolateral position in the thigh. It has two proximal attachments. One, the long head, arises from an inferomedial impression on the upper area of the ischial tuberosity (see Fig. 77.4B), via a tendon that it shares with semitendinosus, and some superficial fibres blend with the lower part of the sacrotuberous ligament. The other, the short head, arises from the lateral lip of the linea aspera, between adductor magnus and vastus lateralis. This attachment extends proximally almost to gluteus maximus and distally along the lateral supracondylar line to within 5 cm of the lateral femoral condyle, and from the lateral intermuscular septum. The long head forms a fusiform belly that descends laterally across the sciatic nerve. The fibres end in an aponeurosis that covers the posterior surface of the muscle. This

aponeurosis receives on its deep surface the fibres of the short head, and gradually narrows to a tendon (the lateral hamstring). The main part of the tendon splits round the fibular collateral ligament and is attached to the head of the fibula. The remainder splits into three laminae. The intermediate lamina fuses with the fibular collateral ligament, while the others pass superficial and deep to the ligament to attach to the lateral condyle of the tibia.

The short head may be absent. Additional slips may arise from the ischial tuberosity, linea aspera or medial supracondylar line.

Relations Proximally, biceps femoris is covered by gluteus maximus, but elsewhere it lies relatively superficially. Deep to it lie semimembranosus proximally, and the sciatic nerve, adductor magnus and the lateral head of gastrocnemius more distally. Semitendinosus and semimembranosus lie medially. A bursa may lie between the tendon and the fibular collateral ligament. The common fibular nerve descends along the medial border of the tendon of biceps femoris, separating it distally from the lateral head of gastrocnemius.

As a guide during surgery, it is safest to find a nerve proximally and dissect it free distally. The common fibular nerve is found emerging posterior to the biceps femoris tendon, which is a useful guide to locating the nerve and avoiding iatrogenic injury. The nerve is adherent to the tendon; if part of the fibular head or the attachment of the tendon of biceps femoris, usually with the insertion of the fibular collateral ligament, is avulsed, then the tendon will exert proximal traction on the nerve, which may contribute to common fibular nerve traction injury. When the lateral meniscus is sutured arthroscopically, care must be taken that all needle passages are anterior to biceps femoris. A proximal fibular fracture may result in the nerve being trapped in the fracture line.

Vascular supply The long head of biceps femoris is supplied by the first and second perforating arteries. There are accessory supplies at the ischial attachment from the inferior gluteal and medial circumflex femoral arteries, and in the distal quarter from the superior lateral genicular artery. The short head is supplied superiorly by the second or third perforating artery and inferiorly by the superior lateral genicular artery.

Innervation Biceps femoris is innervated by the sciatic nerve, L5, S1 and S2: the long head through the tibial division and the short head through the common fibular division, a distribution that reflects the composite derivation from flexor and extensor musculature.

Actions of the hamstrings

Acting from above, the posterior thigh muscles flex the knee. Acting from below, they extend the hip joint, pulling the trunk upright from a stooping posture against the influence of gravity. When the knee is semi-flexed, biceps femoris can act as a lateral rotator and semimembranosus and semitendinosus as medial rotators of the lower leg on the thigh at the knee. As is the case with quadriceps femoris, the adductors and gluteus maximus, the hamstrings are typically quiescent in easy symmetrical standing. However, any action that takes the centre of gravity in front of a transverse axis through the hip joints, e.g. forward reaching, forward sway at the ankle joints or forward bending at the hips, is immediately accompanied by strong contraction of the hamstrings. This is in marked contrast to gluteus maximus, which contracts only when there is a call for powerful extension at the hip joint.

Often, activation of the hamstring muscles occurs in conjunction with simultaneous movements of the hip and the knee. For example, consider rising from a deep squat position by combining simultaneous extension of the hips and knees. In this example, the activated hamstrings are pulling the hips into extension, while they are simultaneously being elongated as they cross the posterior side of the extending knee. Such a biomechanical scenario (which is typical in most biarticular muscles throughout the body) helps maintain an overall muscle length that is conducive to effective force production (Neumann 2017).

When relaxed, these muscles show considerable variation in length; in some individuals, the muscles are so short as to impose a serious limitation on flexion of the trunk at the hip joints when the knees are kept extended. Movements such as stooping must then be accomplished by flexing the vertebral column or squatting. Perhaps the need for more stress on the lumbar spine accounts for the occurrence of hamstring tightness in adolescents who develop spondylolysis. These muscles are prone to tearing, which may be related to the relative complexity of muscles that cross two joints, or to the fact that they are subject to large forces being produced as the muscles are active in an eccentric fashion.

Testing The posterior thigh muscles are tested clinically by active knee flexion against resistance in the supine or prone position. In the prone position, the individual hamstring tendons can be identified more easily. When the knee is flexed against resistance, the tendon of biceps femoris can be felt lateral to the popliteal fossa. Medial to the fossa, the tendons of gracilis (which is the more medial) and semitendinosus stand out sharply. The semimembranosus tendon is just palpable in the interval between them (and also by deep pressure from a 'pincer' grip beyond their margins).

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

Common iliac and external iliac arteries and veins

The common iliac and external iliac arteries and veins are described in Chapter 71.

Gluteal vessels

The superior and inferior gluteal arteries (see Fig. 77.47) are described in Chapter 71.

Arteria comitans nervi ischiadici (artery to sciatic nerve)

The arteria comitans nervi ischiadici is a direct or indirect branch of the internal iliac artery, and runs on the surface of, or within, the sciatic nerve. It represents the primitive axial artery of the lower limb. The artery is usually a very small vessel; occasionally, it persists as a large vessel, in which case the femoral artery is correspondingly reduced in size. The artery may participate in collateral circulatory pathways.

Femoral artery

The femoral artery (see Figs 77.2, 77.43–77.44; **Fig. 77.48**) is a continuation of the external iliac artery (Benninger 2014). It begins behind the inguinal ligament, midway between the anterior superior iliac spine and the pubic symphysis, descends along the anteromedial part of the thigh in the femoral triangle, enters and passes through the adductor (subsartorial) canal, and becomes the popliteal artery as it passes through an opening in adductor magnus near the junction of the middle and distal thirds of the thigh. Its first 3 or 4 cm are enclosed, with the femoral vein, in the femoral sheath. The femoral artery gives off several branches in the proximal thigh, including the superficial epigastric, superficial circumflex iliac, superficial external pudendal, deep external pudendal and the profunda femoris artery. It gives off the descending genicular artery within the adductor canal.

Rarely, the femoral artery divides, distal to the origin of the profunda femoris artery, into two trunks that reunite near the adductor opening. The inferior gluteal artery, accompanying the sciatic nerve to the popliteal fossa and representing a persistence of the original axial artery, may replace it. The external iliac artery is then small, ending as the deep artery of the thigh.

Relations Anterior to the artery in the femoral triangle are the skin, subcutaneous tissue, superficial inguinal lymph nodes, fascia lata, femoral sheath, superficial circumflex iliac vein (crossing in the subcutaneous tissue) and the femoral branch of the genitofemoral nerve (which is at first lateral and then anterior). Near the apex of the triangle, the medial femoral cutaneous nerve crosses in front of the artery from the lateral to the medial side. Posteriorly, the posterior wall of the femoral sheath separates the artery from the tendons of psoas, pectineus and adductor longus. The artery is separated from the hip joint by the tendon of psoas major, from pectineus by the femoral vein and deep femoral vessels, and from adductor longus by the femoral vein. Proximally, the nerve to pectineus passes medially behind the artery. The femoral nerve lies lateral to the artery, outside the femoral sheath. The femoral vein is medial to the artery in the proximal part of the triangle and becomes posterior distally at the apex.

Within the adductor canal, the artery is covered by skin, subcutaneous tissue, deep fascia, sartorius and the fibrous roof (subsartorial fascia) of the canal. The saphenous nerve lies at first lateral, then anterior and finally medial to the artery. Adductor longus and adductor magnus are posterior, vastus medialis and its nerve are anterolateral, and the femoral vein is also posterior proximally but it becomes lateral distally (see Fig. 77.48; **Fig. 77.49**).

Compression of the femoral artery is most effective just distal to the inguinal ligament, where it is superficial and separated from the bone (iliopubic ramus) only by the psoas major tendon. For this reason, arterial injury proximal to the inguinal ligament, such as laceration by

a knife, cannot be controlled simply by compression. Gaining proximal control of bleeding involves major exposure of the more proximal arteries as a life-saving manoeuvre.

Branches

The branches of the femoral artery include the superficial epigastric, superficial circumflex iliac, superficial external pudendal, deep external pudendal arteries, muscular branches, the profunda femoris artery and the descending genicular artery (see Fig. 76.4).

Superficial epigastric artery

The superficial epigastric artery arises anteriorly from the femoral artery approximately 1 cm distal to the inguinal ligament, and traverses the cribriform fascia to ascend anterior to the ligament and run in the abdominal subcutaneous tissue almost to the umbilicus. It supplies the superficial inguinal lymph nodes, subcutaneous tissue and skin, and anastomoses with branches of the inferior epigastric artery and its contralateral fellow.

Superficial circumflex iliac artery

The superficial circumflex iliac artery is the smallest superficial branch of the femoral artery and arises near or with the superficial epigastric artery. It usually emerges through the fascia lata, lateral to the saphenous opening, and turns laterally distal to the inguinal ligament towards the anterior superior iliac spine. It supplies the skin, subcutaneous tissue and superficial inguinal lymph nodes, anastomosing with the deep circumflex iliac, superior gluteal and lateral circumflex femoral arteries.

The superficial circumflex iliac artery is the basis for the important axial-pattern pedicled groin skin flap. Free flaps based on the vessel may also be raised.

Superficial external pudendal artery

The superficial external pudendal artery arises medially from the femoral artery, close to the preceding branches. Emerging from the cribriform fascia, it passes medially, usually deep to the long saphenous vein, across the spermatic cord (or round ligament) to supply the lower abdominal, penile, scrotal or labial skin, and anastomoses with branches of the internal pudendal artery.

Deep external pudendal artery

The deep external pudendal artery passes medially across pectineus and anterior or posterior to adductor longus, covered by fascia lata, which it pierces to supply the skin of the perineum and scrotum or labium majus. Its branches anastomose with the posterior scrotal or labial branches of the internal pudendal artery.

Muscular branches
These branches supply sartorius, vastus medialis and the adductors.

Profunda femoris artery (deep artery of the thigh)
The profunda femoris artery (see Figs 77.40, 77.43B, 77.48–77.49) is a large branch that arises posterolaterally from the femoral artery about 3.5 cm distal to the inguinal ligament. At first lateral to the femoral artery, it spirals posterior to this and the femoral vein to reach the medial side of the femur. It passes between pectineus and adductor longus, then between the latter and adductor brevis, before it descends between adductor longus and adductor magnus. It pierces adductor magnus and anastomoses with the upper muscular branches of the popliteal artery. This terminal part is sometimes named the fourth perforating artery.

The profunda femoris artery is the main supply to the adductor, extensor and flexor muscles, and also anastomoses with the internal and external iliac arteries above and with the popliteal artery below. It is a major collateral artery of the lower limb in patients with femoropopliteal arterial occlusive disease (see Fig. 77.49) (Shakeri et al 2010).

The profunda femoris artery sometimes arises from the posterior aspect of the femoral artery, and more rarely from the medial aspect. If it arises posteriorly, it may cross anterior to the femoral vein and then pass backwards around its medial side.

Relations Posteriorly, in proximodistal order, lie iliacus, pectineus, adductor brevis and adductor magnus. Anteriorly, the femoral and deep femoral veins, and distally, adductor longus, separate the profunda femoris artery from the femoral artery. Laterally, vastus medialis separates the proximal part of the artery from the femur.

Branches The profunda femoris artery gives off the lateral and medial circumflex arteries in the proximal thigh, and perforating and muscular branches more distally.

Lateral circumflex femoral artery The lateral circumflex femoral artery (see Figs 77.48–77.49) is a laterally running branch given off near the root of the profunda femoris artery. It passes between the divisions of the femoral nerve, posterior to sartorius and rectus femoris, and divides into ascending, transverse and descending branches. The ascending branch ascends along the intertrochanteric line, under tensor fasciae latae, lateral to the hip joint. It anastomoses with the superior gluteal and deep circumflex iliac arteries, supplying the greater trochanter, and, with branches of the medial circumflex femoral, forms an anastomotic ring round the femoral neck, from which the femoral neck and head are supplied. The ascending branch forms the pedicle of the tensor fasciae latae musculocutaneous flap. The descending branch descends posterior to rectus femoris, along the anterior border of vastus lateralis, which it supplies; a long branch descends in vastus lateralis to the knee (Tayfur et al 2010), anastomosing with the superior lateral genicular branch of the popliteal artery, accompanied by the nerve to vastus lateralis. The fasciocutaneous perforators that arise from the descending branch supply the anterolateral thigh fasciocutaneous flap. The transverse branch, the smallest, passes laterally anterior to vastus intermedius and pierces vastus lateralis to wind round the femur, just distal to the greater trochanter. It anastomoses with the medial circumflex, inferior gluteal and first perforating arteries, forming a cruciate anastomosis.

The lateral circumflex femoral artery may arise from the femoral artery or as a common trunk with the profunda femoris artery and the medial circumflex femoral artery. The ascending and descending branches may occasionally arise separately (Siddharth et al 1985).

Medial circumflex femoral artery The medial circumflex femoral artery (see Figs 77.48–77.49) usually originates from the posteromedial aspect of the profunda femoris artery, but sometimes originates from the femoral artery itself or as a common trunk with either the profunda femoris artery or the lateral circumflex femoral artery or both (Siddharth et al 1985). It supplies the adductor muscles and curves medially round the femur between pectineus and psoas major and then obturator externus and adductor brevis, finally appearing between quadratus femoris and the upper border of adductor magnus, dividing into transverse and ascending branches. The transverse branch takes part in the cruciate anastomosis. The ascending branch ascends on the tendon of obturator externus, anterior to quadratus femoris, to the trochanteric fossa, where it anastomoses with branches of the gluteal and lateral circumflex femoral arteries. An acetabular branch at the proximal edge of adductor brevis enters the hip joint under the transverse acetabular ligament with one from the obturator artery. It supplies the fat in the fossa and reaches the femoral head along its ligament. For details of the blood supply of the proximal end of the femur, consult Crock (1996).

Perforating arteries The perforating arteries (see Fig. 77.40) perforate the femoral attachment of adductor magnus to reach the flexor aspect of the thigh. There are three perforating branches, and the terminal part of the profunda femoris artery itself becomes the fourth perforator. They pass close to the linea aspera under small tendinous arches and give off muscular, cutaneous and anastomotic branches. Diminished, they pass deep to the short head of biceps femoris (the first usually through the attachment of gluteus maximus), traverse the lateral intermuscular septum and enter vastus lateralis. The first arises proximal, the second anterior and the third distal to adductor brevis. The first perforating artery passes back between pectineus and adductor brevis (sometimes through the latter), pierces adductor magnus near the linea aspera to supply adductor brevis, adductor magnus, biceps femoris and gluteus maximus, and anastomoses with the inferior gluteal, medial and lateral circumflex femoral and second perforating arteries. The larger second perforating artery, often arising with the first, pierces the attachments of adductor brevis and magnus, divides into the ascending and descending branches supplying the posterior thigh muscles and anastomoses with the first and third perforating arteries. The femoral nutrient artery usually arises from it. When two nutrient arteries exist, they usually arise from the first and third perforators. The third perforating artery starts distal to adductor brevis, pierces the attachment of adductor magnus and divides into branches to the posterior thigh muscles. It anastomoses proximally with the perforating arteries, and distally with the end of the profunda femoris artery and muscular branches of the popliteal. The femoral nutrient artery may arise from it. Side branches of the diaphysial nutrient and other branches of the profunda femoris artery provide subsidiary cortical arteries.

The perforating arteries form a double chain of anastomoses, initially in the adductor muscles and subsequently near the linea aspera.

Muscular branches Numerous muscular branches arise from the profunda femoris artery. Some end in the adductors, and others pierce adductor magnus, supply the flexors and anastomose with the medial circumflex femoral artery and superior muscular branches of the popliteal artery. The profunda femoris artery is thus the main supply to the thigh muscles.

Descending genicular artery
The descending genicular artery (see Figs 77.48–77.49, 78.1), the distal branch of the femoral artery, arises just proximal to the adductor opening and immediately supplies a saphenous branch. It then descends in vastus medialis, anterior to the tendon of adductor magnus, to the medial side of the knee, where it anastomoses with the superior medial genicular artery. Muscular branches supply vastus medialis and adductor magnus, and give off articular branches that anastomose around the knee joint. One articular branch crosses above the femoral patellar surface, forming an arch with the superior lateral genicular artery and supplying the knee joint. The saphenous branch (saphenous artery) emerges distally through the roof of the adductor canal to accompany the saphenous nerve to the medial side of the knee. It passes between sartorius and gracilis, and supplies the skin of the proximomedial area of the leg; it anastomoses with the inferior medial genicular artery.

Arterial anastomoses around the hip
In the fetus, a peri-acetabular vascular circle formed by the superior and inferior gluteal, internal pudendal and obturator arteries reduces the risk of bony necrosis of this region in children. However, there is a zone at the anterior portion of the acetabulum where the blood supply is less abundant (Damsin et al 1992).

Anastomoses on the posterior aspect of the thigh
An important chain of anastomoses extends on the posterior aspect of the thigh from the gluteal region to the popliteal fossa. It is formed in proximodistal order by anastomoses between the gluteal arteries and terminal branches of the medial circumflex femoral artery; the circumflex femoral arteries and the first perforating artery; the perforating arteries themselves; and between the fourth perforating artery and the superior muscular branches of the popliteal artery (see Fig. 76.4). The trochanteric and cruciate anastomoses are the proximal elements of this chain.

Trochanteric anastomosis
The trochanteric anastomosis lies near the trochanteric fossa of the femur and is an anastomosis between the ascending branch of the medial circumflex femoral artery and descending branches of the superior and inferior gluteal arteries. The lateral circumflex femoral artery and the first perforating artery from the profunda femoris artery may also contribute, creating an extracapsular 'arterial ring of the femoral neck' (Crock 1996). Branches from this ring, the retinacular vessels,

pierce the capsule and ascend along the femoral neck to give the main blood supply to the head of the femur.

Cruciate anastomosis

The cruciate anastomosis lies at the level of the lesser trochanter, near the lower edge of the femoral attachment of quadratus femoris, and is an anastomosis between the transverse branches of the medial and lateral circumflex femoral arteries, a descending branch of the inferior gluteal artery and an ascending branch from the first perforating artery.

Collateral circulation in proximal femoral artery occlusion

After occlusion of the femoral artery proximal to the origin of the profunda femoris artery, five main anastomotic channels are available. These are between branches of the superior and inferior gluteal arteries, the medial and lateral circumflex femoral arteries and the first perforating branch of the profunda femoris artery; the obturator branch of the internal iliac artery and the medial circumflex femoral artery; the internal pudendal branch of the internal iliac artery and the superficial and deep external pudendal branches of the femoral artery; a deep circumflex iliac branch of the external iliac artery, the lateral circumflex femoral branch of the deep artery of the thigh and the superficial circumflex iliac branch of the femoral artery; and the inferior gluteal branch of the internal iliac artery and perforating branches of the profunda femoris artery.

Perforator flaps in the hip and thigh

Gluteal region

The gluteal region of the lower limb has an average of 21 perforators, which arise from three main source arteries: namely, the superior and inferior gluteal and the internal pudendal arteries (see Fig. 76.7). The flaps based on these perforators are used as free flaps for breast reconstruction and as local flaps for covering defects in the sacral and perineal region.

Hip and thigh region

The hip and thigh region has six source arteries and an average of 50 arterial perforators. The thigh can be divided into four areas: anteromedial; anterolateral and trochanteric; posteromedial; and posterolateral. The perforators that supply the anteromedial thigh are derived from the femoral artery, and those for the anterolateral thigh are derived from branches of the lateral circumflex femoral artery. Perforators that supply the skin over the posteromedial and posterolateral thigh regions are derived from the profunda femoris artery and the popliteal arteries. Skin flaps based on the superficial circumflex iliac, superficial external pudendal and superficial inferior epigastric arteries have been used as local flaps, tube pedicles and free tissue transfers. Other popular skin flaps are tensor fasciae latae (TFL) perforator flaps, anterolateral thigh (ALT) and anteromedial thigh (AMT) flaps, the gracilis perforator flap and posterior thigh flaps.

Veins

Femoral vein

The femoral vein accompanies its artery, beginning at the adductor opening as the continuation of the popliteal vein, and ending posterior to the inguinal ligament as the external iliac vein (see Figs 77.1–77.2, 77.44, 76.8). The vein is posterolateral to the femoral artery in the distal adductor canal. More proximally in the canal, and in the distal femoral triangle (i.e. at its apex), the vein lies posterior to the artery and proximally, at the base of the triangle, the vein lies medial to the artery. The vein occupies the middle compartment of the femoral sheath, between the femoral artery and femoral canal; fat in the canal permits expansion of the vein.

The femoral vein has numerous muscular tributaries. The profunda femoris vein (deep vein of the thigh, deep femoral vein) joins the femoral vein posteriorly 4–12 cm distal to the inguinal ligament, and the long saphenous vein then enters anteriorly. Veins accompanying the superficial epigastric, superficial circumflex iliac and external pudendal arteries join the long saphenous vein before it enters the saphenous opening. Lateral and medial circumflex femoral veins are usually tributaries of the femoral vein. There are usually four or five valves in the femoral vein; the two most constant are just distal to the entry of profunda femoris and near the inguinal ligament.

Profunda femoris vein (deep vein of the thigh)

The profunda femoris vein lies anterior to its artery and receives tributaries corresponding to the branches of the artery. Through these tributaries it connects distally with the popliteal vein and proximally with the inferior gluteal veins. It sometimes drains the medial and lateral circumflex femoral veins and has a valve just before it empties into the femoral vein.

Long saphenous vein

The long (great) saphenous vein (see Fig. 76.9A), the longest vein in the body, starts distally as a continuation of the medial marginal vein of the foot, and ends in the femoral vein a short distance distal to the inguinal ligament. It ascends immediately anterior to the medial malleolus, crosses the distal third of the medial surface of the tibia obliquely in an anteroposterior direction to reach its medial border, and then ascends a little behind the border to the knee. Proximally, it is posteromedial to the medial tibial and femoral condyles and then ascends the medial aspect of the thigh. It passes through the saphenous opening and finally opens into the femoral vein. The 'centre' of the opening is often said to be 2.5–3.5 cm inferolateral to the pubic tubercle, and the vein is then represented by a line drawn from this point to the adductor tubercle. However, the saphenous opening varies greatly in size and disposition so that this 'centre' is not a reliable surface marking for the saphenofemoral junction.

In its course through the thigh, the long saphenous vein is accompanied by the medial branches of the anterior cutaneous branches of the femoral nerve. At the knee, the saphenous branch of the descending genicular artery (the saphenous artery) and, in the leg and foot, the saphenous nerve all lie anterior to the vein. The vein is often duplicated, especially distal to the knee. It has 10–20 valves, which are more numerous in the leg than in the thigh. One is present just before the vein pierces the cribriform fascia, another at its junction with the femoral vein. In almost its entire extent the vein lies in subcutaneous tissue, but it has many connections with the deep veins, especially in the leg.

Tributaries

At the ankle, the long saphenous vein drains the sole of the foot by medial marginal veins. In the leg, it often connects with the short saphenous vein and with deep veins via perforating veins. Just distal to the knee, it usually receives three large tributaries from the front of the leg, the medial malleolar region (connecting with some of the 'perforating' veins) and the calf (communicating with the short saphenous vein). The tributary draining the medial malleolar region is formed distally from a fine network or 'corona' of delicate veins just over the medial malleolus, and then ascends the medial aspect of the calf as the posterior arch vein. This vein was first illustrated by Leonardo da Vinci, whose name is sometimes given to it. It connects with posterior tibial venae comitantes by a series of perforating (communicating) veins. There are usually three, equally spaced between the medial malleolus and the mid-calf. More than three such perforators are uncommon, and an arch vein perforator above mid-calf is only very rarely found.

Above the posterior crural arch vein, perforating veins join the long saphenous vein or one of its main tributaries at two main sites. The first is at a level in the upper calf indicated by its name, the tibial tubercle perforator; the second is in the lower/intermediate third of the thigh, where it perforates the deep fascia roof of the subsartorial canal to join the femoral vein.

In the thigh, the long saphenous vein receives many tributaries. Some open independently, while others converge to form large named channels that frequently pass towards the basal half of the femoral triangle before joining the long saphenous near its termination. These may be grouped as follows: one or more large posteromedial tributaries, one or more large anterolateral tributaries, and four or more peri-inguinal veins. The posteromedial vein of the thigh, large and sometimes double, drains a large superficial region indicated by its name; it has (as have the other tributaries) radiological and surgical significance. One of its lower radicles is often continuous with the short saphenous vein. The posteromedial vein is sometimes named the accessory saphenous vein, though some restrict the term accessory to a lower (more distal) posteromedial tributary when two (or more) are present. Another large vessel, the anterolateral vein of the thigh (anterior femoral cutaneous vein), usually commences from an anterior network of veins in the distal thigh and crosses the apex and distal half of the femoral triangle to reach the long saphenous vein. As the latter traverses the saphenous opening, it is joined by the superficial epigastric, superficial circumflex iliac and superficial external pudendal veins. Their mode of union varies. Superficial epigastric and circumflex iliac veins drain the inferior abdominal wall, the latter also receiving tributaries from the proximolateral region of the thigh. The superficial epigastric or the femoral vein may connect with the lateral thoracic veins by means of a thoracoepigastric vein that runs superficially on the anterolateral aspect of the trunk. This vein connects the inferior and superior caval areas of drainage and may be dilated and visible in cases of inferior caval obstruction. Superficial external pudendal veins drain part of the scrotum/labia; one is joined by the superficial dorsal

vein of the penis/clitoris. The deep external pudendal veins join the long saphenous vein at the saphenous opening.

The long saphenous vein is often harvested for grafts used in both peripheral and coronary arterial surgery.

Lymphatic drainage

Superficial inguinal nodes

The superficial inguinal nodes form proximal and distal groups. The proximal group usually consists of five or six nodes just distal to the inguinal ligament. Its lateral members receive afferent vessels from the gluteal region and the adjoining infra-umbilical anterior abdominal wall. Medial members receive superficial vessels from the external genitalia (including the inferior vagina), inferior anal canal and perianal region, adjoining abdominal wall, umbilicus and vessels accompanying the round ligament. The distal group usually consists of four or five nodes along the termination of the long saphenous vein. They receive all the superficial vessels of the lower limb, except those from the posterolateral calf. All superficial inguinal nodes drain to the external iliac nodes, some via the femoral canal and others anterior or lateral to the femoral vessels. Numerous vessels interconnect individual nodes.

Superficial inguinal nodes are frequently enlarged in disease or injury in their region of drainage. Thus the proximal inguinal nodes are almost invariably affected in malignant or infective disease of the prepuce, penis, labia majora, scrotum, perineum, anus and lower vagina, or in diseases affecting the skin and superficial structures in these regions, in the infra-umbilical part of the abdominal wall or in the gluteal region. The distal group is implicated only in disease or injury of the limb.

Deep inguinal nodes

The deep inguinal nodes vary from one to three, and are situated medial to the femoral vein. One lies just distal to the saphenofemoral junction, another in the femoral canal, and the most proximal node lies laterally in the femoral ring. The middle node is the most inconstant and the proximal node is often absent. All receive deep lymphatics that accompany the femoral vessels, lymph vessels from the glans penis or clitoris and a few efferents from the superficial inguinal nodes. Their own efferents traverse the femoral canal to the external iliac nodes.

INNERVATION

Lumbar plexus and branches

The lumbar plexus is formed by the first three and most of the fourth lumbar ventral rami (see Fig. 61.16). The iliohypogastric, ilioinguinal and genitofemoral nerves are described in Chapter 61.

Lateral femoral cutaneous nerve

The lateral femoral cutaneous nerve (lateral cutaneous nerve of the thigh) arises from the dorsal branches of the second and third lumbar ventral rami and emerges from the lateral border of psoas major, crossing iliacus obliquely towards the anterior superior iliac spine. It supplies the parietal peritoneum in the iliac fossa. The right nerve passes posterolateral to the caecum, separated from it by the iliac fascia and peritoneum; the left passes behind the lower part of the descending colon. Both pass behind or through the inguinal ligament, variably medial to the anterior superior iliac spine (commonly 1 cm) and anterior to or through sartorius into the thigh, where they divide into anterior and posterior branches. The anterior branch becomes superficial approximately 10 cm distal to the anterior superior iliac spine and supplies the skin of the anterior and lateral thigh as far distally as the knee. It connects terminally with the cutaneous branches of the anterior division of the femoral nerve and the infrapatellar branch of the saphenous nerve, forming the peripatellar plexus. The posterior branch pierces the fascia lata higher than the anterior, and divides to supply the skin on the lateral surface from the greater trochanter to about mid-thigh. It may also supply skin of the gluteal region.

Lesions of the lateral femoral cutaneous nerve

The lateral femoral cutaneous nerve may become entrapped at three sites along its course: close to the vertebral column; within the abdominal cavity as the nerve travels across the pelvis; and as it leaves the pelvis. This last site is where the nerve is most commonly damaged, and entrapment is thought to occur as the nerve passes through or deep to the inguinal ligament just medial to the anterior superior iliac spine. The angulation of the nerve as it crosses the iliac crest means that it is vulnerable to compression during movement, e.g. hip extension may increase angulation and tension on the nerve.

Injury produces an area of impaired sensation, often with pain and paraesthesia on the anterolateral aspect of the thigh (meralgia paraesthetica) in the distal cutaneous distribution of the nerve. This area does not extend across the midline anteriorly, it does not extend below the knee and it does not extend behind the hamstring tendons laterally. Symptoms may be exacerbated when wearing tight belts or tight-waisted clothes or as a result of a recent weight gain or pregnancy. Exceptionally, the posterior branch of the lateral femoral cutaneous nerve, which supplies a thin strip from the greater trochanter of the femur down about two-thirds of the way to the knee, may be affected separately. This branch leaves the main trunk of the nerve, usually distal to the inguinal ligament, and it then turns laterally to pierce tensor fasciae latae, where it may become entrapped.

Femoral nerve

The femoral nerve is the largest branch of the lumbar plexus and arises from the dorsal branches (posterior divisions) of the second to fourth lumbar ventral rami (see Figs 77.44, 77.48–77.49, 76.11A). It descends through psoas major, emerging low on its lateral border, and then passes between psoas and iliacus, deep to the iliac fascia. Passing behind the inguinal ligament into the thigh, it is split into anterior and posterior divisions by the lateral circumflex femoral artery. Behind the inguinal ligament, it is separated from the femoral artery by part of psoas major. In the abdomen, the nerve supplies small branches to iliacus and pectineus and a branch to the proximal part of the femoral artery; the latter branch sometimes arises in the thigh.

Nerve to pectineus

The nerve to pectineus branches from the medial side of the femoral nerve near the inguinal ligament. It passes behind the femoral sheath and enters the anterior aspect of the muscle.

Anterior division of the femoral nerve

The anterior division of the femoral nerve supplies intermediate and medial femoral cutaneous nerves and branches to sartorius.

Medial femoral cutaneous nerve of the thigh The medial femoral cutaneous nerve (medial cutaneous nerve of the thigh) is at first lateral to the femoral artery. It crosses anterior to the artery at the apex of the femoral triangle and divides into anterior and posterior branches. Before doing so, it sends a few fibres through the fascia lata to supply the skin of the medial side of the thigh, near the long saphenous vein; one branch emerges via the saphenous opening, while another becomes subcutaneous about mid-thigh. The anterior branch descends on sartorius, perforates the fascia lata beyond mid-thigh, and divides into a branch that supplies the skin as low as the medial side of the knee, and another that runs lateral to the former and connects with the infrapatellar branch of the saphenous nerve. The posterior branch descends along the posterior border of sartorius to the knee, pierces the fascia lata, connects with the saphenous nerve and gives off several cutaneous rami, some as far as the medial side of the leg. The nerve contributes to the subsartorial plexus (see below).

Intermediate cutaneous nerve of the thigh The intermediate femoral cutaneous nerve (intermediate cutaneous nerve of the thigh) usually pierces the fascia lata some 8 cm below the inguinal ligament, either as two branches or as one trunk that quickly divides into two. These descend on the front of the thigh, supplying the skin as far as the knee and ending in the peripatellar plexus. The lateral branch of the intermediate cutaneous nerve communicates with the femoral branch of the genitofemoral nerve, frequently piercing sartorius and sometimes supplying it.

Nerve to sartorius The main nerve to sartorius arises from the femoral nerve in common with the intermediate cutaneous nerve of the thigh.

Posterior division of the femoral nerve

The branches of the posterior division of the femoral nerve are the saphenous nerve and branches to quadriceps femoris and the knee joint.

Saphenous nerve See Chapter 78.

Muscular branches The muscular branches of the posterior division of the femoral nerve supply quadriceps femoris. A branch to rectus femoris

enters its proximal posterior surface and also supplies the hip joint. A larger branch to vastus lateralis forms a neurovascular bundle with the descending branch of the lateral circumflex femoral artery in its distal part and also supplies the knee joint. A branch to vastus medialis descends through the proximal part of the adductor canal, lateral to the saphenous nerve and femoral vessels, and enters the muscle at about its midpoint, sending a long articular filament distally along the muscle to the knee. Two or three branches to vastus intermedius enter its anterior surface about mid-thigh; a small branch from one of these descends through the muscle to supply articularis genus and the knee joint.

Vascular branches

Vascular branches of the femoral nerve supply the femoral artery and its branches.

Lesions of the femoral nerve

The main trunk of the femoral nerve is not subject to an entrapment neuropathy, but it may be compressed by retroperitoneal tumours or retroperitoneal haemorrhage in patients on anticoagulants or with a bleeding diathesis. A localized lesion of the femoral nerve may occur in diabetes mellitus (one of the forms of diabetic amyotrophy). The most striking feature of femoral neuropathy is wasting and weakness of quadriceps femoris, which results in difficulty in walking and a tendency for the leg to collapse. Pain and paraesthesia may occur on the anterior and medial aspect of the thigh, extending down the medial aspect of the leg in the distribution of the saphenous branch of the femoral nerve.

Obturator nerve

The obturator nerve arises from the ventral branches of the second to fourth lumbar ventral rami. The branch from the third is the largest while that from the second is often very small. The nerve descends in psoas major, emerging from its medial border at the pelvic brim to pass behind the common iliac vessels and lateral to the internal iliac vessels. It then descends forwards along the lateral wall of the lesser pelvis on obturator internus, anterosuperior to the obturator vessels, to the obturator foramen, entering the thigh by its upper part. Near the foramen, it divides into anterior and posterior branches, separated at first by part of obturator externus and lower down by adductor brevis.

Anterior branch

The anterior branch (see Fig. 77.49) leaves the pelvis anterior to obturator externus, descending in front of adductor brevis, behind pectineus and adductor longus. At the lower border of adductor longus it communicates with the medial cutaneous and saphenous branches of the femoral nerve, to form a subsartorial plexus that supplies the skin on the medial side of the thigh (see below). It descends on, and supplies, the femoral artery. Near the obturator foramen, the anterior branch supplies the hip joint. Behind pectineus it supplies adductor longus, gracilis, usually adductor brevis and often pectineus, and connects with the accessory obturator nerve (when present). Occasionally, the communicating branch to the femoral medial cutaneous and saphenous branches continues as a cutaneous branch to the thigh and leg. When this occurs, the nerve emerges from behind the distal border of adductor longus to descend along the posterior margin of sartorius to the knee, where it pierces the deep fascia and connects with the saphenous nerve to supply the skin halfway down the medial side of the leg.

Subsartorial nerve plexus The medial cutaneous nerve of the thigh forms a subsartorial plexus with branches of the saphenous and obturator nerves, deep to the fascia lata, at the lower border of adductor longus. When the communicating branch of the obturator nerve is large and reaches the leg, the posterior branch of the medial cutaneous nerve is small, and ends in the plexus from which it gives rise to a few cutaneous filaments.

Posterior branch

The posterior branch pierces obturator externus anteriorly, supplies it and passes behind adductor brevis to the front of adductor magnus, dividing into branches to this and adductor brevis when the latter is not supplied by the anterior division. It usually sends an articular filament to the knee joint, which either perforates adductor magnus distally or traverses its opening with the femoral artery to enter the popliteal fossa. Within the fossa, the nerve descends on the popliteal artery to the back of the knee, pierces its oblique posterior ligament and supplies the articular capsule. It gives filaments to the popliteal artery.

Lesions of the obturator nerve

Isolated lesions of the obturator nerve are rare, but may occasionally occur as a result of direct trauma (sometimes during parturition) or in anterior dislocations of the hip. The nerve may also be damaged by an obturator hernia, or be involved together with the femoral nerve in retroperitoneal lesions that occur close to the origins of the lumbar plexus. Compression of the nerve by herniated bowel loops at the obturator foramen can result in pain referred to the hip, medial thigh and knee, the so-called Howship–Romberg sign. A more distal nerve entrapment syndrome causing chronic medial thigh pain has been described in athletes with large adductor muscles.

Accessory obturator nerve

Occasionally present, the accessory obturator nerve is small and arises from the ventral branches of the third and fourth lumbar ventral rami. It descends along the medial border of psoas major, crosses the superior pubic ramus behind pectineus and divides into branches; one branch enters the deep surface of pectineus, another supplies the hip joint, and a third connects with the anterior branch of the obturator nerve. Sometimes the accessory obturator nerve is very small and only supplies pectineus. Any branch may be absent and others may occur; an additional branch sometimes supplies adductor longus.

Sacral plexus and branches

The branches of the sacral plexus (see Fig. 76.11B) are shown in **Table 77.1**.

Sciatic nerve

The sciatic nerve is 2 cm wide at its origin and is the thickest nerve in the body. It leaves the pelvis via the greater sciatic foramen, usually below piriformis, and descends between the greater trochanter and ischial tuberosity, along the back of the thigh, dividing into the tibial and common fibular nerves at a varying level proximal to the knee (**Fig. 77.50**; see Fig. 76.11B). Superiorly, it lies deep to gluteus maximus, resting first on the posterior ischial surface with the nerve to quadratus femoris between them. It then crosses posterior to obturator internus, the gemelli and quadratus femoris, separated by the latter from obturator externus and the hip joint. It is accompanied medially by the posterior femoral cutaneous nerve and the inferior gluteal artery. More distally, it lies behind adductor magnus and is crossed posteriorly by the long head of biceps femoris. Its course corresponds to a line drawn from just medial to the midpoint between the ischial tuberosity and greater trochanter to the apex of the popliteal fossa.

Articular branches arise proximally to supply the hip joint through its posterior capsule; these are sometimes derived directly from the sacral plexus. Muscular branches are distributed to biceps femoris, semitendinosus, semimembranosus and the ischial part of adductor magnus.

The point of division of the sciatic nerve into its tibial and common fibular components is very variable. The common site is at the junction of the middle and lower thirds of the thigh, near the apex of the popliteal fossa, but the division may occur at any level above this point and, rarely, may occur below it (Beaton and Anson 1937).

Blood supply to the sciatic nerve

In the gluteal region, the sciatic nerve is supplied by the inferior gluteal artery and cruciate anastomosis (the medial and lateral circumflex femoral arteries, inferior gluteal artery and the first perforating branch of the profunda femoris artery) (see Figs 77.40A, 77.47). On rare

TABLE 77.1 The branches of the sacral plexus

	Ventral divisions	Dorsal divisions
Nerve to quadratus femoris and gemellus inferior	L4–S1	
Nerve to obturator internus and gemellus superior	L5–S2	
Nerve to piriformis		L4–S2
Superior gluteal		L4–S1
Inferior gluteal		L5–S2
Posterior femoral cutaneous	S2, S3	S1, S2
Tibial (sciatic)	L4–S3	
Common fibular (sciatic)		L4–S2
Perforating cutaneous		S2, S3
Pudendal	S2–S4	
Branches to levator ani, coccygeus and external anal sphincter	S4	

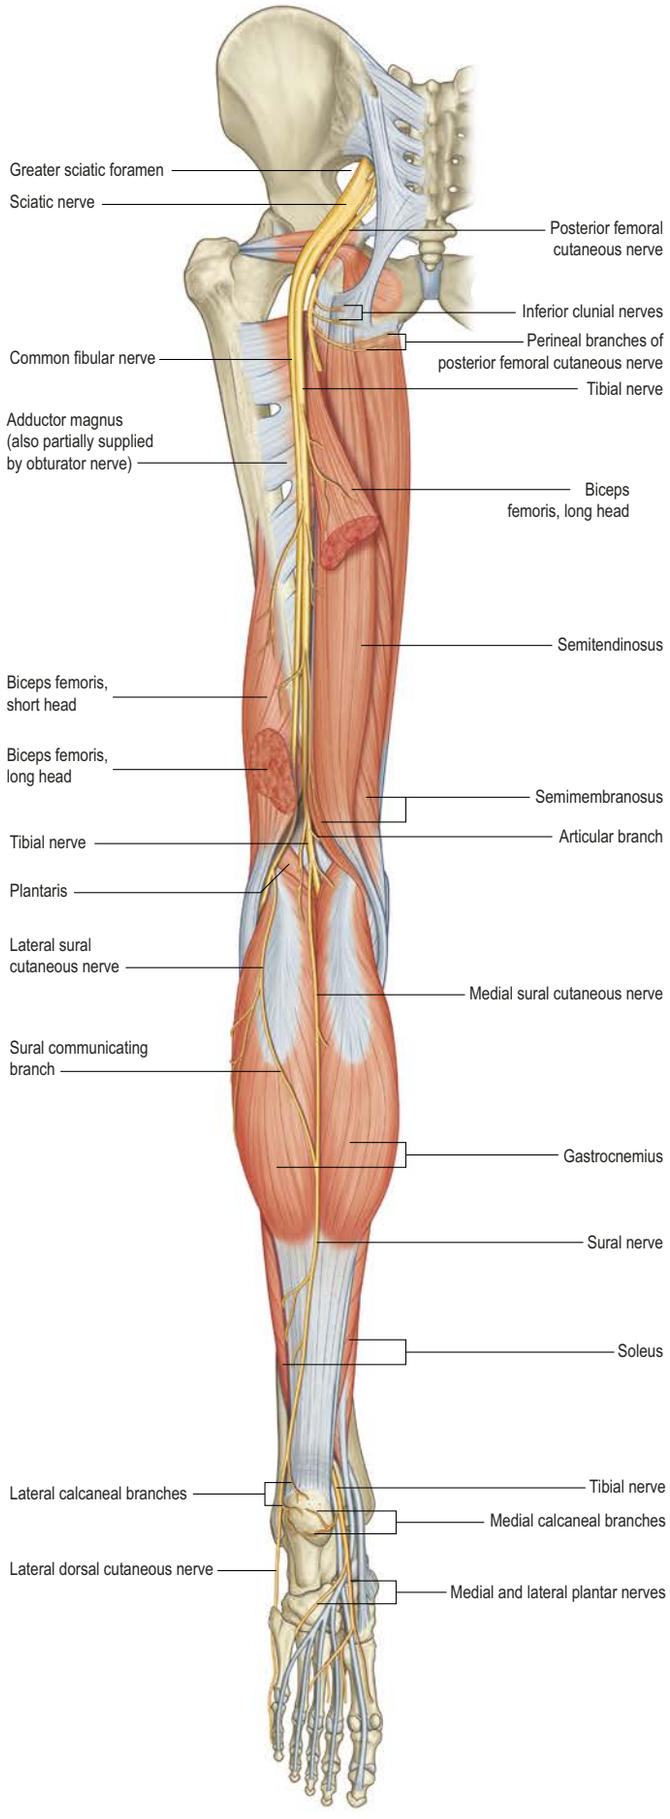

Fig. 77.50 The sciatic nerve and its branches, posterior view.

occasions, it is supplied by branches from the superior gluteal or internal pudendal arteries, which reach the nerve on its medial side. Lower in the thigh, arterial branches derived from the perforating branches of the profunda femoris artery or the anastomotic chain between them or, occasionally, from the popliteal artery, enter the nerve on its lateral or anterolateral side (Sunderland 1945). The numerous arterial branches to the sciatic nerve anastomose with each other to form extraneural and intraneural arterial chains (Sunderland 1945, Ugrenovic et al 2013).

Lesions of the sciatic nerve

The sciatic nerve supplies the posterior thigh muscles and all the muscles below the knee, which means that a complete palsy of the sciatic nerve results in a flail foot and severe difficulty in walking. Fortunately, complete sciatic nerve palsy is very rare. The nerve is vulnerable in posterior dislocation of the hip. As it leaves the pelvis, it passes either below piriformis or sometimes through the muscle, and at that point it may very rarely become entrapped or tethered; the piriformis syndrome is a controversial condition in which an anomalous relationship between piriformis and the sciatic nerve is thought to cause pain in the buttocks and along the course of the sciatic nerve. External compression over the buttock, e.g. in patients who lie immobile on a hard surface for a considerable length of time, can injure the nerve. However, the most common cause of serious sciatic nerve injury (and of the resulting major medicolegal claims) is iatrogenic (Dillow et al 2013). The nerve may be damaged in misplaced therapeutic injections into gluteus maximus. Sciatic nerve palsy occurs after total hip replacement or similar surgery in 1% of cases, and may be caused by sharp injury, burning from bone cement, traction from instruments, manipulation of the hip, inadvertent lengthening of the femur, or haematoma surrounding the nerve. For some reason, possibly anatomical, the common fibular component of the sciatic nerve is more usually affected, resulting in a foot drop and a high-stepping gait.

Inferior gluteal nerve

The inferior gluteal nerve arises from the dorsal branches of the fifth lumbar and first and second sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, and divides into branches that enter the deep surface of gluteus maximus (see Fig. 77.47).

Superior gluteal nerve

The superior gluteal nerve arises from the dorsal branches of the fourth and fifth lumbar and first sacral ventral rami. Accompanied by the superior gluteal vessels, the nerve leaves the pelvis via the greater sciatic foramen above piriformis, and divides into superior and inferior branches (see Fig. 77.47). The superior branch accompanies the upper branch of the deep division of the superior gluteal artery to supply gluteus medius and occasionally gluteus minimus. The inferior branch runs with the lower ramus of the deep division of the superior gluteal artery across gluteus minimus, supplies the glutei medius and minimus, and ends in tensor fasciae latae.

Pudendal nerve

See Fig. 61.16 and Chapter 61.

Perforating cutaneous nerve

The perforating cutaneous nerve usually arises from the posterior aspects of the second and third sacral ventral spinal rami. It pierces the sacrotuberous ligament, curves round the inferior border of gluteus maximus and supplies the skin over the inferomedial aspect of this muscle. The nerve may arise from the pudendal nerve or it may be absent, in which case it may be replaced either by a branch from the posterior femoral cutaneous nerve or from the third and fourth, or fourth and fifth, sacral ventral rami.

Nerve to quadratus femoris

The nerve to quadratus femoris arises from the ventral branches of the fourth lumbar to the first sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, descends on the ischium deep to the sciatic nerve, the gemelli and the tendon of obturator internus, and supplies gemellus inferior, quadratus femoris and the hip joint.

Nerve to obturator internus

The nerve to obturator internus arises from the ventral branches of the fifth lumbar and first and second sacral ventral rami. It leaves the pelvis

via the greater sciatic foramen below piriformis, supplies a branch to the upper posterior surface of gemellus superior, crosses the ischial spine lateral to the internal pudendal vessels, re-enters the pelvis via the lesser sciatic foramen, and enters the pelvic surface of obturator internus.

Posterior femoral cutaneous nerve (posterior cutaneous nerve of the thigh)

The posterior femoral cutaneous nerve (posterior cutaneous nerve of the thigh) arises from the dorsal branches of the first and second, and the ventral branches of the second and third sacral rami. It leaves the pelvis via the greater sciatic foramen below piriformis and descends under gluteus maximus with the inferior gluteal vessels, lying posterior or medial to the sciatic nerve (see Fig. 77.47). It descends in the back of the thigh superficial to the long head of biceps femoris, deep to the fascia lata. It pierces the deep fascia behind the knee and accompanies the short saphenous vein to mid-calf, its terminal twigs connecting with the sural nerve. Its branches are cutaneous and are distributed to the gluteal region, perineum, posterior thigh and proximal posterior leg.

Three or four gluteal branches (inferior clunial nerves) curl round the lower border of gluteus maximus to supply the skin over the inferolateral portion of the muscle. The perineal branch supplies the superomedial skin in the thigh, curves forwards across the hamstrings below the ischial tuberosity, pierces the fascia lata and then runs in the superficial perineal fascia to the scrotal or labial skin. It communicates with the inferior rectal and posterior scrotal or labial branches of the perineal nerve, and gives numerous branches to the skin of the back and medial side of the thigh, the popliteal fossa and the proximal part of the back of the leg. One study found the perineal branch of the posterior cutaneous nerve of the thigh in about one-half of specimens (Tubbs et al 2009).

Nerve to piriformis

The nerve to piriformis usually arises from the dorsal branches of the first and second sacral ventral rami (sometimes only the second) and enters the anterior surface of piriformis.

Visceral and pelvic muscular branches of sacral plexus

Visceral and muscular branches of the sacral plexus are described in Chapter 71.

CHAPTER 78

Knee and leg

The knee is the largest synovial joint in the body. It consists of three functional compartments that collectively form a dynamic, specialized hinge joint. During gait, the knee is able to withstand impressive weight-bearing loads while conducting precision movements, providing a stable yet fluid mechanism for relatively efficient bipedal locomotion. The complex arrangement of intra- and extracapsular ligaments that helps to counter the considerable biomechanical demands that are imposed on the joint can also be involved in disease (i.e. tri-compartment disease). The leg consists of two bones, with an interosseous membrane between them: the larger tibia, which transmits most of the stress of walking, and the smaller fibula, which provides secondary support and ankle stability. Muscles of the three compartments of the leg primarily permit movement of the ankle, foot and toes.

SKIN AND SOFT TISSUES

Skin

Vascular supply and lymphatic drainage

Knee

The arterial supply of the skin covering the knee is derived from genicular branches of the popliteal artery, the descending genicular branch of the femoral artery and the anterior recurrent branch of the anterior tibial artery, with small contributions from muscular branches to vastus medialis and the posterior thigh muscles (Fig. 78.1). For further details, consult Cormack and Lamberty (1994).

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic drainage is initially to the superficial inguinal nodes, possibly also to the popliteal nodes, and then to the deep inguinal nodes.

Leg

The cutaneous arterial supply of the leg is derived from branches of the popliteal, anterior and posterior tibial and fibular vessels (see Fig. 76.5). Multiple fasciocutaneous perforating branches from each vessel pass along intermuscular septa to reach the skin; musculocutaneous perforators traverse muscles before reaching the skin. In some areas there is an additional, direct cutaneous supply from vessels that accompany cutaneous nerves, e.g. the descending genicular artery (saphenous artery) and superficial sural arteries. Fasciocutaneous and direct cutaneous arterial branches are oriented longitudinally in the skin, whereas the musculocutaneous branches are more radially oriented. For further details, consult Cormack and Lamberty (1994).

Cutaneous veins are tributaries of vessels that correspond to the named arteries. Cutaneous lymphatic vessels running on the medial side of the leg accompany the long saphenous vein and drain to the superficial inguinal nodes, and those from the lateral and posterior

sides of the leg accompany the short saphenous vein and pierce the deep fascia to drain into the popliteal nodes.

Innervation

Leg

The skin of the leg is supplied by branches of the saphenous, posterior femoral cutaneous, common fibular and tibial nerves (see p. 1391 and Figs 76.11–76.12, 76.20–76.21).

Infrapatellar branch of the saphenous nerve

The infrapatellar branch of the saphenous nerve reaches the anterior aspect of the knee from the medial side. It is invariably divided in medial surgical approaches to the knee, which accounts for the numbness that inevitably occurs following such procedures. A painful neuroma may form if the nerve is partially sectioned, e.g. by the incision for an arthroscopy portal or a small medial arthrotomy. The position of the nerve relative to the line of the joint is variable. In most cases, it crosses just below the joint line, passing over the patellar ligament at its insertion on to the tibia. For further details, see Tennant et al (1998).

Peripatellar plexus

Proximal to the knee, the infrapatellar branch of the saphenous nerve connects with branches of the medial and intermediate femoral cutaneous nerves, and lateral femoral cutaneous nerve. Distal to the knee, it connects with other branches of the saphenous nerve. This fine, subcutaneous network of communicating nerve fibres over and around the patella is termed the peripatellar plexus.

Soft tissues

Popliteal fossa

The popliteal fossa (**Figs 78.2–78.3**) is a diamond-shaped region posterior to the knee, bordered by muscles in the posterior compartment of the thigh and leg. The boundaries are biceps femoris proximolaterally; semimembranosus and the overlying semitendinosus proximomedially; the lateral head of gastrocnemius with the underlying plantaris distolaterally; and the medial head of gastrocnemius distomedially. The

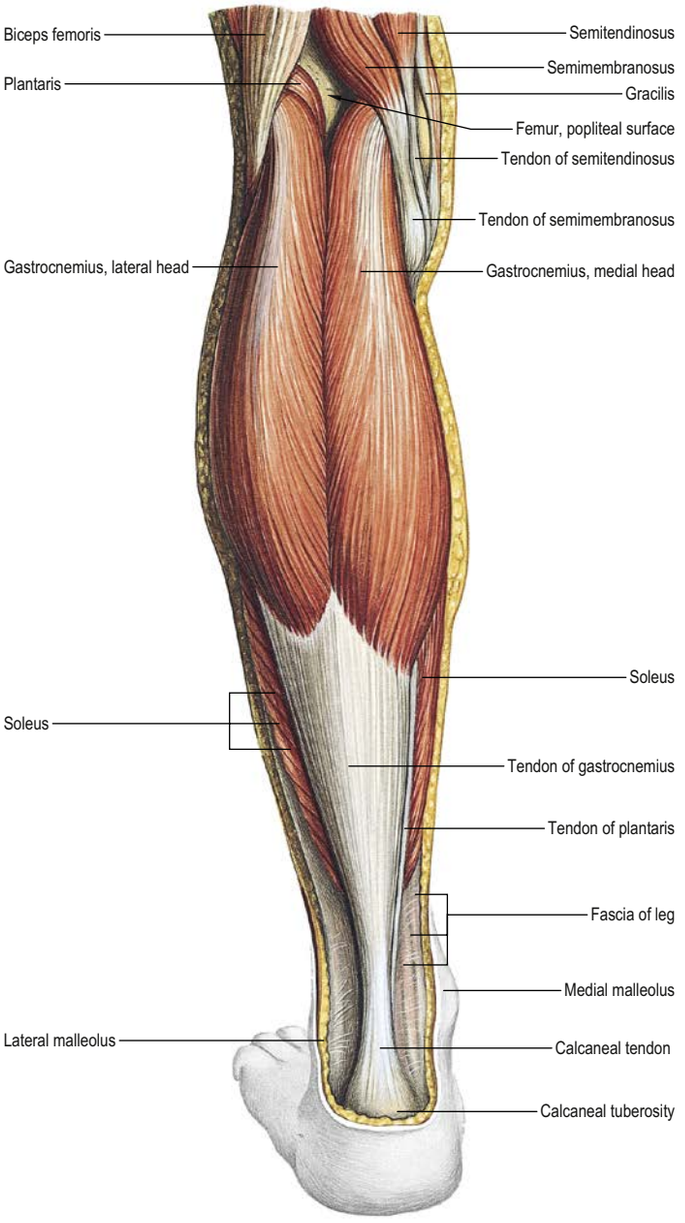

Fig. 78.3 Muscles of the calf, superficial view including the boundaries of the popliteal fossa. (With permission from Waschke J, Paulsen F (eds) Sobotta Atlas of Human Anatomy, 15th ed. Elsevier, Urban & Fischer. Copyright 2013.)

anterior boundary (or floor) of the fossa is formed, in proximodistal sequence, by the popliteal surface of the femur, the oblique popliteal ligament (overlying the posterior surface of the capsule of the knee joint), and the posterior aspect of the proximal tibia covered by popliteus and its fascia. The deep fascia (fascia musculorum) acts as the roof of the fossa and is continuous with the fascia lata proximally and with the deep fascia of the leg distally. It is a dense layer that is strongly reinforced by transverse fibres and is often perforated by the short saphenous vein and medial and lateral sural cutaneous nerves; these structures are useful landmarks in the direct posterior approach to the knee joint.

The popliteal fossa is approximately 2.5 cm wide. Distally, its contents are protected and hidden by the heads of gastrocnemius, which contact each other. The fossa contains the popliteal vessels (see Fig. 78.2; **Fig. 78.4**), tibial and common fibular nerves, short saphenous vein, medial and lateral sural cutaneous nerves, posterior femoral cutaneous nerve, articular branch of the obturator nerve, lymph nodes, fat and a variable number of bursae. The tibial nerve descends centrally immediately anterior to the deep fascia, crossing the vessels posteriorly from lateral to medial. The common fibular nerve descends laterally immediately medial to the tendon of biceps femoris. When the popliteal vessels enter the proximal region of the popliteal fossa, they maintain a side-by-side relationship, which shifts to an over–under relationship as they descend through the fossa and are held together by

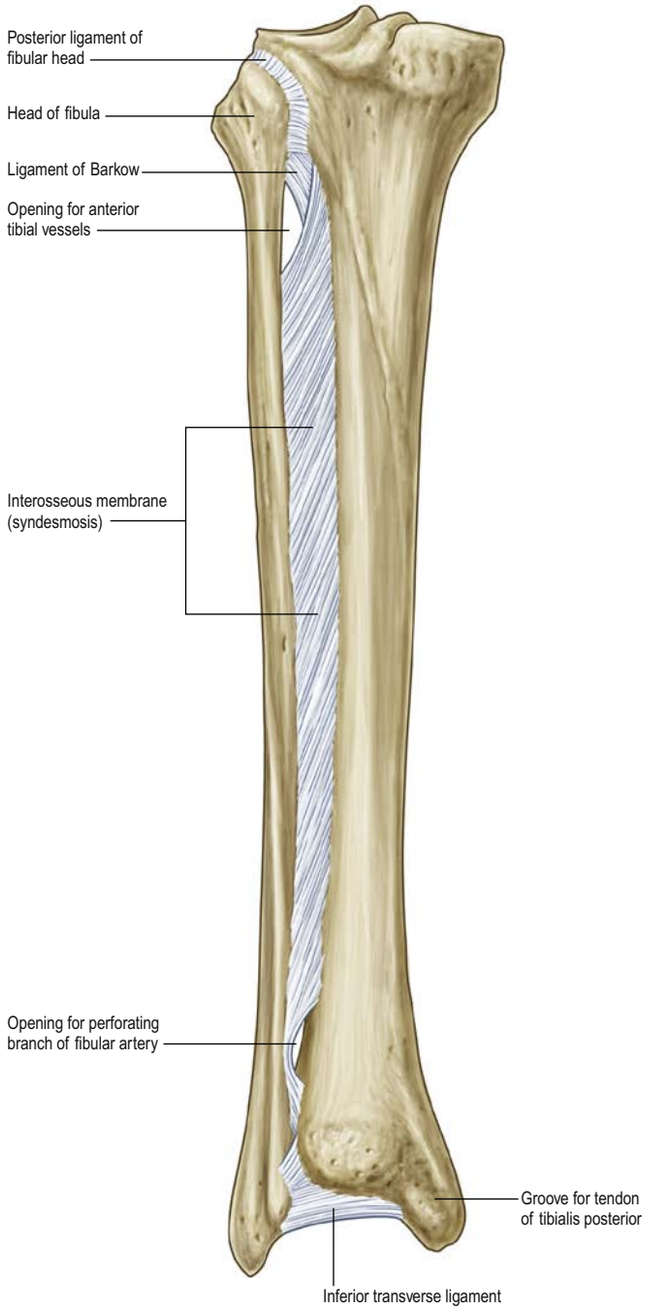

Fig. 78.5 The posterior aspect of the interosseous membrane. Note the contrasting direction of the fibre bundles around the vascular openings.

dense areolar tissue within the fossa. This may potentially compromise the popliteal artery in distal femoral fractures. The popliteal vein is generally located posterior to the artery. Proximally, the vein lies lateral to the artery, crossing to its medial side distally. At times, the popliteal vein may be duplicated, so that the artery lies between the veins, which are usually bridged by connecting channels. An articular branch from the obturator nerve descends along the artery to the knee. Six or seven popliteal nodes are embedded in the fat, one under the deep fascia near the termination of the short saphenous vein, one between the popliteal artery and knee joint, and the others intimate with the popliteal vessels.

Deep fascia

The deep fascia of the leg is continuous with the fascia lata and is attached around the knee to the patellar margin, the patellar ligament, the tuberosity and condyles of the tibia, and the head of the fibula. Posteriorly, it covers the popliteal fossa as the popliteal fascia. It receives lateral expansions from the tendon of biceps femoris and multiple medial expansions from the tendons of sartorius, gracilis, semitendinosus and semimembranosus. The deep fascia blends with the periosteum on the subcutaneous surface of the tibia and the subcutaneous surfaces of the fibular head and lateral malleolus, and is continuous below with the extensor and flexor retinacula. It is thick and dense in the proximal and anterior part of the leg, where fibres of tibialis anterior and extensor digitorum longus are attached to its deep surface, and is thinner posteriorly, where it covers gastrocnemius and soleus. On the lateral side, it is continuous with the anterior and posterior intermuscular septa of the leg, which are attached to the anterior and posterior borders of the fibula, respectively.

Transverse intermuscular septum

The transverse intermuscular septum of the leg is a fibrous stratum between the superficial and deep muscles of the calf. It extends transversely from the medial margin of the tibia to the posterior border of the fibula. Proximally, where it is thick and dense, it is attached to the soleal ridge of the tibia and to the fibula, inferomedial to the fibular attachment of soleus. Between these bony attachments, it is continuous with the fascia covering popliteus, which is, in effect, an expansion from the tendon of semimembranosus. At intermediate levels it is thin but distally, where it covers the tendons behind the malleoli, it is thick and continuous with the flexor and superior fibular retinacula.

Interosseous membrane

The interosseous membrane connects the interosseous borders of the tibia and fibula (Fig. 78.5). It is interposed between the anterior and posterior groups of crural muscles; some members of each group are

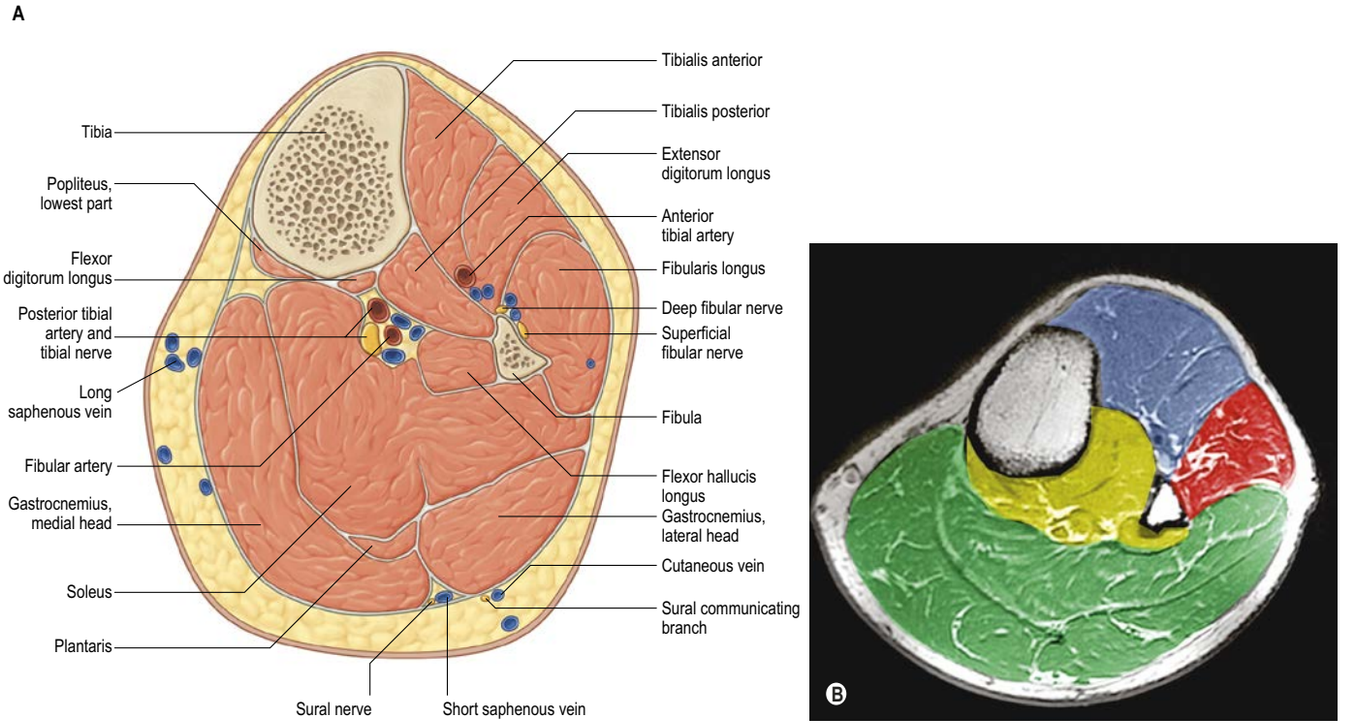

Fig. 78.6 A, A transverse (axial) section through the left leg, approximately 10 cm distal to the knee joint. **B,** A colour-coded axial magnetic resonance image (MRI) of the leg. attached to the corresponding surface of the interosseous membrane. The anterior tibial artery passes forwards through a large oval opening near the proximal end of the membrane, and the perforating branch of the fibular artery pierces it distally. An associated ligament (ligament of Barkow), in the same plane as the interosseous membrane, may be found uniting the proximal tibiofibular joint; when present, it forms the upper half of this oval opening (see Fig. 78.5) (Tubbs et al 2009). Its fibres are predominantly oblique and most descend laterally; those that descend medially include a bundle at the proximal border of the proximal opening. The thickness of the interosseous membrane differs between its thin centre and thick tibial and fibular borders. The membrane is continuous distally with the interosseous ligament of the distal tibiofibular joint.

Retinacula

The retinacula at the ankle joint are described in Chapter 79.

Compartments of the leg

The compartments of the leg are particularly well defined and are the most common sites at which osteofascial compartment syndromes occur. The three main compartments are anterior (extensor), lateral (fibular) and posterior (flexor) (**Fig. 78.6**). The posterior compartment is divided into deep and superficial parts by the transverse intermuscular septum. These compartments are enclosed by the unyielding deep fascia and separated from each other by the bones of the leg and interosseous membrane, and by the anterior and posterior intermuscular septa that pass from the deep fascia to the fibula. The anterior compartment, the least expansile of the three, is bounded by the deep fascia, the interosseous surfaces of the tibia and fibula, the interosseous membrane and the anterior intermuscular septum. The lateral compartment lies between the anterior and posterior intermuscular septa, and is bordered laterally by the deep fascia and medially by the lateral surface of the fibula. The posterior compartment is bounded by the deep fascia, the posterior intermuscular septum, the fibula and tibia, and the interosseous membrane. Its relatively expansile superficial component is separated from the compacted deep component by the transverse intermuscular septum, reinforced by the deep aponeurosis of soleus. Knowledge of the compartmental anatomy of the leg is important in planning the treatment of compartment syndromes and for soft tissue tumour resections of the leg.

The nerve supply of the muscles in the compartments follows the 'one compartment – one nerve' principle: the deep fibular nerve supplies the anterior compartment, the superficial fibular nerve supplies the lateral compartment and the tibial nerve supplies the posterior compartment. Magnetic resonance imaging (MRI) is the best imaging modality for evaluating the soft tissues of the leg. Most of the muscle in the anterior compartment is supplied by the anterior tibial artery, with an additional contribution from the fibular artery to extensor hallucis longus. The muscles of the posterior compartment are supplied by the popliteal, posterior tibial and fibular arteries. The muscles of the lateral compartment are supplied by the anterior tibial and fibular arteries, and to a lesser extent proximally, by a branch from the popliteal artery.

Trauma and soft tissues of the leg

Available with the *Gray's Anatomy* e-book

BONES

The relevant bones are the femur (described in Chapter 77), tibia, fibula and patella.

Tibia

The tibia lies medial to the fibula and is exceeded in length only by the femur (**Figs 78.7–78.8**). The tibial shaft is triangular in section and has expanded ends; a strong medial malleolus projects distally from the smaller distal end. The anterior border of the shaft is sharp and curves medially towards the medial malleolus. Together with the medial and lateral borders, it defines the three surfaces of the bone. The exact shape and orientation of these surfaces show individual and racial variations. In children, the mean tibial length is greater in males than in females (Oeffinger et al 2010).

Proximal end

The expanded proximal end bears the weight transmitted through the femur. It consists of medial and lateral condyles, an intercondylar area and the tibial tuberosity.

Condyles The tibial condyles overhang the proximal part of the posterior surface of the shaft. Both condyles have articular facets on their superior surfaces, separated by an irregular, non-articular intercondylar area. The condyles are visible and palpable at the sides of the patellar ligament, the lateral being more prominent. In the passively flexed knee, the anterior margins of the condyles are palpable in depressions that flank the patellar ligament.

The relative paucity of soft tissue in the shin region and the subcutaneous position of the medial surface of the tibia means that even trivial soft tissue injury may lead to serious problems such as ulceration and osteomyelitis. In the elderly these soft tissues are often especially thin and unhealthy, reflecting the effects of ageing and venous stasis (see p. 1427). Tibial fractures are common in the young and, partly as a result of poor soft tissue coverage, they are often open injuries. Diminished blood supply to the bone, caused by traumatic stripping of attached soft tissues, and the risk of contamination add greatly to the risk of non-union and infection of the fracture. Healing of fractures at the junction of the middle and lower thirds of the tibia is compromised by the relatively poor blood supply to this region. Injury to the leg may result in elevated pressures of one or more compartments (so-called compartment syndrome); this clinical scenario is manifested by the 'six Ps': pain, paraesthesiae, pallor, paralysis, pulselessness and poikilothermia (differing temperatures in the affected and unaffected limbs).

The fibular articular facet on the posteroinferior aspect of the lateral condyle faces distally and posterolaterally. The angle of inclination of the superior tibiofibular joint varies between individuals, and may be horizontal or oblique. Superomedial to it, the condyle is grooved on its posterolateral aspect by the tendon of popliteus; a synovial recess intervenes between the tendon and bone. The anterolateral aspect of the condyle is separated from the lateral surface of the shaft by a sharp margin for the attachment of deep fascia. The distal attachment of the iliotibial tract makes a flat and usually definite marking (Gerdy's tubercle) on its anterior aspect. This tubercle, which is triangular and facet-like, is usually palpable through the skin.

The anterior condylar surfaces are continuous with a large triangular area whose apex is distal and formed by the tibial tuberosity. The lateral edge is a sharp ridge between the lateral condyle and lateral surface of the shaft.

Tibial tuberosity The tibial tuberosity is the truncated apex of a triangular area where the anterior condylar surfaces merge. It projects only a little, and is divided into distal rough and proximal smooth regions. The distal region is palpable and is separated from skin by the subcutaneous infrapatellar bursa. A line across the tibial tuberosity marks the distal limit of the proximal tibial growth plate (see Fig. 78.7). The patellar ligament is attached to the smooth bone proximal to this, its superficial fibres reaching a rough area distal to the line. The deep infrapatellar bursa and fibro-adipose tissue intervene between the bone and tendon proximal to its site of attachment. The latter may be marked distally by a somewhat oblique ridge, on to which the lateral fibres of the patellar ligament are inserted more distally than the medial fibres. This knowledge is necessary for avoiding damage to this structure when performing an osteotomy just above the tibial tuberosity in a lateral to medial direction. In habitual squatters, a vertical groove on the anterior surface of the lateral condyle is occupied by the lateral edge of the patellar ligament in full flexion of the knee.

Shaft

The shaft is triangular in section and has (antero)medial, lateral and posterior surfaces separated by anterior, lateral (interosseous) and medial borders. It is narrowest at the junction of the middle and distal thirds, and expands gradually towards both ends. The anterior border descends

from the tuberosity to the anterior margin of the medial malleolus and is subcutaneous throughout. Except in its distal quarter, where it is indistinct, it is a sharp crest. It is slightly sinuous, and turns medially in the distal quarter. The interosseous border begins distal and anterior to the fibular articular facet and descends to the anterior border of the fibular notch; it is indistinct proximally. The interosseous membrane is attached to most of its length, connecting the tibia to the fibula. The medial border descends from the anterior end of the groove on the medial condyle to the posterior margin of the medial malleolus. Its proximal and distal quarters are ill defined but its central region is sharp and distinct.

The anteromedial surface, between the anterior and medial borders, is broad, smooth and almost entirely subcutaneous. The lateral surface, between the anterior and interosseous borders, is also broad and smooth. It faces laterally in its proximal three-quarters and is transversely concave. Its distal quarter bends to face anterolaterally, on account of the medial deviation of the anterior and distal interosseous borders. This part of the surface is somewhat convex. The posterior surface, between the interosseous and medial borders, is widest above, where it is crossed distally and medially by an oblique, rough soleal line. A faint vertical line descends from the centre of the soleal line for a short distance before becoming indistinct. A large vascular groove adjoins the end of the line and descends distally into a nutrient foramen. Deep fascia and, proximal to the medial malleolus, the medial end of the superior extensor retinaculum are attached to the anterior border. Posterior fibres of the tibial collateral ligament and slips of semimembranosus and the popliteal fascia are attached to the medial border proximal to the soleal line, and some fibres of soleus and the fascia covering the deep calf muscles are attached distal to the line. The distal medial border runs into the medial lip of a groove for the tendon of tibialis posterior. The interosseous membrane is attached to the lateral border, except at either end of this border. It is indistinct proximally where a large gap in the membrane transmits the anterior tibial vessels. Distally, the border is continuous with the anterior margin of the fibular notch, to which the anterior tibiofibular ligament is attached.

The anterior part of the tibial collateral ligament is attached to an area approximately 5 cm long and 1 cm wide near the medial border of the proximal medial surface. The remaining medial surface is subcutaneous and crossed obliquely by the long saphenous vein. Tibialis anterior is attached to the proximal two-thirds of the lateral surface. The distal third, devoid of attachments, is crossed in mediolateral order by the tendons of tibialis anterior (lying just lateral to the anterior border), extensor hallucis longus, the anterior tibial vessels and deep fibular nerve, extensor digitorum longus and fibularis tertius.

On the posterior surface, popliteus is attached to a triangular area proximal to the soleal line, except near the fibular articular facet. The popliteal aponeurosis, soleus and its fascia, and the transverse intermuscular septum are all attached to the soleal line; the proximal end of the line does not reach the interosseous border, and is marked by a tubercle for the medial end of the tendinous arch of soleus. Lateral to the tubercle, the posterior tibial vessels and tibial nerve descend on tibialis posterior. Distal to the soleal line, a vertical line separates the attachments of flexor digitorum longus and tibialis posterior. Nothing is attached to the distal quarter of this surface, but the area is crossed medially by the tendon of tibialis posterior travelling to a groove on the posterior aspect of the medial malleolus. Flexor digitorum longus crosses obliquely behind tibialis posterior; the posterior tibial vessels and nerve and flexor hallucis longus contact only the lateral part of the distal posterior surface.

Distal end

The slightly expanded distal end of the tibia has anterior, medial, posterior, lateral and distal surfaces. It projects inferomedially as the medial malleolus. The distal end of the tibia, when compared to the proximal end, is laterally rotated (tibial torsion). The torsion begins to develop *in utero* and progresses throughout childhood, mainly during the first four years of life (Kristiansen et al 2001), until skeletal maturity is attained. Some of the femoral neck anteversion seen in the newborn may persist in adult females: this causes the femoral shaft and knee to be medially rotated, which may lead the tibia to develop a compensatory external torsion to counteract the tendency of the feet to turn inwards. Tibial torsion is approximately 30° in Caucasian and Asian populations, but is significantly greater in Africans (Eckhoff et al 1994).

The smooth anterior surface projects beyond the distal surface, from which it is separated by a narrow groove. The capsule of the ankle joint is attached to an anterior groove near the articular surface. The medial surface is smooth and continuous above and below with the medial surfaces of the shaft and medial malleolus, respectively; it is subcutaneous and visible. The posterior surface is smooth except where it is crossed near its medial end by a nearly vertical but slightly oblique groove, which is usually conspicuous and extends to the posterior surface of the malleolus. The groove is adapted to the tendon of tibialis posterior, which usually separates the tendon of flexor digitorum longus from the bone. More laterally, the posterior tibial vessels, tibial nerve and flexor hallucis longus contact this surface. The lateral surface is the triangular fibular notch; its anterior and posterior edges project and converge proximally to the interosseous border. The floor of the notch is roughened proximally by a substantial interosseous ligament but is smooth distally and is sometimes covered by articular cartilage. The anterior and posterior tibiofibular ligaments are attached to the corresponding edges of the notch. The distal surface articulates with the talus and is wider in front, concave sagittally and slightly convex transversely, i.e. saddle-shaped. Medially, it continues into the malleolar articular surface, which may extend into the groove that separates it from the anterior surface of the shaft. Such extensions, medial or lateral or both, are squatting facets, and they articulate with reciprocal talar facets in extreme dorsiflexion. These features have been used in the field of forensic medicine to identify the race of skeletal material.

Medial malleolus The short, thick medial malleolus has a smooth lateral surface with a crescentic facet that articulates with the medial surface of the talus. Its anterior aspect is rough and its posterior aspect features the continuation of the groove from the posterior surface of the tibial shaft for the tendon of tibialis posterior. The distal border is pointed anteriorly, posteriorly depressed and gives attachment to the deltoid ligament. The tip of the medial malleolus does not project as far distally as the tip of the lateral malleolus, the latter also being the more posteriorly located of the two malleoli. The capsule of the ankle joint is attached to the anterior surface of the medial malleolus, and the flexor retinaculum is attached to its prominent posterior border.

Muscle attachments

The patellar ligament is attached to the proximal half of the tibial tuberosity. Semimembranosus is attached to the distal edge of the groove on the posterior surface of the medial condyle; a tubercle at the lateral end of the groove is the main attachment of the tendon of this muscle. Slips from the tendon of biceps femoris are attached to the lateral tibial condyle anteroproximal to the fibular articular facet (see Fig. 78.7B). Proximal fibres of extensor digitorum longus and (occasionally) fibularis longus are attached distal to this area. Slips of semimembranosus are attached to the medial border of the shaft posteriorly, proximal to the soleal line. Some fibres of soleus attach to the posteromedial surface distal to the line. Semimembranosus is attached to the medial surface proximally, near the medial border, behind the attachment of the anterior part of the tibial collateral ligament. Anterior to this area (in anteroposterior sequence) are the linear attachments of the tendons of sartorius, gracilis and semitendinosus; these rarely mark the bone. Tibialis anterior is attached to the proximal two-thirds of the lateral (extensor) surface. Popliteus is attached to the posterior surface in a triangular area proximal to the soleal line, except near the fibular articular facet (see Fig. 78.8B). Soleus and its associated fascia are attached to the soleal line itself. Flexor digitorum longus and tibialis posterior are attached to the posterior surface distal to the soleal line, medial and lateral, respectively, to the vertical line (see above).

Vascular supply

The proximal end of the tibia is supplied by metaphysial arteries from the genicular anastomosis. The nutrient foramen usually lies near the soleal line and transmits a branch of the posterior tibial artery; the nutrient vessel may also arise at the level of the popliteal bifurcation or as a branch from the anterior tibial artery. On entering the bone, the nutrient artery divides into ascending and descending branches. The periosteal supply to the shaft arises from the anterior tibial artery and from muscular branches. The distal metaphysis is supplied by branches from the arterial anastomosis around the ankle.

Innervation

The proximal and distal ends of the tibia are innervated by branches from the nerves that supply the knee joint and ankle joint, respectively. The periosteum of the shaft is supplied by branches from the nerves that innervate the muscles attached to the tibia.

Ossification

The tibia ossifies from three centres: one in the shaft and one in each epiphysis. Ossification (**Fig. 78.9**) begins in mid-shaft during stages 21–23 (50–58 days post fertilization). The proximal epiphysial centre is usually present at birth: at approximately 10 years, a thin anterior process from the centre descends to form the smooth part of the tibial tuberosity. A separate centre for the tuberosity may appear at about the

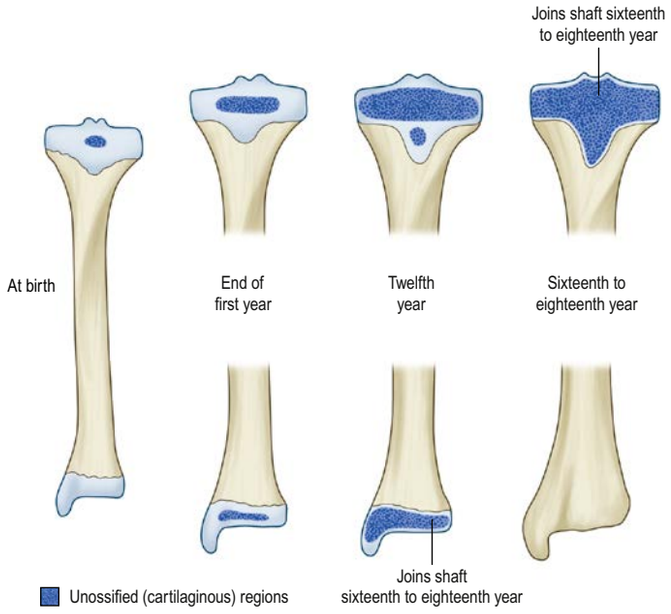

Fig. 78.9 Stages in the ossification of the tibia (not to scale).

twelfth year and soon fuses with the epiphysis. Distal strata of the epiphysial plate are composed of dense collagenous tissue in which the fibres are aligned with the patellar ligament. Exaggerated traction stresses may account for Osgood–Schlatter disease, in which fragmentation of the epiphysis of the tibial tuberosity occurs during adolescence and produces a painful swelling around it. Healing occurs once the growth plate fuses, leaving a bony protrusion. Prolonged periods of traction with the knee extended, both in children and adolescents, can lead to growth arrest of the anterior part of the proximal epiphysis, which results in bowing of the proximal tibia as the posterior tibia continues to grow. The proximal epiphysis fuses in the sixteenth year in females and the eighteenth in males. The distal epiphysial centre appears early in the first year and joins the shaft at about the fifteenth year in females and the seventeenth in males. The medial malleolus is an extension from the distal epiphysis and starts to ossify in the seventh year; it may have its own separate ossification centre. An accessory ossification centre sometimes appears at the tip of the medial malleolus, more often in females than in males. It fuses during the eighth year in females and the ninth year in males; it should not be confused with an os subtibiale, which is a rare accessory bone found on the posterior aspect of the medial malleolus. The average growth rate of the distal tibia decreases from a plateau of about 11 years of age in boys and 10 years of age in girls (Kärrholm et al 1984).

Fibula

The fibula (see Figs 78.7–78.8) is much more slender than the tibia and is not directly involved in transmission of weight. It has a proximal head, a narrow neck, a long shaft and a distal lateral malleolus. The shaft varies in form, being variably moulded by attached muscles; these variations may be confusing.

Head

The head of the fibula is irregular in shape and projects anteriorly, posteriorly and laterally. A round facet on its proximomedial aspect articulates with a corresponding facet on the inferolateral surface of the lateral tibial condyle. It faces proximally and anteromedially, and has an inclination that may vary among individuals from almost horizontal to an angle of up to 45°. A blunt apex projects proximally from the posterolateral aspect of the head and is often palpable approximately 2 cm distal to the knee joint. The fibular collateral ligament is attached in front of the apex, embraced by the main attachment of biceps femoris. The tibiofibular joint capsule is attached to the margins of the articular facet. The common fibular nerve crosses posterolateral to the neck and can be rolled against the underlying bone at this location.

Shaft

The shaft has three borders and surfaces, each associated with a particular group of muscles. The anterior border ascends proximally from the apex of an elongated triangular area that is continuous with the lateral malleolar surface, to the anterior aspect of the fibular head. The posterior border, continuous with the medial margin of the posterior groove on the lateral malleolus, is usually distinct distally but often rounded in its proximal half. The interosseous border is medial to the anterior border and somewhat posterior. Over the proximal two-thirds of the fibular shaft the two borders approach each other, with the surface between the two being narrowed to 1 mm or less.

The lateral surface, between the anterior and posterior borders and associated with the fibular muscles, faces laterally in its proximal three-quarters. The distal quarter spirals posterolaterally to become continuous with the posterior groove of the lateral malleolus. The anteromedial (sometimes simply termed anterior, or medial) surface, between the anterior and interosseous borders, usually faces anteromedially but often directly anteriorly. It is associated with the extensor muscles. Though wide distally, it narrows in its proximal half and may become a mere ridge. The posterior surface, between the interosseous and posterior borders, is the largest and is associated with the flexor muscles. Its proximal two-thirds are divided by a longitudinal medial crest, separated from the interosseous border by a grooved surface that is directed medially. The remaining surface faces posteriorly in its proximal half; its distal half curves on to the medial aspect. Distally, this area occupies the fibular notch of the tibia, which is roughened by the attachment of the principal interosseous tibiofibular ligament. The triangular area proximal to the lateral surface of the lateral malleolus is subcutaneous; muscles cover the rest of the shaft.

The anterior border is divided distally into two ridges that enclose a triangular subcutaneous surface. The anterior intermuscular septum is attached to its proximal three-quarters. The lateral end of the superior extensor retinaculum is attached distally on the anterior border of the triangular area and the lateral end of the superior fibular retinaculum is attached distally on the posterior margin of the triangular area. The interosseous border ends at the proximal limit of the rough area for the interosseous ligament. The interosseous membrane attached to this border does not reach the fibular head, which leaves a gap through which the anterior tibial vessels pass. The posterior border is proximally indistinct, and the posterior intermuscular septum is attached to all but its distal end. The medial crest is related to the fibular artery. A layer of deep fascia separating the tendon of tibialis posterior from flexor hallucis longus and flexor digitorum longus is attached to the medial crest.

Lateral malleolus

The distal end of the fibula forms the lateral malleolus, which projects distally and posteriorly (see Figs 78.7–78.8). Its lateral aspect is subcutaneous while its posterior aspect has a broad groove with a prominent lateral border. Its anterior aspect is rough, round and continuous with the tibial inferior border. The medial surface has a triangular articular facet, vertically convex, its apex distal, which articulates with the lateral talar surface. Behind this facet is a rough malleolar fossa pitted by vascular foramina. The posterior tibiofibular ligament and, more distally, the posterior talofibular ligament, are attached in the fossa. The anterior talofibular ligament is attached to the anterior surface of the lateral malleolus; the calcaneofibular ligament is attached to the notch anterior to its apex. The tendons of fibularis brevis and longus groove its posterior aspect; the latter is superficial and covered by the superior fibular retinaculum.

Muscle attachments

The main attachments of biceps femoris embrace the fibular collateral ligament in front of the apex of the fibular head. Extensor digitorum longus is attached to the head anteriorly, fibularis longus anterolaterally, and soleus posteriorly. Extensor digitorum longus, extensor hallucis longus and fibularis tertius are attached to the anteromedial (extensor) surface. Fibularis longus is attached to the whole width of the lateral (fibular) surface in its proximal third, but in its middle third only to its posterior part, behind fibularis brevis. The latter continues its attachment almost to the distal end of the shaft.

Muscle attachments to the posterior surface, which is divided longitudinally by the medial crest, are complex. Between the crest and interosseous border, the posterior surface is concave. Tibialis posterior is attached throughout the proximal three-quarters of this area, and an intramuscular tendon may ridge the bone obliquely. Soleus is attached between the crest and the posterior border on the proximal quarter of the posterior surface and its tendinous arch is attached to the surface proximally (see Fig. 78.8B). Flexor hallucis longus is attached distal to soleus on the posterior surface and almost reaches the distal end of the shaft.

Vascular supply

A little proximal to the midpoint of the posterior surface (14–19 cm from the apex), a distally directed nutrient foramen on the fibular shaft

receives a branch of the fibular artery. An appreciation of the detailed anatomy of the fibular artery in relation to the fibula is fundamental to the raising of osteofasciocutaneous free flaps. Free vascularized diaphysial grafts may also be taken on a fibular arterial pedicle. The proximal and distal ends receive metaphysial vessels from the arterial anastomoses at the knee and ankle, respectively (Taylor and Razaboni 1994).

Innervation

The proximal and distal ends of the bone are supplied by branches of nerves that innervate the knee and superior tibiofibular joint, and the ankle and inferior tibiofibular joints, respectively. The periosteum of the shaft is supplied by branches from the nerves that innervate the muscles attached to the fibula.

Ossification

The fibula ossifies from three centres: one each for the shaft and the extremities. The process begins in the shaft during stage 23 (approximately 53–58 days post fertilization); in the distal end in the first year; and in the proximal end at about the third year in females and the fourth year in males. The distal epiphysis unites with the shaft at about the fifteenth year in females and the seventeenth year in males, whereas the proximal epiphysis does not unite until about the seventeenth year in females and the nineteenth year in males. A longitudinal radiographic study of children has shown that the proximal growth plate of the fibula contributes more to growth than the proximal growth plate of the tibia, their growth contributions being 61% and 57%, respectively (Pritchett and Bortel 1997).

Patella

The patella is the largest sesamoid bone in the body (**Figs 78.10–78.11**) and is embedded in the tendon of quadriceps femoris, lying anterior to the distal femur (femoral condyles). It is flat, distally tapered and proximally curved, and has anterior and articular surfaces, three borders and an apex, which is the distal end of the bone. Most surfaces and borders are palpable. With the knee in extension, the apex is positioned proximal to the line of the knee joint by 1–2 cm.

The subcutaneous, convex anterior surface is perforated by numerous nutrient vessels. It is longitudinally ridged, separated from the skin by the subcutaneous prepatellar bursa, and covered by an expansion from the tendon of quadriceps femoris, which blends distally with superficial fibres of the patellar ligament (inaccurately named because this structure is the continuation of the tendon of quadriceps femoris). The posterior surface has a proximal smooth, oval articular area, crossed by a smooth vertical ridge, which fits the intercondylar groove on the femoral patellar surface and divides the patellar articular area into medial and lateral facets; the lateral is usually larger. Each facet is divided by faint horizontal lines into approximately equal thirds. A seventh 'odd' facet is present as a narrow strip along the medial border of the patella; it contacts the medial femoral condyle in extreme knee flexion. Distal to the articular surface, the apex is roughened by the attachment of the patellar ligament. Proximal to this, the area between the roughened apex and the articular margin is covered by an infrapatellar fat pad. The patellar articular cartilage is the thickest in the body, reflecting the magnitude of the stresses to which it is subjected.

The thick superior border (surface) of the patella slopes anteroinferiorly. Its medial and lateral borders are thinner and converge distally; the expansions of the tendons of vasti medialis and lateralis (medial and lateral patellar retinacula, respectively) are attached to them. The lateral retinaculum receives contributions from the iliotibial tract. Ossification occasionally extends from the lateral margin of the patella into the tendon of vastus lateralis.

The shape of the patella can vary and certain configurations are associated with patellar instability. Not infrequently, a bipartite and, less commonly, a tripartite patella are seen on imaging (Oohashi et al 2010). The bone seems to be in separate parts, usually with a smaller superolateral fragment: this has long been attributed to the presence of a separate ossification centre but, in some cases, could represent failed union following either a stress fracture or a violent contraction of quadriceps femoris (e.g. landing on the feet after jumping from a substantial height) resulting in a traumatic fracture.

Structure The patella consists of more or less uniformly dense trabecular bone, covered by a thin compact lamina. Trabeculae beneath the anterior surface are parallel to the surface; elsewhere, they radiate from the articular surface into the substance of the bone.

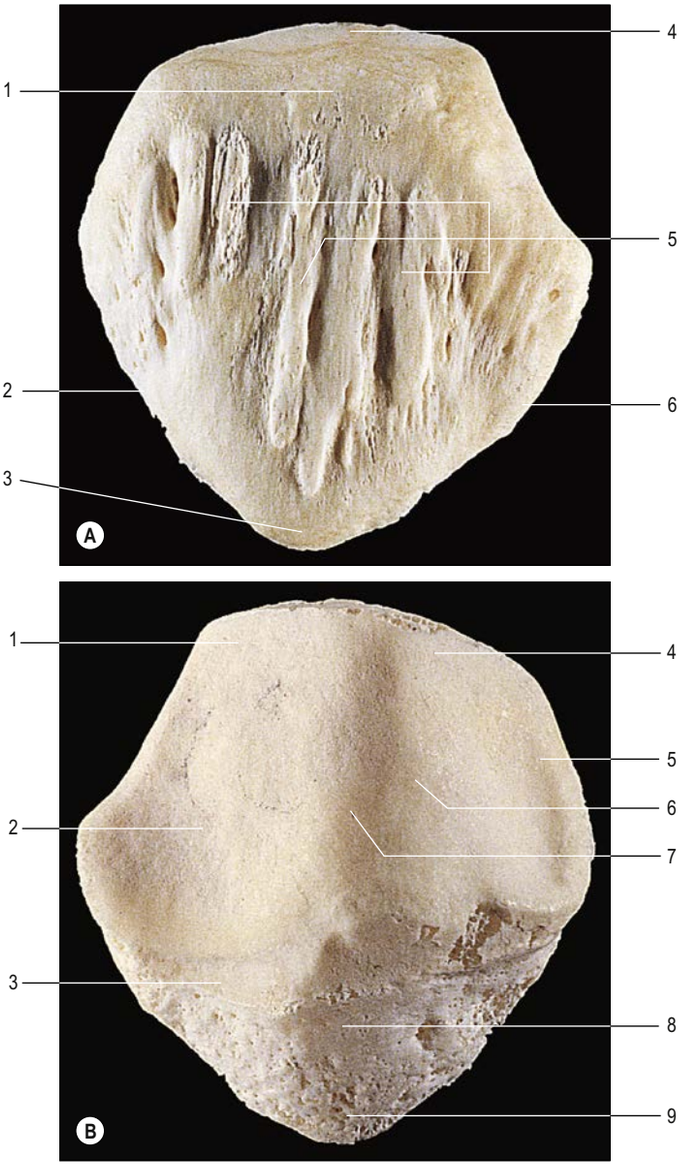

Fig. 78.10 The left patella, showing sites of muscular and soft tissue attachment and articular surfaces. **A**, Anterior aspect. Key: 1, area of attachment of rectus femoris; 2, medial border: attachment of medial retinaculum (expansion); 3, apex; 4, area of attachment of vastus intermedius; 5, markings of attachment of tendon of quadriceps femoris; 6, lateral border, for attachment of lateral retinaculum (expansion). **B**, Articular (posterior) surface. Key: 1, upper lateral facet: in contact with femur in flexion of the knee; 2, lower lateral facet: in contact with femur in extension of the knee; 3, area overlain by edge of circumferential fat pad; 4, upper medial facet: in contact with femur in flexion of the knee; 5, medial vertical ('odd') facet: in contact with femur in extreme flexion of the knee; 6, lower medial facet: in contact with femur in extension of the knee; 7, ridge; 8, area covered by infrapatellar fat pad; 9, area for attachment of patellar ligament.

Muscle attachments Quadriceps femoris is attached to the superior surface, except near its posterior margin; the attachment extends distally on to the anterior surface. The attachment for rectus femoris is anteroinferior to that for vastus intermedius. Rough markings can be traced in continuity around the periphery of the bone from the anterosuperior surface to the deep surface of the apex. Those at the lateral and medial borders represent the attachments of vasti lateralis and medialis, and those at the apex represent the attachment of the patellar ligament.

Vascular supply The arterial supply of the patella is derived from the genicular anastomosis, particularly from the genicular branches of the popliteal artery and from the anterior tibial recurrent artery. An anatomical study in children and fetuses confirmed that this network is already well developed in these age groups (Hamel et al 2012).

Ossification Several centres appear during the third to sixth years and these coalesce rapidly. Accessory marginal centres appear later and fuse with the central mass.

An os subfibulare is an occasional and separate entity and lies posterior to the tip of the fibula, whereas the distal fibular apophysis lies anteriorly. An os retinaculi is rarely encountered; if present, it overlies the bursa of the distal fibula within the fibular retinaculum.

Fibular dimelia is characterized by duplication of the fibula, tibial aplasia and partial duplication of the foot with pre-axial mirror polydactyly, and may be associated with ulnar dimelia and calcaneal duplication. It resembles duplication of the zone of polarizing activity that defines the postaxial border, but along the preaxial limb border of the limb (Ch. 19) (Bayram et al 1996, Ganey et al 2000, Verghese et al 2007).

JOINTS

Superior tibiofibular joint

The superior (proximal) tibiofibular joint is a synovial joint (plane variety) between the lateral tibial condyle and head of the fibula.

Articulating surfaces The articulating surfaces vary in size, form and inclination. The joint line may be transverse or oblique (in the latter case, the joint surfaces are inclined at an angle of greater than 20°). The fibular facet is usually elliptical or circular, and almost flat or slightly grooved. The surfaces are covered with hyaline cartilage. The volume of articular cartilage peaks at Tanner stage 2; boys gain articular cartilage faster than girls. The rate of cartilaginous volume development is +233 µl/year for the patella, +350 µl/year for the medial tibial compartment and +256 µl/year for the lateral tibial compartment (Jones et al 2003).

Fibrous capsule The capsule is attached to the margins of the articular surfaces of the tibia and fibula, and is thickened anteriorly and posteriorly.

Ligaments The ligaments of the superior tibiofibular joint are not entirely separate from the capsule. The anterior ligament is made up of two or three flat bands, which pass obliquely up from the fibular head to the front of the lateral tibial condyle in close relation to the tendon of biceps femoris. The posterior ligament is a thick band that ascends obliquely between the posterior aspect of the fibular head and the lateral tibial condyle, covered by the popliteal tendon.

Synovial membrane The synovial membrane of the superior tibiofibular joint is occasionally continuous with that of the knee joint via the subpopliteal recess.

Vascular supply and lymphatic drainage The superior tibiofibular joint receives an arterial supply from the anterior and posterior tibial recurrent branches of the anterior tibial artery. Lymphatics follow the arteries and drain to the popliteal nodes.

Innervation The superior tibiofibular joint is innervated by branches from the deep fibular nerve and from the nerve to popliteus.

Factors maintaining stability Stability of the superior tibiofibular joint is maintained by the fibrous capsule and the anterior and posterior ligaments, assisted by the biceps femoris tendon and the interosseous membrane of the leg.

Movements Very little movement other than limited gliding takes place at the superior tibiofibular joint. Some movement must occur in conjunction with movement at the inferior tibiofibular joint; however, surgical fusion (arthrodesis) of the superior tibiofibular joint seems to have no effect on movements of the ankle joint.

Relations The common fibular nerve runs posterior to the head of the fibula, medial to the tendon of biceps femoris, which is closely associated with the anterior capsule. The anterior and posterior tibial branches of the popliteal artery, and the fibular artery are all vulnerable inferomedial to the joint.

Patellofemoral joint

The patellofemoral joint is a synovial joint and is part of the knee joint.

Articulating surfaces The articular surface of the patella is adapted to that of the femur. The latter extends on to the anterior surfaces of both femoral condyles like an inverted U. Since the whole area is concave transversely and convex in the sagittal plane, it is an asymmetric sellar surface. The 'odd' facet on the articular surface of the patella contacts the anterolateral aspect of the medial femoral condyle in full flexion, when the highest lateral patellar facet contacts the anterior part of the lateral femoral condyle. As the knee extends, the middle patellar facets contact the lower half of the femoral surface; in full extension, only the lowest patellar facets are in contact with the femur. In summary, on flexion, the patellofemoral contact point moves proximally and the contact area broadens to cope with the increasing stress that accompanies progressive knee flexion.

Fibrous capsule See page 1407.

Ligaments The patellar ligament is an essential component of the extensor mechanism of the knee. The key medial structures involved in

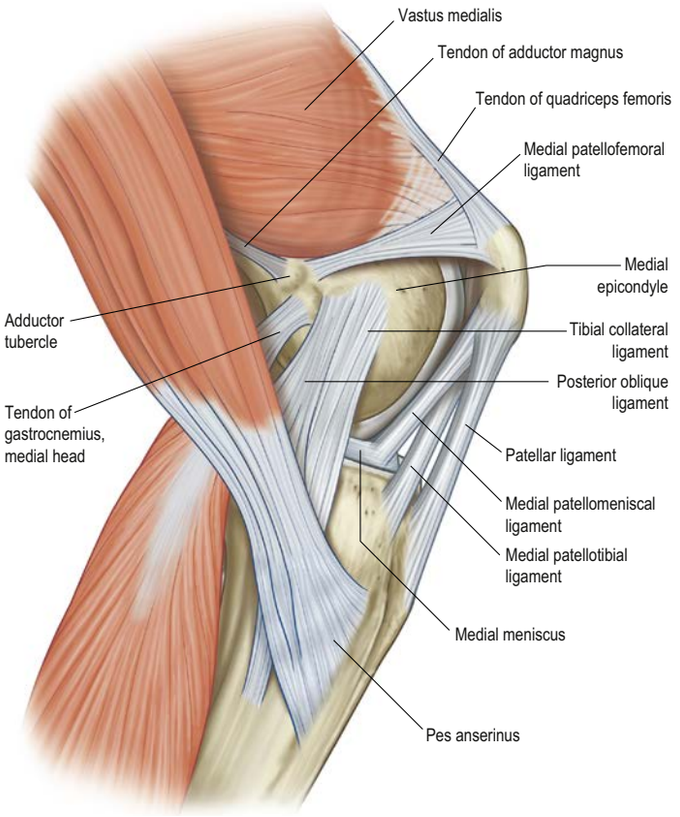

Fig. 78.12 Insertions of the medial patellar ligaments on the femur, patella tibia, and medial meniscus in a left knee (compare with Fig. 78.19).

patellofemoral joint stabilization are the medial patellofemoral, patellotibial and medial patellomeniscal ligaments (**Fig. 78.12**).

Patellar ligament sheath and patellar ligament The patellar ligament is a continuation of the tendon of quadriceps femoris and therefore is a misnomer. It continues from the patella to the tibial tuberosity (see Figs 77.44 and 77.46). It is strong, flat and 6–8 cm in length. Proximally, it is attached to the apex of the patella and adjoining margins, to roughened areas on the anterior surface and to a depression on the distal posterior patellar surface. Distally, it is attached to the superior smooth area of the tibial tuberosity. This attachment is oblique, and is more distal laterally. Its superficial fibres are continuous over the patella with the tendon of quadriceps femoris, the medial and lateral parts of which descend, flanking the patella, to the sides of the tibial tuberosity, where they merge with the fibrous capsule as the medial and lateral patellar retinacula. The patellar ligament is separated from the synovial membrane by a large infrapatellar fat pad and from the tibia by a bursa, and lies within its own well-defined sheath.

In the procedure of tibial osteotomy, the tibia is cut transversely just above the insertion of the patellar ligament. Failure to appreciate the obliquity of the tibial attachment of the tendon may lead to inadvertent division of the tendon during this procedure. The middle third of the patellar ligament may be harvested for surgical repair of a cruciate ligament.

Medial patellofemoral ligament The femoral attachment of the medial patellofemoral ligament is consistently anterior and distal to the adductor tubercle with soft tissue attachments to the tendon of adductor magnus. Its fibres course deep to vastus medialis obliquus to attach broadly to the proximal third of the superomedial aspect of the patella, with a long, thin attachment adjacent to the quadriceps tendon and superficial to the patellar articular cartilage and joint capsule.

Medial patellotibial and patellomeniscal ligaments The medial patellotibial ligament is a thin, single-layered structure (compared to the rounded, cord-like medial patellomeniscal ligament) located superficial and intimately adherent to the medial capsule. Both ligaments insert on the inferomedial patella; a portion of the patellar attachment lies deep to the patellar ligament but superficial to the patellar articular cartilage and deeper joint capsule. From its patellar attachment site, the medial patellotibial ligament passes inferomedially to the medial tibial tubercle of the anteromedial proximal tibia. The medial patellomeniscal ligament courses more horizontally than the medial patellotibial ligament and has a distinct attachment medial to the anterior horn of the medial meniscus (Kruckeberg et al 2018).

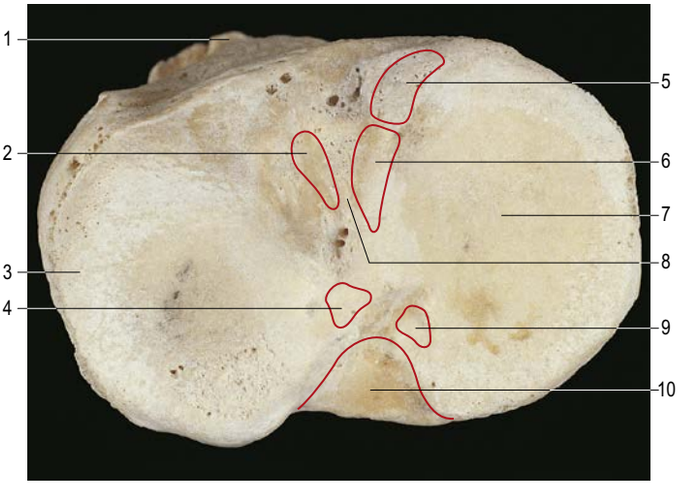

Fig. 78.13 The left tibial plateau, showing sites of ligamentous and meniscal attachments and articular surfaces. Key: 1, tibial tuberosity; 2, attachment of anterior horn, lateral meniscus; 3, lateral condyle; 4, attachment of posterior horn, lateral meniscus; 5, attachment of anterior horn, medial meniscus; 6, attachment of anterior cruciate ligament; 7, medial condyle; 8, intercondylar eminence; 9, attachment of posterior horn, medial meniscus; 10, attachment of posterior cruciate ligament.

Lateral patellar dislocation is a relatively frequent injury, with an overall annual incidence of approximately 23.2 per 100,000 person years; the highest incidence, of approximately 147.7 per 100,000 person years, is in adolescents aged 14–18 years (Sanders et al 2018). The medial patellofemoral ligament is the primary medial stabilizer of the patella throughout the first 30° of flexion and is the most commonly injured ligament with a lateral patellar dislocation. The medial patellotibial and patellomeniscal ligaments have a role in restricting lateral translation, patellar tilt and patellar rotation at increased degrees of knee flexion. They also maintain normal kinematics of the patellofemoral joint, particularly at higher flexion angles. Patellar re-dislocation occurs in 15–72% of patients treated non-operatively. However, significant reductions in patellar re-dislocation rates have been reported following surgical intervention, with medial patellofemoral ligament reconstruction (Zimmerer et al 2018).

All other aspects of the patellofemoral joint are described with the tibiofemoral joint.

Tibiofemoral joint

The tibiofemoral joint is a complex synovial joint and is part of the knee joint.

Articulating surfaces The articulating surfaces of the tibiofemoral joint are the proximal tibial surface, the intercondylar area and the femoral surface.

Proximal tibial surface The proximal tibial surface (unofficially referred to as the tibial plateau) slopes posteriorly and downwards relative to the long axis of the shaft (**Fig. 78.13**). The tilt, which is maximal at birth, decreases with age, and is more marked in habitual squatters. The tibial plateau presents medial and lateral articular surfaces (facets) for articulation with the corresponding femoral condyles. The posterior surface, distal to the articular margin, displays a horizontal, rough groove to which the capsule and posterior part of the tibial collateral ligament are attached. The anteromedial surface of the medial tibial condyle is a rough strip, separated from the medial surface of the tibial shaft by an inconspicuous ridge. The medial patellar retinaculum is attached to the medial tibial condyle along its anterior and medial surfaces, which are marked by vascular foramina.

The medial articular surface is oval (long axis anteroposterior) and longer than the lateral articular surface. Around its anterior, medial and posterior margins, it is related to the medial meniscus; the meniscal imprint, wider posteriorly and narrower anteromedially, is often discernible. The surface is flat in its posterior half and the anterior half slopes superiorly about 10°. The meniscus covers much of the posterior surface so that, overall, a concave surface is presented to the medial femoral condyle. Its lateral margin is raised as it reaches the intercondylar region.

The lateral tibial condyle overhangs the shaft of the tibia posterolaterally above a small circular facet for articulation with the fibula. The lateral articular surface is more circular and coapted to its meniscus. In the sagittal plane, the articular surface is fairly flat centrally, and anteriorly and

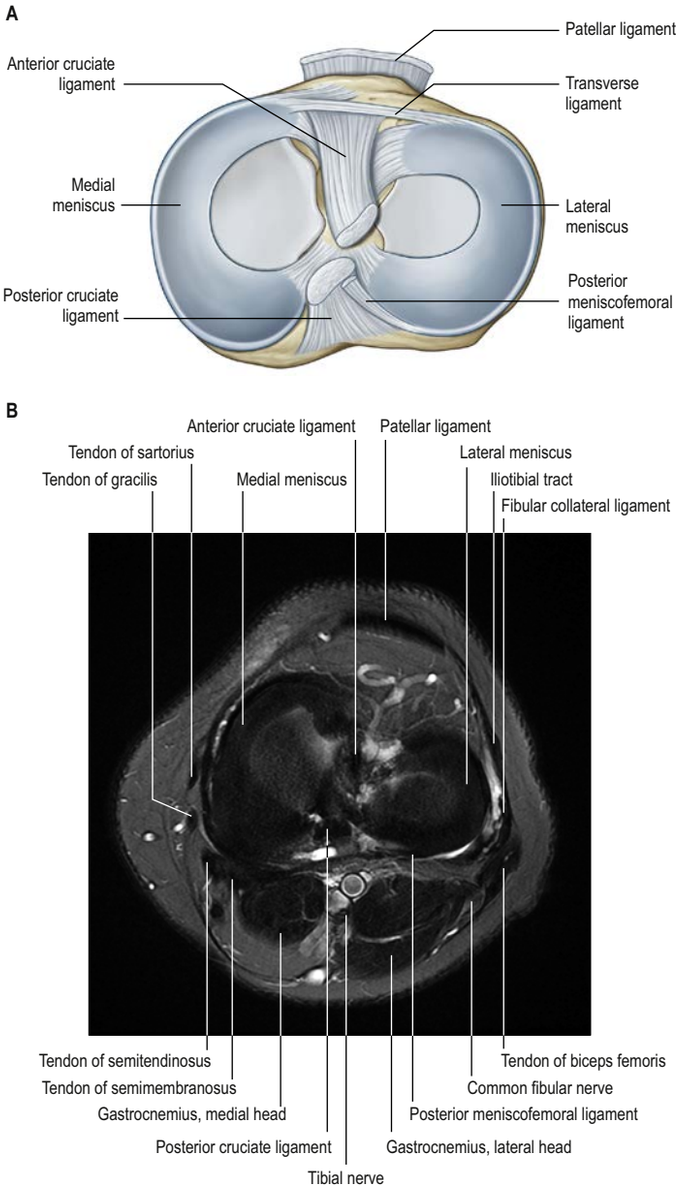

Fig. 78.14 **A**, The superior aspect of the left tibia, showing the menisci and the attachments of the cruciate ligaments. **B**, Compounded image of two sequential axial MRI slices (T2-weighted with fat suppression) at the left knee joint showing the menisci and related ligaments. (A, With permission from Drake RL, Vogl AW, Mitchell A et al (eds) Gray's Atlas of Anatomy. Elsevier, Churchill Livingstone. Copyright 2008.)

posteriorly the surface slopes inferiorly. Overall, this creates a rather convex surface so that, with the lateral femoral condyle in contact, there are anterior and posterior recesses (triangular in section), which are occupied by the anterior and posterior meniscal 'horns'. Elsewhere, the surface has a raised medial margin that spreads to the lateral intercondylar tubercle. Its articular margins are sharp, except posterolaterally, where the edge is rounded and smooth: here the tendon of popliteus is in contact with bone.

Intercondylar area The rough-surfaced area between the condylar articular surfaces is narrowest centrally where there is an intercondylar eminence, the edges of which project slightly proximally as the lateral and medial intercondylar tubercles. The intercondylar area widens behind and in front of the eminence as the articular surfaces diverge (see Fig. 78.13; **Fig. 78.14**).

The anterior intercondylar area is widest anteriorly. Anteromedially, anterior to the medial articular surface, a depression marks the site of attachment of the anterior horn of the medial meniscus. Behind this, a smooth area receives the anterior cruciate ligament. The anterior horn of the lateral meniscus is attached anterior to the intercondylar eminence, lateral to the anterior cruciate ligament. The eminence, with medial and lateral tubercles, is the narrow central part of the area. The raised tubercles are thought to provide a slight stabilizing influence on the femur. It is believed that the eminence becomes prominent once walking commences and that the tibial condyles transmit the weight of the body through the tibia.

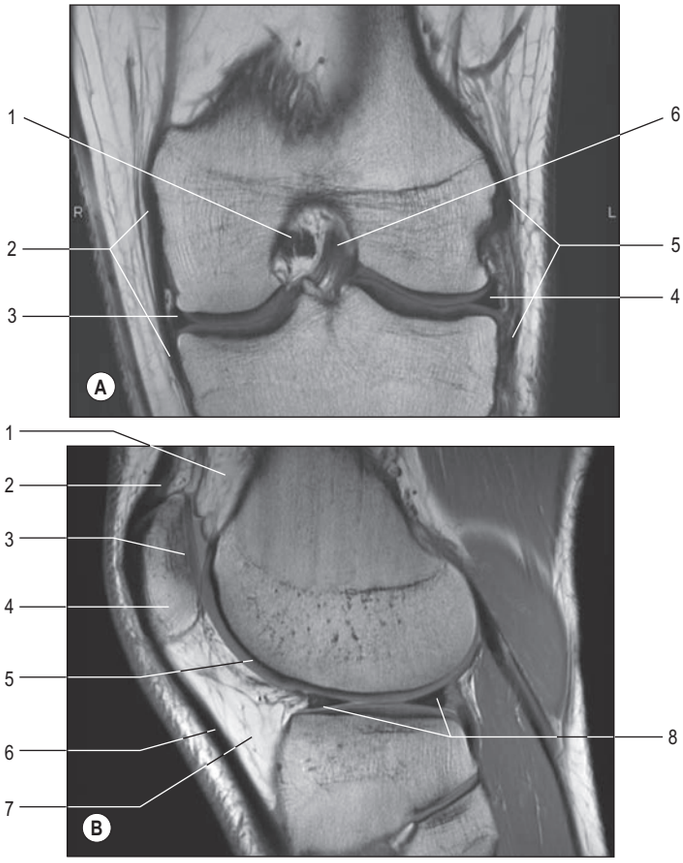

Fig. 78.15 Left knee joint. **A,** T1-weighted coronal magnetic resonance image (MRI). Key: 1, posterior cruciate ligament; 2, tibial collateral ligament; 3, medial meniscus; 4, lateral meniscus; 5, fibular collateral ligament; 6, anterior cruciate ligament. **B,** Medial meniscus, proton density (PD) weighted sagittal MRI. Key: 1, suprapatellar fat pad; 2, tendon of quadriceps femoris; 3, patellar articular cartilage; 4, patella; 5, femoral articular cartilage; 6, patellar ligament; 7, infrapatellar fat pad; 8, medial meniscus.

The posterior horn of the lateral meniscus is attached to the posterior slope of the intercondylar area. The posterior intercondylar area inclines down and backwards behind the posterior horn of the lateral meniscus. A depression behind the base of the medial intercondylar tubercle is for the attachment of the posterior horn of the medial meniscus. The rest of the area is smooth and provides attachment for the posterior cruciate ligament, spreading back to a ridge to which the capsule is attached.

Femoral surface. The femoral condyles, bearing articular cartilage, are almost wholly convex. There are various opinions as to the contours of their sagittal profiles. One view is that they are spiral with a curvature increasing posteriorly ('a closing helix'), that of the lateral condyle being greater. An alternative view is that the articular surface for contact with the tibia on the medial femoral condyle describes the arcs of two circles. According to this view, the anterior arc makes contact with the tibia near extension and is part of a virtual circle of larger radius than the more posterior arc, which makes contact during flexion. The lateral femoral condyle is believed to describe a single arc and thus to possess a single radius of curvature.

Tibiofemoral congruence is improved by the menisci, which are shaped to produce concavity of the surfaces presented to the femur; the combined lateral tibiomeniscal surface is deeper. The lateral femoral condyle has a faint groove anteriorly, which rests on the peripheral edge of the lateral meniscus in full extension. A similar groove appears on the medial condyle but does not reach its lateral border, where a narrow strip contacts the medial patellar articular surface in full flexion. These grooves demarcate the femoral patellar and condylar surfaces. The differences between the shapes of the articulating surfaces correlate with the movements of the knee joint.

Menisci The menisci (semilunar cartilages) are crescentic, intracapsular, fibrocartilaginous laminae (see Fig. 78.14; **Fig. 78.15**). They serve to widen, deepen and prepare the tibial articular surfaces that receive the femoral condyles. Their peripheral attached borders are thick and convex, and their free, inner borders are thin and concave. Their peripheries are vascularized by capillary loops from the fibrous capsule and synovial membrane, while their inner regions are less vascular. Tears of the menisci are common. Peripheral tears (e.g. in the vascularized zone) have the

potential to heal satisfactorily, especially with surgical intervention. Tears in the less vascular or inner zones seldom heal spontaneously; if surgery is indicated, these menisci are often resected. The meniscal horns are richly innervated compared with the remainder of the meniscus. The central one-third is devoid of innervation (Gronblad et al 1985). The proximal surfaces are smooth and concave, and in contact with the articular cartilage on the femoral condyles. The distal surfaces are smooth and flat, resting on the tibial articular cartilage. Each covers approximately two-thirds of its tibial articular surface. Canal-like structures open on to the surface of the menisci in infants and young children, and may transport nutrients to deeper, less vascular areas.

Two structurally different regions of the menisci have been identified. The inner two-thirds of each meniscus consist of radially organized collagen bundles, and the peripheral one-third consists of larger circumferentially arranged bundles (Ghadially et al 1983). Thinner collagen bundles parallel to the surface line the articular surfaces of the inner part, while the outer portion is covered by synovium. This structural arrangement suggests specific biomechanical functions for the two regions: the inner portion of the meniscus is suited to resisting compressive forces while the periphery is capable of resisting tensional forces. With ageing and degeneration, compositional changes occur within the menisci, which reduce their ability to resist tensional forces. Outward displacement of the menisci by the femoral condyles is resisted by firm anchorage of the peripheral circumferential fibres to the intercondylar bone at the meniscal horns.

Alternatively, each meniscus can be considered as consisting of three contiguous segments, namely an anterior horn/root, a body, and a posterior horn/root. The anterior roots of both menisci have relatively simple, planar insertions into the tibial plateau, while the posterior roots reveal complex, three-dimensional insertions into the tibial plateau.

The menisci spread load by increasing the congruity of the articulation, provide stability by their physical presence and proprioceptive feedback, and may cushion the underlying bone from the considerable forces generated during extremes of flexion and extension of the knee. They play a vital role in protecting against osteochondral damage of the tibiofemoral joint with specific importance afforded to the meniscal root. The loss of attachment at the root of the meniscus impairs the ability to maintain hoop strain when loading the tibiofemoral joint. (Hoop strain refers to the circumferential nature of the stress on meniscal fibres during axial loading.) This decrease in hoop strain resistance is responsible for increased articular cartilage contact pressure, which can lead to rapid degenerative changes (Krych et al 2017). An avulsion of the posterior root of the medial meniscus is biomechanically equivalent to a complete meniscectomy due to abnormally high peak tibiofemoral contact pressures (Allaire et al 2008).

Medial meniscus The medial meniscus is broader posteriorly and is almost a semicircle in shape (see Fig. 78.14). The anatomical location of the anterior root attachment of the medial meniscus has been described using surgical and arthroscopic vantage points. With reference to relevant open surgical landmarks, the centre of the anterior root is proximal to the superior aspect of the medial edge of the tibial tuberosity, and proximomedial to the centre of the superior edge of the tibial tuberosity. With regard to arthroscopic landmarks, the centre of the anterior root is anterior to the apex of the medial tibial eminence, anteromedial to the centre of the anterior cruciate ligament, and anteromedial to the centre of the lateral root of the lateral meniscus. The central, prominent root fibres that attach to the tibia encompass an area of approximately 56.3 mm^2 (LaPrade et al 2014). When the transverse (anterior intermensical) ligament is present it spans between the posteromedial aspect of the anterior horn of the medial meniscus and the anterolateral aspect of the anterior root of the lateral meniscus.

The posterior root is attached posterior to the apex of the medial tibial plateau, lateral to the inflection point of the articular cartilage of the medial tibial plateau, and anteromedial to the tibial attachment of the posterior cruciate ligament. The footprint area formed by the central fibres of the posterior root at its attachment is approximately 30.4 mm^2 (Johannsen et al 2012).

The peripheral border of the meniscus is attached to the fibrous capsule and the deep surface of the tibial collateral ligament. The tibial attachment of the meniscus is known as the 'coronary or meniscotibial ligament'. Collectively, these attachments ensure that the medial meniscus is relatively fixed and moves much less than the lateral meniscus.

Lateral meniscus The lateral meniscus forms approximately four-fifths of a circle and covers a larger area than the medial meniscus (see Fig. 78.14). Its breadth, except at its short tapered horns, is more or less uniform. It is grooved posterolaterally by the tendon of popliteus, separating it from the fibular collateral ligament. The central fibres of its anterior root are attached anteromedial to the apex of the lateral tibial eminence, and anterolateral to the centre of the tibial attachment of the anterior cruciate ligament. The tibial attachment area of the anterior root is approximately 140.7 mm^2, and there is significant overlap with the tibial footprint of the anterior cruciate ligament (LaPrade et al 2014).

The posterior root is attached posteromedial to the lateral tibial eminence apex, medial to the edge of the lateral articular cartilage, anterior to the tibial attachment of the posterior cruciate ligament, and anterolateral to the posterior root of the medial meniscus. Its footprint area is approximately 39.2 mm^2. In addition to the main attachment a continuation of the posterior fibres pass to the posterior aspect of the lateral margin of the medial tibial eminence (Johannsen et al 2012). Near its posterior attachment, it commonly sends a posterior meniscofemoral ligament superomedially behind the posterior cruciate ligament to the medial femoral condyle. An anterior meniscofemoral ligament may also connect the posterior horn to the medial femoral condyle anterior to the posterior cruciate ligament. The meniscofemoral ligaments are often the sole attachments of the posterior horn of the lateral meniscus. More laterally, part of the tendon of popliteus is attached to the lateral meniscus, and so mobility of its posterior horn may be controlled by the meniscofemoral ligaments and by popliteus. A meniscofibular ligament occurs in most knee joints. As with the medial meniscus, there is a tibial attachment via the so-called coronary ligament, but the meniscus has no peripheral bony attachment in the region of popliteus; in the surgical literature, this gap is referred to as the popliteus hiatus.

Discoid lateral meniscus A discoid lateral meniscus occasionally occurs, often bilaterally. The distinguishing features of a discoid lateral meniscus are its shape and posterior ligamentous attachments. The following classification of the abnormality is based on the work of Watanabe et al (1979). In its mildest form, the partial discoid meniscus is simply a wider form of the normal lateral meniscus. The acute, medial free edge is interposed between the femoral and tibial condyles but it does not completely cover the tibial plateau. A complete discoid meniscus appears as a biconcave disc with a rolled medial edge and covers the lateral tibial plateau. The Wrisberg type of meniscus has the same shape as a complete discoid meniscus but its only peripheral posterior attachment is by the meniscofemoral ligaments. In this case, the normal tibial attachment of the posterior horn of the lateral meniscus is lacking but the posterior meniscofemoral ligament persists. As a result, this type of meniscus is attached anteriorly to the tibia and posteriorly to the femur, which renders the posterior horn unstable. Under these circumstances, the meniscus is liable to become caught between the femur and tibia: this accounts for the classic presenting symptom of the 'clunking knee' in some patients. The aetiology of discoid meniscus is not clear. Most are asymptomatic and are often found by chance at arthroscopy. However, they may cause difficulty in gaining access to the lateral compartment at arthroscopy. A discoid medial meniscus is extremely rare.

Transverse ligament of the knee The transverse ligament of the knee connects the anterior convex margin of the lateral meniscus to the anterior horn of the medial meniscus (see Figs 78.14, 78.22). It varies in thickness and is often absent. Its exact role is conjectural, although one study found that the ligament was slightly taut in knee extension (Tubbs et al 2008); presumably, it helps to decrease tension generated in the longitudinal circumferential fibres of the menisci when the knee is subjected to load. A posterior meniscomeniscal ligament is sometimes present.

Meniscofemoral ligaments Two meniscofemoral ligaments connect the posterior horn of the lateral meniscus to the inner (lateral) aspect of the medial femoral condyle (**Fig. 78.16B**). The anterior meniscofemoral ligament (ligament of Humphrey) passes anterior to the posterior cruciate ligament. The posterior meniscofemoral ligament (ligament of Wrisberg) passes behind the posterior cruciate ligament and attaches proximal to the margin of attachment of the posterior cruciate.

Anatomical cadaveric studies found that at least one meniscofemoral ligament was typically present in the knees examined; both sometimes coexisted (Gupte et al 2003). Biomechanical studies have revealed the cross-sectional area and strength of the meniscofemoral ligaments to be comparable to those of the posterior fibre bundle of the posterior cruciate ligament.

The meniscofemoral ligaments are believed to act as secondary restraints, supporting the posterior cruciate ligament in minimizing displacement caused by posteriorly directed forces on the tibia. They are also involved in controlling the motion of the lateral meniscus in conjunction with the tendon of popliteus during knee flexion.

Soft tissues

Recent advances in imaging and surgery on knee ligaments have contributed to an improved understanding of anatomy, particularly of the medial and lateral soft tissues of the knee.

Fibrous capsule and retinacula

The joint capsule is a fibrous membrane of variable thickness. Anteriorly it is replaced by the patellar ligament and does not pass proximal to the patella or over the patellar area. Elsewhere it lies deep to expansions from vasti medialis and lateralis, separated from them by a plane of vascularized loose connective tissue. The expansions are attached to the patellar margins and patellar ligament, extending back to the corresponding collateral (tibial and fibular) ligaments and distally to the tibial condyles. They form medial and lateral patellar retinacula, the lateral being reinforced by the iliotibial tract.

Posteriorly the capsule contains vertical fibres that arise from the articular margins of the femoral condyles and intercondylar fossa, and from the proximal tibia. The fibres mainly pass downwards and somewhat medially. The oblique popliteal ligament is a well-defined thickening across the posteromedial aspect of the capsule, and is one of the major extensions from the tendon of semimembranosus.

Medial ligaments and soft tissues

The medial soft tissues are arranged in three layers from superficial to deep (Warren and Marshall 1979).

Layer 1 Layer 1 is the deep fascia that invests sartorius. The saphenous nerve and its infrapatellar branch are superficial to the deep fascia of the leg. Sartorius inserts into the fascia as an expansion rather than as a distinct tendon. The fascia spreads inferiorly and anteriorly to lie superficial to the distinct and readily identifiable tendons of gracilis and semitendinosus and their insertions. These tendons are commonly harvested for surgical reconstruction of damaged cruciate ligaments. To gain access to them, the upper edge of sartorius can be identified and the sartorius (layer 1) fascia is incised to reveal the tendons. Deep to the tendons is the anserine bursa, which overlies the superficial part of the tibial collateral ligament; this bursa sometimes becomes inflamed, especially in track and field athletes. Posteriorly, layer 1 overlies the tendons of gastrocnemius and the structures of the popliteal fossa. Anteriorly, layer 1 blends with the anterior limit of layer 2 and the medial patellar retinaculum. More inferiorly, layer 1 blends with the periosteum.

A condensation of tissue passes from the medial border of the patella to the medial epicondyle of the femur (the medial patellofemoral ligament), the anterior horn of the medial meniscus (the meniscopatellar ligament) and the medial tibial condyle (the patellotibial ligament).

Layer 2 Layer 2 is the plane of the superficial part of the tibial collateral ligament (medial collateral ligament) (**Fig. 78.17**). The tendons of gracilis and semitendinosus lie between layers 1 and 2. The superficial part of the tibial collateral ligament is the largest structure of the medial aspect of the knee, measuring approximately 10–12 cm in length (Fig. 78.17; see Fig. 78.15). It has one femoral and two tibial (proximal and distal) attachments. The femoral attachment is to a small depression just proximal and posterior to the centre of the medial epicondyle of the femur. As the superficial part of the tibial collateral ligament passes distally, it is separated from the tibia by the inferior medial genicular artery and vein, and a corresponding branch from the tibial nerve. Its proximal tibial attachment is primarily to soft tissues (the anterior arm of the tendon of semimembranosus) rather than directly to bone. The distal tibial attachment is broad-based and located just anterior to the posteromedial crest of the tibia: the majority of the fibres are located within the anserine bursa (LaPrade et al 2007). There is a vertical split in layer 2 anterior to the superficial part of the tibial collateral ligament. The fibres anterior to the split pass superiorly to blend with the fascia over vastus medialis and layer 1 in the medial patellar retinaculum. The fibres posterior to the split pass superiorly to the medial epicondyle and continue anteriorly as the medial patellofemoral ligament (see Figs 78.12, 78.17).

Layer 3 Layer 3 is formed by the joint capsule, including the deep part of the tibial collateral ligament (mid-third capsular ligament) and can be separated from layer 2 everywhere except anteriorly close to the patella, where it blends with the more superficial layers. The deep part of the tibial collateral ligament is a distinct thickening of the anterior aspect of the medial joint capsule. It is deep to, and roughly parallels, the anterior aspect of the superficial part of the tibial collateral ligament. The deep part of the tibial collateral ligament consists of two components: the meniscotibial and meniscofemoral ligaments. The meniscotibial component is attached just distal to the tibial joint line. It is shorter and thicker than the meniscofemoral component, which is attached proximal to the femoral joint line (LaPrade et al 2015). Anteriorly the separation of the superficial and deep parts of the tibial collateral ligament is distinct, whereas posteriorly layers 2 and 3 blend to form a conjoined posteromedial capsule.

Factors maintaining medial stability The tibial collateral ligament is important for stabilization of the medial knee, and is the most commonly injured ligament of the knee. The superficial and deep parts of the tibial collateral ligament are the primary and secondary static stabilizers, respectively, to valgus motion. The primary stabilizer for lateral (external) rotation is the distal attachment of the superficial part of the tibial collateral ligament; the proximal attachment of the superficial part of the tibial collateral ligament and the deep part of the tibial collateral ligament have secondary roles. The posterior oblique ligament also plays a significant role in resisting posteromedial rotatory instability of the knee (Griffith et al 2009).

Lateral ligaments and soft tissues

The arrangement of the lateral soft tissues of the knee is controversial. Three distinct layers are recognized (Seebacher et al 1982), but views as to their contents vary. The first layer may be divided into superficial (oblique fibres of the iliotibial tract ending on the patella) and deep (lateral patellofemoral ligament, the transverse retinaculum and the patellotibial band) parts. These two parts are joined posteriorly by the iliotibial tract. The second layer contains the fibular collateral ligament, patellofemoral ligament, fabellofibular ligament and arcuate ligament,

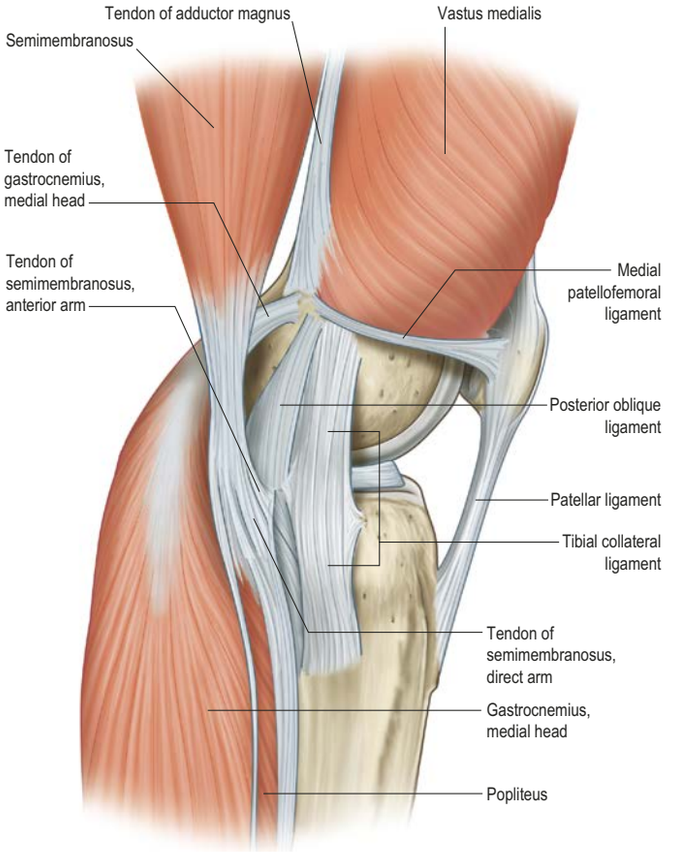

Fig. 78.17 The major components of the medial aspect of the knee.

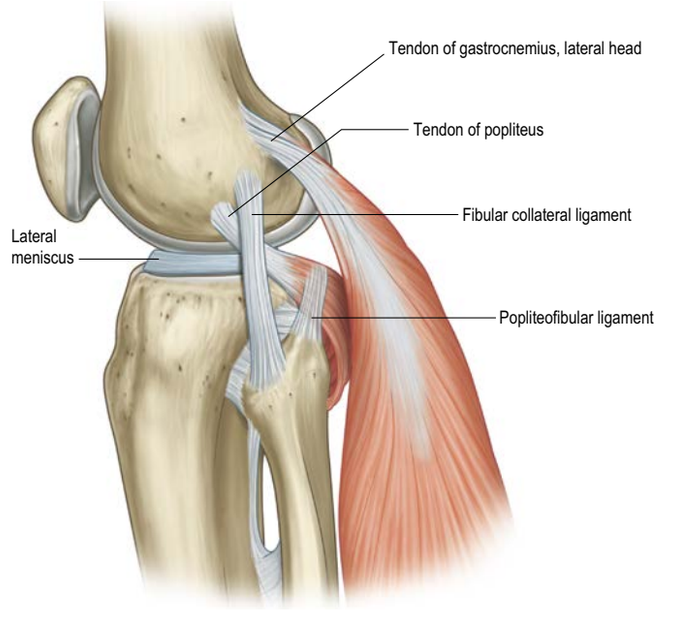

Fig. 78.18 The three major components of the posterolateral corner: lateral collateral ligament, tendon of popliteus and popliteofibular ligament.

and the third layer is the joint capsule. An alternative view is that the first layer consists only of the oblique iliotibial tract fibres; the second layer contains the lateral patellofemoral ligament, the transverse retinaculum and the patellotibial band; and the third layer consists of superficial and deep portions, where the superficial part contains the fibular collateral ligament, patellofemoral ligament, fabellofibular ligament and the arcuate ligament and the deep part contains the joint capsule (Miller and Azar 2017). The recently described anterolateral ligament (Stijak et al 2016) of the knee may be a component of the superficial layer (Claes et al 2013).

The lateral patellar retinaculum consists of superficial oblique and deep transverse portions. The former runs from the iliotibial tract to the patella. The latter is thicker and subdivided into three parts: the lateral patellofemoral ligament, running from the lateral patellar border to the lateral epicondyle of the femur; the transverse retinaculum, running from the iliotibial tract to the mid-patella; and the patellotibial band, running from the patella to the lateral tibial condyle.

The fascia lata and the iliotibial tract lie posterior to the lateral retinaculum. They come together distally to insert on to the tibia at a tubercle (Gerdy's tubercle) on the anterolateral proximal tibia; some fibres continue to insert on the tibial tuberosity. Proximally, the fascia lata merges with the lateral intermuscular septum. Posteriorly, it blends with the fascia over biceps femoris. Here, as it emerges from behind the biceps femoris tendon, the common fibular nerve lies in a thin layer of fat bound by the fascia.

Posterolateral corner of the knee

The posterolateral corner of the knee contains several important structures that maintain varus and rotational stability throughout all ranges of motion; the three primary stabilizers are the fibular collateral ligament, popliteus tendon and popliteofibular ligament (Crespo et al 2015, Serra Cruz et al 2016) (**Fig. 78.17**).

The fibular collateral ligament has a mean length of 7 cm and arises from a depression located just proximal and posterior to the lateral epicondyle, posterior to the insertion of popliteus. It passes underneath the superficial layer of the iliotibial tract and is inserted approximately 2.8 cm distal to the tip of the fibular head, with the majority of fibres extending to encompass the distal one-third of the lateral aspect of the fibular head. The fibular collateral ligament is separated from the capsule by a thin layer of fat and the inferior lateral genicular vessels. It is the primary restraint to varus stress on the knee and assists in limiting lateral rotation when the knee is slightly flexed.

The femoral insertion of the popliteus tendon constitutes the most anterior femoral insertion site of the posterolateral corner (see p. 1416).

The single most important stabilizer of the posterolateral knee is the popliteofibular (short external lateral) ligament that spans between the musculotendinous junction of popliteus and the posteromedial aspect of the fibular head. This ligament has a smaller anterior and a larger posterior division that embrace the musculotendinous junction of popliteus. The distolateral attachment of the anterior division is positioned on the anterior downslope of the medial aspect of the fibular styloid process. In a similar fashion, the posterior division is attached to the tip and posteromedial aspect of the fibular styloid process. The popliteofibular ligament contributes to the external rotatory stability of the knee (Chahla et al 2016). Its connection to the tendon of popliteus also allows 'dynamic' tensioning.

The fabellofibular ligament is a condensation of fibres that runs either from the fabella (a sesamoid bone sometimes found within the tendon of the lateral head of gastrocnemius) or from the lateral head of gastrocnemius (if the fabella is absent), to the apex of the head of the fibula. The arcuate ligament is a condensation of fibres that runs from the apex of the head of the fibula, posteromedially over the emerging tendon of popliteus below the level of the tibial joint surface, to the tibial intercondylar area. The lateral joint capsule is thin and blends posteriorly with the arcuate ligament. Anteriorly, it forms the weak, lax coronary or meniscotibial ligament, which attaches the inferior border of the meniscus to the lateral tibia.

Intra-articular ligaments

Cruciate ligaments

The cruciate ligaments, so named because they cross each other, are very strong, richly innervated intracapsular structures. The point of crossing is located a little posterior to the articular centre. They are named anterior and posterior with reference to their tibial attachments (**Figs 78.19–78.22**; see Fig. 78.25). A synovial membrane almost surrounds the ligaments but is reflected posteriorly from the posterior cruciate ligament to adjoining parts of the capsule; the intercondylar part of the posterior region of the fibrous capsule therefore has no synovial covering.

Anterior cruciate ligament The anterior cruciate ligament is attached to the anterior intercondylar area of the tibia, just anterior and slightly lateral to the medial intercondylar tubercle, partly blending with the anterior horn of the lateral meniscus (see Fig. 78.14). It ascends posterolaterally, twisting on itself and fanning out to attach high on the posteromedial aspect of the lateral femoral condyle (Girgis et al 1975). The average length and width of an adult anterior cruciate ligament are 38 mm and 11 mm, respectively. It is formed of two, or possibly three, functional bundles that are not apparent to the

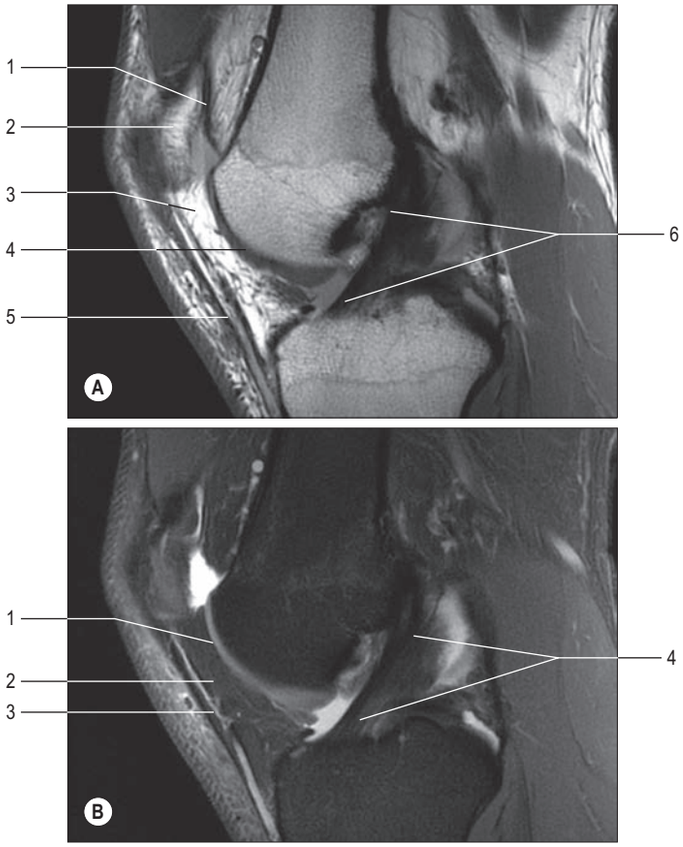

Fig. 78.19 A, MRI of the anterior cruciate ligament. **A**, Proton density (PD)-weighted sagittal view. naked eye but can be demonstrated by microdissection techniques. The bundles are named anteromedial, intermediate and posterolateral, according to their tibial attachments (Amis and Dawkins 1991; Clarke et al 2018).

Posterior cruciate ligament The posterior cruciate ligament is thicker and stronger than the anterior cruciate ligament (see Fig. 78.14), the average length and width of an adult posterior cruciate ligament being 38 mm and 13 mm, respectively. It is attached to the lateral surface of the medial femoral condyle and extends up on to the anterior part of the roof of the intercondylar fossa, where its attachment is extensive in the anteroposterior direction. Its fibres are adjacent to the articular surface. They pass distally and posteriorly to a fairly compact attachment posteriorly in the intercondylar region and in a depression on the adjacent posterior tibia. This gives a fan-like structure in which fibre orientation is variable. Anterolateral and posteromedial bundles have been defined; they are named (against convention) according to their femoral attachments. The anterolateral bundle tightens in flexion while the posteromedial bundle is tight in extension of the knee. Each bundle slackens as the other tightens. Unlike the anterior cruciate ligament, it is not isometric during knee motion, i.e. the distance between attachments varies with knee position. The posterior cruciate ligament ruptures less commonly than the anterior cruciate ligament and rupture is usually better tolerated by patients than rupture of the anterior cruciate ligament.

Synovial membrane, plicae and fat pads

The synovial membrane of the knee is the most extensive and complex in the body. It forms a large suprapatellar bursa between quadriceps femoris and the lower femoral shaft proximal to the superior patellar border (Figs 78.23–78.24). The bursa is an extension of the joint cavity. The attachment of articularis genus to its proximal aspect prevents the bursa from collapsing into the joint. Alongside the patella, the membrane extends beneath the aponeuroses of the vasti, especially under vastus medialis. It extends proximally a hand's breadth above the superior pole of the patella. Distal to the patella, the synovial membrane is

separated from the patellar ligament by an infrapatellar fat pad. Where it lies beneath the fat pad, the membrane projects into the joint as two fringes, alar folds, which bear villi. The folds converge posteriorly to form a single infrapatellar fold or plica (ligamentum mucosum), which curves posteriorly to its attachment in the femoral intercondylar fossa (Fig. 78.25). This fold may be a vestige of the inferior boundary of an

originally separate femoropatellar joint. The extent of the infrapatellar plica ranges from a thin cord to a complete sheet that can obstruct the passage of instruments during knee arthroscopy. When substantial, it has been mistaken for the anterior cruciate ligament, which is directly posterior to it. The medial plica extends in the midline anteriorly from the medial alar fold medially to the suprapatellar bursa. Occasionally, it can be thickened and inflamed, usually following acute or chronic trauma.

The suprapatellar plicae are remnants of an embryonic septum that completely separates the suprapatellar bursa from the knee joint. Occasionally, a septum persists, either in its entirety or perforated by a small peripheral opening.

The infrapatellar fat pad is the largest part of a circumferential extrasynovial fatty ring that extends around the patellar margins (Newell 1991).

At the sides of the joint, the synovial membrane descends from the femur and lines the capsule as far as the menisci, whose surfaces have no synovial covering. Posterior to the lateral meniscus, the membrane forms a subpopliteal recess between a groove on the meniscal surface and the tendon of popliteus, which may connect with the superior tibiofibular joint. The relationship of the synovial membrane to the cruciate ligaments is described above.

Bursae

Numerous bursae are associated with the knee. Anteriorly, there is a large subcutaneous prepatellar bursa between the lower half of the patella and skin; a small, deep infrapatellar bursa between the tibia and patellar ligament; a subcutaneous infrapatellar bursa between the distal part of the tibial tuberosity and skin; and a large suprapatellar bursa, which is the superior extension of the knee joint cavity (see Fig. 78.24). Posterolaterally, there are bursae between the lateral head of gastrocnemius (lateral subtendinous bursa of gastrocnemius) and the joint capsule (this bursa is sometimes continuous with the joint cavity); the fibular collateral ligament and the tendon of biceps femoris; the fibular collateral ligament and the tendon of popliteus; and the tendon of popliteus and the lateral femoral condyle, which is usually an extension of the synovial cavity of the joint. The last two bursae may communicate with each other.

Medially, the arrangement of the bursae is complex. The bursa between the medial head of gastrocnemius and the fibrous capsule is prolonged

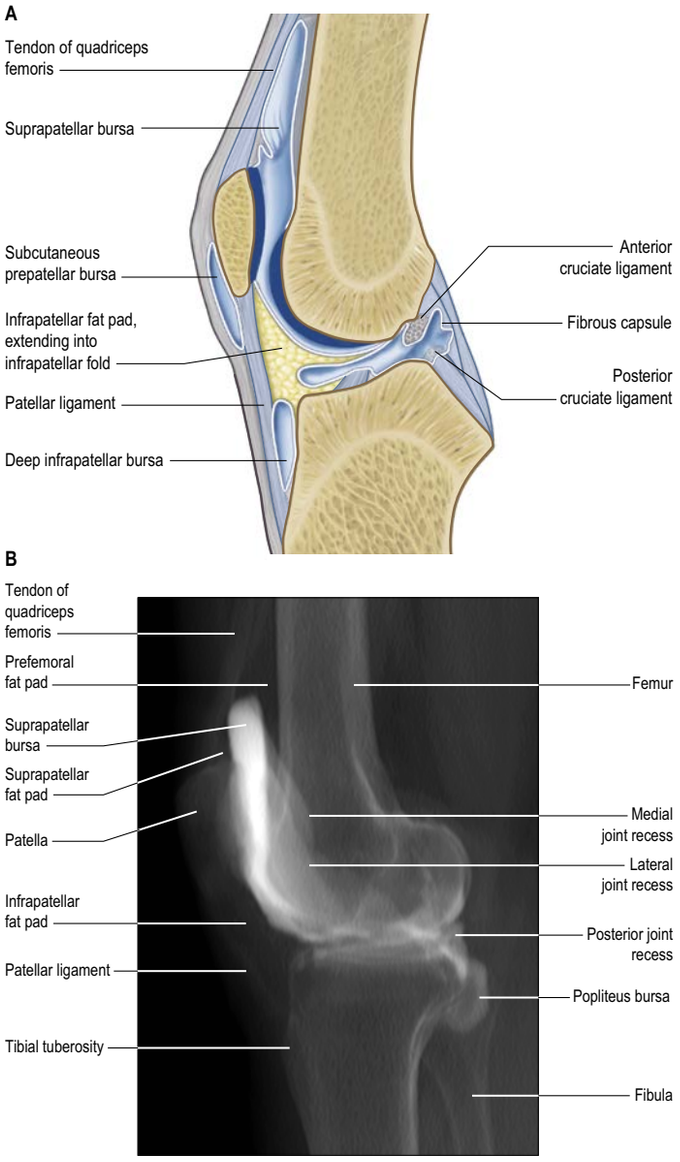

Fig. 78.24 **A**, A sagittal section through the left knee joint, lateral aspect. **B**, Sagittal mean intensity projection of the knee from a CT arthrogram.

between the medial tendon of gastrocnemius and the tendon of semimembranosus (the semimembranosus bursa), and usually communicates with the joint. The bursa between the tendon of semimembranosus and the medial tibial condyle and the medial head of gastrocnemius may communicate with this bursa. The anserine bursa is located between the tibial collateral ligament and the tendons of sartorius, gracilis and semitendinosus. Bursae that vary in both number and position lie deep to the tibial collateral ligament between the joint capsule, femur, medial meniscus, tibia or tendon of semimembranosus. Occasionally, there may be a bursa between the tendons of semimembranosus and semitendinosus. Posteriorly, bursae associated with the knee are variable.

The clinically important bursae are the anterior group, the anserine bursa and the semimembranosus bursa. Inflammation of the subcutaneous prepatellar bursa and infrapatellar bursa are referred to colloquially as 'housemaid's knee' and 'clergyman's knee', respectively. The anserine bursa can become inflamed, especially in athletes. In adults, bursal inflammation producing a popliteal fossa swelling commonly occurs secondary to degeneration within the knee joint; regardless of its size and position, it almost always arises from the plane between semimembranosus and the tendon of the medial head of gastrocnemius.

Relations and 'at risk' structures

The tendon of quadriceps femoris (which encloses and is attached to the non-articular surfaces of the patella), the patellar ligament, tendinous expansions from vasti medialis and lateralis (which extend over the anteromedial and anterolateral aspects of the capsule, respectively), and the patellar retinacula all lie anterior to the knee joint. Posteromedially are sartorius and the tendon of gracilis (which lies along its posterior border); both descend across the joint. Posterolaterally the tendon of biceps femoris and the common fibular nerve (which lies medial to the tendon) are in contact with the capsule, and thereby separated from the tendon of popliteus. Posteriorly the popliteal artery and associated lymph nodes lie posterior to the oblique popliteal ligament; the popliteal vein is posteromedial or medial, and the tibial nerve is posterior to both. The nerve and vessels are overlapped by both heads of gastrocnemius and laterally by plantaris. Gastrocnemius contacts the capsules on either side of the vessels. Semimembranosus lies between the capsule and semitendinosus, medial to the medial head of gastrocnemius.

BIOMECHANICS OF THE KNEE

The knee joint is a complex synovial joint consisting of the tibiofemoral and patellofemoral articulations. It functions to control the centre of body mass and posture in the activities of daily living. This necessitates a large range of movement in three dimensions coupled with the ability to withstand high forces. These conflicting parameters of mobility and stability are only achieved by the interactions between the articular surfaces, the passive stabilizers and the muscles that cross the joint.

The relatively incongruent nature of the joint surfaces makes the knee joint inherently mobile. In addition, because it acts as a pivot between the longest bones in the body, and is subjected to considerable loads in locomotion, the joint is also potentially at risk of injury if any of the multiple factors providing joint stability are compromised. The long bones may act as levers, increasing the stresses on the stabilizing ligaments.

Movements

Movements at the knee are customarily described as flexion, extension, medial (internal) and lateral (external) rotation. Flexion and extension differ from true hingeing, in that the articular surface profiles of the femoral and tibial articular surfaces produce a variably placed axis of rotation during the flexion arc, and when the foot is fixed, flexion entails corresponding conjunct (coupled) lateral rotation. These conjunct rotations are a product of the complex geometry of the articular surfaces and, to an extent, the disposition of the associated ligaments. There is differential motion in the medial and lateral tibiofemoral compartments. Laterally, there is considerable displacement of the femur on the tibia, with rolling as well as sliding at the joint surface. In contrast, medially, for most of the flexion arc there is minimal relative motion of the femur and tibia, and the motion almost exclusively involves one joint surface sliding on the other. In full flexion, the lateral femoral condyle is close to posterior subluxation off the lateral tibial articular surface. Medially, significant posterior femoral displacement only occurs when flexion exceeds 120°. The menisci move with the femoral condyles, the anterior horns more than the posterior, and the lateral meniscus considerably more than the medial.

The axial rotations have a smaller range than the arc of flexion and extension. These rotations are conjunct, and integral with flexion and extension, i.e. they are obligatory. They can also be adjunct and independent, i.e. voluntary, and are best demonstrated with the knee semiflexed. The degree of axial rotation therefore varies with flexion and extension.

The range of extension is 5–10° beyond the 'straight position'. Active flexion is approximately 120° with the hip extended, 140° when it is flexed, and 160° when aided by a passive element, e.g. sitting on the heels. Voluntary rotation is 60–70° but conjunct rotation only 20°.

Conjunct medial rotation of the femur on the tibia in the later stages of extension is part of a 'locking' mechanism, the so-called 'screw-home movement', which is an asset when the fully extended knees are subjected to strain. Full extension results in the close-packed position, with maximal spiralization and tightening of the ligaments. The roles of the articular surfaces, musculature and ligaments in generating conjunct rotations remain controversial (Girgis et al 1975, Rajendran 1985) but the following points can be made. The lateral combined meniscotibial 'receiving surface' is smaller, more circular and more deeply concave. Since the articular surface is virtually convex in sagittal section, the depth of the receiving surface is largely due to the presence of the lateral meniscus. The lateral femoral articular surface is also smaller. Consequently, the lateral femoral condyle approaches full congruence with the opposed surface some 30° before full extension (well before the medial condyle). Simple extension cannot continue, but medial rotation of the femur occurs on a vertical axis through its head and medial condyle; the medial femoral condyle moves very little in the sagittal plane and is stabilized by the 'upslope' of the anterior half of the medial tibia, while rotation of the lateral femoral condyle and meniscus brings the anterior horn of the latter on to the anterior 'downslope' of the lateral tibial condyle. Rotation and extension follow simultaneously and smoothly until final close packing of both condyles is accomplished. At the beginning of flexion from full extension (with the foot fixed), lateral femoral rotation occurs, which 'unlocks' the joint. While joint surfaces and many ligaments are involved, electromyographic evidence reveals that contraction of popliteus is important, and that it pulls down and backwards on the lateral femoral condyle, lateral to the axis of femoral rotation. It also retracts the posterior horn during lateral rotation and continuing flexion, via its attachment to the lateral meniscus, and so prevents traumatic compression.

Any position of extension adopted is a balance between forces (torque) extending the joint and passive mechanisms resisting them. The range near to close packing is functionally important. In symmetrical standing, the line of the body's weight is anterior to the transverse axes of the knee joints, but the passive mechanisms noted above preserve posture with minimal muscular effort (Joseph 1960). Active contraction of quadriceps femoris and a close-packed position only occurs in asymmetrical postures, e.g. in leaning forward, during heavy loading, or when powerful thrust is needed.

In knee extension, parts of the cruciate ligaments, the tibial and fibular collateral ligaments, the posterior capsular region, the oblique popliteal ligament, skin and fasciae are all taut. Passive and sometimes active tension exists in the posterior thigh muscles and gastrocnemius, and the anterior part of the medial meniscus is compressed between the femoral and tibial condyles. During extension, the patellar ligament is tightened by quadriceps femoris but is relaxed in the erect attitude. When the knee flexes, the fibular collateral ligament and the posterior part of the tibial collateral ligament relax but the cruciate ligaments and the anterior part of the tibial collateral ligament remain taut; the posterior parts of the menisci are compressed between the femoral and tibial condyles. Flexion is checked by quadriceps femoris, anterior parts of the knee joint capsule, posterior cruciate ligament and compression of soft tissues behind the knee. In extreme passive flexion, contact of the calf with the thigh may be the limiting factor and parts of both cruciate ligaments are also taut. In addition to conjunct rotation with terminal extension or initial flexion, relaxed collateral ligaments also allow independent medial and lateral rotation (adjunct rotation) when the joint is flexed.

Accessory movements

Wider rotation can be obtained by passive movements when the knee is semi-flexed. To a limited extent, the tibia can also be translated backwards and forwards on the femur. Abduction and adduction are prevented in full extension by the collateral ligaments and secondary

restraints such as the cruciate ligaments. With the knee slightly flexed, limited adduction and abduction are possible, both passive and active. Slight separation of the femur and tibia can be achieved by strong traction on the leg with countertraction applied to the thigh.

Physiological knee joint laxity may occur during puberty. Increased knee joint flexibility is seen more frequently in adolescent girls than boys. There is an inverse relationship between Tanner stage and the degree of laxity with a progressive decrease of sagittal laxity at the onset of Tanner stage 2 (Falciglia et al 2009).

Muscles producing movements

Flexion Flexion is produced by biceps femoris, semitendinosus and semimembranosus, assisted by gracilis, sartorius and popliteus. With the foot stationary, gastrocnemius and plantaris also assist (see Fig. 78.3).

Extension Extension is produced by quadriceps femoris, assisted by tensor fasciae latae.

Medial rotation of the flexed leg Medial rotation of the flexed leg is produced by popliteus, semimembranosus and semitendinosus, assisted by sartorius and gracilis.

Lateral rotation of the flexed leg Lateral rotation of the flexed leg is produced by biceps femoris.

Patellofemoral joint The alignment of the femoral and tibial shafts is such that the pull of quadriceps femoris on the patella imparts a force on the patella that is directed both superiorly and laterally. The static bony factors that counter this tendency to move laterally are the congruity of the patellofemoral joint and the buttressing effect of the larger lateral part of the patellar surface of the femur, which, clinically, is often referred to as the trochlear groove. Instability of the patella may result if the patella is small or if the patellar surface of the femur is too shallow. The static ligamentous factors are the medial patellofemoral ligament and medial patellar retinaculum.

Dynamic neuromuscular control is important. The most distal part of vastus medialis (vastus medialis obliquus) consists of transverse fibres that are attached directly to the medial edge of the patella: these pull the patella medially, countering the tendency to move laterally. This is the muscle that is preferentially strengthened in a physical therapy programme aimed at treating patellofemoral conditions often associated with patella tracking problems such as those seen in growing adolescents.

Tibiofemoral joint The tibiofemoral joint surfaces are inherently mobile, especially laterally. Medially, some stability is afforded by the relatively concave tibial surface and the relatively fixed posterior horn of the medial meniscus. Both medially and laterally the menisci are helpful, particularly as they move with the femoral condyles. Ligaments play a major role in constraining mobility because they bind the bones in positions of extreme stress and also provide proprioceptive feedback, aiding coordination of stabilizing muscle activity. To take a somewhat 'two-dimensional' view, the tibial and fibular collateral ligaments may be considered as sensors (resistors) of valgus and varus forces on the knee, respectively, and the anterior and posterior cruciate ligaments as sensors (resistors) of anterior and posterior tibial translation, respectively. However, in reality the situation is more complex than this. The stresses are rarely applied in orthogonal planes and so a combination of forces, especially rotational, is involved. Moreover, many structures other than the collateral and cruciate ligaments are involved in stabilizing the joint. The 'posterolateral corner', which is the primary restraint to varus and rotational forces of the tibia, consists of the popliteofibular, fabellofibular, arcuate and fibular collateral ligaments and iliotibial tract, together with popliteus, the lateral head of gastrocnemius and biceps femoris (see Fig. 78.21). The 'posteromedial corner', which resists tibial rotation, consists of the posterior oblique portion of the superficial part of the tibial collateral ligament, and the capsule including the oblique popliteal ligament and semimembranosus (see Fig. 78.17). Since stresses are often a combination of force plus rotation, structures usually operate together rather than in isolation.

Loading at the knee

During level walking, the force across the tibiofemoral joint for most of the cycle is between two and four times body weight, and can be more. In contrast, the force across the patellofemoral joint is no more than 50% of body weight. Peak force transmission across the joint increases sequentially as the menisci, articular cartilage and subchondral bone are damaged or removed. Walking up or down stairs has little influence on tibiofemoral forces, but significantly increases patellofemoral forces to two (walking up) or three (walking down) times body weight, reflecting the changed angle of the tendon of quadriceps femoris and patellar ligament during flexion. There are two mechanisms for ameliorating forces transmitted across the patella: the extensor lever arm is lengthened as the axis of rotation moves posteriorly during flexion, and the contact area between the patella and femur almost triples between 30° and 90°. To cope with the potential large forces generated by activities such as running, the patella has the thickest articular cartilage in the body.

Knee joint kinematics

The surfaces of the tibia and femur are not as conforming as those of the relatively congruent hip joint. Although this variation in geometry permits motion to occur in six degrees of freedom (**Fig. 78.26**), the primary motion of the knee occurs in the sagittal plane, and a relatively minor degree of movement occurs in the transverse plane. The knee joint may therefore be described simplistically as a modified hinge joint allowing flexion–extension and a measure of rotatory motion. Knee motion is normally defined as starting from 0° (the neutral position), when the tibia and femur are in line in the sagittal plane. Biomechanically, it is important that the knee reaches the neutral position in extension because that allows the leg to support the body weight like a simple strut when the subject is standing still. When the subject is standing upright, if the knee is flexed, the vertical line of action of the body weight passes posterior to the centre of rotation of the knee, tending to cause the body to tilt posteriorly. To counterbalance this, continuous quadriceps femoris contraction is required, causing expenditure of energy.

Active knee flexion leads to approximately 130° flexion. The active motion is limited by apposition of the soft tissue masses (posterior thigh and calf). Passive flexion may reach 160°. This is required in people who habitually kneel as part of daily life, and is a challenge for designers of knee prostheses. It can be observed that such deep flexion is often accompanied by tibial medial rotation, so that, when the subject is kneeling, the buttocks can rest on the feet. This movement carries the lateral tibial plateau anteriorly, so that it does not engage with the femoral lateral condyle in deep knee flexion. The femoral

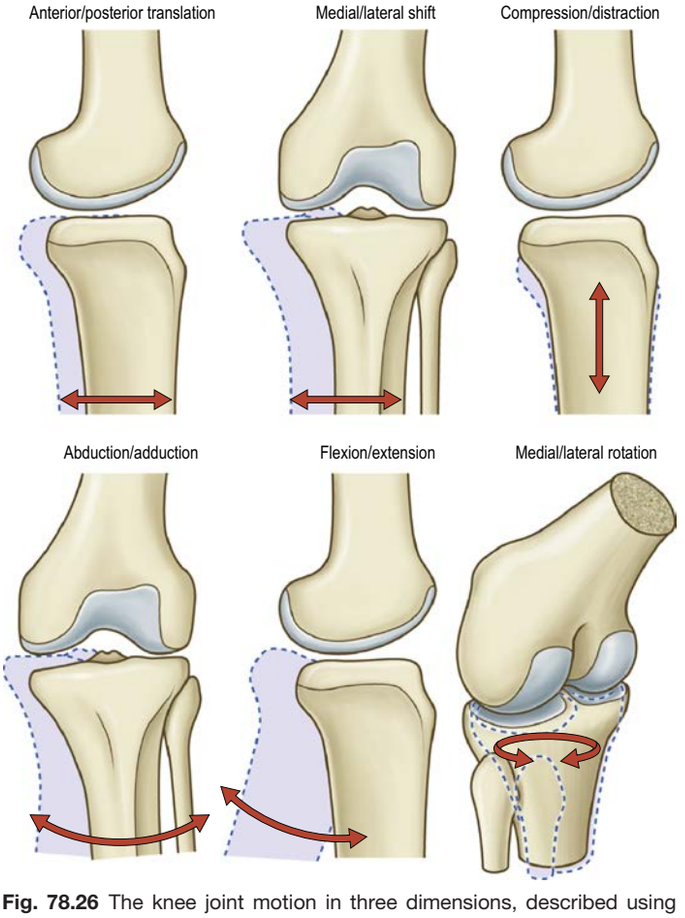

Fig. 78.26 The knee joint motion in three dimensions, described using six independent variables (degrees of freedom).

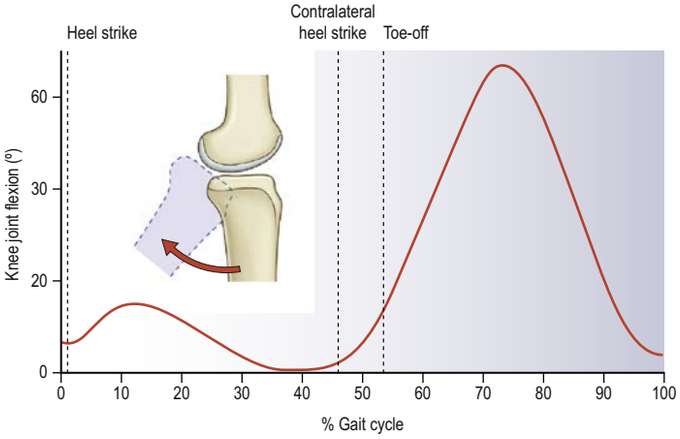

Fig. 78.27 Knee flexion–extension motion during gait.

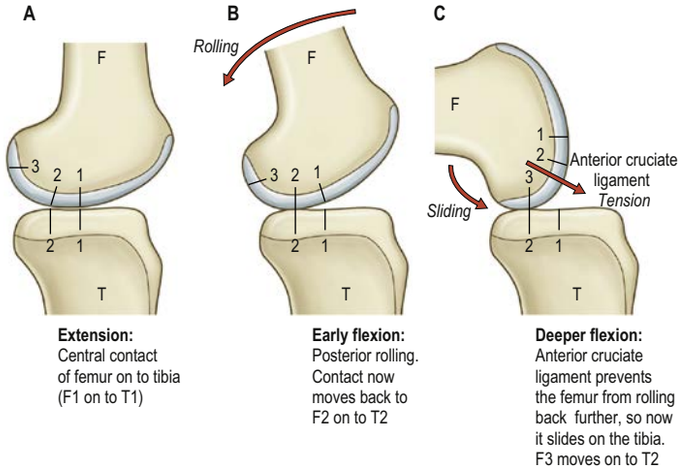

Fig. 78.28 Knee joint kinematics during gait: rolling and sliding (flexion, anterior translation).

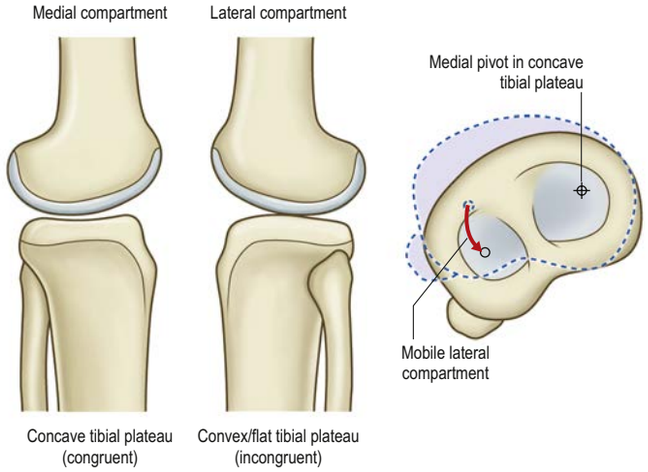

Fig. 78.29 The shape of the articular surfaces providing mobility of the lateral compartment.

condyle passes posteriorly and rides over the horn of the lateral meniscus.

The most frequently employed knee movement occurs when walking (Fig. 78.27). When the leg is swinging past the supporting leg, the knee must be flexed in order to avoid dragging the toes on the ground; this requires approximately 65° knee flexion. When the swinging leg approaches the first contact with the ground, the knee extends, to move the foot forwards for heel contact. If the knee remained extended, this would then cause the body to move in a circular arc, centred at the ankle, causing the centre of gravity to move upwards and then back down again, leading to more energy expenditure. It would also increase the forces on the knee because the leg would act more like a rigid strut, unable to dissipate the impact forces when the foot hit the ground. All these problems are overcome by flexing the knee 15° in the mid-stance phase (see Fig. 78.27); the centre of gravity of the body can move forwards at approximately constant height, and the impact energy is absorbed by stretching quadriceps femoris.

Tibial medial–lateral rotation also occurs during gait: the tibia rotates laterally during terminal extension, a phenomenon known as 'screw-home'. It is surmised that this rotation helps to lock the geometry and tighten the soft tissues, thereby maintaining the knee in a stable position prior to the impact load of weight-bearing. The knee acts as one link in a chain of limb segments, and this screw-home relates to rotation of both the foot and hip. When the foot is swung forwards for heel contact, the pelvis rotates so that the hip is moved forwards, a movement that entails lateral rotation of the hip. During stance, the femur is medially rotated against the locked knee. Tibial lateral rotation also causes inversion of the foot at the subtalar joint, raising the arch and locking the structure of the foot. The knee flexion that occurs after the impact on the ground allows the tibia to rotate medially so that the foot everts, softening its structure and allowing it to deform and absorb energy. Conversely, towards toe-off, the knee extends, rotating the tibia laterally, so the foot is again a rigid lever with which to push the body forwards.

Articular kinematics

Consideration of knee motion at a smaller scale, i.e. within the joint, is difficult to separate from the actions of the ligaments that act as passive restraints to tibiofemoral joint movements, and are discussed below.

Sagittal sections of the knee reveal that the arcs of the femoral condyles are much longer than the anterior–posterior length of the tibial plateau. This means that if the knee flexed with a purely rolling motion, then the femur would roll off the back of the tibia long before the knee reaches full flexion (Fig. 78.28). This does not happen because the femur slides anteriorly at the same time as it rolls posteriorly, and thus remains in correct articulation. If the knee were to possess a fully conforming roller-in-trough geometry, as in the humero-ulnar joint, then flexion would occur by pure sliding movement between the joint surfaces. This conformity is not possible at the knee because it would inhibit the tibial medial–lateral rotation that is needed during locomotion.

In the locked, fully extended knee, the anterodistal femoral articular surfaces press on to the anterior horns of the menisci. This tends to cause the femur to slide posteriorly, tensing the anterior cruciate ligament and slackening the posterior cruciate ligament. With knee flexion, the femur lifts off the anterior horns of the menisci, leading to contact between the smaller radii of the posterior parts of the femoral condyles and the tibial plateau plus the posterior horns of the menisci. This means that the centre of contact moves posteriorly in early knee flexion. After this, the femoral condyles have approximately circular sagittal sections. The femur is now prevented from rolling back any further by tension in the anterior cruciate ligament.

Articular mechanics

The combined effect of the external and internal loads on the knee is to impose considerable forces on the articular cartilage. This may be analysed as a vertical (compressive) component and a horizontal (shear or friction) component. The friction component is a combination of the compressive force and the friction characteristics of the joint surfaces.

Compression

The compressive force is distributed over an area to produce a contact pressure (contact stress). The contact pressure is, therefore, dependent on the area of contact as well as the load itself. Fully conforming articular surface geometry would allow the greatest area of contact, and thus would minimize contact pressure; however, this is not present in the knee. The medial compartment of the knee is semi-conforming with a convex femoral condyle articulating over a concave medial tibial plateau. The lateral compartment has less conformity; the lateral tibial plateau is flat or slightly convex in sagittal sections. These different shapes reflect the differential movement of the medial and lateral compartments. In normal movement, the screw-home rotation of the tibia occurs about a medial axis, which means that most of the rotation of the tibia is due to an anterior–posterior translation of the lateral compartment (Fig. 78.29).

In order to maintain some degree of conformity, and also to minimize contact pressure between the femur and tibia, the menisci are wedge-shaped in cross-section, thereby increasing the area over which the compressive force on the knee is distributed. In the absence of the menisci,

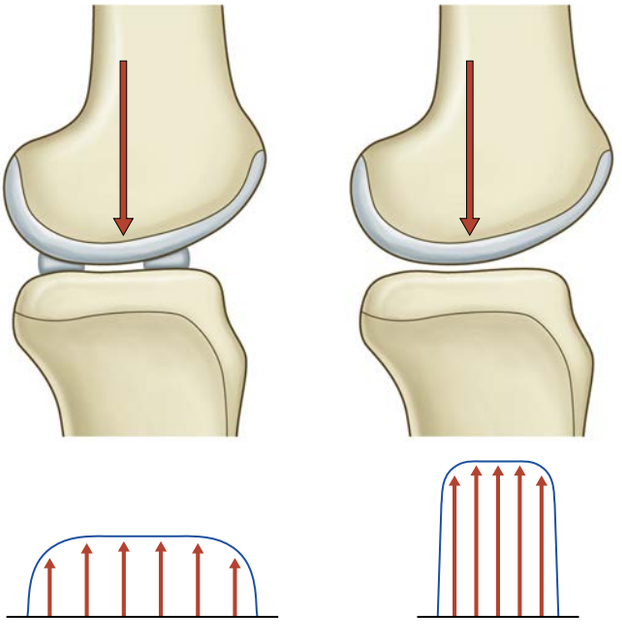

Fig. 78.30 The function of the menisci in increasing articular conformity, with increased peak pressure before and after meniscectomy.

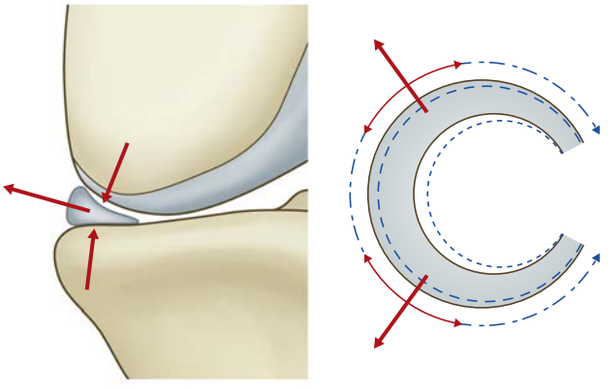

Fig. 78.31 The load-carrying mode of the menisci. Conversion of axial load into meniscal hoop stresses.

the load is carried by a much smaller area of cartilage, resulting in higher contact stresses on the articular cartilage (Fig. 78.30). This helps to explain the prevalence of osteoarthrosis following meniscectomy.

The menisci are most firmly attached at the intercondylar eminence of the tibia, which means that they can translate anteriorly and posteriorly to 'follow' the femoral rollback. The lateral meniscus is more mobile because it is attached to the capsule less tightly than the medial meniscus. The anterior–posterior movement of the menisci is approximately half the magnitude of the anterior–posterior movement of the femur, suggesting that the conformity of the joint changes during flexion of the knee joint.

The distal aspect of the femur, resting on the menisci in the extended knee, has a large radius of curvature and thus fits against the entire area of the menisci. However, as the knee flexes, the smaller radii of the posterior parts of the femoral condyles cause the femur to lift off the anterior horns of the menisci, and the femoral contact is now solely on the posterior horns in the flexed knee. This, combined with the large joint forces that are generated when arising from a seated position, explains why there are often spontaneous tears of the posterior horns in older patients, when standing up from a squatting position.

The load-carrying mode of the menisci is shown in Fig. 78.31. When the femoral condyle presses down on the meniscus, it tends to squeeze the meniscus out of the joint because of its tapered cross-section. This causes the diameter of the circular shape of the meniscus (and therefore the meniscal circumference) to increase. This is resisted by 'hoop tension' in strong fibres that pass around the periphery of the meniscus, and transmit the tension to the tibial plateau via strong insertional ligaments. As the tissue is adapted to resist hoop stresses, it has much greater hoop strength (approximately 100 MPa) than radial strength (approximately 3 MPa), which explains why bucket handle tears occur. It also explains why a circumferential tear does not have such a serious effect on meniscal function because the circumferential fibres can still transmit the loads, whereas a radial tear breaks the load-carrying fibres.

Friction

The knee acts as a bearing that transmits forces and movements between the limb segments. Load-bearing synovial joints move with remarkably little friction and their surfaces must withstand many millions of impact loads, which tend to cause fatigue failure and breakdown of the surfaces.

During walking, every step involves phases of action that vary the loading and velocity conditions at the knee joint. A variety of lubrication mechanisms normally prevent joint surface damage. Thus, in the swing phase, when the foot is off the ground, the joint surfaces are loaded lightly, and have high relative velocity while the knee flexes and extends. This allows the synovial fluid to separate the surfaces, giving fluid film lubrication, with very low friction and no wear (Fig. 78.32). At the time of heel contact, a large impact load acts to compress the surfaces together. At a microscopic level, the surfaces do not come into contact because of the squeeze-film effect: in essence, the impact occurs so rapidly (less than 0.1 sec) that the synovial fluid cannot all be squeezed out of the joint space because of its viscosity and the narrowness of the space. In the mid-stance phase, the flexion–extension motion again entrains the synovial fluid in between the joint surfaces, producing what is known as a hydrodynamic effect: the fluid is trapped between the surfaces by the motion and therefore it acts to separate them. Finally, when the foot is pushing off the body weight, there is little motion and the thin fluid film diminishes under the compressive load. If the squeeze-film effect were insufficient, then the joint surfaces would come into direct contact were it not for the fact that the synovial fluid contains large protein molecules that are trapped on the cartilage surfaces when the fluid is expelled. This molecular layer acts as a boundary lubricant, protecting the cartilage in the same way that grease protects a synthetic bearing.

Many aspects of the arthritic breakdown of the cartilage can be explained on the basis of lubrication biomechanics. Thus, in joints affected by osteoarthrosis, synovial fluid is known to have a lower viscosity than that in normal joints. The viscosity is lower still in joints afflicted with rheumatoid arthritis and is unable to prevent attritional damage to the cartilage surfaces.

Soft tissue mechanics

The knee joint relies on active (musculotendinous) and passive (ligamentous) restraints to maintain its stability. The muscles provide the loading to move the joint: quadriceps femoris, hamstrings and gastrocnemius control both flexion/extension and medial–lateral rotation. However, they also cause anterior–posterior shear forces that are resisted primarily by the cruciate ligaments. This tethering effect is critical in allowing the joint to move physiologically, maintaining congruency and stability.

The passive stabilizers of the joint act by resisting unwanted displacements between the bones. This may be to control the path of motion or to limit the range of motion. When the muscles or some other external force (due to body weight or impact) cause the bones to displace, the ligaments are stretched, and so develop tensile forces that resist the displacement and allow the joint to maintain its stability. Disruption of any of these passive restraints may cause a mechanical instability, which is an abnormally increased displacement due to an applied force (in biomechanical terms this is called excess laxity).

Primary and secondary restraints

On testing the laxity in any of the degrees of freedom of the joint (e.g. in the anterior drawer test, a bedside clinical test in which the subject is placed in the supine position with the knee to be tested flexed to 80–90° before passive forward traction is applied to the tibia), there are usually combinations of ligaments that are tensed. Some of these are better aligned to resist the applied load or displacement. These are termed primary restraints, and are exemplified by the cruciate ligaments and the tibial and fibular collateral ligaments. Secondary restraints are less well aligned but still have a significant restraining effect. These are exemplified by the menisci and by the meniscofemoral ligaments (see p. 1406). In the example in Fig. 78.33, the anterior cruciate ligament is well aligned to resist the applied anterior force. With an absent anterior cruciate ligament, the tibial collateral ligament can resist the applied force; however, it does so by being loaded to a much higher level than the original loading on the anterior cruciate ligament. The size of the lines in the

PL = Patellar ligament force **PF** = Patellofemoral joint reaction force **Q** = Quadriceps femoris traction force

Fig. 78.34 The patellofemoral joint force with knee extension (**A**) and with 90° of knee flexion (**B**).

vector diagram demonstrate this principle: although joint laxity may remain normal initially following rupture of a primary restraint, it may subsequently result in the overload of a secondary restraint and, ultimately, in further soft tissue failure.

The patellofemoral joint is most heavily loaded during weight-bearing activities when the knee is flexed. Analyses of rising from a chair have predicted that the patellar ligament tension at 90° of knee flexion may be greater than the tibiofemoral joint, which is loaded at the same time (Amis and Farahmand 1996).

In the frontal plane, quadriceps femoris and the patellar ligament tensions combine to cause a lateralizing force vector termed the Q-angle effect. The Q angle is defined as the difference between the resultant force vector of quadriceps femoris, which is normally parallel to the femoral shaft, and the patellar ligament (Fig. 78.34). Clinically, the Q angle is changed by the position of hip rotation, tibial rotation and quadriceps femoris tension. The clinical Q angle is 12–15° (males) and 15–18° (females), which means that there is a

greater lateralizing force vector on the patellofemoral joint in females. Contraction of quadriceps femoris, therefore, tends to displace the patella laterally, which is resisted by the geometry of the joint and by the ligaments. Vastus medialis obliquus acts medially and posteriorly as much as it acts proximally, and so its tension helps to resist the Q-angle effect.

MUSCLES

Muscles of the knee

The majority of muscles that act on the knee joint (quadriceps femoris, semimembranosus, biceps femoris, semitendinosus, articularis genus) are described in Chapter 77. Gastrocnemius and popliteus are described below.

Popliteus

Attachments Popliteus is a flat muscle that forms the floor of the lower part of the popliteal fossa (see Figs 78.16A, 78.38A). It arises within the capsule of the knee joint by a strong tendon, 2.5 cm long, which is attached to a depression at the anterior end of the groove (groove for popliteus) on the lateral aspect of the lateral condyle of the femur (see Figs 78.8B, 78.17). Medially, this tendon is joined by collagenous fibres arising from the arcuate popliteal ligament; the fibrous capsule adjacent to the lateral meniscus; and the outer margin of the meniscus.

Popliteus is attached to the medial aspect of the head of the fibula by the popliteofibular ligament, which passes laterally and inferiorly from the popliteus tendon in a sheet of tissue that is normally about 2 cm^2 (see Fig. 78.17). This ligament is the single most important stabilizer of the posterolateral region of the knee and resists lateral rotation of the tibia on the femur. Failure to recognize and reconstruct damage to this ligament and to the related ligamentous structures is the most common reason for a poor result from an otherwise well-performed operation for repair of ruptured cruciate ligaments.

Fleshy fibres expand from the inferior limit of the tendon to form a somewhat triangular muscle that descends medially to be inserted into the medial two-thirds of the triangular area above the soleal line on the posterior surface of the tibia, and into the tendinous expansion that covers its surface (see Fig. 78.8).

An additional head may arise from the sesamoid bone in the lateral head of gastrocnemius. Very rarely, two other muscles may be found deeply situated behind the knee. Popliteus minor runs from the posterior surface of the lateral tibial condyle, medial to plantaris, to the oblique popliteal ligament. Peroneotibialis runs deep to popliteus from the medial side of the fibular head to the upper end of the soleal line.

Relations Popliteus is covered posteriorly by a dense aponeurotic expansion, which is largely derived from the tendon of semimembranosus. Gastrocnemius, plantaris, the popliteal vessels and the tibial nerve all lie posterior to the expansion. The popliteal tendon is intracapsular and is deep to the fibular collateral ligament and the tendon of biceps femoris (see Figs 78.16A, 78.23). It is invested on its deep surface by synovial membrane, and grooves the posterior border of the lateral meniscus and the adjoining part of the tibia before it emerges inferior to the posterior band of the arcuate ligament. This region is called the 'popliteus hiatus'; the lateral meniscus has no peripheral bony attachment here and is therefore rather mobile.

Vascular supply The arterial supply of popliteus is derived mainly from the inferior medial and lateral genicular arteries (see Fig. 78.1). The latter may cross either superficial or deep to the muscle. There are additional contributions from the nutrient artery of the tibia (from the posterior tibial artery), the proximal part of the posterior tibial artery and the posterior tibial recurrent artery.

Innervation Popliteus is innervated by a branch of the tibial nerve (L4, L5 and S1) (see Fig. 78.4) that winds around the distal border of popliteus and enters the anterior surface of the muscle; this nerve also innervates the superior tibiofibular joint and the interosseous membrane of the leg.

Actions Popliteus rotates the tibia medially on the femur or, when the tibia is fixed, rotates the femur laterally on the tibia. It is usually regarded as the muscle that 'unlocks' the joint at the beginning of flexion of the fully extended knee; electromyography supports this view. Its connection with the arcuate popliteal ligament, fibrous capsule and lateral meniscus has led to the suggestion that popliteus may retract the posterior horn of the lateral meniscus during lateral rotation of the femur and flexion of the knee joint, thus protecting the meniscus from being crushed between the femur and the tibia during these movements. The muscle is markedly active in crouching, perhaps to provide stability as the tibia rotates medially during flexion of the knee. However, the main function is likely to be provision of dynamic stability to the posterolateral part of the knee by preventing excessive lateral rotation of the tibia, partly by its direct action, but more significantly by tensing the popliteofibular ligament.

Muscles of the leg

The muscles of the leg consist of an anterior group of extensor muscles, which produce dorsiflexion (extension) of the ankle; a posterior group of flexor muscles, which produce plantar flexion (flexion); and a lateral group of muscles, which evert the ankle and are derived embryologically from the anterior muscle group. The greater bulk of the muscles in the calf is commensurate with the powerful propulsive role of the plantar flexors in walking and running.

Anterior (extensor) compartment

The anterior compartment contains muscles that dorsiflex the ankle when acting from above (**Fig. 78.35A**; see Fig. 78.6). When acting from below, they pull the body forwards on the fixed foot during walking. Two of the muscles, extensor digitorum longus and extensor hallucis longus, also extend the toes, and two muscles, tibialis anterior and fibularis tertius, have the additional actions of inversion and eversion, respectively.

Tibialis anterior

Attachments Tibialis anterior is a superficial muscle and is therefore readily palpable lateral to the tibia. It arises from the lateral condyle and proximal one-half to two-thirds of the lateral surface of the tibial shaft; the adjoining anterior surface of the interosseous membrane; the deep surface of the deep fascia; and the intermuscular septum between itself and extensor digitorum longus (see Figs 78.6A, 78.7B). The muscle descends vertically and ends in a tendon on its anterior surface in the lower third of the leg. The tendon passes through the medial compartments of the superior and inferior retinacula, inclines medially, and is inserted on to the medial and inferior surfaces of the medial cuneiform and the adjoining part of the base of the first metatarsal (see Fig. 79.5B).

Attachments to the talus, first metatarsal head, base of the proximal phalanx of the hallux and extensor retinaculum have been recorded.

Relations Tibialis anterior overlaps the anterior tibial vessels and deep fibular nerve in the upper part of the leg. It lies on the tibia and interosseous membrane. Extensor digitorum longus and extensor hallucis longus lie laterally.

Vascular supply The main body of tibialis anterior is supplied by a series of medial and anterior branches of the anterior tibial artery; the branches may occur in two columns (**Fig. 78.36**). There is a proximal accessory supply from the anterior tibial recurrent artery. The tendon is supplied by the anterior medial malleolar artery and network, dorsalis pedis artery, medial tarsal arteries, and by the medial malleolar and calcaneal branches of the posterior tibial artery (see Fig. 79.10).

Innervation Tibialis anterior is innervated by the deep fibular nerve, L4 and L5.

Actions Tibialis anterior dorsiflexes and inverts the foot. It is most active when both movements are combined, as in walking. Its tendon can be seen through the skin lateral to the anterior border of the tibia and can be traced downwards and medially across the front of the ankle to the medial side of the foot. Tibialis anterior elevates the first metatarsal base and medial cuneiform, and rotates their dorsal aspects laterally.

The muscle is usually quiescent while standing, since the weight of the body acts through vertical lines that pass anterior to the ankle joints. Acting from below, it helps to counteract any tendency to overbalance backwards by flexing the leg forwards at the ankle. It has a role in supporting the medial part of the longitudinal arch of the foot; although electromyographically detectable activity is minimal during standing, it

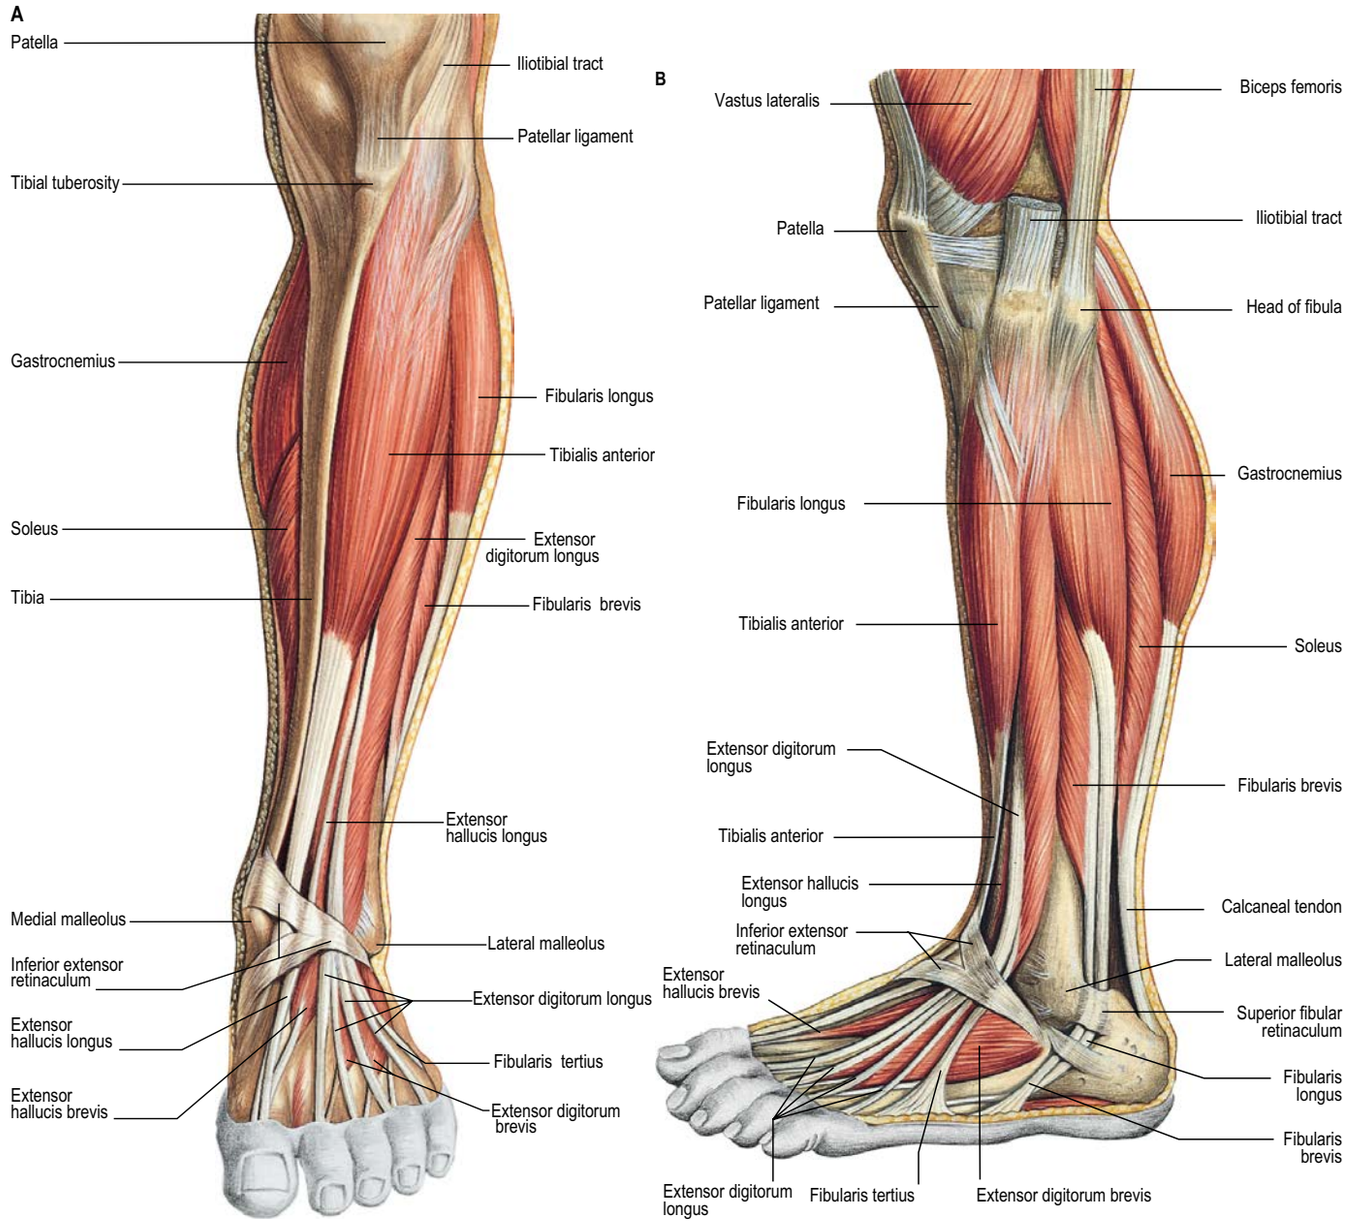

Fig. 78.35 Muscles of the left leg and foot. The fasciae have been removed. **A**, Anterior view. **B**, Lateral view. (With permission from Waschke J, Paulsen F (eds) Sobotta Atlas of Human Anatomy, 15th ed. Elsevier, Urban & Fischer. Copyright 2013.)

is manifest during any movement that increases the arch, such as toe-off in walking and running.

Testing Tibialis anterior can be seen to act when the foot is dorsiflexed against resistance. Dorsiflexion is best tested by asking the subject to walk on their heels.

Extensor hallucis longus

Attachments Extensor hallucis longus lies between, and is partly overlapped by, tibialis anterior and extensor digitorum longus (see Figs 78.6A, 78.35). It arises from the middle half of the medial surface of the fibula, medial to extensor digitorum longus (see Fig. 78.7B), and from the adjacent anterior surface of the interosseous membrane. Its fibres run distally and end in a tendon that forms on the anterior border of the muscle. The tendon passes deep to the superior extensor retinaculum and through the inferior extensor retinaculum, crosses anterior to the anterior tibial vessels to lie on their medial side near the ankle, and is inserted on to the dorsal aspect of the base of the distal phalanx of the hallux (see Fig. 79.5). At the metatarsophalangeal joint, a thin prolongation from each side of the tendon covers the dorsal surface of the joint. An expansion from the medial side of the tendon to the base of the proximal phalanx is usually present (see Fig. 79.1).

Extensor hallucis longus is sometimes united with extensor digitorum longus and may send a slip to the second toe.

Relations The anterior tibial vessels and deep fibular nerve lie between extensor hallucis longus and tibialis anterior. Extensor hallucis longus lies lateral to the artery proximally, crosses it in the lower third of the leg and is medial to it on the foot.

Vascular supply Extensor hallucis longus is supplied by the anterior tibial artery via obliquely running branches, with a variable contribution from the perforating branch of the fibular artery (see Fig. 78.36). More distally, the tendon is supplied via the anterior medial malleolar artery and network, the dorsalis pedis artery and the plantar metatarsal artery of the first digit via perforating branches.

Innervation Extensor hallucis longus is innervated by the deep fibular nerve, L5.

Actions Extensor hallucis longus extends the hallux and dorsiflexes the foot. When the hallux is actively extended, relatively little external force is required to overcome the extension of the distal phalanx, whereas considerable force is needed to overcome the extension of the proximal phalanx.

Testing When the hallux is extended against resistance the tendon of extensor hallucis longus can be seen and felt on the lateral side of the tendon of tibialis anterior.

Extensor digitorum longus

Attachments Extensor digitorum longus arises from the inferior surface of the lateral condyle of the tibia, the proximal three-quarters of the medial surface of the fibula, the adjacent anterior surface of the

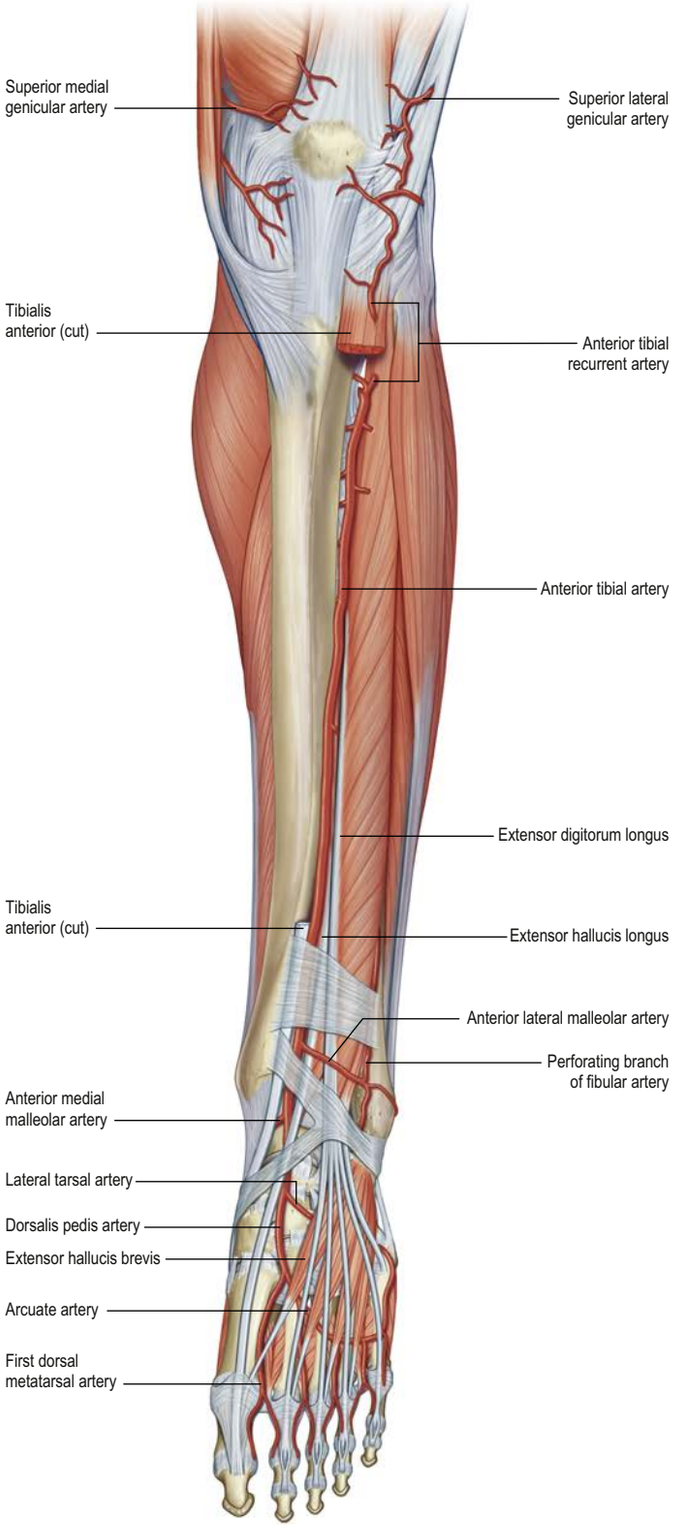

Fig. 78.36 The left anterior tibial and dorsalis pedis arteries. To expose the anterior tibial artery, a large part of tibialis anterior has been excised.

interosseous membrane, the deep surface of the deep fascia, the anterior intermuscular septum and the fascial septum between itself and tibialis anterior (see Figs 78.6A, 78.7B). These origins form the walls of an osseo-aponeurotic tunnel. Extensor digitorum longus becomes tendinous at about the same level as tibialis anterior, and the tendon passes deep to the superior extensor retinaculum and within a loop of the inferior extensor retinaculum with fibularis tertius (see Fig. 78.35A). It divides into four slips, which run forwards on the dorsum of the foot and are attached in the same way as the tendons of extensor digitorum in the hand. At the metatarsophalangeal joints, the tendons to the second, third and fourth toes are each joined on the lateral side by a tendon of extensor digitorum brevis. The so-called dorsal digital expansions thus formed on the dorsal aspects of the proximal phalanges, as in the fingers, receive contributions from the appropriate lumbrical and interosseous muscles. The expansion narrows as it approaches a proximal interphalangeal joint, and divides into three slips. These are a central (axial) slip, attached to the base of the middle phalanx, and two collateral (coaxial) slips, which reunite on the dorsum of the middle phalanx and are attached to the base of the distal phalanx (see Figs 79.1, 79.5A).

The tendons to the second and fifth toes are sometimes duplicated, and accessory slips may be attached to metatarsals or to the hallux.

Relations Extensor digitorum longus lies on the lateral tibial condyle, fibula, lower end of the tibia, ankle joint and extensor digitorum brevis. Tibialis anterior and extensor hallucis longus lie medially in the leg, and the fibular muscles lie laterally. In the upper part of the leg, the anterior tibial vessels and deep fibular nerve lie between extensor digitorum longus and tibialis anterior; the nerve runs obliquely and medially beneath its upper part.

Vascular supply The main blood supply to extensor digitorum longus is derived from anteriorly and laterally placed branches of the anterior tibial artery, supplemented distally from the perforating branch of the fibular artery (see Fig. 78.36). Proximally, there may also be a supply from the inferior lateral genicular, popliteal or anterior tibial recurrent arteries. At the ankle and in the foot the tendons are supplied by the anterior lateral malleolar artery and malleolar network, and by lateral tarsal, metatarsal, plantar and digital arteries (see Fig. 79.10).

Innervation Extensor digitorum longus is innervated by the deep fibular nerve, L5, S1.

Actions Extensor digitorum longus extends the lateral four toes. Acting synergistically with tibialis anterior, extensor hallucis longus and fibularis tertius, it is a dorsiflexor of the ankle. Acting with extensor hallucis longus, it helps tighten the plantar aponeurosis.

Testing The tendons of extensor digitorum longus can be seen when the toes are extended against resistance.

Fibularis tertius

Attachments Fibularis tertius (peroneus tertius) often appears to be part of extensor digitorum longus and might be described as its 'fifth tendon'. The muscle fibres of fibularis tertius arise from the distal third or more of the medial surface of the fibula, the adjoining anterior surface of the interosseous membrane, and the anterior intermuscular septum. The tendon passes deep to the superior extensor retinaculum and within the loop of the inferior extensor retinaculum alongside the extensor digitorum longus (see Figs 78.35, 79.2A). It is inserted on to the medial part of the dorsal surface of the base of the fifth metatarsal; a thin expansion usually extends forwards along the medial border of the shaft of the bone (see Fig. 79.5A).

Relations Fibularis tertius lies lateral to extensor digitorum longus.

Vascular supply Fibularis tertius is supplied by the same vessels as extensor digitorum longus. In the foot it receives an additional supply from the termination of the arcuate artery and the fourth dorsal metatarsal artery.

Innervation Fibularis tertius is innervated by the deep fibular nerve, L5, S1.

Actions Electromyographic studies show that during the swing phase of gait, fibularis tertius acts with extensor digitorum longus and tibialis anterior to produce dorsiflexion of the foot, and with fibularis longus and fibularis brevis to effect eversion of the foot (Jungers et al 1993). This levels the foot and helps the toes to clear the ground, an action that improves the efficiency and enhances the economy of bipedal locomotion. Fibularis tertius is not active during the stance phase, a finding that is at variance with the suggestion that the muscle acts primarily to support the lateral longitudinal arch and to transfer the centre of pressure of the foot medially.

Testing Fibularis tertius cannot be tested in isolation, but its tendon can sometimes be seen and felt when the foot is dorsiflexed against resistance.

Lateral (fibular, peroneal) compartment

The lateral compartment contains fibularis (peroneus) longus and fibularis (peroneus) brevis (see Figs 78.6, 78.35B). Both muscles evert the foot and are plantar flexors of the ankle, and both probably play a part in balancing the leg on the foot in standing and walking.

Fibularis longus

Attachments Fibularis longus is the more superficial of the two muscles of the lateral compartment. It arises from the head and proximal two-thirds of the lateral surface of the fibula, the deep surface of the deep fascia, the anterior and posterior intermuscular septa, and occasionally by a few fibres from the lateral condyle of the tibia (see Fig. 78.6A, 78.7B). The muscle belly ends in a long tendon that runs distally behind the lateral malleolus in a groove it shares with the tendon of fibularis brevis. The groove is converted into a canal by the superior fibular retinaculum, so that the tendon of fibularis longus and that of fibularis brevis, which lies in front of the longus tendon, are contained in a common synovial sheath. If the fibular retinaculum is ruptured by injury and fails to heal, the tendons can dislocate from the groove. The fibularis longus tendon runs obliquely forwards on the lateral side of the calcaneus, below the fibular trochlea and the tendon of fibularis brevis, and deep to the inferior fibular retinaculum. It crosses the lateral side of the cuboid and then runs under the cuboid in a groove that is converted into a canal by the long plantar ligament (see Fig. 79.18). It crosses the sole of the foot obliquely and is attached by two slips, one to the lateral side of the base of the first metatarsal and one to the lateral aspect of the medial cuneiform (see Fig. 79.5A); occasionally, a third slip is attached to the base of the second metatarsal. The tendon changes direction below the lateral malleolus and on the cuboid bone. At both sites it is thickened, and at the second site a sesamoid fibrocartilage (sometimes a bone, the os peroneum) is usually present. A second synovial sheath invests the tendon as it crosses the sole of the foot (see Fig. 79.21B).

Relations Proximally, fibularis longus lies posterior to extensor digitorum longus and anterior to soleus and flexor hallucis longus. Distally, in the leg, it lies posterior to fibularis brevis. Between its attachments to the head and shaft of the fibula there is a gap through which the common fibular nerve passes.

Vascular supply of lateral compartment Usually, the predominant supply of the lateral compartment muscles is derived from branches of the anterior tibial artery; the superior is commonly the larger. There is also a lesser, variable, contribution from the fibular artery in the distal part of the leg (see Fig. 78.4). A fibular branch may replace the inferior branch of the anterior tibial artery; less commonly, the fibular artery provides the main supply to the whole compartment. The upper part of fibularis longus is also supplied by the circumflex fibular branch of the posterior tibial artery, which is usually a branch of the anterior tibial artery. The companion artery to the common fibular nerve, a branch of the popliteal artery, provides a minor contribution proximally. Distally, the tendons are supplied by the fibular perforating, anterior lateral malleolar, lateral calcaneal, lateral tarsal, arcuate, lateral and medial plantar arteries (see Fig. 79.10).

Innervation Fibularis longus is innervated by the superficial fibular nerve, L5, S1.

