The hallmark of cavotricuspid isthmus-dependent atrial tachycardia is the demonstration of continuous propagation of activation around the tricuspid valve annulus which comprises the entire cycle length of the tachycardia. This can be readily demonstrated by electroanatomic mapping and/or by multi-electrode catheters recording activation along both septal and free wall surfaces of the right atrium. Activation within the cavotricuspid isthmus should fall in the "diastolic zone" of atrial activation. However, similar activation can sometimes be observed with other tachycardia circuits, including left atrial tachycardias, atrial septal tachycardias, or "scar-dependent" circuits from the right atrial free wall, depending on the location and timing of breakout to the remainder of the right atrium. This can lead to the erroneous presumption of an isthmus-dependent mechanism. Careful employment of entrainment maneuvers to ensure that the isthmus is within the tachycardia circuit is therefore advisable before commencing with ablation in this area (**Fig. 4**). Successful ablation of cavotricuspid isthmus-dependent flutter is usually performed during ongoing tachycardia; as a line of conduction block nears completion, progressive lengthening of the tachycardia cycle length is observed before termination. Differential pacing is then performed from near the medial and lateral aspect of the cavotricuspid isthmus to demonstrate conduction times >130 ms in both directions, and ensure that activation traverses the upper atrium to the contralateral atrial wall before arriving to the opposite side of the cavotricuspid isthmus. While this is usually a useful predictor of successful ablation, it is sometimes useful to demonstrate the conduction time across the isthmus at baseline (prior to atrial flutter induction) to ensure that a longer than expected delay is not present at baseline.

Scar-dependent

So-called scar-dependent atrial flutter represents a challenge for the purposes of mapping and ablation. A thorough understanding of all preceding surgeries is helpful in order to anticipate the expected locations of surgical incisions. While most scar-dependent flutters are macro-reentrant in nature, cycling around the incision, focal tachycardias likely representing micro-reentry may also be observed. Detailed activation mapping is necessary, with careful delineation of scar edges (as defined by low amplitude local electrogram, typically <0.1–0.2 mV). Additional attention to complex electrograms ("split" and "fragmented" potentials) and how these relate to the tachycardia circuit are important. It is not uncommon to observe tachycardia supported by conduction through a "protected corridor" between the crista terminalis and an adjacent atriotomy scar, and great care and high density recordings may be necessary to identify and correctly characterize this conduction. Entrainment maneuvers become essential in evaluating such circuits.

It is important to recognize that scar may exist in atria due to both surgical incisions and late fibrosis with regional conduction delay due to abnormal loading conditions. As such, complex interplay with the potential for diverse and multiple circuits may be encountered. These may exist as individually distinct circuits that are separately able to be induced and mapped, as spontaneous transitions between circuits (with changes in rate and activation), or as concurrent "double-loop" patterns which may be unmasked as ablation lesions result in an abrupt change in rate and activation (**Fig. 5**). As such, simultaneous recordings from sufficiently numerous sites are helpful to recognize and distinguish between such multiple circuits.

Ablation of incisions related to a right atriotomy carries the additional risks of injury to the right phrenic nerve or the sinoatrial node. Usually, the phrenic nerve lies in close proximity to the crista terminalis, and the normal sinoatrial node is likewise situated

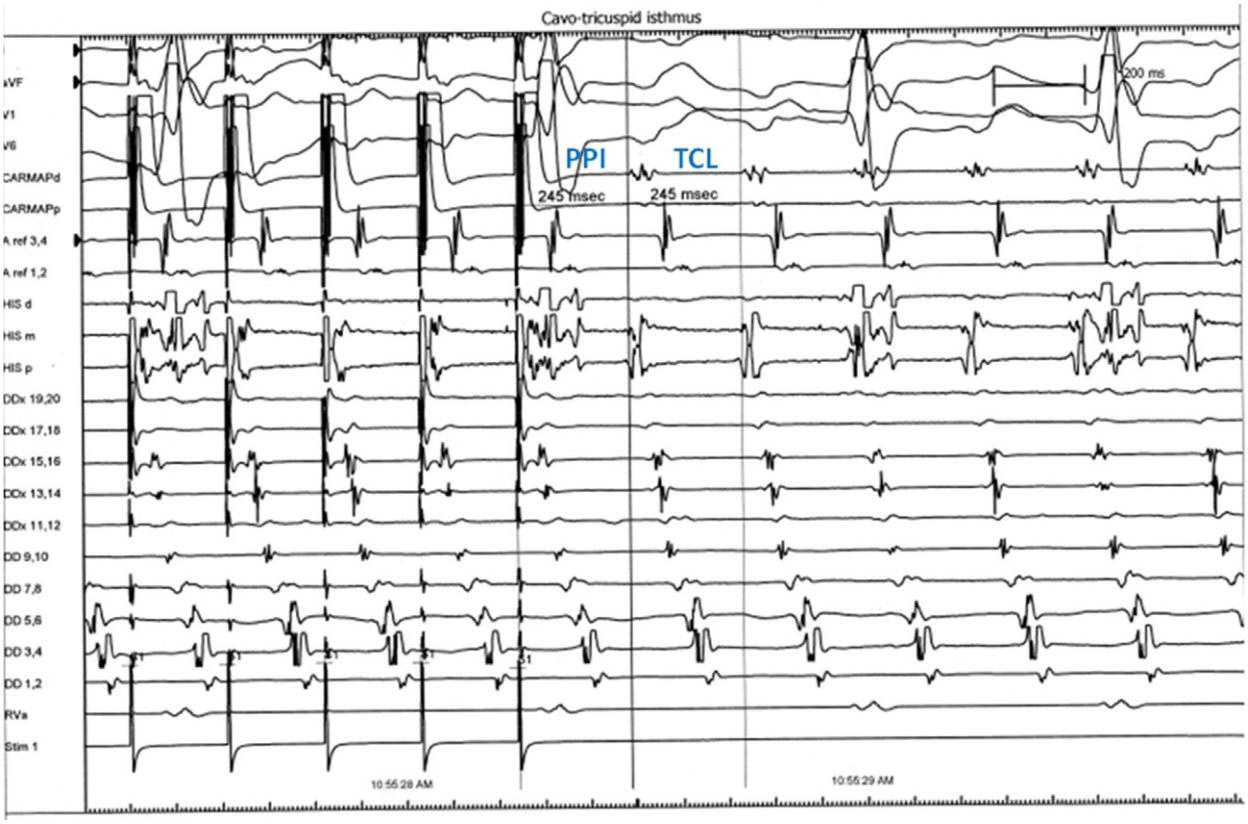

Fig. 4 Entrainment of intra-atrial reentry tachycardia with pacing from the mapping catheter positioned at the cavotricuspid isthmus. Note the concealed fusion, with identical atrial activation pattern during entrainment and tachycardia. The cavotricuspid isthmus is included in the tachycardia circuit, as the post-pacing interval (PPI) and tachycardia cycle length (TCL) are identical. Channels labeled "DD" represent a twenty-pole reference catheter placed from the IVC along the atrial septum and deflected laterally such that poles 1–8 are positioned from low to high along the lateral right atrial wall and poles 11–18 are high to low along the right atrial side of the interatrial septum.

within the crista. To avoid injury to the phrenic nerve, high output pacing while viewing the right diaphragm fluoroscopically should be considered before delivering lesions on the right atrial free wall. When possible, an activation map of the native sinoatrial node at the outset of the study is therefore advisable. Cryoablation may offer less risk of inadvertent injury to these key structures, though may be less likely to be permanently effective in a hypertrophied atrium.

Left-sided circuits

Although most reentrant circuits in adult congenital heart disease patients are right sided, the potential for left-sided circuits may be anticipated in certain lesions, notably patients with mitral valve repair or replacement, repair of partial or total anomalous pulmonary venous connections, and patch repair of an atrial septal defect. Each of these lesions could also predispose to cavotricuspid isthmus-dependent atrial flutter or right-sided scar-related circuits due to the presence of a right atriotomy. The directionality of coronary sinus activation may help in this distinction, but again entrainment maneuvers may be especially important in differentiating between these mechanisms. In the case of reentry around an atrial septal defect patch, it is usually necessary to ablate on the left atrial surface since the medial borders of this circuit are likely to be shielded from right-sided radiofrequency lesions by the patch itself. It may be useful to utilize a double-transseptal technique to deploy both a multi-electrode catheter and a mapping catheter simultaneously in the left atrium.

Junctional Ectopic Tachycardia

Outside of the transient postoperative setting, junctional ectopic tachycardia represents a vexing challenge (Collins et al., 2009). Suppression with antiarrhythmic therapy may be difficult to achieve. The precise mechanism may be unclear, and could include automaticity from within the His bundle (presumed to be the case in the incessant form), intra-Hissian reentry due to partial isolation of parallel tracts within the His bundle, or even a variant of AV node reentrant tachycardia contained within the compact AV node displaying retrograde block. In general, this arrhythmia requires lesions in close proximity to the compact AV node or proximal His bundle, thus carrying an unusually high risk of inadvertent AV block (~20%–30%). When incessant, attenuation of the arrhythmia with catheter pressure may help identify optimal ablation sites. Cryoablation is preferable, both due to the usual advantages of adherence and reversibility in the event of compromised AV node conduction, and to avoid acceleration of the junctional rate which may obscure the endpoint of ablation or make it difficult to ensure the integrity of AV node conduction with radiofrequency lesions. Even so, the increased risk of ablation and potential need for pacing should be clearly outlined with patients and families prior to undertaking ablation for this arrhythmia.

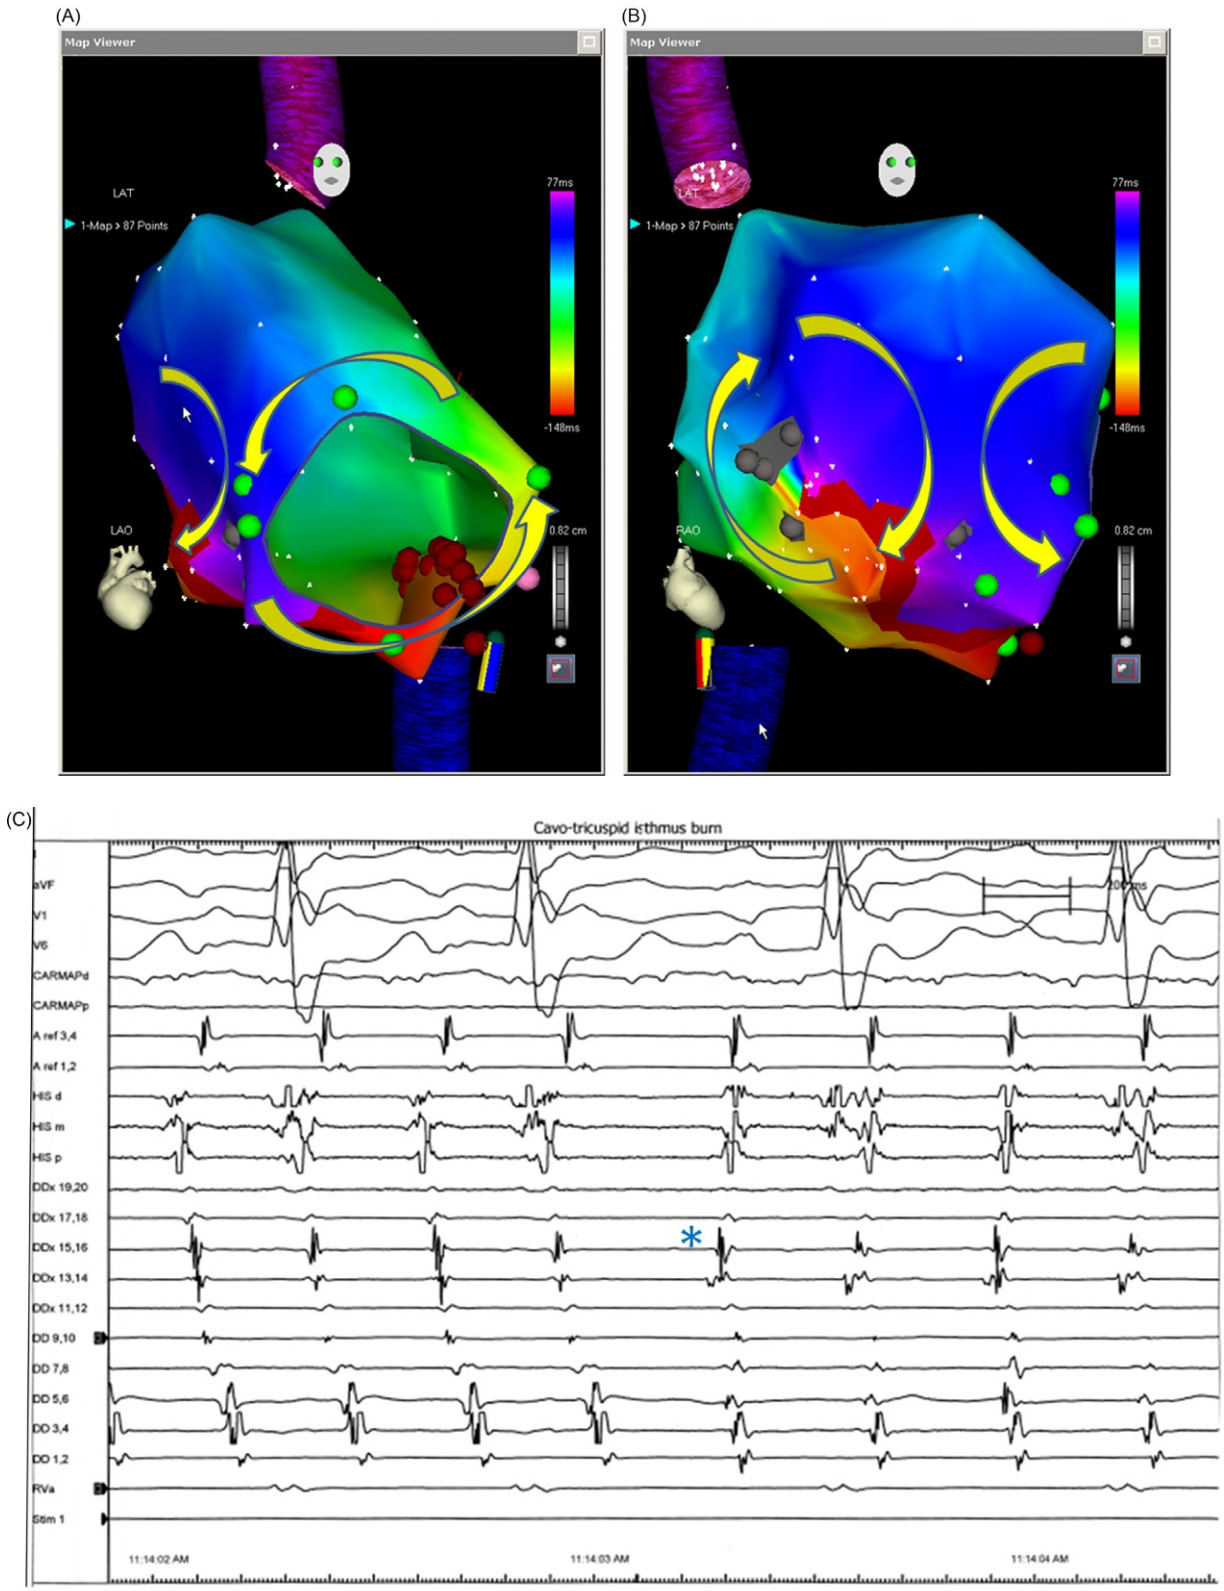

Fig. 5 Example of intra-atrial reentrant tachycardia with a "double-loop" circuit facilitated by both the cavotricuspid isthmus and atriotomy scar. (A) Electroanatomic activation map during tachycardia as viewed from left anterior oblique perspective demonstrating counter-clockwise propagation around the tricuspid annulus. Note proximity of signals in the cavotricuspid isthmus with very early and late timing. Entrainment of this tachycardia from the cavotricuspid isthmus is shown in **Fig. 4**. (B) Electroanatomic activation map of the same patient and tachycardia as seen in Fig. 5A, but from the right anterior oblique perspective. There is clockwise propagation around scar tissue, presumably related to previous lateral atriotomy.

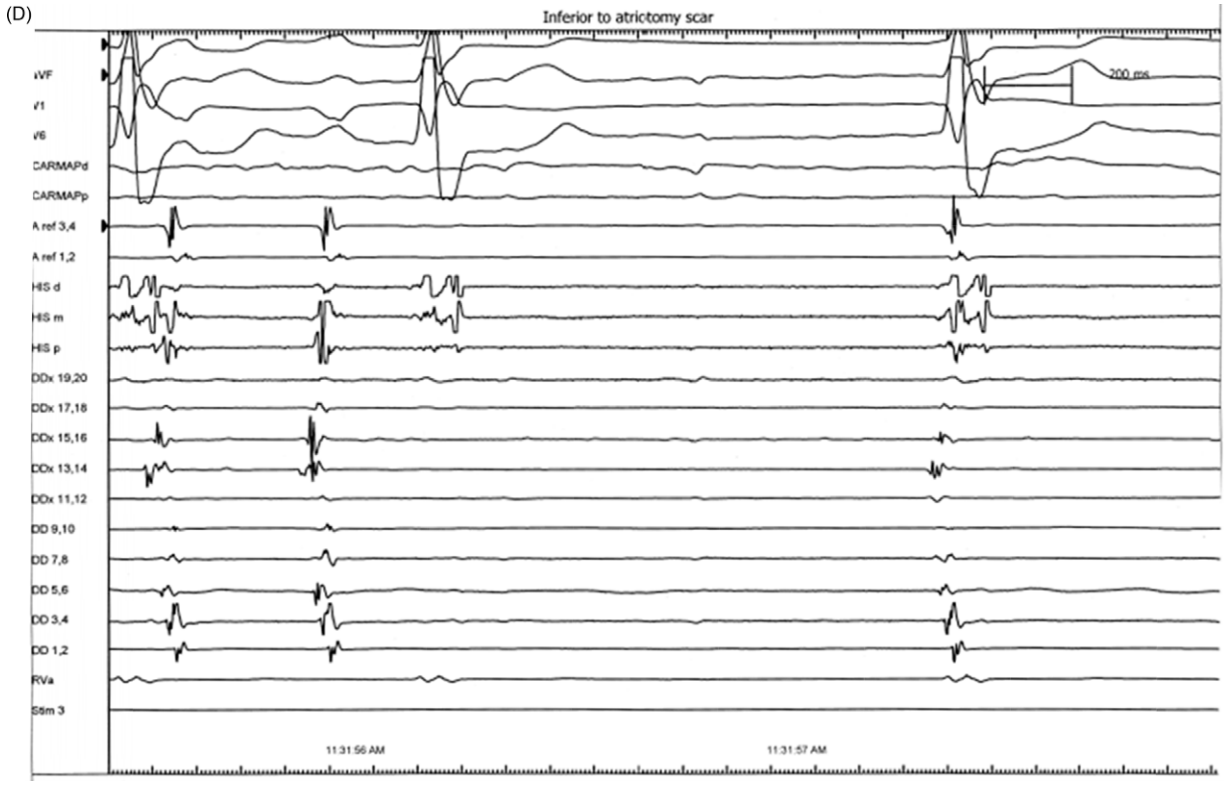

Fig. 5—Cont'd (C) Response of tachycardia shown in **Fig. 4** to completion of line of block across cavotricuspid isthmus (*marks shift from initial tachycardia to new tachycardia). (D) After confirmation of new tachycardia circuit by activation remap and entrainment, acute termination with creation of an additional line of block extended from the lateral atriotomy scar inferiorly to the IVC.

Atrial Fibrillation

While ablation of atrial fibrillation has emerged as the dominant focus of ablation in adults, it remains a very small niche in the pediatric population. Atrial fibrillation is much less common than other supraventricular and atrial arrhythmias among young patients with normal hearts and those with congenital heart disease. When seen, it may be in the context of an intercurrent conduction such as myocarditis or thyrotoxicosis, in certain inherited conditions such as Emery-Dreifuss Muscular Dystrophy, or in congenital defects associated with left-sided valvular disease (Biviano et al., 2010; Boriani et al., 2003; Nazarian et al., 2011). More often, it may represent a secondary rhythm in patients with other arrhythmias such as AVRT, AVNRT, atrial flutter, or chaotic (multifocal) atrial flutter (Ceresnak et al., 2013; Fish et al., 1996). Pacemakers capable of delivering automatic Anti-tachycardia Atrial Pacing are sometimes utilized in CHD patients and may sometimes induce atrial fibrillation, rather than terminate the initial arrhythmia. Care must be made in making the diagnosis of atrial fibrillation electrocardiographically in patients with atypical atrial flutter (IART) in the setting of congenital heart disease; in such patients, typical, saw-toothed "flutter waves" are often lacking, and intermediate atrial rates often result in highly variable atrioventricular conduction patterns with resulting "irregularly-irregular" RR intervals. Indeed, cases are known of patients with IART have undergone ablation inappropriately targeting presumed atrial fibrillation in whom the underlying rhythm was macro-reentrant atrial tachycardia.

In young patients presenting with atrial fibrillation, it is often advisable to perform electrophysiology study in search of other forms of SVT. When identified and targeted, ablation appears to eliminate the likelihood of atrial fibrillation recurrence. In those occasional patients with primary "lone" atrial fibrillation, the relative risk-benefit consideration for ablation is compared with other approaches such as "pill-in-the-pocket" medical therapy or acute DC cardioversion. Most young patients will display a sufficiently rapid ventricular response to allow prompt recognition of arrhythmia recurrence, negating the need for anticoagulation. Likewise, recurrences are often infrequent such that episodic therapy is often adequate. In those with atrial fibrillation in the context of congenital heart disease, it may be preferable to perform surgical ablation at the time of operative interventions addressing the underlying defect.

Limited experience of ablation in pediatric patients with lone atrial fibrillation is beginning to emerge (Balaji et al., 2016).

Ventricular Tachycardias

Ventricular tachycardias in young patients may occur as an idiopathic process, as the result of structural heart disease, or in the context of an inherited arrhythmia syndrome. The latter often predispose to sudden death but are usually polymorphic or pleomorphic in pattern, and thus ablation has little role in their treatment. In contrast, idiopathic ventricular tachycardias from the right and left ventricle are typically non-life-threatening, are amenable to ablation and the relative considerations for ablation vs medical therapy are this similar those for SVT. Monomorphic ventricular tachycardias associated with congenital heart disease are

often amenable to ablation. However, due to a potential risk of sudden death, the role of ablation as primary therapy vs adjunctive therapy in combination with an Internal Cardiac Defibrillator must be an individualized decision based upon lesion, presenting symptoms, and institutional experience and capabilities. Occasionally, recurrent ventricular fibrillation provoked by a focal trigger may offer a target for ablation (Noda et al., 2005; Haissaguerre et al., 2002).

The most common ventricular tachycardias encountered are idiopathic focal tachycardias arising from the right or the left ventricular outflow tract (Badhwar and Scheinman, 2007). These display a characteristic electrocardiographic pattern with a superior QRS axis, tall, typically symmetric QRS complexes in the inferior leads and a left bundle branch block pattern. Often these arrhythmias prevail within an intermediate heart range, and are often partially or completely suppressed during sleep (or while under anesthesia). Likewise, they may increase with physical or emotional stimulation, but suppress during maximal exercise; often sustained tachycardia follows exertion, leading to the notion that this arises from a triggered activity or "triggered automaticity." Sometimes, this rate dependence can be replicated by pacing at a given heart rate to provoke ectopy. However, induction with traditional programmed stimulation suggests a reentrant, rather than focal mechanism and a search for underlying pathology should follow (Stratemann et al., 2008; Hornung et al., 2016).

Catheter ablation of idiopathic outflow tract ventricular tachycardia begins with assessment of the clinical scenario, the electrocardiographic appearance of the VT as well as EKG during sinus rhythm, and imaging to ensure no underlying structural heart disease, particularly Arrhythmogenic Right Ventricular Cardiomyopathy. Note that localized wall motion abnormalities may be seen on MRI in patients with idiopathic RVOT ventricular tachycardia and should not be construed as "diagnostic" of ARVC.

The surface EKG is useful in helping to discern the origin of the tachycardia. As a simple guide, the more rightward the QRS transition from dominant S to dominant R, the more left the origin. More detailed criteria have been described to help distinguish between foci on the anterior RVOT free-wall, ROVT septum, aortic valve cusps, or LV outflow tract (Efimova et al., 2015). This is useful in planning mapping strategy and anticipating the area warranting the most intense mapping focus.

The strategy of activation mapping and ablation for outflow tract ventricular tachycardia is inherently straightforward, targeting the site of earliest ventricular activation which should precede QRS onset by at least 20–30 ms (**Fig. 7A–C**). Pacing at this site should result in a QRS morphology identical to the VT (pacemapping), and algorithms are available to assess the degree of QRS match (Kurosaki et al., 2009). Failure to replicate the VT morphology might indicate that "early activation" was actually recorded during a catheter-induced ectopic beat.

However, a number of pitfalls may be encountered, and it is important that these be anticipated to enable a successful ablation. Perhaps the most important in young patients being the potential for significant, even complete arrhythmia suppression after induction of anesthesia. While it may be feasible to perform mapping and ablation in an awake young patient, his/her ability to remain still and calm for the duration of a case cannot be presumed. It is helpful to monitor a patient for a period of time and obtain a representative 12 lead of the tachycardia to serve as a template for later pacemapping. Indeed, if arrhythmia suppression follows and tachycardia or ectopy cannot be elicited by pacing or pharmacologic maneuvers, pacemapping may be the sole guide for targeting the arrhythmia (Kurosaki et al., 2009).

Electroanatomic mapping is highly advantageous in mapping outflow tract VT. If an otherwise active focus is sudden inhibited by catheter position, the last ectopic complex should be captured and this site should be marked to verify early local activation. If ectopy remains suppressed, and pacemapping at this site is concordant, energy delivery is reasonable (Kühne et al., 2010). Care must be taken to avoid incorporation of ectopy induced mechanically by the catheter into the activation map. This may be more difficult to ensure with automated mapping systems, and use of QRS-matching algorithms can help in this, as can appreciating that the early activation at the ectopic focus is typically low amplitude and fragmented compared to the high amplitude EGM observed during mechanical ectopy. When there is insufficient ectopy for activation mapping, a variety of measures can be attempted, including changing anesthetic agents or allowing the patient to emerge from anesthesia; administering catecholamine infusions (isoproterenol, epinephrine); or administering methylxanthines (aminophylline, caffeine). Sometimes, delivering sustained pacing bursts can provoke transient ectopy (possibly by loading the SR with calcium, inducing calcium transients). When all else fails, pacemapping alone can often lead to successful ablation, but procedural efficacy vs failure becomes evident only during the postprocedural monitoring.

Typically it is our practice to systematically begin with RV mapping then move sequentially to aortic cusps, LVOT, and finally to the cardiac summit. This not only allows transition from lower to higher risk sites but also allows the anatomic geometry to be "built" in a manner that facilitates ablation in more complex areas. When mapping the aortic cusps, it is essential to avoid lesions in or on the coronary arteries by identifying their take-offs; this can be done by angiography, integrated ice images, or directly marking the sites with the mapping system. It is also useful to note the proximity of the left cusp and the high anterior outflow tract at the mitral annulus and the right cusp to the septal RVOT. Note that pacemapping is usually not feasible from the cusps. Occasionally, an outflow focus can only be approached via advancing the catheter via the coronary sinus into the transition from the anterior interventricular vein to the great cardiac vein (**Fig. 8A** and **B**). Typically, RF energy should be delivered at low energy with an irrigated tip catheter to minimize adjacent tissue injury and venous thrombosis. Due to multiple approach to the outflow tracts and relatively thin-walled myocardium in this region, epicardial mapping and ablation is rarely required for this arrhythmia.

The second common idiopathic VT is that arising from the fascicular conduction system, most commonly the left posterior fascicular region, resulting in a QRS activation mimicking Bifascicular conduction block (RBBB with L superior axis) (Collins et al., 2013). This arrhythmia is typically paroxysmal in nature and often provoked during exercise. In the EP laboratory it can sometimes be induced with atrial pacing and sometimes entrained and terminated with atrial pacing as well. Although there is sometimes disagreement as to the underlying mechanism of this arrhythmia, it typically arises in a region on the LV septum roughly half to two-thirds of the distance from base to apex. During activation mapping, pre-QRS potentials are sought, and sometimes these can be simultaneously identified during diastole in pre-systole, confirming a local reentrant circuit (**Fig. 9**) (Nakagawa et al., 1993). Ablation at such sites is typically effective. Of note, when PP potentials can be recorded from adjacent sites during VT and during sinus, the activation pattern should be reversed during VT. Although much less common, VT can also arise from the L anterior

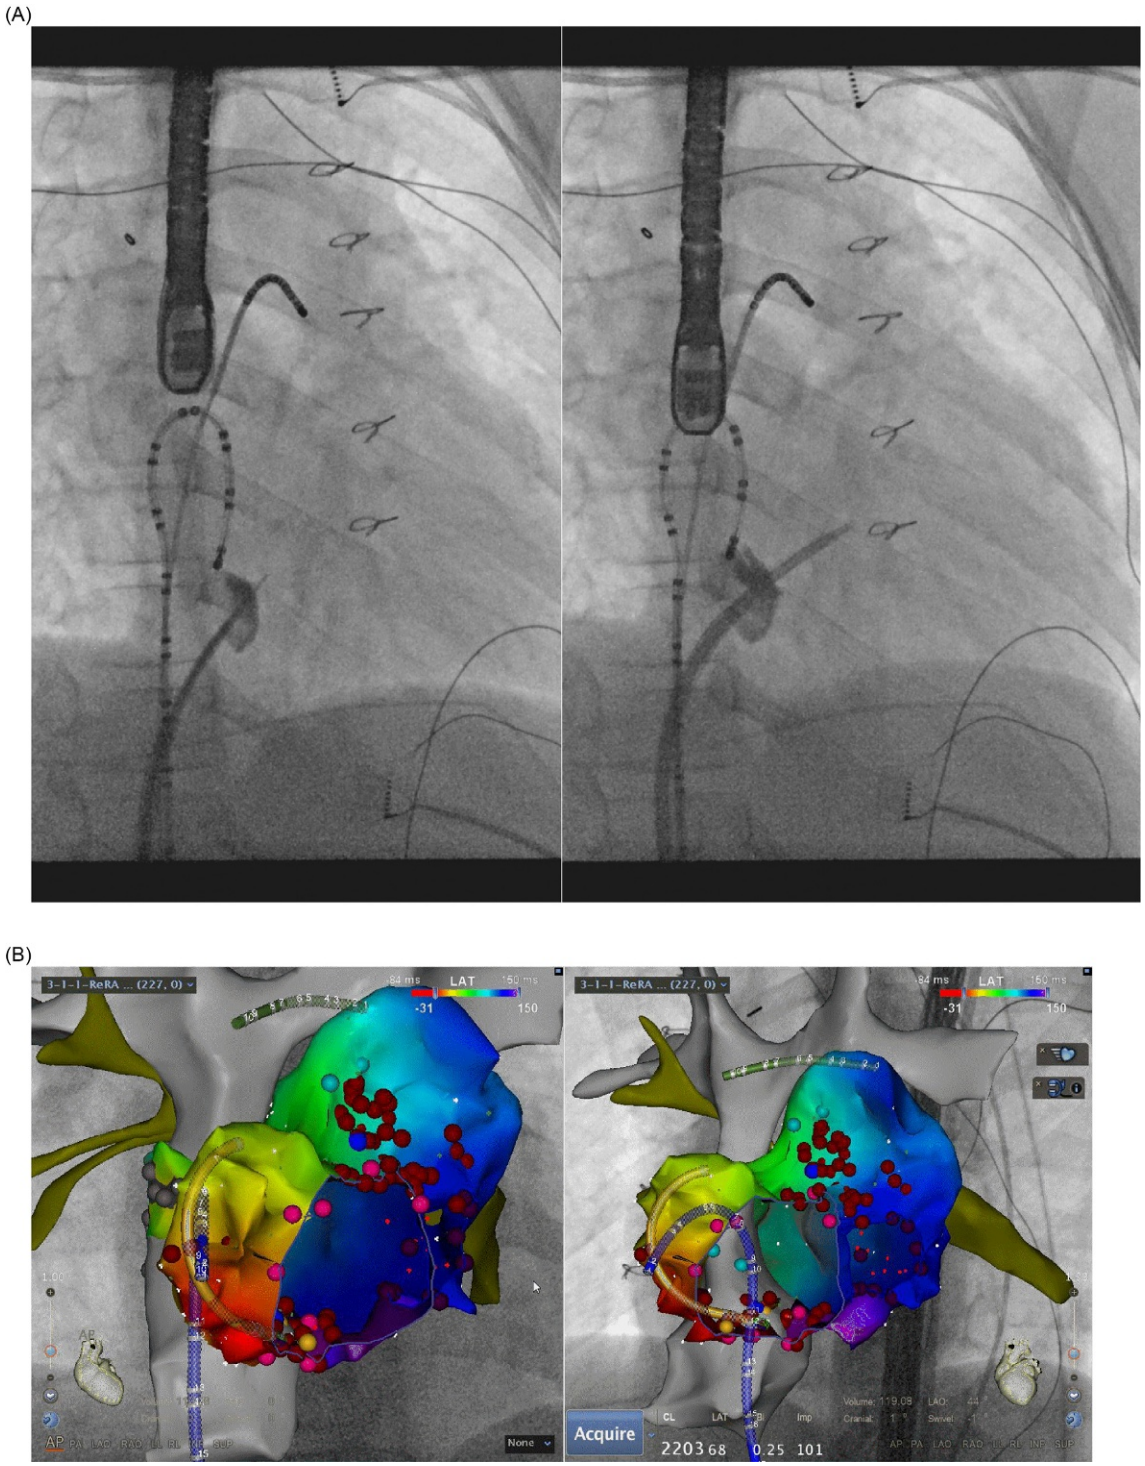

Fig. 6 (A) Puncture from extracardiac conduit fontan into common atrium in patient with double inlet left ventricle and atrial flutter (intra-atrial reentry). (B) Electroanatomic map of atrial flutter (intra-atrial reentry) in 13yo with extra-cardiac conduit fontan for double-inlet left ventricle.

fascicle and is often ablated along the mitral valve annulus. In a large single center series in mostly young adults L anterior fascicular VT accounted for only 2% of fascicular VT cases (Liu et al., 2015).

Pitfalls encountered with this arrhythmia are, as with RVOT, an inability to induce tachycardia despite aggressive stimulation with catecholamine infusions. In such cases, an anatomic approach can be utilized, placing a line of lesions along the mid-apical septum orthogonal to the long axis of the LV (Lin et al., 2005). Of note, activation mapping and pacemapping are of limited value for fascicular VTs. Since the VT engages the rapid conduction system, spread from the focus is rapid, making it difficult to discriminate from sites based on local ventricular activation. Likewise, pacing from multiple sites may replicate the VT if the fascicular system is engaged, whereas capturing local myocardium in addition to the conduction system may actually fail to replicate the VT morphology when pacing from the site of origin (**Fig. 10**).

Ventricular Premature Beats

Ventricular premature beats are a common, often asymptomatic finding in adolescents and teens. Although generally benign in the absence of structural heart disease (Gaita et al., 2001; Guerrier et al., 2015; Niwano et al., 2009; Cha et al., 2012), the potential for the development of ventricular dysfunction has been described, and ablation of VPBs has resulted in recovery of dysfunction (Efremidis et al., 2008; Hasdemir et al., 2013; Satish et al., 2005). While this appears to occur more in older patients, cases have been described of generally mild dysfunction in young patients (Hasdemir et al., 2013; Bertels et al., 2017). Thus, it is deemed appropriate (Class I) to perform VPB ablation in the presence of ventricular dysfunction (Saul et al., 2016). In patients with VPBs describing symptoms, ablation is also deemed appropriate (Class II), though it should be noted that the mere awareness of VPBs

Fig. 7—Cont'd (B) Early (pre-QRS) activation in mapping catheter (CMAPd) at effective ablation site. (C) Acceleration followed by termination of RVOT tachycardia with application of RF energy.

may or may not constitute sufficient rationale for ablation, and the risk vs benefit of ablation should be considered on an individual basis, including the potential need to ablate from an epicardial approach in some cases to achieve success.

Ventricular Tachycardia With Structural Heart Disease

The role of ablation for ventricular tachycardias associated with structural heart disease continues to evolve in young patients, as in adults. This is a consequence of improved tools and strategies for mapping and ablation juxtaposed against an increasing appreciation for the frequency of complications encountered with ICD implantation in young patients (primarily due to lead failure). The approach to VT ablation has been perhaps best studied in patients with postoperative Tetralogy of Fallot in whom 4 potential sites have been described, each of which can serve as the critical isthmus of slow/protected conduction supporting macroreentry (Kapel et al., 2015). The principles of VT mapping and ablation are similar to those described following myocardial dysfunction, though the substrate tends to be more discrete, usually displaying only a single VT morphology. Activation mapping, pacemapping, characterization of the arrhythmia substrate (scar mapping), and careful assessment of putative targets using entrainment maneuvers all play essential roles in achieving an effective result. We have encountered both macroreentrant and focal reentrant mechanisms in this population (**Fig. 11A**). Saline-irrigated and/or large tip catheters are advisable to enhance the likelihood of achieving transmural lesions. In patients with hemodynamically unstable VT, some reports have utilized noncontact mapping to identify critical isthmuses and avoid the need to allow tachycardia to sustain (Schneider et al., 2012). Alternatively, hemodynamic support with ECMO is being increasingly utilized for mapping and ablation of unstable VT in adult patients (Lu et al., 2013; Riskallah et al., 2013), and we have utilized this approach effectively in postoperative VT (**Fig. 11B**). Long-term results have varied so that ICD implantation should be considered not only in those with unsuccessful ablation but also in patients with poor ventricular function. Laredo et al. (2017) recently reported favorable long-term outcomes in a single-center cohort of 34 patients with TOF undergoing VT ablation: freedom from death and arrhythmia recurrence was 94% at 5 years, 81% at 10 years, and 70% at 20 years.

It is especially useful to consider provocative EPS with mapping and ablation in patients with TOF and similar anatomy prior to performing either surgical revision of the RV outflow tract or prior/during placement of a transcatheter pulmonary valve. In the former scenario, the results of mapping and ablation can be utilized to place additional intraoperative cryotherapy at the critical isthmus supporting VT; if immediately postablation, the RF lesions may be grossly visible to the surgeon. In the latter scenario, the concern is that insertion of a stent into the outflow tract may limit access to RVOT tissue which could be critical to the VT circuit. While epicardial ablation could be attempted, access to large regions of the epicardial surface may be limited due to adherence of the

pericardium. Although Nguyen and coworkers reported early reduction in nonsustained ventricular tachycardia (Nguyen et al., 2016), a longer study showed no reduction or prevention of arrhythmias (Prioprintr et al., 2016).

Ablation of ventricular tachycardia has been described in a number of other types of congenital and structural heart disease, including Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) (Philips et al., 2012, 2014) and a recently described entity of focal, reentrant subepicardial VT originating from the RVOT of endurance athletes (Venlet et al., 2017). Although reserved primarily to decrease VT burden and frequency of ICD shocks in patients with ARVC, Pokushalov et al. (2010) reported no VT recurrence during a follow-up of 6 months to 4 years among 16 young patients following epicardial ablation.

With the emergence of the Cone Procedure for addressing severe Ebstein's anomaly, preoperative EPS has identified ventricular tachycardia, often arising from the atrialized region of the RV (Shivapour et al., 2014). TV repair or replacement may completely thwart future access to these regions, whereas preemptive catheter ablation may be curative; as in patients with TOF, catheter mapping and ablation can also guide application of intraoperative cryolesions to the site of VT origin.

Ablation in Infants

As previously discussed, ablation in infants carries an increased risk of complications, including cardiac perforation, AV block, as well as myocardial and coronary injury. This increased risk was observed in patients weighing less than 15 kg (Kugler et al., 1994). Nevertheless, in patients with supraventricular tachycardia refractory aggressive medical therapy, ablation should be considered. Early registry data suggested that experienced centers were capable of performing ablation in infants less than or equal to 18 months old with safety and efficacy comparable to older children (Sheldon et al., 2015). A recent single-center report by Jiang et al. (2016) described ablation of 109 consecutive children under age 3 years with a 94.5% acute success rate, and recurrence rate of 6.8% with no reported complications.

In small patients, vascular complications may be decreased by use of esophageal reference catheters and microcatheters (Van Hare et al., 2002; Blaufox et al., 2001), and there may be avoidance of collateral damage with delivery of test lesions with decreased

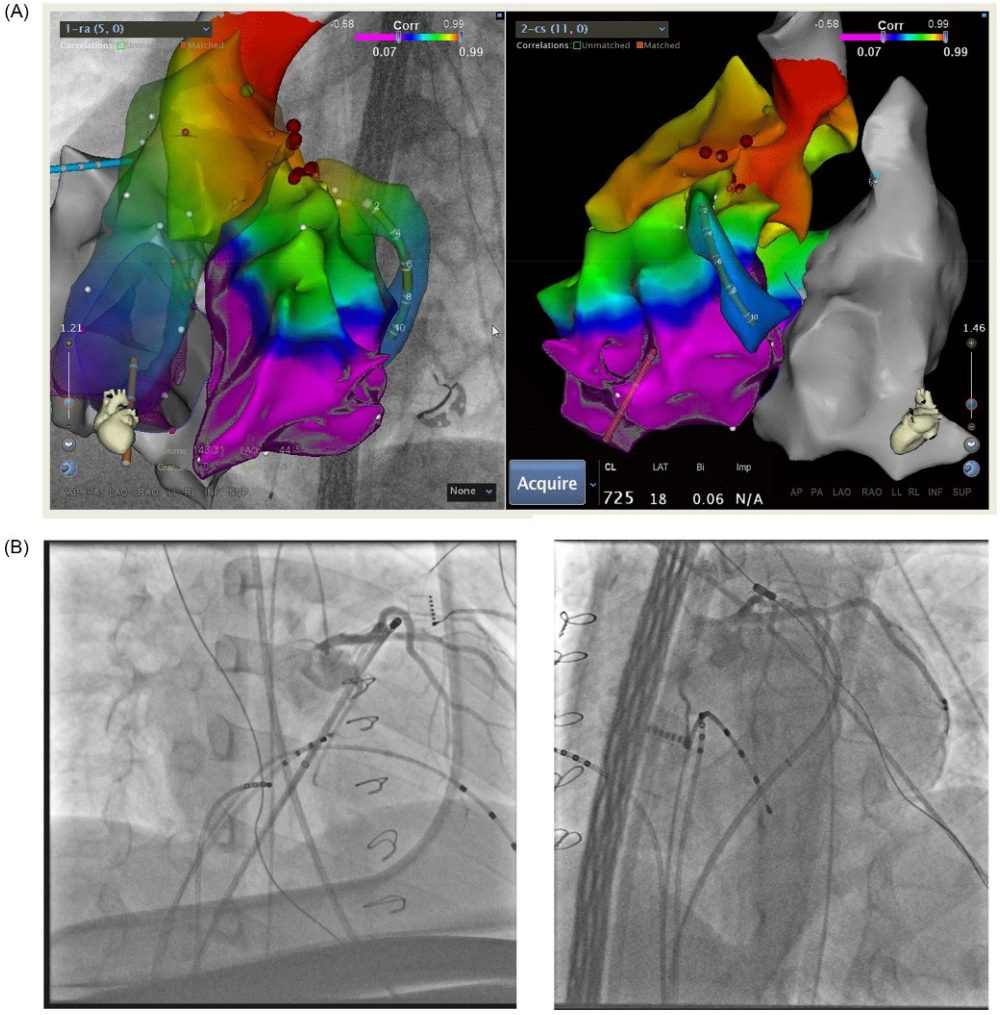

Fig. 8 (A) Idiopathic Ventricular Tachycardia from the Left Ventricular Outflow Tract, accessed via the coronary sinus and great cardiac vein. Note that early activation (depicted by *red*) was recorded in aortic root and septal RVOT, but effective ablation was only achieved via the great cardiac vein. temperature and use of ablation catheters with decreased tip size may all improve safety (Cote et al., 1996; Tanel et al., 1998). Other technical modifications advised in the Pediatric Ablation Guidelines included limiting lesions to 20 s and favoring the use of cryoablation when feasible.

Procedural considerations in young patients

It is paramount for young patients, particularly those under the age of 12 years, that ablation be performed in a setting capable of managing the technical, emotional, and recovery needs of small patients, and especially so for patients <15 kg or with moderate or complex Congenital Heart Disease. Even adolescent and teenage patients display a range of ability to undergo procedures under moderate sedation, and ready availability of anesthesia is advisable even in this older age group. Accordingly, a number of recommendations for ablation in young patients were advised in the 2016 guidelines (Saul et al., 2016). These include:

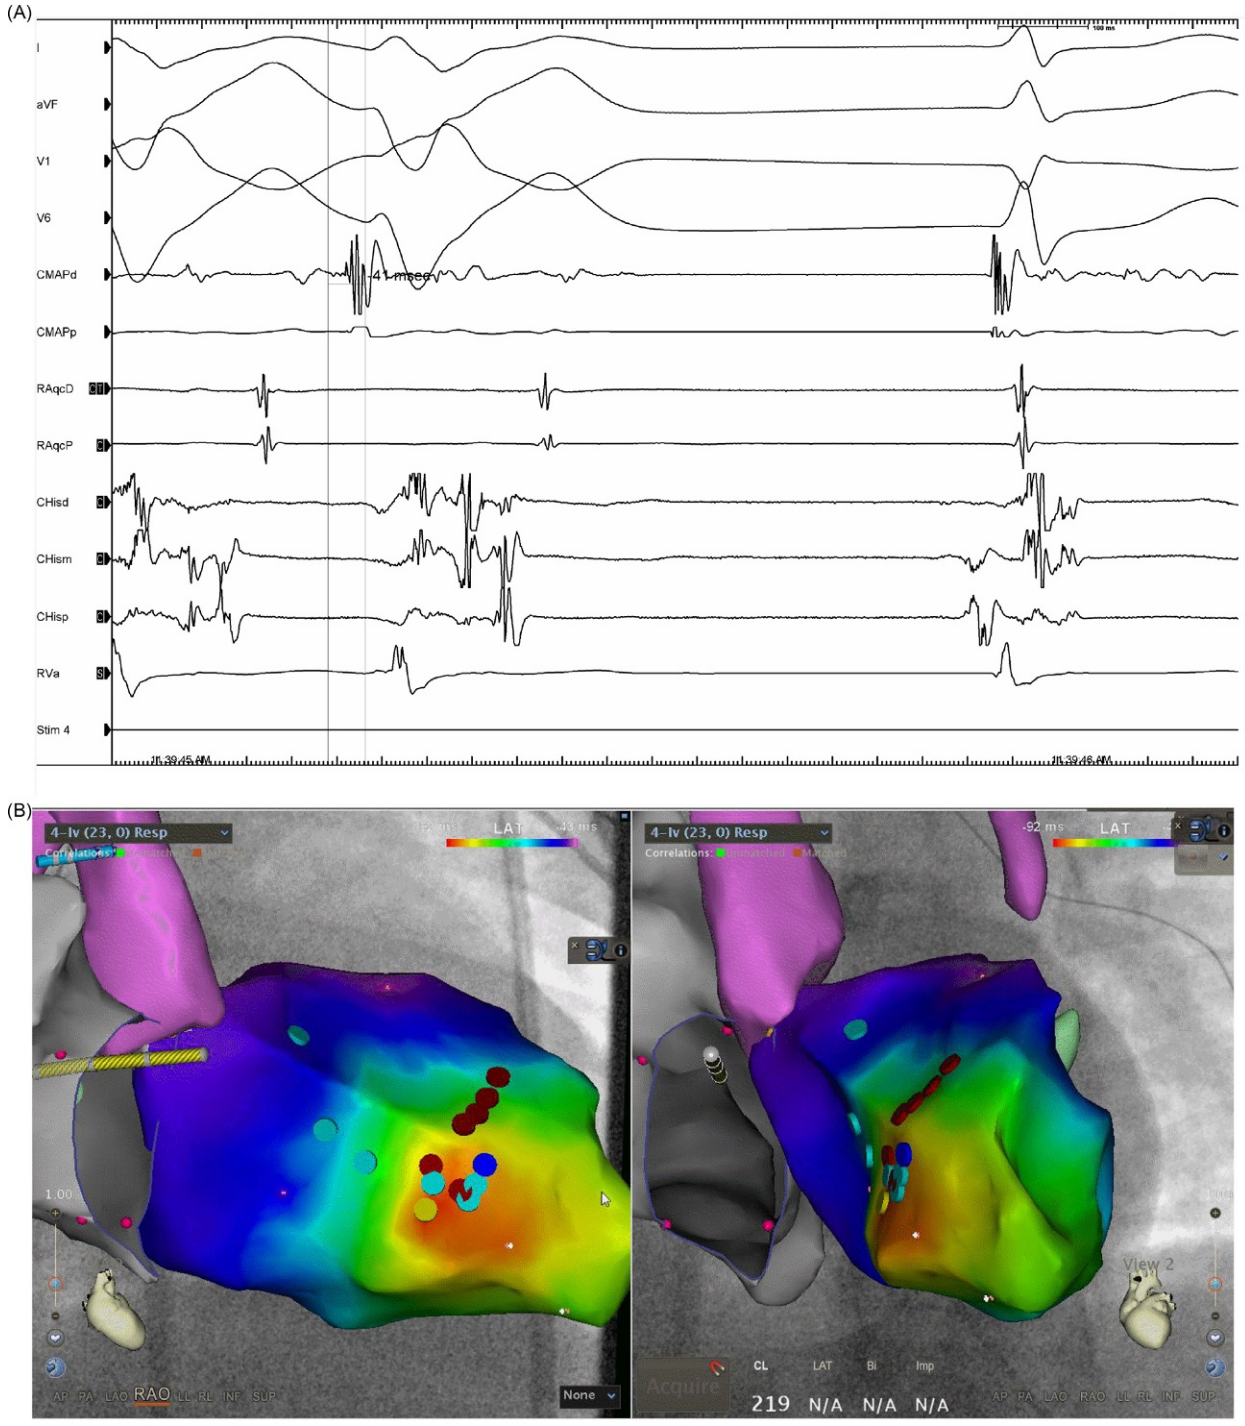

Fig. 11 (A) Left posterior fascicular VT terminating with catheter pressure at site where early diastolic and late diastolic (pre-QRS) potentials were recorded and could not be reinitiated. Linear RF lesion set was delivered. (B) Linear lesion site for left posterior fascicular VT which could not be reinitiated. Red dots indicate RF lesions; dark blue dots indicate site of termination.

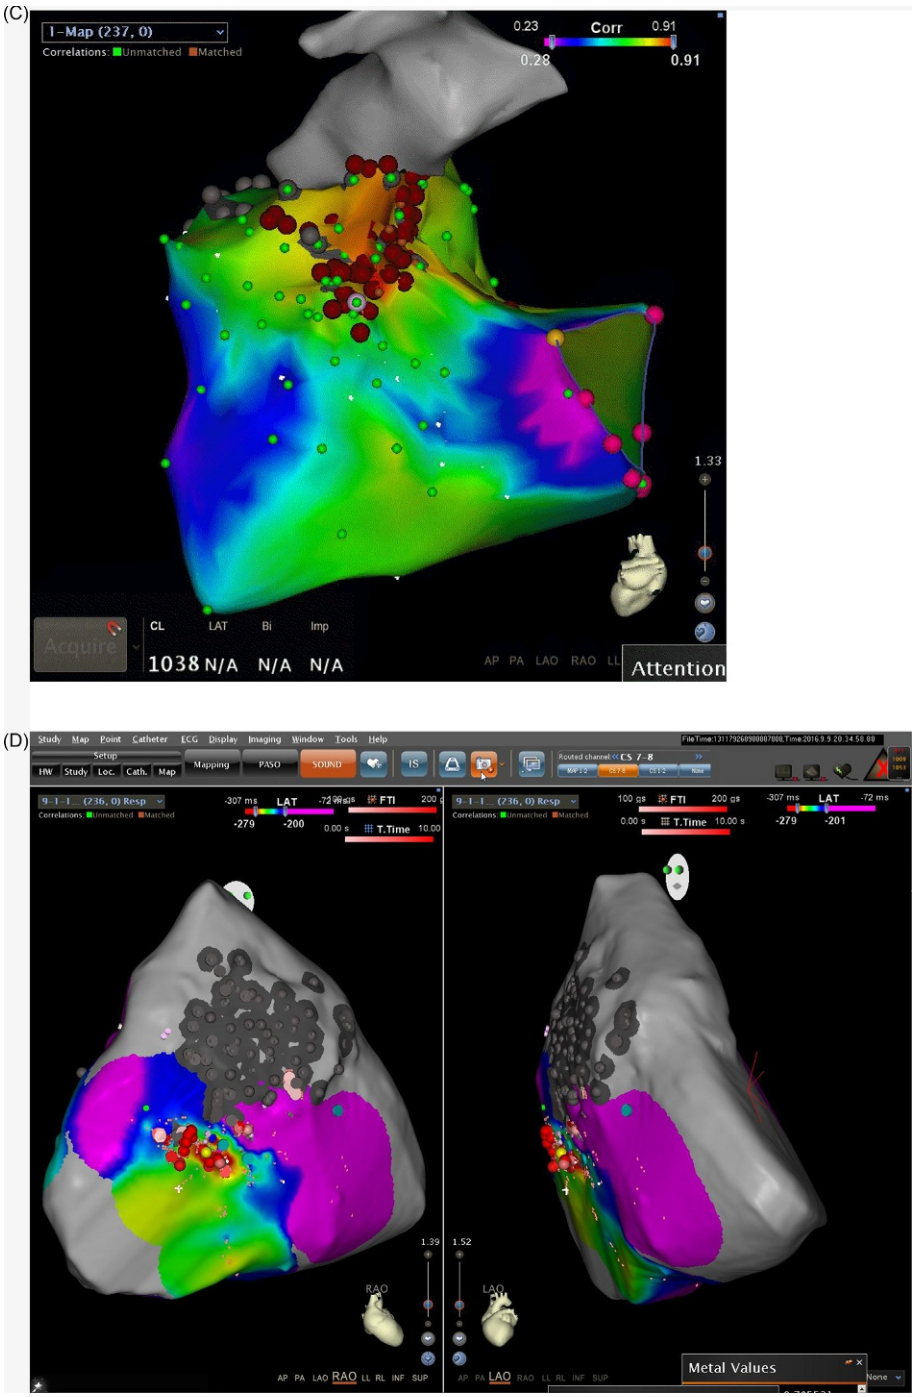

Fig. 11—Cont'd (C) Focal (reentrant) VT in patient with Tetralogy of Fallot, mapped to high RV septum. (D) Electroanatomic map of hemodynamically unstable reentrant VT in patient with Tetralogy of Fallot with early activation (in *red*) along border zone of large RV outflow tract. ECMO support was required to enable mapping and ablation.

1. Available child life support to minimize patient distress and anxiety before the procedure
2. A pediatric (or congenital) cardiovascular surgical program at the same institution where the ablation is performed for patients 12 years of age and younger, and in-house pediatric cardiovascular surgical support for smaller patients (less than 15 kg).
3. 3D nonfluoroscopic imaging as an adjunct for ablation of SVT; and it is recommended that if available, 3D nonfluoroscopic imaging be used for all complex ablation procedures. However, efforts to minimize radiation exposure should not compromise patient safety or procedural success.
4. Routine use of moderate to deep sedation or general anesthesia
5. Removal of sheaths while the patient remains under sedation or anesthesia. Application of local anesthesia at the catheter insertion

6. General anesthesia with endotracheal intubation recommended for (but not limited to): age 12 years and younger; significant CHD or other hemodynamic abnormalities; respiratory comorbidities; other significant systemic comorbidities; anticipation of a prolonged procedure; the need for complete immobility (e.g., a procedure near the coronary orifices or AV conduction system, percutaneous epicardial approach); and patient or parent choice.

Likewise, appropriate follow-up early (within first 2 months of ablation) and later at 6–12 months should be a minimum. Occasional follow-up beyond one year may be useful, both to ensure appropriate evaluation of any late-appearing symptoms suggestive of arrhythmia recurrence or procedural complication, and to ensure that symptom-free patients are not being inappropriately limited or restricted with respect to sports and exercise or access to other appropriate care. It may be necessary to periodically provide ongoing assurance to parents and physicians that it is safe for postablation patients who remain arrhythmia free to receive treatments for conductions such as ADHD or asthma, and may undergo other procedures and options safely without special clearance or perioperative care.

Future Directions

There clearly remain areas for improvement. Although acute efficacy is excellent, recurrences continue to be described following ablation of many substrates. There are opportunities for technical advances facilitating delivery of more lasting lesion formation without extending damage to bystander, normal structures; this is particularly true in those patients with atrial myocardium altered by prior surgeries and longstanding pressure and volume load. There may be further decrease in complication rates by identifying and prioritizing those routine practices yielding safest outcomes, while simultaneously allowing for the elimination of unnecessary precautions. Ongoing minimization of exposure to ionizing radiation by further refinement of nonfluoroscopic techniques remains an area of much current interest. As was previously alluded, to date there has been minimal prospective data regarding patient-oriented outcomes and cost-effectiveness of ablation in children. With all of the above goals in mind, there is currently organization among many pediatric electrophysiologists to establish a prospective quality-improvement database undergirding this next era of pediatric ablation, with anticipated benefits similar to that beginning to be realized in the pediatric cardiothoracic surgical and interventional cardiology disciplines with the STS and IMPACT registries, respectively (Jacobs et al., 2004; Martin et al., 2010).

Introduction

Heart failure (HF) is a clinical syndrome that can result from a variety of lesions of the heart (myocardium, pericardium, heart valves, or great vessels) or metabolic abnormalities, which lead to an impairment of ventricular relaxation, contraction, or both (Writing Committee Members et al., 2013). HF is a public health matter: it becomes more common with age; moreover, aging of global population and improvement of HF therapeutics lead to a raising number of patients with HF condition (Braunwald, 2015). Concurrently, the number of surgical procedures performed in the elderly is regularly increasing, with more than a third of the procedures being performed in patients who are 65 years and older (Semel et al., 2012). As a result, patients with HF undertaking surgery are more and more frequently encountered.

Surgery and anesthesia induce hemodynamic stress as well as fluids and metabolic variations that could be compared to a stressing exercise for the myocardium and lead to acute HF, myocardial ischemia, and death (Devereaux and Sessler, 2015).

The latest guidelines on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery propose to separate the surgical procedures into two categories (Fleisher et al., 2014), according to their risk of perioperative major cardiovascular events (MACE). MACE are defined by death from a cardiovascular cause or nonfatal myocardial infarction. During a low-risk procedure, the combined surgical and patient characteristics predict a risk of perioperative MACE below 1% whereas elevated risk surgeries are associated with MACE of at least 1%.

In this article, we will review the consequences of HF during surgery and the management of HF patients in the perioperative settings.

HF Increases the Risk of Perioperative Morbidity and Mortality

HF is a well-established perioperative risk factor (Hernandez et al., 2004). Among patients of 65 years and older who undergo major noncardiac surgery, the perioperative mortality rate is at least doubled if they have HF (Hammill et al., 2008). Moreover, among patients who have HF, those who have a more severely impaired ejection fraction have a worse outcome: in patients with HF who had a high-risk noncardiac surgical procedure, Healy and colleagues reported that severely reduced ejection fraction (<30%), but not moderately (30%–40%) or mildly (40%–50%) impaired ejection fraction, was associated with more adverse perioperative events including myocardial infarction, HF exacerbation, and mortality within 30 days after surgery (Healy et al., 2010). In this population, the three independent risk factors of adverse perioperative events were an age above 80 years, an ejection fraction below 30%, and diabetes.

Because HF is such a strong risk factor of perioperative morbidity and mortality, it is a component of indices that predict the risk of perioperative MACE. The revised cardiac risk index (RCRI) is the oldest and easiest validated score that predicts the risk of perioperative MACE. RCRI contains six items, including HF, ischemic heart disease, stroke, diabetes, renal dysfunction, and high-risk surgical procedure. Having at least two items of the RCRI classify a patient as high risk of perioperative MACE (Fleisher et al., 2014; Kristensen et al., 2014).

Patients who have a known HF with symptoms can easily be classified. However patients who do not present symptoms but who are at risk in developing HF should be detected as well. In fact, even in the absence of symptoms of HF, isolated diastolic left ventricular dysfunction and systolic left ventricular dysfunction are associated with increased morbidity (30-day cardiovascular events) and long-term cardiovascular mortality (Flu et al., 2010).

Preoperative Time

Before surgery, the consultation with the anesthesiologist is a major step of the care of a HF patient. During that time, clinical examination and the performance of additional tests will allow to specify the cardiovascular state and risks of a patient. Consequently, management of the perioperative time can be planned, with the adaptation of the medical treatment and the timing of the surgery as well as the discussion of the surgical and the anesthetic strategies.

Clinical Examination

In the presence of a known HF, the anesthesiologist should assess the stability of the signs of chronic HF (peripheral venous congestion including jugular venous distention, lower extremity edema, and abdominal ascites) and look for signs of acute HF (dyspnea, weight gain, orthopnea, paroxysmal nocturnal dyspnea).

In the absence of a known HF, the anesthesiologist should inquire for the presence of the different cardiovascular risks factor, quantitate them, and look for signs of either chronic or acute HF.

Because the functional status is a strong predictor of perioperative and long-term cardiac events, it should be assessed during the preoperative time. The functional capacity can be assessed by the ability to perform daily activities, expressed in terms of metabolic equivalents (METs) (Hlatky et al., 1989). One MET is equivalent to the basal metabolic rate of a resting 40-year-old, 70 kg man. A poor functional capacity is considered when METs <4 and is associated with high risk to develop postoperative cardiac events. A good or very good functional status is considered if METs ≥ 4; in the latest recommendations on perioperative cardiovascular evaluation, before high-risk surgery, it excludes the need to investigate for coronary artery disease and likely also for pulmonary and cardiac disease (Fleisher et al., 2014; Kristensen et al., 2014).

Preoperative Investigations

The requirement for additional investigations depends on the patient history, the clinical examination, and the existence of recent tests.

In the case of a patient with a known HF and symptoms that are unchanged since the last investigation (if under one year), no further test is needed. However, if the anesthesiologist suspects HF, the performance of three additional tests should be considered: an electrocardiogram, measurement of plasmatic natriuretic peptides (NP) levels, and a transthoracic echocardiography (TTE).

It is recommended to obtain a 12-lead electrocardiogram in any patients who have coronary heart disease, arrhythmia, peripheral arterial disease, or cerebrovascular disease, unless they undergo a low-risk procedure, or have had an electrocardiogram within 3 months (Fleisher et al., 2014).

A TTE is recommended for patients who undergo high-risk surgery, if signs and symptoms have changed since the last investigation (Fleisher et al., 2014). TTE gives the quantification of the left ventricle systolic and diastolic functions, the assessment of filling pressures, and the search for a cause of HF such as valvular disease. As importantly, TTE should assess right ventricular function, pulmonary artery systolic pressure (if doable), and inferior vena cava diameter as right ventricular loading conditions may change during some high-risk surgeries. Knowledge of TTE abnormalities does not have prognostic value but is of great interest to adapt the perioperative management of patients.

NPs include brain natriuretic peptide (BNP) or the inactive N-terminal fragment (NT-proBNP), which are primarily synthetized by the cardiomyocytes of the ventricles, in response to an increase of cardiac wall stress. NPs are markers of ventricular dysfunction. Other factors, such as age, renal failure, sepsis, and acute coronary syndrome, can participate in increasing plasmatic NPs levels (Writing Committee Members et al., 2013). In case of acute dyspnea, plasmatic levels of BNP are known diagnostic tools to attribute (if BNP >400 pg/mL) or rule out (if BNP <100 pg/mL) congestive cardiac heart failure (Writing Committee Members et al., 2013). In case of chronic HF, NPs are strong prognostic markers that can be used to direct the therapeutic strategy and improve the prognostic of such patients (Pfisterer et al., 2009; Lainchbury et al., 2009). In addition, plasmatic low levels of BNP (<100 pg/mL) or NT-proBNP (<125 pg/mL) exclude a diagnosis of chronic HF.

In perioperative settings, increased BNP or NT-proBNP levels are powerful independent predictors of short- and long-term MACE, as well as all-cause mortality (Rodseth et al., 2011, 2013; Ryding et al., 2009). In noncardiac surgery, the sole value of preoperative BNP levels has a better ability to predict cardiovascular events than the RCRI (Rodseth et al., 2011), and addition of the BNP levels to the RCRI increases its predictive value. These results suggest that measurement of BNP levels could permit a better prediction of cardiovascular risk and stratification of the patients. However, because multiple factors can influence NPs levels, the threshold of NPs levels that would allow a good distinction between high and low risks patients remains uncertain. NPs-guided therapy has not been studied in perioperative settings. However, preoperative NPs levels could be used as a tool to stratified preoperative investigations. In a prospective study, patients who were about to undergo hip surgery had a systematic measurement of plasmatic BNP and a TTE (Pili-Floury et al., 2012). Major echocardiographic abnormalities (defined by increased left ventricular filling pressure, severe systolic dysfunction, pulmonary hypertension, and severe valvular disease) were mostly found in patients with increased levels of plasmatic BNP. Whether patients had a major echocardiographic abnormality or not was best predicted when plasmatic BNP levels were above 285 pg/mL.

Adaptation of the Medical Treatment

Chronic HF treatment is based on beta-blockers, renin-angiotensin-aldosterone system (RAAS) inhibitors, and diuretics (Writing Committee Members et al., 2013). These therapeutics should be stopped for the shortest time possible. However, some particularities exist depending on the class of the agents.

Treatment by beta-blockers should be continued until the day of surgery (Fleisher et al., 2014; Hopper et al., 2014). When needed, a treatment by beta-blockers should be started but not be initiated within days preceding a major surgery (Study Group et al., 2008).

RAAS inhibitors and diuretics could be stopped the day before surgery (Fleisher et al., 2014; Kristensen et al., 2014).

Discontinuation of antiplatelet agents should be discussed according to the reason of the prescription (primary prevention, drug eluting stent, bare-metal stent...), the time between the beginning of antiplatelet agents and surgery, and the bleeding risk of the procedure (Fleisher et al., 2014).

Timing of the Procedure

Decompensated HF forbids any surgical procedure unless life or limb is threatened if not in the operating room within 24 h (Fleisher et al., 2014).

When possible, in the presence of signs of acute HF, postponing surgery by at least 3 months would give time for stabilization and/or improvement of ventricular function and ventricular remodeling before undertaking the stress of a surgical procedure (Upshaw and Kiernan, 2013).

In patients with valvular heart disease, the need for a valvular replacement or valvuloplasty should be discussed depending on the severity of the valvular disease (assessed by clinical symptoms and TTE) as well as the cardiovascular risk and urgency of the surgery (Fleisher et al., 2014).

Before noncardiac surgery, revascularization should be done according to the general guidelines, but not as a prophylactic treatment (Fleisher et al., 2014). If the indication of such revascularization is retained, it can delay the surgery by several months.

For patients with severe alteration of the left ventricular function and left bundle branch block, cardiac resynchronization therapy or defibrillator should be discussed before major surgery (Kristensen et al., 2014).

Surgical Strategies

Advantages of endovascular surgery are not straightforward in patients with multiple comorbidities (Fleisher et al., 2014; Kristensen et al., 2014). Choice of endovascular surgery, over an open procedure, should be done according to the type of surgery and the patient's risks.

Compared to opened abdominal procedures, endoscopic surgery presents benefits in terms of postoperative rehabilitation (bowel movements, pain, and pulmonary function). However, the pneumoperitoneum created during endoscopic procedures induces a decrease in venous return and an increase in cardiac afterload that can be threatening for HF patients. Hence, the choice of endoscopic surgery should be balanced between advantages and risks.

Anesthetic Strategies

The discussion should be focused on the possibility of performing any locoregional anesthesia and on the modalities of general anesthesia.

Neuraxial anesthesia is associated with a sympathetic blockade leading to high variations of intra vascular volume and arterial pressure. Hence, the beneficial effects of neuraxial anesthesia, compared to general anesthesia, are not evident. However, epidural anesthesia should be considered for postoperative pain relief (Fleisher et al., 2014).

Peripheral nerve blockade does not affect the cardiovascular system as much as neuraxial or general anesthesia. Therefore, peripheral nerve blockade should be proposed to HF patients, whenever it is applicable.

During general anesthesia, the objective is to maintain homeostasis as much as possible. In order to control loading conditions on the left ventricle and maintain a balanced rate of fluids infusion/lost, the monitoring of invasive arterial pressure and cardiac output (by the use of esophageal Doppler or pulse contour analysis) should be considered. Anesthetic drugs should be titrated to use the minimal amount of drug to obtain the intended effects with limited adverse effects, by monitoring the depth of anesthesia (using, for instance, the bispectral index). Finally metabolic constrains should be closely watched in order to avoid hypercapnia, hypoxia, hypothermia, and anemia.

Postoperative Time

Postoperative time remains a very sensitive period. Several factors such as withdrawal of anesthetic drugs, awakening, extubation, pain, hypothermia, and anemia participate to activate the sympathetic system and increase oxygen consumption. Additionally, because of the inability to take oral drugs during the postoperative time, after procedures such as major gastro intestinal tract

surgery, the withdrawal of HF drugs can increase the risk of arrhythmia, hypertension, and acute HF. Hence, careful attention should be placed on preventing/treating any tachycardia, preventing the shivering, giving appropriate analgesia and avoiding hypertension. Moreover, regular treatment by RAAS inhibitors and beta-blockers treatment should be restarted as early as possible (Fleisher et al., 2014).

Postoperative observation of patients with severe HF could be done in intensive care. According to the number of cardiovascular risk factors and the perioperative events, a myocardial ischemia should be monitored by the performance of an ECG and troponin levels measurements.

Postoperative increase of NPs levels is associated with increased mortality or nonfatal myocardial infarction within 30 days or 180 days after noncardiac surgery (Rodseth et al., 2011, 2014). However, the interest of postoperative measurement of NPs remains to be demonstrated.

Postoperative HF

The clinical signs of postoperative acute HF are not specific of that time; patients develop signs of acute HF potentially associated with signs of severity such as hypotension, alteration of consciousness, cyanosis, mottling, and renal or hepatic failure.

Several triggers specific of postoperative time such as ischemia, hypoxia, increased systemic blood pressure, fluid overload, or anemia should be searched for. Cardiac surgery is associated with risks of HF related to the specificity of the surgery such as spasm or occlusion of a coronary graft, prosthetic paravalvular regurgitation, cardiac tamponade, or hemothorax.

TTE is a major tool to diagnose postoperative HF.

The management of postoperative HF consists in noninvasive ventilation together with the treatment of the cause, which can include correcting blood pressure, giving appropriate analgesia and discussing a treatment by antiplatelet and anticoagulant agents together with the anesthesiologist, the cardiologist, and the surgeon. Depending on the severity of acute HF, new inotropic drugs (levosimendan, nesiritide) could be more useful than the more traditional treatment to restore hemodynamic balance (Toller and Metzler, 2005).

Conclusion

As the population is aging and the medicine is improving, the perioperative management of HF patients becomes a frequent situation that is associated with increased risk of morbidity and mortality. Every step before, during, and after surgery is sensitive and should be carefully assessed and treated.

Introduction

Cardiovascular disease is an uncommon, yet serious complication of pregnancies worldwide. Heart failure associated with pregnancy was recognized as early as the 1800s (Haghikia et al., 2016; Ritchie, 1849) and was increasingly described in the literature thereafter (Gouley et al., 1937; Hull, 1937; Seftel and Susser, 1961). The term "peripartum cardiomyopathy" was first used and defined by Demakis and others as the development of heart failure in the last month of pregnancy or within 5 months of delivery, in the absence of any preexisting heart disease or other apparent cause (Demakis and Rahimtoola, 1971; Demakis et al., 1971). More recently, an additional criterion was added to incorporate echocardiographic evidence of left ventricular dysfunction: a left ventricular ejection fraction (EF) of <45% (Hibbard et al., 1999; Pearson et al., 2000, Sliwa et al., 2010b). The diagnosis of peripartum cardiomyopathy (PPCM) relies on the exclusion of other etiologies of cardiomyopathy, as well as the normal symptoms of pregnancy.

Epidemiology

The incidence of PPCM varies widely by geographic location, race, and ethnicity and differs between studies. Reported estimates range from as high as 1:100 in Nigeria and 1:300 in Haiti, to as low as 1:4000 in the United States and other Western societies (Brar et al., 2007; Gunderson et al., 2011; Isezuo and Abubakar, 2007; Mielniczuk et al., 2006). Within the United States, the incidence has been shown to be higher in blacks than in whites (Brar et al., 2007; Gentry et al., 2010; Harper et al., 2012). The incidence in the United States also seems to have increased in the last few decades, based on recent data which suggests an incidence closer to 1:1000 (Kolte et al., 2014; Mielniczuk et al., 2006). This may reflect improved understanding and detection of the condition or may mirror demographic trends, such as advancing maternal age, the effects of obesity and insulin resistance, and the increased use of fertility treatments resulting in higher frequencies of multiple gestations.

Risk Factors and Associated Conditions

Several demographic risk factors have been identified in association with PPCM, although the pathophysiology of each is unclear. The odds of developing the condition increase with maternal age; the majority of cases occur after 30 years of age (Arany and Elkayam, 2016). As mentioned earlier, the incidence of PPCM is highest in women of African descent in all geographic locations. However, the incidence in Hispanics is lower than in Caucasians (Kolte et al., 2014).

The relationship of PPCM with multiple gestations and multiparous status is unclear. Many cases of twin and triplet gestations in women who developed PPCM have been reported (Altun et al., 2015). However, in a recent study of 34,000 women with PPCM in

the United States from 2004 to 2011, single gestation pregnancies actually had higher rates of PPCM (Kolte et al., 2014). Sixty-seven percent of women with PPCM in 10 studies reviewed by Bello et al were multiparous (Bello et al., 2013), although recommendations against subsequent pregnancies in these women are expected to decrease this frequency in the coming years.

Hypertension, preeclampsia, and eclampsia, three distinct maternal conditions with considerable continuity and overlap, are all strongly associated with the development of PPCM. A recent metaanalysis found the prevalence of preeclampsia in women with PPCM to be four times higher than in pregnancies not complicated by PPCM (Bello et al., 2013). Another study found nearly half of women with PPCM had hypertension and a third had preeclampsia (Kao et al., 2013). The odds of developing PPCM for a patient with eclampsia has been shown to be 27.9 times higher than in a noneclamptic pregnancy (Kolte et al., 2014). These conditions can all cause pulmonary edema and heart failure on their own, due primarily to prolonged elevations in blood pressure, which often clouds the clinical picture and makes diagnosis challenging. However, preeclampsia and eclampsia also seem to create cardiotoxic conditions predisposing to cardiomyopathy that are independent of elevated blood pressures and are poorly understood (Powe et al., 2011).

Pathogenesis

In the past, PPCM had been attributed to a maladaptive response to the hemodynamic stresses of pregnancy; however, most of the physiologic hemodynamic changes occur in the first two trimesters, whereas PPCM typically arises late in the trimester, or even postpartum, when hemodynamics are returning to their previous (i.e., nonpregnant) state. Myocarditis has been implicated in many documented cases, but there exist many more cases where this has been ruled out. Further confounding this, in comparison studies, evidence of viral infections are often found in control cases as well (Bültmann et al., 2005; Fett, 2006).

In recent years, several new hypotheses have been put forward to explain why some women may be more vulnerable to the physiologic stressors in a normal pregnancy. Focus has surrounded the balance between oxidative stresses and antioxidant capacity. In normal pregnancy, there is an increase in reactive oxygen species (ROS), thought to be part of the physiologic defense system to ward off infection during pregnancy and delivery. However, antioxidant capacity increases in parallel to protect maternal health; when this mechanism is impaired, cellular damage occurs without recourse, and angiogenesis, the generation of new blood vessels, is compromised.

Signal transducer and activator of transcription 3 (STAT3) is a transcription factor involved in the antioxidant pathway, participating in the balance of oxidative stress and angiogenesis. STAT3 expression is reduced in the left ventricles of women with heart failure caused by PPCM. Loss of STAT3 in cardiomyocytes has been shown in mouse models to reduce expression of genes that protect the heart from ROS. In an environment favoring ROS, the hormone prolactin is cleaved into an antiangiogenic 16 kDa fragment, which promotes apoptosis in endothelial cells. In this setting, the mice subsequently developed PPCM (Hilfiker-Kleiner et al., 2007).

The 16 kDa fragment of prolactin does not have a direct effect on cardiomyocytes but activates nuclear factor (NF)-ƙB, which upregulates microRNA-146a (miR-146a). miR-146a enters cardiomyocytes directly and its signaling pathways decrease the metabolic activity of the cells and impair communications between the cardiomyocytes and endothelial cells. Circulating levels of miR-146a are markedly elevated in women with PPCM, and in mouse models, inhibition was able to partially rescue cardiac function (Halkein et al., 2013). Prolactin and its downstream counterpart, miR-146a, seem to play a large role in the imbalances in oxidative stress and angiogenesis, contributing to the development of PPCM.

Another pathway has been proposed involving the relationship between ROS, angiogenesis, and PPCM. Similar to STAT3, proliferator-activated receptor-gamma coactivator-1α (PGC-1α) suppresses ROS and drives the expression of vascular endothelial growth factor (VEGF), an angiogenic factor. In a mouse model with cardiac-specific deletion of PGC-1α, the same 16 kDa prolactin pathway was activated, and VEGF pathways were downregulated. In pregnant mammals, the VEGF pathway is thought to be initiated by secretion of soluble Fms-like tyrosine kinase 1 (sFlt1) by the placenta in late gestation. sFlt1 neutralizes much of the circulating VEGF; this can be circumvented in other organs by local secretion, but in the PGC-1α mouse model, the cardiomyocytes are unable to defend themselves. sFlt1 secretion by the placenta has been shown to be markedly elevated in women with preeclampsia (Powe et al., 2011) and twin gestations (Bdolah et al., 2008). Thus, it appears that ROS and angiogenesis predispose to PPCM through multiple pathways.

Several genes have been linked to the development of PPCM in small studies as well, although familial links are sparsely reported in the literature. *PTHLH*, thought to regulate vascular homeostasis, and *TTN*, which codes for a sarcomeric protein called titin, have both been implicated. Women with gene mutations in these regions may have a higher predilection to develop PPCM, but it is likely that environmental factors, such as the vasculohormonal pathways mentioned above, are required to develop the disease.

Diagnosis

Typical Presentation

Most patients develop symptoms in the early postpartum period, but patients can present in the third trimester or as late as 3–4 months postpartum (Demakis et al., 1971; Elkayam, 2011). Classic symptoms of heart failure are common, such as dyspnea, orthopnea, and paroxysmal nocturnal dyspnea, as well as peripheral edema and palpitations. Many of these symptoms, particularly

exertional dyspnea, are nonspecific and may be experienced as part of a normal pregnancy and delivery, which often delays diagnosis. A high index of suspicion is required for early diagnosis; physical exam and diagnostic studies may be prudent in any uncertain cases.

As expected, physical examination is likely to confirm signs of heart failure, including rales, elevated jugular venous pressure, and peripheral edema. Advanced signs of left ventricular enlargement may be noted, such as a third heart sound (S3) or displaced apical impulse.

Differential Diagnosis

Pulmonary embolism is a risk throughout the peripartum period due to the hypercoagulable state occurring with pregnancy. Infections such as pneumonia and myocarditis should be considered as well. As mentioned earlier, hypertension, preeclampsia, and eclampsia increase women's odds of developing PPCM, but they can also independently cause acute pulmonary edema, most commonly related to hypertensive diastolic dysfunction. Lastly, peripartum myocardial infarction and Takotsubo cardiomyopathy should each be considered.

Laboratory Studies and Electrocardiogram

While no specific biomarkers are currently available, basic laboratory studies may help to differentiate PPCM from symptoms of a normal pregnancy. Brain natriuretic peptide (BNP) and troponin are likely to be elevated in PPCM, whereas they are usually within normal range during a healthy pregnancy or after delivery. BNP and troponin would not, however, separate heart failure related to hypertension, preeclampsia, eclampsia, or other conditions. Novel biomarkers have been proposed; as mentioned above, circulating levels of miR-146a are elevated in women with PPCM, and miR-146a may be useful to differentiate PPCM from other types of heart failure. However, further study is necessary and there is currently no clinical laboratory testing that confirms the diagnosis of PPCM. Given the recent discoveries regarding the proposed vasculohormonal pathways to PPCM, novel biomarker development may be a possibility in the future.

Electrocardiogram (ECG) findings are nonspecific and can range from relatively normal to abnormal, showing sinus tachycardia, T-wave changes, P-wave abnormalities, QRS-axis deviation, or a bundle branch block (Tibazarwa et al., 2012). Since PPCM occurs most often in healthy women, there is rarely a previous ECG available for comparison, making interpretation of acute changes more challenging.

Imaging Studies

Imaging is likely to be most useful in the diagnostic process. A chest X-ray will often show signs of pulmonary congestion and may also reveal cardiomegaly. Echocardiography is useful to evaluate ventricular function in addition to associated abnormalities such as left ventricular dilatation, right ventricular and biatrial enlargement, associated valvular dysfunction, thrombi, pericardial effusion, and pulmonary hypertension (Hibbard et al., 1999). Lastly, an echocardiogram can help to differentiate between other cardiac diagnoses such as myocardial infarction and Takotsubo cardiomyopathy.

The role of cardiac magnetic resonance imaging is yet undefined, but may provide further information regarding myocardial structure, and can also be used when echocardiographic images lead to uncertainty (**Figs. 1** and **2**). Noncontrast MRI can be safely performed in pregnant women; however, gadolinium crosses the placenta and therefore should not be administered (Bouabdallaoui et al., 2015). Contrast agents can be used safely in the postpartum period, with only small amounts being found in breast milk.

Management

Obstetric Considerations

Cases of PPCM occurring during the third trimester require consideration of the fetus as well as the safety of the delivery process. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are contraindicated. Beta-1 selective agents are preferred when using beta blockers to avoid impacting uterine activity. Diuretic therapy may be necessary but must be administered carefully to avoid impacting perfusion of the placenta. There is no evidence to suggest that delivery should be planned early or by caesarian section. Decisions should involve a multidisciplinary team of obstetricians, cardiologists, and neonatologists.

Medical Therapies

Available therapies for PPCM are largely similar to the staples used for other types of systolic heart failure; no studies specifically address these agents in PPCM. Beta-blockers are considered safe, and should be initiated in hemodynamically stable patients and titrated as tolerated for cardioprotection. ACE or ARB agents should be initiated in the postpartum period; enalapril and captopril are preferable during breastfeeding (Bouabdallaoui et al., 2015; Guidelines, 2010). Diuretic therapy is used for volume control; mineralocorticoid receptor antagonists are recommended as part of this regimen, particularly if the patient is not breastfeeding.

Fig. 1 Cardiac magnetic resonance (CMR) delayed enhancement image in the coronal plane, showing diffuse patchy mid-myocardial fibrosis in a patient with PPCM.

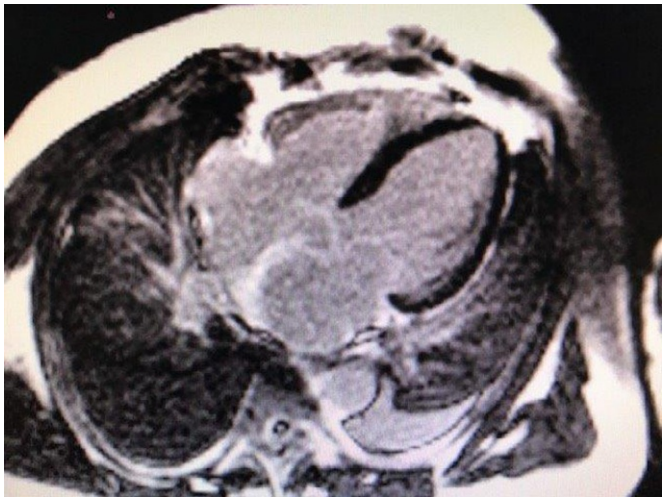

Fig. 2 A CMR delayed enhancement image in the horizontal plane for the same patient pictured in **Fig. 1**

No studies exist to establish the appropriate length of therapy with these agents, but a beta blocker and ACE or ARB (and mineralocorticoid antagonists, if used) should generally be continued for at least 6 months after full recovery of LV structure and function, and weaned off carefully thereafter if desired (Hilfiker-Kleiner et al., 2015). However, many experts recommend continuing therapy for at least 12 months, and in patients with persistently reduced LV function, therapy may be lifelong.

Ivabradine, which blocks f-channels (also called "funny" channels) and has been used successfully in other types of cardiomyopathies, has been used to reduce heart rate in patients with PPCM who cannot tolerate maximal beta blockade due to low blood pressures. A recent retrospective study of 20 patients from the German PPCM Study showed significant improvements in LVEF with ivabradine, used in addition to standard heart failure therapies and bromocriptine (Haghikia et al., 2016).

New and Experimental Therapies

Several targeted therapies are currently being studied for the treatment of PPCM in addition to optimized heart failure therapies. As discussed earlier, prolactin is thought to play a role in the imbalance of oxidative stresses and angiogenesis leading to PPCM. In mouse models, the administration of bromocriptine, which blocks prolactin secretion from the pituitary gland, prevented and even reversed PPCM (Hilfiker-Kleiner et al., 2007). Early studies have shown benefit in human patients as well; one small randomized trial of 20 African women has shown significant benefit of bromocriptine on LV recovery in 6 months (Sliwa et al., 2010a). Larger studies in Europe are ongoing. The benefits of bromocriptine must be weighed against the risks, however; there is a dose-dependent risk of thromboembolic phenomena associated with its use, and consideration of concomitant anticoagulation is strongly encouraged. Adverse events such as myocardial infarction and cerebral ischemia have been reported with its use (Fett, 2008). In addition, bromocriptine use is not compatible with lactation, and the loss of benefits to the infant must be considered, particularly in areas of the world where breast milk is the infant's sole source of nutrition.

Pentoxifylline, a TNFα inhibitor, has also been studied as a possible agent for treatment of PPCM. Thus far, one small study using historical controls has been conducted, which did show improved outcomes in patients treated with pentoxifylline (Sliwa et al., 2002). Further studies are needed with larger sample sizes. Levosimendan, an inotropic agent utilizing calcium sensitization, has been examined for use in PPCM causing cardiogenic shock. Catecholaminergic agents such as dobutamine are less favorable in PPCM than in other causes of acutely decompensated heart failure, which may be related to differences in STAT3 expression (Stapel et al., 2017). Levosimendan does not increase myocardial oxygen demand and may therefore be advantageous. However, studies thus far have showed conflicting results (Biteker et al., 2011; Labbene et al., 2016).

Invasive Therapies

Some women with severe PPCM may require mechanical cardiovascular or circulatory support during the acute phase of illness in cases when inotropic agents are insufficient. Many device options exist. Percutaneously delivered devices, such as intraaortic balloon pumps (IABP) or Impella devices, offer temporary augmentation of cardiac output without requiring open surgery and can be used for patients with adequate oxygenation. Percutaneously delivered devices may also serve as a bridge to more invasive options for support. Extracorporeal membrane oxygenation (ECMO) can be used in the setting of cardiogenic shock with inadequate tissue oxygenation, as a bridge to recovery or to left ventricular assist device (LVAD) placement. LVAD implantation is most appropriately used as a bridge to cardiac transplantation; in a recent study, only 4% of women with PPCM who received LVAD support were able to be weaned and explanted due to recovery, whereas 48% were ultimately transplanted (Loyaga-Rendon et al., 2014). Nearly a quarter of women with PPCM require transplantation, and PPCM accounts for 5% of heart transplants performed in women in the United States (Rasmusson et al., 2012).

Complications and Associated Conditions

Thromboembolism

PPCM is associated with a higher risk of thromboembolic phenomenon than other types of cardiomyopathies, likely owing to the hypercoagulable state of the peripartum period. Presentations of PPCM associated with pulmonary embolism, left ventricular thrombus, and even coronary emboli have been reported (Elkayam, 2011). Thromboembolism was identified as the most common serious complication of PPCM in one database (Kolte et al., 2014). Therefore, anticoagulation should be considered when potential benefits outweigh risks, particularly during pregnancy, and in the first 1–2 months postpartum (Arany and Elkayam, 2016; Bouabdallaoui et al., 2015; Elkayam, 2011). Heparin and its low-molecular-weight varietal are preferred. Vitamin K antagonists, such as warfarin, are known teratogens in the first trimester; although theoretically safe later in pregnancy, difficulties with reversal during delivery make them less desirable agents. Other therapies such as newer oral anticoagulants (NOACs) and synthetic heparins have not been sufficiently studied in pregnant women.

Arrhythmias

PPCM patients are at increased risk of sudden death due to ventricular arrhythmias. However, due to the high rates of recovery of LV function in PPCM, early placement of implantable cardioverter defibrillators (ICDs) is not recommended. Instead, a wearable cardioverter/defibrillator (WCD) should be considered in women with severe LV dysfunction as a bridge to recovery or permanent ICD placement. In a small German study including seven women with WCDs observed over a median follow-up period of 81 days, four events of ventricular fibrillation with successful shocks were recorded (Duncker et al., 2014). Retrospective data from 107 women with PPCM who required a WCD showed that only 20% received a permanent ICD after a 4-month study period (Saltzberg et al., 2012).

Prognosis

In general, the prognosis for patients with PPCM is quite good, particularly when compared to other types of cardiomyopathies. The Investigations of Pregnancy Associated Cardiomyopathy (IPAC) study, recently completed in the United States, included 100 women with 1 year of follow-up. During that period, 71% of women recovered (defined as EF >50%), generally by 6 months. 13%

had persistent cardiomyopathy with EF <35% or experienced major cardiovascular events, and 4% died (McNamara et al., 2015). Older studies both within and outside of the United States have reported recovery rates ranging widely between 20% and 60%, with mortality rates of 0%–28% (Arany and Elkayam, 2016; Bouabdallaoui et al., 2015).

Prognostic indicators include the degree of LV dysfunction and remodeling at the time of presentation, as well as troponin and BNP levels. Higher LVEF at presentation (LVEF >30%) and a lesser degree of LV remodeling (LV end diastolic diameter, LVEDD <55 mm) predicted a greater rate of recovery in several studies (Duran et al., 2008; Goland et al., 2011; Haghikia et al., 2013; Li et al., 2016; Safirstein et al., 2012). In the IPAC study, 90% of women who presented with LVEF >30% recovered (McNamara et al., 2015). Lower levels of troponin and BNP at the time of presentation and throughout the clinical course have also been associated with eventual LVEF recovery (Hu et al., 2007; Li et al., 2016).

African women, both in the United States and within their countries of origin, tend to fare worse than their Caucasian counterparts. LVEF at presentation is often lower in blacks than in whites (Goland et al., 2013; McNamara et al., 2015); however, outcomes have also been shown to be worse in African-American patients even when their LVEF is similar to Caucasians on presentation (Goland et al., 2013). Causes for this discrepancy are unclear, but may reflect genetic differences, which may also explain the increased incidence in this group. Socioeconomic factors likely play a role as well.

Many women with PPCM desire subsequent pregnancies; however, they are at significant risk of adverse results, particularly those who have not achieved complete recovery of LV function. A recent review of 191 pregnancies in women with a history of PPCM revealed a recurrence in 27% of women who had normal LV function prior to the subsequent pregnancy, with no reported deaths. By contrast, 48% of women who had persistent LV dysfunction worsened with the subsequent pregnancy, with 16% mortality (Elkayam, 2014). All women with a history of PPCM should be educated about the risks of future pregnancies, and contraception should be recommended, particularly in the first 6–12 months when LV recovery is ongoing.

Summary

PPCM is an important cause of cardiovascular morbidity and mortality in women, particularly those of African descent. The pathogenesis is thought to be related to an imbalance between oxidative stresses and factors promoting angiogenesis, but studies are ongoing to improve our understanding of this condition and its risk factors. Techniques for diagnosis and management are similar to those utilized for other causes of cardiomyopathy and heart failure, although a higher degree of suspicion is required to recognize PPCM in the healthy young women who are affected. Most women have a positive prognosis, though outcomes can be severe in a minority of patients. Studies providing evidence for new targeted therapies are needed.

Introduction

Herein, we define peripheral arterial disease (PAD) as significant obstructive atherosclerosis in the arterial system of the lower extremities. Representative clinical manifestations of PAD include intermittent claudication and tissue loss of the feet or toes. Both are typically due to the extensive accumulation of atherosclerotic plaques that lead to tissue ischemia and, in the case of tissue loss, necrosis. In some cases, arterial revascularization is performed to restore adequate oxygen supply distal to the obstruction.

The flow-limiting atherosclerosis in the lower extremities of patients with PAD results in a pressure drop distal to the luminal obstruction. Foregoing a diagnosis of subclavian stenosis, this pressure drop results in a lower systolic blood pressure (BP) in the lower extremity relative to the systolic BP in the upper extremity. The ratio of the lower extremity to upper extremity systolic BP is referred to as the ankle-brachial index (ABI). As it is indicative of significant atherosclerotic disease in the lower extremity [or extremities], an abnormal ABI is typically considered diagnostic for PAD. Importantly, an abnormal ABI may be present in the absence of associated symptomatology, while approximately 30% of those with intermittent claudication have an abnormal ABI (Criqui et al., 1985, 1996). In this way, the ABI may be viewed as a measure of subclinical cardiovascular disease (CVD).

Burden of PAD

Globally, and based on 2010 figures, it has been estimated that just over 200 million individuals have PAD (Fowkes et al., 2013). Community-based studies in the United States have estimated the prevalence of PAD to be about 8 million individuals (Allison et al., 2007). PAD is rare in those under age 50, but the prevalence increases rapidly by approximately doubling with every decade increase in age. Moreover, there are significant differences in the prevalence by race or ethnic background. Specifically, African-Americans have been shown to have the highest rates while non-Hispanic Whites and those of Eastern Asian background (i.e., Chinese-Americans) have the lowest (Allison et al., 2007).

Beyond the morbidity associated with lower extremity ischemia, a diagnosis of PAD is important since individuals with this condition have an increased risk for incident total and cardiovascular mortality when compared to those without PAD (see the following text). This, coupled with the relatively high prevalence, makes PAD a significant public health problem. Accordingly, the ABI may be an appropriate candidate for screening of subclinical atherosclerosis to reduce the burden of not only PAD, but also other CVD morbidity and mortality.

The Ankle-Brachial Index

In persons without lower extremity atherosclerosis, and because of increasing impedance associated with taper in the diameter of the arterial system distally, arterial pressures increase with greater distance from the heart. This phenomenon results in higher systolic pressures at the ankle compared to the brachial arteries in persons without PAD.

The ABI is defined as the ratio of Doppler-recorded systolic pressures in the lower to upper extremities that utilizes the increasing distal pressure in the legs to identify significant obstructive disease. The ABI is a simple, noninvasive tool to assess the presence and extent of atherosclerosis in the lower extremities. The methodology for obtaining the systolic BPs necessary to calculate the ABI is standard, but there are variations in how many measurements are obtained in each extremity and which artery is used in the ankles.

ABI Measurement Technique (Fig. 1)

The examination should be conducted in a quiet, warm, and comfortable room. Have the participant lie supine on an examination table. The head and heels must be at the same level. The entire head and both feet must be on the table and not overhanging as having the feet even slightly lower than the rest of the body will produce an invalid ABI measurement.

Have the participant rest quietly for at least 5 min before beginning the measurement. Place an appropriately sized BP cuff around both arms, based on arm circumference at the midpoint. The cuff width must be at least 40% of the arm circumference. The three cuff sizes should be employed as follows:

1. Adult (12 cm width) cuff for an arm circumference of <32 cm
2. Large adult (16 cm width) cuff for an arm circumference of 32–42 cm
3. Thigh (20 cm width) cuff for an arm circumference of ≥ 43 cm

Place an adult (12 cm) cuff size on each ankle. Place the cuff so that the lower portion rests 3 cm above the greatest protuberance of the medial malleolus. All four cuffs should be in place before the first systolic BP is taken.

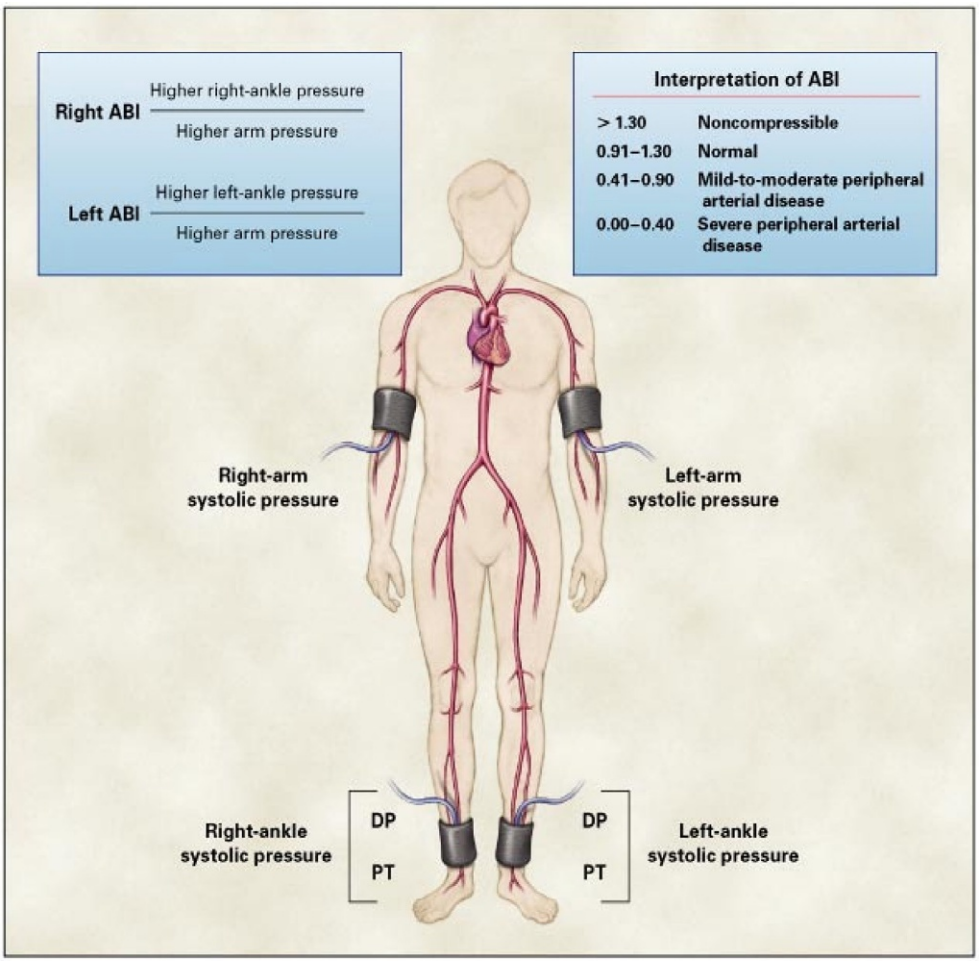

Fig. 1 Method for determining the ankle-brachial index (Hiatt, 2001).

By palpation, locate the brachial artery on both arms as well as the dorsalis pedis and posterior tibial arteries on both legs. Mark the location of each artery. Sometimes, an ankle pulse will not be palpable but can be found with the Doppler probe. Place ultrasound conducting gel over the end of the Doppler. After palpating the location of the pulse, turn on the Doppler and place the probe over the artery. Place the probe in line with the artery, and move it from side to side until the strongest pulse is heard. Inflate the cuff to 20 mmHg above the last audible pulse sound. If the pulse cannot be obliterated, raise the pressure to a maximum of 300 mmHg or to maximum patient tolerance. If not obliterated at this point, the artery is considered "noncompressible." Deflate the cuff slowly allowing the pressure to drop at a rate of 2 mmHg/s. Record the pressure at which the first sustained (more than one beat) pulse reappears. This is the systolic pressure at this location. Deflate the cuff completely. Using the procedure just described, systolic BPs are obtained in the following locations:

1. Right and left brachial arteries
2. Right and left posterior tibial arteries
3. Right and left dorsalis pedis arteries

It is important to record if the pressure in an artery is not detectable or noncompressible as these values will need to be considered when computing the ABI value.

Different Ways of Calculating the ABI

The ABI can be calculated for each lower extremity artery by dividing the systolic pressure measured in the dorsalis pedis and posterior tibial arteries in each limb by the brachial artery pressure. The traditional method of ABI calculation is to use the highest arterial pressure in each limb to calculate the ABI (Fowkes et al., 2013). However, prior studies have shown that the sensitivity of the ABI for diagnosing PAD varies according to how lower extremity arterial pressures are used to calculate the ABI. In one study in which 107 patients (208 limbs) underwent angiographic evaluation using digital subtraction angiography, investigators found that the sensitivity of the ABI for PAD (defined as ABI <0.90) varied from 69% when the highest arterial pressure in the ankle was used to 84% when the lowest arterial pressure in the ankle was used to calculate the ABI (Niazi et al., 2006). Similarly, the specificity of the ABI for a diagnosis of PAD varied from 83% when the highest arterial pressure at the ankle was used to 64% when the lowest arterial pressure at the ankle was used to calculate the ABI. In a separate study of 216 individuals who underwent arterial duplex ultrasonography, the sensitivity and specificity of the ABI for PAD (defined as ABI <0.90) were 89% and 63%, respectively, when the lowest arterial pressure was used to calculate the ABI (Schröder et al., 2006). The sensitivity and specificity of the ABI for PAD were 68% and 99%, respectively, when the highest arterial pressure was used to calculate the ABI (Aboyans et al., 2007).

Interpretation of the ABI

In individuals without manifest CVD, the mean ABI is about 1.13 (Aboyans et al., 2007). Traditionally, an ABI cut point of 0.90 or less has been considered evidence of significant atherosclerosis in the lower extremities and, therefore, PAD. Moreover, an ABI of 0.90 or less has been consistently shown to be associated with prevalent and incident CVD morbidity and mortality (see the following text). There is also evidence that as the ABI value decreases below this cut point, the more severe the atherosclerosis and the more sensitive the ABI is for detecting CVD. However, studies have challenged the use of the 0.90 cut point as the best discriminator of abnormal from normal (Aboyans et al., 2007; Allison et al., 2006; McDermott et al., 2005). These studies suggest that it may be more appropriate to consider the entire range of the ABI values. For example, several studies have now demonstrated that those with an ABI between 0.90 and 1.00 have higher levels of several CVD risk factors and greater subclinical atherosclerosis in other vascular beds compared to those with an ABI above 1.00 (Aboyans et al., 2007; Allison et al., 2006). There is also evidence that those with an ABI between 1.0 and 1.1 have higher levels of carotid intimal medial thickness (McDermott et al., 2005). Finally, when the ABI is analyzed as a continuous variable, those individuals with no CVD risk factors have values closest to 1.13 (Aboyans et al., 2007).

To further substantiate the use of the entire range of ABI values, research has revealed that higher (>1.30 or 1.40) values may be clinically relevant. An ABI value greater than 1.30 is significantly associated with higher levels of coronary artery calcium, diabetes, and higher body mass index (Resnick et al., 2004). Similarly, an ABI >1.40 is associated with a significantly worse quality of life (QOL) on several scales, higher rates of CVD comorbidities, and a higher risk for incident CVD (Resnick et al., 2004; O'Hare et al., 2006). These "high ABI" values represent "stiff" arteries in the lower extremities that may be due to medial calcification that is often present in patients with diabetes mellitus or chronic kidney disease. Importantly, there is a nonperfect overlap between arterial stiffness and atherosclerosis, which begs the question of whether these high ABI values should be classified as PAD or not because they may be masking significant underlying obstructive disease.

PAD and Clinical Outcomes

A wide range of adverse outcomes have been reported in persons with PAD including cognitive decline or bone fracture (Hyde et al., 2013; Laukka et al., 2014). However, in this section, we focus on two types of outcomes that are particularly relevant to patients with PAD and have robust evidence, cardiovascular and limb outcomes.

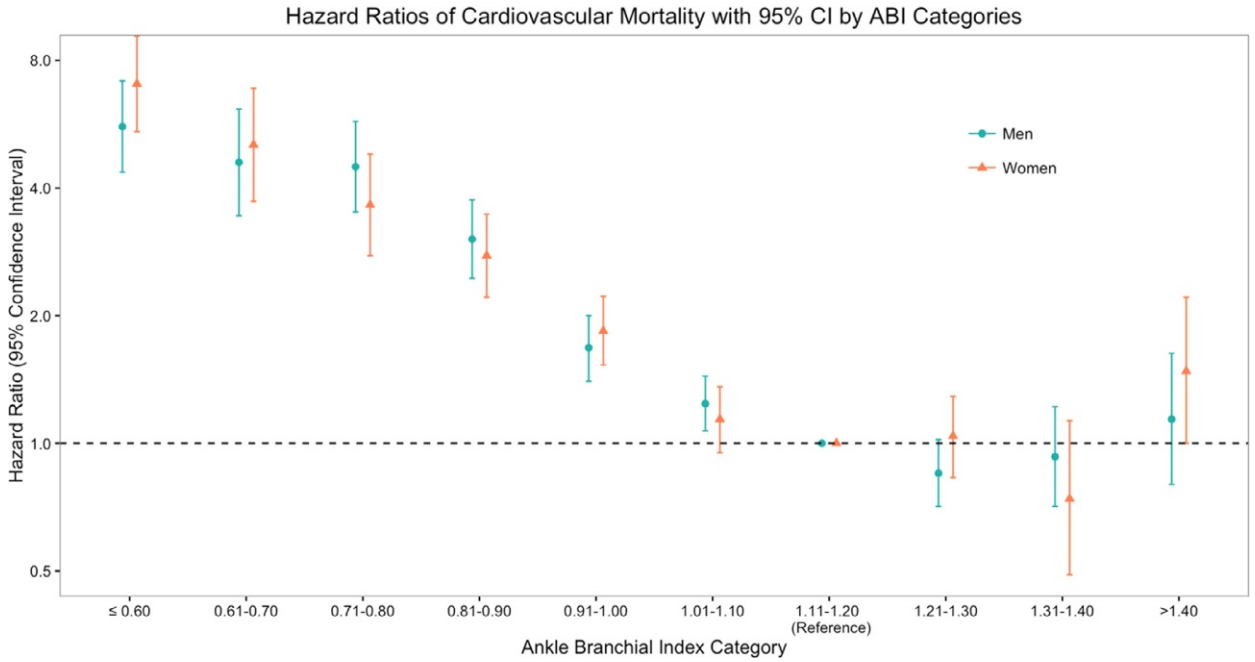

Fig. 2 Crude hazard ratios of cardiovascular mortality according to ABI categories by sex. Modified from Fowkes, F. G. R., Murray, G. D., Butcher, I., et al. (2008). Ankle brachial index combined with Framingham Risk Score to predict cardiovascular events and mortality: A meta-analysis. *JAMA: The Journal of the American Medical Association* **300**(2), 197–208.

PAD and Cardiovascular Outcomes

Persons with PAD have a higher mortality risk compared to those without PAD, mainly due to high short-term risk of cardiac disease and stroke (Criqui et al., 1992). Indeed, the Ankle-Brachial Index Collaboration demonstrated that a low resting ABI is associated with CVD mortality in a graded fashion, with three- to sevenfold increased risk below the ABI $\leq$0.9 compared to the reference ABI of 1.1–1.2 (**Fig. 2**) (Fowkes et al., 2008). Of note, an ABI of 0.9–1.0, the category currently considered borderline (Aboyans et al., 2012), also conferred 70%–80% increased risk of CVD mortality. Importantly, asymptomatic patients with PAD have been reported to have a similar CVD risk as symptomatic PAD patients (Leng et al., 1996).

A low ABI has been associated with myocardial infarction, stroke, heart failure, and atrial fibrillation (Griffin et al., 2016; Gupta et al., 2014; Heald et al., 2006). Therefore, patients with PAD require a comprehensive approach to prevent and manage CVD. Indeed, the American Heart Association (AHA) and American College of Cardiology (ACC) 2016 PAD guideline recommends statin therapy (class I for all PAD patients) and antiplatelet therapy (class I if symptomatic and IIa if asymptomatic) in patients with PAD (more details in the section of **Medical Treatment and Walking Regimen**) (Gerhard-Herman et al., 2017a).

Given its strong association with CVD risk, the AHA/ACC Guideline on the Assessment of Cardiovascular Risk lists ABI along with C-reactive protein and coronary artery calcium as additional biomarkers to be used to refine CVD risk prediction (Goff et al., 2014). Of these nontraditional biomarkers, coronary artery calcium appears to significantly improve the CVD risk prediction beyond traditional risk factors (Blaha et al., 2016; Matsushita et al., 2015). However, the ABI could still serve as a key noninvasive biomarker without radiation exposure (Goff et al., 2014; Kramer et al., 2013). Also, the ABI will uniquely provide information of lower extremity stenosis, which will inform healthcare providers of risk for limb outcomes.

PAD and Limb-Related Outcomes

Critical limb ischemia (CLI) is the most severe manifestation of PAD and is characterized by ischemic nonhealing wounds, tissue loss, or rest pain (Varu et al., 2010). It is estimated that ~1% of PAD patients have CLI as an initial manifestation of PAD, and additional 1%–2% of PAD patients develop CLI in 5 years after the diagnosis of PAD (Hirsch et al., 2006a). Although only a part of PAD patients develop CLI, it is a devastating condition, with ~25% of mortality risk and ~30% of leg amputation risk within 1 year after its diagnosis (**Fig. 3**).

When the limb cannot be salvaged, patients will require limb amputation. Although the rate of leg amputation has decreased by 40% from 1996 and 2011 in the United States (Goodney et al., 2015), approximately 150,000 leg amputations due to PAD are still performed annually in the United States (Hirsch and Duval, 2013). Notably, the dramatic decline of leg amputations is mainly for major amputations such as above-knee amputation, and the rate of forefoot or toe amputations remains similar between 1996 and 2011 (Goodney et al., 2015).

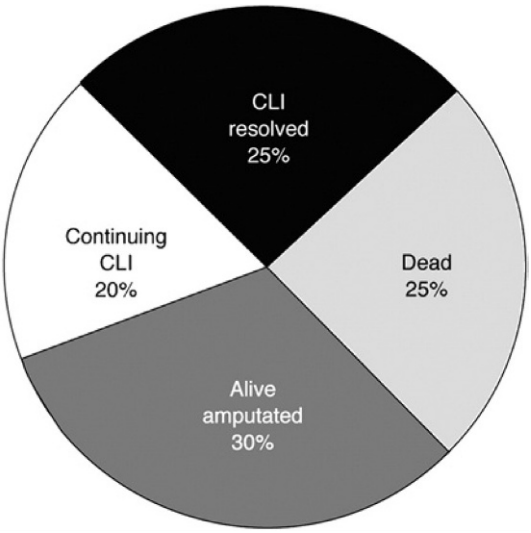

Fig. 3 One-year outcomes of patients presenting with CLI. From *Journal of Vascular Surgery* 2007; **45**(Suppl S), S5–67).

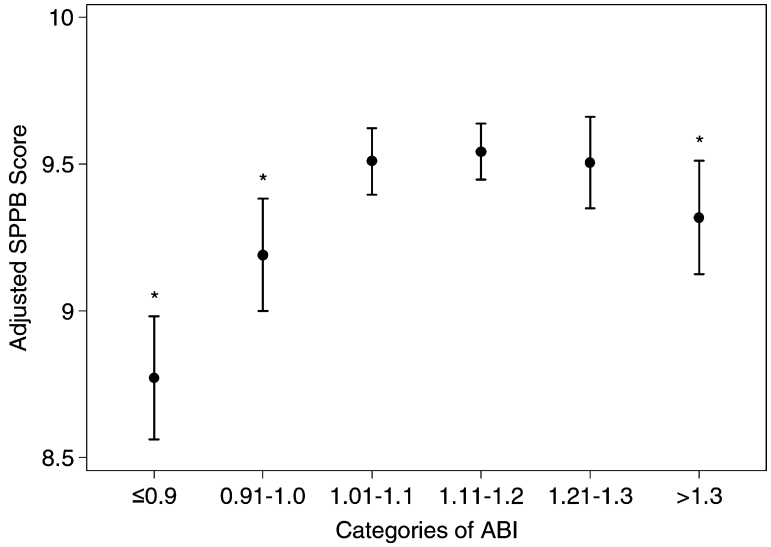

Fig. 4 Adjusted (Adjusted for age, race, sex, education, smoking, alcohol, body mass index, antihypertensive drugs, systolic blood pressure, lipid-lowering drugs, total and hdl cholesterols, diabetes, and history of coronary disease, heart failure, and stroke.) short physical performance battery (SPPB) score according to ABI categories. *Statistical significance with ABI 1.11–1.20 as the reference. From Matsushita, K., Ballew, S. H., Sang, Y., et al. (2017). Ankle-brachial index and physical function in older individuals: The Atherosclerosis Risk in Communities (ARIC) study. *Atherosclerosis* **257**, 208–215.

PAD and Physical Function

Reduced physical function (e.g., slower walking speed) was initially described in patients with PAD referred to vascular laboratory, compared to controls without PAD (Mcdermott et al., 1998, 2001; McDermott et al., 2004). Reduced physical function was identified even in PAD patients without leg symptoms. Recently, two studies have demonstrated a dose–response relationship between lower ABI and reduced physical function among community-dwelling older adults without clinical diagnosis of PAD (Fig. 4). Since this etiology of functional impairment can be improved by several evidence-based therapies (e.g., supervised exercise (Bendermacher et al., 2007) and cilostazol(Regensteiner et al., 2002) [detailed in **Medical Treatment and Walking Regimen**]), identification of PAD as a potential cause of physical dysfunction can have therapeutic implications.

Skeletal muscle atrophy, regenerating muscle fibers, muscle inflammation, and signs of denervation have been reported in the diseased legs of PAD patients (particularly when severe) (Hedberg et al., 1989; Regensteiner et al., 1993), which are considered probable pathophysiologic mechanisms behind reduced physical function. Of note, a recent study has demonstrated the association of low ABI with reduced grip strength (Matsushita et al., 2017). So, it is likely that both leg ischemia due to PAD and systemic atherosclerosis play a role in reduced physical function among patients with PAD.

PAD and QOL

As anticipated from its contribution to physical function and leg pain, several studies have reported reduced health-related QOL in persons with PAD (Inglis et al., 2013; Korhonen et al., 2012; Regensteiner et al., 2008). Most studies consistently showed more evident reduction in physical aspects of QOL (e.g., physical functioning) rather than mental aspects of QOL (e.g., social functioning) in the context of PAD (**Fig. 5**) (Inglis et al., 2013; Korhonen et al., 2012; Regensteiner et al., 2008). The PARTNERS study, a national, community-based PAD detection program, compared PAD with other CVDs (e.g., coronary heart disease and stroke), with respect to their impact on QOL, and reported that PAD may influence QOL similarly as other CVDs (Regensteiner et al., 2008). These findings highlight the importance of multidisciplinary and comprehensive management for patients with PAD.

Medical Treatment and Walking Regimen

Evaluation of the patient with PAD will often start with the primary care physician (PCP). The PCP may start a patient on a walking regimen with medical treatment following sufficient vascular exam and noninvasive studies. The patients suitable for this include those with lifestyle-limiting vascular claudication with abnormal vascular lab testing.

Prior to treatment of the disease itself, PCPs need to also focus on minimizing the risk of concomitant CVD. This is done by thoroughly evaluating the patient's risks factors for coronary artery disease. Antiplatelet therapy, smoking cessation, lipid-lowering therapy, treatment of diabetes and hypertension are central in minimizing CVD risk (Gerhard-Herman et al., 2017b; Alonso-Coello et al., 2012; Society for Vascular Surgery Lower Extremity Guidelines Writing Group et al., 2015). Antiplatelet therapy is particularly helpful in patients with PAD in preventing cardiovascular events (Antithrombotic Trialists' (ATT) Collaboration et al., 2009; Antithrombotic Trialists' Collaboration, 2002; Antiplatelet Trialists' Collaboration, 1994).

Cilostazol, a phosphodiesterase inhibitor that suppresses platelet aggregation and acts as an arterial vasodilator, may also improve the symptoms of claudication (Reilly and Mohler, 2001). This medication should be used carefully in this patient population as many have insufficient cardiopulmonary reserve. Many studies have shown improvement in maximal walking distance (MWD) and pain-free walking distance (PFWD) with cilostazol, as compared to placebo (Bedenis et al., 2014; Thompson et al., 2002; Pande et al., 2010). Other medications under investigation include Naftidrofuryl which is currently available in Europe. Mechanisms of this drug appear to be promoting glucose uptake and increasing adenosine triphosphate levels, and it appears to have equal or greater improvements in PFWD than cilostazol or pentoxifylline (Stevens et al., 2012).

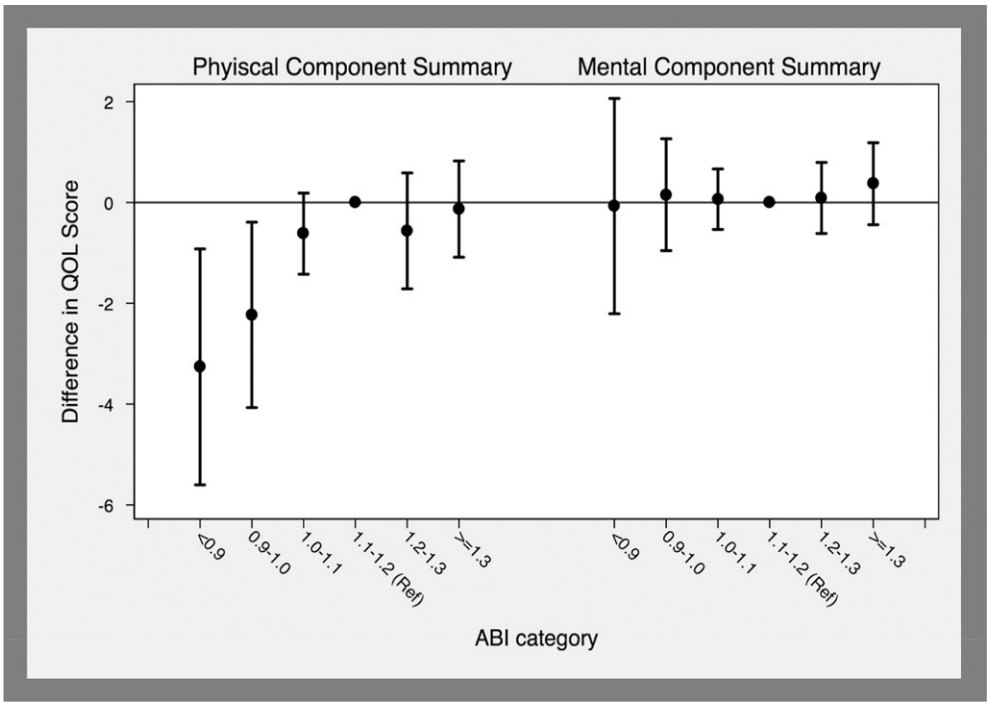

Fig. 5 Adjusted (Adjusted for age, sex, ethnicity, education level, economic status, current smoking/drinking status, body mass index, total cholesterol level, diabetes mellitus, hypertension, history of coronary heart disease, heart failure, stroke, lung disease, and reduced kidney function.) difference in QOL scores (based on SF-12) according to ABI. Modified from *Journal of the American Heart Association* **2017**(6), E004519.

Supervised exercise programs are largely underutilized despite evidence of their benefit. Issues remain regarding the best regimen to help in rehabilitation from claudication symptoms (Fakhry et al., 2012; Gardner et al., 2012). Consistent characteristics among all programs are as follows:

- Supervision by exercise physiologist, physical therapist, or nurse.
- Sessions lasting 45–60 min
- Use of a treadmill
- Three times a week or more
- Total duration of 12 weeks or more

Walking programs appear to double MWD and PFWD when maintained. However, when the program terminates many patients will return to their baseline symptomatology (Hirsch et al., 2006b). Comparing the types of exercise between walking, cycling, and upper extremity devices, there was found to be no difference in the MWD and PFWD improvements (Lauret et al., 2014). Optimal intensity within the regimen is also a matter of debate as many programs have been evaluated with longer duration and less intensity with similar results (Gardner et al., 2005). Other programs, including intermittent compression of the calf, have improved claudication distance (de Haro et al., 2010).

Surgical Intervention

Surgical intervention for PAD, and especially for CLI, has been studied for almost 100 years (Menzoian et al., 2011). Current guidelines are to treat occlusions from proximal to distal, if they coexist. Groups are generally unanimous in recommending intervention for PAD when a patient has rest pain or tissue loss when the ABI is less than 0.8. Another recommendation is to perform inline reconstructions of proximal disease whenever possible (Hirsch et al., 2006b; 2011 Writing Group Members et al., 2011).

Inflow Disease

Open surgery for inflow disease is still the gold standard and, for many, the preferred method of treating symptomatic aortoiliac occlusive disease (AIOD) in low-risk patients. The usual repair is an aorto-bifemoral bypass with prosthetic graft. The perioperative mortality rates are under 5% for severe claudication but 30%–40% for CLI.

Patency rates for open surgical interventions for AIOD are 88% at 5 years and 75% at 10 years. The potential risks of open surgery include graft infection which threaten outcomes including patency and survival (Kieffer et al., 2001). Outcomes for patients undergoing repair for CLI are worse than lifestyle-limiting claudication with 5- and 10-year secondary patencies of 63% and 49%, respectively (Harris et al., 1998; Poulias et al., 1992). Reconstruction methods vary with approaches that are trans-abdominal or retroperitoneal, and reconstructions with ePTFE, Dacron, cryopreserved graft, or varying anastomosis (**Fig. 6**).

Other surgical approaches of reconstruction vary the location of inflow for the femoral vessels. Axillobifemoral bypass offers a reasonable repair to high-risk patients, as there is no clamping of the aorta, entrance into the abdominal cavity, and potential to be done under local anesthesia with cumulative patency of roughly 70% at 5 years in favorable anatomy or similar outcomes in the long term (McPhee et al., 2016; Passman et al., 1996). Other options include femoral to femoral bypass grafting in patients with unilateral iliac occlusive disease or originating the bypass graft from the thoracic aorta.

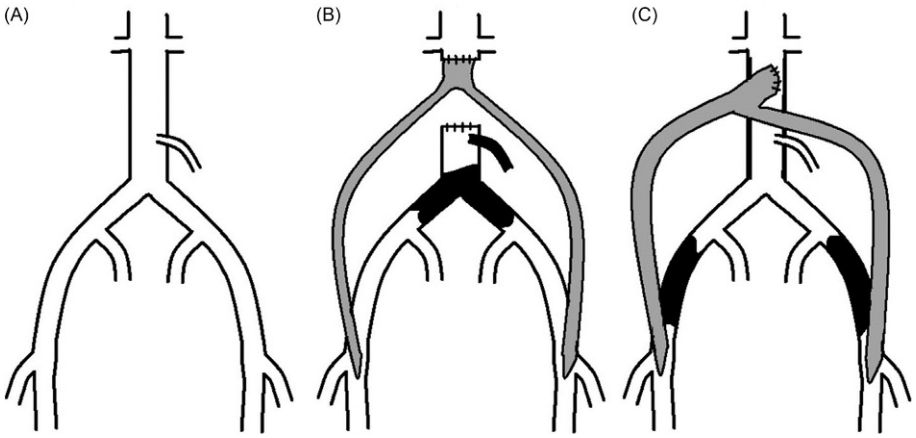

Fig. 6 Reconstruction of AOID with normal vasculature (A), end-to-end proximal reconstruction (B), and end-to-side proximal reconstruction (C) (Gerhard-Herman et al., 2017b).

Graft choice is another opportunity to introduce variability amongst patient outcomes and repair performance. The choice graft for first-time repairs includes PTFE or Dacron with minimal differences in outcomes or complication rates (Davidovic et al., 2004). Formation of a graft from femoral deep or superficial veins or cryopreserved grafts are alternative options, especially in patient with infection of previously placed grafts (Clagett et al., 1993; Fatima et al., 2013).

Infrainguinal Disease

There are several vascular tenants to guide revascularization procedures in the infrainguinal location. For intermittent claudication of the calf, endovascular procedures are usually the intervention of choice. These lesions are often amenable to endovascular intervention, but, when they are not, they require a similar approach, as if it were for CLI. The ideal surgical intervention has normal inflow, normal outflow, and optimal conduit. In most patients, there is some compromise of one of these factors. Many patients with CLI have limited or compromised outflow or other conduits besides autologous vein.

Bypasses often originate from the femoral artery, as it is the closest open proximal vessel to an occlusion with less than 20% stenosis (Hirsch et al., 2006b; 2011 Writing Group Members et al., 2011). Targets vary from above-knee popliteal artery and below-knee popliteal artery to tibial vessels. Bypasses are named by convention with the origin of the bypass, the target, and the conduit used (e.g., fem-peroneal bypass with vein).

The measures of both infrainguinal surgical and endovascular interventions are based on different types of patency. Primary patency is if there is uninterrupted flow without a procedure needed to manage occlusive disease in the conduit or in an adjacent native vessel. Primary assisted patency refers to continuous flow while needing revision either by open surgical revision or endovascular repair prior to occlusion of the conduit. Secondary patency refers to resurrection of a bypass conduit following thrombosis or occlusion from another cause (e.g., neointimal hyperplasia). Other common endpoints for surgical bypass include systemic complications such as myocardial infarction, stroke, respiratory failure, and renal failure. Disease-specific endpoints include the above-mentioned patencies, failure of wound healing, and limb loss (amputation).

In general, shorter bypasses do better than longer bypasses, and bypasses to larger vessels do better than those with smaller caliber target vessels. Superior conduit performance is in the following order: autologous single-segment vein > autologous multiple-segment vein > PTFE > cryopreserved graft. Many studies have also been performed attempting to analyze other aspects of bypass including location of bypass tunnel, orientation of bypass vein, type of PTFE, type of anastomosis with vein or PTFE, and inclusion of surgically created fistula. Level 1 recommendations for surgical intervention are in **Table 1** (2011 Writing Group Members et al., 2011). A summary of randomized trials for surgical intervention is included in **Table 2** (Ziegler et al., 2011).

Endovascular Intervention

Percutaneous in endovascular intervention is a less invasive method at correcting PAD both for AOID and infrainguinal disease. This involves obtaining wire access across an occlusive lesion and treating it with one or multiple devices. There are several devices/treatment modalities approved by the FDA including:

- Subintimal angioplasty
  - Covered stents
  - Coiled stents—e.g., Supera
  - Brachytherapy—e.g., XRT

Table 1 Level 1 recommendations for treatment of critical limb ischemia according to the ACC/AHA guideline summary (Gupta et al., 2014)

Class I—There is evidence and/or general agreement for the following approach to the management of critical limb ischemia
● Rapid evaluation and treatment of factors known to increase the risk of primary amputation. These include significant necrosis of weight-bearing parts of the foot in ambulatory patients, an uncorrectable flexion contracture, paresis of the extremity, ischemic rest pain, sepsis, or limited life expectancy due to comorbid disease.
● The development of acute limb symptoms in patients at risk for CLI (those with diabetes, neuropathy, chronic renal failure, or infection) is a potential vascular emergency that should be assessed immediately and treated by a specialist in vascular disease.
● Prompt initiation of systemic antibiotics in patients with skin ulceration and evidence of limb infection.
● Evaluation for aneurysmal disease (e.g., in the abdominal aorta or popliteal or common femoral artery) in patients with evidence of atheroembolization, such as blue toe syndrome or livedo reticularis.
● Catheter-based thrombolysis for acute limb ischemia (Rutherford category I or IIa) of less than 14-day duration.
● Preoperative estimation of cardiovascular risk if open surgical repair is anticipated.
● When endovascular treatment or surgery is performed for combined inflow and outflow disease, the inflow lesions should be addressed first. If symptoms or infection persist after inflow revascularization, an outflow revascularization should be performed.
● If it is uncertain if there is hemodynamically significant inflow disease, intra-arterial pressure should be measured before and after administration of a vasodilator.
● Patients with skin breakdown should be referred to a healthcare provider with expertise in wound care.
● Patients who have been successfully treated for CLI are at relatively high risk for recurrence. They should be evaluated at least twice yearly by a vascular specialist and be given verbal and written instructions for self-surveillance for recurrence.

Table 2 Aggregate outcomes for surgical infrainguinal revascularization procedures (Goodney et al., 2015)

	Primary patency (%)				*Limb salvage (%)*				*Survival (%)*			
Bypass level	*1 month*	*1 year*	*3 years*	*5 years*	*1 month*	*1 year*	*3 years*	*5 years*	*1 month*	*1 year*	*3 years*	*5 y ears*

Pedal/ankle												
Vein	93	74	64	59	93	74	64	59	98	89	65	63

- Drug-eluting stents—e.g., Zilver PTX
- Cryoballoon—e.g., PolarCath
- Laser atherectomy—e.g., Eximer laser
- Directional atherectomy—e.g., SilverHawk catheter
- Rotational atherectomy—e.g., CSI, Rotablator
- Drug-coated balloons
- Absorbable stents

The treatment of AIOD with percutaneous means has been gaining popularity both with patients, as there are smaller incisions and morbidity, and with practitioners as well. One recent summary found that morbidity, mortality, and outcomes rival those of traditional open repair with 4/5-year primary and secondary patency rates ranging from 60% to 86% and 80% to 98%, respectively (Jongkind et al., 2010). There may also be a patency advantage in this patient population when using covered stents versus uncovered stents likely due to the resistance to neointimal hyperplasis (Mwipatayi et al., 2016; Piazza et al., 2015).

The BASIL trial was the first randomized controlled trial evaluating endovascular approaches to CLI to open surgical approaches. In summary, the data found less short-term morbidity in angioplasty with selective stenting to open surgery. Long-term outcomes supported open surgery first approaches to CLI, especially when patient outcomes were evaluated beyond 2 years (Adam et al., 2005). Other trials have analyzed other datasets for which type of approach leads to improved outcomes. Wiseman et al. found when evaluating 5928 patients following intervention for infrainguinal PAD that an endovascular first approach is associated with improved amputation-free survival over the long term with only a modest relative increased risk of subsequent intervention (Wiseman et al., 2017). Further adjuncts to balloon angioplasty and selective stenting in large series have failed to show a clear advantage such as atherectomy (Ambler et al., 2014; Dattilo et al., 2014; Diamantopoulos and Katsanos, 2014), but other technologies such as drug-coated balloon angioplasty and interwoven stents are showing some advantages in the short term, but long-term data has yet to be collected (Kayssi et al., 2016; Katsanos et al., 2016; Steiner et al., 2016).

Summary

PAD is a relatively common condition that ranges clinically from being asymptomatic to significant pain in the lower extremities. PAD is typically associated with an increased risk for incident CVD and some loss of physical function. In more extreme cases, amputation at some level in the leg may be required. There are several medical and surgical therapies that can be employed, which have been demonstrated to be effective in improving PFWD and/or preventing limb loss.

Introduction

Individuals vary widely in their response to therapy with most cardiovascular drugs. In some patients, drugs are highly effective and cause few or no side effects. In others, the same drug is highly ineffective and produces serious side effects. Antiarrhythmic drugs (AADs) used to treat cardiac arrhythmias are no exception. In fact, variability in membrane-active drug action is so marked that study of the underlying mechanisms has provided important insights into variable responses in general. The sources of inter-individual variability in drug response have traditionally been classified as "pharmacokinetic" and "pharmacodynamic" with the former referring to variability in the conventional measures of drug disposition such as absorption, distribution, metabolism, and elimination, and the latter reflecting the relationship between the drug concentration and its effect. Pharmacokinetic and pharmacodynamic variability as it relates to AAD therapy has extensively been reviewed previously (Darbar and Roden, 2006; Roden et al., 2009). This monograph will outline the challenges and opportunities presented in applying contemporary genetic approaches to better understanding variability in response to AAD therapy for cardiac arrhythmias.

Atrial Fibrillation

Atrial fibrillation (AF), the most common sustained cardiac arrhythmia requiring therapy, is associated with increased risk of stroke, heart failure, myocardial infarction, and death. The global burden of AF was recently estimated at ~33.5 million with progressive increase in incidence, prevalence, and AF-related mortality having major implications for healthcare costs and public health policy (Chugh et al., 2001). The socioeconomic impacts of AF are substantial, as are the consequence of repeated hospital admissions, chronic disease management, and its resultant disabilities. Furthermore, AF remains one of the most challenging cardiac arrhythmias to manage in clinical practice.

Most patients with AF have concomitant conditions such as hypertension that have been associated with the arrhythmia. In a minority, AF occurs in the absence of underlying structural abnormalities and is traditionally termed "lone" but now more correctly categorized as early-onset AF (Kirchhof et al., 2013). A family history of the arrhythmia is common especially in those with early-onset AF (Darbar et al., 2003). Over the last decade, a number of newer risk factors have been identified including race, obstructive sleep apnea, metabolic syndrome, and chemotherapeutic agents (Darbar and Roden, 2013). One setting in which AF is especially common is in patients who have undergone cardiac surgery, where the incidence can be as high 40% in the first week after surgery. Studies suggest that even postoperative AF may also have a genetic basis (Kolek et al., 2015).

Clinical presentations in AF are highly heterogeneous. AF results in loss of atrial activity, with rapid ventricular rates due to conduction of atrial fibrillatory activity down the atrioventricular node (AVN). Therapies are aimed at restoring and maintaining sinus rhythm (rhythm control) or slowing down conduction over the AVN (rate control). Currently, the drug management of AF in

 https://doi.org/10.1016/B978-0-12-809657-4.99763-1

clinical practice varies considerably due to the lack of reliably effective therapies for maintaining sinus rhythm, the toxicities associated with AADs, and the evidence that, on average, rate and rhythm control are approximately equivalent strategies (Wyse et al., 2002). However, a rhythm control strategy is necessary in a large percentage of patients because of intolerable symptoms while in AF and may be appropriate for broader use since patients in the AFFIRM trial had better outcomes if sinus rhythm was achieved and maintained (Corley et al., 2004). Without the ability to match an individual patient with the treatment option most likely to be successful, the current strategy for a trial of AAD therapy focuses primarily not on efficacy, but on the side-effect profile of available medications. In patients who are highly symptomatic with their AF, a rate-control strategy is often ineffective. In such individuals, a trial of AADs is undertaken before consideration of nonpharmacologic, catheter-based ablative therapies. The highly variable clinical presentations of AF including variable and unpredictable responses to drugs and other therapies, unclear etiologies, variable associations with underlying heart disease, and familial aggregation, all support a potential role for genetic variants in the etiology of the arrhythmia as well as in variable response to drugs.

The last decade has witnessed tremendous progress in our understanding the genetic basis of AF. Diverse genetic approaches including linkage analyses and candidate gene approaches as well as next-generation sequencing have identified mutations encoding cardiac ion channels, transcription factors and signaling proteins linked to early-onset familial AF. Conversely, large population-based studies have uncovered common single-nucleotide polymorphisms (SNPs) that modulate AF risk with the strongest association at the chromosome (chr) 4q25 locus (Darbar and Roden, 2013).

Genetic Approaches to AF

One reason for the lack of effective therapies for AF stems from incomplete understanding of the complex pathophysiology of the AF. One approach to unraveling the molecular pathogenesis of AF is through the identification of genes linked with familial early-onset forms of the arrhythmia (Fig. 1).

Evidence for Heritability of AF

Evidence for a genetic contribution to the development of AF was first provided in 1943 by Wolff (Wolff, 1943) who documented transmission of AF in a family with an autosomal dominant pattern of inheritance. Since then, many epidemiologic studies have documented heritability (~62%) in AF especially early-onset AF (Darbar et al., 2003; Fox et al., 2004; Arnar et al., 2006).

Linkage Studies

Several genes and loci have been identified for rare Mendelian forms of early-onset AF (Brugada et al., 1997; Ellinor et al., 2003; Schott et al., 2004; Oberti et al., 2004; Volders et al., 2007). We recently identified a novel AF locus on chromosome 5p15 and established an abnormally prolonged P-wave determined as an "endophenotype" in a family with early-onset AF (Darbar et al., 2002). Linkage analyses have facilitated the identification of individual mutations in several familial AF kindreds. In 2003, the first gene (*KCNQ1*, which encodes a cardiac K^+ channel) responsible for a rare autosomal dominant form of AF was identified (Chen et al., 2003). This discovery was followed by studies that implicated genes encoding additional ion channels and other proteins in the pathogenesis of familial AF. For example, we identified a novel heterozygous frameshift mutation in the natriuretic peptide precursor A (*NPPA*) gene that encodes atrial natriuretic peptide (Hodgson-Zingman et al., 2008). Variations in diverse proteins are

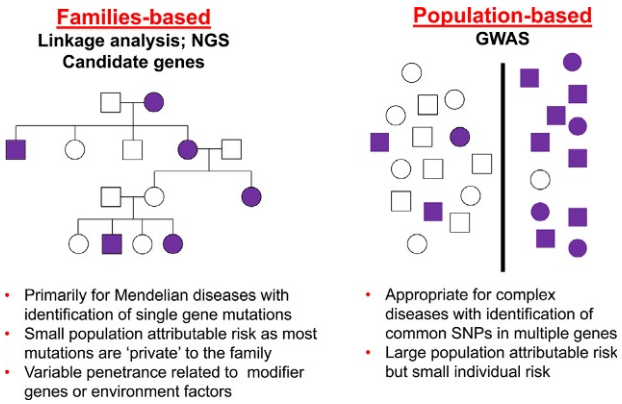

Fig. 1 Genetic approaches to atrial fibrillation (AF). Linkage analysis, next-generation sequencing (NGS) and candidate gene approaches have identified mutations in single genes in large families with early-onset AF. Conversely, genome-wide association studies (GWAS) have uncovered common genetic variants associated with AF in many genes. (Filled in symbols indicate individuals with AF and unfilled symbols represent controls.)

thought to predispose to these uncommon early-onset forms of AF through different mechanisms, a notion that emphasizes the heterogeneity that governs AF initiation and maintenance.

Candidate Gene Studies

Based on the work relating *KCNQ1* to familial AF, investigators considered other potassium and ion channels as potential candidate genes and screened for mutations in AF patients and their families; several rare variants were identified. Otway et al. (2007) examined 50 kindreds with AF and identified a single mutation (R14C) in *KCNQ1* in one family. Although the R14C mutation had no effect on KCNQ1/KCNE1 current amplitudes in cultured cells at baseline, upon exposure to hypotonic solution, mutant channels exhibited a marked increase in currents compared with wild-type channels. Interestingly, only those patients with left atrial dilatation had AF. These findings support the concept of a *double-hit* hypothesis (i.e., the combination of a genetic variant with acquired risk factors, e.g., structural remodeling, is important for AF pathogenesis). A recent study showed that common AF-susceptibility variants on chr4q25 modify the clinical expression of cardiac ion channel and signaling proteins associated with early-onset familial AF—further supporting the double-hit concept (Ritchie et al., 2012).

Association Studies

Most patients with AF have concomitant comorbid conditions such as hypertension or structural heart disease. However, many patients with the same risk factors do not develop the arrhythmia. Thus, a working hypothesis is that genetic determinants increase AF susceptibility in some individuals with identifiable risk factors—a basis for the "double-hit" hypothesis. Initially, association studies comparing AF cases to controls typically tested a small number of variants in candidate genes previously believed to be involved in AF pathogenesis. However, recent advances in next-generation sequencing have made it possible to assay hundreds of thousands of SNPs over the entire human genome and thus made GWAS possible. In 2007, a locus on chromosome 4q25 was identified in a GWAS as having a highly significant association with AF with a relative risk ranging from 1.39 to 1.72 (**Fig. 2**) (Gudbjartsson et al., 2007). Although the mechanism for this observed association remains unknown, the locus is adjacent to the paired-like homeodomain transcription factor 2 (*PITX2*) gene which is critical for left-right cardiac differentiation and development of the pulmonary myocardium. Nine additional AF loci and five novel AF genes were identified when a metaanalysis of AF GWAS was recently conducted (Ellinor et al., 2012; Sinner et al., 2014).

Impact of Genetic Studies of AF

Insights Into Genetic Mechanisms

Genetic approaches to AF have provided important insights into the underlying mechanisms of the arrhythmia. One mechanism by which gain-of-function mutations in genes encoding cardiac potassium, sodium, and calcium channels may lead to AF is reduction in atrial refractoriness creating a substrate for reentrant arrhythmias (Darbar and Roden, 2013). We identified a novel mutation in the gene (*KCNA5*) that encodes for the ultra-rapid potassium current (I_{Kur}) in a family with early-onset AF (Yang et al., 2010). While *NPPA* mutations may also mediate increased risk for AF by modulating the atrial action potential duration (APD), a transgenic mouse model overexpressing the humanized *NPPA* mutation suggests that other mechanisms may also be involved (Savio-Galimberti et al., 2012). A second mechanism by which mutations in cardiac ion channels may predispose to AF is by lengthening of the atrial APD. A loss-of-function mutation in *KCNA5* lengthened the atrial APD and induced early afterdepolarizations in human atrial myocytes (Olson et al., 2006; Yang et al., 2009; Christophersen et al., 2013). A third mechanism involves modulating expression of gap junction proteins important for cell-to-cell communication. Both somatic and germ-like mutations in *GJA5*, encoding connexin-40, have been associated with early-onset AF (Firouzi et al., 2004; Gollob et al., 2006).

Common Genetic Variants Modulate Pulmonary Vein Development

Although the strongest signal consistently associated with AF in GWAS is located at the chr4q25 locus, the precise mechanisms by which these SNPs modulate AF risk remain unclear (Gudbjartsson et al., 2007). The closest gene to the chr4q25 locus is *PITX2* with the "c" isoform implicated in pulmonary vein development. There is emerging evidence that chr4q25 SNPs likely code for a regulatory element that modulates transcription of *PITX2c* (Lubitz et al., 2010; Nobrega et al., 2003; Pennacchio et al., 2006) and signaling pathways that regulate the electrophysiologic substrate responsible for AF by shortening the atrial APD in heterozygous mice that are more prone to inducible AF (Kirchhof et al., 2011). Atrial fibrosis may also play a critical role in the pathogenesis of AF. $Pitx2c^{-/-}$ knock-out mice not only developed 4-chamber cardiac enlargement but also had histological evidence of atrial fibrosis with upregulation of collagen precursor genes (Mommersteeg et al., 2007). In contrast, $Pitx2c^{+/-}$ heterozygous mice show no evidence of cardiac enlargement, but there is increased expression of genes regulating Wnt signaling, a key fibrosis pathway (Kirchhof et al., 2011; Darbar and Roden, 2013; Disertori et al., 2013). However, both the $Pitx2c^{-/-}$ knock-out and heterozygous mice have easily inducible AF. While these studies support a critical role of the pulmonary veins in triggering AF (Haissaguerre et al., 1998), functional studies of PITX2c suggest that modulation of PV development may be one common pathway by which chr4q25 SNPs increase susceptibility to AF.

The Need for a More Rational Approach to AAD Therapy for AF

Despite recent advances in catheter-based and surgical therapies, AADs remain the mainstay of treatment for most patients with symptomatic AF (January et al., 2014). However, response in an individual is highly variable with over 50% of patients treated with AADs having a recurrence of AF over a 6–12 month period. The limited success of therapy is in part related to poor understanding of the underlying mechanisms of AF, heterogeneity of the electrical substrate, and our inability to target mechanism-based therapies in individual patients. In addition, contemporary membrane-active drugs used to suppress AF carry significant risks of serious adverse drug events including drug-induced long QT syndrome, other forms of proarrhythmia, increased mortality, and extracardiac toxicity. Furthermore, this current "one-size fits all" approach to selecting AAD therapy for a patient with symptomatic AF is based largely on minimizing the risk of adverse events rather than on the likelihood of efficacy. There is emerging evidence that variability in response to antiarrhythmic therapy is modulated by common genetic variants associated with AF (Darbar and Roden, 2013).

Genomic Variation Determines Response to AF Therapies

We have used the Vanderbilt and University of Illinois at Chicago (UIC) AF Registries that now include baseline and follow-up clinical information and biosamples in over 3000 subjects with AF and family members to not only identify new common and rare variants that confer increased susceptibility to AF but have also enabled testing of the hypothesis that common SNPs modulate response to drug and catheter-based therapies to control rate or to maintain sinus rhythm (Darbar and Roden, 2013).

Symptomatic Response to AADs Is Modulated by a Common AF Susceptibility Allele

In a retrospective study, Kolek et al. (Parvez et al., 2012) determined whether symptomatic response to AAD therapy is modulated by the three common AF susceptibility loci on chr4q25 (near *PITX2*), 16q22 (in *ZFHX3*), and 1q21 (in *KCNN3*). The discovery cohort consisted of 478 patients with a validation cohort of 198 that were age and gender matched white patients of European American descent. Response was defined as successful rhythm control if the patient remained on the same AAD for a minimum of 6 months with $\geq$75% reduction in AF symptoms. Multiple clinical variables (including age, hypertension, early-onset AF) failed to

Table 1 Response distribution of antiarrhythmic drugs by class among responders for chromosome 4q25 SNP rs10033464

Discovery cohort			
Drug class	*Wild type (n = 309)*	*Minor allele carriers (n = 90)*	P *value*
Class 1	87 (28%)	37 (41%)	0.02
Class III	222 (72%)	53 (59%)	0.02
Validation cohort			
Drug class	*Wild type (n = 97)*	*Minor allele carriers (n = 46)*	P *value*
Class 1	37 (39%)	30 (67%)	0.01
Class III	60 (61%)	16 (34%)	0.02

predict response to AADs. However, a SNP at the 4q25 locus (rs10033464) was significantly associated with successful symptom control (odds ratio (OR) 2.97, 95% confidence interval (CI) 1.42–6.21, $P = 0.003$). Furthermore, individuals who carried the chr4q25 SNP responded better to Class I versus Class III AADs in both the discovery and validation cohorts (**Table 1**). These findings suggest that a common AF risk allele differentially regulates response to Class I versus Class III AADs in patients with frequent symptomatic AF.

The underlying mechanism(s) by which a chr4q25 AF risk allele modulates response to AADs is not well understood (Parvez et al., 2012). However, measurement of left atrial mRNA levels in 95 patients undergoing thoracoscopic AF ablation and assessment of the effects of flecainide and sotalol in *Pitx2c* mice have provided important insights Syeda et al. (2016) not only showed that variable *PITX2* expression modulates atrial resting membrane potential but confirmed our earlier clinical observation that sodium channel blockers are more effective at suppressing AF than potassium channel blockers (**Table 1**) (Parvez et al., 2012). However, it is important to note that our data and the recent study are based on the assumption that chr4q25 SNPs modify *PITX2* expression. However, this association has not definitively been proven. Nonetheless, even if the presumed link between *PITX2* expression and chr25 SNPs remains elusive, these observations clearly show variability in response to AADs in patients with AF based on chr4q25 genotype.

Common AF Risk Alleles at chr4q25 Predict Rafter Catheter-Based AF Ablation and Electrical Cardioversion

To test the hypothesis that 4q25 AF risk alleles can predict response to AF ablation, we studied 378 patients who underwent catheter-based AF ablations (median age 60 years; 71% men; 89% typical AF) between 2004 and 2011. The primary end point was time to recurrence of any nonsinus atrial tachyarrhythmia (atrial tachycardia, atrial flutter, or AF). There were 200 arrhythmia recurrences (53%) and in multivariable analysis, the rs2200733 risk allele predicted a 24% shorter recurrence-free time (survival time ratio 0.76; 95% confidence interval (CI) 0.6–0.95; $P = 0.016$) compared with the reference allele. The heterozygous haplotype demonstrated a 21% shorter recurrence-free time (survival time ratio 0.79; 95% CI 0.62–0.99) and the homozygous risk allele carriers a 39% shorter recurrence-free time (survival time ratio 0.61; 95% CI 0.37–1.0; $P = 0.037$). The second 4q25 SNP (rs10033464) did not affect recurrence-free survival time. In exploratory analyses, the 1q21 rs13376333 risk allele was found to confer a 22% shorter recurrence free time (median survival ratio = 0.78, 95% CI 0.62–0.97, $P = 0.026$) and the 16q22 rs7193343 risk allele did not. Kolek et al. showed that the chr4q25 AF risk SNP is also an independent predictor of AF recurrence after restoration of sinus rhythm after direct current cardioversion (Parvez et al., 2013).

Translation of Genetic Discoveries to the Bedside

Genetic approaches have not only provided important insights into the underlying mechanisms of AF but also identified genetic subtypes with differential response to therapy (Darbar and Roden, 2013). However, the impact of these discoveries have thus far been limited given the lack of evidence-based data to support mechanism- and genotype-based treatment approaches; incomplete understanding of the underlying mechanisms associated with AF genetic variants; limitations of using noncardiac cell lines; animal models failing to recapitulate human cellular electrophysiology; and our inability to study functional atrial myocytes. While in vitro methods for assessing the role of ion channel variants in AF are well-established and have been used by many (Darbar et al., 2008; Abraham et al., 2010), cardiac myocytes have very distinct electrophysiologic properties and heterologous systems cannot capture the full spectrum of functional changes associated with AF-associated genetic variants. Importantly, this discrepancy between in vitro versus in vivo studies was recently highlighted when Vanderbilt investigators showed that an *SCN5A* mutation (D1275N), linked with cardiac conduction disease, dilated cardiomyopathy and arrhythmias when expressed in multiple heterologous expression systems, showed near-normal sodium channel function (Watanabe et al., 2011). However, expression in a mouse model was associated with conduction slowing, AF, and a dilated cardiomyopathy.

Transgenic murine models have provided important insights into the pathogenesis of AF. However, cardiac ion channels are highly species-specific. Hence, mouse models of AF may not reliably and precisely reproduce the human AF phenotype. Recently, we showed that overexpression of the humanized *NPPA* mutation in mice is associated with increased susceptibility to AF (Savio-Galimberti et al., 2012). However, the absence of atrial fibrosis in the mutant mice suggests that atrial structural remodeling does not play a major role in the pathogenesis of AF in this murine model. The limitations of heterologous expression systems and murine models of AF suggest that an alternative system is urgently needed to elucidate the underlying genetic mechanisms by which chr4q25 AF risk alleles modulate response to AAD therapy.

Challenges and Opportunities

AF Burden as an Endpoint to Evaluate Response to AF Therapies

Due to historical limitations in noninvasive ambulatory monitoring technology and lack of reliable algorithms to identify and provide quantitative summaries for specific arrhythmias, AF burden has in general not been used as a clinical or study end point. One widely used symptom-based metric is "time to first symptomatic AF episode," but this correlates poorly with frequency of symptomatic episodes (Savelieva and Camm, 2000). The unreliability of symptoms to estimate AF burden and to identify patients with and without AF have been pointed out by pacemaker trials and also in patients without implanted devices. However, recent technological advances that allow continuous monitoring of cardiac rhythm have now made it possible to rigorously define AF burden as a surrogate end point for AF therapy (Friedman et al., 2001; Israel et al., 2004). Measurement of AF burden includes symptomatic and asymptomatic episodes and may be a more robust end point for AF therapy because it is less subject to investigator bias and does not have the sampling error associated with episodic monitoring or reliance on patient symptoms (Euler and Friedman, 2003). Furthermore, AF burden is favored to become the metric of choice to assess to response to AADs and monitoring after AF ablation therapy (Calkins et al., 2012a). Insertable cardiac monitors (ICMs) are able to continuously monitor the heart through a single-lead ECG based on a specific algorithm that detects AF by evaluating the irregularity of R–R intervals (Euler and Friedman, 2003; Calkins et al., 2012b). These devices are able to correctly classify AF in 96.1% of patients and correctly exclude AF in 97.4% of subjects. The device is able to monitor the heart for up to 3 years.

Lack of randomized genotype-driven pharmacogenomic trials

One reason for the failure to translate genetic discoveries to the bedside care of patients with AF relates is due to the lack of genotype-directed prospective trials (Darbar and Roden, 2013). We showed that a common chr4q25 SNP associated with AF not only predicted successful symptom control in patients treated with AADs for AF but that individuals who carried the risk variant responded better to Class I (sodium channel blockers) versus Class III (potassium channel blockers) AADs (Parvez et al., 2012).

Based on this data and a recently published study confirming the differential response to sodium channel blockers based on reduced PITX2c expression in AF patients (Syeda et al., 2016) a prospective pharmacogenomic trial is being conducted where a cohort of patients with frequent symptomatic AF are randomized to flecainide (Class I) or sotalol (Class III) to determine if response to therapy is differentially regulated by a chr4q25 SNP using AF burden as a metric of drug efficacy (Fig. 3). This study utilizes a crossover design to minimize interindividual variability and maximize statistical power to detect an interaction between chr4q25 genotype and reduction in AF burden with flecainide versus sotalol. Subjects are monitored with an ICM to assess AF burden and will be asked to complete a comprehensive, validated 20-item AF specific questionnaire (AF Effect on QualiTy-of-life) (Spertus et al., 2011) at baseline, and monthly thereafter for the duration of the study. At the end of the 3-month trial period, the AAD is discontinued and patients are switched to the other AAD and followed for another 3-month period in a crossover trial design.

Summary

Over the last 15 years, tremendous advances have been made in defining the genetic basis of AF, identifying the underlying molecular mechanisms, and subtyping response to AAD and other therapies for AF. However, the translation of these discoveries

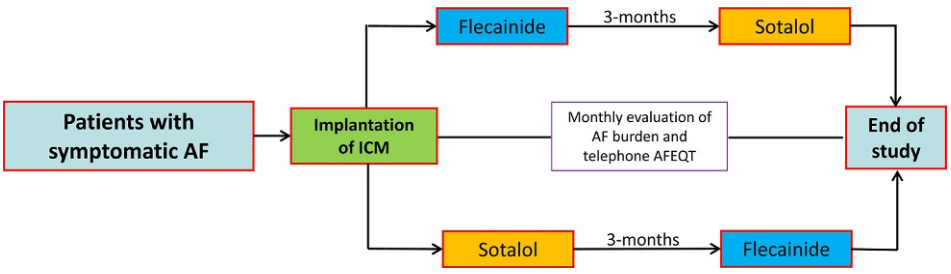

Fig. 3 A randomized sequential crossover study to evaluate if response to sotalol versus flecainide is modulated by chromosome 4q25 associated SNPs. *AFEQT*, AF-specific quality of life questionnaire; *ICM*, insertable cardiac monitor.

when it comes to the bedside management of an individual patient with AF has not yet been fully realized. This may in part relate to the retrospective and observational nature of the studies demonstrating that response to AADs, and other therapies are modulated by common genetic variants at the chr4q25 locus. The time for conducting appropriately-designed pharmacogenomic clinical trials that are genotype driven is upon us.

Atherosclerosis initially occurs asymptomatically, but can progress to cause symptoms of angina and may culminate in coronary thrombosis and acute myocardial infarction (MI). This article discusses the medications used in atherosclerotic cardiovascular disease, focusing on those used in the acute setting following MI, as well as those used in primary and secondary prevention of cardiovascular disease. For each medicine or class of medicines, their mechanism of action, pharmacokinetics, adverse effects, and interactions will be covered. Practical tips for clinical use will also be provided. Symptomatic management of stable angina, which aims to ease cardiac chest pain by reducing cardiac workload, is beyond the scope of this article.

Medication Used in the Treatment of Acute Coronary Syndromes

Preventing or minimizing irreversible myocardial ischemia and avoiding further thrombosis are important aims in the early treatment of MI. Drugs used to restore normal coronary flow will be discussed here. The immediate symptomatic treatment of suspected acute coronary syndrome (ACS), including opioid analgesia, antiemetics, and oxygen are beyond the scope of this article. Oral antiplatelets, which are used both in the acute and long-term management of cardiovascular disease, will be discussed as part of primary and secondary prevention.

Pharmacological action	Mechanism of action	Adverse effects
Relief of pain associated with acute angina through: • Coronary artery dilation, reduced afterload and increased oxygen delivery to the myocardium. • Peripheral venodilation, reduced preload and reduced myocardial oxygen demand.	• Multistep conversion to nitric oxide in the vascular endothelium • Nitric oxide-mediated decrease in intracellular calcium causes smooth muscle relaxation	• Headache • Flushing • Hypotension • Dizziness • Tachyphylaxis and tolerance • Methaemoglobinaemia

Fig. 1 Summary of the pharmacological action, mechanism of action, and adverse effects of nitrates.

Nitrates

Nitrates can be administered intravenously as isosorbide dinitrate or glyceryl trinitrate (GTN) in the management of ACS. Sublingual GTN, in spray or tablet form, is also used to relieve acute episodes of angina. Longer acting formulations, such as GTN patch and isosorbide dinitrate and mononitrate tablets, are used to prevent angina. The focus will be on the use of sublingual and intravenous GTN in the acute setting. **Fig. 1** summarizes the pharmacological action, mechanism of action, and adverse effects of nitrates.

Mechanism of action

Nitrates reduce myocardial workload by causing systemic and coronary vasodilation. Coronary artery dilation reduces afterload, increases oxygen supply to the myocardium, and reduces coronary vasospasm. Dilation of collaterals allows blood to bypass narrowed coronary arteries to improve blood flow and oxygen delivery to the ischemic area (Matsunaga et al., 2000). Perhaps more importantly, peripheral venodilation reduces preload, which reduces left ventricular wall stress and subsequently myocardial oxygen demand (Abrams, 1985). In the vascular endothelium, nitrates undergo a multistep conversion to nitric oxide (NO). The activation of guanylate cyclase by NO increases the concentration of cyclic guanosine monophosphate, which mediates a decrease in intracellular calcium leading to smooth muscle relaxation (Jerca et al., 2002). When high doses of nitrates are administered, blood pressure is reduced, which further reduces myocardial wall stress and oxygen demand.

Pharmacokinetics

GTN is widely distributed in the tissues, particularly to red blood cells and vascular smooth muscle cells. The pharmacological effect is observed within 1–2 min of intravenous and 1–3 min of sublingual administration. It undergoes rapid biotransformation, principally by de-nitration in the liver to less active dinitrate and mononitrate metabolites. The duration of action following intravenous and sublingual administration is 3–5 min and 30–60 min, respectively (Bogaert, 1987).

Adverse effects

Flushing, headache, hypotension, and dizziness are common adverse effects directly related to vasodilation (Joint Formulary Committee, 2016). Nitrates should be avoided in patients with systolic blood pressure lower than 90 mmHg, or with marked brady- or tachycardia, due to the risk of hemodynamic compromise in patients with ischemic heart disease (Kushner et al., 2009). Patients with severe aortic stenosis are at high risk of profound hypotension, therefore nitrates should be avoided. Prolonged intravenous infusion of nitrates can rarely cause methemoglobinemia (Joint Formulary Committee, 2016).

An acute desensitization, termed tachyphylaxis, can occur with prolonged (>24 h) intravenous infusion of intermediate to high dose nitrates (Gruppo Italiano per to Studio della Soprawivenza nell'Infarto Miocardica, 1994); however, prolonged treatment is not usually indicated. Tolerance, a separate phenomenon, is associated with chronic use of longer acting nitrates for prophylaxis of angina. The mechanism by which tolerance develops has not been defined. Hypotheses include reduced conversion of nitrates to NO; reduced bioactivity of NO; or activation of renin–angiotensin–aldosterone-system (RAAS) induced vasoconstriction, which counters the effects of NO (Parker and Parker, 1998). Tolerance is prevented by dosing tablets asymmetrically or removing patches, to allow an 8 h nitrate-free period, usually overnight. It is unlikely to occur with sublingual GTN due to the intermittent nature of administration.

Drug interactions

Caution is required when administering nitrates with antihypertensives due to additive risk of hypotension. Phosphodiesterase type 5 inhibitors can exacerbate the vasodilatory action of nitrates and cause severe, life-threatening hypotension which contraindicates concurrent use (Joint Formulary Committee, 2016). Patients wishing to use both drugs must be provided information on appropriate timing of doses (see practical points).

Practical points

- 10 min sublingual GTN rule for patients—At the onset of angina: stop, sit down, and rest. If pain persists, use 1 spray or tablet and wait 5 min. If pain persists, repeat and wait 5 min. If pain persists, call for an ambulance and unlock your door.

Pharmacological action	Mechanism of action	Adverse effects
• Dissolution of clots and restoration of perfusion	• Catalysis of conversion of plasminogen to plasmin through proteolysis • Clot-selective fibrin degradation	• Haemorrhage • Hypotension • Arrhythmias • Embolisation • Hypersensitivity reactions (streptokinase)

Fig. 2 Summary of the pharmacological action, mechanism of action, and adverse effects of fibrinolytics.

- Sublingual GTN tablets are volatile; therefore they must be kept in their original container and have a reduced expiry once opened. Spray formulations avoid this.
- Phosphodiesterase type 5 inhibitors: patients should not use GTN within 24 h of sildenafil or vardenafil, and 48 h of tadalafil. If chest pain occurs following administration of a phosphodiesterase type 5 inhibitor and does not resolve with rest, an ambulance should be called immediately.

Fibrinolytics

Although largely replaced by primary percutaneous coronary intervention, thrombolytics can be used to dissolve clots and restore perfusion in patients with acute MI with ST elevation (Joint Formulary Committee, 2016). **Fig. 2** summarizes the pharmacological action, mechanism of action, and adverse effects of fibrinolytics.

Mechanism of action

Streptokinase is a protein extracted from streptococci cultures. It forms a complex with plasminogen, promoting the conversion of this inactive precursor molecule to the active plasmin, which degrades fibrin clots by proteolysis (Anderson and Willerson, 1993). It has largely been superseded by recombinant tissue plasminogen activators (tPAs), which have a more acceptable side effect profile.

tPA is a naturally occurring protease released from endothelial cells of occluded blood vessels. Pharmacological tPAs (alteplase, reteplase, and tenecteplase) are modified forms of tPA produced by recombinant DNA technology. They catalyze conversion of fibrin-bound plasminogen to plasmin, causing clot-selective degradation of fibrin (Collen and Lijnen, 2009).

Pharmacokinetics

Streptokinase and recombinant tPAs are catabolized to small peptides in the liver, which are cleared renally. Streptokinse and alteplase have short half-lives and must be administered by intravenous infusion. Reteplase and tenecteplase have longer half-lives due to reduced binding to hepatic receptors (Ulrich et al., 1992; Keyt et al., 1994). Reteplase can be administered as 2 intravenous bolus doses, 30 min apart, and tenecteplase as a single bolus dose (Joint Formulary Committee, 2016).

Adverse effects

The most common adverse effect of fibrinolytics is hemorrhage, ranging from minor bleeding to major gastro-intestinal (GI) bleed and hemorrhagic stroke. Fibrinolytics are contraindicated in active bleeding and in patients at a high risk of bleeding, for example, recent hemorrhage, trauma or surgery, recent history of hemorrhagic stroke, uncontrolled hypertension, coagulation defects, endocarditis, aortic dissection, and esophageal varices. Caution is required in severe hepatic disease due to associated coagulopathies.

Streptokinase, due to its biological origin, can cause fever, hypersensitivity reactions, and anaphylaxis. Antibodies blocking the action of streptokinase appear within 4 days of use, rendering repeated administration of streptokinase therapeutically ineffective and high risk for hypersensitivity. Recombinant tPAs do not stimulate an immune response and use can be repeated.

Other adverse effects include hypotension, arrhythmias and rarely, acute embolization due to break up of the targeted clot (Joint Formulary Committee, 2016).

Drug interactions

Although combination of fibrinolytics with antiplatelets or antithrombins has known therapeutic benefits, caution is required due to increased risk of bleeding. Other groups of medicines which increase bleeding risk, such as nonsteroidal antiinflammatory drugs (NSAIDs), should be avoided or used with caution (Joint Formulary Committee, 2016).

Practical points

- Hypotension may resolve on elevating the patient's legs. Alternatively the infusion rate can be reduced or temporarily stopped.
- Hypersensitivity reactions can be treated with antihistamines and corticosteroids. Adrenaline should be available when administering streptokinase, in case of anaphylaxis.
- Recombinant tPAs can be used in patients who are likely to have antibodies to streptokinase.

Antithrombins

Antithrombins reduce thrombus-related events by inhibiting thrombin generation at various points in the clotting cascade (see Fig. 3). They include unfractionated heparin (UFH), low molecular weight heparins (LMWH), fondaparinux, and bivalirudin. Fig. 4 summarizes the pharmacological action, mechanism of action, and adverse effects of antithrombins.

Heparin and fondaparinux

Mechanism of action

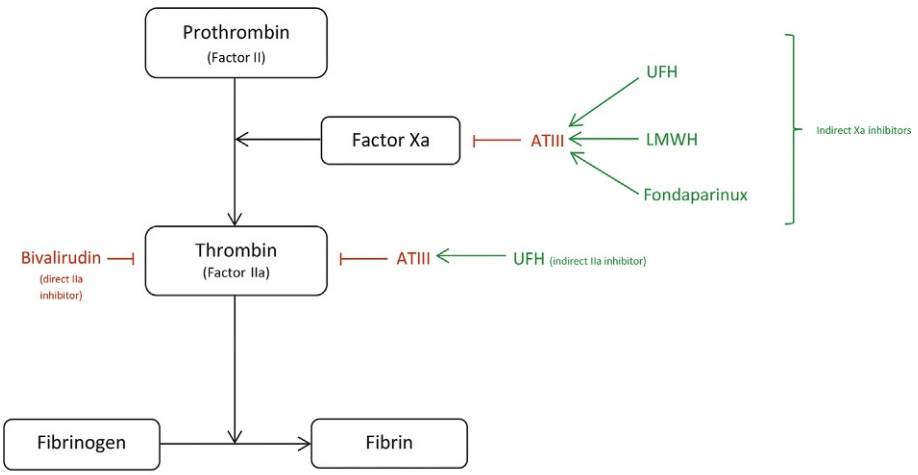
Antithrombin III inhibits clotting factors IIa (thrombin), Xa, and to a lesser extent IXa and XIIa. UFH and LMWH bind to antithrombin III via a pentasaccharide group, inducing a conformational change which enhances antithrombin-mediated inhibition of these clotting factors. Fondaparinux is a synthetic pentasaccharide, with a higher affinity for antithrombin III than UFH or LMWH. To accelerate thrombin inhibition, UFH must bind to thrombin itself, in addition to antithrombin III. LMWH and fondaparinux, which are too small to simultaneously bind antithrombin III and thrombin, selectively inhibit factor Xa, for which the additional binding is less crucial (Hirsh et al., 2001a).

Pharmacokinetics

The effect of UFH occurs immediately following intravenous, or 1–2 h following subcutaneous administration (Hirst et al., 2001b). Binding of heparin to plasma proteins and various tissues contributes to interindividual variability in its effect, necessitating dose adjustment according to regular monitoring of activated partial thromboplastin time (APTT) (Hirsh et al., 2001a). UFH is favorable when a rapid onset and offset of activity is required, for example, patients undergoing angioplasty.

LMWH (dalteparin, enoxaparin, and tinzaparin) and fondaparinux (synthetic pentasaccharide) are administered by subcutaneous injection. They have a greater bioavailability and longer duration of action compared with UFH, allowing once or twice daily dosing (Hirsh et al., 2001b, 2007). Additionally, the therapeutic effect is more predictable than UFH, owing to a smaller degree of binding to plasma proteins and tissues (Hirsh et al., 2001a). Unlike UFH, LMWH and fondaparinux do not require routine monitoring; however, antifactor Xa levels can be monitored.

Clearance of heparins is largely by renal excretion of metabolites and unchanged drug (Hirsh. et al., 2001b). Fondaparinux is excreted unchanged in the urine (Hirsh et al., 2007).



ATIII = antithrombin III; UFH = unfractionated heparin; LMWH = low molecular weight heparin

Fig. 3 Sites of action of antithrombins in the clotting cascade.

Pharmacological action	Mechanism of action	Adverse effects
• Reduction of thrombus related events by inhibiting thrombin or its generation	• Indirect inhibition of thrombin (UFH) or factor Xa (UFH, LMWH, fondaparinux) through potentiating antithrombin III; or direct inhibition of thrombin (bivalirudin)	All: • Haemorrhage UFH/LMWH • Hyperkalaemia • Heparin-induced thrombocytopenia • Osteoporosis (long term use)

Fig. 4 Summary of the pharmacological action, mechanism of action, and adverse effects of antithrombins.

Bivalirudin

Mechanism of action

Bivalirudin is a synthetic 20 amino-acid peptide analog of hirudin. It reversibly inhibits both soluble and clot-bound thrombin by binding both to the active site and at a second, remote binding site (Accord, 2016).