Actions There is little doubt that fibularis longus can evert the foot and plantar flex the ankle, and possibly act on the leg from its distal attachments. The oblique direction of its tendon across the sole also enables it to support the longitudinal and transverse arches of the foot (see p. 1454). With the foot off the ground, eversion is visually and palpably associated with increased prominence of both tendon and muscle. It is not clear to what extent this helps to maintain plantigrade contact of the foot in normal standing, but electromyographic recordings show little or no fibular activity under these conditions. Fibularis longus and brevis come strongly into action to maintain the concavity of the foot during toe-off and tip-toeing. If the subject deliberately sways to one side, fibularis longus and brevis contract on that side, but their involvement in influencing postural interactions between the foot and leg remains uncertain.

Testing Fibularis longus and brevis are tested together by eversion of the foot against resistance; the tendons can be identified laterally at the ankle and in the foot.

Fibularis brevis

Attachments Fibularis brevis arises from the distal two-thirds of the lateral surface of the fibula, anterior to fibularis longus (see Figs 78.7B, 78.8B), and from the anterior and posterior crural intermuscular septa. It passes vertically downwards and ends in a tendon that passes behind the lateral malleolus together with, and anterior to, that of fibularis longus. The two tendons run deep to the superior fibular retinaculum in a common synovial sheath. The tendon of fibularis brevis then runs forwards on the lateral side of the calcaneus above the fibular trochlea and the tendon of fibularis longus, and is inserted into a tuberosity on the lateral side of the base of the fifth metatarsal (see Fig. 79.5).

Relations Anteriorly lie extensor digitorum longus and fibularis tertius. Fibularis longus and flexor hallucis longus are posterior. On the lateral surface of the calcaneus the tendons of fibularis longus and fibularis brevis occupy separate osteofascial canals formed by the calcaneus and the inferior fibular retinaculum; each tendon is enveloped in a separate distal prolongation of the common synovial sheath (see Fig. 79.2A).

Vascular supply This is considered with the vascular supply of the lateral compartment (above).

Innervation Fibularis brevis is innervated by the superficial fibular nerve, L5, S1.

Actions Fibularis brevis may limit inversion of the foot and so relieve strain on the ligaments that are tightened by this movement (the lateral part of interosseous talocalcaneal, lateral talocalcaneal and calcaneofibular ligaments). It participates in eversion of the foot and may help to steady the leg on the foot. See also 'Fibularis longus'.

Testing This is considered with testing of fibularis longus.

Variants of fibular muscles Tendinous slips from fibularis longus may extend to the base of the third, fourth or fifth metatarsals, or to adductor hallucis. Fusion of fibularis longus and brevis has been reported but is rare. Fibularis tertius is highly variable in its form and bulk but is seldom completely absent; its distal attachment may be to the fourth metatarsal rather than the fifth. Two other variant fibular muscles, arising from the fibula between fibularis longus and fibularis brevis, have been described. These are fibularis accessorius, whose tendon joins that of fibularis longus in the sole, and fibularis quartus, which arises posteriorly and inserts on to the calcaneus or on to the cuboid.

Posterior (flexor) compartment

The muscles in the posterior compartment of the lower leg form superficial and deep groups, separated by the transverse intermuscular septum.

Superficial flexor group

The superficial muscles, gastrocnemius, plantaris and soleus, form the bulk of the calf (**Fig. 78.37**; see Figs 78.3, 78.6). Gastrocnemius and soleus, collectively known as the triceps surae, constitute a powerful muscular mass whose main function is plantar flexion of the foot, although soleus in particular has an important postural role (see below). Their large size is a defining human characteristic, and is related to the upright stance and bipedal locomotion of the human. Gastrocnemius and plantaris act on both the knee and the ankle joints, soleus on the latter alone.

Gastrocnemius

Attachments Gastrocnemius is the most superficial muscle of the group and forms the 'belly' of the calf (see Figs 78.3, 78.37). It arises by two heads, connected to the condyles of the femur by strong, flat tendons. The medial, larger head is attached to a depression at the upper and posterior part of the medial condyle behind the adductor tubercle, and to a slightly raised area on the popliteal surface of the femur just above the medial condyle. The lateral head is attached to a recognizable area on the lateral surface of the lateral condyle and to the lower part of the corresponding supracondylar line (see Fig. 77.12B). Both heads also arise from subjacent areas of the capsule of

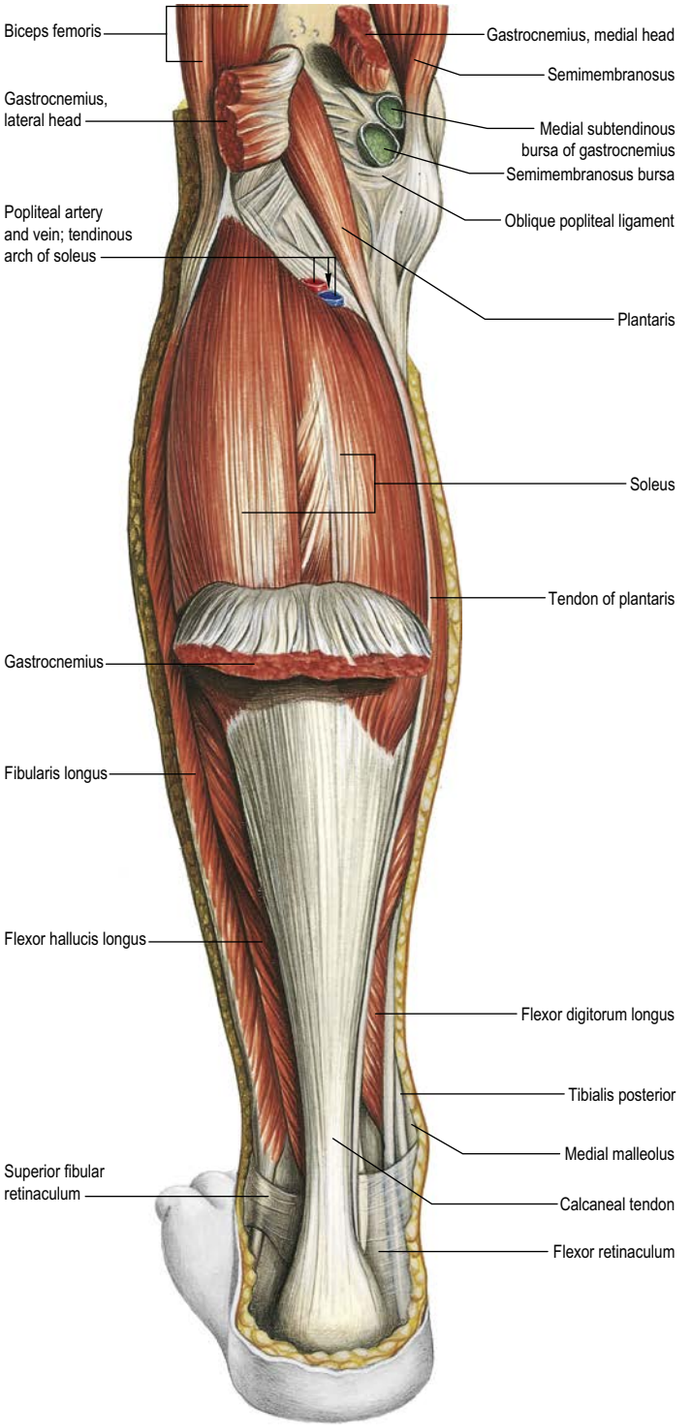

Fig. 78.37 Muscles of the left leg, posterior aspect. Gastrocnemius has been partially removed. (With permission from Waschke J, Paulsen F (eds) Sobotta Atlas of Human Anatomy, 15th ed. Elsevier, Urban & Fischer. Copyright 2013.)

the knee joint. The tendinous attachments expand to cover the posterior surface of each head with an aponeurosis, from the anterior surface of which the muscle fibres arise. The fleshy part of the muscle extends to about mid-calf. The muscle fibres of the larger medial head extend lower than those of the lateral head. As the muscle descends, the muscle fibres begin to insert into a broad aponeurosis that develops on its anterior surface; up to this point, the muscular masses of the two heads remain separate. The aponeurosis gradually narrows and receives the tendon of soleus on its deep surface to form the calcaneal tendon (for a detailed description of the calcaneal tendon, see Chapter 79).

On occasion, the lateral head, or the whole muscle, is absent. A third head arising from the popliteal surface of the femur is sometimes present.

Relations Proximally, the two heads of gastrocnemius form the lower boundaries of the popliteal fossa. The lateral head is partially overlaid by the tendon of biceps femoris, the medial head by semimembranosus (see Fig. 78.2). Over the rest of its length, the muscle is superficial and the two heads can easily be seen in the living subject. The superficial surface of the muscle is separated by the deep fascia from the short saphenous vein and the fibular communicating and sural nerves. The common fibular nerve crosses behind the lateral head of the muscle, partly under cover of biceps femoris. The deep surface lies posterior to the oblique popliteal ligament, popliteus, soleus, plantaris, popliteal vessels and the tibial nerve. A bursa, which communicates with the knee joint, is located anterior to the tendon of the medial head (see Fig. 78.37); if the bursa expands into the popliteal fossa, it does so in the plane between the medial head of gastrocnemius and semimembranosus. The tendon of the lateral head frequently contains a sesamoid bone, the fabella, where it moves over the lateral femoral condyle. A sesamoid bone may occasionally occur in the tendon of the medial head.

Vascular supply Each head of gastrocnemius is supplied by its own sural artery. These arteries are branches of the popliteal artery and arise at variable levels, usually at the level of the tibiofemoral joint line. The medial sural artery almost always arises more proximally than the lateral; the medial may arise proximal to the joint line, the lateral sometimes distal to the line. Each sural artery enters the corresponding muscle head with its nerve of supply, the pedicle entering the muscle near its axial border at the level of the middle of the popliteal fossa. Medial or lateral gastrocnemius musculocutaneous flaps may be raised, each based on its neurovascular pedicle. Minor accessory sural arteries arise from the popliteal or from the superior genicular arteries.

The blood supply to the calcaneal tendon is described in Chapter 79.

Innervation Gastrocnemius is innervated by the tibial nerve, S1 and S2.

Actions The action of gastrocnemius is considered with soleus.

Testing Gastrocnemius is tested by plantar flexion of the foot against resistance, in the supine position and with the knee extended. Plantar flexion (gastrocnemius and soleus) is best tested by asking the subject to perform repetitive unilateral toe rises.

Plantaris

Attachments Plantaris arises from the lower part of the lateral supracondylar line and the oblique popliteal ligament (see Figs 77.12B, 78.37). Its small fusiform belly is 7–10 cm long and ends in a long slender tendon, which crosses obliquely, in an inferomedial direction, between gastrocnemius and soleus, then runs distally along the medial border of the calcaneal tendon and inserts on to the calcaneus just medial to the calcaneal tendon (see Fig. 79.5A). Occasionally, it ends by fusing with the calcaneal tendon.

The muscle is sometimes double, and occasionally absent. Occasionally, its tendon merges with the flexor retinaculum or with the fascia of the leg.

Vascular supply Plantaris is supplied superficially by the lateral sural and popliteal arteries, and deeply by the superior lateral genicular artery. The distal tendon shares a blood supply with the calcaneal tendon.

Innervation Plantaris is innervated by the tibial nerve, often from the ramus that supplies the lateral head of gastrocnemius, S1 and S2.

Actions In many mammals, plantaris is well developed and inserts directly or indirectly into the plantar aponeurosis. In humans, the muscle is almost vestigial and is normally inserted well short of the plantar aponeurosis, usually into the calcaneus. It is therefore presumed to act with gastrocnemius.

Soleus

Attachments Soleus is a broad, flat muscle situated immediately deep (anterior) to gastrocnemius (see Figs 78.6, 78.37). It arises from the posterior surface of the head and proximal quarter of the shaft of the fibula; the soleal line and the middle third of the medial border of the tibia (see Fig. 78.8B); and from a fibrous band between the tibia and fibula (tendinous arch of the soleus) that arches over the popliteal vessels and tibial nerve. This origin is aponeurotic; most of the muscular fibres arise from its posterior surface and pass obliquely to the tendon of insertion on the posterior surface of the muscle. Other muscle fibres

arise from the anterior surface of the aponeurosis. They are short, oblique and bipennate in arrangement, and converge on a narrow, central intramuscular tendon that merges distally with the principal tendon. The latter gradually becomes thicker and narrower, and joins the tendon of gastrocnemius to form the calcaneal tendon. The muscle is covered proximally by gastrocnemius, but below mid-calf it is broader than the tendon of gastrocnemius and is readily accessible on either side of the tendon.

An accessory part of the muscle is sometimes present distally and medially. It may be inserted into the calcaneal tendon, the calcaneus or the flexor retinaculum.

Relations The superficial surface of soleus is in contact with gastrocnemius and plantaris. Its deep surface is related to flexor digitorum longus, flexor hallucis longus, tibialis posterior and the posterior tibial vessels and tibial nerve, from all of which it is separated by the transverse intermuscular septum of the leg.

Vascular supply Soleus is supplied by two main arteries: the superior arises from the popliteal artery at about the level of the soleal arch, and the inferior from the proximal part of the fibular artery or sometimes from the posterior tibial artery. A secondary supply is derived from the lateral sural, fibular or posterior tibial vessels.

There is a venous plexus within the muscle belly that is important physiologically as part of the muscle pump complex (see below). Pathologically, it is a common site of deep vein thrombosis.

Innervation Soleus is innervated by two branches from the tibial nerve, S1 and S2.

Actions These are considered with the actions of triceps surae (below).

Testing Soleus is tested by plantar flexion of the foot against resistance in the supine position, with hip and knee flexed; the muscle belly can be palpated separately from those of gastrocnemius.

Actions of triceps surae

Gastrocnemius and soleus are the chief plantar flexors of the foot; gastrocnemius is also a flexor of the knee. The muscles are usually large and correspondingly powerful. Gastrocnemius provides force for propulsion in walking, running and leaping. Soleus, acting from below, is said to be more concerned with steadying the leg on the foot in standing. This postural role is also suggested by its high content of slow, fatigue-resistant (type 1) muscle fibres. In many adult mammals the proportion of this type of fibre in soleus approaches 100%. However, such a rigid separation of functional roles seems unlikely in humans; soleus probably participates in locomotion, and gastrocnemius in posture. Nevertheless, the ankle joint is loose-packed in the erect posture, and since the weight of the body acts through a vertical line that passes anterior to the joint, a strong brace is required behind the joint to maintain stability. Electromyography shows that these forces are supplied mainly by soleus; during symmetrical standing, soleus is continuously active, whereas gastrocnemius is recruited only intermittently. The relative contributions of soleus and gastrocnemius to phasic activity of the triceps surae in walking have yet to be satisfactorily analysed.

Deep flexor group

The deep flexor group (see Fig. 78.6; **Fig. 78.38**) lies beneath (anterior to) the transverse intermuscular septum and consists of popliteus, which acts on the knee joint, and flexor digitorum longus, flexor hallucis longus and tibialis posterior, which all produce plantar flexion at the ankle in addition to their specific actions on joints of the foot and digits.

Popliteus

Popliteus is described on page 1416.

Flexor digitorum longus

Attachments Flexor digitorum longus is thin and tapered proximally, but widens gradually as it descends (see Fig. 78.38). It arises from the posterior surface of the tibia medial to tibialis posterior from just below the soleal line to within 7 or 8 cm of the distal end of the bone (see Fig. 78.8B); it also arises from the fascia covering tibialis posterior. The muscle ends in a tendon that extends along almost the whole of its posterior surface. The tendon gradually crosses tibialis posterior on its superficial aspect and passes behind the medial malleolus where it shares a groove with tibialis posterior, from which it is separated by a fibrous septum, i.e. each tendon occupies its own compartment lined by a synovial sheath (see Fig. 79.2B). The tendon of flexor digitorum longus then curves obliquely forwards and laterally, in contact with the medial side of the sustentaculum tali, passes deep to the flexor retinaculum, and enters the sole of the foot on the medial side of the tendon of flexor hallucis longus. It crosses superficial to that tendon and receives a strong slip from it (and may also send a slip to it). The tendon of flexor digitorum longus then passes forwards as four separate tendons, one each for the second to fifth toes, deep to the tendons of flexor digitorum brevis. After giving rise to the lumbricals, it passes through the fibrous sheaths of the lateral four toes. The tendons of flexor accessorius insert into the long flexor tendons of the second, third and fourth digits (see Fig. 79.21); flexor hallucis longus makes a variable contribution through the connecting slip mentioned above. The long flexor tendons of the lateral four digits are attached to the plantar surfaces of the bases of their distal phalanges; each passes between the slips of the corresponding tendon of flexor digitorum brevis at the base of the proximal phalanx (see Figs 79.5B, 79.23).

A supplementary head of the muscle, flexor accessorius longus, with its own tendon, may arise from the fibula, tibia or deep fascia and insert into the main tendon or into flexor accessorius in the foot. It may send communicating slips to tibialis anterior or to flexor hallucis longus.

Relations Flexor digitorum longus lies medial to flexor hallucis longus. In the leg, its superficial surface is in contact with the transverse intermuscular septum, which separates it from soleus, and distally from the posterior tibial vessels and tibial nerve. Its deep surface is related to the tibia and to tibialis posterior. In the foot, it is covered by abductor hallucis and flexor digitorum brevis, and it crosses superficial to flexor hallucis longus.

Vascular supply A series of transversely running branches of the posterior tibial artery enters the lateral border of flexor digitorum longus. There may be a secondary supply from fibular branches to flexor hallucis longus. The tendons are supplied by the vessels of the ankle and sole of the foot.

Innervation Flexor digitorum longus is innervated by branches of the tibial nerve, L5, S1 and S2.

Actions These are considered with the actions of the deep digital flexors (below).

Testing Flexor digitorum longus is tested by flexing the toes against resistance. Aberrant function of flexor digitorum longus is implicated in toe deformities such as hammer toe, claw toe and mallet toe. Its tendon may be used in transfer procedures for the surgical treatment of tibialis posterior tendon dysfunction.

Flexor hallucis longus

Attachments Flexor hallucis longus arises from the distal two-thirds of the posterior surface of the fibula (except for the lowest 2.5 cm of this surface); the adjacent interosseous membrane and the posterior crural intermuscular septum; and from the fascia covering tibialis posterior, which it overlaps to a considerable extent (see Fig. 78.38). Its fibres pass obliquely down to a tendon that occupies nearly the whole length of the posterior aspect of the muscle. This tendon grooves the posterior surface of the lower end of the tibia, then, successively, the posterior surface of the talus and the inferior surface of the sustentaculum tali of the calcaneus (see Fig. 79.2B). Fibrous bands convert the grooves on the talus and calcaneus into a canal lined by a synovial sheath. In dancers, overuse causes thickening of the tendon in this region, and pain and even 'triggering' can occur (hallux saltans). In the sole of the foot, the tendon of flexor hallucis longus passes forwards in the second layer like a bowstring. It crosses the tendon of flexor digitorum longus from lateral to medial, curving obliquely superior to it (see Fig. 79.21B). At the crossing point (knot of Henry), it gives off two strong slips to the medial two divisions of the tendons of flexor digitorum longus and then crosses the lateral part of flexor hallucis brevis to reach the interval between the sesamoid bones under the head of the first metatarsal. It continues on the plantar aspect of the hallux, and runs in an osseo-aponeurotic tunnel to be attached to the plantar aspect of the base of the distal phalanx (see Figs 79.5B, 79.23). The tendon is retained in position over the lateral part of flexor

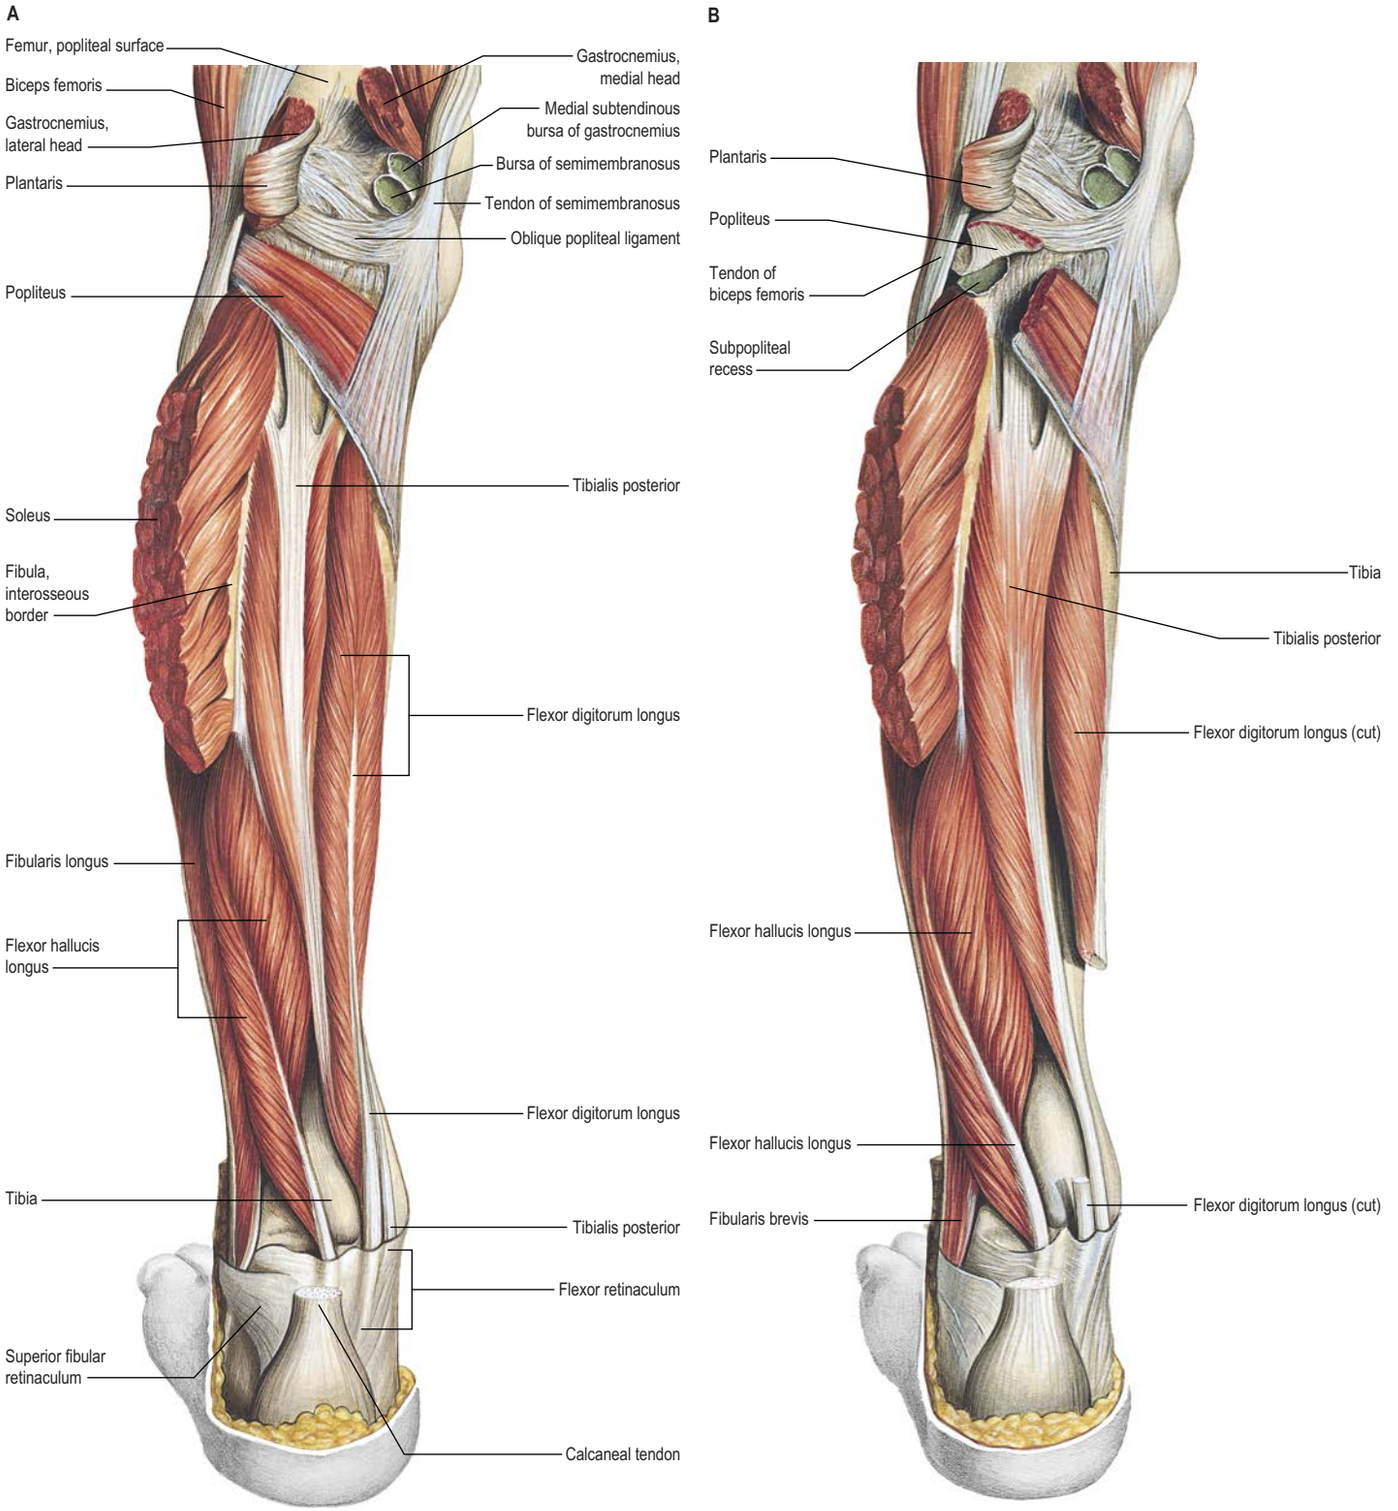

Fig. 78.38 Muscles of the left leg, posterior aspect. **A**, The superficial muscles have been extensively removed. **B**, The superficial muscles have been extensively removed, popliteus has been sectioned and the tendon of flexor digitorum longus removed as it crosses the tendon of tibialis posterior. (With permission from Waschke J, Paulsen F (eds) Sobotta Atlas of Human Anatomy, 15th ed. Elsevier, Urban & Fischer. Copyright 2013.)

hallucis brevis by the diverging stems of the distal band of the medial intermuscular septum.

The distal extent of the muscle belly is a distinctive characteristic; in the posteromedial surgical approach to the ankle, flexor hallucis longus is readily identifiable by the fact that muscle fibres are evident almost to calcaneal level. In athletes, the muscle fibres may be present so far inferiorly into the tendon as to be susceptible to impingement when pulled into the tunnel at the talus.

The connecting slip to flexor digitorum longus varies in size; it usually continues into the tendons for the second and third toes but is sometimes restricted to the second toe and occasionally extends to the fourth toe.

Relations Soleus and the calcaneal tendon lie superficial (i.e. posterior) to flexor hallucis longus, separated by the transverse intermuscular septum. Deeply situated are the fibula, tibialis posterior, fibular vessels, distal part of the interosseous membrane and the talocrural joint. Laterally lie fibularis longus and fibularis brevis; medially are tibialis posterior, posterior tibial vessels and the tibial nerve. Flexor hallucis longus is an important surgical landmark at the ankle; staying lateral to it prevents injury to the neurovascular bundle.

Vascular supply Flexor hallucis longus is supplied by numerous branches of the fibular artery (see Fig. 78.4). The tendon is supplied by arteries of the ankle and foot.

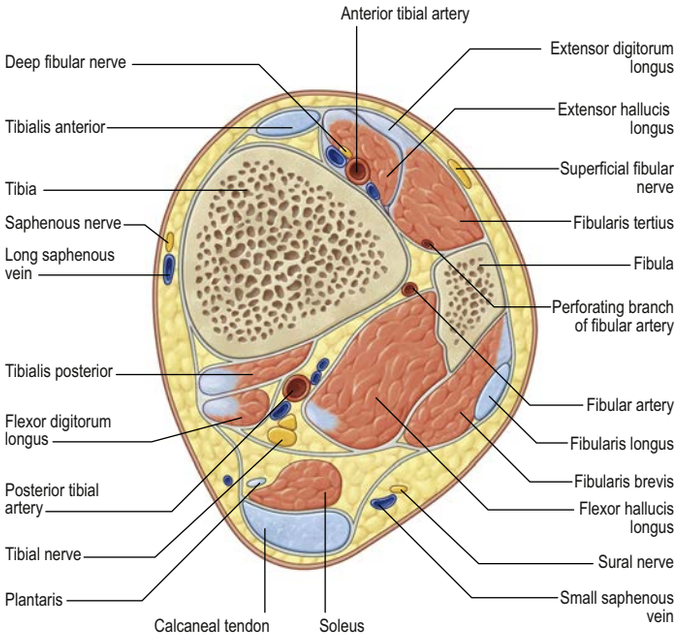

Fig. 78.39 A transverse section through the left leg, approximately 6 cm proximal to the medial malleolus.

Innervation Flexor hallucis longus is innervated by branches of the tibial nerve, L5, S1 and S2 (mainly S1).

Testing Flexor hallucis longus is tested by flexion of the hallux against resistance.

Actions of deep digital flexors

Both flexor hallucis longus and flexor digitorum longus can act as plantar flexors but this action is weak compared with that of gastrocnemius and soleus. When the foot is off the ground, both muscles flex the phalanges, acting primarily on the distal phalanges. When the foot is on the ground and under load, they act synergistically with the small muscles of the foot and, especially in the case of flexor digitorum longus, with the lumbricals and interossei to maintain the pads of the toes in firm contact with the ground, enlarging the weight-bearing area and helping to stabilize the heads of the metatarsals, which form the fulcrum on which the body is propelled forwards. Activity in the long digital flexors is minimal during quiet standing, so they apparently contribute little to the static maintenance of the longitudinal arch, but they become very active during toe-off and tip-toe movements.

Tibialis posterior

Attachments Tibialis posterior is the most deeply placed muscle of the flexor group (see Figs 78.6, 78.38). At its origin it lies between flexor hallucis longus and flexor digitorum longus, and is overlapped by both, but especially by the former. Its proximal attachment consists of two tapered processes, separated by an angular interval that is traversed by the anterior tibial vessels. The medial process arises from the posterior surface of the interosseous membrane, except at its most distal part, and from a lateral area on the posterior surface of the tibia between the soleal line above and the junction of the middle and lower thirds of the shaft below. The lateral part arises from a medial strip of the posterior fibular surface in its upper two-thirds (see Figs 78.7B, 78.8B). The muscle also arises from the transverse intermuscular septum, and from the intermuscular septa that separate it from adjacent muscles. In the distal quarter of the leg, its tendon passes deep to that of flexor digitorum longus, with which it shares a groove behind the medial malleolus, each enclosed in a separate synovial sheath (see Fig. 79.2B). It then passes deep to the flexor retinaculum and superficial to the deltoid ligament to enter the foot. In the foot, it is at first inferior to the plantar calcaneonavicular ligament, where it contains a sesamoid fibrocartilage. The tendon then divides into two. The more superficial and larger division, which is a direct continuation of the tendon, is attached to the tuberosity of the navicular, from which fibres continue to the inferior surface of the medial cuneiform. A tendinous band also passes laterally and a little proximally to the tip and distal margin of the sustentaculum tali. The deeper lateral division gives rise to the tendon of origin of the medial limb of flexor hallucis brevis, and then continues between this muscle and the navicular and medial cuneiform to end on the intermediate cuneiform and the bases of the second, third and fourth metatarsals; the slip to the fourth metatarsal is the strongest (see Fig. 79.5B).

The slips to the metatarsals vary in number. Slips to the cuboid and lateral cuneiform may also occur. An additional muscle, the tibialis secundus, has been described running from the back of the tibia to the capsule of the ankle joint.

Relations The superficial surface of tibialis posterior is separated from soleus by the transverse intermuscular septum, and is related to flexor digitorum longus, flexor hallucis longus, the posterior tibial vessels, the tibial nerve and the fibular vessels. The deep surface is in contact with the interosseous membrane, tibia, fibula and ankle joint.

Vascular supply Tibialis posterior is supplied by numerous branches of small calibre arising from the posterior tibial and fibular arteries. The tendon is supplied by arteries of the medial malleolar network and by the medial plantar artery.

Innervation Tibialis posterior is innervated by the tibial nerve, L4 and L5.

Actions Tibialis posterior is a powerful muscle that, on contraction, has an excursion of only 1–2 cm. It is the principal invertor of the foot and also initiates elevation of the heel; it is responsible for the hindfoot varus that occurs during a single heel raise. Due to its insertions on to the cuneiforms and the bases of the metatarsals, it has long been thought to assist in elevating the longitudinal arch of the foot, although electromyography shows that it is actually quiescent in standing. It is phasically active in walking, during which it probably acts with the intrinsic foot musculature and the lateral leg muscles to control the degree of pronation of the foot and the distribution of weight through the metatarsal heads. It is said that when the body is supported on one leg, the invertor action of tibialis posterior, exerted from below, helps to maintain balance by resisting any tendency to sway laterally.

Tibialis posterior is also important in the maintenance of the medial part of the longitudinal arch of the foot. In overweight individuals with pes planus (flat foot deformity), unaccustomed activity can result in inflammation and degeneration of the terminal portion of the tendon, which leads to elongation of the tendon, attenuation of the spring ligament and progressive collapse of the medial longitudinal arch. As the excursion is so short, the muscle cannot compensate for the lengthening of its tendon, a failure that results in tibialis posterior tendon dysfunction.

Testing Tibialis posterior is tested by asking the subject to move the foot into a position of maximal plantar flexion and inversion against the resistance of the examiner's hand; the tendon can be seen and felt just proximal to the medial malleolus. Testing tibialis posterior function is important in establishing a diagnosis of a common fibular nerve neuropathy and differentiating it from an L5 radiculopathy, which are two common clinical conditions. In a common fibular nerve neuropathy, tibialis posterior has normal function, whereas in an L5 radiculopathy, tibialis posterior is weak.

VASCULAR SUPPLY AND LYMPHATIC DRAINAGE

Arteries

Popliteal artery

The popliteal artery is the continuation of the femoral artery and crosses the popliteal fossa (see Figs 78.1B, 78.2, 78.4). It descends laterally from the opening in adductor magnus to the femoral intercondylar fossa, inclining obliquely to the distal border of popliteus, where it divides into the anterior and posterior tibial arteries. This division usually occurs at the proximal end of the interosseous space between the wide tibial metaphysis and the slender fibular metaphysis. The artery is relatively tethered at the adductor hiatus and again distally by the fascia related to soleus, and is therefore susceptible to damage following knee injuries, e.g. dislocation. Aneurysms of the popliteal artery are not uncommon.

Variations in the popliteal artery The popliteal artery may occasionally bifurcate more superiorly and divide into its terminal branches proximal to popliteus, or it may trifurcate into anterior and posterior

tibial and fibular arteries. Either the anterior tibial or the posterior tibial artery may be reduced or increased in size. The size of the fibular artery is usually inversely related to the size of the anterior and posterior tibial arteries. Rarely, the anterior tibial artery is the source of the fibular artery, a variation that is almost always associated with a high bifurcation of the popliteal artery.

The popliteal and inferior gluteal arteries may be joined by a large anastomotic vessel; in such cases, the femoral artery is hypoplastic (Kawashima and Sasaki 2010). When this occurs, the popliteal artery usually has an abnormal relationship to popliteus, running deep to the muscle before dividing into its terminal branches. The popliteal artery may pass medially beneath the medial head of gastrocnemius, or may pass beneath an aberrant band of muscle in the popliteal fossa; in either case, contraction of the muscles may occlude the artery – a condition that may present with claudication on exertion. The popliteal vein is usually superficial and adjacent to the artery, but it may run deep to the artery, or be separated from it by a slip of muscle derived from the medial head of gastrocnemius.

Relations Anteriorly, from proximal to distal, are the fat covering the femoral popliteal surface, the capsule of the knee joint and the fascia of popliteus. Posteriorly are semimembranosus (proximally) and gastrocnemius and plantaris (distally). In between, the artery is separated from the skin and fasciae by fat and crossed from its lateral to its medial side by the tibial nerve and popliteal vein; the vein lies between the nerve and artery and is adherent to the latter. Laterally are biceps femoris, the tibial nerve, popliteal vein and lateral femoral condyle (all proximal), and plantaris and the lateral head of gastrocnemius (distal). Medially are semimembranosus and the medial femoral condyle (proximal), and the tibial nerve, popliteal vein and medial head of gastrocnemius (distally). The relations of the popliteal nodes are described below.

Branches

Genicular anastomosis

There is an intricate arterial anastomosis around the patella and femoral and tibial condyles (see Fig. 78.1). A superficial network spreads between the fascia and skin around the patella and in the fat deep to the patellar ligament. A deep network lies on the femur and tibia near their adjoining articular surfaces, and supplies the bone, articular capsule and synovial membrane. The vessels involved in this anastomosis are superior medial and lateral genicular; inferior medial and lateral genicular; descending genicular; descending branch of the lateral circumflex femoral; circumflex fibular; and anterior and posterior tibial recurrent arteries. For details, consult Scapinelli (1968).

Superior genicular arteries The superior genicular arteries branch from the popliteal artery, curving round proximal to both femoral condyles to reach the anterior aspect of the knee. The superior medial genicular artery lies under semimembranosus and semitendinosus, proximal to the medial head of gastrocnemius and deep to the tendon of adductor magnus. It divides into a branch to vastus medialis that anastomoses with the descending genicular and inferior medial genicular arteries, and a branch that ramifies on the femur and anastomoses with the superior lateral genicular artery. Its size varies inversely with that of the descending genicular artery. The superior lateral genicular artery passes under the tendon of biceps femoris, pierces the lateral intermuscular septum and divides into superficial and deep branches. The superficial branch supplies vastus lateralis and anastomoses with the descending branch of the lateral circumflex femoral and inferior lateral genicular arteries, while the deep branch anastomoses with the superior medial genicular artery, forming an anterior arch across the femur with the descending genicular artery. The superficial branch is vulnerable if the lateral patellar retinaculum is divided surgically.

Middle genicular artery The middle genicular artery is small. It arises from the popliteal artery near the midpoint of the posterior aspect of the knee joint. It pierces the oblique popliteal ligament to supply the cruciate ligaments and synovial membrane.

Inferior genicular arteries The inferior medial and lateral genicular arteries arise from the popliteal artery deep to gastrocnemius. The inferior medial genicular artery is deep to the medial head of gastrocnemius. It descends along the proximal margin of popliteus, which it supplies; passes inferior to the medial tibial condyle, under the tibial collateral ligament; and then ascends anteromedial to the knee joint at the anterior border of the tibial collateral ligament. It supplies the joint and the tibia, and anastomoses with the inferior lateral and superior medial genicular arteries and with the anterior tibial recurrent artery and saphenous branch of the descending genicular artery. The inferior lateral genicular artery runs laterally across popliteus and forwards over the head of the fibula to the front of the knee joint, passing under the lateral head of gastrocnemius, the fibular collateral ligament and the tendon of biceps femoris. Its branches anastomose with the inferior medial and superior lateral genicular arteries; anterior and posterior tibial recurrent arteries; and the circumflex fibular branch of the posterior tibial artery.

Cutaneous branches: the superficial sural arteries The superficial sural arteries are three vessels that leave the popliteal artery, or its side branches, descend between the heads of gastrocnemius and perforate the deep fascia to supply the skin on the back of the leg. The central or median vessel is usually larger than the medial or lateral vessels, and usually accompanies the sural nerve.

Fasciocutaneous free and pedicled flaps may be raised on the superficial sural arteries.

Superior muscular branches The superior muscular branches are two or three vessels that arise proximally and pass to adductor magnus and the posterior thigh muscles. They anastomose with the termination of the profunda femoris artery.

Sural arteries The two sural arteries are large and arise behind the knee joint to supply gastrocnemius, soleus and plantaris. They are used in gastrocnemius musculocutaneous flaps.

Anterior tibial artery

The anterior tibial artery arises at the distal border of popliteus (**Fig. 78.40**; see Figs 76.4, 78.1, 78.4, 78.36). At first in the flexor compartment, it passes between the heads of tibialis posterior and through the oval aperture in the proximal part of the interosseous membrane to reach the extensor (anterior) compartment, passing medial to the fibular neck; it is vulnerable here during tibial osteotomy. Descending on the anterior aspect of the membrane, it approaches the tibia and, distally, lies anterior to it. At the ankle, the anterior tibial artery is located approximately midway between the malleoli, and it continues on the dorsum of the foot, lateral to extensor hallucis longus, as the dorsalis pedis artery (see Fig. 79.1).

The anterior tibial artery may, on occasion, be small but it is rarely absent. Its function may be replaced by perforating branches from the posterior tibial artery or by the perforating branch of the fibular artery. It occasionally deviates laterally, regaining its usual position at the ankle. It may also be larger than normal, in which case its territory of supply in the foot may be increased to include the plantar surface.

Relations In its proximal two-thirds the anterior tibial artery lies on the interosseous membrane, and in its distal third it is anterior to the tibia and ankle joint. Proximally, it lies between tibialis anterior and extensor digitorum longus, then between tibialis anterior and extensor hallucis longus. At the ankle it is crossed superficially from the lateral side by the tendon of extensor hallucis longus and then lies between this tendon and the first tendon of extensor digitorum longus. Its proximal two-thirds are covered by adjoining muscles and deep fascia, its distal third by the skin, fasciae and extensor retinacula. It is accompanied by venae comitantes. The deep fibular nerve, curling laterally round the fibular neck, reaches the lateral side of the artery where it enters the extensor region, is then anterior to the artery in the middle third of the leg, and becomes lateral again distally.

Branches

The named branches of the anterior tibial artery are the posterior and anterior tibial recurrent, muscular, perforating, and anterior medial and lateral malleolar arteries (see Figs 76.7, 79.10A).

Posterior tibial recurrent artery The posterior tibial recurrent artery is an inconstant branch that arises before the anterior tibial artery reaches the extensor compartment of the leg. It ascends anterior to popliteus, anastomosing with the inferior genicular branches of the popliteal artery. It supplies the superior tibiofibular joint.

Anterior tibial recurrent artery The anterior tibial recurrent artery arises near the posterior tibial recurrent artery. It ascends in tibialis anterior, ramifies on the front and sides of the knee joint, and joins the patellar anastomosis, which interconnects with the genicular branches of the popliteal and circumflex fibular arteries.

Muscular branches Numerous branches supply the adjacent muscles. Some then pierce the deep fascia to supply the skin, while others

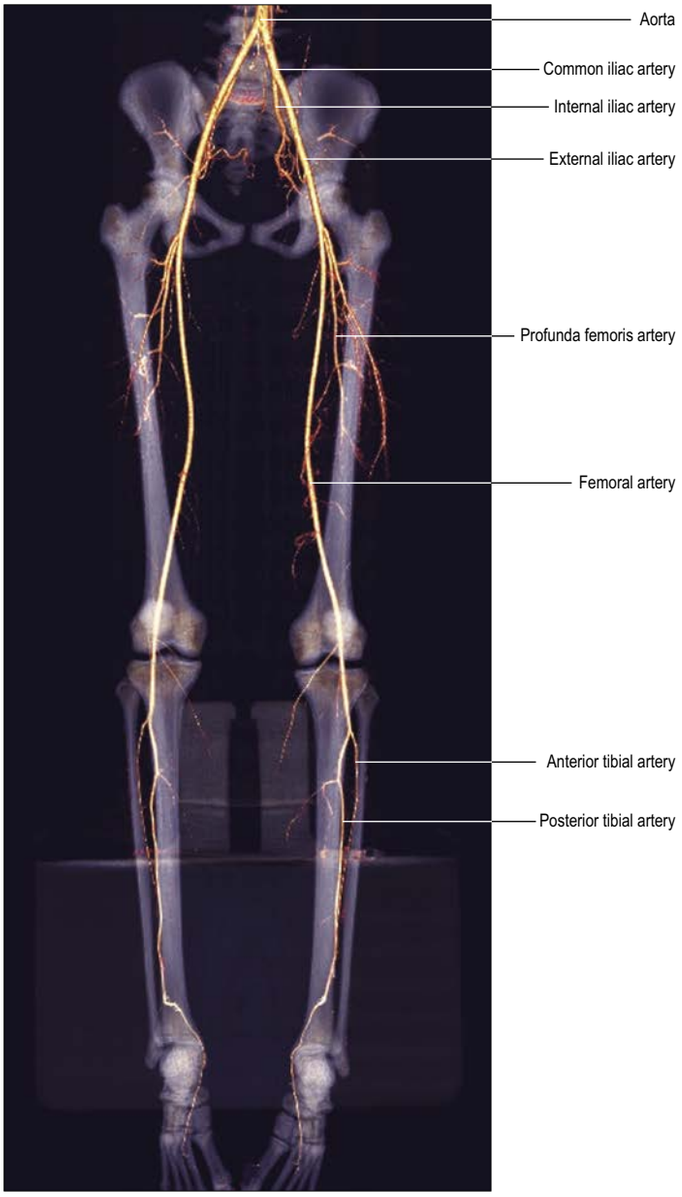

Fig. 78.40 Three-dimensional CT imaging illustrating the arterial supply of the lower limb. Note the relationships of the arteries to the surrounding bones. (Courtesy of Dr Yoginder Vaid and Mr Jon C Betts, Jr.)

traverse the interosseous membrane to anastomose with branches of the posterior tibial and fibular arteries.

Perforating branches Most of the fasciocutaneous perforators pass along the anterior fibular fascial septum behind extensor digitorum longus before penetrating the deep fascia to supply the skin.

Anterior medial malleolar artery The anterior medial malleolar artery arises approximately 5 cm proximal to the ankle. It passes posterior to the tendons of extensor hallucis longus and tibialis anterior medial to the joint, where it joins branches of the posterior tibial and medial plantar arteries.

Anterior lateral malleolar artery The anterior lateral malleolar artery runs posterior to the tendons of extensor digitorum longus and fibularis tertius to the lateral side of the ankle and anastomoses with the perforating branch of the fibular artery and ascending branches of the lateral tarsal artery.

Posterior tibial artery

The posterior tibial artery begins at the distal border of popliteus, between the tibia and fibula (see Figs 76.4B, 78.1B, 78.4, 78.40). It descends medially in the flexor compartment and divides under abductor hallucis, midway between the medial malleolus and the calcaneal tubercle, into the medial and lateral plantar arteries. The artery may be much reduced in length or in calibre; the fibular artery then takes over its distal territory of supply and may consequently be increased in size.

Relations The posterior tibial artery is successively posterior to tibialis posterior, flexor digitorum longus, the tibia and the ankle joint. Proximally, gastrocnemius, soleus and the transverse intermuscular septum of the leg are superficial to the artery, and distally, it is covered only by skin and fascia. It is parallel with and approximately 2.5 cm anterior to the medial border of the calcaneal tendon; terminally, it is deep to the flexor retinaculum. The artery is accompanied by two veins and the tibial nerve. The nerve is at first medial to the artery but soon crosses behind it and subsequently becomes largely posterolateral in position.

Branches

The named branches of the posterior tibial artery are the circumflex fibular, nutrient, muscular, perforating, communicating, medial malleolar, calcaneal, lateral and medial plantar, and fibular arteries (see Figs 76.7B, 79.10).

Circumflex fibular artery The circumflex fibular artery, which sometimes arises from the anterior tibial artery, passes laterally round the neck of the fibula through the soleus to anastomose with the inferior medial and lateral genicular and anterior tibial recurrent arteries. It supplies bone and related articular structures.

Nutrient artery of the tibia The nutrient artery of the tibia arises from the posterior tibia near its origin. After giving off a few muscular branches, it descends into the bone immediately distal to the soleal line. It is one of the largest of the nutrient arteries.

Muscular branches Muscular branches are distributed to the soleus and deep flexors of the leg.

Perforating branches Approximately five fasciocutaneous perforators emerge between flexor digitorum longus and soleus, and pass through the deep fascia, often accompanying the perforating veins that connect the deep and superficial venous systems. The arterial perforators then divide into anterior and posterior branches to supply the regional periosteum and skin. These vessels are utilized in raising medial fasciocutaneous perforator flaps in the leg.

Communicating branch The communicating branch runs posteriorly across the tibia approximately 5 cm above its distal end, deep to flexor hallucis longus, to join a communicating branch of the fibular artery.

Medial malleolar branches The medial malleolar branches pass round the medial malleolus to the medial malleolar network, which supplies the skin.

Calcaneal branches Calcaneal branches arise just proximal to the terminal division of the posterior tibial artery. They pierce the flexor retinaculum to supply fat and skin behind the calcaneal tendon and in the heel, and muscles on the tibial side of the sole; the branches anastomose with medial malleolar arteries and calcaneal branches of the fibular artery.

Medial plantar artery The medial plantar artery is the smaller terminal branch of the posterior tibial artery and passes distally along the medial side of the foot, medial to the medial plantar nerve (see Figs 76.4B, 79.26). At first deep to abductor hallucis, it runs distally between this muscle and flexor digitorum brevis, and supplies both. Near the first metatarsal base its size, already diminished by muscular branches, is further reduced to a superficial stem that divides to form three superficial digital branches. These accompany the digital branches of the medial plantar nerve and join the first to third plantar metatarsal arteries. The main trunk of the medial plantar artery then runs on to reach the medial border of the hallux, where it anastomoses with a branch of the first plantar metatarsal artery.

Lateral plantar artery The lateral plantar artery is the larger terminal branch of the posterior tibial artery (see Figs 76.4B, 79.26). It passes distally and laterally to the fifth metatarsal base, lateral to the lateral plantar nerve. (The medial and lateral plantar nerves lie between the corresponding plantar arteries.) Turning medially with the deep branch of the lateral plantar nerve, it reaches the interval between the first and second metatarsal bases, and unites with the deep plantar artery to complete the plantar arch. As it passes laterally, it is first

between the calcaneus and abductor hallucis, then between flexor digitorum brevis and flexor accessorius. Running distally to the fifth metatarsal base, it passes between flexor digitorum brevis and abductor digiti minimi, and is covered by the plantar aponeurosis, superficial fascia and skin.

Branches Muscular branches supply the adjoining muscles. Superficial branches supply the skin and subcutaneous tissue along the lateral sole. Anastomotic branches run to the lateral border of the foot, joining branches of the lateral tarsal and arcuate arteries. A calcaneal branch sometimes pierces abductor hallucis to supply the skin of the heel.

Fibular artery

The fibular artery arises from the posterior tibial artery approximately 2.5 cm distal to popliteus and passes obliquely to the fibula, descending along its medial crest either in a fibrous canal between tibialis posterior and flexor hallucis longus or within flexor hallucis longus (see Figs 76.4B, 78.4, 78.39). Reaching the inferior tibiofibular syndesmosis, it divides into calcaneal branches that ramify on the lateral and posterior surfaces of the calcaneus. Proximally, it is covered by soleus and the transverse intermuscular septum between soleus and the deep muscles of the leg, and distally it is overlapped by flexor hallucis longus.

The fibular artery may branch high from the posterior tibial artery or may even branch from the popliteal artery separately, resulting in a true 'trifurcation'. It may also branch more distally from the posterior tibial artery, sometimes 7 or 8 cm distal to popliteus. Its size tends to be inversely related to the size of the other arteries of the leg. It may be reduced in size but is more often enlarged, when it may join, reinforce or even replace the posterior tibial artery in the distal leg and foot.

Branches

The fibular artery has muscular, nutrient, perforating, communicating and calcaneal branches (see Fig. 79.10).

Muscular branches Multiple short branches supply soleus, tibialis posterior, flexor hallucis longus and the fibular muscles.

Nutrient artery The nutrient artery branches from the main trunk approximately 7 cm from its origin and enters the fibula 14–19 cm from the apex of the head of the fibula.

Perforating branches The main perforating branch traverses the interosseous membrane approximately 5 cm proximal to the lateral malleolus to enter the extensor compartment, where it anastomoses with the anterior lateral malleolar artery. Descending anterior to the inferior tibiofibular syndesmosis, it supplies the tarsus and anastomoses with the lateral tarsal artery. This branch is sometimes enlarged and may replace the dorsalis pedis artery.

Fasciocutaneous perforators from the lateral muscular branches pass along the posterior fibular fascial septum to penetrate the deep fascia and reach the skin. These vessels are utilized in raising fasciocutaneous posterolateral leg flaps (see below).

Communicating branch The communicating branch connects to a communicating branch of the posterior tibial artery approximately 5 cm proximal to the ankle.

Calcaneal branches Calcaneal (terminal) branches anastomose with the anterior lateral malleolar and calcaneal branches of the posterior tibial artery.

Perforator flaps in the knee and leg

The perforators, which arise from the rich vascular anastomosis around the patella, generally traverse the tendon of quadriceps femoris to supply the skin over the patella and the peripatellar region (see Fig. 76.7). The skin flaps based on these perforators may be used as distally based or proximally based flaps to cover defects over the knee and popliteal region. The direct cutaneous branch of the popliteal artery and a superficial sural artery, which accompanies the sural nerve, provide additional perforators to the skin over the back of the knee. The posterior tibial artery gives off an average of ten perforators to the skin covering the anteromedial and posterior parts of the leg. In the upper third of the leg, the perforating vessels are predominantly muscular and periosteocutaneous, while in the lower third, the perforating vessels are mainly direct subcutaneous types. They anastomose with the perforating branches of the anterior tibial artery anteriorly and fibular artery posteriorly. Inferiorly, the posterior tibial artery forms a rich anastomotic ring around the ankle joint with the fibular and anterior tibial arteries. Perforators from these vessels supply the calcaneal tendon and the overlying skin. The posterior tibial artery gives off three direct cutaneous perforators in the lower part of the leg; a distally based skin or adipofascial flap based on one of these perforators may be used to reconstruct a defect over the anterior or the posterior aspect of the lower leg. The anterior tibial artery gives off an average of six perforators, which supply the anterolateral part of the leg. They emerge in two longitudinal rows; one perforator is fairly large and accompanies the superficial fibular nerve. A small skin flap based on any one of these perforators may be used to cover small defects over the tibia, and a neurocutaneous flap that includes the superficial fibular nerve may be used.

The fibular artery has an average of five perforators. A constant perforator pierces the deep fascia approximately 5 cm above the lateral malleolus and divides into an ascending and a descending branch. A vascularized fibula graft based on the fibular artery is now the standard graft used in reconstruction of the mandible, while small fasciocutaneous and adipofascial flaps based on the perforators of the fibular artery are useful in covering soft tissue defects over the heel and proximal part of the foot.

Veins

Deep veins

The veins draining the knee and leg correspond in name to the arteries and run with them; the named smaller veins drain into the popliteal and femoral veins.

Popliteal vein

The popliteal vein ascends through the popliteal fossa to the opening in adductor magnus, where it becomes the femoral vein (see Figs 76.8, 77.47). Its relationship to the popliteal artery changes as the vein ascends: distally, it is medial to the artery; between the heads of gastrocnemius, it is superficial (posterior) to the artery; and proximal to the knee joint, it is posterolateral to the artery. Its tributaries are the short saphenous vein; veins corresponding to branches of the popliteal artery; and muscular veins, including a large branch from each head of gastrocnemius. There are usually four or five valves in the popliteal vein.

Posterior tibial veins

The posterior tibial veins accompany the posterior tibial artery (see Fig. 76.8). They receive tributaries from the calf muscles (especially from the venous plexus in the soleus) and connections from superficial veins and the fibular veins.

Fibular veins

The fibular veins, running with their artery, receive tributaries from soleus and from superficial veins.

Anterior tibial veins

The anterior tibial veins, continuations of the venae comitantes of the dorsalis pedis artery, leave the anterior compartment between the tibia and fibula, and pass through the proximal end of the interosseous membrane. They unite with the posterior tibial veins to form the popliteal vein at the distal border of popliteus.

Superficial veins

Long saphenous vein

The course of the long saphenous vein is described in Chapter 77.

Short saphenous vein

The short saphenous vein (small saphenous vein) begins posterior to the lateral malleolus as a continuation of the lateral marginal vein (see Fig. 76.9B). In the lower third of the calf, it ascends lateral to the calcaneal tendon, lying on the deep fascia and covered only by subcutaneous tissue and skin. Inclining medially to reach the midline of the calf, it penetrates the deep fascia, within which it ascends on gastrocnemius, only emerging between the deep fascia and gastrocnemius gradually at about the junction of the middle and proximal thirds of the calf (usually well below the lower limit of the popliteal fossa). Continuing its ascent, it passes between the heads of gastrocnemius and proceeds to its termination in the popliteal vein, 3–7.5 cm above the knee joint.

Tributaries

The short saphenous vein connects with deep veins on the dorsum of the foot, receives many cutaneous tributaries in the leg, and sends several communicating branches proximally and medially to join the long saphenous vein. Sometimes a communicating branch ascends medially to the accessory saphenous vein: this may be the main continuation of the short saphenous vein. In the leg, the short saphenous vein lies near the sural nerve and contains 7–13 valves, with one near its termination. Its mode of termination is variable: it may join the long saphenous vein in the proximal thigh or it may bifurcate, one branch joining the long saphenous vein and the other joining the popliteal or deep posterior femoral veins. Sometimes it drains distal to the knee in the long saphenous or sural veins.

Venous disease

Chronic venous disease is common. Sustained overdistension of the superficial veins of the lower limb may result in the development of short, dilated venous segments or varicosities. Varicose veins can occur as a consequence of venous valve failure at the proximal end of the long saphenous vein at the saphenofemoral junction, or in the perforating veins that pass from the superficial system to the high-pressure deep veins. Varicose veins have thin walls and 'leak' red blood cells into adjacent soft tissues. As these cells are broken down, haemosiderin is deposited in the soft tissues, resulting in a brown pigmentation. This phenomenon, together with the fact that venous stasis produces oedema, renders the soft tissues of the leg unhealthy and prone to ulceration, particularly after minor trauma.

Acute venous disease occurs most commonly in the posterior compartment of the leg. This is attributed to the sluggish blood flow that occurs, at times, in the deep veins of the calf. This relative stasis predisposes to the formation of venous thrombi. Fragments of these thrombi may become dislodged and carried in the venous return to the heart to cause a life-threatening pulmonary embolism. Blockage of the normal venous system may contribute to increased local venous pressure and oedema.

Lymphatic drainage

Lymphatic drainage is to the popliteal nodes (see Fig. 76.10). Most of the lymph vessels accompany the genicular arteries; some vessels from the joint drain directly into a node between the popliteal artery and the posterior capsule of the knee joint.

Popliteal nodes

There are usually six small lymph nodes embedded in the fat of the popliteal fossa. One, near the termination of the short saphenous vein, drains the superficial region served by this vessel. Another lies between the popliteal artery and the posterior aspect of the knee, receiving direct vessels from the knee joint and those accompanying the genicular arteries. The remainder flank the popliteal vessels, receiving trunks that accompany the anterior and posterior tibial vessels. Popliteal lymphatic vessels ascend close to the femoral vessels to reach the deep inguinal nodes; some may accompany the long saphenous vein to the superficial inguinal nodes.

INNERVATION

Knee joint

The knee joint is innervated by branches from the obturator, femoral, tibial and common fibular nerves (see Fig. 76.11) (Freeman and Wyke 1967). The articular branch of the obturator nerve is the terminal branch of its posterior division. Muscular branches of the femoral nerve, especially to vastus medialis, supply articular branches to the knee joint. Genicular branches from the tibial and common fibular nerves accompany the genicular arteries, and those from the tibial nerve travel with the medial and middle genicular arteries, while those from the common fibular nerve travel with the lateral genicular and anterior tibial recurrent arteries.

Saphenous nerve

The saphenous nerve is the largest and longest cutaneous branch of the femoral nerve and the longest nerve in the body (see Figs 76.11A, 77.48). It descends lateral to the femoral artery in the femoral triangle and enters the adductor canal, where it crosses anterior to the artery to lie medial to it. At the distal end of the canal, it leaves the artery and emerges through the aponeurotic covering with the saphenous branch of the descending genicular artery. As it leaves the adductor canal, it gives off an infrapatellar branch that contributes to the peripatellar plexus and then pierces the fascia lata between the tendons of sartorius and gracilis, becoming subcutaneous to supply the skin anterior to the patella. It descends along the medial border of the tibia with the long saphenous vein and divides distally into a branch that continues along the tibia to the ankle and a branch that passes anterior to the ankle to supply the skin on the medial side of the foot, often as far as the first metatarsophalangeal joint (see Fig. 76.12A). The saphenous nerve connects with the medial branch of the superficial fibular nerve. Near the mid-thigh, it provides a branch to the subsartorial plexus. The nerve may become entrapped as it leaves the adductor canal.

Tibial nerve

The tibial nerve, the larger component of the sciatic nerve, is derived from the ventral branches (anterior divisions) of the fourth and fifth lumbar and first to third sacral ventral rami. It descends along the back of the thigh and popliteal fossa to the distal border of popliteus. It then passes anterior to the arch of soleus with the popliteal artery and continues into the leg. In the thigh, it is overlapped proximally by the hamstring muscles but it becomes more superficial in the popliteal fossa, where it is lateral to the popliteal vessels (see Fig. 77.47). At the level of the knee, the tibial nerve becomes superficial to the popliteal vessels and crosses to the medial side of the artery. In the distal popliteal fossa, it is overlapped by the junction of the two heads of gastrocnemius.

In the leg, the tibial nerve descends with the posterior tibial vessels to lie between the heel and the medial malleolus (see Fig. 78.4). Proximally it is deep to soleus and gastrocnemius, but in its distal third is covered only by skin and fasciae, and overlapped sometimes by flexor hallucis longus. At first medial to the posterior tibial vessels, it crosses behind them and descends lateral to them until it bifurcates. It lies on tibialis posterior for most of its course except distally, where it adjoins the posterior surface of the tibia. The tibial nerve ends under the flexor retinaculum by dividing into the medial and lateral plantar nerves.

Branches

The branches of the tibial nerve are articular, muscular, sural, medial calcaneal and medial and lateral plantar nerves. The medial and lateral plantar nerves and the medial calcaneal nerve are described in Chapter 79.

Articular branches Articular branches to the knee joint accompany the superior and inferior medial genicular arteries and the middle genicular artery; they form a plexus with a branch from the obturator nerve and also supply the oblique popliteal ligament. The branches accompanying the superior and inferior medial genicular arteries supply the medial part of the capsule. A branch of the nerve to popliteus (tibial nerve) supplies the posterior portion of the superior tibiofibular joint. Just before the tibial nerve bifurcates, it gives off branches that supply the ankle joint.

Muscular branches Proximal muscular branches arise between the heads of gastrocnemius and supply gastrocnemius, plantaris, soleus and popliteus. The nerve to soleus enters its superficial aspect. The branch to popliteus descends obliquely across the popliteal vessels, curling round the distal border of the muscle to its anterior surface. It also supplies tibialis posterior, the superior tibiofibular joint and the tibia, and gives off an interosseous branch that descends near the fibula to reach the distal tibiofibular joint.

Muscular branches in the leg, either independently or by a common trunk, supply soleus (on its deep surface), tibialis posterior, flexor digitorum longus and flexor hallucis longus (see Fig. 78.4). The branch to flexor hallucis longus accompanies the fibular vessels.

Sural nerve The sural nerve descends between the heads of gastrocnemius, pierces the deep fascia proximally in the leg, and is joined at a variable level by the sural communicating branch of the common fibular nerve. Some authors term this branch the lateral sural cutaneous nerve, and call the main trunk (from the tibial nerve) the medial sural cutaneous nerve (see Fig. 76.9B). The sural nerve descends lateral to the calcaneal tendon, near the short saphenous vein, to the region between the lateral malleolus and the calcaneus, and supplies the posterior and lateral skin of the distal third of the leg. It then passes distal to the lateral malleolus along the lateral side of the foot and fifth toe, supplying the

overlying skin (see Fig. 76.12). It connects with the posterior femoral cutaneous nerve in the leg and with the superficial fibular nerve on the dorsum of the foot.

The sural nerve is often used as an autologous peripheral nerve graft on the grounds that it is easily harvested, readily identified and exclusively cutaneous.

Lesions of the tibial nerve

The tibial nerve is vulnerable to direct injury in the popliteal fossa, where it lies superficial to the popliteal vessels at the level of the knee, or to compression at the tendinous arch of the soleus. It may be damaged in compartment syndrome that affects the deep flexor compartment of the calf. The tibial nerve or the medial and lateral plantar nerves may become entrapped beneath the flexor retinaculum or the so-called plantar tunnels (beneath the fascia of the abductor hallucis) at the ankle, resulting in tarsal tunnel syndrome.

Common fibular nerve

The common fibular nerve (common peroneal nerve) is approximately half the size of the tibial nerve and is derived from the dorsal branches of the fourth and fifth lumbar and first and second sacral ventral rami. It descends obliquely along the lateral side of the popliteal fossa to the fibular head, medial to biceps femoris. It lies between the tendon of biceps femoris, to which it is bound by fascia, and the lateral head of gastrocnemius (**Fig. 78.41**; see Fig. 76.11). The nerve then passes into the anterolateral compartment of the leg through a tight opening in the thick fascia overlying tibialis anterior. It curves lateral to the fibular neck, deep to fibularis longus, and divides into superficial and deep fibular nerves; an articular trunk, derived from the deep fibular nerve, provides an articular branch that travels with the anterior tibial recurrent artery and a proximal branch to tibialis anterior.

Branches

The common fibular nerve has articular and cutaneous branches, and terminates as the superficial and deep fibular nerves.

Articular branches There are three articular branches. Two accompany the superior and inferior lateral genicular arteries; they may arise in common. The third, the recurrent articular branch, arises near the termination of the common fibular nerve. It ascends with the anterior recurrent tibial artery through tibialis anterior and supplies the anterolateral part of the knee joint capsule and the proximal tibiofibular joint.

Cutaneous branches The two cutaneous branches, often from a common trunk, are the lateral sural and sural communicating nerves (see Fig. 76.9). The lateral sural cutaneous nerve (lateral cutaneous nerve of the calf) supplies the skin on the anterior, posterior and lateral surfaces of the proximal leg (see Fig. 76.12A). The sural communicating nerve arises near the head of the fibula and crosses the lateral head of gastrocnemius to join the sural nerve. It may descend separately as far as the heel.

Lesions of the common fibular nerve

The common fibular nerve is relatively unprotected as it traverses the lateral aspect of the neck of the fibula and is easily compressed at this site, e.g. by plaster casts or ganglia. The nerve may also become entrapped by a fascial band beneath fibularis longus within the so-called fibular tunnel, between the attachments of fibularis longus to the head and shaft of the fibula (van den Bergh et al 2013). Traction lesions can accompany dislocations of the lateral compartment of the knee, and are most likely to occur if the distal attachments of biceps femoris and the ligaments that insert on to the fibular head are avulsed, possibly with a small part of the fibular head; the nerve is tethered to the tendon of biceps femoris by dense fascia and so is pulled proximally. Severe traction lesions may produce longitudinal injuries affecting a long segment of the common fibular nerve. Torsional injury following ankle injury (sprain or fracture) may result in common fibular neuropathy; the injury is transmitted from the ankle along the interosseous membrane to the proximal leg (Lalezari et al 2012). Patients with such injury present with a foot drop. Physical examination reveals weakness or paralysis of ankle dorsiflexion, toe extension and eversion of the foot, but inversion and plantar flexion are normal. Sensation on the dorsum of the foot, including the first dorsal web space, is diminished. The ankle reflex is preserved. Since the common fibular nerve divides at the fibular neck into the superficial and deep fibular nerves, injuries to the nerve at this level may damage either the main trunk or its branches. Electrodiagnostic studies can help localize a common fibular nerve injury to the fibular neck region. At this level, nerve conduction studies may show slowed velocities and electromyography would demonstrate denervation in the muscles innervated by the common fibular nerve (such as tibialis anterior or fibularis longus), whereas more proximally innervated muscles (particularly the short head of biceps femoris) would be normal.

Superficial fibular nerve

The superficial fibular nerve (superficial peroneal nerve) begins at the bifurcation of the common fibular nerve. It lies deep to fibularis longus at first (see Fig. 78.6A), then passes anteroinferiorly between fibularis longus and brevis and extensor digitorum longus, and pierces the deep fascia in the distal third of the leg (see Fig. 78.41). It divides into a large medial dorsal cutaneous nerve and a smaller, more laterally placed, intermediate dorsal cutaneous nerve, usually after piercing the deep fascia (see Fig. 76.9A), but sometimes while it is still deep to the fascia. As the nerve lies between the muscles it supplies fibularis longus, fibularis brevis and the skin of the lower leg. The deep course, i.e. the compartmental localization, and the peripheral digital distribution of the superficial fibular nerve are subject to considerable variation (Kosinski 1926, Solomon et al 2001).

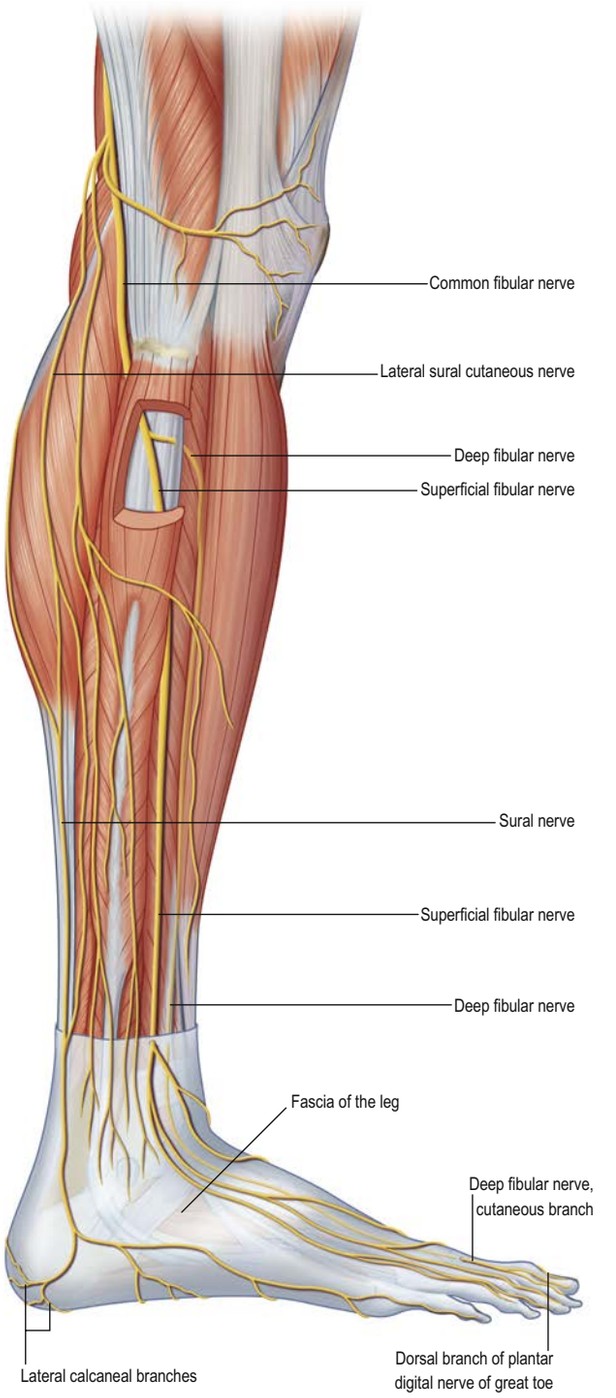

Fig. 78.41 The course, relations and branches of the right common fibular nerve. (Courtesy of Rolfe Birch, all rights reserved, published in Birch R, Surgical Disorders of the Peripheral Nerve, 2nd ed. 2011. Springer-Verlag, London.)

Branches

The medial dorsal cutaneous nerve passes in front of the ankle joint and divides into two dorsal digital branches; one of these supplies the medial side of the hallux and the other supplies the adjacent side of the second and third toes. It communicates with the saphenous and deep fibular nerves. The smaller intermediate branch crosses the dorsum of the foot laterally. It divides into dorsal digital branches that supply the contiguous sides of the third to fifth toes and the skin of the lateral aspect of the ankle (see Fig. 76.12A, C), where it connects with the sural nerve. Both branches, especially the intermediate, are at risk during the placement of portal skin incisions for arthroscopy and during surgical approaches to the lateral malleolus. Branches of the superficial fibular nerve supply the skin of the dorsum of all the toes except that of the lateral side of the fifth toe (supplied by the sural nerve) and the adjoining sides of the great and second toes (supplied by the medial terminal branch of the deep fibular nerve). Some of the lateral branches of the superficial fibular nerve are frequently absent and are replaced by sural nerve branches.

Accessory fibular nerves An accessory superficial fibular nerve and an accessory deep fibular nerve have been described as variant branches of the superficial fibular nerve; both are probably the product of atypical branching of the parent nerve deep to the deep fascia (see above).

Lesions of the superficial fibular nerve

A lesion of the superficial fibular nerve causes weakness of foot eversion and sensory loss on the lateral aspect of the leg that extends on to the dorsum of the foot. The nerve can be subject to entrapment as it penetrates the deep fascia of the leg and it may also be involved in compartment syndrome that affects the lateral compartment of the leg.

Deep fibular nerve

The deep fibular nerve (deep peroneal nerve) begins at the bifurcation of the common fibular nerve, between the fibula and the proximal part of fibularis longus (see Fig. 78.41). It passes obliquely forwards deep to extensor digitorum longus to the front of the interosseous membrane and reaches the anterior tibial artery in the proximal third of the leg. It descends with the artery to the ankle, where it divides into lateral and medial terminal branches. As it descends, the nerve is first lateral to the artery, then anterior and finally lateral again at the ankle.

Branches

The deep fibular nerve supplies muscular branches to tibialis anterior, extensor hallucis longus, extensor digitorum longus and fibularis tertius, and an articular branch to the ankle joint.

The lateral terminal branch crosses the ankle deep to extensor digitorum brevis, enlarges as a pseudoganglion and supplies extensor digitorum brevis. From the enlargement, three minute interosseous branches supply the tarsal and metatarsophalangeal joints of the middle three toes.

The medial terminal branch runs distally on the dorsum of the foot lateral to the dorsalis pedis artery, and connects with the medial branch of the superficial fibular nerve in the first interosseous space. It divides into two dorsal digital nerves, which supply adjacent sides of the great and second toes (see Figs 76.9A, 76.12C). Before dividing, it gives off an interosseous branch, which supplies the first metatarsophalangeal joint. The deep fibular nerve may end as three terminal branches.

Lesions of the deep fibular nerve

Isolated injury to the deep fibular nerve may result from compartment syndrome that affects the anterior compartment of the leg or from an intraneural ganglion cyst (mucinous cyst within the nerve derived from the superior tibiofibular joint via the articular branch that travels with the anterior tibial recurrent artery (Spinner et al 2003)). Individuals with lesions of the deep fibular nerve have weakness of ankle dorsiflexion and extension of all toes but normal foot eversion. Sensory impairment is confined to the first interdigital web space.

CHAPTER 79

Ankle and foot

The ankle joint (talocrural joint) is a diarthrodial articulation involving the distal tibia and fibula and the body of the talus; it is the only example in the human body of a true mortise joint. The human foot is a complex structure adapted to allow orthograde bipedal stance and locomotion and is the only part of the body that is in regular contact with the ground (Jones 1949). There are 28 separate bones in the human foot, including the sesamoid bones of the first metatarsophalangeal joint, and 31 joints, including the ankle joint. The hindfoot comprises the calcaneus and talus; the midfoot comprises the navicular, cuboid and three cuneiforms; the forefoot comprises five metatarsals, 14 phalanges and two sesamoid bones. With regard to the nomenclature of the surfaces of the foot, the terms 'plantar' and 'dorsal' are used to denote inferior and superior surfaces, respectively.

SKIN AND SOFT TISSUES

Skin

Vascular supply and lymphatic drainage

The skin around the ankle is supplied by anterior lateral and anterior medial malleolar arteries from the anterior tibial artery, posterior medial malleolar branches from the posterior tibial artery, posterior lateral malleolar branches from the fibular artery, and fasciocutaneous perforators from the anterior and posterior tibial and fibular arteries. The main blood supply to the medial side of the heel is from the medial calcaneal branches of the posterior tibial artery or, sometimes, the lateral plantar artery passing through the flexor retinaculum (Attinger et al 1997). The skin of the lateral side of the heel is supplied by lateral calcaneal branches of the fibular artery and the lateral tarsal artery. The arterial supply to the skin of the foot is rich and is derived from branches of the dorsalis pedis (the direct continuation of the anterior tibial artery), posterior tibial and fibular arteries. The skin covering the dorsum of the foot is supplied by the dorsalis pedis artery and by its continuation, the first dorsal metatarsal artery, with smaller contributions from the anterior perforating branch of the fibular artery and the marginal anastomotic arteries on the medial and lateral borders of the foot. The skin covering the plantar surface of the foot is supplied by perforating branches of the medial and lateral plantar arteries (the terminal branches of the posterior tibial artery). The skin of the forefoot is supplied by cutaneous branches of the common digital arteries.

Cutaneous venous drainage is via dorsal and plantar venous arches draining into medial and lateral marginal veins. The medial and lateral marginal veins form the long (great) and short (small) saphenous veins, respectively. On the plantar aspect of the foot, a superficial venous network forms an intradermal and subdermal mesh that drains to the medial and lateral marginal veins. Venous branches that accompany the medial and lateral plantar arteries arise from a deep venous network. Uniquely within the lower limb, venous flow in the foot is bidirectional. However, when valves are present, flow is from the plantar to the superficial dorsal system. From here, blood leaves the foot in the superficial and deep veins of the lower limb.

Superficial lymphatic drainage of all areas of the leg and foot (except the superficial posterolateral area) is via lymphatic vessels that accompany the long saphenous vein and its tributaries. The superficial posterolateral foot and leg drain into the popliteal lymph nodes via lymphatic vessels that accompany the short saphenous vein. Deep lymphatic vessels that accompany the dorsalis pedis, posterior tibial and fibular arteries drain into the popliteal lymph nodes.

Innervation

The skin covering the ankle and foot is innervated by nerves derived from the fourth and fifth lumbar and first sacral spinal nerves (see Figs 76.12, 76.14). Innervation of the dorsum of the foot is provided medially by the saphenous nerve, centrally by the superficial fibular nerve and laterally by the sural nerve; the deep fibular nerve supplies the dorsum of the first web space. Dorsal branches of the medial and lateral plantar nerves innervate the nail beds. The plantar aspect of the foot is innervated by the medial and lateral plantar nerves, which arise as terminal branches of the tibial nerve. The medial plantar nerve supplies sensation to the plantar aspect of the great toe and the second, the third and the medial half of the fourth toes. The lateral plantar nerve supplies the remaining lateral aspect of the fourth and the entire fifth toe. The heel is innervated by calcaneal branches of the tibial and sural nerves. Injury to any of these nerves can lead to painful neuromas and loss of protective sensation, the latter is a common complication in diabetic neuropathy, which is one of the major risk factors in developing diabetic foot ulcers.

Nail apparatus

A toenail consists of a nail plate with the underlying nail matrix and nail bed. The nail apparatus is described in Chapter 7. The toenail is commonly a site of several pathologies, including onychomycosis and onychocryptosis (Jules 1989, Eekhof et al 2012).

Soft tissues

Retinacula at the ankle

In the vicinity of the ankle joint, the tendons of the muscles of the leg are bound down by localized, band-shaped thickenings of the deep fascia termed retinacula, which collectively serve to prevent bowstringing of the underlying tendons during muscle contraction. The retinacula can be considered as specialized deep fascia that may have a role in spatial proprioception (Stecco et al 2010).

There are superior and inferior extensor retinacula, a flexor retinaculum and superior and inferior fibular retinacula.

Extensor retinacula

Superior extensor retinaculum

The superior extensor retinaculum binds down the tendons of tibialis anterior, extensor hallucis longus, extensor digitorum longus and fibularis tertius immediately proximal to the anterior aspect of the ankle joint (**Fig. 79.1**). The anterior tibial vessels and deep fibular nerve pass deep to the retinaculum, and the superficial fibular nerve passes superficially. The retinaculum is attached laterally to the distal end of the anterior border of the fibula and medially to the anterior border of the tibia. Its proximal border is continuous with the deep fascia of the leg, and dense connective tissue connects its distal border to the inferior extensor retinaculum. Laterally, it blends with the superior fibular retinaculum and medially it blends with the upper border of the extensor retinaculum. The tendon of tibialis anterior is the only extensor tendon that possesses a synovial sheath at the level of the superior extensor retinaculum, which means that tenosynovitis of tibialis anterior can cause pain at the level of the superior extensor retinaculum (Genç et al 2013).

Inferior extensor retinaculum

The inferior extensor retinaculum is a Y-shaped band lying anterior to the ankle joint (see Fig. 78.35; **Fig. 79.2**). The stem of the Y is at the lateral end, where it is attached to the upper surface of the calcaneus, anterior to the calcaneal sulcus. The band passes medially, forming a strong loop around the tendons of fibularis tertius and extensor digitorum longus (see Fig. 79.2A). From the deep surface of the loop, a band passes laterally behind the interosseous talocalcaneal and cervical ligaments and is attached to the calcaneal sulcus. At the medial end of the loop, two diverging limbs extend medially to complete the 'Y' shape of the retinaculum. The proximal limb consists of two layers. The deep layer passes deep to the tendons of extensor hallucis longus and tibialis anterior, but superficial to the anterior tibial vessels and deep fibular nerve, to reach the medial malleolus. The superficial layer crosses superficial to the tendon of extensor hallucis longus and then adheres firmly to the deep one; in some cases, it continues superficial to the tendon of tibialis anterior, before blending with the deep layer. The distal limb

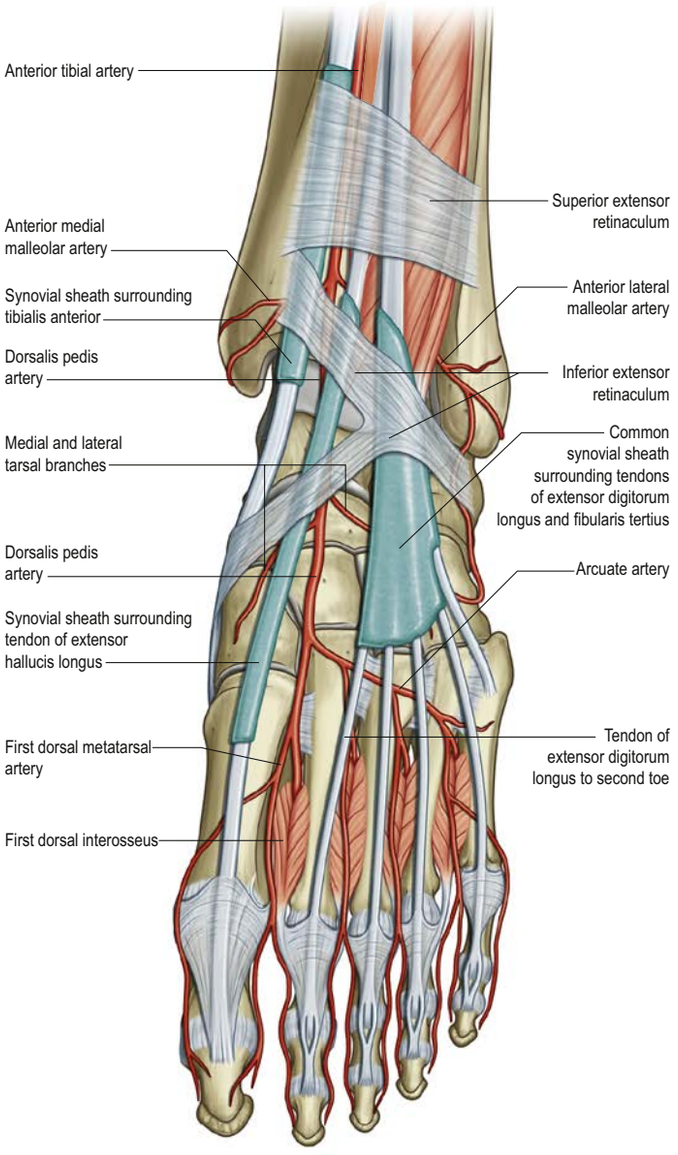

Fig. 79.1 The synovial sheaths of the tendons of the ankle, anterior aspect. (With permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 2nd ed. Elsevier, Churchill Livingstone. Copyright 2010.)

extends downwards and medially and blends with the plantar aponeurosis. It is superficial to the tendons of extensor hallucis longus and tibialis anterior, the dorsalis pedis artery and the terminal branches of the deep fibular nerve.

Flexor retinaculum

The flexor retinaculum is attached anteriorly to the medial malleolus, distal to which it is continuous with the deep fascia on the dorsum of the foot (see Fig. 79.2B). From its malleolar attachment, it extends posteroinferiorly to the medial process of the calcaneus and the plantar aponeurosis. Proximally, there is no clear demarcation between its border and the deep fascia of the leg, especially the deep transverse layer of the deep fascia. Distally, its border is continuous with the plantar aponeurosis and many fibres of abductor hallucis are attached to it. The flexor retinaculum converts grooves on the tibia and calcaneus into canals for the tendons, and bridges over the posterior tibial vessels and tibial nerve. As these structures enter the sole, they are, from medial to lateral, the tendons of tibialis posterior and flexor digitorum longus, the posterior tibial vessels, the tibial nerve and the tendon of flexor hallucis longus (see Fig. 79.15).

Fibular retinacula

The fibular retinacula are fibrous bands that retain the tendons of fibularis longus and brevis in position as these tendons cross the lateral aspect of the ankle region (see Fig. 79.2A).

Superior fibular retinaculum

The superior fibular retinaculum is a short band that extends from the back of the lateral malleolus to the deep transverse fascia of the leg and the lateral surface of the calcaneus. Damage to the retinaculum can lead to instability of the tendons of fibularis longus and brevis.

Inferior fibular retinaculum

The inferior fibular retinaculum is continuous in front with the inferior extensor retinaculum, and is attached posteriorly to the lateral surface of the calcaneus. Some of its fibres are fused with the periosteum on the fibular trochlea (peroneal trochlea or tubercle) of the calcaneus, forming a septum between the tendons of fibularis longus and brevis.

Synovial sheaths at the ankle

Anterior to the ankle, the synovial sheath for tibialis anterior extends from the proximal margin of the superior extensor retinaculum to the interval between the diverging limbs of the inferior retinaculum (see Figs 79.1, 79.2B). A common sheath encloses the tendons of extensor digitorum longus and fibularis tertius, starting just above the level of the malleoli, and reaching to the level of the base of the fifth metatarsal (see Figs 79.1, 79.2A). Although variable, the sheath for extensor hallucis longus begins near that for extensor digitorum longus and extends as far as the base of the first metatarsal (see Figs 79.1–79.2).

Posteromedial to the ankle, the sheath for tibialis posterior starts approximately 4 cm above the medial malleolus and ends just proximal to the attachment of the tendon to the tuberosity of the navicular (see Fig. 79.2B). The sheath for flexor hallucis longus begins at the level of the medial malleolus and extends distally as far as the base of the first metatarsal (see Fig. 79.2B). Occasionally, as a result of overuse, particularly in ballet dancers where balance on the tips of the toes *en pointe* involves sustained extreme plantar flexion of the ankle and great toe in the weight-bearing position, a fibrous nodule may develop in the tendon, just proximal to the tendon sheath. This may result in the thickened tendon being caught intermittently in the sheath, causing pain and 'triggering' of the great toe, a condition referred to as hallux saltans. Surgical opening of the sheath may be required. In athletes, the muscle belly of flexor hallucis longus may be abnormally large and may extend further distally than usual; it can also catch at the opening of the sheath. The sheath for flexor digitorum longus begins slightly superior to the level of the medial malleolus and ends at the level of the navicular.

Posterolateral to the ankle, the tendons of fibularis longus and brevis are enclosed in a single sheath deep to the superior fibular retinaculum. This sheath splits into two separate sheaths enclosing the tendons of fibularis longus and brevis deep to the inferior fibular retinaculum (see Fig. 79.2A): it extends for about 4 cm both proximally and distally from the lateral malleolus.

Plantar aponeurosis

The plantar aponeurosis is composed of densely compacted collagen fibres orientated mainly longitudinally, but also transversely (**Fig. 79.3**). Its medial and lateral borders overlie the intrinsic muscles of the great and fifth toes, respectively, while its dense central part overlies the extrinsic and intrinsic flexors of the digits.

The central part is the strongest and thickest. The fascia is narrow posteriorly, where it is attached to the medial process of the calcaneal tuberosity proximal to flexor digitorum brevis, and traced distally it becomes broader and somewhat thinner. Just proximal to the level of the metatarsal heads, it divides into five bands, one for each toe. As these five digital bands diverge below the metatarsal shafts, they are united by transverse fibres. Proximal, plantar and a little distal to the metatarsal heads and the metatarsophalangeal joints, the superficial stratum of each of the five bands is connected to the dermis by skin ligaments (retinacula cutis) (see Fig. 7.19). These ligaments reach the skin of the first metatarsophalangeal joint proximal to, and in the floors of, the furrows that separate the toes from the sole: Ledderhose's disease (plantar fibromatosis) may involve these ligaments, producing contractures of the affected digits (Espert et al 2018). The deep stratum of each digital band of the aponeurosis yields two septa that flank the digital flexor tendons and separate them from the lumbricals and the digital vessels and nerves. These septa pass deeply to fuse with the interosseous fascia, the deep transverse metatarsal ligaments (which run between the heads of adjacent metatarsals), the plantar ligaments of the metatarsophalangeal joints, and the periosteum and fibrous flexor sheaths at the base of each proximal phalanx. Pads of fat develop in the web spaces between the metatarsal heads and the bases of the proximal phalanges, and they cushion the digital nerves and vessels from adjoining

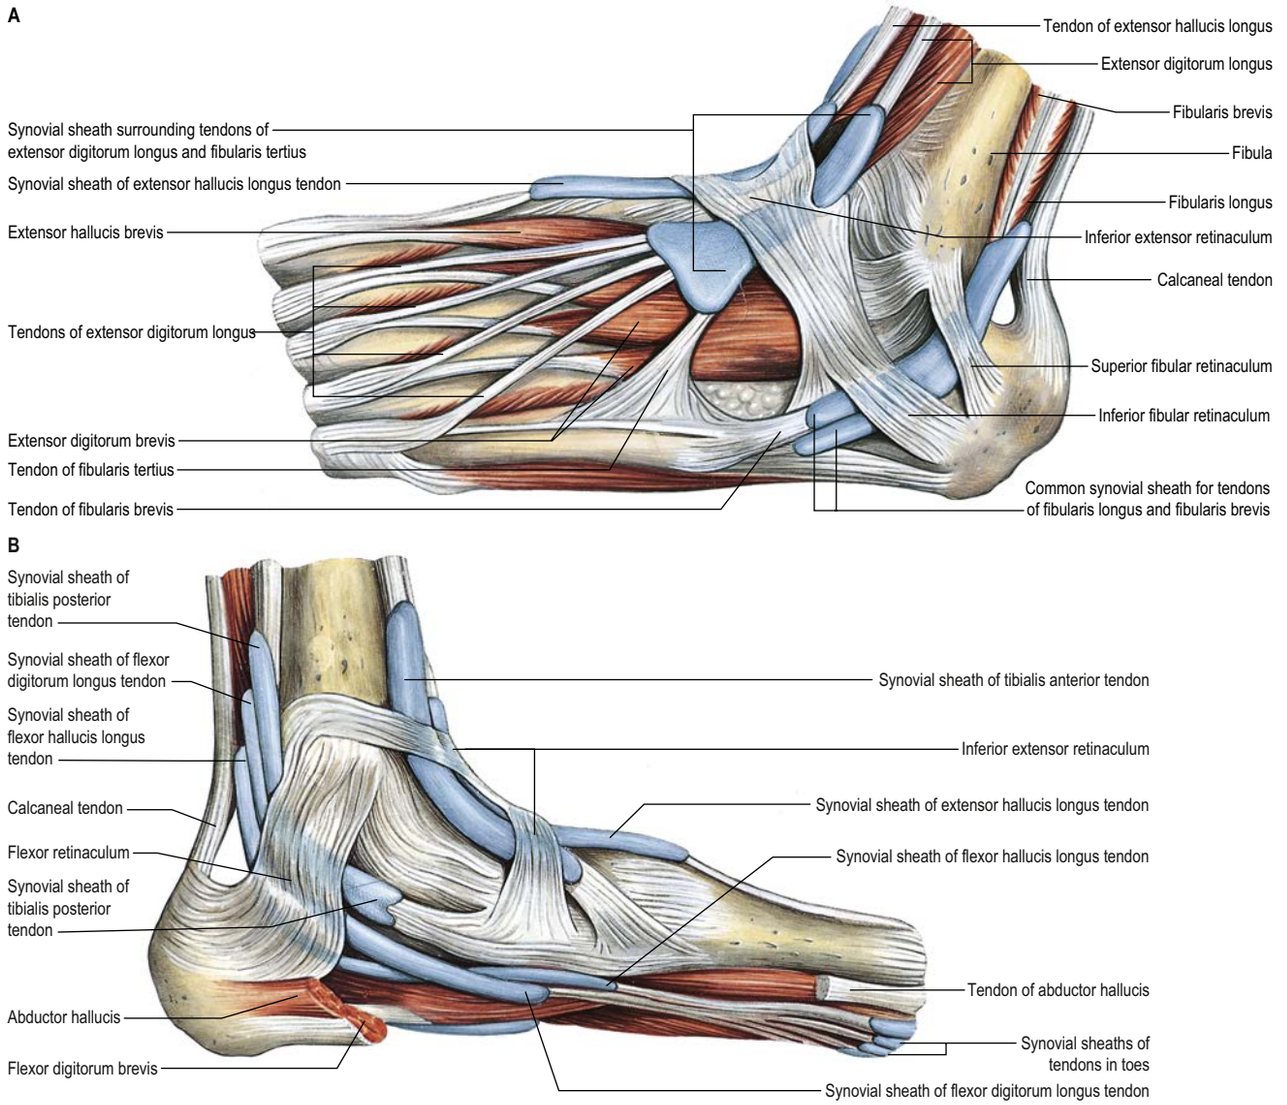

Fig. 79.2 The synovial sheaths of the tendons of the ankle. **A**, Lateral aspect. **B**, Medial aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

tendinous structures and extraneous plantar pressures. Just distal to the metatarsal heads, a plantar interdigital ligament (superficial transverse metatarsal ligament) blends progressively with the deep aspect of the superficial stratum of the plantar aponeurosis where it enters the toes (see Fig. 79.3). The central part of the plantar aponeurosis thus provides an intermediary structure between the skin and the osteoligamentous framework of the foot via numerous cutaneous retinacula and deep septa that extend to the metatarsals and phalanges. The central part is also continuous with the medial and lateral parts: at the junctions, two intermuscular septa, medial and lateral, extend in oblique vertical planes between the medial, intermediate and lateral groups of plantar muscles to reach bone. Thinner, horizontal intermuscular septa, derived from the vertical intermuscular septa, pass between the muscle layers.

The lateral part of the plantar aponeurosis, which covers abductor digiti minimi, is thin distally and thick proximally, where it forms a strong band that sometimes contains muscle fibres, between the lateral process of the calcaneal tuberosity and the base of the fifth metatarsal. It is continuous medially with the central part of the aponeurosis, and with the fascia on the dorsum of the foot around its lateral border. The medial part of the plantar aponeurosis, which covers abductor hallucis, is thin. It is continuous proximally with the flexor retinaculum, medially with the dorsal fascia of the foot, and laterally with the central part of the plantar aponeurosis.

Plantar heel pain

Available with the *Gray's Anatomy* e-book

Fascial compartments of the foot

There are four main compartments of the plantar aspect of the foot: medial, central (or intermediate), lateral and interosseous (Fig. 79.4). The medial compartment contains abductor hallucis and flexor hallucis brevis, as well as the tendon of flexor hallucis longus. The medial compartment is bounded inferiorly and medially by the medial part of the plantar aponeurosis and its medial extension, laterally by an intermuscular septum, and dorsally by the first metatarsal. The central compartment contains flexor digitorum brevis, the lumbricals, flexor accessorius (quadratus plantae), adductor hallucis, and the tendons of flexor digitorum longus. The central compartment is bounded by the plantar aponeurosis inferiorly, the osseofascial tarsometatarsal structures dorsally and intermuscular septa medially and laterally. The lateral compartment contains abductor digiti minimi and flexor digiti minimi brevis, and its boundaries are the fifth metatarsal dorsally, the plantar aponeurosis inferiorly and laterally, and an intermuscular septum medially. The interosseous compartment contains the seven interossei and its boundaries are the interosseous fascia and the metatarsals.

The dorsal aspect of the foot effectively contains a single compartment occupied by the extrinsic extensor tendons and extensor digitorum brevis, and roofed by the deep dorsal fascia. The deep fascia on the dorsum of the foot (fascia dorsalis pedis) is a thin layer, continuous above with the inferior extensor retinaculum and covering the dorsal extensor tendons and extensor digitorum brevis.

Lateral intermuscular septum

The lateral intermuscular septum is incomplete, especially at its proximal end where the lateral plantar artery and nerve enter the lateral compartment. Distally, its deep attachments are to the fibrous sheath of fibularis longus and to the fifth metatarsal.

Medial intermuscular septum

The medial intermuscular septum is incomplete where the tendon of flexor digitorum longus enters the central compartment and where

Plantar fasciopathy (fasciosis) is a common cause of plantar heel pain (Riel et al 2017). Many contributing aetiological factors have been reported, such as age, body weight, systemic disease, genetics, biomechanical dysfunction or deformity, footwear, occupation, activity, or lifestyle. Histological findings show fragmentation and degeneration of the plantar fascia in the absence of inflammatory changes. On imaging, thickening of the plantar fascia together with other findings such as plantar calcaneal spurs, perifascial oedema and bone marrow oedema, may also be present.

Clinically, palpation of the plantar aponeurosis at the medial tubercle of the calcaneus may result in localized tenderness and exacerbated heel pain in patients. Multiple treatment options, from conservative therapy to surgical intervention, may be used to provide pain relief. Non-operative approaches include foot orthoses and night splints, injections with a combination of corticosteroids and local anaesthetics, injections of autologous platelet-rich plasma, extracorporeal shockwave therapy, dry needling, laser therapy and stretching or strengthening exercises (Salvioli et al 2017, Monteagudo et al 2018). Surgical treatments include partial or complete release of the plantar aponeurosis; gastrocnemius recession is considered a safe, current alternative for surgical correction (Molund et al 2018).

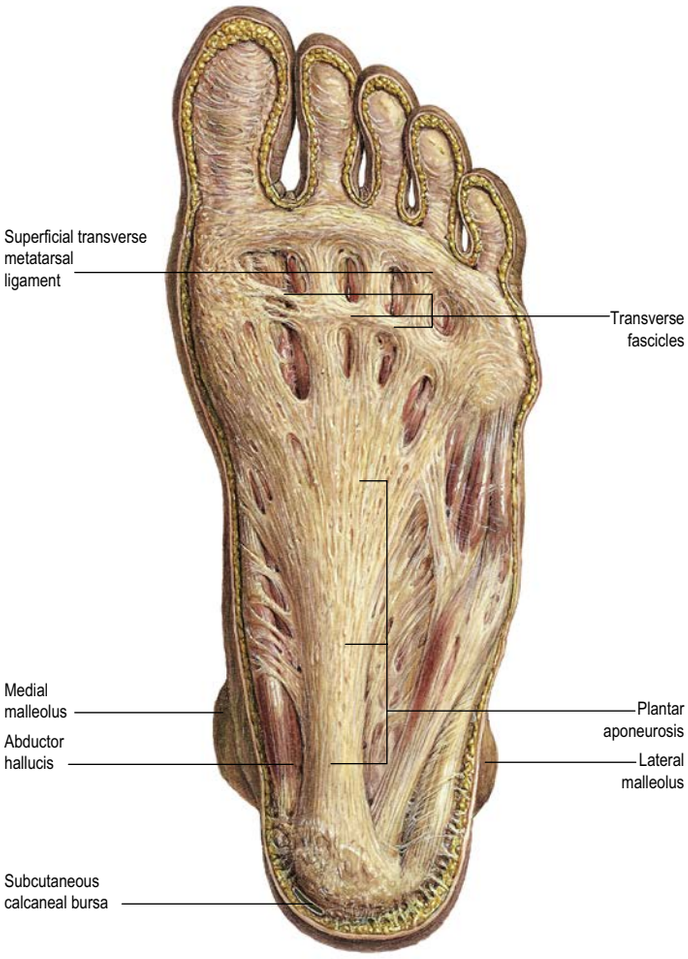

Fig. 79.3 The plantar aponeurosis. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

adductor hallucis and the lateral head of flexor hallucis brevis enter the medial compartment. The septum divides into three bands, proximal, intermediate and distal, each of which displays lateral and medial divisions as it approaches its deep attachments. The proximal band is attached laterally to the cuboid and blends medially with the tendon of tibialis posterior. The middle band is attached laterally to the cuboid and the long plantar ligament and medially to the medial cuneiform. The distal band divides to enclose the tendon of flexor hallucis longus and is attached to the fascia over flexor hallucis brevis.

Compartment syndrome in the foot

A compartment syndrome results from an increase in intracompartmental pressure sufficient to impair venous outflow from that compartment. Blood enters the compartment at arterial pressure, but with no outflow, this increases compartment pressures until they exceed the arterial pressure. At this point the inflow of arterial blood ceases, leading to muscle and nerve ischaemia. Failure to relieve the increased pressure in the compartment surgically results in necrosis of the soft tissues within the compartment. The most common cause of compartment syndrome in the foot is trauma, usually of high-energy (high-impact) type; crush injuries, calcaneal fractures and disruption of the tarsometatarsal joints are the usual antecedents (Dodd and Le 2013).

Specialized adipose tissue (heel and metatarsal pads)

The heel is subject to repeated high impacts and is anatomically adapted to withstand these pressures. The adult heel pad has a mean thickness of 18 mm and a mean epidermal thickness of 0.64 mm (dorsal epidermal thickness averages 0.069 mm). The heel pad contains elastic adipose tissue organized as spiral fibrous septa anchored to each other, to the calcaneus and to the skin. The septa are U-shaped, fat-filled columns designed to resist compressive loads and are reinforced internally with elastic diagonal and transverse fibres that separate the fat into compartments.

In the forefoot, the subcutaneous tissue consists of fibrous lamellae arranged in a complex whorl containing adipose tissue attached via vertical fibres to the dermis superficially and the plantar aponeurosis deeply. The fat is particularly thick in the region of the metatarsophalangeal joints, which cushions the foot during the toe-off phase of gait. Like the heel pad, the metatarsal fat pad is designed to withstand compressive and shearing forces. Atrophy of either may be a cause of persistent pain in the distal plantar region.

BONES

Functionally, the skeleton of the foot may be divided into the tarsus, metatarsus and phalanges. Anatomically, it may be divided into the hindfoot (calcaneus and talus), midfoot (navicular, cuboid and cuneiforms), and forefoot (metatarsals, phalanges and sesamoid bones of the great toe).

Distal tibia

The distal end of the tibia has anterior, medial, posterior, lateral and distal surfaces, and projects inferomedially as the medial malleolus (see Figs 78.7, 79.3). The distal surface, also called the tibial plafond, articulates with the talus and is wider anteriorly than posteriorly. It is concave sagittally and slightly convex transversely, and continues medially into the malleolar articular surface. The medial malleolus is short and thick, and has a smooth lateral surface with a crescentic or comma-shaped facet that articulates with the medial surface of the talar body. The distal end of the tibia, including its ossification, is described in detail in Chapter 78 (see Fig. 78.9).

Ligamentous attachments No muscles are attached to the distal tibia. The interosseous membrane, the deltoid ligament and the anterior and posterior tibiofibular ligaments are attached to the distal tibia.

Vascular supply The distal tibia is supplied by an arterial network formed by branches of the dorsalis pedis, posterior tibial and fibular arteries.

Innervation The distal tibia is innervated by branches from the deep fibular, tibial, saphenous and sural nerves.

Distal fibula

The distal end of the fibula or lateral malleolus projects distally and posteriorly relative to the medial malleolus (see Figs 79.3, 78.7, 78.8). Its lateral aspect is subcutaneous, the posterior surface has a broad groove with a prominent lateral border, and the anterior surface is rough and somewhat rounded and articulates with the anteroinferior aspect of the tibia. The medial surface has a triangular articular facet and is vertically convex with its apex directed distally. It articulates with the lateral talar surface. Behind the facet is a rough malleolar fossa for ligamentous attachment. The distal end of the fibula, including its ossification, is described in detail in Chapter 78.

Ligamentous attachments No muscles are attached to the distal fibula below the level of the interosseous ligament. The ligamentous attachments are those of the lateral ligament complex, i.e. the anterior talofibular, the calcaneofibular and the posterior talofibular ligaments. The interosseous membrane is attached on its medial aspect.

Vascular supply The distal fibula is supplied by an arterial network made up of branches of the dorsalis pedis, posterior tibial and fibular arteries.

Innervation The distal fibula is innervated by the deep fibular, tibial, saphenous and sural nerves.

Tarsus

The seven tarsal bones occupy the proximal half of the foot (Figs 79.5–79.6, 79.8). The tarsus and carpus are homologous, but the tarsal elements are larger, reflecting their role in supporting and distributing body weight. As in the carpus, tarsal bones are arranged in proximal and distal rows, but medially, there is an additional single intermediate tarsal element, the navicular. The proximal row is made up of the talus and calcaneus; the long axis of the talus is inclined anteromedially and inferiorly, and its distally directed head is medial to the calcaneus and at a

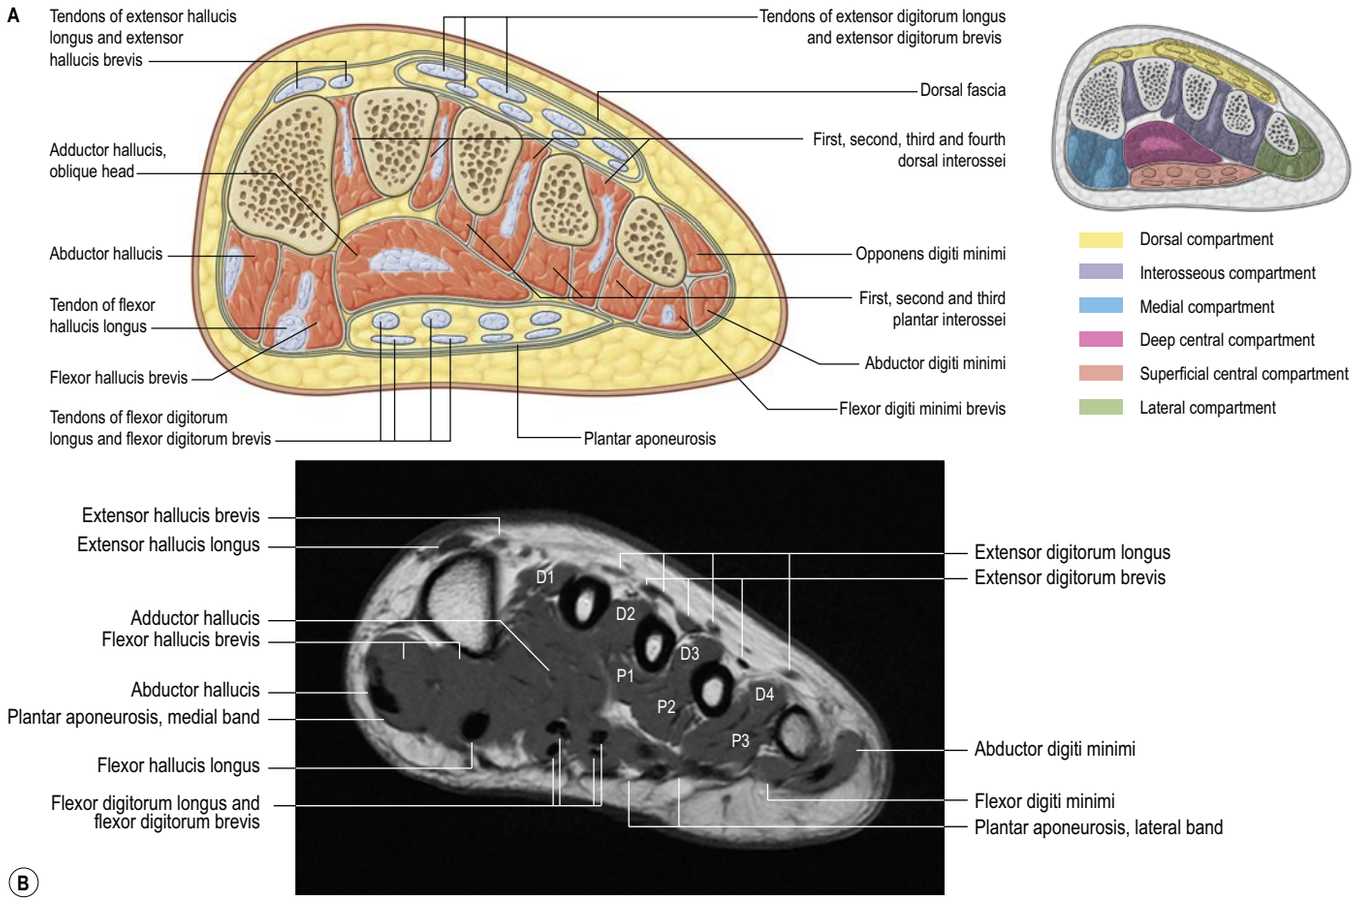

Fig. 79.4 A, A coronal section through the midfoot showing the main fascial compartments. **B**, Coronal T1-weighted MRI through the midfoot.

superior level. The distal row contains, from medial to lateral, the medial, intermediate and lateral cuneiforms and the cuboid. Collectively, these bones display an arched transverse alignment that is dorsally convex. Medially, the navicular is interposed between the head of the talus and the cuneiforms. Laterally, the calcaneus articulates with the cuboid.

The tarsus and metatarsus are arranged to form intersecting longitudinal and transverse arches. Hence, thrust and weight are not transmitted from the tibia to the ground (or *vice versa*) directly through the tarsus, but are distributed through the tarsals and metatarsals to the ends of the longitudinal arches. For the purposes of description, each tarsal bone is arbitrarily considered to be cuboidal in form, with six surfaces. The ossification sites and timing of ossification are summarized in Figs 79.7–79.8A.

Individual tarsal bones

Talus

The talus is an intercalated bone with no tendinous attachments. It is the osseous link between the foot and leg through the ankle joint (see Figs 79.8B, 79.17, 79.19).

Head

Directed distally and somewhat inferomedially, the head has a distal surface which is ovoid and convex; its long axis is also inclined inferomedially to articulate with the proximal navicular surface (see Fig. 79.5A). The plantar surface of the head has three articular areas, separated by smooth ridges (Fig. 79.9C). The most posterior and largest is oval and slightly convex, and rests on a shelf-like medial calcaneal projection, the sustentaculum tali. Anterolateral to this and usually continuous with it, a flat articular facet rests on the anteromedial part of the dorsal (proximal) calcaneal surface; distally, it continues into the navicular surface. Between the two calcaneal facets, a part of the talar head, covered with articular cartilage, is in contact with the plantar calcaneonavicular (spring) ligament, which is covered here, superiorly, by fibrocartilage. When the foot is inverted passively, the dorsolateral aspect of the head is visible and palpable approximately 3 cm distal to the tibia; it is hidden by extensor tendons when the toes are dorsiflexed.

Neck

The neck is the narrow, medially inclined region between the head and body (see Fig. 79.9C). Its rough surfaces are for ligaments. The medial plantar surface has a deep sulcus tali that, when the talus and calcaneus are articulated, forms the roof of the tarsal sinus, which is occupied by interosseous talocalcaneal and cervical ligaments.

The long axis of the neck, inclined downwards, distally and medially, makes an angle of approximately 150° with that of the body; it is smaller (130–140°) at birth, accounting in part for the inverted foot in young children. The dorsal talonavicular ligament and ankle articular capsule are attached distally to the dorsal surface of the talus, which means that the proximal part of this surface lies within the capsule of the ankle joint. The medial articular facet of the talar body and part of the trochlear surface may extend on to the neck. The anterior talofibular ligament is attached on the lateral aspect of the neck, spreading along the adjacent anterior border of the lateral surface. The interosseous talocalcaneal and cervical ligaments are attached to the inferior surface of the neck. A dorsolateral, so-called 'squatting facet' is commonly present on the talar neck in those individuals who habitually adopt the squatting position; it articulates with the anterior tibial margin in extreme dorsiflexion and may be doubled.

Body

The body is cuboidal, covered dorsally by a trochlear surface articulating with the distal end of the tibia. It is anteroposteriorly convex, gently concave transversely, widest anteriorly and, therefore, sellar in shape (see Fig. 79.9C). The triangular lateral surface is smooth and vertically concave for articulation with the lateral malleolus. Superiorly, it is continuous with the trochlear surface; inferiorly, its apex is a lateral process. Proximally, the medial surface is (posterosuperiorly) covered by a comma-shaped facet, which is deeper in front and articulates with the medial malleolus. Distally, this surface is rough and contains numerous vascular foramina. The small posterior surface features a rough projection termed the posterior process. The process is marked by an oblique groove between two tubercles. The lateral tubercle is usually larger; the medial is less prominent and lies immediately behind the sustentaculum tali. The plantar surface articulates with the middle third of the dorsal calcaneal surface by an oval concave facet, its long axis directed distolaterally at an angle of

In a hypermobile flat foot undergoing pronation, the talar head is unsupported medially by the sustentaculum tali. The resulting lack of support results in a visible medial protrusion of the talar head as the foot adducts and plantar flexes towards the ground (Michaud 2011).

approximately 45° with the median plane. The medial edge of the trochlear surface is straight, but its lateral edge inclines medially in its posterior part and is often broadened into a small, elongated triangular area, which is in contact with the posterior tibiofibular ligament in dorsiflexion.

The posterior talofibular ligament is attached to the lateral tubercle of the posterior process (posterolateral tubercle). Its attachment extends up to the groove, or depression, between the process and posterior trochlear border. The posterior talocalcaneal ligament is attached to the plantar border of the posterior process. The groove between the tubercles of the process contains the tendon of flexor hallucis longus and continues distally into the groove on the plantar aspect of the sustentaculum tali. The medial talocalcaneal ligament is attached below to the medial tubercle, whereas the most posterior superficial fibres of the deltoid ligament are attached above the tubercle. The deep fibres of the deltoid ligament are attached more superiorly to the rough area immediately below the comma-shaped articular facet on the medial surface.

Ligamentous attachments No muscles are attached to the talus. However, many ligaments are attached to the bone, and these confer stability to the talocrural, subtalar and talocalcaneonavicular joints.

Vascular supply The talar blood supply is rather tenuous because of the lack of muscle attachments. The first comprehensive account of talar blood supply was provided by Wildenauer in 1950. The extraosseous blood supply is via the posterior tibial, dorsalis pedis and fibular arteries (Fig. 79.10). The artery of the tarsal canal arises from the posterior tibial artery approximately 1 cm proximal to the origin of the medial and lateral plantar arteries (Fig. 79.11) and passes anteriorly between the sheaths of flexor digitorum longus and flexor hallucis longus to enter the tarsal canal, in which it lies anteriorly, close to the talus. (The 'tarsal canal' is the term that is commonly used to describe the tunnel-shaped medial end of the tarsal sinus.) Branches from the arterial network in the tarsal canal enter the talus. The artery continues through the tarsal canal into the lateral part of the tarsal sinus, where it anastomoses with the artery of the tarsal sinus, forming a vascular sling under the talar neck. A branch of the artery of the tarsal canal known as the deltoid branch passes deep to the deltoid ligament and supplies part of the medial aspect of the talar body. Sometimes, it arises from the posterior tibial

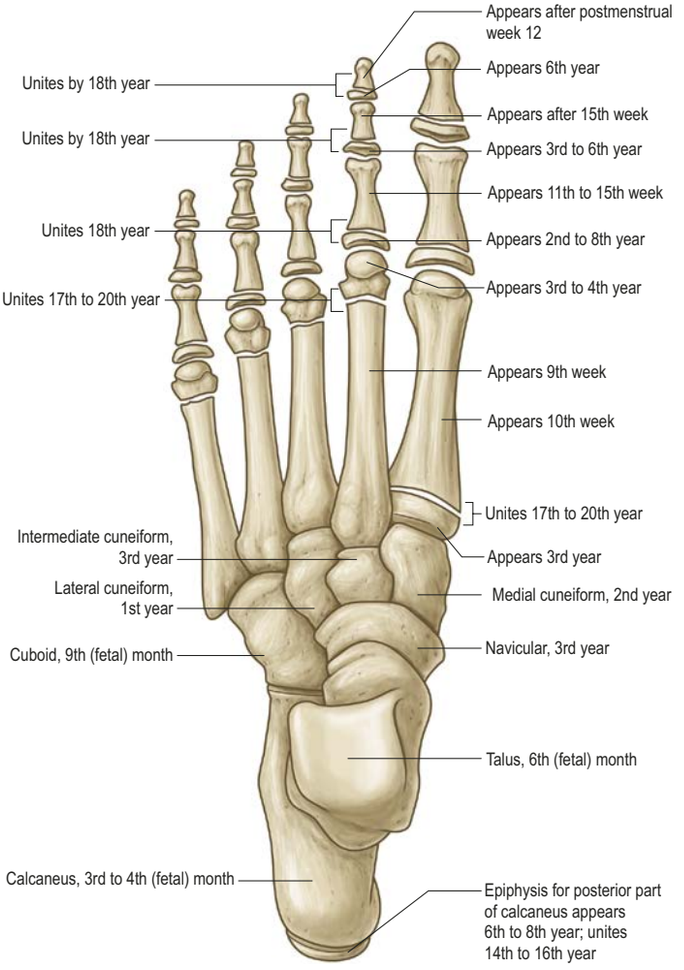

Fig. 79.8 The approximate dates of ossification of the individual bones of the foot and their epiphyses.

artery; rarely, it arises from the medial plantar artery; it may be the only remaining arterial supply to the talus when this bone is fractured. The dorsalis pedis artery supplies branches to the superior aspect of the talar neck and also gives off the artery of the tarsal sinus. This large vessel is always present and anastomoses with the artery of the tarsal canal. The artery of the tarsal sinus receives a contribution from the anterior perforating branch of the fibular artery and supplies direct branches to the talus. The fibular artery provides small branches, which form a plexus of vessels posteriorly with branches of the posterior tibial artery; however, the contribution that the fibular artery makes to the talar blood supply is thought to be insignificant.

The intraosseous blood supply of the talar head arises medially from branches of the dorsalis pedis and laterally via vessels that arise from the anastomosis between the arteries of the tarsal canal and tarsal sinus. The middle third of the talar body, other than its most superior aspect, and the lateral third, other than its posterior aspect, are supplied mainly by the anastomotic arcade in the tarsal canal. The medial third of the body of the talus is supplied by the branch of the artery of the tarsal canal to the deltoid ligament.

Innervation The talus is innervated by branches from the deep fibular, tibial, saphenous and sural nerves.

Ossification A single ossification centre appears during postmenstrual weeks 21–24 (see Fig. 79.8). The posterolateral process sometimes fuses with an accessory bone called the os trigonum.

Talar fractures Since 70% of the surface of the talus is covered by articular cartilage, displaced talar neck fractures, where the blood supply to the talar body is interrupted, may result in avascular necrosis and non-union. A systematic review by Halvorson et al (2012) reported that approximately 33% of talar neck fractures progress to avascular necrosis, 20% progress to malunions and 5% progress to non-unions. In general, these complications do not occur in non-displaced fractures. If a subchondral lucency is seen in the talus on radiographs at 8 weeks after fracture of the talar neck (Hawkins sign), it may be assumed that vascularity to the talar body is intact and that the fracture is likely to heal satisfactorily.

This accessory bone is found occasionally; it arises from a separate ossification centre that appears between 8 and 11 years of age. When the os trigonum fuses to the posterolateral process of the talus it is called the trigonal process (Stieda's process). Another (rare) accessory bone of the foot is the os supratalare, which lies on the dorsal aspect of the talus and rarely measures more than 4 mm in length.

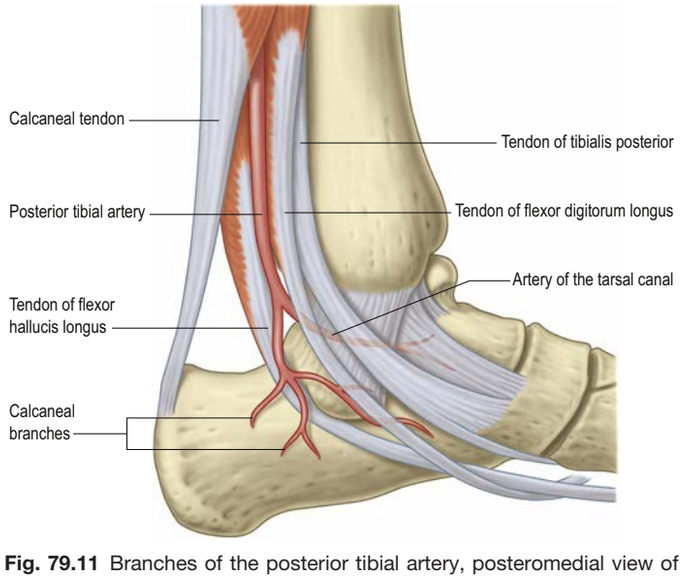

Fig. 79.11 Branches of the posterior tibial artery, posteromedial view of the ankle.

Calcaneus

The calcaneus is the largest of the tarsal bones and projects posterior to the tibia and fibula as a short lever for muscles of the calf attached to its posterior surface. It is irregularly cuboidal, with its long axis inclined distally upwards and laterally (Fig. 79.9A–B). It has a relatively thin cortex (Daftary et al 2005). The superior or proximal surface is divisible into three areas. The posterior third is rough and concavo-convex; the convexity is transverse and supports fibroadipose tissue (Kager's fat pad) between the calcaneal tendon and ankle joint. The middle third carries the posterior talar facet, which is oval and convex anteroposteriorly. The anterior third is partly articular; distal (anterior) to the posterior articular facet, a rough depression, the calcaneal sulcus, narrows into a groove on the medial side and completes the tarsal sinus with the talus (see Fig. 79.9B). (The tarsal sinus is a conical hollow bounded by the talus medially, superiorly and laterally, with the superior surface of the calcaneus below. Its medial end is narrow and tunnel-shaped, and is often referred to as the tarsal canal.) Distal and medial to this groove, an elongated articular area covers the sustentaculum tali (talar shelf) and extends distolaterally on the body of the bone. This facet is often divided into middle and anterior talar facets by a non-articular interval at the anterior limit of the sustentaculum tali (the incidence of this subdivision varies with sex, race and occupation). Rarely, all three facets on the upper surface of the calcaneus are fused into one irregular area.

The anterior surface is the smallest, and is an obliquely set concavo-convex articular facet for the cuboid. The posterior surface is divided into three regions: a smooth proximal (superior) area separated from the calcaneal tendon by a bursa and adipose tissue (tip of the Kager's fat pad); a middle area, which is the largest, limited above by a groove and below by a rough ridge for the calcaneal tendon; and a distal (inferior) area, vertically striated and inclined downwards and forwards, which is the subcutaneous weight-bearing surface.

The plantar surface is rough, especially proximally as the calcaneal tuberosity, which has lateral and medial processes that extend distally, separated by a notch. The medial process is longer and broader (see Fig. 79.9B). Further distally, an anterior tubercle marks the distal limit of the attachment of the long plantar ligament.

The lateral surface is almost flat. Proximally, it is deeper and palpable on the lateral aspect of the heel distal to the lateral malleolus. Distally, it presents the fibular trochlea (see Figs 79.9A–B), which is exceedingly variable in size and palpable 2 cm distal to the lateral malleolus when well developed. It bears an oblique groove for the tendon of fibularis longus and a shallower proximal groove for the tendon of fibularis brevis. About 1 cm or more behind and above the fibular trochlea, a second elevation may exist for attachment of the calcaneofibular part of the lateral ligament.

The medial surface is vertically concave. The concavity is accentuated by the sustentaculum tali, which projects medially from the distal part of its upper border (see Fig. 79.9B). Superiorly the process bears the middle talar facets and inferiorly a groove is continuous with that on the talar posterior surface for the tendon of flexor hallucis longus (see Fig. 79.9A–B). The medial aspect of the sustentaculum tali can be felt immediately distal to the tip of the medial malleolus, and occasionally, it is also grooved by the tendon of flexor digitorum longus.

Muscle and ligamentous attachments The interosseous talocalcaneal and cervical ligaments and the medial root of the inferior extensor retinaculum are attached in the calcaneal sulcus. The non-articular area distal to the posterior talar facet is the site of attachment of extensor digitorum brevis (in part), the principal band of the inferior extensor retinaculum and the stem of the bifurcate ligament.

Abductor hallucis and the superficial part of the flexor retinaculum and, distally, the plantar aponeurosis and flexor digitorum brevis are all attached to the medial process (medial condyle) of the calcaneal tuberosity at its prominent medial margin. The medial process of the calcaneal tuberosity is the primary weight-bearing portion of the calcaneus. Clinically, pain over the medial tuberosity is often associated with plantar fasciopathy) (Yi et al 2011). Abductor digiti minimi is attached to the lateral process, extending medially to the medial process. The long plantar ligament is attached to the rough region between the processes proximally, and extends to the anterior tubercle distally. The plantar calcaneocuboid ligament (short plantar ligament) is attached to the tubercle and the area distal to it. The lateral tendinous head of flexor accessorius is attached distal to the lateral process near the lateral margin of the long plantar ligament. Plantaris is attached to the posterior surface near the medial side of the calcaneal tendon. The anterior part of the lateral surface is crossed by the fibular

A detailed analysis of patterns of anterior talar articular facets in a series of 401 Indian calcanei revealed four types. Type I (67%) showed one continuous facet on the sustentaculum extending to the distomedial calcaneal corner; type II (26%) presented two facets, one sustentacular and one distal calcaneal; type III (5%) possessed only a single sustentacular facet; and type IV (2%) showed confluent anterior and posterior facets (Gupta et al 1977).

tendons but is largely subcutaneous. The calcaneofibular ligament is attached 1–2 cm proximal to the fibular trochlea, usually to a low, rounded elevation.

The dorsal surface of the sustentaculum tali is part of the talocalcaneonavicular joint. The plantar surface is grooved by the tendon of flexor hallucis longus, and margins of the groove give attachment to the deep part of the flexor retinaculum. The plantar calcaneonavicular ligament is attached distally to the medial margin of the sustentaculum tali, which is narrow, rough and convex. A slip from the tendon of tibialis posterior, and superficial fibres of the deltoid ligament and medial talocalcaneal ligaments, are attached proximally. Distal to the attachment of the deltoid ligament, the tendon of flexor digitorum longus is related to the margin of the sustentaculum tali and may form a groove in it. The large medial head of flexor accessorius is attached distal to the groove for flexor hallucis longus.

Vascular supply The calcaneus receives its arterial supply from the medial and lateral calcaneal arteries (arising from the posterior tibial and fibular arteries, respectively), the fibular artery, posterior calcaneal anastomosis (formed from the posterior tibial and fibular arteries), medial and lateral plantar arteries, artery of the tarsal sinus and tarsal canal, branches of the lateral tarsal artery and perforating fibular arteries.

Innervation The calcaneus is innervated by branches of the tibial, sural and deep fibular nerves.

Ossification The calcaneus is the only tarsal bone that always has two ossification centres (see Fig. 79.8). In addition to the main ossification centre, there is a scale-like posterior apophysis that covers most of the posterior, and part of the plantar, surfaces. The main centre appears prenatally during postmenstrual weeks 9–12, whereas the posterior apophysis appears in the sixth year in females and the eighth year in males, fusing in the fourteenth and sixteenth years, respectively.

An os calcaneus secundarius, an accessory bone rather than a secondary ossification centre, occasionally occurs. When present, it is located on the 'anterior process' of the calcaneus, from which the bifurcate ligament arises, in an interval between the anteromedial aspect of the calcaneus, the proximal ends of the cuboid and navicular, and the head of the talus. Other rare accessory bones of the calcaneus include the calcaneus accessorius in the region of the fibular trochlea; the os sustentaculi on the posterior aspect of the sustentaculum tali; the os subcalcis on the plantar aspect of the calcaneus slightly posterior to the origin of the plantar aponeurosis; and the os aponeurosis plantaris, which lies within the plantar aponeurosis in close proximity to the medial process of the calcaneal tuberosity.

Navicular

The navicular articulates with the talar head proximally and with the cuneiform bones distally (see Fig. 79.9A; **Fig. 79.12**). In convex pes planovalgus (vertical talus), the navicular is subluxed dorsally and articulates instead with the talar neck. The downward displacement of the talar head creates a characteristic convex 'rocker-bottom foot'. The distal surface of the navicular is transversely convex and divided into three facets (the medial being the largest) for articulation with the cuneiforms. The proximal surface is oval and concave, and articulates with the talar head. Other than proximal and distal articular surfaces, the remaining surfaces are rough for ligamentous attachments and tendinous articulations. The dorsal surface is convex. The medial surface projects proximally as a prominent tuberosity, palpable approximately 2.5 cm distal and plantar to the medial malleolus. The plantar surface is concave, and separated from the tuberosity medially by a groove for the tendon of tibialis posterior. The lateral irregular surface often bears a facet for articulation with the cuboid.

The facet for articulation with the medial cuneiform is approximately triangular in shape: its rounded apex is medial and its 'base', facing laterally, is often markedly curved; the articular facets for the intermediate and lateral cuneiforms are also triangular, with plantar-facing apices. The facet for the lateral cuneiform may appear as a wide crescent or a semicircle rather than a triangle. Dorsal talonavicular, cuneonavicular and cubonavicular ligaments are attached to the dorsal navicular surface.

Muscle and ligamentous attachments The navicular tuberosity is the main attachment site of tibialis posterior; a groove lateral to the tuberosity transmits part of the tendon distally to the cuneiforms and middle three metatarsal bases. The plantar calcaneonavicular ligament

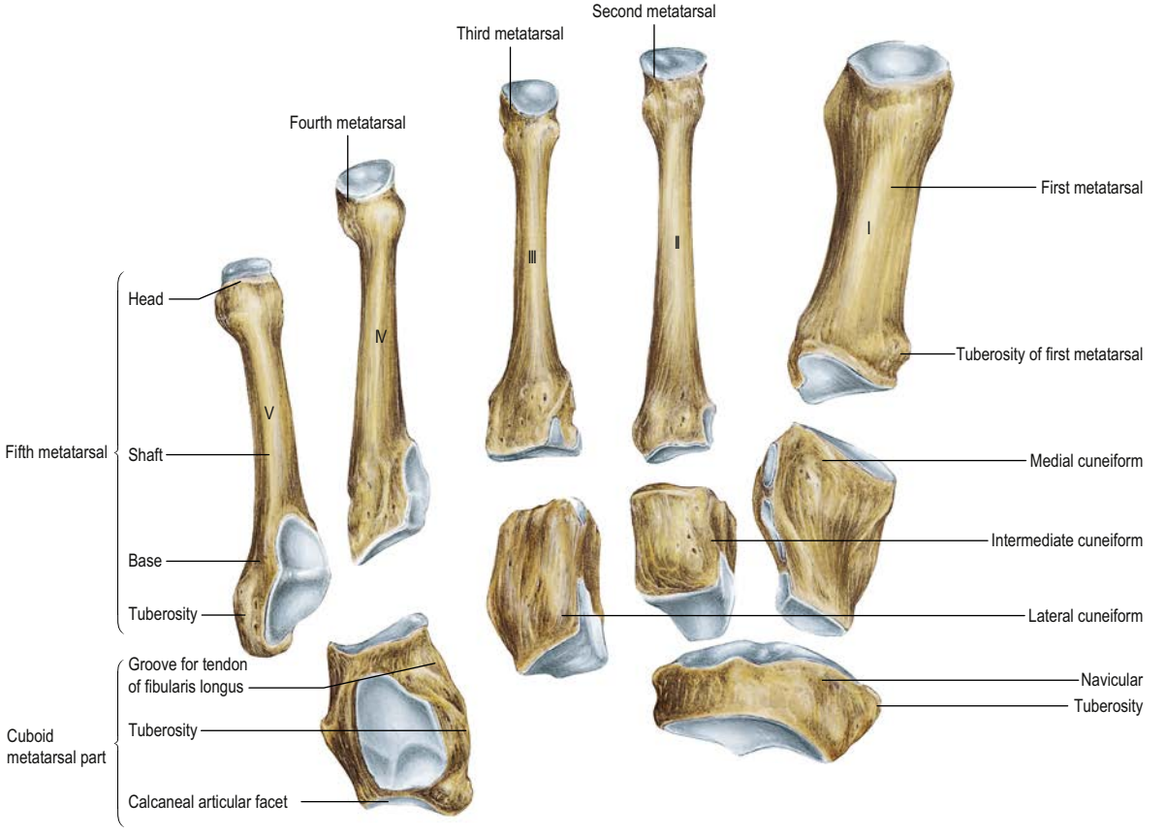

Fig. 79.12 The skeleton of the tarsals and metatarsals, dorsal aspect. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Calcaneal apophysitis (Sever's disease) is a self-limiting inflammatory condition seen in some child athletes, boys more commonly than girls. It is not a true apophysitis and the use of imaging for its initial diagnosis is a subject of controversy (Kose 2010, Rachel et al 2011). Calcaneal apophysitis is often treated with physiotherapy and/or therapeutic heel lifts, but simply monitoring the condition can also be efficacious (Wiegerinck et al 2016).

is attached to a slight projection lateral to the groove and adjacent to the proximal surface (see Fig. 79.5B). The calcaneonavicular part of the bifurcate ligament is attached to the rough part of the lateral surface.

Vascular supply The dorsal aspect of the navicular is supplied by the dorsalis pedis artery, either directly or from a branch of the main artery. The medial plantar artery supplies its plantar aspect, and the tuberosity is supplied by an anastomosis between the dorsalis pedis and medial plantar arteries.

Innervation The navicular is innervated by the deep fibular and medial plantar nerves.

Ossification The navicular ossification centre appears during the third year (see Fig. 79.8). It is sometimes affected by avascular necrosis between the ages of 4 and 7 years (Köhler's disease).

An accessory navicular bone, considered to be an anatomical variant, occasionally occurs (Keles-Celik et al 2017), arising from a separate ossification centre in the region of the posteromedial aspect of the navicular tuberosity. There are three distinct types of accessory navicular. Type I is probably a sesamoid bone within the plantar aspect of the tendon of tibialis posterior at the level of the inferior calcaneonavicular ligament. In type II, the accessory bone is separated from the body of the navicular by a synchondrosis. These types are sometimes known as os tibiale externum or naviculare secundarium. In Type III, commonly called the cornuate navicular or gorilloid navicular (Haffner and Conklin 2016), the accessory bone is united to the navicular by a bony ridge, and may represent the possible end stage of type II. An accessory navicular may be the source of pain in athletes. Type II is the most commonly symptomatic variant: it has been suggested that the pull of the tendon of tibialis posterior, the degree of foot pronation and the location of the accessory bone in relation to the undersurface of the navicular, may produce tension, shear and/or compression forces on the synchondrosis. An accessory navicular is one aetiological factor in posterior tibial tendon dysfunction. The altered mechanics cause abnormal stresses, leading to tendon degeneration, decreased strength and possible tendon rupture.

Rarely, the navicular is bipartite and it arises from two distinct centres of ossification: this can lead to premature degeneration within the talocalcaneonavicular joint (Müller–Weiss disease). Occasionally, a small bone, os talonaviculare dorsale, is found within the talocalcaneonavicular joint on its dorsal aspect: it represents either a separate accessory bone or a fractured osteophyte of the proximal dorsal aspect of the navicular. A bipartite navicular is sometimes found with cuneonavicular coalitions.

Cuboid

The cuboid, the most lateral bone in the distal tarsal row, lies between the calcaneus proximally and the fourth and fifth metatarsals distally (see Figs 79.9A, 79.12). Its dorsolateral surface is rough for the attachment of ligaments. The plantar surface is crossed distally by an oblique groove for the tendon of fibularis longus and bounded proximally by a ridge that ends laterally in the tuberosity of the cuboid, the lateral aspect of which is faceted for a sesamoid bone or cartilage that is frequently found in the tendon of fibularis longus. Proximal to its ridge, the rough plantar surface extends proximally and medially because of the obliquity of the calcaneocuboid joint, making its medial border much longer than the lateral. The lateral surface contains the groove for fibularis longus, extending from a deep notch on its plantar edge. The medial surface, which is much more extensive and partly non-articular, bears an oval facet for articulation with the lateral cuneiform and proximal to this another facet (sometimes absent) for articulation with the navicular; the two form a continuous surface separated by a smooth vertical ridge. The distal surface is divided vertically into a medial quadrilateral articular area for the base of the fourth metatarsal and a lateral triangular area, its apex lateral, for the base of the fifth metatarsal. The proximal surface, triangular and concavo-convex, articulates with the distal calcaneal surface; its medial plantar angle projects proximally and inferiorly to the distal end of the calcaneus.

Muscle and ligamentous attachments The dorsal calcaneocuboid, cubonavicular, cuneocuboid and cubometatarsal ligaments are attached to the dorsal surface. Deep fibres of the long plantar ligament are attached to the proximal edge of the plantar ridge. Slips from the tendons of tibialis posterior and flexor hallucis brevis are attached to the projecting proximomedial part of the plantar surface. Interosseous, cuneocuboid and cubonavicular ligaments are attached to the rough part of the medial cuboidal surface. Proximally, the medial calcaneocuboid ligament, which is the lateral limb of the bifurcate ligament, is also attached to this surface. The placement and trapezoidal shape of the cuboid give it the ability to act as the 'keystone' of the lateral longitudinal arch of the foot. During normal gait, the tension of the calcaneocuboid joint helps 'lock' the mid-tarsal joint and acts as a major stabilizer of the foot.

Vascular supply The cuboid is supplied by deep branches of the medial and lateral plantar arteries and by branches from the dorsal arterial network.

Innervation The cuboid is innervated by branches from the lateral plantar, sural and deep fibular nerves.

Ossification The cuboid frequently begins to ossify before birth, the primary ossification centre appearing just before birth during postmenstrual weeks 37–41 (see Fig. 79.8). An os cuboides secundarium is a rare accessory bone situated on the plantar aspect of the cuboid and is sometimes involved in the infrequently reported cubonavicular coalitions.

Cuneiforms

The wedge-like cuneiform bones articulate with the navicular proximally and with the bases of the first to third metatarsals distally; the medial cuneiform is the largest, the intermediate is the smallest. The dorsal surfaces of the intermediate and lateral cuneiforms form the base of the wedge. The wedge is reversed in the medial cuneiform, which is a prime factor in shaping the transverse arch. The proximal surfaces of all three form a concavity for the distal surface of the navicular. The medial and lateral cuneiforms project distally beyond the intermediate cuneiform and so form a recess (mortise) for the second metatarsal base.

Medial cuneiform

The medial cuneiform (see Figs 79.5, 79.9A, 79.12) articulates with the navicular and base of the first metatarsal. It has a narrow dorsal surface. The distal surface is a kidney-shaped facet for the first metatarsal base, its 'hilum' being lateral. The proximal surface bears a piriform facet for the navicular, which is concave vertically and dorsally narrowed. The medial surface, subcutaneous, is vertically convex; its distal plantar angle carries a large impression that receives the principal attachment of the tendon of tibialis anterior (see Fig. 79.5B). The lateral surface is partly non-articular; there is a smooth right-angled strip along its proximal and dorsal margins for the intermediate cuneiform. Its distal dorsal area is separated by a vertical ridge from a small, almost square, facet for articulation with the dorsal part of the medial surface of the second metatarsal base. Plantar to this, the medial cuneiform is attached to the medial side of the second metatarsal base by a strong ligament (Lisfranc's ligament). Proximally, an intercuneiform interosseous ligament connects this surface to the intermediate cuneiform. The distal and plantar areas of the surface are roughened by attachment of part of the tendon of fibularis longus.

Muscle attachments The plantar surface receives a slip from the tendon of tibialis posterior, in addition to part of the insertion of the tendon of fibularis longus. The medial surface receives the attachment of most of the tendon of tibialis anterior.

Vascular supply The medial cuneiform is supplied via its dorsal, medial and lateral surfaces, mainly from the dorsal arterial network.

Innervation The medial cuneiform is supplied by the deep fibular and medial plantar nerves.

Ossification The medial cuneiform may have two separate ossification centres, which appear during the second year of life (see Fig. 79.8). Very rarely, the medial cuneiform is bipartite and there is a horizontal cleavage plane between the two parts. The os cuneo-1 metatarsale-I plantare is a rare accessory bone that occurs on the plantar aspect of the foot at the base of the first metatarsal and articulates with the plantar base of the first metatarsal and the medial cuneiform.

Intermediate cuneiform

The intermediate (middle) cuneiform articulates proximally with the navicular and distally with the second metatarsal base (see Figs 79.5A, 79.12). It has a narrow plantar surface that receives a slip from the tendon of tibialis posterior. The distal and proximal surfaces are both triangular articular facets. The medial surface is partly articular; it articulates via a smooth, angled region that is occasionally double with the medial cuneiform along its proximal and dorsal margins. The lateral surface is also partly articular; along its proximal margin a vertical segment, usually indented, abuts the lateral cuneiform. Strong

interosseous ligaments connect the non-articular parts of both surfaces to the adjacent cuneiforms. An intricate arrangement of dorsal and plantar ligaments spans the tarsometatarsal joint, connecting the most distal row of tarsals to their respective metatarsals. However, the plantar ligament between the intermediate cuneiform and the base of the second metatarsal is uniquely absent (Castro et al 2010, Chaney 2010).

Muscle attachments Part of the tendon of tibialis posterior is attached to the intermediate cuneiform.

Vascular supply The intermediate cuneiform is supplied via its dorsal, medial and lateral surfaces, mainly from the dorsal arterial network.

Innervation The intermediate cuneiform is innervated by the deep fibular and medial plantar nerves.

Ossification The ossification centre appears during the third year of life (see Fig. 79.8). The os cuneo-2 metatarsale-II dorsale, a rare accessory bone, lies on the dorsal aspect of the joint between the intermediate cuneiform and the second metatarsal. It is wedge-shaped with its base orientated dorsally.

Lateral cuneiform

The lateral cuneiform lies between the intermediate cuneiform and cuboid, and also articulates with the navicular and, distally, with the third metatarsal base (see Figs 79.5A, 79.12). Like the intermediate cuneiform, its dorsal surface, which is rough and almost rectangular, is the base of a wedge. The plantar surface is narrow and receives a slip from tibialis posterior and sometimes part of flexor hallucis brevis. The distal surface is a triangular articular facet for the third metatarsal base. The proximal surface is rough on its plantar aspect, but its dorsal two-thirds articulate with the navicular by a triangular facet. The medial surface is partly non-articular and has a vertical segment, indented by the intermediate cuneiform, on its proximal margin; on its distal margin, a narrower strip (often two small facets) articulates with the lateral side of the second metatarsal base. The lateral surface, also partly non-articular, bears a triangular or oval proximal facet for the cuboid; a semilunar facet on its dorsal and distal margin articulates with the dorsal part of the medial side of the fourth metatarsal base. Non-articular areas of the medial and lateral surfaces receive intercuneiform and cuneocuboid ligaments, respectively, which are important in the maintenance of the transverse arch of the foot.

Muscle attachments The plantar surface of the lateral cuneiform receives a slip from the tendon of tibialis posterior and, occasionally, part of flexor hallucis brevis.

Vascular supply The lateral cuneiform is supplied via its dorsal, medial and lateral surfaces, mainly from the dorsal arterial network.

Innervation The lateral cuneiform is innervated by branches of the deep fibular and lateral plantar nerves.

Ossification The lateral cuneiform ossifies during the first year of life (see Fig. 79.8).

Tarsal coalition

Tarsal coalition is a hereditary condition in which there is a fibrous, cartilaginous or osseous union of two or more tarsal bones. The aetiology of tarsal coalition is unclear; suggestions include genetic predisposition, an autosomal dominant inherited pattern, trauma, arthritic changes, and/or osteochondroses of the tarsal bones (e.g. Köhler's disease) (Klammer et al 2018).

Metatarsus

The five metatarsals lie in the distal half of the foot and connect the tarsus with the phalanges. Like the metacarpals, they are miniature long bones and have a shaft, proximal base and distal head (see Fig. 79.9). Except for the first and fifth, the shafts are long and slender, longitudinally convex dorsally, and concave on their plantar aspects. Prismatic in section, they taper distally. Their bases articulate with the distal tarsal row and with adjacent metatarsal bases. The line of each tarsometatarsal joint, except the first, inclines proximally and laterally with the metatarsal bases being oblique relative to their shafts. The heads articulate with the proximal phalanges, each by a convex surface that passes farther on to its plantar aspect, where it ends on the summits of two eminences. The sides of the heads are flat, with a depression surmounted by a dorsal tubercle for a collateral ligament of the metatarsophalangeal joint.

On occasion, an os intermetatarseum is encountered between the medial cuneiform and the bases of the first and second metatarsals and represents a rare accessory bone in this region.

Individual metatarsals

First metatarsal

The first metatarsal (see Figs 79.5, 79.12) is the shortest and thickest, and has a strong shaft, of marked prismatic form. The base sometimes has a lateral facet or ill-defined smooth area as a result of contact with the second metatarsal. Its large proximal surface, usually indented on the medial and lateral margins, articulates with the medial cuneiform. Its circumference is grooved for tarsometatarsal ligaments and, medially, part of the tendon of tibialis anterior is attached; its plantar angle has a rough, oval, lateral prominence for the tendon of fibularis longus. The medial head of the first dorsal interosseous is attached to the flat lateral surface of the shaft. The large head has a plantar elevation, the crista, which separates two grooved facets (of which the medial is larger), on which sesamoid bones glide. The most common joint deformity related to the first metatarsal is hallux abducto valgus (bunion) (see Fig. 79.20).

Second metatarsal

The second metatarsal is the longest (see Figs 79.5, 79.12). Its cuneiform base bears four articular facets. The proximal one, concave and triangular, is for the intermediate cuneiform. The dorsomedial one, for the medial cuneiform, is variable in size and usually continuous with that for the intermediate cuneiform. Two lateral facets, dorsal and plantar, are separated by non-articular bone, each divided by a ridge into distal demifacets, which articulate with the third metatarsal base, and a proximal pair (sometimes continuous) for the lateral cuneiform. The areas of these facets vary, particularly the plantar facet, which may be absent. An oval pressure facet, caused by contact with the first metatarsal, may appear on the medial side of the base, plantar to that for the medial cuneiform. Because of its length, its steep inclination, and the position of its base recessed in the tarsometatarsal joint, it is at risk of stress overload; perhaps this is why it is a common site for stress fractures (particularly in athletes) and an avascular phenomenon in its head (Freiberg's infraction). The second metatarsal head is affected in 68% of cases, the third metatarsal head in 27% of cases, and the fourth metatarsal head in 3% of cases. Freiberg's disease is the only osteochondrosis more common in females and occurs at a ratio of 5 : 1 with peak age of onset between 11 and 17 years (Carmont et al 2009, Cerrato 2011).

Third metatarsal

The third metatarsal (see Figs 79.5, 79.12) has a flat triangular base, articulating proximally with the lateral cuneiform, medially with the second metatarsal, via dorsal and plantar facets, and laterally, via a single facet, with the dorsal angle of the fourth metatarsal. The medial plantar facet is frequently absent. The third tarsometatarsal joint is relatively immobile and predisposes the third metatarsal to stress fracture.

Fourth metatarsal

The fourth metatarsal is smaller than the third (see Figs 79.5, 79.12). Its base has, proximally, an oblique quadrilateral facet for articulation with the cuboid; laterally, a single facet for the fifth metatarsal; and medially, an oval facet for the third metatarsal. The latter is sometimes divided by a ridge, in which case the proximal part articulates with the lateral cuneiform.

Fifth metatarsal

The fifth metatarsal has a tuberosity on the lateral side of its base (see Figs 79.5, 79.12). The base articulates proximally with the cuboid by a triangular, oblique surface, and medially with the fourth metatarsal. The tuberosity can be seen and palpated midway along the lateral border of the foot; in acute inversion it may be fractured. The metaphysial–diaphysial junction of the fifth metatarsal base is prone to traumatic or stress fractures. It is believed that fractures at this level damage the nutrient artery and the extraosseous arterial plexus, resulting in compromised vascularity of the fracture site, consequent poor fracture healing and non-union that often requires surgical fixation.

Muscle attachments The first metatarsal receives attachments from the tendon of tibialis anterior medially, and the tendon of fibularis longus on its plantar aspect (see Fig. 79.5). It gives origin to the medial head of the first dorsal interosseus on the proximal aspect of the lateral surface. The lateral head of the first dorsal interosseous and the medial head of

Harris and Beath (1948) were the first to recognize an association between tarsal coalitions and 'peroneal (fibular) spastic flat foot'. The two most common examples are talocalcaneal and calcaneonavicular coalitions, which usually present with symptoms early in the second decade of life. They are often, but not invariably, associated with flat feet (pes planus). A talonavicular coalition is rare (Brennan et al 2012), but when present, it is often associated with a 'ball-and-socket' ankle joint. Surgical resection of tarsal coalitions may eradicate associated pain but seldom improves the range of movement.

the second are attached to the medial and lateral surfaces, respectively of the shaft of the second metatarsal. The lateral heads of the second dorsal interosseous and first plantar interosseous are attached to the medial surface of the shaft of the third metatarsal and the medial head of the third dorsal interosseous is attached to its lateral surface. The lateral head of the third dorsal and second plantar interossei are attached to the medial surface of the fourth metatarsal and the medial head of the fourth dorsal interosseous is attached to the lateral surface.

The tendon of fibularis tertius is attached to the medial part of the dorsal surface and medial border of the shaft of the fifth metatarsal, and that of fibularis brevis to the dorsal surface of the tuberosity. A strong band of the plantar aponeurosis, sometimes containing muscle, connects the apex of the tuberosity to the lateral process of the calcaneal tuberosity. It is this attachment, and not that of fibularis brevis, that is responsible for avulsion fractures of the tuberosity. The tendon of abductor digiti minimi grooves the plantar surface of the base of the fifth metatarsal and flexor digiti minimi brevis is attached here. The lateral heads of the fourth dorsal and the third plantar interossei are attached to the medial side of the shaft of the fifth metatarsal.

Vascular supply The first metatarsal is supplied by the first dorsal and first plantar metatarsal arteries and a superficial branch of the medial plantar artery (see Fig. 76.7), together forming a periosteal arterial network. A nutrient artery enters the lateral surface of the mid diaphysis. The head receives a medial, lateral and plantar supply from these arteries. The blood supply of the second, third and fourth metatarsals follows the same pattern as that described for the first metatarsal, i.e. each bone is supplied by branches of the dorsal and plantar metatarsal arteries, the nutrient artery enters the diaphysis on its lateral side near the metatarsal base and a constant plantar vessel supplies the head. The fifth metatarsal is supplied by dorsal and plantar metatarsal arteries and an inconstant fibular marginal artery, and the nutrient artery enters the diaphysis proximally and medially.

Innervation With the exception of the fifth metatarsal, all of the metatarsals are innervated by the deep fibular nerve. The medial and lateral plantar nerves also supply the first and second metatarsals, and the third and fourth metatarsals, respectively. The fifth metatarsal is innervated by branches from the sural, superficial fibular and lateral plantar nerves.

Ossification Each metatarsal ossifies from a primary centre for the shaft and a secondary centre in either the base (first metatarsal) or head (second–fourth metatarsals) (see Fig. 79.8). The two centres of ossification in the first metatarsal, in the shaft and base, appear after postmenstrual week 12 and the third year of life, respectively, and fuse between the seventeenth and twentieth years. There may be a third centre in the first metatarsal head. The second, third and fourth metatarsals have two centres of ossification, one in the shaft and one distally in the metatarsal head. Ossification of the shaft starts after postmenstrual week 12 and ossification of the metatarsal head starts between the third and fourth years; fusion occurs between the seventeenth and twentieth years. There are three centres of ossification in the fifth metatarsal: at the base in the region of the tuberosity (an apophysis), in the shaft, and distally in the metatarsal head. Ossification of the shaft starts after postmenstrual week 12 and ossification of the metatarsal head starts between the third and fourth years. Fusion of the distal and shaft centres occurs between the seventeenth and twentieth years and the proximal apophysis fuses earlier. An os vesalianum pedis is a rare variant that should not be confused with the basal apophysis (**Fig. 79.13**).

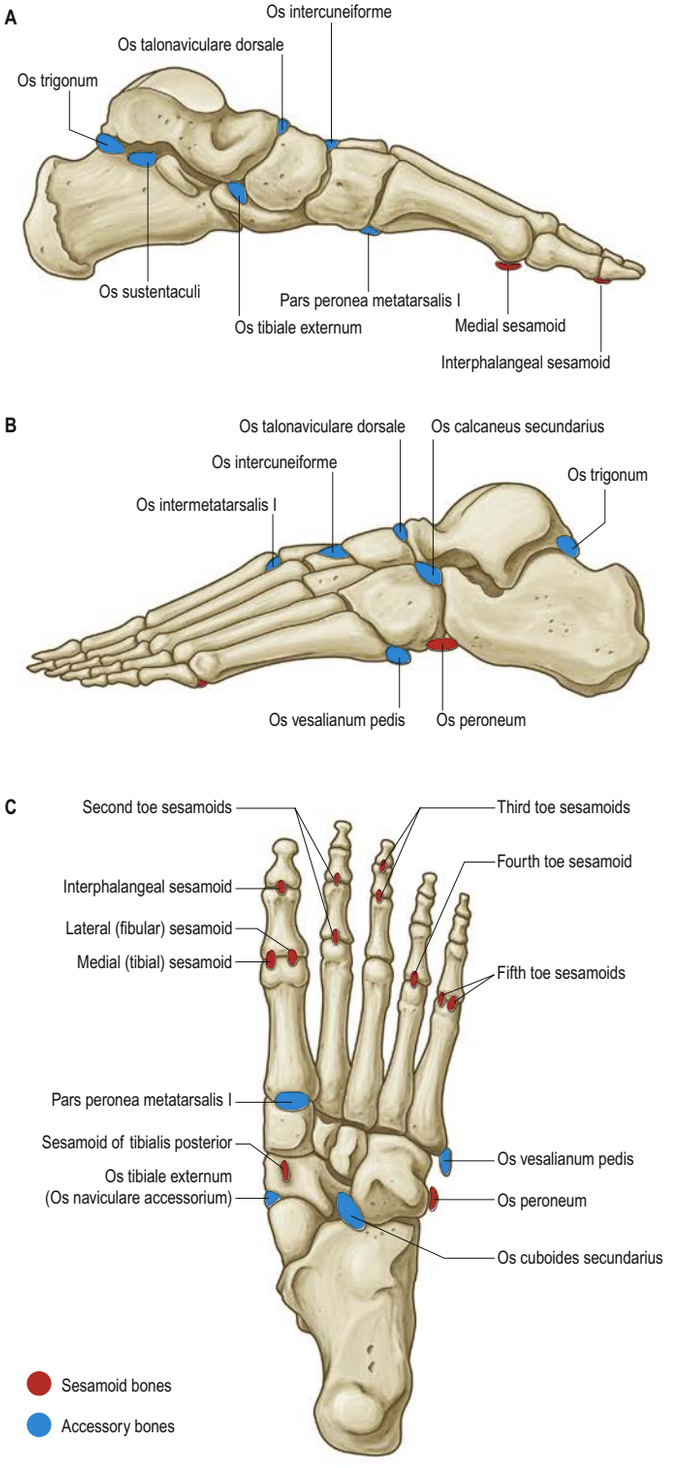

Fig. 79.13 Sites of sesamoid and accessory bones found in the left foot. **A**, Medial aspect. **B**, Lateral aspect. **C**, Plantar aspect.

Phalanges of the foot

In general, the phalanges of the foot resemble those of the hand; there are two in the great toe and three in each of the other toes (see Figs 79.5, 79.9). On occasion, there are only two phalanges in the little toe and, rarely, this is the case with the other toes. The phalanges of the toes are much shorter than their counterparts in the hand, and their shafts, especially those of the proximal set, are compressed from side to side. In the proximal phalanges, the compressed shaft is convex dorsally, with a plantar concavity. The base is concave for articulation with a metatarsal head, and the head is a trochlea for the middle phalanx. Middle phalanges are small and short, but broader than their proximal counterparts. Distal phalanges resemble those in the fingers, but are smaller and flatter. Each has a broad base for articulation with a middle phalanx and an expanded distal end. A rough tuberosity on the plantar aspect of the latter supports the pulp of the toe and provides a weight-bearing area.

Muscle attachments The tendons of the long digital flexors and extensors are attached to the plantar and dorsal aspects of the bases of the distal phalanges of the lateral four toes. Flexor hallucis longus and extensor hallucis longus are similarly attached to the great toe. The tendons of flexor digitorum brevis and extensor digitorum brevis are attached to the bases of the middle phalanges. The proximal phalanges of the second, third, fourth and fifth toes each receive a lumbrical on their medial side; those of the second, third and fourth toes also receive an interosseous muscle on both sides.

Vascular supply The proximal phalanges receive most of their blood supply from the dorsal digital arteries. The middle phalanges are supplied by plantar and dorsal digital arteries. The distal phalanges receive their supply mainly from plantar digital arteries.

Innervation The phalanges are innervated by the plantar and dorsal digital nerves.

Ossification Phalanges are ossified from a primary centre for the shaft and a basal epiphysis (see Fig. 79.8). Primary centres for the distal phalanges appear after postmenstrual week 12 and somewhat later in the fifth digit. Primary centres for the proximal phalanges appear after postmenstrual week 12, and later for the middle phalanges, but there is wide variation. Basal centres appear between the second and eighth years (usually second or third in the great toe), and union with the shaft occurs by the eighteenth year. There is considerable variation in ossification and fusion dates.

Sesamoid bones

Most sesamoid bones are only a few millimetres in diameter and their shape is variable. Some have a predictable location (see below), but many others vary in terms of location and frequency of occurrence (see Fig. 79.13). Some sesamoid bones ossify, whereas others remain cartilaginous. Most sesamoid bones are embedded in tendons in close proximity to joints (Yammine 2015). Their precise role is not understood; it is believed that they may alter the direction of muscle pull, decrease friction and modify pressure.

Medial and lateral sesamoid bones of the first metatarsophalangeal joint

The two constant sesamoid bones within the foot are those of the first metatarsophalangeal articulation (see Figs 79.7, 79.8B, 79.9E). The medial (tibial) sesamoid bone is generally larger than the lateral (fibular) sesamoid bone and lies slightly more distally. During dorsiflexion of the great toe, the sesamoid bones lie below the first metatarsal head, offering protection to the otherwise exposed plantar aspect of the first metatarsal head. The medial sesamoid is approximately 10 mm wide and 14 mm long, and the lateral sesamoid is usually smaller (approximately 8 mm wide and 10 mm long); the overall sizes of the sesamoid bones vary considerably.

The sesamoid bones are embedded within the double tendon of flexor hallucis brevis (see Fig. 79.5B) and articulate on their dorsal surfaces with the plantar facets of the first metatarsal head. They are separated by the crista or intersesamoidal ridge, which provides stability to the sesamoid bone complex. (This ridge can be eroded to the point of obliteration in severe cases of hallux abducto valgus.) The sesamoid bones are connected to the plantar base of the proximal phalanx through the plantar plate. A thin layer of the tendon of flexor hallucis brevis covers the plantar surface of each sesamoid, whereas the dorsal or superior surface is covered by hyaline cartilage. The sesamoid bones are suspended by a sling-like mechanism made up of the collateral ligaments of the first metatarsophalangeal joint and the sesamoid ligaments on either side of the joint. The plantar aponeurosis also has an attachment to the sesamoid bones.

Approximately 30% of these sesamoid bones are bipartite (see Fig. 79.7D). The medial is much more commonly affected and may have two, three or four parts, but the fibular sesamoid rarely has more than two. The condition may be bilateral. The sesamoid bones may be congenitally absent.

Muscle attachments The medial sesamoid bone receives an attachment from abductor hallucis that medially stabilizes the sesamoid complex. The lateral sesamoid receives some fibres from the tendon of adductor hallucis and this provides lateral stabilization. The medial and lateral sesamoid bones are connected by the intersesamoid ligament, which forms the floor of the tendinous canal for the tendon of flexor hallucis longus. The mean length and width of the intersesamoid ligament on its plantar aspect (outside the capsule) is approximately 8.5 mm and 6.3 mm compared to 6.5 mm and 2.2 mm on its dorsal aspect (within the capsule); it is about 3 mm thick. With the application of hallux abducto valgus deforming forces, the size of the sesamoid bones may change, resulting in lengthening of the intersesamoid ligament (Fiacco et al 2017).

Vascular supply There are three patterns of blood supply to the sesamoid bones. In 50% of cases, the arterial supply is derived from the medial plantar artery and the deep plantar arch; in 25% of cases, it is predominantly from the deep plantar arch; and in 25% of cases, from the medial plantar artery alone. The major arterial blood supply to the sesamoid bones enters from the proximal and plantar aspects, and only a minor contribution enters through their distal poles.

Innervation The medial and lateral sesamoid bones are innervated by the plantar digital nerves.

Ossification The ossification centres of the sesamoid bones can be multiple or single.

Other sesamoid and accessory bones

Accessory or inconstant sesamoid bones may occur under any weight-bearing surface of the foot but are most common under the second to fifth metatarsal heads. They are extremely variable in size and their incidence is difficult to determine (Yammine 2015).

A true sesamoid bone occasionally occurs in the tendon of tibialis posterior. It lies on the plantar aspect of the navicular tuberosity within the tendon at the level of the inferior border of the calcaneonavicular ligament (see p. 1441, accessory navicular). Very rarely, a sesamoid bone is found within the tendon of tibialis anterior near its insertion at the level of the anteroinferior corner of the medial cuneiform, where there is an articular facet. An os peroneum is a sesamoid bone within the tendon of fibularis longus that articulates with the lateral surface of the calcaneus, the calcaneocuboid joint or, more frequently, the plantar aspect of the cuboid where there is an articular facet. The bone is situated where the tendon of fibularis longus angles around the plantar aspect of the lateral border of the cuboid and is usually cartilaginous. The frequency of the os peroneum has been reported to be as low as 4.7% and as high as 90% (Oyedele et al 2006, Coskun et al 2009, Muehleman et al 2009).

JOINTS

Ankle (talocrural) joint

The ankle joint is a hinge joint, approximately uniaxial. The lower end of the tibia and its medial malleolus, together with the lateral malleolus of the fibula and inferior transverse tibiofibular ligament, form a deep recess ('mortise') for the body of the talus. Although it appears to be a simple hinge, its axis of rotation is dynamic, shifting during dorsiflexion and plantar flexion. Starting from the plantigrade position, the normal range of dorsiflexion is 10° when the knee is straight, and 30° with the knee flexed (when the calcaneal tendon will be relaxed). The range of normal plantar flexion is 30°. (The values of these ranges are all approximate.) Dorsiflexion results in the joint adopting the 'close-packed' position, with maximal congruence and ligamentous tension; from this position, all major thrusting movements are exerted, in walking, running and jumping. The malleoli grip the talus, and no appreciable lateral movement can occur without stretch of the inferior tibiofibular syndesmosis, even in relaxation. The superior talar surface is broader in front, and in dorsiflexion, the malleolar gap is increased by slight lateral rotation of the fibula, by 'give' at the inferior tibiofibular syndesmosis, and gliding at the superior tibiofibular joint. Normal ankles show valgus inclination at birth. The morphology changes in the first few years of life and the ankle reaches the adult position by the age of three years (Nakai et al 2000).

Articulating surfaces Articular surfaces are covered by hyaline cartilage. The talar trochlear surface is convex sagittally, gently concave transversely and wider anteriorly; the distal tibial articular surface is reciprocally curved. The talar articular surface for the medial malleolus is a proximal area on the medial talar surface, and is fairly flat, comma-shaped and deeper anteriorly. The larger lateral talar articular surface is triangular and vertically concave, while the articular surface on the lateral malleolus is reciprocally curved. Posteriorly, the edge between the trochlear and fibular articular surfaces of the talus is bevelled to a narrow, flat triangular area that articulates with the inferior transverse tibiofibular ligament (**Fig. 79.14A**); all surfaces are contiguous. The bones are held together by a fibrous capsule, and by medial collateral (deltoid), anterior and posterior talofibular and calcaneofibular ligaments.

Fibrous capsule Around the joint, the fibrous capsule is thin anteriorly and posteriorly. It is attached proximally to the borders of the tibial and malleolar articular surfaces, and distally to the talus near the margins of its trochlear surface, except anteriorly where it reaches the dorsum of the talar neck. The capsule is strengthened by strong collateral ligaments. Its posterior part consists mainly of transverse fibres. It blends with the inferior transverse ligament and is thickened laterally where it reaches the fibular malleolar fossa.

Ligaments The ligaments of the ankle joint are the medial and lateral collateral ligaments.

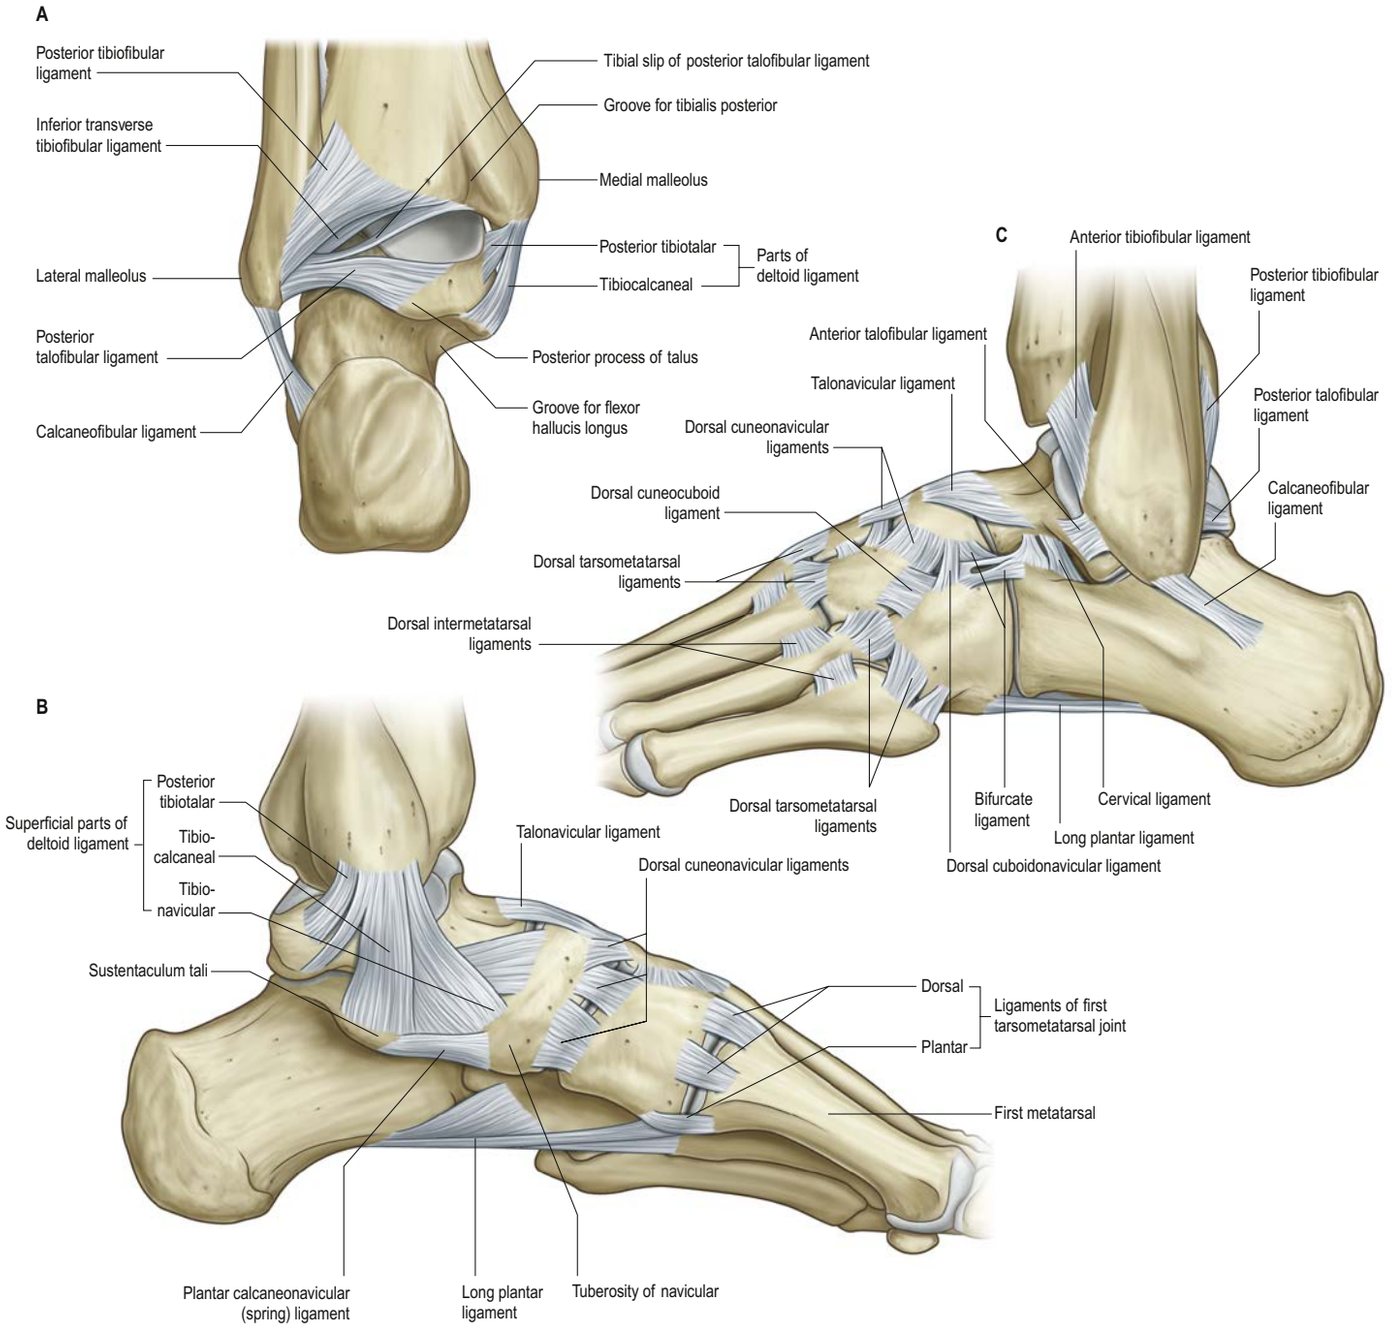

Fig. 79.14 The left ankle and tarsal joints. **A**, Posterior aspect. **B**, Medial aspect. **C**, Lateral aspect.

Medial collateral ligament (deltoid ligament) The medial collateral ligament (deltoid ligament) is a strong, triangular band, attached to the apex and the anterior and posterior borders of the medial malleolus. While up to eight different bands have been reported (Panchani et al 2014), they are variable in their presentation (**Fig. 79.14B**). Of its superficial fibres, anterior (tibionavicular) fibres pass anteriorly to the navicular tuberosity, behind which they blend with the medial margin of the plantar calcaneonavicular ligament (fibers to spring ligament); intermediate (tibiocalcaneal) fibres descend almost vertically to the entire length of the sustentaculum tali; posterior (superficial posterior tibiotalar) fibres pass posterolaterally to the medial side of the talus and its medial tubercle; and additional fibres posterior to the sustentaculum tali (rare variant) have been reported. Of its deep fibres, anterior (anterior tibiotalar) fibres pass from the medial malleolus to the non-articular part of the medial talar surface; intermediate fibres deep to the tibiocalcaneal ligament (rare variant) descend almost vertically to the entire length of the sustentaculum tali; posterior (deep posterior tibiotalar) fibres pass posterolaterally to the medial side of the talus and its medial tubercle; and additional fibres may pass to the spring ligament (Pankovich and Shivaram 1979, Milner and Soames 1998, Boss and Hintermann 2002, Yammine 2017). The tendons of tibialis posterior and flexor digitorum longus cross the ligament. The medial collateral ligament of the ankle is rarely injured alone: tears are commonly associated with a fracture of the distal fibula. Chronic instability is rare.

Lateral collateral ligament The lateral collateral ligament has three discrete parts. The anterior talofibular ligament extends anteromedially from the anterior margin of the lateral malleolus to the talus, attached anterior to its lateral articular facet and to the lateral aspect of its neck (**Fig. 79.14C**). The posterior talofibular ligament runs almost horizontally from the distal part of the lateral malleolar fossa to the lateral tubercle of the posterior talar process (Fig. 79.14A); a 'tibial slip' of fibres, also known as transverse fibres of the posterior talofibular ligament, connects it to the medial malleolus. The calcaneofibular ligament, a long cord, runs from a depression anterior to the apex of the lateral malleolus to a tubercle on the lateral calcaneal surface and is crossed by the tendons of fibularis longus and brevis (see Fig. 79.14A,C). The lateral ligament complex, more specifically, the anterior talofibular ligament, is injured most commonly with inversion sprains; the posterior talofibular ligament is almost always spared. Although the resulting increased laxity is tolerated in most cases, some require surgical reconstruction.

Synovial membrane The joint is lined by a synovial membrane that projects into the inferior tibiofibular joint.

Vascular supply and lymphatic drainage The ankle joint is supplied by malleolar branches of the anterior and posterior tibial and fibular arteries. Lymphatic drainage is via vessels accompanying the arteries and via the long and short saphenous veins, superficially. The blood supply of the medial collateral ligament is derived from three extraosseous arteries (medial tarsal, tibialis anterior and tibialis posterior arteries) and at least one intraosseous source (at the site of its attachments to the medial malleolus and the medial aspect of the talus) (Haynes et al 2017).

Innervation The ankle joint is innervated by branches from the deep fibular, saphenous, sural and tibial nerves (or medial and lateral plantar nerves, depending on the level of division of the tibial nerve). Occasionally, the superficial fibular nerve also supplies the ankle joint. For a comprehensive account of the innervation of the ankle joint (and other foot joints), see Gardner and Gray (1968) and Sarrafian (2011).

Relations Anteriorly, from medial to lateral, are tibialis anterior, extensor hallucis longus, the anterior tibial vessels, deep fibular nerve, extensor digitorum longus and fibularis tertius; posteromedially, from medial to lateral, are tibialis posterior, flexor digitorum longus, the posterior tibial vessels, tibial nerve and flexor hallucis longus; in the groove behind the lateral malleolus are the tendons of fibularis longus and brevis. The tendon of fibularis brevis lies anterior to the tendon of fibularis longus at this level (Fig. 79.15). The long saphenous vein and saphenous nerve cross the ankle joint medial to the tendon of tibialis anterior and anterior to the medial malleolus, the nerve lying posterior to the vein. All of these structures are at risk during surgery on the ankle, the main structures at risk being the neurovascular structures located anteriorly and posteromedially. Branches of the superficial fibular nerve are at risk of injury on the anterolateral aspect of the ankle, particularly during ankle arthroscopy.

Factors maintaining stability Passive stability is conferred upon the ankle mainly by the medial and lateral ligament complexes, the distal tibiofibular ligaments, the tendons crossing the joint, the bony contours and the capsular attachments. Gravity, muscle action and ground

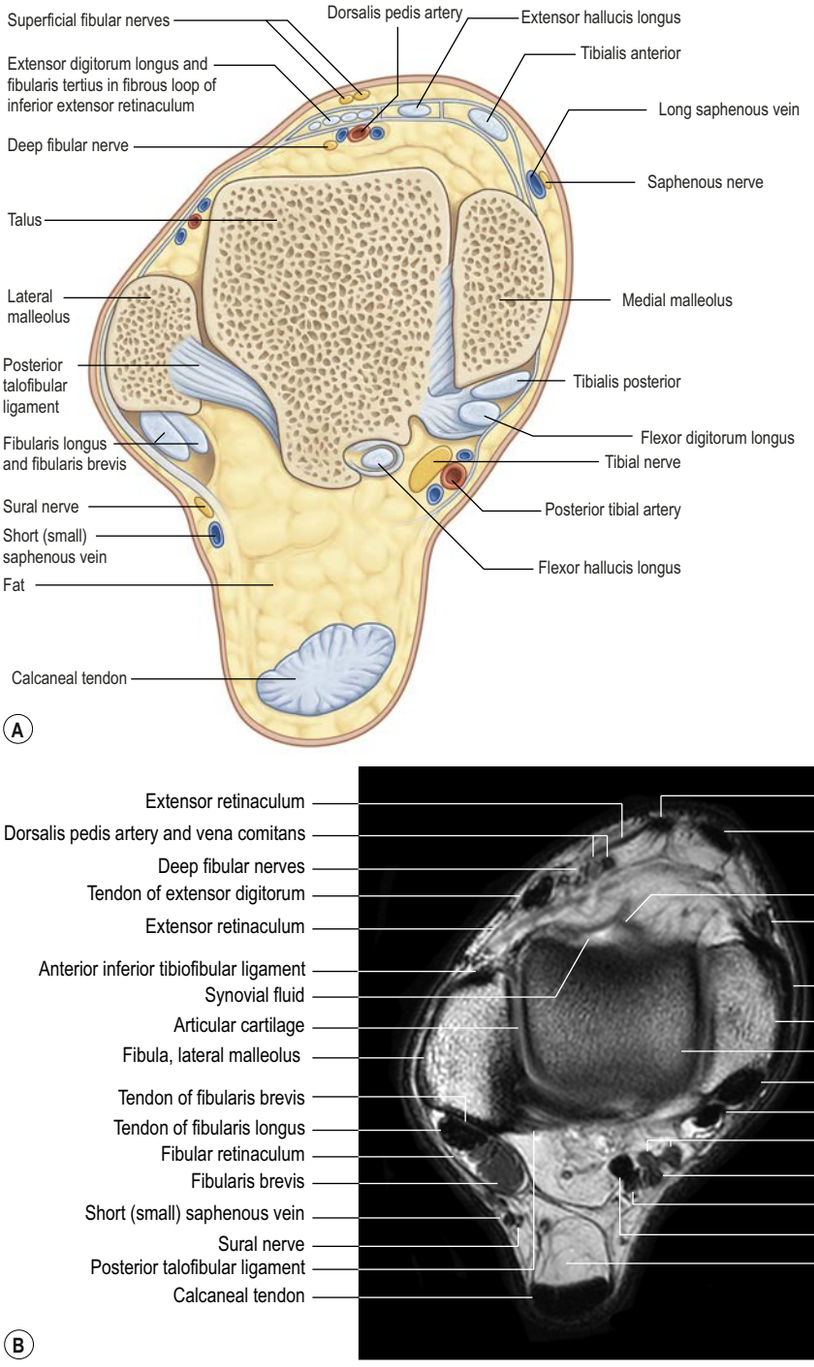

Fig. 79.15 A, A transverse section through the lower part of the left ankle joint, superior aspect. **B**, Axial T2-weighted MRI through the ankle joint, superior aspect.

reaction forces provide dynamic stability. Stability requires the continuous action of soleus assisted by gastrocnemius, increasing when leaning forwards, and decreasing when leaning backwards. If backward sway takes the projection of the centre of gravity ('weight line') posterior to the transverse axes of the ankle joints, the muscles that plantar flex and dorsiflex relax and contract, respectively.

Failure of the fibular muscles can lead progressively to varus instability of the ankle, whereas long-standing failure of the tendon of tibialis posterior, posterior tibial tendon dysfunction, can result in valgus instability of the ankle and particularly a planovalgus foot deformity commonly referred to as adult-acquired flat-foot deformity.

Posterior tibial tendon dysfunction
Available with the *Gray's Anatomy* e-book

Muscles producing movement Dorsiflexion is produced by tibialis anterior, assisted by extensor digitorum longus, extensor hallucis longus and fibularis tertius. Plantar flexion is produced by gastrocnemius and soleus, assisted by plantaris, tibialis posterior, flexor hallucis longus and flexor digitorum longus.

Ankle fractures Ankle fractures are common and of importance because failure to achieve accurate anatomical alignment in the treatment of these fractures often results in significant long-term morbidity. Except for very simple and non-displaced fractures, most ankle fractures are associated with a ligamentous injury. The direction and nature of forces applied to the ankle correlate with the fracture pattern and concomitant ligament injury.

Inferior tibiofibular joint

The inferior tibiofibular joint is usually considered a syndesmosis. It consists of the anterior and posterior tibiofibular and interosseous ligaments.

Articulating surfaces The distal tibiofibular joint is between the rough, medial convex surface on the distal end of the fibula and the concave surface of the fibular notch of the tibia. These surfaces are separated distally for approximately 4 mm by a synovial prolongation from the ankle joint, and may be covered by articular cartilage in their lowest parts.

Fibrous capsule The inferior tibiofibular joint does not have a capsule.

Ligaments The ligaments of the inferior tibiofibular joint are the anterior, interosseous and posterior ligaments.

Anterior tibiofibular ligament The anterior tibiofibular ligament is a flat band that descends laterally between the adjacent margins of the tibia and fibula, anterior to the syndesmosis (see Fig. 79.14C). Bassett's ligament is a variant that presents as a low-lying slip of the ligament inserted so far distally on the fibula that it may cause irritation of the lateral aspect of the talus; it is amenable to arthroscopic removal (Subhas et al 2008).

Interosseous tibiofibular ligament The interosseous tibiofibular ligament is continuous with the interosseous membrane. It contains many short bands between the rough adjacent tibial and fibular surfaces and is the strongest union between the bones.

Posterior tibiofibular ligament The posterior tibiofibular ligament is stronger than the anterior, and is placed similarly on the posterior aspect of the syndesmosis (see Fig. 79.14A). Its distal, deep part is the inferior transverse ligament, a thick band of yellow fibres that crosses from the proximal end of the lateral malleolar fossa to the posterior border of the tibial articular surface almost to the medial malleolus. The ligament projects distal to the bones, in contact with the talus. Its colour reflects its content of yellow elastic fibres.

Synovial membrane The synovial membrane of the ankle joint projects into the distal 4 mm or so of the inferior tibiofibular joint.

Vascular supply and lymphatic drainage The inferior tibiofibular joint is supplied by the perforating branch of the fibular artery and lateral malleolar branches of the anterior and posterior tibial arteries. Lymphatic drainage is via vessels corresponding to the arteries, and via vessels that accompany the long and short saphenous veins.

Innervation The inferior tibiofibular joint is innervated by branches from the deep fibular and sural nerves.

Relations No significant structures pass anterior to the anterior aspect of the inferior tibiofibular joint but the superficial fibular nerve is at risk during surgery to this area. Posteriorly the fibular artery passes over the posterior tibiofibular ligament and is at risk in the posterolateral approach to the fibula.

Factors maintaining stability Stability is maintained in part by the bone contours, but mainly by the dense anterior and posterior tibiofibular and the interosseous ligaments.

Muscles producing movement No muscles act on the inferior tibiofibular joint, which moves only slightly. Because of the varying slope of the lateral surface of the body of the talus, the fibula undergoes a small degree of lateral rotation during dorsiflexion at the ankle, and this results in slight widening of the interval between the bones. Testing for a significant disruption of this joint is usually carried out with the patient under anaesthesia and involves applying a lateral rotation and abduction force, looking for abnormal widening of the syndesmosis. Another helpful clinical test for evaluating a syndesmotic injury is the Hopkinson squeeze test. This test is carried out by compressing the fibula to the tibia at the midpoint of the leg. An injured syndesmosis will result in pain in the area of the inferior tibiofibular joint (Hopkinson et al 1990, Scheyerer et al 2011). Excessive anterior/posterior glide of the fibula relative to the tibia also indicates a disruption of the joint.

Tarsal joints

Talocalcaneal joint

Anterior and posterior articulations between the calcaneus and talus form a functional unit termed the talocalcaneal or subtalar joint (see Fig. 79.17, 79.19). The posterior articulation is referred to as the talocalcaneal joint and the anterior articulation is regarded as part of the talocalcaneonavicular joint. The talocalcaneal joint is a modified multiaxial joint and its permitted movements are considered together with those at other tarsal joints. The bones are connected by a fibrous capsule and by lateral, medial, interosseous talocalcaneal and cervical ligaments.

Articulating surfaces The subtalar joint proper involves the concave posterior calcaneal facet on the posterior part of the inferior surface of the talus and the convex posterior facet on the superior surface of the calcaneus (**Fig. 79.16**).

Fibrous capsule The fibrous capsule envelops the joint; its fibres are short and attached to its articular margins.

Ligaments The ligaments of the talocalcaneal joint are the lateral, medial and interosseous talocalcaneal ligaments and the cervical ligament.

Lateral talocalcaneal ligament The lateral talocalcaneal ligament is a short flat fasciculus that descends obliquely and runs inferoposteriorly from the lateral process of the talus to the lateral calcaneal surface and is attached anterosuperior to the calcaneofibular ligament.

Medial talocalcaneal ligament The medial talocalcaneal ligament connects the medial tubercle of the talus to the posterior aspect of the sustentaculum tali and adjacent medial surface of the calcaneus. Its fibres blend with the medial collateral (deltoid) ligament of the ankle joint; the most posterior fibres line the groove for flexor hallucis longus between the talus and calcaneus.

Interosseous talocalcaneal ligament The interosseous talocalcaneal ligament is a broad, flat bilaminar transverse band in the tarsal sinus (see Fig. 79.16A; **Fig. 79.17**). It descends obliquely and laterally from the sulcus tali to the calcaneal sulcus. The posterior lamina of the ligament is associated with the talocalcaneal joint, and the anterior lamina with the talocalcaneonavicular joint. Its medial fibres are taut in eversion of the foot.

The aetiology of posterior tibial tendon dysfunction is complex. The incidence is greater in obese, middle-aged women. There are multiple contributory factors such as diabetes mellitus and hypertension, which are further complicated by steroid exposure or previous trauma or surgery in the region of the tendon of tibialis posterior. There is often a progressive disruption not only of this tendon, but also of multiple ligamentous complexes such as the spring ligament and those supporting the naviculocuneiform and tarsometatarsal ligaments. This leads to a marked collapse of the medial longitudinal arch, which can be staged using the original Johnson and Strom (1989) classification system and that of Myerson (1997). Along with the varying methods used to diagnose posterior tibial tendon dysfunction, a clinically important test is the single heel-rise test used in the initial stages of adult-acquired flat-foot deformity (Abousayed et al 2017).

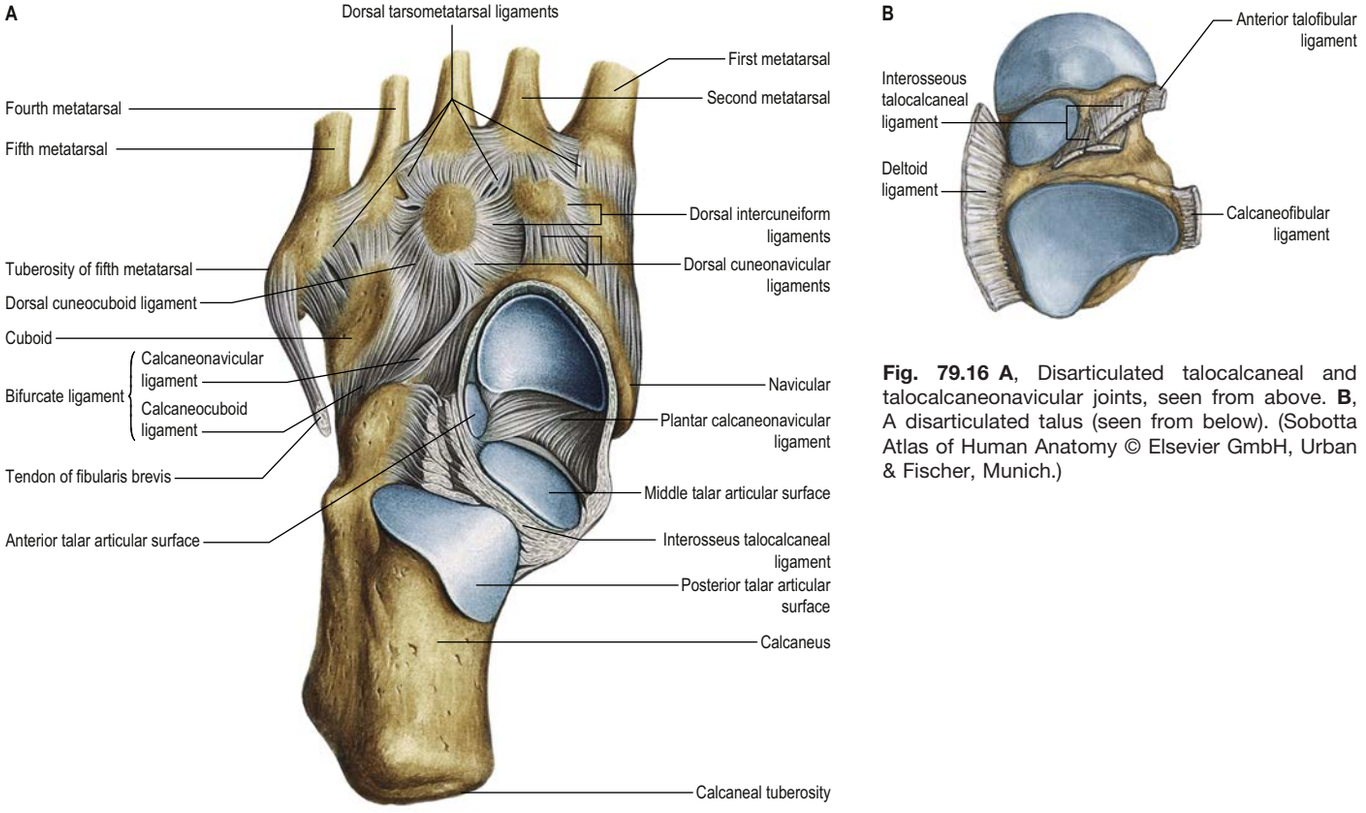

Fig. 79.16 A, Disarticulated talocalcaneal and talocalcaneonavicular joints, seen from above. **B**, A disarticulated talus (seen from below). (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Posterior talocalcaneal ligament The posterior talocalcaneal ligament is attached to the plantar border of the posterior process (posterolateral tubercle) of the body of the talus.

Cervical ligament The cervical ligament is just lateral to the tarsal sinus and attached to the superior calcaneal surface (see Fig. 79.14C). It is medial to the attachment of extensor digitorum brevis, from where it ascends medially to an inferolateral tubercle on the talar neck (Barclay-Smith 1896). It is considered to be taut in inversion of the foot. For morphometric data on the cervical ligament and its relationship to the interosseous talocalcaneal ligament see Poonja et al (2017).

Synovial membrane The synovial cavity of the talocalcaneal joint is usually quite separate and does not communicate with those of other tarsal joints. However, direct communication with the ankle joint has been observed in rare instances.

Innervation The talocalcaneal joint is innervated by branches of the tibial, medial plantar and sural nerves.

Relations Posteromedially, in the region of the posterior aspect of the talocalcaneal joint, and viewed from anterior to posterior, veins are seen on either side of the posterior tibial artery, the tibial nerve and the tendon of flexor hallucis longus. These neurovascular structures are at risk in posteromedial approaches to the ankle and talocalcaneal joints. On the lateral side, the tendon of fibularis brevis lies anterior to the tendon of fibularis longus and both pass behind the lateral malleolus close to the talocalcaneal joint. The sural nerve lies just posterior to the tendons of fibularis longus and brevis.

Factors maintaining stability Stability is conferred by the bony contours of the hindfoot plus the above-mentioned ligaments: it is not known which ligaments provide the most stability. An additional ligamentous restraint is provided by the calcaneofibular component of the lateral ligament complex, and the tendons crossing the articulation add stability.

Muscles producing movement Heel inversion is controlled by tibialis anterior, tibialis posterior and the gastrocnemius–soleus complex via the calcaneal tendon, and the extrinsic flexors of the toes also contribute. Eversion of the foot results from the pull of fibularis longus, brevis and tertius in addition to the extrinsic muscles that extend the toes.

Talocalcaneonavicular joint

The talocalcaneonavicular joint is a compound, multiaxial articulation (see Fig. 79.19A–B). In terms of function, and in clinical practice, it is helpful to regard this complex joint as consisting of two articulations, the anterior part of the 'subtalar' joint and the talonavicular joint. Barclay-Smith provided an eloquent account of the joint in 1896, and for a more recent study see Bonnel et al (2011).

Articulating surfaces The ovoid talar head is continuous with the triple-faceted anterior area of its inferior surface. This part fits the concavity formed collectively by the posterior surface of the navicular, the middle and anterior talar facets of the calcaneus, and the superior fibrocartilaginous surface of the plantar calcaneonavicular ligament (spring ligament). The bones are connected by a fibrous capsule, by the talonavicular and plantar calcaneonavicular ligaments, and by the calcaneonavicular part of the bifurcate ligament.

Fibrous capsule The fibrous capsule is poorly developed, except posteriorly, where it is thick and blends with the anterior part of the interosseous ligament filling the tarsal sinus.

Ligaments The ligaments of the talocalcaneonavicular joint are the talonavicular and plantar calcaneonavicular (spring) ligaments.

Talonavicular ligament The talonavicular ligament is a broad, thin band (see Fig. 79.14B–C). It connects the dorsal surfaces of the neck of the talus and the navicular and is covered by extensor tendons. The plantar calcaneonavicular ligament and the calcaneonavicular part of the bifurcate ligament (see Fig. 79.14B–C) are the plantar and lateral ligaments, respectively, of the joint. Although the calcaneus and navicular do not articulate directly, they are connected by the calcaneonavicular part of the bifurcate ligament and the plantar calcaneonavicular ligament.

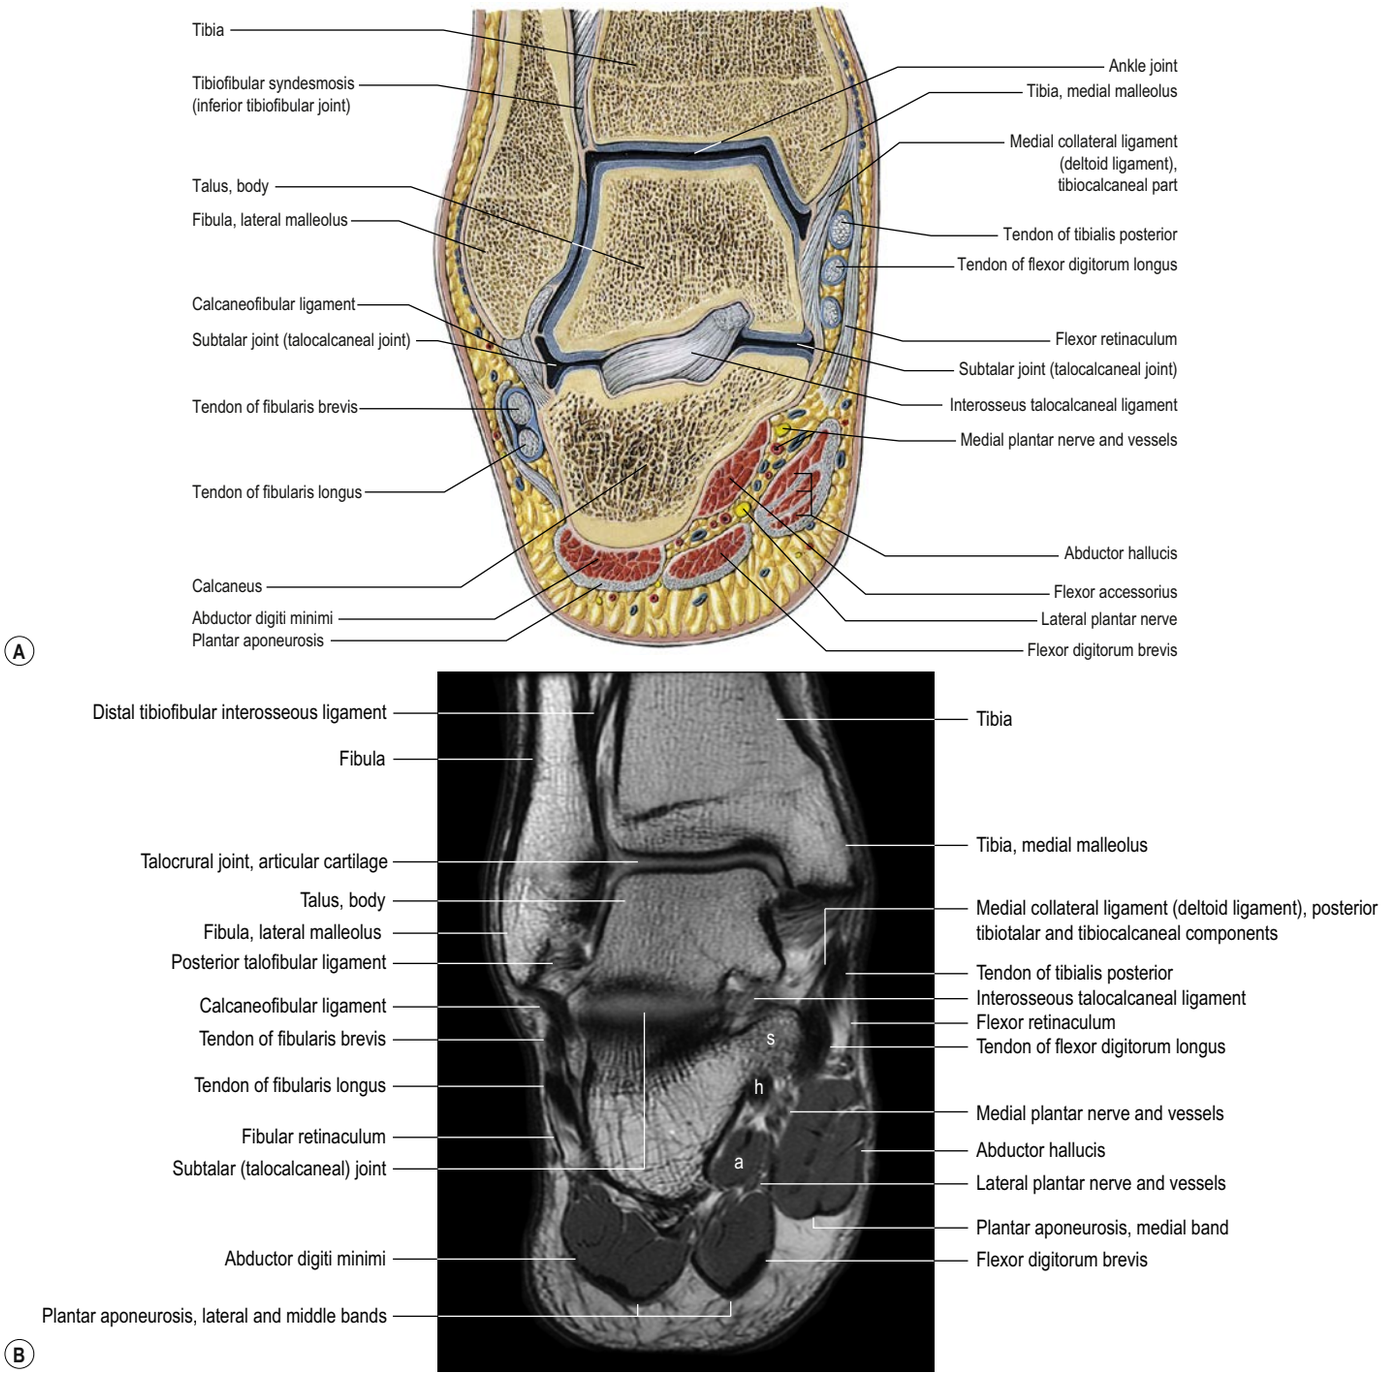

Fig. 79.17 A, A coronal section through the left ankle and talocalcaneal joint (seen from behind). **B**, Coronal proton density MRI of the talocrural joint. Key: a, flexor accessorius; s, sustentaculum tali; h, tendon of flexor hallucis longus. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Plantar calcaneonavicular (spring) ligament The plantar calcaneonavicular (spring) ligament is a broad, thick band connecting the anterior margin of the sustentaculum tali to the plantar surface of the navicular (see Figs 79.14B, 79.16A; **Fig. 79.18**). It ties the calcaneus to the navicular below the head of the talus as part of its articular cavity and it maintains the medial longitudinal arch of the foot. According to Davis et al (1996), the spring ligament is made up of two distinct parts, a superomedial calcaneonavicular portion and an inferior calcaneonavicular portion.

The dorsal surface of the superomedial calcaneonavicular portion has a triangular fibrocartilaginous facet on which part of the talar head rests (see Fig. 79.16A). Its plantar surface is supported medially by the tendon of tibialis posterior and laterally by the tendons of flexors hallucis longus and digitorum longus. Its medial border is blended with the anterior superficial fibres of the medial (deltoid) ligament. Jennings and Christensen (2008) showed that transection of the spring ligament leads to instability of the hindfoot, including talar head plantar flexion and adduction, consistent with pes planovalgus (adult-acquired flat-foot) deformity. The inferior calcaneonavicular portion can become attenuated in adult-acquired flat-foot deformity, and may require surgical correction.

Synovial membrane The talocalcaneonavicular joint is a synovial joint: its cavity sometimes communicates with that of the talocalcaneal joint.

Innervation The talocalcaneonavicular joint is innervated by the deep fibular and medial plantar nerves.

Relations On the medial side, from dorsal to plantar, the tendons of tibialis posterior and flexor digitorum longus lie above the sustentaculum tali, and the tendon of flexor hallucis longus lies below.

The superomedial portion is the larger of the two and originates from the superomedial aspect of the sustentaculum tali and the anterior edge of the anterior facet of the calcaneus. The inferior calcaneonavicular portion originates from between the middle and anterior calcaneal facets on the anterior limit of the sustentaculum tali. Both portions are attached to the inferior surface of the midnavicular; the superomedial portion is attached medial to the inferior portion.

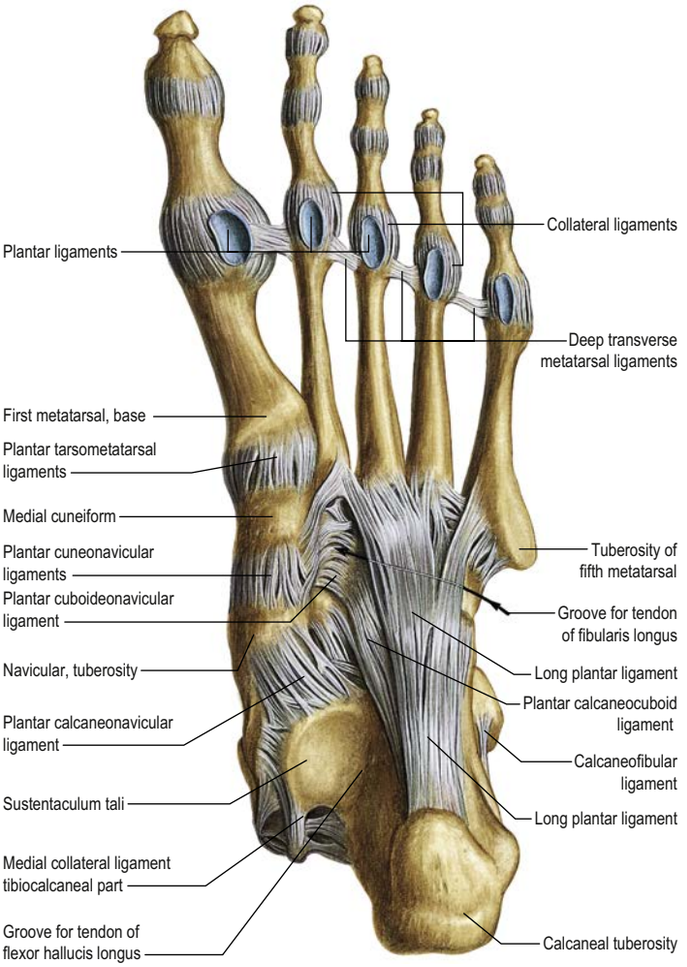

Fig. 79.18 Ligaments on the plantar aspect of the left foot. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

At this point, flexor hallucis longus is deep to the medial and lateral plantar branches of the posterior tibial artery and the tibial nerve. These latter structures are at risk during medial approaches to the joint, e.g. resection of talocalcaneal coalition. Dorsally from medial to lateral, the tendons of tibialis anterior and extensor hallucis longus, the deep fibular nerve, dorsalis pedis artery and the muscle belly of extensor hallucis brevis all pass medially and deep to the tendons of extensor digitorum longus and fibularis tertius. Structures at risk during the dorsal approach to the talonavicular joint include the branches of the superficial fibular nerve superficially and the dorsalis pedis artery and deep fibular nerve deep to the inferior extensor retinaculum.

Factors maintaining stability Stability of the joint is due to a combination of factors, bony contours, the strong plantar calcaneonavicular (spring) ligament and the calcaneonavicular component of the bifurcate ligament.

Muscles producing movement The muscles producing movement are as described above for the talocalcaneal joint.

Calcaneocuboid joint

The calcaneocuboid joint is a saddle (sellar) or biaxial joint with concavo-convex surfaces (Bonnel et al 2013). It is at the same level as the talonavicular joint: together these joints represent the transverse tarsal joint.

Articulating surfaces The articular surfaces of the calcaneocuboid joint, which is 2 cm proximal to the tubercle on the fifth metatarsal base, are between the anterior (distal) surface of the calcaneus and the posterior (proximal) surface of the cuboid.