Pharmacokinetics

Bivalirudin, when administered as an intravenous bolus followed by infusion, has an immediate anticoagulant effect and an approximate half-life of 25 min. Its effect can be monitored using activated clotting time or APTT. It is cleared primarily by protease metabolism and renal excretion, such that the infusion rate must be adjusted for patients with severe renal impairment (Accord, 2016).

Adverse effects

Antithrombins increase the risk of hemorrhage and should not be used in patients who are actively bleeding. Extreme caution is required if heparins must be used in patients with a high risk of severe bleeding, including hemophilias, thrombocytopenia, severe hypertension, and recent high risk surgery. Protamine is a specific antidote, which reverses anticoagulation in patients who experience hemorrhage when treated with UFH. It can also be used to treat bleeding due to LMWH; however, it only partially neutralizes the antifactor Xa activity of LMWH. No specific antidotes exist for fondaparinux or bivalirudin.

UFH and LMWH can increase serum potassium; however, this is usually only important for patients with increased risk of hyperkalemia, for example in diabetes and renal impairment. Hypersensitivity can occur and osteoporosis is associated with long-term use (Joint Formulary Committee, 2016).

Heparin-induced thrombocytopenia (HIT) occurs when the immune system produces antibodies to the antigenic complex formed between heparin and platelet factor 4 (PF4). Binding of antibodies to this complex activates platelets, leading to hypercoaguability, characterized by a fall in platelet count and venous or arterial thrombosis (Linkins, 2015). HIT usually presents after 5–15 days of treatment with heparin, or sooner if the patient has recently received heparin. Baseline and regular monitoring of platelets should be performed. The formation of the PF4 complex is dependent upon the size of the heparin molecule; therefore, HIT is less likely to occur with LMWH (Hirsh et al., 2001b). Fondaparinux has a very low risk of causing HIT, due to its much reduced interaction with proteins and cells (Linkins, 2015). Bivalirudin is not implicated in HIT and may be used as a treatment (Linkins et al., 2012).

In severe renal impairment, fondaparinux is contraindicated and LMWH should be used cautiously. The infusion rate of bivalirudin should be reduced; however the standard bolus dose can be used. UFH may be preferred. Caution is required in severe liver disease due to the inherent increased risk of bleeding.

Drug interactions

Although combination of antithrombins with antiplatelets has therapeutic benefits, caution is required due to increased risk of bleeding. Other agents which increase bleeding risk, such as NSAIDs, should be avoided or used with caution (Joint Formulary Committee, 2016).

Practical points

- UFH and LMWH are porcine-derived. For patient groups where porcine-derived products may not be acceptable, for example, practicing Jewish and Muslim patients, fondaparinux or bivalirudin may provide an appropriate alternative
- Pharmacokinetics of LMWH may be less predictable in obesity, renal impairment, and pregnancy. Consideration to monitoring antifactor Xa levels should be given when treating with LMWH in these patient groups.

Intravenous Antiplatelets

Glycoprotein IIb/IIIa inhibitors

Mechanism of action

Activated platelets undergo a structural change in the active site of the glycoprotein IIb/IIIa (GP IIb/IIIa) receptor, creating a binding site for pro-aggregatory molecules, such as fibrinogen, von Willebrand factor, and prothrombin (Stangl and Lewis, 2010). Intravenously administered GP IIb/IIIa inhibitors block platelet activity at the final point of convergence of platelet activation pathways (Quinn et al., 2002). This has a theoretical advantage of inhibiting platelet activity irrespective of the agonist.

Abciximab is a monoclonal antibody fragment which noncompetitively, irreversibly inhibits GP IIb/IIIa receptors. Eptifibatide—a hexapeptide, and tirofiban—a nonpeptide, are selective, reversible GP IIb/IIIa antagonists (Warltier et al., 2002). **Fig. 5** summarizes the pharmacological action, mechanism of action, and adverse effects of GP IIb/IIIa inhibitors.

Pharmacokinetics

Abciximab has a high affinity for the GP IIb/IIIa receptor, resulting in a long duration of receptor blockade and short plasma half-life. Although platelet function is restored over 48 h, abciximab can remain in the circulation in its platelet-bound form for up to 15 days (Lily, 2013).

Pharmacological action	Mechanism of action	Adverse effects
• Prevention of blood clots and myocardial infarction by inhibiting platelet aggregation	• Inhibition of binding of pro-aggregatory molecules to platelets • Block at the final point of convergence of platelet activation pathways	• Haemorrhage • Thrombocytopenia • Pseudothrombocytopenia • Hypotension • Rash and hypersensitivity

Fig. 5 Summary of the pharmacological action, mechanism of action, and adverse effects of glycoprotein IIb/IIIa inhibitors.

Conversely, eptifibatide and tirofiban have lower affinity for the receptor, resulting in a shorter duration of blockade (Stangl and Lewis, 2010).

Adverse effects

Bleeding is the most common adverse effect of GP IIb/IIIa inhibitors and caution is required in patients at increased risk of hemorrhage (Stangl and Lewis, 2010). Thrombocytopenia has also been reported with all GP IIb/IIIa inhibitors, warranting platelet monitoring in the elderly and those with a low platelet count at baseline. Pseudothrombocytopenia can also occur, due to changes in the structure of the platelet membrane components (Warltier et al., 2002). Other side effects include hypotension, nausea, headache, fever, rash, and hypersensitivity (Joint Formulary Committee, 2016).

Eptifibatide and tirofiban are partially renally cleared and require dose adjustment in renal impairment (Stangl and Lewis, 2010). Caution is necessary if using abciximab in patients with severe renal impairment and avoidance in hemodialysis is recommended. Abciximab administration should not be repeated, owing to the development of antibodies in 5.8% of recipients, which could cause reduced efficacy or hypersensitivity (Lily, 2013).

Drug interactions

Combining GP IIb/IIIa inhibitors with other antiplatelets, antithrombins, and fibrinolytics has known therapeutic benefits; however, caution is required due to increased bleeding risk. Use with other drugs known to increase the risk of bleeding, such as NSAIDs, should be avoided or used with caution.

Practical points

- Intended for use with heparin and oral antiplatelet(s)
- Licensed for both ST and non-ST elevation MI
- Can be used for patients who are at high risk of further coronary thrombosis when PCI is not immediately available

Medication Used in the Primary and Secondary Prevention of Cardiovascular Events

Patients with established atherosclerotic cardiovascular disease should receive medication, in addition to adopting lifestyle changes, as secondary prevention to reduce the risk of future cardiovascular events. Primary prevention is indicated for patients with a 10-year risk of cardiovascular disease of 10% or greater. Patients eligible for primary prevention are likely to have a combination of risk factors including diabetes, obesity, elevated cholesterol, hypertension, and smoking history.

Antiplatelets

Platelets play a pivotal role in atherosclerotic cardiovascular disease, such that platelet activation pathways have become valuable therapeutic targets. The sites of action of the antiplatelets agents to be discussed in this article are shown in **Fig. 6**.

Aspirin

Fig. 7 summarizes the pharmacological action, mechanism of action, and adverse effects of aspirin.

Mechanism of action

Thomboxane A2 is a prostaglandin produced by activated platelets in response to stimuli such as collagen and thrombin. It exerts its prothrombotic effects through promotion of platelet aggregation and activation of new platelets. Arachidonic acid undergoes metabolic conversion by cyclooxygenase-1 (COX-1) enzyme to form prostaglandins G2 and H2, which are converted to a number of prostaglandins, including thromboxane A2 (Awtry and Loscalzo, 2000).

Aspirin exerts its antiplatelet action through the irreversible acetylation and inactivation of COX-1 enzyme, inhibiting synthesis of the precursor prostaglandins G2 and H2. The resultant reduction in platelet thromboxane A2 production reduces platelet activation and aggregation (Awtry and Loscalzo, 2001). Since platelets lack a nucleus, they have limited capacity to synthesize new COX-1 enzyme; therefore, thromboxane A2 production is diminished for the 7–10 day lifespan of the platelet.

In addition to its antiplatelet activity, aspirin may reduce the inflammatory response and slow the progression of atherosclerosis in patients with coronary artery disease, through a combination of antioxidant processes (Awtry and Loscalzo, 2000).

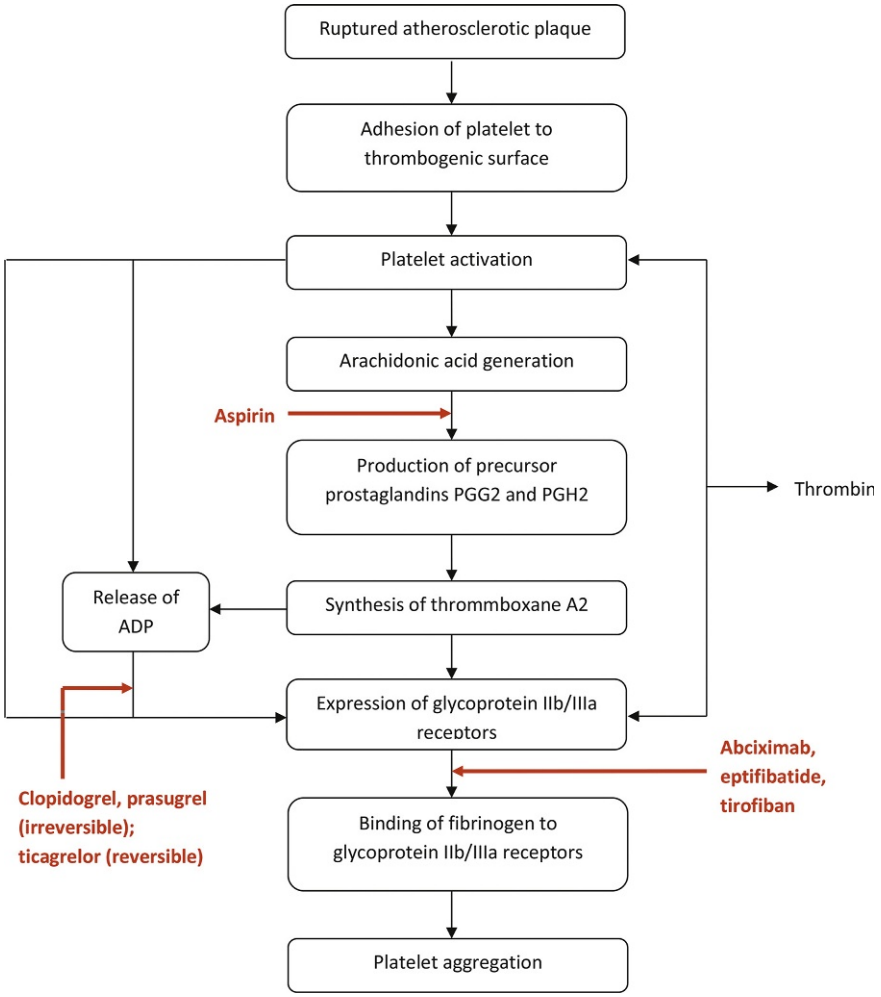


Fig. 6 Sites of action of antiplatelets in the platelet aggregation pathway.

Pharmacological action	Mechanism of action	Adverse effects
• Inhibition of platelet aggregation and activation of new platelets • Possible reduction of inflammatory process and slowing of progression of atherosclerosis	• Irreversible inhibition of cyclooxygenase-1 (COX-1) enzyme, resulting in decreased platelet thromboxane A2	• Haemorrhage • Gastro-intestinal irritation and ulceration • Urticarial rash • Bronchoconstriction

Fig. 7 Summary of the pharmacological action, mechanism of action, and adverse effects of aspirin.

Although there is a multitude of evidence demonstrating the efficacy of aspirin in preventing and treating atherosclerotic cardiovascular disease, it is a relatively weak antiplatelet when used alone. Firstly, aspirin does not completely inhibit thromboxane A2 and secondly, platelet aggregation pathways independent of thromboxane A2 exist and are not affected by treatment with aspirin (Awtry and Loscalzo, 2000). For some indications, better therapeutic outcomes may be achieved by combining aspirin with a newer agent which targets alternative platelet aggregation pathways.

Pharmacokinetics

Aspirin is rapidly absorbed in the acidic conditions of the upper GI tract. It exerts a measurable effect on platelet function within 60 min and has a short plasma half-life of 20 min (Patrono et al., 2001). Cumulative inhibition means that, in chronic administration of low-dose aspirin, the threshold 95% thromboxane A2 inhibition necessary to suppress thromboxane A2-mediated platelet aggregation is achieved after several days (Hoogendijk and ten Cate, 1980). Therapeutic benefits of aspirin have been demonstrated over the dose range 30–1500 mg. In practice, higher doses are associated with an increased risk of adverse effects,

without enhanced therapeutic efficacy (Patrono et al., 2001). Aspirin is 170 times more selective for COX-1 than the COX-2 isoform (Vane et al., 1998), explaining the difference in the dose required for antithrombotic compared with antiinflammatory action.

Enteric coating of aspirin necessitates alkaline conditions for absorption, which is thus delayed until the small intestine (Awtry and Loscalzo, 2000). The link between the resulting reduced bioavailability and therapeutic efficacy of low-dose enteric coated aspirin has not been established; however, it may result in reduced platelet inhibition compared with standard or dispersible aspirin (Hawthorne et al., 1991).

Adverse effects

As described earlier, thromboxane A2 is one of many end products resulting from COX-mediated metabolism of arachidonic acid to prostaglandins (Awtry and Loscalzo, 2000). As aspirin also inhibits COX-1 in gastric mucosa, this suppresses the gastro-protective action of prostaglandin E2, which explains the increased incidence of adverse effects on the GI system in patients receiving aspirin. Dose-related adverse GI effects reported in trials range from minor symptoms (nausea, heartburn, indigestion) to major bleeding (Roderick et al., 1993).

A small proportion of patients suffering with asthma are sensitive to aspirin, which may result in symptoms ranging from urticaria and rhinitis to bronchoconstriction and respiratory compromise.

Drug interactions

Combining aspirin with other antiplatelets, antithrombins, and fibrinolytics has known therapeutic benefits; however, caution is required due to increased bleeding risk. Use with other drugs known to increase the risk of bleeding, such as NSAIDs, should be avoided or used with caution. Antisecretory drugs such as proton pump inhibitors (PPIs) can be used to reduce the risk of GI bleeding.

Adenosine diphosphate inhibitors

Adenosine diphosphate (ADP), which is released from platelet dense granules and damaged cells, binds to P2Y12 receptors on the surface of platelets, causing platelet aggregation and adhesion. ADP binding reduces intracellular cyclic adenosine monophosphate (cAMP), which activates the GP IIb/IIIa receptor and platelet aggregation (Quinn and Fitzgerald, 1999; Kalantzi et al., 2012). ADP inhibitors noncompetitively antagonize the binding of ADP by interacting with the P2Y12 receptor at a site distinct from the ADP binding site. There are the *thienopyridine ADP inhibitors*: clopidogrel, prasugrel, and ticlopidine, and the *cyclopentyltriazolopyrimidine ADP inhibitor*: ticagrelor. **Fig. 8** summarizes the pharmacological action, mechanism of action, and adverse effects of ADP inhibitors.

Mechanism of action

Following the hepatic metabolism of thienopyridine prodrugs to their active forms, covalent disulfide bonding to the P2Y12 receptor facilitates irreversible platelet inhibition (Kalantzi et al., 2012). The inhibitory action of thienopyridines on ADP released from platelet dense granules reduces platelet aggregation induced by other molecules, including collagen, platelet activating factor, and to some extent, thrombin (Quinn and Fitzgerald, 1999). Like aspirin, irreversible inhibition by thienopyridines means platelet function recovers only when new platelets are generated (approximately 7 days) (Patrono et al., 2001).

Ticlopidine is no longer used due to its unacceptable safety profile, namely hematological dyscrasias, and clopidogrel's comparable efficacy (Quinn and Fitzgerald, 1999). The thienopyridines currently in clinical use are clopidogrel and prasugrel.

Tigacrelor exerts its antiplatelets effect by reversible, noncompetitive antagonism of ADP at the P2Y12 receptor (AstraZeneca, 2016a). It inhibits ADP-mediated platelet activation and aggregation more potently than the thienopyridines. The main differences in its mode of action are: firstly, ticagrelor does not require metabolism to an active form, overcoming the delay in therapeutic effect seen with clopidogrel. Secondly, reversible inhibition means that, following cessation of therapy platelet function returns to normal more rapidly, within approximately 5 days (Gurbel et al., 2009).

Pharmacokinetics

Clopidogrel undergoes rapid intestinal absorption and the peak plasma concentration occurs 45 min after oral administration (Sanofi, 2015). The cumulative antiplatelet effect of clopidogrel reaches a maximum of 50%–60% after 4–7 days of repeated administration of 50–100 mg dose (Patrono et al., 2004). A delay in platelet inhibition following administration of clopidogrel is observed, owing to the need for prodrug activation. This two-step conversion, involving cytochrome P450 enzymes, may be the

Pharmacological action	Mechanism of action	Adverse effects
• Reduction in platelet aggregation induced by other molecules, including collagen and platelet activating factor.	• Irreversible (clopidogrel, prasugrel) or reversible (ticagrelor) non-competitive antagonism of ADP at the P2Y12 receptor • Clopidogrel and prasugrel are prodrugs, which undergo hepatic metabolism into their active forms	• Haemorrhage (ticagrelor > prasugrel > clopidogrel) • Hyporesponsiveness to clopidogrel, leading to diminished platelet inhibition • Dyspnoea with ticagrelor

Fig. 8 Summary of the pharmacological action, mechanism of action, and adverse effects of adenosine diphosphate (ADP) inhibitors.

source of interindividual variability in platelet inhibition. Clopidogrel "resistance" or "hyporesponsiveness," seen in up to one-third of patients treated with the drug, can be partially explained by genetic polymorphisms in CYP2C19 alleles coding for loss of function. Additionally, genetic variability in the ABCB1 gene encoding the P-glycoprotein efflux transporter may modulate absorption of clopidogrel (Kalantzi et al., 2012). The active compound undergoes hepatic transformation to inactive metabolites, which are excreted in the urine and feces (Sanofi, 2015).

Prasugrel is rapidly hydrolyzed by intestinal esterases such that the prodrug is not detected in the plasma (Wiviott et al., 2010). The following cytochrome P450 dependent activation results in a peak plasma concentration of active metabolite 30 min after oral administration (Farid et al., 2007). This single cytochrome P450 step facilitates a more rapid onset of antiplatelet activity and renders activation of the parent molecule less susceptible to genetic variation, making prasugrel a more powerful and predictable antiplatelet agent (Kalantzi et al., 2012).

Ticagrelor is rapidly absorbed from the GI tract (Teng, 2012); with a time to maximum therapeutic effect of 2–4 h and a plasma half-life of 7 h (AstraZeneca, 2016a). It undergoes hepatic biotransformation, principally by CYP3A4 and CYP3A5, to a combination of active and inactive metabolites, the majority of which are eliminated by biliary secretion (Teng, 2012).

Adverse effects

Thienopyridines, by their nature, increase the risk of bleeding; however, prasugrel has a greater bleeding risk than clopidogrel (Wiviott et al., 2007). Prasugrel can rarely cause hypersensitivity reactions. Life-threatening blood dyscrasias observed in patients treated with ticlopidine are extremely rare with the newer thienopyridines (Joint Formulary Committee, 2016).

As described earlier, hyporesponsiveness to clopidogrel caused by variant alleles for CYP2C19 can lead to diminished platelet inhibition, and subsequent treatment failure.

Ticagrelor has a higher bleeding risk than the thienopyridine ADP inhibitors owing to its greater potency. The other common side effect is adenosine-mediated dyspnoea, caused by ticagrelor inhibition of cellular uptake and metabolism of adenosine (Cattaneo et al., 2014). Other side effects reported include GI disturbances, headache, dizziness, and raised uric acid levels. Asymptomatic ventricular pauses were reported in early clinical studies (AstraZeneca, 2016a); therefore caution is required when used in patients at risk of bradycardia. Although no dose adjustment in renal function is necessary, increased creatinine levels have been reported during use, warranting monitoring of renal function.

Drug interactions

The heavy reliance on cytochrome P450 enzymes for conversion of clopidogrel to its active metabolite makes it susceptible to metabolic drug–drug interactions. Drugs which inhibit CYP2C19, such as omeprazole, carbamazepine, cimetidine, and erythromycin, may reduce the plasma concentration of clopidogrel's active metabolite, decreasing its antiplatelet action and increasing the risk of therapeutic failure (Bates et al., 2011). The clinical significance of the interaction between clopidogrel and PPIs has come into question due to discrepancy between the randomized clinical trials and observational studies examining this interaction (Melloni et al., 2015).

Prasugrel is not reported to have clinically significant interactions with inhibitors or inducers of cytochrome P450 enzymes.

Strong inducers, such as carbamazepine, and inhibitors, such as ketoconazole, of CYP3A4 can decrease or increase plasma ticagrelor levels, respectively, and concomitant administration should be avoided. Ticagrelor is also a weak CYP3A4 inhibitor; therefore caution is required when administered with CYP3A4 substrates with a narrow therapeutic window. Ticagrelor's interaction with P glycoprotein transporters warrants monitoring of digoxin and ciclosporin levels when administered concurrently (AstraZeneca, 2016a).

Practical points

- Oral antiplatelets require loading on initiation
- Dual antiplatelet therapy increases the risk of hemorrhage. Antisecretory agents, such as PPIs, should be used to reduce the risk of GI ulceration and bleeding
- Combination of one or more antiplatelets with anticoagulants is sometimes indicated, for example, in patients with mechanical valve replacements or atrial fibrillation who present with an ACS. This significantly increases bleeding risk and should be used for the shortest possible time

Lipid-Lowering Therapies

Dyslipidemia is an important risk factor for atherosclerosis and thrombotic MI, which can be modified both by diet and drugs. The lipid-lowering drugs discussed target various lipid transport processes to reduce low-density lipoprotein (LDL)-cholesterol and atheroma.

HMG-CoA reductase inhibitors: statins

Fig. 9 summarizes the pharmacological action, mechanism of action, and adverse effects of statins.

Pharmacological action	Mechanism of action	Adverse effects
• Reduction of LDL cholesterol and atheroma • Mild reduction of triglycerides and increase of HDL cholesterol • 'Pleiotropic' effects, including stabilisation of atherosclerotic plaques against rupture	• Reversible, non-competitive inhibition of 3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase • Upregulation of LDL receptors to increase removal of LDL cholesterol from blood into hepatocyte, where it is enzymatically degraded	• Muscle-related side effects, ranging from myalgia to rhabdomyolysis • Transient elevation of hepatic transaminases • Dose related increased risk of glycaemia and insulin resistance

Fig. 9 Summary of the pharmacological action, mechanism of action, and adverse effects of statins.

Table 1 Grouping of statins and doses according to intensity

	Reduction in low-density lipoprotein cholesterol (%)				
Dose (mg/day)	5	10	20	40	80
Fluvastatin	-	-	21	27	33
Pravastatin	-	20	24	29	-
Simvastatin	-	27	32	37	42
Atorvastatin	-	37	43	49	55
Rosuvastatin		38	43	48	53

Low intensity :20-30%
Medium intensity: 31-40%
High intensity: over 40%

Source: National Institute for Health and Care Excellence (NICE) (2014). *Cardiovascular disease: risk assessment and reduction, including lipid modification [Clinical guideline 181]*. London: National Institute for Health and Care Excellence.

Mechanism of action

3-Hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase catalyzes the metabolism of HMG-CoA to mevalonic acid. Statins are reversible, competitive inhibitors of HMG-CoA (Knopp, 1999) and bind with a higher affinity than the natural substrate (Holdgate et al., 2003). By inhibiting the rate-limiting step in cholesterol synthesis, HMG-CoA reductase inhibitors reduce hepatocyte cholesterol, which leads to upregulation of hepatic LDL cholesterol receptors. Since LDL receptors transport LDL-cholesterol from the plasma into hepatocytes, statins remove LDL-cholesterol from the plasma into hepatocytes, where it subsequently undergoes enzymatic degradation. They also mildly reduce triglycerides and increase HDL-cholesterol. Lowering LDL-cholesterol can reduce the lipid content of atherosclerotic plaques and slow the progression of atherosclerosis (Ferrieres, 2009).

In addition to their cholesterol-lowering action, statins have numerous "pleiotropic" effects. The most important of which, in terms of atherosclerotic disease, is the stabilization of atherosclerotic plaques against rupture. Statins in clinical use are simvastatin, pravastatin, fluvastatin, atorvastatin, and rosuvastatin. Statins vary in potency, with atorvastatin and rosuvastatin producing the greatest reduction in LDL-cholesterol (see **Table 1**). The aim of intensive statin therapy is to achieve a 40% reduction in LDL-cholesterol within 3 months (NICE, 2014).

Pharmacokinetics

Statins are rapidly absorbed following oral administration; however, they are subject to a high degree of first pass metabolism, which limits the amount of drug reaching the systemic circulation (Desager and Horsmans, 1996). Simvastatin is a prodrug, which must undergo hydrolysis to its active form, the beta-hydroxy fatty acid. Fluvastatin, pravastatin, atorvastatin, and rosuvastatin are active in their administered form (Srinivasa et al., 2011).

Short acting statins: simvastatin, fluvastatin, and pravastatin, have a half-life between 0.5 and 3 h. They should be administered at night, to achieve maximal inhibition of cholesterol synthesis in the morning, at its natural peak. Atorvastatin and rosuvastatin are longer acting, with half-lives of 14 and 19 h, respectively (Pfizer, 2016a; AstraZeneca, 2016b); therefore their administration is less time-critical.

Simvastatin, fluvastatin, and atorvastatin are highly hepatically metabolized by cytochrome P450 enzymes. Rosuvastatin undergoes CYP2C9 metabolism to a small degree (AstraZeneca, 2016b), while pravastatin is chemically degraded by cytochrome P450-independent mechanisms (Accord, 2015). This is summarized in **Table 2**. After biotransformation, statins are eliminated primarily in the feces, by biliary excretion, with minimal renal excretion (Srinivasa et al., 2011).

Table 2 Pharmacokinetics of statins (Srinivasa et al., 2011)

	Metabolism			
	Extent	*Mechanism*	*Site*	*Half-life (h)*
Atorvastatin	Extensive	CYP3A4, glucuronidation	Liver	14
Fluvastatin	Extensive	CYP2C9 (CYP2C8, CYP3A4)	Stomach	1.2
Pravastatin	Moderate	Chemical degradation	Liver	1.8
Rosuvastatin	Minimal	CYP2C9 (CYP2C19, CYP2D6, CYP3A4)	Liver	19
Simvastatin	Extensive	CYP3A4	Liver	2.0

Adverse effects

Common unwanted effects of statins include GI disturbance, insomnia, rash, myalgia, and altered liver function tests (Joint Formulary Committee, 2016).

Muscle-related side effects of statins are dose related and range from uncomplicated myalgia to, rarely, serious toxicity including rhabdomyolysis. The most common presentation is myalgia, which is reported at a frequency of 1%–5% in clinical trials and 11%–29% in observational studies (Rosenson et al., 2014). It is important to note that statins are often used in a patient population at an elevated risk of musculoskeletal complaints even in the absence of treatment. Creatine kinase, a marker of muscle breakdown, can be measured if patients present with muscle pain or weakness (Pasternak et al., 2002).

Rises in hepatic transaminases are usually transient and often resolve without cessation or alteration of statin therapy (McKenny et al., 2006). Hepatic failure has been reported rarely with statins in clinical use (Joint Formulary Committee, 2016). Baseline liver function tests should be measured prior to initiation of therapy. Rosuvastatin can cause renal dysfunction, which is more strongly associated with higher doses (AstraZeneca, 2016b).

Statins are associated with an increased risk of type II diabetes. The mechanism is not fully understood; however, glycemia and insulin resistance seen with statins is thought to be associated with HMG-CoA reductase inhibition. The risk is dose-related, with high intensity statins presenting a greater risk than moderate intensity; however, this risk is not thought to outweigh the benefits of improved cardiovascular outcomes (Sattar et al., 2010).

Drug interactions

As many statins are metabolized by cytochrome P450 enzymes, the risk of adverse effects, particularly muscle-related, increases when administered concomitantly with medicines that inhibit this enzyme system. Major examples include azole antifungals, antiretrovirals, macrolides, amiodarone, calcium channel blockers, and grapefruit. It may be necessary to avoid concurrent use or to reduce the dose of the inhibitor to avoid muscle toxicity (Joint Formulary Committee, 2016). Pravastatin and rosuvastatin are not subject to CYP-mediated metabolic interactions.

Cholesterol absorption inhibitor: ezetimibe

Fig. 10 summarizes the pharmacological action, mechanism of action, and adverse effects of ezetimibe.

Mechanism of action

Cholesterol absorption from the small intestinal lumen into endothelial cells is mediated by the transport protein NPC1L1 (Betters and Yu, 2010). Ezetimibe acts at the duodenal brush border to inhibit this protein, preventing the uptake of cholesterol and increasing its excretion in the feces. The resulting decrease in plasma cholesterol causes a reduction in hepatocyte cholesterol stores, which increases expression of LDL receptors to increase clearance of LDL-cholesterol from the plasma into hepatocytes (van Heek and Davis, 2002). Ezetimibe elicits a reduction in LDL-cholesterol of up to 20% (Bruckert et al., 2003).

The additional of ezetimibe to simvastatin has been demonstrated to produce further reductions in cardiovascular risk compared with simvastatin alone in a secondary prevention setting (Cannon et al., 2015a). The synergy observed when ezetimibe is combined with a statin may be explained by the statin off-setting the compensatory increase in cholesterol synthesis caused by ezetimibe (van Heek and Davis, 2002).

Pharmacokinetics

Ezetimibe is rapidly absorbed following oral administration (Merck Sharpe and Dohme, 2016) and is largely glucuronidated to an active metabolite which peaks in the plasma after 1–2 h (Bruckert et al., 2003). Ezetimibe and ezetimibe-glucuronide undergo enterohepatic recycling, which ensure repeated exposure of drug to the site of action in the duodenum (van Heek and Davis, 2002). Both compounds are slowly eliminated in the feces and urine with a half-life of 22 h (Bruckert et al., 2003).

Adverse effects

The most frequent unwanted effects of ezetimibe therapy are abdominal pain, diarrhea, and headache. Rarer side effects include hypersensitivity, altered liver function, hepatitis, pancreatitis, and thrombocytopenia (Joint Formulary Committee, 2016). Muscle

Pharmacological action	Mechanism of action	Adverse effects
• Reduction of plasma LDL cholesterol by up to 20% • No effect on triglycerides • Can be combined with a statin to reduce cardiovascular events in ischaemic heart disease	• Inhibition of the transport protein NPC1L1 at the duodenal brush border to reduce absorption of cholesterol • Subsequent upregulation of LDL receptors and increase in clearance of LDL cholesterol from the plasma into hepatocytes	• Headache • Abdominal pain and diarrhoea • Hepatitis • Pancreatitis • Thrombocytopaenia • Muscle toxicity

Fig. 10 Summary of the pharmacological action, mechanism of action, and adverse effects of ezetimibe.

Pharmacological action	Mechanism of action	Adverse effects
• Significant reduction in plasma cholesterol in patients who are intolerant to statins or have failed to achieve target reductions in cholesterol despite maximal statin therapy	• Fully human monoclonal antibodies • Prevention of PCSK9 mediated degradation of LDL receptors • Increased clearance of LDL cholesterol from the plasma into hepatocytes	• Reaction at the site of subcutaneous injection • Flu-like symptoms • Rash • Nausea

Fig. 11 Summary of the pharmacological action, mechanism of action, and adverse effects of proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors.

toxicity, with raises in creatine kinase and very rarely rhabdomyolysis, has been reported in patients taking ezetimibe (Merck Sharpe and Dohme, 2016).

Drug interactions

Caution is required when ezetimibe is combined with a statin, due to the increased risk of muscle toxicity (Cannon et al., 2015a).

Proprotein convertase subtilisin/kexin type 9 inhibitors

Fig. 11 summarizes the pharmacological action, mechanism of action, and adverse effects of proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors.

Mechanism of action

In 2003, when research highlighted an association between high levels of PCSK9 and familial hypercholesterolemia (Abifadel et al., 2003), PCSK9 became an interesting new target for lipid-lowering therapies.

PCSK9 is a protein produced in hepatocytes. It binds to internalized LDL receptors and labels them for liposomal degradation. In the presence of PCSK9, the increased degradation leads to lower expression of LDL receptors on the surface of hepatocytes, which reduces clearance of LDL-cholesterol from the plasma (Lagace, 2014). PSCK9 inhibitors prevent the targeted degradation of LDL receptors, leading to increased clearance of cholesterol from the plasma.

There are currently two licensed PCSK9 inhibitors: alirocumab and evolocumab. They are fully human monoclonal antibodies, which have a high affinity for the LDL receptor binding domain of PCSK9 (Cicero et al., 2015). Clinical trials have demonstrated significant reductions in cholesterol in participants who are intolerant to statins or have failed to achieve target cholesterol reductions despite maximal statin therapy (Cannon et al., 2015b; Stroes et al., 2014); however, evidence that this translates to a reduction in cardiovascular risk is still awaited (Everett et al., 2015).

PCSK9 inhibitors are thought to work synergistically with statins, by inhibiting the compensatory increase in PCSK9 induced by the inhibition of cholesterol synthesis (Fazio, 2015).

Pharmacokinetics

Both alirocumab and evolocumab are administered by subcutaneous injection and should be given every 2–4 weeks, depending on the agent and the dose (Joint Formulary Committee, 2016). Peak plasma concentrations occur at 3–7 days (Sanofi, 2016; Amgen, 2016).

Evolocumab has a half-life of 11–17 days (Amgen, 2016) and alirocumab 17–20 days, or 12 days when administered with a statin (Sanofi, 2016). Like other monoclonal antibodies, they are eliminated by degradation to short peptides and amino acids.

Adverse effects

Common unwanted effects include injection site reactions, flu-like symptoms, rash, and nausea (Joint Formulary Committee, 2016); however, postmarketing surveillance may highlight further adverse effects when the drugs are used over a wider population.

Drug interactions

PCSK9 inhibitors are not thought to interact with other medicinal products and do not interact with cytochrome P450 enzymes.

Practical points

- Patients should be educated about the risk of muscle toxicity and asked to report signs and symptoms of myopathy.
- If muscle-related adverse effects occur with statins the following strategies may be used: stop the statin and restart the same treatment when symptoms have resolved; reduce the dose of the statin; change to a different statin.
- "Statin intolerance" is used when patients are found to be intolerant to three different statins that they tried (NICE, 2014).

Beta Blockers

When endogenous catecholamines bind to G-protein coupled beta adrenergic receptors, they stimulate an increase in cAMP. This activates protein kinase A (PKA), which:

(a) Phosphorylates membrane calcium channels, resulting in increased intracellular calcium
(b) Increases release of calcium from the sarcoplasmic reticulum (Ladage et al., 2013)

Of the three main beta receptor subtypes, beta-1 receptors are distributed primarily in the heart (and also in the kidneys), beta-2 in the vascular and bronchial smooth muscle, and beta-3 in the adipocytes and heart (Mansoor and Kaul, 2009). Beta adrenergic stimulation causes increased heart rate, increased force of myocardial contraction, increased blood pressure, and relaxation of bronchial smooth muscle. **Fig. 12** summarizes the pharmacological action, mechanism of action, and adverse effects of beta blockers.

Mechanism of action

Beta blockers competitively antagonize the action of norepinephrine and epinephrine at beta receptors to prevent the accumulation of cAMP, activation of PKA, and the subsequent changes in intracellular calcium which mediate the adrenergic response (Mansoor and Kaul, 2009). The adrenergic effects on the cardiovascular system are mediated primarily through beta-1 receptors. Antagonism at beta-1 receptors in the sino-atrial node reduces heart rate, in the myocardium reduces force of contraction, and in the kidney reduces peripheral resistance through inhibition of renin release. These combined actions reduce myocardial workload and oxygen demand to reduce the symptoms of angina and reduce the risk of ACS. By attenuating the damaging effects of excessive adrenergic activity, beta blockers have a protective effect on left ventricular structure and function (Gheorghiade et al., 2003). Their antiarrhythmic properties may also prevent tachyarrhythmias.

Although beta blockers share similar properties, subtle pharmacological differences may affect the choice of agent for an individual patient. They can be categorized according to cardioselectivity, hemodynamic properties, and the presence/absence of vasodilatory activity (Ladage et al., 2013), summarized in **Table 3**.

Cardioselective beta blockers have a higher affinity for beta-1 receptors and subsequently fewer adverse effects of beta-2 blockade, although this can be lost at high doses (Ladage et al., 2003). Nebivolol demonstrates the highest degree of cardioselectivity (Weber, 2005). Beta blockers with intrinsic sympathomimetic activity, mediated through partial agonism, decrease blood pressure with less effect on heart rate and cardiac output (Prichard, 1987); they should not be used in patients with atherosclerotic cardiovascular disease (Freemantle et al., 1999). Beta blockers with vasodilatory effects also reduce peripheral resistance (Joint Formulary Committee, 2016). This can be mediated either by co-existing alpha blockade or, in the case of nebivolol, direct effects on the endothelial production of NO (Weber, 2005).

Pharmacokinetics

Beta blockers are generally well absorbed following oral administration (Wood, 1984) and their biological half-lives are considerably longer than their plasma half-lives (Weber, 2005). The wide pharmacokinetic variability between beta blockers stems from differences in lipophilicity (Weber, 2005). Lipophilic agents such as propranolol, metroprolol, and labetalol are more readily absorbed from the GI tract and exhibit a greater degree of plasma protein binding. Lipophilic beta blockers are highly hepatically metabolized and have short plasma half-lives; whereas hydrophilic beta blockers, such as atenolol and nadalol, undergo direct renal elimination and have longer plasma half-lives (Weber, 2005).

Pharmacological action	Mechanism of action	Adverse effects
• Reduction of myocardial oxygen demand by decreasing heart rate, strength of myocardial contraction and blood pressure • Reduction in symptoms of angina and risk of myocardial infarction • Protection of left ventricular structure and function	• Competitive antagonism of epinephrine and norepinephrine at beta receptors • Cardiovascular effects medicated by action at the beta-1 subtype of receptors located in the heart • 'Cardioselective' beta blockers have a higher affinity for beta-1 receptors and have fewer adverse effects of beta-2 blockade	• Hypotension, bradycardia • Fatigue, malaise • Sexual dysfunction • Cold extremities • Nightmares, hallucinations • Masking of hypoglycaemia and hyperthyroidism • New-onset diabetes • Bronchospasm (beta-2 blockade) • Rebound hypertension, tachycardia and increase in myocardial contractility

Fig. 12 Summary of the pharmacological action, mechanism of action, and adverse effects of beta blockers.

Table 3 Characteristics of beta blockers

	Cardioselectivity	*Intrinsic sympathomimetic activity*	*Direct vasodilation*	*Combined alpha and beta blockade*

Adverse effects

Common unwanted effects of beta blockers include fatigue, malaise, sedation, low mood, and sexual dysfunction. As a direct extension of the therapeutic effect, beta blockers can cause hypotension, bradycardia, and cardiac conduction disturbances including second- and third-degree heart block. Use should be avoided in significant sinus bradycardia and atrioventricular block, and should not be initiated during acutely decompensated heart failure. Beta blockers may also mask signs of hypoglycemia and hyperthyroidism (Joint Formulary Committee, 2016).

Beta blockers have been associated with deleterious effects on glucose and lipid metabolism, including increased risk of new onset diabetes (Weber, 2015). Various factors may contribute to this increased risk, including inhibition of beta-2 receptor-mediated insulin release from the pancreas (Luna and Feinglos, 2001). Weight gain and reductions in insulin sensitivity and lipolysis through beta-3 blockade may potentiate this (Cruickshank, 2007). These metabolic disturbances are much less likely to occur with the most highly selective beta blockers: bisoprolol and nebivolol (Weber, 2005).

Blockade of beta-2 receptors in the airways can induce dyspnoea and bronchospasm. Although nonselective beta blockers are more likely to cause bronchoconstriction, the risk is not absent from even highly cardioselective agents. The use of all beta blockers requires caution in chronic obstructive pulmonary disease and is relatively contraindicated in asthmatics.

Cold extremities and exacerbation of Reynaud's have been reported with beta blockers due to peripheral vasoconstriction; however, there is no evidence of increased claudication or decreased walking distance in patients with peripheral vascular disease (Paravastu et al., 2013).

Effects on the central nervous system (CNS) include hallucinations, nightmares, confusion, and depression (Joint Formulary Committee, 2016). Theoretically, lipophilic beta blockers would be more likely to cause adverse CNS effects, owing to their greater ability to penetrate the blood brain barrier.

Abrupt cessation of beta blockers can lead to hypertension, tachycardia, and increased myocardial contractility. This "rebound phenomenon" may result from an increase in beta adrenergic receptors induced by treatment with beta blockers and the subsequent increased sensitivity to circulating catecholamines when the drug is withdrawn (Karachalios et al., 2005). It is particularly dangerous in patients with atherosclerotic cardiovascular disease, in whom the inability of myocardial oxygen delivery to meet the rapidly increased demand can lead to myocardial ischemia, ACS, and arrhythmias.

Drug interactions

Pharmacodynamic interactions can occur when beta blockers are given concomitantly with other drugs with similar therapeutic effects, including antihypertensives and drugs with negative inotropic and chronotropic effects, such as digoxin, amiodarone, and rate-limiting calcium channel blockers. While there are known therapeutic benefits to combining such drugs in certain patients groups, caution should be exercised. Administration of beta blockers with verapamil is usually contraindicated. Pharmacokinetic interactions do occur, but are unlikely to be of clinical significance since there is poor correlation between plasma concentration and therapeutic effect.

Practical points

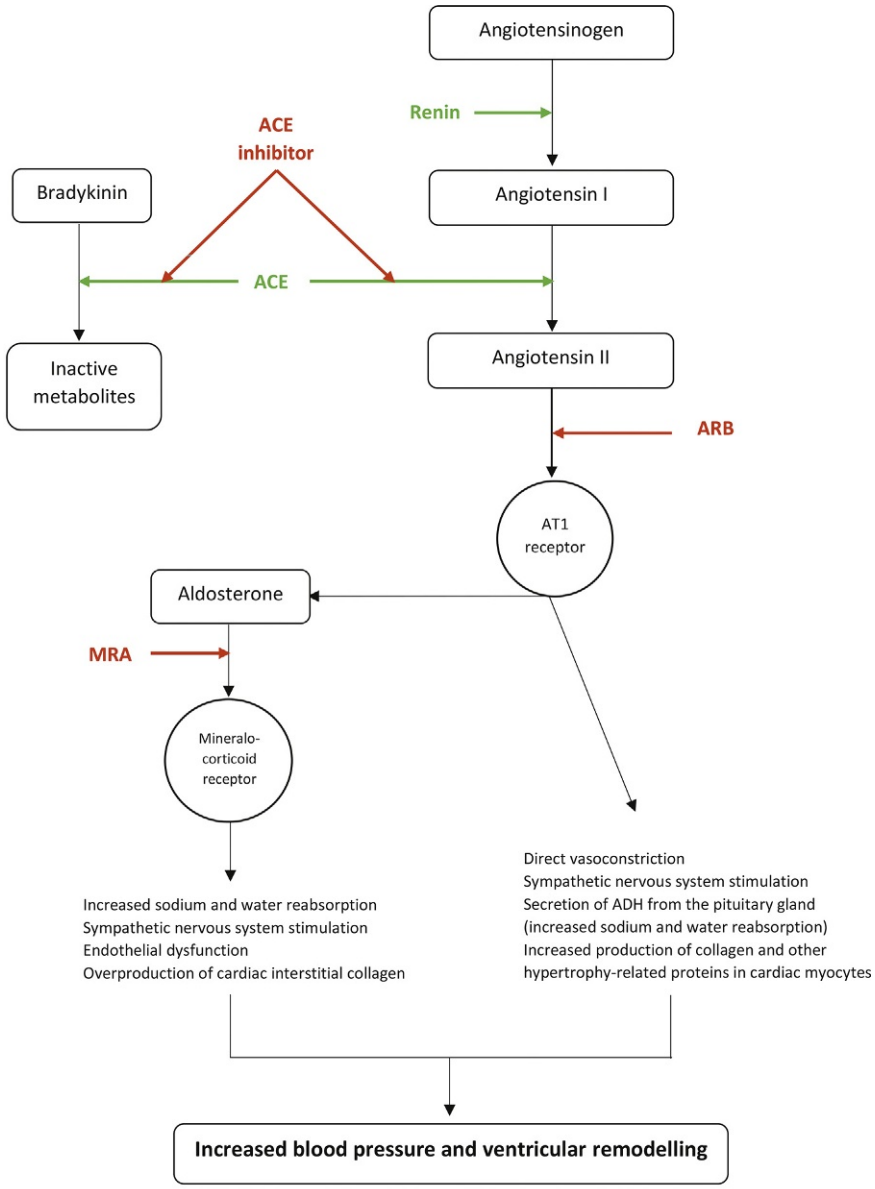
- Systemic absorption can occur following ocular administration of beta blockers and should be borne in mind when considering adverse effects and interactions
- Inform patients about the risks of abrupt cessation of treatment and encourage them to report unacceptable side effects so therapy can be reviewed
- Dose should be started low and uptitrated to a target or maximum tolerated dose. This will be dictated by blood pressure, heart rate, and side effects

Drugs Acting on the RAAS

The RAAS regulates blood pressure and extra cellular volume. Renin is released from the juxtaglomerular apparatus when baroreceptors detect low volume passing through kidneys. This enzyme catalyzes the conversion of circulating angiotensinogen to angiotensin I. When angiotensin I passes through the pulmonary circulation, angiotensin-converting enzyme (ACE) catalyzes proteolysis of angiotensin I to form angiotensin II (Brown and Vaughan, 1998). ACE is a nonspecific enzyme and inactivates a number of other small peptides including bradykinin, a potent vasodilator (Wang et al., 2011). The mechanisms of action of drugs acting on the RAAS are summarized in **Fig. 13** and explained in detail later.

The collective effects of angiotensin II, which are exerted primarily through interaction with angiotensin II type 1 (AT1) receptors distributed in various tissues, lead to increased blood pressure. The effects of angiotensin II, both directly and as a result of aldosterone secretion, are summarized in **Table 4**.

Blocking the effects of angiotensin II has the greatest impact on blood pressure when the RAAS is highly activated; therefore may not be as effective if renin is low, for example, in elderly or Afro-Caribbean patients. Angiotensin II is also implicated in structural changes in the heart through various mechanisms (De Mello and Danser, 2000). Blocking the action of angiotensin II can therefore reduce ventricular remodeling, particularly following acute MI, through the following actions:



ACE = angiotensin converting enzyme; AT1 = angiotensin II type 1; MRA = mineralocorticoid receptor antagonist

Fig. 13 Sites of action of drugs acting on the renin–angiotensin–aldosterone system (RAAS).

Table 4 Summary of the effects of angiotensin II

AT1 receptor location	*Effect of angiotensin II*	*Effect of blocking angiotensin II*
Vascular endothelium	Vasoconstriction (direct effect)	Vasodilation and reduced blood pressure without reflex tachycardia
Sympathetic nervous system	Catecholamine-mediated vasoconstriction (indirect effect)	Reduced norepinephrine, epinephrine, and vasopressin leading to vasodilation
Adrenal gland	Secretion of aldosterone, which acts on mineralocorticoid receptors in the collecting duct of the kidney, causing reabsorption of sodium and water to increase	Increased sodium and water excretion by the kidney, corresponding to decreased blood volume and pressure
Posterior pituitary gland	Release of anti diuretic hormone (ADH), which causes insertion of aquaporins in the collecting duct to further enhance the reabsorption of water by the kidney	Reduced aquaporins in the collecting duct, allowing more sodium and water to be excreted by the kidney, corresponding to decreased blood volume and pressure

Pharmacological action	Mechanism of action	Adverse effects
• Reduction of myocardial oxygen demand by lowering blood pressure • Reduction of left ventricular remodelling	• Competitive inhibition of ACE at the active site to prevent the conversion of angiotensin I to angiotensin II • Vasodilation • Reduced aldosterone, leading to increased sodium and water retention	• Hypotension and dizziness • Profound first dose hypotension • Renal impairment • Hyperkalaemia • Cough (due to increased bradykinin) • Angioedema

Fig. 14 Summary of the pharmacological action, mechanism of action, and adverse effects of angiotensin-converting enzyme (ACE) inhibitors.

- Decreased sympathetic drive reduces the action of norepinephrine at alpha receptors in cardiac myocytes, preventing the expression of genes involved in cardiac myocyte hypertrophy (St. John Sutton and Sharpe, 2000).
- Decreased preload reduces cardiac myocyte membrane stretch and the associated local release of angiotensin II and expression of genes coding for hypertrophy (Morrone and Marzilli, 2010).
- Blocking of AT1-receptor-mediated synthesis of collagen and hypertrophy related proteins in cardiac myocytes (Morrone and Marzilli, 2010).
- Decreased secretion of aldosterone reduces mineralocorticoid-receptor-mediated myocardial fibrosis and collagen synthesis (St. John Sutton and Sharpe, 2000).

ACE inhibitors

Fig. 14 summarizes the pharmacological action, mechanism of action, and adverse effects of ACE inhibitors.

Mechanism of action

ACE inhibitors competitively inhibit ACE by binding to its active site. ACE is found in the circulation; however inhibition of tissue ACE is thought to be more important. ACE is expressed predominantly the lungs, but also the vascular endothelium, kidneys, brain, heart, and adrenal gland.

In the short term, ACE inhibitors reduce levels of angiotensin II and aldosterone, but do not inhibit the effect of angiotensin II produced by ACE-independent dependent pathways. However, with long-term treatment, angiotensin II and aldosterone return to "pretreatment" levels. This indicates that while acute changes in blood pressure are attributed to inhibition of angiotensin II-mediated vasoconstriction and aldosterone and ADH-mediated sodium and water retention, the long-term therapeutic benefits of ACE inhibitors may be more in keeping with increased production of vasodilatory prostaglandins and NO (Hoyer et al., 1993). ACE inhibitors may also improve endothelial function and slow progression of atherosclerosis by increasing bradykinin-induced NO (Lonn et al., 1994).

Pharmacokinetics

Absorption following oral administration is highly variable between different ACE inhibitors. Maximum plasma concentrations are reached within 1–4 h; however, food can affect the rate, but not extent, of absorption (Wang et al., 2011). Captopril and lisinopril are administered in their active form, while all other ACE inhibitors are formulated as prodrugs to increase their lipophilicity and

oral bioavailability (Brown and Vaughan, 1998). They are converted to active drug in the liver and GI tract (Wang et al., 2011). Half-lives vary between 10 and 24 h, allowing for once or twice daily administration. The primary route of elimination for the majority of ACE inhibitors is renal excretion. Trandolapril and fosinapril undergo a combination of hepatic metabolism and renal excretion (Ujhelyi et al., 1989). Accumulation can therefore occur in renal impairment and in other conditions associated with reduced renal perfusion, such as heart failure. Dose adjustment may be necessary.

Adverse effects

ACE inhibitors generally cause unwanted effects as a class, related to their mechanism of action, and include dizziness, fatigue, headache, and nausea (Joint Formulary Committee, 2016).

Profound first-dose hypotension can occur, particularly in patients who are salt-depleted due to co-administration with diuretics (Wang et al., 2011). Caution is required in patients with aortic stenosis and left ventricular outflow obstruction (Joint Formulary Committee, 2016), as severe hypotension can occur if cardiac output cannot increase to counteract the vasodilatory effects.

A persistent dry cough occurs in up to approximately 20% of patients treated with ACE inhibitors (Ravid et al., 1994). The mechanism is unclear; however it may be due to an increase in pulmonary bradykinin or substance P. It can develop as early as 1 week after initiation or can be delayed by months; however, symptoms resolve on cessation of therapy (Wang et al., 2011).

Hyperkalemia, due to decreased aldosterone-mediated regulation of potassium, can be a problem in patients with renal impairment or heart failure, the elderly and those receiving other medicines which increase potassium. ACE inhibitor therapy should be stopped if potassium rises above 6 mmol/L (Wang et al., 2011).

ACE inhibitors can protect the kidneys; however, in patients with reduced renal perfusion, glomerular filtration is reduced, leading to increased creatinine and acute kidney injury. The risk is highest in patients with heart failure, renal artery stenosis, those treated with diuretics, and the elderly. ACE inhibitors should be avoided in patients with bilateral renal artery stenosis or stenosis of the renal artery supplying a single functioning kidney (Joint Formulary Committee, 2016).

ACE inhibitors can rarely cause potentially life-threatening angioedema, which may be related to accumulation of bradykinin. The risk is highest in black American and African Caribbean patients (Gibbs et al., 1999). It usually occurs within hours to weeks of initiating treatment; however delayed presentation has also been observed. It can affect the GI tract, brain, tongue, and larynx. Immediate cessation of ACE inhibitor is necessary and treatment with adrenaline is warranted if there is potential for airway obstruction. ACE inhibitor should not be restarted (Joint Formulary Committee, 2016).

Side effects not attributed to ACE inhibition include taste disturbances, rash, and neutropenia (Brown and Vaughan, 1998).

Angiotensin II receptor blockers

Fig. 15 summarizes the pharmacological action, mechanism of action, and adverse effects of angiotensin II receptor blockers (ARBs).

Mechanism of action

ARBs, including candesartan, irbesartan, losartan, telmisartan, and valsartan, antagonize the effects of angiotensin II at the AT1 receptor. ARBs bind the AT1 receptor competitively and dissociate slowly (Burnier, 2001). Unlike ACE inhibitors, ARBs inhibit the action of angiotensin II produced by all pathways; however the clinical significance of ACE-independent production of angiotensin II is unclear. Despite differences in pharmacology, the clinical effects of ACE inhibitors and ARBs are similar.

Pharmacokinetics

Pharmacokinetic differences between ARBs are linked to differences in their chemical structure (Israili, 2000). Oral bioavailability is variable according to lipophilicity. Valsartan is the only ARB for which absorption is limited by administration with food. Time to peak plasma concentration varies between 0.5 and 4 h and half-life ranges from 6 to 24 h. All ARBs exhibit a high degree of plasma protein binding (>95%) (Barreras and Gurk-Turner, 2003). ARBs are excreted as unchanged drug and metabolites in the urine and via bile in the feces to varying degrees (Burnier, 2001).

Adverse effects

ARBs have a similar side effect profile to ACE inhibitors. Unlike ACE inhibitors, ARBs do not inhibit the degradation of bradykinin and are therefore much less likely to cause cough (Lacourcière et al., 1994). Angioedema, which may also be linked to elevated

Pharmacological action	Mechanism of action	Adverse effects
• Reduction of myocardial oxygen demand by lowering blood pressure • Reduction of left ventricular remodelling	• Antagonism of angiotensin II at the angiotensin-II-type 1 (AT1) receptor • Vasodilation • Reduced aldosterone, leading to increased sodium and water retention	• Hypotension and dizziness • Profound first dose hypotension • Renal impairment • Hyperkalaemia • Angioedema (less frequently than with ACE inhibitors)

Fig. 15 Summary of the pharmacological action, mechanism of action, and adverse effects of angiotensin II receptor blockers (ARBs).

bradykinin, occurs less frequently with ARBs; however, some cases have been reported (van Rijnsoever et al., 1998). ARBs may be an option for patients with a pressing indication for therapy who are unable to take ACE inhibitors due to angioedema; however, extreme caution is necessary as cross-reactivity may occur (Beavers et al., 2011).

Drug interactions

Many interactions of ACE inhibitors and ARBs relate to additive risk of hypotension, hyperkalemia, or renal impairment when used alongside other medications that share these actions. Combining ACE inhibitors with ARBs increases risk of hypotension, hyperkalemia, renal impairment, and angioedema. Careful monitoring is required when ACE inhibitors or ARBs are combined with mineralocorticoid receptor antagonists, potassium sparing diuretics, antihypertensives and ciclosporin. Plasma concentration of lithium and digoxin can be increased in the presence of ACE inhibitors and ARBs; concurrent use warrants therapeutic close monitoring. NSAIDs may counter vasodilatory effects.

Practical points

- Dose should be started low and uptitrated to a target or maximum tolerated dose. This will be dictated by blood pressure, renal function, and serum potassium.
- Administering ACE inhibitors and ARBs in two divided doses may increase tolerability.
- Symptomatic hypotension, particularly profound first-dose hypotension, may be overcome by administering ACE inhibitors or ARBs at night.

Mineralocorticoid receptor antagonists

This class includes both spironolactone and eplerenone. However, currently it is only eplerenone which is licensed for use post MI in patients with reduced left ventricular ejection fraction and hence the focus on eplerenone. **Fig. 16** summarizes the pharmacological action, mechanism of action, and adverse effects of eplerenone.

Mechanism of action

Eplerenone is a competitive antagonist of aldosterone, which selectively binds to the mineralocorticoid receptor over other steroid receptors (Brown, 2003). This prevents the binding of aldosterone and subsequent gene expression. It is used following acute MI only in those patients who experience heart failure symptoms with a left ventricular ejection fraction of less than 40% (Joint Formulary Committee, 2016). Its effects on plasma volume through reduction of sodium and water reabsorption may contribute to its therapeutic benefit; however, it is likely that other mechanisms are more important for its cardioprotective effects (Pitt et al., 2003). Aldosterone, both in the heart and plasma, is increased following acute MI and contributes to ventricular remodeling by stimulating the sympathetic nervous system, endothelial dysfunction, and overproduction cardiac interstitial collagen. Eplerenone reduces these effects, to attenuate ventricular remodeling and improve left ventricular systolic function (Fraccarollo et al., 2003).

Pharmacokinetics

Eplerenone peaks in the plasma 1.5 h after oral administration. It is converted to inactive metabolites, primarily by CYP3A4 and has a half-life of 4–6 h (Brown, 2003).

Adverse effects

Eplerenone may cause headache, drowsiness, GI disturbances, and diarrhea (Joint Formulary Committee, 2016). Hypercholesterolemia and raised liver transaminases have also been reported (Brown, 2003).

Eplerenone decreases excretion of potassium, which can lead to hyperkalemia. The incidence and severity of hyperkalemia is increased in patients with renal impairment, diabetes, and those taking other medication which increase serum potassium. Eplerenone should be avoided in patients with severe renal impairment. Smaller starting doses should be used and potassium monitored closely for those with moderate renal impairment (Pfizer, 2016b).

Due to its selectivity for mineralocorticoid receptors, eplerenone has a lower incidence of hormone-related side effects, such as gynecomastia and mastodynia in men and vaginal bleeding in women, compared to other aldosterone antagonists such as spironolactone (Brown, 2003).

Pharmacological action	Mechanism of action	Adverse effects
• Lowering of blood pressure by reducing sodium and water retention • Prevention of left ventricular remodelling by reducing collagen overproduction and endothelial dysfunction	• Competitive antagonism of aldosterone • Selective for the mineralocorticoid receptor	• Headache • GI disturbance and diarrhoea • Renal impairment • Hyperkalaemia • Gynaecomastia, mastodynia and vaginal bleeding (less frequently than spironolactone)

Fig. 16 Summary of the pharmacological action, mechanism of action, and adverse effects of eplerenone.

Drug interactions

Administration of eplerenone alongside ACE inhibitors, ARBs, potassium sparing diuretics, and trimethoprim can increase the risk of hyperkalemia. Renal function and potassium should be monitored. Similarly, tacrolimus and ciclosporin can adversely affect renal function which, in the presence of eplerenone, further increases the risk of hyperkalemia. Concomitant use should be avoided. NSAIDs should be used with caution due to their potential to cause renal impairment (Joint Formulary Committee, 2016).

Potent inhibitors of CYP3A4 can greatly increase the plasma concentration of eplerenone, thus increasing the risk of adverse effects. Concomitant administration of potent inhibitors such as clarithromycin, itraconazole, and ritonavir should be avoided. Careful monitoring and dose adjustment may be required with mild to moderate CYP3A4 inhibitors, such as erythromycin, amiodarone, diltiazem, and verapamil. Strong inducers of CYP3A4, including carbamazepine, rifampicin, phenytoin, and St John's wort, may reduce the efficacy of eplerenone (Pfizer, 2016b).

Practical points

- Indicated only post-acute MI with evidence of left ventricular failure
- Increased hypotensive effect when administered with other antihypertensives—monitor blood pressure
- ACE inhibitor, ARB, and eplerenone should not be given together as a triple combination

Physician Examination: Heritable Cardiovascular Syndromes

The savvy clinician is a detective in pursuit of keys to unlock the conundrum of a patient's current concerns and future implications. A critical avenue of that pursuit is apprehension of physical exam findings. Physical exam findings are then leveraged by clinical training to induce information on diagnoses, needed treatments, and prognosis. Included in clinical training are education about genetic syndromes, congenital associations, and congenital sequences which exemplify this methodology, allowing one or a collection of particular exam findings to trigger identification of more exam findings, relevant diagnoses, and prognosticate the future. A genetic syndrome or a genetic disorder is defined as a pattern of congenital malformations that are commonly associated together, with a known causal or underlying genetic change. In comparison, a congenital association is a set of physical examination findings occurring together more frequently than would be expected by chance, without a known genetic mutation identified (e.g., VACTERL association). A congenital sequence, finally, is a combination of physical anomalies which occur due to an instigating underlying event or anomaly with other malformations occurring as a consequence (e.g., Pierre–Robin sequence, in which underdevelopment of the mandible leads to a small mouth, posterior displacement of the tongue, cleft palate, and airway difficulties).

While congenital heart disease (CHD) is a common birth defect and is present in about 9 of every 1000 children, the majority of CHD is not associated with genetic syndromes (Blue et al., 2018). With the emergence of widespread, high-throughput gene sequencing and analysis technologies being performed in numbers allowing economics of scale, an increasing number of variations of single-gene mutations, deletions, or duplications with more subtle effect sizes are being associated with CHD, in addition to the more well-known and more penetrant Mendelian disorders. An increasing number of new mutations are being studied in relation to CHD, and broader ranges of presentation are being found for well-known genes. Furthermore, previously well-described, often dismal associations of chromosomal aneuploidy with CHD are also evolving due to clinical courage to treat these children robustly, leading to new, modified natural histories in terms of postoperative care complications, long-term survival, recurrence risk, and care needs (Postma et al., 2015).

What follows is discussion on a selection of genetic syndromes associated with CHD sorted by type of genetic alteration, with specific exposition of dysmorphology, cardiac and noncardiac phenotype, and their genetic testing. In addition, at the end of the chapter, we briefly discuss the arrhythmia-prone long-QT syndromes.

Syndromes With Abnormal Chromosome Number

Down Syndrome

Down syndrome (DS) (Fig. 1) is the most common genetic syndrome associated with CHD, found in about 1 in 1200 live births, and roughly 50% of DS patients will have CHD (Presson et al., 2013; Kazemi et al., 2016). The variety of CHD in these patients is dominated by the atrioventricular septal defects (AVSD), comprising about 60% of CHD in DS patients. The remainder is constituted by secundum atrial septal defects (ASD), ventricular septal defects (VSD), and tetralogy of Fallot (ToF) (Goldmuntz et al., 2016).

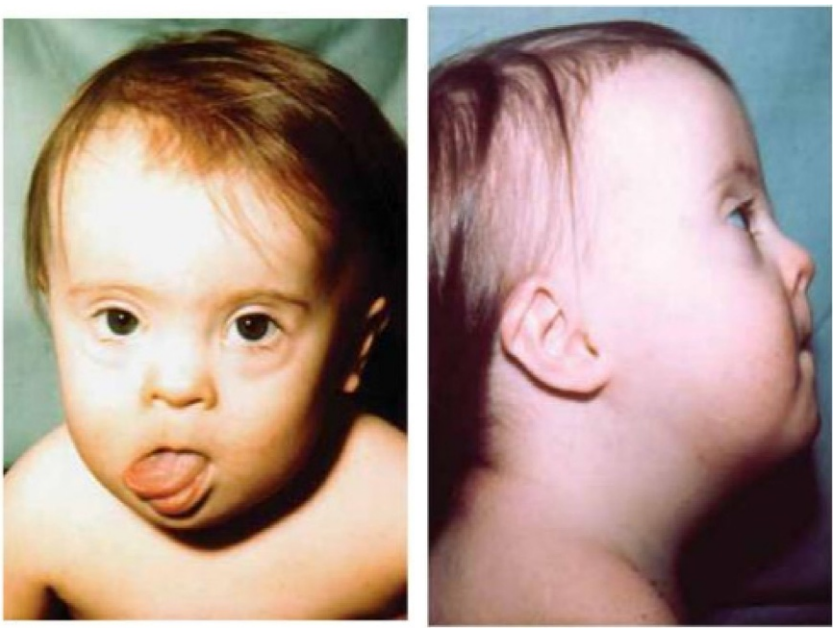

Fig. 1 Down syndrome. Young infant. Flat facies, straight hair, protrusion of tongue. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

Physical exam

In the current era, a majority of DS is diagnosed in the newborn and infant stage, with generalized hypotonia (low muscle tone), protruding tongue, epicanthal fold (skin fold over the eye), transverse palmar crease, shortened and curved fingers due to abnormal development of interphalangeal joints (clinodactyly), and a gap between the first and second toes. As children, they may have difficulty feeding due to poor tone, in addition to possible congestive heart failure (CHF) symptoms. Children with DS with CHD have a 5 times higher risk of dying in the first year of life, but 20-year survival rate is 82% (Presson et al., 2013). Recent reports indicate that the median survival is age 49 years (Presson et al., 2013).

Given the high awareness about the condition, the diagnosis of DS may be made at birth. As per the American Academy of Pediatrics' recommendation for health supervision, all infants diagnosed with DS should undergo an echocardiogram to diagnose CHD (Bull, 2011). The typical CHD lesions (AVSD, VSD) in DS present with features of CHF and pulmonary overcirculation around 2–4 months of age (Goldmuntz et al., 2016). The pulmonary vascular resistance which is high at birth gradually drops which allows the shunting left to right across the lesion to increase, which returns back to the heart and cycle begins again. This progressive cycle overtime leads to much of the heart's work and the baby's energy intake going to the inefficient circular flow from the left heart, across the lesion to the right heart, to the lungs, and back to the left heart. If the CHD goes undiagnosed, these children may continue to overcirculate and then develop pulmonary hypertensive vascular changes. This is accompanied by a seeming improvement in the clinical picture, with lesser overcirculation and better weight gain. However this actually marks a closing window for opportunity for surgical intervention, as the lesions may become inoperable if the pulmonary vascular changes become irreversible (Goldmuntz et al., 2016). After CHD surgery, they have equivalent survival as compared to nontrisomy 21 patients (Goldmuntz et al., 2016; Fudge et al., 2010). While the overall surgical mortality for AVSDs in particular in the current surgical era is less than 3%, the need for reintervention due to atrioventricular valve regurgitation or stenosis remains about 10%–15% at the 5-year postoperative mark (Hoohenkerk et al., 2010; Pontailler et al., 2014).

Children with DS also have a higher risk for development of pulmonary hypertension, with or without preceding pulmonary overcirculation. Autopsy studies and molecular pathology in mouse models has suggested that this may be attributed to the overexpression of antiangiogenic factors from chromosome 21 (Galambos et al., 2016; Bush et al., 2017). This leads to disruption of normal development of alveoli, alveolar simplification, persistence of double capillary networks, and development of intrapulmonary bronchopulmonary anastomoses, leading to pulmonary hypertensive vascular changes (Bush et al., 2017). Several mouse models of trisomy 21 have been developed and studied, with the Ts65Dn being the most popular. It has replicated analogous neurological features of DS, but not the cardiac anatomic lesions (Gupta et al., 2016).

Genetic testing

The most common underlying genetic change is a complete trisomy of the chromosome 21, which are most commonly de novo changes during meiosis during egg or sperm formation (Kazemi et al., 2016). About 90% of these are inherited through the egg, while the remainder are through the sperm. Overall, about 6% of the cases have a partial trisomy due to mosaicism. These may be de

novo, or occur in the parents. The parents are typically unaffected, with a translocation of chromosome 21 material onto another chromosome (Kazemi et al., 2016). During meiosis, this may lead to triple copies of chromosome 21 material, which may also be inherited further. Karyotype can confirm the diagnosis of trisomy 21. While more high-definition testing like chromosomal microarray and sequencing will also make the diagnosis, they are unnecessary unless additional syndromes or defects are suspected.

Turner Syndrome

Turner syndrome (TS) (**Fig. 2**) is present in 1 of 2500 live-born females. About half of the patients with TS have CHD, most commonly left-sided lesions including bicuspid aortic valve (BAV), aortic stenosis (AS), coarctation of the aorta (CoA), or hypoplastic left heart syndrome (HLHS) (Levitsky et al., 2015; Cramer et al., 2014). About 10% of TS patients have CoA. The classic phenotype of a vascular malformation leading to the webbing of the neck and lymphedema is also associated with the findings of left-sided obstructive lesions (Levitsky et al., 2015). This co-occurrence has spurred the hypothesis that the vascular malformations causing the lymphedema may also cause the cardiac lesions. Further, about half of the adults with TS have hypertension (HTN). The risk of aortic dissection in TS is six times that of the general population, and occurs at relatively lesser degrees of aortic dilation (Carlson et al., 2012). These have further prompted the suspicion for an underlying vasculopathic process underpinning these manifestations (Loscalzo et al., 2005).

Physical exam

Fetuses with TS may have lymphedema, hydrops, or lymphatic malformations in the neck. On birth, these newborns may demonstrate neck webbing, low hairline, and puffy extremities (Levitsky et al., 2015). As a child and young adult, they may present with hypertension (about 25% of adolescents), short stature, or infertility, or have a wide carrying angle (cubitus valgus at the elbow) and a broad chest with wide-set nipples on exam. The short stature is thought to be due to decreased sensitivity to growth

Fig. 2 Turner syndrome. Note prominent ears, loose folds of skin in posterior neck with low hairline, broad chest with widely spaced nipples. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

hormone and is responsive to growth hormone administration (Hjerrild et al., 2008). Another common feature is premature ovarian failure, with an accelerated destruction of germ cells starting at 15–18 weeks of gestation. Follicle-stimulating hormone and luteinizing hormone concentrations approach menopausal levels by the end of adolescence. While about 30% of the girls with TS will have some signs of puberty, only about 2%–3% will have spontaneous sustained menstrual cycles (Hjerrild et al., 2008). The deficiency of sex hormones also has a deleterious impact on bone mass, with lower bone mineral density and greater fracture risk. Initiation of sex hormone replacement therapy allows pubertal development at appropriate time, as well as better maintenance of bone health (Hjerrild et al., 2008). TS patients also have neurodevelopmental abnormalities, with average to below-average intelligence and preserved verbal domain skills. However there is impairment of executive functioning and processing, including visual-motor and arithmetic skills (Hong and Reiss, 2014).

Genetic testing

The most common genotype for TS is monosomy of the X chromosome, followed by 46 XY/45 XO mosaicism which is phenotypically less severe (Levitsky et al., 2015; Hjerrild et al., 2008). These aneuploidies are detected by karyotype analysis. Girls with the typical physical exam findings, infertility, primary amenorrhea, or pathologically short stature should undergo karyotype testing for TS (Levitsky et al., 2015; Hjerrild et al., 2008).

Trisomy 18 and 13

Trisomy 18 (Edwards syndrome) (**Figs. 3** and **4**) and Trisomy 13 (Patau syndrome) (**Figs. 5** and **6**) are present in 1 in 6700 and 1 in 12,300 live births, respectively (Bruns, 2011; Macias and Riley, 2016). About 80% of children with trisomy 13% and 90% of the patients with trisomy 18 have associated CHD (Macias and Riley, 2016). The most common lesions in trisomy 13 include double outlet right ventricle (DORV), VSDs and ASDs. The most common lesions in trisomy 18 patients include polyvalvar dysplasia (stenosis or regurgitation), VSDs and ASDs (Bruns, 2011).

There has been a recent shift in the approach to these patients, to enhance quality of life with palliative cardiac surgery in order to obtain stable enough physiology to facilitate the parents taking the baby home (Meyer et al., 2016; Maeda et al., 2011; Janvier et al., 2016). While the greatest mortality for these disorders is in the first week of life, population-based studies have shown an improvement in 1- and 5-year survival in these disorders. Reported 1-year survival from a population cohort from 1999 to 2007 is 11% for trisomy 13% and 13% for trisomy 18, with a 5-year survival of about 10% for trisomy 13 and about 12% for trisomy 18 (Meyer et al., 2016). These numbers are higher than the 1-year survival rate of about 5% reported from a cohort from 1968 to 1999 (Rasmussen et al., 2003). Only in cases of a major CHD like truncus arteriosus, transposition of the great arteries (TGA), ToF, CoA, aortic stenosis, AVSD, or HLHS has CHD been shown to be associated with mortality (Maeda et al., 2011; Janvier et al., 2016).

Fig. 5 Newborn child with trisomy 13 syndrome. Note sloping forehead with variable defect in facial development. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

Physical exam

Trisomy 18 patients have increased extensor muscle tone, with scissoring of the legs and overlapping fingers of the hand, in addition to rocker-bottom feet, small mouth (micrognathia), microcephaly, and renal anomalies (Roberts et al., 2016). Patients with trisomy 13 demonstrate polydactyly, cleft lip/palate, cutis aplasia of the scalp, small eyes (microphthalmia), and holoprosencephaly (cerebral hemisphere division failure) (Rasmussen et al., 2003).

Fig. 6 Aplasia cutis congenital over posterior occiput. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

Genetic testing

Diagnosis of trisomy 13 or 18 can be made on karyotype testing. Any child with polyvalvar disease or multiple valves with dysplasia or thickening should be assessed for these underlying genetic trisomies (Maeda et al., 2011; Janvier et al., 2016).

Deletion Syndromes

22q11 Deletion Syndrome

DiGeorge syndrome, velocardiofacial syndrome, conotruncal anomaly (Takao) syndrome, and isolated outflow tract defects of the heart are different names for what we now understand to be a family of syndromes associated with a microdeletion on the long arm of chromosome 22, the 22q11.2 deletion (**Fig. 7**). This occurs in 1 in about 4000–6000 live births and is associated with CHD in about 75%–80% of the patients (Perez and Sullivan, 2002; Hacıhamdioğlu et al., 2015). The CHD spectrum is quite distinct, including interrupted aortic arch, ToF, truncus arteriosus, and perimembranous VSD with aortic arch anomalies. Children diagnosed with these specific CHD lesions are screened for 22q11.2 deletion due to the strength of the association. The deleted region encapsulates >35 genes; however TBX-1 is the most studied gene in this region (Perez and Sullivan, 2002; Hacıhamdioğlu et al., 2015). It is expressed in the pharyngeal arches, is an important transcription factor for development of the second heart field during cardiac embryogenesis, and is needed for the migration of the cardiac neural crest cells in cardiac outflow tract development and other locations. Hence, a mutation in TBX-1 causes defective development in multiple locations, leading to the cardiac, thymic, and parathyroid deficiencies, as well as the facial anomalies and possibly the feeding difficulties found in these patients (Perez and Sullivan, 2002; Hacıhamdioğlu et al., 2015). As repairs for the associated CHD have improved, longer survival has uncovered myriad manifestations of the syndrome. Children with 22q11.2 deletion often have feeding difficulties, and developmental delay, along with behavioral problems like impulsivity and overactivity (Norkett et al., 2017). Nearly one-third are diagnosed with attention deficit hyperactivity disorders, and autism spectrum disorders or general social impairment in about 20%–30% of the cases. They may also go on to be diagnosed with anxiety and mood disorder and may have progressive decline in cognitive abilities (Roberts et al., 2016). About 20%–30% of the adults with 22q11.2 deletion are unfortunately diagnosed with frank schizophrenia or other psychotic illnesses (Norkett et al., 2017).

Physical exam

In the age of prenatal CHD diagnosis, 22q11.2 deletion syndromes are often detected in during infancy. Physical examination features suggestive of this syndrome are—small mouth (micrognathia), flat cheek bones (malar flattening), small nostrils

Fig. 7 Photograph of 12-year-old boy. Facial features emphasizing the nasal configuration. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

(hypoplastic alae nasi), cleft lip/palate, hypocalcemia, immunodeficiency, airway anomalies due to vascular rings, renal anomalies, developmental delay, and behavioral disorders (Perez and Sullivan, 2002). A memory aid for these syndromes is CATCH-22—CHD, abnormal facies, hypoplasia of the thymus (immunodeficiency), cleft palate, and calcium (hypocalcemia—due to hypoparathyroidism). The presence of an aortic arch anomaly increases the chance of 22.q11 deletion, regardless of the underlying CHD.

Genetic testing

Diagnosis of 22q11.2 deletion can be made on fluorescent in situ hybridization (FISH) testing (Perez and Sullivan, 2002; Hacıhamdioğlu et al., 2015). It may also be made by multiplex ligation-dependent probe amplification (MLPA) or chromosomal microarray analysis, the latter of which will also be beneficial in detecting CHARGE (Coloboma, Heart defects, choanal Atresia, Growth retardation, and Genital anomalies and Ear abnormalities) syndrome, since many of the physical exam findings may overlap with 22q11 deletion syndromes.

Williams–Beuren Syndrome (Williams Syndrome)

Williams syndrome (WBS) (**Figs. 8** and 9) is a multisystem genetic cardiovascular disorder occurring in about 1 in 10,000–20,000 live births (Collins, 2013). It is characterized by typical facial features, hypercalcemia, CHD, and a diffuse arteriopathy with stenotic lesions and fibrosis. Most of these children have developmental delay and cognitive weakness, and a characteristic social personality (cocktail party personality). The elastin (ELN) gene has been mapped to the region which experiences a mutation in WBS. This may explain the vascular findings of the condition discussed below (Merla et al., 2012).

Physical exam

WBS facies are characterized as elfin, with a broad forehead, star-shaped irides, flattened nasal bridge with rounded tip of nose, wide mouth and full lips (Collins, 2013). About half the patients have hypercalcemia, which is noted in infancy and thereafter usually is asymptomatic. CHD is present in about 80% of the patients, with about 75% having supravalvar aortic stenosis, 40%–50% having pulmonary artery stenosis, and about 5% having coronary artery stenotic lesions (Merla et al., 2012; Zalzstein et al., 1991). The pulmonary artery lesions typically involve the branch pulmonary arteries or the more distal branches. While the aortic lesions may remain stable or worsen over time, the pulmonary lesions tend to either remain stable or improve as the child grows older (Zalzstein et al., 1991). However in cases where the pulmonic stenosis do not improve, the stenoses tend to be deep into the lung and diffuse, making them difficult to remediate by surgery or cath. A special concern exists with sedation since coronary artery stenoses can be silent until pharmacologically induced changes in arterial pressure may become insufficient to overcome these coronary stenoses and cause sudden death (Bird et al., 2004). A varied range of patients are also being reported to have stenosis of the thoracic aorta, and the elastin deficiency is the putative mechanism of these systemic vasculopathic features (Bird et al., 2004).

Genetic testing

Williams syndrome can be attributed to 7q11.23 deletion in about 90% of the patients (Morris, 1999). This can be detected on FISH or MLPA testing or chromosomal microarray analysis.

C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

Jacobsen Syndrome

Jacobsen syndrome is a syndrome caused by a deletion on chromosome 11, found in about 1 in 100,000 live births. It is characterized by developmental and behavioral problems, distinctive facial features, coagulopathy, heart defects, and immunodeficiency (Tassano et al., 2016; Dalm et al., 2015).

Physical exam

The typical facies of Jacobsen syndrome include low-set ears, hypertelorism (wide-spaced eyes), ptosis (drooping eyelids), epicanthal folds, broad nasal bridge, downturned corners of the mouth, and a thin upper lip, in the setting of macrocephaly (Tassano et al., 2016; Dalm et al., 2015). Over 90% of the patients have a bleeding disorder called Paris–Trousseau syndrome which affects the alpha-granules in the platelets. This manifests as easy bruising and abnormal bleeding. CHD is present in just over 50% of the patients (Goldmuntz et al., 2016). The cardiac anomalies are predominantly VSDs, followed by left-sided obstructive lesions like mitral or aortic stenosis, Shone's complex and variants, and hypoplastic left heart syndrome (Goldmuntz et al., 2016; Tassano et al., 2016).

Genetic testing

Jacobsen syndrome is caused by deletion of the terminal material of the long arm of chromosome 11 (Tassano et al., 2016; Dalm et al., 2015). This deletion is large enough to be assessed on karyotyping or readily by FISH testing. The mutation is de novo in about 85% of the cases.

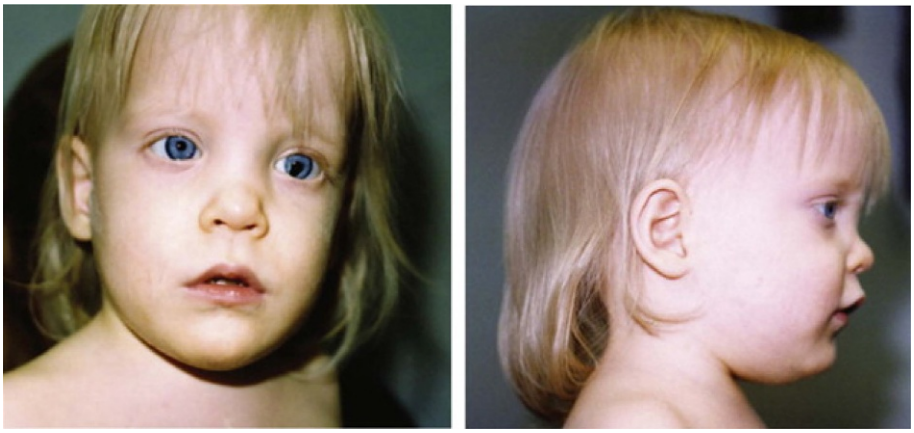

Fig. 10 Cat-eye syndrome. Infant showing coloboma of iris and ocular hypertelorism. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

The cat-eye syndrome (**Fig. 10**) is reported in about 1 in 150,000 live births and is named for its association with vertical colobomas, insensitively called "cat-eye." (Rosias et al., 2001)

Cat Eye Syndrome

Physical exam

The classic triad of this syndrome includes iris colobomas, ear anomalies, and anal malformations (Rosias et al., 2001). Other eye anomalies include hypertelorism and down slanting palpebral fissures, and the facies may also demonstrate ear anomalies and a broad nasal bridge. Cardiac anomalies present in this syndrome include total anomalous pulmonary venous return, ToF, and VSD (Rosias et al., 2001; Timoney and MacNicholas, 2014). Anorectal malformations and genitourinary defects may also be present.

Genetic testing

This syndrome is caused by the partial tetrasomy of chromosome 22, which can be tested for by karyotyping. Confirmatory testing may also be performed by FISH or chromosomal analysis (Rosias et al., 2001; Timoney and MacNicholas, 2014).

Single Gene Deletion Syndromes

Noonan Syndrome

Noonan syndrome (NS) (**Figs. 11** and **12**) is an autosomal dominant condition with characteristics facies and habitus, cardiac disease, and developmental delay. NS occurs in 1 in about 1000–2500 live births (Tafazoli et al., 2017). About 50%–66% of patients with NS have an affected parent. NS is one of a family of disease classified as the RASopathies, conditions with mutations in the RAS-mitogen activated protein kinase (RAS-MAPK) pathway (Tafazoli et al., 2017; Tartaglia et al., 2011). This pathway helps in the communication of growth factor signals into cells, and influences cell division, differentiation and proliferation. These RASopathies include NS, neurofibromatosis type 1, NS with multiple lentigines (discussed below), Costello syndrome, and cardiofaciocutaneous syndrome, among other conditions (Tartaglia et al., 2011). This collection of disorders are seen to have physical craniofacial dysmorphisms, cardiovascular abnormalities, cutaneous findings, musculoskeletal findings, and cognitive impairment. Patients with NS who go on to later develop pigmented spots called lentigines during childhood may be diagnosed with the NS with multiple lentigines. This is a rare multisystem congenital disorder that has findings involving the skin, facial, and cardiac anomalies (Aoki et al., 2016). NS patients commonly suffer from developmental delay as well as growth retardation and short stature. There is also a greater prevalence of attention deficit hyperactivity disorder and learning delays (Tartaglia et al., 2011).

Physical exam

NS has characteristics facies with hypertelorism, micrognathia, low-set fleshy ears, and high-arched palate, a webbed neck, a broad chest with widely spaced nipples, decrease in growth velocity around puberty, and delayed development (Tafazoli et al., 2017; Tartaglia et al., 2011). Their cardiac anomalies include valvar pulmonic stenosis, hypertrophic cardiomyopathy, and electrocardiographic anomalies like right or left axis deviation. Patients with NS with lentigines can also carry the label LEOPARD syndrome: Lentigines, ECG abnormalities, Ocular hypertelorism, Pulmonic stenosis, Abnormal genitalia, Retardation of growth, and Deafness

Fig. 11 Noonan syndrome. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

Fig. 12 Affected mother and daughter. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

Genetic testing

About half of NS patients carry mutations in the PTPN11 gene (Tafazoli et al., 2017; Tartaglia et al., 2011; Aoki et al., 2016). The remainder are accounted for by six other genes—SOS1, RAF1, KRAS, NRAS, SHOC2, and CBL. PTPN11 may be tested by a targeted gene testing. Currently there is a panel that can be ordered which tests for multiple genes whose mutations can lead to a phenotype of or similar to Noonan syndrome (Tafazoli et al., 2017; Tartaglia et al., 2011; Aoki et al., 2016).

CHARGE Syndrome

CHARGE syndrome (**Fig. 13**) abbreviating Coloboma, Heart defects, choanal Atresia, Growth retardation, and Genital anomalies and Ear abnormalities is a multisystem disorder found in 1 in 8500–10,000 live births. When this constellation of findings is suspected, early involvement of the respective specialist is recommended (Lalani et al., 2012; Bergman et al., 2011).

Physical exam

Patients have a typical facies with prominent forehead, flat midface and prominent nasal bridge. Ear anomalies present in over 90% of the patients include low set anteverted cup-shaped ears, and occasionally microtia or preauricular tags (Lalani et al., 2012;

Fig. 13 CHARGE syndrome. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

Bergman et al., 2011). Absence of semicircular canals detected on head imaging is highly associated with CHARGE syndrome. Colobomas can be present in one or both eyes in about 80%–90% of the patients and are most commonly chorioretinal in location (Lalani et al., 2012). CHD is present in about 80% of the patients and are most commonly conotruncal defects (interrupted aortic arch, ToF, DORV) or AVSD, although almost any type of CHD can be found in these patients (Goldmuntz et al., 2016; Lalani et al., 2012). Choanal atresia is reported in about 65% of the patients, although over half of the patients may also have obstruction distal to the choanae and have multiple levels of obstruction. About 15%–20% of the patients may have cleft lip or palate and a similar frequency may have tracheoesophageal fistula (Lalani et al., 2012; Bergman et al., 2011). Genital anomalies include hypoplastic genitalia. Patients with CHARGE syndrome experience somatic growth restriction in late infancy, global developmental delays, and delayed puberty (Bergman et al., 2011).

Genetic testing

CHD7 mutations, most commonly deletions, account for 90%–95% of the patients with CHARGE syndrome (Lalani et al., 2012; Bergman et al., 2011). A vast majority of the mutations occur de novo and there is no family history, although the inheritance pattern thereafter is autosomal dominant (Lalani et al., 2012).

Marfan Syndrome and Loeys–Dietz Syndrome

Marfan syndrome (MFS) (**Figs. 14** and **15**) is an autosomal dominant negative condition, with manifestations involving the connective tissue of the cardiovascular system, the eyes, and the musculoskeletal system. It occurs in 1 in about 10,000–15,000 people (Groth et al., 2015; Loeys et al., 2010). It is caused by the fibrillin gene (FBN1) mutation. It is also a part of the family of conditions impacting the thoracic aorta, known as the heritable thoracic aortic diseases, and FBN1 is one of the 13 genes known to be causative (Loeys et al., 2010; Romaniello et al., 2014). In MFS, the aorta may dilate over time leading to sudden catastrophic rupture. Loeys–Dietz syndrome (LDS) is another vasculopathy with potentially catastrophic outcomes, associated with mutations in the genes for TGF-β receptors, TGFBR1 and TGFBR2. It is characterized by aneurysmal involvement of the aorta, increased vascular tortuosity, and higher risk of aortic dissection (MacCarrick et al., 2014; Van Laer et al., 2014).

Physical exam

MFS is diagnosed by the revised Ghent criteria, which include aortic root dilation, ectopia lentis, and fibrillin gene mutation as cornerstone criteria, the presence of any two of which clinches the diagnosis (**Table 1**) (Romaniello et al., 2014). The presence of any one of these along with a confirmed family history of MFS based on the revised Ghent criteria is also adequate to confirm the MFS diagnosis. Further, a physical exam to evaluate for the "wrist sign" and the "thumb sign," pectus carinatum, hindfoot deformity, decreased upper segment to lower segment ratio and increased arm to height ratio, reduced elbow extension, scoliosis or thoracolumbar kyphosis, skin striae, and facial features including a long face (dolichocephaly), posteriorly displaced eyeballs within socket (enophthalmos), downslanting palpebral fissures, malar hypoplasia and retrognathia, are a part of the systemic

Fig. 14 Marfan syndrome. Note the long slim limbs, pectus excavatum, narrow face, and reduced elbow extension. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

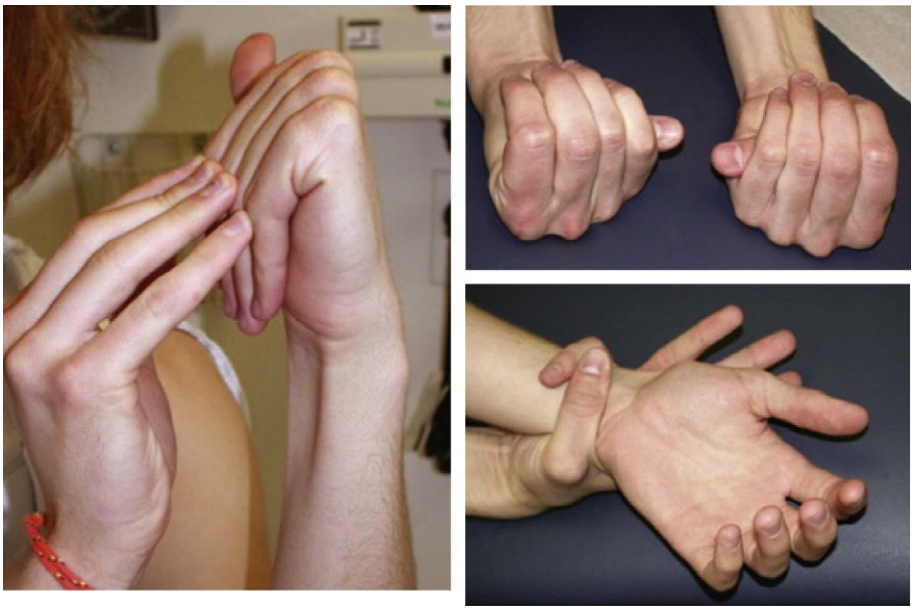

Fig. 15 Joint laxity, Steinberg thumb sign, and ability to join thumb and fifth finger around the wrist (Walker–Murdoch sign). Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

scoring system (Romaniello et al., 2014). A score equal to or greater than 7 along with any one of the 3 major criteria will also confirm the diagnosis of Marfan syndrome (Romaniello et al., 2014).

LDS may be diagnosed in patients with wide-set eyes (hypertelorism), cleft palate, craniosynostosis, and aneurysmal dilation of the aortic root, or other segments of the aorta (MacCarrick et al., 2014; Van Laer et al., 2014). They may also have other skeletal features of kyphosis or joint laxity overlapping with MFS. About 98% of the patients of LDS have aortic root aneurysms, while about 10% have abdominal aortic aneurysms. Patients with LDS are also more likely to have an atrial septal defect or patent ductus arteriosus than the general population, with these lesions found in about 20%–30% of the patients. LDS patients are at greater risk

Table 1 Diagnostic criteria of MFS according to the Ghent-2 nosology

In the absence of family history
1. Aortic root diameter (Z-score ≥2) and ectopia lentis = MFS*
2. Aortic root diameter (Z-score ≥2) and causal *FBN1* mutation = MFS
3. Aortic root diameter (Z-score ≥2) and systemic score ≥7 points = MFS*
4. Ectopia lentis and causal *FBN1* mutation with known aortic root dilatation = MFS

In the presence of family history
5. Ectopia lentis and family history of MFS (as defined above) = MFS.
6. Systemic score ≥7 points and family history of MFS (as defined above) = MFS*
7. Aortic root diameter (Z-score ≥2 above 20 years old, ≥3 below 20 years) and family history of MFS (as defined above) = MFS*

*Caveat: without discriminating features of Shprintzen–Goldberg syndrome, Loeys–Dietz syndrome or vascular form of Ehlers–Danlos syndrome AND after *TGFBR1/2*, collagen biochemistry, *COL3A1* testing if indicated.

Scoring of systemic features of MFS
1. Wrist and thumb sign—3 points (wrist or thumb sign—1 point)
2. Pectus carinatum deformity—2 points (pectus excavatum or chest asymmetry—point)
3. Hindfoot deformity—2 points (plain pes planus—1 point)
4. Protrusio acetabuli—2 points
5. Reduced upper segment/lower body segment ratio and increased arm/height and no severe scoliosis – 1 point
6. Scoliosis or thoracolumbar kyphosis—1 point
7. Reduced elbow extension—1 point
8. Facial features (3/5)—1 point (dolichocephaly, enophthalmos, downslanting palpebral fissures, malar hypoplasia, retrognathia)
9. Pneumothorax—2 points
10. Skin striae—1 point
11. Myopia .3 diopters—1 point
12. Mitral valve prolapse (all types)—1 point
13. Dural ectasia—2 points

The systemic features number 1–13 are used for the systemic score in the Ghent-2 nosology, where a maximum total score points of 20 points can be obtained. We number the systemic features as 1–8 and address these as "skeletal score," and the systemic features as 9–12 and address these as "nonskeletal score".

MFS, Marfan syndrome.

for aortic dissection and aneurysm rupture, and hence typically undergo intervention at an earlier stage of dilation (aortic root diameter >4 cm or increasing at rate >0.5 cm per year) (Williams et al., 2007).

Genetic testing

When a complete diagnosis of MFS can be made by clinical signs, genetic testing is not essential to proceed with management. Testing for FBN1 mutation can help diagnose the mutation and allow for testing of future generations that may meet subdiagnostic clinical criteria (Loeys et al., 2010; Romaniello et al., 2014). The first test recommended is the FBN1 gene sequence analysis, followed by the targeted gene deletion/duplication testing if the sequencing is negative. In patients who have distinct physical examination features raising clinical suspicion for LDS, target gene testing can be performed to confirm diagnosis (MacCarrick et al., 2014; Van Laer et al., 2014). If specific gene testing is normal and the concerning clinical finding is thoracic aortic disease, another panel exists to test for the panel of genes associated with other heritable thoracic aortic diseases.

Alagille's Syndrome

Alagille's syndrome (**Fig. 16**) is an autosomal dominant condition found in about 1 in 30,000 live births (Press, 2016). Alagille's syndrome is diagnosed by the presence of classic phenotypic features in a patient with cholestasis. Alagille's syndrome is a multisystem disorder of varying expression, with studies showing that about half of mutation-positive individuals would not meet clinical criteria (Press, 2016). Prognosis is also determined by the number, extent, and severity of organ involvement.

Physical exam

The following criteria help define Alagille's syndrome: cholestasis, ophthalmologic abnormalities (most commonly embryotoxon), characteristic facial features, skeletal abnormalities, cardiac abnormalities, and renal and vascular problems (Press, 2016; Saleh et al., 2016). The facies are characterized by a prominent forehead, hypertelorism, deep set eyes, and a pointed chin. Posterior embryotoxon of the eye, a thickened and centrally displaced anterior border of the ring of Schwalbe visible on external examination without a slit lamp, occurs in about 80%–90% patients. Cardiac involvement occurs in about 90% of the patients including right-sided obstructive lesions (Press, 2016; Saleh et al., 2016). A majority have pulmonary stenosis (about 67%–70%), with ToF being the second most common (~17%). Pulmonic stenosis in these patients can also be distal in the vascular arborization and poorly responsive to intervention (Sugiyama et al., 2004). Skeletal abnormalities seen commonly are butterfly vertebrae and clefting of vertebral bodies. Renal and vascular anomalies seen in these patients include renal artery stenosis, renal cysts, and intracranial

Fig. 16 Alagille syndrome. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

aneurysms, the latter accounting for up to a third of the mortality in one report. The widespread vascular findings, and the finding of hypertension suggest that there may be an underlying vasculopathy at play in this condition (Salem et al., 2012). Other exam findings associated with cholestasis will include pruritus and subsequent excoriations, scleral icterus, acholic stools, and xanthomas. Liver biopsy reveals a paucity of bile ducts although a biopsy is not essential for diagnosis per the current guidelines, and cholestasis with two other classic phenotypic features with suffice. If there is a first degree relative with Alagille's syndrome, then only 2 of the clinical features suffice to make a diagnosis (Press, 2016; Saleh et al., 2016).

Genetic testing

About 95% of patients Alagille's syndrome have a mutation in chromosome 20p12 in the JAG1 gene for the Notch ligand (Press, 2016; Saleh et al., 2016). The remainder of the patients have a NOTCH2 mutations in the chromosome 1p12-p11 region. Looking for the mutations on chromosomal microarray, MLPA as well as targeted gene sequencing testing for the specific deletions aids in diagnosis.

Holt–Oram Syndrome

Holt–Oram syndrome (**Fig. 17**) is an association of birth defects within the family of so-called heart hand syndromes characterized by cardiac septal defects and limb anomalies. The estimated frequency is about 1 in 100,000 live births (McDermott et al., 2004).

Physical exam

The thumb may be triphalangeal, syndactylized to the index finger or resting in the plane of the fingers. The forearm may be involved, with possible deficient or absent radius (McDermott et al., 2004; Da-guang et al., 1986). The upper limb anomalies are often bilateral. Rarely the lower limbs may be involved. ASDs and VSDs are the most common CHD lesions seen in this condition, followed by conduction defects.

Genetic testing

TBX5 is a transcription factor located at 12q24.1 (McDermott et al., 2004). Mutations in this gene resulting in a deletion are associated with Holt–Oram syndrome, although only about a third of the diagnosed cases are associated with known mutations. The condition demonstrates an autosomal dominant transmission with full penetrance.

Fig. 17 Holt–Oram syndrome. Reproduced from Jones, K. L., Jones, M. C., Del Campo, M. (2014). Moderate short stature, facial and genital. In: Jones, K. L., Jones, M. C., Del Campo, M. (eds.) Smith's recognizable patterns of human malformation (7th edn.), Philadelphia, PA: Elsevier. Permission from Elsevier.

Long-QT Syndrome

Long-QT syndrome (LQTS) occurs in about 1 in 2000 people, and is characterized by an increased risk of sudden cardiac death in an otherwise normal individual with a structurally normal heart (Nakano and Shimizu, 2016; Mizusawa et al., 2014). Some forms of LQTS may have also have associated extracardiac features:

(a) **Jervell and Lange–Nielsen syndrome (JLNS)**—JLNS is a rare multisystem disorder with LQTS, in association with profound sensorineural hearing loss. It occurs in 1 in 2–6 million people, with an exceptionally higher prevalence in the Scandinavian nations of Denmark, Sweden, and Norway, at about 1 in 200,000 (Tranebjærg et al., 2002).

Physical exam

Diagnosis of JLNS is based on presence of QTc interval >480 ms and a history of congenital deafness, and difficult to control tachyarrhythmias inspite of beta blocker therapy (Tranebjærg et al., 2002). These patients are at high risk of sudden cardiac death.

Genetic testing

It is caused by an autosomal recessive mutation in the KCNQ1 (90% cases) or the KCNE1 (10% cases) gene, causing defective outflow of potassium ions across membranes in cardiac cells (Tranebjærg et al., 2002). This defect also leads to deficient production of endolymph leading to the congenital deafness seen in this disorder. Testing for this syndrome includes targeted gene analysis (especially if known gene mutation in family), gene sequence analysis (starting with the KCNQ1 mutation), or multigene testing during LQTS evaluation.

(b) **Anderson–Tawil Syndrome (ATS)** (Statland et al., 2004)—This is a rare disorder that has been reported in about a 100 patients across the world. The chief cardiac finding is a prolonged QTc longer than 480 msec and an increased risk of ventricular tachyarrhythmias and sudden death. Bidirectional ventricular tachycardia is a classic finding, which is otherwise found in only two other situations, namely CPVT and digoxin toxicity.

Physical exam

This diagnosis is suspected in patients with two of the following three criteria: (i) dysmorphic facies, (ii) episodic paralysis, and (iii) history of ventricular tachyarhythmias or prolonged QTc. The dysmorphisms are characterized by micrognathia, hypertelorism, low-set ears, clinodactyly of the fifth digit, syndactyly of second and third toes, scoliosis, and short stature (Statland et al., 2004). The periodic paralysis may be in the setting of hypokalemia (absolute <3 mmol/L or relative drop in potassium within the normal serum range) and can be treated with potassium administration. If an individual has one of the above listed three criteria and has a family member who meets at least two of those criteria may also raise concern for this diagnosis.

Genetic testing

It is caused by a mutation in KCJN2 gene, coding for an inward rectifier potassium channel 2 protein, which leads to delayed repolarization (Statland et al., 2004). ATS is inherited in an autosomal dominant pattern, however is de novo mutation in about half the cases. Specific gene testing using sequence analysis or deletion/duplication analysis for KCJN2 will help make the diagnosis.

(c) **Timothy Syndrome**—Timothy syndrome is a rare LQTS disorder with extra cardiac anomalies in the facies, nervous system, and extremities (Napolitano et al., 2006). The chief cardiac finding is again the prolonged QTc greater than 480 msec, and life-threatening ventricular tachyarrhythmias like torsades de pointes and ventricular fibrillation, although some patients may also have structural findings like patent foramen ovale, patent ductus arteriosus, ToF, and VSDs.

Physical exam

The facies of Timothy syndrome are significant for a flattened nasal bridge, mandibular hypoplasia, thin upper lip, small teeth, and low-set ears (Napolitano et al., 2006). Neurologic and behavioral anomalies seen in this syndrome include autism spectrum disorders or pervasive developmental disorders. The hands and feet may exhibit webbed syndactyly with fusion of the skin between the fingers or toes.

Genetic testing

It is caused by a mutation in the CACNA1C gene, causing a prolonged opening of calcium channels with inward calcium flow. Testing for this syndrome includes targeted gene analysis (especially if known gene mutation in family), gene sequence analysis, or multigene testing during LQTS evaluation. It is considered to have autosomal dominant inheritance, however with its high mortality the average age of death is about 2.5years and hence most of the diagnosed patients exhibit a new mutation with no affected family members (Napolitano et al., 2006).

While, the majority of CHD is not associated with genetic syndromes, more frequent genetic testing and investigation has determined several syndromes associated with CHD (Blue et al., 2018). Well-known Mendelian disorders are being redefined and new genetic associations are being described. Many of these persons are making their way into adulthood where familiarity with these diagnoses is emerging. Whereas in times past the combination of genetic or chromosomal disorder with CHD was a contraindication to intervention, modern intervention safety has arrived at a point where these babies can be helped to a more stable physical status and enjoy time and quality of life with family at home. These new practice paradigms are not only changing the survival curves of these unfortunate persons, but uncovering previously unknown phenotypic characteristics. More investigation may lead to better care for these unlucky members of the human family.

Introduction

Master clinicians place physical examination at the heart of diagnosis, prognosis, and continuing management for good reason (Hurst et al., 2011; Park, 2014). After obtaining the available historical information, the savvy clinician observes and interrogates the patient's body for additional clues to refine the differential diagnosis, evaluate effects of therapy, and suggest events that may occur in the future. In this chapter, physical exam findings are discussed along with a few key clinical insights based on those exam findings for the interested reader. The chapter is presented within the framework order of how a clinician may usually encounter the physical exam finding in the course of real-world clinical evaluation: vital signs, observation, auscultation, and palpation.

Vital Signs

Heart Rate

Tachycardia

Heart rates above the expected normative value for age warrant additional consideration. In practice, consideration of context such as an emergency room location or presenting complaint such as a broken bone is often sufficient to allay concern. If overall clinical

 https://doi.org/10.1016/B978-0-12-809657-4.10971-8

status is compromised, tachycardia may belong to the constellation of physical findings signaling the patient is in extremis. In some cases, investigation is needed often in the form of an electrocardiogram, to distinguish between sinus tachycardia and tachyarrhythmia.

Sinus tachycardia: While some causes of sinus tachycardia can be obvious (e.g., pain, fever, anxiety), others may be more difficult to elicit (dehydration or stimulant exposure). Sinus tachycardia can be a sign of cardiac or noncardiac pathology. A key concern from tachycardia is that it is a signal of myocardial dysfunction since inadequate cardiac output induces sympathetic nervous system activation which in turn elicits sinus tachycardia as a compensatory mechanism to support flagging cardiac output. As the list of potential etiologies for myocardial dysfunction is broad (myocardial infarction, pericardial effusion, cardiomyopathy, myocarditis, etc.), the patient evaluation should be expansive. Potential clues to the underlying etiology suggestive of myocardial dysfunction are described in this chapter. Sinus tachycardia can also be seen in the setting of a pulmonary embolus. In that case, it is frequently associated with tachypnea and hypoxemia. In the absence of a primary cardiac or pulmonary etiology, other relatively serious causes of sinus tachycardia include anemia, hyperthyroidism, or less commonly pheochromocytoma.

Tachyarrhythmia: While the different types of tachyarrhythmias and their diagnosis and management are discussed in other chapters, the physical exam can provide helpful clues regarding type and severity. Hypotension or hypoxemia are concerning findings suggestive of cardiovascular compromise. As outlined below, evaluation of the heart rhythm (especially variability and regularity) as well as associated findings (e.g., cannon a waves) can help develop a differential diagnosis prior to any further work-up.

Bradycardia

A resting heart rate below the lower limits of normal is less likely to be achieved by mental state or other common transient features. Therefore, more attention needs to be paid to other physical signs and ECG in order to distinguish sinus bradycardia from intracardiac conduction abnormalities.

Sinus bradycardia: Sinus bradycardia is frequently seen in healthy athletes as a sign of efficient stroke work allowing for lower resting heart rate to deliver the same cardiac output over a given time period. The heart rate usually increases appropriately with activity (e.g., jumping jacks in the office), followed by a rapid return to baseline during recovery. On the opposite end of the spectrum, sinus bradycardia is not uncommon in the elderly population. In that setting, it may represent degenerative changes of the conduction system. This degeneration can be progressive and, if severe, may require pacemaker implantation. Sinus bradycardia can also be a sign of increased vagal tone (such as with increased intracranial pressure), a side effect of many common medications (beta blockers, digoxin, lithium, etc.) or a finding in patients with hypothyroidism. The two most important cardiac causes of sinus bradycardia are myocardial infarction and primary diseases of the sinus node (sick sinus syndrome) (John and Kumar, 2016). While the latter is rare, the former warrants close attention, and the patient should be examined for other findings suggesting myocardial ischemia (e.g., chest pain, diaphoresis, hypotension, new onset left bundle branch block).

Conduction abnormalities: The different types of heart block should be distinguishable based on a surface ECG. Their pathophysiology and management are discussed in other chapters. However, the physical exam can provide helpful clues regarding cause and severity. Cannon a waves appearing as prominent pulsations in the jugular venous pulse, for example, can be a sign of atrioventricular dissociation by virtue of dyssynchronous atrial pulsations occurring against a closed atrioventricular valve. Hypotension, changes in mental status, or crackles on pulmonary auscultation are concerning findings suggestive of cardiovascular compromise. Hepatomegaly and peripheral edema may indicate a more subacute or even chronic duration.

Blood Pressure

While normotension does not rule out heart disease, the deviations from normal deserve particular attention.

Hypertension: Elevated blood pressure is the most common cause of cardiovascular death around the world and is responsible for substantial morbidity and mortality from myocardial infarction, stroke, and congestive heart failure (Lozano et al., 2012). Hypertension is a virtually ubiquitous part of aging with 90% of Americans developing hypertension by age 80 years (Vasan et al., 2002). In addition to primary hypertension, blood pressure can rise in response to other transient or chronic illnesses as well as due to mental state or inappropriate technique. Therefore true positives, false positives, and false negatives all may transpire with varying consequences. Proper interpretation of blood pressure is predicated on proper technique and recognition of clinical scenario, such as severe pain indirectly causing high blood pressure, or other signs, such as coincident bradycardia and bradypnea signaling an intracranial process. But most importantly, recognition is the first step to proper management.

Hypotension: Hypotension can be secondary to dehydration, increased vagal tone, certain medications (e.g., beta blockers), or hypothyroidism. It can more importantly be an alarming finding in patients especially when accompanied by tachycardia, heart block, signs of myocardial dysfunction, or with mental status changes. This should prompt rapid assessment and management.

Blood pressure gradients: In healthy adults, systolic blood pressures in the lower extremities are usually slightly higher than in the upper extremities, historically attributed to peripheral pulse wave amplification, although this may not be true the entire lifecourse (Mitchell et al., 2010). In patients with coarctation, this physiologic gradient can be absent or even reversed (lower systolic blood pressures in the lower extremities, compared to the upper extremities). As a rule, this finding is always abnormal and should prompt further evaluation to rule out coarctation (Dijkema et al., 2017). Recent evidence suggests a blood pressure gradient between the arms may also signal vascular disease requiring further work-up (Clark et al., 2012).

Pulsus paradoxus: In healthy individuals, the systolic blood pressure decreases slightly (by less than 10 mmHg) with inspiration (Hoit, 2017). This respiratory variation is attributed to increased pulmonary vascular capacitance resulting in a mild decrease in

pulmonary venous blood return to the left ventricle and, consequently, a mild decrease in cardiac output. In patients with a pericardial effusion who develop tamponade physiology, the blood pressure decrease with inspiration is more pronounced (greater than 10 mmHg). This phenomenon is referred to as "pulsus paradoxus." In the setting of cardiac tamponade, the increased right ventricular filling normally seen with inspiration compromises left ventricular diastolic filling since the right ventricle is unable to expand into the pericardial space filled with noncompressible fluid. This decrease in left ventricular filling directly causes a decrease in cardiac output, indicated by an inspiratory blood pressure drop. Pulsus paradoxus is best assessed with a manual blood pressure cuff, although suggestions may be gleaned from amplitude differences in a stable, optimal pulse oximetry waveform. Initially, the first Korotkoff sound will only be audible in expiration, but disappear with deep inspiration. With further deflation of the blood pressure cuff, the first Korotkoff sound will become audible during both expiration and inspiration. The difference between these two systolic blood pressures is noted. Differences greater than 10 mmHg are abnormal and may indicate cardiac tamponade.

Respiratory Rate

Tachypnea: An increased respiratory rate is most commonly secondary to primary lung disease, such as infections, asthma, cystic fibrosis, chronic obstructive pulmonary disease, pleural effusions, or malignancy. It can also be seen in certain metabolic disorders, as respiratory compensation of metabolic acidosis. From a cardiovascular perspective, tachypnea can be a sign of a pulmonary embolus, especially in the setting of risk factors, sudden onset, associated hypoxemia, and an otherwise unremarkable lung exam. Cardiac lesions that cause tachypnea due to pulmonary edema commonly fall into three categories: primary myocardial dysfunction, large left-to-right shunts (VSD, PDA), and left-sided obstructive/regurgitant lesions (aortic stenosis or regurgitation, mitral stenosis or regurgitation, coarctation). However, while tachypnea is a key finding in infants with large left-to-right shunts, adult patients with undiagnosed left to right shunt are more likely to present with signs of pulmonary hypertension, such as dyspnea on exertion or hypoxemia. In patients with suspected left-sided obstructive or regurgitant lesions, cardiac auscultation (outlined below) is crucial for formulating a differential diagnosis. In the setting of coarctation, blood pressure gradients between the upper and lower extremities can be a helpful clue, as outlined above. If pulmonary vascular congestion is secondary to an underlying arrhythmia, examination of heart rate and rhythm is obviously the next and most important step. Tachyarrhythmias can cause pulmonary congestion in different ways: via impaired diastolic ventricular filling due to the fast rate, via the loss of synchrony between atria and ventricles, and/or due to arrhythmia-induced myocardial dysfunction. In the latter case, this will often be accompanied by signs of impaired cardiac output, such as poor perfusion, hypotension, and/or mental status changes. Patients with primary myocardial dysfunction and dyspnea may have signs of impaired cardiac output if there is systolic dysfunction. However, in patients with predominantly diastolic heart failure and preserved systolic function these signs may be absent.

Hypopnea/Bradypnea: Abnormally slow, shallow, and/or irregular respirations can be seen in the setting of intoxication, increased intracranial pressure, or neuromuscular disorders. The latter can be associated with cardiomyopathy and myocardial dysfunction. Hypopnea or bradypnea in isolation represents an unusual circumstance that may require timely support.

Oxygen Saturation

Hypoxemia/cyanosis: An abnormally low oxygen saturation, measured by peripheral pulse oximetry, can represent either peripheral cyanosis or central cyanosis. In peripheral cyanosis, the oxygen content of arterial blood leaving the heart is normal, but it is lower than normal in the peripheral vascular bed due to increased peripheral oxygen extraction or low cardiac output. Peripheral cyanosis from depressed cardiac output is distinctly rare. More commonly, it is caused by peripheral vasoconstriction and sluggish blood flow leading to increased oxygen extraction. In central cyanosis, on the other hand, the arterial blood leaving the heart is already desaturated. On exam, this can be distinguished based on the distribution of cyanosis. If oral mucosa and tongue appear pink and well saturated, the cyanosis seen in the extremities is likely peripheral cyanosis. However, if oral mucosa and periphery appear purplish and dusky, this likely represents central cyanosis. Central cyanosis can be due to intracardiac right-to-left shunting (e.g., Tetralogy of Fallot) or pulmonary venous desaturations. The latter, in turn, can be caused by intrapulmonary right-to-left shunting (arteriovenous malformations), ventilation-perfusion mismatch, intrinsic lung disease, or pulmonary edema. Cardiac lesions leading to pulmonary edema were outlined above under "Tachypnea." The pulmonary exam can be particularly helpful in this setting, since patients with right-to-left shunts will likely have a normal lung exam, whereas adult patients with pulmonary edema will likely be tachypneic and have crackles on lung auscultation. As stated above, tachy- and bradyarrhythmias significant enough to cause pulmonary congestion are often also associated with signs of impaired cardiac output, such as poor perfusion, hypotension, and/or mental status changes. This is similar in patients with primary myocardial dysfunction.

Differential cyanosis: A decrease in oxygen saturation from upper to lower extremities (>5%) in adults can be found in the setting of a PDA and pulmonary hypertension, leading to right-to-left shunting across the PDA. A murmur may be absent in that case, and further testing is warranted.

Anthropometrics

Anthropometric data like height and weight can provide helpful clues in patients with suspected heart disease.

Failure to thrive: Failure to thrive is a common presenting symptom in infants and children with congenital heart disease. In adults, cachexia can be seen in patients with heart failure (cardiac cachexia) and is usually associated with a poor prognosis (von Haehling et al., 2017). In addition, cachexia can be an indicator of an underlying malignancy. This is important to note as

chemotherapy-induced cardiomyopathy is a well-described entity. Furthermore, unintended weight loss can be an early symptom in patients with Takayasu's arteritis (Direskeneli, 2017).

Obesity: Excess body weight is a common component of metabolic syndrome with well-known cardiac sequelae described elsewhere. It can also be an indicator of a sedentary lifestyle that is due to underlying heart disease with poor exercise tolerance. Beyond that, obesity may suggest an underlying genetic syndrome having a cardiomyopathy component, such as Bardet–Biedl syndrome (Suspitsin and Imyanitov, 2016).

Short stature: Unusually low height can be an important clue to an underlying genetic syndrome (Ko, 2015). For example, Turner syndrome is associated with short stature, primary gonadal failure, and in about one-third of cases, congenital heart disease, including excessive risk of aortic dissection. Noonan syndrome is also characterized by short stature and congenital heart disease including pulmonary valve dysplasia, pulmonary stenosis, and hypertrophic cardiomyopathy. Both conditions require lifelong cardiac care.

Tall stature: Unusually large height may reflect a person's unique nutritional and hereditary endowment or may signal more sinister processes. For example, tall stature is a hallmark of patients with Marfan syndrome or other connective tissue disorders, especially when associated with excessive chest wall growth like pectus deformities or excessive back curvature like scoliosis (Loeys et al., 2010). Connective tissue disorders are associated with excesses in valve structure, typically mitral or tricuspid valve prolapse and dysfunction, and aortic dilation (particularly of the aortic root) with its dreaded complication, aortic dissection.

Inspection

Even before laying hands on the patient, vital clues can be gathered from careful, informed, visual inspection.

Distress

Pain, often considered the fifth vital sign, should be assessed in every patient. Although more commonly noncardiac in nature, chest pain in particular can be the hallmark of myocardial ischemia, myo-/pericarditis, aortic dissection, or a pulmonary embolism.

Respiratory distress, as outlined above under "tachypnea" and "hypoxemia," is visually evident by vital signs but also by apperception of labored breathing, excessive muscle use with breathing, and visibly apparent fatigue as an indicator of prolonged accessory muscle use. Respiratory distress may be the result of underlying lung disease or various types of heart disease, both congenital and acquired. The presence of respiratory distress mandates rapid assessment and prompt management to prevent respiratory failure.

More subtle may be *distress that is limited to activity*. Patients may appear comfortable at rest but display significant limitations with activities of daily living. Subconsciously, such individuals may self-limit activity and therefore never consciously appreciate the fairly profound limitation in activities of daily living. In addition to a thorough history, asking the patient to walk across the room, down the hall or up a flight of stairs may reveal otherwise missed signs of heart failure.

Inappropriate diaphoresis at rest or with light activity should also catch the examiners attention. While this is a common presenting sign in infants with congestive heart failure and increased sympathetic tone, in the adult population this can be a consequence of diabetic autonomic neuropathy leading to autonomic dysregulation. If diaphoresis is caused by acute *sense of doom*, it may be an alarming sign associated with myocardial infarction, aortic dissection, or pulmonary embolism.

Similarly subtle to detect on exam may be *changes in mental health, affect, or mood*. While these are more commonly noncardiac in nature, lethargy and fatigue may be signs of underlying heart failure and require specific attention. Less common, but no less severe, is a form of cardiomyopathy referred to as Takotsubo cardiomyopathy or "broken heart syndrome." (Chen and Dilsizian, 2017) As a response to emotional stress, significant organic cardiac dysfunction has been described, similar to myocardial ischemia, but with normal coronary perfusion. Thankfully, Takotsubo cardiomyopathy is often characterized by spontaneous recovery. Finally, mental health disorders are now recognized as cardiometabolic risk factors worthy of attention for cardiovascular prevention (Goldstein et al., 2015).

Dysmorphism

As described extensively in other chapters, several genetic syndromes can be associated with congenital (or acquired) heart disease (Ko, 2015). Many of these syndromes are characterized by classic dysmorphic features that should be assessed in every patient. From a cardiac perspective, the most notable of these syndromes are: Down syndrome, Turner syndrome, Noonan syndrome, Marfan syndrome, Ehlers–Danlos syndrome, Holt–Oram syndrome, 22q11.2 deletion syndromes, CHARGE syndrome, and VACTERL association.

Stigmata of Systemic Disease

Many systemic diseases (or their treatments) can be associated with congenital or acquired heart disease. In the absence of a known diagnosis, small visual clues can be of great importance.

- Osler nodes (painful, red, raised lesions on hands or feet), Janeway lesions (small nontender, erythematous macules on palms or soles), or splinter hemorrhages (tiny linear blood clots of the nailbeds) can be signs of infective endocarditis (Baddour et al., 2015).

- A malar rash, a flat red or purplish eruption of the cheeks and nasal bridge, can be a sign of Systemic Lupus Erythematosus, which, in turn, can be associated with pericarditis, myocarditis, conduction defects, valvular disease, and coronary artery disease (Chen et al., 2016). Malar rash may also suggest dermatomyositis. Dermatomyositis has cardiac involvement with frequent subclinical manifestations including conduction abnormalities and arrhythmia and uncommon clinically overt manifestations of congestive heart failure, arrhythmia/conduction abnormalities, and coronary artery disease, possibly due to small vessel involvement (Lundberg, 2006; Schwartz et al., 2016).
- Skin induration and tightening of the face or the fingers (sclerodactyly) is a classic finding in scleroderma, which, in its systemic form, may lead to myocardial disease, conduction system abnormalities, arrhythmias, or pericardial disease (Lambova, 2014).
- The presence of lupus pernio (bluish-red or violaceous nodules and plaques over the nose, cheeks, and ears) or erythema nodosum (reddish, tender lumps most commonly located in the front of the legs below the knees) may be a sign of sarcoidosis which can involve the myocardium and has been associated with sudden cardiac death (Birnie et al., 2016).
- Characteristic joint deformities can point to Rheumatoid Arthritis (RA). RA significantly increases the risk of atherosclerosis, myocardial infarction, and stroke. Recent data suggest disease modulating therapies also prevent CVD (Prasad et al., 2015).
- The presence of an enlarged thyroid (goiter) should prompt evaluation for thyroid disorders. Thyroid disorders are commonly associated with heart rate changes and/or dyslipidemia.
- Acanthosis nigricans (dark, velvety discoloration in body folds and creases) can point at underlying dysglycemia, whereas xanthomata (yellow to orange papules, commonly over joints and tendons) or xanthelasma (when present over the eye lids) can be associated with dyslipidemia.
- Muscle weakness or atrophy as well as calf pseudohypertrophy are classic findings in patients with muscular dystrophy. Many forms of muscular dystrophy are associated with cardiomyopathy, which requires lifelong cardiac care (Palladino et al., 2016).
- Jaundice, as a nonspecific sign of liver disease, can be important to notice since it may point at congestive hepatopathy or cirrhosis in the setting of heart failure. It may also be a complication of alcoholism which, in turn, can lead to cardiomyopathy. Less commonly, jaundice in an adult can lead to a late diagnosis of Alagille syndrome which is often associated with different types and degrees of pulmonary stenosis (Saleh et al., 2016).
- Lastly, a rare but important clue can be the presence of a cochlear implant, since congenital deafness is part of Jervell and Lange–Nielson syndrome, a subtype of long QT syndrome, associated with ventricular tachycardia and sudden cardiac death (Lu and Kass, 2010).

Cyanosis

Visible cyanosis of the skin is a key hallmark of many forms of congenital heart disease. Central, peripheral, and differential cyanosis are discussed above, under "Oxygen saturation."

Clubbing

Nail clubbing of the fingers and/or toes is a nonspecific finding in many chronic diseases. Among those, chronic lung disease and cyanotic heart disease are most prominent, along with gastrointestinal conditions and various malignancies. From a cardiac perspective, any heart disease associated with chronic hypoxemia can lead to the development of progressive clubbing over time. The ubiquity of clubbing is due to its nature as a nonspecific vascular proliferative response to low-oxygen tension. It is important to note both presence and distribution of nail clubbing. Occasionally, clubbing may occur in the lower limbs only, sparing the upper limbs. This is known as differential clubbing and may occur in patients with a PDA associated with pulmonary hypertension and right to left shunting across the PDA. In this setting, there is also differential hypoxia/cyanosis, as outlined above.

Jugular Venous Distention:

Jugular venous distention is assessed with the patient sitting at a 45 degree angle with the head turned slightly sideways. The height of the oscillating top of the internal jugular venous pulse above the sternal angle is noted. Right atrial pressure is then approximated by adding 5 cm to the height of the venous pulse, since it is assumed that the right atrium is located about 5 cm below the sternal angle. When the venous pressure is high, the venous pulsations are best seen when the trunk is elevated to 90 degree. Elevated venous pressure can be a sign of superior vena cava obstruction (prior surgery, malignancy, etc.) or elevated right atrial pressure, such as with right ventricular dysfunction, pulmonary hypertension, or tricuspid regurgitation. In any case, an elevated venous pressure estimate based on jugular venous distention should prompt further evaluation.

Auscultation

Cardiac auscultation should occur in an environment with minimal noise using the stethoscope on the patient's bare chest. The order of conducting an auscultation exam is probably less important than a complete and thorough evaluation. The following order may serve as a suggestion:

Rate

The heart rate can be assessed and counted manually by auscultation to complement the heart rate measured during vital sign assessment with careful attention to any changes between the two time points. For a differential diagnosis of tachycardia and bradycardia, please refer to the section on "Heart rate" above.

Rhythm

- Normal sinus rhythm should be regular with mild, physiologic variation throughout the respiratory cycle (slight rate increase during inspiration, followed by a decrease during expiration).
- A rhythm that is regular but tachycardic and without obvious variability should raise the suspicion for an arrhythmia, such as atrial flutter, supraventricular tachycardia, or an unusually stable ventricular tachycardia.
- If the rhythm is irregular, it can be helpful to determine whether the rhythm is regularly irregular or irregularly irregular. A regularly irregular rhythm follows a particular pattern, such as a dropped beat every few beats. This could be due to second degree heart block with Wenckebach (Mobitz 1) in which the PR interval progressively lengthens, until a beat is no longer conducted. An irregularly irregular rhythm appears erratic without a particular pattern. This can be due to pronounced sinus arrhythmia, atrial fibrillation, or premature atrial or ventricular contractions

Heart Sounds

S1: The first heart sound is caused by closure of the atrioventricular (tricuspid and mitral) valves. It can be soft/muffled in the setting of pericardial effusion. Rarely, S1 can be split. An abnormally wide split can be found in the setting of right bundle branch block or Ebstein's anomaly of the tricuspid valve. A wide split should be distinguished from an ejection click and S4 gallop described below. In patients following mechanical atrioventricular valve replacement, S1 often has a "metallic" quality.

S2: The second heart sound is caused by closure of the semilunar (pulmonary and aortic) valves and consists of a pulmonary component (P2) and an aortic component (A2). It can be soft/muffled in the setting of pericardial effusion. It is often loud (i.e., louder than S1) in the setting of pulmonary hypertension. In a normal heart, A2 and P2 occur simultaneously during expiration, but split slightly (A2 occurring earlier than P2) during inspiration, secondary to increased right heart filling and flow across the pulmonary valve during inspiration. This behavior is considered physiologic splitting. Abnormally wide or fixed splitting of S2 is seen in the setting of right ventricular volume overload (ASD, partial anomalous pulmonary venous return), right bundle branch block, or severe pulmonary stenosis. Furthermore, the second heart sound can be single if there is only one semilunar valve (e.g., aortic atresia or pulmonary atresia), both semilunar valves are connected to the same vessel (following a Damus–Kaye–Stansel procedure), P2 is early (pulmonary hypertension), or A2 is delayed (severe aortic stenosis). In patients following mechanical aortic or pulmonary valve replacement, S2 often has a "metallic" quality.

S3: A third heart sound is a low-frequency sound in early diastole (following S2), caused by rapid filling of the ventricles. It can be normal in children and young adults. In the setting of tachycardia, however, it constitutes an abnormal S3 gallop and could be a sign of congestive heart failure. A variant of S3 is the so-called *pericardial knock*. This is a somewhat higher pitch early diastolic sound that occurs distinctly earlier than the usual S3, due to rapid ventricular filling being abruptly halted by a restricting pericardium, such as with restrictive pericarditis.

S4: A fourth heart sound is a low-frequency sound in late diastole (preceding S1). It is thought to be caused by turbulent blood flow during atrial contraction into a ventricle with reduced compliance. S4 is always pathologic and commonly associated with heart failure, often in the form of a tachycardic S4 gallop.

Murmurs

A murmur is an audible sound caused by nonlaminar blood flow. As outlined in the following, nonlaminar flow need not always indicate pathology, and most murmurs are benign.

Timing

Systolic

Midsystolic (ejection type): This type of murmur begins shortly after S1 and ends before S2 with a crescendo–decrescendo contour. To define this pattern, S1 and S2 should be clearly audible and unobscured by the murmur. It is usually associated with turbulent flow across semilunar valves (aortic or pulmonary) due to mismatch between the size and shape of the orifice and the flow traversing the orifice. For example, a structural defect in the semilunar valve such as in aortic or pulmonary stenosis may cause this murmur by being an inaudible obstruction to flow until the ventricle generates enough pressure to overcome the obstruction. Once that pressure is achieved, the valve structure itself causes turbulent, nonlaminar flow audible as the murmur. Similarly, an atrial septal defect inducing markedly increased flow across a normal pulmonary valve may lead to nonlaminar flow patterns again causing this murmur. The location of the midsystolic murmur (see below) can help distinguish aortic from pulmonary stenosis. A midsystolic (ejection type) murmur also occurs as an innocent flow murmur (Still's murmur) described below.

Holosystolic (regurgitant): This type of murmur begins with S1 and continues through S2. There is no delay between S1 and the murmur, which is an important feature distinguishing it from a midsystolic murmur. The intensity of the murmur is usually constant throughout systole (band-like). Holosystolic murmurs are cause by mitral regurgitation, tricuspid regurgitation or VSDs, circumstances in which the pressure difference between the two chambers involved is different from very beginning to the end of systole. When the murmur is new onset and associated with clinical compromise an acute life-threatening process may be occurring such as either mitral papillary muscle rupture or necrotic VSD following myocardial infarction.

Early systolic (regurgitant): This type of murmur begins with S1, decreases quickly in intensity (decrescendo), and ends well before S2. It is caused by the same conditions that cause holosystolic murmurs, however, with more rapid equalization of pressures and, hence, earlier cessation of flow.

Late systolic: A late systolic murmur begins in late systole and lasts up to S2. It is most commonly caused by mitral regurgitation due to mitral valve prolapse. In that case it is preceded by a midsystolic click.

Diastolic

Early diastolic: This murmur type begins with or even obscures S2 and quickly decreases in intensity (decrescendo). It is associated with semilunar valve (aortic or pulmonary) regurgitation. Although the location of the murmur is similar in both cases (left sternal border), the murmur of aortic regurgitation tends to be higher pitch due to the higher pressure difference between upstream and backflow chambers.

Mid- or late-diastolic: These low-frequency murmurs begin well after S2 (mid diastolic) or just before S1 (late diastolic). They are caused by turbulent flow across the tricuspid or mitral valve. This can happen due to the mismatch between atrioventricular valve structure and flow. Structural mitral stenosis or less commonly tricuspid stenosis may cause such a murmur. Alternatively, increased flow across a normal valve such as a large VSD or PDA leading to excess flow across the mitral valve or a large ASD or partial anomalous pulmonary venous return leading to excessive flow across the tricuspid valve.

Continuous

Hallmark of a continuous murmur is that it begins in systole and lasts without interruption into diastole. It need not last throughout the entire cardiac cycle since all that is required is a connection between two chambers that have a pressure difference and possible flow in systole and diastole. A continuous murmur can be caused by a PDA, aortopulmonary collaterals, coronary artery fistula, or arteriovenous fistula. Of note, in patients with a PDA and pulmonary hypertension, the diastolic component of the murmur may be abolished due to equalized pulmonary and systemic pressure during diastole. Continuous murmurs are distinct from combined midsystolic and early diastolic murmurs ("to-and-fro" murmurs) which occur with mixed semilunar valve disease (stenosis plus regurgitation).

Intensity

Grade I: Barely audible. Audible to roughly half of examiners.
Grade II: Soft, but easily audible
Grade III: Moderately loud, but not accompanied by a thrill
Grade IV: Loud and associated with a thrill
Grade V: Audible with the stethoscope barely on the chest. Thrill present
Grade VI: Audible with the stethoscope off the chest. Thrill present

Location

See Fig. 1.

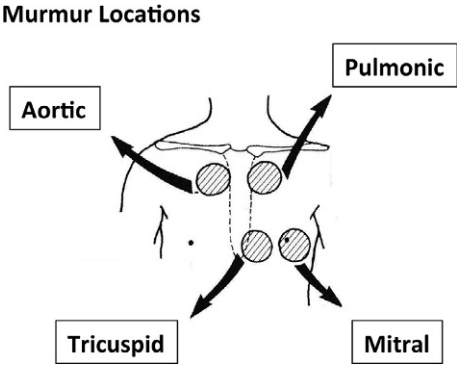

Fig. 1 Murmur locations. Aortic (right upper sternal border); pulmonary (left upper sternal border); tricuspid (left lower sternal border); mitral (apex). Modified from Parks (2014).

Radiation

The pattern of radiation can be useful in determining the etiology of a murmur. Murmurs of aortic origin are more likely to radiate to the right upper sternal border and neck along the course of the downstream chamber, the carotid arteries. Murmurs of pulmonary origin are more likely to radiate into the back and the axillae along the course of the proximal pulmonary arteries. A mitral regurgitation murmur is best heard over the LLSB with radiation into the lower back. A murmur prominently heard in the interscapular area may signal narrowing at classic site for coarctation of the aorta. A continuous murmur in the intraclavicular region with radiation to both left and right chest could indicate a PDA or other aortopulmonary collateral.

Innocent murmurs

Still's murmur: This is the most common innocent murmur. It is a midsystolic ejection type murmur, no more than III/VI in intensity (never with a thrill), and best heard along the left sternal border. The hallmark of this murmur is its vibratory "twangy" quality that is also often described as musical. The murmur is more prominent in the supine position.

Outflow tract murmurs: These murmurs are caused by exaggeration of normal ejection vibrations along the right or left ventricular outflow tract. They are midsystolic ejection type murmurs, no more than III/VI in intensity, and best heard along the left upper sternal border (RVOT) or right upper sternal border (LVOT). Since they occur in the setting of normal anatomy, there are no associated clicks or thrills.

Venous hum: This murmur is caused by turbulence in the jugular venous system. It is a soft, continuous murmur, best heard over the right or left infraclavicular area. It is only heard in the upright position and usually disappears in the supine position. It may be confused with a PDA murmur. However, the diastolic component of a venous hum is louder than the systolic component. The reverse is true for the PDA murmur. In addition, the PDA murmur does not disappear in the supine position. A venous hum can be obliterated in the upright position by turning the neck so as to occlude the jugular vein, or direct application of light pressure, taking care to avoid the carotid bulb.

Clicks

Ejection click: An ejection click is a high-pitch sound that follows S1 closely. It is caused by sudden systolic doming of an abnormal semilunar valve. An aortic click (often in the setting of a bicuspid aortic valve) is best heard at the left lower sternal border. It does not vary with inspiration. A pulmonary click (often in the setting of a dysplastic or bicuspid pulmonary valve) is best heard over the left upper sternal border and becomes softer with inspiration.

Midsystolic click: This sound occurs later is systole in the setting of mitral valve prolapse. If mitral regurgitation is present, it may be accompanied by a late systolic murmur (see above).

Opening snap: This early diastolic sound is caused by the opening of a stenotic atrioventricular valve. It is best heard over the LLSB (tricuspid stenosis) or apex (mitral stenosis).

Other Adventitial Sounds

Rubs: Pericardial friction rubs usually occur in the setting of pericarditis. They are caused by friction between the inflamed pericardial surfaces. It is a rocking to-and-fro sound that resembles walking in fresh snow. It is more pronounced with the patient leaning forward. Of note, once a large pericardial effusion develops, the rub may become softer or disappear. This should not be misinterpreted as a resolution of pericarditis.

Bruits: A bruit is a continuous murmur caused by turbulent arterial flow. This can occur either in the setting of arterial obstruction or due to increased flow through an unobstructed artery.

Carotid and femoral artery bruits should raise concern for peripheral artery disease and warrant further evaluation (Writing Committee M et al., 2017). In patients who have undergone a prior cardiac catheterization with femoral arterial access, a femoral bruit may be a sign of an iatrogenic AV fistula.

Renal artery stenosis can cause a bruit over the renal arteries. This is best auscultated above the level of the umbilicus along the lateral edge of either rectus muscle. This is particularly important in the evaluation of a hypertensive patient.

Bruits heard over the *liver* can be a sign of an underlying liver malignancy, alcoholic hepatitis/cirrhosis, or of an arteriovenous malformation.

Cerebral bruits (auscultated best over the cranium, through a fontanelle, or over the orbit/eyeball) can occur in the setting of high cardiac output or decreased blood viscosity, such as with severe anemia. In the absence of those conditions, cerebral bruits may be a sign of intracranial hemangiomas or arteriovenous malformations. Less commonly, they can be appreciated in the setting of Paget's disease due to increased blood flow through the abnormal bone structure.

Palpation

Palpation, that is, manual investigation, of the cardiovascular system is an ancient practice which is falling out of favor in modern clinical practice. Since personal manual sensation of physical phenomena may not be uniform or easily standardizable among examiners, palpation is in danger of becoming a relic of bygone times. Focusing on aspects still relevant to modern practice,

palpation is classifiable by frequency, duration, timing, and location. Some sources state that while fingertips are the prime tools for palpable investigation, fingertips are ill-suited for long duration events, especially at low frequencies (Hurst et al., 2011). Palms may be better suited to longer duration events.

First palpation of pulses, typically with the examiners fingertips, is a requisite for every physical examination. While much information can be gleaned from pulse qualities since ancient times, in modern practice pulse exam is limited to presence versus absence and timing delay (O'Rourke et al., 2001). Pulses where arteries course over bony prominences like the wrist, dorsum of the foot, medial malleolus of the ankle, neck location of the carotid, and the temporal artery. The absence of pulses must first be investigated as being caused by low cardiac output such as shock. More stable situations where pulses are absent would include very rare Takayasu's arteritis or much more common congenital absence of the dorsalis pedis pulse of the foot (Chavatzas, 1974). The abnormal presence of a brisk or bounding pulse at the palms of a premature infant can be a clue for the presence of an important patent ductus arteriosus, even when the baby might be intubated and covered in monitoring equipment precluding proper auscultative apprehension of a continuous murmur. The timing of pulses can be important such as when a perceptible delay exists between two sites. For example a delay between femoral pulse in the groin versus carotid pulse in the neck may signal collateral vessels supplying the femorals due to coarctation of the aorta. The quality of the palpation may also signal important concerns. For example, "diffusion" of a pulse from a sharp, smooth, brisk phenomenon to a longer sensation described as "worms crawling below the fingertips" signals the presence of a thrill. A thrill suggests the presence of nonlaminar flow, such as a thrill at the carotid site suggesting the occurrence of significant aortic valve stenosis.

Second palpation of the chest and trunk can be informative. Many of the features of palpation in these locations can be enhanced by using the palm rather than the fingertips. The point of maximum impulse is the point usually on the fifth intercostal space at the midclavicular line. This point may show visible pulsation of the heart in small or young people and may have a palpable impulse in larger older persons. However the point of maximal impulse may not always be properly assigned to that location. One example would be the rare circumstance where the cardiac mass is not located in the left chest in so-called dextrocardia when in the right chest or mesocardia when the cardiac mass is more midline. Another example would be changes in LV dimensions such as dilated cardiomyopathy that can lead to the point of maximal impulse to be displaced leftwards. As yet another example, right ventricular pressure overload or right ventricular volume overload can cause a right ventricular heave or palpable pulsation through the chest wall just to the left of the sternum at the fourth or fifth intercostal space, termed an RV heave. Referenced to carotid pulse for timing, sensitive examiners may be able to distinguish an early-in-systole heave consistent with volume overload versus more prominent later-in-systole heave which is more consistent with pressure overload. The difference in timing may be due to the time needed for the ventricle to generate the pressure needed to overcome the pressure overload and initiate outflow. Another key aspect of precordial palpation is the presence of thrill accompanying a murmur defining a more "severe" murmur of at least four out of six on the Levine scale (Freeman and Levine, 1933). Severe chest pain accompanied by a palpable thrill or pulsation in the sternoclavicular area can suggest a prominence of the aortic contour rising to the cranial border of the sternum, possibly due to aneurysm or pseudoaneurysm with impending rupture. Finally, a timing delay between the apical impulse on the chest and the carotid pulse can be a useful signal of important aortic stenosis, especially when echocardiography-based gradient measures can be problematic (Schlingmann et al., 2015).

Conclusion

Physical Examination is still the entry-point for diagnosis and treatment for clinical patients of all ages. Proper attention should be paid to vital signs and general appearance to glean enormous amounts of actionable information. Discovery and confirmation through auscultation and palpation still offer uniquely valuable data points on diagnosis, treatment, and prognosis even in this age of high-resource-intensity solutions to old problems. Retrenchment into time-tested physical exam diagnostic skills would serve modern medicine very well. A lack of focus on the physical exam would be a loss of practical value and an irreparable disruption in the tradition of medical care.

Introduction

Competitive athletes and highly active individuals are a growing segment of the global population. This growth is driven by increasing recognition of the health benefits of routine physical exercise and greater access to competitive sporting opportunities and recreational exercise programs.

The American College of Cardiology and European Society of Cardiology (ESC) (Mitten et al., 2015) identify a qualitative definition for a competitive athlete, as a person who participates in regular competition, in which emphasis is placed on excellence and achievement, with a usual intense systematic training and a tendency to physical limits during exertion.

From a quantitative point of view, an athlete may be considered "elite" if competing regularly at the regional, national, or international level and exercising for ≥ 6 h/week (Sheikh et al., 2014).

Long-term physical training in elite athletes is characterized by physiological adaptation of cardiovascular structures, with functional, structural, and electrical remodeling, defined as athlete's heart.

The identification of these changes is essential to distinguish athlete's heart from other pathological conditions. Moreover some of the exercise-induced changes may be associated with acute and chronic cardiac damage, and in a small number of athletes this may predispose to atrial and ventricular arrhythmias (D'Andrea et al., 2015).

Cardiac remodeling may be evaluated not only at rest but also during exercise with electrocardiography (ECG), standard echocardiography, advanced ultrasound techniques, and other noninvasive cardiac imaging modalities.

The aim of this chapter is to provide a comprehensive assessment of physiological adaption of the heart in elite athletes.

Physiological Adaptation

Morganroth identified two main models of training adaptation characterized by two distinct patterns of cardiac remodeling (myocardial hypertrophy) (Morganroth et al. 1975). Endurance training is typical of aerobic sports with dynamic–isotonic muscular involvement, such as long-distance swimming and running. These activities cause a gradual decrease in systemic arterial resistance and an increase in venous return, with a predominant volume overload, resulting in higher left ventricular (LV) end-diastolic volume (EDV) and stroke volume (eccentric hypertrophy).

In contrast, strength training is typical of anaerobic sports with predominant static–isometric muscular exercise, such as body-building, short-distance running, and swimming. These sport categories cause mainly an increase in myocardial wall thickness rather than cavity diameters (concentric remodeling and hypertrophy), in response to the predominant pressure overload.

Morganroth's original hypothesis has been criticized because cardiac remodeling is also influenced by other factors like ethnicity, age, sex, genetics, and body size. Moreover it has to be noted that most sports are actually characterized by a variable combination of both endurance and strength exercise, rather than only one of them (**Fig. 1**).

Heart rate reduction and stroke volume increases, associated with systemic vascular resistance reduction are typical hemodynamic changes in athlete's heart: it results in a slight elevation of cardiac output ($=SV \times HR$) during exercise. The long-run hemodynamic changes during exercise cause an increase in both left ventricular (LV) internal size (LV dilation) and LV hypertrophy

 https://doi.org/10.1016/B978-0-12-809657-4.99712-6

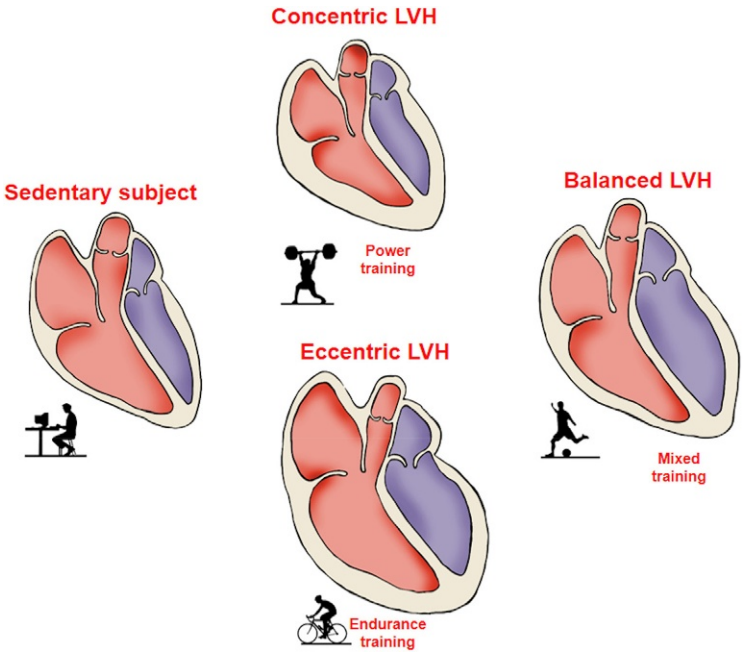

Fig. 1 Models of cardiac remodeling in elite athletes.

(LVH), a response that normalizes LV wall stress. LV dilation and LVH may be pronounced enough to mimic a pathological state. However LV systolic and diastolic function are normal or even supranormal in athlete's heart (Galderisi et al., 2015).

Moreover ejection fraction (EF) calculated as (=100 × SV/LV end-diastolic volume) is normal or can be even marginally reduced at rest in athletes: EF increases markedly during effort when larger LV end-diastolic volume allows to best utilize the Frank–Starling mechanism (the higher preload, the more rapid diastolic filling, and the smaller LV end-systolic volume) and increase SV compared with nonathletes (Abergel et al., 2004).

Concerning the molecular adaptations of the heart, exercise-induced cardiac remodeling is associated with cardiac myocyte hypertrophy and proliferation, sarcomeric and mitochondrial adaptations, electrical remodeling and increased endogenous cardiac stem cell, induced by signaling pathways activated by growth factors, hormones (thyroid and growth), and mechanical stretch. In contrast the adverse effects of endurance training are more similar to the disease-induced pathological remodeling, with beta1-adrenoreceptor desensitization and prolonged tumor necrosis factor alpha-nuclear factor kappa B-p38 signaling (Bernardo and McMullen, 2016).

ECG

The 12-lead ECG in elite athletes has typical characteristics, and it is influenced by the physiologic, electrical, structural, and functional adaptations related to intensive physical activity.

Some ECG findings of athlete's heart may overlap with those described in pathological conditions, thus creating a grey area in ECG interpretation and the need of further investigation (Corrado et al., 2010).

Competitive athletes have increased vagal tone responsible of bradyarrhythmias, such as sinus bradycardia greater than 30 beats/min (bpm), first-degree and second-degree Mobitz type 1 atrioventricular block, sinus arrhythmias, wandering atrial pacemaker, and ectopic atrial rhythm.

Increased vagal tone influences ethnic-specific repolarization changes: white athletes typically show concave ST segment elevation, while Afro-Carribean/black athletes have convex ST segment elevation, often associated with biphasic or deep T-wave inversion in V1–V4 (Yeo and Sharma, 2016).

Manifestation of increased cardiac chamber size and wall thickness includes incomplete right bundle branch block and isolated Sokolow–Lyon voltage criteria (combined amplitude of S wave in V1 + largest R wave in V5 or V6 >3.5 mV, or R wave in aVL >1.1 mV), often regarded as physiologic adaptation in athlete's heart (Yeo and Sharma, 2016).

Standard ECG identifies right atrial abnormalities (RAA) as P-wave amplitude >2.5 mm in DII, DIII, or aVF leads and left atrial abnormalities (LAA) as prolonged P-wave duration greater than 120 ms in leads DI or DII with negative portion of the P-wave greater than or equal to 1 mm in depth and greater than or equal to 40 ms in duration in lead V1. Concerning the prevalence of atrial abnormalities in athletes it may be more common in younger athletes, but there is a low prevalence in adult athletes: Pelliccia et al. (2000) identified the prevalence of LAA to be 4% and RAA to be 0.8% in 1005 trained athletes. As a consequence, in adult athletes, atrial abnormalities should be regarded as abnormal and lead to deeper investigations (Fig. 2).

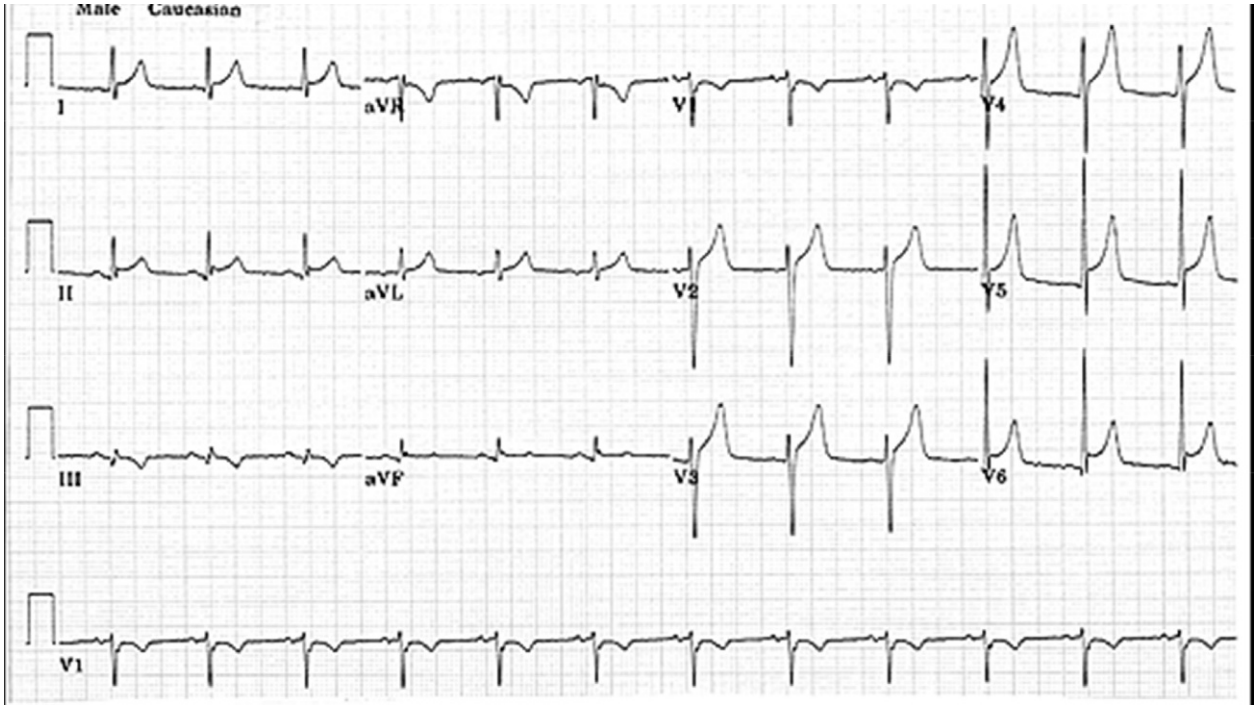

Fig. 2 Common training-related features in an athlete's ECG: isolated QRS voltage criteria for LVH, associated with early repolarization.

ESC 2010 recommendations for interpretation of 12-lead electrocardiogram in the athlete incorporated physiologic adaptations commonly found in athletes, by classifying ECG abnormalities into common and training-related findings versus uncommon and training-unrelated changes, useful to identify those pathological conditions as HCM and arrhythmogenic right ventricle cardiomyopathy (ARVC), with higher risk of sudden cardiac death in competitive athletes (Corrado et al., 2010).

In 2013 the Seattle Criteria (**Table 1**) provided quantitative cut-off, not specified in previous ESC document: these criteria were structured to distinguish normal versus abnormal findings in athletes. The Seattle Criteria include revised contemporary limits for QTc intervals and T-wave inversion and are therefore superior to the ESC criteria in specificity, with further reduction of false-positive findings (Drezner et al., 2013).

The main determinants of ECG patterns in athlete's heart include age, gender, ethnicity, type, and intensity of sport (**Table 2**) (Yeo and Sharma, 2016).

Echocardiographic Analysis of Physiological Adaptations

Echocardiographic analysis is essential in revealing athlete's heart characteristics and in differentiating physiological and pathological LV remodeling.

Left Ventricle

Previous studies on elite athletes reported that 55% had increased LV end-diastolic diameter, and only 15% of them had values >60 mm, with preserved EF; moreover LVH involved all myocardial segments, with a maximal wall thickness <12 mm.(Pelliccia et al., 1991) Conversely an increased wall thickness >15 mm mainly in basal septum is typical of patients with Hypertrophic cardiomyopathy (HCM), with a grey zone between 13 and 15 mm. After a deconditioning period of at least three months a reduction in wall thickness can be observed in athletes, but not in HCM (D'Andrea et al., 2015).

In elite athletes, LV diastolic function is often supranormal (E/A >2 with a low A velocity), in particular in endurance sports, due to a LV remodeling associated with normal or increased myocardial relaxation, as an expression of increased elastic recoil, different from HCM patients, in whom diastolic dysfunction is typically present (E/A < 1) (George et al., 2011).

Pulsed tissue Doppler (TDI)-derived early diastolic myocardial velocity (e') of basal septal and basal lateral wall is increased in athletes, without regional dysfunction ($e'/a' < 1$) and with low E/e' ratio; after ultra long-duration exercise, as marathons, a reduction of e' velocity of both septal and lateral annulus is common (Cardim et al., 2003).

Finally pulsed TDI gives additional information regarding myocardial systolic performance at rest, showing normal or supranormal values in athlete's heart, with normal EF, normal or supranormal stroke volume, and systolic peak velocity (s') > 9 cm/s (Zoncu et al., 2002) (**Fig. 3**).

Table 1 Modified 2013 Seattle criteria (Drezner et al., 2013)

Normal variants in athletes: *do not require further diagnostic evaluation*	
Sinus bradycardia	≥30 bpm
Sinus pauses	<3 s
Ectopic atrial rhythm or junctional escape rhythm	
I AV block	PR interval >200 ms
Mobitz Type 1–II AV block	
Incomplete RBBB	
Isolated QRS voltage criteria for LVH	Except: QRS voltage criteria for LVH occurring with any nonvoltage criteria for LVH (left atrial enlargement, left axis deviation, pathological Q waves, ST segment depression, T-wave inversion)
Early repolarization	J-point elevation, ST elevation, J-waves, or terminal QRS slurring
Convex ST segment elevation associated with T-wave inversion in leads V1–V4 in black/African athletes	
Abnormal variants in athletes: *require further diagnostic evaluation*	
Left atrial enlargement	Prolonged P-wave duration of >120 ms in leads I or II (negative portion of the P wave ≥1 mm in depth and ≥40 ms in duration in lead V1)
Atrial tachyarrhythmias	Supraventricular tachycardia, atrial-fibrillation, atrial-flutter
Extreme sinus bradycardia	<30 bpm
Sinus pauses	≥3 s
Complete LBBB	
Complete RBBB	
Left axis deviation	−30 to −90 degrees
T-wave inversion	>1 mm in depth in two or more leads V2–V6, II and aVF, or I and aVL (excludes III, aVR, and V1)
Right ventricular hypertrophy pattern	R − V1 + S − V5 > 10.5 mm AND right axis deviation >120°
Ventricular preexcitation	PR interval <120 ms with a delta wave and wide QRS (>120 ms)
Long QT interval	QTc ≥ 470 ms (male) QTc ≥ 480 ms (female)
Short QT interval	QTc ≤ 320 ms
Brugada-like ECG pattern	High take-off and downsloping ST segment elevation followed by a negative T wave in ≥2 leads in V1–V3
ST segment depression	≥0.5 mm in depth in two or more leads
Pathologic Q waves	>3 mm in depth or >40 ms in duration in two or more leads (except for III and aVR)
Premature ventricular contractions	≥2 PVCs per 10 s tracing
Ventricular arrhythmias	Couplets, triplets, and nonsustained ventricular tachycardia

AV, atrioventricular; *bpm*, beats per minute; *LVH*, left ventricular hypertrophy; *ms*, milliseconds; *RBBB*, right bundle branch block; *LBBB*, left bundle branch block.

Table 2 Determinants of ECG patterns

Determinants of ECG patterns	*Characteristics*
Age	Adolescent athletes have more frequent juvenile ECG pattern with T-wave inversion in V1–V3 (Migliore et al., 2012)
Gender	Abnormal ECG patterns are four times more frequent in male athletes compared with their female counterparts (Pelliccia et al., 1996)
Ethnicity	Black athletes have more frequent repolarization abnormalities including T-wave inversion, voltage criteria for left and right ventricular hypertrophy, and left and right atrial enlargement (Papadakis et al., 2011)
Type and intensity of sport	Endurance athletes have more common right ventricle hypertrophy and T-wave inversion in V1–V3 Elite athletes show abnormal ECG changes more frequently than amateurs (Pelliccia et al., 1991)

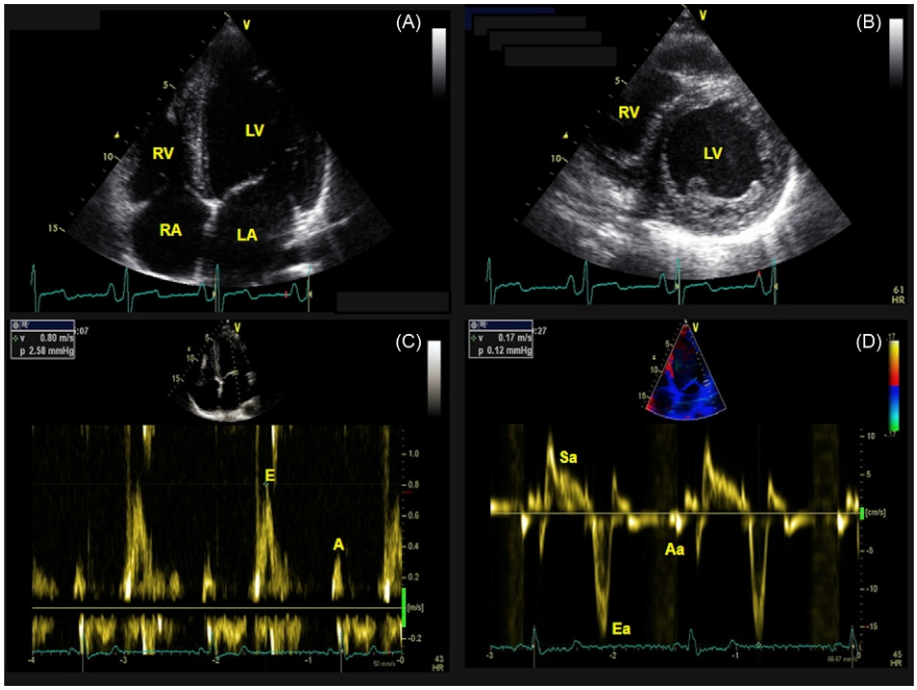

Fig. 3 Standard echocardiography and tissue Doppler in an endurace athlete. Apical 4-chamber view (A) and parasternal short axis view (B) showing eccentric left ventricular (LV) hypertrophy and right ventricular (RV) enlargement. Transmitral flow pattern (C) and Tissue Doppler (D) evidencing "supernormal" early diastolic function. LA: left atrium; RA: right atrium.

Concerning the application of strain variation in competitive athletes at different loading conditions, there is LV adaptation at rest and a load dependency of strain measurements; athletes have normal longitudinal deformation despite left ventricular hypertrophy and higher values for transverse, radial, and circumferential strains when compared with HCM (Richand et al., 2007).

A speckle-tracking echocardiography (STE) analysis shows a different pattern of myocardial deformation between endurance and strength athletes' heart: while global radial strain (GRS) is similar, GLS is lower in runners and global circumferential strain (GCS) is lower in bodybuilders (Szauder et al., 2015).

Finally, STE shows reduction of longitudinal, circumferential, and radial strains and also reduction and delay of peak twisting in triathletes soon after ultra long-duration exercises (Douglas et al., 1990) (**Fig. 4**).

Using three-dimensional (3D) echocardiography Caselli et al. showed LV end-diastolic volumes and mass increases in athletes compared to untrained controls, with preserved LV systolic function; male gender and endurance disciplines had the highest impacts on LV end-diastolic volume and mass (Caselli et al., 2011).

Athlete's heart is characterized by harmonic LV remodeling, differently from patients with hypertrophic or dilated cardiomyopathy. De Castro et al. measured LV remodeling index (LVRI) to describe the pattern of LV remodeling in athletes: athletes' LVRI was similar to that of controls, suggesting that the LV remodeling associated with intensive athletic conditioning does not alter LV geometry (De Castro et al., 2006).

Left Atrium

In a large population of elite athletes, mild left atrial enlargement is relatively common and may be identified as a physiologic adaptation to exercise conditioning. Pelliccia et al. (2005) stated that enlarged left atrial dimension greater than or equal to 40 mm was relatively common in athletes (20%), with the upper limit of 45 mm in women and 50 mm in men, distinguishing physiologic cardiac remodeling from pathologic cardiac conditions. Moreover a mild enlargement of left atrial volume index (LAVi) is relatively common in athlete's heart: D'Andrea et al. (2010) analyzed 615 consecutive elite athletes 370 endurance versus 245 strength-trained and identified a mild enlarged LAVi (29–33 mL/mq) in 150 athletes (24.3%) and a moderate enlarged LAVi (greater or equal to 34 mL/mq) only in 20 (3.2%), all male athletes. Lavi was significantly greater in endurance athletes.

Left atrial myocardial deformation assessed by strain is normal in competitive athletes compared to sedentary controls and hypertensive patients, and it is closely associated with functional capacity.

Especially in middle-aged male athletes with a history of intensive long-term endurance training, left atrial remodeling is associated with a higher risk of atrial fibrillation (D'Andrea et al., 2016).

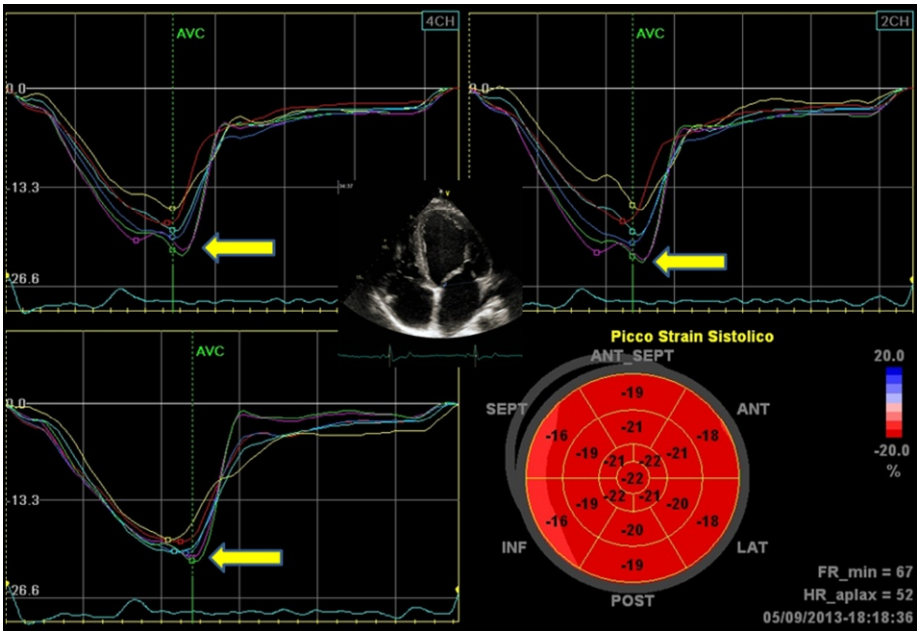

Fig. 4 Automated function imaging (AFI) of left ventricular 2-D strain of endurance athlete, showing normal longitudinal regional myocardial deformation despite left ventricular hypertrophy (arrows) (Douglas et al., 1990).

Right Ventricle

Endurance exercise is associated with cardiac remodeling of the right ventricle (RV), while strength training has minimal impact on RV function. Structural and functional recovery of RV changes in elite athletes might be incomplete after a detraining period (D'Andrea et al., 2009). The right heart (RH) clearly participates in the process of enlargement of the athlete's heart, with an increase in internal diameters and thickness of its free walls.

D'Andrea et al. (2003) documented that RH measures were all significantly greater in highly trained endurance athletes, compared to age and sex-matched, strength-trained athletes.

Resting RV global systolic function, measured by fractional area change (FAC) and Tricuspid Annular Plane Systolic Excursion (TAPSE), may be lower in endurance athletes compared with nonathletic controls. The reduction is more pronounced in the presence of higher RV dilation (D'Andrea et al., 2013).

D'Andrea et al. (2012) identified comparable 2D and 3D RV systolic indexes between endurance athletes and controls. In this setting, a mild reduction in global RV function could be considered a physiological consequence of RV dilation, since an efficient stroke volume will be reached with higher end-diastolic volumes and therefore at lower ejection fraction. On the other hand, a severe reduction in RV global systolic function should be considered an abnormal finding even among athletes (**Fig. 5**).

In athlete's heart RV characteristics can resemble those found in ARVC: in ARVC the enlargement of the RV cavity involves both RV inflow and outflow and may be associated with RV wall segmental morphological and functional abnormalities; in athletes RV enlargement involves only the inflow tract and systolic function is typically normal (Sen-Chowdhry et al., 2004).

The RV is more susceptible than the LV to prolonged exercises, with dysfunction after long-term endurance training (Neilan et al., 2006).

D'Andrea et al. (2010) observed RV dilatation following an ultraendurance triathlon without changes of LV dimension, by using M-mode, 2D echo, and STE (reduction of longitudinal strain about 15% relative to baseline values).

High altitude training induces increased hypoxic pulmonary vasoconstriction and raised hematocrits due to polycythaemia: both changes contribute to raised pulmonary arterial pressure and RV hypertrophy. These RV adaptations are usually reversible in high-altitude sports athletes.

Concerning the pulmonary vascular hemodynamic, whose upper limit of normal was 40 mmHg, endurance-trained athletes show the highest values, compared with strength-trained athletes (D'Andrea et al., 2011).

Finally the inferior vena cava appears to be dilated in a study involving 58 endurance athletes (Goldhammer et al., 1999).

Athlete's Heart and Exercise

Exercise ECG

Dynamic exercise is associated with increased sympathetic drive and a reduction of vagal tone. Rhythm disturbances such as sinus bradycardia, sinus arrest, and wandering pacemaker, as well as the atrioventricular conduction defects, all disappear with exercise.

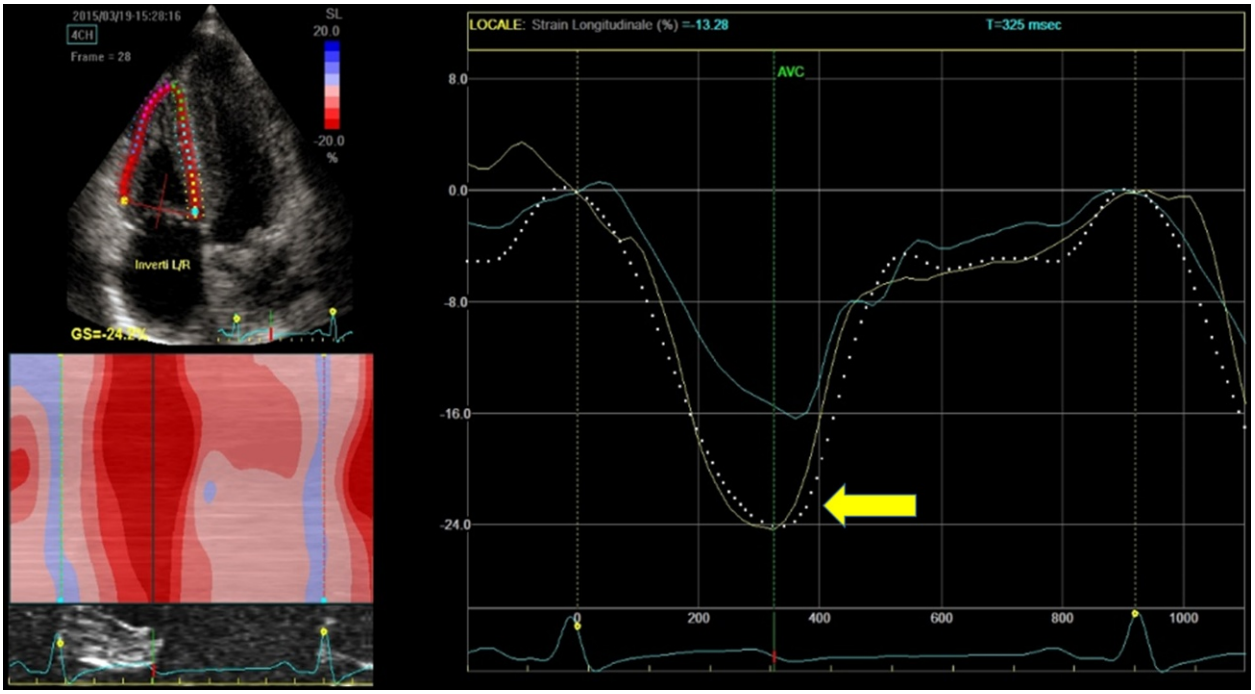

Fig. 5 Right ventricular 2-D strain of endurance athlete, showing normal myocardial longitudinal deformation (arrow) (D'Andrea et al., 2012).