Fibrous capsule The fibrous capsule is thickened dorsally as the dorsal calcaneocuboid ligament. The synovial cavity of this joint is separate, and does not communicate with those of other tarsal articulations.

Ligaments The ligaments of the calcaneocuboid joint are the bifurcate, long plantar and plantar calcaneocuboid ligaments.

Bifurcate ligament The bifurcate ligament (Chopart's ligament) is a strong Y-shaped structure (see Figs 79.14C, 79.16A). It is attached by its stem proximally to the anterior part of the upper calcaneal surface, and distally it divides into flat-shaped calcaneocuboid and cord-shaped calcaneonavicular bands. The mean length and width of the calcaneocuboid band is approximately 11 mm and 7 mm compared to the calcaneonavicular band, which measures 23 mm and 7 mm, respectively (Kafka et al 2019).

Long plantar ligament The long plantar ligament is the longest ligament associated with the tarsus and is a most powerful factor limiting depression of the lateral longitudinal arch (see Figs 79.14B–C, 79.18; **Fig. 79.19**). It extends from the plantar surface of the calcaneus (anterior to the processes of its tuberosity) and from its anterior tubercle, to the ridge and tuberosity on the plantar surface of the cuboid. Deep fibres are attached to the cuboid and more superficial fibres continue to the bases of the second to the fourth, and sometimes the fifth, metatarsals. This ligament, together with the groove on the plantar surface of the cuboid, makes a tunnel for the tendon of fibularis longus.

Plantar calcaneocuboid ligament The plantar calcaneocuboid (short plantar) ligament also supports the lateral longitudinal arch. It is deeper than the long plantar ligament, from which it is separated by areolar tissue (see Fig. 79.18) and is a short, wide and strong band that stretches from the anterior calcaneal tubercle and the depression anterior to it, to the adjoining part of the plantar surface of the cuboid.

Synovial membrane A synovial membrane lines the calcaneocuboid joint.

Innervation The calcaneocuboid joint is innervated on its plantar aspect by the lateral plantar nerve and dorsally by the sural and deep fibular nerves.

Relations Fibularis longus and abductor digiti minimi pass close to the joint, the lateral plantar nerve passes medially, and extensor digitorum brevis overlies the lateral aspect of the joint. The sural nerve and the tendon of fibularis longus are at risk during approaches to an os peroneum.

Factors maintaining stability The calcaneocuboid joint only permits a small amount of movement; its stability reflects the bony contours and strong ligaments described above.

Muscles producing movement Gliding occurs between the calcaneus and cuboid, with conjunct rotation on each other during inversion and eversion of the entire foot. The same muscles that act on the talocalcaneal and talocalcaneonavicular joints bring about these movements.

Naviculocuneiform joint

The naviculocuneiform joint is a compound joint, often described as a plane joint.

Articulating surfaces The navicular articulates distally with the cuneiform bones where the distal navicular surface is transversely convex and divided into three facets by low ridges that are adapted to the proximal, slightly curved, surfaces of the cuneiforms.

Fibrous capsule The fibrous capsule is continuous with those of the intercuneiform and cuneocuboid joints, and it is also connected to the second and third cuneometatarsal joints and intermetatarsal joints between the second to fourth metatarsals.

Ligaments The ligaments of the naviculocuneiform joint are the dorsal and plantar ligaments.

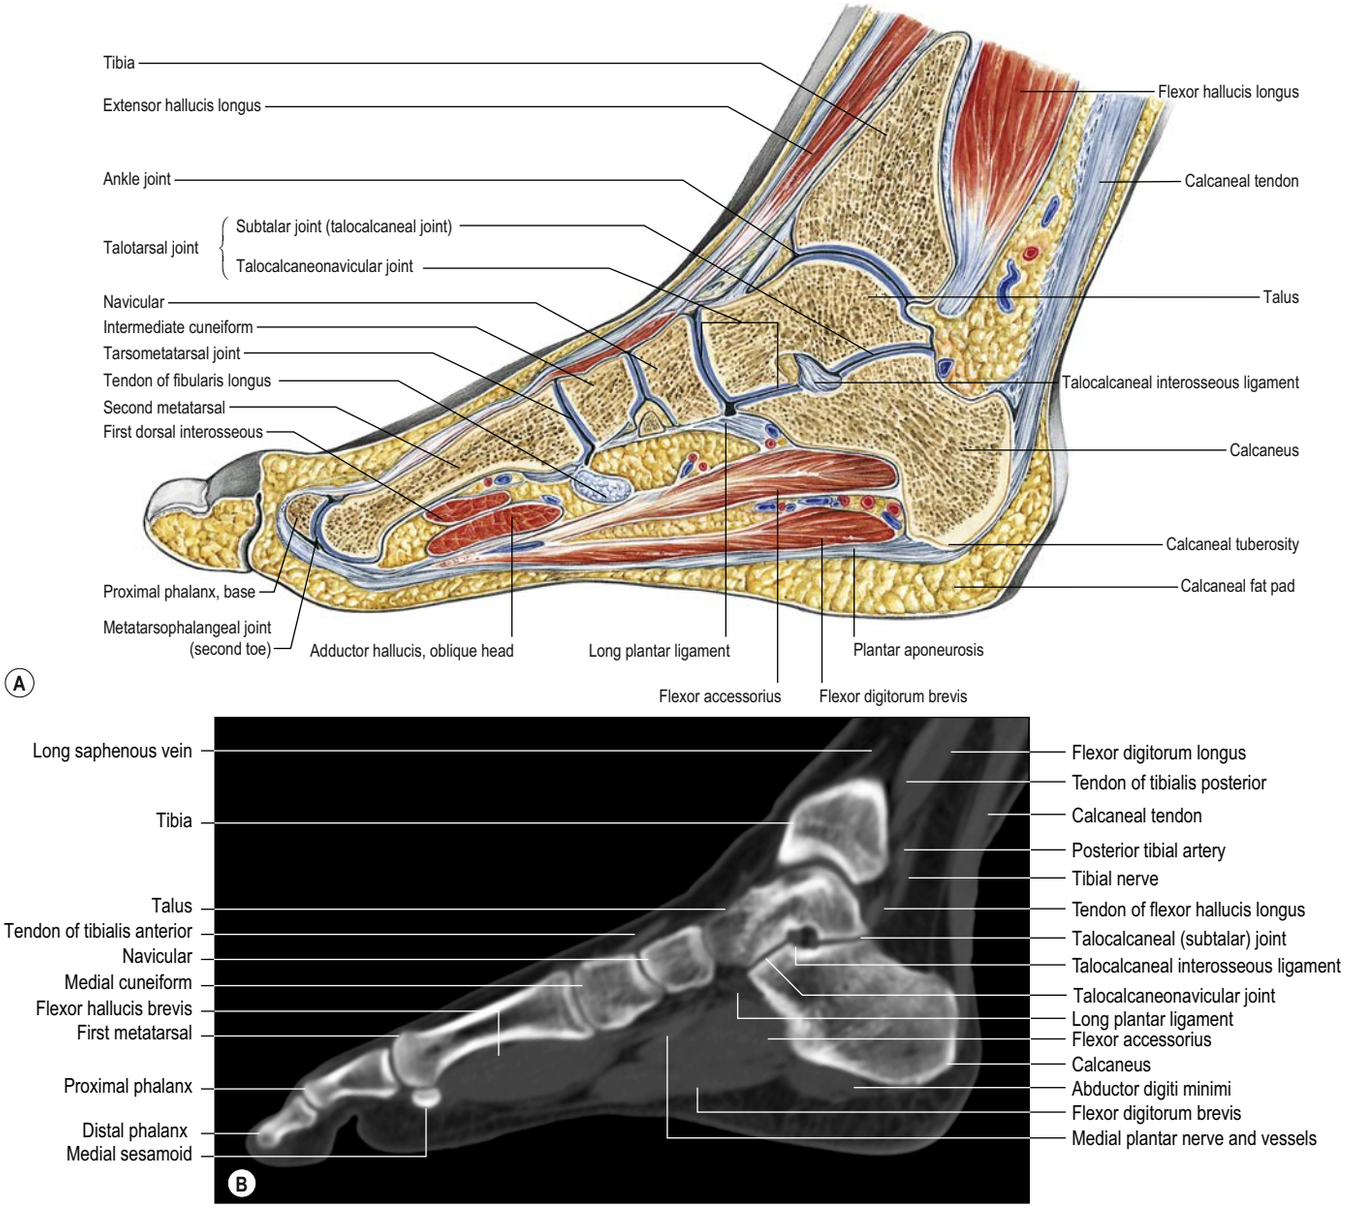

Fig. 79.19 **A**, A sagittal section of the foot showing ankle and tarsal joints. **B**, A sagittal CT multiplanar reconstruction through the medial aspect of the foot. (A, Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.) (C, *continued online*)

Dorsal and plantar ligaments The dorsal and plantar ligaments connect the navicular to each cuneiform; of the three dorsal ligaments, one is attached to each cuneiform. The fasciculus from the navicular to the medial cuneiform is continued as the capsule of the joint around its medial aspect, and then blends medially with the plantar ligament. Plantar ligaments have similar attachments and receive slips from the tendon of tibialis posterior.

Synovial membrane The synovial membrane lines the fibrous capsule in the manner outlined above.

Innervation The naviculocuneiform joint is innervated dorsally by branches from the deep fibular nerve. The medial plantar nerve innervates the medial and intermediate naviculocuneiform joints, and the lateral plantar nerve innervates the lateral naviculocuneiform joint.

Relations The tendon of tibialis posterior sends fibres to the medial cuneiform and crosses the joint on its medial side; it is vulnerable to injury when a medial surgical approach is used, as are the dorsal venous arch and the saphenous nerve. The tendon of tibialis anterior passes over the dorsomedial aspect of the joint and the tendon of extensor hallucis longus is lateral. From medial to lateral, the deep fibular nerve, dorsalis pedis artery and extensor hallucis brevis run over the intermediate cuneiform and all are vulnerable during dorsal exposure of the joint. On the lateral aspect of the joint, the superficial structures at risk are the superficial fibular nerve and the dorsal venous arch of the foot.

Muscles producing movement Movements at the naviculocuneiform, cuboideonavicular, intercuneiform and cuneocuboid joints are slight, subtle gliding and rotational movements that occur during pronation or supination of the foot. When alterations occur in a loaded foot in contact with the ground, they increase suppleness when the forefoot is stressed, e.g. in the initial thrust of running and jumping. The muscles responsible for these slight movements are tibialis anterior, tibialis posterior, fibularis longus and brevis, and the long flexors and extensors of the toes.

Cuboideonavicular joint

The cuboideonavicular joint is usually a fibrous joint in which the bones are connected by dorsal, plantar and interosseous ligaments. However, this syndesmosis is often a synovial joint that is almost plane, and its articular capsule and synovial lining are continuous with that of the naviculocuneiform joint. The dorsal ligament extends distolaterally, and

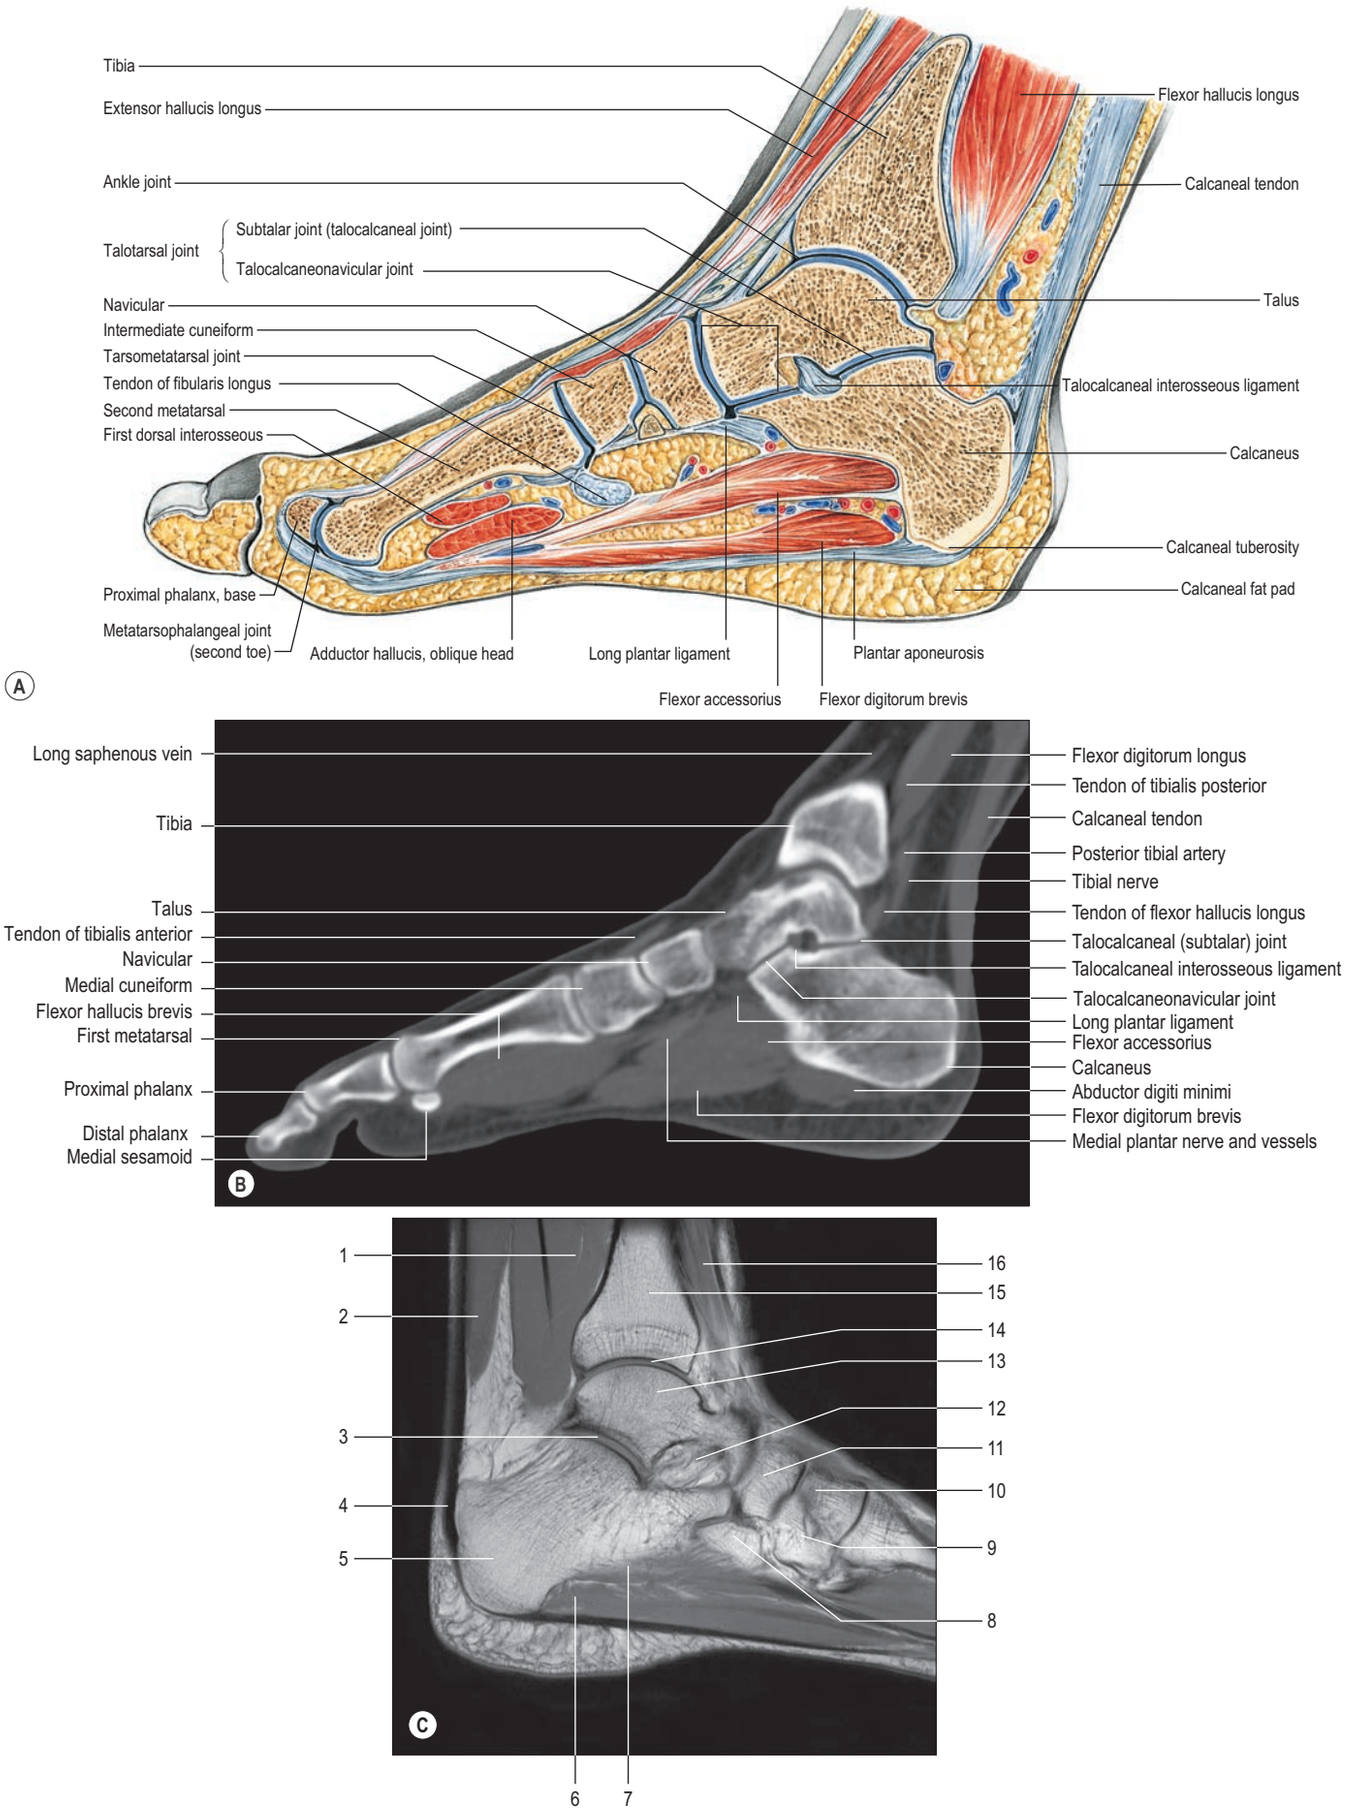

Fig. 79.19 A, A sagittal section of the foot showing ankle and tarsal joints. **B,** A sagittal CT multiplanar reconstruction through the medial aspect of the foot. **C,** A sagittal turbo spin-echo, T1-weighted MRI of the left ankle and hindfoot of a female aged 26 years. Key: 1, flexor digitorum longus; 2, soleus; 3, talocalcaneal (subtalar) joint; 4, calcaneal tendon; 5, calcaneus; 6, flexor digitorum brevis; 7, flexor accessorius; 8, cuboid; 9, lateral cuneiform; 10, intermediate cuneiform; 11, navicular; 12, talocalcaneal interosseous ligament; 13, talus; 14, talocrural joint; 15, tibia; 16, tibialis anterior. the plantar nearly transversely from the cuboid to the navicular. The interosseous ligament is made of strong transverse fibres and connects non-articular parts of adjacent surfaces to the two bones.

Intercuneiform and cuneocuboid joints

The intercuneiform and cuneocuboid joints are all synovial and approximately plane or slightly curved. Their articular capsules and synovial linings are continuous with those of the naviculocuneiform joints. The bones are connected by dorsal, plantar and interosseous ligaments (see Figs 79.14B–C, 79.16A).

Ligaments The ligaments of the intercuneiform and cuneocuboid joints are the dorsal, plantar and interosseous ligaments.

Dorsal and plantar ligaments The dorsal and plantar ligaments each have three transverse bands that pass between the medial and intermediate cuneiforms, the intermediate and lateral cuneiforms, and the lateral cuneiform and cuboid. The plantar ligaments receive slips from the tendon of tibialis posterior.

Interosseous ligaments The interosseous ligaments connect non-articular areas of adjacent surfaces and are strong agents in maintaining the transverse arch.

Innervation The intercuneiform and cuneocuboid joints are innervated dorsally by branches of the deep fibular nerve. The plantar aspect of the medial two joints is innervated from the medial plantar nerve, and the plantar aspect of the lateral joints is innervated by branches of the lateral plantar nerve.

Muscles producing movement The muscles producing movement are as described above for the naviculocuneiform joint.

Tarsometatarsal joints

Tarsometatarsal articulations are approximately plane synovial joints.

Articulating surfaces The first metatarsal articulates with the medial cuneiform; the second is recessed between the medial and lateral cuneiforms and articulates with the intermediate cuneiform; the third articulates with the lateral cuneiform; the fourth articulates with the lateral cuneiform and the cuboid; and the fifth articulates with the cuboid. The joints are approximately on an imaginary line traced from the tubercle of the fifth metatarsal to the tarsometatarsal joint of the great toe, except for that between the second metatarsal and intermediate cuneiform, which is 2–3 mm proximal to this line (see Figs 79.5A, 79.12). Ryan et al (2012) reported that the average joint depths for the first, second and third metatarsal–cuneiform joints were 32.3, 26.9 and 23.6 mm, respectively.

Fibrous capsule The tarsometatarsal joint of the great toe has its own capsule. The articular capsules and cavities of the second and third toes are continuous with those of the intercuneiform and naviculocuneiform joints, but are separated from the fourth and fifth joints by an interosseous ligament between the lateral cuneiform and fourth metatarsal base.

Ligaments The bones are connected by dorsal and plantar tarsometatarsal and cuneometatarsal interosseous ligaments (see Figs 79.16A, 79.18).

Dorsal ligaments The dorsal ligaments are strong and flat. The first metatarsal is joined to the medial cuneiform by an articular capsule, and the other tarsometatarsal capsules blend with the dorsal and plantar ligaments. The second metatarsal receives a band from each cuneiform, the third from the lateral cuneiform, the fourth from the lateral cuneiform and the cuboid, and the fifth from the cuboid alone.

Plantar ligaments The plantar ligaments are longitudinal and oblique bands that are less regular than the dorsal ligaments. Those for the first and second metatarsals are strongest. The second and third metatarsals are joined by oblique bands to the medial cuneiform, and the fourth and fifth metatarsals are joined by a few fibres to the cuboid.

Cuneometatarsal interosseous ligaments There are three cuneometatarsal interosseous ligaments. The strongest, known as Lisfranc's ligament, passes from the lateral surface of the medial cuneiform to the adjacent angle of the second metatarsal and is crucial to the stability of the tarsometatarsal joint complex (Johnson et al 2008). Disruption of this ligament can lead to instability and deformity, and subsequent degenerative changes. A second ligament connects the lateral cuneiform to the adjacent angle of the second metatarsal, but it does not divide the joint between the second metatarsal and lateral cuneiform and is inconstant. A third ligament connects the lateral angle of the lateral cuneiform to the adjacent fourth metatarsal base.

Synovial membrane The first tarsometatarsal joint has its own capsule, with a synovial lining. The other joints are similarly arranged; there is a communication between the second and third and between the fourth and fifth tarsometatarsal joints.

Innervation The interosseous cuneometatarsal ligaments are innervated dorsally via the deep fibular nerve. The plantar aspects of the medial two joints are innervated by branches of the medial plantar nerve, and the plantar aspects of the lateral joints are innervated by branches of the lateral plantar nerve.

Relations From medial to lateral, the saphenous nerve, dorsal venous arch, tendon of extensor hallucis longus, dorsalis pedis artery, deep fibular nerve, extensor hallucis brevis and the tendons of extensor digitorum longus, extensor digitorum brevis, fibularis tertius and fibularis brevis all cross the dorsal aspect of the tarsometatarsal joints. Branches of the superficial fibular nerve are variable in location on the dorsum and the sural nerve lies just inferior to the tendon of fibularis brevis in the subcutaneous tissues. Surgery involving the tarsometatarsal joints is performed through a dorsal approach, and therefore all of these structures are potentially at risk of injury.

Factors maintaining stability The major stabilizers of the tarsometatarsal joints are the associated ligaments. However, despite the strength of the ligaments, this joint complex is vulnerable to injury because of the lack of ligamentous connection between the first and second metatarsal bases. The medial interosseous ligament or Lisfranc's ligament is responsible for the tell-tale avulsion fracture of the second metatarsal base, which may be the only radiographic indication of abnormality after injury to this part of the foot. It is a highly significant injury that is often missed; failure to recognize and treat it by surgical reduction and fixation can lead to long-term disability.

Muscles producing movement Movements between the tarsals and metatarsals are limited to flexion and extension, except in the first tarsometatarsal joint, where some abduction and rotation occur. The muscles that produce this motion are tibialis anterior and fibularis longus. Flexion and extension are brought about by the long and short flexors and extensors of the toes. Movement between the medial cuneiform and first metatarsal, and between the fourth and fifth metatarsal bases and the cuboid, is moderate and allows the foot to adapt to uneven surfaces, whereas movement between the second and third metatarsal bases and their corresponding cuneiforms is very limited.

Intermetatarsal joints

The intermetatarsal ligaments are very strong. They are present between all the lateral four metatarsals, but absent between the first and second metatarsals. The base of the second metatarsal is joined to the first tarsometatarsal joint by the cuneometatarsal interosseous ligament.

Ligaments The ligaments of the intermetatarsal joints include the dorsal and plantar intermetatarsal ligaments (see Fig. 79.14B).

Dorsal and plantar intermetatarsal ligaments As with their dorsal counterparts, the plantar intermetatarsal ligaments are longitudinal, oblique or transverse and they vary considerably in both number and organization. The plantar ligaments are significantly stronger than the corresponding dorsal ligaments. The strongest is the second oblique plantar ligament, which connects the medial cuneiform to the bases of the second and third metatarsals.

Other ligaments All the metatarsal heads are connected indirectly by deep transverse metatarsal ligaments. Dorsal and plantar ligaments pass transversely between adjacent bases. Interosseous ligaments are

strong transverse bands that connect non-articular parts of the adjacent surfaces.

Metatarsophalangeal joints

Metatarsophalangeal articulations are ovoid or ellipsoid joints between the rounded metatarsal heads and shallow cavities on the proximal phalangeal bases. They are usually 2.5 cm proximal to the web spaces of the toes.

Articulating surfaces Articular surfaces cover the distal and plantar, but not the dorsal, aspects of the metatarsal heads. The plantar aspect of the first metatarsal head has two longitudinal grooves separated by a ridge (crista). Each articulates with a sesamoid bone embedded in the capsule of the joint, formed here by the two tendons of flexor hallucis brevis (see Figs 79.5B, 79.13). The sesamoid bones are connected to each other by the intersesamoid ligament, which forms the floor of the tendinous canal for the tendon of flexor hallucis longus. The medial sesamoid bone receives an attachment from abductor hallucis and the lateral sesamoid bone receives an attachment from adductor hallucis, forming the conjoint tendon. Both sesamoid bones act to create a longer lever arm for the tendon of flexor hallucis brevis. Articular areas on the proximal phalangeal bases are concave. The ligaments are capsular, plantar, deep transverse metatarsal and collateral.

Fibrous capsules Fibrous capsules are attached to their articular margins. They are thin dorsally, and may be separated from the extrinsic extensor tendons by small bursae, or they may be replaced by the tendons, but they are inseparable from the plantar and collateral ligaments. The plantar aponeurosis blends with the plantar capsule to form the 'plantar plate', which inserts distally into the base of the proximal phalanx via medial and lateral bundles. Proximally, the plate is attached to the metatarsal head via a thin synovial fold. It also receives an attachment from the accessory collateral ligament.

Ligaments The ligaments of the metatarsophalangeal joints are the plantar, deep transverse metatarsal and collateral ligaments (see Fig. 79.18).

Plantar ligaments The plantar ligaments are thick and dense. They lie between and blend with the collateral ligaments, being loosely attached to the metatarsals and firmly attached to the phalangeal bases. Their margins blend with the deep transverse metatarsal ligaments. Their deep surfaces extend the articular areas for the metatarsal heads. Their plantar surfaces are grooved for the flexor tendons; the fibrous sheaths of the tendons connect with the edges of the grooves (see Fig. 79.18).

Deep transverse metatarsal ligaments The deep transverse metatarsal ligaments are four short, wide, flat bands that unite the plantar ligaments of adjoining metatarsophalangeal joints. The interossei are dorsal to, and the lumbricals, digital vessels and nerves are plantar to, these ligaments. They resemble the deep transverse metacarpal ligaments except that, in the foot, there is a deep transverse metatarsal ligament between the plantar ligament of the second metatarsophalangeal joint and that of the first metatarsophalangeal joint (see Fig. 79.18). Transection of the deep transverse metatarsal ligament during neuroma removal may splay the metatarsals, increasing the intermetatarsal angle (Preston et al 2018).

Collateral ligaments The collateral ligaments are strong cords flanking each joint. They are attached to the dorsal tubercles on the metatarsal heads and the corresponding side of the phalangeal bases, and they slope inferodistally. The first metatarsophalangeal joint also contains metatarsosesamoid ligaments. On either side, the ligaments arise from the metatarsal head with a narrow origin and then fan out to insert on the border of the proximal phalanx and the plantar plate. Each collateral ligament consists of a phalangeal collateral ligament, which inserts into the base of the proximal phalanx, and an accessory collateral ligament, which inserts into the plantar plate.

Synovial membrane Each metatarsophalangeal joint is a separate synovial joint.

Innervation The main nerve supply of the metatarsophalangeal joints is from branches of the plantar digital nerves, which supply the first, second, third and medial half of the fourth metatarsophalangeal joint on their plantar aspects. Digital branches of the lateral plantar nerve supply the lateral half of the fourth joint, and both medial and lateral aspects of the fifth joint, on their plantar sides. The medial dorsal cutaneous branch of the superficial fibular nerve supplies the dorsomedial side of the hallucal metatarsophalangeal joint. The deep fibular nerve supplies the dorsolateral side of the hallucal metatarsophalangeal joint and the medial side of the metatarsophalangeal joint of the second toe.

Relations Dorsally the tendon of extensor hallucis longus lies medial to the tendon of extensor hallucis brevis. The same arrangement occurs in the lateral four toes with the tendons of extensor digitorum longus and brevis. The interossei are plantarmedial and plantarlateral, dorsal to the transverse intermetatarsal ligament, whereas the lumbrical tendons and the digital artery and nerve are plantar to the transverse intermetatarsal ligament. The extrinsic and intrinsic flexors lie on the plantar aspect of the joint in the midline. If approaching the metatarsophalangeal joint surgically from the plantar surface, it is important not to stray from the midline.

Factors maintaining stability The first metatarsophalangeal joint owes its stability to its capsuloligamentous structures and to flexor and extensor hallucis brevis, with a small contribution from flexor and extensor hallucis longus or the bony contours. The collateral ligaments and plantar plates stabilize the metatarsophalangeal joints of the lateral four toes. Rupture of the plantar plate can lead to dorsal dislocation of the digit on its articulating metatarsal. The resulting extension at the metatarsophalangeal joint creates a hammer toe deformity.

Muscles producing movement The types of movements at these joints are like those that occur at the corresponding joints in the hand, but the range of movement is quite different. In contrast to the metacarpophalangeal joints, the range of active extension at the metatarsophalangeal joints (50–60°) is greater than that of flexion (30–40°); this is an adaptation to the needs of walking, and is most marked in the joint of the great toe, where flexion is a few degrees while extension may reach 90°. When the foot is on the ground, the metatarsophalangeal joints are already extended to at least 25° because the metatarsals incline proximally in the longitudinal arches of the foot (see Fig. 79.9A). The range of passive movements in these joints is 90° (extension) and 45° (flexion), according to Kapandji (2011). The muscles producing movements at the metatarsophalangeal joints are as follows.

Flexion Flexor digitorum brevis, lumbricals and interossei, assisted by flexor digitorum longus and flexor accessorius. In the fifth toe, flexor digiti minimi brevis assists. For the great toe, flexors hallucis longus and brevis and the oblique head of the adductor hallucis are the only flexors.

Extension Extensor digitorum longus and extensor digitorum brevis, extensor hallucis longus.

Adduction Adductor hallucis; in the third to fifth toes, the first, second and third plantar interossei, respectively.

Abduction Abductor hallucis; in the second toe, the first and second dorsal interossei; in the third and fourth toes, the corresponding dorsal interossei; in the fifth toe, abductor digiti minimi. Note that the line of reference for adduction and abduction in the foot is along the second digit, which has the least mobile metatarsal. The second toe may therefore be 'abducted' medially and laterally by the first and second dorsal interossei, respectively.

Hallux abducto valgus Hallux abducto valgus is a common condition, occurring mainly in individuals who have a genetic predisposition. Footwear is implicated in this condition, which presumably accounts for the greater incidence in females. This is because high heel shoes can hold the foot in an artificially supinated position, and the pointed toe box of the shoes can compress the toes towards the midline. However, it is more of an accelerating factor than a sole causative one. Hallux abducto valgus is a tri-planar deformity, and is associated with transverse abduction (from the midline of the foot), sagittal elevation and frontal plane rotation of the first metatarsal, which abducts and rotates the hallux in valgus (**Fig. 79.20**). While frontal plane rotation is a prevalent part of hallux abducto valgus, it is rarely considered in surgical correction, which may account for the high recurrence rates of this deformity (Hatch et al 2018).

The more spheroidal the shape of the first metatarsal head, the more likely it is to be unstable. Conversely, a flat metatarsal head is less likely to be associated with hallux abducto valgus. No muscle inserts into the first metatarsal head, and therefore its position is determined by the

Fig. 79.20 Radiograph of the left foot of a skeletally mature adult with a hallux abducto valgus (bunion) deformity.

position of the proximal phalanx. Furthermore, the base of the first metatarsal (the first metatarsal cuneiform joint) has no ligamentous attachments to the lateral four metatarsals. This creates an intrinsic instability that can more easily allow the first metatarsal to drift (Burns and Mecham 2014).

As the proximal phalanx moves laterally on the metatarsal head, it pushes the head medially. This leads to attenuation of the medial soft tissue structures and contracture of the lateral ones. The extensor tendon axis, once midline, becomes a deforming force as the metatarsophalangeal joint is positioned medial to the tendon. The sesamoid sling (i.e. plantar plate and flexor hallucis brevis), which is anchored laterally by adductor hallucis, remains in place as the head moves medially and everts, giving the illusion on a radiograph of displacing the sesamoid bones from beneath the metatarsal head. In reality, the sesamoids stay locked in the sling, and it is the metatarsal head that is displaced and may play a role in the increased size of the medial eminence (the visible medial protuberance of a bunion deformity) as the deformity progresses into late stage changes (Burns and Mecham 2014). As this happens, the weakest point of the medial capsule fails, so that abductor hallucis slips under the metatarsal head. This leads to failure of the intrinsic muscles to stabilize the joint, and the pull of abductor hallucis leads to spinning of the proximal phalanx, which results in a varus deformity. Failure to intervene surgically inevitably results in a progressive deformity.

Interphalangeal joints

Interphalangeal articulations are almost pure hinge joints in which the trochlear surfaces on the phalangeal heads articulate with reciprocally curved surfaces on adjacent phalangeal bases. Each has an articular capsule and two collateral ligaments, as occurs in the metatarsophalangeal joints. The plantar surface of the capsule is a thickened fibrous plate, like the plantar metatarsophalangeal ligaments, and is often termed the plantar ligament.

Innervation The interphalangeal articulations are innervated by branches from the plantar digital nerves. The medial dorsal cutaneous branch of the superficial fibular nerve also supplies the interphalangeal joint of the great toe. Branches of the deep fibular, intermediate dorsal cutaneous and sural nerves sometimes supply the joints of the lateral four toes.

Muscles producing movement Movements are flexion and extension, which are greater in amplitude between the proximal and middle phalanges than between the middle and distal. Flexion is marked, but extension is limited by tension of the flexor muscles and plantar ligaments. Abduction, adduction and rotation occur to a minor extent. The muscles producing movements at the interphalangeal joints are as follows.

Flexion Flexor digitorum longus, flexor digitorum brevis and flexor hallucis longus. Flexor accessorius assists flexor digitorum longus to maintain a flexed toe and neutralize the medial pull of flexor digitorum longus.

Extension Extensor digitorum longus, extensor digitorum brevis, extensor hallucis longus and extensor hallucis brevis.

ARCHES OF THE FOOT

Three main arches are recognized in the foot: medial and lateral longitudinal and transverse. The roles of the arches in the biomechanics of the foot are discussed later in this chapter.

Medial longitudinal arch

The medial margin of the foot arches up between the heel proximally and the medial three metatarsophalangeal joints to form a visible arch (see Fig. 79.9A). It is made up of the calcaneus, talar head, navicular, the three cuneiforms and the medial three metatarsals. The posterior and anterior pillars are the posterior part of the inferior calcaneal surface and the three metatarsal heads, respectively. The bones themselves contribute little to the stability of the arch, whereas the ligaments contribute significantly. The most important ligamentous structure is the plantar aponeurosis, which acts as a tie beam between the supporting pillars (Hicks 1954). Dorsiflexion, especially of the great toe, draws the two pillars together, thus heightening the arch: the so-called 'windlass' mechanism. Next in importance is the spring ligament, which supports the head of the talus. If this ligament attenuates, the navicular and calcaneus separate, allowing the talar head, the highest point of the arch, to descend, leading to a flat-foot deformity. The talocalcaneal ligaments and the anterior fibres of the deltoid ligament, from the tibia to the navicular, also contribute to the stability of the arch. Muscles play a role in the maintenance of the medial longitudinal arch. Flexor hallucis longus acts as a bowstring. Flexor digitorum longus, abductor hallucis and the medial half of flexor digitorum brevis also contribute but to a lesser extent. Tibialis posterior and anterior invert and adduct the foot, and so help to raise its medial border. The importance of tibialis posterior is manifest by the collapse of the medial longitudinal arch that accompanies failure of its tendon (see below, pes planus).

Lateral longitudinal arch

The lateral longitudinal arch is a much less pronounced arch than the medial one. The bones making up the lateral longitudinal arch are the calcaneus, the cuboid and the fourth and fifth metatarsals; they contribute little to the arch in terms of stability (see Fig. 79.9A). The pillars are the calcaneus posteriorly and the lateral two metatarsal heads anteriorly. Ligaments play a more important role in stabilizing the arch, especially the lateral part of the plantar aponeurosis and the long and short plantar ligaments. However, the tendon of fibularis longus makes the most important contribution to the maintenance of the lateral arch. The lateral two tendons of flexor digitorum longus (and flexor accessorius), the muscles of the first layer (lateral half of flexor digitorum brevis and abductor digiti minimi), and fibularis brevis and tertius also contribute to the maintenance of the lateral longitudinal arch.

Transverse arch

The bones involved in the transverse arch are the bases of the five metatarsals, the cuboid and the cuneiforms (see Fig. 79.9A). The intermediate and lateral cuneiforms are wedge-shaped and thus adapted to maintenance of the transverse arch. The ligaments, which bind the cuneiforms and the metatarsal bases, mainly provide the stability of the arch, as does the tendon of fibularis longus, which tends to approximate the medial and lateral borders of the foot. A shallow arch is maintained at the metatarsal heads by the deep transverse ligaments, transverse fibres that tie together the digital slips of the plantar aponeurosis, and, to a lesser extent, by the transverse head of adductor hallucis.

Pes planus and pes cavus

The term pes planus denotes an excessively flat foot. There is no precise degree of flatness that defines pes planus but it may be either physiological or pathological. In physiological pes planus, the feet are flexible and rarely problematic. There is a high prevalence in children of preschool age. In the 2–6 years age group, normal arch volumes in the sitting and standing positions correlate with the height of the navicular (lowest palpable medial projection of the navicular to the floor) (Chang et al 2012). In marked contrast, pathological pes planus is often associated with stiffness and pain. The windlass (or 'Jack's great toe') test involves passively dorsiflexing the great toe at the metatarsophalangeal joint. This tightens the plantar aponeurosis and, in flexible pes planus, results in accentuation of the medial longitudinal arch. In pathological pes planus, no accentuation of the arch is seen. Another test can also be carried out by asking the individual to stand with both feet plantar flexed while viewing the hindfoot from behind. In flexible flat feet, the calcaneus swings into a varus position; in pathological pes planus it does not. Abduction of the forefoot associated with pes planus causes most of the lesser digits to be visible from this view ('too many toes sign'). Causes of pathological pes planus include tarsal coalition, disruption of the tendon of tibialis posterior, rupture of the spring ligament, tarsometatarsal arthritis (and subsequent collapse), and hindfoot (talocalcaneal or subtalar joint) degenerative or inflammatory arthritis.

Pes cavus denotes an excessively high-arched foot. The majority of cases arise as a result of a neurological disorder (e.g. Charcot–Marie–Tooth disease, tethered spinal cord, poliomyelitis). According to the anatomical location of the deformity, pes cavus may be classified into hindfoot, midfoot or forefoot cavus. When pes cavus involves all three parts of the foot, it is called 'global' cavus. In Charcot–Marie–Tooth disease, an overactive fibularis longus leads

to plantar hyperflexion of the first metatarsal. To keep the forefoot in contact with the ground, the patient develops a progressive compensatory hindfoot varus. If ignored, the hindfoot varus, which is initially flexible, becomes fixed. Charcot foot deformity, a relatively rare arthropathy that presents in conjunction with peripheral neuropathy, but separate from Charcot–Marie–Tooth disease, often leads to a total collapse of the midfoot. This creates a pathological flatfoot that can progress to a 'rocker-bottom deformity' as the downward pressure from the leg acts in concert with the upward pull of the calcaneal (Achilles) tendon. As a corrective measure for this, the calcaneal tendon is often lengthened surgically (Ramanujam and Zgonis 2017).

MUSCLES

The muscles acting on the foot may be divided into extrinsic and intrinsic groups.

Extrinsic muscles

The extrinsic muscles are described in Chapter 78. Their tendons cross the ankle and move and stabilize this joint. Distally, the tendons also act on the joints of the foot and help to stabilize them. The muscles can be grouped according to their arrangement in the leg. The extensors arise in the anterior compartment of the leg and their tendons pass anterior to the ankle, where they are bound down by the extensor retinacula. The lateral group arises in the relatively narrow lateral compartment of the leg and their tendons pass posterior to the lateral malleolus, bound down by the fibular retinacula. The flexors arise in the posterior compartment of the leg and their tendons pass posterior to the ankle, where the tendons of the superficial group of flexors are inserted into the calcaneus (see below), and the tendons of the deep group of flexors are bound down by the flexor retinaculum (see Figs 78.36, 79.1–79.2).

Anterior group

Tibialis anterior, extensor hallucis longus, extensor digitorum longus and fibularis tertius are described in Chapter 78.

Lateral group

Fibularis longus and fibularis brevis are described in Chapter 78.

Posterior group

Superficial group

Gastrocnemius, soleus and plantaris are described in Chapter 78; the calcaneal tendon is described below.

Calcaneal tendon

The calcaneal (Achilles) tendon is the common tendon of gastrocnemius and is the thickest and strongest tendon in the human body (see Fig. 79.2). Approximately 15 cm long, it begins near the middle of the calf. Its anterior surface receives muscle fibres from soleus almost to its inferior end. It gradually becomes more rounded until approximately 4 cm above the calcaneus; below this level, it expands and becomes attached to the midpoint of the posterior surface of the calcaneus. Age-dependent variability in the terminal insertion site of the calcaneal tendon (Snow et al 1995, Kim et al 2010, Kim et al 2011) may explain why calcaneal tendinopathy is infrequently found in children and adolescents and also has implications for the appropriate siting of surgical entry portals about the calcaneal tendon insertion in order to reduce the risk of iatrogenic injury to the tendon (Lohrer et al 2008). The fibres of the calcaneal tendon are not aligned strictly vertically and display a variable degree of spiralization (Cummins and Anson 1946, Edama et al 2015). They spiral laterally through 90° as they descend, so that the fibres associated with gastrocnemius are inserted more laterally on the calcaneus, and those associated with soleus are inserted more medially. The fibres in the tendon of plantaris (described in Ch. 78) exhibit varying degrees of blending with the fibres of the calcaneal tendon, sometimes blending entirely at its insertion or inserting into the plantar aponeurosis.

Tensile properties The calcaneal tendon is subjected to large loads: it may reach tensile stresses of up to four times body weight (2600 N) during walking and up to eight times body weight (5330 N) during running (Finni et al 1998, Giddings et al 2000). Despite being the strongest tendon in the body, the calcaneal tendon is particularly susceptible to tendinopathy. In general, tendon disorders are thought to be related to increasing age, yet the association between ageing and the underlying biological and mechanical changes (e.g. stiffness) of the calcaneal tendon is inconclusive (Stenroth et al 2012, Waugh et al 2012).

Vascular supply The blood supply to the calcaneal tendon is poor; the predominant artery is a recurrent branch of the posterior tibial artery, which mainly supplies peritendinous tissues (Salmon et al 1994). There is an additional supply from the paratenon (Carr and Norris 1989, Chen et al 2009), as well as a supply proximally from intramuscular arterial branches and distally from the calcaneus. Microdissection and angiographic studies have identified three main vascular territories: a proximal section, a hypovascular midsection and a distal section (Ahmed et al 1998, Zantop et al 2003, Chen et al 2009). The posterior tibial artery primarily supplies the proximal and distal sections, and the midsection receives a relatively poor blood supply from the fibular artery (Chen et al 2009). These findings support previous work showing that the hypovascular midsection of the calcaneal tendon (the 'watershed area') is the area most prone to rupture and also underscore the importance of avoiding disruption of the vascular supply to the tendon during percutaneous surgery. The vascularity of the skin overlying the calcaneal tendon varies according to location: the skin on the medial side of the tendon is supplied by the posterior tibial artery and on the lateral side by the fibular artery (Yepes et al 2010). The skin covering the posterior aspect of the tendon is the most poorly vascularized: medial or lateral incisions of the skin surrounding the tendon should reduce post-surgical healing complications relative to a direct posterior approach.

The calcaneal tendon is not the only plantar flexor of the ankle, which is one of the reasons why ruptures of the calcaneal tendon may not always be clinically apparent. However, it is a frequent site of pathology because of its susceptibility to rupture, degenerative change (tendinosis) and inflammation (paratendinitis); the area of relative avascularity in the midsection of the tendon is where the majority of problems occur.

Ruptures of the calcaneal tendon are often diagnosed by a palpable dell in the area of the tendon rupture, or by the Simmonds–Thompson test in which the patient lies prone on the examination table with the injured lower leg off the table. As the gastrocnemius–soleus complex is squeezed, a lack of movement at the ankle indicates a complete rupture of the tendon (positive test result). However, this lack of motion is dependent upon the rupture of soleus compared to the aponeurosis of gastrocnemius, and can sometimes result in a false positive (Douglas et al 2009).

Relations The calcaneal tendon is subcutaneous. The sural nerve crosses its lateral border about 10 cm above its insertion. The nerve is especially vulnerable here during surgery: percutaneous Achilles tendon lengthening is usually undertaken with the most proximal incision being performed medially to avoid iatrogenic injury to the nerve. Distally, there are bursae superficial and deep to the tendon. The muscle belly of flexor hallucis longus lies deep to the deep fascia on the anterior surface of the tendon.

Actions The calcaneal tendon produces plantar flexion of the ankle joint.

Heel bursae Bursae are found in three locations about the heel. A retrocalcaneal bursa is almost always present between the calcaneal tendon and the posterior surface of the calcaneus. It has an anterior wall composed of fibrocartilage and a thin posterior wall that blends with the thin epitenon (epitendineum) of the calcaneal tendon. Dorsiflexion of the ankle results in compression of the bursa. A prominent superolateral calcaneal tuberosity, often associated with a retrocalcaneal bursa, may impinge on the deep aspect of the calcaneal tendon where it is inserted onto the calcaneus (Haglund's disease). Symptoms are exacerbated by dorsiflexion of the ankle because this movement increases the pressure within the bursa and causes impingement of the calcaneus against the insertion of the tendon. Less common are an adventitious bursa superficial to the calcaneal tendon, and a subcalcaneal bursa between the inferior surface of the calcaneus and the origin of the plantar aponeurosis.

Plantaris

Plantaris is described in Chapter 78.

Deep group

The deep muscles of the calf include popliteus, which acts on the knee joint, and flexor hallucis longus, flexor digitorum longus and tibialis posterior, which all act on the ankle joint and the joints of the foot.

Flexor hallucis longus

Flexor hallucis longus is described on page 1421. The tendon of flexor hallucis longus is described below.

Flexor digitorum longus

Flexor digitorum longus is described on page 1421.

Tibialis posterior

Tibialis posterior is described on page 1423.

Intrinsic muscles

The intrinsic muscles, i.e. those contained entirely within the foot, follow the primitive limb pattern of plantar flexors and dorsal extensors. Considerable anatomical variation is evident in the intrinsic muscles (Kafka et al 2016).

The plantar muscles may be divided into medial, central, lateral and interosseous compartments. The medial and lateral compartments consist of the intrinsic muscles of the great and fifth toes, abductor hallucis and abductor digiti minimi, respectively; the central compartment includes the lumbricals, intrinsic digital flexors, adductor hallucis and the tendons of flexor digitorum longus; and the interosseous compartment contains the seven interossei. It is customary to group the muscles in four layers because this is the order in which they are encountered during dissection. However, in clinical practice and in terms of function, the grouping into medial, central, lateral and interosseous compartments is often more useful. The vascular supply and innervation of the intrinsic muscles of the foot are given at the end of this section.

Plantar muscles of the foot: first layer

This superficial layer includes abductor hallucis, abductor digiti minimi and flexor digitorum brevis (**Figs 79.21–79.22**). All three extend from the calcaneal tuberosity to the toes, and all assist in maintaining the concavity of the foot.

Abductor hallucis

Attachments The abductor hallucis arises principally from the flexor retinaculum, but also from the medial process of the calcaneal tuberosity, the plantar aponeurosis, and the intermuscular septum between abductor hallucis and flexor digitorum brevis. The muscle fibres end in a tendon that is attached, together with the medial tendon of flexor hallucis brevis, to the medial side of the base of the proximal phalanx of the great toe: some fibres are frequently attached more proximally to the medial sesamoid bone of this toe. The muscle may also send fibres to the dermis along the medial border of the foot.

Relations Abductor hallucis lies along the medial border of the foot and covers the origins of the plantar vessels and nerves (see Fig. 79.22). The space thus created by abductor hallucis and its relationship to the calcaneus is called the porta pedis: it is often manually enlarged during decompression of the tarsal tunnel neurovascular bundle (McSweeney and Cichero 2015).

Actions Abductor hallucis produces abduction of the great toe relative to the longitudinal axis of the foot at the shaft of the second metatarsal.

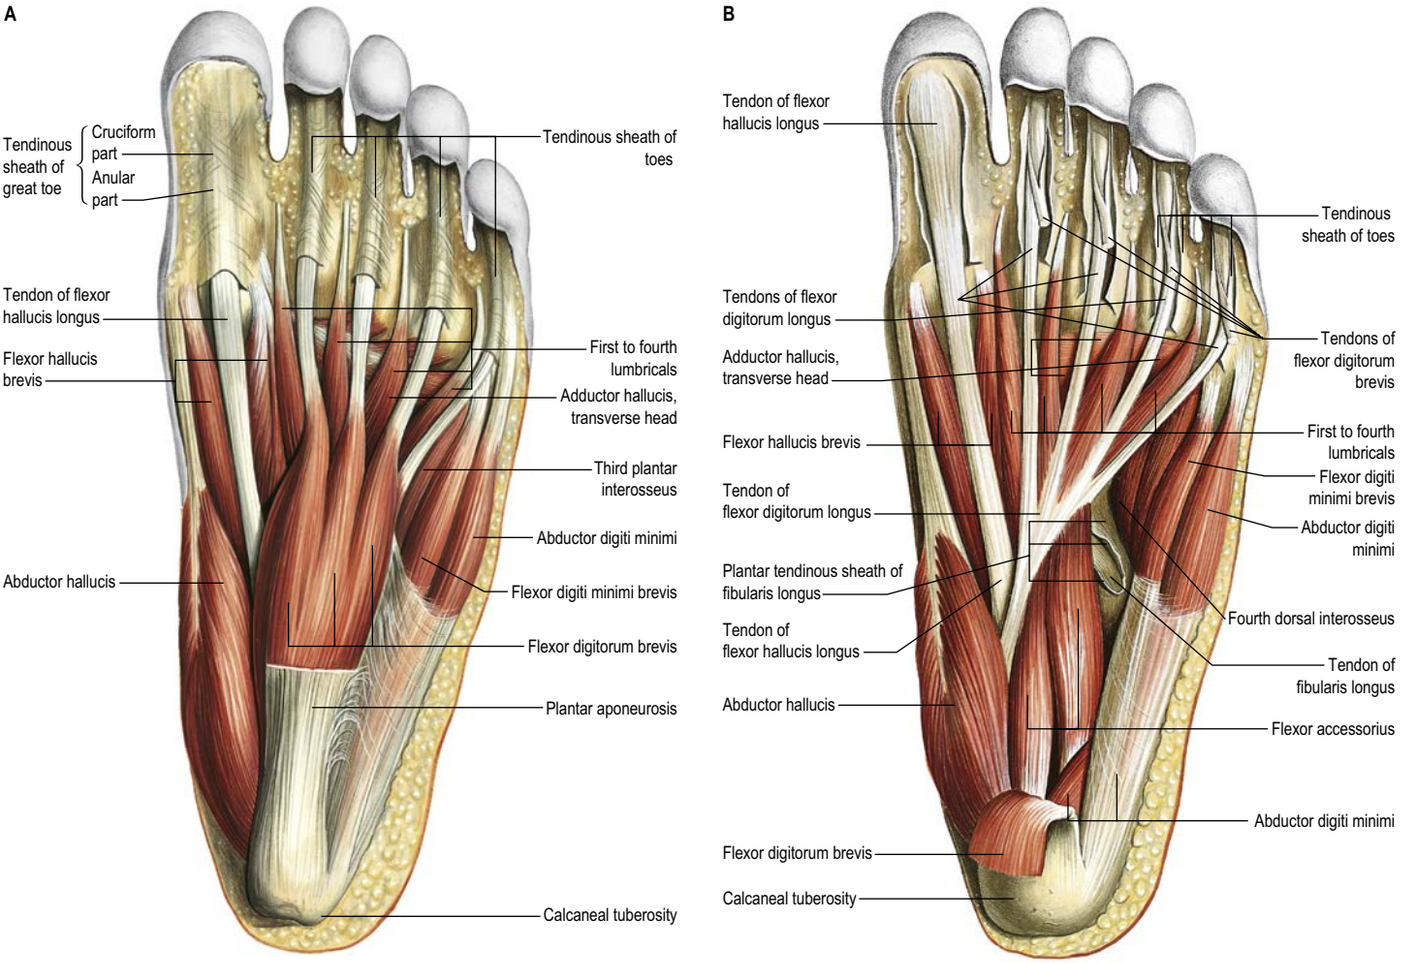

Fig. 79.21 Muscles of the sole of the foot. **A**, First layer. **B**, Second layer. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

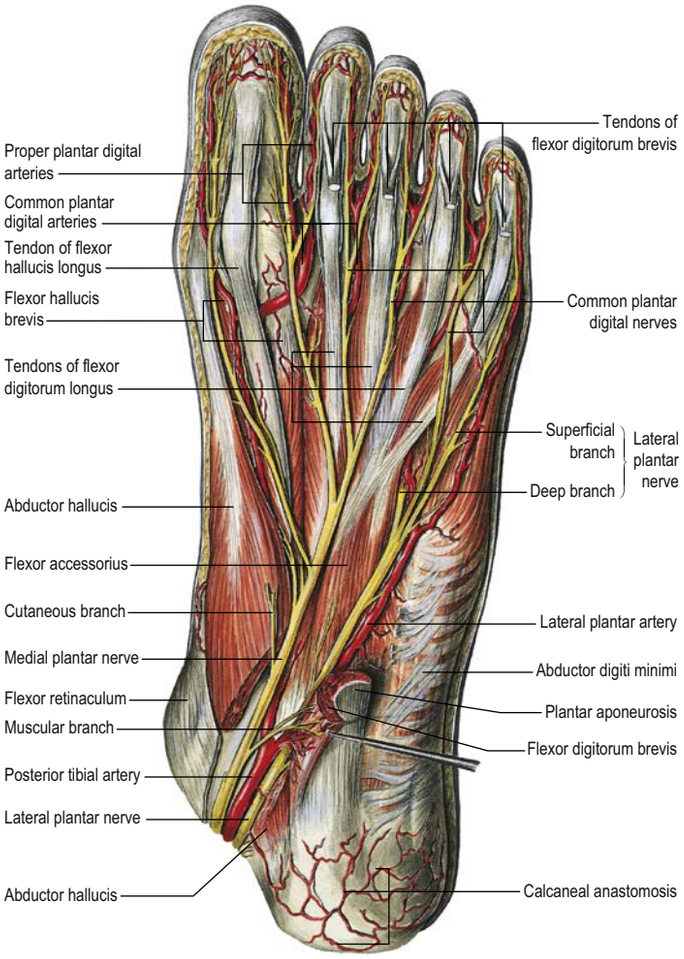

Fig. 79.22 Plantar nerves and vessels in relation to muscle layers. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Testing Abductor hallucis is tested clinically by asking the subject to resist a forcibly applied lateral deviation of the proximal phalanx of the great toe.

Clinical anatomy The abductor hallucis fascia is strong and can be used in soft tissue augmentation following correction of hallux abducto valgus deformity. Rarely, persistent, exaggerated tonus in the muscle may be a cause of varus deformity of the foot, necessitating surgical intervention. An abductor hallucis flap is sometimes used for provision of soft tissue coverage.

Flexor digitorum brevis

Attachments Flexor digitorum brevis arises by a narrow tendon from the medial process of the calcaneal tuberosity, from the central part of the plantar aponeurosis, and from the intermuscular septa between it and adjacent muscles (see Fig. 79.21A). It divides into four tendons that pass to the lateral four toes and enter digital tendinous sheaths accompanied by the tendons of flexor digitorum longus, which lie deep to them. At the bases of the proximal phalanges, each tendon divides around the corresponding tendon of flexor digitorum longus. The two slips then reunite and partially decussate, forming a tunnel through which the tendon of flexor digitorum longus passes to the distal phalanx. The tendon of flexor digitorum brevis divides again and is attached to both sides of the shaft of the middle phalanx. The way in which this tendon divides and is attached to the phalanges is identical to the arrangement of the tendons of flexor digitorum superficialis in the hand. The slip to a given toe may be absent, or it may be replaced by a small muscular slip from the extrinsic flexor tendons or from flexor accessorius. Conversely, the slip may be joined by a second, supernumerary slip.

Relations Flexor digitorum brevis lies immediately deep to the central part of the plantar aponeurosis. Its deep surface is separated from the lateral plantar vessels and nerves by a thin layer of fascia.

Actions Flexor digitorum brevis flexes the lateral four toes at the proximal interphalangeal joint, with equal effect in any position of the ankle joint.

Testing To test the action of flexor digitorum brevis, the examiner passively extends the distal interphalangeal joint and asks the subject to flex the toes at the proximal interphalangeal joint. Contracture of the tendons of flexor digitorum brevis can lead to toe deformities, and release or lengthening procedures may be required. The muscle belly is sometimes excised as a flap to cover a soft tissue defect.

Abductor digiti minimi

Attachments Abductor digiti minimi arises from both processes of the calcaneal tuberosity, the plantar surface of the bone between them, the plantar aponeurosis and the intermuscular septum between the muscle and flexor digitorum brevis. An accessory slip from the base of the fifth metatarsal may be present. The tendon of abductor digiti minimi glides in a smooth groove on the plantar surface of the base of the fifth metatarsal and is attached, with flexor digiti minimi brevis, to the lateral side of the base of the proximal phalanx of the fifth toe, which means that it is more a flexor than an abductor. Some of the fibres arising from the lateral calcaneal process usually reach the tip of the tuberosity of the fifth metatarsal (see Fig. 79.5B) and may form a separate muscle, abductor ossis metatarsi digiti quinti.

Relations Abductor digiti minimi lies along the lateral border of the foot, and its medial margin is related to the lateral plantar vessels and nerve (see Fig. 79.22).

Actions Despite its name, abductor digiti minimi is more a flexor than an abductor of the metatarsophalangeal joint of the fifth toe.

Plantar muscles of the foot: second layer

The second layer consists of flexor accessorius and the four lumbrical muscles. The tendons of flexor hallucis longus and flexor digitorum longus run in the same plane as the muscles of the second layer (see Fig. 79.21B); flexor hallucis longus and flexor digitorum longus are described on pages 1421–1423.

Flexor tendinous sheaths

The terminations of the tendons of the extrinsic and intrinsic flexor muscles are contained in osseo-aponeurotic canals similar to those that occur in the fingers. These canals are bounded above by the phalanges and below by fibrous bands, the digital fibrous tendon sheaths (see Fig. 79.21A), which arch across the tendons and are attached on either side to the margins of the phalanges. Along the proximal and middle phalanges, the fibrous bands are strong and the fibres are transverse (anular part); opposite the joints they are much thinner and the fibres decussate (cruciform part). Each osseo-aponeurotic canal has a synovial lining that is reflected around its tendon. Vincula tendinum are arranged within this sheath, as they are in the fingers.

Flexor accessorius (quadratus plantae)

Attachments Flexor accessorius (quadratus plantae) usually arises by two heads (see Fig. 79.21B), with the long plantar ligament situated deeply in the interval between the two heads (see Fig. 79.23). The medial head is larger and is attached to the medial concave surface of the calcaneus, below the groove for the tendon of flexor hallucis longus. The lateral head is flat and tendinous, and is attached to the calcaneus distal to the lateral process of the tuberosity, and to the long plantar ligament. Flexor accessorius is inserted into the tendon of flexor digitorum longus via muscular, tendinous or aponeurotic insertions at the point where it is bound by a fibrous slip to the tendon of flexor hallucis longus and where it divides into its four tendons.

Either head may be absent (absence of the lateral head is more common than absence of the medial head); complete absence of the muscle or an additional third head are rare (Pretterkleiber 2018, Edama et al 2019). The distal attachment to the tendons of flexor digitorum longus may vary, which means that the fourth and fifth long flexor tendons may, at times, fail to receive slips from flexor accessorius.

Relations The medial plantar nerve passes medial to and the lateral plantar nerve passes superficial to flexor accessorius.

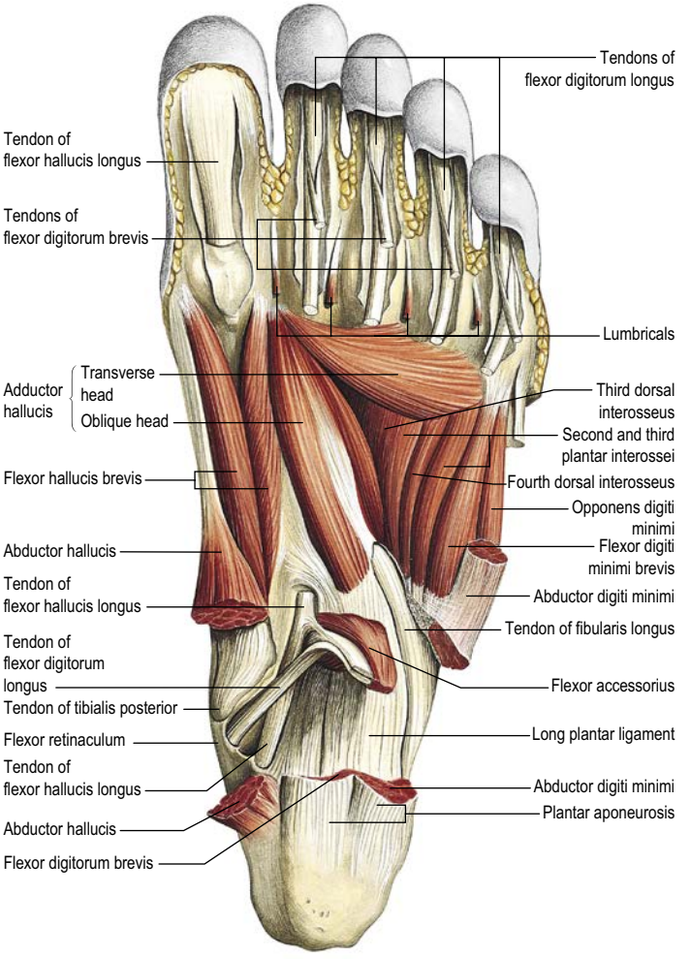

Fig. 79.23 Muscles of the sole of the foot, third layer. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

Actions By pulling on the tendons of flexor digitorum longus, flexor accessorius provides a means of flexing the lateral four toes in any position of the ankle joint.

Lumbrical muscles

Attachments The lumbrical muscles are four small muscles (numbered from the medial side of the foot) that are accessory to the tendons of flexor digitorum longus (see Fig. 79.21). They arise from these tendons as far back as their angles of separation, each springing from the sides of two adjacent tendons, except for the first lumbrical, which arises only from the medial border of the first tendon. The muscles end in tendons that pass distally on the medial sides of the four lateral toes and are attached to the dorsal digital expansions on their proximal phalanges.

Relations The lumbricals are intimately related to the tendons of flexor digitorum longus before the latter enter their corresponding fibrous flexor sheaths. The lumbricals remain outside the fibrous flexor sheaths and cross the plantar aspects of the deep transverse metatarsal ligaments before reaching the dorsal digital expansions.

Actions The lumbricals help to maintain extension of the interphalangeal joints of the toes. In injuries of the tibial nerve, and in conditions such as the hereditary motor–sensory neuropathies (e.g. Charcot–Marie–Tooth disease), lumbrical dysfunction contributes to clawing of the toes.

Plantar muscles of the foot: third layer

The third layer of the foot contains the shorter intrinsic muscles of the toes, i.e. flexor hallucis brevis, adductor hallucis and flexor digiti minimi brevis (**Fig. 79.23**).

Flexor hallucis brevis

Attachments Flexor hallucis brevis has a bifurcated tendon of origin (see Figs 79.21A, B, 79.23). The lateral limb arises from the medial part of the plantar surface of the cuboid, posterior to the groove for the tendon of fibularis longus, and from the adjacent part of the lateral cuneiform. The medial limb has a deep attachment directly continuous with the lateral division of the tendon of tibialis posterior, and a more superficial attachment to the middle band of the medial intermuscular septum. The belly of the muscle divides into medial and lateral parts, with two tendons that are attached to the sides of the base of the proximal phalanx of the great toe: the medial part blends with the tendon of abductor hallucis and the lateral part blends with the tendon of adductor hallucis, as they reach their terminations.

A sesamoid bone usually occurs in each tendon near its attachment. Clinical problems with flexor hallucis brevis are usually related to the associated sesamoid bones. However, excision of both sesamoid bones leads to disruption of both tendons and a subsequent extension deformity at the first metatarsophalangeal joint; such surgery is, therefore, not recommended.

Accessory slips may arise proximally from the calcaneus or long plantar ligament. A tendinous slip may extend to the proximal phalanx of the second toe.

Relations Flexor hallucis brevis lies on the underside of the first metatarsal shaft; abductor hallucis lies medially. The medial digital nerve to the great toe and the tendon of flexor hallucis longus both pass to the great toe on its plantar surface. The medial plantar nerve lies more superficially on its lateral side.

Actions Flexor hallucis brevis flexes the proximal phalanx of the great toe.

Testing The individual is asked to flex the first metatarsophalangeal joint with the interphalangeal joint extended, thereby eliminating the action of flexor hallucis longus.

Adductor hallucis

Attachments Adductor hallucis arises by oblique and transverse heads (see Figs 79.21–79.23). The oblique head arises from the bases of the second, third and fourth metatarsals, and from the fibrous sheath of the tendon of fibularis longus. The transverse head is a narrow, flat fasciculus that arises from the plantar metatarsophalangeal ligaments of the third, fourth and fifth toes (sometimes only from the third and fourth), and from the deep transverse metatarsal ligaments between them. The oblique head has medial and lateral parts. The medial part blends with the lateral part of flexor hallucis brevis and is attached to the lateral sesamoid bone of the great toe. The lateral part joins the transverse head and is also attached to the lateral sesamoid bone and directly to the base of the first phalanx of the great toe. There is no phalangeal attachment for the transverse part of the muscle and fibres that fail to reach the lateral sesamoid bone are attached with the oblique part. The transverse part of adductor hallucis is sometimes absent; part of the muscle may be attached to the first metatarsal, constituting an opponens hallucis; and a slip may also extend to the proximal phalanx of the second toe.

Relations Adductor hallucis lies plantar to the metatarsal shafts and the interossei, and the long and short toe flexors. The medial and lateral plantar arteries and nerves are superficial, and flexor hallucis brevis is proximal and medial.

Actions Adductor hallucis partly flexes the proximal phalanx of the great toe, but also stabilizes the metatarsal heads.

Clinical anatomy Adductor hallucis has traditionally been thought of as a major deforming force in hallux abducto valgus. While this muscle may need to be released during a distal soft tissue release, this procedure is only generally necessary in reducing severe bunion deformities (Yammine and Assi 2018).

Flexor digiti minimi brevis

Attachments Flexor digiti minimi brevis arises from the medial part of the plantar surface of the base of the fifth metatarsal, and from the sheath of fibularis longus (see Figs 79.21, 79.23). It has a distal tendon that is inserted into the lateral side of the base of the proximal phalanx of the fifth toe and usually blends laterally with the tendon of abductor digiti minimi. Occasionally, some of its deeper fibres extend to the lateral part of the distal half of the fifth metatarsal, constituting what may be described as a distinct muscle, opponens digiti minimi.

Relations The fifth metatarsal shaft lies on the deep surface of flexor digiti minimi brevis, the interossei lie medially and abductor digiti

minimi is lateral. The most lateral branch of the lateral plantar nerve lies superficially and just medial to flexor digiti minimi brevis.

Actions Flexor digiti minimi brevis flexes the metatarsophalangeal joint of the fifth toe.

Plantar muscles of the foot: fourth layer

The fourth layer of muscles of the foot consists of the plantar and dorsal interossei and the tendons of tibialis posterior and fibularis longus (tibialis posterior and fibularis longus are described in Chapter 78). The interossei resemble their counterparts in the hand except that, when describing adduction and abduction of the toes, the axis of reference is a longitudinal axis corresponding to the shaft of the second metatarsal (unlike in the hand, where reference is made to the longitudinal axis of the third metacarpal).

Dorsal interossei

Attachments The dorsal interossei (**Fig. 79.24A**; see Fig. 79.1) are situated between the metatarsals and are four bipennate muscles, each arising by two heads from the sides of the adjacent metatarsals. Their tendons are attached to the bases of the proximal phalanges and to the dorsal digital expansions. The first inserts into the medial side of the second toe and the other three pass to the lateral sides of the second, third and fourth toes.

Relations A perforating artery passes to the dorsum of the foot through an angular space between the heads of each of the three lateral muscles. The corresponding space between the heads of the first muscle transmits the terminal part of the dorsalis pedis artery to the sole (see Fig. 79.1).

Actions Dorsal interossei abduct the toes relative to the longitudinal axis of the second metatarsal. They also flex the metatarsophalangeal joints and extend the interphalangeal joints of the lateral four toes. The great and fifth toes have their own abductors.

Clinical anatomy Denervation of the interossei leads to claw-toe deformities: development of clawed toes should alert the clinician to the possibility of a neuropathic process (e.g. Charcot–Marie–Tooth disease, tethered spinal cord, longstanding diabetic neuropathy).

Plantar interossei

There are three plantar interossei (**Fig. 79.24B**). They lie below, rather than between, the metatarsals, and each is connected to only one metatarsal. They are unipennate, unlike the dorsal interossei. They arise from the bases and medial sides of the third, fourth and fifth metatarsals, and are inserted into the medial sides of the bases of the proximal phalanges of the numerically corresponding toes, and into their dorsal digital expansions.

Relations The plantar interossei lie plantar to the dorsal interossei and deep to the muscles of the third layer.

Actions Plantar interossei adduct the third, fourth and fifth toes, flex the metatarsophalangeal joints and extend the interphalangeal joints.

Clinical anatomy The clinical anatomy of the plantar interossei is similar to that of the dorsal interossei.

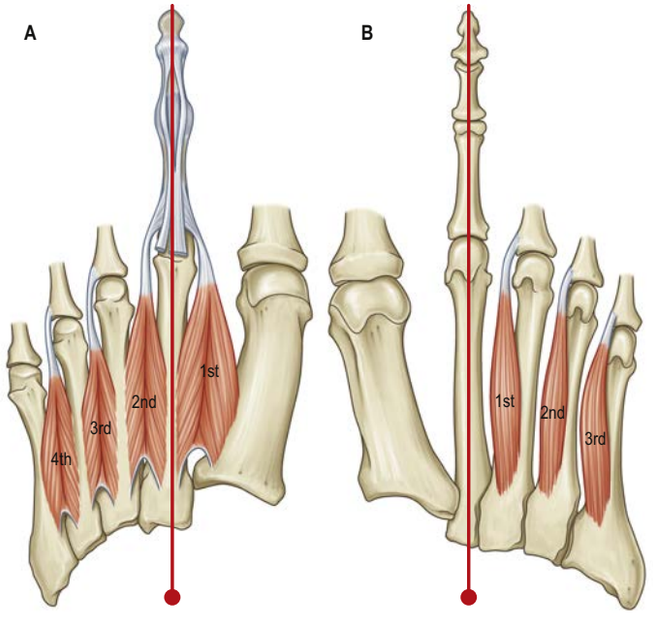

Fig. 79.24 The interossei of the left foot. **A**, The dorsal interossei viewed from the dorsal aspect. **B**, The plantar interossei viewed from the plantar aspect. The axis to which the movements of abduction and adduction are referred is indicated.

Extensor muscles of the foot

Extensor digitorum brevis and extensor hallucis brevis

Attachments Extensor digitorum brevis (see Fig. 79.2A) is a thin muscle that arises from the distal part of the superolateral surface of the calcaneus in front of the shallow lateral groove for fibularis brevis, from the interosseous talocalcaneal ligament, and from the deep surface of the stem of the inferior extensor retinaculum. It slants distally and medially across the dorsum of the foot and ends in four tendons. The medial part of the muscle is usually a more or less distinct slip, ending in a tendon that crosses the dorsalis pedis artery superficially and is inserted into the dorsal aspect of the base of the proximal phalanx of the great toe; this slip is termed extensor hallucis brevis. The other three tendons are attached to the lateral sides of the tendons of extensor digitorum longus for the second, third and fourth toes. Extensor digitorum brevis is subject to variation, e.g. accessory slips from the talus and navicular; an extra tendon to the fifth digit; absence of one or more tendons; additional connections to the adjacent dorsal interossei.

Relations Extensor hallucis brevis, the most medial tendon, courses dorsomedially and passes superficial to the dorsalis pedis artery and the deep fibular nerve. The remaining three tendons pass obliquely deep to the corresponding tendons of extensor digitorum longus.

Actions The muscle assists in extending the phalanges of the middle three toes via the tendons of extensor digitorum longus and assists in extension of the metatarsophalangeal joint of the great toe.

Clinical anatomy Laceration of extensor digitorum brevis leads to little in the way of functional impairment because the long extensors can compensate for the loss of the muscle. The proximal part of the muscle can be used as interposition material to prevent bone fusion after resection of a calcaneonavicular bar (a common tarsal coalition). The muscle belly and tendon of extensor hallucis brevis serve as guides to the location of the dorsalis pedis artery and deep fibular nerve, and the tendon of extensor hallucis brevis can be used as a local graft.

Vascular supply to the intrinsic muscles of the foot

Abductor hallucis is supplied by the medial malleolar network, medial calcaneal branches of the lateral plantar artery (see Fig. 79.10), the medial plantar artery (directly and via superficial and deep branches), the first plantar metatarsal artery and perforators from the plantar arterial arch. Flexor digitorum brevis is supplied by the lateral and medial plantar arteries, the plantar metatarsal arteries and the plantar digital arteries to the lateral four toes. Abductor digiti minimi is supplied by the medial and lateral plantar arteries (see Figs 79.22, 79.26), the plantar digital artery to the lateral side of this muscle, branches from the deep plantar arch, the fourth plantar metatarsal artery and end twigs from the arcuate and lateral tarsal arteries (see Fig. 79.10). Flexor accessorius is supplied by the stem of the medial plantar artery (to the medial head), the lateral plantar artery and the deep plantar arch. The lumbricals are supplied by the lateral plantar artery and deep plantar arch and by four plantar metatarsal arteries (four distal perforating arteries joined by three proximal perforating arteries). Their tendons are supplied by twigs from the dorsal digital arteries and their parent dorsal metatarsal arteries to the lateral four toes. Flexor hallucis brevis is supplied by branches of the medial plantar artery, the first plantar metatarsal artery, the lateral plantar artery and the deep plantar arch. Adductor hallucis is supplied by branches of the medial and lateral plantar arteries, the deep plantar arch and the first to fourth plantar metatarsal arteries. Flexor digiti minimi brevis is supplied by end twigs of the arcuate and lateral tarsal arteries, and the lateral plantar artery and its digital (plantar) branch to the lateral side of the fifth toe. Dorsal interossei are

supplied by the arcuate artery, lateral and medial tarsal arteries, the first to fourth plantar arteries and the first to fourth dorsal metatarsal arteries (receiving proximal and distal perforating arteries), and by the dorsal digital arteries of the lateral four toes. Plantar interossei are supplied by the lateral plantar artery, the deep plantar arch, the second to fourth plantar metatarsal arteries and the dorsal digital arteries of the lateral three toes. Extensor digitorum brevis is supplied by the anterior perforating branch of the fibular artery, the anterior lateral malleolar artery, lateral tarsal arteries, dorsalis pedis artery, arcuate artery, the first, second and third dorsal metatarsal arteries, proximal and distal perforating arteries, and the dorsal digital arteries to the medial four toes (including the great toe).

Innervation of the intrinsic muscles of the foot

Abductor hallucis is innervated by the medial plantar nerve, S1 and S2. Contraction of the muscle confirms an intact medial plantar nerve when the integrity of this nerve is in question. Flexor digitorum brevis is innervated by the medial plantar nerve, S1 and S2. Abductor digiti minimi and flexor accessorius are innervated by the lateral plantar nerve, S1, S2 and S3. The first lumbrical is supplied by the medial plantar nerve, and the other lumbricals are supplied by the deep branch of the lateral plantar nerve, S2 and S3. Flexor hallucis brevis is supplied by the medial plantar nerve, S1 and S2. Adductor hallucis is innervated by the deep branch of the lateral plantar nerve, S2 and S3. Flexor digiti minimi brevis is innervated by the superficial branch of the lateral plantar nerve, S2 and S3. Dorsal interossei are supplied by the deep branch of the lateral plantar nerve, S2 and S3, except that of the fourth intermetatarsal space, which is supplied by the superficial branch of the lateral plantar nerve. Plantar interossei are supplied by the deep branch of the lateral plantar nerve, S2 and S3, except that of the fourth intermetatarsal space, which is supplied by the superficial branch of the lateral plantar nerve. Extensor digitorum brevis is supplied by the lateral terminal branch of the deep fibular nerve, L5 and S1.

VASCULAR SUPPLY

Arteries

Dorsalis pedis artery

The dorsalis pedis artery (see Fig. 79.1; **Fig. 79.25**) is usually the continuation of the anterior tibial artery distal to the ankle. It passes to the proximal end of the first intermetatarsal space, where it turns into the sole between the heads of the first dorsal interosseous to complete the deep plantar arch, and provides the first plantar metatarsal artery. The artery may be larger than normal, to compensate for a small lateral plantar artery. It often diverges laterally from its usual route and, rarely, may be absent (Robertson et al 1990), in which case it is replaced by a large perforating branch of the fibular artery.

Relations The dorsalis pedis artery crosses, successively, the talocrural articular capsule, talus, navicular and intermediate cuneiform and their ligaments. The skin, fasciae, inferior extensor retinaculum and, near its termination, extensor hallucis brevis, are all superficial. The tendon of extensor hallucis longus is medial and the medial tendon of extensor digitorum longus and the medial terminal branch of the deep fibular nerve are both lateral. The tendons and navicular tuberosity are useful landmarks in palpation for the planning of safe anatomical approaches in surgery of the ankle and foot.

Branches

The dorsalis pedis artery gives rise to the tarsal, arcuate and first dorsal metatarsal arteries (see Figs 79.1, 79.10, 79.25).

Tarsal arteries Two tarsal arteries, lateral and medial, arise as the dorsalis pedis artery crosses the navicular (see Fig. 79.25). The lateral tarsal artery runs laterally under extensor digitorum brevis: it supplies this muscle and the tarsal articulations, and anastomoses with branches of the arcuate, anterior lateral malleolar and lateral plantar arteries, and the perforating branch of the fibular artery. Two or three medial tarsal arteries ramify on the medial border of the foot and join the medial malleolar arterial network.

Arcuate artery The arcuate artery (see Fig. 79.25) arises near the medial cuneiform, passes laterally over the metatarsal bases, deep to the tendons of the digital extensors, and anastomoses with the lateral tarsal and plantar arteries. It supplies the second to fourth dorsal metatarsal arteries, running

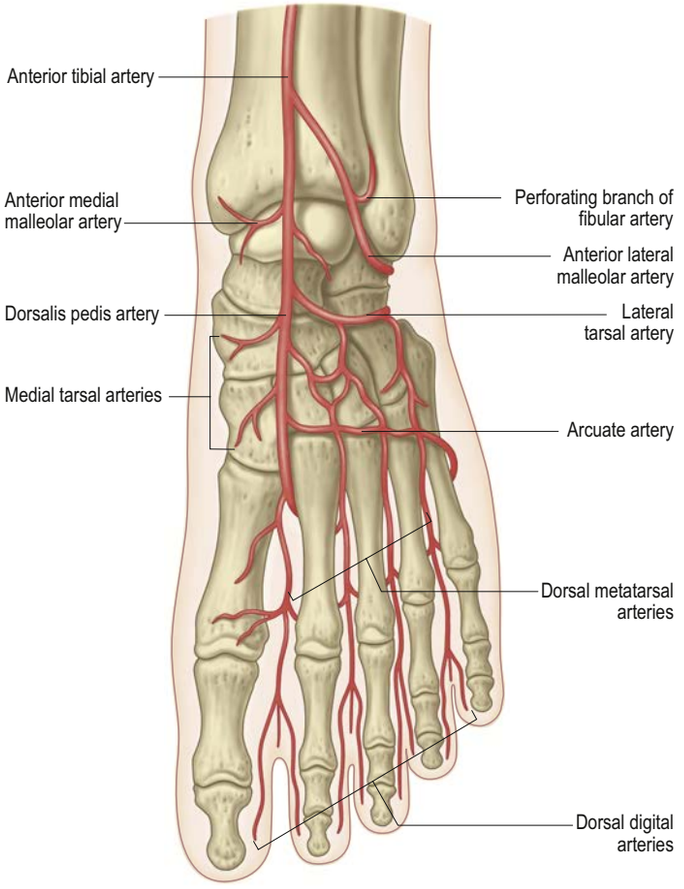

Fig. 79.25 The dorsal arteries of the foot.

distally superficial to the corresponding dorsal interossei, and divides into two dorsal digital branches for the adjoining toes in the interdigital clefts. Proximally, these branches receive proximal perforating branches from the deep plantar arch. Distally, they are joined by distal perforating branches from the plantar metatarsal arteries. The fourth dorsal metatarsal artery sends a branch to the lateral side of the fifth toe. The frequency of the arcuate artery has been reported to range from 10% to 67%, depending on the precise definition of the artery (DiLandro et al 2001).

First dorsal metatarsal artery The first dorsal metatarsal artery (see Fig. 79.25) arises just before the dorsalis pedis artery enters the sole. It runs distally on the first dorsal interosseous and divides at the cleft between the first and second toes. One branch passes under the tendon of extensor hallucis longus and supplies the medial side of the great toe and the other bifurcates to supply the adjoining sides of the great and second toes.

Cutaneous vessels from the dorsalis pedis artery The dorsalis pedis artery and its first dorsal metatarsal branch give rise to small direct cutaneous branches that supply the skin of the dorsal foot between the extensor retinaculum and the first web space. This vessel provides the basis for a fasciocutaneous flap raised from this region that may be used to cover superficial defects elsewhere.

Deep plantar arch

The deep plantar arch (see Fig. 79.26) is deeply situated, extending from the fifth metatarsal base to the proximal end of the first intermetatarsal space. Convex distally, it is plantar to the bases of the second to fourth metatarsals and corresponding interossei, but dorsal to the oblique part of adductor hallucis.

Branches

The deep plantar arch gives rise to three perforating and four plantar metatarsal branches, and numerous branches that supply the skin, fasciae and muscles in the sole. Three perforating branches ascend through the proximal ends of the second to fourth intermetatarsal spaces, between the heads of dorsal interossei, and anastomose with the dorsal metatarsal arteries. Four plantar metatarsal arteries extend distally between the metatarsals in contact with the interossei (**Fig. 79.26**). Each divides into two

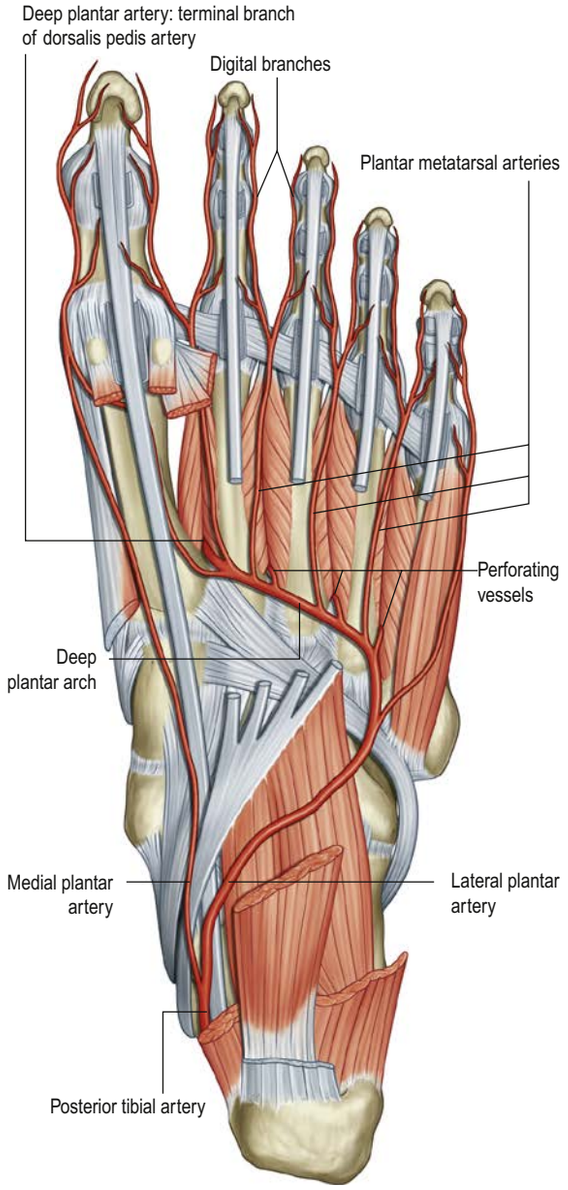

Fig. 79.26 The plantar arteries. (Adapted with permission from Drake RL, Vogl AW, Mitchell A (eds) Gray's Anatomy for Students, 4th ed. Elsevier, Churchill Livingstone. Copyright 2019.)

plantar digital arteries, supplying the adjacent digital aspects. Near its division, each plantar metatarsal artery sends a distal perforating branch dorsally to join a dorsal metatarsal artery. The first plantar metatarsal artery springs from the junction between the lateral plantar and dorsalis pedis arteries, and sends a digital branch to the medial side of the great toe. The lateral digital branch for the fifth toe arises directly from the lateral plantar artery near the fifth metatarsal base. Haemorrhage from the deep plantar arch is difficult to control because of the depth of the vessel and its important close relations.

Surface anatomy

The lateral plantar artery begins between the heel and medial malleolus, and crosses obliquely to a point 2.5 cm medial to the tuberosity of the fifth metatarsal. With a slight distal convexity, it reaches the proximal end of the first intermetatarsal space.

Posterior tibial artery

Before the posterior tibial artery divides into its two main terminal branches, it gives off a communicating branch that runs posteriorly across the tibia approximately 5 cm above its distal end, deep to flexor hallucis longus, and joins a communicating branch of the fibular artery; calcaneal branches that arise just proximal to the termination of the posterior tibial artery, pierce the flexor retinaculum and supply the skin and fat behind the calcaneal tendon; and the artery of the tarsal canal.

Branches The terminal branches of the posterior tibial artery are the medial and lateral plantar arteries.

Branches

Medial plantar artery The medial plantar artery is the smaller terminal branch of the posterior tibial artery (see Fig. 79.26). It arises midway between the medial malleolus and the medial calcaneal tubercle, and passes distally along the medial side of the foot, with the medial plantar nerve lateral to it. At first deep to abductor hallucis, it runs distally between abductor hallucis and flexor digitorum brevis, supplying both muscles. Near the first metatarsal base, when its calibre is already diminished as a result of supplying numerous muscular branches, it is further diminished by a superficial stem. It passes to the medial border of the great toe, where it anastomoses with a branch of the first plantar metatarsal artery. Its superficial stem then trifurcates and supplies three superficial digital branches that accompany the digital branches of the medial plantar nerve and join the first to third plantar metatarsal arteries.

Lateral plantar artery The lateral plantar artery is the larger terminal branch of the posterior tibial artery (see Fig. 79.26). It passes distally and laterally to the fifth metatarsal base; the lateral plantar nerve is medial. Turning medially, and accompanied by the deep branch of the nerve, the artery gains the interval between the first and second metatarsal bases where it unites with the dorsalis pedis artery to complete the deep plantar arch. As it passes laterally, it is first between the calcaneus and abductor hallucis, then between flexor digitorum brevis and flexor accessorius. Running distally to the fifth metatarsal base, it passes between flexor digitorum brevis and abductor digiti minimi and is covered by the plantar aponeurosis, superficial fascia and skin.

Muscular branches supply the adjoining muscles. Superficial branches emerge along the intermuscular septum to supply the skin and subcutaneous tissue over the lateral part of the sole. Anastomotic branches run to the lateral border and join branches of the lateral tarsal and arcuate arteries. A calcaneal branch sometimes pierces abductor hallucis to supply the skin of the heel. The medial and lateral plantar arteries sometimes anastomose superficial to flexor digitorum brevis to form the superficial plantar arch.

Perforator flaps in the ankle and foot region

The arteries around the ankle and in the foot are the medial and lateral calcaneal arteries, medial and lateral plantar arteries and the dorsalis pedis artery (see Figs 76.7, 78.10). In the foot, the two plantar arteries and communicating arteries from the dorsalis pedis artery give rise to multiple small perforators. In the sole of the foot, the perforators emerge on either side of the plantar aponeurosis and also pass through it, to supply the skin. 'Island flaps' from these perforators may be advanced to reconstruct small defects in the weight-bearing area. The skin of the sole of the foot is highly specialized: ideally, defects in this region should therefore be reconstructed using local skin.

Deep and superficial venous systems in the foot

Superficial veins of the foot

The named superficial veins are the long and short saphenous. Their numerous tributaries are mostly unnamed (named vessels will be noted; see Fig. 76.9A). As in the upper limb chapter, the vessels are here described centripetally from peripheral to major drainage channels.

Dorsal digital veins receive rami from the plantar digital veins in the clefts between the toes and then join to form dorsal metatarsal veins, which are united across the proximal parts of the metatarsals in a dorsal venous arch. Proximal to this arch, an irregular dorsal venous network receives tributaries from deep veins and is continuous proximally with a venous network in the leg. At each side of the foot, this network connects with medial and lateral marginal veins that are both formed mainly by veins from more superficial parts of the sole. In the sole, superficial veins form a plantar cutaneous arch across the roots of the toes and also drain into the medial and lateral marginal veins.

Deep veins of the foot

Plantar digital veins arise from plexuses in the plantar regions of the toes. They connect with dorsal digital veins to form four plantar metatarsal veins that run proximally in the intermetatarsal spaces. These connect via perforating veins with dorsal veins to form the deep plantar venous arch situated alongside the deep plantar arterial arch. From this venous arch, medial and lateral plantar veins run near the corresponding arteries,

communicate with the long and short saphenous veins and form the posterior tibial veins behind the medial malleolus (see Fig. 76.8).

Proximal to the deep plantar arch there is a plantar cutaneous venous plexus, especially dense in the fat of the heel. It connects with the plantar cutaneous venous arch and other deep veins, but drains mainly into the marginal veins. The veins of the sole are an important part of the lower limb 'venous pump' system aiding propulsion of blood up the limb (Broderick et al 2008). Intermittent foot compression devices are available to enhance this flow and so reduce the risk of deep vein thrombosis during periods of increased risk, e.g. after surgery.

INNERVATION

Superficial fibular nerve

The superficial fibular nerve is described on page 1428.

Deep fibular nerve

The deep fibular nerve is described on page 1429.

Tibial nerve

The branches of the tibial nerve that innervate structures in the ankle and foot are articular, muscular, sural, medial calcaneal and medial and lateral plantar nerves. The course and distribution of the tibial nerve in the calf are described on page 1427.

Medial calcaneal nerve The medial calcaneal nerve arises from the tibial nerve and perforates the flexor retinaculum to supply the skin of the heel and medial side of the sole.

Medial plantar nerve The medial plantar nerve is the larger terminal division of the tibial nerve, and lies lateral to the medial plantar artery. From its origin under the flexor retinaculum, it passes deep to abductor hallucis, then appears between it and flexor digitorum brevis, gives off a medial proper digital nerve to the great toe, and divides near the metatarsal bases into three common plantar digital nerves (**Fig. 79.27**; see Fig. 79.22).

Cutaneous branches pierce the plantar aponeurosis between abductor hallucis and flexor digitorum brevis to supply the skin of the sole of the foot. Muscular branches supply abductor hallucis, flexor digitorum brevis, flexor hallucis brevis and the first lumbrical. The first two branches arise near the origin of the nerve and enter the deep surfaces of the muscles. The branch to flexor hallucis brevis is from the hallucal medial digital nerve, and the branch to the first lumbrical from the first common plantar digital nerve. Articular branches supply the joints of the tarsus and metatarsus.

Three common plantar digital nerves pass between the slips of the plantar aponeurosis, each dividing into two proper digital branches. The first supplies adjacent sides of the great and second toes; the second supplies adjacent sides of the second and third toes; and the third supplies adjacent sides of the third and fourth toes and also connects with the lateral plantar nerve. The first gives a branch to the first lumbrical. Each proper digital nerve has cutaneous and articular branches, and near the distal phalanges, a dorsal branch supplies structures around the nail. Abductor hallucis, flexor hallucis brevis and the first lumbrical are all supplied by the medial plantar nerve.

Lateral plantar nerve The lateral plantar nerve supplies the skin of the fifth toe, the lateral half of the fourth toe and most of the deep muscles of the foot (see Figs 79.22, 79.27). It is located medial to the lateral plantar artery and courses anteriorly towards the tubercle of the fifth metatarsal. It passes between flexor digitorum brevis and flexor accessorius and ends between flexor digiti minimi brevis and abductor digiti minimi by dividing into superficial and deep branches. Before dividing, it supplies flexor accessorius and abductor digiti minimi, and gives off small branches that pierce the plantar aponeurosis to supply the skin of the lateral part of the sole (see Fig. 79.27). The superficial branch splits into two common plantar digital nerves: the lateral supplies the lateral side of the fifth toe, flexor digiti minimi brevis and the two interossei in the fourth intermetatarsal space; the medial connects with the third common plantar digital branch of the medial plantar nerve and divides to supply the adjoining sides of the fourth and fifth toes. The deep branch accompanies the lateral plantar artery deep to the flexor tendons and adductor hallucis, and supplies

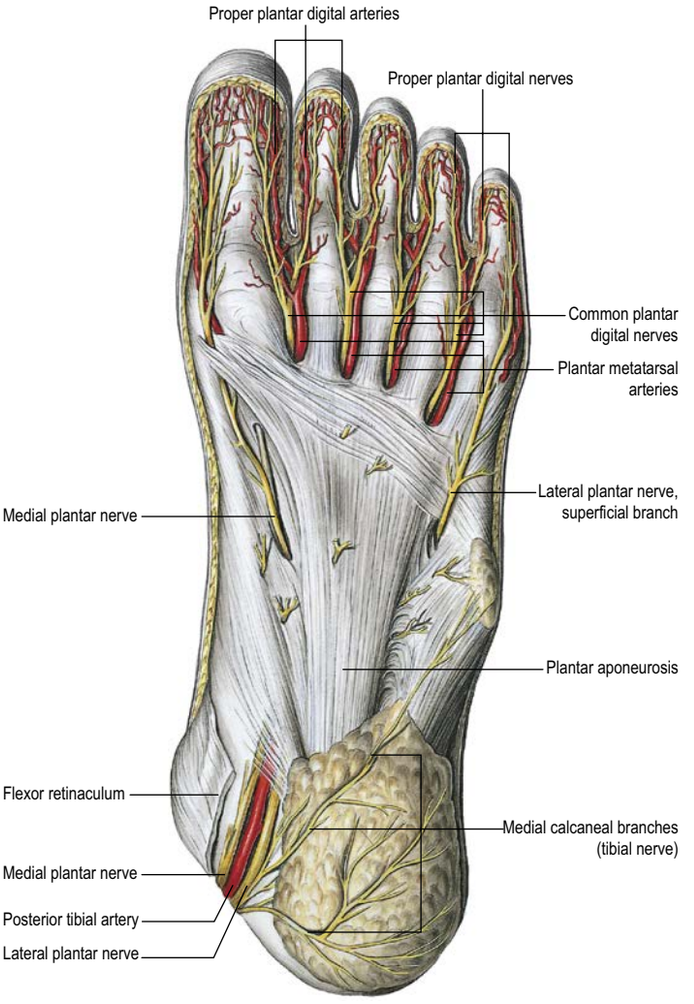

Fig. 79.27 The plantar digital nerves. (Sobotta Atlas of Human Anatomy © Elsevier GmbH, Urban & Fischer, Munich.)

the second to fourth lumbricals, adductor hallucis and all the interossei (except those of the fourth intermetatarsal space). Branches to the second and third lumbricals pass distally deep to the transverse head of adductor hallucis, travelling around its distal border to reach the lumbricals. See Video 79.1.

Nerve entrapment syndromes in the foot

All nerves of the foot can be affected by entrapment, leading classically to a burning sensation in the distribution of that nerve. Tarsal tunnel syndrome is much less common than carpal tunnel syndrome. The flexor retinaculum may compress the tibial nerve or either of its branches (medial and lateral plantar nerves); entrapment at this level is most commonly due to a space-occupying lesion, e.g. a ganglion, or to compression by either a leash of vessels or the deep fascia associated with abductor hallucis. Compression of the first branch of the lateral plantar nerve (Baxter's nerve) by the deep fascia that covers abductor hallucis has been implicated as a possible cause of chronic heel pain and of plantar fasciopathy. (Plantar fasciopathy, often caused by repetitive high-impact injury to the foot, may be associated with pain, especially over the medial calcaneal process, which may be exacerbated by passive ankle or great toe flexion.) The medial plantar nerve can be compressed at the 'knot of Henry', which is the point where the tendon of flexor hallucis longus crosses deep to the tendon of flexor digitorum longus, to reach its medial side in the sole of the foot. The superficial fibular nerve can be damaged in severe inversion injuries of the ankle, and the deep fibular nerve is sometimes compressed by osteophytes in the region of the second tarsometatarsal joint. Sural nerve entrapment is usually not due to compression by fascial elements. Entrapment of the third common digital nerve as it passes deep to the intermetatarsal ligament of the third (or less commonly the second) web space can result in a Morton's neuroma, which is probably the most common form of nerve entrapment in the foot.

Patients with Morton's neuroma usually present with a main complaint of pain in the area of the third and fourth metatarsal heads, and tingling, shooting pain, or numbness over the lateral aspect of the third

and medial aspect of the fourth digits. While there is no pathognomonic clinical test, diagnostic imaging coupled with clinical tests can provide convergent validity to help with diagnosis (Owens et al 2011). Two commonly used clinical tests are web-space tenderness and forefoot squeeze tests. The web-space tenderness test is performed by placing the side of the thumb into the third web space and pressing down. The forefoot squeeze test is performed by squeezing the forefoot from side to side while concurrently performing the web-space test.

BIOMECHANICS OF THE FOOT

Planes of motion

The terms describing movement along the planes of motion in the foot and ankle, particularly in relation to the use of supination and inversion, and pronation and eversion, respectively, are inconsistently applied (Greiner 2007, Doya et al 2010). Plantar flexion and dorsiflexion refer to movement in the sagittal plane and occur principally, but not exclusively, at the ankle, metatarsophalangeal and interphalangeal joints. Motion along the frontal or coronal plane involves inversion, which is a tilting of the plantar surface of the foot towards the midline, and eversion, a tilting away from the midline. These movements take place principally in the talocalcaneal and transverse tarsal joints. Adduction is movement of the foot towards the midline in the transverse plane; abduction is movement away from the midline in the transverse plane. These movements occur in the transverse tarsal joints and, to a limited degree, in the first tarsometatarsal and metatarsophalangeal joints.

Supination describes a tri-planar motion, and is a combination of adduction, inversion and plantar flexion. Pronation is the opposite triplanar motion, i.e. a combination of abduction, eversion and dorsiflexion. Pronation and supination are usually better terms than eversion and inversion, because the latter rarely occur in isolation and the former describe the 'compound' motion that usually occurs.

Active movements occur at the ankle, talocalcaneonavicular and subtalar joints. Movements at the ankle joint are almost entirely restricted to dorsiflexion and plantar flexion, but slight rotation may occur in plantar flexion. The ranges of movement at the talocalcaneonavicular and subtalar joints are greater: supination and pronation mainly occur here.

Standing

Humans are bipedal and stand with an erect trunk and knees that are almost straight. Humans are also plantigrade, i.e. the whole length of the foot is set down on the ground, whereas most medium to large mammals are digitigrade, i.e. they stand and walk on their toes, and ungulates stand on hooves on the tips of their toes. In the sagittal plane, body weight acts along a line that passes a few centimetres anterior to the tibiotalar joint, exerting a moment that must be balanced by the plantar flexor muscles.

Movements of the foot

The foot has two major functions: to support the body in standing and progression, and to lever it forwards and absorb shock in walking, running and jumping (Alexander 1992). To fulfil the first function, the pedal platform must be able to spread the stresses of standing and moving, and be pliable enough to accommodate walking or running over uneven and sloping surfaces. To fulfil the second function, the foot must be transformable into a strong, adjustable lever in order to resist inertia and powerful thrust; a segmented lever can best meet such stresses if it is arched.

In infants and young children, fatty connective tissue on the plantar aspect may give the foot a flat appearance and soft tissues modify its appearance to varying degrees at all ages. The thickness of the medial midfoot plantar fat pad ranges from 3.1 to 4.9 mm (Riddiford-Harland et al 2007). However, the skeleton of the human foot is normally arched, and the sole of the foot is usually visibly concave. These arches vary individually in their height, especially the medial part of the longitudinal arch. Since they are dynamic, their heights also differ in different phases of activity.

The medial longitudinal arch contains the calcaneus, talus, navicular, cuneiform and medial three metatarsals. Its summit, at the superior talar articular surface, takes the full thrust from the tibia and passes it backwards to the calcaneus, and forwards through the navicular and cuneiforms to the metatarsals. When the foot is grounded, these forces are transmitted through the three metatarsal heads and calcaneus (especially its tuberosity). The medial arch is higher, and more mobile and resilient than the lateral arch, and its flattening progressively tightens the plantar calcaneonavicular ligament and plantar aponeurosis. The lateral arch is adapted to transmit weight and thrust rather than to absorb such forces; the long plantar and plantar calcaneocuboid ligaments tighten as it flattens.

The lateral arch makes contact with the ground more extensively than the medial arch. As the foot flattens, an increasing fraction of load traverses the soft tissues that are inferior to the entire arch. The whole lateral border usually touches the ground, whereas the medial border does not. The medial border is visibly concave, usually even in standing, which explains the familiar outline of human footprints (although this varies with the position of the feet, the development of associated soft tissues and the nature of the surface) (Fig. 79.28). In any activity, as soon as the heel rises, the toes are extended and muscular structures (including the plantar aponeurosis) tighten up in the sole, accentuating the longitudinal arches: it has been suggested that tension diminishes in the deeper plantar ligaments in this phase. The sole is transversely concave, both in skeletal form and usually in external appearance; serial transverse arches are most developed inferior to the metatarsus and adjoining tarsus.

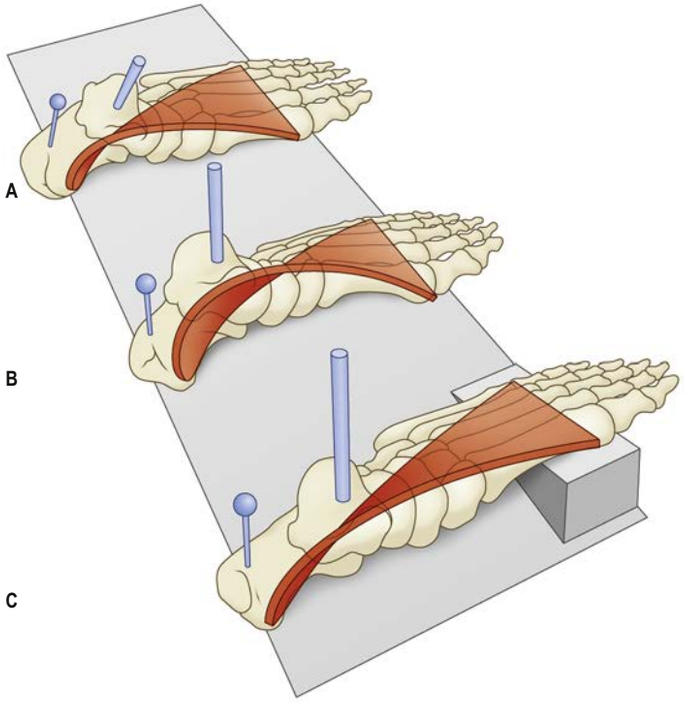

Fig. 79.28 The concept of the foot skeleton as a twisted plate that may be untwisted (supination) or further twisted (pronation) during the maintenance of a plantigrade stance in various positions of the foot. **A**, The foot skeleton in supination, as in standing with the feet widely separated. Note the marked medial tilting of the talus and, to a lesser degree, of the calcaneus and the depression of the medial longitudinal arch. **B**, Relative pronation of the foot, as in standing with the feet close together. **C**, Supination of the foot when standing on an inclined surface; if the position of the wedge had been reversed, the foot skeleton would, of course, approach maximal pronation. (Based on MacConaill MA 1945 The postural mechanism of the human foot. Proc Roy Irish Acad 50:265–78.)

Transmission of force occurs at the metatarsal heads, to some degree along the lateral border of the foot, and through subjacent soft tissues.

In standing, with only body weight to support, both the intrinsic and extrinsic muscles appear to relax (Perry 2010). If the longitudinal arches are allowed to sink as a result of muscular relaxation, the plantar ligaments support the bones in an arched form. The medial arch is more elevated when the feet are together than when they are apart, i.e. inversion with supination increases as the feet are separated. This medial sag can be countered by voluntary contraction of muscles such as tibialis anterior. Whatever the position of the feet, pronation and supination ensure that in standing, a maximal weight-bearing area is grounded from the metatarsal heads along the lateral border of the foot to the calcaneus. The twist of the ligamentous skeleton of the foot imparted by pronation (which is partly undone in supination) prompts the likening of the foot to a twisted but resilient plate (see Fig. 79.28), where adequate ground contact is ensured whatever the angle between the foot and leg, and adaptable resilience is imparted in standing and progression.

COMMENTARY 9.1

Functional anatomy and biomechanics of the pelvis

Andry Vleeming, Frank H. Willard

This commentary focuses on the anatomy and biomechanics of the pelvic girdle and, specifically, the sacroiliac joints. In bipeds, the pelvis serves as a basic platform with three large levers acting on it (the spine and two lower limbs). Movement of the pelvic platform upon the hip joints relative to the femur, such as flexion and extension (pelvic ante- and retroversion), and rotation and abduction/adduction, strongly influences lumbar spinal movement. As well as this substantial external pelvic motion, internal pelvic motion through the sacroiliac joint is essential for effectively transferring loads between the spine and lower limbs. It has been postulated that the sacroiliac joints act as important stress relievers in the 'force–motion' relationships between the trunk and lower limb (Vleeming et al 2007). These joints ensure that the pelvic girdle is a flexible ring of bone that will not easily fracture under the great forces to which it might be subject, either from trauma or from its many bipedal functions (Lovejoy 1988). Analysis of gait mechanics demonstrates that the sacroiliac joints provide sufficient flexibility for the intrapelvic forces to be transferred effectively to and from the lumbar spine and lower extremities (Vleeming et al 2007).

The sacroiliac joint is a highly specialized joint that lends stable (yet flexible) support to the upper body. Both the tightness of the well-developed dorsal fibrous apparatus and the specific architecture of the sacroiliac joint result in limited mobility. Numerous researchers have tried to model sacroiliac joint function by studying its principal displacement characteristics. A common assumption of these studies is that increased loading on the sacrum leads to tilting of the sacrum ventrally (nutation), a process by which most dorsal sacroiliac joint ligaments are stretched and the dorsal aspects of the iliac bones are drawn together (Solonen 1957, Vleeming et al 1990a, Vleeming et al 1990b). Counternutation normally takes place in unloaded situations, such as lying. Nutation implies a forward tilting of the sacrum relative to a posterior rotation of the ilia, and vice versa in counternutation.

Sacroiliac joint movement

Pelvic motion of males and females has been investigated by roentgen stereophotogrammetric motion analysis (RSA). RSA is a technique for measuring small movements and is regarded as the gold standard for determining mobility in orthopaedics (Kibsgård et al 2012). It has been used to measure the mean sacroiliac joint mobility, especially around the sagittal axis, in patients with pelvic girdle pain (PGP; Sturesson 2007). The average mobility for males was about 40% less than for females. However, there was no detectable decrease in total mobility in either gender with age (in patients up to 50 years old). In fact, there was a significant increase of mobility with age for both moving from a 'supine to sitting position' and from 'standing to lying prone with hyperextension' position, particularly in females. Likewise, gender differences of symphysial motion were analysed in a group of 45 asymptomatic individuals. In males, the average frontal plane movement was 1.4 mm, and in nulliparous females 1.6 mm. However, in multiparous females, motion increased to 3.1 mm (Garras et al 2008).

The increased sacroiliac joint mobility in females compared to males has possible anatomical correlates. The curvature of the sacroiliac joint surfaces is usually less pronounced in females to allow for greater mobility (Vleeming et al 1990a). Also, the pubic angle differs between males and females (Vleeming et al 2012). The increase in mobility of the pelvic ring seen in the post-pubescent female pelvis is functional in allowing passage for the child during labour. When the data are combined from published studies employing RSA and appropriate placing of markers, the maximum sagittal rotation of the sacroiliac joint never exceeds 3.6° and translation of the joint never exceeds 2 mm (Kibsgård et al 2012). If these data are amalgamated with the observation that osteophytosis is rare in females, regardless of age (1.83% of females), and is not very common in males (12.27%; Dar et al 2008), it appears that small sacroiliac joint movements are present, even at an advanced age (Vleeming et al 2012).

Sacroiliac joint stability

To illustrate the importance of both myofascial and ligamentous stability of the sacroiliac joint, the biomechanical principles of form and force closure were introduced (Vleeming et al 1990a, Vleeming et al 1990b). Form closure refers to a theoretical stable situation in a joint with closely fitting surfaces, where no extra forces are needed to maintain the state of the system. With force closure (leading to joint compression), both a lateral force and friction are needed to withstand vertical load. The structural features that contribute to sacroiliac joint form closure are complementary ridges and grooves of the articular surfaces; dorsocranial 'wedging' of the sacrum into the ilia; a particular high coefficient of friction in the sacroiliac joint (Vleeming et al 1990a, Vleeming et al 1990b); and the integrity of the dorsal binding ligaments in particular, which are among the strongest in the body (Vleeming et al 1990a). Both form and force closure are necessary for balancing friction/compression in the sacroiliac joint. Force closure is the result of altered joint reaction forces by tensing ligaments, fasciae, muscles and ground reaction forces (Vleeming et al 1990a, Vleeming et al 1990b). Force closure ideally generates a perpendicular compressional reaction force to the sacroiliac joint to overcome the forces of gravity (Vleeming et al 1990b).

Biomechanical considerations and the active straight leg raise test in pelvic girdle pain patients

PGP patients, who test positively on the functional active straight leg raise test, show an inability to raise the leg while lying supine. This test can temporarily be normalized by manual anterior compression of the pelvis or the use of a pelvic belt. This suggests that increased unilateral motion of the sacroiliac joint could lead to impairment and failure to lift the leg (Mens et al 1999).

Likewise, Sturesson (2007), using RSA, studied the effects of surgical application of an anterior external fixation frame for severe PGP patients. This resulted in a mean reduction of movement of the sacroiliac joint around the helical axis of 59% and around the X-axis of 74%. In addition, the active straight leg raise test and other evidence-based PGP tests were normalized (Vleeming et al 2008). When the frame was tightened, a nutation movement of the sacrum was noticed (Sturesson 2007).

This and other studies mentioned in this brief commentary imply that 'too much movement' of the sacroiliac joint could be a significant factor in the onset of PGP (Vleeming et al 2008).

COMMENTARY 9.2

A proposed novel action of psoas minor

Donald Anthony Neumann

Psoas minor is a curious muscle in humans, lacking a clear and universally agreed function and reported to be present in only 33–65% of individuals (Seib 1934, Gandhi et al 2013, Neumann and Garceau 2015, Tubbs et al 2016). This commentary proposes a novel functional role for psoas minor, with the aim of stimulating interest in this muscle, both anatomically and clinically.

Psoas minor is located retroperitoneally deep in the abdomen, running nearly parallel with and immediately anterior to the much larger psoas major (**Fig. 9.2.1**). Although structural variation is not uncommon, it typically originates proximally on the vertebral bodies of T12–L1 and the intervening intervertebral disc (Moore et al 2014; see Ch. 77). The relatively long tendon of psoas minor typically has a distal bony attachment to the iliopubic ramus (see Fig. 9.2.1): this attachment is usually medial to the anterior edge of the acetabulum and medial and slightly superior to the iliopubic eminence (Neumann and Garceau 2015). Therefore, unlike psoas major, psoas minor typically has a bony distal attachment to the pelvis, not to the femur, that likely accounts for its described functions as a weak flexor of the trunk or of the lumbar spine (Oatis 2008, Drake et al 2020). However, given its small muscle belly and the presence of other larger surrounding muscles that are capable of these actions, it seems unlikely that these are either the sole or dominant functions of psoas minor.

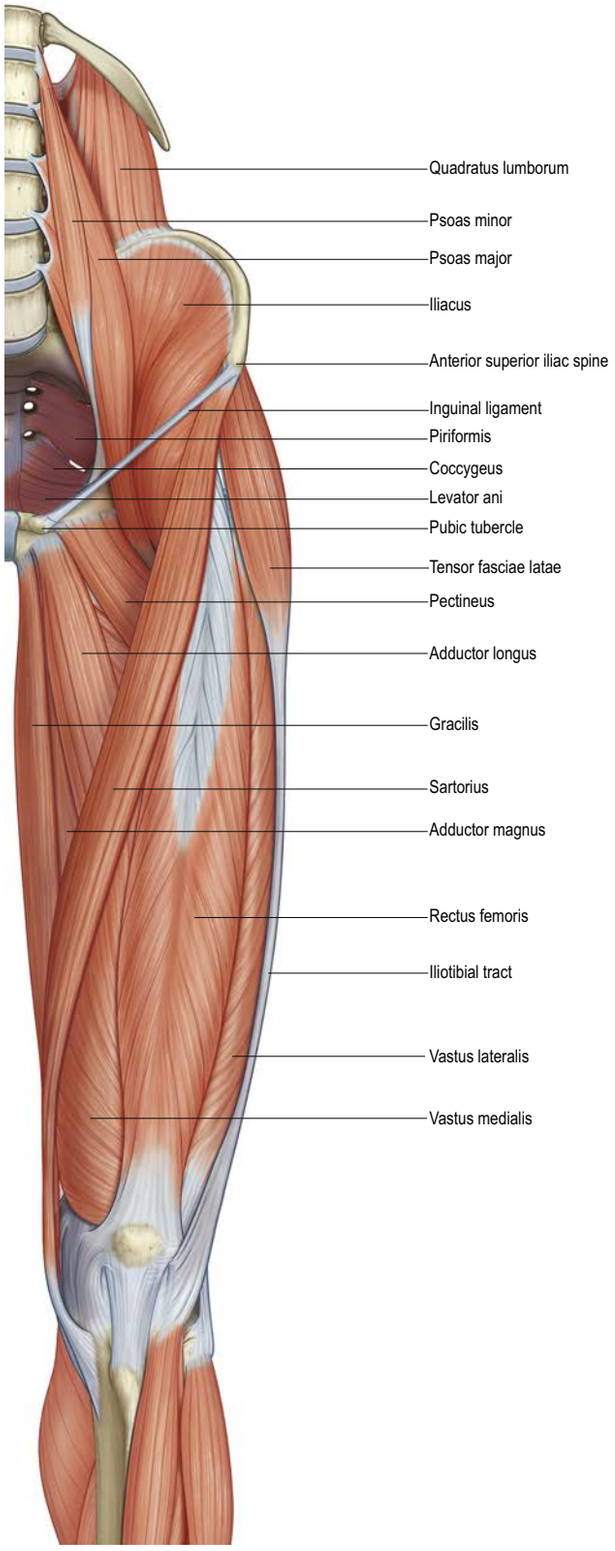
Anatomical connections between the tendon of psoas minor and the iliac fascia

In addition to the distal attachment of psoas minor to the pelvis, anatomy textbooks usually report a secondary attachment into adjacent fascia. In a cadaveric study, the tendon of psoas minor was found to be consistently fused with the structural 'backbone' of the iliac fascia, and the entire musculofascial entity was referred to as the psoas minor–iliac fascia complex (Neumann and Garceau 2015). Detailed measurements showed that the iliac fascia component of this complex draped directly over the distal, pre-tendinous portion of iliopsoas and the femoral nerve (**Fig. 9.2.2A**). The variably curved superior edge of the iliac fascia has been referred to as the iliopectineal arch (Agur and Dalley 2013), and this is the term that will be used throughout this commentary.

A composite tracing of the location of the iliac fascia obtained through study of cadaveric specimens is shown in **Fig. 9.2.2B** (Neumann and Garceau 2015). Of the 21 hips in which psoas minor was present, the muscle was attached distally to bone *and* to the iliac fascia in 19 (90.5%) (see vertical and horizontal red areas in Fig. 9.2.2B, respectively). In the remaining two hips (from the same cadaver) psoas minor was attached distally only to the iliac fascia (which was fully formed). Thus, in all cases, the tendon of psoas minor was firmly blended with the iliac fascia. The location of this tendon–fascial junction was on average 69.9 ± 9.0 mm medial and 29.8 ± 16.1 mm superior to the anterior–superior iliac spine (see Fig. 9.2.2B), placing the tendon–fascial junction immediately lateral and anterior to the sacroiliac joint.

As is apparent in the composite perspective in Fig. 9.2.2B, the arched superior edge of the iliac fascia (i.e. the iliopectineal arch) was generally concave, faced superiorly and could be pulled up and away from the underlying iliopsoas. The superior–medial aspect of the iliac fascia was attached to bone and crossed the sacroiliac joint in 11 hips (52.4%). Inferior to the sacroiliac joint, the fascia was attached to the inner pelvic brim and eventually became continuous with the pelvic attachment of the tendon of psoas minor (see Fig. 9.2.2B). The iliac fascia continued and was attached inferiorly to a point generally medial to the iliopubic junction, i.e. the junction between the anterior ilium and superior pubic ramus. En route, some fibres flowed posteromedially to interlace with the external fascia covering the superior part of obturator internus.

The lateral extent of the iliopectineal arch was attached to bone in a region immediately superior and inferior to the anterior superior iliac spine. However, the posterior side of the iliac fascia lacked



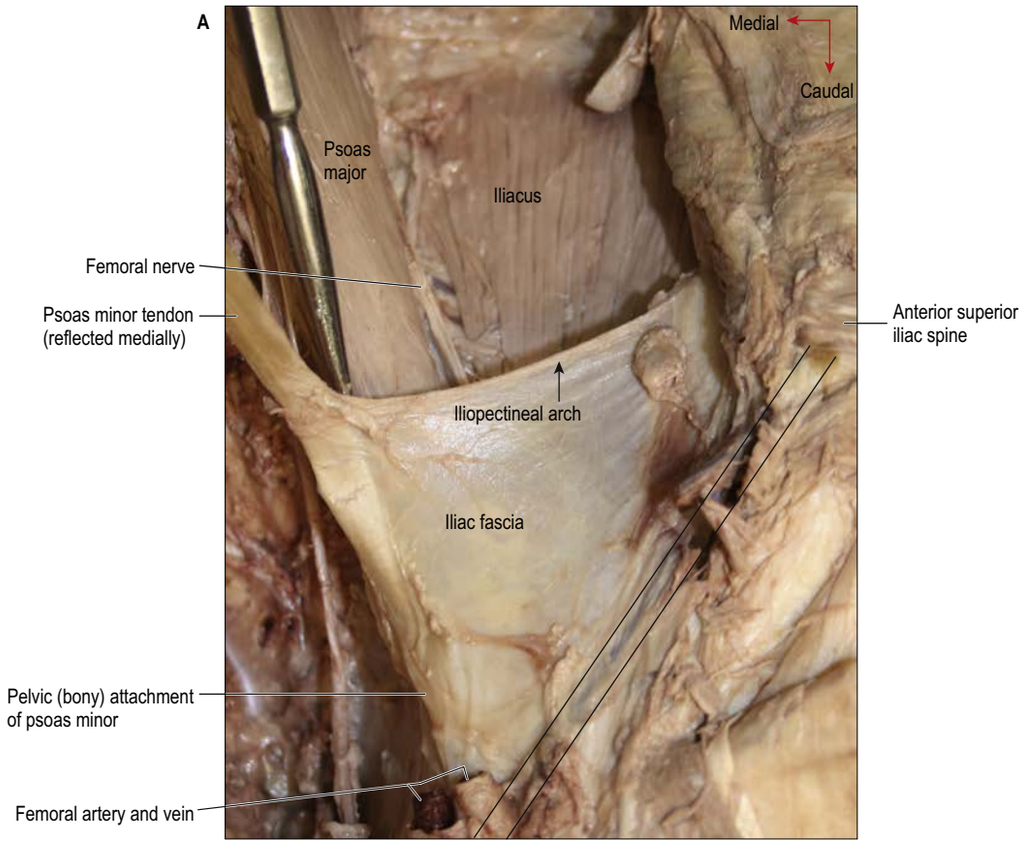


Fig. 9.2.1 Psoas minor running parallel to and in contact with the psoas major.

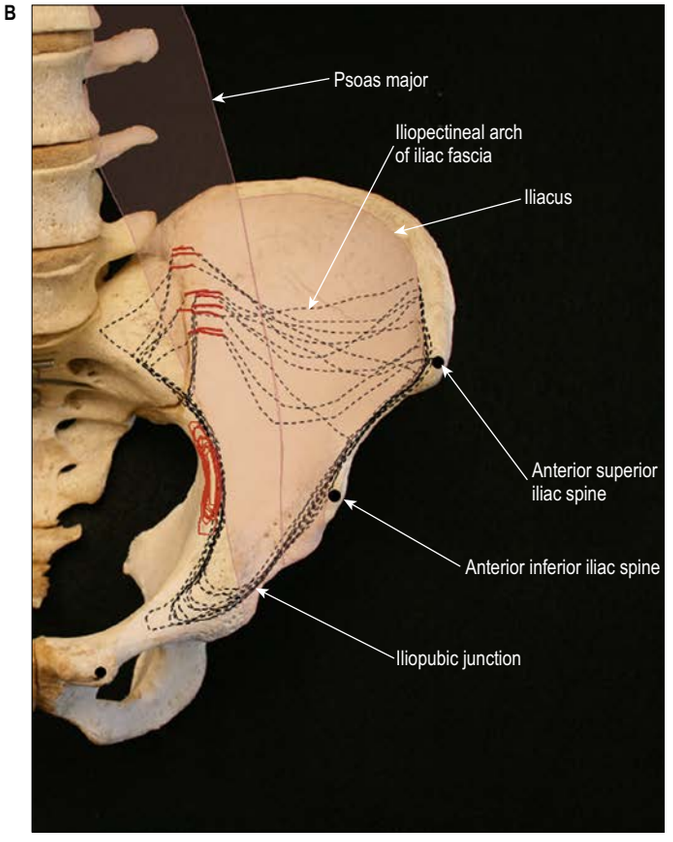

Fig. 9.2.2 Anterior views of the iliac fascia component of the left psoas minor–iliac fascia complex. **A**, Psoas minor tendon blending with the iliac fascia (see tip of probe). Note that the tendon of psoas minor has been manually pulled medially. Normally, *in situ,* the tendon of psoas minor lies nearly parallel and in contact with the anterior belly of psoas major. Parallel black lines show the approximate location of the inguinal ligament. **B**, Pictorial summary of the distal attachments of the psoas minor–iliac fascia complex. The dashed black lines represent the location of the iliac fascia. The locations of the attachment of the tendon of psoas minor into the iliac fascia are indicated by variably spaced, red horizontal areas; and into the pelvic bone by overlapping red, vertical areas. For perspective, the estimated location of psoas major and iliacus, which for the most part lie deep to the iliac fascia, are depicted using a translucent outline. (Adapted with permission from Neumann DA, Garceau LR 2015 A proposed novel function of the psoas minor revealed through cadaver dissection. Clin Anat 28:243–52.)

a pelvic attachment. The anterior surface of the iliac fascia blended with the deep part of the inguinal ligament and the proximal fascia lata of the thigh. A near continuous sheet of iliac fascia therefore existed between the iliopectineal arch superiorly and fascia lata inferiorly, providing an open vertical aponeurotic sleeve that allowed unrestricted passage of the underlying iliopsoas and femoral nerve into the thigh (see **Video 9.2.1** and **Fig. 9.2.3**). Although iliopsoas and the femoral nerve passed posterior to the iliac fascia, the femoral vein and artery (embedded within the femoral sheath) passed superficial to the fascia. The anterior surface of iliopsoas and the femoral nerve were in direct contact with the posterior surface of the iliac fascia, whereas the posterior surface of iliopsoas was in firm contact with a segment of the anterior pelvic brim.

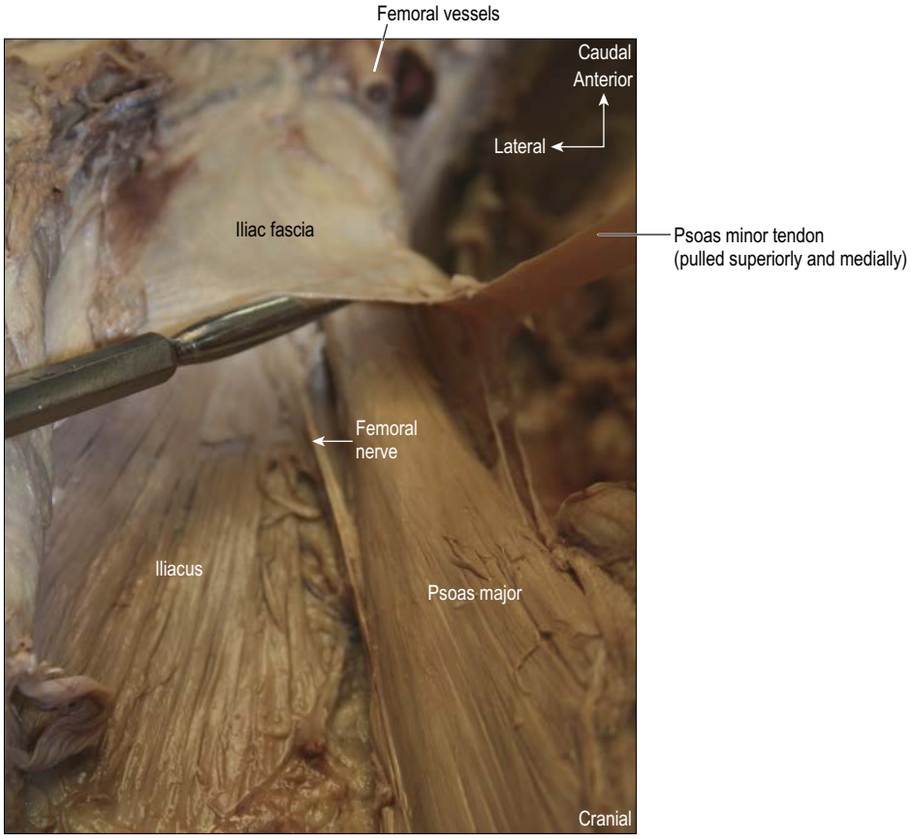

Fig. 9.2.3 Anterior view showing the left pelvic region of a cadaver, with intestines and inguinal ligament removed (orientation seen in Fig. 9.2.2A has been reversed). The probe is shown lifting the iliopectineal arch (and iliac fascia) away from the underlying left iliacus, psoas major and femoral nerve. The tendon of psoas minor has been manually pulled superiorly and medially, adding to the tension in the iliac fascia. Caudally, the iliac fascia blends with the fascia lata of the proximal thigh.

Possible biomechanical and clinical significance of the psoas minor–iliac fascia complex

When present, the tendon of psoas minor is consistently attached to and reinforces the medial and central part of the iliac fascia (Neumann and Garceau 2015). Based on this anatomical connection, an active force produced by psoas minor could, to some degree, adjust the tension within the iliac fascia, and potentially within the proximal part of the fascia lata (see arrows in **Fig. 9.2.4**). In this way, psoas minor may provide some degree of mechanical stability to the underlying iliopsoas as it crosses over the femoral head and across the anterior pelvic brim. Such an active tensioning may confer useful biomechanical functions to iliopsoas as a hip flexor. Although speculative, it may be that the myogenic tensioning within the iliac fascia prevents an activated iliopsoas from 'bowstringing' away from the anterior pelvic brim, especially when strongly contracting to move the thigh into a high flexion angle. Excessive bowstringing of iliopsoas and its tendon away from the femoral head would increase the hip flexion moment arm (leverage) of the muscle, resulting in *less* rotation of the joint (flexion of the hip, in this case) per linear unit of muscle contraction. Such a counterproductive biomechanical scenario would exist for *any* muscle that bowstrings across a joint (Neumann 2017). Excessive bowstringing of the tendon of iliopsoas could reduce the range of available active hip flexion, which may limit the ease of activities that require end range flexion, such as putting on shoes and socks. Whether psoas minor has the physiological strength for generating enough active counter-tension in the iliac fascia to prevent iliopsoas bowstringing during hip flexion is not known. To add insight into this notion, Neumann and Garceau (2015) estimated that, on average, psoas minor could theoretically produce a maximal force of 21 N (2.1 kg) based on an average cross-sectional area of 52.5 mm^2. Although this is an estimate, it does provide some context when considering whether psoas minor has the force potential to offer mechanical stability to the much stronger iliopsoas. Further study is needed to verify this biomechanical proposition.

The mechanism described in the previous paragraph could, in theory, also allow the psoas minor–iliac fascia complex to provide varying control of the *medial–lateral* position of the underlying iliopsoas as it runs across the femoral head, anterior capsule region, iliopectineal eminence and the pelvic brim. Could such control influence the contact stress between the distal region of iliopsoas and adjacent structures? This question is clinically relevant given the many poorly understood painful conditions or pathologies in the anterior hip region that may involve iliopsoas. Such conditions include iliopsoas 'snapping hip' syndrome (Byrd 2006, Lewis 2010, Philippon et al 2014); iliopsoas impingement (Dora et al 2007); iliopsoas bursitis or tendonitis (Blankenbaker et al 2006, Nunley et al 2010, Philippon et al 2011); and, possibly, acetabular labral pathology (Philippon et al 2014). An intriguing question arises as to the possible clinical consequences of not possessing a psoas minor, and therefore lacking the proposed active tensioning mechanism for the iliac fascia. Would absence of psoas minor predispose to developing painful iliopsoas-associated pathology?

A primary fascial-based stabilization role for a muscle: is this a novel concept?

Several examples exist within the body where a sheath of connective tissue *passively* stabilizes the position of underlying muscles or tendons. Consider for example the role of the fibrous lacertus for elbow flexion, the anular pulleys for digital flexion, or the extensor retinaculum for ankle dorsiflexion or wrist extension. This commentary proposes that a similar anatomical mechanism might exist for iliopsoas, with regard to its mechanical potential to bowstring away from the hip during high angle hip flexion (Yoshio et al 2002). It is arguable that this stability could be furnished not only by passive tension, as in the examples cited above, but also through force generated by psoas minor and transferred through the iliac fascia. In theory, sensory receptors within the psoas minor–iliac fascia complex may provide input to the central nervous system. As such, the nervous system may better determine the necessary motor activation of psoas minor to mechanically stabilize the iliopsoas tendon during active motion. Perhaps psoas minor and iliopsoas are activated 'in phase' with each other during vigorous movements

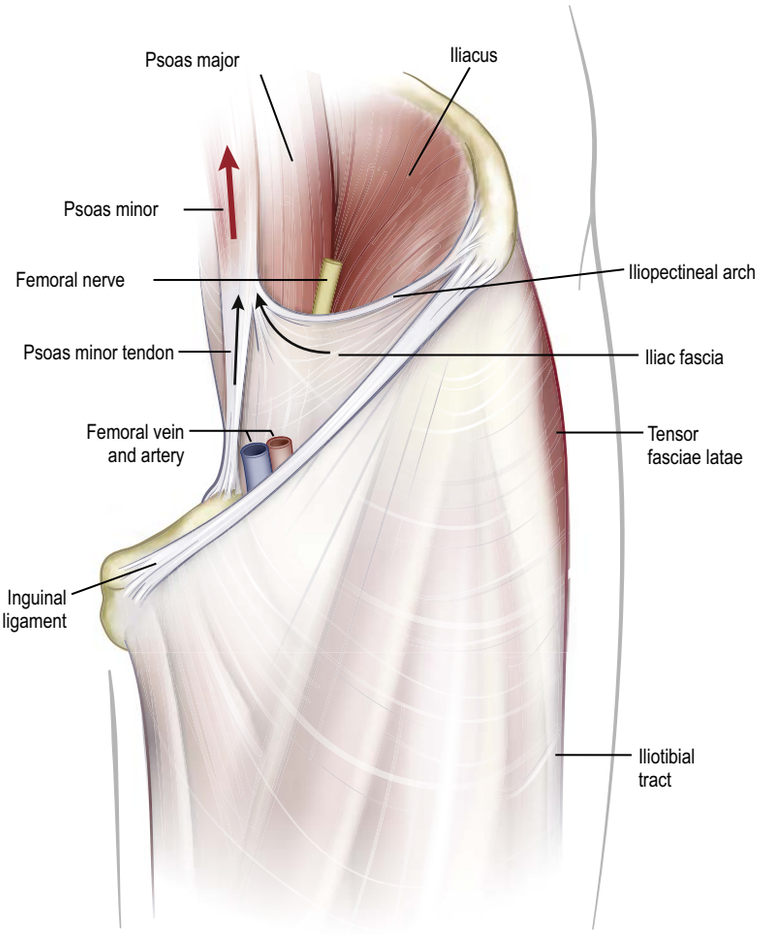

Fig. 9.2.4 The left proximal thigh and pelvic region, intestines removed. Red arrow, active force produced by contraction of psoas minor; black arrows, tension that could be transferred throughout the iliac fascia and into the proximal part of the fascia lata of the thigh.

involving high flexion angles, such as cycling or running up hill, which is an idea that remains unstudied.

The proposition that one muscle can serve as an *active* stabilizer for another, as postulated for psoas minor, is not unique. Examples include quadratus plantae, which may help guide the position of the common tendon of flexor digitorum longus in the foot, and palmaris longus as it stabilizes the palmar aponeurosis in the hand, a structural arrangement that prevents bowstringing of the extrinsic digital flexor tendons and median nerve within the carpal tunnel during extreme wrist flexion.

Closing remarks

Although not proven, it is proposed that psoas minor functions as a dedicated accessory muscle to iliopsoas. More specifically, the primary function of the psoas minor–iliac fascia complex is postulated to enhance the biomechanical stability and function of the underlying iliopsoas. Such a stabilizing role appears more likely than the traditional description of psoas minor as a trunk flexor.

Further study is warranted to test the hypotheses raised in this commentary. Such research could involve: (1) large-scale dissection studies to determine the cross-sectional area, morphological variation, pennation angle and innervation of the psoas minor–iliac fascia complex; (2) measurement of the strength and stiffness characteristics of the iliac fascia; (3) instrumenting the psoas minor–iliac fascia complex and cadaveric hips with force (strain) and kinematic measurement hardware; (4) computer and mathematical modelling; and (5) *in vivo* electromyographical or ultrasound analyses. One specific aim of this research would be to analyse whether psoas minor is physiologically capable of producing enough force to stabilize the position of iliopsoas across a range of hip positions. Ultimately, research may be justified to determine whether an association exists between the presence or absence of psoas minor and the likelihood of developing anterior hip pain and other associated pathologies involving iliopsoas.

Although this commentary has generated more questions than it has answered, it seeks to share a hypothesis with anatomists, kinesiologists, physiotherapists, surgeons and other clinicians who treat musculoskeletal problems involving the anterior aspect of the hip.

COMMENTARY

9.3 Anterolateral ligament of the knee

Robert F. LaPrade

There has been significant interest over the past decade concerning the 'rediscovery' of the anterolateral ligament (ALL) of the knee. The structure was initially defined by Paul Segond in 1879 as a pearly, fibrous band that became tensioned during internal rotation of the knee (Segond 1879). Strictly speaking, the 'rediscovery' of the ALL by Claes et al (2013) was a clarification of the previous literature and reflected increasing recognition that anterior cruciate ligament (ACL) reconstruction alone did not always eliminate a patient's pivot shift test. This fibrous band along the anterolateral aspect of the knee has been variously identified as retrograde iliotibial tract fibres (Lobenhoffer et al 1987), the capsulo-osseous layer of the iliotibial tract (Terry et al 1993), the mid-third lateral capsular ligament (LaPrade et al 2000), and more recently, as the ALL (Vieira et al 2007).

It is important to realise that while the ALL has been recognized as a thickening within the mid-third of the lateral capsular ligament, there is still no clear definition of its anatomical attachment sites. The femoral attachment of the ALL has been identified proximal and posterior to the lateral epicondyle (Kennedy et al 2015) and the tibial attachment has been located consistently midway between the anterior aspect of the fibular head and Gerdy's tubercle (Claes et al 2013, Helito et al 2013, Dodds et al 2014, Caterine et al 2015, Kennedy et al 2015).

The femoral attachment of the ALL has been difficult to define. Some of the first descriptions indicated a femoral attachment on or near the insertion of the popliteus tendon (Vincent et al 2012), or a shared femoral origin with the fibular collateral ligament (FCL), adjacent to the lateral epicondyle (Claes et al 2013). Helito et al (2013) described a femoral attachment anterior and distal to the FCL femoral attachment site, while Dodds et al (2014) reported the femoral attachment as proximal and posterior to the femoral FCL attachment site. Caterine et al (2015) reported significant anatomical variability, identifying attachments at either the proximal and posterior or the anterior and distal attachment sites. Most recently, Kennedy et al (2015) consistently located a femoral attachment approximately 7.0 mm from the lateral epicondyle and 4.7 mm posterior and proximal to the FCL femoral attachment, with an overall attachment area of 67.7 mm^2 (Fig. 9.3.1). Lateral radiographs yielded a relative distance of 8.4 mm posterior and proximal to the lateral epicondyle, and an approximate distance of 22.3 mm proximal to the joint line.

The tibial attachment site of the ALL has been fairly consistently described across multiple studies over the years as a thickening of the lateral capsule, traversing anterodistal from its origin, and coming under tension when an internal rotation load is applied to the knee at 30° of flexion. This insertion has an area of approximately 64.9 mm^2, and is strongly correlated with the location of a bony avulsion on the anterolateral aspect of the knee (Segond fracture) that occasionally accompanies ACL injuries. The attachment is approximately midway between the anterior aspect of the fibular head and Gerdy's tubercle, with relative distances of 26.1 mm and 24.7 mm from these points, respectively (Kennedy et al 2015). It has been estimated radiographically as 13.1 mm distal to the lateral tibial plateau, with anterior–posterior radiographs yielding a planar distance of 19.0 mm posterior and superior to the centre of Gerdy's tubercle. Additional attachments of the ALL to the meniscotibial portion of the mid-third lateral capsular ligament, the anterior arm of the short head of biceps femoris, and the capsulo-osseous layer of the iliotibial tract, have all been identified.

The occurrence of Segond fractures together with ACL injuries and the high failure rate of ACL reconstructions prompted the idea that perhaps the structures responsible for the kinematics associated with these injuries were not being fully restored. Upon concomitant sectioning of the ACL and ALL in a robotic study, Rasmussen et al (2016) found a significant increase in axial plane tibial translation during a simulated pivot shift relative to isolated ACL-deficient states, in addition to increases in internal rotation. This study supported the proposal that the ALL was acting as a secondary stabilizer throughout knee flexion during applied internal rotation torque and pivot shift testing and that its absence altered the stability of the knee and ultimately overburdened grafts utilized for ACL reconstructions. Nitri et al (2016) showed that concurrent reconstruction of both ACL and ALL was successful in improving rotary stability relative to isolated ACL reconstruction in ALL–ACL deficient knees. This was supported by Schon et al (2016) who also showed that ALL reconstructions resulted in a significant overconstraint of internal rotation beyond 30° of knee flexion.

In conclusion, the ALL is a capsular thickening of the lateral knee, originating proximal and posterior to the lateral epicondyle and coursing anterodistal to the anterolateral tibia, which can be reproducibly identified by reference to surrounding anatomical and bony landmarks. Imaging correlates ALL failure with the identical location of Segond fractures on the tibia, reinforcing its importance as a stabilizer of internal rotation in the ACL-deficient knee. Although the ALL appears to be vital for secondary stabilization of internal rotation, especially in conditions of ACL deficiency, further studies are necessary when considering ALL-supplemented reconstructions in the treatment of ACL injuries.

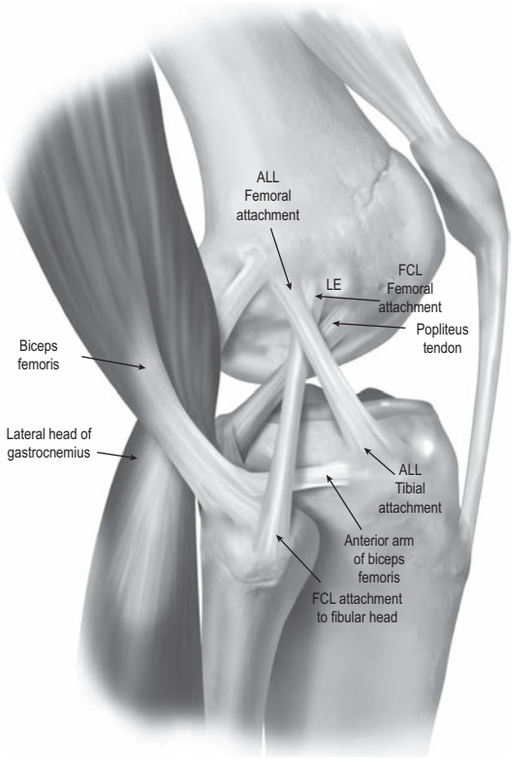

Fig. 9.3.1 Attachment sites for the main structures of the lateral knee (lateral view, right knee). The anterolateral ligament (ALL) is attached posterior and proximal to the femoral attachment of the fibular collateral ligament (FCL), and courses anterodistal to its insertion onto the tibia midway between Gerdy's tubercle and the anterior margin of the fibular head. Abbreviations: ALL, anterolateral ligament; FCL, fibular collateral ligament; LE, lateral epicondyle. CHAPTER 80

The anatomy of the peripheral nervous system

The peripheral nervous system (PNS) is composed of spinal and cranial nerves, their associated ganglia (autonomic and sensory) and their ramifications that transmit afferent and efferent information between the central nervous system (CNS) and the rest of the body. It also includes the peripheral part of the autonomic nervous system (ANS), notably the sympathetic trunks and the sympathetic and parasympathetic ganglia and their ramifications, and the enteric nervous system (ENS), composed of plexuses of nerve fibres and cell bodies in the wall of the gastrointestinal tract, and the visceral afferent system.

CRANIAL NERVES

Cranial nerves are the means by which the brain receives information from, and controls the activities of, the head and neck and the thoracic and greater part of the abdominal viscera. There are 12 pairs of cranial nerves, individually named and numbered (Roman numerals) in a rostrocaudal sequence (see Table 24.1). Unlike spinal nerves, only some cranial nerves are mixed in function, i.e. they carry both sensory and motor fibres; others are purely sensory or motor. The first cranial nerve (I; olfactory) has an ancient lineage and is derived from the forerunner of the cerebral hemisphere. It retains this unique position through the connections of the olfactory bulb, and is the only sensory cranial nerve that projects directly to the cerebral cortex rather than indirectly via the thalamus. The areas of cerebral cortex receiving olfactory input have a primitive cellular organization and are an integral part of the limbic system, which is concerned with the emotional aspects of behaviour. The second cranial nerve (II; optic) consists of the axons of second-order visual neurones and these terminate in the thalamus. Most of the component fibres of the other 10 pairs of cranial nerves originate from, or terminate in, named cranial nerve nuclei in the brainstem.

OLFACTORY NERVE

The olfactory nerve is the first cranial nerve and, as its name suggests, is concerned with olfaction (the sense of smell). It is composed of bundles of very small unmyelinated axons derived from olfactory receptor neurones in the olfactory mucosa. The axons are in varying stages of maturity, reflecting the constant turnover of olfactory neurones that takes place in the olfactory epithelium. Bundles of axons are surrounded by olfactory ensheathing cells and form a plexiform network in the subepithelial lamina propria of the mucosa. The bundles unite into as many as 20 branches that cross the cribriform plate of the ethmoid bone in lateral and medial groups, and enter the overlying olfactory bulb, where they end in glomeruli. Each branch is ensheathed by dura mater and pia/arachnoid as it passes through the cribriform plate (see Fig. 39.13A). The dura subsequently becomes continuous with the nasal periosteum, and the pia/arachnoid merges with the connective tissue sheaths that surround the nerve bundles, an arrangement that may facilitate the spread of infection into the cranial cavity from the nasal cavity.

The olfactory bulb is continuous posteriorly with the olfactory tract, through which the output of the bulb projects directly to the ipsilateral retrobulbar area (anterior olfactory nucleus), olfactory tubercle, prepiriform area, amygdala and rostral entorhinal cortex. There is a clear laminar structure in the olfactory bulb (Fig. 32.32A). Different odour molecules are represented by different patterns of spatial activity in the olfactory bulb (Shepherd 2006).

In severe injuries involving the anterior cranial fossa, the olfactory bulb may be separated from the olfactory nerves or the nerves may be torn, producing anosmia, i.e. loss of olfaction. Fractures may involve the meninges, so that cerebrospinal fluid may leak into the nose, resulting in cerebrospinal rhinorrhoea. These injuries open up avenues for intracranial infection from the nasal cavity.

OPTIC NERVE

The optic nerve is the second cranial nerve and contains the axons of retinal ganglion cells. The two optic nerves join to form the optic chiasma which is usually positioned over the diaphragma sellae and pituitary gland (normofixed), although it may be prefixed (above the tuberculum sellae) or postfixed (above the dorsum sellae). On entering the optic nerve, retinal ganglion cell axons initially maintain their relative retinal positions, with axons from the fovea forming a lateral wedge. This retinotopic mapping is largely maintained within the optic nerve, although nearer the chiasma the foveal axons take a position in the centre of the optic nerve while temporal fibres occupy their previous lateral location. A substantial rearrangement of axons takes place at the chiasma. Most axons arising from the nasal half of a line bisecting the fovea within each retina cross in the chiasma to enter the contralateral optic tract. Fibres from the temporal hemi-retinas do not generally cross in the chiasma.

Th axons within the optic tract were thought to maintain their topographic order and each tract was assumed to be a single representation of the contralateral hemifield. However, it is now clear that axons are mainly organized in functional groupings, larger superficial axons representing the magnocellular pathway and deeper axons originating from midget ganglion cells and forming the parvocellular pathway. This arrangement is chronotopic, the deeper axons developing earlier during axogenesis than the more superficial ones (Reese 1993).

Almost all (90%) of the retinal ganglion cell axons terminate on neurones in the lateral geniculate nucleus. Extrageniculate axons (10%) leave the optic tract before the lateral geniculate nucleus: they may leave the optic chiasma dorsally and project to the suprachiasmatic nucleus of the hypothalamus, or may branch off the optic tract at the superior brachium and project to the superior colliculus, pretectal areas and inferior pulvinar.

The optic nerve is usually described in four parts, intracranial (approximately 10 mm), intracanalicular (approximately 10 mm), intraorbital (25–30 mm), and intraocular (1 mm). The intracranial part arises from the optic chiasma in the suprasellar cistern. It is surrounded by the optic sheath and its dorsal surface is covered by the falciform ligament. The intracanalicular part passes through the optic canal together with the ophthalmic artery: this is the weakest point of the anterior visual pathway because the nerve is fixed to its bony surroundings by fibrous adhesions. The intraorbital part passes forwards, laterally and downwards, and pierces the sclera at the lamina cribrosa, slightly medial to the posterior pole: it has a somewhat tortuous course within the orbit that allows for movements of the eyeball (Demer 2016). The subarachnoid space surrounding the intracranial part is continuous with the subarachnoid space around the intracanalicular and intraorbital parts. The dural sheath surrounding the optic nerve originates at the level of the optic canal and accompanies the optic nerve to the sclera. The intraorbital part of optic nerve has important relationships with other orbital structures (see Fig. 44.4). As it leaves the optic canal, it lies superomedial to the ophthalmic artery, and is separated from lateral rectus by the oculomotor, nasociliary and abducens nerves, and sometimes by the ophthalmic veins. It is closely related to the origins of the four recti, whereas more anteriorly, where the muscles diverge, it is separated from them by a substantial amount of orbital fat. Just beyond the optic canal, the ophthalmic artery and the nasociliary nerve cross the optic nerve to reach the medial wall of the orbit. The central artery of the retina enters the substance of the optic nerve about halfway along its length. Near the back of the eyeball, the optic nerve is surrounded by the long and short ciliary nerves and vessels.

OCULOMOTOR NERVE

The oculomotor nerve is the third cranial nerve and innervates levator palpebrae superioris and four of the extraocular muscles (superior, inferior and medial rectus and inferior oblique) (see Fig. 44.15). It also conveys preganglionic parasympathetic fibres from cell bodies in the Edinger–Westphal nucleus that relay in the ciliary ganglion.

Oculomotor nuclear complex

The nuclear complex from which the oculomotor nerve arises consists of several groups of large motor neurones that are collectively designated the oculomotor nucleus, and the smaller preganglionic parasympathetic Edinger–Westphal nucleus (see Figs 28.3, 28.16). The nuclear complex lies at the ventromedial aspect of the periaqueductal grey matter, superior to the trochlear nuclei and is partially enclosed by the fibres of the median longitudinal fasciculi. It is approximately 5 mm long and is divisible into neuronal groups that correlate with the distribution of motor fibres within the oculomotor nerve. Afferent inputs to the oculomotor nuclear complex include fibres from the rostral interstitial nucleus of the medial longitudinal fasciculus and the interstitial nucleus of Cajal, both of which are involved in the control of vertical and torsional gaze. Other inputs come, directly or indirectly, from the nuclei of the posterior commissure and, via these nuclei, from the frontal eye fields, the superior colliculus, the dentate nucleus and cortical areas. The medial longitudinal fasciculus carries afferent connections from the trochlear, abducens and vestibular nuclei.

The fibres from the medial vestibular nucleus project to the medial rectus subnucleus. In order from dorsal to ventral, the oculomotor neurone groups innervate the ipsilateral inferior rectus, inferior oblique and medial rectus. A medially placed column of cells innervates the contralateral superior rectus through axons that decussate in the caudal part of this subnucleus. A median subnucleus of large neurones, designated the caudal central nucleus, lies at the caudal pole of the oculomotor nucleus adjacent to the superior rectus and medial rectus subnuclei. Fascicles of axons from these subnuclei course forwards in the midbrain, through the tegmentum, red nucleus and medial substantia nigra, to emerge as the oculomotor nerve in the interpeduncular fossa. The fascicles are most probably arranged from medial to lateral subserving the pupil, inferior rectus, medial rectus, levator palpebrae superioris and superior rectus, and inferior oblique.

Intra- and extracranial course

For descriptive purposes, the oculomotor nerve is usually divided into cisternal, cavernous and orbital portions: surgically oriented classifications derived from combined microsurgical and endoscopic cadaveric dissection studies have proposed five or seven parts (Iaconetta et al 2010, Park et al 2017).

The cisternal portion of the oculomotor nerve emerges from the midbrain, either through the medial sulcus of the crus cerebri in the caudal part of the interpeduncular fossa or through the medial or the middle part of the crus cerebri. It usually passes forwards and laterally through the interpeduncular cistern between the posterior communicating artery and the superior cerebellar artery: this portion of the nerve is supplied by the P1 and P2 segments of the posterior cerebral artery. The pupilloconstrictor fibres lie superficially on the dorsomedial surface of the cisternal portion of oculomotor nerve, a location that renders them vulnerable to aneurysmal compression (Kerr and Hollowell 1964, Shechtman et al 2007), whereas a pupil-sparing palsy of the oculomotor nerve is pathognomonic of an ischaemic lesion, which tends to involve the central region of the nerve. The oculomotor nerve next passes inferolateral to the posterior communicating artery and inferomedial to the uncus and enters the roof of the cavernous sinus through the oculomotor trigone. This cavernous portion of the nerve passes along the lateral dural wall of the cavernous sinus, dividing into superior and inferior divisions that run beneath the trochlear and ophthalmic nerves. The two divisions enter the orbit through the superior orbital fissure, within the common tendinous ring of the recti, and separated by the nasociliary branch of the ophthalmic nerve.

The superior division of the oculomotor nerve passes above the optic nerve to enter the inferior (ocular) surface of superior rectus. It supplies this muscle and gives off a branch that runs to innervate levator palpebrae superioris. The inferior division of the oculomotor nerve divides into medial, central and lateral branches. The medial branch passes beneath the optic nerve to enter the lateral (ocular) surface of medial rectus; the central branch runs downwards and forwards to enter the superior (ocular) surface of inferior rectus; the lateral branch travels forwards on the lateral side of inferior rectus to enter the orbital surface of inferior oblique and also communicates with the ciliary ganglion to distribute parasympathetic fibres to sphincter pupillae and the ciliary muscle.

Edinger–Westphal nucleus

The Edinger–Westphal nucleus lies dorsal to the main oculomotor nucleus. It is composed of small, multipolar, preganglionic parasympathetic (general visceral efferent, GVE) neurones. Afferent inputs to the nucleus come primarily from the pretectal nuclei bilaterally, mediating the pupillary light reflex, and from the visual cortex, mediating accommodation. Efferent fibres from the nucleus travel in the oculomotor nerve to synapse with postganglionic neurones in the ciliary ganglion (Kozicz et al 2011), and also descend through the medial longitudinal fasciculus to innervate the medial and descending vestibular nuclei (Nieuwenhuys et al 2008).

TROCHLEAR NERVE

The trochlear nerve is the fourth cranial nerve and innervates superior oblique. It has the longest intracranial course and the smallest diameter of all of the cranial nerves, and is also the only cranial nerve to emerge from the dorsal surface of the brainstem, lateral to the lower edge of the inferior colliculus.

Trochlear nucleus

The trochlear nucleus is a small ovoid mass of grey matter just to the side of the midline (see Fig. 28.15). It is bounded by the periaqueductal grey matter dorsally and is enveloped by the fibres of the longitudinal fasciculi ventrally and laterally (Naidich et al 2009). The nucleus is part of the somatic efferent column in line with the oculomotor, abducens and hypoglossal nuclei. Afferent inputs to the trochlear nucleus include fibres from the rostral intermediate nucleus of the medial longitudinal fasciculus and from the interstitial nucleus of Cajal, both of which are involved in the control of vertical and torsional gaze. Other inputs come from the vestibular, abducens and oculomotor nuclei and, directly or indirectly, from the nuclei of the posterior commissure (nuclei of Darkschewitsch and of Cajal) and, via these nuclei, from the superior colliculus, frontal eye fields and other cortical areas. Other afferents arrive from the nucleus prepositus hypoglossi. Efferent trochlear fibres first course dorsally and caudally, just deep to the outer perimeter of the periaqueductal grey matter and medial to the mesencephalic trigeminal nucleus. The trochlear nerves then decussate within the superior medullary velum of the fourth ventricle. A few fibres may remain ipsilateral.

Intra- and extracranial course

The nerves emerge from the dorsal surface of the brainstem just caudal to the inferior colliculus and to each side of the frenulum veli. At the point of emergence, a variable number of rootlets, usually two, unite to form the nerve trunks that curve ventrally through the perimesencephalic cisterns, between the superior cerebellar arteries below and the posterior cerebral arteries above. The cisternal portion of each nerve courses anterolaterally, winding round the cerebral peduncle toward the tentorium cerebelli through the quadrigeminal and ambient cisterns. The nerve passes anteriorly along the infratentorial groove of the tentorium cerebelli and penetrates the roof of the cavernous sinus at the junction of the anterior and posterior petroclinoid dural folds. The cavernous portion continues along the lateral wall of the cavernous sinus below the oculomotor nerve, crossing this nerve at the level of the optic strut to become the most superior structure in the cavernous sinus. The trochlear nerve enters the orbit through the superior orbital fissure outside the common tendinous ring, superior to levator palpebrae superioris and medial to the frontal and lacrimal nerves (see Fig. 44.16). The orbital portion runs medially across levator palpebrae superior and superior rectus to reach superior oblique: its branches typically end on the posterior one-third of the muscle, most often on the medial aspect (Joo and Rhoton 2015).

TRIGEMINAL NERVE

The trigeminal nerve is the fifth cranial nerve and has extensive sensory, motor and autonomic components.

Sensory nuclei and central connections

The trigeminal nerve has three sensory nuclei (spinal tract, principal and mesencephalic) and one motor nucleus. On entering the pons, the fibres of the sensory root of the trigeminal nerve run dorsomedially towards the principal sensory nucleus. About 50% of the fibres divide into ascending and descending branches and the others ascend or descend without division. The descending fibres form the spinal tract of the trigeminal nerve, which terminates in the medially adjacent spinal nucleus of the trigeminal nerve. Some ascending trigeminal fibres, many of them heavily myelinated, synapse around the small neurones in the principal sensory nucleus, which lies lateral to the motor nucleus and medial to the middle cerebellar peduncle, and is continuous inferiorly with the spinal nucleus of the trigeminal nerve. The principal nucleus

is considered to be mainly concerned with tactile stimuli. Other ascending fibres enter the mesencephalic nucleus, a column of unipolar cells with peripheral branches that may convey proprioceptive impulses from the masticatory muscles, and possibly also from the teeth, the facial and oculogyric muscles. Its neurones are unique in being the only primary sensory unipolar neurones that have cell bodies in the CNS. It is the relay for the 'jaw jerk', the only significant supraspinal monosynaptic reflex. Nerve fibres that ascend to the mesencephalic nucleus may give collaterals to the motor nucleus of the trigeminal nerve and to the cerebellum. Most fibres that arise in the trigeminal sensory nuclei cross the midline, ascend in the trigeminal lemniscus and end in the contralateral ventral posteromedial thalamic nucleus, from which third-order neurones project to the postcentral gyrus (areas 3, 1, 2).

Motor nucleus

The motor nucleus of the trigeminal nerve is ovoid in outline and lies in the upper pontine tegmentum, under the lateral part of the floor of the fourth ventricle. It lies medial to the principal sensory nucleus from which it is separated by fibres of the trigeminal nerve. It forms the rostral part of the pharyngeal (special visceral) efferent column. The motor nucleus contains characteristic large multipolar neurones interspersed with smaller multipolar cells, organized into a number of relatively discrete subnuclei that drive individual muscles. It receives fibres from both corticonuclear tracts. These fibres leave the tracts at the nuclear level or higher in the pons (aberrant corticospinal fibres), descend in the medial lemniscus and may end on motor neurones or interneurones. The motor nucleus receives afferents from the sensory nuclei of the trigeminal nerve, possibly including some from the mesencephalic nucleus, that form monosynaptic reflex arcs for proprioceptive control of the masticatory muscles. It also receives afferents from the reticular formation, red nucleus and tectum, the medial longitudinal fasciculus and possibly from the locus coeruleus. Collectively these represent pathways by which salivary secretion and mastication may be coordinated.

Tensor tympani and stapedius reflex

Loud sound elicits reflex contraction of tensor tympani and stapedius, attenuating movement of the tympanic membrane and the ossicular chain. Afferent impulses travel in the cochlear nerve to the cochlear nuclei in the brainstem. Efferent fibres to tensor tympani arise in the motor nucleus of the trigeminal nerve and travel in the mandibular division of the nerve. Efferent fibres to stapedius originate in the facial nucleus and travel in the facial nerve.

Jaw jerk reflex

The jaw jerk reflex is a deep tendon reflex, elicited by tapping on the midline of the mandible. Rapid stretching of the muscles that close the jaw (masseter, temporalis, medial pterygoid) activates muscle spindle afferents that travel via the mandibular division of the trigeminal nerve to the mesencephalic trigeminal nucleus. Collaterals project monosynaptically to the motor nucleus of the trigeminal nerve in the pons, establishing a two-neurone reflex arc.

Intra- and extracranial course

Embryologically, each division of the trigeminal nerve is associated with a developing facial process that gives rise to a specific area of the adult face: the ophthalmic nerve is associated with the frontonasal process, the maxillary nerve with the maxillary process, and the mandibular nerve with the mandibular process.

Ophthalmic nerve

The ophthalmic division of the trigeminal nerve is a sensory nerve. It arises from the trigeminal ganglion in the middle cranial fossa and passes forwards along the lateral dural wall of the cavernous sinus, giving off three main branches, the lacrimal, frontal and nasociliary nerves, just before it reaches the superior orbital fissure. These branches subsequently travel through the orbit to supply targets that are primarily in the upper part of the face (conjunctiva, skin over the forehead, upper eyelid and much of the external surface of the nose via the supraorbital, lacrimal, infratrochlear and external nasal nerves).

Lacrimal nerve

The lacrimal nerve is the smallest of the main ophthalmic branches. It enters the orbit through the superior orbital fissure, outside the common tendinous ring and lateral to the frontal and trochlear nerves. It passes forwards along the lateral wall of the orbit on the superior border of lateral rectus, and travels through the lacrimal gland and the orbital septum to supply the conjunctiva and skin covering the lateral part of the upper eyelid. The nerve also communicates with the zygomatic branch of the maxillary nerve, which may carry some postganglionic parasympathetic fibres from the pterygopalatine ganglion to the lacrimal gland. Occasionally, the lacrimal nerve is absent, in which case it is replaced by the zygomaticotemporal nerve; the relationship is reciprocal, and when the zygomaticotemporal nerve is absent it is replaced by a branch of the lacrimal nerve. The lacrimal nerve anastomoses with filaments of the facial nerve.

Frontal nerve

The frontal nerve is the largest branch of the ophthalmic nerve. It enters the orbit through the superior orbital fissure outside the common tendinous ring, and lies between the lacrimal nerve laterally and the trochlear nerve medially. It passes forwards towards the rim of the orbit on levator palpebrae superioris, and about halfway along this course it divides into the supraorbital and supratrochlear nerves.

Supraorbital nerve

The supraorbital nerve is the larger of the two terminal branches of the frontal nerve. It continues forwards along levator palpebrae superioris until it leaves the orbit through the supraorbital notch or foramen to emerge onto the forehead. It supplies the mucous membrane that lines the frontal sinus, the conjunctiva and the skin covering the upper eyelid via palpebral branches. It ascends on the forehead with the supraorbital artery, and divides into medial and lateral branches that supply the skin of the scalp nearly as far back as the lambdoid suture. These branches are at first deep to the frontal belly of occipitofrontalis. The medial branch perforates the muscle to reach the skin, while the lateral branch pierces the epicranial aponeurosis. The postganglionic sympathetic fibres that innervate the sweat glands of the supraorbital area probably travel in the supraorbital nerve, having entered the ophthalmic nerve via its communication with the abducens nerve within the cavernous sinus.

Supratrochlear nerve

The supratrochlear nerve is the smaller terminal branch of the frontal nerve. It runs anteromedially in the roof of the orbit, passes above the trochlea for the tendon of superior oblique, and supplies a descending filament to the infratrochlear branch of the nasociliary nerve. The nerve emerges between the trochlea and the supraorbital foramen at the frontal notch, curves up on the forehead close to the bone with the supratrochlear artery, and supplies the conjunctiva and the skin of the upper eyelid. It then ascends beneath corrugator and the frontal belly of occipitofrontalis before dividing into branches that pierce these muscles to supply the skin of the lower forehead near the midline.

Nasociliary nerve

The nasociliary nerve is intermediate in size between the frontal and lacrimal nerves. It is more deeply placed in the orbit, which it enters through the common tendinous ring, lying between the two rami of the oculomotor nerve. It crosses the optic nerve with the ophthalmic artery and runs obliquely below superior rectus and superior oblique to reach the medial orbital wall, where it gives off the anterior and posterior ethmoidal nerves. The nasociliary nerve has long ciliary and infratrochlear branches and a connection with the ciliary ganglion.

Anterior ethmoidal nerve

The anterior ethmoidal nerve passes through the anterior ethmoidal foramen and canal and enters the cranial cavity. It runs forwards in a groove on the upper surface of the cribriform plate beneath the dura mater, descends through a slit lateral to the crista galli into the nasal cavity, where it occupies a groove on the internal surface of the nasal bone, and supplies the roof of the nasal cavity. It gives off medial and lateral internal nasal branches that supply the anterior and upper parts of the septum and the anterior part of the lateral wall, respectively, before emerging at the inferior margin of the nasal bone as the external nasal nerve, which descends through the lateral wall of the nose and supplies the skin of the nose below the nasal bones to the nasal tip but excluding the alar portion around the external nares: damage following nasal trauma may result in paraesthesia of the nasal tip.

Posterior ethmoidal nerve

The posterior ethmoidal nerve leaves the orbit by the posterior ethmoidal foramen and supplies the ethmoidal and sphenoidal sinuses.

Infratrochlear nerve

The infratrochlear nerve leaves the orbit below the trochlea and supplies the skin of the eyelids, the conjunctiva, lacrimal sac, lacrimal caruncle and the side of the nose above the medial canthus.

Long ciliary nerves

Two or three long ciliary nerves branch from the nasociliary nerve as it crosses the optic nerve. They accompany the short ciliary nerves, pierce the sclera near the attachment of the optic nerve, and run forwards between the sclera and choroid. They supply the ciliary body, iris and cornea, and contain postganglionic sympathetic fibres for dilator pupillae from neurones in the superior cervical ganglion. An alternative pathway for the supply of the dilator pupillae is via the sympathetic root associated with the ciliary ganglion.

Ramus communicans to the ciliary ganglion

The ramus communicans to the ciliary ganglion usually branches from the nasociliary nerve as the latter enters the orbit lateral to the optic nerve. It is sometimes joined by a filament from the internal carotid sympathetic plexus or from the superior ramus of the oculomotor nerve as it enters the posterosuperior angle of the ganglion.

Maxillary nerve

The maxillary division of the trigeminal nerve is a sensory nerve. It leaves the skull via the foramen rotundum and enters the upper part of the pterygopalatine fossa where many of its extracranial branches are given off. It crosses the pterygopalatine fossa, giving off two large ganglionic branches that contain fibres destined for the nose, palate and pharynx and that all pass through the pterygopalatine ganglion without synapsing. The maxillary nerve then inclines sharply laterally on the posterior surface of the orbital process of the palatine bone and on the upper part of the posterior surface of the maxilla in the inferior orbital fissure (which is continuous posteriorly with the pterygopalatine fossa): it lies outside the orbital periosteum, and gives off zygomatic, and then posterior superior alveolar branches. About halfway between the orbital apex and the orbital rim, the maxillary nerve turns medially to enter the infraorbital canal as the infraorbital nerve. Named branches from the main trunk are meningeal, ganglionic, zygomatic, posterior, middle and anterior superior alveolar and infraorbital nerves. Named branches from the pterygopalatine ganglion are orbital, nasopalatine, posterior superior nasal, greater (anterior) palatine, lesser (posterior) palatine and pharyngeal nerves.

Meningeal nerve

The meningeal branch of the maxillary nerve arises within the middle cranial fossa and runs with the middle meningeal vessels. It contributes to the innervation of the dura mater (see Fig. 25.3B).

Ganglionic branches

Two ganglionic branches usually connect the maxillary nerve to the pterygopalatine ganglion.

Zygomatic nerve

The zygomatic branch of the maxillary nerve leaves the pterygopalatine fossa through the inferior orbital fissure with the maxillary nerve and lies close to the base of the lateral wall of the orbit. Soon after entering the orbit the nerve divides into two branches, the zygomaticotemporal and the zygomaticofacial nerves, which run within the orbit for only a short distance before passing onto the face through the lateral wall of the orbit. They may enter separate canals within the zygomatic bone or the zygomatic nerve itself may enter the bone before dividing.

Zygomaticotemporal nerve

The zygomaticotemporal nerve traverses a canal in the zygomatic bone and emerges into the anterior part of the temporal fossa, where it ascends between the bone and temporalis before piercing the temporal fascia about 2 cm above the zygomatic arch to supply the skin of the temple. It communicates with the facial and auriculotemporal nerves. As it pierces the deep layer of the temporal fascia, it sends a slender twig between the two layers of the fascia towards the lateral angle of the eye. It was thought that the branch carried parasympathetic postganglionic fibres from the pterygopalatine ganglion to the lacrimal gland, but it is now believed that these fibres innervate the lacrimal gland directly.

Zygomaticofacial nerve

The zygomaticofacial nerve traverses the inferolateral angle of the orbit and emerges on the face through a foramen in the zygomatic bone. It perforates orbicularis oculi to supply the skin on the prominence of the cheek and forms a plexus with zygomatic branches of the facial nerve and palpebral branches of the maxillary nerve. The nerve is absent occasionally.

Infraorbital nerve

The infraorbital nerve can be regarded as the terminal branch of the maxillary nerve. It leaves the pterygopalatine fossa to enter the orbit at the inferior orbital fissure and at first it lies in the infraorbital groove on the floor of the orbit. As it approaches the rim of the orbit it runs into the infraorbital canal through which it passes to emerge onto the face at the infraorbital foramen, where it lies between levator labii superioris and levator anguli oris. It gives off palpebral, nasal and superior labial branches. The palpebral branches ascend deep to orbicularis oculi, pierce the muscle to supply the skin in the lower eyelid, and join the facial and zygomaticofacial nerves near the lateral canthus. Nasal branches supply the skin of the side of the nose, the vestibule and the movable part of the nasal septum, and join the external nasal branch of the anterior ethmoidal nerve. Superior labial branches, which are large and numerous, descend behind levator labii superioris to supply the skin of the anterior part of the cheek and upper lip. They are joined by branches from the facial nerve to form the infraorbital plexus.

Orbital branches

Fine orbital branches enter the orbit through the inferior orbital fissure and supply orbital periosteum. Some fibres also pass through the posterior ethmoidal foramen to supply the sphenoidal and ethmoidal sinuses. The orbital branches probably join branches of the internal carotid nerve to form a 'retro-orbital' plexus from which orbital structures such as the lacrimal gland and orbitalis receive an autonomic innervation.

Posterior superior nasal nerves (lateral and medial)

The posterior superior alveolar nerves enter the back of the nasal cavity through the sphenopalatine foramen. Lateral posterior superior nasal nerves innervate the mucosa covering the posterior part of the superior and middle nasal turbinates (conchae) and lining the posterior ethmoidal sinuses. Two or three medial posterior superior nasal nerves cross the nasal roof below the opening of the sphenoidal sinus to supply the mucosa of the posterior part of the roof and of the nasal septum.

Nasopalatine nerve

The nasopalatine nerve leaves the pterygopalatine fossa through the sphenopalatine foramen and enters the nasal cavity. It passes across the cavity to the back of the nasal septum, runs downwards and forwards on the septum in a groove in the vomer, and then turns down through the incisive fossa in the anterior part of the hard palate to enter the roof of the mouth. When an anterior and a posterior incisive foramen exist in this fossa, the left nasopalatine nerve typically passes through the anterior foramen, and the right nerve passes through the posterior foramen. The nasopalatine nerve supplies the inferior part of the nasal septum and the anterior part of the hard palate, where it communicates with the greater palatine nerve.

Surgical division of the nasopalatine nerve, for example during the removal of an ectopic canine tooth, causes no obvious sensory deficit in the anterior part of the palate, which suggests that either the territory of the greater palatine nerve reaches as far forwards as the gingivae lingual to the incisor teeth or that the nasopalatine nerve has significant regenerative potential.

Palatine nerves (greater and lesser)

The greater and lesser palatine nerves pass downwards from the pterygopalatine ganglion through the greater palatine canal. The greater palatine nerve descends through the greater palatine canal, emerges on the hard palate from the greater palatine foramen and runs forwards in a groove on the inferior surface of the bony palate almost to the incisor teeth. It supplies the gingivae, mucosa and glands of the hard palate and also communicates with the terminal filaments of the nasopalatine nerve. In the greater palatine canal it gives off posterior inferior nasal branches that emerge through the perpendicular plate of the palatine bone and ramify over the inferior nasal turbinate (concha) and walls of the middle and inferior meatuses. As it leaves the greater palatine canal, it gives off branches which are distributed to both surfaces of the adjacent part of the soft palate.

The lesser (middle and posterior) palatine nerves are much smaller than the greater palatine nerve. They descend through the greater palatine canal, from which they diverge low down to emerge through the lesser palatine foramina in the tubercle or pyramidal process of the palatine bone. They innervate the uvula, tonsil and soft palate.

Fibres conveying taste impulses from the palate probably pass via the palatine nerves to the pterygopalatine ganglion. They pass through the ganglion without synapsing, and leave via the greater petrosal nerve. Their cell bodies are located in the facial ganglion and their central processes pass via the sensory root of the facial nerve (nervus intermedius) to the gustatory nucleus in the nucleus of the tractus solitarius.

Pharyngeal nerve

The pharyngeal branch of the maxillary nerve leaves the pterygopalatine ganglion posteriorly. It passes through the palatovaginal canal with the

pharyngeal branch of the maxillary artery and supplies the mucosa of the nasopharynx behind the pharyngotympanic tube.

Superior alveolar nerves

The teeth in the upper jaw are supplied by the three superior alveolar (dental) nerves that arise from the maxillary nerve either in the pterygopalatine fossa or in the infraorbital groove and canal.

The posterior superior alveolar (dental) nerve leaves the maxillary nerve in the pterygopalatine fossa and runs anteroinferiorly to pierce the infratemporal surface of the maxilla, at which point it is possible to perform a local anaesthetic block that will anaesthetize the pulps of the premolar and molar ipsilateral teeth; it then descends under the mucosa of the maxillary sinus. After supplying the lining of the sinus, the nerve divides into small branches that link up as the molar part of the superior alveolar plexus, supplying twigs to the molar teeth. It also supplies a branch to the upper molar gingivae and the adjoining part of the cheek.

The middle superior alveolar (dental) nerve arises from the infraorbital nerve as it runs in the infraorbital groove, and runs downwards and forwards in the lateral wall of the maxillary sinus. It ends in small branches that link up with the superior dental plexus, supplying small rami to the upper premolar teeth. This nerve is variable; it may be duplicated, triplicated, or absent.

The anterior superior alveolar (dental) nerve leaves the lateral side of the infraorbital nerve near the midpoint of its canal and traverses the canalis sinuosus in the anterior wall of the maxillary sinus. It curves first under the infraorbital foramen, then passes medially towards the nose, and finally turns downwards and divides into branches to supply the incisor and canine teeth. It assists in the formation of the superior dental plexus and gives off a nasal branch that passes through a minute canal in the lateral wall of the inferior meatus to supply the mucous membrane of the anterior area of the lateral wall as high as the opening of the maxillary sinus, and the floor of the nasal cavity near the anterior nasal spine. It communicates with the nasal branches of the pterygopalatine ganglion and finally emerges near the root of the anterior nasal spine to supply the adjoining part of the nasal septum.

Mandibular nerve

The mandibular division of the trigeminal nerve is the largest division of the trigeminal nerve and is a mixed nerve. Its sensory branches supply the mandibular teeth and gingivae, the skin in the temporal region, part of the auricle and the lower lip, the lower part of the face and the mucosa of the anterior two-thirds (presulcal part) of the tongue and the floor of the oral cavity. The motor branches innervate the muscles of mastication, tensor veli palatini, tensor tympani, anterior belly of digastric and mylohyoid. The large sensory root emerges from the lateral part of the trigeminal ganglion and exits the cranial cavity through the foramen ovale. The small motor root passes under the ganglion and through the foramen ovale to unite with the sensory root just outside the skull. As it descends from the foramen ovale, the mandibular nerve is usually around 4 cm from the surface and a little anterior to the neck of the mandible. It immediately passes between tensor veli palatini, which is medial, and lateral pterygoid, which is lateral, gives off a meningeal branch and the nerve to medial pterygoid from its medial side, and then divides into a small anterior and large posterior trunk. The anterior trunk gives off branches to the four main muscles of mastication and a buccal branch which is sensory to the cheek. The posterior trunk gives off three main sensory branches, the auriculotemporal, lingual and inferior alveolar nerves, and motor fibres to supply mylohyoid and the anterior belly of digastric.

Meningeal branch (nervus spinosus)

The meningeal branch re-enters the middle cranial fossa through the foramen spinosum with the middle meningeal artery. It divides into anterior and posterior branches that accompany the main divisions of the middle meningeal artery and supply the dura mater in the middle cranial fossa and, to a lesser extent, in the anterior fossa and calvaria (see Fig. 25.3B).

Nerve to medial pterygoid

The nerve to medial pterygoid is a slender ramus that enters the deep aspect of the muscle. It supplies one or two filaments that pass through the otic ganglion without interruption to supply tensor tympani and tensor veli palatini.

Anterior trunk of mandibular nerve

The anterior trunk of the mandibular nerve gives rise to the buccal nerve, which is sensory, and the masseteric, deep temporal and lateral pterygoid nerves, which are all motor.

Buccal nerve

The buccal nerve passes between the two heads of lateral pterygoid, giving off motor fibres to the muscle as it passes through it. The nerve then descends deep to the tendon of temporalis, passes laterally anterior to masseter, and anastomoses with the buccal branches of the facial nerve. It may give off the anterior deep temporal nerve. The buccal nerve supplies sensation to the skin over the anterior part of buccinator, the corresponding buccal mucous membrane and the posterior part of the buccal gingivae opposite the second and third molar teeth. It may also give off a branch that passes through a small retromolar foramen to supply the molar teeth.

Nerve to masseter

The nerve to masseter passes laterally above lateral pterygoid onto the skull base, anterior to the temporomandibular joint and posterior to the tendon of temporalis. It crosses the posterior part of the mandibular notch with the masseteric artery and ramifies on and enters the deep surface of masseter. It provides articular branches to the temporomandibular joint.

Deep temporal nerves

There are usually two deep temporal nerves, anterior and posterior, although there may be a middle branch. They pass above lateral pterygoid to enter the deep surface of temporalis. The anterior branch may arise as a branch of the buccal nerve or from the nerve to masseter; the small posterior nerve sometimes arises in common with the nerve to masseter. Branches from the buccal nerve and the nerve to masseter may supply the inferior aspect of temporalis independently from the deep temporal nerves.

Nerve to lateral pterygoid

The nerve to lateral pterygoid enters the deep surface of the muscle. It may arise separately from the anterior division of the mandibular nerve or from the buccal nerve.

Posterior trunk of mandibular nerve

The posterior trunk of the mandibular nerve is larger than the anterior and is mainly sensory, although it receives fibres from the motor root for the nerve to mylohyoid. It divides into auriculotemporal, lingual and inferior alveolar (dental) nerves.

Auriculotemporal nerve

The auriculotemporal nerve usually has two roots that encircle the middle meningeal artery. It runs back under lateral pterygoid on the surface of tensor veli palatini, passes between the sphenomandibular ligament and the neck of the mandible, and then runs laterally behind the temporomandibular joint related to the upper part of the parotid gland. Emerging from behind the joint, it ascends over the posterior root of the zygoma, posterior to the superficial temporal vessels, and divides into superficial temporal branches. It communicates with the facial nerve and otic ganglion. The rami to the facial nerve, usually two, pass anterolaterally behind the neck of the mandible to join the facial nerve at the posterior border of masseter. Filaments from the otic ganglion join the roots of the auriculotemporal nerve close to their origin. The auriculotemporal nerve emerges onto the face behind the temporomandibular joint within the superior surface of the parotid gland, ascends posterior to the superficial temporal vessels, passes over the posterior root of the zygoma, and divides into superficial temporal branches. The cutaneous branches of the auriculotemporal nerve supply the tragus and part of the adjoining auricle of the ear and the posterior part of the temple. The nerve may be damaged during parotid gland surgery, resulting in impaired sensation over the tragus and temple. The auriculotemporal nerve communicates with the temporofacial division of the facial nerve, usually by two rami that pass anterolaterally behind the neck of the mandible. These communications anchor the facial nerve close to the lateral surface of the condylar process of the mandible and limit its mobility during surgery. Communications with the temporal and zygomatic branches of the facial nerve loop around the transverse facial and superficial temporal vessels.

Lingual nerve

The lingual nerve is sensory to the mucosa of the floor of the mouth, mandibular lingual gingivae and mucosa of the presulcal part of the tongue (excluding the circumvallate papillae, which are supplied by the glossopharyngeal nerve). It also carries postganglionic parasympathetic fibres from the submandibular ganglion to the sublingual and anterior lingual glands. It arises from the posterior trunk of the mandibular nerve and at first runs beneath lateral pterygoid and superficial to tensor veli palatini, where it is joined by the chorda tympani branch of the

facial nerve, and often by a branch of the inferior alveolar nerve. Emerging from under cover of lateral pterygoid, the lingual nerve then runs downwards and forwards on the surface of medial pterygoid, and is thus carried progressively closer to the medial surface of the mandibular ramus. It becomes intimately related to the bone a few millimetres below and behind the junction of the vertical ramus and horizontal body of the mandible. Here it lies anterior to, and slightly deeper than, the inferior alveolar (dental) nerve. It next passes below the mandibular attachment of the superior pharyngeal constrictor and pterygomandibular raphe, closely applied to the periosteum of the medial surface of the mandible, until it lies opposite the posterior root of the lower third molar tooth, where it is covered only by the gingival mucoperiosteum. At this point it usually lies approximately 3 mm below the alveolar crest with a mean distance from the bone of 2 mm: it may be in direct contact with the bone (25%) or lie above the alveolar crest (15%). The nerve next passes medial to the mandibular origin of mylohyoid, and this carries it progressively away from the mandible, separating it from the alveolar bone covering the mesial root of the lower third molar tooth. It then passes downwards and forwards on the deep surface of mylohyoid (i.e. the surface nearer the mucosa covering the floor of the mouth), crossing the lingual sulcus beneath the mucosa. In this position, the lingual nerve lies on the deep portion of the submandibular gland, which bulges over the top of the posterior border of mylohyoid. The nerve passes below the submandibular duct, which crosses it from medial to lateral, and curves upwards, forwards and medially to enter the tongue by medial and lateral branches. Within the tongue, the medial branch sends small branches to the medial part of the ventrolateral tongue, and the lateral branch runs along the lateral border of the tongue and sends larger branches to innervate the mucosa of the anterior tip of the tongue. The lingual nerve is connected to the submandibular ganglion by two or three branches. It forms connecting loops with twigs of the hypoglossal nerve at the anterior margin of hyoglossus (Fitzgerald and Law 1958) and within the tongue (Zur et al 2004).

The lingual nerve is at risk during surgical removal of (impacted) lower third molars: patients occasionally develop lingual sensory disturbance postoperatively but this is rarely persistent (Renton 2011). The nerve is also at risk during operations to remove the submandibular salivary gland because the submandibular duct must be dissected from the lingual nerve, and also because its connection to the submandibular ganglion pulls it into the operating field.

Inferior alveolar (dental) nerve

The inferior alveolar nerve descends behind lateral pterygoid. At the lower border of the muscle the nerve passes between the sphenomandibular ligament and the mandibular ramus and enters the mandibular canal via the mandibular foramen. Just before entering the mandibular canal, the inferior alveolar nerve gives off a small mylohyoid branch that also carries fibres that innervate the anterior belly of digastric. Below lateral pterygoid, the nerve is accompanied by the inferior alveolar artery, a branch of the first part of the maxillary artery, which enters the canal with its associated veins. In the mandibular canal, the inferior alveolar nerve runs downwards and forwards, generally below the apices of the teeth until it is below the first and second premolars, where it divides into terminal incisive and mental branches. The incisive branch continues forwards in a bony canal or in a plexiform arrangement, giving off branches to the first premolar, canine and incisor teeth, and to the associated labial gingivae. The lower central incisor teeth receive a bilateral innervation, fibres probably crossing the midline within the periosteum to re-enter the bone via numerous canals in the labial cortical plate. The mental nerve passes upwards, backwards and outwards to emerge from the mandible via the mental foramen between and just below the apices of the premolar teeth. It immediately divides into three branches, two of which pass upwards and forwards to form an incisor plexus labial to the teeth that supplies the labial gingivae (and probably the periosteum). From this plexus and from the dental branches, fibres turn downwards and then lingually to emerge on the lingual surface of the mandible on the posterior aspect of the mental symphysis or opposite the premolar teeth, probably communicating with the lingual or mylohyoid nerves. The third branch of the mental nerve passes through the intermingled fibres of depressor anguli oris and platysma to supply the skin of the lower lip and chin. Branches of the mental nerve communicate with terminal filaments of the mandibular branch of the facial nerve.

Nerve to mylohyoid

The nerve to mylohyoid is given off from the inferior alveolar nerve just before that nerve enters the mandibular canal. It pierces the sphenomandibular ligament and enters a shallow groove on the medial surface of the mandible, following a course roughly parallel to its parent nerve. It passes below the origin of mylohyoid to lie on the superficial surface of the muscle, between it and the anterior belly of digastric, both of which it supplies. Although primarily a motor nerve supplying mylohyoid and the anterior belly of digastric, the mylohyoid nerve carries some sensory fibres that may enter the mandible via one or more small retromental foramina in the vicinity of the genial tubercles to supply some sensation to the anterior teeth, and it may also give a few filaments to supply the skin over the point of the chin.

Dental extractions

Variations in the fascicular organization of the inferior alveolar nerve are clinically important when extracting impacted third molars. The nerve may appear as a single bundle lying a few millimetres below the roots of the teeth, or it may lie much lower and almost reach the lower border of the bone, so that it gives off a variable number of large rami that pass anterosuperiorly towards the roots before dividing to supply the teeth and interdental septa. Only rarely is it plexiform. The nerve may lie on the lingual or buccal side of the mandible (slightly more commonly on the buccal side). Even when the third molar tooth is in a normal position, the nerve may be so intimately related to it that it grooves its root. Exceptionally, the nerve may be similarly related to the second molar tooth.

Failure to achieve complete anaesthesia to the mandibular teeth following an inferior alveolar nerve block (which should anaesthetize the nerve before it enters the mandibular canal) suggests that there are alternative pathways for sensory nerves to innervate the teeth. Knowledge of these pathways is important in helping clinicians to obtain complete dental anaesthesia. There are anatomical variations in the distribution of the inferior alveolar nerve, the buccal branch of the mandibular nerve, the mylohyoid nerve, the lingual nerve, the deep temporal nerves and the cervical plexus. The inferior alveolar nerve may give multiple branches before entering the mandibular canal that may re-enter the mandible via small accessory foramina in the retromolar region to supply sensation to the molar teeth: one or more of these branches may escape anaesthesia following inferior alveolar nerve block. If a successful inferior alveolar nerve block does not completely anaesthetize teeth in a jaw quadrant, additional local injections of anaesthetic solution around the tooth in question may be necessary to block alternative pathways. There is also the possibility of overlap across the midline involving the incisive and mylohyoid nerves. In children, there is evidence to suggest that the lingula is variable in position and its position from the occlusion plane increases with age: it is therefore not considered an appropriate landmark for inferior alveolar nerve block.

Neural connections between branches of trigeminal and other nerves

Communications exist between the inferior alveolar and lingual nerves. If the lingual nerve is not anaesthetized during an inferior alveolar nerve block, this pathway could account for any remaining sensation in the teeth. Although the deep temporal nerves are primarily motor, it has been suggested that terminal branches may pass from the substance of temporalis to enter the mandible through foramina in the retromolar region to supply some sensation to molar teeth. In the cervical plexus, the great auricular nerve, formed by the anterior primary rami of the second and third cervical spinal nerves, supplies skin over the angle of the mandible: it is possible that this nerve may provide a branch that penetrates the mandible to supply one or more of the cheek teeth.

ABDUCENS NERVE

The abducens nerve is the sixth cranial nerve and innervates the ipsilateral lateral rectus.

Abducens nucleus and central connections

The abducens nucleus lies in the floor of the fourth ventricle, just lateral to the midline, immediately subjacent to the facial colliculus and slightly lateral to the medial longitudinal fasciculus (see Fig. 28.4). The abducens nucleus is composed of approximately 6500 neurones that align with the trochlear, oculomotor and hypoglossal nuclei to form the general somatic efferent column (GSE). Within the nucleus, large motor neurones are intermixed with small multipolar interneurones, the latter being most heavily concentrated in the lateral and ventral aspects of the nucleus. The abducens nucleus receives afferent connections from multiple sources, including corticonuclear fibres (principally contralateral, some of the fibres are aberrant corticospinal fibres that descend from the midbrain to this level in the medial lemniscus); the medial longitudinal fasciculus (connecting the abducens nucleus to oculomotor,

trochlear and vestibular nuclei); the tectobulbar tract (from the deep layers of the superior colliculus); the paramedian pontine reticular formation (rostral and caudal to the nucleus); the nucleus prepositus hypoglossi; and the contralateral medullary reticular formation.

Neural Control of Gaze

Although the detailed anatomical substrates for the different types of eye movement differ, they share common neural circuitry that lies mainly in the pons and midbrain, for horizontal and vertical gaze movements, respectively (see Fig. 44.12). The common element for all types of horizontal gaze movements is the abducens nucleus. It contains motor neurones that innervate the ipsilateral lateral rectus and interneurones that project via the medial longitudinal fasciculus to the contralateral oculomotor nucleus, which controls medial rectus. A lesion of the abducens nucleus leads to a total loss of ipsilateral horizontal conjugate gaze. A lesion of the medial longitudinal fasciculus produces slowed or absent adduction of the ipsilateral eye, usually associated with jerky movements (nystagmus) of the contralateral abducting eye, a syndrome called internuclear ophthalmoplegia (Leigh and Zee 2015). The gaze motor command involves specialized areas of the reticular formation of the brainstem, which receive a variety of supranuclear inputs. The main region for the generation of horizontal saccades is the paramedian pontine reticular formation, located on each side of the midline in the central paramedian part of the tegmentum, and extending from the pontomedullary junction to the pontopeduncular junction. Each paramedian pontine reticular formation contains excitatory neurones (referred to as 'burst' neurones) that discharge at high frequencies just prior to and during ipsilateral saccades. Excitatory burst neurones make monosynaptic connections with the ipsilateral abducens nucleus. Omnipause neurones in the pontine nucleus raphe interpositus, located in the midline between the rootlets of the abducens nerves, discharge tonically during fixation but stop firing immediately prior to a saccade. They appear to exert an inhibitory influence on the burst neurones and act as a switch to change from fixation to saccadic mode (Ramat et al 2007).

The tonic activity of neurones in the nucleus prepositus hypoglossi and medial vestibular nucleus is thought to provide an eye position signal to maintain the eccentric position of the eye against the viscoelastic forces in the orbit. These forces tend to move the eyeball back to looking straight ahead, i.e. the primary position, after a saccade. Vestibular nuclei and the perihypoglossal complex project directly to the abducens nuclei: these projections probably also carry smooth pursuit signals, via the cerebellum.

The final common pathway for vertical gaze movements is formed by the oculomotor and trochlear nuclei. The rostral interstitial nucleus of the medial longitudinal fasciculus contains both excitatory burst neurones that discharge in relation to up-and-down vertical saccadic movements and project to motor neurones involved in vertical gaze, and omnipause neurones that act similarly to those for horizontal gaze. The rostral interstitial nucleus of the medial longitudinal fasciculus projects through the posterior commissure to its equivalent on the other side of the mesencephalon for upgaze, as well as directly to the ipsilateral oculomotor and trochlear nuclei for downgaze (see Fig. 44.12). Neurones in and around the interstitial nucleus of Cajal, which lies slightly caudal to the rostral interstitial nucleus of the medial longitudinal fasciculus, provide signals for vertical gaze holding. Vertical gaze palsies can affect upgaze, downgaze or both. Lesions within the posterior commissure predominantly give rise to disturbances in upgaze, associated with other signs of dorsal midbrain syndrome, e.g. pupillary abnormalities (light–near dissociation). Discrete lesions placed more ventrally in the region of the rostral interstitial nucleus of the medial longitudinal fasciculus may cause mixed up-and-down, or mainly downgaze disturbances (Leigh and Zee 2015).

Intra- and extracranial course

The axons of the motor neurones in the abducens nucleus spread diffusely from the ventromedial aspect of the nucleus. Fifteen to twenty fascicles pass ventrally, laterally and caudally, directly through the intervening reticular formation, trapezoid body, medial lemniscus, pontocerebellar fibres, pontine nuclei and descending corticospinal tracts to emerge from the brainstem at the pontomedullary sulcus about 1–2 cm lateral to the midline. In their course, the rootlets typically coalesce to emerge from the brainstem as a compact bundle of fibres. Occasionally all or some of the rootlets may emerge rostral to the pontomedullary sulcus. The nerve runs upward, anteriorly and slightly laterally across the prepontine cistern between the pons and clivus, pierces the inner layer of dura mater and runs through the inferior venous compartment of the petroclival venous confluence in a bow-shaped canal, Dorello's canal. It then bends sharply across the upper border of the petrous part of the temporal bone to enter the cavernous sinus, where it lies lateral to the cavernous segment of the internal carotid artery but medial to the oculomotor, trochlear, ophthalmic and maxillary nerves that also course through the sinus (but merely invaginate the lateral dural wall of the sinus). The abducens nerve enters the orbit through the inferomedial part of the superior orbital fissure, within the common tendinous ring, at first below, and then between, the two divisions of the oculomotor nerve and lateral to the nasociliary nerve (see Fig. 44.15). It passes forwards to enter the medial (ocular) surface of lateral rectus, most often in the posterior one-third of the muscle (Joo et al 2012).

FACIAL NERVE

The facial nerve is the seventh cranial nerve. It contains special visceral/branchial efferent (SVE) motor axons that supply muscles derived from the second branchial arch, namely the mimetic facial muscles, buccinator, stapedius, platysma, the posterior belly of digastric and stylohyoid. The craniofacial muscles innervated by the facial nerve typically lack muscle spindles: proprioceptive information may be mediated by modified cutaneous mechanoreceptors or capsular corpuscle-like structures within the muscles. The facial nerve contains two, possibly three, types of sensory axon. Special visceral afferent (SVA) axons carry taste from the anterior two-thirds of the tongue via the chorda tympani, and general sensory afferent (GSA) axons carry cutaneous sensation, including pain, from the posterior aspect of the external acoustic meatus, with the caveat that the innervation of this region is complex and largely contributed by Arnold's nerve: these axons are thought to be responsible for coughing during cerumen removal, idiopathic otalgia, Hitselberger's sign and to be the site of vesicular eruptions in Ramsay Hunt syndrome.

General visceral efferent (GVE) fibres in the facial nerve arise from preganglionic parasympathetic neurones in the superior salivatory nucleus and pass via either the chorda tympani to the submandibular ganglion or the greater petrosal nerve and the nerve of the pterygoid canal to the pterygopalatine ganglion. The GVE, SVA, GSA axons form the nervus intermedius (intermediate nerve, nerve of Wrisberg).

Facial nucleus and central connections

The facial (motor) nucleus is situated caudal, ventral and lateral to the abducens nucleus. It lies within the caudal pontine reticular formation, ventromedial to the spinal tract and nucleus of the trigeminal nerve (see Figs 28.11, 28.13) (Haines and Mihailoff 2017). Groups of neurones form columns that innervate individual muscles or that correspond to branches of the facial nerve. The facial nucleus receives corticonuclear fibres for volitional control of the facial musculature. Within the nucleus, neurones that innervate the muscles of the scalp and upper face are innervated by bilateral corticonuclear fibres. They lie dorsal to the neurones that innervate the muscles of the lower face, which receive a predominately contralateral innervation. Clinically, therefore, upper and lower motor neurone lesions affecting the facial nerve can be differentiated because upper motor neurone lesions cause paralysis that is confined to the contralateral lower face (supranuclear facial palsy), whilst lower motor neurone lesions cause complete ipsilateral facial paralysis (Bell's palsy). The facial nucleus also receives ipsilateral afferents from the nucleus solitarius and from the sensory nucleus of the trigeminal nerve, establishing important reflex connections.

Efferent fibres that arise from large motor neurones of the facial nucleus form the motor root of the facial nerve. At first, the facial fibres course dorsomedially towards the floor of the fourth ventricle as a diffuse spread of fibres that pass dorsal and medial to the abducens nucleus. They then coalesce into a defined fibre bundle that re-curves dorsally and laterally over the rostral pole of the abducens nucleus, creating a bulge in the floor of the fourth ventricle, the facial colliculus (see Fig. 28.11). The fibres descend ventrolaterally through the reticular formation and pass between their nucleus of origin medially and the nucleus of the spinal tract of the trigeminal nerve laterally. The facial nerve emerges from the brainstem at the supraolivary fossette, between the olive and restiform body, and passes laterally through the cerebellopontine angle cistern to the porus acusticus of the internal acoustic meatus (internal auditory canal).

Intracranial and intratemporal course

The facial nerve has intracranial (cisternal), intratemporal and extratemporal portions. The intratemporal portion is further divided into meatal, labyrinthine, tympanic (horizontal) and mastoid (vertical) segments (see

Fig. 42.12). The cisternal portion emerges from the ventrolateral aspect of the caudal border of the pons. The meatal portion enters the porus acusticus of the internal acoustic meatus accompanied by the nervus intermedius, the vestibulocochlear nerve and the labyrinthine vessels. In this part of its course, the facial nerve lacks a fibrous sheath or endoneurium and is surrounded by a thin layer of arachnoid. The motor root, which supplies the muscles of the face, and the nervus intermedius, which contains sensory fibres concerned with the perception of taste and parasympathetic (secretomotor) fibres to various glands, are still separate components; they usually merge within the meatus. The labyrinthine segment runs from the fundus of the internal acoustic meatus to the geniculate ganglion, where the nerve makes the first bend or genu (see Fig. 42.12). The labyrinthine segment is the shortest and narrowest part of the facial nerve; its lack of anastomosing arterial cascades renders it susceptible to vascular compression. The tympanic part initially curves around the oval window niche, then lies just anterior and inferior to the lateral semicircular canal and bends again at the second genu to become the vertical or mastoid part. The mastoid part is the longest of the petrous segments and runs from the pyramidal process to the stylomastoid foramen. The tympanic and mastoid segments of the facial nerve are supplied by the facial arch, formed by the petrosal branch of the middle meningeal artery and the stylomastoid branch of the posterior auricular artery.

The branches that arise from the facial nerve within the temporal bone can be divided into those that come from the geniculate ganglion (greater petrosal nerve) and those that arise within the facial canal (nerve to stapedius and chorda tympani).

Greater petrosal nerve

The greater (superficial) petrosal nerve, a branch of the nervus intermedius, is the main branch from the geniculate ganglion. It passes anteriorly, receives a branch from the tympanic plexus and traverses a hiatus on the anterior surface of the petrous part of the temporal bone. It enters the middle cranial fossa, runs forwards in a groove on the bone above the lesser petrosal nerve, and then passes beneath the trigeminal ganglion to reach the foramen lacerum. Here it is joined by the deep petrosal nerve from the internal carotid sympathetic plexus, to become the nerve of the pterygoid canal (Vidian nerve). The greater petrosal nerve contains parasympathetic fibres destined for the pterygopalatine ganglion, and taste fibres from the palate. The geniculate ganglion also communicates with the lesser petrosal nerve.

Nerve to stapedius

The nerve to stapedius arises from the facial nerve in the facial nerve canal behind the pyramidal eminence of the posterior wall of the tympanic cavity and passes forwards through a small canal to reach the muscle.

Chorda tympani

The chorda tympani (see Figs 42.11, 42.12) leaves the facial nerve some 6 mm above the stylomastoid foramen and runs anterosuperiorly in a canal to enter the tympanic cavity via the posterior canaliculus. It then curves anteriorly in the substance of the tympanic membrane between its mucous and fibrous layers, and crosses medial to the upper part of the handle of the malleus to the anterior wall of the tympanic cavity, where it enters the anterior canaliculus. It exits the skull and enters the infratemporal fossa by passing through the medial end of the petrotympanic fissure posterior to the capsule of the temporomandibular joint. It next descends medial to the spine of the sphenoid bone, which it sometimes grooves, lying posterolateral to tensor veli palatini. It is crossed medially by the middle meningeal artery, the roots of the auriculotemporal nerve and the inferior alveolar nerve (see Fig. 38.23) and joins the posterior aspect of the lingual nerve at an acute angle. The chorda tympani carries taste fibres from the anterior two-thirds of the tongue (but not the from the circumvallate papillae) and efferent preganglionic parasympathetic secretomotor fibres destined for the submandibular ganglion in the floor of the mouth.

Dehiscences of the facial nerve canal

The facial nerve may be somewhat variable in its anatomical course through the temporal bone (Proctor and Nager 1982, Proctor 1991). It may split into two or three strands, starting at the geniculate ganglion, and then make its way across the promontory to the stylomastoid foramen, or pass a few millimetres posteriorly to its second genu, before it turns inferiorly posterior to the fossa incudis, a position where it is particularly vulnerable during surgical exploration of the mastoid antrum. The more proximal the division into strands, the more bizarre is the subsequent course. More distal bifurcations pass either side of the fenestra vestibuli. It may be dehiscent, particularly in its second part, when it occasionally overhangs the stapes, or run inferior to the stapedial superstructure, a position that renders it vulnerable during surgery to the stapes (Barnes et al 2001). The motor fibres to the face may be carried through the chorda tympani, which is then enlarged. When this is the case, the distal facial nerve dwindles to a fibrous strand in a narrowed stylomastoid foramen. In chronic bone disease in the tympanic cavity, the facial nerve may be exposed in its canal. Inflammation may lead to facial paralysis of the infranuclear or lower motor neurone type.

Extratemporal course

The facial nerve emerges from the base of the skull at the stylomastoid foramen and almost immediately gives off the nerves to the posterior belly of digastric and stylohyoid and the posterior auricular nerve, which supplies the occipital belly of occipitofrontalis and some of the intrinsic auricular muscles (see Fig. 36.23). The nerve next enters the parotid gland high up on its posteromedial surface and passes forwards and downwards behind the mandibular ramus. Within the substance of the gland, it branches into superior (temporofacial) and inferior (cervicofacial) trunks, usually just behind and superficial to the retromandibular vein. The trunks branch further to form a parotid plexus (pes anserinus). Five main terminal branches arise from the plexus, diverge within the gland and leave by its anteromedial surface, medial to its anterior margin, to supply the muscles of facial expression (see Fig. 36.23). Six distinctive anastomotic patterns were originally classified by Davis et al (1956) and these are illustrated in Fig. 36.24. Numerous microdissection studies have demonstrated considerable individual variation in branching patterns and anastomoses between branches, both within the parotid and on the face (e.g. Lineaweaver et al 1997, Kwak et al 2004): the account that follows is therefore an overview. In surgical terms, these anastomoses are important and presumably explain why accidental or deliberate division of a small branch often fails to result in the expected facial nerve weakness.

The temporal branch usually divides into anterior and posterior rami soon after piercing the parotidomasseteric fascia below the zygomatic arch; there is often a middle (frontal) ramus. These rami cross the arch in subcutaneous tissue, lying in the subgaleal space: their course is extremely variable.

Twigs supply intrinsic muscles on the lateral surface of the auricle and the anterior and superior auricular muscles. They communicate with the zygomaticotemporal branch of the maxillary nerve and the auriculotemporal branch of the mandibular nerve. The more anterior branches supply the frontal belly of occipitofrontalis, orbicularis oculi and corrugator and join the supraorbital and lacrimal branches of the ophthalmic nerve.