Repolarization abnormalities also normalize with exercise. These observations lead to the conclusion that the described alterations are functional characteristics of athlete's heart and not structural abnormalities (Fagard, 2003).

Exercise Stress Echocardiography

Exercise stress echocardiography (SE) is a feasible, low cost, widely available, and safe technique and is better accepted than pharmacological stress echocardiography by athletes. It gives information about cardiac function, reserve, exercise capacity, and arrhythmias.

SE exercise in athletes may have three different clinically relevant targets besides assessment of ischemia: intraventricular gradients (detected by Continuous Wave (CW) Doppler examination of the Left Ventricular Outflow Tract (LVOT)), pulmonary hemodynamic (Systolic Pulmonary Arterial Pressure (SPAP), LV filling pressure), and evolution of mitral regurgitation (by color Doppler echocardiography), lung sonography for detection of pulmonary congestion (as B-lines). An exercise SE test in athletes can give valuable information about cardiac function, reserve, exercise capacity, and arrhythmias (Lancellotti et al., 2016).

Exercise stress echo is of particular interest in endurance-trained athletes with EF <45%–50% at rest to test if there is contractile reserve (EF increase >5%) during exercise; a considerable EF increase suggests low EF at rest to be related to low preload, and not to LV systolic dysfunction (Galderisi et al., 2015).

SE performed in athletes with LV hypertrophy complaining of shortness of breath or tendency to syncope; a suggestive finding could be an LVOT gradient >50 mmHg during or immediately after exercise in the presence of symptoms. The development of a gradient during exercise in symptomatic athletes is, however, a frequent finding and might help link the reported symptoms (postexercise dizziness or syncope) to a potential cause (the development of an intraventricular gradient) (Cotrim et al., 2010).

Finally stress lung ultrasound (B-lines detection during or immediately postexercise) is useful in two separate settings, HF and extreme physiology.

In healthy elite apnoea, high-altitude trekkers, scuba divers, and extreme athletes involved in sports such as triathlon or marathon, B-lines can be detected in the absence of symptoms of pulmonary oedema (Fagenholz et al., 2007).

Cardiopulmonary Exercise Testing

Cardiopulmonary exercise testing (CET) is a clinically useful technique to assess cardiorespiratory function and exercise capacity in elite athletes.

Previous studies indicated that peak oxygen consumption (pVO2) values in elite athletes usually range between 55 and 70 mL/kg/min and exceed predicted maximum values by as much as 50%; these athletes also have a high anaerobic threshold (AT) and oxygen pulse (O2P) (Sharma et al., 2000).

Anastasakis et al. (2005) compared CET metabolic parameters of 9 strength athletes, 20 endurance athletes, and 27 patients with nonobstructive HCM: endurance athletes had higher pVO2, percentage of predicted Vo2, anaerobic threshold, percentage of

Table 3 Cardiopulmonary exercise testing parameters in elite athletes

	Sharma et al. (2000)	*Anastasakis et al. (2005)*
pVO2 mL/kg/min	66.2 ± 4.1	58 ± 4.5
pVO_2 (% VO_2 max)	156.4 ± 6.8	136.40 ± 11.51
AT l/min	–	2.5 ± 0.4
AT (% VO_2 max)	61.6 ± 1.8	74.55 ± 10.99
O2P mL/beat	27.1 ± 3.2	25.3 ± 2.6
ΔVO2/ΔWR mL/min/W	–	9.2 ± 0.8
VE/VCo2 slope	–	22.3 ± 1.8

AT, anaerobic threshold; *AT%*, percentage of predicted anaerobic threshold; *O2P*, oxygen pulse at peak exercise; *pVo2*, peak oxygen consumption; *pVo2%*, percentage of predicted peak oxygen consumption; *VE*, minute ventilation; *VCo2*, carbon dioxide production; *Vo2*, oxygen consumption; *WR*, work rate.

predicted anaerobic threshold, and oxygen pulse than strength athletes and patients with HCM ($p < 0.05$). None of the CET parameters differed significantly between strength athletes and patients with HCM. The minute ventilation/carbon dioxide production (VE/VCo2) slope was decreased ($p < 0.001$) in the endurance athletes, but similar in patients with HCM and strength athletes. The ΔVo2/Δwork rate (WR) slope was not significantly different between the three groups (**Table 3**).

Sharma et al. (2000) demonstrated a separation in pVO2, AT and O2P between elite athletes with physiological LVH and patients with HCM and mild LVH: a pVO2 >50 mL/kg/min or >20% above the predicted VO2 max, an AT >55% of the predicted VO2 max, and an O2P >20 mL/beat would discriminate physiologic LVH from HCM.

The pVO2 is determined by peak cardiac output and the systemic arterio-venous oxygen difference (A-V): athletes obtain high pVO2 values through large increases in cardiac output and greater widening of the A-V during exercise. The augmentation of stroke volume (SV) is mainly responsible for the increase in cardiac output, while the increase in the A-V is due to the enhanced oxidative capacity within the exercising muscle, resulting from a high cellular mitochondrial concentration (Holloszy, 1967).

Analysis of the oxygen pulse profile (product of SV and A-V) provides evidence for the mechanisms responsible for the higher pVO2 in athletes: the O2P is higher throughout exercise in elite athletes with LVH compared with athletes with HCM, indicating a superior SV and A-V from the beginning to the end of exercise and confirming the physiological differences between the two entities outlined above.

Scharhag et al. analyzed right and left ventricular mass and function in male endurance athletes, demonstrating the correlation of left ventricular mass (LVM) and right ventricular mass (RVM) to maximal oxygen uptake (Vo2max) (Scharhag et al., 2002).

Conclusions

Elite athletes have a physiological remodeling of cardiovascular structures, with structural, functional, and electrical characteristics, caused by intensive and competitive training.

Two main models of sport adaptation of athlete's heart are eccentric hypertrophy, typical of endurance training, and concentric hypertrophy, usual of strength training.

Many instruments, as ECG and echocardiography, are useful to study characteristics of elite athlete's heart and to distinguish the physiological training adaptations of cardiac structures from pathological conditions.

Future improvement in differentiating normal and abnormal cardiac features in athletes is essential to recognize at early-stage cardiac disorders and reduce sudden cardiac death risk.

Introduction

Heart failure remains a highly prevalent and morbid disease. Because of its large public health impact, it has been the focus of avid research for the last several decades. Management has evolved significantly in that time with high-quality evidence demonstrating mortality and quality of life benefits of many pharmacologic and nonpharmacologic interventions (Yancy et al., 2013). In spite of these advances, the three most important patient outcomes in heart failure, namely mortality, hospitalization, and quality of life remain poor. Upon diagnosis, the 5-year life expectancy is 50% (Bui et al., 2011). Heart failure continues to be among the leading causes of hospitalization for patients 65 and older (Hall et al., 2012). There are still many gaps in evidence requiring providers to make clinical decisions based on expert opinion and common sense. However, it is also known that providers are significantly under-prescribing guideline-directed therapies to patients (Mosalpuria et al., 2014).

Given the high prevalence of disease, medical complexity, high hospitalization, and mortality rates of patients with heart failure, in addition to the limited time and resources of providers, outpatient management is challenging. It has been observed that patients cared for by internists are less likely to be on guideline-directed medical therapy (GDMT) than patients cared for by cardiologists (Mosalpuria et al., 2014). This may reflect less familiarity with recommended drugs and concerns about adverse effects. It also suggests that wider dissemination of easily accessible clinical practice guidelines with specific suggestions for safely implementing medication use may improve prescribing habits.

With these considerations in mind, the aim of this review is twofold: (1) help providers improve adherence to guideline-directed care by providing detailed information and practical strategies for implementation and (2) offer practical guidance concerning common management decisions that reflects expert opinion when high-quality evidence is lacking.

Patient Assessment

Heart failure is a clinical syndrome, defined by signs and symptoms that can be caused by dysfunction of virtually any aspect of the heart. However, the majority of heart failure cases are caused by impairment of the left ventricle's ability to fill or eject blood (Yancy et al., 2013). The underlying etiology of heart failure must be identified at diagnosis so that the disease process can be treated and progression can be slowed. Because heart failure with reduced ejection fraction (HFrEF) and heart failure with preserved ejection fraction (HFpEF) are importantly different with regard to demographics, prognosis, and response to therapy, evaluation of ejection fraction is an important branch point in diagnosis and treatment (Yancy et al., 2013). **Table 1** offers the diagnostic cutoffs for HFrEF and HFpEF offered by the AHA/ACC guidelines.

NYHA functional class is another important categorization for standardized clinical assessment of patients with heart failure. It is a simple tool that allows clinicians to communicate the patient's current condition based on the severity of symptoms. Although it relies on subjective information that is based on the patient's report and physician's interpretation of symptoms, it has been shown to correlate with objective measures including the 6 min walk test (Yap et al., 2015). More importantly, it is known from the randomized control trial (RCT) data investigating ACE-inhibitors that NYHA class is a powerful predictor of mortality in HFrEF (Swedberg and Kjekshus, 1988; Cohn et al., 1987) and there is retrospective evidence that it is predictive of mortality in the HFpEF population as well (Ahmed et al., 2006).

The RCTs that underlie the clinical practice guideline recommendations regarding heart failure treatment generally base their inclusion criteria on these definitions. Therefore, selecting the appropriate therapy in patients with heart failure requires evaluation of both a patient's ejection fraction and NYHA class upon diagnosis (**Tables 1** and **2**).

Essentials of the Clinic Visit

Monitoring Clinical Indices

Patient behaviors and understanding of prognosis, medications, and self-care behaviors should be evaluated at every visit. This serves to identify gaps in patient knowledge as well as help patients troubleshoot areas of difficulty with adherence.

Given the prevalence of comorbidities among patients with heart failure, medication review is particularly important not only to ensure appropriate use of heart failure medications, but also address polypharmacy and screen for important medication interactions and contraindications. For example, it is not uncommon for a patient with heart failure to assume taking non-steroidal anti-inflammatory drugs (NSAIDs) for arthritis is safe because it can be purchased without a prescription.

Table 1 Definitions of HFrEF and HFpEF

Ejection fraction (%)	*Classification*	*Description*
≤40	Heart failure with reduced ejection fraction (HFrEF)	Formally referred to as systolic HF
≥50	Heart failure with preserved ejection fraction (HFpEF)	Formally referred to as diastolic heart failure
41–49	HFpEF, borderline	Likely have elements of mild systolic dysfunction and diastolic dysfunction. More research needed to define prognosis and treatment in this group
>40	HFpEF, improved	Include the subset of patients that had once had HFrEF with improvement in EF. Further study is necessary to delineate prognosis and effective treatment in this group

Adapted from AHA/ACC 2013 Guidelines.

Table 2 NYHA Functional Classification

I	No limitations of physical activity
II	Slight limitation of physical activity. Comfortable at rest but symptomatic with activities of daily living
III	Marked limitation of physical activity. Comfortable at rest but symptomatic with less exertion than required for activities of daily living
IV	Symptoms at rest

Adapted from AHA/ACC 2013 Guidelines.

Symptoms

Symptoms of decompensation (e.g., decreased exercise tolerance, orthopnea, worsening dyspnea, increased abdominal girth) and medication side effects and toxicity (e.g., dizziness with standing) should be evaluated at every clinic visit. Patient education regarding symptoms can be performed during this assessment. Patients should be taught to recognize their individual signs of decompensation. Not all patients will develop lower extremity edema or an increase in weight Symptom recognition must be patient-centered.

Signs

Signs of decompensation, dehydration, and medication side effect should be evaluated at every visit.

This includes checking heat rate and rhythm, blood pressure both supine and standing, JVP, pulmonary and cardiac auscultation, abdomen, lower extremities and weight.

Investigations

Laboratory values including creatinine, potassium, magnesium, and sodium should be checked every 3–6 months once the patient is on a stable regime. A complete blood count to check for anemia can be performed routinely once annually. Chest radiograph, cardiac enzymes, and echocardiogram should be performed upon clinical change. The use of basic natriuretic peptide in the monitoring of chronic heart failure is controversial. It is not currently recommended by the AHA/ACC, however RCTs evaluating its utility in chronic heart failure patients are ongoing (Okwuosa et al., 2016) (**Table 3**).

Pharmacological Treatment of Heart Failure

In patients with HFrEF, there are multiple guideline-directed pharmacologic therapies that have a demonstrated mortality benefit. All of these drugs work by addressing the neurohormonal derangements seen in HFrEF. In spite of their demonstrated benefits, it is known that only a fraction of eligible heart failure patients are prescribed these life-prolonging medications (Mosalpuria et al., 2014). Guidelines are much less specific regarding pharmacologic management of HFpEF which represents 50% of patients with heart failure. Although patients with HFpEF have slightly better prognosis than those with HFrEF, (Owan et al., 2006) it is known that their hospitalization rate and quality of life are equally poor (Hoekstra et al., 2011). Therefore, efforts to encourage better adherence to treatment recommendations by providers and patients alike should be undertaken for all patients with heart failure. With this in mind, we offer a review of the medications currently recommended by the AHA/ACC and ESC offering specifics regarding indications, contraindications, and strategies for monitoring in order to address potential concerns about appropriate use by providers who may have limited experience using these medications.

Currently, there are five classes of medications that have demonstrated survival benefit through large high-quality RCTs in the HFrEF population and have therefore been given a Class I recommendation by the ESC and AHA/ACC: angiotensin-converting enzyme inhibitors (ACE-inhibitors), angiotensin receptor blockers (ARBs), aldosterone receptor antagonists (ARAs), beta-blockers (BBs), and angiotensin receptor-neprilysin inhibitors (ARNIs). **Table 4** provides a list of these medications in addition to specific indications, contraindications, common adverse effects, target doses, and strategies for safe titration and monitoring (Yancy et al., 2013; Paul and Page, 2016; McMurray et al., 2014; McIlvennan and Page, 2016; Swedberg et al., 2010).

Table 3 Checklist of outpatient clinic assessment*

Symptoms	*Frequency*
Dyspnea, orthopnea, paroxysmal nocturnal dyspnea, decreased exercise tolerance, chest pain, lower extremity swelling, increasing abdominal girth	Every visit
Physical exam	
HR, BP, weight, JVP, cardiac auscultation, abdomen, lower extremities	Every visit
Investigations	
CBC	Annually
Electrolytes/creatinine	2–3 months
Echocardiogram	Clinical suspicion, worsening symptoms
Cardiac enzymes	Clinical suspicion
Chest X-ray	Clinical suspicion
EKG	Clinical suspicion
Medication review	Every visit
Patient education	
Symptom recognition	Every visit
Medication reconciliation/education	Every visit
Exercise	Every visit
Diet	Every visit
Advanced directive	Progression of disease

*Aspects adapted from Nicholis et al., 2007.

Table 4 Drugs that decrease morbidity and mortality in HFrEF

	Common drugs in the class with initial and target doses	[a]*Class Ia ACC/AHA recommendation*	*Contraindications*	*Common adverse effects*	*How to titrate*	*Monitoring*
Angiotensin-converting enzyme	Lisinopril Initial dose 2.5–5 mg daily Target dose 20–40 mg daily Enalapril Initial dose 2.5 bid Target dose 10–20 mg bid	Recommended in all patients with HFrEF and current or prior HF symptoms to reduce morbidity and mortality	Angioedema' Cr > 2.5 mg/dL, pregnancy, bilateral renal artery stenosis, hyperkalemia (K > 5.0 meq/L)	Cough, Hyperkalemia, neutropenia, renal dysfunction, angioedema, hypotension. Dysgeusia	Increase at intervals no less than 2 weeks to the target dose based on blood pressure and renal function	Serum, renal function, CBC, blood pressure
Angiotensin receptor blocker	Losartan Initial dose: 25–50 mg daily Target dose 50–150 mg daily Valsartan Initial dose 20–40 mg bid Target dose 160 mg bid Candesartan Initial dose 4–8 mg daily Target dose 32 mg daily	Recommended in patients with HFrEF who are ACE-inhibitor intolerant (e.g., cough, angioedema)	Angioedema Cr > 2.5 mg/dl, pregnancy, bilateral renal artery stenosis, hyperkalemia (K > 5.0 meq/L),	Hyperkalemia, neutropenia, renal dysfunction, hypotension	Same as ACE-inhibitors	Same as ACE-inhibitors
Aldosterone receptor antagonists	Spironolactone Initial dose 12.5–25 mg daily Target dose 25 mg daily or bid Eplerenone Initial dose: 25 mg daily Target dose 50 mg daily	Recommended in patients with NYHA class II–IV and who have a LVEF <35% unless contraindicated; recommended in patients with NYHA class II with a history of prior CV hospitalization or elevated natriuretic peptide levels	Serum creatinine <2.5 mg/dL in men and <2.0 mg/dL in women; eGRF <30 mL/min/1.72 m^2)	Gynecomastia (with spironolactone), hyperkalemia, renal dysfunction	Increase dose every 2 weeks based on serum potassium and renal function; potassium supplements may need to be reduced or discontinued	
Close monitoring of potassium and serum creatinine should be checked in 3 days of initiation and at 1 week and at least monthly for the first 3 months; the risk of						

Table 4 (Continued)

	Common drugs in the class with initial and target doses	*Class Ia ACC/AHA recommendation*	*Contraindications*	*Common adverse effects*	*How to titrate*	*Monitoring*
	hyperkalemia is increased with higher doses of ACE-inhibitors and in diabetics					
Beta-blockers	Bisoprolol Initial dose: 1.25 mg daily Target dose: 10 mg daily Carvediolol Initial dose: 3.125 mg BID Target dose 25 mg BID; 50 mg BID for patients >85 kg Metoprolol succinate Initial dose: 12.5–25 mg daily Target dose: 200 mg daily	Recommended for all patients with current or prior symptoms of HFrEF unless contraindicated	Acute decompensated heart failure, 2nd or 3rd degree heart block without a pacer, bronchospastic disease	Fatigue, bradycardia, hypotension	Increase dose every 2 weeks based on heart rate, blood pressure, and weight	Close monitoring of heart rate, daily weights, and blood pressure
Angiotensin-neprilysin inhibitors	Sacubitril/valsartan Initial dose dependent on initial ACE-inhibitor or ARB dose[b] Target dose 97/103 mg BID	Recommended as replacement of an ACE-inhibitor or ARB in patients with chronic HFrEF NYHA class II-III who tolerate an ACE-inhibitor or ARB	Concomitant ACE-inhibitor or aliskiren, history of angioedema with prior ACE-inhibitor or ARB use, pregnancy, severe hepatic dysfunction (Child-Pugh Class C)	Hypotension, hyperkalemia, angioedema, renal dysfunction	Increase dose every 2 weeks based on blood pressure, renal function, and serum potassium	Same as ACE-inhibitors
Vasodilators	Hydralazine/Isosorbide (Bidil) Initiate dose: 37.5 mg/20 mg (1 pill) TID Target dose: 2 pills TID	Recommended for self-described African Americans with NYHA class III-IV HFrEF receiving optimal therapy with an ACE-inhibitor or ARB and a BB, unless contraindicated	Concomitant use of phosphodiesterase type-5 inhibitors (i.e., avanafil, sildenafil, tadalafil, vardenafil)	Headache, dizziness, flushing, tachycardia, drug-induced lupus (hydralazine)	Increase dose every 1–2 weeks based on blood pressure and tolerability	Blood pressure, heart rate, CBC

ACC: American College of Cardiology, *ACE*: angiotensin-converting enzyme, *AHA*: American Heart Association, *ARA*: aldosterone receptor antagoinists, *ARB*: angiotensin receptor blocker, *BID*: twice daily, *eGFR*: estimated glomerular filtration rate, *CBC*: complete blood count, *HFrEF*: heart failure with reduced ejection fraction, *NYHA*: New York Heart Association, *TID*: three times daily.

Enalapril $\leq$10 mg/day or equivalent or valsartan $\leq$160 mg/day or equivalent, or no ACE-inhibitor or ARB: Washout ACE-inhibitor or ARB for 36 h, then begin sacubitril/valsartan 24/26 mg daily.

Severe renal dysfunction (eGFR $<$ 30 mL/min/1.73 m^2) or moderate hepatic dysfunction.

(Child-Pugh Class B): Washout ACE-inhibitor or ARB for 36 h, then begin sacubitril/valsartan 24/26 mg daily.

[a]Strongest recommendation, benefit greatly outweighs risks.

[b]Enalapril $>$10 mg/day or equivalent or valsartan $>$160 mg/day or equivalent: Washout ACE-inhibitor or ARB for 36 h, then begin sacubitril/valsartan 49/51 mg daily.

Drugs With Demonstrated Mortality Benefit in HFrEF

Angiotensin-converting enzyme inhibitors, Angiotensin Receptor Blockers and Beta-Blockers

Angiotensin-converting enzyme inhibitors and ARBs work by counteracting the renin angiotensin system thereby reducing cardiac remodeling and fluid retention leading to improved symptoms. In placebo-controlled trials, ACE-inhibitors have been shown to significantly reduce morbidity and mortality (see **Appendix 1**). Additionally, when compared with captopril, losartan was just as effective in reducing all-cause mortality, sudden death, and hospitalization. Due to a lack of effect on bradykinin, ARBs are indicated in patients who cannot tolerate ACE-inhibitors due to cough or angioedema. Use of ACE-inhibitors and ARBs together is not routinely recommended due to lack of mortality benefit and risk of hyperkalemia and hypotension (Yancy et al., 2013).

It is important to note that only certain beta-blockers have been recommended for use in patients with HFrEF consisting of bisoprolol, carvedilol, and metoprolol succinate (**Appendix 2**). These beta-blockers have been shown to reduce mortality and are thought to offer cardio protection by down regulating the sympathetic nervous system, have been shown to reduce remodeling, as well as improve ejection fraction (Yancy et al., 2013) (see **Appendix 2**) (Yancy et al., 2013).

All patients with HFrEF should be treated with an ACE-inhibitor or an ARB and a guideline-based beta-blocker unless there is a documented contraindication. Documentation of both classes of medication is a *JACHO core measure* (JACHO, 2017). This indicates that current standard of care requires providers to ensure patients who can tolerate these medications receive them and that they are titrated to as close to the target dose as the patient is able to tolerate.

Aldosterone receptor antagonists, Hydralazine/Isosorbide and Angiotensin Receptor-Neprilysin Inhibitors

ARAs, hydralazine/isosorbide, and ARNIs are the three remaining drug interventions that have a demonstrated mortality benefit in selected HFrEF populations and currently have Class 1 indications (Yancy et al., 2013; Yancy et al., 2016). These medications are considered "add on" therapy to the patient already on ACE/ARB and BB (see **Appendices 1** and **2**). There are circumstances in which these medications are given to patients without ACE/ARB and/or BB if ACE/ARB and/or BB are not tolerated.

The combination of hydralazine and isosorbide dinitrate has demonstrated mortality benefit in African Americans with heart failure receives a class 1 recommendation for persistently symptomatic Class III–IV African American patients already on an optimal dose of an ACE-inhibitor and BB (Yancy et al., 2013) (see **Appendix 1**). In patients who cannot tolerate an ACE-inhibitor or ARB (e.g., pregnancy, renal dysfunction), the combination of hydralazine and isosorbide dinitrate can be substituted for the ACE-inhibitor or ARB (Yancy et al., 2013).

In HFrEF, the hormone aldosterone has been associated with several negative pleotropic effects within the heart, kidney, and vasculature. In the heart, aldosterone stimulates growth-promoting and profibrotic effects on myocytes, which could lead to ventricular remodeling, myocardial fibrosis, and premature myocyte cell death. Outside of its effects on the reabsorption of sodium and water in the kidney, stimulation of mineralocorticoid receptors in the renal cortex can lead to ischemic injury, mesangial cell proliferation, and nephrosclerosis. Two ARAs are currently available: spironolactone, a nonselective and eplerenone, a selective ARA. Both are recommended in patients with NYHA class II to IV who have an LVEF of 35% or less, an estimated glomerular filtration rate exceeding 30 mL/min/1.73 m^2, and a serum potassium less than 5 mEq/L to reduce morbidity and mortality. In addition, ARAs are recommended to reduce morbidity and mortality after an acute myocardial infarction in patients who have an LVEF of 40% or less who develop symptoms of heart failure or who have a history of diabetes (Yancy et al., 2013). ARAs can be very effective in removing fluid from the periphery especially in combination with loop diuretics.

ARNIs are a new class of medications for heart failure. They work by up regulating several vasoactive peptides including naturetic peptide and bradykinin, thereby decreasing vasoconstriction, sodium retention, and cardiac remodeling. Sacubitril/valsartan demonstrated a mortality benefit over enalapril (see **Appendix 2**). The AHA/ACC were updated its 2016 Heart Failure Management Guidelines in order to incorporate recommendations with regard to its use. The guidelines now recommend ARNIs replace an ACE-inhibitor or ARB in patients with symptomatic HFrEF that are able to tolerate ACE-inhibitors and ARBs. Importantly ARNIs should not be used within 36 h of the last dose of an ACE-inhibitor due to the risk of angioedema. This requires extra attention when switching a patient from an ACE-I to an ARNI in that the patient will need to be completely off ACE at least 36 h before switching to the ARNI. A clinician's oversite to assure this is done correctly is required. ARNIs should not be administered to patients with a history of angioedema. There is a lower incidence of renal dysfunction and hyperkalemia compared to enalapril with ARNI. However, hypotension is a major concern when initiating sacubitril/valsartan, which can be particularly concerning in the older adult (McMurray et al., 2014; Desai et al., 2017). Since central neprilysin is responsible for degradation of Aβ plaques which are associated with dementia and Alzheimer disease, controversy exists regarding the effect of ARNIs on increased neurocognitive disorders (Campbell, 2017).

Other Recommended Agents

Loop diuretics are a class 1 recommendation in patients with overload for relief of symptoms. Although they have not been shown to improve mortality they have been shown to improve exercise capacity (Ponikowski et al., 2016a). Furosemide can be started once or twice daily and titrated to maintain a patient's dry weight. Patients and care givers can be taught to use a flexible diuretic regime that they can titrate to weight or symptoms (Ponikowski et al., 2016a). Patients with HFrEF do not need to take a loop diuretic every day, or perhaps not at all. The use of loop diuretics should be tailored for the individual patient. Reassessment of the use of loop diuretics should take place at every visit and doses/frequency adjusted if needed. Close monitoring of volume status and electrolytes is recommended for all patients on diuretics as fluctuations in fluid and salt intake can disrupt euvolemia leading to hospitalization for decompensated heart failure as well as acute kidney injury and electrolyte disturbance from over diuresis.

Diuretic resistance is a commonly occurring problem often caused by gut edema or worsening renal function. Switching to bumetanide or torsemide is sometimes helpful as these two agents have better oral bioavailablity than furosemide allowing for a more predictable diuretic response (Yancy et al., 2013). Another strategy for improving diuresis in patients already on a loop diuretic is to add a thiazide like metolazone, although this approach requires close monitoring as overdiureses and electrolyte abnormalities is a common problem (Redfield, 2016). Metolazone can be used as an "emergency" diuretic in addition to the loop diuretic but daily dosing is not recommended.

Ivabridine

Another new class of medications are those that reduce heart rate. In patients with HFrEF, resting heart rate is a strong predictor of adverse outcomes. All-cause mortality, cardiovascular mortality, and HF hospitalizations are directly associated with heart rate alteration, and all increase progressively as heart rate rises above 70 beats per minute (bpm) (Ahmadi-Kashani et al., 2009). Ivabridine, an I_f channel blocker, is a sinus node inhibitor which primarily effects chronotropy and not inotropy. Ivabridine has been shown to reduce hospitalizations thereby earning IIa B-R rating for symptomatic HFrEF patients in normal sinus rhythm that are already on a max tolerated beta-blocker or have contraindication to beta blockade (Yancy et al., 2016). Ivabradine should be avoided in patients with acute decompensated heart failure, systolic blood pressures <90 mm Hg, second or third degree AV block without a pacemaker, and a history of atrial fibrillation (Bohm et al., 2010).

Digoxin

Although digoxin has no known mortality benefit, it has been shown to decrease the frequency of hospitalization in patients with HFrEF, thereby earning it a IIA level B recommendation from the AHA which deems it reasonable for patients who are on guideline recommended therapy but still symptomatic (Digitalis, 1997; Batterman and De Graff, 1947). Its inotropic and chronotropic effects make digoxin most useful in HFrEF patients with relative hypotension and atrial fibrillation. Given its narrow therapeutic range and renal clearance providers should watch for toxicity. Serum digoxin levels should be checked within 7 days of initiating therapy with a goal range between 0.5 and 0.9 ng/mL. As digoxin is cleared renally, dose adjustments should be made in patients with renal dysfunction (Yancy et al., 2013). Patients over the age of 75 rarely need more than every-other-day dosing. Withdrawal of digoxin in these patients can result in decompensation and should be done only when absolutely necessary and with close follow-up.

In their 2016 Management Guidelines, the ESC provided a rational approach to the pharmacotherapy of patients with HFrEF (Ponikowski et al., 2016a) (**Fig. 1**).

Pharmacological Treatment of HFpEF

In spite of many RCTs to identify medications that significantly improve mortality in HFpEF patients, none have been identified. Data suggest that HFpEF patients are hospitalized with the same frequency as HFrEF patients but that they are hospitalized and die more often from comorbid conditions than HFrEF patients (Owan et al., 2006). The classic demographic for the patient with HFpEF is an older woman with longstanding hypertension. The pharmacologic management of HFpEF focuses on optimal management of comorbidities. In addition to hypertension, rate control in atrial fibrillation is particularly important in HFpEF so that diastolic filling of the left ventricle is maximized.

Loop diuretics, for symptom and volume control, remain the only Class 1 recommended drug in HFpEF. Careful titration is important as symptoms can easily occur from over diuresis due to preload dependence. Although the recent TOPCAT trial which investigated the utility of spironolactone in HFpEF management did not demonstrate a mortality benefit, it did show a reduction in hospitalization (Pitt et al., 2014). Clinically, spironolactone can be very helpful to reduce volume overload in these patients.

Management of Important Co-morbidities in Heart Failure

Blood pressure management

Optimal blood pressure management is essential in the management of both HFrEF and HFpEF. From a cardiovascular perspective, blood pressure should be kept as low as is tolerated in HFrEF patients, in order to unload a weakened heart. However, in elderly patients, this goal must be tempered with fall risk and a propensity for orthostasis. Because there are several agents indicated in HFrEF that lower blood pressure, it is often difficult to attain target doses due to hypotension leading to both symptoms and renal dysfunction. Many HFrEF patients are not able to tolerate an ACE-inhibitor or ARB in addition to their BB due to renal dysfunction. Providers must consider all aspects of the patient when titrating GDMT in order to avoid iatrogenic complications.

Given the lack of life extending drugs in the management of HFpEF, optimal management of comorbidities, hypertension being among the most important, is the cornerstone of management. The Eighth Joint National Committee guidelines do not offer blood pressure targets for HFpEF but do recommend a target of less than 150/90 mm Hg for patients 60 or older and less than 140/90 mm Hg in patients with chronic renal insufficiency and proteinuria (James et al., 2014). The most recent landmark trial investigating blood pressure targets, SPRINT, demonstrated a mortality benefit at a target of less than 120 systolic however, patients with heart failure were excluded from this trial (Wright et al., 2015).

Anemia

Initial assessment of patients with heart failure should include screening for anemia given the high incidence in this population (Hindricks et al., 2014). Iron-deficiency anemia is associated with decreased exercise capacity in heart failure

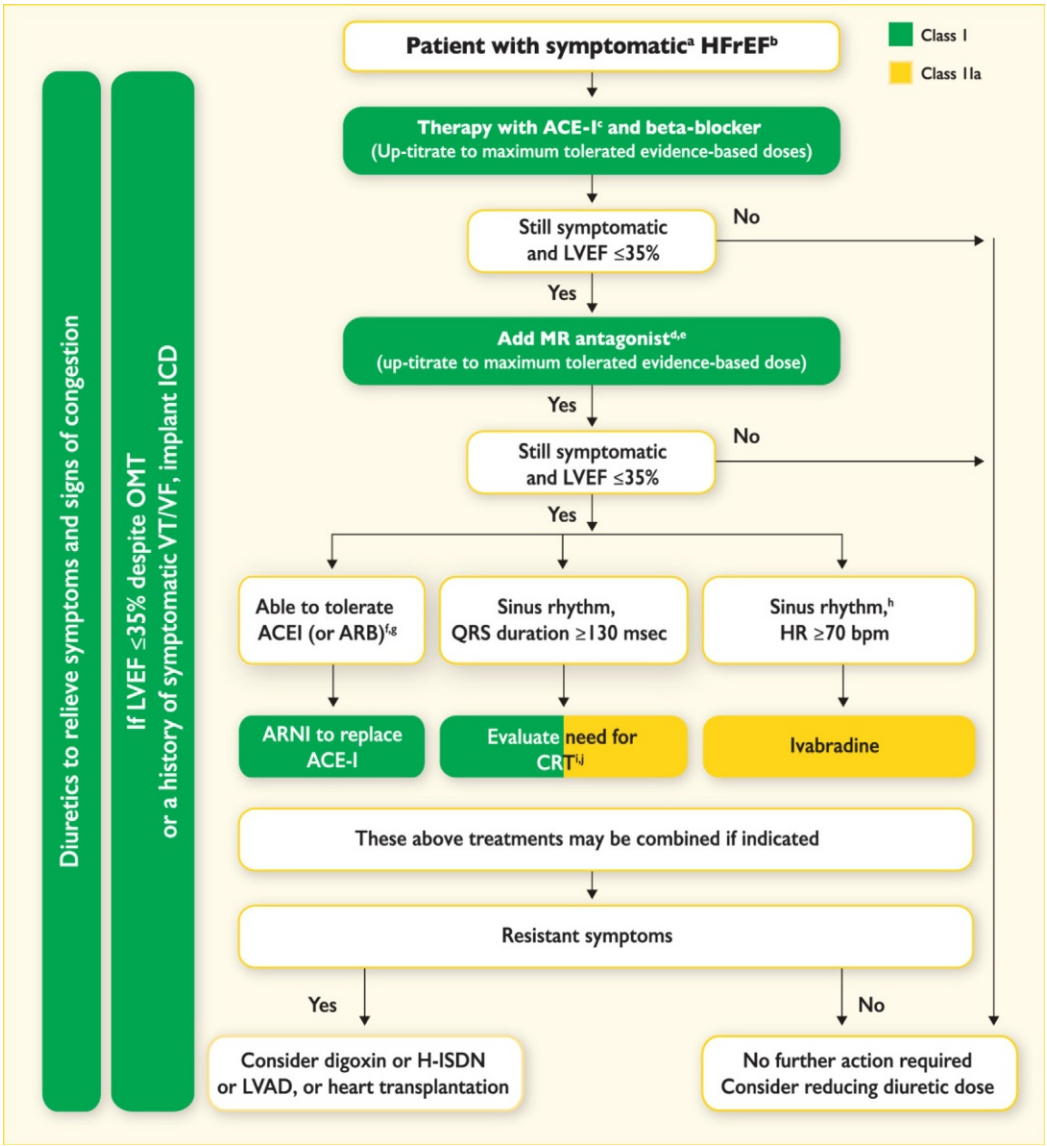

Fig. 1 Therapeutic algorithm for the patient with symptomatic HFrEF. Used with permission for Reference (ESC 2016 Guidelines). *Green* indicates a class I recommendation from the ESC; *yellow* indicates a class IIa recommendation from the ESC. *ACEI* = angiotensin-converting enzyme inhibitor; *ARB* = angiotensin receptor blocker; *ARNI* = angiotensin receptor-neprilysin inhibitor; *BNP* = B-type natriuretic peptide; *CRT* = cardiac resynchronization therapy; *HF* = heart failure; *HFrEF* = heart failure with reduced ejection fraction; *H-ISDN* = hydralazine and isosorbide dinitrate; *HR* = heart rate; *ICD* = implantable cardioverter defibrillator; *LBBB* = left bundle branch block; *LVAD* = left ventricular assist device; *LVEF* = left ventricular ejection fraction; *MR* = mineralocorticoid receptor; *NT-proBNP* = N-terminal pro-B type natriuretic peptide; *NYHA* = New York Heart Association; *OMT* = optimal medical therapy; *VF* = ventricular fibrillation; *VT* = ventricular tachycardia. a = Symptomatic = NYHA Class II-IV. b = HFrEF = LVEF <40%. c = If ACE-inhibitor not tolerated/contraindicated, use ARB. d = If MR antagonist not tolerated/contraindicated, use ARB. e = With a hospital admission for HF within the last 6 months or with elevated natriuretic peptides (BNP > 250 pg/mL or NTproBNP > 500 pg/mL in men and 750 pg/mL in women). f = With an elevated plasma natriuretic peptide level (BNP ≥ 150 pg/mL or plasma NT-proBNP ≥ 600 pg/mL, or if HF hospitalization within recent 12 months plasma BNP ≥ 100 pg/mL or plasma NT-proBNP ≥ 400 pg/mL). g = In doses equivalent to enalapril 10 mg b.i.d. h = With a hospital admission for HF within the previous year. iCRT is recommended if QRS ≥ 130 ms and LBBB (in sinus rhythm). j = CRT should/may be considered if QRS ≥ 130 ms with non-LBBB (in a sinus rhythm) or for patients in AF provided a strategy to ensure biventricular capture in place (individualized decision).

patients (Wright et al., 2015) and the 2017 AHA/ACC/HFDA Management Guidelines now advise intravenous iron repletion as a Class IIb recommendation for patients with NYHA II and III HF with iron deficiency (ferritin <100 ng/mL or 100 to 300 ng/mL if transferrin saturation is <20%). Data from RCTs has suggested that IV iron replacement can improve both functional status and quality of life (Oyanguren et al., 2016; Feltner et al., 2014). Of note, uncertain evidence exists for oral iron repletion in the setting of anemia with heart failure. Additionally, the 2017 Guidelines recommend against erythropoietin-stimulating agents as the body of evidence suggests no benefit and possible harm due to increased risk of venous thromboembolism and stoke (Wright et al., 2015).

Sleep Disordered Breathing

Sleep disorders are a common comorbidity in the heart failure population with 60% having either central or obstructive sleep apnea (Rocha and Menezes Falcao, 2016). The AHA/ACC/HFSA 2017 Management Guidelines recently updated the recommendations to reflect new evidence related to the diagnosis and management of disordered breathing in patients with cardiovascular disease (Wright et al., 2015). The guidelines now deem a formal sleep assessment in patients with NYHA Class II–IV heart failure with suspicion of sleep-disordered breathing or excessive daytime sleepiness as reasonable (Class IIa) because of the importance of distinguishing obstructive from central sleep apnea (Wright et al., 2015). Continuous positive airway pressure (CPAP) is deemed reasonable (Class IIb) in patients with cardiovascular disease based on a recent high-quality RCT demonstrating an improvement in sleep quality, though no difference in the rate of cardiovascular events (Ponikowski et al., 2016c). An increase in mortality has been demonstrated in symptomatic HFrEF patients with central sleep apnea placed on nightly adaptive servo-ventilation and thus it now receives a Class III rating for harm (Wright et al., 2015).

Implantable Cardiac Devices

In addition to medications, certain implantable cardiac devices have been shown to offer mortality benefit in patients with HFrEF. Providers should be aware of guideline indications so that timely referral to an electrophysiologist can be made for placement.

Implantable Cardiac Defibrillators

Implantable cardioverter defibrillators (ICDs) are implantable devices that, depending on the configuration, are able to perform cardioversion, defibrillation, and pacing of the heart in the event of an arrhythmia. The devices are composed of a generator that is implanted in the subcutaneous tissues below the left clavicle and leads that travel from the generator to lodge in the right ventricular septum which is able to cardiovert or defibrillate if an arrhythmia occurs. There is high-quality evidence that ICDs prevent sudden cardiac death (SCD) in patients with both ischemic and nonischemic cardiomyopathy (Okwuosa et al., 2016). Current AHA/ACC guidelines (Yancy et al., 2013) give ICD placement a class IA recommendation for primary prevention of SCD in symptomatic HFrEF patients on optimal GDMT with an EF 35% or less at least 40 days post-MI or 90 days post-PCI or CABG. ICDs receive a Class IB recommendation for primary prevention in NYHA Class I patients on GDMT with an EF of 30% or less at least 40 days post MI. ICDs are not recommended for patients with a prognosis of less than 1 year.

Cardiac Resynchronization Therapy

In patients with significant conduction disease, disynchronous contraction of the left and right ventricles can lead to reduced forward flow and worsening of symptoms. Cardiac resynchronization therapy (CRT) in which both the left and right ventricles are paced has been shown to significantly improve exercise tolerance, ejection fraction, and quality of life in patients with significant systolic dysfunction and intraventricular conduction abnormalities (Okwuosa et al., 2016). CRT is achieved by placement of a biventricular pacing device similar to an ICD but instead of a single lead traveling to the right septum there is a second ventricular lead that travels through the coronary sinus and is lodged in the outer wall of the left ventricle. CRT currently holds an AHA/ACC Class 1A/B recommendation (Yancy et al., 2013) for symptomatic HFrEF patients on GDMT with EF of 35% or less in sinus rhythm with LBBB and QRS of 150 ms or greater.

Implantable Sensors

In an effort to improve outcomes, there have been recent trials investigating the use of implantable monitors that allow earlier detection of volume overload. The information from these implanted devices can be transmitted to providers electronically who can then titrate medications more quickly and frequently, thereby theoretically averting frank decompensation and hospitalization. The two trials that have demonstrated the utility of implantable sensing devices are the CHAMIPION and IN-TIME trials which investigated the use of intrapulmonary pressure monitoring and multiparameter monitoring in patients with ICDs, respectively (Abraham et al., 2016; Hindricks et al., 2014)

In the CHAMPION trial (Abraham et al., 2016), the Cardiomems device was implanted in the pulmonary arteries of study subjects and used to transmit pulmonary artery pressures to study investigators. The transmitted data was reviewed at least weekly and medications were adjusted based on the transmitted information. The device was approved by the FDA for use in chronic heart failure patients after demonstrating a significant reduction in heart failure-associated hospitalizations.

The IN-TIME study (Hindricks et al., 2014) population included HFrEF patients with ICDs. In the intervention group, abnormal telemetry data was transmitted to study investigators at which point weight, medication compliance, and heart failure symptoms were recorded. At 12 months, the mortality rate in the monitored group was lower than that of the control group.

Based on the results of the CHAMPION and IN-TIME trials, these two approaches have received a Class IIB recommendation by the ESC. Whether a provider uses this tool in caring for patients will depend on the resource environment. One of the challenges in using this technology in a real world setting is having the ability to acquire and follow-up on the available data quickly enough to improve outcomes.

Nonpharmacologic, Nondevice Interventions

Multidisciplinary programs

A multidisciplinary approach to the care of patients with heart failure, both HFpEF and HFrEF, has been shown to reduce mortality and readmission rates (Oyanguren et al., 2016; Feltner et al., 2014) and receives a Class IA recommendation by the ESC (Ponikowski et al., 2016a). Although there is heterogeneity among multidisciplinary interventions shown to be effective, key aspects consist of optimization of medical therapy, patient education that focuses on self-care including patient involvement in symptom monitoring, medication adherence, an exercise training (ET) regime, close follow-up and health-care access that allows for prompt assessment and invention when clinical changes occur.

Patient and caregiver education in self-care behaviors

Promoting self-care includes providing patients with information regarding self-monitoring of symptoms, medication adherence, exercise, diet, weight, alcohol consumption, and smoking cessation. There is growing evidence that patient education of self-care practices is an effective way to decrease hospitalization and mortality rates (Rocha and Menezes Falcao, 2016). Thus, a comprehensive patient education program is now considered an essential part of care in patients with heart failure and part of the major society guidelines (Yancy et al., 2013; Ponikowski et al., 2016b).

Time to discuss and clarify aspects of the disease process and management should be part of every clinic appointment. Providers should be prepared to operationalize their recommendations for patients. For example, providers should ensure that patients are weighing themselves in the same way at the same time every morning. Given the time constraints inherent in many physician clinic schedules, mid-level providers as well as pharmacists, physical therapists, and dieticians have become an essential part of many patient education and self-care programs (Mosalpuria et al., 2014). With each clinic visit, patients should receive clarification, coaching, and encouragement on these self-care behaviors. Providers should help patients identify and troubleshoot barriers to self-care.

In addition, a significant proportion of the heart failure population are older adults and cognitive impairment is common (Bressler et al., 2017). Strategies to help improve these patients' ability to adhere to self-care and medication regimes include frequent visits, written directions offered in large print, and importantly, engagement and education of a caregiver (**Tables 5** and **6**).

Behavior change

Even after receiving education regarding self-care, it is often difficult for patients to make the required changes in lifestyle. Given the impact of self-care on patient outcomes, research investigating how providers can effectively facilitate behavioral change is ongoing. Already there is promising data demonstrating that motivational interviewing is associated with improved adherence to self-care behaviors (Masterson Creber et al., 2016) and a decrease in hospitalizations among patients with heart failure (Riegel et al., 2016). Motivate-HF, a RCT designed to confirm the benefit and obtain a better estimate of the magnitude of effect is underway (Vellone et al., 2017). Given the growing evidence for its effectiveness in improving outcomes in patients with heart failure and other chronic diseases, coupled with the relative ease in attaining basic skill in motivational interviewing (Masterson Creber et al., 2015), we encourage providers to seek training and begin engaging heart failure patients in this technique.

Diet

Given one of the common causes of heart failure decompensation is dietary indiscretion, patient education regarding appropriate diet is important. While experts and major society guidelines agree that a low sodium diet is important for the majority of patients

Table 5 Essential goals of patient and caregiver education

Recognize signs and symptoms of early decompensation (which is often individualized) as well as symptoms of drug toxicity
Check and record BP and pulse
Check accurate daily weights (e.g., taken at the same time while wearing the same thing every day on an accurate scale)
Demonstrate an understanding of how to take all prescribed medications and the importance of not missing doses and obtaining refills on time. The provider should assess for rationing of medications and help the patient troubleshoot difficulty with adherence to a medication routine
Participate safely in regular physical activity or structured exercise training program
Impart skills that will allow patients to eat a low sodium diet (e.g., ensure they are able to interpret food labels and have a plan for avoiding convenient but high sodium foods like fast food)

Table 6 Strategies and tools to facilitate self-care

Screen for new barriers at every visit so that the provider can help troubleshoot
Create a learning environment that encourages questions and a feeling of empowerment
Ensure teaching is structured and systematic to help ensure all essential topics are covered
Ensure teaching is at appropriate literacy level and is culturally sensitive
Involve family members and caregivers in teaching sessions so that they can facilitate healthy behaviors
Help patients set realistic short-term goals for themselves
Involve multiple modalities (e.g., provide and encourage symptom, diet, and exercise journaling) and multidisciplinary individuals (e.g., provide referral to nutritionist, pharmacists, physical therapists, and nurses to provide additional education).

with heart failure, there is much controversy regarding exactly how much sodium constitutes a "low sodium" diet. This discrepancy reflects both a paucity of data and conflicting results. Although the current evidence is limited, AHA/ACC recommends a low sodium diet, less than 3 g per day for all symptomatic patients, and those with frequent heart failure exacerbations (Yancy et al., 2013). A careful diet history will help a provider determine if dietary indiscretion is an issue for an individual patient. Further complicating this issue is that patients with heart failure often have additional dietary restrictions secondary to comorbid diseases, like diabetes and chronic renal insufficiency making adherence to all recommendations impractical.

Fluid restriction while not routinely recommended is important in certain patients. Many patients experience excessive thirst due to the upregulation of the renin angiotensin system and antidiuretic hormone. A careful history will help a provider determine if intensification of hormonal blockade will benefit an individual patient in addition recommending limiting fluid intake to 1.5 L per day.

It is important for providers to discuss the details of how patients can adhere to these recommendations effectively. Asking the patient to keep a log of food and fluid consumption to discuss at clinic visits is helpful. Providers should also be mindful of the appropriate diet for a particular patient's comorbidities. Referral to a nutritionist is recommended in order to reinforce and further operationalize recommendations. It should be mentioned that in advanced disease, when goals of care become focused on palliation, dietary recommendations should be changed accordingly.

Exercise

The latest US (Yancy et al., 2013) and European (Ponikowski et al., 2016a) practice guidelines designate ET a Class IA recommendation for patients with stable HFrEF. Evidence underlying this recommendation includes results of HF-ACTION trial, the largest RCT to date evaluating the effects of exercise in HFrEF patients. When its results were adjusted for important prognostic factors, HF-ACTION showed that patients with HFrEF, who were receiving guideline-directed pharmacologic and device therapies plus a supervised home-based aerobic program, had lower rates of hospitalization, all-cause mortality, and better quality of life than patients receiving guideline-directed pharmacologic and device therapies alone (O'Connor et al., 2009). A meta-analysis of earlier smaller RCTs also demonstrated mortality benefit in patients with HFrEF randomized to ET (Piepoli et al., 2004).

Despite the established benefits of regular exercise in patients with HFrEF, only a small percentage of eligible patients are referred to cardiac rehabilitation (Haykowsky et al., 2016). In an effort to improve provider prescription habits, European Association for Cardiovascular Prevention and Rehabilitation have published a position paper (Piepoli et al., 2011) offering practical recommendations regarding how to implement safe and effective ET programs for heart failure patients. The first step in this approach is appropriate patient selection. Major Societal guidelines recommend ET for all clinically stable HFrEF patients, with clinical stability defined as "no recent ($\leq$6 weeks) or planned ($\leq$6 months) major cardiovascular hospitalizations or procedures." by the Centers for Medicare and Medicaid Services (CMS) (CMS, 2017).

Once clinical stability is established, patients must then be evaluated for contraindications to exercise in order to ensure safety. We offer a list of contraindications here (**Table 7**), as uncertainty among providers regarding which patients can safely engage in ET likely contributes to its under prescription. It should be emphasized that several studies, including HF-ACTION, have demonstrated the safety of ET in stable patients (O'Connor et al., 2009; Piepoli et al., 2004).

Exercise training prescriptions should include a clear description of intensity, duration, frequency, type of activity, and location. A rated perceived exertion scale and/or heart rate are recommended ways to quantify intensity. Experts endorse a goal of 30 min daily $\times$ 5 days a week of moderate activity, with a slow uptitration of intensity and duration guided by patients' symptoms and vitals as desirable to obtain and safe to pursue (Piepoli et al., 2011). Whether an individual patient should be monitored while engaging in ET will depend on a patient's risk of adverse events and comorbidities. For instance, patients with known exercise induced ventricular ectopy, supraventricular tachycardia, or baseline hypoxia may benefit from monitoring.

Cardiac rehabilitation receives an AHA/ACC Class IIA recommendation as there is evidence suggesting it improves functional capacity, exercise tolerance, quality of life, and mortality in stable heart failure patients (Yancy et al., 2013). Providers should be aware of the current trends in insurance coverage for cardiac rehabilitation in order to maximize the available resources for their patients. The Centers for Medicare & Medicaid Services (CMS) currently covers at least 6 weeks of cardiac rehabilitation for stable patients with left ventricular ejection fraction of less than 35% who have persistent symptoms (NYAH Class II–IV) despite 6 weeks of optimal heart failure therapy (CMS, 2017).

Presently, third party payers do not cover cardiac rehabilitation for patients with HFpEF. However, although less robust, there is evidence that ET training is beneficial in the HFpEF population as well. It has been shown to improve diastolic dysfunction as measured by echocardiogram (Pearson et al., 2017). In addition, a small pilot RCT, the EX-DHF trial, demonstrated that ET improves quality of life and exercise capacity in patients with HFpEF (Edelmann et al., 2011).

Adherence is known to be low in patients referred to ET (Piepoli et al., 2011). Thus, it is essential that ET programs are adapted to patients' preferences and lifestyles, in order to encourage participation.

While the benefits of a formal ET program are clear, it is important for providers and patients to realize that simply increasing the amount of daily physical activity and having a less sedentary lifestyle will likely provide clinical benefit. This is particularly important for the older adult whose mobility may be limited by comorbidities (e.g., arthritis, frailty) as well as patients struggling with behavioral change for whom a structured exercise program is too daunting a goal. Studies are ongoing to confirm the benefit of this common sense, expert endorsed approach.

Table 7 Summary of contraindications to (A) exercise testing and training exercise, (B) training, and (C) increase risk for exercise training

A. Contraindications to exercise testing and training exercise
Within 2 days of ACS
Untreated malignant cardiac arrhythmias
Decompensated heart failure
Uncontrolled hypertension
Advanced atrioventricular block
Acute myocarditis and pericarditis
Symptomatic aortic stenosis
Severe hypertrophic obstructive cardiomyopathy
Acute systemic illness
Intracardiac thrombus
B. Contraindications to exercise training
Progressive worsening of exercise tolerance or dyspnea at rest over previous 3–5 days
Significant ischemia during low-intensity exercise
Uncontrolled diabetes
Recent embolism
Thrombophlebitis
New onset atrial fibrillation or atrial flutter
C. Increased risk for exercise training
>1.8 kg increase in body mass over the previous 1–3 days
Continuous or intermittent dobutamine therapy
Decrease in systolic blood pressure with exercise
NYHA functional class IV
Complex ventricular arrhythmia at rest or with exertion
Supine resting heart rate of >100 b.p.m
Comorbidities limiting exercise tolerance

Adapted from Haykowsky, M. J., Daniel, K. M., Bhella, P. S., Sarma, S., Kitzman, D. W. (2016). Heart failure: Exercise-based cardiac rehabilitation: Who, when, and how intense? *The Canadian journal of cardiology*.**32** (10s2), S382–s387.

When to Refer to a HF and Advanced HF Program or Cardiologist

Although there is evidence that a general internist can safely manage patients with heart failure that are clinically stable on optimal medical therapy in countries that offer universal access to health care (Ponikowski et al., 2016a), it is unclear if the same is true in the United States. In either case, it is imperative that generalist providers know when referral to a heart failure specialist is needed as life extending advanced therapies such as left ventricular assist devices (LVADs) and heart transplantation may no longer be options if irreversible end organ damage is already present. The ACC/AHA (Yancy et al., 2013) guidelines offer disease milestones that signal end-stage disease and need for evaluation by a heart failure specialist for advanced therapies or referral to hospice:

- NYHA III and IV symptoms in spite of optimal medical therapy
- Worsening renal or liver function
- Bb or ace-inhibitor intolerance due to hypotension
- Diuretic requirements greater than 160 mg/day or use of metolazone
- 2 or more heart failure hospitalization within 6 months
- Cardiac cachexia
- Frequent shocks from implanted cardiac defibrillator
- Worsening hyponatremia, generally less than 133 meq/L

When to Refer Patients to Palliative and Hospice Care

Given the disease trajectory of heart failure and that only a small proportion of NYHA IV patients will be eligible for advanced therapies, major society guidelines now recommend palliative care services be incorporated early into the multidisciplinary team approach to management of patients with heart failure (Yancy et al., 2013; Ponikowski et al., 2016c).

At its inception, the specialty of palliative care was created for end-stage cancer patients in whom effective disease specific treatment was no longer available. Over the last few decades, palliative care has come to encompass a broader scope, becoming more synonymous with "supportive care" rather than simply hospice or end of life care. Palliative care takes a holistic approach to improving the quality of life of patients with highly morbid diseases by addressing the physical, physiological, and spiritual needs of these patients (Chen-Scarabelli et al., 2015). With this change, it can be seamlessly incorporated into the care of patients still receiving disease-targeted therapy. There are multiple advantages to integrating palliative care services to the multidisciplinary care team prior to a patient progressing to end-stage disease. In fact, late referrals to palliative care have been associated with the perception by family of unmet needs, poor care coordination, and poor awareness of prognosis (Fendler et al., 2015). Current evidence indicates that patients' goals for their care change over time and that advanced care planning conversations are an iterative

process that evolve over multiple conversations, typically increasing in frequency as disease becomes more advanced. Palliative care specialists have been shown to facilitate advanced care planning and informed decision making in heart failure patients (Lewin and Schaefer, 2017). In addition, improved provider patient communication, which palliative care specialists can augment, has been shown to enhance patient satisfaction and emotional well-being (Tulsky, 2004).

In contrast to palliative care, which should be introduced early in the disease process, hospice care focuses on aggressive symptom management for patients whose life expectancy is less than 6 months. Providers should recognize when it is appropriate to offer hospice care to patients. Indications include patients with NYHA IV symptoms in spite of optimal medical and device therapies, deemed ineligible for transplant or LVAD, and have recurrent hospitalizations despite good compliance or multisystem organ failure secondary to heart failure or other comorbidities. Given the high symptom burden and poor quality of life associated with end-stage heart failure, all management decisions should be focused on quality of life and alleviation of suffering both physical and psychological. The most common symptoms are dyspnea and fatigue. Opioids, nitrates, and O_2 are effective tools to treat dyspnea. Caffeine and other stimulants may be used to address fatigue.

It should be noted that, hospice care can be quite variable when it comes to the management of end-stage heart failure. Traditionally, hospice care providers have focused on end-stage care of cancer. Many hospice providers will try to decrease or stop heart failure medications (such as ACE-inhibitor or BB). This is the exactly wrong approach in that the patient will decline more rapidly. Discussion with the hospice provider regarding their approach to heart failure and available protocols is important to review.

Discussions and decisions surrounding ICD deactivation arise for many patients with advanced heart failure. The Resuscitation Council of the United Kingdom, British Cardiovascular Society, and National Council for Palliative Care have published a statement to offer guidance to providers for appropriate care surrounding decisions around deactivation of implantable cardiac devices (Pitcher et al., 2016). In it, the authors emphasize that end of life planning should be highly individualized and decisions about Code status and ICD deactivation should be considered separately.

Such discussions must be approached in a sensitive fashion. For patients with an ICD, the decision to be DNR should trigger a conversation about ICD deactivation. Given the discomfort associated with ICD shocks and that tachy-arrhythmias are common in end-stage HF patients, the deactivation of defibrillators is consistent with a focus on comfort and quality of life. By the same reasoning, it is reasonable to continue the CRT capability of an implantable device as it can contribute significantly to symptom management.

Conclusion

While it is true that there continue to be important gaps in the medical literature regarding the outpatient management of heart failure, there are currently many pharmacologic and nonpharmacologic interventions that have been shown to be effective but that are grossly underutilized. While there are many factors that likely contribute to provider variability in prescribing habits of disease modifying interventions, both suboptimal dissemination and difficulties with practical application of clinical practice guidelines likely contribute. In this review, we have attempted to facilitate adherence to clinical practice guidelines by not only reviewing current standard of care but also offering specific practices in an attempt to better operationalize major society recommendations.

It is important to acknowledge that heart failure patients are often elderly, socially isolated individuals with multiple comorbidities that require substantial time and expertise to be managed optimally. Providers caring for heart failure patients are often busy clinicians limited in the amount of time they have available to engage in patient education of self-care activities. We would encourage providers to enlist their pharmacy, dietician, and physical therapist colleagues in the effort to provide essential patient education they may not have the time to offer themselves.

Given the prevalence, poor outcomes, and pace of advances in heart failure treatment, we recommend all providers, particularly generalists, begin or continue referring to the AHA/ACC clinical practice guidelines in order to stay current with standard of care.

Appendix 1

Summary of major clinical trials with vasodilators, ACE-inhibitors, angiotensin receptor blockers, and angiotensin receptor-neprilysin inhibitors in patients with HFrEF

Trial	*Date*	*Study design*	*Treatment arms*	*Population*	*Follow-up time period*	*Primary Outcome*
Vasodilators						
V-HeFT I	1986	RCT	H-ISDN ($n=273$) Prazosin ($n=183$) Placebo ($n=273$)	LVEF < 30%, Mean age 58 years	2.3 years (mean)	H-ISDN was associated with trend in all-cause mortality compared to placebo (38.7% vs. 44.9%, $P=0.09$) by a 34% reduction in morality at 2 years reduced ($P<0.028$)

(*Continued*)

(Continued)

Trial	*Date*	*Study design*	*Treatment arms*	*Population*	*Follow-up time period*	*Primary Outcome*
V-HeFT II	1991	RCT	H-ISDN ($n=403$) Enalapril ($n=401$)	LVEF $<0.45\%$, NYHA II-IV, Mean age: 60.5 years	2.5 years (mean)	Enalapril compared to H-ISDN demonstrated a reduction in all-cause mortality (38.2% vs. 32.8%, $P=0.008$)
A-HeFT	2004	RCT	BiDil ($n=518$) Placebo ($n=532$)	LVEF $\leq 30\%$, NYHA III-IV, Mean age: 57 years	12.8 months (mean)	Bidil demonstrated a better composite score than in the placebo group (-0.1 ± 1.9 vs. -0.5 ± 2.0, $P=0.01$; range of possible values, -6 to $+2$)
ACE-inhibitors						
CONSENSUS (The CONSENSUS Trial Study Group, 1987)	1987	RCT	Enalapril ($n=126$) Placebo ($n=127$)	NYHA IV, mean age:70 years	188 days (mean)	Enalapril was associated with a 40% reduction in all-cause mortality at 6 months compared to placebo (26% vs. 44%, $P=0.002$, respectively) and 31% at 1 year (36% vs. 50%, $P=0.001$, respectively)
SOLVD-Treatment	1991	RCT	Enalapril ($n=1285$) Placebo ($n=1284$)	LVEF $\leq 35\%$, NYHA II-III, Mean age: 61 years	41.4 months (mean)	Enalapril was associated with a 16% RR reduction in all-cause mortality (39.7% vs. 35.2%, $P=0.0036$, respectively) and a 26% RR reduction in the composite of death or hospitalization due to heart failure compared to placebo (47.7% vs. 57.3%, $P<0.0001$, respectively)
SOLVD-Prevention	1992	RCT	Enalapril ($n=2117$) Placebo ($n=2111$)	LVEF $\leq 35\%$, NYHA I-II, Mean age: 59 years	37.4 months (mean)	Enalapril was associated with a 8% reduction in all-cause mortality (95% CI: -8% to 21%, $P=0.30$); 12% reduction in cardiovascular mortality (95% CI: -3% to 26%, $P=0.12$); 37% reduction in the development of heart failure (95% CI: 28%–44%, $P<0.001$); 20 reduction in mortality or heart failure hospitalization (95% CI: 9%–30%, $P<0.001$); 36% reduction in first heart failure hospitalization (22%–46%, $P<0.001$); and a 29% reduction in all-cause mortality or development of heart failure (21%–36%, $P<0.0001$)
SAVE	1992	RCT	Captopril ($n=1116$) Placebo ($n=1115$)	LVEF $\leq 40\%$ post MI, Mean age: 59 years	42 months (mean)	Captopril was associated with a 19% RR reduction in all-cause mortality (95% CI: 3%–32%, $P=0.019$), 21% RR reduction in CV deaths (95% CI: 5%–35%, $P<0.001$), 37% RR reduction in development of severe heart failure (95% CI: 20%–50%, $P<0.001$), and a 22% RR reduction in heart failure hospitalization (95% CI: 4%–37%, $P=0.019$)
ATLAS	1999	RCT	Low-dose lisinopril ($n=1596$) High-dose lisinopril ($n=1568$)	LVEF $\leq 30\%$, NYHA II-IV, Mean age: 64 years	47.5 months (median)	High dose was associated with an 8% reduction in all-cause mortality (HR: 0.92, 95% CI: 0.82–1.03, $P=0.128$) and a 10% reduction in cardiovascular mortality (HR: 0.90, 95% CI: 0.81–1.01, $P=0.073$)
Angiotensin receptor blockers						
ELITE I	1997	RCT	Losartan ($n=352$) Captopril ($n=370$)	LVEF $\leq 40\%$, ACE-inhibitor naïve, NYHA II-IV, Mean age: 74 years	48 weeks	No difference between losartan and captopril in the frequency persisting (confirmed) increases in serum creatinine (10.5% in each group, RR: 2% (95% CI -51% to $+36\%$), $P=0.63$)
ELITE II	2000	RCT	Losartan ($n=1578$) Captopril ($n=1574$)	LVEF $\leq 40\%$, ACE-inhibitor naïve, NYHA II-IV, Mean age: 72 years	555 days (mean)	No difference between losartan and captopril in all-cause mortality (17.7% vs. 15.9%, $P=0.16$, respectively) or the composite or all-cause mortality or all-cause hospital admission (47.7% vs. 44.9%, $P=0.18$, respectively)
Val-HeFT	2001	RCT	Valsartan ($n=2511$)	LVEF $\leq 30\%$, NYHA II-IV,	23 months (mean)	No difference between valsartan and placebo in all-cause mortality (RR: 1.02, 97.5% CI:

(Continued)

Trial	Date	Study design	Treatment arms	Population	Follow-up time period	Primary Outcome
			Placebo ($n=2499$)	93% receiving ACE-inhibitors, Mean age: 63 years		0.88–1.18, $P=0.80$); valsartan had a 13.2% lower risk of the composite of mortality and incidence of cardiac arrest with resuscitation, heart failure hospitalization, or use of intravenous inotropic or vasodilator therapy for at least 4 h (RR: 0.87, 97.5% CI: 0.77–0.97, $P=0.009$)
CHARM-Added	2003	RCT	Candesartan ($n=1276$) Placebo ($n=1272$)	LVEF $\leq 40\%$, NYHA II-IV 100% receiving ACE-inhibitors, Mean age: 64 years	41 months (median)	Candesartan had a 15% reduction in cardiovascular death or unplanned heart failure hospitalization compared to placebo (HR: 0.85, 95% CI: 0.75–0.96, $P=0.011$) and a 9% reduction in all-cause mortality (HR: 0.89, 95% CI: 0.77–1.02, $P=0.86$)
CHARM-ALTERNATIVE	2003	RCT	Candesartan ($n=1013$) Placebo ($n=1015$)	LVEF $\leq 40\%$, NYHA II-IV, Intolerant to ACE-inhibitors, Mean age: 67 years	33.7 months (median)	Compared to placebo, candesartan demonstrated a 30% reduction in the primary endpoint (adjusted HR: 0.70, 95% CI: 0.60–0.81, $P<0.0001$)
HEAAL	2009	RCT	Low-dose losartan ($n=1919$) High-dose losartan ($n=1927$)	LVEF $\leq 40\%$, NYHA II-IV, Intolerant to ACE-inhibitors, Mean age: 66 years	4.7 years (median)	Losartan had a 10% reduction in the composite of all-cause mortality or heart failure hospitalization (HR: 0.90, 95% CI: 0.82–0.99, $P=0.27$)
Angiotensin receptor-neprilysin inhibitor						
PARADIGM-HF[a]	2014	RCT	Sacubitril/valsartan ($n=4187$) Enalapril ($n=4212$)	LVEF $\leq 40\%$, NYHA II-IV, Stable dose of Stabilized on a beta-blocker and an ACE-inhibitor (or ARB) equivalent to at least 10 mg of enalapril daily Mean age: 64 years	27 months (mean)	Compared to enalapril, sacubitril/valsartan demonstrated a 20% reduction in cardiovascular death or heart failure hospitalization (HR: 0.80, 95% CI: 0.71–0.89, $P<0.001$); a 20% reduction in cardiovascular death (HR: 0.80, 95% CI: 0.71–0.89, $P<0.001$); and a 19% reduction in first heart failure hospitalization (HR: 0.79, 95% CI: 0.71–0.89, $P<0.001$)

ACE: Angiotensin-converting enzyme, A-HeFT: African American heart failure trial , ARBs: angiotensin receptor blockers, ATLAS: assessment of the treatment with lisinopril and survival, ARB: angiotensin receptor blocker, CHARM: Candesartan in heart failure assessment of reduction in mortality and morbidity, CONSENSUS: cooperative north scandinavian enalapril survival study , CV: cardiovascular, ELITE: evaluation of losartan in the elderly, LVEF: left ventricular ejection fraction, HEAAL: heart failure endpoint evaluation of angiotensin II antagonist losartan, H-ISDN: hydralazine combined with isosorbide dinitrate, NYHA: New York aeart association functional class, PARADIGM-HF: prospective comparison of ARNI with ACEI to determine impact on global mortality and morbidity in heart failure, RCT: Randomized control trial RR: risk reduction, SAVE: survival and ventricular enlargement, SOLVD: studies of left ventricular dysfunction, Val-HeFT: valsartan heart failure trial, V-HeFT: vasodilator heart failure trial.

Appendix 2

Summary of major clinical trials with β blockers, digoxin, aldosterone antagonists, and ivabridine in patients with heart failure with reduced ejection fraction

Trial	Date	Study design	Treatment arms	Population	Follow-up period	Primary outcome
Beta-blockers						
MDC	1993	RCT	Metoprolol tartrate ($n=194$) Placebo ($n=189$)	LVEF $<40\%$, NYHA II-IV, Mean age: 49 years	12 months	Metoprolol tartrate had a 34% reduction in death or need for transplantation compared to placebo (95% CI: 0.06–0.62; $P=0.058$)

(*Continued*)

(Continued)

Trial	*Date*	*Study design*	*Treatment arms*	*Population*	*Follow-up period*	*Primary outcome*
CIBIS I	1994	RCT	Bisoprolol ($n=320$) Placebo ($n=321$)	LVEF <40%, NYHA III–IV, Mean age: 60 years	1.9 years (mean)	No difference in mortality between bisoprolol and placebo (RR: 0.80, 95% CI: 0.56-1.15; p = 0.22)
CIBIS II[a]	1999	RCT	Bisoprolol (n = 1327) Placebo (n = 1320)	LVEF ≤35%, NYHA III-IV, Mean age: 61 years	1.3 years (mean)	All-cause mortality was significantly lower with bisoprolol than placebo (11.8% vs. 17.3%) (HR: 0.66, 95% CI: 0.54–0.81; $P<0.0001$)
MERIT-HF[a]	1999	RCT	Metoprolol CR/XL ($n=1990$) Placebo ($n=2001$)	LVEF ≤40%, NYHA II-IV, Mean age: 64 years	1 years (mean)	All-cause mortality was significantly lower with metoprolol CR/XL than placebo (7.2%, per patient-year of follow-up vs. 11.0%) (RR: 0.66, 95% CI: 0.53–0.81, $P=0.00009$)
COPERNICUS[a]	2001	RCT	Carvedilol ($n=1156$) Placebo ($n=1133$)	LVEF <25%, Mean age: 63 years	10.4 months (mean)	Carvedilol had a 35% reduction in risk of death compared to placebo (95% CI: 0.19–0.48; $P=0.00013$ [unadjusted])
COMET	2003	RCT	Carvedilol ($n=1511$) Metoprolol tartrate (n = 1518)	LVEF ≤35%, NYHA II-IV, Mean age: 62 years	58 months (mean)	All-cause mortality was 34% for carvedilol vs. 40% for metoprolol (HR: 0.83, 95% CI: 0.74–0.93; $P=0.0017$); the composite endpoint of mortality or all-cause admission occurred in 74% of carvedilol group and 76% of metoprolol group (HR: 0.94, 0.86–1.02; $P=0.122$)
Digoxin						
DIG	1997	RCT	Digoxin ($n=3397$) Placebo ($n=3403$)	LVEF ≤45%, NYHA II-IV, Mean age: 62 years	37 months (mean)	No significant differences in mortality ($P=0.80$); in digoxin group, trend toward a decrease in risk of death due to heart failure (RR: 0.88, 95% CI: 0.77–1.01; $P=0.06$); in digoxin group, 6% fewer hospitalizations and fewer patients hospitalized for heart failure (RR: 0.72, 95% CI: 0.66–0.79; $P<0.001$)
DIG (High Risk Sub-Study)	2013	Posthoc analysis	NYHA III–IV Digoxin ($n=1118$) Placebo ($n=1105$) LVEF ≤ 25% Digoxin ($n=1127$) Placebo ($n=1129$) CTR ≥ 55% Digoxin ($n=1175$) Placebo ($n=1170$)	LVEF ≤45%, NYHA II-IV, Mean age, 62 years	37 months (mean)	Compared to placebo, those receiving digoxin had a significant reduction in the 2-year composite endpoint of HF mortality or HF hospitalization: NYHA III–IV (HR: 0.65, 95% CI 0.57–0.75; $P < 0.001$); LVEF <25% (HR: 0.61, 95% CI 0.53–0.71; $P < 0.001$); and CTR .55% (HR 0.65, 95% CI 0.57–0.75, $P<0.001$)
Aldosterone antagonists						
RALES	1999	RCT	Spironolactone ($n=822$) Placebo (841)	LVEF ≤35%, NYHA III–IV, Mean age: 62 years	24 months (mean)	Spironolactone had a 30% reduction in risk of death compared to placebo (RR: 0.70, 95% CI: 0.60–0.82; $P<0.001$)
EPHESUS	2003	RCT	Eplerenone ($n=3319$) Placebo ($n=3313$)	LVEF ≤40%, Mean age: 64 years	16 months (mean)	Eplerenone had a 15% reduction in risk of death compared to placebo (RR: 0.85, 95% CI: 0.75–0.96; $P=0.008$)
EMPHASIS-HF[a]	2011	RCT	Eplerenone ($n=1364$) Placebo ($n=1373$)	LVEF ≤30%, NYHA II, Mean age: 69 years	21 months (mean)	Eplerenone had a 34% reduction in risk of death from cardiovascular causes or hospitalization for HF compared to placebo (HR: 0.66, 95% CI: 0.56–0.78; $P<0.001$)
Ivabradine						
SHIFT	2010	RCT				

(Continued)

Trial	Date	Study design	Treatment arms	Population	Follow-up period	Primary outcome
			Ivabradine ($n=3241$) Placebo ($n=3264$)	LVEF < 35%, NYHA II-IV, Heart rate > 70 bpm, Stabilized on background treatment including a β blocker, Mean age: 60 years	23 months (median)	Compared to placebo, ivabradine demonstrated an 18% reduction in cardiovascular death or heart failure hospitalization (HR: 0.82, 95% CI: 0.75–0.90, $P<0.0001$)

BPM: Beats per minute, CI: confidence interval, CIBIS: cardiac insufficiency bisoprolol study, COMET: carvedilol or metoprolol European trial, COPERNICUS: carvedilol prospective randomized cumulative survival study, CTR: cardiothoracic ratio, DIG: digitalis investigation group, EMPHASIS-HF: eplerenone in mild patients hospitalization and survival study in heart failure, EPHESUS: eplerenone post-acute myocardial infarction heart failure efficacy and survival study , HF: heart failure, HR: hazard ratio, LVEF: left ventricular ejection fraction, MDC: metoprolol in dilated cardiomyopathy, MERIT-HF: metoprolol CR/XL randomized intervention trial in congestive heart failure, mo: months, NYHA: New York heart association, RALES: randomized aldactone evaluation study, RCT: randomized controlled trial, RR: relative risk, SHIFT: systolic heart failure treatment with the if inhibitor ivabradine trial.

Introduction to Preclinical Imaging

In the past three decades, there have been significant advances in the field of various imaging modalities that enhance visualization of smaller objects. These advances have propelled the field of cardiovascular imaging forward and allowed the use of small rodent animal models for human cardiovascular disease. The goal of this article is to provide an overview of different imaging modalities that are available for cardiovascular research in the preclinical setting. The most commonly used imaging applications are magnetic resonance imaging (MRI), ultrasound imaging, microcomputed tomography (μCT), positron emission tomography (PET), single photon emission computed tomography (SPECT), and optical imaging. **Table 1** provides a quick comparison of the imaging modalities addressed in this article.

Magnetic Resonance Imaging

A Brief History

In 1930, the Austria-born physicist Isidor Isaac Rabi, who was influenced by the work of Bohr, Pauli, and Heisenberg, determined the nuclear spin and magnetic moment of sodium using a modified Stern–Gerlach apparatus. He continued to determine the nuclear spins of hydrogen and deuterium. His work established the nuclear magnetic resonance method, which is the basis for MRI. Rabi correctly predicted the behavior of nuclei in magnetic fields and his laboratory was the first to observe magnetic resonance in 1938 in lithium chloride molecules. He was awarded the Nobel Prize in 1944 for "his resonance method of recording the magnetic properties of atomic nuclei" (Rigden, 1998).

In 1946, Edward Purcell and Felix Bloch independently developed the method to study the resonance properties of nuclei in solids and liquids. Both received the Nobel Prize in 1952. For two decades, magnetic resonance was only used to determine the chemical and physical properties of substances, but in 1971, Raymond Damadian (Kauffman, 2014) showed that tumor tissue and healthy tissue had different nuclear relaxation times, opening the door for clinical applications for MRI. The development of

Table 1 Overview of imaging modalities, with their corresponding resolution, advantages and disadvantages, and contrast agents used

	Resolution	*Radiation*	*Longitudinal studies*	*Endpoint studies*	*Advantages*	*Disadvantages*	*Contrast agents*
Magnetic resonance imaging (MRI)	In vivo: 80–100 μm In vitro: ~27 μm	Radio waves	Yes, unlimited	Specimen imaging possible	Noninvasive, very good soft tissue contrast	Long scan times, high maintenance costs	Gadolinium, SPIO, ferritin
Positron emission tomography (PET)	1–2 mm	γ Rays (high energy)	Limited by radiation exposure	No	Metabolic activity measurements, high sensitivity	Very expensive, radiation exposure, low resolution, cyclotron needed	Radioactive isotopes: ^{82}Rb, ^{18}F, ^{11}C, ^{13}N, ^{15}O Fluorodeoxyglucose (FDG)
Single photon emission computed tomography (SPECT)	1–2 mm	γ Rays (low energy)	Limited by radiation exposure	No	Longer half-lives of radioisotopes, metabolic activity, dual radioisotope use	Radiation exposure, low resolution	Radioactive isotopes: ^{99m}Tc, ^{123}I, ^{111}In
Microcomputed tomography (μCT)	In vivo: ~67 μm In vitro: 10.5 μm	X-rays	Yes, however, limited by radiation exposure	Yes, for vascular imaging	Fast imaging times, excellent resolution, whole body images possible	Poor soft tissue contrast, vascular imaging requires endpoint study	Microfil, barium, iodine
Ultrasound	50 μm	High-frequency sound waves	Yes, unlimited	No	Fast imaging times, good resolution, least expensive imaging modality	Highly trained personnel to interpret images, low tissue penetration	Microbubbles
Optical imaging	1–3 mm	Visible or near infrared light	Yes	No	Fast imaging times, good resolution, inexpensive	Low tissue depth penetration	Fluorescent dyes and labeled molecules

computers and thus the ability to generate images from magnetic resonances led to the first live human MRI on July 3, 1977. The first commercial MRI systems became available in the 1980s and the development of high-strength magnetic field systems continues until today.

Technique Overview

MRI is based on the fact that charged nuclei that spin generate a magnetic field and thus behave like tiny bar magnets. Several elements such as ^{1}H, ^{19}F, ^{23}Na, ^{31}P, and ^{13}C have odd proton numbers in their nuclei and thus have a magnetic dipole moment. When these nuclei are exposed to a constant magnetic field, they will align with (lower energetic state) or against (higher energetic state) the constant magnetic field. The opposite directionality will cancel most of the nuclei out, however, there is a tiny fraction of nuclei that aligns with the magnetic field and these are the nuclei that contribute to the generation of the signal that is used in MRI. These nuclei can be excited with resonant radio frequencies, which increase their energetic state. Once the radio signal is turned off, these nuclei release energy in the form of a radio signal and relax back to their original energetic state. The released energy from every nucleus is slightly different based on the temporal and spatial encoding used in the MRI sequence and the magnetic gradient applied over the field of view. The integration of all frequency information from every nucleus is used to generate the actual image. The time it takes for the nuclei to release energy and return to their prior energetic state is called relaxation time, which can be distinguished further into spin–lattice (T1) or spin–spin (T2) relaxation times. Dependent on the chemical environment of the nuclei, relaxation times vary and can thus be used to generate contrast between tissues (Hashemi et al., 2012; Mitchell, 2004).

Imaging Applications for Cardiovascular Animal Models

MRI imaging in cardiovascular research can be divided into three major categories:

Real-time imaging of the beating heart using dark blood or white blood imaging applications,
Magnetic resonance angiograms with and without contrast enhancement, and
Tissue perfusion imaging with and without contrast enhancement.

Real-time imaging of the beating heart in small mammals

The development of very fast imaging techniques combined with stronger gradients enables MRI of fast beating small mammalian hearts (anesthetized mouse: 350–450 BPM, anesthetized rat: 120–160 BPM). Two methods stand out for their usefulness in

determining heart muscle morphology and ventricular function: black blood spin echo imaging and bright blood gradient echo imaging. Black blood imaging with spin echo techniques requires slightly longer acquisition times, however, it allows for higher resolution images. Black blood images are very useful for detailed morphological analysis of the heart as well as large blood vessels within the thorax. Gradient echo bright blood images are very fast in the acquisition, have a somewhat lower resolution, but allow ventricular function assessment as well as blood flow measurements, myocardial perfusion, and cardiac valve functional determination (Fig. 1).

Magnetic resonance angiograms

Imaging methods for magnetic resonance angiograms can be distinguished into noncontrast and contrast-enhanced imaging. Contrast-enhanced imaging relies on the fast injection of gadolinium into the venous system of the mouse. Gadolinium has a vascular time of approximately 30 s; thus, any contrast enhanced imaging has to be acquired very quickly. The advantage of contrast-enhanced imaging is that smaller blood vessels can be visualized because the method is not dependent on blood flow. In noncontrast enhanced imaging, blood flow itself is important and contrast is gained from fast moving protons. Time of flight imaging relies heavily on spin labeling of blood outside the area of interest that then flows into the area of interest within a tissue that is saturated (= not visible) by rapidly applied radiofrequency pulses (Fig. 2).

Tissue perfusion imaging with contrast enhancement

MRI is a well-accepted method to image the infarcted heart and determine the area at risk, the infarcted area, as well as determine areas with lower perfusion levels. These imaging methods use gadolinium contrast agents that can be divided into two major classes: extravascular and intravascular gadolinium conjugates. For both classes, gadolinium is complexed because free gadolinium is highly toxic. Gadolinium is paramagnetic with seven free electrons and accelerates the relaxation of water protons in its immediate proximity. On a T1 weighted image, the contrast of water will thus be enhanced (=brighter) in the presence of gadolinium. In murine models of cardiac infarction, late gadolinium contrast enhancement is used to determine the infarcted area. This is based on the increase in extracellular space in dead or compromised tissue and the increased accumulation of gadolinium in this

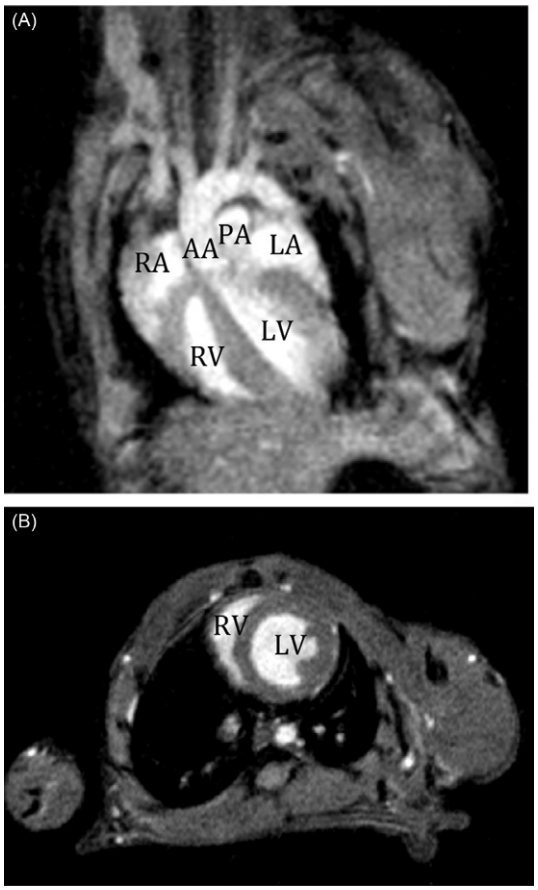

Fig. 1 MRI gradient echo bright blood image of a mouse heart. (A) Four chambers long axis view: ventricular chambers (left ventricle (LV) and right ventricle (RV)) and atrial chambers (right atrium (RA) and left atrium (LA)) can be clearly identified. The ascending aorta (AA) with its three major artery branches can be easily seen as well as the pulmonary artery (PA). The interventricular septum is clearly visible in the long axis and short axis views. (B) Short axis view of the mouse heart during diastole. RV and LV are filled with blood and the papillary muscles can be seen in the LV.

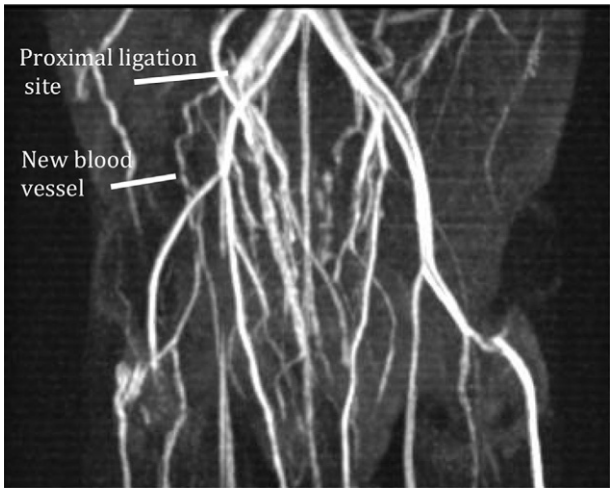

Fig. 2 Magnetic resonance angiogram (MRA) of the lower abdominal and hindlimb area of the mouse. This mouse underwent surgery to resect the left femoral artery and vein. MRA imaging 7 days later showed that blood flow to the ischemic hindlimb was reestablished. In this study, arteries and veins were not distinguished.

extracellular space. A precontrast image is taken and then gadolinium injected. After 10 min (up to 30 min later), a second image is acquired to show enhancement in areas where gadolinium accumulated (Protti et al., 2010; Price et al., 2011; Chapon et al., 2008). Another use of contrast enhancement is in first pass contrast imaging to delineate the perfusion of the myocardium. Initially, this was perceived as too complicated in rodent models of cardiovascular disease; however, several groups have demonstrated that despite high heart rates sufficient contrast can be achieved. Here the image is acquired within seconds after the gadolinium injection to measure "the first pass" through the vasculature before gadolinium diffuses into the extravascular space (Makowski et al., 2010; Coolen et al., 2010).

Ultrasound Imaging

A Brief History

In the 18th century, Carl Linnaeus and Franz Aepinus worked with crystals and found that some crystals generate an electric potential in response to a temperature change. They called this the pyroelectric effect. Pyro is the Greek word for to squeeze or press. René Just Haüy, a French mineralogist, and Antoine César Becquerel (grandfather to Henri Becquerel) continued this work; however, they could never provide proof of the piezoelectric effect. Finally, in 1880, the brothers Pierre and Jacques Curie were successful in demonstrating the direct piezoelectric effect using crystals of tourmaline, quartz, topaz, cane sugar, and Rochelle salt (sodium potassium tartrate tetrahydrate) (Curie and Curie, 1881). They showed that quartz and Rochelle salt exhibited the highest piezoelectricity. In 1881 Gabriel Lippmann (Lippmann, 1881) predicted the reverse piezoelectric effect, which was then confirmed by the Curie brothers.

It took until World War I for the piezoelectrical effect to find an application, which was initially nonmedical with the development of sonar to detect submarines (Katzir, 2012). It took a couple more decades for the technique to be used for human tissue imaging and a landmark paper was published in 1958 (Donald et al., 1958). Just a couple of years later in the early 1960s, the first scanners for clinical imaging were developed and commercially available (see review (Manbachi and Cobbold, 2011)).

Technique Overview

Ultrasound imaging uses sound waves that are emitted into tissue and then reflected back (echoed) from any boundaries these sound waves encounter. The image is constructed from the time differences between returning echoes and the strength of the echoes. The transducer that transmits the sound waves uses piezoelectric crystals to emit the sound and these crystals also receive the echoes back and convert it to an electric current. The development of solid-state transducers for high-resolution ultrasound has improved the user friendliness of these transducers and further improved the resolution for high-resolution ultrasound imaging. This is particularly important for the application of ultrasound imaging in small animal models.

Modes of Imaging

B-mode or 2D mode: In B-mode (brightness mode) ultrasound, a linear array of transducers simultaneously scans a plane through the body that can be viewed as a 2D image on the screen.

M-mode: In M-mode (motion or movie mode) ultrasound, pulses are emitted in quick succession with a stationary transducer while the tissue (for example the heart) moves under the transducer. Over time, this is analogous to recording a video in ultrasound. As the organ boundaries that produce reflections move relative to the probe, this can be used to determine the velocity of heart structures.

Doppler mode: This mode makes use of the Doppler effect in measuring and visualizing blood flow. An analogy to explain Doppler mode is the changing sound of an approaching and then passing ambulance or police car.

Cardiovascular Imaging Applications in Animal Models

- Echocardiography (ECG) is the most utilized method for relatively inexpensive and fast imaging of the heart in mouse and rat models of human heart diseases. The advantages are that images can be obtained fairly quickly with under 15 min of imaging time per animal. The preparation time of the animal uses up most of that time because any fur in the imaging area has to be completely removed, including the hair follicles, using chemical depilators. The disadvantages are that the resolution of the images is low and an experienced and well-trained person is required to interpret the images. **Fig. 3** shows an example of a short axis view of the mouse heart (**Fig. 3A**) with the corresponding M-mode image (**Fig. 3B**) and the ECG tracing (**Fig. 3C**).
- Morphological imaging of blood vessels and Doppler measurements of blood flow:

  Blood vessels can be easily visualized using ultrasound. **Fig. 4** shows an example of the outflow tract of the heart with the ascending aorta and its major branching off blood vessels.
- Contrast enhanced imaging using microbubbles:

  Untargeted: Ultrasound imaging offers a unique approach to measure tissue perfusion or specifically target molecules on the vascular side of blood vessels using microbubbles. Microbubbles are small (~1 μm) lipid micelles that burst when hit by a high-energy ultrasound wave. They can be used untargeted to provide information of tissue perfusion (Qin et al., 2009; Kiessling et al., 2012). In that case, animals receive an intravenous catheter (in the tail vein) and an image of the organ of interest is acquired prior to the microbubble injection. Then microbubbles are injected and the increased return of echo from the bubbles within the blood vessels of the organ reflects the degree of perfusion (**Fig. 5**).

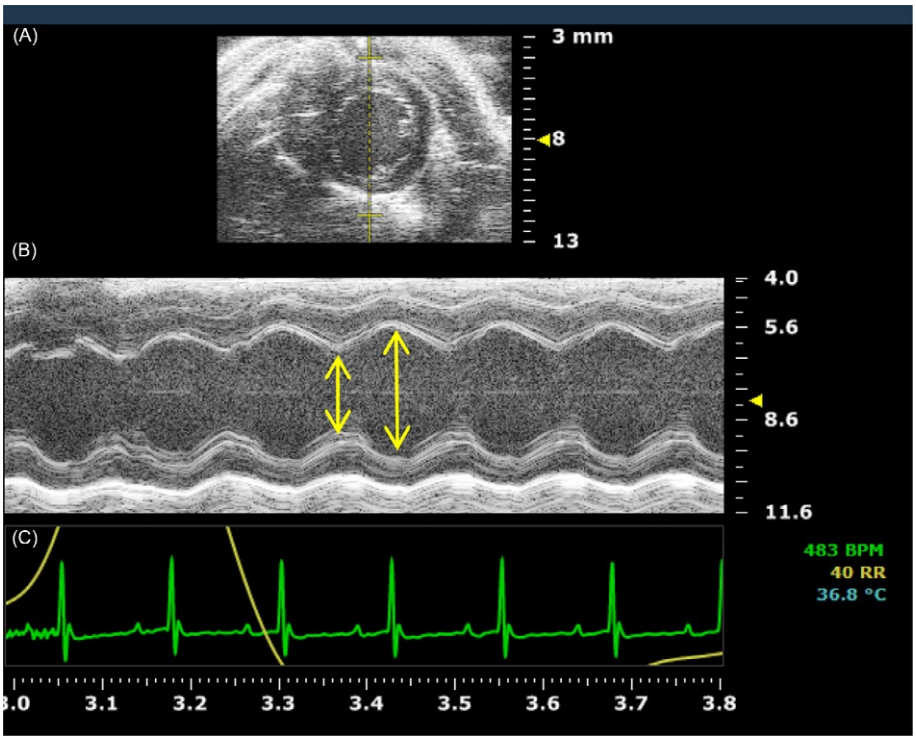

Fig. 3 M-mode echocardiography of a mouse heart. (A) Short axis view through the heart. On the left side and toward the bottom of the left ventricular cavity, the papillary muscle can be seen, which is used as a landmark to position the scan. The *yellow line* marks the position for the M-mode acquisition. (B) M-mode image of the short axis view in (A). The movement of the ventricular walls in diastole ("valleys," longer *yellow double arrow*) and systole ("hills," *shorter yellow arrow*) toward and apart from each other creates the visual appearance of waves. The length of the *arrows* represents the left ventricular chamber size during diastole and systole. The slopes of the waves represent the speed of contraction ("contractility") and the speed of relaxation. The broken *white line* on *top* of the bottom wave reflects the echo shadow of the papillary muscle. (C) Electrocardiogram (*green line*) and respiration (*yellow line*) during the time the M-mode image was taken. Note the disturbance respiration causes at the beginning of the M-mode image.

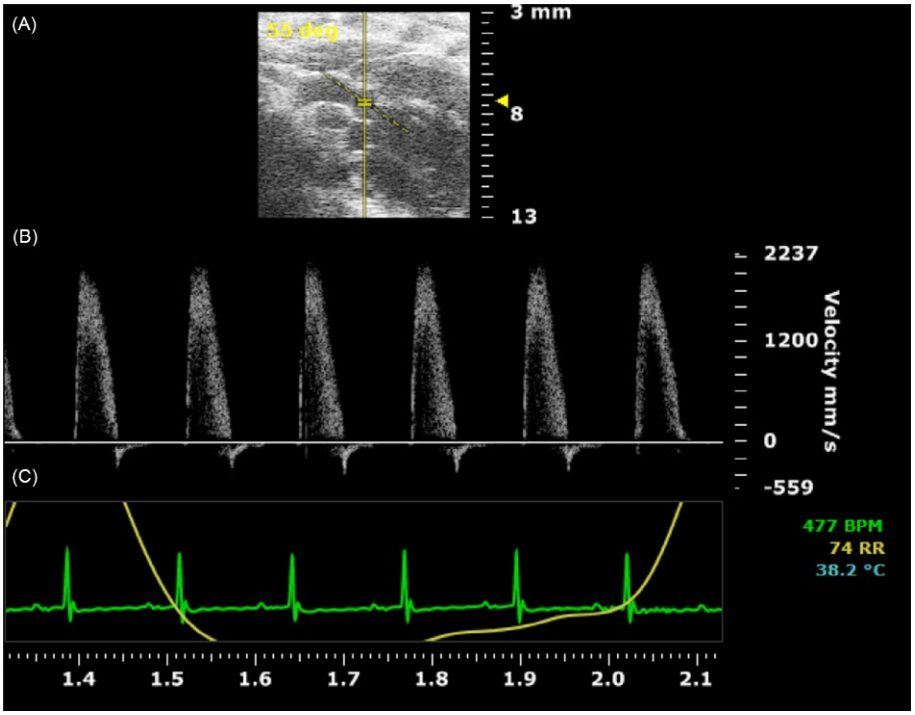

Fig. 4 Blood flow measurement by ultrasound Doppler through the aortic valve of the mouse heart. (A) 2D ultrasound view of the aortic valve. The *solid yellow line* and the equal sign indicate where the measurement is taken. The *broken yellow line* indicates where the maximal velocity of blood flow could be measured. (B) Doppler measurement of the blood flow through the aortic valve in mm/s. The opening of the valve causes the outflow of blood and the fast upstroke of the Doppler signal. The downstroke is blurred due to the changing velocity of blood and the scattering of echoes. There is a very small negative signal that is caused by the closing of the valve and is physiological. (C) Electrocardiogram (*green line*) and respiration (*yellow line*) during the Doppler measurement.

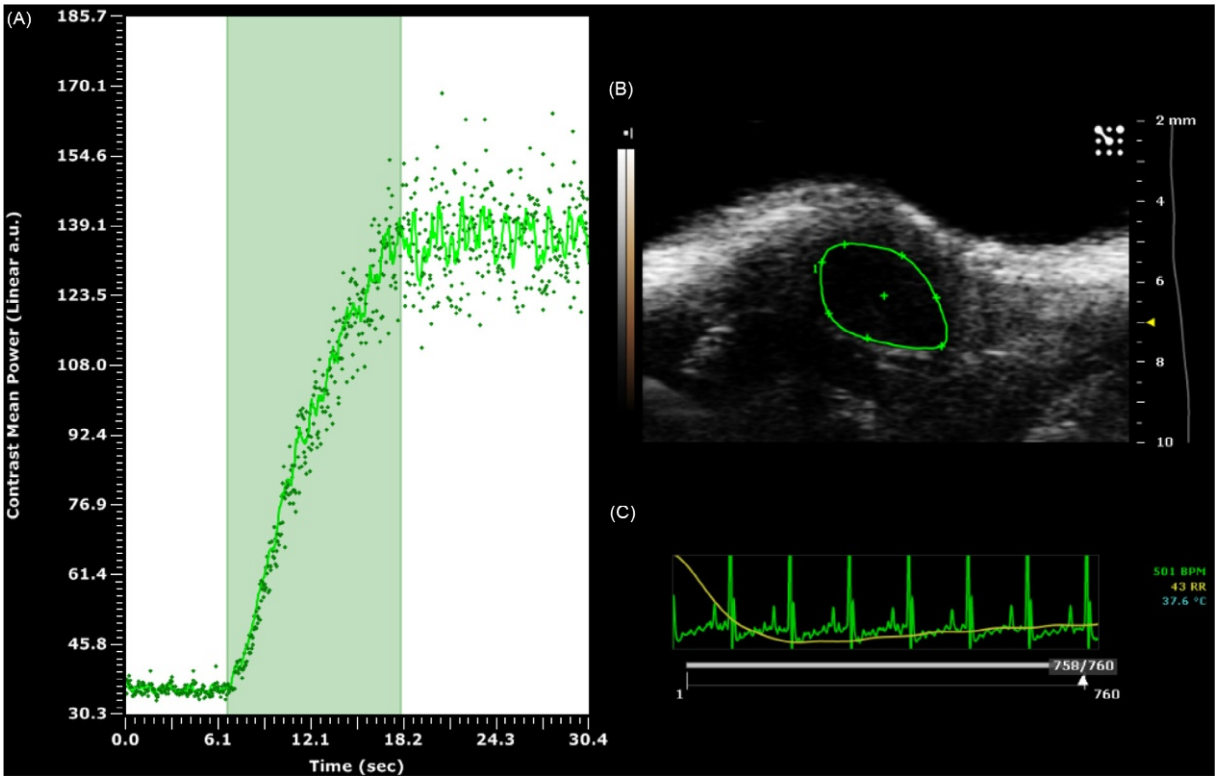

Fig. 5 Cine ultrasound imaging to measure tumor perfusion using untargeted microbubbles. (A) Graphic representation of the contrast change in the area of interest (tumor outline in B) over time. At time 0, untargeted microbubbles were injected in a bolus via a tail vein catheter. The increase in contrast in the *green highlighted box* represents the inflowing microbubbles into the tumor vasculature. The slope of the contrast change, as well as the difference between the minimum and the maximal value of contrast achieved, represents a measure of tumor vascularity. (B) 2D ultrasound image of a tumor in the flank area of a mouse. The tumor is outlined in *green* and delineates where the flow measurement is performed. (C) Corresponding ECG (*green*) and respiration (*yellow*) during image acquisition.

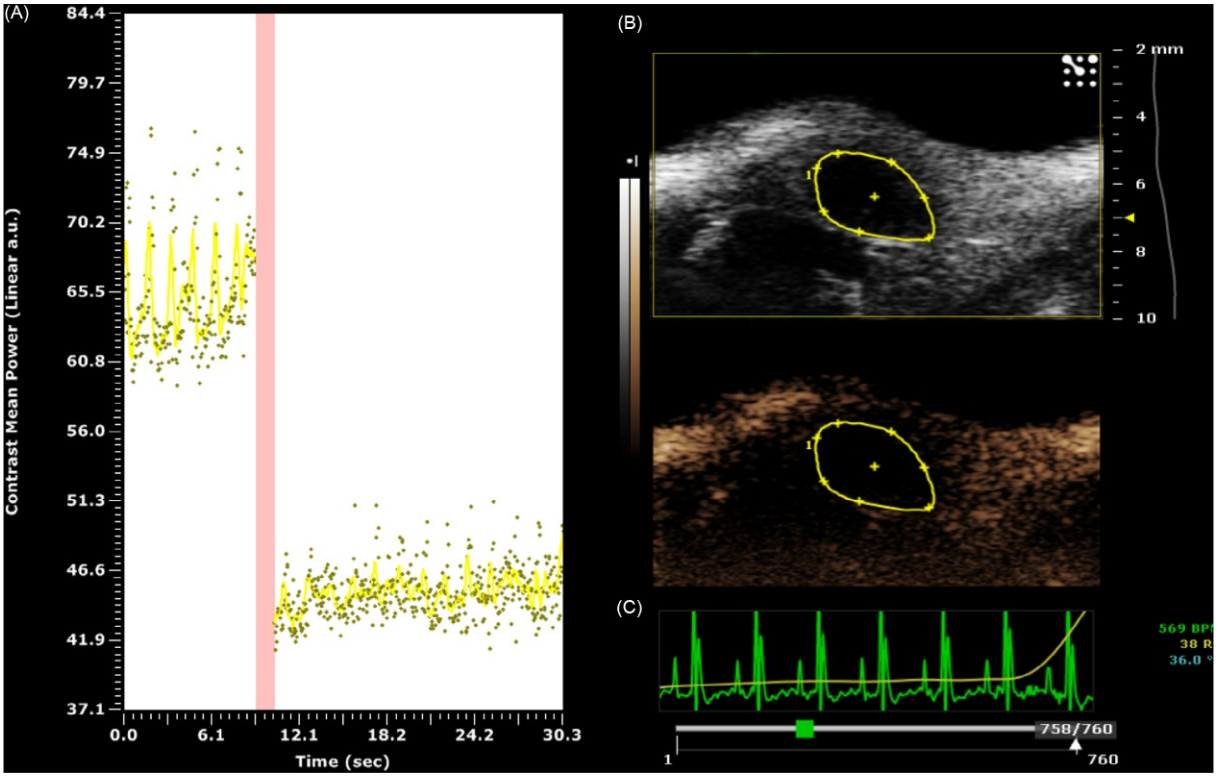

Fig. 6 Targeted microbubbles binding to the vasculature in a mouse tumor. (A) Graphical representation of the change in contrast within the tumor vasculature pre and postburst of microbubbles. Mice were injected with microbubbles targeted to extracellular matrix molecules within the vasculature of tumor tissue. The *yellow line* between 0 and 9 s represents the bound microbubbles. The *pink box* indicates the burst sequence that was applied to burst all bubbles within the area of the tumor. The lower contrast after the burst represents still circulating microbubbles. The difference between pre and postburst contrast is used to calculate the number of microbubbles bound to target molecules and is a measure of the number of target molecules present in the tumor vasculature. (B) 2D images of the tumor pre (*top*) and post (*bottom*) burst. The tumor is outlined in *yellow*. The *mottled gray areas* within the tumor show the echo signal of the bound microbubbles. (C) Corresponding ECG (*green*) and respiration (*yellow*) during image acquisition.

Targeted: Microbubbles can also be specifically targeted to molecules on the intravascular wall by conjugating antibodies to different spacer molecules such as for example biotin or many other chemical conjugation methods (Chopra, 2004; Willmann et al., 2010; Yeh et al., 2015). An isotype control antibody is used as a comparison. For this technique, the microbubbles are injected in a bolus 4–10 min prior to starting a cine loop acquisition. This leaves enough time for the microbubbles to bind their target molecule. The cine loop contains a burst frequence after roughly half of the acquisition time, which bursts all bubbles in the field of view. The difference in contrast between pre and postburst is used to calculate the number of specifically bound microbubbles and can thus be used to quantify target molecules. Fig. 6 shows a representation of pre and postburst signal in a mouse tumor.

Microcomputed Tomography

A Brief History

The development of computer tomography has its beginnings with the findings of Wilhelm Konrad Roentgen, who on November 8, 1895 discovered X-rays. He was awarded the Nobel Prize in Physics in 1901 for his findings that marked the beginning of medical imaging and the term Radiology was born. The Italian scientist Alessandro Vallebona was the first to propose tomographic imaging in the very early 1900s. Tomography meant to obtain an image only from a thin section of the sample. The development of computers in the 1960s accelerated this idea dramatically and also new mathematical methods for image reconstruction were needed to open the field for the wider use of computed tomography. The first computed tomography on a commercial CT scanner was obtained in October 1971 in Great Britain, and the British engineer Sir Godfrey Newbold Hounsfield and the South-African physicist Allan MacLeod Cormack were awarded the Nobel Prize in Medicine in 1979. The continued development of mathematical image reconstruction methods and the increase in computer computational speed, combined with ways to focus the X-ray beam on enabling higher resolution, have led to the development of high-resolution μCT scanners.

Technique Overview

The difference between a preclinical μCT scanner and a clinical CT scanner is that the sample rotates in the preclinical setup and not the X-ray source as in a clinical scanner. In μCT imaging, X-rays are used to obtain a series of 2D planar images that are assembled into 3D images using image analysis software. In high-resolution μCT scanners, the X-ray source sends out highly focused X-ray beams that scan a single slice per view. The sample rotates in small angular increments and an X-ray image is obtained for every angle. Images are then assembled by stacking all 2D images into a 3D image, which in most cases is based on the Feldkamp Cone Beam Reconstruction algorithm (Feldkamp et al., 1984; Johnson et al., 1998). The resolution of μCT is as low as 10.5 μm enabling the visualization of small capillary blood vessels.

Cardiovascular Imaging Applications in Animal Models

The visualization of blood vessel networks using μCT is based on the perfusion of the tissue of interest with Microfil® (FlowTech Inc., Carver, MA), a radiopaque polymer-based solution that solidifies within 2 h after perfusion, leaving a cast of the blood vessel network. This can be imaged using μCT and the number and size of blood vessels can be quantified. Fig. 7 shows an example of a mouse heart, which was perfused in a retrograde fashion with Microfil ex vivo, thus that the ventricular chambers would not fill with the Microfil solution.

Positron Emission Computed Tomography (PET)

A Brief History

The development of PET has its beginning in the early research in isotopes and how to generate them. In 1929, Ernest O. Lawrence invented the cyclotron, which enabled the generation of the isotopes iodine-131, thallium-201, technetium-99m, carbon-14, and gallium-67. In 1939, Lawrence received the Nobel Prize in Physics for his work on isotope generation. To fully use these newly found radiotracers, detectors and scanners were required, thus delaying progress for several decades until 1951, when Benedict Cassen developed the first scanner at UCLA. This was followed just 1 year later by the development of the first gamma camera by Hal Anger at Berkeley, initiating the field of nuclear medicine. In 1953, Gordon Brownell at MIT constructed the first detector for positron–electron annihilation events as an imaging tool, creating, in essence, the first PET scanner. In 1973, scientists developed a faster method for generating thallium-201, enabling routine stress testing in cardiac PET imaging. In 1974, the first PET scanner was built that allowed 3D imaging. In the same year, ^{18}F-flourinedeoxyglucose was synthesized and used for measuring the glucose uptake into various organs, establishing the modern use of PET imaging. In the following decades, the development of more advanced mathematic algorithms and faster computers continued to improve PET imaging (Nutt, 2002; Rich, 1997).

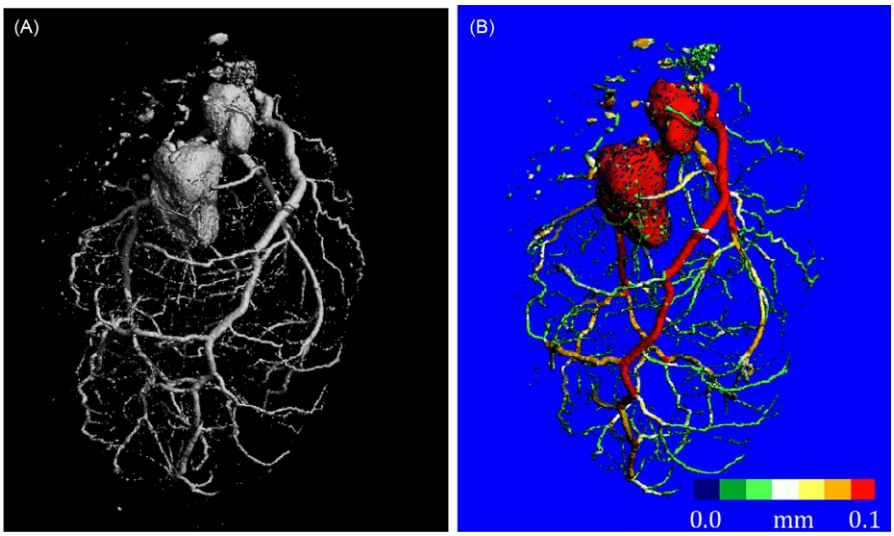

Fig. 7 μCT image of a mouse heart perfused with Microfil. (A) 3D rendering of the coronary vasculature in a mouse heart. The heart was perfused ex vivo in the Langendorff mode to clear blood and then was perfused slowly with Microfil to prevent the ventricular chambers from filling with the contrast agent as well. The specimen was then imaged on a Viva40 (Scanco) high-resolution μCT with a resolution of 10.5 μm. (B) Analysis of coronary artery thickness of the image in (A). This analysis provides the number of the blood vessel at a specific thickness as well as volume calculations for each of the colors.

Technique Overview

PET imaging is the most expensive of all of the imaging techniques covered in this chapter, requiring the generation of very short-lived radiotracers by a cyclotron. Access to a cyclotron is thus a limiting factor and only a few laboratories can use this technique for preclinical imaging. Thus, here we only touch briefly on the advantages of using PET imaging in preclinical cardiovascular imaging and the reader is referred to an excellent review by Kuntner and Stout (Kuntner, 2014) for a detailed overview of preclinical PET imaging.

The biggest advantage of PET imaging is that the metabolic activity of the heart can be imaged in real-time using glucose and lipid analogs that are labeled with radioactive isotopes. As the radioisotope undergoes beta decay, it causes the emission of a positron, an antiparticle of the electron with opposite charge. The emitted positron travels a short distance (less than approximately 1 mm) through tissue (Konopinski and Rose, 1965). Once it has decelerated sufficiently, it can interact with an electron (Ziegler, 2005). The annihilation collision with an electron produces two gamma photons that move in opposite directions from the collision site. These photons are the basis for the image that is generated during PET imaging. The photons are detected by a scintillator within the scanner, which enhances the signal by generating a flash of light that can be detected by photomultiplier tubes. It is important to note that only the simultaneous detection of two photons in opposing directions contributes to image information. Photons that do not arrive in pairs or are not opposite to each other are ignored.

The most commonly used isotope for metabolic imaging in the heart is ^{18}F-fluorodeoxyglucose (^{18}F-FDG) (Higuchi et al., 2007; Rosenbaum et al., 2012). It is a glucose analog that the heart can take up but cannot metabolize past the first phosphorylation step in glycolysis by hexokinase. Thus it accumulates in heart cells and is a direct measure of glucose uptake. FDG can be used to detect hibernating myocardium, in which blood flow and thus glucose uptake is reduced. Similarly, lipids can be labeled with ^{18}F and the uptake measured by PET to complete the picture of substrate utilization by the heart.

In addition, FDG-PET imaging can be used for the detection of atherosclerosis and inflammation. This approach is limited in small animals somewhat by the resolution of PET imaging, however novel multimodal imaging, the combination of two imaging modalities such as PET/CT (Ziegler, 2005) and PET/MRI (Nappi and El Fakhri, 2013), increase the confidence in the low-resolution PET images by overlaying with a high-resolution μCT or MRI scan.

Single Photon Emission Computed Tomography

A Brief History

The early history of the development of SPECT is identical to PET. The development of the gamma camera by Hal Anger in 1952 started the use of SPECT and it soon was used in clinical settings for cardiac stress tests. The availability of isotopes with longer half-lives makes SPECT a more easily accessible method and it is also cheaper than PET imaging.

Technique Overview

SPECT uses radioisotopes to directly measure the perfusion of the heart muscle in an application that is called perfusion imaging. It is cheaper compared to PET imaging because it uses isotopes; for example, ^{99m}Tc-Tetrofosmin (Myoview, GE Healthcare), ^{99m}Tc-Sestamibi (Cardiolite, Bristol-Myers Squibb) that are stable for longer periods of time and less difficult to generate (Kelly et al., 1993). It also relies on the direct detection of emitted gamma rays and is, therefore, more comparable to scintigraphy. However, SPECT provides true 3D images compared to 2D images in conventional scintigraphy. This is achieved by up to three gamma detection cameras that rotate around the imaging object and acquire images at incremental angles of the object, equal to other tomography imaging methods.

Imaging Applications for Cardiovascular Animal Models

In animal models of ischemic heart disease, SPECT imaging allows the detection of underperfused myocardium. Small rodents are anesthetized and injected with a radiotracer. An image is acquired at rest and the heart stressed by applying an adrenergic stimulus (e.g., dobutamine). A second image is acquired shortly after the maximal activity has been achieved, and areas that are ischemic will have lower signal intensity on the SPECT image. SPECT systems specifically for small rodents have been designed, which allow a resolution of structures with about 1 μL volumetric sizes (Beekman et al., 2005). In addition, multimodal imaging in combination with μCT or MRI increases the resolution and interpretation of SPECT images (Hendrikx et al., 2016).

Optical Imaging

Optical imaging of the heart has played an important role in defining physiological processes at the molecular, cellular, and whole organ level. For example, optical imaging has been used to determine calcium transients in isolated cardiomyocytes and hearts, as well as investigate the propagation of the action potential through the heart's conduction system. With the development of new fluorophores and new imaging technologies, optical imaging is emerging as a complementary approach to nuclear imaging modalities.

Fluorescence and bioluminescence are the basis of most optical imaging approaches. Fluorescence imaging is based on the transgenic expression of fluorescent proteins (e.g., green fluorescent protein, GFP or yellow fluorescent protein, YFP) or quantum dots that are used as a source of exogenous contrast agents for in vivo imaging. In fluorescence, the energy of an external photon is absorbed and reemitted at a longer wavelength and lower energy. Biological tissues have a high photon absorbance in both the visible wavelength range (350–700 nm) and in the infrared range (>900 nm; due to lipids and water). However, in the near-infrared region (700–900 nm), the absorbance for all biomolecules is minimal. Thus, near-infrared fluorescence light offers a unique advantage for the imaging of physiological states. The advantage of using near-infrared wavelengths is the relatively deep photon penetration into tissues ($\leq$1 cm), minimal autofluorescence, less scatter, and high optical contrast when exogenous near-infrared fluorophores are used. Near-infrared imaging is now routinely used in animal models of cancer to monitor tumor growth and metastasis.

In bioluminescence, the emitted photons are produced in a chemical reaction for example by luciferin and luciferase. The luciferase enzyme catalyzes the oxidation of luciferin, resulting in light emission.

While there are several advantages in using optical imaging, there are also significant difficulties associated with this technique. First, the shallow penetration depth of most optical imaging probes limits its use for in vivo imaging of the heart. Even with near-infrared imaging, the mice have to undergo major surgery to make the heart directly accessible for the imaging camera. Second, movement artifacts caused by the high heart rate and the high breathing frequency in small rodents can make it difficult to gain useful information from optical in vivo imaging (Efimov, 2004). Image gating on ECG and breathing can prevent some but not all artifacts.

The high heart rate required the development of very high-speed image acquisition capabilities. This was achieved in developing charge-coupled device cameras that allow temporal resolutions to as high as 10,000 frames/s and thus enable imaging of isolated cardiomyocytes and isolated hearts at physiological heart rates of mice.

Optical imaging has been intensely used to describe the calcium transient in isolated cardiomyocytes of different species (Cordeiro et al., 2001; Bing et al., 1991; Pinz et al., 2011), and it has been applied to the study of different cardiac ion channels and gap junctions (Ianoul et al., 2004; Ding et al., 2017; Smyth and Shaw, 2008), as well as investigations in ischemia–reperfusion injury in the mouse heart (Lee et al., 2012).

Acknowledgment

This work was supported by the Mouse Transgenic and In Vivo Imaging Core Facility at Maine Medical Center Research Institute (Core Directors, L. Liaw and I. Pinz), which was funded by NIH COBRE award 8P30GM103392 (R. Friesel, PI).
I thank Marilena Preda and Terry Henderson for their support in image acquisition in the Small Animal Imaging Core.

Introduction

Hypertension in pregnancy, including gestational hypertension, preeclampsia, and eclampsia, complicates 10% of pregnancies and are a leading cause of maternal mortality and morbidity worldwide. Women with chronic hypertension are at risk for developing gestational hypertension and preeclampsia/eclampsia. Those with de novo onset of hypertension in pregnancy are in turn at risk for developing later essential hypertension and cardiovascular disease. In this module we review and summarize the epidemiology, pathophysiology, and clinical management of preeclampsia and hypertension in pregnancy.

Hypertensive Disorders of Pregnancy: Definitions

Hypertensive disorders are among the most common medical problems in pregnancy and consist of chronic hypertension, gestational hypertension, preeclampsia, and preeclampsia superimposed upon chronic hypertension.

Chronic hypertension is defined as a systolic blood pressure $\geq$140 mmHg and/or diastolic blood pressure $\geq$90 mmHg that predates conception, is present before the 20th week of pregnancy, or persists longer than 12 weeks postpartum. Gestational hypertension refers to elevated blood pressure first detected after 20 weeks of gestation in the absence of proteinuria or other diagnostic features of preeclampsia. Gestational hypertension generally resolves before 12 weeks postpartum.

Preeclampsia (and eclampsia) are multisystem disorders that are characterized by new onset hypertension (systolic blood pressure $\geq$140 mmHg or diastolic blood pressure $\geq$90 mmHg) and proteinuria ($\geq$0.3 g in a 24-h urine specimen) and/or end organ dysfunction after 20 weeks of gestation in a baseline normotensive woman (Cunningham and Lindheimer, 1992). Systemic complications of preeclampsia can affect the renal, hematologic, hepatic, neurologic, cardiac and/or pulmonary systems. Specific manifestations include kidney injury, thrombocytopenia, hepatic insufficiency, stroke, seizure, and pulmonary edema. Preeclampsia can also cause fetal growth restriction and result in placental abruption. In most women, these findings are seen later in pregnancy, after 34 weeks of gestation. In only 10% of cases, preeclampsia develops before 34 weeks of gestation (Cunningham and Lindheimer, 1992). Eclampsia is defined as preeclampsia complicated by neurologic defects including seizures and stroke.

When a woman with chronic hypertension develops worsening hypertension with new onset proteinuria or other cardinal features of preeclampsia, this is referred to as preeclampsia superimposed upon chronic hypertension. Distinguishing between worsening chronic hypertension in pregnancy versus new superimposition of preeclampsia has been highlighted as a particularly challenging diagnostic dilemma by the American College of Obstetrics and Gynecology (2013).

Hypertensive Disorders of Pregnancy: Epidemiology

Preeclampsia and other hypertensive disorders are the leading cause of maternal morbidity worldwide. The incidence of hypertensive disorders is estimated to be between 3% and 10% of all pregnancies. Within the past 20 years the rate of maternal chronic hypertension has nearly doubled in the United States, which is in part due to the obesity epidemic and increasing maternal age (Martin et al., 2011). The rates of chronic hypertension have increased for all racial and Hispanic ethnicity groups, with the largest

increase seen among non-Hispanic Black women (Martin et al., 2011). There are increasing trends in the United States for all types of hypertensive pregnancy disorders with the exception of mild preeclampsia (Kuklina et al., 2009; Hutcheon et al., 2011).

Preeclampsia occurs in 5% of pregnancies worldwide. Eclampsia, which is the occurrence of seizures in addition to the preeclampsia syndrome, occurs in one in 100–1700 pregnancies in the developing world and in approximately 2000 pregnancies in Europe. The range of prevalence reflects the differences in maternal age. In the United States the prevalence of preeclampsia is 2.4%, but 1.5- to 2-fold higher in first pregnancy. The reported incidence of preeclampsia is increasing in the United States due to several factors, including the high prevalence of disorders such as hypertension, diabetes, obesity, delay in child bearing, and the use of artificial reproductive techniques. Rates of eclampsia, however, have declined due to antenatal care and magnesium sulfate (Lo et al., 2013).

Physiologic Blood Pressure Changes During Pregnancy

Understanding the physiologic changes of pregnancy is key to understanding the maladaptation that occurs in preeclampsia. Pregnancy is characterized by significant hemodynamic and structural changes in the cardiovascular system that allow for adequate uteroplacental circulation and fetal development. These changes are dynamic and include increased left ventricular size, mass, heart rate, cardiac output, vascular compliance, and capacitance. Systemic vascular resistance (SVR) and blood pressure decrease during pregnancy (Clapp and Capeless, 1997).

Hormones including estrogen, progesterone, and chorionic gonadotropin as well as prostaglandins and nitric oxide act on the vascular endothelium and smooth muscle to alter vessel structure and tone. As early as 5 weeks' gestation, the vasodilatory effects of these hormones and the low-resistance of the uteroplacental flow lead to a significant decrease in SVR (Ouzounian and Elkayam, 2012). In the first trimester, SVR decreases by around 10% and nadirs in the middle of the second trimester. It then plateaus until approximately 32 weeks, when it minimally increases (Clapp and Capeless, 1997). The change in SVR is associated with greater vascular compliance as well as a decrease in blood pressure and an increase in pulse pressure.

Due to the effects on blood vessel tone and the low resistance of the uteroplacental vascular system, a decrease in arterial pressures is seen in pregnancy. Diastolic blood pressure decreases more significantly than systolic blood pressure. Blood pressure nadirs during the second trimester, dropping by 5–10 mmHg below baseline. These changes in blood pressure have been demonstrated in numerous studies. A prospective cohort study by Grindheim et al. confirmed a statistically significant drop in blood pressure in mid-pregnancy followed by a progressive increase until term (Grindheim et al., 2012; Mahendru et al., 2014).

Pregnancy is also associated with increased plasma volume secondary to activation of the renin–angiotensin–aldosterone system. This results in retention of salt and water, which is augmented by increased vasopressin secretion (Sanghavi and Rutherford, 2014). The degree of volume expansion is directly linked to normal fetal growth and birth weight (Ouzounian and Elkayam, 2012). Cardiac output is also seen to increase throughout gestation. A rise in stroke volume accounts for the increase in cardiac output early in pregnancy, while heart rate is the main contributor later in pregnancy. These changes can augment the cardiac output by up to 45% by 24 weeks (Sanghavi and Rutherford, 2014).

The varied and dynamic effects on the cardiovascular system, including the effects on blood pressure, during pregnancy tend to return to baseline 2 weeks postpartum. However, failure to make the above adaptations is associated with uteroplacental insufficiency and pregnancy complications, such as preeclampsia and other hypertensive disorders of pregnancy.

Placentation in Preeclampsia Versus Normal Pregnancy

Normal placentation involves trophoblast invasion into the inner third of the maternal myometrium including the uterine spiral arteries. These trophoblasts replace the endothelial lining of the spiral arteries. The sum of these processes serve to take a high-resistance, low-flow vascular system and convert it to a low-resistance, high-flow system, thus allowing for adequate fetal perfusion. In preeclampsia however, there is often a relatively shallow invasion of the myometrium and an incomplete replacement of the endothelial lining of the uterine spiral arteries as occurs in normal pregnancy. These abnormalities result in an effective decrease to the vascular perfusion to the fetus and placenta resulting in fetal growth restriction in the more severe cases of preeclampsia and in early-onset preeclampsia. The abnormal placentation is accompanied by a maternal inflammatory response.

Chronic hypertension or renal disease is a risk factor for preeclampsia, along with a family history of preeclampsia. It is uncertain which specific factors in hypertensive women directly contribute to the underlying placental abnormalities that characterize preeclampsia.

Preeclampsia Screening

Given that preeclampsia is a leading cause of maternal death and morbidity, as well as numerous fetal complications, multiple studies have attempted to guide screening. The National Institute for Health and Clinical Excellence (NICE) antenatal care

guideline was published in 2003 and updated in 2008 (NICE, 2008). The preeclampsia community guideline (PRECOG) was published in 2005 in the United Kingdom (Milne et al., 2005). Both of these publications attempt to identify women at risk for preeclampsia who require either subspecialty referral or more frequent monitoring. However, the clinical utility of these guidelines remains controversial (Verghese et al., 2012). Furthermore, no single test has been identified to predict preeclampsia adequately enough to be instituted in clinical practice (Magee et al., 2015a). The American College of Obstetricians and Gynecologists (ACOG) recognizes this fact and recommends obtaining a detailed medical history as the only screening for preeclampsia. ACOG further notes that supplemental predictive tests may do more harm than good secondary to their low positive predictive value (Taghiof et al., 2015).

When taking a clinical history, focusing on risk factors for the development of preeclampsia is key. Strong risk factors include previous preeclampsia, preexisting hypertension, chronic kidney disease, type 1 or 2 diabetes, and autoimmune disorders include systemic lupus erythematosus and antiphospholipid antibody syndrome. Other identified risk factors include maternal age $\geq$40 years old, family history of preeclampsia, BMI of 35 or more, first pregnancy, multiple pregnancy, and polycystic ovarian syndrome (Magee et al., 2015a; Mol et al., 2016; North et al., 2011). Based on the medical history, it is up to the provider to refer to subspecialty treatment, more frequent monitoring, and assess for preventative therapy. Magee et al. recommend that these measures be offered if a woman has one or more strong risk factors. Women with two or more "other" factors should also be offered these interventions (Magee et al., 2015a).

Along with a clinical history, a standard physical exam and blood/urine testing are commonly performed. Knowing that a pregnant woman's blood pressure varies greatly on her positioning, blood pressure should be measured in a seated and upright position or in a left lateral recumbent position. Subsequent blood pressure measurements should be taken in the same position for consistency (Mol et al., 2016; Ouzounian and Elkayam, 2012). Recommended testing includes urinalysis, CBC and film, serum creatinine, and liver enzymes as well as function. Proteinuria should be assessed for early in pregnancy to identify patients with preexisting kidney disease and at $\geq$20 weeks to screen for preeclampsia in those identified as at risk (Magee et al., 2015a). This screening is usually performed by dipstick testing, which has a low mean sensitivity of 55% but an adequate mean specificity of 84% (Magee et al., 2015a).

Although current guidelines recommend against further screening, studies are currently evaluating the utility of maternal blood biomarkers, such as placental growth factor (Mol et al., 2016). Other combination screening procedures are also being studied, including the use of late first-trimester uterine artery Doppler ultrasound, placental growth factor, and pregnancy-associated plasma protein A in maternal blood. These tests combined have been shown to predict early-onset preeclampsia with a sensitivity of 93% (95% CI 76%–98%) and specificity of 95% (95% CI 94%–96%) (Mol et al., 2016; Cuckle and Maymon, 2016). However, they have not been externally validated.

Preeclampsia Prevention

Preeclampsia is associated with an imbalance of thromboxane and prostacyclin resulting in platelet activation and endothelial dysfunction (Leslie et al., 2011; Correa et al., 2016). The efficacy of antiplatelet agents has thus been studied in the prevention of preeclampsia.

In 2010, Bujold et al. published a systematic review suggesting that initiation of low-dose aspirin at $\leq$16 weeks in women at high or moderate risk for preeclampsia significantly reduced the occurrence of preeclampsia (RR: 0.47, 95% CI: 0.34–0.65), severe preeclampsia (RR: 0.09, 95% CI: 0.02–0.37), gestational hypertension (RR: 0.62, 95% CI: 0.45–0.84), intrauterine growth restriction (RR: 0.44, 95% CI: 0.30–0.65), and preterm birth (RR: 0.22, 95% CI: 0.10–0.49) (Bujold et al., 2010). A recent meta-analysis further supported the beneficial effects of low-dose aspirin initiated $\leq$16 weeks. However, this study could find little to no reduction on the relative risk of preeclampsia, severe preeclampsia, and fetal growth restriction when aspirin was initiated after 16 weeks (Roberge et al., 2017). Although multiple studies have reaffirmed a benefit of aspirin in reducing the risk of preeclampsia, identifying the appropriate population to treat, when to initiate therapy, and the optimal dose of aspirin remain unclear (Correa et al., 2016). For the time being, ACOG recommends the initiation of low-dose (60–80 mg) aspirin beginning in the late first trimester in women with a medical history of early-onset preeclampsia and preterm delivery at less than 34 weeks, or preeclampsia in more than one previous pregnancy (American College of Obstetricians and Gynecologists, 2013). Prior clinical trials that have additionally focused on the anticoagulant effects of heparin and dalteparin in preventing preeclampsia demonstrate positive effects. These studies, however, were too small to make definitive conclusions (Mol et al., 2016).

Along with antiplatelet and anticoagulant agents, researchers have focused on the connection between low dietary calcium and preeclampsia. Prior studies have shown a link between low dietary calcium and low serum calcium concentrations with higher rates of preeclampsia (Mol et al., 2016). A Cochrane review published in 2014 showed that high-dose calcium supplementation reduced the risk of preeclampsia in women with low dietary calcium intake (RR 0. 36, 95% CI 0.20–0.65) (Hofmeyr et al., 2014). The World Health Organization (WHO) thus recommends calcium supplementation (1.5–2 g daily) in women with low dietary calcium intake in the second half of pregnancy (Correa et al., 2016).

Further studies on diet and lifestyle interventions, antioxidants, fish oils, magnesium, and garlic in preventing preeclampsia were unable to show a clear benefit (Leslie et al., 2011; Correa et al., 2016). L-Arginine, a precursor to nitric oxide, is also being evaluated and more evidence is needed to confirm any protective effect (Mol et al., 2016; Correa et al., 2016). Pravastatin has shown promising effects in preclinical and pilot clinical studies to prevent preeclampsia, but further randomized controlled trials are needed to validate these findings (Marrs and Costantine, 2016).

Preeclampsia Treatment

Once a woman is diagnosed with preeclampsia, the only cure is delivery (Mol et al., 2016). Subspecialty consultation with high-risk perinatology physicians is recommended and inpatient treatment may be necessary if severe hypertension or end-organ damage develop.

Intravenous fluids should be minimized and hypertension with systolic blood pressure ≥ 160 or diastolic blood pressure ≥ 110 should be treated. The recent CHIPS trial found that treatment of maternal hypertension benefits the mother without increasing pregnancy loss or requirement for high-level neonatal care for more than 48 h (Magee et al., 2015b). Appropriate antihypertensives include methyldopa, labetalol, hydralazine, and nifedipine. ACE inhibitors, angiotensin receptor blockers, prazosin, and atenolol are avoided due to known or suspected teratogenicity. In an emergency setting, IV hydralazine, labetalol, and oral nifedipine are commonly used (Berzan et al., 2014). Repeated doses of these medications every 15–30 min control blood pressure in at least 80% of women (Mol et al., 2016).

The WHO and ACOG recommend magnesium sulfate for prevention of eclampsia in women with severe preeclampsia (Organization, 2011; American College of Obstetricians and Gynecologists, 2013). This therapy has been found to more than halve the risk of eclampsia (Berzan et al., 2014). However, around one hundred women with preeclampsia have to be treated with magnesium sulfate to prevent one seizure. Due to cost and a high number needed to treat, guidelines recommend avoiding magnesium sulfate in women without severe preeclampsia (Magee et al., 2015a).

The timing of delivery in women with preeclampsia is key to treatment. ACOG stipulates that expectant management is appropriate for women with preeclampsia without severe features and no indication for delivery at less than 37 weeks. This should only be done if there are adequate resources to ensure close maternal and fetal monitoring. Such monitoring includes daily assessment of symptoms and fetal movement, twice-weekly measurements of blood pressure, and obtaining platelet counts and liver function weekly (American College of Obstetricians and Gynecologists, 2013). Only 40% of women, however, are eligible for expectant care. For women with preeclampsia without severe features at or past 37 weeks, delivery is recommended. Delivery is also appropriate in women with severe preeclampsia at or beyond 34 weeks, and in women who are unstable or have fetal instability no matter what the gestational age (American College of Obstetricians and Gynecologists, 2013). It is up to the clinician to weigh the risks and benefits as well as patient preferences in pursuing delivery.

After delivery, it is imperative to monitor the mother for complications of preeclampsia, especially in the first 48 h postpartum. Blood pressure control and patient education on symptoms and signs are key (Mol et al., 2016).

Pathophysiology of Preeclampsia and CV Risk

Placental abnormalities in preeclampsia mirror many of the vascular changes seen in cardiovascular disease including acute placental arterial atherosis, fibrin deposition, and accumulation of lipid-laden macrophages (Fisher, 2015). Pathologic placental specimens derived from preeclamptic pregnancies demonstrate placental arterial thrombosis and infarction (Gibbins et al., 2016). Several studies now demonstrate that preeclampsia is an independent risk factor for cardiovascular disease including fatal and nonfatal myocardial infarction (Brown et al., 2013). The underlying mechanisms accounting for the increased risk include (1) shared genetic risk factors for hypertension in pregnancy and CVD, (2) other shared risk factors including hypertension, insulin resistance, obesity, thrombophilia, and endothelial dysfunction. Subclinical atherosclerosis as measured by carotid intima media thickness was elevated prior to preeclampsia (Milic et al., 2017). Whether the preeclamptic pregnancy per se increases a woman's risk of CVD is uncertain.

Preeclampsia and Later CVD in Women

In a recent meta-analysis of 43 studies, preeclampsia was associated with increased pooled odds of CVD: OR 2.28 (95% CI 1.87–2.78), of stroke: OR = 1.76, 95% CI 1.43, 2.21) and of hypertension [relative risk (RR) = 3.13, 95%CI 2.51, 3.89] (Brown et al., 2013). As a result of this growing body of evidence, expert panels now recommend taking a history of preeclampsia as part of cardiovascular disease risk stratification in women including the American Heart Association (Mosca et al., 2011) as well as European expert committees (Heida et al., 2016). However, the question of whether preeclampsia has utility as a novel marker for CVD risk prediction in women over and beyond traditional risk factors has not been systematically evaluated. However,

regardless, preeclampsia likely serves as an early window that may reveal which women are at higher risk for hypertension and cardiovascular diseases.

Postpartum Screening and Management of CV Risk Factors in Women With Gestational Hypertension and Preeclampsia

Women with a history of preeclampsia following pregnancy and delivery should be referred to the primary care providers early for close and aggressive monitoring of CVD risk factors including blood pressure, weight, lipids, and lifestyle factors such as smoking and physical activity. Studies have evaluated the feasibility of referral clinics for women with pregnancy complications such as preeclampsia, which focus on cardiovascular risk factor modification (Cusimano et al., 2014).

Conclusions

Preeclampsia and hypertension in pregnancy are disorders with a growing prevalence in the United States and can lead to substantial maternal morbidity and mortality without treatment and intervention. Similar to essential hypertension, the exact etiology of preeclampsia and gestational hypertension is uncertain; however, specific features of the downstream pathophysiology of preeclampsia substantially overlap with cardiovascular disease. Preeclampsia is a risk factor for heart disease, stroke, and hypertension and therefore can identify the woman at risk for developing these conditions, who may benefit from early and intensive lifestyle modification.

Introduction

In western industrialized countries, the prevalence of pregnancies carried by women with cardiovascular disease is 0.2%–4% (Regitz-Zagrosek et al., 2011). This situation poses an increased risk to both mother and fetus. With the declining incidence of rheumatic heart disease in Western countries, most maternal heart disease is now congenital. Other heart diseases include dilated cardiomyopathies, hypertrophic cardiomyopathies, valvular disease, pulmonary arterial hypertension (PAH), and Marfan syndrome. Maternal heart disease remains an important cause of maternal mortality and morbidity during pregnancy. In a report of maternal deaths from 2006 to 2008 in the United Kingdom, heart disease remains the most common cause of indirect maternal death (Cantwell et al., 2011).

Cardiac events may be caused by hemodynamic changes including increased volume load (preload) and hypercoagulable status during pregnancy. It is quite important to understand these physiological changes during pregnancy and the risk factors for cardiac events during pregnancy in each type of heart disease. High-risk pregnancies are shown in **Table 1** (Bonow et al., 2012). Women with pulmonary hypertension, Eisenmenger syndrome, dilated cardiomyopathy (ejection fraction <40%), symptomatic obstructive lesion, Marfan syndrome with aortic root >40 mm, cyanotic lesions, and mechanical prosthetic valves are considered to have high-risk pregnancies. In some cases, patients should avoid pregnancy or in some cases consider termination.

All patients with known cardiac disease, especially these high-risk groups, should be counseled before conception. Risk assessment of cardiac events during pregnancy is important. If possible, needed surgical operations including valvotomy, valve repair, or replacement should be performed before pregnancy. Treatment of arrhythmias and treatment of underlying medical conditions such as hypertension or diabetes should also be performed before pregnancy. To avoid teratogens, medication should be changed before pregnancy; for instance, warfarin or angiotensin-converting enzyme (ACE) inhibitors should be avoided. It is important to discuss anticoagulation factors. Women of child-bearing age using warfarin need to understand its teratogenic potential and the risk of fetal intracranial hemorrhage, and warfarin should be changed, in most cases to heparin, immediately after pregnancy is confirmed, and certainly before sixth weeks of gestation. Women with mechanical valves, in particular, should be counseled on the risk and benefit of warfarin versus low-molecular-weight heparin (LMWH) or unfractionated heparin (UFH), and given the opportunity for an informed choice about their anticoagulant regime during pregnancy. Their pregnancies should be managed by a multidisciplinary team. Especially high-risk patients should be treated in specialized tertiary centers (Regitz-Zagrosek et al., 2011).

Epidemiology

With the decreasing incidence of rheumatic heart disease in Western countries, the most common maternal heart disease is now congenital heart disease. Other maternal cardiovascular diseases include dilated or hypertrophic cardiomyopathies, and peripartum cardiomyopathy, valvular disease, pulmonary hypertension, and Marfan syndrome with aortic root dilatation. In western countries

Modified from Bonow, R. O., Mann, D. L., Zipes, D. P. and Libby, P. (2012). *Braunwald's heart disease: a textbook of cardiovascular medicine* (9th edn.). Philadelphia: Elsevier Saunders.

maternal heart disease is now the predominant cause of maternal death during pregnancy (Cantwell et al., 2011). Hypertensive disorders are the most frequent cardiovascular events during pregnancy, occurring in 6%–8% of all pregnancies (Peters and Flack, 2004).

Physiological Changes in Normal Pregnancy

Hemodynamic Changes in Pregnancy

Hemodynamic changes begin early in the first trimester. The plasma volume begins to increase in the sixth week of pregnancy and at 24 weeks' gestation reaches 30%–50% above baseline. Cardiac output (CO) is increased around 50% (Hunter and Robson, 1992). The heart rate begins to rise at 20 weeks and continues to increase until 32 weeks when it plateaus. It remains high through the immediate postpartum period, 2–5 days after delivery. Total peripheral vascular resistance is reduced. As a result, systemic blood pressure falls early in gestation and diastolic blood pressure is reduced in the second trimester. Increased CO is primarily related to the rise in stroke volume in early pregnancy; on the other hand, heart rate is the major factor in late pregnancy (Robson et al., 1989; Mabie et al., 1994).

These hemodynamic changes may cause problems for pregnant women with cardiac disease. Clearly, the added volume load may compromise a patient who has impaired ventricular function and limited cardiac reserve. Stenotic valvular (e.g., aortic stenosis) lesions are less well tolerated than regurgitant lesions because the decrease in peripheral resistance exaggerates the gradient across the aortic valve. On the other hand, with a lesion such as mitral regurgitation, the afterload reduction helps offset the volume load on the left ventricle that gestation imposes (Bonow et al., 2012).

Hematologic Changes in Pregnancy

During pregnancy, plasma concentrations of coagulation factors are greatly changed (Stirling et al., 1984; Szecsi et al., 2010). The levels of coagulation factors II, V, X, XI, and XII, antithrombin and protein C, as well as the activated partial thromboplastin time (APTT) and prothrombin time remain largely unchanged during pregnancy, delivery, and postpartum, remaining within the nonpregnant reference ranges. However, levels of fibrinogen, D-dimer, and coagulation factors VII, VIII, and IX increase markedly during pregnancy. Protein S activity decreases substantially, while free protein S decreases slightly and total protein S is stable (Szecsi et al., 2010). These procoagulant changes have the physiological function of minimizing intrapartum blood loss, but they do increase the risk of thromboembolism during pregnancy and the postpartum period.

It is also problematic to monitor the anticoagulant effect of a therapeutic dose of heparin during pregnancy. In pregnant women, APTT does not precisely reflect the anticoagulant effect of a therapeutic dose of heparin. However, the measurement of anti-Xa activity can be used to monitor the anticoagulant effect of heparin, since the plasma concentrations of coagulation factors increase in pregnant women. In the presence of UFH, APTT was shortened by increased concentrations of fibrinogen, FVII, or FVIII; the effect was much stronger when the FVIII concentration was increased (Mitsuguro et al., 2015).

Risk Assessment for Pregnancy

Preconception Counseling

Preconception counseling should be offered to all women of reproductive age with known cardiac disease. Risk assessment should focus on both mother and fetus. Risks for the mother include cardiovascular events, maternal death during pregnancy and

postpartum, and persistent deterioration of heart function. Risks for the fetus include the teratogenicity of medication, fetal growth restriction, fetal death, preterm birth, and the inheritance of congenital heart disease, Marfan syndrome, and hypertrophic cardiomyopathy. If necessary, drug schedules should be changed before pregnancy.

Drug Treatment During Pregnancy

There are no standard or uniform recommendations for the medical treatment of pregnant women. Drug treatment during pregnancy should consider both the mother and the fetus. A medication should be given only if the benefits overweigh the potential risk to the fetus. We should consider the use of the lowest dose and shortest duration, if possible. All these issues should be reviewed carefully before pregnancy. Especially we need special caution with the administration of amiodarone, ACE inhibitors, angiotensin II receptor blocker, and warfarin. A list of cardiovascular drugs that might be considered safer options during pregnancy is given in **Table 2**.

Maternal Cardiovascular Risk Assessment

There are some risk stratifications for estimating maternal cardiovascular complications. CARPREG (CARdiac disease in PREGnancy) is the most widely used risk score (Siu et al., 2001). This prospective multicenter study included 599 pregnancies in women with congenital or acquired cardiac lesions or those with cardiac arrhythmias. This study incorporates the four predictors of primary cardiac events as shown in **Table 3**. Predictors of primary cardiac events were incorporated into a revised risk index, in which each pregnancy was assigned 1 point for each predictor when present. The estimated risk of a cardiac event in pregnancies with 0, 1, and >1 points was 5%, 27%, and 75%, respectively. This study showed that pulmonary edema, arrhythmia, stroke, or cardiac death complicated 13% of pregnancies (Siu et al., 2001).

Table 2 Cardiovascular drugs in pregnancy

Drug	*Potential fetal side effects*
Amiodarone (INN)	Thyroid insufficiency, hyperthyroidism, goitre, bradycardia, FGR, premature birth
Angiotensin-converting enzyme inhibitors	Oligohydramnios due to renal failure or renal dysplasia, lung hypoplasia, FGR, IUFD, abnormal bone ossification
Angiotensin II receptor blocker	Oligohydramnios due to renal failure or renal dysplasia, lung hypoplasia, FGR, IUFD, abnormal bone ossification
Acetylsalicylic acid (INN)	Low-dose usage is safe
Beta blockers	Relatively safe; bradycardia and hypoglycemia in fetus; FGR
Calcium channel blockers	Relatively safe; potential synergism with magnesium sulfate may induce hypotension
Digoxin (INN)	Safe; no adverse effects
Flecainide (INN)	Limited data; used to treat fetal arrhythmias
Furosemide (INN)	Safe; caution regarding maternal hypovolemia and reduced placental blood flow; oligohydramnion
Hydralazine (INN)	Safe; no major adverse effects, lupus-like symptoms for mother
Lidocaine (INN)	Safe; high doses may cause neonatal central nervous system depression
Methyldopa (INN)	Safe; one of the choices for hypertension during pregnancy
Procainamide (INN)	Relatively safe; limited data
Warfarin (INN)	Fetal embryopathy (nasal hypoplasia and/or stippled epiphyses; limb hypoplasia) for first-trimester exposure, adverse fetal CNS events and CNS abnormalities with exposure in any trimester, placental and fetal hemorrhage

FGR, fetal growth restriction; *IUFD*, intrauterine fetal death; *INN*, International Nonproprietary Name; CNS, central nervous system.

L., Aarnoudse, J. G., van Veldhuisen, D. J., Pieper, P. G. and Investigators, Z.-I. (2014). Prospective validation and assessment of cardiovascular and offspring risk models for pregnant women with congenital heart disease. *Heart* **100**(17), 1373–1381.

Table 5 Modified WHO classification of maternal cardiovascular risk

WHO class	*Risk for pregnancy by medical condition*
I	No detectable increased risk of maternal mortality or morbidity
II	Small increased risk of maternal mortality or morbidity
III	Significantly increased risk of maternal mortality or severe morbidity. Expert counseling required. If pregnancy is decided upon, intensive specialist cardiac and obstetric monitoring needed throughout pregnancy, childbirth, and puerperium
IV	Extremely high risk of maternal mortality or severe morbidity; pregnancy contraindicated. If pregnancy occurs termination should be discussed. If pregnancy continues, care as for class III

WHO, World Health Organization.
Adapted from Regitz-Zagrosek et al., 2011, which was modified from Thorne, S., MacGregor, A. and Nelson-Piercy, C. (2006). Risks of contraception and pregnancy in heart disease. *Heart* **92**(10), 1520–1525.

The ZAHARA (Zwangerschap bij Aangeboren HARtAfwijkingen) study provides additional risk calculators in pregnant women with congenital heart disease (Drenthen et al., 2010) (**Table 4**). It should be noticed that these CARPREG and ZAHARA studies did not identify important high-risk factors including PAH and dilated aorta, simply because they were underrepresented in these studies.

The Task Force of the European Society of Cardiology (ESC) Guidelines (Regitz-Zagrosek et al., 2011) recommends that maternal risk be assessed according to the modified World Health Organization (WHO) risk classification (Thorne et al., 2006). This risk classification integrates all known maternal cardiovascular risk factors including underlying heart disease and any other comorbidity. It includes contraindications for pregnancy that are not incorporated in the CARPREG and ZAHARA risk scores. The modified WHO classification is shown in **Table 5**. WHO class I indicates low risk, WHO class II indicates low or moderate risk, and WHO class III indicates high risk, for which frequent follow-up by a cardiologist and obstetrician during pregnancy is recommended. WHO class IV constitutes a contraindication for pregnancy; however, if these patients become pregnant and will not consider termination, close and careful follow-up is needed.

Additionally, Balci et al. compared these three maternal cardiovascular risk scores for pregnant women with congenital heart disease: namely, the ZAHARA and CARPREG risk scores and the modified WHO classification. Their study concluded that the WHO classification is the best available risk assessment model for estimating cardiovascular risk in pregnant women with CHD given in **Table 6** (Balci et al., 2014).

Cardiac Events During Pregnancy

Heart failure and arrhythmias are the most common cardiac events during pregnancy.

Heart Failure

Preeclampsia is a common condition that precipitates afterload failure, and chronic hypertension with superimposed preeclampsia is the most frequent cause of heart failure in pregnant women. All patients with heart failure during pregnancy should be admitted to a nursing or medical facility for bed rest. Medical therapy includes diuretics to reduce preload and antihypertensive therapy including hydralazine or another vasodilator to reduce afterload.

Table 6 Modified WHO classification of maternal cardiovascular risk

Conditions in which maternal risk is WHO class I
Uncomplicated, small or mild pulmonary stenosis
Successfully repaired simple lesions (atrial or ventricular septal defect, patent ductus arteriosus, anomalous pulmonary venous drainage)
Conditions in which maternal risk is WHO class II or III
WHO class II (if otherwise well and uncomplicated)
Unoperated atrial or ventricular septal defect, repaired tetralogy of Fallot
WHO class II–III (depending on individual)
Native or tissue valvular heart disease not considered WHO I or IV; repaired coarctation; Marfan syndrome without aortic dilatation, bicuspid valve with aorta <45 mm; mild ventricular impairment
WHO class III
Mechanical valve; systemic right ventricle; Fontan circulation; unrepaired cyanotic heart disease; other complex congenital heart disease; Marfan syndrome with aortic dilation 40–45 mm; bicuspid aortic valve with aortic dilation 45–50 mm
Conditions in which maternal risk is WHO class IV (contra-indicated)
Pulmonary hypertension/Eisenmenger syndrome; systemic ventricular EF <30% or systemic ventricular dysfunction with NYHA class III–IV; severe mitral stenosis, severe symptomatic aortic stenosis, Marfan syndrome with aortic dilation >45 mm; bicuspid aortic valve with aortic dilation >50 mm; native severe coarctation

WHO, World Health Organization; *EF*, ejection fraction.

Adapted from Balci, A., Sollie-Szarynska, K. M., van der Bijl, A. G., Ruys, T. P., Mulder, B. J., Roos-Hesselink, J. W., van Dijk, A. P., Wajon, E. M., Vliegen, H. W., Drenthen, W., Hillege, H. L., Aarnoudse, J. G., van Veldhuisen, D. J., Pieper, P. G. and Investigators, Z.-I. (2014). Prospective validation and assessment of cardiovascular and offspring risk models for pregnant women with congenital heart disease. *Heart* **100**(17), 1373–1381.

During pregnancy, ACE inhibitors, ARBs, and renin inhibitors are contraindicated due to their known fetotoxicity. Hydralazine and nitrates can be used instead of ACE inhibitors and ARBs for afterload reduction. Administration of a β-blocker is indicated for all patients with heart failure, with a preference for β1-selective drugs. Diuretics should be used for only pulmonary edema because they may decrease placental blood flow.

Arrhythmias

Due to the physiological changes of pregnancy, the incidence of arrhythmias may be increased during pregnancy in women with heart disease. If the patient has no underlying heart disease, pharmacologic treatment should be administered when the patient is symptomatic or when arrhythmia is a risk for the mother or fetus. If the patient has underlying heart disease, the precipitating cause should be treated. The most common arrhythmia is atrial reentry tachycardia. The major concern for use of antiarrhythmic drugs during pregnancy is their potential adverse effects on the fetus (**Table 2**). It is important to treat symptomatic tachyarrhythmia by catheter ablation before pregnancy.

High-Risk Maternal Heart Disease: WHO Class III or IV

Pulmonary Hypertension

Pulmonary hypertension is a category of high-risk pregnancy in WHO class IV. PAH is defined as a nonpregnant elevation of the mean pulmonary artery pressure ≥25 mmHg at rest or 30 mmHg at exercise in the absence of a left-to-right shunt (Bedard et al., 2009). Pulmonary artery systolic pressure is usually estimated using Doppler ultrasound to measure the regurgitant jet velocity across the tricuspid valve. A Doppler study is a good diagnostic modality during pregnancy. Pulmonary hypertension includes different pathophysiologies: that is, PAH, pulmonary hypertension due to left heart disease, pulmonary hypertension due to lung disease and/or hypoxia, chronic thromboembolic pulmonary hypertension, and pulmonary hypertension with unclear multifactorial mechanisms (Simonneau et al., 2013). It is important that the pulmonary artery pressure falls in the presence of moderate to severe right ventricular impairment, thus modulating the severity of pulmonary vascular disease. The maternal risk with pulmonary vascular disease is high; previously, the mortality risk for patients with severe PAH and Eisenmenger syndrome was reported as 30%–50% (Weiss et al., 1998), but in recent data the estimate fell to 17%–33% (Bedard et al., 2009), which is still quite significant.

If such patients are pregnant, termination should be considered. Given the risk associated with anesthesia, delivery should be performed in a tertiary center experienced in the management of PAH patients. If patients want to continue pregnancy despite the risk, they should be managed in a center with expertise in PAH with all therapeutic options available (Regitz-Zagrosek et al., 2011).

Marfan Syndrome

Aortic dilatation and dissection are severe complications of pregnancy that may cause maternal death. The overall risk of maternal death is approximately 1%. Women at particularly high risk include those with a poor family history, cardiac involvement and aortic root >4 cm diameter, or a rapidly dilating aorta (Lind and Wallenburg, 2001; Elkayam et al., 1995). Care should be taken during both pregnancy and the postpartum period (Katsuragi et al., 2011). The prevalence of sinus of Valsalva ≥40 mm, aortic size

index (size of sinus of Valsalva/body surface area) ≥ 25 mm/m^2, and faster growth of the sinus of the Valsalva was significantly higher in the group with aortic dilatation or dissection than in groups without aortic dilatation or dissection (Katsuragi et al., 2011).

Mechanical Valve Prosthesis and Anticoagulant Therapy

The management of pregnancy with maternal mechanical valve prosthesis is quite controversial. There is no universal consensus or standard regimen. During pregnancy, maternal blood is highly thrombotic due to increased concentrations of clotting factors and decreased fibrinolysis. These hematological changes increase the risk of valve thrombosis and thromboembolism during pregnancy. Anticoagulant therapy during pregnancy raises specific concerns, because of the increased risk of valve thrombosis, hemorrhagic complications, and offspring complications. At least during the first trimester, that is between the sixth and twelfth weeks of gestation, vitamin K antagonists such as Warfarin should be avoided because of fetal embryopathy (**Table 2**).

Nonetheless, use of such agents still remains despite adverse fetal effects for exposure in each trimester. During the second and third trimesters, in choosing between vitamin K antagonists, UFH, and LMWH, each maternal and fetal risk should be weighed carefully. If vitamin K antagonists are used, their use is limited until 36 weeks of gestation, and then they should be replaced by heparin before delivery (Regitz-Zagrosek et al., 2011).

Conclusion

Heart disease is the major cause of maternal mortality in the United Kingdom. Pulmonary hypertension, Marfan syndrome with aortic dilation more than 40 mm, or mechanical valves are at highest risk of developing cardiac events during pregnancy. These groups are classified as modified WHO class III or IV. All patients with known cardiac disease should be counseled before pregnancy. If at all possible, needed surgical operations should be performed before pregnancy. To avoid teratogens, medication such as warfarin or ACE inhibitors should be swapped out before pregnancy. Such patients should be managed by a multidisciplinary team. Particularly high-risk patients should be treated in specialized tertiary centers. Careful and intensive management is required for these high-risk pregnant women.

Introduction to Proteomics

Proteomics as Part of Systems Biology

Biological processes are not linear systems but represent dynamic networks with cross-talk of their molecular components at multiple levels. This concept is embraced by systems biology and supported by the analytical capabilities of -omics technologies. Systems biology uses a holistic, rather than the traditional reductionist approach of studying only a single gene or protein at a time. Thus, systems biology explores mechanisms and interactions in biological systems in a more unbiased way. Omics experiments have become feasible with the advent of high-throughput technologies to obtain and analyze larger amounts of data. Particularly the *Human Genome Project* paved the way to high-throughput sciences (Lander et al., 2001). Proteomics aims to deliver a "protein complement of the genome" (Lottspeich, 2009). It has evolved as an essential part of systems biology, as reflected in the increasing number of publications (Lindsey et al., 2015).

Proteomics: Definition and Challenges

The term "proteome" was first introduced in the mid-1990s in analogy to the term "genome" and refers to the entire set of proteins produced by an organism, a tissue, or a cell at any given time (Wilkins et al., 1996a,b). Proteomics is the large-scale study of the entire proteome including protein isoforms and modifications, their abundance, and structure as well as the interactions between them (Tyers and Mann, 2003). Thus, the overall aim of proteomics is to contribute to a comprehensive description of cellular function. Since proteins are the major effector molecules in biological processes, proteomics is well suited for assessing phenotypes and has the potential for the identification of novel prognostic and diagnostic targets. By systematically analyzing proteins, proteomics holds promise for better patient stratification based on protein biomarker measurements at an unprecedented scale (Langley et al., 2017; Pechlaner et al., 2017).

Previous achievements of genomics were essential for progress in proteomics, providing the "genetic blueprint" of potential protein products. In contrast to genomics, however, proteomics faces the challenge of a higher degree of complexity and dynamics of the proteome (Lottspeich, 2009). The relationship between the genome and proteome is not linear, that is, the concept that one gene encodes one protein does not apply. Posttranscriptional control such as RNA editing and alternative splicing results in a much greater diversity at the protein than the gene level. Moreover, only a certain set of genes are transcribed in any one cell at a given time point. The dynamic nature of the proteome is also dependent on environmental cues. Further complexity is added by posttranslational modifications (PTM), such as glycosylation or phosphorylation, as well as protein degradation. In addition, a particular challenge is the detection of low-abundant proteins in the presence of very high abundant proteins. Especially the plasma proteome represents a major challenge, with protein concentrations spanning 10–12 orders of magnitude (Anderson and Anderson, 2002). This dynamic range of protein concentrations still exceeds the capabilities of current proteomics technologies, which can currently resolve 5–6 orders of magnitude in protein abundance (Zubarev, 2013).

Unlike genetics, proteomics lacks the ability to amplify their targets. Thus, proteomics relies on enrichment and subfractionation of complex samples. Therefore, appropriate sample preparation is essential for reproducible proteomics experiments. An example is the depletion of highly abundant plasma proteins such as albumin or the immunoglobulins (Fu et al., 2007). Another approach to tackle the dynamic range of the plasma proteome is to shift biomarker discovery approaches from plasma to tissue-based proteomics. In tissues, potential biomarkers are less dilute and their cellular origin is less uncertain (Cuello et al., 2014; Langley et al., 2017). Similarly, extracellular matrix (ECM) proteins tend to be less abundant than cellular proteins and are thus less likely to be identified in tissue homogenates. Methods enriching for ECM proteins can address this issue (Didangelos et al., 2010, 2011). Finally, technological advances in proteomics instrumentation, mainly better mass spectrometry (MS) instruments and analysis techniques, will help to overcome these difficulties and will be discussed in the subsequent sections.

Proteomics Versus Traditional Molecular Research

Traditional molecular approaches using Western blotting or immunostaining rely on antibodies to study proteins. This approach will only shed light on part of the protein network (Walther and Mann, 2010). Notably, these techniques are based on a priori assumptions on the proteins of interest and rely on the availability of good antibodies. Though antibodies usually exhibit great specificity, their use is associated with notorious limitations such as epitope masking, nonspecific binding, or cross-reactivity between species. In contrast, proteomics research is not constrained by a priori assumptions but provides a comprehensive analysis of the protein composition in a sample. Thus, proteomics is less a hypothesis-driven but rather a hypothesis-generating approach (Cravatt et al., 2007), that is complementary to traditional molecular biology techniques, and provides an opportunity for new frontiers in biomedical research.

Proteomics Applications

Types of Proteomics Experiments

Three types of proteomics analysis exist. First, proteomics is used for compositional analysis, which aims to identify all proteins present in a sample. Second, proteomics enables characterization of protein–protein, protein–RNA, and protein–DNA interactions.

This is mainly accomplished by affinity purification before analysis by MS. For protein–protein interactions, the protein of interest (bait protein) together with its interaction partners is captured with a ligand and subsequently analyzed by proteomics (Dunham et al., 2012). A limitation of this application is the potential copurification of nonspecific interactors, so-called background contaminants. A database containing common background contaminants has been published (Mellacheruvu et al., 2013) to facilitate the identification of genuine protein–protein interactions. Finally, the main application of proteomics is differential protein expression profiling. In this approach quantitative protein changes between two or more different, well-defined conditions, such as control and diseased samples, are compared in order to identify relevant differences. Differential regulation is not only reflected in protein abundance but might also include differential regulation of PTMs.

Typical Proteomics Workflow

A typical proteomics study involves the following steps (Fig. 1):

(A) Proteomics must start with a well-conceived *experimental design* (sample size, estimated biological variation, costs, etc.). Proteomics analyses are laborious and expensive and most notably generate vast amounts of data. Thus, without a precisely formulated question and a good experimental design, the data interpretation can become very cumbersome.

(B) *Sample preparation* is paramount for accurate and reproducible proteomics analysis. This includes sample collection, handling, and storage conditions. For example, rapid freezing upon sample collection and treatment with protease inhibitors upon thawing is crucial to prevent protein degradation. Protein extraction from a biological sample can be done in a single lysis step or subfractionation methods can be applied. This is performed to reduce sample complexity or to study a specific subproteome (Barallobre-Barreiro et al., 2013; Didangelos et al., 2012; Matt et al., 2008; Yates et al., 2005). Further sample preparation requirements such as protein labeling, denaturing, reduction, or enzymatic digestion are dependent on the method chosen for protein analysis and will be discussed throughout the respective sections.

(C) Due to sample complexity further *separation* steps are required prior to MS analysis. This is necessary to reduce undersampling of low-abundant proteins. Otherwise, the MS data are dominated by high-abundant proteins. This can be achieved at the protein level by methods such as one- or two-dimensional gel electrophoresis (1-DE, 2-DE) or at the peptide level by high-performance liquid chromatography (HPLC). Due to rapid advances in MS technology, laborious gel electrophoresis methods are receding. On the other hand, HPLC separation is a standard procedure in proteomics. The most commonly applied chromatography is reversed-phase LC using C18 columns. The separation is based on hydrophobic interactions of the peptides with the C18 residues on the stationary phase, the HPLC column. The gradient of the mobile phase has an increasing organic content. Depending on the hydrophobicity, peptides elute at different time points from the column, resulting in different retention times for each peptide.

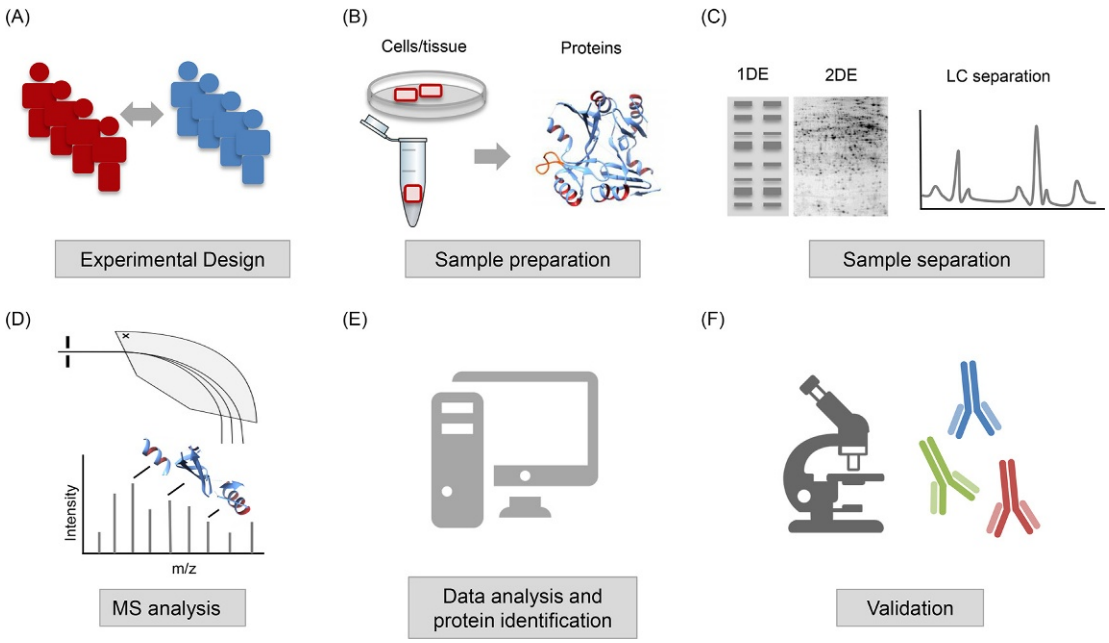

Fig. 1 Proteomics workflow. (A) A proteomics experiment will result in a large number of protein comparisons. Thus, a well-conceived experimental design with sufficient biological and technical replicates is crucial for reliable data interpretation. (B) Protein extraction is critical to obtain a representative sampling of proteins. Certain proteins, that is, membrane proteins or extracellular matrix proteins, are not readily extracted with conventional lysis buffers and may therefore be underrepresented in tissue or cell extracts. (C) Sample complexity is reduced by gel separation of proteins or LC of peptides prior to MS analysis (D). The observed MS spectra are computationally matched to a spectral library to obtain a protein identification (E). Finally, proteins of interest are validated by independent techniques, usually involving antibody-based techniques (F).

(D) Separation is followed by *MS analysis*. MS is the workhorse of modern proteomics and brought the most significant breakthrough in proteomics research. Current MS have exceptional mass accuracy, resolution, and sensitivity, reaching detection limits of attomole concentrations (Thakur et al., 2011). However, the sensitivity of the MS analysis is determined by the complexity of the sample (Nilsson et al., 2010). MS can analyze multiple proteins at the same time and offers high throughput (Arrell et al., 2001). The mass spectrometer determines the mass-to-charge ratio (m/z) of an ionized molecule generating thousands of MS spectra in a single run. A detailed description on MS principles and instrumentation will be given in "MS Principles and Instruments" section.

(E) The next step in the workflow is *data analysis* for *protein identification and quantification*. MS measures the m/z of a peptide. The unambiguous identification of the actual protein occurs by matching the observed MS spectra to a database with the assistance of software tools and scoring algorithms (Martens and Apweiler, 2009). Considering the amount of generated data, this is only possible with automated software solutions. Nevertheless, data analysis can still be a time-consuming part of proteomics analysis. The exact sequence determination process as well as quantification will be discussed in "Protein identification algorithms" section. Another major challenge is to discern the proteins with functional relevance among many differentially expressed proteins. Bioinformatics has become invaluable in harnessing the information obtained from proteomics data. The advent of molecular profiling technologies that focus on a global characterization of whole systems allows exploration of the interconnectivity of biological pathways but brought about the issue of statistical analysis and data integration.

(F) *Validation* is the final step in the workflow after selecting the target proteins for follow-up studies. It is important to realize that proteomics data often require further validation. Usually independent techniques, such as Western blotting or immunohistochemistry, are applied to validate the proteins of interest. Targeted proteomics is also gaining importance as a way to validate findings from discovery-based proteomics, as will be explained in "Targeted Proteomics" section. Follow-up experiments should range from in vitro to in vivo studies to link protein changes to function.

Two-Dimensional Gel Electrophoresis

Even though advances in MS are widely replacing gel-based proteomics techniques, 2-DE is still in use, owing to its unique separation power. It allows the resolution of more than 10,000 proteins on a single gel (Wittmann-Liebold et al., 2006). Since its introduction in 1975 (Klose, 1975; O'Farrell, 1975), the technique has been widely refined, the general principle however is the same: proteins are separated in two dimensions, first based on their isoelectric point and second by their molecular mass using SDS-PAGE. Due to the use of two separation dimensions, 2-DE gels have a higher resolving capacity than 1-DE (SDS-PAGE). In the first dimension, proteins are separated by the concentrating technique of isoelectric focusing (IEF). The sample is loaded onto a strip with an immobilized pH gradient (IPG). These strips consist of acidic and basic buffering groups covalently linked to the gel matrix generating a pH gradient. Wide pH gradients of 3–10 are used for an overview of protein composition, while narrow-range IPG strips of three pH steps provide a better resolution for unambiguous protein identification (Gorg et al., 2004). Upon application of an electric field, proteins migrate according to their intrinsic charge until they reach the pH at which their overall charge is neutral—their isoelectric point. This migration results in focused discrete protein bands on the strip. This strip is then placed on a large SDS polyacrylamide gel for separation in the second dimension. Proteins now migrate orthogonally to their previous movement according to their molecular mass. Thus, 2-DE gels produce a map of intact proteins in form of multiple "spots." The spots are visualized by Coomassie, zinc, silver, or fluorescent staining, with silver being the most commonly applied. Immunodetection or radiolabeling is also used. Following staining, gel images are digitalized and the spots are detected and directly quantified using densitometry. Spot patterns between multiple gels are compared for differential expression with the help of image analysis software, providing automated spot-detection (Kriegel et al., 2000). However, visual inspection is still essential. Spots of interest are excised and the proteins are identified by MS. The same protein can be detected in different spots, since posttranslational modifications, isoforms, or degradation products cause a shift in isoelectric point and molecular weight. Unlike other proteomics techniques, quantitation with 2-DE is performed directly on the gel at the protein level and not by MS. Technical irreproducibility due to gel-to-gel variation remains the main limitation of 2-DE gels.

A significant improvement was achieved with the introduction of difference gel electrophoresis (DIGE) (Unlu et al., 1997). This technique allows the comparison of two or three protein samples simultaneously on the same gel, thus limiting experimental gel-to-gel variation. This is achieved by labeling the proteins of each sample with a different fluorescent Cy-dye (Cy2, 3 and 5), which are designed not to interfere with the migration properties of the labeled proteins. The differently labeled samples are then mixed together in equal amounts and run on the same gel in two dimensions. A differently labeled pool of all experimental samples is included serving as an internal standard for normalization. The gel is analyzed using a fluorescent gel imager detecting the emission wavelength of each Cy-dye. Again, software packages are deployed to determine the differential spots to be picked for MS analysis. DIGE is capable of reliably quantifying protein differences as low as 15% over a protein concentration range of over four orders of magnitude (Viswanathan et al., 2006). However, high-abundant proteins mask less abundant proteins on the gel. Also, DIGE is a tedious process and a bottleneck for large-scale analysis.

Mass Spectrometry-Based Proteomics

MS Principles and Instruments

MS determines the *m/z* of an ionized molecule. Thus, peptides/proteins first need to be transferred from the liquid into the gas phase (volatized) and electrically charged (ionized). This is accomplished using matrix-assisted laser desorption ionization (MALDI) or electrospray ionization (ESI) (Fenn et al., 1989; Karas and Hillenkamp, 1988). It was the advent of these techniques that made MS became applicable for large-scale proteomics analysis, for which John B. Fenn and Koichi Tanaka were awarded the Nobel Prize in Chemistry in 2002. MALDI sublimates and ionizes the samples out of a dry, crystalline matrix via laser pulses (Aebersold and Mann, 2003). In contrast, ESI ionizes proteins/peptides directly out of a solution and is therefore readily interfaced with LC. Thus, ESI-MS coupled to LC is the method of choice for the analysis of complex biological samples.

Briefly, mass spectrometers consist of three parts: (1) an ion source, (2) the mass analyzer(s), and (3) a detector. The mass analyzer records the mass and charge state of the peptide, which is represented in the *m/z* ratio. The detector registers the intensity of ions, thus their relative abundance is displayed as peaks in MS spectra. There are different types of mass analyzers using either static or dynamic and magnetic or electric fields. In proteomics, the main types of mass analyzers are time-of-flight (TOF), ion trap, quadrupole, and Orbitrap analyzers. For a detailed technical review on MS instrumentation see a review by Aebersold and Mann (Aebersold and Mann, 2003). Mass analyzers are characterized by key parameters such as sensitivity, scan speed, resolution, and mass accuracy. A high resolving power allows the MS to distinguish peptides of slightly different *m/z* from each other and display them as separate peaks. Similarly, a high mass accuracy is required for accurate identification. The mass accuracy is measured in parts per million (ppm).

Overview of MS Methods

Due to the rapid development of MS technology, proteomics has shifted from using gel-based (2-DE or 1-DE gel-LC-MS/MS) to gel-free (shotgun proteomics) methods. In terms of quantification proteomics methods use label-free quantitation or isotopic labeling (SILAC, iTRAQ, TMT) techniques. These quantification techniques allow relative but not absolute protein quantification. Further, proteomics is subdivided into "top-down" and "bottom-up" proteomics. "Top-down" proteomics involves the analysis of intact proteins. The "bottom-up" strategy identifies proteins after proteolytic digestion to peptides and is by far the most commonly applied technique. Currently there are three main "bottom-up" strategies (Aebersold and Mann, 2016): The first and most widely used one is "shotgun" or untargeted discovery proteomics with the MS being operated in data-dependent acquisition (DDA) mode. The second strategy is targeted proteomics, carried out by multiple reaction monitoring (MRM). The latest approach is the emerging data-independent acquisition (DIA) method. Both, DDA and DIA are discovery-based methods to profile the proteome of a given sample, while MRM is a targeted method only quantifying preselected proteins of interest with the use of stable-isotope labeled standards. These three "bottom-up" approaches differ with regard to their analytical performance in terms of sensitivity, reproducibility, limit of detection, and resolving power (Domon and Aebersold, 2010). Limit of detection refers to the minimal quantity of an analyte that can be confidently detected. In the following sections, these introduced methods and MS acquisition modes will be discussed in detail. A schematic overview of proteomics approaches is given in **Fig. 2**.

Top-Down Versus Bottom-Up Proteomics

Top-down and bottom-up proteomics are two different approaches for protein and peptide analysis by MS, respectively. In *top-down* proteomics, intact proteins are analyzed by MS without prior digestion of the proteins to peptides. Using MS instruments with high mass accuracy, it initially measures the intact protein before further fragmentation to obtain the amino acid sequence (Kellie et al., 2010). The top-down approach has the advantage that it allows the analysis of protein isoforms and the analysis of the stoichiometry of PTM on a particular protein. The amino acid sequence coverage may vary depending on the size of the protein. Yet, top-down proteomics remains technically challenging, in particular for large proteins and is only feasible in very simple biological matrices, when the protein of interest is present in high abundance. In the *bottom-up* approach, proteins are first digested to peptides. Compared to proteins, peptides have similar chemical properties and are more amenable to separation by liquid chromatography and analysis by MS. Thus, the bottom-up approach has become the method of choice for proteomics analysis. The identified peptides are assigned back to a protein using a method called protein inference (Nesvizhskii and Aebersold, 2005). This computational challenge was solved with the establishment and curation of comprehensive protein databases, the development of algorithms to score MS spectra, and the availability of commercial and open source software (Perkins et al., 1999). A unique peptide can be sufficient to unambiguously identify a protein. However, information on protein isoforms and the stoichiometry of PTMs on a particular protein is lost by peptide analysis as the different protein isoforms generate a set of identical peptides.

Liquid-Chromatography Tandem Mass Spectrometry

Sample preparation

Liquid-chromatography tandem mass spectrometry (LC-MS/MS) is the current gold standard technique for proteomics analysis. It provides a robust method for large-scale, high-throughput protein analysis. Upon protein denaturation (e.g., with urea),

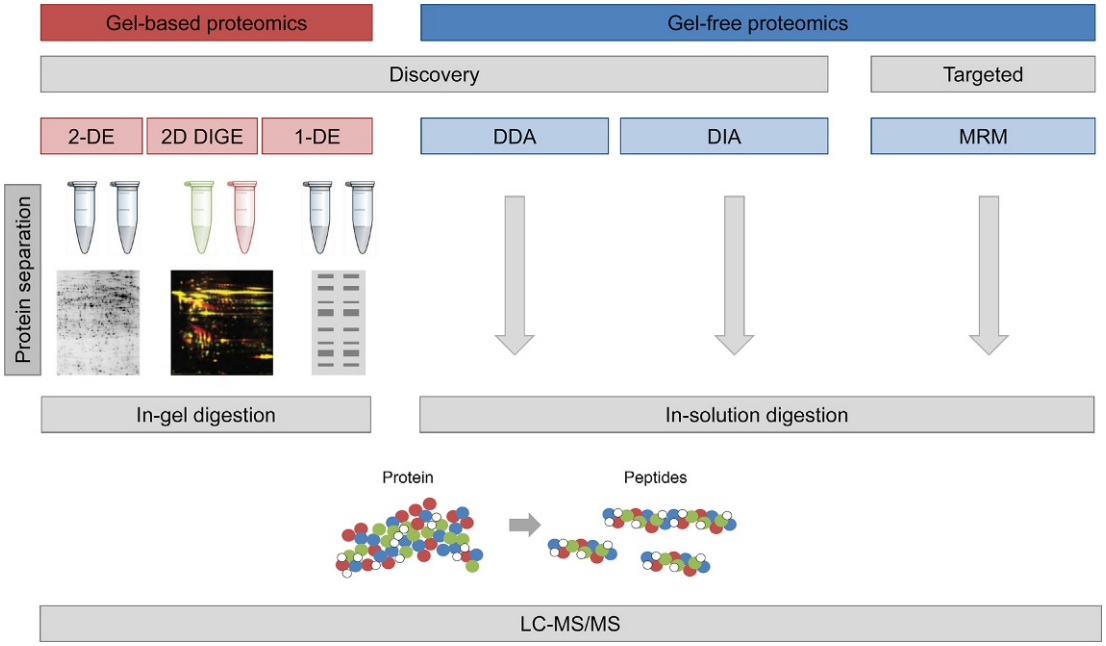

Fig. 2 Overview of proteomics approaches. Using gel-based methods, separation of protein extracts is accomplished at the protein level. Separated proteins are excised and subjected to in-gel digestion before LC-MS/MS analysis. Using gel-free proteomics approaches, protein extracts are directly processed to peptides by in-solution digestion and subject to LC-MS/MS analysis. There are three data acquisition modes in bottom-up proteomics: DDA, DIA, and MRM. MRM is a targeted proteomics approach with a predefined set of proteins of interest, while DDA and DIA are discovery-based approaches without a priori selections of proteins of interest.

reduction (e.g., with dithiothreitol), and alkylation (e.g., with iodoacetamide), proteins are digested into peptides. Trypsin usually generates peptides between 0.5 and 3 kDa, an optimal mass range for chromatographic separation and ionization (Gillet et al., 2016). Enzymatic cleavage with trypsin occurs at the carboxyl side of the amino acids lysine or arginine, except when either is directly followed by proline. Missed cleavages with trypsin need to be considered for the subsequent database search (Siepen et al., 2007). Trypsin has a high cleavage specificity and is efficient and cheap. However, other enzymes are available and can increase the sequence coverage for proteins in LC-MS/MS analyses.

Mass spectrometry analysis

Following enzymatic digestion, peptides are purified mainly using C18 reversed-phase resins and separated by reversed-phase LC according to their hydrophobicity. LC is directly coupled to the MS. Despite high-resolving capabilities of LC, simultaneous coelution and coionization of peptides have an impact on the subsequent MS analysis. The peptides are identified in two steps, hence the term tandem MS or MS/MS: in the first step, MS^1 or survey scan, the m/z and intensity of the intact ionized peptide (precursor ion) is determined. To identify its sequence, in addition to its m/z ratio, the peptide is isolated and fragmented, usually by energetic collision with an inert gas such as helium, nitrogen, or argon, in a process called collision-induced dissociation (CID) (Wells and McLuckey, 2005). The m/z ratios of the generated fragment ions are recorded, resulting in the MS^2 or MS/MS spectrum. Fig. 3A illustrates the LC-MS/MS approach from digestion to protein identification. In a typical LC-MS/MS experiment, an MS^1 spectrum is obtained roughly every one to two seconds. Within this time window, 10–40 peptides are selected for fragmentation and their MS/MS spectra are recorded. Thus, in a usual 2–3 h LC-MS/MS run thousands of spectra are collected (Walther and Mann, 2010).

Protein identification algorithms

Upon obtaining the MS^2 spectra there are two ways of identifying the protein sequence: database search or de novo sequencing (Martens and Apweiler, 2009; Steen and Mann, 2004).

In *de novo sequencing* the sequence is directly retrieved from the spectra, in particular for peptides which did not have a match in the protein databases (Medzihradszky and Chalkley, 2015). Fragmentation at the peptide bond generates peptide fragments of increasing size: b-ions containing the N-terminus or y-ions with the C-terminus. Fragments are numbered depending on the amino acids they contain. For example, a fragment containing the N-terminus with three amino acids is called a b3 ion, while a fragment with the C-terminus and two amino acids is termed a y2 ion. Thus, the sequence information can be deduced from the mass difference between two consecutive fragment ion spectra, each corresponding to an amino acid, for each of which the mass is known (Fig. 3B). However, de novo sequencing is quite an intricate process, and high-throughput experiments are ill-suited for this

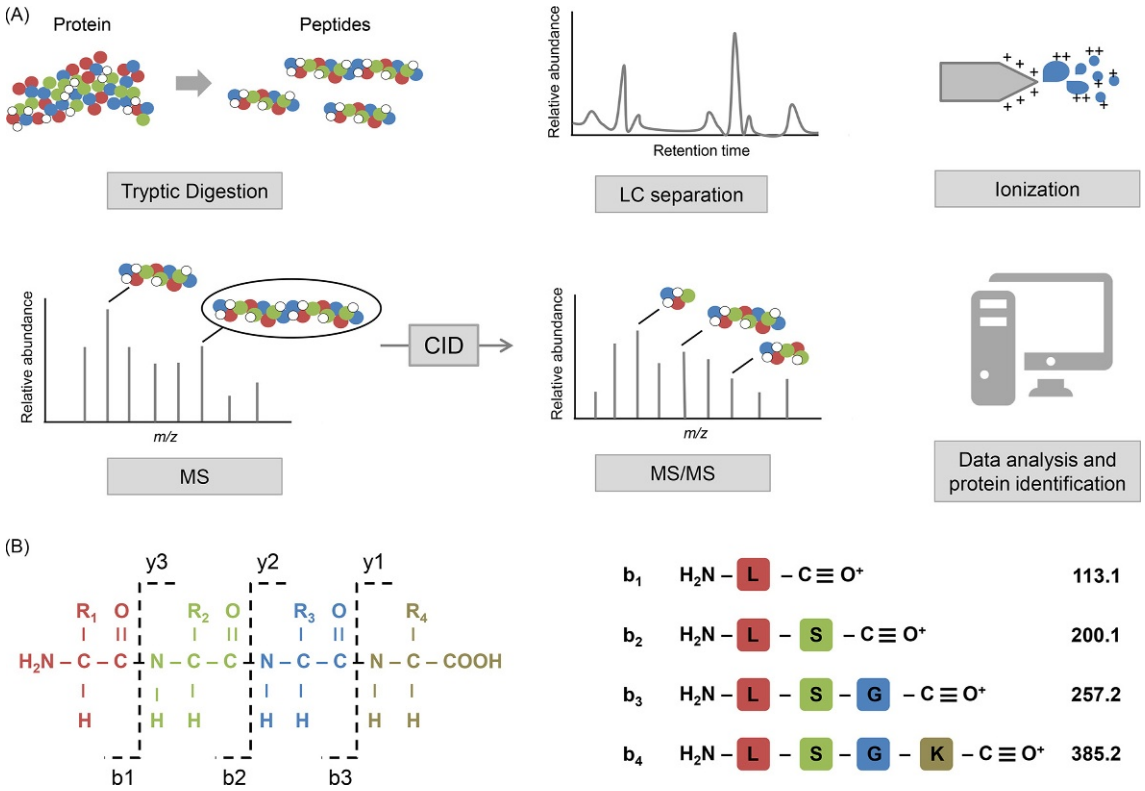

Fig. 3 Protein identification by LC-MS/MS. (A) Tryptic digestion of protein mixtures is followed by LC separation of the resulting peptides to reduce sample complexity. Separated peptides are ionized and injected into the MS. In a survey scan the *m/z* and relative abundance of ionized peptides are determined. Peptides are selected for fragmentation by CID, usually on the basis of their abundance. The *m/z* of the resulting fragment ions is measured by tandem MS (MS/MS). Protein identification is accomplished by database searching, which contains all theoretical MS/MS spectra resulting from in silico fragmentation of all known protein sequences. (B) The protein sequence can also be directly retrieved from the observed MS spectra, independent of protein database matching (de novo sequencing). Fragmentation at the peptide bond generates b-ions containing the N-terminus of the protein and y-ions with the C-terminus. The sequence information is deduced from the mass difference of two consecutive fragment ion spectra, as the mass for each amino acid is known. By analyzing the corresponding b- and y-ion series, the amino acid sequence of the peptide is determined. Here, only b-ions are shown.

approach. Software packages such as PEAKS combine features of de novo sequencing with database search to alleviate these disadvantages (Ma et al., 2003).

A *database search* is more commonly applied for protein identification (Nesvizhskii, 2007; Sadygov et al., 2004). In this approach, the measured fragment spectra are matched against a protein database with a search engine, such as Mascot (Perkins et al., 1999), SEQUEST (Eng et al., 1994), or X!Tandem (Duncan et al., 2005). The databases contain theoretical fragment spectra of in silico digested peptides according to the known cleavage patterns of the used proteases, most commonly trypsin. The match between an observed fragmentation spectrum and a theoretical database spectrum is given a score. Thus, the peptides with the highest matching scores lead to the protein identification. Since mass shifts can result from PTMs or artificial modifications during sample preparation such as a cysteine modification due to alkylation with iodoacetamide, these alterations need to be considered. Spectral matching occurs within a preset mass tolerance. Ultimately, accurate identification relies on the availability of complete and accurately annotated sequence databases (Nesvizhskii and Aebersold, 2005). While for human and mice near complete sequence databases exist, this is more challenging for other species.

Finally, to give confidence in the correct peptide identification or estimate false positive identifications, respectively, a false discovery rate (FDR) can be calculated (Hather et al., 2010). The most common method of estimating FDR is by searching the MS data against a decoy database. A decoy database contains randomized nonnatural peptide sequences, for example, by reversing the genuine amino acid sequences of all database entries. Thus, a match against a decoy database is random and per definition false. FDR can be estimated by comparing distributions of randomized and nonrandomized matches.

Shotgun Proteomics

The term "shotgun proteomics" refers to the application of LC-MS/MS to globally profile proteins in a complex sample in a high-throughput manner. In this method peptide identification is usually accomplished by the DDA method. "Data dependent" in this

context refers to the selection criteria of peptides for fragmentation in MS^2. In complex samples, where multiple peptides are simultaneously ionized, it is not possible to select all peptides in the survey scan for fragmentation, as this would overwhelm the scan speed of most instruments. Instead, a deliberate peptide selection for fragmentation is required, which is based on predefined criteria, hence data dependent. These are abundance, signal intensity, and charge state. Selection is made in real time by the MS software during the survey scan and newer MS are able to select the 15–40 most abundant—"top 15 or top 40"—peptides. Thus, a fixed number of precursor ions is selected in every MS^1 survey scan and analyzed by MS^2. Charge state preselection is used to exclude singly charged ions, which are mostly contaminants (Gillet et al., 2016). In addition, the acquisition parameters can be set to prevent repeated selection of the same peptide, thus reducing interference from high-abundant peptides and also allowing low-abundant peptides to be selected. Nonetheless, undersampling of low-abundant peptides is not eliminated and remains a bias, even in newer instruments with increased scan speed. Also, precursor selection is a stochastic process, which will never be exactly the same between two LC-MS/MS runs due to variability of the chromatographic separation. Thus, reproducible quantification, especially of low-abundant peptides, remains a challenge. However, the run-to-run variability remains within an accepted range for most discovery-based proteomics studies, especially with extensive prefractionation to reduce sample complexity, making shotgun proteomics a robust platform for protein analysis.

Quantitative Proteomics

MS itself is not quantitative due to sequence-specific differences in ionization efficiency of peptides and phenomena such as ion suppression in complex peptides mixtures (high-abundant ions consume most of the charges and reduce the ionization of coeluting low-abundant ions). However, MS-based quantification strategies allow relative quantification between samples. Generally, quantification with MS can be divided into label-free and stable isotope-labeling methods (Mirza, 2012). More precise quantification can be achieved by using internal standard peptides with targeted proteomics as will be discussed in "Quantification using MRM" section.

Label-free quantification

There are two different approaches for label-free quantification using either mass spectrometric signal intensity or spectral counting (Old et al., 2005). The latter is based on the rationale that more abundant peptides are more likely to generate more MS^2 spectra. Therefore, relative quantification can be achieved by counting the number of MS^2 spectra assigned to the same protein across different samples. However, this approach only works in samples with limited complexity and does not take the physical peptide properties into account assuming a linear response for every peptide (Bantscheff et al., 2007). The second approach uses signal intensities (spectral ion currents) for relative quantification of peptides. Advanced pattern comparison software is applied to align ion intensities of the same peptide on MS^1 and MS^2 level in different samples. The main advantages of label-free quantification are that it is cheap, achieves high-proteome coverage, and does not require laborious labeling workflows.

Stable isotope labeling

This approach is based on the incorporation of stable isotope tags into peptides or proteins by a chemical reaction, a metabolic, or enzymatic process. Stable heavy isotopes have the same physicochemical properties as their light counterparts, meaning they behave identically on chromatography. However, due to their slight mass difference, they generate distinguishable signals in the MS, making them ideal for quantification purposes. Compared to label-free methods, the labeling approach provides a higher quantitative accuracy and consistency. This is due to near equal ionization efficiencies of the isotope tags. The most commonly used labeling methods are stable isotope labeling by amino acids in cell culture (SILAC), tandem mass tags (TMT), and isobaric tagging for relative and absolute quantification (iTRAQ) (**Fig. 4**).

Stable isotope labeling by amino acids in cell culture

SILAC is an in vivo metabolic labeling approach on protein level (Ong et al., 2002). Thus, proteins are already labeled during their synthesis. This is achieved by growing cells in a medium containing isotopically labeled amino acids, which are incorporated into the proteins. Mostly arginine and/or lysine are labeled with ^{13}C isotope (instead of ^{12}C) or ^{15}N isotope (instead of ^{14}N) to ensure that all tryptic peptides contain a labeled isotope (**Fig. 4A**). Lysine has the additional advantage of being an essential amino acid, which cannot be produced de novo. At the same time cells of the other experimental condition are grown in normal medium, containing the normal or "light" amino acids. Eventually both samples are multiplexed and analyzed in the same MS run, which reduces experimental variability. The heavy and light labeled protein pairs coelute on chromatography. Due to the characteristic mass shift in their MS^1 spectra (e.g., 6 Da for ^{13}C lysine) the relative quantity for each protein can be calculated. An equal ratio between both samples indicates no difference in abundance. If the heavy labeled peptide exhibits a higher peak intensity, the protein was more abundant in the labeled sample and vice versa.

Application of SILAC goes beyond cells in culture but is also used for mice without affecting their development, growth, or behavior (Kruger et al., 2008) as the proteins are chemically identical except for their mass difference. However, SILAC diet is expensive, thus limiting its use to small animal models. SILAC is also a very useful tool to assess protein turnover (Doherty et al., 2005; Mann, 2006). Upon feeding a SILAC diet to animals the amino acids are gradually incorporated into the newly synthesized proteins and are clearly distinguishable from preexisting proteins. Thus, the ratio between heavy and light peptides indicates the synthesis rate of a protein and can be compared across different proteins.

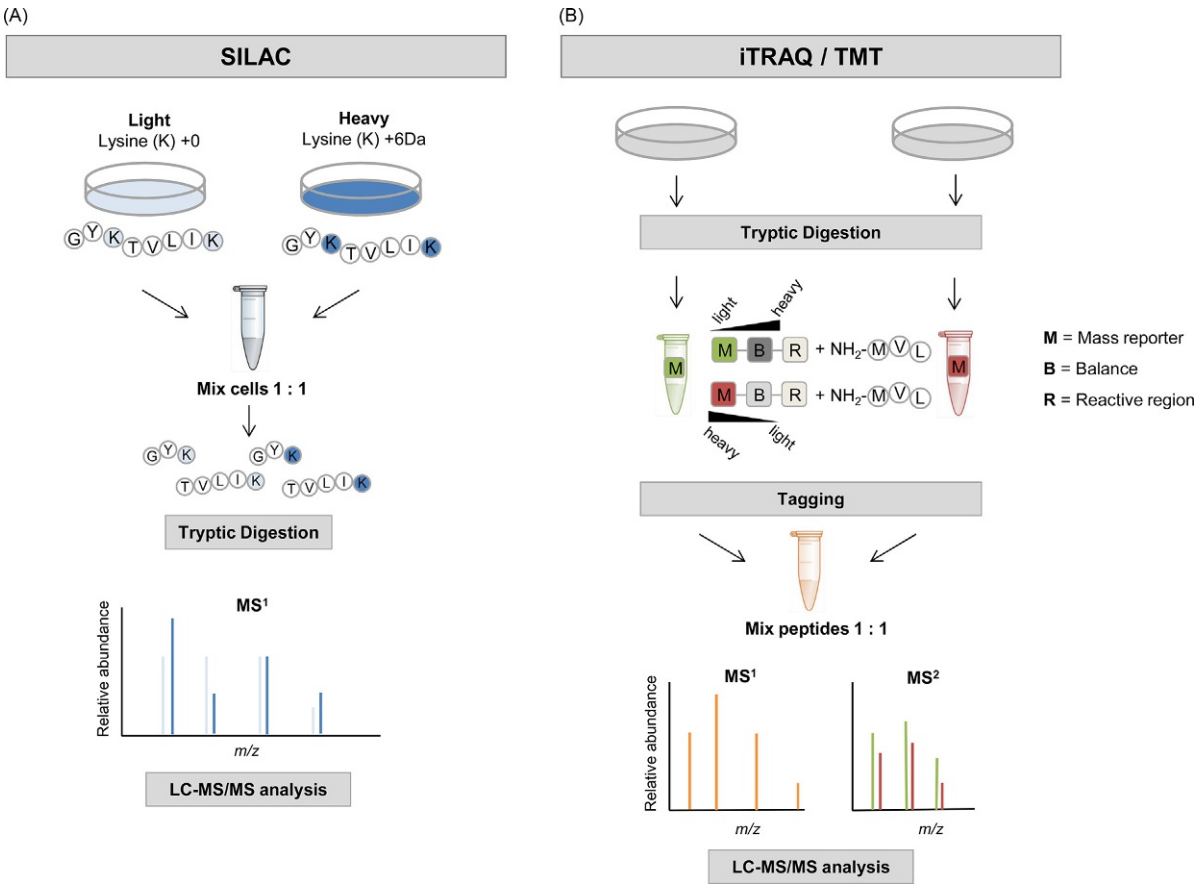

Fig. 4 Stable isotope labeling. (A) The SILAC approach allows metabolic labeling at the protein level during protein synthesis by incorporation of heavy or light amino acids. Protein samples are mixed, digested, and analyzed by LC-MS/MS. Due to their characteristic mass shift in MS^1 the relative quantity of the peptides with light and heavy amino acids can be determined. (B) In contrast, using iTRAQ or TMT labeling is performed at the peptide level. Different tags allow multiplexing and reduce experimental error. Upon individual labeling of each sample, peptides from the different samples are mixed. Both iTRAQ and TMT are "isobaric" tags: the peptides coelute in chromatography and cannot be distinguished in MS^1 due to their balance region. Only in MS^2 peptides can be relatively quantified due to the mass shift in the reporter regions.

Isobaric Tagging

In the mass-tagging approach proteins or peptides are chemically tagged with a stable isotope-containing molecule in vitro. Thus, this approach is also applicable to human tissue samples. The most commonly used tags are TMT (Thompson et al., 2003) and iTRAQ (Ross et al., 2004), both belonging to the category of isobaric mass tags. The tags are available with different isotopic substitutions (reporter regions) creating distinct mass differences to allow multiplexing of currently up to 10 samples with TMT (10-plex) and 8 with iTRAQ (8-plex). Again, multiplexing offers the advantage of reducing experimental error. Each tag consists of three functional regions (Fig. 4B). The amine-reactive region is equal in all tags and allows the binding to the N-terminus and side-chain amines of peptides. In addition, they have a mass reporter and a balance region, which are different and unique to each tag, due to isotopes substituted at various regions. As the name indicates the function of the balance region is to compensate the variable mass of the reporter region so that the intact tag has the same mass in all samples, hence the term "isobaric." Thus, after mixing of all differently labeled samples the peptides remain undistinguishable during chromatographic separation and MS^1. Only upon fragmentation in MS^2, the different reporter regions are released enabling the distinction and quantification of the peptide in different samples.

Cysteine-reactive mass tags are available (iodoTMT) to specifically label cysteine-containing peptides, commonly applied in the field of redox-proteomics. In comparison to the previous isotope-coded affinity tags (ICAT), also with specificity toward sulfhydryl groups, multiplexed quantification (up to 6-plex) is possible. ICAT contains an additional biotin affinity tag (Gygi et al., 1999). This tag enables purification by avidin affinity chromatography. Thus, it allows further reduction of sample complexity. Similarly, TMT-labeled peptides can also be enriched.

The downside of isobaric mass tagging is that labeling occurs at the peptide level, thus later in the experimental workflow. In contrast to the SILAC workflow, potential experimental variations before labeling cannot be excluded. A further caveat is that the complexity of a sample can increase the likelihood of inaccurate quantification. Coisolation of precursors can give rise to mixed MS/

MS spectra from the simultaneous fragmentation of more than one peptide leading to erroneous combinations of reporter ions from different proteins (Langley et al., 2013). This caveat has been addressed in newer instruments by MS^3 fragmentation (Ting et al., 2011).

^{18}O labeling

Another labeling method is the enzymatic incorporation of stable isotopes, such as ^{18}O instead of ^{16}O (Stewart et al., 2001). In this approach, isotopic labeling occurs during the proteolytic digestion of proteins. The cleavage of peptide bonds requires the addition of H_2O. If the reaction is performed in the presence of ^{18}O labeled water ($H_2^{18}O$), the generated peptides have either a 2 or 4 Da mass shift compared to their natural counterparts, depending on cleavage occurring at either one or both ends. Though it is highly specific and universally applicable, a major limitation of this method is the enzyme-mediated back-exchange of ^{18}O with ^{16}O, resulting in complicated data analysis (Mirza et al., 2008). However, by using immobilized trypsin, which is removed upon digestion/labeling, the back-exchange can be prevented (Mirza, 2012; Storms et al., 2006). Also, software tools for efficient quantitative analysis of complex samples have been developed (Hicks et al., 2005).

Further, this principle is also applied for PTM studies, namely for the identification of N-linked glycosylation sites on proteins (Kuster and Mann, 1999). During enzymatic deglycosylation of N-linked glycans under incorporation of H_2O, the enzyme PNGase-F converts asparagine to aspartic acid via a deamidation reaction causing a mass shift of 0.984 Da. Thus, if $H_2^{18}O$ is used, it leads to a mass shift of 2.99 Da, which leads to increased search specificity and indicates the former presence of glycosylation at that particular amino acid.

Targeted Proteomics

In contrast to discovery or shotgun proteomics, targeted proteomics allows the precise quantitation of specific proteins of interest. Thus, it is a hypothesis-driven proteomics strategy (Picotti et al., 2013), which is often employed to validate and complement the findings obtained from discovery approaches. The focus on predetermined target proteins offers higher sensitivity, quantitative accuracy, and reproducibility than the DDA approach. Indeed, due to these characteristics together with its advantages over conventional antibody detection that rely on the specificity of the binder, targeted proteomics has been selected as the method of the year by the journal *Nature Methods (2013)*. The typical MS method for targeted proteomics is selected reaction monitoring (SRM) mainly carried out on triple-quadrupole instruments (QqQ). SRM enables the analysis of multiple peptides in a single run, hence the term MRM is used synonymously with SRM (Picotti and Aebersold, 2012). In SRM, the first mass analyzer (Q1) selects precursor ions within a mass range around the mass of the predetermined target peptides, which are then fragmented by CID in the collision cell (Q2). The specific fragment ions of the targeted peptide are then selected and measured by the second mass analyzer (Q3) (**Fig. 5A**). A specific precursor–fragment ion pair is termed a transition. The high selectivity and specificity of this method is given by the two levels of mass selection in Q1 and Q3 acting as a two-stage mass filter. In principle, the instrument is preprogrammed to consistently monitor the same set of predefined transitions (Q1/Q3 pairs) and record their intensities over the entire chromatography run. This is considered as the basis for its high reproducibility in repeated samples. Thus, analysis time is optimally used on the peptides of interest, largely eliminating interference from high-abundant/contaminant peptides. On the other

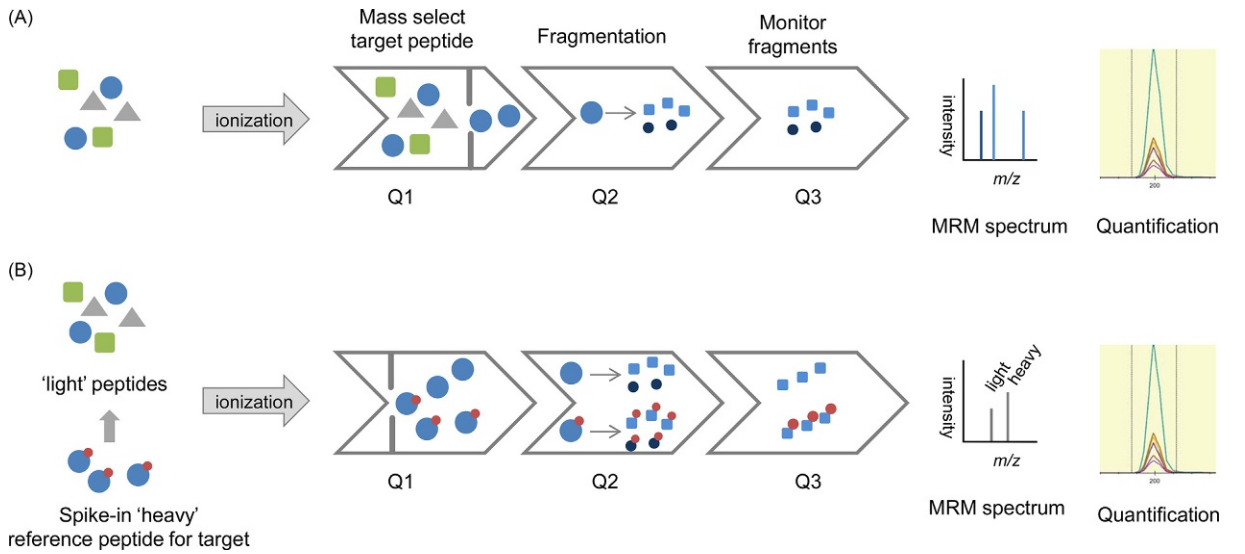

Fig. 5 SRM/MRM analysis on a triple-quadrupole (QqQ) MS. (A) Coeluting peptides are filtered by the first quadrupole (Q1) based on a predetermined list of targeted precursor ions. The selected peptides are subjected to fragmentation by CID in Q2, and their fragment ions are selected and measured by Q3 (transitions). (B) Heavy labeled reference peptides of known concentration can be spiked-in as standards for reliable quantification of the targeted peptides.

hand, it is limited to preselected transitions (Q1/Q3 pairs). Currently the number of peptides that can be monitored in a single run without compromising performance is around 100 peptides. Multiplexing up to 1000 proteins is possible, however, at the cost of reduced quantification accuracy (Picotti et al., 2010).

Multiple reaction monitoring (MRM) assays

A selective transition/inclusion list needs to be generated for MRM experiments. This depends on the knowledge of the MS characteristics of a peptide and its fragmentation products. The required MRM transition data for a given protein is called an MRM assay. This information is mostly derived from previous untargeted MS experiments, or alternatively the MRM assays can be retrieved from an online compendium (see later).

First, a number of rules need to be considered when selecting the optimal peptides (Lange et al., 2008). In essence, the selected peptides need to be unique for the protein of interest (proteotypic). Preferably, the peptide should be of medium length, fully tryptic and should not contain abundant PTMs or amino acids prone to variable chemical modifications such as asparagine (N) deamidation or methionine (M) oxidation. In terms of their MS parameters peptides with the most intense transition peaks are selected. In addition to their m/z values, the optimal collision energy and the chromatographic retention times are retrieved. The latter is used to monitor the expected transitions close to their corresponding elution time (Escher et al., 2012). Due to these timed ion selection windows in the so-called scheduled MRM approach more transitions can be monitored/multiplexed in one run. All these considerations together contribute to the sensitivity of this method. Although initially laborious, once the assays are established, they can be used with great reproducibility across different sample sets. Indeed, the extensive effort required to develop MRM assays has been considered as the main reason for the limited application of MRM in the field of proteomics (Picotti et al., 2010), even though it has been widely applied to the measurement of small molecules such as drugs or metabolites. To facilitate the wider implementation of MRM assays, online transition lists have been made freely accessible, that is, in the SRMAtlas (http://www.srmatlas.org/). This is a compendium of highly specific MRM assays that have enabled the quantification of 99.7% of the >20 000 annotated human proteins (Kusebauch et al., 2016). The assays are developed and validated by the wider proteomics community (Kennedy et al., 2014).

Parallel reaction monitoring (PRM) is a newer targeted proteomics method, where Q3 of a triple-quadrupole MS is replaced with a high-resolution accurate mass analyzer such as TOF or Orbitrap (Peterson et al., 2012). This allows the accurate detection of all fragment ions due to higher resolution, while in MRM the transitions are usually restricted to a maximum of 5. Thus, PRM requires less time for assay development, since it monitors all transitions and alleviates the need for preselecting target transitions.

Quantification using MRM

For analysis of targeted proteomics data, an open-source software *Skyline* is now available and widely used. Even though the software offers an automatic selection of the best transition matches for each peptide, the correct attribution/identification needs to be visually matched and the peak areas manually integrated, making the data analysis a cumbersome process. Most importantly, targeted proteomics allows precise quantification, by spiking-in heavy labeled reference peptides of known concentrations. Briefly, the fragment ion intensities of peptides of interest are related to corresponding signals of isotopically labeled reference peptides with the same sequence (**Fig. 5B**). Without the constraints of antibody-based protein detection and quantification, MRM is emerging as a promising alternative to conventional methods such as enzyme-linked immunosorbent assays (ELISA), at least for medium- to high-abundant proteins. For low-abundant proteins, that is, in the pg/ml range, targeted proteomics may not match the sensitivity of ELISAs. Commercially available kits now allow the quantification of up to 100 proteins in human serum or plasma (Kiseleva et al., 2015). Using MRM, plasma levels of 13 apolipoproteins were compared in a prospective, community-based study and VLDL-associated apolipoproteins were found to predict cardiovascular events (Pechlaner et al., 2017). The increasing importance of targeted MS technologies for clinical application is reviewed by Carr et al. (Gillette and Carr, 2013).

Data-Independent Analysis (DIA)

DIA in comparison with DDA and MRM

Neither the untargeted discovery nor the targeted proteomics approach is able to quantify every detectable component of a proteome. Each method is a compromise that improves analytical performance at some level, while reducing it at another. DDA is biased due to its random selection of peptides for fragmentation. Thus, reproducible quantification, especially of low-abundant peptides, remains its major limitation. On the other hand, MRM is limited to the detection of preselected peptides requiring a priori knowledge. Therefore, it is not suitable for a discovery-based approach. Additionally, it has a limited multiplexing capacity. To overcome the limitations of both methods and combine their advantages the data-independent acquisition (DIA) mode was adopted for proteome analysis. This method aims to obtain the MS^2 spectra of every detectable precursor ion regardless of its abundance or its prior knowledge, hence the term "data independent." Therefore, DIA provides a less biased discovery approach for reproducible and accurate quantification of the detectable proteome in a sample without being restricted to predefined peptides. A comparative summary on the data acquisition mode in all three bottom-up proteomics approaches is given in **Fig. 6**.

Data acquisition in DIA

The key to achieve a comprehensive collection of MS^2 spectra is the sequential isolation window acquisition principle (Sajic et al., 2015). More precisely, the MS triggers fragmentation of *all* precursor ions within a predefined m/z isolation window. Due to

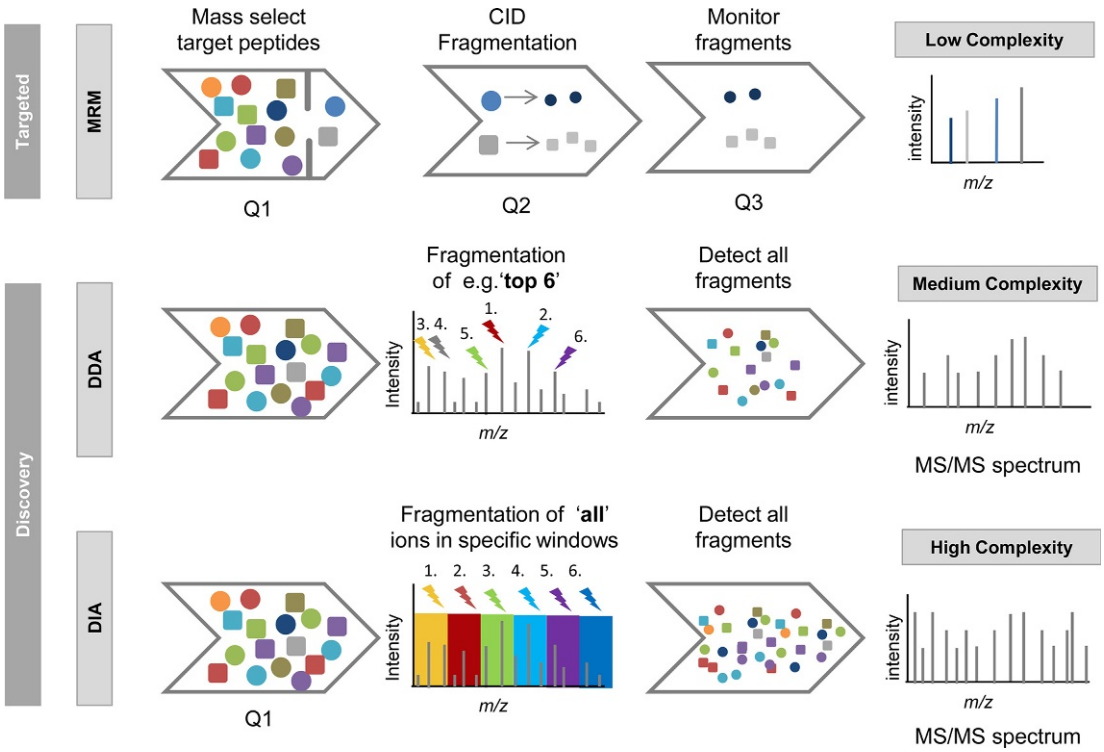

Fig. 6 Comparison of data acquisition using the MRM, DDA, or DIA method. While MRM allows targeted identification of only preselected peptides, both DDA and DIA are discovery proteomics approaches. In the DDA mode, peptides for fragmentation are selected on the basis of their abundance in regular survey scans during the chromatographic separation. The top 6–40 most abundant ions of each survey scan (depending on the MS instruments' scan speed) are fragmented, and their fragment ions result in the full MS/MS spectrum. Due to the stochastic nature of sampling the most abundant ions on a chromatographic time scale, poor run-to-run reproducibility can be a limitation of the DDA mode, especially of low-abundant peptides. In contrast, in the DIA approach all peptides within defined isolation windows are subjected to fragmentation. This results in highly multiplexed MS/MS data, which are analyzed by targeted data extraction based on spectral libraries from these samples.

seamlessly adjacent isolation windows the entire precursor *m/z* range expected for tryptic peptides can be covered in a single duty cycle. The width of a cycle is adjusted to be shorter than the chromatographic elution time of a peptide. Eventually, while the instrument repetitively cycles through the consecutive isolation windows fragmenting each peptide, MS^2 spectra of all possible precursors are recorded in real time. This results in the generation of comprehensive, but very complex fragment ion maps. However, due to this multiplexed recording of MS^2 spectra originating from multiple precursors, the relationship between the fragment ion and its precursor is lost. In comparison, in the DDA method the MS^2 spectrum is generally well associated with the MS^1 spectrum. Thus, the uncoordinated record of precursors and their fragment ions complicates the data analysis. Therefore, the main challenges of the DIA mode are data processing and correct interpretation of multiplexed MS^2 spectra.

Data analysis in DIA

The DIA strategy of unbiased MS^2 data acquisition is not entirely new, several DIA methods with various isolation window widths have been proposed previously (Bern et al., 2010; Panchaud et al., 2009, 2011; Purvine et al., 2003; Venable et al., 2004). However, recent improvements in MS instruments regarding their resolution power, mass accuracy, and scan speed have contributed to the maturation of the DIA strategy. Currently the most advanced DIA strategy is SWATH-MS (sequential windowed acquisition of all theoretical mass spectra) (Gillet et al., 2012). SWATH-MS experiments were first performed on high-resolution quadrupole TOF instruments with fast scan speed. In this setup, 32 fixed precursor isolation windows (swaths) with a width of 25 *m/z* each are used to cover a mass range of 400–1200 *m/z* (allowing an overlap of 1 Da between two adjacent windows). With a dwell time of 100 msec for each window, the total cycle time adds up to 3.2 s. The data from all windows is compiled together in a single map, termed the SWATH map. The reason for the success of SWATH-MS lies in the novel data analysis strategy, which is fundamentally different from the standard database-searching tools applied in previous DIA methods. Though a discovery-based approach, the data analysis is accomplished using a targeted data extraction strategy for confident scoring. The data in generated fragment ion maps are mined using fragment ion spectral libraries supported by software such as OpenSWATH or Skyline. The spectral or assay libraries contain the exact MS coordinates for each targeted peptide including the precursor *m/z*, the fragment ion *m/z*, their intensities, and their chromatographic retention time. Thus, peptides in the map can be uniquely identified with MRM-like reproducibility and quantification accuracy. However, currently DIA cannot compete with MRM in terms of sensitivity, especially

for low-abundant peptides (Sajic et al., 2015; Schmidlin et al., 2016). Moreover, for successful data analysis, availability of high-quality spectral libraries is crucial (Schubert et al., 2015) so that any possible peptide of interest (including isoforms, degradation products, or PTM carrying forms) can be queried in DIA maps. Since the SWATH map is a permanent digital record of fragment ion spectra for all detectable peptides in a sample, it is possible to reanalyze the data as new targets of interest arise. The comprehensive nature of SWATH maps has also compelled researchers to convert tissue biopsy samples or plasma samples into "digital maps" or "digital records" for archiving (Guo et al., 2015). Notably, DIA is quite a recent strategy compared to DDA. Facilitation of DIA analysis by spectral library generation, automated data extraction, or scoring tools is currently work in progress and expected to provide better solutions in the future (Gillet et al., 2016).

Conclusions

A major limitation of cardiovascular research is that a simplistic and reductionist approach is applied to explain different pathologies, often resulting in a focus on few proteins. Proteomics technologies have made tremendous progress over recent years although cardiovascular disease is receiving relatively little attention by the proteomics community (Mayr, 2013). Initiatives, such as the Human Protein Atlas project (www.proteinatlas.org), provide a publically available resource capturing the location of proteins in different tissues. The only cardiovascular tissue in this database is the human heart. No large blood vessels are included. No tissues with different cardiovascular diseases are assessed. It is essential that high-quality cardiovascular proteomics data become publically accessible to advance the field. Proteomics is essential as part of a systems' biology approach to science and offers powerful technologies to place scientific discoveries in a more global unbiased framework by integrating biological information into disease-specific networks that drive pathophysiological changes.

Introduction

The field of pulmonary arterial hypertension (PAH) has progressed significantly in the past 25 years through greater understanding of pathogenic pulmonary vascular biochemical pathways and the development of numerous PAH-targeted medical therapies (Farber and Loscalzo, 2004). With expert management, PAH is now viewed as a chronic condition with a life expectancy from years to decades as opposed to an invariably fatal disease (Simonneau et al., 2013). Periodic international pulmonary hypertension (PH) symposia, which have developed consensus recommendations regarding PH, have been instrumental in furthering our understanding of the syndrome. The fifth World Symposium on Pulmonary Hypertension (fifth WSPH) held in Nice, France, in 2013 included 12 task forces to address multiple aspects of PH. Task forces were convened in the fields of pathology and pathobiology; genetics and genomics; pathophysiology; classification, definitions, and diagnosis; epidemiology and registries; standard of care; treatment goals for PH; new trial designs and potential therapies for PAH; chronic thromboembolic pulmonary hypertension; PH due left heart disease and lung diseases; and pediatric PH. The proceedings of the fifth WSPH have updated PH clinical classification system, PH diagnostic recommendations, consensus treatment advice concerning rehabilitation, combination therapy, new medications, and lung transplantation and discussed new approaches to PAH (Galie et al., 2013; Simonneau et al., 2013; Soubrier et al., 2013; Hoeper et al., 2013b; McGoon et al., 2013; McLaughlin et al., 2013; Gomberg-Maitland et al., 2013).

Clinical Classification of PH

Prior to the second World Symposium on Pulmonary Hypertension (WSPH) in 1998, PH was classified into just two categories: primary PH or secondary PH based on identifiable causes and/or risk factors (Hatano and Strasser, 1975; Simonneau et al., 2004). The PH classification system has since evolved with the development of categories of PH demonstrating similar clinical, pathological, and hemodynamic characteristics. Five PH diagnostic groups are currently delineated: PAH (group 1), PH owing to left heart disease (group 2), PH owing to chronic hypoxia and/or chronic lung disease (group 3), chronic thromboembolic pulmonary hypertension (CTEPH, group 4), and PH due to unclear multifactorial mechanisms (group 5) (Simonneau et al., 2004; **Table 1**). This review will focus exclusively on PH diagnostic group 1 (PAH).

Table 1 Clinical classification of pulmonary hypertension

Group 1: Pulmonary arterial hypertension
Idiopathic PAH
Heritable PAH
Drug- and toxin-induced
Schistosomiasis
Associated with the following:
● Connective tissue disease
● HIV infection
● Portal hypertension
● Congenital heart diseases
Group 2: Pulmonary hypertension owing to left heart disease
Left ventricular systolic/diastolic dysfunction
Mitral or aortic valve disease
Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
Group 3: Pulmonary hypertension owing to chronic hypoxia and/or chronic lung disease
Obstructive sleep apnea
Interstitial lung disease
Other pulmonary diseases with mixed restrictive and obstructive pattern
Sleep-disordered breathing
Alveolar hypoventilation disorders
Chronic exposure to high altitude
Developmental lung diseases
Group 4: Chronic thromboembolic pulmonary hypertension (CTEPH) and other pulmonary artery obstructions
CTEPH
Other pulmonary artery obstructions are as follows:
● Angiosarcoma
● Other intravascular tumors
● Arteritis
● Congenital pulmonary artery stenosis
● Parasites (hydatidosis)
Group 5: Pulmonary hypertension with unclear multifactorial mechanisms
Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy
Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, neurofibromatosis, vasculitis
Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure, segmental PH

M. and Souza, R. (2013). Updated clinical classification of pulmonary hypertension. *Journal of the American College of Cardiology***62**, D34–D41.

PAH Definition

Currently, PAH is defined hemodynamically as having a mean pulmonary arterial pressure (mPAP) greater than 25 mmHg, along with a pulmonary capillary wedge pressure (PCWP) or left ventricular end-diastolic pressure (LVEDP) less than 15 mmHg and a pulmonary vascular resistance (PVR) greater than 3 Wood units. There should be no significant (i.e., hypoxemic) chronic lung disease or CTEPH after thorough investigation. It is a rare condition with a prevalence of about 1 per 100,000 in the general population (McLaughlin et al., 2009; Hoeper et al., 2013b; Authors/Task Force et al., 2015).

Clinical Subgroups of PAH (Group 1 PH)

Over the past decade or so, the nomenclature of the different subtypes of group 1 has markedly evolved (**Table 1**). Idiopathic PAH (IPAH, formerly referred to as "primary pulmonary hypertension" or PPH) is the largest subgroup within group 1 PH and accounts for 46% of PAH patients. IPAH has an incidence of about 0.9 cases per million adults in the United States. Approximately 83% of patients affected by IPAH are women, and patients have a mean age of 50 years at diagnosis (McGoon et al., 2013; McGoon and Miller, 2012). Hereditary PAH (HPAH) cases are identified as patients with PAH with at least one other documented PAH case in their family or who possesses a gene mutation known to strongly associate with PAH (Simonneau et al., 2004). Several genetic mutations have been found to be associated to HPAH and IPAH, including bone morphogenic protein receptor type 2 (BMPR2), activin-like receptor kinase-1 (ALK1), endoglin (ENG), suppressor of mad9 (Smad9), caveolin-1 (CAV1), and KCNK3 (Simonneau et al., 2013; Soubrier et al., 2013; Machado et al., 2009; Austin et al., 2012; Ma et al., 2013). A number of drugs and toxins have also been implicated as risk factors for PAH and categorized according to strength of evidence as definite, likely, possible, or unlikely

Table 2 Drugs and toxins associated with PAH

Strength of association	*Drug/toxin*
Definite	Aminorex, fenfluramine, dexfenfluramine, toxic rapeseed oil, benfluorex, SSRI antidepressants
Likely	Cocaine, phenylpropanolamine, chemotherapy, St. John's wort, interferon alpha and beta, amphetamine-like drugs
Possible	Amphetamines, tryptophan, methamphetamines, dasatinib
Unlikely	Oral contraceptive medications, estrogen, cigarette smoke

Source: Simonneau, G., Gatzoulis, M. A., Adatia, I., Celermajer, D., Denton, C., Ghofrani, A., Gomez Sanchez, M. A., Krishna Kumar, R., Landzberg, M., Machado, R. F., Olschewski, H., Robbins, I. M. and Souza, R. (2013). Updated clinical classification of pulmonary hypertension. *Journal of the American College of Cardiology***62**, D34–D41.

(**Table 2**; Simonneau et al., 2013). A definite association is defined as an epidemic or large multicenter epidemiological studies demonstrating an association between a drug and PAH. A likely association is defined as a single case-control study demonstrating an association or a multiple-case series. A possible association is defined as drugs with similar mechanisms of action as those in the definite or likely category but that have not yet been studied. Lastly, an unlikely association is defined as one in which a drug has been studied in epidemiological studies, and an association with PAH has not been demonstrated (Simonneau et al., 2013). There is a known association between PAH and connective tissue diseases. The prevalence is best established in scleroderma, estimated to be between 7% and 12% (Hachulla et al., 2005; Mukerjee et al., 2003). The prognosis of PAH associated with scleroderma is poor with a 1-year mortality of 30% that is considerably worse than seen in IPAH (1-year mortality about 15%) (Mukerjee et al., 2003; Humbert et al., 2010). PAH is found in about 1%–5% of cases of patients with end-stage liver disease and is termed portopulmonary hypertension (POPH). This condition also has a poor prognosis relative to IPAH. In the US REVEAL registry, patients with POPH had a 3-year survival rate of 40% versus 64% in patients with IPAH (Krowka et al., 2012). Pulmonary arterial hypertension is also associated with HIV infection with a stable prevalence of 0.5% over the past decade (Degano et al., 2010). The survival rate at 5 years in a recent French cohort was more than 70% (Sitbon et al., 2008). Schistosomiasis-associated PAH is potentially the most prevalent cause of PAH worldwide. Pulmonary arterial hypertension occurs in patients with primarily hepatic schistosomiasis with an associated mortality rate of about 15% at 3 years (Lapa et al., 2009; dos Santos Fernandes et al., 2010; **Fig. 1**).

Genetics of PAH

Over 300 independent mutations in the BMPR2 have been identified in approximately 75% of families with HPAH with more than one affected member and up to 25% of cases of isolated IPAH (Machado et al., 2009). The protein BMPR2 is a member of the tumor growth factor (TGF)-beta superfamily, which appears to have a prominent role in the development of PAH. Compared with PAH patients without BMPR mutations, those with a BMPR2 mutation develop PAH about 10 years earlier have worse clinical courses and hemodynamic profiles (lower baseline cardiac index, higher PVR, and less likely to be responsive to acute vasodilators). These patients also have an increased risk of death and transplantation (Pfarr et al., 2011; Sztrymf et al., 2008; Rosenzweig et al., 2008; Humbert et al., 2006; Evans et al., 2016). Pathogenic mutations in activin receptor-like kinase-1 (ACVRL1 or ALK1) have been implicated in PAH associated with hereditary hemorrhagic telangiectasia (HHT) (Harrison et al., 2003). Girerd and colleagues demonstrated that ACVRL1 mutation carriers were diagnosed and died at a significantly younger age compared with BMPR2/ACVRL1 noncarriers (Girerd et al., 2010). Despite less severe baseline hemodynamic characteristics compared with those of BMPR2 mutation carriers, age at death among ACLVRL1 mutation carriers was broadly similar to that of BMPR2 mutation carriers, suggesting a more rapid disease progression (Girerd et al., 2010). ACVRL1 haploinsufficiency may lead to a pulmonary vascular status that predisposes to the development of PAH. Interestingly, ACVRL1 mutation carriers with PAH have a predominance of mutations in exon 10 and particularly in the NANDOR box, which is necessary for regulation of TGF-beta signaling. This further supports the hypothesis that disruption of the TGF-beta pathway is central to the development of PAH (Machado et al., 2009; Girerd et al., 2010). Recently, several novel gene mutations have been discovered. CAV1, which encodes a membrane protein of caveolae, is critical to initiation of a cellular signaling cascade involving the TGF-beta superfamily, nitric oxide pathway, and G-protein-coupled receptors (Soubrier et al., 2013; Austin et al., 2012). Exome sequencing of family members with HPAH but without identifiable known mutations found a novel heterozygous missense variant in the potassium channel KCNK3 (Ma et al., 2013). Analysis for additional HPAH cases and IPAH cases identified five additional heterozygous novel missense variants. KCNK3 encodes a pH-sensitive potassium channel in the two-pore domain superfamily (Patel et al., 1999). This potassium channel has been shown to be sensitive to hypoxia and regulates resting membrane potential and pulmonary vascular tone (Hartness et al., 2001; Olschewski et al., 2006; Osipenko et al., 1997). It has been postulated that KCNK3 is also involved in the regulation of pulmonary vascular remodeling and proliferation in patients with PAH through inhibiting apoptosis (Yu and Choi, 2000). Ma et al. showed that some, but not all, mutations were rescued by the phospholipase inhibitor, ONO RS-082 (Ma et al., 2013). In human pulmonary artery smooth muscle cells, KCNK3 can be activated by treprostinil (a stable prostacyclin analog) through cyclic AMP-dependent phosphorylation of the channel induced by protein kinase A (Higenbottam et al., 1984; Moncada et al., 1976). Identification of KNCK3 and other genes as contributing to the development of PAH potentially opens new paths to PAH therapy. Penetrance of PAH disease in those with the BMPR2 mutation is only about 20%. Members of families with HPAH who have

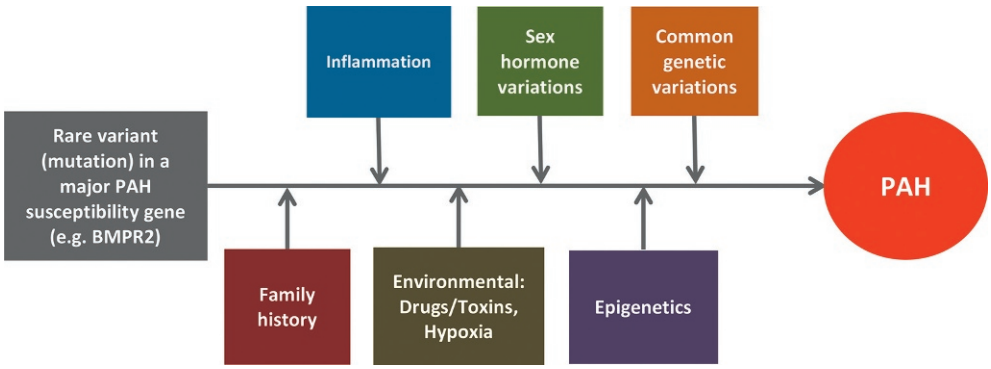

Fig. 2 Factors in the development of PAH.

identified PAH-associated mutations but have no evidence of disease are not uncommonly identified. This may be due to incomplete penetrance of the mutation or due to PAH that has not yet manifested. There is growing evidence to suggest that additional genetic, epigenetic, environmental, and developmental factors exist and modify the development of PAH among susceptible individuals (Austin and Loyd, 2014; **Fig. 2**). Identifying asymptomatic persons who are genetically at risk provides a potential opportunity for early intervention and treatment (Sztrymf et al., 2007; Machado et al., 2005).

Diagnosis of PH

The diagnostic approach to PH is initially based on clinical history and physical exam findings (McGoon et al., 2004). The cardinal symptoms of PH are exertional dyspnea, fatigue, palpitations, and chest discomfort. Syncope is an ominous finding and portends a worse outcome. The most common physical examination finding is an accentuated pulmonic component of the second heart sound

("loud P2") followed by a tricuspid regurgitation murmur (systolic ejection murmur along the left upper sternal border with respiratory variation). A palpable P2, right ventricular heave, and edema are seen in more advanced cases. There may also be symptoms and signs of associated conditions such as Raynaud's phenomenon, liver disease, HHT, left heart disease (systolic or diastolic heart failure and aortic or mitral valve disease), chronic lung disease (chronic obstructive lung disease, pulmonary fibrosis, sleep apnea or kyphoscoliosis), or thromboembolic disease (Badesch et al., 2009). Chest radiograph findings in PAH include prominent central pulmonary arteries, peripheral hypovascularity, and right ventricular enlargement. Signs of associated conditions may also be present. If there is suspicion for PH, transthoracic echocardiography is advised as the preferred initial diagnostic test. Common echocardiographic features of PH include right atrial enlargement, right ventricular enlargement, flattening or reverse curvature of the interventricular septum, and underfilled left heart chambers. The right ventricular systolic pressure (RVSP) can be estimated by measuring the maximal velocity of tricuspid regurgitation and central venous pressure. The RVSP will approximate the peak pulmonary arterial pressure in the absence of pulmonic stenosis. A RVSP of greater than 38–40 mmHg at rest is abnormal. Other findings of PH such as right chamber dilation or reduced right ventricular function (measured by the tricuspid annular plane excursion by "m-mode" or right ventricular fractional area change on a four-chamber view) increase the specificity of echocardiography for the presence of PH. Current guidelines recommend screening high-risk populations for the development of PAH, particularly in cases of limited scleroderma (Hoeper et al., 2013b; Hachulla et al., 2005; Fisher et al., 2009; Brown et al., 2011; Authors/Task Force et al., 2015). Once PH has been identified, additional workup may be indicated to determine the etiology (**Table 3**). Symptomatic patients with an RVSP > 40 mmHg or asymptomatic patients with an RVSP > 50 mmHg should generally undergo further investigation into the etiology of their PH. All therapy for PH is based on the etiology as outlined in the PH classification system. It is therefore important to identify the cause(s) of PH in order to determine the appropriate therapy. The initial diagnostic work up for common etiologies of PH (i.e., groups 2 and 3) includes pulmonary function tests, assessments of oxygenation, EKG, and echocardiogram. Chest computed tomography and polysomnography may also be needed as contingent tests. To exclude group 4 PH (CTEPH), patients should undergo ventilation–perfusion scanning, which has superior diagnostic characteristics to CT pulmonary angiography. A normal or low-probability scan effectively excludes CTEPH. Formal pulmonary angiography by an experienced center is generally needed to confirm the diagnosis (Hoeper et al., 2006; Coulden, 2006). Group 1 PH patients should have further testing performed to exclude collagen vascular disease (ANA and RF) and liver disease (liver function tests and right-upper-quadrant Doppler ultrasound) and thyroid function studies (Hoeper et al., 2013b).

Right heart catheterization (RHC) is essential in all patients with suspected PAH after completion of the noninvasive evaluation. The RHC is the gold standard used for hemodynamic evaluation to confirm the presence of PAH, determine initial prognosis and initial management. There are several essential components to a complete RHC evaluation; this includes oxygen saturations to exclude a left-to-right shunt, cardiac output by the Fick method, right atrial pressure, right ventricular pressure, pulmonary artery pressure (PAP; systolic, diastolic, and mean), PCWP to estimate left atrial pressure, cardiac output and index (traditionally performed by thermodilution method), PVR, systemic blood pressure, and heart rate. If the PCWP is uncertain or elevated, a direct measurement of LVEDP via left heart catheterization is often necessary to definitively exclude left heart disease.

The hemodynamic definition of PAH is a mean PAP greater than 25 mmHg, a PCWP or LVEDP less than 15 mmHg, with a PVR greater than 3 Wood units in the absence of significant (i.e., hypoxemic) chronic lung disease or CTEPH (McLaughlin et al., 2009; Hoeper et al., 2013b; Authors/Task Force et al., 2015). Acute vasodilator/vasoreactivity testing (AVT) should be performed on all IPAH patients. IPAH patients who demonstrate a significant acute vasodilator response have a better prognosis and are more likely to benefit from oral calcium-channel blockers (CCB) (Sitbon et al., 2005; Morales-Blanhir et al., 2004). Once the diagnosis and classification of PAH have been established, exercise testing by 6 min walking distance testing (6MWD) or cardiopulmonary exercise testing should be performed to establish a baseline functional status (Deboeck et al., 2005, 2012; Wensel, 2002; Hansen et al., 2004; ATS/Committee, 2002).

Additional testing	• Acute vasodilator test (for IPAH) • RUQ Doppler ultrasound (for POPH)	• RHC with exercise or volume challenge • LHC (for left heart failure)	• Polysomnogram (for SBD (Sleep Breathing Disorders)) • High-resolution CT (for ILD (Interstitial Lung Disease)) • High altitude simulation test (for flight)	• CTPA (CT Pulmonary Angiogram)	• Other testing as warranted by clinical picture (see **Table 1**)

Clinical Management of PAH

General Measures in the Management of the PAH Patient

General medical care of the PAH patient includes vaccination (influenza and pneumococcal), psychosocial support, and avoidance of pregnancy (Table 4). Supervised exercise training (while avoiding overly strenuous physical activity) is strongly endorsed due to several small but concordant studies demonstrating that PAH patients undergoing supervised cardiopulmonary rehabilitation achieved enhanced physical activity, improved 6MWD testing and patient-reported quality of life, and decreased fatigue when compared with untrained controls (Weinstein et al., 2013; Chan et al., 2013). The optimal timing, methods, intensity, and duration for rehabilitation have yet to be determined. Supplemental long-term domiciliary oxygen should be provided to maintain the partial pressure of blood oxygen above 60 mmHg or oxyhemoglobin saturation above 90% during all conditions encountered (rest, exercise, sleep, and flight/altitude). General medication measures include the use of diuretics to reduce fluid retention (edema or ascites) when necessary. Loop diuretics are generally preferred, and aldosterone antagonists should be added when appropriate. Patients should be monitored for electrolyte derangements, and careful attention should be given to avoiding hypovolemia that can quickly negatively impact renal function. Warfarin anticoagulation should be considered for patients with PAH due to IPAH, heritable PAH, and PAH due to anorexigens. Patients with PAH on long-term IV prostaglandin therapy are generally anticoagulated (absent contraindications) to reduce risk of catheter-associated thrombosis. The targeted international normalized ratio range varies from 1.5–2.5 to 2.0–3.0 depending upon local experience and preferences. Anticoagulation of other group 1 patients is not generally considered beneficial but may be considered for certain individuals where the benefit is thought to outweigh the risks of bleeding. Digoxin may be considered for select PAH patients, however, as with most of the ancillary medications. There are limited data to support this recommendation (Galie et al., 2009).

Acute Vasodilator (Vasoreactivity) Testing and Therapy

Acute vasoreactivity testing (AVT) is mandatory in patients with IPAH to identify patients who are likely to have an excellent long-term outcome to treatment with CCB. AVT should not be performed if the patient is hemodynamically unstable. In cases of associated PAH, AVT is generally not performed due to a very low rate of reactivity found. Inhaled nitric oxide is the preferred agent for acute vasoreactivity testing due to safety, efficacy, and expediency. Epoprostenol or adenosine may also be used; however, these agents carry the risk of systemic hypotension (Galie et al., 2009). Only about 13%–15% of patients with IPAH demonstrate a positive AVT response during the hemodynamic study. This response is defined as a decrease in mPAP by greater than 10 mmHg, a final mPAP under 40 mmHg, and stable or increase in cardiac output (Rich et al., 1992; Sitbon et al., 2005). CCB should only be prescribed to those patients with a positive AVT. Satisfactory results are reported using nifedipine (120–240 mg daily), diltiazem (240–720 mg daily), and amlodipine (up to 20 mg daily). The exact CCB is chosen based upon the baseline heart rate (bradycardia supporting nifedipine or amlodipine and tachycardia supporting diltiazem). The recommended method of beginning CCB is to start with a low dose and increase gradually to the maximum tolerated dose. Patients who meet the criteria for a positive AVT and are treated with CCB therapy must be monitored regularly for safety and efficacy. About half of these patients will continue to do well with CCB in the long run (Rich et al., 1992; Sitbon et al., 2005). If a patient does not show marked hemodynamic improvement to CCB and WHO-FC I or II status within 3–4 months or alternatively loses their responsiveness over time, PAH-specific therapy should be instituted (Galie et al., 2009).

Table 4 General management of the PAH patient

Intervention	*Recommendation(class)*	*Level of evidence*[a]

PAH-Specific Medication Therapy

Presently, in the United States, there are 12 PAH-specific medications in four different classes—endothelin receptor antagonists (ERA), phosphodiesterase-5 inhibitors, soluble guanylate cyclase stimulators, and prostacyclin analogs or agonists. These medications have a variety of administration routes (oral, inhaled, and continuous subcutaneous or intravenous) leading to significant administration complexity. Direct comparisons among different compounds are not available, and there are no evidence-based initial treatment recommendations favoring any specific agent except for the most ill patients. The choice of initial therapy is dependent on a variety of factors including the PAH disease severity (e.g., PAH functional classification), route of administration, side effect profile, and patient preferences. The current standard of care is to use combination therapy with drugs of different classes employed to optimize patient outcomes (Pulido et al., 2013; Galie et al., 2013, 2015; McLaughlin et al., 2010; Ghofrani et al., 2013). A treatment algorithm (**Table 5**) recommends a risk-based management strategy to optimally tailor initial and ongoing therapy based on each individual patient's PAH severity and goals of care (Authors/Task Force et al., 2015; Galie et al., 2013; Taichman et al., 2014). Once initiated on PAH-specific therapy, patients should be regularly monitored with defined treatment goals (McLaughlin et al., 2009, 2013). Treating providers need to be vigilant regarding inadequate clinical responses to initial therapy or clinical disease progression, both of which occur commonly (**Table 6**). Although oral agents are simpler to administer and more commonly used, parenteral therapies remain the preferred treatment as an initial therapy or subsequent intervention for patients with advanced PAH in the appropriate clinical setting (Galie et al., 2013; Authors/Task Force et al., 2015). Continuous IV epoprostenol is recommended as initial therapy for WHO-FC IV PAH patients because of the proved survival benefit in this population. Oral agents are considered as second-line treatments in severely ill patients. Earlier, medical intervention is associated with reduced unwanted clinical outcomes such as hospitalization and urgent initiation of advanced therapies that generally precede death (Burger et al., 2014; Farber et al., 2015a,b; Galie et al., 2015).

Combination PAH-specific medication therapy should be given to patients with a high-risk profile at presentation or who have a continued inadequate clinical response (WHO-FC III or IV, low 6MWD or exercise performance, and elevated biomarkers). The multicenter, prospective, blinded, placebo-controlled AMBITION trial (a randomized, multicenter study of first-line ambrisentan and tadalafil combination therapy in subjects with pulmonary arterial hypertension) compared first-line monotherapy with tadalafil or ambrisentan to combination therapy with tadalafil and ambrisentan as initial treatment strategies for WHO-FC II and III PAH patients. This study showed initial combination therapy resulted in a significantly lower risk of clinical failure events (principally hospitalization for worsening PAH, disease progression, or unsatisfactory long-term clinical response) than either drug as initial monotherapy (Galie et al., 2015). Strategies of "up front" versus sequential combination therapy should both be considered, as the optimal approach and medication combinations are still being determined. For patients with PAH who have a persistently inadequate clinical response and fail to meet treatment goals despite maximal medical therapy, atrial septostomy and/or lung transplantation may be indicated.

Table 5 Recommended initial PAH-specific therapy based on WHO status of most subjects in the pivotal medication clinical trials

Surgical Management of PAH

Atrial Septostomy

Atrial septostomy is a procedure to intentionally create an interatrial right-to-left shunt with aim of depressurizing the right ventricle and improving left ventricular preload to reduce right heart failure and increase cardiac output (Sandoval et al., 1998; Kurzyna et al., 2007). However, these hemodynamic improvements are at the expense of systemic oxygenation due to the inherent right-to-left shunting of venous blood. A majority of patients require supplemental oxygen therapy following atrial septostomy (Olsson et al., 2005). Atrial septostomy was first reported in 1983 as a palliative therapy for patients with refractory PH using a blade balloon technique (Rich and Lam, 1983). The blade-balloon technique has been replaced by graded balloon dilation atrial septostomy (BAS) as it carries reduced risk and equivalent improvement in patient hemodynamics (Rich and Lam, 1983; Althoff et al., 2008). BAS is performed by puncture of the atrial septum with a Brockenbrough needle, followed by serial balloon dilations of the septum (Sandoval et al., 1998). Some patients will have spontaneous closure of the BAS and will need to have the procedure repeated. Smaller defect size is associated with increased incidence of spontaneous closure of the BAS (Olsson et al., 2005).

Patient selection is important to reduce procedural mortality in BAS. The procedure should generally be avoided in patients with right atrial pressure >20 mmHg or oxyhemoglobin saturation <85% at rest on room air. Profound hypoxemia and inability to control the newly created right-to-left shunt is a potential cause of mortality. In the United States, BAS is considered a bridge to transplantation or palliative procedure and is reserved for patients who have refractory right heart failure or syncope and while on maximal medical therapy. In other countries, BAS is performed more commonly related to lack of access to PAH medical therapies (Sandoval et al., 1998; Kurzyna et al., 2007; Chiu et al., 2015; Kuhn et al., 2015). Studies have shown improvement in cardiac index, New York Heart Association functional class and 6 min walk distance, with decreases in right atrial pressure and oxygen saturation post procedure. The BAS procedure should only be performed at centers with experience with the technique (Kurzyna et al., 2007; Chiu et al., 2015; Sandoval et al., 1998).

Transplantation

Transplantation remains a treatment option for patients with PAH despite advances in medical therapy. Referral for transplantation evaluation should occur prior to right ventricular failure. The International Society for Heart and Lung Transplantation found that between 1995 and 2011, about 3% of all lung transplantation procedures in the United States were performed for PAH. The majority of procedures performed for PAH are double-lung transplantations. When compared with the other indicated conditions for lung transplantation, patients with PAH were found to have the highest unadjusted 3-month posttransplantation mortality. PAH is the second most common indication for heart–lung transplantation (Christie et al., 2012).

The survival following lung transplantation for PAH ranges from 52% to 75% at 5 years and between 45% and 66% at 10 years (Toyoda et al., 2008; de Perrot et al., 2012; Fadel et al., 2010). There is debate among transplantation centers whether heart–lung or

double-lung transplantation is superior for patients with PAH, with some centers favoring heart–lung transplantation for those patients with severe right heart failure. Recent studies have shown no significant mortality difference between PAH patients who underwent double-lung transplant and those who underwent heart lung transplantation (Toyoda et al., 2008; de Perrot et al., 2012; Fadel et al., 2010).

Since 2005, the allocation of lungs for transplant has been determined by the lung allocation score (LAS) (Egan et al., 2006). The LAS is calculated from estimates of waiting list survival and posttransplantation survival of each listed patient. Determinants in the LAS calculation include age, body mass index, current mechanical ventilation, diabetes mellitus, diagnosis, forced vital capacity, functional status, oxygen requirement at rest, pulmonary artery systolic pressure, PCWP $\geq$20 mmHg, $PaCO_2$, 6 min walk distance, and serum creatinine (Egan et al., 2006; Colvin-Adams et al., 2012). In patients that are listed for heart–lung transplantation, priority is based on LAS for lung transplantation and medical urgency status code for heart transplant (Colvin-Adams et al., 2012). Since introduction of the LAS, there has been a significant increase in the number of lung transplantations performed (unrelated to an increase in donors), a reduced number of deaths of patients on the waitlist, and an observed increase in 1-year posttransplantation survival (Egan and Edwards, 2016).

Newer Therapies and Approaches to PAH

The majority of the current medical therapies for PAH are focused on well-established biochemical pathways related to pulmonary vasoconstriction and thrombosis. Although a marked improvement in overall survival is associated with appropriate use of the currently available PAH therapies, these agents generally produce only a partial amelioration of abnormal hemodynamics and temporary clinical improvement in for the majority of patients. Current PAH clinical drug development is focused on several areas: use of currently approved agents in combination regimens, use of currently approved agents in specific PAH subpopulations, new delivery methods of currently approved agents, and developing new agents targeted at inflammation and neoplastic pathways implicated in PAH pathogenesis. A novel nonmedical approach involves pulmonary artery denervation (**Table 7**).

Table 7 Current clinical trials in PAH: 2017

Multiagent trials in group 1 PAH	
FREEDOM-Ev	Trial of the early combination of oral treprostinil with background oral monotherapy in subjects with PAH
TAO	Double-blind, randomized, placebo-controlled study of oral treprostinil in combination with tadalafil and ambrisentan compared with tadalafil and ambrisentan alone in WHO group I PAH
TRITON	To compare triple with dual initial oral PAH therapy in newly diagnosed, treatment-naive PAH
"Switch" or treatment strategy trials in group I PAH	
TRANSIT 1	To assess the tolerability and safety of UPTRAVI® (selexipag) in subjects with PAH who transition from inhaled treprostinil to UPTRAVI
REPLACE	Riociguat replacing PDE-5i therapy evaluated against continued PDE-5i therapy
Evaluating efficacy of approved PAH drugs on specific subgroups within group 1	
MAESTRO	Macitentan in Eisenmenger's syndrome to restore exercise capacity
PORTICO	Portopulmonary hypertension treatment with macitentan—a randomized clinical trial
RUBATO	Prospective, multicenter, double-blind, randomized, placebo-controlled, parallel-group study assessing the efficacy and safety of macitentan in Fontan-palliated adult and adolescent subjects
Evaluating efficacy of PAH drugs in groups 2–5 PH	
INCREASE	Safety and efficacy of inhaled treprostinil in adult PH with ILD including CPFE
MELODY 1	Macitentan in combined pre- and postcapillary pulmonary hypertension due to left ventricular dysfunction
MERIT 1	Macitentan in the treatment of inoperable chronic thromboembolic pulmonary hypertension
SOUTHPAW	Double-blind, randomized, placebo-controlled study of oral treprostinil in WHO group 2 PH in HFpEF
IRONS	Phase 3 study of oral treprostinil in patients with sickle cell disease-associated pulmonary hypertension
SOPRANO	Macitentan in pulmonary hypertension post left ventricular assist device implantation
Novel therapeutic agents	
Bardoxolone	LARIAT, CATALYST: investigation of bardoxolone in PAH and CTD-PAH
Dichloroacetate (DCA)	Phase I study of the a proapoptotic molecule in patients with WHO III-IV group 1 PAH
Ubenimex	LIBERTY: phase 2, randomized, placebo-controlled study in patients with FC II/III group 1 PAH
Ralinepag	Phase 2, randomized, double-blind, placebo-controlled trial in patients with group I PAH

Oral Prostacyclin Therapy

Recently, several oral prostacyclin agents and receptor agonists have become commercially available or are in active development.

Oral treprostinil was investigated in the FREEDOM studies, both as monotherapy and in combination with other PAH specific medications. This medication is gradually increased over time, following the paradigm for parenteral dosing. In the FREEDOM-M monotherapy study, significant improvements were seen in 6MWD testing, particularly with dose titrations above 2 mg twice daily (Jing et al., 2013). Higher doses were not well tolerated by many patients due to significant side effects, principally gastrointestinal upset and headaches. The FREEDOM-C studies with background ERA and PDE-5 inhibitors demonstrated no overall improvement in 6MWD test results, time to clinical worsening, mortality, or functional class. Data suggest that significant improvements were possible at higher doses, when these doses were tolerated by patients. Oral treprostinil is currently dosed three times daily, which appears to mitigate the intensity of adverse effects in many patients with the hope of improving tolerability and efficacy (Tapson et al., 2013).

Selexipag, an oral prostacyclin receptor agonist that has both vasodilatory properties and antiproliferation effects, was recently approved at twice daily dosing. The GRIPHON study demonstrated a decrease in the risk of the primary composite end point of death from all causes and complications from PAH, including PAH patients on background therapy (Sitbon et al., 2015). It also requires an up-titration schedule.

A phase 2 study of another oral prostacyclin receptor antagonist, ralinepag, has recently completed enrollment. Pharmacokinetic studies of this agent demonstrate an adequate half-life to potentially allow for once daily dosing (clinicaltrials.gov/ct2/show/NCT02279160).

Upfront Combination PAH-Specific Therapy

The 2015 AMBITION study looked at oral monotherapy with either a PDE5 inhibitor or ERA or the combination of both in patients with both IPAH or CTD-PAH. The event-driven protocol showed that the use of up-front combination therapy decreased death, hospitalization, or clinical worsening by approximately 50% (Galie et al., 2015).

Sitbon and colleagues performed a retrospective analysis pilot study examining 19 patients with FC III/IV PAH treated with up-front triple combination therapy (bosentan, sildenafil, and IV epoprostenol). All patients had improved FC to I/II, and all but one patient showed improvement in 6MWD and right-heart catheterization hemodynamics (Sitbon et al., 2014). The TRITON study, currently recruiting, compares triple with dual initial oral PAH therapy in newly diagnosed, treatment-naive group 1 PAH using the combination of macitentan and tadalafil with either oral treprostinil or placebo. Variations of these up-front studies are abundant (clinicaltrials.gov/ct2/show/NCT02999906).

Inflammation, Immunity and Apoptosis

Plexiform lesions in PAH demonstrate infiltration by variety of immune cells, and the degree of inflammation has been found to correlate with measured mPAPs (Tuder et al., 2013). Bardoxolone methyl is a treprostenoid compound with antioxidative and anti-inflammatory properties, which acts via Nrf2 and NF-κB, suppressing inflammatory mediators and inhibiting the downstream effects of vascular proliferation and remodeling. Since 2013, bardoxolone has been studied in the LARIAT trial, a phase 2, randomized, placebo-controlled study in patients with group 1 PAH (clinicaltrials.gov/ct2/show/NCT02036970). It is also being investigated for use in connective tissue disease associated PAH (CTD-PAH) in the CATALYST trial (clinicaltrials.gov/ct2/show/NCT02657356).

Immune dysregulation in PAH is currently being targeted with both approved medications and novel agents drugs in specific PAH populations (Rabinovitch et al., 2014). Studies are being done within the subgroups of patients with group 1 PAH, with attention to associated diseases. Patients with systemic-sclerosis-associated PAH (SSc-PAH) have higher mortality rates despite use of currently available PAH-specific therapies (Chaisson and Hassoun, 2013). Preclinical data and case reports have suggested a benefit in patients with SSc-PAH who were treated with immunomodulatory therapies. Rituximab, an anti-CD20 monoclonal antibody used in collagen vascular diseases and hematologic malignancies, has been tested in systemic-sclerosis-associated interstitial lung disease and is currently under investigation in a phase 2 studies in patients with SSc-PAH (clinicaltrials.gov/ct2/show/NCT01086540).

Macrophages, regulatory T cells, and leukotrienes have been associated with vascular proliferation in PAH and modification of the leukotriene pathway is currently being investigated as a target in PAH clinical trials (Qian et al., 2015). Inhibition of leukotriene B_4 has been shown to decrease vascular proliferation and occlusion (Tian et al., 2013). Ubenimex, a leukotriene B_4 antagonist, has been in use in Asia as adjunctive therapy in leukemia therapy for more than 2 decades. This agent is being studied in the LIBERTY phase II clinical trial for management of PAH (clinicaltrials.gov/ct2/show/NCT02664558).

Imatinib mesylate, a PDGF inhibitor currently used in hematologic and GI malignancies, which mitigates vascular and smooth muscle cell proliferation, was investigated in the IMPRES study. PAH patients on at least two background therapies were studied for 2 years. Functional class, time to clinical worsening, and mortality did not differ between treatments, and 6MWD was only improved by 32 m at 2 years. Serious adverse events and discontinuations were more frequent with imatinib than placebo, including subdural hematomas in anticoagulated patients (Hoeper et al., 2013a).

The Endothelium in PAH

Pulmonary endothelium is thought to have a pivotal role in the development of PAH, and the role of pathological apoptosis of pulmonary endothelial cells is an area of current investigation. Diminished programmed cell death of pathological endothelial cells may lead to vascular proliferation and remodeling in PAH. Dichloroacetate, a proapoptotic agent that has been shown to cause regression of vascular proliferation, has recently completed early phase testing in PAH patients (clinicaltrials.gov/ct2/show/NCT01083524).

Nonpharmacologic Therapies

Research has shown that obliteration of the sympathetic nerve supply to the renal arteries in severe systemic hypertension can have the effect of lowering systemic blood pressure, albeit with unacceptable risks in most studies. Sympathetic activation has also been shown to be contributing factor to pulmonary arterial pressures. Chen and colleagues safely performed pulmonary artery denervation in 66 PAH subjects resulting in improvement in 6MWD and mean PAP with reduction in PAH medication use (Chen et al., 2015). Studies of the effect of stellate nerve block and/or reserpine in group 2 pulmonary hypertension are in the preclinical stage (NCT02684786).

Current Challenges in the Diagnosis and Management of PAH

With the development of multiple oral agents to treat PAH and expert management, PAH is becoming a chronic condition with an enhanced life expectancy (Simonneau et al., 2013). However, the availability of oral medications for PAH treatment has also seen a migration of care delivery from tertiary care centers to the wider community. Overreliance on oral medication use may lead to a higher rate of emergent interventions for decompensated PAH and reduced survival (Badagliacca et al., 2012). Despite the availability of multiple drugs and evidence-based treatment guidelines for several years, there are ongoing reports of errors of misdiagnosis, delayed diagnosis, and undertreatment of PAH patients within both the community and PAH centers (Deano et al., 2013). Multidisciplinary team-based patient care is felt to be an important strategy to improve health-care quality in chronic diseases (Yarnall et al., 2009). It has been shown that multidisciplinary healthcare teams are clinically effective and can improve the quality of clinical care delivered in a spectrum of acute and chronic care settings (Wagner et al., 2001). Improvements have been demonstrated in medication safety and in clinical and patient-centered outcomes (patient knowledge, medication adherence, and quality of life health scores) (Chisholm-Burns et al., 2010). The fifth World Symposium on Pulmonary Hypertension Task Force on Standard of Care recommends referral of PAH patients to expert centers after diagnosis (Galie et al., 2013). While many areas have well-established centers for the multidisciplinary management of PAH for some time, further organization and coordination between PH centers regionally, nationally, and internationally is progressing and will hopefully positively impact this uncommon but potentially lethal condition (Sahay et al., 2016; Chakinala et al., 2016).

Introduction

Pulmonary embolism (PE) was first alluded to in Indian texts dating back to 1000 BC. Although others previously described PE, the German pathologist Rudolph Virchow is credited with describing PE in 1846 and hypothesizing the relationship between venous thrombosis and obstruction of the pulmonary arteries. His description of factors leading to clot formation is still used today (Wood, 2009).

Definitions

PE is broadly defined as obstruction in one or more of the pulmonary artery branches. PEs are most often due to thrombus embolization from peripheral veins but can also be composed of bacteria, protozoa, tumor, fat, amniotic fluid, and air. Herein, we will focus on thrombus. PE is generally separated into acute and chronic presentations. Acute PE is by far the more common presentation. Rarely, patients present with the subacute onset of signs and symptoms consistent pulmonary hypertension due to chronic thromboembolic disease.

Epidemiology

The incidence of acute PE is reported between 38 and 80 cases per 100,000 persons per year. In the US, there are approximately 237,000 PE cases diagnosed per year. Some databases demonstrate increasing incidence over the last two decades. However, with widespread use of ventilation perfusion scanning and computed tomography with pulmonary angiography, the increased incidence of PE is likely due to increased detection (Alotaibi et al., 2016; Heit et al., 2005; Huang et al., 2014; Martinez et al., 2014; Silverstein et al., 1998; Wiener et al., 2011). Both the incidence and the risk of death are higher in certain subpopulations including those with malignancy, hospitalization, joint replacement, inherited thrombophilias, and autoimmune disease (Alotaibi et al., 2016; Dalen and Alpert, 1975; Horlander et al., 2003; Lilienfeld, 2000; Wiener et al., 2011).

Death

PE is fatal in up to 10% of patients. In the United States, fatalities due to PE are 50% higher in African-Americans than whites, while deaths in whites are approximately 50% higher than Latinos and Asians Within racial strata, mortality rates are 20%–30% higher for males than females. Most commonly, this is due to failure to adequately diagnose PE as well as failure to prevent it via prophylactic interventions in high risk patients. Patients that receive appropriate prophylaxis and treatment typically do not succumb to PE. Mortality from PE appears to have declined over the past several decades coincident with advances in diagnosis and treatment (Horlander et al., 2003; Lilienfeld, 2000). The true incidence of death from PE may be higher than reported. Various autopsy series have noted up to three times higher incidence of death from PE than what is clinically diagnosed (Karwinski and Svendsen, 1989; Morgenthaler and Ryu, 1995; Rubinstein et al., 1988).

Pathophysiology

Inherited Risk Factors

Thrombus formation results from risk factors defined by Virchow's Triad; hypercoagulability, stasis, and vascular endothelial injury. Hypercoagulable states can be hereditary or acquired. Factor V Leiden is the most common inherited thrombophilia, accounting for up to 50% of cases of identified thrombophilia leading to PE. Five percent of Caucasians are heterozygous, which carries a 5- to 10-fold increased lifetime risk for venous thromboembolism (VTE). Homozygosity for Factor V Leiden is much rarer but carries an 80-fold increase risk of thrombosis. The risk increases even more during pregnancy and with the use of estrogen containing contraceptive pills. It is important to note that only 5% of patients with Factor V Leiden deficiency will develop a VTE in their lifetime (Koster et al., 1993; Rosendaal et al., 1995; Simone et al., 2013). Other common inherited hypercoagulable states include Prothrombin Gene Mutation, Antithrombin III Deficiency, Protein C Deficiency, and Protein S Deficiency (Leiden and Society, 2008; System, 2014).

Acquired Risk Factors

Many patients that develop VTE have underlying inherited risk factors that, in combination with acquired risk factors such as endothelial injury, acute illness, and venous stasis, result in clot formation (Anderson and Spencer, 2003).

Major acquired risk factors include pelvic and lower extremity fractures, orthopedic and major surgery, malignancy, prolonged immobility, and autoimmune diseases. **Table 1** summarizes common risk factors.

Various studies have shown that most patients with VTE have multiple risk factors at the time of diagnosis (Anderson and Spencer, 2003; Ocak et al., 2013; Spencer et al., 2006).

Natural History

Thrombi arise at areas of low and turbulent flow such as valvular cusps, areas of endothelial injury, and on foreign bodies such as venous catheters (Nicolaides et al., 1971). After initial clot formation, the size, extent, and morbidity of the clot depend on many

Table 1 Risk factors for venous thromboembolism (Anderson and Spencer, 2003)

Inherited thrombophilias
Factor V Leiden mutation
Protein C deficiency
Prothrombin gene mutation
Hyperhomocysteinemia
Familial plasminogen deficiency
Acquired surgical risk factors
Lower extremity orthopedic surgery
Neurosurgery
Major thoracoabdominal surgery requiring >30 min of general anesthesia
Fractures of the pelvis, hip, or long bones
Major trauma
Acquired medical risk factors
Malignancy
Pregnancy
Estrogen therapy
Autoimmune diseases
Lupus anticoagulant
Prolonged immobilization
Congestive heart failure
Critical illness

patient factors listed previously. The majority of pulmonary emboli result from clot that originates in the deep veins of the proximal lower extremities (Kakkar et al., 1969; van Langevelde et al., 2013; Nicolaides et al., 1971).

Physiologic Response to PE

PE causes pulmonary and cardiovascular derangements well beyond the simple mechanical obstruction of the clot itself. The mechanical obstruction of the pulmonary vascular bed can cause alterations in ventilation perfusion relationships as well as increased pulmonary arterial pressure. Furthermore, release of inflammatory cytokines and serotonin from platelets dysregulates hypoxemic vasoconstriction, increases pulmonary vascular resistance and worsens V/Q mismatch and hypoxia.

Despite increased dead space ventilation, stimulation of irritant receptors causes alveolar hyperventilation and resultant hypocapnia (Huet et al., 1985). If PE are large enough to cause increased right atrial pressure, the event can induce right to left shunting through a patent foramen ovale and further worsen hypoxia. There is also reflex bronchoconstriction which increases airways resistance, and noncardiogenic pulmonary edema that contributes to decreased lung compliance (D'Angelo, 1997; Elliott, 1992).

With small emboli (<20% of pulmonary vascular bed), the cardiovascular system is able to compensate for the increases in pulmonary pressure by augmenting RV pressure and stroke volume in order to preserve cardiac output. However, the native right ventricle (RV), unlike the left ventricle (LV) is a thin walled, crescent shaped pump unable of generating high pressures. As pulmonary vascular resistance and pulmonary arterial pressure rises, the RV wall tension increases, followed by RV dilation and dysfunction. As the RV dilates, LV filling is impaired and leads to decreased cardiac output and decreases in systemic blood pressure. RV wall tension coupled with decreases in systemic blood pressure impairs right coronary artery perfusion, leading to myocardial ischemia, and worsened cardiac function (Gerges et al., 2014). In up to 10% of patients, pulmonary infarction occurs due to small thrombi occluding distal subsegmental vessels. Infarctions are less common than in other organs due to both bronchial and pulmonary artery circulation. However, in patients with underlying cardiac or pulmonary disease, bronchial circulation and venous return may be impaired and lead to higher rates of pulmonary infarction (Dalen et al., 1977; Stein et al., 1991).

Clinical Presentation and Diagnosis

Symptoms of PE are nonspecific and overlap with other disease states, so a high index of clinical suspicion is a key factor in subsequently establishing a diagnosis. The three most common symptoms are dyspnea (77%), pleuritic chest pain (66%), and lower extremity pain and/or swelling (44%). Cough (37%), wheezing (21%), and hemoptysis (13%) can also be present. Syncope is uncommon in patients with PE. However, in patients admitted with a first episode of syncope, PE is identified in almost 20% of patients (Prandoni et al., 2016). Some patients also describe angina and a sense of doom, which is often associated with massive PE. Dyspnea often occurs within minutes of PE. Patients with delayed presentations tend to have larger, more central clot burden than those with more peripheral clot (dyspnea, pleuritic chest pain) (Stein et al., 2007). The most common physical examination findings include tachypnea (54%), leg swelling (44%), and tachycardia (24%). Other less common findings include inspiratory crackles and fever. With massive PE, patients may have evidence of right ventricular failure—hypotension, jugular venous distension, splitting of S2 and an accentuated pulmonic component of the second heart sound (Stein et al., 2007; Stein and Henry, 1997).

Imaging

Computed tomography

Since the 1990s, due to advances in imaging techniques, computed tomography with pulmonary angiography (CTPA) has become the preferred test in the diagnosis of acute PE because of its high diagnostic accuracy and ability to provide alternate diagnosis for diseases of the lung parenchyma, pleura, pericardium, aorta, heart, thoracic lymph nodes, and mediastinum (van Rossum et al., 1998; Sodhi et al., 2010). Contrast media is rapidly injected into a vein, travels to the pulmonary circulation and the scan takes place while the pulmonary arteries have been opacified. The diagnosis of PE is established on CTPA by direct visualization of one or more low attenuation filling defects that partially or completely occlude a contrast filled artery (Kuriakose and Patel, 2010). Other indirect CTPA findings include areas of lung parenchyma with lower attenuation due to decreased pulmonary blood flow or oligemia, evidence of focal pulmonary hemorrhage, atelectasis, small effusions, and RV dilation (Coche et al., 1998). CTPA has traditionally been less sensitive at detecting smaller, more peripheral emboli. However, newer multidetector CTs have improved the detection of smaller segmental and subsegmental PE (Perrier et al., 2005).

Ventilation perfusion scans

Prior to the widespread use of CTPA, radionuclide ventilation perfusion (V/Q) scans were the imaging modality of choice for diagnosing acute PE. Ventilation perfusion scans are still used in patients with contraindications to CTPA and are the preferred imaging technique in the initial evaluation of chronic thromboembolic disease. A V/Q scan with normal findings effectively excludes PE with a negative predictive value close to 100%. A high-probability scan is highly specific for the diagnosis of PE, allowing definitive treatment. Unfortunately, the majority of patients originally studied had an intermediate probability of having a

PE and require more testing to determine the diagnosis (PIOPED Investigators, 1990). However, V/Q technology and radiology reporting has improved significantly over the past two decades making it a much more useful tool in diagnosing thromboembolic disease (Freeman and Haramati, 2009).

Catheter pulmonary angiography

Catheter pulmonary angiography is an invasive means of diagnosing PE. A catheter is inserted into a central vein and advanced through the RA and RV into the pulmonary arteries under fluoroscopy and contrast is injected to obtain radiographic images to visualize a thrombus. With newer, more rapid technologies of diagnosing PE, catheter pulmonary angiography does not play a major role in diagnosing acute PE (Kuriakose and Patel, 2010). However, it is still routinely used as part of the preoperative evaluation for pulmonary thromboendarterectomy.

Plain film radiographs

Plain film radiographs are not adequate to establish the diagnosis of PE but can demonstrate indirect evidence of PE—atelectasis, small effusions, wedge shaped opacities suggestive of infarction, and hypovascularity.

Echocardiography

Similar to radiographs, echocardiography cannot definitively diagnosis PE. However, in a patient with unexplained shock and a high clinical suspicion for PE, echocardiography can help point toward the diagnosis in those with RV dilation, and may sometimes result in clot visualization in the IVC, RA, or RV. Echocardiography can also suggest alternative diagnoses—congestive heart failure, pericardial effusion, myocardial infarction. In the right clinical context in an unstable patient, echocardiography can provide enough information to allow for immediate therapies to be undertaken at the bedside (Goldhaber, 2002; Miniati et al., 2001).

Electrocardiography

The most common ECG finding in PE is tachycardia. Other abnormalities can include a new right bundle-branch block, evidence of RV strain—anterior ST-segment changes, T wave inversions, and Q waves in the inferior leads. With larger and more hemodynamically significant occlusion, the evidence of right strain can be evidenced by "S1Q3T3" pattern, a pseudoinfarction pattern (QR in V1), a complete or incomplete right bundle-branch block, or right axis deviation (Kucher et al., 2003; Stein et al., 1975). Neither the sensitivity nor the specificity of ECG for PE is high.

Lower extremity ultrasound

Lower extremity ultrasound (LE U/S) is very useful in detecting lower extremity thrombus with sensitivity and specificity (Lensing et al., 1989). However, only 10%–20% of patients with clinical suspicion are found to have DVT. Further, only half of patient with proven PE are found to have DVT (Perrier, 2000). Therefore, LE U/S does not reliably diagnose PE and should not be used as the initial imaging modality unless contraindications to CTPE or V/Q exist (Wells et al., 2001).

Laboratory data

Arterial blood gas analysis—arterial hypoxia is often present and correlates to the degree of the obstruction. A widened alveolar-arterial oxygen gradient and hypocapnia occur but is not specific for PE. Hypercapnia is rare and only occurs in patients with a fixed minute ventilation, such as those sedated and paralyzed on mechanical ventilation (Rodger et al., 2000). Brain natriuretic peptide (BNP) is of limited value in diagnosing PE but is useful in risk stratifying those with submassive PE (Sohne et al., 2006). Similarly cardiac markers such as troponin and CK-MB are not sensitive or specific but may also help to risk stratify and define prognosis (Pruszczyk et al., 2003). D-dimer, a fibrin degradation product produced by fibrinolysis, has low specificity but high sensitivity. It is useful in excluding embolism in patients with low clinical probability of disease and is used in some predictions models mentioned in the following.

Clinical Prediction Models

Clinical prediction models have been created and studied to determine who needs more diagnostic testing and in who PE can be ruled out. The two most validated models are the Wells Score and pulmonary embolism rule out criteria (PERC) score. The Wells Score is most validated and has most clinical use. There are seven criteria and each is assigned points. Based on the score, patients are stratified into low, intermediate, and high pretest probability. This risk stratification is then used to determine which diagnostic test is most appropriate (**Table 2**). In patients with low pretest probability of PE, it is appropriate to order a d-dimer test for screening. If this test is negative, it excludes the diagnosis of PE in almost all cases (Van Belle et al., 2006; Lucassen et al., 2011). Rarely, a false negative can occur in older patients with smaller clot burden. Unfortunately, d-dimer often produces false positive results, especially in patient with acute illness, recent surgery, pregnancy, or decreased renal function (Crowther et al., 2005; Karami-Djurabi et al., 2009; Kline et al., 2008). Those who are at intermediate or higher risk need more advanced diagnostic testing such as CTPE or V/Q scan.

An alternative prediction model for patients with a low pretest probability of PE who present to an emergency department is also used. The PERC, is used when clinicians have a low suspicion of PE (<15%) and who meet specific criteria. If all criteria are met, no d-dimer is needed and clinicians can effectively rule of PE (**Table 3**) (Kline et al., 2008).

Table 2 Wells score to predict pretest probability of pulmonary embolism

Clinical signs and symptoms of DVT	3
PE is the leading diagnosis	3
Heart rate greater than 100	1.5
History of VTE	1.5
Hemoptysis	1
Malignancy	1
Score	*Probability*
>6	High
$2 \leq \text{score} \leq 6$	Moderate
<2	Low

Table 3 Pulmonary embolism rule out criteria (PERC)

Age <50 years old
Heart rate <100
Oxygen saturation $\geq 95\%$
No hemoptysis
No estrogen use
No history of VTE
No surgery or trauma requiring hospitalizations in the previous 4 weeks
No unilateral leg swelling

All must be negative in order to forgo further testing.

Treatment

Anticoagulation

Anticoagulation is the cornerstone of treatment for PE. Heparin was first discovered in 1918 but it was not until 1930s that it was used for venous thrombus (Howell and Holt, 1918; Murray GaB, 1938). Unfractionated heparin and low molecular weight heparin (LMWH) have traditionally been the most common initial forms of anticoagulation in patients with PE (Kearon et al., 2008; Wood, 2009). Unfractionated heparin is preferred in patients with anticipated need for discontinuation or reversal, hemodynamic instability, renal failure, those with extensive clot burden who are at risk for deterioration, need an invasive procedure, and those at high bleeding risk. In patients who are pregnant, have cancer and those who will transition to warfarin, LMWH is generally preferred. Compared to unfractionated heparin, data suggest that LMWH has slightly less thrombotic complications, improved clot resolution, reduced rates of major hemorrhage, improved mortality, and lower rates of heparin induced thrombocytopenia (Erkens and Prins, 2010; Weitz, 1997). Long-term anticoagulation in most patients can be accomplished with vitamin K antagonists or newer, direct factor Xa and thrombin inhibitors (direct oral anticoagulants, or DOACs). Due to increasing evidence demonstrating safety, efficacy, and ease of doing, DOACs are now recommended over warfarin therapy in the absence of renal failure (Kearon et al., 2016). Pregnant patients as well as those with cancer should still be managed with LMWH. If renal failure is present, subcutaneous unfractionated heparin is also an option prior to starting warfarin. In patients with a provoked PE, most clinicians recommend at least 3–6 months of treatment with anticoagulation. In those with unprovoked PE or unresolved risk factors as well as a low bleeding risk, many suggest lifelong anticoagulation due to high rates of recurrence after stopping anticoagulation (Kearon et al., 2016; Prandoni et al., 2007).

Systemic Thrombolysis

The administration of thrombolytic therapy in a patient with PE was first described in 1964 in a case series of four patients. All patients survived and were noted to have improvements in hemodynamic parameters. Since this initial report, multiple trials and reports have evaluated the efficacy and safety of thrombolytic therapy in acute PE. Trials in massive PE have been limited by small size, severity of illness and the ethical issue of withholding a potentially lifesaving therapy. However, all trials demonstrated a trend toward increased survival (Jerjes-Sanchez et al., 1995; Wan et al., 2004). Trials in submassive embolism generally show faster improvements in hemodynamics, less escalation of therapy, but no mortality difference with use of thrombolytic therapy. These benefits come at the expense of increased major and fatal bleeding events (Marti et al., 2014). Absolute contraindications to thrombolytic therapy include a history of intracranial neoplasm, recent (<2 months) intracranial or spinal surgery or trauma, a history of hemorrhagic stroke, active bleeding, and recent (<3 months) nonhemorrhagic stroke. Relative contraindications include severely uncontrolled hypertension, any history of ischemic stroke, CPR or surgery within the prior three weeks, recent invasive procedure, pregnancy, noncompressible vascular punctures, pericarditis, current anticoagulant use, age $>$ 75 years.

Hemodynamically Unstable Patients

Less than 10% of patients presenting with PE have signs of hemodynamic instability (Stein et al., 2007). Massive PE is not identified by clot burden, but is defined as hemodynamic instability due to a PE and is a medical emergency. A more detailed definition of massive PE is a systolic blood pressure less than 90 mmHg for greater than 15 min or a reduction of systolic pressure by more than 40 mgHg from baseline. Clinically, patients are in cardiogenic shock. Initial support should focus on restoration of blood pressure with judicious intravenous fluids and vasopressor support to prevent worsening RV ischemia and function as well as supplemental oxygen. Empiric anticoagulation with intravenous unfractionated heparin should be started immediately without waiting for diagnostic confirmation. Ideally, definitive testing with CTPE or V/Q should be performed. However, if a patient is too unstable for transport, bedside echocardiography can help confirm clinical suspicion or provide an alternative diagnosis, as mentioned previously. For patients with persistent cardiogenic shock either a high clinical suspicions or confirmed diagnosis, systemic thrombolytic therapy is indicated in the absence of contraindications (Kearon et al., 2016).

Hemodynamically Stable Patients

In general, patients without hemodynamic compromise should not be administered thrombolytic therapy. However, in some situations certain patients may benefit from thrombolytics. Those include younger patients with radiographically extensive PE, signs of decompensation, cardiopulmonary arrest due to PE, and free floating clot (Kearon et al., 2016) (**Fig. 1**).

Catheter Directed Therapy

Catheter directed therapy has emerged as an adjunctive treatment for PE. Catheter directed thrombolysis typically uses much lower doses of TPA (~10–25 mg), so the bleeding risk may be decreased. Catheter directed thrombolysis is suggested for patients with hemodynamic instability after systemic administration of thrombolytic therapy, those with high risk of bleeding and other contraindications to systemic thrombolysis (Kearon et al., 2016). In patients with submassive PE with significant RV dysfunction and radiographically extensive embolism, catheter directed therapy is preferable to systemic therapy. Catheter directed thrombolysis can be combined with other mechanical therapies such as ultrasound and thrombectomy to further decrease clot burden. Interestingly, the half-life of alteplase is 4 minutes. A normal cardiac output is 5–6 L per minute. Therefore, the effect of recirculating alteplase is approximately five times greater than the first pass effect from directed catheter administration.

Embolectomy

Traditionally, surgical embolectomy has been used in patients in whom thrombolytic therapy has failed or is contraindicated. Other indications may include atrial and ventricular thrombus (Aklog et al., 2002; Keeling et al., 2015). Catheter directed embolectomy has emerged as an alternative to surgical embolectomy. The procedure consists of mechanical fragmentation and aspiration. Percutaneous embolectomy combined with intracatheter thrombolysis appears to be a relatively safe and effective treatment (Kuo et al., 2009). However, large randomized trials demonstrating efficacy are lacking.

Follow Up and Chronic Thromboembolic Pulmonary Hypertension

Most patients fully recover after an acute PE. The thrombus dissolves by native fibrinolysis, typically assisted by the use of anticoagulation management. However, approximately 1%–5% of patients go on to remodel the thrombus into vascular scar, resulting in chronic thromboembolic pulmonary hypertension (CTEPH). CTEPH is defined by mean pulmonary arterial pressure

Fig. 1 Radiographically extensive submassive saddle pulmonary embolism. CT pulmonary angiogram demonstrating large saddle thrombus at the bifurcation of the main pulmonary arteries as well as thrombus in the left upper lobe segmental arteries.

≥25 mmHg and pulmonary capillary wedge pressure ≤15 mmHg in the presence of multiple chronic, organized occlusive thrombi after at least three months of effective anticoagulation (Fedullo et al., 2011; Guérin et al., 2014; Pengo et al., 2004). Risk factors include radiographically extensive thrombus, prior splenectomy, presence of a lupus anticoagulant, and elevated systolic pulmonary artery pressure greater than 50 mmHg at time of diagnosis (Fedullo et al., 2011; Lang and Madani, 2014).

Routine screening for CTEPH is not recommended in all patients who have had a PE. However, high risk populations may benefit from screening with a follow up 6 months after initial diagnosis echocardiogram and ventilation perfusion scan. Diagnosis is confirmed with right heart catheterization to measure pulmonary artery pressures, pulmonary vascular resistance, and cardiac output. The definitive treatment of CTEPH is surgical pulmonary thromboendarterectomy (Fedullo et al., 2011). However, for patients who are not surgical candidates, medical therapy and pulmonary artery balloon angioplasty may be viable treatment options (Fukui et al., 2014; Ghofrani et al., 2013; Lang and Madani, 2014; Mizoguchi et al., 2012) (**Figs. 2** and **3**).

Fig. 2 Pulmonary thromboendarterectomy surgery. Surgical specimen of a patient who underwent pulmonary thromboendarterectomy for chronic thromboembolic pulmonary hypertension.

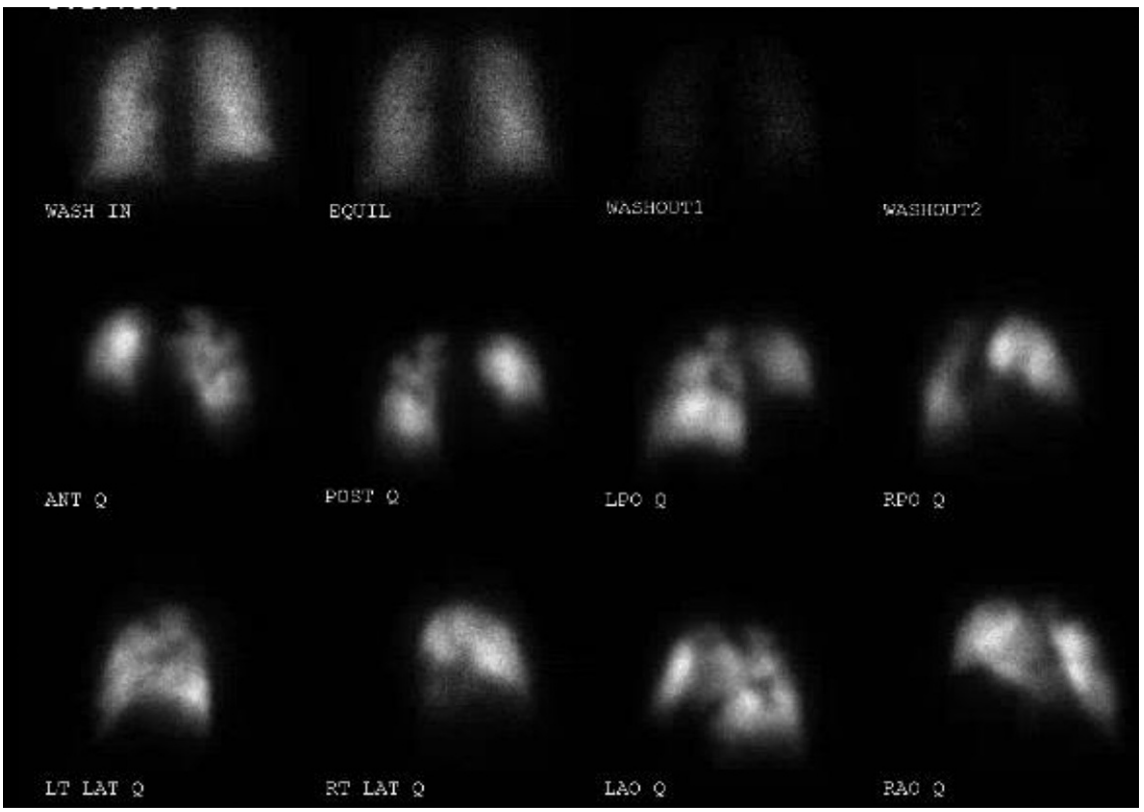

Fig. 3 Abnormal ventilation perfusion scan. The ventilation imaging in the top row demonstrates normal, homogenous uptake, and washout of xenon gas. The perfusion imaging should mirror the ventilation. In this patient, however, there are large unmatched defects in the right middle and lower lobe as well as smaller segmental defects throughout the left lung.

A complex disease of the pulmonary vascular system, pulmonary hypertension (PH) is found to exist as both an isolated disease of small pulmonary arteries and as a complication of numerous chronic diseases. The first description of common morphologic findings of PH is attributed to the German physician Ernst Von Romberg in the late 19th century (Romberg, 1891). The "pulmonary vascular sclerosis" described remains an accurate representation of plexiform lesions and muscularization of small pulmonary arteries and arterioles that identifies the histopathology of pulmonary arterial hypertension today. A disease characterized on autopsy, the accurate identification of PH in living patients would have to wait until the 1940s when Drs. Cournand, Ranges, and Richards developed the techniques for right heart catheterization to directly measure pressures within the pulmonary vascular system that remain in use today (Cournand et al., 1944; Bloomfield et al., 1946). Proper identification of PH led to the development of the first national registry of patients with primary pulmonary hypertension, now known as idiopathic pulmonary arterial hypertension (IPAH). Numerous registries now exist throughout the world identifying patients with various forms of pulmonary hypertension. Registry data has led to a better understanding of the pathophysiology and natural history of the disease, leading to advances in basic science, translational, and clinical research which has been paramount to discovery of therapies. The approval of intravenous epoprostenol as the first treatment of IPAH in 1995 came on the heels of a groundbreaking clinical trial showing survival benefit with the use of this agent. This heralded the development of four classes of drug therapy used for PAH today. The future of pulmonary hypertension focuses on continual growth of our knowledge in this disease state, identifying best practices and novel therapeutics to combat both PAH and other forms of pulmonary hypertension.

Definition and Clinical Classification of Pulmonary Hypertension

Elevations in pulmonary artery pressure result from defects at any site of the pulmonary vascular system including the pulmonary artery and arterioles, capillaries, or pulmonary veins and venules. The system is also intricately coupled with the heart, lung parenchyma, and airways such that any number of disease processes affecting the cardiovascular or pulmonary systems can invariably lead to changes in pulmonary hemodynamic measurements. The diversity of pulmonary hypertension has thus necessitated the use of a clinical classification of pulmonary hypertension (**Table 1**). This classification has evolved and currently separates pulmonary hypertension into five groups based on similarities in both pathophysiologic mechanisms and response to therapy: (i) pulmonary arterial hypertension, (ii) pulmonary hypertension owing to left heart disease, (iii) pulmonary hypertension owing to lung diseases and/or hypoxia, (iv) chronic thromboembolic pulmonary hypertension, and (v) pulmonary hypertension with unclear multifactorial mechanisms (Simonneau et al., 2013).

While the hemodynamic definition of pulmonary hypertension requires a mean pulmonary artery pressure (PAP) greater than 25 mmHg, a more robust description of elevated pulmonary artery pressures also distinguish the region of the pulmonary vasculature accounting for this elevation, pre- versus postcapillary PH, and the pulmonary vascular resistance (PVR) which takes into account the cardiac output within the system (**Table 2**). Precapillary PH specifies that the elevated mean PAP is independent of pressures transmitted from the pulmonary venous system and left heart with pulmonary artery wedge pressure (PAWP) and/or left ventricular end-diastolic pressure (LVEDP) being within normal ranges. Postcapillary PH or pulmonary venous hypertension (PVH) describes PH with elevated PAWP or LVEDP, indicating that elevated pressure is being transmitted back to the pulmonary artery

Table 1 Clinical classification of pulmonary hypertension

1. Pulmonary arterial hypertension (PAH)
   - 1.1 Idiopathic
   - 1.2 Heritable
     - 1.2.1 BMPR2
     - 1.2.2 ALK1, endoglin, SMAD9, CAV1, KCNK3
     - 1.2.3 Unknown
   - 1.3 Drugs and toxins induced
   - 1.4 Associated pulmonary arterial hypertension
     - 1.4.1 Connective tissue diseases
     - 1.4.2 HIV infection
     - 1.4.3 Portal hypertension
     - 1.4.4 Congenital heart disease
     - 1.4.5 Schistosomiasis
     - 1.4.6 Chronic hemolytic anemia

1′ Pulmonary venoocclusive disease and/or pulmonary capillary hemangiomatosis

1″ Persistent Pulmonary Hypertension of the Newborn

2. Pulmonary hypertension owing to left heart disease
   - 2.1 Systolic dysfunction
   - 2.2 Diastolic dysfunction
   - 2.3 Valvular disease
   - 2.4 Congenital/acquired left heart inflow/outflow obstruction
3. Pulmonary hypertension owing to lung diseases and/or hypoxia
   - 3.1 Chronic obstructive pulmonary disease
   - 3.2 Interstitial lung disease
   - 3.3 Mixed restrictive and obstructive pattern
   - 3.4 Sleep-disordered breathing
   - 3.5 Alveolar hypoventilation disorders
   - 3.6 High-altitude pulmonary hypertension
   - 3.7 Developmental lung diseases
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension with unclear and/or multifactorial mechanisms
   - 5.1 Hematologic disorders: chronic hemolytic anemia, myeloproliferative disorders, splenectomy
   - 5.2 Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
   - 5.3 Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
   - 5.4 Others: tumor obstruction, fibrosing mediastinitis, chronic renal failure on dialysis, segmental PH

Table 2 Hemodynamic definition of pulmonary hypertension

Definition	*Hemodynamic measurements*	*Clinical classification*
Pulmonary hypertension	Mean PAP $\geq$25 mmHg	All
Precapillary PH	Mean PAP $\geq$25 mmHg PAWP $\leq$15 mmHg	Group 1—Pulmonary arterial hypertension Group 3—PH owing to lung diseases Group 4—chronic thromboembolic PH Group 5—PH with unclear and/or multifactorial mechanisms
Postcapillary PH	Mean PAP $\geq$25 mmHg PAWP $\leq$15 mmHg Cardiac output normal or reduced	Group 2—PH owing to left heart disease
Passive	DPG $\leq$7 mmHg	
Reactive (out of proportion)	DPG $>$7 mmHg	

PH indicates pulmonary hypertension; *PAP*, pulmonary arterial pressure; *PAOP*, pulmonary artery occlusion pressure; *TPG*, transpulmonary gradient.

from the pulmonary venous system and left heart. This is further subdivided into passive and reactive pulmonary venous hypertension indicative of the amount of vascular remodeling that is present. The diastolic pressure gradient (DPG), the difference between the diastolic pulmonary artery pressure and the PAWP, is normally 7 mmHg or less, and any elevation would suggest remodeling of the pulmonary arteries and arterioles. While the treatment of passive and reactive PVH are similar, there may be important clinical significance to this dichotomy (Grigioni et al., 2006; Tatebe et al., 2012). Furthermore, group 1 PAH requires elevated PVR in which increased mean PAP is not induced merely by a high cardiac output.

Pulmonary arterial hypertension consists of precapillary pulmonary hypertension and includes idiopathic pulmonary arterial hypertension, heritable pulmonary arterial hypertension, drug-induced PAH, PAH associated with connective tissue diseases,

HIV-associated PAH, portopulmonary hypertension, congenital heart disease with systemic-to-pulmonary shunt, and shistosomiasis. Idiopathic pulmonary arterial hypertension most clearly represents the entity previously described as primary pulmonary hypertension. It is defined as pulmonary arterial hypertension that occurs sporadically and has no familial inheritance. Hereditary PAH includes all cases with known germline mutations as well as familial cases without an identified mutation. Germline mutation in the bone morphogenetic protein receptor type 2 (BMPR2) gene has been identified in up to 70% of cases of familial pulmonary hypertension with other identified mutations being much less common (Soubrier et al., 2013).

Pulmonary hypertension owing to left heart disease represents PVH in which left heart disease causes increased left atrial pressure which is transmitted to the pulmonary circulation resulting in pulmonary hypertension. This classification is divided between left heart disease resulting from diastolic or systolic dysfunction and left heart disease caused by mitral or aortic valve dysfunction. This group is thought to be the most common form of PH due to the prevalence of heart disease though therapeutic strategies to date have mostly focused on medical or surgical treatment of the underlying heart dysfunction rather than strategies targeting the pulmonary vasculature (Vachiery et al., 2013). Pulmonary hypertension owing to lung diseases and/or hypoxia includes both obstructive and restrictive lung disease with and without parenchymal lung findings as well as high-altitude-induced pulmonary hypertension and intermittent hypoxia causing PH as a result of sleep-disordered breathing. A majority of these patients exhibit mild to moderate pulmonary hypertension with PAP $\leq$40 mmHg. In the largest subgroup, patients with COPD, studies suggest that only 1% of patients have PAP $\geq$40 mmHg (Chaouat et al., 2005). Thromboembolic disease resulting in PH is due to chronic occlusion of the pulmonary vasculature. Estimates suggest that the rate of CTEPH after acute pulmonary embolism is around 3% and disease can develop in both the proximal and distal pulmonary arteries (Pengo et al., 2004). Pulmonary hypertension with unclear multifactorial mechanisms is a group of miscellaneous disorders that do not clearly fit into the above categories or have a multifactorial etiology that has not been defined earlier. This group is split into subgroups based on hematologic disorders, systemic disorders, metabolic disorders, and miscellaneous conditions. This classification system aims to distinguish patients based on common characteristics, but often patients have multiple comorbid conditions which could contribute to PH. Clinical judgment plays an important role when determining the likely etiology and classification of PH.

Clinical Manifestation and Diagnosis

Symptoms and Signs

Pulmonary arterial hypertension is associated with numerous, non-specific symptoms including dyspnea, weakness, fatigue, chest pain, and syncope (**Fig. 1**) (Jing et al., 2009). Symptoms are often more pronounced with exercise or exertion, but as severity advances, the level of symptoms at rest intensifies. It can be difficult to distinguish symptoms directly related to pulmonary hypertension versus those of common comorbid conditions found in these patients. The lack of specific symptoms, along with delays at both the patient and practioner level, may lead to delay in diagnosis (Strange et al., 2013).

The signs of pulmonary arterial hypertension can be broken down into two groups, those that represent increased pulmonary vascular resistance versus signs of right heart dysfunction and failure. In advanced stages of disease both types of clinical signs are often present. In the absence of coexisting heart or lung disease, the lung examination is most often noted to be normal. Signs of increased pulmonary vascular resistance include a parasternal lift, accentuated pulmonary component of the second heart sound, a

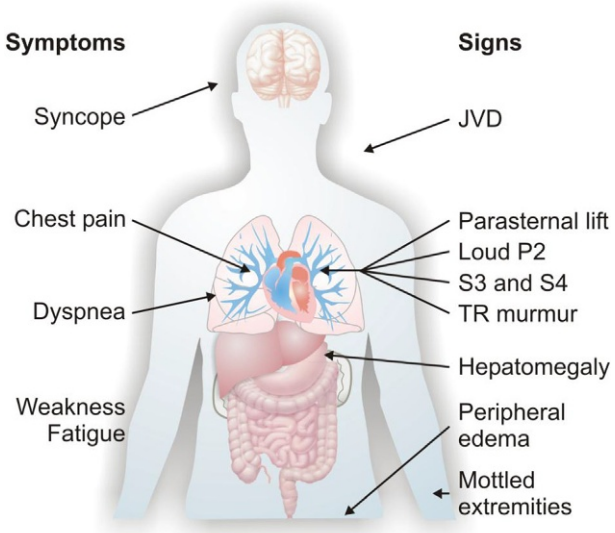

Fig. 1 Symptoms and signs of pulmonary hypertension. JVD, jugular venous distension; P2, second pulmonic heart sounds; S3, third heart sound; S4, fourth heart sound.

soft, pansystolic murmur of tricuspid regurgitation, audible S4, and a diastolic murmur of pulmonary insufficiency. Signs of right heart dysfunction and failure include a third heart sound arising from the right ventricle, best heard at the lower left sternal border and increases with inspiration. Jugular venous distension, peripheral edema, hepatomegaly, hepatojugular reflux and cool, mottled extremities in the setting of severe pulmonary arterial hypertension also indicate right heart failure.

The physical exam is a useful tool in helping to define the etiology of PAH. Signs of scleroderma including sclerodactyly, telangiectasias, Raynaud's phenomenon, and digital ulcers may be present. Connective tissue disease associated with PAH can present with a skin rash and oligoarthritis with synovitis. Advanced liver disease is associated with angiomata, caput madusea, palmar erythema, and testicular atrophy. Fine inspiratory crackles may distinguish a diagnosis of interstitial lung disease.

Noninvasive Testing

There are numerous noninvasive tests that can raise clinical suspicion for PH as well as potentially identify the underlying pathology leading to PH (**Fig. 2**). Electrocardiogram is shown to identify signs of RV hypertrophy in up to 87% of IPAH patients and right axis deviation in 79% though absence of these do not preclude PH (**Fig. 3**) (Rich et al., 1987). Pulmonary function testing is often performed during the routine evaluation of symptoms commonly seen in PH. The most common finding is an impaired lung diffusion capacity for carbon monoxide. Pulmonary function testing can also be used to identify patients with pulmonary hypertension associated with respiratory disorders including airways disease or diffuse parenchymal lung disease. The chest radiograph is also useful to identifying respiratory disorders and can also have findings suggestive of PH (**Fig. 4**). Findings consistent with pulmonary hypertension include central pulmonary arterial dilation; right atrial and ventricular dilation can also be seen. Parenchymal lung disease is often absent or minimal in PAH compared to pulmonary hypertension associated with respiratory diseases. Pulmonary edema and cardiomegaly can be seen with pulmonary hypertension associated with left heart disease. Computed tomography images can identify lung parenchymal abnormalities and thromboembolic disease, both of which can put patients at risk of PH (**Fig. 5**). The ratio of pulmonary artery diameter to aortic diameter has been shown to correlate with directly measured PAP and is predictive of PH when the ratio exceeds 1 (Ng et al., 1999).

A simple, reproducible technique, six-minute walk testing (6MWT) incorporates symptoms, distance, and oxygen saturation in order to define exercise capacity. Two studies have shown worse prognosis in PAH patients when walking distances are limited, $<$332 m or $<$250 m respectively, and desaturation greater than 10% during exercise also indicates worse prognosis (Miyamoto et al., 2000; Paciocco et al., 2001; Sitbon et al., 2002). Test performance is influenced by several factors including height, weight, age, gender, and motivation, which must be considered when interpreting results, yet this remains a vital tool in defining functional capacity to determine prognosis and response to therapy (ATS Committee on Proficiency Standards for Clinical Pulmonary Function Laboratories, 2002). Cardiopulmonary exercise testing has been suggested as a more accurate method to assess exercise capacity. Ventilation and gas exchange are continuously measured during graded exercise. Oxygen uptake at the anaerobic threshold and peak exercise is reduced as disease severity increases in PAH. In IPAH patients, peak O_2 uptake and peak systolic arterial pressure during exercise is an independent predictor of poor prognosis (Oudiz et al., 2006; Wensel et al., 2002).

Serum markers of disease prognosis and/or progression are constantly expanding, yet in clinical practice the markers used most frequently are brain natriuretic protein (BNP) and troponin. BNP levels have been shown to predict the severity of RV dysfunction in PAH, a major determinant of prognosis and mortality (Nagaya et al., 2000; Andreassen et al., 2006; Fijalkowska et al., 2006; Williams et al., 2006). Troponin, a marker of myocardial damage, is shown to be an independent predictor of 2-year mortality in PAH and possibly CTEPH patients (Torbicki et al., 2003). This likely reflects RV failure and ischemia due to increased chamber pressure overcoming coronary perfusion pressure in the RV. Serum lab testing for connective tissue disease serology, HIV disease, liver and renal function, chronic hemolysis, and genetic mutations are commonly used during initial clinical evaluation to correctly classify the etiology of PH.

Echocardiography has been used for both structural and functional evaluation of the heart for decades (**Fig. 6**). Right heart dynamics and function are distinct from the left side, with its function mainly as a capacitance system with low systolic pressures. Increases in pressure in the pulmonary circulation lead to significant changes in the dynamics of the right heart and blood flow. First described in 1984, echocardiogram-derived estimates of right ventricular systolic pressure using Bernoulli's equation ($\bigtriangledown$Pressure = 4 [Velocity], Cournand et al., 1944) have changed the screening and diagnosis of PAH. Using the mean right atrial pressure and tricuspid regurgitant velocity an estimate of right ventricular systolic pressure can be made (Yock and Popp, 1984). Improvements in estimation of right atrial pressure with IVC size and collapsibility along with better measurements of tricuspid regurtitant velocity by improved Doppler resolution and contrast-enhanced echocardiography have made estimates of RVSP a common screening tool for pulmonary hypertension. There still remains some controversy as both over and underestimation with a high degree of error has been reported. In a recent study, examining directly measured pulmonary artery pressures as compared to echocardiographic estimates, less than half of the echocardiographic estimates were within 10 mmHg of the direct measurements (Fisher et al., 2009). Underestimates were attributed to poor quality of the Doppler measurements, and overestimates were most closely correlated with overestimates of RAP by echocardiogram. Using stringent criteria, Kim et al. established that estimated RVSP $\geq$ 50 mmHg correlated with mean PAP $\geq$ 35 mmHg with a sensitivity of 97% (Kim et al., 2000). This was an accurate way of ruling out moderate to severe pulmonary hypertension, but early detection of mild disease would be missed with this criteria. The most clear guidelines regarding screening come from Barst et al., who recommend using echocardiography as a screening tool in patients with a known familial gene mutation or family member with IPAH, systemic sclerosis, congenital heart disease with systemic-to-pulmonary shunt, or portal hypertension during evaluation for liver transplant (Barst et al., 2004). PASP estimates from 36–50 indicate mild or possible PAH,

with PASP estimates over 50 indicate likely moderate to severe PAH (**Table 2**) (Fisher et al., 2009; Launay et al., 2007). For all patients with suspected PAH, right heart catheterization is still indicated to confirm the diagnosis and perform vasoreactivity testing.

Cardiac magnetic resonance imaging (MRI) is a safe, noninvasive test that can assess multiple parameters in the right heart and pulmonary vasculature (**Fig. 7**). Along with the structural definition seen with MRI techniques, ECG triggering has allowed the measurement of right ventricular mass, volume, and contractility. Velocity encoding with phase contrast MR has also allowed flow measurements within the pulmonary circulation with similar predictive power to that of echocardiography (Sanz et al., 2007; Nogami et al., 2009). Limitations of MRI are that this is an expensive modality with limited availability; the testing is done in the supine position and requires breath holding which can be challenging in pulmonary hypertension patients; and claustrophobia has continued to be a limiting factor in many patients.

Right Heart Catheterization and Vasoreactivity Testing

Right heart catheterization (RHC) is an essential study to confirm the diagnosis of pulmonary hypertension as well as to direct therapy following vasoreactivity testing. Measurements of diastolic, systolic and mean PAP are recorded, as well as pulmonary artery wedge pressure (PAWP), right atrial and ventricular pressures (Fig. 8). Cardiac output is measured by thermodilution and/or the Fick method. Oxygen saturation must be measured in the superior vena cava, pulmonary artery, and systemic arteries in order to calculate pulmonary vascular resistance (PVR). Elevated PAWP is seen in pulmonary venous hypertension and precludes the diagnosis of precapillary pulmonary hypertension. Measurement of left ventricular end-diastolic pressure may also be useful to

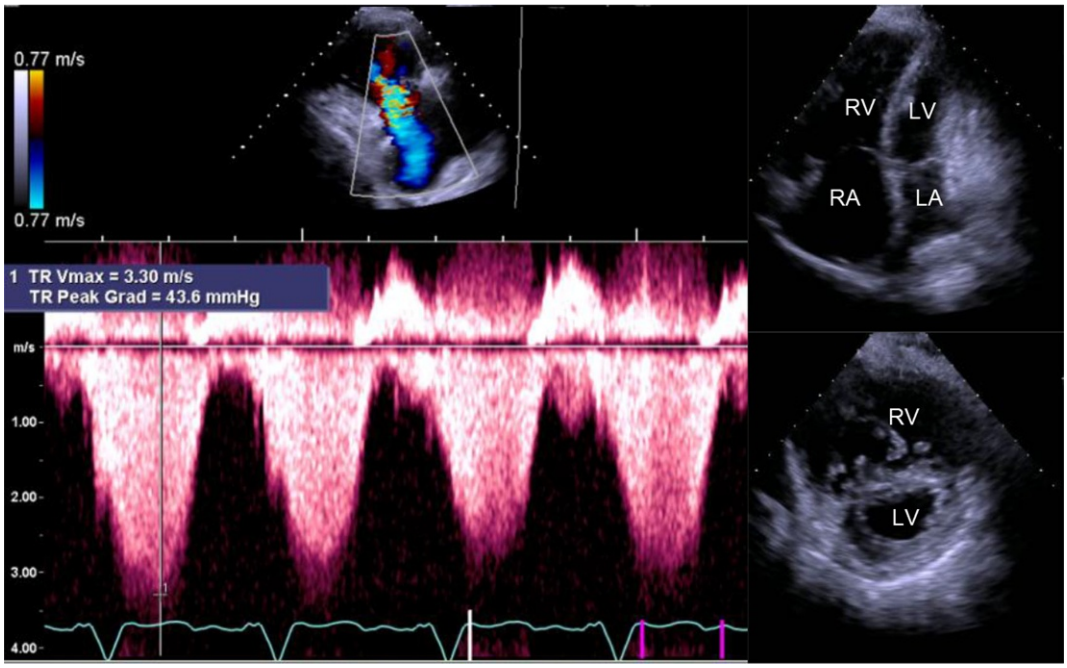

Fig. 6 Echocardiogram of patient with pulmonary hypertension. Echocardiogram with Doppler images showing tricuspid valve regurgitation and elevated TR jet velocity (*left panels*). Right atrium and right ventricular enlargement is seen on a four chamber view (*right-upper panel*) and an enlarged right ventricle with a "D-shaped" bowing of the intraventricular septum is seen on a parasternal short axis view (*right-lower panel*). *TR*, tricuspid regurgitation; *RA*, right atrium; *RV*, right ventricle; *LA*, left atrium; *LV*, left ventricle.

assess left ventricular dysfunction as a source of pulmonary hypertension. RHC is a relatively safe procedure with an estimated morbidity and mortality of 1.1% and 0.055%, respectively and remains the gold standard for diagnosis (Hoeper et al., 2006).

Vasoreactivity testing during RHC is used to identify those patients that may benefit from the use of calcium channel blockers (CCB) (Rich et al., 1992; Sitbon et al., 1998). At the time of diagnosis of PAH, an acute vasodilator challenge should be administered as inhaled nitric oxide (NO), intravenous epoprostenol, or intravenous adenosine (Rich et al., 1992; Galie et al., 1995; McLaughlin et al., 1998; Sitbon et al., 2005). A reduction in mean PAP more $\geq$10 mmHg to an absolute value $\leq$40 mmHg with no reduction in cardiac output represents an acute responder (Sitbon et al., 2005). Acute responders account for about 10% of IPAH patients and represent a population that is more likely to have a long-term response to treatment with high dose CCBs. More importantly, nonresponders have been shown to have increased mortality when treated with high dose CCBs. About 50% of IPAH patients with acute vasodilator response will have persistent, long-term response to CCBs, while the other half will show disease progression despite CCB treatment and will require additional pharmacologic agents. Vasoreactivity testing has been less well studied in other forms of PAH such as those associated with connective tissue disease, HIV, hemolytic anemia, and chronic liver disease, and therefore the rate of acute response to vasodilators and the long-term efficacy of calcium channel blockers remains unknown. There remains no data regarding the use of CCB in other forms of pulmonary hypertension; therefore acute vasoreactivity testing is not recommended.

Pathophysiology

Pathogenic Mechanisms

Pulmonary hypertension develops through pathologic changes at any point along the pulmonary vascular circuit. There are several established mechanisms by which these changes occur, each of which may have unique clinical consequences, with variable progression and reversibility, yet all have been associated with pulmonary vascular remodeling. Obstruction of pulmonary venous outflow, such as left heart disease or mitral stenosis, leads to passive transmission of elevated pressure to the pulmonary artery. Abnormally high blood flow, as seen in congenital heart disease with left-to-right shunt, increases pulmonary artery pressure due to hyperkinetic alterations. Obstruction of the pulmonary artery, seen in pulmonary thromboembolic disease, leads to elevations in pulmonary artery pressure, as does destruction of the pulmonary vascular bed in an obliterative fashion in diseases such as diffuse parenchymal lung disease. Hypoxic vasoconstriction leads to elevated pulmonary vascular resistance in severe lung disease or those residing at high altitudes. Often these mechanisms overlap in complex and end-stage cardiovascular and pulmonary disease. Still, little is known about the inciting mechanism for the persistent pulmonary vascular remodeling encountered in PAH, the idiopathic and hereditary forms in particular.

Cardiac MR images show enlargement of the right ventricle on axial (*top panel*), sagittal (*middle panel*), and coronal (*lower panel*) planes. *RA*, right atrium; *RV*, right ventricle; *LA*, left atrium; *LV*, left ventricle.

Structural and Functional Changes in the Pulmonary Vasculature

Despite this gap in our understanding, much work has been done to describe pathophysiologic mechanisms that lead to increased PVR and thus PAP in PAH. Pulmonary vascular remodeling, sustained pulmonary vasoconstriction, in situ thrombosis, plexiform vasculopathy, and vascular wall stiffening all contribute both individually and collectively in the development and progression of PAH (Fig. 9). Sustained vasoconstriction in small arteries and arterioles powerfully impacts PVR and is the principal functional alteration encountered in PAH. Associated with sustained vasoconstriction are structural changes in which medial hypertrophy is a key feature of changes with the pulmonary vasculature. Pulmonary artery smooth muscle cell hypertrophy and hyperplasia leads to

Fig. 8 Right heart catheter tracings in a patient with pulmonary arterial hypertension. Right heart catheterization with serial pressure measurements in the right atrium (A), right ventricle (B), pulmonary artery (C), and pulmonary artery wedge (D) positions. Elevated mean pulmonary artery pressure is associated with normal pulmonary artery wedge pressure indicating precapillary pulmonary hypertension.

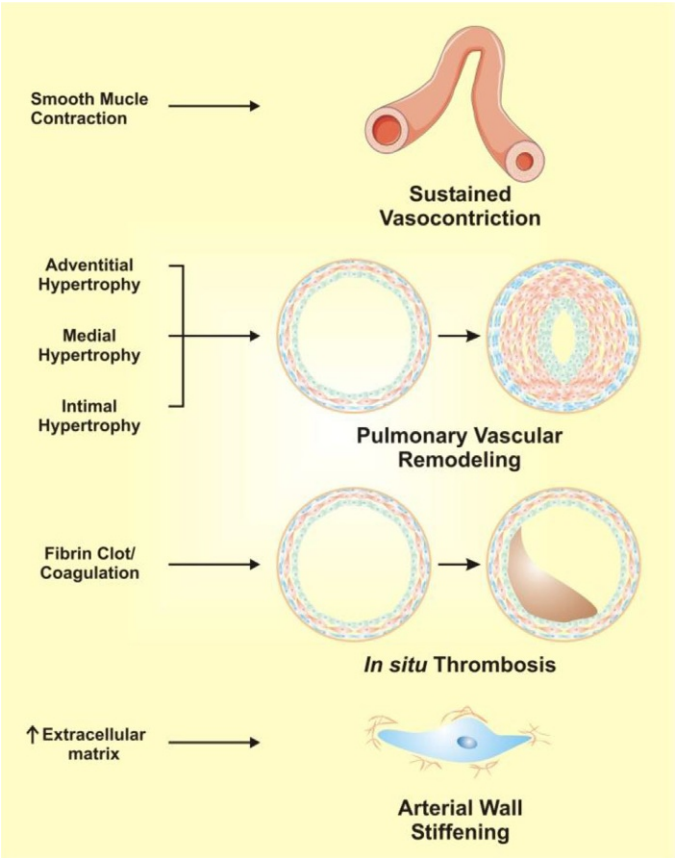

Fig. 9 Major pathogenic components in the development of pulmonary arterial hypertension. Pathogenic factors contributing to the development and progression of PAH include sustained vasoconstriction, pulmonary vascular remodeling, in situ thrombosis, and vascular wall stiffening. *PAP*, pulmonary arterial pressure; *CO*, cardiac output; *PVR*, pulmonary vascular resistance; *r*, radius.

muscularization of small arteries and arterioles which are normally nonmuscularized or only partially muscularized. The elevated PAP and sustained vasoconstriction in PAH can, in turn, enhance PASMC hypertrophy and hyperplasia (Hishikawa et al., 1994; Heath et al., 1987). Pulmonary vascular remodeling also affects the other pulmonary artery cell types, including endothelial cell hyperplasia associated with intimal thickening, extracellular matrix stiffening as fibroblasts differentiate into myofibroblasts (Stenmark et al., 1995). One of the classic structural alterations of small arterioles in PAH is plexiform lesions. These complex lesions result in aneurysmal dilation of arterioles associated with partial or fully occlusive intraluminal collections of various cells and matrix proteins (Mandegar et al., 2004; Pietra, 1997). These functional and structural changes to the pulmonary artery system are explained through numerous cellular and molecular mechanisms in PAH.

Cellular and Molecular Mechanisms of Pulmonary Arterial Hypertension

There are innumerable cellular and molecular mechanisms working in concert to lead to the pathologic changes encountered in PAH. In its simplest design, these entail an imbalance of vasoactive mediators, altered expression, and function of both mitogenic and angiogenic factors, as well as changes to cell survival proteins in each of the various cell types of the pulmonary vasculature. Nitric oxide and prostacyclin, powerful vasodilators in the pulmonary vasculature, are undersupplied when compared to excess of vasoconstrictors such as endothelin-1 and thromboxane A2 (**Fig. 10**). Nitric oxide (NO), released by the vascular endothelial cells (ECs), stimulates the production of cGMP in the PASMC resulting in relaxation and pulmonary vasodilation. A product of the metabolism of arachidonic acid, prostacyclin (PGI_2) in synthesized in the endothelium and secreted, binding to the prostacyclin receptor (IPR) on PASMC which results in increased cyclic adenosine monophosphate (cAMP) to promote vasodilation and exhibit antiproliferative effects (Olschewski et al., 2004). Endothelin (ET-1) plays a central role in the pathogenesis of PAH and exerts its effects as a potent vasoconstrictor which is also shown to increase smooth muscle cell proliferation and decrease apoptosis (Levin, 1995; Yanagisawa et al., 1988). Increased levels of circulating ET-1 have been shown in PAH patients which lead to activation of both ET-A and ET-B receptors (Giaid et al., 1993). ET-A receptors, located on PASMC, are thought to be the primary driver of the vasoconstrictive effect (Seo et al., 1994), while ET-B receptors are primarily located on endothelial cells and have vasodilatory effects (Hirata et al., 1993), though evidence also exists for vasoconstrictive downstream targets of ET-B, including thromboxane A2

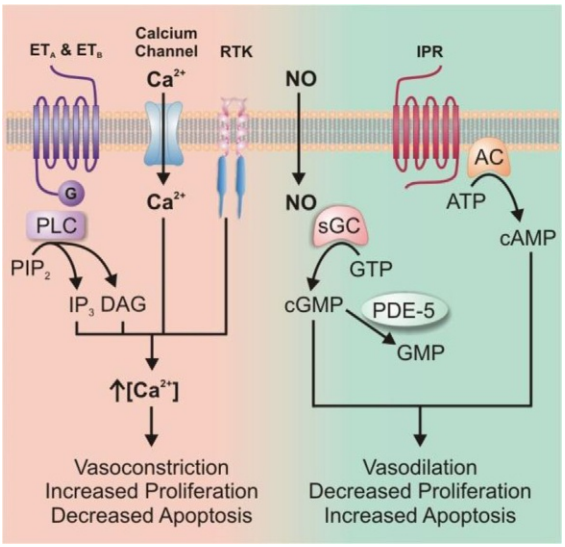

Fig. 10 Cellular and molecular mechanisms of PAH. Pathogenesis of PAH is characterized by an imbalance in vasoactive mediators. Left panel showing major pathways which lead to increased $[Ca^{2+}]_{cyt}$ and resultant vasoconstriction, increased cellular proliferation and decreased apoptosis. The right panel shows pathways by which cGMP and cAMP lead to vasodilation, decreased cellular proliferation, and increased apoptosis. Stimulation of endothelin receptor ET_A, a G-protein coupled receptor, by endothelin-1 leads to activation of phospholipase C and production of IP_3 and DAG, both of which lead to increased $[Ca^{2+}]_{cyt}$. Similarly, distinct receptor tyrosine kinases (RTK), such as PDGF, VEGF, and EGF, can lead to increased IP_3 and DAG and subsequent increases in $[Ca^{2+}]_{cyt}$ through a similar yet distinct pathway. Nitric oxide stimulates soluble guanylate cyclase to produce cGMP which has vasodilatory effects through decreased $[Ca^{2+}]_{cyt}$ as well as anticoagulant and antiproliferative effects that are both dependent on and independent of $[Ca^{2+}]_{cyt}$. cGMP is degraded primarily by phosphodiesterase type 5 in PASMC, which is targeted therapeutically by the PDE-5 inhibitors. The vasodilating properties of cAMP are produced through decreased $[Ca^{2+}]_{cyt}$ as well as anticoagulant and antiproliferative effects that are both dependent on and independent of $[Ca^{2+}]_{cyt}$.

(Dupuis et al., 1985). Other vasoactive mediators such as thromboxane, serotonin, and vasoactive intestinal peptide have various roles in the development and progression of PAH.

Numerous ion channels and membrane receptors have been implicated in the pathogenesis of PAH. Increased cytosolic free Ca^{2+} concentration ($[Ca^{2+}]_{cyt}$) is an important common pathway by which ion channel activity and receptor activation exert there effects in the pulmonary vasculature. Rising $[Ca^{2+}]_{cyt}$ in PASMC is a major trigger for PASMC contraction and vasoconstriction as well as an important mediator for PASMC proliferation/migration that results in vascular remodeling. Ca^{2+}-permeable cation channels and K^+-permeable channels (e.g., KCNA5 and KCNK3) in the plasma membrane of PASMC can influence $[Ca^{2+}]_{cyt}$ both directly and indirectly, through membrane depolarization (Mandegar et al., 2004). G protein-coupled receptors (GPCR) and tyrosine kinases receptors (TKR) have been implicated in the development and progression of PAH. These membrane receptors are shown to have various effects on important second messengers such as cGMP, cAMP, diacylglycerol, and inositol triphosphate that lead to pulmonary vascular remodeling. Numerous other cellular and molecular mechanisms have also been identified, including: (i) altered signaling pathways; (ii) changes in expression and function of growth factors; (iii) microparticle release; (iv) epigenetic modifications; and (v) genetic alterations (Mandegar et al., 2004; Kuhr et al., 2012; Morrell et al., 2009).

Genetics and Genomics

While it has long been clear that familial forms of PAH exist, it was the identification of genetic mutations in bone morphogenetic protein receptor II (BMPR2) that really advanced the knowledge on genetic susceptibility in pulmonary hypertension. Found primarily on endothelium and to a lesser extent smooth muscle cells, both reduced expression and functional impairment of BMPR2 are common in the various types of PAH, most notably those with mutations of the *BMP-RII* gene (Atkinson et al., 2002). Germline mutations in *BMP-RII* have been identified in up to 70% of patients with familial PAH, and in 20% of patients with IPAH (Cogan et al., 2006; Deng et al., 2000; Lane et al., 2000; Machado et al., 2006; Newman et al., 2001, 2004; Thomson et al., 2000), as well as disease associated with anorexigens (Humbert et al., 2002), congenital heart disease (Roberts et al., 2004), and pulmonary venoocclusive disease (Runo et al., 2003). Nearly 300 different mutations of BMPR2 have been identified (Machado et al., 2006). Subsequently, mutations of other important constituents of the TGF-β pathway have been discovered, including activin receptor kinase-like 1 (*ALK1*), endoglin (*Eng*), and Smad 8 (*Smad9*) (Shintani et al., 2009). ALK1 is a receptor for TGF-β and endoglin is its coreceptor, while Smad 8 is a downstream second messenger of BMPR2. Mutations in *ALK1* and *Eng* have been shown to confer susceptibility to the development of PAH in patients with hereditary hemorrhagic telangiectasia (Trembath et al., 2001; Chaouat et al., 2004). Patients have also been identified with concomitant Thrombospondin-1 gene mutation (*THBS1*) which is proposed to promote pulmonary hypertension development and increase genetic penetrance (Maloney et al., 2012). Outside of the TGF-β superfamily there have been discovery of rare mutations in *KCNK3* and *CAV1* what are attributed to the development of HPAH

(Austin et al., 2012; Ma et al., 2013). Mutation of *KCNK3* results in a channelopathy that is thought to facilitate calcium-mediated vasoconstriction leading to PAH, while *CAV1* encodes the protein caveolin-1 which is an important membrane protein that has several functions which include cell signaling and membrane trafficking (Chidlow and Sessa, 2010; Parton and Simons, 2007). Further mutations are likely to be revealed as whole exome and whole gene sequencing can identify gene mutations from previously unidentified HPAH patients. Understanding genetic susceptibility in PH and specific gene mutations responsible for much of HPAH, we now have a better understanding of PAH pathogenesis and these discoveries also raise the possibility of gene therapy in the future.

Treatment

The pulmonary vasculature represents a unique environment with mechanisms that are distinctive from the systemic circulation. Therefore, cellular and molecular pathways common throughout the human body have distinct roles in the pulmonary circulation. By understanding and exploiting these pathways in the pulmonary vasculature, therapeutic approaches have been created for the treatment of PAH (**Table 3**).

Supportive Therapies

Anticoagulants, diuretics, and ionotropes represent treatment used for many decades that target specific consequences of pulmonary arterial hypertension including thrombosis and right heart failure, yet have limited effect with regard to any improvement or reversal of the underlying pathophysiology. Diuretics can improve the fluid balance leading to symptomatic relief and quality of life improvements yet there have been no randomized clinical trials with the use of diuretics in PAH. There is also no clear evidence to suggest that long-term oxygen therapy has an effect on PAH; therefore oxygen therapy is not routinely recommended in the absence of severe hypoxemia ($SpO_2 \leq 88\%$ or $PaO_2 \leq 60$ mmHg at rest), which could intensify vasoconstriction. Anticoagulation has been a mainstay of treatment due to an acquired prothrombotic state and is recommended for all PAH patients unless contraindications exist. Warfarin, a vitamin K antagonist, is the most commonly used anticoagulant for PAH with evidence to support its use coming from multiple nonrandomized trials (Frank et al., 1997; Fuster et al., 1984). Digoxin is used as an adjunctive agent and has been shown to improve cardiac output in severe PAH with right ventricular failure (Rich et al., 1998). Dobutamine increases myocardial contractility and reduces vascular resistance in both the pulmonary and systemic circulation. It is often employed as a first line therapy for patients with acute right heart failure, though the necessity of this therapy portends a poor prognosis with survival found to be independently associated with lower requirements of dobutamine (Sztrymf et al., 2010).

Pulmonary Vasodilator Therapies

Vasodilator therapy has been used for nearly three decades to treat PAH. Calcium-channel blockers (CCBs) represent the first, well-accepted vasodilators for the treatment of PAH, with nondihydropyridines being the most common class, particularly Nifedipine and Diltiazem. In order to establish safety and efficacy with this class of medications, pulmonary vasodilatory testing, as described previously, identifies patients that may benefit from this therapy while excluding patients in which CCB could be detrimental. Only

Table 3 Medication summary for pulmonary arterial hypertension

Medication	*Route*
Prostacyclin and prostacyclin analogs	
Epoprostenol	IV
Treprostinil	IV/SC/Oral/inhaled
Iloprost	Inhaled
Selexipag	Oral
Endothelin receptor antagonists	
Bosentan	Oral
Ambrisentan	Oral
Macitentan	Oral
Phosphodiesterase type 5 inhibitors	
Sildenafil	Oral
Tadalafil	Oral
Vardenafil	Oral
Soluble guanylate cyclase stimulator	
Riociguat	Oral
Calcium channel blockers	
Amlodipine	Oral
Nifedipine	Oral
Diltiazem	Oral

a small proportion of IPAH patients, <10%, will have acute vasoreactivity, and of these patients, only about half will have long-term response to calcium channel blockers (Sitbon et al., 2005).

Prostacyclin (PGI_2) plays an important role in vasodilation and has also been shown to inhibit vascular smooth muscle cell proliferation and migration. The first synthetic prostacyclin, epoprostenol, decreases both SVR and PVR with increased cardiac output in a dose-dependent manner in PAH patients (Rubin et al., 1982). The first successful trial of chronic pulmonary vasodilator therapy compared epoprostenol to traditional therapy in PAH patients over a 12-week period and showed a significant mortality benefit (Barst et al., 1996). It remains a mainstay of treatment, particularly in advanced stages of disease as a potent pulmonary vasodilator, though adverse effects of both the drug and the intravenous delivery system may be encountered. Side effects common to this class of medications include jaw pain, headache, and diarrhea.

A prostacyclin analog, treprostinil, has an increased half-life compared to epoprostenol and is available in multiple formulations including intravenous infusion, continuous subcutaneous injection, inhaled, and oral. The risk of bacteremia or other catheter related complications can be reduced by delivering it subcutaneously, and the extended half-life allows increased time for troubleshooting in the cases of pump malfunction. Intravenous treprostinil shows similar efficacy to epoprostenol with a similar side effects between the two groups (McLaughlin et al., 2003). Subcutaneous treprostinil is comparable to both intravenous treprostinil and epoprostenol while minor adverse events are common, with 94% of patients having erythema at subcutaneous pump site and 88% reporting pain at that site (Simonneau et al., 2002). Inhaled formulation of treprostinil has comparable hemodynamic effects to inhaled iloprost, another prostacyclin analog, and also has favorable effects when added to oral therapy with either a PDE5 or ERA (Voswinckel et al., 2006; Channick et al., 2006; McLaughlin et al., 2010; Benza et al., 2011). Oral formulation of treprostinil is efficacious when used alone in PAH patients with moderate functional impairments, yet initial studies did not show a significant benefit when added to existing background therapy (Jing et al., 2013; Tapson et al., 2013). The first prostacyclin analog to be available in an inhaled formulation, iloprost, was designed to target the pulmonary vasculature with minimal systemic side effects. Long-term treatment was able to show improvements in exercise capacity and hemodynamic measurements which were sustained for 1 year (Hoeper et al., 2000). Side effects specific to the inhaled formulation of both iloprost and treprostinil are cough, though this appears to wane over time.

Selexipag is an orally bioactive, highly selective IP receptor agonist that is chemically distinct with unique pharmacological kinetics compared to other prostacyclin analogs. Selexipag is shown to have an acceptable safety profile and to reduce the risk of morbidity and mortality in PAH patients as either initial or add-on therapy (Simonneau et al., 2012; Sitbon et al., 2015). Adverse effects of selexipag are similar to those of prostacyclin analogs.

Endothelin (ET-1) is believed to play a central role in the pathogenesis of PAH as a potent vasoconstrictor which also increases smooth muscle cell proliferation and decrease apoptosis (Levin, 1995; Yanagisawa et al., 1988). Targeting the endothelin receptor has been a powerful tool in the treatment of PAH. Bosentan targets both endothelin receptor A and B as a dual receptor antagonist and is shown to significantly improvement in 6-min walk testing and pulmonary hemodynamic measurements after 12 weeks of use (Channick et al., 2001). Ambrisentan is a selective endothelin A antagonist that is shown to have comparable efficacy to bosentan in PAH patients (Galie et al., 2005a, 2008). Liver toxicity is a feared adverse effect of this class and ambrisentan may have less elevation in liver function testing during treatment. The most recently developed ERA, macitentan, is an orally active, dual endothelin receptor antagonist that is highly lipophilic with an active metabolite to optimize pharmacokinetics. This agent is shown to have similar efficacy for PAH patients as a single agent or in addition to another class of oral or inhaled therapy (Pulido et al., 2013). Minor adverse effects of the class include headache, anemia, and nasopharyngitis. Liver function testing must be followed during active therapy, and these agents are teratogenic, requiring appropriate birth control when used in women of child-bearing age.

The cyclic guanosine monophosphate (cGMP) pathway is an important target of endothelium-derived nitric oxide (NO), an essential vasodilatory agent (Sausbier et al., 2000). Phosphodiesterase type 5 (PDE5) rapidly hydrolyzes cGMP, inactivating its vasodilatory effects. Sildenafil is a specific phosphodiesterase type 5 inhibitor and the first of the class used for PAH, showing significant improvements in walk distance and pulmonary hemodynamics at both short- and long-term follow-up (Galie et al., 2005b; Rubin et al., 2011). Tadalafil is another agent in the class with a longer half-life than sildenafil and shows similar efficacy in the treatment of PAH patients (Galie et al., 2009; Oudiz et al., 2012). Vardenafil has similar effects, though this agent has not been studied as robustly (Jing et al., 2011). Adverse effects of the class are minor; with headache, edema and esophageal reflux being the most common. Soluable guanylate cyclase converts guanosine triphosphate (GTP) to cGMP, leading to vasorelaxation. Riociguat stimulates soluble guanylate cyclase to increase cGMP and promote vasodilation. This agent is used in both PAH and CTEPH patients, showing significant improvement in symptoms, exercise capacity, and pulmonary hemodynamic measurements. Adverse events include headache, dizziness, and gastrointestinal complaints as well as hypotension.

Surgical Treatment

Surgical management for PAH includes atrial septostomy, pulmonary thromboendarterectomy (PTE), and lung transplantation. Puncture of the atrial septum creates a physiological shunt through the atrial septal defect giving reprieve to the high pressures in the right heart. Atrial septostomy has been shown to improve cardiac output without significant change in mean PAP and at the expense of worsening hypoxemia due to the right-to-left shunt (Law et al., 2007). The procedure is associated with high mortality, particularly in patients with higher presurgical right atrial pressures. PTE is the preferred management of CTEPH and is a surgical procedure to remove thromboemboli from the obstructed pulmonary arterial circulation (**Fig. 11**) (Madani et al., 2012).

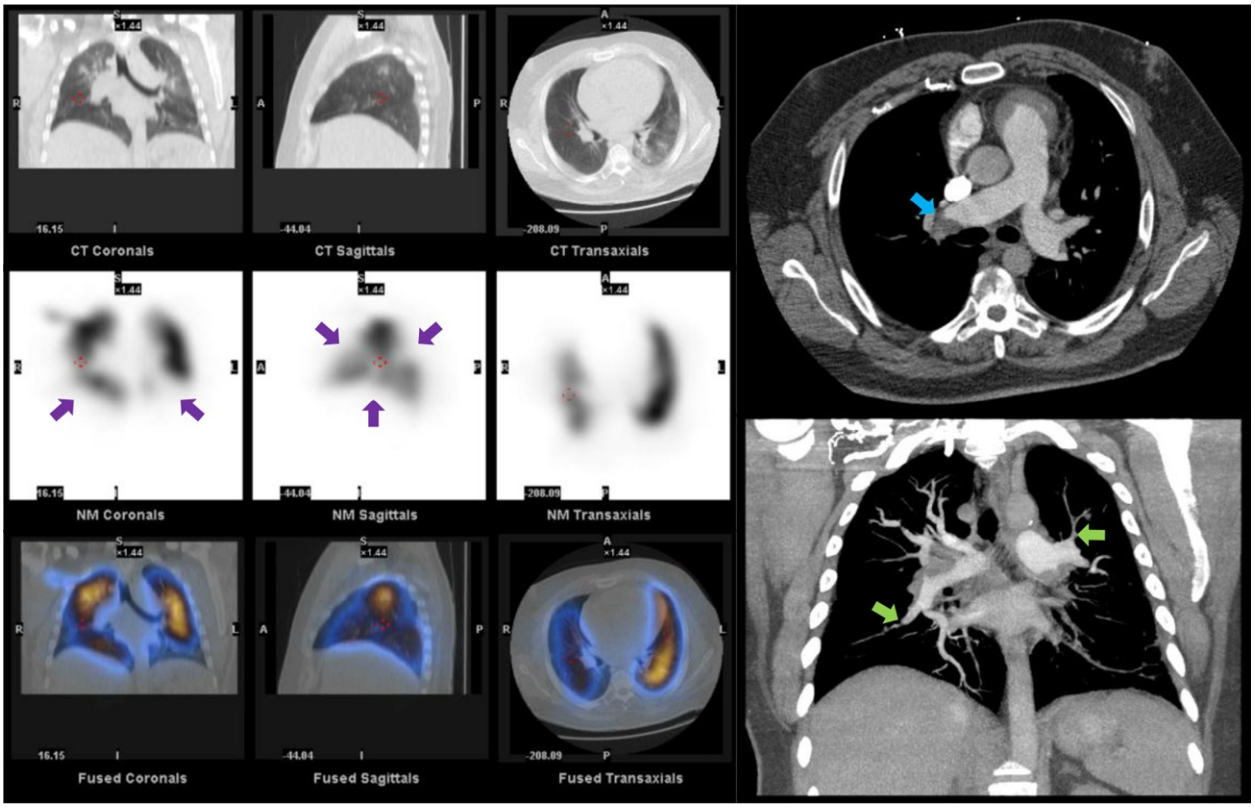

Fig. 11 Imaging findings of a patient with chronic thromboembolic pulmonary hypertension. Perfusion SPECT images (*left panels*) showing unmatched perfusion defects (middle and lower panels). CT angiography (*right panels*) confirms thromboembolic disease through the lung fields, including the main (*blue arrow*) and segmental (*green arrows*) pulmonary arteries.

In operable candidates, this surgery reduces mean PAP and increases cardiac output, though residual pulmonary hypertension can occur in 5%–35% of surgical patients (Condliffe et al., 2008; Corsico et al., 2008; Freed et al., 2011; Thistlethwaite et al., 2006). In these patients, pulmonary vasodilator therapy is used to manage the residual PH. Lung transplant remains the preferred surgical procedure for patients with severe PAH, though significant morbidity and mortality exist, particularly in patients with poor preoperative status (Keogh et al., 2009). The United Network of Organ Sharing showed IPAH lung transplant survival of 83%, 47.5%, and 34.7% at 1, 5, and 10 years, respectively. Surgical management, though associated with high levels of morbidity and mortality, remains essential with insufficient medical therapies available for the most severe patients.

Clinical Management Strategies

Disease severity and prognosis remain a critical step in assessing a patient with PAH. Hemodynamic measurements at the time of RHC have been shown to predict prognosis. Right atrial pressure, CO, and PVR have prognostic relevance and while PAP measurements do show some prognostic correlation, it has repeatedly been shown to be less accurate and declining PAP can result from RV failure in the most severe patients. On echocardiogram, the presence of pericardial effusion, increased right atrium area, decreased tricuspid annular plane systolic excursion (TAPSE), increased LV eccentricity, and RV Doppler index have all been shown to correlate with worse prognosis (Eysmann et al., 1989; Forfia et al., 2006; Raymond et al., 2002; Tei et al., 1996; Yeo et al., 1998). The simplest and most widely used predictor of survival remains WHO functional classification, in which severity of functional limitation increases from class I to class IV. Historical data have shown a median survival of 6 years for WHO functional class I–II drops off precipitously to 2.5 years for WHO class III and 6 months for WHO class IV (D'Alonzo et al., 1991).

Multiple classes of medical therapy with differing potency, adverse effects, and route of delivery require careful consideration and individualization when starting treatment (**Fig. 12**). Patients who fall under WHO functional class II or III, those limited by strenuous or mild to moderate exercise respectively, are shown to benefit from pulmonary vasodilator therapy. Oral formulations, ERAs, PDE5 inhibitors, or sGC stimulators, are usually employed as first line agents due to ease of use, while drug interactions or individual risk factors such as liver disease may favor one agent over another. Patients with symptoms at rest, WHO functional class IV, and those with signs of right heart failure have a much worse prognosis. Treatment in these patients generally involves parenteral therapy with epoprostenol or treprostinil, the most potent pulmonary vasodilators. The goals of treatment include improvement in

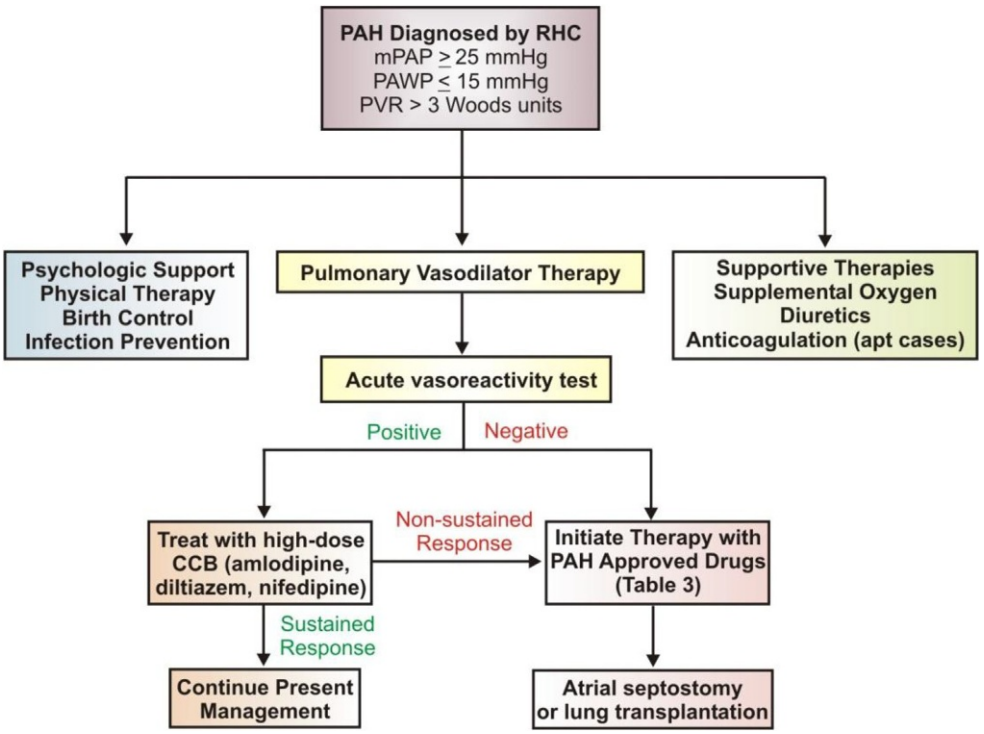

Fig. 12 Treatment algorithm for PAH. Standard care for all individuals diagnosed with PAH includes avoidance of excessive exertion or physical stressors, rehabilitation, and social support services as well as referral to an expert on the treatment of PAH. The patient should undergo vasoreactivity testing to identify the minority of patients who may have a substantial benefit from high-dose calcium channel blocker (CCB) therapy, and these individuals must be monitored closely to ensure a sustained response. Patients without a positive vasodilator response should potentially be started on therapies approved for PAH based on symptoms at presentation. The most severe patient who fails to respond to therapy may need referral for surgical intervention to treat their disease. Adapted with permission from Fraidenburg, D. R., Yuan, J. X. J. and Gaine S.P. (2015). In: Lanzer, P. (ed.) *PanVascular medicine*. Springer, Berlin.

symptoms, such as dyspnea, fatigue, chest pain, and/or syncope; improved functional capacity, including six-minute walk distance; and improvement in pulmonary and right ventricular hemodynamics, as measured by echocardiography and right heart catheterization. Sequential combination therapy with the addition of separate classes of medications is often utilized for severe or progressive disease, and many of the classes of agents have been used concurrently with varying levels of efficacy (Ghofrani and Humbert, 2014). Modest effects with single agents may be enhanced with the use of upfront combinations and could lead to more dramatic improvements in both symptoms and hemodynamic measurements. The most widely used combination for initial treatment of PAH includes an ERA in combination with a PDE5 inhibitor which has shown efficacy beyond the use of either agent alone (Galie et al., 2015). Careful monitoring of side effects and surveillance of disease progression, as either functional limitations or signs of right heart dysfunction, remains critical in adjusting therapy or adding additional agents to existing therapy.

Conclusion

A disorder that carries substantial morbidity and mortality, pulmonary hypertension can often be found as a complication of many serious cardiovascular and pulmonary disorders. In each of these disorders, the presence of pulmonary hypertension is an ominous sign which portends poor outcomes. Early recognition of PH involves connecting non-specific signs and symptoms with findings on both laboratory testing and imaging modalities that may suggest the diagnosis. This will lead to early referral for invasive hemodynamic measurements by right heart catheterization and appropriate diagnosis. The identification of pulmonary arterial hypertension, as idiopathic, hereditary, or linked to one of the many diseases in this category, is important for the initiation of specific pulmonary vasodilators. Prostacyclin analogs, phosphodiesterase type 5 inhibitors, soluble guanylate cyclase stimulators, and endothelin receptor antagonists are all shown to improve symptoms, functional capacity, and pulmonary hemodynamics; representing the armamentarium we have against this progressive disease. The understanding of the precise pathophysiology and genetics of this disorder has consistently advanced; and discovery of novel mechanisms for sustained vasoconstriction, pulmonary vascular remodeling, in-situ thrombosis, plexiform vasculopathy, and extracellular matrix stiffening will broaden our therapeutic possibilities.