Zygomatic branches

Zygomatic branches are generally multiple. They cross the zygomatic bone to the lateral canthus of the eye and supply orbicularis oculi and may also supply muscles innervated by the buccal branch. Twigs communicate with filaments of the lacrimal nerve and the zygomaticofacial branch of the maxillary nerve.

Buccal nerve

The buccal branch of the facial nerve is usually single. It has a close relationship to the parotid duct for about 2.5 cm after emerging from the parotid gland and typically lies below the duct. Superficial branches run beneath the subcutaneous fat and the superficial musculo-aponeurotic system (SMAS). Some branches pass deep to procerus and join the infratrochlear and external nasal nerves. Upper deep branches supply zygomaticus major and levator labii superioris and form an infraorbital plexus with the superior labial branches of the infraorbital nerve. They also supply levator anguli oris, zygomaticus minor, levator labii superioris alaeque nasi and the small nasal muscles (these branches are sometimes described as lower zygomatic branches). Lower deep branches supply buccinator and orbicularis oris and communicate with filaments of the buccal branch of the mandibular nerve.

Marginal mandibular nerve

There are usually two marginal mandibular nerves. They run forwards towards the angle of the mandible under platysma, and then turn upwards across the body of the mandible to pass under depressor anguli oris. The branches supply risorius and the muscles of the lower lip and chin. Filaments communicate with the mental nerve. The marginal mandibular branch has an important surgical relationship with the inferior border of the mandible.

Cutaneous branches

Cutaneous branches of the facial nerve accompany the auricular branch of the vagus and probably supply small areas on both aspects of the auricle, in the depression of the concha and over its eminence.

The facial nerve has intra- or extracranial connections with the cutaneous branches of all three divisions of the trigeminal nerve (including branches of the auriculotemporal, buccal, mental, lingual, infraorbital, zygomatic and ophthalmic nerves); with branches of the vestibulocochlear, glossopharyngeal and vagus nerves; and with branches of the cervical plexus (including the great auricular, greater and lesser occipital and transverse cervical nerves). These cutaneous connections are significant in facilitating the perineural spread of tumours that arise either within the parotid or on the face and explains why some patients with perineural spread from cutaneous or parotid malignancies may present with vocal cord palsy.

Cervical branch

The cervical branch of the facial nerve emerges from the lower part of the parotid gland and runs anteroinferiorly under platysma to the anterior neck. Typically single, it supplies platysma and communicates with the transverse cutaneous cervical nerve.

Lesions of the facial nerve

Facial paralysis may be due to an upper motor neurone lesion (when frontalis is partially spared because of the bilateral cortical representation of the muscles of the upper part of the face) or a lower motor neurone lesion (when all branches may be involved). Lower motor neurone facial paralysis is most commonly idiopathic (Bell's palsy). There are a large number of other recognized causes that include geniculate herpes zoster (Ramsay Hunt syndrome), and malignant tumours of the parotid gland and temporal bone. Iatrogenic damage also accounts for a significant number of palsies, most often acquired in vestibular schwannoma, parotid and middle ear or mastoid surgery.

Bell's palsy

Bell's palsy is an idiopathic lower motor neurone facial palsy. It may be complete or partial, and is characterized by a flaccid paralysis of the ipsilateral mimetic facial muscles (muscles of facial expression); decreased lacrimation in the ipsilateral eye (which is controlled by neurones in the greater petrosal nerve); and hyperacusis or decreased tolerance of loud noises in the ipsilateral ear as a result of paralysis of stapedius. Its cause remains the subject of speculation but is most probably a herpes virus infection (Zandian et al 2014). Magnetic resonance imaging studies suggest that there are inflammatory changes in the labyrinthine and perigeniculate segments of the facial nerve. In the vast majority of cases, spontaneous full recovery takes place after a few weeks.

VESTIBULOCOCHLEAR NERVE

The vestibulocochlear nerve is the eighth cranial nerve. As its name suggests, it consists of two components, the vestibular nerve, concerned with balance, and the cochlear nerve, concerned with hearing.

Vestibular nuclei and central connections

The vestibular nuclear complex is situated beneath the floor of the fourth ventricle. It has traditionally been divided into four cellular masses, the lateral nucleus (of Deiter), medial nucleus (of Schwalbe), superior nucleus (of Bechterew) and inferior (spinal, descending) vestibular nucleus (see Figs 28.8, 28.11) (Haines and Mihailoff 2017). The nucleus prepositus hypoglossi, located medial to the medial vestibular nucleus, may also be regarded as a vestibular nucleus. Cell groups X and Y have been identified as accessory nuclei of the vestibular complex.

The medial vestibular nucleus is the largest of the vestibular nuclei. It lies lateral and superior to the visceromotor nuclei of the glossopharyngeal and vagus nerves, is crossed dorsally by the striae medullares of the fourth ventricle and is continuous with the nucleus intercalatus below. The superior vestibular nucleus is small and lies above the medial and lateral nuclei. It extends higher into the pons than the other subdivisions and occupies the upper part of the vestibular area. The inferior vestibular nucleus is the smallest of the group. It lies between the medial vestibular nucleus and the restiform body, from the level of the upper end of the nucleus gracilis to the pontomedullary junction, and is traversed by descending fibres of the vestibular nerve, from the cerebellum and the vestibulospinal tract. The lateral vestibular nucleus lies ventrolateral to the upper portion of the medial nucleus, just above the inferior nucleus and ascends almost to the level of the abducens nucleus. Its rostral end is continuous with the caudal end of the superior nucleus. It projects to the spinal cord through the lateral vestibulospinal tract (Voogd 2016). The lateral vestibular nucleus can be subdivided into dorsal and ventral components. The dorsal portion contains giant cells and is located within the juxtarestiform body: it receives no direct vestibular afferents, but receives Purkinje cell axons from the anterior vermis, and extends efferent connections to the cerebellum. The ventral portion contains cells of various sizes and is located medial to the juxtarestiform body

Vestibulocerebellar fibres (primary and secondary) travel via the juxtarestiform body mainly to the flocculus and nodule. Cerebellovestibular fibres pass to the nuclei, also via the juxtarestiform body: they arise mainly in the flocculus and nodule (posterior lobe), but some fibres are derived from the anterior lobe and the fastigial nucleus. A few vestibular fibres enter the cerebellum directly through the juxtarestiform body and end in the fastigial nucleus, flocculonodular lobe and uvula.

The vestibular nuclei receive afferent fibres from multiple sources, including the vestibular portion of the vestibulocochlear nerve, cerebellum, brainstem reticular formation and spinal cord. Myelinated fibres in the vestibular nerve enter the medulla between the restiform body and the spinal tract of the trigeminal nerve and bifurcate into ascending and descending branches. Most ascending vestibular fibres end in the superior vestibular nucleus. Descending vestibular fibres traverse the juxtarestiform body and give off extensive transverse collaterals to the inferior and medial (but not the lateral) vestibular nuclei. Additional afferent fibres descend from the cerebral cortex to innervate the vestibular nuclei bilaterally.

Afferent fibres arising from the interstitial nucleus of Cajal descend through the medial longitudinal fasciculus to synapse in the ipsilateral superior and medial vestibular nuclei and the nucleus prepositius hypoglossi. Afferent fibres from the Edinger–Westphal nucleus project to the medial and inferior vestibular nuclei, which also receive root fibres from the upper cervical nerve roots (C2, C3). The lateral vestibular nucleus and inferior portions of the medial and inferior vestibular nuclei receive ipsilateral spinovestibular fibres that ascend from lower spinal levels through the dorsal spinocerebellar tract.

The vestibular nuclei project extensively to the cerebellum and also receive fibres from the cerebellar cortex and the fastigial nuclei. Vestibulocerebellar fibres pass through the juxtarestiform body to the cerebellum (Carpenter and Sutin 1983). A few vestibular nerve fibres bypass the vestibular nuclei and traverse the juxtarestiform body to terminate directly in the fastigial nucleus, the flocculonodular lobe and uvula.

Evidence suggests that the vestibular apparatus is spatially represented in these nuclei. Efferents from the lateral vestibular nucleus descend to the spinal cord through the ipsilateral lateral vestibulospinal tract and extend along the full length of the spinal cord to exert a facilitatory influence on spinal reflex activity and on extensor muscle tone. Vestibular nuclear efferents form a major part of the medial longitudinal fasciculus, through which interconnections between the vestibular and oculogyric nuclei and the pontine reticular formation enable conjugate eye movements that compensate for head movements perceived by the labyrinths. The reflex arcs stabilize visual fixation despite changing head position. Vestibular efferents project to the thalamus (probably via the posterior portions of the ventroposterior complex and the medial pulvinar), which in turn projects to the primary vestibular cortex in the parietal lobe at the junction of the intraparietal and postcentral sulci, adjacent to the head portion of the postcentral gyrus. There may be additional representation of the vestibular system in the superior temporal gyrus near to the auditory cortex.

Vestibular ganglion

The somata of the bipolar neurones that form the vestibular nerve are in the vestibular (Scarpa's) ganglion located in the trunk of the nerve within the lateral end of the internal acoustic meatus (see Fig. 43.12B). They vary considerably in size, with circumferences ranging from 45 to 160 μm (Felix et al 1987): no topographically ordered distribution relating to size has been found. The somata are notable for their abundant granular endoplasmic reticulum, which in places forms Nissl bodies, and prominent Golgi complexes. They are covered by a thin layer of satellite cells and are often arranged in pairs, closely abutting each other so that only a thin layer of endoneurium separates the adjacent coverings of satellite cells. This arrangement has led to speculation that ganglion cells may affect each other directly by electrotonic spread (ephaptic transmission: see Felix et al (1987)). Two distinct sympathetic components have been identified in the vestibular ganglion, a perivascular adrenergic system derived from the stellate ganglion, and a blood vessel-independent system derived from the superior cervical ganglion.

The central processes of the vestibular ganglion cells travel via the vestibular nerve, enter the brainstem at the cerebellopontine angle and terminate in the vestibular nuclear complex (see below). Neurones in this complex project to motor nuclei in the brainstem and upper spinal cord, and to the cerebellum and thalamus. Thalamic efferent projections pass

to a cortical vestibular area that is probably located near the intraparietal sulcus in area 2 of the primary somatosensory cortex.

The peripheral processes of the vestibular ganglion cells are aggregated into definable nerves, each with a specific distribution. The main nerve divides at and within the ganglion into superior and inferior divisions connected by an isthmus. The superior division, the larger of the two, passes through the small holes in the superior vestibular area at the fundus of the internal acoustic meatus (see Fig. 43.3) and supplies the ampullary crests of the lateral and anterior semicircular canals via the lateral and anterior ampullary nerves, respectively. A secondary branch of the lateral ampullary nerve supplies the macula of the utricle; however, the greater part of the utricular macula is innervated by the utricular nerve, which is a separate branch of the superior division. Another branch of the superior division supplies part of the saccule. The inferior division passes through small holes in the inferior vestibular area (see Fig. 43.3) to supply the remainder of the saccule and the posterior ampullary crest via saccular and singular branches, respectively; the latter passes through the foramen singulare. Occasionally, a very small supplementary or accessory branch innervates the posterior crest; it is probably a vestigial remnant of the crista neglecta, an additional area of sensory epithelium found in some other mammals but seldom in humans.

Afferent and efferent cochlear fibres are also present in the inferior division of the vestibular nerve but leave at the anastomosis of Oort to join the main cochlear nerve (see review by Warr (1992)). Another anastomosis, the vestibulofacial anastomosis, is situated more centrally between the facial and vestibular nerves and is the point at which fibres originating in the intermediate nerve pass from the vestibular nerve to the main trunk of the facial nerve.

There are approximately 20,000 fibres in the vestibular nerve, of which 12,000 travel in the superior division and 8000 travel in the inferior division. The distribution of fibre diameters is bimodal, with peaks at 4 µm and 6.5 µm. The smaller fibres go mainly to the type II hair cells and the larger fibres tend to supply the type I hair cells. In addition to the afferents, efferent and autonomic fibres have been identified. Efferent fibres synapse exclusively with the afferent calyceal terminals around type I cells and usually with the afferent boutons on type II cells, although a few are in direct contact with the cell bodies of type II cells. The autonomic fibres do not contact vestibular sensory cells but terminate beneath the sensory epithelia.

Cochlear nuclei and central connections

The primary afferents of the auditory pathway are the central processes of type I and II sensory neurones in the spiral ganglion of Corti in the cochlea. They travel in the cochlear division of the vestibulocochlear nerve and enter the brainstem just caudal to the vestibular division of the vestibulocochlear nerve at the cerebellopontine angle. The axons bifurcate and terminate in the dorsal (posterior) and ventral (anterior) cochlear nuclei lying along the lateral surface of the restiform body. The dorsal cochlear nucleus forms a bulge, the auditory tubercle (auditory eminence) on the posterior surface of the restiform body and also forms the floor of the lateral recess of the fourth ventricle; it is continuous medially with the vestibular area in the floor of the fourth ventricle (see Fig. 28.9). The ventral cochlear nucleus lies between the cochlear and vestibular fibres of the vestibulocochlear nerve. The dorsal and ventral cochlear nuclei are separated only by a thin stratum of nerve cell bodies and fibres.

The axons of type 1 spiral ganglion cells enter the ventral cochlear nucleus and bifurcate within its centre, dividing it into anterior and posterior ventral subnuclei. The fibres are organized into dorsoventrally oriented sheets in which fibres conveying low frequency sounds from apical spiral ganglion cells terminate ventrally and fibres conveying high frequency sounds from the basal turn of the spiral ganglion terminate dorsally. Posterior processes of type I ganglion cells pass to the caudal pole of the ventral nucleus, from which they enter the dorsal cochlear nucleus. Thin unmyelinated axons of type 2 spiral ganglion cells contact clusters of small interneurones scattered through the cochlear nuclei.

The axons that emerge from the cochlear nuclei are aggregated into three, mostly transverse, fibre bundles, the dorsal and intermediate acoustic striae and the trapezoid body. The dorsal cochlear nucleus projects via the dorsal acoustic stria to the contralateral inferior colliculus. The dorsal acoustic stria curves dorsally and medially, dorsal to the restiform body, traverses the reticular formation ventral to the striae medullares, crosses the midline, passes to the contralateral superior olivary complex, and ascends in the contralateral lateral lemniscus. The ventral cochlear nucleus projects via the trapezoid body or the intermediate acoustic stria to relay centres in either the superior olivary complex, the nuclei of the lateral lemniscus, or the inferior colliculus. Initially, the intermediate acoustic stria accompanies the dorsal acoustic stria as they pass medially, immediately dorsal to the restiform body, but it then separates from the dorsal acoustic stria, angles sharply ventrally in the ipsilateral tegmentum, passes through the spinal trigeminal nucleus, joins the trapezoid body, and crosses the midline to join and ascend with the contralateral lateral lemniscus.

The cochlear nerve also conveys efferent fibres that pass outward from the brainstem to terminate on the hair cells and on the cells of the spiral ganglion.

Intratemporal and intracranial course

The vestibulocochlear nerve emerges from the cerebellopontine angle (see Figs 28.4–28.5). It courses through the posterior cranial fossa in close association with the facial nerve, nervus intermedius and labyrinthine vessels. Together with these structures, it enters the petrous temporal bone via the porus acusticus of the internal acoustic meatus (see Fig. 43.3), and divides into an anterior trunk, the cochlear nerve, and a posterior trunk, the vestibular nerve. Both contain the centrally directed axons of bipolar neurones, together with a smaller number of efferent fibres that arise from brainstem neurones and terminate on cochlear and vestibular sensory neurones. In humans, the intratemporal portion of the vestibulocochlear nerve consists of two histologically distinct portions: a central glial zone adjacent to the brainstem, and a peripheral or non-glial zone (Bridger and Farkashidy 1980). In the glial zone, the axons are supported by central neuroglia, whereas in the non-glial zone they are ensheathed by Schwann cells. The non-glial zone sometimes extends into the cerebellopontine angle medial to the internal acoustic meatus in human vestibulocochlear nerves. During development, a gap of several weeks has been reported between the onset of Schwann cell myelination distally and glial myelination proximally; it has been suggested that the gap may coincide with the time of the final maturation of the organ of Corti. For further details about the development of the human cochlear nerve, see Ray et al (2005)).

In audiological practice, it is important to distinguish between intratemporal and intracranial lesions. However, this surgical distinction does not correlate with the precise anatomical description of peripheral and central portions of the auditory and vestibular systems. Clinically, the term 'peripheral auditory lesion' is used to describe lesions peripheral to the spiral ganglion, and the term 'peripheral vestibular disturbance' includes lesions of the vestibular ganglion and the entire vestibular nerve.

GLOSSOPHARYNGEAL NERVE

The glossopharyngeal nerve is the ninth cranial nerve (see Figs 35.8, 35.11, 35.19). It contains motor fibres to stylopharyngeus; parasympathetic secretomotor fibres to the parotid gland (derived from the inferior salivatory nucleus); sensory fibres to the tympanic cavity, pharyngotympanic tube, fauces, tonsils, nasopharynx, uvula and posterior (postsulcal) third of the tongue; and gustatory fibres from the circumvallate papillae.

Nucleus ambiguus

The nucleus ambiguus is a complex group of large motor neurones situated deep in the medullary reticular formation (see Figs 28.3, 28.9). Rostrally, it extends as far as the rostral end of the vagal nucleus and caudally it is in line with, but not continuous with, the nucleus of the accessory nerve. A small retrofacial nucleus separates the upper end of the nucleus ambiguus from the facial nucleus. The nucleus ambiguus contains cellular subgroups that exhibit some topographical representation. Relatively discrete groups of cells in the caudal region innervate individual laryngeal muscles; neurones in the intermediate area innervate the pharynx; neurones in the rostral area innervate the oesophagus and soft palate.

The nucleus ambiguus contributes special visceral efferent fibres to the glossopharyngeal nerve and may give general visceral efferent fibres to the vagus nerve. Fibres emerging from the nucleus ambiguus pass dorsomedially, then curve laterally. Rostral fibres join the glossopharyngeal nerve and caudal fibres join the vagus nerve and are distributed to the pharyngeal constrictors, intrinsic laryngeal muscles and striated muscles of the palate and upper oesophagus. A specific caudal pool of laryngeal motor neurones gives rise to the recurrent laryngeal nerve.

Extracranial course

The glossopharyngeal nerve leaves the skull through the anteromedial part of the jugular foramen, anterior to the vagus and accessory nerves,

and in a separate dural sheath. In the foramen, it is lodged in a deep groove leading from the cochlear aqueductal depression, separated by the inferior petrosal sinus from the vagus and accessory nerves. The groove is bridged by fibrous tissue, which is sometimes calcified. After leaving the foramen, the nerve passes forwards between the internal jugular vein and internal carotid artery, and then descends anterior to the latter, deep to the styloid process and its attached muscles, to reach the posterior border of stylopharyngeus. It curves forwards on stylopharyngeus and either pierces the lower fibres of the superior pharyngeal constrictor or passes between it and the middle constrictor to be distributed to the palatine tonsil, the mucosae of the pharynx and postsulcal part of the tongue, the vallate papillae and oral mucous glands.

Two ganglia, superior and inferior, are situated on the glossopharyngeal nerve as it traverses the jugular foramen. The superior ganglion is in the upper part of the groove occupied by the nerve in the jugular foramen. It is small, has no branches and is usually regarded as a detached part of the inferior ganglion. The inferior ganglion is larger and lies in a notch in the lower border of the petrous part of the temporal bone. Its cells are typical unipolar neurones, their peripheral branches convey gustatory and tactile signals from the mucosa of the tongue (posterior third, including the sulcus terminalis and vallate papillae) and general sensation from the oropharynx, where the glossopharyngeal nerve is responsible for initiating the gag reflex.

The glossopharyngeal nerve has tympanic, carotid, pharyngeal, muscular, tonsillar and lingual branches.

Communicating branches

The glossopharyngeal nerve communicates with the sympathetic trunk and vagus and facial nerves. Its inferior ganglion is connected with the superior cervical sympathetic ganglion. Two filaments from the inferior ganglion pass to the vagus, one to its auricular branch and the other to its superior ganglion. A branch to the facial nerve arises from the glossopharyngeal nerve below the inferior ganglion and perforates the posterior belly of digastric to join the facial nerve near the stylomastoid foramen.

Tympanic nerve

The tympanic nerve leaves the inferior ganglion, ascends to the tympanic cavity through the tympanic canaliculus and divides into branches that contribute to the tympanic plexus on the promontory. The lesser petrosal nerve is derived from the tympanic plexus.

Carotid branch

The carotid branch is often double. It arises just below the jugular foramen and descends on the internal carotid artery to the wall of the carotid sinus and to the carotid body. The nerve contains primary afferent fibres from chemoreceptors in the carotid body and from the baroreceptors lying in the carotid sinus wall. It may communicate with the inferior ganglion of the vagus, or with one of its branches, and with a sympathetic branch from the superior cervical ganglion (see Fig. 35.20).

Pharyngeal branches

The pharyngeal branches are three or four filaments that unite with the pharyngeal branch of the vagus and the laryngopharyngeal branches of the sympathetic trunk to form the pharyngeal plexus near the middle pharyngeal constrictor. They constitute the route by which the glossopharyngeal nerve supplies sensory fibres to the mucosa of the pharynx.

Muscular branch

The muscular branch supplies stylopharyngeus.

Tonsillar, lingual and lesser petrosal branches and the tympanic plexus

The tympanic plexus supplies branches to the mucosa of the tympanic cavity, pharyngotympanic tube and mastoid air cells. The nerves that constitute the tympanic plexus ramify on the surface of the promontory on the medial wall of the tympanic cavity. They are derived from the tympanic branch of the glossopharyngeal nerve and the caroticotympanic nerves. The former arises from the inferior ganglion of the glossopharyngeal nerve and reaches the tympanic cavity via the tympanic canaliculus for the tympanic nerve. The superior and inferior caroticotympanic nerves are postganglionic sympathetic fibres derived from the carotid sympathetic plexus that traverse the wall of the carotid canal to join the plexus.

The lesser petrosal nerve, which may be regarded as the continuation of the tympanic branch of the glossopharyngeal nerve, traverses the tympanic plexus. It occupies a small canal below that for tensor tympani. It runs past, and receives a connecting branch from, the geniculate ganglion of the facial nerve. The lesser petrosal nerve emerges from the anterior surface of the temporal bone via a small opening lateral to the hiatus for the greater petrosal nerve and then traverses either the foramen ovale or the sphenopetrosal fissure or the innominate canal (of Arnold) to join the otic ganglion. Postganglionic secretomotor fibres leave this ganglion in the auriculotemporal nerve to supply the parotid gland. The tympanic plexus sends a branch to the greater petrosal nerve via an opening anterior to the fenestra vestibuli.

The tonsillar region is innervated by tonsillar branches of the maxillary and glossopharyngeal nerves. The fibres from the maxillary nerve pass through, but do not synapse in, the pterygopalatine ganglion; they are distributed through the lesser palatine nerves and form a plexus (the circulus tonsillaris) around the tonsil together with the tonsillar branches of the glossopharyngeal nerve. Nerve fibres from this plexus are also distributed to the soft palate and the region of the oropharyngeal isthmus. The tympanic branch of the glossopharyngeal nerve supplies the mucous membrane lining the tympanic cavity. Infection, malignancy and postoperative inflammation of the tonsil and tonsillar fossa may therefore be accompanied by pain referred to the ear.

Lesions of the glossopharyngeal nerve

There are anastomoses between the glossopharyngeal, vagus, greater auricular and other branches of the cervical plexus that may be significant when treating patients with skull base pathology. Damage to the glossopharyngeal nerve is rarely seen without associated involvement of other lower cranial nerves. Transient or sustained hypertension may follow surgical section of the nerve and indicates involvement of the carotid branch. Isolated lesions of the glossopharyngeal nerve lead to loss of sensation over the ipsilateral soft palate, fauces, pharynx and posterior third of the tongue, although this is difficult to assess clinically, and confirmation requires galvanic stimulation. The palatal and pharyngeal (gag) reflexes are reduced or absent and salivary secretion from the parotid gland may also be reduced. Weakness of stylopharyngeus cannot be tested individually. Glossopharyngeal neuralgia consists of episodic brief but severe pain, often precipitated by swallowing and experienced in the throat, behind the angle of the jaw and within the ear. Superior jugular bulb thromboses (e.g. in otitis media) and jugular foramen syndrome (associated with nasopharyngeal carcinoma or a jugular paraganglioma) may cause lesions of the adjacent glossopharyngeal, vagus and accessory nerves, with associated weakness in the muscles supplied in the pharynx and larynx.

VAGUS NERVE

The vagus is the tenth cranial nerve. It is a large mixed nerve, containing branchiomotor nerve fibres, general visceral afferents and preganglionic parasympathetic fibres. The vagus has a more extensive course and distribution than any other cranial nerve, running through the neck, thorax and abdomen. The proportion of efferent parasympathetic nerve fibres it contains varies at different levels but is small relative to its sensory and sensorimotor content. The branchiomotor fibres arise from neurones in the nucleus ambiguus in the medulla oblongata and are distributed to the constrictor muscles of the pharynx and the intrinsic muscles of the larynx. The preganglionic parasympathetic nerves arise from cell bodies in the vagal dorsal nucleus in the medulla oblongata, travel in the nerve and in its pulmonary, cardiac, oesophageal, gastric and intestinal branches and relay/synapse in minute ganglia in the visceral walls (see Fig. 56.6) (Mussa and Verberne 2013).

The general visceral afferent fibres carry sensation from thoracic and abdominal viscera and from aortic arch baroreceptors and chemoreceptors and end in the nucleus solitarius of the medulla. Their cell bodies are in the superior and inferior vagal ganglia. Their peripheral processes are distributed to terminals in the pharyngeal and oesophageal walls where, acting synergistically with glossopharyngeal visceral afferents in the pharynx, they are concerned with swallowing reflexes. Vagal afferents are also believed to innervate the thyroid and parathyroid glands. In the heart, vagal afferents innervate the walls of the great vessels, the aortic bodies and pressor receptors, where they are stimulated by raised intravascular pressure. In the lungs they are distributed via the pulmonary plexuses: they supply bronchial mucosa, where they are probably involved in cough reflexes; bronchial muscle, where they encircle myocytes and end in tendrils, which are sometimes regarded as muscle spindles and which are believed to be stimulated by change in the length of myocytes; interalveolar connective tissue, where their knob-like endings, together with terminals on myocytes, may evoke Hering–Breuer reflexes; the adventitia of pulmonary arteries, where they may be pressor receptors; and the intima of pulmonary veins, where they may be chemoreceptors. Vagal visceral afferent fibres also end in the gastric and intestinal walls, digestive glands and the kidneys. Fibres ending in the gut and its ducts respond to stretch or contraction. Gastric impulses may evoke sensations of hunger and nausea.

About 5% of the vagal afferents project directly to, and terminate in, the upper cervical spinal cord (C1–C2), where they are believed to contribute to referred sensations, as well as to propriospinal mechanisms of nociceptive modulation. Almost all the central processes of vagal and glossopharyngeal afferent fibres end in the nucleus solitarius of the medulla.

Dorsal motor nucleus of the vagus

The dorsal motor nucleus of the vagus lies slightly dorsolateral to the hypoglossal nucleus, from which it is separated by the nucleus intercalatus (see Fig. 28.8). The vagal nucleus extends caudally to the first cervical spinal segment and rostrally to the open portion of the medulla subjacent to the vagal trigone of the fourth ventricle. It is a general visceral efferent nucleus and is the largest parasympathetic nucleus in the brainstem. Most (80%) of its neurones give rise to the preganglionic parasympathetic fibres that pass into the vagus nerve. The remainder are interneurones or neurones that project centrally. The nucleus innervates the cardiac and smooth muscle of the thoracic viscera (heart, bronchi, lungs, oesophagus) and abdomen (stomach, liver, pancreas, spleen, small intestine and proximal part of the colon), and glandular epithelium. Sparse sensory afferents from the nodose ganglion project directly to the dorsal and lateral edges of the dorsal vagal nucleus, and possibly beyond it into the nucleus of the solitary tract (Holstein 2012).

Neurones within the nucleus are heterogeneous and can be classified into nine subnuclei, grouped into rostral, intermediate and caudal divisions. Topographic maps of visceral representation in animals suggest that the heart and lungs are represented in the caudal and lateral parts of the nucleus; the stomach and pancreas in intermediate regions; and the remaining abdominal organs in the rostral and medial parts of the nucleus.

Extracranial course

The vagus nerve exits the skull through the jugular foramen, accompanied by the accessory nerve, with which it shares an arachnoid and a dural sheath. Both nerves lie anterior to a fibrous septum that separates them from the glossopharyngeal nerve. The vagus descends vertically in the neck in the carotid sheath, between the internal jugular vein and the internal carotid artery, to the upper border of the thyroid cartilage, and then passes between the vein and the common carotid artery to the root of the neck. Its relationships in this part of its course are therefore similar to those described for these structures (see Figs 35.7A, 35.8, 35.17). Its further course differs on the two sides. The right vagus descends posterior to the internal jugular vein to cross the first part of the subclavian artery and enter the thorax. The left vagus enters the thorax between the left common carotid and subclavian arteries, and behind the left brachiocephalic vein.

After emerging from the jugular foramen, the vagus bears two marked enlargements: a small, round, superior (jugular) ganglion and a larger inferior (nodose) ganglion.

Superior (jugular) ganglion

The superior ganglion is greyish, spherical and approximately 4 mm in diameter. It is connected to the inferior glossopharyngeal ganglion and the sympathetic trunk, the latter by a filament from the superior cervical ganglion.

Inferior (nodose) ganglion

The inferior or nodose ganglion is larger than the superior ganglion, and is elongated and cylindrical in shape with a length of 25 mm and a maximum breadth of 5 mm. It is connected with the hypoglossal nerve, the loop between the first and second cervical spinal nerves, and with the superior cervical sympathetic ganglion. Most visceral afferent axons travelling in the vagus nerve are the peripheral processes of cell bodies located in the nodose ganglion.

Both vagal ganglia are exclusively sensory and contain somatic, special visceral and general visceral afferent neurones. The superior ganglion is mainly somatic and most of its neurones enter the auricular nerve, whilst neurones in the inferior ganglion are concerned with visceral sensation from the heart, larynx, lungs and the alimentary tract from the pharynx to the transverse colon. Some fibres transmit impulses from taste endings in the vallecula and epiglottis. Large afferent fibres are derived from muscle spindles in the laryngeal muscles. Vagal sensory neurones in the nodose ganglion may show some somatotopic organization. Both ganglia are traversed by parasympathetic and perhaps some sympathetic fibres, but there is no evidence that vagal parasympathetic components relay in the inferior ganglion. Preganglionic motor fibres from the dorsal vagal nucleus and the special visceral efferents from the nucleus ambiguus, which descend to the inferior vagal ganglion, commonly form a visible band that skirts the ganglion in some mammals. These larger fibres probably provide motor innervation to the larynx in the recurrent laryngeal nerve, together with some contribution to the superior laryngeal nerve supplying cricothyroid.

Vagus nerve in the neck

The branches of the vagus in the neck are the meningeal, auricular, pharyngeal, carotid body, superior and recurrent laryngeal nerves and cardiac branches.

Meningeal branches

Meningeal branches appear to start from the superior vagal ganglion and pass through the jugular foramen to be distributed to the dura mater in the posterior cranial fossa (see Fig. 25.3B).

Auricular branch

The auricular branch (Arnold's nerve) arises from the superior vagal ganglion and is joined by a branch from the inferior ganglion of the glossopharyngeal nerve. It passes behind the internal jugular vein and enters the mastoid canaliculus on the lateral wall of the jugular fossa. Traversing the temporal bone, it crosses the facial canal approximately 4 mm above the stylomastoid foramen and here supplies an ascending branch to the facial nerve. Fibres of the nervus intermedius may pass to the auricular branch at this point, which may explain the cutaneous vesiculation in the auricle that sometimes accompanies geniculate herpes. The auricular branch then traverses the tympanomastoid fissure and divides into two rami. One ramus joins the posterior auricular nerve and the other is distributed to the skin of part of the ear and to the external acoustic meatus.

Pharyngeal branch

The pharyngeal branch of the vagus is the main motor nerve of the pharynx and consists of axons arising from neuronal cell bodies in the nucleus ambiguus. It supplies all the muscles of the soft palate (excluding tensor veli palatini, which is supplied by the mandibular division of the trigeminal nerve via the nerve to medial pterygoid) and all the muscles of the pharynx (excluding stylopharyngeus, which is supplied by the glossopharyngeal nerve). It emerges from the upper part of the inferior vagal ganglion, passes between the external and internal carotid arteries to reach the upper border of the middle pharyngeal constrictor, and divides into numerous filaments that join rami of the sympathetic trunk and glossopharyngeal nerve to form the pharyngeal plexus. It also gives off a minute filament, the ramus lingualis vagi, which joins the hypoglossal nerve as it curves round the occipital artery.

Branches to the carotid body

Branches to the carotid body are variable in number. They may arise from the inferior ganglion or travel in the pharyngeal branch, or in the superior laryngeal nerve. They form a plexus with the glossopharyngeal rami and branches of the cervical sympathetic trunk.

Superior laryngeal nerve

The superior laryngeal nerve is larger than the pharyngeal branch and issues from the middle of the inferior vagal ganglion. It receives one or more communicating branches from the superior cervical sympathetic ganglion; most frequently, the connection is with the external laryngeal nerve. The sympathetic communication contributes to the innervation of the carotid body (Monfared et al 2002) and the thyroid gland (Sun and Chang 1991). The superior laryngeal nerve descends alongside the pharynx, at first posterior, then medial, to the internal carotid artery: it may be found on the lateral side of the artery. It divides into a smaller, external, and a larger, internal, branch, approximately 1.5 cm below the ganglion: rarely, both branches may arise from the ganglion (see Figs 35.8, 41.12).

Internal laryngeal nerve

The internal laryngeal nerve passes forwards approximately 7 mm before piercing the thyrohyoid membrane, usually at a higher level than the superior thyroid artery (Durham and Harrison 1962). It splits into superior, middle and inferior branches on entering the larynx. The superior branch supplies the mucosa of the piriform fossa. The large middle branch is distributed to the mucosa of the ventricle, specifically the quadrangular membrane, and therefore probably conveys the afferent component of the cough reflex. The inferior ramus is mainly distributed to the mucosa of the ventricle and subglottic cavity. On the medial wall of the piriform fossa, descending branches give twigs to the

interarytenoid muscle and share a number of communicating branches with the recurrent laryngeal nerve (Sanders and Mu 1998).

The internal laryngeal nerve is sensory to the laryngeal mucosa down to the level of the vocal folds. It also carries afferent fibres from the laryngeal neuromuscular spindles and other stretch receptors. It descends to the thyrohyoid membrane, pierces it above the superior laryngeal artery and divides into an upper and lower branch. The upper branch is horizontal and supplies the mucosa of the pharynx, the epiglottis, vallecula and laryngeal vestibule. The lower branch descends in the medial wall of the piriform recess, supplies the aryepiglottic fold, the mucosa on the back of the arytenoid cartilage and one or two branches to transverse arytenoid (the latter unite with twigs from the recurrent laryngeal to supply the same muscle). The internal laryngeal nerve ends by piercing the inferior pharyngeal constrictor to unite with an ascending branch from the recurrent laryngeal nerve. As it ascends in the neck, it supplies branches, more numerous on the left, to the mucosa and tunica muscularis of the oesophagus and trachea, and to the inferior constrictor.

External laryngeal nerve

The external laryngeal nerve, smaller than the internal, descends behind sternohyoid with the superior thyroid artery, but on a deeper plane. It lies first on (occasionally within) the inferior pharyngeal constrictor, to which it contributes some small branches, and then pierces it to curve round the inferior thyroid tubercle. It passes beneath the attachment of sternothyroid to the oblique line of the thyroid cartilage to reach cricothyroid, which it supplies. A communicating nerve continues from the posterior surface of cricothyroid, crosses the piriform fossa and enters thyroarytenoid, where it anastomoses with branches from the recurrent laryngeal nerve. It has been suggested that these communicating branches may provide both additional motor components to thyroarytenoid and sensory fibres to the mucosa in the region of the subglottis. An anastomosis between the external and internal laryngeal nerves has also been described (Kochilas et al 2008). The external laryngeal nerve also gives branches to the pharyngeal plexus and communicates with the superior cardiac nerve and superior cervical sympathetic ganglion.

The close relationship of the external laryngeal nerve to the superior thyroid artery puts the nerve at potential risk when the artery is clamped during thyroid lobectomy, particularly when it is close to the artery (in approximately 20% of cases), or where, instead of crossing the superior thyroid vessels approximately 1 cm or more above the superior pole of the gland, it actually passes below this point (in some 20% of cases) (Cernea et al 1992, Kierner et al 1998). The external laryngeal nerve is also at risk in parathyroidectomy, carotid endarterectomy and anterior cervical spine procedures.

Recurrent laryngeal nerve

The recurrent laryngeal nerve supplies all the laryngeal muscles except cricothyroid, communicates with the internal laryngeal nerve and carries sensory filaments from the laryngeal mucosa below the vocal folds and from laryngeal stretch receptors. The nerve differs in origin and course on the two sides. On the right, it almost always arises from the vagus anterior to the first part of the subclavian artery, and curves backwards below and then behind it to ascend obliquely to the side of the trachea behind the common carotid artery. Near the lower pole of the lateral lobe of the thyroid gland, it is closely related to the inferior thyroid artery and crosses either in front of, behind or between its branches. On the left, the recurrent laryngeal nerve arises from the vagus on the left of the aortic arch, curves below it immediately behind the attachment of the ligamentum arteriosum to the concavity of the aortic arch and ascends to the side of the trachea (see Fig. 57.61). As the recurrent laryngeal nerve curves round either the subclavian artery or the aortic arch, it gives cardiac filaments to the deep cardiac plexus.

On both sides, the recurrent laryngeal nerve ascends in or near the tracheo-oesophageal groove. It is closely related to the medial surface of the thyroid gland before it passes under the lower border of the inferior constrictor, and it enters the larynx behind the articulation of the inferior thyroid cornu with the cricoid cartilage, passing either deep to (usually) or between (sometimes) the fibres of cricopharyngeus at its attachment to the lateral aspect of the cricoid cartilage. The nerve supplies cricopharyngeus as it passes. At this point, the nerve is in intimate proximity to the posteromedial aspect of the thyroid gland. The main trunk divides into two or more branches, usually below the lower border of the inferior constrictor, although branching may take place higher up. The anterior branch is mainly motor and is sometimes called the inferior laryngeal nerve (a term that is best avoided to prevent any confusion with a former synonym for the recurrent laryngeal nerve). It ascends posterior to the cricothyroid joint and its ligament, usually covered by fibres of posterior cricoarytenoid, then bends over the joint and continues forwards over lateral cricoarytenoid before terminating within thyroarytenoid. It innervates posterior cricoarytenoid by one or more branches, and interarytenoid, lateral cricoarytenoid and thyroarytenoid (Maranillo et al 2005). The posterior branch of the recurrent laryngeal nerve is mainly sensory and ascends deep to posterior cricoarytenoid to join the descending branch of the internal laryngeal nerve.

The recurrent laryngeal nerve does not always lie in a protected position in the tracheo-oesophageal groove but may be slightly anterior to it (more often on the right), and it may be markedly lateral to the trachea at the level of the lower part of the thyroid gland. The upper part of the nerve has a close but variable relationship to the inferior thyroid artery. On the right, it is as often anterior to, or posterior to, or intermingled with, the terminal branches of the artery; on the left, the nerve is usually posterior to the artery, though occasionally lies anterior to it. The stated incidences of these relationships vary between different authors. The recurrent laryngeal nerve has a highly variable branching pattern (see Fig. 41.13) (Henry et al 2016).

A very rare anomaly of relevance to laryngeal pathology and surgery is the 'non-recurrent' laryngeal nerve, where the right recurrent laryngeal nerve arises directly from the vagus nerve trunk high up in the neck and enters the larynx close to the inferior pole of the thyroid gland. Only the right side is affected, and it is always associated with an abnormal origin of the right subclavian artery from the aortic arch on the left side. If unrecognized, a non-recurrent laryngeal nerve may be susceptible to injury during surgery. It may also potentially be compressed by small tumours of the thyroid gland (Friedman et al 1986).

Pharyngeal plexus

Almost all of the nerve supply to the pharynx, whether motor or sensory, is derived from the pharyngeal plexus, which is formed by the pharyngeal branches of the glossopharyngeal and vagus nerves with contributions from the superior cervical sympathetic ganglion. The plexus lies on the external surface of the pharynx, especially on the middle constrictor. Filaments from the plexus ascend or descend external to the superior and inferior constrictors before branching within the muscular layer and mucosa of the pharynx. Whether a 'cranial root' of the accessory nerve serves as the conduit for the major motor drive to the pharyngeal plexus, albeit via the vagus nerve, is a matter of debate. The plexiform connections that may be demonstrated between the accessory nerve and the vagus nerve within the posterior cranial fossa are too variable and insubstantial to support this function.

Laryngeal nerve anastomoses

Anastomotic communications between the internal, external and recurrent laryngeal nerves probably explain why normal or near normal voice function can be present following neck surgery when one or more branches of these nerves have been divided (Naidu et al 2014, Sanudo et al 1999, Henry et al 2017). Numerous communications have been described (Sanudo et al 1999, Furlan et al 2002). The ansa Galeni, lying on the interarytenoid muscles, forms a direct connection between the recurrent and internal laryngeal nerves: it may be a single or double trunk or a plexus. The cricoid communication connects branches that originate bilaterally from the recurrent laryngeal nerve with the superior branch of the deep portion of the arytenoid plexus. The thyroarytenoid communication links the ascending branch of the recurrent laryngeal nerve and the descending branch from the anterior branch of the internal laryngeal nerve. There are also communications between the external laryngeal and recurrent laryngeal nerves, the internal and external laryngeal nerves and the recurrent laryngeal and superior laryngeal nerves. The anastomosis between the recurrent laryngeal nerve and the sympathetic trunk probably explains why ptosis is a rare complication following thyroidectomy.

Lesions of the vagus nerve and recurrent laryngeal nerve paralysis

The consequences of vagal nerve lesions are complex, reflecting the long course of the nerve and the possible involvement of three of its branches, namely the pharyngeal, superior laryngeal and recurrent laryngeal nerves. Collectively these nerves innervate the muscles of the larynx, soft palate and pharynx, and injury may therefore have deleterious effects on phonation and/or soft palate movements and/or swallowing. A lesion of the vagus nerve above the level at which the pharyngeal branch is given off will affect both the superior and recurrent laryngeal nerves. This causes immobility of the vocal fold on the affected side and imparts a breathy voice with lack of pitch and limited loudness. The affected fold is paralysed and lies in the so-called 'cadaveric' position halfway between abduction and adduction. If the lesion is unilateral, the voice is weak and hoarse, but if it is bilateral, phonation is almost absent, the vocal pitch cannot be altered, and the cough is weak and ineffective. There will also be a degree of hypernasality because of the

effects on movements of the soft palate caused by paralysis of levator veli palatini. Unilateral palsies impact very significantly on the quality of life of the patient because of impaired vocalization and a tendency to aspirate. Bilateral palsies are extremely serious and a tracheostomy may be required to protect the airway.

A lesion affecting the superior laryngeal nerve may be unilateral or bilateral. Complete section is most likely during the ligation of the vessels forming the vascular pedicle of the superior pole of the thyroid gland during thyroid lobectomy. Unilateral lesions may result in the vocal folds appearing relatively normal and the effect on voice is barely noticeable and is often overlooked. A more detailed examination may detect some shortening of the vocal folds on the affected side with asymmetric tilt of the epiglottis and the anterior larynx canted towards the unaffected side. The result is a mildly hoarse voice with loss of pitch control. Bilateral superior laryngeal nerve lesions result in shortening of both vocal folds, the overhanging of the epiglottis over the folds and reduced tilt between the thyroid and cricoid cartilage. Effects on the voice are correspondingly greater, with reduced loudness and pitch but variable breathiness.

Damage to the internal laryngeal nerve causes loss of mechanoreceptive and proprioceptive sensation from the larynx. Unilateral loss produces a feeling that something is stuck in the throat, whereas bilateral loss will result in aspiration and can cause dysphagia, with a risk of choking.

Unilateral complete palsy of the recurrent laryngeal nerve is more common on the left side, presumably because the nerve is longer on this side. There is isolated paralysis of all the laryngeal muscles on the affected side except cricothyroid, which is innervated by the external laryngeal nerve. The patient may be asymptomatic or have a hoarse, breathy voice and there will be diminished ability to manipulate pitch. The hoarseness may be permanent or may become less severe with time as the contralateral fold develops the ability to hyperadduct and oppose the paralysed fold, thereby closing the glottis during phonation and coughing, although this is seldom enough to restore full voice quality. There may be aspiration of food and drink. Bilateral lesions of the recurrent laryngeal nerve result in both vocal folds being paralysed and taking up a paramedian position. Phonation can be nearly normal because the vocal folds lie so close to the midline, but there will be audible stridor and a compromised airway.

Clinically the position of the vocal fold in the acute phase after section of the recurrent laryngeal nerve is very variable. Though stridor is more common after bilateral lesions and sometimes only audible to the educated ear, the folds may be sufficiently abducted so that there is little problem with airway obstruction at rest, although the voice is always weaker in this situation. The folds are slightly more widely separated in chronic lesions, which renders the voice weaker but with a less precarious airway. Atrophy and fibrosis of paraglottic muscles probably affect the position of paralysed vocal folds in chronic lesions to a greater degree than variations in the strength of the apposing adductor and abductor muscle groups.

For many years, conventional wisdom held that movements of abduction were affected to a greater degree than those of adduction when the recurrent laryngeal nerve was partially damaged (Semon's law). This effect was thought to reflect the internal segregation within the recurrent laryngeal nerve of axons supplying the laryngeal abductor muscles. The hypothesis was later undermined by the demonstration that axons destined for particular laryngeal muscles are randomly distributed within the nerve. The weak abductive action of cricothyroid that is said to produce lengthening of the vocal folds has been suggested as the explanation for the relative sparing of abduction in these lesions, but is difficult to reconcile with the alternative view that cricothyroid may be a slight adductor of the vocal folds (Mu and Sanders 2009, Wadie et al 2013). It is likely that predicting the effect of partial lesions of the recurrent laryngeal nerve is complicated by the variable patterns of anastomoses between the laryngeal nerves. For further reading, see Aronson and Bless (2009) and Blitzer et al (2009).

Vagus nerve in the thorax

Preganglionic parasympathetic axons arise from neuronal cell bodies in the dorsal motor nucleus of the vagus in the medulla oblongata. Those destined for the thoracic viscera travel in the pulmonary, cardiac and oesophageal branches of the vagus nerve and synapse in minute ganglia in the walls of the target viscera. Axons travelling in cardiac branches join the cardiac plexuses and synapse in ganglia distributed freely over both atria, the interatrial septum and peri-nodal subepicardial tissue. Postganglionic fibres are distributed to the atria and the atrioventricular bundle and are concentrated around the sinuatrial and, to a lesser extent, the atrioventricular nodes. Cardiac branches slow the heart rate and diminish the force of contraction and may indirectly influence ventricular muscle via their effect on the atrioventricular node. The direct postganglionic parasympathetic innervation of the ventricles is sparse. The smaller branches of the coronary arteries are innervated mainly by parasympathetic vagal neurones, whereas the larger arteries are innervated mainly by sympathetic neurones. All cardiac branches of the vagus nerves contain both afferent and efferent fibres. Pulmonary branches contain axons that synapse in ganglia of the pulmonary plexuses: they are motor (bronchoconstrictor) to the circular non-striated muscle fibres of the bronchi and bronchioles (and therefore bring about bronchoconstriction), and secretomotor to the mucous glands of the respiratory epithelium.

Right vagus nerve

The right vagus nerve descends posterior to the right internal jugular vein in the neck and crosses the first part of the right subclavian artery to enter the thorax; the ansa subclavia is lateral, and the phrenic nerve is further lateral. After giving off the right recurrent laryngeal nerve, it descends through the superior mediastinum, at first posterior to the right brachiocephalic vein, and then lateral to the trachea and posteromedial to the superior vena cava. Superiorly, the right mediastinal part of the parietal pleura and superior lobe of the lung are lateral; inferiorly, the azygos vein and its arching terminal portion separate the right vagus nerve from the parietal pleura (see Fig. 56.7A). The nerve next passes posterior to the right main bronchus and lies on the posterior aspect of the right lung hilum. Here, it gives off posterior bronchial branches that unite with rami from the second to fifth/sixth thoracic sympathetic ganglia to form the right posterior pulmonary plexus. Two or three branches descend from the inferior part of this plexus on the posterior aspect of the oesophagus to join a left vagal branch and form the posterior oesophageal plexus. The anterior vagal trunk, containing nerve fibres from both vagus nerves, leaves the plexus and passes inferiorly on the posterior surface of the oesophagus, entering the abdomen by passing through the oesophageal hiatus in the respiratory diaphragm.

Left vagus nerve

The left vagus nerve enters the thorax posterior to the left brachiocephalic vein, between the left common carotid artery (anterior) and left subclavian artery (posterior). It descends through the superior mediastinum, crosses the left side of the aortic arch, gives off the left recurrent laryngeal nerve and then passes posterior to the left lung hilum (see Fig. 56.7B). Superior to the aortic arch, it is crossed anterolaterally by the left phrenic nerve, and on the arch, it is crossed laterally by the left superior intercostal vein and sometimes by a continuation of the accessory hemiazygos vein. Posterior to the hilum of the left lung, the left vagus nerve gives off posterior bronchial branches that unite with rami of the second to fourth thoracic sympathetic ganglia to form the left posterior pulmonary plexus. Two or three branches descend anteriorly on the oesophagus and join with a ramus from the right posterior pulmonary plexus to form the anterior oesophageal plexus. The posterior vagal trunk, containing nerve fibres from both vagus nerves, passes inferiorly on the anterior surface of the oesophagus and enters the abdomen through the oesophageal hiatus. Numerous branches from the anterior vagal and left sympathetic trunks are distributed to the descending thoracic aorta. This pathway transmits the typical intense, excruciating pain of an intramural aortic haematoma from aortic dissection or laceration.

Vagus nerve in the abdomen

The vagus nerves supply parasympathetic innervation to the abdominal viscera as far as the distal transverse colon, i.e. they supply the derivatives of the foregut and midgut, whereas the derivatives of the hindgut are supplied by parasympathetic fibres travelling via the pelvic splanchnic nerves; the overlap between these two supplies is variable. The vagal trunks are derived from the oesophageal plexus and enter the abdomen via the oesophageal hiatus, closely related to the anterior and posterior walls of the abdominal part of the oesophagus (see Fig. 56.6). The anterior vagal trunk is mostly derived from the left vagus and the posterior vagal trunk from the right vagus. The nerves supply the abdominal part of the oesophagus and stomach directly. The anterior vagal trunk gives off a hepatic branch, which innervates the liver and its vasculature, including the gallbladder and bile ducts, and the other structures in the free edge of the lesser omentum (hepatoduodenal ligament). The posterior vagal trunk supplies branches to the coeliac plexus: these fibres frequently constitute the largest portion of the fibres contributing to the plexus and arise directly from the posterior vagal trunk and from its gastric branch, and run beneath the peritoneum, deep to the posterior wall of the superior part of the omental bursa, to reach the coeliac plexus. Their synaptic relays with postganglionic neurones are situated in the myenteric (Auerbach's) and submucosal (Meissner's) plexuses in the wall of the hollow viscera.

ACCESSORY NERVE

The accessory nerve is the eleventh cranial nerve: its integrity is fundamental to thoracoscapular function and essential for scapulohumeral rhythm (Camp and Birch 2011).

Traditionally, it has been described as having a cranial root composed of a variable number of small rootlets that emerge from the post-olivary groove of the dorsolateral medulla, caudal to the rootlets of the vagus, and a spinal root composed of fibres derived from the cervical segments of the spinal cord (see below). According to this description, the cranial rootlets carry axons of motor neurones located in the caudal part of the nucleus ambiguus, and the spinal rootlets carry axons of motor neurones located in a nucleus in the ventral horn of the cervical spinal cord in line with the nucleus ambiguus. The spinal root ascends within the vertebral canal and enters the skull via the foramen magnum. The cranial and spinal roots join, either before or within the jugular foramen, and the bundle so formed then divides into internal and external branches on leaving the jugular foramen. The internal branch joins the vagus nerve and its fibres innervate branchiomeric muscles via the pharyngeal and laryngeal branches of the vagus nerve and the external branch descends to the neck and innervates sternocleidomastoid and trapezius.

There is an alternative view that the cranial root of the accessory nerve is anatomically and functionally part of the vagus nerve, and that the spinal root is, *de facto*, the accessory nerve. The issue is not simply one of contentious anatomical terminology; rather, it reflects the need to clarify the relevant microsurgical anatomy in order to minimize potential complications during surgery in the region. Paradoxically, meticulous cadaveric dissection studies, often undertaken stereomicroscopically, have failed to reach a consensus, finding either no connections between rootlets arising from the dorsolateral medulla and the spinal root of the accessory nerve because the cranial root was absent, or significant variations in the arrangement and size of plexiform connections between the cranial rootlets and the spinal root. Plexiform interconnections between neighbouring cranial nerves are not uncommon and are certainly not confined to the accessory and vagus nerves (Shoja et al 2014); their functional significance is often uncertain. (For further reading, see Krammer et al (1987), Lachman et al (2002), Ryan et al (2007), Wiles et al (2007), Benninger and McNeil (2010), Skinner (2011), Liu et al (2014), Tubbs et al (2014).)

Spinal nucleus

The (spinal) accessory nerve arises from an elongated nucleus of motor neurones in the lateral aspect of the ventral horn. Some rootlets emerge directly, while others turn cranially before exiting; their line of exit is irregular rather than linear. They join to form a trunk, the accessory nerve, which ascends intradurally within the vertebral canal between the ligamentum denticulatum and the dorsal roots of the spinal nerves. The nerve enters the skull via the foramen magnum, behind the vertebral artery. It then turns upwards and passes laterally to reach the jugular foramen, which it traverses in a common dural sheath with the vagus, but separated from that nerve by a fold of arachnoid mater.

Extracranial course

As the accessory nerve exits the jugular foramen, it runs posterolaterally and passes either medial or lateral to the internal jugular vein; occasionally, it may pass through the vein. The extradural part of the nerve then crosses the transverse process of the atlas and is crossed by the occipital artery before descending obliquely, medial to the styloid process, stylohyoid and the posterior belly of digastric. Running with the superior sternocleidomastoid branch of the occipital artery, it reaches the upper part of sternocleidomastoid and enters its deep surface, to form an anastomosis with fibres from C2 alone, C3 alone, or C2 and C3 (the ansa of Maubrac). It may also communicate with the ventral root of the first cervical nerve (McKenzie branch).

The accessory nerve occasionally terminates in sternocleidomastoid. More commonly it emerges, usually as one trunk, 5–10 mm cephalad to the point where the great auricular nerve winds around sternocleidomastoid, and moves from a plane posterior to the muscle to one that is anterior. The relationship between the accessory nerve and the great auricular nerve in the posterior triangle is the key to exposure of the accessory nerve: the general relations of the posterior triangle vary with individual physique, but this relation between the two nerves is reliably consistent. The accessory nerve then runs across the fatty areolar tissue at the apex of the posterior triangle, in close relation to the superior superficial cervical lymph nodes in levels Va and Vb, deep to platysma. It is separated from the underlying levator scapulae by this areolar tissue, and, more deeply, by the prevertebral fascia (see Fig. 35.7A). One slender branch passes to the upper fibres of trapezius either deep to sternocleidomastoid or just beyond it. The nerve pierces the fascia covering the deep surface of trapezius close to the anterior border of the muscle and then runs caudally about 2 cm from that border. It passes down in a characteristic sinuous fashion, accompanied by slender vessels to the deep, inner face of trapezius. A branch from the cervical plexus (third and fourth cervical ventral rami) joins the nerve just above the clavicle. Intraoperative stimulation of this branch rarely evokes a muscular response; it probably conveys afferent fibres from the middle and lower parts of trapezius. The nerve now turns medially, continuing in parallel to the spine of the scapula about 4 cm above it. At the medial end of the spine, the nerve turns caudally again, passing down parallel to the medial border of the scapula. It divides into terminal muscular branches about 7 cm distal to the scapular spine. Although sternocleidomastoid, and the middle and the lower portions of trapezius, may be partially supplied by branches from the cervical plexus, the upper part of trapezius is innervated solely by the accessory nerve.

The cervical course of the accessory nerve follows a line from the lower anterior part of the tragus to the tip of the transverse process of the atlas, and then across sternocleidomastoid and the posterior triangle to a point on the anterior border of trapezius 3–5 cm above the clavicle.

The accessory nerve is thought to provide the sole motor supply to sternocleidomastoid; the second and third cervical nerves are believed to carry proprioceptive fibres from it. The supranuclear pathway of fibres destined for sternocleidomastoid is not simple; current evidence favours bilateral hemispheric innervation, although opinion varies as to the extent of the ipsilateral input. The motor supply to the descending (upper) and transverse (middle) portions of trapezius is primarily from the accessory nerve under predominantly contralateral supranuclear control. Usually, trapezius receives an innervation from the cervical plexus, in most cases from C3 and C4 (Tubbs et al 2011). A study using intraoperative electroneurography and histochemical analyses found that, when present, the cervical fibres did not consistently innervate all three parts of the muscle (descending, transverse and ascending), and that fibres from C2 usually travelled via the accessory nerve, while fibres from C3 and C4 innervated trapezius independently (Pu et al 2008). In addition, to their motor contribution, C3 and C4 also carry proprioceptive fibres from trapezius.

On the basis of the incomplete denervation of the muscle that sometimes happens following sacrifice of both the accessory nerve and the cervical plexus, it has been suggested that trapezius receives a partial motor supply from other sources, possibly via thoracic roots. (For a detailed review of the applied surgical anatomy of the accessory nerve plexus, see Brown (2002).)

Sensory ganglia have been described along the course of the intradural portion of the nerve.

Lesions of the accessory nerve

Lesions of the accessory nerve may be sustained centrally, at its exit from the skull or in the neck. The supranuclear fibres that influence motor neurones innervating sternocleidomastoid decussate twice; a lesion of the corticospinal system above the pons therefore produces weakness of the ipsilateral sternocleidomastoid and contralateral trapezius. Episodic contraction of sternocleidomastoid and trapezius, often accompanied by contraction of other muscle groups, e.g. splenius capitis, occurs in spasmodic torticollis, a focal dystonia. In jugular foramen syndrome, caused by pathologies including nasopharyngeal carcinoma or a jugular paraganglioma, lesions of the glossopharyngeal, vagus and accessory nerves coexist. The accessory nerve can be injured more distally in the neck by trauma or by surgical exploration in the posterior triangle, particularly at the apex of the triangle. Typically, there is immediate pain, then dropping of the shoulder and a remarkable loss of function. The average ISHA is about 50°. The pain is characteristic: often severe, deep-seated, dull, constant and boring in nature, and felt around the scapula and the posterior aspect of the neck and shoulder. The posture of the scapula is also characteristic: because of the loss of the great suspensory muscle, trapezius, the scapula drops down and away from the spinal column (see Fig. 49.37). There is often winging of the scapula, easily distinguished from that caused by paralysis of serratus anterior by the posture of the scapula (see Fig. 49.38). The nerve appears to be relatively immune to the harmful effects of delayed repair, even as late as 4 years after injury, with early relief of pain long before there is reinnervation of muscle (Camp and Birch 2011).

HYPOGLOSSAL NERVE

The hypoglossal nerve is the twelfth cranial nerve and is motor to all the muscles of the tongue except palatoglossus.

Hypoglossal nucleus and central connections

The hypoglossal nucleus lies near the midline in the dorsal medullary grey matter. It is approximately 2 cm long and extends from the hypoglossal trigone in the floor of the fourth ventricle into the closed part of the medulla (see Figs 28.3, 28.5, 28.8). It consists of large motor neurones interspersed with myelinated fibres and is organized into dorsal and ventral nuclear tiers, each divisible into medial and lateral subnuclei. A musculotopic organization of motor neurones within the nuclei corresponds to the structural and functional divisions of tongue musculature. Experimental evidence suggests that motor neurones of the medial division of the hypoglossal nucleus innervate tongue muscles that are orientated in planes transverse to the long axis of the tongue (transverse and vertical intrinsics and genioglossus), whereas motor neurones of the lateral division innervate tongue muscles that are orientated parallel to this axis (styloglossus, hyoglossus, superior and inferior longitudinal).

The hypoglossal nucleus receives corticonuclear fibres from the precentral gyrus and adjacent areas, predominately from the contralateral hemisphere. The corticonuclear fibres synapse either directly on motor neurones of the nucleus or on interneurones. Most medial hypoglossal subnuclei receive projections from both cerebral hemispheres. The hypoglossal nucleus may connect with the cerebellum via the adjacent perihypoglossal nucleus, and perhaps also with the medullary reticular formation, the trigeminal sensory nucleus and the nucleus solitarius (Holstein 2012).

Hypoglossal fibres emerge from the ventral aspect of the nucleus and traverse the reticular formation lateral to both the medial lemniscus and the medial accessory olivary nucleus. They continue ventrally, between the medial accessory and the principal inferior olivary nuclei, and then curve laterally to emerge from the brainstem as a series of 10–15 rootlets arranged linearly along the preolivary sulcus (see Fig. 28.8) (Yousry et al 2002). These rootlets coalesce into two bundles that exit separately through the hypoglossal canal and unite extradurally.

Extracranial course

The hypoglossal rootlets run laterally behind the vertebral artery, collected into two bundles that perforate the dura mater separately opposite the hypoglossal canal in the occipital bone, and unite after traversing it. The canal is sometimes divided by a spicule of bone. The nerve emerges from the canal in a plane medial to the internal jugular vein, internal carotid artery and glossopharyngeal, vagus and accessory nerves, and passes inferolaterally behind the internal carotid artery and glossopharyngeal and vagus nerves to the interval between the artery and the internal jugular vein (see Fig. 35.8). Here, it makes a half-spiral turn round the inferior vagal ganglion, united to it by connective tissue. It then descends almost vertically between the vessels and anterior to the vagus to a point level with the angle of the mandible, becoming superficial below the posterior belly of digastric and emerging between the internal jugular vein and internal carotid artery. Often associated with a plexus of veins around the junction of the common facial and internal jugular veins (vena comitans nervi hypoglossi), excessive bleeding here during neck dissection can lead to nerve damage. The nerve loops round the inferior sternocleidomastoid branch of the occipital artery, crosses lateral to both internal and external carotid arteries and the loop of the lingual artery a little above the tip of the greater cornu of the hyoid, and is itself crossed by the facial vein (see Figs 35.7A, 35.8, 35.17). The nerve next inclines upwards and forwards on hyoglossus, passing deep to stylohyoid, the tendon of digastric and the posterior border of mylohyoid. Between mylohyoid and hyoglossus, the hypoglossal nerve lies below the deep part of the submandibular gland, the submandibular duct and the lingual nerve, with which it communicates. It then passes on to the lateral aspect of genioglossus, continuing forwards in its substance as far as the tip of the tongue (see Fig. 37.11A). It distributes fibres to styloglossus, hyoglossus and genioglossus and to the intrinsic muscles of the tongue. Cadaveric tongues stained using Sihler's stain (a whole mount nerve staining technique that renders a large specimen transparent while counterstaining all nerves) or acetylcholinesterase or silver stains, show the basic mammalian intralingual pattern of hypoglossal nerve distribution but with notable differences, even from non-human primates. Thus, many muscle fibres, particularly in the transverse group of intrinsic muscles, contain multiple *en grappe* motor end-plates (suggesting that they are some variant of slow tonic muscle fibres). Presumably, these specializations facilitate the fine motor control of tongue shape that is required in speech and swallowing (Mu and Sanders 2010) (see Fig. 37.13).

The hypoglossal nerve has meningeal, descending, thyrohyoid, geniohyoid and communicating branches.

Meningeal branches

Meningeal branches leave the nerve in the hypoglossal canal and return through it to supply the diploë of the occipital bone, the dural walls of the occipital and inferior petrosal sinuses, and much of the floor of the anterior wall of the posterior cranial fossa, probably through pathways other than that of the hypoglossal nerve, e.g. upper cervical spinal nerves (see Fig. 25.3B).

Descending branch

The descending branch (descendens hypoglossi) contains fibres from the first cervical spinal nerve. It leaves the hypoglossal nerve when it curves around the occipital artery, and runs down on the carotid sheath. It provides a branch to the superior belly of omohyoid before joining the descendens cervicalis to form the ansa cervicalis (see Figs 35.7A, 35.8).

Nerves to thyrohyoid and geniohyoid

The nerves to thyrohyoid and geniohyoid arise near the posterior border of hyoglossus and are derived from the first cervical ventral ramus.

Communicating branches

The hypoglossal nerve communicates with the sympathetic trunk, the lingual, glossopharyngeal and vagus nerves and the pharyngeal plexus. Near the atlas it is joined by branches from the superior cervical sympathetic ganglion and a filament from the loop between the first cervical ventral ramus and the ascending branch of the second cervical ventral ramus that leaves the hypoglossal nerve as the upper root of the ansa cervicalis. The vagal connections are close to the skull; numerous filaments pass between the hypoglossal nerve and the inferior vagal ganglion in the connective tissue that unites them. As the hypoglossal nerve curves round the occipital artery it receives the ramus lingualis vagi from the pharyngeal plexus. Near the anterior border of hyoglossus it is connected with the lingual nerve by many filaments that ascend on the muscle.

Lesions of the hypoglossal nerve

The hypoglossal nerve may be damaged during neck dissection. Complete hypoglossal division causes unilateral lingual paralysis and eventual hemiatrophy; the protruded tongue deviates to the paralysed side, and, on retraction, the wasted and paralysed side rises higher than the unaffected side. The larynx may deviate towards the active side in swallowing, as a consequence of the unilateral paralysis of the hyoid depressors associated with loss of the first cervical ventral ramus, which runs with the hypoglossal nerve. If paralysis is bilateral, the tongue is motionless. Taste and tactile sensibility are unaffected but articulation is slow and swallowing very difficult.

The hypoglossal nerve is often used to reanimate the face in patients, particularly the elderly, when their facial nerves have been transected. Direct end-to-end, end-to-side or split-nerve grafts are reliable and offer a robust, effective and quick alternative to more complex reanimation procedures.

SPINAL NERVES

Spinal nerves are the means by which the central nervous system receives information from, and controls the activities of, the trunk and limbs. There are 31 pairs of spinal nerves (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, 1 coccygeal): they contain a mixture of sensory and motor fibres. The abbreviations C, T, L, S and Co, with appropriate numerals, are commonly applied to individual nerves as their 'root value'.

Spinal nerves pass through intervertebral foramina. At thoracic, lumbar, sacral and coccygeal levels, the numbered nerve exits the vertebral canal by passing below the pedicle of the corresponding vertebra, e.g. the fourth lumbar nerve (L4) nerve exits the intervertebral foramen between the fourth and fifth lumbar vertebrae. However, in the cervical region, the upper seven cervical nerves (C1–C7) pass above their corresponding vertebrae. The first cervical nerve (C1) exits the vertebral canal between the occipital bone and atlas, and is often termed the suboccipital nerve. The last pair of cervical nerves does not have a correspondingly numbered vertebra and the eighth cervical nerve passes between the seventh cervical and first thoracic vertebrae.

Appearance and orientation of roots at each spinal level

The size and direction of spinal nerve roots vary. The upper four cervical roots are small, while the lower four are large. Cervical dorsal roots have a thickness ratio to the ventral roots of 3:1, which is greater than in other regions. The first dorsal root is an exception, because it is smaller than its ventral counterpart, and is occasionally absent. The first and second cervical spinal roots are short and run almost horizontally to their exits from the vertebral canal, whereas from the third to the eighth cervical levels the roots slope obliquely down. Obliquity and length increase successively, although the distance between spinal attachment and vertebral exit never exceeds the height of one vertebra. There is an alternative view that the upper cervical roots descend, the fifth is horizontal, the sixth to eighth ascend, the first two thoracic roots are horizontal, the next three ascend, the sixth is horizontal and the rest descend (Kubik and Müntener 1969): this view is based on the observation that the cervicothoracic part of the spinal cord grows more in length than other parts.

Thoracic roots, except the first, are small, and the dorsal root only slightly exceeds the ventral in thickness. They increase successively in length. In the lower thoracic region, the roots descend in contact with the spinal cord for at least two vertebrae before emerging from the vertebral canal.

Lower lumbar and upper sacral roots are the largest, and their rootlets are the most numerous. Coccygeal roots are the smallest. Lumbar, sacral and coccygeal roots descend with increasing obliquity to their exits (Kubik and Müntener 1969). The spinal cord ends near the lower border of the first lumbar vertebra, which means that the lengths of successive roots rapidly increase: the consequent collection of roots forms the cauda equina (see Fig. 47.1A). The largest roots, and hence the largest spinal nerves, are continuous with the spinal cervical and lumbar enlargements and innervate the upper and lower limbs.

Spinal ganglia (dorsal root ganglia)

Spinal ganglia (dorsal root ganglia, DRG) are large groups of sensory neurones on the dorsal spinal roots. Each is oval and reddish: its size is related to that of its root. A ganglion is bifid medially where the two fascicles of a dorsal root emerge to enter the spinal cord. Ganglia usually lie in the intervertebral foramina, immediately lateral to the perforation of the dura mater by the roots (see Fig. 47.6A). However, the first cervical ganglion (when present) lies on the vertebral arch of the atlas and the second lies posterior to the lateral atlanto-axial joint; the sacral ganglia lie inside the vertebral canal; and the coccygeal ganglion usually lies within the dura mater. Small aberrant ganglia sometimes occur on the upper cervical dorsal roots between the spinal ganglia and the cord.

Spinal nerves proper

Immediately distal to the spinal ganglia, ventral and dorsal roots unite to form spinal nerves. These very soon divide into dorsal and ventral rami, both of which receive fibres from both roots (see Fig. 47.6A). At all levels above the sacral, this division occurs within the intervertebral foramen. Division of the sacral spinal nerves occurs within the sacral vertebral canal, and the dorsal and ventral rami exit separately through posterior and anterior sacral foramina at each level. Spinal nerves trifurcate at some cervical and thoracic levels, in which case the third branch is called a ramus intermedius. At or distal to its origin, each ventral ramus gives off recurrent meningeal (sinuvertebral) branches and receives a grey ramus communicans from the corresponding sympathetic ganglion. All the thoracic and first and second lumbar ventral rami each contribute a white ramus communicans to the corresponding sympathetic ganglia. The second, third and fourth sacral nerves supply visceral branches that carry a preganglionic parasympathetic outflow direct to the pelvic plexuses.

Cervical spinal nerves enlarge from the first to the sixth nerve. The seventh and eighth cervical and the first thoracic nerves are similar in size to the sixth cervical nerve. The remaining thoracic nerves are relatively small. Lumbar nerves are large, increasing in size from the first to the fifth. The first sacral nerve is larger than the other sacral nerves, which progressively decrease in size. The coccygeal nerves are the smallest spinal nerves.

In the radicular ('root') canal and intervertebral foramen, a spinal nerve is related to the spinal artery of that level and its radicular branch, and to a small plexus of veins. At the outer end of the foramen, the nerve may lie above or below transforaminal ligaments. The size of a spinal nerve and associated structures within the intervertebral foramen is not in direct relation to the size of the foramen through which the nerve exits: the fifth lumbar nerve is the largest of the lumbar nerves but its foramen is smaller than those of the first four lumbar nerves, and so it is particularly liable to compression.

Meningeal nerves

Recurrent meningeal (or sinuvertebral) nerves (see Fig. 47.9) occur at all vertebral levels. They are mixed sensory and sympathetic nerves, represented by numerous fine filaments amongst which as many as four larger trunks may be evident. At cervical levels the autonomic roots arise from the grey rami that form the vertebral nerve. At thoracic and lumbar levels, each nerve is formed by a somatic root from the ventral ramus and by an autonomic root from the grey ramus communicans of that segment. Each nerve pursues a recurrent course through the intervertebral foramen, passing ventral to the spinal nerve, to enter the vertebral canal, where it divides into ascending, descending and transverse branches. These branches communicate with corresponding branches from the segments above and below, and from the contralateral side, forming arcades along the floor of the vertebral canal. Meningeal branches of the arcades form a plexus on the ventral surface of the dural sac and nerve root sleeves that attenuates laterally; the posterior paramedian dura is devoid of nerve endings. Skeletal branches are distributed to the posterior longitudinal ligament, the periosteum of the vertebral bodies, and to the posterior and posterolateral aspects of the intervertebral discs (Garcia-Cosamalon et al 2010). Vascular branches accompany the veins and arteries of the vertebral canal and those of the vertebral bodies. The upper three cervical meningeal nerves ascend through the foramen magnum into the posterior cranial fossa, where they innervate the dura mater that covers the clivus; en route, they innervate the median atlanto-axial joint and its ligaments.

Variations of spinal roots and nerves

The courses of spinal roots and nerves in relation to the thecal sac and vertebral and radicular canals may be aberrant. An individual intervertebral foramen may contain a duplicated sheath, nerve and roots, which will then be absent at an adjacent level. Abnormal communications between roots may occur within the vertebral canal. These anomalies have been described and classified for the lumbosacral spine by Neidre and Macnab (1983).

Functional components of spinal nerves

A typical spinal nerve contains somatic efferent fibres and somatic and visceral afferent fibres. Some, but not all, spinal nerves also contain preganglionic autonomic fibres.

Somatic components

Somatic efferent fibres innervate skeletal muscles and are axons of α, β and γ neurones in the spinal ventral grey column. Somatic afferent fibres are the peripheral processes of unipolar neurones in the spinal ganglia and convey impulses into the CNS from receptors in the skin, subcutaneous tissues, muscles, tendons, fasciae and joints.

Visceral components

Visceral efferent fibres

Preganglionic visceral efferent sympathetic fibres are axons of neurones in the spinal intermediolateral grey column throughout the thoracic and upper two or three lumbar segments; they join the sympathetic trunk via corresponding white rami communicantes and synapse with postganglionic neurones that are distributed to smooth muscle, myocardium or exocrine glands.

Preganglionic visceral efferent parasympathetic fibres are axons of neurones in the spinal lateral grey column of the second to fourth sacral segments; they leave the ventral rami of corresponding sacral nerves and synapse in pelvic ganglia. Postganglionic axons are distributed mainly to smooth muscle or glands in the walls of the pelvic viscera.

Visceral afferent fibres

General visceral afferent fibres from the viscera and blood vessels accompany their efferent counterparts. They respond to various stimuli including excessive muscular contraction or distension, ischaemia and inflammation; their neuronal somata are located in the glossopharyngeal and vagal ganglia and in thoracic and lumbosacral dorsal root ganglia (visceral afferent fibres that run mainly with sympathetic efferent fibres). Their central projections reach the brainstem and spinal cord, respectively. Sensory fibres in the vagus are more numerous in

the derivatives of the foregut than those of the derivatives of the midgut and are concerned with physiological responses such as satiety, whereas pain and discomfort are mediated by spinal pathways.

The somata of glossopharyngeal general visceral afferents are in the glossopharyngeal ganglia. Their peripheral processes innervate the postsulcal lingual region, the palatine tonsils and pharynx, but they do not innervate taste buds. They also innervate the carotid sinus and the carotid body, which contain receptors sensitive to tension and changes in chemical composition of the blood. Impulses from these receptors are essential to circulatory and respiratory reflexes.

The somata of vagal general visceral afferent fibres are in the superior and inferior vagal ganglia. Their peripheral processes are distributed to terminals in the pharyngeal and oesophageal walls where, acting synergistically with glossopharyngeal visceral afferents in the pharynx, they are concerned with swallowing reflexes. Vagal afferents are also believed to innervate the thyroid and parathyroid glands. In the heart, vagal afferents innervate the walls of the great vessels, the aortic bodies and pressor receptors, where they are stimulated by raised intravascular pressure. In the lungs they are distributed via the pulmonary plexuses. They supply bronchial mucosa, where they are probably involved in cough reflexes; bronchial muscle, where they encircle myocytes and end in tendrils, which are sometimes regarded as muscle spindles and which are believed to be stimulated by change in the length of myocytes; interalveolar connective tissue, where their knob-like endings, together with terminals on myocytes, may evoke Hering–Breuer reflexes; the adventitia of pulmonary arteries, where they may be pressor receptors; and the intima of pulmonary veins, where they may be chemoreceptors. Vagal visceral afferent fibres also end in the gastric and intestinal walls, digestive glands and the kidneys. Fibres ending in the gut and its ducts respond to stretch or contraction. Gastric impulses may evoke sensations of hunger and nausea.

Visceral afferents that enter the spinal cord through spinal nerve roots branch extensively and synapse on viscerosomatic neurones in the dorsal horn and intermediate grey matter. Almost all the central processes of vagal and glossopharyngeal afferent fibres end in the nucleus solitarius of the medulla. About 5% of the vagal afferents project directly to, and terminate in, the upper cervical spinal cord (C1–C2), where they are believed to contribute to referred sensations, as well as to propriospinal mechanisms of nociceptive modulation. Visceral afferents establish connections within the CNS that mediate autonomic reflexes. In addition, afferent impulses probably mediate visceral sensations such as hunger, nausea, sexual excitement, vesical distension, etc. Visceral pain fibres may follow these routes. Although viscera are insensitive to cutting, crushing or burning, excessive tension in smooth muscle and some pathological conditions produce visceral pain. In visceral disease, vague pain may be felt near the viscus itself (visceral pain) or in a cutaneous area or other tissue whose somatic afferents enter spinal segments receiving afferents from the viscus, a phenomenon known as referred pain. If inflammation spreads from a diseased viscus to the adjacent parietal serosa (e.g. the peritoneum), somatic afferents will be stimulated, causing local somatic pain, which is commonly spasmodic. Referred pain is often associated with local cutaneous tenderness. For further reading on visceral pain, see Bielefeldt and Gebhart (2013).

Afferent fibres in pelvic splanchnic nerves innervate pelvic viscera and the distal part of the colon. Vesical receptors are widespread; those in muscle strata are associated with thickly myelinated fibres and are believed to be stretch receptors, possibly activated by contraction. Pain fibres from the bladder and proximal urethra traverse both the pelvic splanchnic nerves and the inferior hypogastric plexus, hypogastric nerves, superior hypogastric plexus and lumbar splanchnic nerves to reach their cell bodies in ganglia on the lower thoracic and upper lumbar dorsal spinal roots; the significance of this dual sensory pathway is uncertain. Lesions of the cauda equina abolish pain from vesical overdistension, but hypogastric section is ineffective. Pain fibres from the uterus traverse the hypogastric plexus and lumbar splanchnic nerves to reach somata in the lowest thoracic and upper lumbar spinal ganglia, and hypogastric division may relieve dysmenorrhoea. Afferents from the uterine cervix traverse the pelvic splanchnic nerves to reach their somata in the upper sacral spinal ganglia; stretching the cervix uteri causes pain but cauterization and biopsy excisions do not.

In general, afferent fibres that accompany pre- and postganglionic sympathetic fibres have a segmental arrangement and end in spinal cord segments from which preganglionic fibres innervate the region or viscus concerned. General visceral afferents entering thoracic and upper lumbar spinal segments are largely concerned with pain. Nociceptive impulses from the pharynx, oesophagus, stomach, intestines, kidneys, ureter, gallbladder and bile ducts seem to be carried in sympathetic pathways. Cardiac nociceptive impulses enter the spinal cord in the first to fifth thoracic spinal nerves, mainly via the middle and inferior cardiac nerves, but some fibres pass directly to the spinal nerves. It is said that there are no general visceral afferents in the superior cardiac nerves. Peripherally, the fibres pass through the cardiac plexuses and along the coronary arteries. Myocardial anoxia may evoke symptoms of angina pectoris in which pain is typically presternal, and is also referred to much of the left chest, and radiates to the left shoulder, the medial aspect of the left arm, along the left side of the neck to the jaw and occiput, and down to the epigastrium. Cardiac afferents carried in vagal cardiac branches are concerned with the reflex depression of cardiac activity. Ureteric pain fibres, also running with sympathetic fibres, are presumably involved in the agonizing renal colic that follows obstruction by calculi. Afferent fibres from the testis and ovary run through the corresponding plexuses to somata in the tenth and eleventh thoracic dorsal root ganglia.

Some primary afferent neurones, innervating the gut, lungs, heart and blood vessels, also appear to have an efferent function in that they release transmitters from their peripheral endings during the axon reflex. The primary substances released in this way are substance P, calcitonin gene-related peptide (CGRP) and ATP. These act on target cells to produce vasodilation, increased venular permeability, changes in smooth muscle contractility, degranulation of mast cells and a variety of effects on leukocytes and fibroblasts, a process collectively known as 'peripheral neurogenic inflammation'. The local release of such substances may play a trophic role in the maintenance of tissue integrity and repair in response to injury (for further reading, see Xanthos and Sandkühler (2014)).

RAMI OF THE SPINAL NERVES

Spinal nerves exit from the vertebral canal via their corresponding intervertebral foramina. They then divide to form a large ventral (anterior) ramus and a smaller dorsal (posterior) ramus. In general terms, the ventral rami innervate the limbs and the muscles and skin of the anterolateral trunk. The axons within the ventral rami serving the neck, upper and lower limbs are redistributed within cervical, brachial and lumbosacral plexuses, respectively. Thoracic ventral rami run independently and retain a largely segmental distribution. Dorsal (posterior) rami of spinal nerves are usually smaller than the ventral rami and are directed posteriorly. Retaining a segmental distribution, all, except for the first cervical, fourth and fifth sacral and the coccygeal, divide into medial and lateral branches that supply the muscles and skin of the posterior regions of the neck and trunk (see Fig. 47.8).

Dorsal rami

Cervical dorsal spinal rami

Each cervical spinal dorsal ramus, except the first, divides into medial and lateral branches that all innervate muscles. In general, only medial branches of the second to fourth, and usually the fifth, supply the skin. Except for the first and second, each dorsal ramus passes posteriorly medial to a posterior intertransverse muscle (which it supplies), curving round the articular process into the interval between semispinalis capitis and semispinalis cervicis.

First cervical dorsal ramus (suboccipital nerve)

The first cervical dorsal ramus, the suboccipital nerve, is larger than the ventral (see Fig. 46.78). It emerges superior to the posterior arch of the atlas and inferior to the vertebral artery, and enters the suboccipital triangle to supply rectus capitis posterior major and minor, obliquus capitis superior and inferior, and semispinalis capitis. A filament from the branch to inferior oblique joins the second dorsal ramus. The suboccipital nerve occasionally has a cutaneous branch that accompanies the occipital artery to the scalp, and connects with the greater and lesser occipital nerves. It may also communicate with the accessory nerve.

Second cervical dorsal ramus

The second cervical dorsal ramus is slightly larger than the ventral and all the other cervical dorsal rami (see Figs 36.22, 46.78). It runs between the lamina of the axis and inferior oblique, below which it divides into a large medial and smaller lateral branch. The dorsal ramus or its medial branch receives communicating branches from the first cervical dorsal ramus that pass both through and around inferior oblique. A descending communicating branch crosses the facet joint between the second and third cervical vertebrae to reach the third cervical dorsal ramus.

Greater occipital nerve

The medial branch, termed the greater occipital nerve, passes transversely across inferior oblique deep to semispinalis capitis, which it innervates. Near the origin of inferior oblique, it turns rostrally along rectus capitis posterior major, where it receives a communicating branch

from the third occipital nerve before turning dorsally to pierce semispinalis capitis. It emerges on to the scalp by passing above an aponeurotic sling between trapezius and sternocleidomastoid near their occipital attachments. It ascends with the occipital artery and divides into branches that connect with the third occipital and lesser occipital nerves, and which supply the back of the auricle and the skin of the scalp as far forwards as the coronal suture. The lateral branch of the second cervical dorsal ramus supplies longissimus capitis, semispinalis capitis and splenius capitis, and sends a communicating branch to the lateral branch of the third cervical dorsal ramus.

Greater occipital neuralgia Greater occipital neuralgia is a syndrome of pain and paraesthesiae felt in the distribution of the greater occipital nerve. This is usually caused by damage or irritation to the greater occipital nerve but more rarely can result from a similar process in the lesser occipital nerve or both greater and lesser occipital nerves. A similar syndrome may be caused by upper facet joint arthritis involving the second cervical root (Vanelderen et al 2010).

Third cervical dorsal ramus

The third cervical dorsal ramus is intermediate in size between the second and fourth. It courses back round the articular pillar of the third cervical vertebra, medial to the posterior intertransverse muscle, and divides into medial and lateral branches. The lateral branch passes dorsally across the surface of semispinalis capitis to supply it and the overlying longissimus capitis and splenius capitis. It receives a communicating branch from the lateral branch of the second cervical dorsal ramus, and sends a similar branch to the lateral branch of the fourth cervical dorsal ramus. The deep medial branch curves dorsally and medially around the waist of the articular pillar before ending in multifidus. It sends an articular branch to the facet joint between the third and fourth cervical vertebrae, and may also send a branch into semispinalis capitis. The superficial medial branch, the third occipital nerve, curves around the lateral and dorsal surfaces of the facet joint between the second and third cervical vertebrae, which it supplies. It continues transversely, deep to semispinalis, which it supplies, and sends a communicating branch to the greater occipital nerve. Just above the second cervical spinal process, the third occipital nerve turns dorsally to pierce semispinalis capitis, splenius capitis and trapezius, and becomes cutaneous over a small area immediately below the superior nuchal line. Communicating branches join the cutaneous branches of the greater and lesser occipital nerves.

Dorsal rami of the lower five cervical nerves

The dorsal rami of the lower five cervical nerves curve back round the vertebral articular pillars and divide into lateral and medial branches. The lateral branches supply longissimus cervicis, splenius cervicis and iliocostalis cervicis. The medial branches curve around the lateral and dorsal surfaces of the articular pillar of their segment, deep to semispinalis capitis. They send articular branches to the facet joints above and below their course before entering and supplying multifidus. Terminal branches reach interspinalis at each segment. Cutaneous branches arise consistently from the fourth, and commonly from the fifth, sixth and eighth, but not usually from the seventh medial branches. These branches pass across multifidus or through semispinalis cervicis and turn dorsally around the medial border of semispinalis capitis, to pierce splenius cervicis and trapezius and reach the skin.

Thoracic dorsal spinal rami

The dorsal rami of the thoracic spinal nerves supply the intrinsic muscles of the back and the overlying postvertebral skin on a segmental basis (see Figs 46.3, 47.8). At each segmental level, they pass dorsally through an aperture bounded by the transverse processes superiorly and inferiorly, the facet joint medially and the superior costotransverse ligament laterally. Thereafter, each dorsal ramus follows a prolonged course laterally, between the anterior lamella of the superior costotransverse ligament anteriorly, and the costolamellar ligament and the posterior lamella of the superior costotransverse ligament posteriorly. In this narrow space, the dorsal ramus divides into lateral and medial branches. The lateral branches continue laterally as far as the costotransverse joint, above which they turn dorsally and inferiorly to supply levatores costarum, and enter longissimus thoracis and iliocostalis. Lateral branches from the upper six thoracic dorsal rami remain intramuscular. Those from the lower six levels emerge from iliocostalis lumborum to pierce serratus posterior inferior and latissimus dorsi in line with the costal angles. They descend across as many as four ribs before becoming superficial. The twelfth thoracic lateral branch sends a filament medially along the iliac crest and then passes down to the anterior gluteal skin. Some upper thoracic lateral branches may become cutaneous.

Each medial branch hooks dorsally around the lateral margin of the posterior lamella of the superior costotransverse ligament, lying a variable distance above the tip of the transverse process. At the first to fourth, and at the ninth and tenth thoracic levels, the medial branches cross the superior tip of the transverse process to turn inferiorly and medially across the posterior surface of the transverse process, lying between the attachment sites of multifidus medially and semispinalis laterally. Each nerve continues this oblique course to supply multifidus and semispinalis. At the fifth to eighth thoracic levels, the medial branches assume a course parallel to that of other levels, but do not reach the transverse process, instead passing superior and dorsal to the plane of the transverse processes. At the eleventh and twelfth levels, in keeping with the relatively short transverse processes at these levels, the medial branches run close to the superior articular processes. Each medial branch supplies articular branches to the facet joints above and below its course. Medial branches of the upper six thoracic dorsal rami furnish cutaneous branches that pierce trapezius and the rhomboids to reach the skin near the spinous processes. Cutaneous branches may occasionally arise from the medial branches of the lower six thoracic dorsal rami.

Lumbar dorsal spinal rami

After leaving its spinal nerve, each of the first to fourth lumbar dorsal rami passes through an aperture in the dorsal leaf of the intertransverse ligament just above a transverse process (see Fig. 47.10). Each dorsal ramus supplies the overlying medial intertransverse muscle before dividing into lateral and medial branches. The lateral branches supply the longissimus and iliocostalis components of the lumbar erector spinae. The upper three lumbar lateral branches emerge from the lateral border of iliocostalis lumborum and pierce the aponeurosis of latissimus dorsi to become cutaneous. They cross the iliac crest to reach the gluteal skin; some reach as far as the level of the greater trochanter. Medial branches cross the junction of the superior articular process and transverse process, and hook medially between the mammillary and accessory processes, deep to the mammillo-accessory ligament. Medial to the ligament, each medial branch sends articular branches to the facet joints above and below its course, before entering multifidus, which it supplies. Medial branch blocks are quite useful in the treatment of facet-mediated low back pain. Terminal branches reach interspinalis at each segment.

The fifth dorsal ramus has a longer course than other dorsal rami. It arches over the ala of the sacrum, lying against the root of the first sacral superior articular process. Opposite the base of the lumbosacral joint, it sends a branch into the lowest fibres of longissimus thoracis, and a communicating branch to the first sacral dorsal ramus, before terminating as a branch that hooks around the lumbosacral joint to end in multifidus.

Sacral dorsal spinal rami

Sacral dorsal rami are small, diminishing in size inferiorly; other than the fifth, all emerge through the dorsal sacral foramina. The upper three are covered at their exit by multifidus, and divide into medial and lateral branches. Medial branches are small and end in multifidus. Lateral branches join together and with branches of the last lumbar and fourth sacral dorsal rami to form loops dorsal to the sacrum. Branches from these loops run dorsal to the sacrotuberous ligament and form a second series of loops under gluteus maximus. From these, two or three gluteal branches pierce gluteus maximus (along a line from the posterior superior iliac spine to the coccygeal apex) to supply the posterior gluteal skin.

The dorsal rami of the fourth and fifth sacral nerves are small and lie caudal to multifidus. They unite with each other and with the coccygeal dorsal ramus to form loops dorsal to the sacrum; filaments from these supply the skin over the coccyx.

Coccygeal dorsal spinal ramus

The coccygeal dorsal spinal ramus does not divide into medial and lateral branches. It communicates with the fourth and fifth sacral dorsal rami.

Ventral rami

Ventral rami innervate the skin of the anterolateral neck and trunk and the skin covering the upper and lower limbs. The second to the fourth cervical ventral rami (C2– C4) innervate the skin of the neck (branches from the cervical plexus); the fifth to the eighth cervical ventral rami (C5–C8) and the first thoracic ventral ramus (T1) innervate the skin of the upper limb (branches from the brachial plexus); the second thoracic to the first lumbar ventral rami (T2–L1) innervate the skin of the anterolateral trunk; the first or second thoracic ventral rami to the third sacral ventral ramus (L1/2–S3) innervate the skin of the lower limb and

perineum (branches of the lumbar and sacral plexuses). Ventral rami supply the flexor musculature of the neck and body wall segmentally and the infrahyoid muscles and the muscles of the limbs via cervical (C1–C4), brachial (C5–T1/2), lumbar (L1–L4/5) and sacral (L4/5–S3) plexuses.

Cervical ventral rami

Broadly speaking, cervical ventral rami innervate the anterior and lateral groups of prevertebral muscles; the respiratory diaphragm (via the phrenic nerve); the muscles and joints of the upper limb and most of the infrahyoid muscles; and the skin of the anterolateral neck, the radial side of the upper limb and the palmar and dorsal surfaces of the hand (via the cervical and brachial plexuses).

Cervical ventral rami, except the first, appear between the anterior and posterior intertransverse muscles. The upper four form the cervical plexus, and the lower four, together with most of the first thoracic ventral ramus, form the brachial plexus. Each receives at least one grey ramus communicans, the upper four from the superior cervical sympathetic ganglion, the fifth and sixth from the middle ganglion, and the seventh and eighth from the cervicothoracic ganglion.

The first cervical ventral ramus, the suboccipital nerve, emerges above the posterior arch of the atlas, and passes forwards lateral to its lateral mass and medial to the vertebral artery. It supplies rectus capitis lateralis, emerges medial to it, descends anterior to the transverse process of the atlas and posterior to the internal jugular vein, and joins the ascending branch of the second cervical ventral ramus.

The second cervical ventral ramus issues between the vertebral arches of the atlas and axis. It ascends between their transverse processes, passes anterior to the first posterior intertransverse muscle and emerges lateral to the vertebral artery, generally between longus capitis and levator scapulae. The ramus divides into an ascending branch, which joins the first cervical nerve, and a descending branch, which joins the ascending branch of the third cervical ventral ramus.

The third cervical ventral ramus appears between longus capitis and scalenus medius. The remaining ventral rami emerge between scalenus anterior and the scalenus medius.

Phrenic nerve

The phrenic nerve is a mixed somatic sensory and motor nerve that provides the sole motor supply to the respective hemirespiratory diaphragm. It is derived mostly from the ipsilateral fourth cervical ventral ramus, with contributions from the ipsilateral third and fifth cervical ventral rami (see Figs 35.17–35.18). The nerve is formed at the upper part of the lateral border of scalenus anterior and descends almost vertically across its anterior surface behind the prevertebral fascia. It descends posterior to sternocleidomastoid, the inferior belly of omohyoid (near its intermediate tendon), the internal jugular vein, transverse cervical and suprascapular arteries and, on the left, the thoracic duct. At the root of the neck, the phrenic nerve runs anterior to the second part of the subclavian artery, from which it is separated by scalenus anterior (some accounts state that on the left side the nerve passes anterior to the first part of the subclavian artery) and posterior to the subclavian vein. The phrenic nerve crosses serratus anterior from lateral to medial (lying under the prevertebral fascia) and enters the thorax by crossing medially anterior to the internal thoracic artery.

In the neck, each nerve receives variable filaments from the cervical sympathetic ganglia or their branches and may also connect with internal thoracic sympathetic plexuses.

Within the thoracic cavity, the right and left phrenic nerves descend anterior to the pulmonary hila, between the fibrous pericardium and mediastinal parietal pleura, accompanied by the pericardiacophrenic vessels. Each phrenic nerve supplies sensory branches to the mediastinal pleura, fibrous pericardium and parietal layer of serous pericardium: the right phrenic nerve supplies the part of the right crus that lies to the right of the oesophagus, and the left phrenic nerve supplies the left crus and the part of the right crus that lies on the left of the oesophagus.

The right and left phrenic nerves differ in their intrathoracic relationships (Rajanna 1947).

Right phrenic nerve

The right phrenic nerve is shorter and more vertical than the left. At the root of the neck it is separated from the second part of the right subclavian artery by scalenus anterior (see Fig. 55.10A). It then passes inferomedially through the superior thoracic aperture between the first part of the right subclavian artery and the right subclavian vein. Occasionally, the right or left phrenic nerves may pass anterior to, or through the anterior wall of, the respective subclavian vein (Paraskevas et al 2011). Around the level of the first rib or the first costal cartilage, the right phrenic nerve crosses the right internal thoracic artery either superiorly between the artery and the first rib, or inferiorly, pressed against the artery by the apex of the right lung and its covering pleura (Owens et al 1994). The nerve continues to descend, passing immediately lateral to the right brachiocephalic vein, the superior vena cava, the fibrous pericardium covering the right side of the right atrium and the inferior vena cava. It branches just superior to, or at the level of, the respiratory diaphragm.

Left phrenic nerve

At the root of the neck, the left phrenic nerve commonly leaves the medial border of scalenus anterior and passes anterior to the first part of the left subclavian artery and posterior to the left subclavian vein and the thoracic duct (see Fig. 55.10B). Sometimes the right and left phrenic nerves are symmetrical in their cervical course, in which case the left phrenic nerve is initially separated from the second part of the left subclavian artery by scalenus anterior. After passing through the superior thoracic aperture the left phrenic nerve crosses the left internal thoracic artery, most commonly superiorly, around the level of the first rib or the first costal cartilage (Owens et al 1994). It descends across the medial aspect of the apex of the left lung and its pleural covering to pass between the left common carotid and left subclavian arteries. The nerve then descends anteromedially and passes anterior and close to the left vagus nerve while in the region superior to the aortic arch and posterior to the left brachiocephalic vein. It continues inferiorly, passing anterior to the left superior intercostal vein, the aortic arch and the left pulmonary hilum, after which it passes inferolaterally and to the left, over the fibrous pericardium covering the left atrium and left ventricle (see Fig. 55.9). As it passes over the fibrous pericardium, the left phrenic nerve is located more anterior than the right phrenic nerve and is therefore at greater risk of damage during the placement of surgical incisions to access the pericardial cavity.

Diaphragmatic relationships The right phrenic nerve passes through the central tendon of the respiratory diaphragm, either via the caval foramen or just lateral to it. The left phrenic nerve passes through the muscular part of the respiratory diaphragm anterior to the central tendon, just lateral to the fibrous pericardium covering the left pulmonary border of the heart, and posterior to the cardiac apex (see Fig. 55.9). At or slightly superior to the respiratory diaphragm each phrenic nerve supplies fine branches to the parietal pleura that lies above the central part of the diaphragm. Typically, the trunk of each nerve then divides into three branches (anterior or sternal, anterolateral and posterior) as it passes through the respiratory diaphragm (see Fig. 55.1A). The main branches may be submerged in diaphragmatic muscle or lie inferior to it. They supply motor fibres to the muscle and sensory fibres to the peritoneum and pleura related to the central part of the respiratory diaphragm. They also relay proprioceptive fibres from the musculature. The anterior (sternal) branch runs anteromedially towards the sternum and connects with its contralateral counterpart. The anterolateral branch runs to the lateral folia of the central tendon. The short posterior branch divides into a posterolateral ramus that passes posterior to the left or right folia of the central tendon and a posterior ramus that supplies the crura of the respiratory diaphragm. The posterolateral and posterior crural branches may arise separately from the phrenic nerve.

Phrenic ganglia The right phrenic nerve continues its course inferior to the respiratory diaphragm and frequently connects to the right phrenic ganglion. An additional, smaller, right accessory phrenic ganglion is sometimes located proximally along the phrenic nerve, close to its exit from the caval foramen. The right phrenic ganglion has plexiform communications with the coeliac and aorticorenal ganglia and with the right suprarenal gland (see Fig. 55.11). A left phrenic ganglion is less commonly seen; when present, it exhibits plexiform communications to several autonomic ganglia. Both phrenic nerves and ganglia are closely related to the diaphragmatic crura, therefore sutures for crural approximation in the repair of hiatal hernia must be placed superior to the ganglia in order to avoid iatrogenic injuries to the autonomic supply of the respiratory diaphragm and abdomen (Loukas et al 2016).

Referred pain Diaphragmatic irritation or pain is frequently felt at the tip of the shoulder, reflecting the common spinal nerve root origins of the phrenic and supraclavicular nerves (the ventral rami of the third and fourth cervical spinal nerves). It usually occurs when there is inflammation of the diaphragmatic parietal pleura, e.g. in basal pneumonia, pleural effusions, malignant disease, or irritation of the diaphragmatic parietal peritoneum, e.g. in pneumoperitoneum or subphrenic abscess, where involuntary diaphragmatic contraction (hiccups) may also occur.

Accessory phrenic nerve

The accessory phrenic nerve is composed of fibres from the fifth cervical ventral ramus that run in a branch of the nerve to subclavius. This lies

lateral to the phrenic nerve and descends posterior (occasionally anterior) to the subclavian vein. The accessory phrenic nerve usually joins the phrenic nerve near the first rib but may not do so until near the pulmonary hilum or beyond. The accessory phrenic nerve may be derived from the fourth or sixth cervical ventral rami or from the ansa cervicalis.

Thoracic ventral rami

Thoracic ventral rami, unlike their cervical and lumbar counterparts, have retained a largely segmental distribution to the body wall (see Figs 24.10, 47.7, 53.3). The first to the eleventh intercostal nerves pass in the intercostal spaces between adjacent ribs, and the twelfth (subcostal nerve) passes below the twelfth rib. Each is connected with an adjacent ganglion of the sympathetic trunk by pre- and postganglionic branches (white and grey rami communicantes, respectively) (see Figs 24.13, 53.21). The majority of the intercostal nerves are distributed to the thoracic and, in the case of the more inferiorly located nerves, abdominal walls. The greater part of the first thoracic ventral ramus passes into the brachial plexus (see Fig. 48.6), together with variable proportions of the second and sometimes third thoracic ventral rami via the intercostobrachial nerves. The fourth to sixth intercostal nerves supply only the thoracic wall, whereas the seventh to eleventh nerves supply the thoracic and abdominal walls. The subcostal nerve is distributed to the abdominal wall and skin covering the superior part of the lateral aspect of the gluteal region and thigh. Communicating branches may link the intercostal nerves across the intercostal spaces posteriorly (see Fig. 56.6). The breast is mainly innervated by the anterior and lateral cutaneous branches of the fourth to sixth intercostal nerves. The nipple is innervated by a plexus formed primarily from cutaneous branches of the fourth intercostal nerve.

The ventral rami of the sixth to eleventh intercostal nerves, the subcostal nerve (twelfth thoracic) and first lumbar nerve (iliohypogastric and ilioinguinal nerves) innervate the muscles and skin of the anterior abdominal wall (Rozen et al 2008). The seventh to the twelfth thoracic ventral rami continue anteriorly into the abdominal wall (see Fig. 60.5). Approaching the costal arch, the seventh to tenth intercostal nerves curve medially across the deep surface of the costal cartilages between the digitations of the respiratory diaphragm and transversus abdominis. The subcostal nerve often gives a branch to the first lumbar ventral ramus (dorsolumbar nerve), and in these cases, therefore, contributes to the lumbar plexus. It accompanies the subcostal vessels along the inferior border of the twelfth rib, passing posterior to the lateral arcuate ligament and kidney, and anterior to the proximal part of quadratus lumborum.

All these segmental nerves run anteriorly within a thin layer of fascia in the neurovascular plane between transversus abdominis and internal abdominal oblique, where they branch and interconnect with adjacent nerves and give off branches to the lateral musculature (Rozen et al 2008). Cutaneous branches supply the skin of the lateral and anterior abdominal walls. The nerves enter the rectus sheath at its lateral margin by penetrating the posterior lamina of internal abdominal oblique and penetrating rectus abdominis on its posterior aspect. Here they give off muscular branches to rectus abdominis, transversus abdominis and pyramidalis and cutaneous branches that pierce the anterior layer of the rectus sheath to supply overlying skin.

The ninth intercostal nerve supplies skin proximal to the umbilicus, the tenth intercostal nerve supplies skin that consistently includes the umbilicus, and the eleventh intercostal nerve supplies skin distal to the umbilicus (see Figs 24.10, 60.5). The subcostal nerve supplies the skin over the anterior gluteal region just distal to the iliac crest and the skin of the distal abdomen and inguinal region (overlapping with the L1 dermatome in this region) (Lee et al 2008). A typical dermatome map of the anterior abdominal wall is shown in Fig. 24.10. The inferior intercostal nerves and subcostal nerve also provide sensory fibres to the costal parts of the respiratory diaphragm and parietal peritoneum.

The anterolateral abdominal wall muscles are innervated by several segmental nerves and injury to a single nerve rarely causes a clinically detectable loss of muscle tone. The overlap between sequential dermatomes means that significant cutaneous anaesthesia and muscle denervation are appreciated only after at least two sequential nerves have been surgically sectioned.

PERIPHERAL NERVE PLEXUSES

Cervical plexus

The cervical plexus is formed by the ventral rami of the upper four cervical nerves, and supplies some neck muscles, including most of the infrahyoid group, and areas of skin on the head, neck and chest (see Figs 33.6, 35.5B). It lies in the neck opposite a line drawn down the side of the neck from the root of the auricle to the level of the upper border of the thyroid cartilage. It lies deep to the internal jugular vein, the deep fascia and sternocleidomastoid, and anterior to scalenus medius and levator scapulae. Each ramus, except the first, divides into ascending and descending parts, which unite in communicating loops. Cutaneous branches from the first loop (second and third cervical ventral rami) supply the head and neck, and those from the second loop (third and fourth cervical ventral rami) supply the shoulder and chest. Muscular and communicating branches arise from the same nerves. The branches are superficial or deep: superficial branches perforate the cervical fascia to supply the skin and either ascend (the lesser occipital, great auricular and transverse cervical nerves) or descend (supraclavicular nerves) (see Fig. 35.1B). Deep branches form medial and lateral series and generally supply muscles.

Lesser occipital nerve

The lesser occipital nerve is derived mainly from the second cervical ventral ramus (although fibres from the third cervical nerve may sometimes contribute). It first passes anterior to the plane of the accessory nerve before winding around it and becoming anterior to it. It next ascends along the posterior margin of sternocleidomastoid. Near the cranium it perforates the deep fascia and passes up on to the scalp behind the auricle to supply the skin and connect with the great auricular and greater occipital nerves and the auricular branch of the facial nerve. Its auricular branch supplies the skin on the upper third of the medial aspect of the auricle and connects with the posterior branch of the great auricular nerve. The auricular branch is occasionally derived from the greater occipital nerve. It has been suggested that compression or stretching of the lesser occipital nerve contributes to cervicogenic headache (Lucas et al 1994).

Great auricular nerve

The great auricular nerve is the largest ascending branch of the cervical plexus. It arises from the second and third cervical ventral rami, encircles the posterior border of sternocleidomastoid, perforates the deep fascia and ascends on the muscle beneath platysma with the external jugular vein. On reaching the parotid gland, it divides into anterior and posterior branches. The anterior branch is distributed to the facial skin over the parotid gland and connects in the gland with the facial nerve. This cross-innervation between somatic sensory fibres and parasympathetic secretomotor fibres is considered to be part of the anatomical basis for the phenomenon of gustatory sweating (Frey's syndrome), seen after parotidectomy with its inherent disruption of the secretomotor nerve supply. The posterior branch supplies the skin over the mastoid process and on the back of the auricle (except its upper part); a filament pierces the auricle to reach the lateral surface, where it is distributed to the lobule and concha. Efforts are made to preserve the posterior branch at parotid surgery in order to avoid a sensory deficit of the auricle. The posterior branch communicates with the lesser occipital nerve, the auricular branch of the vagus and the posterior auricular branch of the facial nerve. Division of the greater auricular nerve during neck surgery results in loss of sensation of a variable amount of the lower half of the auricle, which some patients initially find unpleasant.

Transverse cervical nerve

The transverse cervical nerve arises from the second and third cervical ventral rami. It curves round the posterior border of sternocleidomastoid near its midpoint and runs obliquely forwards, deep to the external jugular vein, to the anterior border of the muscle. It perforates the deep cervical fascia, and divides under platysma into ascending and descending branches that are distributed to the anterolateral areas of the neck. The ascending branches ascend to the submandibular region, forming a plexus with the cervical branch of the facial nerve beneath platysma. Some branches pierce platysma and are distributed to the skin of the upper anterior areas of the neck. The descending branches pierce platysma and are distributed anterolaterally to the skin of the neck.

Supraclavicular nerves

The supraclavicular nerves arise from a common trunk formed from branches from the third and fourth cervical ventral rami and emerge at the posterior border of sternocleidomastoid. Descending under platysma and the deep cervical fascia, the trunk divides into medial, intermediate and lateral (posterior) branches, which diverge to pierce the deep fascia a little above the clavicle. The medial supraclavicular nerves run inferomedially across the external jugular vein and the clavicular and sternal heads of sternocleidomastoid to supply the skin as far as the midline and as low as the second rib. They also supply the sternoclavicular joint. The intermediate supraclavicular nerves cross the clavicle to supply the skin over pectoralis major and deltoid down to the

level of the second rib, next to the area of supply of the second thoracic nerve. Overlap between these nerves is minimal. The lateral supraclavicular nerves descend superficially across trapezius and the acromion, supplying the skin of the upper and posterior parts of the shoulder.

Deep branches – medial series

Communicating branches

Communicating branches pass from the loop between the first and second cervical ventral rami to the vagus and hypoglossal nerves and to the sympathetic trunk. The hypoglossal branch later leaves the hypoglossal nerve as a series of branches, namely: the meningeal, superior root of ansa cervicalis, nerves to thyrohyoid and geniohyoid. A branch also connects the fourth and fifth cervical ventral rami. The first four cervical ventral rami each receive a grey ramus communicans from the superior cervical sympathetic ganglion.

The superior root of the ansa cervicalis (descendens hypoglossi) (see Figs 35.7A, 35.8) leaves the hypoglossal nerve where it curves round the occipital artery and then descends anterior to or in the carotid sheath. It contains fibres from the first cervical ventral ramus. After giving a branch to the superior belly of omohyoid, it is joined by the inferior root of the ansa from the second and third cervical ventral rami. The two roots form the ansa cervicalis (ansa hypoglossi), from which branches supply sternohyoid, sternothyroid and the inferior belly of omohyoid. Another branch is said to descend anterior to the vessels into the thorax to join the cardiac and phrenic nerves.

Muscular branches

Muscular branches supply rectus capitis lateralis (C1), rectus capitis anterior (C1, C2), longus capitis (C1–C3) and longus colli (C2–C4). The inferior root of the ansa cervicalis and the phrenic nerve are additional muscular branches.

The inferior root of the ansa cervicalis (nervus descendens cervicalis) (see Figs 35.7A, 35.8) is formed by the union of branches from the second and third cervical ventral rami. It descends on the lateral side of the internal jugular vein, crosses it a little below the middle of the neck, and continues forwards to join the superior root anterior to the common carotid artery, forming the ansa cervicalis (ansa hypoglossi), from which all infrahyoid muscles except thyrohyoid are supplied. The inferior root almost always comes from the second and third cervical ventral rami, but sometimes from the second to fourth, and occasionally from the third alone. Occasionally, it may be derived either from the second alone or from the first to third cervical ventral rami.

Deep branches – lateral series

Communicating branches

Lateral deep branches of the cervical plexus (C2–C4) may connect with the accessory nerve within sternocleidomastoid, the posterior triangle or beneath trapezius.

Muscular branches

Muscular branches are distributed to sternocleidomastoid (C2–C4), trapezius (C2 and possibly C3), levator scapulae (C3, C4) and scalenus medius (C3, C4). Branches to trapezius cross the posterior triangle obliquely below the accessory nerve.

Brachial plexus

The brachial plexus is formed by the union of the ventral rami of the lower four cervical nerves and the greater part of the ventral ramus of the first thoracic spinal nerve. It may also receive contributions from the fourth cervical and second thoracic ventral rami. As its name suggests, its branches supply the muscles, joints and skin of the upper limb.

At its origin, the brachial plexus lies in the posterior triangle of the neck, in the angle between the clavicle and the lower posterior border of sternocleidomastoid. It emerges between the scaleni anterior and medius, superior to the third part of the subclavian artery, and is covered by platysma, deep fascia and skin, through which it is palpable (see Fig. 35.17). It is crossed by the supraclavicular nerves, the nerve to subclavius, the inferior belly of omohyoid, the external jugular vein and the superficial ramus of the transverse cervical artery. The plexus passes posterior to the medial two-thirds of the clavicle, subclavius and the suprascapular vessels, and lies on the first digitation of serratus anterior and subscapularis. In the axilla, the lateral and posterior cords of the brachial plexus are anterior and lateral to the first part of the axillary artery, respectively, and the medial cord is behind the artery. The cords assume their appropriate relations around the second part of the artery, deep to pectoralis major. In the lower axilla, the cords divide into nerves that supply the upper limb (see Fig. 49.35). Other than the medial root of the median nerve, these nerves are related to the third part of the artery in the same way as their cords are related to the second part, i.e. branches of the lateral cord are lateral to the artery, branches of the medial cord are medial, and branches of the posterior cord are posterior.

Blood supply The blood supply to the brachial plexus is derived from vessels that arise from the subclavian and vertebral arteries. Important branches pass from the vertebral artery to the fifth and sixth cervical ventral rami and the more proximal cervical nerves. Branches from the costocervical trunk provide a rich supply to the eighth cervical and first thoracic ventral rami. Extensive contributions come from the suprascapular and superficial cervical arteries that arise from the thyrocervical trunk. In at least one-third of cases the superficial cervical and dorsal scapular arteries arise from the thyrocervical trunk as the transverse cervical artery. In clinical terms, the arteries arising from the thyrocervical trunk have become the lifeline to the upper limb and must be preserved during operations in cases when the ruptured subclavian artery has not been repaired. The dorsal scapular artery may arise from the third part of the subclavian artery to pass between the upper and middle trunks of the brachial plexus.

Trunks of the brachial plexus

The upper trunk is formed by the fifth and sixth cervical ventral rami, where these nerves emerge from deep to scalenus anterior. The middle trunk is the continuation of the seventh cervical ventral ramus. The lower trunk is formed by the eighth cervical and first thoracic ventral rami, and passes over the anterosuperior surface of the first rib. The first thoracic ventral ramus takes an upward course across the deep face of the neck of the first rib behind the pleura and the vertebral and subclavian arteries towards the lower trunk. The formation of the trunks is fairly consistent; they lie in front of one another rather than side by side, with the subclavian artery passing anteromedially. The phrenic nerve crosses the fifth cervical ventral ramus to pass anteromedially on the surface of scalenus anterior. The upper trunk, its divisions and the suprascapular nerve can all be palpated in the supraclavicular fossa in a subject of normal physique. The examining finger identifies first the subclavian pulse and then the nerves, whilst rolling the fingertip laterally (see Video 48.1).

Divisions of the brachial plexus

The trunks divide into anterior and posterior divisions. The upper trunk divides 2–3 cm above the clavicle, and the divisions of the middle and lower trunks are formed deep to the clavicle. The posterior divisions of the upper and middle trunks are consistently larger than their anterior divisions. The posterior division of the lower trunk is consistently smaller than the anterior division and is absent in about 10% of cases.

Cords of the brachial plexus

The cords are formed by the confluence of divisions: the lateral cord from the anterior divisions of the upper and middle trunks; the posterior cord by all three posterior divisions; and the medial cord by the anterior division of the lower trunk and, sometimes, by a branch from the anterior division of the middle trunks. The divisions of the trunks and the formation of the cords represent an important anatomical and functional differentiation. The posterior divisions and posterior cord innervate postaxial (extensor) musculature; the anterior divisions and the lateral and medial cords innervate preaxial (flexor) musculature.

The formation and relations of the three cords are variable and, indeed, their designations somewhat misleading. Immediately inferior to the clavicle, the posterior cord is lateral, the medial cord is posterior, and the lateral cord is anterior, in relation to the axillary artery; the cords assume their appropriate relations about the axillary artery deep to pectoralis minor. There is considerable variation in this arrangement; most commonly, the axillary artery lies anterior to the three cords and the median nerve.

The branches of the posterior cord, the largest of the three trunks, are consistent. In sequence, they are the upper subscapular, thoracodorsal, lower subscapular, axillary and radial nerves. The branches of the medial cord are usually predictable; the medial pectoral nerve and medial cutaneous nerve of the forearm are succeeded by the division into the medial root of the median nerve and the ulnar nerve. The ulnar nerve may arise as two or three branches. The greatest variation in the formation of trunk nerves is found within the lateral cord. Occasionally, the musculocutaneous nerve arises more distally than usual, either directly from the lateral cord as two or three branches or even from the median nerve itself. Sometimes, the highest of these branches enters coracobrachialis no more than 2 or 3 cm below the coracoid process. The lateral root of the

median nerve may arise as two or three branches, and in some cases, it appears as a branch of the musculocutaneous nerve.

Terminal branches of the brachial plexus

Suprascapular nerve

The suprascapular nerve (fifth and sixth cervical ventral rami) is a large branch of the upper trunk: it is usually the first branch of the upper trunk but frequently arises directly from the fifth cervical ventral ramus (see Figs 35.17, 49.35).

It runs laterally, deep to trapezius and omohyoid, and enters the supraspinous fossa through the suprascapular notch inferior to the superior transverse scapular ligament. It runs deep to supraspinatus and supplies it. It curves round the lateral border of the spine of the scapula with the suprascapular artery to reach the infraspinous fossa, where it gives two branches to infraspinatus and articular rami to the glenohumeral and acromioclavicular joints. The suprascapular nerve rarely has a cutaneous branch: when present, it pierces deltoid close to the tip of the acromion and supplies the skin of the proximal third of the arm within the territory of the axillary nerve.

The suprascapular nerve is essential for abduction and lateral rotation at the glenohumeral joint. When the nerve or the rotator cuff is torn, or both are injured, the ISHA is so reduced that the patient is unable to move the arm away from the body. At rest, the head of the humerus drops inferiorly and migrates proximally in attempted abduction (see Fig. 49.41). In isolated cuff tears, the ISHA opens to about 30° or even more. In isolated axillary palsy, the ISHA is sometimes normal, or, more often, reduced by about 20° (see Figs 49.42–49.43).

Nerve to subclavius

The slender nerve to subclavius (fifth and sixth cervical ventral rami) springs from the upper trunk and passes anteriorly. It descends anterior to the plexus and the subclavian artery and passes above the subclavian vein to supply subclavius.

Lateral pectoral nerve

The lateral pectoral nerve (fifth and sixth cervical ventral rami) is larger than the medial, and may arise either from the anterior divisions of the upper and middle trunks, or by a single branch from the lateral cord, just above or deep to the clavicle. It crosses anterior to the axillary artery and vein, pierces the clavipectoral fascia and supplies the deep surface of pectoralis major. It sends a branch to the medial pectoral nerve, forming a loop in front of the first part of the axillary artery to supply some fibres to pectoralis minor.

Medial pectoral nerve

The medial pectoral nerve (eighth cervical and first thoracic ventral rami) branches from the medial cord while the latter lies posterior to the axillary artery and curves forwards between the axillary artery and vein. Anterior to the artery, it joins a ramus of the lateral pectoral nerve and enters the deep surface of pectoralis minor, which it supplies. Two or three branches pierce pectoralis minor and others may pass round its inferior border to end in pectoralis major.

Upper (superior) subscapular nerve

The superior subscapular nerve is smaller than the inferior. It arises from the posterior cord (fifth and sixth cervical ventral rami), enters subscapularis at a high level, and is frequently double.

Lower (inferior) subscapular nerve

The inferior subscapular nerve arises from the posterior cord (fifth and sixth cervical ventral rami). It supplies the lower part of subscapularis and ends in teres major, which is sometimes supplied by a separate branch.

Thoracodorsal nerve

The thoracodorsal nerve arises from the posterior cord (sixth, seventh and eighth cervical ventral rami) between the subscapular nerves. It accompanies the subscapular artery along the posterior axillary wall and supplies latissimus dorsi, reaching its distal border (see Fig. 49.29). The muscles, joints and skin of the upper limb are innervated by the fifth, sixth, seventh and eighth cervical ventral rami and nearly all of the first thoracic ventral ramus, collectively forming the brachial plexus (see Figs 48.6–48.7). A branch from the fourth and fifth cervical rami, which contributes to the innervation of the glenohumeral and elbow flexor muscles, is seen occasionally at operation: a muscular contribution from the second thoracic ventral ramus is rare. The rami enter the posterior triangle of the neck between scalenus anterior and medius. Rami from the seventh and eighth cervical ventral rami are the largest (C8 contains about 30,000 myelinated axons) and those from the fifth cervical ventral ramus and the first thoracic ventral ramus are the smallest (between 15,000 and 20,000 myelinated axons). An adult brachial plexus contains between 120,000 and 150,000 myelinated axons, of which 25% innervate the shoulder girdle and glenohumeral joint. The proportion of motor fibres is greatest in the fifth and eighth cervical ventral rami; the sensory contribution is greatest in the seventh cervical ventral ramus. A complex interchange of branches, before the main nerves of the upper limb are formed, produces the trunks, divisions and cords of the brachial plexus.

Dorsal scapular nerve

The dorsal scapular nerve arises above the clavicle from the proximal segment of the fifth cervical ventral ramus. It passes posteriorly, piercing scalenus medius, to run down in the plane between levator scapulae and serratus posterior superior and the posterior scalene muscles. It continues along the anterior border of the rhomboid muscles about 1.5 cm medial to the vertebral border of the scapula and is closely related to the dorsal scapular artery. The dorsal scapular nerve innervates the rhomboid muscles and, together with branches from the third and fourth cervical ventral rami, it supplies levator scapulae.

Long thoracic nerve (nerve to serratus anterior)

The long thoracic nerve is formed by branches that arise above the clavicle from the proximal segments of the ventral rami of the fifth, sixth and seventh cervical ventral rami. It innervates serratus anterior, a muscle that is essential for the function of the thoracoscapular joint. The muscular branches from the rami join deep to scalenus medius, and the trunk passes down posterolateral to the muscle, on the floor of the posterior triangle deep to the suprascapular nerve. The branches from the fifth and sixth cervical ventral rami are the largest. The nerve follows a sinuous course deep to the investing fascia covering the anterior faces of the digitations of serratus anterior. It is accompanied here by a branch of the thoracodorsal artery, and inclines posterolaterally towards the mid-axillary line.

The long thoracic nerve is frequently injured during operations around the first rib, in the posterior triangle and in the axilla, and by misplaced intercostal drains. It is particularly susceptible to involvement in neuralgic amyotrophy. Serratus palsy is usual in preganglionic injury to the ventral rami of the fifth, sixth and seventh cervical ventral rami. Pain and loss of function are usual and are only slightly less than those seen after accessory nerve palsy. The signs are characteristic. The active ISHA is, on average, 130°; this is the only nerve lesion in which the active ISHA actually exceeds the total range of active abduction. The scapula is pulled upwards and towards the spine by the unopposed action of trapezius (see Fig. 49.39), an action that is increased by the weight of the limb, which contributes to the winging and is most notable in protraction.

Axillary (circumflex) nerve

The axillary nerve arises from the posterior cord (fifth and sixth cervical ventral rami) (see Figs 48.8, 49.33, 49.35) and innervates teres minor and deltoid, and the skin overlying deltoid on the lateral aspect of the shoulder. Initially it is lateral to the radial nerve, posterior to the axillary artery and anterior to subscapularis. At the lower border of subscapularis, it curves back inferior to the humeroscapular articular capsule and, together with the posterior circumflex humeral vessels, traverses a quadrangular space bounded above by subscapularis (anteriorly) and teres minor (posteriorly), below by teres major, medially by the long head of triceps, and laterally by the surgical neck of the humerus. It divides in the space into anterior and posterior branches. The anterior branch curves round the neck of the humerus with the posterior circumflex humeral vessels, deep to deltoid, to reach the anterior part of the muscle. At the level of the anterior border of the acromion, the nerve often consists of two or more thin filaments that supply the anterior deltoid; it gives off a few small cutaneous branches that pierce deltoid and ramify in the skin over its lower part. The posterior branch courses medially and posteriorly along the attachment of the lateral head of triceps, inferior to the glenoid rim. It usually lies medial to the anterior branch in the quadrangular space. It gives off the nerve to teres minor and the upper lateral cutaneous nerve of the arm at the lateral edge of the attachment of the long head of triceps. The nerve to teres minor enters the muscle on its inferior surface. The posterior branch frequently supplies the posterior aspect of deltoid, usually via a separate branch from the main stem, but occasionally from the superior lateral cutaneous nerve of the arm. However, the posterior part of deltoid has a more consistent supply from the anterior branch of the axillary nerve, which should be remembered when performing a posterior deltoid-splitting approach to the shoulder. The upper lateral cutaneous nerve of the arm pierces the deep fascia at the medial border of the posterior aspect of deltoid, and supplies the

skin over the lower part of deltoid and the upper part of the long head of triceps. The posterior branch is intimately related to the inferior aspects of the glenoid and shoulder joint capsule. There is often an enlargement or pseudoganglion on the branch to teres minor. The axillary trunk supplies a branch to the shoulder joint below subscapularis.

Lesions of the axillary nerve

The axillary nerve innervates deltoid. Although a good range of elevation is usually maintained by an intact abductor mechanism, strength and stamina are greatly reduced. Early diagnosis of rupture of the axillary nerve can prove difficult; the nerve is deeply seated, which means that Tinel's sign is rarely detectable. Active movement is restricted by pain and by the restraint of any sling. The loss of sensation varies and there may not be complete anaesthesia. Patients with an intact suprascapular nerve and an intact rotator cuff are able to initiate abduction and many can fully elevate the arm, or nearly so. The power of forward flexion and of abduction is reduced to, at most, 30–40% of normal, whereas extension, with the shoulder at 90° of abduction, is 10% or less. One useful test is to palpate the posterior third of deltoid with the fingers and ask the patient to move the elbow gently backwards. It should be possible to detect activity in the muscle when the arm is supported in a sling or by the examiner's arm.

Musculocutaneous nerve

The musculocutaneous nerve (fifth, sixth and seventh cervical ventral rami) is one of the two terminal branches of the lateral cord, the other being the lateral root of the median nerve (see Fig. 48.13). This division usually occurs at the level of the third part of axillary artery, where the lateral cord lies lateral to the vessel, but it may occur more proximally, where the cord is anterior to the second part of the artery. The nerve may also arise as two or three branches from the cord, or even from the median nerve. It pierces coracobrachialis a variable distance below the tip of the coracoid process and then descends laterally between biceps brachii and brachialis to the lateral side of the arm. The first branch, to coracobrachialis, may pass into the muscle no more than 2 cm distal to the tip of the coracoid; fibres from C7 may branch directly from the lateral cord. Branches to biceps brachii and brachialis leave after the musculocutaneous nerve has pierced coracobrachialis. There are usually two branches to brachialis, and the lower branch also supplies the anterior aspect of the elbow joint. The nerve to biceps brachii is consistently accompanied by a vascular pedicle. The nerve now inclines lateral and deep, into the plane between brachialis posteriorly and biceps anteriorly, where it supplies a small branch to the humerus that enters the shaft with the nutrient artery. Below the branches to brachialis, the musculocutaneous nerve continues as the lateral cutaneous nerve of the forearm, deep to biceps, before emerging lateral to it about 11 cm above the lateral epicondyle, and then running down the lateral aspect of the forearm.

The musculocutaneous nerve has frequent variations. It may run behind coracobrachialis or adhere for some distance to the median nerve and pass behind biceps brachii. Some fibres of the median nerve may run in the musculocutaneous nerve, leaving it to join their proper trunk; less frequently, the reverse occurs, and the median nerve sends a branch to the musculocutaneous nerve. Occasionally, the musculocutaneous nerve also supplies pronator teres and may innervate the skin over the first metacarpal and the lateral part of the thenar eminence.

Lateral cutaneous nerve of the forearm

The lateral cutaneous nerve of the forearm is the cutaneous division of the musculocutaneous nerve. It lies between biceps brachii and brachialis, inclining from the medial to the lateral side, then passes through the cubital fossa lateral to the tendon of biceps brachii and deep to the cephalic vein and descends along the radial border of the forearm to the wrist (see Figs 49.33–49.34, 50.31–50.32). It supplies the skin of the anterolateral surface of the forearm (see Fig. 49.1) and connects with the posterior cutaneous nerve of the forearm and the terminal branch of the radial nerve by branches that pass around the radial border of the forearm. Its trunk gives rise to a slender recurrent branch that extends along the cephalic vein as far as the middle third of the upper arm, distributing filaments to the skin over the distal third of the anterolateral surface of the upper arm close to the vein. At the wrist joint, the lateral cutaneous nerve of the forearm is anterior to the radial artery. It gives off filaments that pierce the deep fascia and accompany the artery to the dorsum of the carpus. The nerve then passes to the base of the thenar eminence, where it ends in cutaneous rami, some of which connect with the terminal branch of the radial nerve and the palmar cutaneous branch of the median nerve.

Medial cutaneous nerve of the arm

The medial cutaneous nerve of the arm (eighth cervical ventral ramus and first thoracic ventral ramus) is the smallest and most medial branch of the brachial plexus, arising from the medial cord (see Fig. 49.35). It crosses the axilla, either anterior or posterior to the axillary vein, then passes medial to the axillary vein, communicates with the intercostobrachial nerve, and descends medial to the brachial artery and basilic vein. It pierces the deep fascia at the midpoint of the upper arm to supply the skin over the medial aspect of the distal third of the upper arm (see Fig. 49.34). It connects with the posterior branch of the medial cutaneous nerve of the forearm. Sometimes, the medial cutaneous nerve of the arm and the intercostobrachial nerve are connected in a plexiform manner in the axilla. The intercostobrachial nerve may be large and reinforced by part of the lateral cutaneous branch of the third intercostal nerve. In these cases, it replaces the medial cutaneous nerve of the arm and receives a connection representing the latter from the brachial plexus (occasionally, this connection is absent).

Medial cutaneous nerve of the forearm

The medial cutaneous nerve of the forearm comes from the medial cord (first thoracic ventral ramus) (see Fig. 49.34). It lies initially between the axillary artery and vein, and gives off a ramus that pierces the deep fascia to supply the skin over the biceps, almost to the elbow. The nerve descends medial to the brachial artery, pierces the deep fascia with the basilic vein midway in the arm, and divides into anterior and posterior branches before it enters the forearm (see Figs 49.34, 50.31–50.32). The larger anterior branch usually passes anterior to, or occasionally behind, the median cubital vein, and descends anteromedially in the forearm to supply the skin as far as the wrist. It curves round to the dorsum of the forearm, descending on its medial border to the wrist, supplying the skin (see Fig. 50.1). It connects with the medial cutaneous nerve of the arm, the posterior cutaneous nerve of the forearm and the dorsal branch of the ulnar nerve.

Ulnar nerve

The ulnar nerve (seventh and eighth cervical ventral rami and first thoracic ventral ramus) is the continuation of the medial cord (see Fig. 48.12). It usually has no branches in the arm, but occasionally may give a branch to the medial head of triceps. The nerve runs distally through the axilla, medial to the axillary artery and between it and the vein, and continues distally medial to the brachial artery as far as the mid-arm. Here it inclines posteromedially to perforate the medial intermuscular septum about 10 cm proximal to the medial epicondyle and passes through a fibrous canal, the arcade of Struthers, which is between 5 and 6 cm long. The walls of the canal include the medial intermuscular septum and the fascial sheath which invests the medial head of triceps brachii. The nerve passes behind the medial epicondyle in a groove where it is easily palpable (see Fig. 50.29) and runs through the cubital tunnel, between the capsule of the humero-ulnar joint and the overlying arcuate ligament of Osborne (joining the two heads of flexor carpi ulnaris). It gives off articular branches to the elbow as it lies between the medial epicondyle and the olecranon. The ulnar nerve enters the forearm between the two heads of flexor carpi ulnaris, which it supplies by two neurovascular pedicles, the first arising just distal to the cubital tunnel and the second about one-quarter of the way down the forearm: it is superficial to the posterior and oblique parts of the ulnar collateral ligament and deep to the tough deep fascia of flexor carpi ulnaris (Osborne's fascia). The nerve descends on the medial side of the forearm on flexor digitorum profundus, to which it sends several branches (see Fig. 50.32). Proximally, it runs with the ulnar vessels in a well-defined sheath deep to the anterior margin of flexor carpi ulnaris; distally, it lies lateral to the muscle and is covered only by skin and fasciae. In the upper third of the forearm, the ulnar nerve is distant from the ulnar artery but it comes to lie close to the medial side of the artery more distally. Some 5–6 cm proximal to the ulnar styloid it gives off the dorsal cutaneous branch which winds around the ulna, at first deep to flexor carpi ulnaris, and then subcutaneously, and innervates the skin of the dorsum of the hand and little finger, and the medial side of the ring finger. At the wrist the ulnar nerve passes under the superficial part of the flexor retinaculum (in Guyon's canal) with the ulnar artery and divides into superficial and deep branches (see Fig. 51.10). The superficial division innervates the skin of the medial two digits and palmaris brevis. The deep branch passes, with the deep branch of the ulnar artery, between abductor and flexor digiti minimi, pierces opponens digiti minimi and then runs across the deep palmar space with the deep palmar arch. It innervates all the muscles of the hand, except for the first and second (index and middle) lumbricals, abductor pollicis brevis, opponens pollicis and part of flexor pollicis brevis.

The ulnar nerve is accompanied by the superior collateral ulnar vessels in the lower third of the arm as far as the entrance to the cubital tunnel, and then by the posteroinferior ulnar collateral vessels. The anastomosis between these vessels permits the use of most of the ulnar

nerve as a free vascularized graft, in cases where the parent roots, the seventh and eighth cervical ventral rami and the first thoracic ventral ramus, are irreparable.. The ulnar nerve is palpable in the lower arm and behind the medial epicondyle, where it is subcutaneous. There is an important relation here: a posterior branch of the medial cutaneous nerve of the forearm sweeps across the cubital tunnel and gets in the way of medial surgical exposures. Inadvertent injury may cause severe pain. The ulnar nerve is palpable at the wrist where it emerges from under flexor carpi ulnaris. The dorsal cutaneous branch can be palpated in those of slender physique where it crosses the subcutaneous ulna.

Muscular branches

There are two main muscular branches of the ulnar nerve in the forearm. They arise near the elbow and supply flexor carpi ulnaris and the medial half of flexor digitorum profundus.

Dorsal branch

The dorsal branch arises approximately 5 cm proximal to the wrist (see Fig. 51.9). It passes distally and dorsally, deep to flexor carpi ulnaris, perforates the deep fascia, descends along the medial side of the dorsum of the wrist and hand, and then divides into two, or often three, dorsal digital nerves. The first supplies the medial side of the little finger; the second, the adjacent sides of the little and ring fingers; while the third, when present, supplies adjoining sides of the ring and middle fingers. The latter may be replaced, wholly or partially, by a branch of the radial nerve, which communicates with it on the dorsum of the hand. In the little finger, the dorsal digital nerves extend only to the base of the distal phalanx; in the ring finger, they extend only to the base of the middle phalanx. The most distal parts of the little finger and of the ulnar side of the ring finger are supplied by dorsal branches of the proper palmar digital branches of the ulnar nerve. The most distal part of the lateral side of the ring finger is supplied by dorsal branches of the proper palmar digital branch of the median nerve.

Superficial terminal branch

The superficial terminal branch supplies palmaris brevis and the medial palmar skin. It divides into two palmar digital nerves. One supplies the medial side of the little finger; the other (a common palmar digital nerve) sends a branch to the median nerve and divides into two proper digital nerves to supply the adjoining sides of little and ring fingers. The proper digital branches within the digit are distributed like those derived from the median nerve.

Deep terminal branch

The deep terminal branch accompanies the deep branch of the ulnar artery as it passes between abductor digiti minimi and flexor digiti minimi, and then perforates opponens digiti minimi to follow the deep palmar arch dorsal to the flexor tendons. At its origin, it supplies the three short muscles of the little finger. As it crosses the hand, it supplies the interossei and the third and fourth lumbricals. It ends by supplying adductor pollicis, the first dorsal interosseous and, usually, flexor pollicis brevis.

The medial part of flexor digitorum profundus is supplied by the ulnar nerve, as are the third and fourth lumbricals, which are connected with the tendons of this part of the muscle. Similarly, the lateral part of flexor digitorum profundus and the first and second lumbricals are supplied by the median nerve. The third lumbrical is often supplied by both nerves. The deep terminal branch gives branches to some intercarpal, carpometacarpal and intermetacarpal joints; precise details are uncertain. Vasomotor branches, arising in the forearm and hand, supply the ulnar and palmar arteries.

Palmar cutaneous branch

The palmar cutaneous branch of the ulnar nerve arises in mid-forearm, descends on the ulnar artery, which it supplies, and then perforates the deep fascia. It communicates with the palmar branch of the median nerve and ends in the palmar skin. It sometimes supplies palmaris brevis.

Lesions of the ulnar nerve

The ulnar nerve is a mixed nerve and so patients may present with sensory or motor symptoms or a combination of the two, sometimes with additional physical signs of autonomic disturbance. There may be tenderness and a positive Tinel's sign over the nerve at the point of compression. Numbness and paraesthesiae occur early, followed, in more severe cases, by weakness of power grip and, ultimately, atrophy of the lumbricals and interossei with clawing of ring and little fingers.

The ulnar nerve may be compressed by the arcade of Struthers at the level of the medial intermuscular septum; at the level of the flexor/pronator aponeurosis as it enters the forearm between the heads of flexor carpi ulnaris; or deep to the deep fascia of flexor carpi ulnaris which exhibits tough condensations extending up to 9 cm from the medial epicondyle (Siemionow et al 2007). The nerve is most often compressed at the level of the cubital tunnel by the Osborne's arcuate ligament; this is the most common nerve compression syndrome after that of the median nerve in the carpal tunnel.

The cross-sectional area of the cubital tunnel has been shown to narrow by almost 55% in full flexion. Ultrasound studies have suggested that the ratio of the cross-sectional area of radial nerve : cubital tunnel is most strongly linked to reduced conduction velocity (Yoon et al 2007). Combining elbow flexion with direct pressure over the cubital tunnel for 60 seconds will elicit symptoms in most affected patients (Novak et al 1994). Other contributory factors are previous trauma, especially supracondylar and medial epicondyle fractures in childhood, valgus instability of the elbow in athletes involved in throwing sports, and degenerative disease.

The most reliable treatment for patients who fail to respond to nonsurgical remedies is a simple release of the cubital tunnel. The release should be complete and include release of Osborne's ligament and the deep fascia of flexor carpi ulnaris; care should be taken to avoid damage to branches of the medial cutaneous nerve of the forearm that usually cross the line of incision approximately 2 cm above the medial epicondyle and a mean 3.1 cm distal to the medial epicondyle in all patients (Lowe et al 2004). Anconeus epitrochlearis should be excised if present because it is a potential cause for recurrent symptoms. The ulnar nerve should not be circumferentially denuded of its retinaculum because this contains its intrinsic blood supply. Transposition of the nerve should be reserved for cases of persistent subluxation or of failure of a simple release to achieve symptomatic relief. This is relatively unusual and is said to occur in only 7% of cases.

The ulnar nerve can be compressed as it passes through Guyon's canal at the wrist. Causes of compression at this site include a ganglion from the piso-triquetral joint, prolonged compression from a cyclist's handlebars, hook of hamate fracture, and proximity of aberrant or accessory muscles. The symptoms depend on the precise level at which the ulnar nerve and its branches are compressed. Altered sensation is noted in the palmar aspect of the little finger and ulnar half of the ring finger; sensation on the ulnar aspect of the dorsum of the hand is normal due to preservation of the dorsal cutaneous branch. If the motor branch fibres are affected, there is weakness and wasting of the intrinsic muscles of the hand supplied by the ulnar nerve, with clawing posture in severe compression. Weakness of adductor pollicis and first dorsal interosseous substantially degrades pinch strength; if a slip of paper is held in the key pinch position between the pulp of the thumb and the radial side of the index proximal interphalangeal joint, the tip of the thumb involuntarily flexes as flexor pollicis longus contracts to compensate for the absent adductor pollicis and first dorsal interosseous (Froment's sign). Surgical treatment involves decompression of the nerve by division of the roof of Guyon's canal and removal of any causative lesion, such as a ganglion. Ulnar tunnel syndrome can be difficult to distinguish from more proximal causes of ulnar nerve compression, of which the most common is entrapment of the nerve in the cubital canal at the elbow. In this condition, sensory changes would include the dorso-ulnar aspect of the hand and motor changes would involve flexor carpi ulnaris and flexor digitorum profundus to the little and ring fingers. Clawing is less apparent with a more proximal failure of the ulnar nerve (the 'ulnar paradox') because flexor digitorum profundus also fails so there is less flexion force to expose the absent extensor moment of the paralysed intrinsics. In the absence of obvious clinical indicators, an unpleasant tingling sensation (Tinel's sign) over the site of compression, electrophysiological studies and MRI scans may aid diagnosis.

Ulnar nerve division at the wrist paralyses all the intrinsic muscles of the hand (apart from the radial two lumbricals, abductor pollicis brevis, and part of flexor pollicis brevis and opponens pollicis). The intrinsic muscle action of flexing the metacarpophalangeal joint and extending the interphalangeal joints is lost. The unopposed action of the long extensors and flexors of the fingers cause clawing, with extension of the metacarpophalangeal joints and flexion of the interphalangeal joints. The clawing is less intense in the index and middle fingers because their lumbricals are supplied by the median nerve. There is sensory loss over the little finger and the ulnar half of the ring finger. The skin over the ulnar aspect of the dorsum of the hand is spared because the dorsal branch of the ulnar nerve is given off approximately 5 cm proximal to the wrist joint. A combined median and ulnar nerve palsy at the wrist results in a full claw hand with thenar and hypothenar flattening and thumb adduction and flexion (a simian hand).

Median nerve

The median nerve is formed by the union of the lateral root from the lateral cord (sixth and seventh cervical ventral rami), and the medial

root from the medial cord (eighth cervical and first thoracic ventral rami), which meet anterior or lateral to the third part of the axillary artery (see Figs 48.7, 48.10, 49.29, 49.35, 49.44). Some fibres from C7 often leave the lateral root in the lower part of the axilla, pass distomedially posterior to the medial root, and usually anterior to the axillary artery, to join the ulnar nerve. Clinically, they are believed to be mainly motor and to supply flexor carpi ulnaris. If the lateral root is small, the musculocutaneous nerve (fifth, sixth and seventh cervical ventral rami) connects with the median nerve in the arm.

The first branch of the median nerve, to pronator teres, arises 2–3 cm above the medial epicondyle. A second branch, or leash of branches, arises at the level of the tip of the medial epicondyle and innervates palmaris longus, flexor carpi radialis and flexor digitorum superficialis. In the cubital fossa, the median nerve lies medial to the brachial artery, deep to the bicipital aponeurosis and anterior to brachialis. It usually enters the forearm between the heads of pronator teres, although, occasionally, it may pass posterior to both heads of the muscle, or it may pass through its humeral head (see Fig. 50.31; see also Figs 50.21–50.22). The nerve crosses to the lateral side of the ulnar artery, from which it is separated by the deep head of pronator teres, passes behind a tendinous bridge between the humero-ulnar and radial heads of flexor digitorum superficialis, and descends through the forearm posterior and adherent to flexor digitorum superficialis and anterior to flexor digitorum profundus. Just proximal to the tendinous arcade of flexor digitorum superficialis, the median nerve gives off the anterior interosseous nerve. Accompanied by the anterior interosseous vessels, this large branch dives deeply to pass down along the interosseous membrane and supplies flexor pollicis longus, the radial half of flexor digitorum profundus and pronator quadratus. There is no cutaneous distribution.

The main nerve continues in the plane between the superficial and deep digital flexors, supplying two or three branches to the former. About 5 cm proximal to the flexor retinaculum, the median nerve emerges from behind the lateral edge of flexor digitorum superficialis and becomes superficial just proximal to the wrist. Just proximal to the flexor retinaculum the median nerve is lateral and superficial to the tendons of flexor digitorum superficialis and lies between the tendons of flexor carpi radialis and palmaris longus (see Fig. 50.31). It passes under the retinaculum in the 'carpal tunnel', where it may be compressed in carpal tunnel syndrome, and enters the palm. Distal to the retinaculum, the nerve enlarges and flattens, and usually divides into five or six branches; the mode and level of division are variable. The recurrent (motor) nerve to the thenar muscles arises within, or just distal to, the carpal tunnel, usually on the lateral side of the main nerve. The palmar digital nerves are formed within the palm of the hand and pass distally, deep to the superficial palmar arch and its digital vessels, at first anterior to the tendons of the long flexors, to supply the palmar skin of the thumb, index and middle fingers and the lateral side of the ring finger. The palmar cutaneous branch arises 3.5–6 cm proximal to the most proximal wrist crease, and passes lateral to the main nerve and superficial to the flexor retinaculum to innervate the skin of the proximal palm.

Within the carpal tunnel and hand, the median nerve has been shown to glide by up to 3 mm, depending on the position of the elbow and the attitude of the forearm in pronation or supination (Echigo et al 2008). The greatest longitudinal excursion of the median nerve (15.5 mm) is seen just proximal to the carpal tunnel; similar excursion of the ulnar nerve has been recorded as 14.8 mm in cadavers (Wilgis and Murphy 1986).

The median nerve is palpable along its course in the arm, where it is covered by deep fascia and skin, after emerging from deep to coracobrachialis; on the flexor aspect of the elbow, deep to the bicipital aponeurosis; and at the wrist where it emerges from behind the superficial flexor tendons, just lateral to palmaris longus. It is closely related to the brachial artery in the anterior aspect of the elbow, where it courses anterior to brachialis and medial to the artery.

The median nerve has muscular, anterior interosseous, palmar cutaneous and palmar digital branches.

Muscular branches

Muscular branches are given off near the elbow to all the superficial flexor muscles except flexor carpi ulnaris. The branch to the part of flexor digitorum superficialis that serves the index finger is given off near the mid-forearm and may be derived from the anterior interosseous nerve.

Anterior interosseous nerve

The anterior interosseous nerve arises from the posterior aspect of the median nerve between the two heads of pronator teres, just distal to the branches to the superficial forearm flexors and proximal tendinous arch of flexor digitorum superficialis (see Figs 50.10, 50.22). It descends with the anterior interosseous artery anterior to the interosseous membrane, between and deep to flexor pollicis longus and flexor digitorum profundus (see Fig. 50.32), supplying flexor pollicis longus and the lateral part of flexor digitorum profundus (to the index and middle fingers). Terminally, the anterior interosseous nerve lies posterior to pronator quadratus, which it supplies via its deep surface. It also supplies articular branches to the distal radio-ulnar, radiocarpal and carpal joints.

Palmar cutaneous branch

The palmar cutaneous branch emerges from the radial side of the median nerve 3.5 cm to 6 cm proximal to the flexor retinaculum. It runs in a small tunnel alongside the ulnar edge of the sheath of flexor carpi radialis, radial and deep to palmaris longus, before piercing the deep fascia to enter the palm either through or superficial to the flexor retinaculum (see Fig. 51.27B). It usually ends in medial and lateral terminal branches that supply a patch of skin over and just beyond the anterior surface of the palm overlying the scaphoid tubercle and anterior aspect of the carpometacarpal joint of the thumb (Hobbs et al 1990, da Silva et al 1996). The lateral branches connect with the lateral cutaneous nerve of the forearm and the medial branches connect with the palmar cutaneous branch of the ulnar nerve (see Fig. 51.27B).

Muscular branch (recurrent motor branch)

The recurrent motor branch is short and thick, and arises from the lateral side of the nerve; it may be the first palmar branch or a terminal branch that arises level with the digital branches. It runs laterally, just distal to the flexor retinaculum and with a slight recurrent curve beneath the part of the palmar aponeurosis covering the thenar muscles (see Fig. 51.27B). It turns round the distal border of the retinaculum to lie superficial to flexor pollicis brevis, which it usually supplies, and either continues superficial to the muscle or traverses it. It gives a branch to abductor pollicis brevis that enters the medial edge of the muscle, and then passes deep to it to supply opponens pollicis, entering its medial edge. Its terminal part occasionally gives a branch to the first dorsal interosseous, and may be its sole or partial supply. The muscular branch may arise in the carpal tunnel and pierce the flexor retinaculum. Anomalies of the median nerve occur in approximately 10% of patients undergoing a carpal tunnel release. These branches usually arise from the ulnar side of the nerve and may be motor or sensory.

Palmar digital branches

The median nerve supplies palmar cutaneous digital branches to the radial three and a half digits (thumb, index, middle and the lateral side of the ring); sometimes, the radial side of the ring finger is supplied by the ulnar nerve. Occasionally, there is a communicating branch between the common digital nerve to the middle and ring fingers (derived from the median nerve) and the common digital nerve to the ring and little fingers (derived from the ulnar nerve); this may explain variations in sensory patterns that do not conform to the classic pattern.

Various patterns of termination of the palmar digital nerves have been described: the branches are commonly arranged as follows. Distal to the flexor retinaculum, the median nerve splits into a smaller lateral portion and a larger medial portion. The lateral portion gives rise to a recurrent motor branch and divides into three proper digital nerves that supply the thumb and radial index finger. The branch that supplies the radial side of the index finger also supplies the first lumbrical. The medial portion divides into two common palmar digital nerves which each further divide into two proper digital nerves that supply the adjacent sides of the index, middle and ring fingers. The lateral common digital nerve supplies the second lumbrical, and the medial receives a communicating twig from the common palmar digital branch of the ulnar nerve and may supply the third lumbrical. In the distal part of the palm, the digital arteries pass deeply between the divisions of the digital nerves; the nerves lie anterior to the arteries on the sides of the digits.

The digital nerves pass distally, deep to the superficial palmar arch and its digital vessels, at first anterior to the tendons of the long flexors. Together with the lumbricals and palmar digital arteries, they pass dorsal to the superficial transverse metacarpal ligament and ventral to the deep transverse metacarpal ligament. In the digits, the nerves run distally beside the long flexor tendons (outside their fibrous sheaths), level with the anterior phalangeal surfaces and anterior to the digital arteries, between Grayson's and Cleland's ligaments. Each nerve gives off several branches to the skin on the volar and lateral aspects of the digit and sends branches to the metacarpophalangeal and interphalangeal joints.

The digital nerves supply the fibrous sheaths of the long flexor tendons, blood vessels (vasomotor) and sweat glands (sudomotor).

Distal to the base of the distal phalanx, each digital nerve gives off a branch that passes dorsally to the nail bed (see Fig. 51.9). The main nerve frequently trifurcates to supply the pulp and skin of the terminal part of the digit. Distal to the base of the proximal phalanx, each proper digital nerve also gives off a dorsal branch to supply the skin over the dorsum of the middle and distal phalanges. The proper palmar digital nerves to the thumb and the lateral side of the index finger emerge with the tendons of the long flexors from under the lateral edge of the palmar aponeurosis. They are arranged in the digits as described above, except that, in the thumb, small distal branches supply the skin on the dorsum of the distal phalanx only.

Other branches

In addition to the branches of the median nerve described above, variable vasomotor branches supply the radial and ulnar arteries and their branches. Some of the intercarpal, carpometacarpal and intermetacarpal joints are said to be supplied by the median nerve or its anterior interosseous branch; the precise details are uncertain.

Martin–Gruber nerve connection

A motor communicating branch between the median and ulnar nerves in the forearm occurs in approximately one-quarter of patients. The most common variant has a branch passing from the anterior interosseous to the ulnar nerve. A number of patterns have been described where branches pass between flexors digitorum superficialis and profundus, deep to the ulnar artery, to join the ulnar nerve; such branches may explain the variations in innervation of the intrinsic muscles.

Lesions of the median nerve

The median nerve may be compressed at four sites in the elbow and forearm. The most proximal is the ligament of Struthers, where, if the median nerve is accompanied by the brachial artery, vascular symptoms and signs may also be present. More distally, it may become entrapped by a thickened bicipital aponeurosis. The other sites of compression are between the superficial and deep heads of pronator teres, and the proximal fibrous arch of flexor digitorum superficialis.

Median nerve division at the wrist leads to paralysis of the lumbricals to the index and middle fingers and of the thenar muscles (apart from flexor pollicis brevis and adductor pollicis), as well as loss of sensation to the thumb, index, middle and radial half of the ring fingers. The thenar muscles waste, and the adductor pollicis, which is no longer antagonized by flexor pollicis brevis and opponens pollicis, produces an adducted posture of the thumb. Division of the median nerve distal to the origin of its palmar cutaneous branch, which arises somewhere between 3.5 and 6 cm proximal to the proximal edge of the flexor retinaculum and the distal transverse wrist crease, will leave the branch intact to supply the skin over the thenar eminence and radial side of the proximal part of the hand. Careful clinical examination of the sensibility of the skin in this region should help to clarify the level of the lesion. High division of the nerve will, as with compressive lesions at this level, result in weakness of pronation of the forearm, radial flexion of the wrist and the lateral two fingers.

Patients essentially present with one of two syndromes. The anterior interosseous nerve syndrome presents as a failure of pinch grip due to weakness of flexor pollicis longus and the radial portion of flexor or digitorum profundus. This reduces the flexion power of the interphalangeal joint of the thumb and the distal interphalangeal joint of the index finger. The pronator syndrome presents with symptoms and signs that mimic carpal tunnel syndrome. Patients present with pain and altered sensation in the radial three and a half fingers of the hand that are aggravated by activity. However, a Tinel's sign will be positive over the proximal forearm, and sensation over the thenar eminence may be diminished, because the palmar cutaneous branch of the nerve arises above the carpal tunnel. The clinical presentation may vary in the presence of a Martin–Gruber anastomosis (Rodriguez-Niedenführ et al 2002).

Most patients will respond to non-operative treatment but those who fail to do so usually respond well to surgical decompression. Exploration and decompression should address all the potential areas of compression.

Carpal tunnel syndrome

Carpal tunnel syndrome is the most common entrapment mononeuropathy. It is caused by compression of the median nerve as it passes through the fibro-osseous tunnel beneath the flexor retinaculum (see Fig. 51.38).

Carpal tunnel syndrome is usually idiopathic, however, certain diagnoses may predispose to the condition. The carpal tunnel may be narrowed by arthritic changes in the wrist joint, by thickening of the synovium (especially in rheumatoid disease) by soft tissue thickening, as may occur in myxoedema and acromegaly; it is associated with diabetes, oedema, obesity, pregnancy and vibration. The association with repetitive use is controversial and has probably been overestimated. Normally, the median nerve slides smoothly in and out of the carpal tunnel during flexion and extension of the wrist, but when the nerve is compressed this sliding is restricted by traction that aggravates the conduction block. Typically, the syndrome produces painful paraesthesia and numbness in the thumb, index, middle and medial side of the ring fingers, which is worse at night and when performing manoeuvres such as holding a book or telephone. The palmar branch of the median nerve is spared because it does not pass through the carpal tunnel. With time, the compression leads to wasting and weakness of abductor pollicis brevis and loss of sweating in the cutaneous territory of the median nerve, sparing the patch overlying the scaphoid tubercle and palmar side of the carpometacarpal joint which is supplied by the palmar cutaneous nerve. Treatment depends on the cause. If present just at night, due to involuntary flexion of the wrist (which increases pressure in the carpal canal) then a splint may suffice. If the syndrome is of recent onset, especially in association with pregnancy or synovial thickening, then a steroid injection can be curative. For more persistent symptoms, and especially if there is evidence of axonal failure (numbness, loss of sweating, wasting of abductor pollicis brevis) then surgery is recommended. This involves dividing the flexor retinaculum. The most common hazards of decompression are inadequate decompression because of failure to divide the most distal or most proximal part of the flexor retinaculum, damage to the motor branch causing weakness, or palmar cutaneous branch or one or more terminal sensory branches causing scar tenderness and a patch of numbness and damage to the superficial palmar arch causing a haematoma.

Anatomical anomalies of the median nerve in the carpal tunnel are very common (Henry et al 2015) and occur in up to 12% of hands. The most common are variations in the course of the recurrent motor branch in relation to the flexor retinaculum. These may be transligamentous (11.3%), subligamentous (13.5%) or extraligamentous (75.2%). Damage may also occur to the palmar cutaneous branch of the median nerve and to the superficial connections between the median and ulnar nerves (Martin et al 1996), (the Berrettini branch, division of which will leave the patient with numbness in the middle and ring fingers). Stancič et al (1999) noted that this connection was present in 81% of dissected hands and proposed that it should be regarded as a normal anatomical finding.

Radial nerve

The radial nerve (fifth, sixth, seventh and eighth cervical and first thoracic ventral rami) is the terminal branch of the posterior cord (see Fig. 48.9). It is the largest nerve in the upper limb and the most commonly damaged. Between its origin at the level of the base of the coracoid and its entrance into the spiral groove, where it is accompanied by the profunda brachii artery, the radial nerve is supplied by fewer arteries than elsewhere along its course. The first 8–10 cm of the nerve may not have a nutrient artery and will, therefore, be relatively avascular if the nerve is transected at its origin. The nerve lies closest to the bone where it pierces the lateral intermuscular septum to pass through a short tunnel bounded by bone and unyielding fascia. The nerve is tethered here, a common level of rupture, entrapment or compression.

The radial nerve descends behind the third part of the axillary artery and the upper part of the brachial artery, anterior to subscapularis above and the tendons of latissimus dorsi and teres major below, giving branches to the medial head of triceps at this level. With the profunda brachii artery, it inclines dorsally, passing through the lower triangular space below the lower border of teres major, between the long head of triceps and the humerus. It then spirals obliquely across the posterior shaft of the humerus, lying posterior to the uppermost fibres of the medial head of triceps, which separate the nerve from the bone in the first part of the spiral groove. The nerve(s) to the lateral head of triceps arise(s) within the spiral groove; that to the lateral head just before the radial nerve re-enters the anterior compartment. Two cutaneous nerves, the lower lateral cutaneous nerve of the arm and the posterior cutaneous nerve of the forearm, pass away from the main nerve in the final part of the spiral groove and course along the anterior face of the lateral head of triceps to perforate the deep fascia about four fingers' breadths above the lateral epicondyle. They innervate the skin of the lower lateral arm and the posterior aspect of the forearm, respectively. The radial nerve at the elbow lies in the deep groove between brachialis medially and brachioradialis and extensor carpi radialis longus laterally (see Fig. 50.21). The nerve to brachioradialis arises about three fingers' breadths proximal to the lateral epicondyle; the nerve to extensor carpi radialis longus about one finger's breadth more distal; and the nerve to extensor carpi radialis brevis about one finger's breadth above the epicondyle. These

branches arise from the main radial nerve as it runs between brachialis anteriorly and brachioradialis posteriorly; the nerve may be palpable at this level. On reaching the lateral side of the humerus, the radial nerve pierces the lateral intermuscular septum to enter the anterior compartment of the arm. At the level of the tip of the lateral epicondyle, the nerve divides into the posterior interosseous and superficial radial nerves. Another branch to extensor carpi radialis brevis is usually given off here. There is some variation in the level at which branches of the radial nerve arise from the main trunk in different individuals. Branches to extensor carpi radialis brevis and supinator may arise from the main trunk of the radial nerve or from the proximal part of the posterior interosseous nerve, but almost invariably above the arcade of Frohse.

The superficial radial nerve innervates the skin over the dorsum of the radial half of the ring, middle and index fingers, and that of the thumb as far as the distal interphalangeal joint. It often provides important sensation on the skin of the thumb web space and the skin on the adjacent sides of the thumb and index finger.

The branches of the radial nerve are: muscular, cutaneous, articular, superficial radial and posterior interosseous.

Muscular branches

Muscular branches supply triceps, anconeus, brachioradialis, extensor carpi radialis longus and brachialis in medial, posterior and lateral groups. Medial muscular branches arise from the radial nerve on the medial side of the arm and supply the medial and long heads of triceps. The branch to the medial head is a long, slender filament that lies close to the ulnar nerve as far as the distal third of the arm, and is often termed the ulnar collateral nerve. A large posterior muscular branch arises from the nerve as it lies in the humeral groove and divides to supply the medial and lateral heads of triceps and anconeus. The branch to anconeus is a long nerve that descends in the medial head of triceps and partially supplies it; the nerve is accompanied by the middle collateral branch of the profunda brachii artery and passes behind the elbow joint to end in anconeus. Lateral muscular branches arise anterior to the lateral intermuscular septum and supply the lateral part of brachialis, brachioradialis and extensor carpi radialis longus.

Cutaneous branches

Cutaneous branches are the posterior and lower lateral cutaneous nerves of the arm and the posterior cutaneous nerve of the forearm.

Posterior cutaneous nerve of the arm The small posterior cutaneous nerve of the arm arises in the axilla and passes medially to supply the skin on the dorsal surface of the arm nearly as far as the olecranon. It crosses posterior to, and communicates with, the intercostobrachial nerve.

Lower lateral cutaneous nerve of the arm The lower lateral cutaneous nerve of the arm perforates the lateral head of triceps distal to the deltoid tuberosity, passes to the front of the elbow close to the cephalic vein, and supplies the skin of the lateral part of the lower half of the arm.

Posterior cutaneous nerve of the forearm The posterior cutaneous nerve of the forearm arises with the lower lateral cutaneous nerve of the arm. Perforating the lateral head of triceps, it descends first lateral in the arm, then along the dorsum of the forearm to the wrist, supplying the skin in its course. It supplies the central forearm skin along its course and, near its termination, joins the dorsal branches of the lateral cutaneous nerve of the forearm.

Superficial radial nerve

The superficial radial nerve descends from the lateral epicondyle anterolaterally in the proximal two-thirds of the forearm, initially lying on supinator, lateral to the radial artery and behind brachioradialis. In the middle third of the forearm, it lies behind brachioradialis, close to the lateral side of the artery. It runs anterior to pronator teres, the radial head of flexor digitorum superficialis and flexor pollicis longus, and usually leaves the artery 7 cm proximal to the wrist and passes deep to the tendon of brachioradialis. It curves round the lateral side of the radius as it descends, pierces the deep fascia and divides into five, sometimes four, dorsal digital nerves. On the dorsum of the hand, it usually communicates with the posterior and lateral cutaneous nerves of the forearm.

Dorsal digital nerves

There are usually four or five small dorsal digital nerves (see Fig. 51.9). The first supplies the skin of the radial side of the thumb and the adjoining thenar eminence, and communicates with branches of the lateral cutaneous nerve of the forearm. The second supplies the medial side of the thumb; the third, the lateral side of the index finger; the fourth, the adjoining sides of the index and middle fingers. The fifth communicates with a ramus of the dorsal branch of the ulnar nerve and supplies the adjoining sides of the middle and ring fingers, where it is frequently replaced by the dorsal branch of the ulnar nerve. The digital nerves of the thumb reach only to the root of the nail; those in the index finger, midway along the middle phalanx; and those to the middle and the lateral part of the ring finger may reach no further than the proximal interphalangeal joints. The remaining distal dorsal areas of the skin in these digits are typically supplied by palmar digital branches of the median and ulnar nerves. However, the superficial terminal branch of the radial nerve may supply the whole dorsum of the hand.

Posterior interosseous nerve

The posterior interosseous nerve is the deep terminal branch of the radial nerve (see Figs 48.9, 50.21). It reaches the back of the forearm by passing round the lateral aspect of the radius between the two heads of supinator (see Figs 50.25–50.26). It supplies supinator both before entering the muscle and as it passes through it. As it emerges from supinator posteriorly, the nerve gives off three short branches to extensor digitorum, extensor digiti minimi and extensor carpi ulnaris, and two longer branches, a medial branch to extensor pollicis longus and extensor indicis, and a lateral branch that supplies abductor pollicis longus and extensor pollicis brevis. The nerve at first lies between the superficial and deep extensor muscles, but at the distal border of extensor pollicis brevis, it passes deep to extensor pollicis longus and, diminished to a fine thread, descends on the interosseous membrane to the dorsum of the carpus. Filaments arising from its flattened termination supply the carpal ligaments and articulations. Articular branches from the posterior interosseous nerve supply carpal, distal radio-ulnar and some intercarpal and intermetacarpal joints. Digital branches supply the metacarpophalangeal and proximal interphalangeal joints.

The distal portion of the nerve lies in a separate fascial sheath in the radial, deep, aspect of the fourth dorsal compartment of the extensor retinaculum of the wrist, where it is located deep to extensor digitorum and extensor indicis.

Branches of the superficial branch of the radial nerve reach the hand by curving around the wrist over the tendons of abductor pollicis longus and extensor pollicis brevis, and dividing into dorsal digital nerves (see Fig. 51.37). They usually communicate with the posterior and lateral cutaneous nerves of the forearm on the dorsum of the hand.

Lesions of the radial nerve

Radial nerve compression may occur at several sites in the elbow and forearm. The most proximal of these is within the radial tunnel which starts where the deep branch of the radial nerve lies over the radiohumeral joint and ends at the point where the deep branch becomes the posterior interosseous nerve at the distal border of supinator. At the level of the radial head, the nerve may be compressed by fibrous bands. More distally, it has been suggested that branches of the radial recurrent artery may compress the posterior interosseous nerve. Other sites of compression are the tendinous edge of the deep surface of extensor carpi radialis brevis and the point at which the nerve passes under the arcade of Frohse and between the two heads of supinator. Rarely, the nerve can be compressed at the level of the distal border of supinator.

Patients present with one of two syndromes: the radial tunnel syndrome, in which the presentation is that of pain along the lateral border of the elbow and upper forearm (Roles and Maudsley 1972), or the posterior interosseous nerve syndrome, which presents with motor weakness in the distribution of the nerve particularly affecting the extensors digitorum and carpi ulnaris. Primary treatment is non-operative and involves the avoidance of activities that cause pain, aided by appropriate splintage. In resistant cases, surgical decompression may be necessary. A complete release of all potential areas of compression is essential.

The elbow is a notorious site for nerve injuries, especially in children. The close proximity of all the major nerve trunks to bone makes them vulnerable. The ulnar nerve is particularly at risk in elbow dislocation, especially when the medial epicondyle is displaced into the joint. All three nerves are at risk of displacement into a dislocated joint. The posterior interosseous and radial nerves are particularly at risk from a Monteggia fracture-dislocation. Any nerve may become entrapped within a fracture, e.g. the median nerve is often accompanied by the brachial artery in cases of supracondylar fracture. Pain that persists, or worsens, after reduction of a fracture suggests impending critical ischaemia, continuing irritation of the nerve, or both. The nerves are at risk during operations or other medical interventions, particularly so when normal anatomical planes are distorted by haematoma, fibrosis or bone fragments.

Lumbar and sacral plexuses

Nerves derived from the lumbar and sacral plexuses innervate the lower limb (see Fig. 76.11). The lumbar plexus lies deep within psoas major, anterior to the transverse processes of the first three lumbar vertebrae. The sacral plexus lies in the pelvis on the anterior surface of piriformis, external to the pelvic fascia, which separates it from the inferior gluteal and internal pudendal vessels. The lumbosacral trunk (fourth and fifth lumbar ventral rami) emerges medial to psoas major on the posterior abdominal wall and lies on the ala of the sacrum before crossing the pelvic brim to join the first sacral ventral ramus. Contributions to the lumbosacral trunk may also be derived from the third lumbar nerve (Apaydin 2016).

Lesions of the lumbar and sacral plexuses

The deep and protected situation of the plexuses means that lesions are not common. The lumbar plexus may be involved in retroperitoneal pathology and the sacral plexus may be invaded by pelvic malignancies and both may be involved in the reticuloses, affected by plexiform neuromas, or damaged in fractures of the lumbar spine and pelvis or in other conditions that cause severe retroperitoneal and pelvic haemorrhage. Temporary lesions may occur after pregnancy and childbirth, e.g. after difficult forceps delivery of a large baby. Pain, which may be diffuse, is the most common feature. Iatrogenic injury can occur during surgical approaches to the abdomen and pelvis, particularly when operating within the retroperitoneal space and also during the lateral approach to spine.

Sciatica is pain in the lower back and hip region, radiating inferiorly along the posterior thigh to the leg. It is often caused by a herniated intervertebral disc, compressing the fifth lumbar or first sacral ventral rami. The so-called piriformis syndrome, which may result from a variant or anomalous relationship between piriformis and the sciatic nerve, may also produce hip pain that radiates inferiorly along the course of the sciatic nerve. Diagnosis of specific nerve injuries relies on the distribution and characteristics of clinical findings in combination with supportive electrophysiological studies and/or MRI and CT scans. The clinical presentation of lesions can vary as a result of anatomical variation and overlapping innervation patterns. Generally, loss of hip flexion and knee extension indicates a lumbar lesion; loss of hip abduction, knee flexion and plantarflexion and dorsiflexion are symptoms of sacral lesions (Ahmadian et al 2015).

Lumbar plexus

The lumbar plexus is formed by the first three and most of the fourth lumbar ventral rami, usually together with a contribution from the twelfth thoracic ventral ramus (see Fig. 61.16). The lumbar ventral rami pass laterally into the posterior part of psoas major, anterior to the transverse processes of the lumbar vertebrae (Moro et al 2003, Benglis et al 2009). Although there are many variations, the most common arrangement of the plexus is described here (Tubbs et al 2018).

The first lumbar ventral ramus is often joined by a branch from the twelfth thoracic ventral ramus, and these roots contribute to the formation of the iliohypogastric and ilioinguinal nerves, which run laterally on the posterior abdominal wall. A branch from the first lumbar ventral ramus unites with a branch from the second lumbar ventral ramus to form the genitofemoral nerve. The second, third and most of the fourth lumbar ventral rami divide into ventral and dorsal divisions; the ventral divisions unite to form the obturator nerve, while most of the nerve fibres in the dorsal divisions form the femoral nerve. The remaining fibres from the fourth lumbar ventral ramus join the fifth lumbar ventral ramus to form the lumbosacral trunk, which descends to join the sacral plexus. Branches from the dorsal divisions of the second and third lumbar ventral rami unite to form the lateral femoral cutaneous nerve. The accessory obturator nerve, when present, usually arises from the third and fourth ventral rami. The lumbar plexus is supplied by branches from the lumbar vessels that supply psoas major.

The division of constituent ventral rami into ventral and dorsal branches is not as clear in the lumbar and sacral plexuses as it is in the brachial plexus. Lateral cutaneous branches of the twelfth thoracic and first lumbar ventral rami are drawn into the gluteal skin, but otherwise these nerves are similar to intercostal nerves. The second lumbar ventral ramus is more complex. It contributes substantially to the femoral and obturator nerves, and also has an anterior terminal branch (the genital branch of the genitofemoral) and a lateral cutaneous branch that contributes to the lateral femoral cutaneous nerve and the femoral branch of the genitofemoral nerve. Anterior terminal branches of the third to fifth lumbar and first sacral ventral rami are suppressed, but the corresponding branches of the second and third sacral ventral rami supply the perineal skin.

The furcal nerve is an independent nerve with its own ventral and dorsal rootlets most commonly arising alongside the fourth lumbar spinal nerve. Its branches contribute to the femoral and obturator nerves arising from the lumbar plexus and to the lumbosacral trunk (Harshavardhana and Dabke 2014). The term 'furcal' refers to its forked nature, since it links the lumbar and sacral plexuses. Occasionally, the furcal nerve arises at the level of either the third or the fifth lumbar spinal nerves, in which case the sacral plexus is considered prefixed or postfixed, respectively.

Inflammatory processes, such as retrocaecal appendicitis on the right and diverticular abscess on the left, can occur in the posterior abdominal wall in the tissues immediately anterior to psoas major. These may irritate one or more branches of the lumbar plexus, causing pain or sensory disturbance in the distribution of the affected nerves, e.g. the skin of the thigh, hip or buttock.

Terminal branches of the lumbar plexus

Muscular branches

Small branches from the lumbar ventral rami supply adjacent muscles such as psoas major and quadratus lumborum (Mahan et al 2017).

Iliohypogastric nerve

The iliohypogastric nerve usually originates from the first lumbar ventral ramus but may arise wholly or in part from the twelfth thoracic ventral ramus (Klaassen et al 2011). It emerges from the upper lateral border of psoas major and crosses obliquely posterior to the inferior pole of the kidney on the anterior surface of quadratus lumborum. Above the iliac crest it enters the posterior part of transversus abdominis and then runs anteriorly between transversus abdominis and internal abdominal oblique, which it supplies. It gives off a lateral cutaneous branch that pierces internal and external abdominal oblique above the iliac crest and supplies the posterolateral gluteal skin. It continues forwards, pierces internal abdominal oblique approximately 3 cm medial and 1 cm inferior to the anterior superior iliac spine (in adults), and then penetrates the external abdominal oblique aponeurosis approximately 3 cm above and medial to the superficial inguinal ring to supply the skin of the hypogastric region. The iliohypogastric nerve frequently connects with the ilioinguinal nerve and less commonly with the subcostal nerve. Motor branches of the iliohypogastric nerve innervate transversus abdominis and internal abdominal oblique. Cutaneous branches innervate the posterolateral gluteal and skin of the hypogastric region.

Lesions of the iliohypogastic nerve

The iliohypogastric nerve is occasionally injured by a surgical incision in the right inguinal region, e.g. during an inguinal hernia repair, open appendicectomy or abdominal wall trocar placement, but there is rarely any noticeable sensory loss because the skin of the hypogastric region is innervated from several sources. Division of the iliohypogastric nerve above the anterior superior iliac spine may weaken the posterior wall of the inguinal canal and predispose to formation of a direct inguinal hernia.

Ilioinguinal nerve

The ilioinguinal nerve usually originates from the first lumbar ventral ramus but may receive a contribution from the twelfth thoracic or second lumbar ventral rami (Klaassen et al 2011). It emerges from the lateral border of psoas major, with or just inferior to the iliohypogastric nerve, passes obliquely across the anterior aspect of quadratus lumborum and the superior part of iliacus and enters transversus abdominis about 3 cm medial and 4 cm inferior to the anterior superior iliac spine (in the adult); at this site, it is readily blocked by local anaesthetic. In this region, a branch may connect with the iliohypogastric or lateral femoral cutaneous nerve. It pierces internal abdominal oblique more inferiorly, supplies it and then traverses the remainder of the inguinal canal superficial to the spermatic cord or round ligament of the uterus. It emerges with the spermatic cord from the superficial inguinal ring and divides into terminal cutaneous branches.

Numerous anatomical variations have been described (Al-dabbagh 2002, Ndiaye et al 2007). The ilioinguinal and genitofemoral nerves may interconnect within the inguinal canal, so that each innervates the skin of the genitalia to a variable extent (Rab et al 2001, Cesmebasi et al 2015). The ilioinguinal nerve may pierce the aponeurosis of external abdominal oblique proximal to the superficial inguinal ring or divide into terminal branches within the inguinal canal. It may form a common trunk with the iliohypogastric nerve as far as the midpoint of the inguinal canal or may be very small or absent, in which case the iliohypogastric nerve and genital branch of the genitofemoral nerve

supply its territory. Rarely, it arises as a branch of the genitofemoral nerve. Motor branches of the ilioinguinal nerve supply transversus abdominis and internal abdominal oblique; the fibres are given off before the nerve enters the lateral aspect of the inguinal canal. Sensory branches innervate the skin of the proximal medial thigh and the skin over the root of the penis and proximal part of the scrotum in males (anterior scrotal nerve), or the skin covering the mons pubis and the adjoining labium majus in females (anterior labial nerve).

Lesions of the ilioinguinal nerve

The ilioinguinal nerve may be injured or entrapped during inguinal surgery, particularly for inguinal hernia repair, leading to sensory disturbances including pain from the external genitalia and proximal medial thigh (Ndiaye et al 2007).

Genitofemoral nerve

The genitofemoral nerve originates from the first and second lumbar ventral rami and is formed within the substance of psoas major. It descends obliquely anteriorly through the muscle to emerge on its anterior surface nearer the medial border, opposite the third or fourth lumbar vertebra (Moro et al 2003). It then descends deep to the posterior parietal peritoneum overlying psoas major, crosses obliquely posterior to the ureter, and divides into genital and femoral branches; it may divide close to its origin such that its branches emerge separately from psoas major. The genital branch crosses the distal part of the external iliac artery, enters the inguinal canal through the deep ring and accompanies the spermatic cord or round ligament of the uterus. It exits the superficial inguinal ring, usually posterior to the spermatic cord or round ligament of the uterus, and supplies cremaster and the skin of the external genitalia. The femoral branch descends lateral to the external iliac artery before crossing the deep circumflex iliac artery to pass deep to the inguinal ligament (occasionally, through it) (Rab et al 2001) and enter the femoral sheath lateral to the femoral artery. It pierces the anterior aspect of the femoral sheath and fascia lata and supplies the skin over the proximal part of the femoral triangle. It may connect with the lateral femoral cutaneous nerve and anterior femoral cutaneous branches of the femoral nerve. Motor branches of the genitofemoral nerve innervate cremaster via its genital branch. Sensory fibres travelling in the genital branch innervate the skin of the scrotum in males and of the mons pubis and labium majus in females; there is considerable variability and overlap with the cutaneous distribution of the ilio-inguinal nerve (Cesmebasi et al 2015).

Lesions of the genitofemoral nerve

The genital branch of the genitofemoral nerve may be injured during inguinal hernia repair (open or laparoscopic), leading to neuralgia (Cesmebasi et al 2015).

Lateral femoral cutaneous nerve

The lateral femoral cutaneous nerve (lateral femoral cutaneous nerve of the thigh) is usually derived from the dorsal branches of the second and third lumbar ventral rami, but variable contributions from the first to the third lumbar ventral rami have been described (de Ridder et al 1999). The nerve emerges from the posterolateral border of psoas major and crosses iliacus obliquely, running towards the anterior superior iliac spine. It supplies sensory fibres to the parietal peritoneum in the iliac fossa. On the right, the nerve passes posterolateral to the caecum, from which it is separated by the iliac fascia and peritoneum; on the left, it passes posterior to the inferior part of the descending colon. Both nerves usually pass posterior to the inguinal ligament about 1–2 cm medial to the anterior superior iliac spine; occasionally they pass through or, rarely, anterior to the ligament (Tubbs et al 2016): a separate fascial canal for this nerve has been described (Hanna 2017). Occasionally, the nerve lies anterior or superior to the anterior superior iliac spine as it enters the thigh, where it usually passes anterior or lateral to sartorius, but may also pierce the muscle. It divides into anterior and posterior branches. The anterior branch becomes superficial approximately 10 cm distal to the anterior superior iliac spine and supplies the skin of the anterior and lateral thigh as far distally as the knee. It connects terminally with the cutaneous branches of the anterior division of the femoral nerve and the infrapatellar branch of the saphenous nerve, forming the peripatellar plexus. The posterior branch pierces the fascia lata higher than the anterior, and divides to supply the skin on the lateral surface from the greater trochanter to about mid-thigh. It may also supply skin of the gluteal region.

Lesions of the lateral femoral cutaneous nerve

The lateral femoral cutaneous nerve may become entrapped at three sites along its course: close to the vertebral column; within the abdominal cavity as the nerve travels across the pelvis; and as it leaves the pelvis. This last site is where the nerve is most commonly damaged, and entrapment is thought to occur as the nerve passes through or deep to the inguinal ligament just medial to the anterior superior iliac spine. The angulation of the nerve as it crosses the iliac crest means that it is vulnerable to compression during movement, e.g. hip extension may increase angulation and tension on the nerve.

Injury produces an area of impaired sensation, often with pain and paraesthesia on the anterolateral aspect of the thigh (meralgia paraesthetica) in the distal cutaneous distribution of the nerve. This area does not extend across the midline anteriorly, it does not extend below the knee and it does not extend behind the hamstring tendons laterally. Symptoms may be exacerbated when wearing tight belts or tight-waisted clothes or as a result of a recent weight gain or pregnancy. Exceptionally, the posterior branch of the lateral femoral cutaneous nerve, which supplies a thin strip from the greater trochanter of the femur down about two-thirds of the way to the knee, may be affected separately. This branch leaves the main trunk of the nerve, usually distal to the inguinal ligament, and it then turns laterally to pierce tensor fasciae latae, where it may become entrapped.

Accessory obturator nerve

The accessory obturator nerve is sometimes present, more often on the left (Turgut et al 2017). It arises from the ventral branches of the third and fourth lumbar ventral rami, emerges from the medial border of psoas major, lateral to the obturator nerve, descends along the medial border of psoas major, crosses the superior pubic ramus behind pectineus and divides into branches; one branch enters the deep surface of pectineus, another supplies the hip joint, and a third connects with the anterior branch of the obturator nerve. Sometimes the accessory obturator nerve is very small and only supplies pectineus. Any branch may be absent and others may occur; an additional branch sometimes supplies adductor longus.

Femoral nerve

The femoral nerve is the largest branch of the lumbar plexus and is the nerve of the anterior compartment of the thigh. It has motor branches to iliacus, pectineus, sartorius and quadriceps femoris; articular branches to the hip, knee and ankle joints; cutaneous branches that supply most of the skin covering the anterior thigh, medial leg and medial foot and branches to the femoral artery (see Fig. 61.16). It arises from the dorsal branches (posterior divisions) of the second to fourth lumbar ventral rami (see Figs 76.11A, 77.44, 77.49) and descends through psoas major, emerging on or deep to its lateral border, about 4 cm above the inguinal ligament (Moore and Stringer 2011). It next passes between psoas major and iliacus deep to the iliac fascia, lying lateral to the femoral artery and sheath. As it passes behind the inguinal ligament into the thigh, the femoral nerve is split into anterior and posterior divisions by the lateral circumflex femoral artery. The branches of the anterior division are the intermediate and medial femoral cutaneous nerves and the nerve to sartorius. The branches of the posterior division are the saphenous nerve, muscular branches to quadriceps femoris and articular branches to the hip and knee joint. The terminal branches of the femoral nerve form in the femoral triangle about 2 cm distal to the inguinal ligament.

Nerve to pectineus

The nerve to pectineus branches from the medial side of the femoral nerve near the inguinal ligament. It passes behind the femoral sheath and enters the anterior aspect of the muscle.

Medial femoral cutaneous nerve of the thigh

The medial femoral cutaneous nerve (medial cutaneous nerve of the thigh) is at first lateral to the femoral artery. It crosses anterior to the artery at the apex of the femoral triangle and divides into anterior and posterior branches. Before doing so, it sends a few fibres through the fascia lata to supply the skin of the medial side of the thigh, near the long saphenous vein; one branch emerges via the saphenous opening, while another becomes subcutaneous about mid-thigh. The anterior branch descends on sartorius, perforates the fascia lata beyond mid-thigh, and divides into a branch that supplies the skin as low as the medial side of the knee, and another that runs lateral to the former and connects with the infrapatellar branch of the saphenous nerve. The posterior branch descends along the posterior border of sartorius to the knee, pierces the fascia lata, connects with the saphenous nerve and gives off several cutaneous rami, some as far as the medial side of the leg. The nerve contributes to the subsartorial plexus (see below).

Intermediate cutaneous nerve of the thigh

The intermediate femoral cutaneous nerve (intermediate cutaneous nerve of the thigh) usually pierces the fascia lata some 8 cm below the

inguinal ligament, either as two branches or as one trunk that quickly divides into two. These descend on the anterior thigh, supplying the skin as far as the knee and ending in the peripatellar plexus. The lateral branch of the intermediate cutaneous nerve communicates with the femoral branch of the genitofemoral nerve, frequently piercing sartorius and sometimes supplying it.

Nerve to sartorius

The main nerve to sartorius arises from the femoral nerve in common with the intermediate femoral cutaneous nerve.

Saphenous nerve

The saphenous nerve is the largest and longest cutaneous branch of the femoral nerve and the longest nerve in the body (see Figs 76.11, 77.48). It descends lateral to the femoral artery in the femoral triangle and enters the adductor canal, where it crosses anterior to the artery to lie medial to it. At the distal end of the canal, it leaves the artery and emerges through the aponeurotic covering with the saphenous branch of the descending genicular artery. As it leaves the adductor canal, the saphenous nerve gives off an infrapatellar branch that contributes to the peripatellar plexus and then pierces the fascia lata between the tendons of sartorius and gracilis, becoming subcutaneous to supply the skin anterior to the patella. It descends along the medial border of the tibia with the long saphenous vein and divides distally into a branch that continues along the tibia to the ankle and a branch that passes anterior to the ankle to supply the skin on the medial side of the foot, often as far as the first metatarsophalangeal joint. The saphenous nerve connects with the medial branch of the superficial fibular nerve. Near the mid-thigh, it contributes a branch to the subsartorial plexus. The nerve may become entrapped as it leaves the adductor canal.

Muscular branches

The muscular branches of the posterior division of the femoral nerve supply quadriceps femoris. A branch to rectus femoris enters its proximal posterior surface and also supplies the hip joint. A larger branch to vastus lateralis forms a neurovascular bundle with the descending branch of the lateral circumflex femoral artery in its distal part and also supplies the knee joint. A branch to vastus medialis descends through the proximal part of the adductor canal, lateral to the saphenous nerve and femoral vessels, and enters the muscle at about its midpoint, sending a long articular filament distally along the muscle to the knee. Two or three branches to vastus intermedius enter its anterior surface about mid-thigh, and a small branch from one of these descends through the muscle to supply articularis genus and the knee joint.

Vascular branches

Vascular branches of the femoral nerve supply the femoral artery and its branches.

Lesions of the femoral nerve

Partial or complete injury can occur during surgery directed to the hip, pelvis or spine; with femoral artery catheterization; from trauma; or as a result of a retroperitoneal haematoma or mass. The most striking feature of femoral neuropathy is wasting and weakness of quadriceps femoris, resulting in difficulty in walking and a tendency for the leg to collapse. Pain and paraesthesia may occur on the anterior and medial aspect of the thigh, extending down the medial aspect of the leg in the distribution of the saphenous branch of the femoral nerve.

Obturator nerve

The obturator nerve is the nerve of the medial compartment of the thigh: it arises from the ventral branches of the second to fourth lumbar ventral rami. The branch from the third is the largest while that from the second is often very small. The nerve descends within the substance of psoas major, emerging from its posteromedial border near the fifth lumbar vertebra (Kirchmair et al 2008). It passes posterior to the common iliac vessels and lateral to the internal iliac vessels, descends on the lateral wall of the pelvis attached to the obturator fascia, and lies anterosuperior to the obturator vessels before running into the obturator canal to enter the thigh. Near the foramen, it divides into anterior and posterior branches, separated initially by part of obturator externus and further distally by adductor brevis.

The obturator nerve is said to have no branches in the abdomen or pelvis, although it has been reported to send articular branches to the anterior aspect of the sacroiliac joint. Its sensory branches innervate the hip and knee joints, and a small, variable patch of skin on the proximal medial thigh, and its motor branches innervate obturator externus, adductor longus, adductor brevis, adductor magnus, gracilis and sometimes pectineus (see Fig. 61.16) (Tubbs et al 2016).

Anterior branch

The anterior branch (see Fig. 77.49) leaves the pelvis anterior to obturator externus, and descends anterior to adductor brevis, behind pectineus and adductor longus. At the lower border of adductor longus it communicates with the medial cutaneous and saphenous branches of the femoral nerve, to form a subsartorial plexus that supplies the skin on the medial side of the thigh. It descends on, and supplies, the femoral artery. Near the obturator foramen, the anterior branch supplies the hip joint. Behind pectineus it supplies adductor longus, gracilis, usually adductor brevis and often pectineus, and connects with the accessory obturator nerve (when present). Occasionally the communicating branch to the femoral medial cutaneous and saphenous branches continues as a cutaneous branch to the thigh and leg. When this occurs the nerve emerges from behind the distal border of adductor longus to descend along the posterior margin of sartorius to the knee, where it pierces the deep fascia and connects with the saphenous nerve to supply the skin halfway down the medial side of the leg.

Subsartorial nerve plexus The medial cutaneous nerve of the thigh forms a subsartorial plexus with branches of the saphenous and obturator nerves, deep to the fascia lata, at the lower border of adductor longus. When the communicating branch of the obturator nerve is large and reaches the leg, the posterior branch of the medial cutaneous nerve is small, and ends in the plexus from which it gives rise to a few cutaneous filaments.

Posterior branch

The posterior branch pierces obturator externus anteriorly, supplies it and passes behind adductor brevis to the front of adductor magnus, dividing into branches to this and adductor brevis when the latter is not supplied by the anterior division. It usually sends an articular filament to the knee joint, which either perforates adductor magnus distally or traverses its opening with the femoral artery to enter the popliteal fossa. Within the fossa, the nerve descends on the popliteal artery to the back of the knee, pierces its oblique posterior ligament and supplies the articular capsule. It gives filaments to the popliteal artery.

Lesions of the obturator nerve

Isolated lesions of the obturator nerve are rare. However, it may be injured together with other nerves in retroperitoneal lesions that occur close to the origins of the lumbar plexus, or by an acetabular fracture, pelvic tumour, obturator hernia, prolonged labour or direct trauma. It can be damaged iatrogenically following manipulation, transection or retraction during pelvic surgery and can become entrapped within the fascia overlying adductor brevis. Compression of the nerve by herniated bowel loops at the obturator foramen can result in pain referred to the hip, medial thigh and knee, the so-called Howship–Romberg sign. A more distal nerve entrapment syndrome causing chronic medial thigh pain has been described in athletes with large adductor muscles.

Sacral plexus

The sacral plexus is formed by the lumbosacral trunk, the first to third sacral ventral rami, and part of the fourth sacral ventral ramus (the remainder of the fourth sacral ventral ramus joins the coccygeal plexus). The lumbar part of the lumbosacral trunk contains part of the fourth and all of the fifth lumbar ventral rami; it appears at the medial margin of psoas major and descends over the linea terminalis, at first medial to and then distally crossing anterior to the sacroiliac joint, to join the first sacral ventral ramus. The greater parts of the second and third sacral rami converge on the inferomedial aspect of the lumbosacral trunk in the greater sciatic foramen to form the sciatic nerve. The ventral and dorsal divisions of the nerves do not separate physically from each other but their fibres remain separate within the rami; the ventral and dorsal divisions of each contributing root join within the sciatic nerve. The fibres of the dorsal divisions will go on to form the common fibular nerve, and the fibres of the ventral division form the tibial nerve. Occasionally, the sciatic nerve divides into common fibular and tibial nerves inside the pelvis; when this occurs, the common fibular nerve usually runs through piriformis.

The sacral plexus lies against the posterior pelvic wall anterior to piriformis, posterior to the internal iliac vessels and ureter, and posterior to the sigmoid colon on the left. The superior gluteal vessels run either between the lumbosacral trunk and first sacral ventral ramus, or between the first and second sacral rami, while the inferior gluteal vessels lie between either the first and second, or the second and third, sacral ventral rami.

The sacral plexus is not commonly involved in malignant tumours of the pelvis because it lies behind the relatively dense presacral fascia,

which resists all but locally very advanced malignant infiltration. When it occurs, there is intractable pain in the distribution of the branches of the plexus, which can be very difficult to treat. The plexus can also be involved in reticuloses or be affected by plexiform neuromas. The branches of the sacral plexus are shown in Table 77.1.

Sacral visceral and muscular branches

Visceral branches, the pelvic splanchnic nerves, arise from the second to fourth sacral verntral rami and innervate the pelvic viscera.

Several muscular branches arise from the fourth sacral ventral ramus to supply the superior surface of levator ani and the upper part of the external anal sphincter. The branches to levator ani enter the superior surface of the muscle. The branch to the external anal sphincter (also referred to as the perineal branch of the fourth sacral nerve) reaches the ischio-anal fossa by running either through ischiococcygeus or between ischiococcygeus and iliococcygeus: it also supplies the skin between the anus and coccyx.

Superior gluteal nerve

The superior gluteal nerve arises from the dorsal branches of the fourth and fifth lumbar and first sacral ventral rami. Accompanied by the superior gluteal vessels, the nerve leaves the pelvis via the greater sciatic foramen above piriformis, and divides into superior and inferior branches (see Fig. 77.47). The superior branch accompanies the upper branch of the deep division of the superior gluteal artery to supply gluteus medius and occasionally gluteus minimus. The inferior branch runs with the lower ramus of the deep division of the superior gluteal artery across gluteus minimus, supplies the glutei medius and minimus, and ends in tensor fasciae latae.

Inferior gluteal nerve

The inferior gluteal nerve arises from the dorsal branches of the fifth lumbar and first and second sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, and divides into branches that enter the deep surface of gluteus maximus (see Fig. 77.47).

Lesions of the superior and inferior gluteal nerves

Focal lesions of the superior and inferior gluteal nerves usually occur concurrently with those of the sciatic nerve, posterior femoral cutaneous nerve and/or pudendal nerve. However, both gluteal nerves are vulnerable to injury during total hip replacement, and less commonly due to blunt trauma or misplaced gluteal injections. Injury to the superior gluteal nerve causing paralysis of gluteus medius and minimus can result in Trendelenburg's sign, where the pelvis drops on the unsupported side (in the coronal plane) when standing on the affected limb. Injury to the inferior gluteal nerve results in weakness of gluteus maximus causing impaired hip extension (Kretschmer and Heinen 2015).

Pudendal nerve

The pudendal nerve arises from the ventral divisions of the second, third and fourth sacral ventral rami and is formed just above the superior border of the sacrotuberous ligament and the upper fibres of ischiococcygeus (Klink 1953, Sato 1980). It leaves the pelvis via the greater sciatic foramen between piriformis and ischiococcygeus (see Fig. 71.10), enters the gluteal region and passes dorsal to the sacrospinous ligament, close to its attachment to the ischial spine, where it lies medial to the internal pudendal vessels. It accompanies the internal pudendal artery through the lesser sciatic foramen into the pudendal canal on the lateral wall of the ischio-anal fossa. In the posterior part of the canal, it gives rise to the inferior anal (rectal) and perineal nerves; the dorsal nerve of the penis or clitoris continues anteriorly from this origin.

The course of the branches of the pudendal nerve parallels that of the pudendal vessels (see Figs 74.24, 75.4). Muscular branches that arise directly from the pudendal nerve supply the superficial transverse perineal muscles, bulbospongiosus, ischiocavernosus, the external urethral sphincter and the anterior parts of the external anal sphincter and levator ani. In males, the branch to bulbospongiosus pierces this muscle to supply the corpus spongiosum penis, and ends in the urethral mucosa. For the innervation of the female genitalia, see Table 75.2.

The pudendal nerve occupies a constant position over the ischial spine and it can be 'blocked' by infiltration with a local anaesthetic applied via a needle passed through the lateral wall of the vagina to anaesthetize the perineal and anal skin. It can also be palpated over the ischial spine through the lateral wall of the rectum.

Inferior anal nerve

The inferior anal (rectal) nerve runs either through the medial wall of the pudendal canal with the inferior anorectal vessels, or behind the sacrospinous ligament directly from the fourth sacral ventral ramus without passing through the pudendal canal (Maldonado et al 2015), or occasionally it arises directly from the sacral plexus and crosses the sacrospinous ligament or rejoins the pudendal nerve. The nerve crosses the ischio-anal fossa to supply the external anal sphincter, the lining of the distal part of the anal canal and the skin around the anus. It frequently breaks into terminal branches before reaching the lateral border of the external anal sphincter. Its cutaneous branches distributed around the anus overlap the branches of the perineal branch of the posterior femoral cutaneous nerve and of the posterior scrotal or labial nerves. In females, the inferior anal nerve can supply sensory branches to the distal part of the vagina.

Perineal nerve

The perineal nerve is the inferior and larger terminal branch of the pudendal nerve in the pudendal canal. It runs anteriorly, inferior to the internal pudendal artery and accompanies the perineal artery, dividing into posterior scrotal or posterior labial and muscular branches. The posterior scrotal or labial nerves are usually double; they have medial and lateral branches that run over the perineal membrane and pass anteriorly in the lateral part of the urogenital triangle with the posterior scrotal or posterior labial branches of the perineal artery. They supply the skin of the scrotum or labia majora, respectively, overlapping the distribution of the perineal branch of the posterior femoral cutaneous nerve and inferior anal nerve. In females, the posterior labial branches also supply sensory fibres to the skin of the distal vagina.

Dorsal nerve of the penis or clitoris

The dorsal nerve of the penis or clitoris runs anteriorly above the internal pudendal artery along the ischiopubic ramus, deep to the perineal membrane. It supplies the corpus cavernosum and accompanies the dorsal artery of the penis or clitoris between the layers of the suspensory ligament of the penis or clitoris. The dorsal nerve of the penis runs on the dorsum of the penis to end in the glans penis.

Perforating cutaneous nerve

The perforating cutaneous nerve usually arises from the posterior aspects of the second and third sacral ventral spinal rami. It pierces the sacrotuberous ligament, curves round the inferior border of gluteus maximus and supplies the skin over the inferomedial aspect of this muscle. The nerve may arise from the pudendal nerve or it may be absent, in which case it may be replaced either by a branch from the posterior femoral cutaneous nerve or from the third and fourth, or fourth and fifth, sacral ventral rami.

Nerve to quadratus femoris

The nerve to quadratus femoris arises from the ventral branches of the fourth lumbar to the first sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, descends on the ischium deep to the sciatic nerve, the gemelli and the tendon of obturator internus, and supplies gemellus inferior, quadratus femoris and the hip joint.

Nerve to obturator internus

The nerve to obturator internus arises from the ventral branches of the fifth lumbar and first and second sacral ventral rami. It leaves the pelvis via the greater sciatic foramen below piriformis, supplies a branch to the upper posterior surface of gemellus superior, crosses the ischial spine lateral to the internal pudendal vessels, re-enters the pelvis via the lesser sciatic foramen, and enters the pelvic surface of obturator internus.

Posterior femoral cutaneous nerve (posterior cutaneous nerve of the thigh)

The posterior femoral cutaneous nerve (posterior cutaneous nerve of the thigh) arises from the dorsal branches of the first and second, and the ventral branches of the second and third sacral rami. It leaves the pelvis via the greater sciatic foramen below piriformis and descends under gluteus maximus with the inferior gluteal vessels, lying posterior or medial to the sciatic nerve (see Fig. 77.47). It descends in the back of the thigh superficial to the long head of biceps femoris, deep to the fascia lata. It pierces the deep fascia behind the knee and accompanies the short saphenous vein to mid-calf, its terminal twigs connecting with the sural nerve. Its branches are cutaneous and are distributed to the gluteal region, perineum, posterior thigh and proximal posterior leg.

Three or four gluteal branches (inferior clunial nerves) curl round the lower border of gluteus maximus to supply the skin over the inferolateral portion of the muscle. The perineal branch supplies the superomedial skin in the thigh, curves forwards across the hamstrings below the ischial tuberosity, pierces the fascia lata and then runs in the

superficial perineal fascia to the scrotal or labial skin. It communicates with the inferior anal (rectal) and posterior scrotal or labial branches of the perineal nerve, and gives numerous branches to the skin of the back and medial side of the thigh, the popliteal fossa and the proximal part of the back of the leg. One study found the perineal branch of the posterior cutaneous nerve of the thigh in about one-half of specimens (Tubbs et al 2009).

Nerve to piriformis

The nerve to piriformis usually arises from the dorsal branches of the first and second sacral ventral rami (sometimes only the second) and enters the anterior surface of piriformis.

Sciatic nerve

The sciatic nerve is typically 2 cm wide at its origin and is the thickest nerve in the body. It travels in the posterior compartment of the thigh and supplies the leg and foot. It leaves the pelvis via the greater sciatic foramen, usually inferior to piriformis, and descends between the greater trochanter and ischial tuberosity, along the back of the thigh, dividing into the tibial and common fibular nerves at a varying level proximal to the knee (see Fig. 77.50; see also Fig. 76.11B). Superiorly, it lies deep to gluteus maximus, resting first on the posterior ischial surface with the nerve to quadratus femoris between them. It then crosses posterior to obturator internus, the gemelli and quadratus femoris, separated by the latter from obturator externus and the hip joint. It is accompanied medially by the posterior femoral cutaneous nerve and the inferior gluteal artery. More distally, it lies behind adductor magnus and is crossed posteriorly by the long head of biceps femoris. Its course corresponds to a line drawn from just medial to the midpoint between the ischial tuberosity and greater trochanter to the apex of the popliteal fossa. Articular branches arise proximally to supply the hip joint through its posterior capsule; these are sometimes derived directly from the sacral plexus. Muscular branches are distributed to biceps femoris, semitendinosus, semimembranosus and the ischial part of adductor magnus.

The point of division of the sciatic nerve into its tibial and common fibular components is very variable: the two large nerves are only loosely held together as the sciatic nerve and the level of their separation in the thigh is variable. The common site is at the junction of the middle and lower thirds of the thigh, near the apex of the popliteal fossa, but the division may occur at any level above this point and, rarely, may occur below it: the common variations of the sciatic nerve have been classified into six types (Beaton and Anson 1937). The tibial nerve is derived from the anterior divisions of the sacral plexus and the common fibular nerve is derived from the posterior divisions of the plexus. The medial (tibial) component innervates the posterior thigh muscles, including the ischial part of adductor magnus, but not the short head of biceps femoris, which is supplied by the lateral (common fibular) component.

Blood supply to the sciatic nerve In the gluteal region, the sciatic nerve is supplied by the inferior gluteal artery and cruciate anastomosis (the medial and lateral circumflex femoral arteries, inferior gluteal artery and the first perforating branch of the profunda femoris artery) (see Fig. 77.47). On rare occasions, it is supplied by branches from the superior gluteal or internal pudendal arteries, which reach the nerve on its medial side. Lower in the thigh, arterial branches derived from the perforating branches of the profunda femoris artery or the anastomotic chain between them or, occasionally, from the popliteal artery, enter the nerve on its lateral or anterolateral side (Sunderland 1945). The numerous arterial branches to the sciatic nerve anastomose with each other to form extraneural and intraneural arterial chains (Sunderland 1945, Ugrenovic et al 2013).

Lesions of the sciatic nerve

The sciatic nerve supplies the posterior thigh muscles and all the muscles below the knee, which means that a complete palsy of the sciatic nerve results in a flail foot and severe difficulty in walking. Fortunately, complete sciatic nerve palsy is very rare. The nerve is vulnerable in posterior dislocation of the hip. As it leaves the pelvis, it passes either inferior to piriformis or sometimes through the muscle, and at that point it may very rarely become entrapped or tethered; the piriformis syndrome is a controversial condition in which an anomalous relationship between piriformis and the sciatic nerve is thought to cause pain in the buttocks and along the course of the sciatic nerve. External compression over the buttock, e.g. in patients who lie immobile on a hard surface for a considerable length of time, can injure the nerve. However, the most common cause of serious sciatic nerve injury (and of the resulting major medicolegal claims) is iatrogenic (Dillow et al 2013). The nerve may be iatrogenically damaged in misplaced therapeutic injections into gluteus maximus. Sciatic nerve palsy occurs after total hip replacement or similar surgery in 1% of cases, and may be caused by sharp injury, burning from bone cement, traction from instruments, manipulation of the hip, inadvertent lengthening of the femur, or haematoma surrounding the nerve. For some reason, possibly anatomical, the common fibular component of the sciatic nerve is more usually affected, resulting in a foot drop and a high-stepping gait.

Tibial nerve

The tibial nerve, the larger component of the sciatic nerve, is derived from the ventral branches (anterior divisions) of the fourth and fifth lumbar and first to third sacral ventral rami. It descends along the posterior thigh and popliteal fossa to the distal border of popliteus. It then passes anterior to the arch of soleus with the popliteal artery and continues into the leg. In the thigh, it is overlapped proximally by the hamstring muscles but it becomes more superficial in the popliteal fossa, where it is lateral to the popliteal vessels. At the level of the knee, the tibial nerve becomes superficial to the popliteal vessels and crosses to the medial side of the artery. In the distal popliteal fossa, it is overlapped by the junction of the two heads of gastrocnemius.

In the leg, the tibial nerve is the nerve of the posterior compartment. It descends with the posterior tibial vessels to lie between the heel and the medial malleolus (see Fig. 78.4). Proximally, it is deep to soleus and gastrocnemius, but in its distal third is covered only by skin and fasciae, and overlapped sometimes by flexor hallucis longus. At first medial to the posterior tibial vessels, it crosses behind them and descends lateral to them until it bifurcates. It lies on tibialis posterior for most of its course except distally, where it adjoins the posterior surface of the tibia. The tibial nerve ends under the flexor retinaculum by dividing into the medial and lateral plantar nerves.

The branches of the tibial nerve are articular, muscular (to gastrocnemius, plantaris, soleus, popliteus, tibialis posterior, flexor digitorum longus and flexor hallucis longus), sural, medial calcaneal and medial and lateral plantar nerves.

Articular branches

Articular branches to the knee joint accompany the superior and inferior medial genicular arteries and the middle genicular artery; they form a plexus with a branch from the obturator nerve and also supply the oblique popliteal ligament. The branches accompanying the superior and inferior medial genicular arteries supply the medial part of the capsule. A branch of the nerve to popliteus (tibial nerve) supplies the posterior portion of the superior tibiofibular joint. Just before the tibial nerve bifurcates, it gives off branches that supply the ankle joint.

Muscular branches

Proximal muscular branches arise between the heads of gastrocnemius and supply gastrocnemius, plantaris, soleus and popliteus. The nerve to soleus enters its superficial aspect. The branch to popliteus descends obliquely across the popliteal vessels, curling round the distal border of the muscle to its anterior surface. It also supplies tibialis posterior, the superior tibiofibular joint and the tibia, and gives off an interosseous branch that descends near the fibula to reach the distal tibiofibular joint.

Muscular branches in the leg, either independently or by a common trunk, supply soleus (on its deep surface), tibialis posterior, flexor digitorum longus and flexor hallucis longus. The branch to flexor hallucis longus accompanies the fibular vessels.

Sural nerve

The sural nerve descends between the heads of gastrocnemius, pierces the deep fascia proximally in the leg, and is joined at a variable level by the sural communicating branch of the common fibular nerve. Some authors term this branch the lateral sural cutaneous nerve, and call the main trunk (from the tibial nerve) the medial sural cutaneous nerve. The sural nerve descends lateral to the calcaneal tendon, near the short saphenous vein, to the region between the lateral malleolus and the calcaneus, and supplies the posterior and lateral skin of the distal third of the leg. It then passes distal to the lateral malleolus along the lateral side of the foot and fifth toe, supplying the overlying skin. It connects with the posterior femoral cutaneous nerve in the leg and with the superficial fibular nerve on the dorsum of the foot.

The sural nerve is often used as an autologous peripheral nerve graft on the grounds that it is easily harvested, readily identified and exclusively cutaneous.

Medial calcaneal nerve

The medial calcaneal nerve arises from the tibial nerve and perforates the flexor retinaculum to supply the skin of the heel and medial side of the sole.