Introduction

Pulmonary hypertension (PH) affects a significant number of patients with chronic heart and lung diseases contributing to worsening of their dyspnea and fatigue. Early diagnosis, assessment of severity, prognosis, and aggressive treatment strategies play a vital role in management of the condition and limiting associated morbidity.

PH is defined hemodynamically by a right heart catheterization (RHC), by a mean pulmonary arterial pressure $\geq$25 mmHg at rest (Galie et al., 2016). Pulmonary artery wedge pressure (PAWP) distinguishes pre-capillary ($\leq$15 mmHg) and post-capillary (>15 mmHg) PH in setting of normal or reduced left ventricular ejection fraction (LVEF) (Galie et al., 2016). The prevalence of PH in left-sided heart disease (LHD) occurs in 25%–75% of patients (Vachiery et al., 2013). Severity of PH is directly proportional to severity of underlying heart failure or valvular disease. Patients with PH secondary to LHD are more likely to be elderly females with severe hypertension and features of metabolic syndrome. This article focuses on PH secondary LHD, also known as pulmonary venous hypertension

Pathophysiology of Pulmonary Hypertension in Left-Sided Heart Disease

Elevated left-sided filling pressures secondary to diastolic or systolic dysfunction or valvular lesions eventually result in post-capillary pulmonary hypertension. Venous hypertension is back transmitted via capillaries to the pulmonary arterial system initially in a passive fashion resulting in passive pulmonary arterial hypertension (Harvey et al., 1971). During the passive phase, diuresing the patient is likely to result in complete normalization of pulmonary pressures. Over time, long-standing passive PH results in pulmonary arterial endothelial dysfunction leading to elevated levels of endothelin 1 (ET_1), decreased nitric oxide (NO), and decrease in BNP mediated vasodilatation (Moraes et al., 2000; Guazzi and Galie, 2012). These biochemical changes result in active pulmonary arterial vasospasm leading to further increase in pulmonary arterial pressures. Eventually, pulmonary vascular remodeling occurs with fibrosis and decreased vascular compliance resulting in fixed elevation in pulmonary arterial pressures independent of the pressure changes in the left heart, no longer amenable to reversal with resolution of the fluid overload due to underlying LHD. Eventually, PH results in right heart strain and failure, which is associated with worse prognosis. In view of the natural history of the disease, early diagnosis and management, particularly achievement of euvolemia, is the key to favorable outcomes. The goal is to identify and treat the disease prior to onset of fixed pulmonary arterial hypertension and right heart failure.

Due to the wide spectrum of pathology involved, PH in LHD can have different presentations. Patients can present with pure passive pulmonary venous hypertension with elevated PAWP with no pulmonary vascular disease. They may present with elevated PAWP with significant pulmonary vascular disease. Patients who have undergone aggressive management of their underlying LHD may present with normal (previously elevated) PAWP with significant pulmonary vascular remodeling. The myriad presentations pose a formidable diagnostic challenge to distinguish between pulmonary *arterial (fixed primary PH)* versus *venous (secondary to LHD)*. There is often a delay from onset of symptoms to an appropriate diagnosis of up to 2–3 years (Vachiery et al., 2013). The

diagnosis of PAH is a diagnosis of exclusion. PH in LHD is insidious in onset but often rapidly progressive, and it is important to have a high index of suspicion for individuals at risk due to presence of underlying LHD. Presence of associated scleroderma-related disorders and lupus, sleep apnea, cirrhosis with portal hypertension, human immunodeficiency virus (HIV) infection, family history of PAH, chronic cocaine use, and use of anorexigens (Moraes et al., 2000) further increases the risk of developing PH.

Classification of PH and Associated Triggers

Pulmonary hypertension is better understood if considered as a disease of triggers (Fig. 1). A clinical classification was established in order to individualize different categories of PH sharing similar pathological findings, similar hemodynamic characteristics and, similar therapeutic algorithms (Simonneau et al., 2013). The term *secondary* PH has been abandoned and not longer utilized. Five groups of disorders that cause PH were identified: pulmonary arterial hypertension (WHO Group 1); PH due to LHD (WHO Group 2); PH due to chronic lung disease and/or hypoxia (WHO Group 3); chronic thromboembolic PH (WHO Group 4); and PH due to unclear multifactorial mechanisms (WHO Group 5).

Common Signs and Symptoms in PH

Symptoms attributable to PH are similar to those in left-sided heart failure, valvular disease, and lung disease. PH should be suspected as the cause in the setting of risk factors, triggers, and associated diseases. The symptoms depend on the functional limitation and the degree of hemodynamic impairment.

Each of the symptoms has one or more hemodynamic correlates:

1. *Dyspnea and fatigue* are correlated with decrease in stroke volume (SV) (only with exercise initially but in severe disease also present at rest), cardiac output (CO), and oxygen transport.
2. *Angina-like chest pain* on exertion correlates with increased right ventricular (RV) myocardial oxygen demand and pulmonary artery pressures in excess of aortic pressure.
3. *Presyncope and syncope*: postural-, tussive-, and exercise-induced systemic hypotension are correlated with decreased RV filling, decreased left ventricular (LV) filling, and LV compression by the RV.
4. *Signs of RV failure*: Abdominal pain, anorexia, edema, and ascites are correlated with gastric distention, hepatic congestion, increasing jugular venous pressure, and tricuspid insufficiency.

Physical findings depend on the cause and severity of PH. Patients with lung disease severe enough to cause more than moderate PH can be identified by decreased breath sounds, chest deformities, rales consistent with interstitial lung disease, abnormal jugular venous wave or pressure, a murmur of tricuspid insufficiency, and often clubbing of the fingers and toes and cyanosis.

Long-standing Eisenmenger's syndrome (severe PH associated with congenital intracardiac shunt at the atrial, ventricular, or pulmonary artery level) with predominant right-to-left shunting is characterized by cyanosis at rest or with exercise, clubbing of the

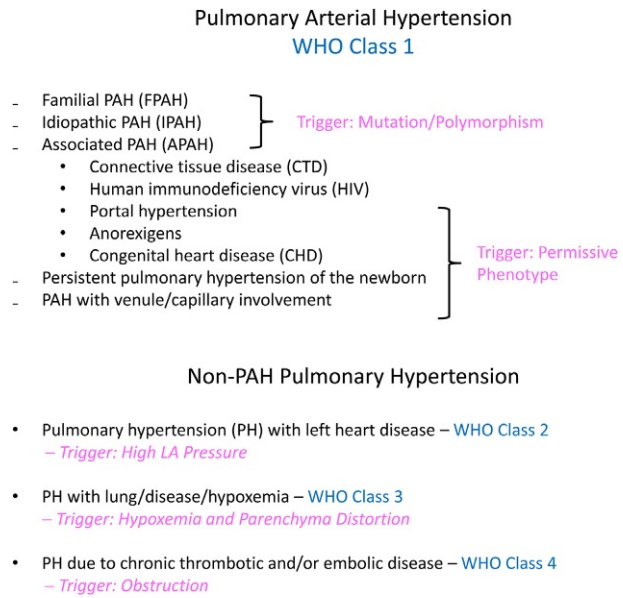

Fig. 1 Pulmonary hypertension a disease of triggers and classification.

fingers and toes, and often murmurs of tricuspid insufficiency and pulmonic insufficiency. Because of the RV hypertrophies over a period of years, patients are often only mildly symptomatic until very late in the course. Patients with atrial septal defects and anomalous pulmonary venous drainage (about 2%) can rapidly develop severe PH that resembles PAH and manifests without clubbing of the fingers and toes or without cyanosis. Cyanosis can be due to intracardiac right-to-left shunting or due to low CO and decreased alveolar-capillary diffusion.

Algorithm for Assessment and Diagnosis of PH

The 5th World Symposium for Pulmonary HTN has proposed a new algorithm for diagnosis of PH to facilitate early identification (Fig. 1) (Hoeper et al., 2013). The algorithm provides a logical sequence to exclude conditions that are mostly associated with PH. The algorithm is aimed at facilitating early and appropriate identification of PH class. PH management requires a multidisciplinary approach and liberal referral to physicians experienced in evaluating and treating PH is emphasized to limit morbidity.

Testing for Evaluation of PH

Electrocardiogram

The electrocardiogram (EKG) has a high degree of sensitivity (more than 75%–80%) (Galie et al., 2016) for detecting RV hypertrophy in symptomatic patients with severe PH. The sensitivity is less than 40% when the EKG is read without clinical information or when the ECG is unedited and computerized. Frequent misdiagnoses include inferior, anterior, and septal infarction; inferior and anterior ischemia; and left posterior fascicular block. EKG is not an effective screening tool in asymptomatic or mildly symptomatic patients.

The most common EKG patterns in PH include right axis deviation, qR in V_1, and increased voltage (>2.5 mm) of the *p* wave in lead II (sometimes called *P pulmonale*). The increased voltage is associated with a fourfold increase in mortality rate (Moraes et al., 2000). Atrial premature beats occur frequently, but atrial fibrillation, atrial flutter, and serious ventricular arrhythmias are not common.

Chest Radiograph

The magnitude of lung disease (emphysema, fibrosis, masses, and skeletal deformity) needed to induce significant PH is usually detectable on the chest radiograph. Chest radiographic indicators of PH include enlargement of the RV, right atrium, superior vena cava, main pulmonary artery, and right/left pulmonary arteries. CXR criteria for PH is found in 95% of patients with primary PH (Class I) and only 4% of controls matched for age, gender, and body surface area.

Echocardiography

Doppler echocardiography is the most effective noninvasive screening tool for detecting PH and for monitoring progression of disease, particularly, the development of RV enlargement and failure (Galie et al., 2016; Simonneau et al., 2013; Franco, 2012). It is an essential test as it is the most useful noninvasive tool to evaluate RV function and estimate pulmonary pressure. An estimated systolic RV pressure (RVSP, equivalent to systolic pulmonary arterial pressure) >40 mm Hg generally warrants further evaluation in the patient with unexplained dyspnea. Although echocardiogram is a very effective screening tool and is useful for monitoring progress of RV size and function, it is less useful in monitoring pulmonary pressures in the setting of severe RV dysfunction.

The tricuspid regurgitant velocity (TRV) is proportional to the gradient between the RV and RA and is used to calculate the RVSP with modified Bernoulli's equation:

$$\text{RVSP} = 4 \times \text{TRV}^2 + \text{estimated RA pressure (mmHg)}$$

RA pressure is estimated from the size of the inferior vena cava and its response to respiration (collapse with inspiration). The TRV (in meters per second) should be provided to allow the clinician to add an estimate of the RA. TRV should be carefully reviewed to assure the tricuspid regurgitation envelop is complete for an adequate estimation of RVSP; otherwise, echo-Doppler is less accurate and it can under- or over-estimate the true pressure compared to cardiac catheterization (Hoeper et al., 2013).

Echocardiography can also identify abnormal systolic and diastolic dysfunction of the left ventricle. An enlarged left atrium in the absence of severe mitral disease suggests elevated left-ventricular pressures. Agitated saline contrast should be used to identify intracardiac (i.e., atrial septal defect) or intrapulmonary shunts. Patent foramen ovale or atrial septal defect can be the explanation for exercise and rest arterial desaturation. The common anatomic findings in severe PH include RA and RV dilatation, flattened or D-shaped interventricular septum, and often a small, compressed left ventricle. Pericardial effusions are not common but may be predictive of poor outcomes regardless of size (Franco, 2012; Benza et al., 2012). Tricuspid annular plane systolic excursion (TAPSE) is a marker of RV function as related to longitudinal axis shortening (thus drawing the tricuspid annular plane toward the apex). A TAPSE ≤18 mm was associated with lower cardiac index, more right heart remodeling, and poorer prognosis in PH patients.

Right Heart Catheterization

RHC is a key diagnostic test in establishing and classifying the diagnosis of PH (Simonneau et al., 2013; Hoeper et al., 2013). Every patient suspected of PH should undergo RHC despite evidence from other diagnostic modalities discussed above. RHC not only confirms and classifies the diagnosis of PH, but also provides information about RV function. An elevated pulmonary capillary wedge pressure (PCWP) (PCWP $\geq$15 mmHg) is indicative of left-sided HF contributing to PH and, if present, a left heart catheterization may also be considered for direct measurement of left ventricular end-diastolic pressure, gradient across mitral valve as well as to perform angiography if coronary artery disease is suspected especially in the setting of systolic dysfunction.

RHC measurements not only aid in diagnosis of PH but also assist in differentiating passive venous pulmonary hypertension from pulmonary arterial hypertension. Up until recently, trans-pulmonary gradient (TPG), defined as the difference of mean pulmonary arterial pressure (PAP) and PCWP (TPG = mPAP − PCWP), was used to identify component of pulmonary vascular disease (mixed disease as a consequence of chronically elevated PCWP that resulted in pulmonary arterial remodeling). If TPG was >12, the terminology "out of proportion" pulmonary hypertension was used to define pulmonary pressure over that can be explained by passive back transmission of elevated left heart pressures, indicative of pulmonary vascular disease. However, "PCWP" is acquired by inflating the right heart catheter balloon in the distal pulmonary arterial system rather than the pulmonary capillaries. Hence, the pressure measured is actually pulmonary arterial wedge pressure (PAWP) and will reflect vascular disease distal to site of RHC balloon inflation in addition to true PCWP/left atrial pressure. Also, TPG is dependent on flow rate and varies with SV/CO. The dependence of TPG on pulmonary vascular flow, resistance, and left heart filling pressures (PAWP) makes it a poor measure of pulmonary vascular disease in setting of LHD (Naeije et al., 2013; Provencher et al., 2008).

In order to accurately assess the development of vascular disease and fixed pulmonary hypertension in patients with LHD, the 5th World Symposium For Management of PH updated guidelines propose the use of diastolic pressure difference (DPD), which is defined as the difference between pulmonary arterial diastolic pressure (dPAP) and PAWP.

$$\mathrm{DPD} = \mathrm{dPAP} - \mathrm{PAWP}$$

dPAP is less sensitive to changes in pulmonary vascular flow rate (SV/CO), resistance, and PAWP (Vachiery et al., 2013; Gerges et al., 2013). It has been shown to be less sensitive to pulmonary vascular distensibility. A study correlating PH with histology has demonstrated that DPD has a higher specificity to identify significant PVD (Gerges et al., 2013). DPD in normal subjects ranges from 1 to 3 mmHg and remains <5 mmHg in most patients with cardiac disease (excluding shunts) (Simonneau et al., 2013; Benza et al., 2012). Elevated DPD is a marker of pulmonary vascular remodeling. Studies correlating DPD with PVR have shown that individuals with DPD <5 mmHg are unlikely to have severe PVD (Rapp et al., 2001). A PAWP >15 mmHg with a DPD <7 mmHg is more likely associated with isolated postcapillary pulmonary hypertension (passive pulmonary venous hypertension). Individuals with PAWP >15 mmHg with a DPD $\geq$7 mmHg have combined pre- and postcapillary pulmonary hypertension ("out-of-proportion" PH) (Gerges et al., 2013). Elevated DPD has been shown to have a prognostic value (Franco, 2012). Patients with TPG >12 mmHg and DPD >7 mmHg have a median survival of ~6.5 years similar to survival in primary pulmonary arterial hypertension. Patients with DPD <7 mmHg have slightly better prognosis with median survival of ~8.4 years.

Fluid challenge and occasional vasoreactive testing are recommended during RHC in cases with borderline PAWP numbers to establish diagnosis of PH secondary to LHD (Hoeper et al., 2013; Robbins et al., 2014). Patients with PAWP in the range of 12–15 mmHg and suspicion of underlying LHD (enlarged left atrium, possible diastolic dysfunction) should undergo fluid challenge with 500 cc normal saline infused over 5 min. If PAWP is >15 mmHg with fluid challenge, patient's PH is most likely secondary to LHD rather than primary pulmonary arterial hypertension. Exercise testing can be used to accomplish a similar outcome; however, as the exercise testing protocols are yet to be standardized, results are subject to speculation. As of today, the role of exercise testing in diagnosing PH in LHD has not been validated but can be used if fluid challenge is not feasible/contraindicated.

The role of vasoreactive testing in diagnosis of PH suspected to be secondary to LHD is not well established. It has been shown to be beneficial in evaluating patients for advanced heart failure therapies and determining transplant candidacy. It is important to choose the appropriate medication to perform testing. Nitroprusside is utilized to determine if pulmonary hypertension is reversible before listing for heart transplantation. It is a strong vasodilator that usually reduced wedge pressure and subsequently PAP. Other pulmonary vasculature vasodilators, like NO or epoprostenol, could potentially precipitate pulmonary edema and hemodynamic decompensations; therefore, it should be reserved for testing in patients with pulmonary arterial hypertension but should be avoided if there is evidence of high wedge pressure. It is best to avoid vasoreactive testing in PH secondary to fixed valvular disease for similar reasons.

Management PH Secondary to LHD

Management Goals

Management of PH secondary to LHD should be geared toward appropriate interventions for the underlying heart disease. Aggressive control of cardiovascular disease risk factors and features of metabolic syndrome is recommended. Systolic and diastolic heart failure should be treated with optimal medical management. Experts recommend a trial of nonspecific vasodilators, nitric oxide, and hydralazine in patients with heart failure with preserved or reduced EF. These have shown improvements in pulmonary pressure especially in patients with diastolic dysfunction and HFpEF. In patients with severe systolic heart failure with secondary PH

not responding to medication should be evaluated for advanced therapy with left ventricular assist device (LVAD). Mechanical LV support has shown to dramatically improve pulmonary pressures and reduce RV failure by unloading the left ventricle. Patients with fixed mitral or aortic valvular disease should be appropriately evaluated for valve repair or replacement. Adequate treatment of the underlying LHD with improvement in left-sided pressures results in significant improvement in secondary PH especially if PVD has not set in. Finally, it is imperative that comorbidities that contribute to PH independently (e.g., lung disease, obstructive sleep apnea, pulmonary thromboembolic disease, obesity) have to be screened for early treatment initiation and treated aggressively in course of the disease.

Pulmonary Vasodilators in Management of Precapillary Pulmonary Hypertension/PVD

Pulmonary vascular remodeling/PVD in PH primarily occurs secondary to endothelial dysfunction with upregulation of endothelin 1 (ET_1) and downregulation of NO with impaired NO-dependent vasodilatation (Moraes et al., 2000; Porter et al., 1993; Spieker et al., 2000). Agents that inhibit ET_1 and upregulate NO have shown to improve pulmonary pressures and exercise capacity in patients with PVD. Inhibition of phosphodiesterase type 5 (PDE5) attenuates LV remodeling and improves vascular, renal, and neuroendocrine function (Tsai and Kass, 2009; Pokreisz et al., 2009; Katz et al., 2000). These are the first-line medication for management of primary pulmonary hypertension. However, in secondary PH, these medications are reserved as second line options for patients not responding to management of underlying LHD or those with persistent PVD despite correction of underlying LHD (e.g., postvalve repair). Utilization of these agents as primary modality of management for PH in LAD carries the risk of pulmonary edema due to increased pulmonary vascular flow in the presence of elevated left heart pressures and further worsening of PH with associated hemodynamic collapse for resultant drop in CO.

There are four major classes of medication available for treatment of PH with PVD: (1) prostanoids (e.g., epoprostenol), (2) endothelin receptor antagonists (e.g., bosentan), (3) phosphodiesterase-5 inhibitors (PDE5I; e.g., sildenafil, tadalafil) and (4) guanyl cyclase stimulators (e.g., riociguat). In large studies, these medications have proven to be valuable in decreasing morbidity in primary pulmonary hypertension. However, there is limited data from small studies that has evaluated the benefit of these medications in PH secondary to LHD with controversial results. Small studies have consistently demonstrated some improvements in hemodynamic status, exercise capacity, and symptoms; sustained and survival benefits remain unclear (Spieker et al., 2000). Also, patients with LHD are on multiple medications with survival benefit that lowers blood pressure making hypotension a limiting factor in the adequate use of pulmonary vasodilators in this group of patients.

Among the pulmonary vasodilators, acute usage of sildenafil 25–50 mg, in prelung transplant patients, has been shown to decrease pulmonary vascular resistance (PVR) with improvement in hemodynamics and oxygen consumption (Barnett and De Marco, 2012; Guazzi et al., 2004; Lewis et al., 2007a; Angel Gomez-Sanchez et al., 2004). Phosphodiesterase-5 inhibitors seem to have a more potent pulmonary vasodilator effect compared to prostanoids. Chronic administration of sildenafil has also been shown to improve pulmonary hemodynamic status before transplantation (Jabbour et al., 2007). In small placebo controlled trials involving patients with PH and reduced EF, sildenafil in dose of 25–75 mg three times a day has shown to improve exercise tolerance (sustained up to 6 months) and decrease PVR even though there was no significant impact on mean PAP (Guazzi et al., 2007; Lewis et al., 2007b). Large trials to evaluate the benefit of PDE5I in PH with LHD are currently underway. PDE5I are not currently FDA approved for PH in LHD but off-label use may be considered in carefully selected cases with evidence of PVD (without fixed valvular disease) when all other modalities of treatment have not resulted in optimal benefits.

Trials that evaluated the benefit of prostanoids and ERA in PH with LHD were negative for benefit with increased adverse reactions from the drugs and a trend to increase in adverse outcomes or mortality (Packer et al., 2005; Kalra et al., 2002; Califf et al., 1997). A small trial looking at the benefit of guanyl cyclase stimulators did not show any benefit in PH with LHD despite the benefit noted in patients with PAH (Bonderman et al., 2013). However, as these act by increasing guanylyl cyclase and hence production of NO, larger trials are currently ongoing to evaluate their benefit in HFpEF (diastolic heart failure). None of these medications have been evaluated in patients with underlying uncorrected fixed valvular disease.

Management of PH in HFpEF

HFpEF is a common cause of PH and is associated with significant morbidity and poor outcomes (Lam et al., 2009; Fang et al., 2012). PH in underlying diastolic dysfunction/HFpEF presents a diagnostic and treatment challenge. In individuals with mean PAP >25 mmHg and borderline normal PAWP, testing with fluid challenge or exercise is recommended to evaluate the presence of diastolic dysfunction especially if there is evidence of diastolic dysfunction on history or imaging. Unfortunately, to date, there are no strong evidence-based recommendations for the management of HFpEF. Despite lack of evidence, optimal medical management as used for HFrEF continues to remain the main stay of therapy. Nonspecific vasodilators (nitrates and hydralazine) have shown to provide only a modest benefit of decrease in PVR and increase in CO at the cost of significant hypotension (Schwartzenberg et al., 2012). Sildenafil has had mixed outcomes in small trials in patients with HFpEF; however, these trials had not appropriately stratified PH to identify the presence of PVD. In one trial, 50 mg of sildenafil three times a day has shown to improve exercise tolerance and hemodynamics at 6 months lasting up to a year in PH with HFpEF (Guazzi et al., 2011). The RELAX study involving a large population of PH with HFpEF did not reveal the benefits of sildenafil. This study however did not evaluate hemodynamics or RV function and nature of PH was not prespecified (Lam et al., 2009). A recently published small randomized controlled trial, use of sildenafil 60 mg three times a day for 12 weeks did not have a favorable effect on PAWP, CO, and peak VO_2 compared with placebo

(Fang et al., 2012). These trials however have validated the safety profile of sildenafil in this subpopulation of patients. Results from larger well-designed trials are awaited. In a recent study, inhaled iloprost resulted in acute reduction of PAP and PVR (Schwartzenberg et al., 2012). Large trials are underway to evaluate the benefit of ERAs, ambrisentan and bosentan, in management of PH in HFpEF. In another randomized controlled trail, riociguat was shown to improve exploratory hemodynamic and echocardiographic parameters with a favorable safety profile but without a significant effect on mPAP (Guazzi et al., 2011). Large well-designed studies are needed to better define the phenotype of patients who may benefit from more selective pulmonary vascular agents.

Summary

Management of PH in LHD is a widely prevalent poorly understood condition lacking evidence-based management approach. A better understanding of the nature of PH in patients with LHD will aid management decisions in this subpopulation of patients. Adequate management of underlying LHD continues to remain the main stay of treatment. There are no approved vasodilator therapies for PH in LHD. Results of large trials evaluating the role of pulmonary vasodilators in PH in LHD are awaited.

Introduction

Cardiovascular disease remains the leading cause of death across the world. According to the World Health Organisation, it was estimated that of the 17.5 million deaths in 2012, 7 million (40%) were due to coronary heart disease (World Health Organization, 2016). However, despite the high death toll, there have been many advancements in coronary heart disease care which have led to improvements in survival over the last 20 years.

The measurement and recording of information that can be used to assess performance within medicine is not a new concept. Dr Codman advocated that surgeons should both track and publish their patient's outcomes to as far back as 1910 to aid their development as surgeons and improve outcomes for patients (O'Leary, 1995). Outcome measurement has been the mainstay of measuring quality of care. One example of this is reporting of operator-level standardized mortality rates for both percutaneous coronary intervention and cardiothoracic surgery by the National Health Service covering all publicly funded procedures performed by all operators within England and Wales.

However, patients' journey from their initial presentation until their discharge and subsequent follow up consists of many more steps than simply the outcome. Therefore, there has been a move to focus on the processes that lead to the outcomes as a method to measure quality (Bebb et al., 2016). The rationale behind this is that if these processes are performed well then this should lead to improved outcomes.

There are several terms used for these new measures including performance measures. Throughout this chapter, however, they will be referred to as quality indicators.

A Brief History of Quality Indicators

The emergence of quality indicators for the measurement of performance first started in 2003 with the publication of the Canadian quality indicators for acute myocardial infarction. The Canadian publication comprised 37 indicators of which 15 were inpatient measures, 13 outpatient measures, and 9 outcome measures (**Table 1**) (Panel et al., 2003). The American Heart Association and American College of Cardiology (AHA/ACC) published their first report on quality indicators for adults with ST-elevation

ACC, American Collage Cardiology; *AHA*, American Heart Association; *ESC*, European Society of Cardiology; *LVSD*, left ventricular systolic dysfunction; *ACEi*, angiotensin converting enzyme inhibitor; *ARB*, angiotensin receptor blocker; *PCI*, percutaneous coronary intervention; *FMC*, first medical contact; *LVSF*, left ventricular systolic function; *PPCI*, primary percutaneous coronary intervention; *DAPT*, dual antiplatelet therapy; *GRACE*, global registry acute coronary events; *CRUSADE*, can rapid risk stratification of unstable angina patients suppress adverse outcomes with early implementation of the ACC/AHA Guidelines; *HF*, heart failure.

myocardial infarction (STEMI) and non ST-elevation myocardial infarction (NSTEMI) in 2006, comprising of 11 measures (**Table 1**) focusing on the inpatient management of STEMI and NSTEMI encompassing medications at arrival and discharge to reperfusion therapy during admission and referral for lifestyle advice at discharge (Krumholz et al., 2006). In 2008, an update of these indicators were published proposing changes to four of the existing measures as well as introducing a further four indicators to include an evaluation of left ventricular function, recording time from arrival in the emergency department to discharge for those patients transferred for percutaneous coronary intervention, and referral to cardiac rehabilitation services (**Table 1**). In the same year, the Canadian society also issued updated quality indicators with 17 inpatient measures and 21 outpatient measures (Tu et al., 2008; Krumholz et al., 2008).

In addition to the quality indicators themselves, the AHA/ACC have published complementary reports on both the classification (Bonow et al., 2008) and methodology (Bonow et al., 2011; Spertus et al., 2010) for defining these quality indicators.

Nearly a decade later, the European Society of Cardiology (ESC) published their own set of 20 quality indicators (Schiele et al., 2016) focussing on the inpatient management of acute myocardial infarction. The ESC indicators offer a more comprehensive set than earlier versions of the AHA/ACC indicators but do not focus on outpatient indicators which feature heavily in the Canadian sets. Moreover, the ESC is the first to include composite measures to assess the overall quality of healthcare providers as part of their quality indicators. Whilst the AHA/ACC have published a position paper on the use of composite measures for healthcare performance assessment, they have not, as yet, recommended their widespread use (Peterson et al., 2010).

Rationale Behind Quality Indicators

Quality indicators are predominantly based upon Class 1A recommendations from the respective national cardiology societies. Class one recommendations are provided for those interventions for which there is agreement that they are beneficial, useful, and

effective. They are usually supported by a level of evidence A (data is based upon multiple randomized clinical trials or metaanalyses).

Quality indicators need to cover all aspects of care that a patient receives on their journey from presentation to diagnosis to discharge and then follow up. These aspects are referred to as either domains or dimensions of care. Initial quality indicator guidelines focussed predominantly on the treatment, in comparison to the ESC guidelines which being the most recent cover seven differing domains of care.

Table 1 compares the different sets of quality indicators that have been recommended by the respective national cardiology societies. It shows that although there is a large degree of overlap between the suggested measures of quality, some key differences remain. Certainly the earlier versions of quality indicators primarily focussed on medication prescription for which there is a plethora of evidence to show their association with improved outcomes both in the form of randomized clinical trials and registry-based analyses (Yusuf et al., 2001; Wallentin et al., 2009; Wiviott et al., 2007; Devita et al., 1994; Pfeffer et al., 1992, 2003; Cannon et al., 2004). However, for some indicators the associations with outcomes are not well evidenced. For example, there is no Class 1A recommendation to show that receipt of echocardiography is associated with outcomes. However, there is an indirect association due to echocardiography being a vital step in identifying patients with an ejection fraction ≤ 0.4 which determines eligibility for angiotensin converting enzyme inhibitors and β-blockers which are both well recognized to improve outcomes and carry Class 1A recommendations.

Several studies have examined the association of quality indicators with mortality (Peterson et al., 2006; Bradley et al., 2006; Bebb et al., 2017). The first considered the association between nine process of care measures (of which six were quality indicators from the 2006 AHA/ACC guidelines) as well as an opportunity based composite score and in-hospital mortality (Peterson et al., 2006). All nine measures were found to have a negative correlation with in-hospital mortality, which was significant for all but β-blocker prescription both acutely and at discharge. Furthermore, improved attainment of the composite score was associated with a significant reduction in in-hospital mortality. The second study examined the relationship between seven measures which were all listed in the AHA/ACC report with 30 day risk-standardized mortality (Bradley et al., 2006). Again an opportunity based composite score (although only five of the seven indicators were included) was calculated and its association with 30 day risk-standardized mortality investigated. The authors demonstrated a negative correlation between all indicators and 30 day risk-standardized mortality, which was greatest for the composite measure. The degree of correlation was not as marked as that shown by Peterson et al. (2006). The most recent analysis by the chapter authors and colleagues used the ESC quality indicators to assess performance and showed that 11 of 12 indicators assessed were associated with a reduction in crude mortality (Bebb et al., 2017).

All three studies demonstrated that in addition to associations with outcomes, there was correlation between the individual quality indicators. The correlations between ESC measures, although evident, were weaker which is likely due to the much wider coverage across the spectrum of care than that covered in the AHA/ACC indicators. It should be noted that the Canadian indicators cover the widest spectrum but as far as the authors are aware there exists no work demonstrating an association between these indicators and outcomes.

In conclusion, although quality indicators are not solely based on Class 1A recommendations, they have been demonstrated to be associated with outcomes such as mortality. Therefore improving adherence to quality indicators should result in a decrease in mortality. One study in Canada examined the effects of publication of "report cards" for acute myocardial infarction patients, they surveyed physicians responses to the "report cards" and over 50% reported launching quality improvement projects as a consequence of the "report cards" (TU and CAMERON, 2003). The Get With The Guidelines program has shown that programs aimed at improved adherence to quality indicators leads to improved outcomes (Lewis et al., 2008).

Design and Attributes of Quality Indicators

Quality Indicators

Quality indicators differ from recommendations as they must not only have a strong evidence base behind them they must also meet further criteria concerning validity and feasibility.

The process of developing a new quality indicator is complex. In this section, the steps in defining quality indicators are explored (**Fig. 1**). Firstly a review of existing evidence is undertaken to identify where guideline recommendations exist and importantly, whether there is variation within provision of these guidelines between providers. These guidelines ideally should cover all domains of patient care. However, there may be some areas where guidelines are lacking and further work is needed, the initial set of indicators proposed by the AHA/ACC covered diagnostics, patient education and treatment, but had no indicators concerning self-management or monitoring of disease states (Krumholz et al., 2006). The European indicators include "the centre should participate in a regular registry or program for quality assessment" which is aimed at developing both regional and national programs to measure quality indicator performance then provide feedback to the individual hospitals (Schiele et al., 2016). This is not based upon any one specific recommendation, but builds upon participation in a regular registry and is a logical next step for the implementation of quality indicators.

Following a review of the evidence, one must determine whether the proposed indicator leads to improved patient outcomes, this is why they are based in the main Class 1A recommendations. The measure also needs to be interpretable by the practitioners who treat patients and finally, the measure must be something that is modifiable.

When indicators are designed they need to have clear precise definitions of the populations for both the denominator (all those eligible for a treatment for example) and numerator (all those receiving a treatment for example) to ensure consistency of

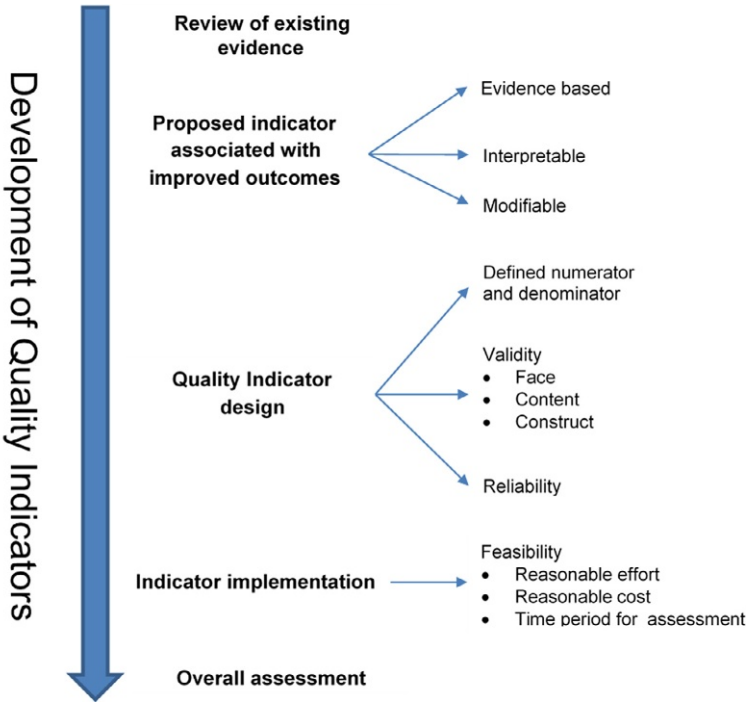

Fig. 1 Flow diagram outlining the process for development of quality indicators.

Box 1 Measuring Time of Reperfusion

There have been several quality indicators for assessing this, the first were time to fibrinolytic therapy and time to PCI, where the numerators are the time from first medical contact to the time that fibrinolysis is initiated or a balloon is inflated.

The reason for choosing these values as opposed to time reperfusion achieved, is that in a small minority of patients despite following all the correct processes, it is not possible to achieve reperfusion. Therefore, these quality indicators provide a more balanced assessment of the care provided, than the outcome of achieving reperfusion. The European guidelines take this a step further and use the passage of the wire as the indicator for the clock to stop, rather than the time of balloon inflation.

calculation and comparability across populations. In addition, indicators must be valid, which can be measured in several different ways including face validity, content validity, and construct validity. Face validity considers whether the indicator assesses what it truly set out to measure. Content validity ensures the indicator captures the most meaningful aspects of care for example you could measure prescription of angiotensin converting enzymes at discharge for all patients, however, the evidence suggests the most benefit is seen in those with heart failure of left ventricular systolic dysfunction. Hence the measure should be prescription for those with heart failure or a left ventricular ejection fraction ≤ 0.4, rather than prescription for all patients (Box 1). Finally, indicators should have construct validity—which means that the measure should correlate well with other measures in the same aspect of care. Lastly when designing new indicators their reliability needs to be considered, will they correctly identify true variation within care or just chance variation, and can they be reproduced across care providers both at a national and international level.

Following the design of an indicator which meets the above criteria, the practical aspects of implementing the indicators need to be considered. First the measure must be feasible, in that it can be measured for a reasonable effort at affordable cost within a predefined time frame. The time frame is an important consideration, as it takes 5 years to measure and report the performance of an indicator, the care that aforementioned indicator covers may have progressed in that time period.

When the proposed indicator has gone through these steps it is put forward to a panel of experts who will then reach a consensus to recommend or reject the indicator.

Quality Metrics

Although the focus of this article is on quality indicators, note should be made of quality metrics which are similar as they both focus on improving the quality of care for patients. The processes for development of quality indicators and metrics are also comparable though quality metrics need not go through the same rigorous process that quality indicators do (Bonow et al., 2008). One fundamental difference between the two is that although quality metrics are developed to support both self-assessment and

quality improvement at all levels (hospital, regional and national), they are not intended for public reporting rather than quality indicators which are primarily intended for public reporting, they do however represent a valuable tool for enhancing patient outcomes. Quality metrics can be often be viewed as tests or preliminary indicators for potential future quality indicators. The AHA/ACC 2008 guideline included nine "test" measures, the majority focusing on anticoagulant management; of these it can be argued that only one of the prescription of clopidogrel at discharge has made the transition to "full" quality indicator (Krumholz et al., 2006).

Types of Quality Indicators

There are several broad classes of quality indicators including process, outcome, structural or system, and composite indicators. Each are discussed later.

Process Indicators

Process indicators focus on measuring aspects of care that if performed well should lead to an improvement in outcomes such as the prescription of medications at discharge, rather than measuring a specified outcome. They can be both pharmacological and nonpharmacological. All three sets of guidelines contain multiple examples of process measures, although there are some such as aspirin on discharge which are found in every set (**Table 1**).

Outcome Indicators

Outcome measures are hard endpoints such as 30-day mortality or readmission to hospital. There remains much debate as to whether outcome measures are still relevant and applicable. A study from 2003 showed that physicians found information regarding prescription rates and waiting times for procedures more useful than outcomes (30-day and 1-year mortality) for driving quality improvement (TU and CAMERON, 2003). They are rather crude measures in that they focus on one outcome that is the consequence of multiple components of care that patients will experience in their journey of treatment (Lilford et al., 2004). The Canadian guidelines (Tu et al., 2008; Panel et al., 2003) have multiple measures focusing on the differing types of acute coronary syndrome, assessing both mortality and readmission at 30 days and 1 year, although these were not cardiac specific or risk adjusted. The American guidelines have no outcome measures within them (Krumholz et al., 2006, 2008) and the European guidelines only contain GRACE adjusted 30-day mortality (Schiele et al., 2016). There is also concern as to whether the methods used for risk adjustment are appropriate, and whether they should be used when considering the quality of care. Finally there is the question of how one differentiates between preventable deaths and deaths from other causes, the Harvard Medical Practice Study showed that only 0.25% of admissions resulted in an avoidable death and hence one can argue that reporting mortality does not reflect the quality of care provided (Brennan et al., 1991).

Structural/System Indicators

Structural measures focus on the facilities and organization of both hospitals and health services, for example the first quality indicator domain from the ESC is that of center organization, the theory behind this being that an organized system designed to facilitate primary PCI will lead to reduced times to reperfusion, without these structural aspects in place it may be harder to deliver an improved service (Schiele et al., 2016). They range from the presence of a system to monitor errors in anticoagulation to the time from call to emergency services to receiving treatment.

Composite Indicators

A composite quality indicator is the combination of a minimum of two or more indicators to summarize performance across multiple dimensions of care. This allows an immediate representation of the global standard of care provided as opposed to one individual clinical parameter. Composite indicators are only officially recommended by the ESC at present, yet there are multiple examples of their use within the cardiovascular literature (Couralet et al., 2011; Eapen et al., 2011; Chen et al., 2013; Simms et al., 2013a,b; Aliprandi-Costa et al., 2016; Bebb et al., 2017).

There are several ways in which a composite score can be achieved and these can be found in **Table 2**. The ESC guidelines advocate the use of both an "opportunity based" and "all or none" approach as each individual method has its own strengths and weaknesses.

The advantages of an opportunity based method is it's reflection of the number of opportunities that a care provider had to offer for a particular patient given their eligibility, which is a fairer method than a simple total or average composite score (total number of times care intervention received over the total number of patients) which could be biased by measures for which some patient groups were not eligible. Although the disadvantage of such measures is that it will be influenced by the most common care indicators, as each indicator is implicitly weighted by the number of eligible patients which can vary between providers. In addition, it may not be apparent whether it is one particular area underperforming or multiple areas.

Table 2 Types of composite measures

Type of composite measure	*Method*
Linear combinations	
Simple average	Take an average of the number of times care indicator provided over the population
Budget allocation	Allows weighting of the indicators
Equal weighted	Every indicator carries the same weight
Unequal weighted	Indicators are weighted differently according to their importance
Opportunity based scores	Number of times care indicator provided over the number of opportunities to provide the care indicator
Logical combinations	
All or none (process measures)	Success is receipt of all care indicators that a patient is eligible for
Any or none (outcome measures)	"Success" is the patient experiencing any adverse outcome from a list of two or more
Incommensurable measurement scales	Where indicators are translated into a common scale prior to being combined together

In contrast, "all or none" measures promote the highest standards of care as only providers giving patients all indicators for which they are eligible can score. Although this is the standard of care which providers should strive towards, the counter argument is that there is a loss of information by reducing the measure to a simple dichotomy and does not account for the relative importance of individual care opportunities. For example, one provider could have achieved optimal care in 60% of patients based on medication prescription and reperfusion therapy, but perhaps was more likely to not provide smoking cessation advice and would therefore be considered as providing suboptimal care. The "lost" information could be important for identifying areas that need quality improvement, hence the supporting information should focus on individual measures alongside composite scores.

Regardless of the method used to calculate the composite score, composite scores have their own strengths and weaknesses. As previously mentioned their strength is in providing an overall assessment of the care provider at a predefined level (patient/care providers), they allow a wider scope of measurement than individual indicators as they can cover all the differing types of indicator. Given that they are a summation of care provided, they can be used for comparing the quality of care provided by care providers, both within and between countries. However, as they are a summation they do not allow easy identification of underperforming areas.

The challenges of using composite measures is in the interpretation, usually this involves benchmarking the composite score against set levels; above national average, within national average, below national average for example. There should be a clear explanation of both, how missing data is dealt with and how the composite is calculated so providers can identify which areas of the composite require improvement.

Finally, just as individual indicators, composite measures have to be valid and they should correlate with an outcome that is regarded as the gold standard of measuring the focus of the composite. For example, for acute myocardial infarction this outcome is usually measured as 30-day mortality. Previous work has demonstrated that composite measures are associated with in hospital mortality (Peterson et al., 2006), and 30-day mortality (Bebb et al., 2017; Eapen et al., 2011; Simms et al., 2013b; Chen et al., 2013; Bradley et al., 2006), whilst some studies have demonstrated the association for 1 year mortality (Simms et al., 2013a). It should be noted that for each of these studies a different composite was used, hence it is important that when a composite indicator is recommended that it undergoes validation promptly, ensuring it is an accurate measure of performance.

Implementation of Quality Indicators

Challenges

Quality indicators cannot always be measured due to the quality and the availability of data. This is one of the obstacles to the widespread implementation of quality indicators. Determining which measures can accurately be assessed from existing data and therefore whether new data needs to be recorded to ensure that all quality indicators to be assessed, is necessary. The Myocardial Ischaemia National Audit Project (Herrett et al., 2010) has been used to validate the recent ESC quality indicator guidelines, the authors showed they could only directly assess 12 of the 20 measures, a further four could be assessed indirectly whilst for the remaining four indicators further data need to be gathered (Bebb et al., 2017).

Secondly, each indicator has very precise numerator and denominator with set exclusion criteria, however it may be that not all the data relating to exclusion criteria is readily available from the hospital records and therefore ineligible patients may be incorrectly included in the denominator which in turn leads to an underestimation of the level of attainment a hospital or provider has achieved.

For those indicators which have a time component, ensuring accurate timing is of paramount importance, ideally all systems used to measure time (ECG machines, emergency service call records, and catheterization laboratory clocks) should all be synchronized, however, this is impractical and unlikely in a busy acute care setting. There is also the issue of transferred patients who in earlier guidelines were excluded from indicators involving timing, in the more recent sets there is differentiation between those admitted to hospitals able to perform primary percutaneous coronary intervention and those who are not. Ensuring these patients are included within quality analysis is important to ensure they are not disadvantaged by requiring transfer between hospitals.

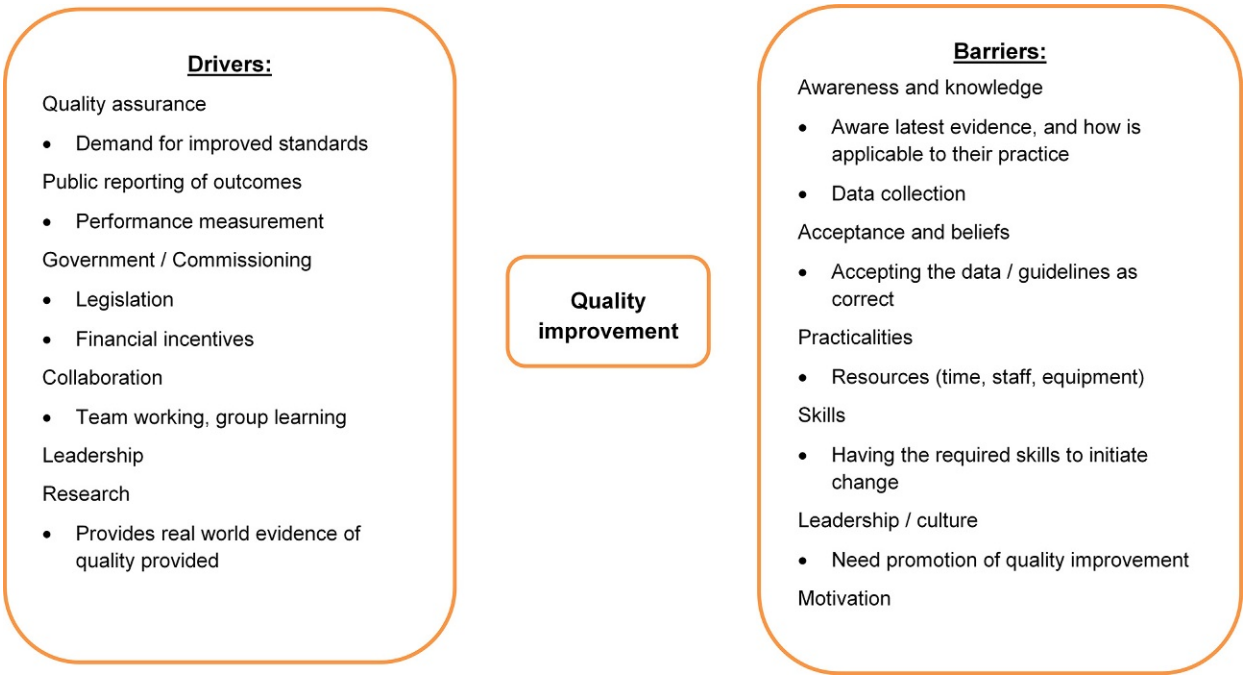

Fig. 2 Schematic representing the drivers and barriers to achieving quality improvement.

There remains a delay for the adoption of new interventions within quality indicators for example there were several randomized control trials demonstrating the benefit of clopidogrel for acute coronary syndrome patients published between 2001 and 2005 (Yusuf et al., 2001; Sabatine et al., 2005; Chen et al., 2005). Nevertheless in their 2008 paper the Canadian society remained unsure of the evidence (Tu et al., 2008), whilst the Americans only considered it as a test measure (Krumholz et al., 2008). For quality indicators to be effective they need to be updated regularly to ensure they are evaluating the most contemporary care interventions (Fig. 2).

Steps for Implementation

For the successful implementation of quality indicators there needs to be accurate and timely recording of the data required in their calculation. Given the increasing use of electronic health records in the modern world, this at face value seems like it should be straightforward. Clinical registries would therefore be an obvious choice for determining levels of performance. However, it is not as simple as it would appear, registries collect patient sensitive information and this must be handled appropriately and confidentiality. The data that registries collect must be both valid and accurate, if the data is to be used to assess and report quality. The collection and subsequent reporting of this data must also be timely to allow identification of underperforming services and allow steps for improvement to be implemented.

One exemplar of successful implementation is the American "Get with the Guidelines" initiative and the ACTION registry. For a hospital to be included in the "get with the guidelines" initiative, they have to pay for participation in the registry. In return, such hospitals receive detailed quarterly risk adjusted reports including both quality indicators and metrics in order to improve their standards (GWTG). In addition they have a hospital profile on the American College of Cardiology patient website highlighting their performance. This approach has been shown to lead to an improvement in guideline adherence that was higher than to be expected from the improvements seen with public reporting of results alone (Lewis et al., 2008). The success of this method, however, heavily depends on the nature of the healthcare system. In America, in a health insurance environment there is strong competition between providers based on hospital performance due to the patient's ability to choose the best performing hospitals. In a nationalized healthcare system, such an implementation strategy would not be possible.

When considering how to integrate the role of registries within quality improvement the 2015 statement by the ACC/AHH provides a framework (Bhatt et al., 2015). They demonstrate how registries can fit within the cycle of quality. (The cycle of quality was proposed by Califf et al. in their paper which considered how quality should be introduced into the therapeutic development cycle (Califf et al., 2002).) Registries can influence every stage of this cycle both by providing the data for analysis, identifying areas of discrepancy, and in time showing an improvement following an intervention. Traditionally registries have had short term or limited outcomes recorded, however, by linking to other data sources, such as the United Kingdom Myocardial Ischaemia National Audit Project and the Office of National Statistics for evaluation of mortality, or insurance claims data in the United States, allows for broader and longer term outcomes to be investigated (Fig. 3).

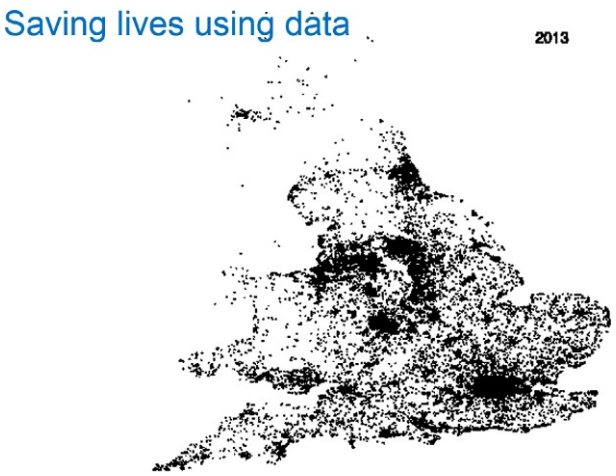

Fig. 3 A graphical representation of 5% of the cases within MINAP from 2003 to 2013, where each dot represents a case of acute myocardial infarction. MINAP is a mandatory registry for all cases of acute myocardial infarction within England and Wales.

Registries can and have been used for both international and within-country analyses of performance and also to assess temporal trends in performance (Chung et al., 2015; Hall et al., 2016; Saunderson et al., 2014; Dondo et al., 2016a,b). However, the measures used for comparison have varied. The existence of quality indicators does not automatically mean that each country collects the necessary data for their assessment. If quality indicators were designated as the standard gauge of quality then not only should it drive improvements in data collection as each registry/country would have to collect the same data, but also allow easier comparison both within and between countries. This in turn leads to more accurate and trustworthy reporting to drive further improvement in quality of care and outcomes.

The Future

Measuring quality is now recognized as a fundamental component of healthcare systems, as they strive for improved care and outcomes. Quality indicators provide a method for assessing the quality of care provided across the full spectrum of domains of patient care. They allow comparison, both within and between countries and the identification of variation can be a driver for change and improvement to lead to reductions in the premature mortality from coronary artery disease.

Introduction

"Recreational drugs" are defined as substances "used without medical justification for. . .psychoactive effects often in the belief that occasional use of such a substance is not habit-forming or addictive" (Recreational Drug, 2017).

They can be delineated into three main subtypes: stimulants, depressants, and psychotropics. This chapter will seek to describe the cardiovascular, myocardial, electrophysiological, and valvular effects of the more commonly used recreational drugs in the world. These include ethanol, marijuana, cocaine, methamphetamine, opioids, psychedelics, and MDMA, along with other substances such as toluene, khat, and anabolic steroids.

Ethanol

Ethanol, known chemically as ethyl alcohol and in vernacular speech as *alcohol*, is a commonly used recreational drug used by millions in the United States. It is most commonly ingested as a liquid beverage. According to studies from the National Institute of Health, 87.6% of people over the age of 18 have used ethanol at some point in their lifetime (Center for Behavioral Health Statistics and Quality, 2014a). Heavy drinking and binge drinking have been proven to result in systemic arterial hypertension, coronary artery disease, cardiac arrhythmia, and sudden cardiac death (Husain et al., 2014).

Ethanol impacts the heart via several mechanisms: it disrupts cardiovascular metabolism by decreasing the amount of oxygen supplied to the heart, reducing levels of adenosine triphosphate and leading to a decrease in aerobic and an increase in anaerobic metabolism. Ethanol's metabolites, acetaldehyde and reactive oxygen species (ROS), decrease protein synthesis and expression; and ethanol increases expression of the *c-myc* gene, which contributes to apoptosis (Walker et al., 2013).

Ethanol has been documented to have both long- and short-term impact on blood pressure. Ethanol exhibits a dose-dependent increase in systolic blood pressure. The acute ingestion of ethanol can cause tachycardia and lower-than-average stroke volume (Guzzo-Merello et al., 2014). Long-term use of ethanol causes multiple pathologic occurrences including impairment of baroreceptors, increased sympathetic activity, and increased cortisol levels in the blood. Ethanol can also cause increased calcium in the blood, stimulation of the RAAS syndrome, and causes oxidative injury in the endothelium resulting in decreased endothelium-related nitric oxide production.

Ethanol also has a direct effect on the myocardium. Detrimental effects are found especially in the cases of heavy chronic ethanol users (over 80 g per day over at least 5 years). For reference, the National Institutes of Health defines one "standard" drink as containing 14 g of pure ethanol, equivalent to 12 oz of beer, 5 oz of wine, or 1.5 oz of hard liquor (Kerr and Stockwell, 2012). Ethanol causes alterations of the excitation–contraction coupling cascade, the structure and function of cardiac mitochondria and

 https://doi.org/10.1016/B978-0-12-809657-4.99731-X

sarcoplasmic reticulum, and decreases contractile proteins. This can result in increased end-systolic and diastolic LV volumes, posterior wall thickening, and a decrease in ejection fraction (Kerr and Stockwell, 2012). Traditionally, such patients develop a dilated cardiomyopathy. However, this does not occur in every person who abuses ethanol.

Retrospective studies have looked at the prevalence of ethanol abuse in those who develop a dilated cardiomyopathy. While not all ethanol users develop a cardiomyopathy, recent studies show a prevalence of 0.43% in women and 0.25% in men who abuse ethanol, compared to a general population prevalence of 0.03%–0.05% (Guzzo-Merello et al., 2014). With cessation of ethanol and prompt treatment of the cardiomyopathy with beta blockers, angiotensin converting enzyme inhibitors, and diuretics, this cardiomyopathy can often be reversed. However, with continued use of ethanol, mortality figures as high as 42% over 3 years have been reported (George and Figueredo, 2010).

Ethanol has a well-established effect on nutritional deficiencies, especially in those with chronic usage. Especially common are deficiencies in magnesium and potassium, which can predispose patients to ventricular arrhythmias (Mahmoud et al., 2007). Magnesium deficiency is associated with ventricular tachycardia, torsades de pointes, and sudden cardiac death. Magnesium deficiency can also result in refractory hypokalemia, again causing ventricular tachycardias such as torsades de pointes.

Ethanol has a strong relationship to supraventricular tachycardias, specifically, atrial fibrillation.

Meta-analysis of numerous studies exploring the connection between ethanol and atrial fibrillation has noticed an increased risk of atrial fibrillation in those with daily heavy ethanol ingestion (approximately 42 g of ethanol a day). The pathologic mechanisms of ethanol affect the myocardium, creating a substrate that is highly proarrhythmic (Samokhvalov et al., 2010). Similarly, binge drinking of ethanol has long been recognized to be a cause of supraventricular tachycardias, even in those without a chronic ethanol habit, resulting in the so-called holiday heart syndrome. This appears to be a more common finding in those with underlying cardiac disease or cardiac comorbidities (Tonelo et al., 2013).

Marijuana—Natural and Synthetic Variations

Marijuana, derived from the plant *cannabis*, is the world's most commonly used illicit drug; the World United Nations Office on Drugs and Crime reporting approximately 3.8% of the world's population used the drug in 2014. Based on this figure, somewhere near 200 million people used cannabis in 2014, representing a 27% increase in users since 1998 (United Nations Office on Drugs, 2014).

In the United States, marijuana is a federally prohibited substance. It is classified as a schedule I substance in the Controlled Substances Act (United States Code, n.d.). In 2012 Colorado and Washington became the first states to legalize marijuana for recreational use by persons aged 21 and older. Since then Alaska, Oregon, Maine, Massachusetts, Nevada, California, and the District of Columbia have followed suit and adopted more expansive laws legalizing recreational marijuana use. Including the aforementioned states, a total of 29 states have adopted the use of medicinal marijuana (ProCon.org., 2017).

Marijuana is made from the drying of the leaves and flowers of the cannabis plant. The drug goes by many names including pot, weed, herb, and ganja. The active substance in marijuana is delta 9-tetrahydrocannabinol, or THC. THC works at the cannabinoid 1 receptor in the brain, adipose tissue, myocardium, vascular endothelium, and sympathetic nerve terminals and the cannabinoid 2 receptor in the lymphatic tissue, macrophages, and the periphery, ultimately producing its psychoactive effects (Steffens and Mach, 2006). The mechanism of delivery is most often inhalation either via combustion or vaporization, though ingestion is also a popular mode of delivery. The majority of data regarding the adverse effects of cannabis on the pulmonary, psychiatric, and cardiovascular system are associated with inhalation of the drug. Interestingly, noninhalational administration of cannabinoids has been shown to have some beneficial effects on the modulation of atherosclerotic processes in animal models (Singla et al., 2012).

More recently, considerable attention has come out about the medical use and potential benefits of cannabinoids. There is strong evidence to support their use in those with chronic pain and spasticity. There is less convincing evidence to support their use to treat nausea and vomiting secondary to chemotherapy and in anorexia secondary to HIV and AIDS (Whiting et al., 2015). Other papers have described the utility of cannabinoid therapy in treating the effects of PTSD, and it has shown some utility in treating symptoms of depression and anxiety; there are currently ongoing randomized placebo-controlled trials to study their efficacy.

Interestingly, although cannabis is the most commonly used illegal psychoactive substance, its use only constitutes a small proportion of the global disease burden relative to other substances. Large cross-sectional epidemiological studies suggest that of the approximately two million total disability adjusted life years lost to substance use disorders (excluding tobacco) marijuana only represented 5.5%, ranking 4th after alcohol (47%), opioids (24.3%), and amphetamines (7%) (Degenhardt et al., 2013). Given the current push for decriminalization, it is likely that this number may increase in the coming years.

Several hemodynamic effects of smoking marijuana have been well described. There is a dose-dependent increase in heart rate, peaking 10–30 min after inhalation. The magnitude of heart rate increase seems to be highly variable amongst users; however it has been shown to range from 20% to 100%. Postural hypotension after smoking marijuana has been well described and there seems to be a decrease in supine blood pressure as well. Onset of symptoms after ingestion of marijuana is typically longer, approximately 1 h, with peak plasma concentrations in the blood after 4–6 h (Huestis, 2007).

One study demonstrated that among patients with chronic stable angina, the anginal threshold is acutely decreased after smoking one marijuana cigarette. In this trial, smoking a marijuana cigarette decreased exercise time to angina by 48%. This represents a significantly greater effect relative to a tobacco cigarette (23%) and placebo (8.6%) (Aronow and Cassidy, 1974).

In the prospective Determinants of Myocardial Infarction Onset Study, 3886 adult in patients with MI were followed. In this cohort, 3.2% of patients had smoked marijuana in the past year. The marijuana user group were more likely to be male (94% versus 67%, $P<.001$), current cigarette smokers (68% versus 32%, $P<.001$), and obese (43% versus 32%, $P=.008$). Interestingly, marijuana users were less likely to have angina or hypertension. Using a case controlled analysis the risk of myocardial infarction onset was elevated 4.8 times over baseline (95% confidence interval, 2.4–9.5) in the 60 min after marijuana use. The elevated risk rapidly decreased thereafter (Mittleman et al., 2001).

In addition to myocardial infarction, marijuana use has been implicated in pathologic disease in other arterial beds. There have been multiple case reports of ischemic stroke during marijuana use in heavy users. Epidemiologic studies have looked at this association in an attempt to demonstrate causality based on the temporal relationship of marijuana use, exclusion of other risk factors for stroke, and recurrence of stroke with resumption of marijuana use (Hackam, 2015). A large cross-sectional survey of patient with acute ischemic stroke found that among younger adults, recreational marijuana use is independently associated with a 17% increased likelihood of hospitalization for acute ischemic stroke (odds ratio 1.17, 95% CI 1.15, 1.20) (Rumalla et al., 2016).

There is an increasing number of case reports describing a link between marijuana use and atrial fibrillation, especially in young people (Korantzopoulos et al., 2008; Krishnamoorthy et al., 2009). The mechanism of this is unclear although it is thought to be related to adrenergic stimulation and related autonomic alterations (Jones, 2002).

Cocaine

Cocaine, a derivative of the *coca* plant, is another commonly used illicit drug with adverse cardiovascular effects. Cocaine is legitimately utilized in some minor medical procedures, such as achieving hemostasis in ENT and nasal surgeries. As an illegal substance, cocaine is either ingested, insufflated, smoked, or injected into the veins. Cocaine can also be altered in a chemical reaction with sodium bicarbonate over heat to produce "crack" cocaine, a potent "free-base" form of cocaine that, when smoked, produces a rapid-onset high (Jeffcoat et al., 1989).

Cocaine is a commonly used stimulant which induces an intense feeling of increased energy and euphoria, due to its effect in the neurotransmitter synapses in the central nervous system. In the cardiovascular system, cocaine operates as an alpha-1 and beta-1 agonist, causing increased heart rate, increased myocardial oxygen uptake, and increased cardiac contractility (Liaudet et al., 2014).

The effect of cocaine in raising systolic blood pressure is due to the stimulatory effect on alpha-1 receptors in the periphery (Schwartz et al., 2010), as well as stimulating the release of endothelin I, a potent vasoconstrictor, from endothelial cells and inhibiting the production of nitric oxide (Schwartz et al., 2010). It also deregulates receptors on the endothelium of blood vessels, making vessels more sensitive to sympathetic stimulation. Additionally, cocaine acts as a platelet activator, increasing levels of von-willebrand factor and fibrinogen, promoting thrombosis (Schwartz et al., 2010).

Cocaine has a direct effect on both the myocardium and conduction system of the heart. The pro-thrombotic state induced by cocaine can result in intra-coronary thrombosis, causing myocardial infarction. Cocaine increases blood pressure, increases heart rate, and increases cardiac contractility, all of which increase myocardial oxygen demand in the setting of vasospasm of the coronary arteries, may result in ischemia and possible infarction (Hollander, 2008).

Cocaine also operates similarly to a class IC antiarrhythmic, blocking sodium and potassium channels and prolonging the effective refractory period, the PR, QRS, and QT intervals, and predisposing patients to arrhythmia (Hoffman, 2010). Commonly, reentry supraventricular tachycardia is seen, and also ventricular tachycardia which can in some cases degrade into ventricular fibrillation, causing cardiac arrest. Atrial fibrillation after cocaine use has also been reported.

Cocaine has no direct effects on the valves of the heart, though those that inject cocaine are more at risk for endocarditis secondary to the effect of contaminated needles and poor hygiene. Chronic cocaine usage has been shown to result in a dilated cardiomyopathy; the mechanism behind this is thought to possibly be due to repeated catecholamine surges and therefore repeated episodes of subendocardial ischemia (Frustaci et al., 2015).

Interestingly, the concurrent metabolism of cocaine and ethanol in the liver by transesterification of cocaine creates a metabolite called cocaethylene, which is structurally similar to cocaine, but has a different effect on central and peripheral neurotransmitters than cocaine alone. Cocaethylene causes a profound decrease in ventricular contractile function and stroke volume, and also has a strong negative inotropic effect (Herbst et al., 2011). In fact, the co-administration of these two substances in an animal trial resulted in a prolonged cardiac depression and also increased the prevalence of ventricular tachycardia.

Methamphetamine/Stimulants

Methamphetamine and related "stimulants" are the second most commonly used illicit drug in the world, second only to cannabis. Methamphetamine is medically indicated for use in patients to treat narcolepsy, attention-deficit hyperactivity disorder, and obesity. Methamphetamine itself is a synthetic derivation of ephedrine, which comes from the Ephedra genus of Chinese shrubs (Won et al., 2013).

Methamphetamine like compounds are derived from the B-phenylethylamine core structure. They easily cross the blood–brain barrier and resist biotransformation and release monoamine neurotransmitters from nerve endings. Different compounds are derived by substitutions at the aromatic ring and the alpha and beta carbons of the aliphatic chain and amine terminal. These substitutions create different characteristics in each compound, some with greater psychomotor stimulation, anorectic, or hallucinogenic effects (Carvalho et al., 2012).

Methamphetamine acts physiologically to release serotonin, dopamine, norepinephrine, and epinephrine into the neuronal synapses. This results in increased alertness, euphoria, energy, and decreased appetite. Cardiovascularly, it can increase both heart rate and blood pressure. It is usually smoked, injected, or insufflated (Won et al., 2013).

Methamphetamine has been strongly associated with both hypertrophic and dilated cardiomyopathies. Histologically, fibrosis and necrosis of cardiac myocytes have been documented. These effects are likely multifactorial in origin. A proposed physiologic mechanism for methamphetamine-associated cardiomyopathy has been catecholamine excess, coronary vasospasm, effects of the generation of reactive oxygen species (Lord et al., 2010).

Interestingly, some methamphetamine derivatives, most notably a diet suppressant called fenfluramine–phentermine (Fen-Phen), have been associated with valvular thickening and dysfunction. This is thought to be due to fibroplasia of the endocardium of the right heart valves, brought by serotonin-rich blood coming back to the right side of the heart following metabolism in the liver. Additional effects of methamphetamine derivatives on the left-sided heart valves have also been described (Connolly et al., 1997). Fenfluramine and other methamphetamine derivatives have also been shown to cause pulmonary hypertension resulting in right heart failure (Mark et al., 1997). It was for its detrimental effects on cardiac valves that the Centers for Disease Control ordered a withdrawal of the sale and distribution of Fen-Phen in 1997 (Centers for Disease Control, 1997).

Limited retrospective studies have shown an increased prevalence of QTc prolongation in subjects with methamphetamine usage, in relation to the general population (Haning and Goebert, 2007).

Opioids

The term opioid refers to natural or synthetic substances that act at the mu, kappa, or delta receptor sites whose biochemical structure is derived from the naturally occurring alkaloids produced by the opium poppy plant (*Papaver somniferum*). Delta and kappa receptors are found in the central and peripheral nervous system and are mainly responsible for analgesic and sedative effects, while stimulation of mu receptors results in respiratory depression and reduction in GI motility (Chen and Ashuburne, 2015).

Their use and abuse go back millennia and were described as far back as 1500 BC when grains of the poppy plant were used to form a paste and administered to prevent "excessive crying in children" as described in the *Ebers Papyrus*. In 1806, the active ingredient in opium was isolated by Serturner, who named the substance Morphine after the god of dreams, Morpheus (Brownstein, 1993). Codeine was isolated from opium several years later. While incredibly effective as analgesics, both of these agents had as much potential for abuse as opium and the search for safer, less addictive alternatives started in the 19th century and continues still. The first of these "safer" opiates was heroin, which was produced in 1898 by the Bayer Company, who pronounced it to be more potent than morphine and initially thought to be free from abuse liability.

By the 1920s, doctors were aware of the highly addictive nature of opioids and tried to avoid treating patients with them. Heroin became illegal in 1924. Methadone is a synthetic compound derived in 1946 as a structurally unrelated compound to morphine with similar pharmacologic properties. Several other synthetic opioids have been engineered since then, none of which have been free of addictive potential. Both the natural and synthetic forms have different onsets and durations of action. For instance, morphine takes approximately 15 min to reach near-full effectiveness, and its analgesic effect lasts approximately 1.5–7 h. Fentanyl, a synthetic opioid more potent than morphine, has an onset of action of 5 min, but duration of action of only 30 min (Vardanyan and Hruby, 2014).

Opioid abuse and addiction is one of our top national health challenges in the United States. Although opioids usually are prescribed to control pain, diminish cough, or relieve diarrhea, they also produce feelings of euphoria, tranquility, and sedation that ultimately lead to abuse. Overall, an estimated 400,000 persons have used heroin in the past month and 4 million have reported nonmedical use of prescription pain relievers in our country (Center for Behavioral Health Statistics and Quality, 2014b).

Heroin and prescription opioids share many routes of administration beyond ingestion. Intravenous is the most rapid route but also the most dangerous to the user while intranasal, subcutaneous injection, and inhalation remain popular routes of delivery for abusers. The cardiovascular effects of opioids are in part related to route of administration, with infective endocarditis being a major problem among intravenous drug users (IVDU) and electrophysiologic consequences present regardless of route of administrations. The incidence of infective endocarditis in injection drug users is thought to be 1.5–3.3 cases per 1000 patient years in the United States (Baddour et al., 2005). Some opioids have been associated with inhibition of the hERG protein which regulates the I_{kr} repolarization channel, responsible for returning the heart to its resting voltage potential during diastole. Theoretically, this causes prolongation of the QT interval. There is a small amount of observational evidence showing a dose-dependent relationship between amount of oxycodone (an opiate derivative) and prolongation of the QT interval.

Methadone is a commonly used replacement therapy for those attempting detoxification from opioid abuse. It is a chiral opioid with primarily mu receptor agonist properties, and influences the release of other neurotransmitters (acetylcholine, norepinephrine, substance P, and dopamine) (Lusetti et al., 2016). It can be taken orally and has a half-life of over a day due to its lipophilicity and ability to remain in the tissues longer than other formulations of opioids. It has been discovered to result in increased prevalence of prolonged QT and incidence of torsades de pointes in patients undergoing methadone replacement therapy, especially within the first two weeks of starting treatment. This is again thought to be due to the effect that opiates seem to have on the hERG protein. Importantly, those of the female gender, those with underlying heart disease, and those with metabolic derangements such as hypokalemia are at an especially high risk of developing prolonged QT from methadone usage (Wedam and Haigney, 2016; Vieweg et al., 2013).

Psychedelics: LSD and Psilocybin

Lysergic acid diethylamide (LSD) and psilocybin are recreational substances that can induce feelings of euphoria, mind alteration, paranoia, and visual and auditory hallucinations. LSD is a derivative of the ergot fungus, originally synthesized by Albert Hoffman in 1938. Psilocybin is the psychedelic compound active in "magic mushrooms." Both of these psychedelics are usually taken by mouth to induce their effects.

The psychedelics chemically resemble serotonin. LSD has agonist, partial agonist, and antagonist effects at serotoninergic, dopaminergic, and adrenergic receptors, in contrast, psilocybin has serotonergic, but no dopaminergic effects (Borowiak et al., 1998). LSD is synthetically derived, and is approximately 100 times more potent than psilocybin. Ingestion of LSD can cause visual and auditory hallucinations, along with episodes of euphoria and paranoia. LSD can induce a mild sympathetic response, though not to the degree that cocaine or other stimulants cause. The effect on adrenergic receptors in the body can lead to tachycardia and hypertension (Ghuran and Nolan, 2000).

Both LSD and psilocybin do not appear to have well-established effects on the myocardium. However, there have been isolated case reports describing psilocybin usage as the possible instigator of myocardial infarction, though this appears exceedingly rare (Borowiak et al., 1998).

MDMA

3,4-Methylenedioxymethamphetamine (MDMA) is a commonly used recreational drug, and is especially popular among the "rave" club culture. It generally promotes a feeling of euphoria, increased self-confidence, increased sociability, and arousability. It is also known by other names including "ecstasy" and "molly." Figures from the 2011 National Survey on Health and Drug use estimated that approximately 14.5 million people in the United States above the age of 14 have tried ecstasy at least once (Badon et al., 2002). It is most commonly ingested by insufflation or by mouth. It has a 30-min onset of action and has a half-life of approximately 6–8 h.

Structurally, it is a ring-substituted amphetamine that mainly induces release of serotonin (SERT), and to a lesser degree, dopamine (DAT) and norepinephrine as well. It mainly acts on the SERT and DAT receptors, modulating serotonin and dopamine reuptake channels, respectively (Hagino et al., 2001).

Cardiovascularly, MDMA has been studied in both human and animal models. Increases in heart rate and blood pressure after administration of MDMA have been documented in rat models (Bexis and Docherty, 2006). In humans, it increases the systolic and diastolic blood pressure, and also increases heart rate, especially when dosed to over 1 mg/kg in human subjects (Dumont and Verkes, 2006).

There has been increasing research into the effects of MDMA on the cardiac tissue itself. It appears as though MDMA has a detrimental effect on the myocardial antioxidant defense system and can cause oxidative stress which disrupts calcium homeostasis in myocytes. In animal models, contraction band necrosis was noticed after only 6 h after MDMA administration (Daniela et al., 2008). MDMA is a modulator of the SERT reuptake channel, and inhibits serotonin from being taken up by the presympathetic innervating cell. Recent research has established a connection between SERT and its modulation of cardiac and smooth muscle contractility, platelet aggregation, and cell mitogenesis, and appears to increase myocardial cell metabolism (Ni and Watts, 2006). These effects increase risk of both myocardial infarction and pulmonary hypertension. MDMA does appear to have in-vitro proliferative effects on human cardiac valvular cells, similar to fenfluramine. It can cause a similar effect of prolonged mitogenic responses indicative of processes similar to heart valve fibroplasia (Setola et al., 2003).

Limited studies have also shown a relationship between MDMA and cardiac arrhythmia, mainly supraventricular tachycardia variants, especially when "binging" on MDMA (Badon et al., 2002). This is thought to be due to the effect that MDMA has on cardiac cell homeostasis and possible sympathetic hyperstimulation.

Other Recreational Drugs

Toluene

Toluene is an aromatic hydrocarbon. It is a mono-substituted benzene derivative, consisting of a CH_3 group attached to a phenyl group in chemical structure. It is a clear and colorless solvent that is often added to various chemical compounds including gasoline. It is also used as a key ingredient in paint thinners and adhesives. Toluene vapor is exhaled unchanged, while the rest enters the bloodstream via absorption from the alveoli. Toluene dose-dependently and reversibly inhibits NMDA receptors and enhances GABA by increasing the intracellular calcium concentration in the presynaptic terminal (Beckley and Woodward, 2013). It is especially popular with teenagers in developing countries, owing to its easy accessibility and relatively low cost. In rat models, high levels of administered toluene resulted in bradycardia and eventual asystole, while subacute levels resulted in repolarization disorders and arrhythmia (Morvai et al., 1976). In case reports of human insufflation, toluene has been reported to cause myocardial infarction. The exact mechanism of this has not been proven, but it appears that toluene causes an increased sensitivity to catecholamines, resulting in tachycardia, coronary vasospasm, and resultant infarction. Toluene also appears to play a role in inhibiting sodium channels in cardiac myocytes which are responsible for depolarization (Daniel, 2008). During acute intoxications of toluene, EKG changes such as bundle branch blocks and prolonged QRS complexes are common, which can lead to ventricular arrhythmias and sudden death.

Khat

Khat is a commonly used recreational substance in the Middle East and the horn of Africa. It is made from the leaves of the *catha edulis forsk* plant, and is structurally related to amphetamine, noradrenaline, and ecstasy (MDMA). The main ingredients of the Khat plant are cathinone and cathine. It is chewed or ingested for its euphoric effects, and is also used to improve performance (Ali et al., 2010). It has central nervous system stimulatory effects derived from the cathinone found in the leaves. It appears to increase the amount of noradrenaline in synapses in the peripheral vasculature, which causes increased stimulation of alpha receptors and amine-associated receptors (Al-Motarreb et al., 2010). Cardiovascularly, khat increases diastolic blood pressure and also increases inotropic and chronotropic effects (Al-Motarreb, 2004). Those who chew khat for longer than 6 h each day are at an increased risk for acute myocardial infarction. There does not appear to be a direct effect of khat on the myocardium, but it is thought that the relationship between khat's vasoconstrictive effects and sympathetic effects may mediate cardiomyopathy and MI as previously described (El-Menyar et al., 2015).

Similar to amphetamine, cathinone causes coronary artery vasospasm, and it also causes a prothrombotic state that can lead to infarction. There are also associations between khat usage and increased prevalence of cardiac arrhythmia. A study done in Yemen, the country with the highest percentage of khat users, used Holter monitoring to track for occurrences of arrhythmia in khat users, with and without underlying cardiac disease. The study revealed a higher prevalence of ventricular tachyarrhythmias (mostly NSVT) in both populations on days where khat was ingested (Jayed and Al-Huthi, 2016). The researchers involved in this particular study even went as far as to suggest prophylactic low dose beta-blocker to prevent arrhythmia in heavy users of khat.

Anabolic and Androgenic Steroids

Exogenous anabolic and androgenic steroids (AAS) are synthetic derivatives of testosterone originally developed in the late 1930s. The chemical structure is derived from cholesterol that is synthesized in the liver, and then metabolized in the adrenal glands and testes to AAS. It is estimated that more than 3 million individuals in the United States abuse AAS. This abuse led Congress to add AAS to Schedule 3 of the Controlled Substances Act (Achar et al., 2010). AAS can be administered orally, parenterally, and transdermally, and act by binding to the nuclear androgen receptor in the cytoplasm, and then translocate into the nucleus. This binding results in sequential conformational changes of the receptor affecting the interaction between receptors and proteins. The basic structure of all AAS is a perhydrocyclopentano phenanthrene ring. Modification of structures side chains allows for production of different designer drugs within this class (Frati et al., 2015).

AAS were also noted as drugs of abuse as early as the mid-1950s, when it was discovered that a championship weightlifting team from the Soviet Union were taking these supplements to contribute to their skeletal muscle strength and weightlifting ability (Golestani et al., 2012). Since that time, AAS have continued to be used drugs of abuse, especially in competitive athletes. It is the most commonly found prohibited substance found in drug tests across the spectrum of different sports. AAS have a number of proven cardiovascular side effects. They have been shown to increase resting diastolic and systolic blood pressures (Grace et al., 2003). AAS also cause a dose-dependent increase in low-density lipoproteins (LDL) and a dose-dependent decrease in cardioprotective high-density lipoproteins (HDL) (Baggish et al., 2010). Supratherapeutic doses of AAS also seem to contribute to decreased ability of coronary arteries to vasodilate, and may promote platelet aggregation through increased expression of thromboxane A2 receptors.

Exogenous AAS have also been shown to contribute to increased left ventricular hypertrophy (LVH) (Baggish et al., 2010). This is thought to be not only by increasing blood pressure, but also through direct stimulation of androgen receptors on cardiac myocytes that cause LVH. Additionally, postmortem studies of those with a history of AAS abuse do show evidence of myocardial fibrosis and cardiac steatosis. This hypertrophy creates a substrate which is more conducive to cardiac arrhythmia with resultant sudden cardiac death (Payne et al., 2004).

Chart: Commonly used recreational drugs and main cardiovascular effects

Drug type	*Physiologic effects*	*Myocardium effects*	*Arrhythmia*	*Valvular*
Ethanol	Acutely: - high heart rate - low stroke volume Chronic usage: - impaired baroreceptor function- increased sympathetic activity - decreased endothelial nitric oxide production	- Increased end-systolic and diastolic LV volumes - Posterior LV wall thickening - Decrease in ejection fraction - Dilated cardiomyopathy	- With nutritional deficiencies, increased risk of ventricular tachycardia, torsades de pointes. - Ingestion of >3 alcoholic drinks a day linked to increased risk for atrial fibrillation	N/A

(*Continued*)

(Continued)

Drug type	*Physiologic effects*	*Myocardium effects*	*Arrhythmia*	*Valvular*
Marijuana	- Increased heart rate - Postural hypotension - Higher incidence of ischemic stroke	- Increased risk of myocardial infarction in time period directly after inhalation	Atrial fibrillation	N/A
Cocaine	- Increased blood pressure - Vasospasm - Platelet activation - Increased vWf activity - Increased thrombosis	- Increased cardiac contractility - Dilated cardiomyopathy - Higher risk for myocardial infarction	- Activity similar to IC antiarrhythmic. - Prolongs effective refractory period, prolongs PR, QRS, QT	- Endocarditis risk in users of intravenous cocaine
Stimulants	- Increased heart rate - Increased blood pressure	- Hypertrophic cardiomyopathy - Dilatory cardiomyopathy - Myocyte fibrosis and necrosis	- QTc prolongation	- Right heart valvulopathy, hyperplasia - Pulmonary artery hypertension
Opioids	- Decreased respiratory drive - Slowed heart rate	- Possibly cardioprotective effects postinfarction	- Prolonged QTc	- Endocarditis risk in users of intravenous opioids
MDMA	- Increased blood pressure - Increased heart rate	- Increased oxidative stress - Increased contraction band necrosis	- Supraventricular tachycardia	- Heart valve hyperplasia

Cardiovascular disease (CVD) is the leading noncommunicable disease (NCD), and caused nearly half of deaths due to NCD (Mendis et al., 2011). To prevent CVD, it is necessary to improve lifestyles and constitutional risk factors such as hypertension, diabetes, and dyslipidemia. The guidelines for prevention of CVD recommend smoking cessation, increased physical activity, weight control, and dietary modifications. Dietary modifications include reduced intakes of total fat, saturated fat, and salt, and increased intakes of fruits and vegetables (World Health Organization, 2007). Diet is an important factor to prevent CVD because habitually diets influence various body metabolisms that are involved in the pathogeneses of CVD. The present review focuses on intakes of fruits and vegetables.

Several studies have shown that higher intakes of fruits and vegetables have been associated with lower risk of CVD, coronary heart disease (CHD), and stroke (**Table 1**). A metaanalysis has shown statistically significant inverse associations between intakes of fruits and vegetables and the risk of CHD in Americans and Europeans, indicating that the pooled relative risks (RRs) and 95% confidence intervals (95%CIs) of CHD for one-portion/day increment were 0.96 (0.93–0.99) in total fruit/vegetable intakes, 0.93 (0.89–0.96) in fruit intakes and 0.89 (0.83–0.95) in vegetable intakes (Dauchet et al., 2006). Two metaanalyses have also reported that intakes of fruits and vegetable were inversely associated with the risk of stroke in Americans, Europeans, and Asians (Dauchet et al., 2005; He et al., 2006), and a subgroup analysis for risk of stroke showed that intakes of total fruits/vegetables had significant protective effect on risk of both ischemic and hemorrhagic strokes; the pooled RRs (95%CIs) of subjects who took fruit and vegetable more than five servings per day were 0.72 (0.66–0.79) and 0.73 (0.61–0.87), compared with subjects who took them less than three servings per day, respectively (He et al., 2006). In a British survey, those who ate more than three portions of total fruits/vegetables daily were significantly at lower risk of mortality from CVD in a dose-response manner; the hazard ratios (HRs) (95%CIs) were 0.82 (0.70–0.95) for 3–5 portions, 0.80 (0.66–0.96) for 5–7 portions, and 0.69 (0.53–0.88) for 7+ portions compared with those who ate <1 portion per day (Oyebode et al., 2014). After further adjustment for intakes of other foods in two Asian cohort studies, the inverse association between intakes of fruits and vegetables with mortality from CVD was significant; HR (95%CI) was 0.74 (0.61–0.91) for the highest quartile of fruit and vegetable intake, compared with the lowest (Okuda et al., 2015), and 0.77 (0.67–0.88) for the highest quartile of fruit intake, compared with the lowest (Nagura et al., 2009). A subgroup analysis by fruits intake in the UK Women's Cohort Study showed that higher intakes of fresh fruit but not dried fruit or fruit juice was associated with

Lai et al. (2015) UK women	UKWCS	30,458 women	35–69	Prospective study	16.7	Dietary intake by FFQ	Age, BMI, physical activity, smoking status, socioeconomic status, alcohol intake, total vegetable intake, and mutual adjustments for fruits that are not in the exposure category	HR = 0.57 (0.34–0.95) of CVD mortality for the highest vs. lowest quintiles of total fruit intake HR = 0.70 (0.35–1.40) of stroke mortality for the highest vs. lowest quintiles of total fruit intake HR = 0.45 (0.21–0.97) of CHD mortality for the highest vs. lowest quintiles of total fruit intake For CVD mortality, HR = 0.56 (0.33–0.96) for fresh fruit, 0.85 (0.53–1.37) for dried fruit, and 0.81 (0.52–1.27) for fruit juice (comparing the highest vs. lowest quintiles) For stroke mortality, HR = 0.78 (0.38–1.59) for fresh fruit, 0.93 (0.48–1.81) for dried fruit and 0.67 (0.35–1.29) for fruit juice (comparing the highest vs. lowest quintiles) For CHD mortality, HR = 0.39 (0.18–0.87) for fresh fruit, 0.79 (0.40–1.54) for dried fruit and 0.99 (0.53–1.85) for fruit juice (comparing the highest vs. lowest quintiles)

ARIC, Arosclerosis Risk in Communities Study; *ATBC*, Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study; *BLSA*, Baltimore longitudinal study of aging; *BMI*, body mass index; *CHD*, coronary heart disease; *DDCH*, Danish Diet, Cancer and Health study; *FFQ*, food frequency questionnaire; *HPFS*, Health Professionals Follow-up Study; *HR*, hazard ratio; *IDF*, insoluble dietary fiber; *JACC*, Japan Collaborative Cohort Study; *LSS*, Life Span Study (Hiroshima/Nagasaki); *NHANES*, National Health and Nutrition Examination Survey; *NHS*, Nurses' health study; *PHS*, Physicians' health study; *RR*, relative risk; *SDF*, soluble dietary fiber; *TDF*, total dietary fiber; *UKWCS*, United Kingdom Women's Cohort Study; *WHS*, Women's Health Study.

lower mortality from CVD; the HRs (95%CIs) were 0.56 (0.33–0.96) for the highest versus lowest quintile of fresh fruits, 0.85 (0.53–1.37) for dry fruits, and 0.81 (0.52–1.27) for fruits juice (Lai et al., 2015). Therefore, higher intakes of fruits and vegetables might have a role in the prevention of CVD, stroke, and CHD.

Through antioxidant effects of vitamins, metabolism-control effect of minerals, and cholesterol-lowering effect of dietary fiber, vegetables and fruits have been postulated in many epidemiological and clinical studies as biological explanations for reducing the risk of CVD.

In this review, we summarize the results of epidemiological studies, which examined the associations between these nutrients intakes with the risk of CVD.

Antioxidant Vitamins

The preventive effects of vegetables and fruits on CVD events such as CHD and stroke have been potentially attributed to the reduced oxidative stress by antioxidants (Asplund, 2002). Carotenoids such as α- and β-carotene and vitamin C exert antioxidant functions by quenching singlet molecular oxygen or free radicals (Tapiero et al., 2004). Vitamin C also reverses endothelial vasomotor dysfunction in the circulatory system (Levine et al., 1996). Vitamin E is an important natural antioxidant which protects against the oxidation of biomembrane lipids, thereby maintaining the stability of the biomembranes (Burlakova et al., 1998). The most common and biologically active form of vitamin E is α-tocopherol, which accounts for 90% of total vitamin E in tissues (Engin, 2009). Here we focus on prospective observational studies that have discussed the associations of dietary and supplemental intakes of these vitamins with the risk of CVD. The interventional studies of vegetables and fruits are summarized in the other section.

Carotenoids

Prospective studies on associations between carotenoid intake and CVD are summarized in **Table 2**. A pooled analysis of nine cohort studies reported no association between intakes of total and specific carotenoid with risk of major CHD events (Knekt et al., 2004). Among eight prospective cohort studies on CHD mortality and incidence (Buijsse et al., 2008; Genkinger et al., 2004; Klipstein-Grobusch et al., 1999; Knekt et al., 1994; Kushi et al., 1996; Osganian et al., 2003; Rimm et al., 1996; Sahyoun et al., 1996), two studies have reported a statistically significant lower risk of CHD incidence for the highest versus lowest quintiles of dietary carotenoid intake; among US male health professionals; the RR (95%CI) for carotene intake was 0.71 (0.53–0.86) (Rimm et al., 1993); among US women; the RRs (95%CI) were 0.80 (0.65–0.99) for alpha-carotene intake and 0.74 (0.59–0.93) for beta-carotene intake. Another study among Dutch elderly men reported inverse associations between dietary carotenoid intake and risk of CVD mortality; the RRs (95%CI) for the highest versus the lowest tertile of intake were 0.82 (0.69–0.98) for total carotenoid, 0.81 (0.66–0.99) for alpha-carotene, and 0.80 (0.66–0.97) for beta-carotene (Buijsse et al., 2008). However, some other studies reported no associations for total or specific carotenoids intakes with the risk of CVD. Among eight prospective cohort studies on stroke mortality and incidence (Ascherio et al., 1999; Daviglus et al., 1997; Del Rio et al., 2011; Hirvonen et al., 2000; Keli et al., 1996Ross et al., 1997; Voko et al., 2003; Yochum et al., 2000), a couple of studies have reported a lower risk of stroke incidence with specific carotenoid intakes; reduced risk of incident ischemic stroke was observed for the highest versus lowest quartiles of dietary lutein intake among US health professionals (Ascherio et al., 1999); the RR (95%CI) was 0.63 (0.40–0.99). Another study among Finnish male smokers reported a lower risk of cerebral infarction incidence in the highest versus lowest quartiles of dietary beta-carotene intake and lycopene intake; the RRs (95%CIs) were 0.74 (0.60–0.91) for beta-carotene intake and 0.74 (0.59–0.92) for lycopene intake. Dietary lycopene was also associated with a lower risk of intracerebral hemorrhage incidence in the same study; the RR (95% CI) for the highest versus lowest quartiles was 0.45 (0.24–0.86) (Hirvonen et al., 2000).

Vitamin C

Prospective studies on the associations between vitamin C intake and CVD are summarized in **Table 3**. A pooled analysis of nine cohort studies reported positive association between risk of major CHD events and dietary vitamin C intake even after adjusting for various confounders; the RR (95%CI) for the highest quintile of intake to the lowest was 1.23 (1.04–1.45) (Knekt et al., 2004). Among 10 studies which reported association between vitamin C and heart disease incidence and mortality (Buijsse et al., 2008; Gale et al., 1995; Genkinger et al., 2004; Klipstein-Grobusch et al., 1999; Knekt et al., 1994; Kubota et al., 2011; Kushi et al., 1996; Osganian et al., 2003; Rimm et al., 1993; Sahyoun et al., 1996), only one study reported a statistically significant inverse association between vitamin C intake and incident CHD among women; the RR (95%CI) for the highest quintile to the lowest was 0.63 (0.41–0.97) (Kubota et al., 2011), while the others reported null association.

A metaanalysis of 12 prospective studies reported statistically significant inverse associations between risk of stroke and dietary vitamin C intake; the RR (95%CI) for the higher versus lower intakes of vitamin C was 0.81 (0.74–0.90) and the RR (95%CI) for an increment of 100 mg/day in dietary vitamin C intake was 0.83 (0.75–0.93) (Chen et al., 2013a). Among 10 prospective cohort studies on stroke mortality and incidence (Ascherio et al., 1999; Daviglus et al., 1997; Del Rio et al., 2011; Gale et al., 1995; Hirvonen et al., 2000; Keli et al., 1996; Kubota et al., 2011; Ross et al., 1997; Voko et al., 2003; Yochum et al., 2000), three studies have indicated statistically significant inverse associations; a significant lower risk of stroke mortality was found for the highest

Table 2 Carotenoid intake from foods and the risk of cardiovascular disease

Published year study population	*Study name or setting*	*Sample size*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure*	*Adjusted variables*	*Relative risk*
Rimm et al. (1993) US male health professionals	HPFS	39,910	40	Prospective cohort	4	Intake from foods by FFQ (carotene)	Age, smoking status, BMI, total calories, dietary fiber, alcohol consumption, reported hypertension, regular aspirin use, physical activity, parental history of myocardial infarction before age 60, profession, and intakes of vitamin C and E	RR = 0.71 (0.53–0.86) for coronary heart disease risk (comparing the highest vs. lowest quintiles of carotene intake)
Knekt et al. (1994) Finnish men and women	FMCS	5133	35	Prospective cohort	14	Dietary intake by diet history	Age, smoking, serum cholesterol, hypertension, BMI, and energy intake	For coronary heart disease mortality, RRs = 1.02 (0.70–1.48) for men, 0.62 (0.30–1.29) for women (comparing the highest vs. lowest tertiles of carotenoid intake)
Sahyoun et al. (1996) noninstitutionalized Massachusetts residents	Nutrition Status Survey	725	60	Prospective cohort	9	Intake from foods and supplements by dietary records	Age, sex, disease status, disabilities affecting shopping	RR = 0.64 (0.33–1.27) for heart disease mortality (comparing the highest vs. lowest tertiles of carotenoid intake)
Kushi et al. (1996) US postmenopausal women	IWHS	41,836	7	Prospective cohort	55	Dietary intake by FFQ	Age, total energy intake, BMI, waist-to-hip ratio, pack-years of cigarette smoking, hypertension, diabetes mellitus, oral contraceptive use, estrogen replacement therapy, physical activity, alcohol intake, marital status, and level of educational attainment	For CHD mortality, RRs = 1.22 (0.76–1.96) for vitamin A, 0.80 (0.50–1.28) for retinol, 1.03 (0.63–1.70) for carotenoids (comparing the highest vs. lowest quintiles)
Keli et al. (1996) Dutch men	ZES	552	50	Prospective cohort	15	Dietary intake by diet history	Age, average systolic blood pressure, serum cholesterol, energy intake, lifetime cigarette smoking exposure, fish consumption, and alcohol consumption habits	RR = 0.54 (0.22–1.33) for stroke, comparing the highest group (>1.37 mg/day) to the lowest (<1.01 mg/day) of beta-carotene intake
Daviglus et al. (1997) Middle-aged US men	Chicago Western Electric Study	1843	40	Prospective cohort	30	Dietary intake by diet history questionnaire	Age, systolic blood pressure, number of cigarettes smoked per day, body mass index, serum cholesterol, total energy intake, alcohol consumption, and diagnosis of diabetes	RR = 0.84 (0.57–1.24) for the risk of stroke (comparing the highest vs. lowest tertiles of beta-carotene intake)
Ross et al. (1997) Chinese men	Shanghai, People's	18,244	45	Prospective cohort	8		Education, marital status, body mass index, lifetime	RR = 1.0 (0.7–1.5) for stroke mortality (comparing the highest vs. lowest tertiles of carotene intake)

	Republic of China					Dietary intake by FFQ (total carotene)	cigarette use, lifetime ethanol intake, and history of hypertension	
Klipstein-Grobusch et al. (1999) Dutch men and women	The Rotterdam Study	5159	4	Prospective cohort	55	Dietary intake by FFQ	Age, sex, body mass index, pack-years, equivalent household income, education, alcohol intake, use of antioxidative vitamin supplements, and categories of energy-adjusted b-carotene, vitamin C, and vitamin E intakes	For the risk of myocardial infarction, RR = 0.55 (0.34–0.83) for beta-carotene (comparing the highest vs. lowest tertiles of intake)
Ascherio et al. (1999) Male health professional	HPFS	43,738	40	Prospective cohort	8	Dietary intake by FFQ	Age, smoking, hypertension, hypercholesterolemia, body mass index, physical activity, parental history of myocardial infarction, alcohol consumption, and total energy intake	For total stroke, RRs = 0.77 (0.54–1.08) for beta-carotene, 0.94 (0.66–1.34) for alpha-carotene, 0.70 (0.49–1.01) for lutein, 1.01 (0.65–1.57) for lycopene. For ischemic stroke, RRs = 0.86 (0.56–1.32) for beta-carotene, 1.11 (0.73–1.70) for alpha-carotene, 0.63 (0.40–0.99) for lutein, 0.96 (0.68–1.36) for lycopene For hemorrhagic stroke, RRs = 0.76 (0.36–1.60) for beta-carotene, 0.50 (0.22–1.13) for alpha-carotene, 0.88 (0.40–1.92) for lutein, 1.04 (0.52–2.07) for lycopene (comparing the highest vs. lowest quartiles of intake)
Yochum et al. (2000) Postmenopausal women	IWHS	34,492	55	Prospective cohort	N/A	Dietary intake by FFQ (vitamin A, retinol, carotenoids)	Age, total energy intake, BMI, waist-to-hip ratio, high blood pressure, diabetes, use of estrogen replacement therapy, alcohol intake, education, marital status, pack-years of smoking, physical activity level, and intakes of cholesterol, saturated fat, fish, vitamin E, vitamin C, dietary fiber, and whole grains	For stroke mortality, RRs = 1.09 (0.62–1.92) for vitamin A, 0.86 (0.52–1.41) for retinol, and 0.88 (0.50–1.54) for carotenoids (comparing the highest vs. lowest quintiles of intake)
Hirvonen et al. (2000) Finnish male smokers	ATBC	26,593	50	Prospective cohort	6.1	Dietary intake by diet history	Age, supplementation group, systolic and diastolic blood pressures, serum total cholesterol, serum HDL cholesterol, body mass index, height, smoking years, number of cigarettes daily, history of diabetes or coronary heart disease, alcohol intake, and education	For cerebral infarction, RRs = 0.74 (0.60–0.91) for beta-carotene, 0.81 (0.66–1.00) for lutein + zeaxanthin, 0.74 (0.59–0.92) for lycopene (comparing the highest vs. lowest quartiles) For subarachnoid hemorrhage, RRs = 0.67 (0.35–1.28) for beta-carotene, 0.47 (0.24–0.93) for lutein + zeaxantin, 0.63 (0.33–1.20) for lycopene (comparing the highest vs. lowest quartiles) For intracerebral hemorrhage, RRs = 0.66 (0.36–1.19) for beta-carotene, 0.81 (0.46–1.43) for lutein + zeaxantin, 0.45† (0.24–0.86) for lycopene (comparing the highest vs. lowest quartiles)

For the risk of coronary heart disease, HRs = 0.86 (0.57–1.31) among men and 0.63 (0.41–0.97) among women. For the risk of total cardiovascular disease, HRs = 0.88 (0.72–1.07) among men and 0.79 (0.66–0.94) among women (comparing the highest vs. lowest quintiles)
Del Rio et al. (2011) Italian men and women	EPIC-Italian	41,620	Not shown	Prospective cohort	7.9	Dietary intake by FFQ	Stratified by center, sex, and age. Adjusted for energy, hypertension, smoking status, education, nonalcohol energy intake, alcohol drinking, waist circumference, obesity, and physical activity	HRs = 0.89 (0.60–1.32) for all types of strokes, 0.58 (0.34–0.99) for ischemic stroke, 1.93 (0.84–4.42) for hemorrhagic stroke (comparing the highest vs. lowest tertiles)

Chen et al. (2013a) 12 prospective studies (6 in Europe, 3 in the US, and 3 in Asia)	ATBC, CVDFACTS, EPIC-Italian, HPFS, IWHS, JACC, WES, the Rotterdam Study, the Zutphen study, cohort of men in Shanghai, China, cohort of men and women lining in eight areas in Britain, cohort of Finnish men and women	29,648	N/A	Metaanalysis	9.5–20	Intake (foods) by FFQ		RR = 0.81 (0.74–0.90) of the risk of stroke for the higher vs. lower intakes. RR = 0.83 (0.75–0.93) of the risk of stroke for an increment in dietary vitamin C intake of 100 mg/day

BMI, body mass index; *FFQ*, food frequency questionnaire; *NHS*, Nurses' health study; *RR*, relative risk; *AHS*, Adventist Health Study; *ARIC*, Arosclerosis Risk in Communities Study; *ATBC*, Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study; *CVDFACTS*, CardioVascular Disease risk FACtor Two-township Study; *EPIC*, European Prospective Investigation into Cancer and Nutrition; *FMC*, Finnish Mobile Clinic Health Examination Survey; *GPS*, Glostrup Population Study; *HPFS*, Health Professionals Follow-Up Study; *IWHS*, Iowa Women's Health Study; *JACC*, Japan Collaborative Cohort Study; *NHS*, Nurses' Health Study; (a) 1980–1986; (b) 1986–1996; *VIP*, Vasterbotten Intervention Program; *WES*, Western Electric Study; *ZES*, Zutphen Elderly Study.

intake group (44.9 mg) versus the lowest (27.9 mg) of dietary vitamin C among British men and women; the RR (95%CI) was 0.4 (0.2–0.6) (Gale et al., 1995); a significant lower risk of intracerebral hemorrhage incidence was found for the highest versus lowest quartiles of dietary vitamin C intake among Finnish male smokers; the RR (95%CI) was 0.39 (0.21–0.74) (Hirvonen et al., 2000); and a significant lower risk of ischemic stroke incidence was found for the highest versus lowest tertiles of dietary intake of vitamin C among Italian men and women; the RR (95%CI) was 0.58 (0.34–0.99) (Del Rio et al., 2011).

Vitamin E

Prospective studies on vitamin E intake and CVD are summarized in **Table 4**. A pooled analysis of nine cohort studies reported significant lower risk of major CHD events for the highest versus lowest quintiles of dietary vitamin E intake after adjusting for age and energy intake. After further adjustment for other confounders, the association remained statistically significant for women but not for men. Altogether, the association was marginally significant; the RR (95%CI) for the highest versus lowest quintiles of intakes was 0.84 (0.71–1.00) (Knekt et al., 2004). Among nine prospective cohort studies on heart disease mortality and incidence (Buijsse et al., 2008; Genkinger et al., 2004; Klipstein-Grobusch et al., 1999; Knekt et al., 1994; Kubota et al., 2011; Kushi et al., 1996; Rimm et al., 1993; Sahyoun et al., 1996; Stampfer et al., 1993), three studies reported statistically significant lower risks of CHD incidence and mortality for higher intakes of vitamin E (alpha-tocopherol); lower risk of CHD incidence was observed for the highest versus lowest quintiles among US health professionals (Rimm et al., 1993); the RR (95%CI) was 0.60 (0.44–0.81), and lower risk of CHD mortality was observed for the highest versus lowest quintiles of vitamin E intakes among Finnish women (Knekt et al., 1994) and US postmenopausal women (Kushi et al., 1996); the RRs (95%CIs) were 0.35 (0.14–0.88) for Finnish women and 0.38 (0.20–0.80) for US postmenopausal women.

Among eight prospective cohort studies on stroke mortality or incidence (Ascherio et al., 1999; Del Rio et al., 2011; Hirvonen et al., 2000; Keli et al., 1996; Kubota et al., 2011, Ross et al., 1997; Voko et al., 2003; Yochum et al., 2000), one study reported a statistically significant lower risk of stroke mortality for the highest versus lowest quintiles of dietary vitamin E intake among US postmenopausal women; the RR (95%CI) was 0.41 (0.20–0.80) (Yochum et al., 2000).

Comment

We reviewed the associations between antioxidant vitamin intakes and risk of CVD. Higher dietary intake of vitamin C and E tended to be inversely associated with risk of CVD. The evidence of protective effect of dietary carotenoid intake on risk of CVD is limited. Further epidemiological studies to clarify the associations between antioxidant vitamins and risk of CVD are needed.

Minerals

Dietary minerals, rich in vegetables and fruits, consist of major minerals and trace minerals. Major minerals include sodium, magnesium, phosphorous, sulfur, chlorine, potassium, and calcium, and trace minerals include iron, zinc, copper, and so on. Of them, iron and zinc account for large proportions of trace minerals in the human body.

In this section, we review the association between dietary minerals intake and risk of CVD.

Tables 5–11 include the summary of the associations between mineral intakes and the risk of CVD, CHD, and stroke.

Major Minerals

Magnesium

A recent metaanalysis showed that dietary magnesium intake was inversely associated with risk of CVD events including incidence and mortality; a 100 mg/day increment of dietary magnesium intake was inversely associated with risk of CVD events; the pooled RR (95%CI) was 0.91 (0.86–0.96) (Qu et al., 2013). However, the association between magnesium intake and the risk of CVD seemed not to be linear. The risk-lowering effect of magnesium intake seemed to be strong between subjects whose daily magnesium intake was low (between 150 and 400 mg) (Qu et al., 2013). As for CHD, two prospective studies have examined the association between dietary magnesium intake/urinary excretion and CHD incidence and mortality (Chiuve et al., 2013; Joosten et al., 2013). Dietary magnesium intake was inversely associated with mortality from CHD, but not with the incidence of CHD in American women (Chiuve et al., 2013). Urinary magnesium excretion, an index of magnesium intake, was inversely associated with the incidence of ischemic heart disease in the Netherlands (Joosten et al., 2013). As for stroke, dietary magnesium intake was inversely associated with the incidence of total stroke, but not of ischemic and hemorrhagic strokes (Adebamowo et al., 2015). Total magnesium intake was not associated with the incidence of stroke and its subtypes (Adebamowo et al., 2015). A possible threshold effect of magnesium intake was suggested for its association with risk of CHD and stroke (Chiuve et al., 2013; Joosten et al., 2013). In these studies, the mortality from CHD and the incidence of total CHD were almost 35% and 40% respectively higher in the lowest quintile of magnesium intake/excretion, while it was even in other higher intake categories from the second to the highest quintile.

Table 4 Vitamin E intake from foods and the risk of cardiovascular disease

Published year study population	*Study name or setting*	*Sample size*	*Age at entry*	*Study design*	*Follow-up years*	*Exposure*	*Adjusted variables*	*Relative risk*
Stampfer et al. (1993) US women	NHS	87,245	35	Prospective cohort	8	Intake from foods by FFQ	Age, smoking	RR = 0.95 (0.72–1.23) for coronary heart disease risk, comparing highest quintile to the lowest
Rimm et al. (1993) US male health professionals	HPFS	39,910	40	Prospective cohort	4	Intake from foods by FFQ	Age, smoking status, BMI, total calories, dietary fiber, alcohol consumption, reported hypertension, regular aspirin use, physical activity, parental history of myocardial infarction before age 60, profession, and intakes of carotene and vitamin C	RR = 0.60† (0.44–0.81) for coronary heart disease risk, comparing highest quintile to the lowest
Knekt et al. (1994) Finnish men and women	FMCS	5133	35	Prospective cohort	14	Dietary intake by diet history	Age, smoking, serum cholesterol, hypertension, BMI, and energy intake	For coronary heart disease mortality, RR = 0.68 (0.42–1.11) for men, 0.35 (0.14–0.88) for women, comparing the highest tertile to the lowest
Sahyoun et al. (1996) Noninstitutionalized Massachusetts residents	Nutrition Status Survey	725	60	Prospective cohort	9	Intake from foods and supplements by dietary records	Age, sex, disease status, disabilities affecting shopping	RR = 0.75 (0.41–1.39) for heart disease mortality, comparing highest tertile to the lowest
Keli et al. (1996) Dutch men	ZES	552	50	Prospective cohort	15	Dietary intake by diet history	Age, average systolic blood pressure, serum cholesterol, energy intake, lifetime cigarette smoking exposure, fish consumption, and alcohol consumption habits	RR = 1.64 (0.54–4.97) for stroke, comparing the highest group ($\geq$21.3 mg/day) to the lowest ($<$14.4 mg/day)
Kushi et al. (1996) US postmenopausal women	IWHS	34,486	7	Prospective cohort	55	Intake from foods by FFQ	Age, total energy intake, BMI, waist-to-hip ratio, pack-years of cigarette smoking, hypertension, diabetes mellitus, oral contraceptive use, estrogen replacement therapy, physical activity, alcohol intake, marital status, and level of educational attainment	For coronary heart disease mortality, RR = 0.38 (0.20–0.80) (comparing highest quintile to the lowest)

Bates et al. (2011) British men and women	The British National Diet and Nutrition Survey	1054 (men and women)	76.6 (mean)	Prospective study	Not shown	Dietary copper intake measured by weighed dietary record of 4 days	Age, sex	HR = 0.92 (0.78–1.10) of the vascular disease mortality for the 1 mg/day increment of copper intake

HR, hazard ratio.

Phosphorous

The evidence between phosphorous intake and risk of CVD is very limited. A prospective study of Americans has shown a U-shaped relation between dietary phosphorous density (mg/kcal) and mortality from CVD (Chang et al., 2014).

Sulfur

There are no epidemiological studies that have examined the association between sulfur intake and risk of CVD so far.

Potassium

A metaanalysis showed that dietary potassium intake was not associated with incidence of CVD or CHD, while dietary potassium intake was inversely associated with incidence of stroke (Aburto et al., 2013). The pooled RR (95%CI) of the protective effect of the higher versus lower potassium intakes on risk of incident stroke was 0.76 (0.66–0.89) (Aburto et al., 2013). A recent report for the prospective study of American women showed that, compared with the lowest quintile of dietary potassium intake, the highest quintile had the lower multivariable-adjusted risk of total and ischemic strokes (Adebamowo et al., 2015); the pooled RRs (95% CIs) for the highest versus lowest quintiles of dietary potassium intake were 0.88 (0.79–0.98) for total stroke and 0.86 (0.74–1.00) for ischemic stroke. However, the association was no longer significant after further adjustment for magnesium and calcium intake (Adebamowo et al., 2015).

Calcium

A metaanalysis showed that dietary and supplemental calcium intakes were not associated with incidence and mortality of CHD or total stroke (Wang et al., 2012). A prospective study of American women showed no significant association between dietary and total calcium intake with incidence of total, ischemic, and hemorrhagic strokes (Adebamowo et al., 2015). However, several prospective studies of Asians, whose dietary calcium intake was lower than that of Westerners, showed that dairy calcium intake was inversely associated with incidence and mortality of stroke (Abbott et al., 1996; Umesawa et al., 2006, 2008). For Westerners, a prospective study of American women showed an inverse association between dairy calcium intake and incidence of stroke; the multivariable HR (95%CI) of total stroke for the highest versus lowest quintiles of dairy calcium intake was 0.70 (0.51–0.97) (Iso et al., 1999), while a prospective study of American men did not show a significant association between them (Ascherio et al., 1998).

A metaanalysis, which examined an effect of calcium supplementation on the risk of CVD incidence and mortality, showed unexpectedly that calcium supplements without coadministered vitamin D were positively associated with the risk of myocardial infarction (MI); the pooled RR (95%CI) of incident MI for calcium supplements versus no supplement was 1.27 (1.01–1.59) (Bolland et al., 2010).

Trace Minerals

Iron

Dietary iron consisted of heme and nonheme irons. Heme iron is rich in meat and fish while nonheme iron is rich in plant foods and eggs. According to a metaanalysis (Hunnicutt et al., 2014), dietary total iron intake was inversely associated with risk of incident CHD; the pooled RR (95%CI) of CHD for the highest versus lowest quintiles of dietary total iron intake was 0.85 (0.73–0.999) (Hunnicutt et al., 2014), while dietary heme iron intake was positively associated with risk of incident CHD; the pooled RR (95% CI) of CHD for the highest versus lowest quintiles of dietary heme iron intake was 1.57 (1.28–1.94) (Hunnicutt et al., 2014). Heme iron, nonheme iron, and total iron intakes were not associated with fatality from CHD (Hunnicutt et al., 2014). A prospective study of British showed that dietary heme iron and nonheme iron intakes were not associated with mortality from CVD (Bates et al., 2011). For stroke, a prospective study of Swedish men showed that dietary nonheme iron intake was not associated with the

incidence of total, ischemic, and hemorrhagic strokes, while dietary heme iron intake was positively associated with the incidence of total and ischemic strokes (Kaluza et al., 2013).

Zinc

A cross-sectional study of Indians showed that low dietary zinc consumption was positively associated with the prevalence of coronary artery disease (Singh et al., 1998). A prospective study, the Multi-Ethnic Study of Atherosclerosis, examined the association between dietary zinc intake and the incidence of CVD (de Oliveira Otto et al., 2012). In that study, dietary zinc intake was not associated with the incidence of CVD, while zinc intake from red meat was positively associated with it; the multivariable-adjusted HR (95%CI) for the highest versus lowest quintiles of zinc intake from red meat was 1.42 (1.07–1.89). However, the association with zinc from red meat was attenuated greatly after adjustment for total heme iron intake; the multivariable HR was 1.36 (0.85–2.17; $P=0.10$) (de Oliveira Otto et al., 2012). As for CVD mortality, a prospective study of British men and women showed that dietary zinc intake was inversely associated with mortality from CVD (Bates et al., 2011); the age and sex-adjusted HR (95%CI) of CVD mortality for the 1-SD increment of dietary zinc intake per day (men: 2.86 mg, women: 2.56 mg) was 0.84 (0.71–0.99). A prospective study of American women showed no association between dietary zinc intake and mortality from CVD (Lee et al., 2005).

Other trace minerals

A metaanalysis showed that serum selenium concentrations were inversely associated with the risk of CHD incidence and mortality, but selenium supplementation was not associated with it (Flores-Mateo et al., 2006).

A prospective study of British men and women showed that dietary copper intake was not associated with mortality from CVD (Bates et al., 2011).

Comment

We reviewed the associations between mineral intakes and risk of CVD incidence and mortality. Magnesium and potassium intakes may be inversely associated with risk of CVD, while heme iron intake has been suggested to be positively associated with risk of CVD. The evidence between trace mineral intake and risk of CVD is limited.

Dietary Fiber

Dietary fiber consists of water-soluble and water-insoluble fibers. The major components of water-soluble dietary fiber were water-soluble pectin and alginic acid, and those of water-insoluble dietary fiber were cellulose, lignin, and water-insoluble pectin.

In this section, we review the associations between dietary fiber intakes and risk of CVD.

Table 12 includes the summary of the associations between dietary fiber intakes and risk of CVD, CHD, and stroke.

Total Dietary Fiber

Three metaanalyses have shown that 7–10 g/daily increment in the intakes of total dietary fiber was associated with lower risk of total CVD, CHD, and stroke; the pooled RRs (95%CIs) were 0.91 (0.88–0.94), 0.91 (0.87–0.94), and 0.93 (0.88–0.98) per 7-g increment respectively, and 0.91 (0.88–0.94) of CVD and 0.89 (0.85–0.93) of CHD per 10-g increment (Kim and Je, 2016; Threapleton et al., 2013b,c). The risk of mortality from CVD, CHD, and stroke in the highest versus lowest category of total dietary fiber intakes was also significant; the pooled RRs (95%CIs) were 0.77 (0.71–0.84), 0.76 (0.67–0.87), and 0.87 (0.77–0.99), respectively (Kim and Je, 2016; Chen et al., 2013b), and when stratified by region, the pooled RRs (95%CIs) of risk of mortality from CVD for the highest versus lowest category intakes of total dietary fiber were 0.71 (0.59–0.86) in Europe, 0.77 (0.65–0.91) in USA, and 0.83 (0.70–0.98) in other regions (Kim and Je, 2016). Furthermore, the significant inverse associations between intakes of total dietary fiber and the incidence of CVD were shown only in nonsmokers; HRs (95%CIs) for the highest quintile of intake to the lowest were 0.59 (0.38–0.90) in men and 0.61 (0.45–0.83) in women, but not in smokers; HRs (95%CIs) were 1.05 (0.79–1.40) in men and 0.58 (0.24–1.39) in women (Kokubo et al., 2011). Because these evidences indicated consistently that intakes of total dietary fiber were associated with lower risk of CVD, CHD, and stroke, increasing intakes of dietary fiber may greatly contribute to the prevention of CVD.

Water-Soluble and Water-Insoluble Dietary Fiber

A metaanalysis reported that highest versus lowest intakes of soluble dietary fiber were associated with reduced risk of mortality from CVD (the pooled RR = 0.85, 95%CI = 0.75–0.96) and CHD (the pooled RR = 0.73, 95%CI = 0.62–0.85), and those of insoluble dietary fiber were also associated with lower risk of mortality from CVD (the pooled RR = 0.77, 95%CI = 0.66–0.90) and CHD (the pooled RR = 0.66, 95%CI = 0.52–0.83) in Americans, Europeans, Australians, and Japanese (Kim and Je, 2016). Intakes of insoluble dietary fiber with 7-g increment were associated with lower risk of CVD (the pooled RR = 0.82, 95% CI = 0.70–0.96) and CHD (the pooled RR = 0.82, 95%CI = 0.68–0.99), respectively, but not significant for those of soluble dietary

fiber (the pooled RRs (95%CIs): 0.88 (0.75–1.03) of CVD and 0.89 (0.78–1.02) of CHD) (Threapleton et al., 2013b). Similarly in US men, each 10-g increment of insoluble but not soluble dietary fiber was inversely associated with the incidence risk of myocardial infarction (MI); the RRs (95%CIs) for the highest quintile of intake to the lowest were 0.75 (0.59–0.94) for insoluble dietary fiber and 1.07 (0.57–2.02) for soluble dietary fiber (Rimm et al., 1996). A cohort study reported that the highest versus lowest quintile of insoluble and soluble dietary fiber intakes were associated with a reduced incidence of CVD in Japanese women; the RRs (95%CIs) were 0.64 (0.47–0.85) for insoluble fiber and 0.74 (0.56–0.97) for soluble fiber, and only insoluble fiber was significantly associated with lower incidence of total stroke (RR = 0.62, 95%CI = 0.45–0.85) and cerebral infarction (RR = 0.62, 95%CI = 0.40–0.98) in women (Kokubo et al., 2011). However in UK women, intakes of both insoluble and soluble were not significantly associated with mortality from CVD, CHD, or stroke (Threapleton et al., 2013a). Accordingly, intakes of soluble or insoluble dietary fiber were likely to associate with lower risk of CVD, CHD, and stroke, but it would be necessary to accumulate more evidence.

Dietary Fiber From Food Source

Two metaanalyses including dietary fiber from different food sources showed that 4–5 g increasing intakes of dietary fiber from vegetables were associated with lower risk of CVD and CHD; the pooled RRs (95%CIs) of CVD were 0.92 (0.87–0.96) per 4 g and 0.92 (0.89–0.95) per 5 g, and those of CHD were 0.94 (0.89–1.00) per 4 g and 0.92 (0.86–0.98) per 5 g), and those from cereals had similar trend for the risk of CVD and CHD; the pooled RRs (95%CIs) of CVD were 0.94 (0.90–0.98) per 5 g and 0.92 (0.84–1.00) per 7 g, and those of CHD were 0.84 (0.76–0.94) per 5 g and 0.84 (0.76–0.94) per 7 g in Americans, Europeans, Australians, and Japanese (Kim and Je, 2016; Threapleton et al., 2013b). In addition, the highest quintile of dietary fiber intakes from nuts and seeds were associated with lower mortality from CVD (RR = 0.61, 95%CI = 0.39–0.96) and stroke (RR = 0.45, 95%CI = 0.23–0.85) in the UK women, when compared to the lowest intakes (Rimm et al., 1996). Two metaanalyses showed that intakes of fiber from fruits per 4–5 g/day increase are likely to be associated with insignificant lower risk of CVD (the pooled RRs (95%CIs): 0.96 (0.93–1.00) per 4-g increment and 0.96 (0.90–1.01) per 5-g increment and CHD (the pooled RRs (95%CI): 0.92 (0.83–1.01) per 4-g increment and 0.89 (0.73–1.10) per 5-g increment (Kim and Je, 2016; Threapleton et al., 2013b). In the highest versus lowest category of fruit fiber intakes, a recent metaanalysis showed significantly a lower risk of CHD mortality (Kim and Je, 2016), and a prospective study of Asians cohort also reported a lower risk of CHD mortality after further adjustment for other types of dietary fibers (cereal and vegetable fibers); the HRs (95%CI) were 0.55 (0.32–0.96) in men and 0.42 (0.33–0.81) in women (Eshak et al., 2010).

Comment

We reviewed the association between dietary fiber intake and the risk of CVD. Intakes of total dietary fiber may be associated with reduced risk of CVD. However the evidence for the associations between soluble and insoluble dietary fiber or dietary fiber from food sources and the risk of CVD needs to be accumulated.

Introduction

The syndrome of heart failure (HF) was once widely considered to be conceptually equivalent and equal to left ventricular systolic dysfunction with reduced left ventricular ejection fraction (LVEF) and compromised contractility. A growing number of patients however would have the bedside clinical syndrome with normal LVEF. This led to the partitioning of HF into two operational and physiological frameworks—HF with reduced ejection fraction (HF*r*EF) was joined by its new comparator, HF with preserved ejection fraction (HF*p*EF).

The HF*r*EF and HF*p*EF distinction is critical as both the underlying pathophysiological drivers of HF subtype and responses to clinical interventions appear distinct (Borlaug, 2011; Paulus and Tschöpe, 2013). The clinical arc of HF*r*EF is altered by neurohormonal blockade provided by oral agents like beta-blockers, angiotensin-converting enzyme inhibitors, aldosterone receptor blockers, neprilysin inhibitors, and mechanical therapies like cardiac resynchronization therapy (CRT) for those with dyssynchrony and concomitant left bundle branch block. By contrast, these therapies fail to confer this benefit to patients with HF*p*EF, leading to static mortality for HF*p*EF patients over time (Massie et al., 2008; Lee et al., 2004). Consequently, LVEF is imperative in driving clinical management in patients with HF.

It has become increasingly recognized that patients with low LVEF can recover and experience substantial improvements in LVEF, which has complicated the HF*r*EF and HF*p*EF dichotomy. This is addressed in the 2013 American College of Cardiology/American Heart Association guidelines, which state the following: "It has been recognized that a subset of patients with HF*p*EF previously had HF*r*EF. These patients with improvement or recovery in EF may be clinically distinct from those with persistently preserved or reduced EF. Further research is needed to better characterize these patients (Yancy et al., 2013)."

This article will summarize existing literature on LVEF recovery and potential clinical and therapeutic implications. Emerging evidence substantiates a distinct clinical arc among patients with LVEF recovery apart from HF*p*EF or HF*r*EF and suggests that HF with recovered LVEF may be a distinct phenotype. How this transitioning population should be classified and treated remains unknown.

Defining Cardiac Remodeling, Remission, and Recovery

The phenomenon whereby a patient with a reduced LVEF subsequently has a higher LVEF has been variably termed improved EF, better EF, and recovered EF (Punnoose et al., 2011; Stevenson, 2014). LVEF recovery highlights the dynamic nature of cardiac function and has reintroduced concepts old and new into the HF vernacular. Because LVEF recovery can be ascertained relatively easily, it has been the focus of most existing clinical studies. However, it is important to define the relationship between LVEF recovery, cardiac remodeling/reverse remodeling, and myocardial remission and recovery.

We define cardiac remodeling as those myocardial adaptations that change the shape, mass, and function of the ventricle. Cardiac remodeling can be both physiological, as seen in elite exercising athletes, and pathological as seen in hypertensive and postinfarction individuals. Reverse remodeling can then be used to describe the reversal of those adaptations, and in this article, we use it to describe the reversal of pathological remodeling. While LVEF recovery is one metric by which reverse remodeling can be

 https://doi.org/10.1016/B978-0-12-809657-4.11048-8

ascertained, other structural abnormalities are not encompassed by LVEF alone, including LV hypertrophy, LV dilation, shape, and sphericity.

Hellawell and Margulies review how reverse remodeling can occur in specific cardiomyopathies from the improvements in LVEF seen in peripartum cardiomyopathy to the improvements that occur after alcohol cessation in patients with alcohol-related cardiomyopathy (Hellawell and Margulies, 2012). Reverse remodeling can occur spontaneously in some cases or in response to medical or device therapies as described in the section to follow. It has been recognized that reverse remodeling is associated with the normalization of underlying molecular and cellular changes that drive remodeling; however, it is important to acknowledge that myocardial recovery is not synonymous with reverse remodeling or LVEF recovery (Mann and Burkhoff, 2012). The term myocardial recovery is reserved for those who both normalize LVEF and appear to have a functional cure from HF by being free of future cardiovascular events. Indeed, in the sections to follow, we show that most patients with LVEF recovery likely carry with them the legacy of HF with residual risk of cardiovascular events and thus more appropriately can be considered to have myocardial remission, rather than myocardial recovery (Fig. 1).

Although LVEF oversimplifies its physiological underpinnings, in the current landscape, where it classifies and guides treatment in HF, it has inherent value in discussing myocardial remission and recovery. LVEF improvement implies the active unraveling of the adverse adaptations of cardiac remodeling that occur in the failing heart. The reversal of these adaptations in the heart with improvements in shape, size, and function, we refer to reverse remodeling. In patients with chronic systolic HF, LVEF improvement therefore is nearly forme fruste of myocardial reverse remodeling. For the remainder of this article, we therefore examine LVEF recovery, with the understanding that this likely implies myocardial reverse remodeling and myocardial remission. Given that these patients appear distinct from those with persistent HF*r*EF or HF*p*EF, we will also refer to those with LVEF recovery as having HF with recovered EF (HFrecEF).

Specific Therapies That Promote LVEF Improvement

Spontaneous Recovery

Although understudied, the spontaneous and unassisted improvement of LVEF has long been appreciated and described. Some of the earliest published works describe improvements in LVEF in nearly 40% of patients with acute myocarditis (Dec et al., 1985), in patients who used chronic alcohol (Francis et al., 1990), and in 27% of patients with recent-onset dilated cardiomyopathy referred for cardiac transplantation (Steimle et al., 1994). Other reversible myopathies extend to include stress cardiomyopathy, tachycardia-mediated cardiomyopathy (McLaran et al., 1985), alcohol-related cardiomyopathy (Nicolás et al., 2002), and peripartum cardiomyopathy.

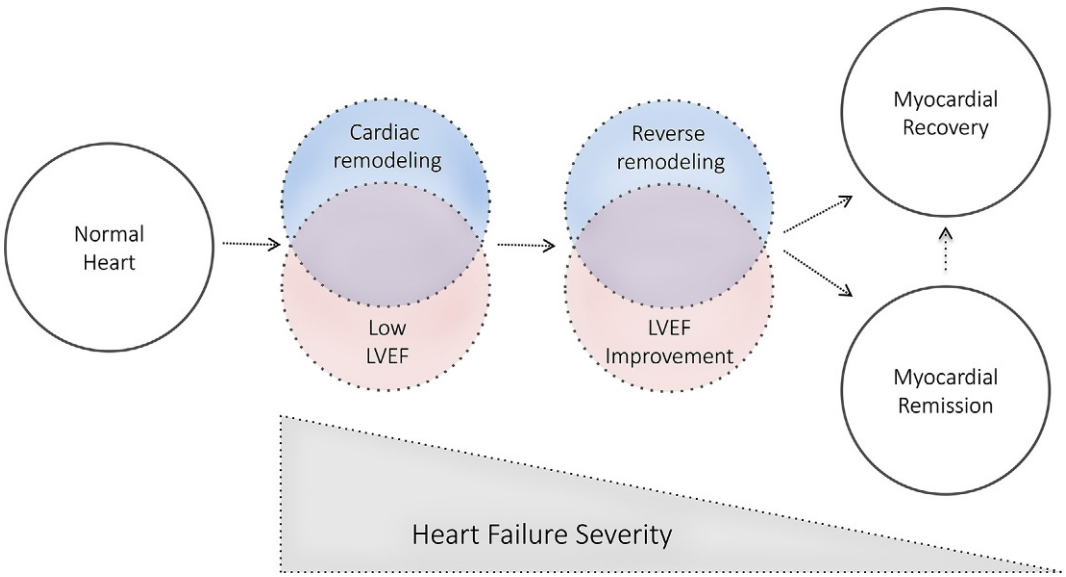

Fig. 1 The progression to recovery and remission. The normal heart, after incurring an insult, is left with impaired systolic function and low EF. Further deterioration occurs by way of pathological cardiac remodeling where the heart increases in mass and becomes dilated and spherical. Reverse remodeling, either spontaneously, or with either drugs or devices, engenders LVEF improvement (or recovered EF) and most often takes the path toward myocardial remission whereby the heart remains at risk of future cardiovascular events. It may however, take a path toward myocardial recovery and achieve functional cure whereby the heart is free from future cardiovascular events. Myocardial recovery is likely rare. After the initial insult and low EF state, reverse remodeling progressively attenuates the severity of heart failure.

Medical Therapy

It is known that medical therapy alone engenders improvements in clinical outcomes, promotes reverse remodeling, and improves LVEF. In a meta-analysis of 86 remodeling trials, the absolute change in LVEF associated with HF therapies was compared with placebo with an average follow-up time of 6 months (Kramer et al., 2010). Kramer and others would find that those drugs that engendered lower mortality also improved LVEF when compared with placebo. Classical mortality improving agents like the beta-blocker bisoprolol decreased end-diastolic volumes and improved LVEF on average +12% after pooling results (Kramer et al., 2010). Carvedilol had a mean increase in LVEF of +6.9%, metoprolol +4.5%, enalapril +2.7%, hydralazine–isosorbide dinitrate +2.9%, and spironolactone +3.0%. These guideline-recommended therapies were consistently observed to improve LVEF in patients with LV systolic dysfunction (Kramer et al., 2010). The principle here is that abrogation of the sympathetic/stress response and the activated neurohormonal cascade can lead to improved hemodynamic and neurohormonal profiles that promote reverse remodeling and overall incremental improvements in LVEF.

Device Therapy

In addition to medical therapy, device therapy is known to promote LVEF improvement. The best example is perhaps CRT or biventricular pacing. Among patients with HF*r*EF, wide QRS, and left bundle branch block, CRT has been shown to target the dyssynchrony seen in the myopathic heart and improve clinical outcomes of symptoms and survival. CRT improves both atrioventricular synchrony and the ventricular pattern of electrical activation that integrates the heart. These features, acting in concert, are thought to be the underlying authors that promote systolic augmentation (Leclercq and Kass, 2002). Kramer and others would show that CRT reduced both end-systolic and end-diastolic volumes (markers of reverse remodeling) and on average had an absolute improvement in LVEF by about +2.7% across four trials and with a mean of 21 weeks of follow-up.

Although these changes are modest, the CRT "super responder" or "hyper responder" has also been described who has marked improvements in LVEF after implantation and initiation of CRT. In a study of patients with nonischemic dilated cardiomyopathy and ejection fractions under 35% with end-diastolic diameters >60 mm, CRT was installed, and patients were followed for 6 months (Castellant et al., 2009). Of the 51 patients with nonischemic cardiomyopathy, 11 were found to be hyper responders who had a mean LVEF increase from an average of 26+/−9% to 59+/−6% ($P < 0.01$). The remaining 40 patients had no functional improvement and a mean LVEF improvement from 21+/−9% to 26+/−12% ($P = 0.03$). Patient characteristics that predict "super responders" have been examined in the Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy (MADIT-CRT) among other studies and include female sex, no prior myocardial infarction, left bundle branch block, QRS duration ≥150 ms, body mass index <30 kg/m^2, and smaller baseline left atrial volume index (Hsu et al., 2012). Not surprisingly, super response has been associated with improved outcomes when compared with hyporesponse to CRT.

A second notable example of LVEF recovery with device therapies is that of marked cardiac reverse remodeling observed with mechanical unloading of the heart with left ventricular assist devices (LVAD) (Westaby et al., 1997). Initial reports supported transient normalization of systolic function with LVAD unloading (Frazier, 1994; Levin et al., 1996). Since then, the possibility of LVAD explantation after LVEF recovery with a combinatorial approach of LVAD unloading and high-dose pharmacological therapy has been reported. In a prospective study of 20 patients with nonischemic cardiomyopathies, a strategy combining LVAD unloading with high-dose pharmacological therapy (carvedilol, digoxin, lisinopril, losartan, and spironolactone followed by the beta-2 agonist clenbuterol) led to LVAD explantation in 12 of 20 patients. The mean preexplant EF was 70%, and the mean postexplant EF was 58%. By comparison, previously published LVAD explantation rates ranged from 11% to 24% among patients with nonischemic cardiomyopathy enriched for acute myocarditis (Dandel et al., 2008; Maybaum et al., 2007; Simon et al., 2005).

Despite the excitement around the possibility of LVAD unloading and recovery, the ability to explant an LVAD still remains rare, with myocardial recovery in only a small percentage of patients with end-stage HF after LVAD therapy. (Mancini et al., 1998). With sufficient time, the vast majority of patients with chronic LV systolic dysfunction do exhibit reverse remodeling with LVAD unloading; however, in the INTERMACS registry, slightly <1% of patients were explanted because of LVEF recovery (Kirklin et al., 2015).

LVEF Recovery Among the HF Population: Determinants and Outcomes

Punnoose, Desai, and others were some of the first to hypothesize that improvements in LVEF occurred in patients with systolic HF and that this represented a clinical entity distinct from the HF*p*EF and HF*r*EF syndromes (Punnoose et al., 2011). They labeled this population as having HF with "recovered LVEF" and systematically studied the emerging phenomenon at their referral institution. They and others have collectively amassed a body of work that suggests that the recovered LVEF population may be phenotypically and prognostically distinct than the current HF*p*EF and HF*r*EF paradigm (Basuray et al., 2014; de Groote et al., 2014; Dunlay et al., 2012; Florea et al., 2016; Joyce et al., 2016; Kalogeropoulos et al., 2016; Lupón et al., 2017; Merlo et al., 2011; Punnoose et al., 2011; Teeter et al., 2012; Zhang et al., 2015).

It is important to acknowledge that LVEF is dynamic and that this dynamism is likely attributable to cardiac remodeling and reverse remodeling. In a health plan-based sample of 2413 patients with HF and ≥2 LVEF measurements, investigators examined transitions between HF*p*EF (classified as EF >40%), HF*r*EF (classified as EF <40%), and death. Over a mean follow-up time of 4.4

years, there were 8183 transitions, highlighting how dynamic LVEF can be (Clarke et al., 2013). Similarly, among 1233 HF patients in the Olmsted county cohort, the mean LVEF decreased by 5.8% among patients with HF*p*EF and increased by 6.9% over 5 years among patients with HF*r*EF (Dunlay et al., 2012). This suggests that patients are not longitudinally restricted to HF*r*EF or HF*p*EF status. In the section that follows, we examine studies focused on patients with HF*r*EF who show LVEF improvement over time. Rather than reclassifying this group as HF*p*EF, these studies substantiate the fact that this group may harbor a unique clinical trajectory; hence, we will refer to this group as HFrecEF.

Determinants of LVEF Recovery

What we know about the recovered EF population comes from a handful of hospital- and community-based cohorts that are summarized in Table 1. The definition of recovered LVEF varies from study to study with reduced ejection fraction having different echocardiographic thresholds that range from less than 35%, 40%, 45%, and 50%. This variability limits some of the interpretation of the studies although certain themes consistently emerge. In patients with HF*r*EF, a substantial number appear to experience LVEF recovery, with estimates ranging from as low as 9% to as high as 43% (Table 1). The true prevalence of the population remains uncertain but probably lies somewhere in between and needs more careful epidemiological study.

There appears to be a theme with regard to the clinical profile of patients with HFrecEF as compared with patients with persistent HF*r*EF. Indeed, patients who experience LVEF recovery tend to be younger, female, and have a nonischemic mechanism of their HF. Recovered EF patients tend to have a shorter duration of HF symptoms and a higher blood pressure, less likely to have LBBB, and more likely to have atrial fibrillation (Lupón et al., 2017; Punnoose et al., 2011). In addition to better renal function and being on higher doses of neurohormonal blockade, they also tend to have structurally more normal hearts with smaller LV end-diastolic dimensions (Florea et al., 2016).

The biochemical signatures of the recovered EF population are also distinct from the HF*r*EF population. A number of biomarkers seem to suggest persistent yet less severe neurohormonal cascade activation. For example, a study from the Val-HeFt trial showed that patients with recovered EF have lower levels of norepinephrine and natriuretic peptides (Florea et al., 2016). In the Penn Heart Failure Study, recovered LVEF patients also had lower levels of natriuretic peptides, troponin I, uric acid, and S-Flt-1 compared with HF*r*EF, although natriuretic peptides remained persistently elevated above the ninety-fifth percentile in about 30% of HFrecEF patients (Basuray et al., 2014). This suggests that despite LVEF recovery, continued neurohormonal activation can still be present.

When comparing HFrecEF with HF*p*EF patients, there a number of clinical factors that distinguish these two phenotypes (Table 1). Patients with LVEF improvement are again younger in age with less coronary disease. They also have less comorbidity like diabetes, CKD, and hypertension and are more likely to be on guideline-directed medical therapy.

Clinical Outcomes After LVEF Recovery

Outcomes for patients with HFrecEF are summarized in Table 1. The recovered LVEF population is consistently associated with improved survival when compared with the persistent HF*r*EF population. One study found that an EF improvement of 5% was associated with a 12% mortality reduction (Dunlay et al., 2012). In addition to lower all-cause mortality, HFrecEF is also associated with the lower risk of need for transplant or LVAD (Basuray et al., 2014) and lower risk of sudden cardiac death and ventricular arrhythmias (Merlo et al., 2011; Zhang et al., 2015). Patients with HFrecEF also have improved outcomes compared with HF*p*EF, with lower all-cause mortality, cardiovascular, HF-related, and sudden death (Lupón et al., 2017), although cardiac hospitalizations appear similar between HFrecEF and HF*p*EF in one study (Basuray et al., 2014). This favorable and improved clinical arc suggests that LVEF recovery (and HFrecEF) is indeed clinically distinct from persistent HF*r*EF or HF*p*EF.

While outcomes in patients with HFrecEF are improved compared with HF*r*EF and HF*p*EF as summarized earlier, there remains residual risk for recurrent and future cardiovascular events. Up to a quarter of patients with HFrecEF can have a subsequent LVEF decline (de Groote et al., 2014). Despite LVEF recovery, patients with HFrecEF also experience persistent HF symptoms and clinical events, including cardiovascular death, HF death, and sudden death (Basuray et al., 2014; Lupón et al., 2017). Another tangible example comes from CRT "super responders" who have marked normalization of EF to >50% after device initiation. Although long-term outcomes in this population are generally considered to be excellent, they continue to experience HF hospitalizations and appropriate CRT-D intervention despite EF normalization (Zecchin et al., 2014). This risk remains latent and can occur years after EF normalization (Zecchin et al., 2014).

Clinical Management of Patients With LVEF Recovery

Given the residual risk of cardiovascular events, how then are we to manage the patient who has achieved LVEF recovery but remains in myocardial remission with HFrecEF? Those with specific etiologic causes of cardiomyopathy require ongoing considerations specific to that etiology and have been reviewed (Basuray and Fang, 2016). With respect to general guideline-directed medical therapies for HF, it remains unclear whether such therapies should be continued, weaned, or discontinued in patients with LVEF recovery. Some studies have shown that discontinuation of beta-blocker or angiotensin-converting enzyme inhibitor therapy results in subsequent LVEF decline and recurrent clinical HF events (Moon et al., 2009; Waagstein et al., 1989). In this context, it is generally recommended that HF medications and lifestyle interventions be continued in those with

Lupón (2017)	Hospital-based cohort: 1057 patients with HF	LVEF <45% at baseline and ≥45% at 1 year	22	Compared with HFrEF: younger age, more women, nonischemic etiology, nondiabetic, more AF, less LBBB, shorter HF duration, and better NYHA class	Lower mortality (HR 1.77, 95% CI 1.20–2.61 in HFpEF vs. HFrecEF and HR 1.54, 95% CI 1.162.04 HFrEF vs. HFrecEF). Also lower CV and HF events. Lower cumulative incidence of CV- and HF-related hospitalizations
Kalogeropoulos et al. (2016)	Hospital-based cohort: 2166 outpatients with HF	LVEF >40% and any previous LVEF ≤40%	16	Compared with HFpEF: younger age, less CAD, DM, CKD, lower BP, more likely on GDMT, less likely ICD/CRT	Lower mortality at 3 years (HR 0.35, 95% CI 0.18–0.70 c/w HFrEF) but not at 1 year. Age- and sex-adjusted 3-year mortality 4.8% (vs. 13.2% in HFpEF and 16.3% in HFrEF)
Florea et al. (2016)	Val-HeFT trial: 3519 with HF, baseline LVEF <35%, and subsequent TTE at 12 months	LVEF <35% at baseline and >40% at 12 months	9	Compared with HFrEF: younger age, less ischemic, more hypertension, lower LVEDD index, higher eGFR, greater BB and ARB use. Biomarkers: less severe neurohormonal activation (lower NE, PRA, ETI, BNP, NT-proBNP). Independent correlates: sex, ischemic pathogenesis, BMI, DBP, LVEDD index, BB use, valsartan use	Survival higher in HFrecEF c/w HFrEF. Mortality rate 2.9 per 100 PY (95% CI 1.8–4.5) in HFrecEF versus 5.8 per 100 PY (95% CI 5.3–6.4) in HFrEF
Joyce et al. (2016)	Hospital-based cohort: 726 ambulatory HF	Prior LVEF <50% with subsequent LVEF ≥50% at study visit	19	Compared with HFpEF: better QOL and breathing by visual analog scale	Not examined
Zhang et al. (2015)	PROSE-ICD (systolic HF eligible for primary prevention ICD): 538 with subsequent LVEF assessment	Absolute increase in LVEF >5%	40	Compared with worse or unchanged LVEF: more likely to have a CRT-D (as opposed to ICD)	Lower mortality at mean follow-up of 2 years (HR 0.33, 95% CI 0.18–0.59) in HFrecEF versus unchanged EF. Also lower risk of appropriate shocks. Among patients with LVEF improvement >35%, four experienced appropriate shock
Basuray et al. (2014)	Hospital-based cohort (Penn Heart Failure Study): 1821 chronic HF	Prior LVEF <50% with subsequent LVEF ≥50% at study visit	10	Compared with HFpEF: younger, less CKD, less HTN, less symptoms, more GDMT. Compared with HFrEF: similar age, less ischemic origin, less CKD, similar HTN. Biomarker profiles: lowest in HFrecEF group, including BNP, troponin I, S-Flt-1, uric acid. However 1/3 of HFrecEF still had BNP >135 pg/mL, other abnormalities in biomarkers	Lower risk of combined death, transplant, or VAD (multivariable-adjusted HR 2.0, 95% CI 1.0–4.0 in HFpEF vs. HFrecEF and HR 3.4, 95% CI 2.0–5.7 in HFrEF vs. HFrecEF). Lower risk of cardiac hospitalization compared with HFrEF (HR 1.8, 95% CI 1.4–2.4 HFrEF vs. HFrecEF) but similar to HFpEF
de Groote et al. (2014)	Hospital-based cohort: 174 with recovered LVEF on beta-blocker	LVEF <45% with subsequent LVEF ≥45% after beta-blocker with ≥5% LVEF increase		No comparator group	Survival rates 90% at 5 years, 75% at 10 years similar to expected survival rates. Subsequent LVEF decline seen in a quarter
Dunlay et al. (2012)	Community-based cohort (Olmsted): 1233 participants with incident HF	LVEF ≥50% with previous LVEF <50%	39	Among HFrEF, LVEF increased by 5.8% on average over 5 years, greater improvement in women, younger patients, without CAD, on medications	Lower mortality: a 5% increase in LVEF was associated with a 12% reduction in mortality (adjusted HR 1.12, 95% CI 1.07–1.16)

(*Continued*)

Table 1 Determinants and outcomes of LVEF recovery in heart failure populations (Continued)

References	*Sample*	*Definition of HFrecEF*	*Percent of LVEF recovery*	*Correlates of HFrecEF*	*Outcomes of HFrecEF*
Teeter et al. (2012)	Hospital-based cohort: 224 with HF <6-month duration and LVEF <30%, 115 with follow-up TTE	LVEF <30% at baseline and subsequent LVEF ≥40%	43	Compared with no LVEF improvement: less ischemic etiology, higher BP, narrower QRS, greater wall thickness, and smaller LV dimensions at baseline, more likely to have achieved target beta-blocker dose	Not compared
Punnoose et al. (2011)	Hospital-based cohort: 358 stable HF outpatients	LVEF <40% and subsequent LVEF ≥40% with ≥5% absolute change	34	Compared with either HFpEF or HFrEF: younger, fewer HF hospitalizations, milder HF symptoms. Compared with HFpEF: less HTN, DM, or AF; lower BP; better eGFR. Compared with HFrEF: more women, less CAD, higher BP	Not examined
Merlo et al. (2011)	Tertiary referral center registry: 361 idiopathic DCM patients, 242 had follow-up TTE	LVEF increase ≥10% or follow-up LVEF ≥50% with baseline LVEF 45%–49% and decrease in LV end-diastolic diameter index ≥10%	37	Compared with nonrecovery: lower LVEF, higher restrictive filling pattern. Independent predictors of recovery—higher systolic BP (OR 1.23, 95% CI 1.01–1.53 per 10 mmHg increase) and the absence of LBBB (OR 2.47, 95% CI 1.25–4.87)	Better transplant-free survival (5- and 10-year survival 94% and 85% in HFrecEF compared with 81% and 63%, respectively, in nonrecovery). Multivariable-adjusted HR for death/transplant HR 0.44, 95% CI 0.25–0.78, for sudden death/ventricular arrhythmia HR 0.39, 95% CI 0.21–0.74

LVEF recovery (Basuray and Fang, 2016) although no clinical trials are available to substantiate this strategy. For those patients receiving unloading therapy with an LVAD, it remains unclear who merits explantation and whether medical therapy should be offered synchronously. Whether LVAD therapy might serve as a durable bridge to either remission or recovery remains to be seen (Drakos et al., 2012).

The management of patients with implantable cardioverter defibrillators (ICDs) and LVEF recovery is also uncertain. A recent study showed that among 126 patients with primary prevention ICDs and LVEF improvement to >35% after device implantation, the risk of appropriate shocks was decreased but not abrogated, with four patients receiving appropriate shocks (Zhang et al., 2015). It thus remains unclear whether routine replacement of ICD generators is warranted in patients with LVEF recovery and how the presence, absence, or frequency of appropriate or inappropriate device therapies inform this decision. The European Society of Cardiology guidelines advocate against routine replacement and for reassessment of patient goals. They write that "patients should be carefully evaluated by an experienced cardiologist before generator replacement, because management goals and the patient's needs and clinical status may have changed (Ponikowski et al., 2016)."

Given that EF normalization likely comes with myocardial remission and not functional cure or recovery, more study is required to define how best to follow these patients, how frequently to obtain EF assessments, and what to do with our therapies once EF has normalized.

Current Knowledge Gaps

There is much that we do not know about LVEF recovery and reverse remodeling. With this emerging population, questions surrounding the diagnosis, follow-up, and management of these patients will become more frequent. Many fundamental prognostic, diagnostic, and therapeutic questions still remain.

One fundamental question that remains is whether there exists a subset of patients with LVEF recovery that also have true myocardial recovery and "cure" from HF. Is it possible to transition from remission to recovery, and can these entities be more robustly predicted and promoted? Part of the difficulty in answering this question may be that LVEF, while simple and easy to use, is a summary metric that does not incorporate many important physiological elements—it is often conflated with contractility but in reality remains conceptually uncoupled (Konstam and Abboud, 2017). Because of these limitations, LVEF may not distinguish between patients who achieve myocardial remission versus myocardial recovery. In the future, more advanced imaging techniques,

including cardiac magnetic resonance imaging and echocardiographic strain, may offer the ability to more closely understand the extent to which reverse remodeling has occurred. Further, biomarker profiles may offer insights into which patients have achieved recovery in contrast to remission and may also uncover other underlying processes at play during reverse remodeling. For example, a specific circulating extracellular microRNA (miR-30d) was associated with LVEF improvement in response to CRT and also appears protective against cardiomyocyte apoptosis (Melman et al., 2015).

A second set of remaining questions centers on how we might tailor treatments to individual patients. The routine use of a given treatment paradigm seems antithetical to the emergence of personalized medicine. Questions still remain over what medications are best to use once LVEF is normalized, and which medications if any should be continued, discontinued, or merely weaned. This extends into the arena of device therapy, and one wonders given the compelling cost and epidemiology of HF whether there are gains and savings to be had in the thoughtful customization and de-escalation of therapy for this unique improving population. With up to 43% of patients experiencing LVEF improvements in some series, this is clearly an important area of further study.

In sum, LVEF improvement can be seen spontaneously or in response to specific medical or device therapies. While certain clinical characteristics predict LVEF improvement and outcomes appear improved when compared with HF*p*EF or HF*r*EF, the trajectory for those with HFrecEF appears most consistent with myocardial remission, rather than true recovery from HF. This population offers new insights into the dynamic and plastic nature of the heart. What is clear is that more study is required in the form of mechanistic fundamental science and future clinical trials to better understand the phenomena of remodeling, remission, and recovery.

Introduction

Cardiovascular implantable electronic devices (CIEDs) have undergone revolutionary changes in the last decade. These changes have permitted an increase in the use of both pacemakers (PM) and implantable cardioverter defibrillators, collectively known as CIEDs. PM were the first generation of CIEDs available for implantation in humans, as early as 1958. Implantable defibrillators in the current form (transvenous) have been available since 1997. CIEDs are increasing in use in North America (Kurtz et al., 2010; Mond et al., 2008; Uslan et al., 2008). These devices are primarily required in older populations, where conduction system disease and significant structural heart disease prevail. As the absolute and relative numbers of the elderly population increase, so do the use of CIEDs. The primary increase in CIED use is due to an increase in the implantation of prophylactic implantable cardioverter and defibrillators (ICDs), rather than PM. Increasing use of cardiac interventions (Cox, 1999), coupled with increasing survival post-MI, a growing number of heart failure survivors (Wijeysundera et al., 2010), and the burgeoning elderly population have all combined to increase the population of patients eligible for implantation of prophylactic ICDs (Moss et al., 2002; Bardy et al., 2005). It is projected that the heart failure population will double by the year 2025 such that the absolute number of patients eligible to receive an ICD for primary prevention will likely rise accordingly (Ross et al., 2006). Recent studies have further expanded indications for cardiac resynchronization therapy (CRT), which has been found to have significant reduction in mortality in mild-moderate heart failure (Tang et al., 2010). This will result in a significantly increased burden on the health care system, whose budget may not be expected to expand at the same rate. The resource implications are not the only consideration in the broader use for these devices.

Over the last decades, CIEDs have evolved in many different ways. Under this acronym are regrouped PM, ICD, and CRT devices. Battery longevity has increased while their volume shrunk, algorithms for detection of arrhythmias were refined, as well as programming strategies to either minimize the impact of pacing (PM) or maximize pacing efficiency (CRT). Likewise, strategies to reduce the rates of inappropriate therapies for ICDs were developed (Moss et al., 2012; Tan et al., 2014). During the life of these patients, many issues may arise, such as atrial or ventricular arrhythmias that may result in syncope, stroke or sudden death, need for increased monitoring resulting from device advisories, or minor programming adjustments to improve device performance, or simply the need for enhanced surveillance as the device battery depletes and replacement is anticipated. Among the improvements in device technology, remote monitoring (RM) capabilities are first and foremost. The main goal behind development of such technology was to allow physician to be promptly made aware of CIED malfunction or a significant change in the patient's clinical status.

With the advent of RM, a few hurdles had to be dealt with. From a physician perspective, liability issues were raised. From a device company and legal perspective, ownership and protection of the data collected had to be debated and organized. From a healthcare perspective, accessibility and costs related to widespread deployment of such technology needed to be assessed. Finally, from a patient perspective, understanding the technology and being able to use it properly at home were certainly the main challenges.

Nevertheless, all major device companies developed their proprietary systems which were integrated to their CIED systems and the technology was tested worldwide. Nowadays, all types of devices have RM capacity but the availability of the technology varies according to legislations, regulatory offices, and local management decisions. The use of RM is well established and supported by data gathered through single-center studies, multicenter randomized control trials, and large population-based registries.

Technology

In order to understand the technology, it is important to review the required tools for RM, the processes behind data collection, transmission, and management (Yee et al., 2013). First and foremost, in order to offer RM to a patient, the selected device must have the built-in capacity. Fortunately, all major companies now offer products with available RM features for PM, ICD, and CRT devices. The second component that is required is a company-specific transmission pod. The latter will transmit data over a phone landline

 https://doi.org/10.1016/B978-0-12-809657-4.99792-8

or more recently over a cellular network. Newer devices have wireless communication with the transmission pod thereby forfeiting the requirement of applying a wand over the device.

RM generally involves three layers of data transfer. First, recorded and measured data must transfer from the device to the patient's pod. It is generally recommended that the patient places the pod in their main bedroom so transmissions may occur at night. Reasons for failure at this level include insufficient power (or outage) from either the device or the pod itself, or inadequate proximity between the patient and the pod. The second level of transmission involves transfer from the patient's home to a web-based server. This occurs in one of the two ways: via a landline or cellular network. In the first generations of RM devices and pods, only landlines allowed for proper transmissions. Therefore, patients living in remote regions or those who did not have a landline in their bedroom could not use the technology. With the advent of cellular transmissions, the technology is now available to more patients. The third level of transmission relates to information that is conveyed to device clinics or physicians. Once stored on a web-based network, alerts can be sent to clinics involved with a given patient and data can be securely accessed by device clinic specialists. Thereafter, how the acquired data is managed relies on individual clinics and local practices.

Data that is monitored, recorded, and relayed via RM pertains to device status and functionality as well as rhythm disturbances and other parameters. The information gathered is transferred through two types of transmissions: scheduled and triggered. *Scheduled* transmissions are either nominally programmed or they are setup by device clinics and care givers. Nominally scheduled transmissions vary from daily to 6 months depending on the device company proprietary system. *Triggered* transmissions are sent when prespecified parameters are reached. Most of these triggers are programmable and include device-specific measurements such as impedances and battery voltage, measured parameters (thresholds and sensing values), and arrhythmias (monitored or treated). As stated previously, for those transmissions to occur, the patient must be in the vicinity of the transmission pod. Therefore, the device of a patient who sustains a significant ventricular arrhythmia and is not physically near the pod will not transfer any data until the proximity requirements are met. Likewise, an arrhythmia that would occur below the predefined thresholds would not be transmitted.

Although relatively simple in design and straightforward in utilization, some hurdles are seen in the day to day use of RM. In essence, to benefit from RM, the ideal setup requires a combination of a patient who understands the technology and uses it properly and a dedicated device clinic that has integrated RM in its workflow.

Benefits of RM

Numerous groups have evaluated the safety and benefits of integrating RM to usual care. Briefly, in randomized control trials, RM proved to be superior in terms of time to detection and management of significant arrhythmic events or CIED malfunction but also in terms of reduction of inappropriate shocks, hospital visits, hospitalizations, and even mortality in one trial. The most relevant literature will be reviewed in the following sections (**Table 1**).

Mortality

Once a given technology or therapy is accepted by regulatory entities and is being used outside the context of a randomized controlled trial, it becomes important to validate in large and real-life cohorts if the benefits previously observed are still accurate. RM is no exception to this tendency and two large database cohort studies that have been published are discussed later.

ALTITUDE is a cohort study that compared patients with ICD and CRT devices who were either using RM or usual care between 2004 and 2009 (Saxon et al., 2010). Overall survival and shock therapies were analyzed in more than 185,000 patients living in the United States. In this large database, RM was associated with statistically significant reduction in 1-year and 5-year mortality rates in the United States. In a matched cohort, RM was associated with a 50% relative reduction in overall mortality (HR: 0.56 for ICD and 0.45 for CRT-D, $P < 0.0001$) (Saxon et al., 2010). Similarly, another cohort study was published in 2015 (Varma et al., 2015). In this second report from a US database, more than 269,000 patients who received PM, ICD, and CRT devices with RM capabilities were analyzed according to the degree to which they actually used RM. High RM users were defined as those patients who sent >75% of weekly transmission during the observation period. Nonusers were those who did not send a single transmission while low users were those who successfully transmitted at least one but no more than 75% of their weekly transmissions. As in the ALTITUDE study, patients using RM had a survival benefit over those not using it (HR 2.10 [2.04–2.16] $P < 0.001$). Furthermore, there was a gradient of increased survival that correlated the intensity at which the technology was being used. In this report, high users had a statistically significant survival benefit over low users (HR 1.32 [1.27–1.36] $P < 0.001$).

When analyzing overall mortality in retrospective cohorts, adjudication of events is usually not an issue. Only patients that were lost to follow-up or became ineligible might have an impact on the overall mortality of that cohort. However, overall mortality should not be seen as a surrogate of net clinical benefit since the relationship between the underlying cause of death and the technology evaluated cannot be ascertained. In ALTITUDE, the authors attempted to attenuate this factor by indicating that there were no differences between the groups in terms of baseline characteristics such as age, gender, type of device implanted, and its duration as well as economic and educational status. Likewise, to account for underlying confounding variables, in the study by Varma, the authors evaluated eight different socioeconomic factors to delineate adherence factors to RM that might have an impact on overall mortality. While there were differences in the intensity of RM usage and six of the eight factors, no relationship between

Table 1 Summary of remote monitoring randomized clinical trials

Study	N	*Device*	*Frequency of transmissions*	*Follow-up (months)*	*Results*
TRUST	1339	ICD	Daily	15	1. RM reduced total in-hospital device evaluations by 45% without affecting morbidity 2. RM: 85.8% of all 6-, 9-, and 12-month follow-ups were performed remotely only 3. Median time to evaluation was less than 2 days in the RM group compared with 36 days in the conventional group ($P=0.001$) for all arrhythmic events
ECOST	473	ICD	Daily	27	1. 38.5% of patients in the active and 41.5% in the control group experienced ≥ 1 major adverse event ($P<0.05$ for noninferiority) 2. Shocks delivered was significantly lower in the RM ($n=193$) than in the control ($n=657$) group ($P<0.05$) 3. Inappropriate shocks were 52% lower in the active ($n=11$) than in the control ($n=22$) group ($P<0.05$) 4. Battery longevity was longer in the active group because of a lower number of capacitor charges (499 vs. 2081)
EVATEL	2011	ICD	n/a	n/a	1. The noninferiority hypothesis with a safety margin of 5% between the two groups is not validated 2. The number of inappropriate therapies was lower in the remote group ($n=33$; 4.7%) as compared with the control group ($n=55$; 7.5%) ($P=0.03$)
COMPAS	2012	Pacemaker	Daily	18	1. 90 patients (18.2%) had experienced a major adverse event, including 43 patients (17.3%) in the active group and 47 (19.1%) in the control group (HR 0.90; 95% CI: 0.59–1.41; $P=0.63$), confirming the noninferiority of remote monitoring 2. 71% of interim follow-ups were noncontributory versus 38% in the RM group ($P<0.001$) 3. Mean 117-day gain in the event detection (95% CI: 49–184 days; $P<0.001$)
CONNECT	2010	ICD/CRT-D	Event-triggered or q 3 months	15	Median time from clinical event to clinical decision per patient was reduced from 22 days in the in-office arm to 4.6 days in the remote arm ($P=0.001$). The health care utilization data revealed a decrease in mean length of stay per cardiovascular hospitalization visit from 4.0 days in the in-office arm to 3.3 days in the RM arm ($P=0.002$)
EVOLVO	2012	ICD/CRT-D	Event-triggered or q 4 months	16	1. Over 16 months, visits were 35% less frequent in the remote arm (75 vs. 117); incidence density, 0.59 versus 0.93 events per year ($P=0.005$) 2. A 21% difference was observed in the rates of total healthcare visits for heart failure, arrhythmias, or ICD-related events (4.40 vs. 5.74 events per year; $P<0.001$) 3. The time from an ICD alert condition to review of the data was reduced from 24.8 days in the standard arm to 1.4 days in the remote arm ($P<0.001$) 4. The patients' clinical status, as measured by the Clinical Composite Score, was similar in the two groups, whereas a more favorable change in quality of life was observed from the baseline to the 16th month in the RM arm ($P=0.026$)
IN-TIME	664	ICD/CRT-D	Daily	12	At 1 year, 63 (18.9%) of 333 patients in the telemonitoring group versus 90 (27.2%) of 331 in the control group ($P=0.013$) had worsened composite score (OR 0.63, 95% CI 0·43–0.90). Ten versus 27 patients died during follow-up

ICD, implantable cardioverter defibrillator; *CRT-D*, cardiac resynchronization therapy defibrillator; *OR*, odds ratio.

those factors and survival was established. Indeed, other factors such as motivation to engage in other treatments and underlying comorbidities and (their severity) might have an impact that cannot be measured by this type of trial. In the end, whereas *association* is demonstrated in those studies, *causality* has yet to be established.

Nevertheless, it is plausible that RM has an impact on mortality given that arrhythmia and device malfunctions can be detected earlier as demonstrated in numerous RCTs as discussed later. For instance, both sustained ventricular arrhythmias and atrial fibrillation have been associated with worsening heart failure and even mortality (Dries et al., 1998; A.V.I.D. Investigators, 1997; Connolly et al., 2000). It seems reasonable to postulate that by identifying those arrhythmias earlier, physicians might intervene earlier and therefore, change the patient's trajectory of care. In turn, this might lead to the overall improved mortality. In fact, a single RCT revealed that mortality was reduced for RM patients: IN-TIME (Hindricks et al., 2014). This multicenter trial randomized 664 symptomatic heart failure patients (NYHA II or III) who received an ICD or a CRT-D device to RM or usual care. Patients had a reduced left ventricular ejection fraction (mean LVEF 26% in both groups), no permanent atrial fibrillation, and were on optimal drug treatment. At the end of the 12-month study period, 10 (3.4%) patients had died in the RM group compared with 27 (8.7%) in the control group, yielding a hazard ratio of 0.36 (95% CI 0.17–0.74) (log-rank $P=0.004$). The wide confidence interval reflects the overall small number of events. However, the difference in the point-estimate is considerable and the strength of association is striking. Furthermore, since biases and potential differences between patients in each group are reduced by randomization, findings in this trial reinforce the mortality benefits that were documented in registries. Again, causality has yet to be determined and all previous comments on overall mortality remain relevant. In search of a plausible hypothesis for the observed superiority of RM,

authors of IN-TIME argued that early detection of suboptimal device function such as reduced percentage of biventricular pacing and inappropriate shocks along with earlier detection of arrhythmias might have had an impact on the mortality benefit. All those arguments provide plausible explanations for the mortality benefit especially since they were all associated with improved outcomes in various trials (Moss et al., 2012; Poole et al., 2008; Ruwald et al., 2015).

Diagnosis Delay

Previous RCTs have evaluated RM in comparison with usual care globally yielding superiority or non inferiority of RM on variable outcomes. One of the first trials to be published in 2010 was TRUST, a multicenter RCT comparing RM to usual care (Varma et al., 2010). This trial evaluated a single RM system (Biotronik HomeMonitor®) and randomized 1339 ICD patients in a 2:1 block randomization fashion. The primary endpoint was reduction of total in-hospital visits which was clearly demonstrated with a 45% reduction in the number of visits in patients randomized to RM. Importantly, there were no differences in adverse event rates despite the reduced number of clinic visits. Moreover, in secondary analyses, when arrhythmias were documented by the ICD, the median time to evaluation was significantly shorter in the RM group (<2 vs. 36 days ($P<0.001$)). In other words, the conclusion that can be derived from those results is that RM enhances device clinics' efficiency. Indeed, given that routine follow-ups are less likely to translate into meaningful interventions, reducing the number of such visits can only increase clinic's efficiency. In this trial, more than 90% of the clinical visits were nonactionable meaning that the device interrogation did not provide any information that resulted in an intervention. In real-life setting, actionable events include modifying the device functional parameters, modifying the patient's medical therapy, ordering relevant tests, and scheduling lead or generator-related procedures. Therefore, device-detected arrhythmias are usually actionable and RM allowed for faster evaluations. This time difference was more than a month in TRUST. Somehow, one might rightfully postulate that reducing the number of contacts with medical personnel might result in an increased risk of unfavorable outcomes such as death and stroke rates. That assumption just could not be verified in this trial nor other alike trials (see later).

Based on that single RCT, safety and efficacy of RM was demonstrated but it is important to notice that Biotronik's RM system sent statutory daily transmissions whereas other companies had weekly (St.Jude Medical Merlin®), monthly (Boston scientific Latitude®), and quarterly (Medtronic Carelink®) statutory transmissions. Nevertheless, trigger-based transmissions when certain prespecified and programmable outcomes are met are sent with all RM systems thereby reducing the risk of missing meaningful device malfunction or arrhythmic events. Therefore, it is reasonable to assume that the results of any trial are generalizable to all RM systems.

In fact, CONNECT is another trial that was published in 2010 that showed superiority of RM compared with usual care (Crossley et al., 2011). In this trial, 1997 patients receiving an ICD or a CRT-D device were randomized in 1:1 ratio to either RM or usual care. The system being evaluated was Medtronic Carelink which sent statutory quarterly or event-triggered transmissions. Again, despite a different philosophy of transmission management, RM allowed faster actionable interrogations as the median time from a clinical event to the clinical decision was significantly reduced from 22 days in the usual care group to 4.6 days in the RM group ($P<0.001$). The two most common events detected were related to atrial tachycardia/fibrillation: its burden and the ventricular rate during AT/AF. In CONNECT, health care utilization was measured somewhat differently than in TRUST. The mean length of stay of hospitalization for cardiovascular reasons was reduced from 4.0 to 3.3 days ($P=0.002$) which resulted in a reduced cost of hospitalization by 1793 $US (95% CI [1644–1940 $US]). How RM impacted hospital stay remains debatable. As mentioned earlier, data acquired through device checks is not always useful. In CONNECT, physicians stated that valuable information was gathered in only 24% of the in-office visits compared with 62% in the RM arm. One last finding from this trial is very important to mention as it outlines the necessity to ascertain that patients understand the technology and that clinicians are aware of what information will be gathered and transmitted by the device. During the 15-month period of follow-up, 329 triggered-activated alerts occurred. However, only 55% resulted in an actual transmission to the clinic. The remaining 45% occurred with patients who had not properly set up and initiated their home monitor to adequately transmit data. Conversely, 246 clinical alerts were not transmitted at all because the specific alert was programmed off (7%) or the alert had not been reset after being previously triggered (93%). Those two findings support an important concept: proper education pertaining to RM technology is mandatory for proper and optimal use in other to enjoy the possible benefits.

Later, these benefits of RM as well as other advantages were also documented in different publications. Also in 2012, EVOLVO showed that patients receiving RM capable devices had a more favorable change in quality of life as measured by the Minnesota Living with Heart Failure Questionnaire over a 16-month period. In that trial, it is possible that some of the improvement on quality of life was related to the less frequent hospital and clinic visits and faster diagnostic time (Landolina et al., 2012). In the EVATEL study enrolling 1501 patients, there was no difference in the primary endpoint of major adverse events (death, hospitalization, inappropriate ICD therapy). (Presented by Mabo et al., European Society of Cardiology, 2011, Paris, France.) A significant reduction in inappropriate or ineffective ICD therapy (8.1% vs. 5.5%, $P=0.04$) was noted. In the ECOST study involving 433 patients, RM was found to be noninferior to in-office follow-up in terms of major safety events including death (Guedon-Moreau et al., 2013). However, RM decreased inappropriate ICD shocks by 52% (5.0% vs. 10.4%, $P=0.03$) and decreased hospitalizations by 72% (3 vs. 11, $P=0.02$). Cost-effectiveness analysis from ECOST reveals a significant cost-saving to the remote management strategy as compared with usual follow-up. Over a follow-up of 27 months, the mean nonhospital costs per patient-year were €1695 ± 1131 in the active, versus €1952 ± 1023 in the control group ($P=0.04$), a €257 difference mainly due to device management.

Pacemakers

Whereas most of the trials were designed to evaluate the efficacy of RM in ICD and CRT-D patients, one trial evaluated PM patients only. COMPAS randomized nonpacemaker dependant patients to RM or usual follow-up, the latter not being prespecified for the trial (Mabo et al., 2012). Interestingly, patients followed in the RM arm had only two scheduled visits: one at the beginning and one at the end of the18-month follow-up period. Accordingly, there were no scheduled visits during the course of the trial but clinicians were made aware of any adverse events to allow proper follow-up. Even though patients were not assessed in device clinics for more than a year, there were no significant differences in the composite endpoint of death, hospitalization for complications related to the pacing system, and hospitalization for an adverse cardiovascular event. During the trial, 43 patients (17.3%) in the active group and 47 (19.1%) in the control group experienced a major adverse event yielding a hazard ration of 0.90 that was statistically nonsignificant (95% CI: 0.59–1.41; $P=0.63$).