Medial plantar nerve

The medial plantar nerve is the larger terminal division of the tibial nerve, and lies lateral to the medial plantar artery. From its origin under the flexor retinaculum, it passes deep to abductor hallucis, then appears between it and flexor digitorum brevis, gives off a medial proper digital nerve to the great toe, and divides near the metatarsal bases into three common plantar digital nerves (see Fig. 79.27; see also Fig. 79.22).

Cutaneous branches pierce the plantar aponeurosis between abductor hallucis and flexor digitorum brevis to supply the skin of the sole of the foot. Muscular branches supply abductor hallucis, flexor digitorum brevis, flexor hallucis brevis and the first lumbrical. The first two arise near the origin of the nerve and enter the deep surfaces of the muscles. The branch to flexor hallucis brevis is from the hallucal medial digital nerve, and that to the first lumbrical from the first common plantar digital nerve. Articular branches supply the joints of the tarsus and metatarsus.

Three common plantar digital nerves pass between the slips of the plantar aponeurosis, each dividing into two proper digital branches. The first supplies adjacent sides of the great and second toes; the second supplies adjacent sides of the second and third toes; and the third supplies adjacent sides of the third and fourth toes, and also connects with the lateral plantar nerve. The first gives a branch to the first lumbrical. Each proper digital nerve has cutaneous and articular branches: near the distal phalanges, a dorsal branch supplies structures around the nail. Abductor hallucis, flexor hallucis brevis and the first lumbrical are all supplied by the medial plantar nerve.

Lateral plantar nerve

The lateral plantar nerve supplies the skin of the fifth toe, the lateral half of the fourth toe, and most of the deep muscles of the foot (see Fig. 79.22). It is located medial to the lateral plantar artery and courses anteriorly towards the tubercle of the fifth metatarsal. Next, it passes between flexor digitorum brevis and flexor accessorius, and ends between flexor digiti minimi brevis and abductor digiti minimi by dividing into superficial and deep branches. Before division, it supplies flexor accessorius and abductor digiti minimi, and gives rise to small branches that pierce the plantar aponeurosis to supply the skin of the lateral part of the sole (see Fig. 79.27). The superficial branch splits into two common plantar digital nerves: the lateral supplies the lateral side of the fifth toe, flexor digiti minimi brevis and the two interossei in the fourth intermetatarsal space; the medial connects with the third common plantar digital branch of the medial plantar nerve and divides into two to supply the adjoining sides of the fourth and fifth toes. The deep branch accompanies the lateral plantar artery deep to the flexor tendons and adductor hallucis, and supplies the second to fourth lumbricals, adductor hallucis and all the interossei (except those of the fourth intermetatarsal space). Branches to the second and third lumbricals pass distally deep to the transverse head of adductor hallucis, and travel around its distal border to reach them (see Video 79.1).

Lesions of the tibial nerve

The tibial nerve is vulnerable to direct injury in the popliteal fossa, where it lies superficial to the popliteal vessels at the level of the knee, or to compression at the tendinous arch of the soleus. It may be damaged in compartment syndrome that affects the deep flexor compartment of the calf. All nerves of the foot can be affected by entrapment, leading classically to a burning sensation in the distribution of that nerve. Tarsal tunnel syndrome is much less common than carpal tunnel syndrome. The flexor retinaculum may compress the tibial nerve or either of its branches (medial and lateral plantar nerves); entrapment at this level is most commonly due to a space-occupying lesion, e.g. a ganglion, or to compression by either a leash of vessels or the deep fascia associated with abductor hallucis. Compression of the first branch of the lateral plantar nerve (Baxter's nerve) by the deep fascia that covers abductor hallucis has been implicated as a possible cause of chronic heel pain and of plantar fasciitis. (Plantar fasciitis, often caused by repetitive high-impact injury to the foot, may be associated with pain, especially over the medial calcaneal process, which may be exacerbated by passive ankle or great toe flexion.) The medial plantar nerve can be compressed at the 'knot of Henry', which is the point where the tendon of flexor hallucis longus crosses deep to the tendon of flexor digitorum longus, to reach its medial side in the sole of the foot. It may also be compressed between abductor hallucis and the navicular bone ('jogger's foot'). Sural nerve entrapment is usually not due to compression by fascial elements. Entrapment of the third common digital nerve as it passes deep to the intermetatarsal ligament of the third (or less commonly the second) web space can result in a Morton's neuroma, which is probably the most common form of nerve entrapment in the foot.

Depending on the level of the injury, damage to the tibial nerve can produce weakness of knee flexion, plantarflexion, inversion and toe flexion, accompanied by sensory loss in the lower lateral leg, heel and sole of the foot.

Common fibular nerve

The common fibular nerve (common peroneal nerve) is the nerve of the anterior and lateral compartments in the leg. It is approximately half the size of the tibial nerve and is derived from the dorsal (posterior) branches of the fourth and fifth lumbar and first and second sacral ventral rami. It descends obliquely along the lateral side of the popliteal fossa to the fibular head, medial to biceps femoris. It lies between the tendon of biceps femoris, to which it is bound by fascia, and the lateral head of gastrocnemius (see Fig. 78.41). The nerve then passes into the anterolateral compartment of the leg through a tight opening in the thick fascia overlying tibialis anterior. It curves lateral to the neck of the fibula, lying on the bone deep to fibularis longus, and divides into superficial and deep fibular nerves; an articular trunk, derived from the deep fibular nerve, provides an articular branch that travels with the anterior tibial recurrent artery and a proximal branch to tibialis anterior.

The common fibular nerve supplies the anterolateral part of the knee joint capsule and the proximal tibiofibular joint and the skin on the anterior, posterior and lateral surfaces of the proximal leg. The superficial peroneal nerve supplies fibulares longus and brevis and the skin of the lower leg before dividing into medial and intermediate dorsal cutaneous nerves. The deep fibular nerve supplies muscular branches to tibialis anterior, extensors hallucis longus and digitorum longus and fibularis tertius, and an articular branch to the ankle joint, before dividing into lateral and medial terminal branches.

The common fibular nerve has articular and cutaneous branches, and terminates as the superficial and deep fibular nerves.

Articular branches

There are three articular branches. Two accompany the superior and inferior lateral genicular arteries; they may arise in common. The third, the recurrent articular branch, arises near the termination of the common fibular nerve. It ascends with the anterior recurrent tibial artery through tibialis anterior and supplies the anterolateral part of the knee joint capsule and the proximal tibiofibular joint.

Cutaneous branches

The two cutaneous branches, often from a common trunk, are the lateral sural and sural communicating nerves. The lateral sural cutaneous nerve (lateral cutaneous nerve of the calf) supplies the skin on the anterior, posterior and lateral surfaces of the proximal leg. The sural communicating nerve arises near the head of the fibula and crosses the lateral head of gastrocnemius to join the sural nerve. It may descend separately as far as the heel.

Lesions of the common fibular nerve

The common fibular nerve is relatively unprotected as it traverses the lateral aspect of the neck of the fibula and is easily compressed at this site, e.g. by plaster casts or ganglia. The nerve may also become entrapped by a fascial band beneath fibularis longus within the so-called fibular tunnel, between the attachments of fibularis longus to the head and shaft of the fibula. Traction lesions can accompany dislocations of the lateral compartment of the knee, and are most likely to occur if the distal attachments of biceps femoris and the ligaments that insert on to the fibular head are avulsed, possibly with a small part of the fibular head; the nerve is tethered to the tendon of biceps femoris by dense fascia and so is pulled proximally. Severe traction lesions may produce longitudinal injuries affecting a long segment of the common fibular nerve. Torsional injury following ankle injury (sprain or fracture) may result in common fibular neuropathy; the injury is transmitted from the ankle along the interosseous membrane to the proximal leg (Lalezari et al 2012). Patients with such injury present with a foot drop. Physical examination reveals weakness or paralysis of ankle dorsiflexion, toe extension and eversion of the foot, but inversion and plantar flexion are normal. Sensation on the dorsum of the foot, including the first dorsal web space, is diminished. The ankle reflex is preserved. Since the common fibular nerve divides at the fibular neck into the superficial and deep fibular nerves, injuries to the nerve at this level may damage either the main trunk or its branches. Electrodiagnostic studies can help localize a common fibular nerve injury to the fibular neck region. At this level, nerve conduction studies may show slowed velocities and electromyography would demonstrate denervation in the muscles innervated by the common fibular nerve (such as tibialis anterior or fibularis longus), whereas more proximally innervated muscles (particularly the short head of biceps femoris) would be normal. Injury specifically to the

superficial fibular nerve will result in paralysis of eversion and sensory loss in the lower lateral aspect of the leg extending onto the dorsum of the foot. Damage to the deep fibular nerve results in paralysis of dorsiflexion and toe extension with sensory loss in the first interdigital web space.

Superficial fibular nerve

The superficial fibular nerve (superficial peroneal nerve) begins at the bifurcation of the common fibular nerve. It lies deep to fibularis longus at first, then passes anteroinferiorly between fibularis longus and brevis and extensor digitorum longus, and pierces the deep fascia in the distal third of the leg (see Fig. 78.41). It divides into a large medial dorsal cutaneous nerve and a smaller, more laterally placed, intermediate dorsal cutaneous nerve, usually after piercing the deep fascia, but sometimes while it is still deep to the fascia. As the nerve lies between the muscles it supplies fibularis longus, fibularis brevis and the skin of the lower leg. The deep course, i.e. the compartmental localization, and the peripheral digital distribution of the superficial fibular nerve are subject to considerable variation (see Kosinksi's classification; Kosinski 1926, Solomon et al 2001).

Cutaneous branches

The medial dorsal cutaneous nerve passes in front of the ankle joint and divides into two dorsal digital branches; one of these supplies the medial side of the hallux and the other supplies the adjacent side of the second and third toes. It communicates with the saphenous and deep fibular nerves. The smaller intermediate branch crosses the dorsum of the foot laterally. It divides into dorsal digital branches that supply the contiguous sides of the third to fifth toes and the skin of the lateral aspect of the ankle, where it connects with the sural nerve. Both branches, especially the intermediate, are at risk during the placement of portal skin incisions for arthroscopy and during surgical approaches to the lateral malleolus. Branches of the superficial fibular nerve supply the skin of the dorsum of all the toes except that of the lateral side of the fifth toe (supplied by the sural nerve) and the adjoining sides of the great and second toes (supplied by the medial terminal branch of the deep fibular nerve). Some of the lateral branches of the superficial fibular nerve are frequently absent and are replaced by sural nerve branches.

Accessory fibular nerves

An accessory superficial fibular nerve and an accessory deep fibular nerve have been described as variant branches of the superficial fibular nerve; both are probably the product of atypical branching of the parent nerve deep to the deep fascia (see above).

Lesions of the superficial fibular nerve

A lesion of the superficial fibular nerve causes weakness of foot eversion and sensory loss on the lateral aspect of the leg that extends onto the dorsum of the foot. The nerve can be subject to entrapment as it penetrates the deep fascia of the leg, be involved in compartment syndrome that affects the lateral compartment of the leg, or be damaged in severe inversion injuries of the ankle.

Deep fibular nerve

The deep fibular nerve (deep peroneal nerve) begins at the bifurcation of the common fibular nerve, between the fibula and the proximal part of fibularis longus. It passes obliquely forwards deep to extensor digitorum longus to the front of the interosseous membrane and reaches the anterior tibial artery in the proximal third of the leg. It descends with the artery to the ankle, where it divides into lateral and medial terminal branches. As it descends, the nerve is first lateral to the artery, then anterior, and finally lateral again at the ankle.

Cutaneous and muscular branches

The deep fibular nerve supplies muscular branches to tibialis anterior, extensor hallucis longus, extensor digitorum longus and fibularis tertius, and an articular branch to the ankle joint.

The lateral terminal branch crosses the ankle deep to extensor digitorum brevis, enlarges as a pseudoganglion and supplies extensor digitorum brevis. From the enlargement, three minute interosseous branches supply the tarsal and metatarsophalangeal joints of the middle three toes.

The medial terminal branch runs distally on the dorsum of the foot lateral to the dorsalis pedis artery, and connects with the medial branch of the superficial fibular nerve in the first interosseous space. It divides into two dorsal digital nerves, which supply adjacent sides of the great and second toes. Before dividing, it gives off an interosseous branch, which supplies the first metatarsophalangeal joint. The deep fibular nerve may end as three terminal branches.

Lesions of the deep fibular nerve

Isolated injury to the deep fibular nerve may result from compartment syndrome that affects the anterior compartment of the leg or from an intraneural ganglion cyst (mucinous cyst within the nerve derived from the superior tibiofibular joint via the articular branch that travels with the anterior tibial recurrent artery (Spinner et al 2003)). The nerve is sometimes compressed by osteophytes in the region of the second tarsometatarsal joint.

Individuals with lesions of the deep fibular nerve have weakness of ankle dorsiflexion and extension of all toes but normal foot eversion. Sensory impairment is confined to the first interdigital web space.

Coccygeal plexus

The coccygeal plexus is formed by a small descending branch from the fourth sacral ventral ramus and by the fifth sacral and coccygeal ventral rami. The fifth sacral ventral ramus emerges from the sacral hiatus, curves round the lateral margin of the sacrum inferior to its cornu, and pierces ischiococcygeus inferiorly to reach its pelvic surface. Here it is joined by a descending branch of the fourth sacral ventral ramus; the small trunk so formed descends on the pelvic surface of ischiococcygeus, joins the minute coccygeal ventral ramus that emerges from the sacral hiatus, and curves round the lateral coccygeal margin, piercing ischiococcygeus to reach the pelvis. The small trunk that is formed in this way is the coccygeal plexus. Anococcygeal nerves arise from it and form a few fine filaments that pierce the sacrotuberous ligament to supply the adjacent skin.

AUTONOMIC NERVOUS SYSTEM

The autonomic nervous system represents the visceral component of the nervous system. It consists of neurones located within the CNS and the PNS that are concerned with the control of the internal environment, through the innervation of secretory glands and cardiac and smooth muscle. Its functions are, however, closely integrated with those of the somatic nervous system.

Visceral efferent pathways differ from their somatic equivalents in that the former are interrupted by peripheral synapses, there being a sequence of at least two neurones between the CNS and the target structure (see Fig. 24.11). These are referred to as preganglionic and postganglionic neurones, respectively. The somata of preganglionic neurones are located in the visceral efferent nuclei of the brainstem and in the lateral horn of the spinal cord. Their axons, which are usually finely myelinated, exit from the CNS in certain cranial and spinal nerves, and then pass to peripheral ganglia, where they synapse with postganglionic neurones. The axons of postganglionic neurones are usually unmyelinated. Postganglionic neurones are more numerous than preganglionic ones; one preganglionic neurone may synapse with 15–20 postganglionic neurones, which permits the wide distribution of many autonomic effects.

The autonomic nervous system is traditionally divided into the sympathetic and parasympathetic systems that coordinate the neural regulation of visceral and homeostatic functions. In general, sympathetic activity results in the constriction of cutaneous arteries (increasing blood supply to the heart, muscles and brain), cardiac acceleration, an increase in blood pressure, contraction of sphincters and depression of peristalsis, all of which mobilize body energy stores for dealing with increased activity. Parasympathetic activity results in cardiac slowing and an increase in intestinal glandular and peristaltic activities, which may be considered to conserve body energy stores.

SYMPATHETIC NERVOUS SYSTEM

Preganglionic sympathetic axons originate from neuronal somata in the intermediolateral nucleus (lateral horn) of the spinal cord from the first thoracic to the second lumbar spinal segments (T1–L2) (see Fig. 24.12). Postganglionic sympathetic axons arise from neuronal somata in the sympathetic (paravertebral) trunk or in a more peripheral plexus. There are between 10 and 12 (usually 11) thoracic ganglia, four lumbar ganglia, and four or five ganglia in the sacral region. Cervical sympathetic ganglia are usually reduced to three by fusion.

Preganglionic axons are myelinated with diameters of 1.5–4 μm and release acetylcholine as their principal neurotransmitter. They travel initially with the corresponding ventral roots and leave the latter as

white rami communicantes to enter the adjacent sympathetic ganglion in the sympathetic trunk (see Fig. 24.13). Their targets vary; some synapse in the sympathetic ganglion that they enter, whereas others ascend or descend in the sympathetic trunk to synapse in cervical or lumbar ganglia, respectively. Axons destined for the cervical ganglia are mainly derived from preganglionic neurones in the first thoracic spinal nerve. Many of the preganglionic axons that originate in the lower thoracic spinal segments (T5–T12) do not synapse locally but enter the abdominal cavity as the thoracic splanchnic nerves. These nerves pass through the posterior mediastinum and respiratory diaphragm to enter the abdominal cavity where they synapse either in prevertebral ganglia that surround the origin of the major visceral arteries arising from the abdominal aorta, e.g. the coeliac and superior mesenteric ganglia, or around the medullary chromaffin cells of the suprarenal gland.

The axons of postganglionic neurones are unmyelinated and generally longer than those of preganglionic neurones, an exception being some of those that innervate pelvic viscera. Postganglionic axons are distributed to target organs in various ways. Those from a ganglion of the sympathetic trunk may return to the spinal nerve of preganglionic origin through a grey ramus communicans, which usually joins the nerve just proximal to the white ramus, and are then distributed through ventral and dorsal spinal rami to blood vessels, sweat glands, hairs, etc., in their zone of supply. Segmental areas vary in extent and overlap considerably and the extent of innervation of different effector systems, e.g. vasomotor, sudomotor, etc., by a particular nerve may differ (a single preganglionic fibre probably synapses with the postganglionic neurones in only one effector system). Alternatively, postganglionic fibres can pass in a medial branch of a ganglion direct to particular viscera, or innervate adjacent blood vessels, or pass along them externally to their peripheral distribution. They may ascend or descend before leaving the sympathetic trunk as described above. Many fibres are distributed along arteries and ducts as plexuses to distant effectors, e.g. the internal carotid nerve, a continuation of the sympathetic trunk, issues from the cranial pole of the superior ganglion and accompanies the internal carotid artery through its canal into the cranial cavity.

The principal neurotransmitter released by postganglionic sympathetic neurones is noradrenaline (norepinephrine). The sympathetic system has a much wider distribution than the parasympathetic system: it innervates all sweat glands, the arrector pili muscles, the muscular walls of many blood vessels, the heart, lungs and respiratory tree, the abdominopelvic viscera, the oesophagus, the muscles of the iris, and the non-striated muscle of the urogenital tract, eyelids and elsewhere. Postganglionic sympathetic fibres that return to the spinal nerves are vasoconstrictor to blood vessels, secretomotor to sweat glands and motor to the arrector pili muscles within their dermatomes. Most, if not all, peripheral nerves contain postganglionic sympathetic fibres. Those reaching the viscera are concerned with general vasoconstriction, bronchial and bronchiolar dilation, modification of glandular secretion, pupillary dilation, inhibition of gastrointestinal muscle contraction, etc.

Sympathetic trunk

The sympathetic trunk is a ganglionated nerve cord that extends on the side of the vertebral column from the cranial base to the coccyx. The ganglia are joined to spinal nerves by short connecting nerves called white and grey rami communicantes. Preganglionic axons join the trunk through the white rami communicantes, while postganglionic axons leave the trunk in the grey rami. In the thorax, the trunks are anterior to the heads of the ribs, in the abdomen they lie anterolateral to the bodies of the lumbar vertebrae, and in the pelvis they are anterior to the sacrum and medial to the anterior sacral foramina. Anterior to the coccyx the two trunks meet in a single, median, terminal ganglion.

Cervical sympathetic system

In the neck, each sympathetic trunk lies posterior to the carotid sheath and anterior to the transverse processes of the cervical vertebrae. The cervical sympathetic trunk lies on the prevertebral fascia behind the carotid sheath and contains three interconnected ganglia: the superior, middle and inferior (stellate or cervicothoracic) (see Figs 35.17–35.18). There may occasionally, however, be two or four ganglia. The cervical sympathetic ganglia send grey rami communicantes to all the cervical spinal nerves but receive no white rami communicantes from them. Their spinal preganglionic fibres emerge in the white rami communicantes of the upper five thoracic spinal nerves (mainly the upper three), and ascend in the sympathetic trunk to synapse in the cervical ganglia. In their course, the grey rami communicantes may pierce longus capitis or scalenus anterior.

Superior cervical ganglion

The superior cervical ganglion is the largest of the three ganglia (see Fig. 35.17). It lies on the transverse processes of the second and third cervical vertebrae and is probably formed from four fused ganglia, judging by its grey rami communicantes to the upper four cervical spinal nerves. The internal carotid artery within the carotid sheath is anterior, and longus capitis is posterior. The lower end of the ganglion is united by a connecting trunk to the middle cervical ganglion. Postganglionic branches are distributed in the internal carotid nerve, which ascends with the internal carotid artery into the carotid canal to enter the cranial cavity, and in lateral, medial and anterior branches. They supply vasoconstrictor and sudomotor nerves to the face and neck, dilator pupillae and smooth muscle in the eyelids and orbitalis.

Lateral branches

The lateral branches of the superior cervical ganglion are grey rami communicantes to the upper four cervical spinal nerves and to some of the cranial nerves. Branches pass to the inferior vagal ganglion, the hypoglossal nerve, the superior jugular bulb and associated jugular glomus or glomera, and to the meninges in the posterior cranial fossa. Another branch, the jugular nerve, ascends to the cranial base and divides into two; one part joins the inferior glossopharyngeal ganglion and the other joins the superior vagal ganglion.

Medial branches

The medial branches of the superior cervical ganglion are the laryngopharyngeal and cardiac branches. The laryngopharyngeal branches supply the carotid body and pass to the side of the pharynx, joining glossopharyngeal and vagal rami to form the pharyngeal plexus. A cardiac branch arises by two or more filaments from the lower part of the superior cervical ganglion and occasionally receives a twig from the trunk between the superior and middle cervical ganglia. It is thought to contain only efferent fibres, the preganglionic outflow being from the upper thoracic segments of the spinal cord, and to be devoid of pain fibres from the heart. It descends behind the common carotid artery, anterior to longus colli, and crosses anterior to the inferior thyroid artery and recurrent laryngeal nerve. The courses on the two sides then differ. The right cardiac branch usually passes posterior, but sometimes anterior, to the subclavian artery and runs posterolateral to the brachiocephalic trunk to join the deep (dorsal) part of the cardiac plexus behind the aortic arch. It has other sympathetic connections. About mid-neck, it receives filaments from the external laryngeal nerve. Inferiorly, one or two vagal cardiac branches join it. As it enters the thorax, it is joined by a filament from the recurrent laryngeal nerve. Filaments from the nerve also communicate with the thyroid branches of the middle cervical ganglion. The left cardiac branch, in the thorax, is anterior to the left common carotid artery and crosses anterior to the left side of the aortic arch to reach the superficial (ventral) part of the cardiac plexus. It may descend on the right of the aorta to end in the deep (dorsal) part of the cardiac plexus. It communicates with the cardiac branches of the middle and inferior cervical sympathetic ganglia and sometimes with the inferior cervical cardiac branches of the left vagus nerve, and forms a plexus on the ascending aorta with branches from these mixed nerves

Anterior branches

The anterior branches of the superior cervical ganglion ramify on the common and external carotid arteries and the branches of the external carotid, and form a delicate plexus around each, in which small ganglia are occasionally found. The plexus around the facial artery supplies a filament to the submandibular ganglion; the plexus on the middle meningeal artery sends one ramus to the otic ganglion and another, the external petrosal nerve, to the facial ganglion. Many of the fibres coursing along the external carotid and its branches ultimately leave them to travel to facial sweat glands via branches of the trigeminal nerve.

Middle cervical ganglion

The middle cervical ganglion is the smallest of the three cervical sympathetic ganglia and is occasionally absent, in which case it may be replaced by minute ganglia in the sympathetic trunk or may be fused with the superior ganglion. It is usually found at the level of the sixth cervical vertebra, anterior or just superior to the inferior thyroid artery, or it may adjoin the inferior cervical ganglion. It probably represents a coalescence of the ganglia of the fifth and sixth cervical segments, judging by its postganglionic rami, which join the fifth and sixth cervical spinal nerves

(but sometimes also the fourth and seventh). It is connected to the inferior cervical ganglion by two or more very variable cords. The posterior cord usually splits to enclose the vertebral artery, while the anterior cord loops down anterior to, and then below, the first part of the subclavian artery, medial to the origin of its internal thoracic branch, and supplies rami to it. This loop is the ansa subclavia and is frequently multiple, lies in close contact with the cervical pleura, and typically connects with the phrenic nerve, and sometimes with the vagus nerve (see Fig. 35.18).

The middle cervical ganglion gives off thyroid and cardiac branches. The thyroid branches accompany the inferior thyroid artery to the thyroid gland. They communicate with the superior cardiac, external laryngeal and recurrent laryngeal nerves, and send branches to the parathyroid glands. Fibres to both glands are largely vasomotor but some reach the secretory cells. The cardiac branch, the largest sympathetic cardiac nerve, arises either from the ganglion itself or more often from the sympathetic trunk cranial or caudal to it. On the right side, it descends behind the common carotid artery and anterior or posterior to the subclavian artery, to the trachea, where it receives a few filaments from the recurrent laryngeal nerve before joining the right half of the deep (dorsal) part of the cardiac plexus. In the neck, it connects with the superior cardiac and recurrent laryngeal nerves. On the left side, the cardiac nerve enters the thorax between the left common carotid and subclavian arteries to join the left half of the deep (dorsal) part of the cardiac plexus. Fine branches from the middle cervical ganglion also pass to the trachea and oesophagus.

Inferior (cervicothoracic/stellate) ganglion

The inferior cervical ganglion (cervicothoracic/stellate) is irregular in shape and much larger than the middle cervical ganglion (see Figs 35.18, 48.16). It is probably formed by a fusion of the lower two cervical and first thoracic segmental ganglia, sometimes including the second and even third and fourth thoracic ganglia. The first thoracic ganglion may be separate, leaving an inferior cervical ganglion above it. The sympathetic trunk turns backwards at the junction of the neck and thorax, and so the long axis of the cervicothoracic ganglion becomes almost anteroposterior. The ganglion lies on or just lateral to the lateral border of longus colli between the base of the transverse process of the seventh cervical vertebra and the neck of the first rib (which are both posterior to it). The vertebral vessels are anterior, and the ganglion is separated from the posterior aspect of the cervical pleura inferiorly by the suprapleural membrane. The costocervical trunk of the subclavian artery branches near the lower pole of the ganglion, and the supreme intercostal artery is lateral.

A small vertebral ganglion may be present on the sympathetic trunk anterior or anteromedial to the origin of the vertebral artery and directly superior to the subclavian artery. When present, it may provide the ansa subclavia. It is also joined to the inferior cervical ganglion by fibres enclosing the vertebral artery and is usually regarded as a detached part of the middle cervical or inferior cervical ganglion. Like the middle cervical ganglion, it may supply grey rami communicantes to the fourth and fifth cervical spinal nerves. The inferior cervical ganglion sends grey rami communicantes to the seventh and eighth cervical and first thoracic spinal nerves, and gives off a cardiac branch, branches to nearby vessels and sometimes a branch to the vagus nerve.

The grey rami communicantes to the seventh cervical spinal nerve vary from one to five (two being the usual number). A third often ascends medial to the vertebral artery in front of the transverse process of the seventh cervical vertebra. It connects with the seventh cervical nerve, and sends a filament upwards through the transverse foramen of the sixth cervical vertebra in company with the vertebral vessels to join the sixth cervical spinal nerve as it emerges from the intervertebral foramen. An inconstant ramus may traverse the transverse foramen of the seventh cervical vertebra. Grey rami to the eighth cervical spinal nerve vary from three to six in number.

The cardiac branch descends behind the subclavian artery and along the anterior aspect of the trachea to the deep cardiac plexus. Behind the artery, it connects with the recurrent laryngeal nerve and the cardiac branch of the middle cervical ganglion (the latter is often replaced by fine branches of the inferior cervical ganglion and ansa subclavia).

The branches to blood vessels form plexuses on the subclavian artery and its branches. The subclavian supply is derived from the inferior cervical ganglion and ansa subclavia, and typically extends to the first part of the axillary artery, although a few fibres may extend further. An extension of the subclavian plexus to the internal thoracic artery may be joined by a branch of the phrenic nerve.

Within the foramina transversaria and intertransverse spaces, the cervical grey rami communicantes form intersegmental arcades as they communicate with one another and the ventral rami of the upper five or six cervical spinal nerves. These arcades accompany the second part of the vertebral artery and create the appearance of a long nerve known as the vertebral nerve. Fine filaments from this nerve and the grey rami communicantes form the vertebral plexus on the surface of the vertebral artery. This plexus contains not only sympathetic efferent fibres but also somatic sensory fibres from the adventitia of the artery with cell bodies in the cervical dorsal root ganglia. The vertebral nerve sends filaments to the posterolateral corners of the cervical intervertebral discs (Bogduk et al 1988), and gives rise to the meningeal branches (sinuvertebral nerves) at each cervical segment. The vertebral plexus, which contains some neuronal cell bodies, continues into the skull along the vertebral and basilar arteries and their branches as far as the posterior cerebral artery, where it meets a plexus from the internal carotid artery. The plexus on the inferior thyroid artery reaches the thyroid gland and connects with the recurrent and external laryngeal nerves, the cardiac branch of the superior cervical ganglion and the common carotid plexus.

Horner's syndrome Any condition or injury that destroys the sympathetic trunk ascending from the thorax through the neck into the face results in Horner's syndrome (Bernard–Horner syndrome, oculosympathetic palsy), characterized by a drooping eyelid (ptosis), sunken globe (enophthalmos), narrow palpebral fissure, contracted pupil (meiosis), and vasodilation and lack of thermal sweating (anhydrosis) of the face on the affected side. Classically, this is seen in patients with bronchial carcinomas that have invaded the sympathetic trunk and it is a recognized complication of cervical sympathectomy or a radical neck dissection. Avulsion of the first thoracic nerve from the spinal cord may be diagnosed by development of the syndrome after closed traction lesion of the supraclavicular brachial plexus. Congenital Horner's syndrome has been reported in association with ipsilateral internal carotid artery agenesis (Fons et al 2009). Special features of congenital Horner's syndrome are unilateral straight hair and abnormalities of iris pigmentation in one or both eyes (heterochromia iridis or heterochromia iridum), usually inherited as an autosomal dominant trait and attributed to disruption of the postganglionic sympathetic pathway producing a neurotropic dysgenesis of iris melanocytes (Rennie 2011). Connections between the recurrent laryngeal nerve, the vagus and cervical sympathetic have been linked with Horner's syndrome complicating thyroidectomy.

Thoracic sympathetic system

The left and right thoracic sympathetic trunks and associated ganglia (commonly 11 in number) sit posterior to the costal part of the parietal pleura on either side of the vertebral column. The majority of the thoracic sympathetic ganglia lie anterior to the head of a rib; the first thoracic and inferior cervical ganglia are fused, and the inferior two or three thoracic ganglia are often located lateral to their correspondingly numbered vertebral bodies (see Fig. 56.6). A tumour of the superior pulmonary sulcus (apex of lung) may compress the ventral ramus of the first thoracic spinal nerve, the cervicothoracic ganglion or the sympathetic trunk (see Fig. 54.2) resulting in a loss of sympathetic innervation to the ipsilateral side of the head (Horner's syndrome) (Nikolaos et al 2014) and pain radiating to the medial aspect of the ipsilateral forearm (Bruzzi et al 2008).

Preganglionic sympathetic axons originate from neuronal somata in the intermediolateral nucleus (lateral horn) of the spinal cord from T1 to L2. They travel initially with the corresponding ventral roots (rami) and leave the latter as white rami communicantes to enter the adjacent sympathetic ganglion in the sympathetic trunk. Their targets vary; some synapse in the sympathetic ganglion that they enter, whereas others ascend or descend in the sympathetic trunk to synapse in cervical or lumbar ganglia, respectively. Many of the preganglionic axons that originate in the lower thoracic spinal segments (T5–T12) do not synapse locally but enter the abdominal cavity as the thoracic splanchnic nerves. These nerves pass through the posterior mediastinum and respiratory diaphragm to enter the abdominal cavity where they synapse either in prevertebral ganglia that surround the origin of the major visceral arteries arising from the abdominal aorta, e.g. the coeliac and superior mesenteric ganglia, or around the medullary chromaffin cells of the suprarenal gland. Axons destined for the cervical ganglia are mainly derived from preganglionic neurones in the first thoracic spinal nerve.

Greater thoracic splanchnic nerve

On each side, the greater thoracic splanchnic nerve is derived from the medial, branches of the fifth to ninth thoracic ganglia. It gives off branches to the descending thoracic aorta and enters the abdomen through the fibres of the ipsilateral crus of the respiratory diaphragm, on which it descends anteroinferiorly. The main trunk of the nerve enters the superior aspect of the coeliac ganglion, where most of the

preganglionic fibres synapse (but not those destined for the medulla of the suprarenal gland).

Lesser thoracic splanchnic nerve

On each side, the lesser thoracic splanchnic nerve is derived from the medial branches of the tenth and eleventh (or ninth and tenth) thoracic ganglia. It enters the abdomen running through the most inferior fibres of the ipsilateral crus of the respiratory diaphragm or under the medial arcuate ligament, and then lies on the crus as it runs anteroinferiorly. The trunk of the nerve joins the aorticorenal ganglion and may give branches to the lateral aspect of the coeliac ganglion. It occasionally joins the greater and least splanchnic nerves as a single splanchnic nerve.

Least thoracic splanchnic nerve

On each side, the least thoracic splanchnic nerve is derived from the medial branches of the eleventh and/or twelfth thoracic ganglion. It enters the abdomen medial to the sympathetic trunk under the medial arcuate ligament of the respiratory diaphragm and runs inferiorly to join the renal plexus. The trunk of the nerve enters the aorticorenal ganglion and may give branches to the lateral aspect of the coeliac ganglion. It is sometimes part of the lesser splanchnic nerve, when it forms a twig that enters the renal plexus just below the aorticorenal ganglion.

The thoracic splanchnic nerves show considerable individual variation in their origin and distribution (Loukas et al 2010). For example, the greater splanchnic nerve can receive a contribution from the fourth or tenth thoracic ganglion of the sympathetic trunk or originate only from the sixth to ninth ganglia.

Lumbar sympathetic system

The lumbar part of each sympathetic trunk usually contains four ganglia lying on the anterolateral aspects of the lumbar vertebrae along the medial margin of psoas major (see Figs 59.2–59.4) (Murata et al 2003). Superiorly, it is continuous with the thoracic part of the sympathetic trunk posterior to the medial arcuate ligament. Inferiorly, it passes posterior to the common iliac vessels and is continuous with the sacral part of the sympathetic trunk. On the right side, it lies posterior to the inferior vena cava; on the left, it is posterior to the lateral aortic nodes. It is anterior to most of the lumbar vessels but may pass behind some lumbar veins.

On each side, the first, second and sometimes the third lumbar ventral rami are connected to the lumbar part of the sympathetic trunk by white rami communicantes. All lumbar ventral rami are joined near their origins by long, slender, grey rami communicantes from the four lumbar ganglia. Their arrangement is irregular: one ganglion can give rami to two or three lumbar ventral rami, one lumbar ventral ramus can receive rami from two ganglia, or grey rami can leave the sympathetic trunk between ganglia (Murata et al 2003).

Somatic and vascular branches

Sympathetic nerve branches accompany the lumbar arteries round the sides of the vertebral bodies, medial to the fibrous arches to which psoas major is attached, to provide sympathetic innervation to the segmental distribution of the lumbar arteries. Branches from the lumbar ganglia innervate the abdominal aorta and common, external and internal iliac arteries, forming delicate nerve plexuses that extend along the vessels. Other postganglionic sympathetic nerves to vessels and skin travel with somatic nerves. Thus, the femoral nerve carries vasoconstrictor sympathetic nerves to the femoral artery and its branches in the thigh, as well as sympathetic fibres in its cutaneous branches. Postganglionic fibres travelling with the obturator nerve supply the obturator artery and a variable patch of skin of the medial thigh. Sympathetic denervation of vessels in the lower limb can occur by removing or ablating the proximal three lumbar ganglia and intervening parts of the sympathetic trunk; this procedure can be useful for treating some varieties of vascular insufficiency of the lower limb.

Lumbar splanchnic nerves

Four lumbar splanchnic nerves pass as medial branches from the ganglia to join the coeliac, inferior mesenteric and superior hypogastric plexuses (see Fig. 59.4). The first lumbar splanchnic nerve, from the first ganglion of the lumbar part of the sympathetic trunk, gives branches to the coeliac, renal and inferior mesenteric plexuses. The second lumbar splanchnic nerve joins the inferior part of the intermesenteric or inferior mesenteric plexus. The third lumbar splanchnic arises from the third or fourth ganglion and joins the superior hypogastric plexus. The fourth lumbar splanchnic nerve from the lowest ganglion joins the distal part of the superior hypogastric plexus, or the hypogastric nerves. It is important to note that lumbar splanchnic nerves contribute to the superior and inferior hypogastric plexuses and therefore to the innervation of the neck of the urinary bladder, ductus deferens and prostate, among other structures. Injury to these nerves, e.g. during aortoiliac surgery, can result in sexual dysfunction.

Pelvic sympathetic system

The sacral part of the sympathetic trunk supplies the pelvic organs and vascular system. It usually consists of four or five interconnected ganglia located medial or anterior to the anterior sacral foramina beneath the presacral fascia (Oh et al 2004) (see Fig. 71.11). Occasionally, one or two coccygeal ganglia are present. The first sacral ganglion is the largest and succeeding ganglia become progressively smaller (Blaszczyk 1981). The sacral sympathetic trunk is often asymmetric, with absent or fused ganglia, and cross-communications between sides are frequent. Each ganglion sends at least one grey ramus communicans to its adjacent spinal nerve but up to eleven such branches from a single ganglion have been reported (Potts 1925).

Superiorly, the sacral part of the sympathetic trunk is continuous with the lumbar part of the sympathetic trunk, and preganglionic fibres descend from the distal lumbar spinal cord segments via this route. The right and left trunks converge distal to the most inferior ganglia and unite to form a solitary retroperitoneal structure, the ganglion impar (ganglion of Walther), which lies at a variable level between the sacrococcygeal joint and the tip of the coccyx; it is occasionally paired, unilateral or absent (Oh et al 2004). Grey rami communicantes pass from the ganglia to sacral and coccygeal spinal nerves and there are no white rami communicantes. Medial branches connect across the midline, and twigs from the first two ganglia join the inferior hypogastric plexus or the hypogastric nerve. Other branches form a plexus on the median sacral artery.

Nociceptive afferents from the perineum and terminal urogenital regions pass to the ganglion impar and the sacral parasympathetic trunks: anaesthetic blockade of the ganglion impar can be used to treat intractable perineal pain carried by visceral afferent fibres in patients with pelvic cancers (Toshniwal et al 2007).

Vascular branches

Preganglionic fibres for the vessels supplying the pelvis and lower limb are derived from the lower three thoracic and upper two or three lumbar spinal cord segments. They reach the lower thoracic and upper lumbar ganglia through white rami communicantes and descend through the sympathetic trunk to synapse in the lumbar ganglia. Postganglionic fibres pass from these ganglia via grey rami communicantes to the second, third and fourth lumbar ventral rami and then to the femoral nerve, which carries them to the femoral artery and its branches. Some fibres descend through the lumbar ganglia to synapse in the upper two or three sacral ganglia, from which postganglionic axons pass through grey rami communicantes to the roots of the sacral plexus. Those in the pudendal and superior and inferior gluteal nerves accompany the arteries of the same name to the gluteal and perineal tissues; branches can also supply the pelvic nodes. Those joining the tibial nerve are carried to the popliteal artery and are distributed via its branches to the leg and foot.

Sympathetic denervation of vessels in the lower limb is used, rarely, for treating vascular insufficiency of the lower limb; it can be effected by removing or ablating the upper three lumbar sympathetic ganglia and the intervening parts of the sympathetic trunk.

Sacral splanchnic nerves

Sacral splanchnic nerves pass directly from the ganglia of the sacral part of the sympathetic trunk to the inferior hypogastric plexus and, from there, to pelvic viscera; they usually arise from the first two sacral ganglia.

Autonomic innervation of the limbs

The autonomic nerve supply to the limbs is exclusively sympathetic. The preganglionic sympathetic inflow to the upper limb is derived from neurones in the intermediolateral nucleus of spinal cord segments from T2 to T6/7. Myelinated preganglionic axons pass from the spinal nerves to the thoracic sympathetic trunk via white rami communicates and pass up the trunk to the middle cervical and inferior cervical (stellate or cervicothoracic) ganglia, where they relay. The unmyelinated postganglionic fibres are distributed by grey rami communicantes to the nerves of origin of the brachial plexus; innervation is particularly rich in the palmar skin of the hand and in the skin of the axilla. C5 and C6 receive grey rami from the middle cervical

ganglion; C7 and C8 receive grey rami from the inferior cervical ganglion; T1 not only receives a grey ramus from the inferior cervical ganglion but also contributes a white ramus to it (see Fig. 48.16). Interruption of this white ramus is one cause of Horner's (Bernard–Horner) syndrome.

The preganglionic sympathetic outflow to the lower limb is derived from neurones in the intermediolateral nucleus of spinal cord segments T10–T12 and L1, L2. Fibres pass in white rami communicantes to the sympathetic trunk and synapse in the lumbar and sacral ganglia. Postganglionic fibres pass in grey rami communicantes to enter the lumbar and sacral plexuses; many are distributed to the skin via the cutaneous branches of the nerves derived from these plexuses. Blood vessels to the lower limb receive their sympathetic nerve supply via adjacent peripheral nerves. Postganglionic fibres accompanying the iliac arteries are destined mainly for the pelvis but may supply vessels in the proximal thigh

PARASYMPATHETIC NERVOUS SYSTEM

Preganglionic parasympathetic neurones are located in the Edinger–Westphal and superior and inferior salivatory nuclei in the brainstem (see Fig. 28.3) and in the intermediate grey matter of the second to fourth sacral segments of the spinal cord. Their axons, which are myelinated, emerge from the CNS only in the oculomotor, facial, glossopharyngeal and vagus nerves, and as the pelvic splanchnic nerves in the second to fourth sacral spinal nerves. Preganglionic parasympathetic neurones are cholinergic. The somata of postganglionic parasympathetic neurones are mostly sited distant from the CNS, either in discrete ganglia located near the structures innervated, or dispersed in the walls of viscera.

Cranial part of the parasympathetic system

The cranial part of the parasympathetic system contains four small paired peripheral ganglia, ciliary, pterygopalatine, submandibular and otic, in which preganglionic axons relay. (These efferent parasympathetic ganglia are unlike the trigeminal, facial, glossopharyngeal and vagal sensory ganglia, all of which are concerned exclusively with afferent impulses and contain the cell bodies of sensory neurones.) The cranial parasympathetic ganglia are also traversed by afferent fibres, postganglionic sympathetic fibres and, in the case of the otic ganglion, by branchial efferent fibres; however, none of these fibres synapses in the ganglia. Postganglionic parasympathetic fibres are usually unmyelinated and shorter than their counterparts in the sympathetic system because the ganglia in which the parasympathetic fibres synapse are either in or near the viscera they supply. Postganglionic parasympathetic neurones are cholinergic. In the head, parasympathetic fibres are secretomotor to the lacrimal and parotid, submandibular and sublingual salivary glands and innervate intraocular smooth muscle (sphincter pupillae and the ciliary muscle).

Otic ganglion

The otic ganglion is a small (major diameter 3–4 mm), oval, flat reddish-grey ganglion situated just below the foramen ovale. It is a peripheral parasympathetic ganglion related topographically to the mandibular nerve but connected functionally with the glossopharyngeal nerve (see Fig. 42.11). Near its junction with the trigeminal motor root, the mandibular nerve lies lateral to the ganglion, tensor veli palatini lies medially, separating the ganglion from the cartilaginous part of the pharyngotympanic tube, and the middle meningeal artery is posterior to the ganglion. The otic ganglion usually surrounds the origin of the nerve to medial pterygoid. It has three roots, parasympathetic motor, sympathetic and sensory: only the parasympathetic fibres relay in the ganglion (see Fig. 33.7). The parasympathetic fibres arise from cell bodies in the inferior salivatory nucleus and travel in the lesser petrosal branch of the glossopharyngeal nerve. The lesser petrosal nerve runs intracranially in the middle cranial fossa on the anterior surface of the petrous temporal bone and passes through either the foramen ovale or the sphenopetrosal fissure or the innominate canal of Arnold (a canal in the greater wing of the sphenoid close to the foramen spinosum), to join the otic ganglion where it synapses. Postganglionic fibres pass by a communicating branch to the auriculotemporal nerve to reach the parotid gland. The sympathetic root arises from a plexus on the middle meningeal artery. It contains postganglionic vasomotor fibres from the superior cervical sympathetic ganglion that pass through the otic ganglion and join the parasympathetic fibres to travel via the auriculotemporal nerve to the parotid gland. Sensory fibres from the parotid gland are derived from the auriculotemporal nerve. Clinical observations suggest that in humans the parotid gland also receives secretomotor parasympathetic fibres through the chorda tympani.

Branches

The otic ganglion is connected by branches to the chorda tympani nerve and the nerve of the pterygoid canal. These branches may form an additional pathway by which gustatory fibres from the anterior two-thirds of the tongue reach the geniculate ganglion without passing through the middle ear: they do not synapse in the otic ganglion. Motor branches to tensor veli palatini and tensor tympani, derived from the nerve to medial pterygoid, pass through the ganglion without synapsing. (For further reading, see Senger et al (2014).)

Ciliary ganglion

The ciliary ganglion is a parasympathetic ganglion concerned with the innervation of the ciliary muscle and sphincter pupillae. It is a small, flat, reddish-grey swelling, 1–2 mm in diameter, connected to the nasociliary nerve, and located near the apex of the orbit in loose fat approximately 1 cm in front of the medial end of the superior orbital fissure. It lies between the optic nerve and lateral rectus, usually lateral to the ophthalmic artery. Its neurones, which are multipolar, are larger than those found in typical autonomic ganglia; a very small number of more typical neurones are also present.

Its connections or roots (motor, sensory and sympathetic) enter or leave the ganglion posteriorly (see Fig. 44.18). Eight to ten delicate filaments, termed the short ciliary nerves, emerge anteriorly from the ganglion, arranged in two or three bundles, the lower being larger. They run forwards sinuously with the ciliary arteries, above and below the optic nerve, and divide into 15–20 branches that pierce the sclera around the optic nerve and run in small grooves on the internal scleral surface. They convey parasympathetic, sympathetic and sensory fibres between the eyeball and the ciliary ganglion; only the parasympathetic fibres synapse in the ganglion.

The parasympathetic root, derived from the branch of the oculomotor nerve to the inferior oblique, consists of preganglionic fibres from the Edinger–Westphal nucleus, which relay in the ganglion. Postganglionic fibres travel in the short ciliary nerves to the sphincter pupillae and ciliary muscle. More than 95% of these fibres supply the ciliary muscle, which is much the larger muscle in volume.

The sympathetic root contains fibres from the plexus around the internal carotid artery within the cavernous sinus. These postganglionic fibres, derived from the superior cervical ganglion, form a fine branch that enters the orbit through the superior orbital fissure inside the common tendinous ring. The fibres may pass directly to the ganglion, or may join the nasociliary nerve and travel to the ganglion in its sensory root; either way, they traverse the ganglion without synapsing to emerge into the short ciliary nerves and are distributed to the blood vessels of the eyeball. Sympathetic fibres innervating dilator pupillae may sometimes travel via the short ciliary nerves (rather than the more usual route via the ophthalmic, nasociliary and long ciliary nerves).

The sensory fibres that pass through the ciliary ganglion are derived from the nasociliary nerve. They enter the short ciliary nerves and carry sensation from the cornea, the ciliary body and the iris.

Pterygopalatine ganglion

The pterygopalatine ganglion, known colloquially as the 'ganglion of hay fever', is the largest of the peripheral parasympathetic ganglia, and is well protected, deep in the pterygopalatine fossa. Immediately anterior to the pterygoid canal, the ganglion lies below and medial to the foramen rotundum and the maxillary nerve and lateral to the sphenopalatine foramen (see Fig. 38.30B). It is flattened and reddish-grey in colour and lies just below the maxillary nerve as it crosses the pterygopalatine fossa. The majority of the 'branches' of the ganglion are connected with it morphologically but not functionally, because they are primarily sensory branches of the maxillary nerve and so pass through the ganglion without synapsing to enter the ganglionic branches of the maxillary nerve.

The deep petrosal nerve (postganglionic sympathetic fibres) and the greater petrosal nerve (preganglionic parasympathetic fibres) converge to form the nerve of the pterygoid canal (the Vidian nerve in the Vidian canal). This nerve is an important landmark to the petrous portion of the internal carotid artery, and rarely can be transected to treat intractable rhinorrhoea. The pterygoid canal enters the pterygopalatine fossa, where the nerve of the pterygoid canal joins the pterygopalatine ganglion posteriorly and the parasympathetic fibres synapse on postganglionic neurones.

Some postganglionic parasympathetic fibres may join the maxillary nerve via a ganglionic branch and then travel via its zygomatic and zygomaticotemporal branches to the lacrimal gland, but most are thought to travel by orbital branches to the gland. The parasympathetic supply to

the preocular part of the central artery of the retina is believed to be derived mainly from the pterygopalatine ganglion and is vasodilatory. Preganglionic secretomotor fibres of uncertain origin also travel in the nerve of the pterygoid canal and synapse in the pterygopalatine ganglion: postganglionic fibres are distributed to palatine, pharyngeal and nasal mucous glands via palatine and nasal branches of the maxillary nerve.

Postganglionic sympathetic fibres pass through the ganglion without synapsing. They arise in the superior cervical ganglion and travel via the internal carotid plexus and deep petrosal nerve to enter the pterygopalatine ganglion within the nerve of the pterygoid canal: they supply blood vessels and orbitalis. General sensory fibres destined for distribution via orbital, nasopalatine, superior alveolar, palatine and pharyngeal branches of the maxillary division of the trigeminal nerve also run through the ganglion without synapsing.

Orbital branches of the pterygopalatine ganglion

Several rami orbitales arise dorsally from the pterygopalatine ganglion and enter the orbit through the inferior orbital fissure. Branches leave the orbit through the posterior ethmoidal air sinus. There is strong experimental evidence from animal studies that postganglionic parasympathetic branches pass directly to the lacrimal gland, ophthalmic artery and choroid.

Lacrimation reflex The lacrimal gland is innervated by secretomotor postganglionic parasympathetic fibres from the pterygopalatine ganglion. They reach the gland either via zygomatic and lacrimal branches of the maxillary nerve, or by passing directly from the ganglion (Ruskell 2004). Postganglionic sympathetic fibres from the superior cervical ganglion supply the lacrimal gland and may be involved in the regulation of blood flow and the modulation of gland secretion (Dartt 2009). The lacrimation reflex produces a significant increase in tear volume and is elicited by thermal, mechanical or chemical stimulation of polymodal nociceptors in the conjunctiva and cornea (Situ and Simpson 2010). The afferent limb of the reflex involves branches of the ophthalmic nerve, with an additional contribution from the infraorbital nerve if the conjunctiva of the lower eyelid is involved. Corneal afferents travelling in these nerves terminate in the nucleus of the spinal tract of the trigeminal nerve: experimental tract tracing studies in animals have implicated the transition between the trigeminal subnuclei caudalis and interpolaris as an important area that projects to preganglionic parasympathetic neurones lying close to or within the superior salivatory nucleus and to the facial motor nucleus, both regions involved in the efferent limb of the blinking reflex (Meng and Kurose 2013). The neural mechanism for controlling and maintaining basal tear production is less clear. Lacrimation may also occur in response to emotional triggers without any irritation of ocular structures, when it may be accompanied by alterations in the mimetic facial muscles, vocalizations and sobbing (Gračanin et al 2014): emotional lacrimation is thought to be mediated by limbic projections to the superior salivatory nucleus.

Submandibular ganglion

The submandibular ganglion is a small, fusiform body that lies on the upper part of hyoglossus, superior to the deep part of the submandibular gland and inferior to the lingual nerve, to which it is connected by several filaments. The posterior filament is the motor, parasympathetic root that conveys preganglionic fibres from the superior salivatory nucleus in the brainstem via the facial, chorda tympani and lingual nerves to the ganglion, where they synapse. Five or six postganglionic secretomotor branches from the ganglion supply the submandibular gland and its duct, and the sublingual and anterior lingual glands, by travelling either through the anterior filaments that connect the submandibular gland to the lingual nerve or along adjacent blood vessels to their targets. Neuronal cell bodies and small ganglia have been described in the interlobular connective tissue stroma of human submandibular ganglia, close to salivary parenchymal cells and blood vessels (Tosios et al 2010). The sympathetic root is derived from the plexus on the facial artery and consists of postganglionic fibres from the superior cervical ganglion that traverse the submandibular ganglion without synapsing. These fibres are vasomotor to the blood vessels of the submandibular and sublingual glands. Sensory fibres derived from the lingual nerve may also pass through the ganglion.

Parasympathetic components of the vagus nerve

Preganglionic parasympathetic axons destined for the thoracic viscera travel in the pulmonary, cardiac and oesophageal branches of the vagus nerve (see Fig. 56.7) and synapse in minute ganglia in the walls of the target viscera. Axons travelling in cardiac branches join the cardiac plexuses and synapse in ganglia distributed over both atria, the interatrial septum and perinodal subepicardial tissue: when stimulated, they normally slow the cardiac cycle and constrict coronary arteries, although low-level stimulation may increase heart rate. Pulmonary branches contain axons that synapse in ganglia of the pulmonary plexuses: they are motor (bronchoconstrictor) to the circular non-striated muscle fibres of the bronchi and bronchioles, and secretomotor to the mucous glands of the respiratory epithelium.

The parasympathetic neurones that innervate viscera in the abdomen and pelvis lie either in the dorsal nucleus of the vagus nerve or in the intermediolateral grey matter of the second, third and fourth sacral spinal cord segments. The vagus supplies preganglionic parasympathetic innervation to the abdominal viscera as far as the distal transverse colon, i.e. it supplies derivatives of the foregut and midgut. Derivatives of the hindgut are supplied by parasympathetic fibres travelling via the pelvic splanchnic nerves; the overlap between these two supplies is variable. The vagal trunks are derived from the oesophageal plexus and enter the abdomen via the oesophageal hiatus, closely related to the anterior and posterior walls of the abdominal part of the oesophagus (see Fig. 56.6). The anterior vagal trunk is mostly derived from the left vagus and the posterior vagal trunk from the right vagus. The nerves supply the abdominal part of the oesophagus and stomach directly. The anterior vagal trunk gives off a hepatic branch, which innervates the liver and its vasculature, including the gallbladder and bile ducts, and the other structures in the free edge of the lesser omentum (hepatoduodenal ligament). The posterior vagal trunk supplies branches to the coeliac plexus and these fibres frequently constitute the largest portion of the fibres that contribute to the plexus. They arise directly from the posterior vagal trunk and from its gastric branch, and run beneath the peritoneum, deep to the posterior wall of the superior part of the omental bursa, to reach the coeliac plexus. Their synaptic relays with postganglionic neurones are situated in the myenteric (Auerbach's) and submucosal (Meissner's) plexuses in the wall of the hollow viscera.

Pelvic splanchnic nerves

Pelvic splanchnic nerves (nervi erigentes) travel in the ventral rami of the second, third and fourth sacral spinal nerves. They leave the nerves as they exit the anterior sacral foramina and pass in the presacral tissue as a fine network of branches distributed to three principal destinations. Most pass anterolaterally into the inferior hypogastric plexus (see below). Some join the hypogastric nerves and ascend out of the pelvis as far as the superior hypogastric plexus, from where they are distributed with branches of the inferior mesenteric artery. A few run superolaterally in the presacral fascia, over the linea terminalis anterior to the left iliac vessels, and pass directly into the tissue of the retroperitoneum toward the sigmoid and descending colons. The pelvic splanchnic nerves are motor to the smooth muscle of the derivatives of the hindgut and the wall of the urinary bladder, are vasodilator to the erectile tissues of the penis and clitoris, and are secretomotor to the derivatives of the hindgut.

An experimental study of the differential expression of transcription factors in embryonic mice has argued that thoracic and sacral pools of preganglionic neurones share a common sympathetic identity and that the sacral autonomic outflow should therefore be regarded as sympathetic (Espinosa-Medina et al 2016). This controversial view has been challenged (Horn 2018).

AUTONOMIC PLEXUSES

The autonomic nervous system in the thorax consists of the right and left sympathetic trunks and left and right vagus nerves, and the cardiac, oesophageal and pulmonary plexuses (see Figs 56.6–56.7). The autonomic supply to the abdominal and pelvic viscera is via the abdominopelvic part of the sympathetic trunk and the greater, lesser and least splanchnic nerves (sympathetic), and the vagus and pelvic splanchnic nerves (parasympathetic).

The somata of preganglionic sympathetic neurones are located in the intermediolateral grey matter (lamina VII) of the thoracolumbar segments of the spinal cord; those destined for the smooth muscle of the wall of the hollow viscera mostly pass through the sympathetic trunk without synapsing and relay in prevertebral ganglia (coeliac, mesenteric and pelvic). Postganglionic sympathetic fibres are distributed with the branches of the coeliac trunk and mesenteric arteries to three principal targets: the myenteric and submucosal ganglia (causing inhibition); blood vessels (inducing vasoconstriction); and sphincter muscles (inducing contraction). The neuronal somata of preganglionic parasympathetic axons are found in the dorsal nucleus of the vagus nerve in the medulla oblongata and in the second to fourth sacral segments of the spinal cord.

Their main targets in the wall of the hollow viscera are the enteric neurones of the myenteric plexus. The vagus nerve plays a major role in oesophageal propulsion, gastric acid secretion and emptying of the stomach, gallbladder contraction and pancreatic exocrine secretion. Pelvic splanchnic nerves innervate the distal colon and rectum.

There are numerous interconnections between plexuses and ganglia, particularly in the major plexuses around the abdominal aorta and therefore descriptions, as here, are simplifications based on the 'main' supply to each organ (see Fig. 59.2).

Thoracic plexuses

Cardiac plexus

The cardiac plexus has a superficial component inferior to the aortic arch, lying between the arch and the pulmonary trunk, and a deep part between the aortic arch and tracheal bifurcation (see Fig. 57.61). The plexus has coronary, pulmonary, atrial and aortic extensions. The superficial (ventral) part is formed by the cardiac branch of the left superior cervical sympathetic ganglion and the inferior of the two cervical cardiac branches of the left vagus nerve. The deep (dorsal) part is formed by the cardiac branches of the cervical and upper thoracic sympathetic ganglia and of the vagus and recurrent laryngeal nerves. The only cardiac nerves that do not join it are those that join the superficial part of the plexus. Branches from the cardiac plexuses subsequently form the left and right coronary and atrial plexuses.

Pulmonary plexus

The autonomic nervous system (either by direct axonal innervation or circulating neurotransmitter) controls many aspects of airway function, including regulation of airway smooth muscle tone, mucus secretion from submucosal glands and surface epithelial goblet cells, vascular permeability and blood flow (Belvisi 2002). The trachea and bronchi are innervated by branches of the vagus nerves, recurrent laryngeal nerves and sympathetic trunks via the anterior and posterior pulmonary plexuses. The plexuses are interconnected and lie anterior and posterior to the structures of the lung root and hilum (see Figs 56.6–56.7, 57.61). The posterior plexus provides the majority of the autonomic innervation to the lung and is formed by approximately 12 (8–18) branches from the vagus nerve (Weijs et al 2015) and cardiac branches from the second to fifth (or sixth) thoracic sympathetic ganglia. The smaller anterior plexus is formed by 3 (2–4) branches of the vagus nerve and cervical sympathetic cardiac nerves via the superficial and deep parts of the cardiac plexus. Branches of the recurrent laryngeal nerves form a plexus on the membranous posterior wall of the trachea; the plexus primarily innervates the trachea and proximal parts of the main bronchi, with branches to the oesophagus.

Efferent preganglionic parasympathetic nerves from the vagus nerve synapse on small ganglia within the walls of the tracheobronchial tree, likely acting as sites of integration and/or modulation of the input from extrinsic nerves or permitting local control of aspects of airway function by local reflex mechanisms. The predominant contractile innervation of airway smooth muscle is parasympathetic cholinergic, while the primary relaxant innervation of the airways is non-cholinergic (parasympathetic nerves containing nitric oxide synthase and vasoactive intestinal peptide). These parasympathetic nerves are anatomically and physiologically distinct from one another and differentially regulated by reflexes. Stimulation of cholinergic nerves also results in mucus secretion and bronchial vasodilation. Sympathetic-adrenergic nerves play little, if any, role in directly regulating smooth muscle tone in the human airways, although they may control constriction of tracheobronchial blood vessels. Circulating noradrenaline (norepinephrine) can bring about bronchodilation through activation of β-adrenergic receptors in the airways. Extrapulmonary afferents may modulate neurally mediated regulation of airway smooth muscle tone (Canning and Fischer 2001). Vagal innervation is involved in the cough reflex, mucous production and control of bronchial diameter; inadvertent transection of the pulmonary vagal nerves during oesophagectomy may be related to the high incidence of postoperative pneumonia and pulmonary complications following oesophagectomy (Weijs et al 2017); preservation of vagal pulmonary branches is therefore desirable (Weijs et al 2016).

Oesophageal plexus

The oesophageal plexus surrounds the oesophagus below the level of the hila of the lungs (see Fig. 56.6). Preganglionic parasympathetic axons from the vagus and recurrent laryngeal nerves travel to ganglia in the oesophageal wall, either directly or through the oesophageal plexus, and are motor to the smooth muscle in the lower oesophagus and secretomotor to mucous glands in the oesophageal mucosa. Vasomotor sympathetic axons arise from the first to sixth (sometimes fewer) thoracic segments of the spinal cord. Those passing from the more superior cord segments often synapse in the middle and inferior cervical sympathetic ganglia; their postganglionic axons are vasomotor to the vessels of the cervical and superior part of the thoracic oesophagus. Preganglionic axons from the fifth or sixth thoracic spinal cord segments pass directly to the oesophageal plexus or to the coeliac ganglion, where they synapse; postganglionic axons innervate the vessels of the distal oesophagus.

Abdominopelvic autonomic plexuses and ganglia

The abdominopelvic autonomic plexuses are somewhat variable and often fuse or are closely interrelated. The following descriptions encompass their main features (see Figs 59.3–59.4, 73.8).

Coeliac plexus

The coeliac plexus is located at the level of the twelfth thoracic and first lumbar vertebrae. It is a dense network that unites the coeliac ganglia, and surrounds the coeliac trunk and the proximal superior mesenteric artery. It is posterior to the stomach and omental bursa and anterior to the crura of the respiratory diaphragm and the beginning of the abdominal aorta, and lies medial to the suprarenal glands. The plexus and ganglia receive the greater and lesser splanchnic nerves and branches from the vagal trunks. The plexus is in continuity with small branches along adjacent arteries and is connected to the phrenic, splenic, hepatic, superior mesenteric, suprarenal, renal and ovarian/testicular plexuses. Visceral afferent fibres in the coeliac plexus convey pain and other sensations from proximal abdominal viscera. Anaesthesia or ablation of these nerves (coeliac plexus blockade) is sometimes undertaken to treat medically intractable pain from pancreatic disorders.

Coeliac and aorticorenal ganglia

The coeliac ganglia are irregular neural masses, measuring approximately 2 cm across, located between the origin of the coeliac trunk and superior mesenteric artery, medial to the suprarenal glands and anterior to the crura of the respiratory diaphragm (Zhang et al 2006). They vary in number, size, shape and precise location; there are often two, one on each side. The right ganglion is frequently posterior to the inferior vena cava, and the left ganglion often lies posterior to the origin of the splenic artery. The ipsilateral greater splanchnic nerve joins the superior part of each ganglion and the lesser splanchnic nerve joins the inferior part. The most inferior part of each ganglion usually forms a distinct subdivision, the aorticorenal ganglion, which receives the ipsilateral lesser splanchnic nerve and gives origin to most of the renal plexus.

Phrenic plexus

The phrenic plexus is a periarterial extension of the coeliac plexus around the right inferior phrenic artery, adjacent to the right crus of the respiratory diaphragm (Rusu 2006). It contains one or two phrenic ganglia and a definable nerve trunk that connects the coeliac plexus and phrenic nerve: the phrenic ganglion is probably sympathetic (Tubbs et al 2008). The phrenic plexus supplies branches to the suprarenal glands and the respiratory diaphragm.

Superior mesenteric plexus and ganglion

The superior mesenteric plexus lies in the pre-aortic connective tissue posterior to the pancreas, around the origin of the superior mesenteric artery. It is an inferior continuation of the coeliac plexus and includes branches from the posterior vagal trunk and coeliac plexus. Its branches accompany the superior mesenteric artery and its branches. The superior mesenteric ganglion lies superiorly in the plexus, usually above the origin of the superior mesenteric artery.

Intermesenteric plexus

Like other parts of the abdominal aortic autonomic plexus, the intermesenteric plexus is not a discrete structure but is part of a continuous periarterial nerve plexus connected to the ovarian/testicular, inferior mesenteric, iliac and superior hypogastric plexuses. It lies on the lateral and anterior aspects of the aorta, between the origins of the superior and inferior mesenteric arteries, and consists of numerous fine, interconnected nerve fibres and a few ganglia continuous superiorly with the superior mesenteric plexus and inferiorly with the superior hypogastric plexus. It is not well characterized but receives parasympathetic and sympathetic branches from the coeliac plexus and additional sympathetic contributions from the first and second lumbar splanchnic nerves.

Inferior mesenteric plexus

The inferior mesenteric plexus lies around the origin of the inferior mesenteric artery and is distributed along its branches. It is formed predominantly from the aortic plexus, supplemented by sympathetic fibres from the first and second lumbar splanchnic nerves and ascending pelvic parasympathetic fibres from the inferior hypogastric plexus (via the hypogastric nerves and superior hypogastric plexus). Disruption of the inferior mesenteric plexus alone rarely causes clinically significant disturbances of autonomic function.

Superior hypogastric plexus

The superior hypogastric plexus lies anterior to the aortic bifurcation, the left common iliac vein, median sacral vessels, fifth lumbar vertebral body and sacral promontory, and between the common iliac arteries. It lies within extraperitoneal connective tissue in the midline, extending a little to the left. The breadth of the plexus and its constituent nerves varies; appearances range from a reticular-like arrangement to a band-like structure or one or two distinct nerve trunks (Paraskevas et al 2008). The medial attachment of the sigmoid mesocolon and superior limit of the mesorectum lie anterior to the distal part of the plexus, separated from it by a thin layer of loose connective tissue. The plexus is formed by branches from three main sources: the abdominal aortic plexus (sympathetic and parasympathetic), lumbar splanchnic nerves (sympathetic) and pelvic splanchnic nerves (parasympathetic), which ascend from the inferior hypogastric plexus via the right and left hypogastric nerves (Kraima et al 2015). Visceral sensory fibres also pass through the plexus. The hypogastric nerves lie in loose connective tissue just posterolateral to the proximal mesorectum and pass over the linea terminalis medial to the internal iliac vessels. The superior hypogastric plexus conveys branches to the inferior mesenteric plexus and to the ureteric, ovarian/testicular and common iliac nerve plexuses; additional small branches turn abruptly forwards into the proximal mesorectum to travel with the superior anorectal artery.

Inferior hypogastric plexus

The inferior hypogastric plexus lies in the thin extraperitoneal connective tissue on the pelvic side wall anterolateral to the mesorectum. The internal iliac vessels and the attachments of levator ani and obturator internus lie laterally, and the superior vesical and occluded part of the umbilical arteries superiorly. In males, the inferior hypogastric plexus lies posterolaterally, on each side of the seminal glands, prostate and the fundus of the urinary bladder: the point where the ductus deferens crosses the ureter provides an approximate guide to the superior limit of the plexus (Mauroy et al 2003). The proximal border of the plexus lies beneath the peritoneum of the rectovesical pouch and is in contact with the lateral aspect of the fundus of the urinary bladder. The anterior border reaches the posterior aspect of the prostate; at its inferior limit, the cavernous nerves of the penis pass forwards to reach the posterolateral aspect of the prostate (see Fig. 73.8). In females, each plexus lies lateral to the cervix of the uterus, vaginal fornix and the fundus of the urinary bladder, often extending into the broad ligament of the uterus; the proximal limit of the plexus corresponds approximately to the level where the uterine artery crosses the ureter (Azaïs et al 2013).

The inferior hypogastric plexus is formed mainly from pelvic splanchnic (parasympathetic) and sacral splanchnic (sympathetic) branches; a smaller contribution is derived from sympathetic fibres (from the inferior lumbar ganglia) that descend into the plexus from the superior hypogastric plexus via the hypogastric nerves. It gives origin to a complex network of small pelvic branches that supply the pelvic viscera either directly or indirectly via periarterial plexuses. The branches of the inferior hypogastric plexus supply the ductus deferens, seminal glands, prostate, bulbo-urethral glands and penis in males; the ovary, uterine tubes, uterus, cervix of the uterus and vagina in females; and the urinary bladder and distal ureter in both sexes. The plexus plays a key role in continence and sexual function.

Hypogastric nerves

The hypogastric nerves are usually paired nerve bundles but can consist instead of multiple filaments. They contain sympathetic fibres (mostly descending from the superior hypogastric plexus) and parasympathetic fibres (ascending from the inferior hypogastric plexus). The nerves run between the superior and inferior hypogastric plexuses on each side posterior to the presacral fascia, medial to the internal iliac vessels, and lateral to the anterior sacral foramina.

Other autonomic plexuses and ganglia

Additional plexuses are described for abdominopelvic viscera, such as the hepatic and ovarian/testicular plexuses. Each plexus tends to lie around the main arterial supply to the named organ, receive both sympathetic and parasympathetic fibres from one or more of the major autonomic plexuses, and contain at least one ganglion. For example, autonomic ganglia supplying the testis are found around the origin of the testicular arteries from the abdominal aorta and have connections with the renal and intermesenteric plexuses and the first and second lumbar splanchnic nerves (Motoc et al 2010).

ENTERIC NERVOUS SYSTEM

The walls of the hollow viscera are densely innervated by both the enteric nervous system (intrinsic control) and the autonomic nervous system (extrinsic control). The latter is not essential for function, as evidenced by intestinal activity after transplantation of the extrinsically denervated part of the gastrointestinal tract. In contrast, neuropathies affecting the enteric nervous system, such as Hirschsprung's disease, are potentially life-threatening. For a detailed description of the enteric nervous system, see Furness et al (2014).

Intrinsic innervation

The intrinsic innervation of the gastrointestinal tract is derived from enteric neurones distributed throughout its wall in thousands of small ganglia, each consisting of neuronal cell bodies supported by enteric glial cells; it is estimated that there are between 200 and 600 million neurones in the human enteric nervous system. Enteric neurones are derived from neural crest cells and innervate the hollow viscera from oesophagus to anus, together with the pancreas and bile ducts.

Most of the enteric neurones in the wall of the gastrointestinal tract are found in two ganglionated plexuses (see Fig. 59.9). The most extensive of these is the myenteric (Auerbach's) plexus, which consists of a network of nerve fibres and small ganglia lying between the circular and longitudinal layers of the muscularis externa. It runs in continuity from the oesophagus to the anus. The submucosal (Meissner's) plexus has outer and inner components and is present throughout the intestines but is absent or minimal in the oesophagus and stomach (Nagy and Goldstein 2017). Interconnecting, non-ganglionated nerve plexuses lie at various levels in the wall of the gastrointestinal tract, including the lamina propria (mucosal plexus); at the interface between the submucosa and muscularis externa; between the circular and longitudinal muscles (the non-ganglionated part of the myenteric plexus); and within the serosa.

Individual enteric neurones function in one of several ways: as afferent (sensory) nerves responding to mechanical and chemical stimuli; as efferent (motor) nerves innervating epithelial cells (influencing absorption, secretion and/or the release of hormones), smooth muscle (excitatory or inhibitory), arterioles (vasoconstriction or vasodilatation) and lymphoid tissue; or as interneurones that relay and integrate signals. Collectively, they are involved in a hierarchy of enteric reflexes that include local reflexes within the wall of the hollow viscera; reflexes mediated through prevertebral ganglia; and reflexes mediated through the central nervous system (the gut–brain axis). The functions of enteric neurones can be further modulated by local environmental factors, e.g. enteric glia, gut microbiota and feeding state, and by general factors in the host, e.g. the immune system, stress and disease (Brierley and Linden 2014). Pathological states become manifest by abnormal secretion, impaired absorption, disordered gastrointestinal motility and pain.

CHAPTER
81

The anatomy of the vascular and lymphatic systems

This chapter brings together the regional descriptions of the arteries, veins and lymphatic vessels and their draining nodes that appear in the relevant sections of chapters 24–79. The text is not illustrated: all cross-referenced figures and videos are HTML-linked to the corresponding figure or video in the appropriate chapter in the eBook.

ARTERIAL SUPPLY OF THE HEAD AND NECK

The head and neck and the brain are supplied by the carotid system of arteries and by many, but not all, of the branches of the subclavian arteries. The carotid system is described here. The subclavian artery is described on pages 1464.e83 et seq.

Carotid system of arteries

The right and left common carotid arteries supply the head and neck Both ascend to just above the level of the upper border of the thyroid cartilage, where each divides into an external carotid artery that supplies the external head, face and most of the neck, and an internal carotid artery that supplies the cranial and orbital contents.

Common carotid arteries

The right and left common carotid arteries differ in their length and origin. The right is exclusively cervical and usually arises from the brachiocephalic trunk posterior to the superior part of the right sternoclavicular joint, or immediately superior to the joint, but it may be a separate branch from the aorta. The left originates directly from the aortic arch immediately posterolateral to the brachiocephalic trunk and therefore has both thoracic and cervical parts (see Figs 35.8, 57.4, 58.1). Its thoracic part (2.0–2.5 cm long) lies initially anterior and then to the left side of the trachea as it ascends to enter the neck by passing through the superior thoracic aperture, posterior to the left sternoclavicular joint.

In the neck, the right and left common carotid arteries follow a similar course. They ascend, diverging laterally from behind the sternoclavicular joint to the level of the upper border of the thyroid cartilage of the larynx (C3–C4 junction), where each divides into external and internal carotid arteries. This bifurcation can sometimes be at a higher or lower level (see Fig. 35.7B). The angle of bifurcation remains unchanged from infancy to adulthood. However, there is a significant change in the angle of the split between the internal and the external carotid arteries relative to the common carotid artery (Seong et al 2005). The artery may be compressed against the prominent transverse process of the sixth cervical vertebra (Chassaignac's tubercle); above this level it is superficial, and its pulsation can be easily felt.

In the lower part of the neck, the common carotid arteries are separated by a narrow gap that contains the trachea. Above this, the arteries are separated by the thyroid gland, larynx and pharynx. Each artery is contained within the carotid sheath of deep cervical fascia, which also encloses the internal jugular vein and vagus nerve, the vein lying lateral to the artery, and the nerve lying between them and posterior to both.

Relations At the level of the cricoid cartilage the common carotid artery is crossed anterolaterally by the intermediate tendon, or sometimes the superior belly, of omohyoid. Below omohyoid, it is sited deeply, and covered by skin, superficial fascia, platysma, deep cervical fascia and sternocleidomastoid, sternohyoid and sternothyroid. Above omohyoid, it is more superficial, and covered merely by skin, superficial fascia, platysma, deep cervical fascia and the medial margin of sternocleidomastoid; it is crossed obliquely from its medial to lateral side by the sternocleidomastoid branch of the superior thyroid artery. The superior root of the ansa cervicalis, joined by its inferior root from the second and third cervical spinal nerves, lies anterior to, or embedded within, the carotid sheath as it crosses it obliquely. The superior thyroid vein usually crosses near the upper border of the thyroid cartilage, and the middle thyroid vein crosses a little below the level of the cricoid cartilage. The anterior jugular vein crosses the common carotid artery above the clavicle, separated from it by sternohyoid and sternothyroid. Posterior to the carotid sheath are the transverse processes of the fourth to sixth cervical vertebrae, to which are attached longus colli, longus capitis and tendinous slips of scalenus anterior. The sympathetic trunk and ascending cervical branch of the inferior thyroid artery lie between the common carotid artery and the muscles. Below the level of the sixth cervical vertebra, the artery is in an angle between scalenus anterior and longus colli, anterior to the vertebral vessels, inferior thyroid and subclavian arteries, sympathetic trunk and, on the left, the thoracic duct. The oesophagus, trachea, inferior thyroid artery, recurrent laryngeal nerve and, at a higher level, the larynx and pharynx are medial to the sheath and its contents. The thyroid gland overlaps it anteromedially. The internal jugular vein lies lateral and, in the lower neck, also anterior to the artery, while the vagus nerve lies posterolaterally in the angle between the artery and vein.

On the right side, low in the neck, the recurrent laryngeal nerve crosses obliquely behind the artery. The right internal jugular vein diverges from it below but the left vein approaches and often overlaps its artery.

Although the common carotid artery usually has no branches, it may occasionally give rise to the vertebral, superior thyroid, superior laryngeal, ascending pharyngeal, inferior thyroid or occipital arteries.

Variants The origin of the arteries may vary: both common carotid arteries may emerge from the brachiocephalic trunk (Panagouli et al 2018), or separately from the aorta, or from a common trunk (Akgun et al 2016). The left common carotid artery varies in origin more than the right. Either common carotid artery may bifurcate higher, near the level of the hyoid bone, or, more rarely, at a lower level alongside the larynx. Very rarely, the common carotid artery ascends without division, so that either the external or internal carotid artery is absent, or separate external and internal carotid arteries may arise directly from the aorta, unilaterally or bilaterally.

Carotid sinus and carotid body

The common carotid artery has two specialized organs near its bifurcation: the carotid sinus and the carotid body. They relay information concerning the pressure and chemical composition of the arterial blood, respectively, and are innervated principally by the carotid branch(es) of the glossopharyngeal nerve, with small contributions from the cervical sympathetic trunk and the vagus nerve.

The carotid sinus usually appears as a dilation of the lower end of the internal carotid in late adolescence (Seong et al 2005) and functions as a baroreceptor.

The carotid body is a reddish-brown, oval structure, 5–7 mm in height and 2.5–4 mm in width. It lies either posterior to the carotid bifurcation or between its branches, and is attached to, or sometimes partly embedded in, their adventitia. Occasionally it takes the form of a group of separate nodules. Aberrant miniature carotid bodies, microstructurally similar but with diameters of 600 μm or less, may appear in the adventitia and adipose tissue near the carotid sinus.

The carotid body is surrounded by a fibrous capsule, from which septa divide the enclosed tissue into lobules. Each lobule contains glomus (type I) cells, which are separated from an extensive network of fenestrated sinusoids by sustentacular (type II) cells (see Fig. 35.10). Glomus cells store a number of peptides, particularly enkephalins, bombesin and neurotensin, and amines including dopamine, serotonin (5-hydroxytryptamine, 5-HT), adrenaline (epinephrine) and noradrenaline (norepinephrine), and are therefore regarded as paraneurones. Unmyelinated axons lie in a collagenous matrix between the sustentacular cells and the sinusoidal endothelium, and many synapse on the glomus cells. They are visceral afferents, which travel in the carotid sinus nerve to join the glossopharyngeal nerve. Preganglionic sympathetic axons and fibres from the carotid sinus synapse on parasympathetic and sympathetic ganglion cells, which lie either in isolation or in small groups near the surface of each carotid body. Postganglionic axons travel to local blood vessels; the parasympathetic efferent fibres are probably vasodilatory and the sympathetic ones are vasoconstrictor.

The carotid body receives a rich blood supply from branches of the adjacent external carotid artery, which is consistent with its role as an arterial chemoreceptor. When stimulated by hypoxia, hypercapnia or increased hydrogen ion concentration (low pH) in the blood flowing through it, it elicits reflex increases in the rate and volume of ventilation via connections with brainstem respiratory centres. The bodies are most prominent in children and normally involute in older age, when they are infiltrated by lymphocytes and fibrous tissue. Individuals with chronic hypoxia, or who live at high altitude or suffer from lung disease, may have enlarged carotid bodies as a result of hyperplasia. Disrupted carotid body maturation may play a role in sudden infant death syndrome (Porzionato et al 2013). Benign and malignant paragangliomas develop in association with succinyl dehydrogenase mutations (SDH).

Other small bodies, resembling carotid bodies and also considered to be chemoreceptors, are present near the arteries of the fourth and sixth pharyngeal arches and hence are found near the aortic arch, ligamentum arteriosum and right subclavian artery; they are supplied by the vagus nerve.

External carotid artery

The external carotid artery (see Figs 35.7A, 35.8) begins lateral to the upper border of the thyroid cartilage, level with the intervertebral disc between the third and fourth cervical vertebrae. A little curved and with a gentle spiral, it first ascends slightly forwards and then inclines backwards and a little laterally, to pass midway between the tip of the mastoid process and the angle of the mandible. Here, in the substance of the parotid gland behind the neck of the mandible, it divides into its terminal branches, the superficial temporal and maxillary arteries. As it ascends, it gives off several large branches and diminishes rapidly in calibre. In children the external carotid is smaller than the internal carotid, but in adults the two are of almost equal size. At its origin, it is in the carotid triangle and lies anteromedial to the internal carotid artery. It later becomes anterior, then lateral, to the internal carotid as it ascends. At mandibular levels, the styloid process and its attached structures intervene between the vessels; the internal carotid is deep, and the external carotid superficial, to the styloid process. A fingertip placed in the carotid triangle perceives a powerful arterial pulsation, which represents the termination of the common carotid, the origins of external and internal carotids, and the stems of the initial branches of the external carotid.

Relations The skin and superficial fascia, the loop between the cervical branch of the facial nerve and the transverse cutaneous nerve of the neck, the deep cervical fascia and the anterior margin of sternocleidomastoid all lie superficial to the external carotid artery in the carotid triangle. The artery is crossed by the hypoglossal nerve and its vena comitans, and by the lingual, facial and, sometimes, the superior thyroid veins. Leaving the carotid triangle, the external carotid artery is crossed by the posterior belly of digastric and by stylohyoid; it ascends between these muscles and the posteromedial surface of the parotid gland, which it next enters. Within the parotid, the artery lies medial to the facial nerve and the junction of the superficial temporal and maxillary veins. The pharyngeal wall, superior laryngeal nerve and ascending pharyngeal artery are the initial medial relations of the artery. At a higher level, it is separated from the internal carotid artery by the styloid process, styloglossus and stylopharyngeus, glossopharyngeal nerve, pharyngeal branch of vagus nerve and part of the parotid gland. The artery is equally likely to lie medial to the parotid gland, or within it.

The external carotid artery has eight named branches distributed to the head and neck. The superior thyroid, lingual and facial arteries arise from its anterior surface, the occipital and posterior auricular arteries arise from its posterior surface, and the ascending pharyngeal artery arises from its medial surface. The maxillary and superficial temporal arteries are its terminal branches within the parotid gland.

Ascending pharyngeal artery

The ascending pharyngeal artery is the first and smallest branch of the external carotid artery. It is a long, slender vessel that arises from the medial (deep) surface of the external carotid artery near the origin of that artery. It is important that it is identified and preserved if the external carotid is being ligated because of its potential to supply to a compromised internal carotid circulation.

The ascending pharyngeal artery ascends between the internal carotid artery and the pharynx to the base of the cranium, crossed by styloglossus and stylopharyngeus; longus capitis is posterior. It gives off numerous small branches to supply longus capitis and longus colli, the sympathetic trunk, the hypoglossal, glossopharyngeal and vagus nerves, and some of the cervical lymph nodes. It anastomoses with the ascending palatine branch of the facial artery and the ascending cervical branch of the inferior thyroid artery.

The ascending pharyngeal artery has the following named branches: pharyngeal, inferior tympanic and meningeal arteries.

Pharyngeal artery

The pharyngeal artery gives off three or four branches to supply the constrictor muscles of the pharynx and stylopharyngeus. A variable ramus supplies the palate and may replace the ascending palatine branch of the facial artery. The artery descends forwards between the superior border of the superior constrictor and levator veli palatini to the soft palate, and also supplies a branch to the palatine tonsil and the pharyngotympanic tube.

Inferior tympanic artery

The inferior tympanic artery is a small branch that traverses the temporal canaliculus with the tympanic branch of the glossopharyngeal nerve and supplies the medial wall of the tympanic cavity.

Meningeal arteries

The meningeal arteries are small vessels that supply the nerves that traverse the foramen lacerum, jugular foramen and hypoglossal canal, and the associated dura mater and adjoining bone. One branch, the posterior meningeal artery, reaches the cerebellar fossa via the jugular foramen and is usually regarded as the terminal branch of the ascending pharyngeal artery.

Superior thyroid artery

The superior thyroid artery is the second branch of the external carotid artery. It arises from the anterior surface of the external carotid just below the level of the greater cornu of the hyoid bone (see Figs 35.7A, 35.8). It descends along the lateral border of thyrohyoid to reach the apex of the lobe of the thyroid gland. The inferior constrictor muscle and the external laryngeal nerve are medial. The nerve is often posteromedial, and therefore at risk when the artery is being ligated, and occasionally it may issue directly from the common carotid.

The superior thyroid artery supplies the thyroid gland and some adjacent skin. Branches to the gland are anterior, running along the medial side of the upper pole of the lateral lobe to supply mainly the anterior surface; a branch that crosses above the isthmus to anastomose with its contralateral fellow; and posterior, descending on the posterior border to supply the medial and lateral surfaces and anastomose with the inferior thyroid artery. A lateral branch sometimes supplies the lateral surface. The superior thyroid artery is often accompanied by the external branch of the superior laryngeal nerve: care should be taken to preserve this nerve when ligating the superior thyroid artery during surgery because it supplies cricothyroid, and iatrogenic damage affects vocal cord function.

Named branches of the superior thyroid artery are the infrahyoid, superior laryngeal, sternocleidomastoid and cricothyroid.

Infrahyoid artery

The infrahyoid artery is a small branch that runs along the lower border of the hyoid bone deep to thyrohyoid and anastomoses with its fellow of the opposite side to supply the infrahyoid strap muscles.

Superior laryngeal artery

The superior laryngeal artery accompanies the internal laryngeal nerve. Deep to thyrohyoid, it pierces the lower part of the thyrohyoid membrane to supply the tissues of the upper part of the larynx. It anastomoses with its fellow of the opposite side and with the inferior laryngeal branch of the inferior thyroid artery.

Sternocleidomastoid artery

The sternocleidomastoid artery descends laterally across the carotid sheath and supplies the middle region of sternocleidomastoid. Like the parent artery itself, it may arise directly from the external carotid artery.

Cricothyroid artery

The cricothyroid artery crosses high on the anterior cricothyroid ligament, anastomoses with its fellow of the opposite side and supplies cricothyroid.

Lingual artery

The lingual artery provides the chief blood supply to the tongue and the floor of the mouth (see Fig. 35.8). It arises anteromedially from the external carotid artery opposite the tip of the greater cornu of the hyoid bone, between the superior thyroid and facial arteries. It often arises with the facial or, less often, with the superior thyroid artery. It

may be replaced by a ramus of the maxillary artery. Ascending medially at first, it loops down and forwards, passes medial to the posterior border of hyoglossus and then runs horizontally forwards deep to it, accompanied by the lingual veins and the glossopharyngeal nerve. At the anterior border of hyoglossus, the lingual artery bends sharply upwards (see Fig. 37.11A). It is covered by the mucosa of the tongue and lies between genioglossus medially and the inferior longitudinal muscle laterally. Near the tip of the tongue, it anastomoses with its contralateral fellow; this contribution is important in maintaining the blood supply to the tongue in any surgical resection of the tongue. The branches of the lingual artery form a rich anastomotic network, which supplies the musculature of the tongue, and a very dense submucosal plexus. Named branches of the lingual artery in the floor of the mouth are the dorsal lingual, sublingual and deep lingual arteries.

Relations Its relationship to hyoglossus naturally divides the lingual artery into descriptive 'thirds'. In its first part, the lingual artery is in the carotid triangle. Skin, fascia and platysma are superficial to it, while the middle pharyngeal constrictor muscle is medial. The artery ascends a little medially, then descends to the level of the hyoid bone, and the loop so formed is crossed externally by the hypoglossal nerve. The second part passes along the upper border of the hyoid bone, deep to hyoglossus, the tendons of digastric and stylohyoid, the lower part of the submandibular gland and the posterior part of mylohyoid. Hyoglossus separates it from the hypoglossal nerve and its vena comitans. Here, its medial aspect adjoins the middle constrictor muscle and it crosses the stylohyoid ligament accompanied by lingual veins. The third part is the arteria profunda linguae, which turns upwards near the anterior border of hyoglossus and then passes forwards close to the inferior lingual surface near the frenulum, accompanied by the lingual nerve. Genioglossus is a medial relation, and the inferior longitudinal muscle of the tongue lies lateral to it below the lingual mucous membrane. Near the tip of the tongue, the lingual artery anastomoses with its fellow of the opposite side. Its named branches are the suprahyoid, dorsal lingual and sublingual arteries.

Suprahyoid artery
The suprahyoid artery is a small branch that runs along the upper border of the hyoid bone to anastomose with the contralateral artery and supply adjacent structures.

Dorsal lingual arteries
There are usually two or three small dorsal lingual arteries. They arise medial to hyoglossus and ascend to the posterior part of the dorsum of the tongue. They supply its mucous membrane and the palatoglossal arch, tonsil, soft palate and epiglottis and anastomose with their contralateral fellows.

Sublingual artery
The sublingual artery arises at the anterior margin of hyoglossus. It passes forwards between genioglossus and mylohyoid to the sublingual gland, and supplies the gland, mylohyoid and the buccal and gingival mucous membranes. One branch pierces mylohyoid and joins the submental branches of the facial artery. Another branch courses through the mandibular gingivae to anastomose with its contralateral fellow. A single artery arises from this anastomosis and enters a small foramen (lingual foramen) on the mandible, situated in the midline on the posterior aspect of the symphysis immediately above the genial tubercles.

Deep lingual artery
The deep lingual artery is the terminal part of the lingual artery and is found on the inferior surface of the tongue near the lingual frenulum.

In addition to the lingual artery, the tonsillar and ascending palatine branches of the facial and ascending pharyngeal arteries also supply tissue in the root of the tongue. In the region of the valleculae, epiglottic branches of the superior laryngeal artery anastomose with the inferior dorsal branches of the lingual artery.

Facial artery
The facial artery (see Figs 35.7–35.8, 36.25) arises anteriorly from the external carotid in the carotid triangle, above the lingual artery and immediately above the greater cornu of the hyoid bone. In the neck, at its origin, it is covered only by the skin, platysma, fasciae and often by the hypoglossal nerve. It runs up and forwards, deep to digastric and stylohyoid. At first on the middle pharyngeal constrictor, it may reach the lateral surface of styloglossus, separated there from the palatine tonsil only by this muscle and the lingual fibres of the superior constrictor. Medial to the mandibular ramus, it arches upwards and grooves the posterior aspect of the submandibular gland. It then turns down and descends to the lower border of the mandible in a lateral groove on the submandibular gland, between the gland and medial pterygoid. It initially lies beneath platysma and passes onto the face at the anteroinferior border of masseter, where its pulse can be felt as it crosses the mandible. The artery is deep to skin, the fat of the cheek and, near the angle of the mouth, zygomaticus major and risorius, and superficial to buccinator and levator anguli oris. It may pass over or through levator labii superioris and pursues a tortuous course along the side of the nose towards the medial corner of the eye. At its termination, it is embedded in levator labii superioris alaeque nasi.

Occasionally the facial artery barely extends beyond the angle of the mouth, in which case its normal territory beyond this region is taken over by an enlarged transverse facial branch from the superficial temporal artery and by branches from the contralateral facial artery. The facial vein is posterior to the artery and runs a more direct course across the face. At the anterior border of masseter, the two vessels are in contact, whereas in the neck the vein is superficial to the artery. The facial artery supplies branches to the muscles and skin of the face (see Fig. 36.20). The part of the artery distal to its terminal branch is called the angular artery.

The facial artery is very sinuous throughout its extent. In the neck, this may be so that the artery is able to adapt to the movements of the pharynx during deglutition, and similarly on the face, so that the artery can adapt to movements of the mandible, lips and cheeks. Facial artery pulsation is most palpable where the artery crosses the mandibular base, and again near the corner of the mouth. There are four branches within the neck and four on the face. The named branches in the neck are the ascending palatine, tonsillar, submental and glandular arteries. The named branches on the face are the premasseteric, inferior and superior labial, and lateral nasal arteries.

Ascending palatine artery
The ascending palatine artery arises close to the origin of the facial artery. It passes up between styloglossus and stylopharyngeus to reach the side of the pharynx, along which it ascends between the superior constrictor of the pharynx and medial pterygoid towards the cranial base. It bifurcates near levator veli palatini. One branch follows this muscle, winding over the upper border of the superior constrictor of the pharynx to supply the soft palate and to anastomose with its fellow of the opposite side and the greater palatine branch of the maxillary artery. The other branch pierces the superior constrictor muscle to supply the tonsil and pharyngotympanic tube, and to anastomose with the tonsillar and ascending pharyngeal arteries (see Fig. 40.7).

Tonsillar artery
The tonsillar artery provides the main blood supply to the palatine tonsil. It ascends between medial pterygoid and styloglossus, penetrates the superior constrictor of the pharynx at the upper border of styloglossus, and enters the inferior pole of the tonsil. Its branches ramify in the tonsil and in the musculature of the posterior part of the tongue. The tonsillar artery may sometimes arise from the ascending palatine artery.

Submental artery
The submental artery is the largest cervical branch of the facial artery (see Fig. 35.7A). It arises as the facial artery separates from the submandibular gland and turns forwards on mylohyoid below the mandible. It supplies the overlying skin and muscles, and anastomoses with a sublingual branch of the lingual and mylohyoid branch of the inferior alveolar artery. At the chin, it ascends over the mandible and divides into superficial and deep branches that anastomose with the inferior labial and mental arteries to supply the chin and lower lip.

Glandular branches
Three or four large vessels supply the submandibular salivary gland and associated lymph nodes, adjacent muscles and skin.

Premasseteric artery
The premasseteric artery is small and inconstant. When present, it passes upwards along the anterior border of masseter and supplies the surrounding tissues.

Inferior labial artery
The inferior labial artery arises near the angle of the mouth, passes upwards and forwards under depressor anguli oris, and then penetrates orbicularis oris to run sinuously near the margin of the lower lip, between the muscle and the mucous membrane. It supplies the inferior labial glands, mucous membrane and muscles, and anastomoses with its contralateral fellow and with the mental branch of the inferior alveolar artery.

Superior labial artery

The superior labial artery is larger and more tortuous than the inferior labial artery. It pursues a similar course along the superior labial margin, between the mucous membrane and orbicularis oris, anastomoses with its contralateral fellow, and supplies the upper lip. It gives off an alar branch and a septal branch that ramifies anteroinferiorly in the nasal septum.

Lateral nasal artery

The lateral nasal artery is given off by the side of the nose, supplies the dorsum and ala of the nose, and anastomoses with its contralateral fellow. The lateral nasal artery can be replaced by a branch from the superior labial artery.

Occipital artery

The occipital artery arises posteriorly from the external carotid artery, approximately 2 cm from its origin (see Figs 35.7A, 35.8). At its origin, the artery is crossed superficially by the hypoglossal nerve, which winds round it from behind. The artery next passes backwards, up and deep to the posterior belly of digastric, and crosses the internal carotid artery, internal jugular vein, and hypoglossal, vagus and accessory nerves. Between the transverse process of the atlas and the mastoid process, the occipital artery reaches the lateral border of rectus capitis lateralis. It then runs in the occipital groove of the temporal bone, medial to the mastoid process and attachments of sternocleidomastoid, splenius capitis, longissimus capitis and digastric, and lies successively on rectus capitis lateralis, obliquus superior and semispinalis capitis. Accompanied by the greater occipital nerve, it finally turns upwards to pierce the investing layer of the deep cervical fascia that connects the cranial attachments of trapezius and sternocleidomastoid. Accompanied by the greater occipital nerve, the occipital artery enters the posterior scalp by piercing the investing layer of deep cervical fascia that connects the cranial attachments of trapezius and sternocleidomastoid. It gives off many tortuous branches that run between the skin and the occipital belly of occipitofrontalis, anastomosing with the contralateral occipital, posterior auricular and superficial temporal arteries, as well as with the transverse cervical branch of the subclavian artery. These branches supply the occipital belly of occipitofrontalis and the skin and pericranium associated with the scalp as far forwards as the vertex. The artery may give off a meningeal branch that traverses the parietal foramen.

The occipital artery has two main branches (superior and inferior) to the upper part of sternocleidomastoid in the neck. The inferior branch arises near the origin of the occipital artery and may sometimes arise directly from the external carotid artery. It descends backwards over the hypoglossal nerve and internal jugular vein, enters sternocleidomastoid and anastomoses with the sternocleidomastoid branch of the superior thyroid artery. The superior branch arises as the occipital artery crosses the accessory nerve and runs down and backwards superficial to the internal jugular vein. It enters the deep surface of sternocleidomastoid with the accessory nerve.

Posterior auricular artery

The posterior auricular artery is a small vessel that branches posteriorly from the external carotid just above digastric and stylohyoid. It ascends between the parotid gland and the styloid process to the groove between the auricular cartilage and mastoid process. It supplies the cranial surface of the auricle via its auricular branch, and the occipital belly of occipitofrontalis and the scalp behind and above the auricle via its occipital branch and anastomoses with the occipital artery.

In the neck, it provides branches that supply digastric, stylohyoid, sternocleidomastoid and the parotid gland. It also gives origin to the stylomastoid artery (described as an indirect branch of the posterior auricular artery in about a third of subjects) that enters the stylomastoid foramen to supply the facial nerve, tympanic cavity, mastoid antrum air cells and semicircular canals. In the young, its posterior tympanic ramus forms a circular anastomosis with the anterior tympanic branch of the maxillary artery.

Superficial temporal artery

The superficial temporal artery is the smaller terminal branch of the external carotid artery (see Figs 33.1A, 36.20). It arises in the parotid gland behind the neck of the mandible, where it is crossed by temporal and zygomatic branches of the facial nerve. Initially deep, it becomes superficial as it passes over the posterior root of the zygomatic process of the temporal bone, where its pulse can be felt. It then ascends in the scalp for approximately 4 cm and divides into frontal (anterior) and parietal (posterior) branches. The artery is accompanied by corresponding veins, and by the auriculotemporal nerve that usually lies just posterior to it.

The superficial temporal artery supplies the skin and muscles at the side of the face and in the scalp, the parotid gland and the temporomandibular joint. It is occasionally biopsied when a histological diagnosis of giant cell arteritis is required. The named branches of the superficial temporal artery are the transverse facial, auricular, zygomatico-orbital, middle temporal, frontal and parietal arteries. The relative sizes of the frontal, parietal and transverse facial branches vary: the frontal and parietal branches may be absent, whereas the transverse facial branch may replace a shortened transverse facial artery arising from the facial artery.

Transverse facial artery

The transverse facial artery arises before the superficial temporal artery emerges from the parotid gland. It traverses the gland, crosses masseter between the parotid duct and the zygomatic arch (accompanied by one or two facial nerve branches), and divides into numerous branches that supply the parotid gland and duct, masseter and adjacent skin. The branches anastomose with the facial, masseteric, buccal, lacrimal and infraorbital arteries, and can have a direct origin from the external carotid artery.

Auricular artery

The branches of the auricular artery are distributed to the lobule and lateral surface of the auricle and to the external acoustic meatus.

Zygomatico-orbital artery

The zygomatico-orbital artery may arise independently from the superficial temporal artery or from its middle temporal or parietal branches. It runs close to the upper border of the zygomatic arch, between the two layers of temporal fascia, to the lateral orbital angle. It supplies orbicularis oculi and anastomoses with the lacrimal and palpebral branches of the ophthalmic artery. A well-developed zygomatico-orbital artery can be associated with a delayed division of the superficial temporal artery into frontal and parietal branches.

Middle temporal artery

The middle temporal artery arises just above the zygomatic arch and perforates the temporal fascia to supply temporalis. It anastomoses with the deep temporal branches of the maxillary artery.

Frontal (anterior) branch

The frontal branch passes upwards towards the frontal tuberosity and supplies the muscles, skin and pericranium in this region. It anastomoses with its contralateral fellow and with the supraorbital and supratrochlear branches of the ophthalmic artery.

Parietal (posterior) branch

The parietal branch is larger than the frontal branch of the superficial temporal artery. It curves upwards and backwards, remains superficial to the temporal fascia, and anastomoses with its contralateral fellow and with the posterior auricular and occipital arteries.

Maxillary artery

The maxillary artery is the larger terminal branch of the external carotid artery. It arises behind the neck of the mandible and is at first embedded in the parotid gland, then crosses the infratemporal fossa to enter the pterygopalatine fossa through the pterygomaxillary fissure. Within the pterygopalatine fossa, the maxillary artery and its branches lie in a plane anterior to the maxillary nerve, pterygopalatine ganglion and the nerve of the pterygoid canal: this spatial arrangement is particularly relevant in endoscopic approaches to the pterygopalatine fossa (see Video 38.2). The veins accompanying the third (pterygopalatine) part of the maxillary artery, in common with those accompanying the second (pterygoid) part, are in the form of a venous plexus and profuse haemorrhage may be encountered from this pterygopalatine venous plexus. The maxillary artery has a variable and tortuous course in its short passage through the pterygopalatine fossa, where it gives off numerous named branches, including the posterior superior alveolar and infraorbital arteries and the artery of the pterygoid canal (Vidian artery), and terminates in the sphenopalatine and greater palatine arteries.

The maxillary artery is widely distributed to the mandible, maxilla, teeth, muscles of mastication, palate, nasal cavity and cranial dura mater (see Figs 38.20–38.21). It is conventionally described in three parts: mandibular, pterygoid and pterygopalatine.

The mandibular part runs horizontally by the medial surface of the ramus and passes between the neck of the mandible and the sphenomandibular ligament, parallel with and slightly below the auriculotemporal nerve. It next crosses the inferior alveolar nerve and skirts the lower border of lateral pterygoid. The pterygoid part ascends obliquely

forwards medial to temporalis and is usually superficial to the lower head of lateral pterygoid. When it runs deep to lateral pterygoid, it lies between the muscle and branches of the mandibular nerve and may project as a lateral loop between the two parts of lateral pterygoid. Asymmetry in this pattern of distribution may occur between the right and left infratemporal fossae. Where the maxillary artery runs superficial to the lower head of lateral pterygoid, the most common pattern is that the artery passes lateral to the inferior alveolar, lingual and buccal nerves. Less frequently, only the buccal nerve crosses the artery laterally, and rarely the artery can pass deep to all the branches of the mandibular nerve. The pterygopalatine part passes between the two heads of lateral pterygoid to reach the pterygomaxillary fissure before it passes into the pterygopalatine fossa, where it terminates as the third part of the maxillary artery.

The mandibular part of the maxillary artery has five branches that all enter bone. The named branches are the deep auricular, anterior tympanic, middle meningeal, accessory meningeal and inferior alveolar arteries.

The pterygoid part of the maxillary artery has five branches that do not enter bone but supply muscle, and include the deep temporal, pterygoid, masseteric and buccal arteries.

The branches of the pterygopalatine part of the artery accompany similarly named branches of the maxillary nerve (including those associated with the pterygopalatine ganglion) and include the posterior superior alveolar and infraorbital arteries, the artery of the pterygoid canal (Vidian artery), and the pharyngeal, greater (descending) palatine and sphenopalatine arteries.

Deep auricular artery

The deep auricular artery pierces the osseous or cartilaginous wall of the external acoustic meatus and supplies the skin of the external acoustic meatus and part of the tympanic membrane. A small branch contributes to the arterial supply of the temporomandibular joint.

Anterior tympanic artery

The anterior tympanic artery passes through the petrotympanic fissure to supply part of the lining of the middle ear and accompanies the chorda tympani nerve.

Middle meningeal artery

The middle meningeal artery is the main source of blood to the calvaria (see Fig. 38.22). It may arise either directly from the first part of the maxillary artery or from a common trunk with the inferior alveolar artery. When the maxillary artery lies superficial to lateral pterygoid, the middle meningeal artery is usually the first branch of the maxillary artery: this is not usually the case when the maxillary artery takes a deep course in relation to the muscle. The middle meningeal artery ascends between the sphenomandibular ligament and lateral pterygoid, passes between the two roots of the auriculotemporal nerve, and leaves the infratemporal fossa through the foramen spinosum to enter the cranial cavity medial to the midpoint of the zygomatic bone. It then runs in an anterolateral groove on the squamous part of the temporal bone, dividing into frontal and parietal branches (see Fig. 25.10A). The larger frontal (anterior) branch crosses the greater wing of the sphenoid and enters a groove or canal in the sphenoidal angle of the parietal bone (the sphenoparietal canal). It divides into branches between the dura mater and cranium; some branches ascend to the vertex. The parietal (posterior) branch curves back on the squamous temporal bone, reaches the lower border of the parietal bone anterior to its mastoid angle and divides to supply the posterior parts of the dura mater and cranium. These frontal and parietal branches anastomose with their fellows and with the anterior and posterior meningeal arteries.

Ganglionic branches supply the trigeminal ganglion and associated roots. The petrosal branch enters the hiatus for the greater petrosal nerve, supplies the facial nerve, geniculate ganglion and tympanic cavity, and anastomoses with the stylomastoid artery (El Khouly et al 2008). The superior tympanic artery runs in the canal for tensor tympani and supplies the muscle and the mucosa that lines the canal. Temporal branches traverse minute foramina in the greater wing of the sphenoid and anastomose with deep temporal arteries that supply temporalis. An anastomotic branch enters the orbit laterally in the superior orbital fissure, and anastomoses with a recurrent branch of the lacrimal artery; enlargement of this anastomosis is believed to account for the occasional origin of the lacrimal artery from the middle meningeal artery.

Accessory meningeal artery

The accessory meningeal artery may arise from the maxillary artery or the middle meningeal artery. It enters the cranial cavity through the foramen ovale and supplies the trigeminal ganglion, dura mater and bone. Its main distribution is extracranial, principally to medial pterygoid, lateral pterygoid (upper head), tensor veli palatini, the greater wing and pterygoid processes of the sphenoid bone, the mandibular nerve and the otic ganglion. It is sometimes replaced by separate small arteries.

Inferior alveolar artery

The inferior alveolar (dental) artery descends in the infratemporal fossa posterior to the inferior alveolar nerve. Here, it lies between the ramus of the mandible laterally and the sphenomandibular ligament medially. Before entering the mandibular foramen it gives off a mylohyoid branch, which pierces the sphenomandibular ligament to descend with the mylohyoid nerve in its groove on the inner surface of the ramus of the mandible. The mylohyoid artery ramifies superficially on the muscle and anastomoses with the submental branch of the facial artery. The inferior alveolar artery then traverses the mandibular canal with the inferior alveolar nerve to supply the mandibular molars and premolars, and divides into the incisive and mental arteries near the first premolar.

The incisive artery continues below the incisor teeth (which it supplies) to the midline, where it anastomoses with its fellow, although few anastomotic vessels cross the midline. In the canal, the arteries supply the mandible, tooth sockets and teeth via branches that enter the minute hole at the apex of each root to supply the pulp. The mental artery emerges onto the face from the mandibular canal at the mental foramen, supplies muscles and skin in the chin region, and anastomoses with the inferior labial and submental arteries. Near its origin, the inferior alveolar artery has a lingual branch, which descends with the lingual nerve to supply the lingual mucous membrane. The pattern of branching of the inferior alveolar artery reflects that of the nerves of the same name.

Arterial supply of periodontal ligaments

The periodontal ligaments supporting the teeth are supplied by dental branches of the alveolar arteries. One branch enters the alveolus apically and sends two or three small rami into the dental pulp through the apical foramen, and other rami into the periodontal ligament. Interdental arteries ascend in the interdental septa, sending branches at right-angles into the periodontal ligament, and terminate by communicating with gingival vessels that also supply the cervical part of the ligament. The periodontal ligament therefore receives its blood from three sources: from the apical region; ascending interdental arteries; and descending vessels from the gingivae. These vessels anastomose with each other, which means that when the pulp of a tooth is removed during endodontic treatment, the attachment tissues of the tooth remain vital.

Deep temporal arteries

The arterial supply to the temporalis in the coronal plane is concentrated mainly on its medial and lateral aspects. The anterior and posterior branches of the deep temporal arteries pass between temporalis and the pericranium, producing shallow grooves in the bone. They anastomose with the middle temporal branch of the superficial temporal artery situated laterally (Cheung 1996). The anterior deep temporal artery anastomoses with the lacrimal artery by small branches that perforate the zygomatic bone and greater wing of the sphenoid.

Masseteric artery

The masseteric artery is small and accompanies the masseteric nerve as it passes through the mandibular incisure (notch), posterior to the tendon of temporalis, to enter the deep surface of masseter (see Fig. 38.20). Its branches can also supply the temporomandibular joint. The masseteric artery anastomoses with the masseteric branches of the facial artery and with the transverse facial branch of the superficial temporal artery. This vessel is at risk and may cause considerable bleeding if damaged when the sigmoid notch is entered or split surgically.

Pterygoid arteries

The pterygoid arteries are irregular in number and origin, and are distributed to lateral and medial pterygoid.

Buccal artery

The buccal artery emerges onto the face from the infratemporal fossa. It runs obliquely forwards between medial pterygoid and the attachment of temporalis, accompanying the lower part of the buccal branch of the mandibular nerve, to supply the skin and mucosa over buccinator (see Fig. 38.21A). It anastomoses with branches of the facial and infraorbital arteries. A small lingual branch may be given off to accompany the lingual nerve and supply structures in the floor of the mouth.

Posterior superior alveolar artery

The posterior superior alveolar artery usually arises from the maxillary artery within the pterygopalatine fossa and runs through the

pterygomaxillary fissure onto the maxillary tuberosity. It gives off branches that penetrate the bone here to supply the maxillary molar and premolar teeth and the maxillary air sinus, and other branches that supply the buccal mucosa. Occasionally the posterior superior alveolar artery arises from the infraorbital artery.

Infraorbital artery

The infraorbital artery often arises with the posterior superior alveolar artery. It enters the orbit posteriorly through the inferior orbital fissure. Accompanying the infraorbital nerve, it passes along the infraorbital groove of the maxilla in the floor of the orbit before entering the infraorbital canal, and emerges onto the face through the infraorbital foramen. On the face the infraorbital artery supplies the lower eyelid, the lateral aspect of the nose and the upper lip.

While in the infraorbital groove, it gives off branches that supply inferior rectus and inferior oblique, the nasolacrimal sac and, occasionally, the lacrimal gland.

Within the infraorbital canal it gives off the anterior superior alveolar artery which curves through the canalis sinuosus to supply the upper incisor and canine teeth and the mucous membrane in the anterior part of the maxillary sinus. The canalis sinuosus swerves laterally from the infraorbital canal and inferomedially below it in the wall of the maxillary sinus, following the rim of the anterior nasal aperture, between the alveoli of canine and incisor teeth and the nasal cavity. It ends near the nasal septum where its terminal branch emerges. The canal may be up to 55 mm long.

A middle superior alveolar artery is often described. When present, it branches from the infraorbital artery within the infraorbital canal and runs inferiorly along the lateral wall of the maxillary sinus towards the region of the canine and lateral incisor teeth, forming anastomotic arcades with the anterior and posterior superior alveolar arteries, and terminating near the canine tooth.

The infraorbital artery has extensive anastomoses with the transverse facial and buccal arteries and with branches of the ophthalmic and facial arteries.

Artery of the pterygoid canal

The artery of the pterygoid canal (Vidian artery) usually arises as a branch of the distal part of the maxillary artery or sometimes as a branch of the petrous segment of the internal carotid artery. It passes through the pterygoid canal and anastomoses with the pharyngeal, ethmoidal and sphenopalatine arteries in the pterygopalatine fossa and with the ascending pharyngeal, accessory meningeal, ascending palatine and descending palatine arteries in the oropharynx and around the pharyngotympanic tube. Through these complex anastomoses, the artery of the pterygoid canal contributes to the supply of part of the pharyngotympanic tube, the tympanic cavity and the upper part of the pharynx. It can also anastomose with the artery of the foramen rotundum and so communicate with branches of the cavernous portion of the internal carotid artery.

The communication between the internal and external carotid arteries via the artery of the pterygoid canal is one of a number of collateral vascular pathways that exist between the external carotid artery and branches of the petrous and intracavernous segments of the internal carotid artery. Albeit small and difficult to demonstrate angiographically, these vascular connections may nevertheless provide the arterial supply for arteriovenous malformations, dural-based fistulae and skull base tumours, and may also compensate for occlusion of the internal carotid artery. They also pose a risk of inadvertent embolization of the brain parenchyma during interventional angiography of the external carotid artery system.

There are extensive communications between the artery of the pterygoid canal and the highly vascular nasopharyngeal mucosa. Embolization of branches of the external carotid artery can result in incomplete obliteration of a vascular nasopharyngeal lesion when the artery of the pterygoid canal arises from the internal carotid artery. The collateral circulation provided by the artery of the pterygoid canal can help to maintain cerebral circulation if there is stenosis of the petrous internal carotid artery proximal to the point where the artery of the pterygoid canal joins it, because blood flow in the post-stenotic segment of the internal carotid artery will be supplemented from the external carotid artery via the artery of the pterygoid canal (see Fig. 38.29) (Allen et al 2005, Takeuchi et al 2005, Tubbs et al 2007).

Pharyngeal artery

The pharyngeal branch of the maxillary artery passes through the palatovaginal canal, accompanying the nerve of the same name, and is distributed to the mucosa of the nasal roof, nasopharynx, sphenoidal air sinus and pharyngotympanic tube.

Greater (descending) palatine artery

The greater palatine artery leaves the pterygopalatine fossa through the greater (anterior) palatine canal, within which it gives off two or three lesser palatine arteries. The greater palatine artery supplies the inferior meatus of the nasal cavity, then passes onto the roof of the hard palate at the greater (anterior) palatine foramen and runs forwards to supply the hard palate and the palatal gingivae of the maxillary teeth. It gives off a branch that runs up into the incisive canal to anastomose with the nasopalatine artery and so contribute to the arterial supply of the nasal septum. The lesser palatine arteries emerge on to the palate through the lesser (posterior) palatine foramen, or foramina, and supply the soft palate.

As the greater palatine artery runs the length of the hard palate, it permits axial mucoperiosteal flaps to be raised, if necessary bilaterally, for the reconstruction of local defects. It is also possible to pedicle the entire mucoperiosteum of the hard palate on a single greater palatine artery. The vascular supply to the denuded palatal bone is sufficient, presumably from its nasal surface, to permit regeneration of the palatal soft tissue. Contracture of the regenerated tissue does not occur because the defect lies over the palatal bone (Gullane and Arena 1977, Gullane and Arena 1985, Salins and Benjamin 2009).

Sphenopalatine artery

The sphenopalatine artery and the greater palatine artery are the terminal branches of the maxillary artery. The sphenopalatine artery is the principal artery that supplies the mucosa of the nasal cavity. It passes through the sphenopalatine foramen posterior to the superior meatus. From here, its posterior lateral nasal branches ramify over the turbinates and meatuses and anastomose with the ethmoidal arteries and nasal branches of the greater palatine artery to supply the frontal, maxillary, ethmoidal and sphenoidal air sinuses. The sphenopalatine artery next crosses anteriorly on the inferior surface of the sphenoid and ends on the nasal septum in a series of posterior septal branches that anastomose with the ethmoidal arteries (see Fig. 39.9).

Ligation of the sphenopalatine artery may be necessary in the control of refractory epistaxis. It is usually located endoscopically at the postero-inferior end of the middle turbinate. Multiple branches may be encountered. The sphenopalatine artery provides the axial blood supply to the nasal septal mucosal flap (nasoseptal flap) used in endoscopic skull-base repair, a reflection of its contribution to the vascular supply to the nasal cavity (Hadad et al 2006).

Internal carotid artery

The internal carotid artery supplies most of the ipsilateral cerebral hemisphere, eye and accessory organs, the forehead and, in part, the nose. From its origin at the carotid bifurcation, approximately at the level of T4 (see Figs 35.8–35.9) where there is usually a carotid sinus, it ascends in front of the transverse processes of the upper three cervical vertebrae to the inferior aperture of the carotid canal in the petrous part of the temporal bone. Here, it enters the cranial cavity and turns anteriorly through the cavernous sinus in the carotid groove on the side of the body of the sphenoid bone. It terminates below the anterior perforated substance by division into the anterior and middle cerebral arteries.

The internal carotid artery may be divided conveniently into cervical, petrous, cavernous and cerebral parts (see Video 26.1). Rarely, persistent embryonic branches to the basilar artery from the cervical part of the internal carotid artery may be encountered at the C1–C2 (persistent hypoglossal artery) and C2–C3 (pro-atlantal intersegmental artery) levels.

Occlusive atherosclerotic disease within either the internal carotid or common carotid arteries may cause strokes or transient ischaemic attacks (TIAs) characterized by weakness of the contralateral side. Visual disturbances experienced in the ipsilateral eye and classically described as a 'curtain' falling down over the visual field (amaurosis fugax) may also occur.

Cervical part

The cervical part begins at the carotid bifurcation and ascends anterior to the transverse processes of the upper three cervical vertebrae and enters the cranial cavity via the carotid canal in the petrous part of the temporal bone. The artery has no branches in the neck and so is easily distinguishable from the external carotid artery, should the latter require ligation, e.g. to control haemorrhage from a penetrating injury to the neck (Nowinski et al 2015).

Relations The internal carotid artery is initially superficial in the carotid triangle, and then passes deeper, medial to the posterior belly

of digastric. Except near the skull, the internal jugular vein and vagus nerve are lateral to it within the carotid sheath. The external carotid artery is first anteromedial, but then curves back to lie superficial. Posteriorly, the internal carotid adjoins longus capitis, and the superior cervical sympathetic ganglion lies between them. The superior laryngeal nerve crosses obliquely behind it. The pharyngeal wall lies medial to the artery, which is separated by fat and pharyngeal veins from the ascending pharyngeal artery and superior laryngeal nerve. Anterolaterally, the internal carotid artery is covered by sternocleidomastoid. Below the posterior belly of digastric, the hypoglossal nerve and superior root of the ansa cervicalis and the lingual and facial veins are superficial to the artery. At the level of the digastric, the internal carotid is crossed by stylohyoid and the occipital and posterior auricular arteries. Above the digastric, it is separated from the external carotid artery by the styloid process, styloglossus and stylopharyngeus, the glossopharyngeal nerve and the pharyngeal branch of the vagus, and the deeper part of the parotid gland. At the base of the skull, the glossopharyngeal, vagus, accessory and hypoglossal nerves lie between the internal carotid artery and the internal jugular vein, which here has become posterior. The length of the artery varies with the length of the neck and the point of the carotid bifurcation. It may arise from the aortic arch, in which case it lies medial to the external carotid as far as the larynx, where it crosses behind it. The cervical portion is normally straight but may be very tortuous, when it lies closer to the pharynx than usual, very near the tonsil. In children, the tonsillocarotid distance increases with growth to a maximum value of 25 mm (Deutsch et al 1995). The internal carotid artery enters the cranium without giving off any branches. It may occasionally be absent.

Petrous part

The petrous part of the internal carotid artery ascends in the carotid canal, curves anteromedially and then superomedially above the cartilage that fills the foramen lacerum, and enters the cranial cavity. It lies at first anterior to the cochlea and tympanic cavity, and is separated from the latter and the pharyngotympanic tube by a thin, bony lamella that is cribriform in the young and partly absorbed in old age. Further anteriorly, it is separated from the trigeminal ganglion by the thin roof of the carotid canal, although this is often deficient. The artery is surrounded by a venous plexus and by the carotid autonomic plexus, derived from the internal carotid branch of the superior cervical ganglion. The petrous part of the artery gives rise to two branches. The caroticotympanic artery is a small, occasionally double, vessel that enters the tympanic cavity by a foramen in the carotid canal and anastomoses with the anterior tympanic branch of the maxillary artery and the stylomastoid artery. The pterygoid artery is inconsistent; when present, it enters the pterygoid canal with the nerve of the same name, and anastomoses with a (recurrent) branch of the greater palatine artery.

Cavernous part

The cavernous part of the internal carotid artery ascends to the posterior clinoid process. It turns anteriorly to the side of the body of the sphenoid within the cavernous sinus and then curves superiorly and medial to the anterior clinoid process, to emerge through the dural roof of the sinus. The oculomotor, trochlear, ophthalmic and abducens nerves are lateral to it within the cavernous sinus. The abducens nerve is closely related to the lateral wall of the internal carotid artery, whilst the oculomotor and trochlear nerves are situated in the lateral wall of the cavernous sinus (see Figs 25.8–25.9). This explains the higher risk of abducens nerve injury secondary to pathology such as aneurysms of the cavernous part of the carotid artery. Occasionally the caroticoclinoid ligament between the anterior and middle clinoid processes becomes ossified, forming a bony ring (caroticoclinoid foramen) around the artery (Ray and Gupta 2006).

The cavernous part of the artery gives off a number of small vessels. Branches supply the trigeminal ganglion, the walls of the cavernous and inferior petrosal sinuses, and the nerves contained therein. A minute meningeal branch passes over the lesser wing of the sphenoid to supply the dura mater and bone in the anterior cranial fossa, and also anastomoses with a meningeal branch of the posterior ethmoidal artery. Numerous small hypophysial branches supply the neurohypophysis, and are of particular importance because they form the pituitary portal system (see Fig. 23.11).

Intracranial part

After piercing the dura mater, the internal carotid artery turns back below the optic nerve to run between it and the oculomotor nerve. It reaches the anterior perforated substance at the medial end of the lateral fissure and terminates by dividing into the anterior and middle cerebral arteries (see Fig. 26.3).

Several preterminal vessels leave the cerebral portion of the internal carotid. The ophthalmic artery arises from the anterior part of the internal carotid as it leaves the cavernous sinus, often at the point of piercing the dura, and enters the orbit through the optic canal. The posterior communicating artery (see Fig. 26.3) runs back from the internal carotid above the oculomotor nerve, and anastomoses with the posterior cerebral artery (a terminal branch of the basilar artery), thereby contributing to the circulus arteriosus around the interpeduncular fossa. The posterior communicating artery is usually very small. However, sometimes it is so large that the posterior cerebral artery is supplied via the posterior communicating artery rather than from the basilar artery ('fetal posterior communicating artery'); it is often larger on one side only. Small branches from its posterior half pierce the posterior perforated substance together with branches from the posterior cerebral artery. Collectively they supply the medial thalamic surface and the walls of the third ventricle. The anterior choroidal artery leaves the internal carotid just distal to its posterior communicating branch and passes back above the medial part of the uncus. It crosses the optic tract to reach and supply the crus cerebri of the midbrain, then turns laterally, recrosses the optic tract, and gains the lateral side of the lateral geniculate body, which it supplies with several branches. It finally enters the inferior horn of the lateral ventricle via the choroidal fissure and ends in the choroid plexus. This small, but important, vessel also contributes to the blood supply of the globus pallidus, caudate nucleus, amygdala, hypothalamus, tuber cinereum, red nucleus, substantia nigra, posterior limb of the internal capsule, optic radiation, optic tract, hippocampus and the fimbria of the fornix.

The combination of the petrous, cavernous and intracranial parts of the internal carotid artery is called the 'carotid siphon' because of its sigmoid course (see Fig. 26.1 and Video 26.1). However, in infants, the parasellar region of the internal carotid artery does not form a siphon but takes a relatively straight course (Weninger and Muller 1999). The cranial and sympathetic nerves therefore have different topographical relationships with the artery in the infant compared with that found in older children and adults.

The initial millimetres of the intracranial part lie between two rings (proximal and distal rings) of dense connective tissue that surround the carotid artery where the ophthalmic artery usually branches. In cases of surgical clipping of ophthalmic artery aneurysms, it is of surgical relevance for neurosurgeons to expose this part of the artery by removing the anterior clinoid process and exposing this segment of the internal carotid artery (see Video 26.1).

Ophthalmic artery

The ophthalmic artery leaves the internal carotid artery as it exits the cavernous sinus medial to the anterior clinoid process. It enters the orbit by the optic canal, inferolateral to the optic nerve and continues forwards for a short distance before turning medially by crossing (almost always) over or under the optic nerve (see Fig. 44.13A). The main trunk of the artery continues along the medial wall of the orbit between the superior oblique and lateral rectus, and divides into supratrochlear (frontal) and dorsal nasal branches at the medial end of the upper eyelid. Although the order of branches from the ophthalmic artery is quite variable, there are several consistent branches, including the central retinal artery, muscular branches, ciliary arteries, lacrimal artery, supraorbital artery, anterior and posterior ethmoidal arteries, meningeal branch, medial palpebral arteries, supratrochlear artery and dorsal nasal artery (Hayreh and Dass 1962a). Many of the branches of the ophthalmic artery accompany sensory nerves with the same name and have a similar distribution to these nerves. Variations in the origin and course of the ophthalmic artery have been described (Huynh-Le et al 2005, Hayreh 2006, Bertelli et al 2017).

Central retinal artery

The small central artery of the retina is the first branch of the ophthalmic artery. It begins below the optic nerve and, for a short distance, lies in the dural sheath of the nerve. It enters the inferomedial surface of the nerve 6.4–15.2 mm behind the eyeball, and runs to the retina (accompanying the central retinal vein) along its axis (Kocabiyik et al 2005). It travels within the optic nerve to its head, where it passes through the lamina cribrosa. At this level, the ophthalmic artery divides into equal superior and inferior branches, each of which, after a few millimetres, give off nasal and temporal branches that supply the 'quadrants' of the retina (see Fig. 45.27). Although similar retinal veins unite to form the central retinal vein, the courses of the arteries and veins do not correspond exactly. These vessels mainly run within the nerve fibre and ganglion cell layers of the retina, a course that accounts for their clarity when seen through an ophthalmoscope (see Fig. 45.20A), and explains why they can serve as an easily accessible indicator of cardiovascular disease. Arteries often cross veins, usually lying superficial to

them; in severe hypertension, the arteries may press on the veins and cause visible dilations distal to these crossings. The vitreal location of arteries, their lighter, bright red coloration and smaller diameter in comparison to veins allow the two vessel types to be distinguished ophthalmoscopically. The detailed pattern of the inner retinal vessels is unique and therefore can be used as a source of biometric information for individual recognition.

From the four major arteries within the inner retina, dichotomous branches run from the posterior pole to the periphery, supplying the whole retina (Zhang 1994). Arteries and veins ramify in the nerve fibre layer, near the internal limiting membrane, and arterioles pass deeper into the retina to supply capillary beds. Venules return from these beds to larger superficial veins that converge towards the disc to form the central retinal vein.

Retinal capillary networks are often in three different layers, the number of layers depending on location. Radial peripapillary capillaries are the most superficial of the capillary networks and lie within the inner nerve fibre layer. A layer of inner capillaries runs within the nerve fibre and ganglion cell layers, and an outer capillary layer is located in the inner plexiform and inner nuclear layers (see Fig. 45.29). Approaching the fovea, capillaries are restricted to two layers, and terminal capillaries eventually join to form a single-layered macular capillary ring, producing a capillary-free zone 450–500 μm in diameter at the fovea. This avascular region is clearly visible in a fluorescein angiogram (see Fig. 45.20B). Capillaries become less numerous in the peripheral retina and are absent from a zone approximately 1.5 mm wide adjoining the ora serrata.

The territories of the arteries that supply a particular quadrant do not overlap, nor do the branches within a quadrant anastomose with each other, which means that a blockage in a retinal artery causes loss of vision in the corresponding part of the visual field. The only exception to this end-arterial pattern is in the vicinity of the optic disc. Here, the posterior ciliary arteries enter the eye near the disc and their rami not only supply the adjacent choroid, but also form an anastomotic circle in the sclera around the head of the optic nerve (circle of Zinn/Haller) (see Fig. 45.30). Branches from this ring join the pial arteries of the nerve (see below). Small cilioretinal arteries derived from any arteries in this region may enter the eye in up to 50% of individuals and contribute to the central retinal vasculature; they may possibly preserve visual function following occlusion of the central retinal artery. Small retinociliary veins may sometimes be present.

The structure of retinal blood vessels resembles that of vessels elsewhere, except that the arteries lack an internal elastic lamina, and their adventitia may contain muscle cells. Capillaries are non-fenestrated; endothelial cells are joined by complex tight junctions, fulfilling the requirements of a blood–retinal barrier. Perivascular cells, including pericytes and glia, play key roles in the development and maintenance of the blood–retinal barrier (Bharadwaj et al 2013). Selective loss of pericytes happens early in the development of diabetic retinopathy and has been linked to the characteristic pathological changes seen in this condition (Park et al 2017). Within the optic nerve, the central artery is innervated by sympathetic and parasympathetic nerves; this innervation does not extend to the retinal vessels. The cholinergic parasympathetic supply is derived mainly from the pterygopalatine ganglion and is vasodilatory. The adrenergic postganglionic sympathetic supply originates in the superior cervical ganglion and travels via a plexus around the internal carotid and ophthalmic arteries; it is unclear whether it elicits vasoconstriction or dilation (Bergua et al 2013).

Although inner retinal blood vessels lie between the incoming light and the photoreceptors, they are not perceived because their location is constant. In marked contrast, the growth of new retinal vessels (neovascularization) is one of the major sight-threatening complications of diseases such as diabetes and retinopathy of prematurity.

Muscular arteries

Branches to the extraocular muscles frequently spring from a common trunk to form superior and inferior groups, most of which accompany branches of the oculomotor nerve. The inferior branch contains most of the anterior ciliary arteries. Other muscular vessels branch from the lacrimal and supraorbital arteries or from the trunk of the ophthalmic artery.

Ciliary arteries

The ciliary arteries are distributed in long and short posterior, and in anterior groups (see Fig. 44.13A). Long posterior ciliary arteries, usually two, pierce the sclera near the optic nerve, pass anteriorly along the horizontal meridian and join the major arterial circle of the iris (see Fig. 45.8). About seven short posterior ciliary arteries pass close to the optic nerve to reach the eyeball, where they divide into 15–20 branches. They pierce the sclera around the optic nerve to supply the choroid, and anastomose with twigs of the central retinal artery at the optic disc (see Fig. 45.30). Anterior ciliary arteries arise from muscular branches of the ophthalmic artery. They reach the eyeball on the tendons of the recti, form a circumcorneal subconjunctival vascular zone, and pierce the sclera near the sclerocorneal junction to end in the major arterial circle of the iris.

Lacrimal artery

The lacrimal artery is a large branch that usually leaves the ophthalmic artery near its exit from the optic canal (see Fig. 44.13A), although it occasionally arises before the ophthalmic artery enters the orbit. It accompanies the lacrimal nerve along the upper border of lateral rectus, supplies and traverses the lacrimal gland, and ends in the eyelids and conjunctiva as the lateral palpebral arteries. The latter run medially in the upper and lower lids and anastomose with the medial palpebral arteries. The lacrimal artery gives off one or two zygomatic branches. The zygomaticofacial artery passes through the lateral wall of the orbit to emerge onto the face at the zygomaticofacial foramen, supplies the region overlying the prominence of the cheek foramen and anastomoses with transverse facial and zygomatico-orbital branches of the facial artery. The zygomaticotemporal artery also passes through the lateral wall of the orbit, via the zygomaticotemporal foramen, supplies the skin over the non-beard part of the temple and anastomoses with the deep temporal branches of the maxillary artery. A recurrent meningeal branch, usually small, passes back via the lateral part of the superior orbital fissure to anastomose with the middle meningeal artery. This branch is sometimes large and replaces the lacrimal artery, in which case it becomes a more significant contributor to the orbital blood supply (Hayreh and Dass 1962b, Uchino et al 2013).

Supraorbital artery

The supraorbital artery leaves the ophthalmic artery where it crosses the optic nerve (see Fig. 44.13A), and ascends medial to superior rectus and levator palpebrae superioris. It accompanies the supraorbital nerve between the periosteum and levator palpebrae superioris, passes through the supraorbital foramen or notch, and divides into superficial and deep branches. These supply the skin, muscles and frontal periosteum, and anastomose with the supratrochlear artery and with the frontal branch of the superficial temporal artery and its contralateral fellow (see Fig. 36.20). The supraorbital artery supplies superior rectus and levator palpebrae superioris, sends a branch across the trochlea to the medial canthus, and often sends a branch to the diploë of the frontal bone at the supraorbital margin; it may also supply the muco-periosteum in the frontal sinus.

Anterior ethmoidal artery

The anterior ethmoidal artery passes with its accompanying nerve through the anterior ethmoidal canal to supply the ethmoidal and frontal air sinuses. Entering the cranium, it gives off a meningeal branch to the dura mater, and nasal branches that descend into the nasal cavity with the anterior ethmoidal nerve (see Fig. 39.9). It runs in a groove on the deep surface of the nasal bone to supply the lateral nasal wall and septum. A terminal branch emerges at the junction of the nasal bone and the lateral nasal cartilage and supplies the skin covering the external nose.

Posterior ethmoidal artery

The posterior ethmoidal artery runs through the posterior ethmoidal canal and supplies the posterior ethmoidal air sinuses. Entering the cranium, it gives off a meningeal branch to the dura mater, and nasal branches that descend into the nasal cavity via the cribriform plate and anastomose with branches of the sphenopalatine artery (see Fig. 39.9).

Meningeal branch

A meningeal branch, usually small, passes back through the superior orbital fissure or its own foramen to the middle cranial fossa, where it anastomoses with the middle meningeal artery. It is sometimes large, in which case it becomes a major contributor to the orbital blood supply.

Medial palpebral arteries

Superior and inferior medial palpebral arteries arise from the ophthalmic artery below the trochlea. They descend behind the nasolacrimal sac to enter the eyelids, where each divides into two branches that course laterally along the edges of the tarsal plates, forming the superior and inferior arches and supplying the eyelids. They anastomose with branches of the supraorbital, zygomatico-orbital and lacrimal arteries. The inferior arch also anastomoses with the facial artery.

Supratrochlear artery

The supratrochlear artery is a terminal branch of the ophthalmic artery. It emerges onto the face from the orbit superomedially with the

supratrochlear nerve at the frontal notch and ascends on the forehead to supply the medial parts of the upper eyelid, forehead and scalp, muscles and pericranium. It anastomoses with the supraorbital artery and with its contralateral fellow.

Dorsal nasal artery

The dorsal nasal artery is the other terminal branch of the ophthalmic artery and emerges from the orbit between the trochlea and medial palpebral ligament. It gives a branch to the upper part of the nasolacrimal sac and then divides into two branches. One branch anastomoses with the terminal part of the facial artery, and the other runs along the dorsum of the nose, supplies its outer surface and anastomoses with its contralateral fellow and the lateral nasal branch of the facial artery.

Anterior cerebral artery

The anterior cerebral artery is the smaller of the two terminal branches of the internal carotid artery (see Fig. 26.1).

Surgical nomenclature divides the vessel into three parts: A1, from the termination of the internal carotid artery to the junction with the anterior communicating artery; A2, from the junction with the anterior communicating artery to the origin of the callosomarginal artery; and A3, distal to the origin of the callosomarginal artery, this segment is also known as the pericallosal artery.

The anterior cerebral artery starts at the medial end of the stem of the lateral fissure. It passes anteromedially above the optic nerve to the great longitudinal fissure where it connects with its contralateral fellow by a short transverse anterior communicating artery. The anterior communicating artery is about 4 mm in length and may be double. It gives off numerous anteromedial central branches that supply the optic chiasma, lamina terminalis, hypothalamus, para-olfactory areas, anterior columns of the fornix and the cingulate gyrus (see Fig. 26.2C).

The two anterior cerebral arteries travel together in the great longitudinal fissure. They pass around the curve of the genu of the corpus callosum and then along its upper surface to its posterior end, where they anastomose with posterior cerebral arteries. They give off cortical and central branches.

The cortical branches of the anterior cerebral artery are named according to their distribution. Two or three orbital branches ramify on the orbital surface of the frontal lobe and supply the olfactory cortex, gyrus rectus and medial orbital gyrus. Frontal branches supply the corpus callosum, cingulate gyrus, medial frontal gyrus and paracentral lobule. Parietal branches supply the precuneus, while the frontal and parietal branches both send twigs over the superomedial border of the hemisphere to supply a strip of territory on the superolateral surface (see Fig. 26.2B). Cortical branches of the anterior cerebral artery, therefore, supply the areas of the motor and somatosensory cortices that represent the lower limb.

Central branches of the anterior cerebral artery arise from its proximal portion and enter the anterior perforated substance (see Fig. 26.3) and lamina terminalis. Collectively, they supply the rostrum of the corpus callosum, the septum pellucidum, the anterior part of the putamen, the head of the caudate nucleus and adjacent parts of the internal capsule. Immediately proximal or distal to its junction with the anterior communicating artery, the anterior cerebral artery gives rise to the medial striate artery, which supplies the anterior part of the head of the caudate nucleus and adjacent regions of the putamen and internal capsule.

Middle cerebral artery

The middle cerebral artery is the larger terminal branch of the internal carotid artery. Surgical nomenclature divides the vessel into four parts: M1, from the termination of the internal carotid artery to the bi-/trifurcation, this segment also being known as the sphenoidal; M2, the segment running in the lateral (Sylvian) fissure, also known as the insular; M3, coming out of the lateral fissure, also known as the opercular; and M4, cortical portions.

The middle cerebral artery runs at first in the lateral fissure, then posterosuperiorly on the insula, and divides into branches distributed to the insula and the adjacent lateral cerebral surface (see Figs 26.2–26.4). Like the anterior cerebral artery, it has cortical and central branches.

Cortical branches send orbital vessels to the inferior frontal gyrus and the lateral orbital surface of the frontal lobe. Frontal branches supply the precentral, middle and inferior frontal gyri. Two parietal branches are distributed to the postcentral gyrus, the lower part of the superior parietal lobule and the whole inferior parietal lobule. Two or three temporal branches supply the lateral surface of the temporal lobe. Cortical branches of the middle cerebral artery therefore supply the motor and somatosensory cortices that represent the whole of the body (other than the lower limb), the auditory area and the insula.

Small central branches of the middle cerebral artery, the lateral striate or lenticulostriate arteries, arise at its origin and enter the anterior perforated substance together with the medial striate artery. Lateral striate arteries ascend in the external capsule over the lower lateral aspect of the lentiform complex, then turn medially, traverse the lentiform complex and the internal capsule and extend as far as the caudate nucleus.

Circulus arteriosus cerebri

The circulus arteriosus cerebri (cerebral arterial circle, circle of Willis) is a large arterial anastomosis that unites the internal carotid and vertebrobasilar systems (see Fig. 26.3). It lies in the subarachnoid space within the basal cisterns that surround the optic chiasma and infundibulum. The anterior cerebral arteries are derived from the internal carotid arteries and are linked by a small, but functionally important, anterior communicating artery. Posteriorly, the two posterior cerebral arteries, formed by the division of the basilar artery, are joined to the ipsilateral internal carotid artery by a posterior communicating artery.

There is considerable individual variation in the pattern and calibre of vessels that make up the circulus arteriosus (Puchades-Orts et al 1976). Although a complete circular channel almost always exists, one vessel is usually sufficiently narrowed to reduce its role as a collateral route and the circle is rarely functionally complete. Cerebral and communicating arteries individually may all be absent, variably hypoplastic, double or even triple. The haemodynamics of the circle are influenced by variations in the calibre of communicating arteries and in the segments of the anterior and posterior cerebral arteries that lie between their origins and their junctions with the corresponding communicating arteries. The greatest variation in calibre between individuals occurs in the posterior communicating artery, which is normally very small, so that only limited flow is possible between the anterior and posterior circulations. Commonly, the diameter of the pre-communicating part of the posterior cerebral artery is larger than that of the posterior communicating artery, in which case the blood supply to the occipital lobes is mainly from the vertebrobasilar system. However, sometimes the diameter of the pre-communicating part of the posterior cerebral artery is smaller than that of the posterior communicating artery, in which case the blood supply to the occipital lobes is mainly from the internal carotids via the posterior communicating arteries. Since the primary purpose of the vascular circle is to provide anastomotic channels if one vessel is occluded, it is important to note that a normal-sized posterior communicating artery cannot usually fulfil this role. Agenesis or hypoplasia of the initial segment of the anterior cerebral artery is more frequent than anomalies in the anterior communicating artery and contribute to defective circulation in about one-third of individuals.

Central or perforating arteries

Numerous small central (perforating or ganglionic) arteries arise from the circulus arteriosus or from vessels near it (see Fig. 26.3). Many of these enter the brain through the anterior and posterior perforated substances. Central branches supply nearby structures on or near the base of the brain together with the interior of the cerebral hemisphere, including the internal capsule, basal ganglia and thalamus. These branches form four principal groups. The anteromedial group arises from the anterior cerebral and anterior communicating arteries, and passes through the medial part of the anterior perforated substance. These arteries supply the optic chiasma, lamina terminalis, anterior, preoptic and supraoptic areas of the hypothalamus, septum, para-olfactory areas, anterior columns of the fornix, cingulate gyrus, rostrum of the corpus callosum and the anterior part of the putamen and the head of the caudate nucleus. The posteromedial group comes from the entire length of the posterior communicating artery and from the proximal portion of the posterior cerebral artery. Anteriorly, these arteries supply the hypothalamus and pituitary gland, and the anterior and medial parts of the thalamus via thalamo-perforating arteries. Caudally, branches of the posteromedial group supply the mammillary bodies, subthalamus, the lateral wall of the third ventricle, including the medial thalamus, and the globus pallidus. The anterolateral group is mostly comprised of branches from the proximal part of the middle cerebral artery that are also known as striate, lateral striate or lenticulostriate arteries. They enter the brain through the anterior perforated substance and supply the posterior striatum, lateral globus pallidus and the anterior limb, genu and posterior limb of the internal capsule. The medial striate artery, derived from the middle or anterior cerebral arteries, supplies the rostral part of the caudate nucleus and putamen, and the anterior limb and genu of the internal capsule. The posterolateral group is derived from the posterior cerebral artery distal to its junction with the posterior communicating artery, and supplies the cerebral peduncle, colliculi, pineal gland and, via thalamogeniculate branches, the posterior thalamus and medial geniculate body.

ARTERIAL SUPPLY OF THE BRAIN AND MENINGES

Meningeal arteries

Despite their names, the cranial meningeal arteries are predominantly periosteal (see Fig. 25.10A). Their main targets are bone and haemopoietic marrow, and only some arterial branches are distributed to the cranial dura mater *per se*.

The branches of the meningeal vessels lie mainly in the endosteal layer of dura. In the anterior cranial fossa, the dura is supplied by the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid arteries and a branch of the middle meningeal artery. In the middle cranial fossa, the dura is supplied by the middle and accessory meningeal branches of the maxillary artery; a branch of the ascending pharyngeal artery (entering via the foramen lacerum); branches of the internal carotid artery; and a recurrent branch of the lacrimal artery. In the posterior fossa, the dura is supplied by meningeal branches of the occipital artery which enter the skull by the jugular and mastoid foramina; the posterior meningeal branches of the vertebral artery; occasional small branches of the ascending pharyngeal artery which enter the skull by the jugular foramen and hypoglossal canal; and dorsal meningeal and tentorial branches from the meningohypophysial trunk. The anatomy of the meningeal arteries explains the vascular supply of tumours arising from the meninges (meningiomas) and the architecture of dural arteriovenous fistulae and malformations. (For detailed information on the surgical anatomy of the meningeal arteries, see Lasjaunias et al (2001), Martins et al (2005).)

Brainstem

The medulla oblongata is supplied by branches of the vertebral, anterior and posterior spinal, posterior inferior cerebellar and basilar arteries, entering along the ventral median fissure and the dorsal median sulcus. Vessels that supply the central substance enter along the rootlets of the glossopharyngeal, vagus and hypoglossal nerves. There is an additional supply via a pial plexus from the same main arteries. The choroid plexus of the fourth ventricle is supplied by the posterior inferior cerebellar arteries. The pons is supplied by the basilar artery and the anterior inferior and superior cerebellar arteries. Direct branches from the basilar artery enter the pons along the basilar sulcus. Other vessels enter along the trigeminal, abducens, facial and vestibulocochlear nerves and from the pial plexus. The midbrain is supplied by the posterior cerebral, superior cerebellar and basilar arteries. The crura cerebri are supplied by vessels entering on their medial and lateral sides. The medial vessels enter the medial side of the crus and also supply the superomedial part of the tegmentum, including the oculomotor nucleus. Lateral vessels supply the lateral part of the crus and the tegmentum. The colliculi are supplied by three vessels on each side from the posterior cerebral and superior cerebellar arteries. An additional supply to the crura, and the colliculi and their peduncles, comes from the posterolateral group of central branches of the posterior cerebral artery.

Cerebellum

The cerebellum is supplied by the posterior inferior, anterior inferior and superior cerebellar arteries. The cerebellar arteries form superficial anastomoses on the cortical surface. Anastomoses between deeper, subcortical, branches have been postulated (Duvernoy et al 1983).

Optic chiasma, tract and radiation

The blood supply to the optic chiasma, tract and radiation is of considerable clinical importance. The chiasma is supplied in part by the anterior cerebral arteries but its median zone depends upon rami from the internal carotid arteries reaching it via the stalk of the hypophysis. The anterior choroidal and posterior communicating arteries supply the optic tract, and the optic radiation receives blood through deep branches of the middle and posterior cerebral arteries.

Diencephalon

The thalamus is supplied chiefly by branches of the posterior communicating, posterior cerebral and basilar arteries (Plets et al 1970). A contribution from the anterior choroidal artery is often noted but this has been disputed. The medial branch of the posterior choroidal artery supplies the posterior commissure, habenular region, pineal gland and medial parts of the thalamus, including the pulvinar. Small central branches, which arise from the circulus arteriosus and its associated vessels, supply the hypothalamus. The pituitary gland is supplied by hypophysial arteries derived from the internal carotid artery, and the anterior cerebral and anterior communicating arteries supply the lamina terminalis.

The choroid plexuses of the third and lateral ventricles are supplied by branches of the internal carotid and posterior cerebral arteries.

Basal ganglia

The majority of the arterial supply to the basal ganglia comes from the striate arteries, which are branches from the roots of the anterior and middle cerebral arteries. They enter the brain through the anterior perforated substance and also supply the internal capsule. The caudate nucleus receives blood additionally from the anterior and posterior choroidal arteries. The posteroinferior part of the lentiform complex is supplied by the thalamostriate branches of the posterior cerebral artery. The anterior choroidal artery, a preterminal branch of the internal carotid artery, contributes to the blood supply of both segments of the globus pallidus and the caudate nucleus. Famously, the ligation of this vessel during a neurosurgical procedure on a patient suffering from Parkinson's disease led to alleviation of the parkinsonian symptoms, presumably as a consequence of infarction of the globus pallidus. This chance observation led to the initiation of pallidal surgery (pallidotomy) for this condition.

Internal capsule

The internal capsule is supplied by central, or perforating, arteries that arise from the circulus arteriosus and its associated vessels. These include the lateral and medial striate arteries that come from the middle and anterior cerebral arteries and also supply the basal ganglia. The lateral striate arteries supply the anterior limb, genu and much of the posterior limb of the internal capsule and are commonly involved in ischaemic and haemorrhagic stroke. One of the larger striate branches of the middle cerebral artery is anachronistically known as 'Charcot's artery of cerebral haemorrhage'. The medial striate artery, a branch of the proximal part of either the middle or anterior cerebral artery, supplies the anterior limb and genu of the internal capsule and the basal ganglia. The anterior choroidal artery also contributes to the supply of the ventral part of the posterior limb and the retrolenticular part of the internal capsule.

Cerebral cortex

The entire blood supply of the cerebral cortex comes from cortical branches of the anterior, middle and posterior cerebral arteries (see Figs 26.1–26.2, 26.4–26.5, Video 26.1; Duvernoy et al 1981). In general, long branches traverse the cortex and penetrate the subjacent white matter for 3 or 4 cm without communicating. Short branches are confined to the cerebral cortex and form a compact network in the middle zone of the grey matter, whereas the outer and inner zones are sparingly supplied. Although adjacent vessels anastomose on the surface of the brain, they become end arteries as soon as they enter it. In general, superficial anastomoses only occur between microscopic branches of the cerebral arteries, and there is little evidence that they can provide an effective alternative circulation after the occlusion of larger vessels.

The lateral surface of the hemisphere is mainly supplied by the middle cerebral artery. This includes the territories of the motor and somatosensory cortices, which represent the whole of the body, apart from the lower limb, and also the auditory cortex and language areas. The anterior cerebral artery supplies a strip next to the superomedial border of the hemisphere, as far back as the parieto-occipital sulcus. The occipital lobe and most of the inferior temporal gyrus (excluding the temporal pole) are supplied by the posterior cerebral artery.

Medial and inferior surfaces of the hemisphere are supplied by the anterior, middle and posterior cerebral arteries. The area supplied by the anterior cerebral artery is the largest; it extends almost to the parieto-occipital sulcus and includes the medial part of the orbital surface. The rest of the orbital surface and the temporal pole are supplied by the middle cerebral artery, and the remaining medial and inferior surfaces are supplied by the posterior cerebral artery.

Near the occipital pole, the junctional zone between the territories of the middle and posterior cerebral arteries corresponds to the visual (striate) cortex, which receives information from the macula. When the posterior cerebral artery is occluded, a phenomenon known as 'macular sparing' may occur, in which vision with the central part of the retina is preserved. Collateral circulation of blood from branches of the middle cerebral artery into those of the posterior cerebral artery may account for this phenomenon. In addition, in some individuals, the middle cerebral artery may itself supply the macular area.

ARTERIAL SUPPLY OF THE SPINAL CORD, ROOTS AND NERVES

The spinal cord and its roots and nerves are supplied with blood by both longitudinal and segmental vessels (see Fig. 47.11). Three major longitudinal vessels, a single anterior and two posterior spinal arteries

(each of which is sometimes doubled to pass on either side of the dorsal rootlets) originate intracranially from the vertebral artery and terminate in a plexus around the conus medullaris. The anterior spinal artery forms from the fused anterior spinal branches of the vertebral artery, and descends in the ventral median fissure of the cord. Each posterior spinal artery originates either directly from the ipsilateral vertebral artery or from its posterior inferior cerebellar branch, and descends in a posterolateral sulcus of the cord. The segmental arteries are derived in craniocaudal sequence from spinal branches of the vertebral, deep cervical, intercostal and lumbar arteries. These vessels enter the vertebral canal through the intervertebral foramina and anastomose with branches of the longitudinal vessels to form a pial plexus on the surface of the cord. The segmental spinal arteries send anterior and posterior radicular branches to the spinal cord along the ventral and dorsal roots. Most anterior radicular arteries are small and end in the ventral nerve roots or in the pial plexus of the cord. The small posterior radicular arteries also supply the dorsal root ganglia; branches enter at both ganglionic poles to be distributed around ganglion cells and nerve fibres (see also Crock (1996).)

Segmental radiculomedullary feeder arteries

Some radicular arteries, mainly situated in the lower cervical, lower thoracic and upper lumbar regions, are large enough to reach the ventral median fissure, where they divide into slender ascending and large descending branches. These are the anterior radiculomedullary feeder arteries (Dommisse 1975). They anastomose with the anterior spinal arteries to form a single or partly double longitudinal vessel of uneven calibre along the ventral median fissure. The largest anterior medullary feeder, the great anterior radiculomedullary artery of Adamkiewicz, varies in level, arising from a spinal branch of either one of the lower posterior intercostal arteries (T9–T11), or of the subcostal artery (T12), or less frequently of the upper lumbar arteries (L1 and L2). It most often arises on the left side (Carmichael and Gloviczki 1999). Reaching the spinal cord, it sends a branch to the anterior spinal artery below and another to anastomose with the ramus of the posterior spinal artery, which lies anterior to the dorsal roots. It may be the main supply to the lower two-thirds of the cord. Central branches of the anterior spinal artery enter the ventral median fissure, and then turn right or left to supply the ventral grey column, the base of the dorsal grey column, including the dorsal nucleus, and the adjacent white matter (see Fig. 47.12).

Each posterior spinal artery contributes to a pair of longitudinal anastomotic channels, anterior and posterior to the dorsal spinal roots. These are reinforced by posterior medullary feeders from the posterior radicular arteries. The latter are variable in number and size, but smaller, more numerous and more evenly distributed than the anterior medullary feeders. The anterior channel is joined by a ramus from the descending branch of the great anterior segmental medullary artery of Adamkiewicz. In all longitudinal spinal arteries the width of the lumen is uneven and complete interruptions may occur. At the conus medullaris they communicate by anastomotic loops. Anastomoses other than those between the pial or peripheral spinal arterial branches may be important, e.g. a posterior spinal series of anastomoses between rami of the dorsal divisions of segmental arteries near the spinous processes.

Intramedullary arteries

The central branches of the anterior spinal artery supply about two-thirds of the cross-sectional area of the cord. The rest of the dorsal grey and white columns and peripheral parts of the lateral and ventral white columns are supplied by numerous small radial vessels that branch from posterior spinal arteries and the pial plexus. In a microangiographic study of the human cervical spinal cord, up to six anterior, and eight posterior, radicular spinal arteries were described, and up to eight central branches arose from each centimetre of the anterior spinal artery (Turnbull et al 1966). Abnormalities of blood vessels in the spinal cord can result in clinically significant haemorrhages and neurological events (see Fig. 47.13).

Spinal cord ischaemia

The spinal cord can rely for neither its transverse nor its longitudinal blood supply entirely on the longitudinal arteries. The anterior longitudinal artery and the intramedullary arteries are functional end-arteries, although overlap of territories of supply has been described (Backes and Nijenhuis 2008). Damage to the anterior longitudinal artery can result in loss of function of the anterior two-thirds of the cord (see Fig. 47.14). The longitudinal arteries cannot supply the whole length of the cord, and the input of the segmental medullary feeder vessels is essential. This is especially true of the artery of Adamkiewicz, which may effectively carry the major supply for the lower cord; damage to this individual artery compromises perfusion of the distal cord and may be responsible for paraplegia following aortic bypass procedures. For many years it was assumed that the anterior spinal artery system provided the dominant supply to the cord, but clinical evidence implies that the posterior spinal arteries may be as important as the anterior system in protecting the cord. The mid-thoracic cord, distant from the main anterior medullary feeders, is particularly liable to become ischaemic after periods of hypotension; T4–T9 has been described as the critical vascular zone of the spinal cord, where interference with the circulation is most likely to result in paraplegia.

ARTERIAL SUPPLY OF THE THORAX, ABDOMEN AND PELVIS

Pulmonary trunk

The pulmonary trunk conveys deoxygenated blood from the right ventricle to the lungs (see Figs 57.4, 57.10). About 5 cm in length and 3 cm in diameter, it is the most anterior of the cardiac vessels and arises from the pulmonary anulus surrounding the subpulmonary conus arteriosus (infundibulum) at the base of the right ventricle, superior and to the left of the supraventricular crest. The pulmonary trunk inclines posterosuperiorly and divides into right and left pulmonary arteries, of almost equal size, at the level of the body of the sixth thoracic vertebra (range, bodies of the fourth to the eighth thoracic vertebrae), 2–3 cm inferior to the sternal plane and inferior to the aortic arch to the left of the midline (see Table 52.2). The bifurcation of the pulmonary trunk commonly lies anteroinferior and to the left of the tracheal bifurcation and the associated subcarinal (inferior tracheobronchial) lymph nodes and deep cardiac plexus. In the fetus, at the level of the tracheal bifurcation, the left pulmonary artery is connected to the aortic arch by the ductus arteriosus, the obliterated remnant of which forms the ligamentum arteriosum in the adult (Ch. 13).

Relations The pulmonary trunk is located entirely within the pericardium, enclosed with the ascending aorta in a common sheath of visceral pericardium (see Figs 57.1, 58.1). The fibrous pericardium gradually blends with and disappears within the adventitia of the pulmonary arteries. Anteriorly, it is separated from the sternal end of the left second intercostal space, and/or the third costal cartilage, by the pericardium, pleura, left lung and the superior part of transversus thoracis. Posterior relations of the proximal part near to its origin are the ascending aorta and left coronary artery, and superiorly, the left atrium. Moving superiorly, the ascending aorta spirals around the pulmonary trunk and comes to lie to the right of its more superior part. The atrial auricles and left and right coronary arteries lie on each side of its origin. The superficial cardiac plexus lies between the branching of the pulmonary trunk and the aortic arch (see Fig. 57.61). The tracheal bifurcation and subcarinal lymph nodes are superior and to the right (see Fig. 52.7).

Variants and congenital anomalies The pulmonary trunk is a relatively constant structure and there are minimal variations in healthy individuals. Congenital anomalies include pulmonary atresia and truncus arteriosus (common truncus).

The coronary arteries usually originate from the aortic sinuses, but occasionally may arise from ectopic locations. Most commonly, an ectopic left coronary artery arises from the pulmonary trunk or one of its branches (Bland–White–Garland syndrome) (see Fig. 58.2). This potentially fatal condition requires urgent surgical correction because the myocardium is supplied with deoxygenated pulmonary blood instead of systemic blood (Loukas et al 2009). Infantile symptoms include pallor, fatigue, irritability, weak cry, cough, dyspnoea, and signs of ischaemia and cardiac failure precipitated during or after feeding, or during defecation or crying. The electrocardiogram may reveal deep narrow Q waves, left ventricular hypertrophy and left axis deviation. Radiologically, cardiomegaly is present with left ventricular and left atrial enlargement. Colour flow imaging can identify the anomalous origin of the left coronary artery. The pulmonary trunk may also give rise to the right coronary artery, the left anterior interventricular branch of the left coronary artery, or even both coronary arteries. Typically, there is an extensive development of collateral vessels in the heart (see Fig. 58.3).

Pulmonary atresia is caused by a complete obstruction of pulmonary outflow and may be due to an absence or defect of the pulmonary valvular leaflets. It is associated with a blind-ending pulmonary trunk that causes right ventricular hypoplasia. Reduced flow may render the

pulmonary trunk atretic, small or even normal in size, making diagnosis challenging. A diminished pulmonary flow is supplied through a patent ductus arteriosus (Smith and McKay 2004), and a concomitant ventricular septal defect may permit outflow from the right ventricle. Surgical repair is necessary to allow adequate oxygenation of blood throughout the body.

In truncus arteriosus (common truncus), a single common arterial trunk exits the heart and subsequently divides into the pulmonary trunk and the ascending aorta. Early neonatal life is possible because there is usually a coexisting ventricular septal defect; expedited surgical repair is necessary to avoid congestive heart failure, failure to thrive and death.

Right pulmonary artery

The right pulmonary artery divides into two large branches posterior to the superior vena cava, or immediately lateral to its right side (see Fig. 54.13). This intimate relationship facilitates the cavopulmonary anastomosis (the Glenn shunt) conceived to bypass the defective right heart chambers in various congenital cardiac disorders. A lymph node usually lies adjacent to the bifurcation. The smaller branch to the superior lobe usually divides again, supplying the majority of that lobe. The inferior branch descends anterior to the bronchus intermedius and posterior to the superior pulmonary vein. It provides a small recurrent branch to the superior lobe, and then, at the point where the horizontal fissure meets the oblique fissure, it gives off the branch to the middle lobe anteriorly, and a branch to the superior segment of the inferior lobe posteriorly. It then continues a short distance before dividing to supply the rest of the inferior lobe segments.

Left pulmonary artery

The left pulmonary artery emerges from under the concavity of the aortic arch and descends anterior to the descending thoracic aorta to enter the oblique fissure. The ligamentum arteriosum passes between the superior aspect of the left pulmonary artery and the proximal descending thoracic aorta; the aorta is relatively fixed in position by the ligament, and so may be ruptured in this region in cases of major trauma associated with rapid deceleration. The left recurrent laryngeal nerve branches from the left vagus nerve, passes inferior to the aorta to the left of the ligamentum arteriosum, and then courses superiorly posterior to the aortic arch; it is a close relation of the superior part of the left lung root and hilum, where it may be compressed or invaded by lung tumour. The branches of the left pulmonary artery are variable (Sivrikoz 2016). The first and largest branch is usually given off to the anterior segment of the left superior lobe. Before reaching the oblique fissure, the artery gives off a variable number of other branches to the superior lobe; it usually supplies a large branch to the superior segment of the inferior lobe as it enters the fissure. Lingular branches arise within the fissure, and the rest of the lower lobe is supplied by many varied branching patterns. It was a surgical aphorism of the late Lord Brock that when performing a left upper lobectomy, 'there was always one more branch of the pulmonary artery than you thought!'

Unilateral absence of a pulmonary artery is a rare congenital anomaly characterized by normal lung volume and anatomy at birth. Revascularization before the age of 6 months avoids the development of lung hypoplasia (Alison et al 2011). The left pulmonary artery sling is a congenital anomaly where the left pulmonary artery arises from the right pulmonary artery, travels posteriorly over the right main bronchus and then passes between the trachea and oesophagus: it is associated with significant tracheobronchial stenosis (Zhong et al 2010).

Pulmonary sequestration

When a portion of lung exists without the appropriate bronchial and vascular connections, it is usually supplied by the systemic vasculature (descending thoracic or abdominal aorta or its branches) and drains into either the atria, superior vena cava or azygos venous system (Clements 1999) (see Figs 54.14–54.15). Extralobar pulmonary sequestration segments are covered by visceral pleura and usually found below the left inferior lobe, whereas intralobar anomalies are usually embedded in normal lung, classically, in the posterior basal segment of the left inferior lobe. Extralobar pulmonary sequestration is normally asymptomatic but often associated with other congenital anomalies such as pulmonary hypoplasia, congenital diaphragmatic hernia, congenital cystic adenomatoid malformation and congenital heart disorders (Stocker et al 1978, Kravitz 1994). A fistula into the oesophagus may also develop. Consideration of differential diagnoses that include mediastinal or pulmonary tumours is mandatory.

Pulmonary embolism and arteriography

A thrombus that has developed in the deep venous system (usually in the lower limb or pelvis) may embolize and travel in the right side of the circulation through the right atrium and right ventricle and lodge in the pulmonary vasculature. The clinical abnormalities observed depend on the size of the embolus and on the number and frequency of embolic episodes. Large emboli may lodge in branches of the main pulmonary artery and cause right ventricular dysfunction and hypoxia, representing a medical emergency. Smaller emboli may lodge in segmental pulmonary arteries and cause pleuritic chest pain, shortness of breath and haemoptysis, although the clinical picture is rarely pathognomonic. Pulmonary emboli cause a ventilation/perfusion ratio mismatch that can have serious physiological implications leading to a significant reduction in the oxygenation of blood. Ventilation/perfusion scans with radiolabelled xenon and technetium usually demonstrate segmental abnormalities in perfusion with normal ventilation in the corresponding regions. Pulmonary emboli may also be evaluated by contrast-enhanced spiral CT or pulmonary angiograms and appear as filling defects. Repetitive embolization may eventually lead to a dramatic reduction of the pulmonary vascular bed and chronic cor pulmonale. Thrombolysis, anticoagulation or inferior vena caval filters prevent progression or recurrence of embolism. A clot may also traverse a patent foramen ovale and lodge in the arterial system (paradoxical embolism), most severely in the cerebral circulation resulting in stroke (Kent and Thaler 2011).

Aorta

For descriptive purposes, the aorta is divided into ascending, arch, descending thoracic and abdominal parts.

Ascending aorta

The ascending aorta is typically about 5 cm in length. It originates at the base of the left ventricle, commonly level with the inferior border of the third left costal cartilage, and initially ascends whilst curving anteriorly and to the right. It passes from posterior to the left half of the sternum to become the aortic arch posterior to the right half of the inferior part of the manubrium sterni, or the manubriosternal joint (level with the right second costal cartilage), or the superior part of the right side of the sternal body (level with the right second intercostal space). In children, the diameter of the thoracic aorta correlates most closely with body surface area (Kervancioglu et al 2006, Kaiser et al 2008).

Relations The ascending aorta lies within the fibrous pericardium, enclosed in a tube of visceral serous pericardium together with the pulmonary trunk (see Figs 57.1, 57.4, 58.1). The conus arteriosus of the right ventricle, initial segment of the pulmonary trunk and right auricle are anterior to its lower part. Superiorly, it is separated from the sternum by the pericardium, the pleura and the anterior border of the right lung, loose areolar tissue and the thymus or its remnants. The left atrium, right pulmonary artery and right main bronchus are posterior. The superior vena cava (also partly posterior) and the right atrium are to the right. The left atrium and, more superiorly, the pulmonary trunk are to the left. At least two para-aortic bodies (aortopulmonary paraganglia) lie between the ascending aorta and the pulmonary trunk. Relative to the ascending aorta, the inferior para-aortic body is located on its anterior surface near to the heart, and the middle para-aortic body is located on its right side.

The aortopulmonary window is a space between the pulmonary trunk and aortic arch, bordered by the ascending aorta anteriorly, the descending aorta posteriorly, the mediastinal part of the parietal pleura laterally and the left main bronchus medially (Deutsch and Savides 2005) (see Figs 58.1, 58.4). It contains lymph nodes, fatty tissue, the ligamentum arteriosum, the superficial cardiac plexus, cardiac nerves and the left recurrent laryngeal nerve.

Coronary arteries

The right coronary artery arises from the right aortic sinus and the left coronary artery from the left aortic sinus of the proximal ascending aorta (see Figs 57.21, 57.24, 57.41); the level of the opening of each artery is variable. The two arteries form an oblique inverted crown (hence their name) within the atrioventricular sulcus. They also form a variable and often insignificant anastomosis (in the non-pathological state) via marginal and interventricular loops that intersect at the cardiac apex. The main arteries and major branches are usually subepicardial, but those in the atrioventricular and interventricular sulci are often deeply sited, and occasionally hidden by or embedded in overlapping myocardium (myocardial bridging). The left or right coronary artery is classed as being dominant if it gives off the inferior interventricular branch, which supplies the inferior part of the ventricular septum and often part of the inferolateral wall of the left ventricle. The right coronary artery is dominant in around 60% of hearts. Anastomoses

between right and left coronary arteries are abundant in the fetus but are much reduced by one year of age. Anastomoses providing collateral circulation may become prominent in conditions of chronic hypoxia and in coronary artery disease. An additional collateral circulation is provided by small branches from mediastinal, pericardial and bronchial vessels.

Normal coronary arterial calibre, based on arterial casts or angiogram measurements, ranges between 1.5 and 5.5 mm. The calibre of the left origin exceeds the right in 60% of hearts, the right being larger in 17%, and both vessels being of approximately equal calibre in 23%. The external diameter of the left coronary artery increases from 2.1 mm at the age of 1 year to 3.3 mm at the age of 15 years (Pesonen et al 1991) and the diameters of the coronary arteries may increase up to the 30th year. A significant association has been found between the diameters of the right and left coronary arteries at 0 (birth), 1 and 6 months of age and birth weight, height and body surface area (Karagol et al 2012).

A wide range of coronary artery anomalies or variants may occur, and are categorized according to the origin (connection), course, area of termination of the artery, or the presence of anastomoses, bridging, fistula or atresia (Muresian 2016).

Congenital anomalies of the coronary arteries are found rarely in children. The two most common anomalies are coronary arteriovenous fistula and anomalous left coronary artery arising from the pulmonary trunk (Uysal et al 2014). Other congenital anomalies include ectopic origin of circumflex artery (normally a branch of the left coronary artery) from right coronary artery, single coronary artery arising from right aortic sinus, ectopic right coronary artery arising from the left aortic sinus, left or right coronary artery arising from the ascending aorta (Clemente et al 2010).

Right coronary artery

The right coronary artery arises from the right aortic sinus; its opening is usually below the sinutubular junction (see Fig. 57.23). The artery is usually single, although up to four openings have been observed, reflecting the independent origins of the conal, sinuatrial nodal and ventricular arteries (see Figs 57.42–57.43). The right coronary artery passes at first anteriorly and slightly to the right between the right atrial auricle and pulmonary trunk. On reaching the atrioventricular sulcus, it descends almost vertically to the right side of the inferior cardiac border, curving around it into the inferior part of the sulcus in which it passes towards the cardiac crux (the junction of the atrioventricular, interatrial and interventricular sulci) (see Fig. 57.4B). The artery ends a little to the left of the crux, often by anastomosing with the circumflex branch of the left coronary artery. The right coronary artery may end near the right cardiac border, between this and the crux, or more often it reaches the left border, replacing the more distal part of the circumflex artery. Its branches supply the right and variable parts of the left chambers and atrioventricular septum. Usually, the first branch is the conal branch of the right coronary artery (Loukas et al 2014). This vessel arises independently from the right aortic sinus in approximately 33% of hearts and is sometimes termed the third coronary artery, but this is an inappropriate term because a similarly named vessel arises from the left coronary circulation. The conal branch of the right coronary artery branches anteroinferiorly over the conus arteriosus (infundibulum) and over the superior aspect of the right ventricle, sometimes anastomosing with a similar branch from the anterior interventricular (left anterior descending) artery to form Vieussens arterial ring, an inconstant anastomosis around the right ventricular outflow tract that may provide an important collateral circulation in cases of arterial occlusion (see Figs 57.44–57.45) (Loukas et al 2009).

The first segment of the right coronary artery (between its origin and the right side of the inferior cardiac margin) gives off anterior atrial and ventricular branches that diverge widely. The ventricular arteries arise at almost 90° from the right coronary artery, an arrangement that is in marked contrast to the more acutely angled origins of the ventricular branches of the left coronary artery. The anterior ventricular branches, usually two or three, ramify towards the cardiac apex, but they rarely reach the apex unless the right marginal artery is included within this group. The right marginal artery is greater in calibre than the other anterior ventricular arteries and reaches the cardiac apex in most hearts. When it is very large, there may be no additional anterior ventricular branch. Two, sometimes three, small inferior ventricular branches, arise from the second segment of the right coronary artery between the right side of the inferior cardiac margin and cardiac crux to supply the inferior aspect of the right ventricle. Their size is inversely proportional to that of the right marginal artery, which usually extends to the inferior cardiac surface. On approaching the cardiac crux, the right coronary artery normally produces up to three inferior interventricular branches (occasionally none). The actual inferior interventricular artery sits within the interventricular sulcus, and may be flanked either to the right or left, or on both sides, by these parallel branches. When these flanking vessels exist, branches of the inferior interventricular artery are small and sparse. The inferior interventricular artery is occasionally replaced by a branch of the left coronary artery. Although the atrial branches of the right coronary artery are sometimes described as part of anterior, lateral (right or marginal) and posterior groups, they are usually small single vessels, 1 mm in diameter (see Figs 57.46–57.48). The right anterior and lateral branches (occasionally double, and very rarely triple) mainly supply the right atrium. The posterior branch is usually single and supplies both atria.

The artery of the sinuatrial node is an atrial branch of variable origin, distributed largely to right atrial myocardium. Its origin is variable: most commonly, it arises as the first atrial branch of the right coronary artery, less often from its right lateral atrial branch, and least often from its inferior atrioventricular part. It may sometimes originate from the circumflex branch of the left coronary artery. It usually passes posteriorly in the groove between the right atrial auricle and ascending aorta, and branches around the junction of the superior vena cava and right atrium, typically as an arterial loop from which small branches supply the right atrium. A large branch, the ramus cristae terminalis, traverses and supplies the sinuatrial node: it would seem more appropriate to name this branch the nodal artery, given that the vessel currently bearing this name is predominantly atrial in distribution.

Septal perforating branches of the right coronary artery are relatively short and leave the inferior interventricular branch to supply the inferior part (about one-third) of the interventricular septum. They are numerous but do not usually reach the apical region of the septum. The largest inferior septal perforating artery, usually the first branch, commonly arises from the inverted loop said to characterize the right coronary artery at the crux and it almost always supplies the atrioventricular node. Small, recurrent atrioventricular branches originate from the ventricular branches of the right coronary artery as they cross the atrioventricular sulcus and supply adjacent atrial myocardium.

Left coronary artery

The left coronary artery is usually larger in calibre than the right. It supplies a greater volume of myocardium, including almost all of the left ventricle and atrium, and most of the interventricular septum (see Figs 57.42, 57.49–57.51). In hearts with right dominance, the right coronary artery supplies a variable amount of the inferior region of the left ventricle (see Fig. 57.41A–C).

The left coronary artery arises from the left aortic sinus. The opening of the artery sometimes lies inferior to the margin of the valve leaflets and may be double, usually leading into the circumflex and anterior interventricular (left anterior descending) branches of the left coronary artery. Its initial portion, between its opening and first branches, varies in length from a few millimetres to a few centimetres. The artery lies between the pulmonary trunk and the left atrial auricle, emerging into the atrioventricular sulcus, where it turns left. This part is loosely embedded in subepicardial fat and usually has no branches, but may give off a small atrial branch and, rarely, the sinuatrial nodal artery. Reaching the atrioventricular sulcus, the left coronary artery divides into its two main branches: the circumflex and anterior interventricular arteries.

The anterior interventricular artery is commonly described as the continuation of the left coronary artery. It descends obliquely forwards and to the left in the interventricular sulcus (see Fig. 57.52), sometimes deeply embedded in or crossed by myocardial tissue (myocardial bridges), and by the great cardiac vein and its tributaries.

Myocardial bridges are reported to have a frequency varying from 0.5 to 40% when identified clinically and from 15 to 85% when found at autopsy (see Fig. 57.53). The wide variation in frequency indicates that many bridges may be asymptomatic during life. The major clinical conditions produced by a myocardial bridge are cardiac ischaemia, atherosclerosis and sudden cardiac death. The incidence of atherosclerosis is increased when the right coronary artery is bridged. Although a relationship between myocardial bridges and sudden cardiac death has not been established, autopsy series have shown histological evidence of otherwise unexplained ischaemia in individuals with myocardial bridges; many died during exercise and had no other risk factors for coronary arterial disease.

Almost invariably, the anterior interventricular artery reaches the cardiac apex, where it terminates in around 33% of hearts. More frequently, it curves around the notch of the cardiac apex into the inferior interventricular sulcus and passes one-third to one-half of the way along its length, meeting the terminal parts of the inferior interventricular branches of the right coronary artery.

The anterior interventricular artery gives off right and left anterior ventricular and anterior septal branches, and a variable number of

corresponding posterior branches. Anterior right ventricular branches are small and rarely number more than one or two; the right ventricle is supplied almost entirely by the right coronary artery. Up to nine large left anterior ventricular arteries branch at acute angles from the anterior interventricular artery, crossing the anterior aspect of the left ventricle diagonally, with the largest reaching the rounded left (obtuse) cardiac border. One, termed the left diagonal artery, often dominates, sometimes arising separately from the left coronary artery, which then ends by trifurcation. It is reported in at least 33–50% of hearts, and may be doubled in around 20%. A small left conal artery frequently leaves the anterior interventricular artery near its origin, and anastomoses on the conus arteriosus with its counterpart from the right coronary artery and with the vasa vasorum of the pulmonary trunk and aorta. The anterior septal perforating branches leave the anterior interventricular artery almost perpendicularly, and pass posteroinferiorly within the septum, usually supplying its anterior two-thirds. The first septal perforator artery usually supplies the atrioventricular bundle at the point of its division. Small inferior septal branches from the same source supply the inferior third of the septum for a variable distance from the cardiac apex (Loukas et al 2009).

The circumflex branch of the left coronary artery, comparable to the anterior interventricular artery in calibre, curves leftwards in the atrioventricular sulcus, and continues around the left cardiac border into the posterior and then inferior part of the sulcus, terminating to the left of the cardiac crux in most hearts, although sometimes continuing as the inferior interventricular artery. Proximally, the left atrial auricle usually overlaps it. A large ventricular branch, the left marginal artery, normally arises from the left circumflex artery at a 90° angle and branches over the rounded left border, supplying much of the adjacent left ventricle, typically to its apex. Smaller anterior and inferior branches of the circumflex artery also supply the left ventricle. Anterior ventricular branches (from one to five, commonly two or three) course parallel to the diagonal artery when it is present, and replace it when it is absent. Inferior ventricular branches are smaller and fewer because the left ventricle is partly supplied by the inferior interventricular artery. When this artery is small or absent, it is accompanied or replaced by often doubled or tripled interventricular continuations of the circumflex artery.

The artery to the sinuatrial node is often derived from the first 1–2 cm of the circumflex artery after its origin from the left coronary artery (anterior circumflex segment) and less often from the remaining length of the circumflex artery. It passes over and supplies the left atrium, encircles the superior vena cava (similar to a right coronary sinuatrial nodal branch) and sends a large branch through the node; despite its name, it is predominantly atrial in distribution. The artery to the atrioventricular node, sometimes the terminal branch of the circumflex artery (20%), arises near the cardiac crux. When this occurs, the circumflex artery usually gives off the inferior interventricular artery, an example of left dominance.

Coronary arterial distribution

Details of coronary arterial distribution should be integrated into a concept of total cardiac supply. Most commonly, the right coronary artery supplies all of the right ventricle (except a narrow strip to the right of the anterior interventricular sulcus); a variable part of the inferior aspect of the left ventricle; the inferior one-third of the interventricular septum; the right atrium and part of the left atrium; the conduction system as far as the proximal parts of the right and left bundles (branches of the atrioventricular bundle). Left coronary distribution is reciprocal and includes most of the left ventricle; a narrow strip of right ventricle; the anterior two-thirds of the interventricular septum; most of the left atrium. Variations in the coronary arterial system mainly affect the inferior aspect of the ventricles and reflect the relative dominance of coronary arterial supply (see Fig. 57.41). The term dominance is misleading because the left artery almost always supplies a greater volume of tissue than the right. In right dominance, the inferior interventricular artery is derived from the right coronary artery, and in left dominance it is derived from the left coronary artery. In the balanced pattern of supply, branches of both the left and right coronary arteries run in or near the inferior interventricular sulcus.

Less is known about variations in atrial supply because the small vessels involved are not easily preserved in the corrosion casts that are used for analysis. In more than 50% of individuals, the right atrium is supplied by the right coronary artery alone. More than 62% of left atria are supplied mainly by the left coronary artery, 27% by the right coronary artery (in each group a small accessory supply from the other coronary artery exists), and 11% are supplied almost equally by both arteries. Arterial supply to the sinuatrial and atrioventricular nodes also varies: the sinuatrial node is supplied more often by the right coronary artery and fewer than 10% of sinuatrial nodes receive a bilateral supply. The atrioventricular node is usually supplied by the right coronary artery.

Uncommonly, variants of coronary arteries may be present and are the second most common cause of sudden cardiac death in young athletes. Anomalous origins of the coronary artery, particularly from the contralateral aortic sinus, is the variant that is most commonly associated with sudden cardiac death. Other anomalies include left coronary artery origin from the pulmonary trunk, coronary fistula and left main stem atresia (Kastellanos et al 2018).

Coronary anastomoses

The cardiac collateral circulation represents a built-in system for coronary arterial bypass. The first few centimetres of the main stems of the left and right coronary arteries are devoid of anastomotic branches. Collateral channels are abundant further distally, exhibiting variable calibres and occupying numerous locations, allowing for bidirectional flow between most arteries. Approximately 30 different sites of collateral extramural vessels have been described, the most frequent being at the cardiac apex; the anterior aspect of the right ventricle; the inferior aspect of the left ventricle; the cardiac crux; the interatrial and interventricular sulci; between the sinuatrial nodal and other atrial vessels (see Figs 57.44–57.45). Anastomoses between branches of the coronary arteries, both subepicardial and myocardial, and between these arteries and extracardiac vessels, are of great clinical importance. Clinical studies suggest that anastomoses cannot rapidly provide collateral routes sufficient to circumvent sudden coronary obstruction (see Figs 57.44–57.45, 57.54). Nevertheless, it has long been established that anastomoses do occur, particularly between fine subepicardial branches, and they may increase during the life of an individual by both angiogenesis and arteriogenesis. The Vieussens arterial ring is a collateral vessel that crosses the conus arteriosus inferior to the pulmonary trunk, and provides an anastomosis between the conal branches of the right coronary artery and the anterior interventricular artery. The artery to the sinuatrial node commonly provides a communication between the proximal parts of the left and right coronary arteries. The apical collateral artery joins the interventricular arteries. The frequent enlargement of the first septal branch of the anterior interventricular artery, Kugel's anastomotic artery (arteria anastomotica auricularis magna), has been described as running between the proximal parts of the coronary arteries along the anterosuperior margin of the fossa ovalis to anastomose with the distal part of the right coronary artery. Clinical imaging (catheter angiography and colour Doppler ultrasound) has led to the development of a grading system to describe the overall pattern of cardiac collateral arteries (see Table 57.1).

Extracardiac anastomoses

Extracardiac anastomoses connect various coronary arterial branches with other intrathoracic vessels, most commonly involving the bronchial and internal thoracic arteries (see Fig. 57.54). To a much lesser degree, anastomoses between coronary arteries and pericardiacophrenic branches of the internal thoracic, anterior mediastinal, intercostal and oesophageal arteries also exist.

The posterior pericardium also receives a direct supply from the bronchial arteries: extracardiac coronary anastomoses involving bronchial arteries are typically found at the pericardial reflections, such as the points of entry of the superior and inferior venae cavae. The most common anastomoses are with the circumflex branch of the left coronary artery via the posterior pericardial reflections and reflect the close proximity of the bronchial arteries within the root of the lung. In pathological conditions, notably those resulting in pericardial adhesions, it is also possible for extracardiac anastomoses to develop through trans-pericardial vascularization. Extracardiac communications also exist with coronary atrial branches, especially the sinuatrial nodal artery. The effectiveness of any of these connections as collateral routes in coronary occlusion is not well quantified. Coronary arteriovenous anastomoses and numerous connections between the coronary circulation and cardiac cavities, producing so-called 'myocardial sinusoids' and 'arterioluminal vessels', have been reported, but their importance in coronary disease remains uncertain.

Coronary angiography

Coronary angiography may be performed by introducing a catheter through the femoral, radial or brachial artery. The femoral artery is punctured with a needle 3 cm below the inguinal ligament while the leg is held adducted and slightly externally rotated. The exact position is guided by palpation of the femoral arterial pulse, and the needle is inserted at an angle of 45° to the artery. After arterial puncture, a fine guidewire is inserted through the needle and fed into the artery. The catheter is then inserted over the guidewire and passed through the external and common iliac arteries into the abdominal aorta, then through the descending thoracic aorta, aortic arch and ascending aorta.

The brachial or radial artery may be used for percutaneous access to the circulation. Once the catheter is located in the ascending aorta, a variety of guidewires may be used to enter the coronary vessels for selective arteriography and interventions. Angiography is performed with standard high osmolality contrast medium and cine-angiography. In selected patients, new-generation, low osmolality contrast medium may be used. All the coronary arteries are catheterized and visualized in a variety of views to obtain a full evaluation of their anatomy and to determine the location and degree of any stenosis (see Figs 57.55–57.56). The opening of the left coronary artery arises from the left aortic sinus and is best viewed in the direct frontal and left anterior oblique projections. The right anterior oblique view is useful in demonstrating the diagonal and anterior interventricular branches of the left coronary artery. The right coronary artery originates from the right aortic sinus and is usually visualized in the right anterior oblique view. Pressure and oxygen saturations can be measured via the catheter; changes in pressure across valves allow the degree of stenosis to be measured. Coronary blood flow and relative flow reserve can also be calculated. Significant stenosis may be treated initially by balloon angioplasty followed by stent insertion. The balloon exerts pressure against the plaque in the arterial wall, fracturing and splitting the plaque. The splinting effect of the plaque and elastic recoil are reduced, resulting in an increase in the arterial lumen. Stent insertion reduces the rate of re-stenosis.

Coronary revascularization

Atherosclerosis causing more than 60% stenosis of the terminal diameter of the coronary arteries is likely to cause significant reduction in myocardial perfusion. Patients with high-grade lesions, left main stem coronary artery or triple-vessel disease with impaired left ventricular function are usually considered for coronary artery bypass grafting. The common grafts that are used are the internal thoracic (mammary) and radial arteries. The left internal thoracic artery and radial artery grafts have a greater patency rate than saphenous vein grafts. Approximately 15% of saphenous vein grafts occlude in 1 year and, from then on, at an annual rate of 1–2% in the first 6 years and 4% thereafter; between 40% and 50% of saphenous vein grafts have occluded by 10 years, whereas only about 10% of left internal thoracic or radial artery grafts will have occluded over this time. The common surgical approach is via a midline sternotomy. If the internal thoracic artery is used as a donor graft, it is divided distally (maintaining its proximal origin from the subclavian artery) and anastomosed to the coronary artery distal to the stenosis. If radial artery grafts are used, they must bridge the stenosis via both proximal and distal anastomoses. In selected cases, minimally invasive direct coronary artery bypass grafting is performed, but the approach is dependent on the vessel being grafted. The anterior approach, via a mini-thoracotomy through the fourth intercostal space, is used for grafting the left anterior interventricular and diagonal arteries. The anterolateral approach, via an incision in the third intercostal space from the mid-clavicular to anterior axillary lines, is used for grafting early marginal branches of the circumflex branch of the left coronary artery. The lateral approach, via a lateral thoracotomy measuring only 10 cm in size through the fifth or sixth intercostal spaces, allows grafting of the circumflex vessels. Extrathoracic approaches that are occasionally used include the subxiphoid approach for the distal part of the right coronary artery and inferior interventricular artery. The vast majority of patients are treated with stent placement (see Fig. 57.57). Port access surgery allows for full revascularization with cardiopulmonary bypass and obviates the need for midline sternotomy.

Coronary artery fistula

A coronary artery fistula is an abnormal connection that directly links one or more coronary arteries to a heart chamber or to major thoracic vessels without an interposed capillary bed.

Coronary artery fistulae are rare (see Fig. 57.58); those that arise from a coronary artery and then terminate in a chamber of the heart are known as coronary cameral fistulae, while those terminating in a vein are coronary arteriovenous fistulae. Fistulae may be congenital or may develop later in life. Congenital fistulae are more common and account for 50% of paediatric coronary vascular aberrations: they are believed to be derived from the smallest cardiac (Thebesian) veins. Acquired coronary artery fistulae are most commonly iatrogenic in aetiology but may also occur after traumatic injury. The most commonly seen are of the coronary cameral type, from the right coronary artery into the right side of the heart.

Aortic arch

The aortic arch continues from the ascending aorta and lies mainly within the superior mediastinum (see Figs 57.4A–C). Its origin, slightly to the right of the midline, is level typically with either the right first intercostal space, the second costal cartilage or the second intercostal space. The arch initially ascends obliquely and posteriorly to the left over the anterior surface of the trachea, and then posteriorly across its left side. It ascends superiorly to the midlevel of the manubrium sterni, and curves around the hilum of the left lung. Posteriorly it descends to the left of the body of the fourth thoracic vertebra: at around the level of the sternal plane, posterior to the second left sternocostal joint, it continues as the descending thoracic aorta. The concavity of the aortic arch may lie superior, on or inferior to the sternal plane: most commonly it is inferior to the plane (see Fig. 52.7).

The shadow of the aortic arch is easily identified in frontal chest radiographs, where it is seen as a rounded leftward projection (aortic knuckle) to the left of the manubrium (see Fig. 56.17). The shadow of the adjacent left superior intercostal vein crossing its left side, from posterior to anterior, may form an additional small rounded shadow termed the 'aortic nipple'. The aortic arch is best visualized in left anterior oblique views on angiography and with equivalent computed tomography (CT) reconstruction planes, when the pulmonary trunk and its left branch will be seen inferiorly occupying the concavity of the arch.

The concavity of the aortic arch is the upper curved limit through which structures gain access to, or leave, the hilum of the left lung. The diameter of the aortic arch initially matches that of the ascending aorta but is significantly reduced distal to the origin of the three large branches to the head, neck and upper limbs. The aortic isthmus, a small stricture at the border of the aortic arch with the descending thoracic aorta, may be followed by a dilation; in the fetus, the isthmus lies between the origin of the left subclavian artery and the opening of the ductus arteriosus (Ch. 13).

Relations The left mediastinal part of the parietal pleura is located anterior and to the left of the arch. Deep to the pleura, the arch is crossed, in anteroposterior order, by the left phrenic nerve, left lower cervical cardiac branch of the vagus nerve, left superior cervical cardiac branch(es) of the sympathetic trunk, and the left vagus nerve (see Figs 56.7B, 57.61). As the latter crosses the aortic arch, its recurrent laryngeal branch hooks inferior to the vessel, to the left posterior aspect of the ligamentum arteriosum, and then ascends on the right of the aortic arch. The left superior intercostal vein ascends obliquely anteriorly on the arch, anterolateral to the left vagus nerve and posteromedial to the left phrenic nerve and pericardiacophrenic vessels. The left lung and pleura separate all these structures from the thoracic wall. Posterior and to the right are the trachea and the deep cardiac plexus, the left recurrent laryngeal nerve, the oesophagus, thoracic duct and vertebral column. Superiorly, the brachiocephalic trunk, left common carotid and subclavian arteries arise from its convexity (from left-to-right), and are crossed anteriorly near their origins by the left brachiocephalic vein. The branching of the pulmonary trunk, left main bronchus, ligamentum arteriosum, superficial cardiac plexus and the left recurrent laryngeal nerve are typically inferior.

Variants The most superior level of the aortic arch is typically about 2.5 cm inferior to the jugular notch, although this may vary. It is located more superiorly, closer to the jugular notch, in infants and again in senescence when it is a result of vascular ectasia.

In a right-sided aortic arch, the aorta curves over the hilum of the right lung and descends to the right of the vertebral column: this is usually associated with transposition of the thoraco-abdominal viscera (situs inversus) (Akgun et al 2016). Less often, after arching over the hilum of the right lung, the aorta may pass posterior to the oesophagus to gain a left-sided position, and this is not accompanied by visceral transposition. The presence of a right-sided aortic arch is of relevance when planning the repair of oesophageal atresia in neonates.

The aorta may divide into ascending and descending trunks, the former dividing into three branches to supply the head and upper limbs. Alternatively, it may divide near its origin, producing a double aortic arch; the two branches soon reunite and the oesophagus and trachea usually pass through the interval between them. Entrapment of the oesophagus and/or trachea by the aorta, ductus arteriosus or descending aorta is referred to as a vascular ring.

There are several variants of this arrangement. The most common are when a right-sided aortic arch and the upper part of the descending thoracic aorta pass anterior to the oesophagus and trachea, and the ductus arteriosus passes posterior to the oesophagus into an aortic diverticulum; a right-sided aortic arch and the upper part of the descending thoracic aorta pass anteriorly, and the ductus arteriosus is inserted into the left subclavian artery that arises as a fourth branch from the aortic arch; a left-sided descending thoracic aorta is attached to a left-sided

ductus arteriosus anterior to the oesophagus, and a right-sided aortic arch passes posteriorly; the right superior part of the descending thoracic aorta wraps around the oesophagus and the ductus arteriosus is right-sided; the right upper part of the aorta wraps around the oesophagus and the ductus arteriosus is left-sided (Akgun et al 2016).

From right to left, the brachiocephalic trunk, left common carotid and left subclavian arteries arise from the convex aspect of the aortic arch (see Figs 57.4, 58.1). These vessels may branch from the beginning of the aortic arch or the superior part of the ascending aorta. The distance between their origins varies, the most frequent being apposition of the left common carotid artery to the brachiocephalic trunk. Multiple variants of their branching pattern have been observed; other branches may arise from the aortic arch, including the inferior thyroid, thyroidea ima, thymic, left coronary and bronchial arteries (Akgun et al 2016). The left vertebral artery may arise between the left common carotid and the left subclavian arteries.

The left common carotid artery may arise from the brachiocephalic trunk, when it is known as a bovine arch (7%), although this does not represent the morphology seen in bovines. Rarely the left common carotid and subclavian arteries may arise from a left brachiocephalic trunk or from the right common carotid artery, with the right subclavian artery arising separately (Akgun et al 2016). The right common carotid and subclavian arteries may arise separately, in which case the right subclavian artery often branches from the left part of the aortic arch distal to the left subclavian artery, and usually passes posterior to the oesophagus as an aberrant right subclavian artery (sometimes referred to as a lusoria artery). A diverticular outpouching (diverticulum of Kommerell) may be present at the origin of an aberrant left or right subclavian artery from a right or left aortic arch, respectively (see Fig. 58.6). It can become aneurysmal and cause fatal haemorrhage during endoscopy and can form a vascular ring around the oesophagus and trachea, presenting in the neonate as a feeding disorder with failure to thrive.

Rare avian forms of branching have been reported. For example, the right common carotid and right subclavian arteries arise from the aortic arch, and the left common carotid and left subclavian arteries arise from the descending aorta (Akgun et al 2016). Alternatively, two common arterial trunks arise from the aortic arch, the right trunk branching into the left and right common carotid arteries, and the left trunk branching into the left and right subclavian arteries. Another rare order of the branching from the aortic arch is (from right to left): the right subclavian artery, left subclavian artery, followed by the right common carotid, and left common carotid arteries, with the latter two arising close together and almost forming a common carotid trunk.

The aortic arch may curve posterior to the oesophagus and trachea, instead of passing anteriorly, and may show variation in its branching. For example, another rare avian form reported is with both carotid arteries originating from the same common trunk, and a left subclavian artery originating from the arch, while the right subclavian artery arises from the descending thoracic aorta. One or more of the ductus arteriosi may remain patent.

Very rarely, the external and internal carotid arteries arise separately from the aortic arch and the common carotid artery is absent on one or both sides, or both carotid arteries and one or both vertebral arteries can be separate branches. When a right aortic arch and aorta occur, the arrangement of its three branches is reversed and the common carotid arteries may have a single trunk. Other arteries may branch from it; most commonly, these are one or both bronchial arteries and the thyroidea ima artery.

Pneumomediastinum and aortic nipple

Pneumomediastinum is an overarching term that describes the presence of air in the mediastinum. It may arise from a wide range of pathological conditions or physiological states, e.g. penetrating trauma, ruptured major airways or oesophagus, hyperventilation or distressed ventilation such as acute asthma, periparturition or diabetic ketoacidosis.

The aortic nipple is the radiographic term used to describe a lateral nipple-like projection located on the aortic knuckle. It corresponds to the end-on appearance of the left superior intercostal vein coursing anteriorly and is not observed in all individuals. It may be mistaken radiologically for lymphadenopathy or an intrapulmonary nodule or neoplasm. Despite their relative independence, the aortic nipple is defined by new contours in cases of pneumomediastinum, taking on an 'inverted aortic nipple' appearance (see Fig. 58.5). In this position, the inverted aortic nipple may facilitate radiographic discrimination of pneumomediastinum from similar conditions. The presence of an aortic nipple has also been shown to precede pathological conditions such as venous obstruction in the superior and inferior vena cavae or left brachiocephalic vein, and has been identified in conditions where venous flow through the left superior intercostal vein is increased (e.g. portal venous hypertension and certain congenital venous anomalies).

Coarctation of the thoracic aorta

The aortic lumen is occasionally partly or completely obliterated, either above (preductal or infantile type), opposite or just beyond (postductal or adult type), the entry of the ductus arteriosus. In the preductal type, the length of coarctation is variable, aortic arch hypoplasia is common, and the left subclavian and even the brachiocephalic trunk may be involved. Severe forms of infantile coarctation and its extreme form (aortic interruption) may be patent ductus arteriosus-dependent, as there is no time for effective collateral circulation to develop. Prostaglandin infusion prior to transfer, and surgery at a tertiary centre, often provide a good mid- to long-term outlook for such infants.

The postductal type of coarctation has been attributed to abnormal extension of tissue of the ductus arteriosus into the aortic wall, stenosing both vessels as the duct contracts after birth. This form may permit years of normal life, allowing the development of an extensive collateral circulation to the aorta distal to the stenosis (see Figs 58.7–58.8). High vascularity of the thoracic wall is important and clinically characteristic. Many arteries that arise indirectly from the aorta proximal to the region of coarctation anastomose with vessels that are connected to the aorta distal to the region of coarctation; these vessels form a bypass route and become greatly enlarged. Thus, in the thoracic wall, the thoraco-acromial, lateral thoracic and subscapular arteries (from the axillary artery), the suprascapular artery (from the subclavian artery) and the supreme intercostal artery (from the costocervical trunk) anastomose with other posterior intercostal arteries and the internal thoracic artery and its terminal branches (e.g. the musculophrenic artery) anastomose with many of the posterior intercostal arteries and the inferior epigastric arteries (from the external iliac artery). Posterior intercostal arteries are always involved, and enlargement of their dorsal branches may eventually groove (notch) the inferior margins of the ribs. The radiographic shadow of an enlarged left subclavian artery is also increased. Enlargement of the scapular vessels and anastomoses may lead to widespread interscapular pulsation which is palpated easily with the palm of the hand, and is sometimes heard on auscultation.

Aortic aneurysm formation

Degeneration of the aortic tunica media and intimal dissection play a major role in the pathogenesis of aneurysms affecting the ascending aorta and aortic arch. Smooth muscle cells are lost and elastic fibres degenerate, producing cystic spaces in the media that then fill with mucoid material. The loss of these structural cells leads to weakening of the wall with progressive dilation. Ageing and hypertension are major predisposing factors to cystic medial degeneration and there is a strong link with cigarette smoking. Thoracic aortic aneurysms are categorized by their location. A particular pattern of aortic root involvement, anulo-aortic ectasia, is seen in Marfan syndrome (Baliga et al 2007). Descending aortic aneurysms are generally caused by atherosclerosis (90%) and the remainder result from mycotic disease or trauma.

Associations also exist between thoracic aortic aneurysm and other connective tissue diseases such as homocysteinuria and Ehlers–Danlos syndrome. A genetic relation is seen in familial thoracic aortic aneurysm syndrome (Baliga et al 2007). Rarely, aneurysms may occur as a result of Takayasu's arteritis, or infections within the aortic wall. Some aortic aneurysms are incidental findings on chest films or CT studies. Symptomatic cases present with breathlessness, unbearable chest and back pain, hoarse voice, cough and haemoptysis. Early diastolic murmurs caused by aortic regurgitation may be audible. Repair is carried out in patients with symptoms or fusiform dilation measuring more than 5 cm in diameter. Aneurysms may also occur in an aberrant right subclavian artery and may involve the diverticulum of Kommerell, leading to dysphagia and even tracheal compression. Inadvertent rupture may occur during endoscopy because of the retro-oesophageal location.

Aortic dissection

Aortic dissection occurs as a result of degeneration of the tunica media of the aortic wall and is associated with senescence, persistent hypertension or collagen vascular diseases such as Marfan syndrome. Many patients with aortic dissection have a pre-existing aneurysm. Other associations include aortic coarctation, Turner's syndrome, cocaine abuse (<1%) and trauma during surgical procedures. There is a higher prevalence in males than females, but after 75 years of age there is no sex difference in prevalence (Baliga et al 2007). In a classic aortic dissection, an intimal tear may occur, producing a split into the tunica media that creates a false lumen (see Fig. 58.9). If another tear occurs, connection can be made once again with the true lumen (double-barrel aorta). Additional aetiopathologies include penetrating atherosclerotic ulceration, where an atherosclerotic plaque ruptures into the aortic tunica media, and aortic intramural haematoma, where the vasa vasorum haemorrhage into the wall of the aorta (Baliga et al 2007).

Aortic dissections are classified as types I, II, IIIa and IIIb (DeBakey classification), or types A and B (Stanford classification). Dissections that include the aorta proximal to the left subclavian artery, with or without distal extension, are classified as type I, II or A. Type I involves up to the entire aorta (ascending, arch and descending), whereas type II involves the ascending aorta only. Dissections that are distal to the left subclavian artery are classified as type IIIa (extend to the respiratory diaphragm), IIIb (extend below the respiratory diaphragm) or B. These cases present acutely with severe retrosternal, neck or interscapular chest pain. Depending on the extent of the dissection, they may be associated with neurological signs, diarrhoea or leg weakness. Extension into the pericardium causes cardiac tamponade and circulatory collapse. Diagnosis is established by echocardiography and on contrast-enhanced CT or magnetic resonance imaging (MRI). Medical management is possible for descending aortic dissections, while surgical repair is essential for ascending aortic or aortic arch dissection.

Para-aortic bodies

Para-aortic bodies (aortopulmonary paraganglia) belong to the branchiomeric category of paraganglia. They are chemoreceptors and respond to changes in arterial gas concentrations such as lowered pO_2, increased pCO_2 and increased hydrogen ion concentration. These microscopic structures occur in several locations within the thorax. Coronary paraganglia lie between the ascending aorta and pulmonary trunk, either anteriorly or posteriorly, adjacent to the proximal aorta (aortic root); pulmonary paraganglia lie in the groove between the ductus arteriosus and the pulmonary trunk; subclavian–supra-aortic paraganglia lie between either the right subclavian and right common carotid arteries, or the left subclavian and left common carotid arteries, or caudal to the left subclavian artery, adjacent to the aortic arch.

Rarely, tumours may arise within the para-aortic bodies (e.g. mediastinal paragangliomas that originate in the pulmonary trunk and aortic arch). Generally, these tumours are asymptomatic and are discovered incidentally, but they may occasionally lead to feelings of pressure and hoarseness (Rooke et al 2007).

The major blood vessels of the thorax include the pulmonary trunk, the thoracic aorta and its branches, and the superior and inferior venae cavae and their tributaries (see Fig. 58.1).

Brachiocephalic trunk

The brachiocephalic (innominate) trunk, the largest diameter branch of the aortic arch, is 4–5 cm in length (see Figs 57.4A–B, 58.1). It arises from the convexity of the aortic arch posterior to the centre of the manubrium sterni, and ascends posterolaterally to the right, initially located anterior to the trachea, then on its right. It divides into the right common carotid and right subclavian arteries level with the superior border of the right sternoclavicular joint. The brachiocephalic trunk and left common carotid artery may share a common origin (Osborn 1998). A thymic, bronchial or thyroidea ima artery can arise from the brachiocephalic trunk (see Fig. 58.1). The thyroidea ima artery is a small and inconstant artery that may also arise from the aortic arch, common carotid, subclavian, pericardiacophrenic or internal thoracic arteries; most commonly it arises from right-sided vessels (Tunali 2016, Yalcin 2016) and ascends on the trachea to the thyroid isthmus, where it terminates.

Relations The anterior surface of the brachiocephalic trunk is separated from the manubrium by sternohyoid and sternothyroid, thymic remnants, the left brachiocephalic and right inferior thyroid veins (crossing its root), and sometimes by the right cardiac branches of the vagus nerve. Posterior relations are the trachea (inferiorly) and the right mediastinal part of the parietal pleura (superiorly). The right vagus nerve is posterolateral (superiorly) and sits lateral to the trachea (inferiorly) (see Fig. 56.7). On its right side are the right brachiocephalic vein and the upper part of the superior vena cava and mediastinal part of the parietal pleura, and on its left side are thymic remnants, the origin of the left common carotid artery, the inferior thyroid veins and the trachea (superiorly).

Left common carotid artery

The left common carotid artery originates directly from the aortic arch immediately posterolateral to the brachiocephalic trunk and therefore has both thoracic and cervical parts. Its course and relations are described on page 1464.e56.

Left subclavian artery

In the majority of individuals, the left subclavian artery originates independently from the aortic arch after the origins of the brachiocephalic and left common carotid arteries. Its course and relations are described on page 1464.83.

Descending thoracic aorta

The descending thoracic aorta is located within the posterior mediastinum (see Figs 52.3, 56.1, 56.6, 56.7B, 56.13, 56.14A, 56.20D–E). It is continuous with the aortic arch, beginning level with the lower border of the body of the fourth thoracic vertebra (typically at the sternal plane, although the level of the plane may vary), and ending anterior to the lower border of the body of the twelfth thoracic vertebra at the aortic hiatus, through which it passes. It is left of the vertebral column at its origin, and reaches the midline, anterior to the vertebral bodies, as it descends.

Relations Anterior to the descending thoracic aorta, from superior to inferior, are the hilum of the left lung, the pericardium separating it from the left atrium, oesophagus and the lumbar part of the respiratory diaphragm. The vertebral column and accessory hemiazygos (superiorly) and hemiazygos (inferiorly) veins are posterior. To the right is the thoracic duct and the azygos vein, and inferiorly, to both the left and right sides, are the pleura-covered parts of the mediastinal surfaces of the respective lungs. The oesophagus with its associated plexus of nerves is closely related to the descending thoracic aorta; it is located to the right of the descending aorta in the upper thorax, anterior to it in the lower thorax, and anterolaterally to the left at the level of the diaphragm. Occasionally the aorta traverses the diaphragm to the left and posterior to the oesophagus (Berdjas and Turina 2011).

The descending thoracic aorta provides visceral branches to the pericardium, lungs, bronchi and oesophagus, and parietal branches to the thoracic wall and vertebral column.

Pericardial branches

A variable number of small vessels are distributed to the posterior aspect of the pericardium.

Bronchial arteries

Bronchial arteries vary in number, size and origin. There is usually only one right bronchial artery that arises from either the right third posterior intercostal artery, or the superior left bronchial artery, or various right posterior intercostal arteries, and runs posteriorly on the right principal main bronchus. The left bronchial arteries, usually two, arise from the thoracic aorta, the superior near the fifth thoracic vertebra, the inferior below the left principal main bronchus, and run posterior to the left main bronchus. The bronchial arteries supply the pulmonary areolar tissue, bronchopulmonary lymph nodes, pericardium and oesophagus.

Oesophageal branches

Two or three bronchial arteries supply the thoracic oesophagus. Two or three oesophageal arteries that arise either anteriorly or from the right side of the descending thoracic aorta supply the distal oesophagus (Norton et al 2008).