Based on all the available literature, it appears that RM benefits both patients and healthcare systems. Overall, studies have demonstrated that RM can be used safely in all device patient-population, with the exception of PM-dependent patients. In a broader perspective, it appears that RM allows for an increased efficiency in care delivery. Arrhythmias and malfunctions are recognized earlier, clinic visits are more efficient as nonactionable visits are reduced and more importantly, the technology does not bare any increased risk of major cardiovascular events. Although, as pointed out earlier, RM requires a comprehensive system that ensures that patients understand and use the technology properly and also that information gathered through remote transmissions are treated promptly and adequately by clinics and physicians. In its design, IN-TIME incorporated a prespecified response to any transmitted alert. Authors support that this protocolled response probably had an impact on the increased survival of patients enrolled in RM. Whereas this remains debatable, this underlies an important concept: in order to be useful, data gathered must be analyzed and treated appropriately otherwise remote technology is unlikely to yield any benefit.

Future

Now that RM is a well-established technology, the next logical step is to evaluate if remote programming is something that is feasible, safe, and beneficial. RPM-CIED is a Canadian three-step study that was designed to evaluate whether remote programming is likely to yield health and efficiency benefits on top of RM (NCT02585817). Yet to be published, the study is underway and beyond evaluating benefits of remote patient management, it will seek to evaluate logistical, legal, and behavioral barriers to implement remote programming.

Introduction

Right heart catheterization (RHC; also called pulmonary artery (PA) catheter or Swan–Ganz catheter) assesses cardiopulmonary hemodynamics and is used in the evaluation of a variety of conditions. RHC allows for the direct measurement of right atrial (RA), right ventricular (RV), and PA pressures (Swan et al., 1970). Left atrial pressure can also be estimated by measurement of pulmonary capillary wedge pressure (PCWP). Cardiac output (CO) is assessed using automated thermodilution techniques or calculated using the Fick method. RHC can be placed in the intensive care unit, cardiac catheterization unit, or operating room. Options for the insertion sites include the internal jugular, subclavian, femoral, or antecubital (basilic or brachial) veins (Summerhill and Baram, 2005). If the catheter is going to remain in for continuous hemodynamic monitoring, the right internal jugular vein is preferable to allow the patient to sit up in bed rather than lie flat. If possible, the target vessel should be visualized with ultrasound to minimize complications. **Table 1** outlines the procedure for RHC insertion.

Indications and Contraindications

The first RHC in a human was performed in Germany by Werner Forssman in 1929. He self-catheterized using a urethral catheter through his antecubital vein into his right ventricle and confirmed placement with a X-ray (**Fig. 1**) (Meyer, 1990). The technique was modified, most notably by Jeremy Swan and William Ganz, allowing quick placement and the ability to remain in situ for prolonged periods of monitoring (Lategola and Rahn, 1953). This led to a surge in use and at their peak, RHC were being used in 45% of critically ill patients in America (Bayliss et al., 2009).

The widespread use of RHC despite some concerns over safety led to a number of studies evaluating their efficacy. Most failed to demonstrate any benefit in survival or reduced days in the hospital with regular RHC use in critically ill patients (Connors et al., 1996; Yu et al., 2003; Sandham et al., 2003; Binanay et al., 2005; Richard et al., 2003; Shah et al., 2005). For this reason, most societal guidelines no longer support their routine use. In a widely referenced observational study of ICU patients, RHC use was associated with increased 30-d mortality and increased resource utilization (Connors et al., 1996). The ESCAPE trial randomized 433 patients with heart failure to therapy guided by clinical assessment and a RHC or by clinical assessment alone (Binanay et al., 2005). There was no difference in mortality or length of hospital stay in patients with a RHC, but there was a higher incidence of in hospital adverse events. With little evidence supporting widespread use in critical care patients, there has been a trend toward decreased routine use in the United States (Wiener and Welch, 2007). Despite this, most experts believe that RHC placement can provide valuable information in the following select populations:

- Unclear volume status in the setting of shock
- Severe cardiogenic shock
- Evaluation for cardiac transplantation or left ventricular assist device

Table 1 Right heart catheterization insertion technique

Obtain informed consent
Review laboratory values to ensure no coagulopathy, electrolyte, or acid–base abnormalities
Select insertion site (internal jugular, subclavian, femoral, or antecubital veins)
Sterilize wide procedural field with aseptic technique
Inject local anesthesia (1% or 2% lidocaine) to superficial insertion site and anticipated needle tract
Insert introducer using modified Seldinger technique
Confirm introducer placement in target vessel
● Visualize dark blood with no pulsatile flow
● Transduce pressure waveform
● Blood gas analysis
Prepare catheter by connecting and flushing all ports
Zero and reference system
Advance catheter under fluoroscopic guidance (preferred) or by guidance of pressure wave forms
● Once tip of catheter is in SVC, inflate balloon
● Catheter should be advanced slowly through RA, RV, and PA
● Once PCWP obtained, balloon should be deflated
Catheter should be left in place for as little time as possible
Catheter should always be removed with the balloon deflated

RA, right atrium; RV, right ventricle; PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure.

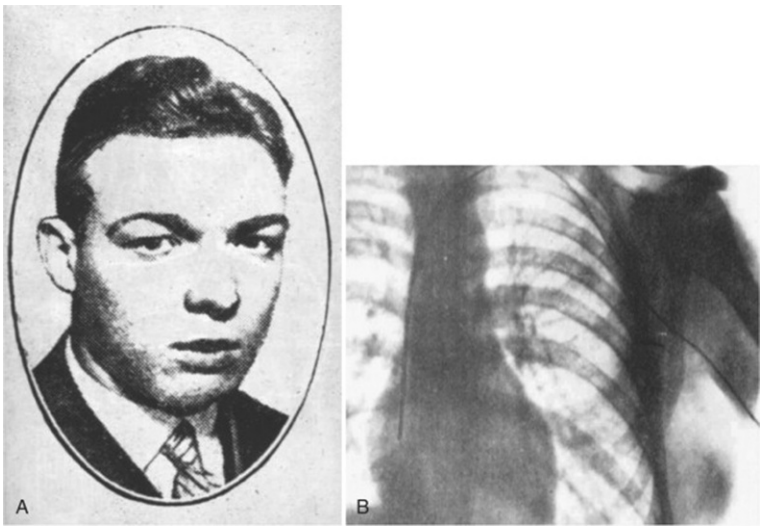

Fig. 1 (A) Werner Forssman. (B) "The catheter extends from the left cephalic vein down into the right atrium."

- Diagnosis and management of PA hypertension
- Severe cardiopulmonary disease patients undergoing corrective or other surgery

Absolute contraindications to RHC placement include lack of consent, significant infection at the insertion site, and the presence of a RV assist device. Coagulopathy and thrombocytopenia are relative contraindications. However, RHC is frequently performed without interruption of anticoagulation and may be safe in patients with an INR of up to 3.5 if done using internal jugular vein or antecubital vein access (Ranu et al., 2010). Severe electrolyte and acid–base disturbances increase the risk of life-threatening arrhythmias and should be corrected prior to RHC placement. Patients with pulmonary hypertension (PH) and Eisenmenger's syndrome are considered increased risk due to possible PA rupture. Other increased risk patients include those with defibrillator (risk of dislodgement), left bundle branch block (risk of complete heart block), prosthetic or stenotic tricuspid valve (risk of difficulty advancing catheter), and persistent left superior vena cava (risk of misplacement in left atrium). RHC can typically be placed safely in these populations by expert providers and with the use of fluoroscopy.

Complications

Though generally considered a safe procedure, several complications can occur due to RHC. Vascular access complications, including bleeding, arterial puncture, and pneumothorax, are the most frequently encountered. When passed through the right ventricle, the catheter commonly causes ventricular ectopy. This typically resolves with advancement of the catheter into the PA. Temporary right bundle branch block is observed in up to 5% of RHC (Putterman, 1989). The most feared and potentially catastrophic complication of RHC placement is PA rupture, which is rare occurring in 0.06%–0.2% of cases (Boyd et al., 1983; Shah et al., 1984). This may present with frank hemoptysis and risk factors include underlying PH, advanced age, mitral valve disease, hypothermia, and anticoagulation or coagulopathy. The risk of PA rupture can be decreased by avoiding distal catheter placement and over inflation of the balloon. Rapid identification and treatment of pulmonary rupture is critical as the mortality rate exceeds 30% (Kearney and Shabot, 1995). Initial treatment may include reinflation of the balloon to occlude the bleeding vessel and temporarily obstruct the feeding artery. If this does not stop the hemorrhage, emergent thoracotomy may be required.

Pressures

RA Pressure

The RA pressure is the "filling pressure" of the right heart. It reflects venous return to the RA and RV end-diastolic pressure. Normal RA pressure is 3–7 mmHg (**Table 2**). The classic RA waveform consists of three discrete positive and two negative deflections (**Fig. 2**). The "a wave" represents the pressure increase in the RA during atrial contraction. This is followed by the "x descent" reflecting the fall in pressure during atrial relaxation. The small "c wave" mirrors the pressure increase in the RA as a consequence of the tricuspid valve bulging into the RA during ventricular isovolumic contraction. Next, a "v wave" is seen reflecting increased atrial pressure from passive blood return while the tricuspid valve remains closed. Finally, the "y descent" is seen with the fall in atrial pressure after the tricuspid valve opens and blood rushes from the atria to the ventricle. Typically, the "a wave" is slightly larger than the "v wave." Several conditions are identified by their characteristic effect on RA pressure waveforms. Tricuspid regurgitation results in large "v waves" due to backflow of blood into the RA during ventricular systole (**Fig. 3**). In atrial fibrillation, there are no "a waves" seen due to the lack of coordinated atrial activity. Atrioventricular dissociation, as seen in complete heart block, ventricular tachycardia, or asynchronous ventricular pacing, may result in large "cannon a waves" (**Fig. 4**). These occur due to atrial contraction against a closed tricuspid valve.

RV Pressure

RV pressure is recorded at the maximal systolic pressure, minimal early diastolic pressure, and end-diastolic pressure (**Fig. 2**). Normal RV systolic pressure is 20–30 mmHg and normal diastolic pressure is 3–7 mmHg (**Table 2**). The RV waveform has a rapid upstroke and downstroke during systole. Ventricular diastole consists of three phases: early rapid filling, slow filling, and atrial systole. The end-diastolic pressure is measured as the pressure after atrial contraction and immediately before the onset of ventricular contraction. RV pressure can be elevated in PH, pulmonary embolism, and pulmonic stenosis.

PA Pressure

The PA waveform consists of a systolic pressure, dicrotic notch (representing closure of the pulmonic valve), and diastolic pressure (**Fig. 2**). Normal systolic PA pressure is 20–30 mmHg and normal diastolic pressure is 8–12 mmHg (**Table 2**). Elevated PA pressure is seen in decompensated heart failure and numerous conditions the result in elevated pulmonary vascular resistance. Distinguishing among etiologies of elevated PA pressure can be challenging and is discussed separately in the section on "**Hemodynamic Interpretation**."

Table 2 Normal pressure measurements

Chamber	*Average (mmHg)*	*Range (mmHg)*
Right atrium	5	±2
Right ventricle	25/5	±5/±2
Pulmonary artery	25/10	±5/±2
Left atrium (PCWP)	10	±2

PCWP, pulmonary capillary wedge pressure.

Fig. 2 Pressure waveforms.

Fig. 3 RA pressure in subject with a restrictive cardiomyopathy breathing spontaneously. The "v" wave (*downward arrow*) is broad, indicating tricuspid regurgitation, and so is the deep "y" descent (*upward arrow*), owing to the restrictive cardiomyopathy. The horizontal lines mark inspiration. The rhythm is atrial fibrillation.

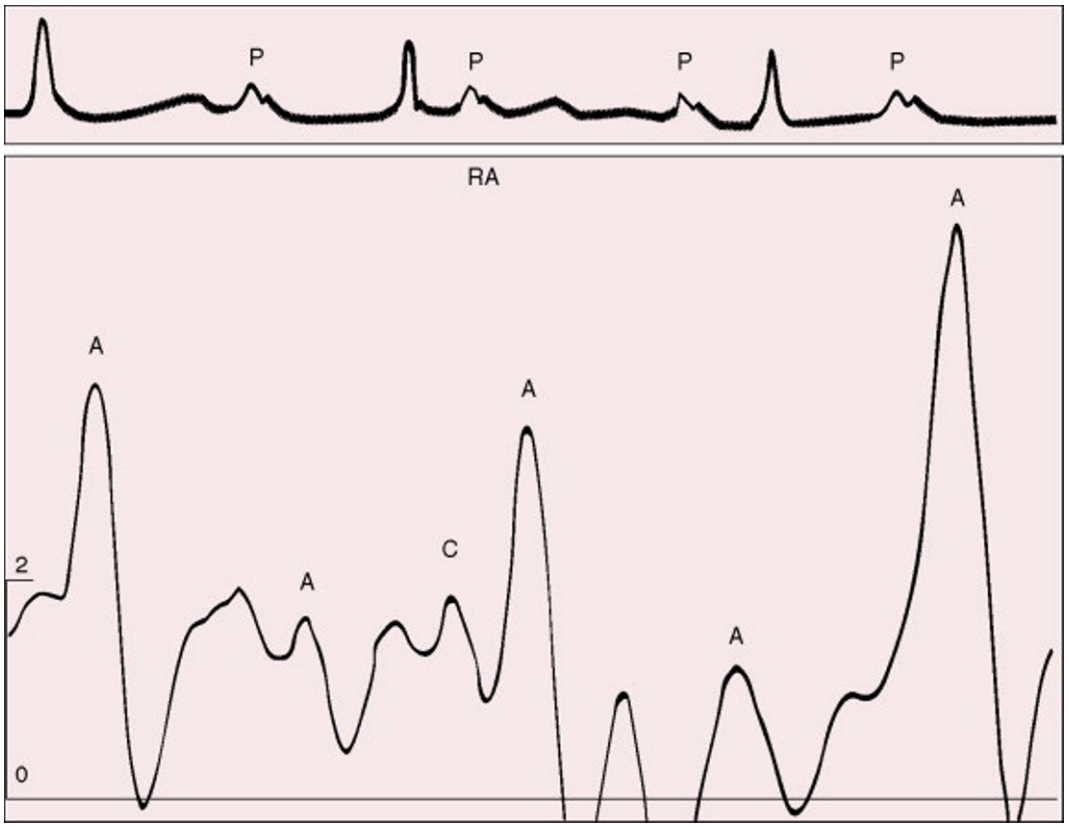

Fig. 4 Electrocardiogram and right atrial (RA) pressure pulse from a 13-year-old boy with isolated congenital complete heart block. The A waves intermittently increase (cannon waves) when a P wave falls between QRS complex and T wave. The increase occurs because the right atrium contracts against a closed tricuspid valve. The A waves are small when a P wave falls between T wave and QRS complex (i.e., when the tricuspid valve is open).

Pulmonary Capillary Wedge Pressure

The PCWP is obtained as an estimate of the left ventricular end-diastolic pressure (LVEDP) or left heart "filling pressure." With the catheter in the PA, a balloon at the distal end of the catheter is gently inflated and "wedged" into a pulmonary capillary. This obstructs blood flow creating a static column of blood between the catheter tip and left atrium. If there is no other anatomic obstruction to blood flow between the PA and left atrium, pressure measurement at the catheter tip estimates the left atrial pressure (Walston and Kendall, 1973; Lappas et al., 1973).

The normal PCWP is 8–12 mmHg (**Table 2**) and the waveform is similar to RA pressure (**Fig. 1**). Atrial contraction produces the "a wave" with the "x descent" seen as a fall in pressure during atrial relaxation. The "c wave," which is often not seen, is due to slight pressure increase from protrusion of the mitral valve into the left atrium during ventricular isovolumic contraction. With passive blood return to the atria with a closed mitral valve, a "v wave" is seen. Finally, the "y descent" occurs after the mitral valve opens and blood rushes from the atrium to the ventricle. In contrast to the RA waveform, the PCWP "v wave" is typically slightly larger than the "a wave." There can be significant respiratory variation in the PCWP measurement, and it should be recorded at end-expiration. The PCWP measurement should be taken at the "a wave" to avoid large "v waves" confounding interpretation. Numerous conditions can cause discordance between the PCWP and LVEDP. The PCWP can be lower than LVEDP in situations with decreased left ventricular compliance (diastolic dysfunction, positive pressure ventilation, cardiac tamponade, or myocardial ischemia) or in conditions such as aortic stenosis that result in premature mitral valve closure (Raper and Sibbald, 1986). Conversely, PCWP can be greater than LVEDP if there is hypoxia or conditions causing constriction of small pulmonary veins. Procedural errors in obtaining data (see "**Data Acquisition Errors**" section) such as over or under wedging of the catheter can also cause PCWP measurements that do not accurately reflect the true LVEDP, making confirmation of PCWP position essential to any hemodynamic assessment. This can be done by fluoroscopy, waveform inspection, and observing that the oxygen saturation of blood drawn distally to the inflated balloon is consistent with systemic arterial oxygen saturations. Several conditions can be identified by their characteristic effect on PCWP waveforms. The "a wave" can be elevated in conditions of increased resistance to LV filling, such as mitral stenosis, volume overload, or decreased LV compliance. Classically, mitral regurgitation may result in prominent "v waves." Prominent "v-waves" are neither sensitive nor specific for mitral regurgitation and their height is not reflective mitral regurgitation severity (Pichard et al., 1982; Fuchs et al., 1982; Schwinger et al., 1988; Snyder et al., 1994).

Cardiac Output

CO may be measured using the Fick or indicator dilution methods. The preferred expression of CO is the cardiac index, which is calculated by dividing the CO by the body surface area (**Table 3**). The PA saturation can also estimate CO.

The Fick method approximates CO using the amount of oxygen extracted by the body as measured by the arterial–venous oxygen difference (**Table 3**). The following formula calculates CO by the Fick method:

$$\text{Cardiac output (L/min)} = \frac{\text{Estimated oxygen consumption}}{10\ (\text{ateriovenous oxygen difference})}$$

While oxygen consumption can be measured directly through exhaled breath analysis, this method is cumbersome, so it is typically estimated from a nomogram based on age, sex, height, and weight. The ateriovenous oxygen difference is calculated as:

$$= (1.34)(\text{Hgb concentration})(\text{arterial oxygen saturation} - \text{mixed venous oxygen saturation})$$

In the presence of a left to right shunt present, the mixed venous oxygen saturation is calculated as [3 × SVC saturation + IVC saturation]/4.

The Fick method has a total error of 10%–15%. It is more accurate in low CO states since lower CO results in a higher ateriovenous oxygen difference. The Fick method is also more accurate in conditions where the heart rhythm is irregular, such as atrial fibrillation. The primary disadvantage of the Fick method is the reliance on estimated oxygen consumption due to the

Table 3 Commonly used calculations during right heart catheterization

Cardiac output (L/min)	$\frac{\text{Estimated oxygen consumption}}{10\ (\text{ateriovenous oxygen difference})}$
Ateriovenous oxygen difference (mL/100 mL)	(1.34) (Hgb concentration)(SaO2–MvO2)
Cardiac Index (L/min/m^2)	$\frac{\text{Cardiac output}}{\text{Body surface area}}$
Transpulmonary gradient (mmHg)	Mean PA pressure—PCWP
Pulmonary vascular resistance (Wood units)	$\frac{\text{TPG}}{\text{Cardiac output}}$
Systemic vascular resistance (Wood units)	$80 \times \frac{[\text{Mean arterial pressure (mmHg)} - \text{right atrial pressure (mmHg)}]}{\text{Systemic blood flow (cardiac output; L/min)}}$

SaO2, arterial oxygen saturation; MvO2, mixed venous oxygen saturation; Hgb, Hemoglobin; PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure; TPG, transpulmonary gradient.

difficulty of direct measurement. Additionally, the Fick method cannot detect rapid changes in CO, so it is not useful in patients undergoing interventions such as valvuloplasty or cardiac surgery.

The indicator dilution method is performed by injecting a bolus of cold saline in the proximal port of the catheter (Ganz et al., 1971). There it mixes with blood lowering the temperature. When blood flows past the distal thermistor port, the temperature change over time is recorded as a temperature–time curve. The area under this temperature–time curve is inversely proportional to CO. The indicator dilution method has the advantage of being simple to perform and having the capacity to take repeated measures to evaluate reproducibility. It is more accurate in high CO states, and there are catheters available that allow for continuous indicator dilution measures. These correlate well with bolus methods (Yelderman et al., 1992) but are more expensive and have not been shown to improve outcomes (London et al., 2002). Serial indicator dilution measures should vary less than 10% to be considered reliable. Tricuspid regurgitation can falsely lower indicator dilution measures due to a prolonged, low amplitude curve produced as blood is recycled back and forth across the tricuspid valve. Indicator dilution measures may also be less accurate with irregular heart rhythms. Both right-to-left and left-to-right shunts can falsely elevate indicator dilution measures of CO. In left-to-right shunts, increased right heart volumes and dilution of the injected cold saline will attenuate the height of the temperature–time curve resulting in an overestimate of CO. In right-to-left shunts, the cold saline can be shunted to the left heart reducing PA cooling which also attenuates the height of the temperature–time curve leading to overestimated CO.

The saturation of PA blood (i.e., mixed venous saturation) is used as an overall estimate of CO. PA saturation less than 65% indicate low output and greater than 80% high output. Compared to the other methods of assessing CO which have multiple potential sources of error, PA saturation has the advantage of being a direct measurement. PA saturation may not be reliable in the setting of shunt, hypoxia, or profound anemia.

Hemodynamic Calculations

Several calculations based on RHC findings can assist in hemodynamic interpretation (**Table 3**). The transpulmonary gradient (TPG) is defined as the difference between the mean PA pressure and PCWP. The normal value is $\leq$12 mmHg and an elevated TPG is suggestive of pulmonary arterial hypertension. Once CO has been determined, vascular resistance can be estimated. Pulmonary vascular resistance (PVR) is calculated as the TPG divided by CO. The normal PVR value is <3 Wood units (or 240 dynes s cm^{-5}) and elevated values also suggest pulmonary arterial hypertension. Systemic vascular resistance is estimated as:

$$\text{SVR} = 80 \times \frac{[\text{Mean arterial pressure (mmHg)} - \text{right atrial pressure (mmHg)}]}{\text{Systemic blood flow (cardiac output; L/min)}}$$

The calculations of vascular resistance are dependent on both direct measures (i.e., pressures) and indirect measures (CO), each of which have sources of error, making them the least accurate of all RHC values.

Hemodynamic Interpretation

Clinicians who order and manage RHC placement should be able to reliably interpret the results. Misinterpretation of RHC data is common and may be a significant contributor to the lack of benefit seen in prior clinical trials (Squara et al., 2002). As fewer RHC are obtained, this may become more challenging as trainees and clinicians have less experience with data interpretation (**Table 4**).

Acute Heart Failure

Acute heart failure is characterized by elevated PCWP. Pulmonary pressure is typically elevated proportionally to PCWP. Likewise, RA pressure may be elevated proportionally to the PCWP. When RA pressure to PCWP ratio exceeds 0.67 it may indicate RV failure (Kormos et al., 2010). The CO may be normal or depressed depending on how advanced is the heart failure.

Table 4 Interpreting hemodynamics

			PH associated with HF	
	Heart failure	*PAH*	*"In proportion"*	*"Out of proportion"*
RA (mmHg)	Normal or ↑	Normal or ↑	Normal or ↑	Normal or ↑
RV (mmHg)	Normal or ↑	↑	↑	↑
Mean PA (mmHg)	Normal or ↑	≥25	≥25	≥25
PCWP (mmHg)	>15	≤15	>15	>15
CO (L/min)	Normal or ↓	Normal or ↓	Normal or ↓	Normal or ↓
TPG (mmHg)	Normal	>12	≤12	>12
PVR (Wood units)	Normal	>3	<3	>3

PAH, pulmonary arterial hypertension; PH, pulmonary hypertension; RA, right atrium; RV, right ventricle; PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure; CO, cardiac output; TPG, transpulmonary gradient; PRV, pulmonary vascular resistance.

Pulmonary Hypertension

RHC is the gold standard for the diagnosis of PH. Pulmonary arterial hypertension (PAH) is defined as mean PA pressure ≥25 mmHg and PCWP ≤15 mmHg. PH associated with heart failure presents a diagnostic challenge. In this case, it must be determined if the elevated pulmonary pressure is secondary to volume retention alone or due to adaptive changes in the pulmonary vasculature. The TPG ≤12 mmHg and PVR <3 Wood units is indicative of PH "in proportion" to heart failure where the elevated pulmonary pressure is a result of volume retention. In this setting, patients should be diuresed to a PCWP <15 with repeat hemodynamic measurements before considering PAH-specific pulmonary vasodilator therapy. In patients with PH and PCWP >15, a TPG >12 mmHg and PVR >3 Wood units suggest PH "out of proportion" to heart failure. In other words, the elevated pulmonary pressure cannot be fully explained by volume retention and may in part be due to changes in the pulmonary vasculature (Naeije et al., 2013). The diastolic pressure gradient (DPG) may be another measure to diagnose "out of proportion" PH. The DPG is calculated by difference between the pulmonary arterial diastolic pressure and PCWP. Both a TPG >12 mmHg and DPG >7 mmHg are associated with lower median survival in patients with PH due to left-sided heart disease (Naeije et al., 2013; Gerges et al., 2013). Patients with PH "out of proportion" to heart failure may benefit from PAH-specific therapy with guidance from a PAH specialist. In patients with PCWP >25 mmHg, PH should be considered "in proportion" to HF regardless of TPG and DPG. These patients should be completely diuresed before considering PAH-specific therapy.

Cardiac Transplantation

RHC is a critical component in the evaluation for cardiac transplantation. Irreversible PH is associated with posttransplant RV failure and subsequent increased morbidity and mortality (Costard-Jackle and Fowler, 1992). Elevated PVR >5 Wood Units and TPG >15 mmHg are potential significant contraindications to cardiac transplantation (Mehra et al., 2016). Because of the difficulty distinguishing the etiology of PH in heart failure, a vasodilator challenge (see "**Acute Vasodilator Testing**" section) is recommended as part of the transplant evaluation when PA systolic pressure is >50 mmHg and PVR is >3 Wood units, with a systolic blood pressure >85 mmHg (Mehra et al., 2016). For patients with secondary PH, ventricular unloading with a left ventricular assist device is often used to successfully bridge patients to transplantation. With LVAD support, significant reductions in TPG and PVR can be seen within 1 month of implantation (Kutty et al., 2013). RHC should be performed in all patients prior to transplant listing and as frequently as every 3–6 months while on the waitlist in patients with secondary PH or who are decompensating.

Cardiac Tamponade

The diagnosis of cardiac tamponade can be confirmed by RHC. In tamponade, the RA, PA diastolic pressure, and PCWP are all elevated and equal within 4–5 mmHg of each other (**Fig. 5**). The RA and PCWP generally have an attenuated or absent "y descent." CO will be reduced and the SVR is elevated. The definitive treatment involves pericardiocentesis to remove pericardial fluid.

Acute Vasodilator Testing

Acute vasodilator testing involves administration of a short-acting vasodilator in patients with PH followed by measurement of the hemodynamic response using a RHC. It can be performed using a variety of agents, including nitroprusside, nitroglycerin, inhaled nitric oxide, or IV epoprostenol. Acute vasodilator testing should be performed in patients with Group 1 PAH to determine potential responsiveness to calcium channel blocker therapy. A positive response in PAH is defined as reduction in mean PA pressure of >10 mmHg to reach a mean of <40 mmHg with increased or unchanged CO. Acute vasodilator testing is also useful to determine

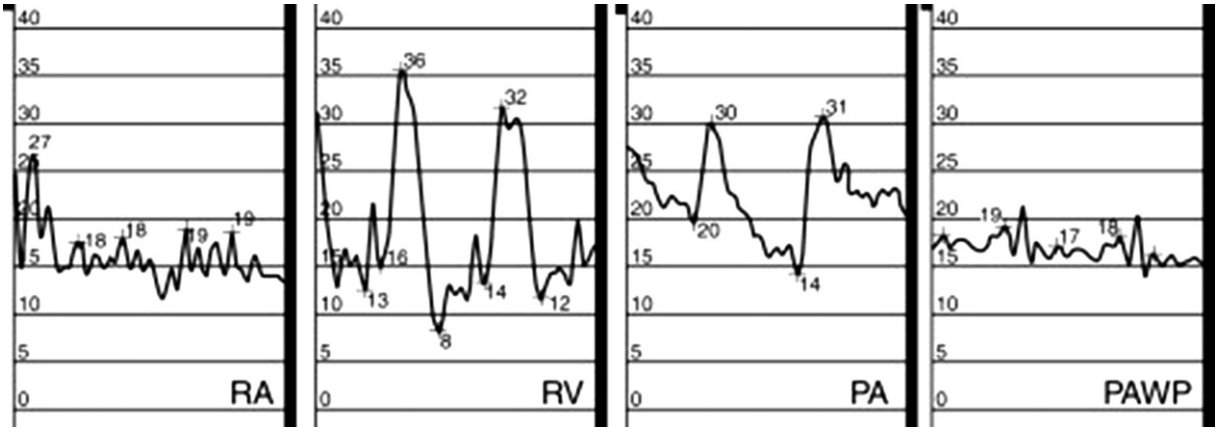

Fig. 5 Pressure tracings in cardiac tamponade. PA, Pulmonary artery; PAWP, pulmonary artery wedge pressure; RA, right atrium; RV, right ventricle. There is equalization of all diastolic pressures across all chambers.

the reversibility of elevated pulmonary pressures in heart failure. The foundation of acute vasodilator testing in heart failure is that PA pressures will rapidly fall (and CO increase) when the left heart is "unloaded." However, some patients with chronic elevations of their LVEDP can have remodeling of their pulmonary arteries resulting in irreversible PH. If there is inadequate response to an acute vasodilator challenge, the patient should be hospitalized with continuous hemodynamic monitoring. The PVR will often decline after 24–48 h of treatment some combination of inotropes, vasodilators, and diuretics. In patients where the PVR is reduced to <2.5, but the systolic blood pressure falls to <85 mmHg, the risk of right heart failure following transplantation remains high (Costard-Jackle and Fowler, 1992; Butler et al., 2005).

Data Acquisition Errors

There are several important sources of error in performing a RHC that physicians should be aware of. Pressure waveforms can become dampened, appearing as rounded contours with delayed upstrokes and downstrokes. This is often due to air bubbles within the catheter or tubing and can be corrected by flushing the system. Catheter "whip" can appear as an erratic waveform with highly variable pressures. This is also typically resolved by flushing the system or repositioning the catheter.

The RHC must be zeroed and referenced to obtain accurate readings. To zero, the system is opened to air to establish atmospheric pressure as zero. Referencing (or "leveling") is done to confirm the air–fluid interface of the transducer is at the level of the patient's heart. If the heart is lower than the transducer level, the pressure will be erroneously low. Conversely, if the heart is higher than the transducer the pressure measure will be falsely high.

Obtaining an accurate PCWP is critical, particularly since it will influence subsequent TPG and PVR calculations. Both over- and underwedging can confound the PCWP results. Overwedging results from excessive inflation of the balloon. It produces a dampened waveform and can lead to falsely elevated PCWP due to transmittal of pressure from the balloon. It usually corrects with partial deflation of the balloon. Overwedging also increases the risk of PA rupture. If the PA is incompletely occluded, underwedging can occur which can also result in artificial elevation of the PCWP. This frequently occurs in patients with high PA pressures due to poorly compliant pulmonary vasculature. Underwedging can be corrected by deflating the balloon and slowly reinflating until the catheter wedges more completely. The catheter can also be taken back into the main PA and guided into a different PA branch.

Summary

RHC remains important in the diagnosis and management of select cardiopulmonary disorders. Direct measure of RA, RV, PA, and PCWP and estimates of CO and vascular resistance can be obtained. These values are particularly useful in the management of advanced heart failure, PH, and in evaluating patients for heart transplantation. Misinterpretation of RHC data is common and clinicians performing and interpreting hemodynamics should understand how to decipher the results and be aware of common data acquisition errors. However, with fewer RHC now being performed this has become more challenging.

Introduction

Understanding the causes of heart disease is a relatively young field in medicine. In fact, heart disease was relatively rare prior to the early 1900s. With the advent of antibiotics and refrigeration, early deaths from infectious disease plummeted. In addition, the advent of automobiles and grocery stores decreased the need for sourcing our own food by farming, and thus more sedentary lifestyles. This combination leads to a rapid rise in heart disease. This transition from a society with the majority of mortality from infectious disease to that of cardiovascular disease follows socioeconomic progression. It can still be seen throughout third world and developing countries today (Yusuf et al., 2001).

But the relationships of diet, smoking, cholesterol, and the causes of heart disease that seem so obvious now were a long time coming (Fig. 1). The connection between cholesterol and heart disease was not made until Virchow found fat in atherosclerotic lesions in 1856, and Anitschkow showed in 1913 that feeding rabbits a cholesterol-rich diet promoted atherosclerosis (Anitschkow and Chatalov, 1913). The connection between smoking and heart disease came slowly with the accumulation of epidemiologic data during the 1940s and 1950s, but was not widely accepted until the report *Smoking and Health: Report of the Advisory Committee to the Surgeon General* was published in 1964.

In addition, determining what is causing heart disease (risk factors) and what is associated with heart disease (risk markers) continues to be debated. Risk factors are causative agents that lead to atherosclerosis and cardiovascular disease. Risk markers are signs of underlying atherosclerosis or factors that occur concurrently, for example, coronary calcification. There is likely crossover of many factors as well, such as obesity, which is likely a risk factor in itself, yet is associated with many other risk factors such as insulin resistance and sedentary lifestyle.

In this article, we will review the known major risk factors for the development of atherosclerosis and cardiovascular disease, and discuss some of the newer factors still being discovered.

Cholesterol

The link between cholesterol and atherosclerosis really developed in the 20th century. The strongest connections came from epidemiologic data such as the Framingham group and the Seven Countries Study. The Framingham group showed that cholesterol level in patients without prior coronary artery disease was linked to the development of coronary heart disease in the future (Castelli et al., 1992). These patients were controlled for other risk factors including hypertension, diabetes, and tobacco use, showing that cholesterol level was an independent risk factor. In 1976, Ancil Keys published the Seven Countries Study that was one of the first to suggest that diet had a significant influence on cholesterol and on cardiovascular risk of death (Keys, 1970). This landmark study followed the diets and cholesterol levels in cohorts of patients in seven different countries to determine if there was an influence on mortality. There was a clear link between a diet low in saturated fats and high in vegetables and reduced mortality. The favorable diet pattern came to be known as the Mediterranean diet. Despite clear evidence of this connection in 1976, the idea of diet to improve cardiovascular health has been slowly adopted in the United States.

Further evidence of cholesterol's contribution to atherosclerosis and coronary artery disease can be found in genetic population studies. Familial hypercholesterolemia (FH) is an autosomal dominant disorder with a prevalence in the United States of approximately 1:250 people (de Ferranti et al., 2016), though it is even more prevalent in certain subgroups, such as those of French Canadian ancestry (1:150–200). FH is actually a combination of genotypes that share the same phenotype of high low-density lipoprotein (LDL) cholesterol level. The most common are abnormalities of the LDL receptor that prevent it from clearing LDL from the bloodstream. There are over 1700 mutations in the LDL receptor alone, which accounts for 90% of the cases of FH (Hartgers et al., 2015). These mutations affect the function of the LDL receptor in one of five ways. Class 1 mutations result in a complete lack of LDL receptors. Class 2 mutations result in the LDL receptors not being transported from the endoplasmic reticulum to the Golgi apparatus. Class 3 mutations result in an LDL receptor that is unable to bind to LDL. The LDL receptor in a class 4 mutation binds LDL, but is unable to

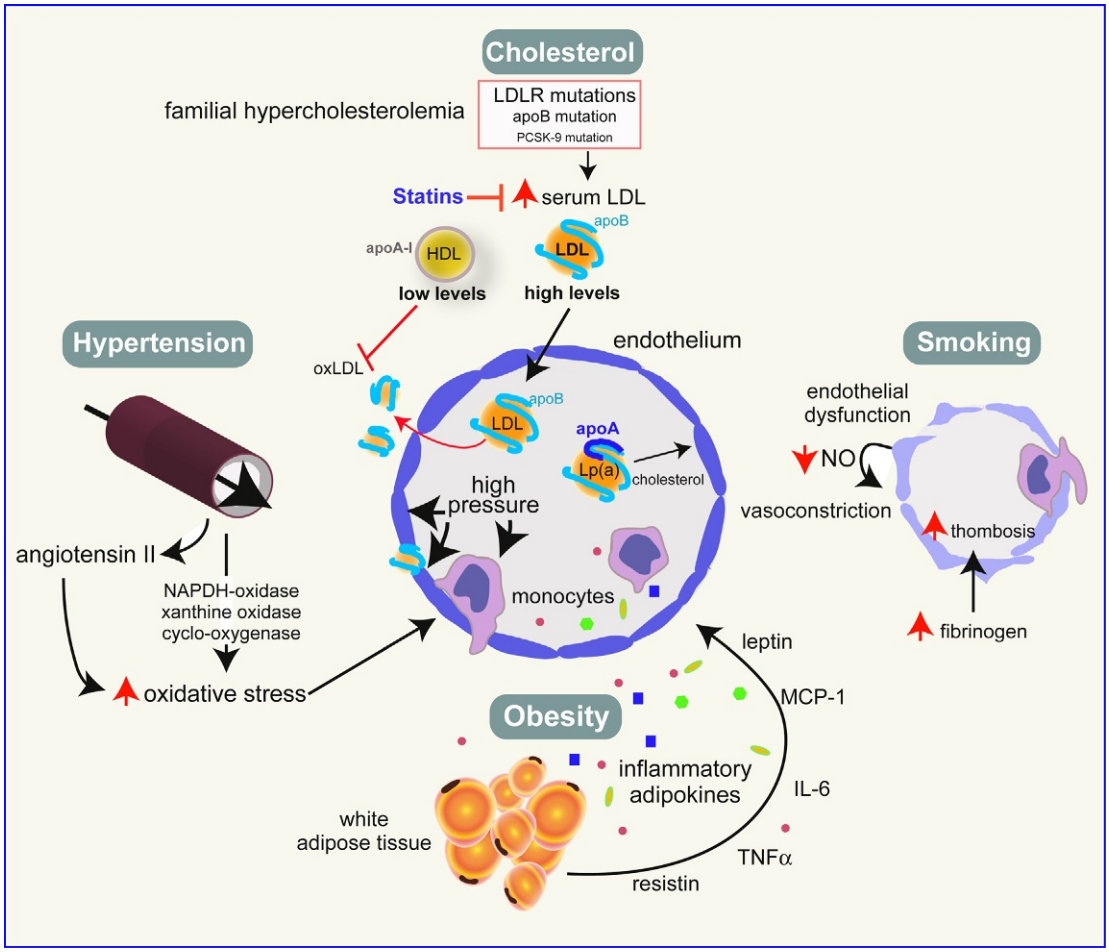

Fig. 1 Relationships of diet, smoking, cholesterol, and the causes of heart disease.

internalize it. Finally, class 5 mutations result in an inability of the cell to recycle the receptor back to the surface. The remaining 10% of genetically identified cases of FH result from abnormalities in two other genes. The first gene codes for apolipoprotein B, the protein portion of LDL that is responsible for facilitating attachment of the LDL molecule to the LDL receptor. The abnormal apolipoprotein B does not adequately bind to the LDL receptor, thereby preventing clearance of LDL from the bloodstream. This defect has a prevalence of roughly 1:1000 (Foody and Vishwanath, 2016). The second is an abnormality in the gene that codes for proprotein convertase subtilisin/kexin type 9 (PCSK-9) (Cohen et al., 2006). PCSK-9 is a protein that helps regulate the number of LDL receptors on the cell surfaces. The more circulating PCSK-9, the more LDL receptor degradation, and the less recycling of the receptors, resulting in higher serum levels of LDL (Cohen et al., 2006). Alternatively, patients with low circulating levels of PCSK-9, due to a loss of function mutation, have higher numbers of LDL receptors and very low cholesterol levels.

Multiple epidemiologic studies have shown an increase in coronary risk in patients with FH that is much higher than matched controls, suggesting that prolonged exposure to elevated blood levels of LDL over a lifetime is a risk factor for coronary heart disease (CHD). Indeed, this relationship is even higher for patients with homozygous FH, suggesting a dose-related response (Austin et al., 2004). Further proof of this concept can be seen in patients with a loss of function in the gene coding for PCSK-9 that results in very low LDL. These patients have a markedly reduced risk of developing CHD, suggesting that a lifetime of reduced LDL exposure is protective (Cohen et al., 2006).

Likewise, multiple randomized controlled clinical trials have shown that lowering serum LDL with medical therapy reduces both the risk of recurrent myocardial infarction (MI) (secondary prevention) and the risk of the development of cardiovascular disease (CVD) (primary prevention). Much of the data on statin therapy for lowering LDL cholesterol have been pooled and evaluated by the Cholesterol Treatment Trialists group, showing a clear correlation between LDL level and cardiac risk (Cholesterol Treatment Trialists' Collaborators, 2012).

Thus, we have data showing that lifetime exposure to high cholesterol increases risk for CVD in a dose-dependent manner, that lifetime exposure to low levels of LDL decreases risk, and that medically lowering LDL cholesterol also reduces risk. Is there molecular data showing a mechanistic explanation for this effect?

Indeed, there is a wealth of evidence showing that LDL movement into the subendothelial layer is one of the earliest phases of the development of atherosclerosis. Once the endothelial layer is disrupted or inflamed, markers on the surface of the endothelium will attract LDL molecules, which then move into the subendothelial layer, beginning the complex formation of the atherosclerotic lesion (Kwak et al., 2014; Libby, 2002b). In addition, research has shown that the higher the circulating level of LDL, the more molecules will travel through the endothelium and promote atherosclerosis (the mass transport theory) (Lusis, 2000; Olgac et al., 2008). Therefore, it is plausible that the lower the level of circulating LDL, the less promotion of atherosclerosis, the cause of vascular disease.

Other lipoproteins play a role in the development of atherosclerosis as well. Low levels of high-density lipoprotein (HDL) have been associated with higher risk of atherosclerosis in epidemiologic studies, though the association is complex (McQueen et al., 2008). HDL has an opposing relationship to LDL in that higher levels of HDL reduce the risk of atherosclerosis, while lower levels increase the risk (Castelli et al., 1992). However, the absolute level of HDL does not seem to have as clear a role in predicting future risk as does the HDL function. HDL plays a major role in reverse cholesterol transport, which is the process by which cholesterol is transported from the circulation to the liver. HDL molecules also reduce the amount of cholesterol in the atherosclerotic plaque by removing it via a mechanism known as cholesterol efflux. The extent to which this occurs is known as the cholesterol efflux capacity. HDL also has an antiinflammatory effect, and can decrease the oxidation of LDL in the subendothelial space, which is a key step in the progression of atherosclerosis (Ansell et al., 2005; Libby, 2002a). Paradoxically, in some situations, for instance during an inflammatory state such as an infection, HDL can be proinflammatory (Ansell et al., 2005).

Despite a wealth of epidemiologic data and clear mechanistic research on how HDL inhibits atherosclerosis, a variety of interventions to raise HDL have yet to show benefit. Though some early studies suggested benefit using niacin to target low HDL (Brown et al., 2001), subsequent larger trials have not been able to reproduce this effect (AIM-HIGH Investigators et al., 2011). A class of drugs called cholesterol ester transfer protein (CETP) inhibitors have been developed, which work to block the enzyme cholesterol ester transfer protein. CETP reduces circulating HDL cholesterol levels by transferring esterified cholesterol ester from HDL to larger lipoproteins, such as chylomicrons, VLDL, and LDL, in exchange for triglycerides. By blocking this enzyme, circulating HDL increases. However, no clinical trial of any of the CETP inhibitors brought to market thus far has shown a clinical benefit (Kingwell et al., 2014). This may in part be due to the finding that inhibiting CETP by some mechanisms also increases the number of small, dense LDL particles, which are atherogenic, thus offsetting the benefit of the increase in HDL (Durrington, 2012).

The connection between elevated serum triglycerides and atherosclerosis has been less clear. It is likely that elevated triglyceride level is more a marker of increased atherogenic risk rather than atherogenic itself. In the Emerging Risk Factors study, a meta-analysis of multiple prospective studies including data on over 300,000 individuals, there was a clear correlation between elevated triglyceride level and future development of cardiovascular disease. However, when the data was controlled for HDL cholesterol and non-HDL cholesterol, the correlation disappeared, suggesting that the association with elevated levels of LDL and low levels of HDL were the driving factors (Emerging Risk Factors Collaboration et al., 2009).

Elevated levels of triglycerides are frequently associated with the metabolic syndrome (increased waist circumference, insulin resistance, low HDL, high blood pressure, and elevated triglycerides) which has been linked to increased cardiovascular risk. Once again, this appears to be primarily an association rather than a causative factor. For this reason, the American Heart Association (AHA) statement on Triglycerides and Cardiovascular Disease suggests that the finding of elevated triglycerides in a patient should prompt aggressive lifestyle intervention including a diet low in simple carbohydrates and higher in omega-3 fats, weight loss, and increased physical activity. Medical therapy aimed at lowering triglycerides with fibrates should be reserved for patients at risk of triglyceride-induced pancreatitis (Miller et al., 2011).

There are other lipoprotein types that are atherogenic as well, such as lipoprotein(a) (Lp(a)). Lp(a) is essentially an LDL molecule that has an apolipoprotein A molecule attached to the apo B molecule. The level of Lp(a) is genetically determined and not influenced by diet. The LPA gene determines the amount of Lp(a) produced by the liver. Lp(a) is particularly atherogenic due to the similarity between apo a and plasminogen, which it competes with for the plasminogen receptor. Lp(a) does not have the fibrinolytic ability, however, so it is thereby somewhat prothrombotic by inhibiting some plasminogen-mediated fibrinolysis. In addition, it has a high affinity for injured endothelial cells, binding to deliver cholesterol. This may have been advantageous at one point in evolution as a cellular membrane repair function, but with our current lifestyles and other cardiovascular (CV) risk factors, it is now proatherogenic (Tsimikas and Hall, 2012).

Hypertension

Hypertension is one of the most prevalent risk factors for cardiovascular disease. The most current data from the National Health and Nutrition Examination Survey 2011–2014 showed a prevalence of 29.1%. The prevalence increases with age, from 7.3% among adults aged 18–39, 32.2% in those aged 40–59, and 64.9% in adults 60 and over (Yoon et al., 2015). The prevalence has not really changed over the last 10 years. Among adults with hypertension, only 53% had controlled hypertension. The prevalence of controlled hypertension increased significantly between 1999 and 2009 from 31.5% to 53.3%, but plateaued from 2009 to 2014 without any further improvement.

The connection between hypertension and vascular disease is well established in epidemiologic and clinical trials. The Framingham study showed a clear connection between hypertension and risk of the development of cardiovascular disease (Franklin et al., 2001). There seems to be a stronger correlation between diastolic hypertension at a younger age, while systolic hypertension and then pulse pressure become more correlated with age.

The treatment of hypertension in multiple large randomized controlled trials has shown clear reduction in event rates of MI, stroke, and death (Turnbull and Blood Pressure Lowering Treatment Trialists' Collaboration, 2003). The level to which blood pressure should be treated, however, has been controversial. Though epidemiologic studies show a graded increase in risk with increasing blood pressure as a continuum, randomized controlled trials have not demonstrated a significant reduction in cardiovascular risk with reductions in blood pressure below 140/90 mmHg (Rosendorff et al., 2015). In addition, some studies have suggested excess risk of aggressive blood pressure lowering in patients over 60 years of age (Bavishi et al., 2016). The most recent guideline released in 2014 therefore recommends target blood pressure lowering to <140/90 in individuals <60 and <150/90 in patients >60 years (Rosendorff et al., 2015). The recently completed SPRINT study, however, may influence future recommendations. This large, prospective, NIH-sponsored trial compared standard (<140 mmHg) vs intensive (<120 mmHg) BP lowering in patients without CVD or diabetes. They found a reduction in major adverse cardiovascular events in patients treated to the lower goal of <120 mmHg (The SPRINT Research Group et al., 2015). However, there has been some controversy on the SPRINT trial, for instance on the methods used to assess BP (Bavishi et al., 2016). Interestingly, another recent large trial (HOPE-3) that looked at treating intermediate risk patients with average systolic blood pressure of 138 failed to show a reduction in major adverse cardiovascular events with a combination of an angiotensin II receptor blocking agent and hydrochlorothiazide (Lonn et al., 2016). Though the exact target to lower blood pressure will likely remain controversial, the NHANES data above clearly shows that we have plenty of room to improve our treatment of hypertension in the United States with still 47% of patients not adequately treated and at least 25% of patients with diagnosed hypertension not taking any medication at all (Nwankwo et al., 2013; Yoon et al., 2015).

There are clear epidemiologic studies showing a connection between hypertension and CVD, and trials showing a reduction in CVD with the treatment of hypertension, but what about a biologic mechanism connecting hypertension and CVD? There are multiple mechanisms by which hypertension contributes to atherosclerosis. First is the increased vascular stress on the endothelium caused by the increased pressure. There is evidence that particularly in areas where there is nonlaminar flow, increased radial forces lead to changes in the endothelial layer that make it more susceptible to LDL movement into the subendothelium, as well as the attachment of monocytes, two of the earliest steps in the development of atherosclerosis (Kwak et al., 2014).

Another link between hypertension and CVD is a result of increased oxidative stress. Several different enzyme systems are activated in the setting of hypertension resulting in increased availability of superoxide anions that decrease the availability of nitric oxide and generate proinflammatory radicals. These enhanced enzyme systems include NADPH oxidase, xanthine oxidase, and cyclooxygenase as well as decreased activity of superoxide dismutase, which works as a detoxifying agent (Zaheer et al., 2016). Angiotensin II is also increased in hypertension and is another strong enhancer of oxidative stress (Luft, 2001). Increased oxidative stress and inflammation has been closely linked to the development of atherosclerosis through a variety of mechanisms including endothelial cell damage, increased expression of adhesion molecules, and activation of inflammatory proteins that promote atherosclerosis (Libby, 2002b).

Smoking

Cigarette smoking remains the single most preventable cause of early death in the United States. The 2014 Surgeon General report states that over 20 million premature deaths can be attributed to smoking over the last 50 years since the first surgeon general report was released. Of these, 7.8 million are attributed to cardiovascular disease in smokers and another 2.2 million are attributed to cardiovascular disease in people exposed to secondhand smoke (General, 2014). Between 2005 and 2009, 32% of all deaths from coronary heart disease were attributable to smoking, making it the strongest risk factor for coronary heart disease other than age. Despite advances in smoking cessation, it is predicted that, at current rates, 5.6 million current Americans younger than 18 years of age are projected to die prematurely of a smoking-related illness.

There are an estimated 1.3 billion smokers worldwide, of which 82% are in developing countries (Shafey et al., 2003). There have been great strides in reducing the number of smokers in the last 50 years since the original surgeon general's report. The prevalence of current cigarette smoking among adults has declined from 42% in 1965 to 18% in 2012. However, there has been a slowing in the rate of decline, particularly in the last 8 years, with the prevalence remaining relatively flat, though the number of cigarettes smoked has dropped, with fewer smokers in the >20 cigarettes per day, but an increase in the number of smokers using 1–10 per day.

There have been many studies looking at the effect of smoking on risk of CHD. The epidemiologic connection between smoking and heart disease was first noted in the 1950s, and gathered more and more data over the years. One of the largest of the more recent studies was the INTERHEART study—a prospective case control study in multiple sites around the world that looked at a variety of risk factors for heart disease, including smoking as well as secondhand smoke (Teo et al., 2006). They found an overall threefold increased risk of acute MI in patients who smoked. The risk was directly proportional to the number of cigarettes smoked, with odd ratios of 1.63 in subjects who smoked 1–9 cigarettes per day, 2.59 for those who smoked 19–20 per day, and 4.59 for the >20 cigarettes/day smokers, but escalate to 9.16 in those who smoked >40 cigarettes/day. These ratios were similar for men and women.

Secondhand smoke exposure was also associated with risk of MI in a graded manner. Compared with subjects reporting no secondhand smoke exposure, those with 1–7 h of exposure per week had an odds ratio of 1.24 for MI, while those with 15–20 h per week increased their risk almost twofold.

It was also interesting to see how quickly risk dropped in nonsmokers. Within the first 3 years after quitting, risk dropped in half, though there did continue to be some excess risk even 20 years after quitting (Teo et al., 2006).

Smoking leads to a variety of abnormalities in the vascular system that ultimately leads to atherosclerosis and CVD. One of the earliest is vasoconstriction due to endothelial dysfunction, as well as an inhibition of nitric oxide production, which further impairs vasodilation. Smoking also appears to contribute to LDL oxidation, another important factor in the early development of atherosclerosis. The general injury of the endothelium causes a change in the adhesive properties that increases the recruitment, adhesion, and migration of monocytes into the subendothelial space, the next step in the development of atherosclerosis. In addition to its role in the development of the atherosclerotic plaque, smoking has been shown to increase levels of fibrinogen, which increases thrombosis and can therefore contribute to the subsequent clot formation in the ruptured plaque that leads to an acute MI (Powell, 1998).

As the largest preventable cause of CVD in the world, there is appropriately much focus on eliminating smoking, like the US Healthy People 2020 initiative, which hopes to reduce the prevalence of cigarette smoking among adults to 12%. With the number still hovering around 16%–18%, and holding steady, this goal may be difficult to attain. The American Heart Association's Million Hearts program targets a variety of cardiovascular risk factors, including smoking, with a goal to save a million lives in 5 years. If we hope to continue to reduce the incidence of heart disease, smoking cessation will need to remain a top priority.

Obesity

Obesity has become a global epidemic that is rampant in the United States. Of US adults, 69% are either overweight or obese and 35% are obese body mass index (BMI >30) (Flegal et al., 2012). Obesity is clearly a risk marker for CVD, in that it is associated with multiple known risk factors such as diabetes, elevated cholesterol, hypertension, and sedentary lifestyle. However, several large trials have established that obesity is an independent risk factor for heart disease as well. The Prospective Studies Collaboration looked at 57 prospective studies with almost 900,000 participants. This study showed a clear correlation of obesity, as measured by body surface area, and risk of CVD adjusted for age, study, and smoking. They found that for each additional 5 kg/m^2 increase in BMI above 25 there was an additional 40% increase in risk of vascular mortality (hazard ratio (HR) 1.41) (Prospective Studies Collaboration et al., 2009). They found a U-shaped curve in the relationship between BMI and mortality in general with the ideal BMI from 22.5 to 25 kg/m^2. The inverse relationship between BMI and mortality below 22.5 was due predominantly to an increase in respiratory diseases and lung cancer.

The Emerging Risk Factors Collaboration looked at 58 prospective studies with data from 221,934 subjects in 17 countries to assess the relationship of BMI, waist circumference, and waist to hip ratio to determine which measure of obesity best correlated with risk of first-onset cardiovascular disease. They found a significant increased risk in CVD with all three measures of obesity when adjusted for age, sex, and smoking status without a clear improvement in correlation with any one. However, the correlation between BMI and CVD risk was significantly attenuated when additional adjustments for systolic blood pressure, history of diabetes, and total and HDL cholesterol were made (from a HR of 1.27 to 1.07) (Emerging Risk Factors Collaboration et al., 2011b).

These studies, and others, suggest that the majority of the connection between obesity and cardiac risk lies in the increase in associated risk factors like diabetes, cholesterol, and decreased activity. However, there are physiologic findings in obesity that promote atherosclerosis. Obesity is an inflammatory state, as adipose tissue is a source of proinflammatory adipokines including tumor necrosis factor (TNF) alpha, IL, monocyte chemoattractant protein-1 (MCP-1), resistin, and leptin. These adipokines have a variety of effects including stimulating vascular reactivity, promoting inflammation, and even promoting coagulation (Mandviwala et al., 2016).

Obesity is therefore both a risk factor and a risk marker for cardiovascular disease, and its rise over the last 20 years remains both a major health risk and an important target for intervention.

Sedentary Lifestyle

Sedentary lifestyle has become a growing concern as a risk factor for cardiovascular disease. Dr. James Levine, director of the Mayo Clinic-Arizona State University Obesity Solutions, has dubbed "sitting the new smoking."

The Australian Diabetes, Obesity and Lifestyle study measured sedentary activity by hours of television viewing. They adjusted for age, sex, waist circumference, and exercise, and found a significant correlation between hours of television watched and cardiovascular mortality. Compared with the baseline of <2 h/day, the HR for >2 to <4 was 1.19, and 1.8 for >4 h/day (Dunstan et al., 2010). Even in patients who exercise, the negative impact of more time spent sitting outweighs the benefit of exercise. This was evaluated in a large prospective study in the United States sponsored by the American Cancer Society that prospectively surveyed 123,216 subjects subsequently followed for 14 years. After adjustment for age, smoking, BMI, alcohol consumption, and comorbidity index (including hypertension, diabetes, and cholesterol), they found that time spent sitting >6 h/day versus <3 h/day was associated with a mortality RR of 1.17 in men and 1.34 in women (Patel et al., 2010). The relative risks were even higher in the group with the most sitting and least exercise combined. The associations were strongest for cardiovascular mortality.

Like obesity, being sedentary is clearly associated with an unhealthy lifestyle that increases cardiovascular risk factors; however, there are some physiologic changes that likely make sedentary behavior both a risk marker and a risk factor in itself. One study has

shown that lipoprotein lipase activity is decreased during sitting, which would result in less catabolism of triglycerides and increase levels of plasma triglycerides (Zderic and Hamilton, 2006). Another possibility is the decrease in endothelial nitric oxide expression caused by lower blood flow in the limbs with prolonged sitting (Stamatakis et al., 2011). Studies have shown that decreased nitric oxide and the subsequent decrease in vascular reactivity is a risk factor for atherosclerosis.

The American Heart Association and American College of Cardiology recommend 30 min of aerobic exercise 5 days a week at a minimum for a healthy lifestyle (Eckel et al., 2014). Many also now recommend limiting prolonged sitting and now recommend getting up and moving for at least 5 min out of every hour of sitting as a separate and equally important way to reduce cardiovascular risk.

Diabetes

Diabetes has long been known as a risk factor for the development of atherosclerosis. As one of the strongest risk factors for coronary artery disease and MI, patients with diabetes at age 50 will be expected to die 6 years earlier than nondiabetic matched controls (Emerging Risk Factors Collaboration et al., 2011a). The risk of vascular death is twice that of nondiabetics even when adjusted for age, sex, BMI, LDL, systolic blood pressure, smoking, and several other risk factors.

Prospective studies have also shown a relationship between elevated glucose at baseline with the development of vascular disease, even without the diagnosis of diabetes (Emerging Risk Factors Collaboration et al., 2010b). In addition, hemoglobin A1c, a marker of longer term glucose control, is correlated with increased risk for the development of coronary artery disease (Turner et al., 1998).

Much research has been done on the mechanisms of how diabetes leads to vascular disease. The mechanism is predominantly related to endothelial dysfunction. The endothelium is the monolayer of cells that lines all vascular beds and regulates the interaction between the vessel wall and the blood. One of the ways diabetes affects the endothelium is by inhibiting endothelial-derived nitric oxide (Beckman et al., 2002). Nitric oxide is the key mediator of vascular relaxation and plays a role in limiting inflammation. Insulin resistance also leads to increased availability of free fatty acids, which further inhibit nitric oxide-mediated vasodilation. Diabetes also increases plaque instability by inhibiting collagen synthesis by smooth muscle cells, affecting the stability of the fibrous cap. Through a variety of mechanisms, diabetes also enhances platelet activation, which, in addition to the augmented blood coagulability, further increases the risk of thrombotic occlusion with plaque rupture (Beckman et al., 2002).

Inflammation

Inflammation is one of the newly identified risk factors for cardiovascular disease. There has been controversy as to whether inflammation is a risk marker (a product of atherosclerosis) or a risk factor, though it appears to be both.

Atherosclerosis is clearly an inflammatory state. Leukocytes attracted to cell surface adhesion molecules, in turn stimulated by cytokines, begin the process of atherosclerosis. One of the best studied markers of inflammation is C-reactive protein (CRP). Studies, such as the Emerging Risk Factors Collaboration, have shown that CRP level is a strong predictor of vascular events in apparently healthy controls, independent of other conventional risk factors such as cholesterol, smoking, and hypertension. In fact, this study suggested the degree of predictive power was similar to that of total and HDL cholesterol (Emerging Risk Factors Collaboration et al., 2010a).

A large randomized controlled trial that compared the use of rosuvastatin vs placebo in patients with elevated CRP but relatively "normal" LDL cholesterol showed that treatment with the statin markedly reduced cardiac events and mortality (Ridker et al., 2008). This benefit held true even in patients that would have been "low risk" according to their conventional risk factors, attesting to the additional benefit of CRP in predicting risk.

Ongoing trials using antiinflammatory medications to reduce risk of cardiac events, such as the NIH-sponsored CIRT trial, should help determine if attenuating inflammation reduces cardiac events. This study is looking at the effect of low-dose methotrexate in patients with coronary artery disease to see if reducing inflammation will reduce recurrent coronary events. Inflammation modulation will certainly continue to be a target for treatments that hope to reduce the development of cardiovascular disease.

Overview

Two complementary strategies for prevention are the population approach and the high-risk approach. The high-risk preventive strategy identifies and targets individuals at elevated risk of developing cardiovascular disease (CVD) who would benefit from preventive therapies such as statins or aspirin as well as effective dietary and behavioral interventions. For this purpose, an algorithm using the Framingham equation for estimating 10-year risk of coronary heart disease (CHD) had been promoted by the Adult Treatment Panel-III (ATP-III) panel for the treatment of hyperlipidemia in the United States since 2001 (National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III), 2002). In 2013, the ACC/AHA risk-based approach using the Pooled Cohort Equations replaced the previous ATP-III algorithm for the primary prevention of atherosclerotic cardiovascular disease (ASCVD) (Goff et al., 2014). The principal assumption of these approaches is that the intensity of preventive therapies should match the level of absolute risk, which had previously been estimated by simply counting the number of risk factors. In this section, the definition, evaluation, application, and future directions of CVD risk prediction models are briefly introduced.

Definition

A CVD risk prediction model is a mathematical equation that combines multiple risk factors for an individual to estimate the absolute probability of developing CVD within a specific time period (Moons et al., 2012a). Correct interpretation of the estimated risk obtained from the model, say, a "10-year CVD risk of 10%," is that 10 out of 100 individuals with the same estimated risk would be expected to sustain a major ASCVD event by the end of 10 years (Lloyd-Jones, 2010). Procedures for the development of multivariable prediction models are described in detail elsewhere (Sullivan et al., 2004).

Framingham Risk Score

The Framingham risk function was the first CVD risk prediction model that was developed from the Framingham Heart Study in the 1970s (Kannel et al., 1976). The function has been updated by adding newer risk factors (Anderson et al., 1991), or employing risk factor categories (Wilson et al., 1998). The Framingham Heart Study website provides online risk calculators (The Framingham Heart Study, n.d.). The Pooled Cohort equations were developed in more racially and geographically diverse US population than Framingham Study alone in order to expand the utility and generalizability of the prediction model (Goff et al., 2014).

Assessment of Predictive Performance: Discrimination

Discrimination is the ability of a model to distinguish individuals who experienced the outcome from those who did not and is usually summarized via the c-statistic (Moons et al., 2012a). The c-statistic is the area under the receiver operating curve and can have values from 0.5 (no discriminative ability) to 1.0 (perfect discrimination). The c-statistics <0.70, 0.70 to <0.80, and >0.80 are judged to have poor, acceptable, and excellent discrimination, respectively (Lloyd-Jones, 2010). Changes in the c-statistics are often used to compare prediction models with or without a novel risk marker. However, achieving clinically meaningful increase in a c-statistic is often difficult even though a novel risk factor may add predictive value (Folsom et al., 2006; Cook, 2007). Instead, other

metrics have been proposed including net reclassification improvement (NRI) and integrated discrimination improvement (IDI) (Pencina et al., 2008).

Risk Reclassification Analysis

The NRI for adding a novel risk factor to a prediction model is the ratio of net increase in risk factor categories among those who developed disease to net decrease among those who did not develop disease (**Table 1**). IDI is another measure of model improvement and is defined as the integrated difference of sensitivity minus "one minus specificity" and is estimated using the difference in discrimination slopes, which is defined as a difference between mean predicted probabilities of an event for those with events and the corresponding mean for those without events. For example, in the Atherosclerosis Risks in Communities Study, adding cardiac troponin T to traditional risk factors improved CVD risk prediction, as indicated by an NRI of 10.1 and an IDI of 0.032 (Saunders et al., 2011; Folsom, 2013).

Calibration

Calibration assesses the ability of a model to predict the absolute level of risk. It is a measure of the model's goodness of fit and is often assessed visually by comparing the observed and predicted numbers of events in quantiles (e.g., deciles) using statistics such as the Hosmer–Lemeshow, Grønnesby–Borgan, or D'Agostino and Nam chi-squared tests (Demler et al., 2015). Calibration slope can be derived from the plot of the observed disease probability (y-axis) versus the expected probability (x-axis) in each decile for a prediction model. If the model is well calibrated, the slope of the plot would be expected to be close to 1 (a 45-degree line) and the constant to be close to 0. See references for examples of calibration figures (Dufouil et al., 2017; Riley et al., 2016).

Internal and External Validation

Because a prediction model is developed using a specific data sample from a source population, the model typically performs better in the development data sample than when applied to a different data sample even from the same population. This phenomenon is called "overfitting" or "optimism" and may be evaluated using only the data at hand by a process called internal validation. The most widely advocated technique for the internal validation is bootstrapping, a statistical method that aims to mimic the sampling process, that is, the development sample from the source population (Moons et al., 2012a). In each bootstrap sample, the data are analyzed as in the original study sample, repeating each step of the model development. The summary statistics (e.g., bootstrap-adjusted c-statistics) represent what can be expected when the model is applied in new individuals from the same source population.

In contrast, external validation applies the original model to a different data sample from the same or a different population using the predictor and outcome values for individuals in the new data sample to quantify the model's predictive performance (Moons et al., 2012b). A recent review of 363 CVD prediction models reported in 136 articles found that 22% were internally validated and 36% were externally validated (Damen et al., 2016).

Table 1 Definition of net reclassification improvement

People who developed disease

		New model		*Reclassification*	
Existing model	Low risk	Intermediate risk	High risk	Up (appropriate)	Down (inappropriate)
Low risk	No change	A	B	A+B+C	D+E+F
Intermediate risk	D	No change	C	Net increase	
High risk	E	F	No change	(A+B+C)-(D+E+F)	

People who did not develop disease

		New model		*Reclassification*	
Existing model	Low risk	Intermediate risk	High risk	Up (inappropriate)	Down (appropriate)
Low risk	No change	a	b	a+b+c	d+e+f
Intermediate risk	d	No change	c	Net decrease	
High risk	e	f	No change	(d+e+f)−(a+b+c)	

NRI=Net increase/Net decrease

Although the number of externally validated models is still low, there seems an abundance of CVD prediction models in the literature (Damen et al., 2016). Yet, many studies do not report fully the development and validation process of their prediction models. The transparent reporting of a multivariable prediction model for individual prognosis or diagnosis (TRIPOD) Initiative developed a set of recommendations, with a checklist of 22 items, to standardize reporting of prediction model studies (Collins et al., 2015).

Application

It has been advocated for decades that the intensity of risk factor management should be matched to the absolute risk of CVD (Califf et al., 1996). The number needed to treat to prevent a CVD event is lowest for those at highest risk. Clinical assessment of estimated 10-year risk was first recommended in the United States by the 2001 ATP-III in order to guide hyperlipidemia treatment (National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III), 2002). This risk-based approach for cholesterol management was adopted worldwide (NICE, 2017; Teramoto et al., 2013; Piepoli et al., 2016; Stone et al., 2014). Although direct evidence from clinical trials about the effectiveness of risk prediction models in clinical practice is limited and inconclusive (Karmali et al., 2017), it was estimated from Copenhagen General Population Study data that more CVD events would be prevented by treating fewer patients by using the 2013 ACC/AHA absolute risk-based approach than approaches based on cholesterol thresholds for inclusion/exclusion from randomized clinical trials (Mortensen et al., 2015).

CVD risk prediction estimates can also inform individuals about their personal risk of CVD so that they may be motivated to modify their behaviors and to adopt healthier lifestyles. Estimated risk can be a tool for shared doctor–patient decision-making regarding the management of risk factors.

Future Directions

Despite the rapid proliferation of literature on CVD risk prediction models, they are underutilized in the clinical setting (Fuster, 2017). Clinicians need to be better informed about when, how, and which model to use. It also would be useful to document whether using risk prediction tools leads to more appropriate initiation of pharmacotherapy or modification of patient behavior.

Introduction

Coronary artery disease is still the most common cardiac pathology leading to heart failure in the industrialized world (Gheorghiade et al., 2006). Studies in the 1970s established the benefit of surgical revascularization in patients with angina and extensive coronary artery disease, but excluded patients with left ventricular (LV) dysfunction (Coronary Artery Surgery Study (CASS), 1983; The Veterans Administration Coronary Artery Bypass Surgery Cooperative Study Group, 1984; Varnauskas, 1988). However, recent observational studies are demonstrating that there may be a benefit for surgical revascularization in patients with ischemic cardiomyopathy (O'Connor et al., 2002; Cleland et al., 2011; Chareonthaitawee et al., 2005). To better understand the role of surgical revascularization in these patients, the Surgical Treatment for Ischemic Heart Failure (STICH) trial was designed. The focus of this article will be to examine the outcome of this trial, and subsequent STICH Extension Study (STICHES) to provide the reader with the most current information regarding the role of coronary artery bypass grafting (CABG) in patients with severe LV dysfunction (ejection fraction <35%) (Velazquez et al., 2011, 2016).

Assessment of Revascularization Potential in Ischemic Cardiomyopathy

All patients with heart failure by the time they arrive for surgical evaluation have had one if not multiple echocardiographic imaging documenting the degree of LV dysfunction. The next step in their evaluation will be to determine if they have coronary artery disease that is amenable for CABG, and then if the myocardium along the diseased coronary artery distribution is viable. If either of these parameters is not met the patient is deemed a poor candidate for CABG, and should be evaluated for a mechanical circulatory support device or heart transplantation (Fig. 1). Moreover, careful evaluation of comorbid conditions is exceedingly important. Patients with few risk factors have an acceptable Society of Thoracic Surgery (STS) predicted risk of death score making CABG compelling. The decision however to proceed with CABG becomes more difficult when risk factors cause a rise in the STS score.

Coronary Artery Disease Evaluation

Coronary angiography is the gold standard and most commonly obtained imaging modality for characterizing coronary artery disease and graft patency. It is a minimally invasive procedure where the right and left main coronary arteries are injected with dye via a peripherally placed catheter, and then X-ray motion pictures are obtained. Despite its invasiveness and associated risks including stroke, vessel dissection, acute myocardial infarction, arrhythmias, puncture site hematomas and pseudoaneurysm, it remains a very safe diagnostic method. Its lack of three-dimensional expositions however has led to the development of coronary computed tomography angiography or multidetector computed tomography (MDCT).

Multidetector Computed Tomography

This imaging modality has the same detection profile as angiography, but is three-dimensional, noninvasive, rapid, and painless. After injecting a nonionic contrast agent and allowing time for it to reach the arterial system, CT data is acquired in a single breath hold of 25–30 s. Further improvement in imaging quality is achieved by slowing the heart rate into the 60s with beta-blockers. Image completion is then facilitated by electrocardiographic gated reconstruction algorithms. In coronary vessels greater than 1.5 mm MDCT has sensitivity, specificity, positive predictive valve, and negative predictive value of 89%, 98%, 90%, and 98%, respectively. Overall, MDCT detected 78% of stenosis revealed by angiography (Bluemke et al., 2008). If the coronary vessels are heavily calcified, intramyocardial, or covered with excess fat newer MDCT scanners are better than coronary angiography at identifying these variations. This feature is especially helpful for minimally invasive coronary procedure where tactile sensation is limited.

Myocardial Viability

The degree of coronary artery stenosis will cause varying degrees of myocardial damage. Nuclear imaging and cardiac magnetic resonance imaging (MRI) have emerged as the two well-validated techniques for uncovering what myocardium remains viable after ischemia. Glucose metabolism substitutes free fatty acid metabolism as the main energy source in ischemic but viable myocardium. The nuclear imaging provided by single photon emission computed topography utilized a glucose analog and tracer, F-fluorodeoxyglucose (F-FDG), to detect glucose metabolism in myocytes. Following detection of a fixed perfusion defect on perfusion imaging, preservation of F-FDG uptake in this region by PET scan is suggestive of viable or hibernating myocardium and therefore indicative of the beneficial effect of revascularization in patients with ventricular dysfunction (Selvanayagam et al., 2004; Kim et al., 1999).

Cardiac MRI lately has been gaining in popularity as a reliable diagnostic method for cardiac structure, and function after ischemia. Kim and colleagues observed that contrast MRI combined with cine MRI showed hyperenhancement and dysfunctional contractility with myocardial infarction, but dysfunctional contractility without hyperenhancement was seen in injured yet viable myocardium. Normal myocardium had no hyperenhancement and normal contractility. The same group went on to investigate the use of contract-enhanced MRI to predict improvements following revascularization in areas of abnormal ventricular contraction. Their data showed that improvement in regional contractility after revascularization decreased progressively as the transmural extent of the hyperenhancement before revascularization increased. The extent of LV tissue dysfunctional that is not hyperenhanced before revascularization was related to the degree of improvement in wall motion scores and ejection fraction after revascularization (Selvanayagam et al., 2004; Kim et al., 1999). Further confirmatory studies regarding enhanced MRI firmly established its ability to predict myocardial viability after surgery (Kim et al., 2000).

Treatment of Coronary Artery Disease With Concomitant Ventricular Dysfunction

Treatment of coronary artery disease in patients with normal LV function has been well established for the past 3 decades. However, the management of coronary artery disease patients with severe LV dysfunction is not as firmly established. Varying data highlights the difficulty in managing this complex group of patients. At the present time the American Heart Association and American College of Cardiology guidelines give coronary revascularization in patients with severe LV dysfunction a level IIb recommendation. In other words, it "may be considered." Conclusions from the recent STICH and STICHES trials have been at odds with this recommendation.

Prior to the STICH trial data regarding coronary artery revascularization in the face of LV dysfunction seemed to support surgical management of these patients. In 1984 the Coronary Artery Surgery Study (CASS) essentially showed that patients with moderate LV dysfunction did not benefit from coronary revascularization while the subgroup of patients with severe LV dysfunction had an improved survival with surgical therapy. Bounous et al. had similar findings in their 1988 study. The major drawback of these and many subsequent studies was the lack of randomization. The retrospective nature of these investigations invariably presented bias in the equation. Moreover, some have argued that medical therapy has improved significantly over the past two decades thus rendering the risks of undergoing surgical therapy in the face of severe LV dysfunction unnecessary. Clearly a large randomized trial comparing the two modalities was necessary.

The STICH trial was a large multi-national study sponsored by the National Institute of Health involving over 1200 patients. All patients had an ejection fraction <35%, which would qualify as severe LV dysfunction. Patients were randomized into either the medical management arm or the surgical management arm; all-cause mortality was the primary outcome tracked. This study was specifically designed to identify the potential benefits of surgical revascularization in this complex group of patients with severe LV dysfunction. Outcomes at 10 years were analyzed in the follow-up STICHES trial.

The 5- and 10-year all-cause mortality were determined to be lower in the patients who underwent CABG, indicating a durable benefit derived from surgical revascularization in the setting of LV dysfunction. CABG was, however associated with a perioperative mortality rate of 3.6%, which was overcome after 2 years of follow-up. Interestingly survival within the two cohorts continued to diverge after the initial perioperative period (Fig. 2). The CABG cohort also showed a 26% relative risk reduction of all-cause mortality at 5 years. After 10 year follow-up this number increased to 28% (Fig. 2). Therefore, overall it seems CABG in the setting severe LV dysfunction is associated with improved survival when compared to medical therapy alone.

While the major conclusion of the STICH trial is obvious, there are numerous trends that become evident upon closer examination of the data. First of all, 10-year all-cause mortality was even higher in younger patients treated with medical therapy alone. In other words, CABG is particularly beneficial in younger patients with ischemic cardiomyopathy and severe LV dysfunction. Second, a substudy found that results of cardiac PET-CT and dobutamine stress echo did not predict mortality in the cohort undergoing CABG. Third, the reduction in cardiovascular mortality was consistent in the CABG group across all ages; however the reduction in all-cause mortality was not.

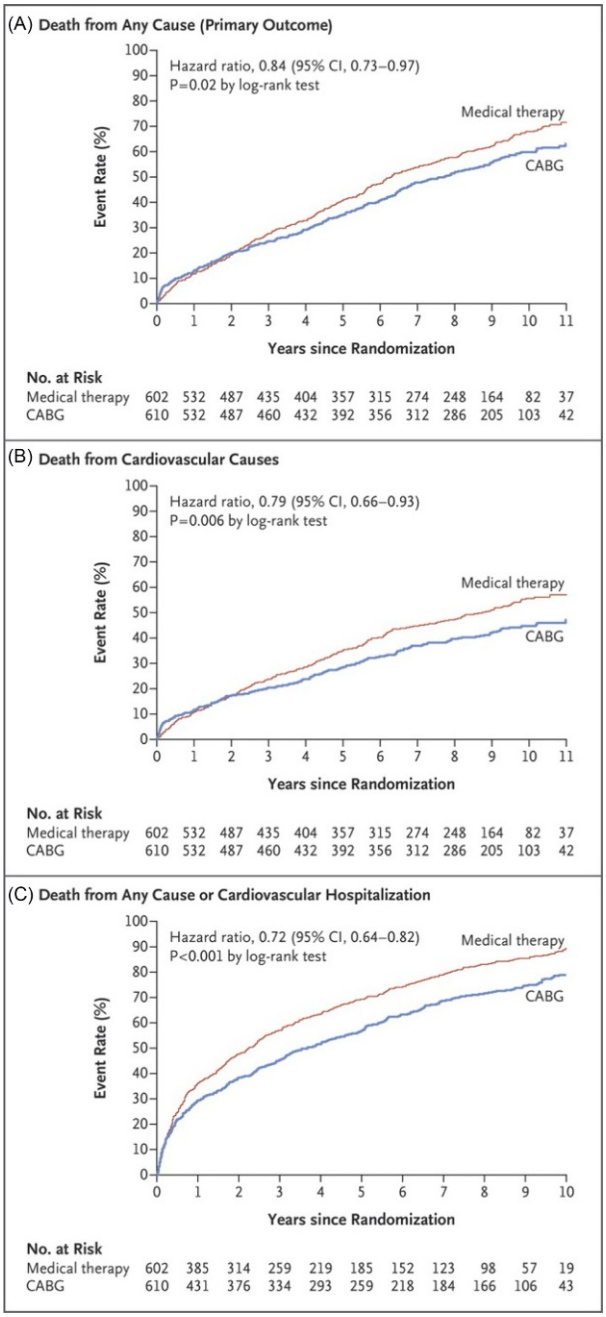

Fig. 2 Kaplan–Meier estimates of the rates of (A) death from any cause, (B) death from cardiovascular causes, and (C) death from any cause or hospitalization for cardiovascular causes. Reproduced from Velazques, E. J., Lee, K. L., Jones, R. H., et al. (2016). Coronary-artery bypass surgery in patients with ischemic cardiomyopathy. *New England Journal of Medicine* **374**, 1511–1520, with permission.

Mitral valve repair/replacement in patients with left ventricular dysfunction and ischemic MR remains a controversial topic. The severity of MR requiring intervention as well as the technique for addressing MR are currently not agreed upon. While it did not offer robust guidelines regarding ischemic mitral valve disease, the STITCH trial did uncover certain trends. First, patients with even mild ischemic mitral regurgitation were at increased risk of poor outcomes versus those without MR. Second, patients with severe left ventricular dysfunction as well as ischemic MR should undergo concomitant mitral valve surgery (repair vs replacement). Third, in this cohort, mitral valve replacement may be the preferred strategy. The management of moderate mitral regurgitation in this group requires further investigation.

Surgical Ventricular restoration (SVR) was also investigated in the STITCH trial. Data prior to this trial were mixed with regards to mortality after SVR and CABG versus CABG alone. Zhaohua and colleagues found one, five, and ten year mortality rates of 95%, 86% and 80% respectively after CABG combine with SVR and mitral valve repair in 61 patients. Shen and colleagues found early improvement in NYHA functional class in patients undergoing SVR plus CABG. However, these differences did were nonexistent in long term followup. No significant differences in survival or major adverse cardiac events were found in mid to long term follow up between the two cohorts. The STITCH data showed similar findings. There was also no difference in quality of live between CABG/SVR patients and isolated CABG patients. This lead authors to conclude that SVR does not add significant clinical benefit while it does add healthcare costs.

It is quite clear that the STICH trial lends support to CABG in patients with severe LV dysfunction; however it did not compare survival in patients undergoing PCI. Some studies have found increased mortality in patients undergoing PCI but to date there are no large randomized trials comparing PCI and CABG in patients with severe LV ejection fraction.

In conclusion a number of retrospective studies have examined the benefit of coronary artery revascularization in patients with ischemic cardiomyopathy-related LV dysfunction; however, prior to the STICH trial there was a lack of large randomized studies examining this topic. The results drawn for the STICH trial support surgical revascularization in patients with severe LV dysfunction. There are numerous caveats. First, perioperative mortality risk must be considered when evaluating this complex group of patients. Those with an excessively high risk of perioperative mortality may not show survival benefit with CABG. Second heart failure patients must have viable myocardium and suitable targets for bypass in order to be considered for surgical revascularization. Third, it is imperative that cardiologists and surgeons work in concert when managing patients with ischemic cardiomyopathy and severely depressed LV ejection fraction. In this manner risk of surgery, as well as alternative options, can be considered in these patients.

Introduction

Digoxin is a cardiac glycoside isolated from the foxglove plant *Digitalis purpurea*. Its effects on the heart were first described by Withering (1785). Over the 230 years since this first description, digoxin is still used in the management of cardiovascular diseases, including heart failure. Specifically, digoxin is recommended by the American College of Cardiology Foundation (ACCF)/American Heart Association (AHA) and the European Society of Cardiology (ESC) to decrease hospitalizations for heart failure, as multiple trials have shown its ability to improve symptoms, quality of life, and exercise tolerance (Dobbs et al., 1977; The Digitalis Investigation Group, 1997; Lee et al., 1982; The Captopril-Digoxin Multicenter Research Group, 1988; Guyatt et al., 1988; DiBianco et al., 1989; Uretsky et al., 1993; Packer et al., 1993; Yancy et al., 2013; McMurray et al., 2012). However, unlike beta-blockers and renin–angiotensin inhibitors, digoxin has not been shown to reduce mortality. This has likely been a contributing factor in the reduction of digoxin use in the management of heart failure, where it is currently reserved for patients with heart failure with reduced ejection fraction (HFrEF) who remain symptomatic despite the use of disease-modifying therapies (Patel et al., 2016; Hussain et al., 2006; Yancy et al., 2013; Goldberger and Alexander, 2014).

Mechanism of Action

Digoxin is a positive inotrope and negative chronotrope with primarily three (3) mechanisms of action—hemodynamic, neurohormonal, and electrophysiological (Eichhorn and Gheorghiade, 2002; Ziff and Kotecha, 2016).

Hemodynamic

Digoxin inhibits the membrane-bound alpha-subunit of the sodium–potassium ATPase pump in cardiac myocytes (Fig. 1; Smith, 1988). This pump is responsible for maintaining the resting membrane potential of the cell by pumping three (3) sodium ions out of the cell and two (2) potassium ions into the cell in a process that consumes energy in the form of adenosine triphosphate. With inhibition of the pump, the intracellular sodium concentration rises. Due to this rise in intracellular sodium, transmembrane sodium–calcium exchangers reach an equilibrium that favors calcium entry into myocytes and a decrease in calcium extrusion from myocytes—the net result is an increase in intracellular calcium. This rise in intracellular calcium increases the force-generating interactions between actin and myosin during myocyte contraction. The result is an increase in contractility—that is, positive inotropy—and, ultimately, an increase in cardiac output.

Neurohormonal

The body responds to heart failure with neurohormonal activation, resulting in the release of hormones such as norepinephrine and angiotensin. Digoxin inhibits the release of such hormones (Gheorghiade and Ferguson, 1991). While the exact mechanism is currently unknown, digoxin induces vagal activation that augments parasympathetic tone and reduces sympathetic outflow (Ziff and Kotecha, 2016). One possible mechanism includes the attenuation of carotid sinus baroreceptor activity by digoxin, resulting in a decrease in efferent sympathetic tone and subsequent decrease in neurohormonal activation (Schobel et al., 1991).

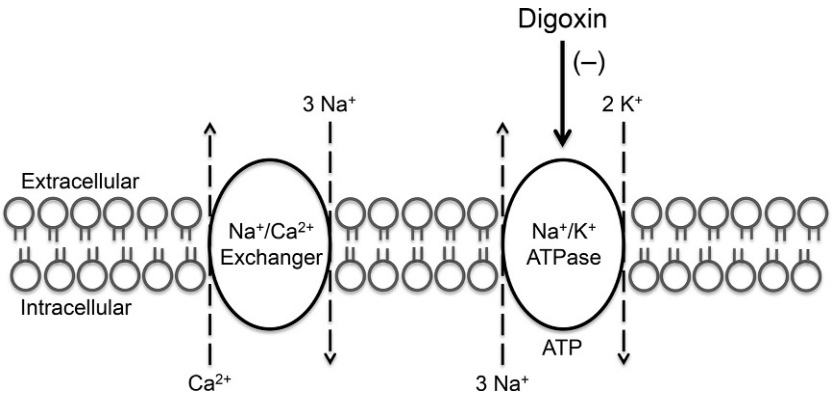

Fig. 1 Mechanism of action of digoxin. Digoxin inhibits the membrane-bound alpha-subunit of the sodium–potassium ATPase pump in cardiac myocytes. As a result, intracellular sodium concentration increases. Due to this rise in intracellular sodium, transmembrane sodium–calcium exchangers reach an equilibrium that favors calcium entry into myocytes and a decrease in calcium extrusion from myocytes—the net result is an increase in intracellular calcium. This causes an increase in myocyte contractility and, ultimately, an increase in cardiac output.

Electrophysiological

Digoxin's induction of the vagal response is associated with a parasympathomimetic effect on atrial myocardium, resulting in a slowing of conduction through the AV node and prolonging refractoriness (Smith, 1988). This ultimately results in a reduction in heart rate or a negative chronotropic effect. Unfortunately, this same mechanism contributes to the arrhythmias associated with digoxin use.

Clinical Use

The ACCF/AHA and ESC recommend the use of digoxin in patients with HFrEF in order to decrease hospitalizations for heart failure (Yancy et al., 2013; McMurray et al., 2012). These guidelines are largely based on the Digitalis Investigation Group (DIG) trial, a randomized controlled trial that suggested digoxin use reduced hospitalizations, but did not demonstrate a decrease in mortality (The Digitalis Investigation Group, 1997). These findings contribute to the use of digoxin in patients with HFrEF who remain symptomatic despite the use of therapies that have shown to reduce mortality, such as beta-blockers, ACE inhibitors, ARBs, and aldosterone receptor antagonists. As reflected by the major society guidelines above, current guidelines dictate the use of beta-blockers and renin–angiotensin inhibitors in the initial management of HFrEF. This is demonstrated in clinical practice by the recent downward trend in the use of digoxin for HFrEF (Patel et al., 2016; Ziff and Kotecha, 2016).

HFrEF With Atrial Fibrillation

Given its properties as both a positive inotrope and negative chronotrope, it seems reasonable that digoxin would be useful in patients with HFrEF and atrial fibrillation with rapid ventricular response. Unfortunately, the benefit of digoxin in this population is not clear. Although the utility of digoxin has been cited in literature, evidence suggesting that it may lead to increased mortality in heart failure patients with atrial fibrillation also exists (Khand et al., 2003; Shah et al., 2014; Vamos et al., 2015). As such, current ACCF/AHA guidelines recommend beta-blockers for rate control in heart failure patients with atrial fibrillation, but acknowledge that digoxin may have a role as an adjunct therapy (Yancy et al., 2013).

Women

A post hoc analysis of data from the DIG trial suggested that digoxin use among women with HFrEF was associated with an increase in mortality (Rathore et al., 2002). A subsequent study, again using data from the DIG trial, evaluated whether serum digoxin levels impacted outcomes in women with heart failure. This study found that low serum concentrations of digoxin were associated with a reduction in hospitalization and no effect on mortality, while higher serum concentrations were associated with an increase in mortality (Adams et al., 2005).

Right Heart Failure

While data are limited, digoxin may have a role in the management of right heart failure secondary to primary pulmonary hypertension (PPH). A prospective study of PPH patients with isolated right ventricular dysfunction showed that short-term administration of digoxin resulted in a modest increase in cardiac output and a significant reduction in plasma norepinephrine (Rich et al., 1998).

Dosing

Digoxin has a narrow therapeutic window. Because higher concentrations—that is, greater than 1.2 ng/mL—are associated with an increase in mortality, the optimal serum digoxin concentration for both men and women with HFrEF appears to be 0.5–0.9 ng/mL, although there have been no prospective, randomized trials to evaluate this (Rathore et al., 2002; Adams et al., 2005). The ACCF/AHA currently recommends daily doses of 0.125–0.25 mg with no loading doses. The lower dose of 0.125 mg is favored in those that are older than 70 years, with renal impairment, or with low body mass, as serum concentrations may rise more in proportion to the dosage (Yancy et al., 2013).

Adverse Effects

The most common side effects associated with digoxin involve the gastrointestinal, cardiovascular, and central nervous systems. In particular, digoxin may cause nausea, vomiting, anorexia, blurred vision, and cardiac arrhythmias. While it is reasonable to simply discontinue digoxin to ameliorate side effects, severe toxicity should be treated with F(ab) fragments of anti-digoxin antibodies (Kelly and Smith, 1992).

In addition to side effects and toxicities, clinical deterioration is seen with the withdrawal of digoxin therapy (The Captopril-Digoxin Multicenter Research Group, 1988; The Digitalis Investigation Group, 1997; Adams et al., 2016). While neurohormonal antagonists such as beta-blockers and renin–angiotensin inhibitors are the preferred treatment for HFrEF, these medications should be added to digoxin monotherapy (Yancy et al., 2013). That is, a patient with HFrEF on digoxin monotherapy should not have this therapy discontinued in favor of starting neurohormonal antagonists—the latter should be added on.

Summary

- While neurohormonal antagonists are preferred for their disease-modifying properties, digoxin is recommended by major societies to decrease hospitalizations for HFrEF.
- Digoxin has hemodynamic, neurohormonal, and electrophysiological mechanisms of action.
- Evidence is unclear on the role of digoxin in HFrEF with atrial fibrillation.
- There was previous concern for an increase in mortality with digoxin use among women with HFrEF; however, more recent evidence suggests that lower serum drug concentrations have no effect on mortality.
- Lower serum digoxin concentrations—that is, 0.5–0.9 ng/mL—are recommended.
- Withdrawal of digoxin therapy has been associated with clinical deterioration.

Introduction

Life-saving circulatory support by ventricular assist devices is an established treatment for end-stage heart failure (HF) and especially left ventricular assist devices (LVADs) have emerged as a valid therapeutic option primarily designed as a bridge to heart transplant (HTx), bridge to transplant candidacy, or as destination therapy for patients who cannot undergo HTx. In a limited number of patents LVADs may also become a bridge to cardiac recovery allowing successful device explantation.

Larger studies and recent guidelines emphasize the important role of echocardiography in LVAD candidate selection including patient screening for cardiac abnormalities with negative impact on LVAD therapy, planning of implant surgery, guiding intraoperative device placement, pump optimization and monitoring of RV function, postoperative surveillance of LVAD and RV function, as well as evaluation of native myocardial recovery with corresponding adjustment of LV unloading, selection of potential weaning candidates, and decision-making in favor of LVAD explantation.

The chapter reviews the knowledge about the role of echocardiography for managing LVAD therapy. Special attention is focused on echo assessment of right ventricular (RV) function before LVAD implantation and the reliability of echo parameters for preoperative prediction of postoperative RV function, as well as on the particular role of echocardiography for weaning decisions in patients showing unloading-promoted LV reverse remodeling with improvement of cardiac function.

Preoperative Role of Echocardiography

In addition to documenting baseline cardiac structure and function, preoperative transthoracic and transesophageal echocardiography (TTE and TEE) are indispensable for LVAD candidate selection and their screening for cardiac abnormalities with negative impact on LVAD therapy. Echocardiography is also necessary for RV assessment and decision-making on the necessity of a mechanical support also for the RV.

Candidate Selection for LVAD Therapy

Proper candidate selection is paramount for successful LVAD therapy but also challenging because congestive HF due to primary impaired LV function is a complex syndrome with many specific risk factors for adverse outcome after LVAD implantation (Cohen et al., 2015; Feldmann et al., 2013; Lund et al., 2010; Stainback et al., 2015). The criteria for the use of LVAD therapy are therefore based on a wide variety of clinical, hemodynamic, laboratory, and cardiac-imaging data. An important part of information necessary for LVAD candidate selection is provided by TTE and TEE.

Evaluation of LV dysfunction and screening for cardiac abnormalities with negative impact on LVAD therapy

Echocardiography is mandatory for evaluation of LV dysfunction in LVAD candidates and also the first-line imaging modality used to screen candidates for cardiac and aortic abnormalities that increase the risk for complications, or may represent contraindications to LVAD implantation (Stainback et al., 2015).

Although LV ejection fraction (LVEF) is by no means the only parameter used for decision-making to implant an LVAD, accurate LVEF measurement is still necessary. It is recommended to use three-dimensional (3D) echocardiography for LVEF measurements (Stainback et al., 2015). The use of a microbubble contrast agent to enhance endocardial definition can improve LVEF measurement (Stainback et al., 2015).

Comprehensive preoperative TTE and/or TEE is particularly useful for the diagnosis of possible intra-cardiac shunting and thrombi, valvular abnormalities, endocarditis, and diseases of the aorta, because their detection before implantation surgery can be decisive for the planned LVAD therapy. Thus, because patent foramen ovale (PFO) and other interatrial communications should be closed at the time of LVAD implantation, attention must be focused on signs which suggest their existence. For detection of intra-cardiac shunting, TEE-color-Doppler scanning of the fossa ovalis margins at low Nyquist-limit plus intravenous agitated saline combined with an appropriately performed Valsalva maneuver are necessary because elevated atrial pressure may reduce the inter-atrial pressure gradient and prevent detection of the defects by color-Doppler imaging alone (Feldmann et al., 2013; Stainback et al., 2015). Congenital or post-infarction septum defects (VSDs) must also be excluded by color-Doppler interrogation because VSDs should be closed during LVAD implantation in order to prevent right-to-left shunting with consecutive hypoxemia and risk of paradoxical embolization during LVAD support (Cohen et al., 2015; Patangi et al., 2013; Rasalingam et al., 2011). In patients with risk for LV thrombus formation (decreased LVEF, LV aneurysm), the use of a micro-bubble contrast agent should also be considered (Cohen et al., 2015; Stainback et al., 2015). Exclusion of relevant aortic valve insufficiency (AI) and mitral stenosis (MS) before LVAD implantation is also necessary. Aortic regurgitation (AR) and MS of $\geq$ moderate degree can importantly impair LVAD therapy and must therefore be considered for correction during LVAD implantation surgery (Cohen et al., 2015; Feldmann et al., 2013; Stainback et al., 2015). However, AR quantification in LVAD candidates is challenging due to the reduced stroke volume (SV) and the low AR velocities (low pressure gradients between the aorta and the LV because of the high LV diastolic pressure and the low diastolic pressure in the aorta). Therefore, the AR volume can also be relatively low despite a high regurgitant fraction and the degree of AI can be underestimated. Accordingly, both Doppler-derived LV outflow-tract (LVOT) SV and regurgitant fraction should be calculated routinely in LVAD candidates (Stainback et al., 2015). Careful search for relevant AI is particularly necessary in patients with aortic root dilatation, aortic valve (AV) degeneration, eccentric AR (especially if associated with a bicommissural AV), or an AV prosthesis (Stainback et al., 2015). Severe AV stenosis (AS) can be tolerated, but patients may have insufficient forward flow in the event of obstructive LVAD failure, even if residual LV function is present (Stainback et al., 2015). In patients with a bio-prosthetic AV, AR of $\geq$ moderate degree requires bio-prosthesis replacement. Also relevant stenoses of prosthetic mitral valves require replacement with a bio-prosthesis at LVAD implantation (Stainback et al., 2015). TTE has important limitations for the assessment of prosthetic valves and therefore, adjunctive TEE is necessary. TR of $>$moderate degree is a potentially ominous finding and recent guidelines recommend that surgical valve repair should also be considered at the time of LVAD implantation (Stainback et al., 2015). Moderate pulmonary regurgitation (PR) may be well tolerated by LVAD recipients with optimal LV unloading. However, PR of $\geq$ moderate degree would require repair in the event of additional RVAD implantation (Feldmann et al., 2013; Stainback et al., 2015). More than mild pulmonary valve stenosis increases the risk for RVF after LVAD implantation (Cohen et al., 2015; Stainback et al., 2015).

Exclusion of endocarditis (contraindication for LVAD implantation) is mandatory. Diseases of the aorta (aneurisma, atheroma, coarctation, dissection) can complicate or might be even contraindications for LVAD implantation and their preoperative detection is therefore necessary (Feldmann et al., 2013; Stainback et al., 2015).

Selection of a particular LVAD for an individual patient is a complex decision-making process where echocardiography is helpful to confirm the etiology and severity of HF and especially to assess the potential reversibility of HF, thus facilitating also the choice between temporary and long-term LVAD support (Saffarzadeh and Bonde, 2015; Stainback et al., 2015).

Echocardiography is also necessary before the decision to use a percutaneous temporary LVAD like Impella or TandemHeart system. Thus, detection of LV thrombi, AS or AI of $\geq$ moderate degree, and aortic abnormalities are contraindications for the use of an Impella system, whereas detection of a $\geq$ moderate AS or a VSD is contraindication for the use of a TandemHeart system (Saffarzadeh and Bonde, 2015).

Decision on the necessity of mechanical support also for the RV

LVADs are more reliable and safer for patients and also provide a better quality of life than biventricular assist devices (BiVADs), but end-stage HF often involves both ventricles, even if its initial cause was left-sided heart disease (Dandel et al., 2015a; Dang et al., 2006; Matthews et al., 2008; Ochiai et al., 2002). Although LVADs can facilitate RV improvement, about 25% of LVAD recipients develop severe RV failure (RVF) associated with increased patient morbidity and mortality even after later implantation of a mechanical support also for the RV (Dandel et al., 2015a; Dang et al., 2006; Matthews et al., 2008; Ochiai et al., 2002). A temporary RVAD in long-term LVAD recipients with high risk for postoperative RVF can avoid permanent BiVAD support. Thus, patients who need a temporary or long-term BiVAD support should already be identified preoperatively or at the latest intra-operatively.

RVF after LVAD implantation appeared related to preoperative RV geometry, contractile function, and TR which are highly load sensitive parameters (Dandel et al., 2013, 2015a; Dandel and Hetzer, 2016; Kukucka et al., 2011a; Potapov et al., 2008). Due to its load dependency, the RV function usually either remains unchanged or will even improve after reduction of pulmonary vascular

resistance (PVR) subsequent to LVAD implantation, as long as the postoperative outcome is not impaired by irreversibly poor end-organ function and LV unloading is properly optimized to avoid excessive septum shifting from right to left (Dandel and Hetzer, 2015a, 2016; Dandel et al., 2013; John and Boyle, 2012; Kukucka et al., 2011a; Potapov et al., 2008).

RVF after LVAD implantation can be classified into three major types:

a. RVF due to preoperatively underestimated irreversible RV alterations (preoperatively often predictable)
b. RVF which becomes manifest only intra-operatively or early postoperatively (less predictable)
c. RVF which develops late after LVAD implant (preoperatively less predictable).

Preoperative detection of risk factors for post-LVAD RV failure

Echocardiography is indispensable for preoperative distinction between patients with and without the potential to remain free from RVF after LVAD implantation, because patients with different post-LVAD course of RV function reveal already preoperatively significant differences in echo-derived right-sided heart morphological and functional parameters (Aissaoui et al., 2015; Atluri et al., 2013; Drakos et al., 2010; Fitzpatrick et al., 2008; Fukamachi et al., 1999; Kato et al., 2013; Vivo et al., 2013). Thus, those with postoperative RVF show before LVAD implantation, significantly larger RV end-diastolic diameters (RVEDD) with higher short/long (S/L)-axis ratios, higher RV/LV diameter ratios, lower RV fractional area change (FAC_{RV}) and EF, lower tricuspid lateral annulus peak systolic amplitude and velocity of displacement (TAPSE and TAPS′, respectively), lower RV free wall peak systolic longitudinal strain and strain rate (PSSL and PSSrL, respectively), higher degree of TR and higher systolic pressure gradients between the RV and right atrium ($\Delta P_{RV\text{-}RA}$) (Aissaoui et al., 2015; Atluri et al., 2013; Dandel et al., 2013; Dang et al., 2006; Drakos et al., 2010; Fitzpatrick et al., 2008; Fukamachi et al., 1999; Grant et al., 2012; Kato et al., 2013; Kavarana et al., 2002; Kukucka et al., 2011a,b; Matthews et al., 2008; Porter et al., 2015; Potapov et al., 2008; Raina et al., 2013; Topilsky et al., 2011a; Vivo et al., 2013). Several preoperative echo-derived measures like RVEDD >55 mm, RV end-diastolic S/L axis ratio >0.57, FAC_{RV} <31%, TAPS′ (also known as S′) <8 cm s^{-1}, PSSL <−9.6%, PSSrL <0.6 s^{-1}, TR >2nd degree, $\Delta P_{RV\text{-}RA}$ <35 mmHg, and RV/LV diameter ratio ≥0.75 were revealed as significant risk factors for RVF after LVAD implantation (**Table 1**) (Aissaoui et al., 2015; Atluri et al., 2013; Dandel et al., 2013; Grant et al., 2012; Kato et al., 2013; Kukucka et al., 2011b; Matthews et al., 2008; Potapov et al., 2008; Raina et al., 2013; Topilsky et al., 2011a; Vivo et al., 2013). However, these variables were not identified in all studies as significant risk factors for RVF (Grant et al., 2012; Raina et al., 2013; Karogelopoulos et al., 2016; Kiernam et al., 2015; Lang et al., 2015; Puwanant et al., 2008; Shiga et al., 2012). This might be mainly due to differences in defining RVF and selection criteria for VAD support, but probably also due to certain limitations of echocardiography for RV assessment (Dandel et al., 2015a; Lang et al., 2015).

Preoperative prediction of post-LVAD RV function

Proper decision-making in favor or against the necessity for implantation of a mechanical support also for the RV is paramount for a successful VAD therapy in patients with congestive HF. However, with few exceptions, the numerous preoperative risk factors for post-LVAD RVF, which were identified by echocardiography, appeared alone unable to predict the necessity of mechanical support also for the RV (Dandel et al., 2013; Neyer et al., 2016; Raina et al., 2013). As shown in **Tables 2** and **3**, at certain cut-off values, several echo-derived parameters can predict freedom from post-LVAD RVF, but only the global PSSrL appeared able to predict also the development of RVF after LVAD implantation (Dandel et al., 2013).

There are particular challenges and limits in RV echo assessment with important impact on the diagnostic and prognostic value of echocardiography (**Table 4**) (Anavekar et al., 2007; Dandel and Hetzer, 2009; Focardi et al., 2015; Kurtz, 2012; Rudski et al., 2010). However, due to the distinct load dependency of RV size, geometry, and function, the main limitation for the clinical value of individual echo-derived RV measurements is their possible alteration already before any alteration in myocardial contractility. This might explain the relative low predictive value of RV echo measurements, which otherwise proved to be relevant risk factors for RVF after LVAD implantation. Especially RVEF, $FAC_{RV,}$ and TAPSE, but also RV systolic wall motion and myocardial deformation velocity, can decrease with increasing PVR even if myocardial contractility remains unaltered. Also TR can induce RVEF, $FAC_{RV,}$ and TAPSE changes, which can be misleading for assessment of RV contractile function (Dandel and Hetzer, 2016; Dandel et al., 2015b). Thus, without the interpretation of parameter values in relation to PVR, PAP, or $\Delta P_{RV\text{-}RA}$, echo assessment of RV function may become unreliable and this could explain its limited ability to predict preoperatively the presence of severe RVF after LVAD implantation (Dandel and Hetzer, 2016; Dandel et al., 2013).

Integrative approaches using combinations of parameters, which include RV afterload, appeared more reliable for evaluation of RV function (Cameli et al., 2012; Dandel et al., 2013, 2015a,b; Di Maria et al., 2015; Frea et al., 2012; Sharma et al., 2005). Thus, the RV stroke work index (SWI_{RV}) obtained from right heart catheterization (RHC) measurements appeared more useful than the currently used standard echo variables for evaluation of RV function in end-stage congestive HF (Cameli et al., 2012). However, because estimation of RA and mean PAP by echocardiography are challenging, echo-derived SWI_{RV} is rarely used for assessment of RV function. Recently, two simplified composite echo-derived variables were identified as easy calculable surrogates for the SWI_{RV} (Di Maria et al., 2015; Frea et al., 2012). One of them, the "simplified RV contraction-pressure index (sRVCPI)," incorporates TAPSE and load, and is derived as $sRVCPI = TAPSE \times \Delta P_{RV-RA}$, where ΔP_{RV-RA} is the pressure gradient between RV and RA (Frea et al., 2012). sRVCPI showed a close correlation with the RHC-derived SWI_{RV} plus a high sensitivity and specificity to predict depressed SWI_{RV} (Frea et al., 2012). The other echo-derived surrogate for the RHC-derived $SWI_{RV,}$ the "RV stroke work (RVSW)," incorporates SV and load and is derived as $RVSW = 4 \times (\text{peak TR jet velocity})^2 \times (\text{pulmonary valve area} \times \text{VTI})$, where VTI is the velocity-time integral of the systolic trans-pulmonary jet and

Table 1 Relevance of the main echocardiography-derived variables generally recognized as preoperative risk factors for RV failure after LVAD implantation

Statistical method	*Selected echocardiographic variables*	*Odds RVF*	*95% CI*	P *value*

	RV end-systolic volume index[a] (RVESVI) (Kiernam et al., 2015)	1.14	1.01–1.28	0.03

[a]Measured by 3-dimensional echocardiography; RV, right ventricle; RVF, right ventricular failure.

showed also a close correlation with the RHC-derived SWI_{RV} (Di Maria et al., 2015). However, the potential usefulness of these two echo-derived composite variables for RV assessment in LVAD candidates remained to be established.

Also recently, composite echo variables which incorporate either longitudinal displacement and load (i.e., TAPSE/systolic PAP and TAPSE/PVR) or velocity of myocardial shortening and load (i.e., "afterload corrected PSSrL") were found suited for assessment of RV contractile function (Dandel et al., 2013, 2015b; Guazzi et al., 2013; Lopez-Candales et al., 2014). The TAPSE/systolic PAP ratio is a simplified approach to assess RV contraction by plotting fiber longitudinal shortening vs. the force generated for overcoming the imposed load (Guazzi et al., 2013). Its limitations are related to the potential limitations of TAPSE and systolic PAP echo measurements. Nevertheless, this index appeared to be a strong and independent predictor of mortality in patients with HF due to primary impaired LV function (Topilsky et al., 2011a). Because PVR is a critical determinant of RV systolic function, its inclusion into echo-derived composite variables can also be beneficial for assessment of the relationship between increased afterload and RV function (Lopez-Candales et al., 2014). The echo-derived "RV ejection efficiency (RVEe)," defined as RVEe = TAPSE/PVR, is such a composite variable which reflects that relationship in a simplified manner (Lopez-Candales et al., 2014). Using TAPSE as a surrogate for RV ejection and echo-derived PVR (PVR = TR peak velocity/RV outflow tract velocity-time integral) as a surrogate for the RHC-derived PVR, the echo-derived RVEe is easily calculable and might be feasible for evaluation of RV systolic performance (Abbas et al., 2013; Lopez-Candales et al., 2014). However, future studies are necessary to determine if echo-derived RVEe might be able to predict post-LVAD RV function.

Two composite echo-derived variables for evaluation of RV function had already confirmed the assumption that the predictive value of certain echo-derived RV parameters for post-LVAD RVF can be improved if RV loading conditions are also considered (Dandel et al., 2013). One of them is the right ventricular "afterload-corrected PSSrL," which is based on the relationship between

Table 2 Predictive value of preoperatively measured most relevant echocardiographic parameters and indexes for postoperative RV failure in patients who underwent LVAD implantation

		Prediction of RV failure			
Parameters and indexes	*Cut-off*[a]	*Sensitivity % (CI)*[b]	*Specificity % (CI)*[b]	*NPV*[c] *% (CI)*[b]	*PPV*[d] *% (CI)*[b]
RV-S/L_{ED} (Dandel et al., 2013)	0.57	84 (72–93)	74 (70–76)	94 (90–94)	46 (40–52)
LA volume index (Raina et al., 2013)	38 mL/m^2	86	56	90	52
$\Delta P_{RV\text{-}RA}$ (Dandel et al., 2013)	35 mmHg	84 (73–92)	93 (89–95)	96 (92–98)	76 (66–83)
TAPS′ (Dandel et al., 2013)	8 cm s^{-1}	84 (73–92)	90 (93–98)	95 (92–98)	70 (61–77)
RV lateral PSSL (Grant et al., 2012)	−9.6%	68	76	76	68
RV global PSSL (Kato et al., 2013)	−14.4%	83	66	92	51
RV global PSSrL (Dandel et al., 2013)	0.6 s^{-1}	80 (70–85)	98 (95–99)	92 (81–98)	95 (92–96)

Table 4 Major challenges and limits in echo assessment in RV assessment (Anavekar et al., 2007; Dandel et al., 2015a; Dandel and Hetzer, 2016; Dandel et al., 2013; Dandel and Hetzer, 2009; Estep et al., 2014a; Feldmann et al., 2013; Focardi et al., 2015; Kassi and Estep, 2016; Kurtz, 2012; Lam et al., 2009; Rich et al., in press; Rudski et al., 2010; Stainback et al., 2015; Cohen et al., 2015; Abbas et al., 2013)

Echo measurements	*Challenges*	*Limitations*
RV volumes and EF	Complex three-dimensional RV shape Limited definition of RV endocardial surface and restricted echo-imaging window due to RV retrosternal position. Dedicated views of the RV can be insufficient for reliable assessment. Measurements require high spatial resolution	2D-echo-derived EF calculation requires geometric assumptions Only 3D-echo-derived measurements are recommended for clinical use Afterload dependency Misleading RVEF changes inducible by TR
RV fractional area-change (FAC_{RV})	Suboptimal RV endocardial definition (especially in systole) Measurements require high spatial resolution	High inter- and intra-observer variability Load dependency Misleading changes inducible by TR.
Tricuspid annulus peak systolic excursion (TAPSE)	Angle dependence of measurements	Describes displacement of single wall segment Poor correlation with MRI-derived RVEF Load dependency of measurements Influenced by overall heart motion and LV function Misleading changes inducible by TR.
Tricuspid lateral annulus peak systolic velocity S′ (TAPS′)	Angle dependence of measurements	Load dependent (less than EF, FAC or TAPSE) Blindness to systolic dysfunction in parts of the RV remote from the tricuspid annulus
TR-derived RV dp/dt	Requires a complete TR spectral Doppler envelope and parallel alignment with the TR jet	Angle and load dependency of measurements Lack of sufficiently validated normative data
Isovolumic contraction peak velocity (IVC_V) and Isovolumic acceleration (IVA)	Angle dependence of measurements	Negative impact of TR Measurements are moderately load-dependent and also dependent on patient age and heart rate RV wall motion during its isovolumic contraction can be affected by the simultaneous LV contraction Lack of recommendable reference values
RV longitudinal strain and strain rate	TDI-derived measurements are angle dependent; acquisition is technically challenging because the thin RV free wall yields a poor signal-to-noise ratio High image quality is required	Relatively low temporal resolution and segmental reproducibility of measurements (especially the 3D-speckle-tracking approach) Influence of RV loading conditions especially on strain values.
Doppler-derived parameters of RV diastolic function (E,A, E/A, E/E′)	Respiration can induce misleading diastolic flow changes	TR, heart rate, and preload changes can induce misleading diastolic parameter changes
RV myocardial performance index (MPI_{RV})	Normal values differ on the basis of whether pulsed or tissue Doppler was chosen for its calculation Pulsed Doppler data necessary for its calculation cannot be obtained from one cardiac cycle	Possible pseudo-normalization in severe RVF RV hypertrophy can shorten the IVRT leading to misleading reduction of the MPI_{RV} Afterload dependence Alteration of its values by severe TR Unreliable when RA pressure is elevated Not recommend by the ASE as the sole quantitative method for evaluation of RV function

RV myocardial shortening velocity and RV load, the other is the "load adaptation index (LAI_{RV})," based on the relationship between RV load and RV dilation, also taking the RA pressure into account. These easily obtainable variables showed high predictive values for both, post-LVAD RVF and freedom from RVF, during LVAD support (**Tables 2** and **3**) (Dandel et al., 2013, 2015a). Both variables appeared also predictive for RVF developing during the next 12 months in patients with end-stage precapillary pulmonary hypertension, which confirmed their usefulness for assessment of RV function and its responsiveness to loading conditions (Dandel et al., 2015b).

The "afterload-corrected PSSrL" is defined as $PSSrL \times \Delta P_{RV\text{-}RA}$ (**Fig. 1A** and **D**) (Dandel et al., 2013, 2015a,b). Because myocardial shortening velocity is load dependent, the PSSrL will decrease with the increase in RV systolic pressure. Nevertheless, as long as RV contractile function remains stable, due to the $\Delta P_{RV\text{-}RA}$ increase, the RV load-corrected PSSrL will remain relatively stable. However, if the afterload increase overwhelms RV ability to adapt its contractile function correspondingly (afterload mismatch), in addition to PSSrL reduction, there will be also a reduction in $\Delta P_{RV\text{-}RA}$ (due to increase of RA pressure), even before the RV systolic pressure

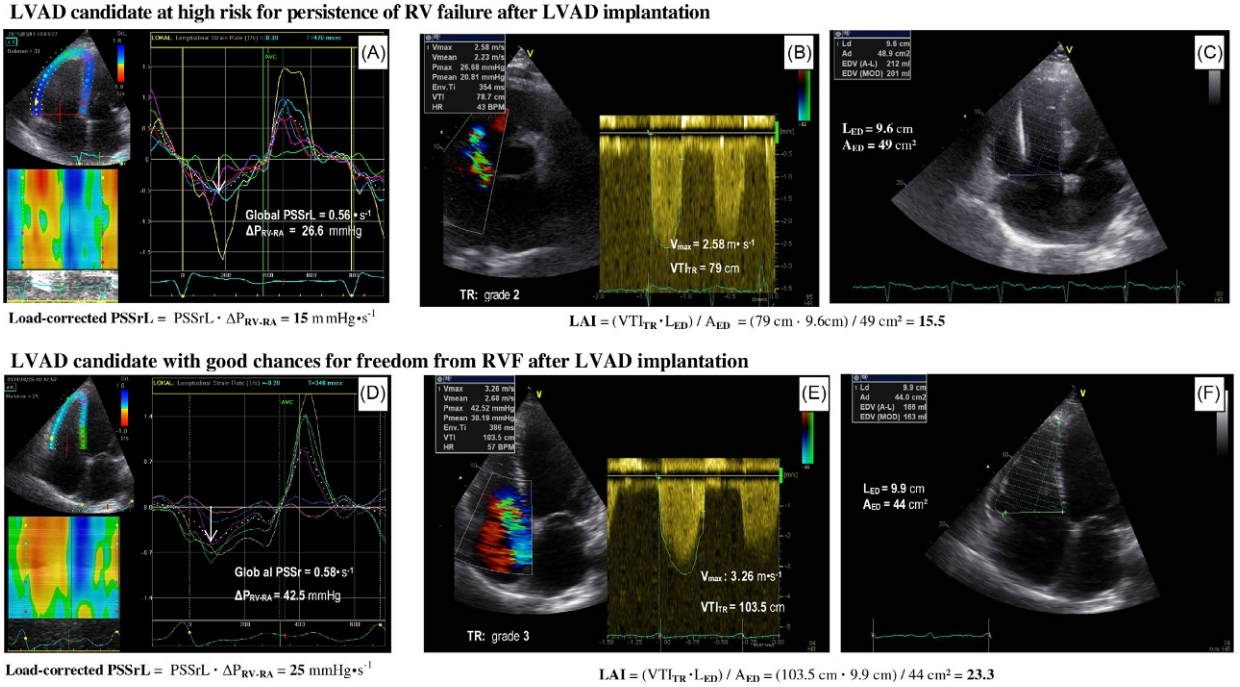

Fig. 1 Right ventricular (RV) load-corrected global peak systolic longitudinal strain rate (PSSrL) and load adaptation index (LAI) in two patients with end-stage congestive heart failure due to primary impaired left ventricular (LV) function. The low LAI and load-corrected PSSrL in the first patient (images A, B, and C) indicate a high risk for persistence of RV failure after LVAD implantation (possible need for temporary or even permanent mechanical support also for the RV). In the second patient (images D, E, and F), the lesser RV dilation (smaller end-diastolic area and less altered geometry) and the higher velocity of RV myocardial shortening (higher global PSSrL), despite higher afterload, yield a 50% and 66% higher LAI and load-corrected PSSrL, respectively, which indicates a high potential for recovery during LVAD support. *TR*, tricuspid regurgitation; VTI_{TR}, TR velocity-time integral; V_{max}, maximum (peak) velocity; L_{ED}, end-diastolic long-axis length; A_{ED}, RV end-diastolic area; $\Delta P_{RV\text{-}RA}$, pressure gradient between RV and right atrium.

finally also becomes lower due to progressive impairment of RV contractility. The load-corrected PSSrL can be therefore more useful for evaluation of RV adaptability to loading conditions than the PSSrL alone.

A distinctly different approach for assessment of RV ability to improve after reduction of its afterload is provided by the LAI_{RV} which is reflected by the ratio between $\Delta P_{RV\text{-}RA}$ and RV end-diastolic volume per long-axis length (EDV/L_{ED}):

$$LAI_{RV} = \frac{\Delta P_{RV-RA}}{EDA/L_{ED}} \approx \frac{VTI_{TR}}{A_{ED}/L_{ED}} = \frac{VTI_{TR}(cm) \times L_{ED}(cm)}{A_{ED}(cm^2)}$$

Thus, using TR velocity-time integral (VTI_{TR}) instead of $\Delta P_{RV\text{-}RA}$ and the easily measurable RV end-diastolic area (A_{ED}) instead of the RV end-diastolic volume (EDV) a dimensionless index of similar value for RV evaluation can be obtained (**Fig. 1**) (Dandel et al., 2013, 2015a,b). Because $\Delta P_{RV\text{-}RA}$ is calculated from the mean velocity of the TR jet, the use of VTI_{TR} instead of $\Delta P_{RV\text{-}RA}$ is unrestricted possible and has the advantage to include also the duration systolic loading. Because the regurgitant jet velocity recorded by continuous wave Doppler is used for the calculation of $\Delta P_{RV\text{-}RA}$ by means of the Bernoulli equation, the replacement of $\Delta P_{RV\text{-}RA}$ by the VTI_{TR} is possible without any restriction and has the advantage to also include the duration systolic loading. The use of A_{ED} instead of EDV is justified by the good correlation between the echo-derived RV-A_{ED} and the MRI-derived RV-EDV (Shiran et al., 2014). Thus, a small RV area relative to long-axis length (size and geometry unaltered) in a patient with high VTI_{TR} (i.e., high RV systolic pressure and relatively low RA pressure) yields a high LAI_{RV} which indicates good RV adaptation to load (ability to increase systolic pressure without dilation and also without RA pressure increase) suggesting a good RV contractile function and the potential of RV to improve its performance after reduction of loading conditions. A large area relative to long-axis length (spherical dilation) despite a relatively low VTI_{TR} (more increase in RA pressure than in systolic RV pressure) yields a low LAI_{RV} which indicates poor adaptation to load (disproportionate RV dilation with limited ability to raise RV systolic pressure in response to increased afterload, consequently also progressive TR and RA pressure rise), suggesting a reduced myocardial contractility and low probability for RV improvement during LVAD support. It was found that LAI_{RV} values <15 indicate low RV adaptability to load which will be insufficient to prevent RVF, even at normal PVR (Dandel et al., 2013, 2015a).

Prediction of Patient Outcome With LVAD Therapy

A major source of LVAD recipients' morbidity and mortality relates to RVF. RV reverse remodeling and functional improvement after LVAD implantation depend not only on the reversibility of RV myocardial alterations but also on the reversibility of pathologic

circulatory and metabolic changes induced by imbalanced neurohumoral/inflammatory reactions to the low cardiac output and congestive HF-related end-organ failure (especially kidney and liver). Conversely, the reversibility of pathologic neurohumoral activation and end-organ failure during LVAD support depend on RV function. Prediction of both RV improvement and outcome during LVAD support is therefore highly complex and is a challenging issue and it is not surprising that the majority of scoring systems which are currently used for decision-making between LVAD and BiVAD implantation are based rather on variables which reflect the preoperative severity of HF-related multi-organ dysfunction than on measurements directly related to RV contractile performance including its potential reversibility (Atluri et al., 2013; Drakos et al., 2010; Fitzpatrick et al., 2008; Matthews et al., 2008). This might explain the different risk discrimination capacities for post-LVAD RVF found in different studies using the same scoring system not containing data on RV size, geometry, and function.

Certain risk scores for post-LVAD RVF with and without incorporated echo-data appeared also able to stratify the risk for death after LVAD implantation (Aissaoui et al., 2015; Cowger et al., 2016; Lietz et al., 2007; Matthews et al., 2008; Miller and Russell, 2012; Potapov et al., 2011a; Drakos et al., 2010; Topilsky et al., 2011a). The highest ability to identify patients at higher risk for postoperative death was shown by the complex scoring systems that incorporate preoperative clinical, hemodynamic, and laboratory data reflecting mainly end-organ dysfunction which can remain a high risk for mortality even after improvement of RV function during LVAD support (Drakos et al., 2010; Lietz et al., 2007; Matthews et al., 2008; Miller and Russell, 2012; Potapov et al., 2011a). However, additional inclusion of certain echo-derived parameters for evaluation of RV function into established risk scores based only on variables reflecting the preoperative severity of HF-related multi-organ dysfunction can improve prediction of post-LVAD RVF and patient outcome (Aissaoui et al., 2015; Grant et al., 2012; Kato et al., 2013).

Role of Echocardiography at LVAD Implantation Surgery

Intraoperative TEE is helpful for cannula placement, assessment, and optimization of LV unloading, assessment of RV function, final evaluation of cardiac valve function, and final exclusion of a PFO that may have been masked by increased left atrial (LA) pressure.

Assessment of Inflow and Outflow Cannula Position and Blood Flow

Blood flow at both cannulas can be evaluated by color flow, pulsed-wave (PW) and continuous-wave (CW) Doppler. Acoustic shadowing (reverberation artifact from the pump) can impede or limit Doppler interrogation. The inflow cannula (IC) should be parallel to the septum and directed toward the mitral valve (MV) and not abutting any ventricular wall (Gelzinis, 2012; Magunia et al., in press; Stainback et al., 2015). An excessive degree of IC deviation toward the ventricular septum may necessitate surgical revision. Correct position of the IC can be confirmed during short-term reduction of LV volume by increasing the pump rate (Kirkpatrick, 2012). Real-time 3D echocardiography may be used for better visualization of the terminal portion of the IC within the LV (Stainback et al., 2015). For continuous flow (CF) devices, the normal color-flow Doppler pattern should consist of unidirectional laminar flow with systolic augmentation (peak velocity: between 1 and 2 m s^{-1}, depending on preload and intrinsic LV function) (Chumnanvej et al., 2007; Gelzinis, 2012). Regurgitation suggests pump malfunction, turbulence/high velocity suggests obstruction (thrombus or intermittent obstruction by LV wall) (Cohen et al., 2015). At the outflow cannula (OC), the normal flow is laminar and unidirectional (peak velocity: 0.5 and 2 m s^{-1}). OC flow patterns can be affected by the insertion angle of the cannula into the aorta. IC and OC peak flows are usually higher for pulsatile devices, but not beyond 2.3 m s^{-1}. Examination of OC anastomosis is also necessary (Chumnanvej et al., 2007; Cohen et al., 2015).

Optimization of LV Unloading and Evaluation of RV Function

The main echo parameters for assessment and monitoring of LV unloading by an LVAD are ventricular and atrial septum position, LVEDD, and AV opening (Chumnanvej et al., 2007). TEE is also mandatory for intraoperative monitoring of RV size, geometry, and function plus close observation of possible changes in TR and/or RA size (Dandel et al., 2015a; Kukucka et al., 2011a,b). After LVAD initiation, acute RV geometry changes during sudden excessive LV unloading can induce RV dysfunction (up to acute RVF). RV overdistension must therefore be strictly avoided. TEE-confirmed neutral ventricular and atrial septum position is essential for avoidance of RV and tricuspid ring-geometry alterations (Chumnanvej et al., 2007; Dembitsky and Naka, 2012; Marzec and Ambardekar, 2013). Worsening of RV function immediately after LVAD initiation, associated with absence of AV opening, leftward septum-shift with extreme LV diameter decrease (± suction events), and TR increase indicate excessive LV unloading (**Fig. 2**) (Dandel et al., 2015a).

Preexisting RV dysfunction is often reversible by LV decompression-induced reduction of RV afterload.

However, if LV unloading shows no effect on RV size and function, the additional implantation of a temporary RVAD can be beneficial because early RVAD implantation improves survival over-delayed placement (Fitzpatrick et al., 2009). After LVAD implantation, reduction of RV afterload is usually followed by reduction of TR. However, leaving greater than moderate TR can induce worsening of RV function with further worsening of TR, which will later need surgical correction (Dembitsky and Naka, 2012; Fitzpatrick et al., 2009; Marzec and Ambardekar, 2013). TV repair performed simultaneously with LVAD implantation in

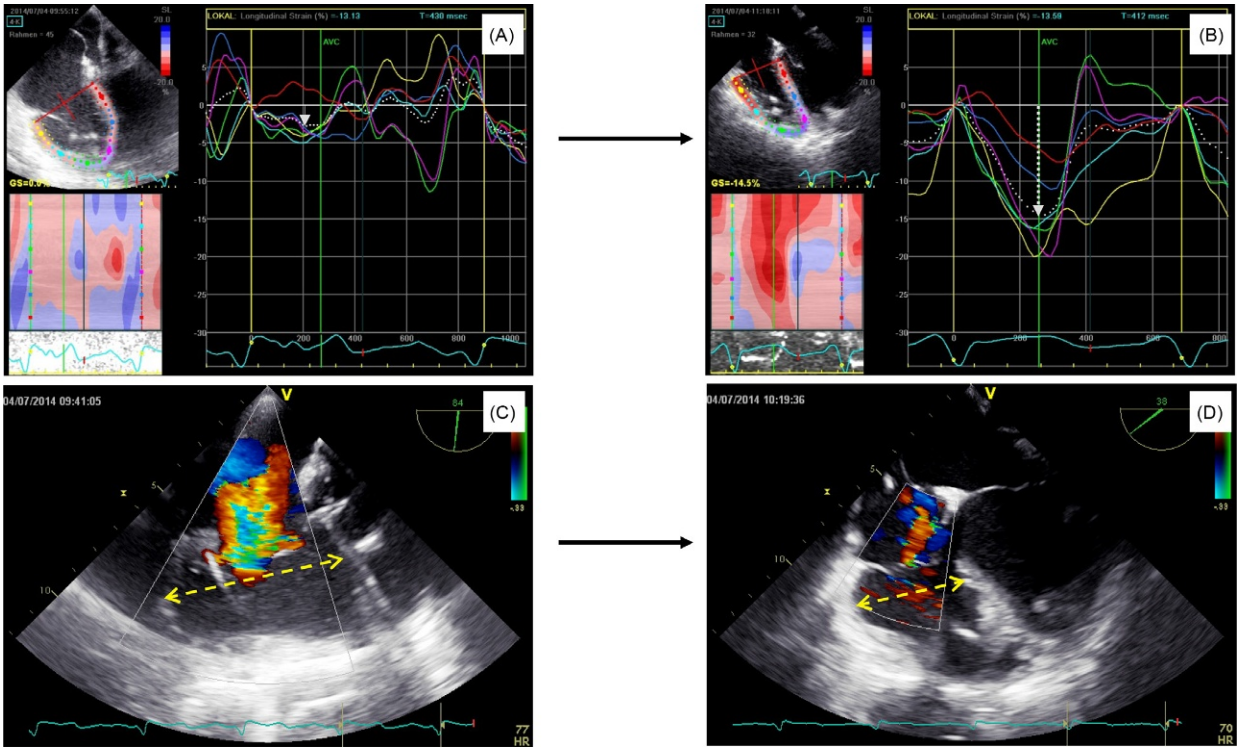

Fig. 2 Intraoperative transesophageal echo images of the right ventricle (RV) during acute severe RV failure induced by excessive unloading of the failing LV shortly after initiation of the implanted LVAD (images A and C) and after reversal of RV failure (B and D) induced by optimization of LVAD support. Image A shows massive RV and right atrial (RA) dilation with ventricular and atrial septum shift to the left as well as extremely altered RV myocardial global and regional longitudinal strain values. In addition to the extremely low global peak longitudinal systolic strain (PSSL), the regional strain curves indicate high asynchrony and dyssynergy of both systole and diastole. Image C also shows a severe TR. Images B and D recorded 1 h after optimization of LVAD function show normalization of RV size and geometry, normal septum position, normal RA size, and striking reduction of TR. PSSL increase from 2.3% to 14.5% plus improvement of synchrony and synergy indicate massive improvement of RV myocardial contractile function.

patients with intraoperative TR ≥ grade 3 associated with preoperative RVF can promote RV reverse remodeling and spare them from permanent BiVAD (Maltais et al., 2012; Potapov et al., 2011b).

After LVAD initiation, TEE is also necessary to reassess AV coaptation, because the decrease in LV pressure increases the transvalvular pressure gradient and therefore aggravates AR, which preoperatively is often underestimated (Dandel et al., 2015a; Rao et al., 2001). AR can further be exacerbated if the OC position is too close to the AV producing valvular distortion and local pressure increase with aortic root dilation and increase of the transvalvular pressure gradient (Dembitsky and Naka, 2012; Rao et al., 2001). Because AR impairs LV unloading and can lead to progressive congestive HF in LVAD recipients, patients with AR ≥ grade 2, especially those who have thin leaflets, require AV repair, closure, or bioprosthesis (Dembitsky and Naka, 2012; Feldmann et al., 2013).

LVAD initiation may create a pressure gradient from the RA to the LA, with exaggerated right-to-left shunting through a PFO. To reveal shunting by TEE it is useful to induce a short-term shifting of atrial septum to the left by increasing the LVAD flow (Dembitsky and Naka, 2012). Intraoperative TEE after LVAD initiation is mandatory because PFO should be surgically closed before leaving the operating room (Dembitsky and Naka, 2012; Patangi et al., 2013). After LVAD initiation, TEE is necessary for guiding pump speed adjustment to optimize LV unloading without any septum shift and if possible with maintaining an AV opening at least once every three heart beats (Cohen et al., 2015; Patangi et al., 2013; Topilsky et al., 2011b). Although maximum achievable LVAD support might be beneficial for patient exercise capacity and LV reverse remodeling, submaximal support in order to keep a near physiologic AV function is preferred in outpatients, because full support can lead to more suction alarms, AV leaflet fusion, aortic rood thrombosis, and development or aggravation of AR by increasing the pressure gradient over the closed AV (Topilsky et al., 2011b).

Role of Echocardiography in the Postoperative Management of LVAD Recipients

Echocardiography is the major tool for routine surveillance of LVAD recipients. It is required for assessment and optimization of LV unloading, for monitoring of RV function, and for early detection of cardiac abnormalities which can impair LVAD therapy. It is also

the mainstay for evaluation of unloading-promoted cardiac improvement and decision-making about the possibility to wean certain patients from their LVAD.

Monitoring and Optimization of LV Unloading

Maintenance of proper LV unloading is paramount for long-term outcome after LVAD implantation, and echocardiography is the imaging modality of choice for surveillance of LV unloading. Abnormal LVAD parameters and/or clinical symptoms of HF need immediate TTE evaluation.

Insufficient or impaired LVAD support causes LV overfilling with all its consequences. Major echo findings during LV overfilling are AV opening associated with increasing LVEDD, rightward septum shift, LA enlargement, increased spontaneous "echo-contrast" in the LV and LA, new appearance or increase of mitral regurgitation (MR), RV and RA diameter increase, TR and PAP increase, and dilated inferior vena cava (Chumnanvej et al., 2007; Kassi and Estep, 2016). Few studies also aimed to define parameters which might be used as echo surrogates for LV filling pressure. In one study, the mitral deceleration index and LA pressure estimated on the basis of diastolic position of atrial septum showed significant correlation with pulmonary capillary wedge pressure (PCWP) (Topilsky et al., 2011b). Other studies showed that prolongation of mitral deceleration time, decrease in trans-mitral early diastolic flow velocity (E), decrease of the ratio between E and the tissue Doppler-derived mitral annular early velocity (e′), and decrease in LA size can be used in LVAD recipients as echo surrogates of decreased LV filling pressure (Lam et al., 2009; Topilsky et al., 2011c). The slope of the anterior mitral leaflet closure after atrial phase of LV diastolic filling obtained from M-mode TTE was also found to be a possible echo surrogate for LV filling pressure (Martinez et al., 2014). In a larger study, an echo-derived algorithm developed for evaluation of LV filling pressures in patients with systolic HF supported by an LVAD appeared able to distinguish normal from elevated LV filling pressures (Estep et al., 2014a). The parameters selected for that algorithm were: trans-mitral early (E) and late (A) diastolic flow-velocity ratio (E/A), systolic PAP, E/e′ ratio, LA volume index, and RAP. Because in CF pumps, changes in PCWP during stepwise pump-speed changes (ramp studies) correlated only weakly with changes in LVEDD, LVEDD alone is not a reliable echo-derived surrogate for PCWP (Jung et al., 2015).

LVEDD, septal position, and AV opening are most often used to optimize LVAD settings (Kirkpatrick et al., 2010; Shah et al., 2012). For CF-LVADs, the rotor speed should be adjusted until the septum is neutrally positioned and the AV opens to a small degree for a brief period of time and/or a reduced frequency at the lowest possible LVEDD (Kirkpatrick, 2012; Kirkpatrick et al., 2010). In patients with unloading-promoted LV improvement, proper adjustment of LVAD function is necessary to prevent excessive unloading. Major echo signs for over-pumping are shrinking of LV cavity size with leftward septum shift (± suction events), no opening of the AV (± spontaneous echo contrast in the aortic root), altered RV geometry with TR increase, reduction in the peak velocity of the TR jet, and worsening of RV function (Kirkpatrick, 2012; Stainback et al., 2005).

Serial assessment of AV opening is mandatory for evaluation and optimization of LV unloading. Because AV opening depends on the aortic-to-LV pressure difference during LV systole, the degree and frequency of openings will increase with LV recovery or when LVAD malfunction leads to high LV pressures. Conversely, AV openings will decrease or even stop with aggravation of LV dysfunction or after excessive LV decompression by the LVAD (LV pressure decrease and aortic pressure increase).

Recently it was shown that 3D echocardiographic assessment of LV and RV volumes and shape can help optimization of LV unloading in LVAD recipients (Addetia et al., 2017). It was also found that adding 3D echocardiographic assessment of the RV to the clinical echo-ramp study may better optimize LVAD speed (Addetia et al., 2017).

Search for Abnormalities Which May Impair LVAD Therapy

Several circumstances and cardiac abnormalities like cannula obstruction, tamponade, AR, intracardiac thrombi, and vegetations, which impair LVAD therapy, are detectable by echocardiography. Early detection of cannula obstruction (partial, intermittent, or complete), which can result from malposition, kinking, thrombosis, or vegetations, can be of vital importance for the patient. LV shrinking by excessive unloading which facilitates IC obstruction by cardiac structures ("suck down" of septum, trabeculations, papillary muscles, chordal structures) and reduction of preload by tamponade or hypovolemia, which also predispose to obstruction of the IC orifice, are other abnormalities easily detectable by follow-up echo controls (Cohen et al., 2015; Kirkpatrick, 2012). In LVAD recipients with progressive LV improvement, with the increasing contribution of the LV to the CO, the initially optimal LV unloading can turn into excessive unloading necessitating adjustment of pumping rates or rotor speed to prevent suction events. High velocity aliased flows with turbulence at the cannulas orifices (for pulsatile devices: >2.3 m s^{-1} peak inflow and >2.1 m s^{-1} peak outflow; for CF- devices: >2 m s^{-1} peak inflow and outflow) suggest obstruction (Kirkpatrick, 2012). Low velocities at the IC may indicate thrombosis inside the cannula. Reduced diastolic flow velocity and increased systolic/diastolic flow velocity ratio suggest thrombosis-induced pump malfunction (Fine et al., 2014). Regurgitant flow at the IC suggests LVAD malfunction. Whereas in pulsatile LVADs, failure of the one-way valve leads to regurgitation, in CF devices regurgitation occurs when pumps are unable to overcome the systemic vascular resistance. Also intermittent low peak velocity flow may suggest LVAD malfunction if a misalignment between flow and ultrasound beam direction or a relevant LV-SV can be excluded. At the IC, PW-Doppler can be used to calculate device SV, but it is challenging to obtain reliable measurements. For the IC the most optimal Doppler angle is usually

found in apical views but interrogation can be impaired by reverberation artifacts from the pump. The OC in the ascending aorta is usually best visualized from a right parasternal view but often difficult to image by TTE (Kirkpatrick, 2012; Stainback et al., 2005).

Echocardiography is also necessary for detection and surveillance of AV dysfunction because significant AR can arise also a month after LVAD implantation and acquired AS due to cusp fusion is a relevant complication of LVADs (Kirkpatrick, 2012; Grinstein et al., 2016; Pak et al., 2010). Because patients without AV opening are at high risk for thrombotic events, follow-up echo controls should be also focused on the search for LV and aortic thrombi (Dobarro et al., in press; Pak et al., 2010). In an LVAD-supported heart, AR can occur also during LV systole if the aortic pressure exceeds LV pressure. Traditional quantification of AI severity using vena contracta, proximal isovelocity surface area, and jet width/LVOT diameter ratio do not take into consideration the pancyclic nature of AR jets in LVAD recipients and may therefore underestimate the severity of AR (Grinstein et al., 2016). Newly developed echo-derived variables like OC diastolic acceleration and systolic-to-diastolic peak velocity ratio (S/D-ratio) appeared more reliable for AR quantification in LVAD recipients (Grinstein et al., 2016).

Assessment of changes in LVEDD, AV opening time, and mitral inflow deceleration time during pump speed-change testing (ramp-tests) appeared also useful in diagnosing CF-LVAD malfunction in the setting of pump thrombosis (Estep et al., 2014b). However, AR or elevated mean arterial pressure can generate false positive ramp tests, whereas a small thrombus can induce false negative results (Adatya et al., 2013).

Surveillance of RV Function

Although LV unloading often induces already intraoperatively acute reduction of the PVR and long-term LVAD support further reduces PVR facilitating RV reverse remodeling and functional improvement, both early and late RVF after LVAD implantation are not always avoidable (Dandel et al., 2015a; Rich et al., in press). Serial follow-up assessment of RV size, geometry, and function is therefore mandatory and TTE is the method of choice for early detection of right-sided heart dysfunction. RVEDD, RA volume, and TR increase are major signs for imminent or already existing RVF and additional signs for insufficient or excessive LV unloading suggest that the alteration of right-sided heart function might be related to the disadvantageous LVAD support. No regression of TR and persistent dilation of RV and RA, after optimization of LV unloading, indicate either reduced RV myocardial contractility or RV overloading or both. Main causes for RV overloading despite optimal LVAD support are pressure overload by increased precapillary vascular resistance (irreducible by LV unloading) and/or volume overload, especially due to severe TR or renal dysfunction. Normal or reduced PVR in such patients indicates that reduced contractile function is mainly responsible for RV dysfunction. Reduction of LAI_{RV} values can also confirm the impairment of RV contractile function.

Evaluation of Unloading-Promoted Cardiac Improvement

Echocardiography is the cornerstone for assessment of cardiac recovery in LVAD recipients allowing both selection of weaning candidates and decision-making in favor of or against LVAD removal. Repeated TTE screenings with normal LVAD function are necessary for selection of potential weaning candidates (i.e., patients with signs of reverse remodeling who also seem to have their contractile function improved to levels deserving further evaluation). Potential weaning candidates are those with LVEDD $<$55 mm (or 55–60 mm at BSA $\geq$1.8 m^2) and fractional shortening $>$15%, no or $\leq$grade 1 MR and/or AR, no RV dilation and no or $\leq$grade 2 TR during LVAD support (Dandel et al., 2011). Repeated short-term interruption of LV unloading (off-pump or turn-down trials) is mandatory for assessment of recovery, regardless of whether the assessment is performed at rest or during exercise. Whereas pulsatile LVADs allow optimal assessment of heart function during complete pump stops (off-pump trials), complete stops of CF pumps lead to retrograde blood flow into the LV which induces misleading LVEDD increase (volume overload) and reduction of the diastolic arterial pressure that, by reducing the LV afterload, can generate overestimations of LV systolic function. The misleading retrograde flow into the LV during off-pump trials is a major negative factor that can interfere with successful LVAD explantation. For such pumps, rotor-speed reduction (turn-down trials) to values resulting in close to zero flow in one cardiac cycle is therefore better than complete pump stop (Birks and Miller, 2012; Cohen et al., 2015; Dandel et al., 2005; Dandel et al., 2011).

Before the first off-pump trial, it is useful to perform stepwise pump-rate reductions under TTE monitoring, to verify whether complete interruption of unloading is possible. If unloading reduction already provokes symptoms (dizziness, sweating, etc.), any turn-down to zero unloading is senseless and risky. If the patient remains asymptomatic but the LVEDD increases beyond 60 mm, or the right-sided heart revealed morphological and functional instability (increasing TR, RV dilation with reduced output), any unloading interruption trials are also senseless, because such a patient is not yet a weaning candidate.

Echo assessment of recovery in weaning candidates is usually based on the results of repeated short-term off-pump or turn-down to zero-unloading trials (Birks and Miller, 2012; Dandel et al., 2005; Dandel et al., 2011; Dandel and Hetzer, 2015a; Dandel et al., 2012; George et al., 2004; George et al., 2007; Müller et al., 1997). After months of continuous LVAD support, even short periods of physiological loading by interruption of LVAD support may represent a serious challenge for a possibly incompletely recovered LV. It therefore appears reasonable to avoid (at least initially) any risk of myocardial exhaustion, which

might interfere with possibly still ongoing recovery. Therefore, all adults and children who were weaned since 1995 in the Berlin Heart Center from long-term VADs underwent assessment of recovery exclusively at rest (Dandel et al., 2011; Dandel et al., 2012). Although at rest the conclusive value of assessments is limited by the lack of information about inotropic reserves and cardiac adaptation to stress, the weaning results obtained in Berlin were not relevantly affected by that, insofar as the results reported by groups who additionally used stress echocardiography and/or exercise testing were not better (Birks and Miller, 2012; Dandel et al., 2011; Dandel et al., 2012; Khan et al., 2001). Nevertheless, stress echocardiography can provide valuable information on inotropic reserves and adaptation to stress, which might be useful for weaning decisions. An absolute EF increase by 5% during dopamine infusion appeared able to indicate preservation of contractile reserve (Birks and Miller, 2012). A possible limitation of dobutamine stress echocardiography (DSE) can be, at least theoretically, the risk of myocardial exhaustion with negative impact on an ongoing myocardial recovery process. Further studies are therefore necessary to establish the real value of DSE for weaning decisions.

In principle, echo assessment of recovery should be as comprehensive as possible, including Tissue Doppler imaging (TDI) and speckle-tracking-derived strain echocardiography (STE) (Dandel et al., 2011; Dandel et al., 2012; Gupta et al., 2014). The advantages of STE are its ability to differentiate between active and passive movement of myocardial segments, the angle independency of myocardial deformation measurements, and the possibility to quantify intraventricular asynchrony and dyssynergy plus to evaluate components of myocardial function, such as longitudinal myocardial shortening, that cannot be visually assessed (Dandel and Hetzer, 2009; Dandel et al., 2014; Formica et al., 2010). The major limitation of STE is its dependence on image quality. **Figs. 3** and **4** show the usefulness of TDI and 2D-STE for assessment of recovery after LVAD implantation. However, not all parameters with impact on weaning decisions can be reliably measured in all patients because of poor image quality in some LVAD recipients, especially if off-pump Doppler and STE measurements had to be performed during rotor speed reduction instead of complete pump stop.

The cornerstones for weaning decisions are echocardiography and RHC (Birks and Miller, 2012; Dandel et al., 2011; Dandel and Hetzer, 2015a; Formica et al., 2010). The main criteria for LVAD removal are shown in **Table 5**. Off-pump LVEF $\geq$45% plus normal LVEDD at rest are weaning requirements and their stability after maximum improvement over the next 2–4 weeks during and between additional off-pump tests appeared predictive for long-term post-explant outcome (Birks and Miller, 2012; Dandel et al., 2011; Dandel et al., 2012; Dandel and Hetzer, 2015b). Other off-pump echo data on LV geometry and function (including TDI and strain data) are useful for weaning decisions especially if their stability after maximum remission is also considered. In borderline cases, STE off-pump data including intraventricular synchrony and synergy of contraction can be useful for final decisions. After maximum improvement, stability of LV size, geometry, and function also during moderate loading by pump reduction for several days can facilitate weaning decisions. Stable normal hemodynamics during the final off-pump trial is required before weaning, but alone it is insufficient predictive for long-term cardiac stability after VAD removal (Dandel et al., 2011). In patients with normal off-pump RHC data and <5 years duration of LV dysfunction before LVAD implantation, echo-derived off-pump measurements obtained at rest revealed high predictive values for post-explant cardiac stability during the next 5 years even in patients with chronic cardiomyopathy as the underlying cause for LVAD implantation (Dandel et al., 2014). The major risk factors for HF recurrence after LVAD explantation which are detectable by pre-explant off-pump trials are shown in **Table 6**.

Conclusions and Future Directions

Echocardiography is the first-line imaging modality to guide the management of LVAD recipients and of major importance for long-term successful LVAD therapy. It is required for preoperative patient selection and detection of cardiac abnormalities which must be corrected at the time of LVAD implantation, timing of LVAD implant surgery, perioperative assessment of RV function, and decision-making about the necessity for a temporary mechanical support also for the RV, intraoperative optimization of LVAD function, postoperative surveillance, and optimization of LVAD function plus evaluation of native myocardial recovery and decision-making about the possibility to wean certain patients from the LVAD.

Because reliable assessment of RV function in LVAD candidates and prediction of the natural history of RV dysfunction after LVAD implantation remains one of the major preoperative challenges, one future goal should be the validation of the more recently introduced echo-based composite variables which focus strictly on RV adaptability to loading conditions and to include also echo-derived parameters for evaluation of RV function into the established risk scores, based only on variables reflecting the preoperative severity of HF-related multi-organ dysfunction, in order to improve their predictive value for RVF after LVAD implantation.

The low number of studies on the usefulness of TDI and myocardial strain imaging for optimization of LVAD therapy and the high degree of methodological heterogeneity are probably the main causes for the underuse of these extremely important diagnostic tools. The use of strain imaging might have additionally been affected by the continuous progression of the technique and device update, which would also explain the inconsistency of certain preliminary findings. Thus, future studies aimed to standardize the methodology for myocardial velocity and deformation assessment before, during, and after LVAD implantation are absolutely necessary.

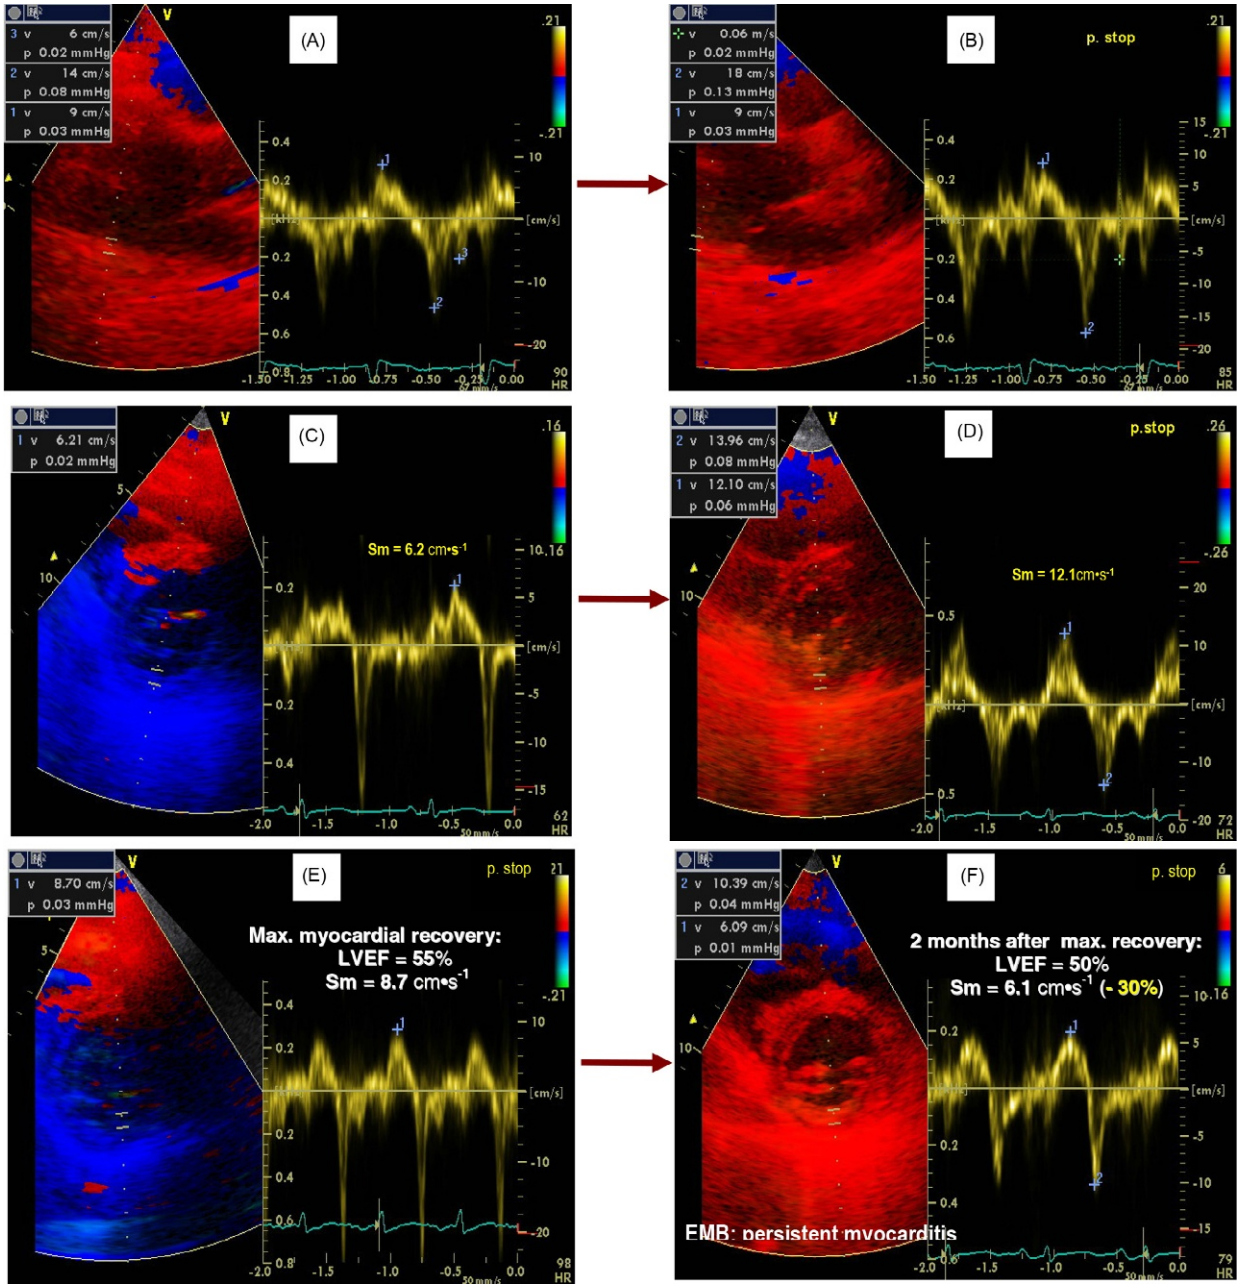

Fig. 3 Usefulness of tissue-Doppler imaging (TDI) for assessment of left ventricular (LV) myocardial improvement in 3 different LVAD recipients. Images A and B show identical peak systolic radial wall motion velocities (Sm) of 9 cm s^{-1} at the LV basal posterior wall (parasternal long-axis view) during full LVAD support (A) and during an off-pump trial. Weeks later, although LVEF remained unchanged at 50%, the off-pump Sm reached a maximum of 11 cm s^{-1}. The LV function remained thereafter stable, also after LVAD explantation. Images C and D recorded from another patient show a striking increase of radial Sm at the LV basal posterior wall (parasternal short axis view) during the off-pump trial from 6.2 to 12.1 cm s^{-1}. The low Sm during full LVAD support was induced by excessive unloading of an already recovered LV with an increasing output through the aortic valve. The LV function remained optimal and stable after LVAD explantation. Images E and F show two off-pump TDI recordings obtained from another patient who showed relatively high off-pump LVEF values, which misleadingly suggested a nearly complete recovery from a giant-cell myocarditis. At the time of maximum improvement (E), the patient had off-pump LVEF and Sm values of 55% and 8.7 cm s^{-1}, respectively. Thereafter, although off-pump EF did not fall below 50%, the Sm dropped continuously during the next 2 months reaching finally only 6.1 cm s^{-1} (F). The suspicion of a recurrence or persistence of myocarditis was finally confirmed by endomyocardial biopsy (EMB). Thus, LVAD explantation was contraindicated despite nearly normal LVEF values.

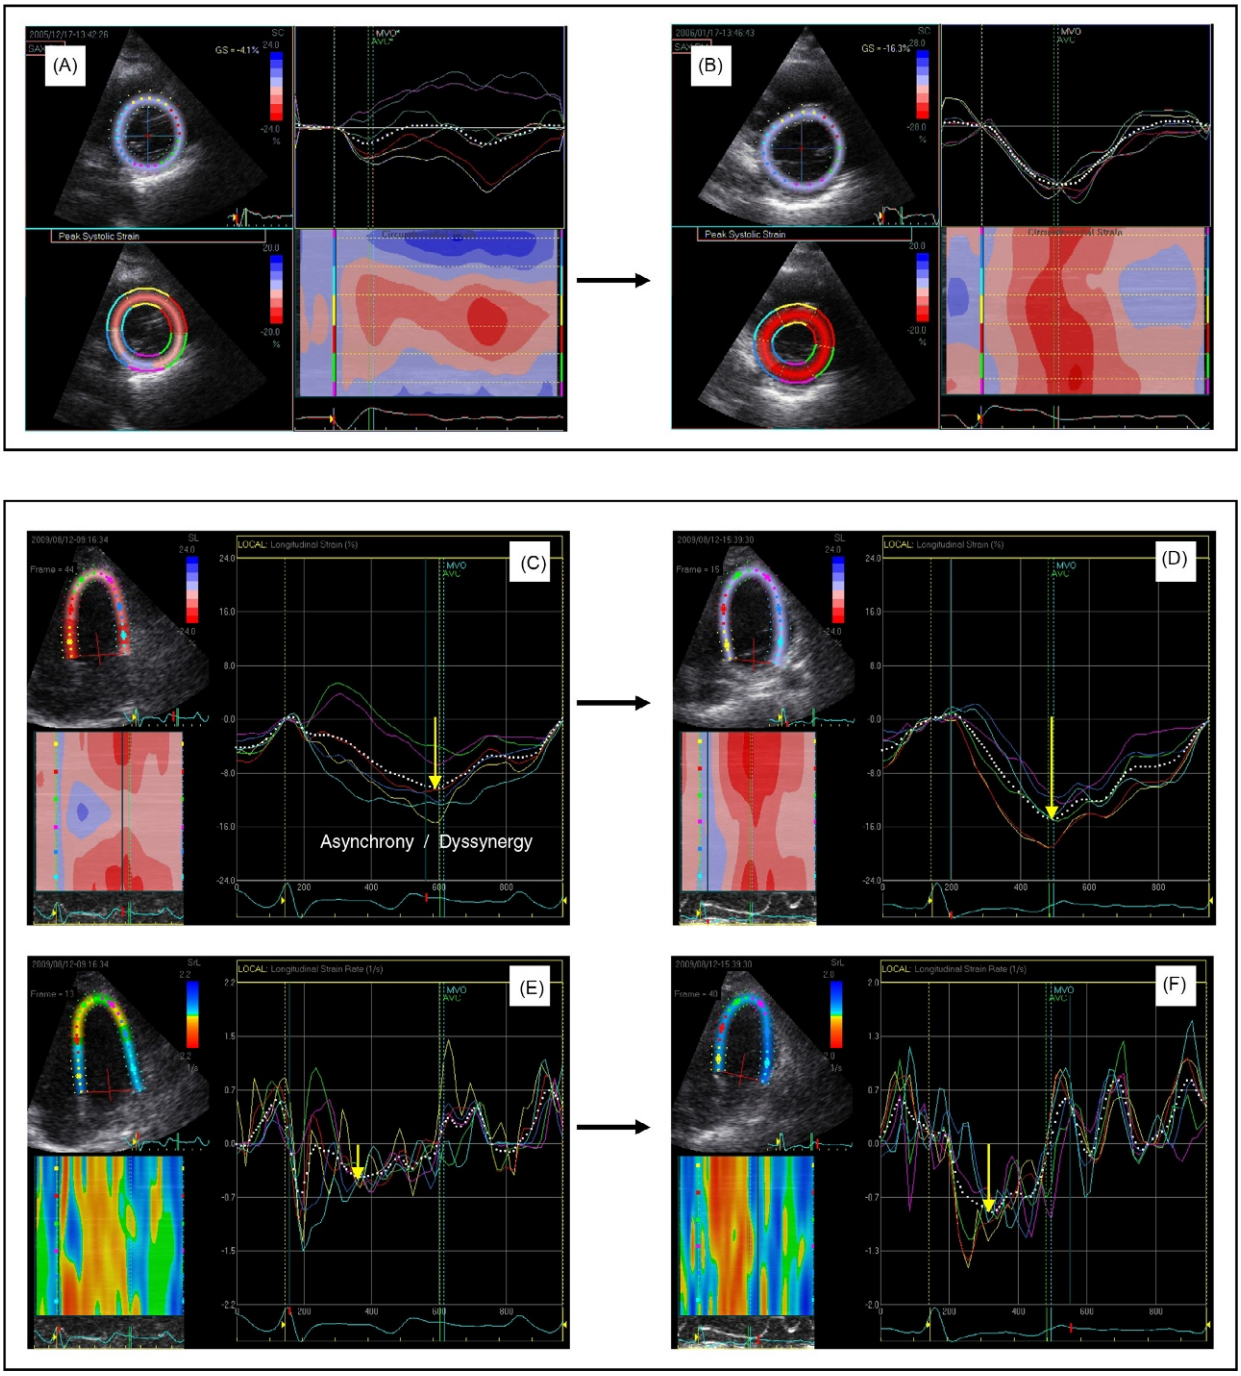

Fig. 4 Usefulness of speckle tracking-derived myocardial strain and strain-rate measurements for assessment of LV improvement during LVAD support. Images A and B show circumferential strain images recorded in a patient before LVAD implantation (A) and 1 month later during an off-pump trial for assessment of myocardial improvement (B). The circumferential peak global strain increased massively from (−) 4.1% to (−) 16.3% and the severe asynchrony and dyssynergy tuned into nearly uniform circumferential shortening during LV systole. Images C, D, E, and F show the longitudinal strain (C and D) and strain-rate (E and F) images recorded in another patient during full pump support (C and E) and during the off-pump trial (D and F). The relevant increase of the global strain (D) and strain rate (E) values with evident improvement of both synchrony and synergy of myocardial deformation during systole and diastole confirms the necessity for a complete interruption of LV unloading during the assessment of LV myocardial recovery.

Table 5 Main Criteria for Possible Explantation of a Left Ventricular Assist Device (LVAD) in Adult Patients with Unloading-Promoted Myocardial Reverse Remodeling and Improvement of Cardiac Function (Birks and Miller, 2012; Dandel et al., 2011; Dandel et al., 2012; Dandel et al., 2014; Dandel and Hetzer, 2015b)

Examination	*Parameters and parameter-derived measurements during pre-explant off-pump trials at rest, without inotropic support*	*Predictive value for ≥5 years cardiac stability*
Echocardiography[a]	LV ejection fraction (LVEF) ≥45% during the final off-pump trial	79%
	Stable pre-explant LVEF ≥45% after maximum improvement and during the final off-pump trial	86%
	LV end-diastolic diameter (LVEDD) ≤55 mm at BSA ≤1.8 m^2 during the final off-pump trial	LVEF ≥45% + LVEDD ≤55 mm: 86%
	Stable pre-explant LVEDD after maximum improvement and during the final off-pump trial	Stable LVEF ≥45% + stable LVEDD ≤55 mm: 94%
	Sm ≥8 cm/s, stable after maximum improvement and during the final off-pump trial	LVEF ≥45% + stable Sm ≥8 cm/s: 87%
	LV end-diastolic relative wall thickness (RWT) ≥0.38	LVEF ≥45% + RWT ≥0.38: 87%
	Stable VTI (PW-Doppler) in the LVOT during the final off-pump trial (stable stroke volume)	Alone not predictive
	No or ≤grade I MR and/or AR	Alone not predictive (requested before weaning)
	No RV dilation (RVOT diameter <35 mm, end-diastolic short-/long-axis ratio <0.6)	Alone not predictive
	Stable RV size and geometry during the final off-pump trial	Alone not predictive
	No, or ≤grade II TR and/or PR during the final off-pump trial	Alone nor predictive
RH Catheterization	Cardiac index (CI) >2.6 L min^{-1}/m^2 BSA (stable during the final off-pump trial)	Alone not predictive (requested before weaning)
	Pulmonary capillary wedge pressure <13 mmHg (stable during the final off-pump trial)	Alone not predictive (requested before weaning)
	Right atrial pressure (mean) <10 mmHg (stable during the final off-pump trial)	Alone not predictive (requested before weaning)
Electrocardiography	Sinus rhythm, heart rate (HR) <90/min and less than 25% HR increase during off-pump trials	Alone not predictive (requested before weaning)
Arterial pressure	Systemic mean arterial pressure ≥65 mmHg	Alone not predictive

[a]In patients with borderline echo data, 2D speckle-tracking imaging parameters, including also their pre-explant stability after maximum improvement and during the final off-pump trial, can be taken into consideration for weaning decisions (Dandel and Hetzer, 2009; Dandel et al., 2011; Dandel et al., 2012; Dandel and Hetzer, 2015b). *Sm*, peak systolic wall motion velocity at the basal posterior wall; *LVOT and RVOT*, left and right ventricular outflow tract. *MR, AR, TR and PR*, mitral, aortic, tricuspid, and pulmonary regurgitation, respectively; *VTI*, velocity-time integral; *PW*, pulsed wave.

Table 6 Pre-explant echocardiographic risk assessment for post-explant heart failure recurrence (Birks and Miller, 2012; Dandel et al., 2011; Dandel and Hetzer, 2015a; Dandel et al., 2012; Dandel et al., 2014)

Echo-approach	*Pre-explant echo parameters*	*Predictive value for HF recurrence during the first 3 post-explant years*
Off-pump standard TTE at rest	LVEF low and/or unstable[a]	89% for LVEF <45%[b]
		100% for LVEF <45% if history length of HF is >5 years
		90% for LVEF ≥45% with pre-explant alteration of >10% of best value
		88% for LVEF <50% with pre-explant alteration of >10% of best value
		89% for LVEDD >55 mm[b] at BSA ≤1.8 m^2
	LVEDD large and/or unstable[a]	90% for LVEDD >55 mm[b] at BSA ≤1.8 m^2 and LVEF <50%
		82% for RWT_{ED} <0.38[b]
	LV end-diastolic RWT reduced and/or unstable[a]	83% for RWT_{ED} <0.38 and LVEF ≤50%
		87% for RWT_{ED} reduction of >8%[b]
		85% for left ventricle S/L_{ED} increase of >10%[b]
	S/L_{ED} unstable[a]	Risk factor but no data on predictive value
	Trans-mitral restrictive flow-profile (accentuation or new appearance)	
	VTI reduction in the LVOT during the off-pump trials	Risk factor but no data on predictive value
	TR (new appearance or accentuation) and/or TR-jet velocity increase during off-pump trials	Risk factor but no data on predictive value
	RVEDD increase ± RV geometry alteration	Risk factor but no data on predictive value
Off-pump TDI and 2D-STE at rest	Sm low and/or unstable[a]	83% for Sm <8 cm s^{-1}[b]
	TAPS′ reduction during off-pump trials	90% for Sm pre-explant alteration of >10%
	LV myocardial asynchrony and/or dyssynergy during off-pump trials	Risk factor; no data on predictive value
Off- pump TTE after exercise with dobutamine	LVEF <50% after 6 MW	Risk factor; not sufficient data on predictive value
	No relevant LVEF increase during DSE	Risk factor; not sufficient data on predictive value

HF, heart failure; *TTE*, trans-thoracic echocardiography; *LVEF*, LV ejection fraction; *LVEDD*, LV end-diastolic diameter; *BSA*, body surface area; *VTI*, velocity-time integral; *S/L_{ED}*, end-diastolic short-/long-axis ratio; *LVOT*, LV outflow tract; *TDI*, tissue Doppler imaging; *2D-STE*, two-dimensional speckle-tracing echo imaging; *RWT_{ED}*, end-diastolic relative wall thickness ([posterior wall thickness + ventricular septum thickness]/LVEDD); *Sm*, systolic peak wall motion velocity measured with the pulsed-wave tissue Doppler at the basal posterior wall (parasternal short- or long-axis view); *6 MW*, 6 minutes walk; *DSE*, dobutamine stress echocardiography.

[a]Unstable: parameter changes during the time between maximum improvement and left ventricular assist device (LVAD) explantation and/or during the final off-pump trial

[b]Unstable during the final off-pump trial.

Introduction

Salt (sodium chloride) is an essential element for life, not only for humans, but also for animals, and even for many plants. Humans have had a long, close, and complex relationship with salt. For instance, salt served as money; salt was the instigator of warfare; salt created trades and cultures; salt was thought to facilitate sexual potency and fertility; and salt was a symbol of loyalty, friendship, truth, and wisdom (because the essence of salt has never changed). Now, we are facing a new challenge: excess salt intake may be hazardous to our health. The salt–human relationship appears to be delicate. This article provides an overview of the current understanding of the relationship between sodium intake and blood pressure (BP), including the prevalence, pathophysiology, and treatment.