Mediastinal branches

Numerous small vessels supply lymph nodes and areolar tissue in the posterior mediastinum.

Superior phrenic branches

Superior phrenic arteries arise from the distal descending thoracic aorta and are distributed posteriorly to the superior (thoracic) surface of the respiratory diaphragm, anastomosing with the musculophrenic and pericardiacophrenic arteries (see Fig. 55.6).

Posterior intercostal arteries

There are usually nine pairs of posterior intercostal arteries. They arise from the posterior aspect of the descending thoracic aorta and are distributed to the lower nine intercostal spaces (third to eleventh spaces). The right posterior intercostal arteries are longer because the aorta deviates to the left (see Fig. 53.18): they cross the vertebral bodies posterior to the oesophagus, thoracic duct and azygos vein, and the parietal pleura covering the right lung. The left posterior intercostal arteries travel posteriorly across the vertebral bodies and are in contact with the parietal pleura covering the left lung; the first and second are crossed by the left superior intercostal vein, and those located inferiorly are crossed by the hemiazygos and accessory hemiazygos veins. The sympathetic trunk and ganglia lie anterior to all of the arteries, and the thoracic splanchnic nerves are anterior to the more inferiorly located arteries.

Each artery crosses its intercostal space obliquely towards the angle of the rib above and continues forwards in its costal groove. It runs between the costal parietal pleura and associated endothoracic fascia, and the internal intercostal membrane as far as the angle of the rib, then passes between the internal and innermost intercostal muscles (see Fig. 53.17) and anastomoses with an anterior intercostal branch from

either the internal thoracic or musculophrenic artery. Each artery is accompanied by a vein above and a nerve below, except in the upper spaces, where the nerve is initially superior to the artery. The third posterior intercostal artery anastomoses with the supreme intercostal artery and may provide the major supply to the second intercostal space. The inferior two posterior intercostal arteries continue anteriorly into the abdominal wall, where they anastomose with the subcostal, superior epigastric and lumbar arteries (see Fig. 52.3). Each posterior intercostal artery has dorsal, collateral, muscular and cutaneous branches (see Fig. 53.18).

Dorsal branch

Each dorsal branch passes posteriorly in the space between the necks of adjacent ribs (superiorly and inferiorly), the adjacent vertebral body (medially) and the superior costotransverse ligament (laterally) (see Fig. 53.11). Each dorsal branch gives off a spinal branch that enters the vertebral canal via the intervertebral foramen and supplies the vertebra, spinal cord and meninges, anastomosing with the spinal arteries located immediately superior, inferior, and contralateral (see Fig. 53.18). It then divides into a medial and a lateral dorsal musculocutaneous branch; occasionally, these arise separately from the posterior intercostal artery rather than from a common trunk. The medial branch crosses the transverse process of a vertebra with the medial dorsal branch of a thoracic spinal nerve to supply spinalis, longissimus thoracis and an area of overlying skin. The lateral branch supplies longissimus thoracis and iliocostalis, and the medial aspects of latissimus dorsi and trapezius, in addition to an area of overlying skin.

Collateral intercostal branch

A collateral intercostal branch arises near the angle of a rib and descends to the upper border of the subjacent rib, along which it courses to anastomose with its partner branch from the anterior intercostal branch of the internal thoracic or musculophrenic artery.

Muscular branches

Muscular branches supply the intercostal and pectoral muscles and serratus anterior, and anastomose with the superior and lateral thoracic branches of the axillary artery. Mammary branches from the anterior intercostal vessels in the second to fourth spaces supply the pectoral muscles, breast tissue and covering skin, and enlarge during lactation.

Lateral cutaneous branch

The lateral cutaneous branch arises in the posterior part of the intercostal space and travels anteriorly for a few centimetres with an accompanying vein and the lateral cutaneous branch of the accompanying intercostal nerve (see Fig. 53.21). This neurovascular bundle pierces the intercostal muscles and passes slightly inferiorly to emerge between the interdigitations of serratus anterior and external abdominal oblique. It divides into anterior and posterior rami that contribute to the blood supply of the skin of the lateral trunk; these vessels are less significant in the upper three intercostal spaces.

Unnamed branches

Unnamed branches supply tissues of the thoracic wall, including the costal periosteum, bone and bone marrow of the ribs, tissues of the synovial and synarthrodial joints, and the parietal pleura and tissues of the extrapleural space.

Clinical significance of the posterior intercostal arteries

Catheter embolization is an interventional radiology technique that can be used to block branches of the posterior intercostal arteries when they are bleeding, e.g. secondary to blunt trauma usually associated with rib fractures, or when there is an abnormality of the vertebrae supplied by the dorsal branch of the posterior intercostal artery. In such cases, the posterior intercostal artery may be accessed by placing a catheter in the thoracic aorta, usually by puncturing the femoral artery in the femoral triangle. A smaller catheter (referred to as a superselective catheter) may then be placed in the posterior intercostal artery and embolic material (metallic coils or glue) is injected to block the artery. This can cause cessation of bleeding in cases of trauma and provide pain relief when, for example, the vertebral body is infiltrated with tumour (see Fig. 53.20).

Subcostal arteries

The subcostal arteries are the last paired branches of the descending thoracic aorta, in series with the posterior intercostal arteries and inferior to the twelfth ribs. Each runs laterally anterior to the body of the twelfth thoracic vertebra and posterior to the thoracic splanchnic nerves, sympathetic trunk, costal part of the parietal pleura and lumbar part of the respiratory diaphragm. The right subcostal artery is also posterior to the thoracic duct and azygos vein, while the left is posterior to the hemiazygos vein. Each artery enters the abdomen at the lower border of the twelfth rib, accompanied by the twelfth thoracic (subcostal) nerve, lying posterior to the lateral arcuate ligament and kidney, and anterior to quadratus lumborum. The right artery courses posterior to the ascending colon, and the left courses posterior to the descending colon. The subcostal arteries pierce the aponeurosis of transversus abdominis to become more superficial, and continue toward the anterior midline in the plane between transversus abdominis and internal abdominal oblique; they anastomose with the superior epigastric, lower posterior intercostal and lumbar arteries. Each has a dorsal branch, distributed like those of the posterior intercostal arteries.

Aberrant artery (right dorsal aorta vestige)

A small artery sometimes leaves the descending thoracic aorta from its right side near the origin of the right bronchial artery. It ascends to the right behind the trachea and oesophagus and may anastomose with the right supreme intercostal artery.

Aortic rupture in trauma

Rupture of the ascending aorta is usually associated with a high immediate mortality (Baliga et al 2007). Blunt aortic rupture commonly occurs in road traffic accidents and has a 20% survival rate. There is usually a transverse tear involving the tunica intima and tunica media of the aortic wall; systemic circulatory pressure may cause the formation of a false aneurysm. Rupture of the isthmus region of the descending thoracic aorta is more common, probably because it marks the junction between the mobile and fixed parts of the aorta. Other sites include the ascending aorta proximal to the origin of the brachiocephalic trunk, the aortic arch and the abdominal aorta. Rupture is likely to be the result of a number of factors, including torsion, shear and stretching forces, possibly compounded by hydrostatic pressure.

Aortic atherosclerosis or calcification

Echocardiography, particularly transoesophageal, allows detailed assessment of proximal aortic atherosclerosis implicated in systemic embolic events and strokes, and the extent of turbulent flow. MRI can allow accurate assessment of the composition and size of atherosclerotic plaques and flow dynamics, permitting assessment of the risk of plaque rupture and thrombus formation.

Abdominal aorta

The abdominal aorta begins at the aortic hiatus of the respiratory diaphragm anterior to the twelfth thoracic vertebra. It descends anterior to the lumbar vertebrae and bifurcates into two common iliac arteries anterior to the fourth lumbar vertebra or the intervertebral disc between the fourth and fifth lumbar vertebrae, slightly to the left of the midline (Mirjalili et al 2012a, 2012b, Moussallem et al 2012) (see Figs 61.8–61.11). The angle of bifurcation is very variable (Moussallem et al 2012). The mean adult diameter of the aorta inferior to the origin of the renal arteries measured by computed tomography is 19–21 mm (males) and 16–18 mm (females) (Rogers et al 2013), but there are ethnic variations (Jasper et al 2014). Measured by ultrasound, equivalent values are 20± 2.5 mm (males) and 17±1.5 mm (females) (Needleman 2006). The mean calibre of the abdominal aorta decreases slightly from proximal to distal. With advancing age, there is a progressive increase in abdominal aortic diameter in both sexes and the tapering becomes more pronounced (Fleischmann et al 2001). In the elderly, the abdominal aorta frequently becomes ectatic and tortuous, changing the angle and position of the bifurcation and rotating the origins of the major branches.

Approximately 80% of abdominal aortic aneurysms occur in the aorta inferior to the origin of the renal arteries. Males with atherosclerosis are most at risk of developing the condition, particularly from the sixth decade onwards (Takayama and Yamanouchi 2013). The high mortality risk from spontaneous rupture has prompted the development of ultrasound screening programmes to detect aneurysms and repair them electively. Overall, surgery is performed in patients with an aneurysm greater than 5.0 cm in diameter (females) and 5.5 cm (males) (Groeneveld et al 2018). Repair is most commonly performed by open surgery or endovascular stenting (endovascular aneurysm repair).

Relations The proximal abdominal aorta is directly related anteriorly to the coeliac trunk and its branches, autonomic nerve plexuses and lymphatics. Inferior to the coeliac trunk, the superior mesenteric artery leaves the aorta and descends anterior to the left renal vein. The body of the pancreas is anterior to these vessels; the splenic vein is on its posterior surface and extends obliquely up and to the left. Further

anteriorly, the omental bursa separates the proximal abdominal aorta from the lesser omentum, stomach and left lobe of the liver. Inferior to the pancreas, the horizontal third part of the duodenum crosses the aorta anteriorly.

The twelfth thoracic vertebra, the upper four lumbar vertebrae, intervening intervertebral discs and the anterior longitudinal ligament lie posterior to the abdominal aorta. Lumbar arteries arise from its dorsal aspect, and the third and fourth (and sometimes the second) left lumbar veins cross posterior to it to reach the inferior vena cava. The abdominal aorta can overlap the medial border of psoas major on the left.

On the right, the abdominal aorta is related superiorly to the cisterna chyli and thoracic duct, the azygos vein and the right crus of the respiratory diaphragm, which overlaps and separates it from the inferior vena cava and right coeliac ganglion. Below the second lumbar vertebra it is closely applied to the left side of the inferior vena cava. This close relationship allows a fistula to develop between the aorta and adjacent inferior vena cava, a rare complication of aneurysmal disease or trauma. On the left, the aorta is related superiorly to the left crus of the respiratory diaphragm and left coeliac ganglion. Level with the second lumbar vertebra, it is related to the ascending part of the duodenum, the left sympathetic trunk and the inferior mesenteric vein.

The branches of the abdominal aorta are described as anterior, lateral and dorsal (see Fig. 61.9). The anterior (unpaired) branches are the coeliac trunk and superior and inferior mesenteric arteries and the lateral (paired) branches are the inferior phrenic, middle suprarenal, renal and gonadal (ovarian or testicular) arteries: both groups are distributed to the viscera. The dorsal branches are the lumbar and median sacral arteries which supply the body wall, vertebral column and the vertebral canal and its contents.

Coeliac trunk

The coeliac trunk is the first anterior branch and arises just inferior to the aortic hiatus, usually at the level of the vertebral body of the twelfth thoracic vertebra. It is 1–3 cm long and passes almost horizontally anteriorly and slightly to the right superior to the body of the pancreas and splenic vein. In most individuals it trifurcates into the left gastric, common hepatic and splenic arteries. Variations occur and include a separate origin of the left gastric artery from the abdominal aorta, one or both inferior phrenic arteries arising from the coeliac trunk, and the superior mesenteric artery or one or more of its branches arising in common with the coeliac trunk (Panagouli et al 2013). Anterior to the coeliac trunk lies the omental bursa. The coeliac plexus surrounds the coeliac trunk, sending extensions along its branches. On the right lie the right coeliac ganglion, right crus of the respiratory diaphragm and the caudate lobe of the liver. To the left lie the left coeliac ganglion, left crus of the respiratory diaphragm and the cardia of the stomach. Rarely the coeliac trunk can be compressed by the median arcuate ligament (Dunbar's syndrome), resulting in visceral ischaemia and abdominal pain (Ho et al 2017).

Left gastric artery

The left gastric artery is the smallest branch of the coeliac trunk. It ascends to the left of the midline and crosses over the distal end of the left crus of the respiratory diaphragm beneath a fold of peritoneum in the upper posterior wall of the omental bursa (the gastropancreatic fold). Here, it lies adjacent to the left inferior phrenic artery and medial or anterior to the left suprarenal gland. It runs forwards into the superior portion of the lesser omentum adjacent to the proximal end of the lesser curvature, and then it turns anteroinferiorly to run along the lesser curvature between the two peritoneal leaves of the lesser omentum. At the highest point of its course it gives off one or more oesophageal branches. In its course along the lesser curvature it gives off multiple branches that run on to the anterior and posterior surfaces of the stomach, after which it anastomoses with the right gastric artery in the region of the angular incisure.

Rarely the left gastric artery (replaced or accessory) arises from the common hepatic or left hepatic arteries, or directly from the abdominal aorta (Panagouli et al 2013). The most common of these variations is an origin from the left hepatic artery, when the left gastric artery passes between the peritoneal layers of the proximal lesser omentum to reach the lesser curvature of the stomach. However, a replaced/accessory left hepatic artery arising from the left gastric artery is more common than a replaced/accessory left gastric artery origin.

Hepatic artery

During fetal and early postnatal life the common hepatic artery is the largest branch of the coeliac trunk, whereas in adults it is intermediate in size between the left gastric and splenic arteries. The common hepatic artery gives off the right gastric and gastroduodenal arteries (see Fig. 66.9A). After originating from the coeliac trunk, it passes anteriorly and laterally, above the superior border of the pancreas, to the superior aspect of the first part of the duodenum. It is subdivided into the common hepatic artery, from the coeliac trunk to the origin of the gastroduodenal artery, and the proper hepatic artery, from that point to its bifurcation. Both parts ascend anterior to the hepatic portal vein and medial to the bile duct within the free margin of the hepatoduodenal ligament in the anterior wall of the omental foramen. The left and right hepatic arteries arise at a variable level below the porta hepatis. The right hepatic artery typically crosses posterior (occasionally anterior) to the common hepatic duct (see Fig. 66.9B). Its usual course is toward the common hepatic duct: it bends inferiorly before crossing posterior to the duct and then bends back up toward the right hepatic duct lateral to the common hepatic duct and hepatic portal vein. Its close proximity to the bifurcation of the bile duct means that it is often involved or encased by bile duct cancers that arise at the bifurcation (hilar cholangiocarcinoma): the right hepatic artery is more frequently involved than the left hepatic artery in bile duct cancers of the porta hepatis. Occasionally the right hepatic artery crosses anterior to the common hepatic duct and is more vulnerable to injury during biliary surgery. It almost always divides into an anterior branch supplying segments V and VIII and a posterior branch supplying segments VI and VII. The anterior division also often supplies a branch to segment I and the gallbladder. The proper hepatic artery sometimes divides at a more inferior level close to its origin, and occasionally it divides at a superior level, well to the left of the porta hepatis. The main significance of an early division is that the right hepatic artery can pass posterior to the hepatic portal vein (Launois and Jamieson 1993). The segmental arteries of the liver are macroscopically end arteries, although some collateral circulation occurs between segments via fine terminal branches.

Anatomical variants of the normal arrangement of the hepatic arteries are found in about one-third of individuals and are important to recognize because they are relevant to surgical and interventional radiological procedures (Michels 1966, Covey et al 2002, López-Andújar et al 2007, Saba and Mallarini 2011). An artery that supplies a part of the liver in addition to the normal artery supplying that part is defined as an accessory artery. A replaced hepatic artery is an artery that does not originate from an orthodox position and provides the sole supply to that part of the liver.

A replaced proper hepatic artery can arise from the superior mesenteric artery (see Fig. 66.10) and can be suspected at surgery by a relatively superficial hepatic portal vein (reflecting the absence of a hepatic artery that would normally ascend in front of the vein). More commonly, a replaced or accessory right hepatic artery arises from the superior mesenteric artery (see Figs 66.10–66.11). In such cases, the variant artery runs in the lesser omentum posterior to the hepatic portal vein and bile duct and can usually be identified at surgery by palpable pulsation posterior to the hepatic portal vein. An accessory right hepatic artery can be injured during resection of the pancreatic head because it lies close to the hepatic portal vein. Occasionally a replaced or accessory left hepatic artery arises from the left gastric artery, entering the liver through the umbilical fissure; this artery provides a source of collateral supply in cases where the arteries at the porta hepatis are occluded, but it can also be injured during mobilization of the stomach as it lies in the superior portion of the lesser omentum. Rarely an accessory left or right hepatic artery arises from the gastroduodenal artery or directly from the aorta. The presence of replaced arteries can be life-saving in patients with bile duct cancer; because they are further away from the bile duct they tend to be spared from infiltration by the cancer, making excision of the tumour feasible. Knowledge of these variations is also essential when whole and split liver transplantation is performed, and their presence often requires reconstruction.

The most common anatomical variants are a replaced or accessory left hepatic artery that arises from the left gastric artery, or a replaced or accessory right hepatic artery that arises from the superior mesenteric artery, both occurring in 10–20% of individuals.

Variations in the intrahepatic arteries are common and can be important surgically. For example, the segment IV artery most commonly arises from the left hepatic artery, but in up to 30% of cases it arises from the right hepatic artery or the proper hepatic artery (Onishi et al 2000). The segment IV artery never arises to the right of the common hepatic duct, which means that if the right hepatic artery is divided to the right of the common hepatic duct, the arterial supply to segment IV is not endangered. Failure to recognize this variation can compromise the blood supply to segment IV following right hepatectomy, and it is especially important during right liver donation for live donor liver transplantation.

Right gastric artery

The right gastric artery is a relatively small artery that usually arises from the proper hepatic artery and runs forwards into the lesser omentum just above the superior part of the duodenum. It then travels within the lesser omentum along the lesser curvature of the stomach, giving off multiple branches to the anterior and posterior surfaces of the stomach, before anastomosing with the left gastric artery. Less commonly, the right gastric artery arises from the common hepatic, left hepatic or gastroduodenal arteries (Tubbs et al 2016).

Gastroduodenal artery

The gastroduodenal artery usually arises from the common hepatic artery posterior or superior to the superior part of the duodenum. It descends posterior to the retroperitoneal portion of the superior part of the duodenum to the left of the bile duct. At the inferior border of the superior part of the duodenum, it is commonly described as dividing into the right gastro-omental and superior pancreaticoduodenal arteries, but this anatomical arrangement is rare (Bradley 1973, Bertelli et al 1995, Bertelli et al 1996a) and its usual branching pattern is as follows. As it descends posterior to the superior part of the duodenum it usually gives off the posterior superior pancreaticoduodenal artery, several retroduodenal branches that supply the superior part and the proximal portion of the descending part of the duodenum, and a supraduodenal artery that supplies the anterosuperior part of the proximal duodenum (Bianchi and Albanèse 1989). As the gastroduodenal artery emerges inferior to the superior part of the duodenum it usually gives off the right gastro-omental artery and several pyloric branches. It then descends on the anterior surface of the pancreas, where it divides into the anterior superior pancreaticoduodenal artery and pancreatic branches. Although the gastroduodenal artery usually branches from the common hepatic artery, it occasionally originates from other sources including the coeliac trunk, the superior mesenteric artery, as a trifurcation with the right and left hepatic arteries, or from the right or left hepatic artery. The gastroduodenal artery or one of its branches can be a source of haemorrhage from a penetrating posterior duodenal ulcer (see above) or a site of aneurysm or pseudoaneurysm formation, and for these reasons, it is an important vessel for interventional radiologists.

Posterior superior pancreaticoduodenal artery The posterior superior pancreaticoduodenal artery usually arises as the first branch of the gastroduodenal artery at the superior edge of the superior (first) part of the duodenum. It runs to the right, anterior to the supraduodenal segment of the bile duct, before spiralling posteriorly around the pancreatic segment of the bile duct and descending on the posterior surface of the head of the pancreas. It gives branches to the duodenum, head of the pancreas and bile duct before anastomosing with the posterior inferior pancreaticoduodenal artery to form the posterior pancreaticoduodenal arcade. The posterior superior pancreaticoduodenal artery can also give origin to the retroduodenal and supraduodenal arteries that supply the duodenum (Bertelli et al 1996a). The spiral course of the posterior superior pancreaticoduodenal artery reflects its embryonic development: it is the artery to the anterior aspect of the ventral pancreatic bud and the bile duct that subsequently rotate clockwise posterior to the duodenum and dorsal pancreatic bud (Bertelli et al 1997).

Anterior superior pancreaticoduodenal artery The anterior superior pancreaticoduodenal artery usually arises as the smaller terminal branch of the gastroduodenal artery, together with the right gastro-omental artery. It originates posterior to the superior portion of the duodenum and runs inferiorly on the anterior aspect of the head of the pancreas at a variable distance medial to the groove between the descending duodenum and head of the pancreas. It passes inferiorly around the right or inferior border of the head of the pancreas, often piercing the gland to reach the posterior surface of the uncinate process, where it joins the anterior inferior pancreaticoduodenal artery to form the anterior pancreaticoduodenal arcade (Bertelli et al 1995).

Right gastro-omental artery The right gastro-omental artery usually originates from the gastroduodenal artery behind the superior part of the duodenum, anterior to the head of the pancreas. It passes inferiorly towards the midline just below the pylorus and then runs laterally along the greater curvature between the layers of the greater omentum about 1–2 cm from the greater curvature of the stomach. It ends by anastomosing with the left gastro-omental artery (although this anastomosis is variably developed (Ndoye et al 2006) and can be absent). The right gastro-omental artery gives off gastric branches that ascend onto the anterior and posterior surfaces of the pyloric antrum and distal body of the stomach, omental branches that descend into the greater omentum, and duodenal branches that contribute to the supply of the inferior aspect of the superior part of the duodenum. The course of the right gastro-omental artery can vary: it can pass down into the greater omentum before arching back towards the greater curvature; it is important that the surgeon appreciates this anatomical variation if relying on the right gastro-omental artery to supply a surgically fashioned gastric conduit during reconstruction following oesophagectomy.

Splenic artery

The artery almost always arises from the coeliac trunk, in common with the left gastric and common hepatic arteries. However, it can originate from the common hepatic artery or the left gastric artery, or, rarely, directly from the abdominal aorta either in isolation or as a splenomesenteric trunk (Tubbs et al 2016). From its origin, the artery runs a little way inferiorly before turning to the left behind the stomach to run horizontally anterior to the left kidney and left suprarenal gland and behind or above the tail of the pancreas in the splenorenal ligament (see Fig. 68.6A). Multiple loops or even coils of the artery appear above the superior border of the pancreas (McFee et al 1995, Pandey et al 2004). The splenic artery gives off multiple small branches along its course that penetrate and supply the pancreas, including the dorsal pancreatic artery, the great pancreatic artery, arising approximately two-thirds of the way along the gland, and the artery to the tail of the pancreas, arising near the tail. These branches lie on or within the posterior aspect of the gland and often anastomose with the inferior pancreatic artery. Anatomical variations are not unusual, and the dorsal, great or inferior pancreatic arteries can be dominant in any one individual (Wu et al 2011). Near its termination, the splenic artery gives off the short gastric arteries and the left gastro-omental artery (Skandalakis et al 1993). Additional variant branches include a posterior gastric artery and small retroperitoneal branches.

The splenic artery is one of the most tortuous arteries in the body (see Fig. 69.6). The reason for the tortuosity, which can become more pronounced with advancing age, is not understood, although there have been several proposals (Cortés and Pellico 1988, García-Porrero and Lemes 1988, Borley et al 1995, Sylvester et al 1995, Liu et al 1996, Pandey et al 2004). The artery is 8–32 cm long and its calibre usually exceeds that of the common hepatic and left gastric arteries, which range from 3 to 12 mm. Splenic arterial blood flow is approximately 3 ml/sec/100 g, corresponding to approximately 7% of cardiac output (Trubel et al 1985, Cortés and Pellico 1988, García-Porrero and Lemes 1988, Nakamura et al 1989, Skandalakis et al 1993, Romero-Torres 1998, Pandey et al 2004).

The splenic artery usually divides into two, or occasionally three, branches before entering the splenic hilum. The superior and inferior branches are sometimes known as superior and inferior polar arteries; as they enter the hilum they divide into four or five segmental arteries, each of which supplies a segment of splenic tissue. There is relatively little arterial collateral circulation between segments, which means that occlusion of a segmental vessel often leads to infarction of part of the spleen. Segmental arteries divide within the splenic trabeculae, becoming trabecular arteries. These leave the trabeculae and give rise to central arterioles that are surrounded by thick lymphoid sheaths of white pulp. Central arterioles ramify into several penicillar arterioles that feed the sinusoids of the red pulp. There is considerable communication among arterioles (Mikhail et al 1979, García-Porrero and Lemes 1988, Trubel et al 1988, Sow et al 1991, Liu et al 1996).

Dorsal pancreatic artery

The dorsal pancreatic artery commonly arises from the initial 2 cm of the splenic artery, although it can also take origin from the common hepatic or superior mesenteric arteries or the coeliac trunk (Horiguchi et al 2008). It is short and gives off numerous branches, including a terminal left branch near the inferior border of the gland. Several right-sided branches run to the head of the pancreas, passing either posterior or anterior to the superior mesenteric vein to supply the posterior or anterior surface of the head of the pancreas, respectively; they anastomose with arteries of the pancreaticoduodenal arcade (Tsutsumi et al 2014). The terminal left branch anastomoses with the inferior pancreatic artery.

The length and course of the dorsal pancreatic artery depend primarily on its site of origin. When it arises from the splenic artery, common hepatic artery or coeliac trunk, it runs inferiorly on the dorsal surface of the pancreas, whereas if it arises from the superior mesenteric artery, it runs superiorly. These variations should be taken into account during organ procurement because injury to the dorsal pancreatic artery, including at its origin, can jeopardize the pancreatic graft as a result of inadequate perfusion of the tail of the pancreas (Baranski et al 2016). The artery uniformly terminates near the inferior border of the pancreas

close to the confluence of the splenic and superior mesenteric veins (Bertelli et al 1998).

Kirk's arcade is formed by a right branch of the dorsal pancreatic artery that emerges on to the anterior surface of the head of the gland and anastomoses with a branch of either the gastroduodenal artery or the anterior pancreaticoduodenal arcade (Woodburne and Olsen 1951). It supplies the ventral surface of the head and neck of the gland.

Inferior pancreatic artery The inferior (transverse) pancreatic artery commonly originates from the left terminal branch of the dorsal pancreatic artery. It runs to the left on the posterior surface of the gland close to its inferior border, gives multiple branches to the body and tail, and anastomoses with other pancreatic branches of the splenic artery. Occasionally the inferior pancreatic artery originates from the gastroduodenal artery or the anterior superior pancreaticoduodenal artery, crossing the anterior surface of the head of the pancreas to reach the inferior border of the neck of the gland and then the tail. In such cases it may be the dominant artery to the body of the pancreas, and its injury or deliberate ligation during pancreaticoduodenectomy can cause ischaemia of the pancreas.

Short gastric arteries

For practical purposes, the short gastric arteries can be defined as those arteries arising above the level of the splenic artery and supplying the fundus of the stomach on its greater curvature. The short gastric arteries vary in number, commonly between five and seven. They arise from the splenic artery or its terminal divisions, or from the proximal left gastro-omental artery, and pass between the layers of the gastrosplenic ligament to supply the fundus of the stomach and cardiac orifice. They anastomose with branches of the left gastric and left gastro-omental arteries. Rarely an accessory left gastric artery arises with these vessels from the distal splenic artery.

Left gastro-omental artery

The left gastro-omental artery is the largest branch of the splenic artery. It arises near the splenic hilum and runs anteroinferiorly between the layers of the gastrosplenic ligament into the proximal gastrocolic part (gastrocolic ligament) of the greater omentum. Here, it descends between the layers of peritoneum close to the greater curvature and often anastomoses with the right gastro-omental artery. It gives off gastric branches to the fundus of the stomach through the gastrosplenic ligament, and to the body of the stomach through the gastrocolic ligament. These are necessarily longer than the gastric branches of the right gastro-omental artery and can be up to 8 cm long. Omental branches arise along the course of the vessel and descend between the layers of the greater omentum. A particularly large omental branch commonly originates close to the origin of the left gastro-omental artery, descends in the lateral portion of the greater omentum and provides a large arterial supply to this part.

Posterior gastric artery

A posterior gastric artery supplying the posterior wall of the upper part of the body of the stomach is commonly present but there has been a lack of consensus regarding its origin, course and distribution. When present, it usually arises from the splenic artery (typically from its midsection) posterior to the body of the stomach (see Fig. 63.11) and ascends behind the peritoneum of the omental bursa towards the fundus to reach the posterior surface of the stomach. It can also arise from the left gastric artery or coeliac trunk (Loukas et al 2007a).

Superior mesenteric artery

The superior mesenteric artery is the artery of the midgut. It originates from the abdominal aorta approximately 1–2 cm below the coeliac trunk, at the level of the body of the first lumbar vertebra (Mirjalili et al 2012b) (see Figs 64.13–64.14).

The angle of the origin of the superior mesenteric artery from the aorta is acute (mean value 45°, range 38–60° and greater in individuals with a greater body mass index; Ozkurt et al 2007). Among the major branches of the descending aorta, the superior mesenteric artery typically has the most acute take-off angle. The result is less turbulent flow, which makes embolic events more likely than in the other visceral arterial branches of the abdominal aorta. The acuteness of the angle between the aorta and superior mesenteric artery can make intravascular cannulation via the transfemoral route somewhat difficult. The artery is usually surrounded by fat, lymphatics and neural tissue at its origin, which helps to increase the angle and the distance between it and the aorta, thereby preventing compression of the duodenum where it is crossed by the artery. The artery runs steeply downwards, anterior to the uncinate process of the pancreas and the horizontal part of the duodenum and posterior to the splenic vein and the body of the pancreas. The left renal vein lies posterior to it and separates it from the aorta (see Fig. 64.15B). Within the small intestine mesentery, the superior mesenteric artery crosses anterior to the inferior vena cava, right ureter and right psoas major. Its calibre progressively decreases as successive branches are given off to the jejunum and ileum, and its terminal branch anastomoses with the termination of the ileocolic artery.

Anatomical variations in the origin and branching pattern of the superior mesenteric artery are well described (Winston et al 2007, Horton and Fishman 2010, Tubbs et al 2016), the most common being an accessory or replaced right hepatic artery arising near the origin of the superior mesenteric artery. Present in about 15% of individuals, the accessory or replaced right hepatic artery courses posterior to the hepatic portal vein and ascends posterolateral to the bile duct (Winston et al 2007). It can be the source of the common hepatic, gastroduodenal, accessory or replaced right hepatic, accessory pancreatic, splenic or rarely the inferior mesenteric artery. Also rare is a superior mesenteric artery arising from a common coeliacomesenteric trunk (Rountas et al 2013). The remnant of the omphalomesenteric artery (vitelline artery) (the embryonic artery that originally connected the intestinal circulation to the yolk sac) is usually obliterated; when present, it forms the artery supplying a congenital ileal diverticulum. It is occasionally represented in the mesentery by a fibrous strand from the termination of the superior mesenteric artery to the ileum.

Branches from the superior mesenteric artery supply the jejunum and ileum. The arteries divide as they approach the mesenteric border of the intestine (see Fig. 64.5), giving off numerous branches that extend between the muscular layers before forming a submucosal arterial plexus that supplies the mucosa. Although there is a rich anastomotic network of arteries within the intestinal mesentery, there are few anastomoses between the terminal branches close to the intestinal wall. The intramural and submucosal arterial networks consist of small-calibre vessels only. Consequently, division or occlusion of several consecutive straight arteries can produce segmental ischaemia of the intestine, while division of more proximal arterial branches in the small intestine mesentery might not cause ischaemia because of collateral flow through vascular arcades.

The superior mesenteric artery usually gives off the inferior pancreaticoduodenal, middle colic, right colic and ileocolic arteries from its right side, and jejunal and ileal arteries from its left side. Its jejunal and ileal arteries form vascular arcades within the small intestine mesentery. The last of these arcades forms an irregular and incomplete marginal artery (of Drummond) of the small intestine. Straight arteries are given off from the most distal arcades and pass directly to the small intestine.

Inferior pancreaticoduodenal artery

An inferior pancreaticoduodenal artery is present in most individuals. It usually arises either directly from the superior mesenteric artery at the inferior border of the pancreas or as a common vessel with the first jejunal artery (a pancreaticoduodenojejunal trunk) from the posterior or left aspect of the superior mesenteric artery (Bertelli et al 1996b, Horiguchi et al 2008). It runs to the right, posterior to the superior mesenteric vein, to reach the posterior surface of the uncinate process, where it divides into anterior and posterior inferior pancreaticoduodenal arteries. The smaller anterior pancreaticoduodenal artery passes to the right, immediately inferior and then anterior to the inferior border of the head of the pancreas, and runs superiorly to anastomose with the anterior superior pancreaticoduodenal artery and form the anterior pancreaticoduodenal arcade. The larger posterior branch runs posteriorly and to the right, posterior to the head of the pancreas, parallel and superior to the anterior inferior pancreaticoduodenal artery, and anastomoses with the posterior superior pancreaticoduodenal artery to form the posterior pancreaticoduodenal arcade (Bertelli et al 1997). Both branches supply the head of the pancreas, its uncinate process and the superior and descending parts of the duodenum. Occasionally the anterior and posterior pancreaticoduodenal arteries arise separately from the superior mesenteric or first jejunal artery. Multiple small arteries run between the anterior and posterior pancreaticoduodenal arcades, either via the pancreaticoduodenal groove or through the substance of the gland. The largest and most consistent of these is the communicating artery (sometimes known as the middle pancreaticoduodenal arcade) that passes between the pancreatic duct and accessory pancreatic duct and connects the anterior pancreaticoduodenal arterial arcade and the posterior superior pancreaticoduodenal artery (Yamaguchi et al 2001; see Fig. 68.6C). This artery gives rise to most of the small arteries that supply the major duodenal papilla (Mirjalili and Stringer 2011).

When it arises as a pancreaticoduodenojejunal trunk, the inferior pancreaticoduodenal artery gives off a jejunal branch and then runs

posterior to both the superior mesenteric artery and vein before dividing into its terminal branches. The inferior pancreaticoduodenal artery is at risk of bleeding during the retroperitoneal dissection of a Whipple procedure. Occasionally it is absent and the anterior and posterior inferior pancreaticoduodenal arteries arise separately from the superior mesenteric artery.

Jejunal branches

Usually, 4–6 jejunal branches arise from the left side of the proximal portion of the superior mesenteric artery (see Figs 64.13–64.14). They are distributed to the jejunum via 1–3 tiers of arterial arcades, the most distal of which gives rise to straight arteries. The latter run almost parallel in the mesentery before being distributed alternately to either side of the small intestine, forming two distinct 'leaves' of vessels within the mesentery separated by a relatively avascular plane (see Fig. 64.5A). This vascular arrangement allows a dilated segment of small intestine to be bisected longitudinally and tubularized to double its length, a potentially useful technique for achieving small intestine lengthening in short bowel syndrome (Bianchi 1984). Small twigs from the jejunal arteries supply regional mesenteric nodes.

Branches from the first jejunal branch of the superior mesenteric artery supply the ascending part of the duodenum and frequently anastomose with a terminal branch of the anterior superior pancreaticoduodenal artery. The ascending part of the duodenum therefore receives a potential collateral supply from the coeliac trunk and superior mesenteric artery, which means that it is not commonly affected by ischaemia.

Ileal branches

Ileal branches are more numerous (around 8–12) and slightly smaller in calibre than jejunal branches. They arise from the left and anterior aspects of the superior mesenteric artery. The length of the mesentery from the superior mesenteric artery to the mesenteric border of the intestine is greater in the ileum, and so the branches form between two and six arcades before giving rise to multiple straight arteries that run directly towards the ileal wall (see Fig. 64.10B). These branches run parallel in the mesentery and are distributed to both aspects of the ileum. They are shorter and thinner than their jejunal counterparts, particularly in the distal ileum, and do not form such distinct parallel 'leaves' of vessels. The terminal ileal arcades are supplied by the ileal branch of the ileocolic artery and the last ileal branch of the superior mesenteric artery (see Fig. 64.13). Few other vessels connect the ileocolic and superior mesenteric artery territories, and this makes surgical dissection of the ileocolic artery up to its origin relatively simple.

Ileocolic artery

The ileocolic artery arises from the superior mesenteric artery near the root of the mesentery of the small intestine, descending within that mesentery to the right towards the caecum, and crossing anterior to the right ureter, gonadal vessels and psoas major. It usually divides into superior and inferior branches, the superior branch running up along the left side of the ascending colon to anastomose with the right colic artery (or right branch of the middle colic artery) (Veeresh et al 2012). The inferior branch runs to the ileocaecal junction and divides into anterior and posterior caecal arteries, the appendicular artery, and an ileal branch that passes to the left in the ileal mesentery to anastomose with a terminal ileal branch of the superior mesenteric artery (see Fig. 65.23). The latter therefore provides a collateral arterial supply to the caecum. The ileocolic artery provides the major arterial supply to the caecum; traction on the caecum in the direction of the anterior superior iliac spine will cause the artery to tent up the mesentery, allowing the vessel to be easily identified.

The appendicular artery usually arises directly from the ileocolic artery and descends posterior to the terminal ileum to enter the meso-appendix a short distance from the base of the appendix (see Fig. 65.23). Here, it gives off a recurrent branch that anastomoses at the proximal appendix with a branch of the posterior caecal artery. The appendicular artery approaches the distal end of the organ, at first near to and then in the edge of the meso-appendix. Its terminal part lies on the wall of the appendix and can become thrombosed in appendicitis, resulting in distal gangrene or necrosis. Less commonly, the appendicular artery arises from the posterior caecal artery or an ileal artery (Ouattara et al 2007) (see Fig. 65.12). Accessory appendicular arteries are common; two or more arteries may supply the appendix.

Right colic artery

The right colic artery is relatively small and variable in its anatomy (Batra et al 2013). It usually arises as a common trunk with the middle colic artery, but can originate directly from the superior mesenteric artery or from the ileocolic artery (when it is referred to as an accessory right colic artery) (see Fig. 65.24). It passes to the right, across the right psoas major and quadratus lumborum, crossing the right gonadal vessels and ureter. Near the left side of the ascending colon it divides into a descending branch, which runs down to anastomose with the superior branch of the ileocolic artery, and an ascending branch, which passes up across the inferior pole of the right kidney to the right colic flexure, where it anastomoses with a branch of the middle colic artery. Together, these anastomoses form the marginal artery at the right colic flexure.

Middle colic artery

The middle colic artery arises from the right side of the superior mesenteric artery, either separately or in common with the right colic artery, just inferior to the neck of the pancreas, and passes anteriorly and superiorly within the transverse mesocolon, just to the right of the midline. As it approaches the colon, it usually divides into right and left branches. The right branch anastomoses with the ascending branch of the right colic artery. The left branch supplies the terminal part of midgut derivatives and anastomoses with a branch of the left colic artery near the left colic flexure. The marginal artery thus formed lies a few centimetres from the mesenteric edge of the transverse colon. Sometimes, the middle colic artery divides into three or more branches within the transverse mesocolon, in which case the most lateral branches form the arterial anastomoses. An accessory, or rarely a replaced, middle colic artery can arise directly from the abdominal aorta (Yoshida et al 1993), dorsal pancreatic, hepatic, inferior mesenteric or left colic arteries (see Fig. 65.25). In addition, an accessory middle colic artery is occasionally found arising from the superior mesenteric artery proximal to the origin of the actual middle colic artery (Turmezei and Cockburn 2009).

Inferior mesenteric artery

The inferior mesenteric artery is smaller than the superior mesenteric artery. It arises from the anterior or left anterolateral aspect of the abdominal aorta at about the level of the body of the third lumbar vertebra, 3–4 cm proximal to the aortic bifurcation and posterior to the inferior border of the horizontal part of the duodenum. It runs obliquely down to the linea terminalis (pelvic brim) initially anterior to and then to the left of the abdominal aorta. It gives off the left colic and sigmoid arteries and crosses the origin of the left common iliac artery medial to the ureter, with the inferior mesenteric vein lying between. Beyond the linea terminalis it continues in the root of the sigmoid mesocolon as the superior anorectal artery.

Left colic artery

The left colic artery usually arises from the inferior mesenteric artery shortly after its origin, ascends within the left colic mesentery and divides into an ascending and a descending branch (see Figs 65.38–65.39). The ascending branch passes upwards across the left psoas major, gonadal vessels, ureter and left kidney, and is crossed by the inferior mesenteric vein; its terminal branches anastomose with those of the left branch of the middle colic artery within the transverse mesocolon. The descending branch passes laterally and inferiorly and anastomoses with branches from the ascending branch and the most proximal sigmoid artery to form part of the marginal artery. The arterial arcades thus formed supply the distal third of the transverse and the descending colon. The left colic artery can originate from or in common with a sigmoid artery (Murono et al 2015). Occasionally an accessory, or rarely a replaced, left colic artery originates from the trunk of the superior mesenteric artery or its middle colic or first jejunal artery. When present, it runs laterally in the upper left colic mesentery just inferior to the duodenojejunal flexure to supply the proximal descending colon, and forms all or part of the marginal artery in the region of the distal transverse colon. The left colic artery can itself give rise to an accessory left middle colic artery. Occasionally it gives rise to a branch shortly after its origin, which ascends in the mesentery and anastomoses directly with a similar descending branch of the left branch of the middle colic artery (the so-called arc of Riolan; van Gulik and Schoots 2005).

The dominant arterial supply of the left colic flexure is usually from the left colic artery but can be from the left branch of the middle colic artery. The marginal artery in this region may be absent or small, but it can enlarge considerably if the inferior mesenteric artery is stenosed or occluded.

Vascular ligation in left colonic resections

During resection of the distal descending and sigmoid colon, ligation of the inferior mesenteric artery close to its origin preserves the bifurcation of the left colic artery and helps to maintain the arterial supply to the proximal descending colon via the anastomosis between the left

branch of the middle colic artery and the ascending branch of the left colic artery. Ligation of the left colic artery close to its bifurcation can interfere with this supply and render the proximal descending colon ischaemic. Similarly, if the inferior mesenteric vein is ligated, then the bifurcation of the left colic vein forms the route of venous drainage from the proximal descending colon to the middle colic vein.

Sigmoid arteries

The inferior mesenteric artery gives rise to between two and five sigmoid arteries, which descend obliquely in the sigmoid mesocolon anterior to the left psoas major, ureter and gonadal vessels. They supply the distal descending colon and sigmoid colon and anastomose superiorly with the left colic artery and inferiorly with the superior anorectal artery. Unlike the arrangement in the small intestine, arterial arcades do not form until the arteries are close to the wall of the colon, when small branches arise to supply the sigmoid colon directly. A true marginal artery is less obvious in the sigmoid colon. There is often a significant interval in the mesentery between the highest sigmoid artery and the descending branch of the left colic artery; this forms a useful guide to the arterial territories during surgical dissection.

Superior anorectal artery

The principal arterial supply to the upper two-thirds of the rectum is via the superior anorectal artery (see Fig. 65.41). The inferior mesenteric artery crosses the left common iliac vessels medial to the ureter and descends in the medial limb of the sigmoid mesocolon, straddled by the hypogastric nerves on either side. As it crosses the linea terminalis it becomes the superior anorectal artery. At the level of the third sacral vertebra, where the rectum begins, the artery enters the proximal mesorectum in the midline and divides into two branches that descend, initially posterolaterally and then on each side of the rectum. Terminal branches pierce the rectal wall and anastomose with branches of the middle rectal and inferior anorectal arteries within the rectal submucosa.

The middle anorectal arteries arise from the internal pudendal, inferior gluteal, internal iliac arteries and less frequently from other internal iliac artery branches (DiDio et al 1986, Bilhim et al 2013). When present, they enter the mesorectum anterolaterally in the 'lateral ligaments' and provide some additional supply to the middle third of the rectum.

Inferior phrenic artery

The inferior phrenic arteries usually arise either from the aorta, just superior to the level of the coeliac trunk, or directly from the coeliac trunk; occasionally, they originate from the renal artery (Loukas et al 2005a, Gwon et al 2007). They contribute to the arterial supply of the respiratory diaphragm. Each artery ascends laterally, anterior to the crus of the respiratory diaphragm, near the medial border of the ipsilateral suprarenal gland and then divides into an ascending and a descending branch. The left ascending branch passes behind the oesophagus and runs anteriorly on the left side of the oesophageal hiatus, where it bifurcates; one branch curves anteriorly to anastomose with its counterpart anterior to the central tendon of the respiratory diaphragm and the other approaches the thoracic wall to anastomose with the musculophrenic and pericardiacophrenic arteries. The right ascending branch passes posterior to the inferior vena cava and then bifurcates; one branch runs anteriorly on the right side of the caval foramen before anastomosing with its counterpart anterior to the central tendon of the respiratory diaphragm, and the other passes laterally on the inferior surface of the diaphragm. The descending branches on each side supply the respiratory diaphragm and anastomose with the lower posterior intercostal and musculophrenic arteries. Each inferior phrenic artery gives off two or three small superior suprarenal arteries. The abdominal part of the oesophagus, fibrous capsule of the liver and the superior border of the spleen may also receive small arterial twigs from this vessel.

The inferior phrenic artery may be a source of significant collateral blood flow to large hepatocellular cancers and is sometimes specifically occluded, along with the relevant hepatic artery, when such tumours are treated by arterial embolization.

Superior suprarenal artery

The superior suprarenal artery usually arises from the ipsilateral inferior phrenic artery and passes to the gland as four or five small branches. It occasionally arises from the abdominal aorta.

Middle suprarenal arteries

The right and left middle suprarenal arteries often arise from the lateral aspect of the abdominal aorta at around the level of the superior mesenteric artery and ascend slightly over the crura of the respiratory diaphragm to anastomose with the suprarenal branches of the ipsilateral inferior phrenic and renal arteries (Toni et al 1988): each is usually single, but can be multiple or absent. The right middle suprarenal artery passes posterior to the inferior vena cava near the right coeliac ganglion. The left middle suprarenal artery passes close to the left coeliac ganglion, splenic artery and the superior border of the pancreas. The middle suprarenal arteries can originate from either the ipsilateral inferior phrenic or renal artery.

Renal artery

The paired renal arteries take about 20% of the cardiac output to supply organs that represent less than 1% of total body weight. They branch laterally from the aorta at right-angles just below the origin of the superior mesenteric artery (see Figs 59.5A, 72.10A). Both cross the corresponding crus of the respiratory diaphragm. The right renal artery is longer and often slightly higher, passing posterior to the inferior vena cava, right renal vein, head of the pancreas, and descending part of the duodenum. The left renal artery is often a little lower and passes behind the left renal vein, the body of the pancreas and the splenic vein. It may be crossed anteriorly by the inferior mesenteric vein.

A single renal artery to each kidney is present in approximately 70% of individuals (see Fig. 72.11). The arteries vary in their level of origin and in their calibre, obliquity and precise relations. In its extrarenal course, each renal artery gives off one or more inferior suprarenal arteries, ureteric and capsular branches, and branches that supply perirenal tissue and the renal pelvis. Near the hilum of the kidney, each artery divides into an anterior and a posterior branch, and these divide into segmental arteries supplying the renal vascular segments. Accessory renal arteries are common (in approximately 30% of individuals) and usually arise from the abdominal aorta above or below (most commonly below) the renal artery and follow it to the hilum (see Fig. 72.10B–D). Accessory vessels to the inferior pole cross anterior to the ureter and can, by obstructing the ureter, cause hydronephrosis. In children with ureteropelvic junction obstruction, a crossing vessel is found in 28% of cases (Veyrac et al 2003). Three anatomical variants of aberrant lower pole crossing vessels have been described: either anterior to the dilated renal pelvis or ureteropelvic junction, or inferior to the ureteropelvic junction, causing kinking of the ureter (Schneider et al 2013). Rarely accessory renal arteries arise from the coeliac or superior mesenteric arteries near the aortic bifurcation, or from the common iliac arteries.

The subdivisions of the renal arteries are described sequentially as segmental, lobar, interlobar, arcuate and interlobular (cortical radiate) arteries, and afferent and efferent glomerular arterioles (see Fig. 72.13).

Segmental arteries

Renal vascular segmentation was originally recognized by John Hunter in 1794, but the first detailed account of the primary pattern was produced in the 1950s from casts and radiographs of injected kidneys. Five arterial segments of the kidney have been identified (see Fig. 72.14). The superior segment occupies the anteromedial region of the superior pole. The anterior superior segment includes the rest of the superior pole and the central anterosuperior region. The inferior segment encompasses the whole inferior pole. The anterior inferior segment lies between the anterior and inferior segments. The posterior segment includes the whole posterior region between the superior and inferior segments. This is the pattern most commonly seen, and although there can be considerable variation, it is the pattern that clinicians most frequently encounter when performing partial nephrectomy. Recent anatomical and radiological analyses have suggested that there could be up to nine arterial segments for each kidney (Macchi et al 2019). Whatever pattern is present, it is important to emphasize that vascular segments are supplied by virtual end arteries. In contrast, the larger intrarenal veins have no segmental organization and anastomose freely.

Brödel described a relatively avascular longitudinal zone (the 'bloodless' line of Brödel) along the convex renal border, which was proposed as the most suitable site for surgical incision (Brödel 1911). However, many vessels cross this zone and it is far from 'bloodless'; planned radial or intersegmental incisions are therefore preferable (Macchi et al 2018). Knowledge of the vascular anatomy of the kidney is important when partial nephrectomy is undertaken for renal cell carcinoma. In this surgery, the branches of the renal artery are defined so that the surgeon can safely excise the tumour while not compromising the vascular supply to the remaining renal tissue (Novick 1998).

Lobar, interlobar, arcuate and interlobular arteries

The initial branches of segmental arteries are lobar, usually one to each renal pyramid. Before reaching the renal pyramid they subdivide into

two or three interlobar arteries, extending towards the cortex around each pyramid. At the junction of the renal cortex and medulla, interlobar arteries dichotomize into arcuate arteries, which diverge at right angles. As they arch between the renal cortex and medulla, each divides further, ultimately supplying interlobular arteries that diverge radially into the cortex. The terminations of adjacent arcuate arteries do not anastomose but end in the renal cortex as additional interlobular arteries. Though most interlobular arteries come from arcuate branches, some arise directly from arcuate, or even terminal, interlobar arteries (see Fig. 72.13). Interlobular arteries ascend towards the superficial cortex or can branch occasionally en route. Some are more tortuous and recurve towards the renal medulla at least once before proceeding towards the renal surface. Others traverse the surface as perforating arteries to anastomose with the capsular plexus (which is also supplied from the inferior suprarenal, renal and gonadal arteries).

Afferent and efferent glomerular arterioles Afferent glomerular arterioles are mainly the lateral rami of interlobular arteries. A few arise from arcuate and interlobar arteries when they vary their direction and angle of origin: deeper ones incline obliquely back towards the renal medulla, the intermediate pass horizontally, and the more superficial approach the surface of the kidney obliquely before ending in a glomerulus (see Fig. 72.13). Efferent glomerular arterioles from most glomeruli (except at juxtamedullary and, sometimes, intermediate cortical levels) soon divide to form a dense peritubular capillary plexus around the proximal and distal convoluted tubules; there are therefore two sets of capillaries – glomerular and peritubular – in series in the main renal cortical circulation, linked by efferent glomerular arterioles. The vascular supply of the renal medulla is largely from efferent arterioles of juxtamedullary glomeruli, supplemented by some from more superficial glomeruli, and 'aglomerular' arterioles (probably from degenerated glomeruli). Efferent glomerular arterioles passing into the renal medulla are relatively long, wide vessels, and contribute side branches to neighbouring capillary plexuses before entering the renal medulla, where each divides into 12–25 descending vasa recta. As their name suggests, these run straight to various depths in the renal medulla, contributing side branches to a radially elongated capillary plexus applied to the descending and ascending limbs of renal loops and to collecting ducts. The venous ends of capillaries converge to the ascending vasa recta, which drain into arcuate or interlobular veins. An essential feature of the vasa recta (particularly in the outer medulla) is that both descending and ascending vessels are grouped into vascular bundles, within which the external aspects of both types are closely apposed, bringing them close to the limbs of the nephron loops (of Henle) and collecting ducts. As these bundles converge centrally into the renal medulla, they contain fewer vessels; some terminate at successive levels in neighbouring capillary plexuses. This proximity of descending and ascending vessels to each other and to adjacent collecting ducts provides the structural basis for the countercurrent exchange and multiplier phenomena (see Fig. 72.15). These complex renal vascular patterns show regional specializations that are closely adapted to the spatial organization and functions of renal corpuscles, tubules and ducts (see below).

The renal arteries are two of the largest branches of the abdominal aorta and arise laterally just inferior to the origin of the superior mesenteric artery at about the level of the body of the first lumbar vertebra (Mirjalili et al 2012b). When the arteries arise at different cranio-caudal levels, the right ostium is usually superior to the left. The right renal artery is longer and passes posterior to the inferior vena cava, right renal vein, head of the pancreas and descending part of the duodenum. The left renal artery passes behind the left renal vein, the body of the pancreas and the splenic vein. Variations in the number, origin, course and branching patterns of the renal arteries are common.

Inferior suprarenal arteries

The inferior suprarenal arteries often contribute most of the arterial supply to the suprarenal gland. One or two arteries usually arise from the ipsilateral renal artery, but the inferior suprarenal arteries can originate from either the abdominal aorta or the ipsilateral gonadal artery.

Testicular artery

The testicular artery usually arises from the abdominal aorta, inferior to the origin of the renal artery, and courses inferolaterally under the parietal peritoneum, along psoas major towards the pelvis. On the right, it courses anterior to the inferior vena cava and posterior to the middle colic and ileocolic arteries and the terminal ileum. On the left, it courses posterior to the inferior mesenteric vein, left colic artery and the descending colon. As the right and left testicular arteries enter the pelvis they lie anterior to the genitofemoral nerves, ureters and external iliac arteries. Both arteries then enter the deep inguinal ring and travel within the ipsilateral spermatic cord in the inguinal canal to the scrotum (see Figs 74.2, 74.5). The origin, number and course of the testicular arteries can vary (Asala et al 2001, Pai et al 2008, Kotian et al 2016, Kayalvizhi et al 2017).

Proximally, the testicular artery supplies the upper and middle parts of the ureter (Daniel and Shackman 1952). Distally, in its course to the testis the testicular artery gives off one or more internal testicular arteries (MacLennan 2012), an inferior testicular artery and branches supplying the head, body and tail of the epididymis (Macmillan 1954). The level at which this branching occurs is variable; in 31–88% of cases it occurs within the inguinal canal (Beck et al 1992, Jarow et al 1992). At the level of the testis, branches of the testicular artery enter the tunica albuginea in the mediastinum of the testis and ramify in the vascular layer before reaching their distribution. The testicular arteries ramify primarily in the anterior, medial and lateral portions of the inferior pole of the testis and in the anterior segment of the superior pole (Jarow 1991, Mostafa et al 2008), which has important implications for planning testicular biopsies.

Ovarian artery

The ovarian artery originates below the renal artery and descends behind the peritoneum, crossing the external iliac artery and vein at the linea terminalis to enter the lesser pelvis. Here, the artery turns medially in the suspensory ligament of the ovary and splits into a branch to the mesovarium that supplies the ovary and a branch that continues into the broad ligament, below the uterine tube, and supplies the tube. There are variations in the site of the division to the ovary and tube (see Fig. 75.21). On each side a branch passes lateral to the uterus to unite with the uterine artery. Other branches accompany the round ligaments through the inguinal canal to the skin of the labium majus and the inguinal region. Early in intrauterine life, the ovaries flank the vertebral column inferior to the kidneys and so the ovarian arteries are relatively short; they gradually lengthen as the ovaries descend into the pelvis.

Lumbar arteries

There are usually four lumbar arteries on each side, in series with the posterior intercostal arteries. They arise from the posterolateral aspect of the abdominal aorta, opposite the lumbar vertebrae. A fifth, smaller, pair occasionally arises from the median sacral artery, but lumbar branches of the iliolumbar arteries often take their place. The lumbar arteries run posterolaterally on the first to the fourth lumbar vertebral bodies, passing behind the sympathetic trunk and tendinous arches formed by the attachments of psoas major to the vertebral bodies. The right lumbar arteries pass posterior to the inferior vena cava. The superior two right lumbar arteries and the first left lumbar artery lie behind the corresponding crus of the respiratory diaphragm. Just beyond the intervertebral foramina, each lumbar artery divides into a medial branch, which gives off spinal and ganglionic branches; a middle branch, from which dorsal and anastomotic branches arise; and a lateral branch, which supplies the abdominal wall (Arslan et al 2011). Of particular importance is the spinal branch known as the great radicular artery (artery of Adamkiewicz), which frequently originates from an upper lumbar artery, particularly on the left side (Biglioli et al 2004). Injury to this vessel, e.g. during thoracoabdominal aortic surgery, can cause spinal cord infarction.

The lateral branch of each lumbar artery runs posterior to psoas major and the lumbar plexus, then across the anterior surface of quadratus lumborum, before piercing the posterior aspect of transversus abdominis to run forwards between it and internal abdominal oblique. Perforating branches pass posteriorly to supply the muscles and skin of the posterior abdominal wall (Kiil et al 2009). The lumbar arteries anastomose with one another and the lower posterior intercostal, subcostal, iliolumbar, deep circumflex iliac and inferior epigastric arteries.

The dorsal branch of each lumbar artery passes backwards between the adjacent transverse processes to supply the back muscles, vertebrae and their joints and the skin of the back.

Median sacral artery

The median sacral artery is a small branch that usually arises from the posterior aspect of the aorta a little above its bifurcation. It descends close to the midline, anterior to the fourth and fifth lumbar vertebrae, sacrum and coccyx. At the level of the fifth lumbar vertebra it is crossed by the left common iliac vein and often gives off a small lumbar artery (arteriae lumbales imae), whose small branches reach the anus and rectum via the anococcygeal ligament. Anterior to the fifth lumbar vertebra, the median sacral artery anastomoses with a lumbar branch of the iliolumbar artery. Anterior to the sacrum, it anastomoses with the lateral sacral arteries and sends branches into the anterior sacral foramina.

Common iliac arteries

The abdominal aorta bifurcates into the right and left common iliac arteries anterolateral to the left side of the body of the fourth lumbar vertebra (Roberts and Krishingner 1967). These arteries diverge as they descend and they divide at the level of the sacro-iliac joint into external and internal iliac arteries. The anteroposterior diameters of the common, external and internal iliac arteries are strongly correlated to body surface area (BSA) in children, in contrast to adults, where the relation is inconsistent. Vessel diameters measured by ultrasonography are significantly larger in boys than in girls (Munk et al 2002).

Each common iliac artery also gives small branches to the peritoneum, psoas major, ureter, adjacent nerves and surrounding areolar tissue. The common iliac artery occasionally gives rise to the iliolumbar artery and accessory or replaced renal arteries if the kidney is low-lying.

Right common iliac artery

The right common iliac artery is approximately 5 cm long. It passes obliquely across part of the bodies of the fourth and the fifth lumbar vertebrae, and is crossed anteriorly by the sympathetic rami to the pelvic plexus and, at its division into internal and external iliac arteries, by the ureter. It is covered by the parietal peritoneum, which separates it from the small intestine. Posteriorly, it is separated from the bodies of the fourth and fifth lumbar vertebrae and the intervening intervertebral disc by the right sympathetic trunk, the terminal parts of the common iliac veins and the start of the inferior vena cava, the obturator nerve, lumbosacral trunk and iliolumbar artery. Laterally, the inferior vena cava and the right common iliac vein lie superiorly and the right psoas major lies inferiorly. The left common iliac vein is medial to the proximal part of the right common iliac artery.

Left common iliac artery

The left common iliac artery is shorter than the right and is approximately 4 cm long. Lying anteriorly are branches of the sympathetic trunk that contribute to the superior hypogastric plexus, the superior anorectal artery and, at its terminal bifurcation, the ureter. The sympathetic trunk, the bodies of the fourth and fifth lumbar vertebrae and the intervening intervertebral disc, the obturator nerve, lumbosacral trunk and iliolumbar artery are all posterior. The left common iliac vein is posteromedial and the left psoas major is lateral.

Internal iliac arteries

The internal iliac arteries provide the principal supply to the walls and viscera of the pelvis, the perineum and the gluteal region. Each internal iliac artery is approximately 4 cm long and begins at the common iliac bifurcation, level with the lumbosacral intervertebral disc and anterior to the sacroiliac joint (see Fig. 71.5). It descends posteriorly to the superior margin of the greater sciatic foramen, where it divides into an anterior division, which continues in the same line towards the ischial spine, and a posterior division, which passes back to the greater sciatic foramen.

The ureter and, in females, the ovary and distal end of the uterine tube, are anterior to the artery. The internal iliac vein, lumbosacral trunk and sacroiliac joint are posterior. Laterally are the external iliac vein, between the artery and psoas major, and the obturator nerve lying inferior to the vein. Medially, the parietal peritoneum and tributaries of the internal iliac vein separate the artery from the terminal ileum on the right and the sigmoid colon on the left. For details of the considerable variation in the anatomy of the internal iliac artery see Tubbs et al (2016).

In the fetus, the internal iliac artery is twice the size of the external iliac artery and is the direct continuation of the common iliac artery. The main trunk ascends on the anterior abdominal wall to the umbilicus, converging on the contralateral artery, and the two arteries run through the umbilicus to enter the umbilical cord as the umbilical arteries. At birth, when placental circulation ceases, only the pelvic segment remains patent as the internal iliac artery and part of the superior vesical artery and the remainder becomes a fibrous medial umbilical ligament. Persistence of the umbilical artery has been described and can cause extrinsic obstruction of the distal ureter (Gupta et al 1999). In males, the patent part (commonly, the superior vesical artery) usually gives off the artery to the ductus deferens.

The anterior division of the internal iliac arteries primarily supply the pelvic organs via the superior and inferior vesical, middle anorectal, vaginal, obturator, uterine, internal pudendal and inferior gluteal arteries (see Fig. 71.5). It should be noted that there is significant variation in the branching patterns of the anterior division and therefore only the general principles will be considered here. The posterior division of the internal iliac arteries primarily supply muscles in the hip and back via the iliolumbar, lateral sacral and superior gluteal arteries.

Superior vesical artery

The superior vesical artery is the first large branch of the anterior division. It lies on the lateral wall of the pelvis, just inferior to the linea terminalis, and runs anteroinferiorly, medial to the periosteum of the posterior surface of the pubis. It supplies the distal end of the ureter, the fundus of the urinary bladder, the proximal end of the ductus deferens and the seminal glands. It also gives origin to the umbilical artery in the fetus, which remains as a fibrous cord – the medial umbilical ligament – in the adult. This vessel occasionally remains patent as a small artery supplying the umbilicus.

The artery to the ductus deferens often originates from one of the branches of the superior vesical artery to the fundus of the urinary bladder: it accompanies the ductus deferens to the testis, where it anastomoses with the testicular artery.

Inferior vesical artery

The inferior vesical artery sometimes arises as a common branch with the middle anorectal artery from the internal iliac artery. In the male, it supplies the fundus of the urinary bladder, prostate, seminal glands and distal ureter and sometimes provides the artery to the ductus deferens. Branches to the prostate communicate across the midline. In the female it supplies the urinary bladder, and is often replaced by the vaginal artery (de Treigny et al 2017).

Middle anorectal artery

The middle anorectal artery runs into the lateral fascial coverings of the mesorectum. It often consists of multiple branches, can be small, and occasionally arises either close to or in common with the origin of the inferior vesical artery in males.

Vaginal artery

In females, the vaginal artery sometimes replaces the inferior vesical artery. It can arise from the uterine artery close to its origin as either a single vessel or multiple branches.

Obturator artery

The obturator artery arises from the anterior division of the internal iliac artery and runs anteroinferiorly on the lateral pelvic wall to the upper part of the obturator foramen. In the pelvis, it is related laterally to the obturator fascia and is crossed on its medial aspect by the ureter and, in the male, by the ductus deferens. The obturator nerve is superior to the artery, the obturator vein inferior to it. The obturator artery provides iliac branches to the iliac fossa that supply the underlying bone and iliacus and anastomose with the iliolumbar artery. It gives off a branch that runs medially to the urinary bladder and sometimes replaces the inferior vesical artery. In the female, the ovary lies medial to the obturator artery. A pubic branch usually arises just before the obturator artery leaves the pelvis and ascends over the pubis to anastomose with the contralateral artery and the pubic branch of the inferior epigastric artery.

The obturator artery leaves the pelvis via the obturator canal. It divides into anterior and posterior branches that encircle the obturator foramen between obturator externus and the obturator membrane. The anterior branch curves anteriorly on the membrane and then inferiorly along its anterior margin to supply branches to obturator externus, pectineus, adductors longus, brevis and magnus and gracilis. It anastomoses with the posterior branch and the medial circumflex femoral artery. The posterior branch follows the posterior margin of the obturator foramen, turning anteriorly on the ischial part to anastomose with the anterior branch. It supplies the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal artery. An acetabular branch enters the hip joint at the acetabular notch, ramifies in the fat of the acetabular fossa and sends a branch along the ligament of the head of the femur.

The obturator artery is occasionally replaced by an enlarged pubic branch of the inferior epigastric artery that descends almost vertically to the obturator foramen. It usually lies near the external iliac vein, lateral to the femoral ring, and is rarely injured during inguinal or femoral hernia surgery. It may curve along the edge of the lacunar ligament, partly encircling the neck of a hernia sac, and can be cut inadvertently during enlargement of the femoral ring in reducing a femoral hernia.

Uterine artery

The uterine artery is large and it usually arises inferior to the obturator artery on the lateral wall of the pelvis, running inferomedially within the cardinal ligament. It may arise directly from the internal iliac artery,

the superior gluteal artery, obturator artery or from a common trunk with the internal pudendal artery (Chantalat et al 2014).

From its origin, the uterine artery crosses the ureter anteriorly in the broad ligament before branching as it reaches the uterus at the level of the cervico-isthmic junction (see Fig. 75.21). One major branch ascends the uterus tortuously within the broad ligament until it reaches the region of the hilum of the ovary, where it anastomoses with branches of the ovarian artery. Another branch descends to supply the cervix and anastomoses with branches of the vaginal artery to form two median longitudinal vessels, the azygos arteries of the vagina, which descend anterior and posterior to the vagina. Although there are anastomoses with the ovarian and vaginal arteries, the dominance of the uterine artery is indicated by its marked hypertrophy during pregnancy.

The tortuosity of the vessels as they ascend in the broad ligaments is repeated in their branches within the uterine wall. Each uterine artery gives off numerous branches. These enter the uterine wall, divide and run circumferentially as groups of anterior and posterior arcuate arteries. They ramify and narrow as they approach the anterior and posterior midline so that no large vessels are present in these regions. However, the left and right arterial trees anastomose across the midline and unilateral ligation can be performed without serious effects. Terminal branches in the uterine muscle are tortuous and are called helicine arterioles. They provide a series of dense capillary plexuses in the myometrium and endometrium. From the arcuate arteries, many helical arteriolar rami pass into the endometrium. Their detailed appearance changes during the menstrual cycle. Helical arterioles are less prominent during the proliferative phase, whereas they grow in length and calibre, becoming even more tortuous, during the secretory phase.

Internal pudendal artery

The internal pudendal artery is the smaller terminal branch of the anterior division of the internal iliac artery. Close to its origin it crosses anterior to piriformis, the sacral plexus and the inferior gluteal artery. It descends laterally to the inferior aspect of the greater sciatic foramen, where it leaves the pelvis between piriformis and ischiococcygeus and enters the gluteal region (see Fig. 75.4). It next curves around the posterior aspect of the ischial spine and enters the ischio-anal fossa via the lesser sciatic foramen. This course effectively allows the nerve to wrap around the posterior limit of levator ani at its attachment to the ischial spine. Posterior to the ischial spine, the artery is covered by gluteus maximus, the pudendal nerve is medial, and the nerve to obturator internus is lateral. The artery passes through the ischio-anal fossa in the pudendal canal (Alcock's canal) in the fascia covering obturator internus, giving off the inferior anorectal artery early in its course through the fossa (see Fig. 71.12). It gives off several muscular branches in the pelvis and the gluteal region to supply adjacent muscles and nerves. The internal pudendal artery enters the perineum around the posterior aspect of the ischial spine and runs on the lateral wall of the ischio-anal fossa in the pudendal canal with the internal pudendal veins and the pudendal nerve. The canal lies about 4 cm superior to the inferior limit of the ischial tuberosity and is formed by connective tissue binding the internal pudendal vessels and pudendal nerve to the medial surface of the fascia covering obturator internus. As the artery approaches the margin of the ischial ramus, it proceeds superficial or deep to the perineal membrane, along the medial margin of the inferior pubic ramus, en route to its target structures.

In the male, the internal pudendal artery distal to the perineal artery gives a branch to the bulb of the penis before it divides into the deep and dorsal arteries of the penis (see Fig. 71.12). In the female, a similar branch of the internal pudendal artery is distributed to the corpus spongiosum and vagina. The deep arteries supply the corpora cavernosa of the clitoris; the dorsal arteries supply the glans and prepuce of the clitoris.

Branches of the internal pudendal artery are sometimes derived from an accessory pudendal artery, which is usually a branch of the internal pudendal artery before its exit from the pelvis.

Inferior anorectal artery

The inferior anorectal artery is a terminal branch of the internal pudendal artery and supplies the internal and external anal sphincters, the anal canal and perianal skin. It arises just after the internal pudendal artery enters the pudendal canal on the lateral wall of the ischio-anal fossa and runs anteromedially through the adipose tissue of the fossa to enter the proximal anal canal laterally. Ascending branches supply the distal third of the rectum, anastomosing with terminal branches of the superior anorectal artery in the rectal submucosa to reach the external anal sphincter: the artery often branches before reaching the sphincter. During dissections of the anal canal, particularly during perineal excisions of the anus or rectum, the inferior anorectal vessels are encountered in the ischio-anal fossa and must be ligated before division, otherwise they tend to retract laterally, where they can cause troublesome bleeding.

Perineal artery

The perineal artery is a branch of the internal pudendal artery that arises near the anterior end of the pudendal canal and runs through the perineal membrane. In the male, it approaches the scrotum in the superficial perineal space, between bulbospongiosus and ischiocavernosus (see Fig. 74.24). A small transverse branch passes medially, inferior to the superficial transverse perineal muscle, to anastomose with the contralateral artery and with the posterior scrotal and inferior anorectal arteries. It supplies the transverse perinei, the perineal body and the posterior attachment of the bulb of the penis. The posterior scrotal arteries are usually terminal branches of the perineal artery but can also arise from its transverse branch. They are distributed to the scrotal skin and dartos in the male and supply the perineal muscles. In the female, the perineal artery runs an almost identical course to that in the male and gives off posterior labial branches (see Fig. 75.4).

Artery to the bulb of the penis

The artery to the bulb of the penis penetrates the perineal membrane to enter the corpus spongiosum from above its posterolateral border and supplies the bulb of the penis and the urethra, in addition to the corpus spongiosum and glans penis.

Dorsal artery of the penis

The dorsal artery of the penis passes between the crus of the penis and the pubis to reach the dorsal surface of the corpus cavernosum. It runs alongside the deep dorsal vein of the penis and the dorsal nerve of the penis and is attached, together with these structures, to the underside of the deep fascia of the penis. As it courses to the glans penis it gives off circumferential branches to the corpus spongiosum and spongy urethra. The rich blood supply to the corpus spongiosum allows the urethra to be divided safely during stricture repair.

Deep artery of the penis

The deep artery of the penis is often a paired vessel that pierces the tunica albuginea of the corpora cavernosa proximally and then travels near the centre of the corporal bodies in the direction of the glans penis. Along its course it gives off several straight and helicine branches at regular intervals; they open directly into the cavernous spaces of the corporal bodies.

Variations in penile vascular anatomy are common and can include a single or absent cavernous artery or the presence of accessory pudendal arteries (Bare et al 1994, Matin 2006). While the penile arterial supply is commonly derived from both accessory and internal pudendal arteries, it can be derived exclusively from either the internal pudendal arteries or the accessory pudendal arteries (Droupy et al 1997). Recognizing such variation is extremely important for any surgeon contemplating penile revascularization surgery.

The artery to the bulb of the penis supplies the corpus spongiosum, and the deep artery of the penis supplies the corpus cavernosum on each side. The dorsal artery runs on the dorsal aspect of the penis and supplies circumflex branches to the corpora cavernosa and corpus spongiosum that end by anastomosing near the corona of the glans and supplying the glans and prepuce of the penis.

Inferior gluteal artery

The inferior gluteal artery is the larger terminal branch of the anterior division of the internal iliac artery. It descends posteriorly, anterior to the sacral plexus and piriformis but posterior to the internal pudendal artery. It passes between either the first and second, or the second and third, sacral ventral rami, then between piriformis and ischiococcygeus, before running through the inferior aspect of the greater sciatic foramen to reach the gluteal region. It next runs inferiorly with the sciatic and posterior femoral cutaneous nerves, deep to gluteus maximus and between the greater trochanter and ischial tuberosity, and continues down the thigh, supplying the skin and anastomosing with branches of the perforating arteries. The inferior gluteal and internal pudendal arteries often arise as a common stem from the internal iliac artery, sometimes with the superior gluteal artery. In the pelvis, the inferior gluteal artery gives branches to piriformis, ischiococcygeus and iliococcygeus, and occasionally gives rise to the middle anorectal artery. It can supply vessels to the seminal glands and prostate.

Arteria comitans nervi ischiadici (artery to sciatic nerve)

The arteria comitans nervi ischiadici is a direct or indirect branch of the internal iliac artery, and runs on the surface of, or within, the sciatic

nerve. It represents the primitive axial artery of the lower limb. The artery is usually a very small vessel; occasionally, it persists as a large vessel, in which case the femoral artery is correspondingly reduced in size. The artery may participate in collateral circulatory pathways.

Iliolumbar artery

The iliolumbar artery is the first branch of the posterior division of the internal iliac artery and ascends laterally anterior to the sacro-iliac joint and lumbosacral trunk. It lies posterior to the obturator nerve and external iliac vessels, and reaches the medial border of psoas major, dividing behind it into the lumbar and iliac branches. The lumbar branch supplies psoas major and quadratus lumborum, and anastomoses with the fourth lumbar artery. It sends a small spinal branch through the intervertebral foramen between the fifth lumbar and first sacral vertebrae to supply radicular branches to the cauda equina. The iliac branch supplies iliacus; between the muscle and bone it anastomoses with the iliac branches of the obturator artery. A large nutrient branch enters an oblique canal in the ilium. Other branches run around the iliac crest, contribute to the supply of gluteal and abdominal muscles, and anastomose with the superior gluteal, circumflex iliac and lateral circumflex femoral arteries.

Lateral sacral arteries

The lateral sacral arteries are usually double. If they are single, they soon divide into superior and inferior branches. The superior and larger branch passes medially into the first or second anterior sacral foramen, supplies the sacrum and contents of the sacral canal, and then leaves the sacrum via the corresponding dorsal foramen to supply the skin and muscles posterior to the sacrum. The inferior branch crosses obliquely anterior to piriformis and the sacral ventral rami, and then descends lateral to the sympathetic trunk to anastomose with its fellow and the median sacral artery anterior to the coccyx. Its branches enter the anterior sacral foramina and are distributed in the same way as the branches of the superior artery.

Superior gluteal artery

The superior gluteal artery is the largest branch of the internal iliac artery and effectively forms the main continuation of its posterior division. It runs posteriorly between the lumbosacral trunk and the first sacral ventral ramus, or between the first and second sacral ventral rami, and then turns slightly inferiorly, leaving the pelvis via the greater sciatic foramen above piriformis and dividing into superficial and deep branches. In the pelvis, it supplies piriformis, obturator internus and a nutrient artery to the ilium. The superficial branch enters the deep surface of gluteus maximus. Its numerous branches supply the muscle and anastomose with the inferior gluteal branches (see Fig. 77.47), while others perforate the tendinous medial attachment of the muscle to supply the skin over the sacrum, where they anastomose with the posterior branches of the lateral sacral arteries. The deep branch of the superior gluteal artery passes between gluteus medius and the ilium, soon dividing into superior and inferior branches. The superior branch skirts the superior border of gluteus minimus to the anterior superior iliac spine and anastomoses with the deep circumflex iliac artery and the ascending branch of the lateral circumflex femoral artery. The inferior branch runs through gluteus minimus obliquely, supplies it and gluteus medius, and anastomoses with the lateral circumflex femoral artery. A branch enters the trochanteric fossa to join the inferior gluteal artery and ascending branch of the medial circumflex femoral artery; other branches run through gluteus minimus to supply the hip joint.

The superior gluteal artery occasionally arises directly from the internal iliac artery with the inferior gluteal artery and sometimes from the internal pudendal artery.

External iliac arteries

The external iliac arteries are the principal arteries of the lower limbs. They are larger than the internal iliac arteries (see Figs 71.5–71.6). Each artery descends laterally along the medial border of psoas major, from the common iliac bifurcation to a point midway between the anterior superior iliac spine and the pubic symphysis, and enters the thigh posterior to the inguinal ligament to become the femoral artery.

The parietal peritoneum and extraperitoneal tissue separate the right external iliac artery from the terminal ileum and, usually, the appendix, and the left external iliac artery from the sigmoid colon and coils of small intestine anteromedially. The external iliac artery can be crossed at its origin by the ureter and it is subsequently crossed by the gonadal vessels, the genital branch of the genitofemoral nerve, the deep circumflex iliac vein, and the ductus deferens or round ligament of the uterus. Posteriorly, the artery is separated from the medial border of psoas major by the iliac fascia. The external iliac vein lies partly posterior to its upper part but is more medial below. Laterally, it is related to psoas major, which is covered by the iliac and psoas fasciae. Numerous lymph vessels and nodes lie on its anterior and lateral aspects. The external iliac artery primarily supplies the lower limb and as such has few branches in the pelvis. It gives off very small vessels to psoas major and neighbouring lymph nodes, but has no other branches until it gives off the deep circumflex iliac and inferior epigastric arteries, near to where it passes deep to the inguinal ligament.

Deep circumflex iliac artery

The deep circumflex iliac artery branches laterally from the external iliac artery almost opposite the origin of the inferior epigastric artery (see Fig. 76.4A). It ascends and runs laterally to the anterior superior iliac spine deep to the inguinal ligament in a sheath formed by the union of the transversalis and iliac fasciae. There, it anastomoses with the ascending branch of the lateral circumflex femoral artery, pierces the transversalis fascia and skirts the inner lip of the iliac crest. About halfway along the iliac crest, it runs through transversus abdominis, and then between transversus abdominis and internal abdominal oblique, to anastomose with the iliolumbar and superior gluteal arteries. It gives off a large ascending branch at the anterior superior iliac spine that runs between internal abdominal oblique and transversus abdominis, supplies both muscles, and anastomoses with the lumbar and inferior epigastric arteries.

Inferior epigastric artery

The inferior epigastric artery originates from the external iliac artery posterior to the inguinal ligament. It curves forwards in the anterior extraperitoneal tissue, ascends obliquely along the medial margin of the deep inguinal ring, and continues as an artery of the anterior abdominal wall.

The inferior epigastric artery (often referred to as the deep inferior epigastric artery in clinical practice in order to distinguish it from the superficial (inferior) epigastric artery) originates from the medial aspect of the external iliac artery just proximal to where the vessels pass deep to the inguinal ligament (see Figs 60.1–60.3). Its accompanying veins, usually two, unite to form a single vein that drains into the external iliac vein (Rozen et al 2009). The vessel curves forwards in the extraperitoneal tissue and ascends obliquely along the medial margin of the deep inguinal ring. It lies posterior to the spermatic cord, separated from it by the transversalis fascia. It pierces the transversalis fascia and enters the posterior layer of the rectus sheath by passing anterior to the arcuate line. In this part of its course it is visible through the parietal peritoneum of the anterior abdominal wall and with this covering forms the lateral umbilical fold. Disruption of the artery by surgical incisions (e.g. insertion of laparoscopic ports, surgical tacks or abdominal drains) can cause a haematoma, which can expand to considerable size because there is no adjacent tissue against which the bleeding can be tamponaded.

The ductus (vas) deferens in males or the round ligament of the uterus in females, pass medially after hooking around the inferior epigastric artery at the deep inguinal ring. The inferior epigastric vessels form the lateral border of the inguinal triangle (Hesselbach's triangle). The boundaries of this anatomical region are seen during laparoscopic inguinal hernia repair: the inferior border of the triangle is formed by the iliopubic tract/inguinal ligament and the medial border by the lateral margin of rectus abdominis. Hernias occurring within the triangle are termed direct inguinal hernias.

The inferior epigastric arteries ascend and anastomose with their superior counterparts as a single vessel in only about 30% of cases (El-Mrakby and Milner 2002). Branching into two vessels before anastomosing is the most common pattern, accounting for almost 60%, with a trifurcation in the remainder. The inferior epigastric arteries have an average diameter of approximately 3 mm at their origin, compared to an average diameter of 1.6 mm at the origin of the superior epigastric arteries, presumably explaining why the inferior epigastric arteries provide the 'dominant' blood supply to rectus abdominis. Preliminary ligation of the inferior epigastric artery is often performed when preparing a myocutaneous flap from the mid or lower rectus abdominis based on the superior epigastric artery; this encourages augmentation of the superior epigastric arterial supply.

Branches of the inferior epigastric artery anastomose with branches of the superior epigastric artery within rectus abdominis at a variable level proximal to the umbilicus (Rozen et al 2008). Other branches anastomose with terminal branches of the distal five posterior intercostal, subcostal and lumbar arteries at the lateral border of the rectus sheath. Inferolaterally, branches anastomose with the deep circumflex

iliac artery. The inferior epigastric artery also gives off the cremasteric artery, a pubic branch, and muscular and cutaneous branches.

Cremasteric artery

The cremasteric artery is a branch of the inferior epigastric artery. It accompanies the spermatic cord and supplies cremaster and other coverings of the cord and anastomoses with the testicular artery. Both the artery to the ductus deferens and the cremasteric artery enter the inguinal canal at the deep inguinal ring and travel the length of the spermatic cord alongside the testicular artery. The testicular artery and pampiniform plexus lie within the internal spermatic fascia, whereas the ductus deferens and its vessels, as well as cremaster and its vessels, lie outside the internal spermatic fascia but within the external spermatic fascia. In the scrotum, there is a rich vascular anastomosis at the head of the epididymis, between the testicular artery and the epididymal artery, and at the tail of the epididymis between the testicular, epididymal, and cremasteric arteries and the artery to the ductus deferens.

In females, the homologous artery is small and accompanies the round ligament of the uterus.

Pubic branch

A pubic branch, near the femoral ring, descends posterior to the pubis and anastomoses with the pubic branch of the obturator artery. The pubic branch of the inferior epigastric artery can be larger than the obturator artery and supply most of the territory of the obturator artery in the thigh, in which case it is referred to as the aberrant obturator artery (Pai et al 2009). It lies close to the medial border of the femoral ring and can be injured during medial dissection of the ring in femoral hernia repair, laparoscopic inguinal hernia repair, or with pelvic fractures.

Muscular and cutaneous branches

Muscular branches supply the abdominal muscles and peritoneum and anastomose with the circumflex iliac and lumbar arteries. Cutaneous branches arise within rectus abdominis, and perforate the aponeurosis of external abdominal oblique to supply the overlying skin; they anastomose with branches of the superficial epigastric artery, contributing to the 'periumbilical perforator vessels'. These perforating vessels have been mapped in detail because they are particularly important in creating large lipocutaneous flaps on the abdominal wall: if this requires ligation of these vessels, the flap is at risk of necrosis (Rozen et al 2008).

Occasionally the inferior epigastric artery arises from the femoral artery. It then ascends anterior to the femoral vein, passing deep to the inguinal ligament and into the abdominal cavity before following its usual abdominal course. Rarely it arises from the external iliac artery in common with an aberrant obturator artery or from the obturator artery itself.

The superior and inferior epigastric arteries are important sources of collateral blood flow between the internal thoracic artery, the external iliac artery and the lumbar vessels when aortic blood flow is compromised. Additionally, small tributaries of the inferior epigastric vein draining the skin around the umbilicus anastomose with terminal branches of the umbilical vein that drain into the liver via the falciform ligament. These portosystemic communications can dilate substantially in patients with portal hypertension, resulting in portal venous blood draining into the systemic circulation via the inferior epigastric veins. Back pressure to the level of the skin leads to a pattern of dilated, serpiginous superficial veins radiating out from the umbilicus, referred to as the 'caput medusae'.

SUBCLAVIAN ARTERY AND ARTERIAL SUPPLY OF THE UPPER LIMB

The stem artery of the upper limb is single as far as the elbow, but its name changes as it traverses different regions. From its origin to the outer border of the first rib it is the subclavian artery. From the outer border of the first rib to the tendon of teres major it is the axillary artery and from the tendon of teres major to its division at the elbow it is the brachial artery.

Subclavian artery

The right subclavian artery arises from the brachiocephalic trunk, the left from the aortic arch (see Figs 35.14, 35.18).

For description, each is divided into a first part, from its origin to the medial border of scalenus anterior; a second part posterior to scalenus anterior; and a third part from the lateral margin of scalenus anterior to the outer border of the first rib, where the subclavian artery becomes the axillary artery. The subclavian artery gives off the vertebral, internal thoracic, thyrocervical, costocervical and dorsal scapular arteries. On the left, all the branches except the dorsal scapular artery arise from the first part. On the right, the costocervical trunk usually arises from the second part. The suprascapular artery (usually a branch of the thyrocervical trunk) may arise from the third part of the subclavian artery.

Each subclavian artery arches over the cervical pleura and pulmonary apex. The first parts differ on the right and left sides, whereas the second and third parts are almost identical.

First part of right subclavian artery

The right subclavian artery arises from the brachiocephalic trunk either posterior to the right sternoclavicular joint or immediately superior to it (level with the body of the second thoracic vertebra or T1–T2 intervertebral disc (Badshah et al 2017)) (see Fig. 52.3). It ascends superolaterally to the level of the first rib, where it is located posterior to both the sternal end of the clavicle and scalenus anterior; it has a minimal intrathoracic presence. The vessel then passes inferolaterally across the superior surface of the first rib, and at the external border of the rib becomes the right axillary artery (see Fig. 48.3). It usually ascends 2 cm above the clavicle but this varies.

Relations The artery is deep to the skin, superficial fascia, platysma, supraclavicular nerves, deep fascia, clavicular attachment of sternocleidomastoid, sternohyoid and sternothyroid. It is at first behind the origin of the right common carotid artery; more laterally, it is crossed by the vagus nerve, the cardiac branches of the vagus and the sympathetic trunk, and by internal jugular and vertebral veins; the subclavian sympathetic loop encircles it. The anterior jugular vein diverges laterally in front of it, separated by sternohyoid and sternothyroid. Below and behind the artery are the pleura and pulmonary apex; they are separated from the artery by the suprapleural membrane, the ansa subclavia, a small accessory vertebral vein and the right recurrent laryngeal nerve, which winds round the lower and posterior part of the vessel.

First part of left subclavian artery

In the majority of individuals, the left subclavian artery originates independently from the aortic arch after the origins of the brachiocephalic and left common carotid arteries. It ascends into the neck posterior to scalenus anterior, then passes inferolaterally towards the external border of the first rib, where it becomes the left axillary artery. A common origin occasionally exists between the left subclavian and vertebral arteries. Bilateral brachiocephalic trunks are rare: they divide on both sides into common carotid and subclavian arteries.

Relations In the thorax, the left subclavian artery is related anteriorly to the left common carotid artery and left brachiocephalic vein (and sometimes the inferior thyroid vein), from which it is separated by the left vagus, cardiac and phrenic nerves. Sternothyroid and sternohyoid lie between the vessel and the upper left aspect of the posterior surface of the manubrium sterni. On the left side of the oesophagus, the thoracic duct and longus colli are posterior. The left subclavian artery is in contact posterolaterally with the left lung and pleura. The trachea, left recurrent laryngeal nerve, oesophagus and thoracic duct are medial. Laterally, the artery grooves the mediastinal surface of the left lung and pleura, which also encroach on its anterior and posterior aspects. In the neck, near the medial border of scalenus anterior the artery is crossed anteriorly by the left phrenic nerve and the termination of the thoracic duct. Otherwise, anterior relations are the same as those of the first part of the right subclavian artery. Posteriorly and inferiorly, the relations of both vessels are identical but the left recurrent laryngeal nerve, medial to the left subclavian artery in the thorax, is not directly related to its cervical part.

Second part of subclavian artery

The second part of the subclavian artery lies behind scalenus anterior; it is short and constitutes the highest part of the vessel (see Fig. 35.18).

Relations The skin, superficial fascia, platysma, deep cervical fascia, sternocleidomastoid and scalenus anterior are anterior. The right phrenic nerve is often described as being separated from the second part of the subclavian artery by scalenus anterior, whereas it crosses the first part of the left subclavian artery. However, both nerves may sometimes lie anterior to the muscle. The suprapleural membrane, pleura and lung, and the lower trunk of the brachial plexus are posteroinferior; the upper and middle trunks of the plexus are superior; and the subclavian vein is anteroinferior, separated by scalenus anterior.

Third part of subclavian artery

The third part of the subclavian artery descends laterally from the lateral margin of scalenus anterior to the outer border of the first rib, where it becomes the axillary artery. It is the most superficial part of the artery and lies partly in the supraclavicular triangle, where its pulsations may be felt and it may be compressed. The third part of the subclavian artery is the most accessible segment of the artery. Since the line of the posterior border of sternocleidomastoid approximates to the (deeper) lateral border of scalenus anterior, the artery can be felt in the anteroinferior angle of the posterior triangle. It can only be effectively compressed against the first rib: with the shoulder depressed, pressure is exerted down, back and medially in the angle between sternocleidomastoid and the clavicle. The palpable trunks of the brachial plexus may be injected with local anaesthetic allowing major surgical procedures to the arm.

Relations The skin, superficial fascia, platysma, supraclavicular nerves and deep cervical fascia are anterior. The external jugular vein crosses its medial end and here receives the suprascapular, transverse cervical and anterior jugular veins, which collectively often form a venous plexus. The nerve to subclavius descends between the veins and the artery; the latter is terminally behind the clavicle and subclavius, where it is crossed by the suprascapular vessels. The subclavian vein is anteroinferior and the lower trunk of the brachial plexus is posteroinferior, between the subclavian artery and the scalenus medius (and on the first rib). The upper and middle trunks of the brachial plexus (which are palpable here) and the inferior belly of omohyoid are superolateral. The first rib is inferior.

The right subclavian artery may arise above or below sternoclavicular level; it may be a separate aortic branch and be the first or last branch of the arch. When it is the first branch, it is in the position of a brachiocephalic trunk. When it is the last branch, it arises from the left end of the arch, and ascends obliquely to the right behind the trachea, oesophagus and right common carotid to the first rib. When this happens, the right recurrent laryngeal nerve hooks round the common carotid artery. Sometimes, when the right subclavian artery is the last aortic branch, it passes between the trachea and oesophagus and can cause dysphagia, a condition known as dysphagia lusoria. It may perforate scalenus anterior, and very rarely may pass anterior to it. Sometimes, the subclavian vein accompanies the artery behind scalenus anterior. The artery may ascend as high as 4 cm above the clavicle or it may reach only its upper border. The left subclavian artery is occasionally combined at its origin with the left common carotid artery.

Branches The branches of the subclavian artery are the vertebral, internal thoracic, thyrocervical, costocervical and dorsal scapular arteries. On the left, all the branches except the dorsal scapular arise from the first part. On the right, the costocervical trunk usually arises from the second part. The suprascapular artery (usually a branch of the thyrocervical trunk) may arise from the third part of the subclavian artery.

Vertebral artery

The vertebral arteries and their major branches (sometimes referred to as the 'vertebrobasilar system') essentially supply blood to the upper spinal cord, the brainstem and cerebellum, and a significant but variable part of the posterior cerebral hemispheres (see Figs 26.4–26.5).

The vertebral artery arises from the superoposterior aspect of the first part of the subclavian artery. It passes through the foramina in the transverse processes of all of the cervical vertebrae except the seventh; occasionally, it may enter the cervical vertebral column via the fourth, fifth or seventh cervical vertebra (see Fig. 35.12). The artery curves medially behind the lateral mass of the atlas and enters the cranium via the foramen magnum (see Fig. 35.11). The right and left vertebral arteries converge medially as they ascend the medulla and unite to form the midline basilar artery at approximately the level of the junction between the medulla and pons.

Relations The first part, V1, passes back and upwards between longus colli and scalenus anterior, behind the common carotid artery and the vertebral vein. It is crossed by the inferior thyroid artery, and by the thoracic duct on the left side and the right lymphatic duct on the right side. The seventh cervical transverse process, the inferior cervical ganglion and ventral rami of the seventh and eighth cervical spinal nerves lie posterior to the artery. The second part, V2, ascends through the transverse foramina of the remaining cervical vertebrae, accompanied by a large branch from the inferior cervical ganglion and a plexus of veins that form the vertebral vein low in the neck. It lies anterior to the ventral rami of the cervical spinal nerves (C2–C6) and ascends almost vertically to pass through the transverse process of the axis, where it turns laterally to gain access to the transverse foramen of the atlas (see Fig. 35.11). The third part, V3, issues medial to rectus capitis lateralis, and curves backwards and medially behind the lateral mass of the atlas, with the first cervical ventral spinal ramus lying on its medial side. In this position, it lies in a groove on the upper surface of the posterior arch of the atlas, and it enters the vertebral canal below the inferior border of the posterior atlanto-occipital membrane. This part of the artery, covered by semispinalis capitis, lies in the suboccipital triangle. The first cervical dorsal spinal ramus separates the artery from the posterior arch. The fourth part, V4, pierces the dura and arachnoid mater, and ascends anterior to the hypoglossal roots. It inclines anterior to the medulla oblongata and unites with its contralateral fellow to form the midline basilar artery at the lower border of the pons.

Cervical branches of the vertebral artery

Spinal branches

The spinal branches enter the vertebral canal via the intervertebral foramina and supply the spinal cord and its membranes. They fork into ascending and descending rami, which unite with those above and below, to form two lateral anastomotic chains on the posterior surfaces of the vertebral bodies near the attachment of their pedicles. Branches from these chains supply the periosteum and vertebral bodies, and others communicate with similar branches across the midline; from these connections small rami join similar ones above and below, to form a median anastomotic chain on the posterior surfaces of the vertebral bodies.

Muscular branches

Muscular branches arise from the vertebral artery as it curves round the lateral mass of the atlas. They supply the deep muscles of the suboccipital region and anastomose with the occipital, ascending and deep cervical arteries.

Cranial branches of the vertebral artery

Meningeal branches

One or two meningeal branches arise from the vertebral artery near the foramen magnum and ramify between the bone and dura mater in the posterior cranial fossa. They supply bone, diploë and the falx cerebelli.

Posterior spinal artery

A posterior spinal artery usually arises from the posterior inferior cerebellar artery, but may originate directly from the vertebral artery near the medulla oblongata. It passes posteriorly and descends as two branches that lie anterior and posterior to the dorsal roots of the spinal nerves. These are reinforced by spinal twigs from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries, all of which reach the vertebral canal by the intervertebral foramina, and sustain the posterior spinal arteries to the lower spinal levels.

Anterior spinal artery

A small anterior spinal artery arises near the end of the vertebral artery, and descends anterior to the medulla oblongata to unite with its contralateral fellow at mid-medullary level. The single trunk then descends on the ventral midline of the spinal cord, and is reinforced sequentially by small spinal rami from the vertebral, ascending cervical, posterior intercostal and first lumbar arteries, which all enter the vertebral canal via intervertebral foramina. Branches from the anterior spinal arteries and the beginning of their common trunk are distributed to the medulla oblongata. Minute medullary arteries are distributed widely to the medulla oblongata.

Posterior inferior cerebellar artery

The largest branch of the vertebral artery (although sometimes absent), the posterior inferior cerebellar artery arises near the lower end of the olive and then ascends behind the roots of the glossopharyngeal and vagus nerves to reach the inferior border of the pons. Here it curves and descends along the inferolateral border of the fourth ventricle before it turns laterally into the cerebellar vallecula between the hemispheres, and divides into medial and lateral branches. The medial branch runs back between the cerebellar hemisphere and inferior vermis, and supplies both. The lateral branch supplies the inferior cerebellar surface as far as its lateral border and anastomoses with the anterior inferior and superior cerebellar arteries (from the basilar artery). The trunk of the posterior inferior cerebellar artery supplies the medulla oblongata dorsal to the olivary nucleus and lateral to the hypoglossal nucleus and its emerging nerve roots. It also supplies the choroid plexus of the fourth ventricle and sends a branch lateral to the cerebellar tonsil to supply the dentate nucleus.

Basilar artery

The basilar artery is a large median vessel formed by the union of the vertebral arteries at the junction of the medulla and pons (see Figs 26.3, 26.5). It lies in the pontine cistern, and follows a shallow median groove on the ventral pontine surface, extending to the upper border of the pons. It ends by dividing into two posterior cerebral arteries at a variable level behind the dorsum sellae, usually in the interpeduncular cistern.

Pontine branches

Numerous small pontine branches arise from the front and sides of the basilar artery along its course and supply the pons.

Labyrinthine artery

The long and slender labyrinthine (internal auditory) artery has a variable origin. It usually arises from the anterior inferior cerebellar artery, but variations in its origin include the lower part of the basilar artery, the superior cerebellar artery or, occasionally, the posterior inferior cerebellar artery. The labyrinthine artery accompanies the facial and vestibulocochlear nerves into the internal acoustic meatus and is distributed to the internal ear.

Anterior inferior cerebellar artery

The anterior inferior cerebellar artery is given off from the lower part of the basilar artery and runs posterolaterally, usually ventral to the abducens, facial and vestibulocochlear nerves. It commonly exhibits a loop into the internal acoustic meatus below the nerves, and when this occurs, the labyrinthine artery may arise from the loop. The anterior inferior cerebellar artery supplies the inferior cerebellar surface anterolaterally and anastomoses with the posterior inferior cerebellar branch of the vertebral artery. A few branches supply the inferolateral parts of the pons and occasionally also supply the upper medulla oblongata.

Superior cerebellar artery

The superior cerebellar artery (see Figs 26.3, 26.5) arises near the distal portion of the basilar artery, immediately before the formation of the posterior cerebral arteries. It passes laterally below the oculomotor nerve, which separates it from the posterior cerebral artery, and curves round the cerebral peduncle below the trochlear nerve to gain the superior cerebellar surface. Here it divides into branches that ramify in the pia mater and supply this aspect of the cerebellum, and also anastomose with branches of the inferior cerebellar arteries. The superior cerebellar artery supplies the pons, pineal body, superior medullary velum and tela choroidea of the third ventricle.

Posterior cerebral artery

The paired posterior cerebral arteries are the terminal branches of the basilar artery (see Figs 26.3–26.5). Surgical nomenclature divides the vessel into three parts: P1 – from the basilar bifurcation to the junction with the posterior communicating artery; P2 – from the junction with the posterior communicating artery to the portion in the perimesencephalic cistern; and P3 – the portion that runs in the calcarine fissure.

The posterior cerebral artery is larger than the superior cerebellar artery, from which it is separated near its origin by the oculomotor nerve and, lateral to the midbrain, by the trochlear nerve. It passes laterally, parallel with the superior cerebellar artery, and receives the posterior communicating artery. It then winds round the cerebral peduncle and reaches the tentorial cerebral surface, where it supplies the temporal and occipital lobes. Like the anterior and middle cerebral arteries, the posterior cerebral artery has cortical and central branches.

The cortical branches of the posterior cerebral artery are named according to their distribution. Temporal branches, usually two, are distributed to the uncus and parahippocampal, medial occipitotemporal and lateral occipitotemporal gyri. Occipital branches supply the cuneus, lingual gyrus and posterolateral surface of the occipital lobe. Parieto-occipital branches supply the cuneus and precuneus. The posterior cerebral artery supplies the visual areas of the cerebral cortex and other structures in the visual pathway.

The central branches supply subcortical structures. Several small posteromedial central branches arise from the beginning of the posterior cerebral artery (see Fig. 26.3) and, together with similar branches from the posterior communicating artery, pierce the posterior perforated substance to supply the anterior thalamus, subthalamus, lateral wall of the third ventricle and globus pallidus. One or more posterior choroidal branches pass over the lateral geniculate body and supply it before entering the posterior part of the inferior horn of the lateral ventricle via the lower part of the choroidal fissure. Branches also curl round the posterior end of the thalamus and pass through the transverse fissure, or go to the choroid plexus of the third ventricle, or traverse the upper choroidal fissure. Collectively these branches supply the choroid plexuses of the third and lateral ventricles and the fornix. Small posterolateral central branches arise from the posterior cerebral artery beyond the cerebral peduncle, and supply the peduncle and the posterior thalamus, superior and inferior colliculi, pineal gland and medial geniculate body.

Internal thoracic artery

The internal thoracic (mammary) artery arises inferiorly from the first part of the subclavian artery, approximately 2 cm superior to the sternal end of the clavicle and opposite the root of the thyrocervical trunk (see Fig. 52.3). It descends posterior to the first six costal cartilages and intervening intercostal spaces, about 1 cm lateral to the lateral sternal border and divides at the level of the sixth intercostal space into musculophrenic and superior epigastric branches.

Both the right and left internal thoracic arteries are used as standard in coronary artery bypass grafting (CABG) reflecting successful long-term outcomes. Variations are rare, however when present, they must be imaged prior to harvesting for CABG: morphologically abnormal internal thoracic arteries have been shown to supply major parts of the gastrointestinal tract (Mashhour et al 2018).

Relations From its origin, the internal thoracic artery descends anteromedially, passing posterior to the sternal end of the clavicle, the internal jugular and brachiocephalic veins, and the first costal cartilage. As it enters the thoracic cavity, the phrenic nerve crosses it obliquely from its lateral side either superior or inferior to the nerve. The artery then descends almost vertically to its bifurcation, lying anterior to transversus thoracis and posterior to the first six costal cartilages, internal intercostals and terminations of the upper six intercostal nerves. Down to the second or third cartilage it is separated from the costal parietal pleura and associated endothoracic fascia by a strong layer of fascia, and below this transversus thoracis intervenes. The artery is accompanied by the parasternal lymph nodes (see Fig. 56.4A) and by venae comitantes that unite at about the third costal cartilage into a single vein medial to the artery. Its intermediate branches are sternal, anterior intercostal and perforating.

Sternal branches

Sternal branches are distributed to transversus thoracis, the periosteum of the posterior sternal surface and the sternal red bone marrow. These branches, together with small branches of the pericardiacophrenic artery, anastomose with branches of the posterior intercostal and bronchial arteries to form a subpleural mediastinal plexus.

Anterior intercostal branches

Anterior intercostal arteries are distributed to the upper six intercostal spaces. They usually arise from the internal thoracic artery as single vessels that promptly divide into two branches (anterior and collateral intercostal arteries) that pass laterally along the superior and inferior borders of each space and anastomose with the posterior intercostal arteries and their collateral branches (see Figs 53.17, 53.19). Occasionally, separate branches of the anterior intercostal artery pass to the intercostal space located superiorly and/or inferiorly and the two branches of an anterior intercostal may sometimes arise separately from the internal thoracic artery. At first, the arteries lie between the endothoracic fascia and associated costal parietal pleura posteriorly, and the internal intercostals anteriorly. As they pass posteriorly within a space they lie between the innermost and internal intercostals. They supply the intercostal muscles and send branches through them to the pectoral muscles, breast and skin.

Perforating branches

Perforating branches traverse the upper five or six intercostal spaces with the anterior cutaneous branches of the corresponding intercostal nerves. They pierce and supply pectoralis major, and then curve laterally to become direct cutaneous vessels that supply the skin (see Fig. 53.19). These cutaneous vessels provide the anatomical basis for surgically raising the deltopectoral skin flap that is used for reconstructing areas of missing tissue in the head and neck. The second to fourth branches supply the breast and become enlarged during lactation (see Fig. 53.22).

Musculophrenic artery

The musculophrenic artery passes inferolaterally posterior to the seventh to ninth costal cartilages, close to the costal arch, then traverses the respiratory diaphragm and terminates near the eleventh (last) intercostal space (see Fig. 55.2). It anastomoses with the inferior phrenic

and lower two posterior intercostal arteries and ascending branches of the deep circumflex iliac arteries. Two anterior intercostal arteries branch from it for each of the seventh to ninth intercostal spaces, and are distributed similarly to their counterparts in other intercostal spaces. The musculophrenic artery also supplies the lower part of the pericardium and the abdominal muscles.

Superior epigastric artery

The superior epigastric artery arises at the level of the sixth costal cartilage and descends between the costal and sternal parts of the respiratory diaphragm, accompanied by two or more veins that drain to the internal thoracic vein (see Figs 60.1–60.2). The vessels pass anterior to the distal fibres of transversus thoracis and the proximal fibres of transversus abdominis before entering the rectus sheath, where they run inferiorly behind rectus abdominis. They anastomose with the inferior epigastric arteries within rectus abdominis in one of several potential branching patterns (Rozen et al 2008).

Vascular branches supply rectus abdominis itself and perforate the anterior layer of the rectus sheath to supply the abdominal skin and subcutaneous fat. These vessels generally penetrate rectus abdominis within a 10 cm circle around the umbilicus and are referred to clinically as 'peri-umbilical perforator' vessels. A branch given off in the proximal rectus sheath passes anterior to the xiphoid process of the sternum and anastomoses with a corresponding contralateral branch. This vessel can give rise to bleeding during surgical incisions that extend up to and alongside the xiphoid process. The superior epigastric artery also gives small branches to the anterior part of the respiratory diaphragm. On the right, small branches reach the falciform ligament, where they anastomose with branches from the hepatic artery.

Clinical significance of the internal thoracic artery

The internal thoracic artery has a number of clinical uses but perhaps most significant is that it is the vessel of choice for coronary artery bypass grafting. It has become a popular recipient vessel for free flap transfers to the chest wall, principally for breast reconstruction (Ninković et al 1995), and has largely superseded the thoracodorsal vessels for this purpose. It is routinely accessed by removing a portion of the third costal cartilage (see Fig. 53.18), although some surgeons prefer to dissect the vessels between the ribs, with a rib-sparing approach (Parrett et al 2008, Malata et al 2011) or even utilizing the anterior perforating branches as they pierce pectoralis major (Park et al 2003, Munhoz et al 2004). The anterior perforating branches form the vascular pedicles for fasciocutaneous flaps raised from the anterior chest wall that have been used for many decades in head and neck reconstruction (Bakamjian et al 1971, Neligan et al 2007). The superior epigastric artery is the main vascular pedicle for the superiorly based rectus abdominis flap, a muscle or myocutaneous flap useful in breast, sternal and chest wall reconstruction (Hartrampf et al 1982). During CT-guided lung and mediastinal biopsies, the internal thoracic vessels must be avoided; exsanguination has been reported following Tru-Cut needle trauma: the approach must be at least 2 cm lateral to the sternal margin. The vessels are not seen easily on non-contrast fluoroscopic CT images.

Thyrocervical trunk

The thyrocervical trunk is a short, wide artery that arises from the first part of the subclavian artery near the medial border of scalenus anterior, and divides almost at once into the inferior thyroid, suprascapular and superficial cervical arteries.

Inferior thyroid artery

The inferior thyroid artery loops upwards anterior to the medial border of scalenus anterior, turns medially just below the sixth cervical transverse process, and then descends on longus colli to the lower border of the thyroid gland (see Fig. 35.17). It passes anterior to the vertebral vessels and posterior to the carotid sheath and its contents (and usually the sympathetic trunk, whose middle cervical ganglion frequently adjoins the vessel). On the left, near its origin, the artery is crossed anteriorly by the thoracic duct as the latter curves inferolaterally to its termination. Relations between the terminal branches of the artery and recurrent laryngeal nerve are very variable and of considerable surgical importance. The artery usually passes behind the nerve as it nears the gland. However, very close to the gland, the right nerve is equally likely to be anterior, posterior or amongst the branches of the artery, and the left nerve is usually posterior. Together with the inferior thyroid and common carotid arteries, the recurrent laryngeal nerve forms one of the sides of Beahr's triangle. Since the nerve winds around the artery of the sixth branchial arch (aortic arch) on the left side, it is 45° to the midline in its ascent from the chest to the neck. However, on the right side it is slightly more superficial and lateral because it goes around the fourth branchial arch artery (subclavian) in the neck: these variations are important in thyroid surgery and are reversed in dextrocardia. The artery is not accompanied by the inferior thyroid vein.

Muscular branches

These supply the infrahyoid muscles, longus colli, scalenus anterior and the inferior pharyngeal constrictor.

Ascending cervical artery

The ascending cervical artery is a small branch that arises as the inferior thyroid turns medially behind the carotid sheath and ascends on the anterior tubercles of the cervical transverse processes between scalenus anterior and longus capitis. It supplies the adjacent muscles and gives off one or two spinal branches that enter the vertebral canal through the intervertebral foramina to supply the spinal cord and membranes and vertebral bodies, and thereby supplement the spinal branches of the vertebral artery. The ascending cervical artery anastomoses with the vertebral, ascending pharyngeal, occipital and deep cervical arteries.

Inferior laryngeal artery

The inferior laryngeal artery ascends on the trachea with the recurrent laryngeal nerve, enters the larynx at the lower border of the inferior constrictor and supplies the laryngeal muscles and mucosa. It anastomoses with its contralateral fellow, and with the superior laryngeal branch of the superior thyroid artery.

Pharyngeal branches

These supply the lower part of the pharynx. Tracheal branches supply the trachea and anastomose with the bronchial arteries; oesophageal branches supply the oesophagus and anastomose with the oesophageal branches of the thoracic aorta; inferior and ascending glandular branches supply the posterior and inferior regions of the thyroid gland and anastomose with the contralateral inferior and ipsilateral superior thyroid arteries. The ascending branch also supplies the parathyroid glands.

Suprascapular artery

The suprascapular artery usually arises from the thyrocervical trunk of the subclavian artery, although it may arise from the third part of the subclavian artery. It first descends laterally across scalenus anterior and the phrenic nerve, posterior to the internal jugular vein and sternocleidomastoid (see Fig. 35.7A), then crosses anterior to the subclavian artery and brachial plexus, posterior and parallel with the clavicle, subclavius and the inferior belly of omohyoid, to reach the superior border of the scapula. Here, it passes above (sometimes, under) the superior transverse ligament, separating it from the suprascapular nerve, and enters the supraspinous fossa (see Figs 49.31, 49.33), where it lies on the bone, and supplies supraspinatus. It descends behind the scapular neck, and passes through the spinoglenoid notch deep to the inferior transverse ligament to gain the deep surface of infraspinatus, where it anastomoses with the circumflex scapular and deep branch of the transverse cervical artery. Its muscular branches supply sternocleidomastoid, subclavius and infraspinatus. It also gives off a suprasternal branch that crosses the sternal end of the clavicle to supply the skin of the upper thorax, and an acromial branch that pierces trapezius to supply the skin over the shoulder. This last branch anastomoses with the thoracoacromial and posterior circumflex humeral arteries.

As the suprascapular artery passes over the superior transverse ligament, it gives off a branch that enters the subscapular fossa beneath subscapularis and anastomoses with the subscapular artery and the deep branch of the transverse cervical artery. It also supplies the acromioclavicular and glenohumeral joints, the clavicle and the scapula.

Superficial cervical artery

The superficial cervical artery is given off at a higher level than the suprascapular artery. It crosses anterior to the phrenic nerve, scalenus anterior and the brachial plexus, and is covered by the internal jugular vein, sternocleidomastoid and platysma. It crosses the floor of the posterior triangle to reach the anterior margin of levator scapulae and ascends deep to the anterior part of the trapezius, which it supplies, together with the adjoining muscles and the cervical lymph nodes. It anastomoses with the superficial ramus of the descending branch of the occipital artery. About a third of the superficial cervical and dorsal scapular arteries arise in common from the thyrocervical trunk, with a superficial (superficial cervical artery) and a deep (dorsal scapular artery) branch (see Figs 33.1A, 33.2A). The latter passes laterally anterior to the brachial plexus and then posterior to levator scapulae.

Costocervical trunk

On the right, this short vessel arises posteriorly from the second part of the subclavian artery, and, on the left, from its first part. It arches back above the cervical pleura to the neck of the first rib, where it divides into supreme intercostal and deep cervical branches.

Supreme intercostal artery

The supreme (highest) intercostal artery arises from the costocervical trunk. It descends between the parietal pleura and associated endothoracic fascia, and the neck of the first and second ribs, and anastomoses with the third posterior intercostal artery. Crossing the neck of the first rib, it lies medial to the ventral ramus of the first thoracic nerve (crossing it at a lower level), and lateral to the stellate ganglion (see Fig. 55.10). In the first intercostal space it gives off the first posterior intercostal artery, which has a similar distribution to the more inferiorly located posterior intercostal arteries. It descends to become the second posterior intercostal artery, usually joining a branch from the third. The artery is not constant, and is more common on the right: when absent, it is replaced by a direct branch from the aorta.

Deep cervical artery

The deep cervical artery usually arises from the costocervical trunk (see Fig. 33.1A). It is analogous in its first segment to a posterior branch of a posterior intercostal artery, and occasionally is a separate branch of the subclavian artery. It passes back above the eighth cervical spinal nerve between the transverse process of the seventh cervical vertebra and the neck of the first rib (sometimes between the transverse processes of the sixth and seventh cervical vertebrae). It then ascends between semispinales capitis and cervicis to the level of the second cervical vertebra. It supplies adjacent muscles and anastomoses with the deep branch of the descending branch of the occipital artery and branches of the vertebral artery. A spinal branch enters the vertebral canal between the seventh cervical and first thoracic vertebrae.

Dorsal scapular artery

In the majority of cases, the dorsal scapular artery arises from the third, or less often the second, part of the subclavian artery. It passes laterally through the trunks of the brachial plexus in front of scalenus medius and then deep to levator scapulae to reach the superior scapular angle. Here, it descends with the dorsal scapular nerve under the rhomboids along the medial border of the scapula to the inferior angle. It supplies the rhomboids, latissimus dorsi and the inferior portion of trapezius and the skin over the inferomedial aspect of trapezius via musculocutaneous perforators. It anastomoses with the suprascapular and subscapular arteries and with posterior branches of some posterior intercostal arteries. It sends a small branch to scalenus anterior; sometimes, this arises directly from the subclavian artery.

Variants About one-third of the superficial cervical and dorsal scapular arteries arise as a common vessel, the transverse cervical artery, from the thyrocervical trunk, which then divides into a superficial and a deep branch (superficial cervical and dorsal scapular arteries, respectively) (see Figs 33.1A, 49.31). In this case, the dorsal scapular artery arises near the superior border of the scapula; it passes laterally, anterior to the brachial plexus and then posterior to levator scapulae.

Axillary artery

The axillary artery, a continuation of the subclavian artery, begins at the outer border of the first rib and ends nominally at the inferior border of teres major, where it becomes the brachial artery (see Fig. 49.31). Its direction varies with the position of the limb; it is almost straight when the arm is raised at right-angles, concave upwards when the arm is elevated above this level, and convex upwards and laterally when the arm is by the side (see Fig. 49.32). At first deep, it subsequently becomes superficial, when it is covered only by the skin and fasciae. Pectoralis minor crosses it and so divides it into three parts, which are proximal, posterior and distal to the muscle.

The branches of the axillary artery are the superior thoracic artery (first part), thoraco-acromial and lateral thoracic arteries (second part), and subscapular, and anterior and posterior circumflex humeral arteries (third part) (see Fig. 49.47).

Relations of the first part The skin, superficial fascia, platysma, supraclavicular nerves, deep fascia, clavicular fibres of pectoralis major and the clavipectoral fascia, lateral pectoral nerve and the loop of communication between the lateral and medial pectoral nerves, and the thoraco-acromial and cephalic veins are all anterior. The first intercostal space and external intercostal, first and second digitations of serratus anterior, long thoracic and medial pectoral nerves, and the medial cord of the brachial plexus are all posterior. The posterior cord of the brachial plexus is lateral and the axillary vein is anteromedial. The first part is enclosed with the axillary vein and brachial plexus in a fibrous axillary sheath, which is continuous with the prevertebral layer of the deep cervical fascia.

Relations of the second part The skin, superficial and deep fascia, and pectoralis major and minor are all anterior. The posterior cord of the brachial plexus and the areolar tissue between it and subscapularis are posterior. The axillary vein is medial, separated from the artery by the medial cord of the brachial plexus and the medial pectoral nerve. The lateral cord of the brachial plexus is lateral, separating the artery from coracobrachialis. The cords of the brachial plexus thus surround the second part on three sides, with the dispositions implied by their names, and separate it from the vein and adjacent muscles.

Relations of the third part Pectoralis major and, distal to the muscle, skin and fasciae are anterior. The lower part of subscapularis and the tendons of latissimus dorsi and teres major are posterior. Coracobrachialis is lateral and the axillary vein is medial. Branches of the brachial plexus are arranged as follows: laterally, the lateral root and then trunk of the median nerve and, for a short distance, the musculocutaneous nerve; medially, the medial cutaneous nerve of the forearm between the axillary artery and vein anteriorly, and the ulnar nerve between these vessels posteriorly; anteriorly, the medial root of the median nerve; and posteriorly, the radial and axillary nerves, the latter only to the distal border of subscapularis. The dispositions of the branches of the brachial plexus around the axillary artery have, therefore, altered: there has been a rotation such that the nerves derived from the lateral cord are now more anterior, those from the medial cord more posterior, and those of the posterior cord come to lie more laterally.

Variants The branches of the axillary artery exhibit considerable variation. An alar thoracic artery, often from the second part, may supply fat and lymph nodes in the axilla. The lateral thoracic artery may be absent, in which case it is replaced by lateral perforating branches of the intercostal arteries; alternatively, it may become, or give off, a direct cutaneous vessel (named the superficial thoracic artery by some sources) that supplies the skin over the lateral border of pectoralis major. In up to one-third of cases, the subscapular artery can arise from a common trunk with the posterior circumflex humeral artery. Occasionally the subscapular, circumflex humeral and profunda brachii arteries arise in common, and in this case, branches of the brachial plexus surround this common vessel instead of the axillary artery. The posterior circumflex humeral artery may arise from the profunda brachii artery and pass back below teres major, instead of passing through the quadrangular space. Sometimes the axillary artery divides into radial and ulnar arteries (anomalous 'high division') and is, occasionally, the source of the anterior interosseous artery.

Superior thoracic artery

The superior thoracic artery is a small vessel that arises from the first part of the axillary artery near the lower border of subclavius; it sometimes arises from the thoraco-acromial artery (see Fig. 49.47). It runs anteromedially above the medial border of pectoralis minor, then passes between it and pectoralis major to gain the thoracic wall. It supplies these muscles and the thoracic wall, and anastomoses with the internal thoracic and upper intercostal arteries.

Thoraco-acromial (acromiothoracic) artery

The thoraco-acromial artery is a short branch that arises from the second part of the axillary artery (see Figs 49.27, 49.47). It is initially overlapped by pectoralis minor, skirting its medial border; it next pierces the clavipectoral fascia and divides into pectoral, acromial, clavicular and deltoid branches, which supply pectoralis major and minor, an area of skin over the clavipectoral fascia, and the anterior portion of deltoid.

Pectoral branch

The pectoral branch is the largest branch. It descends between the pectoral muscles, gives a branch to pectoralis minor, and then continues on the deep surface of pectoralis major. It enters the muscle and anastomoses with the intercostal branches of the internal thoracic and lateral thoracic arteries. It gives off perforating branches to the breast, and musculocutaneous perforators to the skin over pectoralis major.

Acromial branch
The acromial branch crosses the coracoid process under deltoid, which it supplies, then pierces the muscle and ends on the acromion. It anastomoses with branches of the suprascapular artery, the deltoid branch of the thoraco-acromial artery and the posterior circumflex humeral arteries.

Clavicular branch
The clavicular branch ascends medially between the clavicular part of pectoralis major and the clavipectoral fascia. It supplies the sternoclavicular joint and subclavius.

Deltoid branch
The deltoid branch often arises with the acromial branch. It crosses pectoralis minor to accompany the cephalic vein between pectoralis major and deltoid, and supplies both muscles.

Lateral thoracic artery
The lateral thoracic artery arises from the second part of the axillary artery. Following the lateral border of pectoralis minor, it passes to the deep surface of pectoralis major as far distally as the fifth intercostal space (see Fig. 49.45). It supplies serratus anterior and the pectoral muscles, the axillary lymph nodes and subscapularis. It anastomoses with the internal thoracic, subscapular and intercostal arteries, and with the pectoral branch of the thoraco-acromial artery. In females, it is large and has lateral mammary branches, which curve round the lateral border of pectoralis major to the breast. In both males and females, it gives off cutaneous branches that pass around the lateral border of pectoralis major to supply the skin in this region.

Subscapular artery
The subscapular artery is the largest branch of the axillary artery (see Figs 49.31, 49.47). It usually arises from the third part of the axillary artery at the distal (inferior) border of subscapularis, which it follows to the inferior scapular angle where it anastomoses with the lateral thoracic and intercostal arteries and the deep branch of the transverse cervical artery. It supplies adjacent muscles and the thoracic wall. It is accompanied distally by the nerve to latissimus dorsi. Approximately 4 cm from its origin the subscapular artery divides into the circumflex scapular and thoracodorsal arteries.

Circumflex scapular artery
The circumflex scapular artery, the larger of the two terminal branches of the subscapular artery, curves backwards around the lateral border of the scapula, traversing a triangular space between subscapularis above, teres major below and the long head of the triceps laterally (see Fig. 49.33). It enters the infraspinous fossa under teres minor and then divides. One branch (infrascapular) enters the subscapular fossa deep to subscapularis, and anastomoses with the suprascapular and dorsal scapular arteries (or deep branch of the transverse cervical artery). The other branch continues along the lateral border of the scapula between teres major and minor, then, dorsal to the inferior angle, anastomoses with the dorsal scapular artery. Small branches supply the posterior part of deltoid and the long head of triceps, and anastomose with an ascending branch of the profunda brachii artery.

Two significant cutaneous branches arise from the circumflex scapular artery as it emerges through the upper triangular space. The superior, or horizontal, branch is a direct cutaneous artery that passes medially at the level of the deep fascia parallel with the spine of the scapula and supplies a band of skin overlying the spine of the scapula. The lower branch (parascapular branch) is also a direct cutaneous vessel that passes in an inferomedial direction, again at the level of the deep fascia, and supplies an area of skin overlying the lateral border of the scapula. Both of these cutaneous vessels provide the anatomical basis of skin flaps that can be surgically raised in this region (scapular flap based on the horizontal branch and parascapular flap based on the lower, parascapular branch) to reconstruct areas of missing tissue elsewhere in the body.

Thoracodorsal artery
The other terminal branch of the subscapular artery, the thoracodorsal artery, follows the lateral margin of the scapula, posterior to the lateral thoracic artery, between latissimus dorsi and serratus anterior. Before entering the deep surface of latissimus dorsi, it supplies teres major and the intercostals, and sends one or two branches to serratus anterior. It enters latissimus dorsi with the thoracodorsal nerve; this constitutes the principal neurovascular pedicle to the muscle. It provides numerous musculocutaneous perforators that supply the skin over the superior part of latissimus dorsi. The intramuscular portion of the artery anastomoses with intercostal arteries and lumbar perforating arteries.

Anterior circumflex humeral artery
The anterior circumflex humeral artery arises from the lateral side of the axillary artery at the distal border of subscapularis (see Fig. 49.31). It runs horizontally behind coracobrachialis and the short head of biceps, anterior to the surgical neck of the humerus. Reaching the intertubercular sulcus, it sends an ascending branch to supply the humeral head and shoulder joint (Brooks et al 1993), continues laterally under the long head of biceps and deltoid, and anastomoses with the posterior circumflex humeral artery.

Posterior circumflex humeral artery
The posterior circumflex humeral artery is larger than the anterior (see Fig. 49.31). It branches from the third part of the axillary artery at the distal border of subscapularis and runs backwards with the axillary nerve through a quadrangular space bounded by subscapularis, the capsule of the shoulder joint and teres minor above, teres major below, the long head of triceps medially, and the surgical neck of the humerus laterally (see Fig. 49.22B). It curves round the humeral neck and supplies the shoulder joint, deltoid, teres major and minor, and long and lateral heads of triceps (Gerber et al 1990). It gives off a descending branch that anastomoses with the deltoid branch of the profunda brachii artery and with the anterior circumflex humeral and acromial branches of the suprascapular and thoraco-acromial arteries.

Potential vascular anastomoses around the shoulder girdle: clinical relevance
The potential vascular anastomoses around the shoulder girdle are numerous, which means that collateral perfusion of the upper limb is possible in occlusion of the axillary artery or vein. In acute occlusion of the axillary artery, these potential anastomoses are not reliable and clinicians should not rely on anastomotic perfusion of the acutely ischaemic limb. The axillary artery is most 'at risk' of occlusion as a result of intimal separation and dissection in its second part, behind pectoralis minor, an injury associated with infraclavicular brachial plexus traction lesions (Birch 2011). Although magnetic resonance imaging with angiography is recommended for the diagnosis of the poorly perfused limb after distraction trauma, the site of intimal rupture is so consistent as to make urgent surgical exploration without imaging a reasonable clinical decision.

Angiomyosomes
The axillary artery supplies the muscles of the ventral compartments of the shoulder, including the pectoral–deltoid muscle sheet, the scapulohumeral muscles (other than the posterosuperior rotator cuff) and the shoulder joint, including the scapula (with the serratus muscles) and proximal humerus. Its terminal branch, the brachial artery, supplies the muscles of the anterior compartment of the arm. The profunda brachii artery, the major proximal branch of the brachial artery, supplies the muscles of the posterior compartment of the arm and the shaft of the humerus.

Brachial artery
The brachial artery is a continuation of the axillary artery. It begins at the distal (inferior) border of the tendon of teres major and ends about a centimetre distal to the elbow joint (at the level of the neck of the radius) by dividing into the radial and ulnar arteries (see Figs 49.33, 49.44, 50.21–50.22). At first, it is medial to the humerus, but gradually spirals anterior to it until it lies midway between the humeral epicondyles, medial to the tendon of biceps brachii and deep to the bicipital aponeurosis. The latter separates the artery from the anterior structures, namely the skin, superficial fascia and the median cubital vein. The artery divides into its terminal branches, the radial and ulnar arteries, at the level of the radial neck (see Fig. 50.27A).

The branches of the brachial artery are the profunda brachii, nutrient, superior, middle and inferior ulnar collateral, deltoid, muscular, radial and ulnar arteries.

Relations The brachial artery is wholly superficial, covered anteriorly only by skin and superficial and deep fascia: its pulsation can be felt throughout the arm. The bicipital aponeurosis crosses it anteriorly at the elbow, separating it from the median cubital vein; the median nerve crosses it lateromedially near the distal attachment of coracobrachialis. Posterior to the artery are the long head of triceps, separated initially by the radial nerve and profunda brachii artery, and then successively

by the medial head of triceps, the attachment of coracobrachialis and brachialis. Proximally, the median nerve and coracobrachialis lie laterally and the medial cutaneous nerve of the forearm and ulnar nerve lie medially. Distally, biceps brachii overlaps the artery laterally and the median nerve and basilic vein lie medially. The artery is accompanied by two venae comitantes, connected by transverse and oblique branches. At the elbow, the brachial artery sinks deeply into the triangular intermuscular cubital fossa. Posteriorly, brachialis separates it from the elbow joint. The median nerve passes close to the medial side of the artery.

Variants The brachial artery, with the median nerve, may diverge from the medial border of biceps brachii and descend towards the medial humeral epicondyle, usually behind a supracondylar process from which a fibrous arch crosses the artery, and which then runs behind or through pronator teres to the elbow. Occasionally the artery divides proximally into two trunks that reunite. Frequently it divides more proximally than usual into radial, ulnar and common interosseous arteries. Most often the radial branches arise proximally, leaving a common trunk for the ulnar and common interosseous arteries. Sometimes the ulnar artery arises proximally and the radial and common interosseous arteries form the other division, or the common interosseous may also arise proximally. Slender vasa aberrantia may connect the brachial artery to the axillary artery or to one of the forearm arteries, usually the radial. The brachial artery may be crossed by muscular or tendinous slips from coracobrachialis, biceps brachii, brachialis or pronator teres. Rarely the median nerve crosses posterior, rather than anterior, to the brachial artery near the insertion of coracobrachialis.

Profunda brachii artery

The profunda brachii artery (see Figs 49.31, 49.33) is a large branch from the posteromedial aspect of the brachial artery, distal to teres major. It follows the radial nerve closely, at first posteriorly between the long and medial heads of triceps, then in the spiral groove covered by the lateral head of triceps. It supplies muscular branches, and the nutrient artery of the humerus, and finally divides into terminal radial and middle collateral branches. The radial collateral branch pierces the lateral intermuscular septum to reach the anterior aspect of the epicondyle of the humerus in the groove between brachioradialis and brachialis, and takes part in the anastomosis around the elbow. The middle collateral branch runs posterior to the septum and epicondyle.

The profunda brachii may originate from a common origin with the posterior circumflex humeral artery, from the axillary artery proximal to the tendon of latissimus dorsi, or from the distal portion of the axillary artery.

Middle collateral (posterior descending) branch

The middle collateral artery is the larger terminal branch of the profunda brachii artery. It arises posterior to the humerus and descends along the posterior surface of the lateral intermuscular septum to the elbow. Proximally, the artery lies between brachialis (anteriorly) and the lateral head of triceps (posteriorly). Distally, it lies between brachioradialis (anteriorly) and the lateral head of triceps (posteriorly). It may pierce the deep fascia and become cutaneous, or remain deep to the fascia, forming an arch with the inferior ulnar collateral artery proximal to the olecranon fossa before anastomosing with the interosseous recurrent artery behind the lateral epicondyle; it gives off about five small fasciocutaneous perforators and often has a small branch that accompanies the nerve to anconeus.

Radial collateral (anterior descending) branch

The radial collateral artery accompanies the radial nerve through the lateral intermuscular septum, descending between brachialis and brachioradialis anterior to the lateral epicondyle and anastomosing with the radial recurrent artery. It supplies brachialis, brachioradialis, the radial nerve and a few fasciocutaneous perforators.

Nutrient artery of humerus

The nutrient artery of the humerus arises near the mid-level of the upper arm and enters the nutrient canal near the attachment of coracobrachialis, posterior to the deltoid tuberosity; it is directed distally.

Superior ulnar collateral artery

The superior ulnar collateral artery arises a little distal to the mid-level of the upper arm, usually from the brachial artery (see Fig. 48.3), but often as a branch from the profunda brachii. It accompanies the ulnar nerve, piercing the medial intermuscular septum to descend in the posterior compartment and supply the medial head of triceps. It passes between the medial epicondyle and olecranon, ending deep to flexor carpi ulnaris by anastomosing with the posterior ulnar recurrent and inferior collateral arteries. A branch sometimes passes anterior to the medial epicondyle and anastomoses with the anterior ulnar recurrent artery.

Middle ulnar collateral artery

If present, the middle ulnar collateral artery arises from the brachial artery between the superior and inferior ulnar collateral arteries. It passes anterior to the medial epicondyle, anastomoses with the anterior ulnar recurrent artery, supplies triceps and sends small fasciocutaneous perforators to the skin.

Inferior ulnar collateral (supratrochlear) artery

The inferior ulnar collateral artery begins approximately 5 cm proximal to the elbow. It passes medially between the median nerve and brachialis, pierces the medial intermuscular septum and curls round the humerus between triceps and bone (see Figs 48.3, 49.33). It forms an arch proximal to the olecranon fossa with the middle collateral branch of the profunda brachii artery. As it lies on brachialis, it gives off branches that descend anterior to the medial epicondyle to anastomose with the anterior ulnar recurrent artery. Behind the epicondyle, a branch anastomoses with the superior ulnar collateral and posterior ulnar recurrent arteries.

Muscular branches

Muscular branches are distributed to coracobrachialis, biceps and brachialis.

Deltoid (ascending) branch

The deltoid branch ascends between the lateral and long heads of triceps, and anastomoses with a descending branch of the posterior humeral circumflex artery.

Radial artery

The radial artery is smaller than the ulnar artery, yet appears a more direct continuation of the brachial artery (see Figs 50.21–50.22). It may occasionally arise from a continuation of a superficial brachial artery, or as a high proximal division of an otherwise normal brachial artery and it can give rise to the common interosseous artery.

The radial artery passes deep to brachioradialis and gives off the radial recurrent artery before continuing into the forearm. It descends along the lateral side of the forearm, accompanied by paired venae comitantes, from the medial side of the neck of the radius to the wrist. The artery is medial to the radial shaft proximally, and anterior to it distally. Proximally, it is overlapped anteriorly by the belly of brachioradialis, but elsewhere in its course it is covered only by the skin and superficial and deep fasciae. Its posterior relations in the forearm are, successively, the tendon of biceps, supinator, the distal attachment of pronator teres, the radial head of flexor digitorum superficialis, flexor pollicis longus, pronator quadratus and the lower end of the radius (where its pulsation is most accessible). Brachioradialis is lateral to the artery throughout its length. Pronator teres is medial to the proximal part of the artery, and the tendon of flexor carpi radialis is medial to the distal portion. The superficial radial nerve lies lateral to the middle third of the radial artery; multiple branches from the artery supply the nerve throughout its length.

At the wrist, the radial artery passes on to the dorsal aspect of the carpus between the lateral carpal ligament and the tendons of abductor pollicis longus and extensor pollicis brevis (see Fig. 51.37). It crosses the scaphoid bone and trapezium (in the anatomical snuff-box), where again, its pulsation is obvious; as it passes between the heads of the first dorsal interosseous, it is crossed by the tendon of extensor pollicis longus. Between the thumb extensors, it is crossed by the start of the cephalic vein and the branches of the radial nerve that pass to the thumb and index finger. Occasionally it gives off a distal superficial dorsal branch that crosses the radial extensor tendons at the wrist, together with the superficial radial nerve. Branches of the lateral cutaneous nerve of the forearm run along its distal part as it curves round the carpus.

In the hand, the radial artery passes through the first interosseous space between the heads of the first dorsal interosseous and crosses the palm. At first, it lies deep to the oblique head of adductor pollicis and then passes between its oblique and transverse heads or through the transverse head. At the fifth metacarpal base, it anastomoses with the deep branch of the ulnar artery, completing the deep palmar arch (see Fig. 51.36).

Radial recurrent artery

The radial recurrent artery is given off by the radial artery just distal to the elbow joint (see Figs 50.21–50.22, 50.27). It passes between the superficial radial nerve and the posterior interosseous nerve before ascending beneath brachioradialis, anterior to supinator and brachialis. It supplies these muscles and then anastomoses with the radial collateral branch of the profunda brachii artery. The radial recurrent artery also gives branches to extensor carpi radialis longus, extensor digitorum, extensor digiti minimi and extensor carpi ulnaris.

Muscular branches

Muscular branches are distributed to the muscles on the radial side of the forearm. Direct branches from the radial artery supply the radial insertion of pronator teres, the anterolateral aspect of flexor carpi radialis, the lateral surface of flexor digitorum superficialis, the lateral half of flexor pollicis longus, and the distal sections of extensor carpi radialis longus and extensor carpi radialis brevis.

Palmar carpal branch

The palmar carpal branch arises near the distal border of pronator quadratus (see Fig. 50.9B). It crosses the anterior surface of the distal end of the radius, near the palmar carpal surface, and passes medially to anastomose behind the long flexor tendons with the palmar carpal branch of the ulnar artery. This transverse anastomosis is joined by longitudinal branches from the anterior interosseous artery and recurrent branches from the deep palmar arch, forming a cruciate palmar radiocarpal arch that supplies the carpal articulations and bones by descending branches.

Superficial palmar branch

The superficial palmar branch arises from the radial artery just before it curves round the carpus. It passes through, and occasionally over, the thenar muscles, which it supplies, and usually anastomoses with the end of the ulnar artery to complete a superficial palmar arch (see Fig. 51.36). The superficial arch is complete in about 80% of cases (Zarzecki et al 2018).

First dorsal metacarpal artery

The first dorsal metacarpal artery arises from the radial artery just before it passes between the heads of the first dorsal interosseous. It divides, almost at once, into two branches that supply the adjacent sides of the thumb and index finger as far distally as the proximal interphalangeal joint. The radial side of the thumb receives a branch direct from the radial artery proper. In most cases, the first dorsal metacarpal artery follows a fascial course overlying the first dorsal interosseous and parallel to the second metacarpal. Occasionally it may follow an intramuscular course. Distally, it anastomoses with the dorsal branches of the radiopalmar digital artery of the index finger over the proximal phalanx.

Dorsal carpal branch

The dorsal carpal branch of the radial artery arises deep to the tendons of the thumb extensors. It runs medially across the dorsal carpal surface under the tendons and anastomoses with the ulnar dorsal carpal branch, and also with the anterior and posterior interosseous arteries, to form a dorsal radiocarpal arch (see Figs 50.9A, 50.9C, 51.37). The carpal arches are both close to bone and supply the distal epiphysial parts of the radius and ulna. Three dorsal metacarpal arteries descend from the dorsal intercarpal arch on the second to fourth dorsal interossei, and bifurcate into dorsal digital branches to supply the adjacent sides of all four fingers.

Second, third and fourth dorsal metacarpal arteries

The second to fourth dorsal metacarpal arteries arise from the dorsal carpal arch. Near their origins, they anastomose with the deep palmar arch by proximal perforating arteries and, near their bifurcation, with dorsal perforating branches from the palmar metacarpal arteries that pass between the metacarpal necks. They also anastomose distally at the level of the web spaces with dorsal perforating branches from the palmar digital arteries from the superficial palmar arch. The third and fourth dorsal metacarpal arteries are much smaller than the first and second. Cutaneous branches from the dorsal metacarpal arteries supply the dorsal skin as far distally as the proximal interphalangeal joint. At the level of the neck of the second, third and fourth metacarpals, a direct cutaneous branch is given off that passes proximally and supplies an area of skin between the two adjacent metacarpals.

Arteria princeps pollicis

The arteria princeps pollicis (Miletin et al 2017) arises from the radial artery as it turns into the palm to form the deep palmar arch (see Fig. 51.2A). It descends on the palmar aspect of the first metacarpal under the oblique head of adductor pollicis lateral to the first palmar interosseous. At the base of the proximal phalanx, deep to the tendon of flexor pollicis longus, the artery divides into two branches that appear between the medial and lateral attachments of the oblique head of adductor pollicis and run along both sides of the thumb. On the palmar surface of the distal phalanx, the branches form a pollicial arch that supplies the skin and subcutaneous tissue. The arteria princeps pollicis is the usual nutrient of supply to the first metacarpal.

Arteria radialis indicis

The arteria radialis indicis is often a proximal branch of the arteria princeps pollicis, or may arise from the superficial arch or from the first dorsal metacarpal artery, or may combine with the arteria princeps pollicis to form the first palmar metacarpal artery. It descends between the first dorsal interosseous and transverse head of adductor pollicis, and runs along the lateral side of the index finger to its tip (see Fig. 51.27B). It anastomoses with the index medial digital artery and with the arteria princeps pollicis and the superficial palmar arch at the distal border of the transverse head of adductor pollicis.

Deep palmar arch

The deep palmar arch is formed by anastomosis of the end of the radial artery with the deep palmar branch of the ulnar artery (see Figs 51.2A, 51.35G, 51.36). It crosses the bases of the metacarpals and interossei, covered by the oblique head of adductor pollicis, the tendons of the digital flexors and the lumbricals. In its concavity, running laterally, is the deep branch of the ulnar nerve. The deep palmar arch is incomplete in about 5% (Zarzecki et al 2018).

Palmar metacarpal artery

The three palmar metacarpal arteries run distally from the convexity of the deep palmar arch on the interossei of the second to fourth spaces, and join the common digital branches of the superficial arch at the digital clefts (see Fig. 51.36). They supply nutrient branches to the medial four metacarpals.

Perforating branches

Three perforating branches from the deep palmar arch cross the second to fourth interosseous spaces between the heads of the corresponding dorsal interossei and anastomose with the dorsal metacarpal arteries.

Recurrent branches

Recurrent branches ascend proximally from the deep palmar arch anterior to the carpus to supply the carpal bones and intercarpal articulations. They end in the palmar carpal arch.

Ulnar artery

The ulnar artery arises from the brachial artery just distal to the flexion crease of the elbow at the level of the radial neck, and reaches the medial side of the forearm in its upper third (see Figs 50.21–50.22). It is larger than the radial artery and is accompanied throughout its length by venae comitantes. In the forearm, the ulnar artery initially lies on brachialis before passing deep to pronator teres, flexor carpi radialis, palmaris longus and flexor digitorum superficialis. It then lies on flexor digitorum profundus, between flexor carpi ulnaris and flexor digitorum superficialis. At the wrist, the ulnar artery (see Fig. 51.10) is covered by skin, fascia and palmaris brevis. It lies between the superficial and main parts of the flexor retinaculum, lateral to the ulnar nerve and pisiform bone, and enters the hand. The median nerve is a medial relation for approximately 2.5 cm distal to the elbow, and then crosses the artery, from which it is separated by the ulnar head of pronator teres. The ulnar nerve lies medial to the distal two-thirds of the ulnar artery, which supplies the nerve throughout its length; the palmar cutaneous branch of the ulnar nerve descends along the ulnar artery to reach the hand.

The ulnar artery may arise above the elbow, when it can lie superficial to the forearm flexors under the deep fascia; only rarely is it subcutaneous. When this occurs, the brachial artery supplies the common interosseous and the ulnar recurrent arteries.

Anterior ulnar recurrent artery

The anterior ulnar recurrent artery arises from the ulnar artery distal to the elbow and close to the origin of the ulnar artery itself. It ascends between brachialis and pronator teres, which it supplies, then anastomoses with the inferior ulnar collateral artery anterior to the medial

epicondyle (see Fig. 50.27A). It limits distal extension of the medial Hotchkiss approach to the coronoid process.

Posterior ulnar recurrent artery

The posterior ulnar recurrent artery arises from the ulnar artery distal to the anterior ulnar recurrent artery, passes dorsomedially between flexor digitorum profundus and flexor digitorum superficialis, and ascends between the posterior aspect of the medial epicondyle and the olecranon. It is deep to flexor carpi ulnaris, ascending between its heads with the ulnar nerve. It supplies flexor digitorum profundus, flexor digitorum superficialis, flexor carpi ulnaris, the ulnar nerve, underlying bone and the elbow joint, and anastomoses with the ulnar collateral artery and interosseous recurrent artery. The posterior ulnar recurrent artery and ulnar nerve are both vulnerable to injury behind the medial epicondyle (see Figs 50.28–50.29).

Common interosseous artery

The common interosseous artery is a short branch of the ulnar artery (see Figs 50.10, 50.22). It arises just distal to the radial tuberosity and passes back to the proximal border of the interosseous membrane, where it divides into the anterior and posterior interosseous arteries. Occasionally the common interosseous artery is a branch of the radial artery.

Anterior interosseous artery

The anterior interosseous artery arises from the common interosseous artery and descends on the anterior aspect of the interosseous membrane with the anterior interosseous branch of the median nerve (see Figs 50.10, 50.22, 50.27, 50.32A). It is overlapped by contiguous sides of flexor digitorum profundus and flexor pollicis longus. Shortly after its origin, it usually gives off a slender median artery. This accompanies and supplies the median nerve as far as the palm, where it may join the superficial palmar arch or end as one or two palmar digital arteries. The median artery can also arise from the ulnar or the common interosseous artery. Muscular and nutrient branches from the anterior interosseous artery pierce the interosseous membrane to supply deep extensor muscles and the radius and ulna, respectively. A branch descends deep to pronator quadratus before piercing the interosseous membrane to join the anterior 'carpal' arch.

The anterior interosseous artery leaves the anterior compartment by piercing the interosseous membrane proximal to pronator quadratus. It anastomoses with the posterior interosseous artery in the posterior compartment of the forearm, and travels through a tunnel under the extensor retinaculum with the tendons of the digital extensors before joining the dorsal carpal arch. Three small cutaneous perforating branches supply the skin over the lower lateral border of the forearm.

Posterior interosseous artery

The posterior interosseous artery arises from the common interosseous artery and is usually smaller than the anterior interosseous artery (see Figs 50.10, 50.27A). It passes dorsally between the oblique cord and proximal border of the interosseous membrane, and then between supinator and abductor pollicis longus. It descends deep in the groove between extensor carpi ulnaris and the extensor digiti minimi component of extensor digitorum. While in the groove, it gives rise to multiple muscular branches that supply these muscles and fasciocutaneous perforators that travel in the intermuscular septum between extensor carpi ulnaris and extensor digiti minimi. The posterior interosseous artery accompanies the deep branch of the radial nerve (posterior interosseous nerve) on abductor pollicis longus. Distally, it anastomoses with the terminal part of the anterior interosseous artery and the dorsal carpal arch.

Sometimes, the posterior interosseous artery disappears halfway down the forearm, in which case the anterior interosseous artery pierces the interosseous membrane more proximally to anastomose with it. Occasionally the two vessels do not anastomose.

Posterior interosseous recurrent artery

The posterior interosseous recurrent artery leaves the posterior interosseous artery near its origin and ascends between the lateral epicondyle and olecranon, either on or through supinator, and deep to anconeus. It anastomoses with the middle collateral branch of the profunda brachii artery, posterior ulnar recurrent artery and ulnar collateral artery. Occasionally the artery is absent.

Dorsal cutaneous branch

A constant dorso-ulnar perforator vessel is given off distally. It arises 2–5 cm proximal to the pisiform and accompanies the dorsal cutaneous branch of the ulnar nerve. It emerges between flexor carpi ulnaris and extensor carpi ulnaris.

Palmar carpal branch

The palmar carpal branch crosses the distal ulna deep to the tendons of flexor digitorum profundus and anastomoses with the palmar carpal branch of the radial artery to make a palmar radiocarpal arch.

Dorsal carpal branch

The dorsal carpal branch arises just proximal to the pisiform. It curves deep to the tendon of flexor carpi ulnaris to reach the carpal dorsum, which it crosses laterally beneath the extensor tendons. It anastomoses with the dorsal carpal branch of the radial artery to complete the dorsal carpal arch. Near its origin, it sends a small digital branch along the ulnar side of the fifth metacarpal to supply the medial side of the dorsal surface of the fifth finger.

Deep palmar branch

The deep palmar branch is often double. It passes between abductor and flexor digiti minimi, through or deep to opponens digiti minimi, and anastomoses with the radial artery, completing the deep palmar arch. The deep palmar branch accompanies the deep branch of the ulnar nerve.

Superficial palmar arch

The superficial palmar arch is an anastomosis fed mainly by the ulnar artery (see Figs 51.2A, 51.10, 51.36). The latter enters the palm with the ulnar nerve, anterior to the flexor retinaculum and lateral to the pisiform. It passes medial to the hook of the hamate, then curves laterally to form an arch that is convex distally and level with a transverse line through the distal border of the fully extended base of the thumb. About one-third of superficial palmar arches are formed by the ulnar artery alone, a further third are completed by the superficial palmar branch of the radial artery, and a third by the arteria radialis indicis, or a branch of either arteria princeps pollicis or the median artery. The superficial palmar arch is covered by palmaris brevis and the palmar aponeurosis, and it is superficial to flexor digiti minimi, branches of the median nerve and the tendons of the long flexors and the lumbricals.

Common and proper palmar digital arteries

Three common palmar digital arteries arise from the convexity of the superficial palmar arch (see Fig. 51.2A, 51.36). They pass distally on the second to fourth lumbricals, each joined by a corresponding palmar metacarpal artery from the deep palmar arch, and divide into two proper palmar digital arteries. These run along the contiguous sides of all four fingers, dorsal to the digital nerves, between Grayson's and Cleland's ligaments, anastomosing in the subcutaneous tissue of the fingertips and near the interphalangeal joints. Each digital artery has two dorsal branches that anastomose with the dorsal digital arteries and supply the soft parts dorsal to the middle and distal phalanges, including the matrices of the nails (see Fig. 51.2B). The palmar digital artery for the medial side of the little finger leaves the arch under palmaris brevis. Palmar digital arteries supply the metacarpophalangeal and interphalangeal joints and nutrient rami to the phalanges. They are the main digital supply because the dorsal digital arteries are minute. The origins of the palmar digital arteries of the thumb are quite variable. Both may arise from a single arteria princeps pollicis or they may arise separately from the superficial palmar arch. The ulnar digital artery may arise from the first dorsal metacarpal artery.

The terminal branches of the digital arteries contribute to a number of vascular arcades that provide a rich vascular supply for the distal elements of each digit (see Fig. 51.2A, 51.5). Three distal phalangeal dorsal arterial arcades anastomose with each other and with those from the other side of the digit. The superficial arcade occurs at the level of the proximal nail fold and is supplied primarily by a dorsal branch from the palmar digital artery, which is given off at the level of the middle phalanx. The proximal subungual arcade is at the level of the lunula and is supplied by a terminal branch of the digital artery, which passes dorsally. The distal subungual arcade occurs more distally in the nail bed. It is supplied by a dorsal vessel that emerges from the point of confluence of the 'H'-shaped anastomosis between the terminal portions of both digital arteries, and passes from the volar to the dorsal aspect of the digit under the interosseous ligament connecting the proximal and distal parts of the distal phalanx.

Variants

The ulnar and radial arteries to the hand may occasionally be supplemented by a median artery that contributes to, or supplies, the superficial palmar arch and by the anterior interosseous artery, which may make a contribution to the deep palmar arch. The median artery may persist in two different forms, palmar and antebrachial (Rodriguez-Niedenführ et al 1999). The palmar type arises from the junction of the

ulnar artery and its common interosseous trunk; it is long and large, and reaches the palm, usually ending as the first or second common digital artery, or both. The antebrachial type is slender and short, usually arising from the anterior interosseous artery and finishing in the forearm. These variations are seen in about 20% of individuals and tend to be unilateral. Ulnar artery dominance in all digits is rare, complete radial artery dominance has been described in 28% of hands (Kleinert et al 1989).

Collateral circulation at the elbow

The collateral circulation at the elbow is more robust than that at the knee. Alternative pathways include the profunda brachii artery, which accompanies the radial nerve through the lateral intermuscular septum to become the radial collateral artery. The superior ulnar collateral artery accompanies the ulnar nerve: in the adult, it may be as wide as 1.5 mm at its origin; hence its regular use as the artery to a free vascularized ulnar nerve graft. The inferior ulnar collateral artery is regularly seen during medial approaches to the elbow as a vessel that pierces the intermuscular septum to curl around the humerus between triceps and bone. On occasion, there is a substantial artery running with the median nerve. These vessels anastomose with recurrent branches from the ulnar and radial arteries to form a network that may maintain perfusion of the hand and the extensor muscles in cases where the brachial artery has been divided in the lower third of the arm (when there is no associated fracture or dislocation). Collateral circulation will diminish or cease altogether if the ulnar or radial nerve is entrapped within the fracture or compressed by haematoma (Blakey et al 2009, Birch 2011).

Cutaneous vascular supply of the upper limb

The skin over the lateral end of the clavicle is supplied by the supraclavicular artery, which pierces the deep fascia superior to the clavicle and anterior to trapezius. In most cases, this artery arises from the superficial cervical/transverse cervical artery, but it occasionally arises from the suprascapular artery. The area over deltoid is supplied by the anterior and posterior circumflex humeral arteries. The deltoid branch of the thoraco-acromial axis contributes to the blood supply of the anterior aspect of the shoulder via musculocutaneous perforators through deltoid.

The blood supply to the skin of the upper arm may be divided into three regions with separate supplies. The deltoid region is supplied by musculocutaneous perforators, and the medial and lateral regions are supplied by fasciocutaneous perforators (Cormack and Lamberty 1994, Salmon, in Taylor and Razaboni 1994).

The deltoid region is supplied by the posterior circumflex humeral artery via musculocutaneous perforators. After exiting from the quadrangular space, it gives off a descending branch that runs down to the insertion of deltoid and the overlying skin, and an ascending branch that passes superiorly towards the acromion and pierces the edge of deltoid and the deep fascia to fan out and supply the overlying skin.

The medial side of the upper arm is supplied by five or six fasciocutaneous perforators that arise from the brachial artery, the superior ulnar collateral artery and, if present, the single artery to biceps brachii. These perforators pass along the medial intermuscular septum to spread out in the deep fascia and anastomose with perforating vessels superiorly and inferiorly, and from the lateral side. There are virtually no musculocutaneous perforators through biceps or triceps.

The lateral side of the upper arm below deltoid is supplied by perforating vessels from the middle collateral and radial collateral arteries (the terminating bifurcation of the profunda brachii). The middle collateral artery sends perforators to the skin via the lateral intermuscular septum between brachioradialis and triceps, while the radial collateral artery gives off cutaneous perforators via the intermuscular septum between brachialis and brachioradialis. These cutaneous vessels anastomose with those from the medial side.

The skin of the elbow and forearm receives its blood supply from muscle perforators, fasciocutaneous networks and direct cutaneous vessels. The skin of the anterolateral cubital fossa is supplied by muscle perforators arising from the radial collateral and radial recurrent arteries. The skin of the medial cubital fossa receives branches from an anastomosis between the inferior ulnar collateral and the ulnar recurrent arteries. Small direct cutaneous vessels spring from the brachial artery. The skin of the posterolateral aspect of the elbow is supplied by branches of the posterior interosseous recurrent artery and a rich plexus of collateral and anastomosing arteries. The skin of the posteromedial aspect is supplied by branches of the superior and inferior ulnar collateral arteries and the posterior ulnar recurrent artery feeding into the plexus.

The skin of the anterior forearm is supplied by fasciocutaneous perforators; the largest is the inferior cubital artery, which arises from the radial artery at the distal apex of the cubital fossa and extends to midway down the forearm. Fasciocutaneous perforators from the radial artery supply the lateral two-thirds of the anterior surface of the forearm (see Fig. 48.5). The vessels pass in the intermuscular septa between brachioradialis and flexor carpi radialis, and between flexor carpi radialis and flexor digitorum superficialis. Fasciocutaneous perforators from the ulnar artery supply skin over the ulnar side of the anterior forearm and the medial quarter of the posterior forearm from the cubital fossa to the wrist. A small contribution comes from musculocutaneous perforators that pass through brachioradialis and flexor carpi ulnaris.

The skin of the distal third of the lateral forearm is supplied by the terminal perforating branches of the anterior interosseous artery. The central half of the posterior surface of the forearm, from the lateral edge of extensor digitorum, just below the lateral epicondyle of the humerus, to the wrist, is supplied by fasciocutaneous perforators from the posterior interosseous artery that pass along the intermuscular fascia between extensor carpi ulnaris and extensor digiti minimi.

Arterial Supply of the Lower Limb

The femoral artery provides the principal arterial supply to the lower limb distal to the inguinal ligament and the gluteal fold. It courses within the subsartorial (adductor) canal, which is located on the anteromedial aspect of the thigh, passes through the adductor hiatus and becomes the popliteal artery on entering the posterior compartment of the thigh. The popliteal artery soon divides into the anterior and posterior tibial arteries which supply the leg, ankle and foot.

The obturator and inferior gluteal vessels also contribute to the supply of the proximal part of the lower limb. In the embryo, the inferior gluteal artery supplies the main axial artery of the limb, which is represented in the adult by the artery to the sciatic nerve.

The bones of the lower limb receive their arterial supply from nutrient vessels, metaphysial arterial branches of the peri-articular anastomoses, and the arteries supplying the muscles that attach to their periosteum. The pattern of arterial supply is particularly relevant to fracture healing, the spread of infection and malignancy, and the planning of reconstructive surgical procedures. For further details, consult Cormack and Lamberty (1994), Taylor and Razaboni (1994) and Crock (1996).

Ischaemia of the lower limb due to peripheral arterial disease is a tremendous burden on healthcare resources. Obesity and smoking and diseases including diabetes, hypertension and atherosclerosis, contribute to this pathology. Symptoms include intermittent claudication and wounds that do not heal well (see Sampson et al 2017). Physical examination of such patients may reveal decreased distal pulses (e.g. of the posterior tibial artery), pallor or a cool extremity.

Pulses The pulsation of the femoral artery is palpable as it enters the femoral triangle. Posterior to the knee joint, the popliteal pulse is difficult to identify due to the depth of the popliteal artery, and is best assessed with the knee in slight flexion. Distally, the posterior tibial artery is palpable just posterior to the medial malleolus and the dorsalis pedis pulse is located over the tarsal bones, immediately lateral to the tendon of extensor hallucis longus. Clinical signs of decreased or absent peripheral pulses, particularly the pedal pulses (posterior tibial artery and dorsalis pedis) bilaterally may be indicative of peripheral artery disease (Londero et al 2016).

Femoral artery

The femoral artery (see Figs 77.2, 77.43–77.44, 77.48) is a continuation of the external iliac artery (Benninger 2014) and provides the principal arterial supply to the lower limb distal to the inguinal ligament and the gluteal fold (see Figs 76.4–76.5). It begins posterior to the inguinal ligament, midway between the anterior superior iliac spine and the pubic symphysis, descends along the anteromedial part of the thigh in the femoral triangle, enters and passes through the adductor (subsartorial) canal, and becomes the popliteal artery as it passes through an opening in adductor magnus near the junction of the middle and distal thirds of the thigh. Its first 3 or 4 cm are enclosed, with the femoral vein, in the femoral sheath. The femoral artery gives off several branches in the proximal thigh, including the superficial epigastric, superficial circumflex iliac, superficial external pudendal, deep external pudendal

and the profunda femoris artery. It gives off the descending genicular artery within the adductor canal.

Rarely the femoral artery divides, distal to the origin of the profunda femoris artery, into two trunks that reunite near the adductor opening. The inferior gluteal artery, accompanying the sciatic nerve to the popliteal fossa and representing a persistence of the original axial artery, may replace it. The external iliac artery is then small, ending as the deep artery of the thigh.

Relations Anterior to the artery in the femoral triangle are the skin, subcutaneous tissue, superficial inguinal lymph nodes, fascia lata, femoral sheath, superficial circumflex iliac vein (crossing in the subcutaneous tissue) and the femoral branch of the genitofemoral nerve (which is at first lateral and then anterior). Near the apex of the triangle, the medial femoral cutaneous nerve crosses in front of the artery from the lateral to the medial side. Posteriorly, the posterior wall of the femoral sheath separates the artery from the tendons of psoas, pectineus and adductor longus. The artery is separated from the hip joint by the tendon of psoas major, from pectineus by the femoral vein and deep femoral vessels, and from adductor longus by the femoral vein. Proximally, the nerve to pectineus passes medially behind the artery. The femoral nerve lies lateral to the artery, outside the femoral sheath. The femoral vein is medial to the artery in the proximal part of the triangle and becomes posterior distally at the apex.

Within the adductor canal, the artery is covered by skin, subcutaneous tissue, deep fascia, sartorius and the fibrous roof (subsartorial fascia) of the canal. The saphenous nerve lies at first lateral, then anterior and finally medial to the artery. Adductor longus and adductor magnus are posterior, vastus medialis and its nerve are anterolateral, and the femoral vein is also posterior proximally but it becomes lateral distally (see Figs 77.48–77.49).

Compression of the femoral artery is most effective just distal to the inguinal ligament, where it is superficial and separated from the bone (iliopubic ramus) only by the psoas major tendon. For this reason, arterial injury proximal to the inguinal ligament, such as laceration by a knife, cannot be controlled simply by compression. Gaining proximal control of bleeding involves major exposure of the more proximal arteries as a life-saving manoeuvre.

The branches of the femoral artery include the superficial epigastric, superficial circumflex iliac, superficial external pudendal, deep external pudendal arteries, muscular branches, the profunda femoris artery and the descending genicular artery (see Fig. 76.4).

Superficial epigastric artery

The superficial epigastric artery arises anteriorly from the femoral artery approximately 1 cm distal to the inguinal ligament, and traverses the cribriform fascia to ascend anterior to the ligament and run in the abdominal subcutaneous tissue almost to the umbilicus. It supplies the superficial inguinal lymph nodes, subcutaneous tissue and skin, and anastomoses with branches of the inferior epigastric artery and its contralateral fellow.

Superficial circumflex iliac artery

The superficial circumflex iliac artery is the smallest superficial branch of the femoral artery and arises near or with the superficial epigastric artery. It usually emerges through the fascia lata, lateral to the saphenous opening, and turns laterally distal to the inguinal ligament towards the anterior superior iliac spine. It supplies the skin, subcutaneous tissue and superficial inguinal lymph nodes, anastomosing with the deep circumflex iliac, superior gluteal and lateral circumflex femoral arteries.

The superficial circumflex iliac artery is the basis for the important axial-pattern pedicled groin skin flap. Free flaps based on the vessel may also be raised.

Superficial external pudendal artery

The superficial external pudendal artery arises medially from the femoral artery, close to the preceding branches. Emerging from the cribriform fascia, it passes medially, usually deep to the long saphenous vein, across the spermatic cord (or round ligament) to supply the lower abdominal, penile, scrotal or labial skin, and anastomoses with branches of the internal pudendal artery. The anterior scrotal wall is supplied primarily by branches of the external pudendal artery, which run parallel to the rugae and do not cross the raphe of the scrotum; this anatomical detail is important for planning appropriate incisions during scrotal surgery.

Deep external pudendal artery

The deep external pudendal artery passes medially across pectineus and anterior or posterior to adductor longus, covered by fascia lata, which it pierces to supply the skin of the perineum and scrotum or labium majus. Its branches anastomose with the posterior scrotal or labial branches of the internal pudendal artery.

Muscular branches

Muscular branches supply sartorius, vastus medialis and the adductors.

Profunda femoris artery (deep artery of the thigh)

The profunda femoris artery (see Figs 77.40B, 77.43A, 77.48–77.49) is a large branch that arises posterolaterally from the femoral artery about 3.5 cm distal to the inguinal ligament. At first lateral to the femoral artery, it spirals posterior to this and the femoral vein to reach the medial side of the femur. It passes between pectineus and adductor longus, then between the latter and adductor brevis, before it descends between adductor longus and adductor magnus. It pierces adductor magnus and anastomoses with the upper muscular branches of the popliteal artery. This terminal part is sometimes named the fourth perforating artery.

The profunda femoris artery is the main supply to the adductor, extensor and flexor muscles, and also anastomoses with the internal and external iliac arteries above and with the popliteal artery below. It is a major collateral artery of the lower limb in patients with femoropopliteal arterial occlusive disease (see Fig. 77.49) (Shakeri et al 2010).

The profunda femoris artery sometimes arises from the posterior aspect of the femoral artery, and more rarely from the medial aspect. If it arises posteriorly, it may cross anterior to the femoral vein and then pass backwards around its medial side.

The profunda femoris artery gives off the lateral and medial circumflex arteries in the proximal thigh, and perforating and muscular branches more distally.

Relations Posteriorly, in proximodistal order, lie iliacus, pectineus, adductor brevis and adductor magnus. Anteriorly, the femoral and deep femoral veins, and distally, adductor longus, separate the profunda femoris artery from the femoral artery. Laterally, vastus medialis separates the proximal part of the artery from the femur.

Lateral circumflex femoral artery

The lateral circumflex femoral artery (see Figs 77.48–77.49) is a laterally running branch given off near the root of the profunda femoris artery. It passes between the divisions of the femoral nerve, posterior to sartorius and rectus femoris, and divides into ascending, transverse and descending branches. The ascending branch ascends along the intertrochanteric line, under tensor fasciae latae, lateral to the hip joint. It anastomoses with the superior gluteal and deep circumflex iliac arteries, supplying the greater trochanter, and, with branches of the medial circumflex femoral, forms an anastomotic ring round the femoral neck, from which the femoral neck and head are supplied. The ascending branch forms the pedicle of the tensor fasciae latae musculocutaneous flap. The descending branch descends posterior to rectus femoris, along the anterior border of vastus lateralis, which it supplies; a long branch descends in vastus lateralis to the knee (Tayfur et al 2010), anastomosing with the superior lateral genicular branch of the popliteal artery, accompanied by the nerve to vastus lateralis. The fasciocutaneous perforators that arise from the descending branch supply the anterolateral thigh fasciocutaneous flap. The transverse branch, the smallest, passes laterally anterior to vastus intermedius and pierces vastus lateralis to wind round the femur, just distal to the greater trochanter. It anastomoses with the medial circumflex, inferior gluteal and first perforating arteries, forming a cruciate anastomosis.

The lateral circumflex femoral artery may arise from the femoral artery or as a common trunk with the profunda femoris artery and the medial circumflex femoral artery. The ascending and descending branches may occasionally arise separately (Siddharth et al 1985).

Medial circumflex femoral artery

The medial circumflex femoral artery (see Figs 77.48–77.49) usually originates from the posteromedial aspect of the profunda femoris artery, but sometimes originates from the femoral artery itself or as a common trunk with either the profunda femoris artery or the lateral circumflex femoral artery or both (Siddharth et al 1985). It supplies the adductor muscles and curves medially round the femur between pectineus and psoas major and then obturator externus and adductor brevis, finally appearing between quadratus femoris and the upper border of adductor magnus, dividing into transverse and ascending branches. The transverse branch takes part in the cruciate anastomosis. The ascending branch ascends on the tendon of obturator externus, anterior to quadratus femoris, to the trochanteric fossa, where it

anastomoses with branches of the gluteal and lateral circumflex femoral arteries. An acetabular branch at the proximal edge of adductor brevis enters the hip joint under the transverse acetabular ligament with one from the obturator artery. It supplies the fat in the fossa and reaches the femoral head along its ligament. For details of the blood supply of the proximal end of the femur consult Crock (1996).

Perforating arteries

The perforating arteries (see Fig. 77.40A) perforate the femoral attachment of adductor magnus to reach the flexor aspect of the thigh. There are three perforating branches, and the terminal part of the profunda femoris artery itself becomes the fourth perforator. They pass close to the linea aspera under small tendinous arches and give off muscular, cutaneous and anastomotic branches. Diminished, they pass deep to the short head of biceps femoris (the first usually through the attachment of gluteus maximus), traverse the lateral intermuscular septum and enter vastus lateralis. The first arises proximal, the second anterior and the third distal to adductor brevis. The first perforating artery passes back between pectineus and adductor brevis (sometimes through the latter), pierces adductor magnus near the linea aspera to supply adductor brevis, adductor magnus, biceps femoris and gluteus maximus, and anastomoses with the inferior gluteal, medial and lateral circumflex femoral and second perforating arteries. The larger second perforating artery, often arising with the first, pierces the attachments of adductor brevis and magnus, divides into the ascending and descending branches supplying the posterior thigh muscles and anastomoses with the first and third perforating arteries. The femoral nutrient artery usually arises from it. When two nutrient arteries exist, they usually arise from the first and third perforators. The third perforating artery starts distal to adductor brevis, pierces the attachment of adductor magnus and divides into branches to the posterior thigh muscles. It anastomoses proximally with the perforating arteries, and distally with the end of the profunda femoris artery and muscular branches of the popliteal. The femoral nutrient artery may arise from it. Side branches of the diaphysial nutrient and other branches of the profunda femoris artery provide subsidiary cortical arteries.

The perforating arteries form a double chain of anastomoses, initially in the adductor muscles and subsequently near the linea aspera.

Muscular branches

Numerous muscular branches arise from the profunda femoris artery. Some end in the adductors, and others pierce adductor magnus, supply the flexors and anastomose with the medial circumflex femoral artery and superior muscular branches of the popliteal artery. The profunda femoris artery is thus the main supply to the thigh muscles.

Descending genicular artery

The descending genicular artery (see Figs 77.48–77.49, 78.1), the distal branch of the femoral artery, arises just proximal to the adductor opening and immediately supplies a saphenous branch. It then descends in vastus medialis, anterior to the tendon of adductor magnus, to the medial side of the knee, where it anastomoses with the superior medial genicular artery. Muscular branches supply vastus medialis and adductor magnus, and give off articular branches that anastomose around the knee joint. One articular branch crosses above the femoral patellar surface, forming an arch with the superior lateral genicular artery and supplying the knee joint. The saphenous branch (saphenous artery) emerges distally through the roof of the adductor canal to accompany the saphenous nerve to the medial side of the knee. It passes between sartorius and gracilis, and supplies the skin of the proximomedial area of the leg; it anastomoses with the inferior medial genicular artery.

Arterial anastomoses around the hip and thigh

In the fetus, a peri-acetabular vascular circle formed by the superior and inferior gluteal, internal pudendal and obturator arteries reduces the risk of bony necrosis of this region in children. However, there is a zone at the anterior portion of the acetabulum where the blood supply is less abundant (Damsin et al 1992).

An important chain of anastomoses extends on the back of the thigh from the gluteal region to the popliteal fossa. It is formed in proximodistal order by anastomoses between the gluteal arteries and terminal branches of the medial circumflex femoral artery; the circumflex femoral arteries and the first perforating artery; the perforating arteries themselves; and between the fourth perforating artery and the superior muscular branches of the popliteal artery (see Fig. 76.4). The trochanteric and cruciate anastomoses are the proximal elements of this chain.

Trochanteric anastomosis

The so-called trochanteric anastomosis lies near the trochanteric fossa of the femur and is an anastomosis between the ascending branch of the medial circumflex femoral artery and descending branches of the superior and inferior gluteal arteries. The lateral circumflex femoral artery and the first perforating artery from the profunda femoris artery may also contribute, creating an extracapsular 'arterial ring of the femoral neck' (Crock 1996). Branches from this ring, the retinacular vessels, pierce the capsule and ascend along the femoral neck to give the main blood supply to the head of the femur.

Cruciate anastomosis

The cruciate anastomosis lies at the level of the lesser trochanter, near the lower edge of the femoral attachment of quadratus femoris, and is an anastomosis between the transverse branches of the medial and lateral circumflex femoral arteries, a descending branch of the inferior gluteal artery and an ascending branch from the first perforating artery.

Collateral circulation in proximal femoral artery occlusion

After occlusion of the femoral artery proximal to the origin of the profunda femoris artery, five main anastomotic channels are available. These are between branches of the superior and inferior gluteal arteries, the medial and lateral circumflex femoral arteries and the first perforating branch of the profunda femoris artery; the obturator branch of the internal iliac artery and the medial circumflex femoral artery; the internal pudendal branch of the internal iliac artery and the superficial and deep external pudendal branches of the femoral artery; a deep circumflex iliac branch of the external iliac artery, the lateral circumflex femoral branch of the deep artery of the thigh and the superficial circumflex iliac branch of the femoral artery; and the inferior gluteal branch of the internal iliac artery and perforating branches of the profunda femoris artery.

Popliteal artery

The popliteal artery is the continuation of the femoral artery and crosses the popliteal fossa (see Figs 78.1B, 78.2, 78.4). It descends laterally from the opening in adductor magnus to the femoral intercondylar fossa, inclining obliquely to the distal border of popliteus, where it divides into the anterior and posterior tibial arteries. This division usually occurs at the proximal end of the interosseous space between the wide tibial metaphysis and the slender fibular metaphysis. The artery is relatively tethered at the adductor hiatus and again distally by the fascia related to soleus, and is therefore susceptible to damage following knee injuries, e.g. dislocation. Aneurysms of the popliteal artery are not uncommon.

The popliteal artery may occasionally bifurcate more superiorly and divide into its terminal branches proximal to popliteus, or it may trifurcate into anterior and posterior tibial and fibular arteries. Either the anterior tibial or the posterior tibial artery may be reduced or increased in size. The size of the fibular artery is usually inversely related to the size of the anterior and posterior tibial arteries. Rarely the anterior tibial artery is the source of the fibular artery, a variation that is almost always associated with a high bifurcation of the popliteal artery. The popliteal and inferior gluteal arteries may be joined by a large anastomotic vessel; in such cases, the femoral artery is hypoplastic (Kawashima and Sasaki 2010). When this occurs, the popliteal artery usually has an abnormal relationship to popliteus, running deep to the muscle before dividing into its terminal branches. The popliteal artery may pass medially beneath the medial head of gastrocnemius, or may pass beneath an aberrant band of muscle in the popliteal fossa; in either case, contraction of the muscles may occlude the artery, a condition that may present with claudication on exertion. The popliteal vein is usually superficial and adjacent to the artery, but it may run deep to the artery, or be separated from it by a slip of muscle derived from the medial head of gastrocnemius.

Relations Anteriorly, from proximal to distal, are fat covering the femoral popliteal surface, the capsule of the knee joint, and the fascia of popliteus. Posteriorly are semimembranosus (proximally) and gastrocnemius and plantaris (distally). In between, the artery is separated from the skin and fasciae by fat and crossed from its lateral to its medial side by the tibial nerve and popliteal vein; the vein lies between the nerve and artery and is adherent to the latter. Laterally are biceps femoris, the tibial nerve, popliteal vein and lateral femoral condyle (all proximal), and plantaris and the lateral head of gastrocnemius (distal). Medially are semimembranosus and the medial femoral condyle (proximal), and the tibial nerve, popliteal vein and medial head of gastrocnemius (distally). The relations of the popliteal nodes are described below.

Superior genicular arteries

The superior genicular arteries branch from the popliteal artery, curving round proximal to both femoral condyles to reach the anterior aspect

of the knee. The superior medial genicular artery lies under semimembranosus and semitendinosus, proximal to the medial head of gastrocnemius and deep to the tendon of adductor magnus. It divides into a branch to vastus medialis that anastomoses with the descending genicular and inferior medial genicular arteries, and a branch that ramifies on the femur and anastomoses with the superior lateral genicular artery. Its size varies inversely with that of the descending genicular artery. The superior lateral genicular artery passes under the tendon of biceps femoris, pierces the lateral intermuscular septum and divides into superficial and deep branches. The superficial branch supplies vastus lateralis and anastomoses with the descending branch of the lateral circumflex femoral and inferior lateral genicular arteries, while the deep branch anastomoses with the superior medial genicular artery, forming an anterior arch across the femur with the descending genicular artery. The superficial branch is vulnerable if the lateral patellar retinaculum is divided surgically.

Middle genicular artery

The middle genicular artery is small. It arises from the popliteal artery near the midpoint of the posterior aspect of the knee joint. It pierces the oblique popliteal ligament to supply the cruciate ligaments and synovial membrane.

Inferior genicular arteries

The inferior medial and lateral genicular arteries arise from the popliteal artery deep to gastrocnemius. The inferior medial genicular artery is deep to the medial head of gastrocnemius. It descends along the proximal margin of popliteus, which it supplies; passes inferior to the medial tibial condyle, under the tibial collateral ligament; and then ascends anteromedial to the knee joint at the anterior border of the tibial collateral ligament. It supplies the joint and the tibia, and anastomoses with the inferior lateral and superior medial genicular arteries and with the anterior tibial recurrent artery and saphenous branch of the descending genicular artery. The inferior lateral genicular artery runs laterally across popliteus and forwards over the head of the fibula to the front of the knee joint, passing under the lateral head of gastrocnemius, the fibular collateral ligament and the tendon of biceps femoris. Its branches anastomose with the inferior medial and superior lateral genicular arteries; anterior and posterior tibial recurrent arteries; and the circumflex fibular branch of the posterior tibial artery.

Cutaneous branches: the superficial sural arteries

The superficial sural arteries are three vessels that leave the popliteal artery, or its side branches, descend between the heads of gastrocnemius and perforate the deep fascia to supply the skin on the back of the leg. The central or median vessel is usually larger than the medial or lateral vessels, and usually accompanies the sural nerve.

Fasciocutaneous free and pedicled flaps may be raised on the superficial sural arteries.

Superior muscular branches

The superior muscular branches are two or three vessels that arise proximally and pass to adductor magnus and the posterior thigh muscles. They anastomose with the termination of the profunda femoris artery.

Sural arteries

The two sural arteries are large and arise behind the knee joint to supply gastrocnemius, soleus and plantaris. They are used in gastrocnemius musculocutaneous flaps.

Genicular anastomosis

There is an intricate arterial anastomosis around the patella and femoral and tibial condyles (see Fig. 78.1). A superficial network spreads between the fascia and skin around the patella and in the fat deep to the patellar ligament. A deep network lies on the femur and tibia near their adjoining articular surfaces, and supplies the bone, articular capsule and synovial membrane. The vessels involved in this anastomosis are the superior medial and lateral genicular; inferior medial and lateral genicular; descending genicular; descending branch of the lateral circumflex femoral; circumflex fibular; and anterior and posterior tibial recurrent arteries.

Anterior tibial artery

The anterior tibial artery arises at the distal border of popliteus (see Figs 76.4A–B, 78.1, 78.4, 78.36, 78.39, 78.40, 79.10A). At first in the flexor compartment, it passes between the heads of tibialis posterior and through the oval aperture in the proximal part of the interosseous membrane to reach the extensor (anterior) compartment, passing medial to the fibular neck; it is vulnerable here during tibial osteotomy. Descending on the anterior aspect of the membrane, it approaches the tibia and, distally, lies anterior to it. At the ankle, the anterior tibial artery is located approximately midway between the malleoli, and it continues on the dorsum of the foot, lateral to extensor hallucis longus, as the dorsalis pedis artery.

The anterior tibial artery may, on occasion, be small but it is rarely absent. Its function may be replaced by perforating branches from the posterior tibial artery or by the perforating branch of the fibular artery. It occasionally deviates laterally, regaining its usual position at the ankle. It may also be larger than normal, in which case its territory of supply in the foot may be increased to include the plantar surface.

The named branches of the anterior tibial artery are the posterior and anterior tibial recurrent, muscular, perforating, and anterior medial and lateral malleolar arteries.

Relations In its proximal two-thirds the anterior tibial artery lies on the interosseous membrane, and in its distal third it is anterior to the tibia and ankle joint. Proximally, it lies between tibialis anterior and extensor digitorum longus, then between tibialis anterior and extensor hallucis longus. At the ankle it is crossed superficially from the lateral side by the tendon of extensor hallucis longus and then lies between this tendon and the first tendon of extensor digitorum longus. Its proximal two-thirds are covered by adjoining muscles and deep fascia, its distal third by the skin, fasciae and extensor retinacula. It is accompanied by venae comitantes. The deep fibular nerve, curling laterally round the fibular neck, reaches the lateral side of the artery where it enters the extensor region, is then anterior to the artery in the middle third of the leg, and becomes lateral again distally.

Posterior tibial recurrent artery

The posterior tibial recurrent artery is an inconstant branch that arises before the anterior tibial artery reaches the extensor compartment of the leg. It ascends anterior to popliteus, anastomosing with the inferior genicular branches of the popliteal artery. It supplies the superior tibiofibular joint.

Anterior tibial recurrent artery

The anterior tibial recurrent artery arises near the posterior tibial recurrent artery. It ascends in tibialis anterior, ramifies on the front and sides of the knee joint, and joins the patellar anastomosis, which interconnects with the genicular branches of the popliteal and circumflex fibular arteries.

Muscular branches

Numerous branches supply the adjacent muscles. Some then pierce the deep fascia to supply the skin, while others traverse the interosseous membrane to anastomose with branches of the posterior tibial and fibular arteries.

Perforating branches

Most of the fasciocutaneous perforators pass along the anterior fibular fascial septum behind extensor digitorum longus before penetrating the deep fascia to supply the skin.

Anterior medial malleolar artery

The anterior medial malleolar artery arises approximately 5 cm proximal to the ankle. It passes posterior to the tendons of extensor hallucis longus and tibialis anterior medial to the joint, where it joins branches of the posterior tibial and medial plantar arteries.

Anterior lateral malleolar artery

The anterior lateral malleolar artery runs posterior to the tendons of extensor digitorum longus and fibularis tertius to the lateral side of the ankle and anastomoses with the perforating branch of the fibular artery and ascending branches of the lateral tarsal artery.

Posterior tibial artery

The posterior tibial artery begins at the distal border of popliteus, between the tibia and fibula (see Figs 76.4B, 78.4, 78.40). It descends medially in the flexor compartment and divides under abductor hallucis, midway between the medial malleolus and the calcaneal tubercle, into the medial and lateral plantar arteries. In its course, the posterior tibial artery gives off a communicating branch that runs posteriorly across the tibia approximately 5 cm above its distal end, deep to flexor hallucis longus, and joins a communicating branch of the fibular artery; calcaneal branches that arise just proximal to the termination of the posterior tibial artery, pierce the flexor retinaculum and supply the skin

and fat behind the calcaneal tendon; and the artery of the tarsal canal. The posterior tibial artery may be much reduced in length or in calibre, in which case, the fibular artery then takes over its distal territory of supply and may consequently be increased in size.

The named branches of the posterior tibial artery are the circumflex fibular, nutrient, muscular, perforating, communicating, medial malleolar, calcaneal, fibular and medial and lateral plantar arteries.

Relations The posterior tibial artery is successively posterior to tibialis posterior, flexor digitorum longus, the tibia and the ankle joint. Proximally, gastrocnemius, soleus and the transverse intermuscular septum of the leg are superficial to the artery, and distally, it is covered only by skin and fascia. It is parallel with and approximately 2.5 cm anterior to the medial border of the calcaneal tendon; terminally, it is deep to the flexor retinaculum. The artery is accompanied by two veins and the tibial nerve. The nerve is at first medial to the artery but soon crosses behind it and subsequently becomes largely posterolateral in position.

Circumflex fibular artery

The circumflex fibular artery, which sometimes arises from the anterior tibial artery, passes laterally round the neck of the fibula through the soleus to anastomose with the inferior medial and lateral genicular and anterior tibial recurrent arteries. It supplies bone and related articular structures.

Nutrient artery of the tibia

The nutrient artery of the tibia is one of the largest of the nutrient arteries. It arises from the posterior tibial artery near its origin. After giving off a few muscular branches, it descends into the bone immediately distal to the soleal line.

Muscular branches

Muscular branches are distributed to soleus and the deep flexors of the leg.

Perforating branches

Approximately five fasciocutaneous perforators emerge between flexor digitorum longus and soleus, and pass through the deep fascia, often accompanying the perforating veins that connect the deep and superficial venous systems. The arterial perforators then divide into anterior and posterior branches to supply the regional periosteum and skin. These vessels are utilized in raising medial fasciocutaneous perforator flaps in the leg.

Communicating branch

The communicating branch runs posteriorly across the tibia approximately 5 cm above its distal end, deep to flexor hallucis longus, to join a communicating branch of the fibular artery.

Medial malleolar branches

The medial malleolar branches pass round the medial malleolus to the medial malleolar network, which supplies the skin.

Calcaneal branches

Calcaneal branches arise just proximal to the terminal division of the posterior tibial artery. They pierce the flexor retinaculum to supply fat and skin behind the calcaneal tendon and in the heel, and muscles on the tibial side of the sole; the branches anastomose with medial malleolar arteries and calcaneal branches of the fibular artery.

Fibular artery

The fibular artery arises from the posterior tibial artery approximately 2.5 cm distal to popliteus and passes obliquely to the fibula, descending along its medial crest either in a fibrous canal between tibialis posterior and flexor hallucis longus or within flexor hallucis longus (see Figs 76.4B, 78.4). Reaching the inferior tibiofibular syndesmosis, it divides into calcaneal branches that ramify on the lateral and posterior surfaces of the calcaneus. Proximally, it is covered by soleus and the transverse intermuscular septum between soleus and the deep muscles of the leg, and distally it is overlapped by flexor hallucis longus.

The fibular artery may branch high from the posterior tibial artery or may even branch from the popliteal artery separately, resulting in a true 'trifurcation'. It may also branch more distally from the posterior tibial artery, sometimes 7 or 8 cm distal to popliteus. Its size tends to be inversely related to the size of the other arteries of the leg. It may be reduced in size but is more often enlarged, when it may join, reinforce or even replace the posterior tibial artery in the distal leg and foot.

The fibular artery has muscular, nutrient, perforating, communicating and calcaneal branches.

Muscular branches

Multiple short branches supply soleus, tibialis posterior, flexor hallucis longus and the fibular muscles.

Nutrient artery

The nutrient artery branches from the main trunk approximately 7 cm from its origin and enters the fibula 14–19 cm from the apex of the head of the fibula.

Perforating branches

The main perforating branch traverses the interosseous membrane approximately 5 cm proximal to the lateral malleolus to enter the extensor compartment, where it anastomoses with the anterior lateral malleolar artery. Descending anterior to the inferior tibiofibular syndesmosis, it supplies the tarsus and anastomoses with the lateral tarsal artery. This branch is sometimes enlarged and may replace the dorsalis pedis artery.

Fasciocutaneous perforators from the lateral muscular branches pass along the posterior fibular fascial septum to penetrate the deep fascia and reach the skin. These vessels are utilized in raising fasciocutaneous posterolateral leg flaps.

Communicating branch

The communicating branch connects to a communicating branch of the posterior tibial artery approximately 5 cm proximal to the ankle.

Calcaneal branches

Calcaneal (terminal) branches anastomose with the anterior lateral malleolar and calcaneal branches of the posterior tibial artery.

Medial plantar artery

The medial plantar artery is the smaller terminal branch of the posterior tibial artery and passes distally along the medial side of the foot, medial to the medial plantar nerve (see Figs 76.4B, 79.26). At first deep to abductor hallucis, it runs distally between this muscle and flexor digitorum brevis, and supplies both. Near the first metatarsal base, its size, already diminished by muscular branches, is further reduced to a superficial stem that divides to form three superficial digital branches. These accompany the digital branches of the medial plantar nerve and join the first to third plantar metatarsal arteries. The main trunk of the medial plantar artery then runs on to reach the medial border of the hallux, where it anastomoses with a branch of the first plantar metatarsal artery.

Lateral plantar artery

The lateral plantar artery is the larger terminal branch of the posterior tibial artery (see Fig. 79.26). It passes distally and laterally to the fifth metatarsal base; the lateral plantar nerve is medial. (The medial and lateral plantar nerves lie between the corresponding plantar arteries.) Turning medially with the deep branch of the nerve, the lateral plantar artery reaches the interval between the first and second metatarsal bases, and unites with the dorsalis pedis artery to complete the deep plantar arch. As it passes laterally, it is first between the calcaneus and abductor hallucis, then between flexor digitorum brevis and flexor accessorius. Running distally to the fifth metatarsal base, it passes between flexor digitorum brevis and abductor digiti minimi, and is covered by the plantar aponeurosis, superficial fascia and skin.

Muscular branches supply the adjoining muscles. Superficial branches emerge along the intermuscular septum to supply the skin and subcutaneous tissue over the lateral part of the sole. Anastomotic branches run to the lateral border and join branches of the lateral tarsal and arcuate arteries. Sometimes, a calcaneal branch pierces abductor hallucis to supply the skin of the heel. Anastomosis between the medial and lateral plantar arteries superficial to the flexor digitorum brevis is sometimes present and is termed the superficial plantar arch.

Dorsalis pedis artery

The dorsalis pedis artery (see Figs 79.1, 79.25) is usually the continuation of the anterior tibial artery distal to the ankle. It passes to the proximal end of the first intermetatarsal space, where it turns into the sole between the heads of the first dorsal interosseous to complete the deep plantar arch, and provides the first plantar metatarsal artery.

The artery may be larger than normal, to compensate for a small lateral plantar artery. It often diverges laterally from its usual route. It may rarely be absent (Robertson et al 1990), in which event it is replaced by a large perforating branch of the fibular artery.

The dorsalis pedis artery gives rise to the tarsal, arcuate and first dorsal metatarsal arteries (see Figs 79.1, 79.10, 79.25).

Relations The dorsalis pedis artery crosses, successively, the talocrural articular capsule, talus, navicular and intermediate cuneiform and their ligaments; superficial to it are the skin, fasciae, inferior extensor retinaculum and, near its termination, extensor hallucis brevis. Medial to it is the tendon of extensor hallucis longus and lateral to it are the medial tendon of extensor digitorum longus and medial terminal branch of the deep fibular nerve. The tendons and navicular tuberosity are useful landmarks in palpation, or the planning of safe anatomical approaches in surgery of the ankle and foot.

Tarsal arteries

There are two tarsal arteries, lateral and medial (see Fig. 79.25). They arise as the dorsalis pedis artery crosses the navicular. The lateral tarsal artery runs laterally under extensor digitorum brevis; it supplies this muscle and the tarsal articulations, and anastomoses with branches of the arcuate, anterior lateral malleolar and lateral plantar arteries, and the perforating branch of the fibular artery. Two or three medial tarsal arteries ramify on the medial border of the foot and join the medial malleolar arterial network.

Arcuate artery

The arcuate artery (see Fig. 79.25) arises near the medial cuneiform, passes laterally over the metatarsal bases, deep to the tendons of the digital extensors, and anastomoses with the lateral tarsal and plantar arteries. It supplies the second to fourth dorsal metatarsal arteries, running distally superficial to the corresponding dorsal interossei, and divides into two dorsal digital branches for the adjoining toes in the interdigital clefts. Proximally, these branches receive proximal perforating branches from the deep plantar arch. Distally, they are joined by distal perforating branches from the plantar metatarsal arteries. The fourth dorsal metatarsal artery sends a branch to the lateral side of the fifth toe.

The frequency of the arcuate artery has been reported to range from 10% to 67%, depending on the precise definition of the artery (DiLandro et al 2001).

First dorsal metatarsal artery

The first dorsal metatarsal artery (see Fig. 79.25) arises just before the dorsalis pedis artery enters the sole. It runs distally on the first dorsal interosseous and divides at the cleft between the first and second toes. One branch passes under the tendon of extensor hallucis longus and supplies the medial side of the great toe; the other bifurcates to supply the adjoining sides of the great and second toes.

Cutaneous branches

The dorsalis pedis artery and its first dorsal metatarsal branch give rise to small direct cutaneous branches that supply the dorsal foot skin between the extensor retinaculum and the first web space. This vessel provides the basis for a fasciocutaneous flap raised from this region, and which may be used to cover superficial defects elsewhere.

Deep plantar arch

The deep plantar arch (see Fig. 79.26) is deeply situated, extending from the fifth metatarsal base to the proximal end of the first intermetatarsal space. Convex distally, it is plantar to the bases of the second to fourth metatarsals and corresponding interossei, but dorsal to the oblique part of adductor hallucis.

The deep plantar arch gives rise to three perforating and four plantar metatarsal branches, and numerous branches that supply the skin, fasciae and muscles in the sole. Three perforating branches ascend through the proximal ends of the second to fourth intermetatarsal spaces, between the heads of dorsal interossei, and anastomose with the dorsal metatarsal arteries. Four plantar metatarsal arteries extend distally between the metatarsals in contact with the interossei (see Fig. 79.26). Each divides into two plantar digital arteries, supplying the adjacent digital aspects. Near its division, each plantar metatarsal artery sends a distal perforating branch dorsally to join a dorsal metatarsal artery. The first plantar metatarsal artery springs from the junction between the lateral plantar and dorsalis pedis arteries, and sends a digital branch to the medial side of the great toe. The lateral digital branch for the fifth toe arises directly from the lateral plantar artery near the fifth metatarsal base. Haemorrhage from the deep plantar arch is difficult to control because of the depth of the vessel and its important close relations.

Surface anatomy The lateral plantar artery begins between the heel and medial malleolus, and crosses obliquely to a point 2.5 cm medial to the tuberosity of the fifth metatarsal. With a slight distal convexity, it reaches the proximal end of the first intermetatarsal space.

Arterial perforators of the lower limb and surgical flaps

Achieving adequate and aesthetically satisfactory skin and soft tissue cover for large, superficial tissue defects is a perennial challenge in the field of plastic and reconstructive surgery, and accounts for a substantial part of a plastic surgeon's workload. Generally, split-thickness and full-thickness skin grafts are suitable only for very superficial defects. To achieve tissue coverage for deeper and larger tissue defects, one of a variety of autologous tissue flaps may be used. A fasciocutaneous flap is composed of skin, fat and deep fascia (fascia musculorum); a lower-extremity fasciocutaneous flap (Pontén 1981) is very useful in the repair of soft tissue defects of the leg.

The viability of a flap transplanted from one part of the body to another is crucially dependent on the blood supply of the flap. An appreciation of the angiosome concept (Chs 6, 7), coupled with technological advances in reconstructive microsurgery, has stimulated the development and use of perforator (or perforator-based) flaps. These are flaps of skin or subcutaneous tissue supplied by one or more fascial 'perforators', i.e. arteries, which reach the suprafascial plexus either directly from a source vessel, or indirectly from some other neighbouring tissue (Harry et al 2009) (see Fig. 76.6). Perforator-based flaps are typically harvested with sparing of underlying muscle tissue and minimal trauma; their use is said to reduce postoperative pain, donor site morbidity and functional loss.

The lower limb is the largest donor site in the body for perforator-based flaps. Commonly used flaps include anterolateral thigh flaps, which provide a large amount of skin; superior and inferior gluteal artery perforator flaps used in breast reconstruction; vascularized fibular flaps for reconstruction of deficient bone; vascularized tensor fasciae latae flaps for tendon reconstruction; vascularized sural nerve flaps for nerve reconstruction; and the gracilis muscle flap, used for example in the reanimation of paralysed muscle.

In the context of perforator flap surgery, the lower limb may be considered in terms of four anatomic regions: gluteal; anterior hip and thigh; knee and leg; ankle and foot. Each lower limb accounts for approximately 23% of the total body surface area (thigh 10.5%, leg 6.5%, buttock 2.5% and foot 3.5%) and contains an average of 90 arterial perforators.

Gluteal region

The gluteal region of the lower limb has an average of 21 perforators, which arise from three main source arteries: namely, the superior and inferior gluteal and the internal pudendal arteries (see Fig. 76.7). The flaps based on these perforators are used as free flaps for breast reconstruction and as local flaps for covering defects in the sacral and perineal region.

Hip and thigh region

The hip and thigh region has six source arteries and an average of 50 arterial perforators. The thigh can be divided into four areas: anteromedial; anterolateral and trochanteric; posteromedial; and posterolateral. The perforators that supply the anteromedial thigh are derived from the femoral artery, and those for the anterolateral thigh are derived from branches of the lateral circumflex femoral artery. Perforators that supply the skin over the posteromedial and posterolateral thigh regions are derived from the profunda femoris artery and the popliteal arteries. Skin flaps based on the superficial circumflex iliac, superficial external pudendal and superficial inferior epigastric arteries have been used as local flaps, tube pedicles and free tissue transfers. Other popular skin flaps are TFL (tensor fasciae latae) perforator flaps, ALT (anterolateral thigh) and AMT (anteromedial thigh) flaps, the gracilis perforator flap and posterior thigh flaps.

Knee and leg region

The perforators, which arise from the rich vascular anastomosis around the patella, generally traverse the tendon of quadriceps femoris to supply the skin over the patella and the peripatellar region (see Fig. 76.7). The skin flaps based on these perforators may be used as distally based or proximally based flaps to cover defects over the knee and popliteal region. The direct cutaneous branch of the popliteal artery and a superficial sural artery, which accompanies the sural nerve, provide additional perforators to the skin over the back of the knee. The posterior tibial artery gives off an average of ten perforators to the skin covering the anteromedial and posterior parts of the leg. In the upper third of the leg, the perforating vessels are predominantly muscular and periosteocutaneous, while in the lower third, the perforating vessels are mainly direct subcutaneous types. They anastomose with the perforating branches of the anterior tibial artery anteriorly and fibular artery posteriorly. Inferiorly, the posterior tibial artery forms a rich

anastomotic ring around the ankle joint with the fibular and anterior tibial arteries. Perforators from these vessels supply the calcaneal tendon and the overlying skin. The posterior tibial artery gives off three direct cutaneous perforators in the lower part of the leg; a distally based skin or adipofascial flap based on one of these perforators may be used to reconstruct a defect over the anterior or the posterior aspect of the lower leg. The anterior tibial artery gives off an average of six perforators, which supply the anterolateral part of the leg. They emerge in two longitudinal rows; one perforator is fairly large and accompanies the superficial fibular nerve. A small skin flap based on any one of these perforators may be used to cover small defects over the tibia, and a neurocutaneous flap that includes the superficial fibular nerve may be used.

The fibular artery has an average of five perforators. A constant perforator pierces the deep fascia approximately 5 cm above the lateral malleolus and divides into an ascending and a descending branch. A vascularized fibula graft based on the fibular artery is now the standard graft used in reconstruction of the mandible, while small fasciocutaneous and adipofascial flaps based on the perforators of the fibular artery are useful in covering soft tissue defects over the heel and proximal part of the foot.

Ankle and foot region

The arteries around the ankle and in the foot are the medial and lateral calcaneal arteries, medial and lateral plantar arteries and the dorsalis pedis artery (see Fig. 76.7). In the foot, the two plantar arteries with communicating arteries from the dorsalis pedis artery give rise to multiple small perforators. In the sole of the foot, the perforators emerge on either side of the plantar aponeurosis, and also pass through it, to supply the skin. 'Island flaps' from these perforators may be advanced to reconstruct small defects in the weight-bearing area. The skin of the sole of the foot is highly specialized and therefore, ideally, defects in this region should be reconstructed using local skin.

VENOUS DRAINAGE OF THE HEAD AND NECK

The veins of the head and neck can be subdivided into three groups: veins of the exterior of the head and face; veins of the neck; diploic, meningeal, intracranial veins and dural venous sinuses.

Venous drainage of the face

The veins of the face are subject to considerable variations; the following description concerns those that are relatively constant (see Fig. 36.20).

Ophthalmic veins

Superior and inferior ophthalmic veins link the facial and intracranial veins. The superior ophthalmic vein forms posteromedial to the upper eyelid from tributaries that connect anteriorly with the facial and supraorbital veins. It runs with the ophthalmic artery, receiving corresponding tributaries and traverses the superior orbital fissure to end in the cavernous sinus. The inferior ophthalmic vein begins in a network near the anterior region of the orbital floor and medial wall, receiving veins from inferior rectus and inferior oblique, the lacrimal sac and eyelids. It runs back above inferior rectus and often joins the superior ophthalmic vein or may reach the cavernous sinus independently. It is connected with the pterygoid plexus via small branches that pass through the inferior orbital fissure.

Central retinal vein

The central retinal vein traverses the optic nerve then leaves it to pursue a long course in the subarachnoid space before entering the cavernous sinus or the superior ophthalmic veins. It receives a central vein from within the optic nerve.

Supratrochlear vein

The supratrochlear vein starts on the forehead from a venous network connected to the frontal tributaries of the superficial temporal vein. Veins from this network form a single trunk that descends to the bridge of the nose, near the midline and parallel with its contralateral fellow. The veins are joined by a nasal arch across the nose and then diverge, each joining a supraorbital vein to form the facial vein near the medial canthus of the eye.

Supraorbital vein

The supraorbital vein begins near the zygomatic process of the frontal bone, connecting with branches of the superficial and middle temporal veins. It passes medially above the orbital opening, pierces orbicularis oculi and unites with the supratrochlear vein near the medial canthus of the eye to form the facial vein. A branch passes through the supraorbital notch, where it receives veins from the frontal sinus and frontal diploë, and subsequently connects with the superior ophthalmic vein.

Facial vein

The facial vein is the main vein draining the face. After receiving the supratrochlear and supraorbital veins, it travels obliquely downwards by the side of the nose, passes under zygomaticus major, risorius and platysma, descends to the anterior border of masseter and then passes over the surface of the muscle. The facial vein initially lies behind the more tortuous facial artery but it crosses the artery at the lower border of the mandible and enters the neck, where it runs obliquely back under platysma. Here it lies superficial to the submandibular gland, digastric and stylohyoid (see Fig. 35.13). Just anteroinferior to the mandibular angle, it is joined by the anterior division of the retromandibular vein, and then descends superficial to the loop of the lingual artery, the hypoglossal nerve and external and internal carotid arteries, to enter the internal jugular vein near the greater cornu of the hyoid bone, i.e. in the upper angle of the carotid triangle. Near its end, a large branch often descends along the anterior border of sternocleidomastoid to join the anterior jugular vein. Its uppermost segment, above its junction with the superior labial vein, is often termed the angular vein.

Near its origin, the facial vein connects with the superior ophthalmic vein, both directly and via the supraorbital vein, and so is linked to the cavernous sinus. On the face, the facial vein receives tributaries from the side of the nose and, below this, an important deep facial vein from the pterygoid venous plexus. It also receives the inferior palpebral, superior and inferior labial, buccinator, parotid and masseteric veins. The portion of the facial vein that lies below the mandible receives submental, tonsillar, external palatine (paratonsillar) and submandibular veins, vena comitans of the hypoglossal nerve (sometimes), and the pharyngeal and superior thyroid veins.

Superficial temporal vein

A widespread venous network across the scalp receives branches from the supratrochlear, supraorbital, posterior auricular and occipital veins. Anterior and posterior tributaries from this network unite above the zygomatic arch to form the superficial temporal vein on each side. The vein accompanies its artery, usually lying behind it, crosses the posterior root of the zygoma and enters the parotid gland. In its course it receives the parotid veins, rami draining the temporomandibular joint, and the anterior auricular, transverse facial and middle temporal veins. The middle temporal vein receives the orbital vein (formed by the lateral palpebral veins), pierces the temporal fascia and then passes back between the layers of the fascia to join the superficial temporal vein just above the level of the zygomatic arch. The superficial temporal vein joins the maxillary vein in the parotid gland to form the retromandibular vein.

Buccal, mental and infraorbital veins

The buccal, mental and infraorbital veins drain the cheek and chin regions and pass into the pterygoid venous plexus.

Pterygoid venous plexus

The pterygoid plexus is found partly between temporalis and lateral pterygoid and partly between lateral and medial pterygoid. Sphenopalatine, deep temporal, pterygoid, masseteric, buccal, dental, greater palatine and middle meningeal veins and a branch or branches from the inferior ophthalmic vein are all tributaries. The plexus is connected by the deep facial vein with the facial vein and with the cavernous sinus through the sphenoidal emissary foramen, foramen ovale and foramen lacerum. Its deep temporal tributaries are often connected with tributaries of the anterior diploic vein and thus with the middle meningeal veins.

Maxillary vein

The maxillary vein is a short trunk that accompanies the first part of the maxillary artery. It is derived from the confluence of veins from the pterygoid plexus, and passes back between the sphenomandibular ligament and the neck of the mandible, joining the superficial temporal vein to form the retromandibular vein.

Retromandibular vein

The retromandibular vein descends in the parotid gland, between the external carotid artery and, superficially, the facial nerve. It divides into an anterior branch going forwards to join the facial vein and a posterior branch that joins the posterior auricular vein to form the external jugular vein. Occasionally it is not connected to the external jugular vein, which is then small and the anterior jugular is often enlarged.

Posterior auricular vein

The posterior auricular vein arises in a parieto-occipital network that also drains into tributaries of the occipital and superficial temporal veins. It descends behind the auricle to join the posterior division of the retromandibular vein in, or just below, the parotid gland, to form the external jugular vein. It receives a stylomastoid vein and tributaries from the cranial surface of the auricle, drains the region of the scalp behind the ear and drains into the external jugular vein.

Occipital vein

The occipital vein begins in a posterior network in the scalp, pierces the cranial attachment of trapezius, turns into the suboccipital triangle and joins the deep cervical and vertebral veins. It may be joined by a vein draining the diploë in the occipital bone and then passes to either the internal jugular, posterior auricular, deep cervical or vertebral veins. Emissary veins connect the occipital vein to the intracranial venous sinuses via the mastoid and parietal foramina and through the posterior condylar canal and occipital protuberances.

Venous drainage of the neck

Veins in the neck show considerable variation. They are superficial or deep to the deep fascia but are not entirely separate systems. Superficial veins are tributaries – some with specific names, given below – of the anterior, external and posterior jugular veins (see Figs 35.13–35.14). They drain a much smaller volume of tissue than the deep veins. The latter drain all but the subcutaneous structures, mostly into the internal jugular vein and also into the subclavian vein.

External jugular vein

The external jugular vein mainly drains the scalp and face, although it also drains some deeper parts. The vein is formed by the union of the posterior division of the retromandibular vein with the posterior auricular vein and begins near the mandibular angle just below or in the parotid gland (see Fig. 33.3A). It descends from the angle to the mid-clavicle, running obliquely, superficial to sternocleidomastoid, to the root of the neck. Here, it crosses the deep fascia and ends in the subclavian vein, lateral or anterior to scalenus anterior. There are valves at its entrance into the subclavian but they do not prevent regurgitation. Its wall is adherent to the rim of the fascial opening. It is covered by platysma, superficial fascia and skin, and is separated from sternocleidomastoid by deep cervical fascia. The vein crosses the transverse cutaneous nerve and lies parallel with the great auricular nerve, posterior to its upper half. In size, the external jugular vein is inversely proportional to the other veins in the neck and may be double. Between the entrance into the subclavian vein and a point approximately 4 cm above the clavicle, the vein is often dilated, producing a so-called sinus. In addition to formative tributaries, the external jugular receives the posterior external jugular and, near its end, transverse cervical, suprascapular and anterior jugular veins. In the parotid gland, it is often joined by a branch from the internal jugular vein. The occipital vein occasionally joins it.

Posterior external jugular vein

The posterior external jugular vein begins in the occipital scalp and drains the skin and the superficial muscles that lie posterosuperior in the neck. It usually joins the middle part of the external jugular vein.