Salt and BP

Animal experiments, epidemiological studies, and clinical trials have provided compelling evidence that high sodium intake increases BP. The INTERSALT Study (Elliott et al., 1996; Intersalt Cooperative Research Group, 1988), a standardized, worldwide epidemiologic study of large sample size ($n = 10{,}079$ men and women aged 20–59 years from 32 countries) assessed the relationships between 24-h urine sodium excretion and BP both within and across populations, and positive associations were found in many, but not all, populations. The estimated effects of reduced sodium intake on BP are that a 100 mmol day^{-1} (2300 mg day^{-1} sodium or 6 g day^{-1} salt) lower sodium intake is estimated to reduce systolic BP (SBP) by 1–6 mmHg and for diastolic BP (DBP) by 0.03–2.5 mmHg (Elliott et al., 1996; Intersalt Cooperative Research Group, 1988). BP and age were positively associated and BP was further elevated by higher sodium consumption. However, in populations with very low sodium intake (0.2–6 mmol day^{-1}), BP was not found to increase with age. In Western countries, BP tends to rise with age, and the prevalence of hypertension is 60–90% in older adults (Aronow et al., 2011; Benetos et al., 2016; Vasan et al., 2001). Given the findings from the INTERSALT Study, this phenomenon may be partly attributable to high sodium intake. Unfortunately, recent studies have revealed a significant increase in BP among children and adolescents over the last decade, and the BP was positively associated with sodium intake (**Fig. 1**) (Falkner, 2015; Rosner et al., 2013; Yang et al., 2012). Specifically, each 43 mmol day^{-1} (1000 mg day^{-1}) increase of sodium intake, estimated from multiple 24-h dietary recall measures, was associated with $\approx$1.0 mmHg increase in SBP, with a greater effect noted in overweight/obese children (i.e., SBP increase by 1.5 mmHg per each 1000 mg day^{-1} increase of sodium intake). The adjusted odds ratio for prehypertension/hypertension risk in the highest (vs. lowest) quartile of sodium intake was 2.0 (95% confidence intervals (CIs): 0.95–4.1) in overall (Yang et al., 2012), whereas, the odds ratio when comparing the highest to lowest quartile of sodium intake in overweight/obese children was 3.5 (95% CIs: 1.2–9.2).

Measuring Sodium Intake in Populations

Accurate and reliable measurement of individual sodium intake is extremely difficult (Cogswell et al., 2016). Consequently, the methodological challenge may cause inconsistent findings in the relationship between sodium intake and human health. Estimating sodium intake using dietary surveys is inaccurate. Spot urine tests overestimate individual intake at low levels of consumption

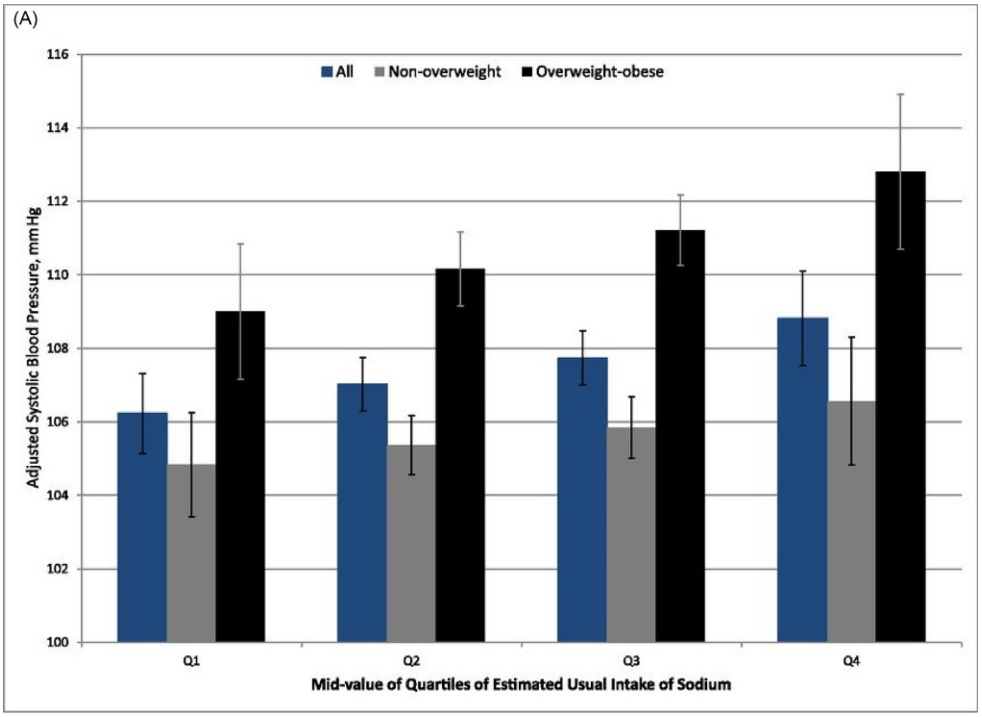

Fig. 1 Sodium intake and SBP among US children and adolescents (NHANES 2003–2008). Bars show adjusted mean (95% CIs) SBP levels by sodium intake quartile and weight status among American children and adolescents 8–18 years of age. Sodium intake and blood pressure among US children and adolescents. *Pediatrics* **130**(4), 611–619.

and underestimate intake at high levels (Brown et al., 2013; Mente et al., 2014). 24-hour urine collection is considered as the gold standard for estimating sodium intake (Cobb et al., 2014). However, because of challenges collecting urine in free-living persons, day-to-day variability in sodium intake, biological variability in urine sodium excretion, and unmeasured extrarenal sodium loss, even single 24-h urine collection may be not accurate. In a strictly controlled environment, 24-h urine samples taken every other day correctly classified a 3-g difference in salt intake for only 49% (Lerchl et al., 2015). By increasing the observations up to three consecutive 24-h collections, the estimation was improved to 75% (**Fig. 2**). Therefore, multiple 24-h urine collections (e.g., weeks) are the most accurate for estimating individual sodium intake estimation (Oh et al., 2016). We need to consider these methodological challenges when we interpret current available observational studies relating sodium intake to health.

Salt Sensitivity

BP response to sodium intake is heterogeneous across individuals, partly because of other components of the diet including potassium and calcium. The relationship between sodium intake and BP becomes stronger if the urinary sodium–potassium ratio rather than the sodium excretion rate itself was considered (Intersalt Cooperative Research Group, 1988). Salt sensitivity is another determinant of individual BP response to sodium intake. In those with salt sensitivity, BP increases when excess sodium was consumed, whereas BP reduces with a low-sodium diet. The trait is reproducible (Elijovich et al., 2016). Although the definition of salt sensitivity has been inconsistent across studies, most defined it as a proportional change ($\geq$3% to $\geq$10%) or an absolute change ($\geq$3 to $\geq$10 mmHg) in mean arterial pressure following low to high sodium intake (Oh et al., 2016). However, these classifications may be arbitrary, since BP response to sodium intake is continuous, with a normal distribution within populations (He et al., 2009). Although it depends on the definition and measurement methods, the proportion of salt sensitivity within populations has been estimated to be 25–50% in normotensives and 40–75% in hypertensives (Oh et al., 2016). Particularly, salt sensitivity is prevalent in African Americans, older persons, and individuals with diabetes, low-renin hypertension obesity (e.g., metabolic syndrome), and chronic kidney disease (Elijovich et al., 2016). BP response to sodium intake substantially increases with age (Weinberger and Fineberg, 1991), suggesting that environmental factors and age-related decline in organ function (kidney in particular) play a crucial role in the pathogenesis of salt sensitivity.

The molecular mechanisms underlying salt sensitivity remain unclear and continue to be debated. Genetic factors may account for 30–50% of the variation in BP response to sodium intake in Asians (Gu et al., 2007) and 75% in African Americans (Svetkey et al., 1996). The heritability estimates of BP change between random-sodium and low-sodium diet among white US

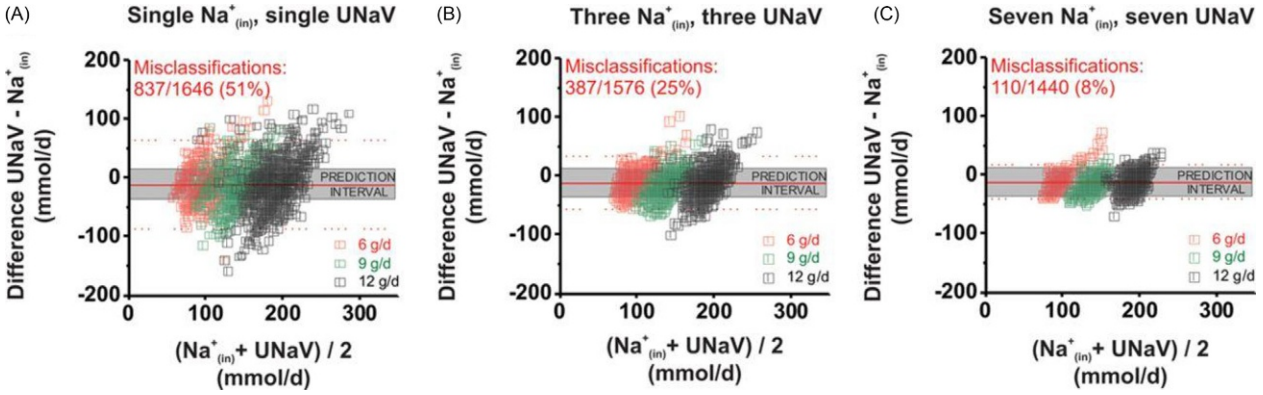

Fig. 2 Analyses of agreement between sodium intake and excretion in Bland–Altman plots. (A) Bland–Altman plot to test the agreement between single recorded 24-h sodium intakes and single UNaV. The prediction interval to accurately predict sodium intake by UNaV is defined as ±25 mmol day^{-1} of the mean difference between sodium intake and UNaV. (B) Analysis of agreement between three consecutively recorded sodium intakes and three UNaV collections. Multiple collections reduce the variability and thereby improve the predictive value of UNaV. (C) Seven consecutive collections reduce the number of misclassifications of UNaV to <10%. *Red solid line* indicates regression line; and *red dotted line*, upper and lower confidence level. UNaV, 24-h urine collection for sodium excretion. Reproduced from Cowley AW Jr (1992) Long-term control of arterial blood pressure. *Physiological Reviews* **72**, 231–300.

families were higher in monozygotic twins versus sibling (0.6–0.7 vs. 0.3–0.5) (Miller et al., 1987). DNA polymorphisms associated with renal sodium handling (e.g., α-adducin molecule and renal isoenzyme of 11-beta-hydroxysteroid dehydrogenase) correlate with salt sensitivity (Bianchi et al., 2005; Lovati et al., 1999). Asians tend to have genetically salt sensitivity. For example, the frequencies of DNA polymorphisms associated with renal sodium handling (e.g., Gly460Trp polymorphism of α-adducing gene; T(−344) C polymorphism of the aldosterone synthase gene (*CYP11B2*); T235 allele of the angiotensinogen gene) are higher in Asian compared with white populations (Katsuya et al., 2003; Kokubo, 2014). In addition, monogenic forms of salt-sensitive human hypertension, which are not applicable to general populations though, are characterized by gene mutations encoding molecules involved in renal sodium handling (Hall, 2016; Lifton et al., 2001). Collectively, these results suggest that kidney may play a critical role in salt–BP association (Hall, 2016). As suggested by Guyton, if natriuresis is impaired in the kidney (i.e., pressure natriuresis is shifted to higher BP) by intrarenal disturbances, extrarenal factors (e.g., increased sympathetic nervous and renin–angiotensin–aldosterone system activity), excessive antinatriuretic hormones, or deficit of natriuretic hormones, BP tends to rise by salt intake (Cowley, 1992; Guyton, 1980; Hall, 2016). Conversely, other studies revealed no sodium retention after salt loading in those with salt sensitivity compared with normal (i.e., salt resistant) individuals (Morris et al., 2016; Schmidlin et al., 2007). Instead, vasodilation to salt loading was impaired in those with salt sensitivity (Laffer et al., 2016; Morris et al., 2016; Schmidlin et al., 2007). This is an alternative view to Guyton's theory, claiming that vasculature rather than kidney dysfunction is a key initiator of salt-induced hypertension. It should be noted, however, that most of the studies used short-term (days or weeks) salt loading or deprivation from salt, meaning the long-term effect of salt intake/reduction on vasculature in those with salt sensitivity is unknown. The underlying mechanisms behind vascular dysfunction in salt sensitivity are not well understood, but may include multiple factors, such as impaired nitric oxide bioactivity, sympathetic nerve activation, activated circulating, and local renin–angiotensin–aldosterone system (Laffer et al., 2016; Morris et al., 2016; Schmidlin et al., 2007, 2011). Increased concentration of sodium or chloride stored in the interstitial space of skin or other tissues (e.g., the vasculature and brain) may also contribute to vascular dysfunction in those with salt sensitivity via inflammation (Machnik et al., 2009). The effects in human, and determination of whether and how altering the distribution of salt and body fluids leads to long-term BP regulation merit further investigation. Salt sensitivity is associated with target organ damage and adverse cardiovascular outcomes, independently—at least in part—of BP level and the occurrence of hypertension (Elijovich et al., 2016; Morimoto et al., 1997). Therefore, unraveling the mechanisms of salt sensitivity would provide promising avenues for therapeutics against salt-induced increases in BP. Another challenge includes difficulty implementing the paradigm of salt sensitivity into clinical practice or population-based interventions due to a lack of accurate assessment of the salt sensitivity phenotype. Ambulatory BP monitoring (Castiglioni et al., 2011), beat-to-beat BP and pulse rate variability (Coruzzi et al., 2005), and urinary biomarkers (e.g., renal tubular cells and exosome miRNome analyses) (Gildea et al., 2013a,b) have been proposed as clinical measures of salt sensitivity, which need to be further replicated and validated.

Effects of Reduced Sodium Intake on BP

Meta-analyses of randomized controlled trials in both adults and children demonstrate that reduced sodium intake led to BP reduction in a dose-dependent fashion (Aburto et al., 2013; He and MacGregor, 2006; Midgley et al., 1996). A reduction of 100 mmol day^{-1} in sodium (2300 mg day^{-1} sodium) intake was associated with SBP/DBP reduction of 7.1/3.9 mmHg in hypertensives and 3.6/1.7 mmHg in normotensives (He and MacGregor, 2002). The effects on BP of reduced sodium intake were

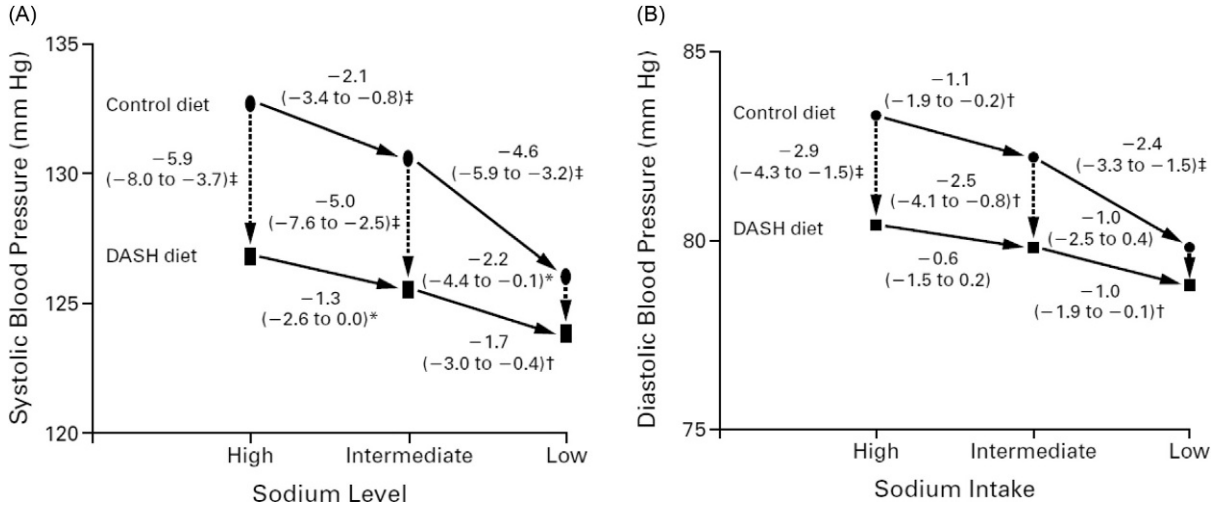

Fig. 3 The effect on SBP (A) and DBP (B) of reduced sodium intake and the DASH diet. The mean changes in BP are shown for various sodium levels *(solid lines)*, and the mean differences in BP between the two diets at each level of sodium intake are shown. Unidirectional arrows are used for simplicity, although the order in which participants were given the sodium levels was random with a crossover design. The numbers next to the *dotted lines* connecting the data points are the mean changes in BP. The 95% CIs are given in parentheses. Asterisks ($P<0.05$), daggers ($P<0.01$), and double daggers ($P<0.001$) indicate significant differences in BP between groups or between dietary sodium categories. *DASH*, Dietary Approaches to Stop Hypertension; *SBP*, systolic blood pressure; *CIs*, confidence intervals. Reproduced from Sacks, F. M., Svetkey, L. P., Vollmer, W. M., Appel, L. J., Bray, G. A., Harsha, D., Obarzanek, E., Conlin, P. R., Miller, E. R. 3rd, Simons-Morton, D. G., Karanja, N., Lin, P. H., DASH-Sodium Collaborative Research Group (2001). Effects on blood pressure of reduced dietary sodium and the Dietary Approaches to Stop Hypertension (DASH) diet. DASH-Sodium Collaborative Research Group. *New England Journal of Medicine* **344**(1), 3–10.

greater in hypertensives (vs. normotensives) and African Americans or Asians (vs. whites) (Graudal et al., 2012). Another meta-analysis including 37 randomized controlled trials observed that: (1) reduced sodium intake led to SBP reduction by 3.4 mmHg (95% CIs: 2.5–4.3) and DBP reduction by 1.5 mmHg (95% CIs: 0.98–2.1 mmHg); (2) when sodium intake was <2000 mg day^{-1} (vs. ≥ 2000 mg day^{-1}), SBP was reduced by 3.5 mmHg (95% CIs: 0.8–6.2 mmHg) and DBP reduction by 1.8 mmHg (95% CIs: 0.5–3.1 mmHg); and (3) reduced sodium intake had no adverse effect on blood lipids, catecholamine levels, or renal function (Aburto et al., 2013). The 37 trials included all allocated at least one group of participants to reduced sodium intake and other groups to higher sodium intake; had a duration of intervention lasting 4 or more weeks (excluding acute salt restriction trials); achieved an sodium intake difference of 40 or more mmol day^{-1} between intervention and control; and had 24-h urinary sodium excretion data (Aburto et al., 2013). A meta-analysis including children and adolescents under 18 years of age observed that reduced mean salt intake by 42% (interquartile range: 7–58%) led to SBP reduction by 1.2 mmHg (95% CIs: 0.6–1.8 mmHg) and DBP reduction by 1.3 mmHg (95% CIs: 0.7–1.9 mmHg) (He and MacGregor, 2006).

The combined effects of a reduced sodium intake with weight loss or the Dietary Approaches to Stop Hypertension (DASH) diet on BP reduction are greater than the effects of either intervention alone (Sacks et al., 2001; Whelton et al., 1998). In the Trial of Nonpharmacologic Interventions in the Elderly that recruited older hypertensives 60–80 years of age ($n=953$), change in mean SBP/DBP by reduced sodium intake alone (80 mmol day^{-1} (1800 mg day^{-1}) or less) was −3.4/−1.9 mmHg, whereas by sodium intake reduction plus weight loss (≥ 4.5 kg (10 lb)) was −5.3/−3.4 mmHg (Whelton et al., 1998). The DASH diet is rich in vegetables, fruits, and low-fat dairy products (e.g., whole grains, fish, and nuts). In the DASH-sodium study, a total of 412 participants were randomly assigned to sodium intake (high: 150 mmol (3450 mg)/day; intermediate: 100 mmol day^{-1}; or low: 50 mmol (1150 mg)/day for 30 days each) with or without consumption of the DASH diet. Reduced sodium intake from the high to the intermediate level reduced SBP/DBP by 2.1/1.1 mmHg during the control diet and by 1.3/0.6 mmHg during the DASH diet. Reduced sodium intake from the intermediate to the low level caused additional SBP reductions of 4.6/2.4 mmHg during the control diet and 1.7/1.0 mmHg during the DASH diet (**Fig. 3**). As compared with the control diet with the high sodium level, randomization to the DASH diet with the low sodium level led to a mean SBP that was 7.1 mmHg lower in those without hypertension, and 11.5 mmHg lower in participants with hypertension. The BP-lowering effect in hypertensives appears to be equal to or greater than a single antihypertensive-drug therapy.

Conclusion

The World Health Organization currently recommends consuming 2000 mg sodium/day (Drewnowski et al., 2015). The American Heart Association recommends a sodium intake <1500 mg day^{-1} for all Americans (Lloyd-Jones et al., 2010). The US Department of Agriculture and US Department of Health and Human Services joint 2010 Dietary Guidelines for Americans endorse

recommendations to reduce sodium intake below 1500 mg day^{-1} in African Americans, those >51 years of age, and those with hypertension, diabetes mellitus, or chronic kidney disease, with a recommendation for sodium intake <2300 mg day^{-1} for all others (US Department of Agriculture and US Department of Health and Human Services, 2010). However, implementation of sodium intake reductions is a grand challenge. Despite BP-lowering effect of reduced sodium intake is obvious, sodium intake remains high in many countries. Nearly half of Americans are trying to reduce their sodium intake, and most prefer consuming low-sodium food (Elijovich et al., 2016; Jackson et al., 2016). Nevertheless, the current mean sodium consumption of Americans is approximately 3400 mg day^{-1} (8.5 g of salt), with 77% of the sodium coming from packaged, processed, and restaurant foods (Centers for Disease Control and Prevention, 2010). How do we bridge this gap between what amount of sodium is preferred and what amount is actually consumed? Efforts to reduce sodium intake should rely both on consumers' selection of low-sodium food, and perhaps more important, on the reduced sodium environment that requires cooperation of manufactures, food-service operators, and policy decision makers (Cogswell et al., 2016). To reduce sodium intake at the population level, reformulation of processed foods should be operated either through negotiation with industry or through regulation by law (Cappuccio, 2007). Such a nationwide salt reduction strategy will lead to cardiovascular disease prevention at the community level and ultimately reduce health care costs substantially (Bibbins-Domingo et al., 2010).

Introduction

Cardiovascular disease (CVD) is the leading cause of death worldwide for men and women. Although the risk factors for CVD are similar in men and women, the impact of some of the risk factors differs by sex, and there are gender and sex differences in the clinical presentation and disease pathophysiology. Sex differences reflect biological influences dictated by the sex chromosomes, genetic polymorphisms, and/or single-nucleotide polymorphisms on the sex chromosomes and autosomes, sex-steroidal modulation of gene expression, and epigenetic modulation resulting from environmental factors. Gender differences relate to societally constructed roles of men and women and can also influence the phenotypic presentation and outcomes of CVD (Fig. 1). This chapter focuses on the biological basis for sex differences and documented sex differences in presentation, treatment, and outcomes of CVD. A better understanding of these differences could ultimately lead to a more personalized management of CVD.

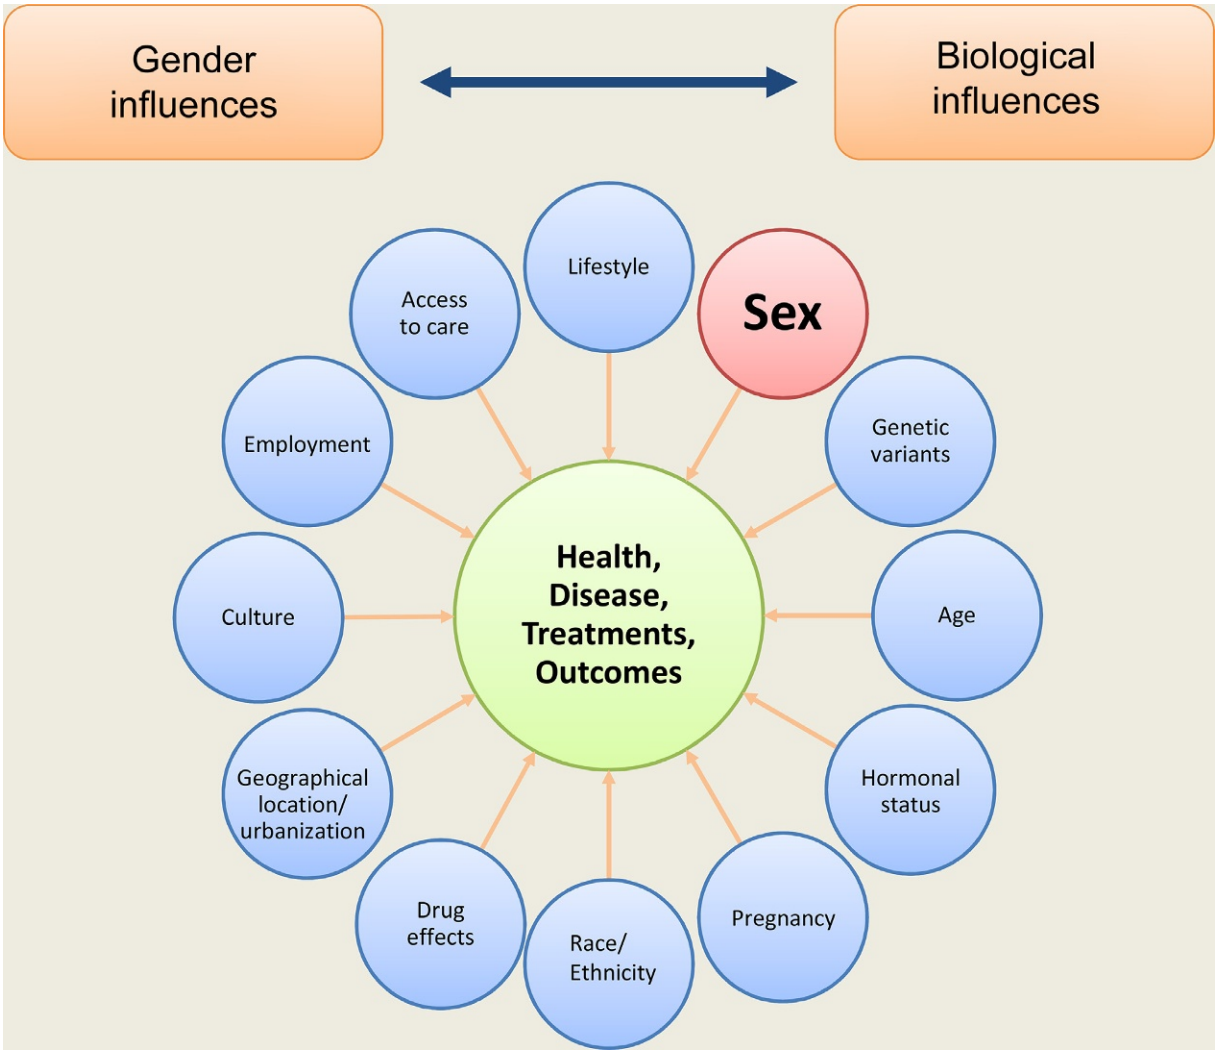

Fig. 1 Influence of biology and gender on sex differences in cardiovascular disease. Sex differences in the individual risk and phenotypic presentation of disease reflects the interactions of biological influences dictated by the sex chromosomes, genetic polymorphisms and/or single nucleotide polymorphisms on the sex chromosomes and autosomes, sex-steroidal modulation of gene expression, and epigenetic modulation resulting from environmental factors. In addition gender differences from societally constructed roles of men and women influences the phenotypic presentation and outcomes of cardiovascular disease.

Biological Basis for Sex Differences in CVD

CVDs involve complex traits. Therefore, sex differences in the individual risk and phenotypic presentation of disease reflect the interactions of genetic differences dictated by the sex chromosomes, genetic polymorphisms, and/or single-nucleotide polymorphisms on the sex chromosomes and autosomes, sex-steroidal modulation of gene expression, and epigenetic modulation resulting from environmental factors (Paynter et al., 2010; Winham et al., 2015).

Genes

In humans, biological sex is determined by the sex chromosomes (X and Y). Females have two copies of the X chromosome; males have one copy of the X and Y chromosome in every cell of the body, except for the gametes. There are some rare exceptions: XXY (Klinefelter's syndrome), X monosomy (Turner's syndrome), XXX, and XYY. In females, to reduce the dose effect of two X chromosomes, one X undergoes incomplete inactivation, which varies by tissue and may change throughout the course of life. It is unclear at this time how patterns of X-inactivation are regulated or how these patterns influence susceptibility or etiology of disease (Berletch et al., 2011; Agrelo and Wutz, 2010; Wu et al., 2014).

Historically, the genes on the Y chromosome, in particular those in the sex-determining region (SRY), were considered primarily involved with sexual differentiation. However, with newer genetic analyses, SRY is identified as a transcription factor that may regulate autosomal genes (Bellott et al., 2014). In addition, a common European lineage group of genes on the Y chromosome is

Haplogroup 1. Men who are carriers for Haplogroup 1 may be at risk for atherosclerosis as these genes regulate functions associated with progression of the disease including inflammation, autoimmunity, and adaptive immunity and resistance to infection (Bloomer et al., 2014; Bloomer et al., 2013). Nongonadal functions associated with the X chromosomes that are important for development of CVDs include coagulation, innate immunity, synthesis of norepinephrine, energy metabolism, blood pressure, and adiposity (Kanehisa et al., 2017). An analysis of RNA levels of 683 genes on the X chromosome in patients who had experienced an ischemic stroke showed a difference in X-related gene expression with upregulation of these genes in females compared to males. These results identify cellular pathways regulated by the X chromosome that may provide future sex-specific therapeutic targets (Winham et al., 2015).

Sex Steroid Hormones

The sex chromosomes induce development of the gonads that synthesize sex steroid hormones. The major sex steroids are testosterone, estrogen, and progesterone. These hormones are synthesized from cholesterol in gonadal and in some extragonadal tissues in both males and females. Testosterone is converted to estrogen by the enzyme aromatase, the activity of which varies by sex and age in men and women.

Sex hormones initiate structural or transient changes in tissues. Structural changes can persist when the hormones are absent, whereas the transient effects, called "activational effects," require the presence of the hormones. The most dramatic activational effects of the sex hormones are observed in women during pregnancy with modulation of functions of multiple organ systems that reverse once the fetus is delivered (e.g., breast development, skeletal adjustments, increases in blood volume and cardiac output, renal function, and nurturing behavior). Sex steroids initiate changes in cellular function through activation of steroid receptors on the cell surface (G-protein coupled receptors, GPR30), and through receptors within the cytoplasm and nucleus that belong to a family of nuclear binding receptors. Tissue-specific responses to sex steroids reflect differences in binding of the hormone–receptor complex to response elements on various genes. The gene for the androgen receptor is on the X chromosome; therefore, variations in this gene will more likely influence androgen insensitivity in males who carry only one copy of the X chromosome. Some cellular functions modulated by sex steroids and related to CVD risk include production of nitric oxide, regulation of angiotensin-converting enzyme (ACE), expression of angiotensin receptors, production of extracellular matrix, regulation of cellular pathways associated with apoptosis and cell survival, mitochondrial energy metabolism, production of oxygen-derived free radicals, and DNA methylation (Gaignebet and Kararigas, 2017; Regitz-Zagrosek and Kararigas, 2017; Miller and Duckles, 2008). The contribution of genetic variants in genes for the estrogen receptors in the etiology of CVD is difficult to define most likely due to the complex nature of CVD in general. However, a man with a mutation in the gene for estrogen receptor-α developed accelerated atherosclerosis, which was related, in part, to the loss of production of nitric oxide from the endothelial cells that line the arterial wall (Sudhir et al., 1997a,b). Other studies of how genetic variants in steroid receptors affect CVD are mixed, most likely reflecting the complex nature of CVD and may be related to metabolic components of cardiovascular risk (Clegg et al., 2017; Winham et al., 2015; Weng et al., 2016).

Sex and Gender Differences in Development and Susceptibility to Risk Factors for CVD

Risk factors can be divided as "conventional" traditionally accepted factors, "nonconventional" risk factors and factors specific to women as they result from the impact of reproductive hormones or disorders. **Table 1** summarizes some of the sex/gender differences associated with these factors.

Conventional Risk Factors

Factors affecting development of CVD can be classified as those that are modifiable (behaviors such as smoking, diet, activity, and exposure to environmental pollutants) and those based on the biology of being male or female. Based on a large population study, a group of "conventional" risk factors for CVD were identified and included in the Framingham Risk Score: age, sex, smoking, systolic blood pressure, use of antihypertensive therapy, dyslipidemia, body mass index, and diabetes (Kannel et al., 1961). Risk for CVD increases with age and the age-associated risk varies by sex (Benjamin et al., 2017). Smoking increases risk for CVD in both men and women. The global prevalence of smoking is lower in women than in men (World Health Organization, 2016a,b); however women who smoke may have a higher relative risk of myocardial infarction (MI) compared to men (Huxley and Woodward, 2011). This greater risk may be more prominent in heavy smokers as shown in an Asian Pacific cohort where hazard ratios for CVD and stroke were significantly higher for women compared to men who smoked more than 20 cigarettes per day (Woodward et al., 2005). High blood pressure is responsible for a large proportion of CVD and develops at younger ages in men than in women. However, on a population level, there is no difference in the risk for CVD between men and women per unit increase in blood pressure (Peters et al., 2013). Cardiovascular risk per equivalent increase in total cholesterol is similar for men and women. Lipid changes occur primarily during the later phases of menopause, with menopause-related changes being similar in magnitude to the impact attributable to aging (Derby et al., 2009). Statin therapy is effective in modulating dyslipidemia in both men and women, but the risk and side effects of these medications may vary by sex (Mosca, 2015). The increased risk of cardiac mortality from excess weight is similar for men and women despite differences in the distribution of body fat around the waist or excess weight on the hips and thighs (Emerging Risk Factors et al., 2011). Increases in weight are associated with type II diabetes mellitus, high blood pressure, and an increase in inflammation, oxidative stress, and impaired endothelial function (King and Grant, 2016). However, type II

Table 1 Sex and gender differences in the development and susceptibility to risk factors for cardiovascular disease (Makkar et al., 1993)

Conventional risk factors	*Sex differences in the relative association of conventional cardiovascular risk factors*
Age	Men develop atherosclerotic disease at earlier ages than women however in both sexes there is a constant linear association of cardiovascular risk with age (Tunstall-Pedoe, 1998; Kannel et al., 1961)
Overweight and obesity	The relative risk of future cardiovascular disease among overweight and obese individuals is similar for both sexes. Menopause is associated with changing body composition with increased visceral adipose tissue (Benjamin et al., 2017; Singh et al., 2013; Lovejoy et al., 2008)
Race and ethnicity	Black men and women have twofold higher rates of fatal coronary heart disease events compared to white men and women. Black men have lower rates of incident nonfatal coronary heart disease events compared to white men, however black women have higher rates of nonfatal coronary heart disease compared to white women (Safford et al., 2012)
Smoking	There is a higher prevalence of smoking in men compared to women. However women smokers have a 25% greater risk of coronary heart disease compared to male smokers (Huxley and Woodward, 2011; World Health Organization, 2016a,b)
Hypertension	The prevalence of hypertension is similar between men and women, and the association with cardiovascular disease does not significantly differ by sex (Benjamin et al., 2017; Peters et al., 2015)
Dyslipidemia	Premenopausal women have higher HDL-cholesterol, and lower LDL-cholesterol and triglycerides compared to men. However, after menopause, the lipid profile changes in women such that LDL-cholesterol and triglycerides increase and HDL-cholesterol decreases (Wang et al., 2011; Derby et al., 2009)
Diabetes mellitus	Prevalence of type II diabetes is higher in men than women. However, diabetes confers a greater risk for stroke, coronary artery disease and heart failure in women compared to men (Peters et al., 2015)
Risk factors that are more predominant in women	*Sex differences in nonconventional cardiovascular risk factors*
Autoimmune disease	Autoimmune and inflammatory disease is strongly associated with cardiovascular disease. There is a strong predominance of autoimmune and inflammatory disease in women compared to men including rheumatoid arthritis, systemic lupus erythematosus and multiple sclerosis (Ngo et al., 2014)
Psychosocial factors (stress and depression)	Women have higher prevalence of psychosocial stressors such as depression and stress compared to men. Women are disproportionately susceptible to the effects of psychosocial stressors on cardiovascular risk (Xu et al., 2015; Vaccarino and Bremner, 2016)
Pregnancy related risk factors	*Evidence for an independent association and existing knowledge gaps*
Hypertensive disorders of pregnancy (preeclampsia [PE] and gestational hypertension [GH])	Hypertensive disorders of pregnancy, particularly PE doubles the risk of future coronary artery disease, stroke, and death, and results in a 4-fold risk of future heart failure (Wu et al., 2017) Controversy remains as to whether PE is an independent risk factor or acts through the increased risk of developing traditional risk factors such as hypertension (Heida et al., 2016)
Spontaneous preterm delivery	Spontaneous preterm delivery is associated with a two-fold increase in future cardiovascular disease. Evidence is limited on whether it is an independent and modifiable risk factor (Heida et al., 2016)
Gestation diabetes (GDM)	Gestational diabetes is associated with the future development of diabetes and metabolic syndrome. There is also an association between GDM and future cardiovascular risk independent of diabetes and metabolic syndrome
Small for gestational age (SGA) infant	There is a positive association between SGA infant and maternal cardiovascular disease, however, evidence is limited and there are no current specific recommendations for management (Heida et al., 2016)
Reproductive health related risk factors	*Evidence for an independent association and existing knowledge gaps*
Early Menarche	Menarche occurring $<$11 years (early) or $>$17 years (late) is associated with a modest increase in future cardiovascular disease risk (Canoy et al., 2015). Early menarche is associated with metabolic syndrome, thus, whether early menarche is independent of metabolic risk factor remains unclear
Natural Menopause	Natural menopause is associated with adverse lipid profile including increased LDL and lower HDL, and changes in body fat composition. There is no evidence of an independent association with future cardiovascular disease Although menopausal hormone therapy is not recommended solely for the primary prevention of cardiovascular disease, such treatments are effective in reducing vasomotor symptoms of menopause and if started soon after menopause in women with low metabolic risk profile may reduce risk; transdermal products carry less risk of venous thromboembolism than oral products (Baber et al., 2016; Canonico et al., 2007; Wild et al., 2013; Miller and Manson, 2013)
Oophorectomy	Bilateral and unilateral oophorectomy before the age of natural menopause carries and increased risk of cardiovascular mortality with is reduced with hormone replacement therapies (Shuster et al., 2010; Rivera et al., 2009)
Premature ovarian insufficiency (POI)	POI is associated with a 1.61 RR of developing or dying from cardiovascular disease. Studies show it is an independent risk factor after adjusting for conventional risk factors. Women with POI may benefit from hormone replacement therapy for symptom management and prevention of adverse cardiovascular effects until they reach the natural age of menopause (Faubion et al., 2015)
Polycystic ovarian syndrome (PCOS)	PCOS is associated with higher risk of developing diabetes, hypertension, dyslipidemia, and obesity. However after adjustment for traditional risk factors, there is no evidence that it is an independent risk factor for developing CVD (Heida et al., 2016)

diabetes confers a greater risk for CVD and stroke in affected women compared to men (Huxley et al., 2006; Peters et al., 2014). The reason for this sex difference in CVD risk with type II diabetes is not known but may reflect discrepancies in the management and treatment of the diabetes (Kramer et al., 2012).

Although these established risk factors have been integrated into various CVD risk calculators used to guide prevention and treatment of CVD, they typically underestimate risk for women, thus there is a need for development of other methods and models to account for conditions specific to women (Mosca et al., 2011; Cook and Ridker, 2014; Goff et al., 2014; Bushnell et al., 2014).

Nonconventional Risk Factors

Autoimmune diseases such as rheumatoid arthritis and systemic lupus erythematous show a female predominance and can lead to accelerated atherosclerosis and premature coronary disease, particularly in younger women (Fairweather et al., 2008). Psychological stress significantly affects the risk of CVD in men and women (Dimsdale, 2008). However, acute stress leading to stress cardiomyopathy, or Takotsubo cardiomyopathy shows a clear predilection in women (Steptoe and Kivimaki, 2012).

Impact of Reproductive Factors on CVD Risk in Women

Ovarian function and estrogen production influence a woman's CV health throughout her life. The risk of CVD is higher in women who reach menopause at an early age such as in those with primary ovarian insufficiency or loss of menstrual periods due to excessive exercise or stress (Muka et al., 2016a). Although polycystic ovarian syndrome is associated with insulin resistance and dyslipidemia, there is ongoing debate as to whether these women have an increased risk of CVD (Shaw et al., 2008; Zhao et al., 2016). Oophorectomy before the natural age of menopause and early natural menopause (<46 years of age) is associated with increased risk of CVD (Rocca et al., 2016; Rivera et al., 2009; Wellons et al., 2012). However, some studies suggest that if estrogen therapy is initiated soon after oophorectomy in women <45 years of age or within 5 years of natural menopause, risk of CVD may be reduced (Rocca et al., 2016; Hodis et al., 2016; Hsia et al., 2006). Women who experience vasomotor symptoms during menopause may also have an increased risk of CVD (Thurston et al., 2017). Estrogen therapies are recommended for treatment of menopausal symptoms, but although such treatments might have associated effects on CVD risk reduction, they are not recommended for primary prevention of CVD (Baber et al., 2016; Salpeter et al., 2006; Mikkola et al., 2015; Boardman et al., 2015; Salpeter et al., 2009). There is a risk of venous thromboembolism with use of exogenous estrogen products; however, this risk is reduced with the use of transdermal compared to oral estrogen compounds (Canonico et al., 2007) (**Fig. 2**).

Regarding parity, there is a trend toward increased risk of CVD in nulliparous women (Simons et al., 2012). However, pregnancy-related complications such as gestational diabetes mellitus predispose women to development of type 2 diabetes later

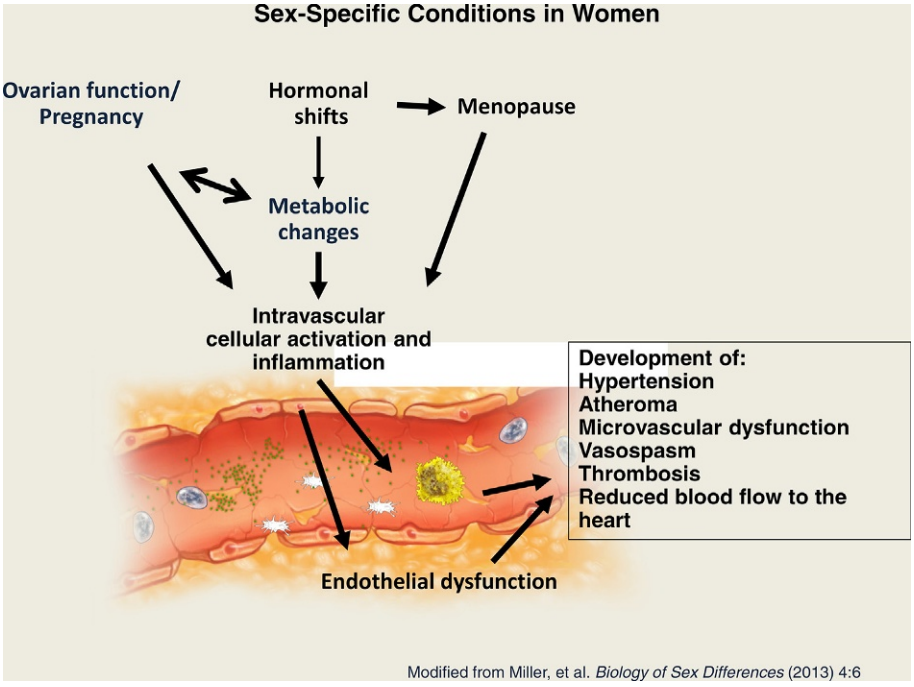

Fig. 2 Ovarian function specifically sex hormone changes at pregnancy, menopause and other states of hormone flux influence a woman's CV health throughout her life. Sex hormones initiate changes in cellular function through activation of steroid receptors on the cell surface, cytoplasm and nucleus. Tissue-specific responses to sex steroids reflect differences in binding of the hormone-receptor complex to response elements on various genes. Ultimately sex hormones modulate tissue responses to various traditional and sex specific risk factors.

in life. Hypertensive disorders of pregnancy (i.e., gestational hypertension, preeclampsia, eclampsia, and HELP syndrome) increase the risk for future CVD as well (Bellamy et al., 2007; Garovic and August, 2013).

Sex and Gender Differences in Ischemic Heart Disease

Definition

Ischemic heart disease (IHD) is a heterogeneous syndrome with many etiologies. It is characterized by myocardial ischemia from decreased oxygen supply to the heart usually as a result of conditions that cause decreased blood flow and/or increased oxygen demand to the myocardium. IHD is also referred to as coronary heart disease and coronary artery disease (CAD). Myocardial ischemia can occur in the absence of atherosclerotic occlusive CAD. Conditions that lead to prolonged ischemia result in myocyte cell death termed MI and the appearance of cardiac-specific proteins, of which troponin is the marker of choice (Thygesen et al., 2007). High sensitivity troponin, a new and more sensitive assay that can detect subclinical myocardial damage, is associated with long-term mortality, but measurement thresholds and prognostic values differ by sex (Everett et al., 2016).

Clinical Presentation

The clinical presentation of IHD varies depending on the chronicity of the underlying disease. One presenting symptom of IHD is substernal chest pain also called *angina pectoris*. However the spectrum can vary from no symptoms (silent MI) to more severe presentations with heart failure, arrhythmias, and sudden death. The vast majority of both men and women presenting with suspected IHD have angina pectoris (Vaccarino et al., 2013). However, there is a higher incidence of women presenting with atypical symptoms such as fatigue, sweating, dizziness, difficulty sleeping, anxiety, palpitations, indigestion, and arm discomfort (Canto et al., 2012; Khan et al., 2016). More men than women present with sudden cardiac death (SCD) from all causes; however, younger women with IHD have a higher incidence of SCD than men (Lewis et al., 2016). Sex and gender differences in the presentation of IHD could reflect differences in the underlying biology of IHD, modulation of the perception of pain by sex hormones, and sociocultural norms resulting in misattribution of symptoms by women (Bairey Merz et al., 2006; Craft, 2007; Lichtman et al., 2015).

Epidemiology

IHD is one of the leading causes of morbidity and mortality in the United States in both men and women (Benjamin et al., 2017). It is estimated that 16.5 million Americans over the age of 20 have IHD. In 2017 it is estimated that about 695,000 Americans will have a new MI or die due to IHD and 325,000 will have a recurrent MI (Benjamin et al., 2017). And while the overall mortality rates from IHD have declined in certain populations in the United States over the last 2 decades, individuals younger than 55 years of age, and young women in particular, have not had similar reduction in mortality rates (Wilmot et al., 2015; Benjamin et al., 2017).

Short- and long-term mortality rates after MI are worse in women, particularly in younger women, than in men (Jneid et al., 2008; Canto et al., 2012; Wilmot et al., 2015; Vaccarino et al., 1999). Sex and gender disparities in mortality rates from MI are multifactorial and include delays in recognition of symptoms and sex differences in the diagnosis, institution of therapy, comorbidities, as well as underlying differences in vascular biology including smaller arteries, diffuse atherosclerosis, and greater coronary microvascular dysfunction in women (Bairey Merz et al., 2006; Khan et al., 2016; Jneid et al., 2008).

Causes of Ischemic Heart Disease

Atherosclerosis and Ischemic Heart Disease

Atherosclerosis is a progressive disease marked by an accumulation of lipids and other fibrous material in the coronary arteries known as atheroma (or plaque) (Libby, 2002). Atherosclerosis is the central mechanism of the majority of IHD presentations. The innermost single layer of cells that line vessels, the vascular endothelium, plays a key role in maintaining homeostasis between vasomotor tone, hemostasis, inflammation, and oxidative stress (Iantorno and Weiss, 2014). Impaired endothelial function due to damage by various risk factors leads to atherosclerosis, with inflammation characterized by activated leukocytes adhering and penetrating into the endothelium causing progression of atherosclerosis (Libby, 2002).

Traditional risk factors as well as risk factors unique to women have different effects on the vascular endothelium and the progression of atherosclerosis (cross reference risk factor section and **Table 1**).

Acute presentations of IHD result from disruption of the cellular layer covering atheroma and exposure of lipid-rich core to intraluminal blood leading to thrombosis resulting in partial or complete occlusion of the coronary arteries, and cardiomyocyte death (Libby, 2008; Ross, 1993). Plaque rupture leading to coronary thrombosis is more common in men than in women, whereas plaque erosion seems to be the major contributor of acute presentations of IHD in women (Virmani et al., 2000; Yahagi et al., 2015). On presentation men have higher burden of plaque, more eccentric atheroma with more obstructive coronary arteries compared to women, who have a greater prevalence of nonobstructive CAD and/or normal coronaries on presentation (Han et al., 2008; Schulman-Marcus et al., 2016; Shaw et al., 2006; Shaw et al., 2009).

Coronary Microvascular Dysfunction

The vascular endothelium through expression of adhesion molecules and release of anticoagulant substances maintains vascular homeostasis (Iantorno and Weiss, 2014). Nitric oxide (NO) is a critical molecule produced by the endothelium that inhibits adhesion of cells to the endothelial surface and causes the underlying smooth muscle of the blood vessel to dilate. Loss of production of NO is sometimes referred to as "endothelial dysfunction." Endothelial function is an early marker of atherosclerosis (Ross, 1993). Coronary microvascular dysfunction (CMD) is defined as having microvascular endothelial and/or nonendothelial dysfunction that results in reduced perfusion leading to myocardial ischemia (Bairey Merz et al., 2017; Bairey Merz et al., 2006). Even with no obstructive epicardial CAD, CMD is associated with ischemic symptoms and is a potent predictor of future cardiovascular events above what might be predicted based on traditional risk factors (Reriani et al., 2016; von Mering et al., 2004; Pepine et al., 2010). CMD, previously thought to be more predominant in women, is present in both men and women and is associated with adverse outcomes in both sexes (Murthy et al., 2014; Reriani et al., 2016).

MI With Nonobstructive Coronary Arteries

MI with Nonobstructive Coronary Arteries (MINOCA) (Beltrame, 2013) is defined as MI without obstructive epicardial stenosis (no epicardial vessel with $\geq$50% stenosis) and is now recognized as a common cause of IHD in individuals, and particularly in women, presenting with IHD symptoms (Bairey Merz et al., 2017; Pasupathy et al., 2015; Planer et al., 2014; Beltrame, 2013). In the Women's Ischemia Syndrome Evaluation (WISE) study, about two-thirds of women who presented with IHD symptoms had nonobstructive CAD (Bairey Merz et al., 2006, 2017), now called Ischemia and No Obstructive Coronary Artery Disease (INOCA). Despite having mild coronary atherosclerosis, adverse CVD event rates and morbidity rates were significantly higher at 10 years in these women compared to asymptomatic women (Sharaf et al., 2013; Shaw et al., 2006; Jespersen et al., 2012; Gulati et al., 2009).

There are several potential etiologies for MINOCA including epicardial coronary artery and microvascular vasospasm, coronary microvascular dysfunction, plaque rupture and/or erosion with spontaneous fibrinolysis, coronary emboli, myocarditis, and spontaneous coronary artery dissection acting alone or in combination (Lanza et al., 2007; Reynolds et al., 2011; Camici and Crea, 2007; Galiuto et al., 2010; Mauricio et al., 2016; Bairey Merz et al., 2017). Both the vascular effects of sex hormones and risk factors unique to women may contribute to the higher predominance of MINOCA in women (Ng, 2007; Muka et al., 2016b). Identifying subtle vascular wall abnormalities in patients with possible MINOCA can be difficult with conventional invasive coronary angiography but can be better elucidated with Intravascular Ultrasound (IVUS) or Optical Coherence Tomography (OCT) (Takahashi et al., 2016).

There are no randomized clinical trials comparing secondary prevention treatment strategies for INOCA and MINOCA. Current treatment strategies are extrapolated from evidence-based treatment of obstructive CAD. However observational and small pilot studies suggest benefit from antiplatelet therapy, angiotensin receptor blockers, beta-blockers, aldosterone antagonists, and statins for both men and women (Camici and Crea, 2007; Lindahl et al., 2017; Bairey Merz et al., 2017).

Nonatherosclerotic Causes of IHD

Nonatherosclerotic causes of IHD are rare in the general population, but they are an important cause in younger people and women in particular (Waller, 1989; Saw et al., 2014). Appropriate diagnosis of these syndromes has critical implications on therapy and prognosis.

Spontaneous Coronary Artery Dissection

Spontaneous coronary artery dissection (SCAD) is a rare cause of MI but has a relatively high incidence in younger women suffering from MI, often related to pregnancy (Saw et al., 2016). Incidence rates are reported to be 22%–43% based on case series of women under age 50 presenting with MI but are likely higher when considering that these numbers miss cases that present with SCD, or younger women who are less likely referred for coronary angiography (Saw et al., 2014; Nakashima et al., 2016; Alfonso et al., 2016). Two proposed mechanisms for SCAD are tears in the intimal layer of the coronary arteries resulting in the accumulation of blood within the tear, and spontaneous rupture of the vasa vasorum leading to hemorrhage into the vessel wall (Saw et al., 2016; Angelini, 2007). Both mechanisms lead to accumulation of intramural hematoma and luminal obstruction leading to myocardial ischemia. There are several conditions that may predispose to SCAD by being associated with abnormal vessel wall integrity including connective tissue disorders, vasculopathies (such as fibromuscular dysplasia (FMD)), and sex hormones (Henkin et al., 2016).

FMD is a rare disorder of the medium-sized arteries that predominantly affects women. A diagnosis of FMD is present in about 72%–86% of women presenting with SCAD (Saw et al., 2016). Approximately 5% of women with SCAD present with acute MI during pregnancy (Saw et al., 2016). A combination of progesterone-related changes in the elastic fibers of the arterial wall weakening the media, estrogen-related prothrombotic effects, and hemodynamic changes associated with pregnancy may also contribute to SCAD (Saw et al., 2016). SCAD is also associated with other states of sex hormone flux including use of oral contraceptive and hormone replacement therapy (Saw et al., 2016). In clinically stable individuals, SCAD is managed conservatively as percutaneous coronary intervention (PCI) risks propagation of the arterial dissection flap, while more severe or unstable cases can

be treated with PCI or coronary artery bypass grafting (CABG) (Tweet et al., 2014). A diagnosis of SCAD is critical to guide acute management, to prognosticate on future events as well as guide further evaluation of extra coronary manifestations such as FMD, cerebral aneurysms, and increased risk in relatives (Saw et al., 2013, 2016).

Stress Cardiomyopathy

Stress cardiomyopathy, also known as Takotsubo cardiomyopathy, is a syndrome of transient reduction in left ventricular cardiac contractility, typically in the left ventricular apex, associated with a drop in ejection fraction, hypotension, electrocardiographic changes, and elevated cardiac enzymes consistent with MI but usually in the absence of angiographic evidence of stenosis (De Caterina et al., 2011). It is often described as being precipitated by sudden and intense emotional or physical stress (Wittstein et al., 2005). It most often (over 80% of cohorts) affects postmenopausal women; however in men it is more frequently related to physical triggers such as extreme exercise and trauma (Templin et al., 2015). The exact pathophysiology is not fully elucidated. One mechanism proposed is that a sudden catecholamine surge leads to myocyte toxicity and apoptosis from excessive stimulation of the β-adrenoreceptors (El-Battrawy et al., 2016; Lyon et al., 2008). Other mechanisms proposed to play a role in stress cardiomyopathy include diffuse epicardial vasospasm, coronary thrombi that spontaneously lyse, and diffuse microvascular dysfunction (Crea et al., 2015). Sex differences in the release of catecholamines by the adrenal medulla to stress, variations in the metabolism of catecholamines, and the loss of vascular protective effects of estrogenic modulation of the microvascular endothelium occurring at menopause may explain the higher incidence in older postmenopausal women (Lyon et al., 2008). Despite only having transient and reversible myocardial dysfunction, stress cardiomyopathy is still an important cause of morbidity and mortality. Thirty-day mortality rates are estimated to be similar to that of acute MI (Kurowski et al., 2007; Templin et al., 2015). In addition, other associated conditions including chronic heart failure, arrhythmias, and thromboembolic events account for significant morbidity from this condition (El-Battrawy et al., 2016; Templin et al., 2015). Acute therapy in stress cardiomyopathy is focused on hemodynamic support, optimization of heart failure therapy, and anticoagulation to prevent thromboembolism, while chronic management can include ACE inhibitors and beta-blockers.

Diagnostic Modalities Ideal for Assessing Nontraditional Causes of Ischemia

The differential diagnosis for ischemic chest pain in women is broad and encompasses atherosclerotic and nonatherosclerotic mechanisms. Recognition of the causes of ischemic chest pain is vital in instituting the appropriate therapy promptly and future secondary prevention strategies. The differential diagnosis and likelihood of the various possible diagnoses vary across women's lifespan (Fig. 3).

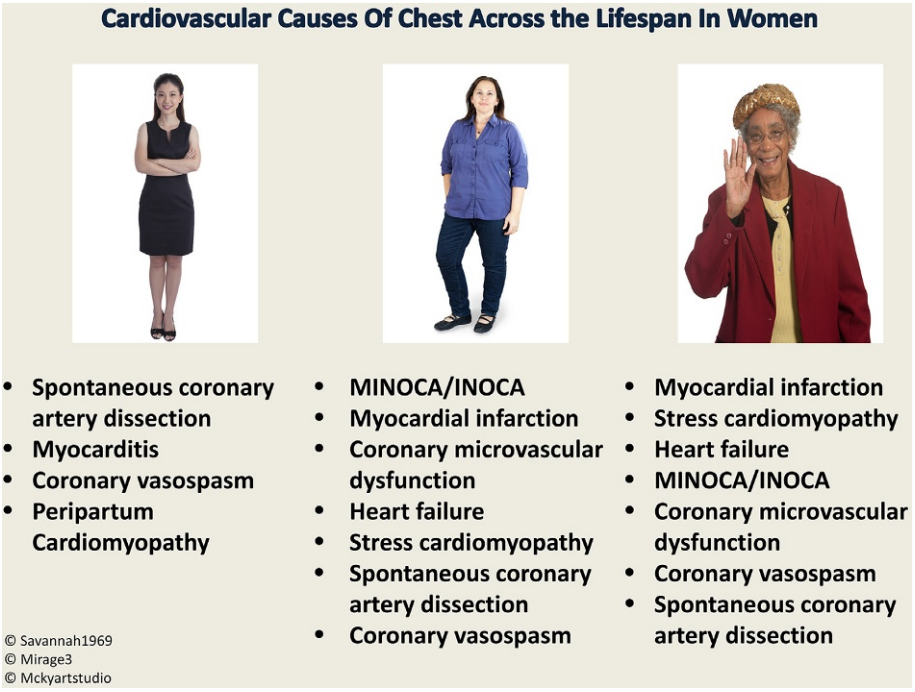

Fig. 3 Differential diagnosis of the cardiovascular causes of chest pain by age group and in order of prevalence. Noninvasive testing is the cornerstone of diagnosis of obstructive CAD and differences in body habitus, breast attenuation, smaller vessels, and predominance of coronary microvascular disease can lead to differences in diagnostic capabilities in women. Invasive coronary angiography, while allowing diagnosis of epicardial coronary stenosis, may be inadequate for diagnosis of MINOCA, INOCA, and CMD. Evolving technology such as optical coherence tomography OCT, coronary computed tomography (CCT), positron emission tomography (PET), and magnetic resonance imaging (MRI) to measure myocardial blood flow may enhance diagnostic capabilities in women who present with IHD (Takahashi et al., 2016; Schindler et al., 2010; Hays et al., 2012).

Prevention and Treatment Strategies

Etiologies of IHD are varied in pathophysiology (atherosclerotic and nonatherosclerotic) and anatomy (obstructive, nonobstructive, and coronary microvascular dysfunction). While landmark clinical trials have guided development of many therapies for obstructive CAD with improvements in mortality, women and especially minority women have been underrepresented in major cardiovascular trials (Ouyang et al., 2016). There is limited knowledge on the optimal management for etiologies of IHD including MINOCA, INOCA, and CMD (Bairey Merz et al., 2017). Current therapeutic strategies are extrapolated from knowledge from primary and secondary prevention clinical trials including antiplatelet therapies, statins, angiotensin receptor blockers, ACE inhibitors, as well as therapies targeted at specific conditions such as coronary vasospasm including nitrates and calcium channel blockers in CMD (Bairey Merz et al., 2017). Further research into roles that sex hormones and sex-specific risk factors contribute to the pathogenesis of IHD in women can potentially lead to successful therapeutic choices.

Heart Failure

Definition

Heart failure (HF) is a clinical syndrome defined by symptoms of fatigue, dyspnea, and fluid retention (Yancy et al., 2013). The causes of HF are diverse, but all lead to structural and/or functional impairment of ventricular filling or ejection of blood (Yancy et al., 2013). The syndrome of HF can result from diseases of the myocardium, pericardium, endocardium, or heart valves, but the majority of people with HF have a disorder of the left ventricular (LV) myocardium (Yancy et al., 2013). Historically HF was characterized by disorders in LV systolic function (currently termed heart failure with reduced ejection fraction, or HFrEF). However, it is recognized that heart failure despite preserved ejection fraction (HFpEF) accounts for nearly half of all HF hospital admissions, with morbidity and mortality rates comparable to HFrEF (Sharma and Kass, 2014).

Epidemiology

The annual incidence of HFrEF has stabilized over the past decade; however the incidence of HFpEF and hospitalizations for HFpEF have continued to rise (Owan et al., 2006; Bhatia et al., 2006). HFpEF has been reported to be more common in women than in men; women with HFpEF present at a later age and with more comorbidities than their male counterparts (Owan et al., 2006; Bhatia et al., 2006; Sharma et al., 2015; Steinberg et al., 2012).

Risk Factors

Sex and gender differences exist in the pathophysiology, presentation, and response to therapy for various etiologies of HF. Some risk factors for HF confer differential risk by sex and gender. Hypertension results in a threefold increased risk of HF in women compared to men, potentially due to differential adaptive mechanisms (Levy et al., 1996). HF risk is fivefold higher in women with diabetes versus twofold higher in men with diabetes (Kannel and McGee, 1979), potentially due to differential LV remodeling in setting of hyperglycemia (Galderisi et al., 1991). Obesity likewise confers a higher risk of HF in women compared to men (Kenchaiah et al., 2002). Other risk factors such as tobacco use, alcohol, and decreased physical activity have not shown significant interaction between sex and HF risk (Kenchaiah and Vasan, 2015).

Heart Failure With Reduced Ejection Fraction

HFrEF is defined as the clinical syndrome of HF and LV ejection fraction $\leq$40% (Yancy et al., 2013). Important risk factors for HFrEF range from traditional cardiovascular risk factors such as hypertension, obesity, IHD, valvular disease, to genetics, infections, infiltrative diseases, and toxins (Yancy et al., 2013). Men have a higher risk of HFrEF compared to women (Ho et al., 2013). However there are two important HF etiologies that are unique in women, peripartum cardiomyopathy, or show a marked preponderance in women, stress cardiomyopathy. Stress cardiomyopathy is described under nonatherosclerotic causes of IHD.

Peripartum Cardiomyopathy (PPCM)

Peripartum cardiomyopathy (PPCM) is defined as heart failure with reduced ejection fraction (≤45%) that presents within the last month of pregnancy or within five months after delivery; lack of an identifiable etiology of HF; and the absence of preexisting structural heart disease (Hibbard et al., 1999; Demakis and Rahimtoola, 1971; Sliwa et al., 2010b; Sharma, 2015). The incidence in the United States is 1/1000 live births; however there are substantial geographic and ethnic variations with reports of 1/300 in Haiti and 1/100 in parts of Nigeria suggesting a genetic and/or environmental component (Arany and Elkayam, 2016; Sliwa et al., 2010b; Sharma, 2015). Risk factors for PPCM include older age, black race, preeclampsia, and multiple gestations (Sliwa et al., 2010b; Arany and Elkayam, 2016). Proposed mechanisms leading to PPCM include viral myocarditis, malnutrition, and microchimerism (persistence of fetal cells in the maternal circulation) (Bultmann et al., 2005; Arany and Elkayam, 2016).

PPCM may also result from a loss of function of signal transducer and activator of transcription 3 (STAT 3), a transcription factor that upregulates antioxidant enzymes and modulates the activity of prolactin, a protein secreted in late pregnancy that is associated with oxidative stress and myocyte cell death (Halkein et al., 2013; Hilfiker-Kleiner et al., 2007). The dopamine 2-receptor agonist bromocriptine inhibits the release of prolactin, and in small-randomized controlled trials has shown benefit in the recovery of LV function, NYHA functional class, and reduction in mortality (Sliwa et al., 2010a; Haghikia et al., 2013). However, side effects, which include cessation of lactation, and concerns for teratogenicity, limit its use (Arany and Elkayam, 2016). Therapeutic targets based on novel cellular pathways described earlier remain to be explored (Arany and Elkayam, 2016; Arany et al., 2008).

Therapeutic Interventions for Heart Failure With Reduced Ejection Fraction

There are no clear sex differences in response to therapy in HFrEF. However, women are underrepresented in clinical trials of HF therapies, so sex differences may be missed (Westerman and Wenger, 2016). In addition women are significantly underrepresented in referrals for guideline-directed, device-based therapies including implantable cardioverter-defibrillators (ICD) (Hernandez et al., 2007) and cardiac resynchronization therapy (CRT-D) (Alaeddini et al., 2008; Hernandez et al., 2007). Probing the underlying reasons for less than optimal referrals for CRT-D and ICD may guide interventions to improve the numbers of these life-saving therapies offered to women.

Heart Failure With Preserved Ejection Fraction

Heart failure with preserved ejection fraction (HFpEF) is a syndrome that includes signs and symptoms of HF, an LV ejection fraction ≥50%, and the absence of valvular heart disease (Yancy et al., 2013). The hallmark of HFpEF is both abnormal relaxation and increased stiffness of the myocardium, typically called diastolic dysfunction (Redfield, 2016). Despite normal LV ejection fraction at rest, individuals with HFpEF are unable to augment LV systolic function appropriately to stress (Redfield, 2016).

Impaired myocardial relaxation has been associated with oxidative stress, depressed β-adrenergic signaling, intracellular calcium handling, and microvascular endothelial dysfunction (Sag et al., 2013; Norman et al., 2011; Sharma and Kass, 2014; Kranias and Bers, 2007). In addition, myocardial stiffness and fibrosis may result from inflammation, neurohormonal activation, and altered cell signaling (Sharma and Kass, 2014; Westermann et al., 2011; Glezeva and Baugh, 2014; van Heerebeek et al., 2008; Redfield, 2016). Animal models show estrogen protects against abnormal LV remodeling through activation of a cellular pathway involving cyclic guanosine monophosphate, protein kinase G, and nitric oxide (cGMP/PKG/NO pathway) (Sasaki et al., 2014). Others have shown that patients with HFpEF have lower myocardial PKG activity and lower cGMP associated with higher myocardial oxidative stress (van Heerebeek et al., 2012; Sharma and Kass, 2014). Better understanding of sex differences in humans is important as this pathway may be a potential therapeutic target of phosphodiesterase (PDE) inhibitors, which have shown therapeutic potential in animal models and in human tissue samples from HFpEF patients (Matyas et al., 2017; van Heerebeek et al., 2012; Takimoto et al., 2005).

Therapeutic Interventions in Heart Failure With Preserved Ejection Fraction

Traditional HF therapies including ACE inhibitors, angiotensin receptor blockers, aldosterone antagonists, and β-adrenergic receptor-blockers have not reduced mortality in HFpEF. Research into novel therapies is underway. These therapies include PDE inhibitors, neprilysin (a neutral endopeptidase) inhibitors, and inorganic nitrates (Bonderman et al., 2014; Boon et al., 2013; Tanaka et al., 2016; Westermann et al., 2011; Chiao et al., 2012; Sabbah et al., 2016; Zamani et al., 2015; Redfield et al., 2015; Borlaug et al., 2015; Borlaug et al., 2016).

In summary, much remains to be learned about the pathophysiology of HFpEF and the associated sex differences. Interventions aimed at HFpEF are further challenged by the clinical and mechanistic heterogeneity of the syndrome. Efforts are underway to further classify patients by symptoms, clinical presentation, and underlying mechanism of disease in order to target therapies based on identified clinical and molecular phenotypes (Shah et al., 2015).

Arrhythmias

Sudden Cardiac Death

Sex differences exist with regard to the frequency and characteristics of SCD. In general, women are more likely to present with SCD at home, have a lower frequency of an initial shockable rhythm, and are less likely to have a witnessed SCD (Bougouin et al., 2015). However, in the young (<40 years of age), two-thirds of SCD occur in men with the remaining one-third in women (Winkel et al., 2017). Further, sports-related SCD is significantly more common in males. Myocarditis and dilated cardiomyopathy appear to contribute to SCD equally between men and women, whereas atherosclerotic CAD, Brugada syndrome, and hypertrophic cardiomyopathy are more common in men and spontaneous coronary dissection (SCAD) and mitral valve prolapse are more common causes in young women (Basso et al., 2015). In middle-aged adults, men are still predominant with higher rates of obesity, sleep apnea, and seizure disorders contributing to the etiology of their SCD than women (Noheria et al., 2013). With regard to prognosis, women are more likely to survive to hospital discharge than men (Bougouin et al., 2015). Women with Brugada syndrome have a more favorable prognosis than men, with a less severe clinical presentation and less spontaneous type 1 Brugada syndrome (Sieira et al., 2016). Further, in arrythmogenic right ventricular dysplasia, men have a higher risk of ventricular fibrillation than women, while women have a higher risk of heart failure or cardiac transplantation (Kimura et al., 2016). With regard to therapy, women have a lower proportion of implantable cardiac defibrillators (ICDs) but once implanted have a similar mortality and less appropriate ICD shocks compared to men (Santangeli et al., 2010).

Endogenous and Exogenous Hormones and the QT Interval

A prolonged QT interval, the measure of the time between the start of the Q wave and the end of the T wave in the cardiac cycle, is a marker for an increased risk of ventricular tachyarrhythmias and SCD (Algra et al., 1991). Sex differences exist in the QT interval between men and women and during puberty; the QT interval in males shortens by 20 ms, whereas the QT of females remains unchanged (Rautaharju et al., 1992). These sex differences in the QT interval are due to sex hormone effects on the expression of ion channels, and direct effects on the activity of ion channels (Kurokawa et al., 2016). In particular, estrogen decreases potassium channel current and may lengthen the QT interval through this mechanism; whereas, progesterone decreases calcium channel current and increases potassium channel current and therefore shortens the QT interval. Both endogenous and exogenous sex hormones affect the QT interval (Zhang et al., 2011). Endogenous testosterone and progesterone shorten the action potential (Rodriguez et al., 2001) while estrogen lengthens the QT interval (Nakagawa et al., 2006). This results in a 6% shorter QT interval in men compared to women. Regarding menopause hormone therapy (MHT) there appears to be a differential effect of estrogen-alone therapy (ET) compared to estrogen plus progesterone therapy (EPT) on the QT interval. Women on ET have longer QT intervals compared with women who were never treated with MHT (Kadish et al., 2004). In contrast, women on EPT show no significant changes in the QT interval (Carnethon et al., 2003). Few studies have investigated effects of oral contraception on QT interval, particularly as QT changes may depend upon formulation. For example, oral contraceptives with antiandrogenic progestins may increase the QT interval (Sedlak et al., 2013). Females have a higher rate of developing drug-related long QT and related arrhythmias (Makkar et al., 1993). Women have a higher rate of developing drug-related long QT and related arrhythmias including life-threatening dysrhythmias such as drug-induced torsades de pointes (Makkar et al., 1993; Trinkley et al., 2013).

Atrial Fibrillation

The prevalence of atrial fibrillation is lower in women compared to men in all age categories; however the risk of subsequent morbidity including stroke and heart failure is higher in women (Rane and Patton, 2015). Further, the risk of thromboembolism is greater in women not treated with oral anticoagulation (Fang et al., 2005). Women are prescribed oral anticoagulants less often than men and when they are treated with anticoagulation, have higher bleeding complications (Rane and Patton, 2015). Women tend to be treated less and treated later and more conservatively than men with less catheter ablation procedures despite equivalent postoperative and long-term outcomes (Forleo et al., 2007).

Conclusion

Sex and gender differences are evident when considering the broad areas of CVD risk factors, myocardial ischemic syndromes, heart failure, and arrhythmias. These differences may be related to sex differences in underlying biological pathways, the impact of genes, epigenetic factors, sex hormones, behavioral and societal factors, or distinct subphenotypes of individuals. This chapter provides a background for students and researchers interested in better understanding these differences. However there are additional areas of importance that we have not addressed, including the impact of gender and transgender on behavioral and societal aspects related to CVD (**Fig. 4**). It is important to consider the multiple levels at which sex and gender affect an individual's susceptibility to disease, its presentation, and how they impact approaches to care. Improving our understanding of these differences has the potential to significantly improve our ability to effectively prevent disease and improve outcome for all patients.

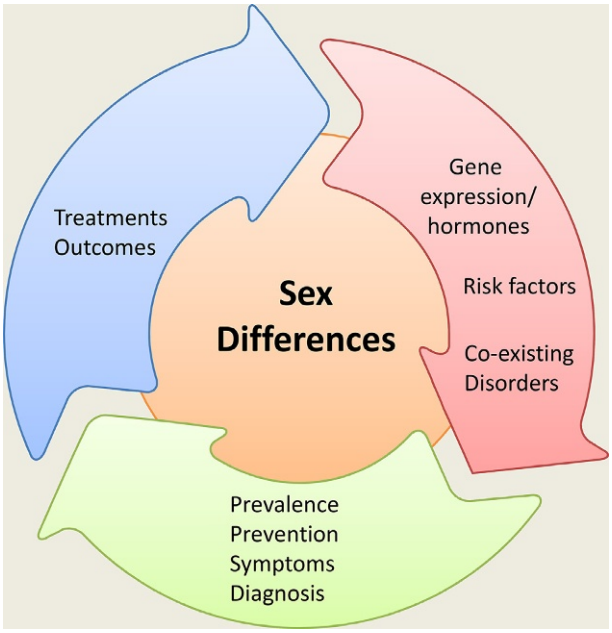

Fig. 4 Sex and gender differences in cardiovascular disease are influenced by genetic, sex hormone, and societal factors. In turn these differences have profound effects on the prevalence of the disease, the symptoms at presentation, the diagnostic capabilities, modalities for primary and secondary prevention and treatment outcomes.

Introduction

The incidence and prevalence of cardiovascular disease (CVD) rise dramatically with age in both sexes. This is perhaps not surprising as there is growing evidence that age itself causes distinct changes in the structure and function of the heart, even in individuals with no obvious signs of CVD. This suggests that age-dependent remodeling may lay the foundation for the development of CVDs later in life. Structural and functional changes associated with cardiac aging have been reported in hearts from humans and animal models of aging although there are characteristic differences between the sexes.

This article reviews the major structural, cellular, and functional changes in the aging heart. Changes at both the macroscopic and microscopic levels are described, and the functional abnormalities that arise from these modifications are discussed. We also highlight key differences in cardiac aging between males and females. Both human and animal studies are considered, as similar changes are seen in both models of cardiac aging. Finally, we discuss how these maladaptive changes affect clinical outcomes and may predispose older men and women to develop characteristic CVDs in old age.

Age-Associated Structural Changes in the Heart

The aging process is characterized by prominent changes in the structure of the heart. Structural changes in the heart involve atrial and ventricular remodeling with variations in wall thickness, dilatation, hypertrophy, fibrosis, and calcification of specific regions, such as the aortic valve, as summarized in **Table 1**. These changes have been identified both in older humans, typically older than 65 years of age, and in various animal models of aging. Most studies of cardiac aging in animals have used approximately 24-month-old mice and rats to model human aging. These rodents have an approximately 50% mortality rate at 24 months of age (Turturro et al., 1999), which is comparable to approximately 85-year-old in humans (Grundy, 2003).

With advancing age there are significant modifications in the gross morphologic structure of the heart. Marked calcification of the aortic valve leaflets with age has been observed in both older humans (New and Aikawa, 2011) and aging rats (Roosens et al., 2012). Whether the prevalence and extent of calcification differs between the sexes is unclear. Roosens et al. (2012) have suggested that mechanical stress and inflammation could be possible mechanisms for aortic valve calcification in rats. Atrial hypertrophy and dilatation also occur commonly in older adults, likely as a consequence of increased diastolic filling pressure (**Table 1**). Boyd et al. (2011) concluded that atrial dilatation becomes significant in older humans after the age of 75 years. Studies in animals have shown similar results, with a marked age-associated increase in left atrial dimensions in older mice and rats (Dai et al., 2009; Lau et al., 2013; Medrano et al., 2015). Whether there are male–female differences in atrial hypertrophy and dilatation has not been clearly investigated in animal models although there is no evidence for such differences in human work (Boyd et al., 2011).

Atrial and ventricular fibrosis also increase with age both in humans (Mirza et al., 2012; Dzeshka et al., 2015; Lam et al., 2012; Ling et al., 2012) and in animals (Lau et al., 2013; Lindsey et al., 2005; Horn et al., 2012). This increase in fibrosis may arise as a consequence of myocyte loss plus changes in loading that promote fibroblast proliferation. Animal studies have not yet addressed whether there is a sex difference in fibrosis with aging although there is no evidence for male–female differences in human work. There is a prominent increase in left ventricular (LV) wall thickness with age, and this increase is much greater in women than in men (Hees et al., 2002; Chen et al., 2016). LV wall thickness also increases with age in mice and rats, but whether this differs between the sexes is not known (Lindsey et al., 2005; Medrano et al., 2015; Fannin et al., 2014). This age-dependent increase in LV wall thickness could be caused by a combination of factors, including myocyte hypertrophy, increased fibrosis, and higher LV afterload due to age-dependent stiffening of the vasculature (Lakatta and Levy, 2003). By contrast, whether LV mass changes with age is controversial although LV mass-to-volume ratio increases with age in both sexes (Chen et al., 2016; Gebhard et al., 2013; Eng et al., 2015; but c.f. Hees et al., 2002). Recently, Chen et al. (2016) reported that women exhibit a greater increase in LV mass than men although this has not been seen in all studies (Hees et al., 2002). LV mass also appears to increase with age in animal models

Table 1 Age-associated structural changes in the heart

Structural change[a]	*Model*	*Aged group*[b]	*Sex difference*	*Possible causes/mechanism*	*References*
Aortic valve calcification	Human	65 years+	No evidence [c]	Calcification due to mechanical stress and/or inflammation	(New and Aikawa, 2011)
	Rats	24–30 months	Not known[c]		(Roosens et al., 2012)
Atrial hypertrophy and dilatation	Human	20–80 year	No evidence	Increased diastolic filling pressure	(Boyd et al., 2011)
	Mouse	15–31 months	Not known		(Dai et al., 2009; Medrano et al., 2015; Lau et al., 2013)
	Rat	15–23 months			
Atrial fibrosis	Human	65 years+	No evidence	Myocyte loss/change in loading promotes fibroblast proliferation and fibrosis	(Mirza et al., 2012; Dzeshka et al., 2015)
	Rats	12–15 months	Not known		(Lau et al., 2013)
Increased LV mass	Human	21–96 years	More prominent in females	Myocyte hypertrophy, increased fibrosis plus vascular changes that increase LV afterload	(Chen et al., 2016; Gebhard et al., 2013; Eng et al., 2015; but *c.f* Hees et al., 2002)
	Mouse	16–29 months	May be more prominent in males		(Dai et al., 2009; Koch et al., 2013; Shinmura et al., 2011)
	Rats	29 months			
Increased LV wall thickness	Human	21–96 years	More prominent in females	Myocyte hypertrophy, increased fibrosis plus vascular changes that increase LV afterload	(Hees et al., 2002; Chen et al., 2016)
	Mouse	15–31 months	Not known		(Lindsey et al., 2005; Medrano et al., 2015; Fannin et al., 2014)
	Rat	26–30 months			
LV fibrosis	Human	75 years+	No evidence	Myocyte loss/change in loading promotes fibroblast proliferation and fibrosis	(Dzeshka et al., 2015; Mirza et al., 2012; Lam et al., 2012; Ling et al., 2012)
	Mouse	15–23 months	Not known		(Lindsey et al., 2005)
	Sheep	>8 years			(Horn et al., 2012)

[a] *LV*, left ventricle.
[b] Compared to young adult humans or animals.
[c] No evidence indicates that studies have included both sexes and found no difference between sexes. Not known indicates that studies have not investigated sex differences.

(Dai et al., 2009; Shinmura et al., 2011). One mouse study showed that LV mass increases with age in male rodents more than females (Koch et al., 2013), whereas the opposite is seen in humans, so more work in this area is required.

These studies demonstrate that age-related changes in the heart occur at the macroscopic level and that there are potentially some differences between the sexes. Still, most studies in animal models have used exclusively male animals, so the question of male–female differences has rarely been addressed. Some of the structural changes described in **Table 1** have cellular correlates, as outlined in the next section.

Age-Associated Cellular Changes in the Heart

It is evident from the preceding discussion that the aging process affects the gross morphological structure of the heart in both humans and animal models. There are also characteristic age-dependent changes in the heart at the microscopic level, as summarized in **Table 2**. The number of pacemaker cells in the sinoatrial node (SAN) of the heart declines markedly with age in humans although it is unclear whether this differs between the sexes (Lakatta, 1993; Mirza et al., 2012). Whether the number of pacemaker cells also declines in aging animals has not yet been investigated. The expression of genes involved in sinoatrial node function does decline with age in rats, but whether these rats were male, female, or both was not specified (Tellez et al., 2011). Studies in humans and nonhuman primates report that the number of ventricular myocytes declines with age, and there is evidence that this cell loss is more prominent in males than in females in both models (Olivetti et al., 1991, 1995; Zhang et al., 2007). The loss of myocytes in aging has been attributed to apoptosis, necrosis, autophagy, and potentially a limited ability of stem cells to regenerate (Sheydina et al., 2011; Dai et al., 2012; Leon and Gustafsson, 2015; Hariharan and Sussman, 2015). Interestingly, apoptosis increases with age in hearts from male but not female monkeys (Zhang et al., 2007). This may help explain the marked ventricular myocyte loss seen in older male hearts although additional experiments in this area would be informative.

The loss of ventricular myocytes with age would be expected to increase the mechanical burden on surviving myocytes and promote their hypertrophy. This has been investigated experimentally in both humans and animal models of aging (**Table 2**). Olivetti and colleagues used morphometric techniques to investigate the impact of age and sex on the human heart (Olivetti et al.,

Table 2 Age-associated cellular changes in the heart

Cellular change[a]	*Model*	*Aged group*[b]	*Sex difference*	*Possible causes/ mechanism*	*References*
Decreased number of SAN (pacemaker) cells	Human	>60 years	Unclear	Unclear	(Mirza et al., 2012; Lakatta, 1993)
Reduced number of ventricular myocytes	Human	16–95 years	More prominent in males	Apoptosis, necrosis, autophagy	(Olivetti et al., 1991, 1995)
	Monkey	17–26 years	More prominent in males		(Zhang et al., 2007)
Ventricular myocyte hypertrophy	Human	16–95 years	More prominent in males	Reactive hypertrophy due to myocyte loss	(Olivetti et al., 1991, 1995)
	Rats	24–31 months	More prominent in males		(Feridooni et al., 2015)
	Mice	24–31 months			
	Guinea pigs	96 months+			
	Rabbits	26 months

1991, 1995). Their studies showed that ventricular myocyte volume increases with age and that this increase is much greater in men than in women (Olivetti et al., 1991, 1995). A number of different laboratories have investigated ventricular myocyte hypertrophy in aging by measuring the length, width, and cross-sectional area of cells isolated from various aging animal models. These studies have shown that age-associated ventricular myocyte hypertrophy occurs in aging male rats, mice, guinea pigs, rabbits, and monkeys (reviewed by Feridooni et al., 2015). Only a few studies have explored the impact of age on ventricular myocyte morphology in female animals, and the results are less clear. Some have reported an age-related increase in cell length, width, and/or cross-sectional area in females while others have not (Mellor et al., 2014; Howlett, 2010; Grandy and Howlett, 2006; Dibb et al., 2004). This suggests that concentric hypertrophy (lateral growth of ventricular myocytes) and eccentric hypertrophy (longitudinal growth) may occur in hearts from older males and perhaps also females. However, whether age-dependent ventricular myocyte loss and hypertrophy occurs at different rates and through different mechanisms in male and female hearts has not been firmly established.

While the number of ventricular myocytes declines with age, there is strong evidence for proliferation of cardiac fibroblasts in the aging heart (Horn and Trafford, 2015), as summarized in **Table 2**. Fibroblasts are the cells that produce both extracellular matrix and collagen, and their proliferation leads to interstitial fibrosis in the atria, sinoatrial node, and ventricles of older adults (Mirza et al., 2012; Dzeshka et al., 2015). Interestingly, studies in humans have shown that this age-dependent increase in fibrosis is more prominent in men than in women, at least in the ventricles (Liu et al., 2013). Studies in animal models including rodents, sheep, and dogs have reported that fibroblast proliferation, collagen accumulation, and interstitial fibrosis increase with age in both the atria and the ventricles although whether this differs between the sexes has not yet been investigated (Horn and Trafford, 2015; Lau et al., 2013; Horn et al., 2012; Jugdutt et al., 2010). These macroscopic and microscopic changes in the structure of the heart with age are thought to be maladaptive and may adversely affect myocardial function, as explored in more detail in the next section.

Age-Related Changes in Heart Function

The previous sections have discussed structural and cellular changes in the heart with age, which along with age-related changes in calcium handling (Feridooni et al, 2015) can lead to changes in cardiac function. Age-associated functional changes are observed in both the electrical and contractile function of the heart at the cellular and organ level. These changes are summarized in **Table 3** and include reduced heart rate variability, slowed conduction, increased action potential duration in atrial myocytes, reduced systolic function, smaller contractions in ventricular myocytes, reduced early diastolic filling of the LV, and increased late diastolic filling. Although some of these changes have been shown in animal studies to be more prominent in males, sex differences in most of these age-related functional changes have not been investigated (**Table 3**).

Table 3 Age-related changes in heart function

Functional changes[a]	*Model*	*Aged group*[b]	*Sex difference*	*Possible causes/mechanism*	*References*
Impaired ability to ↑ HR upon standing from the supine position, lower maximal HR in exercise	Human	19–89 years	No evidence[c]	↓ responsiveness to ß-adrenergic stimulation, ↓ number of pacemaker cells, reduced ion channel expression in SAN cells	(Nes et al., 2013; Mirza et al., 2012; Ferrara et al., 2014; Lakatta and Levy, 2003)
	Rats	24 months	Not known[c]		(Tellez et al., 2011)
Prolongation of the QRS complex and slowed conduction	Human	65 years+	No evidence	↓ expression of connexion-43; leads to fewer cell-to-cell connections	(Mirza et al., 2012)
	Mouse	24 months	Not known		(Bonda et al., 2016)
Atrial myocytes are depolarized, with ↑ APD	Rat	24–28 months	Not known	Changes in underlying Ca^{2+} and K^{+} currents	(Dun and Boyden, 2009)
	Dog	>8 years			
Depressed systolic function (↓ stroke volume, ↓ ejection fraction)	Humans	35–94 years	May be more prominent in males	↓ number of ventricular myocytes, ↓ ability of ventricular myocytes to contract	(Claessens et al., 2007 (but c.f. Eng et al., 2015)
	Rats	26–30 months	More prominent in males		(Fannin et al., 2014; Shinmura et al., 2011; Koch et al., 2013; Dai et al 2009; Dai et al., 2014)
	Mice	12–31 months			
Smaller, slower contractions in isolated ventricular myocytes	Rats	24 months	More prominent in males	↓ peak Ca^{2+} current, ↓ Ca^{2+} release from sarcoplasmic reticulum stores, smaller Ca^{2+} transient	(Howlett, 2010; Grandy and Howlett, 2006; Feridooni et al., 2015)
	Mice	24 months			
Slowed rate of early LV filling in diastole, diastolic dysfunction	Humans	20–80 years	No evidence	Increased LV fibrosis, increased myocyte stiffness mediated by titin, ↓ rate of decay of Ca^{2+} transient	(Boyd et al., 2011; Strait and Lakatta, 2012; Fleg and Strait, 2012)
	Rats	26–30 months	Not known		(Fannin et al., 2014; Medrano et al., 2015; Shinmura et al., 2011; Koch et al., 2013; Dai et al., 2009; Dai et al., 2014)
	Mice	12–31 months			
Increased atrial contraction and ↑ late diastolic filling	Human	20–85 years	No evidence	Slow LV filling ↑ diastolic filling pressure, causes atrial dilation plus hypertrophy and ↑ atrial contraction	(Strait and Lakatta, 2012; Fleg and Strait, 2012)

[a]*APD*, action potential duration; *HR*, heart rate; *LV*, left ventricle; *SAN*, sinoatrial node.

[b]Compared to young adult humans or animals.

[c]No evidence indicates that studies have included both sexes and found no difference between sexes. Not known indicates that studies have not investigated sex differences.

Age does not affect resting heart rate in studies of aging humans and rodents of both sexes (Lakatta and Levy, 2003; Fannin et al., 2014; Medrano et al., 2015; Koch et al., 2013). Aging is associated, however, with an impaired ability of the heart rate to increase when a person moves from a supine to standing position (Lakatta and Levy, 2003), and a reduced maximal heart rate during exercise (Nes et al., 2013). Potential mechanisms for this include a decline in pacemaker cell number (Mirza et al., 2012) and reduced ion channel expression in pacemaker cells in old age (Tellez et al., 2011). Additionally, an impaired responsiveness to ß-adrenergic stimulation with aging (Ferrara et al., 2014) could contribute to this reduced heart rate response. In younger people, activation of the sympathetic nervous system (by exercise, for example) results in an increase in both heart rate and the force of contraction, through the release of catecholamines that activate β-adrenergic receptors. However, in both aging humans and animals there is evidence of a decline in responsiveness to ß-adrenergic stimulation (Ferrara et al., 2014; Farrell and Howlett, 2008; Brodde and Leineweber, 2004; White et al., 1994), which may contribute to a decline in heart rate response. Interestingly, one study in male and female monkeys found an age-related decline in responsiveness to ß-adrenergic stimulation in males but not in females (Takagi et al., 2003). Overall however, as most studies have not explored sex differences, and the majority investigated used only male, the effect of sex on heart rate response in old age and the potential mechanisms involved still remains to be investigated.

Changes in the electrical function of the heart occur in old age. There is an age-associated slowing of conduction, and prolongation of the QRS complex, in humans and animal models (Bonda et al., 2016; Mirza et al., 2012). A recent animal study in aging male mice identified that a potential mechanism for this may be reduced cell-to-cell connections as a result of lower expression of connexion-43 (Bonda et al., 2016). Animal studies have also investigated changes in the electrophysiological properties of atrial myocytes with old age. These have shown that in older animals, compared to young animals, right atrial myocytes are depolarized and have longer action potentials (Dun and Boyden, 2009). These changes are associated with changes in underlying ion currents, including an increase in potassium currents and a decrease in calcium currents with old age (Dun and

Boyden, 2009). There are limited clinical studies using atrial myocytes, so whether these same changes occur in older humans is not yet clear. Potential sex differences in atrial myocyte electrophysiology or changes to conduction speed in old age are not known, and further mechanistic studies including females are needed.

Systolic function has historically thought to be preserved in aging, with no change in measures such as stroke volume and ejection fraction, between younger and older people (Lakatta and Levy, 2003). Recent evidence, however, suggests a decline in systolic function, at least in men, with aging (Claessens et al., 2007; Eng et al., 2015). The extent to which this decline occurs in women is less clear, with one clinical study finding that cardiac contractility is well preserved in women (Claessens et al., 2007), and another showing that stroke volume decreased in men and women to the same extent (Eng et al., 2015). The difference in these findings may be due to the different age ranges of the studies (35–55 years vs 54–94 years, respectively). Interestingly, animal studies also find that measures of systolic function, including stroke volume and ejection fraction, decline with age in males, but not in females (Koch et al., 2013; Shinmura et al., 2011; Dai et al., 2009, 2014; Fannin et al., 2014).

Changes in ventricular myocyte contractile function are also seen with aging. Ventricular myocytes isolated from aged rodents have smaller, slower contractions than cells from young animals (Howlett, 2010; Grandy and Howlett, 2006). Furthermore, consistent with the work cited above in hearts in vivo, the decrease in contractile function in ventricular myocytes is greater in males than in females (Howlett, 2010; Grandy and Howlett, 2006). Changes in calcium handling in aged isolated myocytes provide a potential mechanism for this, with decreases in peak calcium transients in cells isolated from aged male mice (Howlett, 2010; Grandy and Howlett, 2006). There is also a reduction in peak calcium currents, which may result in less calcium influx in myocytes from aged male rodents (Feridooni et al., 2015). In cells isolated from aged female rodents however, there is no change in peak calcium transients or calcium currents (Feridooni et al., 2015) and cells from aged female sheep in fact display an increase in these measures (Dibb et al., 2004). It remains to be confirmed whether these changes in myocyte contractility and calcium handling are seen in humans of both sexes.

Diastolic dysfunction, and a reduction in the heart's ability to relax, is a commonly seen change in the aging heart. Impairment of ventricular relaxation results in left ventricular filling of older hearts that is both slower, and occurs later, than in young adult hearts (Fleg and Strait, 2012; Lakatta and Levy, 2003; Strait and Lakatta, 2012; Boyd et al., 2011). Problems with relaxation, known as diastolic dysfunction, are also seen in both male and female aging animal models (Shinmura et al., 2011; Fannin et al., 2014; Dai et al., 2009, 2014; Medrano et al., 2015; but c.f. Koch et al., 2013). Potential mechanisms for diastolic dysfunction in old age have been investigated in both human and animal studies. Increased LV fibrosis (Horn and Trafford, 2015) may contribute to reduced ventricular relaxation and thus reduced passive filling of the LV (Loffredo et al., 2014). Myocyte stiffness, as a result of age-related changes to the sarcomeric protein titin, may also contribute to ventricular stiffness (Hamdani et al., 2013). There is also a slower calcium transient decay seen in ventricular myocytes isolated from older animals, compared to younger animals (Feridooni et al., 2015). This results in prolonged availability of cellular calcium, which causes ongoing activation of contractile filaments and may delay ventricular relaxation (Loffredo et al., 2014; Dai et al., 2012). As a result of slow early LV filling in diastole, there is increased late diastolic filling, accompanied by an increased force of atrial contraction (Strait and Lakatta, 2012). The contribution of the atria to LV filling in old age is thus much greater than in younger people. This age-related decrease in LV filling speed also results in an increase in diastolic filling pressure, which can result in atrial dilation and hypertrophy (Fleg and Strait, 2012). Although diastolic dysfunction and changes to LV filling appear to occur in both sexes, any changes in underlying causes are unclear as few mechanistic studies have used females, and more studies are needed.

The implications of changes in cardiac function, and any sex differences in these changes, on clinical outcomes and associations with cardiovascular diseases are explored in the next section.

Sex Differences in Clinical Cardiac Outcomes With Aging

Many of the cellular, structural, and functional changes described in the previous sections are maladaptive and can lead to increased risk of serious clinical outcomes in aging patients. Clinical outcomes that are associated with significantly increased risk in old age are summarized in **Table 4** and include heart failure with reduced ejection fraction (HFrEF), heart failure with preserved ejection fraction (HFpEF; characterized by diastolic dysfunction), bradycardia, and the need for pacemaker implantation and atrial fibrillation. Clinical studies have also identified significant differences in risk, prevalence, and outcomes of these clinical cardiac complications between males and females.

Aortic valve calcification increases in old age. This age-associated change in the heart can obstruct outflow from the LV and may lead to the development of heart failure (New and Aikawa, 2011). This risk appears to be higher for men than for women (Milin et al., 2014). The decline in myocyte number, decreased size of myocyte contraction and overall depressed systolic function, associated with old age can also lead to an increased risk of HFrEF. There is some evidence to suggest that each of these mechanisms occurs more in males than in females (Zhang et al., 2007; Olivetti et al., 1991, 1995; Howlett, 2010; Grandy and Howlett, 2006) although most of this research has only been completed in male animals. Nonetheless, these differences may explain why older men are more likely than older women to develop HFrEF (Dunlay and Roger, 2012).

Old age is also associated with an increased risk of HFpEF, which is characterized by diastolic dysfunction with no significant reduction in ejection fraction (Kaila et al., 2012; Dunlay and Roger, 2012). Potential mechanisms for this adverse clinical outcome include slow passive LV filling and slowed relaxation, increased LV fibrosis and thickness and ventricular myocyte changes such as increased stiffness and slowed calcium removal. Overall, these age-associated maladaptive changes can cause the atria to make a

Table 4 Sex differences in clinical cardiac outcomes with aging.

Age-related clinical outcome[a]	*Sex difference*	*Potential mechanisms*	*References*
Increased risk of HFrEF	Risk is higher for men than for women	Aortic valve calcification, obstruction of LV outflow	(New and Aikawa, 2011; Milin et al., 2014)
Increased risk of HFrEF	Increased risk in men	Reduced numbers of ventricular myocytes, and myocyte hypertrophy Decreased myocyte contraction, and decreased Ca^{2+} transients Decreased systolic function	(Dunlay and Roger, 2012)
Increased risk of HFpEF	More prevalent in women but associated with worse outcomes in men	Slow passive LV filling, diastolic dysfunction Increased left ventricular fibrosis, stiffness, and wall thickness Slowed Ca^{2+} removal, increased diastolic Ca^{2+}, and increased myocyte stiffness (titin changes)	(Dunlay and Roger, 2012; Kaila et al., 2012; Loffredo et al., 2014; Greiten et al., 2014; Lam et al., 2012)
Increased risk of bradycardia and pacemaker implantation	Not known	Decreased expression of SAN node channels, SAN dysfunction	(Mirza et al., 2012)
Increased risk of atrial fibrillation	More prevalent in men but associated with worse outcomes in women	Atrial hypertrophy and fibrosis Remodelling of ion channels in atrial myocytes	(Pancholy et al., 2014)

[a]*HFrEF*, heart failure with reduced ejection fraction; *HFpEF*, heart failure with preserved ejection fraction LV left ventricle; *SAN*, sinoatrial node.

significantly larger contribution to ventricular filling, which reduces cardiac output and predisposes older people toward the development of HFpEF (Loffredo et al., 2014; Kaila et al., 2012). The risk factors associated with HFpEF and the risks associated with a diagnosis differ between men and women. Myocardial ischemia is an important risk factor in men, while hypertension is a greater risk factor in women (Greiten et al., 2014). Interestingly, although HFpEF is more common in older women (Dunlay and Roger, 2012; Greiten et al., 2014), it is associated with worse outcomes in men, including increased risk of hospitalization and mortality (Lam et al., 2012). HFpEF represents a significant clinical problem in the older population, with an increasing prevalence, and a lack of treatment options (Greiten et al., 2014; Loffredo et al., 2014).

Age-related dysfunction of the sinoatrial node, including reduced numbers of pacemaker cells and reduced expression of ion channels in these cells is associated with an increased risk of bradycardia and pacemaker implantation in old age (Mirza et al., 2012). Potential sex differences in the risk of developing bradycardia in old age are not known. There are important sex differences, however, in the increased risk of atrial fibrillation with aging. Although there is a higher risk for developing atrial fibrillation amongst men, it is associated with worse outcomes such as stroke or systemic embolization in women (Pancholy et al., 2014). Mechanisms for the increased risk of atrial fibrillation in old age in both sexes include atrial hypertrophy and fibrosis and changes in ion channel expression of atrial myocytes although the potential sex differences in these underlying mechanisms are not yet known.

Overall, there is an increased risk of HFrEF, HFpEF, bradycardia, and atrial fibrillation in old age. There are some important sex differences in both the risk of these clinical outcomes and the associated risk of poor outcomes with these clinical diagnoses. More research is needed to identify potential sex differences in the underlying structural and functional changes that result in these clinical outcomes.

Summary

The age-related changes in the heart at the cellular, structural, and functional level and the clinical implications of these changes for both men and women are summarized in **Fig. 1**. For some of these age-related cardiac changes there is either no evidence of any sex-related differences or no research to date exploring sex differences. Age-related changes without any clear known sex effect include a reduction in sinoatrial node cells, aortic valve calcification, atrial hypertrophy and fibrosis, LV fibrosis, a decrease in maximal heart rate, an increased QRS complex and slowed conduction, prolonged action potential duration in atrial myocytes, diastolic dysfunction, and an increase in atrial contraction force. Additionally, older males and females are at increased risk of bradycardia and pacemaker implantation. There are some clear sex differences, however, in some of the changes that occur to the heart with age. Older males appear to have a greater reduction in myocytes, more significant myocyte hypertrophy, and a greater increase in fibroblasts than older females. These cellular changes may contribute to functional changes seen in older males, such as a more prominent decrease in myocyte contractions and reduced systolic function, when compared to older females. Furthermore, these

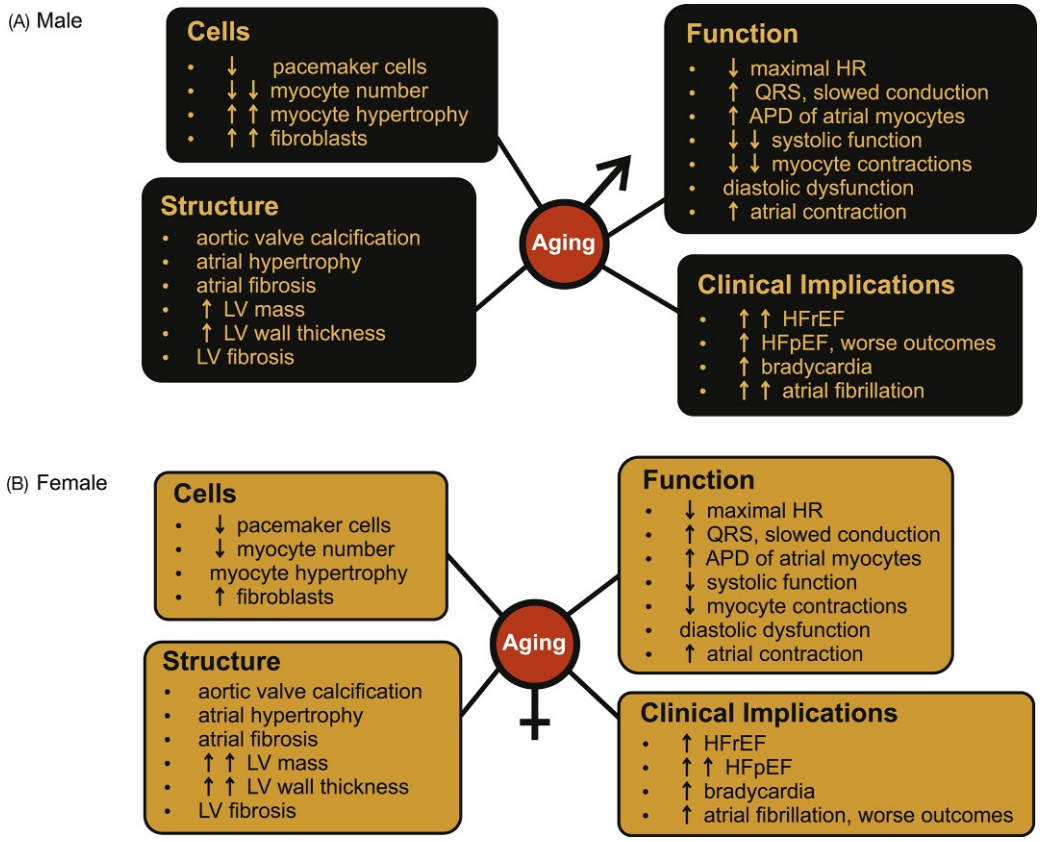

Fig. 1 Major age-related cellular, structural, functional, and clinical changes in the heart. (A) Characteristic cardiac aging changes in the male heart. changes result in differences in clinical outcomes for older males including an increased risk of HFrEF and atrial fibrillation, and worse outcomes associated with HFpEF. Older females, on the other hand, have more significant increases in LV mass and wall thickness, than older males, which may contribute to the increased risk of HFpEF in older females. Older females also have worse outcomes associated with atrial fibrillation. Overall, there are some important sex differences in cardiac changes with aging that result in different clinical outcomes for males and females. More research is needed however, especially in female animals, to further understand these clinical differences, their implications, and their structural and functional mechanisms.

Introduction

Cardiovascular disease (CVD) is a broad spectrum pathology that involves deleterious signaling mechanisms leading to remodeling of blood vessels and the heart manifesting in a disease state. CVD includes coronary artery diseases (CAD), stroke, heart failure, hypertensive heart disease, heart arrhythmia, congenital heart disease, myocarditis, aortic aneurysm, and peripheral artery disease. CVD is a major cause of death in the world, causing almost 17.3 million fatalities per year. Nearly one out of seven deaths in the United States occur due to heart failure, and the majority of the deaths area associated primarily with socioeconomic status. Increasing evidence shows that the African-American population has a higher susceptibility toward manifestation of CVD compared to other ethnicities in the United States (American Heart Association). CVD and stroke account for 80% deaths in males and 75% in females (World Health Organization 2011) with significant occurrence in older adults.

Development/progression of CVD pathologies classically involve the narrowing of vessels that in turn exert mechanical overload on the heart to pump more forcefully to keep the supply intact. Consequently, the vessels undergo remodeling in response to the increased force of flow leading to a cycle of bidirectional remodeling that ultimately underlies heart attack/stroke. Thus, manifestation for each of the CVD pathologies is associated with ongoing chronic remodeling and occurs due to altered signaling mechanisms driven potentially by dysregulated receptor signaling. There are several underlying conditions that can affect CVD pathology and underlying heart health, including diet, physical activity, tobacco consumption, body weight/obesity, high-cholesterol levels, and diabetes (Kenchaiah et al., 2002; Hippisley-Cox and Coupland, 2016a). Despite the plethora of underlying conditions that contribute to the CVD, the majority of current treatments target receptors like angiotensin and/or beta-adrenergic receptors for maintaining cardiac function, while other major mechanisms causing CVD are under intense investigation.

Cardiac Receptor Signaling in Physiology and Failure

Beta-adrenergic receptor (βAR) signaling plays a critical role in the maintenance of cardiac function by integrating cardiovascular and sympathetic inputs (Leimbach et al., 1986; Koch, 2004). Sympathetic overdrive occurs as an adaptive response that initiates cardiac hypertrophic signaling following βAR stimulation. This stimulation leads to receptor activation and series of downstream signals that convert the chemical stimulus to an elevation in physical contractile response. Importantly, at the molecular level, increased βAR activation and signaling leads to myocardial hypertrophy as an adaptive process, improving ventricular function to balance workload. However, sustained cardiac hypertrophy associated with ensuing increase in work load consequently activates sympathetic drive. Chronic sympathetic overdrive in addition to activating βARs also subsequently inactivates or desensitizes the

*Both the authors contributed equally and are joint first authors.

receptors as a feedback mechanism, resulting in reduced cardiac contraction and a greater risk for stroke and heart failure (Leimbach et al., 1986; Koch, 2004; Esler et al., 1997).

Beta-Adrenergic Receptors (βARs)

βARs are prototypical members of the G-protein-coupled receptor (GPCR) family. GPCRs are the largest family of cell surface receptors and are key regulators of cellular processes including cardiac function. They are able to recognize cues from the extracellular milieu and transmit those signals across the membrane into the cell to mediate a response. Given their key role in regulating multiple process, they are also major targets for drugs, and currently >30% of marketed drugs target GPCR function either activating/inhibiting their function in pathology (Stevens et al., 2013). Structurally, GPCRs are membrane proteins characterized by seven transmembrane spanning domains interconnected by three intracellular and three extracellular loops. Despite GPCRs binding to a plethora of agonists, they structurally have a classically conserved core where agonist binds, an extracellular amino terminal (N-terminal) that plays a role in agonist binding, and an intracellular carboxyl terminal (C-terminal) region key for regulating receptor signaling (Madamanchi, 2007). GPCRs are activated following extracellular stimuli such as hormones (epinephrine/norepinephrine), light, sound, and odor that transmit the stimuli into the cell (Rockman et al., 2002). In this context, βARs are the key sensors for epinephrine and norepinephrine and mediate cellular responses through three receptor subtypes: β1, β2, or β3ARs (Xiao, 2001). β2AR is the most ubiquitously expressed receptor subtype, while β1AR is the most abundant subtype in the heart accounting for 75%–80% of βARs. β3AR is expressed almost exclusively in adipose tissues (Madamanchi, 2007; Xiao, 2001). Activation of the βARs subtypes leads to a conformational change in the receptor, allowing interaction with heterotrimeric G-proteins.

Heterotrimeric G-proteins

The heterotrimeric G-proteins are composed of three subunits, α, β, and γ, which are localized to the inner leaflet of the plasma membrane. Conformational changes that occur following activation of the receptor lead to interaction with G-proteins, and dissociation of the heterotrimeric G-protein into Gα and βγ subunits. The dissociation of the Gα from the βγ subunits exchanges GDP with GTP, leading to activation of downstream signals primarily by coupling to effectors like adenylyl cyclase, phosphodiesterases, phospholipase C, and ion channels (Wettschureck and Offermanns, 2005b). Activated effectors in turn tightly regulate the intracellular concentration of downstream secondary messengers like cAMP, diacylglycerol, sodium or calcium cations that titrate the physiological response through posttranslational signaling mechanism for acute responses, and gene transcription/translation for long-term chronic remodeling responses (Wettschureck and Offermanns, 2005a; Wettschureck et al., 2005). Hydrolysis of the GTP-bound Gα subunit to GDP results in reassociation with Gβγ subunits, completing a cycle and terminating the signal initiated by the activated receptors. The length of the G-protein signal is determined by the duration of the GTP-bound Gα-subunit, which could be regulated by regulator of G-protein signaling (RGS) proteins or by covalent modifications of the G-protein subunits (Sato et al., 2006; Sjogren and Neubig, 2010). There are four subtypes of Gα-subunits Gαs, Gαi, Gαq, and Gα12, enabling diversity in responses (Madamanchi, 2007). Gαs is stimulatory while Gαi is inhibitory in the context of adenylyl cyclase activation and cAMP generation following βAR interaction with epinephrine or norepinephrine (Lefkowitz, 1998; Communal et al., 1999). Classically, the Gβγ subunits of the G-proteins were thought to be the brakes on G-protein signaling as their reassociation with Gα leads to termination of signaling. However, increasing evidence shows that the Gβγ subunits themselves also mediate downstream signaling, independent of Gα-subunits, that has significant physiological and pathological implications. The Gβγ subunits are always complexed together and tethered to the membrane by posttranslational prenylation of the γ subunit (Kisselev et al., 1995). Although the role of different isoforms of Gα subunits in regulating downstream signaling is well understood, the role of multiple isoforms of the G β and γ subunits in signaling is being appreciated only recently have studies have shown that the isoform combination of Gβγ subunits can provide diversity in signaling and response to extracellular stimuli (Khan et al., 2013).

βAR Downstream Signaling

Engagement of βAR with agonist classically leads to G-protein activation in the cardiac system, which couples to the stimulatory Gαs G-protein subunit leading to activation of adenylyl cyclase. Consequently, adenylyl cyclase mediates generation of cAMP, activating PKA that in turn through a series of subsequent steps results in increased cardiac contractility (Movsesian, 1998; Zaccolo, 2009). Simultaneously, the dissociated Gβγ subunit of the heterotrimeric G-protein recruits G-protein-coupled receptor kinase 2 (GRK2) that phosphorylates βAR, allowing for β-arrestin binding, which terminates the signals from GPCRs, resulting in desensitization (Wolfe and Trejo, 2007). β-Arrestin is a cytosolic scaffolding protein. However, recent studies have shown that while β-arrestin terminates signals from activated GPCRs, it also simultaneously initiates β-arrestin-dependent signaling (Dorn, 2009b; DeWire et al., 2007). These observations lead to the concept that GPCRs can initiate G-dependent signaling and G-protein independent, β-arrestin-dependent signaling (Dorn, 2009b) (**Fig. 1**). Increasing evidence suggests that β-blockers that traditionally block G-protein signaling may mediate unique beneficial effects via G-protein-independent mechanisms. In addition, stimulation of GPCR leads to unique signals that allow for cross-talk and subsequent activation of traditional receptor tyrosine kinases (epidermal

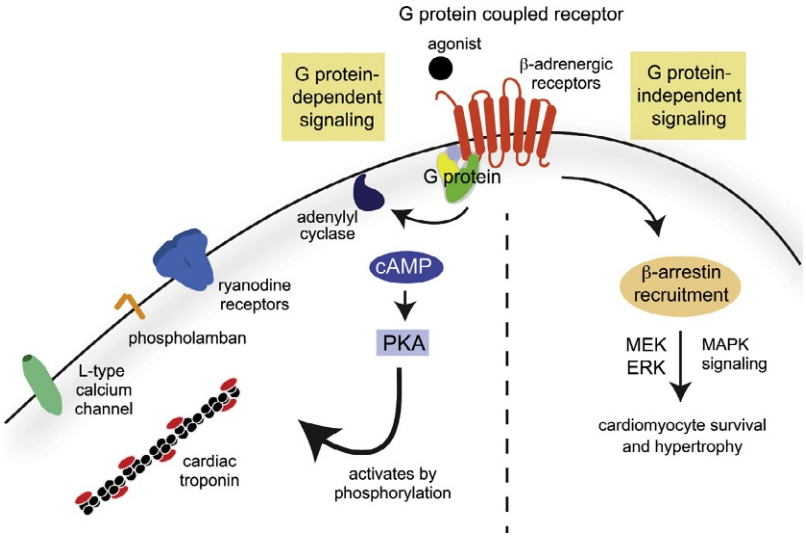

Fig. 1 Illustration of beta-adrenergic receptor (βAR) downstream signaling: G-protein-dependent and G-protein-independent signaling pathways.

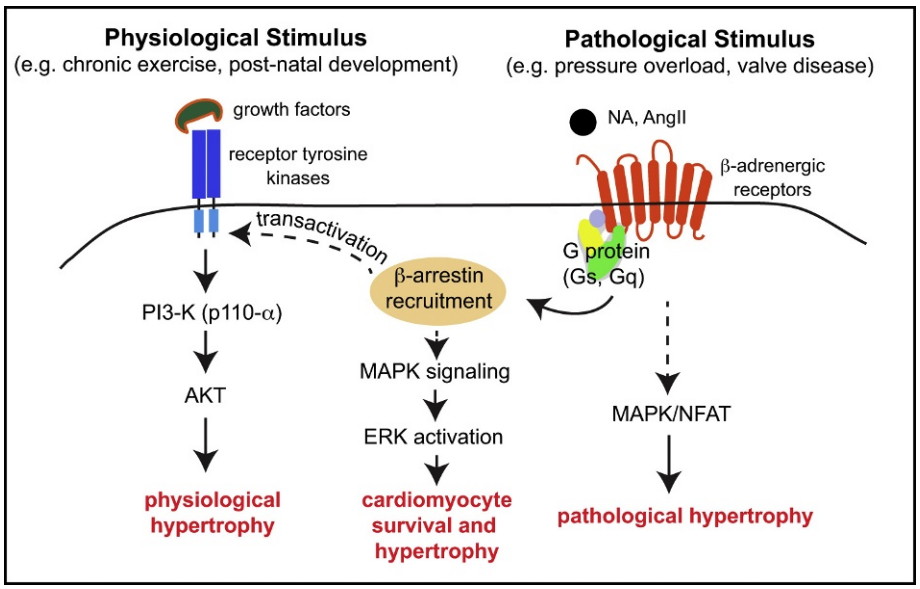

Fig. 2 Illustration showing mechanisms of cardiac remodeling.

growth factor receptor (EGFR), platelet-derived growth factor receptor), resulting in transactivation (Fig. 2). These signaling pathways provide multiple mechanisms by which GPCRs can regulate, titrate, and mediate responses to diverse sets of extracellular stimuli.

G-Protein-Dependent Signaling

Stimulation of β1 and β2AR leads to coupling to stimulatory G-protein Gαs that activates adenylyl cyclase, generating the cAMP that initiates signals mediating inotropic effects. However, persistent stimulation of β2ARs leads to switching of coupling from stimulatory Gαs to inhibitory Gαi resulting in inhibition of adenylyl cyclase activation, reducing cAMP and inotropic effects (Boknik et al., 2009). Interestingly, β3ARs mediate negative inotropic effects by activation of protein kinase G through cGMP pathways showing how a hormonal epinephrine or norepinephrine stimulation response can be diversified in a cell to provide an appropriate contractile response. A primary role of cAMP is to activate PKA, which mediates phosphorylation of a set of regulatory proteins in cardiomyocytes resulting in positive inotropy (increased contraction) and also concomitant increased relaxation (lusitropy) (Zaccolo, 2009; Movsesian, 1998). PKA mediates phosphorylation of proteins in the sarcoplasmic reticulum (SR) that regulate both inotropic and lusitropic effects. PKA phosphorylation of phospholamban releases its inhibitory effect on SR Ca^{2+}

ATPase-2 (SERCA2a), accelerating Ca^{2+} uptake increasing the available pool of Ca^{2+} for the next contraction (Bers, 2002). Similarly, there is increased phosphorylation of the ryanodine receptor, contributing to a faster onset for contraction following βAR stimulation (Maltsev et al., 2006; Tilley and Rockman, 2006). In addition to regulation of SR proteins, PKA also plays a critical role in regulating positive inotropy by phosphorylating the L-type Ca^{2+} channel, increasing the influx of Ca^{2+} (Shaw et al., 2009). Finally, PKA also phosphorylates cardiac troponin I (cTnI), reducing Ca2+ sensitivity to enhance cardiac relaxation (Wattanapermpool et al., 1995). These observations show how G-protein-dependent signaling is a key player underlying the process of cardiac contraction mediated via increased βAR stimulation due to elevated sympathetic drive in response to mechanical demands (Bers, 2002). Although PKA is primarily activated by Gαs-G-protein due to βAR, the cardiac systems also respond to mechanical needs by activating the Gαq-G-protein via angiotensin or endothelin receptors (Rosano and Bagnato, 2009). Gαq initiates phospholipase C (PLC)-mediated hydrolysis of phosphatidylinositol 4,5-bis-phosphate (PIP_2) to diacyl glycerol (DAG) and inositol trisphosphate (IP_3) which acts as second messengers similar to cAMP. DAG activates protein kinase C (PKC), while IP_3 regulates Ca2+ channels in the SR (Carrasco et al., 2004). PKC activation leads to phosphorylation of numerous substrates including activation of the MAPK signaling pathway that primarily drive cell growth responses resulting in cardiac hypertrophy (Kehat and Molkentin, 2010) (Dorn and Force, 2005). In addition, IP_3-mediated Ca^{2+} release regulates calmodulin, which in turn mediates hypertrophic response through calcineurin and Ca^{2+}/calmodulin-dependent protein kinase II (CAMKII) (Kehat and Molkentin, 2010; Chen et al., 2011). These observations show the critical role G-protein-dependent signaling plays in dynamically regulating cardiac responses to the ever changing needs of the body.

G-Protein Independent Signaling

The concept of G-protein independent signaling has evolved only recently, as small molecules have been developed that can generate unique GPCR confirmations to selectively activate specific downstream signaling pathways (Carrasco et al., 2004). This concept came from studies showing unconventional angiotensin receptor desensitization in response to modified peptide agonists (Feng et al., 2005). The findings from this study suggested that agonist binding of the receptor could lead to different confirmations with each of the confirmations potentially coupling to a diverse downstream components including activation of G-protein-independent signaling. β-Arrestins are recruited to the receptor following phosphorylation, initiating signals that are independent of G-proteins, as its recruitment terminates G-protein signaling (Lefkowitz, 1998). The role of β-arrestin 1 and 2 in G-protein-independent signaling is only being appreciated recently, in contrast to their classical role in desensitization and receptor internalization (Shenoy and Lefkowitz, 2011a; Kendall et al., 2011). β-Arrestin 2 forms a signalosome initiating activation of extracellular regulated kinase 1/2 that in turn mediates phosphorylation of ribosomal S6 kinase, mediating proliferation in neonatal cardiomyocytes (Cuello et al., 2011; Ahn et al., 2009). In addition, β-arrestin 1 interacts with Rho GTPase-activating protein that in turn activates Rho, mediating stress fiber formation (Barnes et al., 2005; Anthony et al., 2011). Given the role of β-arrestin as a scaffold that can mediate G-protein-independent signaling, proteomic studies have shown that β-arrestins interact with a large set of key molecules involved in signal transduction that have clear implications in manifestation of the phenotypes. For example, β-arrestins can scaffold exchange protein activated by cAMP (EPAC) and CAMKII to potentially modulate cardiac contractility (Mangmool et al., 2010). Similarly, interaction with actin, cofilin, and myosin could alter actin remodeling and stress fiber formation (Xiao et al., 2007, 2010; Christensen et al., 2010), while interaction with the myosin-binding subunit of myosin phosphatase could be an integral regulator of cardiac contractility (Kooij et al., 2010; Godin and Ferguson, 2010). These observations provide an understanding of the broader scale of β-arrestin activity in mediating cardiac contraction, cytoskeleton remodeling, and proliferation.

β-Arrestin-dependent signaling pathways have attained prominence due to their persistent recruitment to GPCRs following GRK mediated phosphorylation, indicating that they play a key role in G-protein-independent signaling (Dorn, 2009b). GPCRs can be classified into Class A or Class B receptors based on their internalization and strength of interaction with β-arrestin. Class A receptors tend to have preferential binding to β-arrestin 2, which undergoes faster recycling as β-arrestin falls off the receptor complex during internalization of receptors such as β1AR, β2AR, or vasopressin receptors (Luttrell and Gesty-Palmer, 2010). In contrast, Class B receptors undergo internalization but have slower recycling rates because β-arrestin forms a more stable complex with the receptor in the endosome in the case of the angiotensin receptor 1 (AT1R) (Pierce and Lefkowitz, 2001). Interestingly, Class B GPCRs do not have a preference for β-arrrestin 1 or 2 (Zhang et al., 1999; Noor et al., 2011). The formation of the complex with the receptor allows for prolonged cytosolic endosomal signaling via ERK activation (DeWire et al., 2007), which can regulate cardiomyocyte survival and hypertrophy (Tohgo et al., 2002; Aplin et al., 2007). However, release of β-arrestin from Class A receptors including βARs allows for the β-arrestin signals to be more widespread, allowing for increased signals within the cell compared to Class B receptors. This is important given that β-blockers that bind βARs to block G-protein coupling mediate G-protein-independent signaling, which underlies some of the benefits associated with β-blocker treatment.

Transactivation

In addition to the G-protein-dependent and -independent signaling mediated by GPCR ligands, GPCR can also mediate cell survival signal through transactivation of EGFR. It is important to note that β-arrestin plays a key role in the process of the cross-talk between GPCR and EGFR (Heitzler et al., 2009; Cattaneo et al., 2014; Maudsley et al., 2000; Noma et al., 2007; Tilley et al., 2009). Studies have shown that many GPCRs induce EGFR transactivation, wherein ERK1/2 is significantly activated, mediating a cardiac

hypertrophy response (Noma et al., 2007). Importantly, it is known that β1AR-mediated EGFR transactivation is a key pathway in mediating cardiac hypertrophic response, resulting in dilated cardiomyopathy (Toker and Cantley, 1997; Esposito et al., 2011; Kim et al., 2009; Zhai et al., 2006). Although multiple studies have shown the role of β-arrestin in the transactivation pathway, there are also studies that have described the role of G-proteins in the process of transactivation (Cattaneo et al., 2014; Heitzler et al., 2009). This brings forth the idea that depending on the agonist and the GPCR, the GPCR could engage in G-protein-dependent as well as -independent pathways to mediate the downstream effects. However, studies have shown that the cardio-protective effects of β-blocker are mediated by transactivation of EGFRs, which is primarily regulated through β-arrestin (Toker and Cantley, 1997; Kim et al., 2008).

Regulation of βAR Activation/Signaling

It is important for GPCRs like βARs to be activated in response to hormones to initiate signals. On the other hand it is also critical to tightly control termination of signals to prevent overstimulation. This process is choreographed as the activated βARs are phosphorylated by GRKs (Lymperopoulos et al., 2012; Lefkowitz, 1998; Monto et al., 2012; Aguero et al., 2012; Zhu et al., 2012; Belmonte and Blaxall, 2011), resulting in β-arrestin binding and termination of G-protein coupling/signaling. β-Arrestin binding to the phosphorylated βAR leads to endocytosis into endosomes (Lefkowitz, 1998; Shenoy and Lefkowitz, 2011b; Shukla et al., 2011; Lymperopoulos, 2011; Patel et al., 2009; Rajagopal et al., 2010). Resensitization of βARs occurs by dephosphorylation of the receptors by protein phosphatase 2A (PP2A) in the endosomes before being recycled back to plasma membranes (Ferguson, 2001; Rockman et al., 2002; Krueger et al., 1997; Drake et al., 2006).

Desensitization

Epinephrine or norepinephrine binding to βARs results in activation of G-protein and dissociation of Gαs and Gβγ subunits. Agonist bound receptor is then phosphorylated by PKA, protein kinase C, and GRKs to uncouple from the G-proteins, initiating classical desensitization (Walker et al., 2011). In this context, Gαs through cAMP activates PKA, and Gβγ through Ca^{2+} activates PKC, both of which phosphorylate GPCRs indiscriminately, desensitizing the receptors independent of the agonist (Lefkowitz, 1998). Such a phenomenon is termed heterologous desensitization or agonist-independent desensitization, wherein stimulated and unstimulated GPCRs are phosphorylated (Rockman et al., 2002; Penn et al., 1998). In contrast, GRK-mediated phosphorylation and desensitization is an agonist-specific response mediated by GRKs. There are seven GRKs of which GRKs 2, 3, 5, and 6 are ubiquitously expressed, while GRK 1 and 7 are rhodopsin kinases and GRK 4 is expressed primarily in the testis (Sallese et al., 1997, 2000; Virlon et al., 1998; Kearney et al., 2005; Hall et al., 2012; Sato et al., 2015; Pronin et al., 1998). GRK 2, 3, and 5 are abundantly expressed in the heart and play a critical role in regulating βAR function. GRK 2 and 3 are cytosolic proteins and are recruited to the βARs at the plasma membranes by the dissociated Gβγ subunits, while GRK5 is tethered to the membrane by high-affinity association with phospholipids (Pitcher et al., 1998; Pronin et al., 1998). Thus, GRK-mediated phosphorylation of the C-terminal tail of the agonist-bound βAR results in binding of the receptor to β-arrestin (Madamanchi, 2007). In addition to mediating G-protein-independent signaling, β-arrestin acts as an adaptor protein for recruiting molecules in receptor endocytosis, leading to internalization of desensitized βARs (Lefkowitz and Shenoy, 2005).

Oxidative stress and inflammation can also trigger βAR dysfunction potentially by altering desensitization by a distinct mechanism from the classical desensitization pathway. Proinflammatory cytokines such as TNFα, IL-1β, and IL-13 significantly predispose βARs toward desensitization in cardiomyocytes as well as in human airway smooth muscle cells (Prabhu, 2004; Gulick et al., 1989). Reactive oxygen species (ROS) also play an important role in mediating adrenergic function (Gupta et al., 2006; Donoso et al., 2011). In this context, several studies have provided evidence for oxidative stress-mediated modification in the components of the βAR desensitization pathway that underlies the altered receptor response (Whalen et al., 2007; Ozawa et al., 2008). For example, nitrosylation of GRK2 has been shown to attenuate βAR phosphorylation, thereby reducing desensitization and downregulation of βARs (Ozawa et al., 2008; Whalen et al., 2007). Given these observations, proinflammatory cytokines and ROS-dependent oxidative–nitrosylative switches may play an important role in shifting the regulation of kinases, thereby significantly impacting βAR desensitization.

Resensitization

Resensitization is a process of restoration of receptor responsiveness in the presence or absence of a stimulus (Vasudevan et al., 2011). Resensitization of βARs takes place following desensitization by phosphorylation of βARs by GRKs and PKA in response to sympathetic overdrive (Lymperopoulos et al., 2012; Lefkowitz, 1998; Monto et al., 2012; Aguero et al., 2012; Zhu et al., 2012; Belmonte and Blaxall, 2011). Following phosphorylation, receptors are internalized into the endosomes via β-arrestin binding (Lefkowitz, 1998; Shenoy and Lefkowitz, 2011b; Shukla et al., 2011; Lymperopoulos, 2011; Patel et al., 2009; Rajagopal et al., 2010). Once in the endosomes, the phosphorylated βARs are dephosphorylated by protein phosphatase 2A (PP2A). This process is thought to be dependent on the acidification of the endosomes (Gardner et al., 2007). Once βARs are dephosphorylated by PP2A, the naïve receptors are recycled back to the plasma membrane. PP2A is a heterotrimeric holoenzyme characterized by a scaffolding A, regulatory B, and catalytic subunit C (Sontag, 2001; Cohen, 1989). Despite the regulation of the PP2A holoenzyme,

resensitization, which is a key step in reestablishing receptor signaling potential, until now has been considered to be a passive homeostasis process. However, recent studies have shown that resensitization is not a passive process but a tightly regulated mechanism mediated by phosphoinositide 3-kinase γ (PI3Kγ). PI3Kγ regulates a known endogenous modulator of PP2A function called inhibitor of PP2A (I2PP2A) (Oliver and Shenolikar, 1998; Li et al., 1995). PI3Kγ phosphorylates I2PP2A on residues 9 and 93, resulting in enhanced binding of I2PP2A to PP2A, blocking PP2A activity (Nienaber et al., 2003; Naga Prasad et al., 2000). Thus, resensitization mechanisms are only coming to be appreciated, and further studies are required to identify novel regulatory mechanisms that modulate this key process. In addition, there is evidence that βARs can be activated for signaling within endosomes (Ferguson, 2001), outside of the typical pathway of recycling to the plasma membrane. These exciting observations indicate that more studies are needed to comprehensively understand resensitization and suggest a changing paradigm of resensitization mechanisms (Ferguson, 2001).

Receptor Endocytosis and Trafficking

Phosphorylation of βARs in one of the key steps that initiates the process of receptor endocytosis. β-Arrestin binding to phosphorylated βARs not only mediates βAR desensitization and initiation of β-arrestin-dependent signaling but also plays a key role in recruiting molecules critical for endocytosis (Bhatnagar et al., 2001). β-Arrestin mediates its multiple activities by adopting altered confirmations with differential affinity to various proteins. Binding of β-arrestin to phosphorylated βAR results in a conformational change that exposes the C-terminal tail of β-arrestin to allow interaction with the endocytic machinery, including clathrin and adaptor subunit of AP2 (Anthony et al., 2011; Edeling et al., 2006). These interactions drive the βAR/β-arrestin complex toward clathrin-coated pits and subsequent endocytosis. It is important to note that clathrin-mediated endocytosis is a major mechanism by which GPCRs are endocytosed and trafficked in the cell. GPCRs may also use alternative pathways like caveolae for endocytosis of the receptor complex from the cell surface (Rapacciuolo et al., 2003). Although β-arrestin recruitment to the receptor complex is a key determinant in βAR endocytosis, other regulators alter the dynamics of this process. For example, proteins like β-arrestin and AP2 bind to phosphatidylinositol 4,5 *bis*-phosphate (PIP2) to be stabilized (Hinrichsen et al., 2006). However, β-arrestin and AP-2 have log fold higher affinity toward PIP3 (Gaidarov et al., 1999) generated by PI3K, and expression of a kinase-dead PI3K leads to significant impairment in βAR endocytosis (Patrucco et al., 2004). Once the receptor-enriched clathrin-coated vesicle is formed at the plasma membrane, it is pinched off by a scission GTPase dynamin, which is a critical step in the beginning of endosomal trafficking (Edeling et al., 2006; Warren et al., 1998; Santini et al., 1998; Orsini et al., 1999; Signoret et al., 1998). Endosomal trafficking is mediated by significant actin remodeling to provide the rails on which vesicle transport is facilitated either for recycling or lysosomal degradation. The fate of these vesicles was classically considered to be controlled by Rab GTPase family members (belonging to the family of Ras monomeric G-proteins), wherein enrichment of vesicles with specific members were sorted to lysosomes or recycled. For example enrichment of vesicles with Rab5 seem to lead to effective recycling (Seachrist et al., 2002; Zerial and McBride, 2001). However, in addition to Rab family members, receptor ubiquitination determines the fate of the endocytosed βAR (Shenoy et al., 2001, 2008). Ubiquitination is the addition of ubiquitin to a substrate protein. Agonist stimulation of βAR leads to rapid ubiquitination by the E3 ubiquitin ligase Nedd4 (neuronal precursor cell-expressed developmentally downregulated 4). Although Nedd4-directed ubiquitination directs the βAR toward lysosomal compartments (Shenoy et al., 2001, 2008), this process is dynamically regulated by deubiquitinases such as USP20 and USP33, which reverse βAR ubiquitination (Berthouze et al., 2009). The reversal of ubiquitination impairs lysosomal trafficking and shifting the process toward βAR resensitization and recycling. It is important to point out that even though βARs primarily engage and utilize β-arrestin-dependent mechanisms for endocytosis, there is evidence that other GPCRs like protease-activated receptor-1 or 5-hydroxy-tryptamine 2A serotonin receptor undergo endocytosis using β-arrestin-independent pathways (Bhatnagar et al., 2001).

Cardiac Remodeling

The heart functions as a single unit performing cardiac contraction from the time of its inception to death and is composed of multiple cell types that are in perfect synchrony. A major cell type in the heart is represented by cardiomyocytes, which are the primary drivers of contraction and supported by nonmyocytes including fibroblasts, endothelial cells, mast cells, vascular smooth muscle cells, and extracellular matrix providing elasticity to the contracting heart. A key aspect of this elasticity is the innate ability of the heart to change its contractile capacity in response to increasing mechanical load either due to physiological needs like exercise or narrowing arteries in cardiovascular disease. In this context, the mechanical load on the heart could increase due to various stimulus including but not limited to stress, growth, increase in the pressure or volume, mutations in proteins, or loss of contractile tissue (Frey et al., 2004). Therefore, in order to generate greater force to supply the same amount of blood to the body, the heart undergoes remodeling. In the classic response, the heart undergoes cardiac hypertrophy, which is thickening of the myocardium resulting in decrease in size of chambers (atria and ventricles). Selective enlargement of cardiomyocytes is associated with transcriptional upregulation of contractile proteins and their accumulation in the myocytes. The left ventricle is a critical chamber in generation of contractile pumping force and also senses mechanical load/systemic pressure and may respond by left ventricular hypertrophy. Hypertrophy is one of the most common signs of cardiac remodeling and can occur in response to physiological as well as pathological responses (Gradman and Alfayoumi, 2006). The hypertrophic responses of the left ventricle are empirically classified into physiological and pathological hypertrophy (**Fig. 2**) (Gradman and Alfayoumi, 2006; Levy et al., 1988; Frey et al., 2004).

Physiological Hypertrophy

Left ventricular hypertrophy in response to growth signals and/or chronic exercise is considered physiological hypertrophy. A key classical component of such a hypertrophic response is its reversal following the removal of stress. For example, left ventricular changes in athletes are remodeled back to the basal state when the athlete retires. Physiological hypertrophy is associated with an increase in myocyte volume and formation of new sarcomeres (McMullen and Jennings, 2007). At the molecular level, strenuous exercise or regulation of organs during postnatal growth is associated with significant release of insulin-like growth factor 1 (IGF1) (Conlon and Raff, 1999; Serneri et al., 2001). IGF1 acts via its receptor IGF1R, which mediates a series of downstream signals that activate PI3Kα, which enhances antiapoptotic Akt/PKB (protein kinase B) signaling (Schiaffino and Mammucari, 2011). Akt/PKB activates of mTOR (target of rapamycin) signaling, which mediates cell growth and a hypertrophic response (Schiaffino and Mammucari, 2011). Consistent with activation of these pathways, cardiomyocytes-specific overexpression IGFR1 or PI3Kα leads to physiological hypertrophy in the absence of features of apoptosis. Thus, physiological hypertrophy is considered to be beneficial and provides efficient adaptation of cardiac function in response to increasing demands of the body to growth.

Pathological Hypertrophy

Pathological hypertrophy is also characterized by left ventricular hypertrophy and occurs in response to stresses including systemic hypertension, ischemia, and mutations in contractile proteins leading to increased load on myocytes. However, it is not known whether this hypertrophy occurs due to the presence of intermittent unique signals, or a result of chronic stress signals (Frey et al., 2004). One of key outcomes of pathological hypertrophy is that despite management of the stress, ventricular hypertrophy is maintained, and with time can result in dilation and heart failure. In contrast to physiological hypertrophy, pathological hypertrophy is a part of an adaptive response termed "adaptive hypertrophic response" and continues to transition to "maladaptive hypertrophic response" leading to dilation characterized by cardiomyocytes apoptosis (Kehat and Molkentin, 2010; Dorn, 2009a). "Adaptive" and "maladaptive" hypertrophy are on a physiological continuum, and hearts may transition between the two, which are difficult to distinguish. Although there could be molecular signatures identifying these two seemingly similar phenotypes, comprehensive studies are still needed to define these signatures. However, a recurrent observation with pathological hypertrophy is the observation of fibrosis, apoptosis, and necrosis of myocytes (McMullen and Jennings, 2007). It is well known that many GPCRs are activated in response to cardiovascular stress, including both Gαs and Gαq pathways (Smrcka et al., 1991; Taylor and Exton, 1991; Taylor et al., 1991). The Gαq initiates PLCB-mediated phospholipid hydrolysis of PIP_2 to diacyl glycerol (DAG) and inositol trisphosphate (IP_3) (Smrcka et al., 1991; Taylor et al., 1991; Taylor and Exton, 1991). DAG activates PKC-dependent pathways, leading to the activation of ERK, JNK, and p38. The IP_3 generated also induces calcium increase, thereby activating calmodulin. Stress-induced PLC signaling also actively contributes to the development of left ventricular hypertrophy. However, a key question that remains is whether pathological responses observed in the heart due to chronic versus intermittent stress would a) manifest in similar phenotypes and b) activate different molecular signatures. In this context, studies by Perrino et al. suggest differential phenotypic and molecular responses (Perrino et al., 2006), supporting the idea that hearts could respond differently to these insults to remodel appropriately.

Signaling in Heart Failure

Sympathetic overdrive is one of the key factors involved in increased cardiac output, but chronic sympathetic activation also simultaneously leads to phosphorylation of βARs. In addition, increase in catecholamines not only leads to βAR phosphorylation but is also associated with increased GRK2 expression. Thus the concomitant increase in the agonist and elevation in GRK2 results in enhanced β-arrestin binding and loss of G-protein coupling (Lefkowitz, 1998). Increased βAR phosphorylation is a key driving force for cardiac dysfunction and ensuing heart failure (Rockman et al., 2002; Bristow and Ginsburg, 1986). Therefore, impaired G-protein coupling (desensitization) and loss of surface βARs (downregulation) due to elevated GRK2 are key hallmarks of heart failure (Rockman et al., 2002; Hamdani and Linke, 2012; Bristow, 2000; Bristow et al., 1982, 1986; El-Armouche and Eschenhagen, 2009; Murphy et al., 2010; Bristow and Ginsburg, 1986). It is important to note that there is a substantial decrease in the levels of β1AR compared to β2AR in heart failure (Freedman and Lefkowitz, 2004).

In addition to the classic sympathetic overdrive that underlies heart failure, many comorbid conditions such as hypertension, dyslipidemia, obesity, and diabetes are associated with significant proinflammatory cytokines including TNFα (Katsuki et al., 1998; Kenchaiah et al., 2002; Hippisley-Cox and Coupland, 2016b). TNFα is a known cardiac-depressant, and its overexpression in the rodent heart results in deleterious cardiac remodeling and heart failure (Kubota et al., 1997; Feldman et al., 2000). TNFα-dependent effects are thought to be mediated by altered Ca2+, sphingolipid mediators, arachidonic acid, and nitric oxide (Prabhu, 2004). In addition, a recent study showed that elevated TNFα results in increased GRK2 expression, which may noncanonically regulate βAR function by phosphorylating and desensitizing the receptor (Vasudevan et al., 2011). Thus, such a process could alter the canonical response of βARs to sympathetic hormones like epinephrine/norepinephrine. These observations explain the potential mechanistic pathways that underlie the risk factors for heart failure in comorbid conditions. Consistently, β-blockers are contraindicated in diabetes and obesity (Lee et al., 2011), supporting the idea that βARs may be desensitized through noncanonical mechanisms that need better understanding to develop therapeutic strategies in response to increased proinflammatory cytokines like TNFα.

Drug Targets and Impact in Clinical Medicine

Targeting of GPCRs constitutes over a third of all marketed drugs for the treatment of hypertension, heart disease, cancer, Alzheimer's disease, and asthma. β-Blockers have been one of the most clinically proven classes of therapeutics in cardiovascular medicine and are used as a first line of therapy following myocardial infarction and in control of hypertension, arrhythmia, and angina (Rutten et al., 2010; De Caterina and Leone, 2011). β-Blockers bind to βARs and block endogenous catecholamines from binding, thereby regulating inotropic and chronotropic effects through β1ARs in the heart (Rohrer et al., 1996). However, use of β-blockers may impinge on the function of β2ARs in the lungs (Jacobsen, 2011) and in maintaining vascular tone (Pourageaud et al., 2005), causing deleterious side effects. Given the complexity of βAR signaling in different organs, more refined approaches are necessary to specifically target individual aspects of GPCR function. In this context, pharmacological dissection of signal transduction pathways activated by GPCRs becomes an important component as revealed by in-depth studies being performed using "biased agonists" (Marti-Solano et al., 2013). Consistent with the diverse functions mediated by GPCRs, use of biased agonist will become important as they could selectively activate or block a subset of downstream signals allowing for harnessing appropriate signaling repertoire for a specific response (Marti-Solano et al., 2013). Use of these biased agonists would allow for specific targeting of unique GPCR responses without generating off-target signals that could have adverse effects. Further, these biased agonists could selectively target a downstream signaling pathway to provide beneficial clinical outcomes.

Conclusion

This article provides an overview of the current state of understanding of GPCR signaling using βARs as prototypical receptor in the context of desensitization, resensitization, and its significance in the heart. It is evident from many studies that homeostasis of βAR signaling is of utmost importance in cardiac function. Given that βAR activity/function relies on the delicate balance between desensitization and resensitization, i.e., the kinase and the phosphatase arms of maintaining receptor function, it becomes imperative to study the underlying signaling components and mechanisms as we move toward the use of biased agonists.

Introduction

Sinus tachycardia is a normal physiological phenomenon that is described as an appropriate heart rate (HR) increase exceeding 100 beats per minute (bpm) while in sinus rhythm. This normally occurs in response to stress that increases sympathetic nervous system activity. In contrast, there are multiple syndromes in which sinus tachycardia occurs in response to minimal stress and is deemed inappropriate in nature; these include postural tachycardia syndrome (POTS) and inappropriate sinus tachycardia (IST).

POTS is defined by chronic symptoms of orthostatic intolerance that are worse with standing in conjunction with an increase in HR of $\geq$30 bpm within 10 min of standing (Sheldon et al., 2015). Additionally, orthostatic hypotension must be ruled out as a potential cause of symptoms. IST is defined by the presence of sinus tachycardia ($\geq$100 bpm) at rest or a mean 24 h HR $\geq$90 bpm (Sheldon et al., 2015) and results in symptomatic palpitations among other symptoms. To date, there is no known mortality from either of these conditions, but each condition can negatively impact quality of life.

In this article, we will discuss the clinical approach to the patient with symptomatic sinus tachycardia of unknown cause, as well as the epidemiology, pathophysiology, and management of POTS and IST.

Epidemiology

Postural Tachycardia Syndrome

POTS is identified as a syndrome and not a disease with a single discrete pathophysiological mechanism. Its overall prevalence is approximately 0.2% (Sheldon et al., 2015), with an estimated 500,000–3,000,000 individuals affected in the United States alone (Robertson, 1999; Garland et al., 2007). The majority of patients that present with POTS are female, with a female to male ratio of approximately 5:1. The age of onset is typically between the ages of 13 years and 40 years. Moreover, it has been reported that 12.5% of patients have a family history of orthostatic intolerance (Thieben et al., 2007). Little is known about the long-term outcomes of POTS; it is perceived as a chronic condition with no known mortality, and with at least partial improvement in many, but not all, patients (Sheldon et al., 2015).

Inappropriate Sinus Tachycardia

Including both symptomatic and asymptomatic patients, the prevalence of IST is estimated to be approximately 1.2% in a middle aged population (Still et al., 2005). There is also a recognized association between IST and health care workers (Krahn et al., 1995). It is not clear if this is representative of the overall IST population, or if this reflects a subgroup that is more likely to seek medical attention for these symptoms (Pellegrini and Scheinman, 2016). Similar to POTS, patients with IST are primarily young women (Brady et al., 2005), although it has also been reported in older individuals as well (Lopera et al., 2003). There is no known mortality associated with IST (Sheldon et al., 2015).

Associated Conditions

Chronic fatigue syndrome

Chronic fatigue syndrome (CFS) is characterized by persistent or recurrent unexplained fatigue and related symptoms for at least 6 months (Garland et al., 2015). According to the Centers for Disease Control and Prevention (CDC) criteria, CFS is defined as a case-defining fatigue associated with at least four of the following symptoms: impaired short-term memory or concentration, sore throat, tender lymphadenopathy, muscle pain, joint pain, headaches, sleep disturbance, and postexercise malaise (Okamoto et al., 2012). Similar to POTS, it is a clinical syndrome that is more commonly observed in females.

There is a substantial overlap between POTS and CFS. POTS is associated with several symptoms seen in CFS patients, including fatigue, lightheadedness, neurocognitive deficits, and exercise intolerance; it has been identified in 19%–70% of patients with CFS (Hoad et al., 2008; Schondorf et al., 1999; Stewart et al., 1999). Moreover, there is a high prevalence of fatigue (48%–77%) and CFS diagnosis (17%–23%) in POTS patients (Lewis et al., 2013). When POTS patients were grouped according to whether or not they met the criteria for a CFS diagnosis, there were no differences between groups in the magnitude of orthostatic tachycardia or orthostatic hypotension, supine and upright plasma norepinephrine values, or plasma volume (Okamoto et al., 2012). However, CFS in POTS was associated with increased sympathetic tone when supine and greater increases in sympathetic activity during standing. The lack of distinguishing features between POTS patients with and without CFS indicates that they may not be distinct clinical entities. While almost all patients with POTS experience chronic fatigue, a subset of these patients will also meet criteria for CFS. This might represent a distinct subset of the larger CFS population. IST is also speculated to be associated with CFS (Brady et al., 2005). To date there is limited research examining this relationship.

Ehlers–Danlos syndrome—hypermobility type

Ehlers–Danlos syndrome (EDS) is a heterogeneous disorder that presents in several forms (Castori et al., 2017), and is linked to sequence variations in genes encoding for fibrillary proteins and/or collagen processing enzymes (Wallman et al., 2014). It is characterized by fragile connective tissue, skin hyperextensibility, and joint hypermobility. The presence of EDS has been observed to be significantly higher in patients with POTS (18%) compared to autonomic patients without POTS (4%) and the general population (0.02%) (Wallman et al., 2014).

In particular, patients with hypermobile EDS (hEDS) frequently experience symptoms of autonomic dysfunction that are prevalent in POTS patients (Hakim et al., 2017; Tinkle et al., 2017), such as lightheadedness, nausea, sweating, and chest tightness (Gazit et al., 2003). Blood pressure and HR responses consistent with POTS have been observed to be the most typical responses to tilt in patients with hEDS (De Wandele et al., 2014). In addition to standing, POTS-like symptoms and orthostatic intolerance can be triggered by physical exercise, heavy meals, and a warm environment. hEDS is the subtype that is most commonly associated with POTS (Mathias et al., 2011), although the exact mechanisms connecting the two syndromes are unknown.

Vasovagal syncope

Vasovagal syncope (VVS) is a form of neurally mediated (or reflex) syncope that usually occurs with upright posture held for more than 30 s, or with exposure to emotional stress, pain, or medical settings (Sheldon et al., 2015). It is associated with hypotension

and relative bradycardia. POTS is a common confounder of VVS and presyncope. About 25% of patients who fulfill the diagnostic criteria for POTS develop VVS during tilt table testing (Carew et al., 2009). Despite the overlap, these disorders can have distinct hemodynamic patterns during tilt table testing (Nwazue and Raj, 2013). Patients with VVS hold a steady BP for several minutes (often >10 min) prior to developing symptoms and experiencing a rapid drop in BP. In contrast, during head-up tilt, POTS patients experience an excessive increase in their HR often without a decrease in BP. VVS patients typically experience symptoms after prolonged sitting or standing, while POTS patients experience symptoms shortly after a body position change, which is then sustained. Moreover, POTS typically affects individuals between the ages of 13–50 years, while VVS can occur at any age, with the first syncopal episode usually in the second or third decade of life (Nwazue and Raj, 2013; Sheldon et al., 2006). Although both disorders predominantly affect females, POTS does so to a greater extent (85%–90%) compared to VVS (60%).

Psychiatric illnesses

Given the presenting symptoms of POTS and IST, it is not uncommon for these patients to be initially mislabeled as having psychiatric disorders such as anxiety or depression. There is no increased prevalence of major depressive disorders or anxiety disorders in POTS patients in relation to the general population (Raj et al., 2009b). Symptoms of depression and anxiety do exist in this population group, but these are attributed to the underlying disease processes leading to increased sympathetic nervous system activity and sinus tachycardia rather than a primary psychiatric illness (Khurana, 2006; Masuki et al., 2007). Mental clouding, often described as "brain fog," is a particularly common symptom described by POTS patients and may be attributed to deficits in selective attention and cognitive processing (Karas et al., 2000; Arnold et al., 2015). Sleep disturbances and fatigue are also common findings that likely contribute to the decreased quality of life that many of these patients experience (Bagai et al., 2011; Benrud-Larson et al., 2002). For patients with IST, any proposed or theoretical relationship between IST and psychiatric illness has not been well described to date.

Pathophysiology

Postural Tachycardia Syndrome

The characteristic orthostatic tachycardia observed in POTS is known to be a "final common pathway" of multiple pathophysiologic processes; therefore, POTS is more appropriately referred to as a clinical syndrome reflecting several heterogeneous disorders rather than a disease (Garland et al., 2015; Jones et al., 2016). While the exact mechanisms that underlie POTS remain unknown, specific subtypes have been described. Due to the overlapping nature of these subtypes, it is often difficult to identify the clinical distinctions between them in individual patients.

Hypovolemia

A deficit in total blood, plasma, and red cell volume is a fairly common finding in POTS patients, occurring in up to 70% of patients (Sheldon et al., 2015; Raj et al., 2005a). Normally, plasma renin activity and angiotensin II (Ang II) are expected to increase in response to hypovolemia in order to promote blood volume expansion. Compared to healthy subjects, POTS patients have significantly lower serum levels of aldosterone and inappropriately low levels of plasma renin activity (Raj et al., 2005a). It has also been reported that circulating Ang II levels are elevated without a parallel increase in angiotensin (1–7) (Stewart et al., 2009; Mustafa et al., 2011). One possible mechanism for the elevated Ang II in these POTS patients is decreased Ang II degradation as a result of blunted angiotensin-converting enzyme 2 (ACE2) activity. The cause of decreased ACE2 activity and the exact mechanism by which elevated plasma Ang II contributes to POTS remain unclear. There also seems to be blunted angiotensin II receptor type 1 (AT2R) activity, as POTS patients were found to have low levels of aldosterone despite the high levels of Ang II (Mustafa et al., 2011), and had a reduced vasopressor response to an Ang II infusion (Mustafa et al., 2012). These abnormalities in the renin–angiotensin–aldosterone system may contribute to hypovolemia and impaired sodium retention in POTS patients.

Partial autonomic neuropathy

A subset of POTS patients is described to have small fiber neuropathy, usually in the lower limbs (Jacob et al., 2000). This causes sympathetic denervation and an inability to adequately vasoconstrict in response to orthostasis, leading to decreased venous return and stroke volume. This can result in a secondary increase in sympathetic tone and tachycardia in an effort to maintain cardiac output and blood pressure. The small fiber neuropathy in POTS patients is usually painless, and does not present with classic symptoms of a typical length-dependent neuropathy (Gibbons, 2014). It is estimated that approximately 50% of POTS patients may have distal small fiber neuropathy (Peltier et al., 2010; Thieben et al., 2007; Haensch et al., 2014).

Hyperadrenergic state

POTS patients may have elevated levels of plasma norepinephrine, suggestive of a hyperadrenergic state. A hyperadrenergic state in POTS is observed in up to 50% of patients, and is characterized by a systolic BP increase of $\geq$10 mmHg while standing upright for 10 min, and norepinephrine levels $\geq$600 pg/mL while standing (Sheldon et al., 2015). Patients experience similar or greater HR increases than nonhyperadrenergic POTS, but have more symptoms of sympathetic activation, including palpitations, anxiety, tachycardia, and tremulousness (Low et al., 2009). This elevated sympathetic tone can be a primary underlying problem for POTS patients, although it is often secondary to a partial dysautonomia or hypovolemia (Raj, 2013). In addition, prior studies have

shown that an increased phase IV overshoot of the Valsalva maneuver can be seen in this hyperadrenergic state (Gibbons et al., 2013).

Autoimmune autoantibodies

A subset of POTS patients report an acute "viral-like" illness a few weeks to a few months prior to the onset of symptoms, suggesting a potential immune-mediated pathophysiology (Jones et al., 2016). A potential relationship has been identified between circulating autoantibodies and POTS. A low titer of ganglionic acetylcholine receptor (AChR) antibodies was detected in approximately 15% of POTS patients evaluated at the Mayo Clinic between 1993 and 2003 (Thieben et al., 2007), although this might be an overestimate by current standards (Vernino et al., 2016). More recently, autoantibodies (AAb) to α1-adrenergic receptors (α1AR) and β1/2-adrenergic receptors (β1AR/β2AR) receptors have been reported (Li et al., 2014). Both α1AR and βAR AAb can have a direct stimulatory effect on adrenergic receptors. They can also exert an allosteric-mediated positive modulatory effect upon β1AR (pure agonist) and a negative modulatory effect on α1AR activity (partial agonist–antagonist) (Fedorowski et al., 2016). It is postulated that partially blocked α1AR could cause impaired vasoconstriction in response to norepinephrine (the natural ligand), resulting in greater initial hypotension with standing (**Fig. 1**) (Li et al., 2014). This may lead to an exaggerated sympathoneural response (with increased norepinephrine) to achieve adequate vasoconstriction. This may lead to the orthostatic tachycardia that is characteristic in POTS, as the price for BP preservation. Furthermore, the presence of β1AR/β2AR-activating AAb could further contribute to the marked tachycardia seen in POTS patients (Li et al., 2014).

Autoantibodies targeting cardiac lipid raft-associated proteins have also been found in patients with POTS (Wang et al., 2013). Targets include proteins regulating cellular processes such as signaling, metabolism, chaperones, and transcription. The interaction between these autoantibodies and proteins may trigger alterations in signaling pathways, producing cardiovascular abnormalities associated with POTS. However, the specific involvement of such proteins in the pathogenesis of POTS remains unknown.

Norepinephrine transporter deficiency

A rare form of hyperadrenergic POTS is caused by a loss of function mutation in the gene encoding for the norepinephrine transporter (NET) (Shannon et al., 2000). This mutation has only been found in one family. However, it has been observed that a broader group of POTS patients have decreased NET protein expression (from vein biopsies) compared to healthy subjects (Lambert et al., 2008). This deficiency increases synaptic norepinephrine through diminished clearance, and results in greater sympathetic nerve activation. Pharmacological inhibition of NET can also occur with many antidepressant and attention deficit medications, particular those in the serotonin-norepinephrine reuptake inhibitor (SNRI) class (Raj, 2006). Pharmacological NET inhibition can worsen tachycardia and symptom burden in POTS patients when standing (Green et al., 2013).

Mast cell activation disorder

A subset of POTS patients has mast cell activation without an overt trigger. These patients present with severe episodic flushing during tachycardia, have abnormal increases in urine methylhistamine concentrations, and often have hyperadrenergic features accompanying orthostatic hypertension (Jones et al., 2016). It remains unclear whether sympathetic stimulation triggers mast cell activation in these patients, or whether primary mast cell activation induces the release of vasodilators and compensatory sympathetic stimulation occurs (Shibao et al., 2005).

Gravitational deconditioning

Due to their disability, many POTS patients have restrictions on their activity, which can result in physical deconditioning (Garland et al., 2015). Even if this is not the primary cause of their POTS, it is often a contributing factor to their symptoms and functional limitation. When upright, patients exhibit typical indicators of deconditioning, including persistent tachycardia, reduced stroke volume, reduced left ventricular mass, and reduced peak oxygen uptake (Fu et al., 2010). Orthostatic tachycardia improves with a structured exercise program. In contrast, some patients continue to experience symptoms, suggesting that deconditioning may be a secondary mechanism in the development of POTS (Parsaik et al., 2012). For example, patients can become physically deconditioned due to another illness, or with prolonged bed rest, and develop POTS-like symptoms (Garland et al., 2015).

Although it remains unclear whether deconditioning is a primary or secondary phenomenon to POTS, a program of aerobic exercise and resistance training can improve exercise tolerance and ameliorate various features of POTS (Mathias et al., 2011). When POTS patients participated in 3 months of progressive exercise training, maximal oxygen uptake increased by 11%, indicating an increase in physical fitness (Fu et al., 2010). Left ventricular mass, end-diastolic volume, blood and plasma volumes also increased after training. Most importantly to the patients, their quality of life improved if they completed the exercise-training program.

Inappropriate Sinus Tachycardia

The mechanisms underlying IST are not well defined, but they are likely multifactorial and complex. Several associated pathophysiological changes can potentially result in the syndrome, including increased sinus node automaticity, beta-adrenergic receptor hypersensitivity, decreased parasympathetic activity, and impaired neurohumoral modulation (Sheldon et al., 2015; Chiale et al., 2006). The fundamental tension is between whether the underlying pathophysiology of IST results from abnormal autonomic regulation, abnormal sinus node function, or a combination of both (Olshansky and Sullivan, 2013; Nwazue et al., 2014).

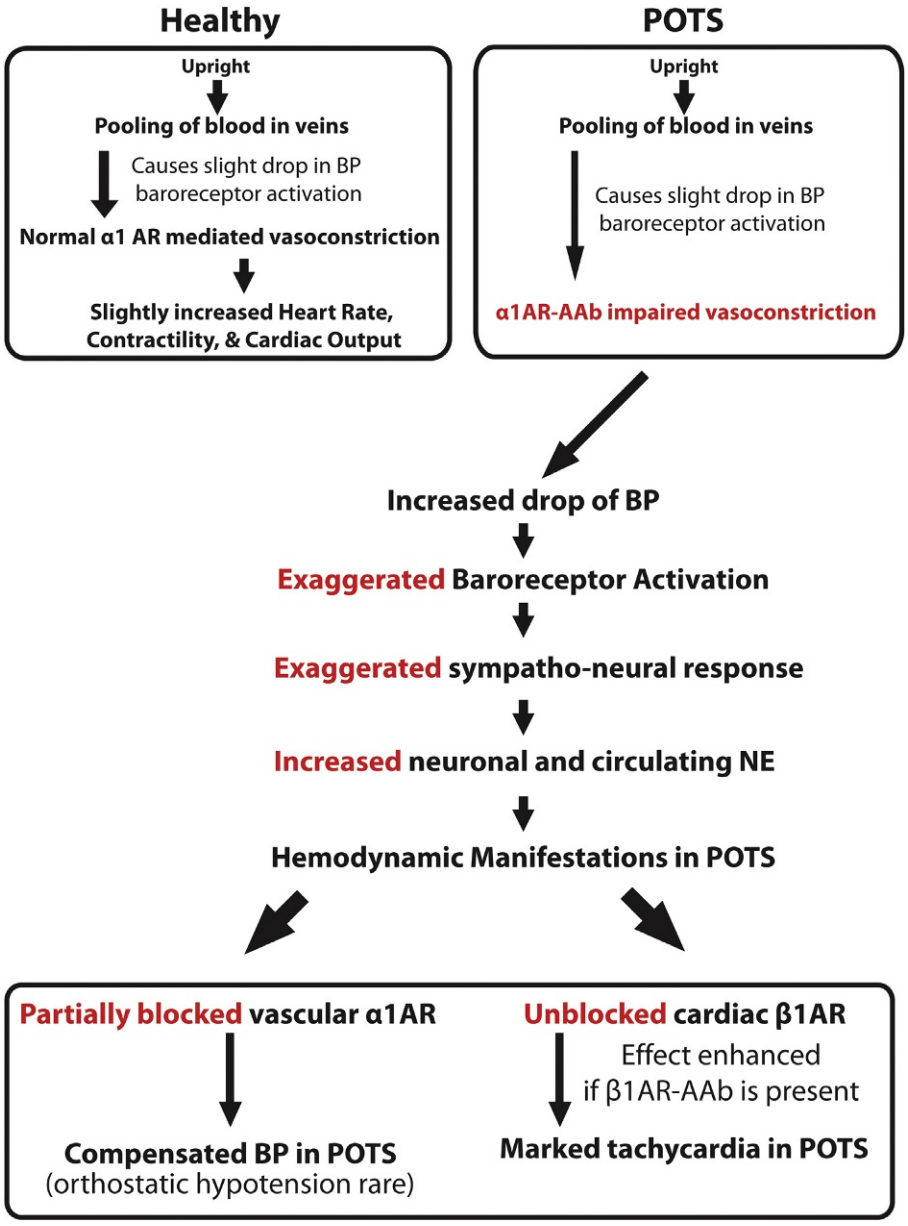

Fig. 1 Postulated mechanisms for α1-adrenergic receptor and β1/2-adrenergic receptor autoantibodies in the pathophysiological development of postural tachycardia syndrome. Serum autoantibodies may have a negative modulatory effect on α1AR activity and a positive modulatory effect on β1/2AR activity. The compensatory responses to these receptor blockades could contribute to hemodynamics of postural tachycardia syndrome. *α1AR*, α1-adrenergic receptor; *β1AR/β2AR*, β1/2-adrenergic receptor; *POTS*, postural tachycardia syndrome. Reproduced from the *Journal of the American Heart Association*, Autoimmune Basis for Postural Tachycardia Syndrome, 2014, H. Li *et al.*, with permissions from Wiley Blackwell.

While both IST and POTS patients appear to have abnormal autonomic modulation, with elevated sympathetic tone and diminished parasympathetic tone, it is more marked in IST patients (**Fig. 2**) (Nwazue et al., 2014). This may indicate a stronger autonomic influence in the pathophysiology of IST compared to POTS. The exaggerated sympathetic tone in IST patients may reflect an increase in antibodies to β-adrenergic receptors. Moreover, there are no significant differences in intrinsic HR (the HR after pharmacological autonomic blockade with propranolol and atropine) between IST, POTS, and healthy subjects (Nwazue et al., 2014). This suggests that abnormal sinus node automaticity may not play an important pathophysiological role in either disorder.

Clinical Evaluation

Sinus tachycardia is a normal response to exertion, but is also a common finding in clinical practice, and can be an important vital sign to help assess whether a patient may be acutely ill. Acute pathologies such as infection or dehydration can result in sinus

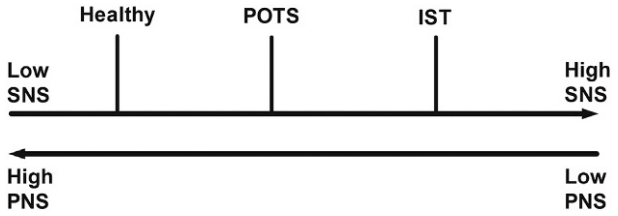

Fig. 2 Spectrum of sympathetic and parasympathetic autonomic nervous system activity in postural tachycardia syndrome and inappropriate sinus tachycardia. Healthy subjects have an appropriate balance of high parasympathetic tone and low sympathetic tone. In contrast, both inappropriate sinus tachycardia and postural tachycardia syndrome patients appear to have abnormal autonomic modulation, with elevated sympathetic tone and diminished parasympathetic tone. This effect is more marked in inappropriate sinus tachycardia patients. *IST*, inappropriate sinus tachycardia; *POTS*, postural tachycardia syndrome. Table 1 Diagnostic criteria for postural tachycardia syndrome and inappropriate sinus tachycardia

Postural tachycardia syndrome
1. Frequent, chronic (>6 months duration), symptoms that occur and worsen with standing
2. An increase in HR of ≥30 bpm (≥40 bpm in patients <18 years of age) associated within 10 min of a position change from supine to standing (held for more than 30 s)
3. The absence of orthostatic hypotension (a sustained decline in BP ≥20 mmHg systolic or ≥10 mmHg diastolic within 3 min of standing)
Inappropriate sinus tachycardia
1. Sinus tachycardia (>100 bpm at rest or a mean 24-h HR >90 bpm)
2. The absence of a primary cause of tachycardia
3. Distressing and disabling symptoms associated with the palpitations

bpm, beats per minute.

Definition adapted from Sheldon, R. S., Grubb, B. P., 2nd, Olshansky, B., Shen, W. K., Calkins, H., Brignole, M., Raj, S. R., Krahn, A. D., Morillo, C. A., Stewart, J. M., Sutton, R., Sandroni, P., Friday, K. J., Hachul, D. T., Cohen, M. I., Lau, D. H., Mayuga, K. A., Moak, J. P., Sandhu, R. K. and Kanjwal, K. (2015). 2015 heart rhythm society expert consensus statement on the diagnosis and treatment of postural tachycardia syndrome, inappropriate sinus tachycardia, and vasovagal syncope. *Heart Rhythm 12*, e41–e63.

tachycardia and will often be fairly obvious on history and examination. In contrast, those patients who presents in sinus tachycardia with no acute cause are more challenging to assess and properly diagnose. In order to know when to suspect a diagnosis of POTS or IST, it is important to first understand the diagnostic criteria for these conditions.

Diagnostic Criteria

The diagnostic criteria for POTS and IST are displayed in **Table 1** (Sheldon et al., 2015; Freeman et al., 2011; Garland et al., 2015). POTS is defined by three criteria: (i) an increase of HR of at least 30 bpm in response to a change in posture from supine to standing within 10 minutes; (ii) symptoms of orthostatic intolerance; (iii) orthostatic hypotension must be absent. Importantly, in order for a diagnosis of POTS to be reached, symptoms should be chronic (≥6 months) in duration. In pediatric patients (age <19 years), a larger HR increase (≥40 bpm) is required to make the diagnosis due to physiological orthostatic tachycardia seen in children and adolescents (Singer et al., 2012).

The symptoms of orthostatic intolerance associated with POTS can both cardiac and noncardiac in nature (Raj, 2013). Cardiac symptoms include palpitations, lightheadedness, chest pain, and shortness of breath (Thieben et al., 2007; Raj, 2013). These symptoms should be worse with standing. Noncardiac symptoms include mental clouding or "brain fog," headache, nausea, exercise intolerance, fatigue, tremulousness, blurred vision, and sleep disturbances (Raj, 2013; Thieben et al., 2007).

IST is defined by: (i) the presence of sinus tachycardia (≥100 bpm) when awake at rest or a 24-h mean HR of ≥90 bpm; (ii) symptomatic palpitations that the patient finds distressing (Sheldon et al., 2015). The symptoms associated with the tachycardia are required for the diagnosis of this syndrome. Symptoms share overlap with POTS patients and include palpitations, chest pain, shortness of breath, fatigue, myalgias, and lightheadedness (Olshansky and Sullivan, 2013; Femenía et al., 2012). In order for a diagnosis of IST to be made, other primary causes for the sinus tachycardia should be ruled out (Sheldon et al., 2015).

Differential Diagnosis

There are a number of primary causes (**Table 2**) for appropriate sinus tachycardia that must be considered and excluded prior to considering POTS or IST as the underlying etiology (Olshansky and Sullivan, 2013; Peyrol and Levy, 2016; Femenía et al., 2012). These primary causes can include acute physiological stimuli, medications, dietary indiscretions, and some other medical conditions. Physiological stimuli such as exercise, panic attacks, pain, and physical deconditioning can cause an increase in HR both at

Table 2 Primary causes of sinus tachycardia

Physiological	Autonomic
Dehydration	Orthostatic hypotension
Exercise	Postural tachycardia syndrome
Emotion	Cardiac
Pain	Acute myocardia ischemia/infarction
Pregnancy	Cardiomyopathy
Medications	Myocarditis
Anticholinergics	Pericarditis
Alcohol	Infection
Caffeine	Metabolic
Sympathomimetics	Anemia
Tobacco	Cushing's disease
	Hyperthyroidism
	Pheochromocytoma
	Psychiatric
	Anxiety/panic attacks
	Respiratory
	Chronic obstructive pulmonary disease
	Pulmonary embolism
	Shock

rest and while standing. There are also multiple classes of medications that can increase HR and present with sinus tachycardia, including sympathomimetics, anticholinergics, and rebound tachycardia from beta-blocker withdrawal (Olshansky and Sullivan, 2013). Dietary intake of alcohol and caffeine can also increase HR. Numerous acute and chronic medical conditions can lead to sinus tachycardia, including relatively common conditions such as hyperthyroidism, anemia, and dehydration (Raj, 2013; Olshansky and Sullivan, 2013).

History and Physical Examination

A detailed history and physical examination are important in the diagnosis of POTS and IST in order to help exclude more common causes of sinus tachycardia. Both patients with POTS and IST should have chronicity to their symptoms, which can be a helpful distinguishing factor from more acute causes of sinus tachycardia. It is important to ask about aggravating and alleviating factors for symptoms. This can be useful for discriminating between POTS and IST. Symptoms associated with IST often worsen in response to physiological or emotional stimuli that increase HR (Sheldon et al., 2015). In contrast, POTS symptoms should primarily be worse in response to standing or orthostatic stress (Sheldon et al., 2015). Additionally, POTS symptoms also tend to be worse in response to alcohol, poor sleep, heat, and exercise (Raj and Sheldon, 2016).

Syncope is another clinical presentation that can have symptoms that are similar to those described by patients with both POTS and IST. Importantly, only a minority of patients with POTS describe a history of fainting (Raj, 2013). Although the prevalence of syncope in patients with IST is currently unknown, it should not be a predominant feature of the syndrome. A history in which fainting is a major complaint may warrant further exploration for other potential etiologies.

A detailed review of past medical history can be very helpful to identify other associated conditions with POTS and IST. POTS is associated with hEDS, and gastroparesis (Garland et al., 2015; Benarroch, 2012). Both POTS and IST may share some overlap with CFS (Brady et al., 2005). The exact nature of the relationships between POTS, IST, and other associated conditions are still being understood.

As part of a review of systems, it is important to ask questions about symptoms of autonomic dysfunction. This should include assessment for autonomic neuropathy, which can be present in neuropathic POTS patients. This should include inquiring about gastrointestinal involvement including symptoms of constipation and irritable bowel syndrome (Sheldon et al., 2015; Wang et al., 2015). An assessment of autonomic function can be helpful for distinguishing these conditions from other autonomic disorders.

Similar to history, the physical exam may be helpful to distinguish POTS and IST from other primary causes of sinus tachycardia. Importantly, a clinical volume assessment and examining for any findings suggestive of hyperthyroidism can be of value. Overall, there are few physical findings in POTS or IST to be found on exam. Approximately 50% of POTS patients will have a dependent acrocyanosis present in their legs; this appears as a red-blue discoloration that is cold to touch (Raj, 2013). A neurological examination is useful to perform to examine for signs of small fiber neuropathy, which may be present in some POTS patients (Jones et al., 2016). There are no reported specific physical findings to be identified in a patient with IST; its diagnosis remains one of exclusion (Olshansky and Sullivan, 2013).

The most valuable part of the physical examination is to obtain a set of orthostatic vital signs in patients presenting with sinus tachycardia. This can be performed most simply by means of a supine to standing maneuver. Ideally, the patient will lie supine for a few minutes before baseline measurements of supine BP and HR. At this point, the patient quickly transitions to an upright position on their own accord and maintains a standing position for up to 10 min with BP and HR measurements made at minutes 1, 3, 5,

and 10 of standing. The HR responses to orthostatic stress can be an important way to distinguish between POTS and IST (Fig. 3). In POTS patients, HR responses are helpful to illustrate whether or not the patient meets the HR criteria for a diagnosis of POTS. Typically, POTS patients will have more severe orthostatic tachycardia in the morning compared to later in the day (Brewster et al., 2012). Importantly, patients with IST can have an orthostatic tachycardia in addition to their resting tachycardia. Unlike in POTS patients, standing is not usually the predominant cause of symptoms in IST. Additionally, this test can be helpful in ruling out orthostatic hypotension as a possible cause for symptoms.

Investigations

The investigative approach to the patient with sinus tachycardia is displayed in Table 3. In addition to a complete history and physical exam, a baseline 12-lead electrocardiogram is essential to distinguish sinus tachycardia from other possible atrial tachyarrhythmias. A basic panel of blood work is useful to help eliminate common causes of sinus tachycardia. This should include a complete blood count with a hematocrit (to exclude anemia) and a thyroid stimulating hormone level (to exclude hyperthyroidism). These are class IIa recommendations (benefit likely to exceed harm) by the Heart Rhythm Society (Sheldon et al., 2015). Other laboratory studies should only be done on a case-by-case basis depending on the clinical suspicion of other primary causes of sinus tachycardia.

A 24-hour Holter monitor can be a useful investigation, particularly for the diagnosis of IST (Sheldon et al., 2015). It can be of use to investigate the trend and fluctuations of HR over an extended period of time, including the relationship between HR and symptoms as well as the responses to stimuli such as physical exertion (Femenía et al., 2012). Additionally, the results of the 24-h Holter may provide objective HR findings that meet diagnostic criteria (24-h HR of $\geq$90 bpm with symptoms) for IST. A Holter may also be of use in both POTS and IST patients if there are ongoing concerns that a transient nonsinus tachyarrhythmia may be contributing to symptoms (Raj, 2013). However, a Holter monitor in the absence of orthostatic vital signs is not adequate for diagnosing POTS as the position/activity during the HR increases are not known.

Other investigations to consider include an exercise stress test and a transthoracic echocardiogram. These tests can be of use to help screen for other primary cardiovascular or systemic pathologies, but should only be considered in select patients in which there is some index of suspicion (Sheldon et al., 2015). An echocardiogram can be useful to rule out structural heart disease, particularly in patients in whom a good cardiac examination is not technically possible. In patients with IST, an exercise stress test may show enhanced HR responses (Morillo et al., 1994). The benefits of this test for the diagnosis of POTS and IST have not been widely reported.

Autonomic Function Testing

Autonomic function testing is not generally needed for a diagnosis of POTS or IST. It should be reserved for cases where there is suspected involvement of the autonomic nervous system and where testing may be of helpful to distinguish from POTS, IST, and other autonomic disorders. A detailed examination of autonomic function can include a head-up tilt test, Valsalva maneuver, supine and upright plasma norepinephrine levels, and an assessment of sudomotor function. The details of these tests are beyond the scope of this article and will not be discussed here.

Head-up tilt test

Head-up tilt testing is appropriate for patients in whom orthostatic vitals do not meet diagnostic criteria for POTS, but there is a strong clinical suspicion. It can be helpful to better characterize the orthostatic tachycardia and BP responses during standing. Passive standing (such as with a head-up tilt table test) can be associated with a greater orthostatic tachycardia than active standing,

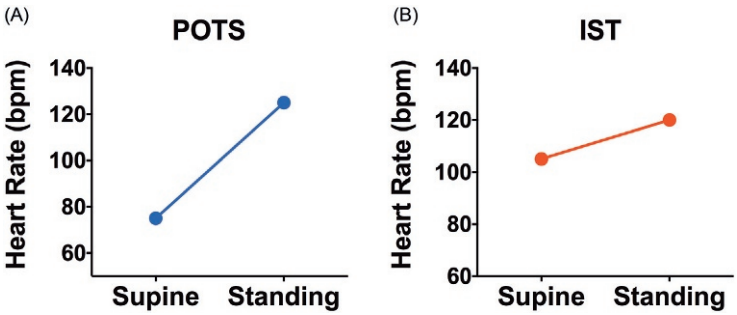

Fig. 3 Heart rate responses during supine and standing positions in patients with postural tachycardia syndrome (A) and inappropriate sinus tachycardia (B). When orthostatic vitals are taken as part of a physical exam, patients with postural tachycardia syndrome should have a normal heart rate while supine, but experience an excessive heart rate increase upon standing. In contrast, patients with inappropriate sinus tachycardia will have sinus tachycardia even while supine. These patients may often have an orthostatic increase in heart rate, but it is not usually as profound as for a patient with postural tachycardia syndrome. POTS, postural tachycardia syndrome; IST, inappropriate sinus tachycardia.

Table 3 Utility of investigations for assessing a patient with sinus tachycardia of unknown cause

Investigation	*Utility*	*Comment*
Orthostatic vitals	Essential	Assess whether patient meets diagnostic criteria for POTS. Rule out OH
Blood work	Essential	Helpful to rule out primary causes of sinus tachycardia
ECG	Essential	Assess for nonsinus tachyarrhythmias
Holter monitor	Most cases	Assess whether patient meets diagnostic criteria for IST. Rule out nonsinus tachyarrhythmias
Echocardiogram	Select cases	Rule out structural heart disease
Exercise stress test	Select cases	Assess heart rate responses to exercise
Head-up tilt test	Select cases	Useful in patients with an unclear diagnosis in which other autonomic disorders need to be ruled out
Valsalva maneuver	Select cases	Useful to differentiate between POTS, IST, and other autonomic disorders. POTS patients with mast cell activation or neuropathic subtypes may have abnormal responses
Plasma norepinephrine levels	Select cases	Elevated upright and absolute change from supine support a hyperadrenergic POTS subtype
Sweat testing	Select cases	Useful in POTS patients suspected of having a neuropathic subtype

POTS, postural tachycardia syndrome; *OH*, orthostatic hypotension; *IST*, inappropriate sinus tachycardia.

although the difference is not that great within the first 10 min (Plash et al., 2013). It can also be useful to distinguish between POTS, IST, and other types forms of orthostatic intolerance, such as VVS (**Fig. 4**).

Valsalva maneuver

A Valsalva maneuver provides an assessment of cardiovagal and adrenergic function. This test can be valuable to help differentiate POTS and IST from other autonomic disorders. In patients with POTS and IST, these responses should be intact and frequently normal compared to healthy subjects (**Fig. 5**) (Palamarchuk et al., 2016). POTS patients that have co-existing mast cell activation may show an exaggerated response, with an overshoot in late phase II and a heightened phase IV overshoot (Shibao et al., 2005). In contrast, patients with a neuropathic subtype of POTS have been found to have blunted phase IV overshoot in comparison to control subjects and patients with nonneuropathic POTS (Gibbons et al., 2013).

Plasma norepinephrine levels

Plasma norepinephrine levels can be obtained while supine and while standing (after at least 5–10 min); the baseline levels as well as absolute change can be helpful toward assessing the functioning of adrenergic terminals and the baroreflex (Low et al., 2013; Low, 2015; Goldstein et al., 1989). In POTS patients, the supine norepinephrine levels are usually normal, whereas absolute change and upright values can be elevated (usually >600 pg/mL) (Raj, 2006; Wagoner et al., 2016; Okamoto et al., 2012). This finding can be supportive of an underlying hyperadrenergic pathophysiological state that may be contributing to symptoms (Benarroch, 2012). Plasma norepinephrine levels are not normally performed in the workup of IST.

Sweat testing

Sweat testing is performed to assess sympathetic sudomotor axon function, and can be helpful for identifying patients with lower limb sympathetic denervation that can be characteristic in POTS patients with a neuropathic pathophysiological subtype (Low et al., 2013; Benarroch, 2012; Gibbons et al., 2013).

Management

There is no gold-standard therapy available for the management of POTS or IST. Both conditions must be managed in a graded approach that should first involve conservative nonpharmacological therapies, followed by pharmacological management as needed. Overall, strong evidence-based recommendations for management are lacking (Lau et al., 2016). A multidisciplinary approach is recommended in the management of POTS, involving different types of health care team members including nursing, physiotherapy, psychology, and physicians support (Kizilbash et al., 2014). This approach can certainly be of benefit for patients with IST as well (Brady et al., 2005; Shen, 2005).

Postural Tachycardia Syndrome

Management options for patients with POTS are displayed in **Table 4**.

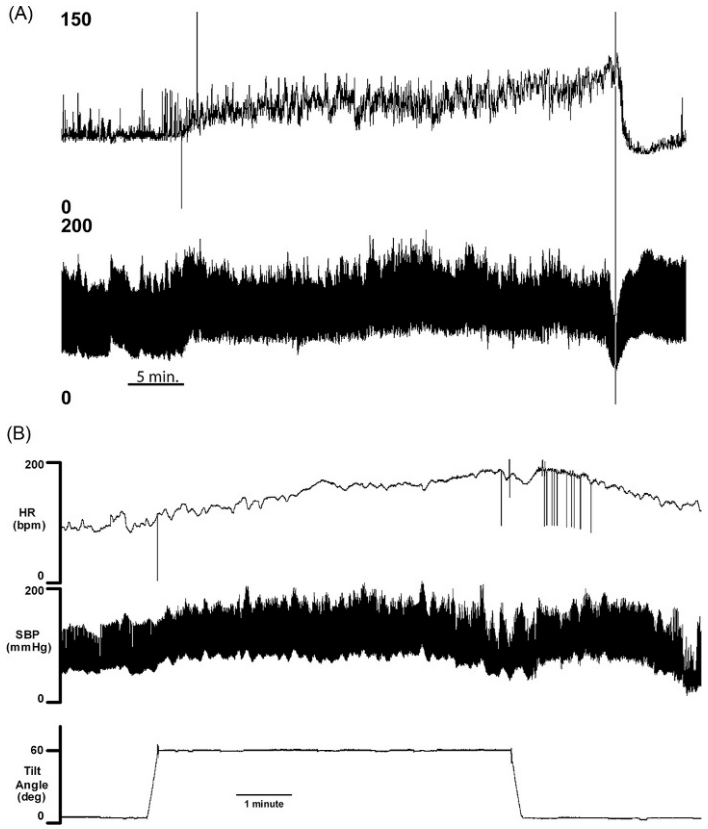

Fig. 4 Blood pressure and heart changes during head-up tilt testing for a patient with (A) vasovagal syncope and (B) postural tachycardia syndrome. Beat-to-beat blood pressure and heart rate responses are shown through the duration of testing. The patient with vasovagal syncope (A) exhibits a slight rise in heart rate over the upright phasing of testing (~35 min). In contrast, the patient with postural tachycardia syndrome (B) has an exaggerated heart rate response within minutes of being tilted upright. Blood pressure is well maintained for both patients through the majority of testing. *HR*, heart rate; *BP*, blood pressure. Reproduced from Electrophysiological Disorders of the Heart: Expert Consult, Chapter 73, 2012, S.R. Raj & R.S. Sheldon, with permission from Elsevier.

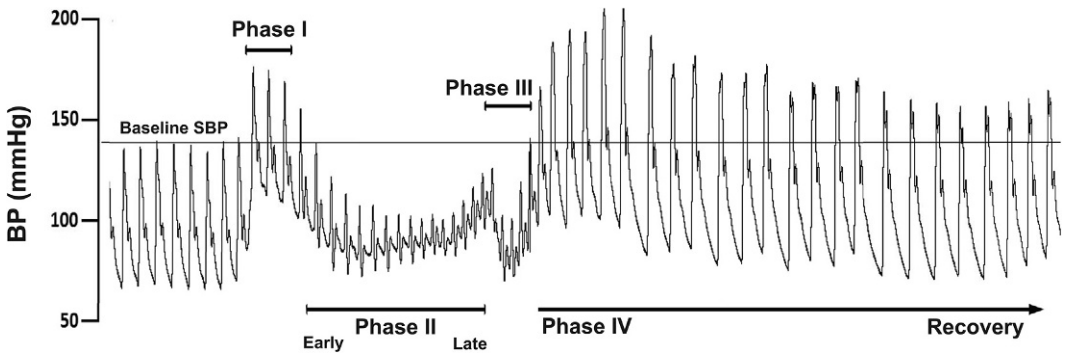

Fig. 5 Valsalva maneuver in a healthy subject. The test is performed by having the patient exhale against a closed glottis generating 40 mmHg of pressure for 15 s. The resulting blood pressure and heart rate waveforms can be broken down into four phases. Phase I represents a transient rise in blood pressure that occurs during the forced expiration. Increased intrathoracic pressure forces blood out of the pulmonary circulation, resulting in increased stroke volume and blood pressure. Phase II is commonly divided into an early (II_E) and late (II_L) interval. As intrathoracic pressure remains high during forced expiration, venous return decreases. This results in reduced stroke volume and blood pressure and represents the II_E component. The reduced blood pressure that occurs during phase II_E triggers a baroreceptor mediated increase in sympathetic tone causing a rise in heart rate and blood pressure that represents phase II_L. Phase III occurs upon termination of forced expiration, resulting in a decrease in intrathoracic pressure. This allows for increased venous return and causes a sudden decrease in blood in the systemic circulation resulting in a further drop in blood pressure. This drop in blood pressure causes another baroreceptor mediated increase in sympathetic tone resulting in a blood pressure overshoot that represents phase IV of Valsalva maneuver.

Table 4 Management of postural tachycardia syndrome

Nonpharmacological	*Comment*
Education	Critical
Exercise training	Very important; not easy
Increase fluid intake (2–3 L/day)	
Increase dietary salt intake (10–12 g/day)	
Pharmacological	
Volume expansion	
1–2 L bolus of normal saline IV	Only for use for acute worsening of symptoms
Fludrocortisone (0.05–0.2 mg/day PO once daily)	
Desmopressin (0.2 mg PO)	Only for occasional use
Antiarrhythmic medications	
Propranolol (10–20 mg PO QID)	Not well tolerated at higher doses
Ivabradine (5–7.5 mg PO once or twice daily)	
Pressor agents	
Midodrine (2.5–10 mg PO q4 hours three times daily)	Should not be taken within 4 h of bed
Clonidine (0.05–0.2 mg twice daily)	Can be associated with rebound hypertension and tachycardia
Methyldopa (125–250 mg PO twice daily)	
Other agents	
Pyridostigmine (30–60 mg PO three times daily)	
Modafinil (100 mg PO twice daily)	

Nonpharmacological

Education is at the forefront of conservative management options for POTS. Patients and families should be reassured that although POTS is a chronic condition, there are no reported cases of mortality from POTS. Additionally, even though the long-term outcomes from POTS are somewhat unknown, in many patients symptoms do seem to improve over time (Sheldon et al., 2015; Kizilbash et al., 2014). Patients should also be educated to limit or avoid triggers or activities that make symptoms worse (Benarroch, 2012).

Exercise-training program

Exercise is encouraged in patients with POTS, but should be undertaken in a gradual, graded approach given that it can also be an aggravating factor for symptoms, especially initially. Several studies have shown benefits from a short-term (3-month) exercise program in which patients first begin exercising in a recumbent or semirecumbent position (Fu et al., 2011; Fu and Levine, 2015). Cycling, swimming, and a rowing machine are activities that can be performed from these positions. These studies used an initial dose of 20–30 min of exercise (with a 5-min warm up and cool down), three times a week, at an intensity of 75% maximal target HR for their age (Fu and Levine, 2015). Additionally, these studies had patients perform strength training for 15–20 min, one to two times per week (Fu and Levine, 2015). Both cardio and strength sessions were increased as subjects became more fit, primarily in the second and third months. These studies found that exercise helped increase peak VO_2 as well as showing echocardiographic findings of significant cardiac remodeling (Fu and Levine, 2015). Another study found that a 3-month exercise program significantly improved quality of life and decreased HR responses to standing (George et al., 2016). In fact, 71% of patients no longer met POTS HR criteria at the end of the program (George et al., 2016).

An important issue raised from studies examining the therapeutic effects of exercise in POTS patients is nonadherence to therapy (Fu et al., 2010; George et al., 2016). In this regard, there are valuable clinical pearls clinicians should know to help patients be successful. Firstly, selecting an activity that can be performed in the recumbent position, such as rowing, swimming, or a cycling is important to minimize the effects of symptoms made worse in the upright position, especially initially (Raj, 2016). Secondly, patients must understand that it will take time (~4–6 weeks) before the benefits of exercise being to take effect (Raj, 2016). In fact, it is not unusual for patients to feel more fatigued upon starting an exercise program. Finally, it is important to educate patients that three months of training is not a "cure" for POTS. Similar to any patient, regular physical activity should be encouraged as a lifelong activity. Overall, the Heart Rhythm Society consensus statement for the management of POTS gives exercise a class IIa recommendation (Sheldon et al., 2015).

Fluids

Patients should be encouraged to increase both fluid (2–3 L) and dietary salt intake (10–12 g) per day if hypovolemia is suspected (Sheldon et al., 2015). POTS patients have been shown to have deficits in their circulating plasma volume (Raj et al., 2005a). It is believed that improved effective blood volume will help reduce the intensity of the reflex tachycardia associated with standing that may be contributing to symptoms.

Avoid potentially deleterious medications

Common medications that worsen symptoms should be avoided. These include nitrates or other diuretics, venodilators, and SNRI medications (Nwazue and Raj, 2013). Diuretics can decrease effective blood volume, and worsen symptoms driven by hypovolemia. Venodilators act to decrease preload and subsequently blood pressure leading to worsening reflex tachycardia. Selective NET inhibitors decrease the clearance of norepinephrine from synaptic terminals, which can lead to increased sympathetic activity resulting worsening symptoms secondary to increased HR.

Pharmacological

There are no drugs currently approved by the US Food and Drug Administration specifically for the treatment of POTS. All agents used are done so "off-label" and few have rigorous randomized clinical trials to support their use. Additionally, there is no "shotgun" first line agent to use for the pharmacological management of POTS. It is very important to consider the clinical features of the POTS and the possible pathophysiology that is leading to symptoms. In this way, medications can be selected that will best treat these deficits. Many of the pharmacological options to treat POTS can be broadly categorized into agents that target volume expansion, antiarrhythmic medications to slow HR, and pressor agents to improve peripheral vasoconstriction.

Blood volume expansion

In a presentation of a POTS patient with acute worsening of their symptoms, an intravenous bolus of 1–2 L of normal saline has been shown to acutely improve orthostatic HR and symptoms (Jacob et al., 1997; Gordon et al., 2000). For a patient with known POTS presenting in an acute care setting, like the emergency department, a normal saline infusion can be an effective option in such a scenario. This treatment modality acts to reduce hypovolemia in these patients. Essentially it follows a similar mechanism, but makes a much more acute impact, as increasing dietary fluid and salt intake. The long-term use of normal saline infusions as a means of treatment is not recommended (Sheldon et al., 2015). Significant risks include complications associated with central intravenous line insertion such as thrombosis and infection.

Fludrocortisone is a modified corticosteroid, which, at low doses (0.05–0.2 mg PO once daily), has predominantly mineralocorticoid activity resulting in sodium and water retention. This can be considered an adjunct to help boost plasma volume in addition to increasing dietary salt and water intake. There are no randomized controlled trials testing the use of fludrocortisone in POTS patients. A trial in patients with CFS and orthostatic intolerance did not find a significant improvement in symptoms, however this study focused on global symptoms rather than those secondary to orthostatic stress (Rowe et al., 2001). In patients with VVS, fludrocortisone may offer benefit in syncope recurrence in patients who reach a stabilized dose (Sheldon et al., 2016). Potential side effects of fludrocortisone include hypertension, fatigue, nausea, and hypokalemia (Lee and Krahn, 2016). The Heart Rhythm Society consensus statement suggests that despite limited evidence for the use of fludrocortisone in POTS patients, the potential benefits likely outweigh the risks (Sheldon et al., 2015).

Desmopressin (DDAVP) is a synthetic version of antidiuretic hormone and promotes free water retention. This has been tested in POTS patients with the hypothesis of eliciting blood volume expansion for POTS patients who are hypovolemic. One study found that DDAVP improved standing HR and symptoms in POTS patients upon acute administration (Coffin et al., 2012). Potential effects of its administration include hyponatremia (especially with the increased water intake advised for POTS patients), headache, and peripheral edema (Nwazue and Raj, 2013).

Antiarrhythmic medications

Propranolol, when used at low doses (10–20 mg PO four times daily), reduces supine and standing HR, and improves symptoms acutely (Raj et al., 2009a). Higher doses were found to make symptoms worse. Quality of life after three months of exercise training has been found to provide superior improvement in quality of life in comparison to long-acting propranolol despite both providing significant reductions in HR (Fu et al., 2011). To date, other beta blockers have not actively studied (Sheldon et al., 2015). Similar to fludrocortisone, the Heart Rhythm Society suggests propranolol can be considered for the treatment of POTS in the absence of evidence contraindicating its use (Sheldon et al., 2015). Some centers consider propranolol as first line treatment for POTS (Garland et al., 2015).

Ivabradine is a selective funny current (I_f) channel blocker that can be used to slow HR (DiFrancesco, 2010). It has been more extensively tested in the treatment of IST, but a retrospective case series of POTS patients prescribed ivabradine found that 60% of patients reported a symptomatic improvement with its use (McDonald et al., 2011). The major downside to this medication is a lack of availability in some countries, although this may change in the near future (Sheldon et al., 2015). Dosing is recommended at 5–7.5 mg once or twice daily.

Pressor agents

Midodrine is a pro-drug that is an alpha-1 adrenergic receptor agonist when converted to its active form. It can increase vascular resistance and venous return through peripheral constriction of arteries and veins. The improved venous return is believed to reduce the reflex tachycardia that accompanies standing. Midodrine may be more useful with the peripheral neuropathy seen in neuropathic POTS, where peripheral vasoconstriction may be impaired (Ross et al., 2014). Several studies in POTS patients have found the effects of midodrine to decrease supine and upright HR and improve symptoms acutely (Jacob et al., 1997; Gordon et al., 2000). Midodrine has several challenges associated with its use including the need for frequent dosing, its brief effect (~4 h), and

side effect of supine hypertension (Raj and Sheldon, 2016). As such, it is not recommended to be taken within 4–5 h of sleep (Jones et al., 2016). Other side effects of midodrine that may contraindicate its use include urinary retention in older men, and possible teratogenic effects when used in pregnant females (Raj and Sheldon, 2016). Expert opinion suggests that midodrine can be attempted for the management of POTS given the absence of contraindications against its use (Sheldon et al., 2015).

Clonidine and methyldopa are centrally acting sympatholytic agents that may be useful in patients with hyperadrenergic POTS. Clonidine is an alpha-2 receptor agonist that may be helpful in reducing symptoms in patients with prominent hyperadrenergic features (Gaffney et al., 1983). Methyldopa is a false neurotransmitter that exudes a similar effect, and has also been suggested for use in patients with a hyperadrenergic state (Shibao et al., 2005). It is thought to be easier to titrate in POTS patients in comparison to clonidine due to its longer half-life (Jacob and Biaggioni, 1999). The tolerability of these medications may be limited due to side effects including worsening drowsiness, fatigue, and mental clouding, all of which can be presenting complaints in POTS patients (Raj, 2013). Additionally, both medications may be less beneficial in POTS patients with significant neuropathic features, although data is lacking.

Droxidopa is a synthetic amino acid precursor for norepinephrine, and acts to increase synaptic levels of the neurotransmitter, enhancing the effects of vasoconstriction. It is postulated to act as an alternative to midodrine in POTS patients with symptoms refractory to treatment. One retrospective study found droxidopa to improve symptoms in POTS patients, but induced no significant reduction in standing HR and did not seem to improve quality of life in these patients (Ruzieh et al., 2017). Given that droxidopa is a norepinephrine precursor, it has the potential side effect of increasing sympathetic activity resulting in further increased HR, possibly worsening symptoms. Overall, there is a fundamental lack of data assessing the efficacy of droxidopa in POTS patients.

Other pharmacological agents

Pyridostigmine is a peripherally acting acetylcholinesterase inhibitor. The mechanism of action of pyridostigmine is to increase transmission of acetylcholine at synaptic junctions equipped with nicotinic or muscarinic AChR. This results in increased cardiovagal tone, helping reduce HR. It has been shown to reduce tachycardia and improve symptoms acutely in POTS patients (Raj et al., 2005b). Unfortunately, there are significant gastrointestinal side effects that limit the efficacy of this medication including severe cramping, nausea, and diarrhea in about 20% of POTS patients (Kanjwal et al., 2011). In patients who can tolerate the drug long-term, it does continue to help control tachycardia and symptoms (Kanjwal et al., 2011); the Heart Rhythm Society provides a modest recommendation for its use (Sheldon et al., 2015).

In patients in whom mental clouding is a predominant symptom, modafinil has anecdotally been used to improve concentration and alertness in POTS patients (Raj, 2013). It is a psychostimulant with similar actions to amphetamine and methylphenidate (Taneja et al., 2004). Additionally, it does not appear to worsen symptoms of orthostatic tachycardia when tested in POTS patients (Kpaeyeh et al., 2014).

Inappropriate Sinus Tachycardia

The treatment of IST is a challenge. A rate control strategy to eliminate the presence of the sinus tachycardia does not always eradicate symptoms (Olshansky and Sullivan, 2013; Sheldon et al., 2015). Additionally, there is little concrete evidence in the literature to develop strong recommendations for the management of IST (Sheldon et al., 2015). With that being said, conservative management with good patient education is key in the initial management. Patients can often be in great distress about their symptoms. Similar to the treatment of POTS, it is important to reassure patients that the disease course is thought to be benign (Abed et al., 2016) and that no known mortality is known to be caused from this condition (Sheldon et al., 2015; Olshansky and Sullivan, 2013).

The use of beta blockers or other negative chronotropic agents for the treatment of IST has been proposed as a means of reducing HR. Experts believe that symptoms often do not disappear while on beta blockers (Sheldon et al., 2015; Olshansky and Sullivan, 2013). Nondihydropyridine calcium channel blockers and amiodarone have also been suggested as potential therapeutic agents, but the benefits of HR reduction are likely outweighed by the adverse effects of these medications (Ptaszynski et al., 2013). Finally, no prospective studies or randomized controlled trials have been conducted to show any benefit for the use of these medications.

Ivabradine has been tested as an off-label product for the treatment of IST (Annamaria et al., 2015). It has been the most vigorously tested medication in the treatment of IST, including having one randomized control trial testing its efficacy. This trial found ivabradine was well tolerated, eliminated 75% of baseline symptoms in its cohort ($n = 21$) and fully eliminated symptoms in approximately 50% of patients (Cappato et al., 2012). In comparison to the beta blocker metoprolol, ivabradine exerts a similar decrease in HR, is better tolerated, and is more effective at relieving symptoms associated with IST (Ptaszynski et al., 2013). A dose of 5–7.5 mg twice daily can slow HR by 14%–31% of baseline (Annamaria et al., 2015).

Sinus node ablation or modification has been explored as a therapeutic option to treat patients with IST. Both radiofrequency and surgical techniques have been tried (Olshansky and Sullivan, 2013). Sinus rate can be significantly improved by these techniques, but there is limited evidence that clinical symptoms are vastly improved (Shen et al., 2001; Olshansky and Sullivan, 2013). Additionally, there are rather significant potential complications secondary to these permanent procedures including surgical risks and making the patient pacemaker dependent (Lee et al., 1995; Man et al., 2000). The Heart Rhythm Society consensus statement strongly recommends against the use of these treatments for patients with IST (Sheldon et al., 2015).

Conclusions

POTS and IST represent etiologies for a patient presenting in sinus tachycardia without any clear primary cause. Neither condition is believed to be linked to an increased risk of mortality, but each can substantially negatively impact a patient's quality of life if not treated. There is no gold-standard treatment for POTS or IST, and there is limited high quality evidence for management of these conditions. Experts agree that a multidisciplinary approach that considers the individual patient's presentation, underlying pathophysiology of the disease, and associated conditions allows for available treatment strategies to be selected and tailored to the patient at hand. Much remains unknown about these conditions and considerable effort is still required to fully understand the pathophysiology and optimal treatment of these conditions.

Heart Failure

Congestive heart failure (CHF) is defined as "a pathophysiological state in which an abnormality of cardiac function is responsible for the failure of the heart to pump blood at a rate commensurate with the requirements of the metabolizing tissues (Francis et al., 2011)." In other words, the heart is unable to adequately perfuse peripheral tissue unless cardiac filling pressures are abnormally high (Lilly and Harvard Medical School, 2011). In the United States, the incidence of CHF is 550,000 cases per year and the prevalence is 5.8 million cases (Lilly and Harvard Medical School, 2011). CHF, which mostly affects older adults, is the most common diagnosis of hospitalized patients 65 years and older (Lilly and Harvard Medical School, 2011; Rich et al., 2016). The prevalence is expected to increase significantly due to associations with age and interventions that increase survival after CHF (Lilly and Harvard Medical School, 2011).

CHF presents as a clinical syndrome (Lilly and Harvard Medical School, 2011). One of the primary features of CHF is exercise intolerance (Fletcher et al., 2011). Patients also present with fatigue, volume overload, shortness of breath, dyspnea, impaired urine output, paroxysmal nocturnal dyspnea, orthopnea, nocturnal cough, dulled mental status, and edema (Lilly and Harvard Medical School, 2011). Patients are progressively restricted in daily activities (Minotti et al., 1992). The severity of physical limitations correlates more closely with prognosis than hemodynamics (Mettauer et al., 2006).

CHF may be classified as either heart failure with reduced ejection fraction (HFrEF) or heart failure with preserved ejection fraction (HFpEF). Most patients diagnosed with CHF have decreased systolic function, which is a form of HFrEF (Sarma and Levine, 2015). Research has historically focused on exercise intolerance in patients with HFrEF (Maurer and Schulze, 2012). The most common type of CHF in older patients, however, is HFpEF (Sarma and Levine, 2015). HFpEF is also more common in women (Sarma and Levine, 2015; Taub, 2016). Patients with HFpEF have similar mortality and rehospitalization rates (Sarma and Levine, 2015). With growing recognition of patients with HFpEF and a lack of specific therapies, researchers are now working to further characterize peripheral abnormalities in HFpEF (Maurer and Schulze, 2012).

Skeletal Muscle in Heart Failure

In CHF, many bodily responses to maintain circulatory function ultimately become maladaptive, contributing to progression over time (Francis et al., 2011). Decreased cardiac performance leads to problems in peripheral circulation, the kidney, and many other organs (Francis et al., 2011).

As in other chronic conditions, such as chronic pulmonary or renal disease, CHF leads to skeletal muscle abnormalities (Zizola and Schulze, 2013). Skeletal muscle changes are clearly identifiable from an early stage in CHF and contribute to disease progression (Tomono et al., 2016; Georgiadou and Adamopoulos, 2012). The changes impact both peripheral and ventilatory muscles (Georgiadou and Adamopoulos, 2012). Alterations are present at rest, but they are exacerbated during exercise (Georgiadou and Adamopoulos, 2012).

Even though changes in CHF are induced by cardiac abnormalities, symptoms like exercise intolerance are often independent of central hemodynamic alterations and reduced blood flow to muscle (Georgiadou and Adamopoulos, 2012; Cicoira et al., 2001). Similarly, hemodynamic improvement does not necessarily reverse symptoms (Georgiadou and Adamopoulos, 2012). These observations suggest that circulatory changes are not primarily responsible for changes in skeletal muscle metabolism. This is in contrast to healthy patients, in whom exercise tolerance is related to cardiac output (Georgiadou and Adamopoulos, 2012). Instead, exercise tolerance in CHF patients with HFrEF and HFpEF is more related to biochemical, metabolic, and histologic changes in skeletal muscle that lead to skeletal muscle dysfunction (Georgiadou and Adamopoulos, 2012; Cicoira et al., 2001; Bowen et al., 2015). Consequently, training improves exercise tolerance through peripheral adaptations without impacting central hemodynamics. This implies that peripheral skeletal muscle plays a significant role in CHF symptoms. Researchers have suggested that the role of circulation may be dependent on the disease stage, with peripheral alterations playing greater roles later in the progression (Piepoli et al., 2001).

Studies have shown that peripheral factors play a role in patients with HFrEF and HFpEF. Many of these factors, which will be explained in depth in this paper, are shown below (**Fig. 1**, **Tables 1** and **2**). Patients with HFrEF and HFpEF have similar levels of exercise intolerance and dyspnea (Sarma and Levine, 2015). A study using soleus tissue in animal models suggested, however, that skeletal muscle alterations are exacerbated in HFrEF compared to HFpEF (Seiler et al., 2016). Diaphragm muscle, on the other hand, was not significantly different between the two groups (Seiler et al., 2016).

Skeletal Muscle Tissue and Muscle Fiber Changes

Skeletal muscle tissue is characterized by strong, quick, discontinuous, and voluntary contractions. The structural unit of skeletal muscle tissue is called a sarcomere. The composition of muscle fibers depends on activity, mechanical load, hormones, and age (Mettauer et al., 2006). Cardiac tissue, on the other hand, is characterized by continuous and involuntary contractions. Significant

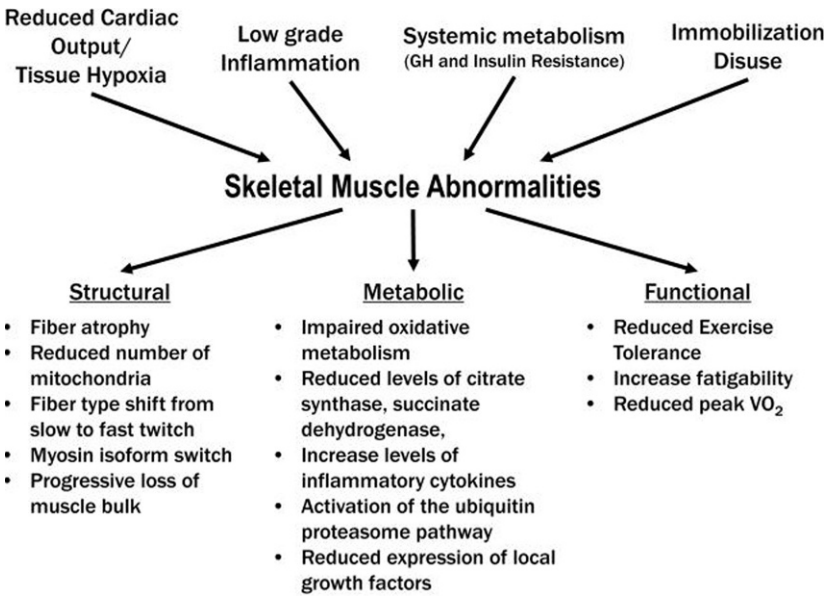

Fig. 1 Skeletal muscle abnormalities in CHF (Zizola and Schulze, 2013).

Table 1 Skeletal muscle changes in heart failure (Piepoli et al., 2001)

Function	↑ Weakness
	↑ Fatigability
Morphology	1. Quantity: Loss of muscle mass (bulk)
	2. Quality: Atrophy, damage and/or necrosis
Blood flow	↓ Capillary density (endothelial cell/fiber)
	↓ mL min^{-1}
	↓ Vasodilatation
Metabolism	↑ Glycolytic
	↓ Oxidative
	↑ Phosphocreatinine depletion
	↑ Intracellular acidosis
Ultrastructural	↓ Type I oxidative slow-twitch
1. Fiber type	↑ Type IIb glycolytic fast-twitch
2. Mitochondrial	↓ Volume density
3. Endothelial dysfunction	↓ Surface density of cristae

Table 2 Skeletal Muscle Abnormalities in Heart Failure (HF) (Liu and Marcinek, 2016)

Author, year (no.)	*Population character*	*Key measurement*	*Outcome and conclusion*
Mancini et al. (1988)	HF and age-matched healthy control male (~54 years)	HF peak VO_2 13.6 ± 5 mL/min/kg In vivo P31-NMR	Lower leg muscle mass loss in HF Calf metabolic abnormality part due to muscle atrophy During exercise Pi/PCr, HF > control Recovery time post Ex, HF > control Impaired metabolic profile suggests intrinsic changes not only due to muscle loss
Southern et al. (2015)	HF and age-matched control (~64 years)	Near-infrared spectroscopy	Oxidative capacity lower in HF and exercise training improved oxidative capacity only in control, suggested reduced oxidative capacity and impaired training adaptation in HF
Mancini et al. (1994)	HF and control (~58 years)	Ventilatory capacity: progressive isocapnic hyperpnea respiratory muscle deoxygenation near-infrared spectroscopy	Reduced respiratory ventilator capacity without respiratory muscle deoxygenation in HF
Wiener et al. (1986)	HF and age-matched control (~60 years)	Forearm blood flow with plethysmography Metabolism ^{31}P NMR	Forearm blood flow was similar, but increased Pi/PCr upon exercise suggested that abnormal metabolism in HF was not due to decreased muscle blood flow rather intrinsic changes in mitochondria or substrate utilization
Mancini et al. (1989)	HF and age-matched control (~57 years)	^{31}P NMR; Pi/PCr and PH changes In vitro muscle biopsy; enzyme activity fiber type	HF fiber shift to increased fast, glycolytic type IIb fibers; decreased fatty acid oxidation enzyme activity; ^{31}P NMR also showed higher Pi/PCr; no correlation between Pi/PCr to VO_2 and enzyme activity suggested intrinsic changes not due to metabolic response (Pi/PCr changes)
Toth et al. (2012)	HF and control, age and physical activity matched	18-Week resistance training (RE) Muscle biopsy, in vitro analysis	Larger but fewer mitochondria per fiber without difference in content between HF and control; no difference in mitochondria enzyme activity and mRNA level of cytochrome oxidase RE increased mitochondrial transcription factor A and muscle strength for both HF and control but did not alter mitochondrial size/content, enzyme, or transcriptional regulator
MiddleKauff et al. (2013)	HF and control (~50 year, peak VO_2 11.6 mL/kg/min)	Muscle biopsy and in vitro biochemistry analysis; fiber typing and mitochondria enzyme activity	HF fibers shift to fast twitch; no difference in vascular index or many of mitochondrial enzyme activities; clonidine revealed no impact for HF suggested skeletal myopathy is not caused by neuroendocrine disuse
Zizola et al. (2015)	Myocardial infarction induced mice	In vitro muscle biopsy: fiber typing and enzyme activity assay; ATP content	Muscle dysfunction associated with impaired PPARδ signaling; upon treating MI mice with PPARδ agonist corrected diminished oxidative capacity and FA metabolism (CPT1) and improved exercise capacity
Schrepper et al. (2012)	Pressure overload hypertrophy in rat heart	In vitro assay from muscle biopsy; isolation of fresh mitochondria mRNA and protein assay	Complexes I and II early increase and then later decline (I, II, and III) in respiratory capacity not due to differences in gene expression or supercomplex assembly
Dai et al. (2011)	Ang II induced cardiomyopathy in mice treated with SS-31	Flow cytometric access MitoSOX and DCFDA signal	SS-31 reduced Ang II-induced ROS signal (mitochondrial superoxide and total cellular ROS)
Kitzman et al. (2014)	HF with preserved ejection fraction (HFpEF)	Peak VO_2 Fiber type Capillary-to-fiber ratio	Reduced type I fiber and capillary to fiber ratio contribute to exercise intolerance among HF

similarities and differences between skeletal and cardiac muscle tissue are shown below (**Table 3**). Skeletal muscle tissue, along with vessels, nerve fibers, and connective tissue, forms the skeletal muscle organ. Skeletal muscle accounts for 40%–45% of body weight, which is more than any other organ of the body (Mohrman and Heller, 2014). Based on functional demands, muscles may be composed of different types of fibers with different capabilities (**Table 4**). Skeletal muscle has high capacity for regeneration and remodeling, making it a good target for therapeutic approaches (Rich et al., 2016).

In patients with CHF, muscle fibers are characterized by abnormalities. Changes are related to different isoforms of myosin heavy chain (MHC), which is the motor protein in the muscle thick filament myosin (Mettauer et al., 2001; Nicoletti et al., 2003). Muscle biopsies and ultrastructural analyses have shown that there are fewer slow fibers and more fast fibers in patients with CHF. The change is due to an increase in the relative content of MHC 2X from active healthy patients to sedentary healthy patients to CHF patients (Mettauer et al., 2001). In other words, patients with CHF have a higher proportion of fast-twitch, type II fibers relative to type I fibers (Georgiadou and Adamopoulos, 2012). These changes in muscle fibers have been confirmed in patients with HFpEF as well (Maurer and Schulze, 2012). This has been supported by observation of splitting of the inorganic phosphate (Pi) peak in patients with CHF, which implies the presence of two types of muscle fibers (Minotti et al., 1992).

Some studies have suggested that no significant fiber difference exists between sedentary controls and CHF patients (Mettauer et al., 2001). This would support the idea that fiber type changes are due to muscle disuse rather than specific effects of CHF. This was supported in studies that showed no fiber type shift compared to deconditioned controls with similar VO_2 max (see the "**Exercise**" section for a further discussion on VO_2 max) (Nicoletti et al., 2003). It has been shown, however, that angiotensin-converting enzyme inhibitor (ACEi) treatment normalizes myosin isoform abnormalities in muscle fibers in CHF patients (Mettauer et al., 2006). This may account for discrepancies between studies.

Muscle fiber type directly impacts metabolism (see "**Metabolic Changes**" section for further discussion). Mitochondrial respiration in active controls favors slow-oxidative muscle (Mettauer et al., 2001). This is characterized by high oxidative capacity, low sensitivity to external adenosine diphosphate (ADP), and control by mitochondrial creatine kinase (CK) (Mettauer et al., 2001). Respiration in sedentary controls and CHF patients, on the other hand, is closer to fast-glycolytic muscle in rodents (Mettauer et al., 2001). Some groups showed that muscle fibers in patients with CHF show decreased activity of oxidative enzymes while activity of glycolytic enzymes is maintained (Minotti et al., 1992). Type II fibers, which have higher oxygen and adenosine triphosphate (ATP) consumption, transition to anaerobic metabolism sooner (Vescovo et al., 2000). Muscle biopsies in patients with CHF showed reduced activity of both lipolytic and oxidative enzymes (Zizola and Schulze, 2013) .Fiber changes cause metabolic signaling to favor replenishment of energy stores instead of modification of energy production based on demands (Mettauer et al., 2006). The fibers also lead to a lower pH during exercise (Minotti et al., 1992).

Muscle fibers in patients with CHF may also be characterized by atrophy, decreased maximal strength, and reduced electromyographic activity (see "**Muscle Atrophy**" section for further discussion) (Georgiadou and Adamopoulos, 2012). Some studies have shown that all fibers have reduced size, whereas some studies suggest that only type II fibers have reduced diameter (Georgiadou and Adamopoulos, 2012). In skeletal muscle from a mouse model of dilated cardiomyopathy, the shift to more fatigable fibers was associated with activation of Wnt (Okada et al., 2015). Through β-catenin, Wnt activates Forkhead box O (FoxO) (Okada et al., 2015). FoxO signaling plays a critical role in the development of skeletal myopathy in CHF (Okada et al., 2015). Overexpression of FoxO1 increases shifts to fatigable fibers, whereas suppression of FoxO1 activity inhibits these changes (Okada et al., 2015). This supports the role of Wnt signaling as a potential target for new therapies against skeletal myopathy in CHF (Okada et al., 2015).

Clinically, muscle fiber changes in CHF are related to exercise intolerance and shortness of breath. There is a positive correlation between the percentage of MHC I and VO_2, ventilator threshold, and oxygen pulse (Nicoletti et al., 2003). Similarly, there is a negative correlation between MHC II and these measures of exercise capacity (Nicoletti et al., 2003). These relationships have been demonstrated in patients with HFpEF as well (Kitzman et al., 2014). Exercise may reverse fiber composition abnormalities, increasing slow-twitch fibers and decreasing fast-twitch glycolytic fibers in skeletal muscle (Piepoli et al., 2001). It may also increase muscle fiber size (Piepoli et al., 2001).

Various other changes in muscle fibers have been identified in patients with CHF. Fibers may be altered due to changes in regulatory components of thin filaments, including troponin, and proteins involved in calcium transport, including Ca^{2+}-ATPase (Georgiadou and Adamopoulos, 2012). There is also a reduction in capillary-to-fiber ratio (Kitzman et al., 2014). Researchers have suggested that there is a decrease in capillary density, although these findings have been controversial (Sarma and Levine, 2015; Mettauer et al., 2001; Georgiadou and Adamopoulos, 2012; Minotti et al., 1992; Mettauer et al., 2006). The decreased capillary density around skeletal myofibrils is related to decreased peak VO_2 (Sarma and Levine, 2015).

Metabolic Changes

Mitochondrial Content

Mitochondria are altered in skeletal muscle in patients with CHF. One study suggested that there is some parallelism between cardiac and skeletal muscle mitochondrial alterations in patients with CHF, and that these alterations begin before the major clinical Framingham criteria are installed (Guzman Mentesana et al., 2014). Ultrastructural analysis showed fewer, smaller mitochondria in patients compared to controls (Guzman Mentesana et al., 2014). Specifically, there are fewer mitochondria per muscle fiber (Zizola and Schulze, 2013). Mitophagy may be enhanced by hypoxia, inflammation, and muscle inactivity (Zizola and Schulze, 2013). In older patients with HFpEF, mitochondrial reductions in skeletal muscle have been demonstrated based on levels of porin expression (Molina et al., 2016). Morphometric analysis of vastus lateralis muscles from patients with CHF showed reduced volume

Table 3 Similarities and differences between skeletal and cardiac muscle (Kennelly and Murray, 2015)

Skeletal muscle	*Cardiac muscle*
Striated	Striated
No syncytium	Syncytial
Small T tubules	Large T tubules
Sarcoplasmic reticulum well developed and Ca^{2+} pump acts rapidly	Sarcoplasmic reticulum present and Ca^{2+} pump acts relatively rapidly
Plasmalemma contains few hormone receptors	Plasmalemma contains a variety of receptors (e.g., α- and β-adrenergic)
Nerve impulse initiates contraction	Has intrinsic rhythmicity
Extracellular fluid Ca^{2+} not important for contraction	Extracellular fluid Ca^{2+} important for contraction
Troponin system present	Troponin system present
Caldesmon not involved	Caldesmon not involved
Very rapid cycling of the cross-bridges	Relatively rapid cycling of the cross-bridges

Table 4 Similarities and differences between type I and type II muscle fibers (Kennelly and Murray, 2015; Kibble and Halsey, 2015)

Characteristic	*Slow twitch (type I)*	*Fast twitch (type II)*
Color	Red (myoglobin)	White (low myoglobin)
Metabolism	Oxidative	Glycolytic
Mitochondria	Abundant	Few
Glycogen content	Low	High
Duration	Prolonged	Short
Fatigability	Low	High
Myosin ATPase	Low	High
Energy utilization	Low	High
Contraction rate	Slow	Fast

density of mitochondria (Mettauer et al., 2006). In a rat model of right ventricular heart failure induced by monocrotaline (MCT) injection, MCT treatment was related to lower mitochondrial volume density and quality (Wust et al., 2012). Remaining mitochondria have fewer cristae (Mettauer et al., 2006; Zizola and Schulze, 2013). It has been noted, however, that skeletal muscle has less clear mitochondrial changes compared to cardiomyocytes (Mettauer et al., 2006). Moreover, a study comparing 13 CHF patients with 14 age- and activity-matched controls suggested that mitochondrial changes in CHF are primarily related to muscle disuse and other disease-related factors (Toth et al., 2012).

Exercise training is typically thought to alleviate quantitative and structural mitochondrial changes in patients with CHF. Exercise has been shown to increase the number of mitochondria in skeletal muscle (Maurer and Schulze, 2012). It also significantly increases the total volume density of mitochondria (Nicoletti et al., 2003). In one study, however, resistance training did not alter mitochondrial size and content in patients with CHF, leading the authors to suggest that impaired oxidative capacity is not related to mitochondrial dysfunction (Toth et al., 2012).

Oxidative Capacity

In addition to structural changes, mitochondria in skeletal muscles from patients with CHF also have impaired function. As in many diseases, mitochondrial alterations contribute to a reduction in oxidative metabolic capacity. Oxidative capacity is defined as the maximal rate at which oxidative phosphorylation may be performed (Leermakers and Gosker, 2016). Reduced oxidative capacity contributes to decreased skeletal muscle oxygen consumption (Sarma and Levine, 2015). Reduced oxygen consumption is further caused by impaired cardiac function in patients with HFrEF and by impaired oxygen diffusion (Sarma and Levine, 2015). Despite these changes, muscles typically are adequately supplied with oxygen during abnormalities, suggesting an intrinsic cause within skeletal muscle (Zizola and Schulze, 2013).

As oxidative metabolism fails, there is a shift to anaerobic, glycolytic energy production. This shift occurs in both patients with HFrEF and HFpEF (Kitzman et al., 2014). Increased anaerobic metabolism causes an earlier increase in the concentration of lactate in the blood, especially during exercise (Schulze et al., 2002). This occurs even in patients with chronic CHF with normal leg blood

flow (Nicoletti et al., 2003). The shift to glycolytic metabolism has been demonstrated in patients with CHF using ^{31}P magnetic resonance spectroscopy (Zizola and Schulze, 2013). Glycolytic metabolism also leads to earlier intramuscular acidosis (Georgiadou and Adamopoulos, 2012). In a rat model of CHF, skeletal muscle metabolic capacity was reduced in both oxidative and glycolytic muscles (Mettauer et al., 2006).

Quantitative, structural, and metabolic changes in mitochondria contribute to exercise intolerance. Mitochondrial alterations affect factors such as peak aerobic exercise capacity (Zizola and Schulze, 2013). In one study, levels of porin and mitofusin-2 (Mfn2) expression were positively correlated with peak VO_2 and 6-min walk distance (see "**Exercise**" section for further discussion) (Molina et al., 2016). Mitochondrial volume density and cristae reductions are proportional to declines in peak VO_2 (Mettauer et al., 2006).

Exercise may restore oxidative capacity in patients with CHF. Mitochondrial improvements from exercise training are significantly correlated with increased peak VO_2 (Piepoli et al., 2001). Exercise also improves metabolic function through slowing utilization of muscle glycogen, increasing reliance on fat oxidation and utilization, and decreasing production of lactate during exercise (Nicoletti et al., 2003). In one study, however, wrist-flexor training induced a 50% improvement in oxidative capacity in patients without CHF but did not induce improvement in patients with CHF (Southern et al., 2015). The authors suggested that CHF patients have impaired oxidative adaptations to endurance exercise compared to healthy controls (Southern et al., 2015).

Changes in oxidative capacity are controversial. Some studies suggest that oxidative capacity in patients with CHF is similar to oxidative capacity in sedentary controls (Mettauer et al., 2001). Further research is required to determine the contributions from atrophy, fibrosis, and inflammation (Zizola and Schulze, 2013). Moreover, mitochondrial abnormalities, reduced blood flow, and decreased oxygen extraction often reverse after administration of ACEi (Minotti et al., 1992). The more recent application of ACEi and β-blocker treatments may account for older studies observing intrinsic skeletal muscle mitochondrial defects while newer studies observe normal mitochondrial function (Mettauer et al., 2006).

Enzyme Abnormalities

In patients with CHF, impaired CK function in skeletal muscle is likely related to abnormal production and handling of high-energy phosphates (Mettauer et al., 2006; Schulze et al., 2002; Hambrecht et al., 1999). CK is an enzyme that adds a phosphate from ATP to creatine to produce phosphocreatine (PCr) (Mettauer et al., 2006). PCr functions as an energy buffer for ATP homeostasis in skeletal muscle (Greenhaff, 2001). Three isoforms of muscle CK are the dimers MM-CK, BB-CK, and MB-CK (Mettauer et al., 2006). There is also a mitochondrial isoform (mi-CK) (Mettauer et al., 2006). In patients with CHF, levels of total cytosolic CK, MM-CK, and mi-CK decrease (Mettauer et al., 2006). Reduced CK function is exacerbated by reduced oxidative capacity, which increases use of PCr as a source of energy. Many studies using ^{31}P magnetic resonance spectroscopy have shown that patients with CHF have increased rates of PCr utilization (Zizola and Schulze, 2013; Schulze et al., 2002; Hambrecht et al., 1999). PCr depletion is accompanied by increased levels of Pi (Minotti et al., 1992). Moreover, a study using ^{31}P magnetic resonance spectroscopy revealed that patients with HFpEF have longer recovery times to regenerate PCr compared to healthy, sedentary, age-matched controls (Sarma and Levine, 2015). Long recovery of high-energy phosphates is proportional to the severity of CHF (Mettauer et al., 2006). In addition, during exercise in patients with CHF, levels of ADP increase faster while pH falls significantly more compared to healthy controls (Nicoletti et al., 2003). Abnormal CK function is independent of peripheral blood flow, histologic changes, muscle mass, and hypoxia (Zizola and Schulze, 2013; Hambrecht et al., 1999). Impaired CK function and lower levels of ATP contribute to early fatigue and muscle intolerance in patients with CHF (Piepoli et al., 2001; Hambrecht et al., 1999). Since these changes may occur prior to atrophy, patients often present with fatigue prior to decreased contractile force (Schulze et al., 2002).

Reduced enzyme activity in the Krebs cycle and electron transport chain is related to energy depletion in patients. In a rat model of CHF induced by MCT injection, succinate dehydrogenase (SDH, complex II) activity and maximal respiratory rate were 15% lower in all muscle fibers (Wust et al., 2012). In patients with HFrEF but not HFpEF, soleus tissue muscle showed a reduced SDH to lactate dehydrogenase (LDH) ratio, which is further impacted by reduced levels of LDH in patients with CHF (Seiler et al., 2016). In the rat model, complex I/IV activity was also 20% lower (Wust et al., 2012). In general, the percentage of mitochondria stained for cytochrome oxidase (complex IV) is reduced in patients with CHF but improves with exercise (Mettauer et al., 2006). Changes in citrate synthase levels are more variable. Some studies have suggested that citrate synthase activity is reduced in skeletal muscle from patients with CHF, including older patients with HFpEF. Other studies, however, state that levels of citrate synthase are unchanged (Mettauer et al., 2001, 2006; Zizola and Schulze, 2013; Molina et al., 2016).

Other proteins are also affected. Reductions in fatty acid metabolism are characterized by low concentrations of skeletal muscle long chain acylcarnitine, increased lipid droplets, and decreased activity of β-hydroxyacyl coenzyme A dehydrogenase, an enzyme involved in β-oxidation of fatty acids (Nicoletti et al., 2003). Reductions in Mfn2 and porin, both of which are proteins that are present on the outer mitochondrial membrane, are correlated to measures of exercise tolerance in patients with HFpEF (Molina et al., 2016). Peroxisome proliferator-activated receptor-γ expression was reduced in soleus tissue from patients with HFrEF but not HFpEF (Seiler et al., 2016). Deactivation of the PPARα/AMPK pathway, which consequently downregulates many enzymes for glucose and free fatty acid metabolism, is also related to skeletal muscle metabolic dysfunction (Sente et al., 2016a).

Exercise may improve enzymatic abnormalities. In an animal model of CHF, exercise training decreased PCr depletion and increased levels of ATP (Piepoli et al., 2001; Nicoletti et al., 2003). In patients with CHF, ^{31}P nuclear magnetic resonance spectroscopy after submaximal exercise showed reduced acidosis, reduced PCr depletion, and increased levels of ADP (Minotti et al., 1992). Moreover, exercise reduced the recovery half-time for PCr (Schulze et al., 2002). Needle biopsies from patients after exercise have shown a significant increase in oxidative enzyme activity along with reduced or unaltered glycolytic enzyme activity

(Piepoli et al., 2001). In a study on rats with CHF, exercise training increased spinotrapezius muscle citrate synthase activity more than it did in sedentary counterparts (Hirai et al., 2014). Exercise has also been shown to increase the concentration of enzymes involved in lipid metabolism (Fletcher et al., 2011).

Oxidative Stress

Oxidative stress is defined as an excess production of reactive oxygen species (ROS) relative to antioxidant defense (Tsutsui et al., 2011). Sources of ROS include mitochondria, NAD(P)H oxidase, xanthine oxidase, and uncoupled nitric oxide synthase (NOS) (**Fig. 2A**; Guzman Mentesana et al., 2014; Tsutsui et al., 2011; Koba et al., 2009). Levels of ROS may also increase due to decreased antioxidative capacity, which may be caused by decreased function of radical scavenger enzymes including superoxide dismutase (SOD) and catalase (**Fig. 2B**; Koba et al., 2009). Increased ROS in mitochondria will damage mitochondrial DNA, which impairs mitochondrial function and further augments generation of ROS (Tsutsui et al., 2011). ROS may also mediate apoptosis (Tsutsui et al., 2011).

Heart failure increases oxidative stress. In patients, levels of ROS, such as superoxide, are increased (Koba et al., 2009). One study, however, found significant changes in markers of oxidative stress, including increased nicotinamide adenine dinucleotide phosphate oxidase and decreased antioxidative enzyme activity, in soleus tissue from patients with HFrEF but not HFpEF (Seiler et al., 2016). Superoxide may partially contribute to symptoms by sensitizing muscle afferents involved in the mechanoreflex (see the "**Neurologic Response and Muscle Reflexes**" section for further discussion) (Koba et al., 2009). Patients with CHF may maintain some antioxidant defense mechanisms. An nitrous oxide (NO)-dependent antioxidant defense may increase skeletal muscle resistance to catabolic processes (Okutsu et al., 2014). In a genetic mouse model of CHF, muscle CK extracellular superoxide dismutase (MCK-EcSOD) significantly attenuated cachexia and exercise intolerance (Okutsu et al., 2014). It also ameliorated MAFbx/Atrogin-1 mRNA expression, loss of mitochondria, and reduction of capillary density in skeletal muscle (Okutsu et al., 2014).

Oxidative stress contributes to the CHF syndrome in many ways. It is related to cachexia, insulin resistance, and exercise intolerance. ROS impair contractile function through modification of proteins related to excitation–contraction coupling (ECC) (see "**ECC and Calcium**" section for further discussion) (Tsutsui et al., 2011). Although muscle contraction increases ROS production in healthy subjects, active muscle in patients with CHF releases higher levels of cyclooxygenase products and bradykinin (BK), which are a source of superoxide generation (Koba et al., 2009). ROS also decrease peripheral perfusion due to endothelial dysfunction (Koba et al., 2009). Clinically, increased oxidative stress in the skeletal muscle is related to fatigue and dyspnea in patients with CHF (Guzman Mentesana et al., 2014). Exercise training may decrease oxidative stress in skeletal muscles (Maurer and Schulze, 2012; Cunha et al., 2012).

ECC and Calcium

Skeletal muscle function relies on intact ECC. The normal steps of this process are shown below (**Fig. 3**). In patients with CHF, ECC in skeletal muscle is abnormal.

Abnormalities in ECC may be due to problems in the neuromuscular junction. In lower limbs of patients with CHF, extension and flexion time-to-peak torque was longer (Brunjes et al., 2016). Furthermore, acceleration and deceleration times in the lower limbs were prolonged (Brunjes et al., 2016). CHF patients had increased adiposity, decreased lean muscle mass, decreased circulating unsaturated fatty acids, and increased ceramides (Brunjes et al., 2016). The researchers suggested that delayed torque development indicates skeletal muscle impairments that may reflect abnormal neuromuscular functional coupling (Brunjes et al., 2016).

There may also be abnormalities with intracellular calcium handling, causing an "intracellular calcium-overload state (Zizola and Schulze, 2013)." In CHF, the muscle-specific type 1 ryanodine receptor (RyR1), which exists on the sarcoplasmic reticulum (SR), becomes leaky (Zizola and Schulze, 2013). This occurs because chronic adrenergic stimulation results in

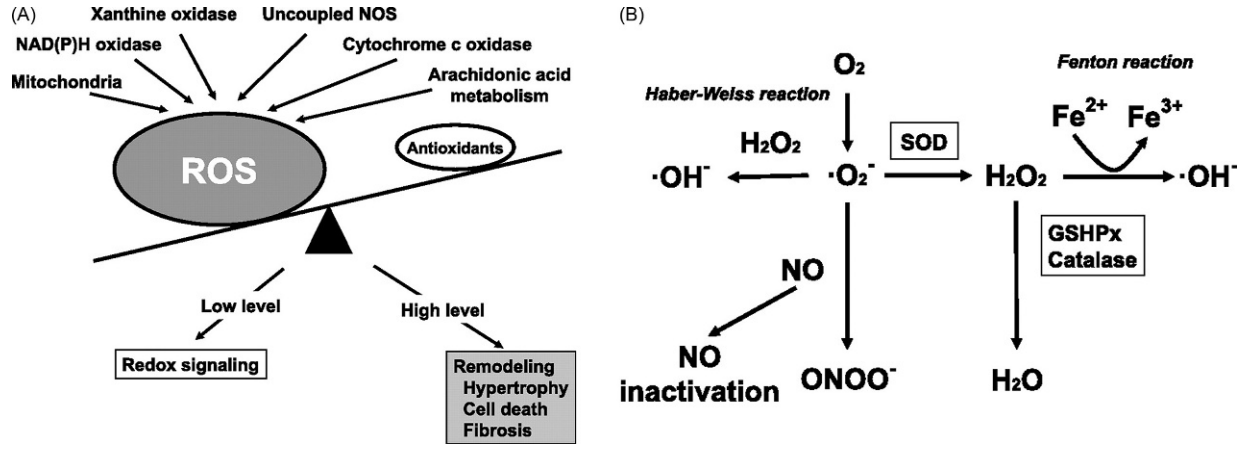

Fig. 2 (A) Sources of ROS (Tsutsui et al., 2011); (B) reactions underlying generation and degradation of ROS (Tsutsui et al., 2011).

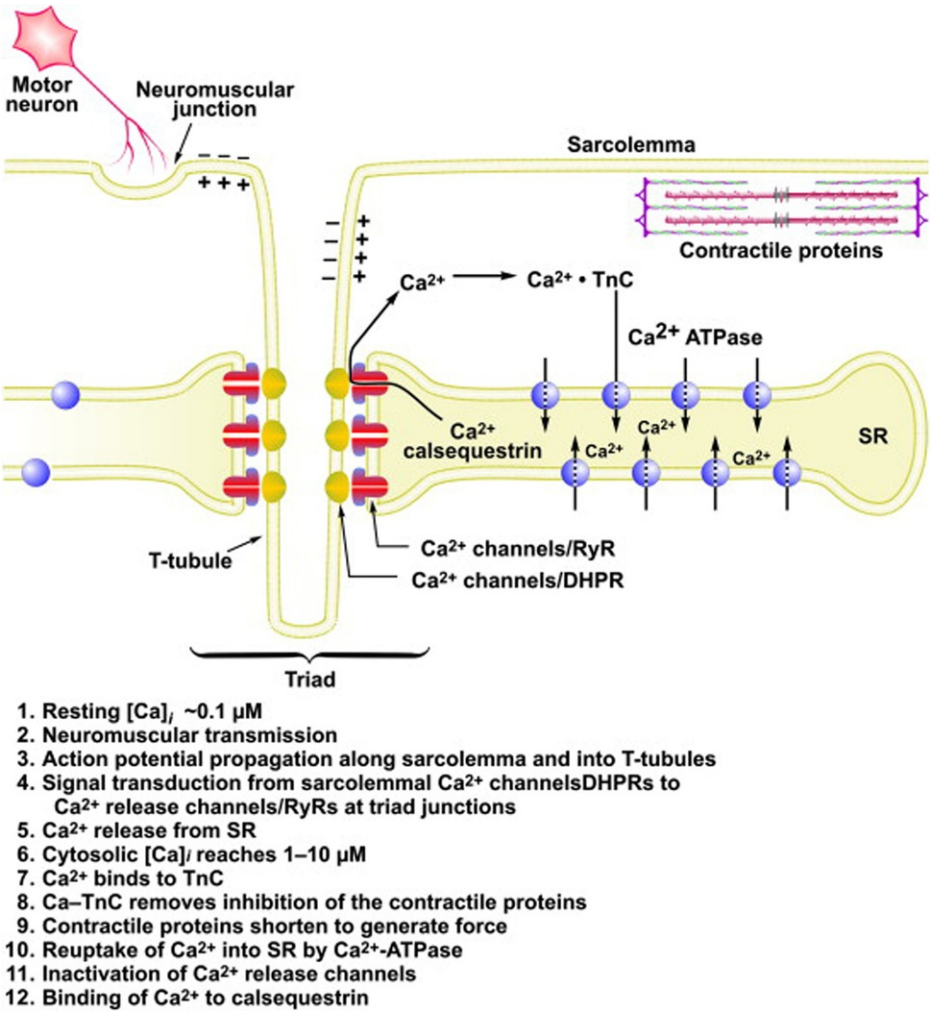

Fig. 3 Excitation–contraction coupling (Heiny and Meissner, 2012).

hyperphosphorylation of the channel (Zizola and Schulze, 2013). Channel hyperphosphorylation causes dissociation of calstabin-1, which is necessary to maintain the closed state of the RyR1 channel (Zizola and Schulze, 2013). A study of eight sedentary HF patients compared to seven age-matched, healthy but sedentary controls further showed that skeletal muscle RyR1 from human heart failure is posttranslationally modified (Rullman et al., 2013). Modifications included excessive phosphorylation, *S*-nitrosylation, and oxidation (Rullman et al., 2013). RyR1 from HF patients had depleted levels of calstabin1 (Rullman et al., 2013). Changes in RyR1 in CHF impair muscle function and exercise tolerance, most significantly via altered SR Ca^{2+} pumping in slow-twitch muscles (Zizola and Schulze, 2013).

A leaky SR with decreased Ca^{2+} content may impair ECC through altered action potential (AP)-evoked Ca^{2+} release, which may be called a "calcium spark (Zizola and Schulze, 2013; DiFranco et al., 2014)." In a study of four patients with CHF, excitability mechanisms seemed to be intact since single APs did not vary between CHF patients and healthy controls (DiFranco et al., 2014). AP-evoked Ca^{2+} release flux in single fibers, however, was significantly reduced compared to fibers from healthy controls (DiFranco et al., 2014). In a different study, skeletal muscle from animals with heart failure exhibited increased Ca^{2+} spark frequency, decreased Ca^{2+} spark amplitude, and increased Ca^{2+} spark duration (Zizola and Schulze, 2013).

Skeletal muscle expression of SR Ca^{2+}-ATPase (SERCA) 1a, the skeletal muscle specific isoform, differ in relation to muscle fiber composition, the degree of functional impairment, and the type of CHF model (Zizola and Schulze, 2013). Expression of SERCA was reduced in rats with post-infarction heart failure, which may explain abnormal calcium handling and accelerated muscle fatigue in CHF (Piepoli et al., 2001). The sarcolemma may also be abnormal (Maurer and Schulze, 2012).

Inflammation and Cytokines

Immune responses and inflammation play a significant role in CHF. Proinflammatory factors involved in CHF include tumor necrosis factor α (TNF-α), interleukin (IL) 1β (IL-1β), IL-1, IL-6 and interferon γ (IFN-γ) (Sente et al., 2016a). Levels of chemokines,

such as IL-8, also increase (Sente et al., 2016a). Biopsy-derived primary skeletal muscle myoblasts from patients with HFrEF also showed loss of antiinflammatory and proliferative activity (Sente et al., 2016b). Cytokines are associated with poor prognosis and recurrent hospitalization (Schulze et al., 2002).

Low-level systemic inflammation in CHF may cause changes in skeletal muscle (Zizola and Schulze, 2013). Plasma levels of circulating inflammatory cytokines differ between patients with HFrEF and HFpEF (Seiler et al., 2016). In HFrEF, plasma concentration of TNF-α was significantly greater (Seiler et al., 2016). In HFpEF, on the other hand, plasma concentrations of IL-1β and IL-12 were significantly greater (Seiler et al., 2016). This may partially explain differences between changes in skeletal muscle in HFrEF and HFpEF (Seiler et al., 2016). Even when circulating concentrations of cytokines are unaltered, CHF increases levels of TNF-α and IL-1β and decreases levels of antiinflammatory IL-10 in skeletal muscle and other tissue (Poole et al., 2012). Cytokines influence the expression of proteins in muscle (Schulze et al., 2002). For example, IL-1β may decrease expression of SERCA and phospholamban mRNA and protein in neonatal myocytes (Schulze et al., 2002). This prolongs the calcium transient (Schulze et al., 2002). TNF-α may initiate a similar effect (Schulze et al., 2002).

In advanced CHF, systemic cytokines may significantly upregulate skeletal muscle expression of inducible nitric oxide synthase (iNOS, NOS II). Increased iNOS was confirmed in skeletal muscle biopsies from patients with CHF (Gielen et al., 2003). NOS II is a calcium-independent enzyme that is expressed in immunologically activated cells in response to TNF-α, IFN-γ, and IL-1β (Riede et al., 1998). These cytokines work through activation of NF-κB (Zizola and Schulze, 2013). NOS II is a source of intracellular NO (Hambrecht et al., 1999). Toxic levels of NO may inhibit enzymes related to oxidative phosphorylation, such as cytochrome c oxidase (COX), and reduce peak oxygen uptake (Gielen et al., 2003). This process may attenuate skeletal muscle contraction and mediate muscle wasting through altered metabolism (Gielen et al., 2003). As a result, increased expression of NOS II is inversely correlated with oxidative capacity, functional work capacity, and exercise tolerance in patients with CHF (Hambrecht et al., 1999). Local inflammation in skeletal muscle with increased levels of IL-1β, TNF-α, and NOS II might further contribute to the progressive deterioration of skeletal muscle structure, function, and metabolism (Maurer and Schulze, 2012).

Exercise training for 6 months was shown to reduce skeletal muscle concentration of IL-1β by 27% and TNF-α by 28%, consequently decreasing iNOS expression by 32% (Adams et al., 2001; Schulze et al., 2001). A separate study on 20 male patients with stable CHF showed that exercise training did not affect serum levels of TNF-α, IL-6, and IL-1β, but did decrease skeletal muscle TNF-α, IL-6, and IL-1β (Gielen et al., 2003). In this study, exercise training reduced skeletal muscle iNOS expression by 52%. Exercise training also restores levels of the antiinflammatory mediator IL-10 (Gielen et al., 2003).

Disuse-induced atrophy promotes skeletal muscle inflammation through multiple pathways (see "**Muscle Atrophy**" section for further discussion). Skeletal muscle inflammation reduces O_2 delivery, decreases local insulin-like growth factor-1 (IGF-1) levels, and increases oxidative stress (Zizola and Schulze, 2013). Muscle inflammation induces cytokines, including IL-6 and TNF-α, which contribute to muscle wasting through activation of the NF-κB pathway (Zizola and Schulze, 2013). In rats, IL-6 increases skeletal and diaphragmatic muscle atrophy (Zizola and Schulze, 2013). It also activates the JAK-STAT and cAMP activated protein kinase (AMPK) pathways (Zizola and Schulze, 2013). Skeletal muscle inflammation increases FoxO activity, causing muscle protein degradation and atrophy through the ubiquitin-proteasome pathway (Zizola and Schulze, 2013). Systemic inflammation may also contribute to muscle atrophy. Local antiinflammatory effects of exercise may attenuate catabolic wasting associated with the progression of CHF (Gielen et al., 2003).

In patients with HFrEF, increased inflammation corresponds with increased levels of adiponectin (Sente et al., 2016a). It has been shown that increased adiponectin has a protective role through antiinflammatory mechanisms (Sente et al., 2016a).

Neurologic Response and Muscle Reflexes

The autonomic nervous system may be divided into the sympathetic and parasympathetic branches. In healthy subjects, exercise generally reduces parasympathetic activity and augments sympathetic activity (Fletcher et al., 2011). Sympathetic activation causes the release of norepinephrine and increases plasma concentrations of epinephrine (EPI) (Fletcher et al., 2011). In patients with CHF, there is abnormally high sympathetic activation and a withdrawal of parasympathetic activity at rest (Piepoli et al., 2001).

Skeletal muscle receptors that are stimulated by work are called ergoreceptors. The two types of ergoreceptors are mechanoreceptors and metaboreceptors (Georgiadou and Adamopoulos, 2012). Mechanoreceptors are myelinated type III afferents that respond to mechanical stimuli (Georgiadou and Adamopoulos, 2012). Metaboreceptors are chemically activated unmyelinated type IV afferents that respond to metabolites (Georgiadou and Adamopoulos, 2012). Metabolites that may stimulate metaboreceptors include acidosis, prostaglandins, BK, potassium, adenosine, and lactate (Georgiadou and Adamopoulos, 2012). One study, however, suggested that $K+$ and phosphate stimulate muscle afferents while $H+$ and lactate do not (Khan and Sinoway, 2000). Some studies have challenged the distinction between the two types of ergoreceptors. The response initiated by ergoreceptors is called the ergoreflex (Georgiadou and Adamopoulos, 2012). Specifically, during exercise, the response may be called the exercise pressor reflex (Wang et al., 2012).

Ergoreceptors are the basis of the muscle theory of sympathetic drive in CHF (Georgiadou and Adamopoulos, 2012). In normal patients, muscle contraction stimulates thin fiber afferents to evoke a change in blood pressure (BP) (Koba et al., 2009). The overall ergoreflex is more strongly stimulated in patients with CHF (Koba et al., 2009). Some studies have shown that responses of both mechanoreceptors and metaboreceptors are increased in CHF (Georgiadou and Adamopoulos, 2012). Others, however, have suggested that the metaboreceptor contribution to increased muscle sympathetic nerve activity is minimal or decreased in CHF

(Koba et al., 2009). Even if metaboreceptor responses are reduced, higher accumulation of metabolites due to slower oxygen uptake, lower VO_2, and other changes will still stimulate the metaboreceptors (Poole et al., 2012). In a study on rats with heart failure induced by coronary artery ligation, it was shown that continuous contraction stimulates both mechanically and metabolically sensitive muscle afferents whereas short, intermittent contraction stimulates predominantly mechanosensitive afferents (Koba et al., 2009).

The ergoreflex causes global sympathetic activation (Poole et al., 2012). This includes activation of cardiovascular pathways in the central nervous system (Koba et al., 2009). Increased responses cause neurohumoral derangement, altered autonomic state, exaggerated ventilatory responses, increased circulatory responses, and exercise intolerance (Georgiadou and Adamopoulos, 2012). Specifically, sympathetic activation reduces blood flow to resting muscle to less than one-fourth of the normal value (Mohrman and Heller, 2014). Since there is usually more blood flow to skeletal muscle at rest than necessary, resting tissue metabolic processes may not be impacted by this (see "**Blood Flow to Skeletal Muscle**" section for further discussion) (Mohrman and Heller, 2014). Due to the large amount of skeletal muscle tissue in the body, however, changes in blood flow due to sympathetic activity play a large role in regulation of BP (Mohrman and Heller, 2014).

Although changes are induced to meet metabolic needs of skeletal muscle, they become maladaptive in CHF (Francis et al., 2011). The decrease in blood flow to the periphery further increases skeletal muscle abnormalities (Francis et al., 2011). Enhanced sympathetic activity may be a factor in skeletal muscle breakdown. This shows that the reflex contributes not only to initiation of symptoms but also to CHF progression.

Neural alterations of vasomotor tone impact blood flow to exercising muscle (Fletcher et al., 2011). These changes are partially induced by the ergoreflex. In healthy subjects, exercise induces sympathetic activation (Fletcher et al., 2011). Sympathetic activation causes most vascular beds to constrict to restrict blood flow to nonexercising muscles (Fletcher et al., 2011). Though sympathetic activation may cause vascular beds for exercising muscle to constrict, the effect is outweighed by vasodilatation due to metabolites (Fletcher et al., 2011). Sympathetic activation serves to prevent peripheral vasculature from dilating beyond the capabilities of maximal cardiac output in order to maintain BP (Khan and Sinoway, 2000).

In patients with CHF, earlier and increased acidification and accumulation of exercising muscle metabolites increase involvement of the ergoreflex (Poole et al., 2012). Increased neurohumoral activation has been confirmed by higher plasma levels of catecholamines, renin activity, and aldosterone in patients with CHF (Piepoli et al., 2001). This increases peripheral vasoconstriction, thereby decreasing blood flow to skeletal muscle. Ergoreflex activation is significantly correlated with exercise capacity through variables including peak VO_2 and the ventilation/carbon dioxide production ratio (Nicoletti et al., 2003). The correlations suggest that increased muscle afferent activity contributes to reduced exercise tolerance (Nicoletti et al., 2003).

One study suggested that muscle reflexes in CHF are different in rhythmic exercise compared to static exercise (Khan and Sinoway, 2000). Using vascular resistance in the calf as a measure of sympathetic activation, it was shown that CHF patients have increased calf vascular resistance and BP during post-ischemia exercise, whereas values in controls decreased to baseline levels (Khan and Sinoway, 2000). The magnitude of the ventilatory response was also greater in patients with CHF (Khan and Sinoway, 2000). Patients with CHF had increased muscle acidosis and accumulation of Pi, which may cause increased activation of the muscle metaboreflex (Khan and Sinoway, 2000).

Data also suggest that purinergic P2X receptors of muscle afferent nerves contribute to enhanced sympathetic activation and BP changes during static exercise in patients with CHF (Xing and Li, 2016). In CHF, there is increased P2X current activity and increased expression of P2X3 and kinin B2 receptors (Xing and Li, 2016). BK at least partially causes modulation of the P2X-driven responses (Xing and Li, 2016). In accordance with this, in rats with heart failure, injection of BK into the arterial blood supply of hindlimb muscles more greatly heightened responses induced by P2X activation (Xing and Li, 2016).

Exercise may benefit patients with CHF by reducing the magnitude of the ergoreflex response. Positive effects may be mediated through a direct mechanism or through indirect effects on concentrations of stimulatory metabolites. In rats with CHF, exercise training prevented the sensitization of group III responses to contraction and stretch and partially prevented the decreased group IV responses to contraction and capsaicin (Wang et al., 2012). Conditioning also increases blood flow to skeletal muscle and increases the capacity for aerobic skeletal muscle metabolism, thereby decreasing anaerobic metabolism (Khan and Sinoway, 2000). As a result, acidification and concentrations of metabolites that stimulate the ergoreflex are decreased (Khan and Sinoway, 2000). These changes reduce ventilatory drive, vasoconstriction, and sympathetic activation (Piepoli et al., 2001). With exercise, the ergoreflex response in patients with CHF may be attenuated toward the level of activation in healthy subjects (Khan and Sinoway, 2000). Exercise training should be started early in CHF progression to maximally limit changes in the ergoreflex.

Over-activation of the sympathetic nervous system from skeletal muscle afferents may contribute to inflammation and cytokine activation. Increased levels of TNF-α and insulin resistance may contribute to catabolic muscle wasting (Nicoletti et al., 2003). These changes may also reduce anabolic function (Nicoletti et al., 2003).

Muscle Atrophy

Atrophy and Cardiac Cachexia

As in many systemic diseases, skeletal muscle atrophy may be observed in patients with CHF. Atrophy occurs early in the progression of CHF prior to documented loss of weight (Georgiadou and Adamopoulos, 2012). Atrophy is indicated by decreased fiber cross-sectional area (CSA) and decreased muscle bulk, especially in the quadriceps (Nicoletti et al., 2003). One paper noted

controversy regarding the effect of clinical status on muscle atrophy in CHF (Zizola and Schulze, 2013). Many studies have suggested that muscle protein metabolism is not impaired in stable patients, suggesting that initiation and progression of atrophy are related to events of disease exacerbation (Zizola and Schulze, 2013). Atrophy probably only plays a minor role in impairment of skeletal muscle energetics in CHF (Mettauer et al., 2006).

Changes in skeletal muscle occur due to suppression of whole-body protein synthesis and augmentation of myofibrillar protein degradation (Francis et al., 2011). In patients with systolic heart failure, skeletal muscle expression of the atrophy-promoting genes FoxO1 and FoxO3 was increased compared to controls (Forman et al., 2014). However, expression of other atrophy-related genes (atrogin-1 and MuRF-1), growth promoting genes (IGF-1), and inflammatory cytokines (TNF-α, C-reactive protein, IL-1β, and IL-6) was similar between groups (Forman et al., 2014). In one study, soleus tissue from patients with HFrEF, but not patients with HFpEF, showed a significant increase in markers of muscle atrophy (MuRF1, calpain, and ubiquitin proteasome) (Seiler et al., 2016). An additional mechanism may include selective atrophy of oxidative fibers (Francis et al., 2011).

Eventually, atrophy transitions to the severe muscle wasting that is characteristic of cardiac cachexia. Cachexia is defined as "non-intentional documented weight loss of at least 7.5% of a previously normal weight (Francis et al., 2011)." Skeletal muscle wasting is a well-known feature of late-stage heart failure (Minotti et al., 1992). Muscle wasting in cardiac cachexia affects all tissue compartments, but it may be more apparent in the legs (Francis et al., 2011; Mettauer et al., 2006). Clinically, muscle wasting is associated with exercise intolerance. Limb and respiratory muscle weakness contribute to increased morbidity and mortality (Mangner et al., 2015). Various factors are involved in skeletal muscle atrophy and wasting.

Sarcopenia

Sarcopenia refers to the normal progressive decline in muscle mass, strength, and function that occurs with aging (Maurer and Schulze, 2012). In research, it may be defined as appendicular skeletal mass (ASM) two standard deviations below the mean of a healthy reference group (Saitoh et al., 2016). As a systemic skeletal muscle disease, it impairs the function of limb skeletal muscles and respiratory muscles (Kinugasa and Yamamoto, 2016). There is a high prevalence of sarcopenia among the elderly and women (Sarma and Levine, 2015).

Sarcopenia is characterized by changes involving skeletal muscle dysfunction, oxidative protein damage, cytokines, and IGF-1 (Maurer and Schulze, 2012). Since these problems are also present in CHF, sarcopenia has been identified as a serious comorbidity in patients with CHF (Dos Santos et al., 2016). Sarcopenia is an independent risk factor for mortality in patients with cardiovascular diseases (Onoue et al., 2016). With this in mind, it was shown that a sarcopenia screening test involving age, grip strength, and calf circumference can predict future adverse events in patients with CHF (Onoue et al., 2016). A Kaplan–Meier curve showed that CHF event-free survival rate was significantly lower in patients with sarcopenia (Onoue et al., 2016).

In regard to CHF, sarcopenia is most often associated with HFpEF, especially in frail patients (Kinugasa and Yamamoto, 2016). Sarcopenia may contribute to the development of HFpEF through different metabolic and endocrine changes (Kinugasa and Yamamoto, 2016). Compared to symptomatic HFpEF patients without sarcopenia, those with sarcopenia performed worse during 6-min walk testing and showed lower absolute peak oxygen consumption (Bekfani et al., 2016). ASM was independently associated with reduced distance during the walk testing (Bekfani et al., 2016). Higher muscle strength and ASM values were associated with higher quality of living (Bekfani et al., 2016).

Deconditioning

Physical deconditioning due to decreased physical activity likely contributes to skeletal muscle wasting in patients with CHF. Deconditioning is typically associated with muscle disuse. Overall, changes in CHF are similar to changes due to deconditioning. It has been observed that biochemical and histological alterations in skeletal muscle in CHF are similar to those caused by deconditioning (Minotti et al., 1992). Specifically, both involve atrophy, metabolic alterations with decreased oxidative enzymes, sympathetic over-activation, and decreased muscle fiber size (Nicoletti et al., 2003). In terms of exercise intolerance, deconditioning and CHF are correlated with decrements in peak systemic VO_2, muscle strength, and endurance (Minotti et al., 1992). Exercise training improves both conditions. Since benefits of exercise training are nonspecific, however, improvements from exercise do not prove that deconditioning is the primary mechanism of skeletal muscle changes in CHF (Minotti et al., 1992). The similarities between CHF and deconditioning are summarized below (**Table 5**).

Although deconditioning may contribute to skeletal muscle alterations in CHF, it does not fully explain changes in muscle structure, metabolism, and function. Some components of the CHF syndrome suggest a generalized metabolic myopathy caused by CHF (Mettauer et al., 2006). In experimental models of CHF, all muscles including the diaphragm are characterized by abnormal enzymatic and mitochondrial function (Mettauer et al., 2006). In deconditioning, only postural oxidative muscles are affected (Mettauer et al., 2006). Moreover, enzymatic changes involving CK and glycolytic systems are present in CHF but not deconditioning (Mettauer et al., 2006). Disuse atrophy causes a shift toward the slow type of MHC, which is the opposite of what occurs in patients with CHF (Nicoletti et al., 2003).

Further studies are needed to fully determine the extent to which deconditioning impacts the syndrome of CHF. Regardless, localized and systemic exercise training and reconditioning may significantly alleviate changes in patients with CHF (Mettauer et al., 2006).

Table 5 Similarities between muscular deconditioning and heart failure (Piepoli et al., 2001)

	Deconditioning	*Heart failure*
Hemodynamics		
Vascular resistance	↑	↑
Resting heart rate	↑	↑
Max A-VO_2 differences	↓	↓/↔
Function		
Exercise tolerance	↓	↓
VO_2 max	↓	↓
Neuroendocrine/autonomic		
Renin/angiotensin	↓	↓
Sympathetic	↑	↑
Vagal activity	↑	↑
Baroreflex sensitivity	↓	↓
HRV	↓	↓
Skeletal muscle		
Muscle mass/bulk	↓	↓
Mitochondrial enzymes		
Oxidative	↓	↓
Glycolytic	↑	↑
Fiber type IIb/IIa ratio	↑	↑
Psychological		
Well-being	↓	↓
Activity scores	↓	↓

Muscle Cell Apoptosis

Apoptosis often occurs in skeletal muscle of patients with CHF. This has been confirmed in skeletal muscle biopsies (Hambrecht et al., 2002). Ultrastructural analysis reveals a higher number of apoptotic myocytes (Nicoletti et al., 2003). Though there are over 100 nuclei in each muscle fiber, only a minority of the nuclei display DNA fragmentation, which indicates cell death (Schulze et al., 2002). Impaired endothelial nitric oxide synthase (eNOS) expression is one factor associated with increased skeletal muscle apoptosis (Georgiadou and Adamopoulos, 2012). Apoptosis leads to decreased muscle bulk, decreased contractility, and increased muscle atrophy (Schulze et al., 2002). As a result, it is also associated with reduced exercise tolerance. It has been suggested, however, that apoptosis may minimally contribute to decreased muscle mass (Mettauer et al., 2006).

Many genes that regulate apoptosis are altered in CHF. Oncogenes including c-myc and bcl2 are reduced (Nicoletti et al., 2003). Tumor suppressor genes, including p53, and other factors that increase apoptosis, including NOS, nitric oxide, caspase-3, and ubiquitin, are increased (Nicoletti et al., 2003).

Growth Hormone/IGF-1 Axis

Many factors influence expression of IGF-1 in skeletal muscle. Serum levels of IGF-1 and growth hormone (GH) influence skeletal muscle expression of IGF-1. Nonhumoral stimuli may also stimulate IGF-1 expression (Schulze et al., 2002). One study showed that 4 days of muscle stretch, the strongest nonhumoral stimulus, induced upregulation of IGF-mRNA as soon as 12 h later (Schulze et al., 2002). Skeletal muscle IGF-1 levels are modified by muscle use (Schulze et al., 2002). In neonatal rats, muscle unloading by zero gravity caused decreased expression of IGF-1 in skeletal muscle (Schulze et al., 2002). The GH/IGF-1 axis is a regulator of normal growth, hypertrophy, and atrophy (Hambrecht et al., 2002). Binding of IGF-1 to receptors induces cellular proliferation and protection from apoptosis. It also prevents TNF-α induced cell death (Hambrecht et al., 2002).

Patients with CHF may have increased levels of GH with unusually normal or low serum levels of IGF-1 (Hambrecht et al., 2002). These findings suggest the development of GH resistance in CHF patients (Hambrecht et al., 2002). Local levels of IGF-1 are reduced before systemic changes are apparent (Hambrecht et al., 2002). Skeletal muscle biopsies from noncachectic patients with CHF had downregulated skeletal muscle expression of IGF-1 but normal serum concentrations of IGF-1 (Schulze et al., 2002). Changes in the GF/IGF-1 axis contribute to the loss of muscle bulk, muscle wasting, and eventually clinically recognizable cachexia (Hambrecht et al., 2002).

Pathophysiological changes related to alterations in the GH/IGF-1 axis in patients with CHF have been characterized. Insulin resistance in CHF may be caused by proinflammatory cytokines and oxidative stress (Georgiadou and Adamopoulos, 2012). Combined with decreased levels of IGF-1, this decreases activation of protein kinase B (Akt) in skeletal muscle (Georgiadou and Adamopoulos, 2012). Decreased Akt activation decreases phosphorylation of mammalian target of rapamycin (mTOR) and

glycogen synthase kinase, thereby decreasing protein synthesis (Georgiadou and Adamopoulos, 2012). Moreover, decreased Akt activation upregulates FoXO transcription factors (Georgiadou and Adamopoulos, 2012). FOXO transcription factors activate the ubiquitin proteasome pathway of protein degradation by activating ubiquitin-protein ligase atrogin-1/MAFbx (Georgiadou and Adamopoulos, 2012). Decreased levels of IGF-1 also activate caspase-3, which also contributes to protein degradation through the ubiquitin proteasome (Georgiadou and Adamopoulos, 2012). In a murine heart failure model with whole body insulin resistance, serine phosphorylation of Akt and glucose transporter 4 (GLUT4) in skeletal muscle is impaired by NAD(P)H oxidase-derived superoxide (Tsutsui et al., 2011). NAD(P)H oxidase inhibitor alleviated insulin resistance and signaling deficiencies in skeletal muscle (Tsutsui et al., 2011). Similarly, in skeletal muscle from post-infarction mice, it was shown that insulin-stimulated serine-phosphorylation of Akt decreased by 57% and GLUT4 translocation decreased by 69% (Fukushima et al., 2016). In this study, aliskiren, a direct renin inhibitor, alleviated changes, inhibited plasma renin, and decreased angiotensin II (Ang II) levels (Fukushima et al., 2016). Increased levels of Ang II suppress IGF-1 signaling through the Akt/mTOR/p70S6k pathway (Zizola and Schulze, 2013). Ang II also activates caspase-3, actin cleavage, ubiquitination, and apoptosis (Zizola and Schulze, 2013).

Renin inhibitors may reduce insulin resistance (Fukushima et al., 2016). It has not yet been determined if ACEi improve skeletal muscle in patients with CHF through the IGF-1 pathway or through direct effects on vascular endothelial function (Zizola and Schulze, 2013).

Skeletal muscle changes due to alterations in the GH/IGF-1 pathway have also been characterized. In noncachectic patients, low levels of systemic IGF-1, which occur in advanced stages of CHF, are associated with decreased leg muscle CSA and strength (Hambrecht et al., 2002). Even when serum IGF-1 levels are not significantly altered in patients with CHF, quadriceps skeletal muscle may have reduced IGF-1 mRNA expression and increased IGF-1 receptor mRNA expression (Hambrecht et al., 2002). Increased receptor expression, however, is unable to compensate for IGF-1 deficits that lead to atrophy (Hambrecht et al., 2002). Atrophy is accompanied by fatigability and reduced total muscle CSA that closely correlates with local IGF-1 expression (Hambrecht et al., 2002).

Exercise training, which serves as a natural cause of muscle stretch, may alleviate CHF symptoms through the GH/IGF-1 pathway (Schulze et al., 2002). One study showed that local IGF-1 expression more than doubled after 6 months of exercise training in patients with CHF (Schulze et al., 2002). Specifically, long-term aerobic exercise training (AET) has been recommended as an intervention for the IGF-1 deficient, catabolic state (Schulze et al., 2002). In mice, AET activated the IGF-1/Akt/mTOR pathway (Bacurau et al., 2016). This reduced exercise intolerance, soleus atrophy, and 26S proteasome hyperactivity (Bacurau et al., 2016). It also decreased levels of myostatin and Smad2 while preventing reduction of IGF-1, pAkt, p4E-BP1, and pP70 (Bacurau et al., 2016). Rapamycin treatment prior to AET limited beneficial effects of AET, showing that AET-mediated benefits may involve the IGF-1 pathway (Bacurau et al., 2016). Alternatively, therapies may focus on reducing GH resistance in patients with skeletal muscle wasting (Nicoletti et al., 2003). Cytokine antagonists, catabolic hormone antagonists, and amino acid supplementation may all reduce problems related to the GH/IGF-1 axis (Pasini et al., 2003).

Biochemical Pathways

Impaired energy metabolism contributes to skeletal muscle wasting. In mice, CK deficiency induced skeletal muscle wasting through activation of AMP-activated protein kinase (Mettauer et al., 2006). In a Wistar Kyoto rat model of CHF, muscle wasting was related to changes in antioxidative capacity (Mangner et al., 2015). In the quadriceps, antioxidative capacity was reduced, as shown by reduced glutathione peroxidase and manganese SOD activity (Mangner et al., 2015). COX activity decreased and LDH activity increased (although other studies have shown that LDH activity decreases—see "**Metabolic Changes**" section for further discussion) (Mangner et al., 2015). On the contrary, in the diaphragm, antioxidative capacity increased, as shown by increased glutathione peroxidase and manganese SOD activity (Mangner et al., 2015). Metabolic enzymes in the diaphragm were unaltered (Mangner et al., 2015). In both quadriceps and the diaphragm, catabolic responses and myopathy were increased, as shown by increased protein expression of the E3 ligase muscle ring finger 1 and proteasome activity (Mangner et al., 2015). Long-term exercise training may improve skeletal muscle COX activity (Schulze et al., 2002).

Protein degradation pathways play a role in muscle wasting. One major protein degradation pathway is the ubiquitin-proteasome pathway. In this pathway, proteins tagged with ubiquitin are degraded through a 26S proteasome in an ATP-dependent manner (Zizola and Schulze, 2013). The ubiquitin-proteasome pathway may be activated by factors in CHF, including Ang II and cytokines (TNF-α and IL-1) (Zizola and Schulze, 2013). A study on skeletal muscle in 4-week old Wistar rats with heart failure induced by MCT showed that the ubiquitin-proteasome and macroautophagolysosome pathways were activated even before morphological changes were present in skeletal muscle (Fujita et al., 2015). Skeletal muscle from mice with left ventricular dysfunction revealed activation of the ubiquitin-proteasome pathway with increased protein ubiquitination, FoxO transcription factor activation, increased expression of muscle-specific atrogenes and overall muscle atrophy (Zizola and Schulze, 2013). Increased activation of the ubiquitin-proteasome system in skeletal muscle was further shown in a sympathetic hyperactivity mouse model of CHF (Cunha et al., 2012). In this study, AET normalized levels of lipid hydroperoxides, carbonylated proteins, and E3 ligase mRNA (Cunha et al., 2012). Moreover, it restored chymotrypsin-like proteasome activity, which has also been observed in human skeletal muscle (Cunha et al., 2012). Studies suggest that physical exercise, especially prior to recognizable skeletal muscle atrophy, should be implemented to reduce over-activation of protein degradation pathways (Fujita et al., 2015). In CHF, increased PGC-1α, which is related to mitochondrial function and moderation of FoxO activity, may also reduce declines due to the ubiquitin pathway (Forman et al., 2014).

Circulating Factors

Patients with advanced CHF and cachexia have increased Ang II levels (Yoshida and Delafontaine, 2016). Ang II, via its type 1 receptor, causes muscle protein breakdown and apoptosis (Yoshida and Delafontaine, 2016). It also inhibits satellite cell proliferation and muscle regeneration (Yoshida and Delafontaine, 2016). Via the type 2 receptor (AT2R), however, Ang II potentiates muscle regeneration (Yoshida and Delafontaine, 2016). In a mouse model of CHF, muscle regeneration was reduced and AT2R expression was slightly increased (Yoshida and Delafontaine, 2016). The researchers suggested that an intronic enhancer (specifically AT2R intron 2) that regulates AT2R expression during stem cell (SC) differentiation is suppressed in CHF, thereby decreasing muscle regeneration (Yoshida and Delafontaine, 2016).

Skeletal muscle biopsies from patients with HFrEF indicate increased local concentrations of adiponectin in addition to circulating levels (Sente et al., 2016a). In patients with HFrEF, circulating adiponectin levels increase relative to the severity of the disease (Sente et al., 2016a). Adiponectin resistance in skeletal muscle may be related to increased free fatty acid availability and skeletal muscle wasting (Sente et al., 2016a).

Various other factors may be involved. Studies have shown an elevated cortisol to dehydroepiandrosterone ratio in patients with CHF (Schulze et al., 2002). In male patients with CHF, deficiencies in anabolic hormones, such as testosterone and dehydroepiandrosterone, correlate with a poor prognosis (Zizola and Schulze, 2013). Studies have also shown high levels of catecholamines, which would influence resting metabolic rate (Schulze et al., 2002; Hambrecht et al., 2002). One abstract focusing on 53 CHF patients with severely impaired exercise intolerance suggested that significantly increased serum concentrations of leptin, a hormone related to energy expenditure and weight loss, may be involved in catabolic alterations in patients with severe left ventricular dysfunction (Adams et al., 2001; Schulze et al., 2001) Many studies have shown that increased levels of circulating myostatin, a factor secreted by skeletal muscle, may contribute to muscle atrophy in CHF through antianabolic and antihypertrophic mechanisms (Zizola and Schulze, 2013). Studies related to changes in the concentration of circulating myostatin in patients with CHF, however, show conflicting results. Alterations involving aldosterone, renin, melanocortins, neuropeptide Y, and ghrelin have been observed (Georgiadou and Adamopoulos, 2012). Finally, sympathetic activation and cytokines (TNF-α, IL-6, IL-1β) contribute to muscle wasting.

Nutrition

Skeletal muscle plays an important role in metabolism. It exchanges amino acids with the liver (Pasini et al., 2003). These amino acids are used to produce glucose through gluconeogenesis during malnutrition (Pasini et al., 2003). Malnutrition has been shown to be related to muscle wasting and cachexia in patients with CHF. One study showed that 24% of patients with CHF are malnourished, whereas 68% have muscle atrophy (Pasini et al., 2003). Another study involving 130 ambulatory patients with CHF showed that poor nutritional status is related to poor clinical outcomes (Saitoh et al., 2016). In the study, patients with muscle wasting had significantly lower values of peak VO_2, 6-minute walk distance, and Mini-Nutritional Assessment-Short Form (MNA-SF) score (Saitoh et al., 2016). In multivariate analysis, MNA-SF remained an independent predictor of muscle wasting and mortality, leading the researchers to suggest that nutritional screening should be included as a fundamental part of patient assessment (Saitoh et al., 2016). Exogenous amino acid supplementation may serve as an alternative therapy for patients with CHF and poor nutritional status (Pasini et al., 2003). Amino acids may increase anabolic processes and reduce catabolic processes (Pasini et al., 2003).

Clinical Muscle Weakness

Reduced skeletal muscle mass, especially at the stage of cachexia, contributes to exercise intolerance in patients with CHF. Patients consistently show a reduction in muscle bulk and endurance. In one study, static and dynamic endurance were markedly decreased in patients with CHF (Minotti et al., 1992). There was a relationship between dynamic endurance and peak systemic VO_2 in patients with CHF (Minotti et al., 1992). In another study, CHF patients underwent localized unilateral arm training (Minotti et al., 1992). The training doubled or tripled wrist flexor endurance although the muscle size did not change (Minotti et al., 1992). The changes were associated with improvements in muscle oxidative metabolism, as shown by a slower increase of Pi and decrease of PCr (Minotti et al., 1992).

Some studies have suggested that muscle strength is not impaired in patients with CHF, although others have reported reduced muscle strength (Nicoletti et al., 2003). A study on patients with severe CHF showed that patients only had 55% of the predicted strength (Minotti et al., 1992). A different preliminary study comparing quadriceps strength and endurance in nine patients with CHF to five sedentary controls found that isometric strength was similar between the groups, although they suggested that this might be due to a wide range of clinical severity (Minotti et al., 1992). After normalizing work load to an individual's maximal strength, a group showed that the maximum load in patients with CHF was 30% lower compared to controls (Minotti et al., 1992).

Muscle contractility may also be altered by atrophy. One study focused on contractility in the soleus because it is a primary site of muscle atrophy (Panizzolo et al., 2016). Compared to age- and activity-matched controls, CHF patients had reduced passive soleus force at the same relative levels of muscle stretch (though the results were not statistically significant) (Panizzolo et al., 2016). The reduction was eliminated when normalized by CSA, showing that force output reduction may be most strongly associated with muscle size (Panizzolo et al., 2016). Passive force was also significantly higher in CHF patients at an absolute muscle length, which

could potentially be explained by shorter muscle slack lengths (Panizzolo et al., 2016). A second study related to muscle shortening showed decreased maximal force, speed, and power (Coggan and Peterson, 2016). This study, however, suggested the changes may be related to decreased NO availability (Coggan and Peterson, 2016).

Blood Flow to Skeletal Muscle

Blood flow to tissue is related to the level of metabolic activity. Cardiovascular hemodynamics are impacted by skeletal muscle due to its large mass (Mohrman and Heller, 2014). At rest, skeletal muscle receives 15%–20% of cardiac output (Fletcher et al., 2011; Mohrman and Heller, 2014). This is partially due to a high basal vascular tone (Mohrman and Heller, 2014). Resting skeletal muscles normally extract only 25%–30% of the oxygen delivered through blood flow (Mohrman and Heller, 2014). This means that, although blood flow to skeletal muscle is relatively low, it is still significantly greater than the flow necessary for metabolic requirements (Mohrman and Heller, 2014). During strenuous exercise, skeletal muscle may receive greater than 80%–85% of cardiac output (Fletcher et al., 2011; Mohrman and Heller, 2014). Specifically, this may be a change from 4–7 mL/min of blood per 100 g of skeletal muscle during rest to 50–75 mL/min of blood per 100 g of muscle during exercise (Fletcher et al., 2011). Blood flow in active skeletal muscle is mostly directed to oxidative portions rather than glycolytic portions (Fletcher et al., 2011).

Patients with CHF have reduced blow flow to skeletal muscle. Due to reduced cardiac output in CHF, circulatory regulation must decrease blood supply to exercising skeletal muscle in order to prevent dangerous changes in BP (Poole et al., 2012). Reduced blood flow impairs peripheral perfusion, causing reduced oxygen supply to skeletal muscle despite increased oxygen demands (Poole et al., 2012). Researchers are unsure if skeletal muscle changes in CHF are related to a CHF-specific myopathy or secondary effects of reduced blood flow in exercising muscle (Nicoletti et al., 2003). Changes secondarily affect respiratory, vascular, and locomotor muscle function (Poole et al., 2012).

Skeletal muscle in patients with CHF has changes related to capillaries. Many studies have shown that capillary density is reduced in the skeletal muscle. In a rat model of heart failure induced by MCT injection, capillary-to-fiber ratio was lower in the oxidative plantaris region but not in the glycolytic region (Wust et al., 2012). Some researchers suggest that, due to fiber atrophy, the number of capillaries per fiber area is unchanged (Mettauer et al., 2006). Post-capillary resistance is increased, which impairs blood flow (Poole et al., 2012). The combination of slowed capillary hemodynamics and reduced blood flow velocity helps to maintain normal levels of oxygen extraction (Mettauer et al., 2006). As a result, arteriovenous oxygen difference is typically normal during exercise in patients with CHF (Mettauer et al., 2006).

Changes in skeletal muscle blood flow are strongly related to alterations in vascular tone. Patients with CHF have increased peripheral vasoconstriction along with defective vasodilatation. Increased vasoconstriction may be caused by increased plasma concentrations of catecholamines, renin, Ang II, vasopressin, and endothelin-1 (Poole et al., 2012). Peripheral chemoreceptors and metaboreflexes also contribute to vasoconstriction through increased sympathetic activation of α-adrenergic tone (Poole et al., 2012). Experimental and clinical studies suggest that decreased vasodilatation, on the other hand, may be caused by vascular stiffness and resistance from alterations in arterial wall sodium content (Minotti et al., 1992). Vasodilatation is impaired by salt and water retention and improved by diuresis (Poole et al., 2012). In a study comparing dynamic, single leg knee-extensor exercise in patients with HFpEF compared to healthy controls, HFpEF patients showed significant attrition during more intensive exercise related to a marked reduction in leg blood flow and leg vascular conductance that was not attributed to disease-related changes in central hemodynamics (Lee et al., 2016). This suggested that impaired vasodilatation in exercising skeletal muscle vasculature impacts exercise intolerance in patients with HFpEF (Lee et al., 2016). Lower vasodilatation capability particularly impacts exercise tolerance in patients with sarcopenia (Dos Santos et al., 2016). Altered vascular tone also decreases flow of nutrients to skeletal muscle during exercise (Mettauer et al., 2006). This decreases oxygen and substrate supply to myocytes and reduces the increase in oxygen uptake at the beginning of exercise (Mettauer et al., 2006).

Vasodilatation may also be impaired through endothelial dysfunction. A study in 228 patients with CHF and sarcopenia confirmed the presence of impaired endothelial function (Dos Santos et al., 2016). Endothelial dysfunction may be augmented by endothelial cell damage and decreased capacity for repair due to low circulating levels of endothelial progenitor cells (Poole et al., 2012). In patients with CHF, there is reduced production and release of endothelium-derived vasodilator factors, such as NO, in response to acetylcholine (Piepoli et al., 2001). Basal release of NO, however, may be preserved or enhanced as a compensatory mechanism (Francis et al., 2011). NO has general antiatherogenic and antithrombotic effects (Fletcher et al., 2011). Decreased NO levels reduce the ability to oppose α-adrenergic vasoconstriction and reduce vasodilatation caused by shear stress (Poole et al., 2012). This causes oxygen delivery-utilization mismatch, in which microvascular oxygenation falls faster during increased metabolic demand (Hirai et al., 2014). It also reduces exercise tolerance in patients with HFrEF (Hirai et al., 2017). Endothelial dysfunction may be partially related to deconditioning, and it may be reversed through exercise (Francis et al., 2011).

Exercise may alleviate changes in skeletal muscle blood flow in patients with CHF. Exercise may increase muscle capillarity in patients with CHF through preservation of vascular endothelial growth factor pathways (Poole et al., 2012). In a study comparing stable patients with CHF to healthy controls, it was shown that acute exercise affects microcirculation in peripheral, nonexercising muscles in a different way in patients with CHF (Tzanis et al., 2016). Specifically, patients with CHF had lower muscle oxygen saturation (StO_2) and reperfusion rate at rest (Tzanis et al., 2016). Oxygen consumption rate increased after exercise in both patients with CHF and healthy controls (Tzanis et al., 2016). StO_2 decreased significantly after maximal exercise in patients with CHF, whereas it returned to preexercise values in healthy subjects (Tzanis et al., 2016). In a study on rats with CHF, exercise training

slowed the overall fall in microvascular oxygenation during contractions (Hirai et al., 2014). This effect was not abolished by *N*(G)-nitro-L-arginine methyl ester (Hirai et al., 2014). Moreover, sodium nitroprusside increased mean response time in both groups, thereby slowing kinetics in trained CHF rats (Hirai et al., 2014). The researchers concluded that improved NO-mediated function is not obligatory for training-induced improvements in skeletal muscle microvascular oxygenation in rats with CHF (Hirai et al., 2014). In a third study, it was shown that exercise training enhances endothelium-dependent coronary and peripheral arterial vasodilatation in patients with CHF (Fletcher et al., 2011). Exercise may improve vascular function through increasing arterial wall shear stress, which promotes enhanced expression and activation of eNOS through Akt-dependent phosphorylation (Fletcher et al., 2011). Exercise may also improve vascular endothelial function through elevation of circulating endothelial progenitor cells and improved endothelial repair (Poole et al., 2012).

Exercise

Exercise intolerance is one of the primary features of CHF. It is often accompanied by fatigue. Patients are often categorized based on results from cardiopulmonary exercise testing (Fletcher et al., 2011). Treadmill exercise time with the Naughton protocol is an alternative method of testing that is simple and accessible (Fletcher et al., 2011). Exercise intolerance is highly related to mortality in patients with CHF (Mettauer et al., 2001). Exercise intolerance is not correlated with left ventricular ejection fraction, which suggests that it may be instead related to peripheral abnormalities including blood flow to muscles and skeletal muscle dysfunction (Francis et al., 2011; Maurer and Schulze, 2012; Nicoletti et al., 2003). As mentioned throughout this paper, many factors contribute to reduced exercise capacity. Many maladaptive changes related to exercise intolerance are reversible.

Systemic exercise capacity is most commonly described in terms of peak oxygen uptake (VO_2 max). In healthy subjects, exercise capacity is related to cardiac output and peripheral oxygen delivery in response to metabolic demands (Minotti et al., 1992). At maximal exercise, VO_2 max is achieved and oxygen uptake plateaus (Minotti et al., 1992). In patients with CHF, however, there is only a weak relationship between VO_2 max and ejection fraction (Minotti et al., 1992). Skeletal muscle CSA, though, is an independent predictor of VO_2 max (Harrington et al., 1997). A study showed that patients with HFpEF had reduced VO_2 max and 6-min walk distances (Kitzman et al., 2014). In another study, addition of arm exercise to maximal leg exercise increased VO_2 max, showing that the decline in VO_2 max is not related to decreased cardiac output (Mettauer et al., 2006). In CHF patients, fatigue occurs prior to reaching VO_2 max (Minotti et al., 1992). These observations suggest that VO_2 max alterations, like other factors in exercise intolerance, are due to skeletal muscle abnormalities.

Exercise capacity may also be characterized by other variables. VO_2 kinetics are related to the speed of adjustments in oxygen uptake (Poole et al., 2012). Kinetics are slowed to several minutes in patients with CHF (Poole et al., 2012). This means that, for any metabolic transition, patients with CHF incur a greater oxygen deficit and more extreme intracellular perturbation of high-energy phosphagens (Poole et al., 2012). Slowed kinetics also accelerate glycogenolysis and contribute to fatigue and exercise intolerance (Poole et al., 2012). Anaerobic threshold (AT), also called lactate threshold, is the level of exercise beyond VO_2 max at which increased anaerobic metabolism results in lactate accumulation (Minotti et al., 1992). Typically, AT occurs at 50%–60% of peak exercise (Tomono et al., 2016). In patients with CHF, however, AT occurs at low absolute VO_2 levels (Poole et al., 2012). This means that patients with the most compromised oxygen delivery to muscle may have the highest oxygen requirements during exercise (Poole et al., 2012). In a study on 194 stable, optimally treated patients with CHF, the ratio of AT to VO_2 max (%AT/peak) showed a significant negative correlation with VO_2 max but not AT (Tomono et al., 2016). Although this showed that decreased VO_2 max is the primary mechanism of decline, AT is still a well-known factor in evaluating patients (Tomono et al., 2016). Lastly, patients with CHF have an increased ventilation response (VE/V_{CO2}) (Cicoira et al., 2001). This means that patients ventilate at a higher level for a given rate of carbon dioxide production (Cicoira et al., 2001). Ventilation is partially stimulated by the muscle metaboreflex. A study showed that skeletal muscle mass independently predicts VE/V_{CO2} (Cicoira et al., 2001). Changes in ventilation may be related to alterations in respiratory muscle (Nicoletti et al., 2003).

Appropriate exercise training is safe in patients with CHF. It may improve exercise tolerance through noncardiac factors including skeletal muscle structure and function, metabolic changes, peripheral blood flow, oxygen utilization, and endothelial function. In a study on patients with CHF, isolated quadriceps training improved maximal exercise capacity (Esposito et al., 2011). Exercise training also increases VO_2 max. In a meta-analysis of trials by the European Heart Failure Training Group, exercise improved VO_2 max by up to 2 $mL/kg/min^{-1}$, which is similar to the most effective pharmaceutical treatments, such as ACE inhibitors (Schulze et al., 2002). In a study on 20 male patients with stable CHF, training improved VO_2 max by 29% (Gielen et al., 2003). Improvements in all of these factors positively contribute to quality of life. Some of the benefits of exercise are summarized below (**Tables 6** and **7**).

Exercise training increases skeletal muscle bulk and CSA in patients with CHF (Piepoli et al., 2001). In male Wistar rats with ascending aortic stenosis that induced CHF, exercise prevented catabolic processes and muscle wasting (Souza et al., 2014). It did not, however, impact expression of anabolic factors (Souza et al., 2014). Similar changes are observed in patients with CHF. Improvements in muscle bulk and CSA lead to improved function in terms of strength, peak work rate, endurance, and fatigability (Piepoli et al., 2001).

Although aerobic exercise is the most often suggested form of exercise, other forms of exercise may have specific effects and benefits. Resistance training may target muscle hypertrophy and lengthening through generation of new sarcomeres (Panizzolo et al., 2016). This was confirmed in one study on patients with CHF with reduced soleus size and passive force

Table 6 Exercise training in CHF (Schulze et al., 2002)

Exercise training in chronic heart failure	
Skeletal muscle	*Endothelial function*
Oxidative enzymes ↑	Agonist-mediated endothelium-dependent peripheral vasodilation ↑
Fiber type shift (type II–type I)	Afterload reduction
Local IGF-1 expression ↑	
iNOS expression ↓	
Skeletal muscle mass ↑?	

Table 7 Skeletal muscle benefit of exercise training (Piepoli et al., 2001)

1. Morphology	↑ Cross sectional area
2. Function	↑ Peak work rate
	↑ Strength
	↑ Endurance
	↓ Fatigability
3. Blood flow	↑ Leg oxygen delivery
	↓ Leg vascular resistance
	↑ O_2 arterio-venous differences
4. Metabolism	↑ Oxidative metabolism
	↑ Adenosine triphosphate re-synthesis
	↓/↔ Anaerobic metabolism
	↓ Lactate accumulation, acidosis
	↓ Phosphocreatinine depletion
5. Ultrastructural	↑ Mitochondria size
	↑ Aerobic enzyme activity
	↑ Fiber size
	↑ Capillary density
	↑ Endothelium function
	↑ NO release

(Panizzolo et al., 2016). In another study, nondominant wrist flexor training improved oxidative capacity in skeletal muscles during submaximal work load (Volaklis and Tokmakidis, 2005). Further studies have shown that resistance training increases CSA of the quadriceps femoris, muscle fiber area, and oxidative capacity (Volaklis and Tokmakidis, 2005). Improvements due to resistance training are related to functional improvements demonstrated in 6-min walking tests (Volaklis and Tokmakidis, 2005). High-intensity interval training (HIIT) is a specific form of AET. In one study on 13 males with CHF, HIIT increased type I fibers, fiber CSA, capillary to fiber ratio, and expression of IGF-1 and insulin-like growth factor binding protein (IGFBP)-3 (Tzanis et al., 2016). In a second study on 26 patients with CHF, 12 weeks of HIIT at 85%–95% of peak VO_2 improved maximal exercise capacity and exercise hemodynamics (Spee et al., 2016). Improvements in recovery were related to attenuated skeletal muscle deoxygenation rather than cardiac output (Spee et al., 2016). HIIT may specifically reduce skeletal muscle myopathy and improve microvascular delivery and utilization (Spee et al., 2016).

Other Approaches to Treatment

This section will briefly list various programs, treatments, and potential therapies that have been suggested in addition to exercise.

Cardiac rehabilitation is increasingly applied to patients with CHF (Taub, 2016). It is newly indicated for patients with stable CHF with an ejection fraction below 35% (Taub, 2016). It may also be helpful in cases of HFpEF, which has limited treatment options (Taub, 2016). Exercise training is still a primary focus in cardiac rehabilitation, but it is combined with nutrition, BP management, and lipid management (Taub, 2016). Two intensive 72-h cardiac rehabilitation approaches include the Ornish and Pritikin programs (Taub, 2016). The Ornish program involves a 100% plant-based diet and live instructors (Taub, 2016). Patients in this program showed regression in coronary atherosclerosis (Taub, 2016). The Pritikin program involves some lean meat and fish, inclusion of video instruction and customizable steps (Taub, 2016). Patients in this program showed improvement in biomarkers like HbA1c (Taub, 2016). Cardiac rehabilitation improves mitochondrial function and nitric oxide function while also inducing antiinflammatory effects (Taub, 2016). Patients who participate in these programs have decreased levels of all-cause mortality, risk of reinfarction, and readmission (Taub, 2016).

A combination of physical training and certain drug therapies, such as administration of ACEi and Ang II-receptor blockers, may better improve exercise tolerance and characteristics of skeletal muscles (Georgiadou and Adamopoulos, 2012). One study showed than irbesartan, an Ang II type I receptor blocker, prevents myocyte apoptosis, muscle atrophy, and changes in MHCs in experimental CHF (Nicoletti et al., 2003). The researchers suggested that irbesartan limits activity of TNF-α and Ang II to reduce levels of apoptosis (Nicoletti et al., 2003). Beta blockers may also be used to reduce sympathetic activation in patients with CHF. It is yet to be determined if pharmacologic interventions including beta blockers and inhibition of the renin-angiotensin-aldosterone system have an impact on maladaptive changes in skeletal muscle (Maurer and Schulze, 2012).

Patients with CHF have elevated GH but reduced IGF-1 and IGFBP-3 (Khawaja et al., 2014). It has been shown that IGF-1 inversely modulates key atrophy induced genes via the PI3K/Akt/mTOR pathway, meaning this pathway may be potentially useful as a target for antiatrophic therapies (Georgiadou and Adamopoulos, 2012). In one study of patients with advanced heart failure, ventricular assist device (VAD) implantation increased skeletal muscle expression of IGF-1 10-fold and IGFBP-3 5-fold (Khawaja et al., 2014). Moreover, implantation enhanced oxidative gene expression (CD36, CPT1, and PGC1α) and oxidation rates (Khawaja et al., 2014). VAD implantation also increased the oxidative muscle fiber proportion, fiber CSA, and hand grip strength (Khawaja et al., 2014).

Studies on the impact of a nitrate-rich diet in patients with CHF have had varied results. In one study on patients with HFrEF, even though nitrate-rich supplementation resulted in a significantly higher plasma nitrite concentration, there was no significant difference in the time to exercise intolerance between nitrate and placebo groups (Hirai et al., 2017). Moreover, there were no significant differences in central hemodynamics, arterial BP, pulmonary oxygen uptake kinetics, skeletal muscle oxygenation, or blood lactate concentrations (Hirai et al., 2017). Other studies, however, have endorsed positive effects of a nitrate-rich diet. One study suggested that dietary nitrate supplementation improves skeletal muscle vascular function during exercise in rats with CHF (Ferguson et al., 2016). Another study on patients with CHF suggested that acute ingestion of nitrate-rich beetroot juice, a source of NO via the NO synthase-independent enterosalivary pathway, increased maximal muscle speed and power (Coggan and Peterson, 2016). A third study on nine patients with systolic heart failure showed that acute dietary nitrate intake is well tolerated, enhances NO bioavailability, and increases muscle power. The treatment did not alter BP or incite adverse clinical events. These three studies support nitrate-rich diet supplementation, especially with beetroot juice, as a novel therapeutic modality for the treatment of patients with CHF (Coggan et al., 2015).

Other potential therapies include enhanced external counterpulsation (Melin et al., 2016), therapeutic ultrasound to modulate inflammation (Rossato et al., 2015), autologous transplantation of satellite cells to reduce myopathy (Castellani et al., 2013), and activation of peroxisome proliferator-activated receptor delta (Myers and Yoshioka, 2015).

Sleep Disturbance and Cardiovascular Disease

Recent studies have demonstrated that sleep disturbance is closely associated with hypertension, metabolic disease, and various types of cardiovascular disease (CVD) (**Fig. 1**) (Shimamoto et al., 2014; Kario, 2015a, 2016; St-Onge et al., 2016; Grandner et al., 2016). Sleep disturbance includes sleep deprivation, shift-working, insomnia, obstructive sleep apnea syndrome (OSAS), restless leg syndrome, narcolepsy, etc.

Obstructive Sleep Apnea Syndrome

OSAS is the most common sleep-related breathing disorder. In OSAS, the throat narrows or collapses repeatedly during sleep, causing apnea events; in addition, intermittent hypoxia and hypercapnia, recurrent arousals, and increase in respiratory efforts lead to secondary sympathetic activation, an increase in intrathoracic pressure, oxidative stress, and systemic inflammation (**Fig. 1**) (Kario, 2009, 2016; Lévy et al., 2015; Malhotra et al., 2015; Bradley and Floras, 2009). OSAS is associated with metabolic syndrome, hypertension, and CVDs including stroke, coronary artery disease (CAD), arrhythmias, heart failure (HF), and aortic dissection. Several population-based studies have demonstrated an increased incidence of baseline and future hypertension in subjects with OSAS (Lévy et al., 2015; Malhotra et al., 2015; Bradley and Floras, 2009). In addition, OSAS is the most common secondary cause of resistant hypertension.

Sleep Deprivation and Insomnia

There is increasing evidence that poor quantity and/or quality of sleep due to causes other than SAS, such as poor sleep hygiene (sleep deprivation, irregular falling asleep time, shift working) and insomnia, are closely associated with cardiometabolic risk factors, hypertension, and various CVDs and poor prognosis (**Fig. 1**) (Shimamoto et al., 2014; Kario, 2015a; St-Onge et al., 2016; Grandner et al., 2016). Sleep deprivation has become an important health problem in our modern 24-h society, with evidence showing that people in Western countries are sleeping on average only 6.8 h per night, 1.5 h less than a century ago (Nagai et al., 2010). Chronic insomnia is disrupted sleep that occurs at least three nights per week and lasts at least 3 months. People with insomnia tend to have difficulty falling asleep (onset) or staying asleep (maintenance), and/or they wake up too early in the morning. People with insomnia can feel dissatisfied with their sleep and usually experience one or more of the following symptoms: fatigue, low energy, difficulty concentrating, mood disturbances, and decreased performance in work or at school. Chronic

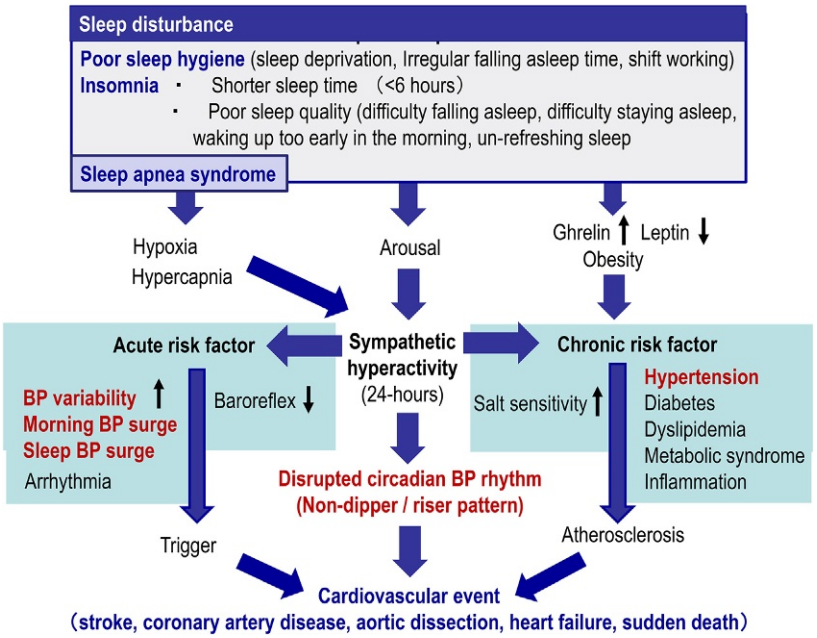

Fig. 1 Sleep disturbance and its relation to the mechanism of cardiovascular disease. *BP*, blood pressure.

insomnia disorders can have many causes. Changes in the environment, unhealthy sleep habits, shift work, other clinical disorders, and certain medications can lead to a long-term pattern of insufficient sleep.

Recent guidelines and/or statements from health organizations stress the importance of sleep hygiene for the management of hypertension and CVD prevention (Shimamoto et al., 2014; St-Onge et al., 2016).

Sleep Duration and Cardiovascular Disease

Both shorter and longer sleep durations are associated with the risk of future CVD events.

In a cross-sectional study of 30,397 individuals $\geq$18 years of age who responded to the 2005 National Health Interview Survey, the adjusted odds ratios (ORs) of CVD were 2.20, 1.33, 1.23, and 1.57 for a sleep duration of $\leq$5, 6, 8, and $\geq$9 h compared with a sleep duration of 7 h (referent). Thus, compared with sleep duration of 7 h, shorter and longer sleep durations are independently related to CVD (Sabanayagam and Shankar, 2010).

In a metaanalysis of multiple prospective studies (24 cohorts; $n=474684$; follow-up: 6.9–25 years) that included 16,067 events (4169 CAD, 3478 stroke, and 8420 CVD events), self-reported short sleep duration was associated with a greater risk of CAD (relative risk 1.48) and stroke (1.15), but not total CVD (1.03). Long sleep duration has also been associated with a greater risk of CAD (1.38), stroke (1.65), and total CVD (1.41) (Cappuccio et al., 2011).

In a case-control study of middle-aged men, long working hours and short sleep duration contributed independently to the risk of CVD in men. Men whose average number of working hours was $\geq$60 h/week were found to have significantly increased risks for CAD (OR 2.2) as compared to those with weekly working hours in the range of 40–48 h, and those with daily sleep duration <6 h were found to have increased risks for CAD (OR 3.0) as compared to those with sleep duration in the range of 6–9 h (Cheng et al., 2014).

In a metaanalysis of population-based cohort studies (27 cohorts; >70,000 elderly individuals aged $\geq$60 years), long and short sleep duration were associated with increased risk for all-cause mortality. Long sleep duration has also been associated specifically with CVD mortality (da Silva et al., 2016).

In a prospective cohort study of 392,164 adults aged $\geq$20 years who attended a health checkup program, when compared to those who slept 6–8 h per night, the risk of CAD death was increased by 34% and 35% in those who slept <4 h and >8 h, respectively. Thus, adequate sleep duration should be considered an important component of a healthy lifestyle (Strand et al., 2016).

In our Jichi Medical School Cohort Study, a nationwide population-based prospective study of 11,367 Japanese with an average follow-up of 10.7 years, the incidences of CVD for individuals sleeping <6 h and $\geq$9 h were 2.14 and 1.33 in men, and 1.46 and 1.28 in women, respectively, relative to those who reported sleeping 7–7.9 h per day (Amagai et al., 2010).

Short sleep is associated with particularly high risk of developing HF in men with CVD, and daytime napping is also associated with greater HF risk in older men. In a population-based prospective study of general practices in 24 British towns, which enrolled men aged 60–79 years without prevalent HF followed for 9 years ($n=3723$), self-reported daytime sleep duration >1 h was

independently associated with significantly greater HF risk (hazard rate (HR) 1.69) than in those who reported no daytime napping. Self-reported shorter nighttime sleep duration <6 h was significantly associated with HF risk in men with preexisting CVD (HR 2.91, vs. nighttime sleep of 7 h) (Wannamethee et al., 2016).

In a metaanalysis of a prospective study including 9692 stroke-free participants aged 42–81 years, there was a higher stroke risk among those who reported persistently long sleep or a substantial increase in sleep duration over time, compared to those reporting persistently average sleep. These findings were compatible with the pooled HRs from an updated metaanalysis, which were 1.15 for short and 1.45 for long sleep durations, respectively. Prolonged sleep may thus be a potentially useful marker of increased future stroke risk in an apparently healthy aging population (Leng et al., 2015).

Shorter sleep duration has been shown to be an independent risk for future incidence of stroke events in hypertensives, especially those with silent cerebral infarcts (SCI). In our study on 1268 elderly hypertensives (mean age 70.4 years), a shorter sleep duration of <7.5 h was independently associated with the risk of stroke (HR 2.21, $P=0.003$). When the subjects were divided into an SCI (+) group and SCI (−) group, the short sleep duration was a significant predictor for incident stroke only in the SCI (+) group (HR 2.52, $P=0.001$) (Eguchi et al., 2010).

Sleep Quality and Cardiovascular Disease

Not only sleep duration but also sleep quality is associated with CVD.

In a Dutch population-based cohort study in 20,432 men and women aged 20–65 years without any CVD history, short sleepers, especially those with poor sleep quality, had an increased risk of CVD and CAD. Sleep duration and sleep quality were assessed by a self-administered questionnaire. During 10–15 years of follow-up, short sleepers (≤6 h) had a 15% higher risk of total CVD (HR 1.15) and a 23% higher risk of CAD (HR 1.23) compared to normal sleepers (7 h). Short sleepers with poor sleep quality had a 63% higher risk of CVD (HR 1.63) and a 79% higher risk of CAD incidence (HR: 1.79) compared to normal sleepers with good sleep quality (Hoevenaar-Blom et al., 2011).

Insomnia is highly prevalent among HF patients. A recent large prospective Norwegian cohort, the Nord-Trøndelag Health study (HUNT) (54,279 men and women aged 20–89 years with a mean follow-up of 11.3 years), demonstrated that self-reported insomnia symptoms (including difficulty initiating sleep, difficulty maintaining sleep, and having nonrestorative sleep) were associated with a risk of future HF. There was a dose-dependent association between the number of insomnia symptoms and HF risk. The adjusted HRs were 0.96, 1.35, and 4.53 for people with one, two, and three insomnia symptoms, compared with those with no insomnia symptoms ($P=0.021$) (Laugsand et al., 2014).

Both SAS and non-SAS sleep quality are associated with atrial fibrillation (AF). In participants of the Multi-Ethnic Study of Atherosclerosis (MESA) Sleep Study who underwent polysomnography (PSG) ($n=2048$), a higher apnea–hypopnea index (AHI) was associated with increased odds of AF. In addition, lower odds of AF associated with longer duration of slow-wave sleep (SWS) (OR 0.66 per SD (34 min), $P=0.01$) was found, and this significance persisted after additionally adjusting for AHI (OR 0.68, $P=0.01$) (Kwon et al., 2015).

Sleep and Subclinical Cardiovascular Disease

Abnormal daily sleep duration and quality are associated with subclinical measures of CVD.

High BP, short sleep duration (≤5 h), poor sleep quality, and insomnia are associated with atherosclerosis risk leading to CVD in the elderly. In a cross-sectional study on 86 elderly aged ≥65 years (mean 74 years), carotid intima-media thickness (IMT) evaluated using ultrasonography was significantly greater in subjects with actigraphy-measured total sleep time (TST) ≤5 h than those with TST >7 h (1.3 vs. 0.9 mm; $P=0.009$). Multiple regression analysis revealed that systolic BP, TST, and the Pittsburgh Sleep Quality Index (PSQI) were significant contributing factors for increased IMT (Nakazaki et al., 2012). In the Coronary Artery Risk Development in Young Adults (CARDIA) Study, 1 h of longer sleep duration, as evaluated by wrist actigraphy monitors, was associated with 0.026 mm less carotid IMT among men ($P=0.02$) and 0.001 mm less carotid IMT among women ($P=0.91$) (Sands et al., 2012).

Longer measured sleep is associated with lower calcification incidence independent of examined potential mediators and confounders. Coronary artery calcification (CAC) is a subclinical predictor of CAD. In an observational cohort of 495 healthy middle-aged participants (35–47 years) from the CARDIA cohort Chicago site, CAC incidence was evaluated by computed tomography after 5-year follow-up. Longer sleep duration (evaluated by wrist actigraphy) was significantly associated with reduced 5-year CAC incidence (OR 0.67 per hour, $P=0.01$) (King et al., 2008). In a cross-sectional study of adults who underwent a health checkup examination, including assessment of sleep duration and quality coupled with either CAC ($n=29,203$) or brachial-ankle pulse wave velocity (PWV) ($n=18,106$), the multivariate-adjusted CAC score ratios comparing sleep durations of ≤5, 6, 8, and ≥9 h with 7 h of sleep were 1.50, 1.34, 1.37, and 1.72, respectively ($P=0.002$). The corresponding average differences in brachial-ankle PWV were 6.7, 2.9, 10.5, and 9.6 cm/s, respectively ($P=0.019$). Poor subjective sleep quality was associated with CAC in women but not in men, whereas the association between poor subjective sleep quality and brachial-ankle PWV was stronger in men than in women. These results underscore the importance of an adequate quantity and quality of sleep to maintain cardiovascular health (Kim et al., 2015).

In a recent systematic review of 32 studies, most of the included studies concluded that sleep duration and quality affect the burden of subclinical CVD in subjects free of clinical CVD. Subclinical CVD measures included coronary artery calcium (CAC) measured by electron beam computed tomography, carotid IMT measured by high-resolution B-mode ultrasound on carotid arteries, endothelial/microvascular function measured by flow-mediated dilation, peripheral arterial tone, iontophoresis or nailfold capillaroscopy, and arterial stiffness measured by PWV or ankle brachial index (Aziz et al., 2016).

Short sleep duration was associated with worse markers of white matter integrity in midlife, indicating a link between poor sleep and risk of dementia and stroke. White matter hyperintensities (WMH) have been associated with an increased risk of stroke and cognitive dysfunction. In a cross-sectional analysis of 514 elderly hypertensives (mean 72 years), short sleep duration was a significantly positive determinant for WMH, especially in those without chronic kidney disease (Nagai et al., 2015). In a prospective cohort of 613 black and white adults (mean 45 years) enrolled in the CARDIA Study, short sleepers ($\leq$6 h) had an elevated ratio of WMH to normal tissue in the parietal region (OR 2.31) compared to moderate sleepers (>6 to $\leq$8 h) after adjusting for confounding factors (Yaffe et al., 2016).

In a prospective cohort study of 4238 participants from the Nurses' Health Study, self-reported sleep duration was significantly associated with a decline in renal function over an 11-year period. Compared with sleeping 7–8 h per night, the adjusted ORs for a rapid decline in renal function (30% or greater reduction in the estimated glomerular filtration rate) were a significant 1.79 for <5 h sleep per night, a significant 1.31 for 6 h sleep per night, and an insignificant 0.88 for $\geq$9 h. Thus, shorter sleep duration was prospectively and independently associated with faster decline in renal function (McMullan et al., 2016).

These data are consistent with the hypothesis that the CVD consequences of short sleep may begin as early as adolescence and persist until older age.

Sleep and Diabetes

Sleep loss is associated with obesity, metabolic syndrome, and diabetes. An increasing number of epidemiological studies show an association between adverse metabolic traits, particularly obesity and type 2 diabetes, and each of short sleep duration, sleep disturbances, and circadian desynchronization of sleep (Schmid et al., 2015; Kawakami et al., 2004; Gottlieb et al., 2005; Tasali et al., 2008; Chao et al., 2011).

U-shaped patterns have been observed for the relationship between sleep duration and diabetes. In conclusion, both short and long sleep durations have been independently associated with newly diagnosed diabetes. In a total of 3470 adults recruited from a health checkup center, the multinomial regression model demonstrated that both short (<6.0 h) and long ($\geq$8.5 h) sleepers had a higher risk of newly diagnosed diabetes, with ORs of 1.55 and 2.83, respectively, compared with normal sleepers (6.0–8.49 h). However, sleep duration was not found to relate to prediabetes (Chao et al., 2011).

Shorter sleep duration may impair insulin sensitivity and beta-cell function in nondiabetic white men, possibly contributing to later type 2 diabetes and CVD. Support for this conclusion was provided by a study in 224 nondiabetic community volunteers (mean 44.5 years), which a 180-min, intravenous glucose tolerance test was administered, followed by laboratory measurement of insulin sensitivity (Si), acute secretion (AIRg), glucose effectiveness (Sg), and disposition index (Di) (Wong et al., 2015).

In addition, both acute total and short-term partial sleep deprivation have been shown to result in elevated high-sensitivity CRP concentrations, a stable marker of inflammation that has been shown to be predictive of CVD (Meier-Ewert et al., 2004).

Sleep and Sympathetic Nervous System

Sleep-associated alterations in the autonomic nervous system may partly account for the association of short sleep duration and poor sleep quality with CVD outcomes.

In an association study of 48 nonsleepy middle-aged volunteers (mean 59 years), recurrent arousal (arousal index) detected by overnight PSG was the single strongest predictor of muscle sympathetic nerve activity burst incidence. This result indicated that frequent arousals during sleep induce sympathetic nervous activity over a 24-h period (**Fig. 1**) (Taylor et al., 2016).

Increased sympathetic activity as measured by 24-h urinary catecholamines might play a critical role in the pathogenesis mediating the relationship of insufficient sleep (quantity and quality) with subsequent CVD and metabolic complications. In a 3-year follow-up study of 114 healthy middle-aged adults, cross-sectional analysis showed that objective poor sleepers (3-day actigraphy sleep efficiency <85%) had a higher 24-h urinary norepinephrine (NE) level (206 vs. 162 nmol/d, $P=0.03$) than good sleepers. However, the linear regression results showed that shorter time in bed, actual sleep time, longer sleep onset latency, and lower sleep efficiency were correlated with higher 24-h urinary NE but not salivary cortisol. The effect of poor sleep quality on 24-h urinary NE was stronger in males than in females (Zhang et al., 2011).

Short sleep duration, low sleep efficiency, and the combination of insomnia plus short sleep duration are associated with markers of autonomic tone that indicate lower levels of cardiac parasympathetic tone and/or higher levels of sympathetic tone. In a cross-sectional analysis of actigraphy-defined sleep duration and efficiency in 527 adults of the MESA, subjects who slept <6 h had a higher baseline heart rate (HR) and greater HR orthostatic reactivity compared to those who slept $\geq$7 h. Participants who slept 6 h to <7 h/night had a lower baseline high-frequency HR variability (HF-HRV) than those who slept $\geq$7 h. Participants with low sleep efficiency had lower baseline HF-HRV than those with higher sleep efficiency (Castro-Diehl et al., 2016).

Sleep loss may increase cardiovascular risk by dysregulating stress physiology. Sleep deprivation has been shown to amplify systolic BP increases in response to psychological stress. In a study in which two standardized psychological stress tasks (a Stroop color-word naming interference task and a speech task) were administered in 20 healthy young adults, the psychological stress-induced pressor effect was greater under the sleep deprivation condition (Franzen et al., 2011).

Sleep and Blood Pressure

The BP profiles related to sleep disturbance are high BP, exaggerated BP variability, and nocturnal hypertension with diminished nocturnal BP fall (**Fig. 1**). These characteristics may be partly explained by increased sympathetic nervous activity over a 24-h period, resulting in increased salt sensitivity and impaired baroreflex (**Fig. 1**) (Kario, 2012; Gangwisch, 2014).

Sleep Duration

Adults

Short sleep duration could be a significant risk factor for hypertension. In the longitudinal analyses of the first National Health and Nutrition Examination Survey ($n=4810$) conducted over an 8- to 10-year follow-up period, sleep durations of $\leq$5 h per night were associated with a significantly increased risk of hypertension (HR 2.10) in subjects between the ages of 32 and 59 years, and this association remained significant even after controlling for obesity and diabetes (Gangwisch et al., 2006). Such an association between short sleep duration and hypertension was also found in a study of 1046 French adults aged >40 years (mean 55.5 years) in a primary care health setting. Compared to the group sleeping 7 h, individuals sleeping <5 h had an increased adjusted OR for the prevalence of hypertension (OR 1.80) (Faraut et al., 2012).

Elderly

However, sleep duration might have less impact on hypertension in the elderly. In the population-based Rotterdam Study, there was no significant association between sleep duration and hypertension in a cross-sectional study of 5058 participants aged 58–98 years (van den Berg et al., 2007).

Sex-difference

Sleep deprivation may produce pressor effects in women. In a cross-sectional analysis of British civil servants aged 35–55 years at baseline ($n=5766$), short duration of sleep ($\leq$5 h per night) was associated with higher risk of hypertension compared with normal duration of sleep (7 h per night) in women (OR 1.72), independent of confounders, with an inverse linear trend across decreasing hours of sleep ($P=0.037$). No association was detected in men (Cappuccio et al., 2007). In a metaanalysis of 13 papers involving 347,759 participants, a U-shaped change in pooled ORs for hypertension due to the change of sleep duration was observed. The unadjusted OR for hypertension of individuals who slept $\leq$5 h vs. 7 h was 1.61; that for individuals who slept $\geq$9 h vs. 7 h was 1.29. Women deprived of sleep (sleep duration $\leq$5 h vs. 7 h; OR 1.68) had a higher risk of hypertension than men (OR 1.30). Thus, excessively longer and shorter sleep may both be risk factors for high BP, and these associations are stronger in women than in men (Wang et al., 2015).

Adolescents

The association between short sleep duration and higher BP and incident hypertension is found not only in adults but also in adolescents. In a study enrolling 246 healthy adolescents (mean 16 years), shorter, actigraphy-assessed sleep duration over 1 week was related to higher 48-h ambulatory BP and higher nighttime BP. Shorter sleep duration was also related to a higher systolic BP sleep/wake ratio. These results were independent of age, race, sex, and body mass index. Follow-up analyses by race revealed that associations between sleep duration and BP were largely present in white, but not black, adolescents (Mezick et al., 2012). In a more precise study using a school-based sample of 366 adolescents aged 11–16 years, ambulatory BP was measured every 30 min for 24 h on a school day; actigraphy was used to measure sleep duration. Longer sleep duration was significantly associated with lower ambulatory BP in adolescents. The mean sleep duration was 6.8 h at night, and 7.2 h over 24 h. Controlling for duration of sleep during the day and covariables, each additional hour of nighttime sleep was associated with a reduction in SBP (-0.57; $P<0.0001$); controlling for nighttime sleep duration and covariables, each additional hour of daytime sleep was associated with a reduction in systolic BP (-0.73; $P<0.001$) and also a reduction in diastolic BP (-0.50; $P<0.001$). These findings have potential implications for cardiovascular health in this age group (Meininger et al., 2014). However, in a study in healthy 8-year-old children without sleep-disordered breathing, neither quantity nor quality of sleep was related to 24-h ambulatory BP ($n=231$) or cardiovascular reactivity ($n=265$) as assessed by the Trier Social Stress Test for Children (Martikainen et al., 2011).

Thus, poor sleep may be associated with an overt, age-associated unhealthy cardiovascular phenotype.

Sleep Quality

In addition to short sleep duration, poor sleep quality may contribute to hypertension.

Chronic insomnia with short sleep duration is associated with an increased risk for incident hypertension to a degree comparable to that of sleep-disordered breathing defined as an obstructive AHI ≥ 5. In the Penn State Cohort study, which was performed using 8-h PSG in a general population sample of 1395 adults followed up for 7.5 years, compared with normal sleepers who slept ≥ 6 h, the highest risk for incident hypertension was in chronic insomniacs (defined as those with a complaint of insomnia lasting ≥ 1 year) with short sleep duration defined as the median polysomnographic percentage of sleep time (i.e., <6 h) (OR 3.8) (Fernandez-Mendoza et al., 2012).

In a multicenter prospective study known as the Outcomes of Sleep Disorders in Older Men Study, which included 784 community-dwelling men aged ≥ 65 years (mean 75 years) who did not have hypertension in an in-home PSG sleep analysis performed at baseline, 243 subjects newly developed hypertension after a mean follow-up of 3.4 years. Incident hypertension was associated with increased hypoxemia, increased sleep stages N1 and N2, and decreased stage N3 (SWS). After adjustment for age, nonwhite race, study site, and body mass index, the only sleep index to remain significantly associated with incident hypertension was the SWS percentage (OR for the lowest to highest quartile of SWS: 1.83). The percentage time in SWS was inversely associated with incident hypertension, independent of sleep duration and fragmentation, and sleep-disordered breathing. Therefore, selective deprivation of SWS may contribute to adverse BP in older men (Fung et al., 2011).

The association between poor sleep quality and a slight increase in BP is found even in adolescents. In a cross-sectional analysis of 238 adolescents, all without SAS or severe comorbidities, after adjustment for sex, body mass index, and socioeconomic status, the odds of prehypertension ($\geq$90th percentile for age, sex, and height) increased 3.5-fold for actigraphy-defined low sleep efficiency (low sleep efficiency $\leq$85%) and 2.5-fold for short sleep ($\leq$6.5 h). Adjusted analyses showed that adolescents with low sleep efficiency had on average a 4.0-mmHg higher systolic BP than other children ($P < 0.01$) (Javaheri et al., 2008).

Li and colleagues performed a study on 219 chronic insomniacs and 96 normal sleepers who underwent one night of in-laboratory PSG testing followed by a Multiple Sleep Latency Test (MSLT), which is the standard test of sleepiness/alertness. After controlling for variables, they found that insomnia combined with hyperarousal (MSLT >14 min) increased the odds of hypertension by 300% (OR 3.27) compared with the risk in normal sleepers with an MSLT $\leq$14 min. Thus physiological hyperarousal was shown to be an underlying mechanism of a higher risk of hypertension in chronic insomniacs (**Fig. 1**) (Li et al., 2015).

Poor sleep quality is significantly associated with resistance to treatment in hypertensive women. In a cross-sectional cohort study in 270 hypertensive patients (mean 57 years) consecutively recruited at the Outpatient Hypertension Unit, University of Pisa, Italy, poor sleep quality evaluated by the PSQI was shown to be an independent predictor of resistant hypertension (defined as office BP $\geq$ 140/90 mmHg with $\geq$3 antihypertensive drugs or controlled BP with $\geq$4 drugs) in women (OR 5.3), but not in men (Bruno et al., 2013).

Sleep and Circadian Rhythm

The sleep and circadian rhythm of the cardiovascular system have physiological effects on the diurnal variation of hemodynamics, and they are also thought to effect the pathophysiology of CVD.

Circadian Rhythm

The onset of CVD shows a circadian rhythm, and the incidence of CVD events such as stroke and myocardial infarction is greater in the early morning than at other times of day. BP also shows a circadian rhythm, decreasing by 10%–20% during sleep. This circadian rhythm in BP is the result of modifications in the clock gene-regulated endogenous sleep–wake rhythm with a cardiovascular response to living environment-based mental and physical activities (Kario, 2015a, 2016). Short-term BP variabilities such as morning BP surge, physical or psychological stress-induced changes in daytime BP, and nocturnal BP surge triggered by hypoxic episodes in OSAS modulate this circadian rhythm of BP, leading to individual differences in the circadian variability of 24-h ambulatory BP and cardiovascular risk (Kario, 2015b; Kario et al., 2003).

Nocturnal Blood Pressure During Sleep

Sleep is the major determinant of the nocturnal dipping status of BP. The sleep architecture (sleep stage) is closely associated with the nocturnal BP level (**Figs. 2** and **3**). Nocturnal BP gradually decreases along with the advance in non-REM sleep stages (from N1, N2, to N3) (Somers et al., 1993). Nocturnal BP surges with an exaggerated peak are frequently found during REM sleep. The basal BP, which is the lowest BP level with the minimal amplitude and frequency of BP surges, is usually found during Stage N3 (SWS) (**Fig. 2**). The basal BP is predominantly determined by the circulating blood volume and cardiovascular structure without any effect of neurohumoral activation (Kario, 2015a). In addition to the BP surges generated during REM sleep, microarousals (unconscious arousals) detected by PSG induce BP surges during non-REM sleep. At the time of apnea episodes, arousals frequently occur. Spontaneous non-SAS arousals increase with aging, and these events induce BP surge independently of apnea (**Fig. 4**). Arousals experimentally induced by auditory tones (range: 40–80 dB; duration: 0.5 s) increase BP by 15%–20% (Bangash et al., 2008).

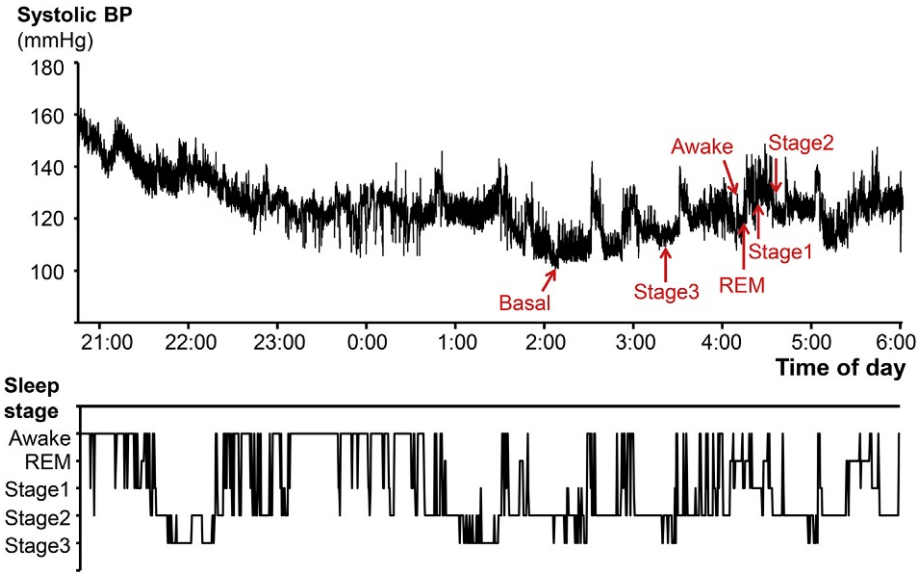

Fig. 2 Beat-by-beat sleep blood pressure continuously monitored by the newly developed tonometry-type wrist surge pressure monitoring-1 (WSP-1) system (The prototype model which is jointly developed by Omron Healthcare Co., Ltd. and Jichi Medical University School of Medicine*) in different sleep stages defined by simultaneous polysomnography. The data were obtained from 43-year-old healthy woman. *REM*, rapid-eye movement. *This research is partially supported by the Research and development of supportive device technology for medicine using ICT from Japan Agency for Medical Research and development, AMED.

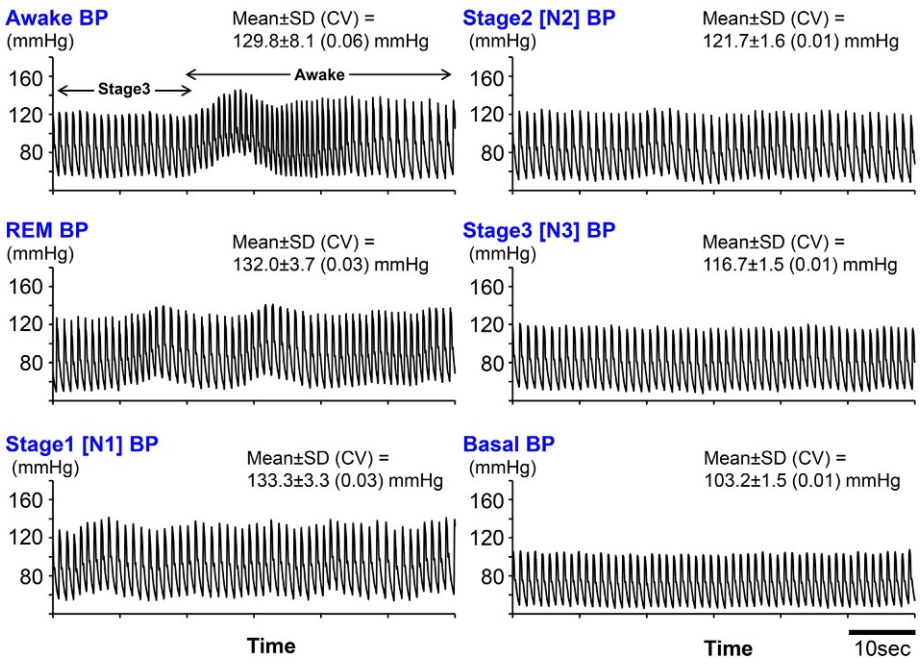

Fig. 3 Beat-by-beat short-term sleep blood pressure variability continuously monitored by the newly developed tonometry-type wrist surge pressure monitoring-1 (WSP-1) system (The prototype model which is jointly developed by Omron Healthcare Co., Ltd. and Jichi Medical University School of Medicine*) in the different sleep stages shown in **Fig. 2**. *REM*, rapid-eye movement. The blood pressure surges during awake or REM sleep are more pronounced than those during slow-wave sleep (N3). The basal BP, the lowest BP, is usually found during N3 sleep. *This research is partially supported by the Research and development of supportive device technology for medicine using ICT from Japan Agency for Medical Research and development, AMED.

Disrupted Circadian Rhythm in Blood Pressure

Disrupted circadian BP rhythm (i.e., the absence of a nocturnal-BP fall in a nondipper, or a nocturnal BP greater than daytime BP in a riser) (Fig. 5) is linked to a cardiovascular risk independent of a high BP level. Abnormality in the circadian rhythm of BP can be evaluated by 24-h ambulatory BP monitoring (ABPM) or home nocturnal BP monitoring (Kario, 2015a, 2016; Kario et al., 2015a).

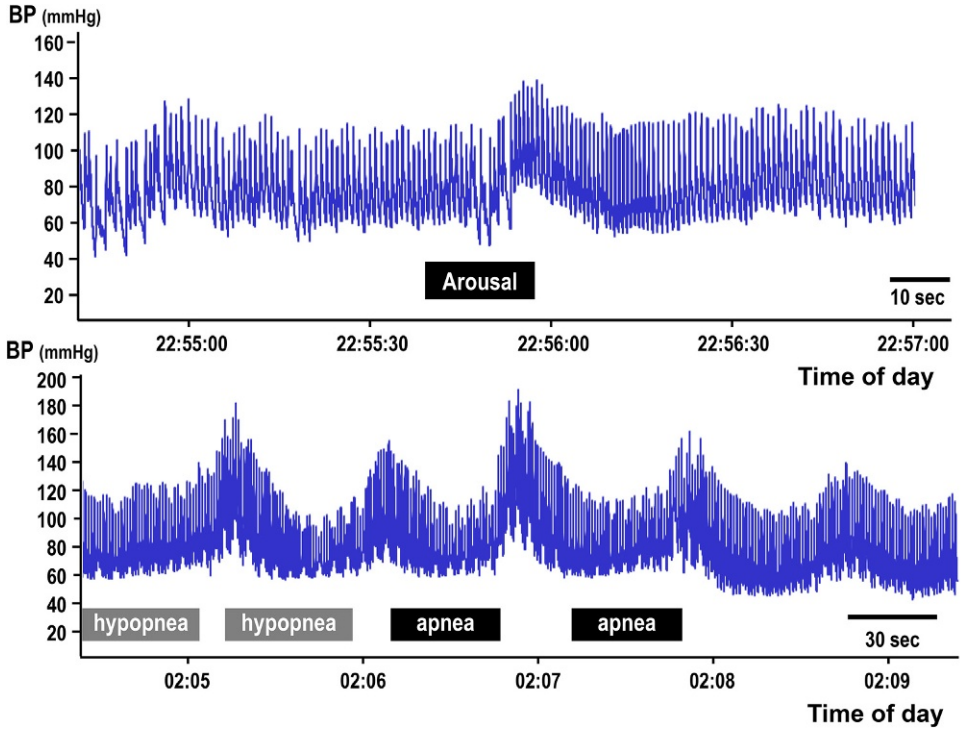

Fig. 4 Nocturnal blood pressure surges triggered by arousal (upper panel: data from 36-year-old healthy man) and apnea/hypopneas (lower panel: data from 50-year-old man with severe obstructive sleep apnea). Beat-by-beat sleep blood pressure was continuously monitored by the newly developed tonometry-type wrist surge pressure monitoring-1 (WSP-1) system (The prototype model which is jointly developed by Omron Healthcare Co., Ltd. and Jichi Medical University School of Medicine*). *This research is partially supported by the Research and development of supportive device technology for medicine using ICT from Japan Agency for Medical Research and development, AMED.

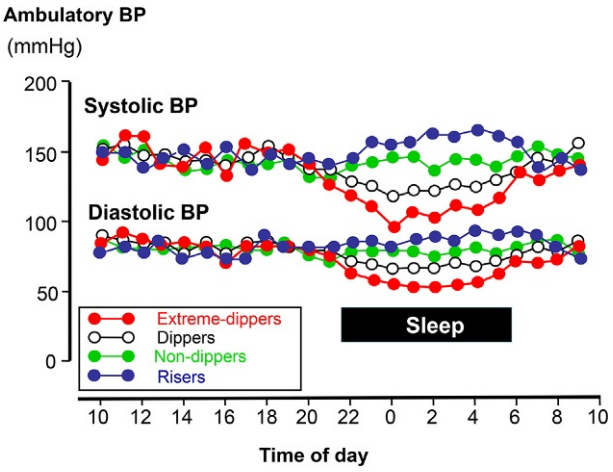

Fig. 5 Four different dipping statuses of nocturnal blood pressure in hypertension. The data shown were evaluated by ambulatory blood pressure monitoring. Reproduced from Kario K, Pickering TG, Matsuo T, Hoshide S, Schwartz JE, and Shimada K (2001) Stroke prognosis and abnormal nocturnal blood pressure falls in older hypertensives. Hypertension 38: 852–857.

Although the fall in nocturnal BP tends to disappear with aging, our ABPM studies in elderly patients with hypertension revealed that risers have a risk of developing SCI or symptomatic stroke (Kario et al., 1996, 2001). The riser pattern is an independent predictor of prognosis in HF patients with a preserved ejection fraction (Komori et al., 2017). A rise in nocturnal BP and being a nondipper/riser are also linked not only to cardiovascular risk but also to brain atrophy (Nagai et al., 2008) and decreased cognitive function/physical activity in elderly patients with hypertension (Yano et al., 2011). On the other hand, although the heart rate also decreases during nocturnal sleep, heart rate nondippers exhibit higher plasma BNP levels than heart rate dippers (Oba et al., 2017). In addition, the risk of stroke in nondippers who show neither a decrease in BP nor a decrease in heart rate during the nighttime

reached 8.9 times that in normal dippers for both parameters, and the risk increased synergistically (Kabutoya et al., 2010). In nondipper/riser subjects with a normal 24-h BP below 125/80 mmHg in a community-dwelling population, increased plasma blood BNP level and increased left ventricular mass on echocardiography were observed with progressive concentric cardiac hypertrophy (Hoshide et al., 2003). Even in normotensive young adults, disrupted circadian rhythms in BP (both a nondipper/riser pattern and an extreme-dipper pattern) are closely associated with the presence of CAC detected by coronary CT after a 10–15 year follow-up period (Viera et al., 2012). The cardiovascular risk of risers may be synergistically augmented by shorter sleep duration. In our prospective study on 1255 elderly hypertensive patients (mean 70.4 years), short sleep duration (<7.5 h (20th percentile)) was associated with incident CVD (HR 1.68), and the combination of a riser pattern in nocturnal BP and short sleep duration was most strongly predictive of future CVD (stroke, fatal, or nonfatal myocardial infarction, or sudden cardiac death) (HR 4.43), independent of ambulatory BP levels (Eguchi et al., 2008). These results indicate that disrupted circadian rhythms of BP or heart rate in relation to sleep are directly linked to hypertensive organ damage and cardiovascular events.

The BP nondipper/riser pattern can be caused by various mechanisms other than sleep disturbance, such as an increased circulating blood volume due to increased salt sensitivity, excessive salt intake, or autonomic nervous dysfunction, and there is a possibility that a clock gene abnormality and hyposecretion of melatonin are involved in these mechanisms (Kario, 2011). In particular, sleep disturbance directly modifies nocturnal BP. In a human intervention study, sleep deprivation was shown to cause nondipper nocturnal hypertension (Tochikubo et al., 1996). In addition, selective SWS deprivation cut the lowest nocturnal BP during sleep, resulting in increased nocturnal BP (Sayk et al., 2010). The patient with OSAS will become a nondipper/riser with an increased nocturnal BP, and sleep apnea episodes may induce nocturnal BP surges (**Fig. 4**) (Kario, 2009, 2015a, 2016). Exaggerated nocturnal BP surge may trigger sleep-onset cardiovascular events in OSAS patients (Kario, 2009, 2015a, 2016; Yoshida et al., 2016). Periodic leg movements induce repetitive nocturnal BP surges (on average, systolic BP 22 mmHg, diastolic BP 11 mmHg), suggesting a risk of CVD in patients with restless legs syndrome, especially in the elderly. The nocturnal BP surges were greater when the leg movements were accompanied with microarousal (Pennestri et al., 2007).

Office and Home BP Variability

In addition to diurnal BP variability, there are various other BP variabilities with different time phases, which could be detected by office and home monitorings (Kario, 2015b; Parati et al., 2013). Recent studies demonstrated that visit-to-visit office BP variability and day-by-day home BP variability are associated with cardiovascular risk independently of the average of BP levels (Rothwell et al., 2010; Johansson et al., 2012). Sleep quality is closely associated with office and home BP variability, especially with morning BP (Kario, 2015a). Uncontrolled morning hypertension is a major independent risk factor for CVD (Kario et al., 2014a, 2016a; Hoshide et al., 2015).

In our prospective study on 201 elderly individuals (80 years old) with one or more cardiovascular risks, long sleep duration and persistent insomnia were significantly associated with higher visit-to-visit BP variability (expressed as a coefficient of variation) and δ (maximum–minimum) BP based on 12 visits, long sleep duration, and persistent insomnia each had synergetic interactions with carotid artery stiffness and with visit-to-visit BP variability (Nagai et al., 2013).

Duration and quality of sleep are associated with great variability in home BP, which is known to have a cardiovascular prognostic value independently of the average of home BP levels. In the 1908 Finn-home study, adult participants aged 41–74 years, morning–evening, day-by-day (morning and evening), and first–second home BP variability variables during 7 consecutive days were significantly higher in participants with persistent insomnia than in those without insomnia. Systolic morning–evening, day-by-day, and morning day-by-day variables of home BP variability were significantly higher in long sleepers, and systolic morning day-by-day, diastolic day-by-day, and diastolic first–second measurement of home BP variability variables were higher in short sleepers than in the reference group. Insomnia combined with short sleep duration further increases home BP and heart rate variability (Johansson et al., 2011).

The Trigger Technique, a Novel Method of Nocturnal Blood Pressure Monitoring at Home

The clinical practice of sleep medicine is changing rapidly, with novel diagnostics and treatments that have established a home-based (rather than laboratory-based) management approach. The diagnostic approach for OSAS is transitioning from the gold standard of PSG in the sleep laboratory to home sleep testing (Malhotra et al., 2015). We have developed a trigger nighttime BP monitoring (TNP) method, which was based on the automated fixed interval-measurement technique with an added trigger function that initiates BP measurement when oxygen desaturation falls below a variable threshold continuously monitored by pulseoximetry (Kario, 2013, 2015a, 2016; Kario et al., 2014b; Kario and Hamasaki, 2015; Kuwabara et al., 2017). The home TNP can detect specific marked nocturnal BP surges triggered by hypoxic episodes in OSAS patients (**Fig. 6**). In addition, the heart rate-trigger function added to TNP is able to determine the "basal BP" based on the circulating volume and structural cardiovascular system without any increase in sympathetic tonus. This double-trigger, nighttime BP monitoring approach is a novel concept for evaluating the pathogenic pressor mechanism of nighttime BP. **Fig. 6** shows the nighttime BP parameters obtained from TNP (Kario et al., 2014b). In the case of nocturnal hypertension that exhibits a similar average of nighttime BPs, there may be a different mechanism: peak nighttime BPs measured by hypoxia trigger are attributed to the sympathetic overdrive, while basal nighttime BPs

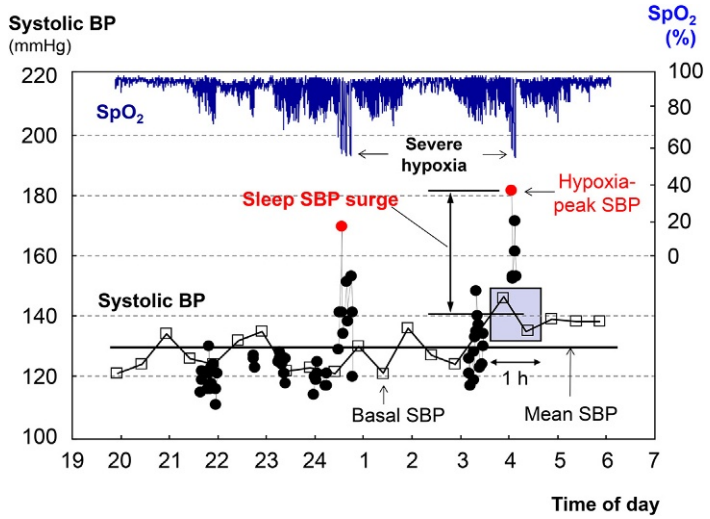

Fig. 6 Definition of nocturnal blood pressure parameters obtained by trigger nocturnal blood pressure monitoring (TNP). *BP*, blood pressure; *SBP*, systolic BP. Proposal of a new strategy for ambulatory blood pressure profile-based management of resistant hypertension in the era of renal denervation. *Hypertension Research 36*, 478–484.

measured by the lowest heart rate trigger are attributed to the circulating volume and vascular structure-related hypertension (Kario, 2015a). The former BP component of nocturnal hypertension may be suppressed by nighttime dosing of sympatholytic drugs, while the latter BP component may be suppressed by diuretics, calcium channel blocker, and/or RAS inhibitors.

The degree of nocturnal BP surge is markedly different among different OSAS patients even with similar AHI. The difference in the individual nocturnal BP surge may be partly due to the difference in altered chemoreflex control of sympathetic activity, and/or in impaired baroreflex due to vascular disease. Fig. 7 demonstrates the nighttime BPs detected by TNP in two cases with drug-resistant hypertension and SAS (Kario, 2013). Although the patients had comparable OSAS severity (as measured by the AHI), the trigger function of TNP revealed quite different nighttime BP surges between these patients. It is well known that cardiovascular events occur more frequently during sleep in patients with OSAS. The hypoxia-induced nighttime BP surge would trigger the