Anterior jugular vein

The anterior jugular vein arises near the hyoid bone from the confluence of the superficial submandibular veins. It descends between the midline and the anterior border of sternocleidomastoid. Turning laterally, low in the neck, deep to sternocleidomastoid but superficial to the infrahyoid strap muscles, it either joins the end of the external jugular vein or may enter the subclavian vein directly (see Fig. 33.3A). In size, it is usually inverse to the external jugular vein. It communicates with the internal jugular vein and receives the laryngeal veins and sometimes a small thyroid vein. There are usually two anterior jugular veins, united just above the manubrium by a large transverse jugular arch, receiving the inferior thyroid tributaries. They have no valves and may be replaced by a midline trunk.

Internal jugular vein

The internal jugular vein collects blood from the skull, brain, superficial parts of the face and much of the neck. It begins at the cranial base in the posterior compartment of the jugular foramen, where it is continuous with the sigmoid sinus. At its origin, it is dilated as the superior bulb, which lies below the posterior part of the tympanic floor. The internal jugular vein descends in the carotid sheath, and unites with the subclavian vein, posterior to the sternal end of the clavicle, to form the brachiocephalic vein (see Fig. 35.14). Near its termination, the vein dilates into the inferior bulb, above which is a pair of valves. The jugular bulb is a dynamic structure; it forms after 2 years of age and its size stabilizes in adulthood (Friedmann et al 2011).

The tributaries are the inferior petrosal sinus, facial, lingual, pharyngeal, superior and middle thyroid veins, and occasionally the occipital vein. The internal jugular vein may communicate with the external jugular vein. The thoracic duct opens near the union of the left subclavian and internal jugular veins, and the right lymphatic duct opens at the same site on the right.

Relations From above, rectus capitis lateralis, the transverse process of the atlas, levator scapulae, scalenus medius, scalenus anterior, the cervical plexus, the phrenic nerve, thyrocervical trunk, vertebral vein and the first part of the subclavian artery all lie posterior to the vein. On the left, the internal jugular crosses anterior to the thoracic duct. The internal and common carotid arteries and the vagus nerve are medial to the vein, the vagus lying between and posterior to the vessels. The accessory nerve is sometimes found posterior to the vein. Superficially, the internal jugular vein is overlapped above, then covered below, by sternocleidomastoid, and is crossed by the posterior belly of digastric and the superior belly of omohyoid. The parotid gland, styloid process, accessory nerve (almost always), and the posterior auricular and occipital arteries cross the vein superior to the posterior belly of digastric. Between digastric and omohyoid, the sternocleidomastoid arteries and the inferior root of the ansa cervicalis cross the internal jugular vein, the nerve often passing between the vein and the common carotid artery. Below omohyoid, the vein is covered by the infrahyoid muscles and sternocleidomastoid and is crossed by the anterior jugular vein. Deep cervical lymph nodes lie along the internal jugular, mainly on its superficial aspect. At the root of the neck, the right internal jugular vein is separated from the common carotid artery, but the left usually overlaps its artery. At the base of the skull, the internal carotid artery is anterior to the vein, separated from it by the ninth to twelfth cranial nerves.

Tympanic body The tympanic body (glomus jugulare) is ovoid, 0.5 mm long and 0.25 mm broad, and lies in the adventitia of the upper part of the superior bulb of the internal jugular vein. It is similar in structure to the carotid body and is presumed to have a similar function. The predominant cell type has morphological similarities to adrenal chromaffin cells, being derived from the neural crest. Cells obtained from glomus jugulare paragangliomas show spontaneous neurite outgrowth in culture and have vasoactive intestinal peptide (VIP)-like activity. The tympanic body may be present as two or more parts near the tympanic branch of the glossopharyngeal nerve or the auricular branch of the vagus as they lie within their canals in the petrous part of the temporal bone. Tumours of tympanic bodies often involve the adjacent cranial nerves and present with pulsatile tinnitus and a husky voice. These tumours grow into the hypotympanum of the middle ear; intraluminal growth, both proximally and distally, is well recognized.

Inferior petrosal sinus

The inferior petrosal sinus leaves the skull through the anterior part of the jugular foramen, crosses lateral or medial to the ninth to eleventh cranial nerves, and joins the superior jugular bulb.

Lingual veins

The lingual veins follow two routes. The dorsal lingual vein drains the dorsum and side of the tongue, joins the lingual vein accompanying the lingual artery between hyoglossus and genioglossus, and enters the internal jugular vein near the greater cornu of the hyoid bone. The deep lingual vein begins near the tip of the tongue and runs back, lying near the mucous membrane on the inferior surface of the tongue. Near the anterior border of hyoglossus, it joins a sublingual vein from the sublingual salivary gland to form the vena comitans nervi hypoglossi, which runs back between mylohyoid and hyoglossus with the hypoglossal nerve to join either the facial, internal jugular or lingual vein (see Fig. 33.3A).

Pharyngeal veins

The pharyngeal veins begin in a pharyngeal plexus external to the pharynx. They receive meningeal veins and a vein from the pterygoid canal, and usually end in the internal jugular vein, but may sometimes end in the facial, lingual or superior thyroid vein.

Superior thyroid vein

The superior thyroid vein is formed by deep and superficial tributaries corresponding to the arterial branches in the upper part of the thyroid

gland (see Figs 35.13–35.14). It accompanies the superior thyroid artery, receives the superior laryngeal and cricothyroid veins, and ends in the internal jugular or facial vein.

Middle thyroid vein

The middle thyroid vein drains the lower part of the thyroid gland and receives veins from the larynx and trachea. It crosses anterior to the common carotid artery to join the internal jugular vein behind the superior belly of omohyoid. The middle thyroid vein is encountered early in thyroid, parathyroid and pharyngeal pouch surgery and usually ligated. It is one of only two structures that lie within the paracarotid tunnel, the other being a non-recurrent laryngeal nerve.

Vertebral vein

Numerous small tributaries from internal vertebral plexuses leave the vertebral canal above the posterior arch of the atlas and join small veins from local deep muscles in the suboccipital triangle. Their union produces a vessel that enters the foramen in the transverse process of the atlas, forms a plexus around the vertebral artery, and descends through successive transverse foramina to end as the vertebral vein. The vein emerges from the sixth cervical transverse foramen, and descends, at first anterior, then anterolateral, to the vertebral artery. It may join the deep cervical vein before it opens superoposteriorly into the brachiocephalic vein (see Fig. 33.4); the opening has a paired valve. As it descends, it passes behind the internal jugular vein and anterior to the first part of the subclavian artery. A small accessory vertebral vein usually descends from the vertebral plexus, traverses the seventh cervical transverse foramen and turns forwards between the subclavian artery and the cervical pleura to join the brachiocephalic vein. The vertebral artery or vein can be encountered deep in Chassaignac's triangle and care should be taken when dissecting this area.

The vertebral vein is connected with the sigmoid sinus by a vessel in the posterior condylar canal, when the latter exists. It also receives branches from the occipital vein, the veins draining the prevertebral muscles, and the internal and external vertebral plexuses. It is joined by the anterior vertebral and deep cervical veins and sometimes, near its end, by the first intercostal vein.

Anterior vertebral vein

The anterior vertebral vein starts in a plexus around the upper cervical transverse processes, descends near the ascending cervical artery between the attachments of scalenus anterior and longus capitis, and opens into the end of the vertebral vein.

Deep cervical vein

The deep cervical vein accompanies its artery between semispinales capitis and cervicis. It is formed in the suboccipital region by the union of communicating branches of the occipital vein, the veins draining the suboccipital muscles, and veins from plexuses around the cervical spines. It passes forwards between the transverse process of the seventh cervical vertebra and the neck of the first rib to end in the inferior part of the vertebral vein.

Subclavian vein

The subclavian vein is the central continuation of the axillary vein (see Fig. 48.4). It starts at the outer border of the first rib, which it crosses. Initially deep to the clavicular head of pectoralis major and then to subclavius, which is a buffer between it and the overlying medial portion of the clavicle, the vein then runs deep to the insertion of sternocleidomastoid. Only the superior margins of the vein may rise above the medial end of the clavicle, or the entire vein may do so. The phrenic nerve and the inferior part of scalenus anterior lie posteriorly. The subclavian vein joins the internal jugular vein to form the brachiocephalic vein at the medial border of scalenus anterior, behind the sternoclavicular joint (see Fig. 35.14). A pair of valves usually lies within 2 cm of this junction. The subclavian vein receives, as tributaries, the external jugular, dorsal scapular and, sometimes, the anterior jugular veins. The trifurcation of subclavian, external and internal jugular veins is demonstrable by a forced expiration (Valsalva) manoeuvre, when the distended veins rise up above the sternoclavicular joint, filling the fossa above the jugular notch of the sternum. Main lymphatic vessels join the subclavian veins at, or very close to, this junction with the internal jugular vein. The left subclavian vein receives the thoracic duct; the right receives the right lymphatic duct (see Fig. 35.16). There is a risk of air embolism after wounding of the subclavian, external or internal jugular veins.

Dural venous sinuses, emissary veins and diploic veins

Dural venous sinuses form a complex network of venous channels that drain blood from the brain and cranial bones (see Figs 25.2, 25.4, 26.10–26.11, 26.13). They lie between the endosteal and meningeal layers of dura mater, are lined by endothelium, lack valves and their walls are devoid of muscular tissue (Kılıç and Akakın 2008). They develop initially as venous plexuses and, to a variable degree, most adult sinuses retain that form. Plexiform arrays of small veins adjoin the superior and inferior sagittal and straight sinuses, and, less frequently, the transverse sinuses. Ridges of 'spongy' venous tissue, venous lacunae, often project into the lumina of the superior sagittal and transverse sinuses (Browder and Kaplan 1976, Kaplan and Browder 1976).

The plexiform nature of the cranial venous sinuses and their wide connections with cerebral and cerebellar veins vary considerably, particularly in earlier years, e.g. in infancy, the falx cerebelli may contain large plexiform channels and venous lacunae that augment the occipital sinus. These variations must be established for each patient by catheter-based angiography, magnetic resonance (MR) venography or computed tomographic (CT) venography, when clinical necessity arises. The existence of arteriovenous shunts has been inferred from the demonstration of a connection between the middle meningeal arteries and the superior sagittal sinus (Browder and Kaplan 1976). Dural arteriovenous fistulae are thought to be acquired lesions that form in an area of thrombosis within a sinus. If the sinus remains completely thrombosed, venous drainage from these lesions takes place through cortical veins: when the sinus remains closed, the elevated pressure within the cortical veins receiving the arterial flow carries the risk of haemorrhage. If the sinus is partially open, venous drainage is usually into the involved sinus.

The named sinuses are the superior and inferior sagittal, straight, transverse, sigmoid, occipital, cavernous, intercavernous, superior and inferior petrosal, sphenoparietal, basilar and marginal.

Superior sagittal sinus

The superior sagittal sinus runs in the attached convex margin of the falx cerebri. It grooves the internal surface of the frontal bone, the adjacent margins of the two parietal bones and the squamous part of the occipital bone (see Figs 25.2, 25.5, 26.10). It begins near the crista galli, a few millimetres posterior to the foramen caecum, and receives primary tributaries from the cortical veins draining the superior part of the frontal, parietal and occipital lobes, and the anterior part of the orbital surface of the frontal lobe. The sinus is triangular in cross-section, with the apex directed downwards, and is continuous with the falx cerebri. Its lumen is invaded in its intermediate third by projections from its dural walls that may divide the lumen into superior and inferior channels. It is narrow anteriorly, and widens gradually to approximately 1 cm in diameter as it runs posteriorly to enter the confluence of the sinuses, situated to one side (usually the right) of the internal occipital protuberance (see Fig. 25.4). (The confluence of the sinuses is also known as the torcular Herophili or the torcula, although the term actually describes the bony gutter in which the confluence lies.) At the confluence of the sinuses, the superior sagittal sinus usually deviates to become continuous with the right transverse sinus, but also usually connects with the occipital and contralateral transverse sinuses. The size and degree of communication of the channels meeting at the confluence are highly variable; any sinus involved may be duplicated, narrowed or widened near the confluence.

There are usually two or three lateral venous lacunae on each side of the midline, named frontal (small), parietal (large) and occipital (intermediate) lacunae; they tend to become confluent in the elderly, producing a single elongated lacuna on each side. Fine fibrous bands cross the lacunae, and numerous arachnoid granulations project into them (see Fig. 25.6). The lacunae mainly drain diploic and meningeal veins. The cortical veins typically pass beneath the lacunae on their way to the sinus. The superior anastomotic vein (of Trolard), the largest cortical vein that connects the superficial Sylvian (middle cerebral) vein and the superior sagittal sinus, often runs in the precentral, central or postcentral sulci. Near its posterior end, the superior sagittal sinus receives veins from the pericranium that pass through parietal foramina. Acute and complete thrombosis of the superior sagittal sinus is an extremely severe condition causing acute elevation of the intracranial pressure and herniation. Slow and progressive occlusion of the sinus, as is typical for sagittal meningiomas, may be compensated by the development of collateral venous drainage with no clinical consequences.

Inferior sagittal sinus

The inferior sagittal sinus is located in the posterior half or two-thirds of the free margin of the falx cerebri (see Fig. 25.2). It increases in size posteriorly, ends in the straight sinus, and receives veins from the falx

and sometimes from the medial surfaces of the cerebral hemispheres (anterior pericallosal veins).

Straight sinus

The straight sinus lies in the junction of the falx cerebri and the tentorium cerebelli (see Figs 25.2, 26.10). It runs posteroinferiorly as a continuation of the inferior sagittal sinus and drains into the transverse sinus, most commonly into the left sinus. It is not (or is only tenuously) continuous with the superior sagittal sinus. Its tributaries include the great cerebral vein (of Galen), formed by the convergence of the internal cerebral and basal veins, and some superior cerebellar veins which may drain initially into the medial tentorial sinus (a short sinus within the tentorium).

Transverse sinus

The transverse sinuses are attached to the internal occipital protuberance (see Figs 25.2, 25.4). They begin at the confluence of the sinuses: one, usually the right, is directly continuous with the superior sagittal sinus, and the other is directly continuous with the straight sinus. The right transverse sinus is typically larger and drains blood from the superficial parts of the brain. The left transverse sinus mainly drains blood from the deep parts of the brain. On each side, the sinuses run in the attached margin of the tentorium cerebelli, first on the squama of the occipital bone, then on the mastoid angle of the parietal bone. Each follows a gentle anterolateral curve, increasing in size as it does so, to the posterolateral part of the petrous temporal bone, where it turns down as a sigmoid sinus that ultimately becomes continuous with the internal jugular vein. The transverse sinuses receive tributaries from the lateral temporal surface and basal surface of the temporal and occipital lobes. The inferior anastomotic vein (of Labbé) is the largest vein that connects the veins of the Sylvian fissure with the transverse sinus. All tributaries of each transverse sinus may drain first into a lateral tentorial sinus. The superior petrosal sinuses drain into the transition between the transverse and sigmoid sinuses on each side (see Figs 25.2, 25.4).

Sigmoid sinus

The sigmoid sinuses are continuations of the transverse sinuses, beginning where these leave the tentorium cerebelli (see Figs 25.4, 25.7). Each sigmoid sinus curves inferomedially in a groove on the mastoid process of the temporal bone, crosses the jugular process of the occipital bone and turns forwards to the superior jugular bulb, lying posteriorly in the jugular foramen. Anteriorly, a thin plate of bone separates its upper part from the mastoid antrum and mastoid air cells. The sigmoid sinus is connected with pericranial veins via mastoid and condylar emissary veins. Neurosurgical approaches to the lateral aspect of the posterior fossa (cerebellopontine angle) are classified as retrosigmoid, when the craniectomy is located just behind the sigmoid sinus, and presigmoid, when the mastoid bone in front of the sinus is drilled away to provide a more anterior corridor into the posterior fossa.

Superior petrosal sinus

The superior petrosal sinuses are small, narrow sinuses that drain the cavernous sinus into the transverse sinus on each side (see Figs 25.2, 25.4, 25.8–25.9). Each leaves the posterosuperior part of the cavernous sinus and runs posterolaterally in the attached margin of the tentorium cerebelli, crosses superior to the trigeminal nerve to lie in a groove on the superior border of the petrous part of the temporal bone, and ends by joining the transverse sinus at the point where this curves down to become the sigmoid sinus. The superior petrosal sinuses may receive cerebellar and brainstem veins, such as the superior petrosal vein, and, rarely, the inferior cerebral and tympanic veins; they are connected with the inferior petrosal sinuses and the basilar plexus.

Inferior petrosal sinus

The inferior petrosal sinuses drain the cavernous sinus into the internal jugular veins (see Figs 25.4, 26.10). They begin at the posteroinferior aspect of the cavernous sinus and run back in the petroclival fissure (a groove between the petrous part of the temporal bone and the basilar part of the occipital bone). On each side, the inferior petrosal sinus then passes through the anteromedial part of the jugular foramen, accompanied by a meningeal branch of the ascending pharyngeal artery, and descends obliquely backwards to drain into the superior jugular bulb. It sometimes drains via a vein in the hypoglossal canal to the suboccipital vertebral plexus.

The inferior petrosal sinuses are often plexiform. Each receives labyrinthine veins via the cochlear canaliculus and the vestibular aqueduct, and tributaries from the medulla oblongata, pons and inferior cerebellar surface. The venous spaces in the sphenopetroclival area, which are filled anteriorly by blood from the cavernous sinus, medially by blood from the basilar plexus, and laterally by blood from the superior petrosal sinus, typically drain into the inferior petrosal sinuses (Iaconetta et al 2003).

Cavernous sinus

The cavernous sinuses are two large venous plexuses that lie on either side of the body of the sphenoid bone (see Fig. 25.4). They extend from the superior orbital fissure to the apex of the petrous temporal bone, with an average length of 2 cm and width of 1 cm. The cavity of the cavernous sinus is formed when the two layers of dura that cover the anterior aspect of the pituitary gland separate from each other at the lateral margin of the sella: the outer (endosteal) layer continues laterally to form the anterior (sphenoidal) wall of the cavernous sinus, and the inner (meningeal) layer remains attached to the pituitary gland and runs back towards the dorsum sellae to form the medial (sellar) wall of the cavernous sinus. The posterior dural wall is posterior to the dorsum sellae and upper clivus, and is shared with the basilar plexus. The lateral wall extends from the superior orbital fissure to the petrous apex, and separates the cavernous sinus from Meckel's cave, which is inferior and posterior to the sinus. The roof of the cavernous sinus is formed by the clinoidal triangle (the dura lining the lower margin of the anterior clinoid process anteriorly), and the oculomotor triangle (the patch of dura between the anterior and posterior clinoids and the petrous apex).

Each sinus contains the cavernous segment of the internal carotid artery which is associated with a perivascular sympathetic plexus. From proximal to distal, the cavernous carotid artery has several portions, named short ascending, posterior genu, horizontal, anterior genu. The anterior genu of the cavernous carotid artery continues as the paraclinoidal segment of the carotid artery, which typically protrudes into the cavity of the sphenoidal sinus. The cavernous carotid gives off two major arterial branches: the meningohypophysial and inferolateral trunks (see Fig. 25.9B). The meningohypophysial trunk typically arises from the posterior genu and gives off the inferior hypophysial, tentorial and dorsal meningeal arteries. The inferolateral trunk arises a few millimetres distal to the meningohypophysial and is distributed around the nerves on the lateral wall of the sinus. (For more detailed descriptions of these branches, including their main variations, see Krisht et al (1994), Reisch et al (1996), Tekdemir et al (1998).)

Several cranial nerves run forwards through the cavernous sinus to enter the orbit via the superior orbital fissure (see Fig. 25.9). The oculomotor and trochlear nerves and the ophthalmic division of the trigeminal nerve all lie in the lateral wall of the sinus. The abducens nerve enters the cavernous sinus by passing inferior to the petrosphenoidal ligament within a dural tunnel (Dorello's canal) just posterior to the short ascending portion of the cavernous carotid artery, and then runs on the inferolateral side of the horizontal portion of the cavernous carotid artery, just medial to the ophthalmic nerve. The space between the trochlear and ophthalmic nerves at the lateral wall of the sinus, known as the infratrochlear or Parkinson's triangle, gives access to the horizontal and posterior genu portions of the cavernous carotid and the meningohypophysial trunk, and the abducens nerve. Unlike the ophthalmic division of the trigeminal nerve, the maxillary division of the trigeminal nerve does not run through the cavernous sinus or its lateral wall, but courses beneath the dura of the middle cranial fossa below the level of the cavernous sinus (Abhinav et al 2017).

Several major venous spaces or compartments can be identified within the sinus in relation to the cavernous carotid artery: superior, posterior, inferior and lateral (Fernandez-Miranda et al 2017, modified from Harris and Rhoton 1976). The superior and inferior ophthalmic veins drain into the inferior space; the basilar plexus and inferior petrosal sinus drain into the posterior space; the superior petrosal sinus opens into the superior space; and the superficial middle cerebral vein, the inferior cerebral veins and the sphenoparietal sinus may drain into the lateral compartment. Veins traversing the emissary sphenoidal foramen, foramen ovale and foramen lacerum and, less frequently, the central retinal vein and frontal tributary of the middle meningeal vein, also drain into the cavernous sinus.

Tumours (meningiomas, haemangiomas, schwannomas) can arise within the cavernous sinus or extend into the cavernous sinus from adjacent regions, typically, these are pituitary adenomas that invade the medial wall of the sinus. Transcranial microsurgical approaches enter the cavernous sinus through the lateral wall (infratrochlear triangle) or roof (oculomotor triangle) of the sinus. Recently introduced endoscopic endonasal approaches facilitate access to the cavernous sinus from its anterior (sphenoidal) and medial (sellar) walls and provide access to the posterior clinoids (Fernandez-Miranda et al 2014). (For more detailed descriptions of the microsurgical anatomy of the

cavernous sinus, see Dolenc (1987), Umansky et al (1994), Seoane et al (1998), Yasuda et al (2004), Dolenc and Rogers (2009), Fernandez-Miranda et al (2014, 2017).)

Caroticocavernous sinus fistula and cavernous sinus thrombosis

Direct communication between the intracavernous portion of the internal carotid artery and the cavernous sinus, creating a caroticocavernous sinus fistula (CCF), may occur as a result of either severe head trauma or aneurysmal vessel disease. The classic signs are ptosis, proptosis (which may be pulsatile), chemosis, periorbital oedema, and extraocular dysmotility causing diplopia secondary to a combination of third, fourth and sixth cranial nerve palsies. Hypo- or hyperaesthesia in the distribution of the ophthalmic division of the trigeminal nerve and a decreased corneal reflex may also be detected. There may be evidence of dilated, tortuous retinal veins and papilloedema. These changes can cause permanent blindness. CCFs are most commonly treated by passing a catheter up the carotid into the fistula, and then occluding it with dilatable balloons or flexible metal coils. Any spreading infection involving the upper nasal cavities, paranasal sinuses, cheek (especially near the medial canthus), upper lip, anterior nares, or even an upper incisor or canine tooth, may very rarely lead to septic thrombosis of the cavernous sinuses; infected thrombi pass from the facial vein or pterygoid venous complex into the sinus via either ophthalmic veins or emissary veins that enter the cranial cavity through the foramen ovale. This is a critical medical emergency with a high risk of disseminated cerebritis and cerebral venous thrombosis.

Intercavernous sinuses

The two cavernous sinuses are connected by superior, inferior and posterior intercavernous sinuses, and the basilar plexus (see Figs 25.4, 25.8). The superior and posterior intercavernous sinuses lie in the anterior and posterior attached borders of the diaphragma sellae and they thus form a complete circular venous sinus. The inferior intercavernous sinuses are irregular and plexiform in nature, and commonly encountered in a surgical transnasal approach to the pituitary gland. Obliteration of any intercavernous sinus has no clinical consequences because all connections are valveless and the direction of flow in them is reversible.

Basilar venous plexus

The basilar sinus and plexus consist of interconnecting channels between the two layers of dura mater on the clivus (see Fig. 25.4). The basilar venous plexus interconnects the cavernous sinuses and inferior and superior petrosal sinuses, and joins the internal vertebral venous plexus.

Sphenoparietal sinus

The sphenoparietal sinuses are inconstant dural venous channels that lie under the lesser wings of the sphenoid bone, near their posterior edge (see Fig. 25.4). Each sinus curves medially to open into the anterior part of the cavernous sinus, and receives small veins from the adjacent dura mater and sometimes from the frontal ramus of the middle meningeal vein. In its middle course, each may also receive connecting rami from the superficial middle cerebral vein, temporal lobe veins and the anterior temporal diploic vein. When these connections are well developed, the sphenoparietal sinus is a large channel. It has been suggested that the term sphenoparietal sinus should be abandoned on the basis that it is not an anatomical entity, but an artificial combination of two independent meningeal vessels, namely the parietal portion of the anterior branch of the middle meningeal veins and the sinus of the lesser wing of the sphenoid (Ruíz et al 2004).

Occipital sinus

The occipital sinus is the smallest of the sinuses and is typically larger in children. It lies in the attached margin of the falx cerebelli (see Fig. 25.4) and is occasionally paired. It starts near the foramen magnum in several small channels, one of which joins the end of the sigmoid sinus and connects with the internal vertebral plexuses. It ends in the confluence of the sinuses.

Marginal sinus

The marginal sinus encircles the foramen magnum. It communicates anteriorly with the basilar plexus and posteriorly with the occipital sinus. It typically drains to the sigmoid sinus or jugular bulb by small sinuses and may connect extracranially to the internal vertebral venous plexus or the paravertebral or deep cervical veins in the suboccipital region.

Emissary veins

Emissary veins traverse cranial apertures and connect intracranial venous sinuses and extracranial veins. Some are relatively constant, others may be absent. These connections are of clinical significance in determining the spread of infection from extracranial foci to venous sinuses, e.g. the spread of infection from the mastoid to the venous sinuses or from the paranasal sinuses to the cavernous sinus, and they may provide alternative drainage pathways in cases of venous sinus thrombosis.

The following emissary veins have been recognized. A mastoid emissary vein in the mastoid foramen connects the sigmoid sinus with the posterior auricular or occipital veins. A parietal emissary vein in the parietal foramen connects the superior sagittal sinus with the veins of the scalp. The venous plexus of the hypoglossal canal (occasionally a single vein) connects the sigmoid sinus and the internal jugular vein. A supracondylar emissary vein connects the sigmoid sinus and veins in the suboccipital triangle via the posterior condylar canal. A plexus of emissary veins (venous plexus of the foramen ovale) connects the cavernous sinus to the pterygoid plexus via the foramen ovale. Two or three small veins traverse the foramen lacerum and connect the cavernous sinus and the pharyngeal veins and pterygoid plexus. A vein in the emissary sphenoidal foramen (of Vesalius) connects the cavernous sinus with the pharyngeal veins and pterygoid plexus. The internal carotid venous plexus, which passes through the carotid canal, connects the cavernous sinus and the internal jugular vein. A vein may traverse the foramen caecum and connect nasal veins with the superior sagittal sinus. An occipital emissary vein usually connects the confluence of the sinuses with the occipital vein through the occipital protuberance, and also receives the occipital diploic vein. The occipital sinus connects with variably developed veins around the foramen magnum (marginal sinuses) and thus with the vertebral venous plexuses; this pathway provides an alternative venous drainage when the jugular vein is blocked or tied. The ophthalmic veins are potentially emissary because they connect intracranial and extracranial veins. The petrosquamous sinus arises from the dorsolateral portion of the transverse sinus before its confluence with the superior petrosal sinus, courses over the lateral superior surface of the petrous part of the temporal bone, and drains anteroinferiorly into the retromandibular vein and anteromedially into the pterygoid venous plexus. It usually disappears during the development of adult venous patterns in the last three months of prenatal life.

Meningeal veins

Meningeal veins include the middle meningeal and diploic veins. They begin from plexiform vessels in the dura mater and drain into efferent vessels in the outer dural layer that connect with lacunae associated with some of the cranial sinuses. Intracranial veins also communicate with extracranial veins via emissary veins.

Middle meningeal vein

The frontal (anterior) branch of the middle meningeal vein crosses the floor of the middle cranial fossa, from either the foramen ovale or foramen spinosum, to the pterion, usually in the form of two parallel channels that accompany the middle meningeal artery. The vein subsequently passes cranially along the anterior margin of the parietal squama to empty into the venous lakes of the superior sagittal sinus. As they course under the most lateral aspect of the lesser sphenoidal wing, the anterior branches of the middle meningeal vessels are contained for a short distance within a bony canal, the sphenoparietal canal (of Trolard), which they leave to enter a groove on the internal surface of the parietal squama. The veins lie closer to the bone than the artery, sometimes occupying separate grooves, and are particularly liable to tear in cranial fractures. Before it enters the sphenoparietal canal, the anterior branch of the middle meningeal vein usually connects with the sinus of the lesser sphenoidal wing, which is connected medially with the anterior and superior aspect of the cavernous sinus by a channel that crosses over the superior ophthalmic vein to reach the sinus. The parietal (posterior) trunk of the middle meningeal vein may traverse the foramen spinosum to end in the pterygoid venous plexus. The frontal trunk may also reach this plexus via the foramen ovale, or it may end in the sphenoparietal or cavernous sinus (see Fig. 25.4). The middle meningeal vein receives meningeal tributaries and small inferior cerebral veins, and connects with the diploic and superficial middle cerebral veins. It frequently bears arachnoid granulations.

Diploic veins

The diploic veins are large, thin-walled vessels that occupy channels in the diploë of the cranial bones (see Fig. 25.10B). Four main trunks are usually described: the frontal, anterior and posterior temporal, and occipital diploic veins. The frontal vein opens into the supraorbital vein and the superior sagittal sinus; the anterior temporal vein is confined mainly to the frontal bone, and opens into the sphenoparietal sinus and one of the deep temporal veins through an aperture in the greater

wing of the sphenoid; the posterior temporal vein lies in the parietal bone and empties into the transverse sinus either through an opening at the mastoid angle of the parietal bone or through the mastoid foramen; the occipital vein, the largest of the four, is confined to the occipital bone and may open externally into the occipital vein or internally into either the transverse sinus or the confluence of the sinuses.

VENOUS DRAINAGE OF THE BRAIN AND SPINAL CORD

Cerebral hemispheres

Superficial and deep cerebral veins drain the surfaces and the interior of the cerebral hemisphere, respectively. The superficial veins may be divided into three groups, namely superior, middle and inferior. Eight to 12 superior cerebral veins drain the superolateral and medial surfaces of each hemisphere. They mainly follow the sulci, although some pass across gyri. They ascend to the superomedial border of the hemisphere, where they receive small veins from the medial surface, and then open into the superior sagittal sinus. Superior cerebral veins in the anterior part of the hemisphere join the sinus almost at right angles. The larger posterior veins are directed obliquely forwards, against the direction of flow in the sinus, an arrangement which may resist their collapse when intracranial pressure is raised.

Middle cerebral veins

The superficial middle cerebral vein drains most of the lateral surface of the hemisphere, and follows the lateral fissure to end in the cavernous sinus. A superior anastomotic vein runs posterosuperiorly between the superficial middle cerebral vein and the superior sagittal sinus, thus connecting the superior sagittal and cavernous sinuses. An inferior anastomotic vein courses over the temporal lobe and connects the superficial middle cerebral vein to the transverse sinus. The deep middle cerebral vein drains the insular region and joins the anterior cerebral and striate veins to form a basal vein. Regions drained by the anterior cerebral and striate veins correspond approximately to those supplied by the anterior cerebral artery and the central branches which enter the anterior perforated substance. The basal veins pass back alongside the interpeduncular fossa and midbrain, receive tributaries from this vicinity and join the great cerebral vein.

Inferior cerebral veins

Inferior cerebral veins on the orbital surface of the frontal lobe join the superior cerebral veins and thus drain to the superior sagittal sinus. Those on the temporal lobe anastomose with basal veins and middle cerebral veins, and drain to the cavernous, superior petrosal and transverse sinuses.

Basal vein

The basal vein begins at the anterior perforated substance by the union of a small anterior cerebral vein, which accompanies the anterior cerebral artery, a deep middle cerebral vein, which receives tributaries from the insula and neighbouring gyri and runs in the lateral cerebral fissure, and striate veins, which emerge from the anterior perforated substance. The basal vein passes back round the cerebral peduncle to the great cerebral vein and receives tributaries from the interpeduncular fossa, inferior horn of the lateral ventricle, parahippocampal gyrus and midbrain.

Internal cerebral vein

The internal cerebral vein drains the deep parts of the hemisphere and the choroid plexuses of the third and lateral ventricles. It is formed near the interventricular foramen, behind the column of the fornix, primarily by union of the thalamostriate and choroidal veins, although numerous smaller veins from surrounding structures also converge here.

Thalamostriate vein

The thalamostriate vein runs anteriorly, between the caudate nucleus and thalamus, and receives many tributaries from both.

Choroidal vein

The choroidal vein runs a convoluted course along the whole choroid plexus, and receives veins from the hippocampus, fornix, corpus callosum and adjacent structures. After their formation, the two internal cerebral veins travel back parallel to one another beneath the splenium of the corpus callosum, where they unite to form the great cerebral vein.

Great cerebral vein

The great cerebral vein is a short median vessel which curves sharply up around the splenium of the corpus callosum and opens into the anterior end of the straight sinus after receiving the right and left basal veins.

Brainstem

The veins of the brainstem form a superficial venous plexus deep to the arteries. Veins of the medulla oblongata drain into the veins of the spinal cord or the adjacent dural venous sinuses, or into variable radicular veins that accompany the last four cranial nerves to either the inferior petrosal or occipital sinuses, or to the superior bulb of the jugular vein. Anterior and posterior median medullary veins may run along the ventral median fissure and dorsal median sulcus, to become continuous with the spinal veins in corresponding positions. Pontine veins, which may include a median vein and a lateral vein on each side, drain into the basal vein, cerebellar veins, the petrosal or transverse sinuses or the venous plexus of the foramen ovale. Veins of the midbrain join the great cerebral vein (of Galen) or the basal vein.

The veins of the cerebellum drain mainly into sinuses adjacent to them or, from the superior surface, into the great cerebral vein. The cerebellar veins course on the cerebellar surface, and consist of superior and inferior groups. Superior cerebellar veins either run anteromedially across the superior vermis to the straight sinus or great cerebral vein, or they run laterally to the transverse and superior petrosal sinuses. Inferior cerebellar veins include a small median vessel that runs backwards on the inferior vermis to enter the straight or sigmoid sinus. Laterally coursing vessels join the inferior petrosal and occipital sinuses.

Spinal cord

Intramedullary veins within the substance of the spinal cord drain into a circumferential plexus of surface veins, the coronal plexus (venous plexus of the pia mater). Six tortuous longitudinal channels are usually identified within this plexus: anterior and posterior spinal veins (anterior and posterior median veins) and four others that run on either side of the ventral and dorsal nerve roots (see Fig. 47.15). Only the anterior spinal vein, which drains the central grey matter, is consistently complete. It receives sulcal veins and small pial veins from the coronal plexus and is largest in calibre in the lumbosacral region. The posterior spinal vein is frequently variable, appearing plexiform in some segments and as a single channel in others. These vessels connect freely and drain superiorly into the cerebellar veins and cranial sinuses, and segmentally into medullary veins mainly. The segmental veins drain into the intervertebral veins and thence into the external vertebral venous plexuses (see Fig. 46.21), the caval and azygos systems.

Segmental veins

Anterior and posterior radiculomedullary veins run along some of the ventral and dorsal roots. Like the medullary feeder arteries, they are largest in the cervical and lumbar regions of the cord, but do not necessarily occur in the same segments as the medullary feeders. They drain the cord but not the roots themselves. Very small anterior and posterior radicular veins occur in most spinal segments, accompanying and draining the ventral and dorsal roots and some of the cord at the points of entry and exit of the rootlets; they usually drain into the intervertebral veins.

VENOUS DRAINAGE OF THE VERTEBRAL COLUMN

Veins draining the vertebral column form intricate plexuses along the entire column, external and internal to the vertebral canal (see Fig. 46.21) (Groen et al 2004). Both groups are devoid of valves, anastomose freely with each other, and join the intervertebral veins. Interconnections are widely established between these plexuses and longitudinal veins early in fetal life. When development is complete, the plexuses drain into the caval and azygos/ascending lumbar systems via named veins that accompany the arteries described above.

The veins also communicate with cranial dural venous sinuses and with the deep veins of the neck and pelvis. The venous complexes associated with the vertebral column can dilate considerably, and can form alternative routes of venous return in patients with major venous obstruction in the neck, chest or abdomen. The absence of valves allows pathways for the wide and sometimes paradoxical spread of malignant disease and sepsis. Pressure changes in the body cavities are transmitted through these venous plexuses and thus to the cerebrospinal fluid, though the cord itself may be protected from such congestion by valves in the small veins that drain from the cord into the internal vertebral plexus.

External vertebral venous plexuses

The external vertebral venous plexuses are anterior and posterior. They anastomose freely, and are most developed in the cervical region. Anterior external plexuses are anterior to the vertebral bodies, communicate with basivertebral and intervertebral veins, and receive tributaries

from vertebral bodies. Posterior external plexuses lie posterior to the vertebral laminae and around spines and transverse and articular processes. They anastomose with the internal plexuses and join the vertebral, posterior intercostal and lumbar veins.

Internal vertebral venous plexuses

The internal vertebral venous plexuses are embedded in epidural fat, supported by a network of collagenous fibres (Chaynes et al 1998). These thin-walled channels receive tributaries from the bones, red bone marrow and spinal cord. They form a denser network than the external plexuses and are arranged vertically as four interconnecting longitudinal vessels: two anterior and two posterior.

The anterior internal plexuses are large plexiform veins on the posterior surfaces of the vertebral bodies and intervertebral discs. They flank the posterior longitudinal ligament, beneath which they are connected by transverse vessels into which the large basivertebral veins open. The posterior internal plexuses, on each side in front of the vertebral arches and ligamenta flava, anastomose with the posterior external plexuses via veins that pass through and between the ligaments. The internal plexuses interconnect by venous rings near each vertebra. Around the foramen magnum, they form a dense network connecting with vertebral veins, occipital and sigmoid sinuses, the basilar plexus, the venous plexus of the hypoglossal canal and the condylar emissary veins.

Basivertebral veins

The basivertebral veins are paired valveless veins that drain the pars spongiosa of the vertebral bodies into the internal and external vertebral venous plexuses. In each segment, they emerge horizontally from foramina in the vertebral bodies. Posteriorly, they drain into the transverse branches of the anterior internal vertebral plexuses. Anteriorly, they drain directly into the anterior external vertebral venous plexus. The basivertebral veins enlarge in advanced age.

Intervertebral veins

Branches of the anterior internal plexuses drain into retrocorporal veins that join the posterior internal venous plexuses to form intervertebral veins. As their name suggests, these veins accompany the spinal nerves through intervertebral foramina; they drain in craniocaudal sequence into the vertebral, posterior intercostal, lumbar and lateral sacral veins. Upper posterior intercostal veins may drain into the caval system via brachiocephalic veins, whereas the lower intercostals drain into the azygos system. Lumbar veins are joined longitudinally in front of the transverse processes by the ascending lumbar veins, in which they may terminate. Alternatively, they may proceed around the vertebral bodies to drain into the inferior vena cava. Whether the basivertebral or intervertebral veins contain effective valves is uncertain but experimental evidence strongly suggests that their blood flow can be reversed (Batson 1957). This may explain how pelvic neoplasms, e.g. carcinoma of the prostate, may metastasize in vertebral bodies: the cells spread into the internal vertebral plexuses via their connections with the pelvic veins when blood flow is temporarily reversed by raised intra-abdominal pressure or postural alterations (Pearce 2006).

VENOUS DRAINAGE OF THE UPPER LIMB

The upper limb is drained by widely interconnected superficial and deep groups of vessels. The superficial veins are subcutaneous and lie in the superficial fascia. The deep group of veins drains the tissues beneath the deep fascia of the upper limb and is connected to the superficial system by perforating veins. The deep veins accompany the arteries, usually as venae comitantes, becoming the axillary vein, and ultimately the subclavian vein. Both groups have valves, which are more numerous in the deep group.

Superficial veins

The superficial group starts as an irregular dorsal arch on the back of the hand and includes the cephalic, basilic, median cubital and additional antebrachial veins and their tributaries.

Dorsal and palmar digital veins

Dorsal digital veins pass along the sides of the fingers, joined by oblique branches (see Fig. 51.4). They unite from the adjacent sides of the digits into three dorsal metacarpal veins that form a dorsal venous network over the metacarpus (see Fig. 51.3). This is joined laterally by a dorsal digital vein from the radial side of the index finger and both dorsal digital veins of the thumb, and is prolonged proximally as the cephalic vein. Medially, a dorsal digital vein from the ulnar side of the little finger joins the network, which ultimately drains proximally into the basilic vein. A vein often connects the central parts of the network to the cephalic vein near the mid-forearm. Palmar digital veins connect to their dorsal counterparts by oblique veins that pass between metacarpal heads. They also drain to a plexus superficial to the palmar aponeurosis, extending over both thenar and hypothenar regions. The venous drainage of the hand is predominantly dorsal: flexion and extension of the digits compresses the veins within the tight dorsal skin envelope, promoting venous return.

Cephalic vein

The cephalic vein usually forms over the anatomical snuff-box on the radial side of the wrist from the radial end of the dorsal venous plexus (see Fig. 48.4). It curves proximally around the radial side of the forearm, receiving tributaries from both radial and ulnar aspects of the forearm, and continues anterior to the elbow, superficial to a groove between brachioradialis and biceps brachii. It crosses superficial to the lateral cutaneous nerve of the forearm, and ascends along the lateral aspect of the arm within the superficial fascia, lateral to biceps and between pectoralis major and deltoid, where it adjoins the deltoid branch of the thoraco-acromial artery (see Fig. 49.34). It enters the infraclavicular fossa, passes posterior to the clavicular head of pectoralis major, pierces the clavipectoral fascia, crosses the axillary artery and enters the axillary vein near the tip of the coracoid (see Fig. 48.4). It may connect with the external jugular vein by a branch anterior to the clavicle.

Accessory cephalic vein

The accessory cephalic vein may arise either from a dorsal forearm plexus or from the ulnar side of the dorsal venous network in the hand. It joins the cephalic vein distal to the elbow. A large oblique vein often connects the basilic and cephalic veins dorsally in the forearm.

Median cubital vein

The median cubital vein links the cephalic and basilic veins on the flexor aspect of the elbow. It receives a number of tributaries from the flexor aspect of the forearm and gives off the deep median vein, which pierces the fascial roof of the antecubital fossa to join the venae comitantes of the brachial artery. When the median cubital vein is large, so that it transfers most blood from the cephalic to the basilic vein, the proximal cephalic vein is either absent or much diminished.

Basilic vein

The basilic vein arises medially in the dorsal venous network of the hand (see Fig. 48.4). It ascends posteromedially in the forearm, inclining forwards to the anterior surface distal to the elbow, where it pierces the deep fascia and is joined by the median cubital vein. It then ascends superficially between biceps and pronator teres, and is crossed by filaments of the medial cutaneous nerve of the forearm that pass both superficial and deep to the vein. The basilic vein joins the venae comitantes of the brachial artery to form the axillary vein at the lower border of teres major.

Median vein of the forearm

The median vein of the forearm drains the superficial palmar venous plexus and ascends through the anterior part of the forearm to join either the basilic or the median cubital vein (see Figs 49.34, 50.30). It may divide distal to the elbow to join both veins.

Deep veins

Venae comitantes run with the radial and ulnar arteries to drain the deep and superficial palmar venous arches, respectively, and unite near the elbow as paired brachial veins. The radial veins are smaller and receive the deep dorsal veins of the hand. The ulnar veins are larger and drain the deep palmar venous arch. They connect with superficial veins near the wrist and receive the venae comitantes of the anterior and posterior interosseous arteries near the elbow. A large branch connects them to the median cubital vein.

Superior and deep palmar venous arches

Superficial and deep palmar venous arches accompany their arterial counterparts and receive correspondingly named tributaries; common palmar digital veins drain to the superficial arch and palmar metacarpal veins join the deep arch.

Palmar and dorsal metacarpal veins

Deep veins accompanying the dorsal metacarpal arteries receive perforating tributaries from the palmar metacarpal veins and end in the radial veins and the dorsal venous network over the metacarpus. This

network is joined laterally by a dorsal digital vein from the radial side of the index finger and by both digital veins of the thumb, and is prolonged proximally as the cephalic vein.

Brachial veins

The brachial veins flank the brachial artery, as venae comitantes with tributaries similar to the arterial branches; they join the axillary vein near the lower margin of subscapularis. The medial branch often joins the basilic vein before it becomes the axillary vein.

Axillary vein

The axillary vein is the continuation of the basilic vein (see Fig. 48.4). It begins at the lower border of teres major and ascends to the outer border of the first rib, where it becomes the subclavian vein. It is joined by the brachial vein near subscapularis, and by the cephalic vein near its costal end; other tributaries follow the branches of the axillary artery. It lies medial to the axillary artery, which it partly overlaps. The medial pectoral nerve, medial cord of the brachial plexus, ulnar nerve and medial cutaneous nerve of the forearm lie between the artery and the vein. The medial cutaneous nerve of the arm is medial to the vein; the lateral group of axillary lymph nodes is posteromedial. There are a pair of valves near the distal end of the vein, and valves near the ends of the cephalic and subscapular veins.

VENOUS DRAINAGE OF THE THORAX

Pulmonary veins

There are usually four pulmonary veins, two from each lung. They originate from capillary networks in the alveolar walls and return oxygenated blood to the left atrium: they are devoid of valves. All the main tributaries of the pulmonary veins receive smaller tributaries, both intra- and intersegmental. By serial junctions, tributaries ultimately form a single lobar trunk (one for each lobe). Usually, there are three trunks in the right lung and two in the left: variations reflect the lobar arrangement of an individual. The right middle and superior lobar veins usually unite so that two veins, superior and inferior, leave each lung at the hilum: the superior pulmonary vein is anteroinferior to the pulmonary artery, and the inferior pulmonary vein is the most inferior hilar structure and slightly posterior (see Fig. 54.3). The right superior pulmonary vein is formed by the union of apical, anterior and posterior veins (draining the upper lobe) with a middle lobar vein formed by lateral and medial tributaries. The right inferior pulmonary vein is formed in the hilar region by the union of superior (apical) and common basal veins from the lower lobe. The union of superior and inferior basal tributaries forms the common basal vein. Occasionally the three right lobar veins remain separate. The right superior pulmonary vein passes posterior to the superior vena cava, and the inferior passes posterior to the right atrium.

The left superior pulmonary vein is formed by the union of apicoposterior, anterior and lingular veins. The left inferior pulmonary vein is formed by the union of the superior (apical) and common basal veins, the latter formed by the union of the superior and inferior basal veins. Both left superior and inferior pulmonary veins pass anterior to the descending thoracic aorta. Sometimes, the two left pulmonary veins form a single trunk, or they may be augmented by an accessory lobar vein from each lobe that unite to form a third left pulmonary vein.

The right and left pulmonary veins pass through the pericardia and open separately in the posterosuperior aspect of the left atrium (see Figs 57.3, 57.4B). Their terminations are separated medially by the oblique pericardial sinus, and laterally by smaller and variable pulmonary venous pericardial recesses that are directed superomedially.

The variable incorporation of the primitive pulmonary vein into the left atrium during development (Ch. 13) means that the number of main pulmonary veins may differ. Pulmonary vein atresia is a rare congenital anomaly (Kozak et al 2011). The left atrium is the heart chamber most posterior and median in position, and so the length of the left and right pulmonary veins is relatively equal, unlike the arteries and bronchi, where there are obvious left–right differences in length. The terminal parts of the pulmonary veins are surrounded by atrial myocardium; these areas represent potential accessory reentrant circuits responsible for the initiation or maintenance of supraventricular tachycardias or atrial fibrillation and may be percutaneously ablated.

Cardiac veins

The cardiac venous system is divided into two major parts. The greater system consists of large vessels that lie within the subepicardial myocardium and drain most of the outer myocardium. These veins extend over the myocardial surface and do not adhere to topographical borders, although the larger collecting vessels lie within the interventricular sulci before draining into the coronary sinus (see Figs 57.4, 57.59). The intercommunicating parts of this system are the coronary sinus and its tributaries, the anterior cardiac venous system and the ventricular septal and atrial veins. The coronary sinus and its tributaries return blood to the right atrium from the entire heart (including its septa), except for the anterior region of the right ventricle and small, variable parts of both atria and the left ventricle. The anterior cardiac veins drain an anterior region of the right ventricle; this expands to include a region around the right cardiac border when the right marginal vein joins this group.

The smaller system functions primarily to return venous blood from the inner myocardial walls into the right atrium and ventricle and, to a lesser extent, into the left atrium and sometimes the left ventricle. It contains the smallest cardiac (Thebesian) veins that drain the subendocardial myocardium either directly, via connecting intramural arteries and veins, or indirectly, via subendocardial sinusoidal spaces.

Variants Attempts to categorize variations in cardiac venous circulation into types have not produced any accepted pattern. The coronary sinus may receive all the cardiac veins, except the smallest (Thebesian) veins, including the anterior cardiac veins, which may be reduced by diversion into the small cardiac vein and then to the coronary sinus.

Coronary sinus

Most cardiac veins drain into the wide coronary sinus, 2 or 3 cm long, lying in the inferior atrioventricular (coronary) sulcus between the left atrium and ventricle (see Fig. 57.4B,E). The sinus opens into the right atrium between the opening of the inferior vena cava and the right atrioventricular orifice. The opening may be guarded by the valve of the coronary sinus (Thebesian valve) a fold of endocardium (see Fig. 57.13); the fold may be absent or may cover completely the opening of the sinus. The tributaries of the coronary sinus are the great, small and middle cardiac veins, the posterior vein of the left ventricle and the oblique vein of the left atrium; all except the oblique vein have valves at their openings. Isolated absence of the coronary sinus has been reported, with coronary venous drainage into the pulmonary trunk (Ogawa et al 2013).

Great cardiac vein

The great cardiac vein begins at the cardiac apex, and ascends in the anterior interventricular sulcus to the atrioventricular sulcus, which it follows, passing to the left and posteriorly to enter the coronary sinus at its origin. It receives tributaries from the left atrium and both ventricles, including the large left marginal vein that ascends the left (obtuse) border of the heart. It usually courses superior to the arterial branches. The valve of Vieussens normally sits at the opening of the great cardiac vein at its junction with the oblique vein of the left atrium (this junction often representing the start of the coronary sinus); smaller diminutive valves may occur. The valve of Vieussens can impede the passage of a catheter into the great cardiac vein.

Small cardiac vein

The small cardiac vein lies in the anterior part of the inferior atrioventricular sulcus between the right atrium and ventricle, receiving blood from the inferior parts of each chamber and opening into the atrial end of the coronary sinus. The right marginal vein passes right, along (or near) the inferior cardiac border, and sometimes joins the small cardiac vein in the atrioventricular sulcus, typically opening directly into the right atrium.

Middle cardiac vein

The middle cardiac vein begins at the cardiac apex and runs posteriorly in the inferior interventricular sulcus to end in the coronary sinus near its atrial end. The vein is also described as meeting the great cardiac vein at the cardiac apex, and so forming, with the coronary sinus, a complete venous circle.

Inferior vein of the left ventricle

The inferior vein of the left ventricle (previously named the posterior vein of the left ventricle) lies on the inferior surface of the left ventricle, a little to the left of the middle cardiac vein. It usually opens into the middle of the coronary sinus, but may sometimes empty into the great

cardiac vein. Rarely the inferior vein of the left ventricle is absent, in which case the left marginal vein drains most of the left ventricular wall.

Oblique vein of the left atrium

The diminutive oblique vein of the left atrium descends obliquely on the posterior aspect of the left atrium to join the coronary sinus. Its junction with the great cardiac vein marks the start of the coronary sinus and, often, the location of the valve of Vieussens. It is continuous above with the ligament of the left superior vena cava.

Left marginal vein

The left (obtuse) marginal vein courses over or near the left border of the heart, draining much of the left ventricular myocardium. It runs superficial to the marginal branch of the left coronary artery and usually drains into the great cardiac vein, although it may sometimes drain directly into the coronary sinus.

Anterior cardiac veins

The anterior cardiac veins drain the anterior part of the right ventricle. Usually two or three, and up to five, they ascend in subepicardial tissue to cross the anterior part of the atrioventricular sulcus, passing deep or superficial to the right coronary artery. They drain into the right atrium, near the atrioventricular sulcus, separately or in variable combinations. A subendocardial collecting channel, into which all may open, has been described.

Right marginal vein

The right marginal vein courses along the inferior (acute) border of the heart, draining adjacent parts of the right ventricle, and usually opens separately into the right atrium, although it may join the anterior cardiac veins or, less often, the coronary sinus. It is often grouped with the small cardiac veins, but it is larger in calibre, being comparable to or even wider than the anterior cardiac veins.

Smallest cardiac veins

The smallest cardiac (venae cordis minimae, Thebesian) veins, opening into all heart chambers, are difficult to demonstrate; their existence is not disputed. Their numbers and size are highly variable: vessels up to 2 mm in diameter open into the right atrium and vessels as small as 0.5 mm in diameter open into the right ventricle, all with valveless openings. Numerous smallest cardiac veins have been identified in the right atrium and ventricle but they are rarely found in the left side. Four types of smallest cardiac veins have been described. Venoluminal veins drain directly into the cardiac chambers; venosinusoidal veins drain into subendocardial sinusoids (which, in turn, drain into the cardiac chambers); arterioluminal veins connect small arteries and arterioles directly with the cardiac chambers; and arteriosinusoidal veins connect thin arteries or arterioles with subendocardial sinusoidal spaces.

Cardiac venous anastomoses

Widespread anastomoses occur at all levels of the cardiac venous circulation, on a scale exceeding that of the arteries and amounting to a venous plexus. Not only are adjacent veins often connected, but connections also exist between tributaries of the coronary sinus and those of the anterior cardiac veins. Abundant anastomoses occur at the cardiac apex and its anterior and posterior aspects. Like the coronary arteries, cardiac veins are connected with extracardiac vessels, particularly the vasa vasorum of the large vessels that are continuous with the heart.

Brachiocephalic veins

The right and left internal jugular and subclavian veins join to form the right and left brachiocephalic veins, respectively. The right and left brachiocephalic veins join to form the superior vena cava (see Figs 35.14, 52.7, 57.12).

In children, the length and diameter of the left brachiocephalic vein are closely related to height; the diameter reaches adult dimensions at around 10–12 years of age (Sanjeev and Karpawich 2006).

Right brachiocephalic vein

The right brachiocephalic vein is about 2.5 cm long. It is commonly formed posterior to the right sternoclavicular joint, although this may vary with study population. It descends almost vertically to join the left brachiocephalic vein, forming the superior vena cava posterior to the right second costal cartilage or first intercostal space and the associated part of the sternum. It is anterolateral to the brachiocephalic trunk and right vagus nerve; the right pleura, phrenic nerve and internal thoracic artery are initially posterolateral, becoming lateral inferiorly (see Figs 35.14, 56.7A). Its tributaries are the right vertebral, right internal thoracic and right inferior thyroid veins, and sometimes the right supreme intercostal (first right posterior intercostal) vein.

Left brachiocephalic vein

The left brachiocephalic vein is about 6 cm long. It arises posterior to left sternoclavicular joint, although this may vary with study population (see Fig. 52.7). It is anterior to the cervical part of the parietal pleura, and descends obliquely and to the right, posterior to the superior half of the manubrium sterni, reaching the right second costal cartilage or first intercostal space and the associated part of the sternum where it joins the right brachiocephalic vein to form the superior vena cava (see Figs 35.14, 57.12, 58.1). It is separated from the left sternoclavicular joint and manubrium by sternohyoid and sternothyroid, the thymus or its remnants, and areolar tissue. Near its junction with the right brachiocephalic vein it is partly covered by mediastinal right parietal pleura. It crosses anterior to the left internal thoracic, left subclavian, left common carotid and brachiocephalic arteries, the left phrenic and left vagus nerves, and the trachea (see Fig. 55.10B). The aortic arch is normally inferior to it. Its tributaries are the left vertebral, left internal thoracic, left inferior thyroid and left superior intercostal veins, and sometimes the left supreme intercostal (first left posterior intercostal), thymic and left pericardiacophrenic veins.

In children, the length and diameter of the left brachiocephalic vein are closely related to height; the diameter reaches adult dimensions at around 10–12 years of age (see Figs 58.10–58.11) (Sanjeev and Karpawich 2006).

Internal thoracic veins

The internal thoracic veins are formed by the union of the venae comitantes associated with the inferior half of the internal thoracic artery. Near the third costal cartilage, the veins unite and ascend medial to the artery to drain into the ipsilateral brachiocephalic vein. The internal thoracic veins have several valves. Their tributaries correspond to the branches of the internal thoracic artery and include the pericardiacophrenic veins, which run parallel to the phrenic nerves. The phrenic nerves are surrogate markers of the thymic border but are difficult to detect on CT: the pericardiacophrenic veins can be used in their place as an important landmark when differentiating thymic versus non-thymic tumours (Ozawa et al 2018).

Left superior intercostal vein

The left superior intercostal vein drains the second and third (sometimes fourth) left posterior intercostal veins (see Fig. 56.7B). It ascends obliquely anteriorly across the left aspect of the aortic arch, lateral to the left vagus nerve and medial to the left phrenic nerve, to open into the left brachiocephalic vein. It usually receives the left bronchial veins and sometimes the left pericardiacophrenic vein, and connects inferiorly with the accessory hemiazygos vein. It may be seen on a chest X-ray as the 'aortic nipple', not to be confused with a small lung nodule.

Superior vena cava

The superior vena cava returns blood to the heart from the tissues above the respiratory diaphragm. It is approximately 7 cm in length and is formed by the junction of the left and right brachiocephalic veins. According to conventional anatomical descriptions, the superior vena cava forms posterior to the right first costal cartilage. However, the majority of *in vivo* CT-based studies show that it forms posterior to the right second costal cartilage or first intercostal space and the associated part of the sternum. It descends vertically, being slightly convex to the right, and drains into the right atrium either posterior to the right third costal cartilage, or the third intercostal space, or the region posterior to the right fourth to fifth costal cartilages (see Fig. 52.4). Its inferior half is within the fibrous pericardium and it is covered anterolaterally by the visceral layer of serous pericardium (from which the retrocaval recess projects) (see Figs 57.1, 57.4A–B, 57.12). In children, the length and diameter of the superior vena cava are closely related to height; the diameter reaches adult dimensions at around 10-12 years of age (see Figs 58.10–58.11) (Sanjeev and Karpawich 2006). The superior vena cava is valveless.

Tributaries of the superior vena cava are the azygos vein and small veins from the pericardium and other mediastinal structures such as the thymus (see Figs 56.7A, 58.1).

Relations The anterior margins of the right lung and pleura are anterior and the pericardium intervenes inferiorly; these structures separate the superior vena cava from the right internal thoracic artery, transversus thoracis and the associated region of the anterior thoracic wall (see Figs

55.10A, 56.7A). The trachea and right vagus nerve are located posteromedially, the pleura and right lung are posterolateral, and the hilum of the right lung is posterior. The right phrenic nerve is an immediate right lateral relation, the brachiocephalic trunk and ascending aorta sit to the left of the superior part, and the aorta sits anteromedial to the inferior part, of the superior vena cava (see Fig. 57.4A).

Superior vena cava obstruction Superior vena cava obstruction is characterized by headaches, facial and neck venous congestion, and oedema, reflecting impaired venous drainage of the head, neck and upper limbs, and of the collateral circulation, resulting in chest wall telangiectasia. Several of the symptoms may subside with recumbency, or may be aggravated by standing up. The obstruction may be either partial or complete, and may occur suddenly or gradually. It is usually caused by mediastinally invasive right upper lobe primary bronchogenic carcinoma, metastatic involvement of the right paratracheal lymph nodes or non-Hodgkin lymphoma.

Haemorrhagic intrathoracic goitre, mediastinitis (either benign, malignant or fibrous), mediastinal haematoma, constrictive pericarditis, mediastinal cyst, thrombosis of the superior vena cava and sarcoidosis are less common aetiologies. Radiographic findings might include widening of the upper mediastinum on the frontal film or obliteration of the retrosternal space on the lateral film. Other correlative findings may include pulmonary or mediastinal masses, lymphadenopathy, an enlarged or obliterated azygos venous system, pleural effusion or rib notching. This is usually considered to be an oncological emergency and symptoms are often completely and promptly relieved by insertion of a vascular stent via the femoral vein or by radiotherapy to the affected region after a tissue diagnosis is established.

Variants of the brachiocephalic veins and superior vena cava The left and right brachiocephalic veins may enter the right atrium separately, the right vein descending like a normal superior vena cava. During embryological development, if the cardinal vein does not obliterate, it will persist as a left-sided superior vena cava. A left superior vena cava may have a slender connection with the right superior vena cava and subsequently cross the left side of the aortic arch to pass anterior to the hilum of the left lung before turning to enter the right atrium. It replaces the oblique vein of the left atrium (of Marshall) and coronary sinus, and receives all the normal tributaries of the coronary sinus. Other variations include drainage of the hemiazygos vein directly into the persistent left superior vena cava (Liu et al 2019). The left brachiocephalic vein sometimes projects above the manubrium (more frequently in childhood) and crosses the midline superior to the jugular notch, immediately anterior to the trachea. A left-sided superior vena cava may cause difficulties when placing a cardiac catheter, pacing or defibrillating electrodes because the angle between the left superior vena cava and the left subclavian vein is more acute than that normally found between the left subclavian and left brachiocephalic vein. Its calibre may also be smaller than that of the right. Even if insertion of a catheter into a left superior vena cava is possible, the angle at which the catheter enters the right atrium causes difficulty when attempting to place it into the right ventricle and pulmonary trunk; this generally leaves the catheter tip against the coronary sinus, making it difficult to obtain blood samples. In the majority of cases of persistent left superior venae cava, blood drains into the right atrium via the coronary sinus. When this does not happen, the coronary sinus is absent, and the persistent left superior vena cava drains directly into the right atrium. Cyanosis reflects a persistent right-to-left shunt and affected individuals have a higher risk for paradoxical embolism. Radiographically, there is a paramediastinal bulge anterior to the aortic arch. Electrocardiograms show a left P-wave axis. Diagnosis can be confirmed by cardiac catheterization and angiography. Persistent left superior vena cava may be associated with extracardiac conditions such as VACTERL association (vertebral defects, anal atresia, cardiac malformations, tracheo-oesophageal fistula with oesophageal atresia, radial and renal dysplasia, and limb anomalies); trisomy 21; 22q11; CHARGE association (coloboma, heart defects, choanal atresia, mental retardation, genital and ear anomalies); and 45 XO karyotype (Turner syndrome).

If the superior vena cava is duplicated, the right superior vena cava may drain into the right atrium and the left superior vena cava into the left atrium. Although double superior vena cava is largely asymptomatic, it is usually (along with a sole left-sided superior vena cava) associated with congenital cardiac anomalies, such as pulmonary stenosis, coarctation of the aorta, tetralogy of Fallot and atrial septal defects.

Azygos vein

The azygos vein has a variable origin at or below the level of the renal veins (see Figs 56.2–56.3, 56.14B). When present, the azygos lumbar vein ascends anterior to the bodies of the upper lumbar vertebrae and passes either posterior to, or through, the right diaphragmatic crus or traverses the aortic hiatus to the right of the cisterna chyli. Anterior to the body of the twelfth thoracic vertebra, it is joined by a venous trunk, formed by the union of the right ascending lumbar and subcostal veins, to form the azygos vein. In the absence of a lumbar azygos vein, this common venous trunk continues as the azygos vein. The azygos vein passes to the right, posterior to the right crus of the respiratory diaphragm, and ascends in the posterior mediastinum to the level of the body of the fourth thoracic vertebra, where it arches anteriorly, superior to the right pulmonary hilum, and joins the posterior aspect of the superior vena cava, just superior to the point where it passes into the pericardium.

In its course, the azygos vein lies anterior to the anterior longitudinal ligament covering the bodies of the lower eight thoracic vertebrae and the intervening intervertebral discs, and the right posterior intercostal arteries. Right lateral relations include the right sympathetic trunk and associated ganglia, the right greater thoracic splanchnic nerve, lung, and parietal pleura. Left lateral relations include the thoracic duct, descending thoracic aorta and, where the vein arches anteriorly, the oesophagus, trachea and right vagus nerve. Aortic pulsations may assist venous return in the azygos and hemiazygos veins, although only a small and variable number of imperfect valves are present. Inferiorly, the azygos vein lies posterior to the oesophagus, from which it is separated by a right-sided pleural recess, the azygo-oesophageal recess. There are age-related differences in the appearance of the contour of this recess on computed tomography (CT); the recess is dextroconvex below the age of 6 years of age, non-concave (equally divided between straight and convex) between 6 and 12 years of age and concave, as in adults, after the age of 12 years of age (Miller et al 1993).

The major tributaries of the azygos vein are the right intercostal veins (excluding the right supreme (first) intercostal vein that drains into the right brachiocephalic vein), the right superior intercostal vein (usually formed by the union of the second to fourth intercostal veins), the right ascending lumbar and subcostal veins, mediastinal, oesophageal, superior phrenic, pericardial and right bronchial veins, and the hemiazygos and accessory hemiazygos veins.

Numerous anastomoses exist between the tributaries and the main trunks of the azygos, hemiazygos and accessory hemiazygos veins, the inferior vena cava and the vertebral venous plexuses. These allow for alternate drainage pathways in case of segmental agenesis ('interruption') or thrombosis of the inferior vena cava.

Hemiazygos vein

The hemiazygos vein represents the left-sided equivalent of the more inferior part of the azygos vein. It originates in a similar fashion, from the union of the left lumbar ascending and subcostal veins, but exhibits greater variability, and may also connect with the left renal vein via the equivalent of the lumbar azygos vein. The hemiazygos vein crosses the midline anterior to the body of the eighth or ninth thoracic vertebra, passing posterior to the aorta and oesophagus, and either anterior or posterior to the thoracic duct, to join the azygos vein (see Figs 56.2, 56.5B). It receives mediastinal, oesophageal and the ninth to eleventh left posterior intercostal veins.

Accessory hemiazygos vein

The accessory hemiazygos vein functions as the left-sided mirror image of the superior portion of the azygos vein. It drains the left fifth to eighth posterior intercostal veins and occasionally the left bronchial veins, and usually crosses the midline anterior to the body of the seventh thoracic vertebra to join the azygos vein. The first left posterior intercostal vein drains directly into the left brachiocephalic vein, while the second to the fourth may connect indirectly to the accessory hemiazygos vein via the left superior intercostal vein (see Fig 56.7). The accessory hemiazygos vein typically joins the azygos vein directly, but it can join the hemiazygos vein before draining into the azygos vein. One or more prevertebral transversal anastomoses can be present.

Variants of the azygos venous system The origin, course, tributaries, anastomoses and termination of the azygos system of veins are all highly variable (Loukas and Tubbs 2016). The arrangement shown in Fig. 56.2 represents the most common pattern with a right-sided azygos vein. The left sided hemiazygos vein can be absent or underdeveloped, allowing direct drainage of the left intercostal veins into the azygos vein and/or the termination of the accessory hemiazygos vein into the left brachiocephalic vein either directly or by joining the left superior intercostal vein. In such cases, the azygos vein is located in a median position. In cases of common cardinal or anterior cardinal vein malformation, the azygos

vein may enter the right atrium, right brachiocephalic vein or right subclavian vein rather than joining the superior vena cava.

In congenital interruption of the inferior vena cava or acquired thrombosis, the azygos system provides an alternative pathway for venous drainage. A higher than usual azygos arch may travel over the apical region of the right upper lobe within an accessory azygos fissure, covered by four pleural layers (two parietal and two visceral), and isolate a portion of the superior lobe of the right lung medially: the 'azygos lobe' (Loukas and Tubbs 2016). If present, the azygos fissure can be identified on chest radiograph as a fine radiopaque line. The azygos vein located within the azygos fissure often presents as a lung 'pseudo-nodule' on a chest radiograph; it is typically comma-shaped and should not be confused with a more rounded early lung carcinoma or metastasis.

Posterior intercostal veins

The 11 pairs of posterior intercostal veins accompany their respective arteries (see Fig. 52.4). Approaching the vertebral column, each vein receives a posterior tributary that returns blood from the dorsal musculature and skin and the external vertebral venous plexuses, and an intervertebral vein that drains the internal vertebral venous plexus. On both sides, the first posterior (supreme) intercostal vein ascends anterior to the neck of the first rib, then arches anteriorly, superior to the suprapleural membrane to drain into the ipsilateral brachiocephalic or vertebral vein. On the right side, the second, third and often the fourth veins form a right superior intercostal vein that drains into the arch of the azygos vein. The more inferior intercostal spaces drain directly into the azygos vein. On the left side, the second, third and sometimes the fourth veins form a left superior intercostal vein. Veins from the fifth (sometimes fourth) to eighth intercostal spaces drain into the accessory hemiazygos vein, and veins from the ninth to the eleventh intercostal spaces drain into the hemiazygos vein; it should be remembered that the azygos system is highly variable.

Posterior intercostal veins are so called to distinguish them from small anterior intercostal veins, which are tributaries of the internal thoracic and musculophrenic veins.

VENOUS DRAINAGE OF THE ABDOMEN AND PELVIS

External iliac vein

The external iliac vein is the proximal continuation of the femoral vein (see Figs 76.8, 77.49). It begins posterior to the inguinal ligament, ascends along the linea terminalis, and ends anterior to the sacro-iliac joint by joining the internal iliac vein to form the common iliac vein. On the right, it lies medial to the external iliac artery, gradually inclining behind it as it ascends. On the left, it is wholly medial. Disease of the external iliac artery can cause it to adhere closely to the vein at the point where it is in contact, and, particularly on the right side, the walls of the vessels can become fused, making dissection hazardous. The external iliac vein is crossed medially by the ureter and internal iliac artery and by the ductus deferens (males) or the round ligament of the uterus and ovarian vessels (females). Psoas major lies laterally, except where the artery intervenes. The vein is usually valveless but sometimes contains a single valve. Its tributaries are the inferior epigastric, deep circumflex iliac and pubic veins. Agenesis of the external iliac vein has been reported in association with Klippel–Trenaunay syndrome (Doğan et al 2003).

Inferior epigastric vein

One or two inferior epigastric veins accompany the inferior epigastric artery and drain into the external iliac vein just proximal to the inguinal ligament.

Deep circumflex iliac vein

The deep circumflex iliac vein is formed from venae comitantes of the corresponding artery. It joins the external iliac vein a little above the inferior epigastric vein after crossing anterior to the external iliac artery.

Pubic vein

The pubic vein connects the external iliac and obturator veins. It ascends on the pelvic surface of the pubis with the pubic branch of the inferior epigastric artery and occasionally replaces the normal obturator vein.

Internal iliac vein

The internal iliac vein is formed by the convergence of several veins above the greater sciatic foramen. It does not have the predictable trunks and branches of the internal iliac artery but its tributaries drain the same territories. It ascends posteromedial to the internal iliac artery to join the external iliac vein, forming the common iliac vein at the linea terminalis, anterior to the lower part of the sacro-iliac joint. It is covered anteromedially by parietal peritoneum. Its tributaries are the gluteal, internal pudendal and obturator veins, which originate outside the pelvis; the lateral sacral veins, which run from the anterior surface of the sacrum; and the middle anorectal, vesical, uterine and vaginal veins, which originate in the venous plexuses of the pelvic viscera (see Fig. 71.8).

The venous drainage of the leg can be blocked by thrombosis involving the external iliac systems and the inferior vena cava. Under these circumstances, the pelvic veins, particularly the internal iliac tributaries, enlarge and provide a major avenue of venous return from the femoral system. Surgical interference with these veins can seriously compromise venous drainage and precipitate oedema of one or both lower limbs.

Superior gluteal veins

The superior gluteal veins are the venae comitantes of the superior gluteal artery. They receive tributaries that correspond to the branches of the superior gluteal artery and enter the pelvis via the greater sciatic foramen, superior to piriformis. They join the internal iliac vein, frequently as a single trunk.

Inferior gluteal veins

The inferior gluteal veins are venae comitantes of the inferior gluteal artery. They begin proximally and posteriorly in the thigh, where they anastomose with the medial circumflex femoral and first perforating veins, and they enter the pelvis low in the greater sciatic foramen, joining to form a vessel that opens into the distal part of the internal iliac vein. The inferior gluteal and superficial gluteal veins connect by perforating veins (Doyle 1970). The gluteal veins probably have a venous 'pumping' role, and provide collaterals between the femoral and internal iliac veins.

Internal pudendal veins

The internal pudendal veins are venae comitantes of the internal pudendal artery and unite as a single vessel that drains into the internal iliac vein. They receive veins from the inferior anorectal veins and either the bulb of the penis and scrotum, or the clitoris and labia. The scrotal vessels are arranged in a dense subcutaneous network, which facilitates heat loss and regulation of scrotal temperature: simple arteriovenous anastomoses are common.

Obturator vein

The obturator vein begins in the proximal adductor region and enters the pelvis via the obturator foramen. It runs posteriorly and superiorly on the lateral pelvic wall below the obturator artery and between the ureter and internal iliac artery, and ends in the internal iliac vein. It is sometimes replaced by an enlarged pubic vein that joins the external iliac or the inferior epigastric veins (Sanna et al 2018).

Lateral sacral veins

The lateral sacral veins accompany the lateral sacral arteries and are interconnected by a sacral venous plexus.

Middle anorectal vein

The middle anorectal vein begins in the rectal venous plexus and drains the rectum and mesorectum. Variable in size, it runs laterally on the pelvic surface of levator ani to end in the internal iliac vein. The middle anorectal vein often receives tributaries from the urinary bladder and either the prostate and seminal gland (males) or the posterior aspect of the vagina (females).

Vesical plexus

The vesical plexus envelops the lower bladder and, in males, the prostatic base. It communicates with the prostatic plexus in males and the vaginal plexus in females and is drained by several vesical veins that usually unite to drain into the internal iliac vein.

Prostatic venous plexus

The prostatic venous plexus is posterior to the arcuate pubic ligament and the lower part of the pubic symphysis, and anterior to the urinary bladder and prostate. Its chief tributary is the deep dorsal vein of the penis and it drains into vesical and internal iliac veins.

Dorsal veins of the penis

Blood leaving the penis is drained by one of three venous systems: superficial, intermediate or deep (see Figs 74.22B, 74.23). The

superficial veins are contained within the superficial fascia of the penis and on its dorsolateral surface. They receive blood from the skin of the body of the penis and prepuce and coalesce to form a single superficial dorsal vein that drains into the long saphenous vein via the superficial external pudendal veins.

The intermediate drainage system contains the circumflex and deep dorsal veins, which lie within and beneath the deep fascia of the penis. This system receives blood from the glans penis, corpus spongiosum and distal two-thirds of the penis. Circumflex veins originate in the corpus spongiosum and course around the corpora cavernosa to meet the deep dorsal vein of the penis perpendicularly. They are only present in the distal two-thirds of the body of the penis and there are 3–10 of them. Intermediate venules in the erectile tissue of the corpora cavernosa arise from the cavernous spaces and drain into a subtunical capillary plexus. This plexus gives rise to emissary veins that course obliquely through the tunica albuginea and drain either into the circumflex veins or directly into the deep dorsal vein. The deep dorsal vein lies in the midline groove between the two corpora cavernosa. It passes inferior to the pubic symphysis at the level of the suspensory ligament of the penis, leaving the body of the penis at the crus, and drains into the prostatic venous plexus.

Deep venous drainage occurs via the crural and cavernous veins of the penis, the latter travel almost the entire length of the corpus cavernosum and ultimately drain independent of the deep dorsal vein of the penis into the prostatic venous plexus (Hsu et al 2003). The emissary veins consolidate into 2–5 veins on the dorsomedial surface of the corpora cavernosa.

Uterine plexuses

The uterine plexuses extend lateral to the uterus in the broad ligaments, and communicate with the ovarian and vaginal plexuses. They are drained by uterine veins to the internal iliac veins.

Vaginal plexuses

The vaginal plexuses flank the vagina and connect with uterine, vesical and anorectal plexuses. They drain by vaginal veins to the internal iliac veins.

Common iliac veins

The common iliac vein is formed by the union of the external and internal iliac veins, anterior to the sacro-iliac joints (see Fig. 76.8). It ascends obliquely to end at the right side of the fifth lumbar vertebra, uniting at an acute angle with the contralateral vessel to form the inferior vena cava. The right common iliac vein is shorter and more nearly vertical, lying posterior and then lateral to its artery; the right obturator nerve passes posteriorly. The left common iliac vein is longer and more oblique and lies first medial, then posterior, to its artery. It is crossed anteriorly by the attachment of the sigmoid mesocolon and superior anorectal vessels. Each vein receives iliolumbar and, sometimes, lateral sacral veins. The left common iliac vein usually drains the median sacral vein. There are no valves in these veins.

The left common iliac vein occasionally ascends to the left of the aorta to the level of the kidney, where it receives the left renal vein and then crosses anterior to the aorta to join the inferior vena cava; this vessel represents the persistent caudal half of the left postcardinal or supracardinal vein.

Median sacral veins

The right and left medial sacral veins accompany the corresponding arteries anterior to the sacrum, where they unite to form a single vein that usually ends in the left common iliac vein, but sometimes ends at the common iliac junction.

Inferior vena cava

The inferior vena cava returns blood to the heart from infradiaphragmatic tissues. It is formed by the junction of the left and right common iliac veins anterior to the body of the fifth lumbar vertebra, about 1 cm to the right of the midline. It ascends anterior to the vertebral column, to the right of the aorta, and lies in a deep groove on the posterior surface of the liver, sometimes completely surrounded by liver tissue. It passes through the caval foramen of the respiratory diaphragm between the right folia and central area of the central tendon of the diaphragm at the level of the superior half of the body of the eleventh thoracic vertebra (see Fig. 55.1), and drains into the inferoposterior part of the right atrium (see Fig. 57.4B). The thoracic part is short, and is partly within and partly outside the pericardial sac. The extrapericardial part is separated from the pleura and right lung by the right phrenic nerve and associated pericardiacophrenic vessels, and the intrapericardial part is covered, except posteriorly, by the visceral layer of serous pericardium (see Fig. 57.4E). Its abdominal portion is devoid of valves.

The inferior vena cava can be encircled and controlled between the renal veins inferiorly and the hepatic veins superiorly, e.g. during operations on a renal cell carcinoma extending into the inferior vena cava. Obstruction of the inferior vena cava from thrombosis, embolism, extrinsic compression (e.g. tumour or pregnancy) or intrinsic disease results in the development of an extensive venous collateral circulation via tributaries that ultimately connect to the superior vena cava. These include the azygos–hemiazygos venous system, the vertebral venous plexuses, and the superficial veins of the thoracic and abdominal walls. The lumbar veins contribute significantly to these pathways (Golub et al 1992).

The inferior vena cava usually receives the common iliac veins at its origin and the lumbar, right gonadal, renal, right suprarenal, hepatic and inferior phrenic veins throughout its course (see Fig. 61.12).

Relations of the abdominal part of the inferior vena cava The inferior vena cava lies behind the parietal peritoneum lining the posterior abdominal wall. At its origin it is related anteriorly to the right common iliac artery. From below upwards, its anterior surface is crossed obliquely by the root of the mesentery of the small intestine and its contained vessels and nerves, the right gonadal artery and the horizontal part of the duodenum. Further cranially, it lies posterior to the head of the pancreas and superior (first) part of the duodenum, separated from those structures by the bile duct and hepatic portal vein. Superior to the duodenum, its anterior surface is covered by the parietal peritoneum lining the posterior abdominal wall, which forms the posterior wall of the omental foramen and separates the inferior vena cava from the right free border of the lesser omentum, i.e. the hepatoduodenal ligament and its contents. Superior to this, it is intimately related to the liver anteriorly.

The posterior relations of the inferior vena cava include the lower three lumbar vertebral bodies and their intervertebral discs, the anterior longitudinal ligament, sympathetic trunk, right third and fourth lumbar arteries, and psoas major on the right. Superior to these structures, it is related posteriorly to the right renal and middle suprarenal arteries, the medial part of the right suprarenal gland, the right coeliac ganglion and the right inferior phrenic arteries.

The right ureter, medial border of the right kidney, descending part of the duodenum and the right lobe of the liver are all lateral to the right side of the inferior vena cava. The abdominal aorta, right crus of the respiratory diaphragm and the caudate lobe of the liver are on its left side.

The normal diameter of an adult inferior vena cava is up to 30 mm (Moeller and Reif 2000); its cross-sectional shape and calibre reflect the degree of venous filling. Anatomical variants, related to its complex embryogenesis, are well described. Among these are a double inferior vena cava (the left-sided vessel usually joins the left renal vein); azygos continuation of the inferior vena cava; a left-sided inferior vena cava (which may exist in isolation or as part of situs inversus) (Ang et al 2013, Spentzouris et al 2014).

Collateral venous channels In obstruction of the superior part of the inferior vena cava, the azygos and hemiazygos veins and vertebral venous plexuses are the main collateral channels that maintain venous circulation. They connect the superior and inferior venae cavae and communicate with the common iliac vein via the ascending lumbar veins and with multiple tributaries of the inferior vena cava.

Variants The inferior vena cava may be congenitally interrupted, duplicated, left-sided or even absent.

Embryologically, if the right subcardinal vein fails to anastomose with the hepatic sinusoids, the hepatic segment of the inferior vena cava fails to develop. When this occurs, the hemiazygos or azygos veins, both of which originate from the cranial supracardinal veins, return blood to the heart. Azygos continuation of the inferior vena cava, characterized by a prominent azygos vein, is a variant that the paediatric surgeon should be aware of when undertaking repair of oesophageal atresia and tracheo-oesophageal atresia in neonates. The azygos vein, which is commonly ligated and divided during this procedure, should be spared because ligation of this vessel in neonates with azygos continuation of the inferior vena cava leads to intraoperative circulatory collapse and death. Double inferior vena cava (right side usually dominant) is a result of the persistence of all or any segments of the subcardinal veins. One of the most common variations is a left-sided inferior vena cava, which is formed if the right supracardinal vein regresses and the left

supracardinal vein persists (Spratt 2016). There may also be a duplication of the inferior vena cava, which typically occurs inferior to the level of the renal veins, and is the result of persistence of the left lumbar and thoracic supracardinal veins and left suprasubcardinal anastomosis as well as malformation of the right subcardinal–hepatic anastomosis. Abnormalities associated with duplication of the inferior vena cava include congenital heart disease, congenital absence of the right kidney, cloacal extrophy, renal ectopia with abdominal aneurysm, right retrocaval ureter, left retrocaval ureter and congenital absence of the iliac anastomosis, abnormal left upper limb drainage and transcaval ureter.

In situs inversus with dextrocardia, the inferior vena cava passes inferiorly along the left side instead of the right. In situs inversus with levocardia, the inferior vena cava remains on the right side. In situs ambiguus (heterotaxy) the major organs are arranged ambiguously within the body. Prominent azygos veins with interrupted inferior vena cava are associated with heterotaxy (Punn and Olson 2010). Situs ambiguus with polysplenia is associated with an absence of parts of the inferior vena cava on the right side (with continuation through the azygos or hemiazygos vein), transposition of the inferior vena cava to the left side, or duplication of the inferior vena cava with one on the right and one on the left. Situs inversus with asplenia is similar to that of polysplenia, in that the inferior vena cava may be absent with azygos continuation or with the inferior vena cava to the left of the midline. In situs inversus totalis, transposition of the inferior vena cava consists of a right-sided inferior vena cava. The inferior vena cava may have an abnormally high insertion into the right atrium.

Scimitar syndrome, a form of anomalous pulmonary venous drainage, occurs when there is an abnormal connection between the right pulmonary vein(s) and the inferior vena cava. This often involves hypoplasia of the pulmonary veins and the pulmonary trunk and arteries, as well as abnormal ipsilateral lung parenchyma. This creates a left-to-right shunt and increases the risk of right ventricular failure as a result of ventricular hypertrophy. Typical symptoms include respiratory insufficiency such as recurrent respiratory infections, heart failure, or pulmonary hypertension.

Congenital agenesis of the inferior vena cava may occur and may be completely asymptomatic because venous drainage of the lower limbs occurs through anastomosed channels of the azygos and hemiazygos veins. However, this condition may be associated with a higher risk for deep vein thrombosis.

Lumbar veins

Four pairs of lumbar veins collect blood from the territories supplied by the corresponding lumbar arteries, including the posterior, lateral and anterior abdominal walls. These branches anastomose posteriorly with tributaries of the azygos and hemiazygos veins, and anteriorly with branches of the epigastric, circumflex iliac and lateral thoracic veins. These superficial anastomoses provide alternative routes of venous drainage from the pelvis and lower limbs to the heart when the inferior vena cava is obstructed. The lumbar veins communicate with the external and internal vertebral venous plexuses, providing an additional collateral pathway for venous return.

The paired longitudinal ascending lumbar veins connect the individual ipsilateral lumbar veins. The third and fourth lumbar veins usually pass anteriorly on the sides of the corresponding vertebral bodies to enter the posterior aspect of the inferior vena cava; the left lumbar veins pass posterior to the abdominal aorta and are therefore longer. The first and second lumbar veins are much more variable and may drain into the inferior vena cava or the ascending lumbar, lumbar azygos or renal veins (on the left); they are often connected to each other. The first lumbar vein often passes inferiorly to join the second lumbar vein or, less commonly, drains either directly into the ascending lumbar vein or passes anteriorly over the body of the first lumbar vertebra to join the lumbar azygos vein. The second lumbar vein may join the inferior vena cava at or near the level of the renal veins or, less commonly, join the third lumbar or ascending lumbar vein.

Ascending lumbar veins

The paired ascending lumbar veins run medial to psoas major and connect the ipsilateral common iliac, iliolumbar and lumbar veins. They are variable in their course and connections; rarely, the whole vein or a segment is absent on one side (Lolis et al 2011). An ascending lumbar vein commonly joins the subcostal vein to form the azygos vein on the right and the hemiazygos vein on the left. The azygos and hemiazygos veins run anteriorly over the body of the twelfth thoracic vertebra and pass deep to or through the right and left crura of the respiratory diaphragm, respectively, into the thoracic cavity. The ascending lumbar vein is usually joined by a small vein, the lumbar azygos vein, from the back of the inferior vena cava or left renal vein. Sometimes, the ascending lumbar vein ends in the first lumbar vein, which then joins the lumbar azygos vein at the level of the first lumbar vertebra. Blood can flow in either direction in the ascending lumbar veins (Morita et al 2007).

Testicular veins

Testicular veins emerge posteriorly from the testis, drain the epididymis, and unite to form several highly anastomotic channels surrounding the testis known as the pampiniform plexus, a major component of the spermatic cord (see Fig. 74.2). This vascular arrangement means that counterflowing arteries and veins are separated only by the thickness of their vascular walls, permitting the exchange of heat and small molecules (Harrison 1949) and facilitating the maintenance of lower testicular temperatures. The pampiniform plexus ascends anterior to the ductus deferens and is drained by three or four veins in the inguinal canal. The veins enter the abdomen through the deep inguinal ring, ascend anterior to psoas major and the ureter on each side, and coalesce into a single testicular vein that drains into the inferior vena cava on the right and the renal vein on the left.

The right testicular vein enters the inferior vena cava directly on its right anterolateral aspect at an acute angle about 2 cm inferior to the left renal vein in adults; occasionally, it drains into the right renal vein (Tubbs et al 2016). The left testicular vein joins the left renal vein at a right-angle (see Fig. 74.8). Both veins may be replaced by multiple vessels in the lower abdomen and sometimes remain double as far as their termination.

The testicular veins contain valves. Varicocele, which is almost always on the left, may be a consequence of the greater length of the left testicular vein and its orthogonal junction with the left renal vein. The testicular veins can anastomose with the external pudendal and cremasteric veins and veins of the ductus deferens, allowing varicoceles to persist or recur after ablative procedures that do not address these potential collaterals.

Ovarian veins

The ovarian veins emerge from the ovary as a plexus (pampiniform plexus) in the mesovarium and suspensory ligament of the ovary (see Fig. 75.3A). Two veins emerge from the plexus and ascend with the ovarian artery, anterior to psoas major and the ureter. They usually merge into a single vessel before entering either the inferior vena cava on the right side or the renal vein on the left.

Renal veins

Fine radicles from the venous ends of the peritubular plexuses converge to join interlobular veins, one with each interlobular artery. Many interlobular veins begin beneath the fibrous capsule of the kidney by the convergence of several stellate veins, which drain the most superficial zone of the renal cortex and so are named from their surface appearance. Interlobular veins pass to the corticomedullary junction and also receive some ascending vasa recta before ending in arcuate veins (which accompany arcuate arteries), and anastomose with neighbouring veins. Arcuate veins drain into interlobar veins, which anastomose and form the renal vein.

The large renal veins lie anterior to the renal arteries and open into the inferior vena cava almost at right-angles (see Figs 59.7, 72.16). The left renal vein is three times longer than the right (7.5 cm and 2.5 cm, respectively): the left kidney is the preferred side for live donor nephrectomy for this reason. However, the left renal vein can also be double, one vein passing posterior and the other anterior to the aorta before draining into the inferior vena cava, an arrangement that is sometimes referred to as persistence of the 'renal collar'. The anterior vein can be absent, in which case there is a single retro-aortic left renal vein. These variations could negate any advantage of using the left kidney as a donor (Phelan et al 2009). The left renal vein runs from its origin in the hilum of the kidney, posterior to the splenic vein and the body of the pancreas, and then across the anterior aspect of the abdominal aorta, just below the origin of the superior mesenteric artery. Anterior nutcracker syndrome, characterized by left renal vein hypertension secondary to compression of the vein between the ventral surface of the abdominal aorta and the dorsal surface of the superior mesenteric artery, has been associated with haematuria and varicocele in children (Kurklinsky and Rooke 2010). The left gonadal vein enters the left renal vein from below, and the left suprarenal vein, usually receiving one of the left inferior phrenic veins, enters it above but nearer the midline. The left renal vein enters the inferior vena cava slightly superior to the right renal vein. The right renal vein lies posterior to the descending part of the duodenum and, sometimes, the head of the pancreas. It can be extremely short (less than 1 cm), such that safe nephrectomy can require excision of a cuff of the inferior vena cava.

The left renal vein may have to be ligated during surgery for aortic aneurysm because it has such a close relationship with the aorta; this seldom results in any harm to the kidney, provided that the ligature is placed medial to the draining gonadal and suprarenal veins, since these usually provide adequate collateral venous drainage. The right renal vein has no significant collateral drainage and cannot be ligated with impunity.

Suprarenal vein

Most commonly, a single vein drains each suprarenal gland. The short right suprarenal vein drains directly into the inferior vena cava at the level of the twelfth thoracic vertebra; the longer left vein usually joins the left renal vein and may receive the left inferior phrenic vein. Numerous anatomical variations of this vein have been described (Cesmebasi et al 2014).

Inferior phrenic veins

The inferior phrenic veins usually originate on the superior surface of the respiratory diaphragm but run mostly on its inferior surface to drain into the posterolateral aspect of the inferior vena cava. Both veins receive several diaphragmatic tributaries. The left vein runs to the left of the oesophageal hiatus, whereas the right courses to the right of the caval foramen; each receives a venous tributary from the oesophagus (Loukas et al 2005b). The left inferior phrenic vein frequently communicates with the left gastric vein and may therefore become prominent in portal hypertension. Both inferior phrenic veins usually drain directly into the inferior vena cava just inferior to the respiratory diaphragm, sometimes joining anteriorly to form a short common trunk. The right occasionally drains into the right hepatic vein or inferior vena cava superior to the respiratory diaphragm, whereas the left frequently drains into the left suprarenal, left renal or left hepatic vein.

Hepatic veins

The liver drains by three major hepatic veins into the suprahepatic part of the inferior vena cava and via numerous minor hepatic veins that drain into the retrohepatic inferior vena cava. The adult retrohepatic inferior vena cava is 6–7 cm long and is surrounded to a variable extent by segment I (Camargo et al 1996). The three major veins are located between the four sectors of the liver (see Figs 66.6A, 66.14–66.15). Thus, the right hepatic vein lies between the right anterior and posterior sectors, the middle hepatic vein lies between the right and left hemilivers, and the left hepatic vein lies between the left medial and lateral sectors. During hepatic resection, the surgeon should transect the liver parenchyma slightly to the left or right of the particular fissure that is being opened to avoid the main trunk of a hepatic vein.

Right hepatic vein

The right hepatic vein is the longest and largest hepatic vein. It is usually single, but occasionally remains as two trunks until it terminates by draining into the inferior vena cava. It runs in the right portal fissure between the right medial and lateral sectors. It drains the whole of segments VI and VII and variable proportions of segments V and VIII, depending on the extent to which these segments drain into the middle hepatic vein. The right hepatic vein is formed anteriorly near the inferior border of the liver and lies in a coronal plane through most of its course. It drains into the inferior vena cava near the superior border of the caudate lobe. Of the three major hepatic veins, the right hepatic vein is most variable in calibre, reflecting the variable contribution of the middle hepatic vein to the drainage of segments V and VIII and the existence of an accessory right inferior (30%) and/or middle hepatic vein (10%) (Fang et al 2012). The hepatic venous anatomy is particularly important in right lobe living donation and can be assessed preoperatively by computed tomography (CT) or magnetic resonance imaging (MRI), and/or by intraoperative ultrasound.

Middle hepatic vein

The middle hepatic vein lies in the main portal fissure between the right and left hemilivers. It usually joins the left hepatic vein and terminates in the inferior vena cava as a short common trunk (about 5 mm long); it ends as a single trunk in the inferior vena cava in fewer than 10% of individuals. The middle hepatic vein drains the central part of the liver and receives constant tributaries from segments IV, V and VIII. The vein from segment IV lies in a sagittal plane and enters the middle hepatic vein on its left side. The vein from segment VIII runs transversely into the right side of the middle hepatic vein and is sometimes large enough to be mistaken for the middle hepatic vein. Anteriorly, the middle hepatic vein drains some of segment V; the calibres of the tributaries draining segments V and VIII are variable. Intrahepatic venous anastomoses between the middle and right hepatic veins, particularly in segment VIII, have been reported in up to one-third of adult livers (Hribernik and Trotovšek 2014).

Left hepatic vein

The left hepatic vein lies between the left medial and left lateral sectors of the liver and drains segments II, III and occasionally IV. Small veins draining segment II and occasionally the superior part of segment IV, can drain directly into the inferior vena cava. The umbilical fissure vein, a major tributary of the left hepatic vein, usually runs between segments III and IV and contributes to their drainage. Occasionally the vein draining segment III ends separately in the confluence of the left and middle hepatic veins. These variations in venous drainage are significant in split liver transplantation and live donor liver transplantation.

Minor hepatic veins

Segment I veins, ranging in number from one to five, drain directly into the inferior vena cava. Since this segment has a venous drainage independent of the rest of the liver, segment I often continues to drain effectively and undergoes compensatory hypertrophy in patients with Budd–Chiari syndrome, where the major hepatic veins are blocked. There can be an accessory inferior or middle right hepatic vein, and several smaller 'retrohepatic' veins that drain the right lobe directly into the inferior vena cava. When present, these veins are surgically important, especially if they exceed 5 mm in diameter. They drain segments V and VI independently of the three major hepatic veins, which means that a tumour involving the latter can be resected safely as long as venous drainage from the accessory veins is preserved. In live donor and split liver transplantation, larger accessory veins must be individually anastomosed to the recipient inferior vena cava to ensure adequate venous drainage.

Hepatic portal system

The liver has two venous systems. The portal venous system conveys blood from the majority of the gastrointestinal tract and its associated organs to the liver and the hepatic venous system drains blood from the liver parenchyma into the inferior vena cava.

Portal vein

The hepatic portal vein is formed posterior to the neck of the pancreas, usually from the convergence of the superior mesenteric and splenic veins (see Figs 59.7, 66.12). Its origin lies in the transpyloric plane between the inferior border of the body of the first lumbar vertebra and the superior border of the body of the second lumbar vertebra (Mirjalili et al 2012c). The hepatic portal vein is approximately 8 cm long and ascends obliquely to the right, posterior to the superior (first) part of the duodenum, bile duct and gastroduodenal artery, and anterior to the inferior vena cava. It enters the hepatoduodenal ligament and ascends anterior to the omental foramen to reach the right end of the porta hepatis, where it divides into right and left main branches that enter the liver. In the lesser omentum, the hepatic portal vein lies posterior to both the bile duct and the hepatic artery. It is surrounded by the hepatic nervous plexus and accompanied by numerous lymphatics and some lymph nodes. The hepatic portal vein contains smooth muscle in its wall and, in experimental animals at least, has well-developed spontaneous contractions with frequencies between 0.01 and 1 Hz (Burt 2003). It is typically valveless.

The hepatic portal vein divides into right and left branches at the porta hepatis of the liver (see Fig. 66.13). The left branch of the hepatic portal vein has a longer extrahepatic course (4–5 cm) than the right branch of the hepatic portal vein, tends to lie more horizontally, and is often smaller in calibre. The horizontal portion runs along the inferior surface of segment IV and invariably gives branches to segment I and sometimes to segment IV. The left branch of the hepatic portal vein continues within the liver, giving off a segment II branch laterally before taking a more anterior and vertical course in the umbilical fissure, where it gives off branches to segments III and IV and receives the obliterated left umbilical vein (round ligament of the liver). Most of the portal venous supply to segment IV comes from the left branch of the hepatic portal vein and only occasionally from either the right branch of the hepatic portal vein or its branches to segments V or VIII. The right branch of the hepatic portal vein is only 2–3 cm in length and usually divides into a right medial (anterior) sectoral division supplying segments V and VIII, and a right lateral (posterior) sectoral division supplying segments VI and VII. The medial division can give a branch to segment I.

The main extrahepatic tributaries of the hepatic portal vein are the left gastric vein, which ends in the left margin of the hepatic portal vein,

and the posterior superior pancreaticoduodenal vein near the head of the pancreas.

Variants Hepatic portal vein variations usually involve the right branch (Covey et al 2004). When this branch is absent (10–15% of livers), the hepatic portal vein usually trifurcates into left portal, right anterior and right posterior sectoral veins. Absence of the right branch of the hepatic portal vein might be considered as a relative contraindication for split liver and live donor liver transplantation because this variation is often associated with a similar variation in biliary anatomy. The right anterior sectoral portal vein can arise from the hepatic portal vein, or the right posterior sectoral portal vein can originate from the left branch of the hepatic portal vein, variations that are important to remember during left-sided liver resection. When the bifurcation of the hepatic portal vein is absent, the hepatic portal vein enters the liver, giving off the right sectoral branches, and then turns left to supply the left lobe, a variation that presents an added complexity in major liver surgery (Chaib 2009).

Left gastric vein

The left gastric vein drains the proximal body and fundus of the stomach. It ascends along the lesser curvature to the gastro-oesophageal junction, where it receives several distal oesophageal veins. It then curves posteriorly and medially behind the posterior wall of the omental bursa. It usually passes anterior or posterior to the common hepatic artery and drains into the hepatic portal vein at the level of the proximal border of the superior part of the duodenum (which corresponds to 1–2 cm from the origin of the portal vein) (Rebibo et al 2012). In up to one-third of individuals, it passes anterior or posterior to the common hepatic artery and terminates in the splenic vein. On rare occasions it drains into the left branch of the hepatic portal vein within the liver (Ohkubo 2000), a variant that may be clinically important in portal hypertension. Knowledge of these venous variations is important during lymphadenectomy for gastric cancer to avoid unexpected venous bleeding.

Right gastric vein

The right gastric vein is typically small and runs along the medial end of the lesser curvature, passing under the peritoneum as it is reflected from the posterior aspect of the pylorus and superior part of the duodenum on to the posterior wall of the omental bursa. It drains directly into the hepatic portal vein at the level of the superior part of the duodenum. It receives the prepyloric vein as it ascends anterior to the pylorus at the level of the pyloric orifice. Rarely the right gastric vein drains directly into a branch of the hepatic portal vein within the liver.

Pancreaticoduodenal veins

The pancreaticoduodenal veins accompany their corresponding arteries. The posterior superior pancreaticoduodenal vein courses adjacent to the distal part of the common bile duct within the pancreatic head. It is the major draining vein of the posterior pancreatic head and adjacent duodenum and usually joins the portal vein just superior to the pancreas.

Cystic veins and venous plexuses draining biliary tract

The venous drainage of the gallbladder is rarely by a single cystic vein and there are usually multiple small veins. Those arising from the superior surface of the body and neck lie in loose connective tissue between the gallbladder and liver and drain into the branches of the hepatic portal vein within the liver. The remainder of the organ drains by one or two small cystic veins into either branches of the hepatic portal vein within the liver or portal venous tributaries draining the hepatic ducts and proximal bile duct (Sugita et al 2000). Only rarely does a single or double cystic vein drain directly into the right branch of the hepatic portal vein.

A delicate epicholedochal venous plexus covers the surface of the bile ducts. A fine paracholedochal venous plexus runs parallel with the bile ducts and typically forms two distinct marginal veins (3 o'clock and 9 o'clock marginal veins). The plexuses and the marginal veins communicate with gastric veins, the posterior superior pancreaticoduodenal vein, the gastrocolic trunk and with the hilar venous plexus that ultimately drains into branches of the portal vein (Vellar 2001, Ramesh Babu and Sharma 2014).

Splenic vein

Blood from the spleen is collected by trabecular veins that join to form segmental veins that drain individual splenic segments. In general, there are no anastomoses between intrasegmental venous tributaries. The segmental veins join to form two (superior and inferior) or three (superior, middle and inferior) 'lobar' veins that emerge from the length of the splenic hilum and unite to form the splenic vein within the splenorenal ligament (see Fig. 69.2). Communicating veins may interconnect lobar veins (Par et al 1965, DeLand 1970, Gupta et al 1980, Sow et al 1991, Liu et al 1996).

The splenic vein most commonly runs posterior to the splenic artery and tail and body of the pancreas (Par et al 1965, Gürleyik et al 2000, Skandalakis et al 2004). It crosses the posterior abdominal wall anterior to the left kidney and abdominal aorta, separated from the left sympathetic trunk and left crus of the respiratory diaphragm by the left renal vessels, and from the abdominal aorta by the superior mesenteric artery and left renal vein (Par et al 1965, Gupta et al 1976, Gupta et al 1980, Liu et al 1996). It ends posterior to the neck of the pancreas, where it joins the superior mesenteric vein to form the hepatic portal vein. Along its course it receives the short gastric veins, left gastro-omental veins, pancreatic veins and the posterior gastric vein. It may also receive the left gastric vein and inferior mesenteric veins in approximately 30% of individuals (Gerber et al 1951). Anastomoses between the splenic vein and left renal vein have been reported, particularly in cases of portal hypertension (Bowdler 2002). Approximately 60% of hepatic portal vein blood flow is derived from the gut and the remainder from the spleen and pancreas (Par et al 1965, Gupta et al 1980, Dawson et al 1986, Oguro et al 1993, Liu et al 1996, Gürleyik et al 2000). Obstruction of the hepatic portal or splenic veins can lead to reversed venous flow through the splenic vein and its tributaries, resulting in splenomegaly and widespread varices (Re et al 1985, Skandalakis et al 1993, Petroianu 2011).

Short gastric veins

Three to five short gastric veins drain the fundus and the upper part of the greater curvature of the stomach into the splenic vein or one of its large tributaries: they travel within the gastrosplenic ligament (Power et al 2001).

Left gastro-omental vein

The left gastro-omental vein drains both the anterior and posterior surfaces of the body of the stomach and the adjacent greater omentum via multiple tributaries. It runs superolaterally along the greater curvature, between the layers of the gastrocolic ligament, and drains into the splenic vein within the gastrosplenic ligament.

Pancreatic veins

Multiple veins drain the pancreas into the hepatic portal, superior mesenteric and splenic veins (Mourad et al 1994; Fig. 68.7). Although variations are common, the anterior superior pancreaticoduodenal vein typically joins either the confluence of the right gastro-omental and right colic veins (the gastrocolic trunk of Henle) or the right gastro-omental vein alone, to drain into the superior mesenteric vein at the inferior border of the neck of the pancreas (Mourad et al 1994, Lange et al 2000). The posterior superior pancreaticoduodenal vein drains cranially into the hepatic portal vein. Both anterior and posterior inferior pancreaticoduodenal veins usually drain directly into the dorsal aspect of the superior mesenteric vein inferior to the uncinate process. These veins can be a major source of blood loss when the uncinate process is dissected off the superior mesenteric vein during a pancreaticoduodenectomy procedure. In most individuals the first and second jejunal veins form a single vein known as the first jejunal trunk that drains into the superior mesenteric vein (Ishikawa et al 2017). Veins from the body and tail of the gland drain directly into the splenic vein. An inferior (transverse) pancreatic vein sometimes runs along the inferior border of the pancreas to join the inferior mesenteric vein. A few pancreatic veins communicate with systemic veins in the retroperitoneum (veins of Retzius), and can form retroperitoneal varices in portal hypertension.

Posterior gastric veins

One or more distinct posterior gastric veins can be present, draining the middle of the posterior surface of the stomach into the splenic vein: they can become particularly prominent in portal hypertension (Kimura et al 1990).

Inferior mesenteric vein

The inferior mesenteric vein drains the rectum and the sigmoid, descending and distal transverse colon (see Figs 65.15, 65.42). It begins as the continuation of the superior anorectal vein from the anorectal plexus, through which it connects with the middle anorectal and inferior anal veins. The inferior mesenteric vein lies to the left of the inferior mesenteric artery in the retroperitoneum and ascends anterior to the left psoas major and left ureter; it may cross the gonadal vessels or ascend medial to them. It lies just lateral or occasionally posterior to

the duodenojejunal flexure, where it can be located intraoperatively. The inferior mesenteric vein receives the superior anorectal vein, several sigmoid veins and the left colic vein. It usually passes posterior to the lower border of the body of the pancreas and anterior to the left renal vein to drain into the splenic vein, but it can also drain into the confluence of the splenic and superior mesenteric veins or directly into the superior mesenteric vein (Graf et al 1997).

Superior anorectal vein

Venous tributaries from the rectal venous plexus ascend in the rectal submucosa and pierce the rectal wall to form the superior anorectal vein. This runs in the upper mesorectum and root of the sigmoid mesocolon to the left of the superior anorectal artery, crossing the linea terminalis and left common iliac vessels to form the inferior mesenteric vein (see Figs 65.15, 65.44).

Rectal venous plexus

The rectal venous plexus surrounds the rectum and connects anteriorly with the vesical plexus in males or the uterine and vaginal venous plexuses in females. It consists of internal veins beneath the mucosa of the rectum and proximal anal canal, and external veins lying outside the muscular wall. The upper two-thirds of the rectum and the internal part of the rectal venous plexus drain mainly to the superior anorectal vein and, from there, to the inferior mesenteric vein; the middle third of the rectum drains via one or more middle anorectal veins into the internal iliac vein; and the lower third of the rectum and anal canal drains via inferior anal veins into the internal pudendal veins. The rectal venous plexus is therefore a site of communication between the portal and systemic venous systems.

Left colic vein

The left colic vein is formed from several tributaries, including ascending and descending branches that correspond to the similarly named arteries. The left colic vein usually lies superior to its corresponding artery, and has a shorter course because the inferior mesenteric vein lies lateral to the inferior mesenteric artery (see Fig. 65.42). Occasionally there are two left colic veins that both drain into the inferior mesenteric vein (Tubbs et al 2016).

Superior mesenteric vein

The superior mesenteric vein drains the small intestine, caecum, ascending and transverse parts of the colon, and parts of the stomach and greater omentum (see Figs 59.8, 64.16). It is formed in the mesentery of the small intestine by the union of tributaries from the terminal ileum, caecum and appendix. It ascends in the mesentery to the right of the superior mesenteric artery, passing anterior to the right ureter, inferior vena cava, horizontal part of the duodenum and uncinate process of the pancreas. It joins the splenic vein posterior to the neck of the pancreas in the transpyloric plane (inferior border of L1 vertebra) to form the hepatic portal vein.

The superior mesenteric vein receives jejunal, ileal, ileocolic, right colic, middle colic, right gastro-omental and inferior pancreaticoduodenal veins. A major proximal jejunal branch usually runs transversely posterior to the superior mesenteric artery to enter the right posterolateral aspect of the superior mesenteric vein (Kim et al 2007). The right colic vein is highly variable. When present, it can drain directly into the superior mesenteric vein or join the right gastro-omental or inferior pancreaticoduodenal vein to form a 'gastrocolic trunk', which then drains into the superior mesenteric vein (Yamaguchi et al 2002). Although the inferior mesenteric vein usually drains into the splenic vein, it can join the superior mesenteric vein directly or its confluence with the splenic vein (Graf et al 1997).

Right gastro-omental vein

The right gastro-omental vein drains the greater omentum, distal body of the stomach and pyloric antrum. It runs medially along the greater curvature in the upper part of the gastrocolic omentum. Just proximal to the pylorus, it passes posteriorly to drain into the superior mesenteric vein posterior to the neck of the pancreas. The right gastro-omental vein can receive the right colic vein (forming a 'gastrocolic trunk') and/or the superior pancreaticoduodenal vein close to its entry into the superior mesenteric vein (Yamaguchi et al 2002, Stefura et al 2018).

Porto-systemic shunts

Increased pressure within the portal venous system can result in dilation of portal venous tributaries and reversed flow at sites of porto-systemic anastomoses. Common sites of porto-systemic shunts are listed in Table 66.1.

In cases of extreme chronic portal hypertension, a large calibre anastomosis between the portal and systemic circulations can be created within the liver parenchyma by inserting a stent between a large hepatic portal vein and an intrahepatic vein (transjugular intrahepatic porto-systemic shunt). The stent is introduced through a catheter inserted into the internal jugular vein and guided into the liver under radiological control (Siramolpiwat 2014). This large shunt relieves the severe portal hypertension but tends to worsen incipient hepatic encephalopathy.

Oesophageal and gastric varices

Blood from the oesophageal mucosa normally drains into a submucosal venous plexus, then into a deeper intrinsic venous plexus and finally into oesophageal veins via perforating veins. In the abdominal part of the oesophagus, the perforating veins drain into tributaries of the left gastric vein, whereas in the distal thoracic part of the oesophagus, they drain into tributaries of the azygos and hemiazygos venous systems. Bidirectional flow is possible in this region and accommodates pressure changes during breathing and Valsalva manoeuvres.

Oesophageal and gastric varices are abnormally dilated veins that occur in the submucosal plexus of the distal oesophagus and fundus of the stomach when portal venous pressure is chronically elevated (typically greater than 15 mmHg). This can arise as a consequence of liver fibrosis or cirrhosis, or hepatic portal vein thrombosis, or from a variety of other causes. Portal hypertension leads to the recanalization of occluded embryonic venous channels connecting tributaries of the portal system and the systemic venous circulation (e.g. the round ligament of the liver), and progressive dilation of small, naturally occurring venous anastomoses between portal and systemic venous tributaries (Paquet 2000). The raised pressure causes the valves within these veins to become incompetent, permitting retrograde flow and the development of varices. Varices in the distal oesophagus are readily visible at endoscopy because they are situated superficially and protrude into the lumen of the oesophagus (see Fig. 63.13A); they are vulnerable to rupture and are a source of major gastrointestinal bleeding. Gastric varices can also be present on the inferior aspect of the cardiac orifice and isolated gastric varices can develop as a result of splenic vein thrombosis. The close anatomical relationship between the splenic vein and the pancreas means that inflammation or cancers of the pancreas can result in the formation of a thrombus in the splenic vein. Because the short gastric veins drain into the splenic vein, thrombosis of that vein will result in increased pressure and engorgement, leading to varices in the fundus of the stomach.

VENOUS DRAINAGE OF THE LOWER LIMB

The veins of the lower limb can be subdivided into a superficial group lying in the subcutaneous tissue and vessels that lie deep to the deep fascia and accompany the major arteries and their branches (see Figs 76.8–76.9). Valves are present in both groups, but are more numerous in the deep veins. (They are also more numerous than in the veins of the upper limb). Venous plexuses occur within and between some of the lower limb muscles. The two principal superficial veins are the long and short saphenous veins; their numerous tributaries are mostly unnamed, however, changes in clinical practice are driving a revision of the terminology (Caggiati et al 2002, 2005). The long saphenous vein can be harvested and used as a graft for peripheral vascular surgery, including coronary artery bypass (Kosinski 1926).

Plantar digital veins arise from plexuses in the plantar regions of the toes, connect with dorsal digital veins and unite to form four plantar metatarsal veins. These run in the intermetatarsal spaces and connect first with dorsal veins by means of perforating veins and then connect with each other to constitute a deep plantar venous arch adjacent to the deep plantar arterial arch. Medial and lateral plantar veins from the venous arch run near the corresponding arteries and communicate with the long and short saphenous veins before forming the posterior tibial veins posterior to the medial malleolus.

The posterior tibial veins accompany the posterior tibial artery. They receive veins from the calf muscles, especially the venous plexus in soleus, and connect with superficial veins and with the fibular veins. The latter accompany the fibular artery and receive tributaries from both soleus and superficial veins. The anterior tibial veins are continuations of the venae comitantes of the dorsalis pedis artery. They leave the extensor region between the tibia and fibula, pass through the proximal end of the interosseous membrane and unite with the posterior tibial veins at the distal border of popliteus to form the popliteal vein.

Venous (muscle) pumps

While standing, venous return from the lower limb depends largely on muscular activity, especially contraction of the calf and foot muscles, known as the 'muscle pump', aided by the tight sleeve of deep fascia (Ricci 2017). 'Perforating' veins connect the long saphenous vein with the deep veins, particularly near the ankle, distal calf and knee. Their valves are arranged so as to prevent flow of blood from the deep to the superficial veins. At rest, pressure in a superficial vein is equal to the height of the column of blood extending from that vein to the heart. When the posterior leg muscles contract, blood is pumped proximally into the deep veins and is normally prevented from flowing into the superficial veins by the valves in the perforating veins. During muscular relaxation, blood is drawn into the deep veins from the superficial veins. If the valves in the perforating veins become incompetent, these veins become sites of 'high-pressure leaks' during muscular contraction, and the superficial veins become dilated and varicose. There are similar perforating connections in the anterolateral region, where varicosities may also occur. Incompetence of the valves in the connecting veins between the long saphenous vein and femoral vein in the adductor canal may predispose to superficial varicosities along the medial aspect of the thigh (Dodd and Cockett 1976). Venous plexuses, which may be intramuscular (soleus) or intermuscular (in the foot and gluteal region), communicate with the axially running deep veins and are components of the 'muscle pump' mechanism.

Venous disease

Chronic venous disease is common. Sustained overdistension of the superficial veins of the lower limb may result in the development of short, dilated venous segments or varicosities. Varicose veins can occur as a consequence of venous valve failure at the proximal end of the long saphenous vein at the saphenofemoral junction, or in the perforating veins that pass from the superficial system to the high-pressure deep veins. Varicose veins have thin walls and 'leak' red blood cells into adjacent soft tissues. As these cells are broken down, haemosiderin is deposited in the soft tissues, resulting in a brown pigmentation. This phenomenon, together with the fact that venous stasis produces oedema, renders the soft tissues of the leg unhealthy and prone to ulceration, particularly after minor trauma.

Acute venous disease occurs most commonly in the posterior compartment of the leg. This is attributed to the sluggish blood flow that occurs, at times, in the deep veins of the calf. This relative stasis predisposes to the formation of venous thrombi. Fragments of these thrombi may become dislodged and carried in the venous return to the heart to cause a life-threatening pulmonary embolism. Blockage of the normal venous system may contribute to increased local venous pressure and oedema.

Superficial veins

Superficial veins of the foot

As occurs in the upper limb, the vessels are described centripetally from peripheral to major drainage channels.

Dorsal digital veins receive rami from the plantar digital veins in the clefts between the toes and then join to form dorsal metatarsal veins, which are united across the proximal parts of the metatarsals in a dorsal venous arch. Proximal to this arch, an irregular dorsal venous network receives tributaries from deep veins and is continuous proximally with a venous network in the leg. At each side of the foot, this network connects with medial and lateral marginal veins, which are both formed mainly by veins from more superficial parts of the sole. In the sole, superficial veins form a plantar cutaneous arch across the roots of the toes and also drain into the medial and lateral marginal veins.

Long saphenous vein

The long (great) saphenous vein (see Fig. 76.9A), the longest vein in the body, starts distally as a continuation of the medial marginal vein of the foot, and ends in the femoral vein a short distance distal to the inguinal ligament. It ascends immediately anterior to the medial malleolus, crosses the distal third of the medial surface of the tibia obliquely in an anteroposterior direction to reach its medial border, and then ascends a little behind the border to the knee. Proximally, it is posteromedial to the medial tibial and femoral condyles and then ascends the medial aspect of the thigh. It passes through the saphenous opening and finally opens into the femoral vein. The 'centre' of the opening is often said to be 2.5–3.5 cm inferolateral to the pubic tubercle, and the vein is then represented by a line drawn from this point to the adductor tubercle. However, the saphenous opening varies greatly in size and disposition so that this 'centre' is not a reliable surface marking for the saphenofemoral junction.

In its course through the thigh, the long saphenous vein is accompanied by the medial branches of the anterior cutaneous branches of the femoral nerve. At the knee, the saphenous branch of the descending genicular artery (the saphenous artery) and, in the leg and foot, the saphenous nerve all lie anterior to the vein. The vein is often duplicated, especially distal to the knee. It has 10–20 valves, which are more numerous in the leg than in the thigh. One is present just before the vein pierces the cribriform fascia, another at its junction with the femoral vein. In almost its entire extent the vein lies in subcutaneous tissue, but it has many connections with the deep veins, especially in the leg.

At the ankle, the long saphenous vein drains the sole of the foot by medial marginal veins. In the leg, it often connects with the short saphenous vein and with deep veins via perforating veins. Just distal to the knee it usually receives three large tributaries from the front of the leg, the medial malleolar region (connecting with some of the 'perforating' veins) and the calf (communicating with the short saphenous vein). The tributary draining the medial malleolar region is formed distally from a fine network or 'corona' of delicate veins just over the medial malleolus, and then ascends the medial aspect of the calf as the posterior arch vein. This vein was first illustrated by Leonardo da Vinci, whose name is sometimes given to it. It connects with posterior tibial venae comitantes by a series of perforating (communicating) veins. There are usually three, equally spaced between the medial malleolus and the mid-calf. More than three such perforators are uncommon, and an arch vein perforator above mid-calf is only very rarely found.

Above the posterior crural arch vein, perforating veins join the long saphenous vein or one of its main tributaries at two main sites. The first is at a level in the upper calf indicated by its name, the tibial tubercle perforator; the second is in the lower/intermediate third of the thigh, where it perforates the deep fascia roof of the subsartorial canal to join the femoral vein.

In the thigh, the long saphenous vein receives many tributaries. Some open independently, while others converge to form large named channels that frequently pass towards the basal half of the femoral triangle before joining the long saphenous near its termination. These may be grouped as follows: one or more large posteromedial tributaries, one or more large anterolateral tributaries, and four or more peringuinal veins. The posteromedial vein of the thigh, large and sometimes double, drains a large superficial region indicated by its name; it has (as have the other tributaries) radiological and surgical significance. One of its lower radicles is often continuous with the short saphenous vein. The posteromedial vein is sometimes named the accessory saphenous vein, though some restrict the term accessory to a lower (more distal) posteromedial tributary when two (or more) are present. Another large vessel, the anterolateral vein of the thigh (anterior femoral cutaneous vein), usually commences from an anterior network of veins in the distal thigh and crosses the apex and distal half of the femoral triangle to reach the long saphenous vein. As the latter traverses the saphenous opening, it is joined by the superficial epigastric, superficial circumflex iliac and superficial external pudendal veins. Their mode of union varies. Superficial epigastric and circumflex iliac veins drain the inferior abdominal wall, the latter also receiving tributaries from the proximolateral region of the thigh. The superficial epigastric or the femoral vein may connect with the lateral thoracic veins by means of a thoracoepigastric vein that runs superficially on the anterolateral aspect of the trunk. This vein connects the inferior and superior caval areas of drainage and may be dilated and visible in cases of inferior caval obstruction. Superficial external pudendal veins drain part of the scrotum/labia; one is joined by the superficial dorsal vein of the penis/clitoris. The deep external pudendal veins join the long saphenous vein at the saphenous opening.

The long saphenous vein is often harvested for grafts used in both peripheral and coronary arterial surgery.

Short saphenous vein

The short saphenous vein (small saphenous vein) begins posterior to the lateral malleolus as a continuation of the lateral marginal vein (see Fig. 76.9B). In the lower third of the calf, it ascends lateral to the calcaneal tendon, lying on the deep fascia and covered only by subcutaneous tissue and skin. Inclining medially to reach the midline of the calf, it penetrates the deep fascia, within which it ascends on gastrocnemius, only emerging between the deep fascia and gastrocnemius gradually at about the junction of the middle and proximal thirds of the calf (usually well below the lower limit of the popliteal fossa). Continuing its ascent, it passes between the heads of gastrocnemius and proceeds to its termination in the popliteal vein, 3–7.5 cm above the knee joint.

The short saphenous vein connects with deep veins on the dorsum of the foot, receives many cutaneous tributaries in the leg, and sends several communicating branches proximally and medially to join the

long saphenous vein. Sometimes a communicating branch ascends medially to the accessory saphenous vein: this may be the main continuation of the short saphenous vein. In the leg, the short saphenous vein lies near the sural nerve and contains 7–13 valves, with one near its termination. Its mode of termination is variable: it may join the long saphenous vein in the proximal thigh or it may bifurcate, one branch joining the long saphenous vein and the other joining the popliteal or deep posterior femoral veins. Sometimes it drains distal to the knee in the long saphenous or sural veins.

Deep veins

The deep veins draining the knee and leg correspond in name to the arteries and run with them; the named smaller veins drain into the popliteal and femoral veins.

Deep veins of the foot

Plantar digital veins arise from plexuses in the plantar regions of the toes. They connect with dorsal digital veins to form four plantar metatarsal veins, which run proximally in the intermetatarsal spaces and connect via perforating veins with dorsal veins, then continue to form the deep plantar venous arch, which is situated alongside the deep plantar arterial arch. From this venous arch, medial and lateral plantar veins run near the corresponding arteries and, after communicating with the long and short saphenous veins, form the posterior tibial veins behind the medial malleolus. Proximal to the deep plantar arch there is a plantar cutaneous venous plexus, especially dense in the fat of the heel. It connects with the plantar cutaneous venous arch and other deep veins, but drains mainly into the marginal veins. The veins of the sole are an important part of the lower limb 'venous pump' system aiding propulsion of blood up the limb (Broderick et al 2008). Intermittent foot compression devices are available to enhance this flow and so reduce the risk of deep vein thrombosis during periods of increased risk, e.g. after surgery.

Posterior tibial veins

The posterior tibial veins accompany the posterior tibial artery (see Fig. 76.8). They receive tributaries from the calf muscles (especially from the venous plexus in the soleus) and connections from superficial veins and the fibular veins.

Fibular veins

The fibular veins, running with their artery, receive tributaries from soleus and from superficial veins.

Anterior tibial veins

The anterior tibial veins, continuations of the venae comitantes of the dorsalis pedis artery, leave the anterior compartment between the tibia and fibula, and pass through the proximal end of the interosseous membrane. They unite with the posterior tibial veins to form the popliteal vein at the distal border of popliteus.

Popliteal vein

The popliteal vein ascends through the popliteal fossa to the opening in adductor magnus, where it becomes the femoral vein (see Figs 76.8, 76.9B, 77.47). Its relationship to the popliteal artery changes as the vein ascends: distally, it is medial to the artery; between the heads of gastrocnemius, it is superficial (posterior) to the artery; and proximal to the knee joint, it is posterolateral to the artery. Its tributaries are the short saphenous vein; veins corresponding to branches of the popliteal artery; and muscular veins, including a large branch from each head of gastrocnemius. There are usually four or five valves in the popliteal vein.

Femoral vein

The femoral vein accompanies its artery, beginning at the adductor opening as the continuation of the popliteal vein, and ending posterior to the inguinal ligament as the external iliac vein (see Figs 76.8, 77.1–77.2, 77.44). The vein is posterolateral to the femoral artery in the distal adductor canal. More proximally in the canal, and in the distal femoral triangle (i.e. at its apex), the vein lies posterior to the artery and proximally, at the base of the triangle, the vein lies medial to the artery. The vein occupies the middle compartment of the femoral sheath, between the femoral artery and femoral canal; fat in the canal permits expansion of the vein.

The femoral vein has numerous muscular tributaries. The profunda femoris vein (deep vein of the thigh, deep femoral vein) joins the femoral vein posteriorly 4–12 cm distal to the inguinal ligament, and the long saphenous vein then enters anteriorly. Veins accompanying the superficial epigastric, superficial circumflex iliac and external pudendal arteries join the long saphenous vein before it enters the saphenous opening. Lateral and medial circumflex femoral veins are usually tributaries of the femoral vein. There are usually four or five valves in the femoral vein; the two most constant are just distal to the entry of profunda femoris and near the inguinal ligament.

Profunda femoris vein (deep vein of the thigh)

The profunda femoris vein lies anterior to its artery and receives tributaries corresponding to the branches of the artery. Through these tributaries it connects distally with the popliteal vein and proximally with the inferior gluteal veins. It sometimes drains the medial and lateral circumflex femoral veins and has a valve just before it empties into the femoral vein.

LYMPHATIC DRAINAGE

Lymphocytes are located in many sites in the body, most obviously at strategic sites that are liable to infection, e.g. the oropharynx. The main areas of lymphocyte concentration are classified as primary or secondary lymphoid organs, according to whether they are involved in *de novo* lymphocyte generation (primary lymphoid organs, e.g. bone marrow, thymus) or are the site of mature lymphocyte activation and initiation of an immune response (secondary lymphoid organs, e.g. lymph nodes, spleen).

All lymphocytes arise from pluripotent haemopoietic stem cells in the bone marrow. The B lymphocyte lineage develops through a series of differentiation stages within the bone marrow. The newly formed B cells then leave through the circulation and migrate to peripheral sites. In contrast, T-lymphocyte development requires the thymus; the bone marrow-derived stem cells must therefore migrate via the blood circulation to the thymus. After their differentiation and maturation into immunocompetent T cells that have survived thymic selection processes (1–3%), they re-enter the circulation and are transported to peripheral sites where they join the pool of naïve lymphocytes that recirculate through the secondary lymphoid organs via blood and lymphatic circulation systems.

The secondary or peripheral lymphoid organs are the specialized sites where B and T lymphocytes and antigen-presenting cells come together to initiate immune responses to foreign antigens (Malhotra et al 2013). They include lymph nodes, spleen, lymphoid tissue associated with epithelial surfaces (mucosa-associated lymphoid tissue, MALT), e.g. the palatine and nasopharyngeal tonsils; Peyer's patches in the small intestine; lymphoid nodules in the respiratory and urogenital systems; the skin. The microstructure of lymph nodes and of MALT in general is described in Chapter 4.

Thoracic duct

The thoracic duct conveys the lymph from the entire body back to the venous circulation, except lymph from the right part of the head, neck and heart, right upper limb, parts of the left and right lung and part of the convex surface of the liver. It usually originates anterior to the body of the first or second lumbar vertebra, where the intestinal and two lumbar lymphatic trunks join to form the cisterna chyli. Both the thoracic duct and the cisterna chyli are variable in their origin, course and length; the latter is even more variable in width and shape than the thoracic duct (Song 2016) (see page 1464.e120 for a description of the cisterna chyli). From the superior aspect of the cisterna chyli, the thoracic duct passes through the aortic hiatus and enters the posterior mediastinum, lying to the right of the midline, between the aorta and the azygos vein, up to the level of the body of the fifth or sixth thoracic vertebra, where it typically crosses over the vertebral column posterior to the oesophagus (see Fig. 56.7B). It may branch or even have duplicate trunks that eventually form a single thoracic duct (Song 2016). It continues superiorly, first posterior to the aortic arch adjacent to the left side of the oesophagus, then posterior to the left subclavian artery in the superior mediastinum. It subsequently arches over the left subclavian artery and descends anteriorly to empty into the venous circulation in the region of the left internal jugular and subclavian veins, either at their very confluence or in proximity, or sometimes into the left brachiocephalic vein (see Fig. 56.5). In the space between longus colli, scalenus anterior and the suprapleural membrane, the duct usually arches 3–4 cm superior to the clavicle, crossing anterior to the vertebral vessels, the left sympathetic trunk, the vertebral ganglion, the left thyrocervical trunk and the left phrenic nerve. The course and position of the thoracic duct determines the location of the effusion seen with duct injury or obstruction.

Two thoracic ducts are sometimes present within the mediastinum and may terminate in veins on their respective side of the body. Occasionally a single thoracic duct may empty into right-sided venous structures, a disposition that is more frequent in individuals with an aberrant right subclavian artery originating from the distal aortic arch ascending posterior to the oesophagus.

The thoracic duct is commonly 36–45 cm in length; its external diameter varies according to region (Song 2016). When present as a single channel it is 5–8 mm in diameter at its origin, narrows to 2–3 mm at mid-thoracic level and then widens again at its termination: the diameter may fluctuate with lymph flow rate (Smith et al 2013). Alternatively, the thoracic duct may divide into two or three branches that eventually reunite or drain into both the left and right venous systems. The duct appears sinuous and has valves throughout its length; a bicuspid valve at its termination may prevent the backflow of blood. As it passes through the mediastinum, the thoracic duct also receives non-chylous lymph from tributaries that drain regions of the pulmonary parenchyma and parietal pleura. The sum of these sources accounts for a total lymphatic flow through the thoracic duct of 1500–2400 ml per day in proportion to the dietary intake of fat, particularly long-chain triglycerides.

The thoracic duct crosses the mediastinum at, or at about, the level of the body of the fifth thoracic vertebra which means that lymphatic injury or obstruction above or below this level results in a left- or right-sided pleural effusion (chylothorax), respectively (Doerr et al 2001). Anomalies and sites of injury to the duct are identified by lymphangiography, with or without post-procedure CT scanning, or lymphoscintigraphy. Lymphangiography is performed after bilateral localization of pedal lymphatics with a subcutaneous injection of methylene blue, followed by a minor surgical procedure to cannulate the lymphatic vessels, and injection of Lipiodol contrast agent. Conventional X-ray and CT imaging (without intravenous contrast) are then undertaken. Lymphangiography can identify areas of chyle leakage and lymphangiectasia in the majority of patients (Deso et al 2012).

Tributaries Some tributaries of the thoracic duct may terminate directly in the venous system. There are numerous anastomoses between visceral, parietal, limb and mammary lymphatics, as is apparent from observed multiple patterns of dissemination of cancer cells (see Figs 56.4–56.5). As well as the cisterna chyli and its tributaries, bilateral ascending lumbar lymphatic trunks from the upper lateral aortic (abdominal part) nodes pierce the corresponding diaphragmatic crus and eventually join the thoracic duct in the posterior mediastinum. The inferior six or seven intercostal lymphatic trunks from the corresponding bilateral intercostal nodes descend to terminate in the duct, either directly or by variable common trunks. The left upper intercostal lymphatics may join the cervical portion of the duct or the subclavian trunk. The left subclavian trunk usually joins the thoracic duct but may open independently into the left subclavian vein. These mediastinal trunks provide lymph drainage paths to the thoracic duct from the convex diaphragmatic aspect of the liver, the respiratory diaphragm, the pericardium, heart and oesophagus; many possess terminal bicuspid valves. The left bronchomediastinal trunk occasionally joins the thoracic duct but usually has an independent venous termination. The left jugular trunk usually joins the thoracic duct but may open independently into the left internal jugular vein (see Fig. 35.16).

LYMPHATIC DRAINAGE OF THE HEAD AND NECK

Lymph nodes in the head and neck are arranged in two horizontal rings and two vertical chains on either side of the neck (see Figs 35.1, 35.15). The superficial ring consists of the occipital, preauricular (parotid), submandibular and submental nodes, and the inner, deep, ring is formed by clumps of mucosa-associated lymphoid tissue (MALT) located primarily in the nasopharynx and oropharynx (Waldeyer's ring). The vertical chain consists of superior and inferior groups of nodes related to the carotid sheath, and known collectively as the deep cervical lymph nodes. All lymph vessels of the head and neck drain into the deep cervical nodes, either directly from the tissues or indirectly via nodes in the outlying groups. Efferents of the deep cervical nodes form the jugular trunk on either side. The right jugular trunk collects lymph from the right head and neck, the right arm and the right half of the thorax, and may end in the jugulosubclavian junction or the right lymphatic duct. The left jugular trunk usually enters the thoracic duct, but it may join the internal jugular or subclavian vein. A summary of the widely used surgical neck lymph node classification system is shown in Table 81.1. (For a concise description of the main anatomical boundaries of each nodal group, the normal structures juxtaposed to these nodes, and the main tumour sites at risk for harbouring metastases in each level, see Grégoire et al 2014.)

TABLE 81.1 Surgical levels of the neck

Level	Boundaries
Level Ia	The submental triangle, bounded by the anterior bellies of the digastric and mylohyoid muscles
Level Ib	The submandibular triangle, formed by the anterior and posterior bellies of digastric and the body of the mandible
Level IIa	The region anterior to the accessory nerve, bounded by the digastric muscle superiorly and either the hyoid bone (clinical landmark) or the carotid bifurcation (surgical landmark) inferiorly, down to the prevertebral fascia
Level IIb	The region above and posterior to the accessory nerve, extending to the skull base
Level III	Extends from the carotid bifurcation superiorly either to the cricothyroid notch (clinical landmark) or to omohyoid (surgical landmark). Note that the position of omohyoid moves with head position and so the inferior extent of this level can be arbitrary
Level IV	Contains the lower jugular nodes extending from omohyoid superiorly to the clavicle inferiorly
Level V	The posterior triangle, bounded posteriorly by the anterior border of trapezius, anteriorly by the posterior border of sternocleidomastoid, and inferiorly by the clavicle. It is divided into level Va (above) and Vb (below) by the accessory nerve as it crosses the posterior triangle
Level VI	The anterior neck compartment, extending from the level of the hyoid bone superiorly to the suprasternal notch inferiorly. On each side the lateral boundary is the medial border of the carotid sheath

Face and scalp

Lymph vessels from the frontal region above the root of the nose drain to the submandibular nodes (see Fig. 36.21). Vessels from the rest of the forehead, temporal region, upper half of the lateral auricular aspect and anterior wall of the external acoustic meatus drain to the superficial parotid nodes that lie just anterior to the tragus, either on or deep to the parotid fascia. These nodes also drain lateral vessels from the eyelids and skin of the zygomatic region, and their efferent vessels pass to the upper deep cervical nodes. A strip of scalp above the auricle, the upper half of the cranial aspect and margin of the auricle, and the posterior wall of the external acoustic meatus all drain to the upper deep cervical and posterior auricular nodes. The posterior auricular nodes are superficial to the mastoid attachment of sternocleidomastoid and deep to auricularis posterior and drain to the upper deep cervical nodes. The auricular lobule, floor of the external acoustic meatus and skin over the mandibular angle and lower parotid region all drain to the superficial cervical or upper deep cervical nodes. Superficial cervical nodes lie along the external jugular vein superficial to sternocleidomastoid. Some efferents pass round the anterior border of sternocleidomastoid to the upper deep cervical nodes, while others follow the external jugular vein to the lower deep cervical nodes in the subclavian triangle.

The occipital region of the scalp drains partly to the occipital nodes, and partly to a vessel that runs along the posterior border of sternocleidomastoid to the lower deep cervical nodes. Occipital nodes are commonly superficial to the upper attachment of trapezius but occasionally lie in the superior angle of the posterior triangle.

There are usually three submandibular nodes, internal to the deep cervical fascia in the submandibular triangle. One lies at the anterior pole of the submandibular gland, and two flank the facial artery as it reaches the mandible. Other nodes are often embedded in the gland or deep to it. Submandibular nodes drain a wide area, including vessels from the submental, buccal and lingual groups of nodes, and their efferents pass to the upper and lower deep cervical nodes. The external nose, cheek, upper lip and lateral parts of the lower lip drain directly to the submandibular nodes; the afferent vessels may have a few buccal nodes along their course and near the facial vein. The mucous membrane of the lips and cheek drains to the submandibular nodes, and the lateral part of the cheek drains to the parotid nodes. The central part of the lower lip, buccal floor and tip of the tongue all drain to the submental nodes lying on mylohyoid between the anterior bellies of the digastric muscles. These nodes receive afferents bilaterally, some decussating across the chin and their efferents pass to the submandibular and jugulo-omohyoid nodes.

The posterior aspect of the auricle (pinna) drains to nodes at the mastoid tip. The tragus and upper part of the pinna drain into preauricular nodes, while the remainder of the pinna drains to upper deep cervical lymph nodes. Lymphatic vessels of the tympanic and antral mucosae drain to the parotid or upper deep cervical lymph nodes. Vessels draining the tympanic end of the pharyngotympanic tube

probably end in the deep cervical nodes. Lymphatic vessels from the conjunctiva drain into pre-auricular and submandibular lymph nodes. The infratemporal and temporal fossae drain to the superior deep cervical nodes. Lymphatics from the temporomandibular joint drain deeply to the upper cervical lymph nodes surrounding the internal jugular vein.

Mouth

Gingivae and teeth

The lymph vessels of the labial and buccal gingivae of the maxillary and mandibular teeth unite to drain into the submandibular nodes; they may drain into the submental lymph nodes in the labial region of the mandibular incisors. The lingual and palatal gingivae drain into the jugulodigastric group of nodes, either directly or indirectly through the submandibular nodes.

The lymph vessels from the teeth usually run directly into the ipsilateral submandibular lymph nodes. Lymph from the mandibular incisors drains into the submental lymph nodes and lymph from the molars may occasionally pass directly into the jugulodigastric group of nodes.

Tongue

The mucosa of the pharyngeal part of the dorsal surface of the tongue contains many lymphoid follicles aggregated into dome-shaped groups: the lingual tonsils. Each group is arranged around a central deep crypt, or invagination, which opens on to the surface epithelium. The ducts of mucous glands open into the bases of the crypts. Small isolated follicles also occur beneath the lingual mucosa. The lymphatic drainage of the tongue can be divided into three main regions: marginal, central and dorsal. The anterior region of the tongue drains into marginal and central vessels, and the posterior part of the tongue behind the circumvallate papillae drains into the dorsal lymph vessels. The more central regions may drain bilaterally, and this must be borne in mind when planning to remove malignant tumours of the tongue that are approaching the midline. If the tumour has a propensity for lymphatic spread, both cervical chains may be involved.

Marginal vessels

Marginal vessels from the apex of the tongue and the lingual frenulum area descend under the mucosa to widely distributed nodes. Some vessels pierce mylohyoid as it contacts the mandibular periosteum to enter either the submental or anterior or middle submandibular nodes, or else to pass anterior to the hyoid bone to the jugulo-omohyoid node. Vessels arising in the plexus on one side may cross under the frenulum to end in contralateral nodes. Efferent vessels of median submental nodes pass bilaterally. Some vessels pass inferior to the sublingual gland and accompany the companion vein of the hypoglossal nerve to end in jugulodigastric nodes. One vessel often descends further to reach the jugulo-omohyoid node, and passes either superficial or deep to the intermediate tendon of digastric.

Vessels from the lateral margin of the tongue cross the sublingual gland, pierce mylohyoid and end in the submandibular nodes. Others end in the jugulodigastric or jugulo-omohyoid nodes. Vessels from the posterior part of the lingual margin traverse the pharyngeal wall to the jugulodigastric lymph nodes (see Fig. 37.12).

Central vessels

The regions of the lingual surface draining into the marginal or central vessels are not distinct. Central lymphatic vessels ascend between the fibres of the two genioglossi; most pass between the muscles and diverge to the right or left to follow the lingual veins to the deep cervical nodes, especially the jugulodigastric and jugulo-omohyoid nodes. Some pierce mylohyoid to enter the submandibular nodes.

Dorsal vessels

Vessels draining the postsulcal region and the circumvallate papillae run posteroinferiorly. Those near the median plane may pass bilaterally. They turn laterally, joining the marginal vessels, and all pierce the pharyngeal wall, passing around the external carotid arteries to reach the jugulodigastric and jugulo-omohyoid lymph nodes. One vessel may descend posterior to the hyoid bone, perforating the thyrohyoid membrane to end in the jugulo-omohyoid node.

Neck

The lymphatics of the skin in the suprahyoid region drain to level I nodes (submental and submandibular lymph nodes). The lymphatics of the skin of the rest of the neck drain to levels II, III and IV, apart from the posterior lateral neck skin lymphatics, which drain into the spinal accessory nodes in the posterior triangle.

Thyroid gland

Lymphatic vessels communicate within the thyroid gland and the tracheal plexus, passing onwards to prelaryngeal nodes just above the thyroid isthmus and then to pretracheal and paratracheal nodes (level VI). Some may also drain into the brachiocephalic nodes related to the thymus in the superior mediastinum (level VII). Laterally, the gland is drained to the deep cervical nodes (level IV) by vessels lying along the superior thyroid veins. Thyroid lymphatics may drain directly, with no intervening node, to the thoracic duct. In summary, the major lymphatic drainage of the thyroid is to the middle and lower jugular lymph nodes in levels III and IV and to the posterior triangle nodes in level VB, supplemented by minor drainage to the pretracheal and paratracheal nodes in level VI and to the superior mediastinal nodes in level VII.

Larynx

The vocal folds, with their paucity of lymphatics at their edges, provide a clear demarcation between the upper and lower areas of the larynx. Above the vocal folds, the rich network of lymph vessels draining the supraglottic part of the larynx accompany the superior laryngeal artery, pierce the thyrohyoid membrane, and end in the upper deep cervical lymph nodes, often bilaterally. The supraglottic lymphatics also communicate with those at the base of the tongue. Below the vocal folds, some of the lymph vessels of the infraglottic cavity pass through the conus elasticus to reach the prelaryngeal (Delphian) and/or pretracheal and paratracheal lymph nodes, while others accompany the inferior laryngeal artery and join the lower deep cervical nodes (Welsh et al 1983, Werner et al 2003).

Nodal spread of laryngeal tumours

The upper deep cervical lymph nodes act as pathways for the spread of malignant tumours of the supraglottic larynx. Up to 40% of these tumours will have undergone such spread at the time of clinical presentation. The glottis is very poorly endowed with lymphatic vessels; some 95% of malignant tumours confined to the glottis will present only with a change in voice or airway obstruction, but will not show signs of spread to adjacent lymph nodes at presentation. Tumours of the subglottic larynx will often spread to the paratracheal lymph node chain prior to clinical presentation. The presenting symptoms are usually voice change and airway obstruction rather than a mass in the neck. The paratracheal lymph nodes occupy a deep-seated position in the root of the neck and so their enlargement may remain occult. They must be looked for carefully at surgery and included in any radiation field.

LYMPHATIC DRAINAGE OF THE THORAX

Thoracic wall

Superficial lymphatic vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes (see Figs 46.5, 53.22). Lymphatic vessels from breast tissue drain mainly to axillary nodes, with some passing initially to parasternal, interpectoral and supraclavicular nodes (see Fig. 53.24). Those superficial to trapezius and latissimus dorsi unite to form up to 12 trunks that end in the subscapular (posterior axillary) nodes. Those in the pectoral region, including vessels from the skin covering the periphery of the breast and its subareolar plexus, run back, collecting those superficial to serratus anterior, to reach the pectoral (anterior axillary) nodes. Vessels near the lateral sternal margin pass between the costal cartilages to the parasternal nodes and anastomose across the sternum, providing a route for contralateral nodal spread in medially located breast carcinoma. A few vessels from the upper pectoral region ascend over the clavicle to the inferior deep cervical nodes. Lymph from the deeper tissues of the thoracic walls drains mainly to the parasternal, intercostal or diaphragmatic (phrenic) nodes.

Parasternal nodes

There are four or five parasternal nodes along each internal thoracic artery at the anterior ends of the intercostal spaces. They drain afferents from the breast, deeper structures of the supra-umbilical anterior abdominal wall, the superior hepatic surface (through a small anterior group of nodes posterior to the xiphoid process) and deeper parts of the anterior thoracic wall. Their efferents usually unite with those from the paratracheal (tracheobronchial) and brachiocephalic (prevascular) nodes to form the bronchomediastinal trunk (see Fig. 56.5). On either side, the bronchomediastinal trunk may either open directly into the

jugulosubclavian junction; into either the internal jugular or subclavian vein near their junction; into the subclavian trunk; or into the lymphatic duct on the right or the thoracic duct on the left.

Intercostal nodes

Intercostal nodes occupy the intercostal spaces near the heads and necks of the ribs. They receive deep lymph vessels from the posterolateral aspects of the chest wall and breast, some of which are interrupted by small more laterally placed intercostal nodes. Efferent vessels from nodes in the lower intercostal spaces unite into a trunk that descends to the abdominal confluence of lymph trunks or to the start of the thoracic duct. Efferent vessels from nodes in the left upper intercostal spaces end in the thoracic duct; those of the right upper intercostal spaces end in one of the right lymphatic trunks.

Breast

The lymphatic drainage of the breast is of great clinical significance because metastatic dissemination occurs principally by the lymphatic routes (the breasts are the site of malignant change in as many as 1 in 8 women; see Commentary 7.1). The dominant lymphatic drainage of the breast is derived from the dermal network (see Fig. 53.24). Breast lymphatics branch extensively; the smallest valveless superficial lymph capillaries (20–70 μm diameter) drain into larger lymph pre-collecting vessels (~300 μm diameter) that contain valves and smooth muscle. These pre-collectors unite to form a subcutaneous network between skin and breast tissue and drain almost always to at least one sentinel node, usually near the lateral border of pectoralis minor (Suami et al 2008). Lymphatic blockage through tumour occlusion may therefore result in reverse flow through the lymphatic channels, resulting in oedema. The direction of lymphatic flow within the breast parallels the major venous tributaries and enters the regional lymph nodes via an extensive periductal and perilobular network of lymphatic channels. Most of these lymphatics drain into the axillary group of regional lymph nodes either directly or through the retro-areolar lymphatic plexus (see Fig. 49.48). Dermal lymphatics also penetrate pectoralis major to join channels that drain the deeper parenchymal tissues, and then follow the vascular channels to terminate in the regional lymph nodes below the level of the clavicle.

Lymphatics from the left breast ultimately terminate in the thoracic duct and, subsequently, the left subclavian vein. On the right, the lymphatics ultimately drain into the right subclavian vein near its junction with the internal jugular vein. Part of the medial sides of the breasts drain to the parasternal nodes, lying along the internal thoracic vessels. These may anastomose across the sternum, providing a route for contralateral nodal spread in medially located breast carcinoma. Parasternal nodes and vessels may drain inferiorly via the superior and inferior epigastric lymphatic routes to the superficial and deep inguinal nodes in the femoral triangle.

Axillary nodes receive more than 75% of the lymph from the breast. There are 20–40 axillary nodes, grouped somewhat artificially as pectoral (anterior), subscapular (posterior), central and apical. Surgically, the nodes are described in relation to pectoralis minor; those lying lateral or inferior to pectoralis minor are the low nodes (level 1), those lying posterior to pectoralis minor are the middle group (level 2), and those lying between the upper border of pectoralis minor and the lower border of the clavicle are the upper or apical axillary nodes (level 3) (see Fig. 53.24). There may be one or two interpectoral (Rotter's) nodes lying between pectoralis minor and major. Efferent vessels may pass directly from the breast around the anterior axillary border and through the axillary fascia to the pectoral (anterior axillary) lymph nodes; some may pass directly to the subscapular (posterior axillary) nodes. A few vessels pass from the superior part of the breast to the apical axillary nodes, sometimes interrupted by the infraclavicular nodes or by small, inconstant, interpectoral nodes. Most of the remainder drain to parasternal nodes from the medial and lateral parts of the breast and accompany perforating branches of the internal thoracic artery. Lymphatic vessels occasionally follow lateral cutaneous branches of the posterior intercostal arteries to the intercostal nodes (see Fig. 56.4A).

Axillary surgery in breast cancer

Axillary lymph node dissection may be performed for diagnostic and therapeutic reasons. The presence of metastases within axillary lymph nodes has strong prognostic significance and may influence decisions on adjuvant therapy. Axillary lymph node dissection can lead to chronic postoperative problems such as pain, seroma formation, reduced mobility of the arm, impaired sensation and lymphoedema.

Nerves and lymph vessels in the axillary region must be considered as anatomical landmarks at surgery and carefully identified and preserved. Chronic neuropathic pain is a common consequence of surgery, with a prevalence of 25–60% (Jung et al 2003). Chronic pain exacerbates the stress associated with the already burdensome management of breast cancer and in many patients adversely impacts their daily life. Complete resection, stretch or compression of the lateral cutaneous branch of the second thoracic ventral ramus (intercostobrachial nerve) may result in numbness or pain in the ipsilateral axilla, medial arm and upper anterior chest. Symptoms are more common and longer lasting when the origin of the nerve is injured as opposed to its peripheral branches (Jung et al 2003). Resection or compression of the long thoracic nerve, which passes below the clavicle through the axillary sheath and then down the chest wall to innervate serratus anterior, can result in palsy (with scapular winging): shoulder pain may be exacerbated by shoulder instability and reduced abduction.

Lymphatic drainage in breast cancer and role of sentinel lymph node biopsy

Lymphatic mapping with sentinel lymph node biopsy has become an important technique in the staging of patients with early breast cancer. Based upon the assumption that the majority of the lymphatic drainage of the breast occurs through the subareolar plexus (Suami et al 2009), a radiolabelled colloid is injected into either the subareolar tissue of the index quadrant of the breast or into the peritumoural and intradermal tissue overlying the primary breast cancer. At the time of surgery, a vital blue dye is injected after general anaesthesia is established. The combination of radioisotope and dye provides the most accurate means of localizing the sentinel node (Tanis et al 2001). The latter represents the first draining node within the axilla and is surgically removed for careful histopathological analysis to detect the presence of metastases. There is a 5–10% false-negative rate for this procedure that can be partly attributed to anatomical differences in lymphatic drainage (Tanis et al 2005, Suami et al 2008).

If the histopathological results prove negative, the morbidity associated with axillary dissection can be avoided. Where metastases to the axillary nodal group are found, axillary completion dissection or radiotherapy is offered. The majority of sentinel nodes are found in the low axilla (level 1) (see Fig. 53.24). Higher-level 'skip' nodes are involved in 5–10% of cases. Occasionally the sentinel node is identified in an extra-axillary position, either within the breast parenchyma as an intramammary lymph node, or as a parasternal (internal thoracic) lymph node or in the supraclavicular fossa.

Deeper thoracic tissues

Collecting vessels of the deeper thoracic tissues include lymphatics that drain the muscles attached to the ribs. Most end in axillary nodes but some from pectoralis major also drain to the parasternal nodes. Intercostal vessels drain the intercostal muscles, tissues of the extrapleural space (e.g. endothoracic fascia) and the costal parietal pleura; those from the anterior thoracic wall end in the parasternal nodes and their posterior counterparts drain to intercostal nodes.

Vessels from the respiratory diaphragm form a thoracic and an abdominal plexus, which anastomose freely, especially in areas covered by diaphragmatic parietal pleura and peritoneum, respectively. The thoracic plexus unites with lymph vessels draining the costal and mediastinal parts of the parietal pleura. Its efferents are anterior, draining to the anterior diaphragmatic nodes near the junctions of the seventh rib and costal cartilage; middle, draining to nodes on the oesophagus (paraoesophageal) and around the intrathoracic part of the inferior vena cava; and posterior, draining to nodes around the aorta at the point where it leaves the thorax. The abdominal plexus anastomoses with the hepatic lymphatics and peripherally with those of the subperitoneal tissue. Efferents from its right half pass to a group of nodes close to the inferior phrenic artery, or in the right lateral aortic nodes. Those from the left half of the abdominal diaphragmatic plexus pass to the pre-aortic, lateral aortic and paraoesophageal nodes.

Heart

Cardiac lymphatic vessels form subendocardial, myocardial and subepicardial plexuses. Efferent vessels from the subepicardial plexuses form the left and right cardiac collecting trunks; two or three left-sided trunks ascend the anterior interventricular sulcus, receiving vessels from both ventricles. On reaching the atrioventricular sulcus, they are joined by a large vessel from the inferior surface of the left ventricle that first ascends in the inferior interventricular sulcus and then turns left along the atrioventricular sulcus. The vessel formed by this union ascends between the pulmonary trunk and the left atrium and usually ends in a subcarinal (inferior tracheobronchial) node. The right cardiac collecting trunk receives efferents from the right atrium and the right border and inferior surface of the right ventricle. It ascends in the atrioventricular sulcus, near the right coronary artery, and then anterior to the

ascending aorta, and ends in a brachiocephalic or prevascular node, usually on the left (see Fig. 57.60) (Loukas et al 2011).

Cardiac lymphatics play a crucial role in cardiac function, such as maintaining fluid balance, removal of extravasated proteins and transport of immune cells (Vuorio et al 2016). The developed lymphatic network of the heart traverses all its layers, including those of the atria and ventricles and extends to the mitral valve. Most lymph drainage of the pericardium is to the thoracic and the right lymphatic ducts; upper mediastinal (e.g. para-aortic, subaortic, retrotracheal, prevascular) and parasternal internal thoracic lymph nodal groups also receive efferents (see Fig. 54.12B). There are two layers of pericardial lymphatic vessels, contacting and surrounding the parietal pericardium and also within the fat and loose areolar tissue. The anterior (sternocostal) part of the pericardium either drains laterally towards the phrenic nerves as they enter the respiratory diaphragm (superior phrenic nodes), or travels along the ventral border of the pericardium to enter the prepericardial lymph nodes located at the pericardio-diaphragmatic junction. Drainage from the lateral pericardium is more variable. Inferiorly, it drains towards the phrenic nerves and the pericardiacophrenic vessels as they reach the respiratory diaphragm, and includes the lateral pericardial nodes; superiorly, it drains into the tracheobronchial (subcarinal) and paratracheal lymph nodes. The posterior pericardium, including the posterior aspect of the associated dome of the respiratory diaphragm and extending as far as the pulmonary veins, drains superiorly to the superior and inferior tracheobronchial (upper and lower paratracheal, and subcarinal) lymph nodes. The portion of the pericardium that adheres to the diaphragm drains via short channels to the lymph nodes at the right border of the inferior vena caval opening in the central diaphragmatic tendon.

Lymphangiogenesis, the formation of new lymphatics, is beneficial in delaying atherosclerotic plaque formation in coronary arteries. In patients with myocardial infarction, lymphangiogenesis is therapeutic during the healing process, reflecting their ability to reduce fluid retention and aid the clearance of inflammatory cells within the cardiac tissues.

Pleura and lungs

Lymph from the costal part of the parietal pleura drains into the parasternal nodes anteriorly and intercostal chains posteriorly, while that from the diaphragmatic pleura drains into the mediastinal, parasternal, para-aortic (phrenic) and coeliac nodes (see Figs 56.4–56.5). The lymphatic drainage of the visceral pleura is initially via the subpleural lymphatic plexus. Lymph can pass via segmental or intersegmental lymphatic pathways, and sometimes peribronchial lymphatic pathways; the exact pattern of drainage varies depending on lobe, segment, side and individual (Fourdrain et al 2018).

The pulmonary lymphatics originate in superficial and deep plexuses. The walls of the alveoli and the alveolar ducts have no lymph vessels, these only start at the bronchioles. The superficial plexus lies deep to the visceral pleura; its efferents pass around the margins of the lung and its fissures, eventually reaching the bronchopulmonary (hilar) nodes (see Fig. 54.12). The deep lymphatics originate at bronchiolar level and follow the bronchial tree divisions and pulmonary vessels to the hilum, ending in the same nodes as the superficial plexus. In larger bronchi, the deep plexus has submucosal and peribronchial parts, but in smaller bronchi there is only a single plexus that extends to the bronchioles. Lymph node groups (stations) sit alongside the bronchi and are classified according to their location, specifically; subsegmental, segmental, lobar and hilar (Rusch et al 2009). Lymph from the hilar nodes drains into subcarinal (inferior tracheobronchial) and lower paratracheal (superior tracheobronchial) node groups (stations).

No free anastomoses exist between the two superficial and deep plexuses, except at the hilum and peripherally, where small but dilatable channels connect superficial and deep lymphatic vessels; these connections direct lymph from the deep to the superficial channels when outflow from deep vessels is obstructed by pulmonary disease. There is a tendency for vessels from the superior lobes to pass to the superior tracheobronchial (lower paratracheal) nodes, and those from the inferior lobes to pass to the inferior tracheobronchial (subcarinal) group. However, lymphatic vessels of adjoining lobes connect deep in the fissures and so these connections are not exclusive. At the level of pulmonary lobation, the arrangement of lymphatic vessels follows the central artery of a lobule and its peripheral veins. Lymphoid aggregations, non-follicular in appearance, occur in peribronchial sites and in 'placoid' formations deep to the visceral pleura.

Pulmonary nodes within the lung parenchyma are continuous with the bronchopulmonary node groups (in order, these include subsegmental, segmental, lobar, interlobar and hilar nodes) (see Figs 54.12, 56.4B). Bronchopulmonary node groups are continuous with inferior tracheobronchial (subcarinal) nodes located inferior to the tracheal bifurcation and the superior tracheobronchial (lower paratracheal) nodes. In turn, these groups are continuous with the upper paratracheal groups of nodes that drain the lungs, bronchi, the thoracic part of the trachea, heart, pericardium and also receive efferent vessels from prevertebral nodes that receive lymph from the posterior respiratory diaphragm, thoracic oesophagus, and intercostal lymph nodes. Efferent vessels ascend on the trachea to unite with efferents from the parasternal and brachiocephalic nodes to become the right and left bronchomediastinal trunks. The right trunk may occasionally join a right lymphatic duct or another right-sided lymph trunk, and the left trunk may join the thoracic duct, but usually they open independently in or near the ipsilateral junction of the internal jugular and subclavian vein (see Fig. 35.16).

Oesophagus

The oesophagus has an extensive, longitudinally continuous submucosal lymphatic system within which flow may be bidirectional: this is pertinent to lymphatic spread in oesophageal carcinoma. Efferent vessels from the cervical oesophagus drain to the deep cervical nodes either directly or through the paratracheal nodes. Vessels from the cervical oesophagus drain to paraoesophageal, deep cervical and supraclavicular nodes; those from the thoracic oesophagus drain directly to the thoracic duct or to paratracheal, retrotracheal, subcarinal and right recurrent laryngeal nodes; and those from the abdominal oesophagus drain to the nodes associated with the left gastric artery or other arteries originating from the coeliac trunk, including those associated with the lesser curvature of the stomach (Wang et al 2018).

The lymphatics of the oesophagus are concentrated into submucosal and intermuscular plexuses. Both of these plexuses receive lymph from all layers of the oesophageal wall (Kuge et al 2003, Rice et al 2016). Terminology is not straightforward. In general, lymphatic drainage from the oesophagus communicates with nodes in the adventitia, paraoesophageal nodes or the thoracic duct directly (Wang et al 2018). However, the lymphatics of the distal third of the oesophagus do not drain to para-oesophageal nodes of the same level but distally to the left gastric nodes and nodes around the cardia, and then to coeliac nodes (Tachimori 2017). Therefore, cancer of the lower thoracic oesophagus tends to metastasize to nodes of the upper abdominal area (Tamaki et al 2012).

Mediastinum

There are multiple groups of lymph nodes throughout the mediastinum. Conventionally they have been named according to their position relative to the nearest mediastinal structure (which they often drain): parietal node groups drain the thoracic wall and visceral groups drain the thoracic viscera (see Figs 54.12, 56.4A). However, this naming system implies that the mediastinal node groups are separate and distinct, whereas in reality they are part of a continuum. To better reflect their regional disposition, and for the purposes of cancer staging and management, mediastinal lymph node groups are categorized into regional lymph node stations and zones (Rusch et al 2009) (see Fig. 56.4B, Table 56.1).

Metastatic involvement of mediastinal lymph nodes has important prognostic implications and influences the choice of treatment (Mountain and Dresler 1997, Rusch et al 2009). The staging system for lung cancer classifies node involvement using a nodal descriptor (N-'Stage'), where N0 indicates no regional lymph node metastases; N1 indicates involvement of ipsilateral peribronchial or hilar lymph nodes and intrapulmonary nodes; N2 indicates involvement of ipsilateral mediastinal and/or subcarinal nodes; and N3 indicates involvement of contralateral mediastinal or hilar nodes, and ipsilateral or contralateral scalene or supraclavicular nodes/scalene nodes (Goldstraw et al 2016, Chansky et al 2017, Lim et al 2018).

Mediastinoscopy

The decision to proceed with mediastinoscopic biopsy depends on whether suitable nodal stations (zones) seem involved on CT scanning and whether there is a history of prior neck and mediastinal surgical procedures. Complications of mediastinoscopy include haemorrhage, iatrogenic injury to the trachea or left recurrent laryngeal nerve, and pneumothorax. Mediastinoscopy can be performed with video-assisted or direct optic visualization. A transverse incision is made at the level of the suprasternal notch; sternohyoid and sternothyroid within the superficial lamina of deep cervical fascia are retracted; the deep lamina of the deep cervical fascia is incised. The pretracheal plane is dissected and a space is created between the anterior aspect of the trachea and the brachiocephalic trunk inferior to the carina and along both sides of the trachea and main bronchi. This space facilitates biopsy of the upper

paratracheal 2R and 2L stations, the right lower paratracheal 4R station and higher nodes from the left lower paratracheal 4L station superior to the aortic arch (see Table 56.1). The anterior part of subcarinal station 7 and bilateral hilar stations 10R and 10L may be accessible but are technically challenging. Lymph nodes can be sampled or removed entirely for histological evaluation.

The anterior part of the superior mediastinum is more difficult to assess by mediastinoscopy and usually requires an anterior mediastinotomy (Chamberlain procedure). This is performed to biopsy nodes from the more inferior aspect of the left lower paratracheal 4L station, subaortic station 5, para-aortic station 6 and subcarinal station 7, and also facilitates anterior mediastinal mass biopsy. Endobronchial ultrasound can be performed to biopsy lymph nodes in stations 1–4, 7 and 10–12, using fine needle aspiration through the tracheal or bronchial walls. In a similar way, transoesophageal ultrasound may help during biopsy of subcarinal station 7, para-oesophageal station 8 and pulmonary ligament station 9.

Respiratory diaphragm

The respiratory diaphragm is drained by anterior, middle and posterior groups of lymph nodes that lie on its thoracic (superior) surface (see Fig. 56.4). These nodes also drain the superior portion of the liver, the gastro-oesophageal junction and the abdominal surface of the respiratory diaphragm. Lymph drains anterosuperiorly to the parasternal and anterior mediastinal nodes, and posterosuperiorly to the posterior mediastinal and brachiocephalic nodes.

Anterior group

The anterior group consists of two or three small nodes posterior to the base of the xiphoid process, draining the convex diaphragmatic surface of the liver, and one or two nodes on each side near the junction of the seventh rib and costal cartilage that receive anterior lymph vessels from the respiratory diaphragm. The anterior group drains to the parasternal nodes.

Lateral groups

The lateral groups each contain two or three nodes and lie close to the point where the phrenic nerves enter the respiratory diaphragm. On the right, some nodes lie within the fibrous pericardium anterior to the intrathoracic part of the inferior vena cava. Their afferents drain the central part of the respiratory diaphragm; those on the right also drain the convex (diaphragmatic) surface of the liver, and their efferents pass to the paraoesophageal (posterior mediastinal), parasternal and brachiocephalic nodes.

Posterior group

The posterior group consists of a few nodes that lie on the posterior aspect of the crura of the respiratory diaphragm and connect with the lateral and posterior aortic (prevertebral) and para-oesophageal (posterior mediastinal) nodes.

LYMPHATIC DRAINAGE OF THE ABDOMEN AND PELVIS

Lymph from the skin and subcutaneous tissues of the abdominal wall drains via small calibre superficial lymphatics to axillary and inguinal nodes (Tourani et al 2013). The midline and the level of the umbilicus form inconstant and variable watershed boundaries for these drainage territories. Lymphatics from the deeper layers of the body wall and the abdominal and pelvic viscera drain almost exclusively to the cisterna chyli and thoracic duct. The former drains via ipsilateral nodes in the retroperitoneum concentrated around the external iliac and common iliac vessels and along the lateral aspects of the aorta and inferior vena cava. There is considerable overlap between the lymphatic drainage of individual viscera. At certain sites there is a cranio-caudal sequence of lymph nodes, e.g. lateral aortic nodes; and parasternal and inferior epigastric nodes. Some lymphatic drainage from the bare area of the liver occurs directly across the respiratory diaphragm to the thoracic cavity. The highest concentration of lymphatic vessels in the anterior abdominal wall is found in the dermis (Friedman et al 2015). Lymphatic vessels from the lumbar and gluteal regions run with the superficial circumflex iliac vessels, and those from the abdominal skin distal to the umbilicus run with the superficial epigastric vessels. Both drain into superficial inguinal nodes. Lymphatic vessels from the proximal umbilical region drain to axillary and parasternal nodes. Enlargement of a lymph node in the umbilical region is rare but can herald an abdominal or pelvic malignancy.

The deep lymphatic vessels accompany the deeper arteries. Laterally, they run either with the lumbar arteries to drain into the lateral aortic nodes, or with the posterior intercostal and subcostal arteries to nodes in the posterior mediastinum. Lymphatics in the proximal anterior abdominal wall run with the superior epigastric vessels to parasternal nodes while those in the distal abdominal wall run with the deep circumflex iliac and inferior epigastric arteries to external iliac nodes.

The paired viscera of the retroperitoneum drain to lateral aortic nodes around the origin of their arterial supply. Thus, the kidneys and suprarenal glands drain to nodes around the hilum of the kidney and to lateral aortic nodes around the origin of the renal arteries (first and second lumbar vertebral levels). The testes drain to lateral aortic and lateral, precaval and retrocaval nodes (approximately second lumbar vertebral level); the pattern of lymphatic spread from a testicular malignancy suggests that lymph from the left testis drains to left lateral aortic nodes en route to the cisterna chyli, whereas lymph from the right testis drains to right and then left lateral aortic nodes before reaching the cisterna chyli. Lymph from the ovary may drain via lymphatics in the broad ligament of the uterus and round ligament of the uterus to internal iliac and inguinal nodes, respectively. Lymphatic drainage of the ureters is less well defined but follows a regional pattern to nearby nodes.

The pancreas drains to numerous pancreatic nodes (Ch. 68) and to nodes between the hepatic portal vein and inferior vena cava (clinically referred to as portacaval nodes), splenic, superior mesenteric and coeliac nodes. The lymphatic drainage of the duodenum is not well described but the lymphatics generally drain to nodes related to local arteries (Ch. 64). Whilst the clinical pattern of nodal metastases usually reflects normal lymphatic drainage pathways, lymphatic obstruction may lead to metastases at unusual nodal sites.

Cisterna chyli and abdominal lymph trunks

The abdominal origin of the thoracic duct usually lies to the right of the midline at the level of the body of the twelfth thoracic vertebra or the intervertebral disc between the twelfth thoracic and first lumbar vertebrae. It receives almost all the lymph from below the respiratory diaphragm via the cisterna chyli, a localized saccular or fusiform lymphatic dilation formed most commonly by the union of the intestinal trunk and the left lumbar trunk (Phang et al 2014). The cisterna chyli is approximately 1 cm wide and 2 cm long in the cadaver (Loukas et al 2007b): studies using magnetic resonance imaging (MRI) *in vivo* have shown that it expands considerably during movement from supine to sitting and again from sitting to standing (Niggemann et al 2010).

The formation of the cisterna chyli is variable and it may be absent. When present, it usually lies anterior to the first and second lumbar vertebrae, posterior to the right crus of the respiratory diaphragm and to the right of the abdominal aorta, but it may be located at a more proximal vertebral level (see Fig. 61.14). The most common configuration, found in approximately two-thirds of individuals, is a single structure formed from the union of the intestinal trunk and the left (or, less commonly, the right) lumbar trunk (Loukas et al 2007b). In most other individuals it is formed by the confluence of the intestinal and both lumbar trunks, with additional small branches from intercostal lymphatics (intercostal trunks) and retro-aortic nodes (Skandalakis et al 2004). The proximal two right lumbar arteries and the right lumbar azygos vein lie between the cisterna chyli and the vertebral column.

The paired lumbar trunks are formed by lymphatic vessels draining lateral aortic nodes. The intestinal trunk (which may be double) receives vessels draining from coeliac, superior and inferior mesenteric nodes that collectively drain the entire abdominal gastrointestinal tract down to the anal canal. The thoracic duct leaves the superior end of the cisterna chyli and passes through the aortic hiatus of the respiratory diaphragm posterolateral to the right side of the aorta. Its thoracic continuation is described on page 1464.e115.

The major lymphatic vessels adjacent to the abdominal aorta are at risk of injury during surgical procedures that involve peri-aortic dissection and/or lymphadenectomy. Injury to these lymphatic vessels or their obstruction by malignant disease can cause leakage of lymph manifesting as chylous ascites or chylothorax.

Retroperitoneal lymph node groups

The lymphatic drainage of the rectum, colon, stomach, pancreas, oesophagus and other organs is often described in terms of lymph node stations and levels of dissection that relate to the management of malignant disease. The terminology and classification of retroperitoneal lymph nodes are based on their location. In classic anatomical descriptions, the lymph nodes of the retroperitoneum around the abdominal

aorta are grouped into pre-aortic, lateral and retro-aortic nodes, but adjacent nodal groups merge into one another with no clear demarcating boundaries. Normal lymph node dimensions are very variable. Cross-sectional imaging frequently uses 10 mm as an approximate measurement for the upper limit of normal lymph node dimensions in the adult (Moeller and Reif 2000): some normal retroperitoneal nodes such as the portacaval nodes are typically larger.

Pre-aortic nodes

Pre-aortic nodes drain the gastrointestinal viscera including the pancreas, liver and spleen. They lie anterior to the aorta clustered around its anterior unpaired visceral branches and can be subdivided into coeliac, superior mesenteric and inferior mesenteric nodes. Their efferent lymphatics contribute to the formation of the intestinal lymph trunk.

Coeliac nodes

Coeliac nodes drain lymph from nodes around the stomach, splenic hilum, porta hepatis, cystic duct, lesser omentum, portacaval nodes, pancreatic nodes and pancreaticoduodenal nodes. They also receive lymph from superior and inferior mesenteric nodes and their efferent lymphatics drain to the intestinal trunks.

Superior mesenteric nodes

Superior mesenteric nodes share an extensive overlap with the drainage territory of coeliac nodes, with subsidiary nodal groups that include pancreatic, pancreaticoduodenal, portacaval, ileocolic, mesenteric and inferior mesenteric nodes. Efferent lymphatics drain to the intestinal trunks either directly or via coeliac nodes.

Inferior mesenteric nodes

Inferior mesenteric nodes such as the superior rectal nodes drain lymph from derivatives of the hindgut, including the distal transverse, descending and sigmoid colon, and the rectum.

Lateral aortic groups

Lateral aortic (para-aortic) nodes lie on either side of the abdominal aorta and inferior vena cava anterior to the medial margins of psoas major, the crura of the respiratory diaphragm and the sympathetic trunks. Constituent nodal groups that are recognized clinically include the retrocrural (posterior to the diaphragmatic crura at the aortic hiatus); left and right hilar (of the kidney); aortocaval, lateral caval, retrocaval and precaval groups. Retro-aortic nodes are sometimes included within the lateral aortic group. The latter drain into the paired intestinal trunks that terminate directly or indirectly in the cisterna chyli and thoracic duct. There are lymphatic connections between lateral aortic, pre-aortic, retro-aortic and contralateral lateral aortic nodes. The lateral aortic nodes drain the deep layers of the body wall, the retroperitoneal paired viscera (including the gonads) and tributaries from the iliac nodes. Lymph from the right ovary or testis drains via lymphatics travelling with the gonadal vessels to the right lateral aortic and pre-aortic nodes at the level of the second lumbar vertebra, whereas lymph from the left ovary or testis drains to the left lateral aortic nodes just inferior to the left renal vein (Morton and Thomas 2008, Paño et al 2011).

Iliac nodes

Paired iliac nodes are distributed around the common, external and internal iliac arteries and veins. Constituent groups include the common iliac, external iliac, internal iliac and obturator nodes. The latter are located near the obturator foramen and, together with the iliac nodes, are a common site of lymph node metastasis in prostate cancer. 'Pelvic side-wall' nodes, lying adjacent to the ilium but not associated with a large artery or vein, are also described in the clinical literature. The iliac nodes drain the pelvic viscera and walls, except for the ovaries and those parts of the rectum drained by superior rectal nodes. They also drain lymph from the inguinal nodes and lower limbs.

Lymphatic drainage of viscera

Duodenum

Duodenal lymphatics run to nodes associated with the superior and inferior pancreaticoduodenal arteries, and from there to nodes related to the common hepatic and superior mesenteric arteries and coeliac trunk and to nodes in supra- and infra-pyloric positions and within the hepatoduodenal ligament. Lymphatic drainage to lateral aortic nodes has also been described (Hirai et al 2001).

Stomach

The stomach has a rich network of lymphatics that connect with lymphatics draining other viscera within the proximal abdomen. At the gastro-oesophageal junction the lymphatics are continuous with those draining the distal oesophagus; in the region of the pylorus they are continuous with those draining the duodenum and pancreas. In general, lymphatics follow the course of the arteries supplying the stomach. However, many separate groups of nodes are now recognized (see Fig. 63.14A) and their relationship to the specific regions and vascular territories of the stomach is of great importance during resection of the stomach, particularly for malignancy. Pancreatic and hepatic lymphatics are significant in draining the stomach during disease.

Gastrectomy and gastric lymphadenectomy

Surgery for gastro-oesophageal malignancy involves various degrees of radical resection of lymph nodes that drain the tumour. Locoregional lymphatic spread can occur in the absence of haematogenous spread and gastric cancer can therefore remain a localized disease, even when lymph nodes are involved (Brierley et al 2017). Hence, gastrectomy with meticulous lymphadenectomy can be curative in a proportion of patients with gastric cancer and lymph node involvement.

The extent of potential/actual lymph node involvement by the tumour is classified as N1 (locoregional nodes specific to the tumour site); N2 (regional and major named vessel nodes draining the tumour); and N3 (wider-draining nodes, including lateral aortic nodes). Gastrectomies can be classified according to the node groups excised with the tumour: D1 (removal of the affected portion of the stomach and *en bloc* resection of N1 nodes); D2 (total gastrectomy, including all N1 and N2 nodes); and D3 (total gastrectomy plus extensive lymphadenectomy that includes the associated proximal abdominal lymph nodes, namely: pancreatic, superior mesenteric, coeliac, hepatic and middle colic) (Japanese Gastric Cancer Association 2011).

Pancreas

The lymphatic drainage of the pancreas is extensive (see Fig. 63.14B), which partly explains the poor prognosis of individuals with pancreatic cancer. Lymphatic vessels start within the connective tissue septa within the gland and join to form larger lymphatics that follow the paths of local arteries (Deki and Sato 1988, O'Morchoe 1997). Lymphatics from the tail and body of the pancreas drain mostly into nodes along the splenic artery and inferior border of the gland, and from there to pre-aortic nodes between the coeliac trunk and superior mesenteric artery. Lymphatics from the neck and head drain more widely into nodes along the pancreaticoduodenal, superior mesenteric and hepatic arteries, and ultimately into pre-aortic nodes (Donatini and Hidden 1992, Cesmebasi et al 2015). There is no evidence of lymphatic channels within the pancreatic islets.

Hepatobiliary system

Lymph from the gallbladder and cystic duct drains via several pathways: to the cystic node, which usually lies above the cystic duct in the cystohepatic triangle, and from there via nodes in the hepatoduodenal ligament and along the common hepatic artery to coeliac nodes; via lymphatics that descend along the bile duct to the superior retropancreaticoduodenal node (which communicates with lateral aortic nodes); and directly to superior mesenteric nodes (Sato et al 2013). Lymphatics on the deep aspect of the gallbladder connect directly with intrahepatic lymph vessels.

Lymphatic vessels accompanying the hepatic ducts and proximal bile duct drain to hepatic nodes at the porta hepatis and then via lymph nodes in the hepatoduodenal ligament to coeliac nodes. Lymphatics from the distal bile duct also drain to the latter but some pass directly to pancreatic and superior mesenteric nodes. Lymph from the liver is rich in protein and is mostly a product of the hepatic sinusoids (Ohtani and Ohtani 2008). It passes via deep and superficial pathways to nodes superior and inferior to the respiratory diaphragm (Trutmann and Sasse 1994). Obstruction of hepatic venous drainage increases the flow of lymph in the thoracic duct.

Superficial hepatic lymphatics

Superficial lymphatics run in subserosal areolar tissue over the surface of the liver and drain in four directions. Lymphatics from most of the posterior surface, including the caudate lobe, drain into nodes alongside the inferior vena cava; a few lymphatics from the posterior surface of the left lobe pass towards the oesophageal hiatus and nodes around the cardia of the stomach. Lymphatics in the coronary and right triangular ligaments can pass directly to the thoracic duct. Lymphatics from most of the inferior, anterior and superior surfaces drain into hepatic nodes at the porta hepatis. A few lymphatics from the right superior

surface accompany the inferior phrenic artery across the right diaphragmatic crus to drain into coeliac nodes.

Deep hepatic lymphatics

Fine lymphatics within the portal triads and around interlobular veins merge to form larger vessels. Some ascend through the parenchyma to pass through the caval foramen in the respiratory diaphragm and drain into inferior mediastinal nodes, but most drain to lymph nodes at the porta hepatis.

Small intestine

The lymphatic system of the small intestine regulates tissue fluid homeostasis, participates in immune surveillance and transports dietary fat and fat-soluble vitamins from the gut lumen. It is organized into two networks. First, lacteals from the villi drain into a plexus of lymphatics in the submucosa and are joined by vessels from lymph spaces at the bases of solitary lymphoid follicles; these lymphatic vessels have few if any valves. Second, a coarse plexus of lymphatics also runs in the muscularis externa between the two muscle layers. The submucosal and muscular networks share few connections but both communicate freely with larger valved collecting lymphatics at the mesenteric border of the small intestine (Miller et al 2010). Mesenteric lymphatics pass between the layers of the mesentery and drain via a series of mesenteric nodes concentrated around the regional mesenteric vessels. Individual segments of small intestine have a relatively wide field of lymphatic drainage, which makes radical surgical resection of draining lymph nodes difficult if the blood supply to the remaining unaffected small intestine is to be preserved. Mesenteric nodes drain into superior mesenteric nodes around the proximal part of the superior mesenteric artery.

Large intestine

Lymph drainage from the large intestine follows the course of the arteries. Thus, lymphatic vessels of the caecum and the ascending and proximal transverse colon drain ultimately into lymph nodes related to the superior mesenteric artery, while those of the distal transverse colon, descending colon, sigmoid colon and rectum drain into nodes following the course of the inferior mesenteric artery (see Fig. 65.16). In cases where the distal transverse colon or left colic flexure is predominantly supplied by vessels from the middle colic artery, most of the lymphatic drainage of this area may be to superior mesenteric nodes.

Lymph nodes related to the colon form four groups: epicolic, paracolic, intermediate colic and preterminal colic. Epicolic nodes are minute whitish nodules on the serosal surface of the colon, sometimes within the omental appendices. Paracolic nodes lie along the medial borders of the ascending and descending colon and along the mesenteric borders of the transverse and sigmoid colon. Intermediate colic nodes lie along the named colic vessels (the ileocolic, right colic, middle colic, left colic, sigmoid and superior anorectal arteries). Preterminal colic nodes lie along the main trunks of the superior and inferior mesenteric arteries and drain into pre-aortic nodes at the origin of these vessels.

Ascending mesocolic nodes are significantly larger than sigmoid mesocolic ones; this is relevant to lymph node retrieval and examination after resection for colonic cancer (Ahmadi et al 2015).

Lymphatic vessels originate from both anterior and posterior aspects of the colon. Lymph drainage from the midgut follows the course of the superior mesenteric artery. Thus, lymph from the caecum and appendix drains to nodes associated with the ileocolic artery, and lymph from the distal ascending colon and right colic flexure drains to nodes along the right colic artery (see Fig. 65.16). When the distal transverse colon and left colic flexure are predominantly supplied by the middle colic artery, lymph drainage of this segment is also largely to superior mesenteric nodes. Lymphatic vessels in the appendix are numerous and combine to form vessels that ascend in the mesoappendix, occasionally interrupted by one or more nodes. They unite to form three or four larger vessels that anastomose with lymphatic vessels draining the ascending colon into ileocolic nodes.

Small lymphoid aggregates measuring no more than a few millimetres are occasionally visible on the surface of the large intestine (epicolic and epirectal nodes). Lymph from the descending colon drains to paracolic nodes in the mesentery adjacent to the colon and from there to intermediate nodes along the left colic artery (Jamieson and Dobson 1909). Lymphatics from the sigmoid colon follow a similar pathway from paracolic to intermediate nodes in the sigmoid mesocolon. Intramural lymph from the rectum and anal canal above the pectinate line drains predominantly to pararectal nodes in the adipose tissue of the mesorectum and then along lymphatics accompanying the superior anorectal artery (see Fig. 65.43). These intermediate nodes then drain to lymph nodes along the inferior mesenteric artery and from there to pre-aortic nodes. Some lymphatics from the distal rectum travel with the middle and inferior anorectal arteries to internal iliac nodes and along the median sacral artery to sacral nodes. The clinical significance of such drainage for the spread of malignancy from the distal rectum is debated (Bell et al 2009).

Radical lymphadenectomy during resection of colorectal cancer requires removal of the highest possible lymph nodes draining the region of colon in which the tumour is located. In cases of cancer of the rectum or sigmoid colon, this usually involves excision of the preterminal colic nodes along the inferior mesenteric artery with ligation of the artery at its root or just below the origin of the left colic artery. At least 12 lymph nodes must be excised in an oncologically resected partial colectomy for cancer.

Kidney, urinary bladder, prostate and urethra

Renal lymphatic vessels begin in three plexuses: around the renal tubules, under the renal capsule and in the perirenal fat (the latter two connect freely). Collecting vessels from the intrarenal plexus form four or five trunks that follow the renal vein to end in the lateral aortic nodes; the subcapsular collecting vessels join them as they leave the hilum of the kidney. The perirenal plexus drains directly into the same nodes.

Lymphatics that drain the bladder begin in mucosal, intermuscular and adventitial plexuses. There are three sets of collecting vessels; most end in the external iliac nodes (see Fig. 75.3B). Vessels from the trigone emerge on the exterior of the bladder to run superolaterally. Vessels from the superior surface of the bladder converge to the posterolateral angle and pass superolaterally to the external iliac nodes (some might drain to the internal or common iliac nodes). Vessels from the inferolateral surface of the bladder ascend to join those from the superior surface or run to the lymph nodes in the obturator fossa. Minute nodules of lymphoid tissue can occur along the lymph vessels of the bladder. In the male, vessels from the posterior urethra pass mainly to the internal iliac nodes; a few end in the external iliac nodes. Vessels from the membranous urethra accompany the internal pudendal artery. Vessels from the anterior urethra accompany those of the glans penis, most ending in the deep inguinal nodes; some can end in superficial inguinal nodes, while others traverse the inguinal canal to end in the external iliac nodes. Lymphatic vessels from the ductus deferens drain into the external iliac nodes, while those from the seminal glands drain to the internal and external iliac nodes. Lymphatic vessels from the prostate end mainly in the internal iliac, sacral and obturator nodes. A vessel from the posterior surface of the prostate accompanies the urinary bladder vessels to the external iliac nodes, and another from the anterior surface of the prostate reaches the internal iliac nodes by joining vessels that drain the membranous urethra. In the female the lymphatics of the distal urethra drain into the internal and external iliac nodes, while those of the proximal urethra drain into the iliac, obturator and sacral nodes.

Uterus, ovaries

There are uterine lymphatics in the superficial (subperitoneal) and deep parts of the uterine wall. Collecting vessels from the body of the uterus and cervix pass laterally in the parametrium to three main groups of lymph nodes, namely the external and internal iliac and the obturator nodes (see Table 75.1). The external and internal iliac nodes surround their corresponding arteries. The obturator nodes lie in the 'obturator fossa' between the external and internal iliac vessels, and the obturator nerve passes through the lower part of this group of lymph nodes. Lymph vessels from the fundus of the uterus and the uterine tubes can accompany the lymph drainage of the ovaries to lateral aortic nodes (see Fig. 75.3B). The region surrounding the isthmus of the uterine tube can drain along the round ligament of the uterus to the superficial inguinal nodes. Lymph drainage from the uterine (Fallopian) tubes is via ovarian vessels to the lateral aortic nodes and uterine vessels to the internal iliac nodes: it is possible for lymph to reach the inguinal nodes via the round ligament of the uterus. The main lymphatic drainage of the ovaries is along vessels that follow the ovarian veins to lateral aortic nodes situated near the origin of the renal arteries. There can also be drainage via pelvic nodes into lower lateral aortic nodes and, less commonly, via the round ligament of the uterus to the inguinal nodes (Kleppe et al 2015).

External genitalia: female

A meshwork of connecting vessels from the skin of the labia, clitoris and perineum join to form three or four collecting trunks that drain to superficial inguinal nodes lying on the cribriform fascia covering the femoral artery and vein; these nodes drain through the cribriform fascia to the deep inguinal nodes lying medial to the femoral vein (Corton 2012). The deep inguinal nodes drain via the femoral canal to the pelvic nodes (see Table 75.1). The last of the deep inguinal nodes lies under

the inguinal ligament within the femoral canal and is often called Cloquet's node. Lymph vessels from the clitoris drain directly to the deep inguinal nodes, and direct clitoral lymphatics may pass to the internal iliac nodes (see Fig. 75.3B). Lymph vessels in the perineum and lower part of the labia majora drain primarily to inguinal nodes.

Vaginal lymphatic vessels link with those of the cervix, rectum and vulva. They form three groups but the regions drained are not sharply demarcated. Upper vessels accompany the uterine artery to the internal and external iliac nodes; intermediate vessels accompany the vaginal artery to the internal iliac nodes; and vessels draining the vagina below the hymen, and from the vulva and perineal skin, pass to the superficial inguinal nodes.

External genitalia: male

The penile and perineal skin is drained by lymphatic vessels that accompany the external pudendal veins to the superficial inguinal nodes. Lymphatics from the glans penis pass to the deep inguinal and external iliac nodes, and those from the erectile tissue and spongy urethra pass to the internal iliac nodes. Scrotal lymphatics do not cross the raphe of the scrotum and therefore lymphatic drainage from the scrotum is always routed to the ipsilateral superficial inguinal nodes.

Testicular lymphatic flow is abundant and consistent and follows the general retroperitoneal scheme of vertical drainage, with lateral flow from right to left. Lymphatic vessels from the right testis drain primarily into the right lateral aortic and lateral caval nodes, with some drainage into the left lateral aortic nodes. Lymphatic vessels from the left testis drain into the left and right lateral aortic and lateral caval nodes.

LYMPHATIC DRAINAGE OF THE VERTEBRAL COLUMN

Little is known in detail about the lymphatic drainage of the vertebral column and its associated soft tissues. In general, deep lymphatic vessels tend to follow the arteries. The cervical vertebral column drains to deep cervical nodes, the thoracic to (posterior) intercostal nodes and the lumbar column to lateral aortic and retroaortic nodes. The pelvic part of the column drains to lateral sacral and internal iliac nodes.

LYMPHATIC DRAINAGE OF THE LIMBS

The subcutaneous tissues of the upper and lower limbs can be divided into five layers: skin (layer 1); subcutaneous fat (2); superficial fascia (3); loose areolar tissue (4); and deep fascia (5). Layer 2 can be subdivided into a superficial (2a) and deep layer (2c) by a thin transparent horizontal septum (2b) (Tourani et al 2014). The main superficial veins and the superficial nerves are found in layer 4 and the lymphatic collectors in layer 2c and layer 4.

Upper limb

Superficial tissues

Superficial lymphatic vessels begin in cutaneous plexuses: in the hand, the palmar plexus is denser than the dorsal plexus. Digital plexuses drain along the digital borders to their webs, where they join the distal palmar vessels, which pass back to the dorsal aspect of the hand. The proximal palm drains towards the carpus, medially by vessels that run along its ulnar border, and laterally to join vessels draining the thumb. Several vessels from the central palmar plexus form a trunk that winds round the second metacarpal bone to join the dorsal vessels that drain the index finger and thumb.

In the forearm and arm, superficial vessels run with the superficial veins. Collecting vessels from the hand pass into the forearm on all carpal aspects. Dorsal vessels, after running proximally in parallel, curve successively round the borders of the limb to join the ventral vessels. Anterior carpal vessels run through the forearm parallel with the median vein of the forearm to the cubital region, then follow the medial border of biceps brachii before piercing the deep fascia at the anterior axillary fold to end in the lateral axillary lymph nodes.

Lymph vessels that lie laterally in the forearm receive vessels that curve round the lateral border from the dorsal aspect of the limb. They follow the cephalic vein to the level of the tendon of deltoid, where most incline medially to reach the lateral axillary nodes; a few continue with the vein and drain into the infraclavicular nodes. Vessels lying medially in the forearm are joined by vessels that curve round the medial border of the limb and follow the basilic vein. Proximal to the elbow, some end in supratrochlear lymph nodes whose efferents, together with the medial vessels that have bypassed them, pierce the deep fascia with the basilic vein and end in the lateral axillary nodes or deep lymphatic vessels.

Collecting vessels from the deltoid region pass round the anterior and posterior axillary folds to end in the axillary nodes. The scapular skin drains either to subscapular axillary nodes or by channels that follow the transverse cervical vessels to the inferior deep cervical nodes.

Deeper tissues

Deep lymph vessels follow the main neurovascular bundles (radial, ulnar, interosseous and brachial) to the lateral axillary nodes. They are less numerous than the superficial vessels and communicate with them at intervals. A few lymph nodes occur along the vessels. Scapular muscles drain mainly to the subscapular axillary nodes, and pectoral muscles drain mainly to the pectoral, central and apical nodes.

One or two supratrochlear nodes are superficial to the deep fascia proximal to the medial epicondyle and medial to the basilic vein; their efferents accompany the vein to join the deep lymph vessels. Small, isolated nodes sometimes occur along the radial, ulnar and interosseous vessels, in the cubital fossa near the bifurcation of the brachial artery, or in the arm medial to the brachial vessels.

Lower limb

Most lymph from the lower limb traverses a large intermediary inguinal group of nodes (see Fig. 76.10). Peripheral nodes are few and are all deeply sited in the popliteal fossa except for an inconsistent node lying proximally on the interosseous membrane near the anterior tibial vessels. Enlarged popliteal nodes, often as a result of inflammation, malignancy or injury to the lateral side of the foot, may be palpated along the line of the popliteal vessels while the passively supported knee is gradually moved from extension to semi-flexion. Inguinal lymph nodes are found superficial and deep to the deep fascia. The superficial nodes may be divided into a lower vertical group that clothe the proximal part of the long saphenous vein, and an upper group that lie parallel to, but below, the inguinal ligament and which are related laterally to the superficial circumflex iliac and medially to the superficial external pudendal vessels. The deep nodes are few and lie alongside the medial aspect of the femoral vein. Lymph from the lower limb passes from the inguinal lymph nodes to the external and common iliac nodes, and ultimately drains to the lateral aortic nodes. Deep gluteal lymph reaches the same group through the internal and common iliac lymphatic vessels.

Superficial tissues

The superficial lymph vessels begin in subcutaneous plexuses. Collecting vessels leave the foot either medially with the long saphenous vein, or laterally with the short saphenous vein. Medial vessels are larger and more numerous. They start on the medial side of the dorsum of the foot, ascend anterior or posterior to the medial malleolus, accompany the long saphenous vein and drain to the distal superficial inguinal nodes. Lateral vessels begin on the fibular side of the dorsum of the foot. Some cross anteromedially in the leg to join the medial vessels and so pass to the distal superficial inguinal lymph nodes, while others accompany the short saphenous vein and drain to the popliteal nodes. Superficial lymph vessels from the gluteal region run anteriorly to the proximal superficial inguinal nodes.

Deeper tissues

The deep lymph vessels accompany the anterior and posterior tibial, fibular, popliteal and femoral vessels. Popliteal nodes interrupt the deep vessels from the foot and leg; deep vessels from the thigh pass to the deep inguinal nodes. The deep lymphatic vessels of the gluteal region follow their corresponding blood vessels. Those accompanying the superior gluteal vessels end in a node near the intrapelvic part of the superior gluteal artery, adjacent to the superior border of the greater sciatic foramen, while those that follow the inferior gluteal vessels traverse one or two of the small nodes inferior to piriformis and then pass to the internal iliac nodes.

COMMENTARY

I.1

A note on anatomy from an imaging perspective

Tom Turmezei

In recent years there have been reciprocal, reinforcing developments between the disciplines of human anatomy and clinical radiology. Most medical schools include medical imaging as a core component of their anatomy syllabus. Ongoing developments in medical technology have enabled us to visualize living anatomy with far greater detail. Higher-field magnetic resonance imaging (e.g. 3 Tesla MRI) is perhaps the best known of these advances, but there have been contributing improvements across all imaging modalities. From a clinical perspective, the ability to see greater detail can be a blessing in disguise: radiologists have had to develop interpretive skills alongside their anatomical knowledge to ensure that they understand what they are seeing.

Limitations on visualization remain, often defined by the modality used to image a particular body region, which means that the wealth of information now available to us must be considered in the context of how the images were acquired. Imaging such as MRI and ultrasound can be pre-arranged for educational purposes, whereas modalities that involve exposure to ionizing radiation such as computed tomography (CT) and radiography cannot. Therefore we must rely on clinical imaging acquisitions to be furnished with as close to ideal anatomy as possible. Patient positioning, physiology and individual anatomical variation all come into the mix, factors that challenge radiologists daily.

Fig. I.1.1 shows how a small change in the axis of multiplanar reformatting through a CT image volume of the thorax can subtly change the anatomy displayed. In the top row, the axial, sagittal and coronal slices are taken with respect to the gantry, while in the bottom row these planes are set with respect to the vertebral body of T5. There are distinct topographical differences within each pair of images. Taking the axial plane as an example, note how the aortic arch (red arrow) is present in the top image, but is not seen in bottom image. Likewise, the carina (green arrow) is not seen in the top image, but is just seen in the bottom image. Finally, the whole chest seems wider (in the anteroposterior dimension) in the bottom image, also with a different configuration of the ribs. If the same patient were to get up and lie down again on the gantry for a second examination just moments later, would they be in the same position and would a slice at T5 axial to the plane of the gantry show the same information? (The answer is no.) Since image plane acquisitions are routinely standardized with respect to the gantry, individual anatomical variations between patients mean that body positioning also affects imaging planes. But as this exercise shows, it is possible to manipulate orthogonal imaging planes with multiplanar reformats to overcome this effect when reviewing an image set at workstation. This at least means that we can attempt to review imaging with some anatomical consistency across individuals.

Physiology also significantly affects the visualization of living anatomy in medical imaging. For example, a different depth of inspiration would give a different lung volume (similar to the effect seen above with respect to the anteroposterior chest diameter) and a different respiratory diaphragm level, shifting mobile abdominal organs to a different position. A hyperdynamic state might also push intravenous contrast medium through the heart and lungs more quickly, meaning

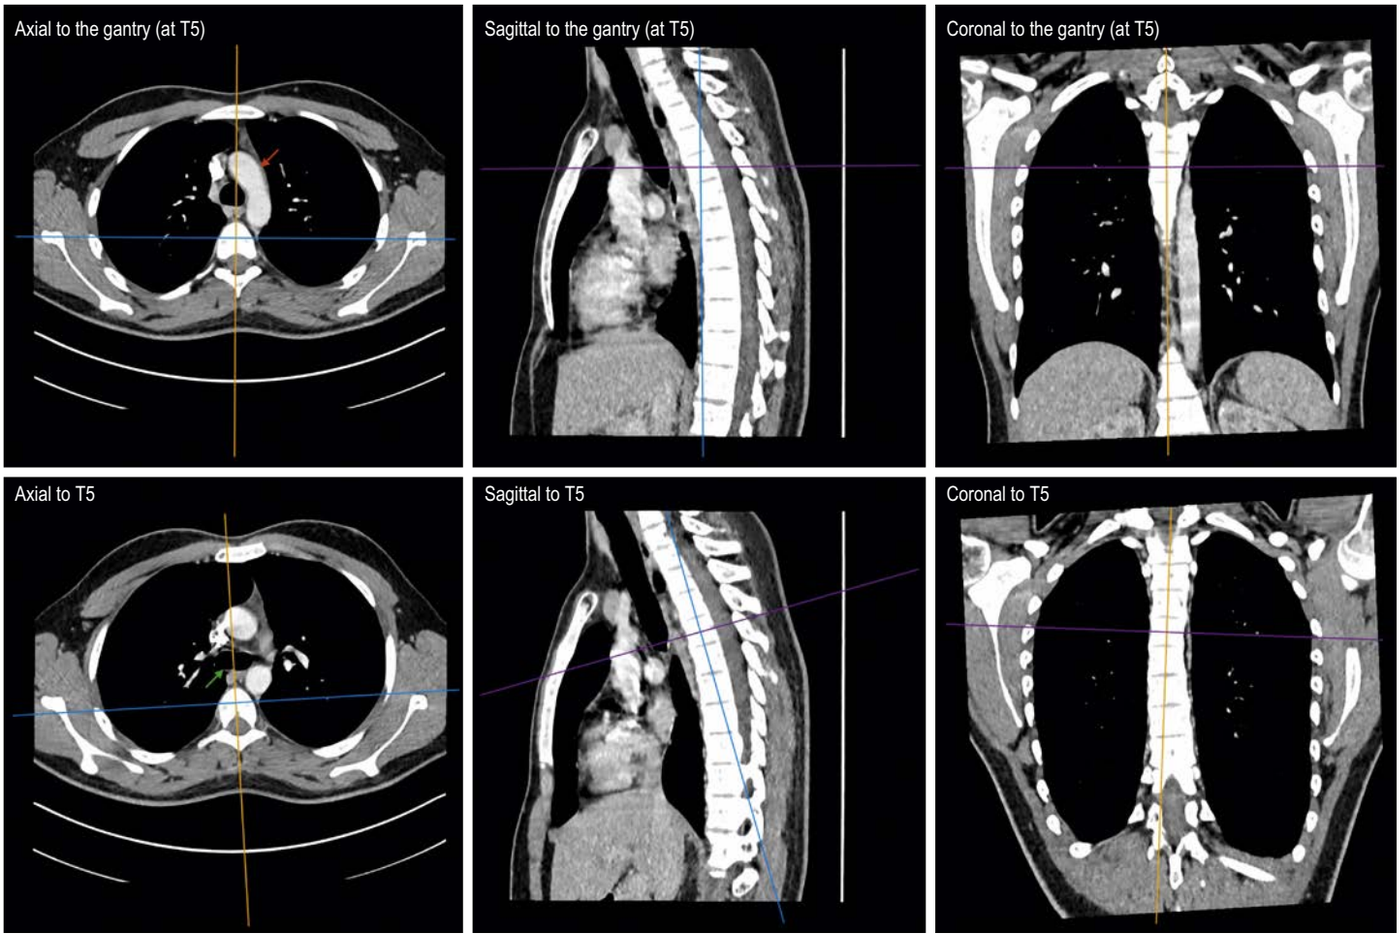

Fig. I.1.1 CT scan of the thorax with intravenous contrast medium. Top row: axial, sagittal and coronal image planes (purple, orange and blue planes, respectively) with respect to CT machine gantry at the level of T5. Bottom row: axial, sagittal and coronal image planes with respect to the T5 vertebral body. Red arrow = aortic arch; green arrow = carina.

that the scan would have to be acquired earlier after injection to achieve the same contrast opacification of the pulmonary vasculature. This is a key skill that radiographers develop in order to see meaningful patterns of contrast opacification in different vessels and perfused tissues. For example, in choosing a protocol in order to visualize the pulmonary arterial system to exclude a pulmonary embolism, if an acquisition is too early, then the contrast medium will sit in the peripheral venous system or right side of the heart, whereas if acquisition is too late, contrast medium will have passed beyond the left side of the heart: both will lead to a non-diagnostic scan from inadequate opacification of the pulmonary arterial tree.

Fig. I.1.2 demonstrates another visualization challenge for radiologists, namely how to see all tissue types in the same image. A feature of most medical imaging is that it can contain more grayscale information than the human eye can process. As a result, information is lost when displayed on screen. In this figure, the same underlying image information has simply been viewed with different brightness and contrast settings, but note how different structures stand out in each. The 'soft tissue' window clearly shows greater definition between fat, muscle, lymph nodes and the vascular structures of the mediastinum; the 'lung' window shows vessels, airways and the septal/lobular structure of the lungs; the 'bone' window shows greater skeletal detail. Each must be reviewed according to the clinical question at hand. In the same way, an appropriate window must be chosen to review certain anatomical structures.

Advances in digital data handling have been essential in making imaging available for anatomical education. They have placed tools for 3D image reconstruction, manipulation and navigation (such as seen in Figs I.1.1–I.1.2) in the hands of anatomists and their students, and have greatly enhanced an understanding of important structural relationships in the human body. However, it is important to remember that a *single* image rarely holds all the necessary cues for learning these relationships and therefore, whenever possible, many slices in different planes should be examined.

One near-certain means to improve educational experiences will be to continue to collaborate in imaging projects and publications. In this way, hopefully the skills of experts in anatomy and medical imaging will continue to bear fruit for the students of both disciplines.

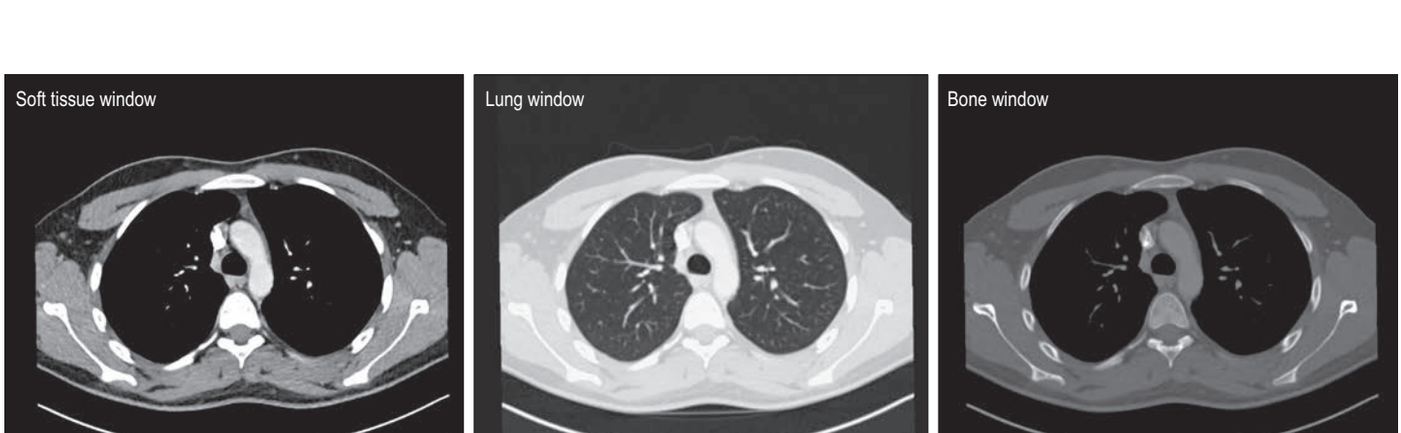

Fig. I.1.2 CT scan of the thorax with intravenous contrast medium at the level of T5. Three different window settings commonly used for looking at the thorax: from left to right these are 'soft tissue', 'lung' and 'bone', each making specific tissue types more apparent.

COMMENTARY

I.2

Technical aspects and applications of diagnostic radiology

Jonathan Spratt

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) produces images by first magnetizing a patient in the bore of a powerful magnet and then broadcasting short pulses of radiofrequency (RF) energy at 46.3 MHz that resonate mobile protons (hydrogen nuclei) in the fat, protein and water of the patient's soft tissues and bone marrow. The protons produce RF echoes when their resonant energy is released; their density and location can be exactly correlated into an image matrix by complex mathematical algorithms.

The spinning proton of the hydrogen nucleus acts like a tiny bar magnet, aligning either with or against the magnetic field, and producing a small net magnetic vector. RF energy from various types of coil, either built into the scanner or attached to specific body parts, generates a second magnetic field perpendicular to the static magnetic field that rotates or 'flips' the protons away from the static magnetic field. When the RF pulse is switched off, the protons flip back (relax) to their original position of equilibrium, emitting the RF energy they had acquired into the antenna around the patient. This information is then amplified, digitized and spatially encoded by the array processor.

MRI systems are graded according to the strength of the magnetic field they produce. Routine high-field systems are those capable of producing a magnetic field strength of 3–7 T (Tesla), using a superconducting electromagnet immersed in liquid helium. Open magnets for claustrophobic patients and limb scanners use permanent magnets of 0.2–0.75 T. For comparison, Earth's magnetic field varies from 30 to 60 μT. MRI does not present any recognized biological hazard. Patients who have any ferromagnetic intracranial aneurysm clips, certain types of cardiac valve replacement or intraocular metallic foreign bodies must never be examined because there is a high risk of death or blindness. Patients with implanted electronic devices such as a cardiac pacemaker or spinal cord stimulator must be screened carefully if MRI is being considered. Many new devices are now MRI-compatible, but the precise product details must be made available to the MRI team to ensure the patient's safety (e.g. the need to induce a 'scanner mode' in the device, or establishing definitive MRI-incompatibility). Many extracranial vascular clips and orthopaedic prostheses are now 'MRI-friendly' but may cause local artefacts; newer sequences exist to reduce artefact. Loose metal items, 'MR-unfriendly' anaesthetic equipment and credit cards must be excluded from the examination room. Pillows containing metallic coiled springs have been known nearly to suffocate patients, and heavy floor-buffing equipment has been found wedged in the magnet bore because domestic staff had been suboptimally informed.

New methods of analysing normal and pathological brain anatomy are now at the forefront of research. These are MR spectroscopy (MRS); functional MRI (fMRI); diffusion tensor imaging (DTI); high angular resolution diffusion imaging (HARDI) for MR tractography (MRT, see below); and molecular MRI (mMRI), which has taken on a new direction since the description of the human genome.

MRS assesses function within the living brain. It capitalizes on the fact that protons residing in differing chemical environments possess slightly different resonant properties (chemical shift). For a given volume of brain, the distribution of these proton resonances can be displayed as a spectrum. Discernible peaks can be seen for certain neurotransmitters: *N*-acetylaspartate varies in multiple sclerosis, stroke and schizophrenia while choline and lactate levels have been used to evaluate certain brain tumours.

fMRI depends on the fact that haemoglobin is diamagnetic when oxygenated but paramagnetic when deoxygenated. These different signals can be weighted to the smaller vessels, and hence closer to the active neurones, by using larger magnetic fields. mMRI uses biomarkers that interact chemically with their surroundings and alter the image according to molecular changes occurring within the area of interest, potentially enabling early detection and treatment of disease and basic pharmaceutical development and quantitative testing.

High-field-strength magnets give significant improvement in spatial resolution and contrast. MR images of the microvasculature of the live human brain that allow close comparison with the detail seen in histological slides have been acquired at 8 T. This has significant implications for the treatment of reperfusion injury and research into the physiology of solid tumours and angiogenesis. There is every reason to believe that continued efforts to push the envelope of high-field-strength applications will open new vistas in what appears to be a never-ending array of potential clinical applications.

T1-weighted images best accentuate fat and other soft tissues, whereas fluid is low-signal; these images are nicknamed the 'anatomy weighting' amongst radiologists who publish or teach anatomy. T2-weighted images reveal fluid as high signal as well as fat. Fat suppression sequences using T2 'fat sat' (T2FS) or short tau inversion recovery (STIR) are very sensitive in highlighting the soft tissue or bone marrow oedema that almost invariably accompanies pathological states such as inflammation or tumours. Contrast-enhanced images with gadolinium, when used with T1 fat saturation (T1FS) sequences, also exquisitely highlight hypervascularity, particularly that associated with tumours and inflammation, especially in pathologies where the blood–brain barrier is compromised. Metallic artefact reduction sequences (MARS) are superior in imaging periprosthetic soft tissues after joint replacement or other orthopaedic metalwork implantation.

MR tractography

MR tractography (MRT) is a three-dimensional modelling technique used to represent neural tracts visually using data collected by DTI or, more recently, by HARDI, with results presented in two- and three-dimensional images (Nucifora et al 2007) (see Chapter 32).

The MRI sequences used look at the symmetry of water diffusion in the brain. Bundles of fibre tracts make the water diffuse asymmetrically in a 'tensor', the major axis parallel to the direction of the fibres. There is a direct relationship between the number of fibres and the degree of anisotropy. DTI assumes that the direction of least restriction corresponds to the direction of white matter tracts. Diffusion MRI was introduced in 1985. In the more recent evolution of the technique into diffusion tensor MRI (DTI), the relative mobility of the water molecules from the origin is modelled as an ellipsoid rather than a sphere. This allows full characterization of molecular diffusion in the three dimensions of space and the formation of tractograms. Barriers cause uneven anisotropic diffusion. In white matter, the principal barrier is the myelin sheath, whereas bundles of axons provide a barrier to perpendicular diffusion and a path for parallel diffusion along the orientation of the fibres. Anisotropic diffusion is expected to be increased overall in areas of high mature axonal order. Conditions where barriers offered by the myelin sheaths or the axons are disrupted, e.g. in trauma, tumours and inflammation, reduce anisotropy and yield DTI data used to seed various tractographic assessments of the brain. Data sets may be rotated continuously into various planes in order to appreciate the structure better; colour may be assigned based on the dominant direction of the fibres. A leading clinical application of MRT is in the presurgical mapping of eloquent regions. Intraoperative electrical stimulation (IES) provides a clinical gold standard for the existence of functional motor pathways that can be used to determine the accuracy and sensitivity of fibre-tracking algorithms.

Intersecting tracts or partial volume averaging of adjacent pathways with different fibre orientations are the reasons why DTI does not accurately describe the microstructure in complex white matter voxels that contain more than one fibre population, e.g. in the centrum semiovale, where major white matter tracts such as the pyramidal tract, the superior longitudinal fasciculus and the corpus callosum intersect. This has hindered preoperative mapping of the pyramidal tract in brain tumour patients. HARDI permits more accurate delineation of pathways within

complex regions of white matter. The q-ball reconstruction of HARDI data provides an orientation distribution function (ODF) that can be used to determine the orientations of multiple fibre populations contributing to a voxel's diffusion MR signal, mapping fibre trajectories through regions of complex tissue architecture in a clinically feasible timeframe.

ULTRASOUND

Uniquely, ultrasound images do not depend on the use of electromagnetic wave forms. The properties of high-frequency sound waves (longitudinal waves) and their interaction with biological tissues are responsible for the production of 'echograms' (Desser and Jeffrey 2001). A sound wave of appropriate frequency (diagnostic range 3.5–20 MHz) is produced by piezo-electric principles. Image production is determined by attenuation and reflection as the beam passes through tissues. Attenuation is caused by the loss of energy due to absorption, reflection and refraction in soft tissues, resulting in a reduction in signal intensity. Reflection of sound waves within the range of the receiver produces the image, and the echotexture is dependent on tiny differences in acoustic impedance between different tissues. Blood flow and velocity can be measured (using the Doppler principle) in duplex mode.

Techniques such as harmonic imaging and the use of ultrasound contrast agents (stabilized microbubbles) have enabled non-invasive determination of myocardial perfusion. These contrast agents also clearly improve the detection of metastases in the liver and spleen. Ultrasound is the most common medical imaging technique for producing elastograms, in which stiffness or strain images of soft tissue are used to detect or classify tumours. Cancer is 5–28 times stiffer than the background of normal soft tissue; when a mechanical compression or vibration is applied, a tumour deforms less than the surrounding tissue. Elastography may be used, for example, to measure the stiffness of the liver *in vivo* or in the detection of breast or thyroid tumours. A correlation between liver elasticity and the cirrhosis score has been shown (Yeh et al 2002, Foucher et al 2006).

Interpretation of anatomy and pathology from static ultrasound images is more difficult than that from other imaging modalities: compare the real-time nature ultrasound in Video 23.1 with the static images in Fig. 23.5. The technique is highly operator-dependent and provides unique information on tissue structure and form not obtained from other imaging techniques.

NUCLEAR MEDICINE

Historically, the field of nuclear medicine began in 1946 when radioactive iodine was administered as an 'atomic cocktail' to treat thyroid cancer. Since that time, nuclear medicine has advanced to the point where it was recognized in the early 1970s as a diagnostic subspecialty.

Unlike diagnostic radiology, where an image is created by passing energy through the body from an external source, nuclear medicine creates an image by measuring the radiation emitted from tracers taken internally. Overall, the radiation dosages are comparable with CT and vary depending on the examination. Nuclear medicine also differs from most other imaging modalities in that the tests demonstrate the physiological function of a specific area of the body. In some instances, this physiological information may be fused with the more anatomical imaging of CT or MRI, combining the strengths of anatomy and function for diagnosis (e.g. Dewey et al 2020).

Nuclear medicine uses pharmaceuticals that have been labelled with a radionuclide (radiopharmaceuticals) and which are administered to patients by intravenous injection, ingestion or inhalation (the method of administration depends on the type of examination and the organ or organ process to be imaged). Emitted radiation is detected and imaged with specialized equipment such as gamma cameras, positron emission tomography (PET) or single photon emission computed tomography (SPECT). Radiation may be measured from parts of the body by the use of probes, or samples may be taken from patients and measured in counters.

Radiopharmaceuticals may be used to image a disease process or to treat diseases. Those used for imaging emit a gamma ray (γ) and those used for treatment emit a beta (β) particle. Gamma rays are of higher energy in order to pass through the body and be detected by a detection camera, whereas β particles travel only short distances and emit their radiation dose to the target organ. For example, ^{99m}technetium or ^{123}iodine may be used to detect thyroid disease, but certain thyroid diseases or thyroid cancer may be treated solely or in part with ^{131}iodine. The difference in the agent used depends on the type and energy levels of the radiation particle that the radioisotope emits.

Radionuclides used in nuclear medicine are often chemically bound to a complex called a tracer. The way the body handles a tracer may differ in disease or pathological processes. For example, the tracer used in bone imaging is methylene-diphosphonate (MDP) bound to ^{99m}technetium. MDP attaches to hydroxyapatite in bone; altered bone physiology, such as occurs in a fracture, metastatic bone disease or arthritic change, produces an increase in biochemical bone activity and an accumulation of MDP that is seen as a focal 'hot spot' of the radiopharmaceutical on a bone scan.

^{99m}Technetium is the major workhorse radioisotope of nuclear medicine. It can be eluted from a molybdenum/technetium generator stored within a nuclear medicine department, allowing for easy access. It has a short half-life (6 hours), which allows for ease of medical imaging and disposal. Its pharmacological properties allow it to be easily bound to various tracers and it emits gamma rays that are of suitable energy for medical imaging. In addition to ^{99m}technetium, the most common intravenous radionuclides used in nuclear medicine are ^{123}iodine and ^{131}iodine, ^{201}thallium, ^{67}gallium, ^{18}fluorodeoxyglucose (FDG) and ^{111}indium-labelled leukocytes. The most common gaseous/aerosol radionuclides used are ^{133}xenon, ^{81m}krypton, ^{99m}technetium (Technegas) and ^{99m}technetium diethylene triamine pentaacetic acid (DTPA).

The images obtained from nuclear medicine imaging can be single or multiple. Image sets may be represented by time sequence imaging (e.g. cine), such as dynamic imaging or cardiac gated sequences, or by spatial sequence imaging, where the gamma camera is moved relative to the patient, e.g. in SPECT imaging. Spatial sequence imaging allows the images to be presented as a slice-stack much in the way that CT or MRI images are displayed. It may also be fused with concomitant CT or MRI to provide combined physiological and anatomical imaging.

A PET scan is a specialized type of nuclear medicine imaging that measures important body functions, such as blood flow, oxygen use or glucose metabolism. It involves short-lived radioactive tracer isotopes that emit positrons (positively charged subatomic particles with the same mass and magnitude of charge as electrons). The radioisotopes are chemically incorporated into biologically active molecules: most commonly, the sugar FDG (2-deoxy-2-[fluorine-18]fluoro-D-glucose). An hour after injection, FDG becomes concentrated into the tissues of interest; images are obtained as the isotope undergoes positron emission decay. A positron travels only a few millimetres before reacting with an electron by annihilation, producing a pair of gamma photons that move in opposite directions. The PET scan detectors process only those photon pairs that are detected simultaneously (coincident detection) to create an image of tissue activity with respect to that particular isotope. These images may subsequently be fused with CT or MR images. The short half-life of the isotopes limits PET imaging; close access to a cyclotron for generation of the isotopes plays an important role in the feasible location of a PET scanner. Typical isotopes used in medical imaging and their half-lives are: ^{11}carbon (about 20 min), ^{13}nitrogen (about 10 min), ^{13}oxygen (about 2 min) and ^{18}fluorine (about 110 min).

ANGIOGRAPHY/INTERVENTIONAL RADIOLOGY

Angiographic imaging was first described in 1927, when Egas Moniz, a physician and neurologist, introduced contrast X-ray cerebral angiography. (Moniz was awarded the Nobel Prize for his work in 1949.) In 1953, the field was revolutionized by the Seldinger technique, in which no sharp needles remained inside the vascular lumen during imaging. Although angiography initially involved X-ray and fluoroscopic imaging of blood vessels and organs of the body after injecting radiopaque contrast agents into the blood stream, it has evolved to encompass so much more. Many of the procedures currently performed by angiography may be diagnostic; following the advent of minimally invasive procedures performed with image guidance, the name of the discipline changed to interventional radiology (or vascular and interventional radiology).

Angiograms are typically performed by gaining access to the blood vessels, through either the femoral artery, femoral vein or jugular vein, depending on the area of interest to be imaged (e.g. cerebral, coronary or pulmonary angiograms). Following vascular access, catheters are directed to the specific location to be imaged by the use of guidewires, and contrast agents are injected through these catheters to visualize the vessels or the organ with X-ray imaging. Imaging of the arterial and venous circulation of the arms and legs may demonstrate peripheral vascular disease.

Treatment and/or interventions can often be performed through similar catheter-based examinations. Such procedures might involve angioplasties, where a balloon mechanism is placed across an area of narrowing (stenosis) in a vessel or lumen. With controlled inflation of the balloon, the area of narrowing can be widened.

Imaging in diagnostic or interventional procedures may produce still or motion (cine) images. The technique often used, digital subtraction angiography (DSA), involves taking images at 2–30 frames per second to allow imaging of the flow of blood through vessels. A preliminary image of the area is taken before the contrast is injected; this 'mask' image is then electronically subtracted from all subsequent images, leaving only the vessels filled with contrast. For optimal subtraction, the patient must remain motionless.

Angiograms of the heart may be performed to visualize the size and contractility of the chambers and the anatomy of the coronary vessels. The thorax may also be studied to evaluate the pulmonary arteries and veins for vascular malformations, blood clots and possible origins of haemoptysis. In the investigation of atherosclerotic disease, vascular malformations or tumoral vascularization, the neck is often imaged in order to visualize the vessels that supply the brain in their entirety, from the points at which they arise from the aortic arch to their termination as cerebral vessels. Renal artery imaging may elucidate the cause of hypertension in selected patients, and imaging of the mesenteric vessels may identify the origin of gastrointestinal bleeding or mesenteric angina.

In addition to angiograms and venograms, the field of interventional radiology also includes such procedures as coil embolization of aneurysms and vascular malformations; balloon angioplasty and stent placement, even now for the endovascular repair of aortic aneurysms; chemoembolization directly into tumours; drainage catheter insertion; embolization (e.g. uterine artery for treatment of fibroids); thrombolysis to dissolve blood clots; tissue biopsy (percutaneous or transvascular); radiofrequency ablation and cryoablation of tumours; line insertions for specialized vascular access; inferior vena cava filter placements; vertebroplasty; nephrostomy placement; gastrostomy tube placement for feeding; dialysis access; transjugular intrahepatic portosystemic shunt (TIPS) placement; biliary interventions; and, most recently, endovenous laser ablation of varicose veins.

COMPUTED TOMOGRAPHY

The limitation of all plain radiographic techniques is the two-dimensional representation of three-dimensional structures; the linear attenuation coefficient of all the tissues in the path of the X-ray beam form the image. CT obtains a series of different angular X-ray projections that are processed by a computer to give a section of specified thickness. The CT image comprises a regular matrix of picture elements (pixels). All of the tissues contained within the pixel attenuate the X-ray projections and result in a mean attenuation value for the pixel. This value is compared with the attenuation value of water and is displayed on a scale (the Hounsfield scale). Water is said to have an attenuation of 0 Hounsfield units (HU); air typically has a HU number of −1000; fat is approximately −100 HU; soft tissues are in the range +20 to +70 HU; and bone is usually greater than +400 HU.

Modern multislice helical CT scanners can obtain images in subsecond times, and imaging of the whole body from the top of the head to the thighs can take as little as a single breath-hold of only a few seconds. The fast scan times allow dynamic imaging of arteries and veins at different times after the injection of intravenous contrast agents. The continuous acquisition of data from a helical CT scanner allows reconstruction of an image in any plane (multiplane reconstruction, MPR), commonly sagittal and coronal, as may be seen in many of the images throughout this forty-second edition of *Gray's Anatomy*. This orthogonal imaging greatly improves the understanding of the three-dimensional aspects of radiological anatomy and now forms part of the standard practice of assessing disease.

No specific preparation is required for most CT examinations of the brain, spine or musculoskeletal system. Studies of the chest, abdomen and pelvis, and those of the brain with complex histories, usually require intravenous contrast medium that contains iodine because this defines vascular relationships and differentiates normal and pathological soft tissues more effectively. Opacification of the bowel in CT studies of the abdomen and pelvis may be accomplished by oral ingestion of a water-soluble contrast medium from 24 hours prior to the examination, in order to outline the colon, combined with further oral intake 0–60 minutes prior to the scan, in order to outline the stomach and small bowel. This procedure is much less frequently performed with the latest generation of scanners, which exquisitely differentiate various enhancing layers within the bowel wall. Occasionally, direct insertion of rectal contrast to show the distal large bowel may be required.

Generally, most studies are performed with the patient supine with images obtained in the transverse or axial plane. Some CT scanners allow up to 25° of gantry angulation, which is particularly valuable in spinal imaging, but multidetector technology and the ability to reconstruct imaging in virtually any plane from the acquired 3D imaging block has obviated this need. Occasionally, direct coronal images are obtained in the investigation of cranial and maxillofacial abnormalities; in these cases, the patient lies prone with the neck extended and the gantry appropriately angled, but this technique has largely been superseded by the orthogonal imaging described above. The ability to acquire time-gated images at the same point in the cardiac cycle with multidetector scanners has also revolutionized 'cold' coronary artery assessment with the detail that is now achievable from these CT coronary angiograms.

COMMENTARY

I.3

Imaging the ageing musculoskeletal system

Andoni P. Toms

How long is a generation? This is a debate that simmers in the disciplines of anthropology, genetics and genealogy. Generations can be very short, with both males and females becoming parents in their early teens, or very long, with men fathering children in their 10th decade, but these variations are uncommon. It is probable that the average male generation is somewhere between 30 and 35 years and that female generations are shorter, at between 25 and 30 years. Despite a long-held assumption that generations were shorter in prehistoric societies there is now evidence to suggest that these mean generational gaps have been stable for millennia (Tremblay and Vézina 2000, Helgason et al 2003).

For genealogists these figures are used as a rule of thumb to assess the integrity of a family tree. Too few generations in a given century alerts them to the possibility of missing data. For geneticists these figures are used to estimate the rate at which mutations have occurred in our genome. And in evolutionary terms these figures may determine the age at which our bodies begin to fail.

It seems reasonable to argue that the child of a parent who remains healthy, until their offspring are independent, is more likely to survive and propagate their genes than the progeny of a weak and feeble parent. The traits of good health in parenthood would therefore be passed on to subsequent generations whereas the weaker phenotype would be less likely to endure. Assuming that the age of independence is 15, then the evolutionary driver is a parent who is healthy until the age of 45. After that a healthy parent is much less likely to contribute to the survival of the offspring; evolution has selected a human phenotype that remains strong until the age of 45 and then starts to fall apart.

While the estimate of intervals between generations has an evidence base, my subsequent argument is a hypothesis. One that is supported by a number of facts: at 45 we go grey (Van Neste and Tobin 2004), we become short sighted (Michael and Bron 2011) and we suffer a peak in short-term musculoskeletal pain (Claus et al 2019). At age 45 the production of new collagen in cartilage and bone falls to the lowest level in our lifetimes (Mouritzen et al 2003) and we start to shrink (Sorkin et al 1999).

Cartilage

Normal hyaline cartilage in a young adult has a laminar appearance on magnetic resonance (MR) imaging (**Fig. I.3.1**). The vertical and oblique zones of type 1 collagen fibres that make up the parabolic arcades of Benninghoff (Benninghoff 1925), and the armour-plated surface layer can be differentiated because the orientation of collagen fibres influences the signal generated by radiofrequency pulses. The extracellular matrix of cartilage, consisting mainly of glycosaminoglycan, is hygroscopic; as water is absorbed the cartilage expands until limited by the collagen arcades. This balanced tension between expanding extracellular matrix and restraining collagen is often referred to as a hydrostatic cushion, implying that hyaline articular cartilage plays a significant role in load distribution. As we shall see later this may not be the case, and the main role of hydrostatic cartilage may be to resist shearing forces.

As we age, our chondrocytes die. Those that survive synthesize less glycosaminoglycan which means that less water is bound into the cartilage, which gets thinner and loses its compressive stiffness (Lotz and Loeser 2012). This age-related biological degeneration is commonly seen in routine clinical practice (Fig. I.3.1) where, paradoxically, many musculoskeletal radiologists will resist describing them as degenerative. This is because in clinical practice the terms 'degeneration' and 'osteoarthritis' are often used interchangeably. An alternative approach is to describe uncomplicated thinning of articular cartilage as normal age-related change, the assumption being that this does not contribute to symptoms. Once the integrity of the articular cartilage has been breached, or there is reactive subchondral bone marrow signal, this may then be described as being 'degenerative'. When the clinical history or secondary signs of inflammation support the diagnosis, then these findings can be interpreted as 'osteoarthritis'.

All these assumptions and tortuous semantic manipulations illustrate one of the principal difficulties that clinicians and scientists have when approaching the ageing musculoskeletal system. We do not have a language that allows us to differentiate normal ageing from degenerative disease and the imaging phenotypes do not allow us to separate the two with any certainty.

For the purpose of clinical practice most clinicians consider diffuse thinning of articular cartilage to be a predictable asymptomatic feature of the ageing musculoskeletal system. This does not mean that it is entirely benign. The thin, soft and collagen-depleted cartilage is less resistant to shearing injuries and is therefore a risk factor for developing osteoarthritis (OA). The knee joint in particular is dependent on the integrity of the cruciate and collateral ligaments, rather than the profile of the articular surfaces, for its stability. As the joint space narrows so these ligaments become redundant and the joint becomes intrinsically less stable; there is a view that the redundancy of stabilizing ligaments caused by joint space narrowing is a significant source of symptoms (Hunter et al 2008).

Bone

The ability of bone to resist fracture is defined by two characteristics: strength, a measure of maximum load without failure, and toughness, the ability to flex under a deforming force. While bone mineral density contributes to both of these functions it appears that ageing type 1 collagen is an important contributor to bone fragility (Boskey and Coleman 2010). The mechanical properties of collagen in bone are determined

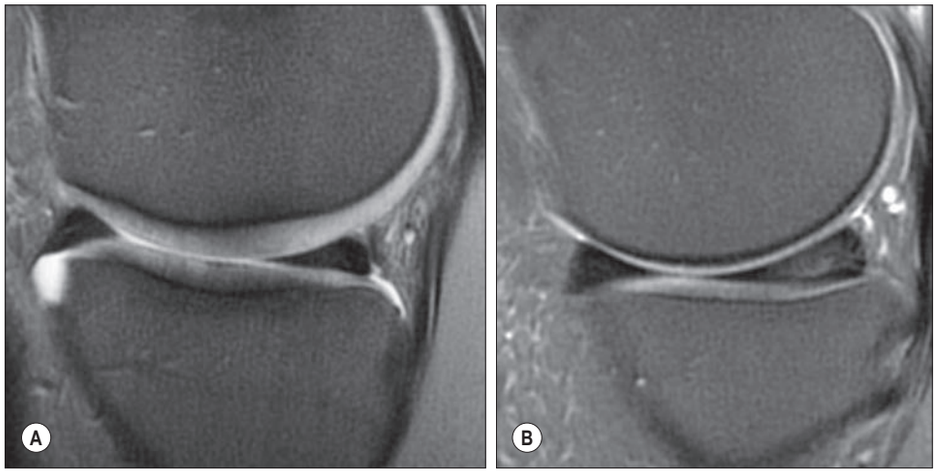

Fig. I.3.1 Sagittal fat-saturated proton density MR images through the medial tibiofemoral compartment of the knee of a 24-year-old (**A**) and a 62-year-old (**B**) male patient.

by the type of cross-link between fibrils. New collagen is connected by cross-links that result from a specific enzymatic reaction. As collagen persists in tissues the method of cross-linkage changes to glycation or oxidation. With increasing age, the production of new collagen slows down and these non-enzymatic cross-links predominate, with a concomitant decrease in bone strength and a reduction in toughness (Saito and Marumo 2010).

The effect of these changes in stiffness can be seen on radiographs in the form of subchondral sclerosis (MacKay et al 2014). This has long been recognized as one of the hallmarks of OA, together with irregular joint space loss, osteophytes and subchondral cysts, but there is evidence that sclerosis can develop in the absence of any of the other features of OA. High resolution MRI of the subchondral bone in asymptomatic middle-aged volunteers demonstrates increased subchondral sclerosis but also significant differences in trabecular architecture when compared to young asymptomatic volunteers (**Fig. I.3.2**) (MacKay et al 2016).

One explanation for this is that bone is a major contributor to the dissipation of loads through a weight-bearing joint, i.e. it is an important shock absorber. Bone has been estimated to account for up to 40% of the load-damping capacity of a limb in some animal models (Dodge et al 2012). One consequence of the increased stiffness of non-enzymatic cross-linked collagen is that these loads will not be as efficiently dissipated along the length of a weight-bearing bone. Therefore loading will become more localized and increased over smaller volumes of bone. According to Wolff's law, that volume of bone will then adapt by laying down more bone and the result will be subchondral sclerosis.

Osteoporosis is reduced bone mineral density that is most commonly related to age and in particular to postmenopausal females. It is an independent risk factor for developing fragility fractures, but it is not the only variable that contributes to bone fragility; ageing collagen also contributes to reduced bone toughness. The anatomical distribution of bone loss is an important independent predictor of fragility fractures. The cross-sectional cortical morphology of bones, their curvature and the cortico-medullary distribution of mineralized osteoid and trabecular organization, all change with increasing age (**Fig. I.3.3**). Which of these traits contribute to disease, and which do not, is only partly understood.

An example of changing anatomy that appears to relate simply to age is 'cortical drift'. This is a process that describes the changing cross-sectional profile of long bones that occurs with increasing age and refers

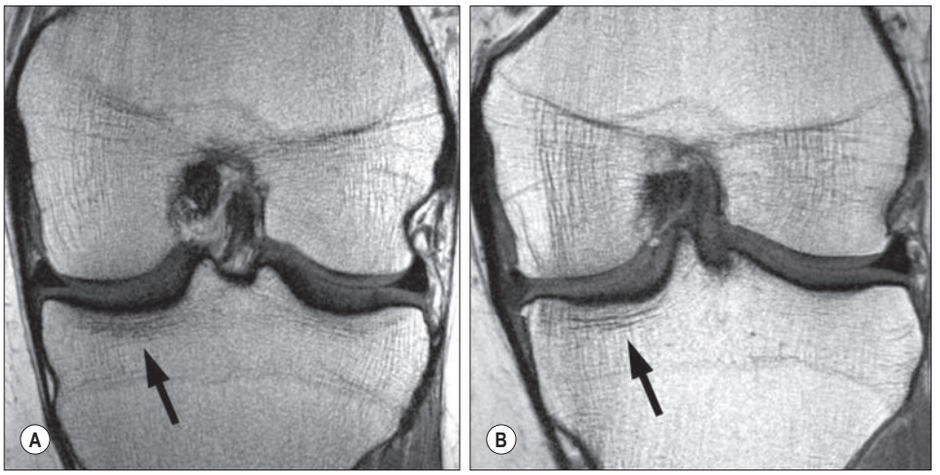

Fig. I.3.2 Coronal high resolution T1-weighted trabecular maps of subchondral bone in (**A**) 27-year-old and (**B**) 46 year-old asymptomatic male volunteers demonstrating changes in the conspicuity and texture of subchondral trabecular bone with age (arrows). (Courtesy of Dr James MacKay, University of East Anglia.)

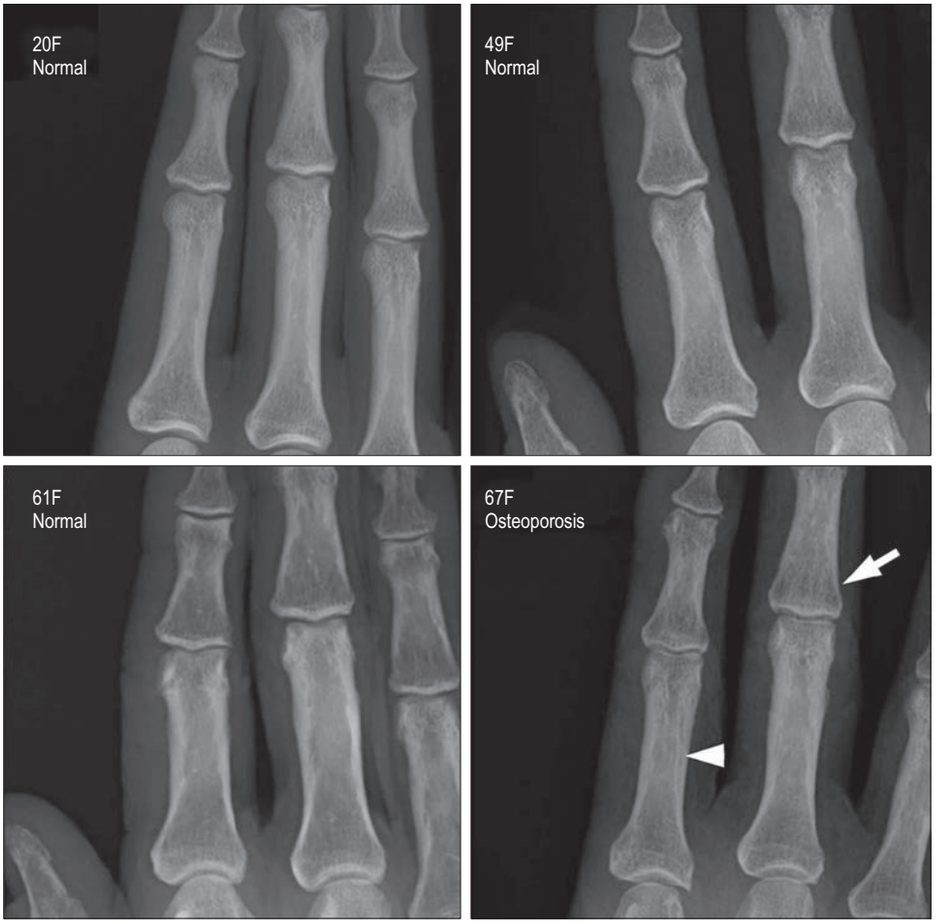

Fig. I.3.3 Conventional dorsopalmar radiographs of the proximal and middle phalanges of the right index and middle fingers of a 20-year-old female (20F) demonstrating the normal proportions of 1/3 cortex, 1/3 medulla and 1/3 cortex at the mid-diaphysis. With increasing age (49F, 61F), and with normal bone mineral density, the width of the medulla increases and the cortex decreases. In osteoporosis these normal age-related changes are accompanied by cortical tunnelling, illustrated by a longitudinal lucency in the ulnar cortex of the proximal phalanx of the index finger, and patchy secondary trabecular bone loss, best seen here at the base of the middle phalanx of the middle finger (arrows).

to the drift away from a perfect circle. During adolescence, remodelling occurs rapidly so that in the femur of a young adult the cross-section looks like a polygon closely fitted to a circle. With increasing years the cross-section becomes more ellipsoid resulting in a wider diameter bone with relatively thinner cortices (**Fig. I.3.4**) (Goldman 2009). What causes this change in shape is not understood, neither has it been associated with any adverse outcomes. This is an example of an age-related anatomical feature that, for the moment, we assume to be a 'normal' finding in the absence of evidence to the contrary.

When it comes to trabecular bone, males tend to lose bone mass diffusely across the struts that comprise the secondary trabeculae, whereas bone loss in females leads to greatly reduced trabecular connectivity (**Fig. I.3.5**) (Aaron et al 1987). The secondary trabeculae are stabilizers of the longitudinal load-bearing primary trabeculae and contribute to the toughness of bone by allowing the longitudinal trabeculae to flex without fracture under increased load. Bone loss in the secondary trabeculae has a disproportionately higher impact on fragility than loss of bone in the primary trabeculae (Pathria et al 2016) which means that it is not only the severity of bone loss, but also the distribution of that loss, that predicts the increased risk of fragility fractures in females.

Tendon

Changes in the prevalence of non-enzymatic cross-links in type 2 collagen might also account for the observation that buckling of the patellar tendon changes with age. The distal patellar tendon in particular buckles during extension of the knee; it has been suggested that this reflects a property that protects the extensor mechanism during sudden extreme contraction. The proposed effect is similar to that seen in crimping of ligament fibrils. Patellar tendon buckling is usually demonstrable at any age but the tendons of the middle-aged and elderly buckle less, and unbuckle more slowly, than those of young adults (**Fig. I.3.6**) (Slane et al 2018).

Muscle

The loss of muscle (sarcopaenia) that occurs with age has been well documented. There is a slow steady decline in muscle volume until the age of 70 and a rapid decline in the 9th and 10th decades of life (Siparsky et al 2014). This decline in muscle volume is accompanied by a loss of strength but this loss is not proportionate; the loss of strength with increasing age is greater than the loss of muscle bulk (Stenholm et al 2008). This mismatch between form and function is one of the limitations of conventional cross-sectional imaging that may be addressed by novel functional imaging techniques (**Fig. I.3.7**) (Yoon et al 2017).

Sarcopaenia is commonly seen in patients with cachexia; related to cancer, cardiovascular disease or inflammatory arthritis; or from disuse as a result of chronic pain. In all these cases, the loss of muscle volume and fatty atrophy may be indistinguishable from the effects of age, especially if combined with obesity (**Fig. I.3.8**).

It is difficult to define the limits of what constitutes a normal ageing musculoskeletal system. In fact, it may be a redundant question. Some might argue that osteoarthritis is so prevalent in old age that OA is 'normal'. Functional impairment in the musculoskeletal system is more strongly associated with psychological profiles than with any degree of joint disruption. In other words, the happier an individual is, the less likely their ageing joints will hurt. Therefore it seems rather insular to

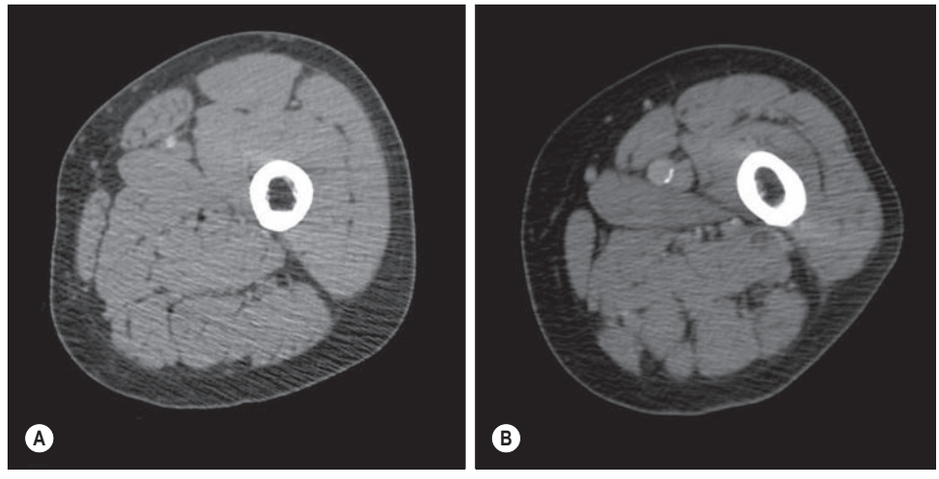

Fig. I.3.4 Axial CT through the left femur of (**A**) a 20-year-old male in whom the cross-section of the femoral diaphysis is roughly circular. In a 76-year-old male (**B**) the left femur is oval in cross-section as a result of progressive cortical drift.

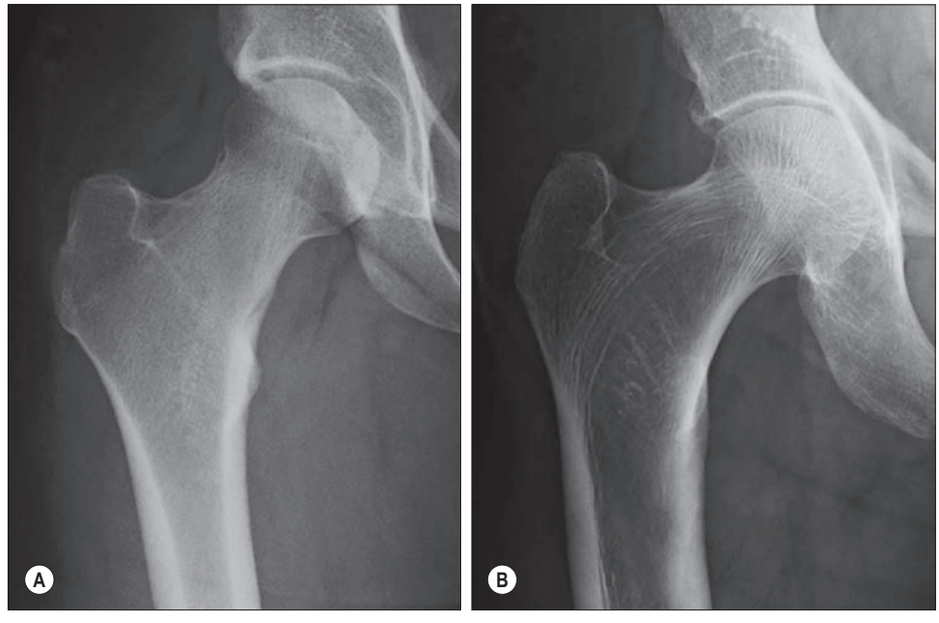

Fig. I.3.5 Anteroposterior radiographs in (**A**) 23-year-old and (**B**) 69-year-old females. The principal tensile and compressive trabeculae are easier to see in the older patient because the small horizontal secondary trabeculae have been resorbed.

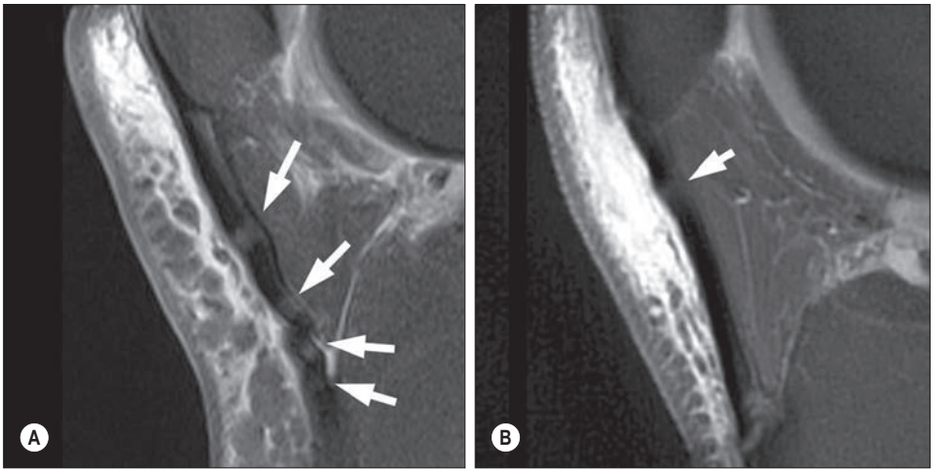

Fig. I.3.6 Sagittal fat-saturated proton density MR images in two patients with acute complete tears of the anterior cruciate ligament that produce anterior translation of the tibia and redundancy of the extensor mechanism. In the 24-year-old male patient (**A**) multiple foci of buckling of the patellar tendon (arrows) are demarcated by high signal generated by the magic-angle phenomenon. In the 46-year-old male (**B**) there is a single barely visible buckle that may reflect stiffer non-enzymatic cross-linking of collagen.

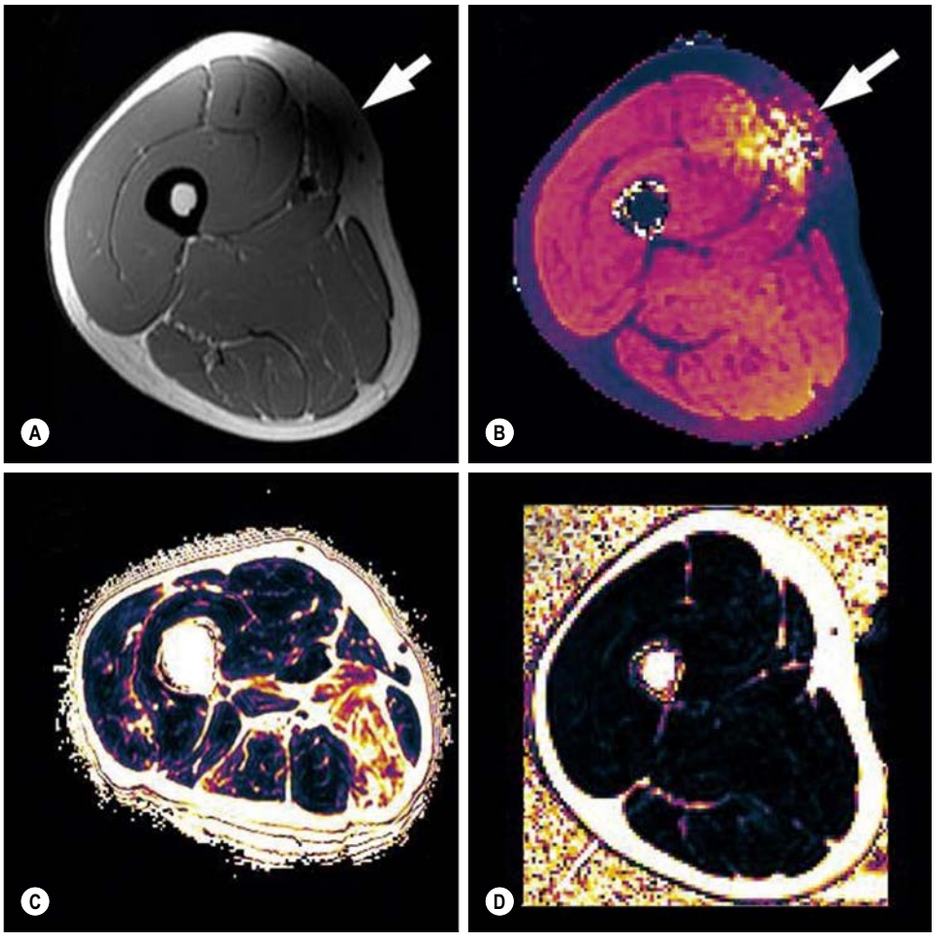

Fig. I.3.7 Axial MR images through the right thigh demonstrating (**A**) anatomy of muscle compartments using T1W, (**B**) T2 map demonstrating muscle activation and (**C–D**) fat fractionation using modified 2-point Dixon techniques. The dark area in the anteromedial thigh (arrow) in **A** and the corresponding bright area in image **B** are the result of inhomogeneity in the magnetic field of the MRI machine caused by the presence of the volunteer. (Courtesy of Dr Donnie Cameron, University of East Anglia.)

define normal anatomical appearances in the elderly without considering the context of their life experience (Creamer et al 2000). Interestingly, strength training in the very elderly has a reassuringly wide range of positive impacts on function and happiness (Marcos-Pardo et al 2018). This is a two-way street: the function of the musculoskeletal system can be dictated by our psychology and the health of the musculoskeletal system can influence our outlook on life.

The linear narrative of the ageing musculoskeletal system in which most of us progress inexorably from health to frailty does not do justice to the heterogeneity of the ageing phenotype. If evolution has selected for relatively homogeneous good health until the age of 45, progress thereafter is increasingly variable. The genes that code for good health in later years probably do not offer an evolutionary advantage and so are not propagated through future generations in favour of genes that code for poor health. Some individuals degenerate rapidly in middle age and present early in their life to radiologists with images demonstrating failure of articular cartilage, and the consequences of degenerating ligaments and tendons. A fortunate few maintain youthful joint alignment, hyaline cartilage integrity, muscle mass and connective tissue elasticity (**Fig. I.3.9**).

An often-cited challenge to clinicians is to define 'healthy ageing' (Mount et al 2016). The corollary for radiologists and anatomists is to try to define what constitutes a 'healthy' older human body. What does a normal old musculoskeletal system look like on imaging? How is that different from a patient in pain, or from someone with functional impairment, or from someone with limited quality of life scores? These are almost impossible questions to answer. Some of the strongest predictors of pain and quality of life, in a patient with a degenerative joint, are psychological status, education and wealth. An absence of pain in old age can be attributable not to 'good health' but rather to decent schooling, a good pension and a close circle of family and friends. The available measurable endpoints of healthy ageing, with which we can correlate anatomical imaging features, are multiple, variable and confounded.

For now, the available scientific methods limit us to hypothesis testing. We can compare quantitative measures of morphology on

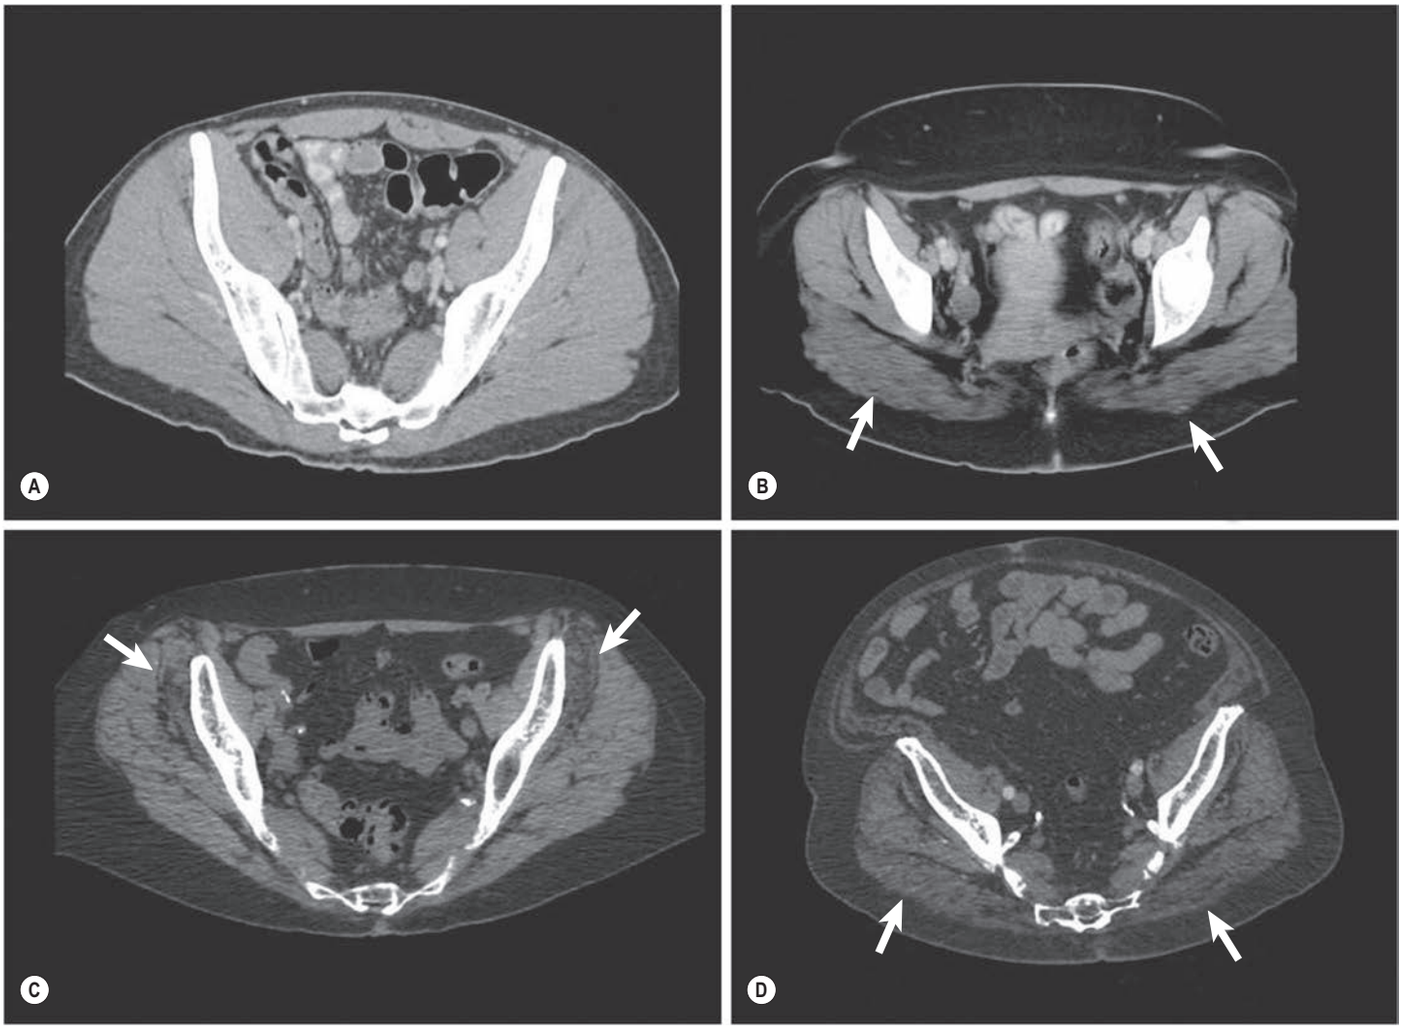

Fig. I.3.8 Axial CT images through the pelvis of a 26-year-old male (**A**) demonstrating normal homogeneous gluteal muscles as intermediate grey with thin dark lines of intermuscular fat. In a 21-year-old obese female (**B**) the gluteus maximus muscles retain their volume but are marbled with fat (arrows). In a 73-year-old female (**C**) there is fatty atrophy of the gluteus minimus muscles (arrows) associated with disuse caused by osteoarthritis of the hips. In a 72-year-old male arteriopath (**D**) with bilateral lower limb arterial claudication, there is diffuse reduction in muscle mass and fatty replacement (arrows).

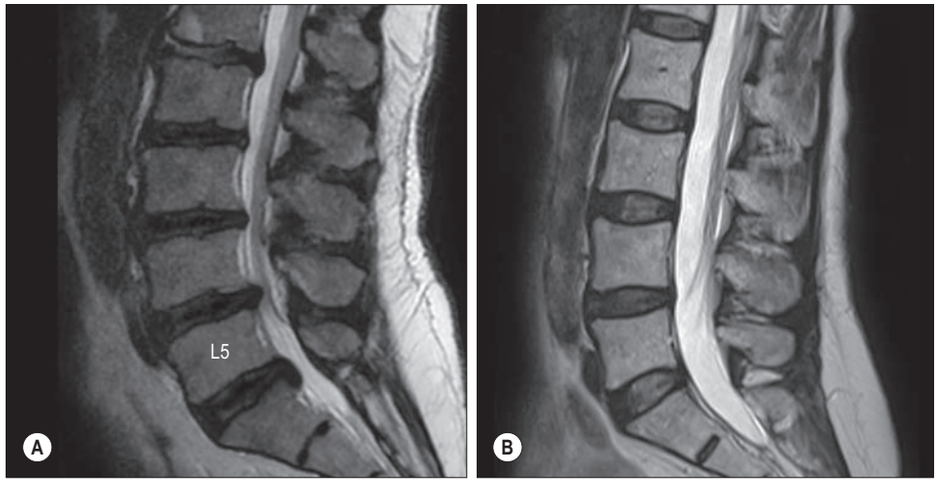

Fig. I.3.9 Sagittal T2-weighted MR images of the lumbar spine in 45-year-old (**A**) and 63-year-old (**B**) male patients. While the 45-year-old has a congenitally narrow vertebral canal and dark black degenerative intervertebral discs with herniations protruding into the canal, the older patient has normal discs and a wide, patent canal.

radiological images against measures of what the scientific community considers to be useful measures of health. We can do these in defined samples of individuals from whom we hope to extrapolate generalizable results. Each study will result in a one-dimensional outcome. In the future we may be able to take a more sophisticated approach to defining normal anatomy in the healthy ageing human. Picture Archiving and Communication Systems (PACS) are now vast archives of anatomical information in digital form. Full integration of healthcare records, including primary and secondary care clinic notes, pharmacy prescriptions and pathology reports, will allow us to data mine whole populations using machine learning algorithms overcoming the one dimensional limitations of hypothesis testing. Of course, this will only succeed if we can decide what it means to be healthy and old.

COMMENTARY

I.4

Cinematic rendering offers entirely new possibilities for studying human anatomy

Andrea Hofbauer, Klaus Engel

Medical images constitute a source of information essential for disease diagnosis, treatment and follow-up. In addition, because of its patient-specific nature, imaging information represents an important component required for advancing patient-tailored precision medicine into clinical practice. By characterizing patient anatomy, physiology and metabolism, medical imaging can enable precise, personalized procedures and predictive, patient-specific therapy selection and delivery. For this reason it is important to continue to develop means of handling image information. Cinematic rendering, a 3D visualization technology, is capable of producing high-quality photorealistic images from traditional computed tomography (CT) or magnetic resonance (MR) volume data, thus potentially enhancing the ease of viewing anatomical structures and their pathologies. These striking new visualizations could simplify communication between physicians and patients or between radiologists and referring clinicians, help surgeons select the most appropriate surgical strategy, and open up new horizons in medical training.

Medical imaging plays an increasingly important role in moving precision medicine, the science of delivering care tailored to each individual patient, into clinical practice. Efficient clinical decisions and procedures require rapid appreciation of relevant information contained within medical images. Although medical image viewing based on multiplanar reconstruction is still dominant in diagnostic imaging, the significance of 3D visualization of medical data is increasing: the methods allow a much faster understanding of the spatial relationships between anatomical structures and they have the potential to increase the sensitivity and specificity of medical image interpretation (Comaniciu et al 2016). Drs Klaus Engel and Robert Schneider (Siemens Healthineers) have developed a visualization technology, cinematic rendering (CR), that provides unprecedented photorealistic clinical images by leveraging the physics of light. Refined in collaboration with Professor Franz Fellner (Head of the Central Radiology Institute at Kepler University Hospital, Linz, Austria and extraordinary professor at the Friedrich-Alexander University Erlangen-Nuremberg (FAU)), CR is a physically based volume rendering method that provides hyper-realistic representations of, for example, fractures, organs or the structure of fine blood vessels (Berger et al 2018, Ebert et al 2017) (Fig. I.4.1).

Physically based volume visualization techniques reproduce complex illumination effects in computer-generated images by mimicking the real-world interaction of light with matter. The results are physically plausible images that are often easier for the human brain to interpret, since the brain is trained to interpret the slightest shading cues to reconstruct shape and depth information (Fig. I.4.2). Shading cues are often missing from computer-generated images based on simpler geometric calculations such as ray casting, which produce images without precisely depicted tissue depth and structure and hence less realistic 3D volume visualization (Comaniciu et al 2016) (Fig. I.4.2).

Photorealistic clinical images obtained by leveraging the physics of light

As its name suggests, CR owes its origins to film technology that enables characters to appear entirely lifelike on screen despite having been digitally added to the scenes in which they appear. Although a character is digitally modelled and post-edited into the film, its lifelike appearance is achieved via a technique known as image-based lighting, where a

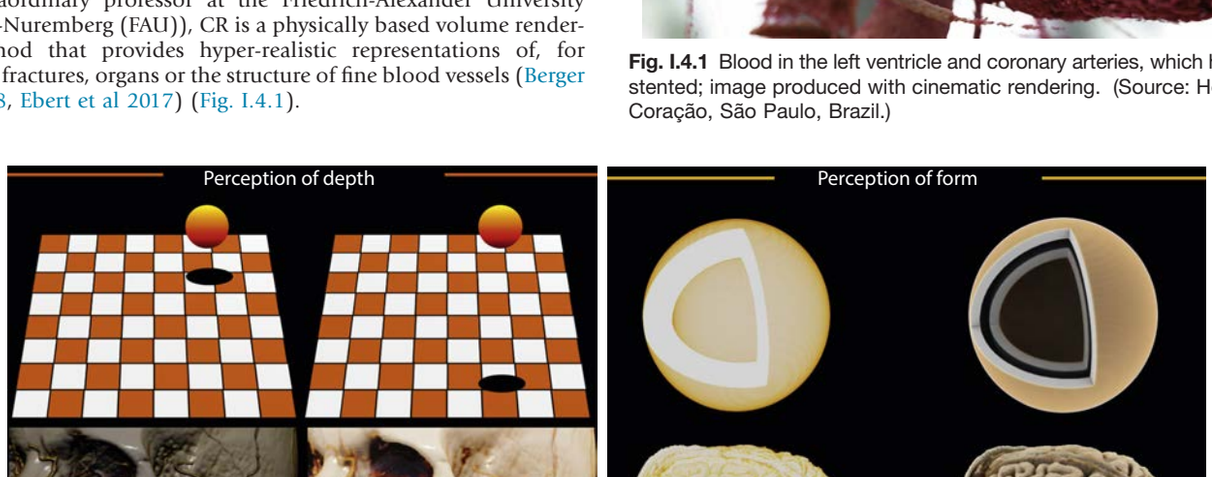

Fig. I.4.2 Traditional versus cinematic rendering. Left: Shadow effects (top) illustrate the distances between cranial bones and blood vessels (bottom). Right: Ambient light masking effects enhance the impression of cortical gyri and sulci (bottom). (Source: Stanford volume data archive/Siemens Healthineers.)

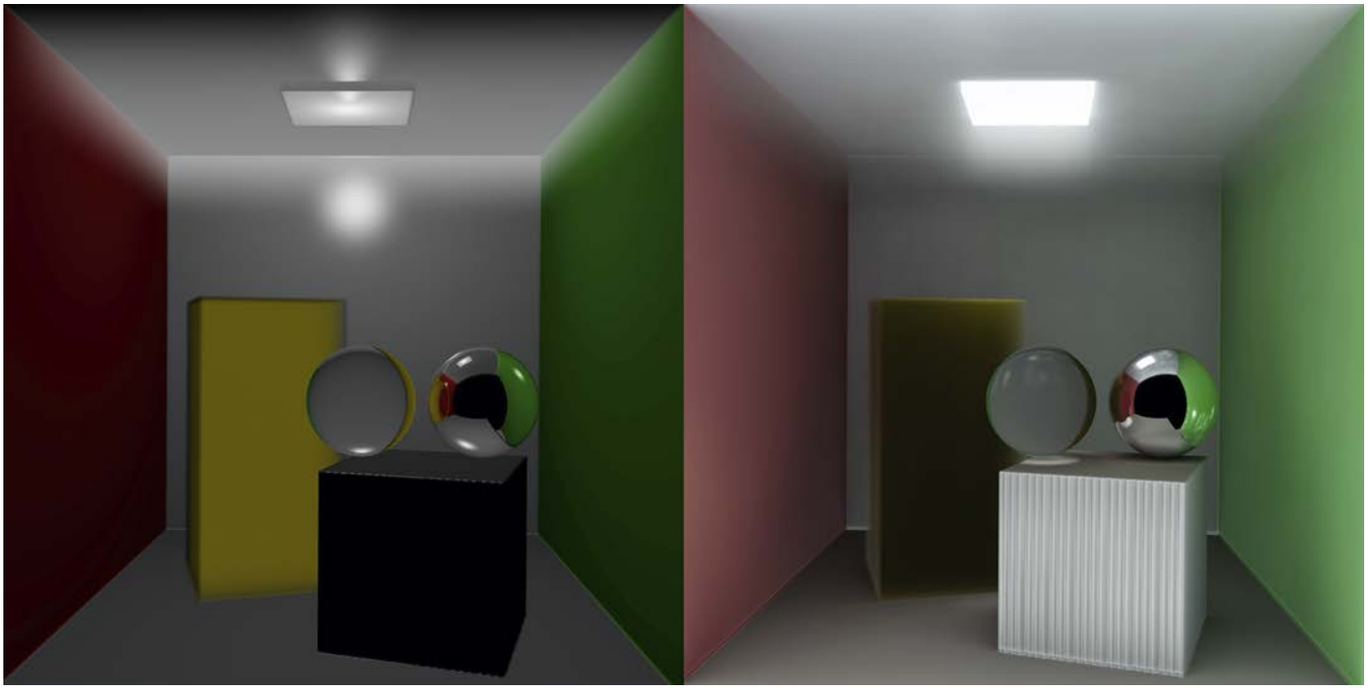

Fig. I.4.3 Volumetric Cornell Box: traditional volume rendering technology (left) versus cinematic rendering (right)**.** The consideration of light shafts, scattering, caustic reflections, ambient occlusion, colour bleeding and soft shadows enables photorealistic representations. (Source: Siemens Healthineers.)

spherical panorama is captured using a reflective sphere. The sphere records the current light environment for subsequent application to image datasets. To understand how these images are rendered, we must turn to the physics of light. Rays of light are made up of particles called photons that interact with their environment. When light encounters matter, it is reflected, bouncing off the surface in various directions: in some places it is absorbed, producing shadows. CR mimics this behaviour.

In the case of CT and MRI images, a physical rendering algorithm which uses a Monte Carlo path tracing method simulates the complex interactions between photons and the scanned images of a patient's body (Comaniciu et al 2016). Unlike the digital modelling used in cinema, CR not only calculates how light is reflected off the surface of the body but also takes into account how light penetrates tissue and is then scattered in different directions. CR generates photorealistic images by calculating realistic lighting by light transport simulation along hundreds or thousands of photon paths per pixel through the anatomical structure using a stochastic process (Fig. I.4.3). In this way, even complex effects such as ambient occlusion (the effect of how hidden a surface is from the ambient lighting) can be modelled. For example, when the depth of a fracture is fed into the calculations, the deeper the fracture, the less light is able to penetrate, resulting in a range of shadows and a more realistic depiction. Diagnostic 3D medical imaging has not previously leveraged these special characteristics of light (Comaniciu et al 2016, Eid et al 2017, Dappa et al 2016). The result is an enhanced depiction of fractures, ivory-coloured bones, and clearly defined organs and blood vessels, all of which can be more easily discerned as a result of the inclusion of shadows and the impression of depth (Fig. I.4.4A). The process requires vast amounts of computing power: depending on the image resolution, hundreds or even thousands of light paths per pixel must be calculated (Novák et al 2018). The images can be rotated on the screen as desired or zoomed in for greater detail (Fig. I.4.4B). Since rendering occurs in the postprocessing stage, the patient is not exposed to additional radiation.

Cinematic rendering in anatomical practice and education

An appreciation of spatial relationships is crucial to understand human topographical anatomy: gaining this understanding not only takes time but also differs from individual to individual (Garg et al 2001, Pandey and Zimitat 2007). CR offers new opportunities for integrating medical imaging into anatomical education from the earliest stages of medical training. Including visualization technology within a blended medical curriculum has the potential to enhance the learning experience, enabling students to gain a clearer understanding of, for example, the bronchial tree, coronary circulation, or skeletal anatomy (Fig. I.4.5) and enhancing self-study away from lecture theatres and cadaveric labs on an electronic device such as a portable tablet. By using augmented reality, virtual dissection offers the opportunity to relive and revise the whole dissection course (Binder et al 2019).

CR has been tested in the setting of an interactive anatomy lecture with first-year undergraduate medical and dental students at the Friedrich-Alexander University Erlangen-Nürnberg (FAU), Institute of Functional and Clinical Anatomy; the majority of students (95.9%) found it enhanced their understanding of anatomy (Binder et al 2019). Commenting on the didactic potential of CR, Professor Dr Michael Scholz (Anatomical Institute at FAU Erlangen) was '*…convinced that this application must and will find its way into the anatomy education in the near future*'. Since 2016, CR has also been used for anatomical teaching at the Ars Electronica Center in Linz, Austria, installed in a high-definition 8K 3D projection space, demonstrating how the study of anatomy can embrace technological learning tools in the 'dissecting theatre of the future' (Fellner et al 2017).

Cinematic rendering has the potential to become an important tool for enhancing the visualization of anatomical structures, and for facilitating the understanding of spatial relationships required in clinical practice, particularly for specialties such as surgery, radiology, orthopaedics and cardiology.

Footnote

Cinematic rendering has been used to produce the cover image of this edition of *Gray's Anatomy*, and is also demonstrated in the context of computed tomography of coronary angiography in the mapping of anomalous coronary artery circulation (see Commentary 7.2).

EPONYMS

An annotated list of eponyms, edited by Harold Ellis, was first published in the 39th edition. That list has now been updated by Susan Standring. An appropriate reference has been cited when it has not proved possible to source biographical information.

Achilles tendon: the calcaneal tendon.
Achilles, in Greek mythology, was slain by a wound in his vulnerable heel, inflicted by Paris in the Trojan War.

Adam's apple: a protrusion in the front of the throat that is part of the larynx.
According to the Old Testament, Adam was the first man.

Adamkiewicz, artery of: the largest anterior medullary feeder artery to the anterior spinal artery. It varies in level, arising from the lower (T9–11) posterior intercostal, the subcostal or, less frequently, the upper, lumbar (L1–2) arteries. Most often occurs on the left side.
Albert Adamkiewicz (1850–1921), Professor of Pathology, University of Cracow, Poland.

Addison's disease: a disease resulting from progressive destruction of the suprarenal gland with deficiency in the secretion of adrenocortical hormones.
Thomas Addison (1795–1860), English physician.

Alcock's canal: canalis pudendalis.
Benjamin Alcock (1801–1833), British anatomist who published an article in 1836 on the iliac arteries.

Allen's test: a test of sufficiency of the blood supply to the hand by compression and release of the ulnar and radial arteries, and observation of the colour change of the hand.
EV Allen (1901–1961), Professor of Medicine, Mayo Clinic, Rochester, Minnesota, USA.

Alport's syndrome: a rare hereditary condition characterized by progressive renal failure.
Arthur Cecil Alport (1880–1959), South African physician.

Alzheimer's disease: the most common form of dementia, characterized at postmortem by neurofibrillary tangles and amyloid plaques.
Alois Alzheimer (1864–1915), neurologist, Breslau, Poland.

Ammon's horn: the hippocampus. Cornu Ammonis, or Ammon's horn, describes the whorled, chambered shells of a fossil genus of Cephalopods. It also refers to the ram-shaped horns on the head of the Egyptian god Amun.

Andresen lines: structural lines within dentine, representing incremental lines that run more or less perpendicular to the direction of the tubules. They represent an incremental period of about 1 week and are best visualized when longitudinal ground sections are viewed between crossed polars.
Viggo Andresen (1870–1950), Norwegian orthodontist.

Angelman syndrome: a chromosome 15 disorder comprising microcephaly with mental and motor retardation, epilepsy, ataxic gait or complete inability to walk, muscle hypotonia, EEG abnormalities and peculiar facies marked by a protruding jaw and tongue, occipital depression and blue eyes.
Harry Angelman (1915–1996), English paediatrician.

Apert's syndrome: a complex of craniofacial abnormalities caused by premature craniosynostosis, usually of the coronal suture, leading to turribrachycephaly, associated with syndactyly and polydactyly.
Eugène Charles Apert (1868–1940), French paediatrician.

Arantius, nodule of: a small nodule in the free border of the aortic valves.
Julio Caesar Aranzio (Arantius) (1530–1589), pupil of Vesalius. Professor of Medicine and Surgery, Bologna, Italy.

Argyll Robertson pupil: a pupil that reacts to accommodation but not light. A highly specific sign in neurosyphilis but may also occur in other conditions such as sarcoidosis, multiple sclerosis, and, occasionally, diabetes mellitus.
Douglas Moray Cooper Lamb Argyll Robertson (1837–1909), ophthalmic surgeon, Edinburgh, UK. Worked in Berlin, Germany, with the German ophthalmologist Albrecht von Graefe.

Arnold: Arnold's bundle – frontopontine fibres;

innominate canal of – the canal in the petrous portion of the temporal bone that transmits the auricular branch of the vagus;

Arnold's nerve – the auricular branch of the vagus.
Friedrich Arnold (1803–1890), German anatomist.

Arnold–Chiari malformation: a congenital brainstem and cerebellar herniation through the foramen magnum.
Julius Arnold (1835–1915), Professor of Pathology, Heidelberg, Germany; Hans Chiari (1851–1916), Austrian pathologist.

Auerbach's plexus: the autonomic nervous plexus between the circular and longitudinal layers of muscle of the intestinal wall.
Leopold Auerbach (1828–1897), Professor of Neuropathology, Breslau, Poland.

Axenfeld–Rieger syndrome: an autosomal dominant disorder characterized by bilateral abnormalities of the anterior segment of the eye in association with extraocular anomalies.
Karl Theodor Paul Polykarpus Axenfeld (1867–1930), German ophthalmologist; Herwigh Rieger (1898–1986), Austrian ophthalmologist.

Babinski reflex, response, sign: an upgoing plantar response in pyramidal tract disturbances.
Joseph Babinski (1857–1922), pupil of Charcot, neurologist, Hôpital Pitié, Paris, France.

Bachmann's bundle: the intra-auricular bundle.
Jean George Bachmann (1877–1959), German–American physiologist, Professor of Physiology, Atlanta College of Physicians and Surgeons 1910–1915, USA.

Baillarger, bands, lines, striae, stripe of: inner and outer white striations on the cerebral cortex.
Jules Gabriel Baillarger (1815–1890), French neurologist and psychiatrist.

Bardet–Biedl syndrome: an autosomal recessive ciliopathy characterized by retinal dystrophy, obesity, postaxial polydactyly, renal dysfunction, learning difficulties and hypogonadism.
Georges Louis Bardet (1885–1966), French physician; Artur Biedl (1869–1933), Hungarian pathologist and endocrinologist.

Barkow, ligament of: the anterior and posterior portions of the fibrous capsule of the elbow joint.
Hans KL Barkow (1798–1873), German anatomist.

Barr body: the inactive X-chromatin mass in the nucleus of female cells.
Murray Llewellyn Barr (1908–1995), Professor of Anatomy, University of Western Ontario, Canada.

Barrett's oesophagus: abnormal columnar mucosa (Barrett's mucosa) that covers a variable length of the distal oesophagus.
Norman Rupert Barrett (1903–1979), consultant thoracic surgeon, Royal Brompton Hospital, London, UK.

Bartholin's: ducts and gland – the sublingual salivary gland and its ducts;

glands – the greater vestibular glands on either side of the vaginal orifice.
Casper Bartholin (1655–1738), Professor of Medicine, Anatomy and Physics, Copenhagen, Denmark.

Bartons' adductor cord: a dense cord on the ulnar side of the little finger that runs from the medial edge of the insertion of abductor digiti minimi (Barton NJ 1984 Dupuytren's disease arising from the abductor digiti minimi. J Hand Surg (Brit & Europ) 9:265–70).

Bassett's ligament: an accessory anterior–inferior tibiofibular ligament that presents as a low-lying slip inserted so far distally on the fibula that it may cause irritation of the lateral aspect of the talus.
Frank H. Bassett III (1928–2007), American orthopaedic surgeon.

Batson's vertebral venous plexus: the valveless vertebral venous veins that communicate with the prostatic venous plexus and explain the readiness of carcinoma of the prostate to spread to the pelvic bones and vertebrae.
Oscar Batson (1894–1979), Professor of Anatomy, University of Philadelphia, USA.

Battle's sign: bruising over the mastoid process developing 2 or 3 days after fracture of the posterior cranial fossa.
William Battle (1855–1936), surgeon, St Thomas Hospital, London, UK.

Baxter's nerve: the first branch of the lateral plantar nerve (Baxter DE, Thigpen CM 1989 Heel pain: operative results. Foot Ankle 5:16–25).
Donald E Baxter, American orthopaedic surgeon.

Beahrs' triangle: otherwise known as Riddle's triangle, the triangle is delimited by the recurrent laryngeal nerve in the tracheo-oesophageal groove, the inferior thyroid artery and the common carotid artery.
Oliver Howard Beahrs (1914–2006), American surgeon.

Bechterew, nucleus of: the nucleus centralis tegmenti superior.
Vladimir M Bekhterev (Bechterew) (1857–1927), Russian neurologist.

Becker muscular dystrophy: muscular dystrophy of the pelvis girdle type.
Peter Emil Becker (1908–2000), German human geneticist.

Beck's triad: a combination of three symptoms that characterize cardiac tamponade: high central venous pressure, low arterial pressure and a small, quiet heart.
Claude Schaeffer Beck (1894–1971), American surgeon.

Beckwith–Wiedemann syndrome: an overgrowth syndrome – main symptoms are gigantism, macroglossia and umbilical abnormalities in the newborn, enlarged liver and spleen, hyperplasia of the kidney, congenital abnormalities of the urinary tract, slight microcephaly, clonic seizures.
John Bruce Beckwith (1933–), American paediatric pathologist; Hans-Rudolf Wiedemann (1915–2006), German paediatrician.

Beighton Scoring System: a system that measures joint hypermobility on a 9-point scale.
Peter H Beighton (1934–), British medical geneticist.

Bell's muscle: a band of muscular fibres forming a slight fold in the wall of the bladder, running from the uvula vesicae to the opening of the ureter on either side, and bounding the trigonum (Fuss FK 1992 Contribution to the trigone musculature in the case of ureteral duplication. J Urol 147:1363–4).

Bell's: nerve – the long thoracic nerve;

palsy – paresis or paralysis, usually unilateral, of the facial muscles, caused by dysfunction of the facial nerve.
Sir Charles Bell (1774–1842), surgeon, Middlesex Hospital, London, UK.

Bennett shift, movement: the lateral shift of the working mandibular condyle during a laterotrusive movement.
Norman Bennett (1870–1947), British dentist.

Bergmann cells, glia: the glial cells of the cerebellum.
Gottlieb Heinrich Bergmann (1781–1861), neurologist and anatomist, Medical Director, Hildersheim Asylum, Germany.

Bernard–Horner syndrome: *see* ***Horner's syndrome***.

Bernoulli effect: the phenomenon in which fluid flowing through a tube of varying diameter travels fastest and exerts the largest lateral pressure at its narrowest point.
Jakob Bernoulli (1654–1705), mathematician, Switzerland. Shares with Isaac Newton the invention of calculus.

Berrettini branch: a superficial connection between the median and ulnar nerves, apparently displayed in an anatomical plate by Pietro Berrettini di Cortona in 1741. Similar communications are said to be shown in a print from Charles Estienne dated 1545 (Berrettini P, Petrioli CR 1741 Tabulae Anatomicae. Rome: Typographia Antonii de Rubeis: 1–4).

Berry's ligament: the thickened elastic bundle connecting the superior horn of the thyroid cartilage to the tip of the greater horn of the hyoid cartilage (synonyms: lateral thyrohyoid ligament; ligamentum thyrohyoideum laterale).
Sir James Berry (1860–1946), Canadian surgeon.

Betz cells: large pyramidal cells of the cerebral cortex.
Vladimir Aleksandrovich Betz (1834–1894), Professor of Anatomy, Kiev, Ukraine.

Bezold's abscess: subperiosteal temporal bone abscess.
Friedrich Bezold (1842–1908), otologist, Munich, Germany.

Bichat, buccal fat pad of: a variable, but usually considerable, amount of adipose tissue in the cheek. It is often encapsulated to form a biconcave mass, that is particularly evident in infants (the suctorial fat pad).
Marie-François Xavier Bichat (1771–1802), Professor of Anatomy and physician, Hôtel Dieu, Paris, France.

Bielschowsky stain: a silver stain for nerve fibres.
Max Bielschowsky (1869–1940), German neuropathologist.

Billroth, cords of: splenic cords found in the red pulp between the sinusoids.
Christian Albert Theodor Billroth (1829–1894), German-Austrian surgeon, considered to be the founder of modern abdominal surgery.

Bill's bar: a vertical crest that separates the superior fundus above the crista falciformis into anterior and posterior portions containing the facial nerve (and nervus intermedius) and the superior vestibular nerve, respectively. It is usually described as a thin layer of arachnoid tissue that may have an osseous medial component.
William Fouts House (1923–2012), American otologist, physician and medical researcher. Developed and invented the cochlear implant.

Birbeck granules: small, cross-striated granules first reported in the Langerhans cells of the epidermis.
Michael S Birbeck (1925–2005), cancer researcher, Institute of Cancer Research, London, UK.

Bland–White–Garland syndrome: an anomalous origin of the left coronary artery arising from the pulmonary artery (ALCAPA) – a rare, but serious, congenital anomaly. The first clinical description in conjunction with autopsy findings was given by Bland and colleagues in 1933 (Bland EF 1933 Congenital anomalies of the coronary arteries: report of an unusual case associated with cardiac hypertrophy. Am Heart J 8:787–801).

Blake's pouch: a temporary outpouching of the posterior membranous area continuous with the fourth ventricle; its neck becomes the foramen of Magendie (Blake JA 1900 The roof and lateral recesses of the fourth ventricle, considered morphologically and embryologically. J Comp Neurol 10:79–108).
Joseph A Blake (1864–1937), American physician.

Blaschko's lines: a pattern of cutaneous mosaicism that can be observed in a range of congenital and acquired skin conditions.
Alfred Blaschko (1858–1892), German dermatologist, Berlin, Germany.

Bloom's syndrome: an inherited disorder characterized by short stature, sun-sensitive skin changes, an increased risk of cancer, and other health problems (Bloom D 1954 Congenital telangiectatic erythema resembling lupus erythematosus in dwarfs; probably a syndrome entity. AMA Am J Dis Child 88:754–8).
David Bloom, American dermatologist.

Bochdalek, triangle of: when present, the lumbocostal triangle of Bochdalek represents a developmental defect resulting from an incomplete formation of the pleuroperitoneal membrane, located in the posterolateral respiratory diaphragm between the lumbar and costal parts, superior to the lateral arcuate ligament;

Bochdalek's hernia: a congenital diaphragmatic hernia due to failure of closure of the pleuroperitoneal hiatus.
Vincent Alexander Bochdalek (1801–1883), Czech anatomist.

Boerhaave's syndrome: spontaneous rupture of the oesophagus, first described in 1723; the patient was Baron Jan von Wassenaer, Grand Admiral of the Dutch Fleet and Prefect of Rhineland.
Herman Boerhaave (1668–1738), Dutch physician, anatomist, botanist, chemist and humanist.

Bolk's ansiform lobules: formerly known as the superior and inferior semilunar lobules in the cerebellum.
Lodewijk Bolk (1866–1930), Dutch anatomist.

Bowman's: anterior limiting lamina, layer – the anterior elastic membrane of the cornea;

capsule – the sheath surrounding the renal glomerulus;

glands – glands in the olfactory mucosa.

space – the space between the two walls of Bowman's capsule, also called the urinary space.
Sir William Bowman (1816–1892), surgeon, Birmingham General Hospital, then Professor of Anatomy and Physiology, King's College Hospital, London, UK.

Braille text: a system of writing consisting of raised dots and points, which can be interpreted by touch as letters of the alphabet.
Louis Braille (1809–1852), French teacher of the blind.

Brissaud's sulcus: the transverse parietal sulcus.
Édouard Brissaud (1852–1909), French physician and pathologist.

Broca lesion: anteroinferior detachment of the glenoid labrum (Broca A, Hartman H 1890 Contribution à l'étude des luxations de l'épaule (luxations anciennes, luxations recidivantes). Bulletins de La Société Anatomique de Paris 5, serie IV, 312–36. June 1890).
Auguste Broca (1859–1924), French orthopaedic surgeon.

Broca's: area – the speech area of the cerebral cortex;

diagonal band – a fibre tract in the basal forebrain;

plis de passage moyen de Broca – Broca described several passages or bridges connecting the frontal and parietal lobes in the vicinity of the central sulcus. The pli de passage fronto-parietal moyen is an elevation in the floor of the central sulcus at its midpoint, constant and occasionally duplicated.
Pierre Paul Broca (1824–1880), Professor of Clinical Surgery, Paris, France.

Brödel, bloodless line of: the line of division between the areas of kidney supplied by the anterior and posterior branches of the renal artery.
Max Brödel (1870–1941), medical artist, Leipzig, Germany, then Director of Institute of Art as Applied to Medicine, Baltimore, USA.

Brodmann's area 17, area 18: the primary visual cortex.
Korbinian Brodmann (1868–1918), Professor of Anatomy, Tübingen, Germany.

Brown-Séquard syndrome: an incomplete spinal cord lesion, characterized by ipsilateral upper motor neurone paralysis and loss of proprioception, as well as contralateral loss of pain and temperature sensation.
Charles E Brown-Séquard (1817–1894), French physiologist and neurologist.

Broyles ligament: the anterior commissure, commissural tendon. A band of fibrous tissue that extends from the vocal ligaments to the midline of the inner surface of the upper thyroid cartilage.
Edwin N Broyles (1894–1977), American laryngologist.

Bruch's choroidal basal lamina, membrane: the basal membrane of the choroid.
Karl Wilhelm Ludwig Bruch (1819–1884), Professor of Anatomy at Basle, Switzerland, and then Giessen, Germany.

Brunner's glands: duodenal glands lying deep to the muscularis mucosae.
Johann Konrad Brunner (1653–1727), Professor of Anatomy successively at Heidelberg, Germany, and Strasbourg, France.

Buck's fascia: the penile fascial sheath.
Gordon Buck (1807–1877), surgeon, New York, USA.

Budd–Chiari syndrome: spontaneous thrombosis (complete or partial) of the hepatic veins, with or without additional inferior vena caval thrombosis.
George Budd (1808–1882), Professor of Medicine, King's College Hospital, London, UK; Hans Chiari (1851–1916), Austrian pathologist.

Budge (and Waller), ciliospinal centre of: neurones located in the intermediolateral cell columns of the spinal cord (C8–T2) that receive a pretectal input and project to the superior cervical ganglion, and are involved in controlling the operation of the ciliary muscle. Associated with a reflex identified by Augustus Volney Waller and Ludwig Julius Budge in 1852.

Buerger's disease: thromboangiitis obliterans (an inflammatory vasculopathy).
Leo Buerger (1879–1943), Austrian-born American physician and urologist.

Buford complex: a combination of an absent anterior superior labrum and a cord-like middle glenohumeral ligament (Williams MM, Snyder SJ, Buford D 1994 The Buford complex – the cordlike middle glenohumeral ligament and absent anterosuperior labrum complex: a normal anatomic capsulolabral variant. Arthroscopy 10:241–7).
Don Buford Jr, American orthopaedic surgeon.

Büngner, bands of: columns of denervated Schwann cells
Otto von Büngner (1858–1905), German surgeon. Studied in Dorpat, Estonia and Halle, Germany, from 1877 to 1883 as a student of Eduard von Wahl (1833–1890) and Richard von Volkmann (1830–1889).

Bunnell tightness test: tests the tightness of the intrinsic muscles of the hand. The metacarpophalangeal joint is held extended by the examiner and the proximal interphalangeal joint is passively flexed. An inability to flex the latter indicates that the intrinsic muscle is foreshortened.
Sterling Bunnell, (1882–1957), American surgeon who is considered to be the 'founding father' of American hand surgery.

Burns, suprasternal space of: a slit-like interval between two layers of the deep investing fascia of the neck that are attached to the anterior and posterior borders of the manubrium. The space contains a small amount of areolar tissue, the lower parts of the anterior jugular veins and the jugular venous arch, the sternal heads of the sternocleidomastoid muscles and sometimes a lymph node.
Allan Burns (1781–1813), Scottish anatomist.

Cajal: **interstitial cells of –** cells in the muscularis externa of the gut wall active as pacemakers in gut motility;

interstitial nucleus of – group of neurones lateral to the Edinger–Westphal nucleus and ventrolateral to the periaqueductal grey in the rostral part of the midbrain within the medial longitudinal fasciculus involved in the vestibulo-ocular response, smooth pursuit and optokinetic eye movements and vertical eye movement during saccades (Cajal, S Ramón Y 1911 Histologie du système nerveux de l'homme et des vertébrés. Paris: Maloine, pp. 263–266).

Cajal–Retzius cell: 'CR cell', a class of neurones with different morphotypes that express Reln in the MZ/layer I.
Santiago Ramón y Cajal (1852–1934), Professor of Anatomy, Valencia, then Barcelona, then Professor of Histology and Morbid Anatomy, Madrid, Spain; Cajal shared the Nobel Prize in Physiology or Medicine (1906) with Camillo Golgi for their work on the structure of the nervous system. Gustav Magnus Retzius (1842–1919), Professor of Anatomy, Karolinska Institute, Stockholm, Sweden. Son of Andreas Adolf Retzius.

Caldwell–Luc procedure: an operation that involves opening the maxillary sinus by way of an incision into the supradental fossa opposite the premolar teeth, usually done to remove tooth roots or abnormal tissue.
George W Caldwell (1867–1946), American physician, writer and painter; Henri Luc (1855–1925), French laryngologist.

Calleja, islands of: aggregations of very small, densely packed granule cell neurones located in the basal forebrain of most vertebrate species. They are found in all layers of the olfactory tubercle and between the tubercle and the ventral striatum.
Julián Calleja y Sánchez (1836–1913), Spanish physician and anatomist.

Calot's triangle: an isosceles triangle based on the common hepatic duct with the cystic artery and cystic duct forming its sides.
Jean-François Calot (1861–1914), surgeon, Rothschild Hospital, Berck-sur-Mer, France. Specialized in the treatment of surgical tuberculosis in children.

Campbell's lines: five lines that should be traced when assessing a coronal radiograph of the facial skeleton (McGrigor B, Campbell W 1950 The radiology of war injuries. IV. Wounds of the face and jaw. Br J Radiol 23:685–96).

Camper's: angle – the line running from the inferior border of the ala of the nose to the superior border of the tragus of the ear;

chiasm(a) – the passage of the tendons of flexor digitorum profundus (flexor digitorum longus in the foot) through the interval left by the decussation of the fibres of the tendons of flexor digitorum superficialis (flexor digitorum brevis in the foot);

fascia – the layer of fascia extending between the ischiopubic rami inferior to sphincter urethrae and the deep transverse perineal muscle;

plane – a plane defined by the inferior border of the right or left ala of the nose and the superior border of the tragus of both ears.

Petrus Camper (1722–1789), Dutch physician and anatomist.

Cantlie's line: a line that separates the right and left lobes of the liver, drawn from the inferior vena cava to just left of the gallbladder fossa.
Sir James Cantlie (1851–1926), Scottish physician, a pioneer of First Aid, and co-founder of the Hong Kong College of Medicine for Chinese (subsequently, the University of Hong Kong).

Cantrell, pentalogy of: a syndrome of congenital defects involving the abdominal wall, sternum, diaphragm, pericardium and heart (Cantrell JR, Haller JA, Ravitch MM 1958 A syndrome of congenital defects involving the abdominal wall, sternum, diaphragm, pericardium, and heart. Surg Gynecol Obstet 107:602–14).

Carabelli's cusp, cusplet, tubercle: an occasional fifth tubercle lingual to the anteromedial cusp of the first upper molar tooth.
Edler Carabelli (1787–1842), Professor of Dental Surgery, Vienna, Austria.

Carnegie stage: not an eponym but a standardized system of 23 stages used to provide a unified developmental chronology of the vertebrate embryo.
Carnegie Institution for Science, organization established to support scientific research, Washington, DC, USA.

Carpenter's syndrome: mental retardation, acrocephaly and syndactyly related to, but genetically distinct from, Alpert's syndrome.
George Carpenter (1859–1910), physician, UK.

Carus, curve of: the lower end of the pelvic curve.
Karl (Carl) Gustav Carus (1789–1869), German anatomist, physiologist and painter.

Chamberlain procedure: anterior mediastinotomy.
J Maxwell Chamberlain (1906–1968), American thoracic surgeon.

Charcot's artery of cerebral haemorrhage: the lenticulostriate branch of the middle cerebral artery.
Jean-Martin Charcot (1825–1893), neurologist and physician, Salpêtrière, Paris, France.

Charcot–Marie–Tooth disease: an inherited disorder of nerves that is characterized by loss of muscle tissue and touch sensation, predominantly in the feet and legs.
Jean-Martin Charcot (1825–1893), French neurologist and physician, Salpêtrière, Paris, France; Pierre Marie (1853–1940), French neurologist, assistant to Charcot; Howard Henry Tooth (1856–1925), British neurologist.

Chassaignac's carotid tubercle: the prominent anterior tubercle of the transverse process of the sixth cervical vertebra, against which the carotid artery can be compressed.
Charles-Marie Édouard Chassaignac (1805–1879), surgeon, Paris, France.

Cheyne–Stokes respiration: breathing pattern characterized by alternating periods of apnoea and hyperpnoea.
John Cheyne (1777–1836), Scottish physician; William Stokes (1804–1878), Irish physician, Regius Professor of Physic at the University of Dublin.

Chiari malformation, Chiari's network: *see* ***Arnold–Chiari malformation.***
Hans Chiari (1851–1916), Austrian pathologist.

Chilaiditi's syndrome: the presence of a long mesentery related to the distal ascending and proximal transverse colon, resulting in the presence of either or both becoming interposed between the right lobe of the liver and the diaphragm, with or without abdominal symptoms.
Demetrius Chilaiditi (1883–1975), Greek radiologist in Vienna, Austria.

Chopart: joint – the transverse tarsal joint or midtarsal joint formed by the calcaneocuboid and talonavicular joints;

Chopart's ligament – the bifurcate ligament (calcaneonavicular ligament and calcaneocuboid ligament).
François Chopart (1743–1795), French surgeon. Professor of Practical Surgery at the École Pratique, Paris, France, from 1771; in 1782, he succeeded Toussaint Bordenave (1728–1782) as Chair of Physiology.

Clara cells: bronchiolar cells secreting surfactant. This is now regarded as a 'tainted eponym'. Max Clara acknowledged that the sample on which he based his work 'was obtained from a prisoner executed by the Nazi justice system'.
Max Clara (1899–1966), Professor of Anatomy, Leipzig, Germany.

Clarke's column: the basal nucleus in the posterior horn of spinal grey matter.
Jacob Augustus Lockhart Clarke (1817–1880), neurologist, Hospital for Epilepsy and Paralysis, London, UK.

Claudius' cells: supporting cells on the floor of the cochlear canal of the inner ear.
Friedrich Matthias Claudius (1822–1869), Professor of Anatomy successively in Kiel and Marburg, Germany.

Cleland's ligament, transverse retrovascular ligament: thin fibres passing from the lateral surfaces of the interphalangeal joints to the skin of the fingers.
John Cleland (1835–1925), Professor of Anatomy, Glasgow, UK.

Cloquet's node, gland: a lymph node in the femoral canal.
Jules-Germain Cloquet (1790–1883), Professor of Anatomy and Surgery, Paris, France.

Colles': fascia – a continuation of Scarpa's layer of abdominal fascia;

fracture – a fracture of the lower end of the radius with dorsal displacement.
Abraham Colles (1773–1843), Professor of Anatomy and Surgery, Royal College of Surgeons of Ireland, Dublin, Ireland.

Conn syndrome: a disorder of excessive aldosterone production.
Jerome W Conn (1907–1994), American endocrinologist.

Cooper's: pectineal ligament – thickened periosteum on the pecten pubis;

suspensory ligaments – suspensory ligaments of the breast.
Sir Astley Pastor Cooper (1768–1841), surgeon, Guy's Hospital, London, UK.

Corti: organ of, rods of – auditory hair cells of the cochlea;

tunnel of – the tunnel between the internal and external pillar cells in the inner ear.
Alfonso Corti (1822–1888), histologist. Held no academic post but worked in Vienna, Austria; Berlin, Germany; Utrecht, Netherlands; and Turin, Italy.

Cowper's glands: the bulbo-urethral glands.
William Cowper (1666–1709), British surgeon and anatomist.

Crouzon's syndrome: craniofacial dysostosis. Premature closures of cranial vault sutures, maxillary hypoplasia and ocular and aural anomalies.
Octave Crouzon (1874–1938), neurologist, Salpêtrière, Paris, France.

Cullen's sign: bluish discoloration at the umbilicus from extravasated blood in ruptured ectopic pregnancy and pancreatitis – an uncommon physical sign.
Thomas Cullen (1869–1953), Professor of Gynaecology, Johns Hopkins Hospital, Baltimore, USA.

Cunningham, sulcus precentralis medialis of: the medial precentral sulcus in the cerebral cortex.
Daniel John Cunningham (1850–1909), Scottish anatomist.

Cupid's bow: the upper curl of the lip, which resembles Cupid's bow.
Cupid, the Roman god of love, pictured as a winged boy with a bow.

Cusco's speculum: a bivalved, self-retaining speculum used to inspect the cervix.
Edward Gabriel Cusco (1819–1894), French surgeon.

Cushing's syndrome: the syndrome produced by glucocorticosteroid excess.
Harvey Cushing (1869–1939), Professor of Surgery, Harvard University, Cambridge, Massachusetts; neurosurgeon, Peter Bent Brigham Hospital, Boston, USA.

Cuvier, duct of: the termination of the cardinal vein in the fetus.
Baron Georges Cuvier (1760–1832), zoologist and palaeontologist, Paris, France.

Dandy–Walker malformation: a variant of Arnold–Chiari syndrome involving the fourth ventricle and cerebellum.
Walter Edward Dandy (1886–1946), American neurosurgeon, pioneer in surgery of the posterior skull cavity and intracranial vascular surgery; Arthur Earl Walker (1907–1995), American neurologist.

Danon disease: a condition characterized by cardiomyopathy, myopathy and intellectual disability; attributed to mutations in the *LAMP2 gene* (Danon MJ, Oh SJ, DiMauro S et al 1981 Lysosomal glycogen storage disease with normal acid maltase. Neurology 31:51–7).

Darkschewitsch, nucleus of: the posterior commissural nucleus.
Liverij Osipovich Darkschewitsch (1858–1925), neuroanatomist, University of Moscow, Russia.

Darwin's tubercle: a slight projection that may be present on the posterior superior aspect of the helix of the pinna (auricle) of the external ear.
Charles Robert Darwin (1809–1882), English naturalist, author of On the Origin of Species by Means of Natural Selection.

DeBakey classification: a system used to classify aortic dissections based upon the site of origin of the dissection. Dissections that include the aorta proximal to the left subclavian artery, with or without distal extension, are classified as type I or II. Dissections distal to the left subclavian artery are classified as type IIIa (extend to the respiratory diaphragm) or IIIb (extend below the respiratory diaphragm).
Michael Ellis DeBakey (1908–2008), American cardiovascular surgeon and pioneer in surgical procedures for treatment of defects and diseases of the cardiovascular system.

Deiters': nucleus – the lateral vestibular nucleus of the vestibulocochlear nerve;

phalangeal supporting cells – outer hair cells in the organ of Corti.
Otto Friedrich Karl Deiters (1834–1863), Professor of Anatomy and Histology, Bonn, Germany.

Delphian node: prelaryngeal (anterior to larynx) lymph node(s), located just above the thyroid isthmus. They may harbour metastatic disease and should be routinely removed as part of a central neck dissection.
Greek Oracle of Delphi, who could predict the future, because the presence of metastatic disease in these lymph nodes predicted that further nodal disease was present in the neck and that the patient had a worse cancer prognosis.

Denonvilliers' fascia: the fascia separating the prostate from the rectum.
Charles-Pierre Denonvilliers (1808–1872), Professor of Anatomy, Paris, France.

de Quervain's tenovaginitis, tenosynovitis: stenosing tenovaginitis of the tendon sheath of abductor pollicis longus and extensor pollicis brevis.
Fritz de Quervain (1868–1940), Professor of Surgery, Berne, Switzerland.

Descemet's posterior limiting lamina, layer, membrane: the posterior membrane of the cornea.
Jean Descemet (1732–1810), Professor of Anatomy and Surgery, Paris, France.

Dieulafoy lesion: rare cause of recurrent gastrointestinal bleeding from ectatic submucosal vessels in the intestinal mucosa.
Paul Georges Dieulafoy (1839–1911), French physician.

DiGeorge syndrome: a congenital disorder in which defective development of the third and fourth pharyngeal pouches results in hypoplasia or aplasia of the thymus and parathyroid glands.
Angelo Mario DiGeorge (1921–2009), American paediatrician.

Dingman approach: a popular method for repairing zygomatic complex fractures (Dingman RO, Natvig P 1964 Surgery of Facial Fractures. Philadelphia: WB Saunders).

Disse, perisinusoidal space of: the space between the venous sinusoid and the hepatic cells.
Josef Disse (1852–1912), German anatomist.

Doppler effect: a change in frequency of an incident sound (or light) wave related to the difference in velocity between the sender and receiver (Doppler CA 1843 Über das farbige Licht der Doppelsterne und einiger anderer Gestirne des Himmels. Abh Königl Böhm Ges Wiss 2:465–82).
Christian Andreas Doppler (1803–1853), Austrian mathematician and physicist.

Dorello's canal: the invagination of the dura in the petroclival region from the petroclival entrance point to the posterior end of the cavernous sinus. It conveys the mid portion of the abducens nerve.
Primo Dorello, Italian anatomist is credited with the discovery of the canal that bears his name in 1905, although it had been described in 1859 by Wenzel Leopold Gruber. Dorello was Professor of Human Anatomy at Peruggia (1926–1946).

Douglas: arcuate line of – the arcuate line of the sheath of rectus abdominis;

pouch of – the rectouterine peritoneal pouch.
James Douglas (1675–1742), anatomist and obstetrician, London, UK.

Down's syndrome: trisomy 21, producing mental retardation and a characteristic facies with variable additional abnormalities.
John Langdon Haydon Down (1828–1896), Cornish physician, UK.

Drummond, marginal artery of, arch of: the anastomoses between the ileocolic, right colic, middle colic, left colic and sigmoid arteries (the arc of Riolan is the part of this arch between the middle and left colic artery).
Hamilton Drummond (1882–1925), surgeon, Newcastle upon Tyne, UK.

Duchenne muscular dystrophy: chronic progressive muscular atrophy due to mutations in the dystrophin gene.
Guillaume Benjamin Amand Duchenne de Boulogne (1806–1875), French neurologist.

Dunbar syndrome: external compression of the coeliac trunk by the median arcuate ligament. The symptoms include abdominal pain, nausea and vomiting (aka median arcuate ligament syndrome (MALS), coeliac artery compression syndrome, coeliac axis syndrome, coeliac trunk compression syndrome, Harjola–Marable syndrome, Marable syndrome) (Dunbar JD, Molnar W, Beman FF, Marable SA 1965 Compression of the celiac trunk and abdominal angina. Am J Roentgenol Radium Ther Nucl Med 95:731–44).

Dupuytren's disease, contracture: contraction and fibrosis of the palmar (and, occasionally, the plantar) fascia.
Baron Guillaume Dupuytren (1777–1835), surgeon, Hôtel Dieu, Paris, France.

Eagle's syndrome: an elongated and/or calcified styloid process and/or a calcified stylohyoid ligament impinge on local structures, triggering sudden sharp pain, e.g. when swallowing.
Watt Weems Eagle (1898–1980), American otorhinolaryngologist.

Eberstaller: sulcus precentralis medialis of, diagonal sulcus of: (Eberstaller, O 1884 Zür Oberflachen Anatomie der Grosshirn Hemisphären. Vienna: Med. 7. Eberstaller O 1890 Das Stirnhirn. Vienna: Urban & Schwartzenberg).

Ebstein malformation: a rare congenital cardiac malformation where the septal and inferior tricuspid valve leaflets are attached abnormally deep into the right ventricular chamber.
Wilhelm Ebstein (1836–1912), German physician.

Ecker: gyrus descendens of – a gyrus that encircles the retrocalcarine sulcus;

paracentral lobule of – a division of the medial aspect of the cerebral cortex formed by the anterior and the posterior paracentral gyri. It lies above the cingulate sulcus and is bounded by the paracentral sulcus anteriorly and the marginal part of the cingulate sulcus posteriorly.
Johann Alexander Ecker (1816–1887), German anthropologist and anatomist.

Edinger–Westphal nucleus: the midbrain nucleus containing preganglionic neurones destined to synapse in the ciliary ganglion; it lies close to the nucleus of the oculomotor nerve.
Ludwig Edinger (1855–1918), Professor of Anatomy, Frankfurt-am-Main, German; Karl Westphal (1833–1890), Professor of Psychiatry, Berlin, Germany.

Ehlers–Danlos syndrome: a group of rare genetic disorders affecting humans and domestic animals, caused by a defect in collagen synthesis.
Edward Ehlers of Denmark (1863–1937) and Henri-Alexandre Danlos of France (1844–1912) identified the syndrome at the turn of the twentieth century.

Eisenmenger complex: the combination of ventricular septal defect with pulmonary hypertension and consequent right-to-left shunt through the defect, with or without an associated overriding aorta.
Victor Eisenmenger (1864–1932), German physician.

Elliot Smith, paramesial sulcus of: paramesial sulcus, certebral cortex.
Sir Grafton Elliot Smith (1871–1937), Australian anatomist.

Ellis–van Creveld syndrome: a very rare autosomal recessive skeletal dysplasia, with inter- and intra-familial variability, characterized by short ribs, short limbs, postaxial polydactyly, and dysplastic teeth and nails. Congenital heart defects occur in 60% of the individuals (Ellis RWB, van Crefeld S 1940 A syndrome characterized by ectodermal dysplasia, polydactyly, chondro-dysplasia and congenital morbus cardis. Arch Dis Child 15:65–84).

Elschnig's layer: the astroglial membrane at the optic nerve head, continuous with the internal limiting membrane of the retina.
Anton Elschnig (1863–1939), Professor, University of Prague Eye Clinic, Czech Republic.

Emery–Dreifuss muscular dystrophy: an X-linked form of muscular dystrophy (Emery AE, Dreifuss FE 1966 Unusual type of benign X-linked muscular dystrophy. J Neurol Neurosurg Psychiatr 29:338–42).

Epley's manoeuvre: canalith repositioning for benign paroxysmal positional vertigo (Epley JM 1980 New dimensions of benign paroxysmal positional vertigo. Otolaryngol Head Neck Surg 88:599–605).

Erb's point: a point on the side of the neck 2–3 cm above the clavicle and in front of the transverse process of the sixth cervical vertebra. Pressure over this point elicits Duchenne–Erb paralysis, and electrical stimulation over this area causes various arm muscles to contract.
Wilhelm Erb (1840–1921), Professor of Neurology, Heidelberg, Germany.

Erb–Duchenne paralysis: the result of injury to the C5 and C6 roots of the brachial plexus.
Wilhelm Erb (1840–1921), Professor of Neurology, Heidelberg, Germany; Guillaume Benjamin Amand Duchenne de Boulogne (1806–1875), French neurologist.

Essex–Lopresti injury: fractures of the radial head with distal radioulnar dislocation (Essex-Lopresti P 1951 Fractures of the radial head with distal radio-ulnar dislocation: report of two cases. J Bone Joint Surg Br 33:244–247).

Eustachian: tube – the pharyngotympanic tube;

valve – the inferior vena caval valve in the right atrium.
Bartolomeo Eustachi (1513–1574), Professor of Anatomy, Rome, Italy, and physician to the Pope.

Fallopian: aqueduct, canal – the canal for the facial nerve in the temporal bone;

tube – the uterine tube.

Gabrielle Fallopio (1523–1562), Professor of Anatomy, Padua, Italy. A pupil of Vesalius.

Fallot's tetralogy: a congenital heart disease comprising pulmonary stenosis, right ventricular hypertrophy, ventricular septal defect and overriding of the aorta.
Étienne-Louis Fallot (1850–1911), Professor of Medicine, Marseilles, France.

Fañanas cells: astroglial subtypes in the deeper molecular layer of the cerebellum (Fañanas JRY 1916 Contribucion al estudo de la neuroglia del cerebelo. Trab Lab Invest Biol (Madrid) 14:163–179).
Jorge Ramon y Cajal Fananas (1886–?) Spanish physician.

Ferguson reflex: enhancement of uterine activity due to mechanical stretching of the lower uterine segment and cervix (Ferguson JKW 1941 A study of the motility of the intact uterus at term. Surg Gynecol Obstet 73:359–66).
James Ferguson, Canadian obstetrician.

Fitz-Hugh–Curtis syndrome: a rare complication of pelvic inflammatory disease involving the liver capsule and leading to the creation of adhesions. Thomas Fitz-Hugh, Jr and Arthur Hale Curtis first reported this condition in 1934 and 1930, respectively.
Arthur Hale 'Art' Curtis (1881–1955), American football player, coach and gynaecologist.
Thomas Fitz-Hugh (1894–1963), American haematologist.

Fleschig's temporal knee: *see* ***Meyer's loop***.

Fordyce spots: small mucosal cysts of the cheeks, lips and tongue.
John Addison Fordyce (1858–1925), dermatologist, New York, USA.

Forel, H field of: ventral tegmental decussation between the red nuclei.
August Forel (1848–1931), anatomist and neurologist, Zurich, Switzerland.

Foville, quadrangular lobule of: the precuneus (part of the medial portion of the parietal lobe), delineated anteriorly by the marginal branch of the cingulate sulcus, posteriorly by the parieto-occipital sulcus, and inferiorly by multiple Y-shaped sulcal segments that constitute the subparietal sulcus.
Achille Louis François Foville (1799–1878), French neurologist.

Fox's sign: ecchymosis of the inguinal ligament due to blood tracking from the retroperitoneum and collecting at the inguinal ligament in haemorrhagic pancreatitis.
George Henry Fox (1846–1937), American dermatologist.

Fox–Fordyce disease: a chronic, papular disease involving apocrine sweat duct obstruction, e.g. in the axilla.
George Henry Fox (1846–1937), American dermatologist; John Addison Fordyce (1858–1925), American dermatologist (see ***Fordyce spots****).*

Freiberg's infraction: osteochondrosis of a metatarsal head, usually the second (more rarely, third or fourth) metatarsal bone of the foot, presenting the picture of subchondral cancellous bone necrosis. Characterized by localized pain and swelling over the metatarsal head, red overlying skin and limitation of movement in an adolescent. X-rays show the head to be crushed and fragmented.
Albert Henry Freiberg (1868–1940), American surgeon.

Frey's syndrome: sweating in the distribution of the auriculotemporal nerve, triggered by eating ('auriculo-gustatory sweating') after injury to the facial nerve.
Lucja Frey (1889–1944), neurologist, Warsaw, Poland.

Frohse (Fröhse), arcade of: an arcade between the two layers of supinator, that transmits the posterior interosseous nerve.
Fritz Frohse (1871–1916), German anatomist.

Fröhlich's syndrome: adiposogenital dystrophy.

Alfred Fröhlich (1871–1953), Austrian pharmacologist in the USA.

Froment's sign: weakness of adductor pollicis and the first dorsal interosseous substantially degrades pinch strength. Froment's sign is positive when a slip of paper is held in the key pinch position between the pulp of the thumb and the radial side of the index proximal interphalangeal joint, and the tip of the thumb involuntarily flexes as flexor pollicis longus contracts to compensate for the absent adductor pollicis and first dorsal interosseous.
Jules Froment (1878–1946), French neurologist.

Fruchaud, myopectineal orifice of: the surgical name given to the inferomedial aspect of the anterior abdominal wall.

Henri Rene Fruchaud (1894–1960), Professor of Clinical Surgery, Angers.

Fuchs, crypts of: large depressions often found on the anterior surface of the iris.
Ernst Fuchs (1851–1930), Austrian ophthalmologist.

Furnas' ligament: retaining ligaments of the cheek (Furnas DW 1989 The retaining ligaments of the cheek. Plast Reconstr Surg 83:11–16).

Futcher's lines: *see* ***Voigt's lines***.

Galeazzi fracture-dislocation: a fracture of the distal part of the radius with dislocation of distal radio-ulnar joint and an intact ulna.
Riccardo Galeazzi (1866–1952), Italian orthopaedic surgeon.

Galen's: nerve, anastomosis (ansa galeni) – the anastomosis between the internal branch of the superior laryngeal nerve and the recurrent laryngeal nerve in the wall of the laryngopharynx;

vein (deep galenic venous system) – the great cerebral vein.
Claudius Galen (130–200 AD), born Pergamum, Asia Minor, studied there and in Smyrna, Corinth and Alexandria. Physician to Marcus Aurelius and teacher of anatomy and medicine in Rome. Author of numerous texts on anatomy, surgery and medicine.

Gans, fissure of: a structure that lies on the undersurface of the right lobe of the liver behind the gallbladder fossa; it often marks the variable site of division of the portal pedicle to the right posterior sector.
Henry Gans (1925–2017), Dutch surgeon.

Gartner's: cyst – usually a benign cyst in the anterolateral wall of the vaginal remnant of Gartner's duct;

duct – the paravaginal duct; a mesonephric duct remnant.
Hermann Treschow Gartner (1785–1827), surgeon in the Norwegian and then Danish armies.

Gasserian ganglion: sensory ganglion of the trigeminal nerve. The ganglion was described in 1765 by Antonius Hirsh, who named it after his teacher.
Johann Lorentz Gasser (1723–1765), Austrian anatomist.

Gennari, stria of, white line of: a white band or stripe in the occipital cortex.
Francesco Gennari (1750–1797), anatomist, Parma, Italy.

Gerdy's tubercle: the attachment of the iliotibial tract to the proximal tibia.
Pierre Nicolas Gerdy (1797–1856), surgeon and pathologist, Paris, France.

Gerota's fascia: the renal fascia, which encapsulates the perinephric fat.
Dumitru Gerota (1867–1939), Professor of Surgery, Bucharest, Romania.

Geschwind's area/territory/region: a region in the inferior parietal lobule.
Norman Geschwind (1926–1984), American behavioural neurologist.

Giacomini, band of: the band on the surface of the uncus.
Carlo Giacomini (1840–1898), Professor of Anatomy, Turin, Italy.

Giemsa staining: a solution containing azure-II, glycerin and methanol. Stained elements appear pink, purple or blue.
Gustav Giemsa (1867–1948), German chemist and bacteriologist.

Gillies approach, flap, operation: a procedure in which the instrument is inserted deep to the deep lamina of temporalis fascia through a scalp incision and used to elevate depressed zygomatic complex fractures.
Sir Harold Delf Gillies (1882–1960), British plastic surgeon.

Giraldes, organ of: a vestige of the Wolffian body on the posterior aspect of the testicle.
Joaquim Albino Cardoso Casado Giraldes (1808–1875), Portuguese anatomist and surgeon.

Glanzmann's thrombasthenia: a hereditary platelet abnormality characterized by defective clot retraction, prolonged bleeding time, and related symptoms such as epistaxis and inappropriate bleeding.
Eduard Glanzmann (1887–1959), Swiss paediatrician.

Glenn shunt: a surgical operation for children born with cyanotic heart disease, in which the superior vena cava is anastomosed to the right pulmonary artery so that blood bypasses the malformed right chambers of the heart and is shunted directly into the lungs to be oxygenated.

William WL Glenn (1914–2003), Chief of Cardiovascular Surgery, Yale University, New Haven, Connecticut, USA.

Glisson's (Glissonian) capsule, sheath: the fibrous capsule of the liver.
Francis Glisson (1597–1677), Regius Professor of Medicine, Cambridge, UK. Described rickets in 1671.

Goethe, ossicle of: the incus (an auditory ossicle).
Johann Wolfgang Goethe (1749–1832), German poet, philosopher and scientist.

Goldenhaar's syndrome: hemifacial microsomia. A syndrome of dermoid cysts, auricular appendices, asymmetrical malformations of the face, and vertebral abnormalities.
Maurice Goldenhaar (1924–2001), American physician.

Golgi: cells, neurones – GABAergic cerebellar interneurones;

complexes, apparatus, bodies – membranous cellular organelles or vesicles;

corpuscles – tactile end organs in skin and muscle;

staining technique – a silver staining method for neurones;

tendon organ – a proprioceptive sensory nerve ending embedded among the fibres of a tendon.
Camillo Golgi (1844–1926), Professor of Histology and Anatomy successively in Padua and then Siena, Italy; shared the Nobel Prize in Physiology or Medicine (1906) with Ramon Santiago y Cajal for their work on the structure of the nervous system.

Goodpasture's syndrome: an autoimmune condition in which autoantibodies damage basal laminae, primarily affecting renal and lung function.
Ernest William Goodpasture (1886–1960), pathologist, Tennessee, USA.

Gorlin syndrome: nevoid basal-cell carcinoma syndrome (NBCC syndrome).
Robert J Gorlin (1923–2006), American oral pathologist and human geneticist.

Graafian follicle: the mature ovarian follicle.
Regnier de Graaf (1641–1673), Dutch anatomist and physician, Delft, Netherlands.

Grapow, vertical bands of: vertical connections between the palmar skin and palmar aponeurosis (Grapow M 1887 Die Anatomie und physiologische Anatomie der Palmaraponeurose. Arch Anat Physiol 2–3:143–58).

Gratiolet, 'pli de passage' of: Gratiolet introduced the term plis de passage for some interconnecting gyri in the cerebral cortex.
Louis-Pierre Gratiolet (1815–1865), anatomist and zoologist, became Professor of Zoology, Paris, France.

Graves' disease: a disorder of the thyroid, usually of autoimmune aetiology, characterized by at least two of the following: hyperthyroidism, goitre and exophthalmos.
Robert James Graves (1796–1853), Irish physician.

Grayson's ligament: fascial fibres that pass from the lateral sides of the phalanges volar to the neurovascular bundle (Grayson J 1941 The cutaneous ligaments of the digits. J Anat 75:164–75).
J Grayson, Professor of Anatomy, Manchester, UK.

Grey Turner's sign: bluish discoloration in the left loin caused by extravasated blood in acute pancreatitis – an uncommon physical sign.
George Grey Turner (1877–1951), surgeon, Royal Victoria Infirmary, Newcastle upon Tyne, and Professor of Surgery, Royal Postgraduate Medical School, Hammersmith, London, UK.

Gruber, petrosphenoidal ligament of: a ligament that spans between the petrous apex and the posterior clinoid process, between the meningeal and periosteal layers of the dura mater; the insertion and thickness of the ligament may vary *(see also **Dorello's canal**)*.
Wenzel Leopold Gruber (1814–1890), Russian anatomist.

Guérin's fracture: a Le Fort I level fracture of the maxilla.
Alphonse Guérin (1816–1895), surgeon, Paris, France.

Guillain–Barré syndrome: acute idiopathic polyneuritis.
Georges Guillain (1876–1951), French neurologist; Jean Alexandre Barré (1880–1967), French neurologist.

Guillain-Mollaret triangle: dentato-rubro-olivary circuit.
Georges Charles Guillain (1876–1961), French neurologist; Pierre Mollaret (1898–1987), French physician.

Guyon's canal: the canal for the ulnar nerve and vessels; defined medially by the pisiform, and posteriorly by the flexor retinaculum.
Jean Casimir Guyon (1831–1920), surgeon, Paris, France.

Haglund's disease, syndrome, deformity: an abnormal prominence of the posterior superior lateral aspect of the os calcis.
Sims Emil Patrik Haglund (1870–1937), Swedish orthopaedic surgeon.

Haller's: arches – the medial and lateral arcuate ligaments (or lumbocostal arches);

cells – infraorbital ethmoidal cells (synonym: orbitoethmoidal cells), which may be specified as either anterior or posterior and which may lie lateral to the infundibulum and then open into the middle meatus. They grow into the bony orbital floor and may obstruct the ostia of either the ethmoidal infundibulum or the maxillary sinus during endonasal procedures;

circle of, zonula of – *see **Zinn, circle of, zonula of;***

layer: a layer of large blood vessels in the choroid derived from the short posterior ciliary arteries.
Victor Albrecht von Haller (1708–1777), Professor of Anatomy, Physiology, Surgery and Botany, University of Göttingen, Germany.

Hallermann–Streiff syndrome: oculomandibulofacial syndrome.
Wilhelm Hallermann (1909–2005), German ophthalmologist; Enrico Bernardo Streiff (1908–1988), Italian-Swiss ophthalmologist.

Hallgren syndrome: *see **Usher syndrome*** (Hallgren B 1959 Retinitis pigmentosa combined with congenital deafness; with vestibulocerebellar ataxia and mental abnormality in a proportion of cases: a clinical and genetico-statistical study. Acta Psychiat Neurol Scand 138:5–101).

Harris's growth lines: transverse juxta-epiphyseal lines of long bones seen on X-ray, which represent temporary growth arrest.
Henry Harris (1886–1951), Professor of Anatomy, Cambridge, UK.

Hartmann's pouch: dilation above the neck of the gallbladder – a pathological entity produced by a contained gallstone.
Henri Hartmann (1860–1952), Professor of Surgery, Faculty of Medicine, Paris, France.

Hasner's valve: otherwise known as the plica lacrimalis, a fold of mucous membrane that forms an imperfect cover at the lower opening of the nasolacrimal duct into the inferior nasal meatus.
Joseph Hasner, Ritter von Artha (1819–1892), Austrian ophthalmologist.

Hassall's corpuscles: spherical or ovoid bodies found in the medulla of the thymus, composed of concentric arrays of epithelial cells that contain keratohyalin and bundles of cytoplasmic filaments.
Arthur Hill Hassall (1817–1894), English chemist and physician.

Haversian: canals – central vascular channels in Haversian systems;

systems – cylindrical units of tissue (osteons) in compact bone.
Clopton Havers (1817–1894), physician practising first in London, then in the Isle of Wight, UK.

Hawkins sign: subchondral lucency of the talar dome, occurring secondary to subchondral atrophy 6–8 weeks after a fracture of the talar neck (Hawkins LG 1970 Fractures of the neck of the talus. J Bone Joint Surg Am 52:991–1002).

Heidenhain's trichrome stain: a stain for connective tissue.
Rudolf Peter Heinrich Heidenhain (1834–1897), Polish physiologist, Breslau.

Heller's myotomy, cardiomyotomy: a surgical procedure in which the muscles of the cardia (lower oesophageal sphincter) are cut, allowing food and liquids to pass to the stomach; the procedure may be open or closed (laparoscopic) (Heller E 1914 Extramuköse Kardioplastik beim chronischen Kardiospasmus mit Dilatation des Oesophagus. Mitt Grenzgeb Med Chir 27:141–9).
Ernest Heller (1877–1964), German surgeon.

Henle's: accessory parafloccculus of Henle – the dorsal leaf of the cerebellar flocculus;

conjunctival crypts of Henle – infoldings of the conjunctiva;

fibres – the 'axons' of foveal retinal cones running parallel to the retinal surface;

gastrocolic trunk of Henle – the confluence of the right superior colic and right superior gastroepiploic veins, draining into the superior mesenteric vein at the inferior border of the neck of the pancreas;

layer – the outer layer of cells in the root sheath of a hair;

loop of Henle – the looped portion of the renal tubule.
Friedrich Gustav Henle (1808–1885), Professor of Anatomy in Zurich, Switzerland, then Heidelberg and Göttingen, Germany.

Henry: anterior approach of – an approach that provides exposure to the volar aspect of the radial shaft;

knot of – the crossing of the tendon of flexor hallucis longus deep to the tendon of flexor digitorum longus in the sole of the foot;

mobile wad of – three muscles, brachioradialis, extensor carpi radialis longus and extensor carpi radialis brevis, that are palpable below the lateral epicondyle of the humerus, lying on the lateral aspect of the radius.
Arnold Kirkpatrick Henry (1886–1962), Professor of Anatomy, Royal College of Surgeons in Ireland, Dublin, Ireland.

Hensen's: cells, stripe – in the ***organ of Corti*** *(see above)* to the outer side of the ***cells of Deiters*** *(see above)*;

node – thickening at the site of the first formation of the primitive streak.
Viktor Hensen (1834–1924), Professor of Physiology, Kiel, Germany.

Hering–Breuer reflex: a lung stretch reflex mediated by the vagus.
Carl Ewald Hering (1834–1918), physiologist, Academy of Military Medicine, Vienna, Austria, and then Leipzig, Germany; Josef Breuer (1842–1925), psychiatrist and physiologist, Vienna, Austria, where he collaborated with Hering.

Hering, canals of: fine terminal ductules lined by cuboidal epithelium, linking the intralobular bile canaliculi with bile ducts in the portal canals.
Carl Ewald Hering (see above).

Heschl: sulcus of – the anterior border of the planum temporale;

Heschl's transverse temporal gyri – gyri on the temporal lobe of the brain.
Richard Heschl (1824–1881), Professor of Pathology, Cracow, Poland, then Professor of Clinical Medicine, Graz, Austria.

Hesselbach's: fascia – the cribriform fascia;

ligament – the interfoveolar ligament;

triangle – the inguinal triangle.
Franz Kaspar Hesselbach (1759–1816), German surgeon and anatomist.

Heubner's artery: the artery that supplies the anteromedial part of the head of the caudate nucleus and the anteroinferior internal capsule.
Johann Otto Leonhard Heubner (1843–1926), German paediatrician.

Heuser's membrane: the parietal hypoblast layer.
Chester Heuser (1885–1965), American embryologist.

Hill–Sachs lesion: cortical depression of the posterolateral head of the humerus related to impaction of the humeral head with the inferior glenoid fossa in anterior shoulder dislocation.
Harold Arthur Hill (1901–1973), American radiologist; Maurice David Sachs (1909–1987), American radiologist.

Hilton's law: nerves crossing a joint supply the joint, the muscles acting on the joint and the skin overlying the joint.
John Hilton (1805–1878), surgeon, Guy's Hospital, London, UK.

Hirschsprung's disease: megacolon resulting from congenital absence of autonomic ganglion cells in the distal contracted segment.
Harald Hirschsprung (1830–1916), physician, Queen Louise Children's Hospital, Copenhagen, Denmark.

His: angle of – the normally acute angle between the abdominal oesophagus and the fundus of the stomach at the oesophagogastric junction;

bundle of – the atrioventricular bundle of the heart;

furcula of – an inverted U that appears in the central wall of the developing pharynx;

sinus of – the caudal portion of the second branchial arch, as well as the third and fourth arches, which becomes submerged in the cervical sinus of His, a shallow ectodermal pit.
Wilhelm His (Junior) (1863–1934), Professor of Anatomy successively at Leipzig, Germany; Basle, Switzerland; and Göttingen and Berlin, Germany. Son of Wilhelm His (Senior).

Hitselberger's sign: loss of sensation in the posterosuperior part of the external acoustic meatus (external auditory canal) that may be an early sign of an acoustic tumour.
William E Hitselberger (1930–2014), American neurosurgeon, a pioneer in developing the auditory brainstem implant.

Hjortsjö's crook: in the biliary tract, the right posterior sectional duct normally hooks over the origin of the right anterior sectional portal vein, forming 'Hjortsjö's crook' (Hjortsjö CH 1951 The topography of the intrahepatic duct system. Acta Anat (Basel) 11:599–615).

Hoboken, valves of: constrictions of the contours of the umbilical arteries along their course through the umbilical cord.
Nicolas van Hoboken (1632–1678), Professor of Anatomy, Harderwyk, then Professor of Medicine and Mathematics, Steinfurt, Netherlands.

Hodgkin's lymphoma: a haematopoietic neoplasm characterized by cancerous Hodgkin and Reed–Sternberg cells (HRS cells) in an inflammatory background. The aetiology of the disease is not well understood.
Thomas Hodgkin (1798–1866), English physician and pathologist.

Hofbauer cells: placental macrophages in the chorionic villi.
J Isfred Hofbauer (1878–1961), American gynaecologist.

Holden, line of: the transverse skin crease at the groin caused by flexion of the hip.
Luther Holden (1815–1905), surgeon, St Bartholomew's Hospital, London, UK.

Holmes tremor: a tremor that is usually slow and large in amplitude, and may be present at rest, with movement, and often with sustained posture.
Gordon Morgan Holmes (1876–1965), British neurologist.

Holmes–Adie syndrome: a disorder characterized by one eye with a pupil that is larger than normal and constricts slowly in bright light (tonic pupil), and absence of deep tendon reflexes, usually in the Achilles tendon.
Gordon Morgan Holmes (1876–1965), Irish neurologist; William John Adie (1886–1935), British physician and neurologist.

Hopkinson squeeze test: a test to assess the inferior tibiofibular joint, by compressing the fibula to the tibia at the midpoint of the leg: an injured syndesmosis will result in pain felt in the area of the inferior tibiofibular joint (Hopkinson WJ, St Pierre P, Ryan JB et al 1990 Syndesmosis sprains of the ankle. Foot Ankle 10:325–30).

Horner's syndrome, Bernard–Horner syndrome: ptosis and pupillary constriction following interruption of the sympathetic supply to the eyelid and pupil, respectively (hemifacial anhidrosis may also occur).
Johann Horner (1831–1886), Professor of Ophthalmology, Zurich, Switzerland; Claude Bernard (1813–1878), French physiologist, considered one of the founders of experimental medicine.

Hotchkiss approach: anteromedial 'over the top' surgical approach to the elbow performed between flexor carpi ulnaris and flexor carpi radialis (or palmaris longus, when present); it provides good access to the tip of the coronoid process and the whole anterior elbow joint (Hotchkiss R 1998 Surgical technique. In: Hotchkiss R (ed) Compass Universal Hinge. Surgical Technique. Memphis: Smith & Nephew, 8–12).
Robert N Hotchkiss, American orthopaedic surgeon.

Houston, valves of: three intraluminal folds in the wall of the rectum.
John Houston (1802–1845), Irish surgeon and anatomist.

Howship's lacunae: absorption spaces in bone.
John Howship (1781–1841), surgeon, St George's and Charing Cross Hospitals, London, UK. Suffered from osteomyelitis of the tibia and made a special study of bone pathology.

Howship–Romberg sign: *see* ***Romberg sign.***

Humphrey, ligament of: meniscofemoral ligament – Humphrey described this ligament as running from the lateral meniscus to the posterior cruciate ligament.
George Murray Humphrey (1820–1896), Professor of Anatomy and then of Surgery, Cambridge, UK. Founder of Journal of Anatomy.

Hunter's canal: the subsartorial canal.
John Hunter (1728–1793), surgeon, St George's Hospital, London, UK. Described ligation of the femoral artery in the subsartorial canal for popliteal aneurysm. John Hunter is often described as the Founder of Scientific Surgery.

Huntington's disease, chorea: an autosomal dominant disease characterized by chronic progressive chorea and mental deterioration.
George Sumner Huntington (1850–1916), American physician.

Hurler's syndrome: a genetic disorder resulting in a deficiency in breakdown of mucopolysaccharides in the extracellular matrix.
Gertrud Hurler (1889–1965), German paediatrician.

Huschke: foramen of – otherwise known as the foramen tympanicum. An uncommon developmental defect in the anteroinferior aspect of the bony external acoustic meatus. which usually closes by the fifth year but may persist throughout life;

inferior longitudinal sulcus of – (synonym: collateral sulcus) a structure that separates the fusiform gyrus from the parahippocampal gyrus of the limbic lobe.
Emil Huschke (1797–1858), German anatomist and embryologist.

Hutchinson's incisors: pegged lateral incisors and notched central incisors, seen in congenital syphilis.
Sir Jonathan Hutchinson (1828–1913), British surgeon, pathologist, pioneer in the study of congenital syphilis.

Huxley's layer: the inner layer of cells of the root sheath of a hair.
Thomas Henry Huxley (1825–1895), lecturer in Natural History, Royal School of Mines, UK. An early supporter of Darwinism.

Hyrtl's anastomosis: an occasional anastomosis between umbilical arteries in the placenta.
Joseph Hyrtl (1811–1894), Austrian anatomist.

Jackson's membrane: a peritoneal fold between the caecum or ascending colon and the lateral abdominal wall.
Jabez North Jackson (1868–1935), Professor of Anatomy and Surgery, Kansas City, USA.

Jacobson's organ: otherwise known as the vomeronasal organ. A bilateral structure in the anteroinferior wall of the nasal septum just dorsal to the paraseptal cartilages, presumed to be analogous to the vomeronasal organ of other vertebrates: function in humans not yet established, but might be involved in the detection of pheromones.
Ludwig Lewin Jacobson (1783–1843), Danish surgeon.

Jacoby, border tissue of: a posterior extension of astrocytes from the intermediary tissue of Kuhnt, located internal to the border tissue of Elschnig at the optic nerve head (Jacoby E 1905 Über die Neuroglia des Sehnerven. Klin Mbl Augenheilk 43:129–37).

Jadassohn–Lewandowsky syndrome: an autosomal dominant skin disorder characterized predominantly by thickened nails, palmoplantar hyperkeratosis, keratosis pilaris, hyperkeratotic follicular papules on the sites of friction, hair abnormalities and hyperhidrosis of the palms and soles (Jadassohn J, Lewandowsky F 1906 Jacob's Ikonographia Dermatologica. Berlin: Urban & Schwarzenberg).

Jensen, intermediate sulcus of: a downward-projecting side branch of the intraparietal sulcus that descends across the inferior parietal lobule. It starts at the dorsal hemispheric margin and divides the area between the posterior ascending ramus of the Sylvian gyrus and the angular gyrus as it courses ventrally (Jensen J 1870 Die Furchen und Windungen der menschlichen Grosshirn-Hemisphären. Berlin: Georg Reimer).

Jeune syndrome: asphyxiating thoracic dystrophy (Jeune M, Carron R, Beraud C et al 1954 Polychondrodystrophie avec blocage thoracique d'évolution fatale. Pediatrie, Lyon 9:390–2).
Mathis Jeune (1910–1983), French paediatrician.

Joll's triangle: otherwise known as the sternothyrolaryngeal triangle and used to identify the external laryngeal branch of the superior laryngeal nerve during thyroid surgery, the triangle is formed laterally by the upper pole of the thyroid gland and the superior thyroid vessels, superiorly by the attachment of the strap muscles to the thyroid cartilage and medially by the midline.
Cecil Augustus Joll (1885–1945), English surgeon.

Joubert's syndrome: a ciliopathy, one of a group of rare genetic disorders characterized by decreased muscle tone, difficulties with coordination, abnormal eye movements, abnormal breathing pattern and cognitive impairment (Joubert M, Eisenring JJ, Robb JP et al 1969 Familial agenesis of the cerebellar vermis. A syndrome of episodic hyperpnea, abnormal eye movements, ataxia, and retardation. Neurology 19:813–25).
Marie Joubert, paediatric neurologist.

Kager's fat pad: (synonym: pre-Achilles fat pad) a structure located in Kager's triangle between the Achilles tendon, the superior cortex of the calcaneus and flexor hallucis longus (both muscle and tendon) (Kager H 1939 Zur Klinik und Diagnostik des Achillessehnenrisses. Der Chirurg 11:691–5).

Kartagener's syndrome: a genetic disorder (immotile cilia syndrome) affecting axonemal dynein function.
Manes Kartagener (1897–1975), Swiss physician.

Kawase's triangle of the middle fossa: an area that lies between the lateral margin of the greater petrosal nerve (medial border), the lateral edge of the trigeminal nerve behind the point where the greater petrosal nerve passes below its lateral surface to the crest of the petrous apex (lateral border), and a line along the connection of the posterior border of the mandibular division of the trigeminal nerve and the trigeminal ganglion (the crest of petrous apex) to the centre of the geniculate ganglion (Kawase T, van Loeren HR, Keller JT et al 1996 Meningeal architecture of the cavernous sinus: clinical and surgical implications. Neurosurg 39:527–36).

Keen approach: Keen categorized zygomatic fractures as those of the arch, the body or the sutural disjunction. He was the first to introduce an intraoral approach to the zygomatic arch, in which an incision is made in the gingivobuccal sulcus (Keen WW 1909 Surgery: Its Principles and Practice. Philadelphia: WB Saunders).

Kehr's sign: the occurrence of acute pain in the tip of the shoulder due to the presence of blood or other irritants in the peritoneal cavity when an individual is lying down and the legs are elevated. Kehr's sign in the left shoulder is considered a classic symptom of a ruptured spleen.
Johannes Otto Kehr (1862–1916), German surgeon.

Kerckring: valves of – the plicae circulares;

Kerckring's centre – an occasional independent centre of ossification in the occipital bone.
Theodor Kerckring (1640–1693), Dutch anatomist.

Kienböck's disease: slowly progressing degeneration of the lunate bone of the wrist.
Robert Kienböck (1871–1953), Austrian radiologist.

Kiesselbach's plexus: a site of haemorrhage on the nasal septum.
Wilhelm Kiesselbach (1839–1902), ear, nose and throat surgeon, Erlangen, Germany.

Killian's: dehiscence – a gap between the attachments of the inferior constrictor of the pharynx to the cricoid and thyroid cartilages. Site of origin of a pharyngeal pouch;

sling – the cricopharyngeal sphincter;

triangle – a triangular area in the wall of the pharynx between the oblique fibres of the inferior constrictor muscle and the transverse fibres of cricopharyngeus, through which a Zenker's diverticulum may occur.
Gustav Killian (1860–1921), Professor of Laryngorhinology, successively in Freiburg and Berlin, Germany.

Kindler's syndrome: congenital poikiloderma with bullae and progressive cutaneous atrophy.
Theresa Kindler (1890–1975), Austrian-born dermatologist.

Kirk's arcade: an anastomosis between branches of the dorsal pancreatic artery and the right gastro-epiploic artery (Kirk E 1931 Untersuchungen über die gröbere und feinere topographische Verteilung der Arterien, Venen und Ausführungsgänge in der menschlichen Bauchspeicheldrüse. Z Ges Anat 94:822–75).

Klingler's method/technique: a method of brain fixation and dissection based on freezing and thawing the brain and subsequently peeling away tissues to expose white matter tracts (Agrawal A, Kapfhammer JP, Kress A et al 2011 Josef Klingler's models of white matter tracts: influences on neuroanatomy, neurosurgery, and neuroimaging. Neurosurgery 69:238–52).
Josef Klingler (1888–1963), Swiss neuroanatomical 'technician'.

Klippel–Feil syndrome: congenital fusion or reduction in number of the cervical vertebrae.
Maurice Klippel (1858–1942), neurologist, Salpêtrière, Paris, France; André Feil (1884–1955), French neurologist.

Klippel–Trenaunay syndrome: a rare congenital condition where blood vessels and/or lymph vessels fail to form properly.
Maurice Klippel (1858–1942), French physician; Paul Trénaunay (1875–?), French neurologist.

Klumpke's paralysis: injury to lowest root of brachial plexus (T1).
Augusta Déjerine-Klumpke (1859–1927), neurologist, Paris, France. Married to another neurologist, Joseph Déjerine.

Koch, triangle of: a triangular area in the wall of the right atrium that marks the site of the atrioventricular node.
Walter Karl Koch (1880–1962), physician and pathologist, Berlin and Freiburg, Germany.

Kocher's manoeuvre, method: an invagination method for radical operation for an inguinal hernia.
Theodor Kocher (1841–1917), made numerous contributions to surgery. Awarded Nobel Prize in Medicine or Physiology (1909) for his pioneering work on physiology, pathology and surgery of the thyroid gland.

Köhler's disease: avascular necrosis of the tarsal navicular bone and, less frequently, the patella, possibly due to repetitive compressive forces that cause a loss of blood supply and fragmentation in a

bone that is not fully ossified. More common in males; onset at 3–8 years of age. Asymptomatic or painful on the medial side of the foot; tenderness on palpation and swelling over area of navicular bone; slight, usually unilateral, limp.
Alban Köhler (1874–1947), German radiologist.

Kohn, interalveolar pores of: pores that link adjacent alveolar air spaces of the lung.
Hans Kohn (1866–1935), pathologist, Berlin, Germany.

Kölliker–Fuse nucleus: the substantia intermedia centralis in the spinal cord.
Rudolf Albert von Kölliker (1817–1905), Swiss anatomist.

Kommerell, diverticulum of: an aortic diverticulum associated with an aberrant right subclavian artery.
Burckhard Friedrich Kommerell (1901–1990), German radiologist.

Kooy, dorsal cap of – a subnucleus of the inferior olive: processes optokinetic information and projects to the contralateral flocculus and nodulus (Kooy FH 1916 The inferior olive in vertebrates. Thesis, Haarlem: Erven Bohn; Kooy FH 1917 The inferior olive in vertebrates. Folia Neurabiol 10:205–369).

Körner's septum: a dense bony plate in the mastoid process that represents the persistence of the petrosquamous suture line. The septum divides the mastoid process into a superficial squamous portion and a deep petrous portion (Korner O 1926 Das Septum petrosquamosum (mastoideum) und seine klinische Bedeutung. Arch Ohren Nasen Kehlkopfheilk 17:137).

Korsakoff psychosis, syndrome: a syndrome of anterograde and retrograde amnesia with confabulation, associated with alcoholic or non-alcoholic polyneuritis, described as 'cerebropathia psychica toxaemia' by Korsakoff; currently used synonymously with 'amnestic syndrome'.
Sergei Sergeievich Korsakoff (1854–1900), Russian neuropsychiatrist.

Kraissl's lines: the lines of greatest tension in the skin.
Cornelius Kraissl (1902–1999), plastic surgeon, New Jersey, USA.

Krause, glands of: accessory lacrimal glands in the subconjunctival tissue of the upper fornix.
Karl Friedrich Theodor Krause (1797–1868), Professor of Anatomy, Hanover, Germany.

Krebs' cycle: the citric acid cycle – the oxidative energy production pathway in mitochondria.
Sir Hans Adolf Krebs (1900–1981), German-born British biochemist.

Kugel's anastomotic artery: the arteria anastomotica auricularis magna (synonym: atrial anastomotic branch of circumflex branch of left coronary artery) (Kugel MA 1927 Anatomical studies on the coronary arteries and their branches. I. Arteria anastomotica auricularis magna. Am Heart J 3:260–70).

Kuhn classification: a classification of frontal ethmoidal cells into types 1 to 4 (Kuhn FA 1996 Chronic frontal sinusitis: the endoscopic frontal recess approach. Oper Techn Otolaryngol Head Neck Surg 7:222–9).

Kuhnt: central tissue meniscus of – a thickening of the astroglial membrane (of Elschnig) covering the optic nerve head at the centre of the disc;

intermediary layer of, intermediary tissue of – a collar of astrocytes that separates the optic nerve head from the retina.
Hermann Kuhnt (1850–1925), German ophthalmologist.

Kulchitsky cells: neuroendocrine cells in the lung and gut.
Nicholas Kulchitsky (1856–1925), Professor of Histology, Kharkov, Russia. After the Russian Revolution, went to London, UK, to continue his work in neuropathology at University College.

Kuntz, nerve of: an inconstant intrathoracic ramus that joins the second intercostal nerve to the ventral ramus of the first thoracic nerve, proximal to the point where the latter gives a branch to the brachial plexus.
Albert Kuntz (1879–1957), American anatomist.

Kupffer cells: resident liver macrophages.
Karl Wilhelm von Kupffer (1829–1902), Professor of Anatomy successively at Kiel, Königsberg and Munich, Germany.

Labbé, inferior anastomotic vein of: a vein that connects the superficial middle cerebral vein to the transverse sinus.
Léon Labbé (1832–1916), French surgeon.

Ladd's bands: congenital bands across the duodenum in volvulus neonatorum.
William Edward Ladd (1880–1967), surgeon, Boston Children's Hospital, USA.

Laimer's: diverticulum – a pulsion diverticulum located below cricopharyngeus;

triangle – *see* ***Killian's triangle.***
Eduard Laimer (1857–1934), anatomist, Graz, Austria.

Lancisi, muscle of: the main medial papillary muscle of the right ventricle (quoted in: Tandler J 1913 Anatomie des Herzens. In: Bardeleben's Handbuch der Anatomie des Menschen. Jena: Gustav Fischer).
Giovanni Maria Lancisi (1654–1720), Italian physician, epidemiologist and anatomist.

Landsmeer's ligaments: the transverse and oblique retinacular ligaments of the fingers.
Johan Landsmeer (1919–1999), Professor of Anatomy, Leiden, Netherlands.

Langer's lines: cleavage or crease lines in the skin produced by the arrangement of the subcutaneous fibrous tissues.
Karl Ritter von Edenberg Langer (1819–1887), Professor of Anatomy, Hungary, and then Vienna, Austria.

Langerhans: cells – dendritic cell of haemopoietic origin, in the epidermis and other epithelia;

islets of – clumps of insulin- and other hormone-secreting cells of the pancreas.
Paul Langerhans (1847–1888), Professor of Pathology, Freiburg, Germany. Described the islet cells in his doctoral thesis in 1869, at the age of 22.

Langhans cells: cells of the villous cytotrophoblast.
Theodor Langhans (1839–1915), pathologist, Berne, Switzerland.

Laplace's equation: the prototypical elliptic partial differential equation.
Pierre-Simon Laplace (1749–1827), French mathematician and astronomer.

Ledderhose's disease: plantar fascial fibromatosis.
Georg Ledderhose (1855–1925), German surgeon. Discovered glucosamine while working on cartilage with Ernst Felix Immanuel Hoppe-Seyler (1825–1895) in Strasbourg, France.

Le Fort I, II and III fractures: a system of classification of facial fractures.
René Le Fort (1869–1951), surgeon, Lille, France.

Legueu and Juvara, vertical septa of: vertical septa that pass from the transverse fibres of the palmar aponeurosis to the underlying deep transverse metacarpal ligament, forming fibro-osseous compartments (Legueu F, Juvara E 1892 Des aponévroses de la paume de la main. Bull Soc Anat Paris 6:383–400).

Leydig cells: the interstitial testosterone-secreting cells of the testis.
Franz von Leydig (1821–1908), Professor of Histology successively at Würzburg, Tübingen and Bonn, Germany.

Lieberkühn, crypts of: tubular glands of the small intestine.
Johann Nathaniel Lieberkühn (1711–1756), physician and anatomist, Berlin, Germany. These glands were described in 1688 by Marcello Malpighi (1628–1694), Italian physician and biologist, often cited as 'the father of microscopical anatomy and histology'.

Li Fraumeni syndrome: a rare autosomal dominant cancer predisposition syndrome first reported in 1969 by Frederick Li and Joseph Fraumeni from the National Cancer Institute, Rockville, Maryland, USA (Li FP, Fraumeni JF Jr, Mulvihill JJ et al 1988 A cancer family syndrome in twenty-four kindreds. Cancer Res 48:5358–62).

Liliequist's membrane: an arachnoid membrane passing from the dorsum sellae to the anterior edge of the mammillary body. Described by Key and Retzius in 1875 and 'rediscovered' in 1956 in Liliequist's cadaveric pneumoencephalographic studies. (Liliequist B 1956 The anatomy of the subarachnoid cisterns. Acta Radiol 46:61–71).

Lisfranc: joint – the tarsometatarsal joint;

Lisfranc's ligament – an interosseous ligament between the second metatarsal and first cuneiform bone of the foot.
Jacques de St Martin Lisfranc (1790–1847), Professor of Surgery, Paris, France.

Lissauer, fasciculus of, tract of: the ascending tract in the spinal cord.
Heinrich Lissauer (1861–1891), neurologist, Breslau, Poland.

Lister's tubercle: a prominence on the posterior surface of the distal radius, ulnar to the groove for the tendon of extensor pollicis longus.

Lord Joseph Lister (1827–1912), successively Professor of Surgery at Glasgow, Edinburgh and King's College, London, UK.

Little's area: a site of haemorrhage on the nasal septum.
James Laurence Little (1836–1885), Professor of Surgery, University of Vermont, USA.

Littre, glands of: small mucous glands of the male urethra.
Alexis Littre (1658–1726), French anatomist and surgeon.

Lockwood, suspensory ligament of: the thickened area of contact between Tenon's capsule and the sheaths of inferior rectus and inferior oblique in the orbit.
Charles Barrett Lockwood (1856–1914), British surgeon and anatomist, St Bartholomew's Hospital, London, UK.

Louis, angle of: the sternal angle – the angle formed on the anterior surface of the sternum at the junction of its body and manubrium.
Antoine Louis (1723–1792), Maître de Chirurgie and later Professor of Physiology, Royal College of Surgeons, Paris, France. He designed the prototype of the guillotine, which was originally nicknamed the 'Louison' or 'Louisette'.

Lower, intervenous tubercle of: a structure that lies between the fossa ovalis and the superior vena cava. *Richard Lower (1631–1691), English physician.* (Lower R 1669 Tractatus de corde. Item de motu, colore sanguinis et chyli in eum transitum. London: J Redmayne & J Allestry, p. 22).

Ludwig's angina: a potentially life-threatening, rapidly expanding, diffuse inflammation of the submandibular and sublingual spaces, occurring most often in young adults with dental infections.
Wilhelm Friedrich von Ludwig (1790–1865), German surgeon and obstetrician.

Lugaro cell: an inhibitory interneurone in the cerebellum.
Ernesto Lugaro (1870–1940), Italian neuropsychiatrist.

Luschka: bursa of (lateral Luschka aperture) – an accessory pharyngeal recess in front of the anterior arch of the atlas;

duct of – small, gland-like tubular structures in the wall of the gallbladder adjacent to the liver, especially in the part covered with peritoneum;

foramen of – the lateral aperture in the roof of the fourth cerebral ventricle;

uncovertebral joints of – small synovial joints on either side of the intervertebral cartilaginous joint in cervical vertebrae C3–C7 (between the uncinate process of the inferior vertebral body and the bevelled lateral border of the superior body at each level).
Hubert Luschka (1820–1875), Professor of Anatomy, Tübingen, Germany.

McBurney's point: the reputed site of maximal tenderness in appendicitis.
Charles McBurney (1845–1913), American surgeon.

Macewen's triangle: the surface marking of the mastoid antrum.
Sir William Macewen (1848–1924), Scottish surgeon. Established the treatment of intracranial complications of middle ear suppuration.

McGregor's patch: an area of fibrous attachment between the anterior edge of the parotid fascia and the dermis of the skin of the cheek (Rossell-Perry P 2013 The zygomatic ligament of the face: a critical review. OA Anat 1:3).
McLaughlin lesion: reverse ***Hill–Sachs lesion*** – an impaction fracture of the anteromedial aspect of the humeral head following posterior dislocation of the humerus.
Harrison Lloyd McLaughlin (1906–1970), American orthopaedic surgeon.

Mackenrodt, ligament of: the transverse cervical (or cardinal) ligament of the uterus.
Alwin Mackenrodt (1859–1925), Professor of Gynaecology, Berlin, Germany.

McKenzie branch of first cervical nerve: a communicating branch between the (spinal) accessory nerve and the anterior root of the first cervical nerve (McKenzie KG 1955 The surgical treatment of spasmodic torticollis. Clin Neurosurg 2:37–43).

Magendie, foramen of, aperture of: the median aperture in the roof of the fourth ventricle.
François Magendie (1783–1855), physician to the Hôtel Dieu, Paris, France.

Malassez, rests of: epithelial remnants of the enamel organ found in the periodontal ligament.
Louis Charles Malassez (1842–1909), French surgeon and physiologist.

Mallory's triple stain: Mallory's acid fuchsin, orange G and aniline blue stain for connective tissue.
Frank Burr Mallory (1862–1941), pathologist, Boston, USA.

Marfan: aortic dissection – *see below;*

syndrome – an autosomal genetic disorder of the connective tissue characterized by a long body and extended limbs and fingers, often associated with cardiovascular abnormalities such as dissecting aortic aneurysms and valve defects, as well as subluxated ocular lenses.
Antoine Bernard-Jean Marfan (1858–1942), Professor of Infantile Hygiene, Paediatric Clinic, University of Paris, France.

Marshall, vein of: the left atrial oblique vein, an embryonic remnant of the left superior caval vein which is enclosed within the Marshall ligament (Marshall J 1850 On the development of the great anterior veins in man and mammalia: including an account of certain remnants of fetal structure found in the adult, a comparative view of these great veins in the different mammalia, and an analysis of their occasional peculiarities in the human subject. Philos Trans R Soc Lond 140:133–69).
John Marshall (1818–1891), English surgeon and anatomist.

Martin–Gruber anastomosis: an anomalous connection between the median and ulnar nerves in the forearm (Martin R 1763 Om nervernas allmänna egenskaper i menniskans kropp jemte nervernas särskilda anatomiska beskrifning. Stockholm: Lars Silvius. Gruber W 1870 Über die Verbindung des Nervus medianus mit dem Nervus ulnaris am Unterarme des Menschen und der Säugethiere. Archiv für pathologische Anatomie und Physiologie und für klinische Medizin 37:501–22); *see* ***Gruber*** *above.*

Martinotti cell, neurone: a fusiform neurone in the deepest layer of the cerebral cortex.
Giovanni Martinotti (1857–1928), pathologist, Bologna, Italy.

Martius fat pad flap: a procedure used for complex fistula repair and as an interposition graft with vaginal reconstructive surgery (Martius H 1928 Die operative Wiederherstellung der vollkommen fehlenden Harnrohre und des Schlessmuskels derselben. Zentralbi Gynakol 52:480–6).

Masson's trichrome stain: a stain for connective tissue.
Claude Laurent Pierre Masson (1880–1959), French-born Canadian pathologist.

Mattox manoeuvre: a left medial visceral rotation – a surgical step to explore and handle Zone 1 and 2 retroperitoneal injuries (aorta, left iliac and pelvic vessels).
Kenneth L Mattox (1938–) American surgeon.

Maubrac, ansa of: an obsolete term for an anastomosis between the lateral deep branches of the cervical plexus and the accessory nerve (Maubrac G 1883 Recherches anatomiques et physiologiques sur le nerf SCM. Thesis, Bordeaux University (no. 38)).

Mayer–Rokitansky–Küster–Hauser syndrome: a syndrome characterized by congenital absence of the vagina, primary amenorrhoea, rudimentary cornua uteri and morphologically normal ovaries and Fallopian tubes situated on the side wall of the pelvis.
August Franz Joseph Karl Mayer (1787–1865), German anatomist and physiologist; Karl Freiherr von Rokitansky (1804–1878), Austrian pathologist; Hermann Küster (1879–1964), German gynaecologist; Georges André Hauser (1921–2009), Swiss gynaecologist.

Mayo, prepyloric vein of: a tributary of the right gastric vein that passes anterior to the pylorus at the gastroduodenal junction, also called vena prepylorica [TA], and Latarget's vein.
William James Mayo (1861–1939), American physician and surgeon, one of the founders of the Mayo Clinic.

Meckel's: cartilage – the cartilage of the first branchial arch;

cave – a cerebrospinal fluid-containing arachnoidal pouch protruding from the posterior cranial fossa. Located near the apex of the petrous part of the temporal bone, it houses the trigeminal ganglion and extends forwards, rather like an open-ended, three-fingered glove, enveloping the rootlets of the trigeminal nerve, the trigeminal ganglion and the ophthalmic, maxillary and mandibular divisions of the trigeminal nerve;

diverticulum – the remains of the vitellointestinal duct.
Johann Meckel (1781–1833), Professor of Anatomy, Halle, Germany. His grandfather was Professor of Anatomy in Berlin and described the pterygopalatine ganglion and the dural sac, which contains the ganglion of the trigeminal nerve. His father was also Professor of Anatomy in Halle.

Meibomian glands: the tarsal glands of the eyelid. If blocked, they become distended into Meibomian cysts.

Heinrich Meibom (1638–1700), Professor of Medicine, History and Poetry, Helmstadt, Germany.

Meissner's: corpuscles – tactile nerve endings in skin;

plexus – the submucosal autonomic plexus of the intestine.
George Meissner (1829–1905), Professor of Anatomy and Physiology, Basle, Switzerland; Zoology and Physiology, Freiburg, Germany; and Physiology, Göttingen, Germany.

Mendel's laws: the laws of inheritance of single-gene traits that form the basis of the science of genetics, first described by Gregor Mendel in 1865.
Gregor Johann Mendel (1822–1884), abbot and pioneer of genetics from Brno, Czech Republic.

Ménière's disease: aural or auditory vertigo.
Prosper Ménière (1799–1862), French otorhinolaryngologist.

Mercier's bar: a curved fold of mucous membrane extending across the bladder between the two ureteric orifices, produced by a transverse bundle of muscle fibres.
Louis Auguste Mercier (1811–1882), French urologist.

Merkel: cells, corpuscles – sensory cells in the skin;

disc – a slowly adapting type I receptor, which lies in the basal epidermis of glabrous skin and is sensitive to sustained pressure.
Friedrich Sigmund Merkel (1845–1919), Professor of Anatomy successively at Rostock, then Göttingen, Germany.

Meyer's loop: the fibres of the geniculocalcarine tract that loop forwards in the temporal lobe.
Adolf Meyer (1866–1950), American psychiatrist.

Meynert, basal nucleus of: part of the 'substantia innominata' of the basal forebrain; contains large cholinergic neurones that project to the cerebral cortex, amygdala and thalamus.
Theodore Herman Meynert (1833–1892), Professor of Neurology, Vienna, Austria.

Mikulicz angle: the angle formed between the head and neck of the femur and its shaft.
Johann (Jan) Freiherr von Mikulicz-Radecki (1850–1905), Polish surgeon in Germany.

Minor's syndrome: dehiscence of the roof of the superior semicircular canal (Minor LB 2000 Superior canal dehiscence syndrome. Am J Otol 21:9–19).

Mirizzi syndrome: partial obstruction to the flow of bile and the appearance of mild jaundice as a result of biliary stones.
Pablo Mirizzi (1893–1964), Argentinian physician.

Moll, glands of: modified sweat glands associated with the eyelashes.
Jacob Antonius Moll (1832–1914), ophthalmologist, The Hague, Netherlands.

Monro, foramen of: the foramen between the lateral and third ventricles of the brain.
Alexander Monro (1733–1817), Professor of Anatomy, Edinburgh, UK. The chair was also held by his father and his son – both also named Alexander.

Monteggia injury: a fracture of the upper portion of the ulna combined with dislocation of the radial head.
Giovanni Battista Monteggia (1762–1815), Italian physician and surgeon.

Montgomery, glands of, tubercles of: sebaceous glands situated in the areola of the breast (previously described by Morgagni; *see below*).
William Montgomery (1797–1859), Professor of Midwifery, Dublin, Ireland.

Morgagni: columns of – the columns of the anal canal;

concha – otherwise known as concha nasalis suprema, superior nasal choncha;

hernia – a congenital diaphragmatic hernia between the sternal and costal attachments of the diaphragm;

hydatid of – (synonyms: appendix testis, appendices vesiculosae epoophori) a cyst-like remnant of the Müllerian duct attached to a testis;

sinus – a sinus that lies between the superior pharyngeal constrictor and the base of the skull. Internally it is covered by mucosa and posteriorly by the pharyngobasilar fascia and is a route for the spread of neoplasms and infection from the nasopharynx to the base of the skull;

triangle(s) of – the right and left sternocostal triangles of Morgagni are openings in the anterior part of the respiratory diaphragmatic muscle, between the sternal and costal parts;

Morgagni's tubercle – otherwise known as the tuberculum septi nasi or the septal tubercle, it is a focal bulge of the anterior nasal septum at the level of the middle turbinate.
Giovanni Battista Morgagni (1682–1771), Professor of Anatomy, Padua, Italy, for 59 years. Described as the founder of modern morbid anatomy.

Morgenstern, 'criminal' fold of: a constant peritoneal fold attached to the lower pole of the spleen near to the splenic flexure but distinct from the splenocolic ligament. It is most commonly responsible for iatrogenic injuries to the lower pole of the spleen during operation on the left upper quadrant.
Leon Morgenstern (1919–2012), American surgeon.

Morison, hepatorenal pouch of: the right subhepatic space.
James Rutherford Morison (1853–1939), Professor of Surgery, Durham, UK.

Moro reflex: the startle reflex.
Ernst Moro (1874–1951), German physician.

Morquio syndrome: mucopolysaccharidosis type IV (MPS IV), an autosomal recessive disorder in which there is an inability to process keratan sulphate.
Luis Morquio (1867–1935), Uruguayan physician.

Morton's neuroma: a disease of the foot characterized by a sudden cramp-like pain in the metatarsal area radiating to the fourth and fifth toes, and sometimes to the calf of the leg. Compression of the plantar nerve by a tumour, arthritic changes or bursitis is the common cause.
Thomas George Morton (1835–1903), American surgeon.

Müller: cells – neuroglial cells in the retina;

orbital muscle of – a collection of smooth muscle fibres spanning the infraorbital fissure. Its functions are uncertain;

superior tarsal muscle of – a thin lamina of smooth muscle that passes from the underside of levator palpebrae superioris to the upper margin of the superior tarsus.
Heinrich Müller (1820–1864), Professor of Anatomy, Würzburg, Germany.

Müllerian duct (also Müllerian duct syndrome)**:** paramesonephric ducts. Persistent Müllerian duct syndrome is a disorder of sexual development that affects males. Males with this disorder have normal male reproductive organs but also have a uterus and uterine tubes.
Heinrich Müller (1820–1864), Professor of Anatomy, Würzburg, Germany.

Müller–Weiss disease: spontaneous osteonecrosis of the navicular in the adult.
Walther Müller (1888–1949), German orthopaedic surgeon; Konrad Weiss (1891–1976), Austrian radiologist.

Nabothian cyst, follicle: a retention cyst of the uterine cervix.
Martin Naboth (1675–1721), Professor of Medicine, Leipzig, Germany.

Newton: Newtonian equations – equations using the SI unit of force (N), which, when applied in a vacuum to a body having a mass of 1 kg, accelerates it at the rate of 1 m/sec^2;

Newton's second law of motion – applied force = mass × acceleration.
Sir Isaac Newton (1643–1727), English mathematician and physicist.

Nissl: bodies, granules – basophilic granules in the cytoplasm of neuronal somata;

staining technique – a specific stain for Nissl granules.
Franz Nissl (1860–1919), neurologist successively at Frankfurt, Heidelberg and Munich, Germany.

Nitabuch's layer, stria: a layer of fibrinoid matrix between the basal plate of the placenta and the endometrium.
Raissa Nitabuch, nineteenth-century German physician.

Noonan syndrome: autosomal dominant RASopathy. Clinical features are short stature, low-set ears and minor skeletal deformities of which the commonest are pectus excavatum and cubitus valgus.
Jacqueline Anne Noonan (1928–), American paediatric cardiologist.

Nuck, canal of: a diverticulum of the peritoneal membrane extending into the inguinal canal, accompanying the round ligament in the female, or the testis in its descent into the scrotum in the male; usually completely obliterated in the female.
Anton Nuck (1650–1692), Dutch anatomist.

Nuel, spaces of: spaces between the outer rods of Corti and hair cells.
Jean Pierre Nuel (1847–1920), Professor of Otology, Louvain and later Liège, Belgium.

Oddi, sphincter of: the sphincter at the termination of the common bile duct. The sphincter had already been described by Glisson *(see above)* in the seventeenth century.
Ruggero Oddi (1845–1906), surgeon, Rome, Italy.

Odland bodies: small, lamellated structures (keratinosomes) in the granular layer of the epidermis, containing hydrophobic phospholipid.
George Fisher Odland (1922–1997), American dermatologist and electron microscopist.

Ondine's curse: primary alveolar hypoventilation.
Ondine, a sea nymph in German mythology, who cursed an unfaithful human lover by abolishing the automaticity of his bodily functions.

Onodi cell: a sphenoethmoidal cell formed by lateral and posterior pneumatization of the most posterior ethmoid cells over the sphenoid sinus.
A Onodi, twentieth-century Hungarian laryngologist.

Onuf, nucleus of: neurones in lamina IX of the sacral spinal cord involved in the maintenance of micturition and defecatory continence.
Bronislaw Onuf-Onufrowicz (1863–1928), Russian-born American neurologist of Polish descent.

Oort, anastomosis of: a link between the saccular and cochlear nerves at the bottom of the internal auditory meatus (Oort H 1918 Über die Verästelung des Nervus octavus bei Säugetieren (Modell des Utriculus und Sacculus des Kainchens). Anat Anz 851:272–80).
H Oort, Dutch anatomist, Utrecht.

Oppenheim's dystonia: Oppenheim described dystonia musculorum deformans (DMD), a movement disorder characterized by twisting or turning movements and abnormal postures. Now called early-onset primary torsion dystonia, this condition is an autosomal dominant disorder most commonly associated with deletion of GAG in the coding region of the DYT1 gene encoding torsinA. It has been suggested that the condition should be referred to as 'Oppenheim's dystonia'.
Hermann Oppenheim (1858–1919), German neurologist.

Osborne, arcuate ligament: otherwise known as the cubital tunnel retinaculum, Osborne's fascia, Osborne's band, or the tendinous arch. A band of fibrous tissue that spans between the humeral and ulnar heads of flexor carpi ulnaris and forms the roof of the cubital tunnel.
Geoffrey Vaughan Osborne (1918–2005), Welsh surgeon.

Osgood–Schlatter disease: osteochondrosis of the tibial tuberosity.
Robert Bayley Osgood (1873–1956), Professor of Orthopaedic Surgery, Harvard University, Cambridge, Massachusetts, USA; Carl Schlatter (1864–1934), Professor of Surgery, Zurich, Switzerland.

Ostmann's fat pads: two small fat deposits medial and lateral in the membranous part of the Eustachian tube.
Paul Ostmann (1859–1945), German otologist.

Owen, contour lines of: accentuated incremental lines in the dentine, thought to be due to disturbances in the mineralization process. Defined by parallel deviations of neighbouring dentinal tubules.
Sir Richard Owen (1804–1892), English anatomist and palaeontologist.

Pacchionian bodies: arachnoid granulations.
Antoine Pacchion (1665–1726), physician and anatomist, Rome, Italy.

Pacinian corpuscle: a pressure-sensitive mechanoreceptor.
Filippo Pacini (1812–1883), Professor of Anatomy and Physiology, successively at Pisa and then Florence, Italy.

Paget's disease: chronic localized disorder of bone remodelling, with increased bone formation and resorption, often resulting in major long-bone and skull deformities.
Sir James Paget (1814–1899), British surgeon and physiologist.

Palomo procedure: retroperitoneal ligation of the internal spermatic vein between the anterior superior iliac spine and the renal vein (Palomo A 1949 Radical cure of varicocele by a new technique: preliminary report. J Urol 61:604–7).

Pancoast tumour: an apical carcinoma of the lung involving C8 and T1 nerves, the cervical sympathetic chain and upper ribs.
Henry Pancoast (1875–1939), Professor of Radiology, University of Pennsylvania, USA.

Paneth cells: bacteriocidal lysozyme-secreting cells.
Joseph Paneth (1857–1890), Professor of Physiology, first at Breslau, Poland, then Vienna, Austria.

Papez circuit: a neuroanatomical circuit mediating emotion, involving the hippocampal formation, mammillary body, anterior nuclei of the thalamus and cingulate gyrus.
James Wenceslas Papez (1883–1958), American neurologist.

Parkinson's syndrome, disease: the main symptoms of tremor, rigidity and slowness of movement caused by degeneration of dopaminergic neurones in the substantia nigra, usually occcur in late life and are more common in men.
James Parkinson (1755–1824), English physician and paleontologist. In his Essay on the Shaking Palsy (1817), Parkinson established the disease that now bears his name as a clinical entity.

Parkinson's triangle: the infratrochlear triangle. Defined by the inferior margin of the trochlear nerve from its beginning in the lateral wall of the cavernous sinus to its transit through the superior orbital fissure (medial border); the superior margin of the ophthalmic division of the trigeminal nerve (lateral border); and a line connecting the entry points of these nerves into the cavernous sinus (base) (Parkinson D 1965 A surgical approach to the cavernous portion of the carotid artery. Anatomical studies and case report. J Neurosurg 23:474–83).

Parks, mucosal suspensory ligament of: a condensation of fibres at the level of the dentate line (Parks AG 1954 A note on the anatomy of the anal canal. Proc R Soc Med 47:997–8).

Passavant's: muscle – the upper fibres of palatopharyngeus;

ridge, bar – a projecting ridge, or bar, on the posterior wall of pharynx, which appears during swallowing.
Phillip Gustav Passavant (1815–1893), surgeon, Frankfurt, Germany.

Petit's triangle, lumbar triangle of Petit: the inferior lumbar triangle bounded inferiorly by the iliac crest, anteriorly by external oblique and posteriorly by latissimus dorsi.
Jean L Petit (1640–1750), French surgeon.

Peyer's patches: lymphoid aggregates in the ileum.
Johann Conrad Peyer (1653–1712), Professor of Logic, Rhetoric and Medicine in Schaffhausen, Switzerland.

Peyronie's disease: induration of the corpora cavernosa of the penis, producing a fibrous chordee.
François de la Peyronie (1678–1747), French surgeon.

Pfannenstiel incision: a transverse curved abdominal incision with downward convexity, above the symphysis pubis.
Hermann Johann Pfannenstiel (1862–1909), German gynaecologist.

Pfeiffer's syndrome: a congenital syndrome characterized by craniostenosis, abnormal skull shape, facial anomalies, syndactyly of hands and feet, and broad thumbs and great toes.
Rudolf Arthur Pfeiffer (1931–2012), human geneticist, Saarbrücken, Germany.

Pierre Robin sequence: micrognathia, U-shaped cleft palate and glossoptosis.
Pierre Robin (1867–1950), French dentist.

Poirier, space of: a discrete interval between the inferior margin of the fibres of the radioscaphocapitate ligament that attach to the body of the capitate and the palmar horn of the lunate.
Paul Poirier (1853–1907), French surgeon.

Poiseuille's law: a mathematical expression of the flow rate for the laminar (nonturbulent) flow of fluids in circular tubes.
Jean-Louis-Marie Poiseuille (1799–1869), French physician and physiologist.

Poland's syndrome: a condition that is comprised of ipsilateral breast and nipple hypoplasia and/or aplasia, deficiency of subcutaneous fat and axillary hair, absence of the sternal head of pectoralis major, hypoplasia of the rib cage, and hypoplasia of the upper extremity, including cutaneous syndactyly.
Sir Alfred Poland (1822–1872), English surgeon.

Poswillo approach: a percutaneous closed reduction technique for management of fractures of the zygoma.
David Ernest Poswillo (1927–2003), maxillofacial surgeon, New Zealand.

Potter's syndrome: a rare condition combining a characteristic facial appearance with renal agenesis or hypoplasia and other defects.
Edith Louise Potter (1901–1993), early twentieth-century American paediatric surgeon.

Pott's abscess: a tuberculous abscess of the spine.
Sir Percivall Pott (1713 or 1714–1788), British surgeon.

Prader–Willi syndrome: a rare genetic condition that causes a wide range of physical symptoms, learning difficulties and behavioural problems.
Andrea Prader (1919–2001), Swiss paediatrician and endocrinologist; Heinrich Willi (1900–1971), Swiss paediatrician.

Pringle manoeuvre: the application of digital or mechanical pressure across the entire free edge of the lesser omentum, resulting in complete, temporary occlusion of the hepatic portal vein, hepatic artery and common bile duct.
J Pringle the Elder (1863–1941), Australian surgeon.

Prinzmetal's angina: variant angina occurring at rest, manifesting on electrocardiography as episodic ST segment elevations, and caused by coronary artery spasms with or without superimposed coronary artery disease.
Myron Prinzmetal (1908–1987), American cardiologist.

Probst, commissure of, Probst bundle: a callosal longitudinal bundle, seen in agenesis of the corpus callosum, when callosal fibres from the hemispheres fail to cross the midline and, instead, form thick bundles.
Moriz Probst (1867–1923), Austrian psychiatrist.

Prussak's: fibres – elastic and connective tissue fibre bounding the pars flaccida membranae tympani;

space – the superior recess of the tympanic membrane.
Alexander Prussak (1839–1897), Russian otologist.

Purkinje: cells, neurones – large neurones forming a single eponymous layer in the cerebellar cortex;

fibres – subendocardial muscle fibres.
Johannes Purkinje (1787–1869), Professor of Physiology, Breslau, Poland, and then Prague, Czech Republic.

Ramsay Hunt syndrome: herpes zoster involvement of the geniculate ganglion associated with facial paresis, hyperacusis, unilateral loss of taste, decrease in lacrimation and salivation, and otalgia.
James Ramsay Hunt (1874–1937), Professor of Neurology, Columbia University, New York, USA.

Ranvier, nodes of: short (~1 μm) gaps between adjacent myelin sheaths that are essential for the propagation of action potentials via saltatory conduction along myelinated axons.
Louis-Antoine Ranvier (1835–1922), French anatomist and histopathologist, Paris, France.

Raschkow's plexus: a plexus of myelinated nerve fibres located between the core of the pulp of the tooth and the cell-rich zone; axons lose their myelin sheath (but not their Schwann cells) as they penetrate the cell-rich and cell-free zones to make synaptic contact with the odontoblast cell body in the pulp or odontoblastic process within the dentinal tubule; responsible for transmitting pain sensation from the pulp of the tooth.
I *Raschkow (1811–1872), German physician.*

Rasmussen: bundle of – the olivocochlear tract;

Rasmussen's encephalitis – a rare, progressive, inflammatory disorder of the central nervous system.
Theodore Brown Rasmussen (1910–2002), neurologist, Utah, USA.

Rathke's pouch: a diverticulum of the roof of the stomodeum, which forms the anterior pituitary gland.
Martin Heinrich Rathke (1793–1860), Professor of Zoology and Anatomy, Königsberg, Germany.

Rayleigh scatter: the scattering of light or other electromagnetic radiation by particles much smaller than the wavelength of the light.
John William Strutt, 3rd Baron Rayleigh OM (1842–1919), Cavendish Professor of Physics, University of Cambridge, UK.

Raynaud's disease: idiopathic paroxysmal bilateral cyanosis of the digits due to arterial and arteriolar contraction, caused by cold or emotion.
Maurice Raynaud (1834–1881), French physician.

Reichert's cartilage: a cartilage in the mesenchyme of the second branchial arch in the embryo, from which the stapes, styloid processes, stylohyoid ligaments and lesser cornua of the hyoid bone develop.
Karl Bogislaus Reichert (1811–1883), German anatomist.

Reid's baseline: a plane that passes through the inferior margin of the orbit and the superior margin of the external acoustic meatus (external auditory canal).
Robert William Reid (1851–1939), Scottish surgeon and anatomist. He proposed a method of cerebral localization where the topography of the brain could be related to a system of lines drawn between large and easily felt landmarks on the surface of the head.

Reil: **circular sulcus of –** the peri-insular sulcus (synonym: sulcus circularis insulae); the insular surface is delineated peripherally by the peri-insular sulcus, which is interrupted by the transverse insular gyrus running across the limen insulae;

island of – the insular lobe.
Johann Christian Reil (1759–1813), German physician.

Reinke's: crystals – rod-shaped crystals in the interstitial cells of the testis and hilus cells of the ovary;

oedema – chronic laryngitis with swelling of the membranous part of the vocal cords;

space – a potential space between the vocal ligament and the overlying mucosa.
Friedrich Berthold Reinke (1862–1919), French anatomist.

Reissner's membrane: the vestibular membrane of the cochlea.
Ernst Reissner (1824–1878), Professor of Anatomy, Tartu, Estonia, and then Breslau, Poland.

Renshaw's cells: inhibitory interneurones modulating the response of anterior horn cells.
Birdsy Renshaw (1911–1948), American neurologist.

Retzius: space of, cave of – the prevesical space or retropubic space;

veins of, retroperitoneal venous plexus of – porto-caval anastomoses formed from veins in the walls of the retroperitoneal viscera, forming communications between the mesenteric veins and the inferior vena cava.
Andreas Adolf Retzius (1796–1860), Professor of Anatomy, Karolinska Institute, Stockholm, Sweden.

Retzius: cell – see *Cajal–Retzius cell*;

gyrus – two small bulges on the medial segment of the hippocampal tail that consist of a CA1 subfield and the subiculum (Ziogas IA, Triarhou L 2016 Anders Retzius and his gyri. Neurol Sci 37:1861–6);

inferior sagittal sulcus of the cuneus of – a structure that lies superior to the posterior part of the calcarine sulcus;

lines of, striae of – brown lines in the dental enamel;

superior sagittal sulcus of – a paracalcarine sulcus (Retzius G 1896 Das Menschenhirn. Königliche Buchdruckerei PA Norstedt und Söner, Stockholm).

Gustav Magnus Retzius (1842–1919), Professor of Anatomy, Karolinska Institute, Stockholm, Sweden. Son of Andreas Adolf Retzius.

Rexed's lamina: subdivisions of cells of spinal cord grey matter.
Bror Rexed (1914–2002), Swedish neuroanatomist.

Riolan, arc of: the anastomosis between the middle and left colic arteries.
Jean Riolan (Secondus) (1577–1657), Professor of Anatomy and Botany, Paris, France.

Rives–Stoppa–Wantz technique: a technique that involves incising the posterior layer of the rectus sheath just lateral to the linea alba, allowing a retromuscular dissection to the lateral edge of the rectus sheath.
Jean Rives (1922–2012), Rene Stoppa (1921–2006), French-Algerian surgeons; George E. Wantz (1923–2000), American surgeon.

Rolando: cruciform sulcus of – the H-shaped orbital sulcus;

Rolandic fissure – the central fissure of the cerebral hemisphere.
Luigi Rolando (1773–1831), Italian anatomist.

Romberg sign: swaying of the body or falling when standing with the feet close together and the eyes closed.
Moritz Heinrich Romberg (1795–1873), German physician.

Rosenmüller, fossa of: the pharyngeal recess.
Johann Christian Rosenmüller (1779–1820), Professor of Anatomy and Surgery, Leipzig, Germany.

Rosenthal: basal vein of – a vein that courses from the premesencephalic cistern, through the ambient cistern, and terminates in the quadrigeminal cistern;

Rosenthal's canal – the spiral canal in the modiolus of the cochlea.

Isidor Rosenthal (1836–1915), physiologist, Greifswald, Germany.

Roser–Nelaton's line: a line drawn from the anterior superior iliac spine to the ischial tuberosity.
Auguste Nélaton (1807–1873), French physician and surgeon; Wilhelm Roser (1817–1888), German surgeon and ophthalmologist.

Rotter's node: the lymph node between pectoralis major and minor.
Josef Rotter (1857–1924), German surgeon.

Rouvière's sulcus: the incisura hepatis dextra (synonym: Gans incisura) (see Stringer MD 2009 Eponyms in Surgery and Anatomy of the Liver, Bile Ducts and Pancreas. London: Royal Society of Medicine).

Ruffini endings, bodies, corpuscles: sensory nerve endings, originally described in the skin of the fingers.

Angelo Ruffini (1887–1929), Professor of Histology, Bologna, Italy.

Russell, hook bundle of: uncinate fasciculus, where the crossed fibres from the fastigial nucleus pass dorsal to the superior cerebellar peduncle.
James Samuel Risien Russell (1863–1939), Guyanese-British neurologist.

Sachs, sagittal striata of: extrastriate thalamocortical projections (internal sagittal stratum of Sachs); association fibres of the inferior longitudinal fasciculus (external sagittal stratum of Sachs).
Heinrich Sachs (1863–1928), German neurologist and a student of Carl Wernicke in Breslau.

Saethre–Chotzen syndrome: acrocephalosyndactyly type III. A very rare disorder characterized by the fusion of cranial structures, which sometimes produces an asymmetric head and face; low-set hairline; ptosis and/or widely spaced eyes; 'beaked' nose and possible deviated septum; and, sometimes, brachydactyly and syndactyly.
Haakon Saethre (1891–1945), Norwegian psychiatrist; F. Chotzen (1932), German psychiatrist.

Santorini: duct of – the accessory pancreatic duct;

fissures of – two fissures in the anterior cartilaginous wall of the external acoustic meatus;

plexus of – the retropubic venous plexus giving rise to the pudendal vein.
Giovanni Domenico Santorini (1681–1737), Professor of Medicine and Anatomy, Venice, Italy.

Satiro's ear: usually known as Stahl's syndrome or Satyr's ear. A common congenital deformity of the auricle in which the helix is flattened and the upper crus of the antihelix is duplicated.
Friedrich Stahl (1811–1879), German physician.

Sattler's layer: a layer of medium-sized blood vessels in the choroid, derived from the short posterior ciliary arteries.
Hubert Sattler (1844–1928), Professor of Ophthalmology, Leipzig University Eye Hospital, Germany.

Scarpa's: fascia – the fibrous layer of the superficial fascia of the lower abdomen;

ganglion – the vestibular ganglion.
Antonio Scarpa (1747–1832), Professor of Anatomy, Padua, Italy.

Schaffer collaterals: the projections from pyramidal cells of fields CA3 and CA2 to CA1 in the hippocampus.
Max Schaffer (1852–1923), German neurologist.

Scheuermann's osteochondritis, disease, kyphosis: osteochondrosis of the vertebrae.
Holger Werfel Scheuermann (1834–1915), German biochemist.

Schiff's stain, reagent: a stain for aldehydes, used with periodic acid (PAS) to detect carbohydrates.
Hugo Schiff (1834–1915), German biochemist.

Schirmer test: a test that measures lacrimal gland secretory capacity; used principally to diagnose dry eye syndrome.
Otto Schirmer (1864–1918), German ophthalmologist.

Schlemm, canal of: a canal at the junction of the cornea and sclera.
Freidrich Schlemm (1795–1858), Professor of Anatomy, Berlin, Germany.

Schmidt–Lanterman incisures, cleft: a helical inclusion of glial cytoplasm within the myelin sheaths of central and peripheral nerves.
Henry Schmidt (1823–1888), pathologist, Charity Hospital, New Orleans, USA; AJ Lanterman, nineteenth-century anatomist, Strasbourg, France.

Schütz, fasciculus of: the dorsal longitudinal fasciculus.
Hugo Schütz (1859–1923), neurologist, Leipzig, Germany.

Schwalbe: **line of, ring of –** the anterior border ring of the cornea;

nucleus of – the vestibular nucleus;

pocket – a depression between the tendinous arch of levator ani and the lateral wall of the pelvis.
Gustav Albert Schwalbe (1844–1916), German anatomist and anthropologist.

Schwann cell: the major glial cell of the peripheral nervous system.
Theodor Schwann (1810–1882), Professor of Anatomy first in Louvain and then Liège, Belgium. One of the instigators of the cell theory.

Seessel's pouch: a small endodermal diverticulum that projects towards the brain from the cranial end of the foregut, immediately caudal to the buccopharyngeal membrane.
Albert Seessel (1850–1910), American embryologist.

Segond fracture: an avulsion fracture of the lateral margin of the lateral tibial plateau, with a significant association with anterior cruciate ligament and meniscal injuries.
Paul Ferdinand Segond (1851–1912), French orthopaedic surgeon.

Semon's law: an obsolete 'law' stating that injury to the recurrent laryngeal nerve results in paralysis of the abductor muscles of the vocal cords before paralysis of the adductor muscles.
Sir Felix Semon (1849–1921), German laryngologist in the UK.

Sertoli cells: the supporting cells of the testicular tubules.
Enrico Sertoli (1842–1910), Professor of Experimental Physiology, Milan, Italy.

Sever's disease: inflammation of the calcaneal apophysis in children and adolescents.
James Warren Sever (1878–1964), American orthopaedic surgeon.

Sharpey's fibres: connective tissue joining periosteum to bone.
William Sharpey (1802–1880), Professor of Anatomy successively at Edinburgh and University College, London, UK.

Sibson's fascia: the suprapleural membrane.
Francis Sibson (1814–1846), English surgeon.

Simmonds–Thompson test: a diagnostic tool for Achilles tendon rupture: absence of foot plantar flexion on calf compression is interpreted as a positive test result.
Franklin Adin Simmonds (1910–1983), English orthopaedic surgeon; Theodore Campbell Thompson (1902–1986), American orthopaedic surgeon.

Sistrunk's procedure: a procedure for removal of a thyroglossal duct cyst. It involves resection of the entire cyst, the central portion of the hyoid bone, and the thyroglossal duct tract that terminates at the foramen caecum. Several modifications of the procedure have been described.
Walter Ellis Sistrunk (1880–1933), American surgeon; originally described this operation in 1920.

Sjögren's connective tissue disease: a chronic autoimmune disease characterized by keratoconjunctivitis sicca and many other symptoms.
Henrik Samuel Conrad Sjögren (1899–1986), Swedish ophthalmologist.

Skene's glands: the paraurethral ducts of the female urethra.
Alexander Johnston Chalmers Skene (1838–1900), gynaecologist, New York, USA.

Skoog, fibres of: transverse fibres of the palmar aponeurosis of the hand.
Tord Skoog (1915–1977), Foundation Professor of Plastic Surgery, University of Uppsala, Sweden.

Sly syndrome: mucopolysaccharidosis type VII (MPS-VII), an autosomal recessive lysosomal storage disease caused by a deficiency of β-glucuronidase.
William S Sly (1932–), American physician.

Sondergaard: see ***Waterston, groove of.***
Tyge Sondergaard (1914–1990), Danish cardiac surgeon. The first surgeon to use cold chemical cardioplegia in open heart surgery.

Spence, tail of: the projection of mammary glandular tissue extending into the axillary region, sometimes forming a visible mass that may enlarge premenstrually or during lactation.
James Spence (1812–1882), Scottish surgeon.

Spiegel, Spigelian, Spieghel: **hernia –** (1–2% of all hernias – the protrusion of extraperitoneal fat, peritoneal sac or organ(s) through a congenital or acquired defect in the Spiegelian aponeurosis (i.e. the aponeurosis of transversus abdominis limited by the semilunar line laterally and the lateral edge of rectus muscle medially). Although named after Adriaan van der Spieghel, the semilunar line (linea Spiegeli) was only described by Spieghel in 1645. Josef Klinkosch first defined the Spiegelian hernia as a defect in the semilunar line in 1764. Defects in the aponeurosis of transversus abdominis (mainly distal to the arcuate line and more often in obese individuals) have been considered the principal aetiological factor;

line – the linea semilunaris (semilunar line);

lobe – the caudate lobe of the liver.
Adriaan van den Spiegel (1578–1625), Flemish anatomist and botanist. Name also written as Spieghel, Spigel, Adrianus Spigelius, Spiegelius, Adriano Spigeli.

Sprengel deformity: congenital elevation of the scapula with rotation of its lower angle towards the spine.

Otto Gerhard Karl Sprengel (1852–1915), German surgeon.

Stahl's deformity: congenital deformity of the ear characterised by a broad helix, absence of the fossa of the antihelix and upper scaphoid fossa.
Friedrich Stahl (1811–1879), German physician.

Stanford classification: a widely used system of classifying aortic dissections first proposed by a group of cardiovascular surgeons at Stanford University, in which dissections that involve the ascending aorta are classified as type A, regardless of the site of the primary intimal tear, and all other dissections as type B (Daily PO, Trueblood HW, Stinson EB et al 1970 Management of acute aortic dissections. Ann Thorac Surg 10:237–47).

Stener lesion: the ulnar collateral ligament is normally covered by the aponeurotic fibres of the tendon of adductor pollicis. Following avulsion, the proximal end of the ligament can become superficially displaced around the proximal free edge of the aponeurotic insertion of adductor pollicis, producing a Stener lesion (Stener B 1962 Displacement of the ruptured ulnar collateral ligament of the metacarpo-phalangeal joint of the thumb. J Bone Joint Surg Br 44:869–79).
Bertil Stener, Swedish orthopaedic surgeon.

Sternberg's canal: otherwise known as the lateral craniopharyngeal canal. Originally described as a membranous space in the lateral wall of the sphenoid sinus, this rare small canal was once believed to be the primary cause of spontaneous lateral sphenoid CSF leaks.
Maximilian Sternberg (1863–1934), Austrian physician.

Stickler syndrome: hereditary progressive arthro-ophthalmodystrophy, characterized by a distinctive flattened facial appearance, numerous ocular abnormalities, sensorineural or conductive hearing loss, and skeletal abnormalities that affect the joints.
Gunnar B Stickler (1925–2010), German paediatrician.

Stieda's process: the lateral tubercle of the talus, when elongated.
Christian Hermann Ludwig Stieda (1837–1918), German anatomist.

Struthers: arcade of – a thickening of the anteromedial aspect of the medial intermuscular septum, forming a myofibrous sheath around the ulnar nerve after it passes from the anterior to the posterior compartment of the arm;

ligament of – a ligamentous or muscular structure (often an extension of the humeral head of pronator teres), passing between the medial epicondyle and supracondylar processes of the humerus in approximately 1% of individuals.
Sir John Struthers (1823–1899), Scottish anatomist, professor and surgeon.

Sylvian: aqueduct – the midbrain channel connecting the third and fourth cerebral ventricles;

cistern – the subarachnoid space associated with the lateral cerebral sulcus (Sylvian fissure). It contains the M1 segment of the middle cerebral artery, the origin of the lenticulostriate arteries, and proximal parts of the middle cerebral artery;

fissure – the lateral cerebral fissure;

vein – the superficial middle cerebral vein.
François de la Boe Sylvius (1614–1672), Professor of Medicine, Leiden, Netherlands.

Takayasu's arteritis: a granulomatous vasculitis with massive intimal fibrosis and vascular narrowing mainly affecting the aorta and its large branches (aka aortic arch syndrome, nonspecific aortoarteritis, pulseless disease).
Mikito Takayasu (1860–1938), Japanese ophthalmologist.

Tamm–Horsfall protein: the most abundant protein in normal urine.
Igor Tamm (1922–1995), virologist, New York, USA; Frank Lappin Horsfall (1906–1971), American clinician and virologist.

Tanner's stages: scales for stages of sexual development in puberty.
James Mourilyan Tanner (1920–2010), British paediatric endocrinologist.

Taussig–Bing anomaly, syndrome, disease: transposition of the aorta to the right ventricle and malposition of the pulmonary artery with subpulmonary ventricular septal defect.
Helen B Taussig (1898–1986), American paediatrician; Richard Bing (1909–2010), American physician.

Tay–Sachs disease: a lysosomal storage disorder affecting neurones.
Warren Tay (1843–1927), ophthalmologist, London, UK; Bernard Sachs (1858–1944), neurologist, New York, USA.

Tenon's capsule: the fascial sheath of the eyeball.
Jacques René Tenon (1724–1816), Professor of Pathology, Academy of Sciences, Paris. Chief Surgeon, Salpêtrière, Paris, France. Specialized in ophthalmology.

Testut, ligament of: a radio-scaphoid-lunate connection.
Leo Testut (1849–1925), Professor of Anatomy, Lyons, France.

Thebesian: valve – the valve at the orifice of the coronary sinus;

veins – venae cordis minimae of the heart.
Adam Christian Thebesius (1686–1732), anatomist and pathologist, Leiden, Netherlands.

Thomine, retrovascular cord of: a pathological cord formed from the retrovascular fascia or band of Thomine (longitudinally oriented fibres dorsal to the neurovascular bundle) (Thomine JM 1985 The development and anatomy of the digital fascia. In: Hueston JT, Tubiana R eds, Dupuytren's Disease, 2nd ed. New York: Churchill Livingstone, pp. 3–12).

Thompson, posterior (dorsal) approach of: a surgical approach to treat fractures of the proximal and middle thirds of the radius and to address injury to the proximal radioulnar joint (Thompson JE 1918 Anatomical methods of approach in operations on the long bones or extremities. Ann Surg 68:309–29).

Thornwaldt cyst: a benign cyst located in the upper posterior nasopharynx, covered by mucosa anteriorly and bounded by longus muscles posteriorly.
Gustav Ludwig Tornwaldt/Thornwaldt (1843–1910), German physician.

Tinel's sign: the fact that lightly tapping (percussing) over a nerve trunk that has been damaged or is regenerating following trauma causes a sensation of tingling and pain in its distribution up to the site of regeneration. In closed injuries, percussion of the skin over a nerve in which axons have been ruptured evokes sensations that are usually described as a wave or surge of pins and needles into the cutaneous distribution of the nerve.
Jules Tinel (1879–1952), French neurologist.

Todaro, tendon of: a variable tendinous strand attached to the valvular fold at the termination of the inferior vena cava. It forms the superior border of the triangle of Koch.
Francesco Todaro (1839–1918), Professor of Anatomy at Messina and then Rome, Italy.

Toldt's fascia, fusion fascia of Toldt: an avascular fascial plane posterior to the ascending or descending colon and mesocolon, kidney and tail of the pancreas.
Carl Toldt (1840–1920), Austrian anatomist.

Towne's projection: positioning of the head in the radiological examination of the foramen magnum and posterior cranial fossa.
Edward Towne (1883–1957), neurosurgeon, Stanford Medical School, California, USA.

Treacher Collins syndrome: mandibulofacial dysostosis.
Edward Treacher Collins (1862–1932), English surgeon.

Treitz: fascia of, fusion fascia of – the fascia behind the head of the pancreas;

ligament of – a fold of peritoneum over the suspensory muscle of the duodenum;

muscle of – the suspensory muscle of the duodenum (musculus suspensorius duodenii).
Václav (Wenzel) Treitz (1819–1872), Professor of Pathological Anatomy, Jagellonian University, Prague, Czech Republic.

Trendelenburg's sign, gait: a dipping gait due to hip abductor dysfunction, e.g. in congenital dislocation of the hip or paralysis of gluteus medius and minimus.
Friedrich Trendelenburg (1844–1924), Professor of Surgery successively at Rostock, Bonn and Leipzig, Germany.

Treves, bloodless fold of: a peritoneal fold adjacent to the mesoappendix.
Sir Frederick Treves (1853–1923), surgeon, London Hospital, UK. Drained the appendicular abscess of King Edward VII in 1902.

Trolard: canal of – the sphenoparietal canal: a short bony canal that contains the anterior branches of the middle meningeal vessels;

superior anastomotic vein of – the vein that connects the superior sagittal sinus and the superficial middle cerebral vein (of Sylvius).
Paulin Trolard (1842–1910), French anatomist.

Tsai, ventral tegmental area of: the ventral tegmental area.
Tsai Chiao (1897–1990), Chinese physiologist.

Tuffier's line: a line that may be drawn between the highest points of the iliac crests on which the spine of L4 usually lies in adults.

Théodore Tuffier (1857–1929), French surgeon.

Türk, bundle of: corticopontine fibres that originate from parietal, occipital and temporal lobes.
Ludwig Türck (1810–68), Austrian neurologist.

Turner syndrome: a disorder of gonadal differentiation, marked by short stature, undifferentiated (streak) gonads and variable anomalies that may include webbing of the neck, low posterior hair line and cardiac defects.
Henry Hubert Turner (1892–1970), American endocrinologist.

Twining's line: the line between the tuberculum sellae and the torcular.
Edward Wing Twining (1887–1939), often cited as the 'father of British neuroradiology'.

Urbach–Wiethe syndrome: lipoid proteinosis, an autosomal recessive multisystem genodermatosis that primarily affects the skin, oral cavity and larynx, with the deposition of an amorphous hyaline material as a consequence of mutation of extracellular matrix protein 1 (ECM1). Neurological complications include basal ganglia calcification, usually bilaterally symmetrical.
Erich Urbach (1893–1946), Austrian dermatologist; Camillo Wiethe (1889–1949), Austrian otorhinolaryngologist.

Usher syndrome, Usher–Hallgren syndrome: a condition characterized by hearing loss or deafness and progressive loss of vision caused by retinitis pigmentosa. The three major types of Usher syndrome (types I, II and III) are distinguished by their severity and the age at which signs and symptoms appear (synonyms: Hallgren syndrome, dysacusis syndrome, dystrophia retinae dysacusis syndrome).
Charles Howard Usher (1865–1942), Scottish ophthalmologist.

Valoean sheath: the connective tissue capsule surrounding the liver.
Valoeus, an anatomist from the Middle Ages, who first described the liver capsule.

Valsalva: aortic sinuses of – the aortic sinuses;

manoeuvre – any forced expiratory effort ('strain') against a closed airway, whether at the nose and mouth or at the glottis.
Antonio Maria Valsalva (1666–1723), Professor of Anatomy, Bologna, Italy.

van de Woude's syndrome: an autosomal dominant syndrome characterized by a cleft lip or cleft palate, and/or distinctive pits of the lower lips, the most common syndrome associated with cleft lip or cleft palate (Van der Woude A 1954 Fistula labii inferioris congenita and its association with cleft lip and palate. Am J Hum Genet 6:244–56).

van Gieson technique, elastic van Gieson technique: a solution of trinitrophenol and acid fuchsin used to stain connective tissue elastin on histological sections.
Ira Thompson van Gieson (1866–1913), American neuropathologist, New York, USA.

Vater, ampulla of: the ampulla at the junction of the common hepatic and pancreatic ducts.
Abraham Vater (1684–1751), Professor of Anatomy, Botany, Pathology and Therapeutics, Wittenburg, Germany.

Velpeau, space of: (quadrangular space, quadrilateral space, foramen humerotricipitale): a space bounded by subscapularis, the capsule of the shoulder joint and teres minor superiorly, teres major inferiorly, the long head of triceps medially and the surgical neck of the humerus laterally. The axillary nerve and the posterior circumflex humeral artery and vein pass obliquely through the space.
Alfred-Armand-Louis-Marie Velpeau (1795–1867), French anatomist and surgeon.

Vesalius, foramen of: a small foramen for the emissary vein immediately anterior and medial to the foramen ovale in the sphenoid bone.
Andreas Vesalius (1514–1564), Professor of Anatomy, Padua, Italy.

Vicq d'Azyr, band or stripe of: a white band or stripe in the occipital cortex; also described by Gennari in 1782.
Félix Vicq d'Azyr (1748–94), French physician, anatomist, historian and social reformer who is often described as the greatest comparative anatomist of the eighteenth century before Cuvier.

Vidian: canal – the pterygoid canal;

nerve – the nerve of the pterygoid canal.
Guido Guidi Vidius (1500–1561), Professor of Medicine, Pisa, Italy.

Vieussens: anulus of – the ansa subclavia of sympathetic nerves; a tenuous anastomosis around the right ventricular outflow tract

arterial ring – an inconstant anastomosis around the right ventricular outflow tract that may provide an important collateral circulation in cases of arterial occlusion.
Raymond de Vieussens (1641–1715), physician and anatomist, Montpellier, France.

Virchow–Robin space: a perivascular space in the central nervous system.
Rudolf Ludwig Virchow (1821–1902), Professor of Pathological Anatomy, Würzburg, and then Berlin, Germany; Charles-Philippe Robin (1821–1885), Professor of Histology, Paris, France.

Vogt, palisades of: crests of epithelial folds at the limbus that run radially towards the cornea from the bulbar conjunctiva.
Alfred Vogt (1879–1943), Swiss ophthalmologist.

Voigt's lines, Voigt–Futcher lines: pigmentary demarcation lines or hair tracts (synonym: Futcher's lines).
Christian August Voigt (1809–1890), Professor of Anatomy, Vienna, Austria; Palmer Howard Futcher (1910–2004), US–Canadian physician.

Volkmann's: canals – osseous canals carrying blood vessels from the periosteum and between osteons;

ischaemic contracture – a permanent flexion contracture of the hand at the wrist, resulting in a claw-like deformity of the hand and fingers.
Alfred Wilhelm Volkmann (1800–1877), Professor of Anatomy and Physiology, first at Dorpat, Estonia, and later Halle, Germany.

von Brunn's nests: ectopic (subepithelial) urothelial masses in the urinary tract.
Albert von Brunn (1849–1872), Professor of Anatomy, Göttingen, Germany.

von Ebner's: fissure – in the development of the back, sclerotomal populations form from the ventral half of the epithelial somite. An intrasegmental boundary (fissure or cleft, sometimes termed von Ebner's fissure), which is initially filled with extracellular matrix and a few cells, appears within the sclerotome and divides it into loosely packed cranial, and densely packed caudal, halves;

glands – serous glands of the tongue, located beneath the circumvallate and foliate papillae;

lines – incremental lines of dentine.
Anton Gilbert Viktor von Ebner (also commonly called Viktor von Ebner-Rofenstein) (1842–1925), Professor of Histology and Embryology, Innsbruck, Austria.

Von Economo neurone: spindle neurone characterized by a single apical dendrite, a single basal dendrite and a long projection axon.
Constantin von Economo (1876–1931), Austrian psychiatrist and neurologist.

von Hippel–Lindau disease: an autosomal dominant genetic condition with high penetrance resulting from a deletion or mutation in the VHL tumour suppressor gene on chromosome 3p25.3. Characterized by retinal and CNS haemangioblastomas, pheochromocytomas, multiple cysts in the pancreas and kidneys. Benign tumours have an increased potential for malignant transformation.
Eugen Adolf Arthur von Hippel (1867–1939), German ophthalmologist; Arvid Vilhelm Lindau (1892–1958), Swedish pathologist and bacteriologist.

von Willebrand factor: the factor released from endothelial cells and platelets, promoting platelet adhesion and blood clotting. Deficient or defective factor production (usually inherited as an autosomal dominant trait) causes von Willebrand disease.
Erik Adolf von Willebrand (1870–1949), Finnish haematologist. Described the eponymous hereditary clotting disorder in 1926.

Waardenburg type II syndrome: a deafness syndrome associated with pigmentary disturbances. A group of heterogeneous entities distinguished from Waardenburg type I syndrome by the absence of dystopia canthorum.
Petrus Johannes Waardenburg (1886–1979), Dutch ophthalmologist and geneticist.

Waldeyer: presacral fascia of – the floor of the retrorectal space (Jin ZM, Peng JY, Zhu QC et al 2011 Waldeyer's fascia: anatomical location and relationship to neighboring fasciae in retrorectal space. Surg Radiol Anat 33:851–4);

Waldeyer's ring – a ring of lymphoid tissue that includes the palatine, pharyngeal, tubal and lingual tonsils;

Waldeyer's sheath – adventitia of distal segments of the ureter.

Heinrich Wilhelm Waldeyer (1836–1921), Professor of Pathology at Breslau, Poland, and then Berlin, Germany.

Wallenberg's syndrome: a lesion of the lateral medullary region of the brainstem.
Adolf Wallenberg (1862–1949), German physician.

Wallerian degeneration: degeneration of myelinated and unmyelinated axons distal to any injury that transects the axons and separates their distal segments from their centrally placed neuronal cell bodies.
Augustus Volney Waller (1816–1870), British neurophysiologist.

Walther, ganglion of: the solitary, retroperitoneal median ganglion impar or sacrococcygeal ganglion, which lies anterior to the sacrococcygeal junction; it represents the distal termination of the sympathetic chains.
August F Walther (1688–1746), German anatomist.

Wartenberg's disease, sign, symptom: radial sensory nerve entrapment.
Robert Wartenberg (1866–1956), American neurologist.

Warwick's foramen: a foramen located between the inferior end of the superior orbital fissure and the foramen rotundum.
Roger Warwick (1912–1991), English anatomist.

Waterston, groove of/interatrial sulcus of: the sulcus separating the right and left atria of the heart (aka Sondergaard's groove).
David Waterston (1910–1985), Scottish cardiothoracic surgeon.

Weigert–Meyer rule: the rule that, when complete, duplicated ureters insert separately into the bladder; the upper pole ureter is the ectopic ureter and its orifice inserts inferomedially in the bladder; the lower pole ureter is the normal ureter
Carl Weigert (1845–1904), German pathologist; Robert Meyer (1864–1947), German gynaecologist and pathologist.

Weigert, staining technique of: histological stains for myelin and for elastic fibres. The former uses a solution of ferric chloride and haematoxylin that stains myelin sheaths deep blue and degenerated tissue a pale yellow; the latter uses a resorcin–fuchsin solution that stains elastic fibres blue–black.
Carl Weigert (1845–1904), German histopathologist, Frankfurt-am-Main, Germany.

Werner's syndrome: a rare, autosomal recessive progeroid syndrome, characterized by the appearance of premature ageing.
Carl Wilhelm Otto Werner (1879–1936), German physician.

Wernicke: frontomarginal sulcus of – frontomarginal sulcus in the cerebral cortex;

Wernicke's speech area – the motor speech area in the superior temporal lobe of the cerebral cortex;

Wernicke's syndrome – a syndrome characterized by mental and ocular disorders and ataxia. Mental disturbances include listlessness, disorientation, confusion, hallucinations, Korsakoff psychosis and other behavioural symptoms.
Karl (or Carl) Wernicke (1848–1904), German physician, anatomist, psychiatrist and neuropathologist. Breslau, Poland, and then Halle, Germany.

Wharton's: duct – a duct of the submandibular salivary gland;

jelly – a homogenous intercellular substance of the umbilical cord; gives a reaction for mucin and contains thin collagenous fibres that increase in number with fetal age.
Thomas Wharton (1614–1673), physician and anatomist, St Thomas's Hospital, London, UK. Remained on duty there during the Great Plague of 1665.

Whipple procedure: pancreaticoduodenectomy.
Allen Oldfather Whipple (1881–1963), American surgeon.

Whitnall: transverse ligament of – a ligament that originates from the trochlea and inserts into the lateral orbital wall, approximately 10 mm above Whitnall's tubercle;

Whitnall's tubercle – a tubercle on the orbital surface of the zygomatic bone.
Samuel Ernest Whitnall (1876–1950), Professor of Anatomy, successively at McGill University, Montreal, Canada, and Bristol, UK.

Wiebel–Palade bodies: rod-shaped storage granules in endothelial cells.
Euald Wiebel, Swiss physician; George Emil Palade (1912–2008), Romanian cytologist, Rockefeller Institute, New York, USA, awarded the Nobel Prize for Medicine or Physiology in 1974.

Williams–Campbell syndrome: a rare form of congenital cystic bronchiectasis, in which distal bronchial cartilage is defective (Williams H, Campbell P 1960 Generalized bronchiectasis associated with deficiency of cartilage in the bronchial tree. Arch Dis Child 35:182–91).
Howard Williams, twentieth-century Australian physician; Peter E Campbell, twentieth-century Australian physician.

Willis, circle of: circulus arteriosus cerebri (cerebral arterial circle); the arterial anastomosis at the base of the brain.
Thomas Willis (1621–1675), physician to King James II, practised first in Oxford, then London, UK.

Wilson's pencils, pencil fibres of Wilson: the striatopallidal fibres (Wilson SAK 1914 An experimental research into the anatomy and physiology of the corpus striatum. Brain 36:427–92).
Samuel Kinnier Wilson (1878–1937), American-born British neurologist.

Winslow, foramen of: the epiploic foramen leading to the lesser sac.
Jacob B Winslow (1669–1760), Professor of Anatomy and Surgery, Paris, France.

Wirsung, duct of: the main pancreatic duct.
Johann Georg Wirsung (1589–1643), German physician, Prosector in Anatomy, Padua, Italy.

Wiskott–Aldrich syndrome: primary immunodeficiency resulting from an X-linked recessive mutation.
Alfred Wiskott (1898–1978), German paediatrician; Robert Anderson Aldrich (1917–1998), American paediatrician.

Wolffian: body – the mesonephros;

duct – the mesonephric duct.
Caspar Wolff (1733–1794), born in Berlin, Professor of Anatomy, St Petersburg, Russia, one of the pioneers of embryology.

Wolff's law: states that changes in the stresses on bones are reflected in their internal structure.
Julius Wolff (1836–1902), orthopaedic surgeon, Berlin, Germany.

Wolff–Parkinson–White syndrome: bundle-branch block with short P–R interval in healthy young people prone to paroxysmal tachycardia.
Louis Wolff (1898–1972), American cardiologist; John Parkinson (1885–1976), English cardiologist; Paul Dudley White (1886–1973), American cardiologist.

Wolfring, glands of: small tubuloalveolar glands in the subconjunctival tissue above the upper border of the tarsal plate.
Emilij Franzevic von Wolfring (1832–1906), Polish ophthalmologist.

Wormian bones: small bones that occasionally occur along the lambdoid suture of the human skull (synonym: sutural bones).
Ole Worm (1588–1654), physician, Professor of Medicine, University of Copenhagen, Denmark.

Wright's stain: a mixture of eosin and methylene blue, used for demonstrating blood corpuscles and malarial parasites on histological sections or blood smears.
James Homer Wright (1869–1928), pathologist, Harvard University, Cambridge, Massachusetts, USA.

Wrisberg, ligament of: a band attached to the posterior cruciate ligament of the knee.
Heinrich August Wrisberg (1739–1808), Professor of Anatomy, Göttingen, Germany.

Yakovlev's circuit: one of the divisions of the limbic system, a circuit involving the orbitofrontal, insular and anterior temporal lobe cortex, the amygdala and the dorsomedial nucleus of the thalamus, involved in emotion, reward and social behaviour.
Paul Ivan Yakovlev (1894–1983), Russian-born neurologist and neuropathologist who worked in the USA from 1925.

Young's modulus: sometimes called Young's modulus of elasticity: a measure of the ability of a material to withstand changes in length when under lengthwise tension or compression.
Thomas Young (1773–1829), British physician and physicist.

Zeis, glands of: modified rudimentary sebaceous glands attached directly to the follicles of the eyelashes.
Edward Zeis (1807–1868), German ophthalmologist.

Zellweger's syndrome: an inherited defect in peroxisome biogenesis and functioning.
Hans Ulrich Zellweger (1909–1990), Swiss–American paediatrician.

Zencker's diverticulum: a posteromedial pulsion diverticulum through Killian's dehiscence that causes debilitating dysphagia and regurgitation.
Friedrich Albert von Zenker (1825–1898), German physician and pathologist.

Zinn: anulus of – otherwise known as the common tendinous ring, it is a fibrous ring that surrounds the optic canal and part of the superior orbital fissure at the apex of the orbit and gives origin to the four recti;

circle of, zonula of – an (often incomplete) vascular circle within the sclera, formed by branches of the short posterior ciliary arteries, whose centripetal branches supply the laminar region of the optic nerve head (synonym: circle of Haller, zonula of Haller).
Johann Gottfried Zinn (1727–1759), Professor of Medicine and Director of Botanical Gardens, Göttingen, Germany.

Zuckerkandl: fascia of – the fascia posterior or anterior to the kidney;

organ of – the para-aortic bodies (also known as paraganglia) are collections of neural crest-derived chromaffin tissue found in close relation to the abdominal aortic plexus;

tuberculum of, tubercle of – a projection of normal thyroid tissue from the posterior or lateral lobes of the thyroid gland.
Emil Zuckerkandl (1849–1910), Professor of Anatomy at Graz and then Vienna, Austria.

Many of the eponyms in this list are described in more detail in Firkin BG, Whitworth JA 2001 Dictionary of Medical Eponyms. London: Parthenon. A concise illustrated account of the derivation and individuals behind the more common eponyms associated with liver anatomy and surgery is provided in Stringer MD 2009 Eponyms in Surgery and Anatomy of the Liver, Bile Ducts and Pancreas. London: Royal Society of Medicine.
